Preface

New medical imaging technologies can improve the diagnosis and clinical management of many diseases. Furthermore, advanced imaging also contributes to a better understanding of pathogenesis and therefore to the development of new pharmaceuticals and novel therapies. Thus, imaging plays a critical role in modern medical research and clinical practice. Noninvasive or minimally invasive imaging techniques have revolutionized diagnostic medicine during the last decades, e.g., X-ray computed tomography (CT), magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), radioisotope imaging (position emission tomography (PET)), single-photon emission computed tomography (SPECT), and diffuse optical tomography (DOT). These techniques permit three-dimensional visualization; however, their spatial resolution is typically limited to a few millimeters in standard clinical practice. Optical imaging techniques such as conventional, confocal, fluorescence, as well as two-photon or multiphoton microscopy enable high axial and transverse ($\leq$1 μm) resolution imaging but with limited penetration in biological tissues. Excisional biopsy and histopathology remains the gold standard for many clinical applications including cancer diagnosis. However, biopsy is hazardous or impossible in some tissues, and it can suffer from unacceptable false-negative rates because of sampling errors.

An imaging modality that enables noninvasive or minimally invasive three-dimensional imaging with near cellular resolution or tissue morphology as well as function could significantly improve early diagnosis, contribute to a better understanding of disease pathogenesis, and enable improved monitoring of disease progression and response to therapy. Optical coherence tomography (OCT) is a noninvasive, optical medical diagnostic imaging modality, which enables in vivo cross-sectional and three-dimensional tomographic visualization of internal microstructure in biological systems. Since its invention in the late 1980s and early 1990s, the original concept of OCT was to enable noninvasive optical biopsy, i.e., the in situ imaging of tissue microstructure with a resolution approaching that of histology but without the need for tissue excision and postprocessing. In order to accomplish – or to approach – this challenging goal, recent efforts in OCT research focused on improvements in resolution, data acquisition speed, optimization of tissue penetration, as well as contrast enhancement. The development of state-of-the-art medical devices and patient interfaces facilitated the application of OCT in a variety of medical fields, enabling access to internal body organs using a variety of catheters,

endoscopes, needles, and other imaging probes. Furthermore, extensions of OCT have been developed that enable noninvasive *depth-resolved* functional imaging, providing spectroscopic, polarization-sensitive, blood flow, or physiological tissue information. These functional extensions of OCT not only enhance image contrast but also promise to enable improved differentiation of pathologies via localized metabolic properties or functional (physiological) states.

As a consequence, there have been numerous recent innovations in OCT technology and considerable interest in this topic – especially in the fields of ophthalmology, gastroenterology, and cardiology. OCT is one of the most innovative and rapidly emerging optical imaging modalities in the last decades since unlike histology, it is capable of noninvasively exploiting the wealth of morphological and functional tissue information in living tissues and performing repeated imaging to elucidate dynamics, progression, and treatment response. To date, more than 50 OCT companies have been created; more than 100 international research groups are involved in OCT; over 1,000 OCT patents have been granted; and more than 10,000 research articles have been published – mostly in ophthalmology, followed by technology-related and cardiovascular publications (http://www.octnews.org/; Eric Swanson). In ophthalmic diagnosis, OCT was the fastest adopted imaging technology in the history of ophthalmology. In 2010, there were 108 million X-ray, 30 million SPECT, PET, and CT, and 26 million MRI examinations compared with approximately 30 million ophthalmic OCT scans. In more than 110 years of X-ray imaging development, ionizing radiation dose was reduced by 1,500 times; imaging speed became 257,000 times faster; contrast increased significantly; and the images became of much finer resolution. It is interesting to note that in less than 20 years of OCT development, its axial resolution has improved by more than 10 times; imaging speed has increased by more than half a million times; image contrast is greatly enhanced; and many functional extensions of OCT have been developed.

In 2008, the first edition of this book was successfully published and has contributed to the extremely rapid development and dissemination of OCT. Since then, significant advances in photonics, detection and OCT technology, as well as a broad and continuously growing spectrum of successful OCT applications in a variety of medical fields have occurred. The second edition of this book seeks to comprehensively summarize and critically highlight the state of the art of OCT technology and its applications. The book includes contributions from the leading international experts in OCT technology and its clinical applications. The number of chapters more than doubled from 42 in the first edition to more than 80 in this second edition. The chapters have been grouped into five themes:

- Two chapters present an overview, history, and basic theory of OCT. Modeling of light tissue interactions in OCT systems is described in the third chapter.
- In Part II, 21 chapters summarize the state-of-the-art *OCT Technology* including Spectral/Fourier, Frequency Domain OCT, Swept Source OCT, Inverse Scattering OCT, Ultrahigh-Resolution OCT, Ultrahigh-speed OCT, superluminescent diodes, rapid swept sources, ultrashort pulse and tuneable light sources for OCT as well as optical designs, linear OCT systems, and OCT signal and image processing, including digital signal processing enhancements.

- In Part III, seven chapters focus on *Optical Coherence Microscopy* including flying spot-based en face OCT, scanning OCM, time domain, spectral domain and swept source full field OCT, OCM with engineered wavefront, interferometric synthetic aperture microscopy, and holographic OCT.
- In Part IV, 23 chapters introduce *extensions of OCT* describing Doppler flow, microangiography, polarization-sensitive, spectroscopic, molecular contrast, phase-resolved OCT, OCT combined with fluorescence, multiphoton microscopy, ultrasound, photoacoustic imaging, fluorescence laminar tomography, elastic scattering spectroscopy combined with OCT, optical tissue clearing for OCT, nonlinear interferometric vibrational imaging, optical coherence elastography, as well as multimodal OCT endoscopy.
- In Part V, the final 31 chapters summarize the broad spectrum of medical OCT applications including tissue engineering, developmental biology, ophthalmology (including 2 chapters on cellular resolution (adaptive optics) OCT, small animal retinal OCT, as well as choroidal OCT), gastrointestinal and intracoronary endoscopy, dermatology, laryngology, neuroscience, dentistry, kidney transplantation, as well as applications in the oral cavity, pulmonary area, gynecology, urology and large hollow organs, but also nondestructive material testing and examination of artwork by OCT. A final chapter describes the OCT technology transfer and the OCT market.

Three-dimensional ultrahigh-resolution OCT in combination with ultrafast scanning/data acquisition enabled a quantum leap in OCT performance. OCT can now be considered as an optical analogue to CT or MRI but with microscopic resolution. OCT is in a unique position because it enables not only three-dimensional structural imaging of tissue architecture and pathology but also depth-resolved, three-dimensional imaging of functional tissue information. Integrated structural and functional imaging might ultimately be performed with a single acquisition combined with innovative data post processing. With the continuing development of functional OCT, this technique has the potential to revolutionize medical diagnosis in multiple specialties in the near future. It is unlikely, however, that OCT will replace excisional biopsy and histology or other existing diagnostic modalities. Rather, it would be used as an adjunct to increase coverage, reduce sampling error, and improve sensitivity. In addition, OCT promises to have impact on the screening and diagnosis of diseases and to enable new insight into the pathogenesis and therapy of many diseases. The unique features of this technology enable a broad range of research and clinical applications, which not only complement the existing imaging technologies available today but can also reveal previously unseen morphological, dynamic, and functional changes in applications spanning different biological tissues and medical fields.

Due to recent dramatic technological advances, there may be a concern that key OCT performance parameters, e.g., resolution, scanning/data acquisition speed, sensitivity, and penetration may have reached a plateau. At the same time, it is difficult to predict the future of a technology. Ten years ago, it was difficult to predict the development of Fourier domain detection methods that enabled multiple-order-of-magnitude increases in imaging speed. The full impact of these

extremely high data rates remains yet to be realized, especially in the context of new functional imaging methods. In addition, many challenges in medical device development for OCT remain to be solved.

However, it is clear that the future of OCT clinical applications requires major research efforts by multidisciplinary teams of investigators spanning academics, industry, and clinical medicine. Fundamental studies, engineering, clinical feasibility studies, product development, and multicenter clinical trials must be performed to demonstrate efficacy and outcome. Regulatory and reimbursement hurdles must be addressed and development and educational efforts undertaken to disseminate OCT into the international clinical community. This represents an enormous effort because it must be performed on a specialty-by-specialty and indication-by-indication basis. This translational process requires partnerships between engineers and clinicians, academics and industry, as well as government funding and regulatory agency involvement. These challenges are great, but the potential impact on health care and society is also great.

The editors are especially grateful to the numerous coeditors and their teams for their significant efforts and indispensable contributions that resulted in an extremely comprehensive, state-of-the-art description of OCT. The editors and coeditors have all agreed not to accept any royalty income for this book in order to maintain a low sales price, making it accessible to the widest possible audience. We wish to offer special thanks to the numerous companies and organizations who are advertisers of this book. Their contributions enabled the book to be printed with full color (rather than black and white) figures at an economical price. Finally, we are also especially grateful to Springer Publishing for their efforts to make this book possible.

On behalf of all the coeditors, we hope you find this book and the field of OCT as interesting, enlightening, and stimulating as we do.

Editors

Contents

Volume 1

Part I Introduction to OCT 1

1 Introduction to OCT 3
James G. Fujimoto and Wolfgang Drexler

2 Theory of Optical Coherence Tomography 65
Joseph A. Izatt, Michael A. Choma, and Al-Hafeez Dhalla

3 Modeling Light–Tissue Interaction in Optical Coherence Tomography Systems 95
Peter E. Andersen, Thomas M. Jørgensen, Lars Thrane, Andreas Tycho, and Harold T. Yura

Part II OCT Technology 141

4 Inverse Scattering and Aperture Synthesis in OCT 143
Adolf F. Fercher

5 Spectral/Fourier Domain Optical Coherence Tomography 165
Johannes F. de Boer

6 Complex and Coherence-Noise Free Fourier Domain Optical Coherence Tomography 195
Rainer A. Leitgeb and Maciej Wojtkowski

7 Optical Frequency Domain Imaging 225
Brett E. Bouma, Guillermo J. Tearney, Benjamin Vakoc, and Seok Hyun Yun

8 Complex Conjugate Removal in SS Optical Coherence Tomography 255
Oscar Carrasco-Zevallos and Joseph A. Izatt

9 Ultrahigh Resolution Optical Coherence Tomography 277
Wolfgang Drexler, Yu Chen, Aaron D. Aguirre, Boris Považay, Angelika Unterhuber, and James G. Fujimoto

10 Ultrahigh Speed OCT 319
Ireneusz Grulkowski, Jonathan J. Liu, Benjamin Potsaid, Vijaysekhar Jayaraman, Alex E. Cable, and James G. Fujimoto

11 Optical Design for OCT 357
Zhilin Hu and Andrew M. Rollins

12 Linear OCT Systems 385
Gereon Hüttmann, Peter Koch, and Reginald Birngruber

13 Data Analysis and Signal Postprocessing for Optical Coherence Tomography 407
Tyler S. Ralston, Daniel L. Marks, Adeel Ahmad, and Stephen A. Boppart

14 DSP Technology and Methods for OCT 437
Murtaza Ali, Adeel Ahmad, and Stephen A. Boppart

15 OCT Motion Correction 459
Martin F. Kraus and Joachim Hornegger

16 Image Processing in Intravascular OCT 477
Zhao Wang, David L. Wilson, Hiram G. Bezerra, and Andrew M. Rollins

17 Superluminescent Diode Light Sources for OCT 505
Vladimir R. Shidlovski

18 SLEDs and Swept Source Laser Technology for OCT 527
Marcus Duelk and Kevin Hsu

19 Broad Bandwidth Laser and Nonlinear Optical Sources for OCT 563
Angelika Unterhuber, Boris Považay, Aaron D. Aguirre, Yu Chen, Franz X. Kärtner, James G. Fujimoto, and Wolfgang Drexler

20 Wavelength Swept Lasers 619
Seok Hyun Yun and Brett E. Bouma

21 Swept Light Sources 639
Bart Johnson, Walid Atia, Mark Kuznetsov, Christopher Cook, Brian Goldberg, Bill Wells, Noble Larson, Eric McKenzie, Carlos Melendez, Ed Mallon, Seungbum Woo, Randal Murdza, Peter Whitney, and Dale Flanders

22 VCSEL Swept Light Sources 659
Vijaysekhar Jayaraman, James Jiang, Benjamin Potsaid, Martin Robertson, Peter J. S. Heim, Christopher Burgner, Demis John, Garrett D. Cole, Ireneusz Grulkowski, James G. Fujimoto, Anjul M. Davis, and Alex E. Cable

23 Akinetik Swept Sources 687
Michael Minneman, Jason Ensher, Michael Crawford, Marco Bonesi, Behrooz Zabihian, Paul Boschert, Erich Hoover, Dennis Derickson, Brian E. Applegate, Thomas Milner, and Wolfgang Drexler

24 FDML (incl. Parallelization) 741
Robert Huber

Volume 2

Part III Optical Coherence Microscopy 789

25 Time Domain Full Field Optical Coherence Tomography Microscopy 791
Fabrice Harms, Anne Latrive, and A. Claude Boccara

26 Assessment of Breast, Brain and Skin Pathological Tissue Using Full Field OCM 813
Eugénie Dalimier, Osnath Assayag, Fabrice Harms, and A. Claude Boccara

27 Digital Holoscopy 839
Dierck Hillmann, Gesa Franke, Christian Lührs, Peter Koch, and Gereon Hüttmann

28 Optical Coherence Microscopy 865
Aaron D. Aguirre, Chao Zhou, Hsiang-Chieh Lee, Osman O. Ahsen, and James G. Fujimoto

29 OCM with Engineered Wavefront 913
Rainer A. Leitgeb, Theo Lasser, and Martin Villiger

30 Holographic Optical Coherence Imaging 941
David D. Nolte, Kwan Jeong, John Turek, and Paul M. W. French

31 Interferometric Synthetic Aperture Microscopy (ISAM) 965
Steven G. Adie, Nathan D. Shemonski, Tyler S. Ralston, P. Scott Carney, and Stephen A. Boppart

Part IV Contrast Enhanced, Functional and Multimodal OCT 1005

32 Optical Coherence Elastography 1007
Brendan F. Kennedy, Kelsey M. Kennedy, Amy L. Oldenburg, Steven G. Adie, Stephen A. Boppart, and David D. Sampson

33 Polarization Sensitive Optical Coherence Tomography 1055
B. Hyle Park and Johannes F. de Boer

34 MUW Approach of PS OCT 1103
Christoph K. Hitzenberger and Michael Pircher

35 Jones Matrix Based Polarization Sensitive Optical Coherence Tomography 1137
Yoshiaki Yasuno, Myeong-Jin Ju, Young Joo Hong, Shuichi Makita, Yiheng Lim, and Masahiro Yamanari

36 Spectroscopic Low Coherence Interferometry 1163
Nienke Bosschaart, T. G. van Leeuwen, Maurice C. Aalders, Boris Hermann, Wolfgang Drexler, and Dirk J. Faber

37 Motility Contrast Imaging and Tissue Dynamics Spectroscopy 1189
David D. Nolte, Ran An, and John Turek

38 Elastic Scattering Spectroscopy and Optical Coherence Tomography 1207
Adam Wax, Michael Giacomelli, and Francisco Robles

39 Nonlinear Interferometric Vibrational Imaging (NIVI) with Novel Optical Sources 1237
Stephen A. Boppart, Matthew D. King, Yuan Liu, Haohua Tu, and Martin Gruebele

40 Ultrasensitive Phase-Resolved Imaging of Cellular Morphology and Dynamics 1257
Michael A. Choma, Audrey Ellerbee, and Joseph A. Izatt

41 Doppler Optical Coherence Tomography 1289
Zhongping Chen and Jun Zhang

42 Doppler Fourier Domain Optical Coherence Tomography for Label-Free Tissue Angiography 1321
Rainer A. Leitgeb, Maciej Szkulmowski, Cedric Blatter, and Maciej Wojtkowski

43 Dual Beam Doppler Optical Coherence Angiography 1353
Yoshiaki Yasuno, Shuichi Makita, and Franck Jaillon

44 Optical Microangiography Based on Optical Coherence Tomography 1373
Roberto Reif and Ruikang K. Wang

45 Optical Coherence Tomography in Cancer Imaging 1399
Ahhyun Stephanie Nam, Benjamin Vakoc, David Blauvelt, and Isabel Chico-Calero

46 Clinical Applications of Doppler OCT and OCT Angiography 1413
Ou Tan, Yali Jia, Eric Wei, and David Huang

47 Molecular Optical Coherence Tomography Contrast Enhancement and Imaging 1429
Amy L. Oldenburg, Brian E. Applegate, Jason M. Tucker-Schwartz, Melissa C. Skala, Jongsik Kim, and Stephen A. Boppart

48 Optical Tissue Clearing to Enhance Imaging Performance for OCT 1455
Ruikang K. Wang and Valery V. Tuchin

49 Second Harmonic OCT and Combined MPM/OCT 1489
Zhongping Chen and Shuo Tang

50 Combined Endoscopic Optical Coherence Tomography and Laser Induced Fluorescence 1515
Jennifer K. Barton, Alexandre R. Tumlinson, and Urs Utzinger

51 Integrated Optical Coherence Tomography (OCT) with Fluorescence Laminar Optical Tomography (FLOT) 1557
Chao-Wei Chen and Yu Chen

52 Photoacoustic / Optical Coherence Tomography 1579
Michelle Gabriele Sandrian, Edward Zhang, Boris Považay, Jan Laufer, Aneesh Alex, Paul Beard, and Wolfgang Drexler

53 Multi-modal Endoscopy: OCT and Fluorescence 1599
Jessica Mavadia-Shukla, Jiefeng F. Xi, and Xingde D. Li

Volume 3

Part V OCT Applications 1615

54 Application of Fourier Domain OCT Imaging Technology to the Anterior Segment of the Human Eye 1617

1.1 Introduction

Optical coherence tomography (OCT) has evolved to become a major optical imaging modality in biomedical optics and medicine. OCT performs high-resolution, cross-sectional, and three-dimensional volumetric imaging of the internal microstructure in biological tissues by measuring echoes of backscattered light [1]. Tissue pathology can be imaged in situ and in real time with resolutions of 1–15 μm, one to two orders of magnitude finer than conventional ultrasound. The unique features of OCT make it a powerful imaging modality with applications spanning many multiple clinical specialties as well as fundamental scientific and biological research.

OCT performs cross-sectional and volumetric imaging by measuring the magnitude and echo time delay of backscattered light. Cross-sectional images are generated by transversely scanning the incident optical beam and performing sequential axial measurements of echo time delay (axial scans or A-scans), as shown in Fig. 1.1.

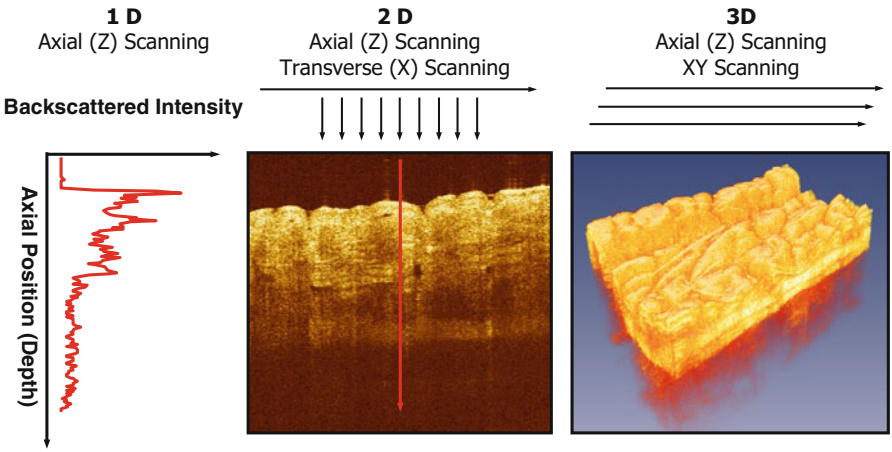

Fig. 1.1 Optical coherence tomography (OCT) generates cross-sectional or three-dimensional images by measuring the magnitude and echo time delay of light. Measurements of backreflection or backscattering versus depth known as axial scans (A-scans). Cross-sectional images are generated by scanning the OCT beam in a transverse direction to acquire a series of axial scans. This generates a two-dimensional data set (B-scan) which can be displayed as a gray scale or false color image. Three-dimensional volumetric data sets (3D-OCT) can be acquired by raster scanning to generate a series of two-dimensional data sets (B-scans)

This produces a two-dimensional data set which represents the optical backscattering in a cross-sectional plane through the tissue. Images, or B-scans, can be displayed in false color or gray scale in order to visualize internal tissue structure of pathology. Three-dimensional, volumetric data sets are generated by acquiring sequential cross-sectional images, scanning the incident optical beam in a raster or other two-dimensional pattern. Three-dimensional OCT (3D-OCT) data contains comprehensive volumetric structural information and can be displayed similar to MR or CT images.

OCT is a powerful medical imaging technology because it performs "optical biopsy," the real time, in situ visualization of tissue microstructure and pathology, without the need to remove and process specimens [2, 3]. Although histopathology is the gold standard for assessing pathology, it requires excision, fixation, embedding, microtoming, and staining of tissue specimens. OCT has applications in several general clinical situations: (1) Where standard excisional biopsy is hazardous or impossible. Applications include tissues such as the eye, arteries, or nervous tissues. (2) Where standard excisional biopsy has sampling error. Excisional biopsy and histopathology is used for diagnosis of many diseases including cancer; however, if the biopsy misses the lesion, this causes a false negative. OCT can guide excisional biopsy to reduce the number of biopsies required and to improve sensitivity by reducing sampling errors. If sufficient sensitivities and specificities can be achieved, OCT may be used to diagnose pathology in real time. Since imaging is performed in situ, OCT has the advantage that much larger regions of tissue can be assessed than by excisional biopsy. (3) For guidance of interventional procedures. In ophthalmology, OCT can visualize changes in retinal structure and markers of disease such

as neovascularization or edema to assess pharmaceutical treatment response. In cardiology and intravascular imaging, the ability to see cross-sectional and three-dimensional structure enables the guidance of procedures such as stent placement. The ability to see beneath the tissue surface enables guidance of ablative therapies such as laser or radio-frequency ablation, as well as surgical and microsurgical procedures. (4) For performing functional measurement and imaging. Doppler OCT enables quantitative measurement of blood flow. Complementary methods such as OCT angiography enable three-dimensional imaging of vascular structure using motion contrast from moving blood cells. Polarization-sensitive OCT enables measurement of birefringence, a marker for cellular and subcellular organization. Spectroscopic, displacement, vibrometry, and many other measurements are possible. Although the imaging depth of OCT is limited by attenuation from light scattering, OCT can be integrated with many medical devices such as catheters, endoscopes, laparoscopes, or needles, to access luminal organ systems such as the GI tract and airway as well as solid organs and masses.

OCT has become a standard of care in clinical ophthalmology and promises to have a powerful impact on many medical applications ranging from intravascular imaging to the assessment of neoplasia and guidance of minimally invasive surgical procedures. This chapter reviews the background and development of OCT.

1.2 OCT and Ultrasound

OCT has features which are common to both ultrasound and microscopy. In order to understand OCT imaging, it is helpful to compare it with these related medical imaging techniques. Figure 1.2 shows the resolution and imaging depth for several imaging modalities. The resolution of clinical ultrasound imaging is typically 0.1–1 mm and depends on the frequency of the sound wave (3–40 MHz) used for imaging [4–6]. Sound waves at standard ultrasound frequencies are transmitted with minimal absorption in biological tissue and it is possible to image structures deep in the body. High frequency ultrasound has been used for research and clinical applications such as intravascular imaging. Resolutions of 15–20 μm and finer have been achieved with frequencies of ~100 MHz. However, these high frequencies are strongly attenuated in biological tissues and imaging depths are limited to only a few millimeters.

Microscopy and confocal microscopy are examples of imaging techniques which have extremely high transverse image resolutions of 1 μm or finer. Imaging is typically performed in an en face plane and resolutions are determined by optical diffraction. The imaging depth in biological tissue is limited because image signal and contrast are significantly degraded by unwanted scattered light. In most biological tissues, imaging can be performed to depths of only a few hundred microns.

OCT fills a gap between ultrasound and microscopy. The axial image resolution in OCT is determined by the bandwidth of the light source. OCT technologies have axial resolutions ranging from 1 to 10 μm, approximately 10–100 times finer than standard ultrasound imaging. The high resolution of OCT imaging enables the visualization of tissue architectural morphology. OCT has become a clinical

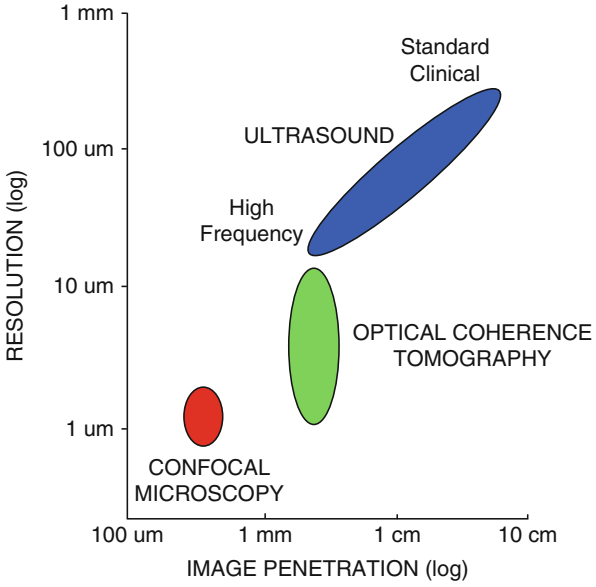

Fig. 1.2 Comparison of ultrasound, OCT, and confocal microscopy resolution and imaging depth. Standard clinical ultrasound achieves deep imaging depths, but has limited resolution. Higher sound frequencies yield finer resolution, but ultrasonic attenuation increases, reducing image penetration. OCT axial image resolution ranges from 1 to 15 μm, determined by the coherence length of the light source. In most biological tissues attenuation from optical scattering limits OCT imaging depth to 2–3 mm. Confocal microscopy has submicron resolution, but imaging depth is only a few hundred microns in most tissues

standard in ophthalmology, because the transparency of the eye provides easy optical access to the retina and noncontact high-resolution imaging is possible [7]. The major limitation of OCT is that light is highly scattered by most tissues and attenuation from scattering limits the imaging depths to ~2 mm in most tissues. However, because OCT uses fiber optics, it can be integrated with a wide range of medical instruments such as catheters, endoscopes, laparoscopes, or needles which enable imaging in luminal organ systems or even solid tissues inside the body.

OCT imaging is analogous to ultrasound imaging except that it uses light instead of sound. There are several different detection methods for performing OCT, but essentially imaging is performed by measuring the magnitude and echo time delay of backreflected or backscattered light from internal microstructures in materials or tissues. OCT images are two-dimensional or three-dimensional data sets which represent optical backreflection or backscattering in a cross-sectional plane or 3D volume. Ultrasound and OCT are analogous in that when a beam of sound or light is incident into tissue, it is backreflected or backscattered differently from structures which have varying acoustic or optical properties, as well as from boundaries between structures. The dimensions of these internal structures can be determined by measuring the "echo" time it takes for sound or light to travel different axial distances.

In ultrasound, the axial measurement of distance or depth is called A-mode scanning, while cross-sectional imaging is called B-mode scanning. Volumetric or 3D imaging can be performed by acquiring multiple B-mode images. The principal difference between ultrasound and optical imaging is that the speed of light is extremely high. The speed of sound is ~1,500 m/s, while the speed of light is approximately 3×10^8 m/s. In order to measure distances with a 100 μm resolution, a typical resolution for ultrasound imaging, a time resolution of ~100 ns is required. This resolution is well within the limits of electronic detection. Ultrasound technology has advanced significantly in recent years with the availability of high-performance, low-cost analog to digital converters and digital signal processing technology. Unlike sound, the detection of light echoes requires much higher time resolution. Light travels from the moon to the earth in only ~2 s. The measurement of distances with a 10 μm resolution, a typical resolution for OCT imaging, requires a time resolution of ~30 fs (30×10^{-15} s). A femtosecond is extremely fast; the ratio of 1 fs–1 s is equal to the ratio of 1 s to the time since the age of dinosaurs. Direct electronic detection is impossible with this time resolution and measurement methods such as high-speed optical gating, optical correlation, or interferometry must be used.

1.3 Measuring Optical Echoes

1.3.1 Photographing Light in Flight

Using optical echoes to see through biological tissue was proposed by Michel Duguay, more than 30 years ago, in 1971 [8, 9]. These pioneering studies demonstrated an ultrafast optical shutter based on the laser-induced Kerr effect which could "photograph light in flight." Figure 1.3 shows a schematic of the ultrahigh-speed Kerr shutter and an ultrashort light pulse propagating though a scattering solution of diluted milk [9]. The Kerr shutter operates by using an intense laser pulse to induce birefringence (the Kerr effect) in an optical medium placed between two crossed polarizers. If the induced birefringence is electronically mediated, it has an extremely rapid response time and the Kerr shutter can achieve picosecond or femtosecond time resolution.

Optical scattering limits the ability to image biological tissues, and Duguay proposed that an ultrahigh-speed shutter could remove unwanted scattered light and detect light echoes from inside tissue [9]. Ultrahigh-speed optical shutters might be used to "see through" tissues and noninvasively image internal pathology. The major limitation of the high-speed optical Kerr shutter is that it requires high intensity, short laser pulses to induce the Kerr effect and operate the shutter.

1.3.2 Femtosecond Time Domain Measurement

An alternate method for detected optical echoes is to use nonlinear optical processes such as harmonic generation, sum frequency generation, or parametric

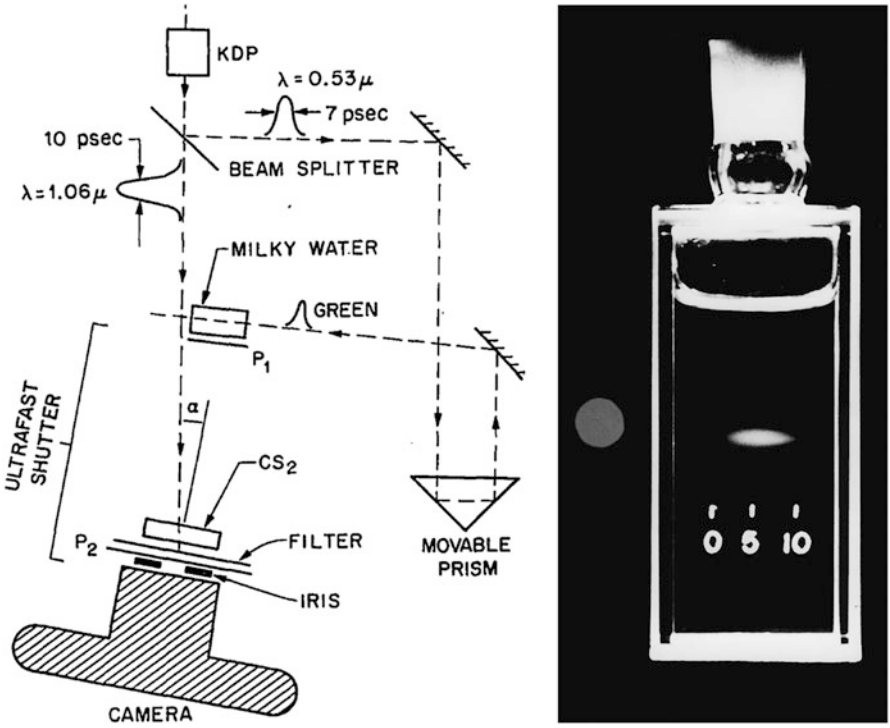

Fig. 1.3 Photographing light in flight. (*left*) A high-speed optical shutter is created using a CS2 cell placed between crossed polarizers. An intense laser pulse induces transient birefringence (the Kerr effect) and opens the shutter (*right*). Photograph of an ultrashort laser pulse propagating through a cell of milk and water. The shutter speed was 10 ps. These early studies suggested that high-speed optical gating could be used to see inside biological tissues by rejecting unwanted scattered light (Duguay and Mattick [9])

conversion [10–12]. Short pulses illuminate the tissue and the backscattered light is nonlinearly mixed with a reference pulse in a nonlinear optical material. The nonlinear process can measure the intensity and time delay of the optical signal with a time resolution determined by the pulse duration. Figure 1.4 shows a schematic of how transient light echoes are detected using nonlinear second harmonic generation cross correlation. The reference pulse is generated by the same laser source and is delayed by a variable time delay ΔT using a mechanical optical delay line. The nonlinear mixing process creates an ultrahigh-speed optical gate. If $I_S(t)$ is the signal that is being detected and $I_r(t)$ is the reference pulse used as the gate, the response function $S(\Delta T)$ is

$$S(\Delta T) \sim \int_{-\infty}^{\infty} I_s(t) I_r(t - \Delta T)\, dt$$

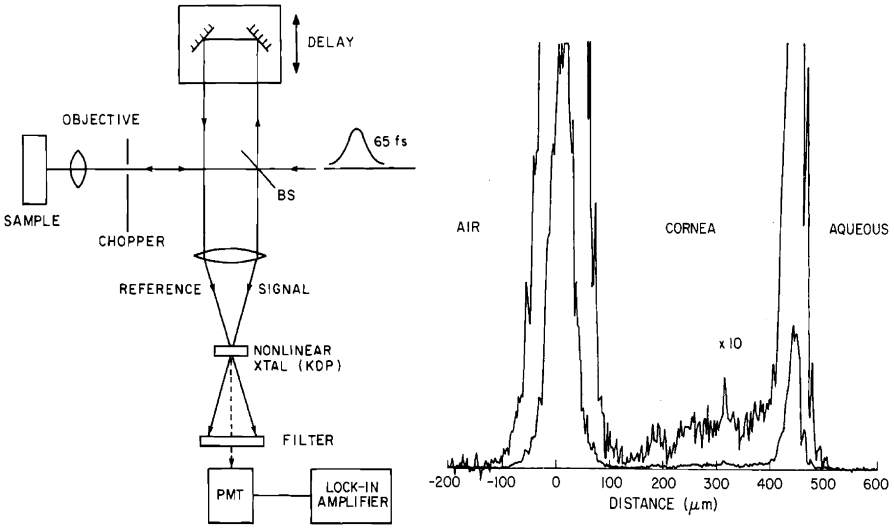

Fig. 1.4 Early demonstration of femtosecond optical ranging in biological systems. (*left*) Femtosecond echoes of backscattered light (signal) are detected using nonlinear second harmonic generation, mixing the signal with a delayed reference pulse. (*right*) Measurement of corneal thickness in an in vivo rabbit eye using femtosecond pulses, showing an axial scan of backscattering versus depth. An axial resolution of 15 μm (in air) was achieved using a femtosecond dye laser generating 65 fs pulses at 625 nm wavelength. The detection sensitivity was −70 dB or 10^{-7} (From Fujimoto et al. [12])

Figure 1.4 shows a measurement of corneal thickness in a rabbit eye in vivo. Very low scattering from the corneal stroma can be detected. The measurement had a 15 μm axial resolution and was performed using 65 femtosecond duration pulses from a femtosecond dye laser at 625 nm wavelength. Sensitivities of −70 dB or 10^{-7} of the incident intensity were achieved. However, these sensitivities were still not high enough to image most biological tissues. Current OCT systems achieve sensitivities 1,000× higher, approaching −100 dB or 10^{-10} of the incident intensity.

1.3.3 Low-Coherence Interferometry

Interferometry is a powerful technique for measuring the magnitude and echo time delay of backscattered light with very high sensitivity. OCT is based on a classic optical measurement technique known as low-coherence interferometry, or white light interferometry, first described by Sir Isaac Newton. Low-coherence interferometry was used in photonics to measure optical echoes and backscattering in optical fibers and waveguide devices in the 1980s [13–15]. The first biological application of low-coherence interferometry for the measurement of axial eye length was reported by Fercher et al. in 1988 [16]. Different versions of low-coherence interferometry were developed for noninvasive measurement in biological tissues [17–20].

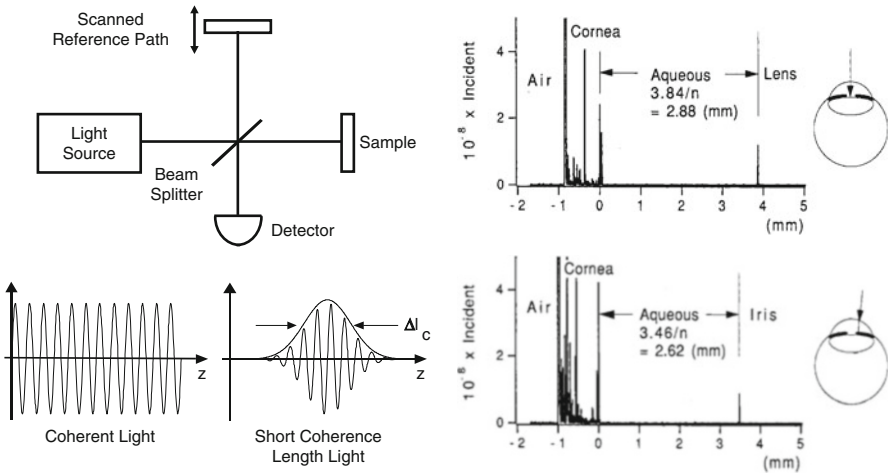

Fig. 1.5 Low-coherence interferometry. (*left*) Backreflected or backscattered light is interfered with light from a scanning reference path delay. Using low-coherence length light, interference only occurs when the path lengths are matched to within the coherence length. The interferometer output is detected as the reference path delay is scanned (time domain detection). The echo magnitude versus delay or axial scan is obtained by demodulating the interference signal. (*right*) Measurement of the anterior chamber in an ex vivo bovine eye. A 10 μm axial resolution was achieved using a low-coherence diode light source at ~800 nm. Interferometry enables high sensitivity detection of optical echoes and is the basis for optical coherence tomography (From Huang et al. [21])

Interferometry techniques perform correlation measurements by interfering light that is backscattered from the tissue with light that has traveled through a reference path with a known time delay. Also, interferometry measures the electric field of the light wave rather than its intensity. Figure 1.5 shows a schematic diagram of a classic Michelson interferometer. The incident light source is divided into a reference beam $E_r(t)$ and a measurement or signal beam $E_s(t)$ which travel different distances in the two interferometer arms. The electric field of the interferometer output is the sum of the signal and reference fields, $E_r(t) + E_s(t)$, and a detector measures the output intensity, which is proportional to the square of the total field:

$$I_o \sim |E_r|^2 + |E_s|^2 + 2 \cdot E_r \cdot E_s \cos(2 \cdot k \cdot \Delta L)$$

ΔL is the path length difference between the signal and reference arms of the interferometer. If the reference path length is scanned, interference fringes will be generated as a function of time. This process can also be understood by noting that the scanning reference arm produces a Doppler shift of the reference field. If a coherent (narrow linewidth) light source is used, interference will be observed over a wide range of path length differences. However, in order to detect optical echoes, a low-coherence (broad bandwidth) light source is required.

Low-coherence light can be characterized as having statistical phase discontinuities over a distance known as the coherence length, which is inversely proportional to the frequency bandwidth of the light. When low-coherence light is used, interference is only observed when the measurement and reference path lengths are matched to within the coherence length. The interferometer essentially measures the field autocorrelation of the light wave. The magnitude and echo time delay of light echoes can be measured by scanning the reference arm and demodulating, detecting the envelope of the interference signal. The coherence length of the light source determines the axial image resolution. Shorter coherence lengths from broadband light sources provide finer resolution.

Figure 1.5 shows an early ex vivo measurement of the anterior chamber of the bovine eye with a 10 μm axial resolution using an 800 nm wavelength, low-coherence diode light source with a bandwidth of 29 nm [21]. Sensitivities of −100 dB or 10^{-10} of the incident intensity were achieved. Scanning the beam in the transverse direction yielded information on different structures, such as the lens and iris. The axial measurements of backscatter versus depth using low-coherence interferometry provided the foundation for optical coherence tomography. Low-coherence interferometry has the advantage that can be performed with continuous wave light sources, without requiring short pulse lasers. Since interferometry measures the field rather than the intensity, it is equivalent to heterodyne detection in optical communication. Weak signals $E_s(t)$ are multiplied by a strong reference field $E_r(t)$ to produce heterodyne gain and very high, shot noise-limited sensitivities can be achieved. In addition, since the intensity is the square of the field, very high dynamic ranges are possible.

1.4 The Development of OCT

1.4.1 Early OCT Technology and Systems

Optical coherence tomography imaging was demonstrated in 1991 by Huang et al. [1]. Figures 1.6 and 1.7 show the first OCT images of the retina and human coronary artery ex vivo with corresponding histology [1]. These examples demonstrate OCT imaging in transparent as well as optically scattering tissues. Imaging was performed with 15 μm axial resolution in tissue at 830 nm wavelength. The image is displayed using a log false color scale with a signal level ranging between ∼ −60 and −90 dB of the incident intensity. The OCT image of the retina in Fig. 1.6 shows the contour of the optic nerve head as well as retinal vasculature near the nerve head. The retinal nerve fiber layer can also be visualized emanating from the optic nerve head. This image was ex vivo and postmortem retinal detachment is evident. The OCT image of the coronary artery in Fig. 1.7 shows fibrocalcific plaque on the right of the specimen and fibroatheromatous plaque on the left. The plaque scatters light and therefore attenuates the OCT beam, limiting the image penetration depth. Ophthalmic and intravascular imaging have emerged as two of the major applications of OCT which are now in clinical practice.

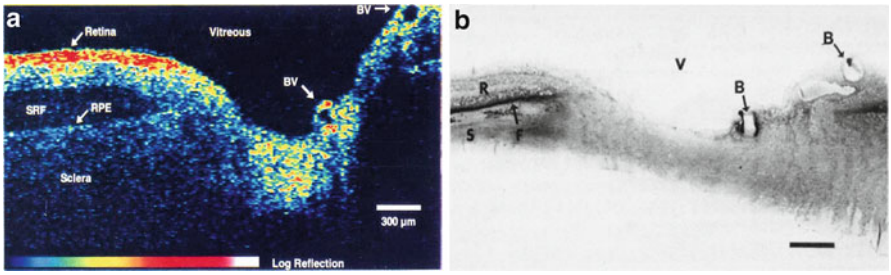

Fig. 1.6 OCT image of the human retina ex vivo and corresponding histology. Imaging was performed with 15 µm axial resolution in tissue at 830 nm wavelength. The OCT image is displayed using a log false color scale spanning –60 to –90 dB of the incident light intensity. The image shows the optic nerve head contour and vasculature. The retinal nerve fiber layer can be visualized and there is postmortem retinal detachment with subretinal fluid accumulation (From Huang et al. [1])

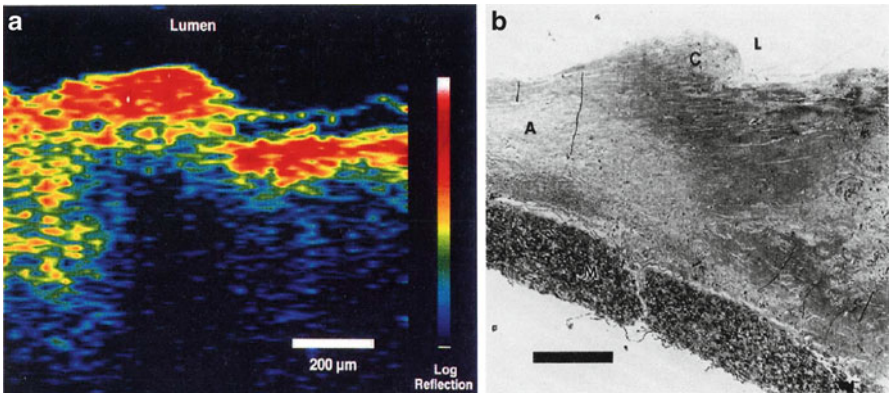

Fig. 1.7 OCT image of human artery ex vivo and corresponding histology. The OCT image shows fibrocalcific plaque (*right* three-quarters of specimen) and fibroatheromatous plaque (*left*). The fatty-calcified plaque scatters light and attenuates the OCT beam, limiting the image penetration depth (From Huang et al. [1])

Optical coherence tomography has the advantage that it can be implemented using fiber-optic components and integrated with a wide range of medical instruments. OCT systems can be divided into an imaging engine (consisting of an interferometer, light source, and detector) and imaging devices or probes. Early OCT imaging engines employed time domain detection with an interferometer using a low-coherence light source and scanning reference arm delay. Figure 1.8 shows an example of an OCT system using a fiber-optic Michelson-type interferometer with time domain detection. A low-coherence light source is coupled into the interferometer. One arm of the interferometer emits a beam which is directed and scanned on the sample being imaged, while the other arm is a reference with

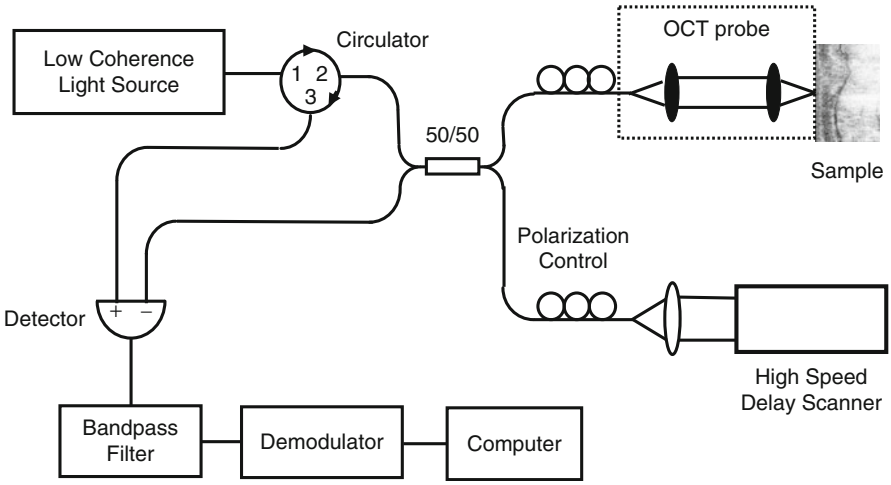

Fig. 1.8 OCT imaging system based on a fiber-optic Michelson interferometer. OCT has the advantage that it uses photonics and fiber optics technology. This schematic shows a Michelson interferometer with a circulator for dual balanced detection. Dual balanced detection adds the signal from the interference of the sample and reference arms and subtracts excess noise from the light source. The sample/probe arm may be interfaced to a variety of imaging devices. OCT interferometers can be built in many different configurations depending on design requirements

a scanning delay. The interferometer shown in Fig. 1.8 uses a circulator to collect the interference signal which returns to the light source to improve efficiency. This interference signal is out of phase with the other interferometer output. When these two signals are subtracted, the desired interference signal adds and excess noise from the light source is cancelled. This configuration is known as dual balanced detection and is used in coherent optical communications systems [22]. There are many different embodiments of the interferometer and imaging engine which have different power delivery and detection efficiency advantages [23]. ▶ Chapter 11, "Optical Design for OCT," discusses aspects of OCT system design in more detail.

Because the eye is optically accessible and optical imaging methods are widely used in ophthalmology, many of the earliest OCT studies were in the eye. The first in vivo retinal images were obtained independently in 1993 by Fercher et al. [24] and Swanson et al. [25]. Figure 1.9 shows an early in vivo OCT image of the normal human retina from Hee et al. in 1995 [26]. Imaging was performed at 800 nm wavelength with ~10 μm axial resolution in tissue. The nerve fiber layer as well as other architectural features can be visualized with higher resolution than was previously possible. Several thousand patients were imaged at the New England Eye Center in the mid-1990s. These early clinical studies investigated OCT for the diagnosis and monitoring of a variety of macular diseases [27], including macular edema [28, 29], macular holes [30], central serous chorioretinopathy [31], and age-related macular degeneration and choroidal

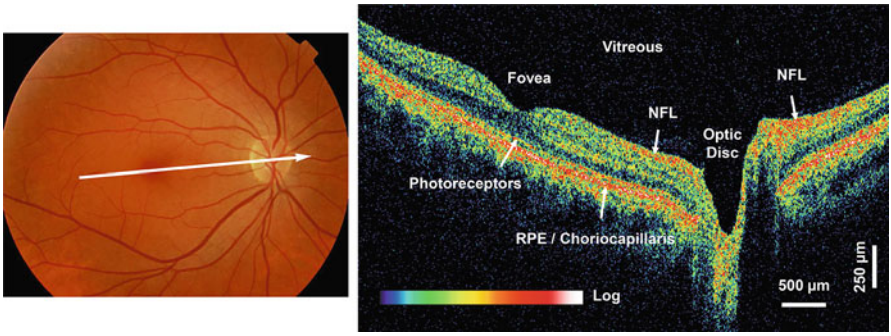

Fig. 1.9 Early in vivo OCT image of the normal retina in a human subject. Imaging was 10 µm axial resolution at 800 nm wavelength. The retinal pigment epithelium, choroid, and retinal nerve fiber layers are visible as highly backscattering layers. OCT can noninvasively visualize and quantitatively measure retinal pathology and is now a standard of care in clinical ophthalmology (From Hee et al. [26])

neovascularization [32]. The retinal nerve fiber layer thickness, an indicator of glaucoma, can be quantified in normal and glaucomatous eyes and correlated with conventional measurements of the optic nerve structure and function [33,34]. Many of the measurement protocols that were developed in these early studies were adopted in current OCT ophthalmic instruments [7].

The high detection sensitivity of OCT enables imaging structures such as the retina which have very low optical scattering. Typical retinal images have signal levels of −50 to −90 dB of the incident intensity. For retinal imaging, safety standards govern the maximum permissible light exposure and set limits for OCT imaging speeds [25, 26]. However, the majority of OCT applications require imaging in tissues which are not transparent, but instead are highly scattering. In this case, detection sensitivity is also important because light is highly attenuated by scattering and the sensitivity determines the imaging depth.

OCT imaging in tissues other than the eye became feasible with the recognition that using longer optical wavelengths can reduce scattering and increase image penetration depths [3, 35, 36]. Figure 1.10 shows an early example from Brezinski et al. 1996 showing OCT imaging in a human epiglottis ex vivo, comparing imaging at 850 nm and 1,300 nm wavelengths [3]. The dominant absorbers in most tissues are melanin and hemoglobin, which have absorption at visible and near-infrared wavelengths [37]. Water absorption becomes dominant for longer wavelengths, approaching 1,900–2,000 nm. In most tissues, scattering at near-infrared wavelengths is one to two orders of magnitude higher than absorption, and scattering decreases for longer wavelengths. Therefore, imaging at 1,300 nm improved image penetration and has become a standard wavelength for most non-ophthalmic OCT applications.

Early studies investigated the mechanisms of OCT image contrast as they are related to tissue optical properties [35, 38]. ▶ Chapter 3, “Modeling Light–Tissue Interaction in Optical Coherence Tomography Systems” considers these

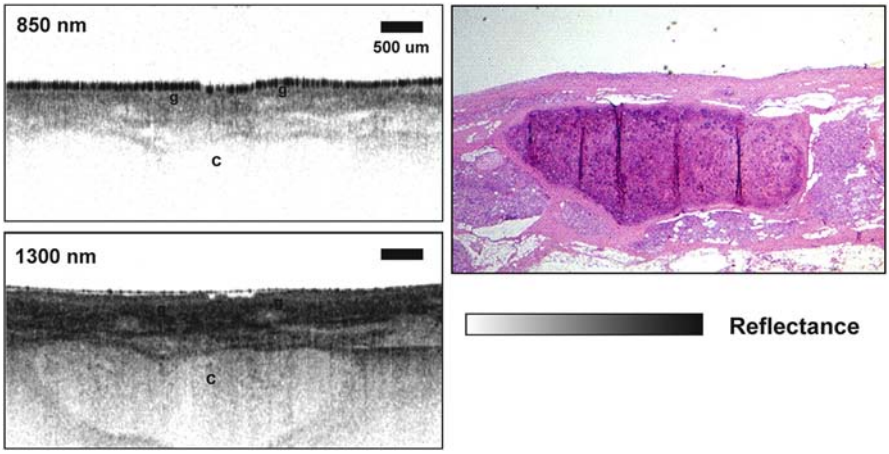

Fig. 1.10 OCT imaging penetration depth. OCT in scattering tissues was made possible using longer wavelengths which are less attenuated by scattering. OCT images of human epiglottis ex vivo performed with 850 nm and 1,300 nm wavelengths. Superficial glandular structures (*g*) can be seen in images with 850 nm and 1,300 nm wavelengths, but the underlying cartilage (*c*) is better visualized with longer 1,300 nm wavelength. With a detection sensitivity of ~90–100 dB, image penetration depths of up to 2–3 mm are possible in most scattering tissues (From Brezinski et al. [3])

mechanisms in detail. In OCT images, tissue structures are visible because they have different optical scattering properties. OCT images show true tissue dimensions (correcting for index of refraction and beam refraction effects); however, if OCT is displayed using a false color image, the colors represent different optical properties and not necessarily different tissue morphologies. In histology, histological sections are stained in order to produce selective contrast between different tissue structures. There are multiple stains available for histology which are highly specific. OCT relies on intrinsic differences in optical properties of different tissues in order to produce image contrast. On one hand this is a limitation because tissue structures, for example, nuclei of cells, may not have contrast in OCT imaging. However, histology is a time-consuming process which requires tissue excision, processing, embedding, sectioning, and staining, while OCT imaging can be performed on tissue in situ and in real time, without the need for excision and processing.

Several early OCT imaging studies were performed using ex vivo surgical specimens [3, 39–50]. These studies helped to define which structural features were visible using OCT and to establish a baseline for comparison to histology. Figure 1.11 shows an example of one of the first OCT images of arterial plaque ex vivo and corresponding histology from Brezinski et al. 1996 [3]. The OCT image has an axial resolution of ~15 μm in tissue and imaging was performed at 1,300 nm wavelength. The figure shows an unstable plaque characterized by a thin intimal cap layer, adjacent to a heavily calcified plaque with low lipid content.

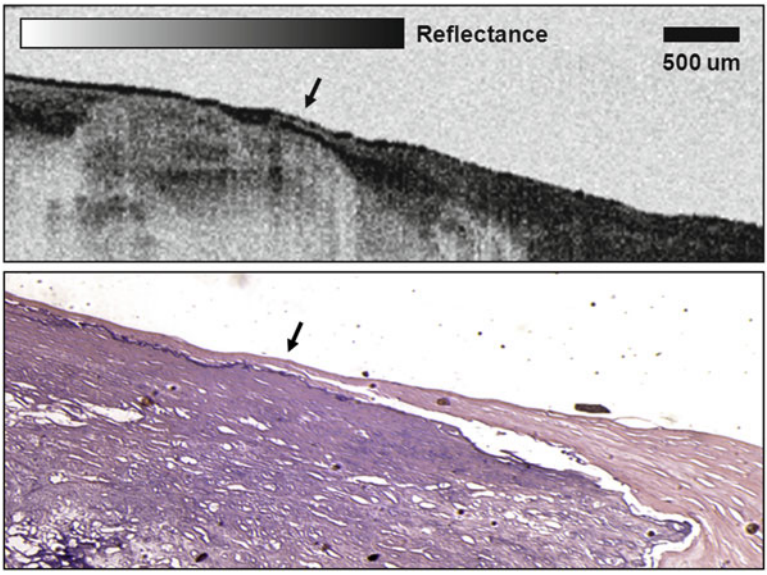

Fig. 1.11 Early OCT image of atherosclerotic plaque ex vivo and corresponding histology. The plaque is highly calcified with relatively low lipid content and a thin intimal cap. This result demonstrated that OCT can resolve morphological features associated with unstable plaques (From Brezinski et al. [3])

The demonstration that OCT could resolve unstable plaque in ex vivo specimens was an important milestone which helped lead to the later clinical development of intravascular OCT imaging.

Another active area of OCT research is the detection of neoplastic changes. Early studies were performed ex vivo to correlate OCT images with histology for gastrointestinal [40, 41, 44, 50], biliary [45], female reproductive [47, 49], pulmonary [46], and urinary [42, 48] pathologies. Figure 1.12 shows an example from an early OCT imaging study of gastrointestinal neoplasia. The figure shows OCT images and corresponding histology of normal colon and adenocarcinoma ex vivo. Imaging was performed with an axial resolution of ~15 μm in tissue at 1,300 nm wavelength. The OCT image of normal colon shows normal glandular organization associated with columnar epithelial structure. The mucosa and muscularis mucosa can be differentiated by the different backscattering characteristics within each layer. Architectural morphology, such as crypts or glands within the mucosa, can be visualized. The OCT image of adenocarcinoma shows disruption of architectural morphology or glandular organization. However, assessing cancer pathology is an extremely challenging application. OCT has significant limitations in both tissue contrast and resolution compared with the gold standard of excisional biopsy and histopathology. These challenges have been a factor in the slower development of OCT for cancer applications.

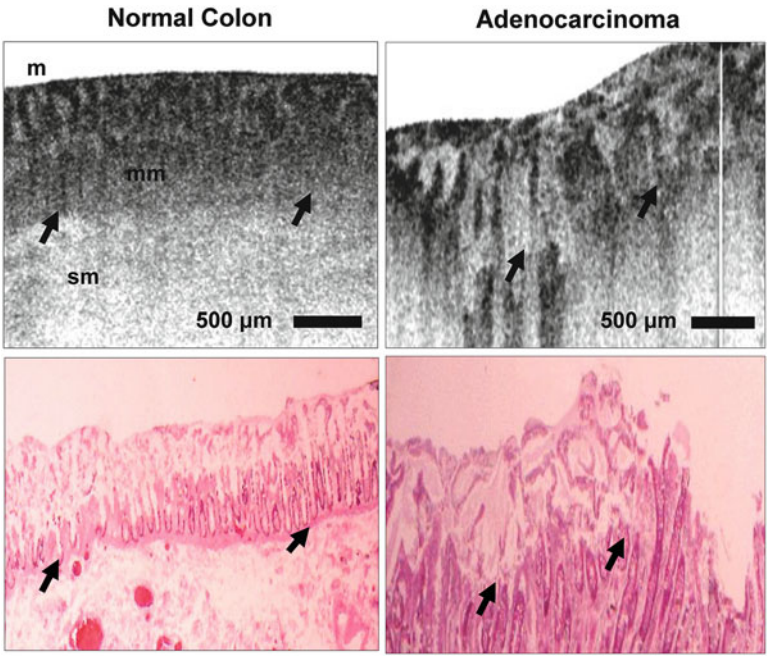

Fig. 1.12 OCT imaging of neoplastic changes. Early ex vivo OCT image of normal colon (*left*) and adenocarcinoma (*right*) with corresponding histology. The mucosal (*m*), muscularis mucosa (*mm*), and submucosal (*sm*) layers of the normal colon are visible. Dilated and disorganized crypts (*c*) are visible in the specimen with adenocarcinoma. OCT can visualize changes in architectural morphology (Pitris et al. [50])

1.4.2 Ophthalmic OCT Imaging

The earliest clinical studies with OCT were performed in ophthalmology, and to date OCT has had the largest clinical impact in this specialty. OCT is a powerful technique in ophthalmology because it can identify markers of early disease at treatable time points before visual symptoms and irreversible vision loss occurs. Furthermore, repeated imaging can be performed to track disease progression or monitor the response to therapy. The development of a prototype clinical instrument was a key step to enabling early studies in ophthalmology. Figure 1.13 shows a photograph of an early prototype instrument for OCT retinal imaging that was designed and built by Eric Swanson at MIT Lincoln Laboratories in the mid-1990s. The instrument was based on a slit lamp biomicroscope and provided a simultaneous view of the retinal fundus for aiming and registering the OCT imaging beam. This instrument was used in the New England Eye Center to perform the first clinical studies of OCT in ophthalmology [25–27, 51]. Several thousand patients were imaged in cross-sectional as well as longitudinal studies during the mid-1990s.

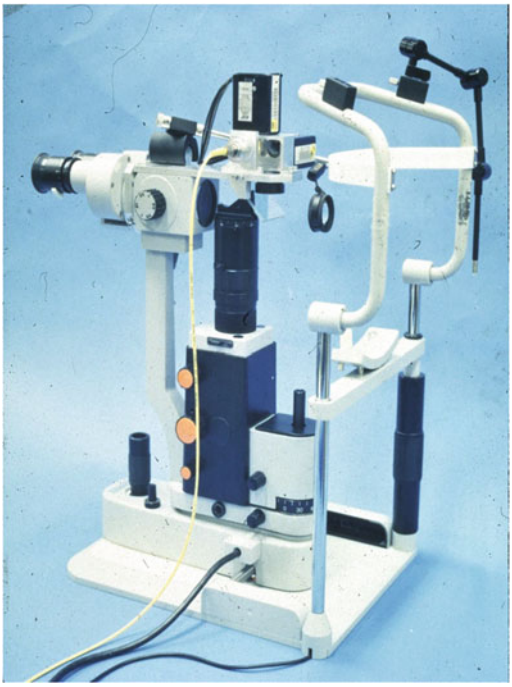

Fig. 1.13 Photograph of an early retinal imaging prototype instrument. The OCT system is interfaced with a slit lamp biomicroscope. The OCT beam is scanned using a pair of galvanometer-actuated mirrors. This system was used at the New England Eye Center and imaged several thousand patients during the mid-1990s (Courtesy of Eric Swanson)

Figure 1.14 shows a schematic diagram of the optical design for retinal imaging. Similar design principles were used for OCT using low numerical aperture microscopes imaging developmental biology specimens in vivo as well as for surgical imaging applications [39, 52, 53]. An objective lens relays an image of the retina onto an intermediate image plane where it can be viewed by the operator or a video camera. The OCT beam is coupled into the instrument using a beam splitter and focused onto the intermediate image plane using a relay lens and then imaged onto the retina by the objective lens and the subject's eye. The transverse spot size of the OCT beam on the retina is typically ~20 μm and is limited by ocular aberrations. The transverse position of the OCT beam is scanned by two perpendicular x-y galvanometer scanning mirrors. The optical system is designed so that the beam pivots about the pupil of the eye when it is scanned. This prevents the OCT beam from being vignetted by the pupil and enables a wide field of view on the retina. OCT imaging can be performed at different locations on the retina by controlling the scanning of the OCT beam. When the OCT beam is scanned, it is visible on the retina that is visible to the operator, enabling aiming. The OCT beam is also visible to the patient as a small spot or scanned line, whose position in the patient's visual field corresponds to the points on the retina that are being scanned. Since the scanning trajectory of the OCT beam on the retina can be controlled, different scan patterns can be designed and adopted as part of the diagnostic protocol for specific retinal diseases.

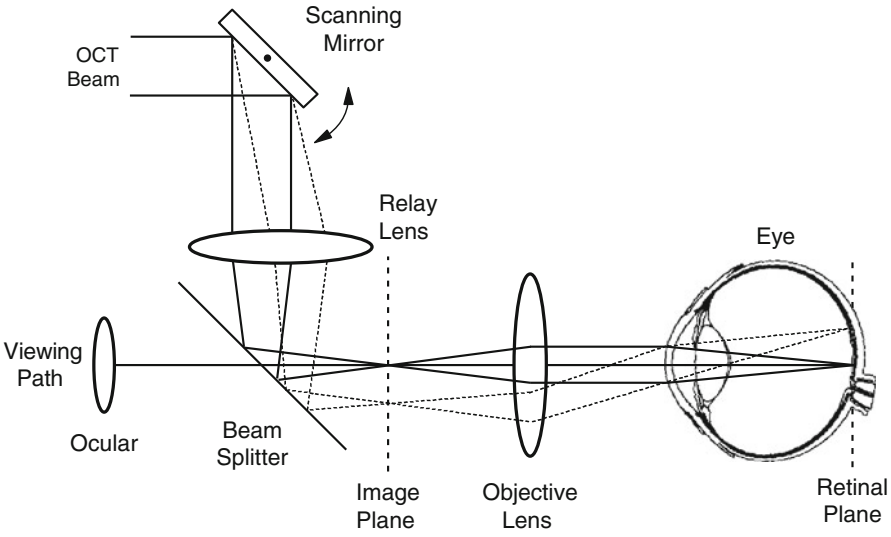

Fig. 1.14 Schematic of OCT instrument design for retinal imaging. An objective lens relay images the retina to a plane in the OCT instrument. Operator viewing of the fundus is performed by imaging with a video camera. Computer-controlled galvanometer scanning mirrors positions and scan the OCT beam. A relay lens focuses the OCT beam onto the image plane, and the objective lens directs the OCT beam through the pupil onto the retina. The OCT beam is focused on the retina by adjusting the objective lens. The OCT beam pivots about the pupil of the eye in order to minimize vignetting

OCT is important for the diagnosis and monitoring of diseases such as glaucoma, age-related macular degeneration, and diabetic retinopathy because it provides quantitative information on retinal pathology which is a measure of disease progression or response to therapy [29, 33, 54]. Images can be analyzed quantitatively and processed using intelligent algorithms to extract features such as retinal or retinal nerve fiber layer thickness. Mapping and display techniques have been developed to display OCT data in alternate forms, such as thickness maps, in order to aid interpretation. Figure 1.15 shows an early example of an OCT topographic map of retinal thickness [29]. The thickness map was constructed by performing six standard OCT scans at varying angular orientations through the fovea. The OCT images are segmented to detect the retinal thickness which is then linearly interpolated over the macular region and represented as a false color topographic map. For quantitative interpretation, the macula is divided into different regions and averaged values of retinal thickness are displayed. The ability to reduce image information to numerical information is important because it enables the development of normative databases and the use of statistical criteria for disease diagnosis.

OCT technology was transferred to industry by our group at MIT and introduced commercially for ophthalmic diagnostics in 1996 (Carl Zeiss Meditec). Early instruments had an axial resolution of 10 um and an imaging speed of 100 A-scans/s.

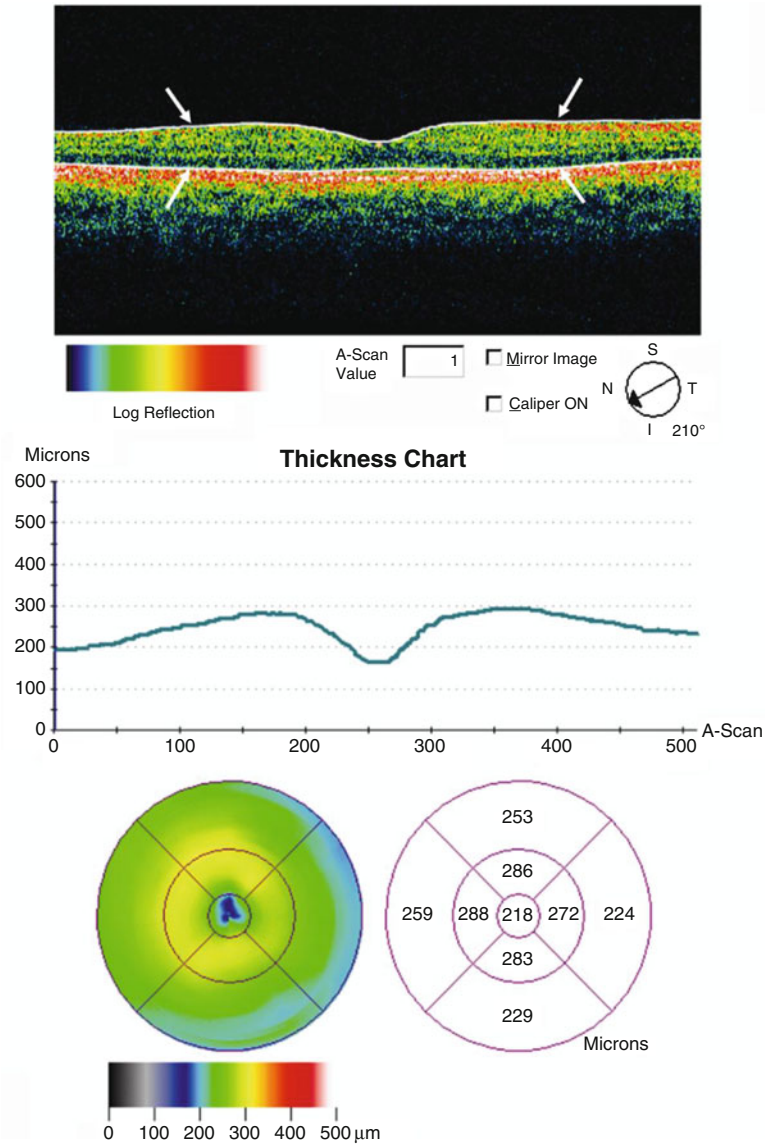

Fig. 1.15 OCT topographic map of retinal thickness. (*Top*) OCT image of the macula which has been segmented in order to measure retinal thickness. The anterior and posterior retinal surfaces are automatically identified. (*Middle*) Quantitative measurement of retinal thickness based on the segmented OCT image. (*Bottom*) Topographic map of macular retinal thickness. The topographic map is constructed by segmenting multiple OCT scans which are radially oriented in the macula, measuring the retinal thickness, and interpolating the retinal thickness in the regions between the scans. Retinal thickness is represented by a color table and has the advantage that it can be directly compared with the retinal fundus image

A third generation ophthalmic instrument, the Stratus OCT, was introduced in 2002 which had similar resolution, but faster speed of 400 A-scans/s. The increased speed enabled an increase in image pixel density. The large amount of published clinical data from previous generation instruments, coupled with technological improvements and reimbursement, helped the clinical adoption of OCT. By the mid-2000s, OCT became a standard of care in ophthalmology and is considered essential for the diagnosis and monitoring of many retinal diseases [7]. With increases in imaging speed provided by spectral/Fourier domain detection, many companies entered the ophthalmic marketplace in the mid-2000s.

1.4.3 Catheter and Endoscopic OCT Imaging Technology

Flexible imaging probes such as catheters and endoscopes were key to enabling internal body OCT imaging [55, 56]. Figure 1.16 shows one of the first OCT catheter/endoscopes devices. This device was a prototype for modern OCT intravascular imaging catheters and endoscopic probes. The catheter/endoscope has a single-mode optical fiber in a hollow rotating torque cable, coupled to a distal lens and microprism that reflects the OCT beam radially. The torque cable and distal optics are contained in a transparent housing. The OCT beam is scanned by rotating the torque cable to generate a transverse image in luminal structures or hollow organs. Imaging may also be performed in a longitudinal plane by push-pull movement or a spiral rotation and pullback of the torque cable assembly [57]. The early catheter/endoscope shown in Fig. 1.16 had a diameter of 2.9 French or 1 mm, similar to a standard IVUS catheter. The development of catheter imaging devices is challenging because of the simultaneous mechanical, optical, and biocompatibility requirements. Early commercial devices (such as the LightLab

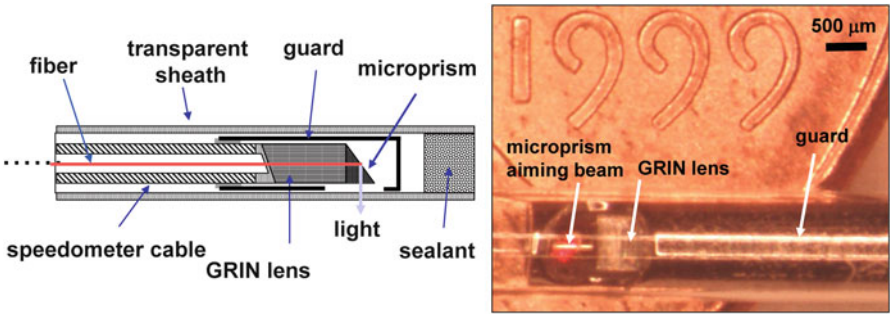

Fig. 1.16 Catheter/endoscopic OCT imaging. Schematic and photograph of an early OCT catheter/endoscope for intraluminal imaging. A single-mode fiber is contained in a rotating flexible speedometer cable which is enclosed in a protective plastic sheath. The distal end has a lens and prism/mirror which focuses the beam at 90° from the catheter axis. The diameter of the catheter is 2.9 French or ~1 mm. The catheter is shown on a United States coin for scale. OCT can be integrated with a wide range of diagnostic and interventional devices

Imaging ImageWire™ and Helios™ occlusion balloon catheters) used micro-optic fabrication methods to create lenses and beam-directing elements which have diameters of optical fibers (80–250 μm), significantly smaller than can be achieved with IVUS catheters.

1.4.4 Intravascular OCT Imaging

Intravascular imaging is the second most developed clinical OCT application. Figure 1.17 shows the first catheter-based image of a human coronary artery ex vivo using an early prototype 2.9 F OCT catheter, from Tearney et al. in 1996 [58]. The figure shows a comparison of OCT with 30 MHz intravascular ultrasound (IVUS). The OCT image shows excellent differentiation of the intima, media, and adventitia and suggested the utility of intravascular OCT. In vivo intravascular OCT imaging was challenging because of the need to develop suitable catheter imaging devices which could be used in animals and human subjects. In addition, since blood is highly optically scattering, it was necessary to develop saline/contrast flushing or balloon occlusion protocols to remove blood or to significantly dilute the hematocrit in the imaging field. Intravascular OCT animal imaging studies were performed in a rabbit model by Fujimoto et al. in 1999 [59]. Imaging was performed using a 2.9 F optical catheter using a time domain OCT system with a broadband femtosecond laser at 1,280 nm wavelength to achieve 10 um axial resolution. Imaging speeds were 4 frames/s with a 512 axial pixel images. Because blood is highly optically scattering at normal hematocrit, saline flushing was required to dilute the hematocrit during imaging. Intravascular animal imaging studies were performed in a porcine model using saline flushing by Tearney et al. in 2000 [60].

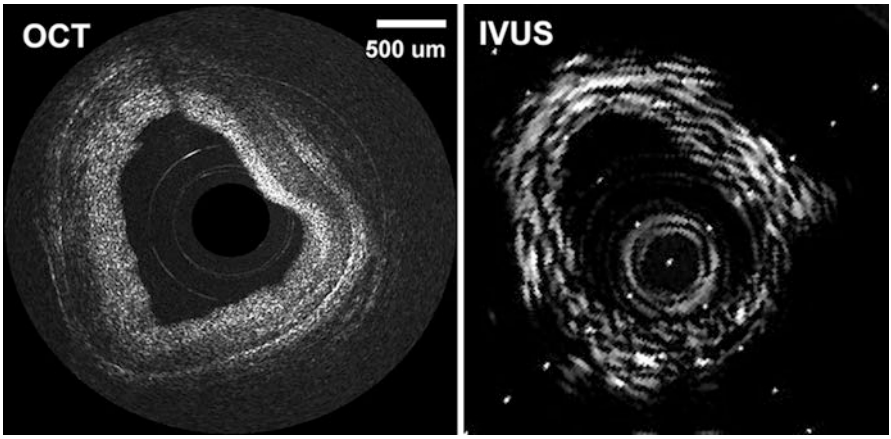

Fig. 1.17 Early OCT image of a human artery ex vivo and comparison with intravascular ultrasound (*IVUS*). The OCT image has 15 μm axial resolution and enables the differentiation of the intima, media, and adventitia. Intimal hyperplasia is evident. IVUS has deeper image penetration, but lower resolution (From Tearney et al. [58])

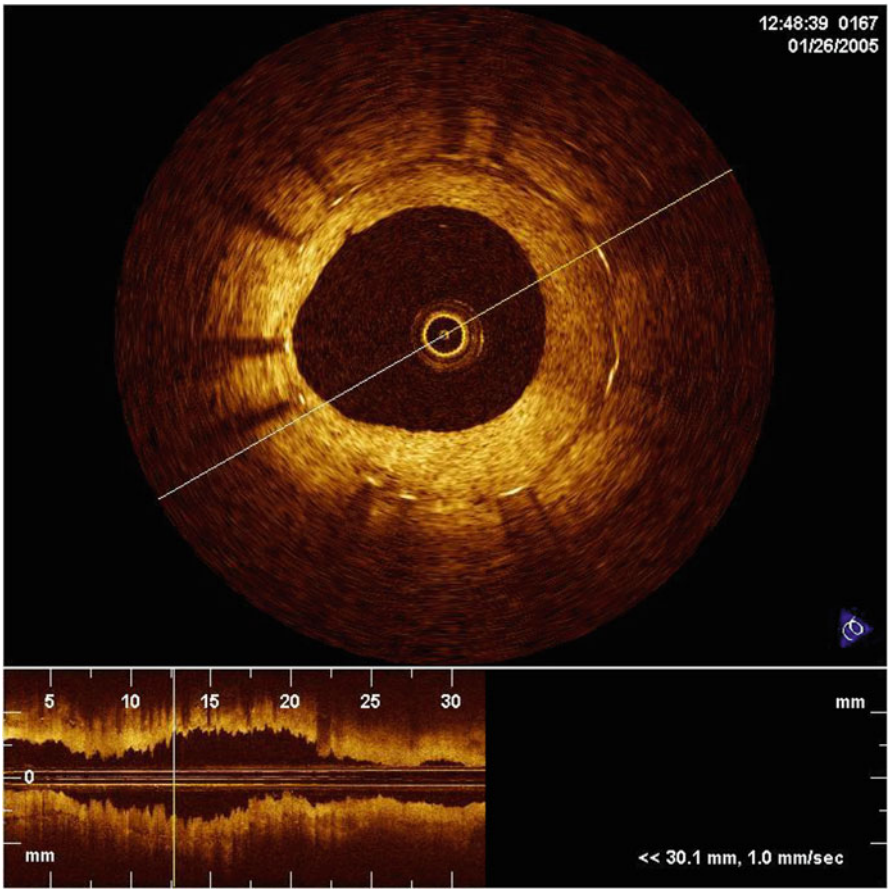

Fig. 1.18 Intravascular OCT. Early OCT image and pullback of a stent with neointimal growth in a human artery in vivo. Saline flushing was used to remove blood from the imaging field. Imaging was performed with the LightLab M2 and an occlusion balloon catheter. Modern intravascular OCT instruments use contrast flushing without occlusion (Courtesy of LightLab Imaging)

This study reported OCT imaging of normal coronary arteries, intimal dissections, and stents with 10 μm resolution.

OCT imaging in human patients was first reported by Jang et al. in 2001 [61]. This pioneering study used a 3.2 F OCT imaging catheter and demonstrated imaging of tissue prolapse in a stent, comparing OCT with IVUS. The study was a significant landmark because it addressed multiple technological, clinical, and administrative challenges. Independent clinical demonstrations by Grube et al. at the Siegburg Heart Center were reported in 2002 using a prototype instrument developed by LightLab Imaging [62]. Other early studies compared OCT with IVUS for visualization of stent placement and apposition [63, 64]. Figure 1.18 shows an early example of intravascular OCT imaging of a partially restenosed

stent with a corresponding L-mode pullback image (courtesy of Osaka City University Hospital and LightLab Imaging). This image was acquired using an occlusion balloon catheter and shows neointimal growth over a stent. Modern intravascular OCT instruments use flushing with contrast agents to dilute hematocrit combined with high-speed imaging.

Intravascular OCT imaging is currently an active area of both research and commercialization. The commercial development of intravascular OCT was performed by an MIT startup in 1998. The first commercial intravascular OCT instrument generated images with 200 A-scans at 15 frames/s and was introduced in Europe in 2004. A higher performance system with 240 A-scan per frame at 20 frames/s was introduced in 2007. A system based on swept source/Fourier domain detection achieved 500 A-scans per frame at 100 frames per second, and FDA approval was obtained in 2010. ▶ Chapters 69, "Imaging Coronary Atherosclerosis and Vulnerable Plaques with Optical Coherence Tomography" and ▶ 70, "Cardiovascular Optical Coherence Tomography" describe intravascular OCT in more detail. ▶ Chapter 71, "Intravascular OCT" discusses the process of commercialization of OCT from the perspective of intravascular imaging.

1.4.5 Endoscopic OCT and Cancer Detection

The first demonstrations of in vivo endoscopic OCT imaging were performed in 1997 [56, 65]. Figure 1.19 shows an example of OCT imaging of the rabbit esophagus in vivo and corresponding histology, from Tearney et al. [56]. This image demonstrates visualization of the esophageal layers including the mucosa (m), the submucosa (sm), the inner muscularis (im), outer muscularis (om), and serosa (s). The first clinical studies of endoscopic OCT imaging in human subjects were reported by Sergeev et al. in 1997 [65] and Feldchtein et al. in 1998 [66].

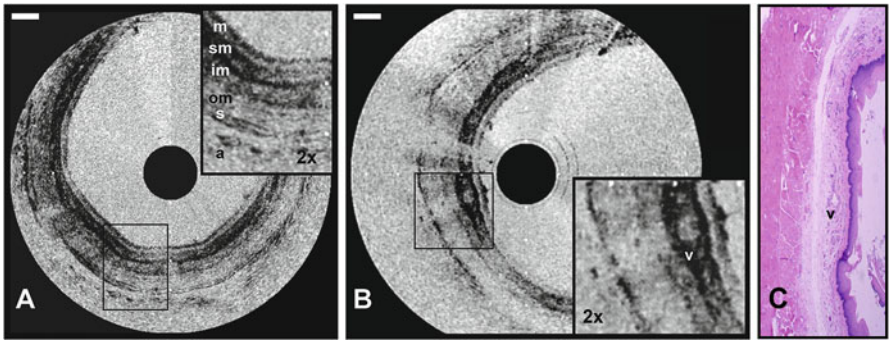

Fig. 1.19 Endoscopic OCT image of the rabbit esophagus in vivo demonstrating internal body imaging. (**a**) Esophageal layers including the mucosa (*m*), submucosa (*sm*), inner muscular layer (*im*), outer muscular layer (*om*), serosa (*s*), and adipose and vascular supporting tissues (*a*) can be visualized. (**b**) A blood vessel (*v*) can be seen within the submucosa. (**c**) Corresponding histology. Scale 500 um (Tearney et al. [56])

OCT imaging was performed with a flexible forward scanning probe in the working channel of a standard endoscope, bronchoscope, or trocar. The imaging device was a 1.5–2 mm diameter probe which used a miniature magnetic scanner to image in the forward direction. These early studies demonstrated the feasibility of performing clinical OCT imaging of organ systems such as the esophagus, larynx, stomach, urinary bladder, and uterine cervix.

Gastrointestinal (GI) endoscopy received considerable attention due to the prevalence of esophageal, stomach, and colon cancers. In contrast to conventional endoscopy that visualizes surface features, OCT can image subsurface tissue morphology. Early studies of endoscopic OCT imaging suggested the ability of OCT to differentiate GI pathologies such as the Barrett's esophagus, adenomatous polyps, and adenocarcinoma [57, 65, 67–73]. However, the development of OCT imaging for cancer detection remains extremely challenging. Conventional histopathology is an extremely powerful diagnostic technique because it enables the use of selective stains to enhance contrast between different cellular or tissue structures. Histology also provides extremely fine image resolutions, enabling the visualization of not only larger scale tissue architectural morphology but also subcellular structure. OCT imaging relies on intrinsic contrast produced by variations in scattering properties of different tissue structures. On the positive side, OCT enables real time imaging of tissue pathology in situ, without the need for excision and processing as in conventional biopsy and histopathology. When used to guide biopsy, it is not necessary for OCT to perform at the level required for diagnosis, but it must have sufficient sensitivity to detect pathology and improve the sensitivity of excisional biopsy by reducing sampling errors.

The development of OCT for cancer detection will require detailed clinical studies which investigate its ability to identify relevant pathologies. These types of studies are challenging because the sensitivity and specificity of OCT imaging must be evaluated relative to biopsy and histopathology which is the gold standard for diagnosis. Since pathology varies depending upon location, precise registration of OCT imaging and excisional biopsy is required. This is an especially challenging problem in endoscopic applications. Sufficient numbers of patients having a given pathology must be investigated in order to ensure that the sample size is large enough to generate statistically significant results. Because many types of dysplasia or cancer have a low incidence, patient enrollments may be large. For these reasons, the investigation and development of OCT for cancer diagnosis remains a challenging and ongoing area of research. Part 2 of this book, Optical Coherence Tomography Applications, includes several chapters which survey a broad range of OCT applications, including the detection of early neoplastic changes in different organ systems.

In addition to catheters and endoscopes, many other early OCT imaging instruments were developed including forward imaging devices that perform one- or two-dimensional beam scanning. Rigid laparoscopes use relay imaging with Hopkins-type relay lenses or graded index rod lenses. OCT can be integrated with laparoscopes to permit internal body OCT imaging with a simultaneous en face view of the region being imaged [65, 74, 75]. Handheld imaging probes have

also been demonstrated [75, 76]. These devices resemble pens and use piezoelectric or galvanometric beam scanning. Handheld probes can be used in open field surgical situations to enable the clinician to view subsurface tissue structure by aiming the probe at the desired location. These devices can also be integrated with conventional scalpels or laser surgical devices to permit simultaneous, real time viewing as tissue is being resected. There has been considerable interest in the use of MEMS scanning devices for OCT imaging probes. MEMS devices enable one- or two-dimensional beam scanning and are a promising technology for developing miniature OCT imaging devices [77–80].

1.5 Advances in Image Resolution

1.5.1 Axial Resolution and Depth of Field

Image resolution is one of the most important parameters governing OCT image quality and developing methods to achieve ultrahigh resolution was a major focus of early research. In contrast to standard microscopy, OCT can achieve fine axial resolution independent of the beam focusing and spot size. The axial image resolution in OCT is determined by the measurement resolution for echo time delays of light. In low-coherence interferometry, the axial resolution is given by the width of the field autocorrelation function, which is inversely proportional to the bandwidth of the light source. For a Gaussian-shaped spectrum, the axial resolution is

$$\Delta z = \frac{2\ln 2}{\pi} \cdot \frac{\lambda^2}{\Delta\lambda}$$

where Δz is the full-width-at-half-maximum of the autocorrelation function, $\Delta\lambda$ is the full-width-at-half-maximum of the power spectrum, and λ is the center wavelength of the light source [81]. Figure 1.20 shows a plot of axial resolution versus bandwidth for light sources with different wavelengths. Since axial resolution is inversely proportional to the bandwidth of the light source, broad bandwidth light sources are required to achieve high axial resolution.

The transverse resolution in OCT imaging is the same as in optical microscopy and is determined by the diffraction limited spot size of the focused optical beam. The diffraction limited minimum spot size is proportional to wavelength and inversely proportional to the numerical aperture or the focusing angle of the beam. The transverse resolution is

$$\Delta x = \frac{4\lambda}{\pi} \cdot \frac{f}{d}$$

where λ is the wavelength, d is the size of the incident beam on the objective lens, and f is the focal length. Fine transverse resolution can be obtained by using a large numerical aperture that focuses the beam to a small spot size. At the same time,

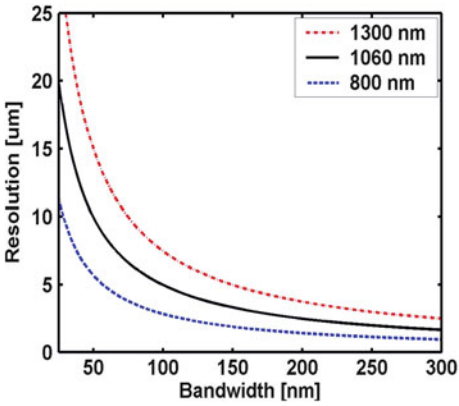

Fig. 1.20 Axial image resolution in OCT. Axial resolution versus light source bandwidths for center wavelengths of 800 nm, 1,000 nm, and 1,300 nm. Micron scale axial resolution requires extremely broad optical bandwidths and bandwidth requirements increase dramatically for longer wavelengths

because of diffraction, the transverse resolution also governs the depth of field or confocal parameter b, which is $2z_R$ or two times the Rayleigh range:

$$b = 2z_R = \frac{\pi \Delta x^2}{\lambda}$$

Thus, there is a trade-off between transverse resolution and depth of field; increasing the transverse resolution decreases the depth of field.

Figure 1.21 shows the relationship between focused spot size and depth of field for low and high numerical aperture focusing. Typically, OCT imaging is performed with low numerical aperture focusing in order to have a large depth of field. The confocal parameter is larger than the coherence length, $b > \Delta z$, and the axial resolution is governed by the measurement resolution for echo time delays of light. In contrast to microscopy, OCT can achieve fine axial resolution independent of the numerical aperture of the focusing. This feature is especially powerful for applications such as ophthalmic imaging or catheter/endoscope imaging, where numerical apertures are limited. However, low numerical aperture focusing also limits the transverse resolution because the focused spot sizes are large.

1.5.2 Optical Coherence Microscopy and En Face OCT

In order to improve the transverse image resolution, it is necessary to perform OCT imaging with high numerical aperture focusing to decrease the focused spot size (see Fig. 1.21). However, this results in a decreased depth of field. High numerical aperture imaging with fine transverse resolution is the typical operating regime for microscopy or confocal microscopy. Because of the limited depth of field, if very fine transverse resolution imaging is required, then it is more efficient to perform en face imaging, rather than cross-sectional imaging. In the limiting case of very high numerical aperture focusing, the depth of field can be comparable to or shorter than the coherence length, $b < \Delta z$, and a combination of confocal as well as coherence

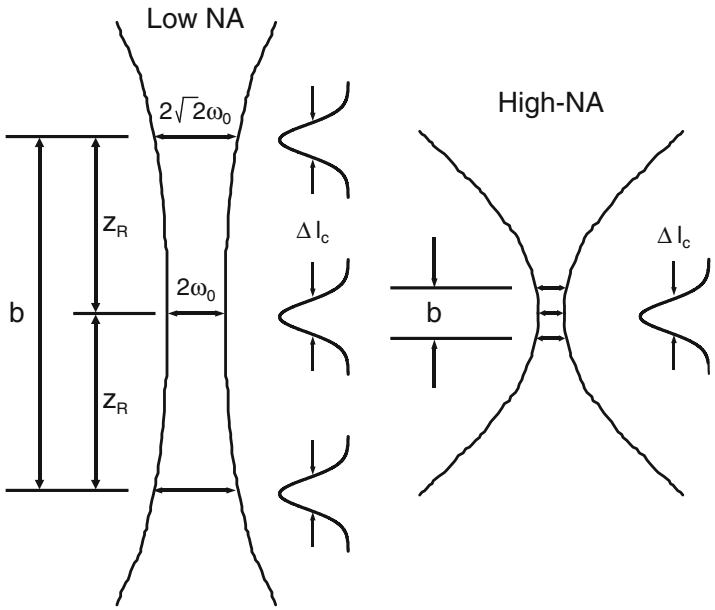

Fig. 1.21 Transverse image resolution in OCT. Transverse image resolution is determined by the focused spot size of the OCT beam and diffraction forces a trade-off between resolution and depth of field. OCT imaging is usually performed with low numerical aperture (*NA*) focusing, with the confocal parameter much longer than the coherence length, in order to generate cross-sectional images. A high NA focusing limit achieves fine transverse resolution, but has reduced depth of field. High NA focusing is used in optical coherence microscopy (*OCM*) for en face imaging

gating can be used to detect backscattered or backreflected signals from different depths and reject unwanted scattered light. This mode of operation is known as optical coherence microscopy (OCM) [40, 82, 83]. OCM achieves extremely fine transverse image resolution, on the order of 1–2 μm, and is useful for imaging tissues because the coherence gating rejects unwanted scattered light more effectively than confocal gating alone. OCM can achieve improved imaging depth and contrast compared with confocal microscopy.

Figure 1.22 shows an early example of OCT and OCM imaging of ex vivo lower GI pathology specimens [84]. Imaging was performed using a Nd:glass femtosecond laser at 1,060 nm that was spectrally broadened in a high numerical aperture optical fiber to a bandwidth of ~200 nm, yielding a 4 um axial image resolution. A combined OCT/OCM system was developed where OCM was performed by modulating the reference beam in the interferometer, raster scanning the sample beam, and demodulating the interference. The sample interface resembled a scanning confocal microscope and used 40× water immersion microscope objective which achieved <2 um transverse image resolution. The system imaged at 2 frames/s with 500 × 750 en face pixels over a 400 × 400 um field of view. Figure 1.22a, b shows ultrahigh-resolution cross-sectional OCT images of

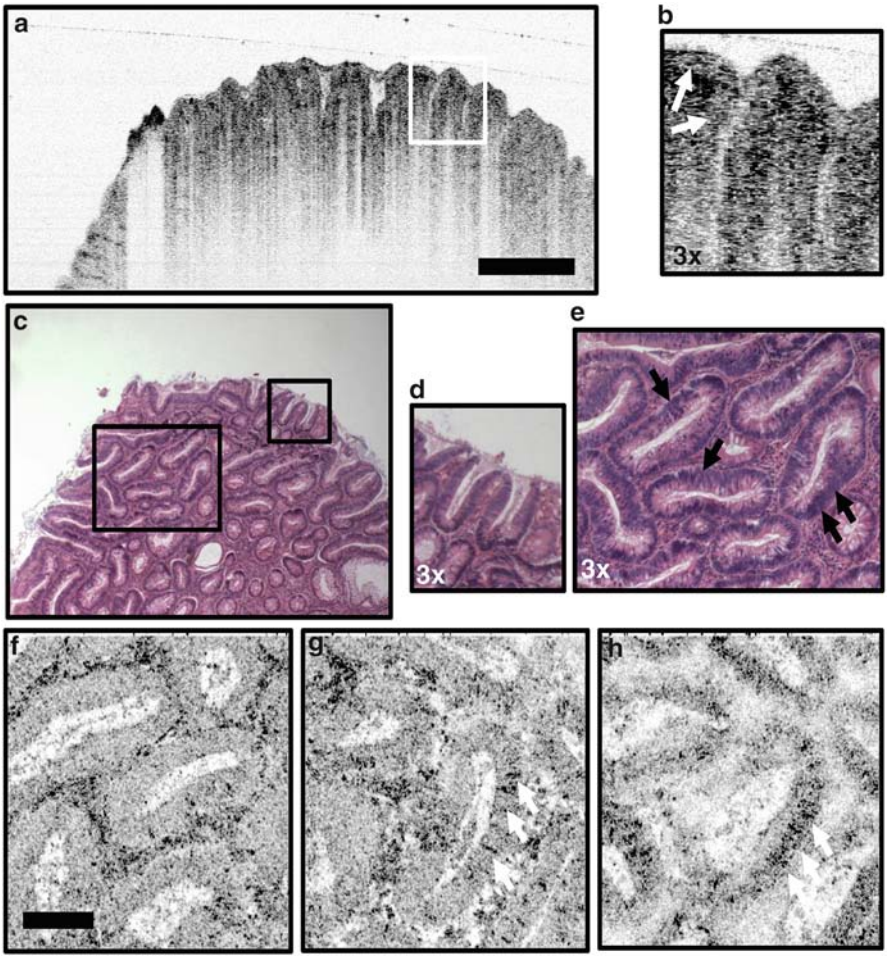

Fig. 1.22 OCT and OCM images of lower GI pathology ex vivo. (**a**, **b**) OCT of tubular adenoma shows parallel arrangement of long, slender crypt units, with the crypt epithelium identifiable from the lamina propria (**b**, *arrows*). (**c**–**e**) Corresponding histology. (**f**–**h**) OCM visualizes architecture en face, showing eccentric crypt lumens with varying shape and arrangement as well as oval-shaped nuclei. (**e**) Histology in the transverse plane shows corresponding features. OCM image depths for (**f**–**h**) were 80, 90, and 190 um, respectively. Scale bars: (**a**, **c**) 500 um; (**f**–**h**) 100 um (Aguirre et al. [84])

a tubular adenoma. The cross-sectional structure of the crypts is visible, but the OCT signal decreases with depth because of scattering as well as depth of field limitations, producing a signal gradient in the cross-sectional image. In contrast, the OCM images of Fig. 1.22f–h have uniform intensity and resolution because they are in en face planes. OCM images can be obtained at different depths by adjusting the focus depth while matching the reference arm path delay to the focus depth.

The en face OCM images have excellent image resolution, enabling visualization of the columnar epithelial structure as well as cell nuclei.

Although OCM has advantages in resolution, early OCM methods were difficult to implement because it was necessary to match the interferometer reference arm delay to the scanned beam path delay in the microscope sample arm interface. Standard confocal or multiphoton microscopes do not require constant path delay beam scanning and therefore it was difficult to make early OCM technology compatible with existing microscope designs. In addition, OCM requires acquiring one axial scan for each pixel in the image, because the image is in the en face plane. Therefore, high imaging speeds were needed in order to generate high pixel resolution images using standard OCT detection methods. Advances in OCT image speeds using spectral/Fourier domain and swept source/Fourier domain OCT (described in the next section) provided a solution to the problem of path delay matching because the dramatic increase in imaging speed enabled multiple en face depths, spanning the focal depth, to be acquired during a fast raster scan [85]. Related techniques, known as en face OCT, were developed in fields such as ophthalmology [86–88]. With the advent of high-speed imaging techniques, the low numerical aperture focusing meant that en face images at multiple depths could be generated from a single volumetric data set [89–91]. This was especially powerful in ophthalmology because it enables direct comparison with standard clinical imaging methods such as fundus photography or fluorescein angiography which image the retina in an en face plane.

The development of a technique known as full-field optical coherence tomography enabled optimized en face plane imaging and achieved extremely high pixel density images over wide fields of view [92–94]. Full-field OCT performs high-resolution en face imaging with coherence-gated detection using a Linnik interferometer and CCD cameras. Full-field OCT achieves cellular resolution imaging, and because a single spatial mode light is not required, it has the advantage that high axial resolution is possible using low-cost thermal or gas discharge light sources. Part II of this book, Optical Coherence Microscopy, includes several chapters which describe different approaches for en face imaging.

Since improving transverse resolution requires a trade-off in depth of field, to date, the majority of early studies have focused on improving axial resolution. Early OCT systems had axial resolutions of 10–15 μm. However, OCT systems can now achieve ultrahigh axial image resolution of <5 μm for endoscopic and catheter imaging and 2–3 μm for ophthalmic imaging [95–97]. These improvements in axial image resolution have been primarily driven by advances in superluminescent and laser light sources. ▶ Chapter 9, "Ultrahigh Resolution Optical Coherence Tomography" describes ultrahigh-resolution OCT in more detail.

1.5.3 Light Sources for Ultrahigh-Resolution OCT

Superluminescent diodes (SLDs) are the most commonly used light sources in OCT because they are compact and relatively inexpensive. Early ophthalmic OCT

instruments employed commercially available, GaAs superluminescent diodes which operated near 800 nm with bandwidths of ~30 nm to achieve axial resolutions of ~10 μm in tissue. Imaging in scattering tissues requires the use of longer wavelengths. Commercially available superluminescent diodes operating at 1,300 nm achieved axial resolutions of ~10 μm in tissue with output powers of several tens of mW. Since their early development, the performance of superluminescent diode light sources has improved dramatically and it is possible to multiplex diodes to achieve bandwidths of >150 nm, corresponding to axial resolutions as fine as 3–5 μm. ▶ Chapters 17, "Superluminescent Diode Light Sources for OCT" and ▶ 18, "SLEDs and Swept Source Laser Technology for OCT" describe advances in superluminescent diode technologies.

For research applications, femtosecond lasers are powerful light sources for ultrahigh-resolution OCT imaging because they can generate extremely broad bandwidths across a range of wavelengths in the near IR. Figure 1.20 shows the axial resolution in air as a function of bandwidth at center wavelengths of 800 nm, 1,000 nm, and 1,300 nm. These wavelengths can be generated using solid-state Ti:Al_2O_3, Nd:glass or Yb fiber, and Cr:forsterite lasers.

The Kerr lens mode-locked (KLM) Ti:Al_2O_3 laser is the most commonly used laser in femtosecond optics and ultrafast phenomena. Early OCT imaging studies by Bouma et al. in 1995 used Ti:Al_2O_3 lasers to demonstrate an axial image resolution of ~4 μm [98]. More recently, high-performance Ti:Al_2O_3 lasers have been made possible through the development of double-chirped mirror (DCM) technology [99]. Double-chirped mirrors can compensate high-order dispersion and have extremely broadband reflectivity, enabling the generation of few cycle optical pulses. Ti:Al_2O_3 lasers can achieve pulse durations of ~5 fs, corresponding to only two optical cycles and octave bandwidths at 800 nm [100–102]. Using state-of-the-art Ti:Al_2O_3 lasers, record OCT axial image resolutions of ~1 μm have been demonstrated [103]. Figure 1.23 shows a comparison of the optical bandwidth and interferometer traces showing the axial resolution of a superluminescent diode (SLD) and a Ti:Al_2O_3 laser. Optical bandwidths of ~260 nm were transmitted through the OCT instrument, corresponding to axial image resolution of ~1 μm. The first studies of ultrahigh-resolution imaging in the retina were reported by Drexler et al. in 2001 [95]. Figure 1.24 shows an example of the first ultrahigh-resolution OCT image of the human retina. The figure shows a ~3 μm axial resolution OCT obtained using a femtosecond laser light source. The middle and bottom images show enlargements of the macular region showing individual retinal layers. For ophthalmic applications, ultrahigh-resolution OCT enables visualization of internal retinal layers, including detailed features of the photoreceptors and photoreceptor outer segments which could be early markers of disease [104, 105].

Femtosecond Ti:Al_2O_3 lasers, in combination with high nonlinearity, air-silica microstructure fibers, or tapered fibers, can generate a broadband continuum. These fibers have enhanced nonlinearity because of their dispersion characteristics, which shift the zero dispersion to shorter wavelengths, and the small core diameters, which provide tight mode confinement. Microstructure and tapered fibers have been used with femtosecond Ti:Al_2O_3 lasers to achieve bandwidths spanning the

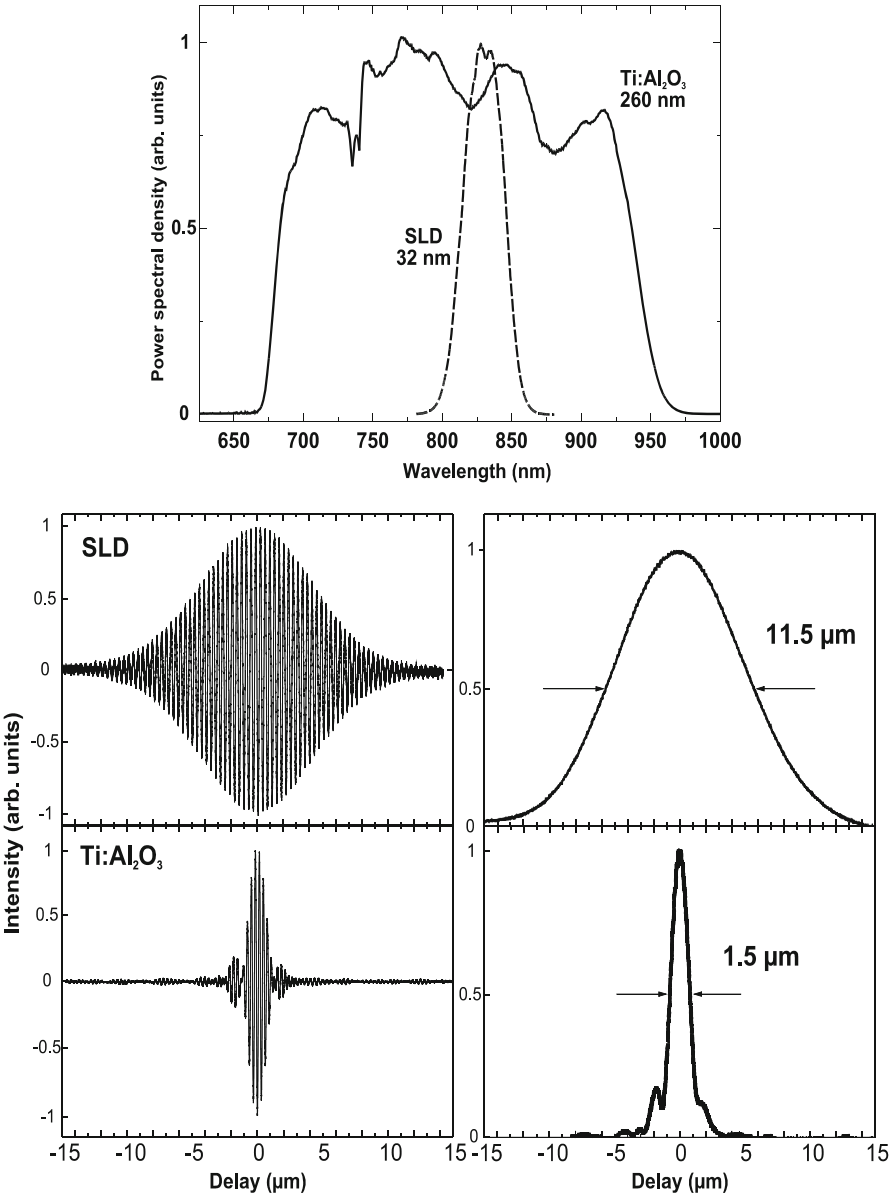

Fig. 1.23 Ultrahigh-resolution OCT. Optical spectrum, OCT interference signals and point spread functions using femtosecond Ti:Al_2O_3 laser versus a standard resolution superluminescent diode light source. The femtosecond laser has a bandwidth of 260 nm and achieves an axial resolution of 1.5 μm in air, corresponding to ~1 μm in tissue. In contrast, the superluminescent diode has a bandwidth of 32 nm and achieves a resolution of 11.5 μm (Drexler et al. [103])

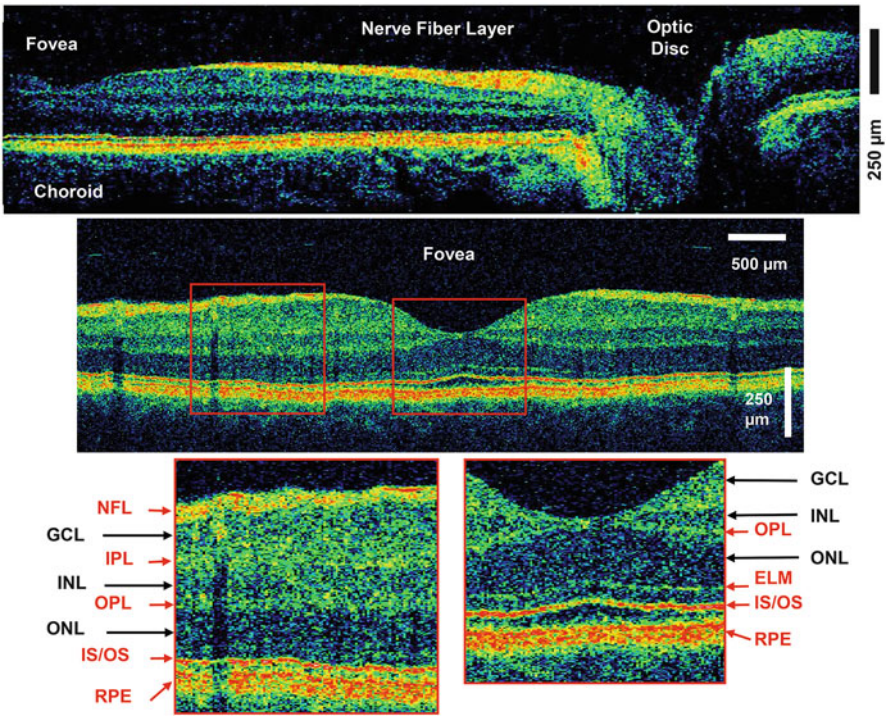

Fig. 1.24 Ultrahigh-resolution OCT image of the normal human retina in vivo. Ultrahigh-resolution OCT with 3 µm axial resolution at 800 nm wavelength enables visualization of the individual retinal layers including the nerve fiber layer (*NFL*), ganglion cell layer (*GCL*), inner and outer plexiform layers (*IPL* and *OPL*), inner and outer nuclear layers (*INL* and *ONL*), external limiting membrane (*ELM*), boundary between the inner and outer segments of the photoreceptors (*IS/OS*), and the retinal pigment epithelium (*RPE*) (Drexler et al. [95])

visible and near-infrared [106, 107]. Continuum generation from a femtosecond Ti:Al_2O_3 laser with air-silica microstructured photonic crystal fibers was demonstrated to achieve OCT axial image resolutions of 2.5 µm in the spectral region 1.2–1.5 µm [108], resolutions of 1.3 µm in the spectral region 800–1,400 nm [109], and record resolutions of <1 µm in the spectral region of 550–950 nm [110]. Although they have outstanding performance, femtosecond laser light sources are relatively costly and complex. Recently new Ti:Al_2O_3 lasers have been developed that can operate with much lower pump powers than previously thought possible, thereby greatly reducing cost [111, 112]. At the same time, there have been advances in multiplexed superluminescent diode SLD technology, and bandwidths >150 nm can be achieved, but with limited output power [113].

Longer wavelengths of 1,300 nm are required for most OCT imaging applications because they enable deeper imaging than shorter wavelengths.

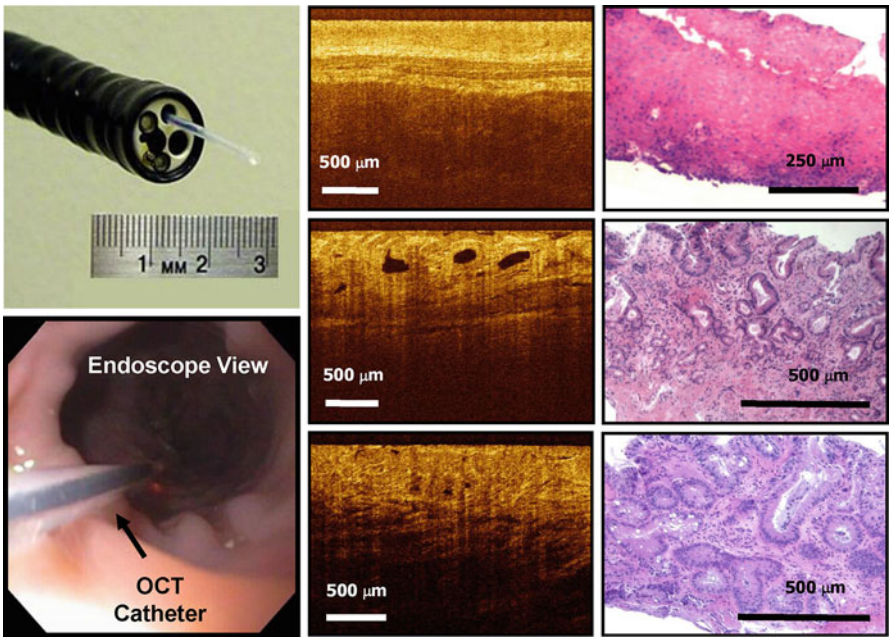

Fig. 1.25 Ultrahigh-resolution endoscopic OCT. (*left*) OCT imaging can be performed using an imaging probe introduced in the biopsy port of a standard endoscope. (*right*) Ultrahigh-resolution endoscopic OCT images of the esophagus in a human subject, acquired with 5 μm axial resolution at 1,300 nm wavelength and pinch biopsy histology. (*right*, *top* to *bottom*) Normal squamous epithelium, Barrett's esophagus, and high-grade dysplasia (From Chen et al. [97])

KLM femtosecond Cr^{4+}:forsterite lasers operate at wavelengths near 1,300 nm and have the advantage that they can be directly pumped at 1 μm wavelengths using compact Yb fiber lasers. OCT imaging studies using femtosecond Cr^{4+}:forsterite lasers were performed as early as 1996 and demonstrated axial image resolutions of 5–10 μm by coupling the femtosecond laser output into a nonlinear fiber and broadening the spectrum by self-phase modulation [114]. Early Cr^{4+}:forsterite laser technology was challenging to use because the lasers required intracavity prisms for dispersion compensation. However, with the development of double-chirped mirror technology, femtosecond Cr^{4+}:forsterite laser performance improved significantly and it became possible to generate pulse durations as short as 14 fs and bandwidths of up to 250 nm directly from the laser [115]. The Cr^{4+}:forsterite laser can also be operated with longer duration pulses and broad bandwidths obtained using nonlinear self-phase modulation in optical fibers. Bandwidths of ∼180 nm, corresponding to OCT axial image resolutions as fine as ∼3.7 μm in tissue have been achieved [96]. Figure 1.25 shows an early example of an ultrahigh-resolution in vivo endoscopic OCT image of the human gastrointestinal tract [97]. Imaging was performed with <5 μm axial resolution in tissue with an imaging speed of 3,000 axial scans/s. The images show normal squamous

mucosa, glandular architecture associated with Barrett's metaplasia, and high-grade dysplasia. Improved axial image resolution reduces speckle noise as well as improves the visibility of clinically significant features. Advances in resolution promise to be important for improving the identification of early neoplastic changes and guiding excisional biopsy.

Imaging at 1,000 nm wavelengths is an attractive compromise between the fine axial resolution, but limited image penetration available at 800 nm wavelengths, versus the reduced resolution, but increased image penetration at 1,300 nm wavelengths [116]. A wide range of commercially available femtosecond laser sources, including mode-locked Nd:glass lasers and Yb fiber lasers, are available at 1,000 nm. Commercial femtosecond lasers in combination with high nonlinearity optical fibers are an attractive and robust approach for achieving the broad bandwidths necessary for ultrahigh-resolution OCT imaging. Femtosecond Nd:glass lasers and nonlinear fibers can generate bandwidths of 200 nm centered around 1,050 nm, corresponding to axial image resolutions of ~3.5 μm in tissue [117]. Commercial laser systems such as femtosecond Nd:glass or Yb fiber lasers are well suited for in vivo ultrahigh-resolution OCT imaging studies that would be performed outside the research laboratory. ▶ Chapter 19, "Broad Bandwidth Laser and Nonlinear Optical Sources for OCT" describes ultrahigh-resolution OCT light sources in more detail.

1.6 Advances in Imaging Speed

There have been powerful advances in OCT detection technology which enable dramatic increases in imaging speeds. These techniques are known as spectral/Fourier domain OCT (SD-OCT) and swept source/Fourier domain OCT (SS-OCT), also termed optical frequency domain imaging (OFDI) [118–125]. Early OCT instruments used a low-coherence light source and interferometer with a scanning reference delay arm. This method is known as time domain detection. However, it is also possible to perform detection in the Fourier domain using a low-coherence interferometer with a broadband light source, measuring the interference spectrum with a spectrometer and a high-speed line scan camera [118, 126–129]. This method is known as spectral/Fourier domain OCT and was first proposed by Fercher et al. almost two decades ago in 1995 [118]. In 2003, three different research groups, working independently, demonstrated that spectral/Fourier domain detection (SD-OCT) has a powerful sensitivity advantage over time domain detection, since spectral/Fourier domain detection essentially measures all of the echoes of light simultaneously [123, 130, 131]. This discovery drove a boom in OCT research and development. The sensitivity is enhanced by the ratio of the axial resolution to the axial imaging depth. For most OCT systems, this corresponds to a sensitivity increase of 50–100 times, enabling a corresponding increase in imaging speeds. ▶ Chapter 2, "Theory of Optical Coherence Tomography" presents a comprehensive theoretical description of sensitivity and imaging speed for different Fourier domain techniques. ▶ Chapters 5, "Spectral/Fourier Domain

Optical Coherence Tomography" and ▶ 6, "Complex and Coherence-Noise Free Fourier Domain Optical Coherence Tomography" describe this technique in detail.

The second type of Fourier domain detection, known as swept source/Fourier domain OCT (SS-OCT), or optical frequency domain imaging (OFDI), uses an interferometer with a narrow-bandwidth, frequency swept light source and detectors which measure the interference output as a function of time [119, 121, 123]. Swept source/Fourier domain OCT has the advantage that it does not require a spectrometer and line scan camera. Therefore, it can operate at longer wavelengths where camera technology is less developed and it can achieve imaging speeds which are much faster than spectral/Fourier domain OCT which is limited by the camera speed. The primary challenge in swept source/Fourier domain OCT is that it requires a high-speed, swept narrow linewidth light source. ▶ Chapters 7, "Optical Frequency Domain Imaging" and ▶ 8, "Complex Conjugate Removal in SS Optical Coherence Tomography" describe swept source/Fourier domain OCT.

1.6.1 Spectral/Fourier Domain OCT

Spectral/Fourier domain OCT (SD-OCT) detection uses a broad bandwidth light source and detects the interference spectrum from the interferometer using a spectrometer and a line scan camera [118, 126–129]. Spectral/Fourier domain OCT has had a major impact in the field of ophthalmology. The first demonstration of retinal imaging was performed by Wojtkowski et al. in 2002 [126]. This result demonstrated that high enough sensitivities to image the retina could be achieved using spectral/Fourier domain OCT and motivated a renewed interest in this technology. Pioneering studies by Nassif et al. demonstrated video rate retinal imaging using spectral/Fourier OCT with line scan cameras to achieve 29,000 axial scans per second with 6 μm axial image resolution [132]. Cense et al. demonstrated ultrahigh-resolution spectral/Fourier domain OCT retinal imaging with 3.5 μm resolution in tissue at 14,600 axial scans per second using a multiplexed superluminescent diode light source [128]. Wojtkowski et al. demonstrated ultrahigh-resolution retinal imaging with 2.1 μm resolution in tissue at 19,000 axial scans per second using a femtosecond laser light source [129].

Figure 1.26 shows a schematic of how spectral/Fourier domain OCT detection works. Spectral/Fourier domain can be understood by recalling that a Michelson interferometer acts like a periodic frequency filter, where the periodicity depends on the path difference between the sample and reference arms. The output from a broad bandwidth light source is split into two beams. One beam is directed onto the tissue to be imaged and is backreflected or backscattered from internal structures at different depths. The second beam is reflected from a reference mirror whose position is fixed. The signal beam and the reference beam have a relative time delay determined by the path length difference, which is related to the depth of the structure in the tissue. The interference of the two beams will have a spectral modulation as a function of frequency which can be measured using a spectrometer. The periodicity of this modulation will be inversely related to the echo time delay.

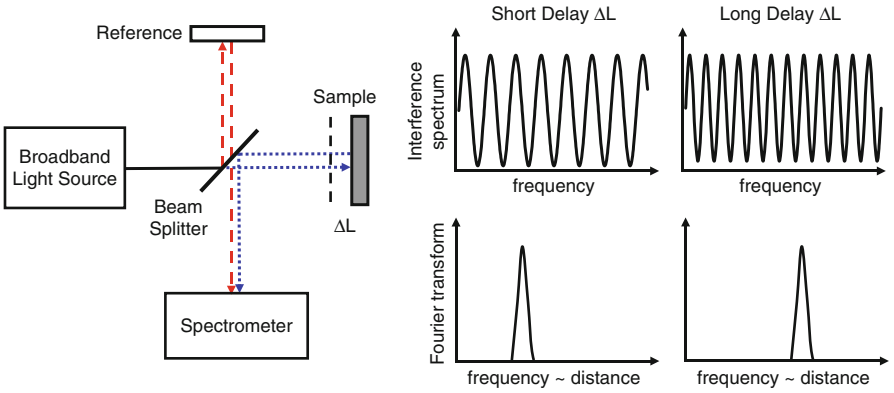

Fig. 1.26 Spectral/Fourier OCT detection. Spectral/Fourier domain OCT uses an interferometer with a broadband light source. The spectrum of the interferometer output is measured with a spectrometer. The Michelson interferometer acts like a spectral filter which has a periodic output spectrum depending on path length mismatch ΔL. Fourier transforming the interference spectrum yields axial scan information (echo magnitude vs. time delay). The technique is somewhat analogous to MR imaging in that spatial information is encoded as frequency

Therefore, different echo delays will produce different frequency modulations. The echo delays can be measured by rescaling the spectrometer output from wavelength to frequency and then Fourier transforming the interference signal. This results in an axial scan measurement of the magnitude and echo delay of the light signal from the tissue.

Figure 1.27 shows a schematic of a typical spectral domain OCT instrument. The light source is a broad bandwidth superluminescent diode or femtosecond laser and the interferometer is implemented using fiber optics. The example shows an ophthalmic imaging instrument where the interferometer sample arm is a patient interface which directs the OCT beam through the pupil and scans the retina. The interferometer reference path has an attenuator to set the reference power as well as materials which approximately match the dispersion in the patient interface and eye. The interference signal is measured by a spectrometer and a high-speed line scan camera. The line scan rate of the camera determines the axial scan rate of the OCT instrument. The spectrometer is typically a refractive spectrometer, using lenses for collimating the optical fiber output onto a diffraction grating and for focusing the angularly dispersed spectrum on the line scan camera. Lenses are superior to mirrors for obtaining diffraction limited focusing of the spectrum over the wide field of view required by most line scan cameras. Transmission diffraction gratings are typically used because the diffraction efficiencies are less polarization dependent than reflective gratings. The spectrometer generates an interference spectrum which is a function of wavelength; therefore, the spectrum must be numerically resampled from wavelength to frequency or wavenumber k before Fourier transforming. The Fourier transform of the spectrum generates the axial scan.

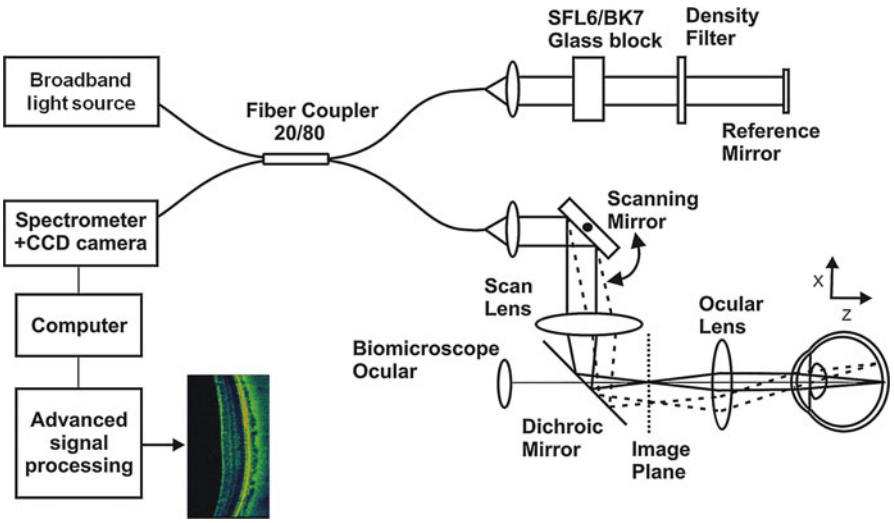

Fig. 1.27 Schematic of a typical spectral domain OCT instrument. This system consists of a fiber-optic interferometer with a low-coherence light source. The reference arm has a fixed delay and is not scanned. The example shows a sample arm with an ophthalmic user interface. Interference is detected with a spectrometer and a high-speed, line scan camera. A computer reads the spectrum, rescales it from wavelength to frequency or k, and Fourier transforms to generate axial scans. Spectral domain OCT has a dramatic sensitivity and speed advantage because it simultaneously detects light from all delays. It also allows direct access to the spectrum which enables numerical dispersion compensation and spectral shaping

Although OCT using spectral/Fourier domain detection has powerful imaging speed advantages, it also has artifacts which are not present in OCT time domain detection. Spectral/Fourier domain OCT is subject to "mirror" artifacts in the images, when the sample is positioned incorrectly or when features span a large depth range. As shown in Fig. 1.27, spectral/Fourier domain detection measures axial scans from the Fourier transform of the interference spectrum of backreflected or backscattered light from the sample with light from a reference path delay which determines a "zero delay." Standard spectral/Fourier domain detection cannot distinguish between positive versus negative time delays compared to this zero delay. Therefore, if the sample is exactly at the reference zero delay position, or if features cross this zero delay, then the OCT image appears folded about this zero delay producing a "mirror" artifact. Stated another way, the magnitude of the Fourier transform is symmetric for positive or negative values and therefore cannot distinguish positive or negative time delays. In addition, measuring a spectrum with N samples results in an axial scan with $N/2$ samples and therefore line scan cameras with large numbers of pixels are required to generate axial scans with high pixel resolution.

In addition to the "mirror" artifact, the detection sensitivity varies as a function of the measurement range in spectral/Fourier domain detection. This is often referred to as "sensitivity roll-off." Spectral/Fourier domain detection is most sensitive to echoes which are close to the zero delay position and sensitivity

decreases further from zero delay. This occurs because the spectrometer has a limited spectral resolution. Echoes which are further from the zero delay position produce progressively high frequency spectral oscillations which can no longer be resolved. The spectral resolution is governed by multiple factors including the optical aberrations in the spectrometer lenses, the resolution of the diffraction grating, camera pixel size, and electronic pixel cross talk.

Figure 1.28 shows a series of OCT retinal images which illustrate the mirror artifact. The different images, from the top to the bottom, are acquired by moving the OCT instrument toward the eye, so that the distance to the eye is decreasing. The echoes of light from the retina are measured with respect to a specific delay, the "zero delay" position from the instrument, which is determined by the interferometer reference path. The retina appears in a normal position when it is farther than the zero delay. However, when the instrument is moved toward the eye so that the retina is exactly at the zero delay reference position, the portions of the retina which cross the zero delay appear folded or mirrored around the zero delay because positive versus negative delays are not distinguishable. Finally, when the instrument is moved even closer to the eye, the retina is closer than the zero delay reference position and the retina appears inverted. The sensitivity roll-off can also be seen in the images of Fig. 1.28, where the retina appears brighter when it is near zero delay. Conversely, features which are further from zero delay appear dimmer. Depending upon the application, it may be desirable to set the zero delay position in order to have increased sensitivity to signals from deeper in the sample versus avoiding mirror artifacts.

Spectral/Fourier domain detection enables OCT imaging with a ~50–100 times increase in imaging speed compared with first generation OCT systems. At the same time it is important to note that spectral/Fourier domain detection must be operated at high speeds because specimen motion produces averaging of the interference fringes if the acquisition speed is too slow. High-speed imaging is a major advance because it is possible to increase the number of axial scans or transverse pixels per B-scan image to yield high-definition images as well as to increase the number of cross-sectional or B-scan images acquired in a sequence to yield denser three-dimensional data (3D-OCT). Figure 1.29 shows a comparison of standard OCT and high-speed, ultrahigh-resolution OCT images of the optic nerve head of the human retina. Figure 1.29a shows a standard 10 μm axial resolution OCT image with 512 axial scans, acquired in ~1.3 s. Figure 1.29b shows a high-speed, ultrahigh-resolution OCT image with ~2 μm axial resolution and 2,048 axial scans, acquired in 0.13 s. The higher resolution and greater number of transverse pixels in the high-speed, ultrahigh-resolution OCT image improve the visualization of internal retinal structure. The ability to visualize internal retinal features promises to enable the identification of early markers of disease and disease progression.

In addition, high-speed OCT imaging enables the acquisition of complete 3D-OCT data sets in a time comparable to that of first generation OCT protocols that acquired several individual images [133]. Figure 1.30 shows 3D-OCT imaging of the optic disc using a raster scan pattern [134]. The 3D-OCT volumetric data set contains comprehensive structural information. An en face OCT image, identical to a standard retinal fundus view, can be generated by summing the data in

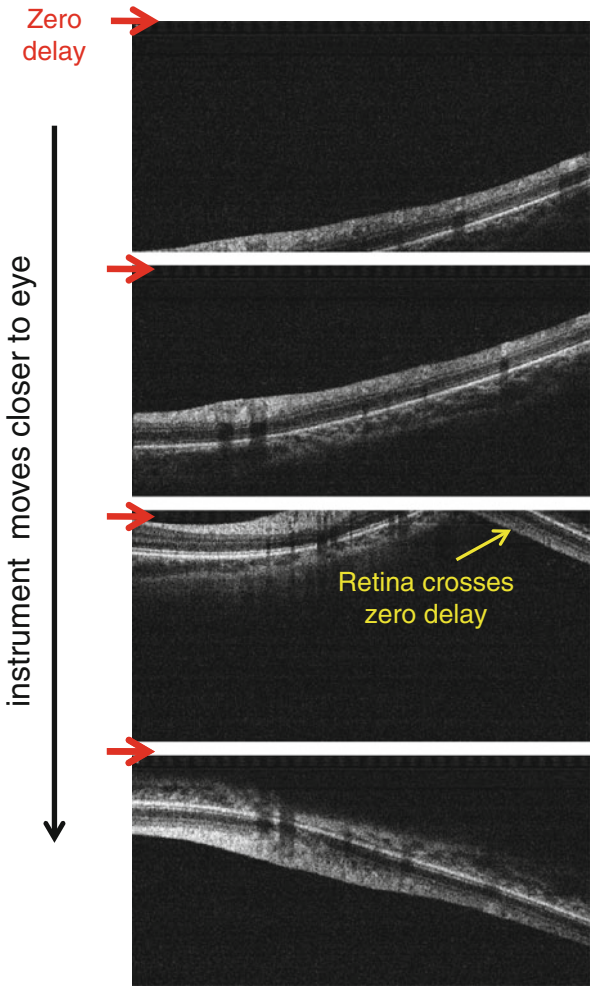

Fig. 1.28 Artifacts in spectral/Fourier domain OCT detection. Spectral/Fourier domain detection cannot distinguish between positive or negative echo time delays and has a "mirror image" artifact. The series of OCT retinal images (*top* to *bottom*) was acquired as the instrument was moved closer to the eye. When the retina crosses the interferometer zero delay position, it produces a folded or mirror image appearance in the OCT image. When the instrument is even moved closer, with the retina in back of the zero delay, the image appears inverted. Care must be taken to avoid misinterpreting mirror artifacts in OCT images

the axial direction. Individual cross-sectional OCT images can be precisely and reproducibly registered to en face features of the retina. Figure 1.31 shows an example of retinal nerve fiber layer (RNFL) thickness measurement from a 3D-OCT data set. Figure 1.31a shows an RNFL thickness map, Fig. 1.31b shows a measurement of RFNL thickness in a virtual circumpapillary scan, and Fig. 1.31c shows a virtual circumpapillary scan extracted from the 3D-OCT data set. Because 3D-OCT contains comprehensive structural information, the position of the circumpapillary scan can be adjusted in post processing to achieve precise registration with fundus features and improve measurement reproducibility.

With the development of improved camera technology, it became possible to increase spectral/Fourier domain imaging speeds. In 2008, Potsaid et al. demonstrated record imaging speeds of up to 312,500 axial scans per second using

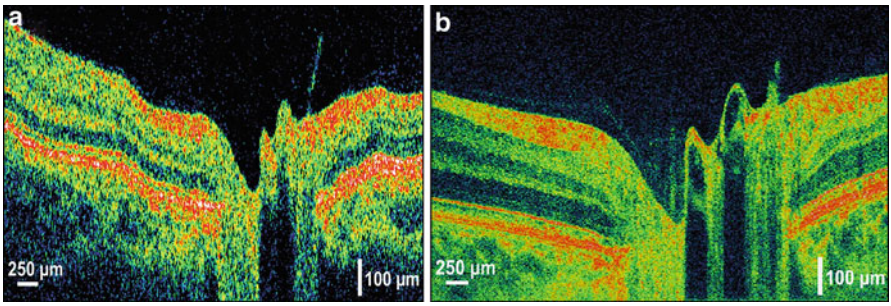

Fig. 1.29 Spectral/Fourier OCT imaging of the retina. Comparison of standard time domain OCT and high-speed, ultrahigh-resolution OCT using spectral/Fourier domain detection. (**a**) Standard OCT of the optic nerve head with ~10 µm axial image resolution and 512 axial scans, acquired in ~1.3 s. (**b**) High-speed, ultrahigh-resolution image with ~2 µm axial resolution and 2048 axial scans, acquired in 0.13 s

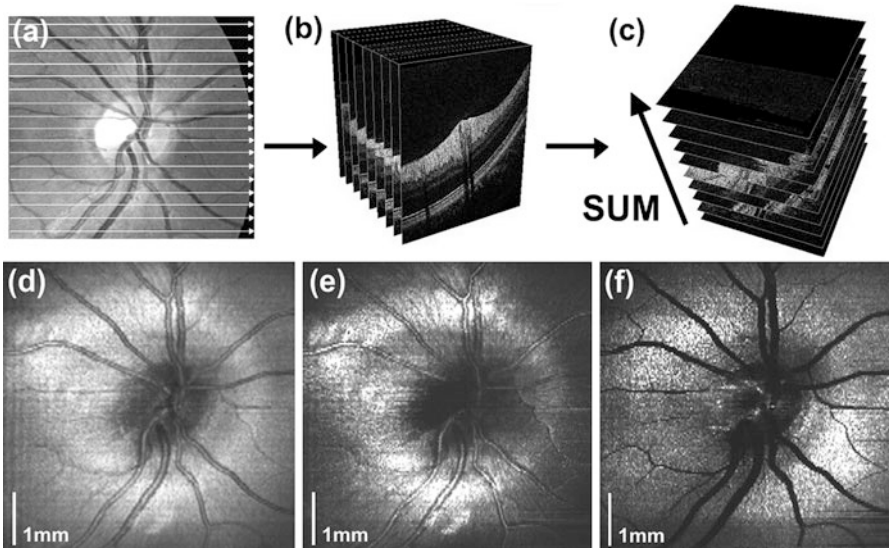

Fig. 1.30 En face imaging using 3D-OCT data. (**a**, **b**) High-speed OCT enables the acquisition of 3D-OCT data which contains comprehensive volumetric information. (**c**, **d**) An en face OCT retinal fundus image can be generated directly from 3D-OCT data by summing the signal along the axial direction. Individual images in the data set are precisely registered with fundus features. (**e**, **f**) En face OCT images can also be generated by displaying individual retinal layers such as (**e**) the nerve fiber layer or (**f**) retinal pigment epithelium, enabling visualization of specific features (Wojtkowski et al. [134])

a CMOS line scan camera [135]. The camera (Sprint spL4096-140 k from Basler Vision Technologies) had 4 k pixels that were read at 70 kHz line rate, but progressively higher rates could be achieved by reducing the number of pixels used. Line rates of 312.5 kHz could be achieved by reading 576 pixels. The ability

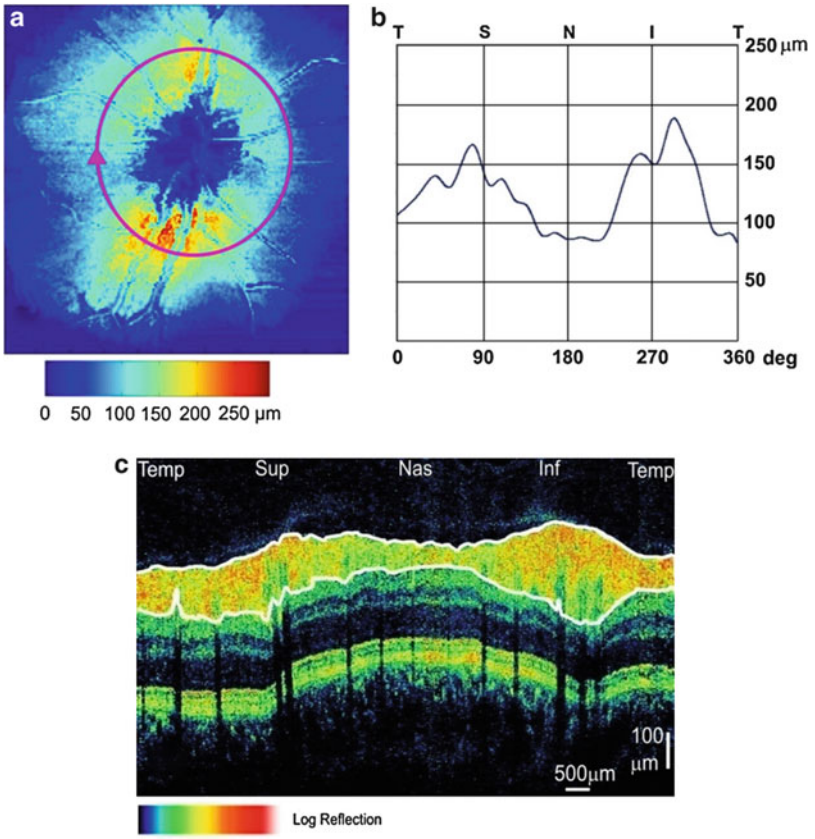

Fig. 1.31 3D-OCT. (**a**) RNFL thickness map from 3D-OCT data. (**b**) Plot of RNFL thickness on a 3.4-mm diameter circumpapillary circle from 3D-OCT. (**c**) Virtual circumpapillary image extracted from 3D-OCT. (INF) inferior, (NAS) nasal, (SUP) superior, and (TEMP) temporal portions of NFL (Wojtkowski et al. [134])

to adjust the number of pixels enables optimization of performance. Ultrahigh axial image resolutions of 2.5–3 um can be achieved with 100 kHz read speeds, while ultrahigh speeds of 312.5 kHz require a trade-off in axial resolution to ~9 um. Reducing parasitic sensitivity roll-off requires a spectrometer design that uses more pixels for a given wavelength span, resulting in slower imaging speeds.

Spectral/Fourier domain OCT has had a dramatic impact in ophthalmology. The improved imaging capabilities promise to provide earlier diagnosis of retinal disease as well as more sensitive assessment of progression and response to therapy. Numerous commercial organizations have developed spectral/Fourier domain OCT instruments for the ophthalmic marketplace and the technology is now widely available to the clinical community.

1.6.2 Swept Source/Fourier Domain OCT

Swept source/Fourier domain detection (SS-OCT), also known as optical frequency domain interferometry (OFDI), uses an interferometer with a frequency swept, narrow-bandwidth light source [119, 121, 123]. The sweep in frequency with time essentially labels different time delays in the light beam, which can then be detected by interference and Fourier transforming. The basic concept of SS-OCT was described in patents as early as 1991 and experimental studies in 1997 [119, 120, 136]. These detection techniques were used in the 1990s to perform measurements in fiber optic and photonics components [137–139]. The basic concept of frequency chirped coherent ranging and imaging, as well as the associated signal-to-noise and performance advantages, actually date back to the 1980s and where they were used in coherent laser radar [140]. OCT using swept source/Fourier domain detection was demonstrated as early as 1997 by Chinn et al. [119] and Golubovic et al. [120], but the sensitivity and speed advantages were not recognized in these studies and performance was limited by the available laser technology. Pioneering studies by Yun et al. in 2003 demonstrated OCT imaging with 19,000 axial scans per second and 13–14 μm axial resolution in free space [121]. Record imaging speeds of 115,000 axial scans per second were achieved in 2005 using a novel swept laser technology based on a grating and rotating polygon mirror filter [141].

Figure 1.32 shows a schematic of how swept source/Fourier domain detection works. The output from a narrow-bandwidth, frequency swept light source is divided into a signal and a reference beam. The signal beam is directed onto the tissue to be imaged and is backreflected or backscattered from internal structures at different depths. The reference beam is reflected from a reference mirror at a fixed delay. The signal and reference beams have a time offset determined by the path length difference, which is related to the depth of the structure in the tissue. Because the frequency of the light is swept as a function of time, the light echoes in the signal beam will have a frequency offset from the reference beam. When the signal and reference beams interfere, a modulation or beat in intensity is produced at a frequency which is given by this frequency offset. Therefore, different echo delays will produce different frequency modulations. The axial scan can be measured by digitizing the photodetector signal over a single frequency sweep of the light source, correcting any nonlinearity in the frequency sweep as a function of time and then Fourier transforming this beat frequency signal. This results in an axial scan measurement of the magnitude and echo delay of light from the tissue.

Figure 1.33 shows a schematic of a typical swept source OCT instrument. The light source is a swept laser with a narrow instantaneous linewidth. The example shows a catheter/endoscopic imaging instrument where the interferometer sample arm is a fiber-optic imaging probe. The interferometer uses circulators in both the sample and reference paths to extract the return light from the sample and references arms which are then interfered in a 3 dB coupler. This configuration provides access to two interference signals and enables dual balanced detection where the reference arm power and excess noise in the light source are subtracted, while the interference signal is added. This interferometer configuration is more

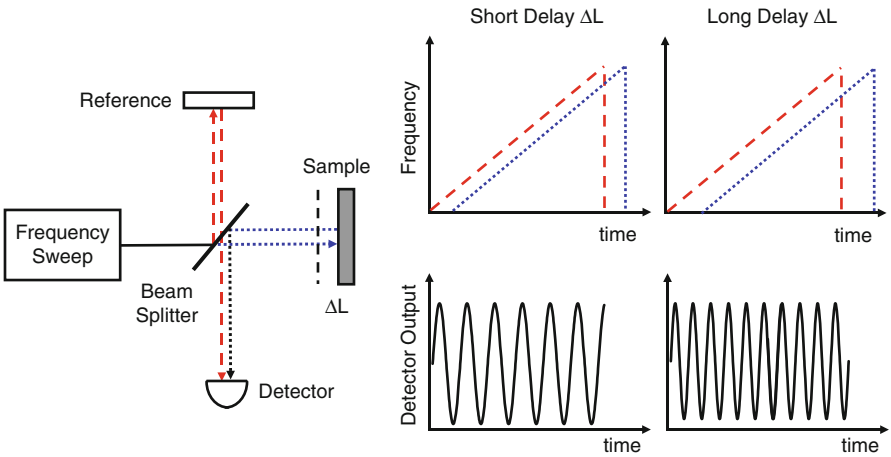

Fig. 1.32 Swept source/Fourier domain OCT detection. Swept source/Fourier domain OCT uses an interferometer with a narrow-band, frequency swept laser and photodetectors. The Michelson interferometer interferes two frequency sweeps which are time delayed with respect to each other and generates a beat frequency which is proportional to the path length mismatch ΔL. Fourier transforming the beat signal from the detector yields axial scan information (echo magnitude vs. time delay)

efficient than the classic Michelson interferometer because all of the light is detected. The output of the dual balanced detector is digitized by a high-speed A/D.

Frequency swept light sources usually generate frequency sweeps that are not linear in time. Therefore, it is necessary to either rescale the digitized interference signal so that it is sampled with equal frequency or k intervals rather than equal time intervals. If a calibration of frequency versus time is available, this resampling can be performed by numerically processing the interference signal. However, modern swept source/Fourier domain detection systems avoid this computational cost by clocking the A/D at equal frequency or k intervals. This optical clocking or k-clocking is typically performed using a Mach-Zehnder interferometer to detect the frequency sweep and clock the A/D at a variable rate corresponding to the frequency sweep rate. The technique of optical clocking has the advantage that it increases data processing speed by removing the computationally expensive step of resampling the interference signal and also reduces the amount of data that is acquired, but it requires special A/D instrumentation which can clock accurately with a variable clock rate. Furthermore, the optical and electronic propagation delays in swept source/Fourier domain instruments must be carefully managed because a timing mismatch between the clock and interference signal results in sampling at incorrect times which distorts the interference signal. The requirement of high-speed A/D as well as precise synchronization makes swept source/Fourier domain detection more challenging than spectral/Fourier domain detection.

Like spectral/Fourier domain detection, swept source/Fourier domain detection measures all of the optical echoes at the same time, rather than sequentially as in

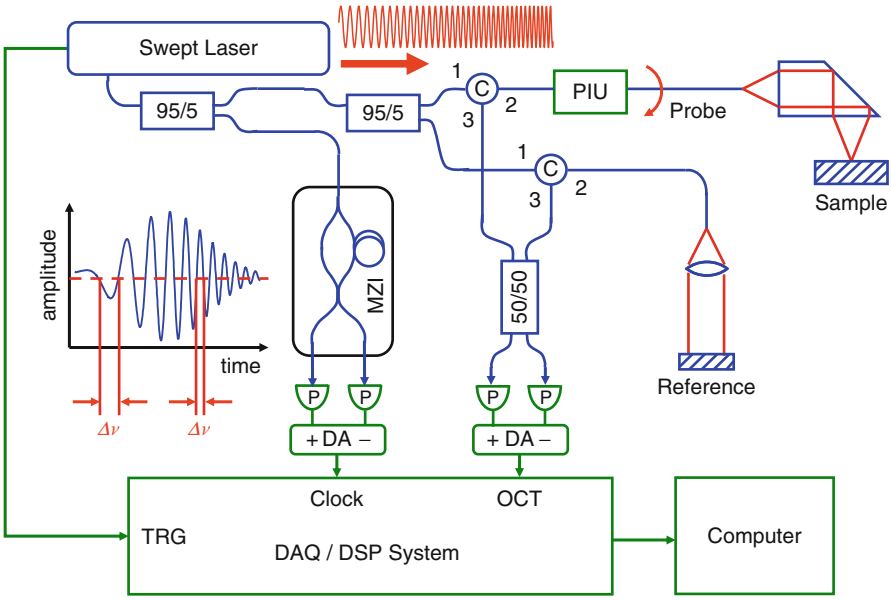

Fig. 1.33 Schematic of a typical swept source OCT instrument. This system consists of a fiber-optic interferometer with a frequency swept light source. The reference arm has a fixed delay and is not scanned. The example shows a sample arm with catheter/endoscope interface and the system is assumed to operate at 1.3 um wavelengths. Two circulators are used to collect light from the sample and reference arms and generate interference in a 50/50 coupler. This geometry enables dual balanced detection, cancelling excess noise in the laser for better utilization of the D/A dynamic range. A portion of the frequency swept light is directed into a Mach-Zehnder interferometer (*MZI*) which acts as a periodic frequency filter to generate a clock signal for the D/A. This optical clock triggers that D/A at varying time intervals to remove frequency sweep nonlinearity, yielding spectral data sampled with constant frequency or k interval. Swept source OCT is extremely versatile and avoids the spectral resolution and pixel limitations which are inherent in spectrometers and line scan cameras

time domain detection. This enables a dramatic improvement in detection sensitivity. Swept source/Fourier domain methods have the advantage that they can be used in the 1,300 and 1,000 nm wavelength ranges where silicon-based cameras lack sensitivity and more expensive InGaAs cameras are required. The axial image resolution and axial scan rate in swept source OCT are determined by the sweep range and sweep repetition rate of the laser, respectively. If the laser can achieve high sweep repetition rates, imaging can be performed much faster than spectral domain OCT which is limited by camera read rates.

1.6.3 Light Sources for Swept Source OCT

Because swept source OCT can achieve high imaging speeds at wavelengths of 1,300 nm, it has had a powerful impact on intravascular and endoscopic

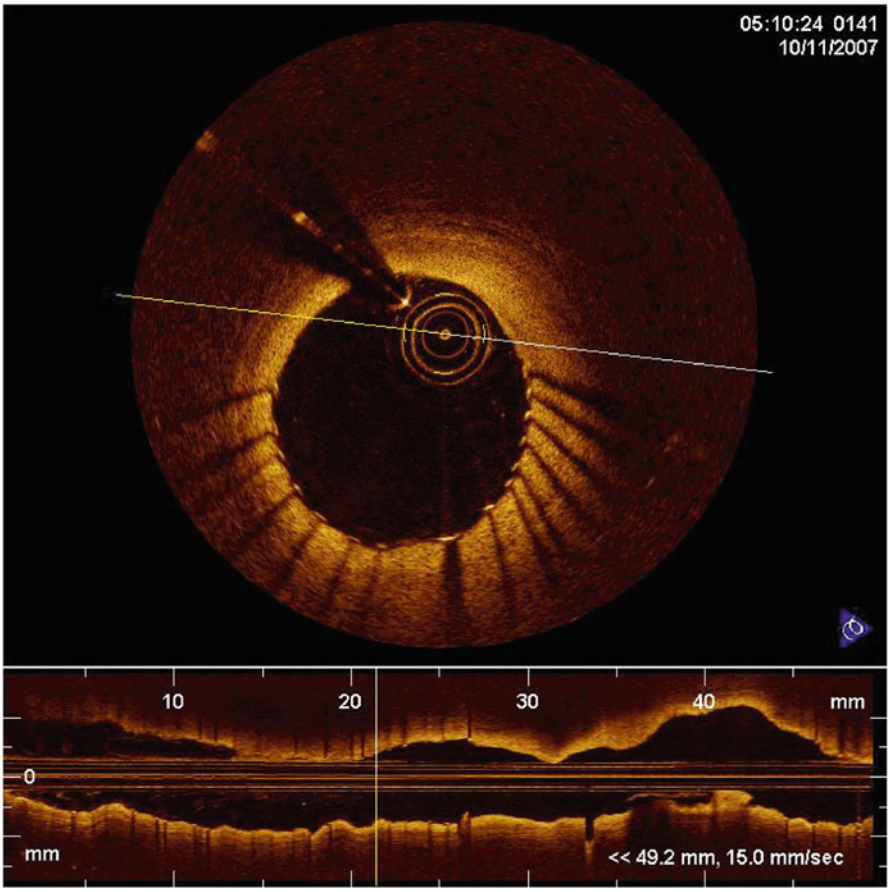

Fig. 1.34 High-speed intravascular OCT imaging. High-speed OCT imaging using swept source/Fourier domain OCT with a Fourier domain mode-locked (FDML) laser. The image shows a stented human LAD coronary artery in vivo using a LightLab M4 prototype instrument operating at 45,000 axial scans per second and 100 frames/s with a 15 mm/s pullback speed. Imaging speeds are ~100 times faster than previous generation OCT systems enabling rapid imaging with minimal ischemia (Courtesy of LightLab Imaging)

imaging applications. Swept source 3D-OCT imaging was demonstrated in the porcine esophagus and coronary artery at speeds of 10,000 and 54,000 axial scans/s, respectively [142, 143]. Figure 1.34 shows an example of high-speed OCT intravascular imaging in the porcine artery in vivo using a LightLab prototype instrument which operates at 45,000 axial scans/s, acquiring 100 frames per second with a 15 mm/s pullback speed using a 10 mL contrast injection to remove blood from the imaging field. These high imaging speeds enable rapid pullbacks, mapping long segments of artery while minimizing ischemia.

Figure 1.35 shows an example of in vivo endoscopic 3D-OCT imaging in the rabbit, using high-speed, swept source/Fourier domain OCT [144]. In vivo 3D-OCT

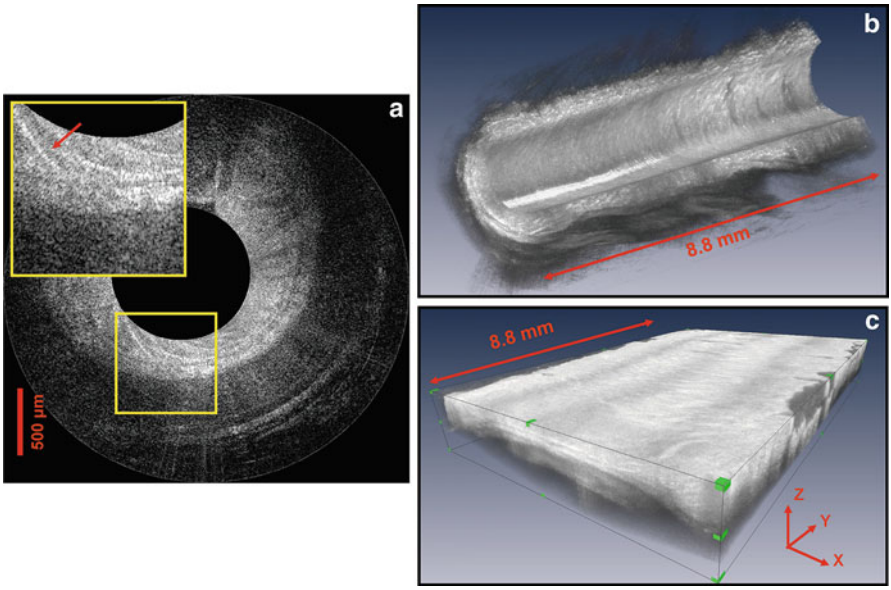

Fig. 1.35 High-speed endoscopic OCT. Volumetric data is acquired at 100,000 axial scans per second and 50 frames/s using a rotary fiber-optic endoscope probe with swept source/Fourier domain OCT and a Fourier domain mode-locked (FDML) laser. Volumetric renderings of the rabbit colon in vivo. (**a**) Single radial frame acquired in 20 ms. Inset shows enlarged view of epithelium, with crypt indicated by *red arrow*. (**b**) Cutaway view of the rendered volume. (**c**) Unfolded data set showing the cylindrical volume as a rectangular tissue slab. The entire volume was acquired in 17.7 s (Adler et al. [144])

was demonstrated with axial image resolutions of 5–7 µm, at speeds of 100,000 axial lines/s, equivalent to 50 frames/s and rates of 61 Megavoxels/s. 3D-OCT enables virtual manipulation of tissue geometry, speckle reduction, synthesis of en face views similar to endoscopic images, generation of virtual cross-sectional images with arbitrary orientation, and quantitative measurements of morphology. These technological advances promise to enable a wide range of applications.

Because the performance of swept source OCT systems depends directly on the swept light source, advances in laser technology have become an active area of research in OCT. Frequency swept lasers consist of a laser gain and a tunable filter. There is a fundamental limit on the tuning rate of a frequency swept laser because the lasing of a given frequency must build up from spontaneous emission and be amplified up to saturation as the filter is tuned in order to achieve a narrow linewidth [145]. Therefore, short laser cavities which have a rapid round trip time can tune faster than long cavity lasers. However, the development of Fourier domain mode locking (FDML) in 2006 by Huber et al. provided a novel approach for breaking the tuning speed limit [125]. FDML lasers use a long optical fiber delay inside the laser which stores the entire frequency sweep in the cavity and synchronously tune the filter such that a given frequency arrives at the filter when it is tuned

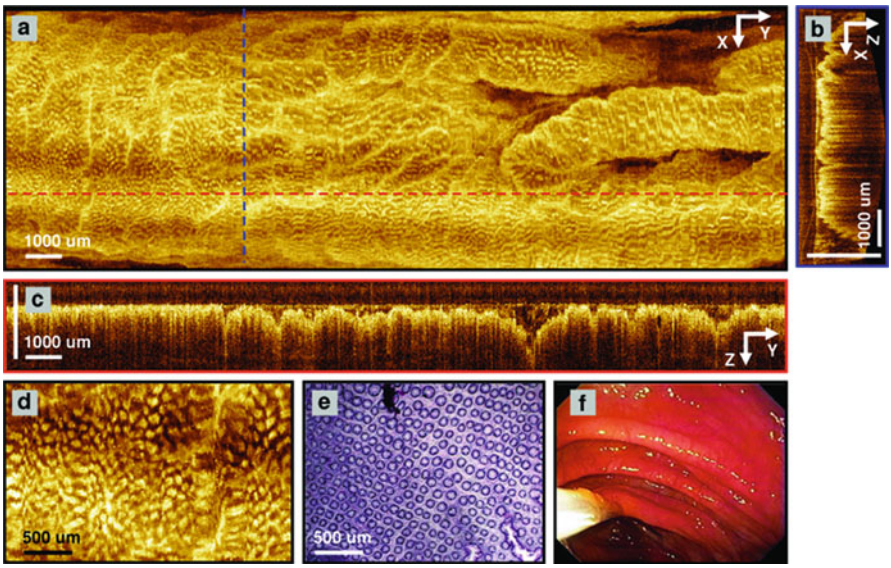

Fig. 1.36 Endoscopic OCT imaging of the normal human colon. 3D-OCT images of columnar epithelial tissue in the human colon. (**a**) En face OCT image constructed by axial summation of the data set. *Dashed lines* show locations of cross sections. (**b**) XZ cross section showing typical columnar epithelial structure. (**c**) YZ cross section. (**d**) Enlarged view of (**a**), showing en face crypt pattern. (**e**) Representative en face histology of human colon. (**f**) White light video endoscopy of region imaged with 3D-OCT (Adler et al. [148])

to pass it. This avoids the need to build up lasing at each frequency and enables record sweep speeds. Fourier domain mode locking is described in detail in ▶ Chap. 24, "FDML (incl. Parallelization)". Early FDML lasers achieved record imaging speeds of 370,000 axial scans per second [146]. This technology was enabling for both endoscopic/catheter as well as ophthalmic applications. Record catheter/endoscope imaging speeds of 100,000 axial scans per second with 5–7 μm axial resolutions were demonstrated in an animal model in 2007 [147]. FDML lasers were also demonstrated in human endoscopic imaging studies and achieved a 62 kHz axial scan rate with 180 nm tuning range at 1,310 nm, corresponding to an axial image resolution of 5 um in tissue [148]. Figure 1.36 shows an example of endoscopic imaging in the normal human colon. A volume of $7 \times 20 \times 1.6$ mm in dimension was acquired in 20 s using rotary fiber-optic probe with pullback. The volumetric data enables the generation of arbitrary cross sections as well as en face images which display the uniform crypt pattern in the normal epithelium of the colon. The ability to assess the 3D structure of crypts is therefore of potential value for future applications in cancer detection and treatment. Ophthalmic imaging with speeds of greater than one million axial scans/s has recently been achieved [149]. These extremely rapid imaging speeds enable wide-field retinal coverage.

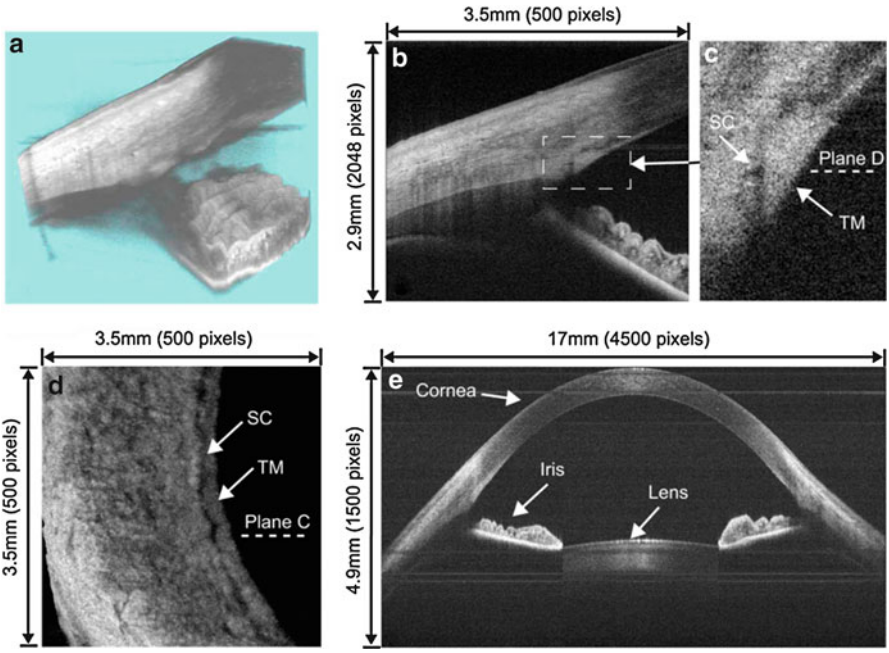

Fig. 1.37 Anterior eye OCT. Example showing a 10 mm imaging range in air (7.5 mm in tissue) acquired at 100 kHz axial scan rates. (**a**) 3D-OCT of the angle consisting of 500 × 500 axial scans over 3.5 × 3.5 mm acquired in 2.6 s. (**b**) Cross-sectional image of the angle from (**a**) averaging two adjacent cross-sectional images. (**c**) Enlarged region from (**b**) showing Schlemm's canal (*SC*) and the trabecular meshwork (*TM*). (**d**) En face OCT image extracted from (**a**) averaging over two en face planes showing a coronal section through structures related to outflow. (**e**) OCT cross-sectional image of the cornea, iris, and anterior lens acquired using 1 GSPS sampling with an oscilloscope to achieve high axial resolution over a long imaging range. The image is cropped in depth to span 4.9 mm (Potsaid et al. [150])

In addition to research systems, commercial swept laser technologies also made critical advances. The development of a commercial short cavity swept laser (Axsun Technologies) enabled intravascular as well as ophthalmic applications. The short cavity swept laser uses a high finesse tunable filter and a gain medium with a few centimeter cavity length. Retinal imaging with a 5.3 um axial resolution at 1,050 nm wavelength was demonstrated at 100 kHz axial scan rates using direct swept laser output, and 200 kHz scan rates were achieved by multiplexing the laser sweeps [150]. The short cavity laser also enabled narrower instantaneous linewidths and therefore supported longer imaging ranges than previous swept lasers. Figure 1.37 shows an example imaging the anterior eye with a 10 mm imaging range in air (7.5 mm in tissue) acquired at 100 kHz axial scan rates. The long image range required an A/D acquisition at a 1 GSPS rate. Short cavity swept laser technology is described in more detail in ▶ Chap. 21, "Swept Light Sources" entitled 1,060 nm Swept Source OCT Engine.

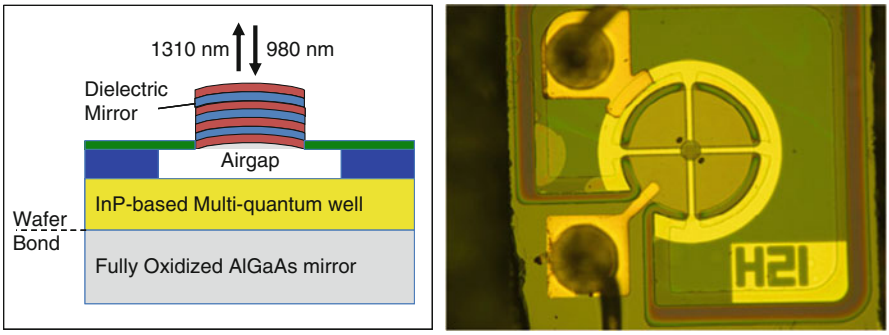

Fig. 1.38 Schematic and photograph of a VCSEL laser. The laser consists of a semiconductor mirror, quantum well gain material, and dielectric mirror fabricated on a MEMS. The gain is optically pumped by a laser diode (not shown). The VCSEL cavity is short and can operate in a single longitudinal mode providing very narrow linewidth. The MEMS mirror is electrostatically actuated and can vary the cavity length to sweep the laser frequency/wavelength. The MEMS mirror can achieve rapid sweep rates as well as adjustable sweep ranges

The development of the vertical cavity surface-emitting laser (VCSEL) enabled advances in both imaging speed and imaging range. Figure 1.38 shows a schematic and photograph of a VCSEL laser. The laser is optically pumped and consists of a quantum well gain medium in a micro-cavity formed by a semiconductor mirror and a dielectric mirror on a MEMS structure [151]. The MEMS is electrostatically actuated in order to change the cavity length and tune the laser. Because the MEMS can be actuated at high speed and the cavity is extremely short, the laser can be frequency swept at high repetition rates. ▶ Chapter 22, "VCSEL Swept Light Sources" describes VCSEL light sources in more detail.

Figure 1.39 shows an example of wide-field retinal and choroidal imaging using SS-OCT with the VCSEL at 580 kHz axial scan rate [152]. A wide-field 12 × 12 mm region of the retina can be imaged with 1,000 × 1,000 axial scans acquired in ~2 s. The high axial scan density enables high-resolution en face OCT images where each pixel in the en face image requires an axial scan in the volumetric data. The longer 1,050 nm wavelength compared with 840 nm in standard OCT instruments enables increased penetration into the choroid and reduced attenuation from ocular opacities.

Depending on the swept laser linewidth as well as the A/D sampling rate, swept source OCT can achieve much longer imaging ranges than spectral domain OCT, with reduced sensitivity roll-off. Swept source OCT also has the advantage that the resolution, axial scan rate, and imaging range can be dynamically adjusted by adjusting the laser sweep range, repetition rate, and A/D sampling rates. Since VCSEL lasers operate with a single longitudinal mode, instantaneous linewidths are much narrower than other swept lasers and they can achieve extremely long imaging ranges. Figure 1.40 shows an example of full eye length imaging at 45 kHz axial scan rate [152]. The VCSEL sweep range was reduced to 45 nm centered around 1,050 nm, corresponding to an axial resolution of 12.4 um in tissue. An A/D rate of 1 GSPS was used to achieve an imaging range of 37.7 mm in tissue. The extremely narrow

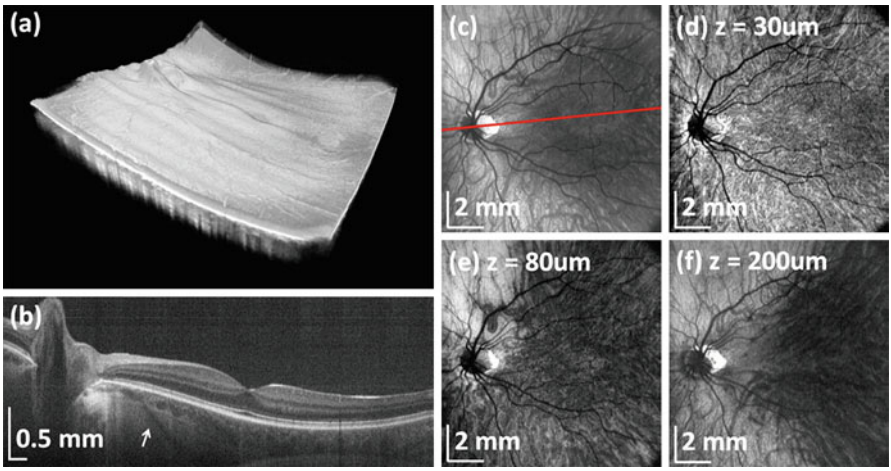

Fig. 1.39 Wide-field retinal and choroidal OCT imaging. Swept source OCT using VCSEL light source at 580 kHz axial scan rate. (**a**) Rendering of volumetric wide-field 3D-OCT data. (**b**) Virtual (arbitrary) cross-sectional image showing deep image penetration and ability to visualize choroid and sclera. *Arrow* indicates scleral vessel. (c) En face OCT image of the choroid obtained by integrating signal below the RPE. *Red line* indicates orientation of cross section in (**b**). En face OCT images at depths (**d**) 30 μm, (**e**) 80 μm, and (**f**) 200 μm below the RPE showing choroidal layers and sclera. Signal was integrated from 40 μm thick slices (Grulkowski et al. [152])

instantaneous linewidth of the VCSEL means that there is virtually no sensitivity roll-off across the imaging range, enabling a wide range of new applications [153].

1.7 Functional OCT

There are many methods for functional OCT which enhance tissue contrast or assess physiological state, as well as multimodal techniques which integrate other imaging modalities with OCT. Here we only briefly mention early methods for functional OCT which involve Doppler flow, polarization-sensitive, and spectroscopic techniques. Early Doppler OCT was performed using techniques that directly detected the interferometric output in the time domain, rather than demodulating the interference fringes [154–157]. Movement or flow produces a Doppler shift in the backscattered or backreflected light which can be measured by Fourier transforming the interference fringe signal. The development of spectral as well as swept source/Fourier domain detection enabled direct access to the phase of the interference signal and enabled a wide range of Doppler techniques [158, 159]. Related techniques, broadly known as OCT angiography, use customized OCT scanning protocols to detect changes in successive B-scan images to assess either phase or speckle variation [160–163]. These techniques can generate motion contrast from moving blood and enable visualization of microvasculature in three dimensions. Polarization-sensitive OCT (PS-OCT) techniques were

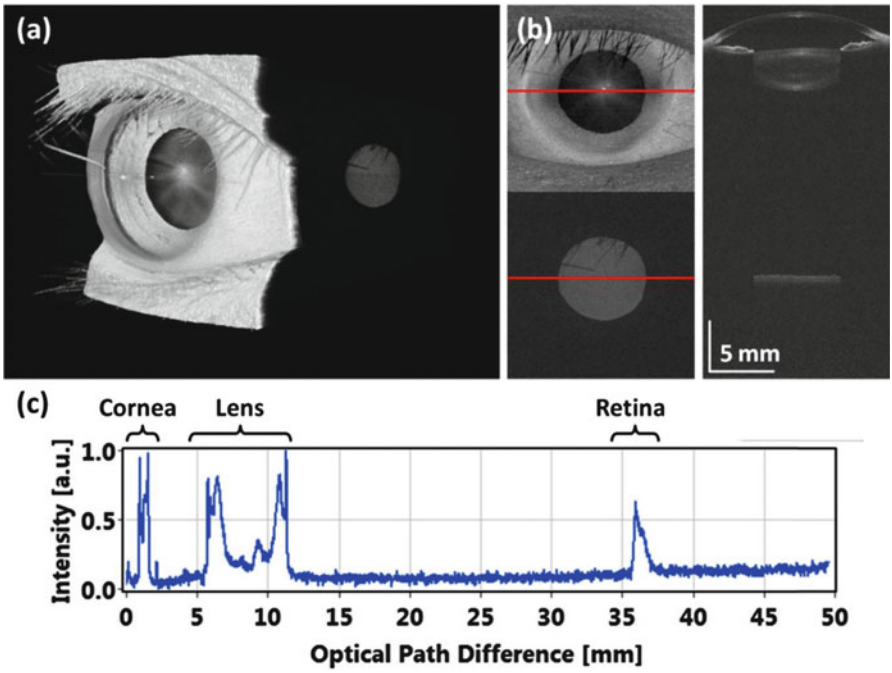

Fig. 1.40 Full eye length imaging. Swept source OCT using a VCSEL light source with ultralong depth range at 45 kHz axial scan rate. (**a**) Rendering of 3D-OCT data showing anterior eye and retina. (**b**) En face OCT images and central B-scan extracted from 3D-OCT data set uncorrected for light refraction. (**c**) Axial scan with echoes from the cornea, crystalline lens, and the retina enables measurement of intraocular distances (Grulkowski et al. [152])

developed using multichannel interferometers that simultaneously detect different interference polarization states [164, 165]. These techniques permit quantitative imaging of the birefringence properties of materials and tissues. Early studies also demonstrated the feasibility of obtaining spectroscopic information by detecting and Fourier transforming the interferometric output [166, 167]. The development of Fourier domain detection has been an enabling advance for many of the functional techniques because there is now direct access to the phase and spectral components of the interference. In addition, many functional methods require high data rates which are supported by Fourier domain detection. These methods are described in more than 20 chapters in Part IV of this book.

1.8 Conclusion

OCT is a powerful imaging technology in biomedical research and medicine because it enables in situ visualization of tissue structure and pathology without the need to excise and process specimens, as in conventional excisional biopsy and

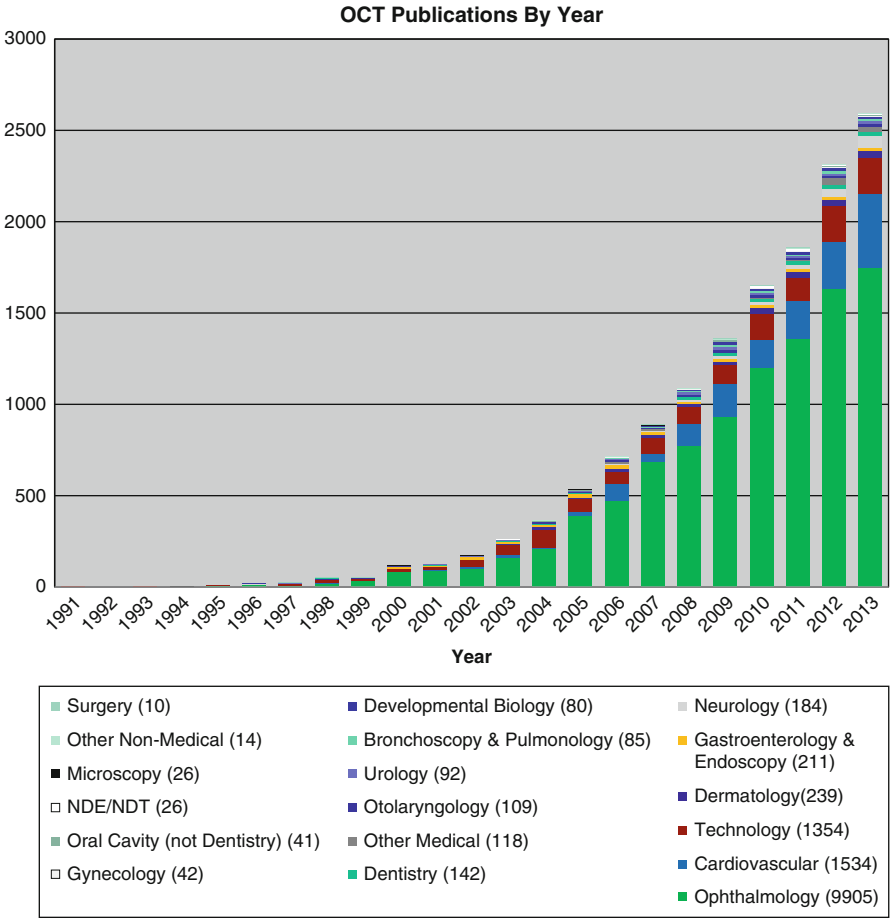

Fig. 1.41 Growth of journal publications involving OCT. Publications are an indicator of scientific and clinical progress. Ophthalmology and cardiovascular imaging are currently the largest applications of OCT. OCT technology remains an active area and was in second place until 2010 when cardiology applications increased. The growth in clinical publications is closely linked to commercial development of technology and is one indicator for clinical impact (Courtesy of E. Swanson)

histopathology. Non-excisional "optical biopsy," the ability to visualize tissue morphology in real time under operator guidance, can be used for a wide variety of applications. Figure 1.41 shows a plot of journal publications which involved OCT as a function of year. Journal articles are one marker for scientific development as well as clinical adoption. The factors which govern the adoption of OCT in different clinical specialties as well as the technology translation process are discussed in detail in ▶ Chap. 84, "OCT Technology Transfer and the OCT Market".

The largest number of publications is in ophthalmology. OCT has had the most clinical impact in ophthalmology, where it provides structural, quantitative, and functional information that cannot be obtained by any other modality. OCT improves the diagnosis of retinal disease as well as the monitoring of disease progression and response to therapy. In ophthalmology OCT played a significant role in the development of new therapies for age-related macular degeneration. It is now a standard clinical imaging modality in this clinical specialty.

The second largest number of publications at the time this book is written is in cardiology. Intravascular OCT has contributed to the understanding of plaque morphology and its role in myocardial infarction as well as percutaneous coronary interventions such as the implantation of stents. OCT is a powerful imaging modality for cardiovascular research; however, it is not yet widely used in interventional cardiology. Extensive clinical studies are still required to determine if OCT will become a standard imaging modality in this specialty. If successful in cardiology, OCT could have a major impact on morbidity and mortality from heart disease and the market could far surpass that in ophthalmology.

The third largest volume of publications is in technology research. Technology development has been an active area of research for more than a decade and although there may be the perception that technology development is saturating, it is difficult to predict future enabling advances. The development of Fourier domain detection not only enabled dramatic improvements in imaging speed, but will also enable countless new functional imaging methods. However, these advances would have been difficult to predict before 2003. Additional powerful new technologies and methods for OCT may be discovered in the near future.

Irrespective of innovations in OCT technology, there are many clinical specialties where OCT can be applied. OCT can be interfaced to a wide range of instruments and devices such as endoscopes, catheters, laparoscopes, and imaging needles, which enable the imaging of luminal or solid organs. The application of OCT in oncology is an active area of investigation and, although this is challenging area, OCT could have a significant impact on improving cancer diagnosis by guiding excisional biopsy to reduce sampling errors. OCT could also be integrated with therapies to guide methods such as ablative therapy or surgical resection. A wide range of smart surgical devices using image guidance remain to be developed and validated.

From the viewpoint of fundamental research, OCT has a broad spectrum of applications spanning such diverse topics as materials research, tissue engineering, developmental biology, and small animal imaging. Preclinical applications of OCT are especially interesting because imaging technologies which enable longitudinal follow-up can improve the speed of pharmaceutical discovery and development. The development of clinical applications across multiple specialties and subspecialties is an enormous task requiring extensive clinical studies to assess efficacy on an indication-by-indication basis. These studies will be performed by multidisciplinary collaborative teams of scientists, engineers, and clinicians. The infrastructure to perform these studies will require government, industry, and foundations support as well as academic and industrial innovation. However, despite these

challenges, there is an enormous potential to advance scientific and clinical knowledge, improve patient care, and reduce morbidity and mortality.

2.1 Introduction

Several previous publications have addressed the theory of optical coherence tomography (OCT) imaging. These have included original articles [1–12], reviews [13, 14], and books/book chapters [15, 16]. Many of these publications were authored before the major revolution that Fourier-domain techniques (here termed FDOCT) brought to OCT since their sensitivity advantage was confirmed in 2003 [10–12]. Thus, many of these prior works were written primarily from the perspective of time-domain OCT (TDOCT). Also, relatively few prior publications have addressed lateral resolution in OCT systems, which, from an end user perspective, is of equal importance to the axial resolving power derived from low-coherence interferometry. The goal of this chapter is to present a unified theory of OCT, which includes a discussion of imaging performance in all three dimensions and which treats both Fourier- and time-domain OCT on equal footing as specializations of the same underlying principles.

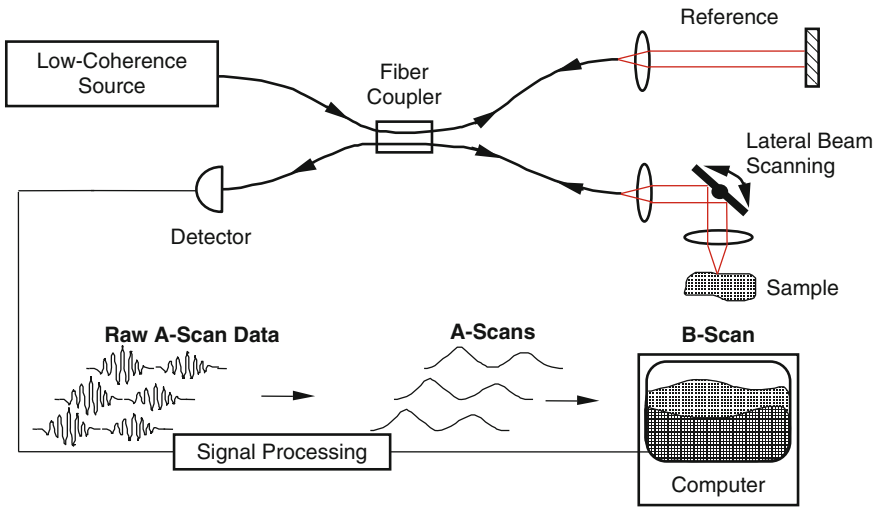

Fig. 2.1 Schematic of a generic fiber-optic OCT system. *Bold lines* represent fiber-optic paths, *red lines* represent free-space optical paths, and *thin lines* represent electronic signal paths

A generic OCT system schematic is illustrated in Fig. 2.1. Light from a low-coherence source is directed into a 2 × 2 fiberoptic coupler implementing a simple Michelson interferometer. The coupler is assumed to split the incident optical power evenly into sample and reference arms, although many practical OCT system designs take advantage of unbalanced power splitting, as has been described both theoretically and experimentally [8, 9]. Light exiting the reference fiber is incident upon a reference delay path and redirected back into the same fiber. Light exiting the sample fiber is incident upon an optical subsystem designed to focus the beam on the sample and to scan the focused spot in one or two lateral directions, typically under computer control. Many specialized scanning systems have been developed for OCT imaging applications in microscopy, ophthalmoscopy, endoscopy, catheterization, and others. The light backscattered or reflected from the sample is redirected through the same optical scanning system back into the sample arm fiber, where it is mixed with the returning reference arm light in the fiber coupler, and the combined light is made to interfere on the surface of a photoreceiver or detector. The electronic signals detected at the photoreceiver are processed into an A-scan, representing the depth-resolved reflectivity profile of the sample at the focal spot of the sample beam at a fixed lateral position of the scanning mechanism. As the scanning mechanism sweeps or steps the focused beam position across the sample, multiple A-scans are acquired and assembled in the computer into a two-dimensional cross-sectional image of the sample in the vicinity of the focal spot, termed a B-scan. Optionally, various alternative combinations of multidimensional lateral scanning and A-scan acquisition under computer control may be combined to create repeated A-scans at the same location as a function of time (termed M-scans), B-scans with lateral rather than depth priority, en face images at a fixed axial depth position (termed C-scans),

three-dimensional OCT volume data sets, and/or image improvement from OCT signal averaging in various combinations of dimensions.

In the case of TDOCT, the low-coherence source in Fig. 2.1 is broadband and continuous wave (cw), the reference arm delay is repetitively scanned in length, a single-channel (spectrally integrating) photoreceiver is employed, and the required signal processing consists of detecting the envelope of the detected fringe burst pattern corresponding to constructive interference between the reference arm light and each successive scattering site in the sample. FDOCT systems are subdivided into spectral-domain (or spectrometer-based) systems referred to as SDOCT and swept-source systems termed SSOCT (alternatively called OFDI by some authors). In the case of SDOCT, the source is broadband and cw, the reference arm length is fixed at a position approximately corresponding to the position of the sample, and the spectral interference pattern between the light returning from the reference arm and all depths in the sample is dispersed by a spectrometer and collected simultaneously on an array detector such as a charge-coupled device (CCD) or complementary metal-oxide-semiconductor (CMOS) camera. In the case of SSOCT, the source has narrow instantaneous linewidth but is rapidly swept in wavelength, and the spectral interference pattern is detected on a single photoreceiver as a function of time. The reference arm length is also fixed in SSOCT. In both SDOCT and SSOCT forms of FDOCT, the spectral interference pattern encodes in its spectral frequency content the entire depth-resolved structure of the sample at the position of the focal spot, and the A-scan may be recovered as described below using inverse Fourier transformation. Additional signal processing steps may also be required in FDOCT to prepare the spectral interferogram for the inverse Fourier transform, such as interpolation, so that the data is linearly sampled in wave number, addition of phase terms to correct for dispersion mismatches between the sample and reference arms, and others.

2.2 Confocal Gating and Lateral Resolution in OCT Systems

Some previous analyses have described the lateral resolution and axial field of view of OCT systems, as illustrated in Fig. 2.1 as the spot size and depth of focus of an assumed Gaussian profile sample arm beam in the region of the beam focus. This approach is a reasonable approximation and provides useful insight into the trade-off between these quantities specifically that spot size is proportional to the numerical aperture (NA) of the sample arm focusing optics, while the depth of focus is proportional to NA^2. However, it is more correct to treat the sample arm of an OCT system as a reflection-mode scanning confocal microscope, in which the single-mode optical fiber serves as a pinhole aperture for both illumination and collection of light from the sample. Even for OCT systems that do not employ fiber optics, the antenna response function of the homodyne wave mixing inherent to OCT can be shown to be equivalent to confocality [17]. Confocal microscopes using fiberoptic delivery and detection have been well described in the literature, including their lateral and axial point spread function behavior for single- and multimode fiber operation [18–20]. For single-mode optical fibers such as those used in OCT, the expressions for both lateral

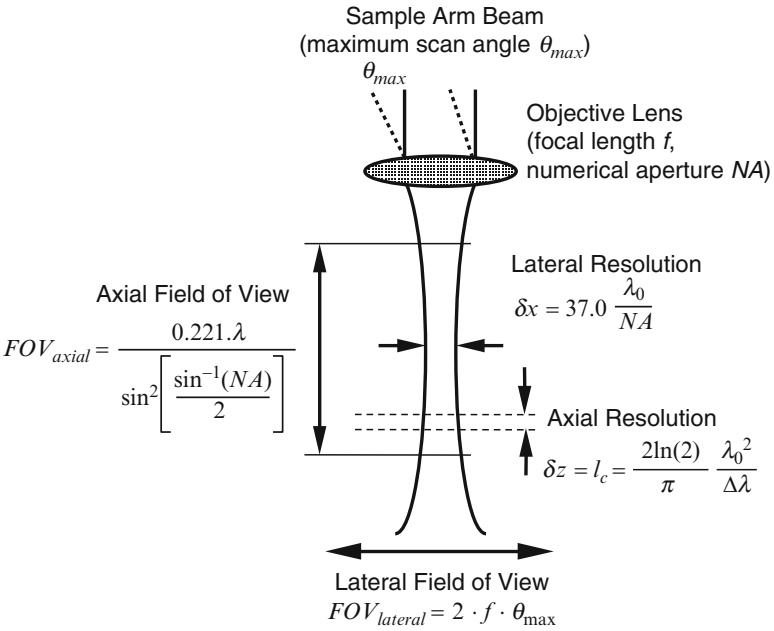

Fig. 2.2 Schematic of generic OCT sample arm optics. Formulas are provided for axial field of view FOV_{axial} and lateral resolution δx (assuming these quantities are dominated by the confocal geometrical optics), axial resolution δz (assuming it is limited by the low-coherence interferometer), and for lateral field of view FOV_{lateral} (assuming a simple f-theta scanning system)

and axial detected intensities reduce to those for an ideal confocal microscope with a diminishingly small pinhole aperture. Confocal microscopes have the advantage of slightly improved lateral resolution over conventional bright-field microscopes and the ability to perform "optical sectioning" due to their peaked axial response (unlike conventional bright-field microscopes, for which out-of-focus light is blurred, but not attenuated). A summary of results characterizing these quantities in lateral and axial directions is presented in Fig. 2.2. The optical system is assumed to be cylindrically symmetric, so only one lateral dimension is depicted.

An expression for the detected intensity from a point reflector placed in the focal plane of an ideal reflection confocal microscope as a function of lateral position is given by

$$I(v) = \left(\frac{2 \cdot J_1(v)}{v}\right)^4, \tag{2.1}$$

where $J_1(v)$ is a first-order Bessel function of the first kind and v is the normalized lateral range parameter defined by $v = 2\pi \cdot x \cdot \sin(\alpha)/\lambda_0$. Here, x is the lateral distance from the optical axis, α is half the angular optical aperture subtended by the objective, and λ_0 is the center wavelength of the light source. Note that the numerical aperture of the objective is given by $NA = \sin(\alpha)$, assuming that it is properly filled. We interpret Eq. 2.1 as the lateral point spread function of an OCT system at the

position of its focal plane and characterize it by defining the lateral resolution δx as its full width at half-maximum (FWHM) power, which calculates to

$$\delta x = 0.37 \cdot \frac{\lambda_0}{\sin(\alpha)} = 0.37 \frac{\lambda_0}{NA}. \tag{2.2}$$

The lateral field of view for an OCT system depends greatly upon the details of the lateral scanning system employed. A particularly simple scanning system employs some means to rotate the sample arm beam through the input aperture of the objective lens to a maximum one-sided scan angle $\theta_{\max}$ in one or two lateral dimensions. In this case, the lateral field of view of the OCT system is simply given by

$$FOV_{lateral} = 2 \cdot f \cdot \theta_{\max}.$$

We follow the convention in confocal microscopy [18, 19] and describe the axial response of the OCT sample arm optics as the confocal response to a planar rather than point reflector. The detected intensity of an ideal confocal microscope from a planar reflector as a function of the reflector position along the optic axis is given by

$$I(u) = \left(\frac{\sin(u/2)}{(u/2)} \right)^2, \tag{2.3}$$

where u is the normalized axial range parameter defined by $u = 8\pi \cdot z \cdot \sin^2(\alpha/2)/\lambda_0$. The axially peaked response of a confocal microscope gives it its well-known depth-sectioning capability. This is also the response we would expect by translating a mirror axially through the focus of an OCT sample arm. If the length of this function is comparable to the axial response of the OCT system arising from low-coherence interferometry (as described below), then the overall axial response of the OCT system should properly be described as the convolution of these two functions. OCT systems operating in this regime have been referred to as optical coherence microscopy or OCM systems [2, 21, 22]. In OCM, however, considerable effort must be expended to align the "confocal" and "coherence" gates and to keep them aligned as depth scanning is performed. In most OCT applications designed for practical clinical and research applications, a relatively low numerical aperture objective is used so that the lateral resolution δx is approximately matched to the axial resolution δz defined by the low-coherence interferometer (see Eq. 2.8), and thus approximately isotropic resolution imaging is performed. Under this condition, the confocal gate length is much larger than the lateral resolution since it scales as the square of the numerical aperture. However, the confocal gate length still limits the axial range over which the low-coherence interferometric depth scanning may usefully operate. We define the FWHM power of the confocal axial response function as the axial field of view FOV_{axial} of the OCT system, which calculates to

$$FOV_{axial} = \frac{0.221 \cdot \lambda}{\sin^2[\alpha/2]} = \frac{0.221 \cdot \lambda}{\sin^2\left[\frac{\sin^{-1}(NA)}{2}\right]}. \tag{2.4}$$

2.3 Spatial Coherence Gating in Full-Field OCT Systems

While the preceding discussion has assumed a point-scanning implementation of OCT, the expressions derived for lateral resolution and axial field of view are equally applicable for full-field OCT (FFOCT). FFOCT refers to a class of techniques wherein the entire en face slice of an OCT volume is acquired simultaneously by using a two-dimensional array camera as the detector in a wide-field interferometer. FFOCT has been demonstrated in both time-domain [23, 24] and Fourier-domain [25, 26] implementations. Fourier-domain FFOCT has only been demonstrated using swept sources since a three-dimensional camera would be necessary to obtain the two spatial and one spectral dimensions that would be required for spectrometer-based spectral-domain FFOCT.

An important consideration in the design of FFOCT systems is the management of multiple scattering and crosstalk artifacts [27, 28]. Cross talk originates in scattering samples when multiply scattered light reaches the detector and interferes with singly scattered light originating from the coherence-gated imaging depth in the reference. In point-scanning OCT, the confocal aperture of the single-mode fiber largely rejects multiply scattered light. However, FFOCT systems are implemented in free space and thus lack this confocal aperture. Therefore, multiply scattered photons are detected by the camera, and a subset of these multiply scattered photons will have traveled the correct optical path length to interfere with the reference field.

Cross talk artifacts can be avoided by employing a light source with low spatial coherence [29]. This prevents multiply scattered light in the sample arm from interfering with the reference field, effectively creating a spatial coherence gate that serves the same function as the confocal pinhole in point-scanning OCT. Because of this, thermal sources are often used in FFOCT systems [30, 31]. However, the average number of photons within a coherence volume of blackbody radiation is always on the order of unity [32], which limits the speed and sensitivity of OCT systems employing thermal sources [29, 33, 34]. A strategy to overcome this limit, while still achieving cross talk rejection, is to reduce the spatial coherence of a coherent source, such as a superluminescent diode or femtosecond laser. This can be achieved by piping light of high spatial but low temporal coherence through a multimode fiber that is either dynamically mode mixed [34] or whose length is appropriately selected [35]. In addition, "random" lasers can also produce light with moderate temporal coherence and low spatial coherence and have been used to demonstrate speckle-free laser imaging [36] and cross talk reduction in FFOCT [37].

2.4 Axial Ranging with Low-Coherence Interferometry

The fundamental quality that differentiates optical coherence tomography (OCT) from other forms of optical microscopy is that the predominant axial component of image formation derives from a ranging measurement performed using low-coherence interferometry. Consider the Michelson interferometer illustrated in Fig. 2.3. The interferometer is illuminated by a polychromatic plane wave whose

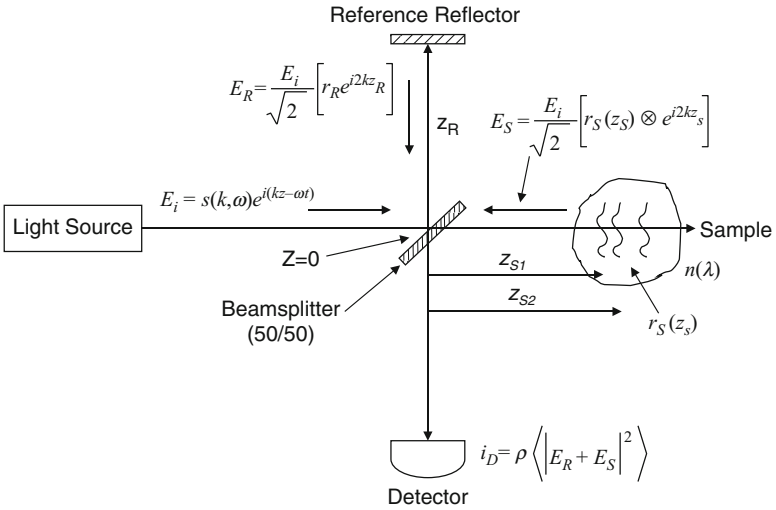

Fig. 2.3 Schematic of a Michelson interferometer used in OCT

electric field expressed in complex form is $E_i = s(k, \omega)e^{i(kz-\omega t)}$. Here, $s(k, \omega)$ is the electric field amplitude as a function of the wave number $k = 2\pi/\lambda$ and angular frequency $\omega = 2\pi v$, which are respectively the spatial and temporal frequencies of each spectral component of the field having wavelength λ. The wavelength λ and frequency v are coupled by the index of refraction $n(\lambda)$ (which is wavelength dependent in dispersive media) and vacuum speed of light c according to $c/n(\lambda) = \lambda v$. For simplicity of exposition in this section, all distances are assumed to be in free space and thus must be scaled by the appropriate index of refraction to obtain real-space measurements; the detailed effects of sample index and dispersion in OCT are discussed in Sect. 2.7. The beam splitter is assumed to have an achromatic (wavelength-independent) power splitting ratio of 0.5, although a generalization of OCT systems to unequal power splitting [8, 9] or other interferometer topologies (e.g., [8, 38]) is straightforward. The reference reflector is assumed to have electric field reflectivity r_R and power reflectivity $R_R = |r_R|^2$. The reference path is assumed to be in air, and the distance from the beam splitter to the reference reflector is z_R.

The sample under interrogation is characterized by its depth-dependent electric field reflectivity profile along the sample beam axis $r_s(z_s)$, where z_s is the path length variable in the sample arm measured from the beam splitter. In general, $r_s(z_s)$ is continuous, resulting from the continuously varying refractive index of biological tissues and other samples. It may also be complex, encoding the phase as well as the amplitude of each reflection. However, for an illustrative example, we assume a series of N discrete, real delta-function reflections of the form $r_S(z_s) = \sum_{n=1}^{N} r_{Sn}\delta[(z_S - z_{Sn})]$, with each reflection characterized by its electric field reflectivity r_{S1}, r_{S2} ... and path length from the beam splitter of z_{S1}, z_{S2} ... (see Fig. 2.4).

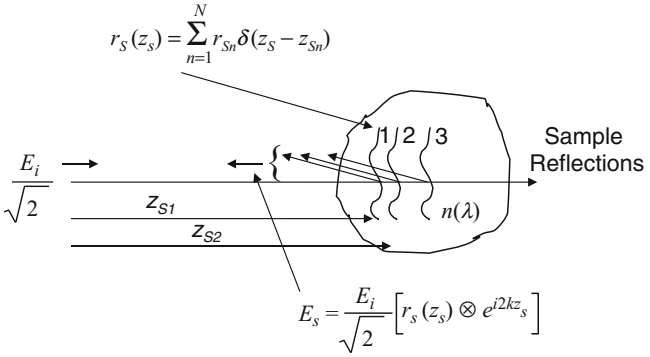

Fig. 2.4 Exemplary model for a sample comprising a series of discrete reflectors

The power reflectivity of each reflector is given by the magnitude squared of the electric field reflectivity, for example, $R_{S1} = |r_{S1}|^2$. **The reconstruction of the function $\sqrt{R_S(z_s)}$ from noninvasive interferometric measurements is the goal of low-coherence interferometry in OCT**. The electric field passing through the beam splitter after returning from the sample arm is $E_s = \frac{E_i}{\sqrt{2}}\left[r_s(z_s) \otimes e^{i2kz_s}\right]$, where $\otimes$ represents convolution and the factor of 2 in the exponential kernel accounts for the round-trip path length to each sample reflection. Note that for most samples such as biological tissues imaged with OCT, sample reflectivities R_{S1}, R_{S2} ... are typically very small (on the order of $\sim 10^{-4}$ to 10^{-5}); thus, the returned reference field typically dominates the reflected sample field. Indeed, selection of the appropriate reference reflectivity is an important criterion in OCT system design [7, 8].

For the example of discrete reflectors, the fields incident on the beam splitter after returning from the reference and sample arms are given by $E_R = \frac{E_i}{\sqrt{2}} r_R e^{i2kz_R}$ and $E_s = \frac{E_i}{\sqrt{2}} \sum_{n=1}^{N} r_{Sn} e^{i2kz_{Sn}}$, respectively. The returning fields are halved in power upon passing through the beam splitter again and interfere at the square-law detector, which generates a photocurrent proportional to the square of the sum of the fields incident upon it, given by $I_D(k,\omega) = \frac{\rho}{2}\left\langle |E_R + E_S|^2 \right\rangle = \frac{\rho}{2}\langle (E_R + E_S)(E_R + E_S)^* \rangle$. Here, ρ is the responsivity of the detector (units amperes/watt), the factor of 2 reflects the second pass of each field through the beam splitter, and the angular brackets denote integration over the response time of the detector. Arbitrarily setting $z = 0$ at the surface of the beam splitter and expanding for the detector current give

$$I_D(k,\omega) = \frac{\rho}{2}\left\langle \left| \frac{s(k,\omega)}{\sqrt{2}} r_R e^{i(2kz_R - \omega t)} + \frac{s(k,\omega)}{\sqrt{2}} \sum_{n=1}^{N} r_{Sn} e^{i(2kz_{Sn} - \omega t)} \right|^2 \right\rangle. \tag{2.5}$$

Expanding the magnitude squared functions in Eq. 2.5 eliminates the terms dependent upon the temporal angular frequency $\omega = 2\pi v$, which is reasonable

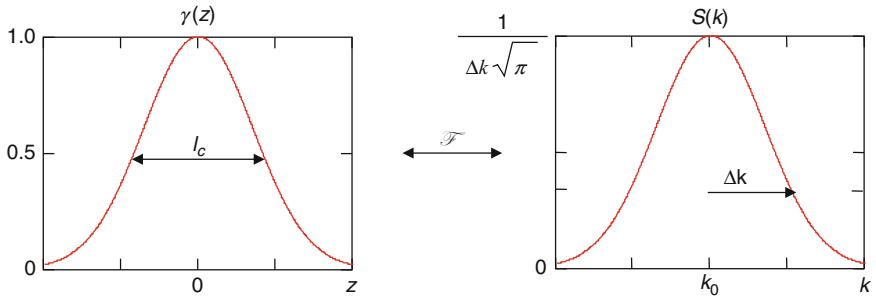

Fig. 2.5 Illustration of Fourier transform relationship between the Gaussian-shaped coherence function $\gamma(z)$ (characterized by the coherence length l_c) and the light source spectrum $S(k)$ (characterized by the central wave number k_0 and wave number bandwidth Δk)

since v oscillates much faster than the response time of any detector. This leaves the temporally invariant terms:

$$\begin{aligned} I_D(k) = &\frac{\rho}{4}\left[S(k)\cdot(R_R + R_{S1} + R_{S2} + \ldots)\right] \\ &+ \frac{\rho}{4}\left[S(k)\sum_{n=1}^{N}\sqrt{R_R R_{Sn}}\left(e^{i2k(z_R - z_{Sn})} + e^{-i2k(z_R - z_{Sn})}\right)\right] \\ &+ \frac{\rho}{4}\left[S(k)\sum_{n\neq m=1}^{N}\sqrt{R_{Sn}R_{Sm}}\left(e^{i2k(z_{Sn} - z_{Sm})} + e^{-i2k(z_{Sn} - z_{Sm})}\right)\right]. \end{aligned} \tag{2.6}$$

Here, $S(k) = \langle |s(k,\omega|^2 \rangle$ is substituted, which encodes the power spectral dependence of the light source. As an illustrative example, a Gaussian-shaped light source spectrum is convenient to use in modeling OCT because it approximates the shape of actual light sources and also has useful Fourier transform properties. The normalized Gaussian function $S(k)$ and its inverse Fourier transform $\gamma(z)$ are given by

$$\gamma(z) = e^{-(z)^2\Delta k^2} \xleftrightarrow{F} S(k) = \frac{1}{\Delta k\sqrt{\pi}} e^{-\left[\frac{(k-k_0)}{\Delta k}\right]^2} \tag{2.7}$$

and are illustrated in Fig. 2.5. Here, k_0 represents the central wave number of the light source spectrum, and Δk represents its spectral bandwidth, corresponding to the half-width of the spectrum at $1/e$ of its maximum. As will be seen below, the inverse Fourier transform $\gamma(z)$, hereafter called the "coherence function," dominates the axial point spread function (PSF) in OCT imaging systems (in OCT systems employing a low numerical aperture focusing objective, as pointed out in Sect. 2.2). The PSF is commonly characterized by its full width at half the maximum (FWHM) value and is the definition of the round-trip "coherence length" of the light source l_c. The free-space coherence length is an explicit function of the light source bandwidth, stated in both wave number and wavelength terms as

$$l_c = \frac{2\sqrt{\ln(2)}}{\Delta k} = \frac{2\ln(2)}{\pi}\frac{{\lambda_0}^2}{\Delta\lambda}. \tag{2.8}$$

Here, $\lambda_0 = \frac{2\pi}{k_0}$ is the center wavelength of the light source, and $\Delta\lambda$ is its wavelength bandwidth, defined as the FWHM of its wavelength spectrum $\left(\text{so that } \Delta k = \frac{\pi}{\sqrt{\ln(2)}}\frac{\Delta\lambda}{\lambda_0^2}\right)$. Note the inverse relationship between the coherence length and the light source bandwidth.

Using Euler's rule to simplify Eq. 2.6 generates a real result for the detector current as a function of wave number, commonly known as the "spectral interferogram":

$$\begin{aligned} I_D(k) = {} & \frac{\rho}{4}[S(k)[R_R + R_{S1} + R_{S2} + \ldots]] \quad \text{“DC Terms”} \\ & + \frac{\rho}{2}\left[S(k)\sum_{n=1}^{N}\sqrt{R_R R_{Sn}}(\cos[2k(z_R - z_{Sn})])\right] \quad \text{“Cross-correlation Terms”} \\ & + \frac{\rho}{4}\left[S(k)\sum_{n\neq m=1}^{N}\sqrt{R_{Sn}R_{Sm}}\cos[2k(z_{Sn} - z_{Sm}]\right] \quad \text{“Auto-correlation Terms”} \end{aligned} \tag{2.9}$$

The result in Eq. 2.6 includes three distinct components:

1. A path length-independent offset to the detector current, scaled by the light source wave number spectrum and with amplitude proportional to the power reflectivity of the reference mirror plus the sum of the sample reflectivities. This term is often referred to as "constant" or "DC" component. This is the largest component of the detector current if the reference reflectivity dominates the sample reflectivity.
2. A "cross-correlation" component for each sample reflector, which depends upon both the light source wave number and the path length difference between the reference arm and sample reflectors. This is the desired component for OCT imaging. Since these components are proportional to the square root of the sample reflectivities, they are typically smaller than the DC component. However, the square root dependence represents an important logarithmic gain factor over the direct detection of sample reflections.
3. "Autocorrelation" terms representing interference occurring between the different sample reflectors appear as artifacts in typical OCT system designs (exceptions occur in common-path system designs, in which the autocorrelation component represents the desired signal). Since the autocorrelation terms depend linearly upon the power reflectivity of the sample reflections, a primary tool for decreasing autocorrelation artifacts is the selection of the proper reference reflectivity so that the autocorrelation terms are small compared to the DC and interferometric terms.

It is useful to gain an intuitive understanding of the form of Eq. 2.9, as well as the effect that different source spectra and different numbers of sample reflectors and

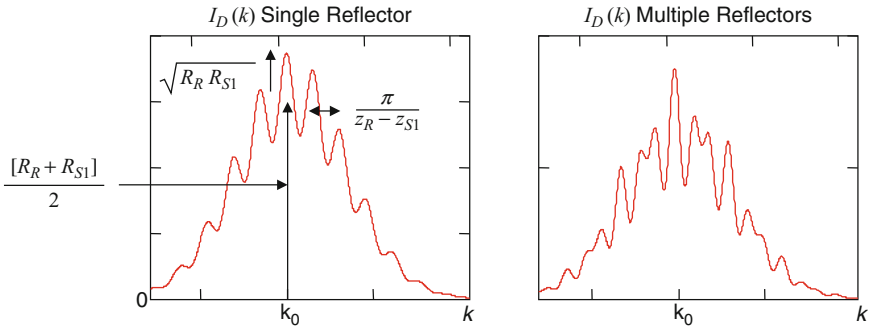

Fig. 2.6 Important features of the spectral interferogram. For a single sample reflector of field reflectivity $r_{S1} = 0.1$ (*left*), the cross-correlation component with amplitude $\sqrt{R_R R_{S1}}$ and wave number period $\frac{\pi}{z_R - z_{S1}}$ rides on top of the DC term of amplitude $\frac{[R_R + R_{S1}]}{2}$ (factors of $\rho S(k)$ are left out for clarity). For multiple reflectors, the cross-correlation component is a superposition of cosinusoids

their distributions have upon it. For a single reflector, only DC and a single interferometric term are present, and the source spectrum is modulated by a simple cosinusoid whose period is proportional to the distance between the sample and reference reflectors, as illustrated in Fig. 2.6. In addition, the amplitude of spectral modulation or "visibility" of the spectral fringes is proportional to the amplitude reflectivity of the sample reflector $\sqrt{R_{S1}}$. For the case of multiple reflectors, the spectrum is modulated by multiple cosinusoids, each having a frequency and amplitude characteristic of the sample reflection that gives rise to it. In addition, if more than one reflector is present in the sample, autocorrelation components modulated according to the path length difference between the sample reflectors and proportional to the product of their amplitude reflectivities also appear. Since the sample amplitude reflectivities are usually small compared to the reference reflection, the autocorrelation terms are usually small compared to the cross-correlation terms. Also, since reflections in the sample tend to be clumped closely together compared to the distance between the sample and the reference reflector, the autocorrelation term modulation frequencies also tend to be small.

2.5 Fourier-Domain Low-Coherence Interferometry

In Fourier-domain OCT (FDOCT), the wave number-dependent detector current $I_D(k)$ in Eq. 2.9 is captured and processed using Fourier analysis to reconstruct an approximation of the internal sample reflectivity profile $\sqrt{R_S(z_s)}$. The process for capturing $I_D(k)$ depends upon the experimental details of the detection apparatus. In spectral-domain OCT (SDOCT, also called spectrometer-based OCT), a broadband light source is used, and all spectral components of $I_D(k)$ are captured simultaneously on a detector array placed at the output of a spectrometer [39–41]. In swept-source OCT (SSOCT, also called optical frequency-domain imaging or OFDI), the spectral

components of $I_D(k)$ are captured sequentially by recording the signal in a single detector while synchronously sweeping the wave number of a narrowband swept-laser source [42–45].

The sample reflectivity profile $r_s(z_s)$ is estimated from the inverse Fourier transform of $I_D(k)$. Making use of the Fourier transform pair $\frac{1}{2}(\delta[(z+z_0)]+\delta[(z-z_0)]) \overset{F}{\longleftrightarrow} \cos kz_0$ and the convolution property of Fourier transforms $x(z)\otimes y(z) \overset{F}{\longleftrightarrow} X(k)Y(k)$, the inverse Fourier transform of Eq. 2.9 may be calculated as

$$\begin{aligned} i_D(z) = {} & \frac{\rho}{8}[\gamma(z)[R_R + R_{S1} + R_{S2} + \ldots]] \text{“DC terms”} \\ & + \frac{\rho}{4}\left[\gamma(z)\otimes\sum_{n=1}^{N}\sqrt{R_R R_{Sn}}(\delta[(z\pm 2(z_R - z_{Sn}))])\right] \text{“Cross-correlation terms”} \\ & + \frac{\rho}{8}\left[\gamma(z)\otimes\sum_{n\neq m=1}^{N}\sqrt{R_{Sn}R_{Sm}}(\delta[(z\pm 2(z_{Sn} - z_{Sm}))])\right] \text{“Auto-correlation terms.”} \end{aligned} \tag{2.10}$$

Note that the desired sample field reflectivity profile $\sqrt{R_S(z_s)} = \sum_{n=1}^{N}\sqrt{R_{Sn}}\delta[(z_S - z_{Sn})]$ is indeed embedded within the cross-correlation terms of Eq. 2.10, although it is surrounded by several confounding factors. Carrying out the convolutions by taking advantage of the sifting property of the delta function, we obtain the result of the interferometric measurement, referred to as the “A-scan”:

$$\begin{aligned} i_D(z) \quad = {} & \frac{\rho}{8}[\gamma(z)[R_R + R_{S1} + R_{S2} + \ldots]] \\ & + \frac{\rho}{4}\sum_{n=1}^{N}\sqrt{R_R R_{Sn}}[\gamma[2(z_R - z_{Sn})] + \gamma[-2(z_R - z_{Sn})]] \\ & + \frac{\rho}{8}\sum_{n\neq m=1}^{N}\sqrt{R_{Sn}R_{Sm}}[\gamma[2(z_{Sn} - z_{Sm})] + \gamma[-2(z_{Sn} - z_{Sm})]]. \end{aligned} \tag{2.11}$$

The results in Eqs. 2.10 and 2.11 for the example of discrete sample reflectors and a Gaussian-shaped source spectrum are plotted in Fig. 2.7. As can be seen in the figure, the sample field reflectivity profile $\sqrt{R_S(z_s)} = \sum_{n=1}^{N}\sqrt{R_{Sn}}\delta[(z_S - z_{Sn})]$ is reproduced in the cross-correlation terms, with the following modifications: First, the sample reflectivity profile appears as a function of the reference coordinate z_R, rather than the sample coordinate z_S. Second, the apparent displacement of each sample reflector from the reference position is doubled (which can be understood from the fact that the interferometer measures the round-trip distance to each reflector). We accommodate this by defining a new single-pass depth variable $\widehat{z} = 2z$.

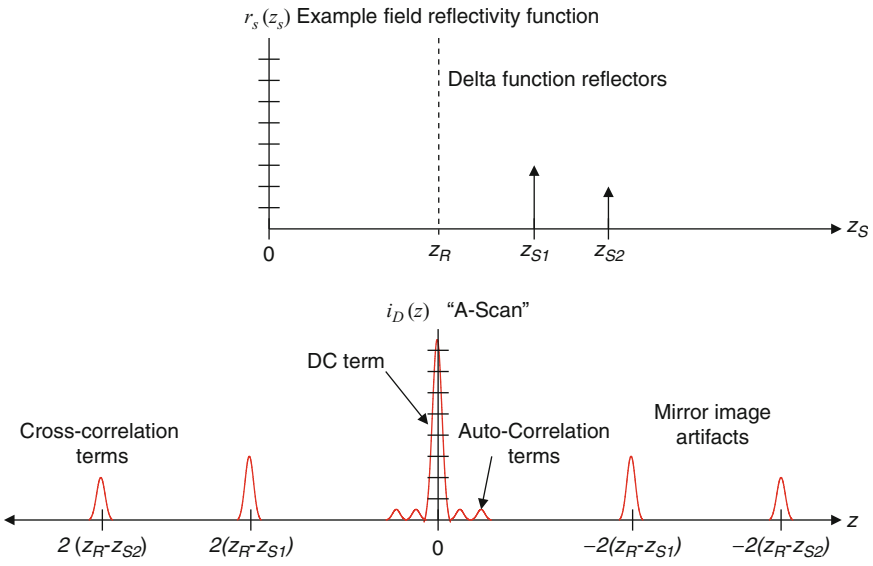

Fig. 2.7 Illustration of the example discrete-reflector sample field reflectivity function $r_S(z_s) = \sum_{n=1}^{N} r_{Sn}\delta(z_S - z_{Sn})$ (*top*) and the A-scan resulting from Fourier-domain low-coherence interferometry

Third, each reflector appears broadened or blurred out to a width of about a coherence length by convolution with the function $\gamma(z)$. This is precisely the definition of an imaging system PSF. Given the inverse relationship of the coherence length to the light source bandwidth, the clearest path to increasing the fidelity of the estimate of $\sqrt{R_S(z_s)}$ is to use as broad-bandwidth sources as possible. Fourth, the magnitude of the detected sample reflectivity, which can be very small, is amplified by the large homodyne gain factor represented by the strong reference reflectivity $\sqrt{R_R}$. All of the modifications listed so far can be dealt with through proper interpretation of the data, that is, the realization that the zero position corresponds to the position of the reference reflector, relabeling axial distances to account for the factor of 2, and accounting for the homodyne gain factor.

A number of additional modifications to the field reflectivity profile are termed artifacts and are more serious. First, as seen in the cross-correlation terms in Eqs. 2.10 and 2.11, a mirror image of the blurred version of $\sqrt{R_S(z_s)}$ appears on the opposite side of zero path length, that is, the reference reflector position. This is termed the complex conjugate artifact in FDOCT and is simply understood from the fact that since the detected interferometric spectrum is necessarily real, its inverse Fourier transform must be Hermitian symmetric, that is, its values at positive and negative distances are complex conjugates of each other, and therefore if they are real, they must be identical. This artifact is not disabling so long as the sample can be kept entirely to one side of zero path length, in which case it can be dealt with by

simply only displaying the positive or negative distances. However, if the sample strays over the zero path length border, it begins to overlap its mirror image, an effect that cannot be removed by image processing alone. A number of approaches have been described for removing this complex conjugate artifact ([46–53]; also see Sect. 2.8.2).

Additional image artifacts also arise from the DC and autocorrelation terms in Eqs. 2.10 and 2.11. The DC terms give rise to a large artifactual signal centered at zero path length difference. The FWHM value of the DC artifact is only one coherence length wide; however, the signal amplitude is so much larger than the desired cross-correlation terms that the wings of the Gaussian-shaped PSF from Eq. 2.7 can overwhelm the desired signal components much farther away. Since the largest component of the DC artifact comes from the reference reflector (with reflectivity near 1), a simple method to eliminate that component is to record the amplitude of the spectral interferometric signal Eq. 2.9 with the reference reflector but no sample present and then to subtract this signal component from each subsequent spectral interferometric signal acquired. The autocorrelation terms in Eqs. 2.10 and 2.11 also give rise to artificial signals at and near the zero path length position, since the distance between reflectors in a sample is typically much smaller than the distance between the sample reflectors and the reference arm path length. The best method to eliminate the autocorrelation signals is to ensure that the reference reflectivity is sufficient so that the amplitude of the autocorrelation terms is very small compared to the cross-correlation terms.

2.6 Time-Domain Low-Coherence Interferometry

In traditional or time-domain OCT (TDOCT), the wave number-dependent detector current $I_D(k)$ in Eq. 2.9 is captured on a single receiver, while the reference delay z_r is scanned to reconstruct an approximation of the internal sample reflectivity profile $\sqrt{R_S(z_s)}$. The result is obtained by the integration of Eq. 2.9 over all k:

$$I_D(z_R) = \frac{\rho}{4}[S_0[R_R + R_{S1} + R_{S2} + \ldots]] \quad \text{“DC offset”}$$
$$+ \frac{\rho}{2}\left[S_0 \sum_{n=1}^{N} \sqrt{R_R R_{Sn}}\, e^{-[(z_R - z_{Sn})]^2 \Delta k^2} \cos\left[2k_0(z_R - z_{Sn})\right]\right] \quad \text{“Fringe bursts.”} \tag{2.12}$$

Here, $S_0 = \int_0^\infty S(k)dk$ is the spectrally integrated power emitted by the light source. The time-domain “A-scan” resulting from such a measurement is illustrated in Fig. 2.8. Note that the sample reflectivity profile convolved with the source coherence function is again recapitulated in the result, resident on a DC offset proportional to the sum of the reference and sample power reflectivities. In addition,

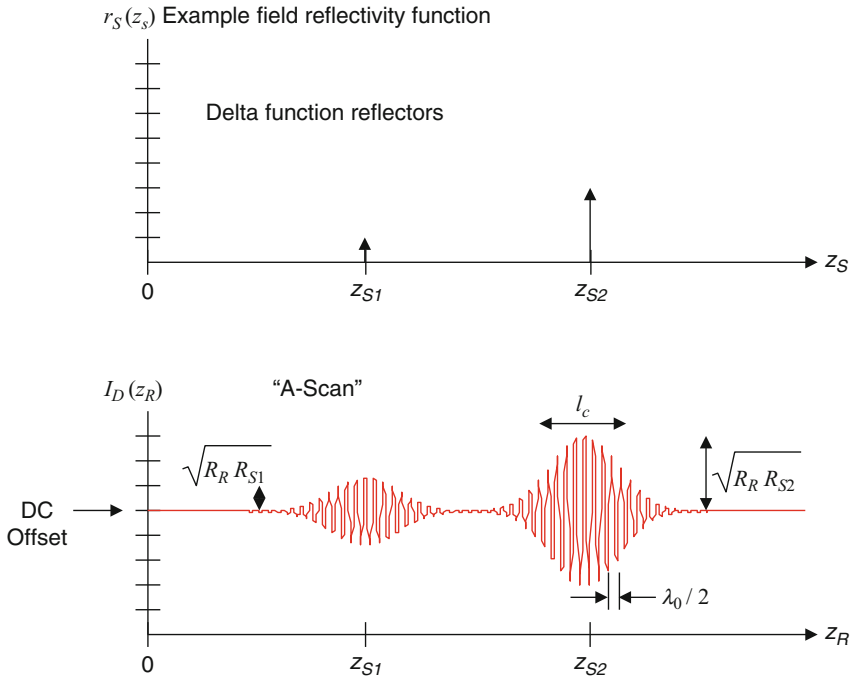

Fig. 2.8 Illustration of the example discrete-reflector sample field reflectivity function $r_S(z_s) = \sum_{n=1}^{N} r_{Sn}\delta(z_S - z_{Sn})$ (*top*) and the A-scan resulting from time-domain low-coherence interferometry

the convolved sample reflectivity profile is modulated by a cosinusoidal carrier wave modulation at a frequency proportional to the source center wave number k_0 and the free-space difference between reference and sample arm lengths $(z_R - z_{Sn})$. Since the reference arm length z_R is typically scanned as a function of time in TDOCT systems, this carrier provides a convenient modulation frequency for lock-in detection, which provides for high-sensitivity detection of the reflectivity envelope and rejection of the DC offset.

2.7 Effects of Index of Refraction and Dispersion

In the preceding sections, all distances were assumed to be in free space, and the effects of varying media in the interferometer arms were not considered. In reality, both reference and sample arms may contain a variety of materials with various indices of refraction, such as optical fiber, glass, air, and biological tissue. In this case, the fields returning from the reference and each reflection from the sample are more correctly written as

$$E_R = \frac{E_i}{\sqrt{2}} r_R \exp\left[i2\int \beta_R(\omega) dz_r\right]; \qquad E_S = \frac{E_i}{\sqrt{2}} r_S \exp\left[i2\int \beta_S(\omega) dz_s\right], \tag{2.13}$$

where $\beta_R(\omega)$ and $\beta_S(\omega)$ are the frequency-dependent propagation constants of the respective media. As is clear from Eq. 2.6, in OCT only the difference in net propagation between reference and sample arms is preserved; thus, so long as all fiber and air path lengths in each arm are closely matched, we denote the residual difference in propagation between the arms as occurring in a single medium (corresponding perhaps to the residual unmatched fiber length between the arms or to tissue in the sample, which is not present in the reference) with propagation constant $\beta(\omega)$. Similar to the analysis performed for optical pulse propagation in dispersive media, for low-coherence light, the dispersion constant $\beta(\omega)$ may be expanded as a Taylor series expansion around the central frequency ω_0, as

$$\begin{aligned} \beta(\omega) &= \beta(\omega_0) + \beta'(\omega_0)(\omega - \omega_0) + \frac{1}{2}\beta''(\omega_0)(\omega - \omega_0)^2 + \ldots \\ &= \frac{\omega_0}{v_p} + \frac{\omega - \omega_0}{v_g} + \ldots . \end{aligned} \tag{2.14}$$

Here, the first three terms of the approximation correspond to zero-order (nondispersive), first-order, and second-order dispersion, respectively, and the zeroth and first-order terms are expressed in terms of the phase velocity (v_p) and group velocity (v_g) of light in the medium at the central frequency. Hee [15] and Dhalla [54] have performed analyses of the cross-correlation component of the OCT signal up to second order for time-domain and Fourier-domain OCT, respectively.

The effects on the OCT signal of unmatched dispersion up to first order result in simple modifications to the A-scan expressions derived above. Directly analogous to pulse propagation in dispersive media, the "fringe bursts" in TDOCT are modulated according to the phase velocity, while the coherence function in both TDOCT and FDOCT is both scaled by and delayed by the group velocity. Particularly, simple expressions result from expressing the phase and group velocities in terms of phase (n_p) and group (n_g) indices of refraction, expressed as

$$n_p = c/v_p = n(\lambda_0); \;\; n_g = c/v_g = n_p - \lambda_0 n'(\lambda_0). \tag{2.15}$$

Here, $n(\lambda)$ is the index of refraction, λ_0 is the central wavelength as above, and c is the vacuum speed of light. Expressions correct to first order in dispersion for the coherence length in the medium and the A-scan signal in FDOCT and TDOCT appear in Table 2.1.

In practical terms, the effect of dispersion up to first order in media of practical interest is quite small if limited to small unmatched path lengths. For example, the difference between phase and group index averages less than 0.015 index units over the wavelength range 0.6–1.3 μm in fused silica optical fibers. For many purposes, the phase index (i.e., the index of refraction at the central wavelength

Table 2.1 Real-space expressions for the coherence length, Fourier-domain OCT A-scan signal, and time-domain OCT A-scan signal in a sample, correct to first-order dispersion. Expressions are in terms of the phase (n_p) and group (n_g) indices of refraction of the sample

Coherence length	$l_c = \frac{2\sqrt{\ln(2)}}{\Delta k \cdot n_g} = \frac{2\ln(2)}{\pi \cdot n_g}\frac{{\lambda_0}^2}{\Delta\lambda}$
Fourier-domain OCT detector current (A-scan)	$i_D(z) = \frac{\rho}{8}\left[\gamma(z/n_g)\left[R_R + R_{S1} + R_{S2} + \ldots\right]\right]$ $+ \frac{\rho}{4}\sum_{n=1}^{N}\sqrt{R_R R_{Sn}}\left[\gamma\left[2(z_R - z_{Sn})/n_g\right] + \gamma\left[-2(z_R - z_{Sn})/n_g\right]\right]$ $+ \frac{\rho}{8}\sum_{n\neq m=1}^{N}\sqrt{R_{Sn}R_{Sm}}\left[\gamma\left[2(z_{Sn} - z_{Sm})/n_g\right] + \gamma\left[-2(z_{Sn} - z_{Sm})/n_g\right]\right]$
Time-domain OCT detector current (A-scan)	$I_D(z_R) = \frac{\rho}{4}\left[S_0\left[R_R + R_{S1} + R_{S2} + \ldots\right]\right]$ $+ \frac{\rho}{2}\left[S_0\sum_{n=1}^{N}\sqrt{R_R R_{Sn}}e^{-\left[\left(z_R - z_{Sn}/n_g\right)\right]^2\Delta k^2}\cos\left[2k_0(z_R - z_{Sn})/n_p\right]\right]$

of the light source) is sufficiently accurate. However, it is important to realize that all free-space distances in other sections of this chapter must be divided by the appropriate index of refraction to obtain real-space measurements.

On the other hand, second-order (group velocity) and higher-order dispersion can distort OCT signals substantially, particularly for unmatched path lengths exceeding several mm in highly dispersive glasses or away from the minimum dispersion wavelength in optical fibers.

2.8 Practical Aspects of FDOCT Signal Processing

2.8.1 Sensitivity Falloff and Sampling Effects in FDOCT

While the FDOCT spectral interferogram of Eq. 2.9 and its continuous-time inverse Fourier transform (Eq. 2.11) illustrate the fundamental principle underlying spectrometer-based (SD) and swept-source (SS) OCT, in practical implementations of these devices, several additional factors must be taken into account. The spectral interferogram data is generated by instrumentation having real-world limitations and is typically acquired by a sampling operation for rapid digital signal computation of its inverse Fourier transform. Figure 2.9 illustrates conceptually the effects of finite spectral resolution and sampling upon the spectral interferogram and its inverse Fourier transform.

First, the instrumentation for acquiring the spectral interferogram always has limited spectral resolution, here denoted by $\delta_r k$. In SSOCT, $\delta_r k$ is limited by the instantaneous line shape of the swept-laser source, while in SDOCT, $\delta_r k$ is the spectral resolution of the spectrometer (including the finite spacing of the CCD or CMOS pixels, whose effect on resolution in SDOCT has also been modeled explicitly [55]). We model the effect of finite spectral resolution by convolving the ideal spectral interferogram from Eq. 2.9 with a Gaussian function having

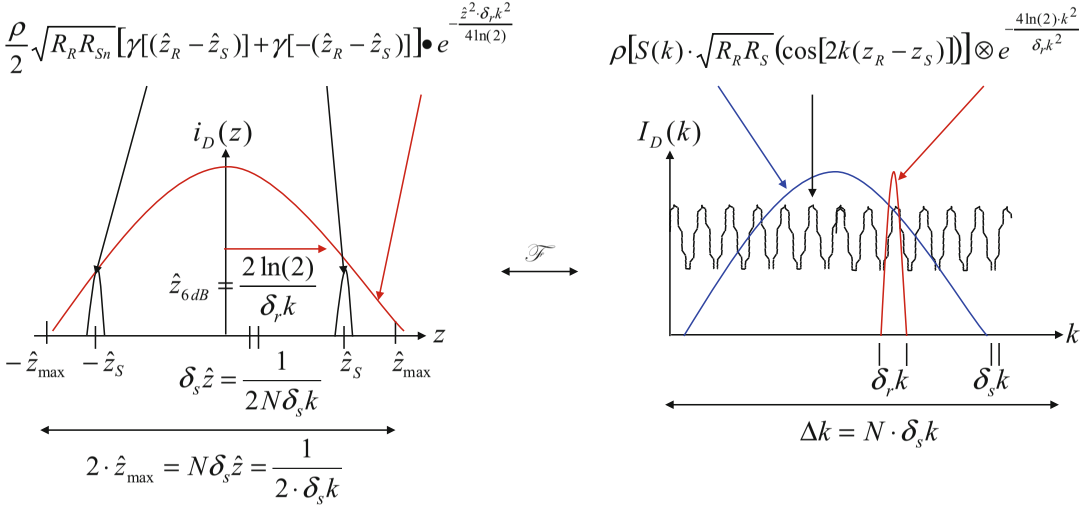

Fig. 2.9 Conceptual basis for sensitivity falloff and maximum imaging depth in FDOCT. Note that the depth-dependent falloff in sensitivity is directly related to the resolution of the interference spectrum, which is dominated by the source linewidth in SSOCT and the spectrometer resolution in FDOCT

half-maximum width $\delta_r k$, which we interpret as the FWHM spectral resolution. Via the convolution property, the A-scan data is thus multiplied by a sensitivity "falloff" factor whose shape is given by the inverse Fourier transform of the Gaussian-shaped resolution factor, which is also a Gaussian:

$$i_D(\hat{z}) \bullet \exp\left[-\frac{(\hat{z})^2 \cdot \delta_r k^2}{4\ln(2)}\right] \overset{F}{\longleftrightarrow} I_D(k) \otimes \exp\left[-\frac{4\ln(2) \cdot k^2}{\delta_r k^2}\right]. \tag{2.16}$$

The use here of the rescaled depth variable $\hat{z} = 2z$ removes the apparent depth-doubling factor in FDOCT and allows processed A-scan data to be compared directly to the sample structure. The exponential falloff of sensitivity with depth can be understood as the decreasing visibility of higher fringe frequencies corresponding to large sample depths. It may be characterized by defining the one-sided depth at which the sensitivity falls off by a factor of ½ or 6 dB in optical SNR units:

$$\hat{z}_{6dB} = \frac{2\ln(2)}{\delta_r k} = \frac{\ln(2)}{\pi} \frac{{\lambda_0}^2}{\delta_r \lambda}. \tag{2.17}$$

Here, $\hat{z}_{6dB}$ is given in terms of the FWHM spectral resolution in both wave number ($\delta_r k$) and wavelength ($\delta_r \lambda$) terms, the latter of which is recognizable as one-half of the coherence length corresponding to the spectral resolution.

The second major consideration in real-world processing of FDOCT data is that computer-based detection involves sampling the spectral interferogram. We assume that the interferogram is sampled with spectral sampling interval $\delta_s k$ into M spectral channels linearly spaced in k. The total wave number range collected is thus $\Delta k = M \cdot \delta_s k$, and this in turn sets the sampling interval in the z-domain $\delta_s \hat{z} = 2\pi/(2\Delta k)$, where the extra factor of 2 in the denominator arises from the use of the rescaled depth parameter $\hat{z}$. The maximum and minimum depth samples are thus given by the Nyquist criterion as

$$\pm z_{\max} = \pm \frac{\pi}{2 \cdot \delta_s k} = \pm \frac{n_0 {\lambda_0}^2}{4 \cdot \delta_s \lambda}. \tag{2.18}$$

A summary of the results of this section is provided in Table 2.2. In addition to these limitations imposed by spectral resolution and sampling, which are difficult to overcome, additional real-world complications arise that can be handled with appropriate digital signal processing. First, the spectral interferogram data may not be acquired as a linear function of optical wave number, which is the required conjugate variable for imaging depth in the inverse Fourier transform operation underlying FDOCT. For example, grating-based spectrometers typically disperse spectra approximately linearly in wavelength rather than wave number, and swept-wavelength laser sources may be subject to any number of nonlinearities. For each of these cases, solutions involving clever spectrometer designs, clever k-triggering schemes, or, as a last resort, digital spectral resampling after acquisition have all been described. In addition, dispersion effects due to mismatched glass or tissue

Table 2.2 Effects of sampling and finite spectral resolution in Fourier-domain OCT (FDOCT) systems. δ_s and δ_r represent the spectral sampling interval and FWHM spectral resolution, respectively. The maximum imaging depth $z_{\max}$ may be doubled by the use of methods for removing the complex conjugate ambiguity artifact. Depths listed are in free space and should be divided by the group index of refraction in media

	Maximum one-sided imaging depth $\widehat{z}_{\max}$	6 dB SNR falloff point $\widehat{z}_{6dB}$
Wave number units ($k = 2\pi/\lambda$)	$\frac{\pi}{2 \cdot \delta_s k}$	$\frac{2\ln(2)}{\delta_r k}$
Wavelength units	$\frac{{\lambda_0}^2}{4 \cdot \delta_s \lambda}$	$\frac{\ln(2)}{\pi} \frac{{\lambda_0}^2}{\delta_r \lambda}$

lengths in the sample and reference arms may also be corrected by the addition of appropriate phase factors to the spectral interferometric data prior to inverse Fourier transformation.

2.8.2 Artifact Removal in FDOCT by Phase Shifting

The DC, autocorrelation, and complex conjugate artifacts in FDOCT may in principle be removed by utilizing principles and techniques borrowed from phase-shift interferometry [47, 48, 56, 57]. If the interferometer is modified to provide for the introduction of a variable single-pass phase delay ϕ (round-trip phase delay 2ϕ) between the reference and sample arms, then a set of spectral interferograms may be acquired with different phase delays that can be combined in signal processing to eliminate the undesired artifacts. For example, Fig. 2.10 illustrates an FDOCT interferometer with a variable phase modulator placed in the reference arm, such that the reference field returning from the reference arm is modified to $E_R = \frac{E_i}{\sqrt{2}} r_R e^{i(2kz_R + 2\phi)}$. There are a number of approaches for introducing such phase delays. Phase modulators based on electro-optic, acousto-optic, and photoelastic modulators may be utilized, or the reference mirror itself may be dithered by mounting it on a piezoelectric transducer. Such transducers have the advantage of relative simplicity; however, their use requires that phase-shifted spectral interferograms be acquired sequentially; thus, the resulting artifact reduction occurs at the cost of increased acquisition time. Phase-shifted spectral interferograms may also be acquired simultaneously on separate detectors by employing interferometer topologies that intrinsically separate phase-shifted signals into different detector channels. Such simultaneous phase-shifted interferometers have been constructed that use orthogonal polarization states to carry phase-shifted signals or that employ 3×3 or higher-order fiber couplers to separate phase channels. While the analysis to follow assumes that the phase delay is inserted in the reference arm, it is the phase difference between reference and sample arms that matters; thus, phase-shifting elements may be placed in either arm.

Rewriting the spectral interferogram from Eq. 2.5 with this additional phase delay explicitly included yields

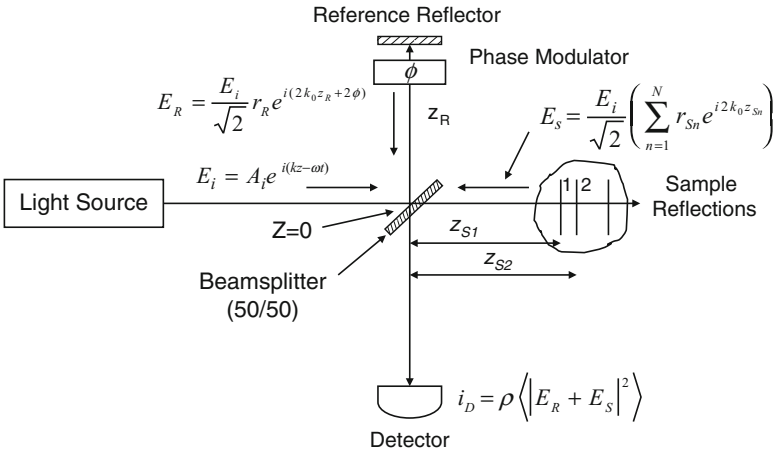

Fig. 2.10 FDOCT interferometer with addition of variable round-trip phase delay ϕ in the reference arm

$$
\begin{aligned}
I_D(k,2\phi) \;=\; & \frac{\rho}{4}[S(k)[R_R + R_{S1} + R_{S2} + \ldots]] \text{ “DC Terms”} \\
& + \frac{\rho}{2}\left[S(k) \sum_{n=1}^{N} \sqrt{R_R R_{Sn}} (\cos[2k(z_R - z_{Sn}) + 2\phi]) \right] \text{ “Cross-correlation Terms”} \\
& + \frac{\rho}{4}\left[S(k) \sum_{n \neq m = 1}^{N} \sqrt{R_{Sn} R_{Sm}} \cos[2k(z_{Sn} - z_{Sm}] \right] \text{ “Auto-correlation Terms”}
\end{aligned}
\tag{2.19}
$$

2.8.2.1 Stepped Phase-Shifting Interferometry Approach

If a spectral interferogram with round-trip phase delay $2\phi = \pi$ is acquired and subtracted from a spectral interferogram acquired with no phase delay, then it follows from Eq. 2.9 that the DC and autocorrelation terms will be eliminated and the cross-correlation terms doubled:

$$
I_D(k, 2\phi = 0) - I_D(k, 2\phi = \pi) = \rho \left[S(k) \sum_{n=1}^{N} r_{Sn} (\cos[2k(z_R - z_{Sn})]) \right]. \tag{2.20}
$$

The reversal of the sign of the cosine, which gives rise to this result, clearly depends only upon the $2\phi = \pi$ phase difference between the spectral interferograms and not upon any arbitrary phase offset to both of them; thus, it is important for this and all of the following results in this section that the phase-shifted interferograms be acquired either simultaneously or else quickly compared to any substantial phase drifting time in the interferometer. The A-scan that results from the inverse Fourier transform of Eq. 2.10 also contains only cross-correlation terms; thus, the DC and autocorrelation artifacts (but not the complex conjugate artifact) may be eliminated using this 2-step algorithm:

$$\begin{aligned} & i_D(z, 2\phi = 0) - i_D(z, 2\phi = \pi) \\ & = \frac{\rho}{2} \sum_{n=1}^{N} \sqrt{R_R R_{Sn}} [\gamma[2(z_R - z_{Sn})] + \gamma[-2(z_R - z_{Sn})]]. \end{aligned} \tag{2.21}$$

To remove the complex conjugate artifact, at least two spectral interferograms with noncomplementary phase delays (i.e., with 2ϕ different than π radians) must be acquired. For example, if a spectral interferogram with round-trip phase delay $2\phi = 3\pi/2$ is subtracted from a spectral interferogram acquired with round-trip phase delay $2\phi = \pi/2$, the result is a spectral interferogram containing only cross-correlation terms, which is in phase quadrature with the previous result:

$$\begin{aligned} & I_D(k, 2\phi = 3\pi/2) - I_D(k, 2\phi = \pi/2) \\ & = \rho \left[S(k) \sum_{n=1}^{N} \sqrt{R_R R_{Sn}} (-\sin [2k(z_R - z_{Sn})]) \right]. \end{aligned} \tag{2.22}$$

Combining all four phase-shifted interferograms yields the result:

$$\begin{aligned} & I_D(k, 2\phi = 0) - I_D(k, 2\phi = \pi) + j[I_D(k, 2\phi = \pi/2) - I_D(k, 2\phi = 3\pi/2)] \\ & = \rho \left[S(k) \sum_{n=1}^{N} r_{Sn} (\cos [2k(z_R - z_{Sn})] - j \sin [2k(z_R - z_{Sn})]) \right]. \end{aligned} \tag{2.23}$$

This 4-step combination of phase-shifted spectral interferograms inverse transforms to an A-scan free of DC, autocorrelation, and complex conjugate artifacts:

$$\begin{aligned} & i_D(z, 2\phi = 0) - i_D(z, 2\phi = \pi) + j[i_D(z, 2\phi = \pi/2) - i_D(z, 2\phi = 3\pi/2)] \\ & = \rho \sum_{n=1}^{N} \sqrt{R_R R_{Sn}} [\gamma[2(z_R - z_{Sn})] + \gamma[-2(z_R - z_{Sn})] + \gamma[2(z_R - z_{Sn})] - \gamma[-2(z_R - z_{Sn})]] \\ & = \rho \sum_{n=1}^{N} \sqrt{R_R R_{Sn}}\ \gamma[2(z_R - z_{Sn})]. \end{aligned} \tag{2.24}$$

It should be noted that if the DC and autocorrelation artifacts are removed through some independent means, that is, by subtracting averaged spectral interferogram data as described above, then only two-phase steps separated by $2\phi = \pi/2$ are required, that is,

$$i_D(z, 2\phi = 0) + j[i_D(z, 2\phi = \pi/2)] = \rho \sum_{n=1}^{N} \sqrt{R_R R_{Sn}} \gamma[2(z_R - z_{Sn})] \tag{2.25}$$

is also true if the component A-scans contain only cross-correlation terms.

2.8.2.2 Quadrature Projection Phase Correction

In many practical implementations, the phase shifts imposed through external means may not be achievable exactly or may be achromatic. For example, the phase shift imposed on reference arm light by physical modulation of the reference arm delay by, for example, a piezoelectric modulator depends upon wave number. In this case, an additional signal processing step may be introduced to ensure that the supposedly orthogonal signal components are in fact exactly orthogonal, independent of wave number. Sarunic has introduced a technique termed quadrature projection phase correction for complex conjugate resolution in FDOCT, which achieves this goal by simply taking the projection of phase-separated signal components upon orthogonal basis vectors [58]. For the example of the simplest two-phase techniques such as in the last section, this procedure proceeds as follows:

First, the inverse Fourier transforms of the ostensibly real and imaginary phase-separated signal vectors are separately computed, creating intermediary complex functions A and B:

$$\begin{aligned} A &= I.F.T[-E_1 + E_2 + E_3 - E_4] \\ B &= I.F.T[-E_1 + E_2 - E_3 + E_4]. \end{aligned} \tag{2.26}$$

Second, the vectors A and B are rotated to lie exactly on the real and imaginary axes. This is done by zeroing out the phase of vector A and subtracting the phase of vector A from that of vector B:

$$\begin{aligned} A' &= |A| \\ B' &= |B| e^{\angle B - \angle A}. \end{aligned} \tag{2.27}$$

Finally, the completely complex conjugate resolved output is computed from the following combination of A' and B':

$$\text{Output} = \text{Im}[\text{Re}(A') + j\,\text{Im}(B')]. \tag{2.28}$$

2.9 Sensitivity and Dynamic Range in OCT Systems

One of the advantages of OCT among biophotonic sensing techniques is that since it borrows so heavily from optical communication technologies, well-developed and inexpensive methodologies for signal optimization are available to approach the quantum detection limit of a single reflected photon. Sensitivity, signal-to-noise ratio (SNR), and dynamic range are often used interchangeably in the OCT literature to denote the minimum detectable reflected optical power compared to a perfect reflector, usually expressed in decibel units. Here, we concur with the first two definitions but reserve dynamic range to refer to the dynamic range of optical reflectivities observable within a single acquisition or image.

2.9.1 SNR Analysis for Time-Domain OCT

The signal-to-noise ratio for any system is defined as the signal power divided by the noise process variance. We follow the historical development of SNR analysis in OCT by first deriving expressions for TDOCT and then extending the analysis to FDOCT. SNR analysis in TDOCT followed directly from its predecessor technique of optical low-coherence domain reflectometry [59]. To simplify the analysis, we consider only a single sample reflector at position z_S and neglect autocorrelation terms. In this case, we can write the total detected photocurrent in a TDOCT system from Eq. 2.12 as

$$I_D(z_R) = \frac{\rho S_{TDOCT}}{2}\left[R_R + R_S + 2\sqrt{R_R R_S}e^{-(z_R - z_S)^2\Delta k^2}\cos\left[2k_0(z_R - z_S)\right]\right]. \quad (2.29)$$

Here, $S_{TDOCT} = \frac{S_0}{2}$ is the instantaneous source power incident in the sample and reference arms and is thus the quantity limited by ocular or skin maximum permissible exposure [] and other safety considerations. The desired OCT signal resides in the third term, whose mean-square peak signal power occurs at $z_R = z_S$ and is given by $\langle I_D\rangle^2_{TDOCT} = \frac{\rho^2 S_{TDOCT}{}^2}{2}[R_R R_S]$. Complete SNR analysis for OCT systems requires consideration of many possible noise sources in addition to shot noise (i.e., bandlimited quantum noise), which is the fundamental limiting noise process for optical detection. The contributions of these noise sources to OCT system performance including design approaches for obtaining shot noise-limited operation have been described in detail for both TDOCT and FDOCT systems. Here, we derive expressions for shot noise-limited performance. Shot noise variance in an optical receiver is given by $\sigma^2_{sh} = 2e\bar{I}B$, where e is the electronic charge, $\bar{I}$ is the mean detector photocurrent, and B is the electronic detection bandwidth. In a TDOCT system whose reference arm scans over a depth range $z_{\max}$ during an A-scan acquisition time Δt with velocity $v_{ref} = z_{\max}/\Delta t$, the reference light frequency is Doppler shifted by $f_D = 2v_{ref}/\lambda_0 = k_0 z_{\max}/(\pi\Delta t)$, and the resulting FWHM signal power bandwidth is $\Delta f_D = \Delta k_{FWHM} z_{\max}/(\pi\Delta t)$ (in Hz). The optimal detection bandwidth is approximately twice this value or $B_{TDOCT} \approx 2\Delta k_{FWHM} z_{\max}/(\pi\Delta t)$ [59]. Assuming the light intensity backscattered from the sample is much smaller than that reflected from the reference, the mean detector photocurrent is dominated by the reference arm power and thus, $\sigma^2_{TDOCT} = \rho e S_{TDOCT} R_R B_{TDOCT}$. The well-known expression for the SNR of a TDOCT system is thus given by

$$SNR_{TDOCT} = \frac{\langle I_D\rangle^2_{TDOCT}}{\sigma^2_{TDOCT}} = \frac{\rho S_{TDOCT} R_S}{2eB_{TDOCT}}. \quad (2.30)$$

This result, that the SNR is proportional to the detector responsivity ρ and to the power returning from the sample ($= S_{TDOCT}R_S$) but is independent of the reference arm power level, is reasonable. Note that the detection bandwidth must be increased to accommodate either increased image depth for a given resolution or increased resolution for a given scan depth for a given A-scan acquisition time; thus, these modifications are penalized in TDOCT.

2.9.2 SNR Analysis for Fourier-Domain OCT

The first indication that the techniques of Fourier-domain OCT may provide a significant SNR advantage over TDOCT was published by Hausler et al. in 1997 [60]. The analysis was not experimentally confirmed and as a conference proceedings paper was not widely available. It was not until late 2003 that the publication of three papers in quick succession by independent groups confirmed the advantage both theoretically and experimentally for the case of spectrometer-based FDOCT or SDOCT [10–12]. One of these papers was also the first to recognize the inherent connection between swept-source and spectrometer-based systems and to demonstrate the identical advantage both theoretically and experimentally for both implementations [11].

To obtain comparable expressions to that of Eq. 2.20 for SSOCT and SDOCT systems, we must understand how both signal and noise propagate through the spectral sampling and inverse Fourier transform processes. Under the same assumptions of a single sample reflector and no autocorrelation terms, the sampled version of the spectral interferogram in FDOCT systems (from Eq. 2.9) is

$$I_D[k_m] = \frac{\rho}{2} S_{FDOCT}[k_m]\left[R_R + R_S + 2\sqrt{R_R R_S}\cos\left[2k_m(z_R - z_S)\right]\right]. \tag{2.31}$$

Here, $S_{FDOCT}[k_m] = \frac{S(k)|_{k=k_m}}{2}$ is that portion of the instantaneous power incident on the sample that corresponds to spectral channel m of the detection system, whether time multiplexed in SSOCT or on separate detectors in SDOCT. In the discrete case, the inverse Fourier transform operation is implemented as an inverse discrete Fourier transform:

$$i_D[z_m] = \sum_{m=1}^{M} I_D[k_m] e^{+ik_m z_m/M}. \tag{2.32}$$

Again, for the special case of a single sample reflector located at depth $z_R = z_S$, the peak value of the interferometric term in Eq. 2.21 inserted into Eq. 2.22 is

$$\begin{aligned} i_D[z_m = (z_R - z_S) = 0] &= \frac{\rho}{2}\sqrt{R_R R_S}\sum_{m=1}^{M} S_{FDOCT}[k_m] \\ &= \frac{\rho}{2}\sqrt{R_R R_S} S_{FDOCT}[k_m] \cdot M, \end{aligned} \tag{2.33}$$

the latter expression being under the assumption that each spectral channel has equal power in it (i.e., for a rectangular-shaped source spectrum). For a more realistic Gaussian-shaped source spectrum centered at pixel $M/2$ and clipped at its $1/e^2$ points, that is, $S_{FDOCT}[k_m] = S_{FDOCT}[k_{M/2}]\exp[-2 \cdot (k_m - k_{M/2})^2/(k_{M/2})^2]$, then the last factor is $\sum_{m=1}^{M} S_{FDOCT}\left[k_{M/2}\right] = S_{FDOCT}\left[k_{M/2}\right] \cdot M \cdot 0.598$. The interpretation of Eq. 2.23 is that the cosinusoidal spectral interference pattern in each separate detection channel from a single reflector adds coherently to give a peak signal

Table 2.3 Shot noise-limited SNR expressions for time-domain (TDOCT), spectral-domain (SDOCT), and swept-source OCT (SSOCT), normalized to the sample arm instantaneous power S_{TDOCT} and detection bandwidth D_{TDOCT} used in TDOCT

	Time-domain OCT (TDOCT)	Swept-source OCT (SSOCT)	Spectral-domain OCT (SDOCT)
Mean-square peak signal power $\langle I_D \rangle^2$	$\frac{\rho^2 S_{TDOCT}{}^2}{2}[R_R R_S]$	$\frac{\rho^2 S_{TDOCT}^2}{4}[R_R R_S] \cdot M^2$	$\frac{\rho^2 S_{TDOCT}^2}{4}[R_R R_S]$
Noise variance σ^2	$\rho e S_{TDOCT} R_R B_{TDOCT}$	$e\rho S_{TDOCT} R_R B_{TDOCT} \cdot M$	$\frac{e\rho S_{FDOCT}[k_m] R_R B_{FDOCT}}{M}$
Signal-to-noise ratio $SNR = \frac{\langle I_D \rangle^2}{\sigma^2}$	$\frac{\rho S_{TDOCT} R_S}{2eB_{TDOCT}}$	$\frac{\rho S_{TDOCT} R_S}{2eB_{TDOCT}} \cdot \frac{M}{2}$	$\frac{\rho S_{TDOCT} R_S}{2eB_{TDOCT}} \cdot \frac{M}{2}$

power much greater than the signal power in each channel alone. Each detection channel in FDOCT senses interference over a much longer coherence length than the single detection channel in TDOCT due to its restricted spectral extent. This coherent addition of signal power in FDOCT is not isolated to the trivial choice of $z_m = (z_R - z_S) = 0$ in Eq. 2.23; any other choice of $z_m = (z_R - z_S)$ would give rise to phase factors in the Fourier kernel, which would still coherently sum to an equivalent combined signal peak. The mean-square peak signal power in FDOCT is thus $\langle i_D \rangle^2_{FDOCT} = \frac{\rho^2 S^2_{FDOCT}[k_m]}{4}[R_R R_S] \cdot M^2$.

To complete the calculation of the SNR of FDOCT, we must address the issue of how noise transforms from the k-domain to the z-domain. $I_D[k_m]$ can be generalized to include an additive, uncorrelated Gaussian white noise term $\alpha[k_m]$. $\alpha[k_m]$ has a mean of zero, a standard deviation $\sigma[k_m]$, and a lower limit set by shot noise. Again, assuming $R_R >> R_S$, in the shot noise limit, $\sigma^2_{TDOCT}[k_m] = e\rho S_{FDOCT}[k_m] R_R B_{FDOCT}$. In this case, however, the noise in each spectral channel is uncorrelated; thus, the noise variances add incoherently in the inverse discrete Fourier summation to give $\sigma^2_{FDOCT}[z_m] = \sum_{m=1}^{M} \sigma^2_{FDOCT}[k_m] = e\rho S_{FDOCT}[k_m] R_R B_{FDOCT} \cdot M$. Thus, the SNR of FDOCT in general is given by

$$SNR_{FDOCT} = \frac{\langle i_D \rangle^2_{FDOCT}}{\sigma^2_{FDOCT}} = \frac{\rho S_{FDOCT}[k_m] R_S}{4eB_{FDOCT}} \cdot M. \tag{2.34}$$

To specialize this general expression for SDOCT and SSOCT specifically and to compare the resulting sensitivities to that of TDOCT, we assume an identical A-scan length $z_{\max}$ and acquisition time Δt for all three systems and that the instantaneous sample arm power (which is limited by safety or source availability considerations in practice) is the same. We also assume a source with rectangular-shaped spectrum, at least initially. A summary of the results of this section is provided in Table 2.3. For an SSOCT system, the allowable sample illumination power for each spectral channel is the same as the total illumination power in TDOCT since only one channel is illuminated at a time. Thus, $S_{SSOCT}[k_m] = S_{TDOCT}$. The detection bandwidth in

SSOCT is limited by the analog-to-digital sampling frequency $f_s = M/\Delta t = 1/(2\pi) \cdot 4z_{\max}\Delta k/\Delta t = 2\Delta k z_{\max}/(\pi\Delta t)$, where Eq. 2.15 relates $z_{\max}$ to $\delta_s k$ and $\Delta k = M \cdot \delta_s k$ is the entire range of wave numbers scanned. Assuming a scanning range of $\Delta k = 2 \cdot k_{FWHM}$ is chosen and that an antialiasing filter is used to limit the detection bandwidth to $B_{SSOCT} = f_s/2$, then $B_{SSOCT} = B_{TDOCT}$. For an SDOCT system, where all spectral channels are illuminated and detected simultaneously, the allowable power per spectral channel is decreased by the factor M, that is, $S_{SDOCT}[k_m] = S_{TDOCT}/M$. Also, the SDOCT detection bandwidth $B_{SDOCT} = B_{TDOCT}/M$ since the signals from each channel are integrated over the entire A-scan time. Thus, we can write expressions for the SNR of both SSOCT and SDOCT systems compared to TDOCT:

$$SNR_{SDOCT} = SNR_{SSOCT} = \frac{\rho S_{TDOCT} R_S}{4eB_{TDOCT}} \cdot M = SNR_{TDOCT} \cdot \frac{M}{2}. \tag{2.35}$$

The factor of $M/2$ improvement in both SSOCT and SDOCT over TDOCT can be simply understood from the fact that both FDOCT methods sample all depths all of the time, giving rise to a potential SNR improvement by a factor M; however, both FDOCT methods generate redundant data for positive and negative sample displacements relative to the reference position, decreasing the SNR improvement by a factor of 2. The factor M in Eq. 2.35 also depends upon the assumption of the source having equal power in all spectral channels, which is unrealistic and would lead to undesirable ringing in the inverse transformed data in any case. More realistic spectral shapes, such as the Gaussian shape discussed above, would decrease the SNR by an additional factor of about 2. It is clear, however, that filling the spectral channels with as much power as possible translates directly into increased SNR. Taking these factors into account and assuming that $M \approx 10^3$ for a realistic swept-source laser or detector array, we conclude that FDOCT systems are theoretically capable of up to 20 dB greater sensitivity than TDOCT systems.

It is also important to note that the theoretical SNR gain of SDOCT and SSOCT compared to TDOCT derived above rests upon the assumption of shot noise-limited detection in each detection channel. As has been addressed in previous publications for the case of TDOCT, achievement of this limit requires sufficient reference arm power to assure shot noise dominance but usually requires significant reference arm attenuation to minimize excess noise. In the case of SSOCT, the SNR of the spectral-domain interferometric signal output by the photodetector is equal to the SNR of a time-domain OCT system photodetector output operating at the same line rate and reference arm power; thus, the optimal reference arm power level for SSOCT is expected to be similar to that for TDOCT. In SDOCT, where the reference arm power is dispersed onto M photodetectors, the total reference power required to achieve shot noise-limited detection on all receivers simultaneously is more than that required for SSOCT and TDOCT by a factor of M. However, whether or not this requires a redesign of the interferometer coupling ratio depends upon the desired A-scan rate and the noise performance of the detectors used.

Acknowledgments We gratefully acknowledge the contributions of past and present graduate student and postdoctoral members of the Izatt Biophotonics Laboratory at Duke University.

3.1 Introduction

Optical coherence tomography (OCT) has developed rapidly since its potential for applications in clinical medicine was first demonstrated in 1991 [1]. OCT performs high-resolution, cross-sectional tomographic imaging of the internal microstructure in materials and biologic systems by measuring backscattered or backreflected light.

Mathematical models [2–11] have been developed to promote understanding of the OCT imaging process and thereby enable the development of better imaging instrumentation and data processing algorithms. One of the most important issues in the modeling of OCT systems is the role of the multiple-scattered photons, an issue which has become fully understood through the works of Thrane et al. [12] and Turchin et al. [13] representing the most comprehensive modeling.

Experimental validation of models on realistic sample structures, e.g., layered sample structures, would require manufacturing of complex tissue phantoms with well-controlled optical properties. However, a useful alternative to validate the analytical predictions on such geometries is to apply a Monte Carlo (MC)-based simulation model [14], because there are few limitations on which geometries may be modeled using MC simulations. MC models for analyzing light propagation are based on

simulating the radiative equation of transfer by tracing a large number of energy packets each considered to represent a given component of the incident light energy [15, 16]. Hence, as a numerical experiment, one has full control of all parameters.

The scope of this chapter is to present analytical and numerical models that are able to describe the performance of OCT systems including multiple-scattering effects in heterogeneous media. Such models, where the contribution to the OCT signal from multiple-scattering effects is taken into account, are essential for the understanding and in turn optimization of OCT systems. An analytical model based on the extended Huygens–Fresnel (EHF) principle meeting these requirements is presented here. An MC analysis is presented in order to handle the modeling of heterodyne/coherent detection OCT systems with a radiative transfer-type photon packet MC approach. Using this MC model results are obtained, which validate the EHF model. In general, these models, analytical as well as numerical, may serve as important tools for improving the interpretation of OCT images.

3.1.1 Modeling Light–Tissue Interactions Relevant to OCT

Since the first paper describing the use of the OCT technique for noninvasive cross-sectional imaging in biological systems [1], various theoretical models of the OCT system have been developed. The primary motivation for deriving an appropriate model has been the potential optimization of the OCT technique leading to an improvement in imaging capabilities and to the possibility of extracting physical parameters.

The first theoretical models were based on single-scattering theory [2, 3]. These models are restricted to superficial layers of highly scattering tissue in which only single scattering occurs. Single scattering or single backscattering refers to photons which do not undergo scattering either to or from the backscattering plane of interest, i.e., ballistic photons.

At larger probing depths, however, the light is also subject to multiple scattering. The effects of multiple scattering have been investigated on an experimental basis [5], by using a hybrid Monte Carlo/analytical model [6] and analysis methods of linear systems theory [7], on the basis of solving the radiative transfer equation in the small-angle approximation [8, 13], by using models based on the extended Huygens–Fresnel (EHF) principle [9, 12, 17], and MC simulations [10, 14]. Note that modeling using MC simulations is treated in greater detail in Sect. 3.4.2.

In the present context, the main objective is the analysis of multiple-scattering effects. As shown by several investigations, the primary effects of multiple scattering are a reduction of the imaging contrast and resolution of the OCT system. In Ref. [4], the authors suggested solving the multiple-scattering problem by using the EHF principle [9] known from atmospheric propagation of laser beams [18]. Their analysis contains one important inaccuracy because in their end result, the ballistic component is included twice leading to erroneous calculations. As a result, their analysis should be applied with care. In addition, the effects of the so-called shower-curtain effect [18] are not accounted for in their analysis. Thrane et al. [12] succeeded in applying the EHF principle for the OCT geometry; see Sect. 4.2. Following their analysis,

Feng et al. [17] aimed at expanding on the use of EHF in modeling the OCT geometry. In particular, their aim is to simplify the analysis, but several mistakes are introduced in the attempt: firstly, an imaginary lens is introduced with the purpose of obviating the shower-curtain effect leading to errors in the final calculation of the OCT signal. Secondly, an erroneous lateral coherence length is introduced, i.e., the lateral coherence length should be calculated as resulting from reflecting off a rough surface and not, as done in Ref. [17], a specular surface. Hence, their model should be approached with caution.

A statistical optics approach to adequately model the effects of multiple scattering was proposed by Karamata et al. [19]. However, their analysis, based on a heuristic argument, is misleading and incorrect. The main error is due to their assumption regarding spatial coherence, where it is alleged that transverse spatial coherence is not degraded due to multiple scattering. The argument used by Karamata et al. [19] is valid only for the case of a focused beam reflecting off a rough surface with no scattering medium in between the reflection site and the collection aperture; see, for example, pages 210–211 of Ref. [20]. This is definitely not the case for OCT in turbid media (i.e., tissue). The degradation of spatial coherence of a beam propagating through a multiple-scattering media is well known and documented in the literature; see Ref. [21] and references therein. Therefore, the analysis given in Ref. [19] is not considered further, and the results and conclusions should not be used in modeling light propagation in turbid media.

Turchin et al. [13] expanded the analysis of Dolin [8] to an OCT geometry. Their analysis is based on the radiative transfer equation (RTE) in the small-angle approximation, of which Arnush [22] first obtained the closed-form solution. It should be noted that in this approximation, the solution of the RTE and the EHF is identical [23, 24]. In general, the analysis of Ref. [13] is consistent with that of the EHF model, which is presented below. However, technically there are two important differences that need to be pointed out. Firstly, the choice of scattering phase function in Ref. [13]: as in Ref. [12], the forward scattered part is modeled by a Gaussian distribution, but additionally a small backscattered fraction is included. This way of taking into account tissue backscattering was previously suggested by Raymer et al. [25–27] and discussed by Yura et al. [24]. However, it was not included in the EHF analysis of the OCT geometry [12], but it is incorporated below. Hence the RTE [13] and EHF [12] descriptions are equivalent. Secondly, Thrane et al. [12] present an analytical engineering expression for the OCT signal current based on an accurate analytical approximation for the irradiance distribution in the backscatter plane (see Appendix for details). Turchin et al. [13] do not use this approximation, and consequently their end results require numerical computations, which yield highly accurate values for the OCT signal current. They also obtain accurate results in the extraction of optical scattering properties of the sample, which is further addressed in Sect. 3.5.1. Furthermore, it is noted that the analysis of Turchin et al. [13] is restricted to the special case where the focusing lens in the sample arm is in direct contact with the tissue being investigated. This is in contrast to the analysis of Ref. [12] where the ABCD ray-matrix formalism was used to readily include an arbitrary configuration of the sample arm. Finally, in

contrast to the totally numerical results of Ref. [13], the multiple-scattering EHF analysis presented below yields accurate analytical expressions for the OCT signal for a wide range of optical configurations that both are amenable to physical interpretation (see, e.g., [28]) and are desirable for use in parametric studies for OCT system optimization.

Strictly speaking, the OCT model developed in Ref. [12] and further extended here is based on the assumption that the detected signal return arises only from photons that have been backscattered from a target layer selected by the coherence gate of the light source. Backscattered photons from the bulk tissue between the light source and the target layer have been assumed to be negligible in comparison with photons arising from the tissue discontinuity. Realistically, photons backscattered from the intervening bulk tissue whose optical path-length difference between the reference light is within the coherence length will also be detected. Bulk backscattered detected light contributes to the noise in the OCT signal because it does not furnish any local information about the target layer. Yao and Wang [29] used a Monte Carlo-based technique to simulate the OCT signal from homogeneous turbid medium. They considered a single mode fiber emitting a pencil beam that is in direct contact with the turbid medium and divided the OCT signal return into two categories: one from a target imaging layer in the medium (Class I photons) and the other from the intervening bulk tissue (Class II photons). The simulation results of Ref. [29] reveal that these two classes of photons have very different spatial and angular distributions which make OCT possible. The Class II signal has a much broader spatial distribution than the Class I signal. Although the spatial distributions of both signals broaden with probing depth, the Class II signal is broadened much faster than the Class I signal, and thus, limiting the detection area will reject most of the Class II signal. Additionally, Class II photons have a wider angular distribution than the corresponding Class I photons, and a correspondingly larger fraction of Class II photons that impinge on the detector area will not be effectively heterodyne coupled with the reference light. For large probing depths, however, the simulation results for the homogeneous turbid medium indicated that Class II signal photons will eventually become dominant. The actual crossover point is ultimately related to the efficiency of Class II signal rejection, whether or not the medium contains refractive index discontinuities, and the effects of Class II photon rejection due to imaging configurations such as dynamic focusing. With these considerations in mind, the extended Huygens–Fresnel-based OCT model developed in Ref. [12], updated to incorporate the attenuating effects of tissue backscatter, is presented below.

3.1.2 Organization of this Chapter

The chapter is divided into three sections covering specific topics in modeling OCT systems. In Sect. 3.2, an analytical model for the detected OCT signal is derived based on the EHF principle. In Sect. 3.3, the effects of multiple scattering on the detected Doppler OCT signal are investigated. In the field of biomedical optics, Monte Carlo simulations have already proved their value. In Sect. 3.4, an advanced

Monte Carlo model for calculating the OCT signal is presented, and comparisons to the analytical model are made. In general, good agreement is obtained, thus validating the EHF model. Section 3.5 overviews the impact of extracting optical scattering properties from OCT images on the diagnostic potential of OCT.

3.2 Analytical OCT Model Based on the Extended Huygens–Fresnel Principle

In the present section, a general theoretical description [12, 30, 31] of the OCT technique when used for imaging in highly scattering tissue is presented, which is valid for an arbitrary ABCD optical configuration. The description is based on the EHF principle. In a standard OCT system [1] with diffuse backscattering from the tissue discontinuity being probed, and a distance between the focusing lens and the tissue, the so-called shower-curtain effect [18, 32] is present, which is uniquely included in Ref. [12]. This effect is not described by previous ad hoc theoretical models [9]. Furthermore, because the sample arm focusing lens in Turchin et al. [13] is assumed to be in direct contact with the tissue being probed, shower-curtain effects are not present in the geometry and hence not in their analysis.

3.2.1 The Extended Huygens–Fresnel Principle

When an optical wave propagates through a so-called random medium, e.g., tissue, both the amplitude and phase of the electric field experience fluctuations caused by small random changes in the index of refraction across the sample. For tissue [33] it can in general be assumed that the depolarization term of the associated vectorial wave equation can be neglected, if the wavelength of the radiation, λ, is much smaller than l_0, where l_0 is a measure of the smallest random inhomogeneities in the medium [34, 35] (the structures that dominate light propagation in tissue, e.g., cells, have a size of 2 μm or more). With this assumption, the wave equation can be simplified to three scalar equations, one for each component of the field. Letting $U(\mathbf{R})$ denote one of the scalar components transverse to the direction of propagation along the positive z-axis, the following scalar stochastic equation is obtained:

$$\nabla^2 U + k^2 n^2(\mathbf{R}) U = 0, \tag{3.1}$$

where k is the wave number, $\mathbf{R}$ is a point in space, and $n(\mathbf{R})$ is the index of refraction. Considering a random medium, $n(\mathbf{R})$ acts as a stochastic variable for different realizations of tissue with given macroscopic optical parameters. Equation 3.1 cannot be solved exactly in closed form. Some early attempts to solve Eq. 3.1 were based on the geometric optics approximation [36], which ignores diffraction effects, and on perturbation theories widely known as the Born

approximation and Rytov approximation [37]. An alternative method was developed, independent of each other, by Lutomirski and Yura [38] and by Feizulin and Kravtsov [39]. This technique is called the extended Huygens–Fresnel (EHF) principle. It extends the Huygens–Fresnel principle to deal with media that exhibit a random spatial variation in the index of refraction. This principle follows directly from Green's theorem [40] and the Kirchhoff approximation [40] applied to the scalar wave equation together with the use of a field reciprocity theorem. Yura and Hanson [41, 42] have applied the EHF principle to paraxial wave propagation through an arbitrary ABCD system in the presence of random inhomogeneities. An arbitrary ABCD system refers to an optical system that can be described by the so-called ABCD ray-transfer matrix [43]. For the present cases of interest, the ABCD ray-transfer matrix is real, and the field in the output plane is then given by [41]

$$U(\mathbf{r}) = \int U_0(\mathbf{p}) G(\mathbf{p},\mathbf{r}) d\mathbf{p} \tag{3.2}$$

where $\mathbf{r}$ and $\mathbf{p}$ are two-dimensional vectors transverse to the optical axis in the output plane and input plane, respectively. The spatial integrals are to be carried out over the entire plane in question. The quantity $U_0(\mathbf{p})$ is the field in the input plane, and $G(\mathbf{p},\mathbf{r})$ is the EHF Green's function describing the response at $\mathbf{r}$ due to a point source at $\mathbf{p}$ given by [38, 41]

$$G(\mathbf{p},\mathbf{r}) = G_0(\mathbf{p},\mathbf{r}) \exp[i\varphi(\mathbf{p},\mathbf{r})], \tag{3.3}$$

where $G_0(\mathbf{p},\mathbf{r})$ is Huygens–Fresnel Green's function for propagation through an ABCD system in the absence of random inhomogeneities and $\varphi(\mathbf{p},\mathbf{r})$ is the random phase of a spherical wave propagating in the random medium from the input plane to the output plane. Huygens–Fresnel Green's function $G_0(\mathbf{p},\mathbf{r})$ is given by [41]

$$G_0(\mathbf{p},\mathbf{r}) = -\frac{ik}{2\pi B} \exp\left[-\frac{ik}{2B}\left(Ap^2 - 2\mathbf{p}\cdot\mathbf{r} + Dr^2\right)\right], \tag{3.4}$$

where A, B, and D are the ray-matrix elements for propagation from the input plane to the output plane.

3.2.2 Calculating the OCT Signal: Time Domain

A time-domain OCT system [1] is based on a broad bandwidth light source (SLD), a Michelson interferometer with a movable reference mirror, and a photodetector. The rotationally symmetric sample arm geometry of such an OCT system is depicted in Fig. 3.1, where a lens with focal length f is placed at a distance d from the tissue surface. The optical path length of the reference arm in the

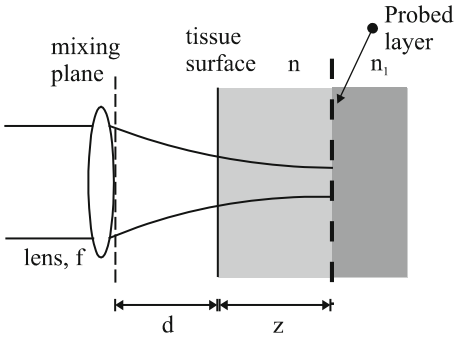

Fig. 3.1 Sample arm geometry of the OCT system

Michelson interferometer is matched to the optical depth of the focal plane, whereby the configuration – due to backscattering – is probing the layer of the tissue coinciding with the focal region.

For the wavelengths of interest in the NIR region and, e.g., in the case of human skin, light scattering in the bulk tissue is predominantly taking place in the forward direction [44]. Hence, the scattering phase function $\sigma(\theta,z)$ can be modeled as a sum of a small-angle scattering phase function $\sigma_1(\theta,z)$ that tends to zero for $\theta > \pi/2$ and a constant but relative small isotropic term included to incorporate a backscattered contribution [8, 13]:

$$\sigma(\theta, z) = [1 - 2p_b(z)]\sigma_1(\theta, z) + 2p_b(z), \tag{3.5}$$

where $p_b(z)$ denotes the backscattering coefficient as a function of the depth. For tissues, the quantity p_b will normally be much smaller than unity, i.e., $p_b << 1$; see, for example, Ref. [13].

It was noted above that the EHF principle is based on the paraxial approximation and therefore valid for small-angle forward scattering. In particular, it can be shown that the paraxial approximation is valid up to 30°, i.e., 0.5 rad [43]. Because most tissues are characterized by *rms* scattering angles below this limit, the EHF principle may be used to describe light propagation in tissue retaining both amplitude and phase information. Also, the bulk tissue absorption is neglected in the present calculation, because in the case of most tissues, the scattering essentially accounts for the signal attenuation [44]. Basically including the absorption would result in an overall exponential decay. Thus, bulk homogeneous tissue is characterized by a scattering coefficient μ_s, a root-mean-square scattering angle θ_{rms} or asymmetry parameter g [45], and a mean index of refraction n. Furthermore, the bulk tissue is modeled as a material with scatterers randomly distributed over the volume of interest.

Consider an optical field that is narrowband and non-monochromatic, i.e., the spectral width of the light source $\Delta\nu$ is much smaller than the center frequency ν. Light sources characterized as "broad band" in relation to OCT also fulfills this condition. At a spatial coordinate $\mathbf{p}$ and time t, such an optical field may be expressed in terms of a (temporally) slowly varying complex amplitude $A(t)$

where the characteristic temporal scale of the complex envelope amplitude A is much less than $1/\nu_0$. In addition it is assumed that the reference field, U_R, and the incident sample field, U_{Si}, are of Gaussian shapes:

$$U_R(\mathbf{p},t) = \sqrt{\frac{P_R}{\pi w_0^2}\exp\left[-\frac{|\mathbf{p}|^2}{2}\left(\frac{1}{w_0^2}+\frac{ik}{f}\right)\right]}A(t)\exp[i\omega_R t+\varphi_R(t)], \tag{3.6}$$

$$U_{Si}(\mathbf{p},t) = \sqrt{\frac{P_s}{\pi w_0^2}\exp\left[-\frac{|\mathbf{p}|^2}{2}\left(\frac{1}{w_0^2}+\frac{ik}{f}\right)\right]}A(t)\exp[i\omega_s t+\varphi_s(t)], \tag{3.7}$$

where P_R and P_S are the powers of the reference and input sample beams, respectively; w_0 is the $1/e$ intensity radius of these beams in the lens plane, $k = 2\pi/\lambda$; λ is the center wavelength of the source in vacuum; ω_R and ω_S are the angular frequencies of the reference and input sample beams, respectively; and φ_R and φ_S are the phases of the reference field and input sample field, respectively.

The mixing of the backscattered or reflected sample field U_S from the probed layer with the reference field U_R on the photodetector of the OCT system gives rise to a heterodyne signal current $i(z)$ [9]:

$$i(z) \propto |\gamma(\tau)|\mathrm{Re}\left[\int U_R(\mathbf{p})\,U_S^*(\mathbf{p})d\mathbf{p}\right], \tag{3.8}$$

where the integration is taken over the area of the photodetector. Re[·] denotes the real part, and τ denotes the time difference between the propagation times of the reference and sample beams. $|\gamma(\tau)|$ is the modulus of the normalized temporal coherence function of the source.

Because a random medium is considered, the mean square heterodyne signal current $\langle i^2(z)\rangle$ should be calculated, which is proportional to the heterodyne signal power. It can be shown to be given by [9, 18]:

$$\langle i^2(z)\rangle = 2\alpha^2|\gamma(\tau)|^2\mathrm{Re}\left[\iint \Gamma_S(\mathbf{p}_1,\mathbf{p}_2;z)\Gamma_R(\mathbf{p}_1,\mathbf{p}_2)d\mathbf{p}_1 d\mathbf{p}_2\right], \tag{3.9}$$

where

$$\Gamma_R(\mathbf{p}_1,\mathbf{p}_2) = \langle U_R(\mathbf{p}_1)U_R^*(\mathbf{p}_2)\rangle = U_R(\mathbf{p}_1)U_R^*(\mathbf{p}_2) \tag{3.10}$$

$$\Gamma_s(\mathbf{p}_1,\mathbf{p}_2;z) = \langle U_s(\mathbf{p}_1;z)U_s^*(\mathbf{p}_2;z)\rangle \tag{3.11}$$

are the mutual coherence functions of the reference and the reflected sample optical fields in the mixing plane. The angular brackets denote an ensemble

average over the statistical properties of the tissue. Physically, the heterodyne mixing process takes place on the photosensitive surface of the detector in the focal plane of the "mixing" lens. However, Fried [46] has shown mathematically that one can identically compute the mean square heterodyne photocurrent in a plane directly in front of the mixing lens at the side facing the sample, and, accordingly, $\mathbf{p}_1$, $\mathbf{p}_2$ are two-dimensional vectors in this plane transverse to the optical axis. The quantity α is a conversion factor for power to current and equals $(q_e\eta/h\nu)$, where q_e is the electronic charge, η the detector quantum efficiency, ν the optical center frequency, and h Planck's constant. In the present analysis, without loss of generality, the temporal coherence function is approximated with a rectangular function of width τ_c, the coherence time of the source.

Details of the derivation of the mutual coherence function Γ_S are given in Appendix under the assumption that the forward propagated light can be considered statistically independent from the backscattered light. To obtain a closed-form expression including the intermediate ranges of propagation, the single-scattering solution and the solution for large optical depths are interpolated, as outlined in Appendix, yielding the following squared signal contribution from within the coherence gate around the depth z:

$$\left\langle i^2(z)\right\rangle_{coh_gate} \approx \frac{2\alpha^2 P_R P_S \sigma_b}{\pi^2} \int \left[\frac{e^{-\mu_s z}\exp\left\{-r^2/w_H^2\right\}}{w_H^2} + \frac{(1-e^{-\mu_s z})e^{-2p_b\mu_s z}\exp\left\{-r^2/w_S^2\right\}}{w_S^2}\right]^2 d\mathbf{r}, \tag{3.12}$$

where the effective backscattering cross section of the layer being probed is defined as $\sigma_b = 4\pi p_b \mu_s l_c/k^2$. Here l_c denotes the coherence length of the source given by $c\tau_c$. In Eq. 3.12 it is assumed that $\mu_s l_c << 1$.

The quantities w_H and w_S are the $1/e$ irradiance radii in the target plane in the absence and presence of scattering, respectively, given by [12]

$$w_H^2 = w_0^2\left(A - \frac{B}{f}\right)^2 + \left(\frac{B}{kw_0}\right)^2, \tag{3.13}$$

$$w_S^2 = w_0^2\left(A - \frac{B}{f}\right)^2 + \left(\frac{B}{kw_0}\right)^2 + \left(\frac{2B}{k\rho_0}\right)^2, \tag{3.14}$$

where ρ_0 denotes the lateral coherence length of the reflected sample field in the plane in which the mixing calculated [12]

$$\rho_0(z) = \sqrt{\frac{3}{\mu_s z}}\frac{\lambda}{\pi\theta_{\text{rms}}}\left(\frac{nB}{z(1-2p_b)}\right). \tag{3.15}$$

Here the root-mean scattering angle, θ_{rms}, is related to the anisotropy parameter g:

$$\theta_{\mathrm{rms}} \approx \sqrt{2(1-g)}. \tag{3.16}$$

Performing the integration over the probed layer (see Fig. 3.1) in Eq. 3.12 and simplifying, the following expression for the mean square heterodyne signal current is obtained:

$$\begin{aligned}\left\langle i^2(z)\right\rangle_{coh_gate} &\approx \frac{\alpha^2 P_R P_s \sigma_b}{\pi w_H^2} \\ &\times \left[e^{-2\mu_s z} + \frac{4e^{-\mu_s z}e^{-2p_b\mu_s z}(1-e^{-\mu_s z})}{1+\frac{w_S^2}{w_H^2}} + (1-e^{-\mu_s z})^2 e^{-4p_b\mu_s z}\frac{w_H^2}{w_S^2} \right] \\ &= \left\langle i^2\right\rangle_0 \Psi(z).\end{aligned} \tag{3.17}$$

Assuming $p_b << 1$, Eq. 3.17 reduces to

$$\begin{aligned}\left\langle i^2(z)\right\rangle_{coh_gate} &\approx \frac{\alpha^2 P_R P_s \sigma_b}{\pi w_H^2} \\ &\times \left[e^{-2\mu_s z} + \frac{4e^{-\mu_s z}(1-e^{-\mu_s z})}{1+\frac{w_S^2}{w_H^2}} + (1-e^{-\mu_s z})^2 \frac{w_H^2}{w_S^2} \right] \\ &= \left\langle i^2\right\rangle_0 \Psi(z).\end{aligned} \tag{3.18}$$

The quantity $\langle i^2\rangle_0 = \alpha^2 P_R P_S \sigma_b/\pi(w_H)^2$ is the mean square heterodyne signal current in the absence of scattering, and the terms contained in the brackets are the heterodyne efficiency factor $\Psi(z)$. The quantity $\Psi(z)$ is the reduction in the heterodyne signal-to-noise ratio due to the scattering of the tissue. The first term in the brackets of Eq. 3.17 represents the contribution due to single scattering. The third term is the multiple-scattering term, and the second term is the cross term. Physically, the cross term is the coherent mixing of the unscattered and the multiple-scattered light. A comparison between the analytical approximation of $\Psi(z)$, given in Eq. 3.17, and the exact numerical calculation is given in Ref. [47] showing reasonable agreement. The validity of the above expression has been explored by comparing the model with advanced Monte Carlo studies and confirms that the analytical result provides a feasible model for investigating the qualitative behavior of the OCT configuration; see Sect. 3.4.

3.2.2.1 Dynamic Focusing: Diffuse Reflectance

If one applies dynamic focusing, the focal plane will ideally be arranged to move in accordance with the position of the coherence gate. This situation can be analyzed by setting $fA = B$ and $A = 1$ in Eqs. 3.13 and 3.14:

$$w_H = \frac{f}{kw_0}, w_S = \sqrt{w_H^2 + \left(\frac{2f}{k\rho_0}\right)^2}, \tag{3.19}$$

$$\frac{w_H^2}{w_S^2} = \frac{1}{1 + \left(\frac{2w_0}{\rho_0(z)}\right)^2}. \tag{3.20}$$

For lateral separations much less (greater) than the coherence length, $\rho_0(z)$, the field can be considered to be mutually coherent (incoherent). Because of the diffuse backscattering from the layer being probed, $\rho_0(z)$ is determined only by the propagation back through the tissue from this layer to the mixing plane. As a consequence, $\rho_0(z)$ is the lateral coherence length in the mixing plane of a point source located in the tissue plane being probed. For the geometry of interest, it can be shown [47] that

$$\rho_0(z) = \sqrt{\frac{3}{\mu_s z}} \frac{\lambda}{\pi\theta_{\text{rms}}} \left(\frac{z + nd(z)}{z\sqrt{1 - 2p_b}}\right) \tag{3.21}$$

where $d(z) = f - z/n$, and $\theta_{\text{rms}} \approx [2(1 - g)]^{1/2}$. The second term in the brackets of Eq. 3.21 indicates that the lateral coherence length increases with increasing distance between the tissue surface and the mixing plane.

The dependence of the lateral coherence length on the position of the scattering medium relative to the observation plane is the so-called shower-curtain effect [18, 32]. In general, the shower-curtain effect implies that the lateral coherence length obtained for the case when the scattering medium is close to the radiation source is larger than for the case when the scattering medium is close to the observation plane. Physically, this is due to the fact that a distorted spherical wave approaches a plane wave as it further propagates through a non-scattering medium. As a consequence, e.g., from a distance, one can see a person immediately behind a shower curtain, but the person cannot see you. The effect is well known for light propagation through the atmosphere as discussed by Dror et al. [32], but has been omitted in previous theoretical OCT models [9]. However, due to the finite distance between the focusing lens and the tissue, the effect is inevitably present in practical OCT systems. Finally, the reflection characteristics of the tissue play a vital role for the shower-curtain effect.

It is only in the very superficial layers of highly scattering tissue that it is possible to achieve diffraction-limited focusing. In this region, the spot size is given by $2w_H$. At deeper probing depths, the spot size is dependent on the scattering properties and

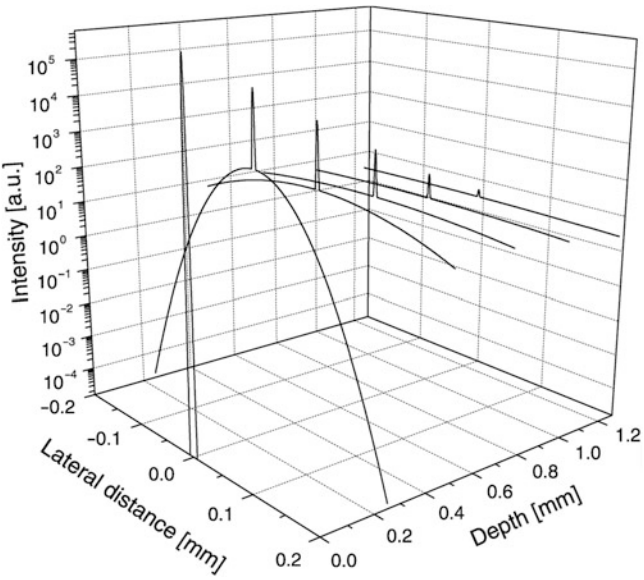

Fig. 3.2 The intensity pattern as a function of the probing depth z in the tissue ($\lambda = 814$ nm, $\mu_s = 10\ \text{mm}^{-1}$, $g = 0.955$ ($\theta_{\text{rms}} = 0.3$ rad), $n = 1.4, f = 5$ mm, $w_0 = 0.5$ mm)

given by $2w_S$. It is seen from Eqs. 3.20 and 3.21 that the spot size is degraded due to multiple scattering when the probing depth is increased. This is illustrated in Fig. 3.2, where the intensity pattern is shown as a function of the probing depth z in the tissue using Eq. 3.72, thus illustrating spot size degradation in, e.g., microscopy.

From Eq. 3.18 an expression for the OCT signal for large optical depths can be obtained as

$$\left\langle i^2(z)\right\rangle \propto \frac{\exp(-4p_b\mu_s z)}{\mu_s(1-g)z^3}, \mu_s z >> 1. \tag{3.22}$$

From this expression it is observed that the denominator is proportional to the reduced scattering coefficient $\mu_s(1\text{-}g)$, while the numerator will be close to 1 for small values of p_b. Consequently, if the signal for large optical depths is observed, it cannot be expected to derive both μ_s and g from the measured depth profiles.

3.2.2.2 Dynamic Focusing: Specular Reflectance

If, instead of diffuse backscattering, one had a specular reflection at the layer being probed, the corresponding mutual coherence function for plane waves would apply. Using this mutual coherence function and $p_b << 1$, the following expression is obtained for the heterodyne efficiency factor:

$$\Psi(z) = \left[e^{-2\mu_s z} + \left(1 - e^{-2\mu_s z}\right) \frac{w_H^2}{w_s^2} \right] \tag{3.23}$$

and

$$\rho_0(z) = \sqrt{\frac{1}{2\mu_s z}} \frac{\lambda}{\pi \theta_{rms}}. \tag{3.24}$$

It is obvious from Eq. 3.24 that the shower-curtain effect would not be present in the case of specular reflection at the tissue discontinuity, in contrast to the case of diffuse backscattering. However, it is important to note that it is diffuse backscattering which actually occurs in the case of tissue.

3.2.2.3 Collimated Sample Beam

In the case of a collimated sample beam, the expressions for w_H and w_S in Eqs. 3.13 and 3.14 need to be rewritten:

$$w_H^2 = \lim_{f \to \infty} \left[w_0^2 \left(1 - \frac{d + z/n}{f} \right)^2 + \left(\frac{d + z/n}{k w_0} \right)^2 \right] = w_0^2 + \left(\frac{d + z/n}{k w_0} \right)^2 \tag{3.25}$$

$$\begin{aligned} w_S^2 &= \lim_{f \to \infty} \left[w_H^2 + \left(\frac{2(d + z/n)}{k \rho_0} \right)^2 \right] \\ &= w_0^2 + \left(\frac{d + z/n}{k w_0} \right)^2 + \left(\frac{2(d + z/n)}{k \rho_0} \right)^2, \end{aligned} \tag{3.26}$$

where it has been used that $A = 1$ and $B = d + z/n$. In order to find the heterodyne efficiency factor, these expressions must be inserted in Eq. 3.17, and moreover, the expression for ρ_0 should be chosen in accordance with the reflection characteristics of the probed layer.

3.2.2.4 Numerical Results

In Fig. 3.3, the calculated heterodyne efficiency factor $\Psi(z)$ from Eq. 3.18 is shown as a function of depth z of the tissue sample for typical parameters of human skin tissue. The curves are shown for the cases of diffuse backscattering with (dashed) and without (dash-dot) the shower-curtain effect included and for the specular reflection (solid), respectively. In addition, the case of pure single scattering (dotted) is included for comparison. At shallow depths single backscattering dominates. Due to multiple scattering, the slope is changed and $\Psi(z)$ becomes almost constant for three cases (curves 1–3). The important difference is, however, that the change of slope occurs at different depths. This is due to the shower-curtain effect leading to an appreciable

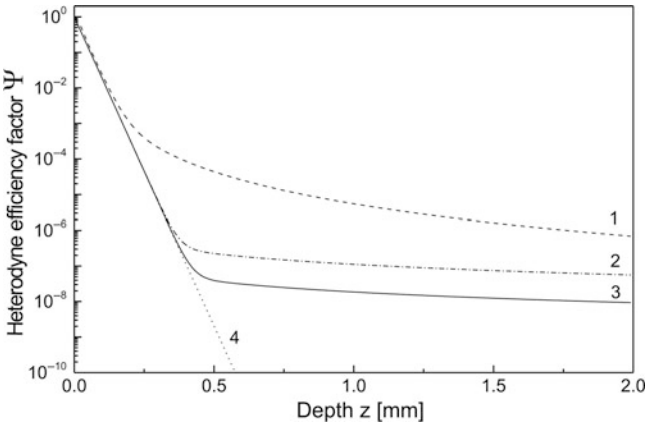

Fig. 3.3 $\Psi(z)$ as a function of z for diffuse backscattering with the shower-curtain effect included (curve 1) and for specular reflection (curve 3). Curve 2 is calculated for diffuse backscattering without the shower-curtain effect, and curve 4 is the case of pure single backscattering; $\lambda = 814$ nm, $\mu_s = 20\ \text{mm}^{-1}$, $g = 0.955$ ($\theta_{\text{rms}} = 0.3$ rad), $n = 1.4$, $f = 5$ mm, $w_0 = 0.5$ mm (From Ref. [12])

enhancement of $\Psi(z)$ and with it the heterodyne signal, which is obtained by comparing curves 1 and 2 in Fig. 3.3. Physically, this increase in the heterodyne signal is due to an enhanced spatial coherence of the multiple-scattered light.

In Fig. 3.4, $\Psi(z)$ from Eq. 3.18 is shown as a function of depth z for $\mu_s = 10\ \text{mm}^{-1}$ and three values of g within the range of validity of the EHF principle. The curves are computed for the case of diffuse backscattering. This figure demonstrates the degree of sensitivity of the heterodyne efficiency factor with respect to changes in the asymmetry parameter. Moreover, in Fig. 3.5, $\Psi(z)$ from Eq. 3.18 is shown as a function of depth z for $g = 0.95$ and three values of μ_s within the range of interest with respect to tissue [44]. The curves are again computed for the case of diffuse backscattering. This figure demonstrates the degree of sensitivity of the heterodyne efficiency factor with respect to changes in the scattering coefficient.

3.2.2.5 Choice of Scattering Function

In the present modeling of the OCT geometry, a Gaussian volume scattering function [20] for the forward scattered part is used; see Eqs. 3.5 and 3.64. The motivation for this choice of scattering function is the ability to obtain an accurate analytical engineering approximation, valid for all values of the optical depth. Using the Henyey–Greenstein scattering function [48], which is widely used in approximating the angular scattering dependence of single-scattering events in some biological media [44, 49], the corresponding analytical approximation is not as accurate as for the case of a Gaussian scattering function. However, a numerical computation using the exact expressions may be carried out instead. Hence, both scattering functions may be used in the modeling of the OCT geometry presented in this chapter.

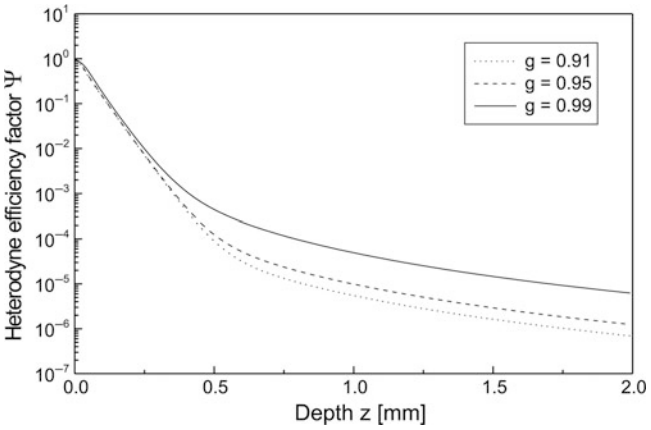

Fig. 3.4 $\Psi(z)$ as a function of z for $\mu_s = 10\ \text{mm}^{-1}$ and three values of g. The curves are for the case of a diffuse backscattering at the discontinuity and inclusion of the shower-curtain effect ($\lambda = 814$ nm, $n = 1.4, f = 5$ mm, $w_0 = 0.5$ mm)

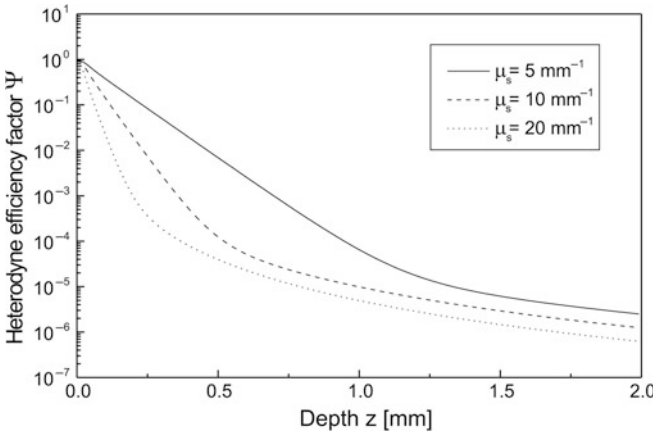

Fig. 3.5 $\Psi(z)$ as a function of z for $g = 0.95$ and three values of μ_s within a range of interest with respect to tissue. The curves are for the case of a diffuse backscattering at the discontinuity and inclusion of the shower-curtain effect ($\lambda = 814$ nm, $n = 1.4, f = 5$ mm, $w_0 = 0.5$ mm)

3.2.2.6 Signal-to-Noise Ratio (SNR) and Estimation of the Maximum Probing Depth

Without loss of generality, an OCT system with shot-noise-limited operation is considered here for calculating the signal-to-noise ratio (SNR) with the purpose of estimating the maximum probing depth. The only significant source of noise is the shot noise caused by the reference beam. For a photoconductive detector, the mean square noise power N_p can then be expressed as [50]

$$N_p = 2\alpha q_e G_{ca}^2 R_l B_w P_R, \tag{3.27}$$

where R_l is the resistance of the load, G_{ca} the gain associated with the current amplifier, and B_w the system bandwidth. The corresponding mean heterodyne signal power $S(z)$ is given by [46]

$$S(z)\langle i^2(z)\rangle G_{ca}^2 R_l \tag{3.28}$$

where $\langle i^2(z)\rangle$ is given by Eq. 3.17. Hence, the mean signal-to-noise ratio $SNR(z)$ is given by

$$SNR(z) = \frac{S(z)}{N_p} = (SNR)_0 \Psi(z), \tag{3.29}$$

where the signal-to-noise ratio in the absence of scattering $(SNR)_0$ is given by

$$(SNR)_0 = \frac{\eta P_S}{2h\nu B_w}\left(\frac{\sigma_b}{\pi w_H^2}\right). \tag{3.30}$$

In the case of interest where the focal plane coincides with the probed layer, the following expression for $(SNR)_0$ is obtained:

$$(SNR)_0 = \frac{4p_b \eta P_S}{h\nu B_w}\left(\frac{w_0}{f}\right)^2, \tag{3.31}$$

where it has been used that $\sigma_b = 4\pi p_b \mu_s l_c / k^2$.

The maximum probing depth is of considerable interest in the characterization and optimization of an OCT system when used for imaging in highly scattering tissue. The maximum probing depth may be calculated by using the model presented above. Details of the calculation are found in Ref. [31], where the calculation of the maximum probing depth z_{max} is based on the minimum acceptable SNR in the case of shot-noise-limited detection. In the calculations, a value of 3 is used as the minimum acceptable signal-to-noise ratio, i.e., $SNR(z_{max}) = 3$.

An important conclusion of Ref. [31] is that, in general, z_{max} depends on the focal length at small values of the scattering coefficient, but is independent of the focal length at larger values of the scattering coefficient. A similar behavior is observed for z_{max} as a function of μ_s and the $1/e$ intensity radius of the sample beam being focused. This behavior is due to multiple scattering of the light in the tissue. At scattering coefficients found in human skin tissue [44, 51], for example, it is concluded that the maximum probing depth is independent of the focal length f. This is an important conclusion because the depth of focus and the lateral resolution of the OCT system may then be chosen independently of z_{max}. For example, if no scanning of the focal plane in the tissue is desirable and, therefore, a large depth of

focus has been chosen, the same maximum probing depth is obtained as for a system with a short depth of focus where the focal plane is scanned to keep it matched to the reference arm. This conclusion is not surprising or contrary to assumptions already held in the field. However, the theoretical analysis in this section provides a theoretical foundation for such statements. Moreover, this agreement may also be taken as a further validation of the OCT model presented here.

3.3 Doppler OCT Analysis

Noninvasive localization and measurement of blood flow is of great interest in many medical applications, e.g., ophthalmology, dermatology, and gastroenterology. Optical Doppler tomography (ODT) [52, 53] combines Doppler velocimetry and optical coherence tomography. Thus, ODT is feasible for noninvasive localized diagnostics of particle flow velocity in highly scattering media, and it is important for functional imaging. In contrast to conventional OCT, where the reflectivity profile of the sample is obtained by envelope detection of the interferometric signal, ODT employs coherent phase-sensitive demodulation of the heterodyne detector current to obtain depth profiles of blood flow velocity. Basically, depth-resolved velocity estimates are obtained directly from the corresponding mean [52, 53] or standard deviation [54, 55] of the observed Doppler-frequency spectrum.

In this section, the results of a theoretical analysis of ODT based on EHF with multiple-scattering effects included are presented. Experiments by Yazdanfar et al. [56] suggest the presence of multiple-scattering effects in ODT. Another study also confirmed the impact of multiple-scattering effects estimating the impact on the determination of flow parameters [57]. The purpose of the analysis below is to determine how multiple scattering affects the estimation of the depth-resolved localized flow velocity, i.e., to obtain the dependence of the mean and standard deviation of the Doppler-frequency spectrum on the scattering properties of the medium.

3.3.1 Multiple-Scattering Effects in ODT

The ODT probe geometry being analyzed is shown in Fig. 3.6. In the absence of multiple scattering, and if the scattering geometry is precisely known, an estimate of the blood flow velocity at a given probing depth can be obtained as [52, 53]

$$V = \frac{f_S \lambda_0}{2n \cos \varepsilon}, \tag{3.32}$$

where λ_0 is the center wavelength of the light source, n is the index of refraction of blood, ε is the angle between the incident light and the direction of blood flow, and f_S is the centroid frequency of each depth-resolved spectrum, which is used as a measure of the corresponding backscattered Doppler frequency.

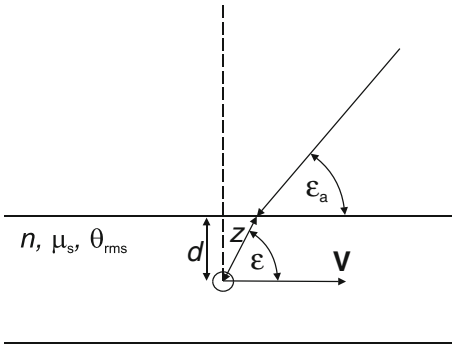

Fig. 3.6 The ODT probe geometry

In a multiple-scattering analysis of ODT, two effects must be taken into account: (a) the incident light on a moving particle contains a stochastic distribution of wave vectors at each optical frequency, and (b) in the round-trip propagation path to the backscattering event, the light will accumulate a random series of Doppler shifts due to the light being scattered by moving constituents along the path. Taking these multiple-scattering effects into account, the following equation for the mean Doppler shift may be derived [58]:

$$\overline{f}_D(d) = \frac{2n\cos\varepsilon}{\lambda_0}\left\{V(d)\exp\left(-\left\langle\theta^2\right\rangle/2\right) + \overline{V}(d)\left[1-\exp\left(-\left\langle\theta^2\right\rangle/2\right)\right]\right\}, \tag{3.33}$$

where $\langle\theta^2\rangle = \mu_s z\theta^2{}_{\mathrm{rms}}$. The quantities μ_s and θ_{rms} are the scattering coefficient and root-mean-square scattering angle of blood, respectively, and the probing depth $z = d/\sin\varepsilon$, where d is the transversal position in the vessel as indicated in Fig. 3.6. Furthermore, $V(d)$ is the flow velocity as a function of the transversal position in the vessel, and $\overline{V}$ is the mean velocity of the flow along the propagation path to the probing depth z. If multiple-scattering effects are neglected, Eq. 3.33 reduces to Eq. 3.32 as expected. In addition, for a constant velocity profile where $\overline{V} = V_0$, Eq. 3.33 yields $\overline{f}_D = 2V_0 n\cos\varepsilon/\lambda_0$ in agreement with Eq. 3.32, i.e., no multiple-scattering effects are present in this case as expected [59]. In the case of laminar flow in the vessel, the velocity and mean velocity profiles are given by [58]

$$V(d) = V_0\left[1-(1-d/a)^2\right] \quad \text{for} \quad 0 \le d \le 2a \tag{3.34}$$

$$\overline{V}(d) = V_0\frac{d}{a}\left(1-\frac{d}{3a}\right), \tag{3.35}$$

where a and V_0 are the radius of the vessel and the flow speed at the center of the vessel, respectively. In Fig. 3.7, the mean Doppler shift for laminar flow is shown with and without multiple-scattering effects included using Eqs. 3.33 and 3.32, respectively. The multiple scattering gives rise to a bias at the proximal end of the

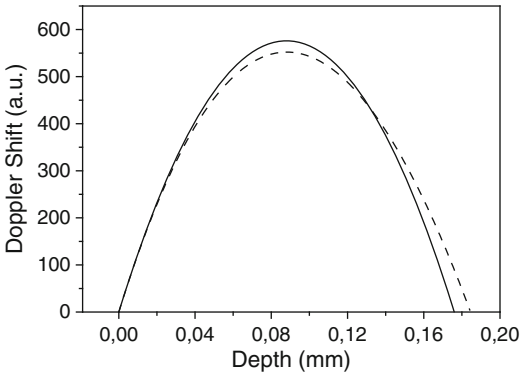

Fig. 3.7 The mean Doppler shift for laminar flow is shown with (*dashed*) and without (*solid*) multiple-scattering effects included using Eqs. 4.33 and 4.32, respectively ($\lambda_0 = 832$ nm, $\varepsilon = 80°$, $a = 88$ μm [56]; $\mu_s = 150\ \text{mm}^{-1}$, $\theta_{\text{rms}} = 0.141$ rad. [59]; $n = 1.38$ [91])

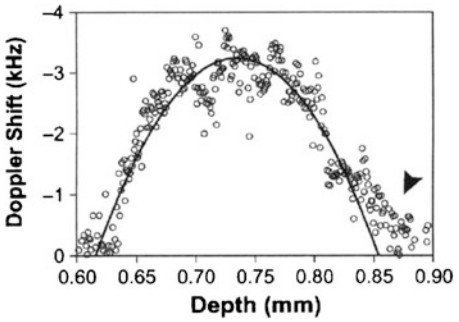

Fig. 3.8 Measurement of depth-resolved retinal flow profile taken (From Ref. [56]). The *arrow* indicates the effect of multiple scattering

profile, which is in qualitative agreement with ODT measurements of a depth-resolved retinal flow profile obtained by Yazdanfar et al. [56] and shown in Fig. 3.8. Typical scattering parameters for blood [59] are used in Fig. 3.7 together with ODT system parameters and vessel diameter from Ref. [56]. The bias increases with larger μ_s and θ_{rms} (or smaller anisotropy factor). No such bias was predicted by Lindmo et al. [59] because of their neglect of the stochastic distribution of wave vectors incident on the backscattering particle.

Furthermore, the dependence of the standard deviation of the Doppler-frequency spectrum on the scattering properties of the flowing medium is also obtained. Thus, the following approximate expression of the standard deviation of the Doppler-frequency spectrum valid for all values of $\mu_s z$ is obtained [58]:

$$\begin{aligned}\Delta f_T(d) &= \sqrt{\Delta f_D^2 + \Delta f_{D0}^2} \\ &= \sqrt{\frac{V^2(d) n^2 \sin^2 \varepsilon}{\lambda_0^2} \mu_s z \theta_{\text{rms}}^2 [2 + p(d)] + \Delta f_{D0}^2}\end{aligned} \tag{3.36}$$

where Δf_{D0} is the standard deviation of the Doppler-frequency spectrum in the absence of multiple scattering as reported previously in Ref. [55] and Δf_D is

the multiple-scattering contribution to the standard deviation of the ODT signal. The quantity $p(d)$ is given by [58]

$$p(d) = \frac{V_{\mathrm{rms}}^2(d) + \overline{V}(d)^2 - 4V(d)\overline{V}(d)}{V^2(d)}, \tag{3.37}$$

where $V_{\mathrm{rms}}(d)$ is the root-mean-square velocity of the flow along the propagation path to the probing depth z and is given by [58]

$$V_{\mathrm{rms}}(d) = \sqrt{\frac{1}{d}\int_0^d V^2(t)dt}. \tag{3.38}$$

The standard deviation increases with larger μ_s and θ_{rms} (or smaller anisotropy factor). As expected, a multiple-scattering contribution to the standard deviation of the ODT signal is obtained, which is identically zero for a constant velocity profile. This is in contrast to the work by Lindmo et al. [59], who arrived at a nonzero contribution from multiple scattering for this case.

3.4 Advanced Monte Carlo Simulation of OCT Systems

In the present section, the derivation of a Monte Carlo (MC) model capable of dealing with the heterodyne detection scheme. Adequate MC modeling may serve as a numerical phantom for further theoretical studies in cases where analytical modeling may be cumbersome.

It is important to note that the MC method only describes the transport of energy packets along straight lines and therefore the approach is incapable of describing coherent interactions of light. These energy packets are often referred to as photon packets or simply photons, and this terminology is adopted here. However, it should be emphasized that no underlying wave equation is guiding or governing these photons. Accordingly, any attempt to relate these to real quantum mechanical photons should be done with great care as argued in Ref. [60] commenting on a suggested approach of including diffraction effects into MC simulations [61, 62]. An MC photon packet represents a fraction of the total light energy, and for some applications, especially continuous wave, it may be useful to think of the path traveled by a photon as one possible path in which a fraction of the power flows. A collection of photon packets may then be perceived as constituting an intensity distribution due to an underlying field, and it can, accordingly, seem tempting to infer behavior known to apply to fields upon photon packets. Consider, as an example, that one wishes to determine whether the photon packets are able to enter an optical fiber. It can then seem intuitively correct to restrict the access of photons impinging on the fiber end to those which fall within the numerical aperture of the fiber. However, such an angular restriction may not be correct, because the individual photon packet does not carry information of the

entire field and its phase distribution. It is therefore impossible to determine whether a portion of the energy carried by a photon packet will enter the fiber due to a mode match between the fiber mode and the field underlying the collective intensity distribution of the photon packets. This discussion is treated in greater detail in Ref. [14].

With the above discussion of MC photons in mind, it may seem futile to investigate if MC simulation is applicable to estimate an OCT signal, which is the result of heterodyne mixing, and thus depends upon the coherence properties of the light. However, the problem may be reformulated to investigate whether or not the effect of the lack of coherence information in an MC simulation may be circumvented, or at least minimized. Others [63–66] have attempted to model similar optical geometries by interpreting the heterodyne process as a rejection process in which the detected photons must conform to a set of criteria on position and angle. Such a set of criteria is referred to as a detection scheme. However, these criteria were found by ad hoc considerations of the optical system, which may easily lead to incorrect results as exemplified above. Instead a mathematical derivation of the true criteria of the detection scheme will be given in the present section.

3.4.1 Theoretical Considerations

In the following, the EHF principle is used to derive an important result: an expression for the OCT signal depending on the intensity of the light only. This is obtained by calculating the mixing of the reference and sample beams in the plane conjugate to the plane in the sample probed by the system. The result is surprising, because the expression for the OCT signal depends on the coherence properties of the light [12]. However, it is shown that the formula used for calculating the OCT signal in this particular plane is mathematically identical to the result obtained in Ref. [12]. These results are valid for the, from a biomedical point of view, important case of a signal arising from a diffusely reflecting discontinuity embedded in a scattering sample. Note that this proves the viability of MC simulation to model the OCT technique, because it is shown that only intensity, and not field and phase, is necessary for this case.

The optical geometry of the sample arm is shown in Fig. 3.9, and it should be noted that the enclosed section corresponds to the geometry used for the EHF calculation in Sect. 3.2.2. An optical fiber end is positioned in the p-plane. The fiber emits a beam, which hits the collimating lens L1. The focusing lens L2 is positioned in the r-plane, and in this plane, the beam is a Gaussian beam with $1/e$ width, w_0, of the intensity. The beam is focused by L2 upon a diffusely reflecting discontinuity positioned at the depth z_f inside a scattering sample a distance d from L2. The sample is taken to be a slab infinite in the transverse direction. The part of the light that is reflected from the discontinuity propagates out through the sample, through lenses L2 and L1 to the optical fiber, where it is collected. The lenses L1 and L2 have the focal length f and are taken to be identical, perfect, and infinite in

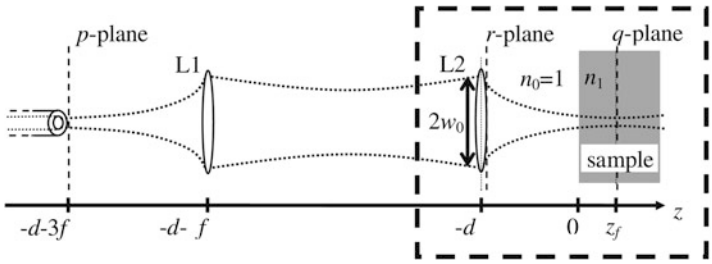

Fig. 3.9 Sample arm setup of the OCT system. The lenses L1 and L2 are considered to be identical, perfect, and have infinite radius. The setup is essentially a 4 F system (From Ref. [14])

radius. This means that the q- and p-planes are conjugate planes with magnification unity. The purpose of using the 4 F geometry is to have a physical representation of the conjugate plane to the probe plane. However, in Ref. [14] it is shown that the OCT signal term calculated from the conjugate plane is mathematically equivalent to the OCT signal calculated in the plane where the mixing physically takes place. Accordingly, the important result of Eq. 3.40 below is not restricted to the 4 F geometry. Hence, this proves the feasibility of using MC modeling in the analysis of OCT systems.

The OCT signal is produced by the mixing of the light from the reference and sample arms on the photodetector of the OCT system. Due to the symmetry of the system, in Sect. 3.2.2 the EHF prediction of the mixing between signal and reference beam was conveniently calculated at the r-plane. The mean square of the signal current $\langle i^2 \rangle$ is given by Eq. 3.9 and rewritten according to the notation in Fig. 3.9 to yield

$$\langle i^2(z) \rangle = 2\alpha^2 |\gamma(\tau)|^2 \mathrm{Re}\left[\iint \Gamma_S(\mathbf{p}_1, \mathbf{p}_2; z) \Gamma_R(\mathbf{p}_1, \mathbf{p}_2; z) d\mathbf{p}_1 d\mathbf{p}_2 \right] \equiv \Psi_r \langle i_0^2 \rangle, \quad (3.39)$$

where $\Gamma_R(\mathbf{r}_1, \mathbf{r}_2) = \langle U_R(\mathbf{r}_1) U_R{}^*(\mathbf{r}_2) \rangle = U_R(\mathbf{r}_1) U_R{}^*(\mathbf{r}_2)$ is the cross correlation of the scalar reference field, $\Gamma_S(\mathbf{r}_1, \mathbf{r}_2) = \langle U_S(\mathbf{r}_1) U_S{}^*(\mathbf{r}_2) \rangle$ is the cross correlation of the sample field, and $\mathbf{r}_1$ and $\mathbf{r}_2$ are vectors in the r-plane; see Fig. 3.9. Ψ_r is the heterodyne efficiency factor (defined in Eq. 3.17; subscript r refers to it being calculated in the r-plane), which quantifies the reduction in signal due to scattering, and $\langle i_0{}^2 \rangle$ is the OCT signal current in the absence of scattering.

It is important to note that by using the EHF principle, the investigation is limited to the paraxial regime as discussed in Sect. 3.2.1. In addition, most tissues are highly forward scattering in the near-infrared regime in which most OCT systems operate. It is assumed that the coherence length of the light source is short enough that signal powers from other reflections than the probed discontinuity are negligible. On the other hand, the coherence length is assumed long enough so that the temporal distortion of the sample field, or the path-length distribution of the reflected photons, is assumed negligible compared to the coherence length of the

light source. Assuming that the optical path length of the reference beam and sample beam reflected from the discontinuity are perfectly matched, then $\gamma(\tau) \approx 1$. To obtain the best comparison with the EHF model, the MC model presented in this section adopts this approximation.

The approximation of $\gamma(\tau) \approx 1$ is a justified approximation for highly forward scattering tissues [9]. However, it does render the EHF model unsuitable to investigate the effect of scattering on the axial resolution of an OCT system in general, because the coherence gate due to the limited coherence length of the light source is not incorporated. Others have suggested using MC simulation and the total optical path length traveled by a photon packet to determine the influence of the coherence gate [10, 29, 66]. While this may very well be a valid approach, it is clear from the above discussion of photon packets and coherence that, how intuitively correct it may seem, this may not be the case. However, no efforts have been published to establish the meaning of a photon packet in such a temporal mixing of fields, so future work is required to establish such a relation. It is the intention that the MC model of the OCT signal presented in this chapter may be instrumental in such studies.

The OCT signal depends upon the lateral cross correlation of the light from the scattering sample, as indicated by Eq. 3.17, and the lateral coherence length ρ_0 of the sample field in the r-plane for a single layer in front of the discontinuity is given by Eq. 3.21. With a nonzero lateral coherence length, ρ_0, it is seen that the OCT signal depends heavily upon the coherence properties of the field from the sample. As discussed above, an MC simulation does not describe the spatial coherence properties of light, and thus a direct simulation of Eq. 3.39 is not possible. As in Sect. 3.2.2, it is assumed that the discontinuity is diffusely reflecting, and this infers that the lateral coherence will be zero immediately after reflection. The motivation for envisioning the system geometry considered in Sect. 3.2.2 as part of a 4 F setup is to obtain a conjugate plane to the q-plane, here the p-plane; see Fig. 3.9. Through the conjugate relation, it is given that, in the absence of scattering, the lateral coherence length in the p-plane will also be zero. Hence, the sample field will be delta-correlated [20] and the OCT signal will only depend upon the intensities of the reference and sample field. In Appendix B of Ref. [14], it is shown that within the paraxial regime, the sample field is delta-correlated even in the presence of scattering. It is also shown that the heterodyne efficiency factor calculated in the p-plane Ψ_p is mathematically identical to the heterodyne efficiency factor calculated in the r-plane, so that

$$\Psi_p = \frac{\langle i^2 \rangle}{\langle i_0^2 \rangle} = \frac{\int I_R(\mathbf{p}) \langle I_S(\mathbf{p}) \rangle d^2\mathbf{p}}{\int I_R(\mathbf{p}) \langle I_{S0}(\mathbf{p}) \rangle d^2\mathbf{p}} = \Psi_r, \tag{3.40}$$

where I_R is the intensity at the reference beam and I_S, I_{S0} are the received intensities of the sample beam with and without scattering, respectively. The quantity $\mathbf{p}$ is

a vector in the p-plane; see Fig. 3.9. Equation 3.40 shows the viability of applying an MC simulation to an OCT system provided a good estimate of the intensity distribution of the sample field is achieved. This requires a method to simulate a focused Gaussian beam, and a method for modeling such a beam using MC simulation is discussed in Ref. [14]. Note that the identity proven in Eq. 3.40 is only strictly valid within the approximations of the EHF principle and thus also within the paraxial regime. However, for geometries with scattering that is not highly forward, directed coherence effects are expected to be of even less importance, and thus Eq. 3.40 should at least be a good first approximation even when the paraxial approximation is not strictly valid.

3.4.2 Monte Carlo Simulation of the OCT Signal

In Sect. 3.4.1, it is shown that the heterodyne efficiency factor of the OCT signal may be found using the knowledge of the intensity distributions of the sample and reference fields in the p-plane (see Fig. 3.9), where the fiber end is situated:

$$\Psi_p = \frac{\int I_R(\mathbf{p})\langle I_S(\mathbf{p})\rangle d^2\mathbf{p}}{\int I_R(\mathbf{p})\langle I_{S0}(\mathbf{p})\rangle d^2\mathbf{p}}. \tag{3.41}$$

In the EHF principle, the effect of a scattering medium is treated as a random phase distortion added to the deterministic phase of the light as it propagates through the medium. In the derivation of Eq. 3.41 (see also Appendix B of Ref. [14]), it is necessary to assume that the phase distortion added to the light propagating towards the discontinuity is statistically independent from the phase distortion added to the light propagating away from the discontinuity. It is important to note that this assumption is inherently fulfilled by MC methods such as that used by the MCML computer code [67]: a photon is traced through a dynamic medium in the sense that the distance to the next scattering event and scattering angle is a random variable independent upon the past of the photon. Hence, after each stochastic event, the photon experiences a different realization of the sample. Therefore, an ensemble averaging over the stochastic sample in Eq. 3.41 is carried out through a single simulation. Moreover, to also obtain an averaging in the modeling of the diffusely reflecting discontinuity, each reflected photon must experience a new realization of the discontinuity. Thus, the macroscopic intensity distribution of a Lambertian emitter [20] to sample the reflected angle is used

$$I_r(\theta_r) = I_T \cos\theta_r. \tag{3.42}$$

Here I_T is reflected intensity at $\theta_r = 0$ and θ_r is the reflected angle. By following the method outlined by Prahl et al. [68] of sampling a physical quantity using a computer-generated pseudorandom numbers, the following relations are obtained:

$$\theta_r = \arcsin(\xi), \tag{3.43}$$

$$\varphi_r = 2\pi\xi, \tag{3.44}$$

where φ_r is the azimuthal angle of the reflected photon and ξ and ζ are both random numbers uniformly distributed between 0 and 1.

Accordingly, the method of simulating the OCT signal is carried out as follows. The MC photon packet is launched from the focusing lens in the r-plane (see Fig. 3.9), using the focusing method (new hyperboloid method, Ref. [14]). The interfacing with specular surfaces, such as the sample surface and the propagation through the scattering medium, is carried out using the MCML computer code. When a photon packet is reflected off the diffusely reflecting discontinuity,[1] Eqs. 3.43 and 3.44 are used to determine the direction of the photon after reflection. As a photon exits the sample after interaction with the discontinuity, its position and angle are used to calculate its position in the p-plane after propagation through the 4 F system. To evaluate Eq. 3.41 numerically, consider that the mth photon packet exiting the medium contributes to the intensity at the point p_m in the p-plane by the amount

$$I_{S,m} \propto \frac{w_m}{\Delta p^2}, \tag{3.45}$$

where w_m is the energy, or weight, carried by the photon packet and Δp^2 is a differential area around p_m. Using this and Eq. 3.41, the MC estimated heterodyne efficiency factor Ψ_{MC} is then given by

$$\Psi_{\mathrm{MC}} = \frac{\sum_m^M I_R(p_m) I_{S,m} \Delta p^2}{\langle i_0^2 \rangle} = \frac{\sum_m^M I_R(p_m) W_m}{\langle i_0^2 \rangle}, \tag{3.46}$$

where $I_R(p)$ is the intensity distribution of the reference beam in the p-plane, and it is noted that the reference beam has a Gaussian intensity distribution of width w_f in the p-plane. The signal in the absence of scattering $\langle {i_0}^2 \rangle$ may be either simulated or calculated. The latter is straightforward, because with the conjugate relationship between the p- and q-plane, the intensity distribution of the sample beam will be identical to that of the reference beam in the absence of scattering.

[1] The reflection can also be treated as bulk backscattering; see, e.g., Ref. [28].

Equation 3.46 reveals the important detection criterion of the MC simulation of the OCT signal: a photon must hit the p-plane within the extent of the reference beam. While detection schemes of previously published MC models of OCT also incorporate that photons must hit the detector, the key element of this detection scheme is the analytically derived size and necessary position in the p-plane. Furthermore, contrary to these schemes, the model does not incorporate an angular criterion that a photon packet must fulfill in order to contribute to the signal. It may seem counterintuitive that photon packets contribute to the desired signal without penalty regardless of the angle of incidence upon the fiber in the p-plane. However, as demonstrated in Ref. [14], the inclusion of an angular criterion related to the angular extent of the incident beam, or equivalently the numerical aperture of the fiber, yields incorrect results.

3.4.3 Validation

3.4.3.1 Comparison to Experimental Data

The MC model has been verified by comparison to experimental data. In Ref. [12], an experimental setup is described and from this experimental data are obtained. The sample is an aqueous (refractive index 1.33) solution of microspheres (refractive index 1.59; diameter 2.04 μm). The experiment is carried out with the following parameters: source center wavelength $\lambda = 814$ nm, anisotropy $g = 0.929$ (calculated from Mie theory [45] using the particle diameter and refractive index), cuvette thickness $z = 0.5$ mm, focal length $f = 16$ mm, and beam radius $w_0 = 0.125$ mm. Hence, the probe depth remains fixed at $z = 0.5$ mm, and then the scattering coefficient is varied by changing the particle concentration.

From the experimental data, the heterodyne efficiency Ψ factor is derived. The result is plotted in Fig. 3.10 showing Ψ as a function of the scattering coefficient for the above parameters. The measurements are shown as open circles (○) connected with a straight dashed line. The MC data is shown as stars (*) connected with a solid line. For reference, the single-scatter case is plotted as the dotted line. As indicated in Fig. 3.10, good agreement between experiments and the MC model is obtained.

3.4.3.2 Beam Geometries for Numerical Comparison

A set of beam geometries has been selected for numerical comparison between the EHF model and the MC model. These geometries are selected so that the two approaches are compared for different degrees of focusing and distances between the lens L2 and the sample. The selected cases are listed in Table 3.1 and are referred to as cases 1 through 4, respectively.

For all cases the mean refractive index of the sample before the discontinuity and the surroundings are assumed to be matched so that $n_0 = n_1 = 1$. The subject of the investigation is the effect of scattering on the OCT signal. A difference in the refractive index between the sample and the surroundings will impose a Snell's law refraction at the interface, which in turn imposes a focus distortion not treated in the paraxial approximation ($\sin\theta \approx \theta$) and thus not described by the EHF model.

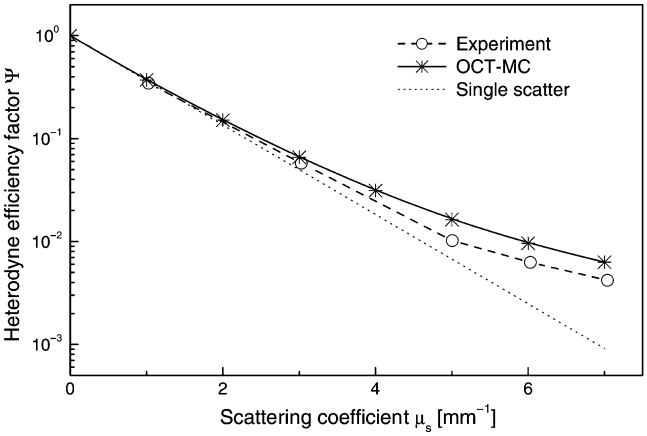

Fig. 3.10 Heterodyne efficiency factor as a function of the scattering coefficient for an aqueous solution of microspheres. Experimental data: *open circles* (○) connected with *dashed line*. MC simulations: stars (*) connected with *solid line*. *Dotted line* shows single-scatter regime for reference. Parameters used: source center wavelength $\lambda = 814$ nm, anisotropy $g = 0.929$ (calculated from the particle diameter and refractive index), cuvette thickness $z = 0.5$ mm, focal length $f = 16$ mm, and beam radius $w_0 = 0.125$ mm

Table 3.1 Beam geometries for the four cases

Case number	f [mm]	d [mm]	z [mm]	w_0 [mm]	w_0/f
1	16.0	15.5	0.5	0.125	0.008
2	8	7.5	0.5	0.4	0.05
3	0.5	0.0	0.5	0.125	0.25
4	16.0	15.0	1.0	4	0.25

Such a distortion will be difficult to separate from the effects of scattering and is thus omitted here. As discussed in Ref. [14], there is only a severe distortion for very tightly focused beams.

In all cases discussed in the following, the wavelength of the light is chosen to be 814 nm, which is one relevant wavelength for biomedical applications of OCT. The sample is assumed to exhibit scattering described by a Gaussian scattering function (see, e.g., Chap. 13 in Ref. [37]). The motivation for this choice is to enable comparison to analytical models of the propagation of Gaussian beams in random media [41] and the OCT signal (see Sect. 3.2.2), which both applies the Gaussian scattering function. The comparisons presented here are carried out for different degrees of scattering and for two relevant values of the asymmetry parameter in tissue [44]: very highly forward scattering ($g = 0.99$) and highly forward scattering ($g = 0.92$). The value $g = 0.92$ was the value of the asymmetry factor in the experiments performed to validate the EHF model by Thrane et al. [12]. With these two cases, the two approaches are compared for a sample geometry where the paraxial approximation is well satisfied

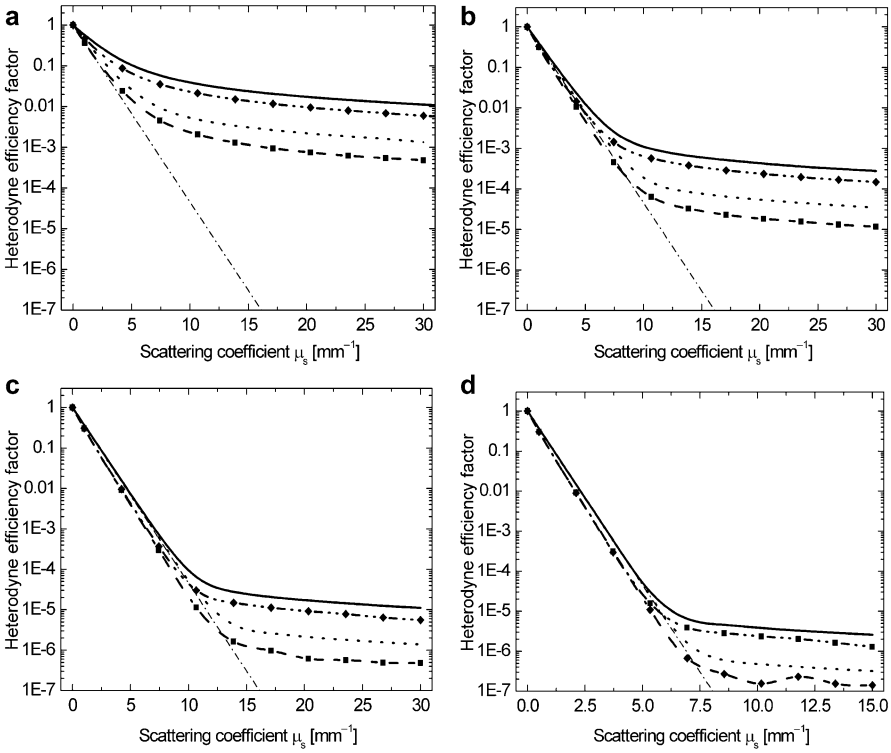

Fig. 3.11 Heterodyne efficiency factors estimated using, respectively, the EHF model and the MC method for two cases of g. (**a–d**) Show the estimated values for geometries 1, 2, 3, and 4 in Table 4.1, respectively. The *solid line* and *dotted line* curves are the results of the EHF model for $g = 0.99$ and $g = 0.92$, respectively. *Dash-dot-dot* and *dashed curves* are the results of the MC simulations for $g = 0.99$ and $g = 0.92$, respectively. *Diamonds* (◆) and *squares* (■) mark the actual data points obtained by the MC simulation method. For comparison, the exponential reduction in signal due to scattering obtained by a single-scatter model is shown as a *dash-dot curve*

and for a sample geometry, which is close to the limit of the paraxial approximation. Accordingly, it is expected that the best agreement will be found for $g = 0.99$.

3.4.3.3 Comparison to Analytical Model

In Fig. 3.11, Ψ is plotted for cases 1 through 4 as a function of the scattering coefficient μ_s, and for reference the case of single backscattering, i.e., $\Psi_{\text{single}} = \exp(-2\mu_s z)$, has been included. Three important observations may be made from Fig. 3.11. Firstly, fine agreement between the MC method and the EHF model for the four cases tested is observed. Thus, these plots are considered the validation of the MC model. Alternatively, the MC results can be considered as the confirmation of the EHF results. Secondly, it is inferred that the OCT signal for high optical depths is a result of multiple-scattering effects in agreement with Sect. 3.2.2. This is seen by

comparing the single-scattering curve to the plots of the MC and EHF. Finally, an important result of Sect. 3.2.2 was the inclusion of the so-called shower-curtain effect [18]. It is an effect caused by multiple scattering and thus plays an important role in calculating the OCT signal as the optical depth increases. Omitting this effect leads to an underestimation of the OCT signal of several orders of magnitude. Due to the good agreement between the EHF model (with the shower-curtain effect included) and the MC model, the important result that the MC model inherently takes the effect into account is obtained.

For cases where the approximation of the EHF model is well satisfied, the observed deviation between the EHF and MC models is likely to be caused by coherence effects in the intensity distribution of the sample field. Apparently, from Fig. 3.11, the lack of coherence information leads to an underestimation of Ψ, but the specific cause for this has yet to be determined. Ψ is by definition unity in the absence of scattering, and for large optical depths, coherence effects are expected to be negligible. Accordingly, the two models are expected to agree for small and large values of the optical depth of the discontinuity, whereas some deviation is to be expected in the intermediate region. As a highly forward scattering event perturbs the field only to a small degree, it is expected to distort coherence effects less than a more isotropic scattering case. In order to plot the relative deviation as a function of the effective distortion of the coherence, the ratio $\Psi_{\mathrm{EHF}}/\ \Psi_{\mathrm{MC}}$ is considered as a function of the transport reduced optical depth of the discontinuity given by

$$S_{tr} = \mu_s z_f (1 - g). \tag{3.47}$$

The relative difference between the EHF model and the MC method behaves, qualitatively, identical as a function of s_{tr} independent of beam geometry and g. This is illustrated in Fig. 3.12 for cases 2 ($g = 0.92$ and 0.99), 3 ($g = 0.92$), and 4 ($g = 0.92$), respectively. The difference between the two approaches increases as a function of s_{tr} until $s_{tr} \approx 0.5$ after which it levels off. This is mainly attributed to the coherence effects in the intensity distribution discussed above. The more abrupt behavior of the curve for geometry 4 is attributed to a higher numerical uncertainty in the case, caused by a more tightly focused beam. According to the detection scheme applied in these simulations, this implies that fewer photons will contribute to the signal resulting in an increased variance. Therefore, due to the good agreement between the results of the EHF model and MC simulations borne out in Figs. 3.11 and 3.12, it is concluded that the MC simulation presented in this section is a viable method of simulating the heterodyne efficiency factor of an OCT signal.

3.5 Applications of Modeling in OCT

The interpretation of OCT images displaying structural information only may be a difficult task, i.e., making adequate assessment of the imaged sample or tissue.

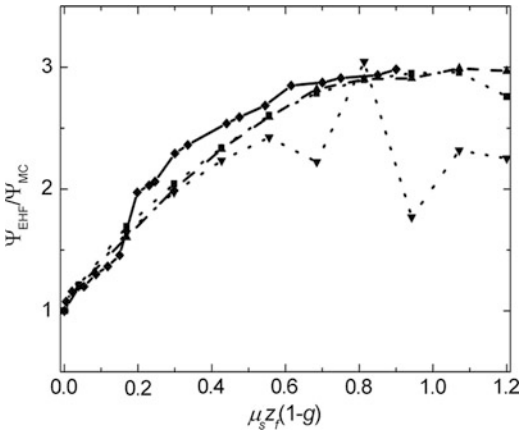

Fig. 3.12 The relative numerical difference between the results of the EHF model and the MC model from Fig. 4.11 for a representative selection of the considered geometries. The ratio Ψ_{EHF}/Ψ_{MC} is plotted for case 2 and $g = 0.99$ with symbols (♦) and *solid curve*, for case 2 and $g = 0.92$ with symbols (■) and *dash-dot-dot curve*, for case 3 and $g = 0.92$ with symbols (▼) and *dashed curve*, and for case 4 and $g = 0.92$ with symbols (•) and *dotted curve* (From Ref. [14])

An OCT signal, i.e., the detected envelope function of the A-scan, measured at a given position in a nonabsorbing scattering medium is the result of the amount of light reflected at the given position and the attenuation due to scattering when the light propagates through the scattering medium. Therefore, in order to make images, which give a direct measure of the amount of light reflected at a given position, it is necessary to be able to separate reflection and scattering effects; see, e.g., Refs. [47, 69] for details on the so-called true-reflection OCT imaging algorithm. Such kind of post processing is similar to the correction for attenuation well known in ultrasonic imaging. In that field, a mathematical model describing the relationship between the received signal and the two main acoustic parameters, backscatter and attenuation, has been considered [70]. The model has then been used to guide the derivation of a processing technique with the aim of obtaining ultrasonic images that faithfully represents one acoustic parameter, such as backscatter [70].

Extraction of optical scattering parameters from OCT images is a method to obtain more quantitative information from these images in order to improve the diagnostics (see, e.g., Ref. [71]), i.e., an alternative method of functional imaging. Accordingly, one may envisage a novel functional imaging method where, in addition to tissue morphology, parameters such as the scattering parameters, g and/or μ_s, or mean refractive index is obtained.

In the following, the viability of the suggested approach in OCT is briefly overviewed. First, a method based on the modeling in Sect. 3.2 is discussed showing that the method may be expanded to more than one layer and that optical scattering properties may be successfully extracted. Finally, some examples highlighting the extraction of optical scattering properties in tissues in vitro and in vivo are given.

3.5.1 Extracting Optical Scattering Properties from an MC-Simulated Heterogeneous Multilayered Sample

It was shown in Sect. 3.2.2 that the mean square heterodyne signal current for light reflected at depth z in the tissue may be expressed as $\langle i^2(z)\rangle = \langle i^2(z)\rangle_0 \Psi(z)$, where $\langle i^2(z)\rangle_0$ is the mean square heterodyne signal current in the absence of scattering and $\Psi(z)$ is the heterodyne efficiency factor, which includes all of the scattering effects. The maximum of the envelope of the measured interference signal corresponds to $[\langle i^2(z)\rangle]^{1/2}$. In practice, μ_s and θ_{rms} may be obtained by fitting the expression for $[\langle i^2(z)\rangle]^{1/2}$ to a measured (or simulated) depth scan of the homogeneous backscattering tissue. It is important to note that in addition to the system parameters λ, f, and w_0, knowledge about the mean index of refraction n of the scattering medium is necessary in order to perform the fitting. Otherwise, the refractive index should be fitted as well as in Ref. [72].

For OCT images of tissue, a multilayered analytical OCT model with multiple-scattering effects included is essential in order to extract optical scattering parameters. In this section, details are given of a method for multilayered extraction of optical scattering parameters [69] by expanding the OCT model developed in Sect. 3.2. Thus, the model makes it straightforward to model OCT imaging in heterogeneous multilayered tissue together with different focusing conditions, i.e., dynamic focusing or fixed focus position.

3.5.1.1 Expressions for Two-Layered Medium

The analytical expressions for the OCT signal of the two layers are obtained from the general expression given by Eq. 3.18. Note that the OCT signal is the root-mean-square (rms) heterodyne signal current $\langle i^2(z)\rangle^{1/2}$. In the case of dynamic focusing, $\langle i^2\rangle_0$ is a constant proportional to the effective backscattering cross section of the sample. For the first layer, characterized by the optical parameters μ_{s1}, θ_{rms1}, and n_1, μ_s and z in Eq. 3.18 are replaced by μ_{s1} and z_1, respectively, where z_1 is the probing depth in the first layer. The lateral coherence length $\rho_{01}(z)$ is then given by [69]

$$\rho_{01}(z_1) = \sqrt{\frac{3}{\mu_{s1} z_1}} \frac{\lambda}{\pi \theta_{\text{rms1}}} \left[\frac{n_1 f}{z_1}\right]. \tag{3.48}$$

For the second layer, characterized by μ_{s2}, θ_{rms2}, and n_2, z and $\mu_s z$ in Eq. 3.18 are replaced by z_2 and $\mu_{s1}\Delta_1 + \mu_{s2} z_2$, respectively, where Δ_1 is the thickness of the first layer and z_2 is the probing depth in the second layer. Furthermore, for the second layer, $\rho_{02}(z)$ is given by [69]

$$\rho_{02}(z_2) = \frac{\sqrt{3}}{\pi} \sqrt{\frac{\left\{\lambda n_2 \Delta_1 + \lambda n_1 \left[z_2 + n_2\left(f - \frac{\Delta_1}{n_1} - \frac{z_2}{n_2}\right)\right]\right\}^2}{n_2^2 \Delta_1 \left(\Delta_1^2 + 3\Delta_1 z_2 + 3z_2^2\right)\theta_{\text{rms1}}^2 \mu_{s1} + n_1^2 z_2^3 \theta_{\text{rms2}}^2 \mu_{s2}}}. \tag{3.49}$$

Table 3.2 The input parameters of the MC simulation together with the extracted parameters obtained by using the EHF model and the relative difference (%). Leave-one-out cross-validation [92] with respect to the MC data points has been used to estimate the standard deviations

Layer	MC input μ_s [mm^{-1}]	Extracted μ_s [mm^{-1}]	Rel. diff. [%]	MC input g-	Extracted g-	Rel. diff. [%]
1	5.000	4.98 ± 0.05	−0.4	0.9900	0.974 ± 0.007	−1.6
2	4.000	4.4 ± 0.1	10	0.9200	0.940 ± 0.003	2.2
2	6.000	6.3 ± 0.1	5.0	0.9200	0.893 ± 0.003	−2.9
2	8.000	8.2 ± 0.1	2.5	0.9200	0.874 ± 0.005	−5.0
2	10.00	9.9 ± 0.2	−1.0	0.9200	0.864 ± 0.006	−6.1

3.5.1.2 Extracting the Optical Scattering Parameters from Layered MC Model

The MC model presented in Sect. 3.3 is used as a numerical phantom. Hence, the versatility of the MC model is demonstrated; for example, it may be used to investigate the performance of the EHF model for sample geometries difficult to produce in the laboratory. By using this model, depth scans of layered scattering structures (tissue) may be obtained. In the present context, a layer is here defined as a plane-parallel homogeneous region characterized by a scattering coefficient μ_s, an anisotropy factor g, and an index of refraction n.

Next the two-layer EHF expression for the OCT signal is fitted to the MC-simulated signal, the optical scattering properties μ_s and g of each of the two layers are extracted, and the MC input values are compared with them. Strictly speaking, the extracted g is the effective anisotropy factor given by the cosine of θ_{rms}, where θ_{rms} is the rms scattering angle defined as the half-width at $1/e$ maximum of a Gaussian curve fit to the main frontal lobe of the scattering phase function of the sample [12]. Because the scattering phase function used in the MC OCT model is also Gaussian, the extracted g values can be directly compared with the MC input g values. The system parameters in this case are $\lambda = 800$ nm, $w_o = 0.4$ mm, and $f = 8.0$ mm. The first layer is 0.3 mm thick (Δ_1) with $\mu_{s1} = 5.0\ mm^{-1}$ and $g_1 = 0.99$. The second layer is 0.9 mm thick with $\mu_{s2} = 10.0\ mm^{-1}$ and $g_2 = 0.92$. Without the loss of generality, the refractive indices of the sample and the surroundings are matched and equal unity.

Table 3.2 shows the main result by comparing the input optical scattering parameters used in the MC simulation to the extracted values including the relative difference. The absolute relative differences between the extracted mean values and the values used in the MC simulation follow a kind of structured pattern with increasing values of μ_{s2}, and the "true" values are not contained within the estimated standard deviations. This observation is an indication of a bias between the EHF model and the MC simulations. On the other hand, the small relative differences demonstrate the capability of the EHF OCT model to extract optical scattering parameters from multilayered tissue. In general, the index of refraction of each layer may also be extracted, but that is outside the scope of the present analysis.

Notice that μ_s and g_{eff} can only be separated if the optical depth of each layer is sufficiently large that multiple scattering occurs. In case the optical depth is too small, only single scattering occurs and therefore only μ_s can be extracted. For large optical depths, i.e., totally diffused light, the EHF model predicts the OCT signal to be determined by the reduced scattering coefficient, and hence, μ_s and g_{eff} cannot be separated for this case (cf. Eq. 3.22, Sect. 3.2.2.1).

3.5.2 Extraction of Optical Scattering Properties from Tissues

As mentioned at the beginning of the present section, attenuation compensation is widely accepted within ultrasonic imaging. Therefore, it has also been among the first attempts to improve on OCT imagery. In fact, attenuation compensation is a method to remove the attenuation caused by scattering in OCT images. This should improve the diagnostic capabilities due to a better differentiation of different tissue types. There have been few attempts to do attenuation compensation in OCT images of tissue by using the single-scattering OCT model [73]. However, due to the fact that multiple-scattered photons contribute to the OCT signal, the single-scattering OCT model is insufficient for this purpose. Attenuation compensation was verified on a single-layer phantom by using an OCT model taking multiple-scattering effects into account [74].

The optical scattering properties themselves, however, also contain information about the tissue. For example, cell mitochondria are affected or changed in several malignant conditions, and through these changes the scattering changes. Conversely, provided that information about the scattering properties can be obtained with good accuracy and good (high) spatial resolution, new diagnostics can be performed [71]. This fact is one important motivation for attempting to extract optical scattering properties in order to improve the diagnostic potential of OCT.

By using the single-scattering OCT model [2], studies have been carried out with the aim to extract only the scattering coefficient μ_s from OCT images of tissue. This approach was applied in various important applications. For example, glucose monitoring was investigated by using the single-scatter approach [75] and expanded to include phase-sensitive OCT [76]. The anisotropy factor g may also be extracted as demonstrated by Kodach et al. [77]. In their study, they showed that monitoring this parameter might offer a contrast mechanism for changes in back-scattering and, hence, indicate morphological changes. Determining optical scattering properties of blood is also of high importance. Faber et al. [78, 79] demonstrated that the optical absorption spectra of oxygenated and deoxygenated hemoglobin, corrected for optical scattering, may be obtained by using spectral OCT. The underlying OCT modeling was based on a single-scattering approach.

Important contributions have been made in in vitro characterization of atherosclerotic plaque by several groups. Studying in vitro samples with various stages of atherosclerotic plaque, van der Meer et al. extracted the optical scattering coefficient [80]. Although the model applied was based on a single-scattering model, their findings provide important data on the optical scattering coefficient of these plaques. A larger study also demonstrated that the scattering coefficient may provide valuable,

additional information, thus improving diagnosis [81]. Some data for the scattering coefficients reported in [81] correlate well with other findings, but some data showed significant deviations: these deviations can, however, be explained by different sample handling and fit to different models, respectively; see also below. In their review paper, Kubo et al. [82] provided an excellent overview on sample handling, extraction of optical parameters, and its diagnostic potential in the clinic. Because OCT is established in cardiology, e.g., stent deployment, such added diagnostic potential seems highly feasible.

Extraction of optical properties has also been investigated targeting other diseases. Quantitative analysis of rectal cancer by spectral domain OCT was demonstrated [83]. Their study involved 16 samples in vitro comprising 1,000 measurement: one half benign and one half malignant. In particular, their results showed that the quantitative analysis of rectal tissue can be used as a promising diagnostic criterion of early rectal cancer. This is noteworthy because early diagnosis has great value for clinical application and earlier onset of treatment. Oral mucosal tissue has also been investigated [84] by using swept source OCT showing promise for early diagnosis. Both studies were carried out under the assumption that single scattering was sufficient to describe the light–tissue interaction. Woolliams and Tomlins [85] claimed that multiple scattering is not affecting the OCT signal at longer wavelengths, but this seems to have been dismissed by several other reports showing clear evidence of the opposite fact. Their statement [85] might, however, be correct with respect to their specific system (data fitting) or application (also mentioned by the authors [85]). Note that for superficial lesions, multiple scattering might be negligible; hence for such applications simplified modeling may suffice.

In general, multiple scattering is impacting the formation of the OCT signal (A-scan). Provided an OCT model is used that takes into account multiple scattering, both μ_s and the anisotropy factor g may be extracted. Extraction for a two-layer geometry has been carried out [69, 86], where both μ_s and g were obtained for each (tissue) layer. In Ref. [69] MC simulations were used as numerical phantom as discussed in detail in the previous subsection.

Lee et al. [28] compared single-scattering and multiple-scattering models for extracting optical scattering properties, and using calibrated scattering phantoms, the validity of the single-scattering and multiple-scattering models for both highly scattering and weakly scattering media was investigated. They showed, with a proper correction for the confocal properties of the sample arm, both models are appropriate to extract the scattering coefficients of weakly scattering media. For highly scattering media, the multiple scattering must be taken into account, and the multiple-scattering model provides much higher accuracy. In their study, they applied the EHF model described in this chapter and in Ref. [12] modeling the multiple scattering. They also investigated the scattering properties of in vitro rat liver and in vivo human skin and concluded that the EHF model is useful for quantitatively characterizing tissue scattering.

A number of in vitro studies have been reported. The characterization of atherosclerotic plaque using a single, multiple-scattering layer model has been reported [87]. The method of extracting the optical scattering properties was

verified using well-controlled and calibrated, single-layer tissue-like phantoms. The study provided the optical scattering properties in 1,300 nm range for lesions in different stages including the anisotropy parameter. Based on the extracted parameters, normal tissue could be separated from malignant tissue. It should be noted that some discrepancies occur between the reported values for the scattering coefficients in Refs. [87, 80]. Possible explanations for the differences may be due to different sample handling and fit to different models. The results reported in both Refs. [87, 80] are encouraging although further studies are required to fully establish these criteria and thereby demonstrate the feasibility of the method in this particular area.

The EHF model, as described in the present chapter and Ref. [12], has been validated and expanded by other groups. Most notably, the work of Kuo et al. [88] concluded that multiple scattering had to be taken into account in the assessment of arterial characteristics in human atherosclerosis. Moreover, they expanded the extraction to also include polarization parameters, thus establishing a refined criterion as compared to previous work; see, e.g., [87].

In Ref. [13], an excellent study comprising rigorous application of the RTE modeling (small-angle approximation) in the extraction of optical parameters is presented. First, the authors verified their modeling on a well-controlled tissue-like phantom. By estimating covariance and confidence regions for the extracted optical properties, they point to specific regimes of the OCT signal decay where extraction is likely to fail. These regimes depend on both the optical properties and sample beam geometry. Hence, their findings provide important insight of how to optimize the OCT system for a specific application. The authors applied their method to cervical tissue (cervical dysplasia 2–3 and leukoplakia). In their in vitro investigation, they demonstrated that cervical dysplasia 2–3 and leukoplakia could be distinguished on the basis of the extracted optical scattering properties. Hence, their excellent contribution should be an encouragement for expanding to other clinical applications and finally in vivo applications.

In vivo studies are sparse; however, Knüttel et al. [72] took the approach of extracting optical scattering properties using the EHF model [12] and refractive index aiming at relating the effects of skin hydration to the optical properties extracted from OCT images. Their investigation showed the applicability of the approach and the potential in dermatology to provide new diagnostic information.

3.6 Summary

Advanced models for describing the light–tissue interactions in optical coherence tomography (OCT) systems have been reviewed. Firstly, an analytical model based on the extended Huygens–Fresnel (EHF) principle is presented valid for the single- and multiple-scattering regimes simultaneously. Because the model is based on the general *ABCD*-matrix formalism, it is applicable to any sample arm geometry, and it leads to closed-form solutions for the OCT heterodyne signal. Expressions for

static and dynamic focusing were presented. Furthermore, expressions for the effects of multiple scattering on the detected OCT signal in Doppler OCT were presented and reasonable agreement with experimental data shown. Notice that the multiple-scattering EHF analysis presented here yields accurate analytical expressions for the OCT signal for a wide range of optical configurations that both are amenable to physical interpretation and are desirable for use in parametric studies for OCT system optimization.

From the EHF model a mathematical proof may be established showing that Monte Carlo (MC) simulations indeed may be used to model OCT system despite the fact that the MC model is restricted to the calculation of intensities and calculation of the OCT heterodyne signal involves the optical fields. Both the analytical and the numerical model compared favorably to experimental data. Moreover, good agreement between the analytical model and the MC simulations was found over a large range of optical scattering parameters and sample arm geometries.

Extraction of optical scattering parameters from OCT images is a method to obtain more quantitative information from these images in order to improve the diagnostics, i.e., an alternative method of functional imaging. Accordingly, one may envisage a novel functional imaging method where, in addition to tissue morphology, parameters such as the optical scattering parameters or mean refractive index are obtained. In addition, other functional parameters, such as polarization properties, can also be combined with the aforementioned scattering properties. The optical scattering properties themselves contain information about the tissue. For example, cell mitochondria are affected or changed in several malignant conditions, and through these changes the scattering changes. Conversely, provided that information about the scattering properties can be obtained with good accuracy and good (high) spatial resolution, new diagnostics can be performed. A survey highlighting important investigations aiming at bringing the modeling of the light–tissue interaction into OCT diagnostics was presented. The examples spanned theoretical/numerical in vitro and in vivo investigations. Although further work is needed, it seems that, in addition to or in combination with other functional imaging modalities, the extraction of optical scattering properties seems feasible and may ultimately improve OCT imagery and its diagnostic potential.

Appendix: Calculation of Γ_S

In the determination of the mutual coherence function Γ_S in Eq. 3.9, the EHF principle is applied in order to obtain a viable expression for $U_S(\mathbf{p};z)$, i.e., the reflected sample optical field. Using Eq. 3.2, $U_S(\mathbf{p};z)$ is related to the reflected sample field $U_B(\mathbf{r};z)$ in the probing plane, where $\mathbf{r}$ defines a two-dimensional vector in this plane:

$$U_S(\mathbf{p};z) = \int U_B(\mathbf{r};z)G(\mathbf{r},\mathbf{p};z)d\mathbf{r}. \tag{3.50}$$

Here $G(\mathbf{r},\mathbf{p};z)$ is Green's function response at $\mathbf{p}$ due to a point source at $\mathbf{r}$, which includes the effects of scattering in the intervening medium. Combining Eqs. 3.11 and 3.50 yields

$$\Gamma_S(\mathbf{p}_1,\mathbf{p}_2;z) = \iint \langle U_B(\mathbf{r}_1;z)U_B(\mathbf{r}_2;z)G(\mathbf{r}_1,\mathbf{p}_1;z)G^*(\mathbf{r}_2,\mathbf{p}_2;z)\rangle d\mathbf{r}_1 d\mathbf{r}_2, \quad (3.51)$$

where $\mathbf{r}_1$, $\mathbf{r}_2$ are associated two-dimensional vectors in the transverse plane. For simplicity in notation, the explicit dependence of the various quantities on z is omitted in the following.

If the forward propagated light is assumed to be statistically independent from the backscattered light, thereby neglecting coherent backscattering, the following relation holds:

$$\left\langle U_B(\mathbf{r}_1)U_B^*(\mathbf{r}_2)G(\mathbf{r}_1,\mathbf{p}_1)G^*(\mathbf{r}_2,\mathbf{p}_2)\right\rangle = \left\langle U_B(\mathbf{r}_1)U_B^*(\mathbf{r}_2)\right\rangle \langle G(\mathbf{r}_1,\mathbf{p}_1)G^*(\mathbf{r}_2,\mathbf{p}_2)\rangle. \quad (3.52)$$

If, furthermore, diffuse backscattering is assumed from the layer being probed, one gets [18, 89]

$$\left\langle U_B(\mathbf{r}_1)U_B^*(\mathbf{r}_2)\right\rangle = \frac{4\pi}{k^2}\delta(\mathbf{r}_1-\mathbf{r}_2)\langle I_B(\mathbf{r}_1)\rangle, \quad (3.53)$$

where $\delta(\mathbf{r})$ is the two-dimensional Dirac delta function and $I_B(\mathbf{r}_1)$ is the mean backscattered irradiance distribution in the plane of the discontinuity. Combining Eqs. 3.51, 3.52, and 3.53 and simplifying yields

$$\Gamma_S(\mathbf{p}_1,\mathbf{p}_2) = \frac{4\pi}{k^2}\int \langle I_B(\mathbf{r})\rangle \langle G(\mathbf{r},\mathbf{p}_1)G*(\mathbf{r},\mathbf{p}_2)\rangle d\mathbf{r}. \quad (3.54)$$

Using Eq. 3.3, the second term in the integral on the right-hand side of Eq. 3.54 may be written as

$$\langle G(\mathbf{r},\mathbf{p}_1)G^*(\mathbf{r},\mathbf{p}_2)\rangle = G_0(\mathbf{r},\mathbf{p}_1)G_0^*(\mathbf{r},\mathbf{p}_2)\Gamma_{pt}(\rho), \quad (3.55)$$

where $G_0(\mathbf{r},\mathbf{p})$ is Huygens–Fresnel Green's function when propagating from the probing plane to the lens plane and Γ_{pt} is the mutual coherence function of a point source located in the probing plane and observed in the lens plane given by

$$\Gamma_{pt} = \langle \exp[i\{\phi(\mathbf{p}_1)-\phi(\mathbf{p}_2)\}]\rangle. \quad (3.56)$$

The mutual coherence function Γ_{pt} contains the effects of the scattering inhomogeneities. Using Eq. 3.4, Green's function $G_0(\mathbf{r},\mathbf{p})$ is given by

$$G_0(\mathbf{r},\mathbf{p}) = -\frac{ik}{2\pi B_b}\exp\left[-\frac{ik}{2B_b}\left(A_b r^2 - 2\mathbf{r}\cdot\mathbf{p} + D_b p^2\right)\right], \tag{3.57}$$

where A_b, B_b, and D_b are the ray-matrix elements for back propagation to the lens plane. These quantities are given by $A_b = D = 1$, $B_b = B = d + z/n$ and $D_b = A = 1$ [39].

$\langle I_B(\mathbf{r})\rangle$ in (3.54) is simply related to the incident mean irradiance distribution $\langle I(\mathbf{r})\rangle$ in the probing layer dz around z by the following relation:

$$\langle I_B(\mathbf{r})\rangle = p_b \mu_s dz \langle I(\mathbf{r})\rangle \tag{3.58}$$

The EHF principle yields that the mean irradiance distribution is given by [39]

$$\langle I(\mathbf{r})\rangle = \left(\frac{k}{2\pi B}\right)^2 \int K(\rho)\exp\left\{\frac{ik}{B}\rho\cdot\mathbf{r}\right\}\Gamma_{pt}(\rho)d^2\rho, \tag{3.59}$$

where

$$K(\rho) = \int \exp\left\{-\frac{ikA}{B}\boldsymbol{\rho}\cdot\mathbf{P}\right\} U_{Si}(\mathbf{P} + \boldsymbol{\rho}/2)U_{Si}^*(\mathbf{P} - \boldsymbol{\rho}/2)d^2P, \tag{3.60}$$

and $\boldsymbol{\rho} = \mathbf{p}_1 - \mathbf{p}_2$. With the considered OCT setup focusing at depth z, $A = 1$ and $B = f$. The mutual coherence function Γ_{pt} can then be found to be [89]:

$$\Gamma_{pt} = \langle \exp\{i[\phi(\mathbf{p}_1) - \phi(\mathbf{p}_2)]\}\rangle = \exp\{-s[1 - b_\phi(\rho)]\}, \tag{3.61}$$

where it has been assumed that the phase ϕ is a normally distributed zero-mean random process. The quantity s is the phase variance, and $b_\phi(\rho)$ is the normalized phase autocorrelation function for a point source whose origin is at the probing depth z. It can be shown [90] that the phase variance is equal to the optical depth, $s = \mu_s z$. The normalized phase autocorrelation function $b_\phi(\rho)$ is given by [89]

$$b_\phi(\rho) = \frac{\int_0^L dz' \int_0^\infty \sigma(\theta; z')J_0(kp_s\theta)\theta d\theta}{\int_0^L dz' \int_0^\infty \sigma(\theta; z')\theta d\theta}, \tag{3.62}$$

where J_0 is the Bessel function of the first kind and of order zero, and

$$P_s = \frac{B_b(z')}{B_b}\rho, \tag{3.63}$$

where $B_b(z')$ is the B-matrix element for back propagation from the probing depth z to a distance z' and $\sigma(\theta; z')$ is the volume scattering or phase function with θ being the scattering angle. For the OCT geometry treated here $B_b(z') = z'/n$ for $0 \le z' \le z$, $L = d + z$, and $\sigma(\theta; z') = \sigma(\theta)$ for $0 \le z' \le z$, and zero otherwise. As described in Eq. 3.5, the phase function is modeled as a combination of a forward scattering term and a small isotropic term. The forward part is modeled here as a Gaussian volume scattering function, which in the small-angle approximation gives a phase function of the following form:

$$\sigma_1(\theta, z) = \exp\left[-\theta^2/\theta_0^2\right], \tag{3.64}$$

where $g = \langle \cos\theta \rangle \approx 1 - \langle\theta^2\rangle/2$, and $\theta_0 = \sqrt{\langle\theta^2\rangle} \approx \sqrt{2(1-g)}$. Substituting Eqs. 3.63 and 3.64 into Eq. 3.62 and performing the indicated integrations yield the following equation for the normalized phase autocorrelation function:

$$b_\phi(\rho) = \frac{\sqrt{\pi}}{2}\frac{\rho_\phi}{\rho}\mathrm{erf}\left(\rho/\rho_\phi\right)[1 - 2p_b], \tag{3.65}$$

where erf(·) denotes the error function and ρ_ϕ is the phase correlation length given by

$$\rho_\phi = \frac{\lambda}{\pi\sqrt{2(1-g)}}\left(1 + \frac{nd}{z}\right). \tag{3.66}$$

Hence, the mutual coherence function Γ_{pt} is given by Eq. 3.61 with $b_\phi(\rho)$ defined by Eq. 3.65. Thus, for specific values of both s and g, the mutual coherence-function is completely determined, and for a given value of the initial optical wave function U_{Si}, numerical results for the mean irradiance can be obtained directly from Eq. 3.59. Here U_{Si} is given by Eq. 3.7, and the following expression for the mean irradiance distribution is obtained at the probing depth z in the tissue:

$$\langle I(\mathbf{r})\rangle = \frac{P_S}{2\pi(f/kw_0)^2}\int_0^\infty \exp\left\{-x^2/4\right\} x J_0(ux)\Gamma_{pt}(xw_0)dx, \tag{3.67}$$

where J_0 is the Bessel function of the first kind of order zero and

$$u = \frac{r}{f/kw_0} \tag{3.68}$$

is a normalized transverse coordinate.

As indicated above, numerical results can readily be obtained. However, it is useful to have an analytical approximation so that OCT system parameter studies can be performed. Examination of Eq. 3.61 reveals for large values of the optical depth that Γ_{pt} is nonzero for $s\{1 - b_\phi(\rho)\}$ less than the order unity, i.e., for $b_\phi(\rho)$

near unity. Expanding $b_\phi(\rho)$ in powers of ρ and retaining the first two nonzero terms yield from Eq. 3.65 that $b_\phi(\rho) \approx (1 - \rho^2/3(\rho_\phi)^2)(1 - 2p_b)$ from which it follows that

$$\Gamma_{pt} \approx \exp\left[-2p_b s - \rho^2/\rho_0^2\right], s >> 1, \tag{3.69}$$

where the lateral coherence length, ρ_0, is defined as $\rho_0 = \rho_\phi[(3/s)/(1 - 2p_b)]^{1/2}$. It is expected that the ballistic, i.e., unscattered, component of the irradiance pattern is proportional to $e^{-\mu s z}$. Thus, by interpolation [12]

$$\Gamma_{pt} \approx \exp(-\mu_s z) + [1 - \exp(-\mu_s z)]e^{-2p_b\mu_s z}\exp\left(-\rho^2/\rho_0^2\right). \tag{3.70}$$

Substituting Eqs. 3.7 and 3.70 into Eq. 3.59 and performing the integration yield the following approximate expression for the mean irradiance distribution at the probing depth z in the tissue:

$$\langle I(\mathbf{r})\rangle \approx \frac{P_S}{\pi}\left[\frac{e^{-\mu_s z}\exp\left\{-r^2/w_H^2\right\}}{w_H^2} + \frac{(1 - e^{-\mu_s z})e^{-p_b\mu_s z}\exp\left\{-r^2/w_S^2\right\}}{w_S^2}\right]. \tag{3.71}$$

For p_b<<1 the expression can be further simplified:

$$\langle I(\mathbf{r})\rangle \approx \frac{P_S}{\pi}\left[\frac{e^{-\mu_s z}\exp\left\{-r^2/w_H^2\right\}}{w_H^2} + \frac{(1 - e^{-\mu_s z})\exp\left\{-r^2/w_S^2\right\}}{w_S^2}\right]. \tag{3.72}$$

The first term in the brackets on the right-hand side of Eq. 3.72 can be interpreted to represent the attenuated distribution obtained in the absence of the inhomogeneities, and the corresponding second term represents a broader halo resulting from scattering by the inhomogeneities. The quantities w_H and w_S are the $1/e$ irradiance radii in the absence and presence of scattering, respectively, given by

$$w_H^2 = w_0^2\left(A - \frac{B}{f}\right)^2 + \left(\frac{B}{kw_0}\right)^2, \tag{3.73}$$

$$w_S^2 = w_0^2\left(A - \frac{B}{f}\right)^2 + \left(\frac{B}{kw_0}\right)^2 + \left(\frac{2B}{k\rho_0}\right)^2. \tag{3.74}$$

For the OCT system in question,

$$w_H = \frac{f}{kw_0}, \tag{3.75}$$

$$w_S = \sqrt{w_H^2 + \left(\frac{2f}{k\rho_0}\right)^2}. \tag{3.76}$$

From Eqs. 3.58 and 3.72, an expression for the intensity is obtained:

$$\langle I_B(r)\rangle \approx \frac{p_b \mu_s dz P_s}{\pi}\left[\frac{e^{-\mu_s z}\exp\{-r^2/w_H^2\}}{w_H^2} + \frac{(1-e^{-\mu_s z})\exp\{-r^2/w_S^2\}}{w_S^2}\right]. \tag{3.77}$$

Substituting Eqs. 3.10, 3.6, 3.77, 3.54, 3.55, 3.57, and 3.70 into Eq. 3.9 and performing the indicated Gaussian integrations over $\mathbf{p}_1$,$\mathbf{p}_2$ and simplifying finally yield for p_b<<1

$$\begin{aligned}\left\langle i^2(z)\right\rangle \approx{}& \frac{8\alpha^2 P_R P_S \pi p_b \mu_s |\gamma(\tau)|^2 dz}{\pi^2 k^2} \\ &\int\left[\frac{e^{-\mu_s z}\exp\{-r^2/w_H^2\}}{w_H^2} + \frac{(1-e^{-\mu_s z})\exp\{-r^2/w_S^2\}}{w_S^2}\right]^2 d\mathbf{r}.\end{aligned} \tag{3.78}$$

Performing the integration over the probed plane in Eq. 3.12 and simplifying, the following expression for the mean square heterodyne signal current is obtained:

$$\begin{aligned}\left\langle i^2(z)\right\rangle \approx{}& \frac{4\alpha^2 P_R P_s p_b \mu_s |\gamma(2(z-l_r)/c)|^2 dz}{w_H^2 k^2} \\ &\times\left[e^{-2\mu_s z} + \frac{4e^{-\mu_s z}(1-e^{-\mu_s z})}{1+\frac{w_S^2}{w_H^2}} + (1-e^{-\mu_s z})^2\frac{w_H^2}{w_S^2}\right], \\ ={}& \left\langle i^2\right\rangle_0 \Psi(z)\end{aligned} \tag{3.79}$$

where l_r is the traversed optical path length of the reference beam and c is the speed of light in vacuum. In order to incorporate the total signal contribution obtained from within the coherence gate of the sample volume, we finally integrate (3.79) along the z-axis. This corresponds to a convolution with respect to the square modulus of the temporal coherence function $|\gamma(z/c)|^2$. Assuming a rectangular coherence function of width l_c/c, where l_c is the coherence length of the source, and $\mu_s l_c$ <<1,

$$\begin{aligned}\left\langle i^2(z)\right\rangle_{coh_gate} &\approx \frac{\alpha^2 P_R P_s \sigma_b}{\pi w_H^2} \\ &\times \left[e^{-2\mu_s z} + \frac{4e^{-\mu_s z}(1-e^{-\mu_s z})}{1+\frac{w_S^2}{w_H^2}} + (1-e^{-\mu_s z})^2 \frac{w_H^2}{w_S^2} \right] \\ &= \left\langle i^2 \right\rangle_0 \Psi(z)\end{aligned} \tag{3.80}$$

where $\sigma_b = 4\pi p_b \mu_s l_c / k^2$ denotes the effective backscattering cross section of the backscattering volume selected by the coherence gate. The quantity $\langle i^2 \rangle_0 = \alpha^2 P_R P_S \sigma_b / \pi (w_H)^2$ is the mean square heterodyne signal current in the absence of scattering, and the term contained in the brackets is the heterodyne efficiency factor $\Psi(z)$.

OCT Technology

Inverse Scattering and Aperture Synthesis in OCT

4

Adolf F. Fercher

Keywords
OCT • Inverse scattering • Aperture synthesis (AS) • Optical diffraction tomography • 3D imaging • Interferometric synthetic aperture microscopy (ISAM)

Scattering and diffraction are basically the same basic physical phenomena, though their treatments tend to be separated, depending on the dimensions of the light propagation obstacle compared to the wavelength. Scattering (diffraction) theory determines the relation between the input and output waves, given the details of the target met by light (or other waves). Inverse scattering (IS) determines properties of the target, given sufficiently details of input and scattered waves [1–3].

Many important tomographic techniques, like X-ray and emission photon tomography in the medical field, can rely on straight rays. With ultrasound, microwaves, and optical waves, diffraction plays an important role [4]. Here, IS is dominated by the problem of diffraction inversion; E. Wolf has presented a general solution for a wave field $U^{(s)}(\mathbf{r})$ diffracted by a sample, now known as "basic theorem of optical diffraction tomography (ODT)" [5]. Carney and Wolf [6] also discuss the use of the power extinguished on scattering from weakly scattering objects to obtain three-dimensional reconstructions of the object structure. This so-called power-extinction diffraction tomography relies on interference within the domain of the scatterer; it does not require the phase of the scattered field to be measured. Another IS approach, based on spectral changes, yields the correlation function of the scattering potential of the medium [7].

Diffraction-limited resolution is a concern in many imaging systems. Using two-photon entangled states can lead to a twofold increase in resolution due to its doubled photon energy [8]. Another approach to break the diffraction limit and substantially increase optical resolution is near-field optics. Bao et al. [9] have developed a regularized recursive linearization method for two-dimensional inverse medium scattering arising in photon scanning tunneling microscopy and numerically demonstrate its capability to provide subwavelength resolution.

Explicit inversion formulas for inverse scattering with diffusing optical waves have been presented by Konecky et al. [10]. Quantitative images of complex phantoms with millimeter-sized features located centimeters deep within a highly scattering medium were reconstructed using a fast image reconstruction algorithm based on an analytic solution.

This chapter concentrates on optical backscattering-based IS techniques; we shall, however, not be concerned with related problems like enhanced intensity in coherent backscattering [11] and the T-matrix method [12].

Inversion of optical backscattered fields has led to extremely successful distance measurement (partial coherence interferometry, PCI) and imaging techniques (optical coherence tomography, OCT), in particular in the medical field [13]. Since imaging based on inverse scattering replaces the imaging lens by photoelectric detection of the complex amplitude of light scattered by the sample, its detection area can be adapted to various requirements. Besides aiming an optimal reconstruction of the sample structure, an objective is to extract the structure of anomalous areas that differ from a predefined set of features [14].

The techniques described below are based on linearized inverse scattering. In a mathematical linear imaging system, there is an object function and an image function; both are elements of the same or of different ($\mathbf{r}$ versus $\mathbf{K}$) Euclidian spaces. Here, the object function is the sample source strength $S(\mathbf{r})$; the image function is the scattered wave spectrum $\hat{U}^{(S)}(\mathbf{K})$. A linear mapping is assumed which associates the two functions:

$$\hat{U}^{(S)}(\mathbf{K}) = \mathrm{O} \cdot S(\mathbf{r}) + N. \tag{4.1}$$

(Usually, there will be some noise N too.) O is a linear operator describing the scattering process. Here, the experimental procedure involves sampling and in particular severe bandwidth limitations (Fig. 4.2); hence, an inversion of Eq. 4.1 is not a well-posed problem. A similar problem occurs in optical imaging by lenses; here aperture limits of the spatial frequency components in image are countersteered by deconvolution techniques. Such ill-posed problems are usually treated by regularization. The regularization method is based on approximate solutions depending on a regularization parameter that tends to zero, when the approximate solution converges to the exact solution [15].

4.1 Optical Diffraction Tomography-Based Inverse Scattering

4.1.1 Basic Theorem of Diffraction Tomography

Optical diffraction tomography (ODT) is based on IS. The scattering operator O essentially is a three-dimensional (3D) Fourier transform (FT). Tikhonov regularization [16] can be used to improve both, signal-to-noise ratio and image qualities. In formulating the basic theorem of diffraction tomography [5], E. Wolf considers direct scattering on a nonmagnetic sample with an isotropic dielectric constant varying weakly over distances of the order of a wavelength. That sample is assumed illuminated by a plane wave or positioned at the beam waist of a monochromatic Gaussian beam with amplitude

$$U^{(i)}(\mathbf{r}) = A^{(i)}(\mathbf{r})\exp[-i\omega t]. \tag{4.2}$$

Wolf's solution is based on the first-order Born approximation as an approximate solution for weak scatterers. Weyl's expansion of the 3D free-space Green function of the wave equation lets him represent the scattered field as an angular spectrum of plane waves. In a first step Wolf thus obtains an expression for the angular spectrum of homogeneous waves of the scattered field $\hat{U}^{(S)}(\mathbf{K})$ in terms of the 3D Fourier inverse of the sample scattering potential $F(\mathbf{r})$. As a second step Wolf determines the homogeneous part of the angular spectrum of scattered waves by a two-dimensional (2D) FT $\hat{U}_h^{(S)}(\mathbf{K})$ of the scattered field $U^{(s)}(\mathbf{r})$ in detection planes in front and behind the scattering object and adds a phase factor corresponding to the distance between sample and detection plane [1].

Alternative approaches to determine the spatial distribution of magnitude and phase of wave fields under far-field and near-field conditions have been given by Schmidt-Weinmar [17, 18]. The first applications of the ODT theorem were demonstrated by Carter [2], who considered the special case of a rectangular scatterer and compared the computed projection of the scattering potential along a planar section through the object with experimental measurements and furthermore, by Carter and Ho [19], who considered a semitransparent bar with nonuniform index of refraction and stated agreement between the computed 1D (one-dimensional) scattering potential along a line through the object with known object parameters within errors of a few percent.

Another frequently used solution of the inverse scattering problem is the Rytov expansion; it models the phase of the scattered field as exponentially dependent on the scattering potential [5]. Whereas the first-order Born approximation is accurate when the product of the index contrast and object size is less than one-quarter wavelength, the Rytov approximation is accurate when the square of the phase gradient is much less than the index contrast divided by the wavelength squared [20]. If continuities of the sample parameters are located on smooth surfaces, the Kirchhoff approximation is a preferred solution [21].

In 2002 Lauer [22] has presented a new approach to optical diffraction tomography. In this technique the sample is successively illuminated by a series of plane waves having different directions; the sample structure is then reconstructed from these recorded waves.

At present, the basic theorem of diffraction tomography forms the physical basis of many PCI and OCT techniques as well as of the recently put forward synthetic-aperture technique [23].

4.1.2 Far-Field Approximation

Far-field diffraction or Fraunhofer conditions are defined with respect to sample size and detection plane to sample distance. In this case the scattered field is observed at a distance $d \gg a^2/\lambda$ or at a Fresnel number $FN = \frac{a^2}{d\cdot\lambda} \ll 1$; a is a length of the order of the size of the sample. Under these conditions the first-order Born approximation for an incident wave $U^{(i)}(\mathbf{r}') = A^{(i)} \cdot \exp[i \cdot \mathbf{k^{(i)}} \cdot \mathbf{r}']$ yields a spherical wave for the scattered field at the detection plane with a complex amplitude determined by the FT of the sample scattering potential $F(\mathbf{r})$ [3]:

$$U^{(S)}(\mathbf{r},k) = -\frac{1}{4\pi}\int\limits_{Vol} U^{(i)} \cdot (\mathbf{r}') \cdot F(\mathbf{r}') \cdot \frac{\exp[i\cdot k\cdot|\mathbf{r}-\mathbf{r}'|]}{|\mathbf{r}-\mathbf{r}'|} \cdot d^3\mathbf{r}'; \tag{4.3}$$

the fraction in this equation is the Green function of the wave equation. With direct space origin in or close to the sample, we can use the approximation $k \cdot |\mathbf{r} - \mathbf{r}'| \approx \mathbf{k^{(S)}} \cdot (\mathbf{r} - \mathbf{r}')$, $k = |k^{(i)}| = |k^{(S)}| = 2\pi/\lambda$. $\mathbf{r}$ is the far-field position vector. (We have omitted the self-evident time-dependence $\exp[-i \cdot \omega \cdot t]$.)

Equation 4.3 can now be written as

$$\begin{aligned}\hat{U}^{(S)}(\mathbf{K}) &= -\frac{1}{4\cdot\pi}\int\limits_{Vol} F(\mathbf{r}')\cdot A^{(i)}(\mathbf{r}')\cdot\frac{\exp\left[i\cdot\mathbf{k^{(S)}}(\mathbf{r})\right]}{|\mathbf{r}-\mathbf{r}'|}\cdot\exp[-i\cdot(\mathbf{r}'\cdot\mathbf{K})]\cdot d^3\mathbf{r}' \\ &= -\frac{\exp(i\cdot k\cdot d)}{4\cdot\pi\cdot d}\int\limits_{Vol} A^{(i)}(\mathbf{r}')\cdot F(\mathbf{r}')\cdot\exp(-i\cdot\mathbf{K}\cdot\mathbf{r}')\cdot d^3\mathbf{r}',\end{aligned} \tag{4.4}$$

since, in the far-field, both the scattering vector $\mathbf{K} = \mathbf{k}^{(S)} - \mathbf{k}^{(i)}$ and the vector of the scattered wave $\mathbf{k^{(S)}}$ can be used to define the position $\mathbf{r}$ of field detection. $\mathbf{k^{(i)}}$ is the wave vector of the incident wave ($|\mathbf{k^{(i)}}| = |\mathbf{k^{(S)}}| = k = 2\pi/\lambda$). d is the distance between direct space origin at or near the sample and the field position. $F(\mathbf{r})$ is the sample scattering potential – see Eq. 4.7 below. Hence, the scattered wave comprises a spectrum of spherical waves with radius of curvature d and a complex amplitude equal to the inverse Fourier transform of the sample source strength

$$S(\mathbf{r}) = A^{(i)}(\mathbf{r}) \cdot F(\mathbf{r}); \tag{4.5}$$

This corresponds to the first step of Wolf's solution. In the far-field approximation Wolf's second step occurs by light propagation to the detector matrix. Using that facilitation Fercher et al. [3] were the first to demonstrate a full 3D reconstruction of a 3D object based on ODT. Computer simulations based on Mie scattering by coated spheres and reconstructions based on experimentally obtained scattered field data were presented. However, these early (1979) investigations suffered from limitations of light source and computer technology at that time.

For simplification of the subsequent discussion of the properties of diffraction tomography, we shall use the far-field approximation of the basic ODT theorem. This approximation in particular describes digital microscopic imaging but is easily extended to large samples as well; see Sect. 4.2.1.6 below. In this approximation the complex amplitude of the scattered wave $\hat{U}^{(S)}(\mathbf{K})$ represents the Fourier components of the sample source strength accessible by scattered field measurements:

$$S(\mathbf{r}) = FT\left\{\hat{U}^{(s)}(\mathbf{K})\right\} \tag{4.6}$$

As depicted in Fig. 4.1 forward and backward scattering provide access to quite different Fourier components of the sample structure.

4.1.3 Basic Properties of Optical Diffraction Tomography-Based Inverse Scattering

1. Sample structure, represented as source strength $S(\mathbf{r}) = A^{(i)}(\mathbf{r}) \cdot F(\mathbf{r})$, is obtained from a Fourier transform of the complex amplitude of the far-field scattered sample wave.
2. Source strength structure is mainly determined by the scattering potential $F(\mathbf{r})$ (also called "scattering contrast," or "sample susceptibility") of the sample:

$$F(\mathbf{r}) = k^2 \cdot \left[m^2(\mathbf{r}) - 1\right], \tag{4.7}$$

   $m(\mathbf{r}) = n(\mathbf{r}) \cdot [1 + i \cdot \kappa \cdot (\mathbf{r})]$ is the complex refractive index distribution of the sample structure, with $n(\mathbf{r}) =$ phase refractive index and $K(\mathbf{r}) =$ attenuation index. (A more general expression of the scattering potential is achieved if the changes in refractive index are measured relative to the background refractive index [24].)
3. Far-field scattered field data $\hat{U}^{(S)}(\mathbf{K})$ are located on a sphere in $\mathbf{K}$-space (Ewald sphere) [5].
4. The lateral extent of the transfer function for both, forward and backscattering, is the same. In both cases lateral resolution is the same (depending on aperture angle ß).

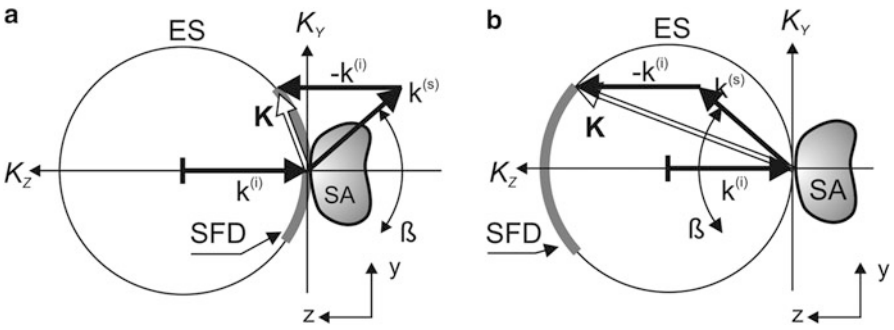

Fig. 4.1 Forward and backward far-field scattering: (**a**) scattered field data (*SFD*) in forward scattering are located around $K_Z \sim 0$; (**b**) scattered field data in backscattering are located around $K_Z \sim -2k$. *ES* Ewald sphere, *SA* sample, *SFD* accessible scattered field data. ß is the aperture angle

4. Forward scattering, even at moderately large aperture angles, provides access only to Fourier data near the K_x–K_y plane ($K_z \sim 0$). Hence, with respect to depth structure, forward scattering techniques act as low-pass filter. The image obtained in standard optical imaging, for example, by lenses, is a projection of the sample structure in z-direction [25]. High depth resolution in standard imaging demands for rather large aperture angles, as used, e.g., in high-resolution microscopy.
6. Standard OCT techniques use low numerical apertures (NAs) of the probing sample beam optics. Hence, the major contribution to the detected light comes from backscattering. For further details see Sheppard et al. [24].
7. Backscattering techniques act as high depth frequency band-pass filter and, therefore, show corresponding structures. However, single Fourier components sample different parts of the whole object's spatial frequency spectrum [26, 27] but do not yield depth resolution.
8. Resolution is determined by the Fourier uncertainty relation:

$$\Delta j \cdot \Delta K_j \sim \frac{1}{2}; j = x, y, z. \tag{4.8}$$

Even at moderate aperture angles ß (Fig. 4.1), relatively large ranges of transversal Fourier components are accessible in forward and backward scattering, and thus relatively high transversal resolution Δx and Δy can be obtained. In contrast to standard optical imaging, high depth resolution in PCI and OCT A-scan signals is provided by a broad wavelength spectrum $\Delta\lambda$. Here depth resolution is usually defined by the coherence length $l_C = \frac{2\ln 2}{\pi} \frac{\overline{\lambda}^2}{\Delta\lambda}$ (Gaussian spectrum assumed, $\overline{\lambda}$ is the mean wavelength).

9. Backscattering detector signal strength is, besides its dependence on the detector aperture, proportional to K^2 and, therefore, proportional to the second-order derivative $F^{(2)}(z)$ of the scattering potential [26]:

$$F^{(2)}(z) = -2 \cdot k_0^2 \cdot \left[n^{(1)}(z)^2 + n(z) \cdot n^{(2)}(z) \right]. \tag{4.9}$$

LCI and OCT signals, therefore, increase with increasing steepness and variability of the sample refractive index. (The same prediction has recently been obtained from another scattering model, based on the Kirchhoff approximation [24].)

10. Finally, the photoelectric OCT signal is proportional to the interferogram intensity at the photodetector and its quantum efficiency.

In this chapter, inversion of backscattered light in the far-field approximation provides the key to Fourier domain PCI and OCT. However, inversion problems also occur in forward scattering, for example, in near-field optics; in diverse areas of biological and industrial applications, such as the imaging of biological samples; in the inspection and manipulation of nano-electronic components in semiconductor technology; and in the inspection and activation of nano-optical devices.

4.2 Inverse Scattering-Based OCT Techniques

4.2.1 Far-Field Diffraction Techniques

In near-field Fresnel diffraction tomography, the operator O comprises two consecutive FTs [1]. Far-field diffraction tomography, on the other hand, is based on one FT only. Hence, we shall concentrate on far-field diffraction tomography and may expect most results to be applicable in near-field Fresnel diffraction tomography as well.

Based on optical diffraction tomography, a hierarchy of tomographic techniques can be formulated [28, 29], each based on a wavelength spectrum from λ_1 to λ_2 – starting from 3D imaging as indicated in Fig. 4.2 down to the point detector that measures scattering strength of the complete illuminated volume of a sample.

Note: In the subsequent figures standard illumination and reference beam optics as indicated in Fig. 4.2a are omitted.

4.2.1.1 Inverse Scattering 3D Imaging

The optical scheme depicted in Fig. 4.2a is a basic arrangement for 3D ODT giving access to the full 3D sample structure. Basically, in each detector pixel amplitude and phase of the interferogram, formed by the scattered sample wave and the reference wave, have to be measured for the wavelength range $\lambda_1 \rightarrow \lambda_2$. In the first approach monochromatic light had been used [3]. However, a 3D sample requires the recording of a 3D scattering data set. This can be achieved by illuminating the sample in more than one direction and/or by more than one wavelength [30]. Figure 4.2 depicts the situation when light of a wavelength range $\lambda_1 \leq \lambda \leq \lambda_2$, for example, from a swept source (LS), is used. Here, scattered field data between Ewald sphere windows ES1 and ES2 can be recorded.

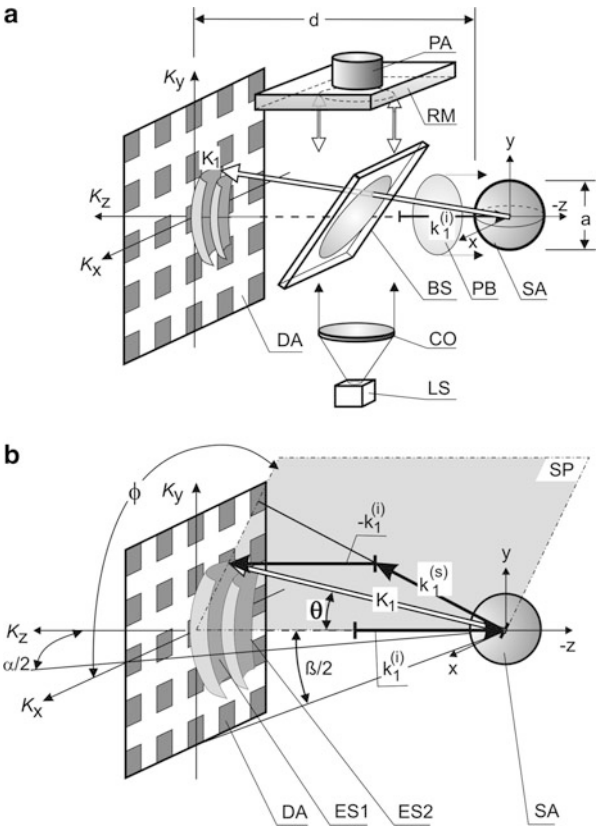

Fig. 4.2 3D far-field DOT. (**a**) basic optical scheme for inverse scattering-based OCT (and PCI). The illuminating beam vector is assumed antiparallel to the K_z-axis of the 2D detector-matrix DA. *BS* beam splitter, *CO* collimator, *LS* tunable or frequency-swept light source, *PA* piezo actuator for phase-shifting technique, *PB* probe beam cross section (sample illumination), *RM* reference mirror, *SA* sample (homogeneous sphere assumed); (**b**) **K**-space geometry of backscattering. Note: here, and in the subsequent figures, the $K_z = 0$ position is at the origin of the x,y,z-system. *ESi* scattered field data Ewald spheres of wavelength λ_i, *SP* scattering plane. K_1 = scattering vector of wavelength λ_1; $\mathbf{k}_1^{(i)}$ = wave vector of illuminating wave of wavelength λ_1; $\mathbf{k}_1^{(s)}$ = wave vector of scattered wave of wavelength λ_i. Fourier data points of wavelength λ_n are in a rectangular window ESn on the surface of the corresponding Ewald spheres. a is the sample size, d is the distance sample/image sensor, ß is the aperture angle, ϕ is the scattering azimuth, θ is the scattering angle

Basically, spectral amplitude and spectral phase have to be determined at each detector pixel. Spectral amplitude can easily be obtained from the pixel signal magnitude. There are several approaches to retrieve spectral phase data. For example, the phase-shifting technique enables registering the phase of the scattered

field at each detector pixel. In phase-shifting interferometry [31–33], the relative phase of the reference beam is shifted by discrete steps. From the interferometic intensity variation generated by these phase shifts, the phase of the scattered object wave is obtained. Hlubina et al. record two spectral interferograms to obtain the spectral interference signal and retrieve from it the spectral phase [34]. Also, a fast Gabor wavelet transform for high-precision phase retrieval in spectral interferometry that is significantly insensitive toward experimental noise has been described [35]. Using a swept source requires sampling the 2D interferogram intensity formed by the scattered sample wave and the reference wave at each pixel while the frequency of the source is scanned.

These methods are somewhat hindered by the fact that interference spectrum data recorded by single photodetector elements have to be rescaled from wavelength to frequency; furthermore, wavelength-dependent scattering vector space coordinates have to be scaled for wavelength, scattering azimuth, and scattering angle. Such a data set, however, enables a 3D reconstruction of the sample structure, also providing the basis for 2D tomograms.

In contrast, today, standard 3D OCT-based instruments typically use two-axis galvano mirrors for transverse 2D sample scanning by an A-scan probing beam. A-scan information is acquired by spectral interferometry (SI) by either using a broad-bandwidth light source and a spectrometer, spectral domain (SD)-PCI, or sweeping a narrow-bandwidth source through a broad range of frequencies, swept source (SS)-PCI. In both cases A-scan depth information is obtained by a Fourier transform of the detected spectra [36]. A comparison of a recently available commercial 3D OCT system operating at 800 nm with three laboratory systems operating with higher A-scans/s and one different wavelength can be found by Povazay et al. [37].

4.2.1.2 Inverse Scattering Sample Slice Generation

Direct access to tomographic sample sections is provided by projected scattering data. This follows from the Fourier projection/slice theorem [38]. Section position and orientation can be chosen within wide limits. For example, a slice $S(x_0, y, z)$ of the sample source strength in the y–z plane at x-coordinate x_0 is obtained from a projection of the scattering data including a phase factor:

$$S(x_0, y, z) = \iint \left\{ \left[\int \hat{U}^{(s)}(\mathbf{K}) \cdot \exp(i \cdot x_0 \cdot K_x) \cdot dK_x \right] \cdot \exp\left[i \cdot \left(y \cdot K_y + z \cdot K_z \right) \right] \right\} \cdot dKy \cdot dKz. \tag{4.10}$$

(In case of $K_x - K_y - K_z -$ factorizable spectra, a sequence of 1D FTs could be used.)

A slice at $x = 0$ is simply obtained as a 2D FT of the complex scattering data $\hat{U}^{(s)}(\mathbf{K})$ projected in K_x-direction in the detection plane

$$S(0,y,z) = \iint \left\{ \left[\int \hat{U}^{(s)}(\mathbf{K}) \cdot dK_x \right] \cdot \exp\left[i \cdot \left(y \cdot K_y + z \cdot K_z \right) \right] \right\} \cdot dKy \cdot dKz. \tag{4.11}$$

Such a projection performance in the detection plane can be achieved by binning sensor pixels of the detector matrix to form corresponding super-pixels in various azimuthal directions. Using programmable detector arrays very flexible OCT sample data acquisition systems can thus be implemented: Besides full 3D imaging, sample slices and sample projections in various orientations could be quickly achieved with such a system.

Projection performance in the detection plane can also be achieved by a linear detector array with reasonable large detector height:

Sample slice generation is analogous to parallel 2D FD-OCT: Grajciar et al. [39], for example, used a cylindrical lens to produce a sheet-of-light illumination on the sample in a study on a fully parallel FD-OCT system that allowed real time imaging of human eye structures. An alternative has been proposed by Zuluaga et al. [40]. These authors used a spatially resolved spectral interferometer. Here the depth in the sample is encoded as wavelength-dependent spatial frequency in the spectrogram whereas transverse information is imaged directly.

4.2.1.3 Inverse Scattering Sample Projection

Consider a 2D slice through the scattered field in the K_y–K_z plane at $K_x = 0$:

$$\begin{aligned} \hat{U}^{(S)}\left(0,K_y,K_z\right) &= \iiint S(x,y,z) \cdot \exp\left[-i \cdot \left(x \cdot K_x + y \cdot K_y + z \cdot K_z \right) \right] \cdot dx \cdot dy \cdot dz|_{K_x=0} \\ &= \iint \left\{ \left[\int S(x,y,z) \cdot dx \right] \cdot \exp\left[-i \cdot \left(y \cdot K_y + z \cdot K_z \right) \right] \right\} \cdot dy \cdot dz \end{aligned} \tag{4.12}$$

Hence, an FT of that 2D slice through the scattered field yields a parallel projection of the sample source strength onto the y–z plane:

$$P_x(y,z) = \int S(x,y,z) \cdot dx = \iint \hat{U}\left(0,K_y,K_z\right) \cdot \exp\left[i \cdot \left(y \cdot K_y + z \cdot K_z \right] \right] \cdot dK_y \cdot dK_z, \tag{4.13}$$

See Figs. 4.3 and 4.4.

4.2.1.4 Inverse Scattering Line Projection

Next we consider a linear stitch $\hat{U}^{(s)}\left(0,K_y,0\right)$ through the scattered field along the K_y-axis at $K_x = K_z = 0$. A Fourier transform yields a condensation of the sample source strength $S(x,y,z)$ along the y-coordinate. Slightly modifying Eq. 4.12 for $\hat{U}^{(s)}\left(0,K_y,0\right)$ readily yields the sample source strength condensed onto the y-axis:

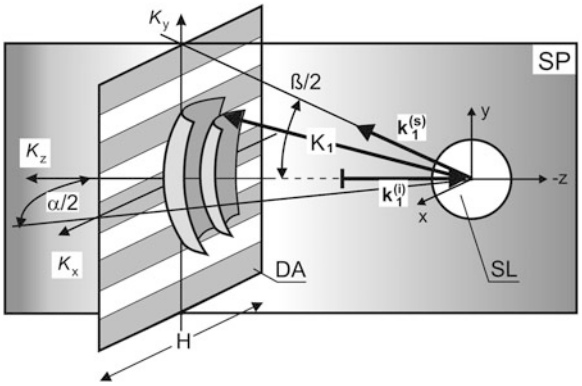

Fig. 4.3 IS sample slice generation by scattered field data projection. Here a line-array detector integrates the complex scattering amplitudes $\hat{U}^{(s)}(\mathbf{K})$ along the height H of the detector elements normal to the symmetry axis (K_y). Inversion reconstructs an OCT slice SL through the sample (a sphere) along the illuminating beam axis ($\mathbf{k}_\mathbf{n}^{(\mathbf{i})}$) and contains the detector symmetry axis (K_y). *DA* detector array, *SP* slice plane. Note: here, and in the subsequent figures, the $K_z = 0$ position is at the origin of the x,y,z-system

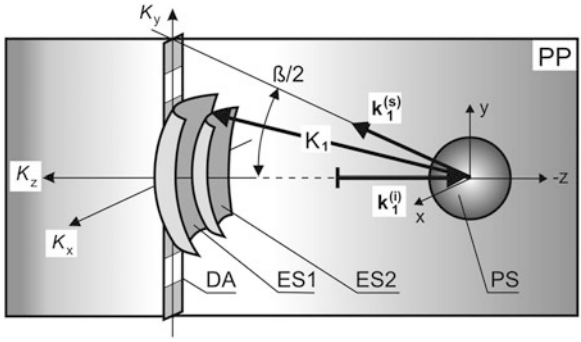

Fig. 4.4 IS sample projection. Projection plane PP is parallel to the illuminating beam axis ($\mathbf{k}_\mathbf{n}^{(\mathbf{i})}$) and contains the array axis (K_y). PS, projected sample structure. *DA* detector array, *ESi* scattered field data Ewald spheres of wavelength λ_i

$$P_{x,z}(y) = \iint S(x,y,z)\cdot dx.dz = \int \hat{U}^{(S)}(0,K_y,0)\cdot\exp\left[i\cdot y\cdot K_y\right]\cdot dK_y,$$

See Figs. 4.5 and 4.6.

Such a projection might not be useful. However, a linear field slice $\hat{U}^{(s)}(0,0,K_z)$ yields a central projection of the sample source strength along the z-direction:

$$P_{x,y}(z) = \int U^{(s)}(0,0,K_z)\cdot\exp(i\cdot z\cdot K_z)\cdot dK_z \tag{4.14}$$

Using a slim focused probing beam, that equation is the A-scan signal in FD-PCI and FD-OCT [41]. Transversal resolution is provided by the transverse diameter of the probing beam – leading to the resolution/depth-of-field contradiction (!). Depth

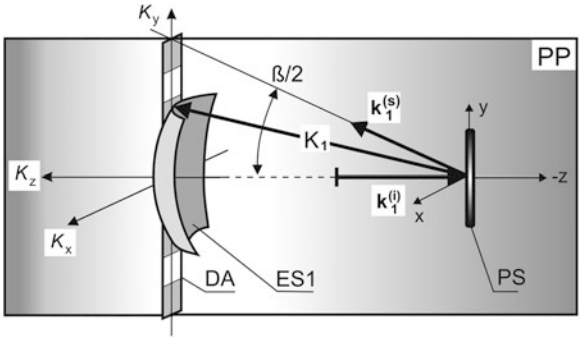

Fig. 4.5 Twofold IS sample projection. Sample = homogeneous sphere. Projection plane # 1 = PP ($K_y - K_z -$ plane). Projection plane # 2 = $K_x - K_y -$ plane. PS, projected sample structure (homogeneous sphere assumed as sample). *DA* detector array, *ES1* scattered field data Ewald spheres of wavelength λ_1

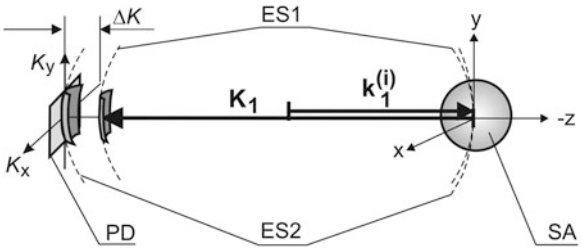

Fig. 4.6 Line projection. A single photodetector PD records a point in the scatter field spectrum. Depth distribution of the scattering potential along the z-axis is obtained from the $\hat{U}^{(s)}(0,0,K_z)$ spectrum. ES_n Ewald sphere of wavelength λ_n, *SA* sample. ΔK determines depth resolution

resolution is determined by the coherence length. This technique (together with an interferometric reference beam) has been implemented as spectral interferometry (SI), using a spectrometer, or as wavelength tuning interferometry (WTI) based on wavelength tuning or swept lasers. Taking the Fourier transform of $\hat{U}^{(s)}(0,0,K_z)$ yields the z-dependent "time-domain" A-scan signal. The logarithm of that signal is used as standard OCT image function. FD techniques provide superior sensitivity [42–44] compared to the original time-domain PCI [45–48] used in early OCT and related techniques [49–51].

Early wavelength tuning techniques have used a grating-tuned external cavity superluminescent LED or injection current modulation [52–54]. However, these techniques suffered either from low wavelength precision or from low tuning speed. Recently, high-speed frequency-swept laser sources have been used by Huber et al. [55], for wavelength tuning interferometry and OCT imaging. These laser sources use a fiber-coupled semiconductor amplifier and a tunable fiber Fabry-Perot filter yielding, for example, 20 kHz sweep rates with a tuning range of ~120 nm full width (mean wavelength 1,300 nm, ~ 45 mW instantaneous peak power). 108 dB sensitivity and ~10 μm axial resolution in tissue have been achieved.

Modern ultrafast wavelength-swept lasers achieve scan speeds >9,000 nm/ms, repetition rates >100 kHz, and tuning ranges >50 nm [56]. Tsai et al. [57] have demonstrated a frequency comb (FC)-swept laser and a frequency comb Fourier domain mode locked (FC-FDML) laser for applications in optical coherence tomography (OCT). A 135 nm tuning range centered at 1,310 nm with average output powers of 50 mW at a sweep rate of 1 kHz and 120 kHz has been achieved. The narrow bandwidth (0.015 nm) of the frequency comb filter enabled an ~ -1.2 dB sensitivity roll off over ~3 mm range, compared to conventional swept source and FDML lasers which have −10 dB and −5 dB roll offs, respectively.

4.2.1.5 Definite Integral Theorem

Finally, for scattered field data recorded by a single detector, the definite integral theorem says that

$$\iiint S(x,y,z)\cdot dx\cdot dy\cdot dz = \hat{U}^{(s)}(0,0,0); \tag{4.15}$$

i.e., scattering strength, cumulated over the complete illuminated volume of a sample, determines the power of the beam backscattered against the direction of the illuminating beam. This retraces time-domain PCI and OCT: Transverse resolution is defined by the illumination beam diameter, whereas depth resolution is provided by the interferometric coherence gate.

Other projections and slices are easily obtained by modification of the above examples.

Resolution vs depth-of-field. It should be noted that the techniques 4.2.1.1 to 4.2.1.5 do not need a focusing lens, hence do not suffer from the usual transverse-resolution vs depth-of-field contradiction of standard OCT. Nevertheless, smart focusing the illuminating wave into the region of interest can be desirable in many situations, since, besides resolution, it will also improve the signal-to-noise ratio.

4.2.1.6 Large Samples

Far-field techniques typically require small samples and/or scattered field detection at large distances from the sample plane. That limits their applicability. However, in case of plane samples or plane areas of interest in large samples, and as an approximation, the spatial Fourier transforming property of lenses can be used. Corresponding smart optics allow Fourier transforming of thin samples with large transversal extension. This approach requires an aberration free lens with the sample at the one focal plane of the lens and the detector array at the other focus of the lens [58].

4.2.2 Inverse Scattering in Near-Field Fresnel Diffraction Techniques

Near-field Fresnel *diffraction* is specified by Fresnel numbers $FN \sim 1$, whereas far-field diffraction optics on the other hand is specified by Fresnel numbers $FN \ll 1$.

Near-field *optics* is concerned with evanescent waves that appear in the passage of light through subwavelength structures within a few wavelengths from the diffracting feature. IS plays a role here too [59]; however, we only consider near-field diffraction PCI and OCT.

The operator O in near-field diffraction comprises two steps: (1) to determine a 2D FT of the homogeneously scattered field $U_h^{(S)}(\mathbf{r})$ in planes in front and/or behind the scattering object and (2) to determine a 3D FT of the angular spectrum $\hat{U}_h^{(S)}(\mathbf{K})$ of the scattered field with a phase factor to obtain the scattering potential $F(\mathbf{r})$ [1]. Hence, Fourier projection/slice theorem-based techniques, as described above for far-field techniques, could be used in both steps. Keeping in mind that a projection yields a slice in the Fourier transformed data and a slice yields a projection in the Fourier transformed data suggests the following: A slice- or a projection-procedure performed on the scattered field data $U_h^{(S)}(\mathbf{r})$ at step 1 yields a slice respectively a projection of the final sample data as well, whereas performing a slice- or a projection-procedure on the angular spectrum of the scattered field $\hat{U}_h^{(S)}(\mathbf{K})$ yields a projection respectively a slice of the final sample data.

Note: Since aperture data in DOT are registered mutually coherent, ODT is conformed to aperture synthesis, even if, from practical reasons, the aperture form is rather restricted.

4.3 Aperture Synthesis-Based Inverse Scattering

Aperture synthesis (AS) in imaging means to synthesize a large aperture by a series of smaller and more easily accessible apertures. AS needs both amplitude and phase of the fields to be measured. For radio frequencies, this is possible by electronics. Hence, AS synthesis imaging has been introduced at radio wavelengths by M. Ryle [60]. Optically, to record these data, the electromagnetic field cannot be measured directly and correlated in software, but must be propagated by sensitive optics and interfered [61]. The earliest synthetic-aperture experiments in the optical domain were performed by T. S. Lewis and H. S. Hutchins [62] using moving targets. The first image of a fixed, diffusely scattering target generated by synthetic-aperture imaging laser radar (SAIL) has been reported in 2005 [63].

Recently, former incoherent compiling of A-scan signals to form the OCT B-scan has obtained an alternative by coherently assembling A-scan signals forming a synthetic aperture, also called "interferometric synthetic-aperture imaging" [64]. The initial promise of AS in PCI and OCT has been to provide space-invariant resolution, in particular to suspend the resolution/depth-of-field contradiction. Since aperture synthesis requires phase stability between signals to be assembled, its demands on mechanical stability in optics are considerable. A closely related synthetic-aperture tomography technique in the terahertz field has been reported by Heimbeck et al. [65]. Sheppard et al. [24] state that these synthetic-aperture techniques use the same hardware like standard OCT; however, those image reconstruction techniques resemble known holographic image reconstruction.

4.3.1 B-Scan-Based Aperture Synthesis

Ralston et al. [64] have developed a solution to the inverse problem for OCT with a linearly scanned Gaussian beam. The mathematical model connects the acquired OCT A-scan signal with the three-dimensional object structure, taking into account scattering, diffraction, and probe beam parameters like transverse position, its finite width and focusing under paraxial approximation. A linear relationship between sample susceptibility η and the measured signal V is assumed:

$$V = O \cdot \eta. \tag{4.16}$$

O is an operator characterizing the OCT system. Light propagation is described by a scalar model based on the reduced wave. The sample is assumed to be illuminated by a Gaussian beam emerging from the sample fiber of a Michelson interferometer, projected by a thin lens onto the sample and laterally displaced for consecutive A-scans with its transverse position registered. Backscattered light is collected and projected back into the fiber. The light at the detector is determined assuming the first-order Born approximation and Green function formulation. A 2D photoelectric signal is assembled from the series of 1D A-scan photoelectric signals coherently detected at adjacent lateral positions. For such a multiplexed signal, mutual phase stability of the single A-scan signal is essential. Since, due to noise and bandwidth limitations, the inverse problem is ill-conditioned, a minimum norm solution of the least-squared error problem has been used. Analogous to Wolf's result [1], the Fourier transform of the observed signal is related to the Fourier transform of the sample susceptibility.

The potential of that solution has been explored by numerical simulation. A synthetic object was created as a collection of sub-resolution-sized point scatterers randomly distributed throughout a simulated imaging area of 1,024 μm by 1,024 μm. The simulated lens had a focal length of 10 mm, a spot size of 4 μm, and a confocal parameter of 30 μm, corresponding to an NA of 0.2. Gaussian white noise was added to simulate SNRs of 35 dB and -5 dB. In both cases the Tikhonov regularized solution [16, 66] resolved objects outside of the confocal region with minimal loss.

In a further step Ralston et al. [67] optimized the IS algorithm to improve the speed. An optimized algorithm has been presented that can generate cross-sectional reconstructed images at frame rates of 2.25 frames per second for 512 × 1,024 pixel images on a personal computer with two 3.0 GHz processors.

4.3.2 AS in Microscopy

Microscopy usually requires high NA optics. Hence, Ralston et al. [68] have resolved the inverse scattering problem analytically relying on a scalar wave model without resorting to the paraxial approximation. The results are demonstrated by numerical simulation. Spatial invariant resolution has been confirmed.

Any computational model for image formation in a high numerical aperture microscope must account for polarization effects on scattering and propagation. Hence, the vectorial diffraction theory is needed to predict imaging correctly. Davis et al. [69] have extended interferometric synthetic-aperture microscopy (ISAM) to non-paraxial full vectorial treatment of the light waves and to describe the effects of polarization on scattering and propagation. Numerical simulations confirm that the depth of focus is limited only by measurement noise and/or detector dynamic range. Furthermore, their model is suitable for the quantitative study of polarimetric coherent microscopy systems. Extensive numerical and noise simulations confirm inter alia diffraction-limited resolution even outside the focal plane.

Ralston et al. have presented the first ISAM photomicrographs of human tissue [23]. A fiber-optic Michelson interferometer illuminated by femtosecond pulses has been used. A spectral interferometer at one of the interferometer exits measures the interferometric cross-correlation between a fixed-delay reference pulse and the pulses reflected back from the sample. Transverse resolution is determined by the NA of the probing beam objective. A planar scanning geometry has been used: The probing beam is laterally translated in two dimensions through the sample by moving a stage or by steering the beam with a pair of galvanometer-driven mirrors before entering the objective.

Human breast tumor tissue was resected and imaged ex vivo. Sections were marked with India ink after imaging and before embedding to register locations. Whereas the histological images were obtained by destroying the sample, ISAM could readily be applied for in vivo applications because signal collection is in the backscattered epi-direction. Figure 4.7 presents images for depths of $z = 591$ μm (Sect. 4.3.1) and $z = 643$ μm (Sect. 4.3.2), where $z = 0$ μm is the focal plane. The ISAM reconstructions resolve features in the tissue that are not decipherable from the unprocessed data (Fig. 4.8).

4.3.3 ISAM with Computational Adaptive Optics

In retinal and catheter-based OCT imaging, astigmatism is a common aberration that becomes more prominent at higher resolution. Adie et al. [70] have demonstrated that ISAM, of course, does not correct aberrations of the sample probing beam. However, with computational adaptive optics correction of aberrations, high-resolution reconstruction of the tissue is obtained. Astigmatism correction in ISAM provides high-resolution reconstruction of the tissue structures and, additionally, a significant increase in signal-to-noise ratio of point-like scatterers.

Furthermore, Davis et al. [71] have shown that ISAM does not suffer from autocorrelation and conjugate image artifacts. ISAM algorithm defocuses the autocorrelation and conjugate image artifacts, mitigating their effects in most cases without requiring supplementary instrumentation or signal processing.

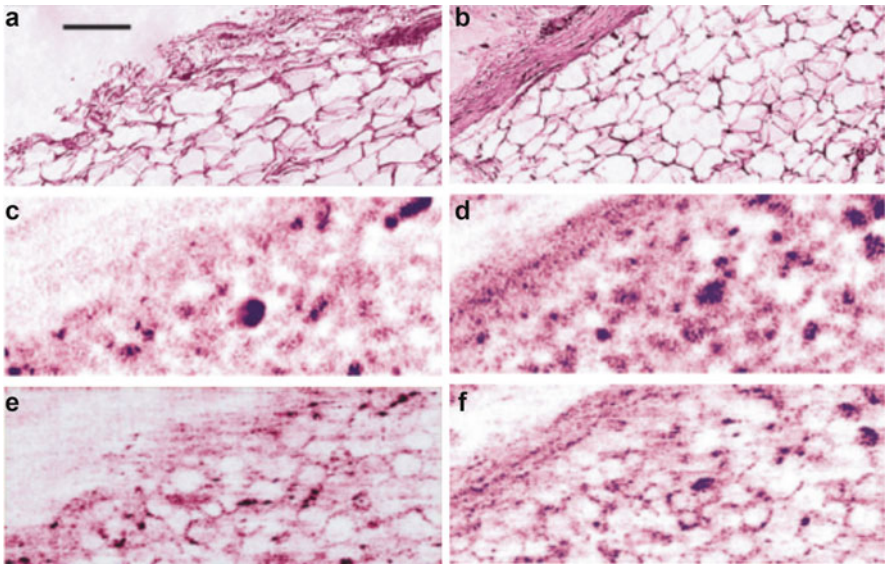

Fig. 4.7 Histological sections (**a**, **b**) show comparable features with respect to the unprocessed interferometric data (**c**, **d**) and the ISAM reconstructions (**e**, **f**). The scale bar represents 100 μm (From [23], by permission from the author)

4.3.4 Rotationally Scanned Synthetic Aperture in OCT

Another adaptation of IS is presented by Marks et al. [72] to angularly scanned OCT. Angularly scanned OCT is used in endoscopic OCT to explore tubular lumens within the human gastrointestinal tract or, for example, in cardiovascular imaging. Here the sample probing beam is typically focused at a fixed distance from the catheter. Hence, in standard endoscopic OCT instruments, the depth of focus of the resulting images is confined to a narrow annulus making clear interpretations of clinical findings difficult. An algorithm based on earlier-developed IS scheme [64] has been developed to compensate for that resolution localization. The simulation performed with a synthetic object comprising of point-like scatterers in fact demonstrated a clear improvement; however, a range-dependent resolution remained: Resolution is high between OCT catheter and focus radius of the Gaussian probing beam but decreases farther from the catheter.

4.3.5 Aperture Synthesis in Full-Field OCT

Full-field OCT images an entire plane of scatterers simultaneously, for example, in OCT microscopy: The objective is focused at the depth of features of interest. The reference beam path length is matched to that plane forming an interferogram that is

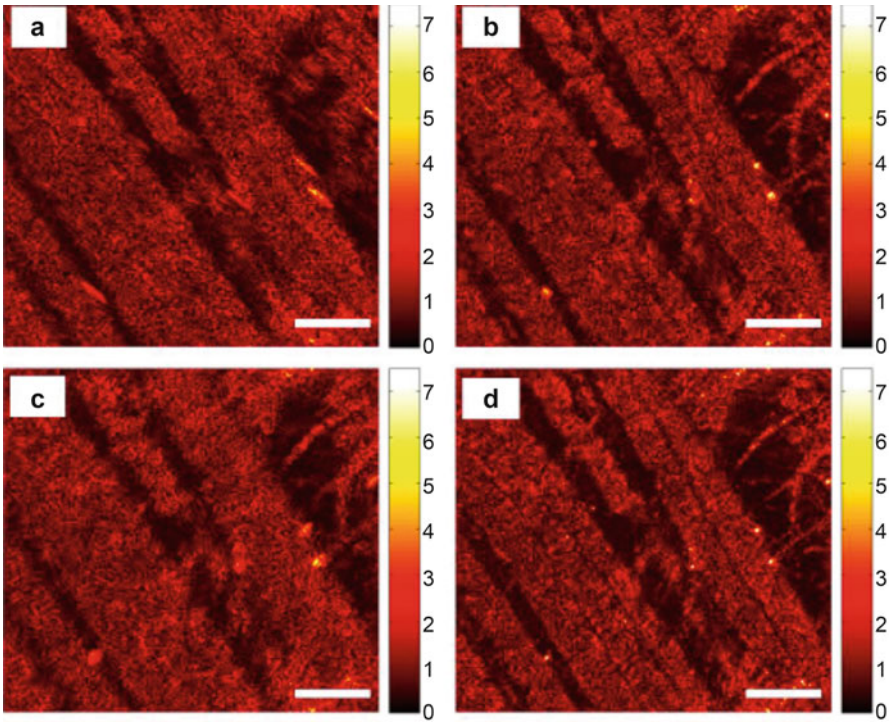

Fig. 4.8 ISAM and aberration correction in highly scattering rabbit muscle tissue. En face planes from 3D data acquired with a highly astigmatic illumination beam. (**a**) Uncorrected OCT, (**b**) aberration-corrected OCT, (**c**) uncorrected ISAM, and (**d**) aberration-corrected ISAM. The scale bar denotes 200 μm. (Note the structure at the top right of the images) (By permission from the author [70])

imaged onto a matrix array. By recording the interferogram, an image of a slice of the sample around the focal plane is obtained, and the out-of-focus contributions are removed by coherence gating. The usual technique is then to translate the sample through the focal plane so that the scatterers at many different depths may be imaged and a 3D structure obtained. This, however, requires a delicate movement of sample and microscope objective relative to each other.

Marks et al. [73] analyzed a full-field OCT system that uses a Köhler-type illumination system. By adjusting the size of the aperture iris, the spatial coherence of the beam illuminating the sample can be varied from very low (when the iris is opened) to very high (when the iris is closed). Both, sample plane and reference beam, are imaged by relay telescopes afocally and telecentrically to the focal plane detector array. The intensity of the interference pattern produced by the superimposed reference and sample signals is recorded there.

In the case of scanned-beam OCT, a focused beam is scanned through the sample, and data measured at each transverse position of the beam are taken at different times. Hence, no interference can occur between the fields produced for

different scan positions. Using incoherent full-field illumination of the sample is equivalent to a superposition of discrete mutually incoherent beams in the transverse direction, since here too, no interference can occur between the fields produced at different scan positions. Such an instrument may produce data similar to those that can be acquired with the scanned-beam implementations, but in a highly parallel fashion. Varying the source spatial coherence by adjusting the iris size allows a transition from full-field to confocal operation. In the one limit inverse scattering is identical to the inverse scattering for the full-field system, and in the other limit it reduces to the confocal ISAM inverse processing. The intermediate regime has also been examined, with the result that the ISAM Fourier domain resampling varies as a function of the source coherence.

The performance of partially coherent full-field AS with regard to image reconstruction and rejection of multiple scattering has been investigated using numerical simulations. These demonstrate the main points of full-field ISAM: High spatial coherence (multiple scattering tolerant) can produce artifacts corrupting the desired single-scatter signal; for the low spatial coherence case (single-scatter signal), ISAM processing corrects the blurring observed in OCT outside the depth of focus. Decreased spatial coherence of the source can thus be used to reduce the multiple-scatter artifact. The depth over which the signal strength is constant can be made many times larger than the Rayleigh range given a prudent choice of coherence properties.

Note: Since aperture data in DOT are registered mutually coherent, ODT is conformed to aperture synthesis, even if, from practical reasons, the aperture form is rather restricted.

Note: Full-field OCT can also be implemented as IS sample slice generation in Fourier domain based on projected scattering data (Sect. 4.2.1.2) obtained from DOT, either based on scattered field detection at large distances from the sample or based on the spatial Fourier transforming property of lenses (Sect. 4.2.1.6).

Acknowledgment The author thanks primarily his colleagues at the former Institute of Medical Physics at the Medical University of Vienna, in particular W. Drexler, C. K. Hitzenberger, M. Pircher, and B. Grajciar as well as M. Wojtkowski and R. Zawadzki (then) from the University of Torun/Poland.

The author is furthermore indebted to Tyler Ralston, Steven G. Adie, and Stephen A. Boppart from the University of Illinois at Urbana-Champaign, USA, for permission to reproduce Figs. 4.7 and 4.8.

5.1 Introduction

Optical coherence tomography is a low-coherence interferometric method for imaging of biological tissue [1, 2]. For more than a decade after its inception between 1988 and 1991, the dominant implementation has been time domain OCT (TD-OCT), in which the length of a reference arm is rapidly scanned. The first spectral or Fourier domain OCT (SD/FD-OCT) implementation was reported in 1995 [3]. In SD-OCT the reference arm is kept stationary, and the depth information is obtained by a Fourier transform of the spectrally resolved interference fringes in the detection arm of a Michelson interferometer. This approach has provided a significant advantage in signal-to-noise ratio (SNR), which despite reports as early as 1997 [4, 5] has taken about half a decade to be recognized fully by the OCT community in 2003 [6–8]. The first demonstration of SD-OCT for in vivo retinal imaging in 2002 [9] was followed by a full realization of the sensitivity advantage by video rate in vivo retinal imaging [10], including high-speed 3-D volumetric imaging [11], ultrahigh-resolution video rate imaging [12, 13], and Doppler blood flow determination in the human retina [14, 15]. The superior sensitivity of SD-OCT, combined with the lack of need for a fast mechanical scanning mechanism, has opened up the possibility of much faster scanning without loss of image quality and provided a paradigm shift from point sampling to

volumetric mapping of biological tissue in vivo. The technology has been particularly promising for ophthalmology [16, 17]. In this chapter, the principles and system design considerations of SD-OCT will be discussed in more detail.

5.1.1 Introduction to Signal to Noise

In the standard time domain (TD) implementation of OCT, the position of the reference mirror in the interferometer is rapidly scanned by mechanical means in order to obtain a depth profile (A-line) within a sample. An alternative method of retrieving depth information examines the cross-spectral density by detecting the interference signal in the detection arm of a Michelson interferometer as a function of wavelength [3, 4, 18]. In spectral domain OCT (SD-OCT), also known as Fourier domain OCT (FD-OCT), no mechanical scanning of the reference arm is required. Instead, the cross-spectral density at the detection arm of the interferometer is measured by means of a spectrometer [3]. In SD-OCT, the depth range z is inversely proportional to the spectral resolution $\delta\lambda$ and given by [4] $z = \lambda_0^2/4n\delta\lambda$. Although this technique has been demonstrated for in vivo dermal and retinal imaging [4, 9], it has only recently been demonstrated both theoretically and experimentally that a sensitivity improvement of several orders of magnitude could potentially be realized in SD-OCT compared to TD-OCT [6, 7]. SD-OCT does not require modulation of the reference arm length and therefore has potential for faster image acquisition rates.

TD-OCT has been applied extensively in ophthalmology, where cross-sectional OCT images of the retina have provided useful information regarding the presence or progression of specific ocular diseases [19]. The acquisition rate of current clinical and preclinical TD-OCT systems is limited by sensitivity and the maximum permissible incident power on the eye [20], preventing comprehensive screening of large retinal areas. The sensitivity improvement of SD-OCT allows for dramatically increased acquisition speeds without compromising image quality. Three-dimensional data sets can therefore be rapidly acquired, opening the possibility of comprehensive screening.

Although this method has long been proposed and demonstrated, only recently have there been efforts to explicitly show that SD-OCT can produce a better detection sensitivity than the time domain method [6–8]. Recent work has experimentally demonstrated a 148-fold (21.7 dB) sensitivity improvement with SD-OCT [10] and a near shot noise limited performance. Reaching shot noise limited performance in SD-OCT requires a careful analysis of noise contributions, which will be presented first.

In essence the SNR advantage of SD-OCT over TD-OCT is based on the significant reduction of shot noise obtained by replacing the single-element detector with a multielement array detector. In a TD-OCT system, each wavelength is uniquely encoded as a frequency by scanning the length of the reference arm, and shot noise has a white noise characteristic. In a single detector TD-OCT system, the shot noise generated by the power density at one particular wavelength is present at all frequencies and therefore adversely affects the SNR at all other wavelengths.

By spectrally dispersing each wavelength to a separate detector, the cross shot noise term is eliminated in both hybrid and fully parallel SD-OCT systems [7].

5.1.2 Noise Analysis of SD-OCT Using Charge-Coupled Devices (CCDs)

The core of an SD-OCT system is the spectrometer in the detection arm. In general, light detection in the spectrometer is achieved by a charge-coupled device (CCD) like a line array. Alternative implementations have been suggested that require individual processing of pixel charges [21]. To facilitate the noise analysis in the case of detection by CCDs, the signal and noise terms will be expressed in charge squared (e^2). Only the real part of the complex cross-spectral density is detected in SD-OCT, resulting in a signal S_{SD} given by [6, 7]

$$S_{SD} = \frac{\eta^2 e^2 P_{ref} P_{sample} \tau_i^2}{E_v^2} \left[e^2\right] \tag{5.1}$$

with e the electron charge; P_{ref} and P_{sample}, respectively, the reference arm and sample arm power per detector element at the detection arm fiber tip; τ_i the integration time; and E_v the photon energy.

The readout and dark noise, shot noise, and relative intensity noise (RIN) contributions to the overall noise in electrons squared per read out cycle and per detector element are given by, respectively [6, 7],

$$\sigma_{noise}^2 = \sigma_{r+d}^2 + \frac{\eta e^2 P_{ref} \tau_i}{E_v} + \left(\frac{\eta e P_{ref}}{E_v}\right)^2 \tau_i \tau_{coh} \quad \left[e^2\right], \tag{5.2}$$

where the sample arm power was assumed to be much smaller than the reference arm power [22], with σ_{r+d}^2 the sum of readout noise and dark noise and $\tau_{coh} = \sqrt{2 \ln 2/\pi}\ \lambda_0^2/c\delta\lambda$ the coherence time, with c the speed of light [23]. The optimal signal-to-noise performance is achieved when shot noise dominates both readout noise and relative intensity noise (RIN) [22]. Shot noise dominates readout noise and dark noise when $\eta e^2 P_{ref} \tau_i / \sigma_{r+d}^2 E_v > 1$, and shot noise dominates RIN when their ratio is larger than one, i.e., $E_v/\eta P_{ref}\ \tau_{coh} > 1$. The optimal reference arm power is found when readout noise and dark noise are equal to the RIN [24]:

$$\sigma_{r+d}^2 = \left(\frac{\eta e P_{ref}}{E_v}\right)^2 \tau_i \tau_{coh}. \tag{5.3}$$

Thus, for a system to operate close to shot noise limited performance, shot noise should dominate thermal and RIN at the optimal reference arm power:

$$P_{ref} = \frac{\sigma_{r+d} E_v}{\eta e \sqrt{\tau_i \tau_{coh}}}. \tag{5.4}$$

At this optimal reference arm power, the inequalities describing shot noise dominance over readout noise and RIN, respectively, reduce to the same equation:

$$\frac{e\sqrt{\tau_i}}{\sigma_{rd}\sqrt{\tau_{coh}}} > 1. \tag{5.5}$$

In general, one would like to choose the integration time τ_i as short as possible and the coherence time τ_{coh} as long as possible. The coherence time is inversely related to the spectral resolution of the spectrometer which in turn relates linearly to the maximum depth range of the system. In conclusion, the parameter that most determines the system performance is the readout and dark noise of the detector σ_{rd}.

5.1.3 Autocorrelation Noise: Dynamic Range and Digitization Depth

SD-OCT is based on spectral interferometry, where recombined light from reference and sample arms is spectrally separated, detected, and converted into a depth profile. The detected interference signal at the spectrometer may be expressed as [4]

$$I(k) = I_r(k) + 2\sqrt{I_s(k) I_r(k)} \sum_n \alpha_n \cos(k z_n) + I_s(k) \tag{5.6}$$

where $I_r(k)$ and $I_s(k)$ are the wavelength-dependent intensities reflected from reference and sample arms, respectively, and k is the wave number. The second term on the right-hand side of Eq. 5.6 represents the interference between light returning from reference and sample arms. α_n is the square root of the sample reflectivity at depth z_n. Depth information is retrieved by performing an inverse Fourier transform of Eq. 5.6, yielding the following convolution [4]:

$$\left|FT^{-1}[I(k)]\right|^2 = \Gamma^2(z) \otimes \left\{ \delta(0) + \sum_n \alpha_n^2 \delta(z - z_n) + \sum_n \alpha_n^2 \delta(z + z_n) + \; O\left[I_s^2/I_r^2\right] \right\}, \tag{5.7}$$

with $\Gamma(z)$ representing the envelope of the coherence function. The first term in the braces on the right-hand side describes the autocorrelation signal from the reference arm and has magnitude unity. The second and third terms are due to interference between light returning from reference and sample arms and form two images, where each has magnitude on the order of I_s/I_r. These two terms provide mirror images, where one is retained. The final term, with magnitude on the order of I_s^2/I_r^2,

describes autocorrelation noise due to interference within the sample arm [4, 9]. I_s and I_r represent the total intensity reflected from sample and reference arms, respectively. Equation 5.7 indicates that the relative contribution of sample autocorrelation noise can be reduced by increasing the reference arm power with respect to the signal. Decreasing the detector integration time permits an increase in the reference arm power without saturating the detector, decreasing the ratio I_s^2/I_r^2 and consequently reducing the contribution of autocorrelation noise in ultrahigh-speed SD-OCT.

In the shot noise limit, the signal-to-noise ratio (*SNR*) in the spectral domain system has been shown to be [7]

$$SNR_{SD} = \frac{\eta P_{sample} \tau_i}{E_v}, \tag{5.8}$$

where η is the spectrometer efficiency, P_{sample} is the sample arm power returning to the detection arm, τ_i is the detector integration time, and E_v is the photon energy. Unlike the SNR in the time domain, Eq. 5.8 demonstrates that in the shot noise limit, SNR_{SD} is independent of the spectral width of the source. This implies that the axial resolution can be increased at no penalty to the SNR, provided that the full spectral width of the source can be imaged onto an array detector. However, this result should be interpreted with some care. The sample arm power returning to the detection arm is assumed to come from a single reflecting surface. In tissue, however, the reflected power comes from multiple structures along a depth profile. The SNR for a particular position along the depth profile is given on average by the total power reflected by all structures within the coherence length of the source. As the resolution increases (the coherence length decreases), the total reflected power within the coherence length decreases. As a consequence, the SNR at a particular position along the depth profile will reduce as the resolution increases by increasing the source optical bandwidth.

5.1.4 Bit Resolution and Well Depth of the CCD, Dynamic Range, and Sensitivity

Earlier SD-OCT system designs emphasized the necessity of large well depth (number of electrons that could be stored in a single element of the CCD) and large bit depth as an important consideration to realize the high sensitivity and dynamic range that can be achieved by OCT. Sensitivity is the ratio of maximum signal over noise floor, where the maximum signal is defined by placing a perfect reflector in the sample arm. The dynamic range of a system is the maximum signal over the noise floor that a particular system can measure without, e.g., saturating a detector, overloading an amplifier, or exceeding a digitization range. In practice, no TD- or SD-OCT system realizes a dynamic range equal to the sensitivity, which can easily be over 100 dB. In general, this is not necessary, since tissue reflectivity

is at least four orders of magnitude smaller than a perfect reflector. A system dynamic range of 40–60 dB suffices in most cases.

A 60-dB dynamic range in a TD-OCT system would require at least a 10-bit A/D range (6 dB per bit) digitizing the interference modulation on the DC background. An advantage of TD-OCT systems is that the signal can be high-pass filtered to remove the DC component and only pass the interference modulation to the digitization circuitry. In SD-OCT, the CCD detectors do not easily permit removal of a DC component, and considerations similar to that for a TD-OCT system suggest that for an SD-OCT system the A/D range needed to capture the interference modulation on top of the DC background with sufficient resolution to provide 40–60-dB dynamic range would require an A/D resolution significantly exceeding that of a TD-OCT system. Fortunately, the required bit resolution capturing the interference modulation to achieve 40–60-dB dynamic range turns out to be much smaller.

In SD-OCT the reflectivity in z-space is given by the square of the Fourier component in k-space (Eq. 5.7). The resolution of the Fourier component is proportional to the resolution of the modulation depth of the spectrum, multiplied with the number of illuminated pixels of the camera (on the order of ~1,000). Thus, a relative small resolution of the modulation depth of the spectrum (on the order of a few bits) gets amplified by the number of illuminated pixels, easily providing a dynamic range in z-space exceeding 40–60 dB. The presence of multiple reflecting structures complicates matters. For example, two strong reflectors in the sample arm each create a periodic modulation of the spectrum. These modulations are summed and create a larger modulation depth of the spectrum on the DC background that should be captured without saturation of the CCD or clipping of the digitization circuitry. Therefore, the calculation of the dynamic range of an SD-OCT system is not a straightforward calculation of the strongest single reflector that can be measured, but depends on the total power reflected by the sample. As the total reflected power increases, the dynamic range with which the reflectivity of a particular location can be measured decreases.

5.1.5 Experimental Demonstration of SNR Advantage

A number of groups have presented empirical evidence demonstrating the SNR advantage of SD-OCT over time domain OCT. The following section describes a direct comparison between a TD-OCT and an SD-OCT system [10]. To compare directly the SNR performance of TD- and SD-OCT, a weak reflector was placed in the sample arm of our system (Fig. 5.1).

The power reflected by the weak reflector measured at the fiber tip in the detection arm was 1.3 nW. The polarization states of sample and reference arm light were carefully aligned to maximize interference. First, 256 depth profiles at a speed of 4 ms per depth profile were acquired with our TD-OCT system, scanning over a depth of 1.4 mm in air. The signal pass bandwidth (BW) was 100 kHz. Then the detection arm was connected to the spectrometer, and 256 spectra were acquired

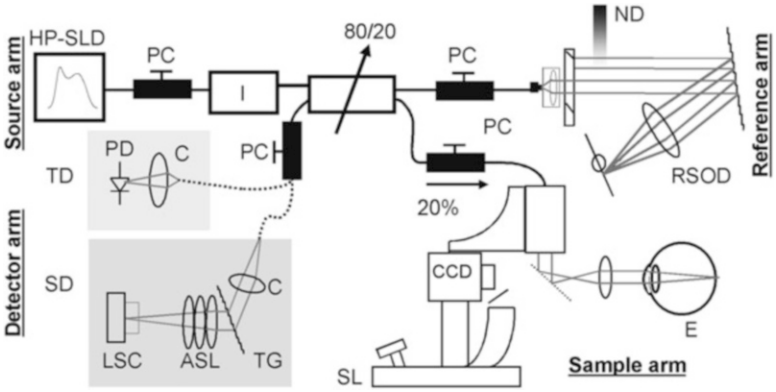

Fig. 5.1 Time and spectral domain system integrated into a single instrument for a direct comparison of the SNR (Reproduced from Ref. [10] with permission from the Optical Society of America)

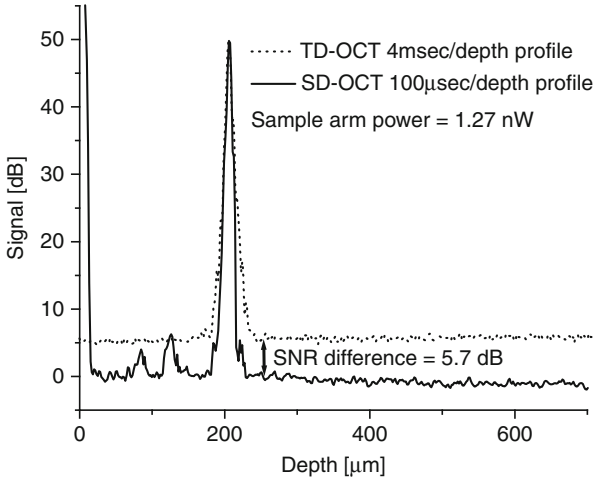

Fig. 5.2 Direct comparison of the SNR between SD- and TD-OCT (Reproduced from Ref. [10] with permission from the Optical Society of America)

at a speed of 100 µs per spectrum. To reduce fixed pattern noise in the SD-OCT measurement [6], each individual spectrum was divided by the average spectrum of 1,000 reference arm spectra. The resulting spectrum was multiplied by a Gaussian to reshape the spectrum [25]. A Fourier transform links z- and k-space. Because of the nonlinear relation between k and λ, the spectra were interpolated to create evenly spaced samples in the k domain [9] before Fourier transformation of the spectra to generate depth profiles.

Figure 5.2 shows the averaged depth profiles acquired with the respective configurations, demonstrating an SNR of 44.3 and 50 dB for TD- and SD-OCT, respectively. Both depth profiles were normalized on the reflectivity peak. The TD measurement was shifted such that the peaks coincide. Some fixed pattern noise

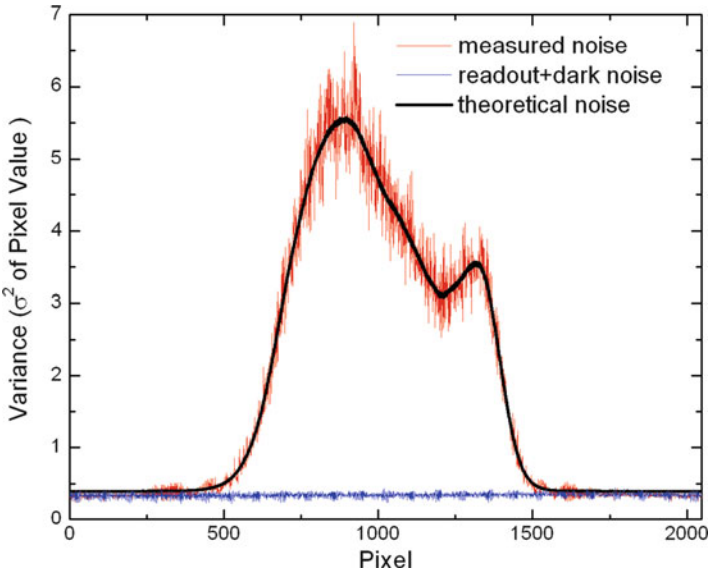

Fig. 5.3 Noise components in the detector. The shot noise level was determined with illumination of the reference arm only and was used to determine the A/D resolution of the detector. The theoretical shot noise curve was fit using Eq. 5.10 to the measured noise, giving a Δe of 173 electrons and a corresponding well depth of 177,000 electrons (Reproduced from Ref. [11] with permission from the Optical Society of America)

was still present in the SD-OCT measurement, resulting in peaks at 84 and 126 μm. Since the SD-OCT system was 5.7 dB more sensitive, operated at a speed 40 times faster (corresponding to 16 dB) than the TD-OCT system, the combined sensitivity improvement was 21.7 dB or a factor of 148. The theoretical shot noise limited SNR in TD and SD is given by, respectively [6, 7],

$$SNR_{TD} = \frac{\eta P_{sample}}{E_v BW}, \quad SNR_{SD} = \frac{\eta P_{sample} \tau_i}{E_v} \tag{5.9}$$

resulting in 46.7 dB (TD) and 51.9 dB (SD), where $\eta = 0.85$ was used for a PIN diode in TD. The measured TD and SD SNRs were, respectively, 2.4 and 1.9 dB less than the theoretical optimal performance, where 1 dB in TD was determined to be due to thermal noise contributing to the total noise. The measured coherence function FWHM in air was 6.3 μm in both TD and SD.

5.1.6 Shot Noise Limited Detection

The different noise components present in the system were measured and analyzed to demonstrate that performance was shot noise limited. The readout and shot noise at a 29.3 kHz readout rate are shown in Fig. 5.3.

The noise was determined by calculating the variance at each camera pixel for 1,000 consecutive spectra. Dark noise measurements were taken with the source light off. Only light returning from the reference arm was used to measure the shot noise in the system. The shot noise expressed in number of electrons is $(I_{PV}(\lambda)\Delta e)^{1/2}$, where $I_{PV}(\lambda)$ is the pixel value corresponding to the intensity at each CCD element, with values ranging from 0 to 1,024 (10 bits), and Δe is the analog-to-digital conversion resolution, which corresponds to the number of electrons required for an incremental increase of 1 pixel value. Thus, the variance as measured in pixel values is defined as

$$\sigma^2(\lambda) = I_{PV}(\lambda)/\Delta e \ + \sigma^2_{r+d}. \tag{5.10}$$

The first term on the right-hand side of Eq. 5.10 is the shot noise contribution and the second term is the readout contribution to the total noise. The CCD well depth was determined by fitting the theoretical expression for shot noise to the measured shot noise, using Δe as the fitting parameter, and limiting the fit to the central 700 pixels. From this measurement, Δe was calculated to be 173 electrons. Assuming that the maximum pixel value corresponds to the full well depth, a well depth of 177,000 electrons was calculated, in agreement with our previously published result [10]. Shot noise dominated readout and dark noise when the intensity reached 6 % of the saturation value. Relative intensity noise (RIN) is never dominant in this setup, since the maximum power per pixel (4.6 nW) at a 34.1 μs integration time does not meet the criteria for RIN-dominated noise [10].

5.1.7 Remapping to k-Space, Sensitivity Drop-Off as a Function of Depth, Spectrometer Resolution, Fixed Pattern Noise Removal

In SD-OCT, the structural information, i.e., the depth profile (A-line), is obtained by Fourier transforming the optical spectrum of the interference as measured by a spectrometer at the output of a Michelson interferometer [3, 9]. Fourier transformation relates the physical distance (z) with the wave number ($k = 2\pi/\lambda$). The spectra obtained with SD-OCT are not necessarily evenly spaced in k-space. A proper depth profile can be obtained only after preprocessing to obtain data that is evenly spaced in k-space [9], and this requires accurate assessment of the wavelength corresponding to each spectral element.

Determination of this wavelength mapping is typically performed using separate measurements of a reflective surface at different positions in the sample arm [9, 26]. The importance of proper wavelength assignment for SD-OCT was first noted by Wojtkowski et al. [9]. Incorrect wavelength mapping generates a depth-dependent broadening of the coherence peak similar in appearance to dispersion in structural OCT images. The disadvantage of such calibration methods is that they typically require separate measurements of a reflective surface. Using the example of a clinical ophthalmic system, calibration data from a model eye are acquired

before or after imaging of the patient in order to later determine the appropriate wavelength mapping. The calibration procedure may be necessary for each measurement session due to thermal and mechanical instabilities of the spectrometer, which is not practical in a clinical setting. Recently we proposed an autocalibration technique wherein the calibration data does not have to be acquired separately, but is contained within the data of interest [27].

Proper wavelength assignment can be achieved by imposing onto the spectrum a known modulation that can be used for calibration. In the system presented here, we introduce a perfect sinusoidal modulation as a function of k by passing the light through a microscope cover slip in the interferometer's source arm. This slide creates spectral modulation by combining the light that passes directly through the glass with the light that is internally reflected twice before transmission. The interference can be characterized by an optical path mismatch of $2dn$, where n is the refractive index and d is the thickness of the glass cover slip, and is of the form $\cos(2dnk)$. This spectral modulation is a perfect cosine as a function of k, assuming that n is independent of the wavelength for the bandwidth of the light source.

The presence of this spectral modulation is key in assigning the correct wavelength to each pixel of the CCD in the spectrometer case. In general, the pixels do not correspond to evenly distributed k, and therefore, the detected intensity modulation is not a perfect sinusoid. The autocalibration technique alters the wavelength assignments until the resulting spectral modulation matches a perfect sinusoid as a function of k. This sinusoidal intensity modulation produces in all A-lines an identical strong peak along z corresponding to the optical thickness of the slide. This peak can be easily removed as fixed pattern noise from the structural intensity images in a patient scan.

Figure 5.4a shows a typical intensity modulation generated by the slide for the spectrum of a Ti:sapphire laser (INTEGRAL OCT, FEMTOLASERS, Austria) with a spectral bandwidth of 150 nm centered at 800 nm. This spectrum has been obtained from a patient scan by taking the mean of 1,000 spectra corresponding to one OCT image. The interference fringes resulting from the retinal structure are washed out in this mean, while the fringes from the slide in the source arm are unaffected since they are the same in each spectrum. The spectral interference fringes from the slide are isolated with a band-pass filter in Fourier space, and the result is shown in Fig. 5.4b in the CCD pixel space. By keeping only the peak from the slide, we also remove the DC component of the spectral interference, illustrated in Fig. 5.4b as a zero-mean interferogram. When represented as a function of k, the fringes in Fig. 5.4b should be perfectly periodic. For a perfect sinusoid, the phase, or the argument of the sinusoidal oscillation, is linearly related to k. This condition is used to determine the accuracy of the wavelength assignment; an improper wavelength assignment results in phase nonlinearity as a function of k. The wavelength mapping is determined by minimizing the nonlinearity of this phase. An initial estimate of the wavelength array W is generated using the grating equation based on the geometrical design of the spectrometer [26] or, alternatively, with a third-order polynomial bringing the generated wavelengths in the spectral range of the light source. W is used to interpolate the spectral interference fringes to equally spaced

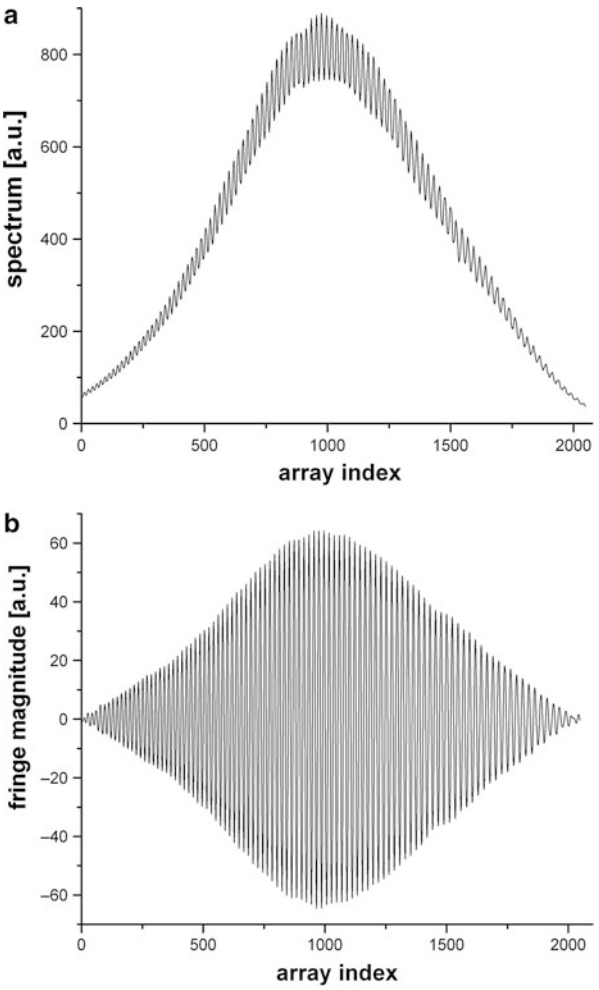

Fig. 5.4 (**a**) Spectrum (in arbitrary units) of interference generated by the slide as a function of the index of the CCD pixels. The spectrum was obtained by averaging 1,000 spectra from a retinal scan of a patient. Since the retinal structural information changes in each consecutive spectrum, but the spectral modulation by the glass cover slip is constant, only the spectral modulation by the cover slip is retained after averaging 1,000 spectra. (**b**) Spectral interference fringes (in arbitrary units) corresponding to the slide, shown in CCD pixel space (Reproduced from Ref. [27] with permission from SPIE)

k values. The quality of this interpolation process is improved by zero padding the spectrum. The next step is to iteratively determine and apply corrections to the wavelength assignment by reducing the phase nonlinearity. The phase of the zero-padded and k-space interpolated spectrum is determined and fit with a third-order polynomial. The nonlinear part $\sigma(k)$ of the polynomial fit (which only has the quadratic and cubic dependence on k and represents the deviation from a perfect linear phase) is used for correcting the wavelengths W based on the assumption that this nonlinearity is generated by wrong wavelength assignment.

Therefore, we calculate a new k-array k', starting from the previous $k = 2\pi/W$ array and $\sigma(k)$, using the equation $k' = k + \sigma(k)/z_{peak}$, where z_{peak} is given by $z_{peak} = 2\pi\text{Peak_Index}/(k_{\max} - k_{\min})$. Peak_Index is the location of the coherence

peak corresponding to the slide in index space, and k_{max} and k_{min} are the extremes of k. This correction is applied iteratively to the original spectral interference, and the final result is the wavelength array $W' = 2\pi/k'$ that corresponds to basically linear phase as a function of k'. The condition to be met in order to exit the loop could be either a maximum number of iterations or a tolerance in the change of the wavelength array after each iteration. The wavelength array W' can now be used to map the spectrometer data to the correct k values for processing the data into depth profiles.

5.1.8 Dispersion Compensation

One difficulty that arises from using ultra-broadband sources in a fiber-based OCT setup is chromatic dispersion in optically dense materials like glass, tissue, and water. The speed of light depends on the refractive index *n(k)* of the material, slowing down certain spectral components to a greater extent than others, hence dispersing the light. The total amount of dispersion increases linearly with length of the dispersive medium as well. Chromatic dispersion in air is negligible. Considerable amounts of dispersion can be tolerated if the dispersion in the two arms of the interferometer is equal, thus creating a coherence function that will be free of dispersion artifacts. However, when sample and reference arms contain different lengths of optical fiber or other dispersive media, a dispersion mismatch occurs. In the sample arm, the introduction of an eye with unknown axial length creates a similar effect. The coherence function will not only be broadened by unbalanced dispersion, but its peak intensity will decrease as well [28]. Second-order or group-velocity dispersion can be compensated for by changing the lens to grating distance in a rapid-scanning optical delay line [29]. However, this method does not compensate for higher orders of dispersion. Alternatively, one can balance dispersion in an OCT system by inserting variable-thickness BK7 and fused silica prisms in the reference arm [30]. The previously mentioned unknown factor introduced by an eye with unknown axial length requires a flexible method for dispersion compensation. An alternative to compensation in hardware is dispersion compensation in software. De Boer et al. induced dispersion in the delay line of a TD-OCT system equipped with an optical amplifier-based source (AFC technologies, $\lambda_0 = 1{,}310$ nm, $\Delta\lambda = 75$ nm) and compensated for dispersion artifacts in structural intensity images obtained in an onion [31]. Fercher et al. compensated for dispersion induced by a glass sample [32, 33]. Other dispersion compensation algorithms are described by Marks et al. [34, 35]. Below we will give an example of compensation in software for dispersion induced by an ultra-broadband source and remove artifacts from retina data [12]. A nearly identical approach was virtually simultaneously published [13].

A dispersion mismatch introduces a phase shift $e^{i\theta(k)}$ in the complex cross-spectral density *I(k)* as a function of wave vector. Since spectrometer data is acquired as a function of wavelength, data has to be transformed to *k*-space first

as detailed above. The relation between the phase $\theta(k)$ and the multiple orders of dispersion can best be described by a Taylor series expansion:

$$\theta(k) = \theta(k_0) + \left.\frac{\partial\theta(k)}{\partial k}\right|_{k_0}(k_0 - k) + \frac{1}{2}\cdot\left.\frac{\partial^2\theta(k)}{\partial k^2}\right|_{k_0}(k_0 - k)^2 + \ldots + \frac{1}{n!}\cdot\left.\frac{\partial^n\theta(k)}{\partial k^n}\right|_{k_0}(k_0 - k)^n \tag{5.11}$$

with λ_0 the center wavelength and k_0 equal to $2\pi/\lambda_0$. The first two terms describe a constant offset and group velocity, respectively, and are not related to dispersive broadening. The third term represents second-order or group-velocity dispersion. Dispersion mismatch in sample and reference arms is largely compensated by this term, although adjustment of higher-order dispersion can be necessary as well, especially when an ultra-broadband source is used. Dispersion can be removed by multiplying the dispersed cross-spectral density function $I(k)$ with a phase term $e^{-i\theta(k)}$.

We will illustrate a method to obtain the phase term $e^{-i\theta(k)}$. To determine this phase term for dispersion compensation of data obtained in the human eye in vivo requires a coherence function obtained from a well-reflecting reference point in the eye. We found that it is possible to use the center of the fovea (foveal umbo) for this purpose because this part of the eye acts as a good reflector [12]. To determine the phase term, after linear interpolation to k-space, the spectrum is Fourier transformed to z-space, where it is shifted such that the coherence function is centered on the origin. A complex spectrum in k-space is obtained after an inverse Fourier transformation. The phase term $\theta(k)$ is equal to the arctangent of the imaginary component divided by the real component and indicates how much subsequent wave numbers k are out of phase with each other. This function was fit to a polynomial expression of the 9th order, yielding a set of coefficients α_{1-9}. Individual spectra obtained from a volunteer were first multiplied with a phase $e^{-i\theta(k)}$ as determined from the last seven polynomial coefficients and then inversely Fourier transformed into A-lines, thus removing dispersion.

The source was a BroadLighter (Superlum, Russia), in which two super luminescent diodes at center wavelengths of approximately 840 nm and 920 nm were combined in one system with a center wavelength of 890 nm, an FWHM bandwidth of over 150 nm, and an optical output power of approximately 4.5 mW. Figure 5.5 shows the source spectrum and a reference arm spectrum that were recorded with a commercial optical spectrum analyzer (OSA). The reference spectrum was also recorded with our high-speed spectrometer (HS-OSA). By comparing the blue and red curves of Fig. 5.5, one can see a significant drop in sensitivity of the line scan camera above 850 nm. The plot amplitudes are adjusted so that all three curves fit within the same graph.

A detailed description and drawing of our setup can be found in our earlier work [10, 11]. In order to compensate for dispersion, coherence functions were obtained from a reflecting spot in the foveal umbo of a human eye, from a mirror in a

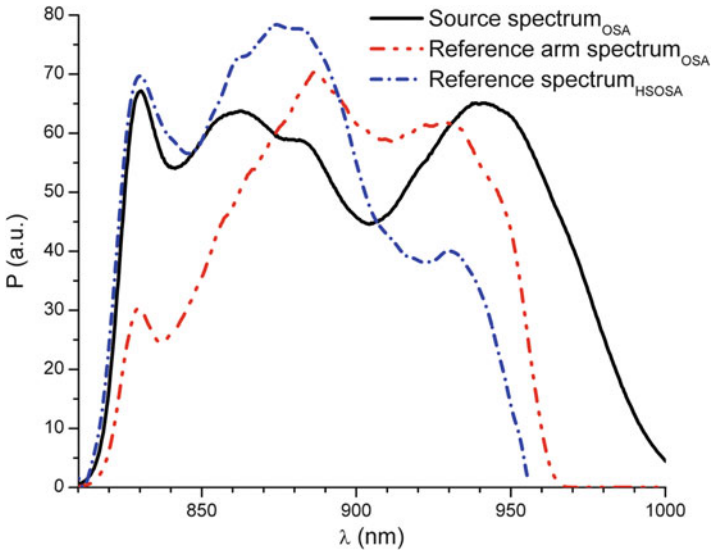

Fig. 5.5 Source spectrum of the BroadLighter (*black*); spectrum returning from the reference arm (*red*). Both spectra were measured with a commercial optical spectrum analyzer. The reference spectrum in blue was recorded with our high-speed spectrometer, and by comparing the blue and red line, it demonstrates the decrease in sensitivity of the line scan camera above 850 nm. Spectrum amplitudes were adjusted so that all three curves fit within the same graph (Reproduced from Ref. [12] with permission from the Optical Society of America)

water-filled model eye (Eyetech Ltd.) and a mirror in air. In vivo measurements were performed on the undilated right eye of a healthy volunteer. The right eye was stabilized using an external fixation spot for the volunteer's collateral eye. Multiple sets of B-scans were taken in the macular area. B-scans that contain specular reflections from the foveal surface were analyzed in detail to compensate for dispersion.

In the graph of Fig. 5.6, the phase term $\theta(k)$, obtained from a mirror in a model eye (black line, averaged over 100 A-lines) and from a specular reflective spot in the fovea (red line, averaged over 5 A-lines), is shown. The quadratic phase term (group-velocity dispersion) was minimized in hardware by a rapid-scanning optical delay line (RSOD) [29]. Figure 5.6 shows that the dispersion is dominated by a cubic phase term. The differences between the measured phase terms and polynomial fits (9th order) to the data are shown as well (light and dark blue lines), with the corresponding axis on the right. Both phases show the same pattern, which indicates that both the model eye and the real eye experience similar amounts of dispersion. The in vivo image shown in Fig. 5.7 was compensated using the phase that was obtained from the specular reflection of the fovea itself (red curve of Fig. 5.6).

In the graph of Fig. 5.8, the coherence function obtained from a mirror in air is plotted. The data shows the amplitude as a function of depth, where the amplitude is given by the absolute value of the Fourier components after transform of the measured spectrum. In the same graph, a coherence function compensated for dispersion is plotted. For this plot, the same technique as applied in Fig. 5.6 was

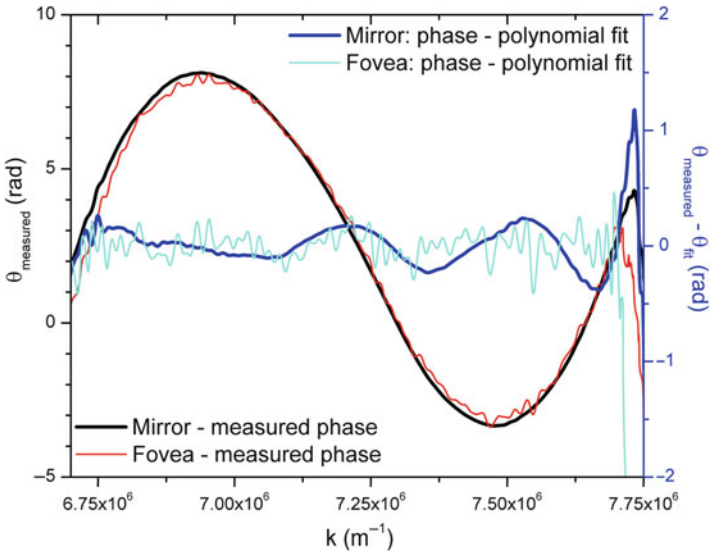

Fig. 5.6 The phase $\theta(k)$ obtained from a mirror in a model eye and from a specular reflection in the fovea (*left axis*). The residual dispersion not compensated for by the polynomial fit is given as a function of k (*right axis*) (Reproduced from Ref. [12] with permission from the Optical Society of America)

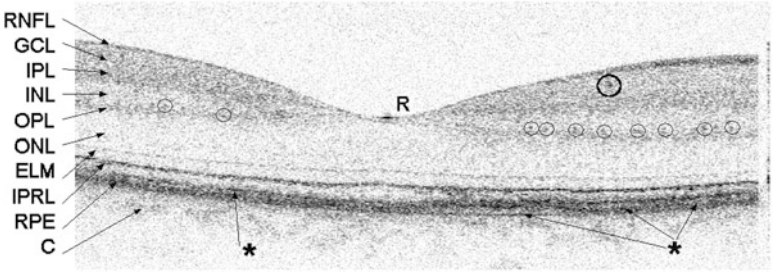

Fig. 5.7 Structural image of the fovea. The dimension of the image is 3.1 × 0.61 mm. The image is expanded in vertical direction by a factor of 2.5 for clarity. Layers are labeled as follows: *RNFL* retinal nerve fiber layer, *GCL* ganglion cell layer, *IPL* inner plexiform layer, *INL* inner nuclear layer, *OPL* outer plexiform layer, *ONL* outer nuclear layer, *ELM* external limiting membrane, *IPRL* interface between the inner and outer segments of the photoreceptor layer, *RPE* retinal pigmented epithelium, *C* choriocapillaris and choroid. A highly reflective spot in the center of the fovea is marked with an *R*. A blood vessel is marked with a large circle (*BV*). Small highly reflecting black dots can be seen in the outer plexiform layer (marked with smaller *circles*). We conclude that they are not caused by speckle because they consistently appear at the same location over consecutive images. The dots seem to be almost regularly spaced in the outer plexiform layer. We believe that these black dots are very small blood vessels. Snodderly et al. measured the distribution of blood vessels in an enucleated macaque eye by means of microscopy in frozen samples [36]. They report a very similar spacing of small blood vessels in the plexiform layers near the fovea. Two layers at the location of the RPE at the left and right are marked with *arrows* and an *asterisk* (*) (Reproduced from Ref. [12] with permission from the Optical Society of America)

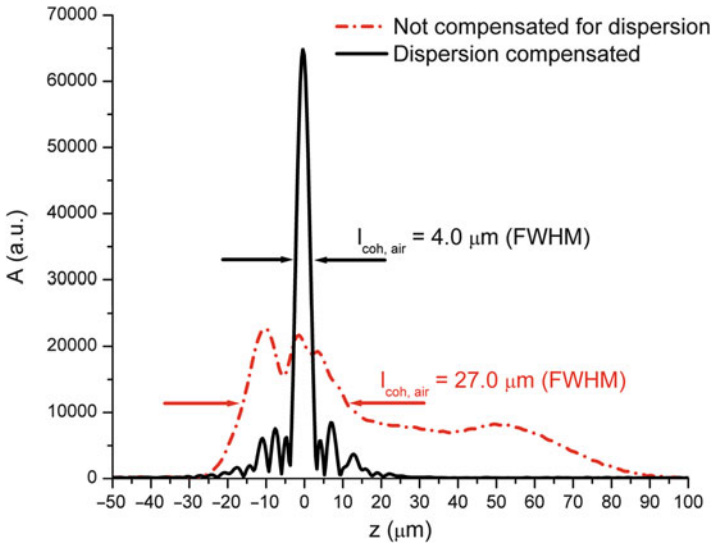

Fig. 5.8 Coherence function obtained from a mirror in air. Uncompensated data (*red*) is compared with a coherence function after dispersion compensation (*black*). The density of points was increased by a factor of 8 using a zero-padding technique (Reproduced from Ref. [12] with permission from the Optical Society of America)

used, yielding a different set of coefficients, since the mirror was not located in the water-filled model eye.

The dispersion compensation technique gives a significant reduction in coherence length as well as a threefold increase in peak height. Without dispersion compensation, the coherence length was 27.0 μm. After dispersion compensation it was estimated to be 4.0 μm ($n = 1$), equivalent to 2.9 μm in tissue with a refractive index of $n = 1.38$. After dispersion compensation, side lobes are present at both sides of the coherence function. These side lobes are a result of the non-Gaussian-shaped reference arm spectrum (Fig. 5.5).

An alternative method to compensate for dispersion exploits the observation that the maximum peak height is achieved when the dispersion compensation is optimized [13, 37]. In this method, the variance of an OCT image is calculated, and the variance is used as a figure of merit for optimal dispersion compensation. In an iterative procedure, quadratic dispersion is introduced to maximize the variance. Next, cubic and higher-order dispersion terms can be optimized for. The advantage of this method is that it does not require a priori knowledge of the dispersion in the system.

5.1.9 Fixed Pattern Noise Removal

The interference of sample with reference arm light generates a modulation of the spectrum that is associated with structural properties of the sample

(second term in Eq. 5.6). There are other effects that cause modulation of the spectrum, which can lead to structural artifacts in SD-OCT images. Many of these modulations are constant or fixed over many spectra. Examples are variations in the response of pixels in the CCD camera or spurious etalons in the interferometer, such as the deliberately introduced cover slip in the section **remapping to k-space** to calibrate the mapping to wave vector (see Fig. 5.4). The artifacts or fixed pattern noise associated with constant modulations of the spectra can be removed by generating a reference spectrum, either by a recording of the reference arm spectrum or by averaging many spectra of an actual measurement. The latter method assumes that spectral modulation caused by structural information changes from spectrum to spectrum by translating the sample arm beam over the sample to generate a 2-D image. The reference spectrum can be subtracted from each spectrum. In a slightly improved version of the fixed pattern removal algorithm, for each image, two background spectra are generated: one by averaging all spectra from that image and the second by subsequently low-pass filtering this averaged spectrum to represent a smooth source spectrum. Each individual spectrum is then divided by the averaged background spectrum and then multiplied by the smoothed spectrum [11]. The latter method has the advantage of removing sidebands generated by particularly strong fixed spectral modulations.

5.1.10 Post Processing

After acquisition data is first processed to remove fixed pattern noise as described above. Next, spectrometer data is mapped as a linear function of k prior to Fourier transformation to recover the depth information. Mapping errors due to linear interpolation can appear at greater depths as an increased background signal or shoulders around the peaks [8, 38]. This error can be corrected by using a zero-filling technique [38] to quadruple the number of points in the spectrum. This correction included Fourier transformation, zero padding to increase the data array length fourfold, and inverse Fourier transformation back to the spectral domain but with 4 times as many points in the data array compared to the original. This spectrum was then linearly interpolated in k-space [9] and Fourier transformed into z-space to recover the depth profile, free of shoulders at longer depths. Results of this procedure are shown in Fig. 5.9.

5.1.11 Depth-Dependent Sensitivity

In SD-OCT, signal sensitivity is strongly dependent on depth within an image. To characterize system sensitivity as a function of ranging depth, 1,000 A-lines were acquired at an acquisition speed of 34.1 μs/A-line for nine different positions of a weak reflector in the sample arm. The reflected sample arm power was 1.18 nW for all reflector positions. The noise floor without zero padding decayed by 5 dB between a depth of 500 μm and 2 mm, and the peak signal dropped by 21.7 dB over the first 2 mm. Due to fixed pattern noise, the true noise floor could not be

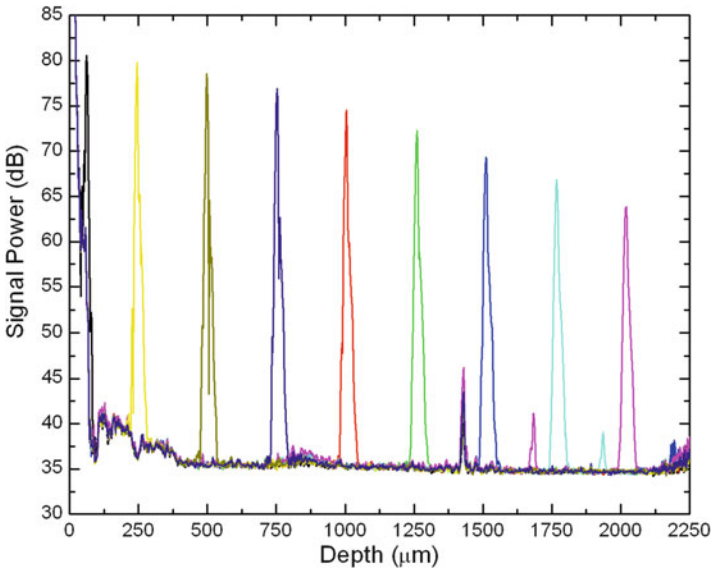

Fig. 5.9 The depth-dependent loss in signal sensitivity from a weak reflector. The signal decayed 16.7 dB between 0 and 2 mm. The peaks at 1.4 mm, 1.6 mm, and 1.85 mm are fixed pattern noise (Reproduced from Ref. [11] with permission from the Optical Society of America)

determined between 0 and 500 μm. The removal of fixed pattern noise as described above was not applied to this sensitivity measurement. After zero-filling to correct mapping errors as described above, a 16.7-dB loss in peak signal was noted across the first 2 mm, whereas the noise level dropped by only 0.4 dB between 500 μm (35.1 dB) and 2 mm (34.7 dB) (Fig. 5.9). The zero-filling method produced a nearly constant noise level and improved the signal by more than 5 dB at the greatest depths in the scan. Although zero-filling did not change the local SNR, this method eliminated the shoulders that are present at larger scan depths [8]. The decay in both the signal and the noise level across the entire scan length of 2.4 mm has been theorized to amount to 4 dB as a result of the finite pixel width [6]. As demonstrated by the experimental data, the noise level decayed by less than 4 dB over the entire scan length, which we attribute to the statistical independence of the shot noise between neighboring pixels of the array. Thus, the finite pixel width does not introduce a decay of the noise level.

The finite spectrometer resolution introduces a sensitivity decay [24] similar to that introduced by the finite pixel size [6]. Convolution of the finite pixel size with the Gaussian spectral resolution yields the following expression for the sensitivity reduction, R, as a function of imaging depth, z [24]:

$$R(z) = \frac{sin^2(\pi z/2d)}{(\pi z/2d)^2} \exp\left[-\frac{\pi^2\omega^2}{8\ln 2}\left(\frac{z}{d}\right)^2\right] \tag{5.12}$$

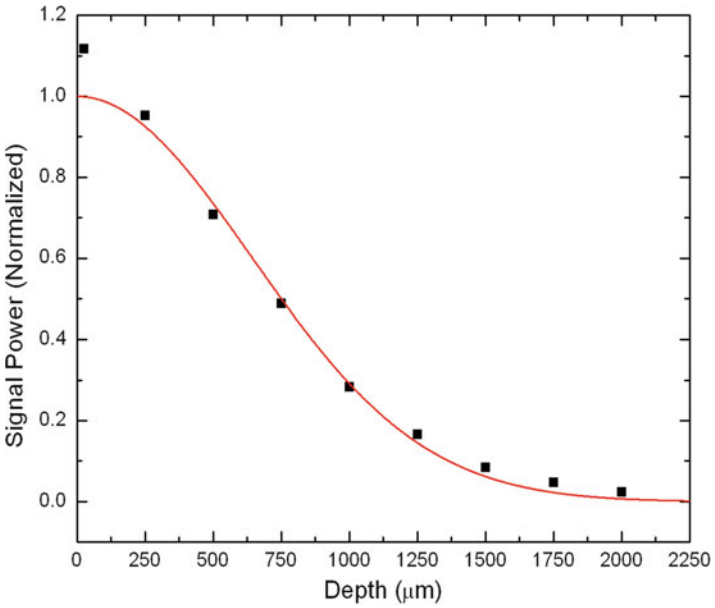

Fig. 5.10 Decay of sensitivity across the measurement range. Symbols: peak intensities of data presented in Fig. 5.9. Solid line: fit of Eq. 5.12 to the data points (Reproduced from Ref. [11] with permission from the Optical Society of America)

where d is the maximum scan depth and ω is the ratio of the spectral resolution to the sampling interval. Equation 5.12 was fit to the signal decay data presented in Fig. 5.9 with ω as a free parameter and the result shown in Fig. 5.10. Due to its proximity to the autocorrelation peak, the first data point was not included in the fit. The value for ω obtained from the fit was 1.85, demonstrating that the working spectral resolution was 0.139 nm.

The SNR was determined by the ratio of the peak at 250 μm (79.8 dB) and the noise level. Due to the fixed pattern noise at 250 μm, the noise level was determined to be 35.2 dB by extrapolation of the linear region between 0.5 and 2 mm. The resulting SNR of 44.6 dB for 1.18 nW returning to the detection arm was 2.2 dB below the theoretical value given by Eq. 5.8 of 46.8 dB, for an integration time of 34.1 μs, a central wavelength of 840 nm, and a spectrometer efficiency of 28 %. With 600 μW of power incident on an ideal reflector in the sample arm, the measured power returning to the detection arm was 284 μW. The sum of the SNR at 1.18 nW (44.6 dB) and the 10 Log ratio of maximum (284 μW) over measured (1.18 nW) power (53.8 dB) gives a sensitivity of 98.4 dB.

5.1.12 Motion Artifacts and Fringe Washout

As OCT utilizes lateral point scanning, motion of the sample or scanning beam during the measurement causes SNR reduction and image degradation in SD-OCT

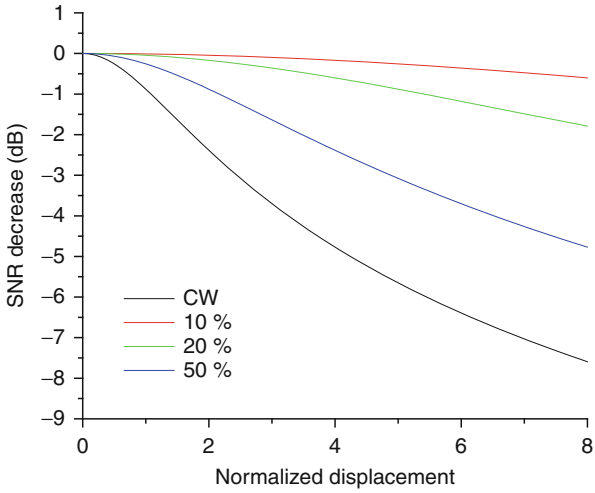

Fig. 5.11 Theoretical SNR decrease due to lateral motion for a CW source and for pulsed illumination with different duty cycles (Reproduced from Ref. [42] with permission from the Optical Society of America)

and OFDI [39]. Yun et al. theoretically investigated axial and lateral motion artifacts in continuous wave (CW) SD-OCT and swept-source OFDI and experimentally demonstrated reduced axial and lateral motion artifacts using a pulsed source and a swept source in endoscopic imaging of biological tissue [39, 40]. Stroboscopic illumination in full-field OCT was demonstrated, resulting in reduced motion artifacts for in vivo measurement [41]. In ophthalmic applications of SD-OCT, SNR reduction caused by high-speed lateral scanning of the beam over the retina may be dominant over axial patient motion. Using pulsed illumination can reduce lateral motion artifacts. We analyzed the SNR benefit of pulsed illumination over CW SD-OCT, demonstrating that pulsed illumination provides a better SNR for in vivo high-speed human retinal imaging.

For a CW source, the SNR decrease is given by [39]

$$\text{SNR decrease} \cong -5\log_{10}\left(1 + 0.5\frac{\Delta x^2}{{w_o}^2}\right), \tag{5.13}$$

where Δx is the scanning distance during the camera integration time and w_o denotes full width at half maximum (FWHM) of the beam profile. The normalized displacement is defined as $\Delta x/w_o$. For pulsed illumination, Δx is replaced by $(\tau_{pulse}/\tau_{camera})\cdot\ \Delta x$, where τ_{pulse} is the pulse width in time and τ_{camera} is the integration time of the camera for a single A-line. As can be seen in Fig. 5.11, pulsed-illumination SD-OCT has a significant SNR benefit over CW SD-OCT when the displacement Δx is larger than the FWHM w_o of the beam profile with the same average power. For example, at a normalized displacement of 4, a 20 % duty cycle pulsed illumination has a 4.2 dB better SNR than CW illumination.

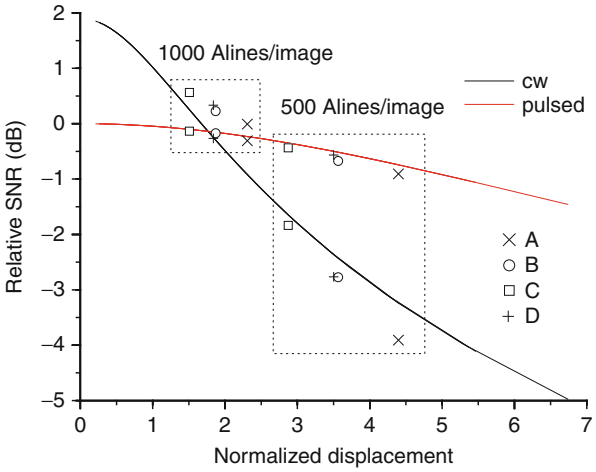

Fig. 5.12 Relative SNR for CW and pulsed illumination, fitted with w_o and offset as parameters for the four different zones *A–D* as a function of normalized displacement. The theoretical fit for CW illumination (*continuous line*) starts 1.9 dB above the theoretical fit for pulsed illumination (*dotted line*) because of the higher average CW power. Despite the lower average power for pulsed illumination, the SNR is better for normalized displacements larger than 2 (Reproduced from Ref. [42] with permission from the Optical Society of America)

Figure 5.11 also shows that for CW illumination, a normalized displacement of 1 gives 1 dB decrease in SNR. At a source center wavelength of 841 nm, an axial motion of 50 nm per A-line would also result in a 1-dB SNR reduction [39]. At an A-line rate of 29.3 kHz, this corresponds to an axial velocity of about 1.5 mm/s, which for retinal imaging is, in general, much higher than encountered in practice.

According to the ANSI standard for safe use of lasers, the maximum permissible exposure expressed as the average power of a pulse train depends on the repetition rate and increases with the pulse repetition rate up to a frequency of 55 kHz, where the limit to continuous wave exposure is reached. Due to this safety restriction, the average power for pulsed illumination was lower than the average power for CW illumination in these experiments [42]. The sample arm power after the slit lamp of CW and pulsed illumination was set to 600 μW and 385 μW, respectively. The 385 μW average power for pulsed illumination will cause a 1.9 dB smaller SNR compared to the 600 μW for CW. This has been accounted for in the SNR analysis comparing pulsed and CW illumination.

Pulsed illumination was applied to human retinal imaging, and the SNR was analyzed by direct comparison with CW illumination. The pulse width was 8 μs and the pulse repetition rate was 29.3 KHz, synchronized with the integration time of the high-speed line scan camera. Four different zones (A–D) on the retina were analyzed. The actual scan range was 8.6 mm on the retina and the normalized displacement was calculated based on a fit of a constant spot size within each zone

to the data for two different lateral scan speeds (500 and 1,000 A-lines over the 8.6-mm scan range), giving two different normalized displacements in each of the four zones (A–D). The normalized displacement is slightly different in each zone due to the variation of w_o. The SNR values in each zone and the theory are shown in Fig. 5.12.

The 1.9 dB better relative SNR for CW illumination over pulsed illumination at zero normalized displacement in Fig. 5.12 reflects the higher average power permitted under the ANSI standards. We can see that the SNR was almost the same at 1,000 A-lines per image with CW and pulsed illumination, but it was 1.4–3.0 dB higher with pulsed illumination for larger normalized displacement. The variation in beam diameter is attributed to a difference in curvature between the retina and the focal plane of the imaging system, where the best overlap between retina and focal plane was realized in zone A, good overlap was realized in zones B and D, and the worst overlap was realized in zone C.

5.1.13 The Effect of Pulsed Illumination on RIN

One consideration that should be taken into account is that shortening the pulse length while maintaining average power and pulse repetition rate will decrease the lateral motion artifact but also increases the ratio of RIN over shot noise. For a shot noise limited system, this ratio needs to be smaller than 1. Using Eq. 5.2 in ref [10] and replacing P_{ref} with J_p/τ_i, with J_p the energy of the pulse and τ_i the pulse duration, gives

$$\sigma^2_{\text{noise}} = \sigma^2_{r+d} + \frac{\eta e^2 J_p}{E_v} + \left(\frac{\eta e J_p}{E_v \tau_i}\right)^2 \tau_i \tau_{coh} \quad \left[e^2\right] \tag{5.14}$$

The reference arm pulse energy J_p to saturate the spectrometer to 90 % of the full well capacity is independent of pulse length. The pulse energy for which the shot noise still dominates over RIN is given by $J_p < \frac{E_v \tau_i}{\eta \tau_{coh}}$, which shows that reducing the pulse length also reduces this pulse energy. In our case of an 8 μs pulse length, the pulse energy is still more than a factor of two below the value where RIN is equal to shot noise [10].

5.1.14 Phase Stability and Doppler

In the past, phase-resolved optical Doppler tomography (ODT) based on time domain OCT (TD-OCT) has proven able to make high-resolution, high-velocity-sensitivity cross-sectional images of in vivo blood flow [43–48]. ODT measurements of blood flow in the human retina have been demonstrated [49, 50],

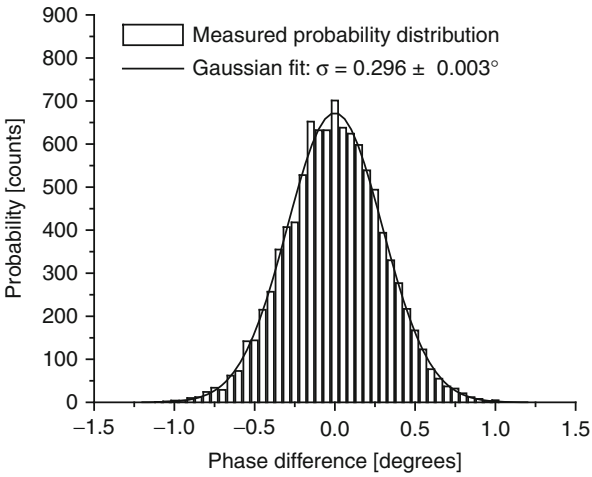

Fig. 5.13 Probability distribution of the measured phase difference between adjacent A-lines, with a stationary reflector in the sample arm. *Bars*: counted phase difference for 9990 A-lines. Bin size = 0.05°. *Solid line*: Gaussian fit to the distribution, with a measured standard deviation of 0.296 ± 0.003° (Reproduced from Ref. [15] with permission from the Optical Society of America)

yet the accuracy and sensitivity were compromised by A-line rate and patient motion artifacts, which can introduce phase inaccuracy and obscure true retinal topography. Combining optical Doppler tomography with the superior sensitivity and speed of SD-OCT has allowed a significant improvement in detecting Doppler signals in vivo. In the first combination of these technologies, velocity of a moving mirror and capillary tube flow was demonstrated [51], followed by in vivo demonstration of retinal blood flow [14, 15].

In SD-OCT, a phase-sensitive image is generated by simply determining the phase difference between points at the same depth in adjacent A-lines. This parallels the time domain method pioneered by Zhao et al. [43, 44]. The superior phase stability of SD-OCT, due to the absence of moving parts, is demonstrated in Fig. 5.13. The data was acquired with a stationary mirror in the sample arm, without scanning the incident beam. Ideally, interference between sample and reference arm light should have identical phase at the mirror position for all A-lines. This condition underlies the assumption that any phase difference between adjacent A-lines is solely due to motion within the sample. The actual phase varies in a Gaussian manner about this ideal, as demonstrated in Fig. 5.13, where we present the measured probability distribution of phase differences with a standard deviation of 0.296 ± 0.003°. This value is over 25 times lower than previously quantified figures for time domain optical Doppler tomography systems [31, 48] and at an acquisition speed of 29 kHz corresponds to a minimum detectable Doppler shift of ±25 Hz. With a time difference of 34.1 μs between acquired A-lines, phase wrapping occurs at Doppler shifts greater than 15 kHz. Thus, the system dynamic range described by the ratio of maximum to minimum detectable Doppler shifts before phase wrapping occurs is a factor of 600.

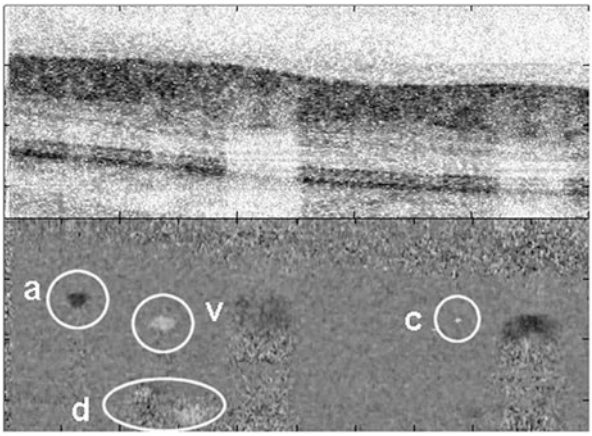

Fig. 5.14 Movie of structure (*top panel*) and bidirectional flow (*bottom panel*) acquired in vivo in the human eye at a rate of 29 frames per second. The sequence contained 95 frames, totaling 3.28 s (See Ref. [15]). Image size is 1.6 mm wide by 580 μm deep. *a* artery, *v* vein, *c* capillary, *d* choroidal vessel (Reproduced from Ref. [15] with permission from the Optical Society of America)

In vivo images of structure and Doppler flow were acquired at 29 frames per second (1,000 A-lines per frame) and subsequently processed. The images presented in Fig. 5.14 are 1.6 mm wide and have been cropped in depth to 580 μm, from their original size of 1.7 mm. The layers of the retina visible in the intensity image have been identified and described previously [19], with the thick, uppermost layer being the nerve fiber layer and the thinner, strongly scattering deep layer being the retinal pigmented epithelium. One can see the pulsatility of blood flow in the artery (a), while the flow in the vein (v) is less variable (See Ref. [15]). At the lower left center of the image, it is possible to distinguish blood flow deep within the retina (d). With reference to the intensity image, one can see that this blood flow is being detected *below* the retinal pigmented epithelium, and we believe this is the first time that optical Doppler tomography imaging techniques have been able to observe and localize blood flow within the choroid. To the left of the large vessel on the right-hand side of the image, note the appearance of a very small vessel (c). The diameter of this vessel is slightly under 10 μm.

5.1.15 Retinal Imaging with SD-OCT

Many examples of retinal imaging with SD-OCT are available in the literature. Commercial systems are being introduced into the market at this point. Below, two typical examples of high-quality SD-OCT images are presented, acquired with a system providing a depth resolution of 3 μm in tissue. Both figures consist of approximately 1,000 A-lines or depth profiles. Figure 5.15 shows a cross section centered on the optic nerve head and the corresponding en face image (Fig. 5.16) generated from the 3-D data set. Figure 5.17 shows an image centered on the fovea and the corresponding en face image (Fig. 5.18) generated from the 3-D data set.

Fig. 5.15 High-resolution SD-OCT image of a human retina in vivo, centered on the optic nerve head. The image is magnified in depth by a factor of 2. Image size, 4.662 × 1.541 mm

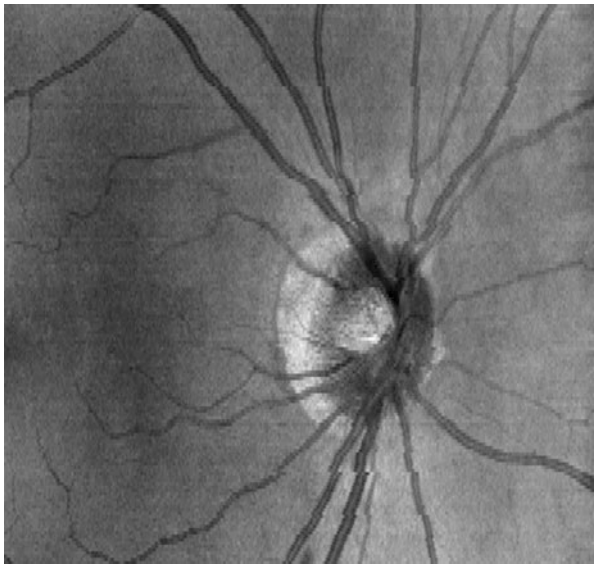

Fig. 5.16 En face reconstruction of the optic nerve head region of the retina from a 3-D volumetric SD-OCT data set of 170 images. Image size, 4.66 × 4.41 mm

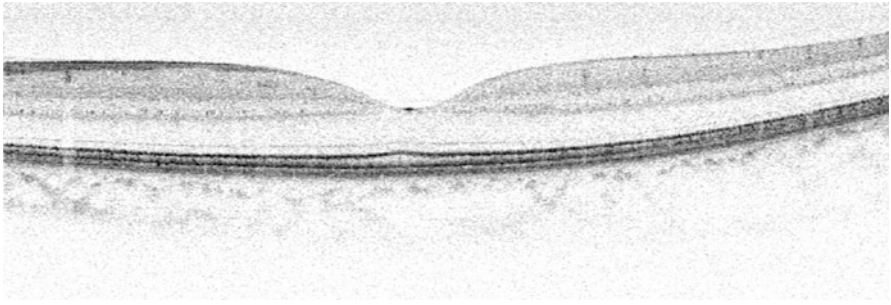

Fig. 5.17 High-resolution SD-OCT image of a human retina in vivo, centered on the fovea. The image is magnified in depth by a factor of 2. Image size, 4.973 × 0.837 mm.

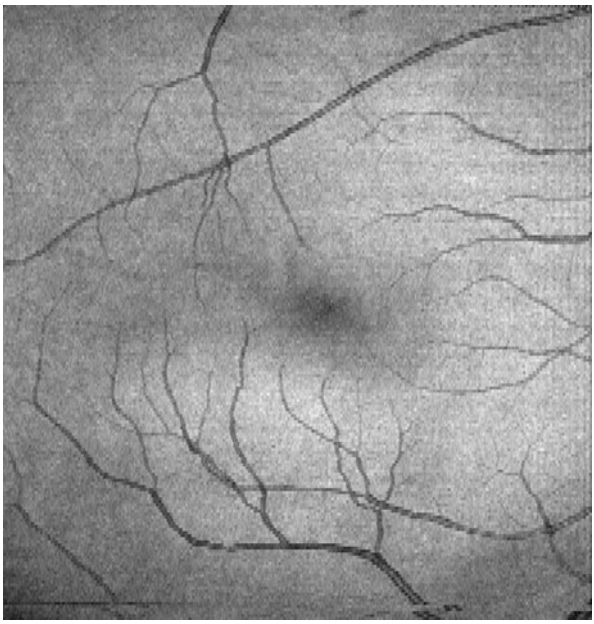

Fig. 5.18 En face reconstruction of the fovea region of the retina from a 3-D volumetric SD-OCT data set of 200 images. Image size, 4.97 × 5.18 mm

5.2 Conclusion

Spectral domain or frequency domain OCT (SD/FD-OCT) has become the preferred method for retinal imaging owing to its high imaging speed [10, 11], enhanced signal-to-noise ratio (SNR) [5–8], and the availability of broadband sources permitting ultrahigh-resolution retinal imaging [12, 13]. However, the state-of-the-art spectrometers are hindering further improvements (1) with limited detection efficiency (∼25 %) [11], and (2) the obtainable spectral resolution causes approximately a 6-dB sensitivity drop over a 1-mm depth range [11]. Furthermore, rapid scanning of the probe beam in SD-OCT has the adverse effect of fringe washout, which causes SNR to decrease [40]. The limited depth range can be addressed by acquiring the complex cross-spectral density as described in the next chapter. Fringe washout can be addressed by pulsed illumination [42]. A competing technique such as optical frequency domain imaging (OFDI), the dominant implementation of Fourier domain OCT technologies at 1.3 μm [52], has the advantage of larger depth range and better immunity to motion artifacts. OFDI has recently been demonstrated in the 800- and 1,050-nm range [53–55], but has not reached the superior resolution of SD-OCT [12, 13].

Acknowledgment This research was supported in part by research grants from the National Institutes of Health (1R24 EY12877, R01 EY014975, and RR19768), Department of Defense (F4 9620-01-1-0014), CIMIT, and a gift from Dr. and Mrs. J.S. Chen to the optical diagnostics program of the Wellman Center of Photomedicine. The author would like to thank a number of

graduate students and postdoctoral fellows that have contributed to the results presented in this chapter, Barry Cense, Nader Nassif, Brian White, Hyle Park, Jang Woo You, and Mircea Mujat. Special thanks to Teresa Chen, MD, my invaluable collaborator at the Massachusetts Eye and Ear Infirmary, without whom all this work would not have been possible.

6.1 Introduction

Fourier domain optical coherence tomography (FdOCT) [1, 2] provides significant improvement of detection sensitivity and imaging speed as compared to time domain OCT [3–5]. The delay and magnitude of backscattered or back-reflected light detected by any OCT system carry information about axial structure of semitransparent objects. FdOCT devices reconstruct the sample structure by spectral analysis of the spectral interference fringe signal. FdOCT detection can be performed in two ways: spectral OCT using a spectrometer with an array or matrix of photodetectors (CCD, CMOS, or photodiode arrays) [1, 6–9] and swept source OCT using a tunable laser source [1, 10–17]. Spectral OCT has demonstrated superior imaging speed as compared to time domain OCT when applied to ophthalmic imaging in the anterior eye segment and the retina [7–9, 18–22]. Spectral OCT and swept source OCT are also promising for ultrahigh-resolution imaging because they overcome imaging speed limitations of time domain OCT. Therefore, it is possible to use these techniques for three-dimensional ultrahigh-resolution imaging [8, 18–20, 23].

An advantage of Fourier domain OCT is the possibility of having direct access to the spectral fringe pattern, enabling a wide range of novel applications such as tissue absorption measurement [24] and tissue contrast enhancement [25]. Additionally the high speed combined with simultaneous registration of all spectral components (spectral OCT) provides stable phase information. The availability of signal phase information due to the coherent signal detection is one of the most important advantages of OCT. It allows pushing the resolution limits down to the nanometer range and extending the capabilities of FdOCT from purely structural towards a potential functional imaging modality with high temporal resolution [26–28].

It is beyond the scope of the chapter to give an entire overview of all the various facets of phase-sensitive detection. The main motivation is to clarify the notions of signal phase and to introduce the reader to the problem of phase-sensitive FdOCT detection and complex FdOCT signal formation. We discuss the meaning of complex signal content and the implications of complex FdOCT signal reconstruction for cross-sectional image formation. We will also demonstrate the potential of phase-sensitive FdOCT techniques for improving the quality of obtained FdOCT reconstructions [29–39].

6.2 The Complex OCT Signal

Optical coherence tomography (OCT) is an interferometric imaging modality. This simple fact has several far-reaching implications on the achievable system performance and on the amount of information that is contained in an OCT signal. This is best seen by first analyzing the properties of a complex OCT signal and in particular of a Fourier domain OCT (FdOCT) signal.

6.2.1 The Signal Registered by FdOCT Instrument

Assume ρ_R to be the in general complex valued amplitude reflection coefficient of the reference and accordingly ρ_i the coefficients of the backscattering sample sites along the optical axis located at z_i. Clearly the amplitude of the field that is backscattered at a certain sample interface will be apart from the actual interface reflectivity also affected by all previous interfaces. The situation is schematically shown with the layer model of Fig. 6.1 where $E_i(z,t)$ are the individual optical fields back-reflected from interfaces z_i. The interfaces are artificial boundaries separating two regions at which the refractive index difference causes a reflected wave that can be detected by the OCT system. The optical fields $E_i(z,t)$ are not independent but related via

$$E_i(z,t) = \sigma_{i-1}{}^2 \rho_i E_{i-1}(z,t), \tag{6.1}$$

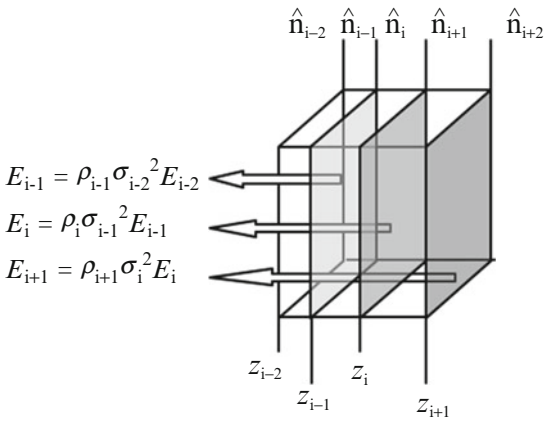

Fig. 6.1 Layer model to describe the field contributions to the OCT signal. The layers are described by their complex refractive index $\hat{n}$

where σ_{i-1} is the amplitude transmission of the $(i-1)$th interface. It is related to the reflectivity coefficient of the corresponding interface via $|\sigma_{i-1}|^2 = 1 - |\rho_{i-1}|^2$. One can account for the effective amplitude attenuation as the beam propagates through the different interfaces in a non-absorbing sample by introducing a reduced amplitude reflectivity:

$$\rho_i' = \prod_{j=0}^{i-1} \sigma_j^2 \rho_i, \tag{6.2}$$

with $\sigma_0 = 1$. Standard OCT systems actually display logarithmic plots of the reduced rather than actual sample structure reflectivities. The structure function including the reference interface is therefore approximated by a sum of delta functions as

$$g(z) = \sum_i \rho_i' \delta(z - (z_0 - z_i)) + \rho_R \delta(z - (z_0 - z_R)), \tag{6.3}$$

where z_R, z_i relate to optical distances with respect to a common reference point z_0. For a certain layer with refractive index n, the optical distances are related to the corresponding geometric values by $z_{opt} = n \cdot z_{geom}$.

Again standard OCT displays optical distances rather than geometric ones. The true geometric sample structure can be retrieved by using elaborate ray tracing algorithms [40, 41].

Having now set the model for the sample structure, we come back to the actual OCT signal. There we measure the coherent superposition of all waves scattered back from the sample together with the reference wave. Assume the power spectral density of the employed broad-bandwidth light source to be $P(\nu)$, where ν is the optical frequency. Then the total optical power at the interferometer entrance is

$$P_0(\nu_C, \Delta\nu) = \int_{-\infty}^{\infty} P(\nu, \Delta\nu) d\nu, \tag{6.4}$$

where Δv is the optical line width, usually the full width at half maximum value, and v_C the center frequency of the employed light source. The total backscattered wave at the common reference point, which is without loss of generalization assumed to be the detector position, can be written as

$$E_D(z_0, t, K) = \int g(z - z_0) E_0(k) \exp(-i2\pi \nu t - iKz) dz. \tag{6.5}$$

The integral ranges over the axial sample structure including the reference site, E_0 is the incident field amplitude, $g(z)$ represents the in general complex valued sample structure, and K is the absolute value of the scattering wave vector, $K = -2\,k$. The expression for the scattering field can be rewritten as

$$E_D(z_0, t, K) = E_0(k) \exp(-i2\pi \nu t) FT_K\{g(z - z_0)\}, \tag{6.6}$$

with $FT\ g(z)\}$ being the Fourier transform of $g(z)$. The intensity of this field becomes:

$$I_D(K) = E_0(k) {E_0}^*(k) |FT_K\{g(z)\}|^2. \tag{6.7}$$

The simple layer model that is used for describing the backscattering structure may be extended to include absorption and scattering losses by introducing a complex refractive index $\hat{n} = n + i\alpha$. A monochromatic wave of wave number k and optical frequency v that travels along z within an homogeneous and isotropic medium of complex refractive index $\hat{n}_i$ is then written as

$$E_i(z, t) = E_{i,0} \exp\{-i[2\pi \nu t - k n_i z]\} \exp(-k \alpha_i z). \tag{6.8}$$

Comparing the expression for the intensity of this wave with Lambert-Beer's law allows immediately finding the relation of α with the extinction coefficient μ_e as

$$\alpha = \mu_e \lambda / 4\pi. \tag{6.9}$$

As indicated by the layer model in Fig. 6.1 and the explanations in the text, the sample function basically represents abrupt changes in refractive index along the axis that give rise to reflection and scattering. Within the layers the complex refractive index $\hat{n}(v)$ can assumed to be an analytic function. Hence its components the dispersion $n(v)$ and the absorption $\alpha(v)$ are linked via Kramers-Kronig (KK) relations. We give the definitions of Ahrenkiel [42] for singly subtractive KK relations that include a known reference point and converge more rapidly than the original integrals:

$$\alpha(v) = \alpha(v_0) - \frac{2}{\pi}\left(v^2 - v_0^2\right)P\int_0^\infty \frac{v' n(v')}{\left(v^2 - v'^2\right)\left(v_0^2 - v'^2\right)}dv',$$
$$n(v) = n(v_0) + \frac{2}{\pi}\left(v^2 - v_0^2\right)P\int_0^\infty \frac{v' \alpha(v')}{\left(v^2 - v'^2\right)\left(v_0^2 - v'^2\right)}dv', \tag{6.10}$$

where P indicates the Cauchy principal value of the integrals. Later Palmer et al. [43] introduced multiply subtractive algorithms to optics that allow including more than one reference point. The KK equations state that with known dispersion over a certain optical frequency range, it is possible to reconstruct the absorption and vice versa. Faber et al. [44] used the simply subtractive KK relations of Eq. 6.10 to calculate the complex index of refraction of oxygenated and deoxygenated hemoglobin by using the accurately known absorption spectra together with a reference measurement at a single wavelength.

The phase as argument of the Fourier transform in FdOCT has no direct meaning; only the phase difference over time or spatially allows to access in a quantitative way changes of the optical path length down to small fractions of the central wavelength. The optical path length is defined by the transit time of light as $OD = \Delta z\, n$, where Δz is the geometric distance and n is the refractive index of the medium. In OCT broadbandwidth light sources are applied and therefore the displacement Δz is multiplied to the group refractive index $n_g = d\omega/dk$, where ω is defined as $w = 2\pi v$. However, the phase of the spectral interference pattern recorded in FdOCT contains in fact the full dispersion properties of the medium. The slope of this phase at the central wavelength is related to the group refractive index, whereas higher-order phase terms relate to higher-order dispersion contributions. In order to extract this spectral phase curve, we need a Hilbert transform or Fourier filtering of the recorded signal. This is easily done by filtering the FdOCT signal of clear sample interfaces, e.g., cuvette interfaces, or glass slides of microscopy samples. Analyzing the spectral phase offers the possibility to extract additional chemical sample information, due to dispersion properties of the sample. It has been demonstrated how to measure analyte concentrations in mixture based on the spectral phase information [45]. Recent work demonstrated the possibility to use the spectral phase information for highly sensitive label-free investigation of cell dynamics [46–48]. Finally, the access to the spectral phase allows in combination with high-speed swept source FdOCT to access fast vibrations with subnanometer resolution on time scales of down to 10^{-9} s. This has been used for all optical detection of photoacoustic signals and parallel acquisition with FdOCT [49].

6.2.2 Reconstruction of Structural Information from FdOCT Signal

The inverse Fourier transform of the field intensity at the detector Eq. 6.7 retrieves the structure function $g(z)$. In fact it yields the autocorrelation function of the structure convoluted with the inverse Fourier transform of the spectral field intensity, i.e.,

$$FT^{-1}{}_z\{I_D(k)\} = FT^{-1}{}_z\{I_0\} \otimes ACF\{g(z)\} \\ = \tau_{\exp} P_0 \gamma(\tau = z/c) \otimes ACF\{g(z)\}. \tag{6.11}$$

For the last step we used the Wiener-Khintchin theorem according to which the complex degree of coherence $\gamma(\tau)$ is connected to the power spectral density via a Fourier transform:

$$\gamma(\tau) = 1/P_0 \int_{-\infty}^{\infty} P(v) \exp(-i2\pi v\tau) dv. \tag{6.12}$$

The importance of this Fourier relation cannot be overemphasized. It is the basic theorem that links time domain with frequency domain interferometry. The superposition of the individual backscattered fields together with the reference wave will form interference fringes only if the temporal delays between the different light fields are smaller than the range of temporal coherence. According to the bandwidth product, the width of the coherence function must be inversely proportional to the spectral bandwidth of the light source. For Gaussian-shaped power spectral density, the expression for the coherence length becomes

$$l_c = \frac{4 \ln 2}{\pi} \frac{{\lambda_c}^2}{\Delta\lambda}. \tag{6.13}$$

The axial resolution of any OCT system is given by half the coherence length since the wave travels twice the sample arm. The temporal coherence function is equal to the normalized field autocorrelation function $\Gamma(\tau) = \langle E(t), E(t-\tau) \rangle$, with brackets indicating an ensemble average. In the case of statistically stationary fields, the ensemble average equals time average. The complex degree of coherence is then defined as the normalized temporal coherence function $\gamma(\tau) = \Gamma(\tau)/\Gamma(0)$. If we use now our definition of the structure function $g(z)$, we finally obtain from Eq. 6.11 the expression for the absolute value of the measured Fourier domain signal:

$$|I_D(\tau)| \propto I_0|\gamma(\tau)| \left[\sum_i |\rho_i|^2 + |\rho_R|^2\right] + I_0|\gamma(\tau)| \\ \otimes \left[\sum_{i,j;i>j} \rho_i {\rho_j}^* \delta\left[\tau - \left(\tau_i - \tau_j\right)\right] + \sum_i \rho_i {\rho_R}^* \delta[\tau - (\tau_i - \tau_R)]\right] + c.c. \tag{6.14}$$

where $\tau = z/c$ and $\delta(\tau)$ is the Dirac delta function. The first term of the rhs corresponds to the total intensity of the signal that appears as DC term at $\tau = 0$. The following two terms are self-cross correlations between fields back-reflected at individual sample structure layers. These terms are commonly referred to as autocorrelation terms or coherence noise terms. Only the last two terms actually display the actual axial sample structure. Still there is an ambiguity with

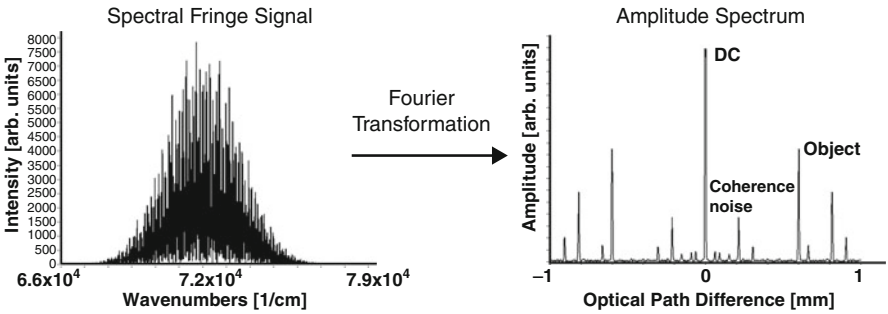

Fig. 6.2 Reconstruction of the axial structure of an object in FdOCT: structural information, DC signal, and coherence noise terms are residual in the amplitude spectrum of the spectral fringe signal

respect to the zero delay associated with the Hermitian nature of the inverse Fourier transform as it is applied to the real-valued signal I_D. Each structure term has its mirror term in the adjoint Fourier space. Figure 6.2 shows the signal measured by FdOCT instrument and how this signal is processed to obtain the reconstruction corresponding to amplitudes of back-reflected intensity versus one-dimensional distribution of scattering points (optical A-scan).

All three extra signal components described by Eq. 6.14 (DC signals, coherence noise, and symmetrical redundant image) limit the useful measurement range and can lead to misinterpretation of reconstructed structure. There are two main types of the coherence noise in FdOCT. The first type represented by term is associated with mutual interferences of light waves back-reflected or scattered from different points within a measured object, located along the penetration beam. In this case each light wave can interfere with others and gives contribution to OCT signal. This signal is present in OCT images even if the reference arm of the interferometer is blocked. Another source of coherence noise affecting Fourier domain imaging is caused by interference of light waves scattered from optical components of the OCT system. Due to the high sensitivity of FdOCT imaging and relatively long axial coherence range (some millimeters), the contribution of light scattered on optical components of the OCT device can be significant. In order to avoid an overlap between various signal components, one needs to take care that all structure terms are confined to one half space.

In practice one adjusts the reference arm delay accordingly. Figure 6.3 shows results of image reconstruction for a sample consisting of four reflecting interfaces. Three measurements have been simulated with different positions of the reference mirror. In the first case (Fig. 6.3a), the optical distance (optical path delay) between reference mirror and the sample is longer than the thickness of the entire set of four interfaces. This enables distinguishing between sample and coherence noise artifacts. Shortening the distance between the reference mirror and the sample can lead to overlapping of terms representing the sample and the coherence noise. In result the structure cannot be distinguished (Fig. 6.3b). The situation can be even more

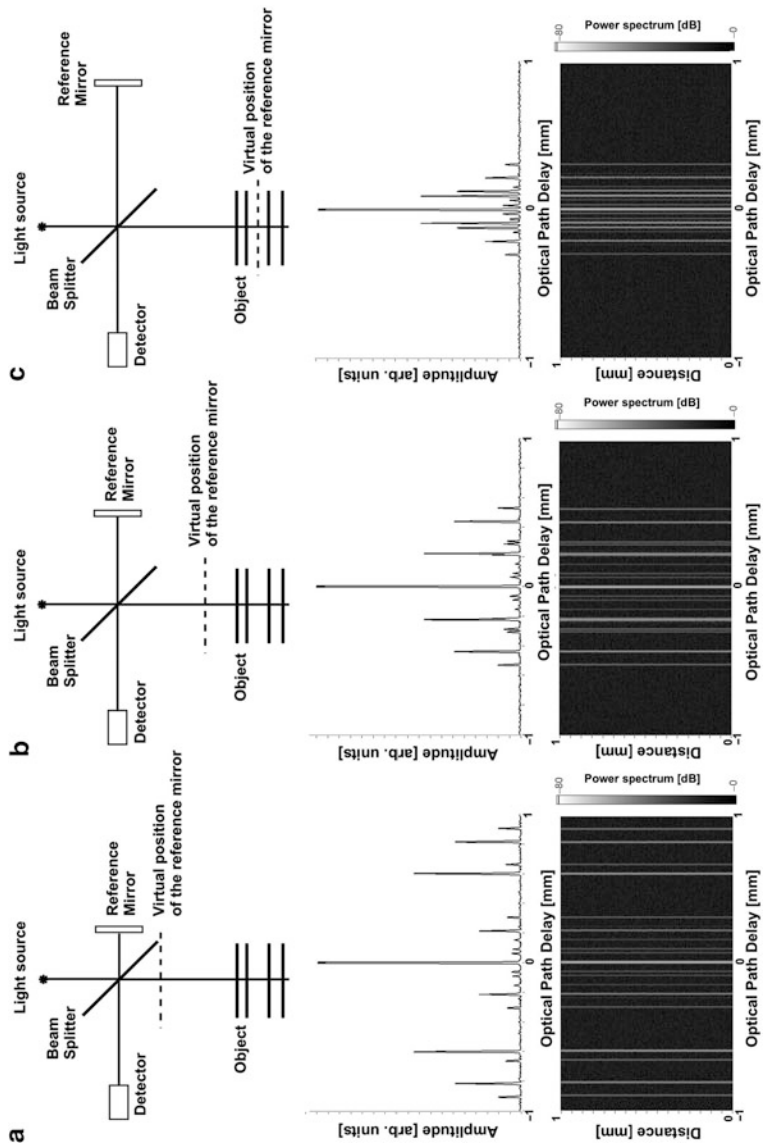

Fig. 6.3 Simulation of Fourier domain OCT reconstruction for a sample comprising four smooth reflecting interfaces registered for three different positions of the reference mirror. *Upper row* shows the scheme of the interferometer configuration chosen for each measurement. *Middle* and *bottom rows* demonstrate axial scans and cross-sectional images, respectively

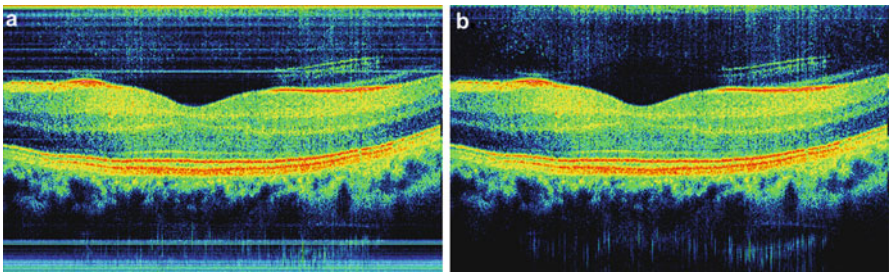

Fig. 6.4 Cross-sectional images of the human retina in vivo (macular region) obtained by FdOCT: (**a**) including all coherence noise terms, (**b**) after background subtraction

complex when the virtual position of the reference mirror is placed "inside" the object. In this case both the coherence noise terms and symmetrical images mix altogether with the signal representing the actual axial sample structure. In both cases (Fig. 6.3b, c), direct reconstruction of true architecture of the measured sample is impossible.

Usually the coherence noise components introduced by the object structure are irregular and distributed close to the zero optical path delay. In contrary coherence noise terms associated with light reflections from optical components of the device usually create characteristic regular stripe patterns, which are randomly distributed along the axial direction (Fig. 6.4). To eliminate such coherence noise terms, it is sufficient to register the spectral fringe pattern in the absence of the sample (background) and subtract it from the spectral fringes registered with the sample in place. Assuming that mutual interferences between light waves scattered from optical components of the OCT system and sample interfaces are negligible, the simple subtraction procedure can effectively reduce the regular stripe pattern that otherwise disturbs the reconstructed cross-sectional image. Practically it is possible to measure the background signal by deflecting the sample beam in an OCT interferometer during the background measurement. Random instabilities of the optical system, which are usually present in OCT devices, such as mechanical vibrations of optical components or thermal expansion of optical fibers can be taken into account and compensated by using an average over several spectral fringe patterns of the background signal. Figure 6.4b shows an example of the background subtraction algorithm applied to a FdOCT tomogram of the human retina measured in vivo.

Nevertheless the autocorrelation terms will still be present (Fig. 6.4) and give rise to coherent noise background that may lead to misinterpretation of the actual sample structure. The question arises whether it is possible to remove all coherence noise terms together with the inherent ambiguity of the FdOCT signal. An answer can be found by taking advantage of the fact that FdOCT being an interferometric method is sensitive to the relative phase between the individual fields that coherently add up at the detector. Note that in particular any reference delay τ_R will only affect the phase of the structure terms in Eq. 6.14

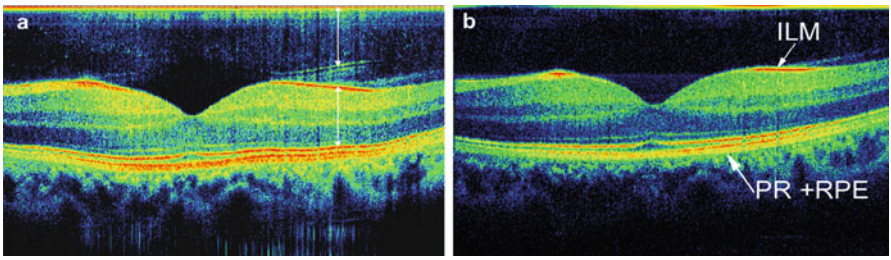

Fig. 6.5 Spectral OCT cross-sectional images of the retina in vivo (macular region). The images were taken with (**a**) 256 μs/A-scan (103 dB sensitivity) and (**b**) 32 μs/A-scan (94 dB sensitivity). Coherence noise components are clearly visible in the top of the panel (**a**), while for (**b**) the dominant noise is the shot noise; *ILM* inner limiting membrane, *PR* photo receptors, *RPE* retinal pigment epithelium. *Arrows* in (**a**) indicate the equal optical distances

but has no effect on the autocorrelation and the DC terms. This observation is the basis for phase-shifting techniques that eventually allow for the elimination of all signals apart from the true structure terms. The important fact is that these methods allow a direct reconstruction of the true depth resolved phase function of the sample field and thus of the complex valued structure function $g(z)$ Eq. 6.3.

In practice it is often impossible to predict the thickness of measured sample. Artifacts created by coherence noise terms may be misinterpreted as details of a real structure. This problem arises, paradoxically, as a result of the high sensitivity of FdOCT. The FdOCT imaging is performed at an optical energy (optical power multiplied by exposure time) that is about hundredfold lower than for traditional time domain OCT. It is therefore tempting to increase optical power to the same energy level in order to enhance sensitivity. Unfortunately, beneficial results of higher power on the sensitivity level are counterbalanced by the fact that simultaneously artifacts caused by coherence noise will emerge and will be visible above shot noise. However, it is possible to choose optimal optical power levels used for FdOCT imaging to keep the coherence noise components under the shot noise level [50]. Illustration of this phenomena is presented in Fig. 6.5. Coherence noise artifacts can be observed, for example, in retinal imaging as a result of cross-interference of waves originating from two strongly reflecting layers in the retina: internal limiting membrane (ILM) and retinal pigment epithelium (RPE). Figure 6.5 demonstrates an influence of the total exposure time (sensitivity) on the visibility of the coherence noise artifacts in retinal FdOCT imaging. Using 740 μW of optical power of light entering the eye and 256 μs of exposure time, several parasitic cross correlations produce artificial features, which are especially visible above the right part of the retinal surface in Fig. 6.5a. It is easy to verify that distances between ILM and structures around RPE match distances between position $\tau = 0$ and corresponding artifacts. The eightfold reduction of the exposure time (−9 dB in sensitivity) results in strong suppression of those artifacts (Fig. 6.5b). Under these circumstances the quality of the image is sufficient to delineate all retinal layers.

Considering the measurement configuration with significant contribution of the coherence noise terms, their amplitudes may be expressed as

$$|\Xi(\tau_{nm})| = \rho \frac{P_0 \kappa}{N} \sum_{n,m} \sqrt{R_m R_n} \tag{6.15}$$

where $\rho = e^{-}\eta/hv$ is the efficiency of photoelectric conversion of photodetector, e^{-} is an electron charge, η is the total efficiency of the spectrometer, h is Planck's constant, P_0 is the integrated optical power of the beam entering the interferometer assumed to be Gaussian across optical frequencies $\omega\left(P_0 = \sqrt{\pi/4\ln 2} P(\omega_0) FWHM\{P(\omega)\}\right)$, $\kappa - a$ double path coupling ratio of the beam splitter, N is the number of samples taken in optical frequency domain, and $R_{m,n}$ are reflectivities of consecutive back-reflecting or scattering points in the object distributed along the probing beam.

The most optimal performance of OCT instruments is usually achieved with shot noise as the dominant source of noise. In FdOCT the signal registered by the detector is Fourier transformed. Therefore, the power spectrum of the resultant shot noise may be expressed as [50]

$$N_{shot} = \frac{e^{-}\rho}{T} \frac{P_0}{N^2} \kappa \left(R_{ref} + \sum_n R_n \right), \tag{6.16}$$

where T is the exposure time needed to register one A-scan (N samples in Fourier domain), R_{ref} is the effective reflectivity of the reference mirror, and R_n is the reflectivity of consecutive back-reflecting or scattering point in the sample distributed along the probing beam. The ratio of coherence noise to shot noise in terms of electrical power of obtained signals is expressed by

$$\frac{N_{coherence}}{N_{shot}} = \frac{|\Xi(\tau_{nm})|^2}{N_{shot}} = \frac{\rho T P_0 \kappa}{e^{-}} \frac{\left(\sum_{n,m} \sqrt{R_m R_n} \right)^2}{\left(R_{ref} + \sum_n R_n \right)}. \tag{6.17}$$

In order to simplify Eq. 6.17, let us assume that there are only two strongly reflecting interfaces with identical reflectivity R contributing to the coherence noise. In this case the ratio of the coherence noise terms to the shot noise may be expressed as

$$\left(\frac{N_{coherence}}{N_{shot}} \right)' = \frac{\rho T P_0}{e^{-}} \frac{R^2 \kappa}{(R_{ref} + 2R)} = Sensitivity(T) \cdot \frac{R^2}{(R_{ref} + 2R)}. \tag{6.18}$$

Plots of the ratio of coherence noise to shot noise level as a function of sample reflectivity calculated according to Eq. 6.18 are shown in Fig. 6.6. These theoretical

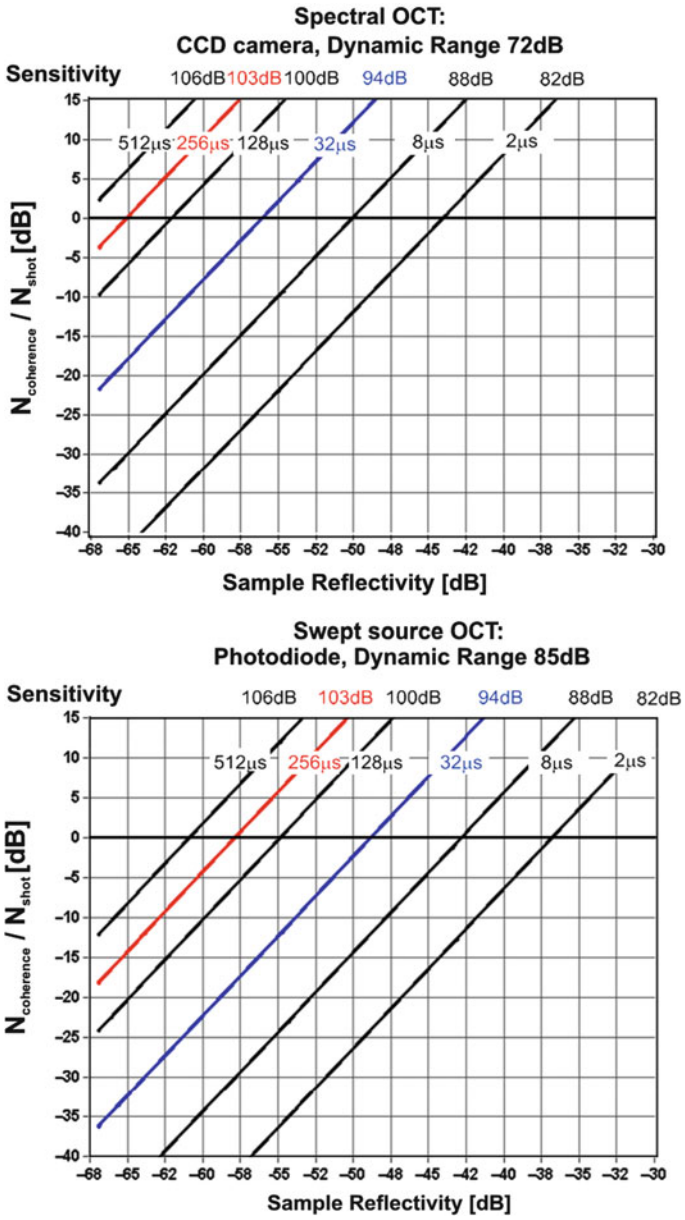

Fig. 6.6 Ratio of coherent noise to shot noise versus reflectivity of the sample calculated from (Eq. 6.17) for different values of exposure time, corresponding sensitivity, and dynamic range. The optimal exposure time to perform an experiment avoiding coherence noise terms from two surfaces of reflectivity R can be chosen by taking exposure time values, for which the oblique lines presented in the graphs are localized below 0 dB horizontal line. *Red* and *blue* lines were calculated for exposure times used in the retinal experiment, which results are shown in Fig. 6.5

plots are calculated for two values of dynamic range corresponding to detection using spectrometer ($DR = 72$ dB) and swept source system with photodiode in dual balanced configuration ($DR = 85$ dB). For these calculations the value of input optical power was assumed to be $P_0 = 2$ mW (740 uW reaching the object), the double path coupling ratio $\kappa = 0.20$, and the spectrometer efficiency $\eta = 0.14$ and the double path losses associated with collimating, back coupling to the fiber, passing through X–Y scanner to be 0.4. These parameters give sensitivities from 82 to 106 dB for exposure times varying from 2 to 512 μs per A-scan measured close to the zero path delay.

The analyzed range of reflectivity values (i.e., −30 dB to −70 dB) and sensitivities (82–106 dB) covers the typical values of reflectivity and sensitivity used in biomedical imaging. For example, in retinal OCT imaging the most reflective layers in the posterior eye are inner limiting membrane (ILM) and retinal pigment epithelium (RPE). Coming back to results presented in Fig. 6.5, the imaging parameters of FdOCT system are given above and were also used to plot relations presented in Fig. 6.6. Cross-sectional retinal images were obtained twice in the same subject using two values of exposure time: 32 us and 256 us. Taking into account the exact value of the instrument sensitivity, it was possible to find the effective average reflectivities of ILM in the presented OCT scans to be approximately −60 dB. Using the graph shown in Fig. 6.6 along with measured values of effective reflectivity of retinal layers, it is possible to estimate the maximum sensitivity corresponding to coherence noise-free imaging of the posterior segment of the human eye to be approximately 97 dB in spectral OCT systems (72 dB of dynamic range) and 102 dB (85 dB of dynamic range) in swept source OCT. The abovementioned optimization causes a limitation of the sensitivity and dynamic range. For example, in the system characterized by the dynamic range of originally 85 dB, it is possible only to image without coherence noise artifacts within a dynamic range of 45 dB.

The limitation of dynamic range due to power optimization can be overcome by using a dual balanced detection (called also differential Fourier domain detection method (dFdOCT)) [6, 51]. This method takes advantage of the fact that terms carrying direct information on the location of reflecting layers depend on the reference mirror position, while the remaining coherence noise terms do not (see Eq. 6.14). In order to completely remove the parasitic terms, it is sufficient to measure one additional spectral fringe pattern $I_D(k)$, with a phase shift of π introduced into the reference arm. Subtraction of these two spectral fringe patterns will yield terms associated exclusively with the sample structure. The π phase shift of the reference beam in differential measurements can be achieved either mechanically by attaching the reference mirror to a moving element such as a piezo actuator or electro-optically, e.g., by a phase modulator placed in the reference arm of the interferometer. The effective measurement time is doubled as compared to standard FdOCT. In swept source OCT it can be also realized by using differential measurement with additional fiber coupler introducing adequate phase shift for two detection channels (the so-called dual balanced detection). Figure 6.9a, b show examples of cross-sectional images of porcine anterior segment obtained with standard and the differential FdOCT technique. The coherence noise and strong DC signal in the central part of the image representing zero path delay are totally removed after two-frame procedure.

Nevertheless, the overlap between conjugate images is still present and can only be removed by application of complex FdOCT techniques.

6.3 Complex Fourier Domain Optical Coherence Tomography

The Fourier transform of the real-valued spectrum yields redundant information for positive and negative fringe frequencies corresponding to positive and negative path length differences between the sample and the reference. Even using the coherence noise-free imaging, one needs to adjust the reference arm delay so that it is slightly shorter than the relative distance of the first sample interface. In this case the axial structure does not mix with its mirrored representation in the conjugate Fourier half space. Hence only half of the Fourier space can be used for the sample structure.

The reconstruction of the complex representation of spectral fringe signal resolves this ambiguity and the image space is doubled (Fig. 6.9c). This needs at least two phase-shifted copies (the so-called frames) of the cross correlation between sample and reference signal. The most straightforward realization of the phase shift is done by changing the path length of the reference arm using, for example, a mirror mounted on a moving mechanical element (Fig. 6.7). A faster and more precise way of shifting the optical delay in the reference arm using electro-optic modulator has been reported by Gotzinger et al. [37]. An alternative approach has been used by Yasuno et al. where phase-shifted spectra are recorded

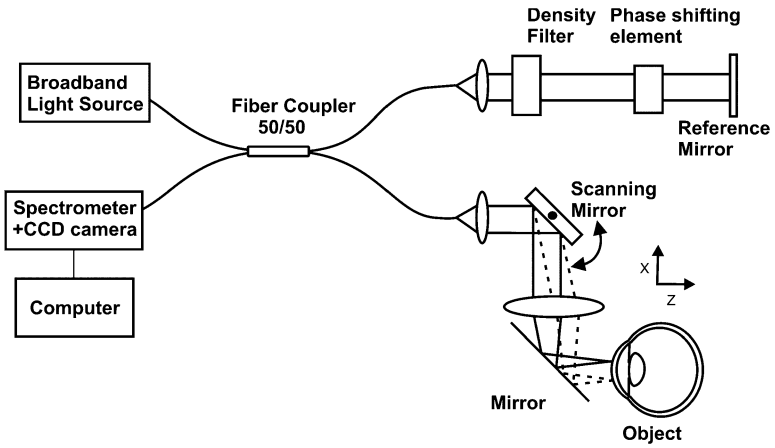

Fig. 6.7 Drawing of spectral OCT system with phase-shifting element used for complex OCT measurements. Similar to other SOCT devices, the system is based on the Michelson interferometer setup with custom-designed highly efficient spectrometer with high-speed linear photodetector. The sample arm enables lateral scanning of probing light beam. The difference between complex SOCT instrument and standard spectral OCT system is in additional phase-shifting device placed in the reference arm and more complex electronic synchronization of the lateral scanners, the phase shifter, and the spectrometer

simultaneously on different lines of an area detector [38]. However, the need for an area detector reduces the speed performance of the technique and the light efficiency is critical.

6.3.1 Complex Two-Frame Technique

In principle the complex reconstruction can be based only on two frames with a relative phase shift of $\pi/2$ [29]:

$$\hat{I}_D(k) = I'_D{}^{(0^\circ)}(k) - jI'_D{}^{(90^\circ)}(k), \tag{6.19}$$

where the role of the dashes will be explained in due course. A simple combination of two shifted spectra will still suffer from a strong DC component as well as coherence noise terms. The necessary approximation is that the reference intensity is much larger than the sample intensity which is the case in most biomedical applications. Then it is sufficient to subtract a reference spectrum from each spectral interference pattern and one is effectively left with a small sample intensity DC term together with the cross-correlation terms.

In this case the dashes in Eq. 6.19 indicate that a reference subtraction has been applied. Since only two phase-shifted copies of the recorded interference pattern are needed, it is possible to realize fast complex in vivo spectral FdOCT systems [37]. However, as pointed out such method works only well for a limited range of optical bandwidths.

For wavelength tuning FdOCT on the other hand, it is possible to perform true heterodyne detection by locking the detector to a sinusoidal reference arm delay modulation. In this case the dashes indicate that only the modulated cross-correlation terms between reference and sample are considered.

One way to achieve a wavelength-independent modulation of the actual structure terms in Eq. 6.14 is to employ frequency-shifting devices such as acousto-optic frequency shifters (AOFS). They are easy to implement into FdOCT systems based on wavelength tuning and allow for high-speed quadrature detection with fast PIN diodes [33, 34]. Nevertheless for spectral FDOCT systems, the array detectors cannot follow the fast signal modulations in the MHz range. Bachmann et al. demonstrated a solution using two slightly detuned AOFS in the sample and reference arm respectively [52]. A quadrature detection scheme is realized by locking the array detector to the resulting lower beating frequency and recording the shifted spectral interference patterns via an integrated bucket method as shown in Fig. 6.8b. Figure 6.8a shows a tomogram of the fingernail region evaluated with standard FdOCT. The strong overlapping between sample structure and its mirror adjoint renders it impossible to determine the actual structure. Figure 6.8d demonstrates the capability of complex signal reconstruction based on Eq. 6.19. A reference subtraction has been performed; nevertheless a spurious DC term might still be visible. Figure 6.8c shows the result if a complex differential technique is applied. Such reconstruction is

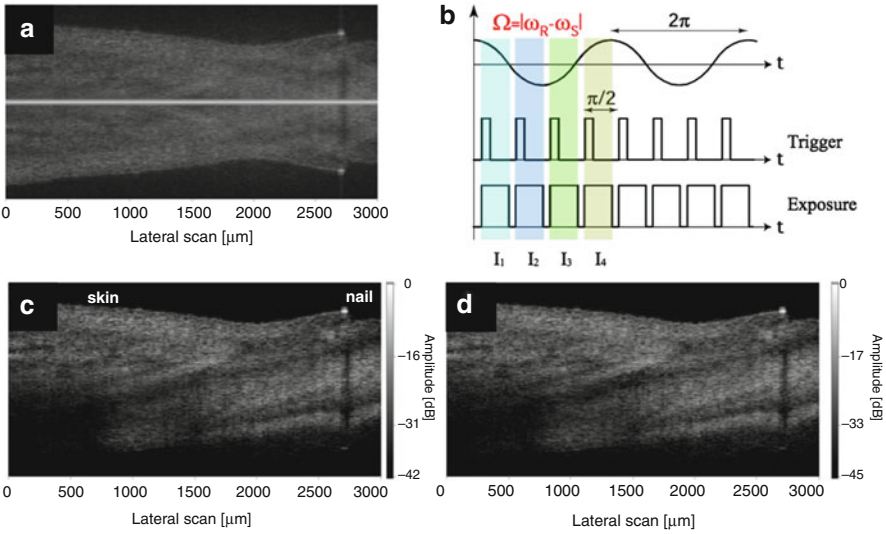

Fig. 6.8 (**a**) Tomogram of a fingernail fold region with standard FDOCT [52]. The zero delay is clearly visible as bright line due to the strong DC signal. (**b**) Integrated bucket method: the detector integrates over sections within the beating signal period. Four successive spectra I_{1-4} have an incremental delay of $\pi/2$. (**c**) Result of complex signal reconstruction according to Eq. 6.19 with reference subtraction. (**d**) As (**c**) but reconstruction of complex signal according to differential complex method. All tomograms are based on the same dataset. The depth range is 1.75 mm (in air)

achieved by the substitution $I'_D{}^{(0°)} = I_1 - I_3$ and $I'_D{}^{(90°)} = I_2 - I_4$ (Fig. 6.8b) into Eq. 6.2 [52]. It should however be mentioned that integrated bucked methods used in spectral OCT suffer in general from fringe washout, an effect discussed in Sect. 6.3.6. Still, this method has the potential together with array detectors based on CMOS technology to perform true heterodyne detection with spectral OCT. CMOS technology allows on-chip demodulation of the heterodyne signal such that only the AC part will subsequently be amplified and digitized.

Choma et al. followed a completely different approach by using the phase relation between the arms of a 3 × 3 fiber coupler and recording two phase-shifted copies of the interference pattern on separate detectors [53, 54].

6.3.2 Complex FdOCT with Phase-Shifting Techniques: *N* Frames

The first complex FdOCT systems [30, 55] needed five phase-shifted signals for five-frame phase retrieval algorithms adapted from white light interferometry [56]. In the simplified case of an interferometric setup with two virtual light sources, the light intensity measured by the detector is expressed as

$$I_D(\tau,\omega) = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\left(\phi(\tau,\omega)\right) \tag{6.20}$$

where I_1 and I_2 are DC light intensities and ϕ is the phase of the interferometric fringe signal, which can be analyzed as a function of optical delay (time domain) or optical frequencies (Fourier domain). I_1, I_2, and $\phi(\omega,\tau)$ are in general unknowns. In order to calculate these three unknowns, it is necessary to create set a minimum three linearly independent equations. This can be done by measuring three times the intensity signal with the additional phase shift introduced to each interference fringe pattern. The phase shift between adjacent measurements can be anything between 0 and π. Taking into account the phase shift errors, it is also possible to create overdetermined system of equations measuring $N > 3$ fringe patterns:

$$I_D^{[n]}(\tau,\omega) = I_1 + I_2 + 2\sqrt{I_1 I_2}\cos\left(\phi(\tau,\omega) + \Delta\phi_n\right) \qquad n = 1\ldots N, \tag{6.21}$$

with $\Delta\phi$, for example, given by $\Delta\phi = (n-1)\pi/2$. There are many possible algorithms retrieving the phase information based on extended set of measurements with linear phase shifts including three-, four-, five-, and six-frame techniques; Carre method; and others [56]. The five-frame method has been chosen for OCT applications because of its optimal performance in phase reconstruction [57] already known from white light interferometry. In this technique five consecutive measurements of the spectral fringes $I(\omega)$ are needed with a phase increment of π/2. The phase $\phi(\omega,\tau)$ and the amplitude of the fringe signal are calculated according to the following formulas:

$$\phi = \arctan\frac{2\left(I^{[2]} - I^{[4]}\right)}{2I^{[3]} - I^{[5]} - I^{[1]}} \tag{6.22}$$

$$2\sqrt{I_1 I_2} = \frac{1}{4}\sqrt{\left[2\left(I^{[2]} - I^{[4]}\right)\right]^2 + \left[2I^{[3]} - I^{[5]} - I^{[1]}\right]^2}, \tag{6.23}$$

where $\Delta\varphi = (n-1)\frac{\pi}{2}, \qquad n = 1, 2, \ldots, 5$, according to Eq. 6.21.

Figure 6.9 shows results of complex FdOCT imaging of porcine anterior segment in vitro obtained by the five-frame technique. The reconstruction is free from any ambiguities caused by the overlapping mirror images as well as presence of the coherence noise and DC terms. As a result the maximum achievable depth range is doubled.

6.3.3 Heterodyne Fourier Domain OCT Techniques

Fourier domain detection can be applied to optical coherence tomography either by simultaneous measurement of all spectral components of applied light by a spectrometer (Spectral OCT) or by detecting each single spectral component in

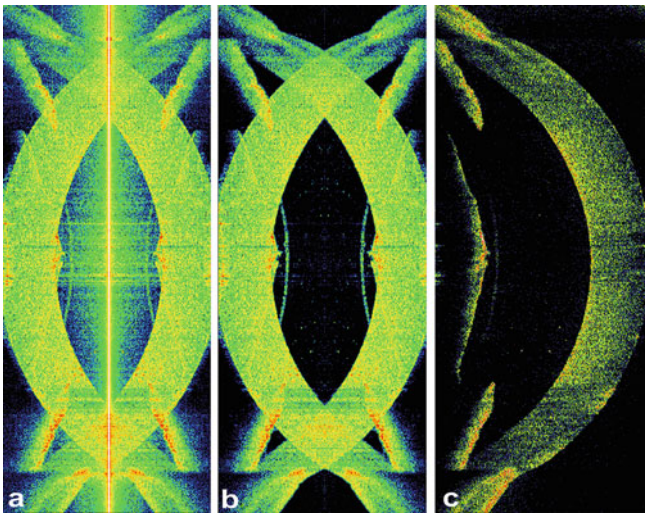

Fig. 6.9 Cross-sectional images of porcine anterior segment in vitro obtained with: (**a**) standard FdOCT technique, (**b**) differential FdOCT, (**c**) five-frame complex FdOCT

time by current generating photodiode synchronized with optical frequency sweeping light source (swept source OCT). The latter technique enables overlapping time-dependent effect of heterodyne beating with also time-dependent sweeping of optical frequencies. In result it is possible to introduce the carrier frequency to the spectral fringe signal and remove the complex conjugate artifacts by quadrature detection without doubling the measurement range. This idea has been introduced simultaneously by three groups [33, 34, 36] In the case of frequency shift of the spectral fringe signal, the carrier frequency introduced by the phase modulator placed in the reference arm of the OCT interferometer establishes the reference point for the zero optical path delay. The frequency shift is possible because the time domain and frequency domain detection both are mixed in the single OCT measurement:

$$I^{(\omega)}(\tau) = I_1^{(\omega)}(\tau) + I_2^{(\omega)}(\tau) + 2\sqrt{I_1^{(\omega)}(\tau) I_2^{(\omega)}(\tau)} \cos\left(\omega \cdot \tau_{Av} + \omega \cdot \tau(t)\right), \qquad (6.24)$$

where the measured light intensity fluctuation $I^{(\omega)}(\tau)$ is a function of optical delay τ varying in time with the parameter ω, which is also continuously swept in time, and τ_{Av} denotes the optical delay between the reference mirror and an object interface at the moment when the phase modulation is switched off. Even for very small amplitudes of $\tau(t)$ (order of magnitude of one optical wavelength), there is a full modulation of the detected light intensity signal – time domain interference fringe pattern. The optical delay $\tau(t)$ can vary periodically (phase modulator introduced to the reference arm of the OCT interferometer) giving the carrier frequency for the

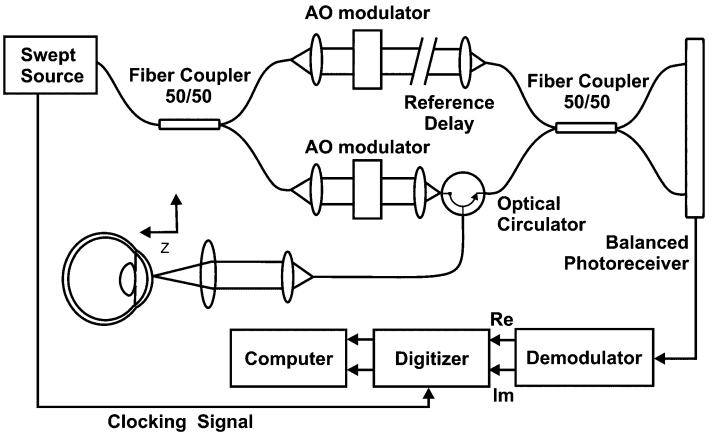

Fig. 6.10 Drawing of the heterodyne complex swept source FdOCT system with courtesy from Davis et al.

light intensity fluctuation signal. Additional sweep of the optical frequencies ω in time will provide light intensity fluctuations with the signal frequency proportional to the average optical delay between the reference mirror and an object – frequency domain interference fringe pattern. The carrier frequency from the time domain heterodyne modulation is then added to the Fourier domain frequency corresponding to the position of measured object, and in turn the zero path delay is shifted to arbitrary chosen position. Coherence noise terms and DC terms are automatically separated from the signal representing the axial structure of measured object. Appropriate frequency shift enables reconstructing OCT images without any image cross talk between positive and negative optical delays [36]. Also the real and imaginary terms of the interferometric signals can be found either numerically [34, 35] or by quadrature demodulation [33], and in turn the complex representation of the spectral interference fringe signal can be calculated. Figure 6.10 shows simplified schematic of the swept source OCT system with heterodyne complex detection proposed by Davis et al. Slightly different systems were also used by Zhang et al. and Yun et al. Davis et al. proposed design of the heterodyne complex FdOCT system using swept source with 1,310 nm central wavelength with 250 Hz sweeping rate, pair of acousto-optic modulators enabling the differential frequency shift of 1 MHz, and dual balanced receiver as a detector. Additional quadrature analog demodulation was applied. Part of the optical energy was also split to generate frequency clock enabling wavelength number triggering.

6.3.4 B-Mode Complex FdOCT Signal

Another interesting concept of complex OCT system combining heterodyne time domain beating with Fourier domain detection was proposed by Yasuno et al. [39].

This technique works analogically to the heterodyne complex method of the previous chapter. Instead of the carrier frequency in the single A-scan introduced by the phase modulator, the entire set of cross-sectional OCT data (B-scan direction) is analyzed. The phase modulation is introduced by periodical and continuous axial movement of the reference mirror synchronized with the lateral scanning. The time-dependent lateral scanning and time-dependent phase modulation mix together. Assuming low speed of the transverse scanning and analyzing each optical frequency separately, the low-frequency light intensity modulation caused by the lateral structure of an object and speckle pattern is now shifted by the frequency introduced by the beating of the time domain signal. In turn the low-frequency cross-correlation and DC terms are separated from the signals corresponding to the lateral structure of measured object. Similarly like in [34], a numerical Hilbert transformation is used, which together with high-pass filtering enables reconstructing the complex and coherence noise-free Fourier domain OCT signal. This technique has later on been reformulated for continuous reference arm shifting using the Hilbert transform [58].

Analysis of the influence of phase-shifting errors on the performance of this B-mode complex reconstruction shows much higher stability with respect to phase fluctuations. The same holds true for chromatic phase-shifting errors. This is manifested in terms of high mirror term suppression. Still, optimal B-mode reconstruction depends on the width of the lateral spatial frequency spectrum. It should be avoided that the width of the spatial frequency spectrum extends to the conjugate frequency plane. In case of under-sampling, in the presence of large motion artifacts, or for signals of flowing blood, conjugate mirror terms might be visible again, or structures might appear flipped in the conjugate Fourier plane.

The B-mode technique is the basis for an elegant, robust, and low-cost complex OCT system realization: instead of using a phase-shifting device such as piezo, electro-optic modulator, or AOFS, the natural path length change in case of off-pivot scanning is used for modulating the phase. Transverse scanning of the sample will then automatically produce a dynamic phase shift that serves as carrier frequency across the B-scan [59, 60]. The only drawback of this system is the rigid coupling between beam offset on the scanner from the pivot, scanning distance, and A-scan rate.

The essence of B-mode reconstruction is to analyze the signal in the spatial frequency domain. This opened in fact new perspectives not only for complex signal retrieval but also for advanced Doppler OCT methods [61–67]. Furthermore, the spatial carrier frequency across the B-scan can be used to encode signals for parallel registration, with a simple spatial Fourier filtering as decoding step. The latter principle of spatial frequency signal multiplexing has been applied for high-speed PSOCT with a single CMOS sensor [68]. A further extension is to use a time sequence of B-scans and analyze after careful registration the spatial frequency content in the temporal direction for each pixel. Such technique has been used for extracting stimulus responses from retinal photoreceptors using optical testing by FdOCT [69].

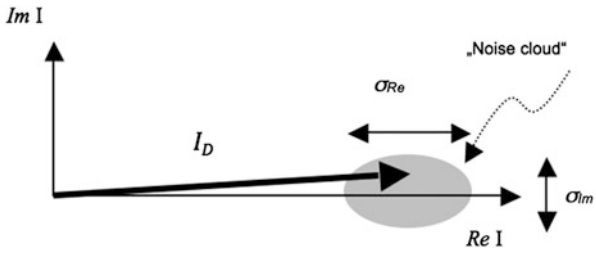

Fig. 6.11 Fluctuations of OCT signal phasor describe a "noise cloud" in the complex plane

6.3.5 Phase-Shifting Errors

The accuracy of reconstruction of the full complex sample field depends on the accuracy of the phase shift and on the phase stability of the interferometer in general. Phase-shifting errors will reduce the ability of the complex signal reconstruction to suppress the mirrored sample structure associated with the complex ambiguity. The most efficient way to reduce such errors is to increase the imaging speed. This has however the drawback of decreasing the system sensitivity. Another more time-consuming way are image processing techniques applied in a post-processing step. One can distinguish between system intrinsic statistical phase noise and systematic phase errors that are due to the phase-shifting process.

6.3.5.1 Statistical Phase Noise

Mechanical instabilities of the phase-shifting unit will contribute to stochastic errors. Such stochastic sample motion during in vivo measurements is in general problematic for phase-shifting methods. It might cause insufficient suppression of mirror terms and eventually deteriorate the actual sample structure reconstruction. Assuming that the FdOCT signal after Fourier transform is $\tilde{I}_D = \mathrm{Re}\,\tilde{I}_D + j\,\mathrm{Im}\,\tilde{I}_D$, both real and imaginary parts are subject to statistical noise. Hence the tip of the actual signal phasor lies within a noise cloud which boundaries are defined by the standard deviation of the complex signal fluctuations (Fig. 6.11). Without loss of generality we can assume the average signal phasor to point along the real axis. The fluctuations may be due to photon shot and excess noise, 1/f noise, detector dark and readout noise, or Johnson noise of the electronic amplification circuit. Let us assume that the system is shot noise limited, i.e., that photon shot noise is the dominating noise source.

Following Goodman [70], the noise variances of the real and imaginary part of the Fourier transformed spectral interference pattern $\tilde{I}_D$ are un-correlated and can be individually analyzed. In the shot noise limit, both variances are shown to be identical, i.e., $\sigma_{\mathrm{Im}}{}^2 = \sigma_{\mathrm{Re}}{}^2$. Now in view of Fig. 6.11, we can assume that the amplitude error is related to the fluctuations of the real part, whereas the phase error is related to the variance of the imaginary part which is responsible for the angular deviation from the original orientation along the real axis. The signal-to-noise ratio (SNR) can then be defined as $SNR = \left|\tilde{I}_D\right|^2 / \sigma_{\mathrm{Re}}{}^2$. In general the length of the phasor will

be much larger than the extensions of the noise cloud. Thus one can finally write for the statistical phase error in the shot noise limit

$$\sigma_{\varphi} \cong \sigma_{\mathrm{Im}} / \mathrm{Re}\, \tilde{I}_D \cong 1/\sqrt{\mathrm{SNR}}. \tag{6.25}$$

This phase error corresponds to a path length jitter amplitude of $\delta z = \lambda / \left(4\pi n \sqrt{SNR}\right)$, where λ_C is the center wavelength of the source and n is the refractive index of the medium. The same result was obtained by Choma et al. [71] with an alternative approach.

6.3.5.2 Systematic Phase-Shifting Noise

The main source of systematic errors is related to the fact that OCT employs broad optical bandwidth sources to achieve high axial resolution. A change in optical path length of the reference arm causes a corresponding phase shift of the cross-correlation terms according to

$$\Delta\Phi = \frac{4\pi\Delta z}{\lambda_c}, \tag{6.26}$$

where we took already into account the round trip path length in a Michelson interferometer setup. The associated change in reference arm delay is $\Delta\tau_R = \Delta\Phi\lambda_C/4\pi c$. Note the dependency on wavelength of the phase shift. A phase shift of $\pi/2$ corresponds therefore to different changes in path length Δz for each wavelength. Hence a phase shifting that is realized via reference path length variation gives rise to chromatic phase errors. As result one needs to look for achromatic phase-shifting techniques that allow combining high-axial-resolution OCT with complex detection. Section 6.3.5 gives an overview to different phase-shifting techniques including multiframe techniques to reduce systematic phase errors such as chromaticity. Creath and Schmid give a thorough phase error analysis for different multiframe phase reconstruction methods [57].

Nevertheless they are only of limited use for in vivo applications since sample motion introduces stochastic phase errors that can only be handled by elaborate post-processing algorithms. We saw earlier that under certain conditions, it is possible to reconstruct the complex sample structure by simply combining two frames with a $\pi/2$ phase shift. Equation 6.20 describes the chromatic phase errors that have to be considered, if the phase shifting is realized via reference path length modulation. If the chromatic phase error increases, the mirror terms in the adjoint Fourier space will no longer be suppressed and the complex reconstruction fails. Figure 6.12 shows a simulated FdOCT signal based on a simple two-frame complex signal reconstruction. The right Fourier half space contains the actual signals that correspond to a single interface in the sample arm. A central wavelength of 800 nm is assumed keeping always the same ratio between spectral width of the spectrum and that of the spectrometer. The adjoint mirror peak P* is visible in the gray-shaded left half space. The signal peaks are

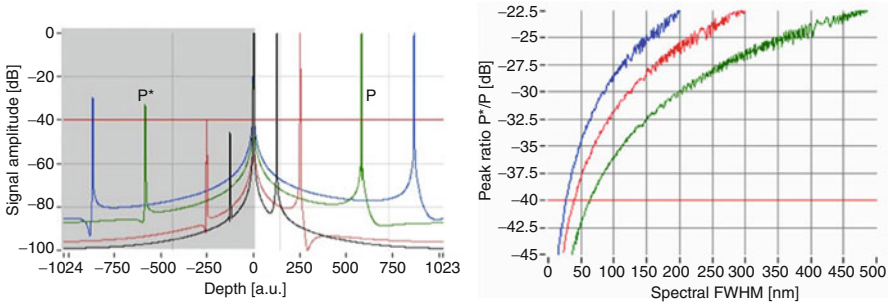

Fig. 6.12 Above −40 dB mirror terms become visible and the reconstruction algorithm fails. Leakage after discrete FFT causes the "noisy" characteristics of the curves on the (rhs) at larger bandwidths. The simulations assume Gaussian-shaped spectra

normalized to the true signal peak maximum P. The resulting signals for four different optical bandwidths are shown (20 nm (black), 40 nm (red), 100 nm (green), and 150 nm (blue)). Figure 6.12 (rhs) displays the suppression ratio of the mirror term peak P* with respect to the actual signal peak P for three different central wavelengths as a function of optical bandwidth ($\lambda_0 = 550$ nm (blue), $\lambda_0 = 800$ nm (red), $\lambda_0 = 1{,}300$ nm (green)). Assuming a typical dynamic range in an OCT tomogram of 30–40 dB, we observe that the mirror terms are suppressed only for standard resolution complex FdOCT corresponding to a bandwidth at 800 nm of ∼20 nm. However, for high-resolution systems with bandwidths above 40 nm, mirror terms become visible. The two-frame algorithm is better suited for in vivo complex FdOCT due to higher registration speed than multiframe algorithms. The simulation presented in Fig. 6.12 however stresses the need for a true achromatic complex reconstruction scheme in particular for high-resolution FdOCT.

6.3.6 Fringe Washout

Spectral OCT has the advantage of being highly phase stable since the full interference pattern is recorded at once. This advantage is shared neither by conventional time domain OCT nor by wavelength tuning FdOCT. Nevertheless this advantage turns to a disadvantage in the presence of relative axial movements between sample and reference. In this case the fringe pattern across the array detector will shift during the signal integration. As a result the effective modulation depth and thus the system sensitivity decrease. This effect has been first pointed out in 2003 [3, 29] and has been analytically analyzed by Yun et al. [72] and later on by Bachmann et al. [73]. Let us assume for the sake of simplicity a single interface in the sample arm of a Michelson interferometer that is moving a distance $\delta z = v\tau$ at constant speed v during integration time τ. Neglecting the intensity DC offset, the spectral interference pattern $I_{AC}(k)$ becomes

$$I_{AC}(k) = 2\sqrt{I_r I_s} \int_{-\tau/2}^{+\tau/2} \cos\left[2k(\Delta z + vt)\right]dt = 2\sqrt{I_r I_s}\,\mathrm{sinc}(k\delta z)\cos\left(2k\Delta z\right). \quad (6.27)$$

The axial motion gives then approximately rise to decay in SNR proportional to $\mathrm{sinc}^2(k_0\delta z)$, with k_0 the center wavenumber of the source spectrum. The approximation holds for small displacements during integration $|\delta z| << \Delta z$. In 2002 first in vivo images of retinal structures obtained with spectral OCT were presented by employing a chopper to limit the exposure time to reduce fringe washout [6]. Yun et al. [74] suggested to use pulsed sources for in vivo imaging. In both cases the actual illumination time is much shorter than the overall integration time, and motion artifacts are less prominent.

The effect of fringe washout is even more critical in case of Doppler OCT when structures with axial motion components need to be resolved. Large blood vessels appear therefore often with empty central areas in spectral OCT, since the high velocities cause interference fringe blurring at thus complete SNR loss. The associated effect for swept source FdOCT in the presence of axial motion is a spectral chirp. As a consequence the swept source FdOCT signal will be broadened. This causes as well-reduced signal peak height, since the OCT signal energy needs to be conserved. Nevertheless, the experienced loss due to axial motion as much less pronounced than for spectral OCT.

As a final remark, fringe washout can also be turned to an advantage, especially when used as filtering technique. Using a heterodyne signal modulation, for example, by oscillating the reference path length causes static structures to be reduced in SNR, whereas commonly fluctuating sample signals will be enhanced. This principle is used in resonant Doppler OCT [73] as well as in a recent realization of thermal contrast OCM [75].

6.3.7 Software Methods (Ghosts Cleaning Algorithms, Dispersion)

Discrete frame methods have the advantage of being quasi achromatic and correct for the intrinsic phase error. Nevertheless their use for in vivo imaging [32] is limited since motion artifacts introduce stochastic phase errors that can only be handled by elaborate post-processing algorithms [31, 76]. Phase errors cause the appearance of residual conjugate images. In order to cancel such "ghost" images Targowski et al. [31] proposed a post-processing iterative phase optimization technique. In this technique the first approximation of phase shifts $\Delta\phi_n$ may be determined from known N mirror displacements. These phases are introduced into the system of Eq. 6.26, and an "unwrapped" image can be reconstructed using a general least square algorithm [56]. In order to remove "ghost" images caused by sample motion (stochastic phase error), N values of $\Delta\phi_n$ have to be adjusted to minimize the function:

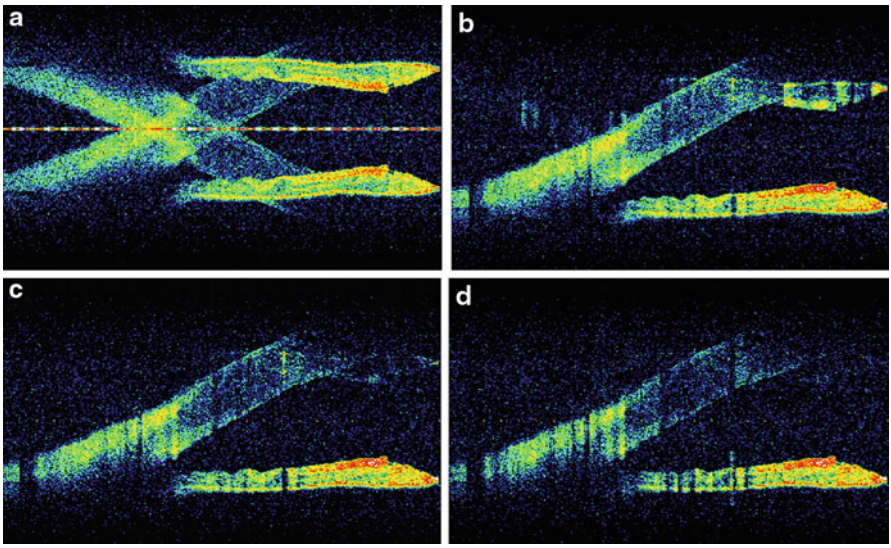

Fig. 6.13 Cross-sectional images of the corneoscleral angle of the human eye in vivo obtained with: (**a**) regular spectral OCT system, (**b**) complex FdOCT measurement with random value of the phase shift increment, (**c**) complex FdOCT measurement with calibrated value of the phase shift increment and (**d**) complex FdOCT measurement with optimized phase shift increment

$$R(\Delta\phi_1, \Delta\phi_2, .., \Delta\phi_N) = \frac{1}{K}\sum_k [\mathbf{V}_k \cdot \mathbf{V}_{k-k}] \tag{6.28}$$

where $\mathbf{V}_k$ is the intensity in kth point of A-scan obtained with complex method, $\mathbf{V}_{K-\,k}$ is the intensity at its mirror image, and the function R represents the level of correlation between the A-scan ($\mathbf{V}_k$) and its mirror image ($\mathbf{V}_{K-k}$).

Directly measured SOCT image and three complex SOCT images of human corneoscleral angle in vivo reconstructed by different algorithms are compared in Fig. 6.13. Application of the complex technique with random value for the phase shift increment causes appearance of a strong residual conjugate image that overlaps with the actual structure of the measured sample (Fig. 6.13b). Exact calibration of the phase shift increment based on complex measurements of a single reflector reduces the intensity of the "ghost" image. Still, involuntary movements of the subject's head prevent its complete cancellation (Fig. 6.13c). Additional iterative phase optimization Eq. 6.28 enables a total removal of the parasitic images from the cross-sectional complex reconstruction.

For completeness we should mention two additional techniques that allow for suppression of coherent FdOCT imaging artifacts in post-processing without the need for phase-shifting devices. The first technique offers the possibility to reduce autocorrelation noise artifacts. This is achieved by adapting a technique known from ultrasound imaging that operates on the logarithmically scaled recorded

spectrum, the so-called cepstrum [77]. The logarithm basically allows separation of autocorrelation from cross-correlation terms Eq. 6.14, in case, the cross-correlation terms do not overlap with their complex conjugate. Hence it does not yield the full complex sample signal by suppressing also the complex conjugate mirror terms. This is possible with the second mentioned technique that uses the fact that dispersion acts differently on the signal and its complex conjugate. This is easily seen from expanding the dispersion into a Taylor series and from the fact that the complex conjugate term exhibits negative path length differences. Hence impair terms flip the sign of path length differences of the complex conjugate term causing an asymmetry with respect to dispersion. Dispersion encoded complex reconstruction (DEFR) iteratively broadens and as such reduces then the complex conjugate signals by adapting a numerically introduced dispersion term [78].

6.4 Summary

This chapter gives a detailed analysis of phase-sensitive FdOCT detection starting from modeling of a complex sample structure to explaining the meaning of FdOCT signal phase and demonstrating different phase reconstruction schemes. For a better understanding of limitations of signal phase reconstruction, a full section is devoted to phase errors. The chapter outlines the problems of FdOCT detection and gives solutions of how to avoid, reduce, and remove FdOCT signal reconstruction artifacts. Some examples of phase-sensitive FdOCT applications are added to underline the potential of coherent detection having phase information at hand.

Acknowledgments We would like to acknowledge Andrzej Kowalczyk and Maciej Szkulmowski from NCU Torun for their assistance in the theoretical and experimental work on phase-sensitive SOCT. We also gratefully acknowledge helpful advices from Robert Zawadzki from UC Davis; Christoph Hitzenberger, Wolfgang Drexler, Leopold Schmetterer, and Michael Pircher from Medical University of Vienna; and Theo Lasser and Adrian Bachmann from EPFL Lausanne. We also would like to place special acknowledgments to Prof. Adolf Fercher for his scientific contribution and support.

7.1 Introduction

In most OCT systems, one-dimensional (depth) ranging is provided by low-coherence interferometry [1, 2] in which the optical path length difference between the interferometer reference and sample arms is scanned linearly in time. This embodiment of OCT, referred to as "time-domain OCT," has demonstrated promising results for minimally invasive, early detection of disease. The relatively slow imaging speed (approximately 2 kHz A-line rate) of time-domain OCT systems, however, has precluded its use for the screening of large tissue volumes, which is required for a wide variety of medical applications. Imaging speed has a fundamental significance because of its relationship to detection sensitivity (minimum detectable reflectivity). As the A-line rate increases, the detection bandwidth should be increased proportionally, and therefore, the sensitivity drops. The sensitivity of state-of-the-art time-domain OCT systems that operate at 2 kHz ranges between −105 and −110 dB. Most biomedical applications require this level of

sensitivity for sufficient depth of penetration and cannot tolerate a reduction in sensitivity to achieve a higher frame rate. Although increasing the optical power would, in principle, improve the sensitivity, available sources and maximum permissible exposure levels of tissue represent significant practical limitations.

One potential solution to high-speed imaging is offered by spectral-domain OCT ("spectral radar") where individual spectral components of low-coherence light are detected separately by the use of a spectrometer and a charge-coupled device (CCD) array [3, 4]. The fast readout speed of CCD arrays and the signal-to-noise ratio (SNR) advantage of the spectral-domain OCT [5–7] make it promising for some high-speed and low-power applications. However, the use of CCD arrays may cause problems associated with phase washout by changes in the sample-arm length during the pixel integration time [7]. Furthermore, for this scheme, the implementation of balanced detection and polarization diversity which may be needed for in vivo endoscopic imaging is challenging.

In this chapter, we discuss another frequency-domain approach, optical frequency-domain imaging (OFDI), which is based on optical frequency-domain reflectometry [8–10] and uses a wavelength-swept laser and standard single-element photodetectors. The chapter begins with an overview of the fundamental aspects of the technology, including the detected signal, sensitivity, depth range, and resolution, and then goes on to discuss specific component technologies including the light source, interferometer and acquisition electronics, and image processing. The final section of the chapter provides a brief glimpse at some of the biomedical applications that most directly take advantage of the improved speed and sensitivity of OFDI.

7.2 Principles of Operation

7.2.1 Frequency-Domain Signal

Figure 7.1 shows the basic configuration of OFDR using a tunable light source and a fiber-optic interferometer. The output of the source is split into a reference arm and a sample arm which illuminates and receives the light reflected from within the sample. The interference between the reference- and sample-arm light is detected with a square-law photodetector, while the wavelength of the monochromatic source is swept and the path lengths of the reference and sample arm are held

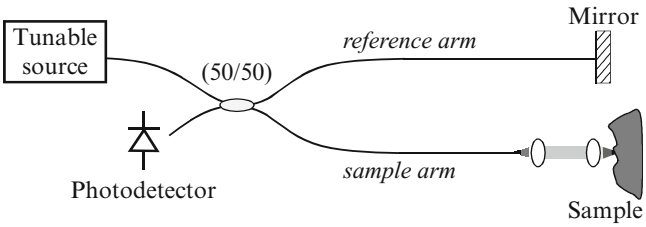

Fig. 7.1 Basic configuration of OFDR optical system

constant. The axial reflectivity profile (A-line) is obtained by discrete Fourier transform (DFT) of the sampled detector signals [8].

The detector current can be expressed as

$$i_{\mathrm{det}}(t) = \frac{\eta q}{hv}\left(P_r + P_o\int r^2(z)dz + 2\sqrt{P_r P_o}\int r(z)\Gamma(z)\cos\left(2k(t)z + \phi(z)\right)dz\right), \tag{7.1}$$

where η is the detector sensitivity, q the quantum of electric charge (1.6×10^{-19} C), hv the single photon energy, P_r the optical power reflected from the reference arm at the photodetector, and P_o the optical power illuminating the sample. The third term represents the interferometric signal, and the first and second terms contribute to the noninterference background. Here, z is the axial coordinate where $z = 0$ corresponds to zero optical path length difference between the two interferometric arms, $r(z)$ and $\phi(z)$ are the amplitude and phase of the reflectance profile of the sample, respectively; $\Gamma(z)$ is the coherence function of the instantaneous laser output; and $k(t) = 2\pi/\lambda(t)$ is the wavenumber which is varied in time monotonically by tuning of the laser. It can be readily seen that the interferometric signal current is related to the reflection profile via the Fourier transform relation. In practice, the detector output is digitized and sampled into a finite number of data points, and a discrete Fourier transform (DFT) is performed to construct an axial scan or A-line.

For a wavelength-swept laser with a Gaussian-profile spectral envelope, the axial resolution is given by [11]

$$\delta z = \frac{2\ln 2}{\pi}\frac{{\lambda_o}^2}{n\Delta\lambda}, \tag{7.2}$$

where λ_o is the center wavelength, $\Delta\lambda$ is the full width at half maximum (FWHM) of the spectral envelope (tuning range), and n is the group refractive index of the sample. The depth range Δz in the Fourier domain is given by [4]

$$\Delta z = \frac{{\lambda_o}^2}{4n\delta\lambda}, \tag{7.3}$$

where $\delta\lambda = \Delta\lambda/N_s$ is the sampling wavelength interval and N_s is the number of samples within FWHM range of the spectrum $\Delta\lambda$. The sampling interval should be smaller than the instantaneous linewidth of the source; otherwise, the amplitude of the coherence function will decay with z, limiting the usable ranging depth.

7.2.2 Detection Sensitivity

For simplicity, let us consider the case of a single reflector located at $z = z_0$ with reflectivity r^2. We assume that the linewidth is sufficiently narrow so that $\Gamma(z) = 1$ within the depth range. The signal current, $i_s(t)$, can be expressed as

$$i_s(t) = \frac{\eta q}{h\nu} \cdot 2\sqrt{P_r P_s} \cos\left(2k(t)z_0\right), \tag{7.4}$$

where $P_s = r^2 P_0$ denotes the optical power reflected from the sample at the photodetector. In reality, the detector current consists of both signal and noise components such that $i(t) = i_s(t) + i_n(t)$. The well-known expression for the noise power $\langle {i_n}^2 \rangle$ is given by [12]

$$\left\langle i_n^2(t) \right\rangle = \left(i_{th}^2 + 2\frac{\eta q^2}{h\nu}(P_r + P_s) + \left(\frac{\eta q}{h\nu}\right)^2 RIN(P_r + P_s)^2 \right) BW, \tag{7.5}$$

where the three terms on the right-hand side represent thermal noise, shot noise, and the relative intensity noise (RIN) of the source (polarized), respectively. Brackets $< >$ denote a time average, *i*th the detector noise current, *RIN* the relative intensity noise given in unit of Hz^{-1}, and *BW* the detection bandwidth. The detection bandwidth can be chosen equal to half the sampling rate as specified by the Nyquist.

For simplicity, let us assume a square-profile spectral envelope and 100 % tuning duty cycle, i.e., the output power of the source is constant in time. Let F_s and F_n denote the Fourier transform samples of signal and noise currents, i_s and i_n, respectively, following DFT via

$$F(z_l) = \sum_{\mathrm{m}=0}^{\mathrm{N_s}-1} i(k_m) \cdot \exp^{-j2\pi lm/N_s} \tag{7.6}$$

Note that the wavenumber and axial coordinate are conjugates to each other through DFT. In the Fourier domain, the absolute square of the peak value of F_s at $z_l = z_0$ is proportional to the reflectivity. Parseval's theorem, $\sum F^2 = N_s \sum i^2$, holds for both signal and noise. In the case of Nyquist sampling (i.e., the sampling rate is equal to twice the detection bandwidth), the sampled data of noise current are mutually uncorrelated [6, 7]. Therefore, the noise power level in the Fourier domain is given by $\langle F_n^2 \rangle = N_s \langle i_n^2 \rangle$. On the other hand, the signal power ${F_s}^2$ is zero except at $z_l = z_0$. Since there are two peaks corresponding to positive and negative frequency components, using $|F_s(z_0)|^2 = (N_s^2/2)\langle i_s^2 \rangle$ leads to

$$(SNR)_{FD} = \frac{|F_s(z_0)|^2}{\left\langle F_n^2 \right\rangle} = \frac{N_s}{2}(SNR)_{TD}, \tag{7.7}$$

where

$$(SNR)_{TD} = \frac{\left\langle i_s^2(t) \right\rangle}{\left\langle i_n^2(t) \right\rangle} \tag{7.8}$$

Here, the latter is defined as the ratio of the signal and noise power in the time domain. These equations indicate that frequency-domain ranging provides an SNR

improvement by a factor of $N_s/2$ compared with time-domain ranging [13]. A similar expression to Eq. 7.7 has been identified by Leigeb et al. [7] and de Boer et al. [6] for spectral-domain OCT and also by Choma et al. [5] for OFDR using a wavelength-swept laser.

It can be shown that Eq. 7.7 is valid for a more general case where the tuning duty cycle is less than 100 %, the source's spectral envelope has a Gaussian profile, and the sampling range spans beyond the FWHM of the source spectrum. In this case, N_s is the number of sampling points within the FWHM of the source and the optical powers, P_r and P_s, would be the time-average value over one tuning cycle. For a shot-noise-limited system, Eqs. 7.5 and 7.7 with $P_s \ll P_r$ lead to

$$(SNR)_{FD} \approx \frac{\eta P_s}{h\nu f_A}, \tag{7.9}$$

where f_A is the A-line rate which is the same as the tuning rate of the source. Therefore, the effective detection bandwidth in OFDR is equal to the A-line scan rate instead of the detector bandwidth.

Equation 7.7 can also be expressed in terms of the number of spatially resolvable points in a ranging depth, $N_R = \Delta z/\delta z$, as

$$(SNR)_{FD} = N_R (SNR)_{TD} \tag{7.10}$$

This expression compares the SNR of two ranging methods, time domain and frequency domain, at the same imaging speed (A-line rate), axial resolution, and ranging depth. Note that a time-domain OCT system requires a detection bandwidth of $N_R f_A$, whereas the effective noise bandwidth of OFDI is f_A.

The sensitivity is defined as the reflectivity that produces signal power equal to the noise power. Therefore, it follows from Eq. 7.9 and $P_s = r^2 P_0$ that

$$Sensitivity[dB] = -10 \log\left(\frac{\eta P_0}{h\nu f_A}\right) \tag{7.11}$$

The relative intensity noise (RIN) of polarized thermal light is proportional to the reciprocal of the linewidth [12] and would have a value of −97 dB/Hz for a linewidth of 0.06 nm (10 GHz). In general, RIN of laser light is different from that of thermal light. However, laser light consisting of many longitudinal modes with random phases would exhibit a peak RIN level similar to that of thermal light of the same linewidth. The mode hopping associated with wavelength tuning and mode competition contributes to the frequency dependence of RIN. The RIN level of our laser had a peak value of approximately −100 dB/Hz near DC frequency, decreasing to −120 dB/Hz at 5 MHz. To reduce the source's RIN, dual-balanced detection was employed [14]. The differential current of two InGaAs detectors D1 and D2 was amplified using transimpedance amplifiers (TIA, total gain of 56 dB) and passed through a low-pass filter (LPF) with a 3-dB cutoff frequency at 5 MHz and excess voltage loss of 3 dB. The common-noise rejection efficiency of the

receiver was approximately 25 dB in the range between DC and 5 MHz. In addition to RIN reduction, the balanced detection provides multiple benefits; it suppresses self-interference noise [7] originating from multiple reflections within the sample and optical components; it also improves the dynamic range and reduces fixed-pattern noise by greatly reducing the strong background signal from the reference light.

In the case of dual-balanced detection, the signal power in Eq. 7.4 can be expressed as

$$\left\langle i_s^2(t)\right\rangle = \left(\frac{\eta q}{h\nu}\right)^2 \left\langle \sum^2 2p_r p_s \cos\left(kz\right)\right\rangle^2 = 8\left(\frac{\eta q}{h\nu}\right)^2 p_r p_s, \tag{7.12}$$

where $p_r = P_r/2$ and $p_s = P_s/2$ denote the reference and signal power per photodiode. The noise power expression in Eq. 7.5 can be modified to

$$\begin{aligned}\left\langle i_n^2(t)\right\rangle = &\left(\frac{i_{qn}^2}{G^2} + \frac{i_{ex}^2}{G^2} + i_{th}^2 + 2\frac{\eta q^2}{h\nu}\sum^2 \left(p_r + p_s\right)\right.\\ &\left. + \left(\frac{\eta q}{h\nu}\right)^2 RIN\left\{\sum^2 \zeta\left(p_r^2 + p_s^2\right) + \sum^2 2p_r p_s\right\}\right) BW\end{aligned} \tag{7.13}$$

Here, the first and second terms are introduced to take into account the quantization noise and excess electrical noise generated in the DAQ board. G denotes the total gain of the receiver. The third term is the thermal noise of the dual-balanced receiver. The fourth term represents the total shot noise which is a sum of the shot noise from the individual photodiodes. The fifth term expresses the RIN noise with ζ denoting the common-mode rejection efficiency of the balanced receiver. It should be noted that the dual-balanced receiver provides RIN suppression only to the RIN component associated with intraband self-beating. The cross-beating noise, as a result of the incoherent interference between p_r and p_s, is not canceled. When $\zeta \ll 1$, the cross-beating RIN component may not be negligible compared to the self-beating RIN component although p_s is weaker than p_r. In practice, the first two terms, quantization and excess noise, can be made negligible by choosing a sufficiently high gain (e.g., $G = 2 \times 10^5$) [13].

7.3 Instrumentation

7.3.1 Light Source and Interferometer

Light sources appropriate for OFDI are discussed in detail in ▶ Chap. 12, "Linear OCT Systems". In the context of this chapter, it will be sufficient to briefly consider the relevant laser characteristics and their implications for high-speed imaging.

The laser specifications having the greatest significance for OFDI include wavelength sweep range, sweep repetition rate, linearity of sweep, power, and instantaneous linewidth. The primary relevance of the source wavelength-scanning range for OFDI is axial resolution. For imaging at a center wavelength of 1.3 μm where attenuation in biological tissues is low, a scanning range of more than 100 nm is required to achieve a resolution comparable with previous-generation time-domain OCT systems. Consideration of laser repetition rate is similarly straightforward; the image A-line acquisition rate is directly determined by the laser repetition rate. For imaging at speeds of 100 frames per second, a repetition rate of >50 kHz is required. The linearity of the wavelength-scan, however, is somewhat more subtle. Although nonlinear scanning can, in principle, be accommodated by sophisticated acquisition electronics, the ideal laser for OFDI would provide a highly linear k-space scan. Fortunately, achieving all of these specifications is now possible while simultaneously producing sufficient power in order to preserve clinically relevant sensitivity. Typical performance specifications have been on the order of 10s of mW of polarized laser power.

As described in the previous sections of this chapter, the instantaneous linewidth of the laser determines the ranging depth and the falloff of sensitivity with ranging depth. For many OFDI applications, an instantaneous linewidth of 0.1 nm-0.2 nm (roughly 20–40 GHz) is sufficient. It is interesting to note that this linewidth is significantly greater than that provided by most wavelength-swept lasers that preceded the development of OFDI. Prior swept lasers were primarily developed for high-resolution spectroscopy where single-longitudinal-mode oscillation is essential and linewidths below 1 MHz are routinely achieved. Relaxing the linewidth specification allows for more rapid tuning without concerns for longitudinal mode hopping.

In order to achieve the greatest possible ranging depth, it would be preferred to use the full instantaneous coherence length of the laser source. Equation 7.4, however, indicates that positive and negative depths, relative to the reference delay, are encoded by the same magnitude of frequency. Since it is not possible to distinguish between a positive and negative electrical frequency in conventional interferometry, OFDI requires alternative interferometer designs to break the depth degeneracy and achieve full ranging depth. Solutions to this challenge can be achieved through the use of quadrature interference signals. Approaches have included active- or passive-phase biasing using piezoelectric actuators [15], birefringent plates [16], and fused fiber 3 × 3 couplers [17]. These techniques can unfold otherwise overlapping images associated with positive and negative depths, but tend to leave residual artifacts due to the difficulty of producing stable quadrature signals. An alternative approach uses an optical frequency shifter in the interferometer to provide a constant frequency shift of the detector signal. This method allows both sides of the coherence range to be used without crosstalk and doubles the ranging depth. The same concept has been described previously in the context of 1-dimensional optical frequency-domain reflectometry using rotating birefringent plates [19] at 58 Hz or a recirculating frequency-shifting loop [16].

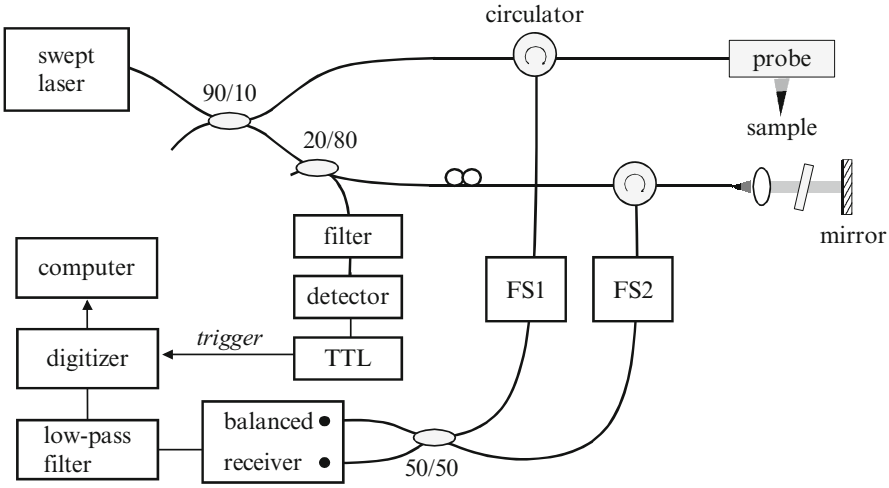

Fig. 7.2 OFDI system schematic

Figure 7.2 depicts a simplified OFDI system comprising a wavelength-swept source, a single-mode-fiber interferometer employing an optical frequency shifter in the reference arm, a photodetector, and a signal processor [18]. Since the optical glass used in acousto-optic frequency shifters can exhibit high dispersion, it is preferable to insert a matching glass within the interferometer sample arm. With a round-trip frequency shift of Δf in the reference arm and an interferometer path length difference (or depth) of z, the detector signal can be expressed as

$$i_s(t) = 2\eta\sqrt{P_r(t)P_s(t)}\int \sqrt{R(z)}\;\; G(|z|)\cos\left[\frac{4\pi}{c}v(t)z + \phi(z) + 2\pi\Delta f t\right]dz, \quad (7.14)$$

where η denotes the quantum efficiency of the detector; $P_r(t)$ and $P_s(t)$ the optical powers of the reference and sample-arm light, respectively; $R(z)$ the reflectivity profile of the sample; $G(|z|)$ the coherence function corresponding to the fringe visibility; c the speed of light; $v(t)$ the optical frequency; and $\phi(z)$ the phase of backscattering. For linear tuning, i.e., $v(t) = v_0 - v_1 t$, the frequency of the detector signal is given by

$$f_s = \left|v_1\frac{2z}{c} - \Delta f\right|. \quad (7.15)$$

A signal frequency of zero (DC) corresponds to a depth $z = c\Delta f/(2v_1)$. Therefore, by choosing Δf and v_1 to have opposite signs, the zero signal frequency can be made to point to a negative depth.

7.3.2 Sampling and Data Processing

Nonlinearity in the frequency sweep of the laser results in a chirping of the signal at a constant depth and causes a degradation of axial resolution [16, 19]. As a solution to this problem, the detector signal may be sampled with nonlinear time intervals compensating for the frequency chirp. Alternatively, the detector signal can be sampled with a constant time interval if the sampled data is remapped to a uniform v-space by interpolation prior to discrete Fourier transform (DFT) [20]. Both methods have been demonstrated to yield a transform-limited axial resolution given by the tuning spectral range of the source.

These methods, however, are not directly applicable in the frequency-shifting technique. Both nonlinear sampling and the interpolation method result in artificial chirping of the frequency shift, leading to suboptimal axial resolution. Alternatively, a modified interpolation method based on frequency shifting and zero padding can be used to achieve nearly transform-limited axial resolution over the entire ranging depth. An exemplary algorithm includes the following:

Step 1. Obtain N samples of the signal with uniform time interval during each wavelength sweep of the source.
Step 2. Calculate DFT of N data points in the electrical frequency domain.
Step 3. Separate two frequency bands below and above Δf corresponding to negative and positive depths, respectively.
Step 4. Shift each frequency band such that the zero depth is aligned to the zero electrical frequency.
Step 5. Apply zero-padding to each frequency band and calculate inverse DFT resulting in an array of increased number of samples in the time domain with smaller time interval for each frequency band.
Step 6. Interpolate each array in the time domain into a uniform v space using a mapping function calibrated to the nonlinearity of the source with linear interpolation. The mapping function can be obtained using an unbalanced interferometer.
Step 7. Calculate DFT of each interpolated array.
Step 8. Combine the two arrays (images) by shifting the array index.

Yun et al. [18] have demonstrated that the above algorithm, coupled with the interferometer design of Fig. 7.2, can be used to achieve a twofold increase of the effective ranging depth of OFDI. Measurements of the system axial resolution indicated that the interpolation algorithm compensated for laser tuning nonlinearity and yielded transform-limited resolution throughout the extended ranging depth.

7.4 Motion Artifacts

Image artifacts resulting from motion have been important topics of research in nearly all medical imaging modalities because they may degrade the image quality and cause inaccurate clinical interpretation of images [21–23]. Artifacts can arise when an object being imaged (sample) is moved during data acquisition but is assumed stationary in the image reconstruction process. In each imaging modality, motion artifacts can present in different forms and with different magnitudes. Understanding basic motion effects in a particular imaging method is an essential step toward the development of techniques to avoid or compensate resulting artifacts.

In the following analysis, it is assumed that the source emits light according to $k(t) = k_0 + k_1 t$, where $k = 2\pi/\lambda$ is the wavenumber, λ is the optical wavelength, t is the time spanning from $-T/2$ to $T/2$, and T is the wavelength-sweep period or equivalently A-line period. Further, we assume a Gaussian tuning envelope given by

$$P_{out}(t) = P_0 \ \exp\left[-4\ln 2 t^2/(\sigma T)^2\right], \tag{7.16}$$

where $P_{out}(t)$ denotes the output power of the source and σT the full width at half maximum (FWHM) of the tuning envelope. Equation 7.16 also describes the Gaussian spectral envelope of the source, where $\sigma k_1 T$ corresponds to the FWHM tuning range in wavenumber. Let (x, y, z) denote the coordinate of a reference frame fixed to the sample, $r(x, y, z)$ represents the complex-valued backscattering coefficient of the sample which is characterized by both local variations of the refractive index and the round-trip attenuation of light in the sample, $g(x, y, z)$ denotes the intensity profile of the probe beam normalized to $\int\int g\, dx\, dy = 1$, and (x_b, y_b, z_b) denotes the coordinates of the probe beam at zero path length difference of the interferometer. For a Gaussian beam with a large confocal parameter, the intensity profile is given by

$$g(x, y, z) \approx \frac{4\ln 2}{\pi {w_0}^2} \exp\left[-4\ln 2\left(x^2 + y^2\right)/{w_0}^2\right], \tag{7.17}$$

where w_0 denotes the full width at half maximum (FWHM) of the beam profile. The explicit dependence of the OFDI signal on the intensity profile, g, rather than an electric field profile of the probe beam can be understood by considering the mode field profile of the sample-arm fiber, which is by definition given by Eq. 7.17 at the sample location. The amplitude of the backscattered light received by the sample-arm fiber is determined by an overlap integral between the scattered field and the mode field.

It has been shown [24] that the complex-valued depth profile can be represented using the above notation as

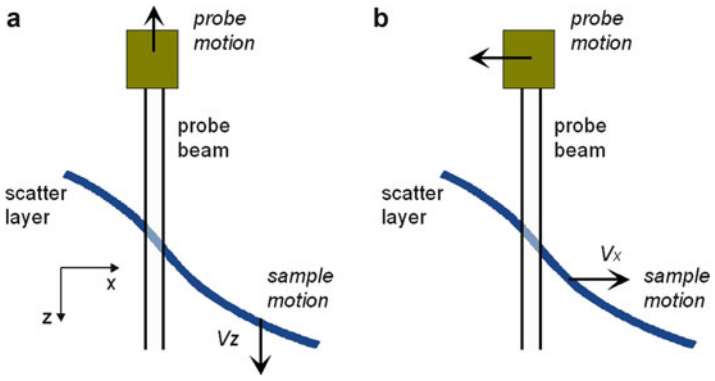

Fig. 7.3 Geometry for considering the effects of axial and transverse motion

$$F(Z) \propto \frac{\gamma P_0}{{w_0}^2 \delta z_0} \iiint dxdydz \;\; r(x,y,z) e^{-i2k_0(z-z_b)} \\ e^{-4\ln 2 \frac{(x-x_b)^2}{{w_0}^2}} e^{-4\ln 2 \frac{(y-y_b)^2}{{w_0}^2}} e^{-4\ln 2 \frac{\{Z+z_b-z(x,y)\}^2}{{\delta z_0}^2}}, \tag{7.18}$$

where $\delta z_0 = 41\mathrm{n}2/(k_1 T\sigma)$ denotes the FWHM axial resolution neglecting the effect of truncation of a Gaussian spectrum. Equation 7.18 states that the amplitude of $F(Z)$ is proportional to a coherent sum of all backscattered light from a coherence volume that has a size $w_0 \times w_0 \times \delta z_0$ and is located at a depth Z in the sample.

7.4.1 Axial Motion

Figure 7.3a depicts a situation with an axially moving sample and probe. The interference signal is solely dependent on the relative motion between the scatterer and the probe beam; sample motion is identical to probe motion with the opposite velocity. Therefore, we will assume a stationary probe and consider a sample moving at a uniform velocity without loss of generality.

The signal in the presence of axial motion can be obtained by substituting $z_b(t) = z - z_0 - v_z t$ into Eq. 7.18 where $z_0 = z\text{–}z_b(0)$ denotes the mean path length difference and v_z the axial velocity of the sample. The depth profile is obtained via the Fourier transform:

$$F(Z) \approx \gamma P_0 \iiint dxdydz \;\; r(x,y,z) g(x-x_b, y-y_b) \\ \int_{-\infty}^{\infty} e^{-4\ln 2 \frac{\kappa^2}{(2k_1 T\sigma)^2}} e^{i(2k_0+\kappa)\left(Z - z_0 - \frac{v_z}{2k_1}\kappa\right)} d\kappa \tag{7.19}$$

$$\propto \frac{\gamma P_0}{{w_0}^2 \delta z} \iiint dxdydz \;\; r(x,y,z) e^{-i2k_0 z_0} e^{-4\ln 2 \frac{(x-x_b)^2}{{w_0}^2}} e^{-4\ln 2 \frac{(y-y_b)^2}{{w_0}^2}} e^{-4\ln 2 \frac{\{Z-[z_0+(k_0/k_1 T)\Delta z]\}^2}{{\delta z_0}^2 (1+4\sigma^2 \Delta z^2/{\delta z_0}^2)}} \tag{7.20}$$

where $\Delta z = v_z T$ denotes the axial displacement of the sample during a single A-line acquisition time. Equation 7.20 illustrates two effects of axial motion. First, depth in the image is given by $Z = z_0 + z_D$, where

$$z_D \equiv \frac{k_0}{k_1 T} \Delta z = \frac{\pi \sigma}{2\ln 2} \frac{\delta z_0}{\lambda} \Delta z. \tag{7.21}$$

The axial shift, z_D, originates from the Doppler frequency shift generated by the moving sample. That is, a moving sample would create a signal modulation even in the absence of tuning. The Doppler frequency is given by $(2v_z/c)v$, where c is the light speed and v is the optical frequency. For frequency-swept light, the Doppler frequency is added to the original modulation frequency of the OFDI signal, resulting in an erroneous depth offset. Typical values for σ and $\delta z_0/\lambda$ may be 0.5–0.8 and 4–12, respectively. Therefore, the Doppler error could be 5–22 times the actual displacement Δz.

The second effect is broadening in axial resolution, given by

$$\frac{\delta z}{\delta z_0} = \sqrt{1 + 4\sigma^2 \frac{\Delta z^2}{{\delta z_0}^2}} \tag{7.22}$$

The broadening arises due to signal chirping represented by the κ^2 term in the phase in Eq. 7.19. Even a modest displacement equal to the unperturbed axial resolution, i.e., $\Delta z = \delta z_0$, could result in a 70 % broadening ($\sigma = 0.71$).

7.4.2 Transverse Motion

Figure 7.3b illustrates a situation where the probe and sample are moved relative to each other along a transverse coordinate, x. Without loss of generality, we will assume a stationary probe again and consider a scattering layer (sample) moving at constant velocity v_x. Substituting $x_b(t) = x_b - v_x t$ in Eq. 7.18, we get

$$F(Z) \approx \frac{\gamma P_0}{{w_0}^2} \iiint dxdydz \;\; r(x,y,z) e^{-i2k_0 z_0} e^{-4\ln 2 \frac{(y-y_b)^2}{{w_0}^2}} \int_{-k_1 T}^{k_1 T} e^{-4\ln 2 \frac{\kappa^2}{(2k_1 T\sigma)^2}} e^{-4\ln 2 \frac{\left(x - x_b + \frac{\Delta x}{2k_1 T}\kappa\right)^2}{{w_x}^2}} e^{i\kappa(Z-z_0)} d\kappa, \tag{7.23}$$

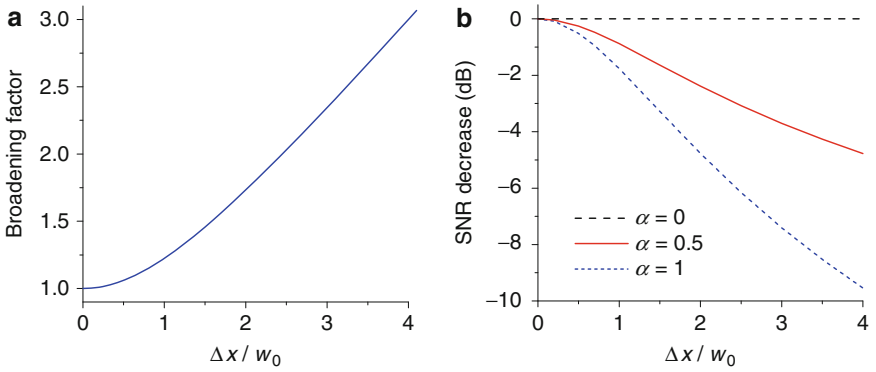

Fig. 7.4 (**a**) The magnitude of broadening in axial and transverse resolution and (**b**) SNR decrease arising from transverse motion as a function of normalized displacement Dx/ w_0 for $s^2 = 0.5$

where $\Delta x = v_x T$ denotes the transverse displacement of the sample during the acquisition of a single A-line.

For a scattering sample, the integral over κ can find an approximate solution which yields

$$F(Z) \propto \frac{\gamma P_0}{w_0 w_x \delta z_0} \iiint dxdydz \; r(x,y,z) e^{-i2k_0 z_0} e^{-4\ln 2 \frac{(y-y_b)^2}{w_0^2}} e^{-4\ln 2 \frac{(x-x_b)^2}{w_x^2}} e^{-4\ln 2 \frac{(Z-z_0)^2}{\delta_{z^2}}}, \tag{7.24}$$

where

$$\frac{w_x}{w_0} = \frac{\delta z}{\delta z_0} = \sqrt{1 + \sigma^2 \frac{\Delta x^2}{w_0{}^2}}. \tag{7.25}$$

This equation describes a broadening of the axial and transverse resolution due to transverse motion. Figure 7.4a shows a plot of the broadening factor as a function of normalized displacement $\Delta x/w_0$ *for* $\sigma = 0.71$. The broadening in transverse resolution is obvious because the effective size of the probe beam is increased by the transverse motion. The broadening in axial resolution occurs because the spectral width that one scattering point on the sample experiences during a single A-line acquisition is reduced as a result of the transverse motion. For a mirrorlike sample, represented by $r(x, y, z) = r_0\delta(z)$, Eq. 7.23 can be readily solved by performing the space integration first to show that both transverse and axial resolutions are invariant as anticipated since the beam scanning over a mirror does not alter the signal. Equations 7.24 and 7.25 are valid for a random scattering sample.

Equation 7.24 also describes the effect of the transverse motion in signal-to-noise ratio (SNR). The SNR is influenced by the transverse motion because a larger number of scatterers are illuminated with motion, but the signal from each scatterer

is collected by only a fraction of the duration of each A-line acquisition. Here, we define the SNR as a ratio $|F_s(z)|^2/|F_n(z)|^2$ where $F_s(z)$ and $F_n(z)$ denote the signal and noise components, respectively, obtained from a DFT of signal and noise photocurrents. The change in SNR by motion depends on the specific type of a sample. For a mirrorlike sample, SNR is invariant since the transverse motion does not alter the signal and noise, as can be derived from Eq. 7.23. For a single-point scatterer sample expressed as $r(x, y, z) = r_0\delta(x)\delta(y)\delta(z)$, it can be shown from Eq. 7.24 that the SNR decrease is given by $(1 + \sigma^2\Delta x^2/{w_0}^2)^{-1}$. For a bulk random scattering medium which leads to a fully developed speckle [25], the speckle-averaged signal power is given as an incoherent sum of signal powers from individual scatters. Assuming a homogenous scattering coefficient, it can be shown from Eq. 7.24 that the mean signal power is proportional to $1/({w_0}^2\delta z)^2$ $\iiint e^{-8\ln 2\frac{(x-x_b)^2}{{w_x}^2}} e^{-8\ln 2\frac{(y-y_b)^2}{{w_0}^2}} e^{-8\ln 2\frac{(Z-z_0)^2}{\delta z^2}} dxdydz$ which is invariant against the transverse motion. On the other hand, for a 2-dimensional scattering layer oriented in the x-y or y-z plane, the SNR is given by $(1 + \sigma^2\Delta x^2/{w_0}^2)^{-0.5}$. The scattering property of the actual biological sample may vary between a point scatterer and bulk homogenous random scattering medium. Therefore, we may expect that the SNR decrease for a biological sample may be given by

$$SNR\ \ decrease \approx \left(1 + \sigma^2 \frac{\Delta x^2}{{w_0}^2}\right)^{-\alpha}, \tag{7.26}$$

where α ranges from 0 to 1 depending on the sample. Figure 7.4b depicts the SNR decrease for three different α values.

As defined in Eq. 7.16, σT is equal to a FWHM width of optical intensity profile and, therefore, can be interpreted as an effective integration time of the signal. This accounts for the dependence on σ in Eqs. 7.21, 7.25, and 7.26 since Δz and Δx were defined as total displacements integrated over the entire A-line acquisition time of T rather than σT.

7.4.3 Nonlinear Tuning Slope

In general, the tuning of a swept source is not always linear in k-space and it is well known that nonlinear sampling in k-space gives rise to a poor spatial resolution [8]. To avoid this problem, the detector output may be sampled with nonuniform time intervals so as to produce uniform sampling in k-space. Alternatively, the detector output may be sampled with a uniform time interval, and subsequently, the acquired data is resampled by interpolation to a uniform spacing in k-space. This method is commonly implemented in practice. Mathematically, both methods are equivalent to a coordinate transform from t to a normalized time variable τ, defined as

$$t = T\tau - (k_2/k_1)T^2\tau^2 + \left[2(k_2/k_1)^2 - (k_3/k_1)\right]T^3\tau^3 + ..., \tag{7.27}$$

where τ spans from -0.5 to 0.5 for a single A-line acquisition. The wavenumber function then becomes linear in τ, i.e., $k(\tau) = k_0 + k_1 T\tau$. The depth profile is readily obtained with transform-limited spatial resolution by a Fourier transform with respect to $\kappa = k_1 T\tau$.

Let us consider an axially moving sample described as $z_b(t) = z - \sum z_m t^m$ where $z_0 = z - z_b$ (0) denotes the mean path length difference, $z_1 = v_z$ the velocity, and z_2 the acceleration. Using Eq. 7.27, we get

$$i(\xi) = \gamma\sqrt{P_r(\tau)P_s(\tau)}\iiint dxdydz \;\; r(x,y,z)g(x-x_b, y-y_b)\exp\left[-i\sum \omega_m \tau^m\right], \tag{7.28}$$

where

$$\begin{aligned} \omega_0 &= 2k_0 z_0, \omega_1 = 2(k_1 z_0 + k_0 z_1)T, \\ \omega_2 &= 2\left\{k_1 z_1 - \frac{k_0 k_2}{k_1}\right)z_1 + k_0 z_2\Big\}T^2. \end{aligned} \tag{7.29}$$

Here, ω_0 is a constant-phase term. ω_1 corresponds to the signal frequency in τ and is responsible for the Doppler shift in Eq. 7.21. ω_2 represents quadratic signal chirping and therefore results in broadening of the axial resolution. The coefficient of the cubic term, ω_3, plays a similar role to third-order chromatic dispersion, leading to asymmetry of the point spread function.

It can be shown [24] that the axial resolution is given by

$$\frac{\delta z}{\delta z_0} = \sqrt{1 + \frac{\sigma^4 \omega_2^2}{(4\ln 2)^2}}. \tag{7.30}$$

This leads to Eq. 7.22 for the special case of linear-k tuning and linear motion. For linear-λ tuning (linearly varying output wavelength in time), the axial resolution is found to be independent of z_1; a pure linear motion does not affect the axial resolution in this special case.

7.5 Phase-Sensitive (Doppler) OFDI

The foregoing sections of this chapter described the core OFDI system element and explored fundamental aspects of the technology. The system architecture that was considered reflects what has become the standard implementation for OFDI. This section will focus on a measurement technique that extends the core capabilities of OFDI to include Doppler-flow characterization through phase-sensitive detection.

Phase-resolved OCT systems measure both the amplitude and phase of the light reflected from the sample as a function of depth. The amplitudes are used to

generate intensity-based structural images. Although the phases are generally random for biological samples, additional functional information can be obtained by measuring changes in phase. For example, spatially resolved flow imaging can be accomplished by comparing the phases between successive A-lines at the same depth. A translation of the sample by distance δ during the time interval between two A-lines will induce a change in the measured phase of the reflected light given by $\Delta\phi = 2n\langle k\rangle\delta$, where n is the refractive index of the sample and $<k>$ is the average wavenumber of the OCT source ($k = 2\pi/\lambda$). Calculating this phase difference at each depth yields spatially resolved measurements of both the magnitude and direction of the axial (parallel to the imaging beam) flow velocity. Assuming that the imaging beam intersects the flow velocity vector at an angle β, the flow velocity is given by $v = \Delta\phi(2n\langle k\rangle\tau\cos(\beta))^{-1}$ where τ is the time between A-lines. This method was originally demonstrated in TD-OCT [26] and later in SD-OCT [27] and is the method applied in the current work. To ensure correlation between the phase measurements of successive A-lines, the transverse displacement of the imaging beam between A-lines must be small relative to the beam size. This constraint can be met by effectively oversampling in the transverse direction.

The sensitivity of the flow measurement is fundamentally limited by the phase sensitivity of the OCT system, which, in turn, is limited by the OCT system noise floor. It has been shown that the noise in the measured phase difference of a given signal, $\sigma^2_{\Delta\phi}$ (rad^2), with an SNR given by X can be written as [28, 29]

$$\sigma^2_{\Delta\phi} = \left(\frac{1}{X}\right). \tag{7.31}$$

Note that because calculation X of the phase difference requires two measurements of phase, the noise level of phase difference measurements as given by Eq. 7.31 is twice that of single-phase measurements. Most signals reflected from biological samples have SNRs below 50 dB, suggesting an ultimate phase difference measurement accuracy of ~3 mrad, corresponding to a flow velocity of 0.02 mm/s at $\beta = 80°$, $n = 1.3$, and $\tau^{-1} = 15.6$ kHz. Signals returning from depths greater than several hundred microns, where blood vessels are likely to be located, typically have SNRs below 30 dB and would yield ultimate phase accuracies of ~30 mrad. To achieve high-sensitivity flow imaging, other (less fundamental) noise sources, including interferometric instabilities, should be minimized such that phase sensitivity is SNR-limited up to an SNR of approximately 50 dB.

Because flow is calculated from the phase difference between successive A-lines, it is essential that phase measurements be repeatable from one A-line to the next. Changes in the measured phase resulting from systematic or interferometric instabilities increase the phase noise floor of the system, reducing the ability of the system to image low flow rates. In SD-OCT, the inherent stability of the source, interferometer, and spectrometer enables highly repeatable phase measurements and, correspondingly, high-sensitivity flow imaging. In OFDI, variations in the synchronization/timing of the wavelength-swept source relative to the

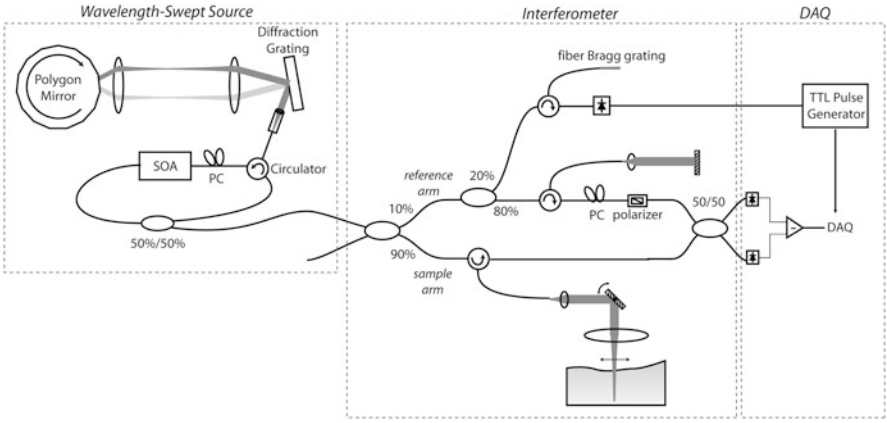

Fig. 7.5 Basic configuration of a phase-sensitive OFDI system

acquisition electronics can induce variations in the measurement of phase that degrade sensitivity. This effect is examined in the following section.

Figure 7.5 depicts the OFDI system configuration that will be discussed in this section [13]. The system comprises three modules: the wavelength-swept source, the interferometer, and the digital acquisition (DAQ) electronics. The source is constructed from a fiber ring laser using a semiconductor optical amplifier (SOA) as the gain element and a narrowband sweeping filter based on a polygon scanner [30]. The polarized source output is coupled to the interferometer where it is split into a reference arm and a sample arm. The sample-arm light is delivered to and collected from the sample through a single fiber. An optical circulator directs the reflected light to the interferometer output coupler. The reference-arm light reflects from the reference mirror, passes through a polarizer to remove any acquired variation in polarization state as a function of wavelength, and is directed to the other port of the output coupler. Resulting interference fringes are detected on both output ports. These signals are subtracted in a balanced-receiver configuration that reduces source intensity noise as well as autocorrelation noise from the sample. A portion of the reference-arm light is directed to a narrowband fiber Bragg grating (FBG) to generate a synchronization pulse for the acquisition electronics. This pulse is detected and converted into a TTL signal with a low-to-high transition that is coincident with the optical pulse and a high-to-low transition that is electrically tunable.

The DAQ board digitizes the balanced-receiver output using the high-to-low transition of the FBG-generated TTL pulse as a trigger signal. In response to the trigger signal, the DAQ board performs N analog-to-digital (A2D) conversions at its internal sample clock rate where the conversion occurs on the sample clock transitions. Although the polygon filter is driven by a signal derived from the sample clock, the phasing of the swept source output and the sample clock drifts slowly over time, causing the trigger signal to fall arbitrarily within the sample clock cycle. As a result, the delay between the trigger signal and the subsequent A2D conversion can vary by one period of the sample clock.

To understand how this variation in delay affects phase-resolved measurements, consider the interference fringe resulting from a stationary mirror at depth z with reflectivity R. The resulting interference signal, $S(t)$, is given by

$$S(t) \propto \sqrt{R}\cos\left(2k_o z + 2\alpha z[t+\varepsilon]\right) \tag{7.32}$$

where the laser is assumed to sweep linearly in wavenumber, i.e., $k(t) = k_o + \alpha t (\alpha = -6.1 \times 10^9 \mathrm{m}^{-1}\mathrm{s}^{-1}$ for our source. Because in practice the source sweep contains higher-order terms, the detected signal is resampled in time to recover the signal given by Eq. 7.32 [13]. The parameter ε describes the delay between the trigger signal and the subsequent A2D conversion. This delay ranges from 0 to the sample clock period T_{cl} (= 0.1 μs) and is different for each A-line. The phase of the interference fringe associated with the mirror is given by $\phi = 2k_o z + 2\alpha z\varepsilon$, and the range of phase differences between successive A-lines, $\Delta\phi$, is given by

$$|\Delta\phi| = 2\alpha z|\Delta\varepsilon| \leq 2\alpha z T_{cl} \equiv \pi Z. \tag{7.33}$$

where $\Delta\varepsilon$ is the change in the delay, ε, from one A-line to the next and is maximally equal to T_{cl}. A normalized depth parameter $Z = 2z\alpha T_{cl}/\pi$ has been defined where $Z = 0$ at the path-matched depth and $Z = 1$ at the Nyquist-limited imaging depth. Equation 7.33 indicates that timing variations produce phase jumps that increase linearly with depth up to a maximum value of π at the Nyquist-limited imaging depth ($Z = 1$). As shown previously, SNR-limited noise levels can be as low as a several mrads, and therefore, phase differences of the magnitude predicted by Eq. 7.33, if uncorrected, would severely degrade the sensitivity of the system.

There are several potential methods to correct the timing-induced phase jumps. Optical generation of the sample clock would improve the synchronization between the source and the DAQ board and reduced timing-induced phase jumps. To achieve this, a small portion of the source output could be directed to a periodic optical filter, generating an optical clock signal that is converted to a suitable TTL sample clock signal [31]. When the laser sweeps nonlinearly in k, the resulting sample clock is frequency chirped and abruptly changes frequency between the end of one sweep and the beginning of the next. As such, there are potential compatibility issues between optically generated clocks and higher-speed (∼100 MS/s) DAQ boards which incorporate phase-locked loop circuits on the external sample clock input. A second solution is to subtract from the measured phase difference of each A-line pair that portion which varies linearly with depth in a manner similar to a correction technique applied in phase-resolved TD-OCT systems [32]. Although straightforward and likely valid for cases in which flow is localized in a small region, this approach can distort the measured flow by subtracting linear portions of actual flow distributions.

To allow for the accurate measurement of arbitrary flow distributions, we have implemented a solution in which a separate calibration signal is used to measure timing-induced phase variations. These variations are then subtracted from the

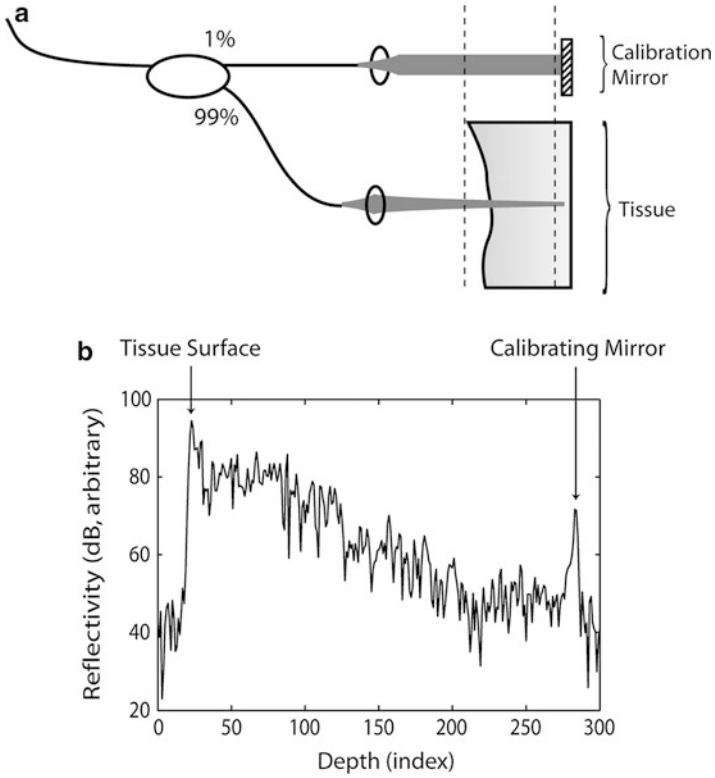

Fig. 7.6 (**a**) The implementation of a calibration mirror used to generate a calibration signal which allows measurement of the timing-induced phase variations for each A-line pair. (**b**) A representative A-line showing the signal from the sample (tissue) and the calibration signal

measured phase differences at all remaining depths. Figure 7.6a shows a sample arm modified to provide this calibration signal. A 1 % tap coupler is used to direct light to both a stationary calibration mirror (1 % port) and the sample to be imaged (99 % port). The calibration mirror is positioned such that its resultant signal appears near the maximum imaging depth, which is optimal for two reasons. Firstly, the calibration mirror creates a line artifact in the image. By locating the calibration mirror near the maximum imaging depth, this artifact appears near the image edge, minimizing the degree to which it can obscure the sample image. Secondly, the magnitude of the timing-induced phase differences is maximized at large depths and can therefore be most accurately measured at these depths. Hereafter, the signal from the calibration mirror is referred to as the calibration signal and the signal from the sample is referred to as the sample signal. The amplitude of the calibration signal is adjusted to ensure that it is large enough to dominate the sample signal at large depths but not so large that it induces significant autocorrelation noise [4]. Figure 7.6b shows a representative A-line

from a tissue image. Notice that the calibration signal obscures only a small portion of the image near the edge of the imaging depth.

Corrected phase differences are calculated by subtracting a fraction of the measured phase difference of the calibration signal from the measured phase difference of the sample signal. The magnitude of the applied correction is scaled linearly with the sample signal depth as dictated by Eq. 7.33. In the following, the parameters $\Delta\phi_{i,j}$ and $\Delta\hat{\phi}_{i,j}$ are used to describe the directly measured phase difference and calculated corrected phase difference, respectively, at depth index i between A-lines j and (j-1). If the calibration signal is located at depth index m, the corrected phase difference at depth index i is calculated as

$$\Delta\hat{\phi}_{i,j} = \Delta\phi_{i,j} - \left(\frac{i}{m}\right)\Delta\phi_{m,j}. \tag{7.34}$$

The first term is the measured phase difference at depth index i and the second term is the applied correction, scaled according to the sample signal depth by the multiplicative factor (i/m). Appropriate phase unwrapping is performed on all measurements. Finally, bulk motion artifacts can be removed by subtracting the median phase difference from each A-line pair [32].

The phase sensitivity of the system is given by the noise level of the corrected phase differences. Ideally, the correction procedure described by Eq. 7.34 reduces the impact of timing-induced phase jumps to negligible levels, leaving only the fundamental SNR-limited noise. To test this, a stationary mirror was used to generate a sample signal and corrected phase differences were calculated according to Eq. 7.34. The measured phase (ϕ), phase difference ($\Delta\phi$), and corrected phase difference ($\Delta\hat{\phi}$) of a sample signal at depth $Z = 0.54$ are plotted in Fig. 7.7a–c, respectively. A depth of $Z = 1$ corresponds to 2.6 mm in these measurements. The imperfect synchronization between the source and sample clock can be seen in the slow drift of the measured phase (Fig. 7.7a). The large jumps in phase occur when the acquisition delay switches by one clock cycle. The magnitude of these phase jumps (see scale bar on right of Fig. 7.7b) is in agreement with the prediction of Eq. 7.33 for a signal at this depth. Figure 7.7c shows that the large phase jumps have been eliminated in the corrected phase difference. Additionally, the baseline noise level has been reduced by 7 dB due to the correction of smaller phase jumps resulting from variations in acquisition delay that are less than one clock cycle.

To confirm the effectiveness of the correction method, the noise on the corrected phase differences was measured and compared to the SNR-limited noise predicted by Eqs. 7.31 and 7.34 as

$$\sigma^2_{\Delta\hat{\phi}} = \left(\frac{1}{X_s}\right) + \left(\frac{Z_s}{Z_c}\right)^2\left(\frac{1}{X_c}\right) \tag{7.35}$$

where X_s is the SNR of the sample signal located at depth Z_s and X_c is the SNR of the calibration signal located at depth Z_c. Phase difference measurements were performed at sample signal depths of $Z_s = 0.07$ (0.2 mm), 0.54 (1.4 mm),

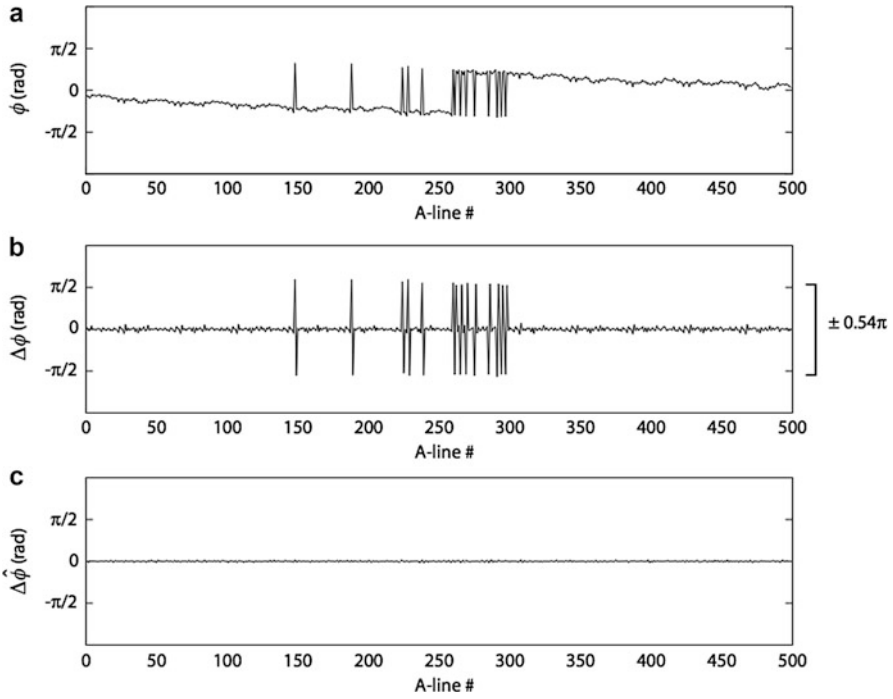

Fig. 7.7 A typical measured phase (**a**), phase difference (**b**), and corrected phase difference (**c**) for a sample signal at depth Z = 0.54

and 0.84 (2.2 mm). In all measurements, the calibration signal was located at depth $Z_c = 0.96$ (2.50 mm) and had an SNR $X_c \sim 31$ dB. The sample signal SNR, X_s, at each depth was adjusted from 10 dB to 50 dB through the use of a variable neutral-density filter located in the sample arm. Figure 7.8 plots the measured noise (calculated from 500 measurements) as a function of the sample signal SNR for two of the measured depths. The measurements show excellent agreement with the predicted noise level given by Eq. 7.35. Measurements at the intermediate depth of $Z_s = 0.54$ (not shown) also show excellent agreement with predictions. This agreement indicates that the proposed correction method is able to reduce timing-induced phase noise to negligible levels for this range of SNRs.

As indicated by Eq. 7.35, both the noise in the sample signal (first term) and the noise in the calibration signal (second term) contribute to the noise in the corrected signal, with the calibration signal contribution scaling with the sample signal depth, Z_s. At the large depth shown in Fig. 7.8b, the calibration signal noise dominates when the sample signal SNR exceeds ~35 dB. Assuming that, in practice, the SNR of sample signals from large depths is limited below 30 dB, and that from shallow depths is limited below 50 dB, one can see from Fig. 7.8 that the resulting noise over this range is sample signal SNR-limited. In the event of higher sample signal SNRs, the calibration signal SNR can be increased to reduce its noise contribution.

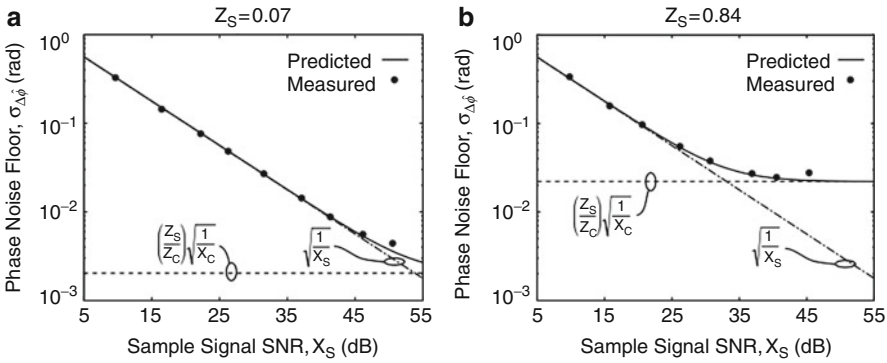

Fig. 7.8 The measured (*circle*) and predicted (*solid curve*) phase noise as a function of the sample signal SNR (X_s) at depths (**a**) $Z_s = 0.07$ and (**b**) $Z_s = 0.84$. The individual contribution to the overall noise resulting from only the sample signal noise (*dash-dot curve*) and calibration signal noise (*dashed curve*) are also shown. In both cases, the calibration signal was located at a depth $Z_c = 0.96$ with $X_c \sim 31$ dB

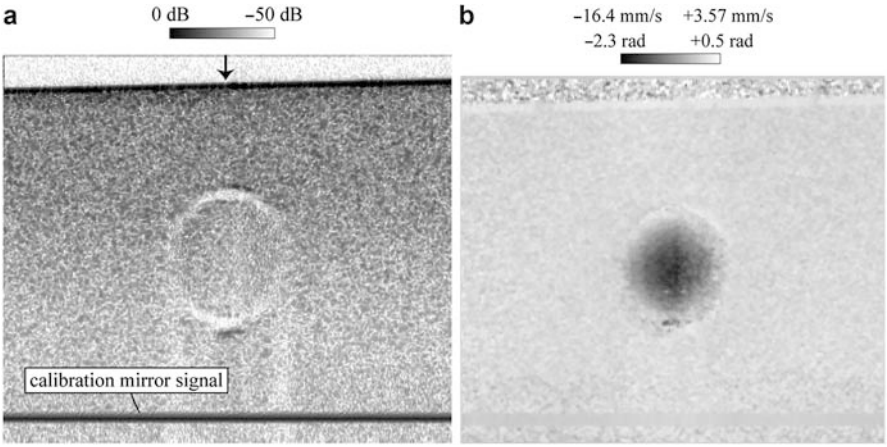

Fig. 7.9 Images of Intralipid flow through an 800-μm tube immersed in stationary Intralipid. (**a**) Structural image. (**b**) Flow image. The transverse distance is 3 mm and the imaging depth is 2.6 mm in air. Each image comprises 2,000 A-lines

As a test of the phase-resolved OFDI system and correction method described above, pulsatile flow of 0.25 % Intralipid in an 800-μm tube surrounded by stationary Intralipid of the same concentration was imaged. The angle between the tube and imaging beam was set at 80°. Figure 7.9 shows the resulting structural and flow images. The images were acquired at an A-line rate of 15.6 kHz and are 3 mm in width and 2.6 mm in depth (in air). Each frame contains 2,000 A-lines (displacement of 1.5 μm per A-line) yielding a frame rate of 7.8 frames per second. A moving median filter of size 20 × 3 pixels (30 × 25 μm) was applied to the corrected

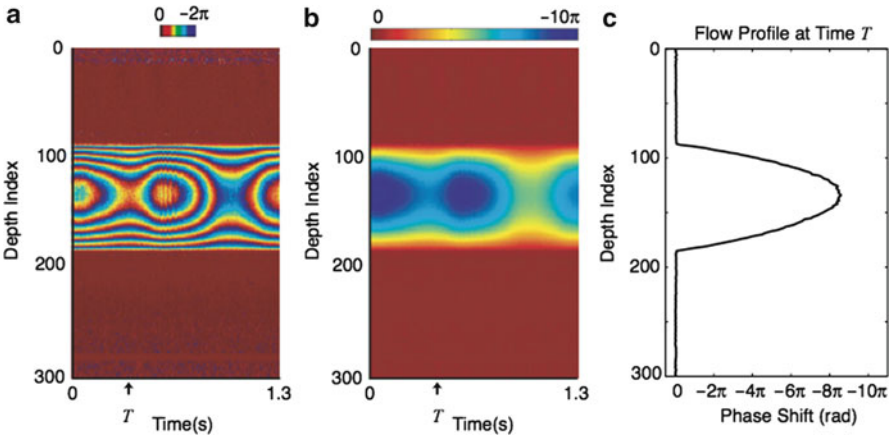

Fig. 7.10 M-mode image showing depth-resolved Intralipid flow as a function of time for high-rate, pulsatile flow. The beam was positioned at the center of the tube (see *arrow* in Fig. 7.5). In (**a**), the measured phase difference is shown without unwrapping phase discontinuities. In (**b**), a phase unwrapping algorithm is used to reconstruct the flow. Note the difference in scale between the images. In (**c**) the flow profile at time T (indicated on the time axis) is plotted. The maximum flow in (**c**) induced a phase difference of -8.5π corresponding to a flow rate of 61 mm/s

phase (flow) image. The flow image clearly differentiates the region of flow inside the tube from the surrounding stationary Intralipid. The phase difference and corresponding flow velocity (assuming an index of refraction of $n = 1.32$) are given in the colorbar. As mentioned previously, OFDI does not suffer from fringe washout due to sample motion. As such, phase-resolved OFDI is well suited to measure high flow rates that induce phase shifts greater than 2π. To demonstrate this, the imaging beam was positioned at the center of the tube shown in Fig. 7.9 and A-lines were recorded without scanning the beam while an increased pulsatile flow rate was induced. Figure 7.10a shows the resulting M-mode image. Phase is mapped to a color scale and the image coordinates are depth index (vertical axis) and time (horizontal axis). The increased flow rate results in measured phase differences that exceed 2π and produce phase wrapping artifacts. Because OFDI does not suffer from fringe washout effects, no SNR penalty is incurred as a result of these large phase shifts. The apparent depth, however, is displaced from the actual depth due to the large Doppler shift [33], an artifact that does not directly impact the ability of OFDI to measure large flow rates. Figure 7.10b shows the phase image unwrapped to remove discontinuities of 2π, yielding the depth-resolved time-varying flow distribution in the tube. Note the change of color scale between Fig. 7.10a, b. Figure 7.10c shows an unwrapped flow profile acquired at the time T as marked in the phase images. The images shown in Fig. 7.10 are constructed by averaging over 100 consecutive A-lines. Figure 7.11 shows cross-sectional structural and flow images obtained from a human nail bed in vivo. The image size is the same as in Fig. 7.10. Two blood vessels (circled), not observed in the structural image, can be clearly seen in Fig. 7.11b.

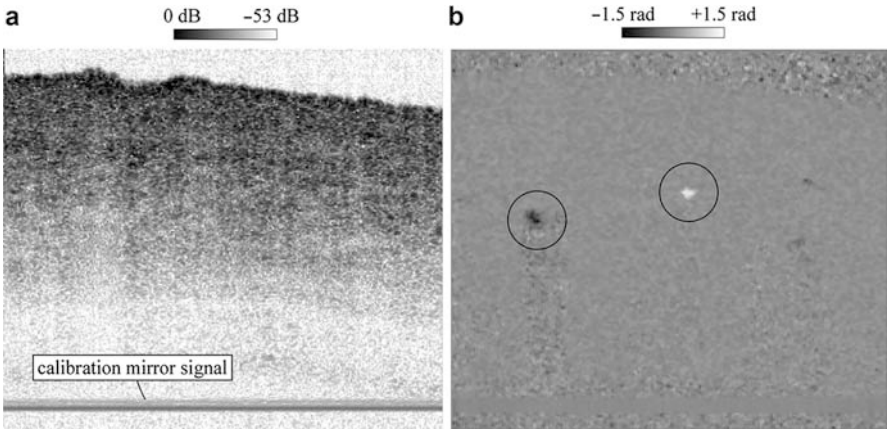

Fig. 7.11 Images of the human finger near the nail bed. Figure 7.6a shows the structural image and Fig. 7.6b shows the flow image. Two blood vessels (*circled*) are clearly visible in the flow image. The transverse dimension is 3 mm and the depth is 2.6 mm. Each image contains 2,000 A-lines

7.6 Applications

Comprehensive volumetric microscopy with OFDI is performed using a minimally invasive procedure such as catheterization or endoscopy is used to deliver the OFDI probe to the target organ or system (Fig. 7.1) [34]. Through rotation and longitudinal pullback of the internal portion of the probe, the OFDI system records the full three-dimensional microstructure of the tissue. Subsequent image processing can then be used to produce a form of virtual histology, where arbitrary cross-sectional views of the tissue can be viewed to screen for disease. The OFDI systems developed for these studies provide an approximately 30-fold increase in imaging speed over prior time-domain OCT systems. Given the individual voxel dimensions of 15 μm × 15 μm × 10 μm, the systems obtain data at a rate of 60 mm^3/s, permitting visualization of large tissue volumes with microscopic resolution.

7.6.1 Gastrointestinal Tract Imaging In Vivo

The management of patients with specialized intestinal metaplasia (SIM) of the esophagus (Barrett's esophagus) exemplifies the need for comprehensive volumetric microscopy. The standard protocol comprising undirected (random) four-quadrant biopsy provides only sparse sampling and is prone to sampling artifacts in the search for focal dysplasia and cancer. The inadequacy of biopsy surveillance is highlighted by the common recommendation for esophagectomy following diagnosis of high-grade dysplasia, a rare scenario in which a costly and highly

morbid procedure is indicated without histopathologic evidence of cancer. The high speed of OFDI imaging may provide a solution for this problem by enabling comprehensive imaging of the esophagus. Figure 7.12 depicts data acquired in the esophagus of a living swine. A 4-cm segment of the esophagus was imaged using a balloon catheter to stabilize and center the optics of the OFDI catheter within the esophageal lumen [34]. The entire volume of data was acquired in 5.8 min using an OFDI system operating at an A-line repetition rate of 10 kHz. This rate was reduced from the maximum operating speed of 64 kHz in order to facilitate continuous data archival to a computer hard drive. One volumetric dataset comprises 14 GB. Volumetric renderings (Fig. 7.12a) depict the tubular anatomy and allow visualization of the vascular network supplying the esophagus. Two-dimensional cross sections can be rendered from this volume in arbitrary orientations (Fig. 7.12b, c) and permit identification of each layer of the esophageal wall including the squamous epithelium, lamina propria, submucosa, and inner and outer muscularis propria (Fig. 7.12d and corresponding histology Fig. 7.12e). The dimension and optical properties of these anatomical features are similar in swine and humans.

7.6.2 Intracoronary Imaging In Vivo

One of the most significant current topics in interventional cardiology is the hypothesis of a vulnerable plaque. Autopsy studies have found that most acute myocardial infarctions (AMIs) are secondary to thrombotic occlusion at the site of a disrupted lipid-rich plaque. It is hypothesized that prior to disruption, these plaques are characterized by large necrotic, lipid-rich cores, thin fibrous caps, and abundant macrophages and represent a significant risk for AMI. In order to test this hypothesis, develop appropriate therapeutic measures, and potentially guide intervention, there is a clear need for a screening technology capable of identifying these lesions in living patients prior to disruption. OCT criteria for the focal characterization of coronary atherosclerotic plaques have previously been identified and validated [35, 36]; the missing capability, however, has been for comprehensive coronary screening. Images acquired in the right coronary artery of a living swine following balloon angioplasty and stenting are shown in Fig. 7.13 [34]. Image data was acquired at an A-line rate of 54 kHz and an imaging speed of 108 images per second using a coronary OFDI catheter that operated at a rotational speed of 6,480 RPM. The volumetric OFDI image (Fig. 7.13a) delineates the metallic wire mesh of the stent (color-coded blue), the intima and media (red), and the remainder of the vessel and surrounding tissues including denuded adventitia (gray). The luminal diameter in the region of balloon inflation (Fig. 7.13c–e) is considerably expanded relative to the reference vessel diameters (Fig. 7.13b, f). The wire struts of the stent are opaque to infrared light and appear as bright local reflections at the lumen with occluded sectors radially behind them. Cross-sectional images revealed portions of the dissected intima and media inside the stent (Fig. 7.13c, d) and exposed adventitia and flaps of intima and media (Fig. 7.13d, e).

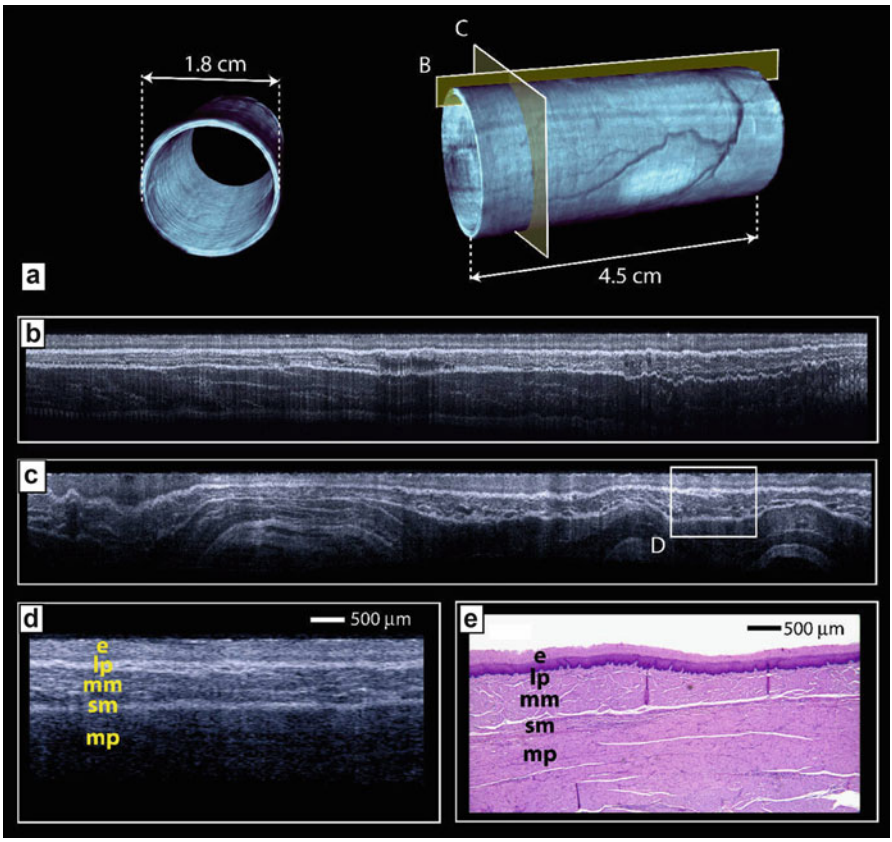

Fig. 7.12 Comprehensive microscopy of a porcine esophagus in vivo [34]. (**a**) The 14 GB volumetric dataset can be rendered and downsampled for presentation in arbitrary orientations and perspectives. The vascular network within the submucosa is readily apparent without image enhancement or exogenous contrast agents. Cross-sectional images can be located on the volume image for higher-resolution viewing. (**b**) Longitudinal cross section through the esophageal wall at location denoted in A (inverted with epithelium at the *top*; dimensions: 45 mm horizontal, 2.6 mm vertical). In the raw data, we observed a periodic vertical offset corresponding to the motion of the beating heart. A simple surface-aligning algorithm was used to reduce this artifact, but a residual vertical banding can still be observed with a period of 300 µm corresponding to a heart rate of 90 beats/min. The longitudinal pitch between adjacent A-lines was 32 µm. (**c**) Unwrapped transverse section (cylindrical coordinates r & θ are mapped to vertical and horizontal) at location denoted in A (dimensions: 57 mm horizontal, 2.6 mm vertical). Both sections (**b**) and (**c**) demonstrate imaging through the entire esophageal wall and permit identification of the squamous epithelium (*e*), lamina propria (*lp*), muscularis mucosa (*mm*), submucosa (*s*), and muscularis propria (*mp*), as labeled in expanded panel (**d**). (**e**) Representative histology section (H&E stain) obtained from the anatomical region corresponding to (**d**)

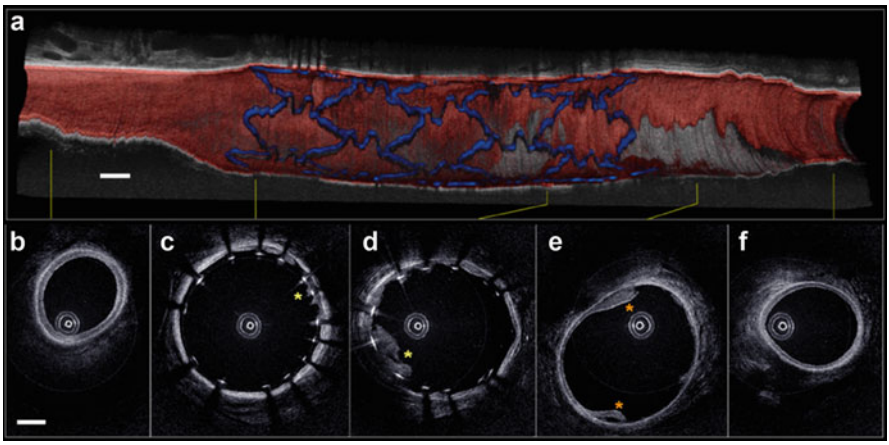

Fig. 7.13 Volumetric imaging of a stented porcine coronary artery in vivo [34]. (**a**) Three-dimensional cutaway rendering of the volumetric dataset acquired with an intravascular catheter in the circumflex coronary artery of a living swine after balloon angioplasty and stent implantation. The stent is represented as *blue*, the intima and media as *red*, and the adventitia and surrounding tissue as a *gray* scale. The volume comprises 500 circular (r-θ) sections at a pitch of 50 μm acquired in 6 s during the injection of saline at a rate of 3 cm^3/s. (**b–f**) Individual OFDI cross-sectional images at corresponding locations marked in (**a**). The metal-based stent produces strongly reflected signals and leaves radial shadow patterns in (**c**) and (**d**). The dissected intima and media layers are shown (**e** *orange asterisk*). Tissue prolapse between the stent struts is visualized in (**c**, **d** *yellow asterisk*). Scale bars, 1 mm

7.6.3 4-Dimensional Imaging of an Embryo Heart

In addition to screening and surveillance, high-speed OFDI also enables dynamic processes to be captured. This capability may be particularly useful in 4-dimensional phenotyping of the heart in models for developmental biology. Using a two-dimensional galvanometric scanner, the entire volume of the heart can be imaged in a xenopus embryo with a three-dimensional image acquisition rate of 20 Hz (Fig. 7.14) [34]. The real-time dynamics of the ventricle, atrium, and truncus arteriosus were recorded without the need for time-gating techniques. The displacements associated with cardiac dynamics were calculated directly from the volumetric images by computing the distance between homologous locations on the cardiac surface at end diastole and end systole on a frame-by-frame basis. Displacement was displayed using a color lookup table. At end systole, OFDI demonstrated that the ventricle was at its smallest volume; the volumes of the atrium and truncus were conversely at their maxima. At end diastole, the ventricle was dilated to its greatest volume, whereas the volumes of the atrium and truncus were at their minima.

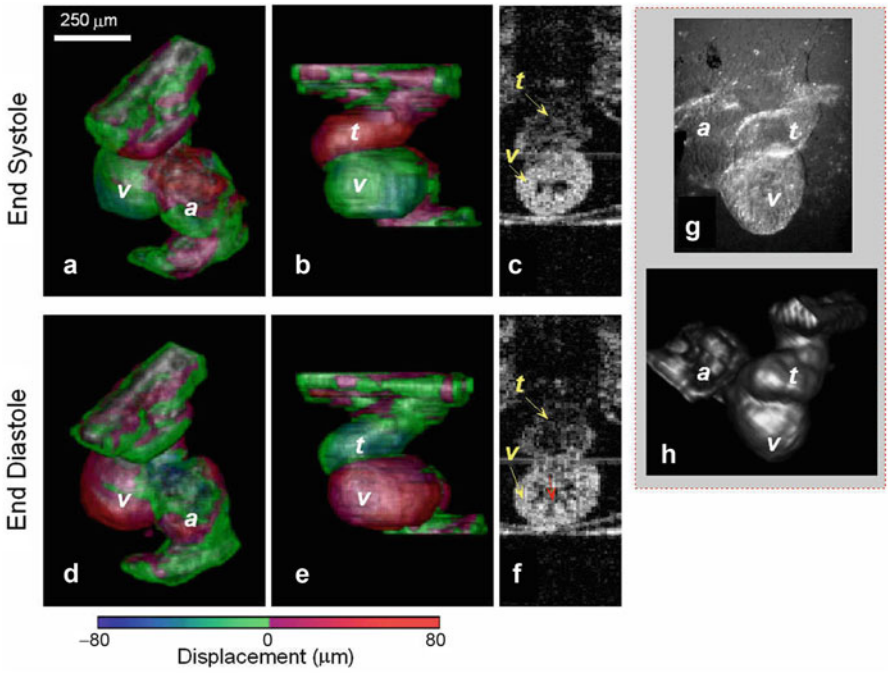

Fig. 7.14 Three-dimensional rendered images of xenopus embryo heart in vivo. The dynamics of the heart motion are visualized by the color-coded displacement maps, which have been overlaid on rendered three-dimensional datasets. Volumetric images including the entire heart were acquired in 50 ms, considerably shorter than the period of the heart beat (approximately 0.5 s). In end systole (**a**, **b**, **c**), the atrium (*a*) is expanded and the ventricle (*v*) is compressed. During diastole, the atrium gets compressed and the ventricle expands. At end diastole (**d**, **e**, **f**), the ventricle is at its largest size. In systole, it compresses and the truncus arteriosus (*t*), expands, and rotates. (**c**, **f**) represent cross-sectional images showing trabeculae (*red arrow*, **f**) in compressed and expanded ventricles, respectively. Each cross-sectional image was acquired in 1 ms. A bright-field picture of the dissected heart and corresponding image are shown (**g**, **h**). Scale bar, 250 μm

Complex Conjugate Removal in SS Optical Coherence Tomography

8

Oscar Carrasco-Zevallos and Joseph A. Izatt

Keywords

Complex conjugate removal • Increased axial range • Fourier domain Optical Coherence Tomography • Complex conjugate ambiguity

8.1 Introduction

Optical coherence tomography (OCT) enables tomographic imaging with micron-scale axial and lateral resolution. Since its inception in 1991 [1], OCT revolutionized ophthalmic imaging by visualizing retinal layers with exquisite detail for the first time. OCT was also extended for imaging of the anterior segment of the eye [2].The development of Fourier domain OCT (FDOCT) systems significantly improved sensitivity and imaging speed, catalyzing the commercialization of OCT technology. FDOCT is now the clinical gold standard for retinal imaging. However, the transition from time-domain OCT to Fourier domain detection was not without cost; imaging artifacts inherent to FDOCT acquisition and processing were introduced. The most prominent, the complex conjugate artifact, results in reducing the OCT depth imaging range by a factor of 2. In this chapter, techniques for complex conjugate removal in swept-source OCT (SSOCT) are discussed. Complex conjugate removal in spectral domain OCT (SDOCT) will be only briefly reviewed; a thorough analysis of such techniques can be found in ► Chap. 7, "Optical Frequency Domain Imaging".

8.1.1 Fourier Domain Optical Coherence Tomography

Direct detection of the interferometric OCT signal in the Fourier domain revolutionized OCT and increased imaging speeds dramatically. FDOCT can be separated into two categories, SDOCT and SSOCT. In SDOCT, a broadband source, such as a super-luminescent diode, is utilized similar to time-domain OCT. However, instead of detecting with a photodiode, the backscattered spectrum is now collected with a spectrometer, comprised of an array or matrix of photodetectors [3, 4]. As discussed in ▶ Chap. 3, "Modeling Light–Tissue Interaction in Optical Coherence Tomography Systems," collection in the Fourier domain introduces a "signal fall-off" effect, in which the imaging depth range is governed by the spectral resolution of the detected interferogram. Spectral resolution of SDOCT is given by the spectral resolution of the spectrometer. To mitigate this effect, swept-source technology was introduced in OCT. In SSOCT, a tunable source that is swept as a function of time is used and the interferogram is collected with a photodiode [5, 6]. The spectral resolution in SSOCT is determined by the instantaneous linewidth of the swept source, which has much finer spectral resolution than any spectrometer.

As alluded to above, FDOCT enabled faster imaging than time-domain OCT due to increased sensitivity [7–9]. This paradigm shift in OCT had significant impact in ophthalmology. Faster line-rates enabled volumetric imaging, noise reduction via averaging, and real-time imaging, with both SDOCT [10–14] and SSOCT [15–20]. Additionally, simultaneous detection of the backscattered spectra in SDOCT facilitated functional extensions of OCT that measure wavelength-dependent scattering and absorption [21, 22]. Furthermore, the phase stability of FDOCT enables detection of nanometer-scale motions [23–25].

Despite these numerous advantages, the shift from time domain to Fourier introduces several nontrivial artifacts. Included are autocorrelation artifacts, which result from interference from separate reflectors in the sample located within a coherence length from each other. In addition, the so-called DC artifact is introduced after Fourier transforming the backreflected spectra to the spatial domain. Finally, the complex conjugate artifact, which is the focus of this chapter, originates from performing a Fourier transform on real data resulting in a Hermitian symmetric A-scan. The origins of these artifacts are evident from the theoretical treatment of FDOCT, which will be briefly reviewed here. For more in-depth analysis, see ▶ Chap. 3, "Modeling Light–Tissue Interaction in Optical Coherence Tomography Systems".

Assuming a standard Michelson interferometer, photocurrent at the detector is given by

$$D_i[k_m] \propto \rho \cdot S[k_m] \cdot \left(R_R + R_S + 2\sqrt{R_R R_S}\cos\left(2\Delta x k_m + \varphi_i\right)\right) \tag{8.1}$$

where D_i is the photocurrent at one detector; k_m is the wavenumber; ρ is the detector responsivity; S is the source spectral density in watts per wavenumber; R_R and R_S are the reflectivity from the reference and sample arm, respectively; and φ_i is

a trivial phase offset of the interferometric signal. The detector elements are $i = 1$: M where, in SDOCT, M is the number of pixels of the camera in the spectrometer or, in SSOCT, M is the number of spectral samples over the entire bandwidth of the wavelength-swept laser. The difference in optical path length between the reflectors in the sample and the reference arm is encoded by the frequency of the cosine term, and sample reflectivity is encoded in the fringe visibility of the interferometric signal. The detected signal in FDOCT essentially represents the real part of a Fourier transform of an OCT A-line given by

$$D_i[x_m] = \sum_{m=1}^{M} D_i[k_m] e^{-(j2\pi(2k_m x_n))}, n \in \{1, M\} \tag{8.2}$$

In the space domain, the channel spaces are given by $1/\Delta k$ where Δk is the bandwidth of the source in wavenumber units. As previously mentioned, the scan depth is given by the spectral resolution of system $1/\delta k$ where δk is the spectral resolution. Performing the Fourier transform shown in (8.2), the OCT A-line in the space domain is then represented by the following:

$$D_i[x_n] \propto S[x_n] \bigotimes \left((R_R + R_S)\delta(x_n) + 2\sqrt{R_R R_S}(\delta(x_n + \Delta x) + \delta(x_n - \Delta x)) \right) \tag{8.3}$$

Because the detected signal is necessarily real, the resulting Fourier transform will result in a Hermitian symmetric A-line, evidenced by the presence of two delta functions offset by $+\Delta x$ and $-\Delta x$ from DC. Therefore, a reflector at $+\Delta x$ cannot be distinguished from a reflector located $-\Delta x$. This ambiguity is termed the complex conjugate artifact [26], which effectively reduces the scan depth by a factor 2. Lastly, the DC artifact is given by the first delta function in the brackets.

The typical manner of resolving the complex conjugate artifact is to ensure that the region of interest in the sample is located solely on one side of the zero path length position, given by the position of the reference mirror. Duplicate data from the other side of the zero path length position is simply cropped out. While the majority of FDOCT systems utilize this technique, it is inefficient since half of the collected data is redundant and thus discarded. Complex conjugate removal (CCR) techniques in FDOCT aim to suppress or altogether eliminate this artifact to double imaging range, thereby enabling the entire collected data to be utilized efficiently. Some CCR techniques, such as phase-shifting OCT, are applicable in either SD or SSOCT, while others such as Heterodyne OCT are more suitable for SSOCT, as discussed below. This chapter will focus on CCR in SSOCT, while CCR in SDOCT, which is the focus of ▶ Chap. 7, "Optical Frequency Domain Imaging," will be briefly reviewed.

8.1.2 Complex Conjugate Removal in Spectral Domain OCT

As previously stated, the main drawback of adopting FDOCT is the complex conjugate artifact. Therefore, a major focus of OCT research was on techniques

that suppress or eliminate the complex conjugate artifact. The majority of these techniques were developed for SDOCT and will be reviewed here. CCR in SSOCT will be discussed in the following sections.

The complex conjugate artifact originates from the collection of only the real part of the complex OCT signal in FDOCT. However, if the entire complex OCT signal can be collected, then the Fourier transform of the complex signal back to the spatial domain would yield a complex conjugate free A-line. Because optical detectors necessarily acquire real data, reconstructing the complex OCT signal is not trivial. A method of acquiring both the real and imaginary components of the complex OCT signal involves acquiring multiple (at least two) interferograms at the same location but with a relative phase shift – a technique termed phase-shifting OCT. Phase shifting can be done in a variety of ways, including dithering the reference mirror with a piezoelectric transducer (PZT) [26, 27] or incurring a phase shift with an electro-optic modulator [28]. Using a PZT for phase stepping tends to severely hinder imaging speed since the OCT frame rate is now limited by the response time of the PZT. As a consequence, phase stepping with a PZT is more sensitive to patient motion than when using electro-optic modulator.

Once the phase-shifted interferograms are acquired, the complex OCT signal must be reconstructed. The first phase-shifting OCT systems employed a five shifted frame algorithm, first developed for white-light interferometry [29]. Five frames were necessary to correct for chromatic phase error induced by phase shifting using the reference mirror. Once again, collecting five frames sequentially is time consuming, and therefore the algorithm is vulnerable to patient motion that may introduce phase error. Other algorithms have been developed that only necessitate two phase-shifted to reduce imaging time; however, such algorithms are only applicable for limited optical bandwidths [28, 30]. Another group developed a system in which the phase-shifted spectra can be collected on different line arrays of a 2D detector to increase speed of imaging [31]. However, five phase-shifted frames were still necessary for every complex conjugate-resolved B-scan.

In addition to phase shifting, other phase modulation techniques for CCR in SDOCT have been developed. Sinusoidal phase modulation of the reference mirror and a high-speed integrating buckets acquisition scheme has also been utilized for reconstruction of the complex OCT signal [32]. Another algorithm was explored to retrieve the in-phase and quadrature components of the complex OCT signal from the first and second harmonics of the phase-modulated interferogram [33]. Instead of moving the reference arm, phase modulation of the interferogram can also be induced by offsetting the beam away from the pivot of the fast scanning mirrors. This incurs a phase shift that is proportional to the rate of the scanning mirrors and is therefore a simple way in which the complex OCT signal can be reconstructed after phase modulation [34, 35]. Another technique, termed B-M-mode OCT, uses phase modulation of a reference beam while transverse scanning to retrieve the complex OCT signal [36].

A completely different approach utilizes multiple reference arms to circumvent the complex conjugate artifact rather than suppress it. This technique simply uses two

reference arms, with the zero path length of each located at different positions in the sample. Therefore, two images, collected from different regions of the sample, can be captured and later registered to produce an image with greater depth range and free of the complex conjugate ambiguity. A fiber-based optical switch can be used to minimize the time it takes to switch between reference arms [37].

Another method to obtain for CCR is applying an electronic carrier frequency to the interferogram using frequency-shifting devices. This method does not induce any chromatic phase shift error, unlike most phase-shifting techniques, and allows for quadrature detection of the OCT signal. Frequency shifting in OCT is termed Heterodyne OCT and is more suitable for SSOCT since spectral domain detectors cannot follow MHz signal modulations. However, frequency shifting has also been applied to SDOCT using acousto-optic frequency shifters [38]. After applying a constant carrier frequency to the spatial OCT interferogram, a Hilbert transform can be used to capture the quadrature components of the OCT signal [39].

There are some disadvantages with the previously discussed methods, which include reduced imaging time since most CCR techniques in SDOCT necessitate the acquisition of multiple, phase-shifted frames or the use of multiple reference arms. Furthermore, phase-stepping or modulation techniques are subject to phase noise incurred by either patient movement or mechanical instability of the system. The accuracy of the complex OCT signal is dependent on the phase stability of the system. That is, for phase-shifting OCT, "phase calibration" is usually required, in which the phase shift between frames is predetermined and chosen carefully for the algorithm to work. Any phase noise will cause deviations from these predetermined phase shifts and therefore cause errors in the reconstruction of the complex FDOCT signal, resulting in "ghost images" because the complex conjugate artifact is not fully suppressed. Furthermore, chromatic phase error is incurred when phase shifting by dithering the reference mirror and can again contribute to ghost images. These phase-shifting techniques described above are more suitable for SDOCT because of greater source phase stability than in SSOCT. A true achromatic method for CCR is heterodyne OCT, in which a frequency carrier is imparted on the interferometric signal. This technique is more suitable for SSOCT since spectral domain detectors cannot follow fast signal modulations in the MHz range.

8.2 Heterodyne SSOCT

A method for true achromatic complex FDOCT signal reconstruction uses frequency shifting devices to create a beating signal with the detected interferometric signal. Termed heterodyne OCT, this technique is especially suitable for SSOCT in which large bandwidth detectors that can capture fast signal modulations in the MHz to 1 GHz range are used. A carrier signal can be imparted to enable quadrature detection of the complex OCT signal and subsequent suppression of the complex conjugate ambiguity. Furthermore, frequency shifting can also be used to establish a new zero optical path delay and eliminate the complex conjugate ambiguity altogether.

8.2.1 Heterodyne SSOCT Theory

As stated previously, the photocurrent collected by the detectors can be expressed as (8.1). In the case for SSOCT, the wavenumber k is swept as a function of time and can be represented as $k = k_0 + t(\mathrm{d}k/\mathrm{d}t)$ where k_0 is the starting wavenumber in the sweep and $\mathrm{d}k/\mathrm{d}t$ is the instantaneous sweep velocity. Optical sweeping in the time domain leads to the conversion of the cross-correlation and autocorrelation to electronic frequency in the time-varying photocurrent $D[t]$. Note that in Eq. 8.1, photocurrent is expressed as a function of k. However, since wavenumber is swept as function of time in SSOCT, photocurrent can be recast in terms of t.

The cross-correlation frequencies can be represented by the multiplication of OPL mismatch between the sample and reference arm and the sweep velocity $\omega_n = (\mathrm{d}k/\mathrm{d}t)\ (z_R - z_n)$, while the autocorrelation frequencies are given by $\omega_{nm} = (\mathrm{d}k/\mathrm{d}t)\ (z_n - z_m)$. If a beat frequency ω_d is induced in the reference arm, then the time-varying photocurrent can be represented by

$$D_i[t] \propto \rho \cdot S[t] \cdot \left\{ R_R + \sum\nolimits_n R_n + 2\sqrt{R_R}\sum\nolimits_n \sqrt{R_n}\cos\left[(\omega_n + \omega_D)t + \varphi_n\right] \right.$$
$$\left. +2\sum\nolimits_n \sum\nolimits_{m\neq n} \sqrt{(R_n R_m)}\cos\left(\omega_{nm}t + \varphi_{nm}\right) \right\} \tag{8.4}$$

where φ_n and φ_{nm} are trivial initial phase offsets. As evident in the equation, the autocorrelation artifacts, given by the last term inside the brackets, are still centered around the baseband, while the cross-correlation terms, given by the third term inside the brackets, are now shifted away from DC and centered around the carrier frequency ω_D. Although the Fourier transform of the frequency-shifted signal is still Hermitian symmetric, the frequency-shifted fringes are far away enough from baseband such that negative and positive displacements can be differentiated. Positive displacements are located above ω_D, while negative displacements are below ω_D but above the baseband, as long as ω_D is higher than the highest frequency signal, i.e., the maximum ω_n.

A frequency shift of ω_D corresponds to a path length shift of z_D, where $z_D = \omega_D \Delta t/(2\Delta k)$ where Δt is the time it takes for the source to sweep over the entire bandwidth and Δk is the bandwidth of the source in wavenumber units. This shift in frequency is not subject to conventional FDOCT signal falloff, governed by the spectral source instantaneous linewidth in SSOCT. Instead, the frequency shift merely creates a time-varying beat frequency that is not dependent on source linewidth or source sweep rate.

8.2.2 Heterodyne OCT with Frequency-Shifting Devices

There are several algorithms in heterodyne OCT to recover a complex conjugate-free image. The first to be discussed, implemented by Davis et al. [40], utilized

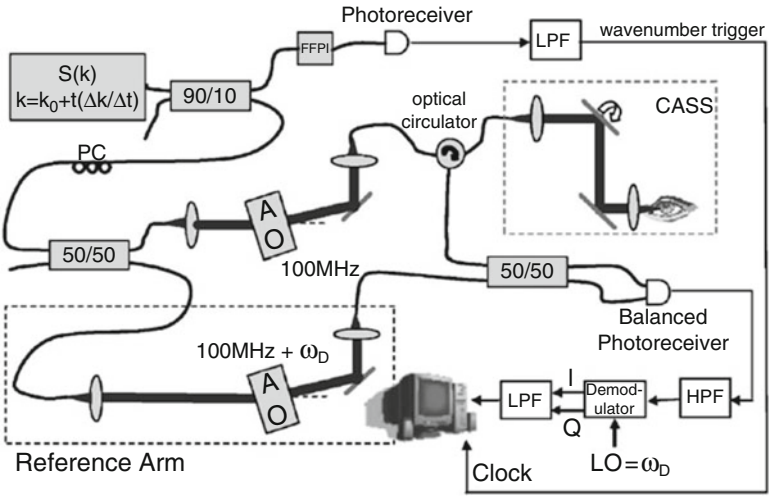

Fig. 8.1 Heterodyne SSOCT system using AOMs to frequency upshift interferogram. The swept laser was centered at 1,300 nm with a bandwidth of 100 nm. Balanced detection is used for common noise rejection. *AO* acousto-optic modulator, *PC* polarization controller, *FFPI* Fabry-Perot interferometer, *CASS* corneal anterior segment scanner

a band-pass filter around the carrier frequency and subsequent demodulation to recover the inphase and quadrature components of the complex OCT signal. The optical setup, depicted in Fig. 8.1, employed two acousto-optic modulators centered at 100 MHz, with a user tunable offset frequency in one modulator to provide the carrier frequency. Circulators were used to minimize the amount of optical power loss through the AOMs. Wavenumber triggering was used to remap the sweep linearly in wavenumber.

After the heterodyned interferometric signal was collected, a high-pass filter was used to remove the DC and autocorrelation artifacts. The filtered signal is then demodulated by mixing with a local oscillator of the same frequency as the carrier frequency. The in-phase and quadrature components can then be recovered to reconstruct the complex OCT signal. Furthermore, after demodulation, the resulting signal is only dependent on ω_n; therefore, conventional wavenumber triggering can be used to remap the sweep linearly in time. Figure 8.2 depicts captured interferometric fringes with and without the frequency shift. Two different interferograms are analyzed, with frequencies corresponding to reflectors at +/−50 μm displacements. As evident, with no frequency shift, the interferograms cannot be differentiated due to the complex conjugate ambiguity. However, collection of the same exact reflectors but with a carrier frequency of 20 kHz depicts how the two interferograms are now at different frequencies and can be easily differentiated. The fringe frequency for the positive displacement is greater than the fringe frequency for the negative displacement.

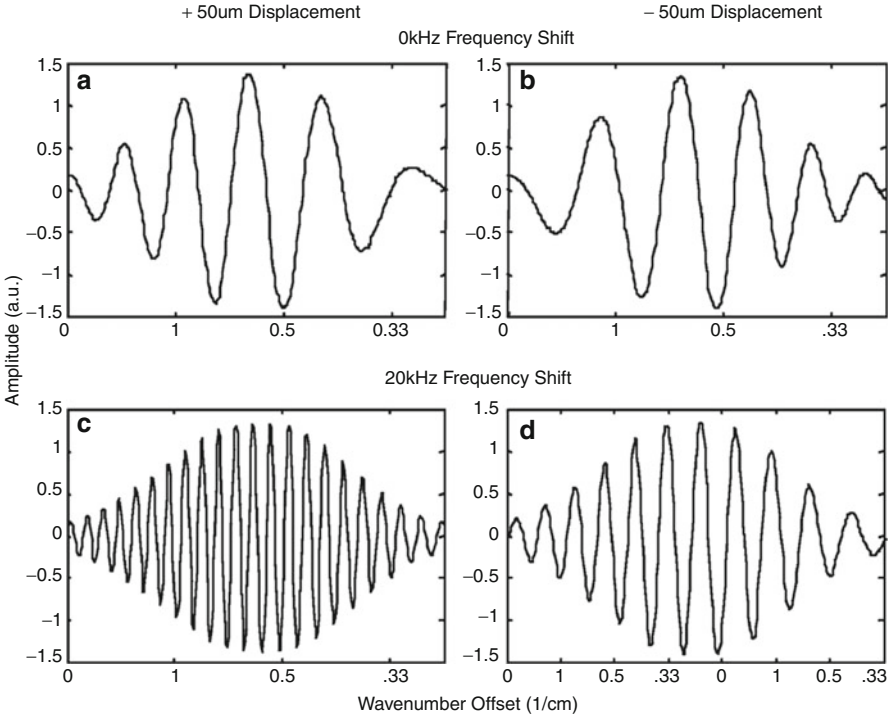

Fig. 8.2 Interferograms captured from reflectors at +/−50 μm displacements using homodyne and heterodyne SSOCT. The top row illustrates the homodyne case, while the bottom row illustrates the effect of frequency shifting by 20 kHz. As evident, the two reflectors in the homodyne case are indistinguishable, while the reflector at the positive displacement has much higher frequency fringes than the reflector at the negative displacement. Notice that the frequency-shifted signals are chirped, indicating that the signal must first be demodulated before wavenumber triggering

As previously mentioned, frequency shifting not only resolves the complex conjugate ambiguity but also eliminates the DC and autocorrelation artifacts. The anterior segment of the eye was imaged using heterodyne SSOCT to illustrate the utility of frequency shifting. The power on the eye was 60 μm and the images were constructed using 500 lines/image acquired at 250 Hz. With homodyne SSOCT, the entire anterior segment cannot be visualized simultaneously; however, frequency shifting doubles the imaging depth range and enables simultaneous imaging of the cornea, sclera, and iris, as shown in Fig. 8.3.

Zhang et al. utilized an electro-optic phase modulator (EOM) to induce a carrier frequency, similar to the frequency-shifting process described above [41, 42]. To compensate for group-velocity dispersion mismatch induced by the EOM, a rapid scanning optical delay line was used. The upshifted signal was band-pass filtered and demodulated to retrieve the complex OCT signal and resolve the complex conjugate ambiguity. As mentioned before, the demodulation of the

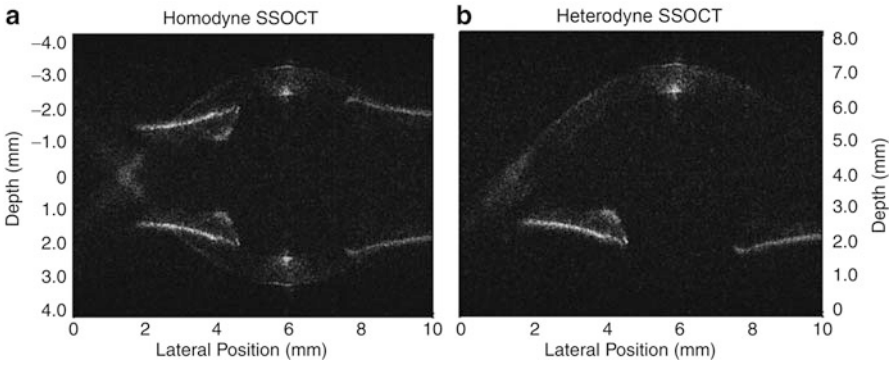

Fig. 8.3 In vivo images of the anterior segment of a human eye with homodyne (**a**) and heterodyne (**b**) SSOCT. The complex conjugate artifacts are resolved in the heterodyne case, doubling depth imaging range to about 8 mm and enabling visualization of the entire anterior segment

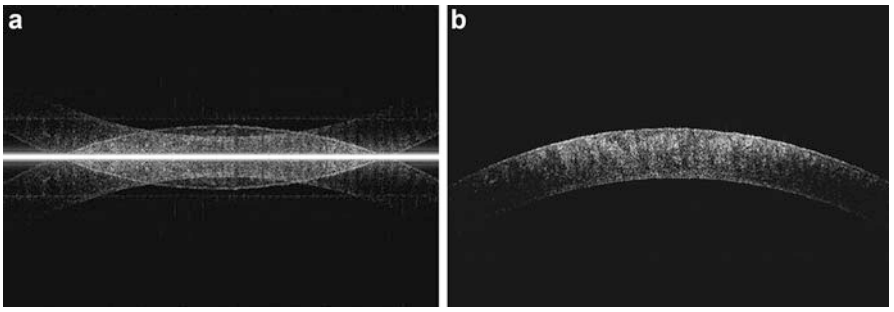

Fig. 8.4 Images of rabbit cornea obtained without (**a**) and with (**b**) the EOM. As evident, frequency upshifting results in a doubling of imaging depth range. The entire corneal curvature can be imaged only after removal of the complex conjugate ambiguity

frequency-shifted signal before remapping the source sweep linearly in wavenumber is necessary to avoid chirping. Furthermore, removal of low-frequency noise as well as autocorrelation artifacts improved system sensitivity by 20 dB. As with the previous technique, removal of the complex conjugate artifact resulted in an increased imaging range by a factor of 2 and was demonstrated by imaging rabbit cornea. Figure 8.4 illustrates the ability to image the entire corneal depth after removal of the complex conjugate artifact.

Another group demonstrated CCR with AOMs, similar to Davis et al. As before, a carrier frequency was applied to electronically shift interferometric signal away from baseband. However, unlike the previously discussed techniques, IQ demodulation was not performed, and the interferometric signal at the carrier frequency was digitized and processed. Instead of performing IQ demodulation to reconstruct the complex OCT signal, the authors relied on the frequency shift induced by the AOMs to be far away enough from baseband such that the negative

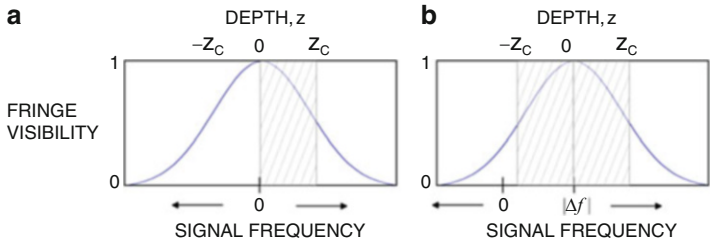

Fig. 8.5 Plot of fringe visibility versus fringe signal frequency without (**a**) and with (**b**) frequency shifting. Frequency shifting enables both sides of the coherence range to be utilized, therefore doubling the imaging range. Negative and positive path lengths are readily differentiated after frequency shifting

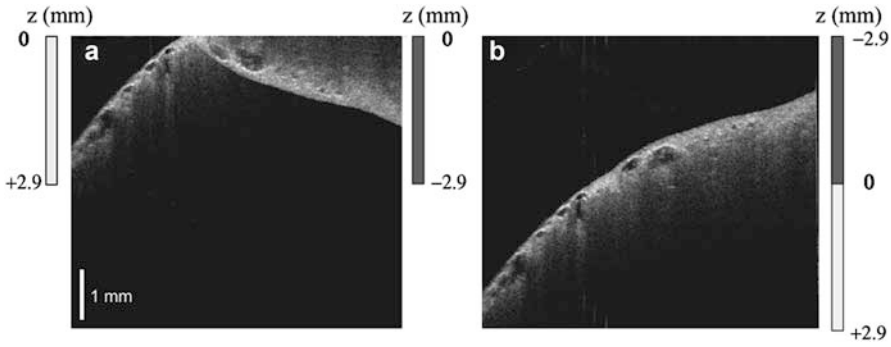

Fig. 8.6 Heterodyne (*right*) and homodyne (*left*) OCT ex vivo images of human lung tissue. The frequency shift of −2.5 MHz corresponds to a path length shift of 2.9 mm. The frequency-shifted image results in doubling of the depth range

path length differences are still above DC. A Fourier transform of this signal is still Hermitian symmetric; however, the complex conjugate ambiguity is still resolved since the entire imaging range is located above baseband. Therefore, as long as a digitizer and photoreceiver with large enough bandwidths are utilized, the upshifted interferometric signal can be collected directly, resulting in a complex conjugate free A-line. Figure 8.5 illustrates this concept. As shown, the zero path delay is now upshifted to some carrier frequency, resulting in locating the entire coherence range on the positive frequency side of DC, doubling the effective ranging depth [43].

CCR was demonstrated on ex vivo images of human lung tissue. A −2.5 MHz frequency shift, corresponding to a 2.9 mm path length shift, was induced using AOMs. The upshifted interferogram was captured and digitized without any demodulation. Therefore, the zero path length position in the heterodyne OCT image is now located 2.9 mm deeper relative to the homodyne OCT image, effectively doubling the imaging range, as shown in Fig. 8.6.

8.2.3 Heterodyne OCT with Coherence Revival

Coherence revival refers to observing interference fringes in an interferometer not only when the sample and reference arms OPLs are matched but also when the OPL mismatch is an integer multiple of the cavity length of the source [44]. This phenomenon can occur if the laser oscillates at multiple longitudinal modes simultaneously; if so, then the multimode field emitted exhibits periodicity. The period at which the interference fringes are seen is equal to the reciprocal of the mode space or alternatively equal to the round-trip optical delay of the cavity length. Therefore, by inserting a "virtual" cavity in either the sample or reference arm by mismatching the OPL difference by an integer multiple of the cavity length, interference fringes are still observed. This phenomenon is present in some external cavity lasers used in SSOCT.

Of particular importance is frequency shifting in coherence revival. For the two swept-source lasers investigated in [45], inserting a virtual cavity also results in phase modulation of the interferometric fringes seen in coherence revival. This phase modulation results in a frequency upshift, equivalent to imparting a carrier frequency with AOMs, as described above. Therefore, phase modulation in coherence revival enables CCR by the same principles as frequency upshifting with AOMs. Although the exact origin of the phase modulation in coherence revival is unknown, it is suggested that a change in the physical length of the cavity or a modulation of the refractive index of the gain media may be responsible [46]. Nevertheless, coherence revival heterodyne OCT behaves exactly the same as the previous heterodyne OCT methods, except that it does not require a frequency-shifting device such as an AOM.

CCR using coherence revival is illustrated in Fig. 8.7, shown below. Falloff plots, which are compiled plots of A-lines for a single, perfect reflector located at different depths, are illustrated for −1, 0, and +1 cavity length offsets. Notice that at −1 and +1 cavity length offsets, the peak sensitivity of the fall of plots is upshifted to around 6 mm, indicating that the interferogram has been upshifted with a carrier frequency corresponding to a path length shift of 6 mm. Coherence revival results in almost doubling the imaging, as defined by the −6 dB cutoff in the falloff plots.

The increased imaging range was illustrated in volumetric in vivo imaging of the anterior segment of the human eye, depicted in Fig. 8.8. Two swept sources (centered at 840 and 1,050 nm) exhibiting coherence revival were used.

Coherence revival OCT was further extended for whole eye imaging [47]. Using polarization encoding, a hybrid anterior segment and retinal imaging system was constructed, as seen in Fig. 8.9. A cavity length offset was added to the sample OPL of the beam focused at the anterior segment to enable CCR. The OPL of the beam focused at the retina and the reference arm were matched. Therefore, the interferogram signal collected from the retina was centered at the baseband, while the upshifted interferogram signal from the anterior segment was centered at a carrier frequency far enough away from baseband to prevent crosstalk between the two interferograms.

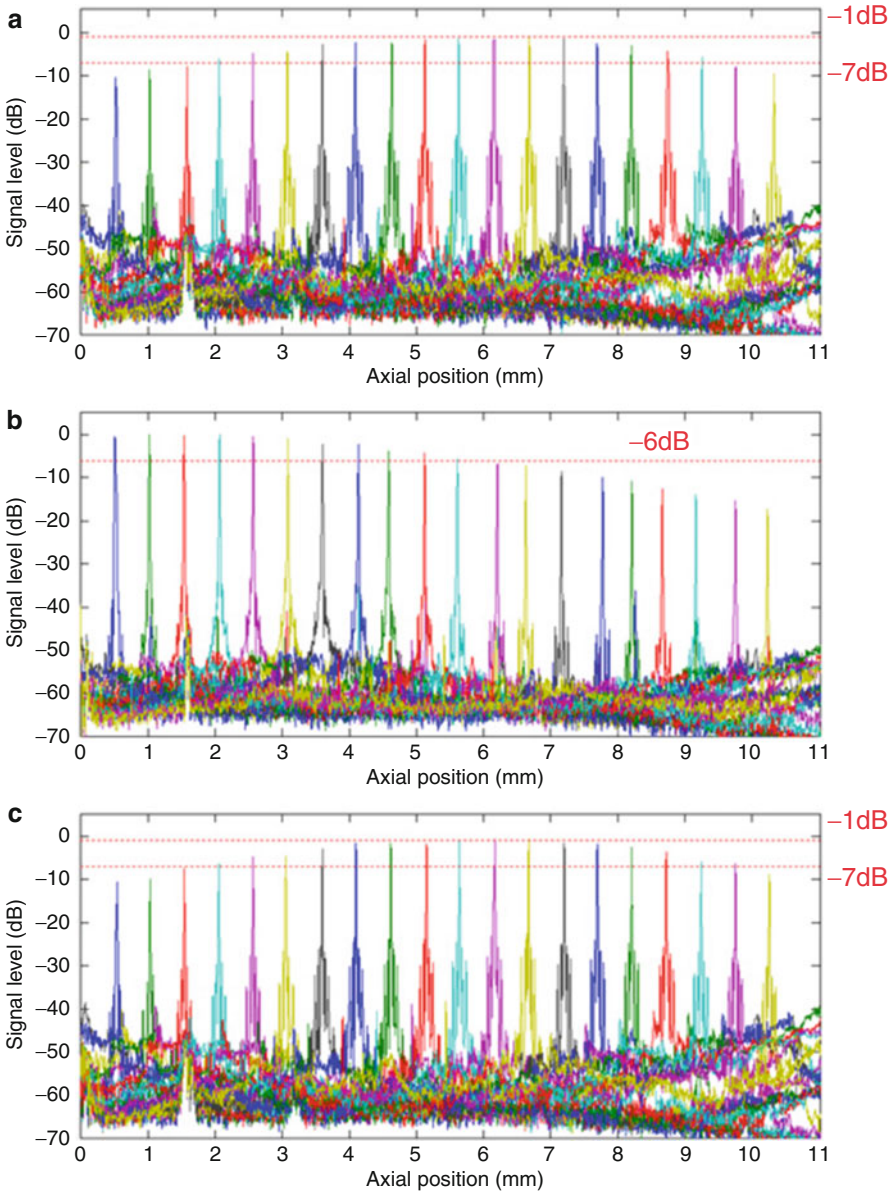

Fig. 8.7 Falloff plots, generated by recorded the reflection of a mirror at different depth locations, are shown for −1 (**a**), 0 (**b**), and +1 (**c**) cavity length offsets. Offsetting the OPL mismatch between the reference and sample arm by +/−1 cavity length results frequency-shifted interferograms, as evidenced by a shift in the peak sensitivity to about 6 mm

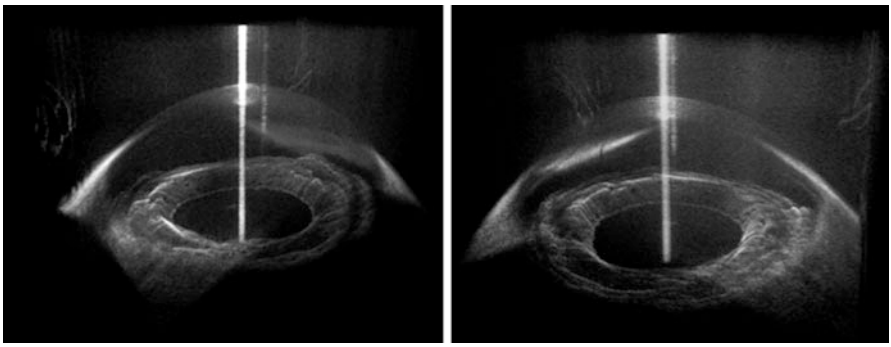

Fig. 8.8 Volumetric imaging of the anterior segment of the human eye with an 840 nm (*left*) and 1,040 nm (*right*) systems. CCR via coherence revival enables imaging of the full anterior segment, including the cornea, iris, and sclera

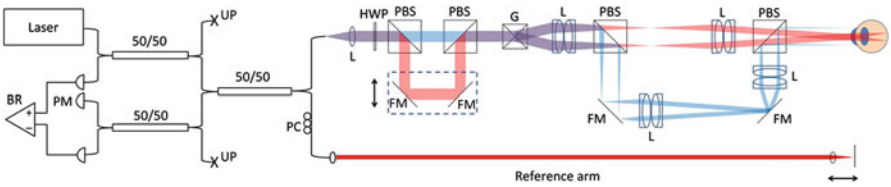

Fig. 8.9 A coherence revival heterodyne OCT system that enables whole eye imaging. Polarization encoding is used to simultaneously image the anterior eye segment and the retina. A cavity length offset in the sample arm enables CCR imaging of the anterior segment of the eye. Simultaneous detection of the baseband and frequency-shifted interferogram, from the retina and anterior segment, respectively, is achieved with a balanced receiver

Whole eye imaging with polarization-encoded coherence revival OCT is shown in Fig. 8.10. The zero path length position and the one cavity length offset position are labeled. The frame acquired before cropping the image is shown in (A) and illustrates how both the retina and anterior segment can be imaged simultaneously.

It is important to note the nonlinear sweep of the source as a function of time in relation to frequency shifting. That is, in standard homodyne SSOCT, the nonlinear sweep causes chirping of the interferometric signal resulting in a loss of axial resolution. Several techniques can be implemented to compensate for the nonlinear sweep. The detector can be sampled at nonlinear time intervals, utilizing an interferometric clock (or "optical clock"), which essentially provides an interferometric signal at a constant frequency. The zero crossings of the fringes of the interferometric clock are used to trigger the detector to enable nonlinear sampling of the OCT interferometric signal. This technique is usually referred to as wavenumber triggering. Another technique simply employs linear time sampling of the OCT signal and subsequent interpolation to remap the sweep linearly in

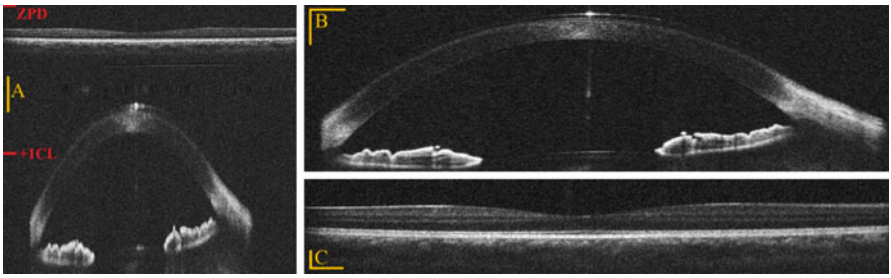

Fig. 8.10 Whole eye imaging with coherence revival OCT. (**a**) shows the simultaneously acquired images of the anterior segment and retina. (**b**) and (**c**) show cropped and average B-scans of the CCR anterior segment and retina, respectively

wavenumber before Fourier transforming to the space domain. When frequency shifting, these standard sampling techniques can result in chirping of the upshifted interferometric signal if it is not demodulated back to baseband. This problem is particularly relevant to frequency-shifting CCR by Yun et al. [43] and coherence revival CCR by Dhalla et al. [48].

To mitigate chirping of the upshifted interferogram, Yun et al. proposed the following algorithm. First, the OCT upshifted interferometric is sampled at uniform time intervals. The DFT is calculated to obtain the electronic frequency of the signal. The frequency bands above and below the carrier frequency are separated and downshifted such that the zero position for each frequency band is aligned with the zero electrical frequency. Zero padding is then applied on each frequency band to increase time resolution in the electrical time domain. With higher time resolution, each band can now be linearly interpolated using a mapping function calibrated for the nonlinear sweep of the source, as is done with conventional SSOCT.

Dhalla et al. proposed a much simpler algorithm. The optical clock from the swept source is designed for calibrating a mapping function such that the interferometric signal can be resampled linearly in wavenumber. However, some of these interferometric clocks are typically designed for maximum imaging depths of 3.7 mm (Axsun Technologies). For imaging depths greater than 3.7 mm, achieved by heterodyne SSOCT, using the conventional optical clock to sample the signal will result in chirping of frequencies corresponding to depths greater than 3.7 mm. The optical clock can then simply be interpolated to increase the fringe frequency to correspond to a depth at least twice that of the carrier frequency. Then, this interpolated calibration vector can be used to interpolate and resample the upshifted SSOCT signal linearly in wavenumber.

Heterodyne OCT is a useful technique that allows complete elimination of the complex conjugate artifact. The complex OCT signal can be retrieved by IQ demodulation or the upshifted interferogram can be directly captured to achieve CCR SSOCT. Heterodyne OCT necessitated the use of frequency-shifting devices such as AOMs, but the recent discovery of coherence revival and phase modulation in popular swept-frequency lasers allow for frequency shifting by simply offsetting

the OPL difference between the sample and reference arms by an integer multiple of the roundtrip delay of the laser cavity length. Heterodyning is an attractive choice for CCR SSOCT due to its simplicity and complete elimination of the complex conjugate artifact.

8.3 Phase-Shifting SSOCT with 3 × 3 Fiber Coupler

Another method for CCR, which is applicable to both SD and SSOCT, utilizes the inherent phase shift in 3 × 3 fiber couplers to enable simultaneously acquisition of phase-shifted interferograms to reconstruct the complex OCT signal [49–51].

8.3.1 3 × 3 Fiber Coupler Phase-Shifting Theory

Phase shifting with 3 × 3 couplers enables instantaneous acquisition of the in-phase and quadrature components of the complex OCT waveform, unlike typical phase-shifting OCT techniques which necessitate the sequential acquisition of phase-shifted frames, resulting in increased imaging time. As discussed above, reconstruction of the complex OCT signal yields a complex conjugate-resolved A-line. Note that unlike the heterodyne CCR SSOCT techniques above, using 3 × 3 fiber couplers suppresses the complex conjugate artifact rather than completely eliminating it, where the suppression ratio is dependent on the reconstruction accuracy of the complex OCT signal.

Recall that the detectors utilized in SSOCT necessarily acquire the real part of the complex OCT signal given by (8.2). As discussed above, the Fourier transform of the real part of (8.2) yields a Hermitian symmetric signal resulting in the complex conjugate ambiguity. To further discuss phase-shifting theory in CCR SSOCT, it proves helpful to rewrite the complex OCT signal in terms of its in-phase and quadrature components. These can be obtained by collecting two interferograms with a relative $\pi/2$ phase shift:

$$D_i[k_m] = D_i^0[k_m] + jD_i^{90}[k_m] \tag{8.5}$$

Recasting Eq. 8.5 and in terms of trigonometric functions and taking the Fourier transform of the complex signal yields an A-scan in which the negative and positive displacements can be unambiguously determined, as shown below:

$$D_i[k_m] \propto S[k_m] \cdot \left(2(R_R + R_S) + 2\sqrt{R_R R_S}\cos\left(2\Delta x k_m + \varphi_i\right) + j2\sqrt{R_R R_S}\sin\left(2\Delta x k_m + \varphi_i\right)\right) \tag{8.6}$$

$$D_i[x_n] \propto S[x_n] \bigotimes \left(2(R_R + R_S)\delta(x_n) + 4\sqrt{R_R R_S}(\delta(x_n + \Delta x))\right) \tag{8.7}$$

As previously mentioned, to acquire the complex OCT signal, other phase-shifting techniques necessitate dithering or stepping of the reference arm to acquire sequential, phase-shifted interferograms. A Michelson interferometer constructed with a 3 × 3 fiber coupler, as shown in Fig. 8.10, introduces an inherent phase delay between the detector ports. If the 3 × 3 fiber coupler has even power splitting rations, then the phase shift between the detector ports is ideally 120° [50]. The true advantage of phase shifting with higher-order couplers is that the phase-shifted interferograms can be acquired simultaneously on the two different ports, which allows for instantaneous CCR SSOCT.

Once the phase-shifted interferograms are collected and assuming that the splitting ratios of the 3 × 3 coupler are know, the in-phase and quadrature components of the complex OCT signal can then be retrieved. Defining the first and second interferograms collected as i_n and i_m, respectively, one of the collected interferograms can be treated as the real part of the complex signal ($i_n = i_{Re}$ shown in (8.5). The imaginary component i_{Im} can be obtained through trigonometric manipulation, as follows:

$$i_{Im} = \frac{i_n \cos\left(\Delta\phi_{mn}\right) - \beta_{mn} i_m}{\sin\left(\Delta\phi_{mn}\right)} \tag{8.8}$$

where ϕ_{mn} is the relative phase shift between the detector ports and β_{mn} is the wavelength-dependent power splitting ratio, which is further discussed in [50].

8.3.2 CCR SSOCT imaging with 3 × 3 Fiber Couplers

Using a 3 × 3 fiber coupler and the system shown in Fig. 8.11, suppression of the complex conjugate-resolved ambiguity was demonstrated [51]. Figure 8.12 shows falloff plots depicting the complex conjugate-resolved A-scans for various path lengths. The peak SNR of the SSOCT system was 112 dB, while the maximum suppression of the complex conjugate artifact was about 25 dB.

An anterior eye segment SSOCT imaging system with a conventional imaging depth of 4 mm, as defined by the finite linewidth of the swept source, was utilized.

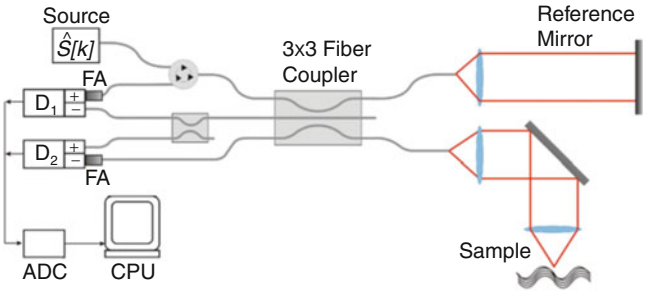

Fig. 8.11 Phase-shifting OCT using a 3 × 3 fiber coupler. The phase-shifted interferograms are simultaneously acquired at the two separate detectors to reconstruct the complex OCT signal

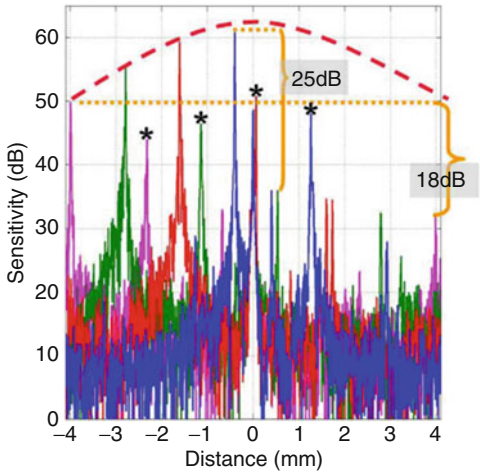

Fig. 8.12 Complex conjugate-resolved A-scans. Maximum suppression of about 25 dB of the complex conjugate artifact is shown. The asterisks indicate peaks corresponding to reflections from an attenuation filter

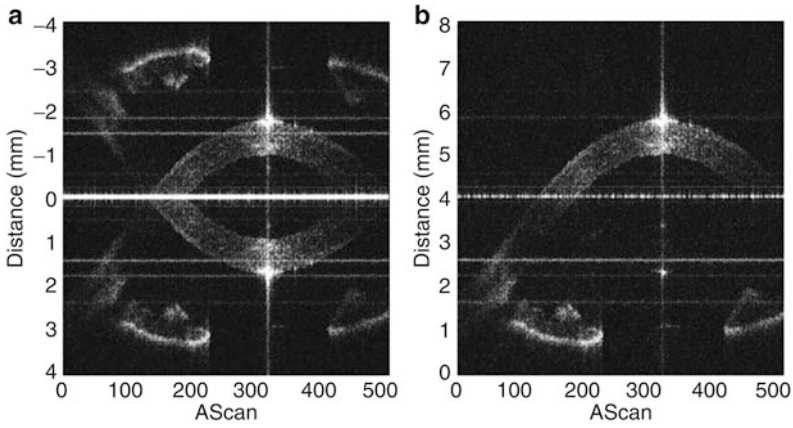

Fig. 8.13 Conventional SSOCT (**a**) and CCR SSOCT (**b**) imaging of the anterior segment of the eye. The origin of the spurious reflections between 1.5 and 2.6 mm is unknown

Resolving the complex conjugate ambiguity with the 3 × 3 fiber coupler doubled the imaging depth to 8 mm, enabling visualization of the entire anterior eye segment, shown in Fig. 8.13.

It should be noted that the wavelength-dependent power splitting is a limiting factor in the reconstruction of the complex OCT single and contributes to the imperfect suppression of the complex conjugate artifact. Furthermore, similar to the phase-stepping techniques used in CCR SDOCT, introducing additional phase steps by using higher-order coupler (e.g., 4 × 4) may improve reconstruction accuracy of the complex signal. As noted above, a suppression of 25 dB was achieved with this previously discussed implementation.

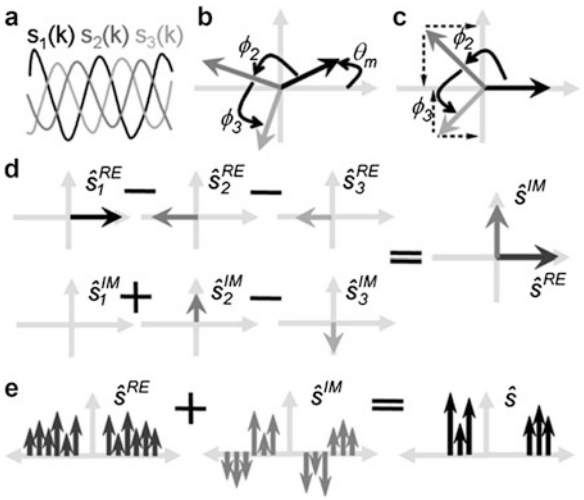

Fig. 8.14 Quadrature projection processing for complex conjugate-resolved FDOCT. The processing steps are described in detail in the text. 3 × 3 fiber coupler phase-shifting OCT does not necessitate any mechanically induced phase shifting. Instead, the phase shift between collected interferograms is inherent to the fiber coupler. Furthermore, multiple detector ports enable simultaneous acquisition of the shifted interferograms and reduce imaging time compared to other phase-shifting OCT techniques

Phase-shifting OCT techniques in general usually have imperfect suppression of the complex conjugate ambiguity because of miscalibration of the phase shift and chromatic phase shift error when dithering the reference mirror. When using 3 × 3 couplers, chromatic phase shift error is not induced; however, the technique may still be sensitive to phase shift miscalibration. A different complex OCT reconstruction algorithm – intended for use in 3 × 3 coupler phase shifting but applicable to any phase-shifting OCT techniques – is insensitive to miscalibrated phase shifts in 90° interferometry and only requires knowledge of the Re/Im quadrant location for each phase in non-90° interferometry [49]. In this algorithm, illustrated in Fig. 8.14, the phase-shifted interferograms can be represented in the Fourier domain (a) and the complex plane (b). Phase subtraction enables the phase shift of the first signal to align onto the real positive axis. The shifted interferograms are now offset from the real positive axis by some angle ϕ given by the relative phase shift (c). The real and complex projections of each vector can then be summed to obtain a single complex signal (d). The complex conjugate ambiguity can then be resolved by summing the real and imaginary components of the reconstructed complex signals (e). A more detailed description and analysis of the algorithm can be found in [49]. This algorithm is advantageous since it can be utilized with an arbitrary number of phase shifts and enabled complex conjugate artifact suppression of >30 dB with 3 × 3 fiber coupler phase-shifting OCT.

8.4 Polarization-Based Optical Demodulation in SSOCT

Another method for retrieving the IQ components of the complex OCT signal in SSOCT is through polarization-based optical demodulation [52]. In essence, the detected interferogram is polarization encoded such that one polarization state (first interferogram) is 90° out of phase with the second polarization state (second interferogram), thereby allowing reconstruction of the complex signal. The system utilized is depicted in Fig. 8.15, where the dashed box delineates the optical demodulation circuit [53, 54] for retrieval of the IQ components.

Light from the sample and reference arm paths are orthogonally polarized using a polarized beam combiner. The light is then coupled to a 50/50 coupler where each arm of the coupler directs light to a polarization controller and then a polarized beam splitter. The output from the polarized beam splitter converts polarization modulation to intensity modulation detected by a balanced receiver. It is important to note that the phase shift between light in each arm of the 50/50 splitter can be arbitrarily set by the polarization controllers. Therefore, to retrieve the IQ components of the complex OCT signal, the polarization-encoded interferograms can be phase-shifted by 90°. CCR SSOCT using polarization-encoded optical demodulation was demonstrated with images of a finger, shown in Fig. 8.16.

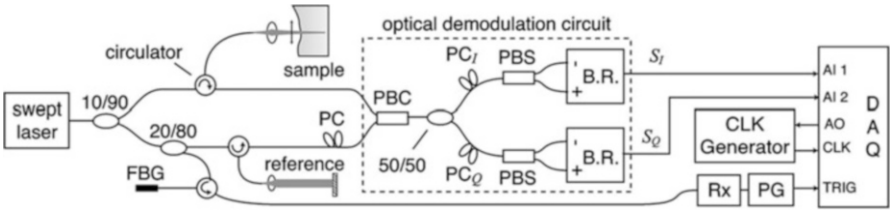

Fig. 8.15 Retrieval of IQ components using polarization-encoded optical demodulation. *PC* polarization controller, *PBC* polarization beam combiner, *PBS* polarized beam splitter, *BR* balanced receiver

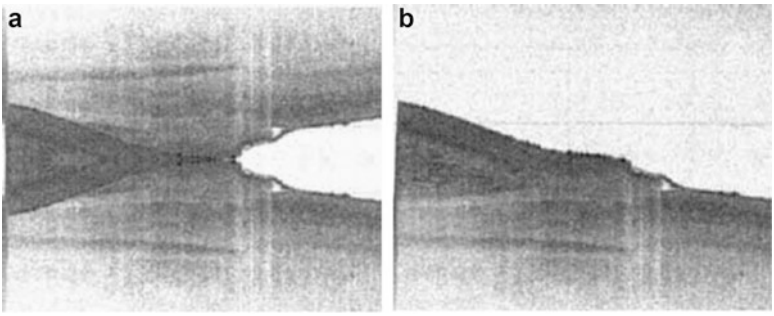

Fig. 8.16 Images of a human finger without (**a**) and with (**b**) optical demodulation

Polarization-based optical demodulation is unique since it does not require RF demodulation or phase shifting. As long as the relative phase delay between the orthogonally polarized interferograms is carefully controlled, the complex OCT signal can be readily reconstructed.

8.5 Conclusion

The complex conjugate ambiguity is a nontrivial artifact resulting from direct Fourier detection in FDOCT. While most FDOCT systems avoid this artifact by limiting their imaging range, CCR FDOCT seeks to suppress or eliminate the complex conjugate ambiguity. CCR for SSOCT, by either phase shifting, heterodyning, or optical demodulation, increases the imaging range by a factor of 2 compared to conventional FDOCT. This technological development is important in many OCT applications, including ophthalmology in which the increased imaging range in necessary to visualize the entire anterior segment of the human eye.

Keywords

Ultrahigh axial resolution • Broad bandwidth light sources • Ti:sapphire • Super continuum • Resolution limitations

The performance of an OCT system is mainly determined by its longitudinal (axial) resolution, transverse resolution, dynamic range (i.e., sensitivity), and data acquisition specifications, including digitization resolution and speed [11]. For application in medical diagnosis, additional factors, e.g., noncontact vs. contact applicability,

possible penetration into the investigated tissue, image contrast, as well as extraction of functional or biochemical information in addition to the visualization of micro-structural morphology, have to be considered. In addition, for clinical applications, compactness, user-friendliness, robustness, flexibility, overall costs of the OCT system, as well as the possibility to interface it to existing diagnostic technology are decisive factors.

9.1 Longitudinal and Transverse Resolution in OCT

In contrast to conventional and confocal microscopy, OCT achieves very high-axial image resolutions independent of focusing conditions (cf. Fig. 9.1). The axial and transverse resolutions of OCT are decoupled:

- Axial (depth) resolution – defined by the coherence length of the light source (rather than the depth of field as in microscopy)
- Transverse resolution – defined by the focal spot size

As in conventional microscopy the transverse resolution and the depth of focus are determined by the focused transversal spot size, defined as the $1/e^2$ beam waist of a Gaussian beam (cf. Fig. 9.1). Assuming Gaussian rays and only taking into account Gaussian optics, the transverse resolution can be defined by

$$\Delta x = \frac{4\lambda}{\pi}\frac{f}{d}, \tag{9.1}$$

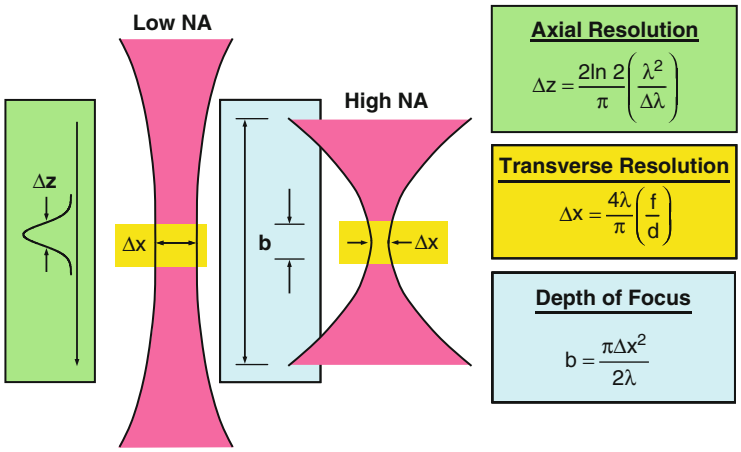

Fig. 9.1 *Resolution limits of OCT*. OCT can achieve high-axial resolutions independent of numerical aperture. Using low-coherence interferometry, the axial resolution is inversely proportional to the bandwidth of the light source. The transverse resolution is given by the focus spot size. The depth of field is determined by the confocal parameter of the focused beam

where f is the focal length of the lens and d is the spot size on the objective lens. Increasing the numerical aperture of the objective increases the transverse resolution by reducing the focal spot size, but it decreases the depth of field, quantified by the confocal parameter b, which is $2z_R$ or twice the Rayleigh length $2z_R = b = \pi\Delta x^2/2\lambda$. Thus, improving the transverse resolution can be accomplished by increasing the numerical aperture (NA) of the objective, but at the same time decreasing b. A solution to this limitation is the use of a dynamic focus tracking system. Especially for ophthalmic retinal OCT imaging, low numerical aperture focusing is employed, because it is desirable to have a large depth of field and to use OCT to achieve high-axial resolution.

The interference signal detected at the output of the interferometer is the electric field autocorrelation of the light source. As mentioned before, the full width at half maximum (FWHM) of this autocorrelation is the coherence length l_c, which gives the axial resolution Δz and is inversely proportional to the width of the power spectrum. The envelope of this field autocorrelation is equivalent to the Fourier transform of the power spectrum. For a source with a Gaussian spectral distribution, the axial resolution Δz is primarily determined by the coherence length of the optical light source given by

$$\Delta z = \frac{2\ln 2}{\pi} \frac{\lambda^2}{\Delta\lambda}, \tag{9.2}$$

where λ is the center wavelength of the source and $\Delta\lambda$ the spectral bandwidth (cf. Fig. 9.1) [12]. Hence, high-axial resolution may be achieved even with low numerical aperture (NA) beam delivery optics. Since the coherence length of a light source is inversely proportional to its spectral bandwidth, broad-bandwidth optical sources are required to improve the axial resolution in OCT, which are important to detect early changes of various diseases occurring at cellular level. To improve axial OCT resolution, the spectral bandwidth must be either increased or the center wavelength decreased. Therefore, novel light sources are necessary – ultrabroad bandwidth solid state lasers have the advantage of providing broad bandwidths necessary for high resolution as well as high power [13]. Since the wavelength in material with a higher refractive index becomes shorter, the actual axial resolution within the imaged tissue can be estimated by dividing the free space resolution by the group refractive index, i.e., 1.35–1.4 for most of the biological tissue. Nevertheless, the axial resolution is also limited not only by the dispersion of the sample but also by absorption and scattering within the sample, where photons with the same path, but backreflected from various imaging depths, are detected.

Improving the axial resolution in OCT is challenging and requires the use of highly sophisticated ultrabroad bandwidth light sources. Figure 9.2 depicts "iso-resolution lines," i.e., the optical bandwidth (at full-width-at-half-maximum (FWHM)) for a given central wavelength necessary to achieve a desired axial OCT resolution. The iso-resolution lines range from 16 to 0.125 μm, measured in free space. For the standard wavelength region used for OCT retinal imaging (800 nm), assuming a Gaussian spectrum of the light source as well as nondispersive imaging medium, this

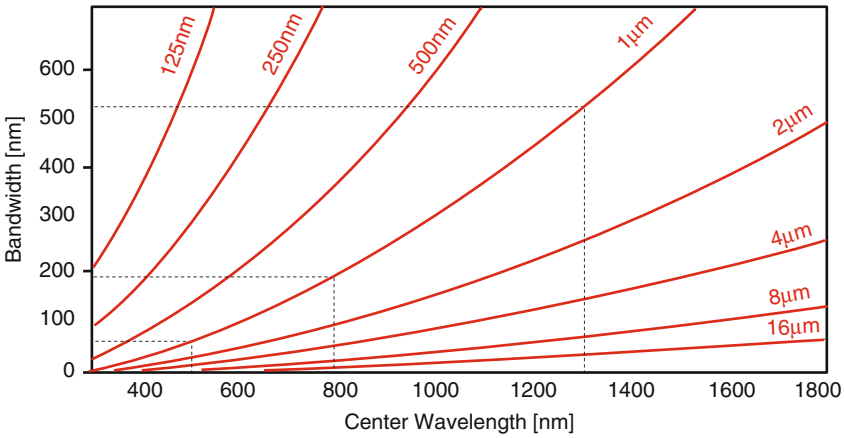

Fig. 9.2 *Axial OCT resolution*. "Iso-resolution lines" for certain axial OCT resolutions (ranging from 16 to 0.125 µm) indicating necessary optical bandwidth as a function of central wavelength. Significantly broader optical bandwidth is needed for the same axial OCT resolution with increasing central wavelength (cf. *dashed lines* for 500 nm, 800 nm, and 1,300 nm, respectively)

figure shows that for 1 µm axial resolution, an optical bandwidth of ~200 nm is needed. It also illustrates that in order to achieve the same axial resolution at 1,300 nm, more than 500 nm of optical bandwidth (FWHM) is needed, i.e., more than two times more, compared to what is needed at 800 nm. Finally, in the visible wavelength region (500 nm), only 75 nm is need to achieve 1 µm axial OCT resolution. This demonstrates the significant wavelength dependence and the challenge to balance resolution versus penetration/contrast depending on the particular OCT application.

9.2 Axial Resolution Limits for OCT

9.2.1 Group Velocity Dispersion Limitations to Resolution

Group velocity dispersion (GVD) causes different frequencies to propagate with nonlinearly related phase velocities. A short pulse in dispersive media will broaden if significant dispersion is present. In analogy to the case for short pulses, the interferometric autocorrelation (i.e., the axial PSF) will also broaden if there is GVD mismatch between reference and sample arms. Both the fiber optics and the sample may introduce a significant amount of GVD. To include GVD in the analysis, the propagation constants β_R and β_S used in the propagation equation are Taylor expanded to second order around the central frequency ω_0.

$$\beta(\omega) = \beta(\omega_0) + \beta^{(1)}(\omega_0)(\omega - \omega_0) + \frac{1}{2}\beta^{(2)}(\omega_0)(\omega - \omega_0)^2 + \ldots \qquad (9.3)$$

where a GVD mismatch is assumed in a length L of the sample and reference paths. The frequency-dependent phase mismatch

$$\Delta\phi(\omega) = 2\beta_S(\omega)l_S - 2\beta_R(\omega)l_R \tag{9.4}$$

is

$$\begin{aligned}\Delta\varphi\ \ (\omega) &= \beta\,(\omega_0)(2\Delta l) + \beta^{(1)}(\omega_0)(\omega-\omega_0)(2\Delta l)\\ &\quad + \frac{1}{2}\Delta\beta^{(2)}(\omega_0)(\omega-\omega_0)^2(2L) + \ldots,\end{aligned} \tag{9.5}$$

where Δl is defined as the additional geometric path difference and $\Delta\beta'' = \beta''_S(\omega_0) - \beta''_R(\omega_0)$ is the GVD mismatch between the reference and sample paths. Note that only the difference in GVD between the two interferometer arms enters Eq. 9.5. Thus, the deleterious effects of dispersion may be decreased by equalizing the GVD in the two interferometer arms. Inserting $\Delta\phi(\omega)$ into the propagation equation gives the photocurrent

$$\begin{aligned}I \propto \Bigg\{ &\exp[-j\omega_0\Delta\tau_P]\int_{-\infty}^{\infty} S(\omega-\omega_0)\exp\left[-j\frac{1}{2}\Delta\beta''(\omega_0)(\omega-\omega_0)(2L)\right]\\ &\times\exp\left[-j(\omega-\omega_0)\Delta\tau_g\right]\frac{d(\omega-\omega_0)}{2\pi}\Bigg\},\end{aligned} \tag{9.6}$$

where $\Delta\tau_P$ is the phase delay mismatch and $\Delta\tau_g$ is the group delay mismatch. The GVD mismatch multiplies the source power spectral density $S(\omega - \omega_0)$ in a frequency dependent, quadratic phase term. The interferometric signal looks like a short pulse, with its Fourier transform being $S(\omega - \omega_0)$, which propagates through a length L of dispersive medium with second-order dispersion equal to the difference in GVD between the interferometer arms. Thus, just as a short pulse broadens and chirps after propagation through a dispersive medium, the interferometric signal should also broaden and chirp due to GVD mismatch in the two interferometer arms.

To establish the analogy further, we assume that the source has a Gaussian power spectral density distribution and after substitution into Eq. 9.6 a modulated interferometric signal with a complex Gaussian envelope is obtained

$$I \propto \frac{\sigma_\tau}{\Gamma(2L)}\exp\left[-\frac{\Delta\tau_g}{2\Gamma(2L)^2}\right]\exp\left[-j\omega_0\Delta\tau_p\right], \tag{9.7}$$

where σ_τ is the single-sided standard deviation. The characteristic width of the axial point spread function in the presence of dispersion $\Gamma(2L)$ is a complex parameter that depends on both the round trip length of GVD mismatch $2L$ and σ_τ via

$$\Gamma(2L)^2 = \sigma_\tau^2 + j\Delta\beta''(\omega_0)(2L). \tag{9.8}$$

The real and imaginary components of $1/\Gamma(2L)^2$ describe the broadening and chirping, respectively, of the interferometric signal and are

$$\frac{1}{\Gamma(2L)^2} = \frac{\sigma_\tau^2}{\sigma_\tau^4 + \tau_{\text{critical}}^4} - j\frac{\tau_{\text{critical}}^2}{\sigma_\tau^4 + \tau_{\text{critical}}^4}, \tag{9.9}$$

where we have defined the dispersion parameter

$$\tau_{\text{critical}} = [\Delta\beta''(\omega_0)(2L)]^{\frac{1}{2}}. \tag{9.10}$$

Substituting the expression for $1/\Gamma(2L)^2$ into Eq. 9.7, we discover that the Gaussian envelope is broadened to the new standard deviation width

$$2\widetilde{\sigma}_\tau = 2\sigma_\tau\left[1 + \left(\frac{\tau_{\text{critical}}}{\sigma_\tau}\right)^4\right]^{\frac{1}{2}}. \tag{9.11}$$

The broadening factor becomes appreciable when the magnitude of the dispersion parameter τ_{critical} becomes greater than the non-broadened temporal standard deviation σ_τ. For a typical fused silica fiber at 800 nm, $\beta'' = 350\ \text{fs}^2/\text{cm}$. For a standard resolution achieved by OCT, $\Delta l = 10\ \mu\text{m}$, implying $\sigma_\tau = 28$ fs. Thus, dispersive broadening becomes a factor if the fiber arm lengths are mismatched by at least 1 mm.

The chirping of the interferometric signal with increasing path length mismatch Δl can be described by differentiating the phase in the exponent of Eq. 9.7, leading to

$$k = \frac{d\phi}{d\Delta l} = 2\beta(\omega_0) - \frac{\tau_{\text{critical}}^2}{\sigma_\tau^4 + \tau_{\text{critical}}^4}\left[4\Delta\beta''(\omega_0)^2\right]\Delta l, \tag{9.12}$$

where k describes the spatial frequency of the interference fringes versus the distance measured Δl. For example, in the positive dispersion mismatch regime $\Delta\beta''(\omega_0) > 0$, when the reference arm path length is increased, Δl decreases, the wavenumber k increases, and the interference fringes occur at the detector more often. It is important to note that GVD changes the phase but not the bandwidth of the interference signal.

Dispersion mismatch also degrades the peak height of the interferometric envelope, which reduces the system dynamic range. The degradation in the photocurrent amplitude is described by the multiplicative factor of Eq. 9.7.

$$\frac{\sigma_\tau}{|\Gamma(2L)|} = \frac{1}{\left[1 + (\tau_{\text{critical}}/\sigma_\tau)^4\right]^{\frac{1}{4}}}. \tag{9.13}$$

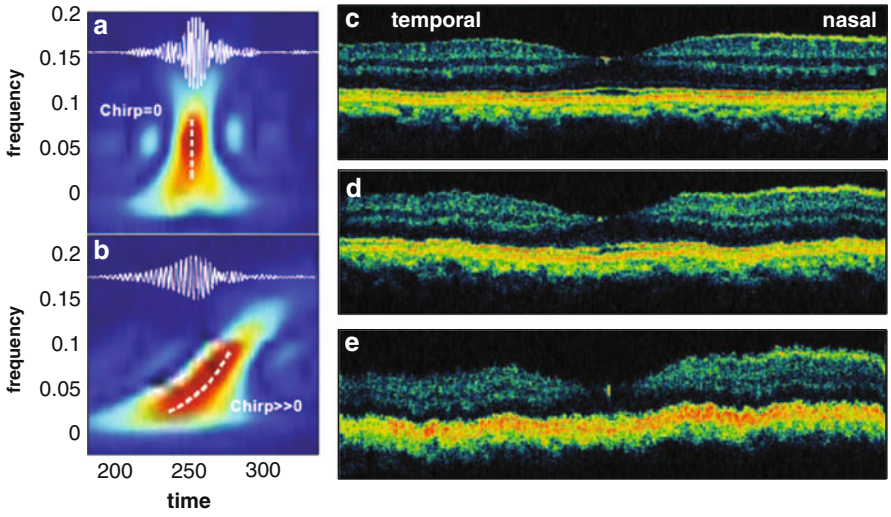

Fig. 9.3 *Group velocity dispersion effect on axial resolution in ultrahigh-resolution OCT*. Dispersion effect on an actual pulse (**a**, **b**); inlet: measured cross-correlation interference pattern and time-frequency diagram of a pulse pair without (**a**) and with (**b**) high-order dispersion difference. Frequencies are shifted in time (*chirp*) and the amplitude is reduced, while the envelope is broadened. Effect of dispersion mismatch in in vivo ultrahigh-resolution retinal imaging (**c**–**e**). Dispersion matched (**c**); artificially introduced dispersion mismatch by 3 mm (**d**) as well as 9 mm (**e**) fused silica in the reference arm. Clear axial resolution as well as sensitivity (–5 dB) degradation is observed

The reduction of the signal amplitude peak scales as the square root of the broadening. Assuming that the dynamic range is measured in terms of reflected optical power, which is proportional to photocurrent power, the loss in dynamic range scales linearly with the broadening.

While first-order dispersion only affects the electromagnetic phase inside the envelope of the signal, leaving the envelope itself unaffected, the second-order frequency dependent refractive index of material introduces a time-dependent change of the instantaneous frequency and an increase of the envelope's width, which are associated with a loss of signal intensity. Commonly this effect is also called "chirp," since the acoustic analogue for dispersion is found in the sound that songbird makes. The different frequencies are also shifted in respect to each other, resulting in a high pitched tone that falls for each chirp. The zero-order term of dispersion only introduces a temporal shift of the whole pulse and is equivalent to the refractive index; the higher indices distribute the phase of different frequencies in time and alter the shape of the pulse envelope (cf. Fig. 9.3). Dispersion distributes signal power away from the central peak where all spectral components are in phase to the wings, thereby distorting the envelope of the signal. In case of an originally unchirped pulse with Gaussian envelope second-order dispersion, also called group dispersion delay (GDD) generates symmetric side lobes where parts of the different continuous wave components interfere constructively. Higher-order dispersion,

such as third-order dispersion (TOD) or fourth-order dispersion (FOD), introduces satellite pulses, in the form of a pulse train. In contrast to the generation of ultrashort pulses, the dispersion effects in OCT do not involve complete reversion, but can be cancelled (in the case of static dispersion) by balancing the dispersion in both arms of the interferometer. Therefore, the cross-correlation becomes a linear autocorrelation again, which is indistinguishable if the spectral content is constant. Compensation of a lens systems consisting of multiple exotic glass types involves a comparable, complex mixture of dispersion compensation materials.

In summary, the two arms of an OCT interferometer must have almost the same delay as well as similar second- and higher-order dispersion (GDD, TOD). The first-order dispersion, however, does not play a role for the interference envelope and therefore is irrelevant for measuring the position. However, FOD does affect the phase and changes the readings for complex analysis of material properties (see in the following chapters). For ultrahigh-resolution retinal OCT imaging, the dispersion of approximately 25 mm ocular media can be compensated by using 25 mm of water in the reference arm, since previous in vivo studies of dispersion measurements have shown that the dispersion of ocular media averaged over 25 mm is similar to the that of 25 mm of water [14]. Balancing the higher-order contributions to dispersion of the 25 mm ocular media in front of the retina is more critical for obtaining high resolution than balancing the dispersion of the system itself. Figure 9.3 depicts the effect of dispersion mismatch in the case of in vivo ultrahigh-resolution retinal imaging of a normal human fovea (cf. Fig. 9.3c). By artificially introducing dispersion mismatch by inserting 3 mm (cf. Fig. 9.3d) and 9 mm (cf. Fig. 9.3e) fused silica in the reference arm of the OCT interferometer, it is obvious that both OCT resolution and sensitivity (up to –5 dB) decrease. Clinical studies with ultrahigh-resolution ophthalmic OCT utilizing ~100 nm broad spectra revealed that by using a dispersion compensation of 25 mm of water in the reference arm of the interferometer, patients with axial eye lengths between 23 mm and about 27 mm can be imaged with tolerable dispersion mismatch-induced axial resolution loss. Furthermore, numeric compensation can be used for further enhancement and fine tuning of the physical compensation, but not as a replacement. This is the result of the inevitable detection and amplification noise in the original signal. In case the signal is so strongly dispersed, that it is below the noise level, the signal is completely corrupted by noise and cannot be recovered numerically. Therefore, it is favorable to physically compensate static dispersion mismatch.

9.2.2 Dispersion and Resolution in FD OCT

The interference signal in spectrometer-based frequency-domain OCT can be recorded as a function of wavelength rather than time. In case of a single reflecting surface in the sample arm, it is of the general form

$$I(\lambda) = I_r(\lambda) + I_s(\lambda) + 2\sqrt{I_r(\lambda)I_s(\lambda)}\cos\left(2f(\lambda)\Delta z + g(\lambda)\right), \tag{9.14}$$

where I_r and I_s are the intensity of the reference and sample arm light, respectively, and Δz is the relative optical path length between both arms. The functions $f(\lambda)$ and $g(\lambda)$ are crucial, since they determine the resolution of the OCT system. In general one needs to Fourier transform the backscattered intensity as a function of wavenumber k or frequency v in order to reconstruct the associate time-domain depth profile. Ideally $g(\lambda)$ is only an arbitrary phase constant that can be neglected without loss of generality, and $f(\lambda) = K = 2\pi/\lambda$. Assuming, however, a dispersion mismatch between both arms associated with a material thickness d, $g(\lambda)$ will no longer be constant but of the form $g(\lambda) = 2d/f(\lambda)(n(\lambda) - 1)$, where $n(\lambda)$ is the wavelength-dependent refractive index of the dispersive material. It is well known that the dispersion $dn(\lambda)/d\lambda$ and higher-order terms cause a broadening of the envelope of the time-domain signal; therefore, the dispersion mismatch between reference and sample arm needs to be minimized to achieve optimal depth resolution. Especially in the case of retinal imaging, one also needs to compensate for the dispersive ocular media that the light double passes on its way to the retina and back to the detector [15].

In order to minimize $g(\lambda)$ one needs to balance the dispersion mismatch between both interferometer arms. Once $g(\lambda)$ has been optimized, we are still left with $f(\lambda)$ which describes a nonlinear phase as a function of wavelength λ in the cosine term of Eq. 9.14. This nonlinearity causes an additional broadening of the coherence envelope after discrete Fourier transform (DFT) of Eq. 9.14. Apart from the relation $\lambda \leftrightarrow K$, it is due to dispersion of the diffraction grating, imaging errors of the optical system in front of the CCD, misalignment, finite CCD pixel sizes, or surface imperfections of the optics. The actual nonlinear phase function needs to be resampled to provide equally spaced interference fringes. There is a residual nonlinearity due to the factors that have been mentioned previously which causes a broader coherence envelope as compared to that obtained with the resampling technique. It is obvious that a small nonlinearity already causes a significant decrease of depth resolution. Further resolution and sensitivity loss occurs as a result of the finite pixel width of the spectrometer together with the limited dynamics of the individual pixel. Due to the recorded chirped interference pattern, there will be always higher frequencies at one end of the modulated spectrum which appear with a reduced modulation depth, as will be explained in the next section. Hence, the effective spectral width of the FD OCT signal is reduced, which results in a resolution loss for structures which are closer to the maximal depth position.

9.2.3 Spectral Shape of Ultrabroad Bandwidth Light Sources

Light sources for UHR OCT not only require high spatial coherence and ultrabroad bandwidth emission with enough output power and low noise but should also have an optimal spectral shape. Since the coherence length is defined as the full width at half maximum of the field autocorrelation measured by the OCT interferometer, the width and also the shape of the coherence function of an OCT system depend on the spectral shape of the light source as well as on the transfer function of the OCT

system. The transfer function is mainly determined by the optical properties of the interferometer, as described in detail later. The ideal spectrum for OCT would have Gaussian spectral shape, resulting in a Gaussian coherence function with no side lobes. Large spectral modulations would reduce sensitivity and resolution, due to the presence of side lobes in the fringe pattern that appear symmetrically to the coherence-function maximum. There are several approaches to change the shape of the emission spectrum of the light source. The easiest way is to introduce optical dichroic or interference filters that suppress certain wavelength regions. Another possibility, especially for very wide spectra, is to spatially disperse the optical beam with prisms and to induce local and therefore wavelength-dependent losses by filtering the dispersed light beam. Especially for nonlinear laser sources, the temporal stability of the spectral properties, i.e., at the time frame of the single depth measurement is essential to maintaining high resolution. Spectral noise, which cannot be optically filtered, can be reduced numerically during post-processing, but always results in a loss of dynamic range and reduction in the full spectral potential.

9.2.4 Chromatic Aberration Limitations to Resolution

Another limitation for achieving ultrahigh resolution is the chromatic aberration of the optics used in the system. Conventional lenses have a focal length which varies with wavelength and thus focus ultrabroad bandwidth light to different planes. This variation in focal position for different wavelengths alters the local effective bandwidth and therefore degrades resolution. For specially corrected achromatic optics, different imaging distances introduce a wavelength-independent attenuation of the whole spectrum, thereby maintaining the spectral shape, optical bandwidth, and therefore axial resolution. Hence, appropriate achromatic objectives have to be used to maintain the ultrabroad bandwidth of the light in order to achieve ultrahigh resolution. Alternatives are reflective objectives like catadioptrics, consisting of parabolic mirrors that have no chromatic aberration and do not introduce dispersion as found in transmittive elements. For ophthalmic OCT chromatic aberration of the eye itself ultimately limits the axial resolution of ultrahigh-resolution retinal OCT imaging if not properly compensated [16–18].

9.2.5 Other Limitations to Resolution

9.2.5.1 Polarization

Another effect that limits axial OCT resolution in UHR OCT systems is polarization mismatch between the interferometer arms and polarization dispersion (loss of polarization) that introduce a phase difference and therefore a change in the shape of the coherence function and axial resolution, respectively. Polarization changes of the static system can be compensated; however, the loss of a single polarization state and sample birefringence leads to an improper overlapping of the reference

and sample light, with severe modulations of the interference spectrum. UHR OCT therefore requires careful polarization control and the polarization dependence of light sources is also an important parameter.

9.2.5.2 Optical Components

The optical transmittance, coating, and wavelength-dependent losses of the bulk or fiber optics, delivery system optics, and also the human eye itself – in case of ultrahigh-resolution ophthalmic OCT – strongly influence the axial resolution as well as the sensitivity of the OCT system. Single-mode and sometimes polarization-maintaining fibers with appropriate cutoff wavelengths should be used to provide light propagation without intra- and inter-fiber interference. Conventional fiber couplers are designed to maintain 3 dB splitting over a narrow wavelength range of typically $\pm$ 10 nm. By using these fiber couplers for delivery of broad bandwidth laser light, unequal beam-splitting with respect to wavelength and power can occur and reduce resolution. Hence, special broad bandwidth and wavelength flattened fiber or bulk optic beam splitter have to be used to maintain broad bandwidths and consequently high-axial resolution. Optical circulators are often used in OCT systems in order to design more power efficient and sensitive interferometers, since nonreciprocal elements reduce power delivery losses from the source to the sample and signal losses from the sample to the detector. However, the large optical bandwidths of more than a fourth of an optical octave (e.g., 200 nm bandwidth at 800 nm) require extremely broad band components to avoid impose wavelength-dependent losses.

9.2.5.3 Detection System

Depending on the method of acquiring the interference signal, the detection system, including electronics as well as digitization and acquisition of the interference signal, must avoid degradation of axial OCT resolution. Hence, the transimpedance amplifier used in time-domain and tunable laser-driven FD-OCT systems, and in particular the electronic band pass filtering, must be designed properly and adapted to the ultrabroad optical bandwidth. The electronic bandwidth of the band pass filter must not be too narrow to reduce the axial resolution, but must also not be too broad to reduce sensitivity by introducing noise. Real-time adaptive filtering can help to optimize sensitivity and maintain axial resolution. In time-domain OCT hardware demodulation must be adapted to the scanning speed and optical bandwidth to avoid broadening caused by the time response of the electronics, resulting in a larger coherence length of the envelope as compared to the full interference fringe signal. Finally, the signal must be correctly temporally digitized with at least five to ten times over sampling in respect to the central wavelength, Doppler shift, as well as scanning speed in order to not degrade the achieved axial resolution. With tunable lasers, the linearity of the scan has to be adjusted or alternatively the k-trigger can be used to generate a scan discretely sampled in k-space. Most tunable laser technology, however, usually is limited to standard bandwidths and cannot achieve ultrahigh resolution. To utilize broadband light sources in the frequency domain, the camera technology and the already-mentioned nonlinearities and sampling problems are the factor that can be compensated with sophisticated post-processing techniques.

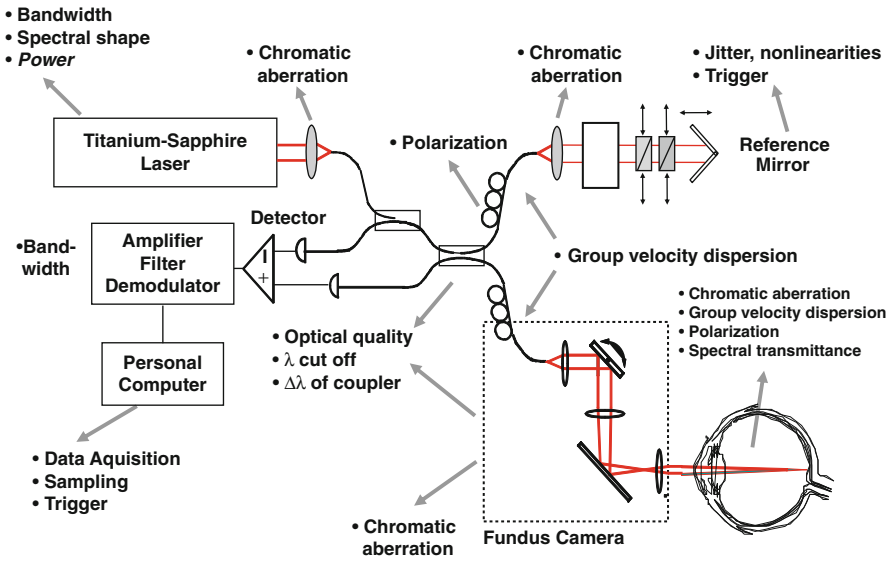

Fig. 9.4 *Axial resolution limits in ultrahigh-resolution OCT*. Summary of all limitations for a time-domain OCT based system for ophthalmic imaging: light source, spectral transmittance of OCT system, delivery system, spectral properties of sample (in this case the human eye), as well as detection and data acquisition specifications

9.2.5.4 Mechanical Components

Finally the mechanical performance of the scanners used for transverse and/or depth scanning should be accurately selected and correctly controlled. Mechanical jitter or displacement of adjacent depth scans as well as noisy control signals of the scanner might result in distorted and therefore degraded resolution UHR OCT tomograms.

Figure 9.4 summarizes the different factors that limit axial resolution performance in OCT for a time-domain-based ophthalmic UHR OCT system. In this case, the delivery systems as well as the eye itself impose challenges for accomplishing ultrahigh-axial OCT resolution. The limitations indicated are also valid for swept source OCT and Fourier-domain OCT systems. In addition to the limitations mentioned in Figure 9.4, specifications of the tunable light source (e.g., linearity, speed, and linewidth of the sweep across a certain optical bandwidth) for swept source/Fourier-domain OCT as well as specifications of the spectrometer for spectral/Fourier-domain OCT have to be taken into account.

9.3 Ultrahigh-Resolution OCT at 800 nm

As mentioned above, a significant difference between OCT and conventional microscopy is that OCT achieves very high-axial image resolutions independent of focusing conditions, because the axial and transverse resolution are determined

independently by different physical mechanisms. The axial OCT resolution can be enhanced using broad bandwidth, low-coherence length light sources. It is important to note that the light source not only determines axial OCT resolution via its bandwidth and central emission wavelength but also influences both the penetration in the sample (biological tissue) and the OCT transverse resolution. A tissue-specific output power and low noise is necessary to enable high sensitivity and high-speed, real-time, OCT imaging. Hence, it is obvious the light source is *the* key technology for an OCT system and proper choice is imperative [13].

Historically the longitudinal resolution of OCT systems was limited by the optical bandwidth of the light source. Typically superluminescent diodes with 20–30 nm bandwidth yielded ~10–15 μm axial resolution. In ophthalmic applications, this provided more detailed structural information than any other standard retinal imaging technique. However, the resolution is significantly below what can be achieved technically and is insufficient to identify individual cells or to assess subcellular structures such as nuclei or mitotic figures. Due to the lack of broad bandwidth, spatially coherent light sources, OCT imaging has been mainly limited to the 800 nm and 1,300 nm wavelength region. Incandescent light sources, although broad bandwidth, produce very little intensity in a single spatial mode. Nevertheless, some research groups have demonstrated these broadband light sources for improving axial imaging resolution by employing a technique that uses a multitude of mutually incoherent low-coherence interferometry channels in order to increase the probe beam power [19] or by using a Linnik-type interference microscope in combination with a CCD camera-based parallel detection scheme [20, 21]. 1 μm isotropic free space axial resolution could be accomplished for in vitro UHR OCT. The first demonstration of sub-10-μm-axial-resolution was achieved by using broadband fluorescence from organic dye [22] and fluorescence from titanium:sapphire [23]. However, biological imaging could not be performed with these light sources due to their low brightness. By multiplexing spectrally displaced superluminescent diodes to increase optical bandwidth [24–26], OCT tomograms with improved ~7 μm axial resolution in the retina were demonstrated several years ago [27]. More recently, cost-effective, broad bandwidth advanced SLD light sources have become available which approach the image resolutions achieved by femtosecond lasers [28, 29]. These light sources are multiplexed SLDs consisting of two or three spectrally displaced SLDs which are combined to synthesize a broad bandwidth spectrum. Multiplexed SLD light sources have the disadvantage of having spectrally modulated emission spectra that can produce sidelobes in the coherence function or axial point spread function, resulting in image artifacts. In addition, the emission wavelength of multiplexed SLDs is typically centered at the longer 900 nm wavelength range, overlapping the water absorption at 980 nm, which can limit the resolution for retinal imaging. On the positive side, multiplexed SLD light sources are much lower cost and more robust than femtosecond lasers and promise to enable wider availability of ultrahigh-resolution OCT. However, at the present time, the price vs. performance trade-off remains such that UHR OCT instruments with 2–3 μm axial resolution are still

limited to research applications. The newest commercial ophthalmic instruments have broad bandwidth, single SLDs and provide 5–8 μm axial image resolution.

Nowadays, ultrashort light pulses can be generated by a range of laser technologies and have widespread applications for ultrafast measurement. Femtosecond laser development has concentrated mainly on the temporal features of the pulses, which were sometimes optimized to the detriment of the spectral shape. In OCT, the pulse shape and duration are irrelevant, while the spectral shape and width play a crucial role. However, unlike ultrafast femtosecond time-resolved measurements where special care must be exercised to maintain the short pulse duration, OCT measurements depend on field correlation, rather than intensity correlation, and every wavelength component interferes independently. Field correlation is preserved even if the pulse duration is long. Femtosecond mode-locked solid state lasers can generate ultrabroad bandwidth, low-coherence light with a single spatial mode and high power, providing both high resolution and high power necessary for high-speed OCT imaging. These lasers can operate over a broad range of wavelengths extending beyond their gain bandwidth by employing nonlinear broadening effects. These spectra are useful for ultrahigh-resolution as well as spectroscopic OCT imaging in tissue. In an early demonstration, a titanium:sapphire laser was used for in vitro OCT imaging in nontransparent tissues with 4 μm axial resolution [30]. In preliminary studies, an OCT system was developed and optimized to support 260 nm of optical bandwidth from a state-of-the-art titanium:sapphire laser [8]. This laser was developed in collaboration with other investigators (Franz Kaertner and Erich Ippen) at M.I.T. and generated pulses of <5.5 fs duration, corresponding to bandwidths of more than 350 nm at 800 nm center wavelength [31]. This high performance was achieved using specially designed double chirped mirrors with high reflectivity bandwidth and controlled dispersion response. Figure 9.5 shows a comparison of the spectra and resolution of an OCT

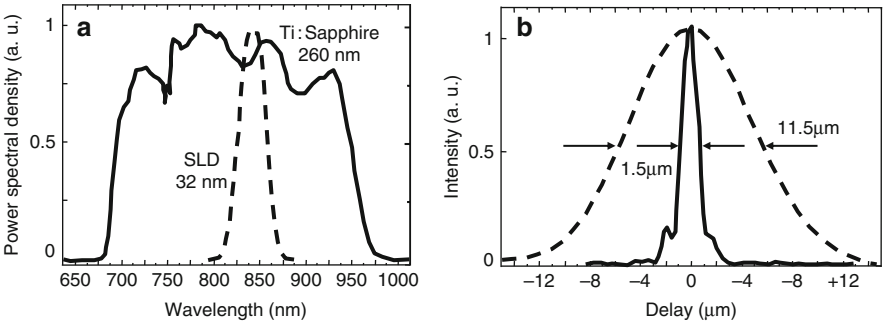

Fig. 9.5 *Light source technology for ultrahigh-resolution OCT*. Solid state laser light sources enable ultrahigh-resolution imaging. The spectrum of the titanium:sapphire laser versus a standard superluminescent diode (*SLD*) is shown depicting their respective wavelength bandwidths (**a**). Demodulated OCT axial scan showing the axial resolution of OCT using titanium:sapphire (*solid*) versus a superluminescent diode SLD (*dashed*) light sources (**b**). Solid state lasers enable almost a 10× improvement in resolution [8]

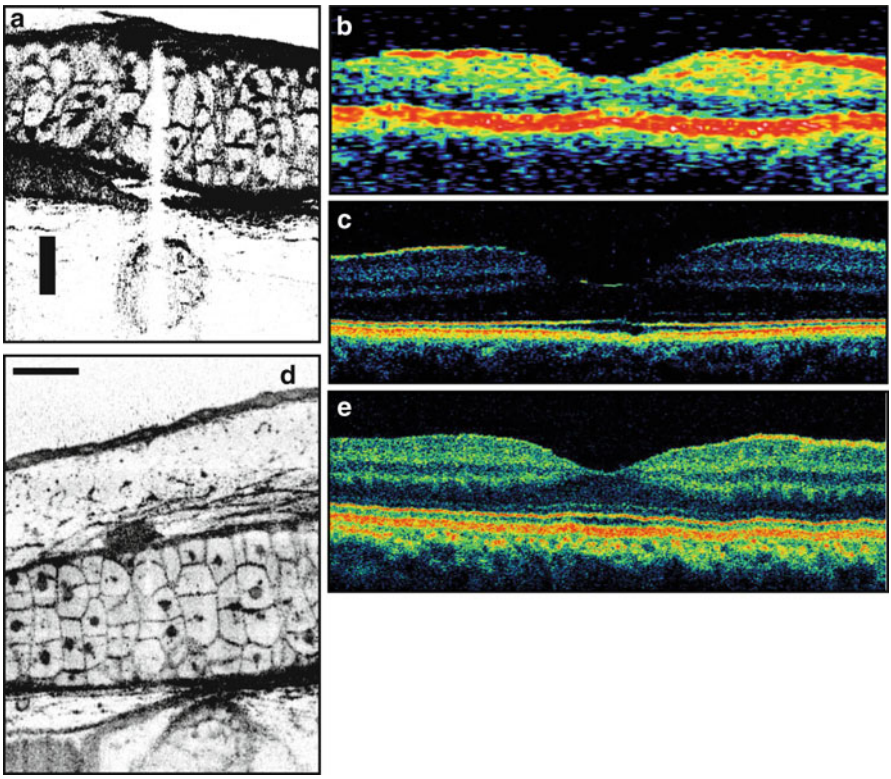

Fig. 9.6 *First in vivo ultrahigh-resolution OCT*. In vivo subcellular resolution OCT (**a**, **d**) in a developmental biology animal model (African tadpole). Standard resolution OCT (performed with the second generation commercial OCT system – OCT II; **b**) versus ultrahigh-resolution ophthalmic OCT (**c**–**e**) of the living human retina. Preliminary results presented in 1999 at SPIE Photonics West (**a**–**c**); improved results published in [8, 9] (**d**, **e**)

A-scan using a conventional superluminescent diode light source versus the femtosecond titanium:sapphire laser source. The ultrabroad bandwidths which are generated by the femtosecond laser enable the axial resolution of OCT to be improved by a factor of nearly 10× compared to standard OCT technology. This femtosecond laser source was used for imaging studies using an OCT microscope as well as an ophthalmic system interfaced to a biomicroscope system.

Figure 9.6a, d show the first in vivo UHR OCT results (presented at SPIE – Photonics West in San Jose, CA in January 1999). The images demonstrate the feasibility of this novel OCT system for in vivo subcellular imaging of a *Xenopus laevis* (African tadpole, left) mesenchymal cells at 1 × 3 μm (longitudinal × transverse) resolution, consisting of 1,600 × 1,200 pixels and 0.4 × 0.5 μm pixel spacing. Figure 9.7b, c, d show preliminary results demonstrating in vivo ultrahigh-resolution retinal OCT imaging in human subjects [9, 32]. These results were achieved with an ultrahigh OCT system based on

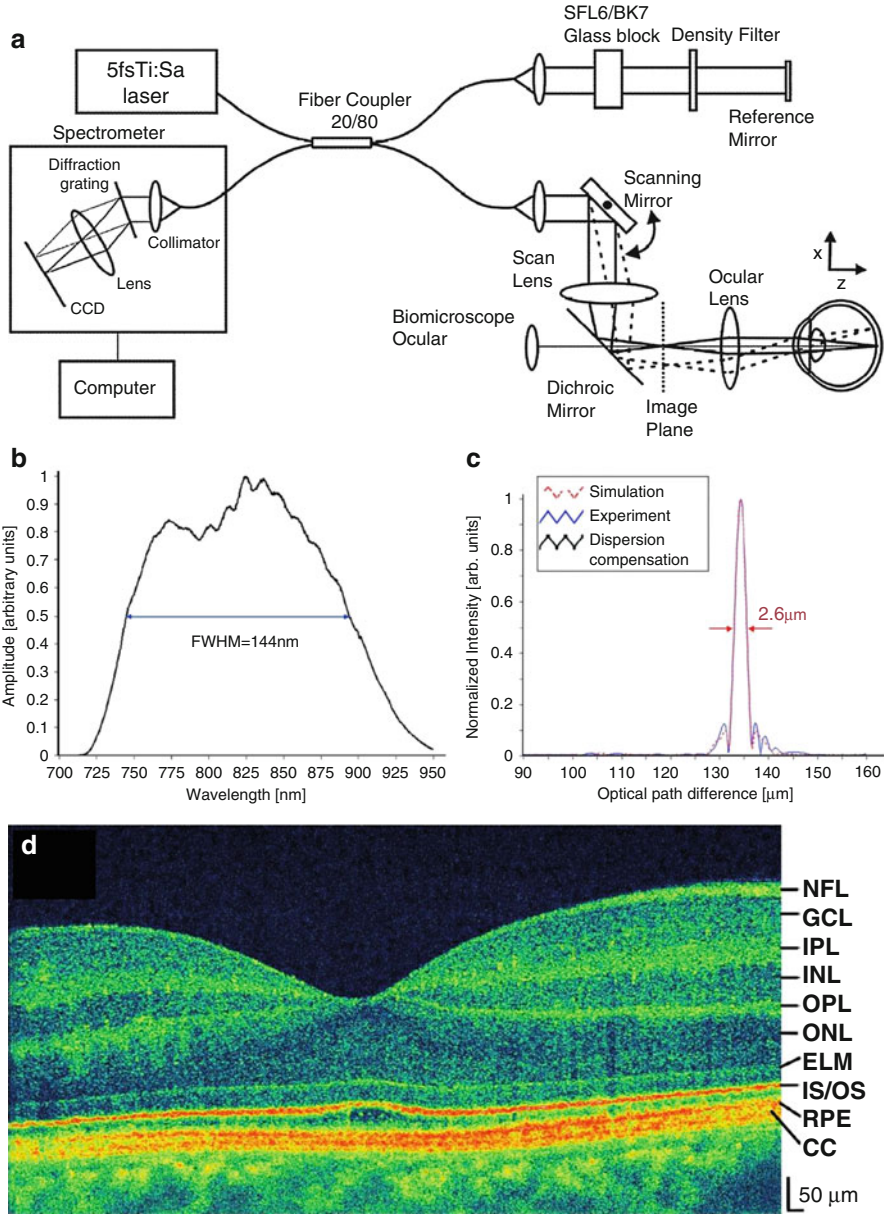

Fig. 9.7 *High-speed, ultrahigh-resolution OCT imaging of the human retina*. A spectral/Fourier-domain OCT system (**a**) using a 5 fs laser was used to demonstrate high-speed, ultrahigh-resolution imaging with an axial line rate of 16,000 lines/s. Source bandwidth (**b**) measured ~144 nm, which provided resolution of ~2.1 um in tissue (**c**). The system enabled high-definition, motion-free imaging of the human retina (**d**)

a laboratory laser system that was not suited for clinical studies. Therefore, a new generation of compact ultrahigh-resolution OCT system was developed. Femtosecond lasers with record low pump requirements enabled a significant reduction in cost [33]. With advanced mirror technology, dispersion control, and adapted cavity design, optical bandwidth of up to 300 nm at full width of half maximum (FWHM) centered at 790 nm could be achieved resulting in sub-μm axial resolution OCT in tissue. Light sources were optimized with respect to compactness, cost-effectiveness, and applicability in the clinical environment with the aim of realization of a commercially available product for UHR OCT. An integrated and sealed system including a low-cost pump laser on a small footprint of about 500 mm × 180 mm was developed. Due to its compactness, the system shows a high stability and reproducibility and facilitated the technology transfer to a commercial product. With the release of compact, cost-effective, user-friendly state-of-the-art titanium:sapphire laser (*Integral* OCT), Femtolasers Produktions GmbH has established this novel OCT light source in industry. A compact design as well as active feedback loops guarantees output parameters of unprecedented quality, stability, and reproducibility. In addition, recently reported, cost-effective approaches for broad bandwidth light sources also took advantage of the lower power demand with ultrahigh-resolution OCT imaging [33–37].

Ophthalmic UHR OCT using these state-of-the-art light sources achieves superior axial image resolutions of 2–3 μm as compared to ∼10 μm resolution in standard OCT, enabling the visualization of intraretinal structure. UHR OCT is a key step toward achieving noninvasive optical biopsy of the human retina, i.e., visualization of intraretinal morphology in retinal pathologies approaching the level achieved with histopathology. UHR OCT technology has been investigated in clinical settings to assess its clinical utility. Cross-sectional studies in ∼1,000 eyes with different pathologies demonstrated unprecedented visualization of all major intraretinal layers and provided especially significant information about the photoreceptor layer [10, 38–46]. These studies demonstrated visualization of photoreceptor layer impairment in macular pathologies such as macular holes, central serous chorioretinopathy, age-related macular degeneration, foveomacular dystrophies, Stargardt's dystrophy, and retinitis pigmentosa (cf. also ▶ Chap. 34, "MUW Approach of PS OCT").

More recently, high-speed and three-dimensional techniques have been developed for ultrahigh-resolution ophthalmic OCT. Spectral/Fourier-domain OCT methods make use of a spectrometer and a line scan camera to acquire all depths of the OCT axial scan simultaneously in the frequency domain [47, 48]. Fourier-domain OCT can also be performed using the swept source method, whereby a narrowband laser source is scanned in wavelength over a broad bandwidth and the frequency encoded OCT axial scan is acquired as a function of time with a balanced photoreceiver [49]. In either case, the signal is reconstructed using a Fourier transform. The Fourier-domain approaches are performed without the need for moving part scanners in the reference arm and are therefore scalable to

much higher speeds than traditional time-domain OCT scanners. High-speed imaging is further facilitated by the fact that spectral and swept source OCT leads to a sensitivity advantage compared to time-domain OCT that scales with the number of points in the acquired data set and is typically in the range of 20–30 dB improvement [50–52]. High-speed ophthalmic OCT was first demonstrated with standard resolution using the spectral domain approach at 800 nm [47, 48]. Subsequent work then demonstrated high-speed, ultrahigh-resolution OCT [53–55]. Figure 9.7 presents results from a high-speed, ultrahigh-resolution OCT system using a 5 fs Ti: Sapphire laser source [53]. The system schematic in Fig. 9.7a illustrates the spectrometer detection system and the static reference arm. The broadband spectrum measuring ~144 nm FWHM is shown in Fig. 9.7b. This resulted in an axial resolution of 2.1 um in tissue, shown in Fig. 9.7c. The high-phase stability of Fourier OCT systems facilitates numerical processing techniques there were previously difficult with time-domain OCT, such as numerical dispersion compensation. A representative image of the human macula is shown in Fig. 9.7d. High-speed acquisition of ultrahigh-resolution scans enables motion-free, high-definition images.

High-speed, ultrahigh-resolution OCT imaging has also been investigated as a research tool for assessment of retinal disease in rodent model systems [56]. Rat and mouse models of ocular disease provide powerful tools for analysis and characterization of disease pathogenesis and response to treatment, but retinal imaging in these models is challenging because of the small size and thin retina of the animal eye compared to the human eye. The advent of ultrahigh-resolution OCT promises to overcome these limitations, however. Similarly, the development of high-speed, ultrahigh-resolution OCT provides for high-quality two- and three-dimensional OCT imaging of the retina with minimal motion artifact. Figure 9.8 presents high-speed ultrahigh-resolution OCT imaging results from the rodent retina [56]. The optical spectrum from a multiplexed superluminescent diode laser source was spectrally shaped to provide axial resolution of 2.8 um in tissue with low sidelobe levels. High-speed acquisition enabled three-dimensional volumetric imaging of the rodent retina. Figure 9.8c demonstrates a 3D OCT volume rendering of the rat retina. Individual cross-sectional OCT images with ultrahigh resolution demonstrate excellent visualization of fine retinal layers and compare well to histology.

To test the performance of the novel, compact, and cost-effective ultrabroad bandwidth titanium:sapphire laser, as well as the ability of sub-μm axial resolution OCT to image subcellular morphological features, tomograms were acquired from sympathetic ganglion cell cultures obtained from rat superior cervical ganglia. The cultures were prepared on protein-coated glass cover slips and were placed in a custom-designed perfusion chamber filled with nutritious solution to preserve the normal condition and electrical activity of the cells. Tomograms were acquired with 0.9 μm axial and 2 μm transversal resolution and SNR of 100 dB, for 2 mW average incident power. Figure 9.9c–e shows tomograms of single and groups of cells as compared to representative images of the cells obtained with a regular microscope (Fig. 9.9a) and scanning electron tunneling microscope (Fig. 9.9b). The

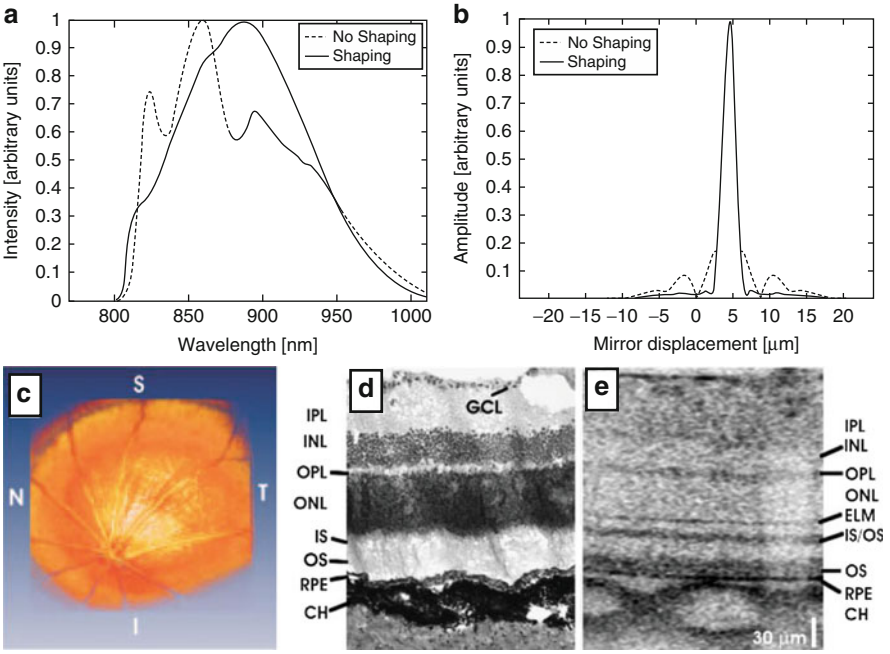

Fig. 9.8 *High-speed, ultrahigh-resolution OCT retinal imaging in rodent models*. A small animal imaging system was constructed using a multiplexed superluminescent diode light source with 145 nm optical source bandwidth at 800 nm center wavelength (**a**) capable of producing ~2.8 um axial resolution in tissue (**b**). The high-speed system acquired 24,000 axial scans per second and was capable of generating in vivo 3D volumetric renderings of the retina (**c**). Individual cross-sectional images (**e**) with ultrahigh resolution compared well with histology (**d**) in visualizing the many fine layers of the retina

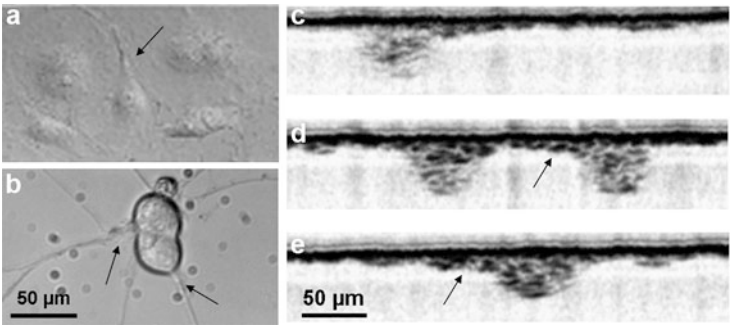

Fig. 9.9 *In vivo ultrahigh-resolution OCT of ganglion cells*. Images of living ganglion cells acquired with scanning electron microscope (**a**), regular optical microscope (**b**) and UHR OCT (C-E). The OCT tomograms (0.34 mm × 0.07 mm) were obtained at $\lambda_c = 785$ nm with spatial resolution 0.9 μm × 2 μm (axial x lateral) and sensitivity of 100 dB for 2 mW optical power at the sample. *Black arrows* indicate axono-dendritic extensions of the ganglion cells

thick black line in the upper part of all OCT images corresponds to a reflection from the glass cover slip, to which the cells tend to attach themselves. The highly reflective (black) spots most likely correspond to various cell organelles, judging from the high optical density and the size of the objects. Although the cell membrane is not clearly visualized, the boundaries of the cell cytoplasm (pale gray color) are distinctly visible. Furthermore, the high spatial OCT resolution permits imaging of the thin axonal extensions of the ganglion cells (marked with black arrows on Fig. 9.9). Therefore, UHR OCT might be capable of acquiring information on the dynamic interaction of neuronal cells via the synaptic connection between the cell dendrites and the axon.

To investigate the feasibility of UHR OCT for imaging brain tissue morphology and to evaluate the potential of this technique as an intraoperative optical biopsy tool in neurosurgery, OCT images were acquired from both healthy and pathological human brain tissues including transitional, fibrous, and atypical meningioma and ganglioglioma [57, 58]. The objective of this research project was to investigate the ability of UHR OCT to discriminate between healthy and pathological human brain tissues by visualization of fine morphological features characteristic for neuropathologies and normally absent in healthy brain tissue. In addition, this study aimed to establish a correlation between structural details present both in the OCT tomograms and in the corresponding histological cross sections. Because postmortem brain tissue quickly looses optical quality due to cell death, all brain tissue samples were fixed in 4 % paraformaldehyde solution. The brain slices were placed in a custom-designed chamber with an optical window (~150 μm thick glass cover slip), through which the tissue was imaged. The OCT system was evaluated to provide 1.3 × 3 μm (axial × lateral) resolution in air, ideally corresponding to 0.9 × 2 μm in biological tissue, and sensitivity of 112 dB for 5 mW at the sample surface. During the imaging procedure care was taken to properly compensate the dispersion mismatch introduced by the glass cover slip and the excess fixation solution between the glass and the tissue surface in order to preserve the high OCT axial resolution in all imaged tissue samples. Standard histological cross sections of the imaged brain tissue samples were prepared after completion of the imaging procedure and compared with the acquired UHR OCT images.

In addition to healthy brain tissue, three different types of meningiomas and one type of ganglioglioma were imaged. Figure 9.10a shows a representative OCT tomogram acquired from a fibrous meningioma biopsy, while the corresponding H&E-stained histological section is presented in Fig. 9.10b. Under the current imaging conditions, the image penetration depth in the fibrous meningioma tissue appears limited to about 400 μm and no structural details can be distinguished deeper in the sample. The dark horizontal line in the tomogram is an imaging artifact. At shallow depths up to ~250 μm, clusters of highly reflective (black) spots are distinctly visible even after application of a speckle reduction [59, 60] image processing algorithm (oversampling of the acquired data – 20 nm separation between adjacent points in a single A-scan, 0.5 μm separation between adjacent A-scans, and subsequent application of directional spatial averaging). An enlarged view (Fig. 9.10c) of a selected region in the biopsy sample, marked with red dotted

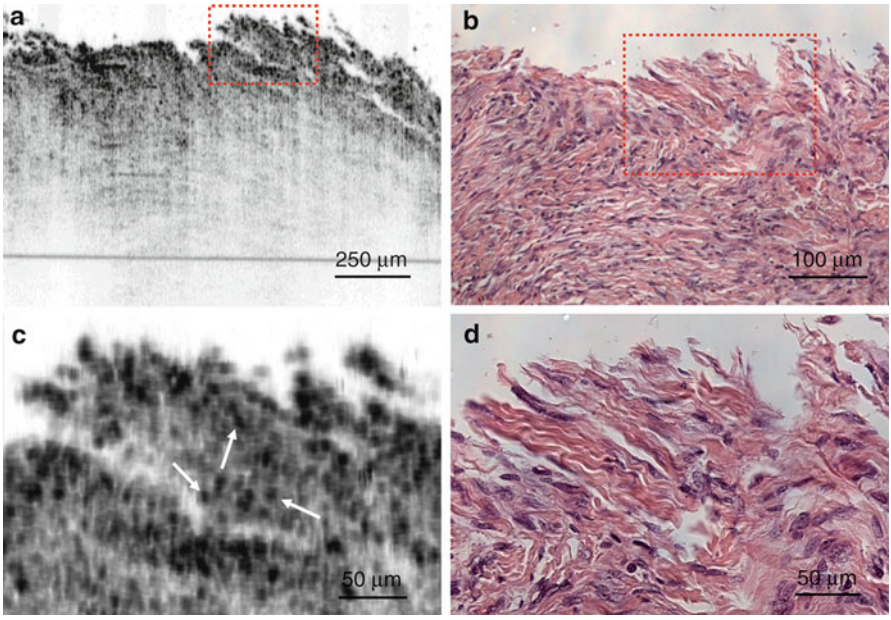

Fig. 9.10 *In vitro ultrahigh-resolution OCT of neuropathologic biopsies*. UHR OCT tomogram (1 mm × 0.69 mm) of fibrous meningioma (**a**) and corresponding H&E-stained histological section (**b**). (**c**) shows an enlarged view of the region in the tomogram (**a**) marked with the *red dotted line*, while (**d**) shows a proportional enlargement of the histological image. *White arrows* in (**c** and **d**) indicate enlarged nuclei of tumor cells [58]

line in Fig. 9.10a, shows that the black spots (marked with white arrows) vary in shape and range in size between 5 and 15 µm. A magnified view of the histological section (Fig. 9.10d) reveals that the nuclei of tumor cells are ∼2–5 times larger than the nuclei of normal neuron/glial cells and that they fill up to ∼80 % of the cell volume. Since cell nuclei are optically much denser than the cell cytoplasm, they scatter light more strongly. Therefore, it is very likely that the highly reflective black spots observed in the UHR OCT tomogram correspond to enlarged nuclei of tumor cells (marked with white arrows). The fact that no highly reflective small spots are visible on the OCT tomogram beyond a depth of ∼300 µm most probably results from loss of contrast and resolution with imaging depth.

The dimension, architecture, and accessibility of human skin make dermatology a compelling field of application for OCT imaging. Current clinical diagnosis by human- or camera-assisted visual inspection is advantageous for fast screening of large surfaces. However, almost no depth information is included and pathologies are mainly distinguished by overall appearance and symptoms. This is not easily possible for diseases like melanoma (cancer) in their early stages, which are often developing at the dermal-epidermal (D-E) junction. OCT with radiation in the near-infrared enables visualization of the full epidermis and can give access to the D-E junction and

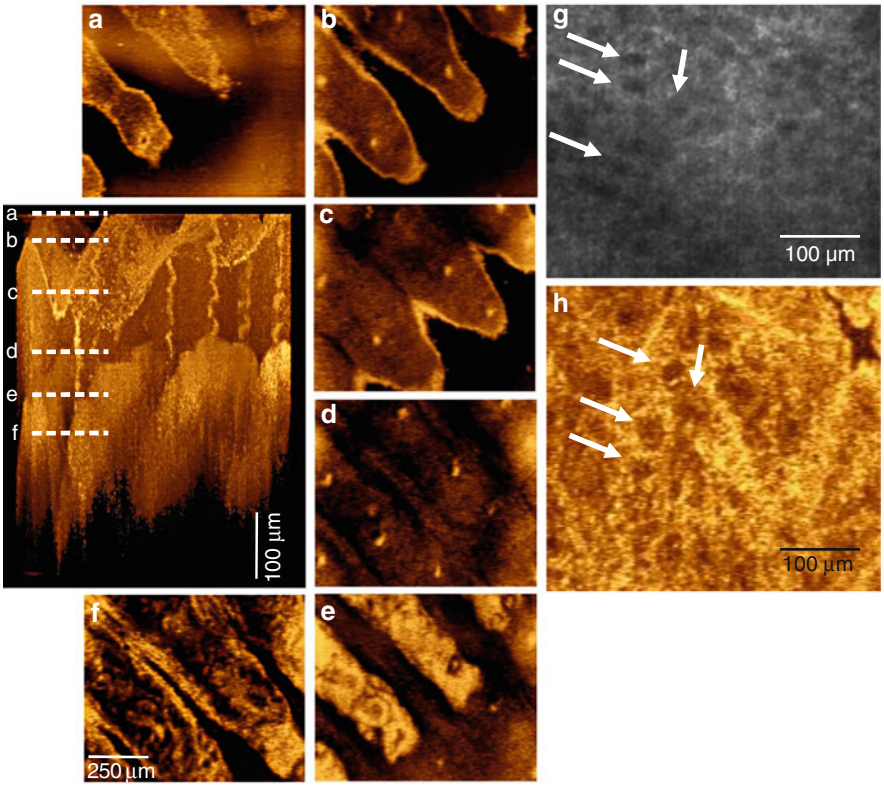

Fig. 9.11 *In vivo ultrahigh-resolution OCT of human skin*. Three-dimensional rendering and C-mode sections (**a**–**e**) of a human finger tip. Consecutive sections extracted from the data stack (**a**–**e**). Comparison to scanning laser microscopy (**g**) with ultrahigh-resolution OCT (**h**) at stratum basale (thin skin). *Arrows* depict cellular structures that might resemble stronger absorbing melanocytes next to the less scattering keratinocytes, though further investigation has to prove the origin of the enhanced contrast

structures below already in vitro. For in vivo imaging, contrast usually improves due to stronger differences between cells and intracellular material in living tissue.

A common problem with time-domain OCT is the slow speed (about 5 s per 1,000 sampling points). Frequency-domain OCT enables scanning of volumetric data sets of 512^3 sample points, equaling ~130 million voxels, within a time frame of about 10–30 s. High-speed frequency-domain OCT is compatible with ultrahigh resolution as well, with systems demonstrating to date about 3 µm axial resolution and less than 6 µm transversal resolution. Results in dermatology using high-speed, frequency-domain OCT are shown in Fig. 9.11. A cube of 512^3 voxels with lateral excursion of 1.5 mm and 1 mm sampling depth was acquired. A volume rendering of the glabrous skin including the typical ripple of dermatoglyphics (responsible for the fingerprints) is shown, with individual en face renderings at varying depths displayed in Fig. 9.11a–f.

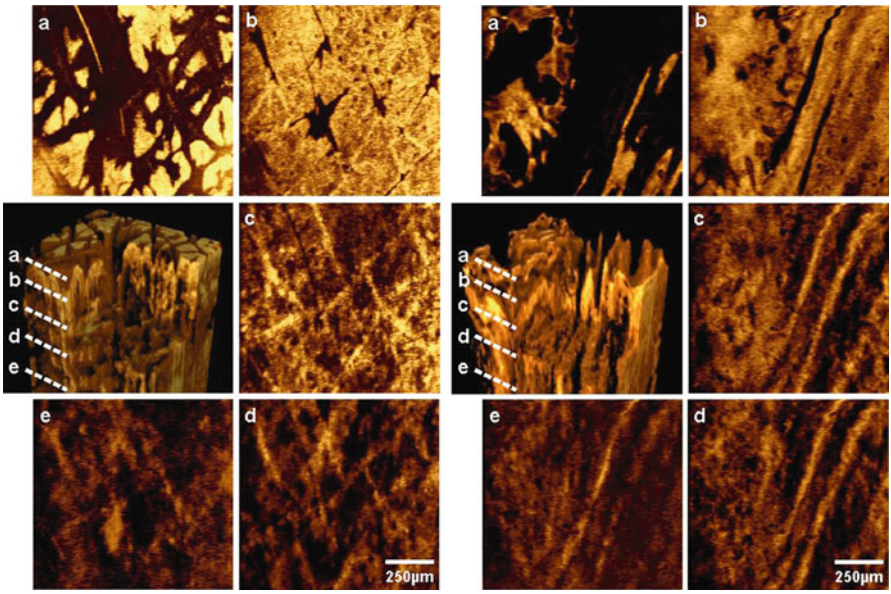

Fig. 9.12 *In vivo ultrahigh-resolution OCT of human skin*. Rendering and virtual C-mode scans (**a**–**e**) of a pigmented mole (*left*). The epidermis is much thinner than at the fingertip. Penetration is lower, but highly absorbing structures of about 10–30 µm at the basal layer (**b**, **c**) and a wide vascular meshwork can be appreciated in the deeper dermal layers (**d**, **e**). Vascular nevus (*right*); strongly folded surface with an unordered network of capillaries, missing mesoscopic structure visualized in virtual C-mode scans (**a**–**e**)

As an example of highly absorbing tissue, a nevus was investigated in vivo. This structure either appears as a mole, as a benign pigmented cluster of melanocytes with tan brown appearance, or as a vascular nevus being a benign blood vessel tumor consisting of a high concentration of capillaries. In Fig. 9.12 the rendering of the pigmented nevus (mole) is demonstrated, located in an area of thin skin. In contrast to the fingertip, the epidermis is much thinner and the dermal layers show a loose vascular reticulum (cross sections C, D). Just beneath the epidermis already, a high concentration of strongly absorbing spheroids, 10–30 µm in diameter, can be visualized, which seem to be interconnected by fine, almost vertical capillaries that are part of the larger vascular meshwork. At an alternate location OCT in vivo imaging at 800 nm of a vascular nevus is demonstrated in Fig. 9.12. Already the overall appearance at the surface is completely different. Deep puckers with a single main orientation separate the tissue. The reflectivity change with depth is not as prominent as with the mole and the internal structuring is much less ordered. Although tiny vessels appear already close to the surface, their squamous fabric seems to lack any alignment. En face sections taken at different depth already loose connections within 20 µm and lack of mesoscopic structure, although their overall texture seems to stay constant.

For investigation of internal organs with ultrahigh resolution, OCT miniaturized probes that can be positioned in the vicinity of the respective surfaces are needed. Several catheter imaging probes for UHR OCT at 800 nm have been demonstrated [61, 62]. Widespread clinical application of OCT endoscopy requires that probes be quickly replaceable by hospital staff, however. Since uncompensated inter-endoscope path length differences of less than 1 mm adversely affect performance of conventional Michelson interferometer-based OCT devices, designs insensitive to minor variations in the endoscopes geometry are desirable. UHR OCT presents a special challenge because chromatic aberrations must be minimized over a large optical bandwidth and dispersion and polarization matching between arms of the interferometer must be performed over a wide bandwidth that may be centered far away from the zero dispersion point of the materials used. Numerical methods for compensating dispersion are computationally expensive, are sensitive to noise, and perform best when the real dispersion mismatch is already well compensated in the system. Endoscopic ultrahigh-resolution optical coherence tomography OCT enabled collection of minimally invasive cross-sectional images in vivo, which may be used to facilitate rapid development of reliable mouse models of colon disease as well as assess chemopreventive and therapeutic agents [63, 64]. The small physical scale of mouse colon made light penetration less problematic than in other tissues and high resolution acutely necessary. In a 2 mm diameter endoscopic time-domain OCT system, isotropic ultrahigh resolution is supported by a center wavelength of 800 nm and full-width-at-half-maximum bandwidth of 150 nm mode-locked titanium:sapphire laser combined with 1:1 conjugate imaging of a small core fiber. A pair of KZFSN5/SFPL53 doublets provides excellent color correction to support wide bandwidth throughout the imaging depth (Fig. 9.13). A slight deviation from normal beam exit angle suppresses collection of the strong back reflection at the exit window surface. UHR endoscopy with axial resolution of 3.2 μm in air and 4.4 μm lateral spot diameter with 101 dB sensitivity could be accomplished. Microscopic features too small to see in mouse tissue with conventional resolution systems, including colonic crypts, are clearly resolved (Fig. 9.13). Resolution near the cellular level is potentially capable of identifying abnormal crypt formation and dysplastic cellular organization.

9.4 Ultrahigh-Resolution OCT at 1,300 nm

For OCT to be successfully used as an in vivo optical biopsy tool in nontransparent tissue, micrometer-scale resolution and millimeter range penetration depth is required. In the range between 800 and 1.8 μm, scattering is the predominant mechanism limiting image penetration depth. Since scattering depends strongly on wavelength and decreases for longer wavelengths, a much higher image penetration depth in nontransparent tissue can be achieved with light at 1.3 μm than at 800 nm. It has been shown that optimum wavelengths for imaging in nontransparent biological tissues are in the 1.3–1.5 μm range [65]. In this wavelength range imaging depths of 2 mm are possible before multiple scattering blurs the OCT

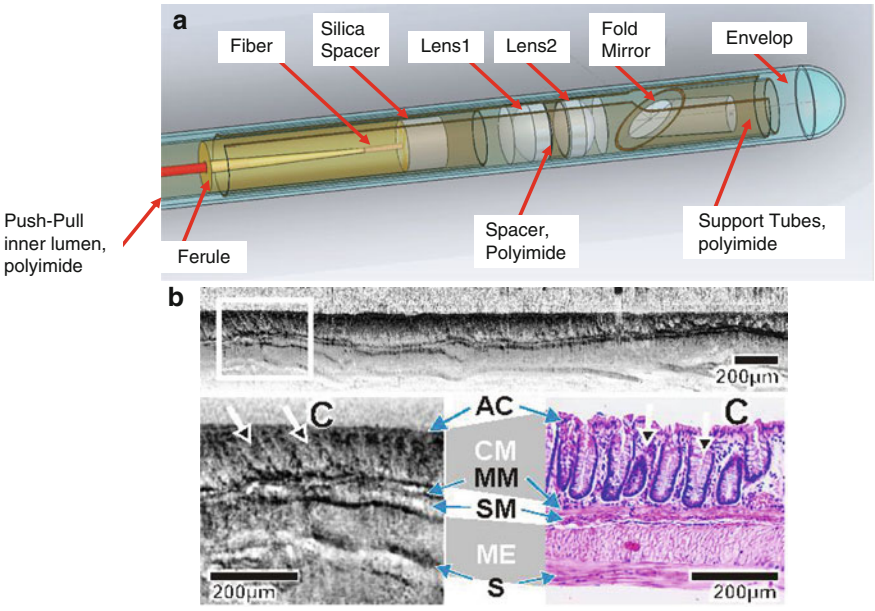

Fig. 9.13 *In vivo ultrahigh-resolution endoscopy of mouse colon*. Solid model shows the mechanical construction of the endoscope tip. The outer dimension of the tubing is 2 mm. The scanning range is 35 mm. All parts are designed to be aligned by location in tight tolerance polyimide tubing (**a**). Endoscopic UHR OCT tomogram (**b** *top* and *left*) versus stained histologic cross section (**c** *right*) of in vivo mouse colon with distally integrated beam splitter enables visualization of colonic mucosa (*CM*), muscular mucosa (*MM*), submucosa (*SM*), muscularis externa (*ME*), and serosa (*S*) layers. Contrast-enhanced portion, using local histogram equalization, shows a surface layer of apical crypt cells (*AC*) as well as vertical structures in the mucosa that may correspond to crypt boundaries (**c**). Corresponding structures are marked in the age and strain matched histology image. Inset graph shows axial point spread function detail [63, 64]

signal. In the 1,300 nm wavelength region, ultrashort pulse solid state lasers are also promising light sources for ultrahigh-resolution OCT. In an early demonstration, a self-phase-modulated KLM Cr:forsterite laser was used for in vivo OCT imaging in nontransparent tissues with 6 µm axial resolution [66]. Recent efforts focused on developing even broader bandwidth light sources in the 1,300 nm wavelength range that would permit OCT micrometer-scale resolution along with millimeter range penetration depth. As an example, broad bandwidth light covering the 1,230–1,580 nm wavelength region with an optical bandwidth of 250 nm (FWHM) was generated directly from an all-solid state Cr:forsterite laser [67].

Figures 9.14 and 9.15 show examples of ultrahigh-resolution OCT imaging of normal and pathologic human tissues ex vivo [68–70]. OCT imaging was performed on surgical specimens in the hospital pathology laboratory. Imaging in the pathology laboratory enables the access to tissues with various pathologies immediately after surgical excision and allows for the precise registration of OCT images and histology. In addition, imaging in a pathology laboratory is also an

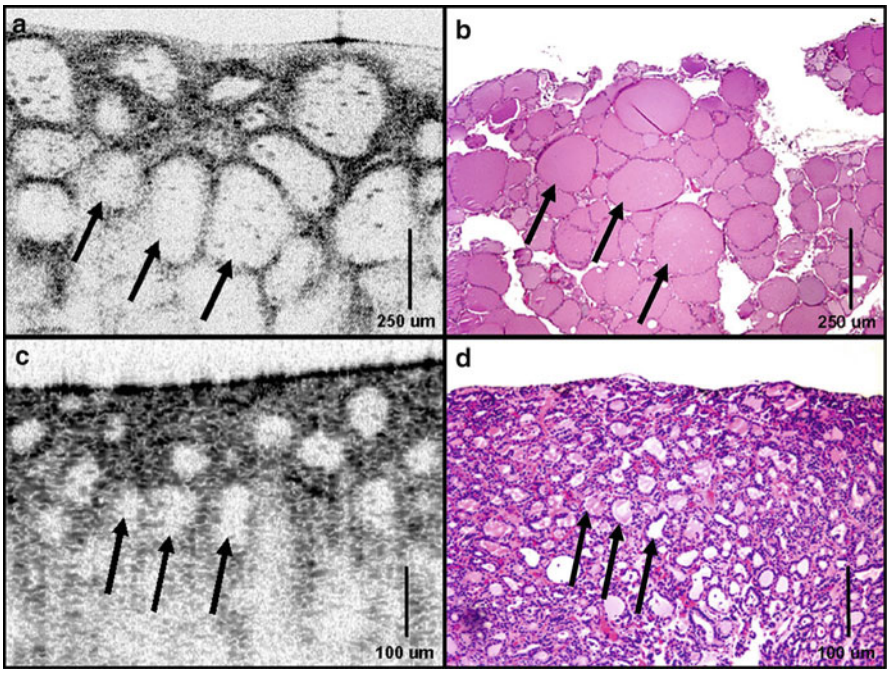

Fig. 9.14 *Ultrahigh-resolution OCT of human thyroid* ex vivo. (**a**) Normal thyroid tissue imaged ex vivo showing multiple colloid-filled follicles (*arrows*), and the corresponding histology is shown in (**b**). (**c**) Thyroid adenoma comprised of a predominantly microfollicular growth pattern, and the corresponding histology is shown in (**d**). *Arrows* indicate microfollicles. OCT images were obtained at central wavelength of 1.26 μm with resolutions of 4.5 μm axial × 11 μm transverse [70]

important step toward developing and validating new technology for future endoscopic studies. OCT imaging was performed with a 4.5 μm axial resolution and 11 μm transverse resolution using a Cr:forsterite laser light source. Since the OCT imaging light was in the near-infrared range and invisible to the naked eye, tissue registration was performed with a visible green light guiding beam. When necessary, irrigation of specimens (isotonic saline or RPMI 1640) was used to prevent dehydration during imaging. Specimens were marked with India ink to designate the plane of OCT imaging. The samples then underwent routine histologic processing. Figure 9.14a shows an OCT image of normal thyroid. Individual follicles with lumens containing colloid could be identified. The smallest follicle visible measured 15 μm in greatest dimension. In normal thyroid glands the follicles were found to be round to oval in shape, with only occasional focal irregularities noted. Colloid appeared low scattering, and occasional follicles contained colloid with focal regions of high scattering. Normal follicular epithelium appeared as a thin, highly scattering, dark layer lining larger follicles and as a slightly thicker, dark rim around smaller follicles. In contrast, adenomas consist predominantly of microfollicles averaging 90 μm in greatest diameter (Fig. 9.14c).

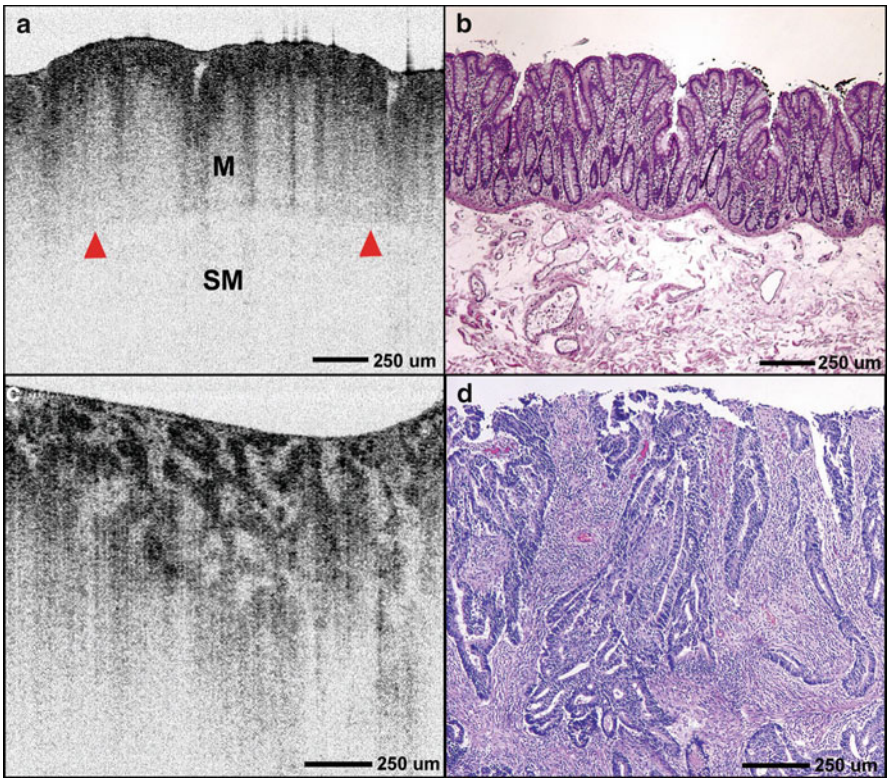

Fig. 9.15 *Ultrahigh-resolution OCT of human colon ex vivo*. (**a**) Ultrahigh-resolution OCT image of normal colon. Mucosa (*M*) is clearly delineated from underlying submucosa (*SM*) by a scattering band corresponding to the thin muscularis mucosa (*arrows*). The submucosa is visible as less optically scattering layer. (**b**) Corresponding histology. (**c**) Ultrahigh-resolution OCT image of well-differentiated adenocarcinoma. Highly irregular invasive glands are visible in a desmoplastic stroma. No clear boundary between mucosa and submucosa is evident in this case. (**d**) Corresponding histology. OCT images were obtained at central wavelength of 1.26 μm with resolutions of 4.5 μm axial × 11 μm transverse [70]

Even small abortive follicles could be recognized. Many of the follicles present within adenomas were oval in shape. Figure 9.15a, b shows a representative ultrahigh-resolution OCT image of the normal colon and corresponding histology. OCT clearly visualized the full thickness of the colonic mucosa. The submucosa appeared as a lighter and less optically scattering layer. The muscularis mucosa appeared as a scattering band in the OCT image separating the mucosa and submusoca. Figure 9.15c, d show an OCT image and corresponding histology of adenocarcinoma. OCT image of adenocarcinoma revealed complete loss of normal mucosal architecture and invasion of the submuscosa. Highly scattering and irregular invasive glands were visible in OCT images of adenocarcinoma.

In vivo ultrahigh-resolution endoscopy imaging of the rabbit gastrointestinal tract was demonstrated at a threefold higher resolution (3.7 μm in tissue), using

such a broadband Cr:forsterite laser as the optical light source [71]. Images acquired from the esophagus, trachea, and colon reveal high-resolution details of tissue architecture. Definitive correlation of architectural features in OCT images and histological sections could be shown. The ability of ultrahigh-resolution endoscopic OCT to image tissue morphology at an unprecedented resolution in vivo advances the development of OCT as a potential imaging tool for the early detection of neoplastic changes in biological tissues. A rapid scanning delay line in the reference arm provided real-time imaging at up to 3,125 axial scans per second. Imaging was performed at a frame rate of 4 Hz, which corresponded to a transverse pixel image density of up to 780 axial scans per image. The OCT beam was scanned in both longitudinal and rotational directions to generate cross-sectional images of tissue structures in orthogonal imaging planes. To match optical dispersion within the system, SFL6 and LaKN22 dispersion-compensating glasses were inserted in the reference arm to compensate for the catheter focusing optics in the sample arm, and an air gap coupling was used in the sample arm to compensate for the air path in the reference arm from the collimator to the scanning delay mirror. The use of the dispersion-compensating glass and air gap coupling allowed precise dispersion compensation for ultrahigh-resolution imaging performance. The backcoupled OCT signal was divided into two orthogonal polarization channels by a polarizing beam splitter, and the two detector outputs were digitally demodulated using a DSP board. A polarization diversity signal was obtained from the square root of the sum of the squared signal intensities from the two polarization channels.

Figure 9.16a shows an in vivo OCT image of the esophagus in the rabbit taken with the linear scanning catheter. The corresponding histology is also shown in Fig. 9.16b. The layered structure of the esophagus is clearly delineated, with good definition to the squamous epithelium (e), lamina propria (lp), muscularis mucosa (mm) submucosa (sm), and the inner (im) and outer muscular (om) layers. The OCT image correlated well with the histology in both the order of the layers and the layer thickness. Figure 9.16c shows a composite image of five OCT linear scans acquired sequentially as the catheter was withdrawn during imaging. Images were acquired over a 12 mm scanning range from the epiglottis to the inner esophagus. This image illustrates the capability to visualize continuous morphology over a large field of view at ultrahigh resolution, a method that permits suspect regions to be rapidly surveyed. Figure 9.17a shows an in vivo OCT image of the esophagus and trachea in the rabbit. The tracheal hyaline cartilage (hc) is visible through the esophageal wall, thus demonstrating the ability of the endoscopic OCT system to image deeply within the tissue. In addition, the structural details of the tracheal mucosa and trachealis muscle are visible. The vacuous region below the tracheal wall located at the bottom of the image is the tracheal airway. The corresponding histology in Fig. 9.17b shows good correlation with the architecture seen in the OCT image. Trichrome staining was used in the histological section to enhance delineation of cartilage rings in the trachea. With the high speed of the OCT system used for this study, it was possible to image large regions within the gastrointestinal tract while maintaining high-axial and transverse image resolutions.

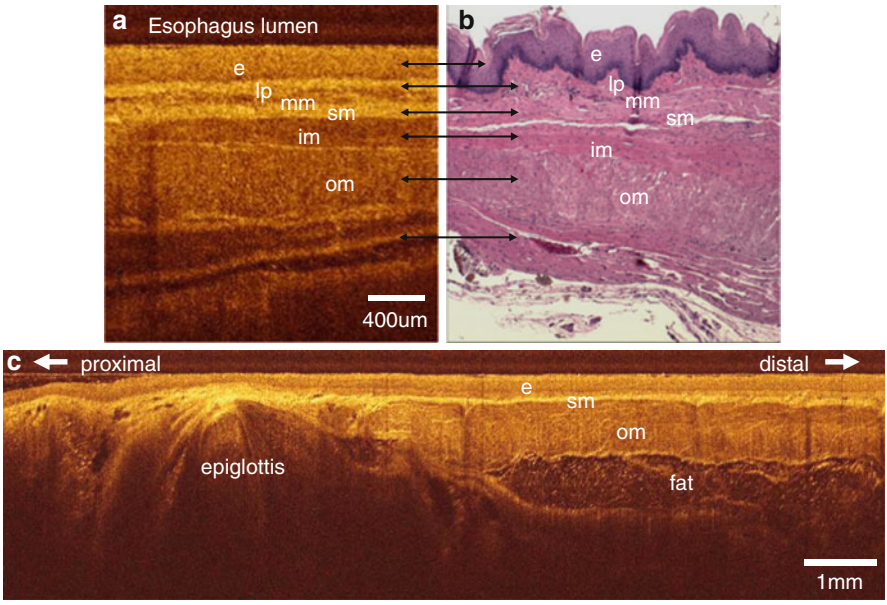

Fig. 9.16 *In vivo ultrahigh-resolution endoscopy of the rabbit gastrointestinal tract.* In vivo endoscopic OCT image of rabbit esophagus (**a**) with corresponding histology (**b**). Good correlation is seen between OCT and histology. The epithelium (*e*), lamina propria (*lp*), muscularis mucosa (*mm*), submucosa (*sm*), inner (*im*), and outer muscular (*om*) layers are visible on both the OCT image and histology. In vivo UHR OCT image (**c**) showing sequential OCT scans spanning the rabbit epiglottis to the inner esophagus. Ultrahigh-resolution imaging capability is maintained over a large field allowing detailed discrimination of tissue structure. Architectural morphology of the proximal esophagus is well defined, as is the transition from the mouth to the esophagus at the epiglottis [71]

Clinical endoscopic OCT studies have been performed using UHR OCT in patients previously diagnosed with Barrett's esophagus [72]. UHR OCT images were compared with endoscopic diagnosis and pinch biopsy histology. UHR OCT images of normal esophagus, Barrett's esophagus, high-grade dysplasia, and esophageal adenocarcinoma were evaluated. UHR OCT images of the normal esophagus exhibited characteristic layered architecture with uniform epithelium, while images of Barrett's esophagus corresponded to crypt-like glandular structures (cf. Fig. 9.18). High-grade dysplasia and esophageal adenocarcinoma images exhibited more heterogeneous structures corresponding to irregular, heterogeneous tissue morphology from distorted and cribriform or villiform glandular architecture. Fine features can be discerned more clearly with endoscopic UHR OCT. Additional studies are required to evaluate the impact of improved resolution on the sensitivity and specificity for detecting high-grade dysplasia.

Spectra much broader than one optical octave can be produced via nonlinear propagation of laser pulses in microstructured fibers. Owing to the geometry of these fibers, the cross section of the fundamental mode is unusually small, which enhances the peak power and thus the nonlinearity. At the same time, the fiber

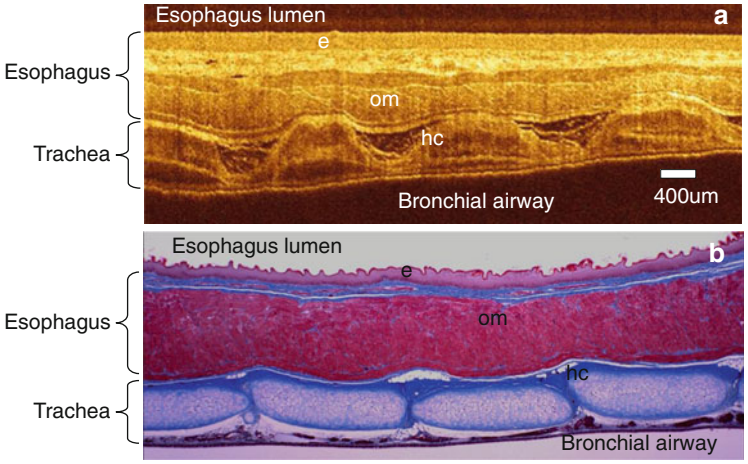

Fig. 9.17 *In vivo ultrahigh-resolution endoscopy of the rabbit gastrointestinal tract*. In vivo UHR OCT image (**a**) and histology (**b**) of rabbit esophagus and trachea viewed intraluminally from the esophagus. Tracheal hyaline cartilage (*hc*) between the tracheal mucosa and trachealis muscle is well defined. The image demonstrates the ability of the endoscopic OCT system to image deeply within the tissue. Trichrome stain was used to highlight cartilage and muscle layers [71]

dispersion can be engineered to avoid rapid temporal broadening. Due to these effects, spectra covering more than one optical octave can be produced even with pulses having moderated energies of a few nJ. This spectral width could never be generated directly from the linear laser oscillator, because it exceeds the fluorescence bandwidth of the crystal. In order to avoid an excessively strong spectral modulation (inherent to the spectral broadening processes – self phase modulation and four wave mixing), only moderate spectral broadening should appear during the nonlinear fiber propagation, i.e., the initial bandwidth of the pulses emerging from the oscillator should already be as broad as possible. High nonlinearity, air-silica microstructure fibers [73] or tapered fibers [74] have been used to generate an extremely broadband continuum using low-energy femtosecond pulses. So far, the highest reported OCT axial resolution in biological tissue in the 1,300 nm wavelength region was realized by use of a complex laboratory prototype PCF-based light source [75]. With a bandwidth of 450 nm at a 1.3 μm center wavelength, 2.5 μm axial resolution in free space, corresponding to 2 μm in tissue, was achieved by employing an OCT system that could support 370 nm bandwidth. In vivo ultrahigh-resolution image of a Syrian hamster's cheek pouch could be demonstrated. Unprecedented sub-2 μm axial resolution OCT in the 1,300 nm wavelength range in nontransparent biological tissue was achieved with a broad bandwidth light source, based on a several meter long dispersion matched optical fiber (Menlo Systems) [68]. This light source is based on a pulsed erbium fiber laser, the amplified output of which is coupled into a highly nonlinear fiber to generate a supercontinuum ranging from 1,100 to 1,800 nm at its pedestal, with a power output of ∼50 mW at 50 MHz repetition rate. Because of a 12 dB modulation

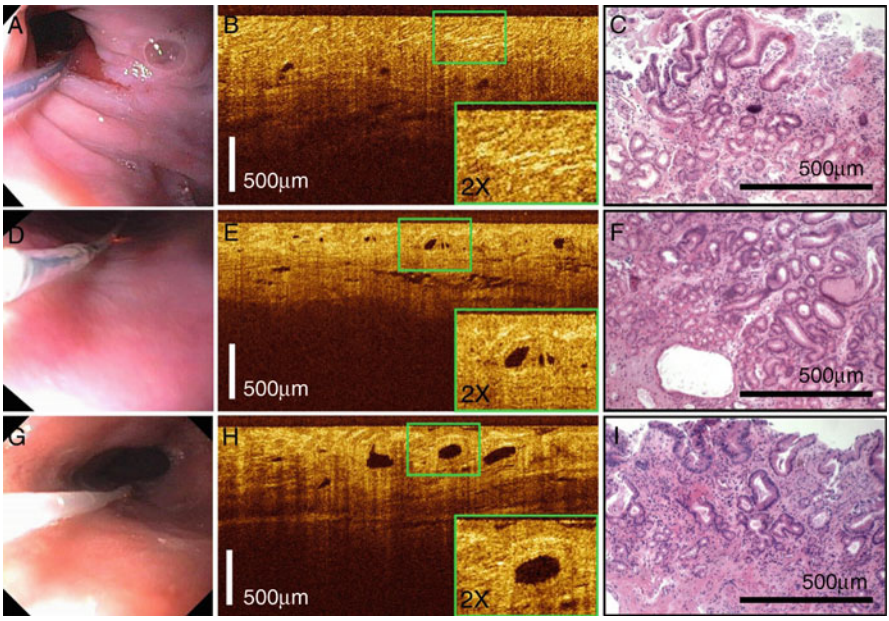

Fig. 9.18 *In vivo ultrahigh-resolution endoscopy of the human gastrointestinal tract*. Endoscopic view (**a**, **d**, **g**), in vivo UHR OCT images (**b**, **e**, **h**), and corresponding histology (**c**, **f**, **i**) of Barrett's esophagus. OCT images were obtained at central wavelength of 1.26 µm with resolutions of 5 µm axial × 15 µm transverse. As compared to normal esophagus that exhibited characteristic layered architecture with uniform epithelium, images of Barrett's esophagus reveal crypt-like glandular structures [72]

at ∼1,550 nm, only the shorter wavelength portion of the emission spectrum was utilized for OCT imaging by blocking the wavelength range beyond 1,550 nm with an edge filter. The filtered fiber laser spectrum was moderately modulated, centered at 1,375 nm with a full width at half maximum (FWHM) of 470 nm and a power output of 4 mW. By interfacing the light source to a free space OCT system, resolution of 2 µm in axial and 4 µm in lateral direction (measured with a resolution target), corresponding to ∼1.4 µm and ∼3 µm in biological tissue, respectively, and 95 dB sensitivity for 500 µW incident power were achieved. The feasibility for ex vivo sub-2 µm axial resolution OCT was demonstrated, but due to insufficient power and noise problems, this source was not used for in vivo OCT studies.

9.5 Ultrahigh-Resolution OCT at 1,000 nm

Imaging at 1,000 nm wavelength range represents an attractive compromise between the ultrahigh-axial resolution, but limited image penetration at 800 nm wavelength range, and the reduced resolution, but enhanced image penetration at 1,300 nm wavelength range. In addition, it has been shown that at 1,000 nm the water dispersion is near zero; therefore, it is possible to eliminate the influence of

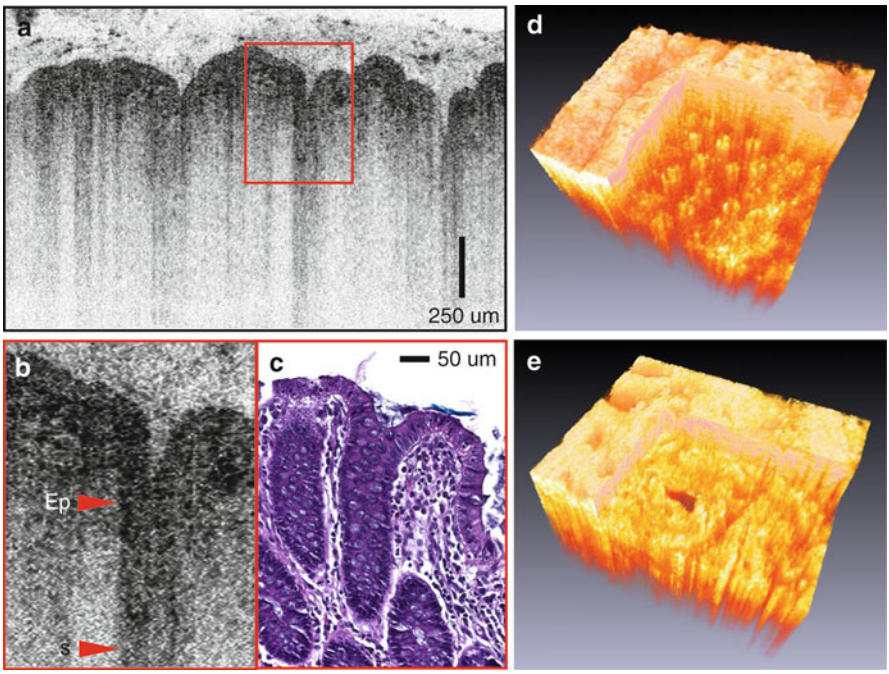

Fig. 9.19 *Ultrahigh-resolution and three-dimensional OCT imaging of human colon ex vivo.* (**a**) Ultrahigh-resolution OCT image of normal colon mucosa with enlarged view (**b**). (**c**) Corresponding histology. (**d**) Volume rendering of normal colon mucosa showing organized crypt pattern. (**e**) Volume rendering of a polypoid adenoma of the colon showing irregular glandular structures. OCT images were acquired at 1,000 nm wavelength range with the resolution of 3.5 μm axial × 6 μm transverse. 3D volume size: 1 mm × 1.2 mm × 1.3 mm [70]

depth-dependent dispersion in tissue by choosing OCT light sources at 1,000 nm [76]. Furthermore, a wide range of commercially available femtosecond laser sources including mode-locked Nd:glass lasers and Yb fiber lasers are available at this wavelength range. The use of these commercial femtosecond lasers in combination with high nonlinearity optical fibers represents an attractive and robust approach for achieving bandwidths necessary for ultrahigh-resolution OCT imaging. For example, the compact diode-pumped femtosecond Nd:glass laser (High Q Laser Productions) can generate pulse durations of $<$100 fs at repetition rates of $\sim$50 MHz with average powers of $\sim$100 mW. Nonlinear self phase modulation in a high numerical aperture fiber can be used to generate bandwidths of $>$200 nm centered around 1,050 nm [77]. The measured FWHM of the point spread function is 4.2 μm in air, corresponding to 3.5 μm in tissue. The Nd:glass laser is robust and provides turn-key operation. This system is well suited for in vivo ultrahigh-resolution OCT imaging studies which would be performed outside the research laboratory, especially in the clinic settings.

Figure 9.19 shows an example of an ultrahigh-resolution OCT image of the human colon ex vivo [70]. Imaging was performed with a 3.5 μm axial resolution

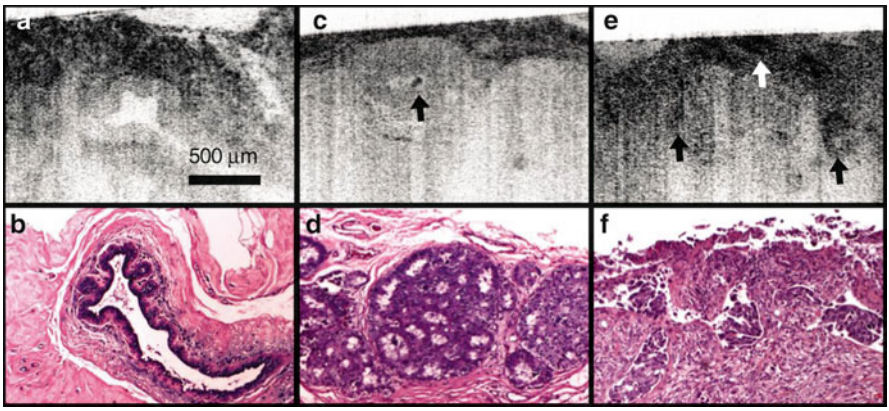

Fig. 9.20 *OCT imaging of normal and neoplastic breast tissue*. (**a**, **b**): normal lactiferous duct. (**c**, **d**): ductal carcinoma in situ with microcalcifications (*arrow*). (**e**, **f**): infiltrating ductal carcinoma (*arrows*)

and 6 µm spot size using a Nd:glass laser light source. Figure 9.19a–c shows a representative OCT image and corresponding histology of normal colon at 1 µm wavelength. The finer transverse resolution more clearly delineates the individual crypt structures and the epithelial layer than images at 1.3 µm wavelength. The epithelium is visible as a distinct layer, approximately 40–50 µm in thickness, delineated by a thin, highly scattering band from the supporting lamina propria. Individual crypts as well as the epithelial layer lining the crypts are visible. Figure 9.19d, e shows representative 3D OCT volume renderings of normal colon and a polypoid adenoma of the colon, respectively. Rendered 3D OCT data can be viewed from a virtual surface perspective, yielding a view similar to that of magnification endoscopy. Normal colon exhibits a well-organized distribution of crypts which are uniform in size and spacing in the en face plane. In contrast, polypoid adenoma exhibits irregular glandular structure.

Ultrahigh-resolution OCT imaging of human breast specimens was also performed using a Nd:glass laser system at 1 um wavelength [78]. Imaging was performed in 119 freshly excised specimens from 35 women with 3.5 µm axial × 6 µm transverse resolution at 1,060 nm wavelength. Both cross-sectional and 3D OCT images were acquired. Microstructure of normal breast parenchyma, including glands, lobules, and ducts, as well as stromal changes associated with infiltrating cancer, was visible from OCT images. Furthermore, fibrocystic changes and benign fibroadenomas were identified. Imaging of ductal carcinoma in situ revealed microcalcifications. Figure 9.20 shows example of OCT images of the breast. A normal lactiferous duct is shown in (a, b) with low scattering epithelium compared to surrounding fibrous stroma. Ductal carcinoma in situ (DCIS) is shown in (c, d) with dilation and distortion of lobules and the presence of a microcalcification. Infiltrating ductal carcinoma (e, f) shows heterogeneous, patchy scattering consistent with disorganized glandular elements within tumor

stroma. The results of this study suggest the potential of OCT to visualize breast disease and motivate further investigation.

9.6 Ultrahigh-Resolution OCT in the Visible Wavelength Region

Using PCF fibers in combination with femtosecond light sources, extremely broad spectra can be generated in the visible wavelength range. A stable, slightly modulated spectrum ranging from 550 to 950 nm (at its pedestal) supercontinuum (SC) spanning more than 325 nm (FWHM) with spectral modulations less than 1.5 dB, centered at 725 nm and providing 27 mW of average output power, was generated starting with a titanium:sapphire laser generating sub-10 fs pulses with 120 nm bandwidth (FWHM) an average output power of 400 mW at 100 MHz repetition rate. The fiber was a PCF with a 2.3 μm core diameter and 6 mm length and matching polarization to the main polarization axis of the fiber and precompression of the pulses to compensate for the positive chirp introduced by the air and the coupling elements was required [79]. This study achieved 0.5 μm axial image resolutions in the visible. The broad bandwidth of this light source also provides access to a spectral region covering the absorption bands of a number of biological chromophores; thus, it has great potential for spectroscopic OCT. This new spectral region is interesting because of the ultrahigh resolution of the OCT images (sub-μm resolution, rather than several microns in the near-infrared) and also the fact that changes in refractive index and therefore image contrast are stronger in this wavelength region and absorption of biological chromophores is stronger. These three properties are extremely interesting for medical applications, since human cells with common sizes of several micrometers can only be visualized with sub-μm resolution. In addition, intra- and extracellular processes involve changes in optical properties in this range of the optical spectrum and can be observed in real time, without additional staining.

Imaging of in vitro human cancer cells could be performed using OCT in combination with this light source. Intracellular structures obtained by visible light OCT were compared with histologically stained samples of the same cells. Nucleoli and the Golgi apparatus might be visualized. Further investigations will help to interpret the results with more accuracy. Considering that the emission bandwidth of the light source overlaps with the so-called therapeutic window, covering absorption features of several biological chromophores, such as melanin, oxyhemoglobin, and desoxyhemoglobin, visible OCT also offers the potential for enhanced noninvasive spatially resolved spectroscopy. To test the ability of UHR OCT to image cellular morphology, tomograms of human colorectal adenocarcinoma cells HT-29 as well as animal ganglion cells were acquired in vitro. In the case of HT-29 cells, monolayers of cultured cells were grown on glass plates at 37 °C in a humidified atmosphere of 95 % air and 5 % CO_2. OCT tomograms of these specimens were obtained 48 h after seeding. Subsequently the cells were fixated and stained and histological cross sections of 1 μm thickness in

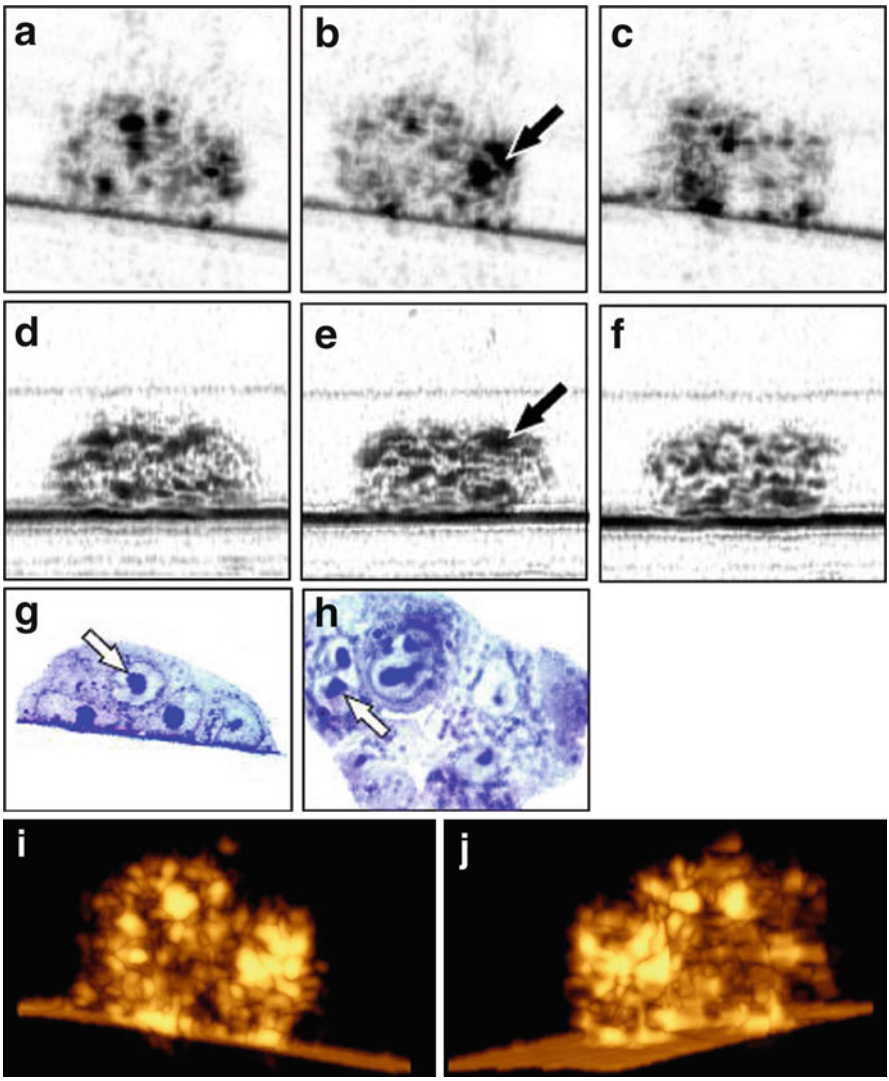

Fig. 9.21 *In vitro sub-micrometer resolution OCT of human colorectal adenocarcinoma cells HT-29*. UHR OCT with 0.5 μm axial and ~2 μm transverse resolution, covering an area of 50 × 50 μm, equally spaced by 2 μm. (**a**–**f**). *Arrows* indicate features that may correspond to nucleoli with ~3–5 μm diameter. Histological sections parallel (**g**, **h**) to the OCT imaging direction. Three-dimensional rendering (**i**, **j**); the different size of three-dimensional scatters, possibly associated with the dense nucleoli of these highly active cells is clearly visible [79]

direction parallel and perpendicular to the OCT imaging direction were prepared and analyzed using standard light microscopy with comparable but isotropic resolution and obvious reduced contrast-at-depth and penetration (Fig. 9.21). Multiple OCT cross-sectional images of a group of HT-29 cells, equally spaced by

2 μm, were acquired in vitro with 0.5 μm axial and ~2 μm transverse resolution (PCF-based light source with visible spectrum) and SNR of 87 dB for 1 mW average power at the sample surface and covering an area of 50 × 50 μm (500 × 500 pixels, Fig. 9.21). In addition, tomograms of the same cells were acquired with the picosecond laser pumped fiber based light source centered at 1,130 nm, with 1.1 axial and 2.5 μm transverse resolution in tissue, and SNR of 93 dB for 11 mW average incident power. The UHR OCT images were compared with histological cross sections of the cells (Fig. 9.21g, h). The observed cell size was ~20 μm, while the nucleoli, parts of the active nucleus, were about 2–3 μm. Comparison with histology revealed that the intercellular-structures visualized in the OCT tomograms might correspond to some cell components as nuclei or mitochondria as well as other intracellular components. Due to the better contrast in the 700 nm region (Fig. 9.21a–c), small features can easily be resolved with the visible light source, while the tomograms acquired at 1,130 nm (Fig. 9.21d–f) look less distinct regardless of the higher intensity.

Since the OCT axial resolution scales with the center wavelength of the optical source, smaller bandwidths are required to achieve micrometer scale resolution in the visible wavelength range. Here the image contrast is enhanced due to stronger modulation of the backscattering profile of biological tissue. Major limitations for UHR OCT in the visible wavelength range are the relatively low image penetration depth as well as stability and inherent noise of current light sources. Dispersion mismatch which deteriorates the imaging quality is more critical in the visible than in the near-infrared wavelength regime especially at 1,060 nm where the zero dispersion point of water is located. The diversity in nonlinear fiber-based light sources with respect to center wavelength, bandwidth, and output power makes them extremely attractive for UHR OCT applications. However, their excess noise is higher compared to Kerr lens mode-locked lasers, and currently their setup is more complex and therefore not easy to handle.

9.7 Conclusion

Novel ultrabroad bandwidth light source technology has been developed to enable UHR OCT imaging in the visible and near-infrared wavelength region with unprecedented axial resolution. Subcellular structures were resolved with sub-micrometer axial resolution in human cancer and animal ganglion cells, while the different contrast and improved penetration depth with increasing wavelength were demonstrated. Different medical fields such as ophthalmology, gastroenterology, dermatology, neurology, gynecology, urology, laryngology, etc. impose various demands to the performance, size, and user-friendliness of UHR OCT systems.

Since its first biological application in the early 1990s, OCT has successively matured from a simple cross-sectional imaging method to a complex, ultrahigh-

resolution, volumetric imaging technique. Broadband light sources and frequency-domain detection were major milestones at the laboratory stage and promise to achieve widespread application. The majority of time-domain instruments with narrow bandwidth and much lower speeds will ultimately be replaced by this newer technology. These developments promise to make OCT as well known as computer-assisted tomography or magnetic resonance imaging. Meanwhile, extremely fast tunable and broader bandwidth light sources at new wavelengths as well as sensitive, fast, high-resolution detectors are emerging. All these technologies can be explored, tested, and evaluated for OCT applications in medicine and other fields, and promising results are rapidly emerging.

Ultrahigh-resolution OCT has the potential to provide real-time, in situ visualization of tissue microstructure without the time intensive need to excisionally remove and process a specimen as in conventional biopsy and histopathology. Non-excisional optical biopsy and the ability to visualize tissue morphology in vivo at the cellular level resolution can be used both for diagnostic imaging and for guiding therapeutic and surgical intervention. By improving axial resolution by two orders of magnitude as compared to conventional ultrasound, ultrahigh-resolution OCT represents a quantum leap in imaging performance. By providing unprecedented noninvasive in vivo optical sectioning to visualize microscopic morphometric features with subcellular level resolution in tissue at depths approaching that of in vitro conventional bright-field and confocal microscopes, OCT promises to enhance early cancer diagnosis as well as the early detection of ocular pathologies that are worldwide leading causes of blindness.

In tissues other than the eye, optical scattering limits image penetration depths to 2 mm. However, because OCT is an optical technology, it can be interfaced to a wide range of instruments such as endoscopes, catheters, or laparoscopes, which enables the imaging of internal organ systems. UHR OCT promises to have a powerful impact on many medical applications ranging from the screening and diagnosis of neoplasia to enabling new microsurgical and minimally invasive surgical procedures.

The broad bandwidths available from short pulse light sources also enable spectroscopic OCT imaging which may be used analogously to stain in histopathology, to enhance image contrast, and to provide better differentiation of tissue pathologies. With further development, spectroscopic techniques hold the promise of enabling functional imaging, for example, cross-sectional mapping of tissue oxygenation at micron level resolution. This extension should not only improve image contrast, but should also enable the differentiation of tissue pathologies via localized spectroscopic properties and functional state.

10.1 Introduction

Optical coherence tomography (OCT) is an imaging modality that can generate micrometer resolution, two-dimensional cross-sectional images, and three-dimensional volumetric data on the internal structure of optically scattering and reflective tissues and materials. OCT has been integrated with a wide range of imaging devices and has numerous applications. First-generation OCT systems detected the time delay of optical echoes by mechanically scanning the path length of an interferometer reference arm (time-domain OCT; TD-OCT) [1]. The development of Fourier-domain detection enabled a breakthrough in OCT imaging

sensitivity and speed. The performance advantages of Fourier-domain OCT were recognized independently by several research groups in 2003 [2–5]. Although most current commercial OCT instruments are built with spectrometers and line-scan cameras (spectral/Fourier-domain OCT; SD-OCT), the newest generation of OCT is based on wavelength swept light sources (swept source/Fourier-domain OCT; SS-OCT) [4, 6–8]. The advantages offered by SS-OCT are especially important for in vivo biomedical imaging applications, yet SS-OCT can also be applied to many other scientific disciplines and industrial applications.

SS-OCT uses high-speed, balanced photodetectors instead of a spectrometer and line-scan camera that is used in SD-OCT. SS-OCT detection losses are reduced compared with SD-OCT because of the higher detection efficiency of photodetectors. In addition, the parasitic signal roll-off with imaging depth which is present in SD-OCT can be significantly reduced in SS-OCT due to the coherence properties of tunable lasers and the ability to detect high-frequency signals with broad bandwidth detection and data acquisition systems. Moreover, SS-OCT systems imaging at 1,000 nm and 1,300 nm wavelengths, longer than typical wavelengths of 840 nm which are used in SD-OCT, enable better penetration of light and improved imaging depths in scattering tissues. These features allow greater optimization of OCT performance parameters, i.e., to achieve high imaging speeds, image deep tissue structures, and achieve long imaging range, which increases the functionality of OCT instruments and enables a broader range of applications.

Advances in swept laser technology have helped achieve high sweep rates, which have a number of important implications. High speeds enable decreasing the acquisition time for in vivo imaging to reduce motion artifacts. High speeds also enable the acquisition of more data to achieve denser sampling within a given acquisition time or a wider field of view for a given sampling density. Moreover, advances in imaging speed are critical for en face OCT imaging, providing a high-transverse resolution visualization perspective perpendicular to standard cross-sectional OCT images in volumetric (3-D) data sets. High-speed imaging is also enabling for functional imaging methods which extract additional contrast parameters from the OCT data. High speed facilitates techniques such as Doppler OCT which measures blood flow and OCT angiography which visualizes vasculature without requiring exogenous contrast agents. Finally, the measurement of dynamic structural and functional processes using 4-D (3-D + time) imaging, which require repeated acquisition of volumetric data sets as a function of time, is also possible with high-speed OCT technology.

SS-OCT imaging has recently benefited from advances in high bandwidth A/D systems and developments in laser technology. Using high bandwidth detection, it is possible to achieve imaging ranges that are not accessible with SD-OCT. The improvement in the instantaneous coherence length of swept light sources using microelectromechanical systems (MEMS technology) reduces parasitic sensitivity roll-off and enables more efficient use of the available imaging range and detection bandwidth. Extended imaging ranges make OCT a viable tool for imaging and measuring larger objects and enable new classes of applications, including large-scale 3-D profiling for nondestructive evaluation and metrology.

Finally, SS-OCT using new vertical cavity surface-emitting laser (VCSEL) light sources has the advantage that the wavelength sweep range and repetition rate can be adjusted in order to tailor the image resolution, imaging range, and imaging speed to match specific applications. Different operating modes of the system enable versatile functionalities and multimodal applications. This adjustability is not possible with SD-OCT because these operating parameters are set by the spectrometer optical design.

Wavelength swept lasers are a key technology for SS-OCT. One of the first wavelength swept lasers in 1997 used in OCT employed a cavity design with either a galvanometer-tuned grating or prism sequence, where 10 Hz and 2 kHz sweep repetition rates were achieved, respectively [6, 7]. Dramatic increases in speed were achieved when improved tuning elements such as dispersion prisms, rotating polygons, resonant scanning mirrors, diffraction gratings, and scanning Fabry-Perot filters were used [9–15]. Conventional tunable lasers use bulk optics or fiber components, which make resonators relatively long and therefore limit the sweep rate because of the long round trip time. This limitation was overcome using a new laser technique known as Fourier-domain mode locking (FDML) [16]. FDML lasers have long optical fiber cavities which store the entire sweep in the laser cavity, overcoming the laser buildup times which limit conventional swept lasers. Current swept laser designs can achieve MHz range sweep rates [17, 18]. Recent advances include the development of fully integrated lasers as well as miniaturization using microelectromechanical systems (MEMS) technology [19–24]. New swept light sources using vertical cavity surface-emitting laser (VCSEL) technology offer many advantages for OCT imaging [25–28]. The micron-scale cavity length of the VCSEL and the rapid MEMS response enable high imaging speeds as well as real-time adjustability of both the sweep rate and wavelength sweep range [29]. Moreover, the VCSEL operates with a single longitudinal mode instead of multiple modes and therefore has an extremely narrow instantaneous linewidth. This yields a very long coherence length and enables long imaging ranges. Therefore, MEMS-tunable VCSELs can serve as platform for the exploration and demonstration of both high-speed and long-range OCT imaging.

In this chapter, we will describe high-imaging speed and long-depth range SS-OCT with an emphasis on SS-OCT technology using VCSELs operating at 1,050 nm and 1,310 nm wavelengths. We will also review representative applications using high-speed and long-range SS-OCT including ophthalmic imaging (retinal, anterior segment, and full eye length imaging), optical coherence microscopy, endoscopy, ocular biometry, metrology, profilometry, and nondestructive material evaluation.

10.2 Swept Source OCT Technology

A schematic diagram of a typical SS-OCT imaging system and photograph of an ophthalmic prototype OCT instrument (designed and built at the Massachusetts Institute of Technology) are shown in Fig. 10.1. The VCSEL was designed and

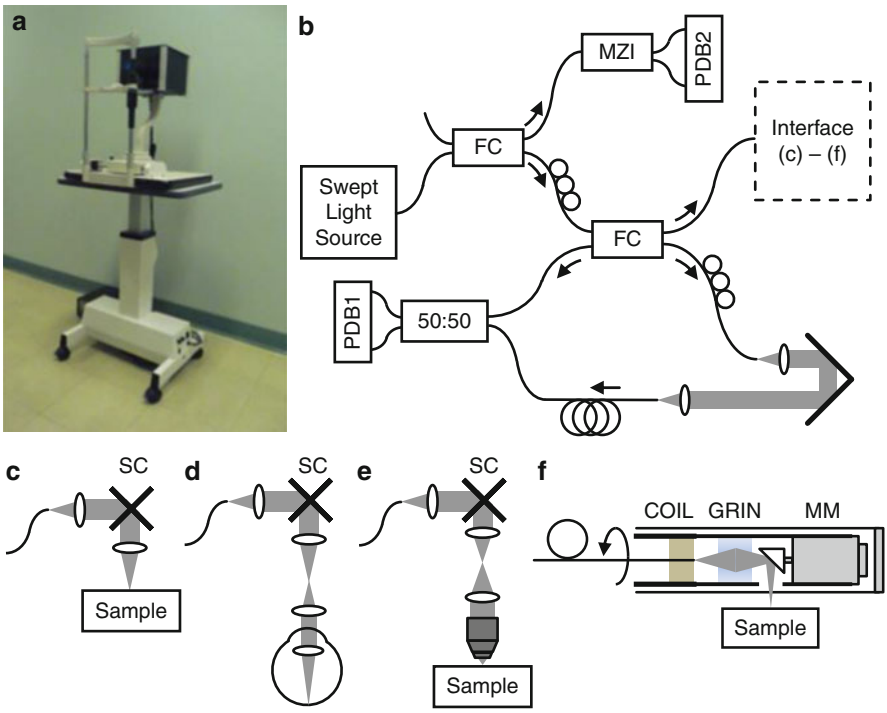

Fig. 10.1 SS-OCT system and examples of imaging interfaces. (**a**) Photograph of the SS-OCT ophthalmic interface. (**b**) Schematics of the SS-OCT system along with the different interface designs for (**c**) anterior segment, full eye length imaging and long-range OCT imaging, (**d**) retinal imaging, (**e**) SS-OCM, and (**f**) endoscopic imaging (micromotor probe). *FC* fiber coupler, *PDB1*/*PDB2* balanced photodetector, *MZI* Mach-Zehnder interferometer, *SC* galvanometric scanners, *COIL* torque coil, *GRIN* gradient index lens, *MM* micromotor

manufactured by Praevium Inc. and Thorlabs Inc. The output of the swept source laser was divided between the OCT interferometer and a sweep calibration Mach-Zehnder interferometer (MZI). The light entering the OCT interferometer was split into the sample and reference arms by a second fiber coupler. The sample arm of the OCT interferometer was attached to an imaging interface.

Figure 10.1 shows a schematic for a representative swept source imaging system at 1,050 nm wavelengths. The system uses a transmission geometry for the reference arm because high-quality optical circulators are not available at this wavelength. Several different OCT imaging systems were used to generate the data shown in this chapter. SS-OCT systems can be interfaced to microscopes, handheld imaging probes, as well as catheters and endoscopes. Different interface designs can be developed depending on the application (Fig. 10.1c–f). In the simplest microscope configuration, the interface has galvanometric scanners at the back focal length of a lens to provide telecentric scanning (Fig. 10.1c). This design is used to image the anterior segment and the full eye length as well as to image non-biomedical objects with long-range OCT. Retinal imaging requires an interface with an adapter lens to collimate the

incident beam on the eye and relay the beam scanning to pivot at the pupil of the eye (Fig. 10.1d) [30]. For swept source optical coherence microscopy (SS-OCM), the sample arm is interfaced to a scanning confocal microscope (Fig. 10.1e) [31]. The fiber output is collimated and relayed to the objective by a pair of compound lenses. Objectives with 10×, 20×, and 40× magnifications can be used, thereby enabling imaging with different fields of view and transverse resolutions. Another example configuration shown in Fig. 10.1f is a micromotor-based miniature catheter for ultrahigh-speed endoscopic OCT imaging [32]. The OCT beam was focused by a fiber-GRIN lens assembly, reflected by the rotating microprism, and focused outside the catheter sheath. The motor and GRIN lens are mounted inside a metal hypotube, and the entire assembly is covered by a transparent plastic sheath. The rotating optics could be pulled back within the sheath to produce a spiral volumetric scan pattern. The endoscopic configuration operated at 1,310 nm wavelength, and circulators were used in the interferometer for improved light collection efficiency.

In the SS-OCT configuration shown in Fig. 10.1b, light from the sample and reference arms was interfered with a fiber coupler and the signal was detected by a high-speed, dual-balanced InGaAs photodetector receiver PDB1. The photodetector signal was digitized by a high-speed A/D converter. A trigger for starting sweep acquisition was synchronized with the MEMS VCSEL. A second dual-balanced photodiode PDB2 detected interference fringes from an MZI to generate an optical clock signal. When fixed frequency A/D clocking is used, the MZI signal is used to recalibrate the OCT interference fringes, i.e., to resample the OCT signal from constant time interval to evenly sampled frequency or wave number before Fourier transforming to obtain the axial scan. If optical clocking is used, the MZI generates the optical clock signal with a constant frequency or wavenumber interval determined by the MZI delay. Several A/D acquisition boards (digitizers) were used including a 12-bit 500MSPS A/D converter (ATS9350; Alazar Technologies Inc.) and 8-bit card 1GSPS A/D converter (ATS9870; Alazar Technologies Inc.).

Frequency swept lasers are a core technology for SS-OCT. The studies presented in this chapter were performed with two types of swept light sources utilizing MEMS technology: a short cavity laser (Axsun Technologies Inc.) and a vertical cavity surface-emitting laser (VCSEL, Praevium Inc./Thorlabs Inc.). The short cavity laser had few centimeter cavity lengths and was tuned with an MEMS-tunable Fabry-Perot filter. The VCSEL had a micrometer length cavity and was tuned with a movable MEMS cavity mirror. The micrometer cavity length means that only one longitudinal mode is within the laser gain bandwidth. Single mode operation and absence of mode hopping makes the VCSEL coherence length extremely long and significantly reduces parasitic sensitivity roll-off with imaging range. The coherence length of the VCSEL was compared with an MEMS Fabry-Perot tunable short cavity laser by acquiring interference signals from a Mach-Zehnder interferometer with high bandwidth oscilloscope. Figure 10.2 shows sensitivity versus depth, where the total optical path delay is two times the depth. The VCSEL light source coherence length exceeds 1 m (measurement limited by the oscilloscope bandwidth), whereas the commercial MEMS Fabry-Perot tunable short cavity laser has a coherence length of ~12 mm.

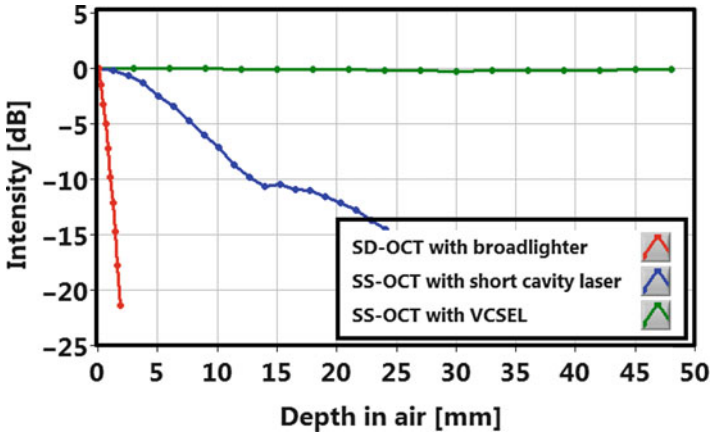

Fig. 10.2 Comparison of the parasitic sensitivity roll-off with depth: MEMS-tunable short cavity laser (sweep rate 100 kHz, tuning range 100 nm), MEMS VCSEL (sweep rate 50 kHz, tuning range 45 nm), and typical high-resolution SD-OCT (810 nm broadband light source)

10.3 High-Speed Imaging with SS-OCT

10.3.1 Imaging Speed in OCT

The imaging speed in OCT is typically specified as the axial scan rate or number of axial scans acquired per unit time. Imaging speed also governs the system sensitivity, i.e., the ability to detect weak signals trades off with increased imaging speed. The imaging speed and the resulting acquisition time is one of the key parameters for ophthalmic imaging as well as many other in vivo imaging applications. With the maturation in OCT technology, systems with higher and higher speeds have become available. The imaging speed in TD-OCT is determined by the periodic mechanical scanning of the reference arm. In practice, TD-OCT instruments are unable to reach speeds higher than ~2 kHz due to mechanical limitations in the reference arm as well as limitations in detection sensitivity [33]. In SD-OCT, imaging speed is determined by the reading speed of the line-scan camera in the spectrometer. Early SD-OCT instruments operated at 19 kHz axial scan rates, but the development of new line-scan camera technology allowed significant increases in speed so that current SD-OCT systems can operate at more than 100 kHz rates [34]. On the other hand, the imaging speed in SS-OCT is determined by the sweep repetition rate of the swept light source, and modern systems can achieve MHz axial scan rates [18, 26, 32, 35].

Different techniques have been developed to increase OCT imaging speed. The use of multiple beams in the sample arm enabled multiplication of the effective speed, although this approach is complex and requires more sophisticated hardware [18, 22, 36–38]. A parallel solution in SD-OCT is to use a dual-camera system which doubles the acquisition speed [39]. Multiboard acquisition and optical

demultiplexing has been used to achieve speeds of 60,000,000 axial scans per second [40]. Using certain swept light sources, it is possible to obtain higher SS-OCT imaging speeds by more efficient usage of the sweep duty cycle. In this approach, imaging speeds can be increased by using both forward and backward sweeps or buffering to combine time-delayed copies of the sweep [16, 22, 41].

10.3.2 High-Speed Retinal SD-OCT and SS-OCT Imaging

The most common application of OCT is retinal imaging. OCT enables imaging the morphology of retinal layers in the fovea and optic disc regions for diagnosis and monitoring therapeutic response in diseases such as age-related macular degeneration, glaucoma, and diabetic retinopathy. Initial retinal TD-OCT instruments had imaging speeds of a few hundred axial scans per second [1, 42, 43]. The introduction of Fourier-domain detection resulted in a sensitivity increase of 50–100 times over previous time-domain technology. These increases in speed enabled dramatic improvements in image quality and retinal coverage, as well as three-dimensional OCT (3-D OCT) imaging. SD-OCT retinal imaging was first demonstrated by Wojtkowski et al. in 2002 [44]. With high-speed line-scan cameras, studies demonstrating SD-OCT at 26,000–29,000 axial scans per second were reported by several groups [45–47]. Ultrahigh SD-OCT imaging speeds of >300,000 axial scans per second were demonstrated by Potsaid et al. in 2008 using advanced CMOS camera technology [34]. Meanwhile, SS-OCT has also undergone similar development. The first SS-OCT retinal instruments operated at imaging speeds of 19,000 axial scans per second [6]. With the advent of new laser technologies, ultrahigh-speed OCT imaging of the retina became possible. Although fundamental laser sweep rates reach 400 kHz, different methods to increase the effective sweep rate were developed including buffering or simultaneous multi-spot imaging. These advances enabled imaging at the rates of several MHz [18, 48]. With these technological improvements, the term “high-speed imaging” was extended to hundreds of thousands of axial scans per second and the term “ultrahigh-speed imaging” referred to speeds which approach ∼1,000,000 axial scans per second [18]. By contrast, current commercial retinal SD-OCT and SS-OCT instruments at 840 nm and 1,050 nm wavelengths have imaging speeds of up to ∼100 kHz.

High acquisition speeds enable 3-D OCT volumetric imaging by raster scanning multiple cross-sectional images. Unlike standard ophthalmic examination techniques such as fundus photography, OCT provides depth-resolved information and enables visualization of 3-D retinal structure. Volumetric data sets provide detailed structural information on the retina that is unavailable with other imaging modalities. The volumetric data sets can be displayed in multiple ways. Figure 10.3 shows SS-OCT retinal imaging with a short cavity laser at 1,050 nm wavelength. Methods of OCT data presentation include 3-D rendering, cross-sectional images, and en face views (OCT projection and C-scan images). Another advantage of 3-D OCT imaging is the ability to extract arbitrary (virtual) cross-sectional images which are precisely registered to retinal fundus features. OCT retinal fundus images

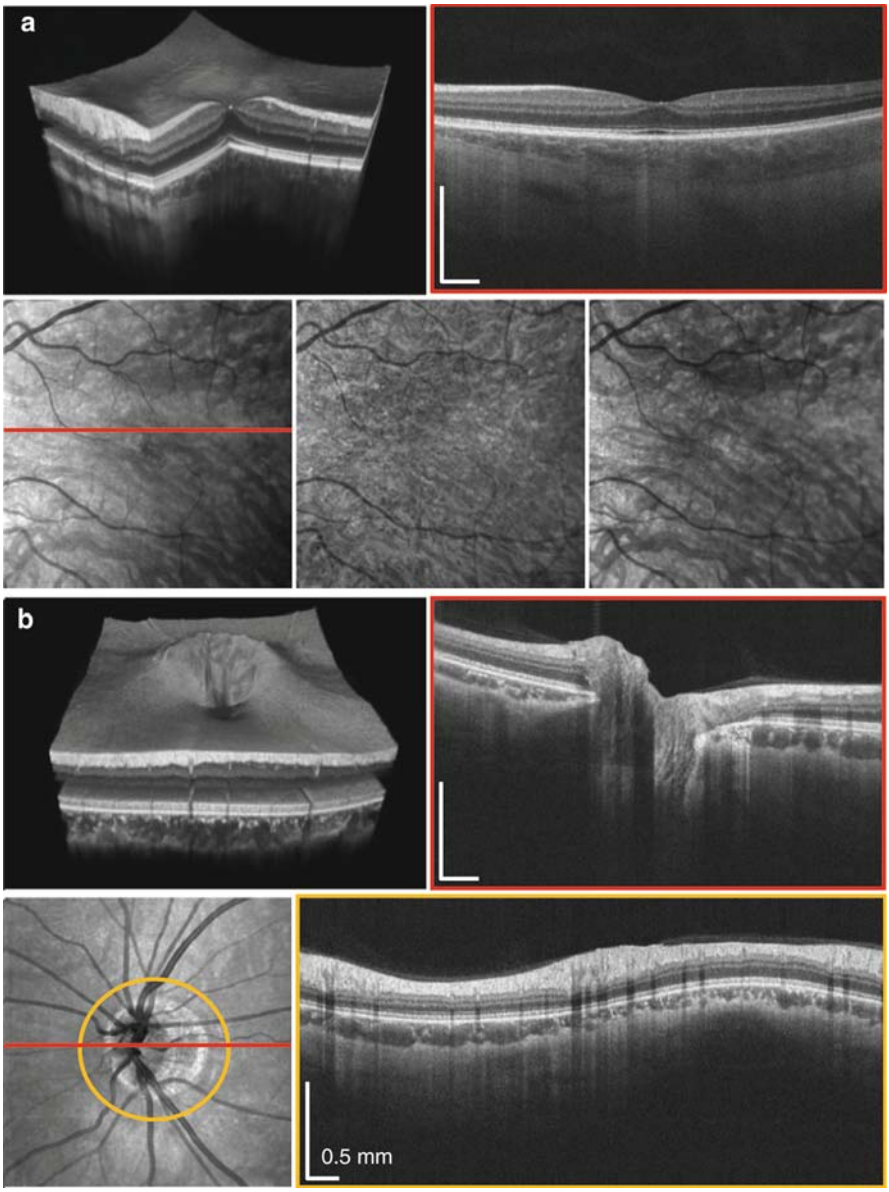

Fig. 10.3 Volumetric SS-OCT retinal imaging at 1,050 nm of the macula (**a**) and optic nerve head (**b**) at 1,050 nm wavelength. 3-D data sets enables generation of generating volumetric renderings, OCT fundus images, different cross-sectional images, and C-scans or en face images. Two perpendicularly scanned data sets, each with 700 × 700 axial scans, were acquired at 100 kHz, and an OCT motion correction algorithm was applied to remove motion artifacts

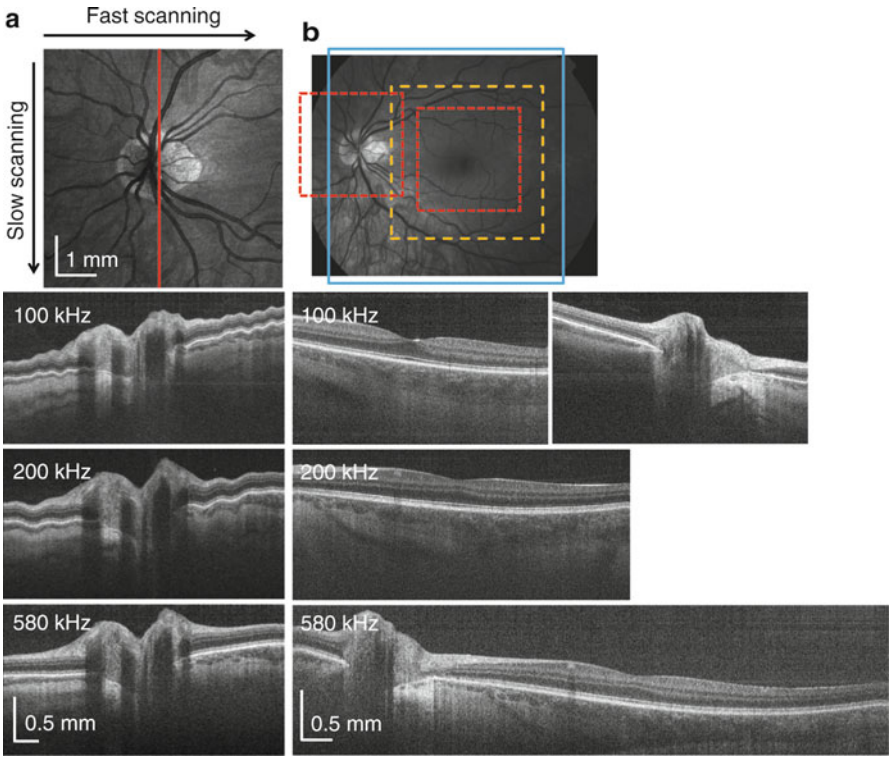

Fig. 10.4 Retinal OCT imaging using SS-OCT with a VCSEL light source. (**a**) Imaging of the optic nerve head region at different speeds. Extracted central cross sections in the slow scan direction, perpendicular to the raster scan directions, show reduced motion artifacts with increased speed. In each case, the data consisted of 500 × 500 axial scans from a 6 × 6 mm^2 area. (**b**) Impact of the imaging speed on retinal coverage. Red-free fundus photograph indicates scanned areas at different speeds. Selected cross sections from volumetric data sets acquired at 100 kHz, 200 kHz, and 580 kHz. Transverse sampling density and acquisition time are kept constant. Aspect ratios of all cross sections are the same (From Ref. [30])

can be obtained by summing the entire signal in axial direction. Other types of en face images include projection views that can be generated either by choosing specific depth level or by integrating the signal from selected depth range [49]. The wide variety of data presentation options enhances the diagnostic utility of 3-D OCT imaging in clinical practice and forms a basis for quantitative data analysis.

Eye and head motion during acquisition generates artifacts in OCT images. Different approaches have been developed to minimize or compensate motion artifacts, including reducing acquisition times, software-based methods (e.g., OCT registration and motion correction) [50], and hardware techniques (e.g., eye tracking) [51]. Ultrahigh imaging speeds enable rapid acquisition of dense volumetric data to reduce motion artifacts. Figure 10.4a shows 3-D OCT data sets of the

optic nerve head of the same subject acquired at three different speeds. Since the lateral scanning density (500 axial scans and 500 B-scans over a 6 × 6 mm^2 retina area) was kept constant, different axial scan rates resulted in reduced acquisition times ranging from 2.6 to 0.5 s. Fundus features were used to confirm that corresponding cross-sectional OCT images are extracted from the same position for comparison. These data demonstrate that motion artifacts in the slow scan direction, perpendicular to the raster, are significantly reduced as the imaging speed increases.

High-speed OCT imaging of the retina also enables better retinal coverage for a given sampling density. This feature of high-speed imaging is shown in Fig. 10.4b. Volumetric OCT data sets were acquired by raster scanning at axial scan rates of 100 kHz, 200 kHz, and 580 kHz. Fundus views and corresponding cross-sectional images are presented. A measurement time of ∼2 s was used for each volume, consistent with a typical clinically acceptable acquisition time. The data sets comprise of 400 × 400, 600 × 600, and 1,000 × 1,000 axial scans and cover areas of 5 × 5 mm^2, 7 × 7 mm^2, and 12 × 12 mm^2 at the sweep rates of 100 kHz, 200 kHz, and 580 kHz, respectively. Whereas at 100 kHz the scanned area requires separate acquisitions for the central macular region versus the optical nerve head, imaging at 580 kHz enables an almost sixfold increase in scanned area covering both the macular region and optical nerve head in a single scanned area. In this case, a wide-field OCT coverage comparable to standard fundus photography is achieved (Fig. 10.5b compared to Figs. 10.4a and 10.5h), and the sampling density in the transverse direction is high enough to image focal retinal pathologies. Whereas fundus photographs reveal two-dimensional information, OCT volumetric data can be used to display cross-sectional and en face projections of different retinal and choroidal layers. Cross-sectional images in Fig. 10.4 demonstrate the ability to visualize deep choroidal layers, the choroid-scleral interface, and even scleral vasculature due to the high sensitivity and deep image penetration at 1,000 nm wavelengths. Axial summation of the OCT signal intensity from 40 μm thick slices at different depths below the retinal pigment epithelium (RPE) was used to generate projection OCT en face images of the choroid. OCT projection images corresponding to the chriocapillaris, Sattler's layer, and Haller's layer can be identified and characterized by choroidal structure and vasculature appearance, as shown in Fig. 10.5 d–g.

Standard clinical angiographic modalities require intravenous administration of dyes such as fluorescein or indocyanine green (ICG). However, OCT can be used to visualize vascular networks and generate images analogous to angiography without the need for exogenous contrast agents. This complementary information can be obtained from the same OCT data sets. Figure 10.5 c, h–k show comparisons of ICG angiography and OCT intensity-based retinal and choroidal images. Since retinal vessels generate shadows in OCT cross-sectional images, it is possible to increase contrast in a projection image by summing the intensity from a 50 μm thick layer around the RPE. On the other hand, choroidal vasculature can be visualized by using an inverted gray scale in the projection image of the signal below the RPE. Due to shadowing effects, retinal vessels also appear in the choroidal vasculature

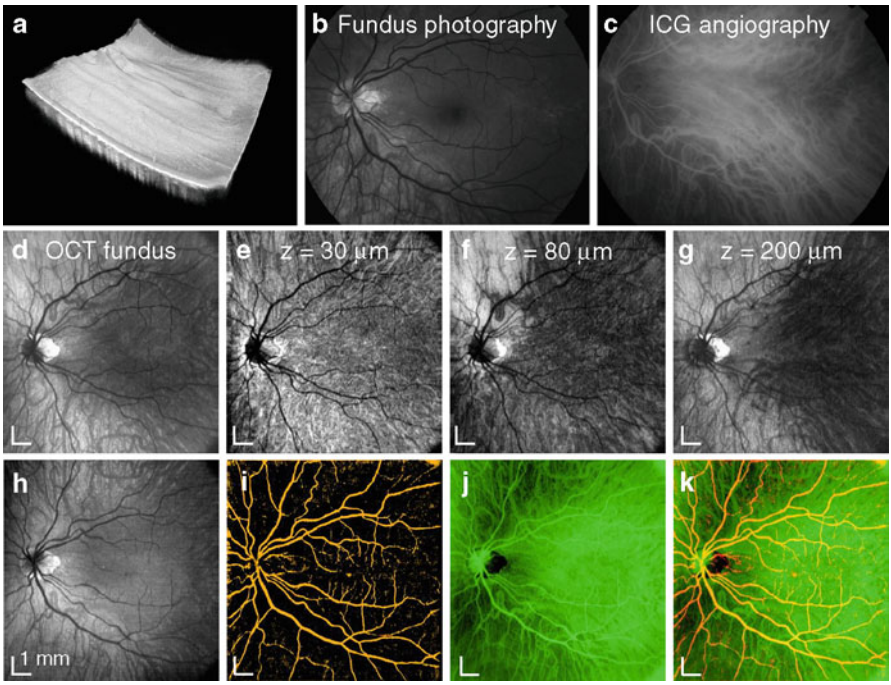

Fig. 10.5 Wide-field choroidal OCT imaging using SS-OCT with a VCSEL light source. (**a**) Rendering of a volumetric wide-field data set. (**b**) Red-free fundus photography and (**c**) indocyanine green (ICG) angiography of the same subject. (**d**) OCT fundus image. (**e**) – (**g**) OCT projection images at different depths below RPE showing choroidal layers and sclera. The OCT signal was integrated from 40 µm thick slices. (**h**) OCT wide-field fundus image. OCT angiographic images showing: (**i**) segmented retinal, (**j**) choroidal vasculature and (**k**) combined angiographic image. (From Ref. [30])

en face image. Volumetric OCT data can be used to visualize vascular networks in the eye by a combination of retinal and choroidal projection OCT images. In addition, a variety of Doppler and angiographic OCT methods have been developed that can measure flow using the Doppler phase shift or enhance the contrast of vasculature using phase variance or intensity speckle decorrelation [52–62].

10.3.3 High-Speed Anterior Segment Imaging with SS-OCT

Imaging the anterior segment of the eye requires a combination of long depth range and high imaging speed to obtain clinically useful information. Generally speaking, the challenge of anterior segment OCT imaging comes from the fact that the anterior segment has multiple structures: some of which are anatomically thick, others are heavily pigmented, and one, the cornea, has steep curvature. Additionally, as in other ophthalmic applications, high acquisition speeds are important to minimize motion artifacts.

The first demonstration of anterior segment OCT imaging was performed in 1994 by Izatt et al. [63]. Multiple studies demonstrated time-domain OCT and Fourier-domain OCT for anterior segment imaging at different wavelengths and speeds [11, 22, 64–68]. Challenges encountered in SD-OCT could be addressed by reducing parasitic sensitivity roll-off and improving light penetration into tissue [69, 70]. These requirements can also be fulfilled by SS-OCT technology which offers better performance over SD-OCT at wavelengths longer than the traditional 840 nm used for retinal imaging [4]. Light at wavelengths longer than 840 nm exhibits less scattering and therefore enables deeper imaging [71, 72]. The first SS-OCT systems for anterior segment imaging utilized light sources at 1,300 nm wavelength, and the imaging speed increased from 20 to 200 kHz [11, 66]. Recent demonstrations of anterior segment imaging achieved imaging speeds of 1,600 kHz at 1,310 nm wavelength and 100 kHz at 1,050 nm wavelength [22, 73]. Finally, SD-OCT and SS-OCT systems for simultaneous anterior segment and retinal imaging have also been demonstrated [74, 75].

High-speed and reduced parasitic sensitivity roll-off is important for 3-D imaging of the anterior eye. Figure 10.6a shows a rendering of a volumetric data set covering a 13 × 13 mm^2 area of the anterior eye. The volume consists of 500 × 500 axial scans acquired in 2.6 s. The en face image of the anterior segment reveals a rhombus-like polarization artifact from the cornea. Due to the long coherence length of the VCSEL light source, there is virtually no parasitic sensitivity roll-off. This enables direct visualization of the entire anterior segment. The cross-sectional image in Fig. 10.6a shows the cornea, iris, and entire crystalline lens and spans the entire transverse width of the anterior chamber, from limbus to limbus. The crystalline lens is not an optically homogenous structure; the nucleus and cortex can be distinguished. It should be noted that anterior segment OCT images do not display the true shape of the eye unless refraction correction algorithms are used. The refraction-corrected cross-sectional image where the OCT beam propagation direction has been corrected using the interfaces and refractive indices of ocular structures is also shown. The uncorrected image has an artificial posterior displacement of the iris and anterior lens which is produced by refraction of the OCT beam at the air-corneal interface, while the refraction-corrected image displays the iris and anterior lens in their true anatomical positions.

The same scanning protocol was applied to scan the eye of a subject after cataract surgery. As shown in the en face image in Fig. 10.6b, the intraocular lens (IOL) causes strong reflections in OCT images. Visualization of 3-D data enables identification of regions with floaters behind the posterior IOL surface.

In addition to wide-field OCT, scanning can be performed over specific structures such as the limbus and anterior chamber angle [76]. Figure 10.6c shows corneoscleral imaging of the anterior eye. This does not require long imaging range, and therefore the system was operated at 100 kHz in high-resolution mode, similar to that used for retinal imaging. The volumetric data set consisted of 500 × 500 axial scans and covered a 7 × 7 mm^2 area. This dense scan over the anterior chamber angle enabled visualization of the limbal region along with

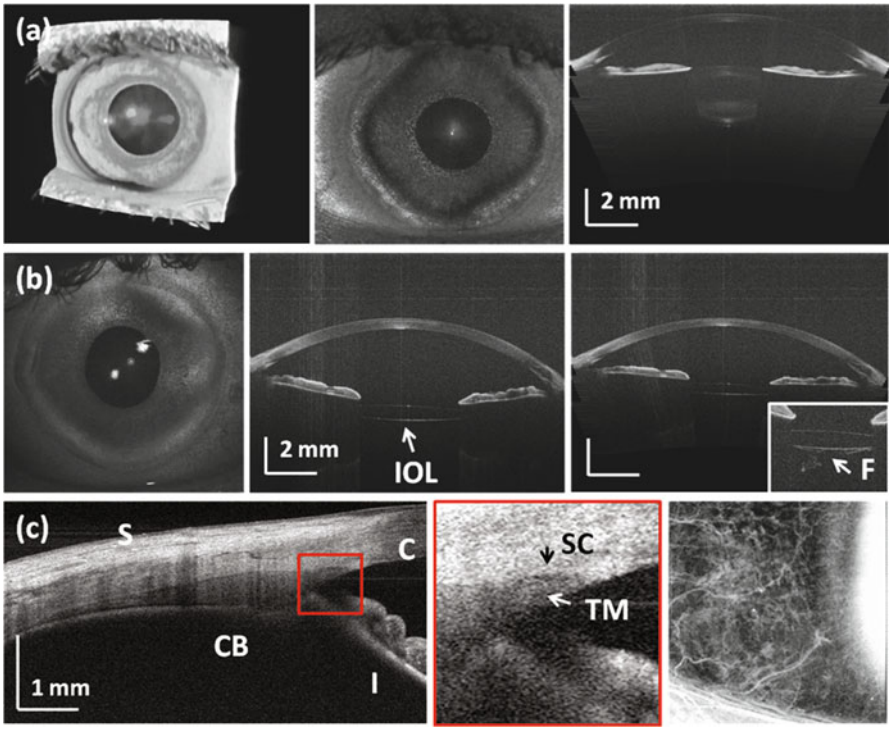

Fig. 10.6 Anterior segment imaging with SS-OCT. (**a**) Volumetric rendering, en face OCT, and cross section taken from the volumetric OCT data of a healthy subject. (**b**) En face OCT and cross-sectional images of an eye after cataract surgery and intraocular lens (*IOL*) implantation (*F* floaters). (**c**) Cross section and en face image of the corneoscleral junction with enlargements showing Schlemm's canal and scleral vasculature (*S* sclera, *CB* ciliary body, *C* cornea, *I* iris, *SC* Schlemm's canal, *TM* trabecular meshwork)

landmarks such as the corneoscleral junction and rich scleral vasculature. Elements of the outflow system such as Schlemm's canal can also be identified.

After refraction correction of anterior segment OCT data sets, qualitative 3-D structure can be accurately visualized and quantitative information about the shape of ocular structures can be extracted. Figure 10.7 shows example maps of clinically relevant parameters which can be measured from 3-D OCT data. Mapping biometric parameters is important for the diagnosis of ocular diseases as well as in pre-and postoperative assessment of the eye for keratorefractive surgery or IOL implant.

10.3.4 Dynamics of the Anterior Segment of the Eye and 4-D OCT Imaging

Apart from its structural complexity, the eye is also a highly dynamic organ that can adapt to changing conditions and provide the best optical imaging of objects

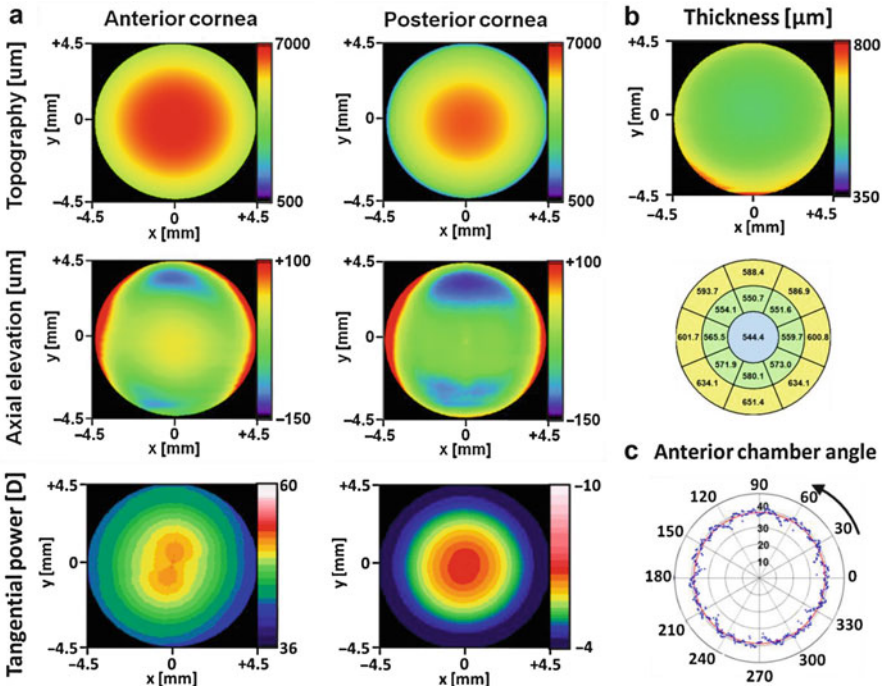

Fig. 10.7 OCT ocular biometry. (**a**) Topography, elevation, and tangential power (keratometry) maps of both corneal surfaces obtained from 3-D OCT data. (**b**) Corneal thickness map and corresponding sector map showing average thickness in central (0–3 mm diameter), paracentral (3–6 mm diameter annulus), and pericentral (6–9 mm diameter annulus) region. (**c**) Polar plot of anterior chamber angle for different meridionals. Mean anterior chamber angle is shown in *red*

onto the retina. Ultrahigh-speed OCT enables visualization of dynamic processes within the eye [77]. Studies of dynamic processes are an important indicator of ocular functionality and can be performed using rapid, repeated volumetric scanning in time. This demanding scanning mode combines 3-D scanning with time as the fourth dimension and therefore is often described as 4-D imaging. In this subsection, we will discuss applications of high-speed anterior segment imaging for visualizing processes such as tear film breakup and pupillary reflex.

The first example demonstrates measurement of tear film dynamics for tear evaluation and diagnosis of dry eye. The tear film is the first refractive surface for light incident on the eye and plays an important role in the optical quality of the eye. Tear film breakup time is usually measured with fluorescein dye [78]. OCT can enable indirect but noninvasive imaging of tear film dynamics by integrating the detected OCT signal over the lens region where optical shadowing from tear film breakup appears. Figure 10.8a shows the shadows caused by tear film breakup which appear over the lens region in repeated volumetric OCT data sets. A 4-D scan protocol was used with 300 × 300 axial scan volumes over a central 8.5 × 8.5 mm^2 area at a rate of ~0.5 volumes per second for 20 s with an axial scan rate of 50 kHz. The shadowing

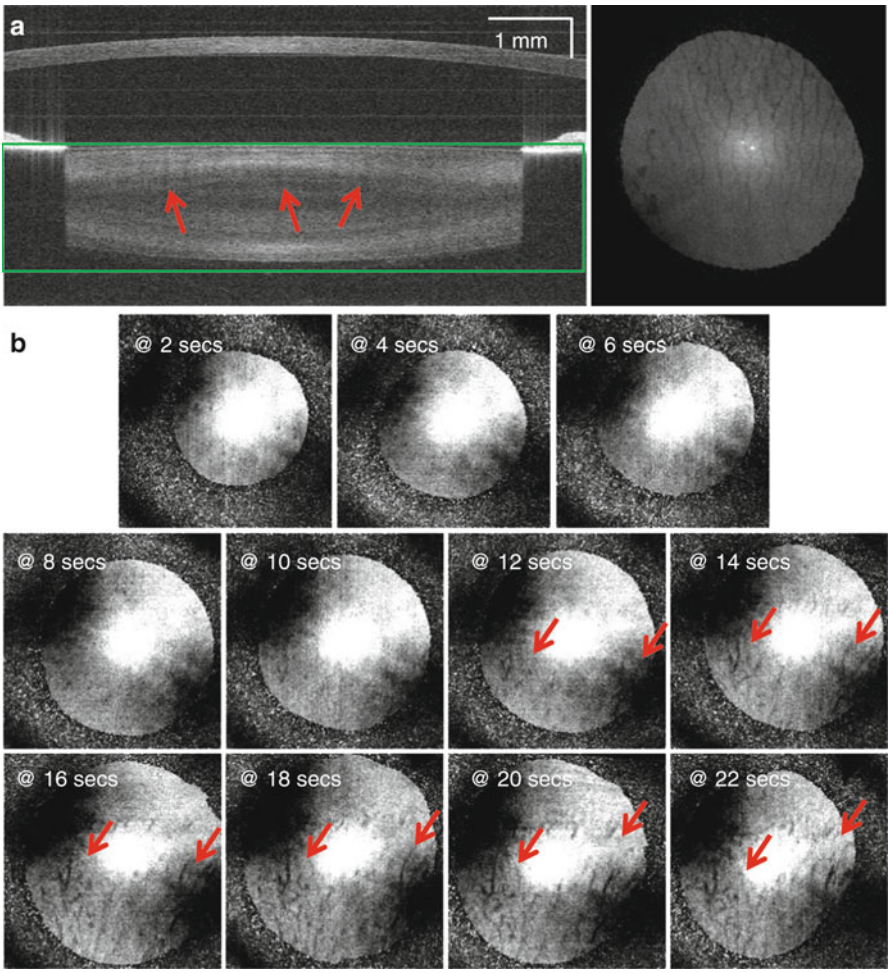

Fig. 10.8 SS-OCT visualization of tear film breakup. (**a**) Shadowing effect in a cross-sectional image of the anterior segment. The signal from the crystalline lens region can be integrated to generate projection OCT image with a characteristic pattern which shows tear film breakup. (**b**) Tear film breakup observed in en face images from 4-D OCT data. Tear film breakup is observed to begin at ~12 s (From Ref. [77])

effect can be observed, and the signal between the anterior and posterior surface of the crystalline lens was used to generate projection OCT images (Fig. 10.8b). Tear film breakup appears as randomly distributed spots in the OCT projection image within the pupil area. Tear film breakup can be determined by the frame-by-frame analysis of the projections and is approximately 12 s in the example shown.

The iris is a dynamic structure whose configuration changes in response to light and during accommodation. Studying the dynamic response of the pupil to dark-light stimulus may provide a more comprehensive assessment of risks from

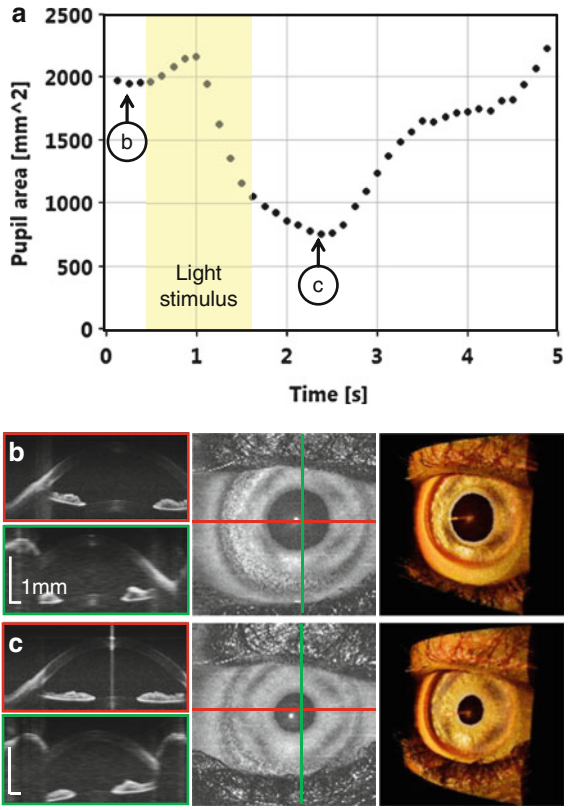

Fig. 10.9 4-D OCT imaging of pupillary reflex. (**a**) Plot of pupil area versus time measured from 3-D OCT data. Application of light stimulus is indicated in yellow. (**b**) 3-D rendering, en face OCT, and cross-sectional images extracted from the volumetric OCT data of the eye before light stimulus. (**c**) 3-D rendering, en face OCT, and cross-sectional images extracted from the volumetric OCT data of the eye at the time of maximum pupil constriction (From Ref. [77])

primary-angle closure development and may help understand the pathophysiology of angle closure glaucoma [79, 80]. Figure 10.9 shows the pupil response to light stimulus from an LED positioned adjacent to the eye. Sequential 150 × 150 axial scan volumes over a 17 × 17 mm^2 area were acquired with an ~8 volumes per second volume rate at an axial scan rate of 200 kHz. The acquisition required ~5 s and enabled visualization of 3-D changes in the iris as a function of time. The pupillary response to light stimulus can be quantitatively analyzed by measuring the pupil size/area changes. As shown in Fig. 10.9, the pupil area decreased rapidly when light stimulus was applied. In contrast, the time constant of the pupil recovery was longer than the constriction reflex.

10.3.5 High-Speed Microscopy and Endoscopy

High imaging speeds which can be achieved with SS-OCT are also important for applications such as microscopy and endoscopy. In conventional microscopy, transverse resolution is determined by the numerical aperture of the objective, which in turn limits the depth of field. OCT has the advantage that it decouples

the diffraction-limited axial and transverse parameters of the focused beam. In most OCT applications, high axial resolutions can be achieved with broadband light sources, but the transverse resolution is not sufficient to reveal cellular or subcellular features. Optical coherence microscopy (OCM) combines low coherence detection with confocal microscopy to improve the transverse resolution of OCT images [81, 82]. The utility of OCM to identify pathologies has been demonstrated in ex vivo studies on human breast, thyroid, and renal tissue [81–83]. OCM also has a broad range of applications in research and biological microscopy, ranging from cellular level imaging of the cortex in small animals to in vivo imaging of developmental biology specimens.

OCM has several advantages over traditional confocal microscopy. OCM uses coherence gating to remove out-of-focus light, and compared with confocal microscopy, OCM can image scattering tissues with improved contrast [84, 85]. The imaging depth in confocal microscopy is limited by loss of contrast due to unwanted scattered light and aberrations. The optical sectioning provided by coherence gating significantly improves image quality by removing unwanted scattered light, and OCM enables deeper imaging of biological specimens. OCM was originally developed using time-domain detection, which allows video-rate en face imaging [81]. However, since time-domain OCM (TD-OCM) enables acquisition of only a single coherence-gated depth, both confocal and coherence-gate depths must be carefully matched. This increases the complexity of the system. In addition, variations in path length delay arising from the non-coincident pivot locations of the galvanometer mirrors in scanning microscope systems produce a curved en face image surface which does not match the objective focal plane [86]. Fourier-domain detection enables simultaneous imaging of multiple depths, which reduces the complexity of acquiring en face images and enables the reconstruction of en face images at multiple depths [87, 88]. Post-processing algorithms may be applied to volumetric Fourier-domain OCM data in order to compensate for path length variations across the scan field as well as dispersion mismatch between sample and reference arms [89, 90]. However, since each en face OCM pixel requires the acquisition of an axial scan, ultrahigh imaging speeds are important in order to achieve acceptable en face frame rates. Swept source OCM (SS-OCM) offers ultrahigh speed that is critical for real-time imaging and display to provide diagnostic feedback in clinical settings such as the pathology laboratory or endoscopy suite. SS-OCM systems also require wide wavelength sweep bandwidths to achieve high axial resolution at 1,000 nm and 1,300 nm wavelengths.

High-speed OCT/OCM can be performed using swept source/Fourier-domain detection with a VCSEL light source. VCSEL light sources are well suited for SS-OCM because they can operate at MHz sweep rates and are broadly tunable at 1,000 nm and 1,300 nm wavelengths. The example shows a VCSEL operating at 1,310 nm with a 280 kHz sinusoidal sweep frequency and bidirectional axial scan rate of 560 kHz [31]. A tuning range of 117 nm was achieved, which provided an axial resolution of 13.1 μm in air, corresponding to 8.1 μm in tissue. Fourier-domain detection has the advantage that the dispersion mismatch between the sample and reference arms can be numerically compensated enabling sample arm

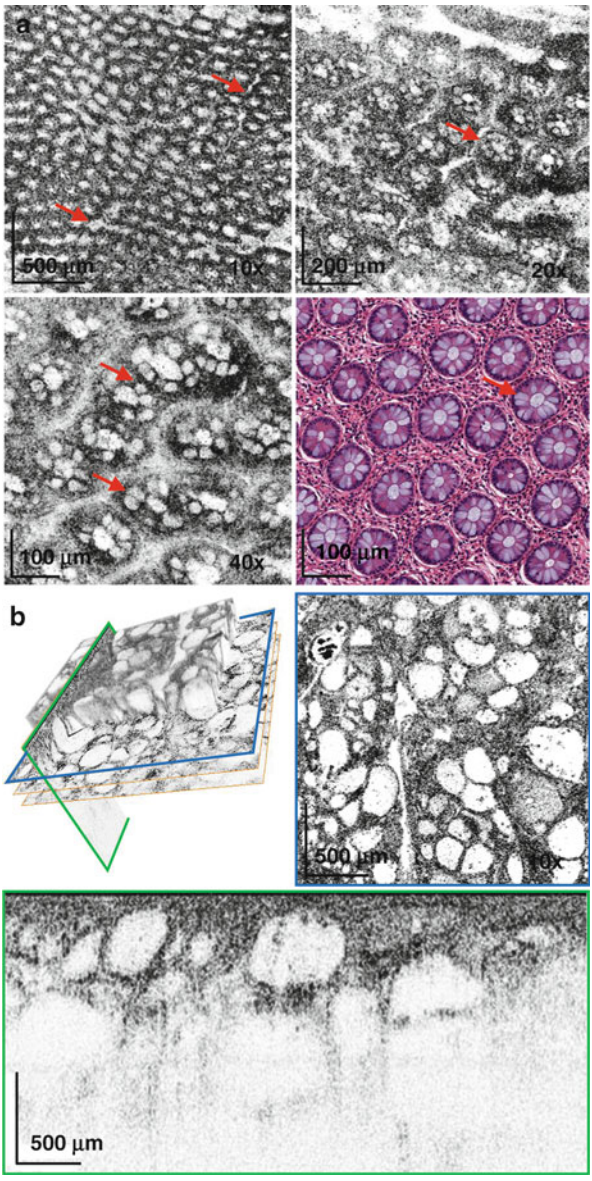

Fig. 10.10 High-speed ex vivo optical coherence microscopy (OCM) using swept source/Fourier-domain detection with a VCSEL light source at 1,310 nm wavelength and 560,000 axial scans per second imaging speed. (**a**) SS-OCM images of a fresh ex vivo human colon specimen with different magnification objectives. Goblet cells are indicated with arrows. Lower right image shows corresponding histology image of colon tissue for comparison. (**b**) Volumetric SS-OCM of a fresh ex vivo thyroid specimen. En face OCM images provide high transverse image resolution and uniform signal compared with cross-sectional images (Figure from Ref. [31])

optics and magnification to be easily changed. As mentioned in Sect.10.2, SS-OCT can be interfaced to a confocal microscope. The microscope had interchangeable objectives (40×, 20× and 10×) for different transverse resolutions (0.86–3.42 µm) and different fields of view (600 × 600 µm^2, 1 × 1 mm^2 and 2 × 2 mm^2). Figure 10.10a shows example ex vivo OCM images of a normal human colon

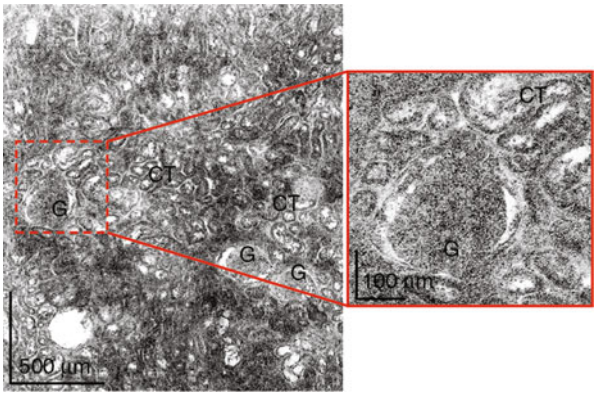

Fig. 10.11 Example mosaic large-field SS-OCM image of a normal human kidney specimen ex vivo. Stitching of 30 individual en face images was performed. *CT* convoluted tubules, *G* glomerulus (Figure from Ref. [31])

specimen taken with three different magnification objectives demonstrating multi-scale imaging. The specimen can be surveyed with a low magnification 10× objective with large field of view (FOV; 2 × 2 mm^2) to show the general architecture of the specimen. With the aid of higher magnification 20× and 40× objectives, details of the colon crypt structures can be visualized. SS-OCM images delineate the mucin secreting goblet cells residing in the crypts and correspond well with features visualized in histology.

SS-OCM also enables volumetric imaging by simultaneously acquiring signals from multiple en face depths. Figure 10.10b shows a 3-D rendering of a fresh ex vivo human thyroid specimen where different en face images and cross sections can be extracted from the volumetric data, similar to the 3-D ophthalmic images presented previously. As an example, an en face plane from the same volumetric data set was selected 50 μm below the specimen surface. Depth-dependent features of follicular architecture can also be clearly observed in the OCM images. The en face images enable high transverse image resolution, but the ability to extract multiple depths is limited by the depth of field and confocal parameter which trades off against high transverse resolution.

Another approach is to perform image mosaicking to preserve high resolution but also obtain wide field of view. A large specimen area can be imaged at high resolution using a high magnification objective and acquiring multiple partially overlapping volumes with a small field of view which are stitched to generate a large field of view image. Figure 10.11 shows an example of a wide-field SS-OCM image from a fresh ex vivo normal human kidney specimen. The image was generated by combining 30 frames taken with a 40× objective to obtain a 1.8 × 2.1 mm^2 total field of view. Glomeruli and convoluted tubules can be observed throughout the imaging field, consistent with the characteristics of normal renal cortex. Detailed examination can be performed by zooming into regions of interest.

OCT imaging has also been applied in fiber-optic-based endoscopes [91, 92]. OCT can visualize microstructural features of internal luminal organs to detect pathology associated with disease such as cancer or atherosclerosis. However, in vivo endoscopic OCT imaging is challenging because high-speed optical

scanning must be implemented inside a miniaturized imaging probe [93]. Many scanning mechanisms have been realized in catheter-based endoscopic OCT systems, such as proximal rotation of a torque cable and fiber with a distal microprism [91, 94–96], actuating a distal fiber tip using a galvanometer [97], actuating a fiber on a cantilever by piezoelectric transducer [98–100], beam scanning using microelectromechanical systems (MEMS) [101–104], and rotary beam scanning in a tethered capsule [105].

High-speed SS-OCT endoscopy requires high-speed endoscopic scanning devices. This example shows ultrahigh-speed endoscopic SS-OCT imaging using a VCSEL light source at 1,310 nm wavelength with a micromotor imaging catheter [32]. The system imaged at 400 frames per second with 1 MHz axial scan rate, 11 μm axial resolution, 7 μm transverse resolution, and 1.65 mm imaging range in air (corresponding to 8 μm axial resolution, 8 μm transverse resolution, and 1.2 mm imaging range in tissue). The micromotor could operate at 1,200–72,000 rpm (corresponding to 20–1,200 fps). Volumetric data sets were obtained by proximally pulling back the micromotor and optics inside the endoscopic probe sheath in order to obtain a spiral scan pattern. The high frame rate can reduce the total data acquisition time, while distal actuation reduces nonuniform rotation artifacts, improving volumetric data acquisition. Image quality can also be enhanced by averaging consecutive frames to reduce speckle.

High imaging speed enables rapid acquisition of a densely sampled 3-D volumetric data set covering a wide field with minimum motion artifacts in vivo. In the following example, volumetric data in the rabbit colon consisting of 3,000 frames of 2,500 axial scans each was acquired in 7.5 s, covering an area of 7.5×7.5 mm^2. Figure 10.12a shows volumetric data and representative cross sections. The image quality was improved by averaging three consecutive images perpendicular to the viewing direction. The en face image in Fig. 10.12a shows crypt structures in the colon as well as vessels below the surface (indicated with arrows). The megahertz speed imaging also makes 3-D-OCT acquisition less sensitive to motion, which can be seen in cross sections. Two cross-sectional images are also included in Fig. 10.12a: a cross-sectional image along the longitudinal pullback direction and a cross-sectional image along the rotary direction. The architectural morphology of the colon, such as the epithelium, mucosa, submucosa, and muscular layers can be identified and correspond to representative histology of the rabbit colon.

Figure 10.12b shows example 3-D SS-OCT data from the rabbit esophagus. The scanning protocol was similar to the previous example. The cross-sectional OCT images allow visualization of normal esophageal layers including the epithelium, lamina propria/muscularis, submucosa, circular muscle, and longitudinal muscle. The layered structure in the OCT images correlates well with representative histology. The projection view in Fig. 10.12b shows features such as vessels over a large field of view. Although vessels have similar structures to dilated glands in cross-sectional images, they are distinguishable in en face images. Periodic motion due to the cardiac cycle is also visible in the en face view.

[32])

10.4 Long-Range Imaging and Optical Metrology

10.4.1 Depth Range in OCT

The performance of Fourier-domain OCT systems is also governed by the axial imaging range (depth range), which is limited by the coherence length of the light source and the highest detectable OCT fringe frequency. The imaging range of the OCT system and light source is often characterized by the −6 dB intensity roll-off depth, i.e., the range at which the interference amplitude signal decreases to one half of its maximum [106].

The imaging range in TD-OCT depends on the mechanical scanning range of the reference arm. However, the imaging range (maximum detectable optical path difference) in SD-OCT systems is limited by the spectral resolution of the spectrometer. Therefore, the spectrometer design (optics, dispersive element, and camera specifications) plays a key role in determining the imaging range in SD-OCT. On the other hand, SS-OCT systems detect interferometric signals in time, and therefore different factors determine the imaging range. The light source coherence

length, related to its instantaneous linewidth, is a key parameter which determines the imaging range in SS-OCT. The maximum range which can be measured by an SS-OCT system also depends on other laser and hardware specifications such as sweep rate of the swept light source, the wavelength sweep range, the detector bandwidth, and the sampling rate (bandwidth) of the acquisition (A/D card).

Currently, standard clinical ophthalmic SD-OCT instruments have imaging ranges of 2–3 mm which are sufficient to image the retina assuming moderate patient eye motion. Additionally, current clinical ophthalmic or intravascular SS-OCT devices can image up to ~6 mm range, sufficient for imaging the anterior chamber of the eye for ophthalmic applications or imaging a typical coronary artery diameter for intravascular applications.

10.4.2 Hardware Requirements for Long-Range OCT

OCT systems require special design in order to image long ranges. First, the OCT sample arm depth of focus of the beam incident on the sample should match the imaging range of the system. This provides optimized light collection efficiency from all depths imaged. In practice, if high transverse resolution is desired, it is difficult to meet this requirement even for standard imaging range systems. When the imaging range increases, the numerical aperture of the lens decreases, and long focal lenses should be used resulting in a loss of transverse resolution (Fig. 10.13). Methods using non-diffracting beams (e.g., Bessel beams) or a combination of multiple focal depths have been investigated to address these depth of focus limitations [107–110].

In SS-OCT, given the availability of high bandwidth detection and acquisition electronics, the primary factor determining the ability to image large depths is the coherence length of the swept laser. MEMS VCSEL laser technology enables mode-hop-free tuning which in turn allows coherence lengths of much more than 10 cm. Furthermore, state-of-the-art signal detection and acquisition systems for SS-OCT can acquire signals at GHz sampling rates. Both of these features improve the performance of new SS-OCT instruments, enabling imaging far beyond previous depth ranges [73, 111, 112].

10.4.3 Methods for Depth Range Extension

Early optical methods for measuring depth profiles of samples were based mainly on interferometric reflectometry [113, 114]. Early long image range OCT systems used time-domain detection and were driven by anatomical OCT applications which required reconstructing the internal anatomy of large hollow organs [115, 116]. With the development of Fourier-domain OCT technology, multiple approaches for extending imaging range were investigated. A twofold increase of available imaging range can be obtained using complex conjugate removal techniques. However, these full-range techniques require varying the reference arm

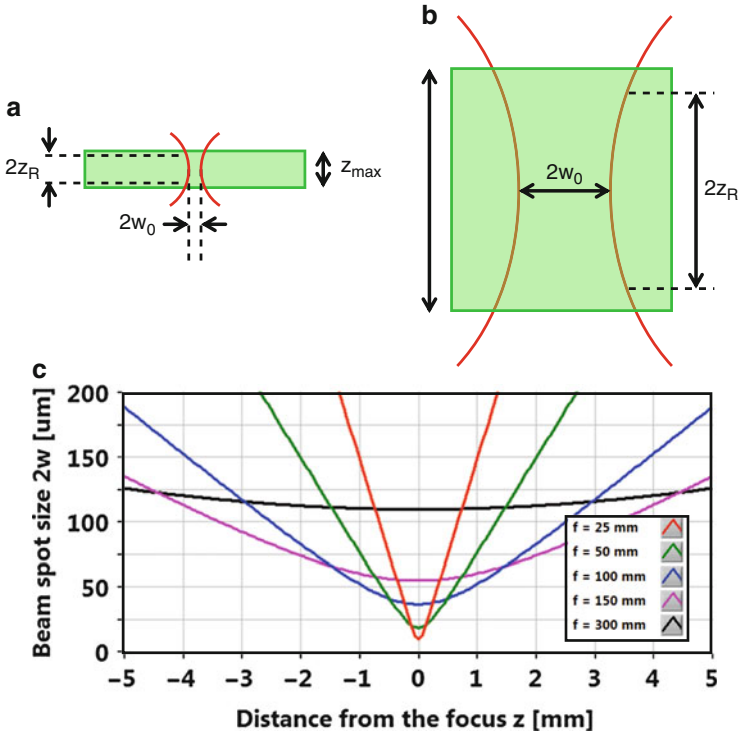

Fig. 10.13 Relationship between the imaging lens numerical aperture and depth range: (**a**) standard OCT system, (**b**) long-range OCT requires longer depth of focus, (**c**) lateral resolution is sacrificed if longer depth of focus is required

length by phase modulation, frequency shifting (acousto-optic modulation), numerical approaches, interpixel shifting, Talbot band effects, or recirculation loops [117–119]. Other approaches use two or more reference arms with a well-defined offset, or optical switches, which enable simultaneous measurement of different imaging ranges within an object when a single imaging range is insufficient to accommodate the entire depth [120–122]. Similar concepts have been demonstrated with polarization-encoded, dual depth range SS-OCT [75].

10.4.4 Full Eye Length OCT Imaging and OCT-Based Ocular Biometry

Measurements of intraocular distances, known as ocular biometry, are essential for accurate outcomes in cataract and keratorefractive surgeries. Precisely measured axial intraocular distances are important for proper intraocular lens (IOL) power calculation [123]. Early studies in the late 1950s and early 1960s used ultrasound for measuring intraocular distances [124]. Currently, ocular biometry with

ultrasound is a gold standard in ophthalmology. Ultrasound devices can perform axial length measurements with a resolution of ~200 μm. However, ultrasound techniques require contact of the eye by a transducer in order to measure axial distance. Early optical methods based on interferometry utilized short pulse light sources [113]. Full eye length measurement using partial coherence interferometry and related methods was demonstrated by multiple groups [2, 125–129]. The most important advantages of optical biometry are that it is noncontact and has higher resolution (10–20 μm) compared with ultrasound. Investigation and validation studies resulted in the introduction of commercial optical devices based on low coherence time-domain interferometry including the IOL Master (Zeiss) and LensStar (Haag-Streit) [130–132]. Other modalities used clinically for postoperative axial eye length measurements include MRI and x-ray tomography, although these have limited resolution and are not clinical standards [133, 134].

The initial reports showing the ability to generate cross-sectional images of the entire eye were confined to small animal studies. Whole mouse eye imaging by TD-OCT at 1,300 nm wavelength and pig and rodent eye imaging with SS-OCT at 1,050 nm wavelength were reported [112, 135, 136]. Fourier-domain reflectometry with two reference arms (well-defined offset) for eye length measurement was also reported [117, 137]. Recently, multiple imaging range OCT systems for simultaneous anterior segment and retinal imaging as well as for full eye length imaging have been demonstrated [74, 121, 138].

OCT full human eye length imaging requires an axial measurement range of at least ~40 mm in air, accounting for refractive indexes of ocular components and patient eye length variations. Full eye length imaging can be achieved using SS-OCT with VCSEL light source technology. The VCSEL light source can be adjusted to optimize the imaging range, while trading off the sweep range and imaging speed. Figure 10.14 shows a 3-D rendering of a volumetric OCT data set obtained at an acquisition rate of 50 kHz with an axial resolution of 23 μm in tissue. Ocular structures such as the cornea, crystalline lens, iris, and retina are displayed with different colors. Telecentric scanning of the cornea was used; therefore, with the refraction of the eye, it means that the spot position on the retina is not scanned. The retinal image converges to a single point after correction for OCT beam refraction (Fig. 10.14b, c).

Apart from imaging from the anterior eye to posterior pole, full eye length imaging is extremely useful in ocular biometry, i.e., in quantitative measurements of intraocular distances. This can be performed by constructing an averaged depth profile of the eye from the central area of the pupil which enables reflections from ocular interfaces to be identified and intraocular distances measured [139, 140]. OCT-based biometry was validated and compared with a clinical ocular optical biometer (IOL Master, Carl Zeiss Meditec) and an immersion A-scan ultrasound biometer (Axis II PR, Quantel Medical) with excellent reproducibility and repeatability. Table 10.1 shows the precision of intraocular distance measurements, and Fig. 10.15 shows the correlation of axial eye length measurements with SS-OCT,

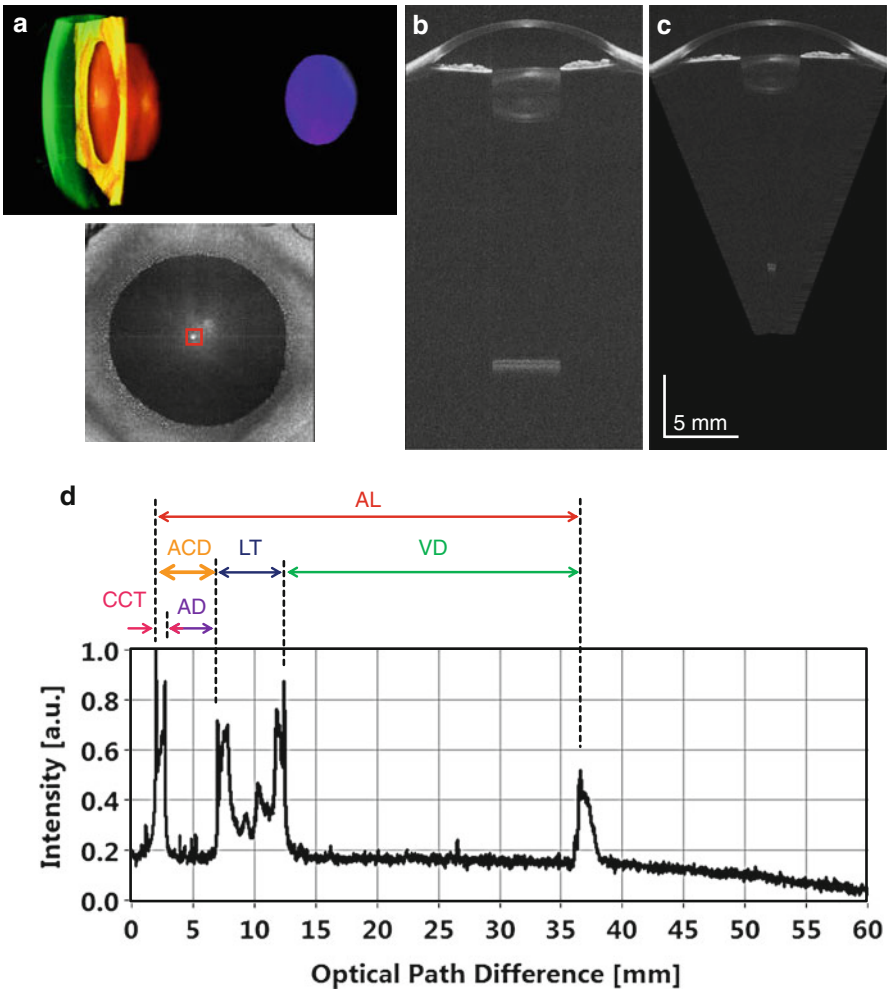

Fig. 10.14 Full eye length SS-OCT imaging using a VCSEL light source. (**a**) 3-D rendering of volumetric OCT data and the en face OCT image. (**b**) Central cross section before refraction correction. (**c**) Central cross section after refraction correction. (**d**) Averaged axial scan (depth profile) generated from the center region of the pupil enables the identification of light reflections from intraocular surfaces and measurement of intraocular distances: *CCT* central corneal thickness, *ACD* anterior chamber depth, *AD* aqueous depth, *LT* lens thickness, *VD* vitreous depth, *AL* axial eye length (From Ref. [139])

the IOL Master, and immersion ultrasound. SS-OCT can provide comprehensive biometric information needed for intraocular lens (IOL) power calculation, is noninvasive and noncontact, and promises to be useful in patients with lens opacities.

Table 10.1 Precision of the measurement of intraocular distances with long-range SS-OCT (From Ref. [139])

Parameter	Mean (mm)	Standard deviation (mm)	Coefficient of variation (%)
Central corneal thickness (CCT)	0.519	0.006	1.08
Anterior chamber depth (ACD)	3.743	0.016	0.43
Aqueous depth (AD)	3.225	0.014	0.42
Lens thickness (LT)	3.810	0.013	0.34
Vitreous depth (VD)	18.304	0.014	0.08
Axial length (AL)	25.857	0.016	0.06

10.4.5 Non-biomedical Applications of Long-Depth Range and Ultralong-Depth Range OCT

10.4.5.1 Optical Profilometry, Metrology, and Testing

SS-OCT can be used to image surface topography as well as the internal structure of turbid objects such as plastic polymers, material coatings, and circuit components to verify manufacturing processes and to assess possible flaws [141–143]. Figure 10.16a shows 3-D OCT data obtained from a printed circuit board that shows both the layout and cross sections of circuit components. Information on internal structures in multilayer boards can be obtained nondestructively. Figure 10.16b shows a commercial MEMS mirror device imaged with SS-OCT at 1,050 nm wavelength which is transmitted through silicon. The support structure on the bottom of the scanning mirror can be seen by displaying signals from behind the

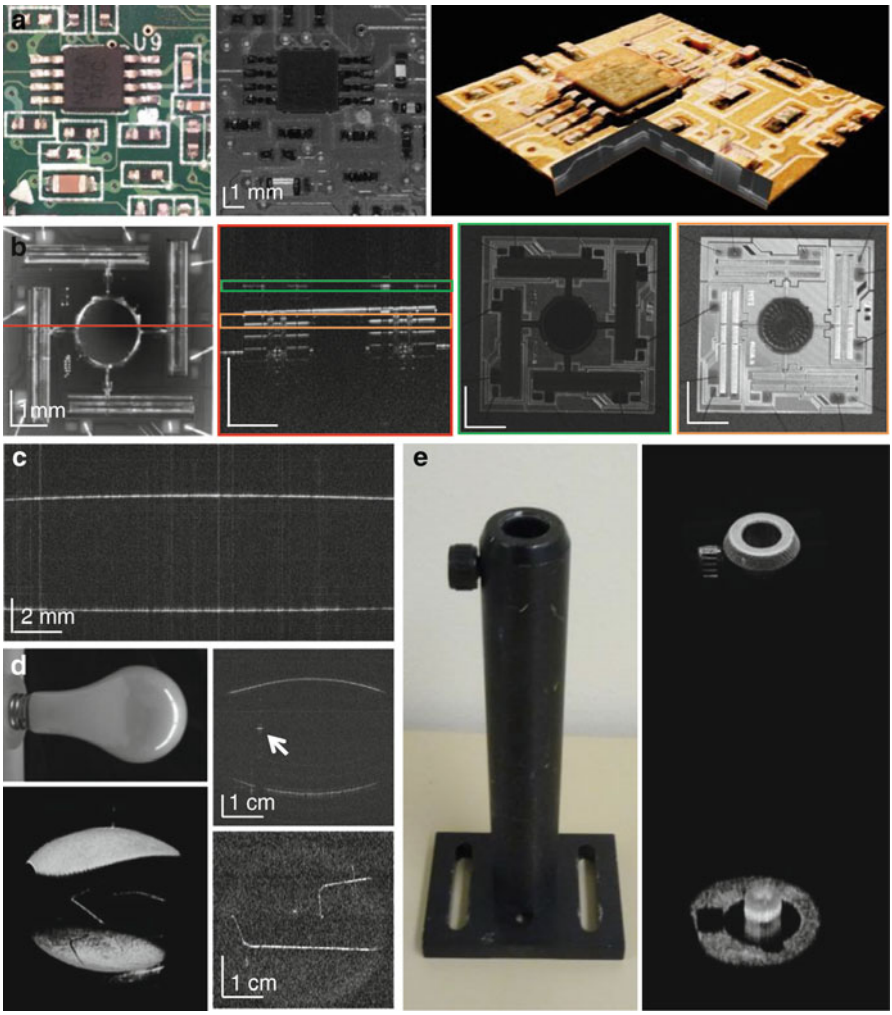

Fig. 10.16 Material applications of long-range SS-OCT imaging. (**a**) OCT profilometry of a circuit board. (**b**) Imaging of an MEMS mirror. (**c**) Imaging of a singlet lens for extracting data on the radii of curvature and thickness. (**d**) Long-range imaging in a light bulb as an example of an opaque material. Both surfaces of the bulb can be visualized along with the filament. (**e**) Ultralong range imaging of the 6 in. tall optomechanical component (Figures (**a**, (**b**) courtesy of Chen D. Lu, Massachusetts Institute of Technology. Figures (**c**, **d**, **e**) from Ref. [140])

mirror surface. In these two examples, SS-OCT was performed using an MEMS Fabry-Perot tunable short cavity laser. The high imaging speeds enable multiple scanned volumes to be obtained versus time to perform four-dimensional (4-D) imaging for MEMS mirror vibration analysis.

Optical component evaluation plays an essential role in optical fabrication since the measurement accuracy of the optics directly limits the fabrication accuracy. Optical testing entails the measurement of geometry, such as surface curvature, surface homogeneity, and surface roughness [144, 145]. The advantage of long-range OCT is that it can distinguish and measure multiple surface layers simultaneously with micrometer resolution, without requiring a reference test plate. Therefore, OCT has the unique capability to provide information on not only surface profiles but also multiple surface curvatures and refractive indices. As an example, the optical properties of a lens were characterized using long-range OCT measurement of the front and back surfaces. Figure 10.16c demonstrates visualization of a thick singlet lens where the top and bottom surfaces of the lens are clearly visualized with an imaging range of 26 mm. The axial resolution was 25 μm in air and imaging was performed at 1,050 nm wavelength. The radius of curvature and central thickness were measured based on OCT images and compared with manufacturer specifications.

Long-range OCT enables nondestructive evaluation and inspection of nontransparent objects. Figure 10.16d shows an example of imaging inside a frosted white light bulb. SS-OCT was performed at 25 kHz axial scan rate with an axial resolution of 30 μm and a record depth range of 15.5 cm in air. 3-D volumetric images showing wires leading to the filament in the light bulb were obtained through the optically scattering light bulb glass. Long depth range can be also used for 3-D visualization of large objects. A 300 mm focal length objective lens was used to provide a long depth of focus and SS-OCT was performed at 25 kHz axial scan rate. Figure 10.16e shows renderings of volumetric OCT data sets (250×250 axial scans). Ultralong imaging depth range enabled visualization of a 6-in. tall optomechanical element from its top to base. This example geometry was chosen because it is difficult to perform precise measurements of high-aspect ratio objects, such as bore holes, using other measurement methods.

10.4.5.2 Reflectometry

Optical reflectometry enables measurement of optical reflections versus delay or distance, equivalent to an axial scan, and can be regarded as the precursor of OCT. There are multiple approaches to optical reflectometry [146]. In the classic optical reflectometer, distance information is obtained using time delay measurement, but these methods were typically applied to long distances of the order of several kilometers and with meter resolution. In optical coherence domain reflectometry (OCDR), a low coherence interferometer with a scanning reference arm path length is used, and in optical Fourier-domain reflectometry (OFDR), wavelength swept light sources are used [147]. An attractive feature of OFDR is that the measurement can be performed without scanning the reference arm path delay. Other reflectometry techniques use light intensity modulation with vector signal analysis or mixing the detected signal with RF frequency-swept waveform modulating the laser output [148, 149]. Very long-range depth measurements are possible with limited resolution. The applications of optical reflectometry include metrology, optical component evaluation, nondestructive fiber inspection

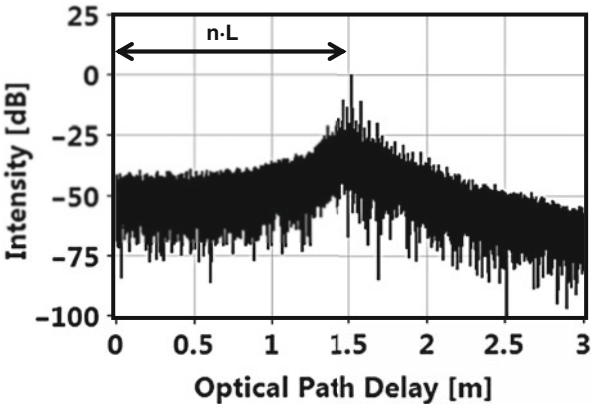

Fig. 10.17 Optical reflectometry using SS-OCT with the VCSEL light source. The example demonstrates the measurement of a length of optical fiber length and represents a record range for SS-OCT (From Ref. [140])

(e.g., differential group delay, distributed birefringence, strain, distributed gain in optical fiber amplifiers), and remote spectroscopic sensing of environmental conditions and industrial processes [114, 148–153].

VCSEL-based SS-OCT can also be used for optical reflectometry. This example shows precision measurement of a length of optical fiber. The VCSEL operated at the sweep rate of 20 kHz with an axial resolution of 70 μm, and the interference signal was recorded using a 1 GHz bandwidth oscilloscope. Figure 10.17 shows the light reflection profile versus depth. In order to obtain the geometric length of the fiber, the optical path measurement must be corrected for the refractive index of fiber ($n = 1.4696$). There was excellent correlation between the measurements using the reflectometer and physical fiber length [140].

10.5 Summary and Perspectives

Modern SS-OCT systems using state-of-the-art swept laser technologies provide powerful platforms for both high-speed and long-range OCT imaging. MEMS VCSEL light sources have the advantage that laser operating parameters can be adjusted to enable imaging with different imaging speeds, resolutions, and ranges, optimizing performance within detector and A/D bandwidth limits. High imaging speeds enable rapid acquisition times as well as wider field of view and are especially important for applications which involve en face OCT imaging. High speeds are also important for functional imaging techniques such as Doppler flow or OCT angiography which use repeated scan protocols. High speed also enables 4-D imaging of dynamical processes where 3-D volumetric data is acquired as a function of time. Long imaging range trades off against high speed or high resolution. The MEMS VCSEL provides unprecedented imaging ranges due to its long coherence length. These extended imaging ranges promise to enable a wide range of new applications in nondestructive evaluation, industrial imaging, and process control. In biomedical applications, long imaging ranges have immediate applications in ophthalmology for biometry of the anterior eye and full eye length

imaging as well as diverse applications ranging from anatomic OCT and surgical guidance. These exciting developments suggest that SS-OCT may become the dominant implementation of OCT in the future.

Optical Design for OCT

11

Zhilin Hu and Andrew M. Rollins

This chapter aims to provide insights and tools to design high-quality optical subsystems for OCT. First, we discuss the various optical subsystems common to OCT and relevant optical design criteria. Second, we review several fundamental optical design principles important for OCT designs. Finally, we discuss a number of examples of designed optical systems for OCT.

To simplify the discussion, the following schematics of OCT in the time domain and spectral domain (or frequency or Fourier domain) are shown below in Fig. 11.1. The major subsystems are labeled by Roman numerals. Illumination sources and sample scanners are labeled by I and II, respectively, in both schematics in Fig. 11.1. Numeral III refers to a scanning optical delay line (ODL), while numeral IV refers to a fixed-path length ODL. Numeral V refers to a single-point detector, and numeral VI refers to an array-based spectrometer (for spectrometer-based frequency-domain OCT). This notation will refer to these subsystems throughout the chapter.

11.1 Optical Design Considerations for OCT

11.1.1 Unique Optical Design Needs for OCT

OCT presents unique design needs different than, for example, microscopy or photography or laser scanning. Therefore, custom optical subsystems are typically designed especially for OCT and often for a specific application. For example, OCT sample scanning optics (II) are typically confocal systems that scan 0.05–0.1 NA beams over a range of several millimeters. Time-domain OCT (TD-OCT) systems typically use fast-scanning, reflective ODLs (III). In spectrometer-based frequency

domain OCT (FD-OCT) (or spectral domain OCT, SDOCT) systems, the interfering spectra are collected by a linear array spectrometer (VI). The following six design considerations will be discussed:

1. Clear sample spot profile
2. Uniform chromatic coupling and high coupling efficiency
3. Spectral response
4. Depth of focus versus lateral resolution (numerical aperture)
5. Frequency resolution
6. Spectrometer spot size and falloff

Where items 1–3 are critical for the optical delay line design (III or IV), 1–4 are important for scanner optics (II), and 1–3 and 5–6 are key for the spectrometer designs (VI). The next three subsections *b*, *c*, and *d* will discuss these items in more detail. As a general principle, telecentric and achromatic optics will be used in the system designs to help achieve the design goals.

11.1.2 Sample Scanners

11.1.2.1 Clear Spot Profile

To achieve a high-resolution, high-contrast OCT image, a clean probe beam spot profile is necessary. Ideally, the clean spot profile will be maintained over the entire range of the scan, not merely on the optical axis. OCT makes two-dimensional or three-dimensional images by using spot scanning optics. The spot profile of the paraxial beam is usually closer to Gaussian than the skew beams or the beam significantly off the optical axis because of spherical and chromatic aberrations of the optical components. Sometimes, commercially available lenses with a small aperture are used to build scanners with a large lateral scanning range that degrades the spot profile toward the edge the lenses due to significant spherical and chromatic aberrations.

The use of certain lens types and design principles can be used to reduce design time, construction difficulties, and alignment issues. To minimize difficult design considerations, achromatic and aspheric lenses and a telecentric configuration are suggested in the sample arm scanner (II) design. Design software such as Zemax is usually a suitable tool for optimizing the spot profiles over the entire scanning range, while a beam analyzer is useful for measuring the real spot profile to optimize the assembled design [1]. The use of these tools will help to ensure a minimum amount of work and maximum results when designing OCT optical systems.

11.1.2.2 Uniform and High Coupling Efficiency

Coupling efficiency refers to any point where the light enters and or exits the OCT system. The efficiency refers to both the amount of power lost during transitions from, for example, air to fiber or fiber to air and the chromatic efficiency of the transitions. Proper consideration of these parameters will ensure that optimal use of the light source occurs, and maximum axial resolution is maintained throughout the length of the scan.

The sample scanner of an OCT system typically delivers the light to the sample and collects the scattered light back from the sample through the same optics, as shown in Fig. 11.1. The higher the coupling efficiency, the lower the source power that is needed to achieve the same image quality. Besides the neutral attenuation due to optical surfaces, both the spherical and the chromatic aberrations of the lenses affect the coupling efficiency. In most scanner designs, the light is delivered by an optical fiber to the scanner (II). The wavefront of the back-reflected (scattered) beam is changed because of spherical and chromatic aberrations. These changes result in both misalignment and mode mismatch between the fiber and the back-reflected beam, which lead to some loss of the coupling efficiency. Coupling efficiency may also vary as a function of the lateral scan position.

A telecentric optical configuration can minimize misalignment, while achromatic and aspheric lenses can minimize spherical and chromatic aberrations. Optical design software can help the designer create an optimum arrangement of the components to build a scanner with a uniform and high coupling efficiency.

11.1.2.3 Spectral Response

The spectral response of an OCT subsystem affects the axial resolution of the images, the system's sensitivity to dispersion, and the degree to which optical corrections have to be made. Appropriate design, taking into account the spectral response, can ensure that image quality remains high even in conditions such as imaging through large volumes of water. Designing for an appropriate spectral response profile will result in optimal use of the bandwidth of the light source and the highest quality images.

The variation of the coupling efficiency as a function of wavelengths filters the spectrum of the light. The center wavelength, bandwidth, and amplitude are all altered by the optics and the sample between the light source and the detector. These variations may not be identical in the sample arm scanner (II) and the optical

delay line (III or IV). In general, this filter function generated by the nonconstant spectral response of the optics affects the signal amplitude and the axial resolution of the OCT image [2]. Since the coupling efficiency may be different at different transversal positions, the spectral response will be different as well.

11.1.2.4 Depth of Focus Versus Resolution

To obtain high lateral resolution and large depth of focus are always the goals in an OCT scanner design. Unfortunately, the depth of focus and the lateral resolution vary inversely so that increasing the depth of focus typically worsens the lateral resolution. An optical designer must consider the tradeoff between the two parameters. The intended application must be carefully considered when designing these parameters.

Assuming the OCT beam is Gaussian, the depth of focus is defined as twice the Rayleigh range [3]:

$$2z_0 = \frac{2\pi W_0^2}{\lambda}, \tag{11.1}$$

where W_0 and λ are the radius of the beam waist at focus and the wavelength, respectively. The Rayleigh range z_0 is measured from the waist to the spot size $\sqrt{2}$ times of the waist. For instance, if the wavelength is $\lambda = 1.3$ μm and the radius of waist is $W_0 = 5$ μm, the depth of focus will be 121 μm. The dependence of the beam radius on z is expressed as

$$\begin{aligned} W(z) &= \left[W_0^2 + \left(\frac{\lambda}{\pi W_0} z \right)^2 \right]^{1/2} \\ &= \left[\left(\frac{\lambda}{\pi \theta_0} \right)^2 + (z\theta_0)^2 \right]^{1/2}, \end{aligned} \tag{11.2}$$

where the beam divergence $\theta_0 = W_0/z_0$ and the distance variable z is measured from the point of the waist. The value of $\sin(\theta_0)$ is defined as the numerical aperture (NA). Equation 11.2 indicates that the spot size is smaller for a higher numerical aperture and that the higher the lateral resolution, the shorter the depth of focus.

11.1.3 Scanning Optical Delay Lines

11.1.3.1 Uniform Coupling Efficiency

In OCT, the function of the optical delay line (ODL) (III or IV) is to produce the optical path or the phase match with the sample arm (II). Numerous scanning ODL designs have been demonstrated [4]. Although only a small amount of reference light is needed, the coupling efficiency can affect system sensitivity. More importantly, the reference ODL should have a uniform coupling efficiency. The coupling pattern of the rapid scanning optical delay line (RSOD) is described in Sect. 11.3.

11.1.3.2 Spectral Response

The spectral response requirement in the reference arm or the optical delay line is of the same importance as discussed previously for the sample arm scanner design. Although the optics of the optical delay line are usually simpler than that of the sample scanner, they still normally create a nonuniform coupling efficiency over the spectrum. This creates a curved spectral response filter that operates on the spectrum of the light source. This spectral response is normally different from the spectral filter of the scanner, which results in a degradation of the amplitude and the axial resolution of OCT signal [2].

11.1.4 Spectrometers

11.1.4.1 Resolution

In spectrometer-based frequency domain OCT, three parameters primarily influence the quality of the spectrometer and hence the OCT image quality: the frequency resolution, spectral response, and spot size of the beam. These determine the falloff characteristic and the axial resolution of the image.

A spectrometer based on a linear detector array samples the spectrum illuminating the array, resulting in a discrete signal. The frequency interval of the pixels in the dispersive direction of the spectrum (i.e., the distance between each pixel) determines the un-aliased imaging range of FD-OCT according to the sampling theorem. The higher the frequency resolution, the longer the image range of the FD-OCT. Because the pixel number of the detector array is finite, the tradeoff between the imaging range and the axial resolution (spectrum bandwidth) should be considered in the spectrometer design.

11.1.4.2 Spectral Response

The spectral response of the spectrometer is important in the same way as discussed previously for both scanner and delay line designs. Besides going through the reference and sample arms, the light travels through the optics of the spectrometer before it is collected by the detector array. A nonuniform spectral response filters the interfering spectra, which changes the axial resolution and the contrast of the OCT image.

One of the design goals is to minimize the difference between the coherence spectra and the spectrum of the light source in order to achieve an optimum image quality. The design example of a spectrometer in Sect. 11.5.1 presents an example of a case where there is a trade-off between the flatness of the spectral response and the throughput of the spectrometer.

11.1.4.3 Spot Size and Falloff

The penetration depth of spectrometer-based FD-OCT is also limited by the signal falloff due to the interference fringe washout due to the window in frequency space. In other words, the falloff is mostly determined by the spot size of a single wavelength component of the beam illuminating the array and the pixel width of

the detector in the spectral dispersion direction [5] such that the smaller the spot size or the pixel size, the better the falloff.

11.2 Some Key Optical Design Principles for OCT

11.2.1 Telecentric Optics

Telecentric optical systems are characterized by a flat imaging plane and are important to the design of OCT systems because they increase coupling efficiency. The flat imaging plane decreases the amount of post-image processing needed to display geometrically correct images and increases the coupling efficiency because the back-reflected light returns close to the same incident path.

The definition of a telecentric optical system is a system in which all of the chief rays on the image side are parallel to the local optical axis and perpendicular to the planar image plane. Telecentric optics generally reduce image artifacts caused by off-axis optical aberrations. This leads to several advantages for an OCT scanner, including constant magnification, constant spot size both on- and off-axis, and a flat imaging plane. Figure 11.2 shows the ray trace of three examples of approximately telecentric lens systems (modeled by Zemax) in which the stop is located at the front focus. Three collimated incident beams at different angles pass through the optical system and are focused on the almost-flat image plane at the back focus. All of the chief rays on the image side are parallel to the optical axis. This feature results in a maximum reflection or scattering from the sample at and around the focus and back through the same optics.

In Fig. 11.2(a1–a3), the foci of off-axis beams were closer to the lens than the paraxial focus by 0.36 mm, 3.15 mm, and 0.012 mm, respectively, for the three simulated configurations. Figure 11.2(a1) is sometimes the most economical configuration since a singlet is much cheaper than a second achromatic doublet (a3), yet the performance is much superior to a doublet alone (a2). For a telecentric design, the scanning mirrors of an OCT scanner (or their image) should be placed at the front focus of the optics, which results in a more consistent image quality over a wide lateral scanning range. It should be noted that telecentric optics do not necessarily require an achromatic doublet, but the achromatic doublet generally provides good performance.

11.2.2 Aspheric Optics

The use of aspheric optics in an OCT system provides several distinct advantages. First, it reduces the effects of spherical aberrations in the system. Second, because of this reduction, imaging spot profiles are more clean. Third, a clean spot profile results in an increased coupling efficiency.

The curvature of an aspheric surface varies with the height of the incident ray [6]. Aspheric surfaces are usually used to collimate a beam with a large

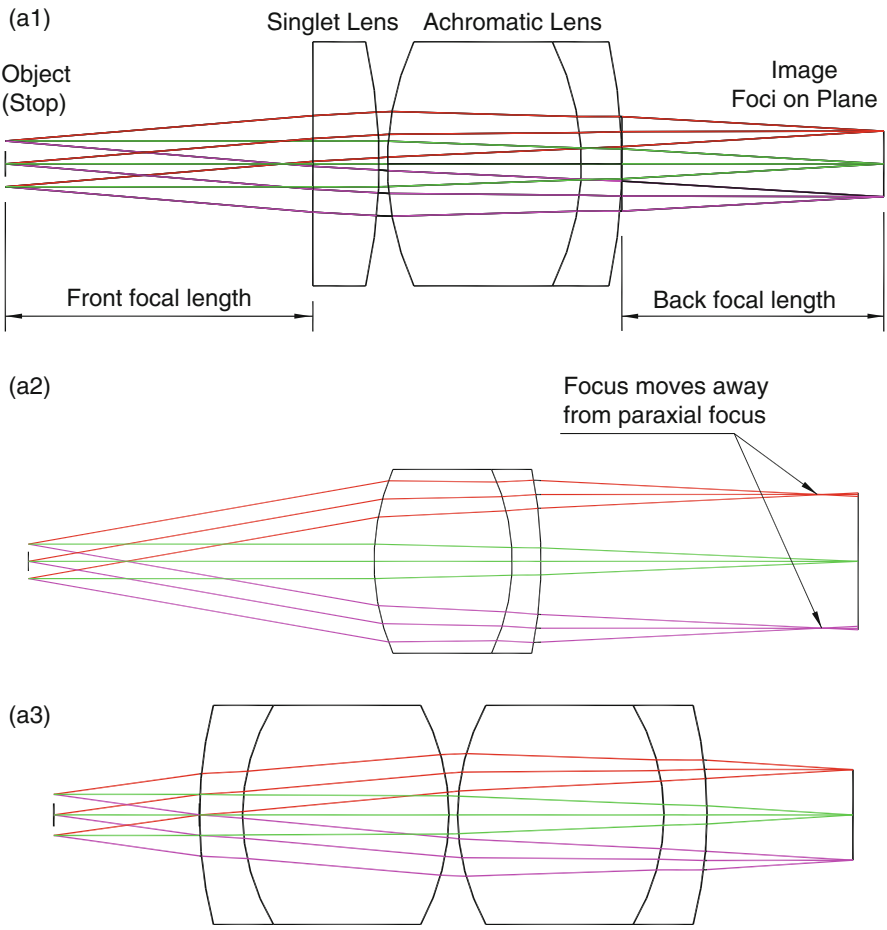

Fig. 11.2 Telecentric setup by Zemax

numerical aperture. Spherical aberration is defined as the variation of the focus with the aperture, which is because a spherical surface is only an approximation of an ideal focusing surface. Figure 11.3(b1) is a somewhat exaggerated sketch of a simple lens forming an "image" of an axial object point a great distance away. The ray close to the optical axis comes to a focus (intersects the axis) very near the paraxial focus position. The higher the ray height at the lens, the farther the position of the ray intersection with the optical axis moves from the paraxial focus. The distance between the paraxial focus and the axial intersection of the ray is also called the longitudinal spherical aberration.

The spherical aberration can be improved by correctly orienting the lens. For instance, the aberration of the optics in Fig. 11.3(b1) was improved by just flipping this lens to Fig. 11.3(b2). It is always a preferred setup that the more curved surface

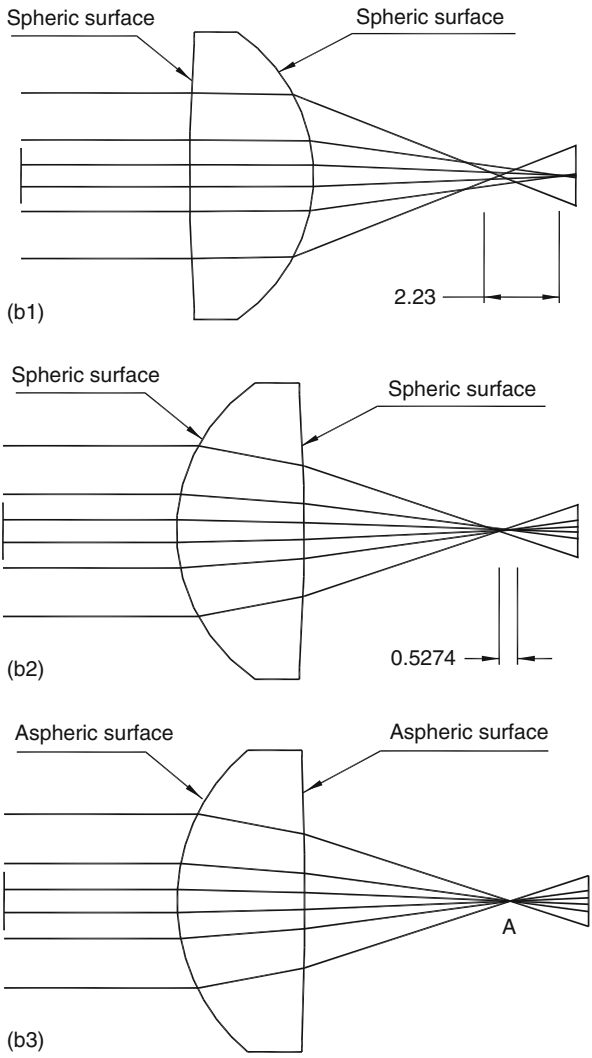

Fig. 11.3 A simple converging lens with under-corrected spherical aberration. (**b1**) The rays farther from the axis are brought to a focus nearer the lens; (**b2**) a correctly oriented spherical lens; (**b3**) an aspheric collimator

faces the collimated beam and the less curved surface faces the focused beam. In order to achieve high-order removal of the spherical aberration, an aspheric lens should be used as shown in Fig. 11.3(b3).

11.2.3 Achromatic Optics

The use of achromatic optics in an OCT system has several advantages. They preserve axial resolution, reduce the dispersion effects of the optical system, improve coupling efficiency, and produce a clean spot profile. For these reasons,

it is advantageous to use achromatic optics when designing an OCT system. Again, achromatic optics are more expensive, but the result is typically worthwhile.

Chromatic aberration is the longitudinal variation of focus (or image position) with wavelength. The refractive index of the glass varies as a function of the wavelength of light, which results in the focal length of the lens varying as a function of the wavelength. For most optical materials, the longer the wavelength, the lower the refractive index. This index feature of the material causes the short wavelengths to be more strongly refracted than the long wavelengths at the surface. For example, the blue light rays (shorter wavelengths) going through a simple positive lens are brought to a focus closer to the lens than the red rays (longer wavelengths) as shown in Fig. 11.4(c1) (detailed later). The distance along the axis between the two focus points is the longitudinal axial chromatic aberration [7].

To clearly demonstrate chromatic aberration, we virtually "dissected" an achromatic doublet lens (Edmund Optics 45805), shown in Fig. 11.4. The lens materials are, respectively, LAKN22 (index: 1.6536@550 nm; 1.6333@1,350 nm) for the AB layer and SFL6 (index: 1.8118@550 nm; 1.7665@1,350 nm) for the BC layer. The radii of curvature of surfaces A, B, and C are, respectively, 43.96 mm, −43.96 mm, and −321.46 mm. The center thicknesses are 6 mm for AB and 4 mm for BC. After the removal of the BC layer, Fig. 11.2c1 shows the significant chromatic aberration of a simple positive element. In Fig. 11.4(c1), the short (550 nm) and long (1,350 nm) wavelength rays incident at point A on the first surface of the lens were separated by the dispersion of the glass shown in the zoom-in window at point B of the second surface. The zoom-in window at focus F indicates an aberration of 1.12 mm for a beam with height of 12 mm and that the focal length of the long wavelength is longer than that of the short wavelength.

Compared to the first piece AB, the second piece BC is made of a glass with different dispersion and polished to lower power (curvature). Figure 11.4(c2) shows that an achromatic doublet lens is made by bonding pieces AB and BC together using an index matching epoxy. Observe that the positions of long and short wavelengths are swapped during propagation from surface B to C, and the longitudinal aberration at the focus is reduced to 0.005 mm from 1.12 mm for the wavelengths of 550 nm and 1,350 nm.

OCT optics must support broad optical bandwidths in order to achieve high-quality, high-resolution imaging.

11.3 Scanning ODL Design Example

All OCT systems require an optical delay line (ODL) to provide a reference field to interfere with the sample field. A FD-OCT system uses a fixed-path ODL, but a TD-OCT system requires a high-speed scanning ODL for real-time imaging. The most commonly used ODL for real-time TD-OCT in the Fourier-domain rapid-scanning ODL (RSOD) [8–11].

In this section, we will review the optical design and the performance analysis of the RSOD and demonstrate how to address the design requirements 2–3 in Sect. 11.1.1

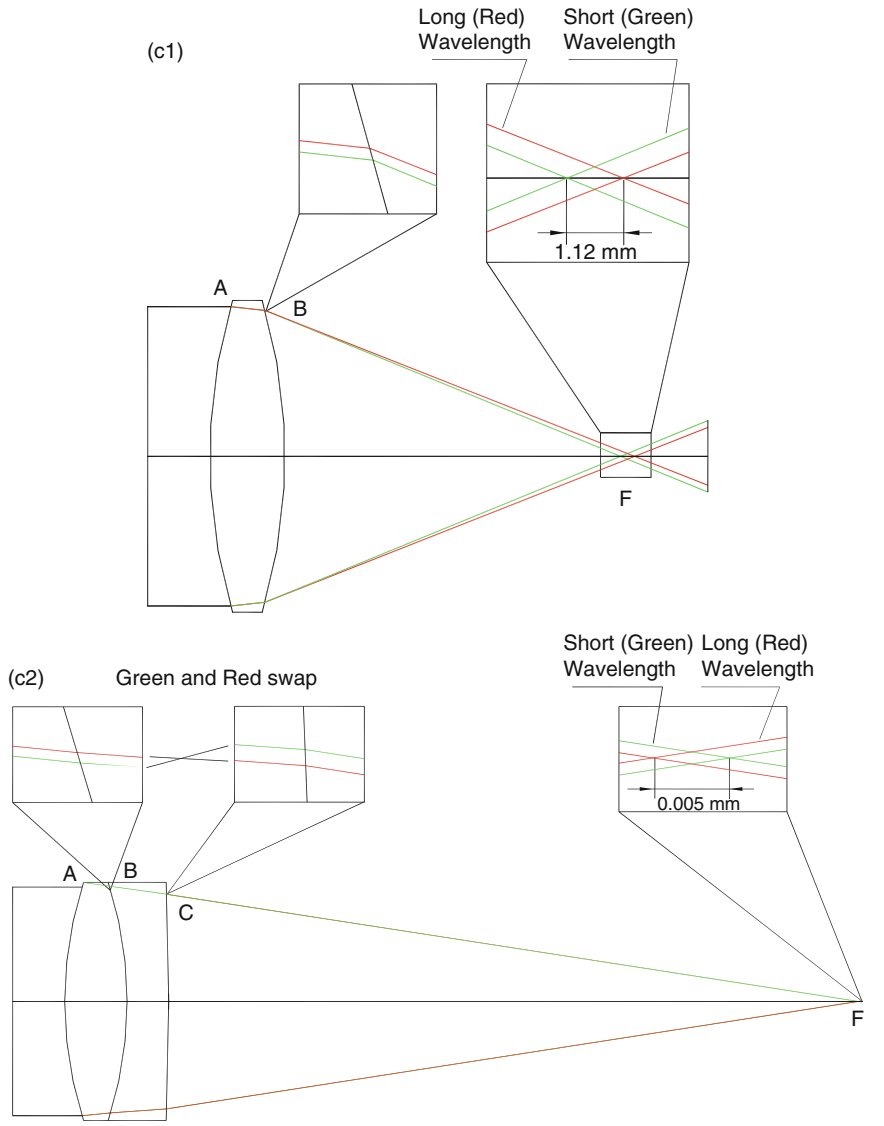

Fig. 11.4 Schematic diagram of chromatic aberration and correction by use of an achromatic doublet. The lens is simulated by Zemax. (**c1**) is a simple double convex positive lens and part of the doublet of (**c2**). (**c2**) is the achromatic doublet lens. *Green* and *red* represent the short and long wavelengths, respectively

and the use of telecentric and achromatic optics in Sects. 11.2.1 and 11.2.3. The coupling efficiency and the spectral response will be addressed by simulations using a Zemax model of a previously reported RSOD design [11]. Figure 11.5b1 shows a schematic drawing of the RSOD [11], while the Figs. 11.5b2, b3 are

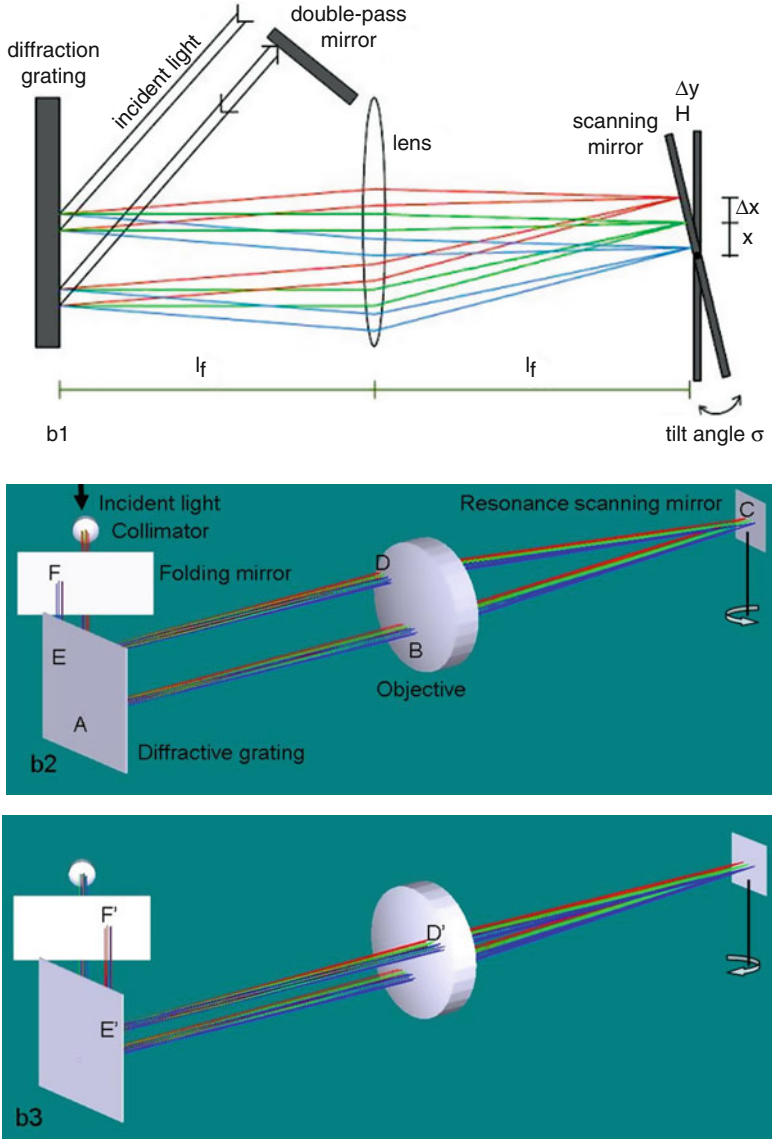

Fig. 11.5 Schematic of the Fourier domain optical delay line. (**b1**) The top view from ref. [11]. (**b2**, **b3**) Zemax modeling at two different scanning angles. Round trip by going through the fiber – collimator – A – B – C – D (D′) – E (E′) – F (F′) – E (E′) – D (D′) – C – B – A – collimator – fiber. The incident and output rays at the lower parts of the grating and the objective in b2 and b3. The folded part of the travel are scanning in horizontal lines from D to D′, E to E′, and F to F′ on the upper part of the objective, grating, and folding mirror, respectively

the Zemax models at two different scanning angles showing the ray propagation step by step on which we will discuss the design procedure.

Figures 11.5b2 and b3 show that the collimated broadband light is dispersed by a diffraction grating at point A. The dispersed beam passes through the lower part of the objective at point B before it is focused onto a resonant scanning mirror at point C (an alternative design is a galvanometric scanning mirror). The objective collimates the spectrum and images or focuses every wavelength onto the scanning mirror. The resonant scanning mirror vibrates on a vertical axis reflecting the dispersed beam back to the upper part of the objective from D to D′. Then, the objective collimates each single wavelength and reconverges the spectrum to point E (through E′ when the resonant mirror scans) on the diffraction grating which recombines the dispersed spectrum into a single collimated beam and directs the collimated beam toward the folding mirror at point F (through F′ when the resonant mirror scans). To the folding mirror, one-half of the round trip is completed. The next propagation is identical to the first series but opposite in order. In summary, the ray finishes a round trip by going through the following steps: the fiber – collimator – A – B – C – D (D′) – E (E′) – F (F′) – E (E′) – D (D′) – C – B – A – collimator – fiber.

The group delay (in the units of distance) resulting from the tilting of the resonant scanning mirror can be expressed as

$$\Delta l_g = 4\sigma\left(x - \frac{l_f \lambda}{p}\right), \tag{11.3}$$

where x is the offset distance between the mirror pivot and the center wavelength, σ is the tilting angle in radians of the resonance mirror, l_f is the effective focal length (not the back focal length) of the objective, λ is the center wavelength of the light source, and p is the pitch of the diffractive grating [11]. The design goal is to achieve a large scanning range and fast scanning speed without significantly distorting the spectrum. The first step is to determine the required axial scanning range. For this design example, we select the axial scanning range to be about 4 mm, which is reasonable considering that the penetration depth of 1310 nm OCT is no more than 3 mm for most biological tissue. The second step is to begin selecting components based on design equations and commercial availability. For example, for this design, we choose a commercially available 2 kHz resonant scanner, a 600 lines/mm (pitch = 1.667 μm) diffraction grating optimized for 1,310 nm light, and a 77 mm focal-length achromatic doublet for the objective lens. The design also assumes a usable duty cycle of $\eta = 0.86$ because the resonant scanner motion is a sinusoidal function of time, so the ends of the scan will not be used.

With the assumed duty cycle, the group delay $\Delta l_g = 4$ mm can be calculated by substituting the above parameters and the titling angle $\sigma = \pm 0.5°$ into Eq. 11.3. A telecentric configuration shown in Fig. 11.5b1 is advantageous because this objective lens is used to collimate the spectrum and focus the beam on the scanning mirror (although for purposes of dispersion compensation, the grating-lens distance

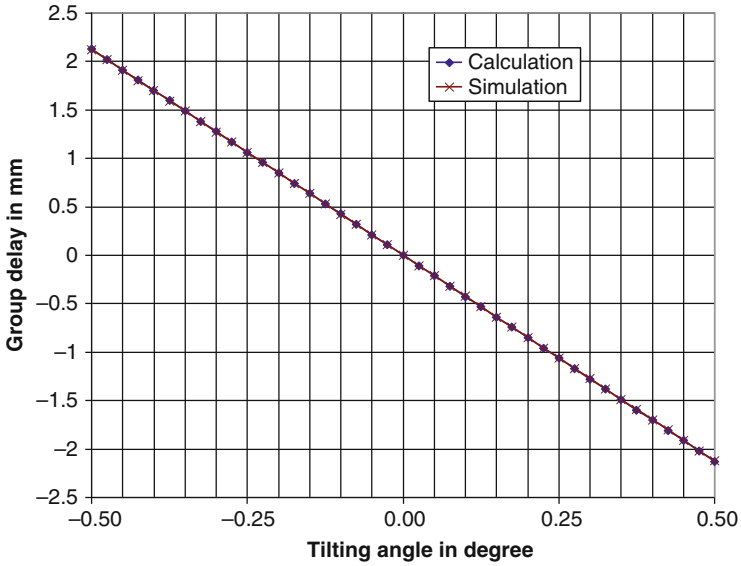

Fig. 11.6 Group delay as a function of the angle of the tilting mirror. Cross is simulated by Zemax simulation and diamond is calculated by Eq. 11.3

is often adjusted after the delay line is aligned). Therefore, the grating should be at the front focus, while the scanning mirror should be at the back focus of the lens. The grating is modeled as normal to the diffracted forward ray. The exact alignment of the components is optimized using optical design software (Zemax).

Three characteristics of the delay line will be evaluated at two opposite tilting angles using the Zemax model: the group delay, the coupling efficiency, and the transmission spectrum as a function of the tilting angle.

First, the group delay is evaluated by comparing the calculation using Eq. 11.3 and the simulation using Zemax, as shown in Fig. 11.6. The delay versus the tilting angle is very linear. The delay produced by this Zemax RSOD model agrees closely with the calculation of Eq. 11.3 in which the effective focal length is used.

Second, a uniform coupling efficiency is important for preserving image quality across an image. The coupling efficiency varies with the tilting angle of the resonance mirror and this variance changes significantly with slight changes in the alignment of the optical components. The goal is to minimize this variance. The achromatic lens combination as shown in Fig. 11.2a1 was used in this design in order to minimize the chromatic dispersion, improving uniformity of coupling efficiency. The coupling efficiencies for three wavelengths versus the tilting angle are shown in Fig. 11.7. The upper three curves are the coupling efficiencies at three different wavelengths, while the lower three are the relative variations versus the scanning angle corresponding to each wavelength. It indicates that the maximum relative tolerance is less than 5/10,000 in the scanning range −0.5, 0.0, and +0.5° and that the coupling efficiency is quite stable in the scanning range.

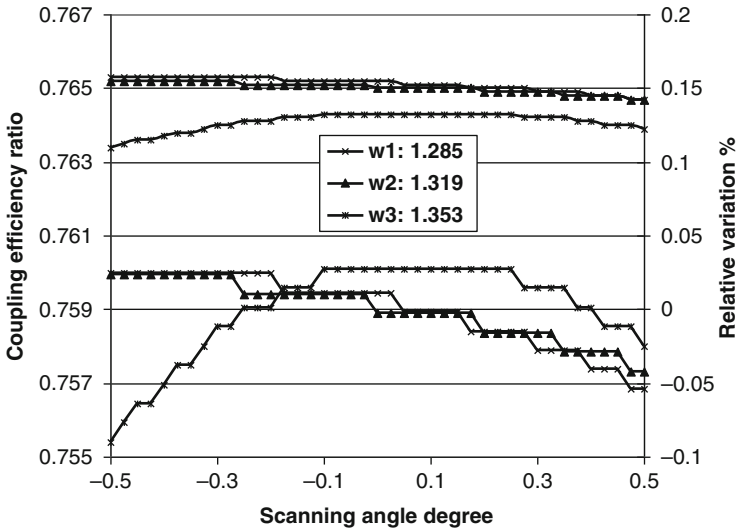

Fig. 11.7 Coupling efficiency as a function of wavelength and tilt angle. Upper three curves: the coupling efficiencies at three wavelengths (*left*). Lower three curves: the relative tolerances at each wavelength (*right*)

Third, the spectral response versus tilting angle is another critical parameter of the RSOD because a filtered spectrum will affect the axial resolution and the amplitude of the interference signal [2]. In order to obtain the spectral response of the optical system using optical design software, we calculate the coupling efficiency as a function of wavelength. The spectral responses are obtained at the angles −0.5, 0, and +0.5° and shown in Fig. 11.8. The upper three curves represent the coupling efficiencies at the three different tilting angles, −0.5, 0, and +0.5°, respectively, while the lower one represents averaged relative variation of the scanning at each wavelength. The results indicate that the spectrum of the light source is just very slightly filtered by the optics, about one percent at shorter wavelengths, and that the relative variation of the spectra is less than 6/10,000.

In summary of this section, we designed and analyzed an RSOD using optical design software and making use of telecentric and achromatic optics. The simulated group delay agrees with the theoretical predication; the coupling efficiency varies only slightly with the tilting angle of the scanning mirror and with wavelength. An achromatic lens is necessary for the objective because the incident light has a broad bandwidth spectrum. A telecentric design is also required because the lens should collimate the spectrum and focus the beam for every single wavelength. Notable lessons from this design example are that the recoupling as a function of tilt angle and wavelength is much worse without the use of achromatic and telecentric optics and that the distance between the lens and the scanning mirror is much more critical than the distance between the lens and the grating.

11.4 OCT Scanner Design Examples

11.4.1 Overview of OCT scanners

The OCT sample scanner (II) is one arm of the two-beam OCT interferometer and is used to deliver and focus the probe light into the tissue and to collect the scattered light back to the interferometer to generate the image signal by interference of the sample light with the reference light returned from the ODL.

Many types of scanners have been demonstrated for a variety of applications [4]. Recent developments include high-resolution devices involving adaptive optics [12, 13, 20] and high numerical aperture systems [14, 15], high scanning speed using micro-motors [16, 17], and three-dimensional imaging [18, 19, 21].

In the rest of this section, we will discuss two examples of OCT sample arm (II) designs. For sample arm design, as with reference arm design, coupling efficiency and spectral response are important. In addition, the spot profile and the scanning range are critical parameters.

11.4.2 Design Example: Bench-Top Scanner

The purpose of this design example is to demonstrate how to address the design requirements 1–4 in Sect. 11.1.1 by making use of telecentric and achromatic optics (Sects. 11.2.1, 11.2.2, and 11.2.3). The example that will be used in the design

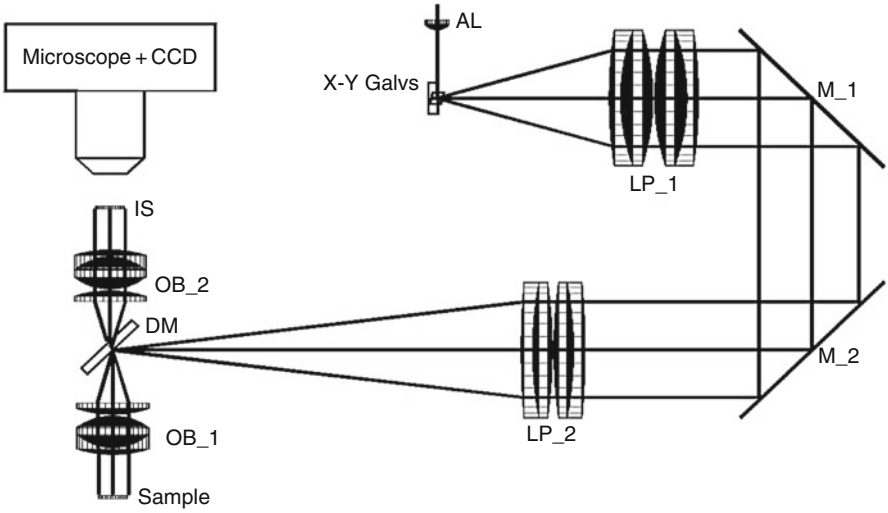

Fig. 11.9 Layout of quasi-telecentric OCT scanner optical design with view port and microscope, modeled by Zemax. *AL*, aspheric lens; *X-Y Galvs*, x-y galvanometric scan head; *LP-1* and *LP-2*, achromatic lens pairs; *M_1* and *M_2*, folding mirrors; *OB-1* and *OB-2*, identical objectives; *DM*, dichroic mirror; *IS*, 1:1 image of sample (view port)

discussion is a bench-top OCT scanner described previously [1]. The goal of this design was to develop an OCT scanner with high lateral resolution, long working distance (the distance between the final optical component and the sample), and large lateral scanning range. In addition, we attempted to achieve a uniform spot size and image quality over the entire lateral scan range. Another design goal was to provide a view port for a microscope to visualize the sample simultaneously while OCT imaging. The primary purpose of this scanner is for use with an OCT system intended for bench-top studies of biomedical samples under the guidance of a microscope [1].

Figure 11.9 shows the optical design of the scanner [1]. The illuminating light delivered via optical fiber is collimated by an aspheric lens AL (see Sect. 11.2.2) into a diameter of 2.2 mm and then deflected by a commercially available, small, and compact x-y galvanometric scan head. The x-y scan head (Cambridge Technology, Cambridge, MA) used in our design provides high scanning speed and has a distance (d) of 5.4 mm between the x and y mirrors which leads to a small deviation from telecentric optics. The relay optics consist of two pairs of achromatic lenses, LP-1 and LP-2, which magnify the OCT beam by a factor of two. In order to minimize spherical aberration in a large angle scan, LP-1 and LP-2 are pairs of identical achromatic lenses face-to-face (see Fig. 11.2(a3)). The focal lengths of LP-1 and LP-2 are $f_1 = 62$ mm and $f_2 = 124$ mm, respectively, and they are separated by $f_1 + f_2$. Folding mirrors M1 and M2 are used to make the scanner compact. A dichroic mirror DM at 45° incident angle is employed to deflect infrared light and transmit visible light and is located at the back focus f_2 of LP-2

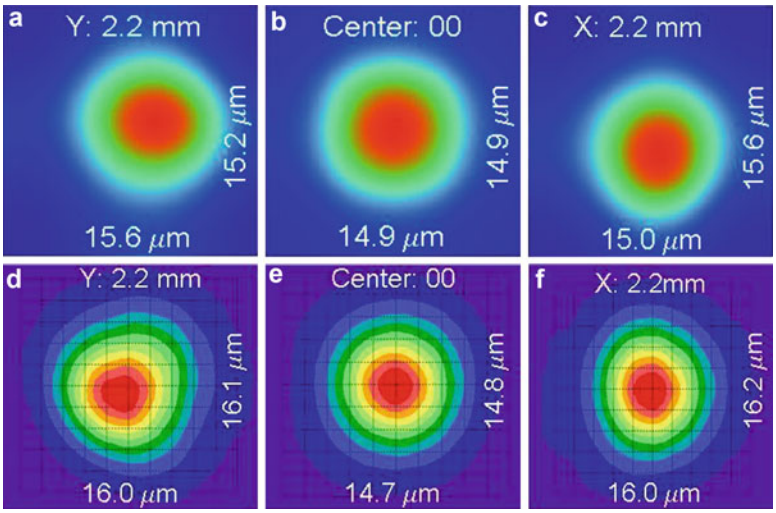

Fig. 11.10 (**a–c**) Cross-section profiles of the spots simulated by Zemax; (**d–f**), spot profiles corresponding to (**a–c**) measured by beam analyzer. Mesh grid and Zemax windows are 20×20 μm. Center means the beam goes through the center of the optics (on axis), while x and y mean tilting the x and y mirrors, respectively, to translate the beam in either x or y direction by 2.2 mm

and the front focus $f_3 = 20$ mm of the objective OB-1. DM deflects the OCT beam through the objective lens OB-1 which then focuses the beam onto the sample. OB-1 is a combination of singlet and achromatic lenses, which is a simplified method of minimizing spherical aberration similar to LP-1 or LP-2. The OCT signal reflected or scattered from the sample placed at the back focus f_4 of OB-1 is collected back through the same path to the OCT detector, while visible light passes through OB-1, DM and OB-2 to the microscope and CCD camera. OB-2 is identical to OB-1, so that they constitute a finite conjugate system to provide a 1:1 image of the sample at conjugate plane IS and allows the microscope to indirectly image the sample at IS. All optical components used in the design are commercially available and the alignment was optimized using optical design software (Zemax).

Spot analysis and characterization: Fig. 11.10(a)–(c) shows the spot profiles on the flat image plane simulated by Zemax in physical optics propagation (POP) mode, while Fig. 11.10(d)–(f) shows the same spot profiles measured by a beam analyzer placed at the image plane 16.5 mm away from last surface of the objective lens. The $1/e^2$ diameter of the simulated central spot was 14.9 μm, while the diameter of the simulated 2.2 mm y-offset spot was 15.4 μm, and the diameter of the simulated 2.2 mm x-offset spot was 15.3 μm. This achieves our design goal of not exceeding 17 μm $1/e^2$ spot diameter. The maximum fractional spot size deviation is 2.3 % over the full lateral scan range of 4.4 mm, which is better than our tolerance criterion of 5 %. The average ellipticity of x- and y-scans is 3.2 %, which also meets our tolerance criterion of 5 %. The measured $1/e^2$ diameter of the central beam was 14.8 μm, while the measured diameters of the 2.2 mm y-offset

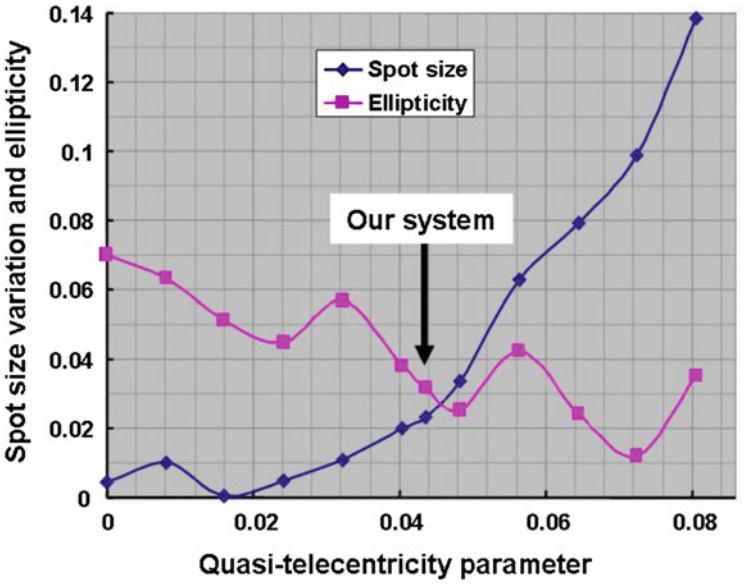

Fig. 11.11 Simulations showing variation of the relative off-axis spot profile with QTP. Diamond and square represent spot size variation and ellipticity respectively

beam and 2.2 mm x-offset beam were 16.1 μm. This corresponds well to above-simulated spot profiles. The spot size remained below our design goal of 17 μm over the full scan range, and the maximum fractional spot size deviation of 4.4 % meets our tolerance criterion. The average measured ellipticity of x- and y-scans in Fig. 11.10 is 1 %, which is better than our tolerance criterion of 5 %.

Comparing Fig. 11.10(a)–(c) with (d)–(f), we note that except for the central beam, the spot size measured by the beam analyzer is slightly larger than the one simulated by Zemax. One possible explanation is that we assumed the core diameter of the SMF-28 optical fiber to be 9 μm, but the diameter of the actual fiber may vary by ±0.4 μm. Another possible explanation is that the beam analyzer might not be precisely aligned with the image plane. The off-axis spot profiles are slightly elliptical, which is a typical problem for a system with slight uncorrected spherical aberration. The further the spots are from the optical axis, the more elliptical they become. Another important property shown in Fig. 11.10 is the purity of the spot profile. There are no side lobes, which would decrease the image contrast.

In order to investigate the effects of varying the degree of quasi-telecentricity, we varied the distance between the two scanning mirrors in our Zemax model while keeping both the front focal length of LP-1 constant and the focus of LP-1at the middle distance between the two mirrors (see Fig. 11.9). The quasi-telecentricity parameter (QTP, the ratio of the half separation between the two scanning mirrors to the front focal length of the optics that follow) value of zero in Fig. 11.11 represents a telecentric system. We varied the distance between the mirrors up to 10 mm, which varies the quasi-telecentricity parameter up to approximately 8 %.

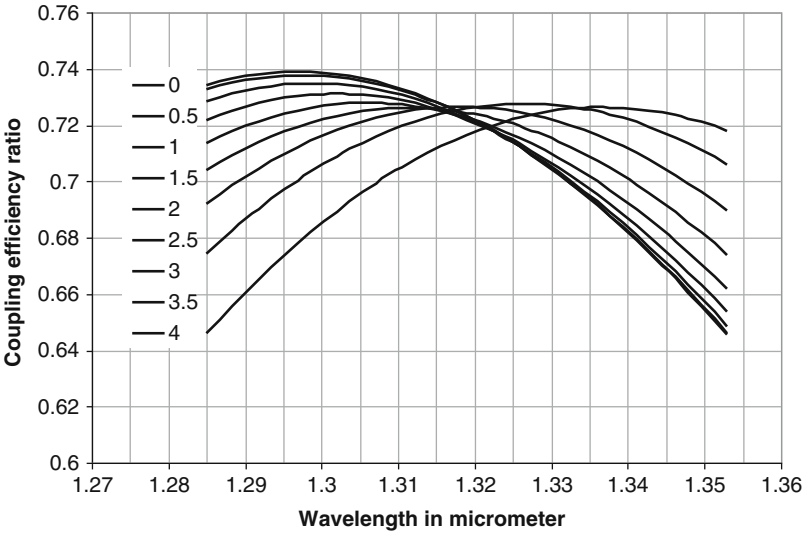

Fig. 11.12 Coupling efficiencies versus wavelength at different tilting angles in degree

In Fig. 11.11, we plotted the variation of the two spot parameters at the maximum of the lateral scan range as a function of the quasi-telecentricity parameter: the spot size variation and spot ellipticity. The average values for the x- and y-spots are plotted.

The results shown in Fig. 11.11 indicate that the relative spot size increases slowly until the QTP reaches approximately 5 % then increases more rapidly. The ellipticity generally decreases slowly with QTP. We observe an oscillation in ellipticity with QTP, but have no explanation for this observation at this time. The arrow in Fig. 11.11 represents the QTP of our implemented system, 4.4 %. At this value, as discussed above, both spot size variation and ellipticity are well below our tolerance criteria.

Coupling efficiency: As discussed in Sect. 11.4.2, the coupling efficiency directly relates the signal amplitude and affects the axial resolution since it filters the spectrum of the light source. Evaluating the coupling efficiency of this scanner via the Zemax model requires ray-tracing the light propagating through the optical components from the optical fiber to the sample (the end mirror in Zemax model) and reflected through the same optical path back to the optical fiber. The model should be built as a round trip, and both the emission and receiving fibers should have the same numerical aperture at the given wavelength before evaluating the coupling efficiency. For instance, the numerical aperture of SMF-28 fiber is 0.14 at 1,550 nm wavelength but is 0.118 at 1,310 nm wavelength. Steering the optical beam by tilting the scanning mirror from the center to the edge of the field of view, we obtained the coupling efficiencies as a function of wavelength at different transversal positions, as shown in Fig. 11.12. The incident spectrum in the simulation was normalized to unity in the calculation range. Figure 11.12 shows that the

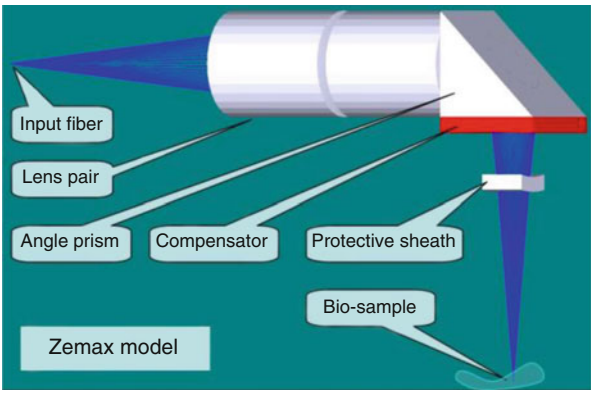

Fig. 11.13 Zemax model of a high NA, long working distance catheter probe design using refractive lenses, and a cylindrical lens for the compensation of the astigmatism due to the protective sheath

spectral bandwidth will be slightly narrowed by the filtering effect of the wavelength-dependent coupling efficiency and that the peak of the function shifts toward the longer wavelengths as the tilting angle increases from 0 to 4° or the beam is moved toward the edge of the scanning range. For a typical OCT light source, this filter function will not significantly affect the spectrum. In the case of a light source with ultra-broad bandwidth, for instance, 200 nm, this effect could be significant and require more careful design. To achieve a flat spectral dependence of the coupling efficiency, telecentric optics for the last objective and careful compensation of chromatic dispersion are essential.

11.4.3 Design Example: Catheter Probe

In this section, we examine the design of a relatively high numerical aperture (NA) and long working distance catheter probe (II). Catheter probes with high NA require a beam with a large diameter to produce a sufficiently small spot size that leads to a high-resolution image. A probe with a long working distance requires an even larger beam in order to maintain a small spot size. This requirement of a large beam makes careful optical design important in order to meet design specifications. A GRIN lens is typically used in catheter probe designs in order to achieve a small probe diameter. Here, we choose conventional refractive lenses with around 2 mm diameter to achieve a high NA and a long working distance probe because of improved off-axis performance. The astigmatism due the probe sheath also needs to be compensated in the design of high NA probe.

Figure 11.13 shows the Zemax model of a catheter probe using conventional lenses. The light out of the fiber is focused by a spherical lens pair, reflected by an angle prism and adjusted by two orthogonal cylindrical lenses as well as the compensator and the protective sheath. The working distance between the outside surface of the sheath and the focus is about 2.6 mm. The outer diameter of the sheath is 3 mm. Figures 11.14, 11.15, and 11.16 compare the spot profiles of the probe design with and without astigmatism compensation. The spot achieved with

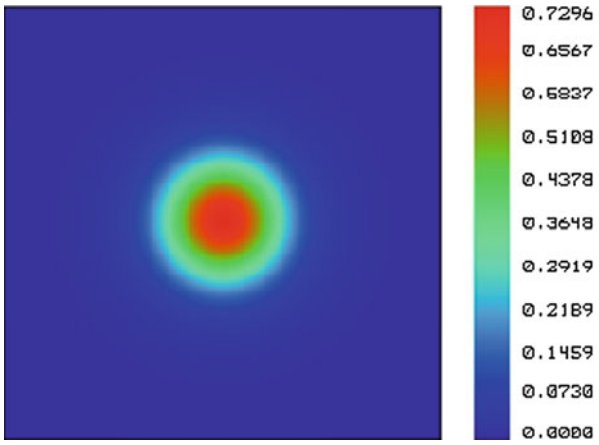

Fig. 11.14 Spot profile of the high NA catheter probe design with astigmatism compensation. Image window is 32 × 32 μm

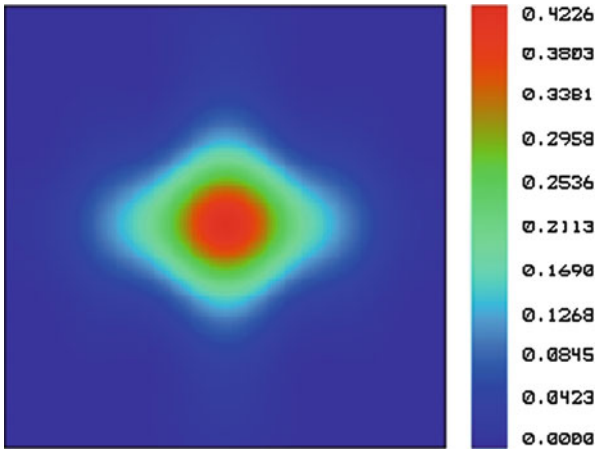

Fig. 11.15 Spot profile of the high NA catheter probe design without astigmatism compensation. Image window is 32 × 32 μm

the compensation lens, shown in Fig. 11.14, shows a clear profile with a high relative irradiance and a Strehl ratio of 0.73. The spot achieved without the compensation, shown in Fig. 11.15, shows some fuzzy or star pattern with a lower relative irradiance of 0.423. The "star pattern" spreads the energy from the peak of the spot, which reduces the contrast and the resolution of the image. Figure 11.16 shows the cross section of the spot profiles achieved with and without astigmatism compensation, which are normalized to the spot with compensation. The curves represent the cross sections through the center of the spot images orthogonally in two directions. The $1/e^2$ diameters of the spots are 13 μm and 20 μm, respectively, for the designs with and without the compensator. The profile of spot with the compensation lens is symmetric around the center, while the profile without the compensation lens is not symmetric.

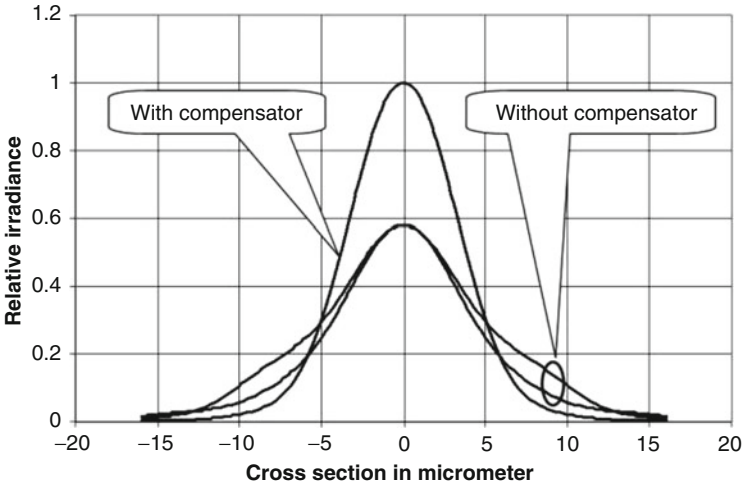

Fig. 11.16 Cross sections of the spot profiles for the high NA catheter probe design with and without compensation. The orthogonal cross sections with compensation are identical, whereas the orthogonal cross sections without compensation are not

As a summary of this subsection, in order to accommodate the relatively large beam necessary for a higher NA and longer working distance catheter probe, refractive optics may be advantageous, and correction for the astigmatism caused by the curved catheter probe sheath is important.

11.5 SD-OCT Spectrometer Design Example

The spectrometer (VI) is a critical component of array-based frequency-domain OCT (SD-OCT). The typical components of a fiber-coupled spectrometer include the collimator, diffractive grating, objective lens, and linear detector array as shown in Fig. 11.17. The spectral coverage of the spectrometer determines the axial resolution of the FD-OCT system together with the bandwidth of the light source. The spectral range integrated by each pixel, together with the optical resolution of the spectrometer, determines the axial signal falloff, which is a result of fringe visibility washout. The spectral spacing between pixels determines the unambiguous imaging range (limited by aliasing). To design a high-quality spectrometer, the chromatic aberration, optical resolution, and detector array resolution should be taken into account. Chromatic aberration could be avoided by using all reflective optics, i.e., curved mirrors, but the optical resolution (the spot profile) would be more difficult to control than if refractive lenses were used. The following two subsections will describe a refractive lens-based spectrometer design and the performance analysis.

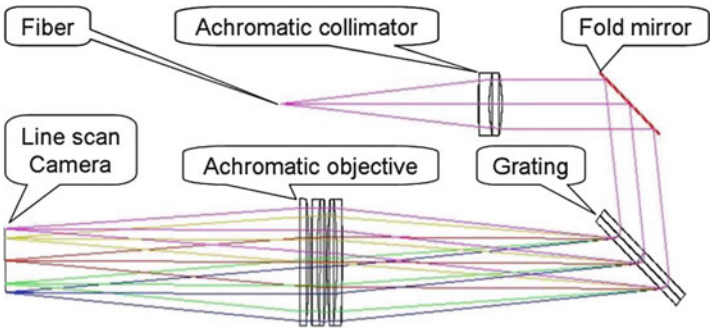

Fig. 11.17 Zemax model of spectrometer for FDOCT at 1,310 nm. Pixel number of detector array: 512; Pixel size: 50 μm; average wavelength spacing: 0.2 nm

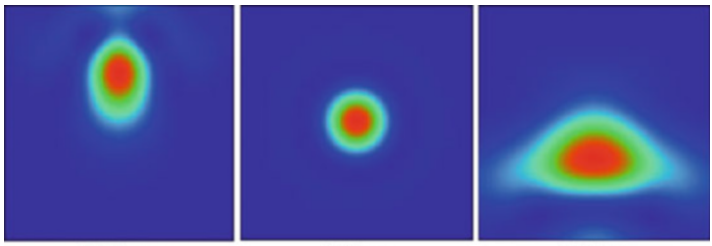

Fig. 11.18 Spot images at wavelengths 1,257 nm, 1,310 nm, and 1,359 nm, window size: 50 × 50 μm. Vertical is the dispersion direction

11.5.1 Achromatic Spectral Response

In this subsection, we discuss the correction of chromatic aberration due to the dispersion of the glass of the lenses and analyze the spectral response in this design. Figure 11.17 is the Zemax model of a refractive lens-based spectrometer. The specifications of this spectrometer are the following: The wavelength coverage is 102 nm and the center wavelength of the spectrum, located at the center of the detector array, is 1,310.6 nm. The detector array contains 512 pixels; this is 50 μm wide. The orientation of the grating is fixed at the optimum incident angle at the center wavelength for the expected light source spectrum, which makes the design relatively simple. The broad bandwidth coverage requires good achromatic optics. According to the principles discussed in Sect. 11.2, we used one achromatic lens to collimate the beam before the grating and three lenses for the objective. This consideration provided acceptable spot profiles through the entire spectrum of the light source as shown in Fig. 11.18. Figure 11.18 shows in that the spot sizes at wavelengths 1,257 nm and 1,359 nm are slightly broader in the dispersive direction than the spot at the center wavelength, 1,310 nm, which is optimized in this design. They are all significantly smaller than the pixel width of 50 μm. The optimized

optical design gives a flat throughput covering the entire spectrum of this spectrometer (data not shown).

11.5.2 Spectral Resolution and Optical Resolution

Both spectral resolution and detector array resolution affect the axial image range of the spectrometer-based FD-OCT. According to the Nyquist theorem, the maximum axial imaging range ΔD is limited by the following equation:

$$\Delta D = \frac{1}{4}\frac{{\lambda_c}^2}{\Delta\lambda}N. \tag{11.4}$$

where λ_c, $\Delta\lambda$, and N are the center wavelength, spectral range covered by the spectrometer, and the pixel number of the detector array. The spectral resolution $\delta\lambda$ is defined as $\delta\lambda = \Delta\lambda/N$ and represents the spectral range integrated by a single pixel. According to Eq. 11.4, the better the spectral resolution $\delta\lambda$, the larger the imaging range ΔD. For instance, at $\lambda_c = 1{,}307.8$ nm, $\Delta\lambda = 102$ nm, and $N = 512$, the maximum imaging range ΔD is 2.142 mm. This distance can be thought of as the "folding range," or the maximum range from which an image signal can be collected without aliasing. The imaging range will be doubled to 4.284 mm if the pixel number N is increased by a factor of 2 or the spectral coverage is alternatively decreased by the same factor. In other words, the smaller the wavelength or frequency spacing, the longer the folding range will be. Therefore, for a given number of pixels available, there is a design tradeoff between axial resolution and axial range.

In addition, the resolution of the spectrometer determines the falloff of the FD-OCT. The signal amplitude $I(x_j)$ at pixel number j can be expressed as [5],

$$\begin{aligned} I(x_j) = {} & \frac{1}{4}Erf\left(\frac{\Delta y\sqrt{\ln 2}}{a}\right) \\ & \cdot \int_0^\infty \left[Erf\left(\frac{(\Delta x - 2x(k) + 2x_j)\sqrt{\ln 2}}{a}\right) + Erf\left(\frac{(\Delta x + 2x(k) - 2x_j)\sqrt{\ln 2}}{a}\right)\right] \\ & \cdot \left[S_{ref}(k) + S_{sam}(k) + 2\sqrt{S_{ref}(k)S_{sam}(k)}\cos(2k\,\Delta D)\right]dk. \end{aligned} \tag{11.5}$$

where coordinate function $x(k)$ varies with wave number k and is defined by the optical design of the spectrometer. Where Erf, Δy, Δx, and x_j are, respectively, the error function, the pixel height, the pixel width of the detector array, and the position of the center of pixel j. The spot diameter a is defined as the FWHM of the beam focused on the detector and is assumed to be constant. The variable in the error function $k = 2\pi/\lambda$ is the wave number of the illuminating light. The spectral densities of reference and sample fields S_{ref} and S_{sam} are not necessarily the same. In Eq. 11.5, the quantum efficiency is assumed to be constant and the system

attenuation factor was normalized. The pixel height Δy in Eq. 11.5 comes out of the integral and does not affect the spectral interference or the falloff of the FD-OCT signal, but it affects the amplitude when it is not large enough compared to the spot size a. The pixel width Δx of the detector and the spot diameter a determine the fall-off of FD-OCT.

In the extreme condition when the spot diameter a goes to infinitely small, the sum of the two error functions under integral in Eq. 11.5 degrades into three special expressions: a step function either 2 in the pixel area or 0 outside the pixel if Δx has a finite and nonzero size ($\Delta x > a$), a Delta function with a maximum value of 1.68 if Δx goes to infinitely small ($\Delta x = a$), and zero if $\Delta x = 0$. Therefore, Eq. 11.5 degrades correspondingly into the following expressions:

$$I(x_j) = \frac{1}{2}\left[S_{ref}(k_j) + S_{sam}(k_j) + \sqrt{S_{ref}(k_j)S_{sam}(k_j)} \bullet \cos\left(2\Delta D k_j\right) \frac{\sin\left(\Delta D \Delta k_j\right)}{\Delta D \Delta k_j}\right] \quad (\Delta x > a), \tag{11.6}$$

$$I(x_j) = \frac{1}{2}\left[S_{ref}(k_j) + S_{sam}(k_j) + \sqrt{S_{ref}(k_j)S_{sam}(k_j)} \bullet \cos\left(2\Delta D k_j\right)\right] \quad (\Delta x = a). \tag{11.7}$$

where k_j is the wave number at position x_j and Δk_j is the segment of wave number around k_j covered by the j^{th} pixel. Equation 11.6 shows a clear sinc falloff when Δk_j is a constant over the spectrum, representing the case where the spectral resolution is dominated by the pixel size. Equation 11.7 is the familiar formula describing OCT interference, representing the case of infinitesimal spectral resolution and negligible falloff.

As an example, we evaluate the falloff versus different spot sizes for a spectrometer at center wavelength 1307.8 nm with bandwidth coverage of 102 nm. The design layout of this spectrometer is similar to the one in Fig. 11.17 except the grating is aligned for the center of the spectrum to be 1,307.8 nm. After integrating Eq. 11.5 over k space and Fourier transforming, the falloff curves at different ratios of the spot size to pixel size (pixel width: 50 μm), 0, 0.002, 0.25, 0.5, 0.75, 1.0, and 1.5 from top to bottom, are shown in Fig. 11.19. As expected, the calculations show that the smaller spot size leads to a better falloff. In the cases of the ratio < 0.25, the falloff is close to a sinc function, dominated by the pixel width. In order to easily compare the image attenuation versus the spot size ratio, we evaluated the image attenuation at -3 dB and -10 dB as a function of the spot size ratio (Fig. 11.20). This plot indicates that as long as the spot size ratio is less than 0.25, the falloff is near optimum.

11.5.3 Linear-k Spectrometer in OCT

A linear wavenumber (k) spectrometer design significantly improves the reliability and performance of SD-OCT [22], providing several advantages. First, there is no

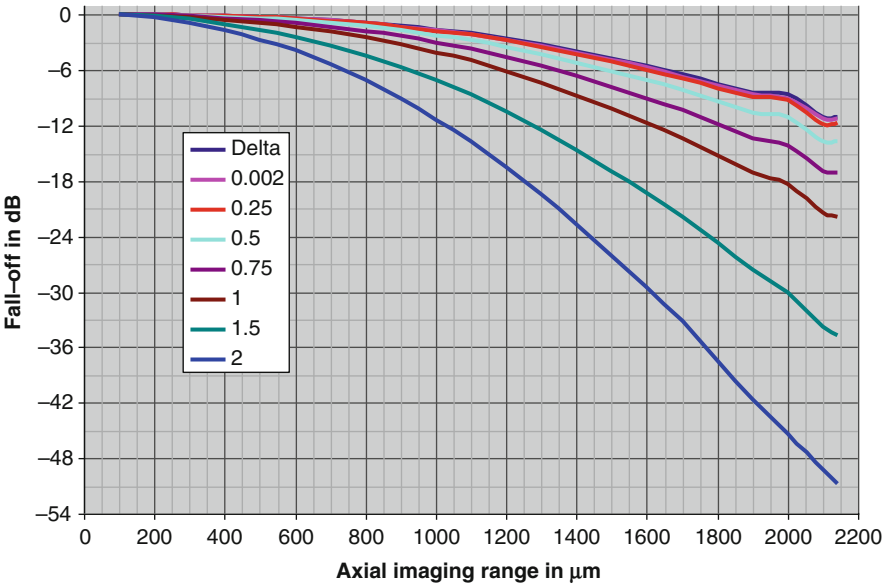

Fig. 11.19 Falloff curves at 8 different spot sizes ratios, falloffs for 0, 0.002, and 0.25 are very close. The higher the curve, the smaller the spot size. Pixel size = 50 μm; center wavelength = 1307.8 nm; wavelength coverage = 102 nm

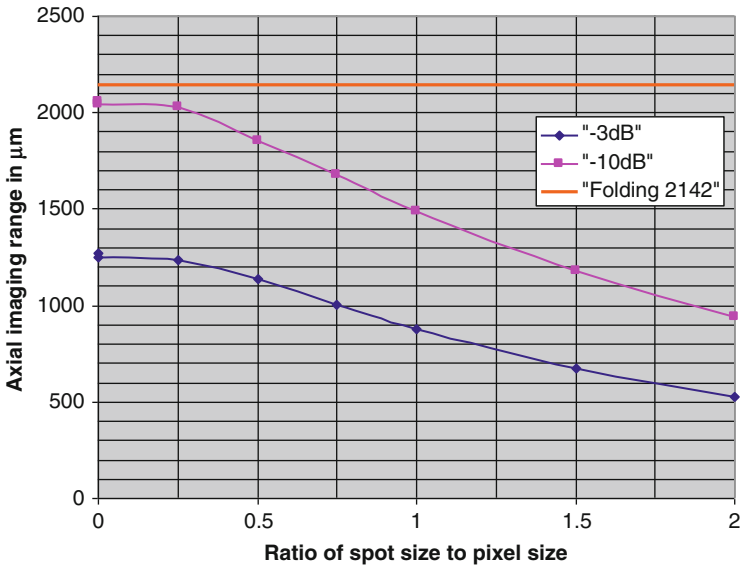

Fig. 11.20 Falloff distances at −3 dB ad −10 dB as a function of the ratio of spot size to pixel size. The falloff is near optimum when the ratio is less than 0.25

need to numerically transform the spectral interferogram into a function of k, which saves imaging reconstruction time. Furthermore, there is no need for a lookup table and wavelength calibration that requires the alignment of the camera to specific wavelengths of the spectrum. Also, the axial imaging falloff and SNR are significantly improved because of the uniformity of spectral sampling.

11.6 Conclusion

In summary, the quality of the design of critical components, including sample scanners, spectrometers, and delay lines, will significantly impact the performance of OCT imaging systems. The conscientious use of appropriate optics (e.g., achromatic and aspheric optics), design strategies (e.g., telecentric systems), and design tools (e.g., optical modeling software for computer-aided design) are important ways to design high-quality OCT subsystems.

12.1 Introduction

Optical coherence tomography (OCT) determines the distances of scattering structures by interferometry in order to reconstruct A-scans and B-scan images of three-dimensional objects. In time-domain OCT (TD-OCT) the intensity at the output of the interferometer is measured with a point detector, while the optical path length in one interferometer arm is changed [1]. As an approach to avoid moving parts, linear OCT (L-OCT) employs a parallel detection scheme to measure the interference by introducing spatially varying path length differences on an array of individual detectors. According to Fig. 12.1, L-OCT is one of the four basic groups of OCT systems, which can be distinguished by the measured parameter (interference pattern or spectrum) and the type of acquisition (time-dependent point measurement or spatially multiplexed parallel measurement). TD-OCT and L-OCT measure an interference pattern, whereas spectral or Fourier domain OCT (FD-OCT) [2, 3] and swept source OCT (SS-OCT) [2, 4], which is also named optical frequency domain imaging (OFDI), measure the cross-correlation spectrum, which is converted to the A-scan by a Fourier transform.

Fig. 12.1 The four fundamental implementations of OCT

FD- and SS-OCT offer superior sensitivity and signal-to-noise ratio (SNR) over time-domain and linear OCT. But they also have some disadvantages. FD-OCT needs high performance optics for the spectrometer, SS-OCT is based on sophisticated rapidly tunable light sources, and the necessary Fourier transform requires some processing power. Additionally, the correlation of the reflectivity distribution in the sample, which is incorporated in the FD- and SS-OCT signals, may obscure the image. This is especially the case when strong reflecting surfaces are present in the image. By their working principle, TD-OCT and L-OCT avoid the autocorrelation problem and give unique information about the structure of the sample.

One of the main technological challenges for TD-OCT was to build an optical delay line that worked at high frequencies with a constant velocity [5], and still the delay line is an important factor that limits the acquisition speed and makes TD-OCT systems complex and sensitive to unwanted changes of the alignment. Obviously, TD-OCT without moving parts would be of great advantage, especially for commercial systems.

Linear OCT, which combines the principle of TD-OCT with a parallel detection scheme, is a way to overcome these limitations by projecting the interference pattern on a line detector. A problem of L-OCT was the high number of pixels which were needed to sample the interference pattern without aliasing. At a wavelength of 800 nm a ranging depth of 2 mm required at least 10,000 pixels. This problem was overcome by optically reducing the fringe frequency of the interference pattern without influencing the information-carrying parts. The advances in CCD and CMOS detector technology in the recent years made linear OCT devices possible.

This chapter describes theory, implementation, and performance of linear OCT systems and discusses possible applications. Line-field versions of linear OCT are briefly introduced.

12.2 Theory

12.2.1 The Principle of Linear OCT

The depth z_s of reflecting or scattering tissue structures can be measured by interferometry because the propagation time of radiation with a frequency ω travelling through tissue with a phase velocity c introduces a phase shift of $\Phi_S = (\omega/c)\, z_S$. In OCT this phase shift is recovered by superposing the radiation from the sample with a reference beam. With the electric fields for sample and reference radiation given by $\sqrt{j_S(\omega)}\exp(i\,\Phi_S(\omega))$ and $\sqrt{j_R(\omega)}\exp(i\,\Phi_R(\omega))$, respectively, the intensity of the interference signal on a detector at the output of the interferometer results in

$$I = j_S + j_R + 2\sqrt{j_S j_R}\cos(\Delta\Phi) \tag{12.1}$$

$\Delta\Phi = \Phi_S - \Phi_R = \omega/c\,(2z_S - 2z_R)$ is the phase difference between sample and reference irradiation. For monochromatic light the interference signal I changes periodically with the difference $\Delta z = z_S - z_R$ of the path lengths in sample and reference arm and gives no unique information for a Δz larger than the half of the wavelength λ. Therefore, OCT uses polychromatic light to recover Δz. The phase difference and subsequently the interference pattern are dependent on the frequency of the radiation. Hence the change of $\Delta\Phi$ with the frequency contains in a unique way the depth information. In TD- and L-OCT a nearly zero phase difference is detected by superposing all frequency components on the detector. This is described mathematically by integrating Eq. 12.1 over the whole frequency range of the radiation.

$$I = I_S + I_R + 2\int \sqrt{j_S(\omega) j_R(\omega)}\cos(\Delta\Phi(\omega))d\omega \tag{12.2}$$

I_s and I_R are the integrals over spectral densities j_s and j_R which yield the intensities for reference and sample radiation. When the dispersions in both arms of the interferometer are balanced, the interference signal consists of a harmonic function with the central frequency ω_0, which is modulated by the Fourier transform $\sqrt{2\pi}F\{S(\omega-\omega_0)\} = \sqrt{j_S j_R}\,\gamma(2\Delta z/c)$ of the radiation spectrum $s(\omega)$ [6]:

$$I = I_S + I_R + 2\sqrt{I_S I_R}\gamma(2\Delta z/c)\cos(\omega_0/c\,2\Delta z) \tag{12.3}$$

The modulation of the cosine actually contains the normalized coherence function γ of the radiation source. The interference pattern is only observed if the difference of the optical path lengths $2\Delta z/c$ is within the width of the coherence function γ. This coherence gate allows to separate the signals from different depths in the sample by evaluating I, while the optical delay in one arm of the interferometer is changed over a certain range.

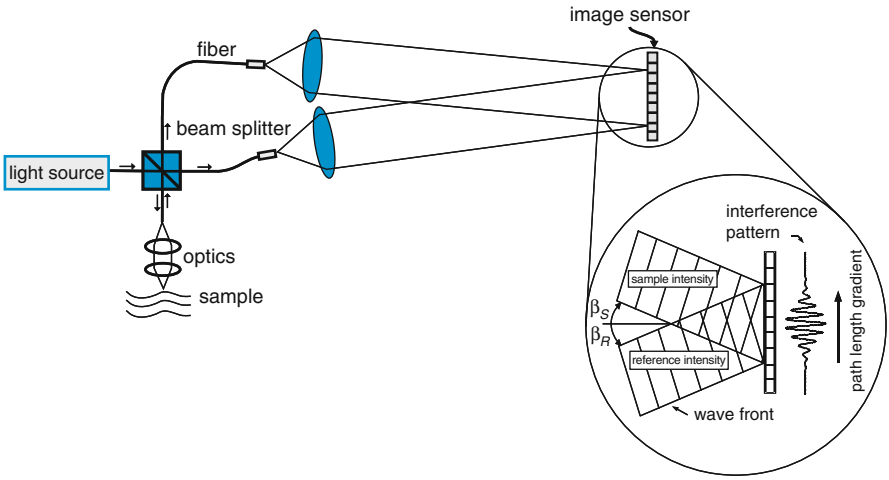

Fig. 12.2 The basic principle of linear OCT (L-OCT). An interference pattern is formed on the image sensor by the tilted sample and reference beams

In linear OCT the interference pattern is measured in parallel by spatially extending the interference pattern on a line or array detector (Fig. 12.2). A simple way for this is to expand sample and reference beam and superpose them under the angles β_s and β_R on the detector (see inset in Fig. 12.2).

In that case, the phases of both beams depend linearly on the lateral position on the detector and the resulting phase difference is given by

$$\Delta\Phi = \omega/c\,(2\Delta z + x(\sin\beta_S - \sin\beta_R)) \tag{12.4}$$

With this expression for the phase difference, Eq. 12.3 changes to:

$$I = I_S + I_R + 2\sqrt{I_S I_R}\gamma((x\xi\lambda_0 + 2\Delta z)/c)\cos(2\pi x\xi + \omega_0/c\;2\Delta z) \tag{12.5}$$

The interference pattern now contains the carrier frequency $\xi = (\sin\beta_S - \sin\beta_R)/\lambda_0$, which can be controlled by the incidence angles of both beams. Without moving parts a whole A-scan can be measured.

The time-dependent modulation of a signal from a single point detector at the output of the interferometer is exchanged by the measurement of a spatial intensity distribution with an extended detector. Differences in the performance and layout between TD-OCT and L-OCT arise, therefore, only from the parallel acquisition of data for the complete A-scan, the discrete sampling of the interference pattern, and the performance characteristics of the different classes of detectors used.

One important restriction for L-OCT is that the pixel frequency ξ_P of the detector has to be at least two times the modulation frequency ξ to fulfill the Nyquist criterion. Since a full cycle of the interference signal corresponds to a path length difference of $\lambda/2$, at least $4\Delta d/\lambda$ pixels are needed for a certain

measurement depth Δd. Hence, the depth range is limited by the number of available pixels. The information that is detected by OCT has a bandwidth that is the reciprocal of the coherence length l_c (typically 5–20 μm), which is significantly smaller than ξ. To reduce the number of necessary pixels, it would be desirable to reduce the bandwidth of the interference pattern by reducing or removing the carrier frequency ξ. In fact there is the possibility of an optical control of the carrier frequency without loss of information.

12.2.2 Optical Control of the Carrier Frequency

12.2.2.1 Transmission Grating in Near Field

In radio technology, a reduction of the carrier is often done by mixing, i.e., the multiplication with a second fixed frequency. Optically, this can be facilitated by the transmission of the interference pattern through a mask with a periodically changing absorption, i.e., by a transmission grating (Fig. 12.3). The intensity directly behind the grating is the product of the interference pattern with the transmission of the mask. With a grating of a frequency ξ_g and a harmonic transmission $\tau = (1 + \cos(2\pi\xi_g x))/2$, the following intensity pattern results to [7].

$$I(x) = \frac{1}{2}(I_S + I_R)\left(1 + \cos\left(2\pi\xi_g x\right)\right) + \frac{1}{2}\sqrt{I_S I_R}\gamma((x\xi\lambda_0 + 2\Delta z)/c)$$
$$\left(\cos\left(2\pi\left(\xi - \xi_g\right)x + \omega_0/c\,2\Delta z\right) + \cos\left(2\pi\xi x + \omega_0/c\,2\Delta z\right) + \cos\left(2\pi\left(\xi + \xi_g\right)x + \omega_0/c\,2\Delta z\right)\right) \tag{12.6}$$

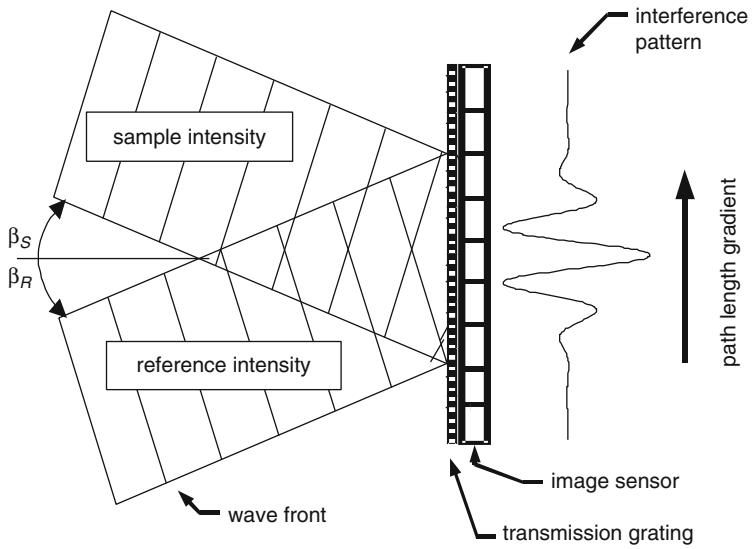

Fig. 12.3 Reduction of the fringe frequency of the interference pattern by a periodic transmission grating

$I(x)$ now consists of four bands with the center frequencies at $\xi - \xi_g$, ξ_g, ξ, and $\xi + \xi_g$. All frequency components but ξ_g are modulated by the information from the sample. With choosing ξ_g and ξ in a way that $\xi - \xi_g$ is below the half sampling frequency and that ξ and $\xi + \xi_g$ are above the pixel frequency ξ_P, the Nyquist criterion can be fulfilled and the high-frequency components of the interference pattern will be averaged out on the light-sensitive area of the pixels [7]. Only the signal component $1/2\sqrt{I_S I_R}\gamma((x\xi\lambda + 2\Delta z)/c)\cos\left(2\pi\left(\xi - \xi_g\right)x + \omega_0/c\,2\Delta z\right)$ and a constant background will be measured. The spectral components of the coherence function γ and, therefore, the structure information of the sample are not affected by the transmission mask.

By this principle, the carrier frequency can be reduced to any value. If ξ_g is exactly ξ, the carrier is completely removed, and only the modulation multiplied by a phase term will appear on the sensor. In this case the intensity on the detector becomes sensitive to the relative phase between reference and sample irradiation which modulates the signal between zero and the maximal level. The simplest way to avoid the resulting ambiguity is to use a low-frequency carrier. For a reconstruction of γ, two cycles of the carrier per coherence length l_c are sufficient. Without transmission mask l_c/λ cycles, which appear under γ, have to be sampled. Therefore, at a fixed number of pixels the grating increases the image depth by a factor of $l_c/2\lambda$. At 800 nm wavelength and 15 µm coherence length, this is about an order of magnitude. Unfortunately the mask reduces the signal due to transmission losses of the grating and the fact that 50 % of the signal power is mixed into the sum frequency where it cannot be detected. The modulation amplitude of the signal is thereby reduced to 25 % compared to L-OCT without transmission mask.

12.2.2.2 Diffraction by a Phase Grating

A control of the fringe frequency of the interference pattern with minimal signal loss is possible by the use of a phase grating. In a beam diffracted by a grating, parallel light rays, which emerge from each groove, have different propagation times. The direction of the newly formed phase front, which determines the carrier frequency in the interference pattern, is decoupled from the group front (the time delay of wave packages), which determines the width of the coherence function (Fig. 12.4). An individual control of the group and phase delay across the beam diameter is therefore possible by a phase grating. This principle, which was used for femtosecond pulse measurements [8, 9], in delay lines for TD-OCT [10, 11], and for coherent microscopy [12], can also be applied to L-OCT [13].

A reduction of the fringe frequency occurs when different diffraction orders of the reference and sample beam are superposed on the detector (Fig. 12.4). The m^{th} diffraction order introduces an achromatic phase shift of $2\pi m$ between parallel rays from neighbored grating lines. Therefore, a phase which varies by $2\pi\ m\ \xi_g\ x$ is introduced across the beam. This phase term changes Eq. 12.3 to

$$I(x) = I_S + I_R + 2\sqrt{I_S I_R}\gamma((x\ \xi\ \lambda_0 + 2\Delta z)/c)\cos\left(2\pi\left(\xi - \Delta m\xi_g\right)x + \omega_0/c\ 2\Delta z\right), \quad (12.7)$$

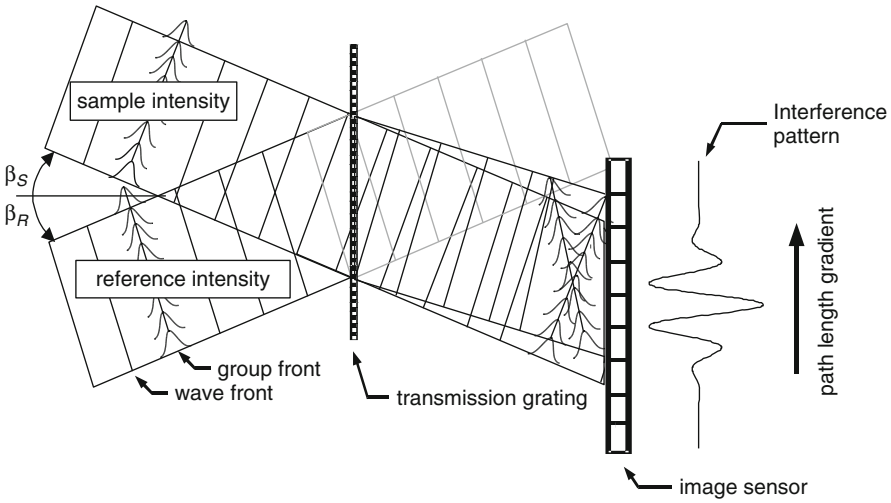

Fig. 12.4 Reduction of the fringe frequency by a diffraction grating. A grating forms new phase fronts in the diffracted beam, in which the propagation time varies across the diameter. Phase and group fronts are tilted against each other

where Δm is the difference of the diffraction orders of the sample and reference beam which interfere on the detector. Compared to Eq. 12.5, an expression appears, in which the fringe frequency is reduced by Δm times the grating frequency ξ_g. In contrast to the transmission mask, only the term with the difference frequency appears, and the losses in the sample beam can be kept small by adequate design. In the configuration of Fig. 12.4, a low diffraction efficiency of the grating causes only negligible losses to the sample beam. The high losses to the reference beam can be tolerated, because only the intensity from the sample is affecting the sensitivity of the system. Therefore, with a phase grating a control of the fringe frequency is possible without compromising the sensitivity of the OCT signal. With an additional beam splitter, a reflection grating can be used as well (Fig. 12.5). An open Michelson interferometer, in which the reference mirror is replaced by a grating in Littrow configuration, offers here an elegant way [14, 15]. The carrier frequency is adjusted by the angle between reference and sample beam. The path length difference over the detector is determined by the tilt angle of the grating.

12.2.3 Sensitivity and Signal-to-Noise Ratio (SNR)

In principle L-OCT can reach the same sensitivity and signal-to-noise ratio (SNR) as T-OCT [16]. According to Eq. 12.3 the OCT signal S, which shall reflect the intensity of the radiation scattered by tissue structures, is calculated as the square of the detected modulation integrated over the coherence function γ.

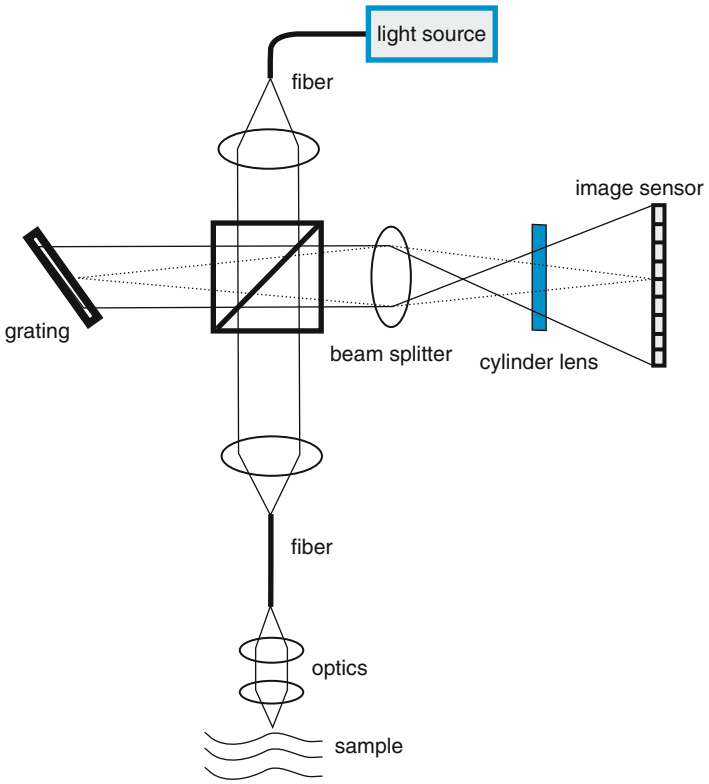

Fig. 12.5 Reduction of the fringe frequency by a reflection grating

$$S = 4n_R n_S \int \gamma^2(2\Delta z/c)\cos^2(\omega_0/c2\Delta z)d\Delta z \approx l_c n_R n_S, \tag{12.8}$$

where n_R and n_S are the numbers of photoelectrons generated by the reference and the sample radiation, respectively. Noise arises from the shot noise mainly generated by the constant background signal n_B in the interference pattern and the noise n_D of the detector and electronics.

$$N = n_B \int \gamma^2(2\Delta z/c)d\Delta z + n_D \approx l_c n_B + n_D, \tag{12.9}$$

For small signal intensities (the reference intensity is much larger than the sample intensity) and quantum noise limited performance (detector noise is smaller than shot noise), n_B is given by n_R and the SNR is just the number n_S of detected photons from the sample. n_S can be expressed by the intensity I_s received from the sample, the exposure time τ, and the quantum efficiency η of the detector:

$$SNR = \frac{S}{N} = n_S = I_s \tau \frac{\eta}{\hbar\omega} \frac{l_c}{\Delta d} \tag{12.10}$$

Besides the power I_S from the sample, also the ratio between coherence length l_c and measuring range Δd determines the SNR, because I_S, which is spread over the whole detector length, only contribute to the signal n_s within the window of the coherence function γ. This fraction can be approximated by $l_c/\Delta d$. A similar equation is obtained for TD-OCT systems. In FD- and SS-OCT the SNR is higher by the factor $\Delta d/l_c$, because the sample intensities from all depth contribute to the signal in every pixel of the detector [3]. Hence, the number of signal photons n_s is only given by $I_s\tau\eta/\hbar\omega$.

In contrast to standard TD-OCT systems, in L-OCT as well as FD-OCT incident power on their primary sensors is limited. The photodiodes used in TD-OCT show a linear response up to a few mW well exceeding the output power of standard OCT light sources like SLDs. Here the analog demodulation electronics is the bottleneck. It is especially difficult to build a rectifier with a dynamic range larger than 80 dB. In L-OCT devices the full well capacity (FWC) of the image sensors is the limiting factor. The number of detectable sample electrons n_s in one readout cycle cannot be larger than the half of FWC times the average number of pixels under the coherence function, which is given by the total pixel number N_P times $l_c/\Delta d$. Therefore, the maximum SNR_{max} can be expressed in terms of the FWC by

$$SNR_{max} = \frac{FWC}{2} \frac{N_P l_c}{\Delta d} \tag{12.11}$$

For a measurement range of 1 mm, a coherence length of 20 μm, a line detector with 1,024 pixel, and 6 million electrons FWC, SNR_{max} is 78 dB. Equation 12.11 also gives the dynamic range of an L-OCT system, defined by the highest detectable signal divided by the signal which can be detected with an SNR of one.

The sensitivity σ of an OCT device is defined by the reciprocal of the smallest reflectivity in the sample that can be detected with an SNR larger than one. It is calculated by replacing I_S by $1/\sigma$ times the irradiation I_{OS} falling on the sample

$$\sigma = \frac{\eta\tau I_{OS} l_c}{\hbar\,\omega\Delta z} \tag{12.12}$$

In principle σ can be increased arbitrarily by increasing the light level that falls on the sample. However, in practical applications the sensitivity is limited by the dynamic range of the OCT system, because usually high and low reflection should be measured at the same time. If, for example, a specular reflection at the surface of the tissue should not saturate the detector, the sensitivity is approximately given by the dynamic range divided by the surface reflectivity (about 4 %).

12.3 Detectors for Linear OCT

The detector arrays for L-OCT should be selected with great care because their performance is crucial for the quality of the L-OCT images. In biomedical applications a high sensitivity is necessary to visualize internal tissue structures. This means that small modulations on a large background signal have to be detected with low noise. Relevant properties of the detectors are noise, linearity, maximum signal (FWC), pixel size and number. Similar criteria, as will be discussed in the following section, are also valid for FD-OCT detectors, but a high dynamic range of the line detector is even more important for L-OCT, because a strong signal from one image point is not distributed over all the pixels, but sampled locally.

12.3.1 Systematical Errors and Detector Noise

For an optimal performance the systematic measurement errors, which are always present in image sensors, have to be removed. Every pixel of the sensor has a specific offset error, which is usually called dark signal nonuniformity (DSNU), and a certain gain error, the pixel response nonuniformity (PRNU). DSNU is in the order of a few percent of the full well capacity. PRNU is usually also about a few percent. To gain an optimal performance, DSNU has to be removed by subtracting the dark response of the sensor from every scan. Gain errors are corrected by dividing the measured data by a reference scan which is obtained under uniform illumination of the sensor.

If all systematic errors are removed properly, a noise floor N of the sensor is left which depends on the photon shot noise N_{PSN} of the photoelectrons n_{Ph}, the dark noise N_{Dark}, which is the shot noise of dark signal electrons n_{Dark}, and the additional signal-dependent noise components from the sensor and the electronics N_{Elec}.

$$N^2 = N_{PSN}^2 + N_{Dark}^2 + N_{Elec}^2 = n_{Ph} + n_{Dark} + N_{Elec}^2 \tag{12.13}$$

For a quantum noise limited performance of an L-OCT system, the photon shot noise must be larger than the two other noise contributions. This is achieved by increasing the number of photoelectrons n_{Ph} in the pixel until the sensor nearly saturates. The maximal exposure (FWC) and the dark noise actually define the optimal working range of the sensor and determine the achievable SNR of the L-OCT system.

For a quantitative comparison of different detectors, the photon transfer function (PFT) can be used [17], which relates the noise N of the output to the average number n_{Ph} of measured photoelectrons. The PTF allows to identify the exposure region in which the performance of the sensor is closest to the quantum noise limit. The closer the PTF of a detector is to the straight line $N = \sqrt{n_{Ph}}$ of an ideal detector, the better the performance. A real sensor (e.g., the LIS 1024 CMOS sensor from Photon Vision Systems) has usually three distinct areas (Fig. 12.6). At very low intensities a constant dark noise is dominant. In the case of CMOS sensors, the dark noise is generated by switching the different pixels on a common video signal bus. At medium intensities the quantum noise is the dominant noise source, and at very

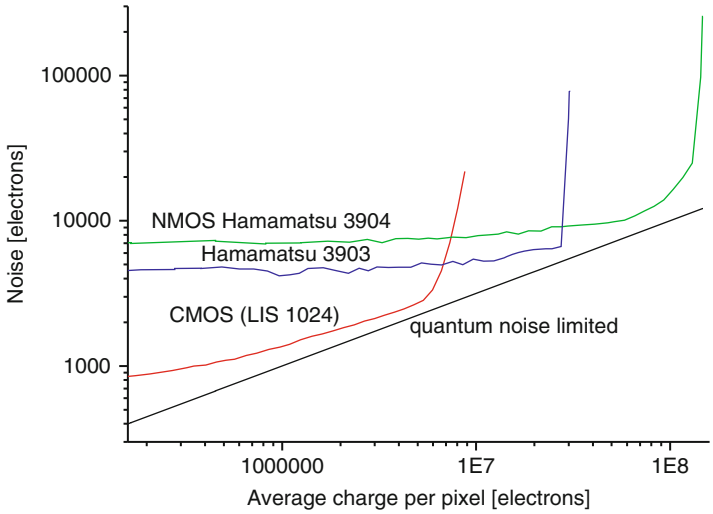

Fig. 12.6 Photon transfer functions (PTF) of different image sensors. The Hamamatsu 3903 and 3904 are passive NMOS diode array detector and the LIS 1024 (Photo Vision Systems) is a CMOS image sensor with an active pixel technology

high intensities close to the FWC, the performance is degraded by nonlinearities of the image sensors.

For useful L-OCT devices the design has to allow for some fluctuations of the reference intensity. Therefore, it is important for an image sensor to have a certain range of intensities in which quantum noise limited performance is possible.

Compared to PIN photodiodes, which are used in TD-OCT, line detectors have a considerably smaller intensity range (an order of magnitude or less) in which they work with optimal performance.

12.3.2 Spatial Resolution and MTF

The spatial resolution of the image sensor has to be high enough to measure the interference pattern with good contrast. The sensitivity of an array detector to a harmonic wave of a given frequency is described by the modulation transfer function (MTF). The MTF can be calculated by the Fourier transformation of the point spread function (PSF), which is the spatial sensitivity distribution of a pixel to a point illumination. For an ideal pixel the PSF would be a rectangular function with the width of the pixel pitch. Correspondingly, the MTF of an ideal sensor would be a sinc function (Fig. 12.7). The modulation would decrease with increasing spatial frequencies of the fringe pattern and reach zero, when the period of the modulation equals the pixel pitch. At higher frequencies the side lobes of the sinc function cause a certain modulation response, which gives an ideal sensor a sensitivity to frequency components higher than the pixel frequency. This would cause additional

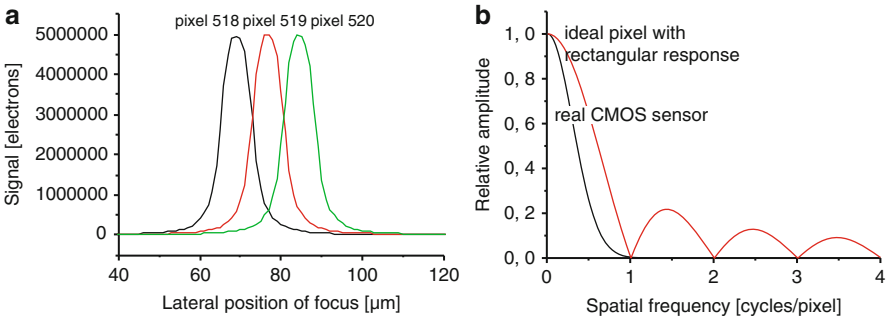

Fig. 12.7 (**a**) Sensitivity distribution of three neighboring pixels measured with a CMOS image sensor (LIS 1024, Photo Vision Systems). The sensor was illuminated with monochromatic light ($\lambda = 830$ nm) focused on the detector by a microscope objective. (**b**) Modulations transfer function (MTF) from calculated the measured data in comparison to the MTF of an image sensor with a rectangular pixel response

interfering signals when a transmission grating attached to the sensor is used for a reduction of the fringe frequency. In reality cross talk between the pixels (see Fig. 12.7a) results in a more or less bell curve-shaped spatial sensitivity of a pixel and therefore also in a bell curve-shaped MTF, which does not extend beyond the pixel frequency. The MTF of real sensors can already drop by almost an order of magnitude toward half of the pixel frequency (Nyquist frequency). Measurements with a contrast close to one are therefore limited to spatial frequencies significantly below that frequency.

12.3.3 Practical Considerations and Choice of the Detector

Price and performance of the detectors favor today linear OCT in the spectral range from the visible down to 1,000 nm, because inexpensive, high performance silicon-based detectors are available for that spectral range. However, IR line detectors were used for FD-OCT [18] and should also be applicable for L-OCT. A small pitch is advantageous for building compact systems. A high aspect ratio of the pixels makes the devices robust against misalignment and a large number of pixels enable a high imaging depth or according to Eq. 12.11 a high maximum SNR. Additionally, large pixel numbers allow to work in a range of high MTF values. However, since usually the pixel readout frequency is limited to a certain value, increasing the number of pixels decreases the A-scan rate.

Three different kinds of detectors (CCD, CMOS, and NMOS) were used for L-OCT [7, 13, 16, 19]. They work on different power levels due to different readout noise and different maximal signal levels. Nearly quantum noise limited performance was only demonstrated with CMOS and CCD detectors. NMOS diode array with a photodiode and a storing capacitor at each pixel have a relatively high readout (switching) noise of 5,000–10,000 electrons and large pixel to pixel

variation, which prevent shot noise limited performance despite of the high full well capacity of 10^7–10^8 electrons (Fig. 12.6).

CMOS sensors have active pixels with an integrated readout amplifier, which reduces the readout noise to less than 1,000 electrons. The saturation level lies between that of CCD and NMOS diode array. Nearly shot noise limited performance over one order of magnitude is possible with these characteristics (Fig. 12.6).

CCD detectors which shift the trapped photogenerated charges from the pixels to an optimized readout amplifier can reach readout noise and pixel response nonuniformity (PRNU) down to a few tens of electrons. With values between 10^5 and 10^6 electrons, the full well capacity of CCD detectors is quite small compared to CMOS and NMOS diode arrays. Two-dimensional CCD detectors provide increased FWC by binning or the simultaneous acquisition of complete B-scan images [12, 14].

Usually, OCT uses superluminescent diodes with a power of a few mW of which due to losses at the beam splitter and other optical components, typically only 100 μW fall onto the detector. This corresponds at 800 nm to 4×10^{14} photons per second. With a quantum efficiency of 25 % and a line detector with 1,000 pixel, 10^{11} electrons per second and pixel are generated. Depending on the FWC of the detector, scan times between 1 μs and 1 ms provide an optimal exposure. CCD detectors are therefore suited for limited sample exposure and high-speed applications, whereas CMOS sensors are very attractive at lower and high readout frequencies offering shot noise performance over one order of magnitude and high SNR.

A uniform illumination of an array detector without intensity losses is difficult, because the spatially coherent radiation, which has to be used in OCT, has usually a Gaussian intensity profile. Either the illumination at the rim of the detector is smaller than at the central part or photons from the sample have to be discarded. In both cases the sensitivity is reduced.

12.3.4 Signal Processing

In TD-OCT, the output of the photodetector is either demodulated by analog electronics or sampled by a fast A/D converter. In principle, both analog and digital processing of the output of the array detector are also possible for L-OCT. However, up to now only a direct digitalization with a software-based demodulation was demonstrated.

The standard procedure for signal processing in L-OCT, which consists of band-pass filtering, rectification, and low-pass filtering, is shown in Fig. 12.8. As an example, the digitized signal of a single glass-air interface is depicted in the leftmost graph. The Gaussian beam profile causes the intensity distribution to drop toward the left most and rightmost pixel to about a third of the maximum value. The fringe pattern caused by the object is visible around pixel number 500.

In a first processing step, the offset error is subtracted for every pixel. Following the A-scan is divided by a calibration dataset to compensate for the different gains and exposure of the pixels. The graph in the middle of Fig. 12.8 shows the normalized signal. In the next step, excess noise is removed by digital band-pass

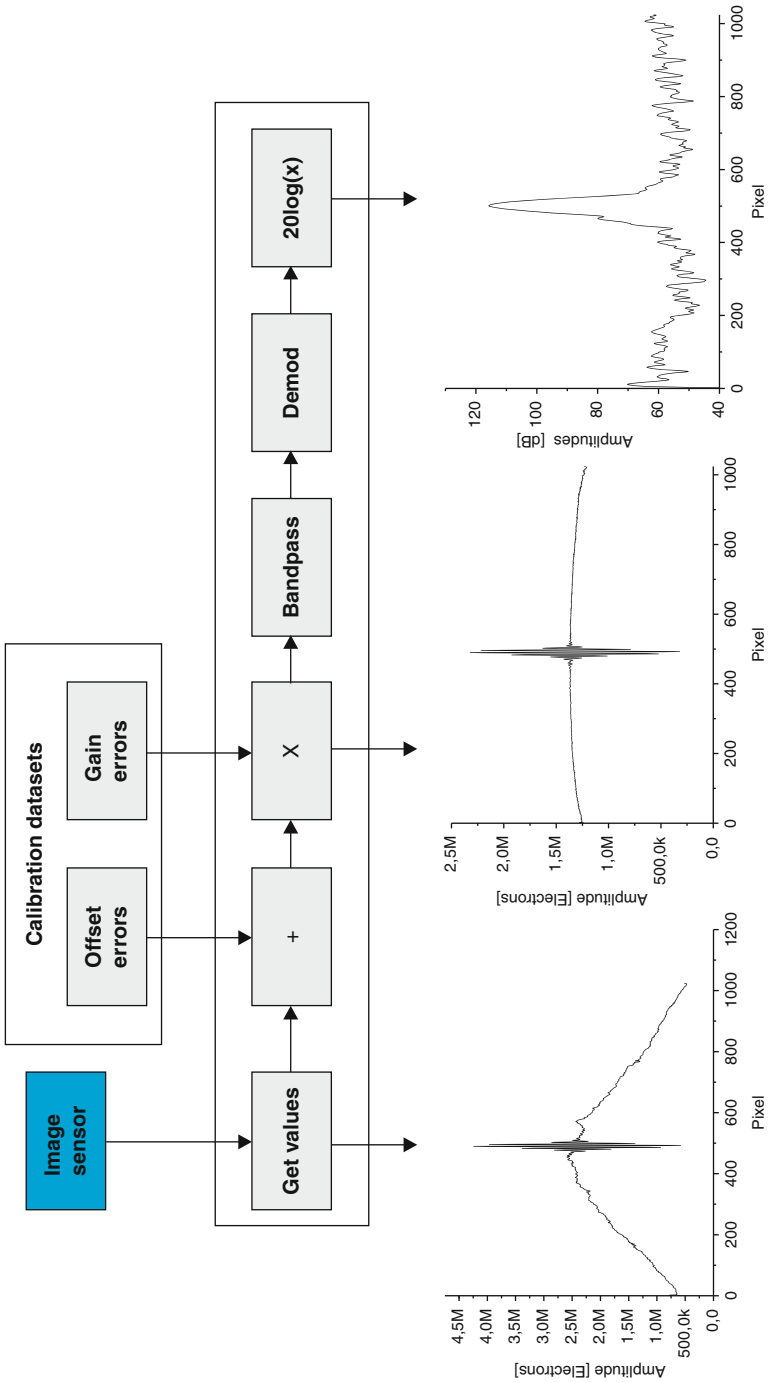

Fig. 12.8 Signal processing in L-OCT

filtering. The center frequency f_c of the filter is adjusted to the fringe frequency of the interference pattern. The demodulation is either done by taking the absolute value (rectification) and averaging (low-pass filtering) or by directly sampling of the signal at fixed intervals (e.g., after each $\lambda/3$). The demodulated amplitude is depicted on a logarithmic scale in the rightmost graph in Fig. 12.8. The noise floor which is in the order of 50 dB in the center of the image sensor increases toward the right most and leftmost pixel by about 10 dB, because at the edges the SNR is reduced by the significant smaller light intensity from the sample. Correction to a constant amplitude over the sensor area causes the increased noise level.

With a reflection grating in Littrow configuration, which replaces the reference mirror of a Michelson interferometer, OCT imaging at zero carrier frequency was demonstrated [15]. The phase changes, which are needed for the demodulation of the interference signal, were generated either by moving the grating by a piezo transducer or by lateral gradients in the phase when the sample was scanned.

12.4 Examples of L-OCT Systems

Only a few L-OCT systems were described up to now. As far as we know, the first system built was based on an NMOS diode array with 512 pixels and provided a ranging depth of only 70 μm [19]. The interferometer was built with a fiber coupler, and the two output fibers were positioned side by side in a certain distance from the detector (Fig. 12.9). One fiber carried the radiation from the reference arm, the other the radiation from the sample. Similar to Young's double slit experiment, a spatially varying interference pattern with a nearly constant frequency was formed on the detector. This setup demonstrated that L-OCT systems can be built of a few simple optical components: superluminescence diode, fiber coupler, cylindrical lens, and detector array. The performance of the system was demonstrated by scanning the surface of an MEMS acceleration sensor (Fig. 12.10). Here the required imaging depth was less than 70 μm, and the advantage of stable phase measurements due to the lack of moving parts was exploited for high-resolution profiling. The reflection signal from a surface consisted only of the coherence peak. By either calculating the centroid or fitting a Gaussian curve to the measured data, the position of the surface was determined with submicrometer resolution though the coherence length was 13 μm. Additionally, the phase of the OCT signal which is sampled together with the amplitudes could be used in order to increase the resolution.

With a similar interferometer design and a 7,926 element CCD image sensor, Hauger et al. demonstrated for the first time L-OCT images of biological tissue. They verified theoretical predictions of the fringe frequency and the depth resolution and showed with 0.6 mW illumination on the sample and 200 Hz A-scan rate images of porcine brain and heart in vitro, as well as human skin in vivo. Quantitative numbers on SNR and sensitivity were not given.

L-OCT with 1.1 mm measuring range was demonstrated with a transmission mask attached in front of a 1,024 pixel CMOS sensor [7]. Due to losses caused by the mask and the common path interferometer design, which introduced an additional

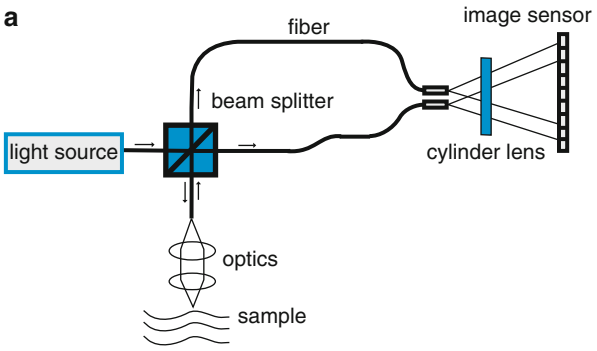

Fig. 12.9 (**a**) Simple setup for an L-OCT system, based on Young's double slit experiment. (**b**) Image of the main optical components

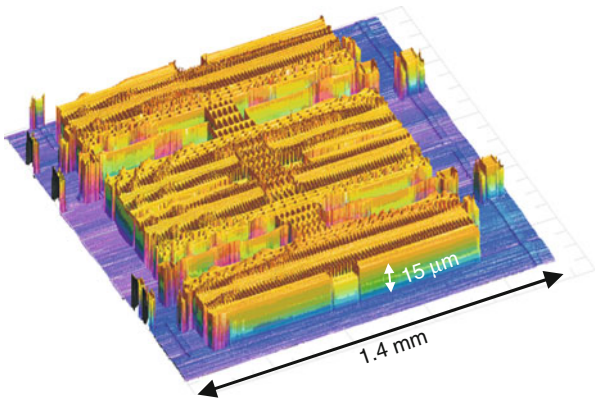

Fig. 12.10 Surface structure of an MEMS technology acceleration sensor measured by linear OCT (*L-OCT*)

incoherent background, a sensitivity below 61 dB was attained and only images of surface structures were possible with good quality. The common path interferometer enabled a flexible system with a high phase stability which is well suited for profilometry. However, the sensitivity was too low for imaging tissues with satisfactory quality.

Using the same CMOS sensor with a phase grating for the reduction of the fringe frequency and a modified Mach-Zehnder interferometer, a sensitivity of 80 dB was

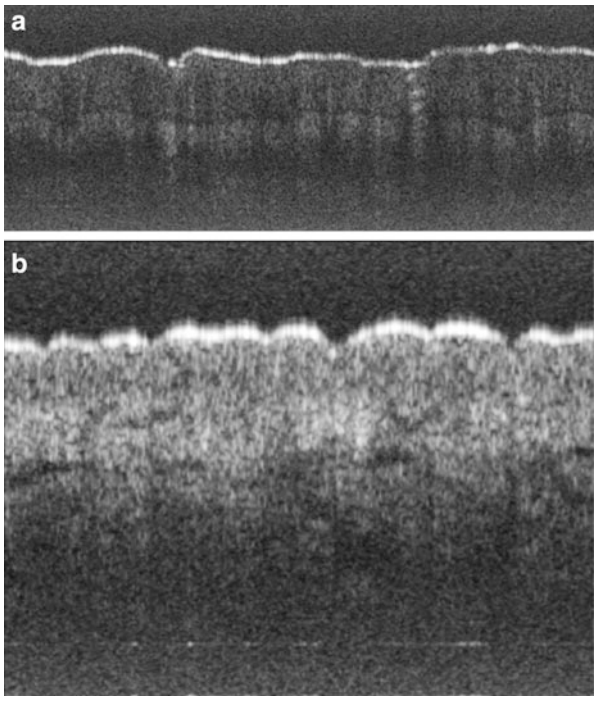

Fig. 12.11 In vivo images of human skin acquired by linear OCT (*L-OCT*) with a 1,024 pixel CMOS sensor and a phase grating at 1,200 A-scans per second were acquired. (**a**) Skin of the thumb with visible boundary between horny layer and dermis. Ducts of sweat glands are visible in the right half of the B-scan. The image dimensions were 940 µm × 4 mm. (**b**) B-scan image of the skin of the forearm. The boundary between dermis and epidermis and single vessels were observed. Measured range was 940 µm × 2 mm

possible [13]. This allowed imaging of skin at 1.2 kHz A-scan rate with good quality (Fig. 12.11). With increased output from the SLD, even scan rates of more than 5 kHz should be possible with this detector. The image quality was comparable to standard TD-OCTs which usually work at lower scan rates of 20–200 Hz [20, 21]. However, with an FD-OCT system based on the same detector, a significantly better image quality was possible [22] due to the fundamentally higher SNR of OCT systems working in the spectral domain.

With high-speed line cameras and 3 mW exposure to the tissue at a wavelength of 1,300 nm, imaging faster than video rate is possible [15]. With the variant of L-OCT, which used a Michelson interferometer with a reflection grating and a fast InGaAs-camera, images of human skin were demonstrated at 94 frame/s corresponding to 47,000 kHz A-scans rate. A sensitivity of 93 dB was reached. Structures of the skin near the nail fold were visible 1 mm deep.

12.5 Extensions of Linear OCT

12.5.1 Discontinuous Depth Range

Some applications require a long measurement range, which is essentially discontinuous. For example, for the measurement of the positions of the refractive surfaces of the anterior part of the eye and the retina, an imaging depth is needed, which is

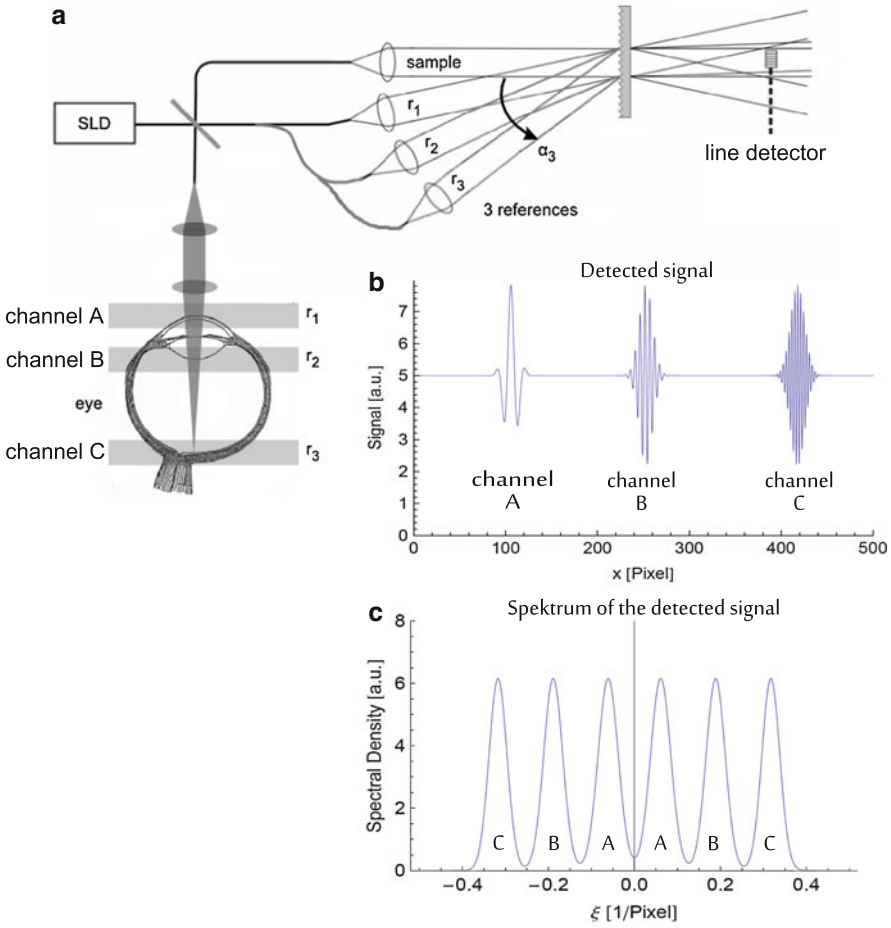

Fig. 12.12 Principle of multiple-reference linear OCT (*MRL-OCT*). Several reference waves interfere with the sample radiation at different angles α_i (**a**). The interference signals of the channels (here **a**, **b**, and **c**) are separated by different carrier frequency (**b**). The *angles* of the reference beams define the carrier frequencies (**c**)

difficult to achieve with Fourier domain OCT in one continuous A-scan, because either a spectrometer with a very high resolution or a tunable laser with a very high coherence is needed. With TD-OCT a large depth range is possible, but the signal-to-noise ratio (SNR) scales directly with the ratio between depth resolution and depth range [23]. A long imaging depth will significantly decrease the SNR.

L-OCT with a discontinuous measurement range is possible by using multiple-reference waves with different path lengths (Fig. 12.12a). An unambiguous discrimination of the information from the depth ranges is possible by introducing different carrier frequencies in the interference patterns, which result from different angles between the sample beam and the reference beams (Fig. 12.12b, c).

In multiple-reference linear OCT (MRL-OCT), the sample wave E_S interferes with n reference waves E_i. The intensity distribution I, which is measured by the line detector, then consists of the reference and sample intensity ($R_i = |E_i|^2$ and $S = |E_i|^2$), the interference of the complex sample wave with the n reference waves ($I_{si} = E_s E_i^* + E_s^* E_i$), and the $n(n-1)/2$ mutual interferences between the different reference waves ($I_{ij} = E_i E_j^* + E_i^* E_j$).

$$\begin{aligned} I &= \left(E_s + \sum E_i\right)\left(E_s^* + \sum E_i^*\right) \\ &= S + \sum_{i=1}^{n} R_i + \sum_{i=1}^{n} I_{si} + \sum_{i<j}^{n} \sum I_{ij} \end{aligned} \tag{12.14}$$

Different angles α_i of the reference beams result in different carrier frequencies which can be used to record the sample radiation in n different channels. The zero position of each channel can be adjusted individually by the length of the delays z_i of the respective reference beams. It can be shown that the width of the channels is approximately given by reciprocal depth resolution of L-OCT, which itself is given by spectral width δk of the OCT light source. By choosing an appropriate grating frequency and suitable angles, the usable bandwidth of the line detector, which is limited according to the Nyquist criterion to 0.5 per pixel distance, can be filled with several channels (Fig. 12.12c). The frequency distance of the channels depends on the acceptable cross talk (i.e., frequency overlap) and a proper sampling of the envelope of the coherence function γ. The reference waves will also interfere with each other on the detector. Combinations of angles and path length differences between the reference beams exist so that all signals are separated, either by the carrier frequency or by placing the interference outside the measurement range.

With multiple-reference beams each channel will experience an additional noise contribution of the noninterfering reference arm intensities, which will increase the quantum noise without increasing modulation by the signal. For equal reference intensity R_i, the SNR is reduced by the number n of reference arms:

$$SNR_{MRL-OCT} = \frac{SNR_{TD-OCT}}{n} \propto \frac{n_s}{n} \frac{\delta z}{\Delta z}, \tag{12.15}$$

where n_s is the number of photons detected from a reflecting structure during one A-scan. Though in each channel the SNR is reduced by the number of channels, MRL-OCT can cover a depth range of approximately $n\ \Delta z$. Measuring this depth range with only one reference arm would result in a similar SNR. The use of several reference arms in MRL-OCT does not systematically decrease nor increase the SNR compared to L-OCT. For a proof of concept, an L-OCT with a phase grating for fringe frequency reduction [13] was amended by a second reference arm (Fig. 12.13a). The sample light was collimated to a parallel beam and then focused by a further achromat. A glass plate, which was placed in the parallel sample beam, and a mirror in the focus of the second achromat served as two objects which were separated by 69 mm. By the two reference arms two carrier frequencies (0.063 per

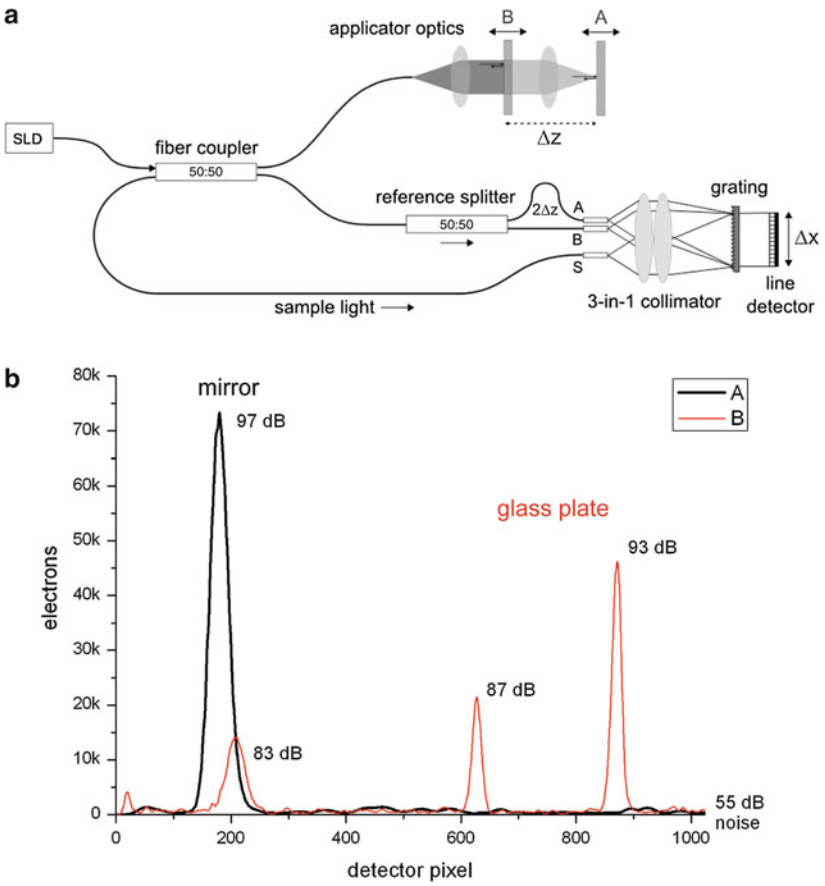

Fig. 12.13 (**a**) Setup of an MRL-OCT with two reference arms. (**b**) Demodulated signals when imaging a mirror in channel A and glass plate with two surface in channel B

pixel and 0.19 per pixel) are introduced, which defined the channels A and B. The mirror signal in channel A was recorded with an SNR of 42 dB. In channel B both surface reflections of the glass plate were measured with an SNR of 32 dB and 38 dB, respectively. The cross-channel rejection was about 35 dB in channel A but only 15 dB in channel B. MRL-OCT with multiple reference beams offers a simple and robust approach for parallel OCT measurements in different depths. However, a certain cross talk has to be expected.

12.5.2 Line-Field Linear OCT

The main advantage of L-OCT is the simplicity of the setup. No moving parts are needed for the depth scan. A line-field L-OCT, i.e., an L-OCT which measures

a B-scan without scanning does further simplify the device. On a two-dimensional camera, one axis can be used for L-OCT and the other axis for imaging one coordinate of the sample. A first device was demonstrated by Zeylikovich and Alfano [12]. Here a reflection grating was used in a Mach-Zehnder type interferometer to completely remove the fringe frequency. The thickness of the fiber cladding was measured. Later a simplified version using a Michelson interferometer was demonstrated [14] and applied to biological tissues [24]. In-vivo measurements were not demonstrated possibly because of fringe washout caused by the long exposure time of the camera. With the introduction an ultrahigh-speed CMOS camera, in-vivo images of human skin became possible [25]. With a zoom lens and by varying the diffraction order of the grating, lateral and axial field of view were adjustable [26].

12.6 Conclusion

Linear OCT which works without moving parts is in principle able to give a similar image quality than TD-OCT. Disadvantages are a higher sensitivity to movements and some signal losses at the edges of the detector due to the Gaussian beam profiles, with which the detector is illuminated. The progress in sensor technology and the control of the fringe frequency by a phase grating allowed to build a compact L-OCT system which can be used for imaging scattering tissues with a quality comparable to that of TD-OCT, avoiding the problems of a scanning optical delay line. Simple and rugged design, fast acquisition speed, and stable phase detection are advantages over TD-OCT. These properties are also shared by FD-OCT which offers a significantly higher sensitivity. However, the lack of interfering autocorrelation signals, a simpler signal evaluation without Fourier transform, and a less complex optical layout, which does not need high-quality optics to achieve diffraction limited resolution of the spectrometer, are advantages over FD-OCT.

L-OCT systems might be the better choice in cases where the superior SNR of FD-OCT is not needed and complexity and price are important design parameters. This may be in applications with low to moderate resolution where a stable and simple system without the ultimate dynamic range is needed. L-OCT may find its place in profilometry and measurements of distances in low scattering technical and biological objects.

13.1 Introduction

The quality of images obtained with optical coherence tomography (OCT), like many other imaging modalities, can be enhanced by using signal processing to numerically infer properties of the object being studied. While a great deal of insight can be gained by understanding OCT intuitively as a range-finding mechanism, more sophisticated analysis can reveal additional detail and features to the extent data quality allows. To maximize the utility of the data, signal processing is used to reject noise and to ensure the resulting image conforms to known properties of the object. We briefly summarize concepts of inference in signal processing. These ideas are applied when reviewing and examining methods of reducing noise, improving resolution through deconvolution, reducing speckle, correcting for material dispersion and OCT system imperfections, and deblurring the defocusing effects outside of the depth-of-field of the OCT instrument.

To understand the rationale for signal processing, we consider the process of imaging with OCT. The goal of OCT imaging is to determine which one of many possible objects are being imaged. In this context, an "object" does not refer simply to an entire class of objects, such as tadpoles or retinas. Rather, an object refers to all possible variations on a type of object that could be plausibly expected to be imaged. For example, for tadpoles, this would include all tadpoles, of all sizes, shapes, relative body dimensions, etc., that one would expect to find. All possible objects are those mutually distinguishable by the operator and would not be rejected as impossible or overly unlikely to be observed by the operator.

When an object is measured by an OCT instrument, the OCT instrument produces data. The data is all of the information learned about the object using the instrument. All measurements, including those of OCT, are subject to noise and uncertainty. Therefore, the observation of a given object may produce one of many possible data sets because of randomness introduced by the measurement process. In particular, two different objects may randomly produce the same data; so based on the data alone, it is not possible to specify incontrovertibly that the data was observed from any of the objects that could have produced that data.

To represent the object in a way that the operator can perceive visually, the data is transformed using signal processing into an image. An image ideally relays enough information about the object to the operator to distinguish which objects are consistent with the data. Images are typically employed because the human visual system can more readily assimilate and process the large amount of data as an image rather than as raw samples or other descriptions of the data. A human operator can also be trained to interpret the data in a more flexible and versatile manner than most automated data processing methods.

In general, there will be a multitude of similar images that correspond to physical objects that could be explained by the data. The image produced by signal processing should at the very least be plausible given what is known about the object and ideally would be a unique estimate given the data. Often, signal processing is neglected or grossly simplified because the resultant images are similar enough to a plausible image to satisfy the operator. However, when there is a large amount of uncertainty or noise or there is specific information about the object that one wishes to incorporate into the image, the methods of signal processing must be carefully considered.

As a simple example of inference for a particular set of objects, the measured data, and their corresponding images, consider Fig. 13.1. In this case, we know that we have only one of two possible objects, either the smiling tadpole or the frowning tadpole. Because of noise, the data measured for each of the tadpoles will not map onto a unique data set. Rather, some data sets may be observed for only smiling or frowning tadpoles, and some may be observed for either object. Each of the data sets will be processed into an image, which is shown on the right side of Fig. 13.1. While being noisy, two of the images will correspond to one of the objects. However, one of the images is ambiguous and could be observed for either tadpole.

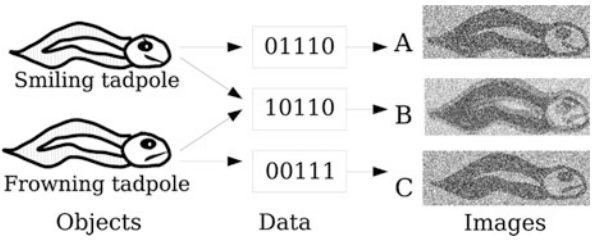

Fig. 13.1 A simple object, data, and image combination to illustrate the process of inference

Signal processing ideally presents the data, often in the form of an image, to the operator so that there will be the minimal ambiguity inferring which object is present. The process of inference can be seen as a mapping from data outcomes to the most likely object that the data could have been observed for.

Unfortunately, in practice, we usually do not have the possible objects narrowed down to two possibilities, and there are a nearly unlimited number of data observations one could make for these objects. While a rigorous enumeration of all possibilities is almost always not practical or even possible, we can still specify the general properties of what is known about the object and tailor the signal processing to produce images of these objects consistent with the data and the prior knowledge of the object. Within the limits of the available computational devices and methods, signal processing can help relieve the operator of some of the burden of recognizing and classifying the image by removing artifacts and noise in the image that is not consistent with what the object is believed to be.

There are two properties that a useful signal processing method must have. First, a method must be stable. This means that very small changes in the data should not produce large changes in the reconstructed image or ultimately in the object that is believed to correspond to the data. This is necessary so that the image is robust to the variations in the data produced by noise and measurement error. Also, there should be a unique image estimate corresponding to a particular data set. This is so that the operator is not confronted with one of many possibly very different images given the same data. Both of these problems can be addressed partially by the use of regularization. Regularization is a constraint on the image that specifies aspects of the image that cannot be determined by the data. For example, a common regularization method penalizes the energy of an image. If an OCT system is designed to measure an object using wavelengths between 1,250 and 1,350 nm, the instrument does not provide information about the scattering of the object outside of this bandwidth. By minimizing the energy of the image, the estimate of the scattering of the object outside the bandwidth of the OCT system, say between 500 and 600 nm, is estimated to be zero. This is a reasonable assumption and one that is commonly made (implicitly or explicitly) when analyzing OCT data. By examining the stability, uniqueness, and the properties of an image that a given signal processing algorithm assumes, one can better understand whether a given signal processing algorithm will be useful in a specific situation.

13.2 Speckle Reduction and Signal Improvement

Speckle is one of the most distracting artifacts of OCT images (and other coherent ranging techniques such as ultrasound). It is often difficult to separate the features that are caused by speckle, and those of other features of interest. However, the phenomenon of speckle is what enables methods such as OCT to be useful. Because scatterers tend to be randomly placed in most objects, every frequency band in which the object can be probed contains some useful details of the object. This is why most coherent ranging techniques are useful in practice. If scatterers were not randomly placed so that speckle did not occur, it is possible that the object may not yield any detail whatsoever in the frequency band in which it is being probed (an example is when one images a Bragg grating with a resonant frequency outside the probed bandwidth). Unfortunately, if one is distinguishing detail at the resolution limit of the instrument, it is likely that it will be modulated by speckle and therefore appear very noisy.

Speckle occurs when the scatterers are randomly placed, and their backscattered reflections each superimposes with a random phase and amplitude in the OCT interferogram. This can be visualized as a "random walk" of two-dimensional vectors [1], each vector representing the complex-valued reflectance of each unresolved scatterer. The sum of these vectors is approximated by a complex-Gaussian random variable [1], which has a length given by a Rayleigh probability distribution. Note that this implies that the magnitude squared of the vector has an exponential or Boltzmann probability distribution. When multiple polarizations of return signal are accounted for, the magnitude squared of the reflectance conforms more to a gamma distribution [2, 3].

This persistent problem has been addressed by several different approaches. One method [4], the sticks method adapted from ultrasound, was used to despeckle coronary artery images. This method fits short line segments of various orientations to features in the image to approximate the boundaries of the vessel. Another method [5] applies the rotating kernel transformation to coronary images, which matches edges in the image to a set of binary-valued two-dimensional square kernels to enhance the edges and suppress speckle noise. A promising technique [6] uses an undecimated wavelet filter transformation on the logarithm of the magnitude of the OCT image to remove the uncorrelated speckle features but retain the scale-invariant features that produce the largest wavelet coefficients. This method enhances the discrimination of noise by exploiting the correlations between wavelet coefficients at multiple scales due to object features. The logarithm of the magnitude is processed because speckle can be modeled as multiplicative noise to the image, which becomes additive noise once the logarithm is taken. Additionally, a multidimensional wavelet method utilizes correlations in time-series data to suppress noise via decorrelation [7]. An example of denoising using this technique is shown in Fig. 13.2. A similar method, except based on the curvelets transform, has also been demonstrated as shown in Fig. 13.3 [8, 9]. Another speckle suppression method [10] simultaneously constrains the magnitude to match a blurred version of the image, while retaining the detail by constraining the image to fit

Depth-resolved line-plots (**c**) along the vertical dashed lines in (**a** and **b**) illustrate speckle reduction, making features more distinguishable (*white arrows*) (Images used with permission from [8])

the data in a least-squares sense. The blurred OCT image acts as a "default" image that is used to assign the magnitude of the data where the data leaves the magnitude of the reconstructed image unspecified. The actual constraint used is a relative entropy constraint called the I-divergence [11] between the default image and the reconstructed image.

One straightforward way to remove the effects of speckle is to incorporate several images into a single image [2, 3]. The speckle effect occurs because most objects have features at length scales smaller than the smallest resolvable area of an OCT instrument. Speckle is caused by the interference between randomly placed scatterers that are individually unresolvable due to the finite bandwidth and focused spot size of the OCT instrument. In OCT images, speckle appears as a random modulation to the demodulated amplitude image due to the interference between the scattered waves from these unresolved scatterers. Unfortunately, in practice, the features caused by the random interference of speckle and those of other features of interest are frequently indistinguishable.

Two or more images of the same object that does not itself change between the image acquisition sequences will exhibit identical speckle patterns even if the noise is independent between the images. Therefore, if these images are averaged together, the speckle pattern will remain even if the signal-to-noise ratio is improved. To reduce speckle, the averaged images must each be slightly different by probing different coherent superpositions of the sub-resolution scatterers that produce the speckle. To achieve this, one may employ a diversity mechanism intended to vary the phase of the interference between the sub-resolution scatterers. The diversity mechanism ideally produces an independent amplitude modulation due to speckle at each resolvable point in each image. By measuring different combinations of interference between the sub-resolution scatterers, the density of scatterers in the image can be better estimated by averaging together the randomized amplitudes of the constituent images.

There are four main diversity methods used to reduce speckle. Frequency compounding [12] merges the images of the same object taken in two different optical frequency bands. Most particles will scatter at wavelengths in the near infrared (NIR). By choosing two different frequency bands in the NIR, the phase shift of the interference between scatterers is altered to produce two different speckle patterns in each band. Because the speckle patterns in both frequency bands are largely uncorrelated, compounding them significantly decreased the speckle in the image. Polarization diversity [13] measures the same object with orthogonal polarizations with the goal of producing different speckle patterns for each polarization that can be averaged. Angular compounding [14–16] measures the sample with various tilts of the axial scan relative to the transverse scan direction, rather than always having the axially focused beam normal to the transverse scanning direction. By illuminating the scatterers in the object at different angles, different combinations of the scatterers are measured to change the speckle pattern. Finally, spatial compounding [17] reduces speckle noise by averaging together various parts of an image, which is helpful when the object properties are uniform such as a sample of human skin. In some recent methods, an

increasing strain is applied to the sample, which effectively decorrelates the speckle between successive B-scans. Incoherent averaging of these decorrelated images reduces the speckle noise [18, 19]. In another method, image registration followed by averaging of multiple B-scans is used to reduce speckle [20].

Similar signal processing methods have been developed to remove and suppress image artifacts commonly seen in spectral-domain OCT systems. Fixed pattern noise artifacts which show up in OCT images as horizontal lines are the most prominent. These artifacts can come from the non-flatness of the reference spectrum, spectral structure in the source spectrum, and optical interferences from spurious back-reflections [21]. These artifacts can be removed by measuring the reference spectrum in the absence of the sample and subtracting it from the measured spectrum. The reference spectrum can be estimated from the acquired data itself. A common method is to average several A-scans, and due to the sample inhomogeneity, the random phase distribution would wash out the fringe pattern leaving behind the reference spectrum. Subsequently, each interferometric spectrum is subtracted by the reference spectrum to remove the fixed-pattern noise. However, a small number of high-amplitude back-reflections mainly due to the air–tissue interface can cause errors in estimating the mean reference spectrum [21, 22]. A number of alternative approaches to overcome this limitation of the mean-spectrum subtraction method have been proposed. In one technique called the minimum-variance mean-line subtraction, each horizontal line is divided into segments and the mean value corresponding to the segment having the minimum variance is assigned to a given axial position. As the segment containing high-amplitude reflection points would exhibit higher variances, this method can potentially give more robust estimates [21, 23]. Another method is based on the median estimator which is known to be less sensitive to high-amplitude data points. In this method, a complex median value is calculated for each axial position and this complex median A-line is then subtracted from each of the A-lines to remove the fixed-pattern noise artifacts [21–23].

One of the simplest and most intuitive ways in which images can be enhanced is to take several images of the same object and incorporate these into a single image with superior resolution and/or signal-to-noise ratio to any of the individual images. The resultant denoised image is often the average of the samples of the individual images. There are two reasons that signal averaging is done to OCT images. This first is to improve the signal-to-noise ratio of the resultant image. If one can assume that the noise component of each of the constituent images is independent of each other, then averaging together several images of the same object (which are ideally identical except for different realizations of added noise), the average of the images will converge to an image with a lower variance than the constituent images. This averaging can be done on the interferograms of the OCT axial scans or more often is performed on the demodulated gray-scale image. While this method works, the penalty is a slower data acquisition which is often not acceptable in practice.

Recent attention has been given to compressive sampling (CS) strategies for image recovery in medical sensors [24, 25]. The idea behind CS is to exploit an

aspect of sparsity in a transform domain where fewer measurements can be used to recover missing data with higher accuracy. Of course, this is reliant on the accuracy of your choice of transform domain. This means that the choice of sparse representation is a key to recovering good image quality. Some authors have described a method that exploits the sparsity in point-like scattering within an A-mode OCT scan [26, 27]. By using the fact that the frequency domain representation of a sparse numbers of point-scatterers is overdetermined, fewer measurements of the Fourier signal space can be used to form a reconstruction. Other methods rely on the spatial sampling as the sparsity constraint [28, 29]. For instance, if one intends to reconstruct an object with three to five times oversampling, then the redundancy in the measurements can be exploited by using CS. That is, fewer measurements can be used to reconstruct the object to full oversampled resolution. This method has been demonstrated with both B-mode and 3-D imaging in real-time systems [28]. One study evaluated the performance of different transform domains for recovery of OCT volumes from sparse data sets [30]. The Fourier basis, wavelet basis, Dirac basis, discrete-cosine basis (DCT), and surfacelet basis are examples of common bases examined. Another study showed an approach for using a modified-CS algorithm to increase the local contrast, the signal-to-noise ratio (SNR), and the contrast-to-noise ratio (CNR) [31]. Further quality improvements are gained from averaging the reconstructions.

13.3 Deconvolution and Spectral Shaping

Another common goal of post-processing is to achieve the best resolution and highest signal-to-noise ratio that the data will allow. In OCT, the primary limiting factor for axial resolution is the bandwidth of the source, and the limiting factor for transverse resolution is the focused spot size. The process of deconvolution attempts to extrapolate somewhat more detail from the data limited by the signal-to-noise ratio of the data. In addition, deconvolution can reject noise and remove sidelobes from the image.

To understand what deconvolution does, we consider Fig. 13.4 which contains the interferogram of an axial scan of a reflection off of a glass–air interface in an OCT system. This interface between glass and air is extremely abrupt and so is much sharper than the features that can be resolved with a typical OCT system. The length of the interferogram in this case is limited by the bandwidth of the source and not by the detail of the object.

Because we know this interferogram corresponds to a single reflection, we may decide to infer the location and the position of the surface as the peak of the interferogram. The error in the estimate of the position of the surface is potentially much less than that suggested by the width of the interferogram, because we already have knowledge that there is only one reflector. By using a priori knowledge about the object and the optical source spectrum, scatterers can be better resolved than would be suggested by the interferogram width alone.

If there are multiple reflections, each of the reflections produces an interference pattern that is superimposed on the interferogram. The mathematical operation that

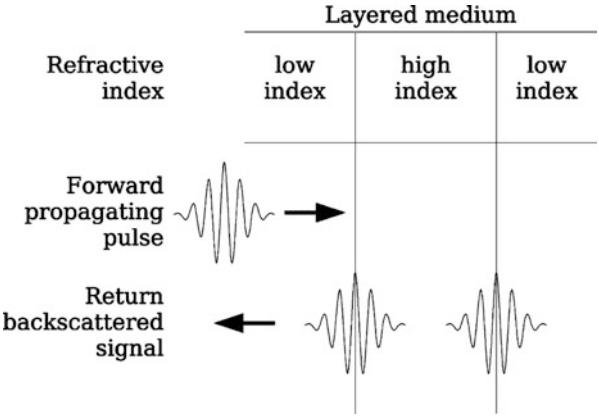

Fig. 13.4 A diagram showing how an optical pulse reflects off of interfaces between regions of varying indices of refraction. Even though the interfaces are sharp, the reflections are all copies of the original pulse and therefore the length of the pulse

finds the interferogram caused by a set of reflectors by superimposing the interference patterns for each reflector is called convolution. Therefore, the operation of finding the reflectors based on the interferogram is called deconvolution. Because of the relatively wide width of the interferograms and noise, deconvolution is necessarily an imperfect process where the reflectors corresponding to a particular interferogram cannot be recovered with certainty.

A simple way of locating reflectors in an OCT image is based on the CLEAN algorithm [32, 33]. In this algorithm, one attempts to locate the highest reflectivity scatterer in the data by scanning for the largest magnitude interference pattern. The position and magnitude of this interference pattern is used to infer the location of the scatterer in the final image, and then the interference pattern due to the scatterer is subtracted from the data. This process is repeated on the data to successively infer the positions and magnitudes of weaker scatterers as they are subtracted from the data. Because this method identifies individual point scatterers, it tends to work best on objects with discrete particles. However, many biological specimens are not similar to a collection of point-like reflectors. In one method, it is assumed that the signal at each point is superimposed by the sidelobes of other points in the same A-scan. A method to suppress the sidelobes called gradual iterative subtraction is implemented by iteratively subtracting the influence of the sidelobes from other points in an A-scan [34].

Rather than determining the position and magnitude of every point scatterer in the sample, most deconvolution methods produce an image where the features appear more point-like. This is done by applying a post-processing filter to concentrate the signal of a scatterer around its center position on the interferogram. Highly nonuniform spectra will cause the image of a point scatterer to have many and large-amplitude sidelobes. Sources such as ultrahigh numerical aperture fibers [35, 36] and microstructured fibers [37, 38] produce a large bandwidth, but the sidelobes caused by these sources can severely degrade the practically achievable resolution. Deconvolution methods help improve resolution, reject noise outside of the laser spectrum, and make the resolution more robust to variations in the source spectrum.

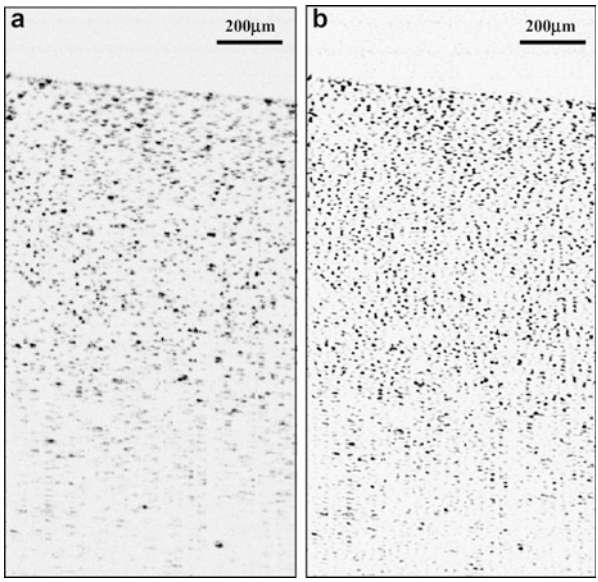

Fig. 13.5 Deconvolution using the Richardson–Lucy algorithm on a tissue phantom. (**a**) Original and (**b**) Richardson–Lucy corrected image (Images used with permission from [46])

To apply these methods, the interferograms themselves [39] need to be sampled rather than just the demodulated envelope. A method of deconvolution of the demodulated magnitude data [40] has been achieved, but may have problems accounting for interference effects between scatterers. Many OCT systems provide only demodulated interference fringes. This method uses a positivity constraint to somewhat overcome the lack of phase information. The benefit of directly processing the interferograms is that they are typically linear in the scattering amplitude of the sample (in the weak scattering approximation). One of the simplest methods [41] infers what the image would have looked like if it was taken with a low-sidelobe Gaussian source rather than the actual source used. This method effectively numerically "reshapes" the spectral envelope of the laser to become Gaussian-like which helps reduce sidelobes, perhaps at the expense of increasing noise. Other methods [42] apply a linear filter that inverts the source spectrum shape, to attempt to make the numerically reshaped source spectrum uniform. Another method applies a filter that provides the linear least-squares estimate of the sample scattering [43], taking into account the quantum efficiency and photon noise of photodetection. A further method [44] modifies this result to reduce sidelobes. Additional methods use deconvolution in conjunction with dispersion management to minimize the point-scatterer image size [45]. Another paper describes regularized inversion methods for deconvolution that mitigate the depth-dependent blurring of the transverse point spread function caused by the focusing optics [46]. An example is shown in Fig. 13.5 where after the deconvolution operation, the point scatterers in the image are sharper and better defined. In a similar method described, a set of Gaussian PSFs of different spot sizes were used to deconvolve defocused images using the Richardson–Lucy algorithm. The Richardson–Lucy algorithm is based on

the maximum-likelihood solution in regard to Poisson statistical data. One study introduced a method to improve the resolution on OCT system by step-frequency encoding [47]. In this method, two A-scans of slightly different frequencies are added together resulting in a beating pattern which reduces the FWHM of the central lobe in the interferograms. However, the beating also introduces sidelobes in the interferograms which can lead to artifacts in the reconstructed images [47].

While many of these methods successfully mitigate the blurring of OCT, a full formalized quantitative deconvolution of the focusing optics is solved in interferometric synthetic aperture microscopy (ISAM) [48]; the details of which can be found in ▶ Chap. 31, "Interferometric Synthetic Aperture Microscopy (ISAM)".

13.4 Dispersion Correction

Apart from speckle, the chromatic dispersion of the OCT signal is one of the most image-degrading distortions. Dispersion appears in OCT images as the blurring and interference of adjacent reflectors. A signal pulse propagating through a dispersive medium tends to develop a "chirp," so that the signal increases or decreases in frequency as it passes a particular point in the medium. This changes a formerly sharp point in an image into a blurred region within an axial scan. Dispersion degrades the axial resolution because of this blurring. However, dispersion can be corrected. A simple way to do this is to insert a dispersive medium into the reference arm to balance the dispersion of the sample signal. However, it is desirable to correct dispersion using digital post-processing rather than a physical adjustment. Signal processing is more flexible and can adapt to the dispersion of the medium of the object. In addition, it is possible to automatically adjust digital post-processing without necessarily knowing the medium dispersion beforehand.

The dispersion of a medium is usually characterized by a dispersion relation. This relation can be specified in a number of ways: commonly by the index of refraction as a function of wavelength or the spatial frequency wavenumber in the medium as a function of temporal frequency. This dispersion determines the total propagation phase a particular temporal frequency component of the signal acquires when traveling a certain physical distance in the medium. By applying the opposite phase to each frequency component of the detected interference signal in post-processing, the effect of dispersion can be cancelled out. This method has been successfully demonstrated on OCT interferograms [49, 50] to produce the digital equivalent of optical dispersion balancing. The method is implemented as a cross-correlation and therefore can be implemented together with other convolution signal processing techniques as used for resolution enhancement, sidelobe reduction, and noise reduction.

One disadvantage of optical or digital dispersion balancing is that the dispersion is only compensated at one depth in the axial scan. To overcome this, consider that the interferogram in OCT is typically measured in the time domain using a delay line. The interferogram may be Fourier analyzed to find the temporal frequencies in the measured interferogram. Each temporal frequency has a corresponding spatial frequency in the sample medium. Because of medium dispersion, the spatial and

temporal frequencies in media are not necessarily proportional to each other, as they are in free space. The relationship between temporal and spatial frequency is given by the medium dispersion relation. Compensating for material dispersion involves changing the coordinates of the Fourier representation of the interferogram from temporal frequency to spatial frequency. In practice, this is achieved numerically by a resampling or "warping" of the Fourier space. This process has been demonstrated [43, 51] to correct the dispersion for all of the points in the axial scan simultaneously. This resampling method can be performed more easily in spectral domain OCT [51] where the interferogram data is already measured in the Fourier domain and needs to be resampled anyways to compensate for nonlinearities in the spectrometer. Parameterizing a Taylor series expansion of the frequency-dependent dispersion often allows estimation of the dispersion correction [52].

In addition, it is possible in some cases to determine the amount of dispersion directly from the data without previous knowledge of the composition of the sample. A method of automatically finding the dispersion parameters minimizes the entropy of the image given a set of dispersion parameters [51]. Minimizing entropy tends to produce point-like and sharp features in the reconstructed image. Because uncorrected dispersion is expected to blur out the image, minimizing entropy tends to favor the images with the least dispersion. The method adjusts trial dispersion parameters and recomputes an image corrected by the trial parameters, searching for the parameters that produce an image with minimum entropy. Others find the best parameters by using a metric that minimizes the total number of points in the axial scan above some threshold [53].

Several others have described approaches to achieve dispersion compensation with similar results using noteworthy estimation techniques or advanced interpolation schemes. One paper describes a method in analogy to the Shack–Hartmann wavefront sensor, which provides an equivalent solution [54]. Here a short-time Fourier transform provides a means to calculate the nonlinear phase. A fractional Fourier transform has been used to achieve an optimal rotation of the time-frequency plane for correcting second-order dispersion [55]. Nonuniform discrete Fourier transforms or nonuniform fast Fourier transforms are methods of correcting the nonlinear frequency-dependent dispersion effect [56, 57]. These transforms perform as highly accurate band-limited interpolators. Additional dispersion compensation methods have been developed for nonconventional scanning methods, such as an electro-optical modulator [58]. This method involves making two measurements with a mirror at two different depths and subtracting the phases of the spectral fringes to get the resampling parameters.

To see the effect of dispersion correction on OCT axial scan data, Fig. 13.6 shows the measured interferogram before and after correction. This data is measured from the air–glass and polymer–glass interfaces of a polydimethylsiloxane microfludic channel. By applying a resampling to the interferogram in the Fourier domain, the effect of material dispersion can be compensated for, to restore the bandwidth-limited resolution. An example of dispersion compensation applied to data in a tadpole image is shown in Fig. 13.7. In this case, the dispersion parameters were inferred from the image itself and then were used to correct the image.

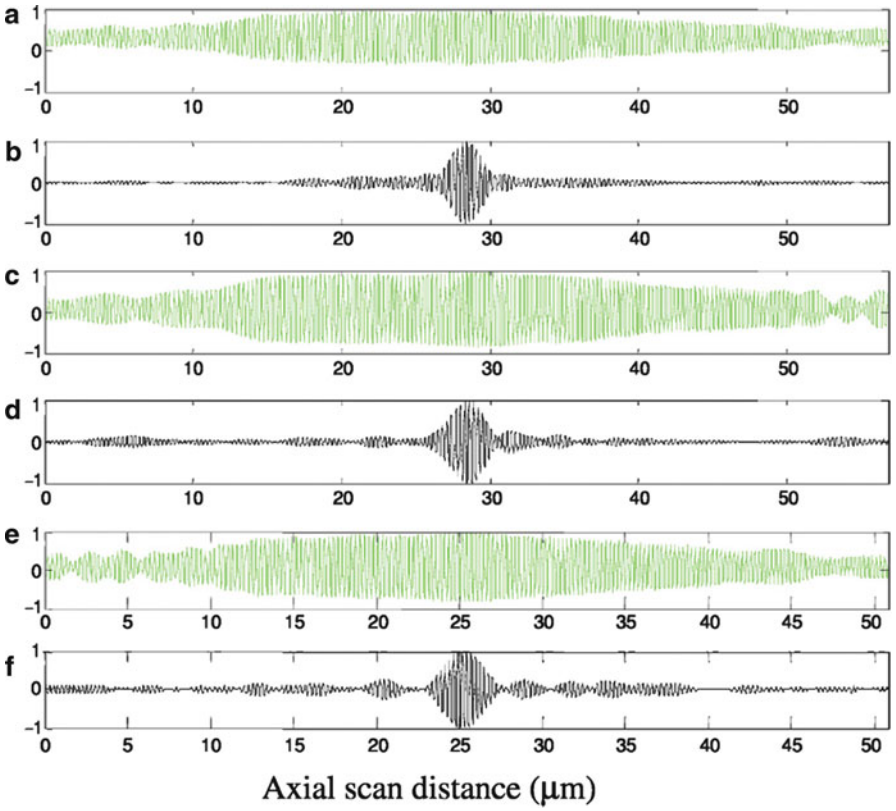

Fig. 13.6 Interferograms of reflections of air-glass and polymer-glass interfaces measured by OCT from a polydimethylsiloxane microfluidic channel. Parts (**a**), (**c**), and (**e**) are the interferograms before digital dispersion correction and (**b**), (**d**), and (**f**) are after correction (Image used with permission from [43])

In swept source (SS-) OCT, the sweep of the wavelength happens over a time frame, whereby phase coherency can be lost with motion. The motion induces a Doppler effect on the chirp sweep, which has a similar appearance to that of dispersion. A method of cross-correlation of sub-bandwidth reconstructions has been used to compensate for this motion-induced dispersion [59]. Other OCT modalities, where the compressed pulse is used for imaging, do not have this effect within the A-scans. In the next section, these motions that affect the consecutive A-scans, and motion compensation algorithms, are discussed.

A sample having a nonuniform medium can also suffer other distortions due to the refraction of the focused OCT beam as it scans through the sample. The refraction of the beam can change the apparent dimensions of the sample and the apparent locations of scatterers in the sample. It is then desirable to find the true spatial locations of scatterers inside the medium with knowledge of the refractive indices of the layers that comprise the medium. A method has been proposed [60] to

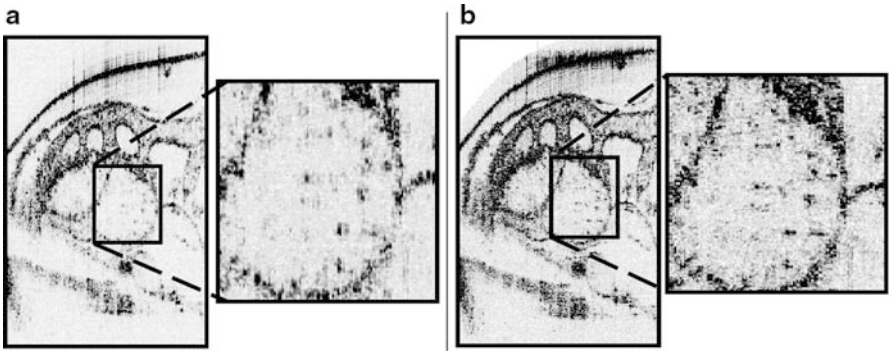

Fig. 13.7 Example of automatic removal of dispersion artifacts from an image of *Xenopus laevis* tadpole. The image (**a**) is the original OCT image, and (**b**) is the image with the dispersion parameters inferred from the image, and then used to remove the speckle from the image. This method uses an entropy minimization criterion to determine the dispersion parameters (Image used with permission from [51])

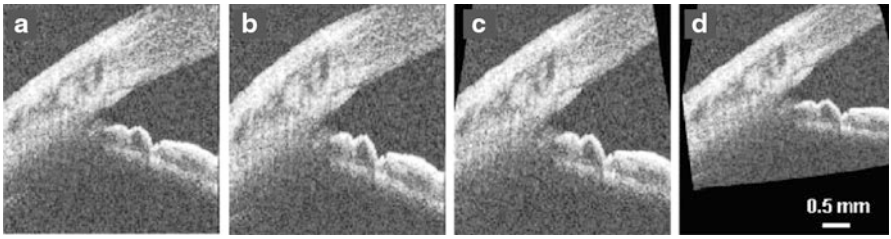

Fig. 13.8 Example of refraction correction of an image of the anterior chamber angle of a human eye. Image (**a**) is the raw acquired OCT image. Image (**b**) includes the correction for the nonlinear delay of the axial scanner. Image (**c**) further includes the correction of the divergent scan geometry due to telecentric scanning. Image (**d**) corrects for the refraction at the air–cornea and endothelium–aqueous boundaries (Images used with permission from [60])

correct for the refraction of the object and was demonstrated on a phantom and on the anterior chamber angle of a human eye. This method can correct the nonlinear scanning profile of a resonant scanning delay line and also non-telecentric imaging distortions. An example of an image corrected this way is given in Fig. 13.8. It accounts for the refraction of the OCT beam at the surfaces of the object by using ray tracing. Another method [61] uses the distortions caused by the refractive index variations to find the refractive index of the medium itself. Another method [62, 63] measures the refractive index by using coherence gating to measure the delay between light scattered from two foci in the medium along the axial scan. In another approach, the refractive index and thicknesses of multilayered phantoms were calculated by utilizing a matrix formulation of Fresnels's equations [64]. One study used the Delaunay triangulation method to represent the surfaces in ocular images followed by 3-D ray tracing to correct for optic distortions caused by

refractive index variations [65]. With knowledge of the refractive index, it seems likely that the refraction of a non-layered medium can be corrected as well.

13.5 Motion and Phase

Motion estimation and compensation methods have widespread applicability in imaging modalities including OCT. Numerous OCT modalities such as Doppler OCT [66], speckle variance imaging [67], optical micro angiography (OMAG) [68], optical coherence elastography (OCE) [69], and magnetomotive OCT (MM-OCT) [70] explicitly rely on motion for estimating the flow and viscoelastic properties of the specimen. Motion artifacts arising from physiological fluctuations such as heart beat and respiration and involuntary movement of a living subject, in addition to fluctuations caused by a noisy environment and galvanometer jitter, can be detrimental to these imaging modalities. Motion artifacts can not only degrade image quality but also limit the accuracy and reproducibility of quantitative measurements in OCT [71]. Motion artifacts arise when the sample moves during data acquisition and the OCT image reconstruction process assumes the sample to be stationary. High-speed data acquisition can mitigate the impact of motion artifacts to some extent; however, acquiring OCT volumes for a large field-of-view still takes a few seconds, and motion compensation algorithms need to be applied in post-processing to minimize the impact of motion artifacts.

Techniques based on the cross-correlation have been widely used for motion compensation and estimation. These methods are primarily based on finding the shifts corresponding to the maximum cross-correlation values. It is usually helpful to upsample the data prior to finding the cross-correlation values to detect sub-pixel shifts. Cross-correlations between successive A-scans have been used to correct for axial motion [72], while others used cross-correlations between orthogonal B-scans to correct for both axial and transverse motion [73]. Similar techniques were used to correct phase fluctuations due to cardiac and respiratory motions [74]. Some of the more recent methods include optimizing a set of objective functions for image registration [75]. Histogram-based bulk motion estimation methods have been applied to phase-resolved techniques such as Doppler OCT and optical angiography. In these methods, the phase differences between two adjacent A-scans are calculated and the bulk motion is estimated based on the phase difference corresponding to the mode of histogram distribution of these phase differences. This phase difference is then subtracted from the second A-scan to compensate for motion artifacts [76]. Motion compensation techniques have also been used for OCT image formation while manually scanning a probe over a sample. By measuring the de-correlation of the adjacent A-scans, the velocity of the movement of the probe can be measured and used to correct for motion artifacts due to nonuniform scanning [77, 78].

Sub-wavelength motion can induce a phase change in the measured OCT signal. With the advancement of phase-stable Fourier-based systems, techniques have been

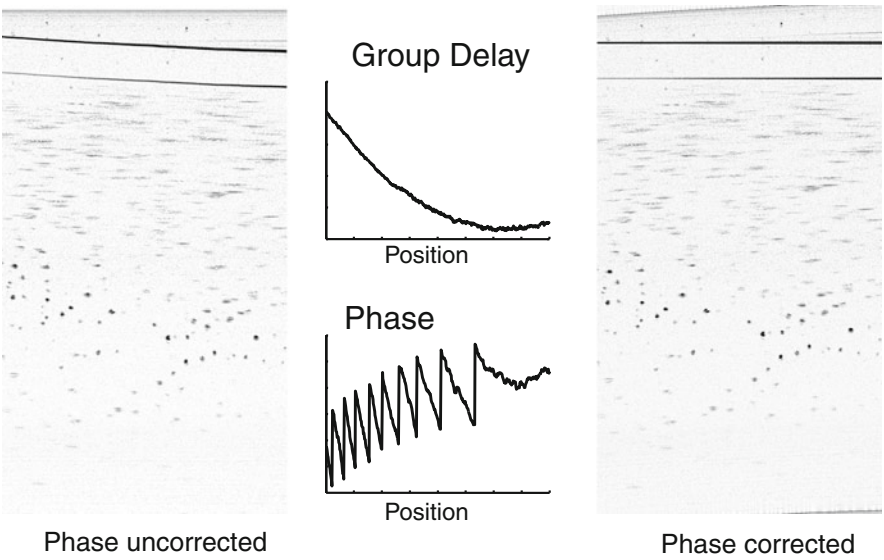

Fig. 13.9 Example of phase correction by using a coverslip placed on the top of the tissue phantom as a phase reference. Phase uncorrected image (*left*). Image after phase correction (*right*). Images used with permission from [80]. The plots show the group delay and phase as a function of transverse position on the coverslip interface

developed to estimate the phase values and infer a displacement. Furthermore, based on these phase measurements, some authors use a finite difference (numerical derivative) approach to solve the velocity or acceleration. Some authors use this approach combined with cross-correlation to improve sensitivity of the OCT system [79]. One study used the group velocity and phase of a common scatterer to stabilize the system before solving the inverse problem of interferometric synthetic aperture microscopy (ISAM) [80]. Figure 13.9 shows an example where phase correction was applied using a coverslip as a phase reference. Another study performed Doppler flow imaging of cytoplasmic streaming using a common path interferometer [81]. One study developed a magnetomotive optical coherence elastography approach to detect the elastic moduli of a medium by detecting the position and displacement of nanoparticles, which have displacements induced by an external magnetic field that switches on and off [82]. Measuring phase to within a wavelength can be difficult, so some authors use phase unwrapping techniques. One technique in particular involves calculating a synthetic wavelength, longer than the center wavelength, by dividing the spectra into subbands for processing [83].

A range of techniques based on taking the Fourier transform along the lateral direction (time or the coupled transverse-time (x-t) axis) have been proposed for detecting moving scatterers within a sample. Spatial oversampling is necessary to separate out the static sample structure from the moving scatterers within the sample. In OMAG, for instance, the separation is obtained by applying a constant

carrier frequency during B-scan acquisition, and a subsequent Hilbert transform is used to separate out the moving scatterers from the static tissue structure [68]. In some techniques such as OCE [84] and MM-OCT [70], the displacements induced by an external modulating force are detected by bandpass filtering the Fourier transform of the phase differences around the modulation frequency. In one study, the peak of the Fourier transform at the modulation frequency was used to calculate the sub-nanometer displacements [85].

13.6 Analysis and Classification

The purpose of OCT, as with any other biomedical imaging technique, is to extract diagnostically important information from acquired images. Many times, this information may not be apparent from the displayed data and further data analysis might be required. Computational techniques, being quantitative in nature, can give an objective assessment of the images, reduce inter-observer and intra-observer variability, extract diagnostically significant image features not easily observable by the human eye, and greatly increase the speed and accuracy of diagnosis. Moreover, with the rapid increase in OCT data acquisition speeds, analyzing these volumetric data sets can be challenging. Automated image analysis can reduce the burden of analyzing all these images and alert the user to significant landmarks and important information in these data sets.

The methods developed for automated image classification in OCT can be divided into two broad categories, i.e., algorithms that evaluate A-scans by exploiting differences in the attenuation coefficients, intensity histograms, spatial frequencies, etc. [86, 87], and techniques that take into account the 2-D and 3-D spatial information of OCT images such as differences in the texture patterns [88, 89].

Scattering properties of tissues can change due to morphological changes induced by disease progression. For instance, tumor tissues are in general known to be highly scattering due to changes in the regular cellular structure and the increase in the nuclear-to-cytoplasmic ratio. These changes can be quantitatively evaluated by measuring the attenuation coefficients from the OCT data and can be used for classifying different tissue types. The two main models used for the description of the OCT signal are the single-backscattering and the multiple-backscattering model. In the single-backscattering model, it is assumed that only light that has been scattered once contributes to the OCT signal. Beer's law can be used to express the attenuation of the OCT signal in single backscattering where the intensity of the OCT signal is represented by an exponential relation, related to the depth and the attenuation coefficient. A more accurate description of the OCT signal can be obtained by taking into account the confocal properties of the OCT beam in the sample arm. The attenuation coefficients are usually calculated by performing an exponential fit onto the intensity of the A-scan or a linear fit after taking the logarithm of the A-scan data [90]. This method has been used to differentiate between normal and tumor tissues in rectal [91] and renal tissues [92], characterization of atherosclerotic plaques [93], and classification of human

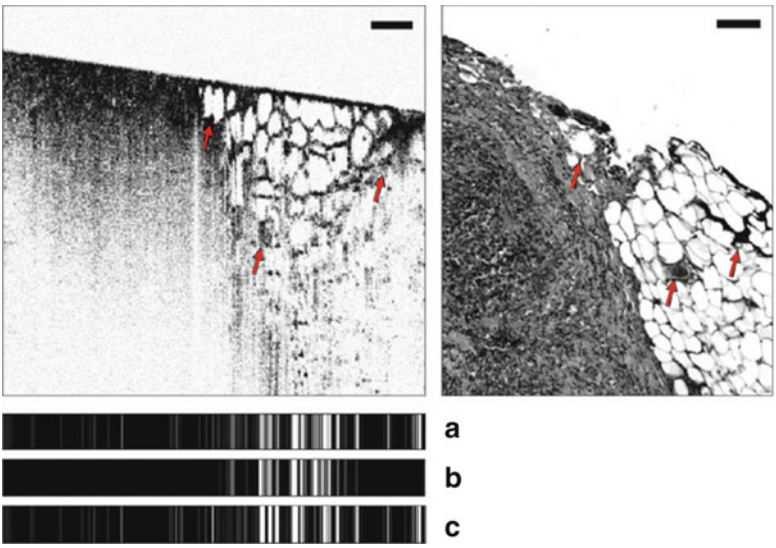

Fig. 13.10 OCT image of a vertical tumor margin (*left*) and the corresponding H&E stained histology (*right*) from human breast tissue. Highly correlated image features are indicated with *arrows*. An A-scan-based analysis was performed for each A-scan within the image using (**a**) both Fourier domain and periodicity analysis, (**b**) Fourier domain classification, and (**c**) periodicity analysis, for each scan line. *Black*, *white*, and *gray* regions represent tumor, adipose, and stroma classifications, respectively. Scale bars represent 200 μm (Images used with permission from [87])

breast tissue types [86, 87, 93]. In Fig. 13.10, information content in the A-scan data such as the spatial frequencies and the mean distances between the high-intensity back-reflections were used for classification of stroma, tumor, and adipose tissues in the human breast [87].

The spatial variation in image intensities forming certain repeated patterns constitutes texture. Texture in OCT images may arise due to the tissue structure or the speckle pattern. Speckle is an important contributor to the texture patterns in OCT images, especially when morphological features are not apparent in the image. Since speckle depends upon the size and distribution of the scatterers within the sample, different tissue types would form distinct speckle patterns. Texture analysis of these speckle patterns can potentially be used for tissue classification [88]. Three main approaches have traditionally been used to quantify texture: statistical methods, structural methods, and model-based methods. In structural methods, it is assumed that a set of texture units and primitives define the texture of the image and the geometric properties of these textural units are used to classify texture. In the model-based approach, an image-based model is used to describe and synthesize the image texture, and the model parameters are used for the purpose of classification. Statistical methods are based on the spatial distributions of the gray-level values between each pixel and its neighboring pixels. Gray-level co-occurrence matrices calculate the second-order joint conditional probability

distribution of intensity values between two pixels for various distances and specified directions. Texture features such as contrast, correlation, homogeneity, entropy, and energy can be calculated from these matrices. Usually, a number of texture features are calculated from an image or a subset of the image and it is not very apparent as to which image features would give the best discriminating power. Moreover, for optimum classification and to overcome the so called curse of dimensionality, dimensionality reduction techniques such as principal component analysis are applied prior to classification [94, 95]. With an optimum combination of the features, it is hoped that the feature vector would cluster into distinct groups corresponding to each tissue type in the multidimensional feature space. The extracted features are compared with the features calculated from the training set and classified into a tissue type. Texture analysis due to its intuitive simplicity has been widely applied to OCT images. Texture analysis has been used for diagnosis of dysplasia in Barrett's esophagus [96], for automated classification of gastrointenstinal tissues [97], and for differentiating between different human breast tissue types [98]. Texture analysis has also been combined with wavelets to improve classification performance by reducing the impact of system-dependent variations in the speckle pattern [99]. More recently, the fractal dimension, which is a measure of the self-similarity and complexity of the object, has been used to characterize texture. One-dimensional fractal analysis has been applied for distinguishing between stroma and tumor tissues in the breast [100] and arterial tissue [101].

13.7 Visualization and Representation

An issue perhaps equally as important as the computational post-processing of data is how this data is to be presented as an image. The same data can be presented in many ways that can help, hinder, aid, or mislead the instrument operator. OCT data is 3-D in nature and can potentially include many properties such as Doppler shift, polarization, birefringence, and spectral shift, among others. Careful consideration to the representation of data is essential to maximize the utility of the data and ensure that the relevant features can be rapidly ascertained.

The conventional way standard 2-D OCT images are represented is using a density plot. The horizontal axis typically corresponds to the direction of transverse scanning, and the vertical axis corresponds to sample depth, with the downward direction in the image corresponding to increasing depth. A gray level is usually plotted at a particular pixel on an image corresponding to the magnitude of the interferogram at a particular depth and transverse scanning position. Usually, the pixel intensity is mapped to the logarithm of the interferogram magnitude because of the high dynamic range and speckle noise present in OCT images, but visual improvements can be made by using an adaptive method [102] of selecting the lookup tables between pixel intensity and interferogram magnitude. In addition to gray levels, lookup tables utilizing color can aid the human visual system by varying hue as well as pixel intensity. Lower and upper thresholding of the pixel values is

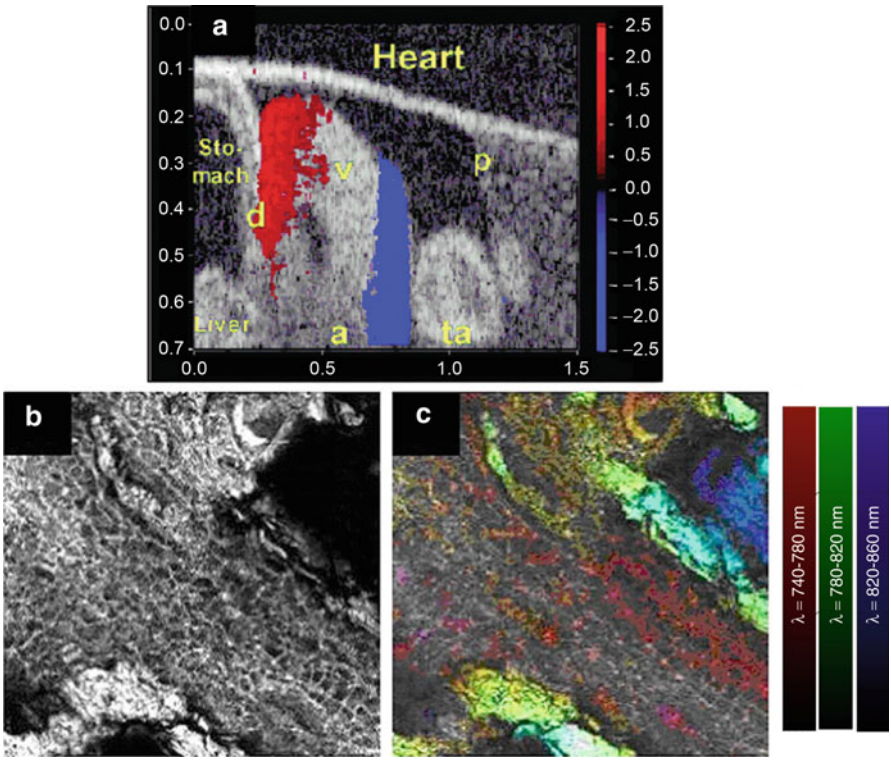

Fig. 13.11 Image (**a**) is an example of color Doppler and structure superimposed on the image of a *Xenopus laevis* heart. Image used with permission from [104]. Images (**b**, **c**) show a representation of spectroscopic OCT data. (**b**) Structural optical coherence microscopic image of a rat tissue showing regions of adipose cells and muscle and the corresponding spectroscopic representation (**c**) generated by assigning the intensity in three equally spaced subbands to the *red*, *green*, and *blue* channels (Images used with permission from [107])

commonly done to conserve the dynamic range of the display device, especially when the dynamic range is dominated by large magnitude specular reflections.

False color images where the colormaps represent different optical properties of the tissues rather than the tissue structure are also widely used. This method has been commonly used in ophthalmological imaging to overlay the thickness of different segmented layers over the structural image. The use of color for Doppler imaging in OCT is a practice adopted from Doppler ultrasound imaging. Typically, a reddish hue is used to denote movement away from the source of the illumination beam (for a "red-shifted" or lower-frequency Doppler signal) and blue is used to denote movement towards the beam (likewise for a "blue-shifted" higher-frequency signal). Note that in standard Doppler imaging, only the component of velocity parallel to the illumination beam can be measured. The red-blue coloring method

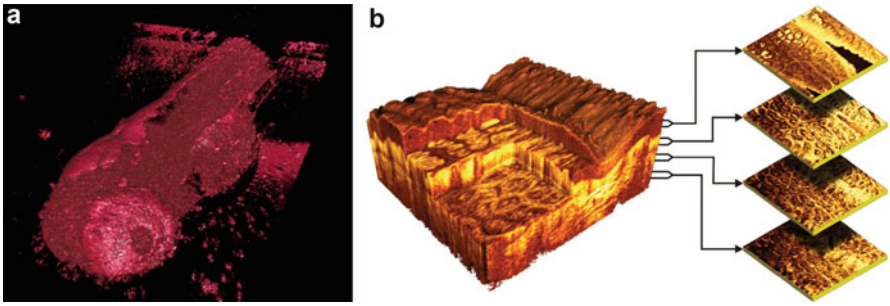

Fig. 13.12 Examples of 3-D volumetric renderings of (**a**) a zebra fish (at the fry stage of development) using a transfer function for isosurface generation and (**b**) human skin showing different sublayers of epidermis and dermis. The en face sections are separated in depth by 360 μm (Image used with permission from [130])

typically superimposes a red-blue hue on an otherwise gray-level image of structure [103, 104], but it can also be plotted separately [105] so the intensity better indicates the magnitude of the Doppler shift. Figure 13.11a shows an example of color Doppler OCT, with the color Doppler information superimposed on the structural information. The color Doppler representation has been commonly used, but others have been proposed, such as using colors to denote the frequency band of the Doppler-shifted OCT signal [106], which indicates the magnitude of the velocity shift. Spectroscopic OCT data can be represented in the form of images in a variety of ways. One commonly used approach is metameric imaging shown in Fig. 13.11c where the source spectrum is divided into three equally spaced subbands, and the intensity from these frequency bands are assigned to the red, green, and blue channels [107, 108]. Another method maps the center of mass of the spectrum onto a red–green hue in the image where a green hue shows a spectral shift to shorter wavelengths and a red hue indicates a shift to longer wavelengths [109]. A nontraditional way to represent data is in the form of nonspeech audio signals. This process known as sonification has been used for OCT data where different parameters extracted from the data were mapped into an audio signal for the purpose of tissue classification [110].

One innovation that has made a major impact on medical imaging and OCT in particular is computer-based volume-rendered 3-D OCT images. A 2-D image can be insufficient to recognize a feature of interest, e.g., a blood vessel or tissue boundary, because the planes in which the individual images are taken each contains only one cross section of the larger feature. By using 3-D rendering, the operator is not required to mentally assemble a complete picture of a feature, so the operator can concentrate on recognizing and classifying features. With the advent of Fourier/spectral domain OCT, data acquisition has become very rapid [111], and complete 3-D data sets can be acquired within seconds. This rapid acquisition and the large quantities of data produced need ingenious ways to convey their

significance to the operator, and 3-D rendering is a good candidate for this. When mapping a 3-D voxelized data set to a scene, there are several options for rendering and thresholding. For rendering, the volume surfaces may be rendered by slices or ray casting. In an isosurface, some voxels as indicated by a boundary intensity value may be interconnected into a polygonal mesh and rendered. Regardless of the rendering type, the thresholds for every channel (red, blue, green, alpha) may be selected. These channel thresholds are often set based on a histogram of voxel intensity values. The alpha channel allows for transparency through the object. In more sophisticated thresholding schemes, a 2-D transfer function is used to map the voxels based on intensity and gradient values. Examples of 3-D rendered volumetric data sets are shown in Fig. 13.12. With ongoing developments in 3-D computation hardware, the widespread availability of hardware acceleration devices such as graphics processing units (GPUs), display technology, and user interfaces, volume rendering will almost certainly be standard technology for OCT data visualization.

To see what has been done, we consider examples taken from the electronic and free Optical Society of America Optics Express journal (World Wide Web address: http://www.opticsexpress.org/) which has readily downloadable animations of 3-D renderings. One of the simplest ways to represent a 3-D volume is by an animation of B-mode slices. For example, animations of a human finger and tadpole [36] and a retina [53] show adjacent two-dimensional slices in successive frames. B-scan images can be synthesized from C-scan (en face) images and then animated, showing a projection image of a human retina in a manner similar to a confocal scanning laser ophthalmoscope [112]. Animations of B-scan images [113, 114] include color-coding of the fast-axis of the birefringence and the retardation. However, full 3-D rendering can help one visualize the complete object and not just individual sections. Volume rendering allows the visualization of a discretely sampled 3-D data set in the form of 2-D projections. A simple example [115] is a 3-D volume rendering of a "cloud of points" representing the scattering of an object, in this case a frog, where the spinal cord and notochord can be identified. Several examples exist where authors both plotted slices and created an animation of 3-D surface rendering, which provides a good comparison between the utility of the two methods. Two examples include renderings of a Syrian hamster cheek pouch [116] and a human finger pad [113]. The maximum intensity projection method, which is based on projecting the voxels in the projection path that correspond to the maximum intensities, has been used to visualize vascular perfusion [117, 118]. More recently, the processing capabilities of GPUs have been utilized for real-time volume rendering of OCT data. A ray-casting method was used to demonstrate real-time rendering of the human finger at the rate of 10 volumes/s. In addition, multiple 2-D frames were rendered in real-time using different model view matrices [119, 120]. A further example shows a hair being burned by a laser both as three orthogonal sections and an animated 3-D rendering [121]. In another example, volumetric rendering at 41 volumes/s is

shown as the human eye undergoes constriction and dilation on the shining of a laser beam [122]. These are examples of rendering a four-dimensional data set, including both three dimensions of space and one of time.

13.8 Conclusions

Great strides have been made to increase the utility of OCT images by using image post-processing. It seems likely that future OCT instruments will feature combinations of post-processing that include deconvolution, despeckling, dispersion correction, and 3-D visualization. Such advances will almost certainly provide the clinician with a portable, noninvasive, cellular level, in vivo diagnostic tool perhaps capable of obviating the need for many biopsies. Perhaps one day, OCT may even provide the physician with a 3-D visualization of cellular-level structure and processes inside the living human. While this may perhaps not be as complete as the intravascular submersible imagined in the science fiction film Fantastic Voyage, these capabilities may still be well beyond the mostly static 3-D images of tissue and organ structures that physicians use today.

Further improvements are needed to make many of these methods cost-effective and practical. To be useful clinically, processing methods must work in real time, presenting processed and analyzed results to the operator with little delay or lag time. Furthermore, processing methods must operate automatically, requiring little or no adjustment by the operator. Advances in digital signal processing and computational hardware continue to close the gap between the possible and the practical. The 3-D rendering hardware commonly used for computer gaming will also benefit portable medical imaging. Clinicians will need to be trained to interpret the images with the additional processing and hopefully with feedback on which methods enhance their diagnostic accuracy. Eventually, methods of image enhancement will be standardized among OCT instruments.

It is important to note that other coherent ranging modalities have already developed a body of knowledge on signal processing, much of which is likely useful to the OCT community. The similarities between ultrasound imaging and OCT are great, though they use different types of radiation at vastly different frequencies. How signal processing has been incorporated into ultrasound instruments [123] can provide guidance on how to succeed in integrating signal processing into OCT. In addition, tomographic algorithms [124, 125] developed for ultrasound may also find use for OCT. Synthetic aperture radar (SAR) extensively utilizes image processing because of the inherently tomographic nature of the backscattered signal in this method. For example, methods of deconvolution and despeckling [126–128], which are developed within the formalism of statistical signal processing, may serve as a starting point for similar algorithms developed for OCT. In fact, there is a resemblance between the method of stripmap SAR and axial priority scanning OCT [129]. Additionally, methods in magnetic resonance

imaging and X-ray computed tomography also have algorithms that may translate well to OCT, particularly in the sampling strategies. It seems likely that such cross-fertilization of disciplines and modalities will continue the convergence and use of medical imaging techniques.

DSP Technology and Methods for OCT

14

Murtaza Ali, Adeel Ahmad, and Stephen A. Boppart

14.1 Introduction

Medical imaging devices are continually changing and evolving. In recent years, these devices have been evolving towards portable and handheld point-of-care systems. This is reminiscent of many other industries where semiconductors play a key role. A PC with a 1 GB hard drive and a 100 MHz processor was considered state of the art about 15 years ago. Cell phones were brick-sized voice-only devices. Today, processors ten times faster are available in handheld smartphones that run for days without recharging. These phones now are smaller than a deck of cards, are capable of streaming TV-quality video, and have become an integral part of personal entertainment. This has been possible with the advancement of both analog and embedded processing technology available from the semiconductor industry. This technology today powers consumer and industrial electronics, including medical imaging devices.

Ultrasound imaging devices used for medical evaluations and diagnostics are prime examples of how the advanced analog and embedded processing technology

is changing the use of these devices. Cart-based systems were the only devices available a few years ago. Now these systems are being complemented by portable and handheld devices. Portability of medical devices creates a paradigm shift by bringing advanced health care to the patient instead of forcing the patient to travel to a facility. This allows development of new devices for use by medical professionals, in patient rooms in hospitals, in disaster and remote areas, in assisted living facilities, and even in ambulances. Portable devices complimented with wireless communication systems have been increasingly used for telemedicine in rural areas, which lack both medical experts and diagnostic facilities.

Today, optical coherence tomography (OCT) systems are mostly cart-based or desktop systems. Like ultrasound imaging devices, we expect portable and handheld OCT systems to open up new opportunities for their use. Recent advances in optics and scanning techniques have led to miniaturization of the optics used to acquire the raw data. This has certainly opened up the potential for creating smaller OCT systems. However, we have also seen the development of very high data acquisition rate systems that can operate at a rate on the order of several hundred thousand A-lines per second, or more [1]. This high rate of acquisition allows 3D volume imaging in real time, as well as imaging fast moving structures at high temporal resolution. The signal processing chain to convert the raw acquired data into a useful structural image is computationally intensive. In addition to the formation of the structural image, many advanced computational techniques like interferometric synthetic aperture microscopy (ISAM) have been proposed to improve the image quality [2]. Additional processing is also necessary to extract further information like Doppler-shifted signals for velocity information [3, 4], elasticity [5], birefringence, and optical axis rotation [6] of the tissues. Today, researchers have responded to this computational need through the use of high-performance personal computers (PC) that include high-end general purpose multi-core central processing units (CPU) coupled with graphics processing units (GPU) [7–9]. While these systems serve well the need for cart-based and desktop systems available today, creating a true embedded system for portability and low-power operation requires coupling the available miniaturized optics with high-performance embedded processing elements.

Digital signal processor (DSP) technology has served the signal processing community over the last three decades by providing low-power, computationally efficient, programmable embedded solutions [10]. DSPs are especially designed for real-time, deadline critical, compute-intensive operations as well as for harsh operating conditions. DSPs have been processing signals in many forms, e.g., to transmit and receive signals through wired and wireless media; to encode and decode speech, audio, and video signals; to identify objects for surveillance; to extract structural and Doppler information in medical ultrasound imaging machines; to enhance images in consumer cameras and camcorders; and in medical devices like X-ray machines. DSP technology is, therefore, an excellent choice of an embedded processor for developing low-power, low-cost, handheld, and portable OCT systems.

14.2 DSP Technology and Medical Imaging

DSPs are among a class of embedded processors that are often used for low-power, low-latency signal processing functions. Modern DSPs can be broadly grouped into three categories:

- Single-core DSP: These DSPs are mostly used in very low-power, low-frequency signal processing. Though there are many medical applications that benefit from these devices, these devices are not suitable for the OCT signal chain.
- Multi-core DSP: These devices bring a large amount of computational power at a comparatively low power through the use of parallel instantiations of DSP cores. These devices are widely used in the wireless infrastructure market. They are also used in various compute-intensive medical imaging modalities. These devices seem to be the most appropriate to handle the compute-intensive signal processing challenges encountered in OCT.
- Systems-on-chip (SoC): These devices are typically based on heterogeneous compute elements that include graphics, display, user input, as well as control. Some versions of these devices also have decent compute capabilities. These devices are ideal for performing the back-end tasks typical in medical imaging applications.

Embedded processors like DSPs are playing a key role in developing both new medical imaging devices and new imaging modalities [11, 12]. Some of the key advantages of DSPs in medical imaging systems are noted below:

- Reduced research to development time: DSPs are programmable devices just like a CPU or GPU in a PC. They are programmed in standard "C" with some specialized extensions called "intrinsics." The programming paradigm is very similar to PC-based programming methods where researchers originally develop their new algorithms. Thus, DSPs provide a much faster path to implementation compared to field-programmable gate arrays (FPGAs) or application-specific integrated circuits (ASICs). FPGA development time is shorter than ASIC and is often used for prototyping complex systems. FPGAs are useful to bring in and process a large number of parallel data and perform fixed tasks which are not expected to change during the lifetime of the product.
- Field upgradability: Due to the programmable nature of DSPs, they provide a path to future proofing the system. New algorithms and new tasks can be easily brought in within the limits of the available computational power. DSP-based systems are often designed with enough headroom to account for future extensions. ASICs functionality cannot be changed without changing the chip. FPGA is, in theory, configurable, but the design and verification time for FPGA implementation is much longer than software-based implementation in DSPs.
- Real-time processing: DSPs are designed to be deterministic in compute time. They have very low-latency interrupt reaction time. In addition, they run low-overhead, real-time operating systems. As a result, they can respond to time critical events quickly. This allows the system to perform low-latency implementations which can be very important in surgical imaging systems.

DSPs also have very low boot-up or start-up time since they do not need to run a full operating system. This is an advantage where it is critical to reduce the time from device start-up to medical image acquisition, such as in ambulances and field medical stations. The operating systems in PCs are inherently non-real time and the response time to a particular event cannot be guaranteed. Though there are embedded operating systems running on PCs which alleviates this problem somewhat, they do not come close to the response time of DSP-based solutions.

- Reliability: The components that are used to build a medical imaging system must be highly reliable. The components must not fail even after years of rough handling in the field. Reliability also includes the ability to recover quickly from failures due to software bugs and immunity to electromagnetic interference. Reliability affects a system's total cost of ownership for the end user, such as hospitals and physician groups. It also affects brand reputation and the competitive positions of system vendors. DSPs have a history of operating under extreme conditions in industrial electronics as well as under rough handling in consumer electronics.
- Scalability: The multi-core DSP platforms provide the system vendor a choice of scaling the end system based on specific needs. Many medical imaging technologies have the same underlying technology but need to scale the functionalities based on capabilities and usage. For example, some ultrasound systems measuring blood flow will require high rates of acquisition, some will require larger depths in imaging, and some will require additional functionalities like elasticity imaging. Similarly, OCT systems, providing various functionalities like B-mode imaging versus 3D volume imaging, and structural versus flow or polarization-sensitive imaging, will benefit from the scalable nature of this class of embedded processors. The functionalities can be implemented for a given architecture of DSP core once, and then various instantiations of the multi-core DSP can be used based on the scale of computation needed for a particular implementation.
- Low power: DSPs are designed for power-sensitive battery-operated systems. The specific architectural features of a DSP core, coupled with the already discussed low-overhead real-time operating systems and the ability to use the compute elements with very high efficiency, all contribute to a low-power system when designed with these embedded processors. Multi-core DSPs usually run from a few watts to a few tens of watts, thereby giving the system vendor the capability to trade off computational need with power need. DSPs are considered to be the lowest power for programmable or configurable embedded processing elements commercially available. A properly designed ASIC will definitely be lower power, but that low power comes with inflexibility of future extension and long development time.

As with many other established and new medical imaging modalities, DSP-based embedded systems will provide the necessary platforms for portable and handheld OCT devices. Multi-core DSPs are suited to take the signal processing tasks from the raw data processing to the manipulation of displayed images. In addition to multi-core DSPs to handle the OCT signal chain, a complete system will potentially be composed of other embedded processing elements. This may include FPGAs to collect and manage the raw data, to transfer the data to the DSP as well as an SoC at

the back-end to control the system, to drive a user interface, and to display the processed images along with any other relevant information.

14.3 Architectural Overview of a Multi-core Digital Signal Processor (DSP)

In this section, we provide an overview of the architectural aspects of the TMS320C6678 multi-core DSP from Texas Instruments (TI) [13]. This is currently the highest performance DSP commercially available. This device is capable of a peak performance of 128 billion floating-point operations per second (GFLOPS) running at 1 GHz clock frequency with a power dissipation of only 10 W. The OCT implementations described in this chapter are based on this particular DSP. Some results on DSP-based embedded implementation of OCT signal processing have been reported in the literature [14, 15]. The results in [14] are based on an earlier generation of DSP architecture and the analysis in [15] is on the architecture described here.

This device incorporates eight DSP cores code-named C66x [16]. The block diagram of each core is shown in Fig. 14.1. Each core is based on very long instruction word (VLIW) architecture. The core has eight units arranged in two sides. The four units on each side are termed as L, M, S, and D units. Each unit is

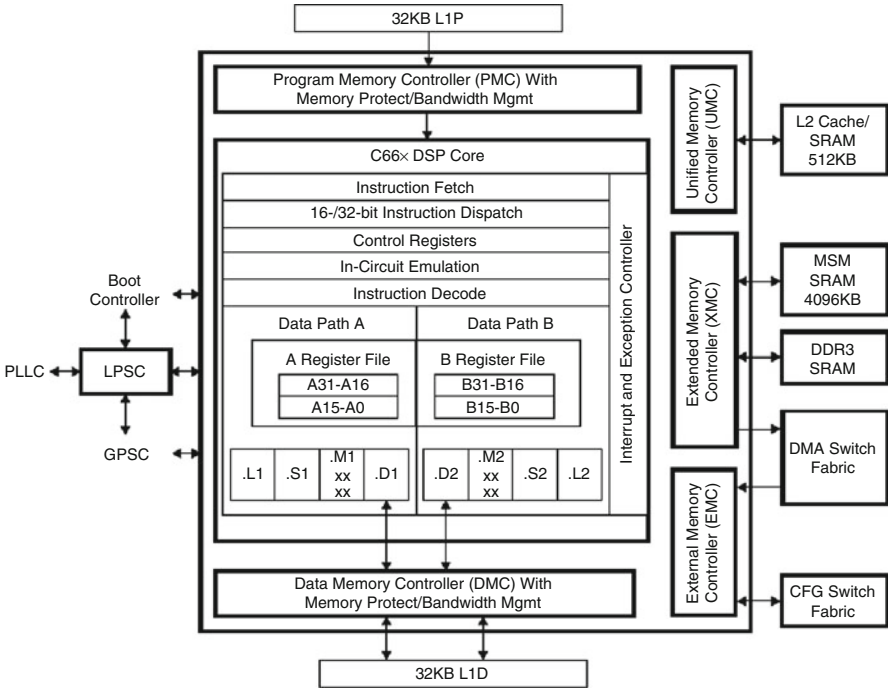

Fig. 14.1 Block diagram of an individual C66x DSP core

designed to perform different sets of operations. For example, the M unit primarily performs multiply operations. The D unit is used for load/store operations from memory. The additions and logical operations are distributed across the L and S units. This is thus an 8-way VLIW machine where eight instructions can be issued across these eight parallel units in one cycle.

The instruction set also includes single instruction, multiple data (SIMD) format. SIMD is often used for vector data processing where the same processing (multiplication, addition, etc.) can be done in parallel on multiple input datasets producing multiple output datasets. This architecture allows up to 128-bit vector processing. The 128-bit vector can hold up to four single precision numbers in IEEE754 format. The M unit can do four single precision multiply operations per cycle. Each of L and S can do two single precision additions per cycles. The two sets of L, S, and M can then do eight single precision multiply-add operations per cycle (i.e., 16 floating-point operations or FLOP per cycle). There is also the ability to do double precision operations as well as integer operations of various widths (8 bit or byte, 16 bit or half word, and 32 bit or full word). Various mixed mode operations are also allowed.

There are two general purpose register files, one on each side, which feeds data to the units of that side. There is also a cross connect so that units on one side can use the data from the units on the other side. The art of efficient programming a VLIW engine like the C66x DSP core lies in the ability to feed as many instructions as possible to the parallel units without overwhelming the registers. Fortunately, a large amount of the standard signal and image processing functions is available as standard libraries, and the user would not need to write optimized functions for these.

The overall block diagram of the TMS320C6678 DSP with eight cores is shown in Fig. 14.2. In addition to the eight cores, the device comes with a rich set of standard interfaces like PCI express, Serial Rapid I/O (SRIO), and gigabit Ethernet.

14.3.1 Memory Hierarchy

The memory hierarchy available in a particular processor is an important design consideration for embedded processors. The TMS320C6678 DSP has 32 KB of L1 program (L1P) and 32 KB of L1 data (L1D) cache memory, as well as 512 KB of L2 cache memory per core, integrated in the chip. Unlike a conventional CPU, both L1 and L2 memory in the TMS320C6678 can be configured as RAM or cache or part cache/part RAM. This flexibility is exploited in this implementation of the OCT signal chain. In addition to this per-core memory, the device also integrates 4,096 KB of multi-core shared memory (referred to as MSMC). This part of the memory is accessible by all the cores.

All L2 memory incorporates error detection and error correction which acts as auto fault detection and correction for device and memory errors. This may be an important aspect in safety critical applications like medical imaging devices. The device includes 64-bit DDR3 external memory which runs at 1,333 MHz, giving a maximum DDR3 (with error correction DRAM support) bandwidth of about

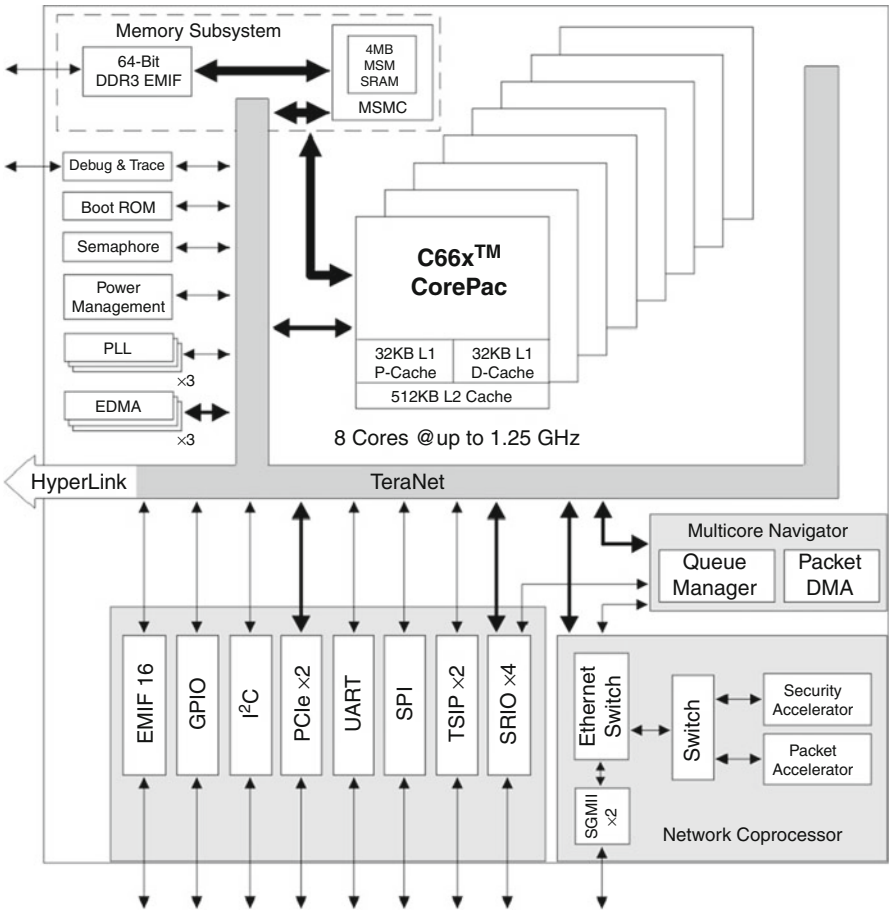

Fig. 14.2 Block diagram of the eight-core TMS320C6678 DSP

10.6 GB/s. The total addressable memory of this device is 8 GB. This gives enough space to hold a 3D volume of OCT images. For example, a $512 \times 512 \times 512$ volume of single precision data requires 0.5 GB of memory space.

14.3.2 Programming Model

The TMS320C6678 is mainly programmed through standard C. Texas Instruments provides a C/C++ compiler as part of its code generation tools. Virtually all C89 compliant C programs can be directly ported to this device. To achieve efficient implementation tuned to the architecture, the compiler provides a rich set of optimization and tuning flags. It supports optimizations through the use of pragma

```
omp_set_num_threads(NUM_THREADS);  // set thread count
#pragma omp parallel for private(i) shared(a, b, c, n)
// The following for loop will be parallelized across multiple threads
// variables a, b, c and n are shared across all threads
// variable i is unique/private to each core
For(i=0;i<n;i++)
{
    c[i] = a[i] + b[i]
}
```

Fig. 14.3 Simple OpenMP-based parallelization of vector addition

and intrinsic. The pragmas can be used to provide useful information to the compiler (e.g., certain variables are multiples of a number; certain addresses are double word aligned) which allows the compiler to perform important optimizations to extract as much efficiency as possible from the underlying core architecture. The intrinsics allow the programmer to guide the compiler to use specific instructions available in the architecture. The compiler also provides important feedback to the programmer, such as how much the units are loaded in a particular loop. This lets the programmer understand bottlenecks and rewrite the code to remove these bottlenecks as he/she iterates through the compiler searching for an optimum implementation. This allows quick port and optimizations of existing code into DSP-based embedded systems.

TI's DSPs run a lightweight real-time native operating system known as SYSBIOS available through the multi-core software development kit (MC-SDK) [17]. SYSBIOS is highly configurable. The user can choose specific parts of the operating system that are needed. This is also an important difference compared to general purpose CPUs available in PCs. Such configurability allows low memory footprint implementation of a system, thereby reducing overall cost, size, and power.

TI's multi-core DSPs support multi-threading through the use of an OpenMP 3.0 model [18]. A simple example of OpenMP-based parallelization is shown in Fig. 14.3. The pragma allows defining shared variables that are accessible by all threads as well as private variables which will be local to each thread. The "#pragma omp parallel" statement shows the boundaries of the parallel regions. The "#pragma omp for" statement tells the device that the "for loop" will need to be distributed across parallel threads. In the multi-core DSP, one thread corresponds to one core.

TI's compiler translates OpenMP into a multi-threaded code with calls to a custom runtime library. The runtime library provides support for thread management, scheduling, and synchronization. The current implementation of the runtime library sits on top of the SYSBIOS operating system and uses the interprocess communication (IPC) protocols running on each core of the DSP. Since these multi-core DSPs have both local private and shared memory, they map well into the OpenMP framework. Shared variables are stored in shared on-chip or DDR3 memory, while private variables are stored in local on-chip L1 or L2 memory.

However, there is no hardware support for cache coherency of data between cores. Hence, special care may need to be taken to keep the data in shared memory coherent. TI's OpenMP implementation does allow support for software cache coherency of DDR3 memory. This can be enabled with a slight loss of computational efficiency, if desired.

14.4 OCT Signal Chain on Multi-core DSP

In this section, we analyze the implementation details of a typical OCT signal chain in the TMS320C6678 multi-core DSP. In spectral-domain OCT systems, a single A-scan is normally acquired simultaneously, and as the beam scans over the sample, the sequence of A-scans collected can be assembled to form 2D or 3D datasets. The typical OCT image reconstruction steps are shown in Fig. 14.4. These steps, which include background subtraction, linearization in wave number (k), dispersion compensation, Fourier transforms, and dynamic range compression, can be performed independently on each A-scan. This parallel nature of OCT image reconstruction can be exploited by parallel processing techniques and multi-core platforms to significantly increase the speed for processing. DSPs have several cores that can process the data independently and in parallel to each other. Efficient utilization of the multi-core capabilities of the DSP would require partitioning the data and algorithms into independent subunits and assigning these to the DSP cores. In addition, memory hierarchy needs to be taken into consideration for efficient implementation. The data-intensive operations should be performed by placing the data in the limited but fast internal memory.

14.4.1 Dataflow

Typically, an acquired OCT frame would be copied from the frame grabber or data acquisition device onto the external memory on the DSP board. The OCT processing can be partitioned in a number of ways using the DSPs. An example

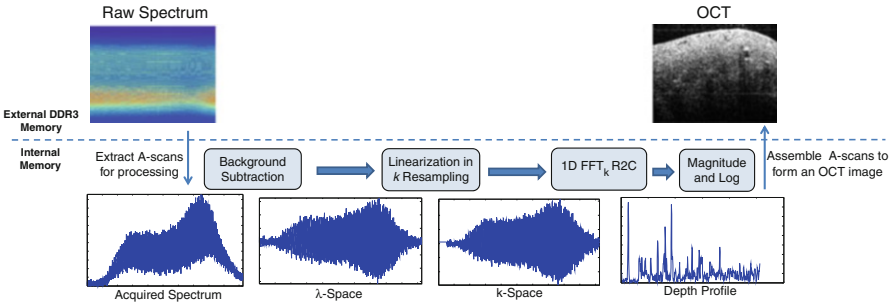

Fig. 14.4 Steps in the OCT signal chain. R2C is real-to-complex

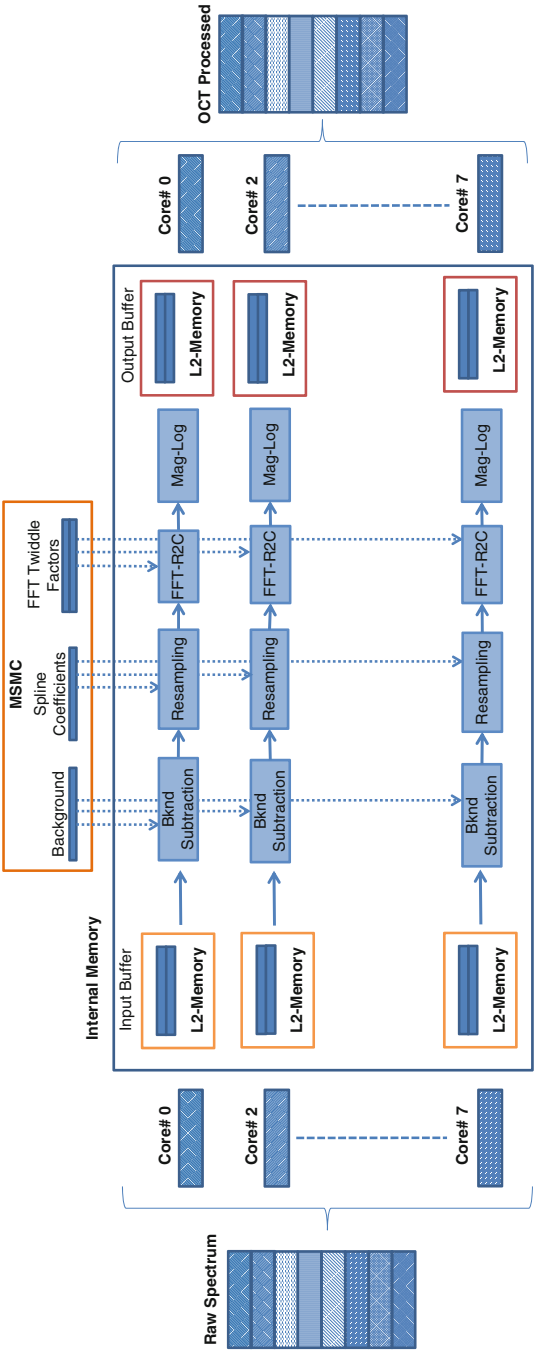

Fig. 14.5 OCT implementation on the multi-core DSP

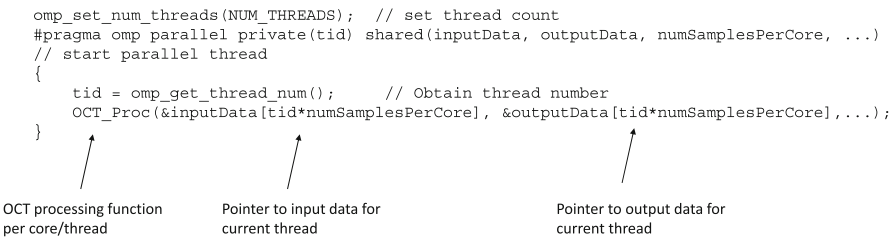

Fig. 14.6 Partitioning of OCT frames through OpenMP pragma

is shown in Fig. 14.5 where a single OCT frame is partitioned into several subsets of A-scans and each of these subsets would be operated independently and in parallel by a different DSP core. Within each core, all the processing on the A-scans are done serially, and finally the processed subsets from all the cores are assembled back to form the final processed frame. The partitioning of the frames into subsets can easily be done using OpenMP pragmas as shown in Fig. 14.6.

In principle, all processing on the data can be performed with the data residing in external memory. However, it is preferable to do the data-intensive operations by moving the data into the fast internal memory available on the DSP chip itself. Often it would be necessary to further divide the data subsets (that have been assigned to each core) into small enough patches that can fit within the limited amount of available internal memory. Each of these patches would contain several A-scans depending on the initial frame size, the number of available cores, and the amount of available internal memory. Each patch once moved inside the internal memory can be accessed at high speeds and, after completion of the processing, is copied back to the external memory. This additional overhead due to memory transfers between the external and internal memory can be minimized using direct memory access (DMA) controllers which can overlap the data transfer with data processing. Typically, memory buffers are configured in the internal memory and are operated as ping-pong buffers (double buffering) to overlap data transfer with the processing. An example of this dataflow within a single core is shown in Fig. 14.7, where the data subset assigned to the core is divided into patches and moved into the internal memory using the DMA controller. Four buffers each of which has a size equivalent to a single patch are configured in internal memory and are used for input, output, and processing purposes. As the Nth patch is being processed by utilizing the processing buffer (and temporary buffer for holding intermediate values), the (N – 1)th patch is copied back to the external memory from the output buffer after undergoing processing in the previous iteration. At the same time, the (N + 1)th patch is being copied into the input buffer, which would be processed in the next iteration. These buffers are then interchanged at the end of each iteration and hence are used alternatively for input, data processing, and output tasks. This procedure continues until all the N patches within the core have been processed.

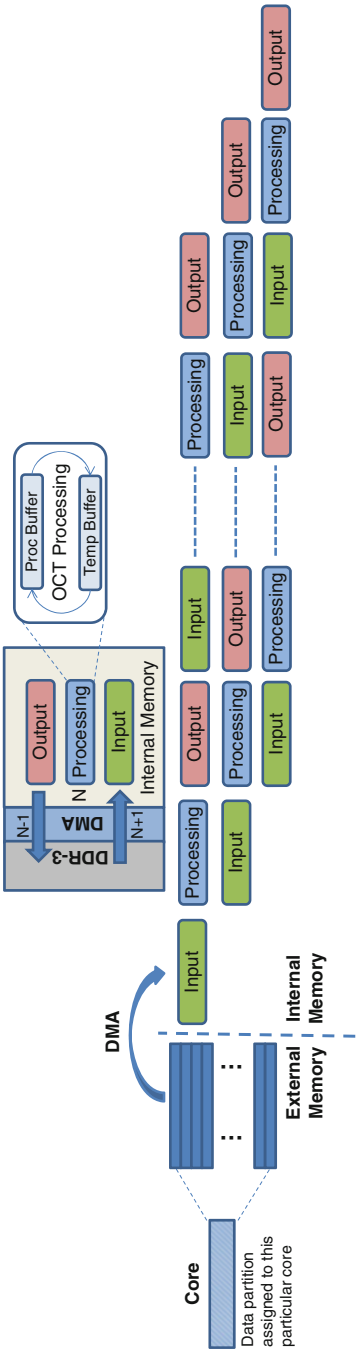

Fig. 14.7 Dataflow through buffers for OCT/ISAM implementation

14.4.2 OCT Data Processing on the DSP

Several chapters in this book present OCT processing methods in detail. Therefore, in this chapter, we will only focus on DSP implementation of standard OCT processing tasks which primarily include resampling and Fourier transform operations. In OCT, several inputs such as background spectrum, resampling indices, and the twiddle factors for the fast Fourier transform (FFT) can be precomputed. These precomputed values will need to be accessed by all the A-scans in each of the cores; hence, it is generally preferable that they be stored in a global memory with fast access times. One such option is utilizing the MSMC.

14.4.2.1 Resampling

The acquired spectrum measured by the spectrometer or obtained from swept-source OCT systems is a function of wavelength, hence, making the λ-k resampling a necessary step in OCT processing. A variety of interpolators (e.g., linear, cubic B-spline) have been employed by different OCT groups to perform the resampling. There is always an inherent compromise between the computational complexity and image quality of the different interpolators employed. Cubic spline interpolation, however, remains a relatively popular interpolator and its implementation on the DSP will be discussed here.

The resampling indices can be computed using a third-order polynomial function: $i_n = n + \beta_2\left(\frac{n}{N} - \omega_{ctr}\right)^2 + \beta_3\left(\frac{n}{N} - \omega_{ctr}\right)^3$, where ω_{ctr} is the center wavelength and N is the number of points in a single A-scan. The nonlinear mapping between the k-domain and the wavelength is adjusted using the parameters β_2 and β_3. These parameters are used to compute the integer and fractional parts that can be subsequently used to determine the spline table coefficients. The resampling indices/spline table coefficients, however, only need to be calculated once in the initialization phase, and the same indices can be reused for resampling every A-scan.

In our implementation, we have followed the technique described in [19]. Prior to using the interpolator, first-order causal and noncausal infinite impulse response (IIR) filters were employed to prefilter the data. This prefiltering is necessary to obtain an exact interpolated value at the original sampling indices. A first-order causal IIR filter, i.e., $b_k = x_k + \alpha b_{k-1}$, would require that the previous output value be available before the current output value can be computed. This operation is inherently serial in nature. Implementation of straightforward IIR filtering cannot take advantage of the parallelism available inside a core through the availability of multiple compute units and SIMD instructions. In order to improve the parallelization of computations, the equation $b_k = x_k + \alpha b_{k-1}$ was unrolled to up to three levels, as shown below.

$$
\begin{aligned}
b_{k-3} &= x_{k-3} + \alpha b_{k-4} \\
b_{k-2} &= x_{k-2} + \alpha x_{k-3} + \alpha^2 b_{k-4} \\
b_{k-1} &= x_{k-1} + \alpha x_{k-2} + \alpha^2 x_{k-3} + \alpha^3 b_{k-4} \\
b_k &= x_k + \alpha x_{k-1} + \alpha^2 x_{k-2} + \alpha^3 x_{k-3} + \alpha^4 b_{k-4}
\end{aligned}
$$

Four output values can now be calculated at each iteration. Though this unrolling increases the total number of computations per output value, the number of cycles used to produce the output, on average, is reduced due to better use of available compute units and SIMD instructions.

Similarly, first-order noncausal IIR filtering, i.e., $c_k = \alpha(c_{k+1} - b_k)$, was also executed by unrolling the equation to up to three levels to generate four outputs per cycle, as shown below.

$$
\begin{aligned}
c_{k+3} &= \alpha(c_{k+1} - b_{k+3}) \\
c_{k+2} &= \alpha^2 c_{k+4} - \alpha^2 b_{k+3} - \alpha b_{k+2} \\
c_{k+1} &= \alpha^3 c_{k+4} - \alpha^3 b_{k+3} - \alpha^2 b_{k+2} - \alpha b_{k+1} \\
c_k &= \alpha^4 c_{k+4} - \alpha^4 b_{k+3} - \alpha^3 b_{k+2} - \alpha^2 b_{k+1} - \alpha b_k
\end{aligned}
$$

After pre-filtering the data, the cubic spline interpolator based on the Farrow structure was employed. Mathematically, the output from the structure can be expressed as

$$
y_k = \begin{bmatrix} 1 & d & d^2 & d^3 \end{bmatrix}
\begin{bmatrix} 1 & 4 & 1 & 0 \\ 3 & 0 & -3 & 0 \\ 3 & -6 & 3 & 0 \\ 1 & -3 & 3 & -1 \end{bmatrix}
\begin{bmatrix} c_{k+1} \\ c_k \\ c_{k-1} \\ c_{k-2} \end{bmatrix}
$$

where each row in the second matrix corresponds to one of the four filters, d is the fractional part of the resampling indices, and c_k is the prefiltered data. The amount of run-time computations can be significantly reduced (up to four times) if the first two matrices are combined together and the resulting coefficients are precomputed during the initialization phase and stored in memory.

$$
y_k = \begin{bmatrix} bm0 & bm1 & bm2 & bm3 \end{bmatrix}
\begin{bmatrix} c_{k+1} \\ c_k \\ c_{k-1} \\ c_{k-2} \end{bmatrix}, \text{ where }
\begin{aligned}
bm0 &= 1 + 3d + 3d^2 + d^3 \\
bm1 &= 4 - 6d^2 - 3d^3 \\
bm2 &= 1 - 3d + 3d^2 + 3d^3 \\
bm3 &= -d^3
\end{aligned}
$$

Although this significantly reduces the processing time, the storage requirements for these coefficients (5 coefficients per output value) can be prohibitively large.

14.4.2.2 Fast Fourier Transform

TI provides optimized 1D FFT functions as part of its offering in MC-SDK. However, only a complex-to-complex FFT is currently available in this library. Our implementation uses the following steps to obtain a 2 N point 1D real-to-complex FFT from the available N point 1D complex-to-complex FFT:

1. The even and odd indices of a 2 N sequence of real numbers are combined to form an N-point sequence of complex numbers.
2. An N-point complex-to-complex FFT $X(k)$; $0 \leq k \leq N - 1$ is computed of the N-point complex sequence.

3. 1D FFT real-complex $G(k)$ is then computed by using the expression

$$G(k) = X(k)\left\{\frac{1}{2}\left(1 - jW_{2N}^{k}\right)\right\} + X^{*}(N-k)\left\{\frac{1}{2}\left(1 + jW_{2N}^{k}\right)\right\}, \quad 0 \le k \le N-1$$

where $W_N = e^{-j(2\pi/N)}$ and the factors $A(k) = \frac{1}{2}\left(1 - jW_{2N}^{k}\right)$ and $B(k) = \frac{1}{2}\left(1 + jW_{2N}^{k}\right)$ are precomputed and stored in memory.

14.5 2D ISAM Signal Chain on Multi-core DSP

In addition to the standard OCT processing, more computationally demanding operations can be performed using the DSP. As an example, we discuss the implementation of a computationally intensive technique called interferometric synthetic aperture microscopy (ISAM) on the DSP. The basic motivation behind ISAM is to overcome one of the inherent limitations that exists in traditional OCT, i.e., the trade-off between higher (better) transverse resolution and depth-of-field where tighter focusing degrades the transverse resolution outside the confocal region. ISAM is a computational technique that solves the depth-of-focus problem in OCT, hence yielding a spatially invariant transverse resolution throughout the imaging depth.

Briefly, ISAM solves the inverse scattering problem for OCT [2]. An exact ISAM reconstruction would require manipulating the 3D Fourier space of the volumetric data to correct for blurring in both transverse axes. We will describe the 2D implementation of ISAM, which can be easily extended to 3D [21]. The processing steps for ISAM processing are shown in Fig. 14.8. ISAM is an extension of OCT processing with some additional steps shown in the shaded box that are required for the Fourier domain manipulation of the data. After the traditional OCT processing, the complex form of an OCT image is used for further ISAM processing, as ISAM requires access to both the amplitude and the phase of the data. 2D ISAM requires an

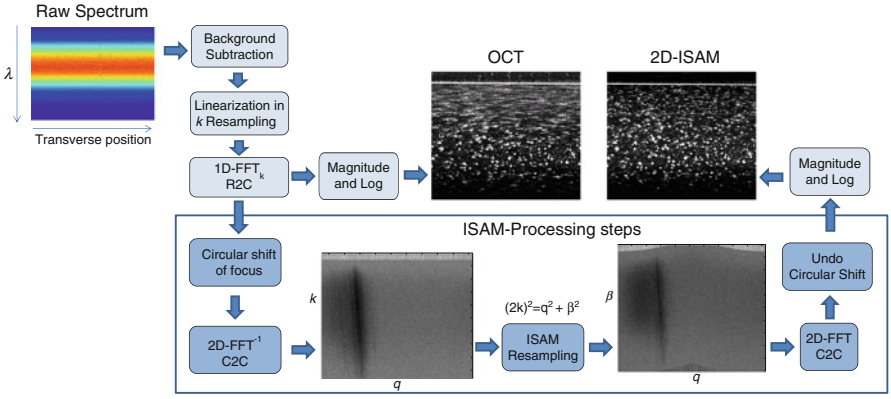

Fig. 14.8 Steps in the 2D ISAM signal chain. The shaded blocks are the additional processing steps required for ISAM. R2C is real-to-complex and C2C is complex-to-complex

inverse 2D FFT to move the data into the Fourier domain, resampling of the Fourier space, followed by another 2D FFT to bring back the data into the spatial domain. As the Fourier transforms and resampling operations are performed on the complex data, constraints are placed on the data sizes and the memory transfer overheads associated with moving the data in and out of the memory [15].

14.5.1 ISAM Dataflow

A 2D ISAM algorithm can be implemented as a sequence of 1D operations on the individual A-scans as shown in Fig. 14.9. The same general framework mentioned in Sect. 14.4 can be used for distributing the data among the cores and partitioning it further into patches to make use of the fast on-chip memory. Each patch containing multiple A-scans is then processed serially by a sequence of 1D operations. It is desirable to complete all the necessary operations while the data is residing in the internal memory. However, if the data size becomes too large, it would be inevitable to move it back to the external memory. Once each core operates on all the A-scans assigned to it, the A-scans are assembled back to a frame. The same procedure is repeated again until the ISAM processing is completed. A total of eight external and internal memory transfers were performed for the 2D ISAM implementation.

The two main building blocks for 2D ISAM are the 2D FFTs and the ISAM resampling. In the following sections these two modules are described in more detail.

14.5.2 Two-Dimensional FFT

The 2D FFT can be divided into a two-step process where 1D FFTs are taken along each of the dimensions alternatively. However, its implementation as a sequence of 1D FFTs would require transposing the data (as the data is accessed in the row-major order) prior to taking the 1D FFT along the second dimension. If the 1D FFT operations are performed on the data residing in the internal memory, the matrix transpose operation would require copying the data into either the shared RAM or the external memory to form another 2D frame with the dimensions now interchanged. Then, the data is again copied back to the internal memory to take the 1D-FFT along the orthogonal dimension.

14.5.3 ISAM Resampling

The ISAM resampling indices depend on the axial and transverse spatial frequency coverage of the imaging system and can be precomputed using the relationship $k = 0.5\sqrt{q^2 + \beta^2}$ where q is the transverse and β is the axial spatial frequency coordinate, respectively [20]. The resampling indices would, however, be different for every A-scan within the cross-sectional plane and once calculated and stored, can be used for every cross-sectional plane in the volume (they do not need to be

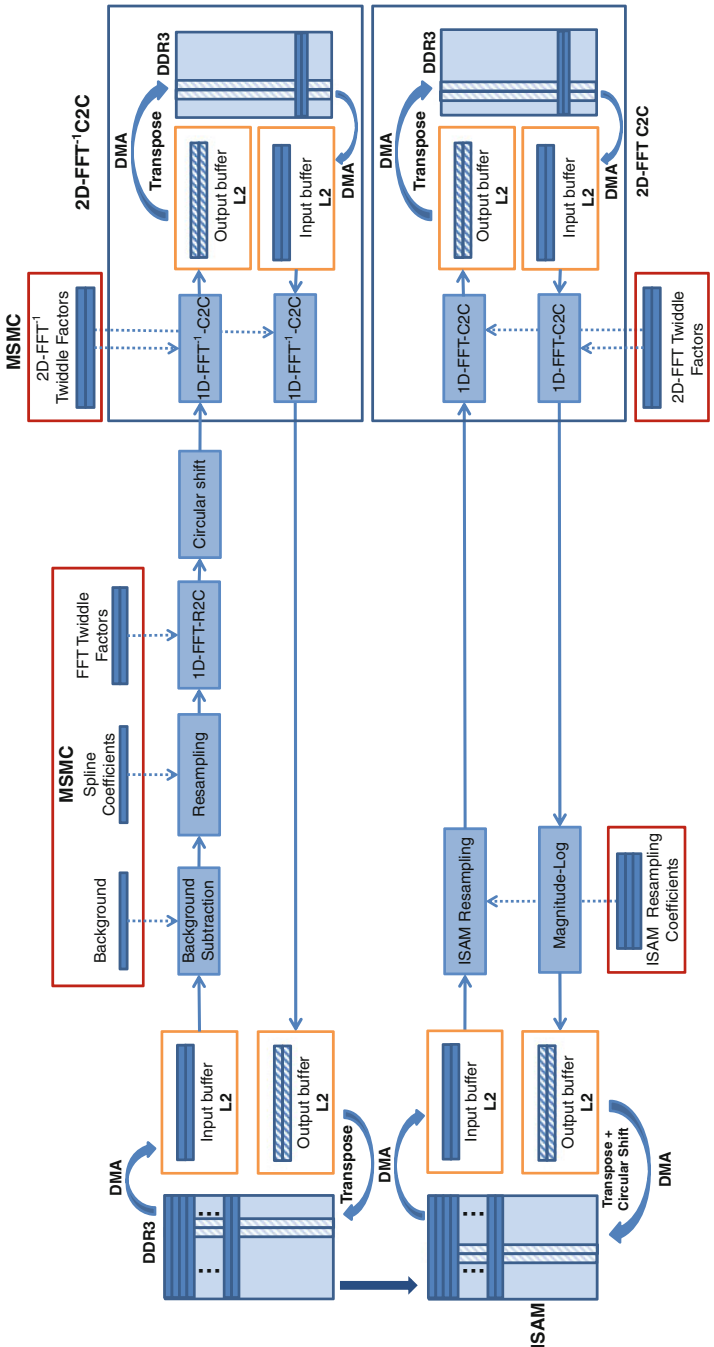

Fig. 14.9 2D ISAM implementation on the multi-core DSP

computed for each cross-sectional plane). These indices are then used to calculate the cubic spline parameters as described in Sect. 14.4.2.1. For each pixel in the image, four spline coefficients (bm0, bm1, bm2 and bm3) and an index need to be computed and stored in the memory. These spline coefficients will be heavily accessed using ISAM resampling; hence, it is desirable to store these in the MSMC RAM to make use of the fast access times. The large storage requirements and the memory access latencies make ISAM resampling consume a significant amount of processing time. The same resampling scheme mentioned in Sect. 14.4.2.1 can be applied individually to the real and imaginary part of the complex data. However, because of the complex nature of the data, the prefiltering was implemented by unrolling the causal and noncasual IIR filter equations up to one level, thereby computing two complex outputs per iteration.

14.6 Results

The volumetric datasets (1,024 × 512 × 512 pixels) corresponding to a field-of-view of 2.8 mm in depth and 1 mm × 1 mm in the transverse dimensions were acquired with a 1,300 nm spectral-domain OCT system operating at an A-scan rate of 91,912 kHz (with a line-scan array of 1,024 pixels). The data was transferred to the external memory on the DSP and was processed post-acquisition using single precision operations on the standard TMS320C6678 DSP evaluation module [22].

Figure 14.10 shows OCT and 2D ISAM cross-sectional planes processed using the DSP. The sample consisted of TiO_2 scattering particles embedded in a silicone matrix. The blurring outside the focal region is clearly evident in the OCT image, and after applying 2D ISAM on the cross-sectional plane, depth invariant transverse resolution is achieved.

The 2D ISAM applied to the cross-sectional planes can be extended to do a full 3D ISAM reconstruction by applying the same 2D ISAM reconstruction on the

orthogonal cross-sectional planes in the volumetric dataset. Each frame, after undergoing 2D ISAM processing, was assembled back into a volume. Subsequently, the orthogonal axis frames were extracted from this volume and 2D ISAM was performed on these planes for a full 3D ISAM reconstruction [21]. 3D ISAM was performed on an output volume comprising of 512 × 512 × 512 pixels using the DSP. The en face plane taken at 855 μm above the focus in the tissue-mimicking phantom is shown in Fig. 14.11 where isotropic transverse resolution can be seen after applying 3D ISAM. Results using ex vivo mouse lung tissue are shown in Fig. 14.12. Significant improvements in the ISAM processed dataset can be seen, compared to the OCT processed dataset. A qualitative comparison between a DSP-based implementation of 3D ISAM (Fig. 14.12b) and a double precision implementation in Matlab (Fig. 14.12c) shows no visible differences in reconstruction quality.

Functions	Time

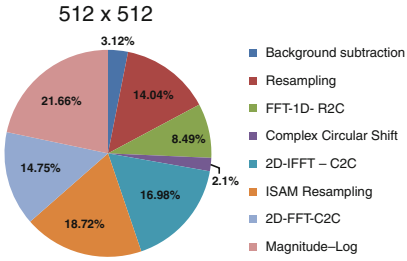

Fig. 14.14 ISAM timing results. The pie chart shows processing speeds of the individual modules as a percentage of total processing time (does not include memory transfer overheads) (Adapted from Ref. [15])

We also present timing results of our evaluation of OCT and 2D ISAM processing (Fig. 14.13 for the OCT signal chain and Fig. 14.14 for the ISAM signal chain) for output frame sizes of 512 × 512 and 512 × 1,024. These timing results show that 2D ISAM can be processed at 70,000 A-lines/sec and OCT at 180,000 A-lines/sec with the current implementation. The computation of magnitude (square root) and dynamic range compression (log) for visualization takes a considerable percentage of computational time in this implementation, especially for the OCT signal chain. We have used the full single precision accuracy for these computations. This computational time can be reduced considerably by using table-based dynamic range compression. Due to the parallel nature of computations, the processing rate can be scaled up by using multiple TMS320C6678 devices. For example, the quad/octal DSP PCI express board can be used to demonstrate full volume rate ISAM processing [23, 24]. The standard boards mentioned here can be used to quickly demonstrate the potential of DSP technology for OCT applications. However, an embedded system designed specifically for OCT applications will be preferred to take full advantage of the computational and power advantages of a DSP.

14.7 Conclusion

OCT systems have been steadily finding commercial applications in many medical and surgical areas including ophthalmology, optometry, cardiology, surgical oncology, gastroenterology, and dentistry. Many of these systems are currently based on desktop PC systems. As these systems evolve, the need for solutions based on embedded and scalable processing increases. This chapter discussed DSP technology, especially the multi-core version of this technology, and its potential use in OCT systems. As used in many other systems, DSP technology will help develop portable and handheld OCT systems. This will open new opportunities to bring OCT-based devices into point-of-care health-care systems.

Acknowledgment The contributions and helpful discussions with Fredrick South, Guillermo Monroy, Nathan Shemonski, Dr. Steven Adie, and Prof. Scott Carney from the University of Illinois at Urbana-Champaign are gratefully acknowledged. We would also like to thank Dan Wang at Texas Instruments, Inc. for the help provided in DSP implementation. This research was supported in part by a Bioengineering Research Partnership grant from the National Institutes of Health (R01 EB013723, S.A.B..) and a research agreement with Texas Instruments, Inc.

15.1 Introduction

From the introduction of time domain OCT [1] up to recent swept source systems, motion continues to be an issue in OCT imaging. In contrast to normal photography, an OCT image does not represent a single point in time. Instead, conventional OCT devices sequentially acquire one-dimensional data over a period of several seconds, capturing one beam of light at a time and recording both the intensity and delay of reflections along its path through an object. In combination with unavoidable object motion which occurs in many imaging contexts, the problem of motion artifacts lies in the very nature of OCT imaging. Motion artifacts degrade image quality and make quantitative measurements less reliable. Therefore, it is desirable to come up with techniques to measure and/or correct object motion during OCT acquisition. In this chapter, we describe the effect of motion on OCT data sets and give an overview on the state of the art in the field of retinal OCT motion correction.

15.2 OCT Scanning

Both 2D and 3D OCT images are composed of a high number of 1D depth profiles of backscattered intensity along the beam of an OCT probe. Each of these axial scans or A-Scans is acquired at slightly different points in time. Usually, a pair of galvanometer mirrors is used to programmatically deflect the OCT beam along two principal directions x and y. These two directions are called transverse directions. Simultaneous transverse scanning of the beam using the mirrors while acquiring A-Scans is used to acquire multidimensional images in OCT. Since the basic unit of acquisition in OCT is 1D, additional spatial dimensions are encoded in time by scanning the beam over the object. To acquire a 2D OCT image or B-Scan, the OCT beam is swept in a linear trajectory while acquiring A-Scans. Similarly, 3D OCT volumes are acquired by raster scanning a grid of A-Scan sampling positions while acquiring A-Scans. In a raster scan, the grid of A-Scans is acquired as a series of linear B-Scans. After each B-Scan the mirrors are repositioned at the start of the next B-Scan. During this time, no acquisition takes place and a certain downtime called flyback time is incurred. Figure 15.1 shows a schematic overview of 1D, 2D, and 3D OCT imaging.

The direction that is rapidly scanned in each B-Scan is called transverse direction or the fast direction. In contrast, the orthogonal direction on the grid is scanned much slower, hence its name slow direction. The effect of the priority scanning in

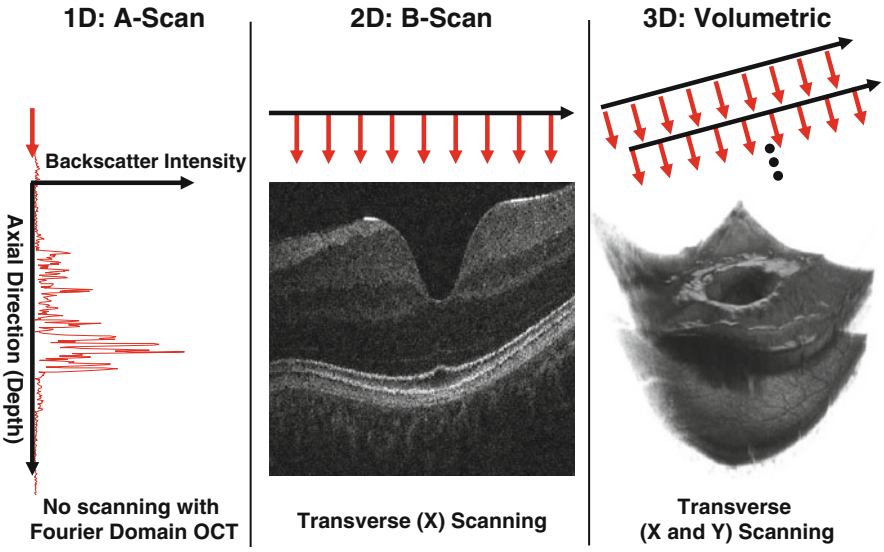

Fig. 15.1 OCT scanning and scanner coordinate system schematic. *Left*: 1D acquisition (A-Scan). A single depth profile is acquired which measures backscattered intensity vs. axial dimension (depth). *Middle*: 2D imaging (B-Scan). The OCT beam is scanned in a transverse direction while A-Scans (*red arrows*) are acquired. *Right*: 3D acquisition. Multiple B-Scans are acquired such that A-scans are sampled on a 2D grid in the transverse plane

one direction is that neighboring A-Scan samples on the grid along the slow scan direction are acquired much more apart from each other in time, compared to the fast scan direction.

OCT scanning takes place in a scan coordinate system that consists of x and y galvanometer mirror positions and axial depth along the light beam z. Given a static object that does not move relative to the OCT system, every set of galvanometer mirror positions maps to a certain beam path through the object. In combination with the axial coordinate z, a fixed relationship between scan coordinate system coordinates and positions on the object exists. However, especially in in vivo imaging, the relative position between the OCT system and the object can change over time. We can think of this as having another coordinate system called the object coordinate system that has a time-dependent relation to the scan coordinate system. Any relative motion between OCT system and imaged object changes this relationship.

OCT acquisition times in in vivo imaging can take as much as several seconds, due in part to the way spatial dimensions are encoded in time, the scan pattern used, and the speed of typical OCT systems. Object motion during this time leads to a deviation of the beam paths of individual A-Scans relative to the case of there being no motion. The deviation leads to the object being sampled at locations inconsistent with the time/space encoding and results in spatially distorted data. Motion can cause parts of the object to be imaged multiple times, while other parts might not be sampled at all. These effects cause errors in quantitative measurements on the OCT data that rely on the accurate measurement of spatial features of the object. If multiple spatial dimensions are encoded, we can expect that the potential distortion that is caused by motion is much larger in the direction that has the larger acquisition time difference between samples, i.e., the slow scan direction in a 3D raster scan pattern. Conversely, if the encoding is done very fast relative to the speed of the relative motion, the motion is effectively frozen out and the image shows no noticeable spatial distortion. This is, for example, the case for a 2D B-Scan image on a commercial Fourier domain OCT system of the current generation.

Motion correction approaches in OCT try to enforce that the individual A-Scans of a corrected acquisition show the expected locations, regardless of motion during the acquisition. In the following sections, we restrict ourselves to the motion problem and possible solutions in the context of OCT imaging of the retina. This is because retinal imaging is the most important in vivo application of OCT and the focus of most efforts in the area of motion correction.

15.3 Retinal Imaging

OCT is a standard of care for ophthalmologic examinations of the retina due to its high resolution and noninvasiveness. It has key applications in early detection and monitoring of common eye diseases such as glaucoma and age-related macular degeneration (AMD). As such, it is important for quantitative measurements that are extracted from retinal OCT data to be reliable and reproducible. However, when

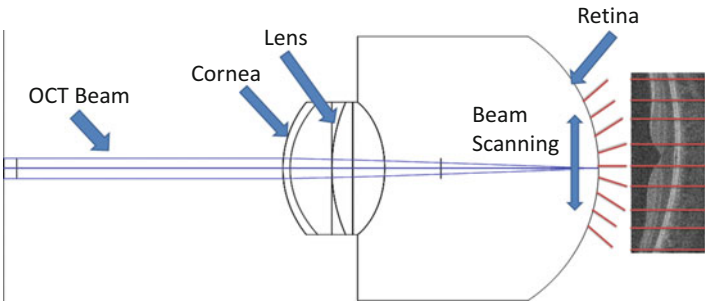

Fig. 15.2 Baseline situation of imaging an eye using OCT. A collimated beam originating from the OCT system passes through cornea and lens and is focused onto the retina. By changing the angle of incidence of the beam on the eye, the beam is scanned over the retina. During scanning, A-Scans are acquired (*red lines*). Because of the optics of the eye, the A-Scans are in a fanlike geometry. An OCT image is created by showing these A-Scans as parallel lines (*right image*)

imaging the eye in vivo, several sources of motion are not avoidable and motion artifacts occur that limit the reliability of quantitative measurements. In the following sections, we consider aspects of ophthalmologic imaging that are relevant to the motion correction problem.

15.3.1 Eye Optics/OCT Scanning

One peculiarity of retinal imaging is that the eye itself becomes part of the optics of the system, i.e., the combination of cornea and lens of the eye focuses the OCT beam onto the retina. This is different from an OCT microscope, for example, where all the optical elements such as lenses are fixed relative to the system. In retinal imaging, ideally the eye is aligned to the OCT system such that the scanning OCT beam is pivoted in a fixed point $\mathbf{P}_{pivot}$ in the center of the pupil of the eye. This minimizes vignetting of the beam by the pupil of the eye and enables imaging the largest possible area on the retina. Figure 15.2 shows a schematic view of the optics involved for imaging the retina. The OCT beam is collimated incident on the cornea which in combination with the lens focuses the beam onto the retina. Scanning of the retina is performed by changing the incident angles of the OCT beam relative to the optical axis using galvanometer mirrors. The eye optics maps the two incoming angles in x and y direction onto corresponding angles on the retina. Since the OCT beam is pivoted during scanning, the beam paths for each A-Scan during a linear scan create a fanlike pattern on the retina. This means that the beam paths of neighboring A-Scans are not actually parallel. When the OCT data is displayed though, the individual A-Scans are seen as parallel lines that form 2D and 3D images. Therefore, the OCT data is displayed as a 2D or 3D function of one or two galvanometer mirror positions and an axial depth. This representation maps approximately to Euclidian coordinates on the retina. However, for considering the possible effects of motion, it is important to consider the actual scan geometry.

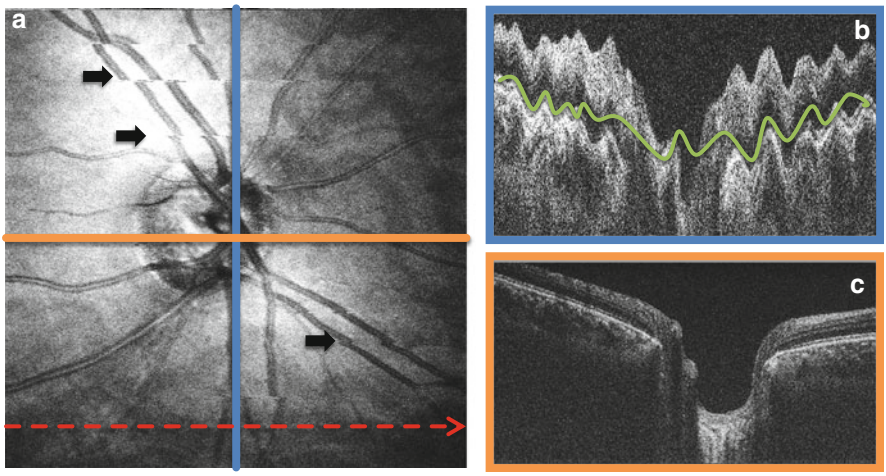

Fig. 15.3 Example of motion artifacts in a raster-scanned 3D OCT volume. The volume consists of 400 by 400 A-Scans sampled over 6 by 6 mm centered on the optic nerve head. The system was running at 90 kHz A-Scan rate, leading to a total acquisition time of approximately 2.5 s including flyback. (**a**) En face fundus projection of the volume. The *dotted red line* marks the fast scan direction of the volume. The *black arrows* indicate motion artifacts caused by transverse eye motion that create discontinuities in the vessel pattern. (**b**) Excerpt of the central slice of the volume along the slow scan direction (*blue line* in **a**). Axial motion leads to a wavy deformation of the retina in axial direction (*green curve*). (**c**): Excerpt of the central slice of the volume along the fast scan direction (*orange line* in **a**). The spatial structure of the retina remains intact along the fast scan direction

15.3.2 Motion Types/Effects

In eye motion, we can distinguish between transverse eye motion and axial eye motion. These names relate to the direction of displacement they cause within the scan coordinate system. Transverse eye motion is equivalent to a change in fixation of the subject. Here, muscles rotate the eyeball in the left/right and up/down directions. Transverse motion can further be subdivided into slow drifts of fixation and fast saccadic motion. Saccadic motion typically occurs up to two times a second and can lead to a change in fixation angle of up to 4° [2, 3]. The duration of saccadic motion itself can range from 20 ms to 100 ms and can be very fast with angular velocities of up to 300° per second [4]. The second fundamental type of eye motion is motion in the axial direction. This is equivalent to the eyeball and/or retina moving toward or away from the OCT system. Axial eye motion can be caused by changes in blood pressure caused by the heartbeat and by respiration. Compared to saccadic transverse motion, axial motion is slow and has low frequency. Figure 15.3 shows an example of the effect of different types of motion on a 3D-OCT data set.

Motion of the eye relative to the system causes two primary effects: For one, the angle of incidence of the OCT on the pivot point can change. The second effect is

that the *actual* pivot point of the combined system can deviate significantly from the ideal pivot point $\mathbf{p}_{pivot}$. Assuming that only the incident angles change about δx and δy and that the pivot point stays the same, this change in incident angle gets transformed to a change in angle within the coordinate system of the retina. The incident angle can also be changed using the galvanometer mirrors, though. Given the right correction on the mirror angles, the beam path can be the same as if there was no eye rotation. Therefore, if the beam always pivots a single point, transverse motion of the eye causes a transverse displacement of the beam on the retina that could also be reached by applying an offset to the incident galvanometer mirror positions.

If due to motion the actual pivot point is different from the reference pivot point $\mathbf{p}_{pivot}$, the light focuses at the same lateral position on the retina; however the optical path length changes. The dominant effect is a translation of the A-Scan content in the axial direction. This is usually seen as an axial tilt of the retina within the B-Scan. A secondary effect is that the incident angle of the A-Scan on a specific position on the retina changes with beam translation in the pupil plane. This means that the actual beam path through a certain point on the retina deviates from the beam path of a normally pivoted point. Both beams intersect in the same point on the retina, but due to the different angle of incidence, the beams do not sample the same transverse positions closer and farther down the axial dimension. If this effect were significant, it would mean that the effect of a change in pivot point could not be compensated by applying an offset on the galvanometer positions.

As an example for the size of this effect in a typical eye, a simulation using ZEMAX and an eye model was performed. A 2 mm translation of the beam in the pupil plane results in a change in the angle of incidence of the OCT beam on the retina of about 5°. Over the thickness of the retina of about 300 μm, the maximum deviation in the beam path which is caused by the change in pivot point is 13 μm. This is less than a typical spot size diameter of 20 μm. Also, this deviation is two orders of magnitude smaller than the effects of eye rotation. Assuming a typical pupil size of the eye of 4 mm and an OCT beam diameter of 2 mm incident on the pupil, any greater shift in beam position would already cause vignetting of the beam by the pupil, causing visible signal loss in the OCT data set. Furthermore, according to [2], the angular rotation induced by involuntary eye motion such as drifts and saccades does usually not exceed 4°. Using the simplifying assumption that the eye is spherical with a radius of about 11 mm and rotates around the center of the sphere, a 4° rotation corresponds to a lateral translation of the pupil with respect to the OCT beam of about 0.8 mm ($displacement = \sin(\alpha) radius$). This is well below the 2 mm shift for which the minimal change of the beam path was calculated and therefore leads to an even smaller effect.

In practice, both the incident angle and the pivot point position change because of motion. However, from these simplified sample calculations, we can conclude that in ophthalmologic imaging, the effects of eye motion in transverse and axial direction move the content of the A-Scan in a way that is consistent with applying a corresponding offset to the galvanometer positions and moving the content of the A-Scan in axial direction. Higher-order effects such as those resulting from

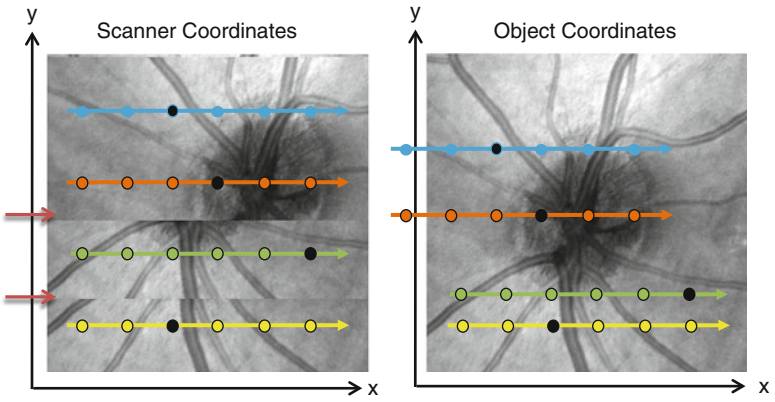

Fig. 15.4 Schematic showing relation between object and scanner coordinate system when affected by motion. *Left*: En face view in the scanner coordinate system. *Dotted colored arrows* indicate B-scans; *dots* indicate individual A-scans. The background shows an en face fundus projection as it would be acquired given motion. The two *red arrows* indicate discontinuities from motion. *Right*: En face view in the object coordinate system. Corresponding *color arrows* indicate where B-scans from the scanner coordinate system are located in the object coordinate system. The background shows an en face view of the object in the object coordinate system

a change in pivot position can be considered negligible for explaining the effects of normal eye motion. This is consistent with the effects that are due to motion and are observed in practice.

Figure 15.4 shows a schematic view of the relation between the scanner and object coordinates under the effects of motion. Due to saccadic motion of the eye, the relation in the transverse coordinates between the scan and object coordinate system changes rapidly. This leads to discontinuities in the acquired en face fundus projection. In addition, certain areas are missed during scanning, while others are imaged repeatedly. For a certain A-Scan, the difference in position between the two coordinate systems corresponds to the deviation in galvanometer mirror positions that was caused by motion at the time the A-Scan was acquired.

15.4 Motion Correction Approaches

Since motion artifacts constitute a serious issue, especially for retinal OCT imaging, considerable work has been performed by different groups to help solve the problem. In the following sections, we give an overview of the state of the art in OCT motion correction techniques.

One basic feature of a particular motion correction technique is whether it needs additional hardware support, i.e., the OCT system needs to be built with the motion correction technique in mind or additional imaging modalities need to be available. There are two basic ways to address the problem. Hardware-based methods try to avoid motion artifacts during the acquisition itself though a specific system design:

- Freeze out motion by improving the encoding of spatial dimensions in time, i.e., acquire the data set in a shorter time.
- Measure the deviations that originate from changes in relative position, and actively apply corrections to the galvanometer mirror positions during acquisition: tracking OCT.

Software-based methods on the other hand try to correct motion artifacts retrospectively using image processing:

- Use images from another modality that does not suffer from motion artifacts as OCT does as a reference to correct the OCT data.
- Correlate consecutively acquired data to filter out the effects of motion.
- Correct motion artifacts using additional OCT data with orthogonal fast scan axis.

In the following sections, we review selected state-of-the-art methods for each approach.

15.4.1 Hardware-Based Methods

15.4.1.1 High-Speed OCT

One fundamental way to alleviate the motion artifact problem in OCT is to increase the imaging speed of the OCT system, which continues to be important. Higher speed means that a higher number of A-Scans can be sampled per unit of time and that therefore a certain scan pattern can be sampled in less time. Since motion requires time to pass, short enough acquisition times can effectively be used to "freeze out" motion in parts or even in the whole OCT acquisition and minimize motion-induced spatial distortion.

Historically, the move from time domain to Fourier domain OCT [5] enabled an order of magnitude increase in acquisition speeds. This was mainly due to the inherent advantage of sensitivity of Fourier domain OCT [6]. In addition, the reference arm did not need to be scanned anymore during the acquisition of a single A-Scan. It is a reasonable assumption in time domain OCT that there is effectively no motion within an A-Scan. The higher speed of Fourier domain OCT systems allows current commercial systems to effectively disregard motion within a single 2D B-Scan, simply because the acquisition time is short enough compared to the speed and frequency of eye motion.

Within the realm of existing Fourier domain OCT technology, it has been shown that system speed can be improved tremendously with respect to standard commercial systems which operate at around 25 kHz A-Scan rate. Using Fourier domain mode locked (FDML) swept source lasers, retinal OCT operating at up to 6.7 MHz has been shown [7–9], albeit with reduced sensitivity and resolution compared to commercially available systems.

There is an inherent sensitivity loss associated with running faster than the maximally allowed light exposure on the eye, which is limited by safety standards. This puts an upper bound to the number of photons that can be collected per unit of time. Now, if one runs twice as fast, there are only half as many

photons available to be collected per A-Scan. All other things being equal, this means that one pays an increase in speed with a loss in sensitivity. Especially for clinical applications, where subjects might have bad eye optics, opacities, and floaters, system with sufficient sensitivity headroom is necessary for imaging.

Another issue is that one might want to use the high speed of a system not just to lower the overall acquisition time and motion artifacts. Instead one might choose to acquire more A-Scans in total, e.g., to sample more densely and/or to sample a larger area. This trade-off depends on the concrete data that one wants to collect.

Pending significant improvements in sensitivity, speed alone is unlikely to be the only solution to motion artifacts in OCT, at least as long as dense sampling of a clinically relevant area with good sensitivity and resolution is required. Such improvements might come from entirely alternative forms of OCT such as full-field OCT which has already been demonstrated for retinal imaging [10]. This technique illuminates the full field at once and does not require the scanning of the OCT beam. This helps in achieving high speeds and allows for a higher light exposure. However, as of now, low sensitivity and axial resolution as well as issues with cross talk and uniform image quality limit the practicality of the technique.

15.4.1.2 Tracking OCT

The approach of tracking OCT is to continuously measure the motion-induced deviation from a reference position and to apply a corresponding offset to the galvanometer mirrors and/or the reference arm mirror to cancel this deviation, effectively compensating for the deviation in scan position that is caused by object motion and therefore removing motion artifacts. Key factors in tracking OCT are the accuracy of measurement of the deviation and its correction and the update rate of the system, i.e., how fast the system can react to a motion-induced change in relative position.

Pircher et al. employed axial tracking of the eye motion in the context of retinal imaging using time domain en face OCT [11]. This modality acquires one en face plane of information at a time using rapid scanning. Therefore, it is very sensitive to axial motion even in the order of the axial resolution of the system. Axial deviation due to motion was measured by using a second Fourier domain channel at 1,300 nm that was used to continuously track the position of the cornea. The measured deviations in cornea position were used to generate a correction signal for a voice coil in the reference arm to rapidly change the reference arm length. This system achieved an update rate of 200 Hz.

Although there is some work on axial tracking, more commonly tracking in OCT is used to correct for transverse motion. Ferguson et al. used a secondary sensing beam that rapidly scans a circular area on the fundus, for example, around the optic nerve head [12–14]. The system extracts correction information from this secondary channel in a closed loop running at 1 kHz and applies the correction to the galvanometer mirrors. The reported accuracy of the technique is less than one spot diameter.

Transverse tracking is also employed in commercial OCT devices such as the Heidelberg Engineering Spectralis [15]. A scanning laser ophthalmoscope (SLO) is used to rapidly acquire 2D images of the fundus. These images are then registered to a reference SLO view. The shift between the two images corresponds to the deviation in scan angle. A correction signal is then applied to the galvanometer mirrors to compensate for this deviation. The use of this technique allows the system to acquire multiple 2D B-Scans at roughly the same location and average them in order to remove speckle noise and increase signal-to-noise ratio.

15.4.2 Software-Based Methods

The second fundamental class of motion correction methods is not relying on additional hardware, but instead motion correction of the OCT data is performed retrospectively in post-processing.

15.4.2.1 Use of Additional Modalities

This class of motion correction approach employs reference image data from a different modality that is not suffering from motion artifacts as OCT is. By registering the OCT data to the reference modality, image one can find corresponding locations between the two images. The OCT data can then be mapped into the space of the reference image. Since the reference image contains virtually no motion, the OCT data can be motion corrected if the mapping between the two images is accurate.

Two modalities that are used for retinal imaging and which are not suffering from OCT like motion artifacts are fundus camera photography and imaging using a scanning laser ophthalmoscope (SLO). Motion in fundus photography will lead to a blurring effect. However, typical exposures are short enough to prevent this problem. SLO is a scanning imaging modality that is similar to OCT in this respect. However, SLO typically scans much faster than OCT and can more effectively freeze out object motion. Capps et al. used an adaptive optics SLO that is running simultaneously with the OCT acquisition to estimate and correct for lateral motion [16]. After imaging, the OCT data is registered to the AO-SLO data in order to calculate the displacement caused by motion per A-Scan. Subsequently, the OCT data is resampled onto a regular grid. Ricco et al. registered the OCT fundus view to an SLO reference image in order to correct for motion [17]. The algorithm uses the vessel pattern visible in both modalities as features for the registration. After vessel detection, registration is performed in a two-step process: First, drift and tremor is corrected for by using an elastic registration technique that is based on patch-wise constant affine transformations between the two images. Over all pixels (x,y), the sum of the terms

$$\left(m_7 I^{SLO}(x,y) + m_8 - I^{OCT}(m_1 x + m_2 y + m_5, m_3 x + m_4 y + m_6)\right)^2 \qquad (15.1)$$

is minimized, where $I^{SLO}(x, y)$ and $I^{OCT}(x, y)$ are the two images and $\mathbf{m} = (m_1, \ldots, m_8)$ is the parameter vector. The same parameters $\mathbf{m}$ are shared over one patch. The second step attempts to correct discontinuities caused by microsaccades along the fast scan direction. The OCT en face pixels are treated as a time domain signal, and the best alignment with the reference image is found using dynamic time warping.

15.4.2.2 Consecutive Data Correlation

The underlying idea of consecutive data correlation algorithms is to assume that the imaged object is inherently smooth and densely sampled by the OCT scan pattern. Therefore, high-frequency spatial patterns in the data, i.e., jumps between consecutively acquired A-Scans or B-Scans, are induced by motion only. By correlating consecutive data and shifting it such that the smoothness of the result is maximized, the high-frequency artifacts that are induced by motion can be removed.

Early on Swanson et al. used 1D cross correlation between neighboring time domain OCT A-Scans within a 2D intensity B-Scan $I(x, z)$ to try to remove motion artifacts [18]. The axial shift $\delta z(x)$ between consecutive A-Scans that maximizes the cross correlation

$$\sum_z I(x, z) I(x + 1, z + \delta z(x)) \tag{15.2}$$

is calculated for every A-Scan. An absolute motion profile $motion_z(x)$ is calculated by cumulating the relative shifts such that $motion_z(x) = \sum_1^x \delta z(x)$. This 1D motion profile is subsequently filtered based on prior knowledge on the frequency distribution of axial motion. Specifically, the motion profile needs to be high-pass filtered; otherwise, the low-frequency curvature of the retina is removed. Finally, the filtered motion profile was applied to each A-Scan to remove axial motion.

A very widespread ability of current commercial clinical Fourier domain OCT systems is the ability to produce high-quality 2D B-Scans by repeated scanning of the same location, subsequent registration, and averaging of intensity values. This technique is implemented in all major commercial Fourier domain OCT systems in one form or another and is used in clinical practice [19, 20]. Motion during the repeated scans is likely to cause slightly different speckle patterns in each of the acquired B-Scans. By registering and averaging the subsequently acquired B-Scans, this change in speckle pattern is used to remove the speckle noise from the images and increase the signal-to-noise ratio of the B-Scan. To register two intensity B-Scans $I_1(x, z)$ and $I_2(x, z)$, a measure of similarity between two images as well as a parameterization of the degrees of freedom for the deviation in position between the two scans has to be chosen. A simple approach is to maximize the cross correlation while allowing a global 2D shift $(\delta x, \delta z)$ in position between the images. The objective function in this case becomes

$$\sum_x \sum_z I_1(x,z) I_2(x+\delta x, z+\delta z) \tag{15.3}$$

which can be effectively maximized using FFT. This simple approach does not model tilt in axial direction, which can result from transverse eye motion. By maximizing the function

$$\sum_x \sum_z \left(I_1(x,z) - I_2(x+\delta x, z+\delta z+m_z x)\right)^2 \tag{15.4}$$

according to $(\delta x, \delta z, m_z)$, tilt is also corrected. This objective function uses the sum of squared differences (SSD) measure as opposed to cross correlation. This function can be minimized using numerical optimization techniques [21]. Sub-pixel accurate registration can be obtained by making $I_2(x, y)$ interpolate values between image grid positions. In practice, more advanced methods are readily available for use, such as the StackReg plug-in [22] for the ImageJ software package.

In 3D volumetric imaging using raster scans, correlation and/or registration can similarly be used to estimate the motion-induced shift between consecutively scanned neighboring B-Scans within the volume. The registration of subsequent B-Scans in a volume is analogous to the repeated B-Scan case. Once consecutive B-Scans have been registered, the shifts can again be filtered in order to preserve low-frequency curvature of the scanned object. The underlying motion model assumes that motion only occurs in between B-Scans, i.e., that B-Scans themselves are rigid. Furthermore, the correlation of consecutive B-Scans can only correct for *in-plane* motion, which is motion that causes a shift of the image content in axial and/or in the direction of the fast scan direction of the raster scan. In reality however, transverse motion such as that caused by saccades can also take place in the direction of the slow raster scan direction. In this case, techniques that are based on subsequent B-Scan correlation produce inadequate results. Zawadski et al. used consecutive B-Scan registration, for example, [23]. Antony, et al. [24] corrected for axial motion artifacts in 3D raster scans using an approach based on layer segmentation and fitting of a thin-plate spline surface to the said segmentation followed by multiple steps of smoothing.

15.4.2.3 Orthogonal Scanning Based

The final class of motion correction algorithms applies to 3D volumetric imaging and employs orthogonal data. This means that one or more B-Scans are acquired with a fast scan axis that is orthogonal to the B-Scan direction of the 3D raster scan, which is to be corrected. In the extreme case, two or more full raster scans with orthogonal fast scan axis are acquired and all of them are corrected.

One idea of using orthogonal scans is to acquire a few orthogonal B-Scans in addition to a raster-scanned volume and use the orthogonal B-Scans as "guideposts" to which the raster-scanned volume is registered. It is assumed that no motion takes place during the acquisition of the guidepost scans. Within the context of these algorithms, they function as a motion-free reference. When the raster-scanned

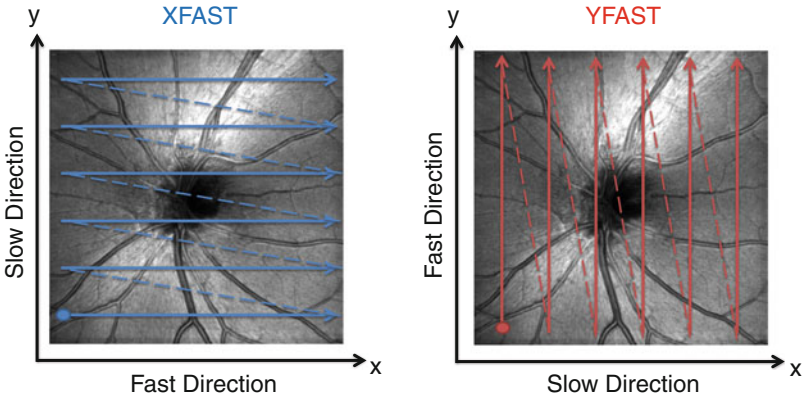

Fig. 15.5 Schematic of orthogonal raster scanning. The *full arrows* indicate B-Scans, and the *dotted arrows* indicate flyback. *Left*: XFAST type scan pattern. The X-direction is the fast scan direction, Y is slow. *Right*: YFAST-type scan pattern. The fast and slow scan directions are exchanged

volume can be accurately registered to the guidepost scans, it can be roughly motion corrected.

After consecutive B-Scan registration to remove axial and in-plane transverse motion, Zawadzki et al. used a single orthogonal guidepost B-Scan $I_{GP,x_{center}}(y,z)$ in the center of the volume (x coordinate x_{center}) to remove the flattening artifact that results from unfiltered correlation of B-Scans [23]. For each B-Scan along the slow scan axis with coordinate y, an A-Scan $I_{GP,x_{center}}(y,z)$ of the guidepost scan is associated with one A-Scan $I_{Vol}(x_{center}, y, z)$ of the raster-scanned volume. These matched A-Scans are again aligned by maximizing the correlation in dependence of an axial shift. The found shift is then applied to the corresponding B-Scan. This way reference information from the guidepost scan is used to try to accurately correct the flattening artifact and residual axial motion within the raster-scanned volume. Potsaid et al. extended this concept and used three instead of one guidepost scan [25]. This allows for increased robustness as instead of one pair of A-Scans, three pairs are correlated to find the axial motion profile.

A consequent extension of the guidepost concept is to acquire an additional orthogonal whole raster-scanned volume. Figure 15.5 shows a schematic of orthogonal raster scanning. The concept is that the fast direction of one scan can be used to correct the slow direction of the other and vice versa. We call these volume types XFAST and YFAST, respectively, or for brevity $I_x(x, y, z)$ and $I_y(x, y, z)$. The dense data that is available allows for unique opportunities to correct motion in all three directions, including out of plane motion.

Tolliver et al. used two orthogonal raster scans and an approach based on matching A-Scans from the two volumes to each other to estimate and recover motion in all three dimensions [26]. In a first step, each A-Scan is transformed into a feature vector using a shift invariant 1D Haar wavelet transform. Then a classifier

with the goal of assessing the probability whether two A-Scans are similar, i.e., they were sampled from close locations on the retina, is trained. Here, A-Scans that are on the same B-Scan and spatially close to a certain A-Scan are assumed to be similar for the purpose of training the classifier. The classifier is used to compute "pseudo-match probabilities" between A-Scans from both volumes. In a subsequent step, Bayesian smoothing is used to incorporate the prior knowledge of piecewise smooth eye motion. Instead of choosing the most likely matches given the classifier output, a less likely but piecewise smooth set of matches is favored. In addition, axial motion correction is performed.

Kraus et al. also uses multiple full orthogonal raster scans and can correct for motion in all three dimensions [27]. Two or more volumes with orthogonal scan patterns are each deformed using a dense 3D displacement field per A-Scan in order to register and motion correct them. Registration is performed by optimizing a global objective function that captures two ideas. First, after registration the set of volumes should be as similar as possible to each other. This is motivated by the fact that the same static object is imaged multiple times. Therefore, if the registration successfully maps corresponding anatomical locations onto each other, the resulting volumes should fundamentally be identical, discounting noise and other high-order effects. In the case of two orthogonal input intensity volumes $I_X(x, y, z)$ and $I_Y(x, y, z)$, we can express this goal using the similarity term

$$\begin{aligned} S = \sum_x \sum_y \sum_z & [I_X(x + \delta x_X(x,y), y + \delta y_X(x,y), z + \delta z_X(x,y)) \\ & - I_Y(x + \delta x_Y(x,y), y + \delta y_Y(x,y), z + \delta z_Y(x,y))]^2 \end{aligned} \tag{15.5}$$

that is parameterized using the two displacement fields $\mathbf{d}_X(x, y) = \{\delta x_x(x, y), \delta y_x(x, y), \delta z_x(x, y)\}$ and $\mathbf{d}_Y(x, y) = \{\delta x_Y(x, y), \delta y_Y(x, y), \delta z_Y(x, y)\}$.

The second part of the objective function captures the idea that within very short time spans, i.e., from one A-Scan to the next, we expect very little motion. This goal is incorporated by adding a term for each volume that penalizes changes in the value of the 3D displacement field over time. Based on the scan pattern for each volume, the time t is known from the 2D transverse A-Scan coordinate. Therefore the displacement functions can also be seen as functions in time $\mathbf{d}_X(t)$ and $\mathbf{d}_Y(t)$. The goal can be expressed as minimizing the term

$$R = \sum_t \left| \frac{d\mathbf{d}_X(t)}{dt} \right|^2 + \sum_t \left| \frac{d\mathbf{d}_Y(t)}{dt} \right|^2. \tag{15.6}$$

The complete objective function is a weighted combination of the two terms

$$F = S + \alpha R \tag{15.7}$$

with α being a positive number that is used to tune the relative importance of the two possibly conflicting goals. The registration is performed by employing a nonlinear

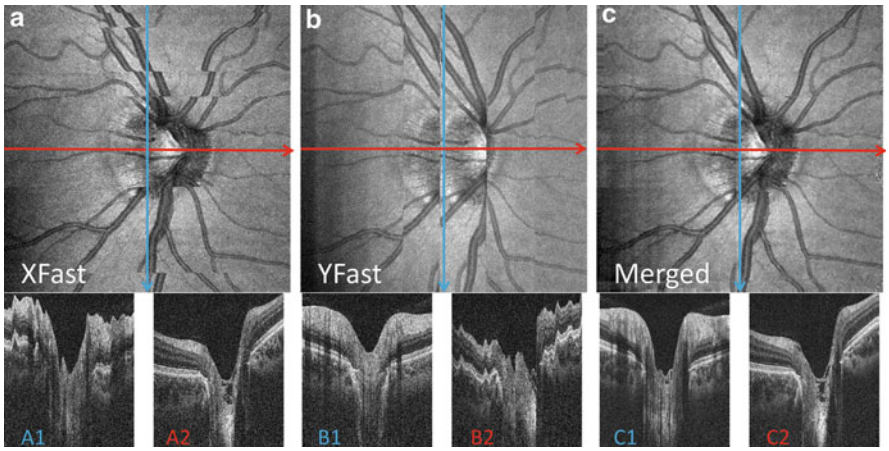

Fig. 15.6 Example of motion correction using orthogonal scan patterns [27]. (**a**, **b**) En face projections of input OCT volumes of the optic nerve head of a healthy subject with orthogonal fast scan axes captured with a 1,050 nm spectral/Fourier domain system at 47 kHz. 400 by 400 A-Scans were acquired in ~4 s each. Significant motion artifacts because of saccadic changes of the subject's fixation can be seen which completely destroy the topology of the object. (**c**) En face projection of registered and merged volume generated from **a** and **b**. *Lower row*: Cross-sectional slices of respective volumes at positions marked by the *red* and *blue arrows* in the en face views. No motion artifacts can be seen in (**c**), as opposed to **a** and **b**. Significant signal-to-noise ratio improvements are achieved by merging volumes

multi-resolution numerical optimization technique to minimize the objective function. Once optimization is finished, the resulting displacement functions are used to construct registered and motion corrected versions of each of the input volumes.

Given a set of registered and motion corrected 3D OCT volumes, it becomes possible to merge the data into a single volume. This is very useful as it allows averaging out speckle and other noise and leads to increased signal-to-noise ratio. Key to enabling merging without the loss of small details is accurate registration. This is enabled by allowing for 3D motion per A-Scan and for sub-pixel displacements.

The evaluation of registration performance and result stability as well as visual inspection shows that the algorithm can correct for motion in all three dimensions and on a per A-scan basis. Figure 15.6 shows an example case of the application of the algorithm.

15.5 Summary

Motion artifacts have been and continue to be a major issue in OCT imaging. They originate from the need to encode spatial dimensions in time, in combination with object motion. The most important application for OCT imaging is in imaging the retina in vivo. In this context, the effects of relative motion are consistent

with an axial displacement of the content of the A-Scan combined with the imaging of a different transverse position on the retina. A corresponding offset to the galvanometer mirror positions changes the transverse location to the same effect. Higher-order effects of motion do not play a significant role for normal eye motion.

We looked at a representative selection of approaches to perform motion correction in OCT. Approaches range from simply improving the system speed over the use of additional imaging modalities. Also, online tracking methods have been developed by various groups to solve the problem. In addition to hardware-based methods, a range of software-based post-processing methods have been presented. These range from maximizing the correlation of neighboring data to methods that employ orthogonal data. Initially orthogonal data was employed as a few "guide-post" B-Scans that acted as a reference to a dense raster-scanned volume. More recently advanced methods that employ two or more whole raster-scanned volumes have been developed. Given highly accurate motion correction and registration of multiple 3D-OCT volumes, the OCT data can also be merged to reduce speckle and increase SNR.

In the future, we expect motion correction in OCT to continue to play an important role. Accurate motion correction promises to increase to the reliability of quantitative measurements that are extracted from the OCT data. Also, multiple approaches can work together. For example, a system with high speed makes a software-based motion correction easier. On the other hand, the lower sensitivity of a high-speed system benefits a lot from accurate data merging that can be achieved using advanced post-processing-based motion correction algorithms. Likewise, a relatively low-accuracy, low-update-rate tracking system could be used as an initialization for a post-processing-based motion correction approach.

Image Processing in Intravascular OCT

16

Zhao Wang, David L. Wilson, Hiram G. Bezerra, and Andrew M. Rollins

16.1 Introduction

Coronary artery disease is the leading cause of death in the world [1]. Intravascular optical coherence tomography (IVOCT) [2] is rapidly becoming a promising imaging modality for characterization of atherosclerotic plaques [3, 4] and evaluation of coronary stenting [5]. OCT has several unique advantages over alternative technologies, such as intravascular ultrasound (IVUS), due to its better resolution and contrast. For example, OCT is currently the only imaging modality that can measure the thickness of the fibrous cap of an atherosclerotic plaque in vivo [6]. OCT also has the ability to accurately assess the coverage of individual stent struts by neointimal tissue over time [2, 5, 7, 8].

Figure 16.1 illustrates the major vascular features that can be visualized by IVOCT. The lumen boundary is the distinctive vessel inner boundary. A guide wire is commonly used during OCT imaging to guide the catheter through the coronary artery. It highly reflects light and creates a long dark shadow behind it in the image. Calcified plaque is a signal-poor region delineated by sharp boundaries [4]. It is associated with the extent and severity of atherosclerosis [9]. Superficial calcification also plays a determinant role in successful stent deployment [10]. The lipid plaque (necrotic core) is a signal-poor region delineated by diffuse boundaries [4]. It highly attenuates light, and therefore, the abluminal boundaries of the plaque are usually not visible in OCT images. Advanced lipid plaques are usually covered

by a fibrous cap infiltrated by macrophages. A fibrous cap appears as a signal-rich region. If the thickness of the fibrous cap is less than 65 μm, the plaque is often referred to as thin-cap fibroatheroma (TCFA). Rupture of TCFA has been considered the most frequent cause of acute coronary events including heart attack and sudden deaths [11]. Coronary stenting is the most common technique for coronary revascularization. The most commonly used stents are metallic stents. They strongly reflect light and manifest as bright reflections coupled with dark shadows in OCT images.

The typical speed for current IVOCT imaging is 50,000 lines/s and 100 frames/s (this is the specifications for C7-XRTM OCT Intravascular Imaging System, St. Jude Medical Inc., St. Paul, Minnesota, the current IVOCT system from Terumo Europe N.V. has higher speed, as will the next generation system from St. Jude Medical). The amount of image data and details generated by OCT can be overwhelming to the practicing clinician. Currently, analysis of OCT images has been typically conducted manually in an extremely time-consuming manner. For instance, for stent analysis, analysts need to manually mark every stent strut in a pullback. Based on our experience, it usually takes more than 7 h to analyze all the frames in a single pullback. In addition, many quantitative metrics of potential clinical diagnostic values are difficult to be generated by manual-based methods. Automated image analysis can (1) greatly alleviate the burdens of analysts, (2) provide more comprehensive metrics for diagnosis, (3) help reduce interobserver variability, and (4) be potentially used for live-time analysis during clinical procedures.

16.2 Image Display and Calibration

IVOCT images are naturally acquired in polar coordinates (Fig. 16.2). After logarithmic compression, images are typically converted from polar to Cartesian

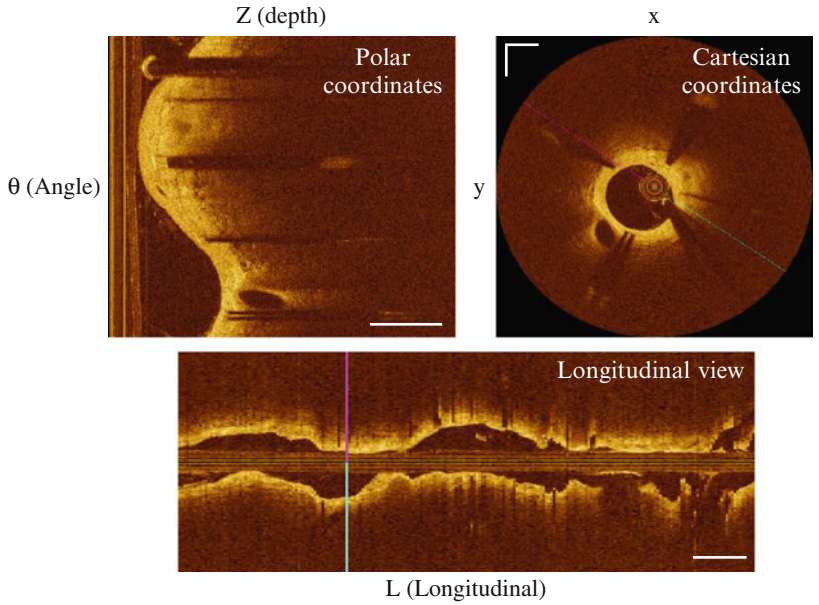

Fig. 16.2 Visualization modes of IVOCT images. Scale bar: 1 mm for the top panels; 5 mm for the bottom panel

coordinates for display. Notice that due to the helical scanning pattern during imaging, the cross-sectional plane is actually oblique with respect to the pullback direction. In commercial OCT systems, longitudinal view (L-mode) image is also used. It is obtained by combining all image pixels at the plane intersects the catheter center at one rotation angle (Fig. 16.2 bottom).

Before any image analysis, calibration must be performed to ensure accurate measurements [12]. Calibration is performed by adjusting the z-offset, which is the optical path length of the optical fiber within the catheter. In practice, cross-sectional images in Cartesian coordinates are adjusted to match the outer boundary of the catheter with the actual diameter. In the corresponding polar coordinates, adjusting the z-offset is equivalent to translating the image in the A-line direction. As the optical path length may change during a single pullback, the z-offset often needs to be adjusted multiple times during the analysis of a single pullback.

16.3 Segmentation, Detection, and Quantification Methods

Segmentation refers to partitioning an image into meaningful regions with different labels. It is fundamental for IVOCT image analysis and is the basis for quantification, plaque characterization, recognition, and 3-D visualization. Detection is to automatically detect meaningful features (e.g., stent struts) from original images and is often the basis for tissue quantification, recognition, and 3-D visualization.

16.3.1 Lumen Segmentation

Lumen segmentation is often the basis for more advanced plaque and stent analysis. In addition, lumen area itself is a direct indicator of vessel stenosis. In OCT images, luminal boundary is very distinctive, and it is likely that many image processing techniques can succeed in this task [13–16]. We describe two methods here, and both have been proved to be robust in practice. The first one is a 2-D optimization method using dynamic programming [17, 18], and the second one is a 3-D optimization method using closure graph and graph cut [19]. Later, one can see that the basic principles of the two methods can be easily extended to other applications.

16.3.1.1 2-D Dynamic Programming Method

Searching for the vessel luminal boundary in the polar coordinates of OCT images fits the graph search family of optimization problems naturally. The lumen boundary is unique and the accumulated optical intensity difference between the pixels from the vessel and luminal side along the contour is maximum. The globally optimal boundary can be efficiently found using a classic optimization method, dynamic programming (DP).

DP is a general technique used to solve certain optimization problems [20]. The basic concept is to find the globally optimal solution to the original problem by building on optimal solutions to subproblems. It is very robust in the presence of noise, and this is attractive to OCT image analysis because OCT images often suffer from speckle noise and various artifacts. Consider the OCT images in polar coordinates (θ, r) where θ is angle and r is depth. Suppose there are m A-lines in one image. We assign each pixel at row i and column j an objective function $f(i, j)$ favoring the characteristics of lumen boundary. Our goal is to search for a path from row 1 to row m with the optimal cost C. We can break the problem into subproblems such that the path to row i is always coming from the path to $i-1$ with some connectivity constraint. Therefore, we have the following recursive function:

$$\begin{aligned} C(i,j) &= \max_{j-n\le j^{*}\le j+n}\left\{C\left(i-1,j^{*}\right)\right\}+f(i,j) \qquad 1<i\le m \\ C(i,j) &= f(i,j) \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad i=1 \end{aligned} \tag{16.1}$$

where $C(i, j)$ is the accumulated cost from row 1 to point (i, j), j^* is adjacent to j, and n specifies connectivity. The globally optimal boundary can be found by selecting the point in row m with the maximum accumulated cost and back tracking the path [17, 18]. $f(i, j)$ can be simply defined as the intensity difference between image pixels on the vessel side and the luminal side:

$$f(i,j)=\bar{I}(i,j\le j_{\alpha}\le j+w)-\bar{I}(i,j-w<j_{\alpha}<j) \tag{16.2}$$

where $\bar{I}$ refers to the average of pixel value and w is the length of the window for averaging. When the guide wire stays close to the lumen boundary, its bright reflections may obscure the lumen boundary and need to be excluded from lumen

segmentation. This can be achieved by guide wire segmentation introduced in Sect. 16.3.2. For image segmentation, the advantages of DP include its global optimum nature, simplicity, and stability. The limitation is that it is not easy to be generalized to 3-D or higher dimensional space.

16.3.1.2 3-D Method: Surface Segmentation Using Graph Cut

The 3-D lumen segmentation method is based on the surface segmentation method proposed by Li et al. [21]. It is worth mentioning that this method has been successfully applied to intraretinal layer segmentation in ophthalmic OCT images by Garvin et al. [22]. The main idea of the method consists of two steps [21]. First, the volumetric images are transformed into a closure graph, where the optimal closed set corresponds to the optimal surfaces in the original images. The second step is to search for the optimal closed set using graph cut algorithms. We next introduce the method.

We denote a voxel V in the IVOCT pullback as $V(z, \theta, l)$, where z, θ, l are the coordinate in the axial, lateral, and longitudinal direction, respectively. We first look at how we can transform the image stack into a closure graph according to the work by Wu et al. [23] and Li et al. [21]. Consider a directed graph $G = (V, E)$ with nodes V and edges E. Each node is formed by a voxel in the IVOCT pullback in polar coordinates. Each node is associated with a weight $c(z, \theta, l)$ (*node weight*) penalizing the probability of it being located on the lumen boundary, taking the form defined in Eq. 16.2.

We denote the farthest plane from the catheter in the IVOCT pullback as the *base layer* ($z = 0$). Then, the top plane (closest to the catheter) is represented by $z = \mathrm{N}-1$, where N is the number of points in each A-line. We change the *node weight* from $c(z, \theta, l)$ to $w(z, \theta, l)$ as follows:

$$w(z,\theta,l) = \begin{cases} c(z,\theta,l) & z = 0 \\ c(z,\theta,l) - c(z-1,\theta,l) & z > 0 \end{cases} \tag{16.3}$$

Each node $V(z, \theta, l)$ on layer $z = 1,\ldots\mathrm{N}-1$ has a direct edge linked to $V(z\text{-}1, \theta, l)$ We further denote θ_{adj} and l_{adj} as the sets of adjacent A-lines of θ and adjacent frames of l, respectively. We then make a direct edge linking V to the farthest node it could reach in every adjacent set under some smoothness hard constraint Δz:

$$E_V = \left\{V(z,\theta,l), V\left(\max(0, z-\Delta z), \theta_{adj}, l_{adj}\right)\right\} \tag{16.4}$$

Notice that we can incorporate the special helical scanning pattern of IVOCT into the neighborhood definition, i.e., the last A-line in frame i is adjacent to the first A-line in frame $i + 1$. These directed edges will be assigned infinite *edge weight*, and this ensures that the resulting surface intersects each A-line exactly once, and the surface is also smooth as defined by the smoothness hard constraint. In addition to the hard constraints, one can also add soft constraints between neighboring A-lines by assigning the edges finite *edge weights* [24, 25]. Soft constraints allow, but can penalize, the surface boundary deviating from predefined shape

priors [24]. Finally, we make the *base layer* strongly connected (every node in this layer is reachable from any other node) by making infinite edge links between the nodes in the layer such that this layer cannot be cut. Now, one can see that the optimal surface of the original IVOCT pullback corresponds to the optimal closed set (constituted by all the nodes on and below the surface) in the graph G [21, 23].

Searching for the optimal closed set in a graph can be efficiently solved using max-flow/min-cut algorithm, as shown by Picard in the 1970s [26]. Briefly, we construct a closure graph G^C from G by adding two special nodes source s and sink t. We create directed edges linking s to all the nodes with negative weights and edges connecting all nodes with positive weights to t, with the *edge weight* equal to the absolute value of the *node weight*. A cut in a graph partitions the graph into two disjoint sets containing s and t, respectively. The minimum cut is the cut where the sum of edges it severs is minimum. The minimum cut is also a finite cut and can only sever finite edges connected to s/t in G^C. One can easily prove that after a finite cut, the set containing s becomes a closed set and the optimal closed set corresponds to the minimum cut of this closure graph [26, 27].

The surface segmentation method presented above is ideal for robust 3-D lumen segmentation due to its global optimum nature. However, the time and space complexity of the method is huge. For typical IVOCT image stack consisting of 500*1,000*271 pixels, it takes several hours for state-of-the-art graph algorithms to compute the optimal surface, which is impractical for real applications. We can use a simple multi-resolution approach [28] to overcome this computation burden effectively. Consider a coarse level image stack obtained by downsampling the original image stack in axial and lateral directions. As the lumen boundary is very distinct, it still remains the globally optimal boundary although some details are lost in the coarse level. Hence, we can perform graph cut to obtain the optimal surface at this coarse level and then map it back to the original fine level. We know that the true optimal surface should be close to the mapped surface. Hence, we can perform the second round graph cut on the fine level, but only consider the voxels within a narrow band around the mapped surface. This allows the total computation time to be reduced to <1 min for a whole pullback (downsample by 8).

Examples of lumen segmentation results in challenging images are shown in Fig. 16.3.

Remark: distinction should be made between this surface segmentation method and the general graph cut method used for image segmentation proposed by Boykoy et al. [29, 30]. The major difference lies in the graph construction stage. The surface segmentation method uses closure graphs and strictly separates the nodes above the below the surface. Therefore, it is limited to terrain-like surfaces [21]. In comparison, general graph cut [29, 30] does not use closure graphs, and it allows for segmentation of contours/surfaces with arbitrary shape but typically requires user input of seed points indicating the foreground and background. Despite these differences, the same graph cut algorithm can be used in both methods. As IVOCT images are naturally acquired in polar coordinates, the surface segmentation method can guarantee an optimal terrain-like lumen

surface. However, it is important to note that the general graph cut is a powerful, globally optimal N-D segmentation method, with a wide range of applications in computer vision. More details of the method can be found in [29, 30]. For state-of-the-art graph cut algorithms, please refer to [30–33].

16.3.2 Guide Wire Segmentation

We describe a guide wire segmentation method that is able to extract the globally optimal guide wire positions of all the frames in the entire pullback at once [17, 18]. Briefly, we create an *en face* projection image where 2-D images of the pullback are projected to 1-D curves and combined into one image (Fig. 16.4b). The regions of the guide wire shadow become a continuous dark band. Similar to lumen

segmentation, an objective function of pixel value difference is applied to the two boundaries of the dark band but with different signs. DP is then applied twice to find the two boundaries. More robustly, the two coupled boundaries could also be found simultaneously using a multiple-surface segmentation technique in higher dimensions [21], or using higher-dimension DP [34], but at the expense of increased computation time. The above described method only applies to OCT pullbacks with a single guide wire. Sometimes, there could be more than one guide wire inserted in the same vessel. In such cases, the *en face* view image can be combined with other methods for guide wire segmentation.

16.3.3 Calcified Plaque Segmentation

16.3.3.1 Level Set Segmentation Method

Level set is a popular method used for image segmentation [35–37]. It tracks the object boundaries by minimizing an appropriately designed energy function on a continuous grid using partial differential equations. Instead of explicitly representing the evolving contours using parametric models like snakes [38], level set implicitly represents a contour using the zero level set of a higher dimension function and can treat topological changes such as contour break and merge easily. We define ϕ(t, x, y) (to simplify description, we use a 2-D grid, but level set can be easily generalized to higher dimensions) as the level set function in a higher dimension, and the zero level set $C = \{(x, y)|\phi = 0\}$ represents the evolving contour. Image segmentation using level sets begins with an initial contour and then evolves it in the normal direction based on the following general equation:

$$\frac{\partial \phi}{\partial t} = F|\nabla \phi| \tag{16.5}$$

where F is a speed function and is related to the image data.

For calcified plaque (CP) segmentation, we describe a level set approach combining the work of Li et al. [39] and Chan and Vese [40]. We define ϕ as a signed distance function (SDF) with its zero level curve represented by C. $\phi < 0$ if ϕ is outside C; $\phi > 0$ if ϕ is inside C. The initial contour C_0 is driven to the desired CP boundary by minimizing the following energy term:

$$\begin{aligned} E = \mu \int_\Omega \frac{1}{2}(\nabla \phi - 1)^2 dxdy + \lambda \int_\Omega g' \delta(\phi)|\nabla \phi| dxdy + \upsilon \int_\Omega g' H(-\phi) dxdy \\ + \kappa \left(\int_\Omega |I_0(x,y) - c_1|^2 H(\phi) dxdy + \int_\Omega |I_0(x,y) - c_2|^2 (1 - H(\phi)) dxdy \right) \end{aligned} \tag{16.6}$$

$\delta(\phi)$ is a 2-D smoothed Dirac function; H is the Heaviside function; I_0 is the original image; and $g' = 1/(1 + g)$, where g is the gradient image which is

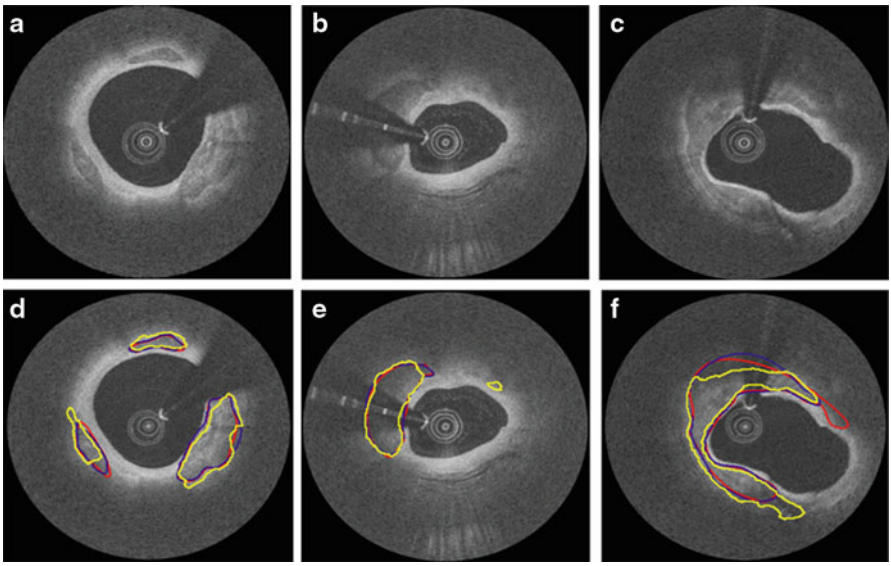

Fig. 16.5 Examples of calcified plaque segmentation results. (**a**–**c**) Original images. (**d**–**f**) Corresponding manual and automatic segmentation results. *Red*: observer 1; *blue*: observer 2; *yellow*: automatic method. Reprinted from Wang et al. [41]

determined by convolving the original image with different orientations of edge filters and selecting the maximum response for each point [41]. c_1 is the average intensity inside C; c_2 is the average intensity of an outer ring of thickness w surrounding C, μ, λ, ν; and κ are weighting terms. The first term is to keep ϕ as a SDF. The second term is a length term regulating the smoothness of the contour. The third term is an area term indicating whether the curve will grow or shrink. In our implementation, it was set positive to shrink the contour. The fourth term contains region-based intensity information. The minimization of E is based on the following gradient flow:

$$\frac{\partial \phi}{\partial t} = -\frac{\partial E}{\partial \phi} \tag{16.7}$$

The evolving contour is stopped if its speed is close to zero. In the discrete image space, all the terms in the above equations are numerically approximated. More details of the method can be found in [41]. The advantage of the level set method is its flexible topology for contour merge and break. The limitation is that it may find a local minimum instead of a global minimum. Therefore, the initial contour is often required to be placed close to the desired boundaries. Examples of automated CP segmentation results with comparison with human analysts are shown in Fig. 16.5. More details about level sets can be found in [35–37, 42].

16.3.3.2 Calcified Plaque Quantification

Based on the segmentation, the depth, area, volume, thickness, and angle fill fraction (AFF) of CP can be calculated automatically. The calculation of area is trivial. The volume of a lesion can be calculated from CP areas in individual frames using Simpson's rule. For depth and thickness, we typically use the rays radiating from the centroid of the lumen as the direction for calculation. AFF is simply the largest angle between the rays spanned across the CP [41].

16.3.4 Fibrous Cap Quantification

The conventional method to assess the fibrous cap (FC) thickness is to quantify only the minimum cap thickness (MCT). However, as FC is a 3-D structure, the single-point/single-frame representation is unable to capture the volumetric profile of FC. In addition, we have found that significant interobserver variations exist between different analysts in assessing the MCT [17]. Here, we describe a method that is able to quantify the volumetric morphology of FC and also the conventional MCT more accurately. In this method, users first select the circumferential boundaries (start and end angle) of FC, and the algorithm automatically determines the optimal FC boundaries in the radial dimension. Quantitative metrics can then be derived from the FC segmentation.

16.3.4.1 Fibrous Cap Segmentation

FC is delineated by a luminal boundary and an abluminal boundary. The luminal boundary coincides with the vessel lumen contour. The abluminal boundary is commonly described as the "diffuse border" created by the interface between the FC and the underlying lipid pool. In the polar coordinates, searching for the FC abluminal boundary can be treated as a similar graph search problem as lumen segmentation, but with different objective function. Essentially, the goal is to design an objective function such that its optimal value corresponds to the optimal boundary that best separates the FC from the underlying lipid plaque. The FC has been defined histologically as a distinct layer of connective tissue covering the lipid core and consists purely of smooth muscle cells in a collagenous-proteoglycan matrix, with varying degrees of infiltration by macrophages and lymphocytes [43]. The fibrous tissue appears bright by OCT and has a low attenuation coefficient, whereas the lipid pool appears dark and strongly attenuates the light [44, 45]. Therefore, the FC abluminal boundary has a high intensity difference between the FC and lipid pool and also a high gradient. Hence, we define the following objective function:

$$f_FC(i,j) = \bar{I}(i, j - d_l \le j_\alpha \le j) - \bar{I}(i, j < j_\alpha \le d_{\max}) - \lambda\mu \tag{16.8}$$

where d_l and $d_{\max}$ are predefined depths to calculate pixel intensity difference, μ is the slope of pixel value attenuation extracted from the A-line segment of length L across (i, j), and λ is a weighting term. The parameter values $d_l = 75$ μm, $d_{\max} = 0.38$ mm, $\lambda = 7$ and $L = 38$ μm are determined experimentally using

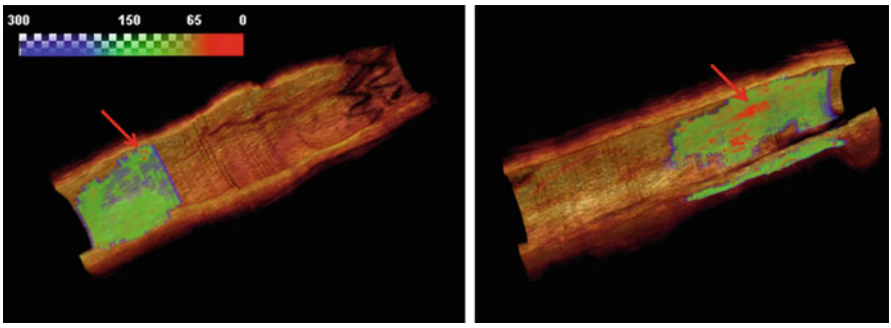

Fig. 16.6 Two coronary arteries used in the validation study with fibrous caps (*FC*) rendered in a continuous color map indicating the thickness. Both of the two lesions contain TCFA (*red arrows*) and similar minimum cap thickness. However, the plaque shown on the right panel contains a significantly larger surface area with thin cap as compared to the plaque in the left panel. Reprinted from Wang et al. [17]

training data [17]. With this objective function, the optimal FC abluminal boundary can be obtained using the same DP algorithm (Sect. 16.3.1) in the region bounded by the luminal boundary and $d_{\max}$ in the radial dimension and by the user-selected angle in the circumferential direction. Automation of the angle selection is possible but is presently hindered by the lack of a validated, reproducible criterion for FC circumferential boundaries.

16.3.4.2 Quantification and 3-D Visualization

With the fully segmented FC, we can quantify the thickness at each point of the FC luminal boundary, defined as the minimum distance from this point to the FC abluminal boundary. The conventional metric MCT can be accurately found from the pool of the thicknesses of all the points. In addition, volumetric metrics of the FC can be derived. The FC surface area (SA) of a lesion can be calculated as the product of the frame interval and the arc length of FC summed over involved frames. The absolute and fractional FC categorical surface area (ACSA and FCSA) of a lesion can be calculated as the absolute and relative FC area in a thickness category (e.g., <65 μm, 65–150 μm, and >150 μm). Other possible volumetric metrics can also be found in [17].

The segmented FC can be visualized in 3-D with a continuous color map indicating the FC thickness. Figure 16.6 illustrates two cases, both with TCFA, with FC thickness rendered in 3-D. If assessed using only the conventional methodology, the morphological differences between the cases would not be apparent. However, the 3-D visualization demonstrates dramatically different characteristics.

16.3.5 Stent Detection

Stent analysis is one of the most common tasks for IVOCT image analysis. Several automated stent detection methods have been reported [14–16, 46–49]. Due to

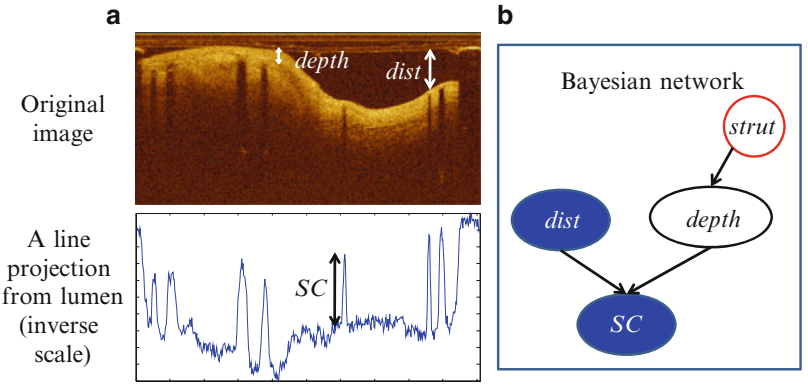

Fig. 16.7 The Bayesian network for inference of strut presence. (**a**) *Top*: original OCT image in polar coordinate. *Bottom*: by calculating the mean intensity of the A-line within a fixed depth from the lumen boundary, the 2-D image is projected into a 1-D curve (plotted in an inverse scale). Searching for strut locations is equivalent to searching for peaks in the 1-D curve. (**b**) A Bayesian network representation based on principles of OCT image formation

space constraint, we describe one method that has the advantage of having few empirical parameters and that has been validated using a large clinical dataset [50]. The method consists of two major steps, (1) probabilistic detection of strut positions and (2) simultaneous localization of all strut depths.

16.3.5.1 Probabilistic Detection of Strut Positions

As the metallic stent strongly reflects light, the struts cast clear shadows in intersecting A-lines. In comparison, surrounding tissues not covered by stents are free of strut shadows. Therefore, strut locations typically appear as extreme points in the 1-D projection, which is generated by taking the mean intensity of a fixed depth (1.5 mm) from the luminal boundary (Fig. 16.7).

We consider physical principles in the detection of struts in the 1-D projection curve. If we define the relative difference between the adjacent extreme peak and valley points to be shadow contrast (*SC*), it can be seen that real struts generate larger *SC* as compared to surrounding non-strut regions, but the size of *SC* depends on how far the lumen wall is from the catheter (represented by *dist*) and how deep the tissue is covering the strut (represented by *depth*). We can model these cause-effect relationships using a Bayesian network [51–53] as shown in Fig. 16.7b. It encodes the causal dependencies between variables and, more importantly, compactly represents the full joint probability distribution of the atomic event defined by all the variables. For example, the node *SC* encodes the conditional probability P(*SC*|*dist*,*depth*), i.e., probability of *SC* being a certain value given the observed values of *dist* and *depth*. For baseline cases where the OCT is performed immediately after stent implantation, the network can be simplified by not considering the strut depth.

In the stent detection problem defined in Fig. 16.7, our task is to query the probability of strut presence among all the peaks given our observations. Here, we can directly observe the values of *SC* and *dist*. We can also estimate the probabilities of P(*strut*) and P(*SC*|*dist*,*depth*) from manually analyzed training data. As *SC*, *dist*, and *depth* are continuous variables, we can discretize them into bins to generate the conditional probability tables (for *depth*, we include an additional variable, undefined, to make it compatible with presence of no strut). Note that the strut depth is still unknown at this point. According to probability theory, we can directly query P(*strut*|*SC*,*dist*) by marginally summing over all the possible depths a strut could occupy:

$$P(strut|SC, dist) = \frac{\sum_{depth} P(SC, dist, depth, strut)}{\sum_{strut}\sum_{depth} P(SC, dist, depth, strut)} \tag{16.9}$$

However, such an approach is noisy for non-strut and ambiguous strut positions. Instead, we adopt the following algorithm in which we first get a quick estimate of strut depth and then improve estimates of the probability of a strut and strut depth in subsequent steps.

Estimate-Strut-Presence

Step 1: Roughly estimate the strut depth bin for each of the peaks in the 1-D projection (i.e. suspected struts) using maximum likelihood estimation (MLE):

$$depth_{MLE} = \arg\max_{depth} P(SC|dist, depth) \tag{16.10}$$

Step 2: Estimate P(*strut*|*SC*,*dist*) and select only the peaks that are associated with high probability (e.g., 0.7) of strut presence. Notice that we can now treat strut depth as a deterministic variable by using the depth evidence from Step 1. Equation 16.9 can now be evaluated using equations below:

$$\begin{aligned} P(strut|SC, dist) &= \frac{P(SC, dist, depth_{MLE}, strut)}{\sum_{strut} P(SC, dist, depth_{MLE}, strut)} \\ &= \frac{P(SC|dist, depth_{MLE})P(dist)P(depth_{MLE}|strut)P(strut)}{\sum_{strut} P(SC|dist, depth_{MLE})P(dist)P(depth_{MLE}|strut)P(strut)} \\ &= \frac{P(SC|dist, depth_{MLE})P(depth_{MLE}|strut)P(strut)}{\sum_{strut} P(SC|dist, depth_{MLE})P(depth_{MLE}|strut)P(strut)} \end{aligned} \tag{16.11}$$

Step 3: Determine strut depths for high-confidence peaks found in Step 2 and then use these high-confidence depth locations to interpolate strut depths for other peaks in the 1-D projection curve. The refined strut depth is determined by searching the A-line for the point x^* that optimizes the objective function associated with strut features within the depth range found in Step 1. For a given point x, we use a linear objective function that models the strut presence by combining the features of bright strut reflection, low intensity of dark shadow, and high attenuation within the strut-shadow transition:

$$f_x = S_x + \mu I_x + \lambda M_x \tag{16.12}$$

where S_x is the slope of the A-line segment r_x (70 μm) following x. I_x is the intensity of x and M_x is the mean intensity of the A-line segment (500 μm long) after r_x, representing the intensity of the shadow. μ and λ are weighting terms and can be determined using a linear classifier using training data [54]. Interpolation uses the same method as used for stent area quantification. For those cases where there is not a high-confidence peak, Steps 3 and 4 are not executed, and the result from Eq. 16.11 will be directly used.

Step 4: Determine the final probability P(*strut*|*SC*,*dist*) using Eq. 16.11 with the updated depth information found in Step 3 for all peaks.

For baseline cases, P(*strut*|*SC*,*dist*) can be directly estimated without considering the strut depth. Once we have the probability map for all the peaks, we can simply classify strut locations using the Bayes decision rule, i.e., P(*strut*|*SC*,*dist*) > 0.5.

16.3.5.2 Simultaneous Localization of All Strut Depths

So far, we have identified A-lines containing stent struts. The next step is to determine the precise depth location of the strut in each A-line, with consideration to 3-D spatial information. We determine depths considering all struts in a pullback simultaneously making use of the spatial constraint between adjacent struts. Such an approach tends to be robust against outliers as the added spatial constraint forces the outlier to "come close" to the adjacent struts. A stent is a tubular structure which is expanded at implantation. Unless there is a rupture, a very rare event, the implanted stent will maintain its tubular shape with some deformations caused by resistance from the vessel, as in the presence of a calcification. This will be the case both at implantation and at follow-up. Choosing the centroid of the vessel lumen as the reference point, distances to struts are not likely to vary dramatically between adjacent struts. In fact, if we consider only the pixels in the A-lines containing stent struts (*strut lines*), all the struts in a pullback form a surface in the polar coordinates. If we associate each pixel with a cost penalizing the presence of strut-like features, given in Eq. 16.12, the problem becomes the optimal surface searching problem and can be efficiently solved using graph cut (Sect. 16.3.1).

This stent detection method has been shown to be robust in clinical images with different quality and artifacts. Some examples are shown in Fig. 16.8. The limitation of the method is that it is not effective for struts with very thick coverage where no shadow is present. For such cases, other methods may be considered, such as [46].

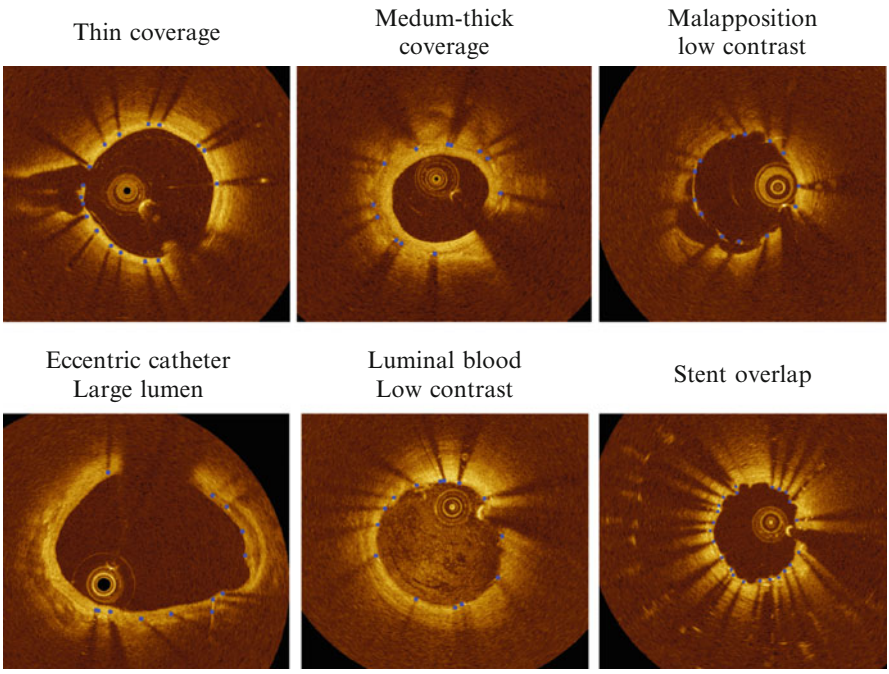

Fig. 16.8 Examples of automated stent strut detection in images with different thickness of strut coverage and diverse quality. *Blue dots* indicate the automatically detected struts

16.3.5.3 Area Quantification and Strut-Level Analysis

After identifying stent struts, we can make various clinically relevant area measurements, including *stent area*, *malapposition area*, and *neointima area* (*tissue coverage area*), as illustrated in Fig. 16.9. We can also perform *strut-level measurements*, including individual strut coverage thickness, malapposition distance, type (covered, malapposed, and apposed), etc. For a more complete list of possible quantitative metrics that can be derived from the image, please refer to [12]. Once all the stent struts and the luminal boundary of the vessel are detected, any quantitative metrics defined above can be computed. Specifically, all area measurements rely on obtaining a virtual stent contour, which is simply interpolated from the detected struts. In images where there are very few stent struts present, it may be challenging to reconstruct the stent contours accurately. Incorporating the strut information from neighboring slices for interpolation is therefore recommended.

16.4 Tissue Characterization, Classification, and Machine Learning

Tissue characterization means quantifying various tissue properties or features that can then be used for tissue classification. Tissue characterization is usually

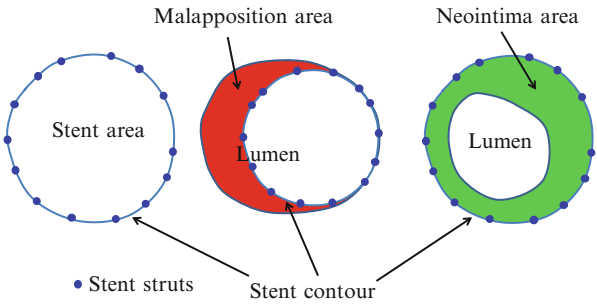

Fig. 16.9 Illustration of *stent area* (the area enclosed by the stent struts), *malapposition area* (the area enclosed by the lumen boundary and malapposed struts), and *neointima area* (the area enclosed by the lumen boundary and tissue covered stent struts)

performed first by establishing criteria for different tissue types by matching image features with a gold standard (typically histology). Then, when the features are validated, human experts can use these criteria to classify tissue types. Computers can also be used for tissue characterization. We can design algorithms to extract features with good correspondence with visual cues. Compared to human analysts, the advantages of automated tissue characterization methods are that they can extract quantitative features, are not subject to intra- nor interobserver variability, are repeatable, and can be fast. However, it is generally difficult for computers to utilize high-level knowledge, which is often key for tissue characterization and is being used by human analysts effortlessly and effectively all the time. After information-bearing image features are extracted, the computer algorithm can classify the tissue into appropriate categories using a variety of machine learning methods.

Here, we focus our discussions on automated or computer-assisted tissue characterization/classification (also called computer-aided diagnosis, CAD). For IVOCT, the most important and common task is to characterize/classify atherosclerotic plaques, namely, fibrous plaques, calcified plaques, and lipid plaques (necrotic cores) [4]. Other important tasks include characterization of coronary thrombosis [55], neointima hyperplasia [56], etc.

16.4.1 Tissue Characterization Using Optical Properties

Optical properties of tissues have been used to characterize and classify different tissue types in IVOCT. Xu et al. [45] proposed a single scattering model to extract the backscattering and attenuation coefficients of tissue. Consider a single A-line with $P(z)$ representing the power of the signal at depth z. The single scattering model can be represented as

$$\log(P(z)/P(z_0)) = \log(\mu_b/\mu_{b0}) - 2\mu_t z/n \tag{16.14}$$

where μ_b and μ_t are the backscattering and attenuation coefficients, respectively. $P(z_0)$ and μ_{b0} are measured from phantoms with negligible attenuation coefficient and are used to cancel light source-specific parameters. n is the refractive index of

the tissue. After the IVOCT image is logarithmically compressed, a straight line can be least squares fitted to the A-line profile, and the intercept and slope are related to the backscattering and attenuation coefficients, respectively. As both specular reflections and noise can affect the fitting, according to [45], the fit is restricted to region from 50 μm below the surface to the point where the signal is attenuated 1/e of the starting point. Results from this study demonstrate that fibrous plaques have high backscattering and low attenuation ($\mu_b = 18.4 \pm 6.4$ mm^{-1}, $\mu_t = 6.4 \pm 1.2$ mm^{-1}), calcified plaques have low backscattering and low attenuation ($\mu_b = 4.9 \pm 1.5$ mm^{-1}, $\mu_t = 5.7 \pm 1.4$ mm^{-1}), and lipid plaques have high backscattering and high attenuation ($\mu_b = 28.1 \pm 8.9$ mm^{-1}, $\mu_t = 13.7 \pm 4.5$ mm^{-1}). Therefore, plaques can be classified by combining both backscattering and attenuation coefficients. However, the above numbers are derived from transversal scanning OCT on paraffin-embedded sections, not radial scanning at the endothelial surface as used in clinical IVOCT. van Soest et al. [44] proposed a similar single scattering model and applied it to rotary IVOCT. The attenuation coefficient of every A-line was extracted, with additional considerations of tissue discontinuity. Similar attenuation coefficients were found for the major types of plaques. The entire image was then color coded with the attenuation map. More complex multiple scattering models have also been proposed [57, 58].

Tissue characterization using optical properties provides physical explanations of the image formation for various tissues, is easy to be interpreted by human analysts, and can be verified by experiments. However, directly applying the method to the original image is noisy, as only single A-line or averaged A-lines are used without considering the global properties of the image.

Other feature extraction methods have been employed for CAD in OCT imaging that make use of 2-D image properties. For example, texture analysis methods have been used for classification of dysplasia and cancer in Barrett's esophagus using catheter-based endoscopic OCT [59, 60].

Generally, selection of regions of interest for analysis is important. Segmentation methods (Sect. 16.3) can help constrain the feature extraction to single-type tissues or homogeneous regions and will help improve the performance of the methods. After segmentation and image feature extraction, machine learning methods can be employed for tissue classification (Sect. 16.4.2).

16.4.2 Machine Learning Methods for Tissue Classification

Machine learning refers to the ability of the system to improve its performance on the same task through experience [61]. In the context of IVOCT image analysis, we mainly focus our discussions on the tissue classification task. The inputs to the system are quantitative image features, and the performance measure of the task is how accurately the algorithm can classify a tissue type (by comparison to a gold standard, usually a human expert observer and/or histology). Further, we restrict ourselves to supervised learning, i.e., some training data with target's output are first provided to the system, and the system *learn*s to match the target during the training stage.

During the testing stage, the learned system can operate on unseen data. Notice that machine learning is not to simply memorize examples but to learn the underlying concept behind the examples, so the system can be generalized to new data.

Standard machine learning procedures typically include feature extraction (as introduced above), feature selection, and classification. Feature extraction is crucial to the final performance of the classification. During the feature extraction stage, various features are extracted from regions of interest. These features could include optical properties of tissues (Sect. 16.4.1), intensity features (e.g., pixel or region intensity), gradient features (e.g., edge strength and orientations, histogram of oriented gradients [62]), texture features (e.g., standard deviation and entropy of a region), shape descriptors, location information (e.g., distance to the lumen boundary), scale-invariant features (e.g., SIFT [63] and SURF features [64]), etc. Whether a feature is effective depends on the specific task. Irrelevant features do not contribute to prediction accuracy and may negatively affect the generalizability of the algorithm and increase the computation burden. Therefore, feature selection is important before classification and should result in a set of image features that are information rich, have strong contrast to tissue classes of interest, and are not redundant with each other. For more information on feature selection methods, we refer readers to [65–69].

Classification methods are broad and rich, and a detailed discussion is beyond the scope of this chapter. We provide a brief summary of the most commonly used classification methods as a practical guide (Table 16.1). For details, please refer to [61, 70]. It is important to note that there is no best learning algorithm for all cases [71]. In practice, the method that is best for a particular problem is usually the one that explores the most suitable hypotheses for that problem.

16.5 Interesting Topics and Future Directions

16.5.1 Macrophages

Macrophages (foam cells) are key players in the formation and progression of atherosclerotic plaques [72]. Macrophages can degrade the integrity of atherosclerotic plaques and make them more prone to rupture [73]. In OCT images, macrophages are strong scatters and often attenuate the light significantly. Tearney et al. [74] first suggested the ability of IVOCT to quantify the macrophage density. In this method, normalized standard deviation (NSD) within a region of interest (ROI) in the fibrous caps was quantified using linear OCT data for macrophage density estimation [74]. Another image analysis method has been proposed by Tahara et al. [75] to quantify the macrophage area in mouse aorta. This method considers both intensity and texture features at different scales for macrophage detection. In both methods, selection of ROI is important because macrophages should only be evaluated in the context of fibroatheroma [12]. The fibrous cap segmentation (Sect. 16.3.4) method may facilitate this task. It is important to note that whether current IVOCT systems can visualize individual macrophages is unknown [12].

Table 16.1 Commonly used machine learning methods

Method	Key concepts	Advantages	Disadvantages
Decision trees	Use tree structure, with internal nodes representing tests on features and leaves indicating class labels	Easy to interpret, simple to implement, widely used	Not very effective for continuous variables
	For learning, recursively select and remove the feature with the most predictive label, partition the training examples into disjoint sets until data are pure or no attributes are left	Good for nominal variables	Learning the optimal decision tree structure is NP-complete. Heuristic algorithms may lead to overfitting, often need post-pruning
	For classification, start from the root, check each feature test, move along the path until reaching the leaf	Can handle missing values	
Artificial neural networks	Mimic human brains using a large number of neurons, connect them with weighted edges	Can learn very complex hypotheses	Easy to overfit
	Can represent any Boolean function and continuous function using a network with one hidden layer, can represent any function in R^n using two hidden layers	Builds useful representations automatically	Typically require a large amount of data to train, slow training
	For learning, iteratively update weight parameters by minimizing the loss function through backpropagation starting from output neurons to hidden layers and to the input layer		Not very effective for nominal data
Support vector machines	Try to find a separating hyperplane with maximum margins between positive and negative instances	Powerful, elegant	Sensitive to noise with nonlinear kernels
	Implicitly represent high-dimensional features using kernels; kernel selection is flexible, can be linear or nonlinear	Robust to errors in data	Does not handle multi-class (>2) classification naturally
	Optimization can be performed in primal or dual space	Can handle high-dimensional and nonlinear features easily	Hard to implement
		Has "built-in" overfitting control	
		Good performance in a wide range of applications	

(*continued*)

Table 16.1 (continued)

Method	Key concepts	Advantages	Disadvantages
Bayesian networks	Directed acyclic graph with each node representing its conditional probability distribution given its parents	Powerful expressive representations, easy to incorporate real-world knowledge	Exact probabilistic inference in a general Bayesian network is #P-hard (harder than NP) but is easier in restricted structures (e.g., polytrees) and small networks
	Each variable is independent of its non-descendents given its parents. With this conditional independence, joint probability distributions can be compactly factorized	Probabilistic output, model uncertainty	If network structure is unknown, learning optimal network structure is NP-hard, heuristic optimization methods are often used to learn "good enough" structures
	For learning, estimate the conditional probabilities using training data	Can learn arbitrary shape of decision boundaries	
	For classification and inference, find the most probable class of a new example given the observations. There are both exact and approximate inference algorithms	Can encode causal relationships between variables	
		Can do inference both forward and backward. Inference can be facilitated by graph algorithms	
Ensemble methods	Combine a collection of classifiers (often called weak or base learners) and use some voting scheme for classification	Can be applied to any single classifier to improve its performance	The classification boundary of ensemble methods can be hard to interpret
	Most commonly used methods include bagging and boosting		
	Bagging – to generate replicates by uniformly sampling the training data with replacement and use majority voting for classification	Bagging can reduce the variance of noisy data, almost never hurt accuracy	The improvements of bagging over base learners are usually very small
	Boosting – one commonly used method is Adaboost. It works by maintaining a weighted training set and iteratively adjusting the weights of training examples based on the classification of the previous iteration. The classification is performed by a weighted vote	Boosting can reduce bias and can sometimes improve the performance of the base learner significantly. Can possibly maximize the margin and reduce the generalization error of the classifier	In most cases, boosting can outperform base classifiers; but it can also perform worse in some cases

16.5.2 Neointimal Hyperplasia

Drug-eluting stents (DES) are widely used clinically and can significantly reduce development of neointima hyperplasia (NIH) after stent implantation as compared to bare-metal stents. However, the potential risk of DES leading to late-stent thrombosis has become an important concern. Characterization of NIH and correlation of different NIH patterns with clinical events may provide insights on the safety of DES, as well as the underlying mechanisms of pathology, and therefore help future stent designs and potential treatment. Templin et al. [76] pioneered OCT characterization of fibrin vs. neointima coverage using a simple metric termed "optical density," defined as the pixel intensity of strut coverage normalized by the pixel intensity of struts. The method has been shown promising by correlation with scanning electron microscopy findings. More studies are needed to confirm and extend the findings.

16.5.3 Bioabsorbable Stents

Bioabsorbable stents [77, 78] use degradable polymers instead of metals and are likely to be the next generation stent designs. Under IVOCT, bioabsorbable stents exhibit very different characteristics from metallic stents. For instance, one type of bioabsorbable stent, BVS [77], presents as box-like shape at baseline and may change appearance thereafter before being fully absorbed by the tissue. Different bioresorbable stents may have different appearances. All automated stent detection methods proposed so far are for metallic stents. More studies on bioabsorbable stents are needed.

16.5.4 Stent Registration

The vascular response to stent implantation can be better understood if the IVOCT pullbacks at different time points can be registered at strut level. Ughi et al. [79] proposed a rigid registration method based on iterative closest point algorithm for registrations of IVOCT pullbacks at different time points. Promising results have been demonstrated. More research is needed in this area.

16.5.5 3-D Image Processing Methods

IVOCT images are intrinsically 3-D. As the longitudinal resolution of future IVOCT systems is expected to be further improved, 3-D image processing methods will play more and more important roles. Many segmentation, detection and classification tasks can be facilitated using neighboring frame information. As additional information is taken into account, 3-D methods are potentially more robust than 2-D methods. In addition, some feature morphology is better visualized in 3-D than in 2-D, such as side branches and stent fracture [80, 81]. Likewise, 3-D

quantification methods may provide additional clinically relevant metrics for diagnosis. However, very few studies so far have proposed 3-D image processing methods for IVOCT.

16.5.6 GPU-Accelerated Image Processing

A graphics processing unit (GPU) with hundreds of cores allows massively parallel computing and can significantly boost the performance of suitable algorithms. In many applications, GPU-based computing can be ten times faster more than its CPU equivalent. Recently, GPU processing has become popular in the OCT community and has been used in many tasks such as real-time OCT signal processing and volume rendering [82–85]. Most IVOCT image analysis methods involve the same processing operated on many A-lines or on many frames, and parallel computing can be naturally applied to these methods.

16.5.7 Image Understanding

Ideally, a fully automated tool to identify, segment, and quantify important vascular features (lumen, plaques, stents, thrombosis, etc.) could be very useful for real-time decision-making. This will require the algorithm to understand the IVOCT image content very well. This is a challenging task and may require combination of multiple image segmentation, detection, characterization, and classification methods, as well as expert medical knowledge into a meaningful hierarchical model. Without complicating the clinical task too much, some user input may be acceptable, and this will reduce the complexity of the problem significantly. High-level image understanding research is needed. The basis of human image understanding can be found in [86]. Some image understanding methods are introduced in [87, 88]. With the advance of IVOCT image analysis research, it is expected that more and more tasks can be automated towards this goal.

16.6 Conclusions

IVOCT image analysis is a relatively new area. The high resolution, superior image contrast, fast imaging speed, and volumetric profile of IVOCT make possible many high-impact image processing tasks. Significant advances have been made to automate various tasks, yet there are more to be explored. It can be expected that the research and development of IVOCT image analysis methods will have a direct impact on the diagnosis and treatment of coronary artery diseases.

Superluminescent Diode Light Sources for OCT

17

Vladimir R. Shidlovski

Contrary to laser diodes, the way of superluminescent diodes (SLDs) to their wide use in practice was much longer. There was always a certain scientific interest to "superluminescent" light output from laser diode structures slightly below threshold that might be considerably enhanced by "damping" of laser resonator (e.g., by tilting of mesa structures) [1–3]. However, there was no considerable practical interest to such light sources until it was proved that SLDs are the real "light sources of choice" for fiber-optic gyroscopes [4]. Successful use of first SLDs in gyros in the early 1980s, as well as some overestimated market demand for gyros, had considerably intensified SLD design efforts. This resulted in the development of "first generation of SLDs" with gyro-rated output power, a few milliwatt or less in single-mode (or polarization maintain) fiber at 800–850 nm and 1,300–1,550 nm bands. Development of gyro-graded SLDs also gave some additional impetus to their usage as light sources in other prospective sensing systems, such as Faraday effect electric current sensors, distributed Bragg grating sensor systems, and some others.

The "second wave" of interest to SLDs as light sources came after successful demonstration of OCT technique and its advantages comparing with other probing techniques in medicine, as well as in other applications [5]. OCT required much more powerful SLDs than those existed in the earlier 1990s, particularly with output power of at least 10 mW from SM fiber with still wide and flat optical spectrum of few tens of nanometers. At the same time, other new applications for such SLDs appeared, for example, testing of fiber-optic telecom components (including WDM/DWDM). This additionally intensified design efforts, which resulted in the development of SLDs with outputs comparable to that of laser diodes, thus ensuring their successful usage in applications where high spatial but low temporal coherence is required.

Each application has its own specific requirements to SLD performance parameters, but OCT requirements are the most hard to meet. The main reason for this is

DOI 10.1007/978-3-319-06419-2_18

the fact that high optical power, very wide-spectrum, and negligible parasitic spectral modulation must be realized simultaneously. From this point of view, OCT may be considered as "the main driving vehicle" for significant improvement of SLD performance and for developing of new approaches to increase SLD power and decrease coherence length. We will overview and discuss the main principles of developing of powerful broadband SLDs and their performance parameters. Some important aspects of SLD use in practice will be discussed. We will also describe ultra-low-coherence light sources based on the combination of different SLD modules. Possibilities for further improvement of SLDs and SLD-based light sources will be discussed as well.

17.1 Main Principles of SLD Operation and SLD Spectrum Broadening

The unique property of superluminescent diodes is the combination of laser diode-like output power and brightness with broad, LED-like, optical spectrum. Such combination is allowed by high optical gain and wide gain spectrum in semiconductor laser materials.

In fact, any "ideal" SLD is optimized traveling wave semiconductor optical amplifier (SOA) with zero reflections from the ends of active channel ("end reflections" below). In every SLD, two counterpropagating beams of amplified spontaneous emission are traveling along the active region. For estimation of its output power, SLD may be described relatively well by a simple model that does not take into account spectral effects and considers uniform distribution of carriers' density in SLD active region [6, 7]. Stationary distributions of photon densities in each direction, carrier density, and driving current density are described by well-known rate equations of traveling wave laser diode amplifier [6, 7]:

$$c\frac{dS^+}{dz} = c(g-\alpha)S^+ + \beta\frac{N}{\tau_{sp}}, \tag{17.1}$$

$$-c\frac{dS^-}{dz} = c(g-\alpha)S^- + \beta\frac{N}{\tau_{sp}}, \tag{17.2}$$

$$Q(z) = N/\tau_{sp} + cg(S^+ + S^-), \tag{17.3}$$

where S^+ and S^- are photon densities of forward and backward propagated waves in active region, g is modal optical gain, α is non-resonant optical losses of waveguided mode, β is fraction of spontaneous emission coupled into guided mode, N is carrier density, τ_{sp} is spontaneous lifetime, Q is driving current density, and c is the velocity of light.

Equations 17.1–17.3 may be solved analytically assuming that carrier density is constant across the active region [6], that should be a good approximation in the

case of superluminescent diodes, at least with reasonable (1.5 mm or less) length of active region. In such a case, SLD output power $P^+(O)$ on the "output end" of active region of the length L and residual end-reflection coefficients R_{out} and R_b may be expressed from Eq. 17.1 as

$$P_{out}{}^+(O) \propto S^+(O) = R_b S^-(L)\exp[(g-\alpha)L] + \frac{\beta N}{c\tau_{sp}} \frac{\exp[(g-\alpha)L]}{g-\alpha} \tag{17.4}$$

and SLD power $P^-(L)$ on the back end of the active region may be expressed as

$$P_{back}{}^-(L) \propto S^-(L) = R_{out} S^+(O)\exp[(g-\alpha)L] + \frac{\beta N}{c\tau_{sp}} \frac{\exp[(g-\alpha)L]}{g-\alpha} \tag{17.5}$$

In case of "ideal SLD," end-reflection coefficients are zero and SLD output power is expressed as

$$P_{out}{}^+(L) = h\upsilon \Pi c S^+(L) = h\upsilon \Pi \frac{\beta N}{\tau_{sp}} \frac{\exp[(g-\alpha)L]-1}{g-\alpha}, \tag{17.6}$$

where Π is the cross-section of active region.

For simple estimations, linear dependence of modal gain on carrier density may be used, i.e.,

$$g(N) = \Gamma \frac{dg}{dN}(N - N_0), \tag{17.7}$$

where Γ is optical confinement factor.

Expressions (17.6) and (17.7) allow to estimate optical gain required to get high output powers. Particularly, considering SLD at 850 nm, carrier density $N = 2 \times 10^{19}$ cm^{-3}, transparency threshold $N_0 = 5 \times 10^{17}$ cm^{-3}, differential gain $dg/dN = 0.5 \times 10^{-16}$ cm^{-2}, optical confinement factor $\Gamma = 0.3$, spontaneous emission factor $\beta = 5 \times 10^{-4}$, $\tau_{sp} = 2$ ns, size of optical mode 0.3×5 μm, losses $\alpha = 5$ cm^{-1} and length of SLD active waveguide of 1 mm, net gain $G = exp[(g-\alpha)L]$ of ~30 dB is necessary to realize output power of 30–50 mW. Similar gain is required to make powerful SLDs at other wavelengths.

However, it is practically impossible to achieve zero reflections from the ends of semiconductor optical amplifiers due to high reflection coefficient of as-cleaved semiconductor crystals. Such residual reflections always result in parasitic Fabry-Perot modulation (so-called spectral ripple) with period and depth determined by length of amplifier, optical gain, losses, and reflection coefficients. This parasitic modulation results in so-called secondary coherence subpeaks in coherence function, as it is shown on Fig. 17.1. Averaged spectral modulation of 2–4 % usually results in intensity of correspondent secondary coherence subpeak of −25…−20 dB that may cause problems in OCT systems due to correspondent "ghost" images. In case of low modulation index, parasitic Fabry-Perot modulation depth of SLD spectrum may be expressed as [8, 9]

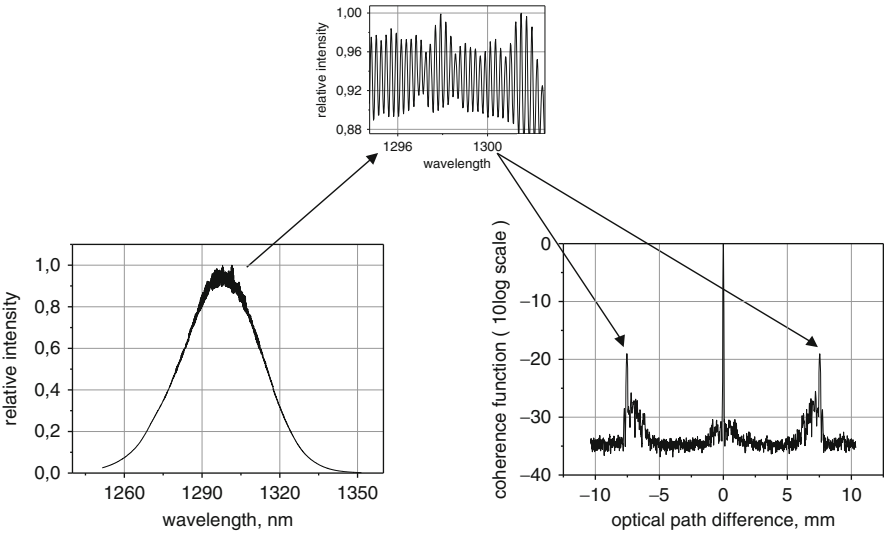

Fig. 17.1 Residual Fabry-Perot spectral modulation in SLD centered around 1,300 nm and correspondent secondary coherence subpeaks

$$m = 2G(R_{out}R_b)^{1/2}. \tag{17.8}$$

Comparison of (17.6) and (17.8) leads to one of the most important properties of SLD performance that is linear increasing of SLD spectral ripple with output power. In fact, both power and residual spectral modulation indices depend linearly on net gain G (6,8) because $N>>N_0$ (17.7) and $g>>\alpha$ in all high-power (i.e., high optical gain) SLDs.

Let us now estimate values of end reflections from SLD active region that are necessary to keep residual spectral modulation at low level. As it was pointed out above, net optical gain around 30 dB is required to produce output power of few tens of milliwatt per facet in single-transverse-mode SLDs. Therefore, product $R_{out}R_b$ must be as low as 10^{-10} (i.e., 10^{-5} per "reflective end") in order to keep residual spectral modulation in a range of 1–2 % in high-power SLDs.

This is very hard to do such low residual reflections in laser diode materials. Reflection coefficient of as-cleaved crystal facets in most of laser diode structures at 600–1,600 nm is around 0,35. Although a possibility for reaching of 10^{-5} residual reflection coefficient in AR-coated laser diode crystals was demonstrated in [10], in practice, all SLDs made by AR coating of laser diodes show very strong, 10 % and much higher, residual Fabry-Perot ripple starting some "low-to-moderate," 3–5 mW, output power per facet (see, e.g., [11, 12]; *to our knowledge*, *there are no reports about SLDs based on AR-coated lasers with better performance parameters*). Most probably, the reason for why it is impossible to do even "low-to-moderate" power low-rippled SLDs by simple antireflection coating of

laser diode crystals is that required residual reflection cannot be realized technologically on big lots due to minor lot-to-lot variations of center wavelength and far-field divergence in laser diode structures. The problem of high spectral ripple in SLDs based on AR-coated laser diodes resulted in the development of specific SLD geometries that allowed strong damping of residual "end reflections."

All low-rippled SLD geometries may be divided into two main categories: so-called "angled" (tilted, slanted) structures, where active waveguide is tilted to SLD crystal facet [2], and structures where ends of SLD active region are followed by relatively long "transparent window" regions and/or integrated absorbing region on the back side of SLD waveguide [7]. All modern powerful and low-rippled SLDs are based either on "tilted" or "transparent window" or "integrated absorber" designs, or on their combinations [see, e.g., 13–17].

But even after the problem of end reflections is solved on "design level" by appropriate SLD geometry, it is still necessary to apply antireflection coating on at least output facet of SLD crystal. Although "simple" AR coating may be used for medium-power SLDs, specific coating, that is not only antireflective but also protective, should be used in powerful diodes, especially in AlGaAs-based SLDs (AlGaAs is known for its relatively low catastrophic optical damage, COD, threshold). This problem may be solved by double-layer coating of output facet with the first layer working as protective layer and finishing layer optimized for best antireflection properties of resulted multilayer structure [18].

Let us now consider spectrum width of SLDs. Obviously, SLD spectrum is determined by the width of optical gain spectrum of active media. Optical spectrum width of the first SLDs, all based on bulk semiconductor heterostructures with relatively thick active layer, varied from (typical) 15–20 nm in 850 nm AlGaAs emitters to 30–40 nm in 1,300–1,550 nm InGaAsP SLDs. Although some exotic designs were proposed to broaden spectrum of "bulk" active layer SLD (particularly "stacked-layer-SLD" with two active layers with different material composition [19]), the real progress in SLD spectral broadening started after successful demonstration of quantum-well (QW) SLDs in [20].

Spectral broadening in QW SLDs is based on two main principles. The first one is a possibility for spectral broadening of optical gain due to very high density of states in QW structures with respect to bulk structures in case of the same driving current density [20]. Additional possibility for spectral broadening appears when transitions from different subbands in QW active layers are utilized to produce SLD output [21, 22]. Particularly, in single-quantum-well (SQW) AlGaAs laser structures, transitions from two, $n = 1$ (sometimes called "ground state") and $n = 2$ (sometimes called "excited state"), states in conductive band are possible [21]. While output power of only 3 mW and 50 nm spectrum width was realized in [20] for the first time from QW SLDs at 850 nm, it was shown in [22] that optimization of SLD active length and geometry allows additional spectral broadening by simultaneous amplification at $n = 1$ and $n = 2$ transitions and further increasing of SLD power; spectrum width of 70 nm was realized at 10 mW output power. Possibility for considerable spectral broadening by MQW (multiple-quantum-well) SLDs at longer wavelength (1,550 nm) was also demonstrated for the first time

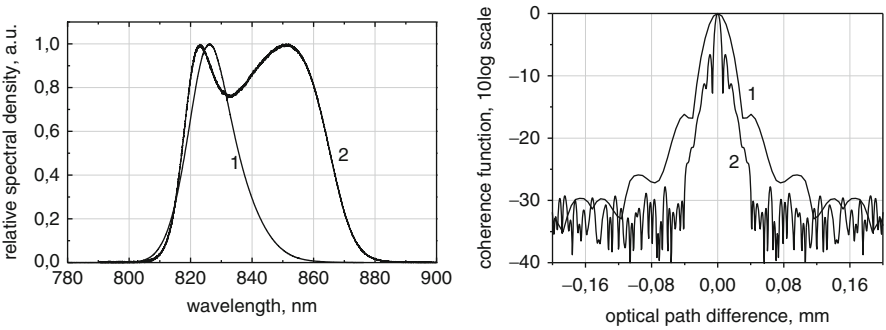

Fig. 17.2 Spectrum and coherence functions of bulk (*1*) and SQW (*2*) SLDs at 820 nm band. It is seen that unless SQW SLD coherence function is much narrower, sidelobes in main autocorrelation maximum of bulk SLD with Gaussian spectrum are well below –15 dB and are roughly 10 dB less than that of SQW SLD with "double-humped" spectrum

in [22]. Nowadays most of powerful and broad-spectrum SLDs at all spectral bands are based on SQW or MQW structure.

It should be pointed out, though, that SQW/MQW SLD spectrum width may depend on drive current much stronger than that of bulk SLD. Particularly, in bulk AlGaAs/GaAs heterostructures, spectrum width of optical gain is usually around 20 nm (around room ambient temperature; it may depend slightly on material composition and active layer doping, see, e.g., [23]). This is why all ever-reported bulk active region AlGaAs SLDs had spectrum width of 15–20 nm with weak dependence of spectrum width on drive current. In SQW/MQW SLD, spectrum width depends on drive current much stronger [21, 22]; particularly, it was broadened by 2–3 times in 820 nm and 1,550 nm SLDs reported in [21, 22] but became strongly non-Gaussian reaching its widest value at some "fixed" value of output power and driving current. Spectral shape of such SLDs is usually "double humped" due to energy separation between different subbands in quantum wells. Changing of driving current results in domination of one of the spectral maxima and narrowing of optical spectrum. Note also that complex form of spectrum may result in strong distortions of coherence function. Figure 17.2 shows main autocorrelation maxima of "bulk" and broadband SQW AlGaAs SLDs. Though some negligible distortions of coherence function due to spectrum asymmetry are seen in bulk SLD, they are much less than that of SQW SLD with very wide but double-humped spectrum.

During the last couple of few years, a possibility of further broadening of SLD spectrum by using quantum dot (QD) structures had been studied [24–26]. Principle of spectral broadening in QD structures is similar to that in QW structures. Considerable broadening is obtained when optical gains at "ground state" and "excited state" in QDs are equal. Additional broadening of entire spectrum is possible due to considerable fluctuation of dots size in today's QD structures. Electroluminescence covering almost 350 nm had been reported in QD structures centered at ~1,200 nm [27]. However, performance of QD SLDs reported so far (which will be reviewed below) is comparable with that of QW SLDs (in terms of

combination of high power and wide spectrum, although wider spectra were demonstrated at low levels of output power).

17.2 Reported SLD Performance Parameters

In this chapter we will review main achievements in development of very high-power and broad-spectrum SLDs at different spectral bands. The main attention will be paid to SLD output power and spectrum width, but some other issues like far-field, polarization, and noise will be discussed as well.

17.2.1 AlGaInP SLDs at 680 nm

Output power up to 4 mW was realized from bulk SLD [15]; output power was increased considerably, up to 50 mW, by using MQW active layer [28]. However, spectrum width of only 8–10 nm was reported in both publications. Commercially available SLDs have the same width of spectrum and output power of up to 5 mW from SM fiber.

17.2.2 AlGaAs SLDs at 780–870 nm Band

A lot of powerful SLDs at this spectral band had been reported. Output power of ~100 mW before COD was successively demonstrated in [18, 29]. It was also shown in [30] that COD threshold may be increased considerably by adding of short unpumped regions near SLD crystal facets. Free-space output power 250 mW per facet was realized by optimization of the length of such regions. SM fiber output power in excess of 100 mW was realized from such SLDs by coupling via cylindrical microlens on the fiber end. Such output power is comparable with powerful single-mode fiber-coupled laser diodes at this band.

In QW SLDs, output power up to 100 mW with 50 nm FWHM was realized by optimization of SLD structure and length of active region [28]. Commercially available SLDs at this spectral band now produce up to 30 mW output with up to 60 nm spectrum width. This spectrum width corresponds to coherence length in the air of less than 10 μm.

Possibilities to realize much broader spectrum in 820 nm SLDs were also demonstrated in [31, 32]. In [31], 100 nm averaged spectrum width was obtained by combined DC and pulse driving of SQW SLD. In [32], up to 90 nm spectrum width was obtained in SLDs with MQW active layer consisted of four layers with thickness varied from 2 to 12 nm. Though reaching of 100 nm spectrum width will allow ultrahigh-resolution OCT at 850 nm band by "single-SLD-emitter" light source, until now there are no commercially available powerful SLDs at 820 nm band with spectrum width exceeding 65 nm.

17.2.3 InGaAs SLDs at 920–1,060 nm Spectral Band

Very broad-spectrum and very high output power had been demonstrated for InGaAs SLDs at 920–980 nm, too. In [9, 28], output power in excess of 100 mW was reported for SLDs around 960–980 nm with bell-like spectrum with approximately 25–30 nm spectrum width and 70 nm wide spectrum with output power around 30 mW. Later, 100 nm spectrum width was realized from optimized QW SLD at 920 nm with free-space output power up to 30 mW (>10 mW ex SM fiber) [33]. Commercial SLDs emit up to 30 mW (SM fiber) output power with 50 nm wide bell-like spectrum and up to 100 nm wide spectrum and 10 mW SM fiber power.

It should be pointed out again that the most broadband and powerful SLDs at 780–1,000 nm have "double-humped" spectrum as simultaneous emission from different subbands of QW active region is used for spectral broadening. Figures 17.3 and 17.4 show spectrum of single-mode fiber-coupled SLD modules emitting

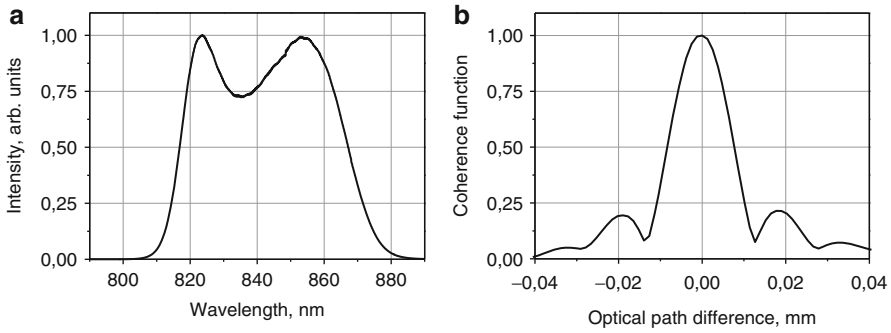

Fig. 17.3 Spectrum and coherence function of 35 mW SM fiber output power QW SLD module at 840 nm

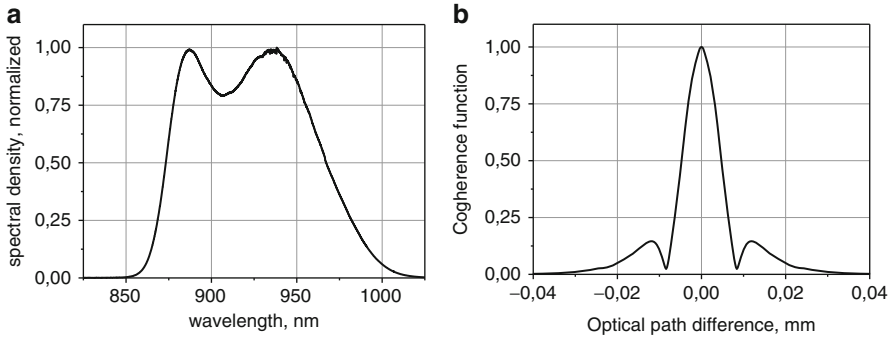

Fig. 17.4 Spectrum and coherence function of 10 mW SM fiber output power QW SLD module at 930 nm

35 mW at 840 nm with 50 nm spectral bandwidth and 10 mW at 930 nm with 100 nm spectral bandwidth and their coherence functions.

InGaAs/GaAs heterostructures were also used to make SLDs at 1,060 nm, the wavelength of growing interest for OCT [34, 35]. The first SLDs reported at this spectral band had output power less than 10 mW (less than 2 mW ex SM fiber [18]). Output power around 50 mW and spectrum width of 110 nm were demonstrated in SLDs centered at 1,030 nm later [36]. Currently, SLDs with spectrum width of ~50–60 nm (bell-shaped spectrum) and ~100 nm (double-humped spectrum) are commercially available.

A possibility of further improving of SLD output power and spectrum width in devices emitting around 1,000–1,060 nm was demonstrated by using of quantum dot (QD) structures. As mentioned above, such structures allow additional broadening of optical gain spectrum due to inhomogeneous dot size distribution in QD active layers. Being a disadvantage to do high-performance QD lasers such "QD dispersion" allows considerable broadening of SLD spectrum [37]. Very broad spectrum had been obtained in SLDs centered at 1,180 nm (up to 150 nm), but SLD power was below 100 μW in this case [38]. However, spectrum width became comparable with that possible by QW structures when shorter wavelengths were targeted. Particularly, free-space output power up to 200 mW with spectrum width around 60 nm was realized in such SLDs centered around 1,000 nm [39].

17.2.4 InGaAsP/InP SLDs at 1,300–1,600 nm Spectral Band

SLDs at this band, especially those centered around 1,300 nm, are very attractive for OCT due to better penetration into tissue. However, increasing of wavelength results in decreasing of coherence length proportionally to square of wavelength. This makes requirements to a long-wavelength SLDs more "stressed" as, for example, spectrum of 1,300 nm SLD must be at least 2.5 times broader with respect to 800 nm counterpart in order to get the same spatial resolution.

Numerous efforts had been put for the development of powerful and broadband SLDs at this spectral band, including optimization of quantum-well (usually multiple QWs) structures and QD structures [26, 39–45]. High output power and wide bell-shaped spectrum had been demonstrated at different center wavelengths. SLD modules with single-mode fiber output of 10–20 mW and spectrum width of up to 80 nm (bell-shaped) and 100 nm (double-hump) are now commercially available.

Let us now discuss briefly other important SLD performance parameters, starting from far-field pattern.

In principle, far field of any single-transverse-mode SLD should be similar to that of conventional single-transverse-mode laser diode (LD) as similar waveguide structures are used in both. However, analysis of SLD literature shows that in most of powerful SLDs active waveguide is tilted to crystal facets. Such tilting results in "crescent" structure of far field, like it is shown on Fig. 17.5 for SLD at 680 nm reported in [28]. Therefore, though conventional LD-graded optics may be used for collimation/focusing of SLD beams, additional optical elements may be required

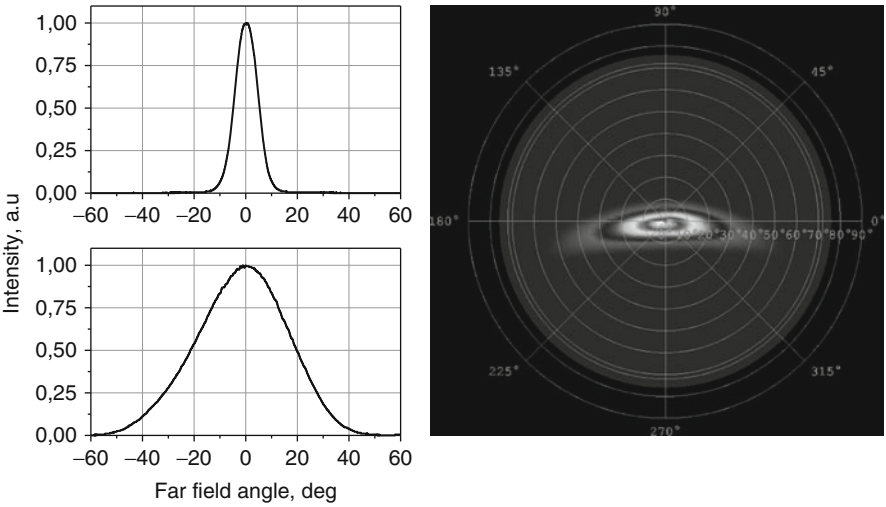

Fig. 17.5 Far-field distribution of angled waveguide SLD at 680 nm [24]

for focusing to diffraction-limited spots. As well, detailed study of spatial coherence [46] shows that even narrow active waveguide SLDs with far-field pattern similar to single-transverse-mode structure may be not 100 % spatially coherent, most probably due to additional high-order mode(s) of lower intensity. From this point of view, SM fiber-coupled SLDs may be more useful also for free-space OCT systems.

SLD polarization may be also important for OCT devices. Usually, there is no gain anisotropy in nonstressed bulk SLDs. Two main factors affecting bulk SLD polarization had been reported: different absorption of TE and TM polarized modes in upper metal contact layer [7] and stress-induced gain anisotropy [47] (residual stresses may be caused, e.g., by mounting SLD crystal onto carrier). Contrary to bulk counterparts, polarization-resolved spectrum of SQW and MQW SLDs may be considerably different to that "polarization non-resolved." In [48], different polarization of light correspondent to transitions from different subbands in AlGaAs SQW was obtained that resulted in considerable difference in spectrum of TE and TM modes. In [49], considerable (about 1.5 times) difference in spectral width of TE and TM polarized modes was obtained in MQW SLDs around 1,550 nm. Unfortunately, there are very few reports on the study of SLD polarization, so there are no more data available.

SLD noise parameters are also very important for OCT systems. The most common approach considers SLD as Gaussian light source with excess noise due to beating of independent spontaneously emitted photons, and spectral density of detector's current fluctuations is expressed as

$$<dI^2>= 2eI(1 + I/I_0), I_0 = e\mathrm{M}dv, \tag{17.9}$$

where e is elementary charge, I is photocurrent, dv is spectrum width, and M is coefficient that depends on polarization and number of modes. For polarized single-transverse-mode SLD at 830 nm with 50 mW output power and 0.4 A/W photoreceiver sensitivity, this model predicts relative intensity noise RIN = $<dI^2>/I^2$ of around –130 dB/Hz for 50 nm wide SLD and –127 dB/Hz for 20 nm wide SLD. Moreover, no any dependence of SLD noise on output power should be obtained accordingly to this model because second term in Eq. 17.9 exceeds shot noise limit $2eI$ by orders of magnitude starting SLD power of few milliwatts. However, different RIN values to those predicted by such model were obtained even in low power, 3 mW SLDs at 820 nm [45]. Moreover, SLD noise saturation was obtained in medium-power [14] and high-power [24] SLDs at 820 nm. In [28], reduction of RIN value by approximately ten times from –130 dB/Hz at 1 mW to –138 dB/Hz at 50 mW in 20 nm wide SLD at 820 nm was obtained, which cannot be explained by the abovementioned model of photon beat noise.

Another model of SLD quantum noise that takes into account amplifier nature of SLD was developed in [50]. Accordingly to this model, excess noise factor X over shot noise $2eI$ may be expressed in terms of transmission losses η, modal gain g, optical losses α, and net gain G as

$$X = e\eta(g + \alpha)(G - 1)/(g - \alpha), \tag{17.10}$$

or, assuming modal gain g much higher than non-resonant losses α,

$$X = e\eta(G - 1) \tag{17.11}$$

It is seen that within this model, excess noise factor is determined by optical gain in SLD. Gain saturates when SLD power increases, so this model may explain noise saturation in powerful SLDs. Good correspondence between results of SLD noise estimations and measurements was obtained in [45]; unfortunately there were no further detailed studies of SLD noise.

It should be pointed out that even in high-power SLDs, intensity noise is more than two orders of magnitude higher than shot noise limit $2eI$. So optimization of power in reference arm of interferometer for the best signal-to-noise ratio in OCT systems is necessary [51].

17.3 SLD Based Broadband and Powerful Light Sources

Previous section shows that a lot of powerful and wide-spectrum SLDs at different spectral bands have been successfully demonstrated. Moreover, further improvement of SLD performance should be possible including development of more powerful and broadband emitters. However, there is also other advantage of SLDs that allows further spectral broadening in SLD-based light sources, namely, easy variation of SLD wavelength by minor change of active layer composition and thickness.

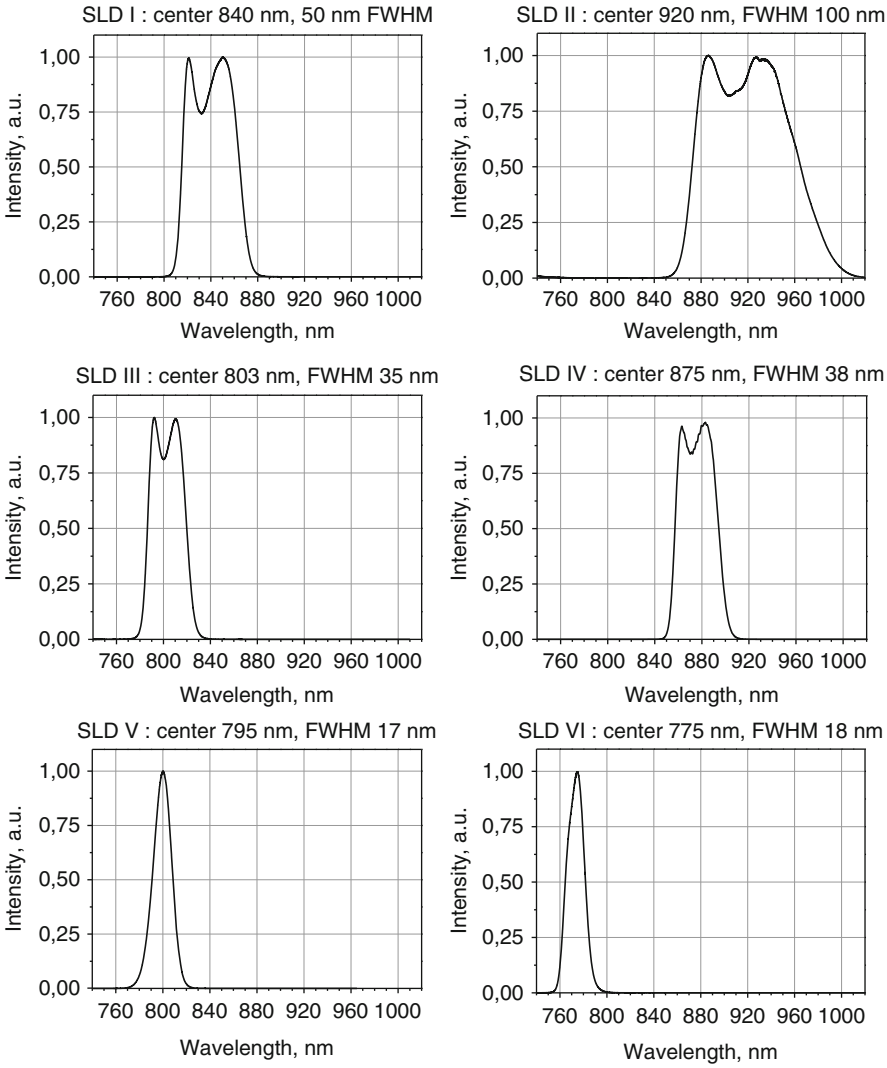

Fig. 17.6 Emission spectra of AlGaAs/GaAs and InGaAs/GaAs SLDs with different active layer composition and geometry

For example, Fig. 17.6 shows spectrum of different SLDs at 780–1,000 nm that were obtained by variation of active layer structure/composition in AlGaAs/GaAs and InGaAs/GaAs SLDs QWs [52, 53]. Most of SLDs had SM fiber-coupled power of 10 mW or more [53]. Combining of two and more of such SLDs by appropriate couplers may result in very broad optical spectrum.

Particularly, combining of "SLD I" and "SLD II" allows broadband light source with total 150 nm linewidth and output power of few milliwatts; see Fig. 17.7a. Images of human retina with 3.5 μm resolution and images of skin layers

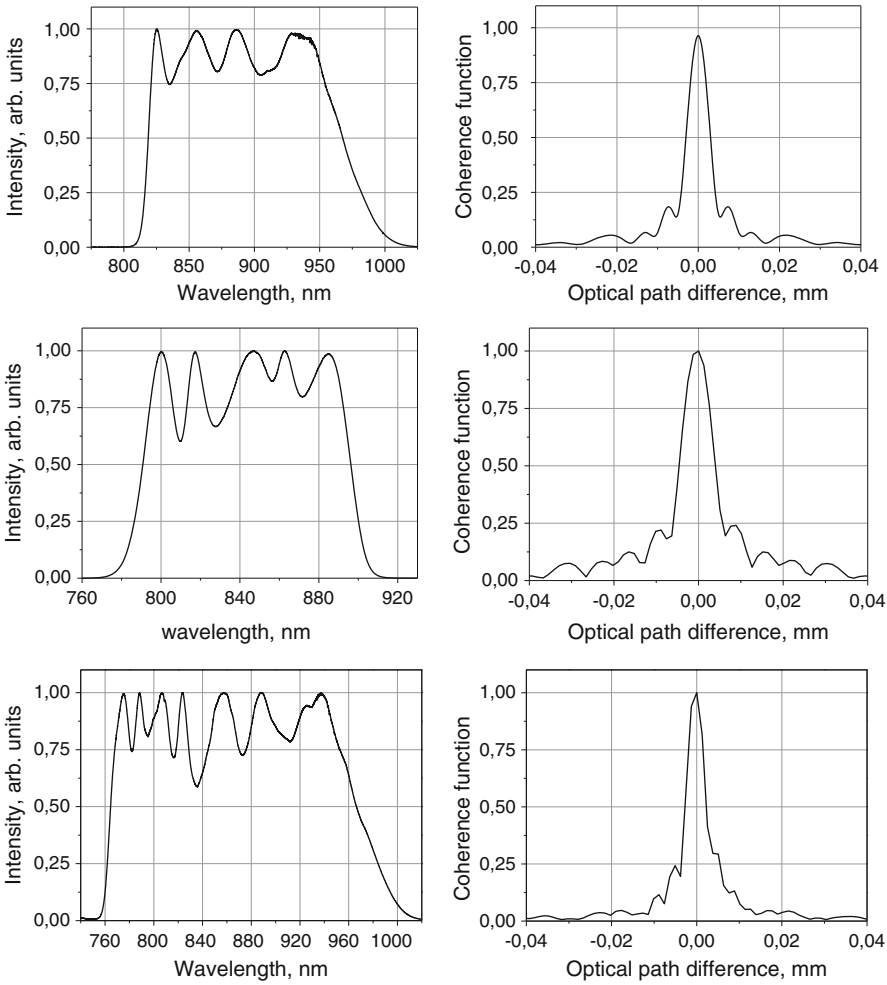

Fig. 17.7 (**a**) Spectrum and coherence function of 150 nm wide 2-SLD light source; coherence function FWHM 5,7 μm. (**b**) Spectrum and coherence function of 100 nm wide 3-SLD light source; coherence function FWHM 8,3 μm. (**c**) Spectrum and coherence function of 200 nm wide 4-SLD light source; coherence function FWHM 4,5 μm

with 2.3 μm resolution had been successively acquired using such light source [54]. This is nearly the same resolution as that obtained using femtosecond laser sources. More powerful and broadband "combined SLD light sources" at 800–1,000 nm range were developed in [55] by using of couplers with optimized coupling ratio and by varying of SLD operation conditions.

Figures 17.7a–c demonstrate spectra of broadband light sources based on different combinations of SLDs I–VI. Particularly, Fig. 17.7b demonstrates spectrum and coherence function of 18 mW 3-SLD light source with spectrum width exceeding 100 nm. Combination of four SLDs, Fig. 17.7c allowed 200 nm

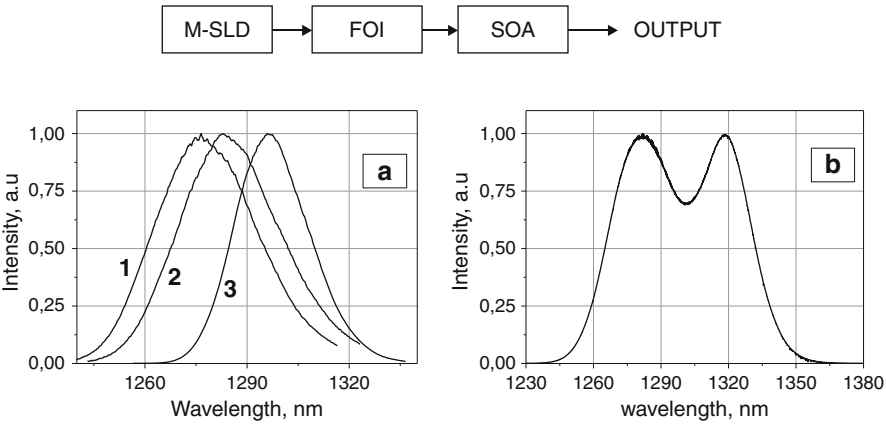

Fig. 17.8 (**a**, **b**) SLD-MOPA configuration and results. *M-SLD*: master SLD, *FOI* – optical isolator, *SOA* – amplifier. On the (**a**): *1*: SOA ASE spectrum; *2*: master SLD spectrum, *3*: resulted spectrum. Same amplifier was used to produce broad spectrum on (**b**) master SLD had center wavelength 1,318 nm in this case

wide light source centered around 890 nm with output power exceeding 5 mW from SM fiber.

Other possibility for improvement of performance of SLD-based light sources is so-called "SLD-MOPA (master oscillator power amplifier)" design. Feasibility of such an approach was first demonstrated by using of Er-doped fiber amplifier to increase output power of 1,550 nm SLD [56]; 20 mW output was obtained by amplifying of 1 mW output power SLD. Later, similar method had been used to do high-power SLD by integration of SLD and tapered MOPA in the same semiconductor chip. Output power in excess of 300 mW was obtained from 130 μm output aperture, integrated SLD-MOPA light emitters [57]. Possibility for considerable increase SLD output power and its spectral broadening by "SLD-MOPA" light source was demonstrated at 1,300 nm, too [58, 59]. Medium- to high-power master SLD at 1,300 nm and high gain SOA were used in experiments. Appropriate broadband optical isolator was placed between master SLD and SOA to exclude cross-coupling between them, like it is shown on the Fig. 17.8. When SLD with center wavelength close to spectral gain maximum of SOA was used as master source, output power up to 100 mW from SM fiber with 26 nm spectrum width was obtained on SOA's output (Fig. 17.8a). When SLD with "red-shifted" spectral center with respect to SOA spectral gain maximum was used as master oscillator, widening of output spectrum by a factor of two was obtained after SOA (Fig. 17.8b). Recently, up to 500 mW pulse power and 85 nm wide spectrum was demonstrated by QD SLD-MOPA device at 1,300 nm in [60].

SLD-MOPA configuration was also used successfully for increasing of SLD output power at 830 nm band. In particular, output power of 50 mW in single-mode fiber MOPA source had been obtained in [61], although with relatively narrow spectrum. Up to 500 mW had been obtained from a multimode design using tapered MOPA [62].

17.4 SLDs and Optical Feedback. Important Aspects of SLDs Use in Practice

It is well known that usage of semiconductor light sources similar to laser diodes requires essential practical experience. Particularly, such well-known problem as transient current/voltage surges in electronic drivers may be fatal to laser diodes and SLDs because of catastrophic or latent damage. However SLDs, especially high power ones, require additional safety measures due to their strong sensitivity to optical feedback and non-uniform distribution of drive current inside active region.

As it was pointed out above, 30 dB net optical gain is required to do powerful SLDs. It means that if there will be some optical feedback to SLD, reflected light will be amplified very effectively. Particularly, it is seen from Eq. 17.5 that if modal gain $G = \exp[(g-\alpha)L]$ is 30 dB then optical feedback of 10^{-3} will increase power of back-propagated light inside SLD by two times (assuming no gain saturation by this feedback; note real changes may be less because −30 dB feedback may already saturate optical gain in high-power SLD). This will also change output power and SLD spectrum considerably due to gain saturation effect. Most of OCT systems may result in optical feedback to SLD emitter due to "back-reflective" nature of Michelson interferometers with reflective mirror in reference arm. Of course, optical isolators may be good solution to protect SLDs from optical feedback, but usually this is hard to obtain broadband isolators with high optical isolation. As well, isolators at short (<1,000 nm) wavelength are still bulk and expensive. Let us discuss effects of optical feedback on SLD performance in more details.

Figure 17.9a shows the results on simulation of performance of powerful AlGaAs SLDs at 820 nm reported in [18] with mode size of 0.3 × 5 μm in free-running operation assuming zero end reflections in active region. Simulation of light-current characteristics was done using the most common parameters of

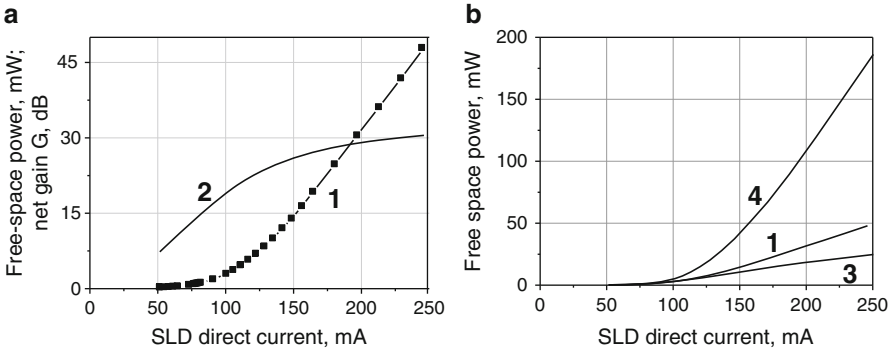

Fig. 17.9 (**a**) Light current characteristics (*1*) and net gain (*2*) of high-power AlGaAs SLD reported in [18], squares show measured power; (**b**) calculations in case of 1 % feedback, output facet (*3*) and back facet (*4*); "free-running" light-current characteristic is also shown for comparison. In case of 1 % feedback front output power decreases due to gain saturation effect

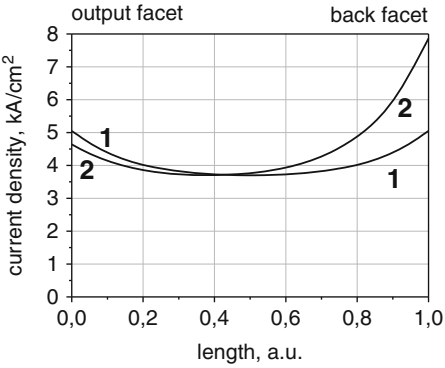

Fig. 17.10 Redistribution of driving current density in active region at 190 mA SLD current (30 mW free-space power); *1* – free-running, *2* – 1 % optical feedback

AlGaAs heterostructures similar to those mentioned above and described in details in [7]. Linear dependence of gain on carrier density Eq. 17.7 was used for calculations in low-power (<2 mW output power) operation mode. Differential gain $\Gamma dg/dN$ in Eq. 17.7 and spontaneous emission factor β were varied for the best fitting of measured SLD light-current characteristics in low-power area. At higher operation power, additional non-linear gain term was introduced for the best fitting of light-current characteristic.

Calculated light-current characteristics in case of 1 % optical feedback to the same SLD are shown on the Fig. 17.9b; dependence of optical gain on carrier density obtained by fitting of free-running light-current characteristic (curve 1) was used for calculations. It is seen that 1 % feedback deteriorates SLD performance considerably, resulting in increased back-propagated power and decreased output power. Distribution of driving current density inside the active region in case of free-running operation and 1 % feedback at 190 mA (30 mW free-space power in free-running mode) is shown on the Fig. 17.10. It is seen that optical feedback results in re-distribution of driving current density inside SLD active region. Current density near back facet becomes 1,5 times higher than "feedback-free" value. All these events (increased power of back-propagated light and increased driving current density at back SLD crystal facet) may have very strong impact on SLD performance in the system and result in fatal damage of COD-sensitive devices and decreased lifetime of SLDs based on materials sensitive to high driving current densities.

Experimental study on sensitivity of powerful SLDs to weak optical feedback was done in [63]. Changes of back facet SLD power of about 15–20 % at −30 dB optical feedback were obtained in 840 nm band SLDs emitted 50 mW of free-space power. This is less than estimations above because such a weak feedback already saturated optical gain in powerful SLDs. In addition to this, spectral changes due to feedback-induced gain saturation were obtained in powerful broad-spectrum QW SLDs starting −30 dB optical feedback (see also [63]).

Such a strong sensitivity to optical feedback requires special measures for SLD protection in optical systems. One of the main important problems arose is a possibility of catastrophic damage of SLD's back facet by optical feedback.

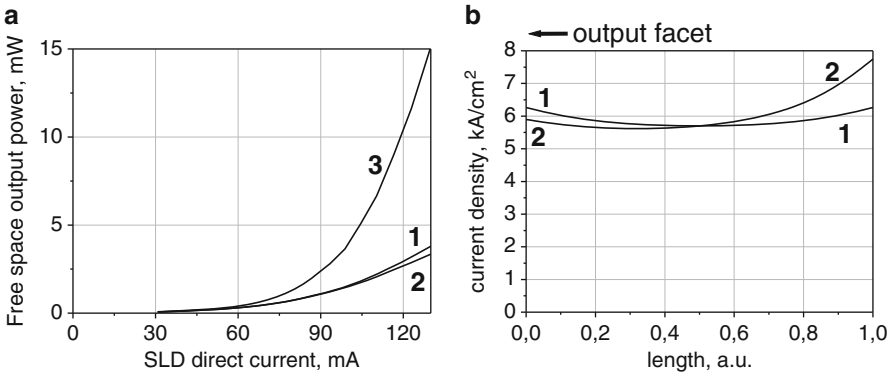

Fig. 17.11 (**a**) Light current characteristics of medium-power SLD (optical gain 19 dB at 130 mA in case of free-running operation), (*1*) – no feedback, (*2*) – output power, 5 % feedback, (*3*) – back facet power, 5 % feedback; (**b**) distribution of driving current density inside active region at 15 mW/130 mA, (*1*) – free-running, *2*–5 % feedback

Under certain circumstances, constant power (CP) driving mode by stabilizing of back facet power by monitor photodiode (when available) may be a good "protective measure" for SLDs in OCT systems without optical isolators. Feedback in OCT is usually relatively slow with respect to potential bandwidth of feedback loop via PD monitor (up to 1 MHz electrical feedback loop bandwidth via PD monitor should be possible when appropriate PD monitor is placed inside SLD module). However, it may be considered only as a "protection" of SLD against optical feedback (at least when optical feedback is relatively slow) and may result in a huge output power degradation in presence of any "essential" feedback. Particularly, in case of feedback-free operation at 160 mA (see Fig. 17.9), 1 % optical feedback will result in SLD drive current decreasing down to 110 mA in case of CP mode, with correspondent 4 times output power degradation form 20 mW to 5 mW. This may also result in very strong change of SLD spectrum [63].

Note that 1 % optical feedback may be applied to SLD easily. Particularly, coupling efficiency to single-mode optical fiber in powerful SLD modules is usually around 50 % (see, for example, [19]). Normal cleave of SM silica fiber results in 4 % reflection back to the fiber, thus in total 1 % back to SLD.

It should be pointed out that optical feedback may cause problems even in medium-power SLDs (see also [63] for experimental results). Figure 17.11a, b show estimations of feedback-induced changes of output power in "medium-power" SLD design for which high optical gain is not necessary. It is seen that for this SLD there are no considerable changes of output power in case of relatively strong, 5 %, feedback. However, it is also seen that driving current density near back facet increases by approximately 25 %, that may be the reason for SLD latent damage and shorter SLD lifetime. As well, strong decreasing of output power will be obtained if such SLD is driven in CP mode.

Unfortunately, influence of optical feedback on SLD performance and methods for decreasing of SLD sensitivity to optical feedback are not studied well enough so far. For example, increasing of spontaneous emission coupled to guided mode may be an effective way in decreasing of SLD reaction to feedback. As follows from Eq. 17.8 above, SLD power is proportional to the product of spontaneous emission coupled to guided mode and modal gain. If so, SLD with higher spontaneous emission will require lower gain for getting the same power. Therefore, such SLD should be less sensitive to feedback as the sensitivity is determined by optical gain, too. However, possibilities for considerable increasing of coupling of spontaneous emission to guided mode in SLDs have not been studied deeply until now. Some reduced sensitivity to feedback in single-mode fiber-coupled SLD modules had been reported in [64], however, physical reasons for observations had not been explained. Moreover, "weaker" sensitivity reported in [64] could be caused by relatively low coupling efficiency to single-mode fiber.

One effective method for increasing of SLD power and decreasing of its sensitivity to optical feedback is usage of SLD-MOPA configurations [61]. High gains are not required in power amplifiers, therefore sensitivity to feedback will be reduced. This design may be very useful for applications (including OCT) requiring powerful low coherent sources at wavelengths below 1,000 nm were broadband isolators with high enough isolation have relatively high insertion losses and are bulky and expensive.

17.5 Conclusions

Significant improvement of SLD performance parameters resulted in development of very high-power and broadband SLD-based light sources at different spectral bands from 680 to 1,600 nm. SLDs now have output power comparable with that of single-mode laser diodes and coherence length down to 10 μm and less, at least at some particular wavelengths. "Combined" SLD light sources on the base of two and more SLDs allowed ultrahigh, 2.5–3.5 μm, resolution OCT images of human eye and tissue, comparable with results obtained using bulky, noisy and expensive femtosecond laser light sources.

Further improving of SLD performance should be possible, too. Particularly, SLDs and SLD-based light sources with SM fiber output power of 100 mW and more were demonstrated at all wavelengths-of-OCT-interest, particularly at 800 nm and 1,300–1,600 nm spectral bands. The use of specially designed multi-quantum-well and quantum dot structures may allow SLDs with spectrum width of 100 nm and much broader, thus opening possibilities for OCT systems with 1–2 μm resolution basing on a single-SLD-emitter light source.

SLEDs and Swept Source Laser Technology for OCT

18

Marcus Duelk and Kevin Hsu

18.1 Broadband SLEDs for OCT

Broadband and high-power superluminescent light-emitting diodes (SLEDs) can be fabricated at wavelengths ranging from 390 nm to 2700 nm. They can be realized in GaN (390–630 nm), GaAs (630–1,150 nm), InP (1,150–2,000 nm) or GaSb ([1], up to 2,700 nm). The vast majority of SLEDs used for OCT today is in the wavelength range of 800–900 nm and is employed in ophthalmic spectral-domain (SD) OCT systems. Broadband SLEDs at 1,300 nm have been used in time-domain (TD) OCT systems in industrial applications such as high-resolution thickness measurements. With the recent advent of high-speed InGaAs cameras having 2,048 pixels [2], SD-OCT systems at 1,060 nm or 1,300 nm may also be realized in the coming years for biomedical or other applications.

18.1.1 Coherence Function and Coherence Length

The coherence length l_{coh} and time τ_{coh} of a broadband light source is given by

$$l_{coh} = \gamma . \frac{2\ln 2}{\pi} . \frac{\lambda_0^2}{\Delta\lambda} \quad \tau_{coh} = \frac{l_{coh}}{c}$$

with λ_0 being the center wavelength and $\Delta\lambda$ being the 3-dB optical bandwidth. The factor γ accounts for the fact that many broadband SLEDs do not have a perfect Gaussian shape but rather a flat-top spectrum. For Gaussian-shaped SLEDs, this factor is unity ($\gamma = 1$), while for SLEDs with a flat-top spectrum, $\gamma = 1.186$ is typically used, i.e., there is almost a 20 % penalty in coherence length by deviating

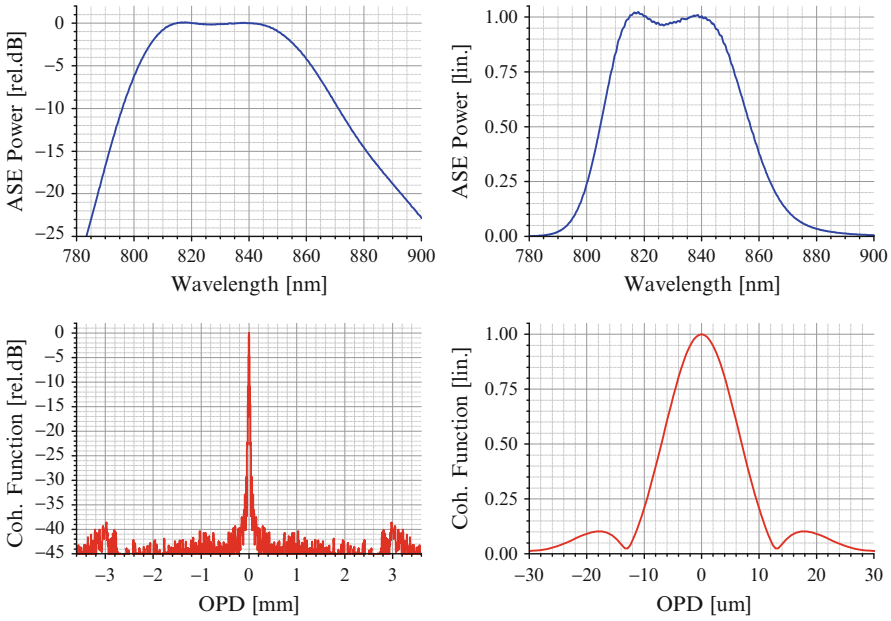

Fig. 18.1 ASE spectrum (*upper row*, in *blue*) of an 840-nm SLED with ~50-nm full width at half maximum (*FWHM*) optical bandwidth (EXS210022) and corresponding imaging or coherence function (*lower row*, in *red*) plotted versus optical path length difference (*OPD*). The half-width at half maximum (*HWHM*) of the coherence function shows a coherence length of 7–8 μm (in air)

from a perfect Gaussian shape. The coherence length of the SLED specifies the theoretical limit for the axial resolution of an OCT imaging system. For example, with $\lambda_0 = 840$ nm and $\Delta\lambda = 50$ nm, a coherence length $l_{coh} = 7.4$ μm is calculated when assuming a flat-top shape, as shown in Fig. 18.1.

The coherence function is equivalent to the autocorrelation function of an SLED, which is, according to the Wiener-Khinchin theorem, the Fourier transform of the ASE spectrum [3]. According to Parseval's theorem, the Fourier transform of a power spectrum represents again power, which means that the coherence or autocorrelation function represents optical power in the spatial domain. It is calculated by applying the FFT to the linear ASE spectrum that has been resampled with equidistant steps in the frequency domain. The magnitude of the FFT output is the linear coherence function, and its logarithmic counterpart is calculated by $10{\cdot}\log_{10}$ and not by $20{\cdot}\log_{10}$, as sometimes found as well. Since the ASE power spectrum is real-valued, the Fourier transform is Hermitian and hence symmetric in space or time, as shown in Fig. 18.1.

The drop-off of the coherence function from its maximum (at zero) to 50 % is the coherence length, i.e., the coherence length is the half width at half maximum (HWHM) and not the full width at half maximum, as sometimes referred to. This can be easily verified by the example given in Fig. 18.1.

The logarithmic coherence or imaging function plotted over a wide range may reveal *secondary coherence peaks* at a certain optical path length difference (OPD).

For the example shown in Fig. 18.1, secondary coherence peaks can be seen at an OPD of ~3 mm with a suppression of close to 40 dB. Typically, a secondary peak suppression ratio (SPSR) of 25–35 dB is needed in order to avoid OCT imaging artifacts like horizontal lines in a B-scan image. Such SPSR corresponds to a (peak-to-valley) ripple amplitude of the ASE spectrum in the range of 0.10–0.20 dB. This is achieved through an advanced SLED chip design and through high-performance antireflection coatings (ARC) at the chip facet.

The coherence function near the central peak (at zero) may reveal *sidelobes* when the ASE power spectrum deviates from a Gaussian shape. The example of Fig. 18.1 shows sidelobes with a suppression of ~10 dB (not considering any windowing prior to the FFT). The sidelobe suppression ratio (SLSR) is only given by the spectral shape of the SLED, and high SLSR values are needed particularly for TD-OCT systems where additional signal processing like spectral windowing is not implemented. Gaussian-shaped SLEDs have a high SLSR (i.e., no or little sidelobes), while SLEDs with a flat-top spectrum have a lower SLSR.

18.1.2 SLEDs at 400–500 nm

SLEDs in the blue-to-green spectral range are realized in the GaN material system [4]. The short emission wavelength may, in combination with broadband emission, allow for realizing SLEDs with a coherence length of 1–3 μm in air. However, due to very high absorption of blue light in hemoglobin, biomedical OCT for tissue diagnostic is rather unlikely. Instead, those sources may be deployed in nondestructive testing (NDT) or ultra-high-resolution optical coherence microscopy (OCM) systems [5]. Due to extensive work on the reliability of GaN SLEDs [6], blue SLEDs have been commercially available until very recently [7] such that OCT and OCM in this spectral region have not been explored yet. Figure 18.2 shows the electro-optic properties of high-power SLEDs in the wavelength range of 400 to 450 nm. The achievable output power and the slope efficiencies are nearly comparable with GaN single-mode laser diodes. The ASE emission spectra of the currently available SLEDs have a Gaussian shape with a typical 3-dB optical bandwidth of 4-5 nm. Similar to design efforts that were done for SLEDs at 800 to 900 nm, the ASE emission spectrum of such GaN SLEDs could be increased to achieve ultra-short coherence lengths or coherence times.

18.1.3 SLEDs at 840 nm

Most SD-OCT systems deployed today are used for retina imaging in ophthalmology and are based on an 840-nm SLED featuring a 3-dB (FWHM) optical bandwidth of 50 nm and a 10-dB bandwidth of 80 nm. Those SLEDs are used in combination with a spectrometer that spans 80 nm and a line camera with 2,048 pixels, resulting in a wavelength resolution of ~0.04 nm or a frequency resolution of ~17 GHz, which then translates into an axial resolution of 7–8 μm in air (without windowing) and an imaging depth of ~4.5 mm.

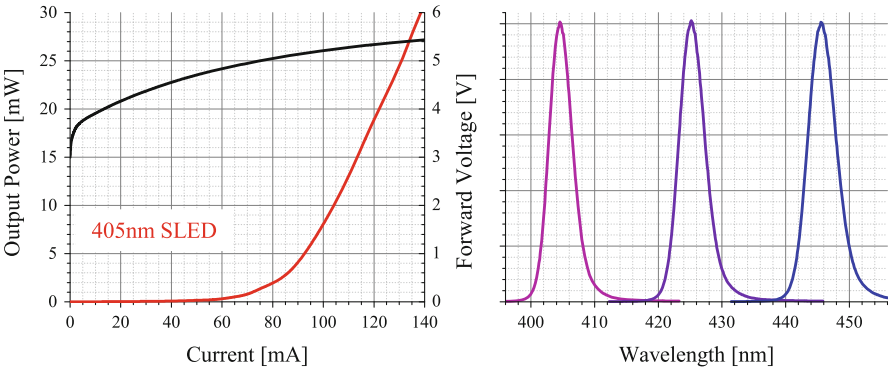

Fig. 18.2 Ex-facet output power and forward voltage of high-power single-mode 405-nm SLED as function of drive current (*left*). ASE emission spectra on a linear scale of SLEDs at 405, 425 and 445 nm with optical bandwidths of 4-5 nm (*right*)

The maximum permissible exposure (MPE) limit according to laser class 1 is ~750 μW at a wavelength of 840 nm [7]. Considering a 75:25 splitter in the OCT interferometer and an additional 2–3 dB loss in the optical train or delivery optics, the required output power of an 840-nm SLED is typically in the range of 2.5–4.5 mW.

Spectrometer-based OCT system may trade off resolution with imaging depth, for example, in anterior-chamber eye surgical systems where SD-OCT systems with an imaging depth of 8–10 mm are used. This is achieved by using a 2,048-pixel line camera in combination with a spectrometer that spans only 40 nm instead of 80 nm; hence, those systems typically use an SLED with a 3-dB optical bandwidth of 25 nm instead of 50 nm. Because of higher insertion losses in the optical train due to combining the diagnostic OCT system with the laser surgical system, SLEDs with an output power of 10–20 mW are typically needed. Similar considerations in terms of SPSR and SLSR apply here as well.

18.1.4 SLEDs at 1,060 nm

Cost-effective and high-speed InGaAs line cameras with a pixel count of 2,048, similar to silicon-based CMOS or CCD line cameras, may enable commercial SD-OCT systems based on broadband SLEDs. Due to deeper penetration into the choroid of the retina, the expected imaging range might be somewhat larger than in the 840-nm spectral range. Naturally, the axial resolution of such systems would be lower, requiring SLEDs with a 3-dB optical bandwidth of 60–70 nm and a 10-dB optical bandwidth of ~110 nm.

The class 1 MPE limit at 1,060 nm is ~2.0 mW and hence almost three times higher than at 840 nm. Therefore, higher power 1060-nm SLEDs (~10–15 mW) can be used to help increase sensitivity.

18.1.5 SLEDs at 1,300 nm

Broadband SLEDs at 1,300 nm are used for NDT or other type of industrial TD-OCT systems. State-of-the-art SLEDs achieve a 3-dB optical bandwidth of up to 120 nm from a single SLED chip with a low output power of 5 mW ex-fiber, or 90–100 nm with a medium output power of 10–15 mW, or 70–75 nm with a high output power of 20–30 mW. The class 1 MPD limit at 1,300 nm is ~15.6 mW; therefore, mainly high-power SLEDs with 20–30 mW are used in such OCT systems. As mentioned earlier, for TD-OCT systems, a good SLSR is typically required, which puts a preference on Gaussian-shaped SLEDs.

18.1.6 Combined Broadband Sources

For ultra-high-resolution SD-OCT systems, broadband light sources based on spectrally combined SLEDs are used. Those combined SLED sources are realized in the 750–900 nm range, for example, where a 3-dB optical bandwidth of 150–160 nm and a 10-dB optical bandwidth of 180 nm are achieved with a total output power of 5 mW. Such an ultra-broadband source has a coherence length of ~2.5 μm in air and hence less than 2 μm in tissue, achieving a similar axial resolution than a fs-pulsed laser with a pulse duration of 8–9 fs.

Similar broadband sources with a 3-dB optical bandwidth of 180–200 nm at a center wavelength of 1,060 nm or 1,300 nm can be realized [9].

18.1.7 Back-Reflection Immunity of SLEDs

SLEDs can be considered a broadband source of spontaneous emission that is connected to a high-power and high-gain optical amplifier, which then generates amplified spontaneous emission (ASE) in a single optical path, i.e., without any optical resonator like a laser. However, the on-chip high-gain amplifier amplifies ASE light not only in forward direction, i.e., towards the output facet of the SLED, but also in backward direction when light from is reflected back from an optical setup, for example. A good chip design prevents the SLED from being destroyed in the presence of back-reflections (BR); however, optical BR may reduce the amount of free carriers in the active region of the SLED, resulting in reduced output power and a reduction of optical bandwidth and in a redshift of the spectrum [10]. The amount of BR that can be tolerated depends on the application and on the SLED, i.e., high-power SLEDs will generally be more sensitive to BR than low-power SLEDs. Similarly, SLEDs with a flat-top optical spectrum will show stronger spectral changes due to BR than Gaussian-shaped SLEDs. Still, a negative impact of BR on the long-term reliability of SLEDs could not be found [10], and those findings have been confirmed by various lifetime experiments over several thousands of hours.

In order to avoid any kind of impact of BR on the SLED output performance, though, an optical return loss of less than −30 dB is recommended.

18.2 Broadband and High-Speed Swept Sources

High-speed wavelength-swept laser technology offers versatile applications in optical coherence tomography (OCT) [11–13], biochemical spectroscopy [14], and fiber-optic sensing [15]. Particularly in recent years, swept laser technology has been critical in advancing OCT applications in the field of biomedical imaging and industrial imaging, imparting the advantages of real-time in vivo diagnostics and high sensitivity. To realize real-time clinical imaging and broad-base commercial deployment, compact, small, and stable swept sources are of utmost importance. To meet such demands, wavelength-flexible swept sources between 400 and 1,700 nm with sweep rates from 1 to 200 kHz can be realized in a miniaturized optical butterfly package that also allows the integration of optical reference (k-clock) interferometers or other optical reference filters for spectral calibration [16]. The salient advantages of EXALOS' swept source technology include the following:

1. Wavelength flexibility: currently over various spectra from 800 to 1,650 nm; potentially reaching the visible spectrum near 400 nm or the near-infrared spectrum up to 2,500 nm
2. High phase stability: suitable for phase-sensitive applications such as Doppler OCT
3. Ultra-stable long-term operation: enables spectral calibration with fixed remapping vectors
4. Clean imaging performance: no secondary coherence peaks as well as sharp and narrow PSF peaks without sidelobes throughout the imaging range
5. Symmetric bidirectional sweeps: allows high duty cycle and efficiency
6. Customizable bidirectional or unidirectional operation
7. Small size: optical module in 26-pin butterfly package; packaged with electronics in hard disk drive (HDD) form factor

For biomedical OCT applications, different imaging system requirements would demand an optimum combination of spectral region, sweep range, sweep frequency, coherence length, average power, and frequency calibration (k-space remapping) methods.

18.2.1 Diverse Swept Source Requirements

In the following sections, we will discuss some key requirements of swept sources before explaining the EXALOS swept source architecture and demonstrating its performance characteristics.

18.2.1.1 Wavelength Region

The selection of the proper spectral region for OCT applications depends mainly on the scattering and absorption property of the targeted biological tissue. The 840-nm spectrum has been historically used for retinal imaging due to low water absorption through the entire eye length and high scattering in the retinal layers. The 1,060-nm

spectrum has been actively investigated in recent years due to a favorable combination of high penetration in retinal (choroidal) layers and better visualization in patients with hazy ocular media (e.g., cataract). The 1,310-nm spectrum is useful for imaging of the anterior chamber of the eye, for dermatology, for cardiology or for other areas due to its lower scattering and hence deeper tissue penetration. The 1,550-nm spectrum is more suitable for industrial imaging, e.g., NDT, or fiber-optic sensing but has also been investigated for the hope of deeper imaging in bone structures due to their lower water content.

To address higher-resolution SS-OCT applications with near-micrometer resolution, multiple sources can be spectrally combined in order to form an ultra-broadband swept source. The unique flexibility of the EXALOS laser architecture allows for tailored specifications at multiple wavelengths and for concatenating swept sources of different wavelengths in a synchronized master-and-slave sweep operation. Figure 18.3 shows optical spectra of five different lasers covering a wavelength range between 800 and 1,600 nm. As discussed in more detail in Sect. 18.3, the typical sweep spectrum has a rectangular shape with sharp spikes at the edges, which originates from the turning points of the resonant MEMS scanner. 10-dB sweep ranges as wide as 80 nm at 840 nm, 130 nm at 1,060 nm, 100 nm at 1,220 nm, 160 nm at 1,300 nm, and 200 nm at 1,550 nm, respectively, have been achieved.

18.2.1.2 Sweep Range and Axial Resolution

For Fourier domain OCT (FD-OCT), which includes both SS-OCT and SD-OCT, the spectral bandwidth defines the axial imaging resolution. Assuming a Gaussian shape for the spectral power distribution, the axial resolution (δz) is related to the 3-dB (FWHM) sweep range $\Delta\lambda$ through the relation 0

$$\delta z = \frac{2\ln 2}{\pi} \cdot \frac{\lambda_0^2}{\Delta\lambda}$$

with λ_0 being the center wavelength of the source. This is the same formula used to calculate the coherence length or axial resolution of SLEDs with $\Delta\lambda$ being the 3-dB bandwidth of the SLED. However, the sweep range of a swept source is typically specified as the range over which the spectral power drops to -10 dB relative to the peak value. For a Gaussian-shaped spectrum, the 10-dB optical bandwidth is 1.83 times larger than the 3-dB optical bandwidth, which needs to be considered when translating the sweep range of a swept source into axial resolution.

The sweep range is typically measured using an optical spectrum analyzer (OSA), which measures *average* optical power but does not capture the *instantaneous* output power of the swept source. For sources sweeping in a nonlinear fashion like sinusoidal swept sources, the optical spectrum is given by the convolution of the instantaneous output power of the source in the wavelength domain with the sweep characteristics in the time domain. It is therefore more appropriate to measure the optical sweep range and hence the axial resolution of a swept source in the time domain and, by means of a calibration, convert the time-domain signal into the wavelength domain.

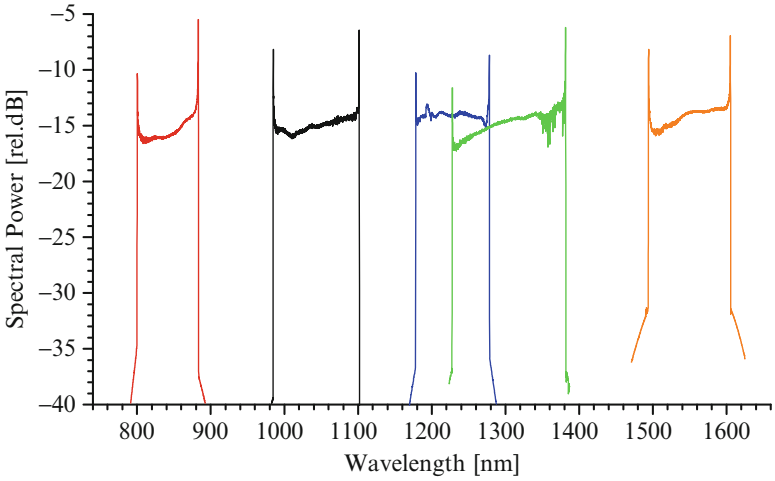

Fig. 18.3 Spectra of swept sources in different spectral regions

Generally, SS-OCT systems are expected to deliver an axial resolution that is comparable to SD-OCT systems based on SLEDs and spectrometers. In most cases, this means that the specified (10-dB) sweep range has to be larger than the specified (3-dB) optical bandwidth of SLEDs.

18.2.1.3 Coherence Length and Imaging Depth

In practical SS-OCT imaging implementations, the imaging depth is inherently governed by two parameters: the finite linewidth of the source $\delta\lambda$ in wavelength or δv in frequency $\left(\text{with } \delta\lambda = \frac{c}{v^2}\delta v\right)$, which leads to a sensitivity fall-off with imaging depth, and the spectral sampling interval (dk), which limits the observable imaging range. Assuming a Gaussian-shaped linewidth, the coherence length (l_c) is related to the dynamic or instantaneous linewidth through the relation [17]

$$l_c = \frac{2ln2}{\pi} \cdot \frac{\lambda_0^2}{\delta\lambda} = \frac{2ln2}{\pi} \cdot \frac{c}{\delta v}$$

Similar to SLEDs, the coherence length is defined as the optical path length difference (OPD) over which the coherence or autocorrelation function drops from its maximum to 50 %. Since OCT is a reflective interrogation technique, the so-called imaging depth captures the double path in the interferometer and is therefore half the coherence length of the source, i.e., a swept source with a coherence length of 10 mm has an imaging depth of 5 mm.

Optical and Electrical PSF

In many imaging applications and in the field of Fourier optics, the term "point spread function" (PSF) is being used. In analogy to RF systems, it can be thought of

the impulse response of an imaging system that is applied to an object through a convolution and that yields an image:

$$Image = PSF * Object$$

Applying this concept to OCT means that the OCT image (A-scan) can be thought of the convolution of the PSF of the light source with the object that is being scanned. Using an interferometer with zero OPD, the resulting image (A-scan) is the autocorrelation (coherence) function of the light source that is therefore equivalent to the "*optical PSF*" (PSF_o).

In the theoretical analysis of FD-OCT, the electrical currents and the electrical power signals that are generated through the detection of the optical fringe signals are considered [12], [18], 19], [29]. Therefore, to describe the imaging performance of an SD-OCT or SS-OCT system, it is common to calculate the square of the magnitude after the FFT [20] or to use 20·log10 [12] when plotting the "electrical PSF" (PSF_e) or when calculating the SNR and hence the system sensitivity. As a result, the coherence function or optical PSF will drop to 50% while the electrical PSF will drop by 6 dB over the specified coherence length.

To make it more challenging, the "coherence length" is a performance parameter of the source, while the "imaging depth" is a performance parameter of the SS-OCT imaging system. While most system vendors specify a minimum coherence length (amplitude fall-off) of the swept source, the imaging performance of the OCT system is given by the signal-to-noise ratio (SNR) fall-off behavior of the source and of the entire system, including linearization algorithms. It is commonly expected that the 6-dB SNR fall-off (imaging depth) is identical to the 6-dB amplitude fall-off of the source, which is most often not the case, though.

The imaging depth and hence the required coherence length or SNR fall-off is typically dictated by the application, e.g., retina OCT imaging requires an imaging depth of 3–4 mm, while anterior-chamber imaging needs an imaging depth of 7–8 mm, similar to endoscopic OCT applications where an imaging depth of 5–10 mm is often required.

In swept laser designs, many performance parameters are interrelated and may require trade-offs in order to optimize the most critical parameters. For example, a long photon lifetime is required to provide a large coherence length, and this is achieved by minimizing cavity loss and thus maximizing the number of cavity round trips for a given gain medium. A high spectral slew rate or sweep speed (expressed in nm/ns) can increase loss due to a fast-moving spectral filtering window and hence simultaneously reduce the photon lifetime, sweep range, and output power. For applications such as biometry where imaging depth is more critical than axial resolution, the sweep range or the sweep speed can be compromised to help increase the coherence length.

18.2.1.4 Secondary Peak Position and Suppression

Secondary peaks of the coherence function or PSF shall be well suppressed within the imaging range in order to not produce horizontal lines on a B-scan. A typical

SNR value of a swept source near the zero delay or zero OPD is 60 dB on a $20 \cdot \log_{10}$ scale. This means that, similar to SLEDs, a secondary peak suppression of 25–35 dB (50–70 dB on a $20 \cdot \log_{10}$ scale for the electrical PSF) within the imaging range is required.

18.2.1.5 Axial Scanning Frequency (Sweep Rate)

SS-OCT has the potential to deliver faster A-scan rates compared to camera-based SD-OCT systems and therefore allows addressing the needs for certain applications. For example, in high-resolution or wide-angle retinal OCT imaging, an A-scan rate of 100–200 kHz (or even more) is desired in order to avoid motion artifacts or to allow for imaging a larger area of the retina. For example, a 200-kHz swept source could enable B-scan imaging with a width of 1,000 A-scans and 8 times averaging with a video rate of 25 fps. In cardiovascular OCT applications, the maximum allowable time for flushing and the chosen artery length for imaging define the pullback rate of the catheter, which then defines the required A-scan rate of the swept source in order to maintain a certain spatial sampling resolution during the pullback. For such applications, A-scan rates in the range of 50–100 kHz are currently required.

The A-scan frequency of SS-OCT systems directly defines the spectral sweep frequency of the laser. In swept laser designs, an excessively high sweep frequency generally compromises the sweep range, the coherence length, and the output power in addition to imposing constraints on the sweep mechanisms whether mechanical or electronic.

Similar constraints may exist on system level as higher A-scan rates require faster and hence more expensive A/D converter (ADC), faster signal processing engines, and larger data throughput towards the host. Furthermore, faster electronics typically mean larger analog bandwidths and hence lower SNR performance, higher power consumption, and lower resolution. The A-scan rate and the imaging depth in conjunction with the linearity of the swept source define the required sampling rate of the ADC. A typical sampling rate for a 100-kHz A-scan rate is 500 MSPS that provides sufficient imaging depth for most sources.

Finally, for a given MPE level, faster A-scan rates will mean fewer photons per sweep (i.e., per A-scan) and therefore lower OCT system sensitivities.

18.2.1.6 Average and Instantaneous Output Power

The swept laser power is dependent on the cavity loss, the sweep frequency, and on the gain and saturation power of the optical gain chip. Furthermore, the average sweep power also depends on the sweep duty cycle. Because the average power directly affects the SNR, one often tries to maximize output power without exceeding the safety limits for biomedical imaging (after accounting for losses through the imaging system). Typically, the average output power of a swept source is specified. However, in case the MPE limit changes over the sweep range of the laser, the instantaneous spectral output power of the laser may need to be considered as well.

18.2.1.7 Relative Intensity Noise (RIN), SNR, and OCT Sensitivity

Noise in laser sources is generally characterized by relative intensity noise (RIN) and phase noise. Phase noise defines the laser linewidth (coherence length). RIN manifests itself in the SNR, the sensitivity, and in the dynamic range of a measurement system, which are critical parameters that determine image clarity against background noise in OCT imaging. Both SNR and OCT sensitivity quantify the minimum detectable reflected optical power for an ideal sample (metal mirror). Dynamic range describes the range of optical reflectivity values detectable in OCT imaging, i.e., the capability of detecting weak signals in presence of large-amplitude signals. Typical RIN values of both SLEDs and swept sources are in the range of −125 to −145 dBc/Hz. RIN of SLEDs is measured in the frequency domain using an electrical spectrum analyzer with a high sensitivity, while RIN of swept sources is typically measured in the time domain using sampling of consecutive sweeps over a certain period of time [21].

18.2.1.8 Sweep Linearity in Frequency

The ideal swept source for OCT applications has a constant sweep speed in the frequency domain, i.e., its sweep is linear in k. The corresponding k-clock signal will then have a constant frequency during the sweep. However, most high-speed swept sources exhibit some nonlinear sweep behavior with respect to optical frequency and therefore require a recalibration of the interferometric fringe patterns in k-space before the inverse Fourier transform can be applied in order to extract accurate spatial-domain (depth ranging) information. It is therefore useful to provide the k-clock signal as an integral part of the swept laser.

Nonlinear sweep in k also means that the sweep speed and hence the k-clock frequency varies over the sweep time of the laser. Depending on the amount of sweep nonlinearity, faster sampling rates of the ADCs and larger analog bandwidths of the receivers need to be considered. Additionally, fast-varying k-clock frequencies (strong frequency modulation) may challenge the acquisition electronics when direct k-clocking is employed.

18.2.1.9 Duty Cycle

In SS-OCT two types of duty cycles are of interest: the duty cycle of the swept source and the duty cycle for the OCT imaging. The duty cycle of the source describes the amount of time the laser spends for the wavelength sweep relative to the sweep period. The sinusoidal and bidirectional swept sources from EXALOS have a high duty cycle of 80–100 %, for example. Lower duty cycles translate into faster sweep times or slew rates and hence into higher fringe frequencies, which require faster sampling rates. The duty cycle for the OCT signal processing describes the percentage of the actual sweep time of the laser that is used for the generation of an A-scan. For example, the duty cycle of the laser might be 100 % but the duty cycle used for OCT signal processing is actually only 75 % of the sweep time because 25 % of the sweep time will be discarded for certain reasons.

18.3 Swept Source Architecture

EXALOS has developed a miniature external-cavity swept laser based on a micro-optic integrated platform that allows for compact embodiments, performance flexibility, field reliability, and economy of scale (Fig. 18.4). This laser architecture integrates a broadband semiconductor optical amplifier (SOA) gain chip, a high-speed resonant 1D micro-electro-mechanical system (MEMS) scanning mirror, and a proprietary diffraction grating on a temperature-controlled optical bench inside a 26-pin butterfly package (Fig. 18.5). In the category of longitudinal multimode lasers, this is a truly self-contained compact packaging. Contrary to monolithic devices such as the Vernier-tuned distributed Bragg reflector (VT-DBR) laser [22] and MEMS-tuned vertical-cavity surface-emitting laser (MEMS-VCSEL) [23], this hybrid platform offers realizing lasers in different spectral regions (from 400 to 2,500 nm) and at different sweep frequencies (currently 1–200 kHz).

Numerous design parameters for the critical components must be well-matched in order to generate a high-performance swept source. First, the high-performance SOAs are designed in-house for a wide spectral gain and linear behavior to enable long coherence sources in various spectral regions. Second, the wavelength scanning mechanism is based on a MEMS mirror. The long-term stability of the MEMS is extremely high as it is based on mono-crystalline electro-static MEMS scanners that do not degenerate or degrade over time. Changes in resonance frequency are mainly due to temperature effects (e.g., warm-up effects from light on/off) but are minimized by the temperature-controlled optical platform. The custom-designed MEMS scanners offer high mechanical stability (shock resistance >5,000 g), high phase stability, and low jitter. Novel diffraction gratings are designed for ultra-high effective resolvance to achieve narrow filtering and hence long coherence lengths while maintaining high diffraction efficiency over a wide spectral range. Optical retarders are used to achieve the right cavity length in order to optimize laser dynamics and minimize mode-hopping noise. A free-space k-clock interferometer followed by balanced detection simplifies post-processing in OCT systems. The A-scan trigger is directly derived from the MEMS clock and therefore is always in sync with the MEMS movement. The sweep is sufficiently stable such that one can create a remapping vector for initial calibration and continue to use the same remapping vector for hours of continuous use. The electronic A-scan trigger used in the swept source is derived from a crystal oscillator, which gives a timing jitter down to a few picoseconds. Due to the high Q factor, there is only little noise transferred from the electronics driver to the MEMS scanner.

The laser cavity is manufactured in a fully-automated micro-optic assembly station. This packaging platform offers highest flexibility, alignment accuracy, reproducibility, long-term stability, and high production rate. More details are given in Sect. 18.3.4.

The resultant wavelength-swept laser provides a bilateral and sinusoidal sweep operation driven by a resonant MEMS scanner. As illustrated in Fig. 18.6, the laser spectrum is continuously and repetitively tuned from short to long wavelengths (“up-sweep”) and from long to short wavelengths (“down-sweep”). The sweep duty

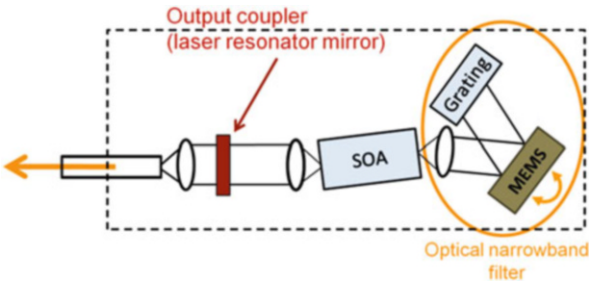

Fig. 18.4 Schematic of external-cavity swept laser with Littrow configuration. The dashed line represents the optical butterfly module, indicating that the entire laser cavity is contained inside the module

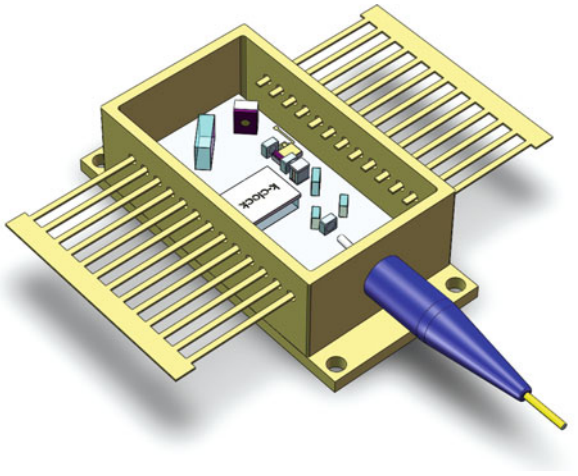

Fig. 18.5 3D model of the external-cavity swept laser in a butterfly package

cycle defines the relative portion of the sweep in either up- or down-sweep direction that can be used for the OCT scan. This duty cycle depends on a combination of the laser gain bandwidth, the scanning amplitude of the MEMS scanner, and the SOA modulation. The SOA modulation can be selected to turn off either the up-sweep or the down-sweep, thereby converting a bidirectional sweep operation into a unidirectional sweep operation.

Due to the harmonic oscillation of the resonant MEMS scanner, the sweep speed is reduced to nearly zero at the turning points of the sinusoidal movement. If the laser still has sufficient gain at the spectral edges of the sweep spectrum, it will remain on (100 % duty cycle). Consequently, the average optical output power at the edges of the spectrum will increase despite the fact that the instantaneous output power is lower than in the center of the sweep spectrum, resulting in a more rectangular shape of the optical spectrum of the swept sources with potentially pronounced spikes at the edges, as shown in Figs. 18.3 and 18.6.

For OCT signal processing, a typical duty cycle of 70–80 % of the sweep time of those sinusoidal lasers is used. However, a duty cycle of 80 %, for example, still

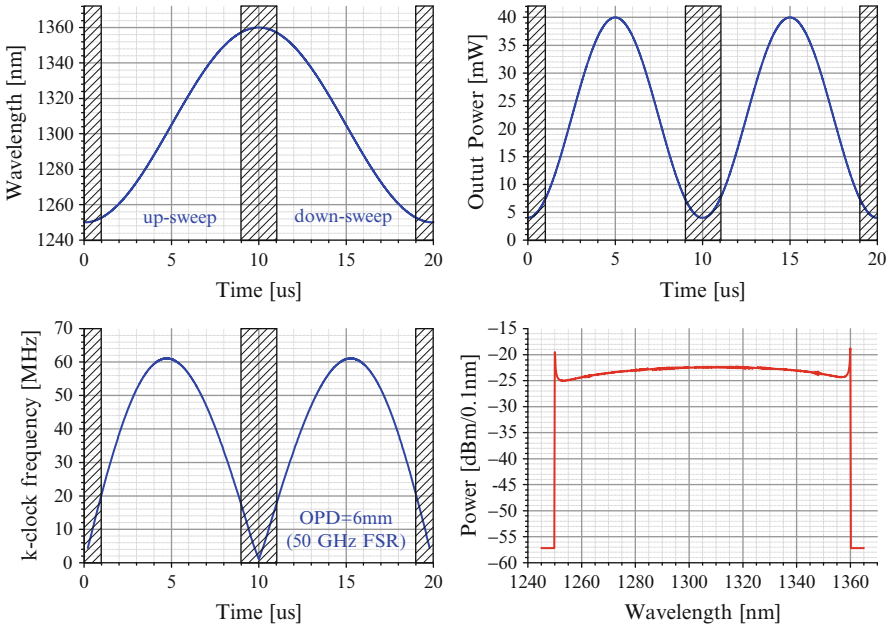

Fig. 18.6 Illustration of a 100-kHz bidirectional swept source with a sweep range of 1,250–1,360 nm and an average output power of 22 mW. The shaded areas indicate periods of time that will not be used for OCT imaging, i.e., the non-shaded areas represent the actual sampling periods with an 80 % duty cycle

covers 95 % of the sweep spectrum. Furthermore, as shown in Fig. 18.6, the 10 % that is ignored at the upper and lower edge of the sweep contains low-power sampling points that are typically outside the 6–7 dB bandwidth range; hence, the total loss in energy is below 10 % and the loss in axial resolution is in the range of 2 %.

18.3.1 Broadband Gain Chips

The semiconductor optical amplifier (SOA) gain chips are designed in-house and are fabricated using the same production and supply chain as SLED chips. Extensive device simulations that account for a variety of quantum-mechanical, carrier-transport, and thermal effects allow realizing SOA gain chips featuring wide spectral gain for high-resolution OCT, linear characteristics for long coherence lengths, fast carrier dynamics for fast tuning sources, high-power robustness for long-term reliability, and low noise for good image quality. Such SOA gain chips have been realized at various spectral regions (840, 1,060, 1,220, 1,310, 1,550 nm) using GaAs and InP material systems.

A good measure for broadband SOAs is the peak gain and the 10-dB gain bandwidth. For the latter, 1,060-nm gain chips with a 10-dB gain bandwidth of

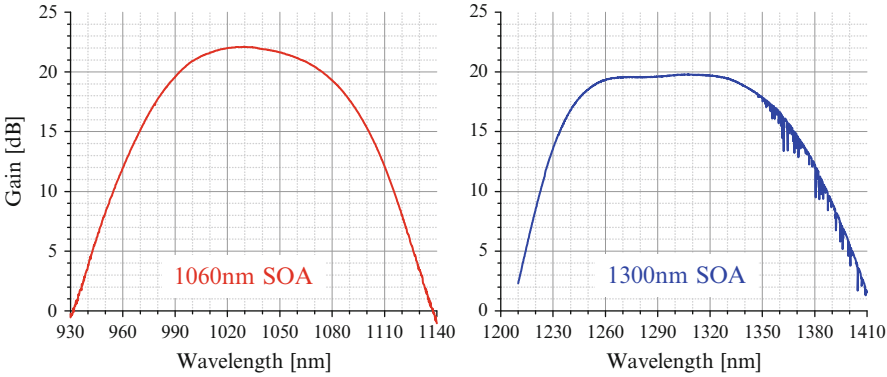

Fig. 18.7 Example of gain spectra of a broadband 1,060-nm (*left*) and a 1,310-nm (*right*) semiconductor optical amplifier (*SOA*). The 10-dB gain bandwidth is 960–1,110 nm (150 nm) and 1,220–1,390 nm (170 nm), respectively

150 nm have been realized, as shown in Fig. 18.7, as well as 1,310-nm gain chips with an equivalent bandwidth of 170 m.

18.3.2 MEMS Scanner

Based on a well-proven technology, the custom-designed MEMS scanner is a resonant structure made of mono-crystalline silicon (Fig. 18.8). Given its high Q factor (500–1,000) and high mechanical stability, it can provide an extremely deterministic oscillation behavior with high phase stability. The reflective metal coating provides an efficient reflectivity over a wide spectral range (visible to near-IR).

By design, this resonant scanner has a single operating frequency and hence a sinusoidal scan function at a fixed A-scan rate. For example, a MEMS scanner with a mechanical resonance frequency of 50 kHz and with a Q factor of 1,000 will perform (harmonic) oscillations only within an actuation frequency window of 50 Hz. Such a mirror could be used in a 100-kHz bidirectional source or a 50-kHz unidirectional source, for example.

Generally, there is a trade-off between scanning speed, mirror size, and scanning angle. A smaller mirror size is required for a higher scan frequency, which is one of the limiting factors for the filter bandwidth and hence for the coherence length of the laser. Practically, shorter-coherence (5–10 mm) swept sources can be realized with A-scan rates up to 200 kHz, and longer-coherence (10–30 mm) swept sources can be realized with A-scan rates up to 50 kHz. The sinusoidal wavelength dependence as a function of time demands careful considerations for the k-space recalibration. To synchronize with the MEMS scanner movement and the swept source spectrum, the A-scan trigger is directly derived from MEMS clock. Together with the highly stable resonant operation, one may use the same k-space recalibration vector for hours of continuous operation.

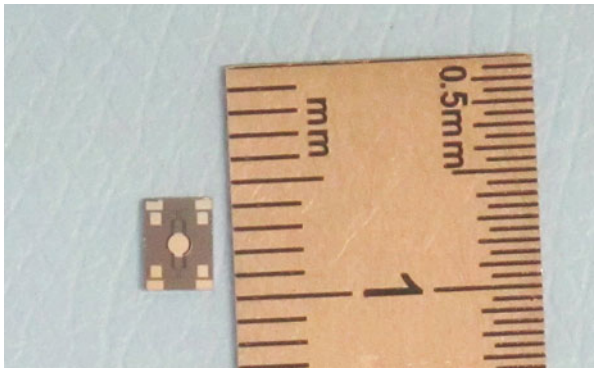

Fig. 18.8 Resonant MEMS scanner chip

18.3.3 Diffraction Gratings

The diffraction gratings are designed to have high dispersion and line densities for narrow band-pass filtering, as well as high diffraction efficiency over a wide spectral range. The resultant patented "grating optical engine" is fabricated with well-proven telecom-qualified processes.

As an example, to design for a spectral filter bandwidth of ~13 GHz (i.e., ~10 mm coherence length), the required grating effective resolvance (defined as the center wavelength divided by linewidth, equivalent to the number of illuminated grating lines in the first diffraction order) would need to be approximately 17,000. The effective spectral bandwidth also inevitably dictates the laser cavity length. For a swept source in which the lasing line structure is made of multiple longitudinal modes, it is important to have sufficient number of modes within the laser line profile to minimize the effect of mode-hopping noise in OCT applications. Therefore, given the spectral bandwidth of the filter and the minimum number of longitudinal modes required within, the minimum laser cavity length is subsequently defined.

18.3.4 Hybrid Optical Packaging Platform

An optical packaging platform is critical in the process of realizing the construction of complex optical system that can only exhibit the intended functionalities in a miniature embodiment. EXALOS has co-developed a unique hybrid optical packaging platform (HOPP) machine for (semi-)automated micro-optic assembly with unprecedented alignment accuracy (down to 50 nm or 1 arcsec) for free-space propagating beams. This HOPP machine has 21 motorized stages, six cameras, epoxy dispenser, machine vision, and custom programming interfaces and performs active or passive alignment of all optical elements inside the butterfly package. Advanced design rules are embedded into the process programming and machine training (alignment algorithms) for the laser cavity and its optical components to

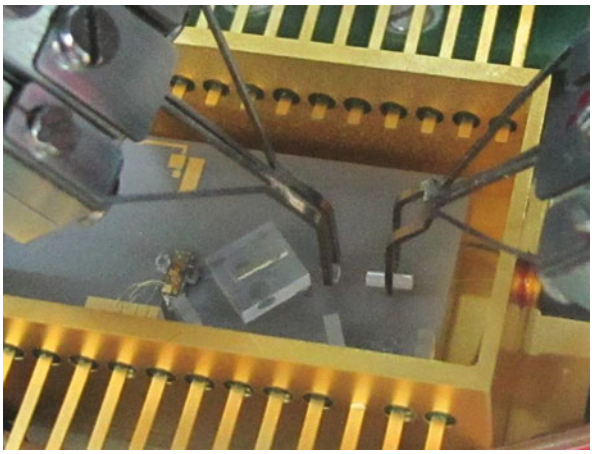

Fig. 18.9 Automated alignment process of optical components inside butterfly package

achieve required optical performance (low wavefront distortions, suppression of unwanted reflections, etc.). During the optical assembly process, the HOPP machine can perform active alignment of optical components, characterize each micro-optical component (size, flatness, optical axis, etc.), and measure optical near/far field and beam propagation through lenses, filters, etc. Once the machine has learned the alignment procedure, fabrication of swept source modules is highly repeatable.

The swept sources are operated while they are built on the HOPP machine, and certain target performance parameters like SNR or coherence fall-off can be used as active feedback signals to align critical components. This means that the laser performance is monitored throughout the whole manufacturing process, allowing high-yield manufacturing on module level.

18.3.5 Compact OEM Swept Source Module

The swept source optical modules (SSOMs) described above are assembled on electronic driver boards, as shown in Fig. 18.10. Those fiber-coupled turnkey swept sources are available either as a benchtop version or as an OEM module in 3.5″ HDD format (footprint 101.6 × 147.0 mm) that can be mounted inside a disk cage of a PC. The OEM module operates on 12 V or 24 V DC with a typical power consumption of 10 W.

18.4 Performance of Swept Sources

This chapter discusses some of the performance characteristics of EXALOS' swept sources at 1,060, 1,310, and 1,550 nm, including the instantaneous coherence length and its measurement, the fall-off amplitude (FOA), and the SNR.

Fig. 18.10 Swept source optical module (*SSOM*) mounted on a compact electronic driver board, enabling OEM swept sources (with metal case) in 3.5″ HDD form factor, as shown for comparison on the right side

18.4.1 Fall-off Measurements

For swept-wavelength lasers, the instantaneous linewidth tends to vary across the sweep spectrum because of a wavelength dependence of the laser dynamics and other certain cavity parameters. Due to the difficulty of characterizing the instantaneous linewidth of rapidly sweeping lasers and the need for accurately mapping the time–wavelength relation between successive sweeps, two indirect approaches are commonly adopted.

18.4.1.1 Time-Domain Analysis of Coherence Length

One method is to deduce the coherence length by measuring the interference fringe pattern of a Michelson or Mach–Zehnder interferometer for a set of varying OPD values. With a calibrated OPD value, the corresponding free-spectral range (FSR) of the interferometer can be calculated, (FSR = c/OPD), which is then used to convert the x-axis from time to relative frequency. Using an optical spectrum analyzer or absolute wavelength reference filters, an absolute frequency or wavelength scale can be calculated for the x-axis. At the same time, the decay of coherence with increasing OPD values is analyzed by comparing the amplitude values of the fringe envelope at certain time or spectral positions [24] (Fig. 18.11).

Therefore, for any wavelength position the particular OPD value can be determined at which the amplitude of the fringe envelope has dropped to 50 % of its initial value at an OPD close to zero. Typically, the reference position is an OPD value of 0.1–0.2 mm as the fringe pattern practically disappears at the exact zero path length difference.

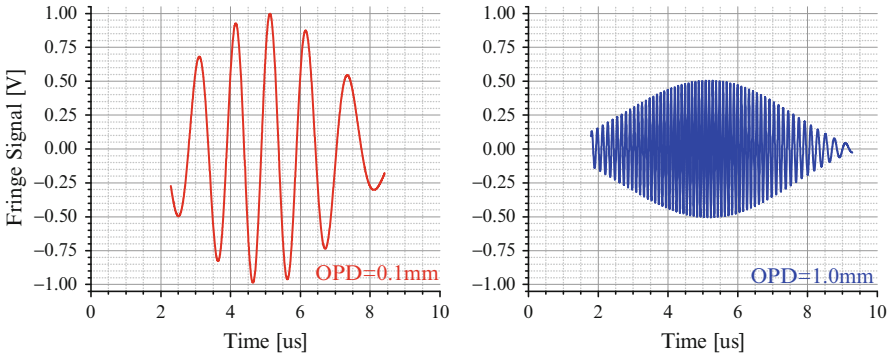

Fig. 18.11 Characterization of the instantaneous (spectral) coherence length by a time-domain measurement of the fringe amplitude fall-off after an interferometer. This example shows a 100-kHz swept source with a coherence length of 1.0 mm. The horizontal axis can be converted from time to wavelength

This time-domain approach allows characterizing the coherence length variation across the entire swept spectrum [24]. Note that due to laser cavity dynamics and alignment, the coherence characteristics may differ for the up-sweep and down-sweep direction [25] such that extra engineering effort is required to equalize the amplitude (and noise) fall-off for bidirectional swept sources.

18.4.1.2 Spatial-Domain Analysis of Coherence Length and SNR

Often it is more convenient and useful to provide an "average" coherence of the swept source that also accounts for phase fluctuations in the sweep. This average coherence length is derived by calculating the coherence or point spread functions (PSF) from the interference fringe pattern through an inverse Fourier transform at incremental OPD positions [17]. For swept sources that are not sweeping perfectly linear in the frequency domain and show a variation of the k-clock frequency across the sweep, the acquired fringe pattern in the time domain has to be resampled prior to the FFT, which means that the coherence length is not directly measured as in Sect. 18.4.1.1 but is calculated and extracted from the amplitude fall-off of the PSF in the spatial domain. Hence, the resulting coherence length also depends on the accuracy and effectiveness of the remapping algorithm that is used. The "average" coherence length is then expressed as the 50 % fall-off of the optical PSF amplitude PSF_o or the 6-dB fall-off of the electrical PSF amplitude (PSF_e).

The noise background of the electrical PSF (on a linear scale) is determined left and right of the PSF peak with a certain offset (e.g., five times the PSF width) and over a certain imaging depth (e.g., 100 sample points in space) where the RMS value and the standard deviation of the noise background are calculated. The corresponding SNR is then commonly given by

$$SNR[dB] = 20 \cdot \log_{10}\left(\frac{Magnitude(PSF_e) - RMS(Noise_e)}{StdDev(Noise_e)}\right)$$

The SNR of a swept source is typically determined with an adjustable interferometer where both arms of the interferometer have roughly the same insertion loss. High SNR values in the range of 50 dB to 65 dB, depending on the speed and the RIN of the swept source, are common near the "zero delay" (zero OPD) of the interferometer.

Many swept sources have higher-frequency noise contributions such that the noise floor increases slightly with increasing OPD values. This results in the 6-dB SNR fall-off being not as good as the 6-dB amplitude fall-off of the source. To describe just the performance of the source, both values are typically plotted as a function of OPD.

18.4.1.3 Sensitivity Fall-Off

For an OCT imaging system, the ultimate performance parameter is the sensitivity fall-off as a function of the imaging depth. To convert the x-axis to imaging depth, the OPD values are divided by two, as mentioned earlier. To measure the OCT system sensitivity, the adjustable interferometer is considered being constituted of a *reference arm* with higher optical power (typically 1.0–2.0 mW in front of the optical splitter used for balanced detection) and of a *sample arm* with lower optical power.

Depending on the wavelength and the class 1 allowable MPE level, the optical power in the sample arm is adjusted to a certain value (e.g., 1.5 mW at 1,060 nm) and then strongly attenuated by a certain value (typically 50–60 dB). In this condition, the SNR of the PSF (e.g., A-scan of a metal mirror) near the zero delay is measured and the OCT sensitivity is expressed as

$$Sensitivity[dB] = SNR[dB] + Sample\text{-}Attenuation[dB]$$

Sensitivity values of 95–105 dB are desired for commercial OCT systems. Consequently, with a sample attenuation of 60 dB, the measured SNR near the zero delay needs to be in the range of 35–45 dB.

Using a balanced interferometer with roughly similar insertion loss on both arms (see Sect. 18.4.1.2), an SNR of 52–62 dB is typically required to achieve such sensitivity values.

18.4.2 1,060-nm Swept Sources

Swept sources at the 1,060-nm spectral region are being considered for biometric, retinal, and whole-eye imaging. The benefits of this wavelength range comprise relatively low water absorption, lower scattering (compared to 800–900 nm) and hence better penetration into the retina or in patients with lens opacities (cataracts), truly invisible light for patients or higher laser safety power limits. For biometry, long coherence lengths are of primary importance, along with a desirable sweep range of 25–40 nm and an A-scan rate of 1–20 kHz. Figure 18.12 illustrates, for an A-scan rate of 20 kHz and a sweep range of 40 nm, an average coherence

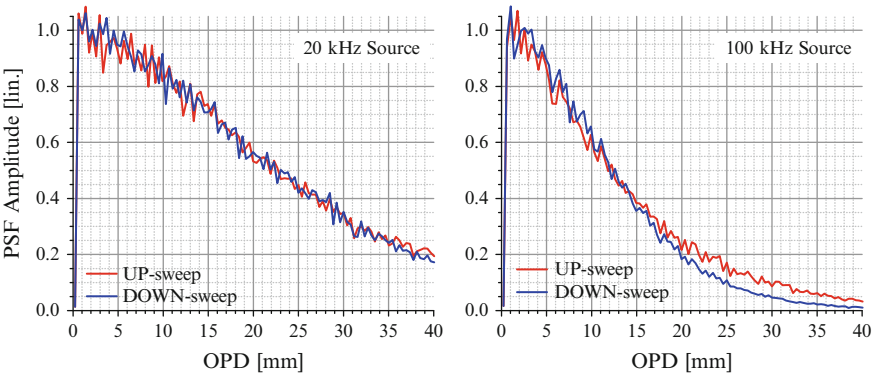

Fig. 18.12 PSF fall-off amplitude (*FOA*) for a 1,060-nm swept source with 40-nm sweep range: ~23 mm coherence length (50 % drop) at a 20-kHz sweep rate and ~12 mm coherence length at a 100-kHz sweep rate. This bidirectional source provides a symmetrical amplitude fall-off for both up- and down-sweep

length (50 % FOA) of ~23 mm. Furthermore, a coherence length of ~12 mm can be achieved at an A-scan rate of 100 kHz. The average output power for this source is 20 mW.

Retinal imaging experiments (Figs. 18.13 and 18.14) have been performed by using a 1,060-nm swept source with an A-scan frequency of 110 kHz. The laser is adjusted to a duty cycle of 100 % with a sweep range of 97 nm and center wavelength of 1,070 nm. Optical sweep power at the fiber output is ~10 mW. An instantaneous coherence of ~3–5 mm is obtained for up- and down-sweep with high sweep symmetry. The maximum SNR of this source near the zero delay is rather low (48 dB), which results in an OCT sensitivity of only 92 dB for a sample power of 1.5 mW. Figure 18.13 shows a tomogram without averaging (left) and with 5× averaging (right) of such source. The high degree of sweep symmetry is seen in the fact that the tomograms do *not* exhibit an alternating noise pattern for every second column (A-scan) considering the bidirectional sweep behavior.

Other retina measurements based on the same bidirectional swept source in combination with 20× averaging are shown in Fig. 18.14 and demonstrate that good penetration into the choroid of the retina can be achieved.

Analyzing not only the magnitude but also the phase of the Fourier transform, the temporal evolution of the phase of the PSF peak was investigated. Figure 18.15 shows such PSF phase variation over a longer period of time. The left graph shows three sets of measurements of ~4,300 consecutive A-scans in up-sweep direction only, each set spanning a time of nearly 80 ms. As can be seen, the phase of the PSF peak varies by ±3° over a longer period of time and shows some distinct pattern, which is an indication that in this source the low amount of *random* phase noise is overlaid by some slowly varying *patterned* phase noise that is coming from the drive electronics.

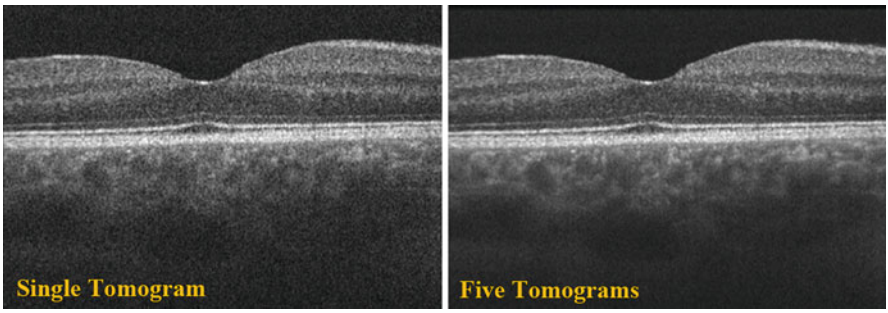

Fig. 18.13 ESS-1060/110 kHz: Retina measurements using a bidirectional swept source (Courtesy of Prof. Leitgeb's group, Medical University of Vienna, Nov. 2011)

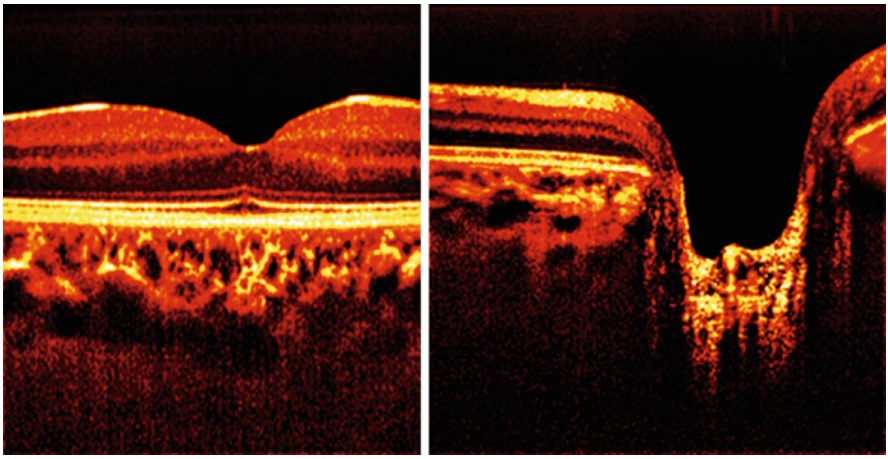

Fig. 18.14 ESS-1060/110 kHz: Retina measurements using both up-sweep and down-sweep of the source in combination with 20× averaging (Courtesy of Prof. Leitgeb's group, Medical University of Vienna, Nov. 2011)

The right graph of Fig. 18.15 shows ~8,600 consecutive bidirectional A-scans that are split into a set of ~4,300 up-sweeps and ~4,300 down-sweeps. This figure shows that the phase evolution in the down-sweep direction has the inverted pattern of the phase evolution in the up-sweep direction and that the phase difference between both sweep directions is within $\pm 1^\circ$ at all times. This level of phase noise is sufficiently small to perform Doppler measurements at full speed (bidirectional scanning).

The latest generation of drive electronics features significantly reduced timing jitter in operating the resonant MEMS scanners and will therefore further reduce the phase noise of such swept sources. Another contribution to an improved phase noise is coming from the fact that more recent swept sources are having a higher SNR, which scales inversely with the variance of the phase noise [26, 27].

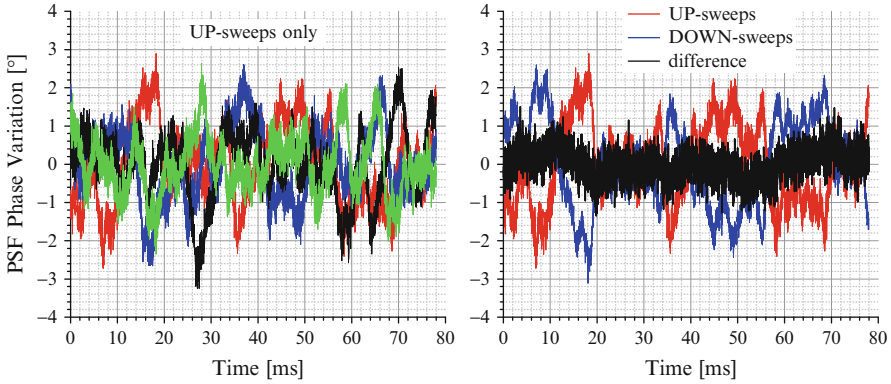

Fig. 18.15 ESS-1060/110 kHz: Temporal phase variation between different forward sweeps (Courtesy of Prof. Leitgeb's group, Medical University of Vienna, Nov. 2011)

18.4.3 1,310-nm Swept Sources

The measurement examples of Figs. 18.16, 18.17, and 18.18 are for a 1,310-nm swept source operating at an A-scan rate of 40 kHz (ESS-1310/40 kHz). The laser is adjusted to a duty cycle of 100 % with a sweep range of 100 nm and center wavelength of 1,310 nm, as shown in Fig. 18.16. Average optical sweep power at the fiber output is 20 mW with a peak power of ~40 mW. The laser shows high sweep symmetry with an instantaneous coherence of up to 10–12 mm for up- and down-sweep, as seen in the right graph of Fig. 18.16, which was generated using the time-domain analysis described in Sect. 18.4.1.1.

Using the spatial-domain analysis of Sect. 18.4.1.2 based on remapping and Fourier transform, the PSF fall-off graphs of Fig. 18.17 have been generated, showing that for both up-sweep and down-sweep directions, a clean imaging performance with narrow and sharp PSF peaks can be achieved. The 6-dB fall-off of the PSF_e magnitude occurs at an imaging depth of 5 mm. This is in agreement with the PSF_o amplitude fall-off graph in Fig. 18.18 that shows a 50 % drop at an OPD value of 10 mm. The maximum SNR of this 40-kHz source near the zero delay is ~63 dB, measured with a balanced interferometer as described in Sect. 18.4.1.2. This corresponds to an OCT sensitivity of ~105 dB for a power of 1.5 mW in the sample arm.

18.4.4 1,550-nm Swept Sources

For industrial OCT and certain sensor applications, swept sources in the 1,550-nm spectral range can provide distinct advantages, for example, reduced scattering coefficients that are useful for deeper imaging into scattering media with lower content of water (e.g., bones), non-destructive testing (NDT) of semiconductor devices that are more absorptive at shorter wavelengths, or industrial surface profiling.

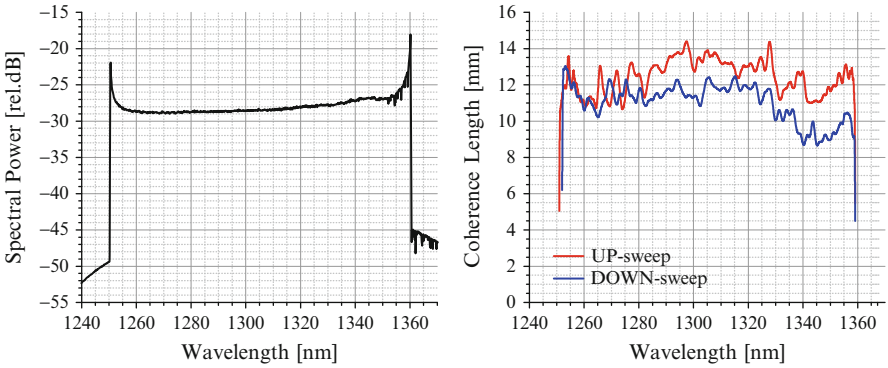

Fig. 18.16 ESS-1310/40 kHz: Sweep spectrum (*left*) and instantaneous coherence length for up- and down-sweep (*right*)

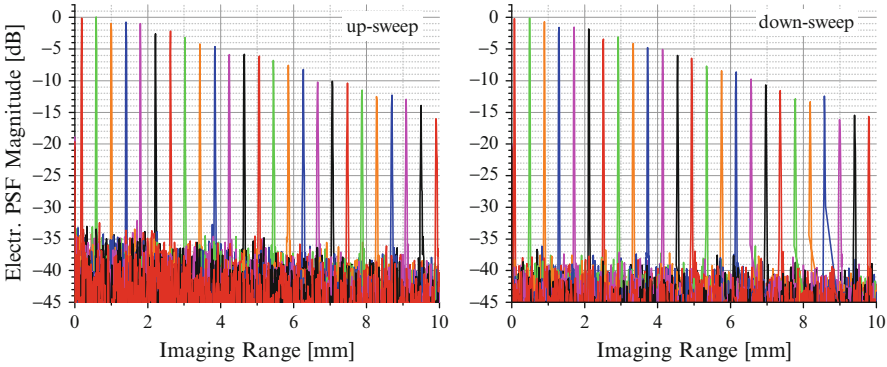

Fig. 18.17 ESS-1310/40 kHz: Electrical point spread function (PSF_e) for up- and down-sweep at various positions within the imaging range (imaging range is half of OPD)

Figure 18.19 shows two sweep profiles of the instantaneous output power of a 40-kHz (left) and a 150-kHz (right) swept source at 1,550 nm with a sweep range of 110 nm. As can be seen, these sources provide good symmetry in output power for the up- and down-sweep that does not significantly change in shape for sweep rates from 2 to 150 kHz. Those sources were adjusted for a 100 % duty cycle and exhibited a drop of instantaneous output power over the sweep range from ~100 to ~20 (factor 5 = 7 dB), as shown in Fig. 18.19.

The measured optical spectra of those sources, shown in Fig. 18.20, span a spectral range of ~1,505 nm to ~1,615 nm. The spectrum of the slower 2-kHz source shows a higher optical signal-to-noise ratio (OSNR) compared to the faster sources operating at 40 kHz or 150 kHz, still the shape of the spectrum being very similar. Figure 18.21 shows that the slower and faster sources also differ in their

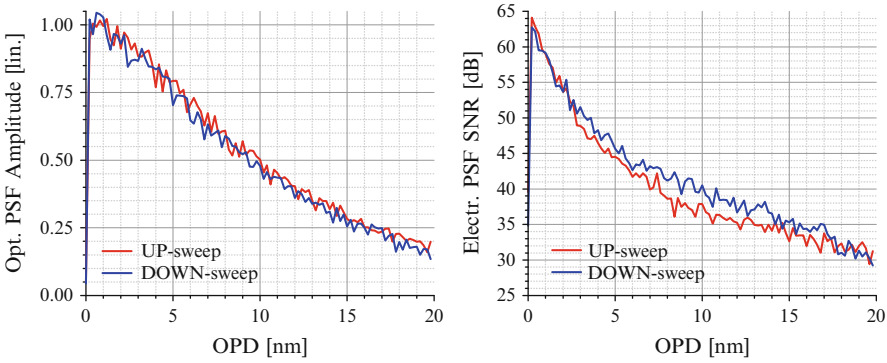

Fig. 18.18 ESS-1310/40 kHz: Amplitude fall-off of optical PSF (*left*) and SNR fall-off of electrical PSF (*right*) as function of the optical path length difference (*OPD*)

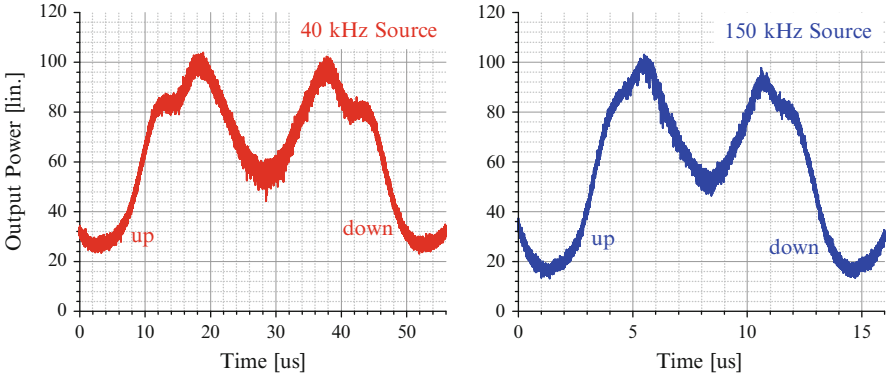

Fig. 18.19 ESS-1550: Temporal swept power profiles from 1,550-nm swept sources operating at 40 kHz (*left*) and 150 kHz (*right*). The turning points of the resonant MEMS scanners are at 3, 28, and 53 µs (*left*) and 1.3, 8.0, and 14.6 µs (*right*)

spectral coherence characteristics: While the 2-kHz source has an instantaneous coherence length of ∼14 mm (linewidth ∼75 pm), the faster 40-kHz source achieves a coherence length of ∼9 mm (linewidth ∼120 pm), which drops to ∼5 mm (linewidth ∼200 pm) at 150 kHz.

18.5 Detection and OCT Signal Processing

Proper optical and electrical detection in SS-OCT systems is as important as having a good swept source with sufficient imaging depth and low RIN. Besides highlighting a few technical considerations of the detection side, this chapter discusses real-time signal processing concepts for so-called OCT engines.

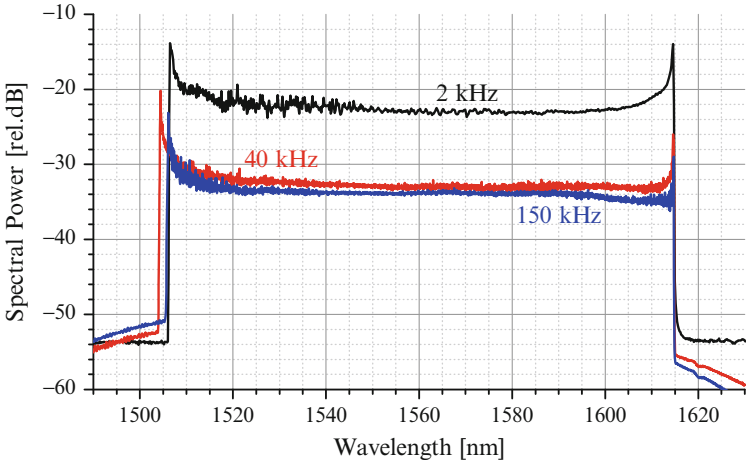

Fig. 18.20 ESS-1550: Optical spectra from 1,550-nm swept sources operating at 2 kHz (*black*), 40 kHz (*red*), and 150 kHz (*blue*). The sweep range is set to ~110 nm for all three lasers

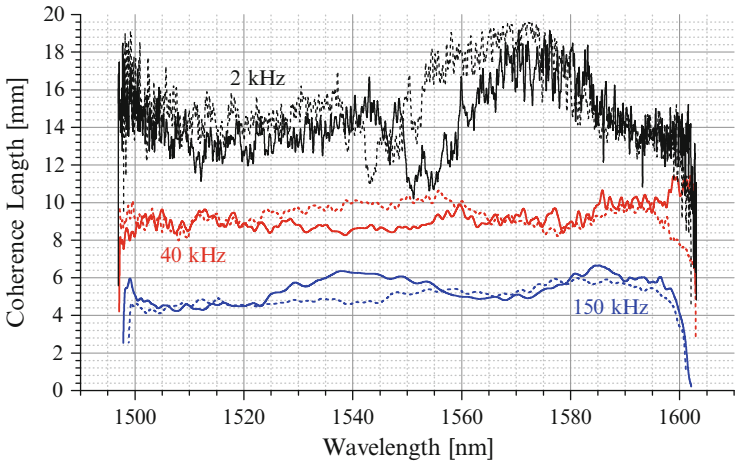

Fig. 18.21 ESS-1550: Instantaneous coherence length as a function of wavelength (*solid line*: up-sweep, *dashed line*: down-sweep) for 1,550-nm swept sources operating at 2 kHz (*black*), 40 kHz (*red*), and 150 kHz (*blue*)

18.5.1 Balanced Optical Detection

The promises of SS-OCT compared to SD-OCT include better sensitivity due to the fact that the OCT signal is received with a balanced optical receiver. As shown in Fig. 18.22, the OCT signal coming from the sample arm is interfering with light

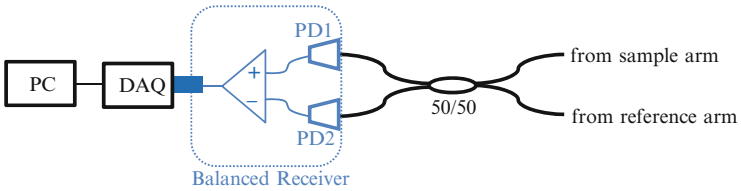

Fig. 18.22 Detection unit in a SS-OCT system, comprising of an optical 50:50 coupler in front of a balanced receiver that is connected to a data acquisition (*DAQ*) card

from the reference arm through a 50:50 optical coupler in front of the optical receiver. This balanced detection removes the DC component (common mode) of the light such that the relevant AC components of the fringe signal can be acquired with sensitivities near the shot-noise limit of the receiver.

In order to achieve a good SNR of the interference term and hence a good OCT system sensitivity, the power of the reference signal is increased to average values of 500–1,000 μW on each photodiode. At the same time, the common-mode rejection ratio (CMRR) of the whole detection unit needs to be high, which means that the optical power needs to be well balanced across the entire sweep range of the source [28].

Besides high CMRR, it is important for the balanced receiver to have a high gain but a low noise-equivalent power (NEP). The NEP is a measure of the receiver sensitivity and is the sum of the electrical shot noise, the thermal (Johnson or Nyquist) noise, and any other excess amplifier noise:

$$NEP.\sqrt{BW} = \sigma^2_{shot,el} + \sigma^2_{therm} + \sigma^2_{amp} = \sigma^2_{BR}$$

The total noise power of the balanced receiver, σ^2_{BR}, contributes to the noise of the electrical signal detected in SS-OCT [12, 19]:

$$\sigma^2_{OCT} = \sigma^2_{BR} + \sigma^2_{Shot,opt}\left(\alpha P_{ref}\right) + \sigma^2_{RIN,opt}\left(\alpha P^2_{ref}\right)$$

SS-OCT systems are operated in the shot-noise limit, which means that the optical power of the reference signal (P_{ref}) is adjusted such that the total noise is governed by the second term of the above equation and not by the RIN of the swept source (third term) or the receiver noise (first term). Also, due to the balanced optical detection, the RIN term is typically well suppressed if the CMRR of the receiver is high and the wavelength dependency of the 50:50 splitter in front of the receiver is small [28]. Consequently, the lower the NEP, the larger the dynamic shot-noise range, the higher the SNR of the OCT signal, and hence the better the system sensitivity.

EXALOS offers high-speed balanced receivers for SS-OCT with one of the lowest NEP values on the market [29], for example, a 380-MHz receiver with a high gain of 10,000 V/A and low NEP of 5 pW/√Hz (measured from DC to 100 MHz).

In general, the gain and the analog bandwidth of the balanced receiver shall be matched to the A-scan rate of the swept source, the imaging depth of the application, and the sampling rate of the data acquisition circuitry.

18.5.2 Data Acquisition and Digitization

Acquiring the analog fringe signals and converting them into digitized signals that can be processed in a field-programmable gate array (FPGA), a digital signal processor (DSP), a graphical or central processing unit (GPU/CPU) is an important task that decides upon the imaging performance of an OCT system. Key parameters of any DAQ card are sampling rate, voltage range, nominal resolution (Q), effective number of bits (ENOB), jitter, quantization error, and other parameters, such as the support for external clocking.

A general and typical architecture of a DAQ card is shown in Fig. 18.23. Here, two ADCs are clocked either from an internal clock (provided, e.g., by an on-board FPGA or by another clock source) or from an external clock, for example, the k-clock of the swept source (see Sect. 18.5.2.1). A second ADC might be needed in a polarization-diverse SS-OCT detection scheme, for example for endoscopic OCT with a highly-birefringent sample arm, or for polarization-sensitive OCT. It may be also needed to acquire the k-clock of the swept source in parallel to the OCT signal in order to perform real-time remapping (see Sect. 18.5.2.2). If the swept source is sufficiently stable over time, a fixed remapping vector could be used that was generated during a calibration procedure using the same ADC that is otherwise used for OCT signal detection (see Sect. 18.5.2.3).

Most DAQ cards feature an on-board FPGA anyway for various control tasks related to the data acquisition in the ADCs or related to the data exchange with the host, for example, through a PCIe bridge. Such an on-board FPGA can also be used to perform real-time OCT pre-processing and to transfer high-quality A-scans instead of raw data to the host PC (see Sects. 18.5.3 and 18.5.4). This FPGA may also be involved in the control of external peripherals such as optical scanners or other delivery optical systems.

18.5.2.1 ADC Resolution

Under certain conditions, a sampling resolution of 8 bits or less is sufficient for SS-OCT [30]. However, in order to support a larger dynamic range and to handle DC offsets through imperfect balancing, a nominal resolution of 12 bits or even more is used in many systems.

The resolution Q of an ADC determines the signal-to-quantization noise ratio (SQNR), which is equivalent to the maximum *theoretical* SNR that could be measured for a full-scale input sine wave [31]:

$$\max SNR_{\text{theo}}\ [dB] = 20 \cdot \log_{10}\left(2^{Q}\right) + 20 \cdot \log_{10}\left(\sqrt{\frac{3}{2}}\right) = 6.02 \cdot \mathrm{Q} + 1.76$$

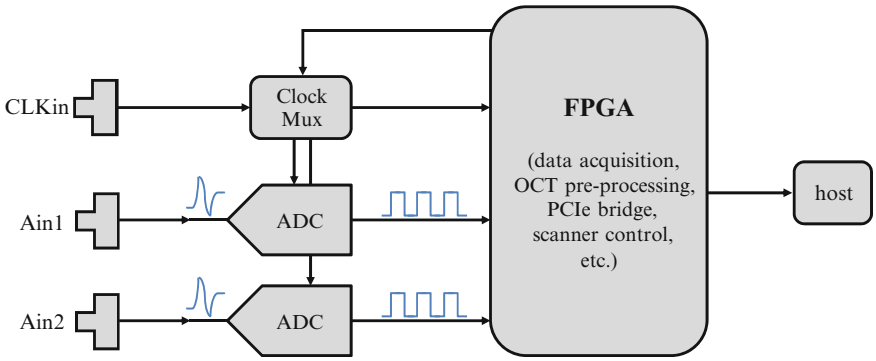

Fig. 18.23 Generic dual-channel DAQ card architecture with an onboard FPGA handling the data acquisition with the A/D converters and managing the data exchange to the host, for example, via an PCI Express bus. The DAQ card may support clocking of the ADCs through an external clock input

This means an 8-bit DAQ card could theoretically deliver a maximum SNR of 49.9 dB, while a 12-bit DAQ card could deliver a maximum SNR of 74.0 dB. However, due to signal distortions and other noise contributions besides the quantization noise, the maximum *effective* SNR that is measured with an ADC is always smaller than the theoretical value [32]:

$$\max SNR_{\text{eff}} \ [dB] = 6.02 \cdot ENOB + 1.76$$

For example, an 8-bit ADC achieving an SNR of 48.4 dB has an ENOB of 7.7 or a 12-bit ADC achieving an SNR of 65.4 dB has an ENOB of 10.7. The ENOB is dependent on the input frequency and is different for single-ended or differential detection.

18.5.2.2 Maximum SNR of PSF

It needs to be stressed that the maximum effective SNR is *not* describing the noise floor of the FFT and hence not the noise floor that the coherence function or PSF can have. This is because the FFT acts like an analog spectrum analyzer with a bandwidth proportional to the inverse of the number of FFT points N. The theoretical FFT noise floor is therefore $10 \cdot \log_{10}\left(\frac{N}{2}\right)$ dB below the quantization noise floor due to the processing gain of the FFT [31]. Some examples are given in Table 1.

The maximum SNR values that are practically achieved for a PSF are well below the theoretical limit due to various noise sources but also due to contributions from the OCT signal processing like an insufficient interpolation or resampling before the FFT.

18.5.2.3 ADC Sampling Rate

The required sampling rate (SR) of the DAQ card directly depends on the A-scan rate f_A and the duty cycle (DC) of the swept source, its sweep nonlinearity (ε),

Table 1 Maximum theoretical SNR of the PSF for DAQ cards with different resolutions as a function of the number N of FFT points

Resolution	$N = 2048$	$N = 4096$	$N = 8192$
6 bits	68.0 dB	71.0 dB	74.0 dB
8 bits	80.0 dB	83.0 dB	86.0 dB
10 bits	92.1 dB	95.1 dB	98.1 dB
12 bits	104.1 dB	107.1 dB	110.1 dB

the spectral sweep range in the frequency domain ($\Delta\nu$), and the targeted imaging depth (ID) of the application. It can be estimated as follows:

$$\mathrm{SR[MSPS]} \approx 6500 \cdot 2 \cdot \Delta\nu[\mathrm{THz}] \cdot \frac{(f_A)[\mathrm{kHz}]}{\mathrm{DC}} \cdot \varepsilon \cdot \mathrm{ID[mm]}$$

For example, a 100-kHz bidirectional sinusoidal swept source ($\varepsilon = 1.57$) with a sweep range of 1250–1360 nm ($\Delta\nu$ = 20 THz) and with a duty cycle of 100 % will require a DAQ card with a minimum sampling rate of ~408 MSPS for an imaging range of 10 mm. A 100-kHz linear swept source ($\varepsilon = 1.0$) with a 50 % duty cycle will require a minimum sampling rate of ~520 MSPS for the same imaging depth of 10 mm.

18.5.2.4 Direct k-Clocking

In this approach, the ADCs of the DAQ card are clocked directly from the k-clock of the swept source. However, most high-speed ADCs require continuous clocking operation, which means that an additional electrical circuitry has to generate a dummy clock for all periods of time at which the swept source does not provide a proper k-clock directly [33], for example, during a dark period of the laser or for a vanishing k-clock near the edges of the optical sweep spectrum. Furthermore, many high-speed swept sources exhibit nonlinear sweep characteristics with a k-clock that varies quickly in frequency. Such frequency-modulated external k-clock signals may cause dither and jitter problems in the ADCs, which can deteriorate the sampling performance. Finally, a lower-grade electrical k-clock signal may cause malfunction of the ADCs and may result in a complete A-scan loss.

18.5.2.5 Real-Time Resampling

In this approach the ADCs are clocked from an internal, continuous and fixed-rate clock that is provided by the DAQ card. The k-clock signal is acquired through a second ADC channel for every A-scan of the swept source and is used to generate in real time a calibration vector. This calibration vector is then used to resample the OCT signal prior to performing the FFT. Dynamic remapping is typically the method of choice to achieve the highest possible image quality with changing environmental influences or to get the highest degree of automation. On the other hand, dynamic calibration requires more hardware as well as more computing power than static calibration. Therefore, static calibration is typically used when hardware resources are limited. Nonetheless, dynamic and real-time remapping has been demonstrated for A-scan frequencies up to 100 kHz (further discussed in Sect. 18.5.4).

18.5.2.6 Resampling with Fixed Remapping Vector

In case the swept source is sufficiently stable over longer periods of time, a fixed remapping vector that is stored in memory may be used for linearization of the OCT signal. This remapping vector is generated through a calibration procedure where the fringe signal of a calibrated sample is recorded, typically using the same ADC channels that are otherwise used for OCT data acquisition. This method is least demanding in terms of detection hardware and processing infrastructure.

18.5.3 OCT Signal Processing Data Flow

Figure 18.24 shows the typical data flow used in SS-OCT signal processing based on remapping. This processing flow can be also realized in real-time OCT engines that perform signal processing in FPGA hardware (see Sect. 18.5.4). After acquisition of the OCT signal, a measured and stored background signal may be subtracted before the OCT signal is resampled using an interpolation algorithm (see Sect. 18.5.3.2). The resampling of the OCT signal is done through a calibration vector that is generated from the k-clock signal (see Sect. 18.5.3.1).

The inverse Fourier transform (FFT^{-1}) is applied to the resampled OCT signal that now has sample points being equidistant in k. The result of the FFT is an A-scan where typically the magnitude is plotted on a $20 \cdot \log_{10}$ scale. An optional final step of A-scan averaging may be implementing, as shown in Fig. 18.24. Furthermore, spectral windowing and dispersion compensation may be used prior to the FFT in order to improve the SNR of the A-scan.

18.5.3.1 Generation of Calibration Vector

Basically two approaches can be used to generate a calibration vector in order to resample the OCT signal.

The first approach relies on *amplitude detection* of the k-clock signal where certain reference points such as zero-crossings, peaks, or valleys are used to extract the timing positions of those points with an equidistant k-spacing.

The second approach relies on *phase unwrapping* through Hilbert transform. This Hilbert transform provides a phase rotation through a positive or negative 90° phase shift, which, in combination with a two-argument arc tangent operation, is used to extract the instantaneous phase of the k-clock signal, as shown in Fig. 18.25.

18.5.3.2 Interpolation and Resampling

The final step in the remapping process is the application of a linearization algorithm. The selection of an appropriate algorithm hinges on the balance between achieving a high-quality OCT tomogram and processing speed. In order to achieve high-performance remapping of nonlinear swept sources, it might be important to apply a nonlinear interpolation approach in real time unless the OCT signal is sufficiently oversampled (approximately by a factor 1.5–2). Several useful examples of signal processing methods to handle sweep nonlinearities in SS-OCT were reported in [20, 34, 35].

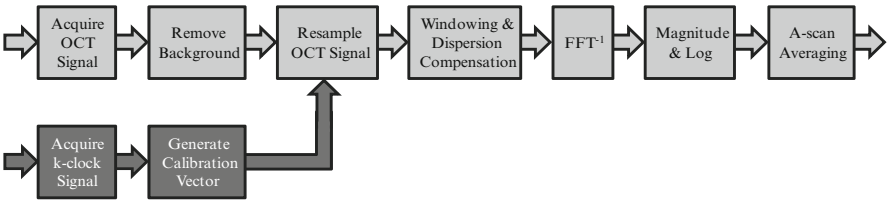

Fig. 18.24 Typical data flow of OCT signal processing based on remapping, here shown in a real-time architecture with acquisition of the k-clock reference signal in a parallel ADC port (*lower path*)

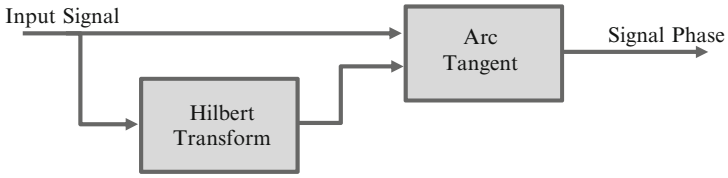

Fig. 18.25 Block diagram showing the use of Hilbert transform to extract the instantaneous phase information of the swept source

18.5.4 Real-Time OCT Engines

As mentioned in Sect. 18.5.2, real-time SS-OCT engines can be implemented on a variety of hardware platforms including FPGAs, DSPs, GPUs, or CPUs. In either of those choices, a DAQ card is needed that performs data acquisition and data transfer to the host PC. In many systems, an FPGA is employed anyway on the DAQ card such that the realization of an onboard real-time OCT engine inside the FPGA seems an interesting value proposition. In that approach, the DAQ card does not forward raw data to the host PC but preprocessed high-quality A-scans [36]. All the algorithms related to remapping and OCT signal processing are performed at real time on the DAQ card such that the host PC is mainly responsible for displaying of A-scan, B-scans, and C-scans and optional post-processing steps.

Such an FPGA-based SS-OCT engine for real-time linearization and remapping of nonlinear (e.g., sinusoidal) swept sources has been realized at A-scan frequencies of 40–100 kHz [37]. The two ADCs are clocked either at 250 MSPS for slower swept sources or at 500 MSPS for faster swept sources and feature a resolution of 12 bits. Real-time and unlimited generation of A-scans is performed using on-the-fly remapping in the FPGA. Each A-scan comprises 2,048 data points and could be extended to 4,096 data points to support longer imaging ranges. In addition, real-time A-scan averaging inside the FPGA is realized for

up to 32× averages. Video-rate B-scan displaying with 25 fps is supported on the host PC. OCT sensitivities of more than 100 dB (at a power of 1.5 mW in the sample arm) have been measured with a similar fall-off performance to off-line processing and spline interpolation. This platform is sufficient for 150 kHz swept sources and could be further extended to incorporate full-range imaging by using dispersion encoding or to a polarization-diverse detection scheme. By applying advanced real-time nonlinear interpolation algorithms, this system can be tailored to handle a wide variety of swept sources. This SS-OCT engine is also available as an OEM DAQ card to be integrated in a customer-specific system.

Keywords

Fibers • Lasers • Optical coherence tomography • Solid-state • Supercontinuum generation • Ultrafast lasers • Ultrafast technology

OCT achieves very high axial image resolutions independent of focusing conditions because the axial and transverse resolution are determined independently by different physical mechanisms. This implies that axial OCT resolution can be enhanced using broad bandwidth, low-coherence length light sources. The light source not only determines axial OCT resolution via its bandwidth and central emission wavelength but also determines the penetration in the sample (biological tissue), the contrast of the tomogram, and the OCT transverse resolution. A minimum output power with low amplitude noise is also necessary to enable high sensitivity and high-speed – real time – OCT imaging. Furthermore, ultrabroad bandwidth light sources emitting at different wavelength regions enable a potential extension of OCT, e.g., spectroscopic

OCT. Hence, it is obvious that the light source is *the* key technological parameter for an OCT system, and proper choice is imperative [1].

Several main criteria have to be considered when choosing a light source for OCT imaging. A light source and its usability for OCT can be characterized by:

- Center wavelength
- Bandwidth, spectral shape
- Power
- Noise
- Single transverse mode
- Stability

In principle, thermal light sources are capable of achieving high axial resolution because of their large spectral bandwidth, but their use for clinical OCT applications is limited by the low power contained in a single spatial mode which is necessary for high sensitivity, high-speed in vivo clinical OCT imaging. As stated previously, the depth resolution of OCT is defined as being equal to the coherence length of the light source.

Ti:sapphire lasers are excellent light sources for ultrahigh-resolution (UHR) OCT due to the extraordinary large gain bandwidth and high optical output power. With advanced mirror technology, dispersion control, and adapted cavity design, optical bandwidth of up to 300 nm at full width of half maximum (FWHM) centered at about 800 nm could be achieved resulting in sub-μm axial resolution OCT in tissue. Broad bandwidth Cr^{3+}:LiSGaF lasers are cost-effective, directly diode-pumped alternative solid-state light sources for OCT in the 800 nm wavelength region. Efforts also focused on developing broad bandwidth light sources in the 1,300 nm wavelength range permitting OCT micrometer-scale resolution along with millimeter range penetration depth. A laser spectrum covering the 1,230–1,580 nm wavelength region with an optical bandwidth of 250 nm (FWHM) was generated directly out of an all-solid-state Cr:forsterite laser. Cr^{4+}: YAG lasers have the ability to produce sub-20 fs pulses enabling broad optical bandwidth laser emission in the wavelength range from 1,300 to 1,600 nm. These

lasers operate at room temperature, do not require a vacuum, and have larger gain bandwidths than Er-doped fiber lasers. Microstructured fibers (MF) have been investigated and explored in terms of nonlinear effects and corresponding supercontinuum generation over the past years. Different Ti:sapphire, Nd:Glass, and other ultrashort solid-state and fiber lasers have been adapted in respect of pulse duration (bandwidth), output power, and repetition rate and coupled to MFs and waveguides with varying parameters concerning diameter, length, and in case of waveguides doping and doping concentration. Supercontinua in the visible and near-infrared wavelength region can be generated.

19.1 Solid-State Lasers

The term solid-state laser is generally reserved for lasers that rely on a gain medium in crystalline or glass form having ions introduced as an impurity in an otherwise transparent dielectric host material (in crystalline or glass form). They have been of great research interest since the first ruby laser was invented by Maiman in 1960 [2]. This laser was based on an aluminum crystal (Al_2O_3) doped with Cr^{3+}. Several solid-state lasers provide optical gain over a broad frequency range, corresponding to that of ultrashort pulses. High output powers with ultrabroad bandwidth laser emission are achievable. The excess noise is higher than in conventional superluminescent diodes (SLDs) but comparable to multiplexed SLDs. Traditionally, the bandwidth of laser materials, $\Delta\lambda$, is defined as full width at half maximum (FWHM) of the gain cross-sectional spectrum in the wavelength domain. The bandwidth of the ultrashort optical pulse, $\Delta\nu$, is commonly defined at its intensity FWHM in the frequency domain. Finally, the pulse duration, $\Delta\tau$, is usually referred to as the FWHM of its intensity profile in the time domain. The uncertainty relation $\Delta\nu\Delta\tau \approx 1/\pi$ provides a measure of the minimum frequency bandwidth of the ultrashort pulse. The bandwidth $\Delta\lambda$ required from the amplifying medium depends on the central wavelength $\Delta\lambda \approx \Delta\nu\lambda^2/c$. On the contrary, the relative bandwidth $\Delta\lambda/\lambda$ provides a more convenient and natural bandwidth measure because it does not depend on the central wavelength, it is the same in wavelength and frequency domains, and it is directly connected to the number of cycles per pulse $(\Delta\lambda/\lambda)^{-1} \approx (\Delta\nu/\nu)^{-1} \propto N$.

Ions belonging to one of the series of transition elements of the Periodic Table, in particular rare earth (RE) or transition-metal (TE) ions, are generally used as the active impurities in lasers. These active ions are embedded in either oxides, e.g., Al_2O_3, or fluorides, e.g., $YLiF_4$. The Al^{3+} site is too small to accommodate RE ions, so it is generally used for transition-metal ions, while the Y^{3+} site can be used for RE ions. Also, $LiSrAlF_6$ (LiSAF) or $LiCaAlF_6$ (LiCAF) are used for transition metals – most common for Cr^{3+} ions. Oxides are very hard and offer good mechanical and thermomechanical properties. In contrast, fluorides are soft, but also have good thermo-optical properties (i.e., low thermal-induced birefringence and lensing). Glasses have a low melting temperature, so they can be produced very cheap, but they have a low thermal conductivity, thus bad thermomechanical and thermo-optical properties. We will only review transition-metal-doped materials,

since rare earth-doped materials offer bandwidths and wavelengths that have not typically been used for OCT.

19.1.1 Transition-Metal-Doped Materials

The electronic configuration of Cr can be written as (Ar)3d54s1, while those of Ti, Co, and Ni can be written in the general form (Ar)3dN4s2 (with $N = 2$ for Ti, 7 for Co, and 8 for Ni). By adding a chromium atom to an ionic crystal, the one electron belonging to its 4 s orbital and two 3d electrons are used for ionic binding, and Cr is found as a triply ionized ion with three electrons left in the 3d shell. In titanium, the two 4s electrons and one 3d electron are used for ionic binding, and Ti is again present as a triply ionized ion with only one electron left in the 3d shell. All absorption and emission features of transition-metal ions arise from 3d-3d transitions. The 3d states interact strongly with the crystal field of the host leading to the vibronic character of the corresponding transitions and to ultrabroad absorption and emission bands. Electric-dipole transitions within the 3d shell are parity forbidden. The crystal field is much stronger than in RE materials. As a result, the 3d-3d transitions are more readily allowed, and the lifetimes are significantly shorter (a few microseconds) than those of the 4f-4f transitions in RE ions. Doping of crystals or glasses with transition-metal ions supports a strong coupling of the electronic levels of the doped laser ion to the phonon relaxations of the host lattice leading to a good separation of absorption and emission spectra.

19.1.1.1 Ti:Sapphire

Since the reporting of laser action by Moulton in 1982 [3], the Ti:sapphire laser has been the subject of intensive investigations and has become the most widely used tunable solid-state laser and the medium of choice for ultrafast pulse generation because of the broad amplification bandwidth. Ti:sapphire systems provide a tuning range of about 400 nm (corresponding to $\Delta v_0 \approx 100$ THz) with a relatively large gain cross section centered at 800 nm, thus providing the largest bandwidth of any lasers shown to date. This large optical bandwidth has made Ti:Sapphire a medium of choice for UHR OCT in the NIR regime.

19.1.1.2 Alternative Solid-State Light Sources

Cr^{3+}:LiSAF and Cr^{3+}:LiCAF offer a wide tuning range, and the corresponding lasers can be either flash lamp pumped or diode-laser pumped. In both systems, Cr^{3+} ions replace some of the Al^{3+} ions in the lattice, and the impurity ion occupies the center of a (distorted) octahedral site surrounded by six fluorine ions. Due to its wider tuning range and higher n_2, Cr:LiSAF is generally preferred to Cr:LiCAF. Due to the large gain linewidth centered around 850 nm and the possibility of diode pumping with laser diodes at 670 nm wavelength, these media are also attractive for generating femtosecond pulses. Sub-10 fs pulses from diode-pumped Kerr-lens mode Cr-doped colquirite laser have been reported [4, 5], making these systems competitive with Ti:sapphire lasers in terms of performance. Other interesting broadband lasing materials include Cr:LiSGaF in the 800 nm regime, Cr^{4+}:$MgSiO_2$ in the

Table 19.1 Optical properties of broadband laser materials

Material	Pump band λ (μm)	Emission cross-section σ (10–19 cm^2)	Upper state lifetime τ (μs)	Absorption band λ (μm)
Ti^{3+}:sapphire	0.45–0.6	3.8	3.2	0.6–1.05
Cr^{3+}:LiSGaF	0.60–0.7	0.33	88	0.7–1.05
Cr^{4+}:forsterite	0.85–1.2	1.1	15	1.1–1.37
Cr^{4+}:YAG	0.88–1.1	8	4	1.35–1.65

1,350 nm regime, and Cr^{4+}:YAG in the 1,500 nm regime. Interesting lasing materials in the infrared are Cr^{2+}:ZnSe operating at 2.5 μm or Co^{2+}:MgF_2 centered at 2 μm. Table 19.1 compares the optical properties of these gain media.

19.1.2 Femtosecond Lasers

Ultrashort light pulses represent the shortest, controlled, and technically produced events. To put the time scale of the femtosecond pulse in context, consider that one femtosecond compared to a second is equivalent to 5 min compared to the age of the universe. Such short laser pulses are very attractive for two reasons: they concentrate a large amount of energy within a short time interval and offer a broad bandwidth coherent pulse spectrum. Femtosecond laser development to date has mainly concentrated on the temporal features of the pulses, which were often optimized to the detriment of the spectral shape. In OCT imaging, however, the spectral width and shape rather than the pulse duration is most important. Since shorter pulse width corresponds to broader spectrum, short pulses and broadband spectrum cannot be regarded as independent. They are connected via a time/frequency uncertainty relationship (time-bandwidth product). Short pulse duration allows for time-resolved studies of fast processes occurring on a time scale of the pulse width, while applications like OCT benefit from the broad coherent pulse spectrum.

However, unlike ultrafast femtosecond time-resolved measurements where special care must be exercised to maintain the short pulse duration, OCT measurements depend on field correlations rather than intensity correlations. Field correlation is preserved even if the pulse duration is long. Femtosecond mode-locked solid-state lasers can generate ultrabroad bandwidth, low-coherence light with a single spatial mode and high power, providing both high resolution and high brightness necessary for high-speed OCT imaging. These lasers can operate over a broad range of wavelengths that are desirable for ultrahigh-resolution as well as spectroscopic OCT imaging in tissue. Since the early days of OCT Ti:sapphire lasers have widely been used for in vitro and in vivo OCT imaging in nontransparent tissues [6].

19.1.3 Mode Locking

The ability to deliver high brightness, broadband light from solid-state lasers for OCT imaging is, in turn, intimately linked to the ability to generate ultrashort

optical pulses through mode-locking techniques. In a free-running laser, typically a large number of transverse and longitudinal modes are oscillating simultaneously without fixed mode-to-mode amplitude and phase relationships. The resulting laser output is a time-averaged statistical mean value. The formation of a mode-locked pulse train from noise starts with the selection of one peak fluctuation or at least a small number. By forcing the longitudinal modes to oscillate with some definite relation between their phases, the modes interfere and produce short pulses in the pico- or femtosecond regime which is referred to as mode-locked. In this case, very short pulses with high intensities can be generated, especially when the phase offset between different frequencies approaches zero. In the frequency domain, mode-locking corresponds to a frequency comb of equally spaced synchronized modes. A short pulse corresponds to a broad frequency comb. In the time domain, it corresponds to a light pulse traveling inside the laser cavity.

A large number of mode-locking techniques have been developed to generate short pulses in solid-state lasers:

- Active mode-locking – the longitudinal modes are locked by a phase or frequency modulator driven by an external source. An RF signal is applied to the modulator at exactly the frequency interval of the longitudinal modes.
- Passive mode-locking – the longitudinal modes are locked by an element that is not driven externally but instead exploits some nonlinear optical effect, such as saturation of a saturable absorber or a nonlinear refractive index change in a suitable material.

Nowadays, Kerr-lens mode-locking is the state-of-the-art method for sub-10 fs pulse generation directly from a mode-locked laser. In Kerr-lens mode-locking [7], strong nonlinear refraction at high peak intensities causes self-focusing of Gaussian beams. Since it relies on a nonresonant electronic nonlinearity, its response time is less than a femtosecond. The fast self-amplitude modulation of the pulses due to the Kerr effect can shape and stabilize extremely short pulses. The pulse propagates with the group velocity which can be expressed by

$$\frac{dvg}{dv} = -v_g^2 \beta'', \tag{19.1}$$

where β'' is the group dispersion of the medium. Materials in the visible region of the spectrum have positive or normal dispersion, i.e., $\beta'' > 0$. Therefore in a laser crystal, v_g decreases with increasing frequency. Longer wavelengths travel faster than shorter ones, causing a redshift of the pulse. High-intensity mode-locked pulses are redshifted due to self-phase modulation and normal dispersion. Positive self-phase modulation and positive group-velocity dispersion in the Kerr medium can be compensated for by a dispersive delay line based on prism pairs introducing negative dispersion into the resonator. Although the glasses of the prisms have normal dispersion, the geometry of the ray path can be arranged such that the blue components of the pulse pass the prisms in a shorter time than the red components. Although a number of prism arrangements can be devised, usually two prisms are used at minimum deviation and Brewster's angle incidence at each

surface. Also dispersive (chirped) mirrors are widely used for dispersion compensation.

Since the Kerr nonlinearity is usually not strong enough for the cw mode-locking process to self-start, usually a strong fluctuation must be induced by either perturbing the cavity or by adding nonlinearity to the system (saturable absorber). The simplest method to start KLM in a laboratory setup is to slightly tap one of the resonator mirrors. Disturbing the cavity mirrors will sweep the frequencies of competing longitudinal modes, and strong amplitude modulation due to mode beating will occur. The most intense mode-beating pulse will be strong enough to initiate mode locking.

19.1.4 Resonator Design

A resonator commonly employed for KLM is an astigmatically compensated cavity consisting of a pair of focusing mirrors and one or two flat mirrors. The laser crystal as a Kerr medium is inserted into a tightly focused section of the resonator for high nonlinearity. KLM can be established as a trade-off between output power, stability, and tolerance to the exact position of the components. An analytical treatment of nonlinear resonators has shown that for a given pump power and pump spot size, the most critical parameters are the distance of the two focusing mirrors and the location of the Kerr medium with respect to the mirrors [8].

In a basic oscillator-cavity configuration, the laser is pumped from a continuous-wave (cw) laser source, which is usually now an intracavity-doubled diode-pumped neodymium laser. Recently also compact frequency-doubled DBR-tapered diode lasers for direct pumping of Ti:sapphire lasers have been demonstrated [63]. This pump light is focused into a Brewster's angle cut crystal, collinearly with the laser axis, through the back side of one of the focusing mirrors and the fluorescent light (laser light) bounces between two concave focusing mirrors placed around it, several dispersive mirrors, and an output coupler. High doping concentration and reasonable lengths of laser crystals are necessary for efficient absorption of the pump radiation.

19.1.4.1 Cavity Dispersion in Femtosecond Mode-Locked Lasers

In the generation of ultrashort pulses, a key limitation poses the linear dispersion within the laser material itself, which causes a wavelength-dependant delay: long-wavelength components of the pulse spectrum propagate faster than the short-wavelength components.

For this reason, the concepts of phase velocity, group velocity, and group delay dispersion in a dispersive medium have to be reviewed.

The electric field $E(t,z)$ of a plane, linearly polarized, monochromatic electromagnetic wave traveling at a frequency ω in the z-direction in a transparent medium can be written as

$$E = A_0 \exp\ j(\omega t - \beta z) \tag{19.2}$$

with A_0 as a constant and β as the propagation constant which is a function of the angular frequency ω. In this case, the propagation constant $\beta = \beta(\omega)$ is a characteristic of the given medium, referred to as the dispersion relation of the medium. The total phase of the wave is now $\phi_t = \omega t - \beta z$. Elemental changes dt and dz of the temporal and spatial coordinates of the velocity of a given phase front must fulfill the condition $d\phi_t = \omega dt - \beta dz = 0$ giving

$$v_{ph} = \frac{dz}{dt} = \frac{\omega}{\beta} \tag{19.3}$$

where v_{ph} is the phase velocity of the wave.

Since a light pulse is generally traveling in the medium and ω_L is the center frequency and $\Delta\omega_L$ the width of the corresponding spectrum, the dispersion relation over the bandwidth $\Delta\omega_L$ can be approximated by a linear law

$$\beta = \beta_L + (d\beta/d\omega)_{\omega=\omega_L}(\omega - \omega_L) \tag{19.4}$$

with β_L as propagation constant corresponding to the frequency ω_L, where the electric field can be expressed as

$$E(t,z) = A\left[t - \left(z/v_g\right)\right]\exp[j(\omega_L t - \beta_L z)] \tag{19.5}$$

and A is the pulse amplitude, $\exp[j(\omega_L t - \beta_L z)]$ is the carrier wave, and v_g is the group velocity given by

$$v_g = \left(\frac{d\omega}{d\beta}\right)_{\beta=\beta_L} \tag{19.6}$$

Due to the fact that the pulse amplitude is a function of the variable t–(z/v_g), the pulse propagates at a speed v_g without changing its shape. After traversing the length l of the medium, the pulse experiences a time delay

$$\tau_g = \frac{l}{v_g} = l\left(\frac{d\beta}{d\omega}\right)_{\omega_L} = \phi'(\omega_L) \tag{19.7}$$

where the phase ϕ is dependent on the frequency ω

$$\phi(\omega - \omega_L) = \beta(\omega - \omega_L)l \tag{19.8}$$

and

$$\phi'(\omega_L) = [d\phi(\omega - \omega_L)/d\omega]_{\omega_L} \tag{19.9}$$

is referred to as the group delay of the medium at the frequency ω_L

When two pulses with bandwidths $\Delta\omega_1$ and $\Delta\omega_2$ centered at ω_1 and ω_2 travel in the medium ($\omega_2 > \omega_1$), the two pulses travel at different group velocities v_{g1} and v_{g2}. Thus, if the peaks of the two pulses enter the medium at the same time, then, after traversing the length l of the medium, they become separated in time by a delay

$$\Delta\tau_g = \phi'(\omega_2) - \phi'(\omega_1) \cong \phi''(\omega_1)(\omega_2 - \omega_1) \tag{19.10}$$

with

$$\phi''(\omega_1) = \left[d^2\phi/d\omega^2\right]_{\omega_1} \tag{19.11}$$

Light pulses with large bandwidths $\Delta\omega_L$ cannot any longer be described by the linear dispersion relation. Different spectral regions of the pulse travel with different group velocities resulting in a pulse broadening. Assuming that the dispersion relation within the bandwidth $\Delta\omega_L$ can be approximated by a parabolic law, the pulse broadening due to dispersion $\Delta\tau_d$ is given approximately by the difference in group delay between the fastest spectral component and the slowest one

$$\Delta\tau_d \cong |\phi''(\omega_L)|\Delta\omega_L \tag{19.12}$$

The quantity $\phi''(\omega_L)$ is referred to as the group delay dispersion (GDD) of the medium at frequency ω_L and is a measure for the pulse broadening per unit bandwidth of the pulse. It can also be written as

$$\Delta\tau_d \cong l\left|\left(\frac{d^2\beta}{d\omega^2}\right)_{\omega_L}\right|\Delta\omega_L \tag{19.13}$$

where the quantity group-velocity dispersion (GVD) at frequency ω_L is given

$$GVD = \left(\frac{d^2\beta}{d\omega^2}\right)_{\omega_L} = \left[\frac{d\left(1/v_g\right)}{d\omega}\right]_{\omega_L} \tag{19.14}$$

Its magnitude gives the pulse broadening per unit length of the medium and per unit bandwidth of the pulse. This concept for the GVD can only be applied for homogeneous media. For an inhomogeneous or multicomponent medium, GDD is differently to consider.

19.1.4.2 Introducing Negative Dispersion into the Laser Cavity: Dispersion Management

Since the laser crystal provides positive or normal dispersion, a suitable element providing negative or anomalous dispersion is required for the compensation of the cavity GDD. Advances in crystal growth have allowed for thinner and thinner

crystals with higher doping levels, but crystals ~2 mm thick are still required to achieve a reasonable gain. Compensation of the crystal's positive group delay dispersion with the opposite negative group delay dispersion introduced by an intracavity prism pair [9] ultimately led to fourth-order dispersion limited pulses of sub-10 fs duration.

A four-prism sequence allows for accurate dispersion compensation and low losses since all surfaces are at Brewster's angle to the beam path so that the GDD of the laser rod can be compensated for. The negative value of GDD can be coarsely changed by changing the separation l of the two prism pairs. By translating any one of the prisms along an axis normal to its base, the total length of the optical medium traversed by the beam can be changed. This motion introduces, in a finely controlled way, a positive (material) dispersion of adjustable size without altering the ray directions and hence the negative dispersion due to the geometry of the ray path. Since the transmitted beam is collinear with the incident beam, this facilitates inserting the four-prism sequence in an already aligned cavity. One of the drawbacks is that not only second-order dispersion but also third-order dispersion is introduced (fused quartz is one of the best optical materials with a very low ϕ'''/ϕ'' ratio). Simultaneous third-order dispersion (TOD) compensation is possible only at specific wavelengths depending on the rod and prism material. Therefore, limitations are due to the insufficient cancellation of higher-order dispersion terms (third, fourth, etc.) resulting in pulse duration of about 10 fs in Ti:sapphire oscillators. For Ti:sapphire lasers, simultaneous GDD and TOD compensation can be achieved in wavelengths ranges of a few nanometers around 800 nm with beryllium oxide (BeO) prisms, around 850 nm with fused silica and around 880 nm with BK7. Using solely fused silica prisms for the dispersion compensation, sub-10 fs pulses were reported for the first time directly from an oscillator [10]. These pulses showed M-shaped spectra owing to the fourth-order dispersion that was found to limit the achievable bandwidth. There exist compensation schemes with only one or more than two intracavity prisms, but none seems to allow for the intracavity dispersion compensation required for pulse durations below 8 fs. For even shorter pulse generation in the regime of one optical cycle, the development of dispersive high-reflective broad bandwidth mirrors is mandatory. Szipöcs [11, 12] set a new milestone in ultrashort pulse generation with the invention of chirped mirrors (CM). These first CM designs were obtained by computer optimization of "chirped" Bragg reflectors (cf. Fig. 19.1). Szipöcs reported a design consisting of 42 alternating layers of SiO_2 and TiO_2, which had a bandwidth of 200 nm at a center wavelength of 800 nm. Other than the geometric dispersion approaches, they allow for compensation of arbitrary higher-order dispersion. Several advances in laser technology with chirped and double-chirped mirrors have resulted in octave-spanning spectra.

19.2 Ti:Sapphire Laser Development

Recent advances in laser technology resulted in development of ultrafast solid-state lasers capable of emitting powerful spectra with bandwidths spanning several

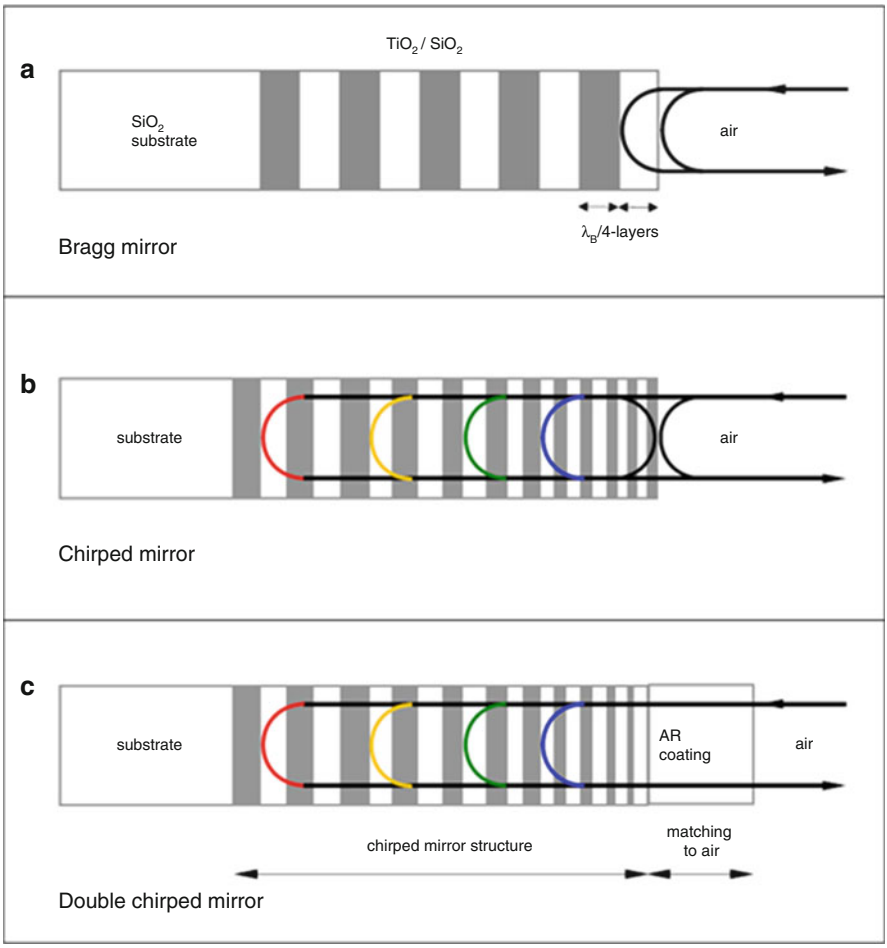

Fig. 19.1 *Mirror technology for Ti:sapphire lasers*. Comparison between Bragg mirror (**a**), chirped mirror (**b**), and double-chirped mirror (**c**)

hundred nanometer at full width at half maximum (FWHM) [13]. Pulses in the 8–10 fs range can easily be generated from prism-pair oscillators. Since pulse duration has been pushed towards the theoretical limit of one optical cycle, which is approximately three femtosecond, accurate dispersion control over a broad wavelength range is demanded, and dispersion effects have to be minimized in the design of these femtosecond lasers. The two major sources of dispersion in a mode-locked laser are self-phase modulation that is a part of the Kerr effect and normal dispersion in the laser crystal or any other optical component in the resonator.

Pulses significantly shorter than 10 fs could be generated from mirror-dispersion-controlled oscillators, whereas oscillators employing both prism pairs and chirped mirrors for dispersion control allowed the generation of sub-6 fs pulses. Moreover, external spectral broadening in special fibers, pumped by ultrashort

(picosecond to femtosecond) laser pulses, enabled the generation of so-called supercontinua (SC). While the bandwidth of a solid-state laser is limited by the gain spectrum of the laser crystal as well as the mirror technology, nonlinearly broadened light sources utilizing microstructured fibers like photonic crystal fibers (PCF) [14] or tapered fibers [15] do not exhibit such limitations. Spectra covering more than one octave or even more than two octaves are generally achievable. However, this kind of external broadening often results in significant power fluctuations, spectral modulations, and excess noise (in addition to the noise of the pump source) [16, 17] in the optical output, which limit clinical applications of OCT. Therefore, it is desirable to generate an ultrabroad spectrum directly from a compact solid-state laser. Octave-spanning (at the pedestal) Ti:sapphire lasers that use chirped mirrors in combination with prism pairs and some other intracavity elements such as a glass plate for enhanced self-phase modulation with a two-foci laser for broadening were demonstrated [18]. It was also demonstrated that a broad bandwidth optical output can be generated by self-phase modulation in a Ti:sapphire crystal in a prismless oscillator [19]; however, the spectra exhibited strong modulations, severely compromising applications where a clean temporal structure of the generated pulses or the first-order autocorrelation of the laser output is essential. The latter requirement applies to ultrahigh-resolution and spectroscopic OCT [20–22]. Further limitations of all these systems were the need of highly sophisticated, bulky, and very expensive pump sources and the lack of reliability and long-term stability. Each system represented a unique laboratory prototype with almost no chance of doubling. OCT imaging on a daily base was not feasible. With advanced mirror technology the generation of ultrabroad bandwidth ($>$277 nm at FWHM) and smooth spectra directly out of a prismless Ti:sapphire was reported [23].

19.2.1 Mirror Technology for Femtosecond Pulse Ti:Sapphire Lasers

Standard dielectric quarter-wave Bragg mirrors are inappropriate for the generation of sub-10 fs pulses because of their restricted high-reflectance bandwidth and the strong higher-order dispersion near the edges of the HR range. Metal mirrors do not experience these restrictions, but suffer from high insertion losses. Nevertheless, the first sub-10 fs pulses directly from an oscillator were achieved by using silver mirrors instead of dielectric mirrors and additional prism pair for dispersion control [10]. However, considerable residual higher-order dispersion prevented such lasers from producing pulses shorter than $\sim$8.5 fs. This restriction demanded alternative methods for dispersion compensation. Even for propagation in air, the group velocity of electromagnetic signals depends on the carrier frequency. Ultrashort pulses contain broad frequency spectra, and the varying propagation speed of the different spectral components will always cause the pulse to change its shape during propagation. Optimal performance can only be obtained if all spectral components arrive at the same time meaning that the spectral phase is the same for all frequency components. Such pulses are called “transform limited” because

they have a minimum root-mean-square time-bandwidth product. By introducing dispersive materials in the beam path, the resulting group delay between different spectral components will lead to a pulse whose instantaneous frequency (the derivative of the temporal phase with respect to time) depends on time. Such pulses are called "chirped." There are attributes like "down-chirped," "up-chirped," and "unchirped" for a pulse whose instantaneous frequency falls (blue-first, negative chirp) or rise (red-first, positive chirp) with time or remain constant ("transform limited"). Parallel to the standard design approach, chirped mirror technology allows minimizing the system complexity.

For ultrashort pulse generation, the round trip time τ_r in the resonator for all frequency components of the mode-locked pulse must be the same, i.e., $\tau_r = d\varphi/d\upsilon = \text{constant}$, where φ is the phase change after one round trip. Otherwise, frequency components that experience a cumulative phase shift no longer add constructively and are attenuated. This limits the bandwidth of the pulse and leads to pulse width broadening. The frequency-dependent phase shift of the pulse during one round trip can be expressed in a Taylor series about the center frequency v_0,

$$\frac{d\varphi}{dv} = \varphi'(v_0) + \varphi''(v_0)\Delta v + \frac{1}{2}\varphi'''(v_0)\Delta v^2,$$

with φ', φ'' and φ''' as the derivatives of the phase with respect to frequency. When φ'' is nonzero, the pulse will have a linear frequency chirp, while a nonzero third-order dispersion will induce a quadratic chirp on the pulse.

19.2.1.1 Quarter-Wave BRAGG Mirrors

Standard high-reflectance laser mirrors typically consist of quarter-wave stacks (cf. Fig. 19.1) and therefore are limited in the maximum reflectance which is given by the BRAGG wavelength λ_B that is twice the optical thickness of the unit cell defining the quarter-wave structure. It can be seen that in the stop band around the angular frequency $\omega_B = 2\pi c/\lambda_B$, the condition $(\cos\phi - r^2)/(1 - r^2) \leq -1$ holds, where $\phi = \pi\omega/\omega_B$ is the phase acquired after propagation through a layer pair and where Fresnel's reflectance for the index step is given by

$$r = (nH - nL)/(nH + nL) \tag{19.15}$$

The stop band covers the wavelength range between $\lambda_{St} = n\lambda_B/[2\pi - 2(\arccos(r))]$ and $\lambda_{St} = \pi\lambda_B/2\arccos(r)$ only in an ideal case when the wavelength dependence of the refractive index is neglected. Then its fractional width $\Delta\omega/\omega_B$ depends only on the index ratio between the high- and the low-index material:

$$\frac{\Delta\omega}{\omega_B} = \frac{4}{\pi}\arcsin(r) \tag{19.16}$$

For epitaxially grown semiconductor quarter-wave mirrors, all refractive indices are typically between 3.0 and 3.6, enabling bandwidths of about 10 %.

For amorphous coatings, typical materials with low indices are between MgF_2 ($n = 1.37$) and SiO_2 (n = 1.44), and high-index materials like Ta_2O_5 ($n = 2.1$) and TiO_2 ($n = 2.35$), which results in fractional bandwidths of about 30 %.

The maximum achievable reflectance in case of small absorption coefficients $\alpha_{H,L}$ for an infinite number of layers [24] is approximately given by $R(\lambda_B) = R_0(\lambda_B)$ $[1 - (\lambda_B/2)(\alpha_H + \alpha_L)n_l/(n_H^2 - n_L^2)]$. So the maximum reflectance of a quarter-wave mirror can be assumed for a lossless quarter-wave mirror and is given by

$$R_0(\lambda_B) = \left(\frac{1 - aqp^{m-1}}{1 + aqp^{m-1}}\right)^2 \tag{19.17}$$

It will already be approached for a limited number of layers. Assuming that the absorption in the mirror can be neglected which is especially valid for ion-beam sputtered coatings made of TiO_2 and SiO_2, the maximum reflectance will approach unity with increasing layer pairs. Since quarter-wave mirrors introduce significant amounts of negative dispersion for wavelengths $\lambda > \lambda_B$, they can be used for dispersion compensation over a small region of their high-reflectance bandwidth. Broadband mirrors can be designed by several quarter-wave sections whose stop bands overlap. Since such mirrors exhibit regions of extreme phase variations, they cannot be used for femtosecond or OCT applications.

19.2.1.2 Chirped Mirrors

UHR OCT demands for ultrabroad Gaussian-like stable spectra generated directly out of the Ti:sapphire. The proper choice of broad bandwidth dispersive mirrors is mandatory for accurate dispersion compensation in the spectral range approaching or even exceeding one optical octave (cf. Fig. 19.1). These mirrors have contributed significantly to enhancement of the performance, compactness, and reliability of femtosecond laser sources. The generation of sub-10 fs pulses directly from the oscillator can now be achieved routinely with CM dispersion-controlled oscillators. Progress in CM design and manufacturing in combination with advanced oscillator designs have permitted the direct generation of sub-6 fs pulses. Such extreme bandwidths create new challenges and difficulties making some of the small-bandwidth approaches ineffective and deserve special treatment.

CMs are custom-tailored multilayer dielectric mirrors, where the thickness of each layer is carefully chosen so that the whole system has special dispersion properties. The BRAGG wavelength is gradually decreased during deposition (at least in the initial design, which may be altered by subsequent computer optimization) so that the incident light is reflected with a wavelength-dependent group delay. The average group delay of such simple chirped mirrors can be increased with wavelength, but with the drawback of the superimposing of a strong wavelength-dependent dispersion oscillation [25]. The mirror consists of a large number (∼40) of alternating low- and high-refractive index layers whose thickness progressively increases going towards the substrate. Layers with

increasing thicknesses (e.g., quarter-wave layers with a gradually increasing local Bragg wavelength) are stacked such that longer wavelengths penetrate deeper into the mirror structure, producing negative group delay dispersion (GDD). Due to the chirp of the Bragg wavelength, the high-reflectivity bandwidth is larger compared to standard dielectric quarter-wave mirrors. Both features together allow for a more efficient compensation of higher-order dispersion over a broader spectral range. Interference of light waves reflected from different plane-parallel interfaces results in a certain frequency-dependent reflectance $R(\lambda)$ and phase shift $\varphi(\lambda)$ of the incident light, where $\varphi(\lambda)$ is directly connected to the group delay (GD) and the GDD introduced by the mirror:

$$\mathrm{GD}(\omega) = -\varphi'(\omega)$$

$$\mathrm{GDD}(\omega) = -\varphi''(\omega)$$

It is the same principle that works in the Bragg reflectors (stack of layers with a fixed optical thickness equal to $\lambda_0/4$). But CMs possess another very important property: they can be designed in such a way that the frequency-dependent phase shift $\varphi(\lambda)$ matches dispersion properties of materials common in laser systems (air, fused silica, or Ti:sapphire), which is essential for the generation of ultrashort pulses. A desirable dispersion can be achieved if optical layer thicknesses gradually change along the coating, so that a component with wavelength λ is reflected from the part of the stack, where the optical thickness of layers is close to $\lambda/4$. This gradual change of optical layer thicknesses is referred to as "chirping"; hence, this type of mirror is named "chirped mirror."

The GD of the reflected beam increases with decreasing values of ω, thus giving $\phi'' < 0$. One can obtain a value of ϕ'' that, within the bandwidth of interest, is approximately constant with frequency $\phi''' \cong 0$, but the GDD can also be designed to exhibit a slight linear variation with frequency and a slope suitable for compensating the TOD of other cavity components. GDD per bounce is in general $-50\ \mathrm{fs}^2$.

Of particular interest are the so-called double-chirped mirrors: an analytic approach based on the coupled-mode theory for multilayer interference coatings. In this approach, a chirped mirror is composed of Bragg cells, where each cell is characterized by a corresponding Bragg wavelength and the thickness of the high-refractive index layer. Both these parameters are chirped in order to achieve a smooth increase of the coupling coefficient, which was recognized as a prerequisite for suppression of GDD oscillations [26]. A perfect AR coating is assumed to match the impedance from air to the first low-index layer. Although the recently found improved implementations and the analytical predesign methods were essential for enhancing the performance of CMs, they did not obviate the need for efficient computer optimization techniques. On the one hand, the request for mirror designs with even larger bandwidth, which would permit the generation of nearly single-cycle pulses for scientific applications, makes the requirements for chirped mirrors extreme that even small improvements may play a crucial role. On the other hand, the high production cost of chirped mirrors demands designs

with reduced sensitivity to small discrepancies between the layer thicknesses of a calculated design and those of the manufactured mirror, especially if the mirror is designed for a broad spectral range.

Nevertheless, impedance matching with AR coatings or edge filters can only be achieved over a limited bandwidth. This drawback can be overcome by coating the CM on a thin wedged substrate and illuminating it from the substrate side. With this approach, the incident medium is glass (to which the multilayer can be perfectly impedance matched over an arbitrary broad bandwidth). The impedance mismatch will occur now at the substrate air interface, resulting in an additional reflected beam. This beam will not distort the GDD characteristic of the mirror because it cannot interfere with the main (useful) beam, having a different propagation direction. TFICM (tilted-front-interface chirped mirrors) [27] might allow enhancing the bandwidth of pulses emitted directly from the oscillator far beyond 300 nm.

19.2.2 Ultrabroad Bandwidth Ti:Sapphire

19.2.2.1 Sub-Two-Cycle Pulse Oscillator with Intracavity Prisms

In the early days of OCT a Ti:sapphire laser with 4 μm axial resolution has been used for in vitro OCT imaging in nontransparent tissues to improve OCT axial resolution [6]. Consequently, in preliminary UHR OCT studies, a system was developed and could be optimized to support 260 nm of optical bandwidth from a state-of-the-art Ti:sapphire laser [28] resulting in 1 μm axial resolution [20, 21]. This laser generated pulses of <5.5 fs duration corresponding to bandwidths of more than 350 nm at 800 nm center wavelength. This high performance was achieved using specially designed double-chirped mirrors with high-reflectivity bandwidth and controlled dispersion response. The resonator was a standard z-fold design, as shown in Fig. 19.2a. Figure 19.2b depicts the measured reflectivity of the DCM and the output-coupling mirror (OC) (top), the desired condition for perfect dispersion compensation, and the designed and the measured GDD of one bounce on the DCM (second from top), the measured spectrum behind the output coupler (third from top), as well as the measured intracavity spectrum with a silver mirror instead of the output coupler (bottom). An interferometric autocorrelation as shown in Fig. 19.2c was accomplished. A fit to the interferometric autocorrelation of a sech-shaped pulse would result in a pulse width of 4.3 fs FWHM, a fit to a Gaussian in 4.8 fs. The most conservative assumption for the pulse shape is the sinc function and results in 5.4 fs. The good agreement of the measured interferometric autocorrelation with those derived from the spectrum and the sinc function indicates a pulse width between 4.9 and 5.4 fs, which is shorter than two optical cycles at the center wavelength of 800 nm.

Necessary light source specifications for ultrahigh-resolution OCT include not only spatial coherence, ultrabroad bandwidth emission with enough output power, and good amplitude stability but also optimum spectral shape. Since the coherence length is defined as the full width at half maximum of the field autocorrelation measured by the OCT interferometer, the width and also the shape of the coherence

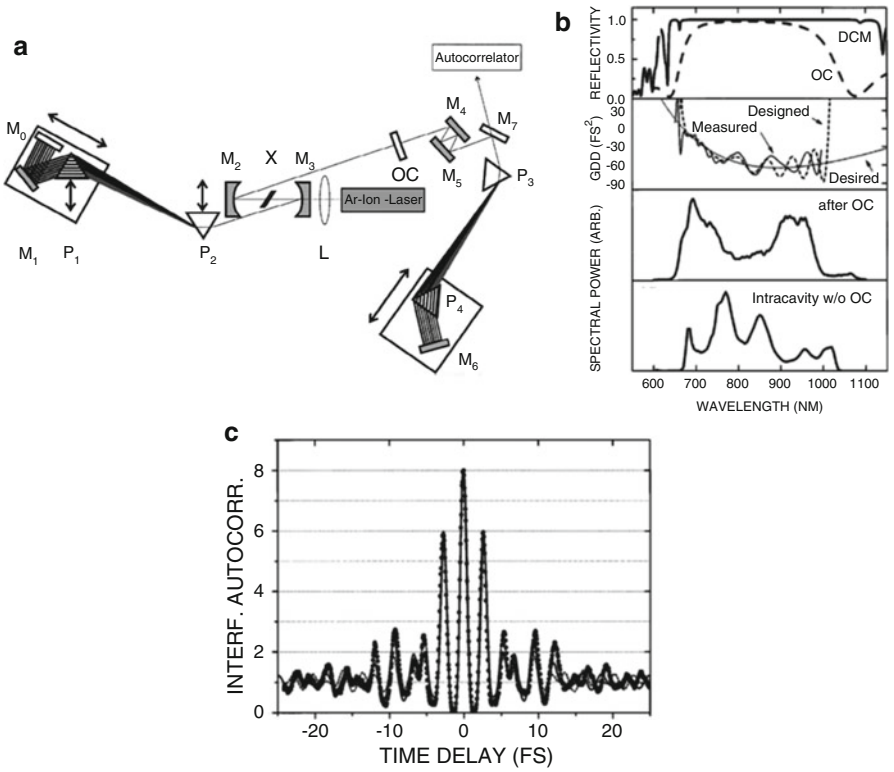

Fig. 19.2 *Sub-two-cycle pulses from a Kerr-lens mode-locked Ti:sapphire laser*. Cavity setup (**a**) with crystal X; curved mirrors M_2 and M_3; flat mirrors M_0, M_1, and M_4, M_7; output-coupling mirror OC; and prism sequence P_1, P_2. All double-chirped mirrors (*DCM's*) are *gray*; the other mirrors are silver mirrors. Lens L focuses the pump beam into the crystal. The prism sequence P_3, P_4 is necessary for extracavity dispersion compensation. (**b**) Depicts the measured reflectivity of the DCM and the output-coupling mirror (*OC*) (*top*), the desired condition for perfect dispersion compensation, and the designed and the measured GDD of one bounce on the DCM (second from *top*), the measured spectrum behind the output coupler (third from *top*), as well as the measured intracavity spectrum with a silver mirror instead of the output coupler (*bottom*). (**c**) Measured interferometric autocorrelation of the Ti:sapphire laser. The *dashed curve* is a fit of a sinc^2 function with a FWHM of 5.4 fs, and the *solid curve* is the calculation from the spectrum [28]

function of an OCT system are dependent on the spectral shape of the light source as well as on the transfer function of the OCT system. The latter one is mainly determined by the optical properties of the interferometer, e.g., wavelength-dependent losses and splitting ratios of beam splitter and lenses, as well as cutoff wavelength of employed single-mode fibers as well as the wavelength-dependent sensitivity of the employed photodetectors. The ideal spectrum for OCT would have Gaussian spectral shape, resulting in a Gaussian coherence function with no sidelobes. Large spectral modulations would reduce sensitivity and resolution, due to the presence of sidelobes in the fringe pattern that appear symmetrically to the coherence functions maximum. There are several possibilities to change the shape

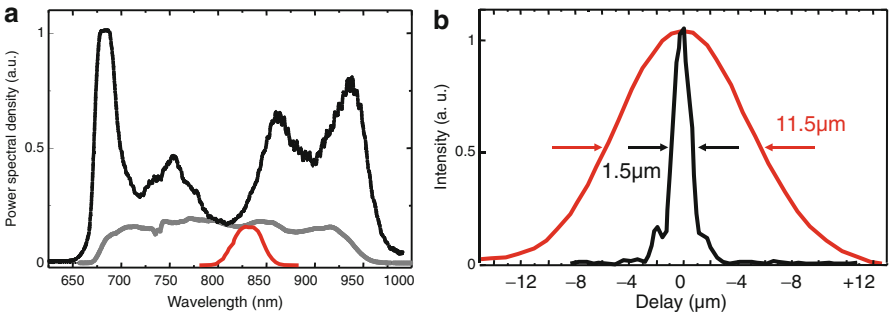

Fig. 19.3 *Ultrahigh-resolution OCT using a sub-two-cycle pulse Kerr-lens mode-locked Ti:sapphire laser*. Original spectrum from Ti:sapphire (**a**, *black*) and reshaped spectrum (**a**, *gray*) using wavelength-dependent attenuation compared to a spectrum from a standard superluminescent diode (**a**, *red*). (**b**) Demodulated OCT axial scan showing the axial resolution of OCT using this Ti:sapphire (*black*) versus a standard superluminescent diode SLD (*red*) light sources. Solid-state lasers enable almost a 10× improvement in resolution [21]

of the emission spectrum of the used light source. The easiest way is to introduce optical dichroic or interference filters that suppress certain wavelength regions. Another possibility is to spatially disperse the optical beam with prisms and to induce local and therefore wavelength-dependent losses by introducing razor blades or thin objects into the dispersed light beam. Figure 19.3a demonstrates the effect of this shaping method when applied to a strongly modulated spectrum of the sub-two-cycle pulses from the Kerr-lens mode-locked Ti:sapphire laser described above (cf. Fig. 19.2). It also shows a comparison of the spectra and resolution (Fig. 19.3b) of an OCT A-scan using a conventional superluminescent diode light source versus this femtosecond Ti:sapphire laser source. The ultrabroad bandwidths which are generated by the femtosecond laser enable the axial resolution of OCT to be improved by a factor of nearly 10× better than standard OCT technology.

19.2.2.2 All-Chirped Mirror Oscillator (ACM Oscillator)

An ultrabroad bandwidth complementary chirped mirrors pair, compensating for Ti:sapphire dispersion in the wavelength range 600–1,000 nm with maximal spectral intensity loss of 1 %, has been designed for an all-CM oscillator (cf. Fig. 19.4) [23].To design these mirrors, a suitable compromise between the bandwidth, dispersion, and reflectance has to be found. A major goal was to keep the dispersion fluctuations of each mirror as small as possible since we found that in this way, we can improve the manufacturing reproducibility of the design. Each of the mirrors consists of 63 layers. If the mirror is used in pair with the input coupler, the net GDD and the net reflectance are closer to their targets. The small positive second-order dispersion of the complementary mirror can be compensated with other chirped mirrors. For the implementation of CMs in an octave-spanning oscillator, the previously designed complementary pair of an input coupler (IC) and a chirped mirror (CM) has to be redesigned. The IC has transmission >99 % in the

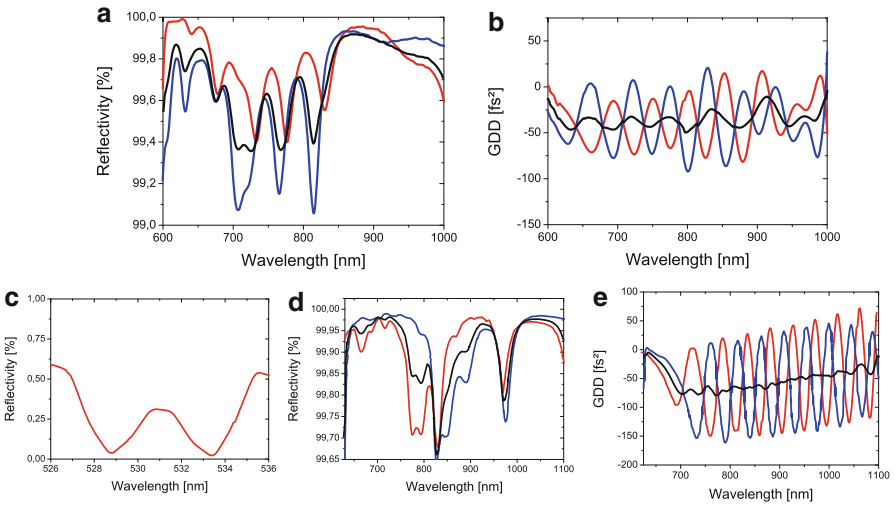

Fig. 19.4 *Chirped mirror technology for ultrabroad bandwidth Ti:sapphire lasers*. Reflectance (**a**) and GDD (**b**) of a chirped mirror pair. A broadband input coupler (**c**, **d**) and a complementary chirped mirror (**e**)

wavelength range 525–539 nm. Both IC and CM have reflectance >99.5 % in the range 625–1,110 nm, as well as a "smooth" dispersion in the range 700–1,100 nm.

Optimization of Ti:sapphire oscillators has resulted in lasers with short (few millimeters) highly doped active media – 2–3 mm in the experiments mentioned in the previous paragraphs. Consequently, the amount of positive dispersion to be compensated is limited and can be balanced by using 4–6 bounces of CMs. The total number of bounces of cavity mirrors is typically higher. One would thus be inclined to use a minimum number of CMs and employ the much cheaper and easier to manufacture standard Bragg mirrors (BMs) in addition. Although TiO_2/SiO_2 BMs exhibit high reflectance over ~200 nm at 800 nm (bandwidths that can support pulses with 120–140 nm at FWHM), the range within which GDD remains constant is smaller. Furthermore, deviations from GDD = 0 add up constructively, as all BMs have identical dispersion. In an oscillator employing both CMs and BMs, the bandwidth over which mode locking can be achieved is severely limited by the range within which the GDD of BMs remains constant. With accurate dispersion management, spectra slightly below 200 nm at FWHM are feasible. Nevertheless, a lot of effort is needed to obtain such spectra, and no reliable performance and reproducibility can be expected. In such laser cavities, BMs with enhanced transmittance at the pump wavelength have been widely used as input couplers because design and particularly manufacturing of dichroic CMs rise serious problems (mainly because of the high sensitivity of the dichroic CMs transmittance to manufacturing errors). However, comparing the dispersion and reflectance characteristics of BMs and dichroic CMs, the advantages of the latter are overwhelming. With the advent of highly accurate deposition methods

like magnetron sputtering tailored for CM coatings, manufacturing of dichroic CM has become possible. As the dichroic BM input coupler acted so far as a bottleneck on the bandwidth of the mode-locked pulsed lasers, there was no motivation to replace other BMs in the cavity with broader bandwidth CMs. Nevertheless a Ti:sapphire oscillator employing dichroic CMs enormously benefits in terms of bandwidth and pulse duration if all the other reflectors in the cavity are CMs.

Therefore, further increasing of the bandwidth using a compact oscillator design is feasible by replacing all high-reflecting mirrors by broadband dispersive mirrors and employing a single frequency 532 nm pump source on a platform of 600 × 400 mm. Ultrabroad bandwidth and smooth spectra from a prismless Ti:sapphire laser can be generated making additional external shaping not longer necessary.

Therefore, two main goals had to be followed in the development of dispersive dielectric multilayer coatings:

- One effort was the increasing of the bandwidth of chirped mirrors from 200 nm to as large as possible (>400 nm)
- Simultaneously search for a technology suitable for the accurate and reproducible high-yield production of CM in large quantities

Fulfilling these two criteria a laser formed by a standard x-folded resonator [29] composed of chirped, mirrors, a broadband output coupler, and a pair of wedges for fine tuning the dispersion in the cavity was built. The major benefit of the prismless laser is the compactness and stability of the cavity. The generated spectrum has a 277 nm bandwidth at FWHM and with only 2 dB spectral modulation. In addition, the spectral bandwidth is ~380 nm at −10 dB below its maximum, which is suitable for phase stabilization and frequency metrology based on interference of second- and third-harmonic light [30, 31]. The schematic of the laser cavity is shown in Fig. 19.5a. The laser is pumped by a diode-pumped, frequency-doubled Nd:YVO4 laser (Verdi, Coherent Inc.). The thickness and the absorption coefficient of the Ti:sapphire crystal are 2.5 mm and 5.0 cm^{-1}, respectively. The radius of curvature of the concave mirrors is $r = -50$ mm. All-chirped mirrors in the cavity were designed for minimal fluctuations and manufactured by Layertec GmbH. The transmission of the output coupler is 10 %. A pair of thin fused silica wedges is inserted at the Brewster's angle for intracavity dispersion control. The prismless laser generates an average output power of 250 mW for 3.65 W pump power and 64 MHz repetition rate.

The spectrum generated from the oscillator and measured with an optical spectrum analyzer with single monochromator mode is shown in Fig. 19.5b in linear (green) as well as logarithmic representations (red). The bandwidth of the spectrum is 277 nm (141 THz) at FWHM. The fine spectral modulations at long wavelengths are caused by vapor absorption and/or the structure of the reflectivity spectrum of the chirped mirrors in the cavity. On the logarithmic scale, spectral components can be observed at ~625 nm and 1,005 nm at −10 dB below maximum. Although the chirped mirrors and the output coupler only support a spectrum from 700 to 900 nm, the generated spectrum from the oscillator extends beyond this region. This means that most of the light at the wings of the spectrum is not generated through lasing but by self-phase modulation in the crystal, a phenomenon

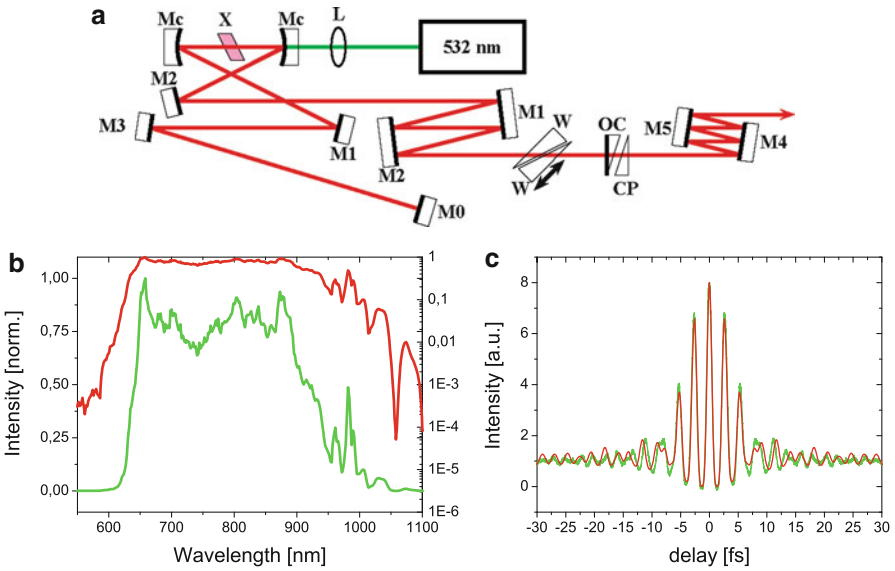

Fig. 19.5 *Ultrabroad bandwidth Ti:sapphire*. Schematic of prismless Ti:sapphire laser with extracavity dispersion control (**a**). *L* incoupling lens, *Mc* dichroic input coupler, *M1-5* dispersive mirrors, *W* wedge, *OC* output coupler, *CP* compensating plate. (**b**) Spectrum generated from the mirror-dispersion-controlled oscillator depicted on a logarithmic and linear scale. (**c**) Measured and reconstructed interferometric autocorrelation traces of the pulse. A phase-retrieval algorithm reveals a pulse width of 6.5 fs. The *red line* shows the retrieved IAC trace from the *Spider* measurement [23]

previously observed [32]. The output pulses are compressed by six reflections of the chirped mirrors, and the temporal characteristics of the pulses are measured using an interferometric autocorrelator designed for sub-10 fs pulse diagnostics (Femtometer, Femtolasers Produktions GmbH). The frequency-doubling crystal is a 10 μm thick BaB_2O_4 (BBO) crystal (type I, $\Theta = 29°$). Figure 19.5c shows the measured interferometric autocorrelation trace (IAC). The FWHM of the intensity envelope has been evaluated as 6.5 fs by using a phase-retrieval algorithm.

19.2.2.3 Ultrabroad Bandwidth Laser Sources with Modulations Below 3 dB

For UHR OCT imaging, a good compromise between high resolution and contrast has to be found. Especially the sharp spectral feature in the longer wavelength region is extreme prominent and would significantly impair OCT image quality. One possible solution to overcome these problems is the use of edge filters and to cut off this peak. Another possibility is to change the dispersion in the cavity. In a first trial, a slightly modified mirror arrangement with an edge filter could improve the spectral shape. An output power of 250 mW at 2.8 W pump power and a spectrum of 255 nm shown in Fig. 19.6a enabled 1.4 μm axial OCT resolution (Fig. 19.6b). Further investigations did not result in additional improvement neither

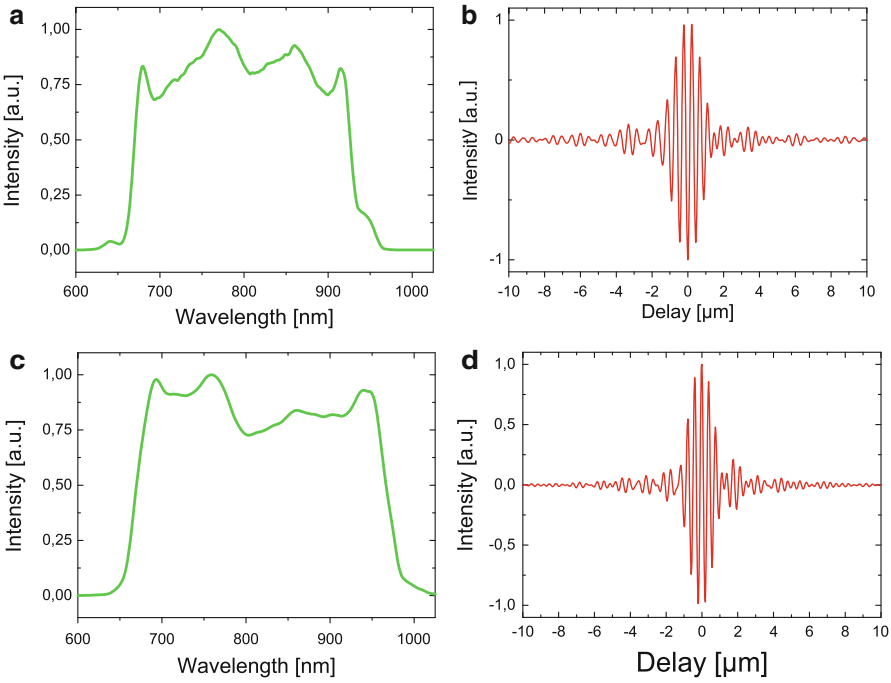

Fig. 19.6 *Ultrabroad bandwidth laser sources with modulations below 3 dB*. Typical output spectrum generated from the ultrabroad bandwidth all-chirped mirror oscillator with edge filter (**a**, 255 nm; **c**, 300 nm) and interference signal (**b**, **d**) corresponding to the spectrum resulting in a free-space axial resolution of 1.4 µm (**b**) and 1.3 µm (**d**), respectively

in terms of the spectral bandwidth or in the spectral shape. Therefore, ultrabroad bandwidth CMs were necessary. Insertion of one of the ultrabroad bandwidth CMs covering a wavelength range from ~600 to 1,000 nm allowed for a spectral bandwidth of 300 nm at FWHM with a nice spectral shape (Fig. 19.6c) enabling 1.3 µm axial OCT resolution (Fig. 19.6d). Careful balance of dispersion and reflectivity in the laser cavity plays a crucial role in the laser development. Oscillations in GDD and relative large losses in reflectivity produce large spectral ripples of more than 3 dB. Tilt and position of CMs have drastic effects and change the spectrum. By variation of the position of the CMs inside the laser cavity, the tilt can be changed. Hence, dispersion and reflectance characteristics can be improved and adapted to the demanded requirements. Slightly manufacturing errors in shifting the spectral wavelength of CMs can be balanced.

19.2.3 Low Pump Power Broad Bandwidth Laser Sources

State-of-the-art commercially available laser systems are producing sub-20 fs and sub-12 fs Ti:sapphire lasers for scientific applications (Femtolasers Produktions

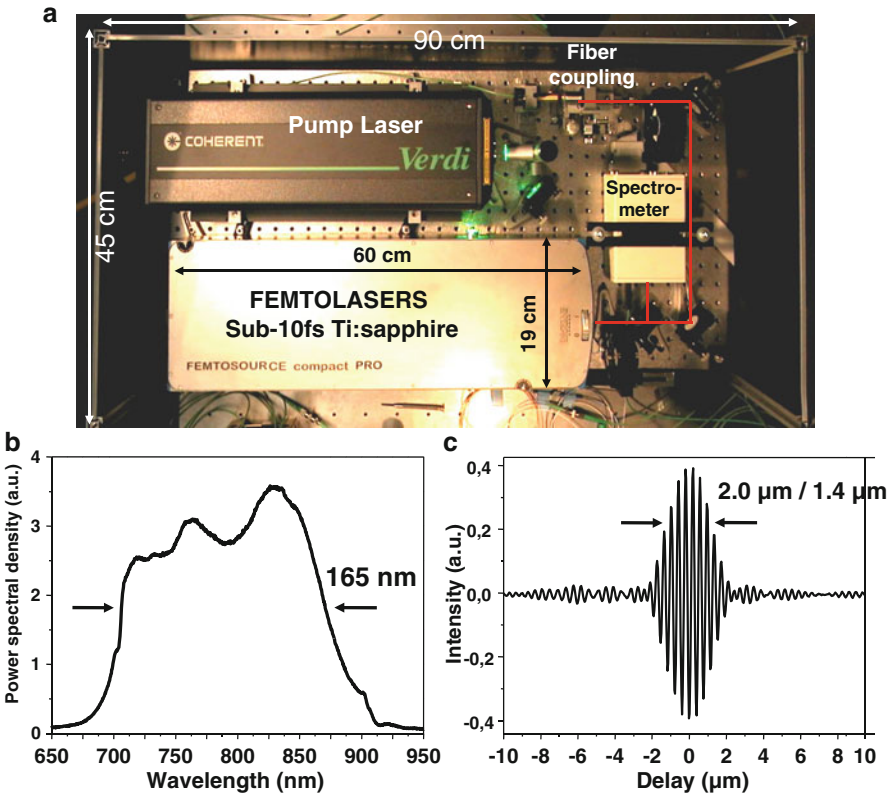

Fig. 19.7 *Ti:sapphire laser*. Schematic diagram (**a**) of a high power Ti:sapphire laser (FEMTOSOURCE COMPACT PRO, Femtolasers GmbH). Typical optical output power spectra of this Ti:sapphire laser (**b**) and corresponding interference signal (**c**) enabling a free-space axial resolution of 2 µm corresponding to 1.4 µm in biological tissue

GmbH). For a long time, the standard pump system for Ti:sapphire lasers has been the Argon:ion laser (cf. Fig. 19.7). This laser has an operating wavelength of 514 nm and suits the absorption maximum of Ti:sapphire. The Argon:ion laser, however, was expensive, bulky, and needed regular maintenance. These facts increased the complexity and susceptibility to faults. Nowadays, they are fully replaced by frequency-doubled diode-pumped lasers with neodymium as the active ion in a variety of hosts (YAG, YLF, etc.). These lasers operate at 532 nm. The pump sources are quite reliable, but bulky and extremely expensive. Since they are not operating at the absorption maximum of Ti:sapphire, they are less efficient. Nonetheless, they offer excellent beam quality and maintenance-free reliable operation. Clinical applications demand compact, user-friendly, cost-effective, and highly stable systems. Reducing the threshold of the laser system with newly developed low loss laser mirrors allows employment of cost-effective 1 W pump sources instead of expensive 5 W pump sources. A compact pump source in combination with an optimized cavity layout is

another prerequisite of increasing compactness and stability of the Ti:sapphire oscillator itself. This can be achieved with the elimination of prism pairs in the cavity, since chirped mirrors show a superior behavior in terms of performance as well as compactness and user-friendliness.

Development of state-of-the-art femtosecond laser technology that establishes a new generation of ultrabroad bandwidth, high-energy, compact, user-friendly light sources was achieved with a diode-pumped solid-state 1 W laser from Laser Quantum Ltd., namely, the *excel 1,000*. The *excel 1,000* was characterized in terms of its beam quality and stability. The *excel 1,000* was tested concerning its ability for pumping compact femtosecond Ti:sapphire oscillators. Nowadays the excel is a well established pump source for ultrabroad bandwidth Ti:sapphire lasers. For integration in a clinical viable system the laser has to meet some requirements concerning short- and long-term stability, reliability on a daily basis, and a reasonable price and size to transfer a high sophisticated ultrabroad bandwidth Ti:sapphire laser prototype from the optical bench to real-world applications.

The cavity of the compact, low-cost Ti:sapphire oscillator is a standard astigmatism compensated x-folded cavity with an incoupling lens with $f = 35$ mm, 50 mm folding mirrors, and a 3 mm thick Ti:sapphire laser crystal that has an absorption coefficient $\alpha = 5.0\ \mathrm{cm}^{-1}$ and where the pump source was implemented (cf. Fig. 19.8). Low-loss resonant dispersive "chirped" mirrors were designed to precisely compensate for second- and third-order dispersion of the laser crystal and air, keeping the reflectivity almost as high as for high-reflecting mirrors for a design bandwidth of about 200 nm. Two of these mirror pairs were implemented in the oscillator. The resonator is asymmetrical folded, and some mirrors are used in double pass for reducing the laser size. The laser can be mode locked without prisms. A compact low-cost frequency-doubled, diode-pumped Nd:vanadate laser has been used as a pump source, which emits as much as 1.5 W of pump power. The size of this pump source is 158 × 104 mm. The advantage of this prismless Ti:sapphire laser is that the cavity can be designed more compact and can act as a hands-off OCT laser source. Due to the compact size, the 1.5 W solid-state pump laser (158 × 104 × 45 mm) could be integrated into the resonator layout. The overall dimension of the setup is 500 × 200 mm including the pump laser. Kerr-lens mode-locking is starting by rapid translation of the end mirror which is mounted on a translation stage to induce intensity fluctuations. Due to the good beam quality of the pump source, the Ti:sapphire oscillator also shows satisfying beam quality in cw mode as well in the mode-locked regime. Since the laser beam has to be launched into a single-mode fiber to interface it to an OCT apparatus, good beam quality is an essential parameter for high-coupling efficiency and stable output power. The output power of the compact, low-cost Ti:sapphire laser was strongly dependent on the bandwidth of the laser and varied from 180 mW with 40 nm at full width at half maximum (FWHM) to 20 mW with 176 nm at FWHM [1, 33]. The cavity length varied between 1.8 and 2.4 m for fine tuning of the dispersion. This results in repetition rates between 62 and 83 MHz. The systems well-reproducible spectra and output power lead to high reliability on a day-to-day performance. Ex vivo OCT imaging was performed with the broadest possible bandwidth

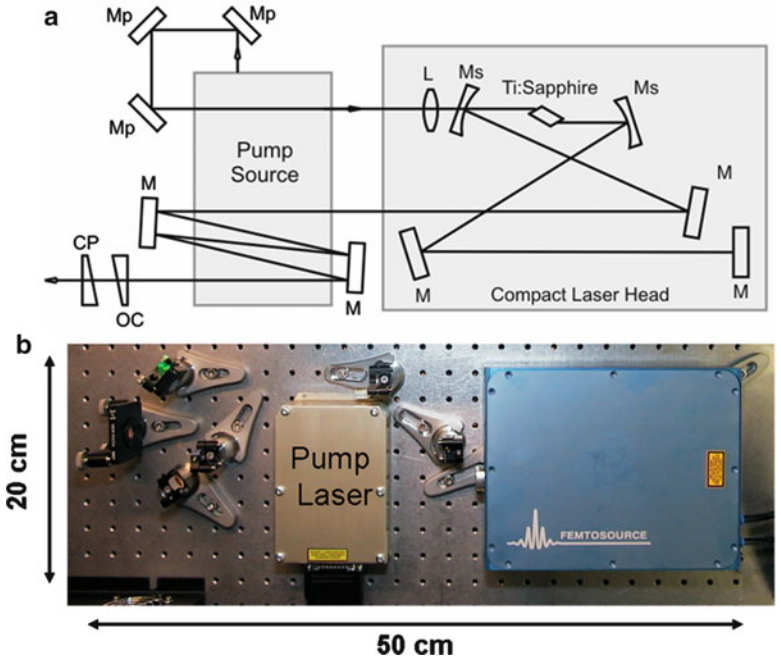

Fig. 19.8 *Low pump power broad bandwidth Ti:sapphire laser*. Schematic diagram (*top*) and a photograph (*bottom*) of the compact, low-cost Ti:sapphire laser. A commercially available compact (158 × 104 mm) 1.5 W pump source is used to pump a standard astigmatism compensated x-folded cavity. *Mp* pump mirror, *L* coupling lens, *Mc* 50 mm folding mirror, *M* mirror, *OC* output coupler, *CP* compensation plate [33]

(176 nm centered at 776 nm with 20 mW output power, cf. Fig. 19.9a, black line) enabling an axial resolution of 1.7 μm in free space corresponding to about 1.2 μm in tissue (cf. Fig. 19.9b). For ultrahigh resolution in vivo imaging in normals and patients, a less modulated, Gaussian-like spectrum with a bandwidth up to 135 nm at FWHM and 95 mW output power was used (Fig. 19.9a, gray line), enabling ∼3 μm axial resolution in the retina, similar to what has been achieved so far. The repetition rate of the compact low-cost Ti:sapphire laser was set to 72 MHz. The system shows extremely reproducible spectra, output power, and user-friendliness on a day-to-day performance. Stable operation for more than 12 h with less than 2 % power loss and less than 2–5 % loss in spectral bandwidth are usual.

Another demonstration of an ultralow-threshold Kerr-lens mode-locked Ti:sapphire laser pumped by the *excel 100* uses an extended cavity design shown in Fig. 19.10a [34]. The cavity is an astigmatically compensated, x-folded configuration with a 2 mm thick Ti:sapphire laser crystal. The focusing mirrors have 7.5-cm radii of curvature and transmit more than 95 % of the pump beam at 532 nm. The output coupler has a transmission of ∼1 % from 700 to 900 nm. All the mirrors are commercially available Bragg stacks with low dispersion. Because this laser uses commercially available mirrors and intracavity prisms rather than double-

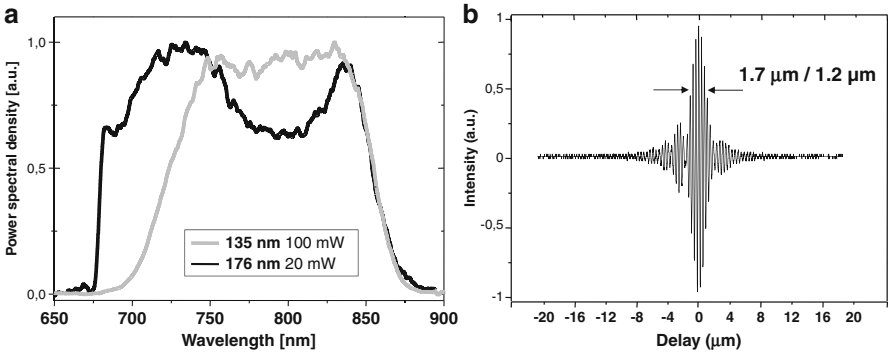

Fig. 19.9 *Specifications of a compact, low-cost Ti:sapphire laser*. Typical optical output power spectra of the compact, low-cost Ti:sapphire laser (*bottom*, *left*) and interference signal (*bottom*, *right*) corresponding to the spectrum indicated with the *solid black line* resulting a free-space axial resolution of 1.7 µm corresponding 1.2 µm in biological tissue [33]

chirped mirrors for dispersion compensation, third-order dispersion limits the pulse duration and bandwidth. Previous studies showed that third-order dispersion is minimized when the laser wavelength is shifted to longer wavelengths. A mirror set was chosen to shift the laser wavelength to be centered at approximately 840 nm. Intracavity dispersion compensation is accomplished with a pair of fused silica Brewster prisms separated by 45 cm. We tune the dispersion by varying prism insertion. Mode-locking thresholds as low as 156 mW were accomplished. Pulses with durations as short as 14 fs and bandwidths of 100 nm with output powers of ~15 mW at 50-MHz repetition rates were generated by only 200 mW of pump power (Fig. 19.10b, c).

Ultrastable diode-pumped, solid-state lasers with output powers from 2 up to 10 W are extremely expensive and dramatically increase the cost of a femtosecond Ti:sapphire laser. With pump power requirements of only 1–1.5 W, commercial available low-cost systems reduce the cost of a factor 5–6, but with still efficient output power for ultrahigh-resolution, spectroscopic OCT. The compact Ti:sapphire lasers presented here have sufficient output power and spectral bandwidth for ultrahigh-resolution and spectroscopic OCT. Total costs of the light source compared to commercial available state-of-the-art femtosecond Ti:sapphire laser could be reduced by a factor of 5–6 only by employing a 1.5 W pump source but achieving similar OCT performance as employing a 5 W single frequency-doubled, diode-pumped Nd:vanadate laser. This light source could be transferred from a laboratory prototype into the industrial environment. The result was a commercially available product from Femtolasers Produktions GmbH. This *Integral* poses an all-in-one system with integrated pump source, integrated diagnostics system, active stabilization of system parameters, >150 nm spectral bandwidth, >50 mW fiber-coupled output power, sealed cavity, low noise, and compact footprint (500 × 260 mm).

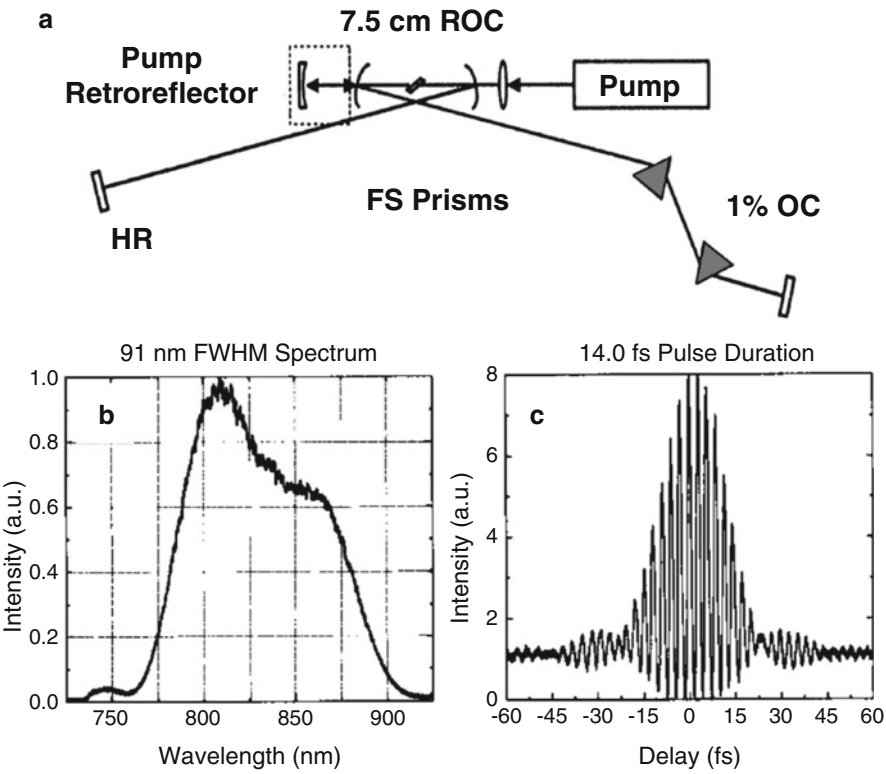

Fig. 19.10 *Ultralow-threshold Kerr-lens mode-locked Ti:sapphire laser*. (**a**) Schematic diagram of the ultralow-threshold Ti:sapphire laser. The pump lens has a 50 mm focal length, and the folding mirrors have 7.5-cm radii of curvature (*ROC*). The cavity is an astigmatically compensated x design, with arm lengths of 130 and 162 cm for the highly reflecting (*HR*) arm and the prism arm, respectively. A pair of fused silica (FS) prisms separated by 45 cm is used for compensating and tuning intracavity dispersion. (**b**) Output spectrum at 91 nm FWHM. (**c**) Corresponding interferometric autocorrelation measurement of a 14.0 fs pulse (assuming a sech2 fit) generated with 200 mW of pump power [34]

19.2.3.1 Ultrabroad Bandwidth Compact Laser Sources

Several approaches can be taken in improving solid-state laser sources for industrial and clinical applications. First, the length of the laser resonator can be reduced. The system can be realized on a smaller footprint with less mechanical components, but with a higher repetition rate at the expense of lower peak power. Second, the arms of the resonator can be folded more effectively. The all-chirped mirror designs with ultrabroad bandwidths facilitate this development of a compact user-friendly and extremely stable platform.

The technology of an ultrabroad bandwidth Ti:Sapphire laser could be transferred into a compact low pump power (<2 W) ultrastable design with more than 200 nm at FWHM. Pumping with an 1.9 W Nd:YVO_4 laser (*excel 1,000*, Laser Quantum Ltd.) resulted in a mode-locked output power of 95 mW and a bandwidth

of 240 nm at FWHM. With a cavity length of 2 m, a repetition rate of 75 MHz could be realized. The fiber output power was 56 mW. The resonator consisted of a standard x-folded cavity with a double pass in the long arm, a pair of wedges in the long arm, a 3 mm crystal, and a 5 % standard output coupler. Dispersive mirrors spanning from 640 to 920 nm were used in the cavity. This laser also enables ~1 μm axial OCT resolution in tissue and offers sufficient performance for real-time in vivo clinical UHR OCT applications.

Reliable mirror manufacturing technology combined with exact dispersion compensation in the cavity achieved with chirped mirrors and a pair of wedges reduces the overall modulations of the dispersion in the wavelength range between 640 and 950 nm to less than 70 fs^2 and thus permits generation of a smooth almost Gaussian-shaped output spectrum. Compared to state-of-the-art commercially available Ti:sapphire lasers with 140–160 nm bandwidth (FWHM), the use of this prototype Ti:sapphire laser results in twofold improvement of OCT axial resolution. With a slightly modified and reoptimized laser setup but almost the same parameters compared to the high-power all-chirped mirrors oscillator, an all-chirped mirrors oscillator was realized with a 1.8 W *excel* with the compact footprint of about 550 × 220 mm for the whole setup. Only the dispersive mirrors were adapted to the low pump power. With a repetition rate of 75 MHz, the mode-locked output power was in the range between 50 and 90 mW with 1–5 % out coupling efficiency. In the best case, 56 mW directly out of the fiber were achieved with a spectral bandwidth of 260 nm at FWHM. This bandwidth of 260 nm at 775 nm resulted in an axial resolution of 1.3 μm in air which corresponds to sub-μm resolution in biological tissue. Additional experiments with higher repetition rates resulted in no further improvements. These systems exhibited a much higher mode-locking threshold due to the reduced peak power. Bandwidths up to 300 nm at FWHM could be realized with low-loss RDMs (resonant dispersive mirrors) at repetition rates up to 200 MHz (Fig. 19.11). The system consists of seven chirped mirrors, a pair of wedges, and an output coupler. High mirror quality with low scattering is one important criteria to succeed. Otherwise, reliable operation at higher repetition rates might become more sensitive. The starting mechanism could become more difficult due to the low peak power and makes effective dispersion and reflectivity management essential. About 2.5 W of pump threshold with 200 nm and an output power of about 80 mW could be realized at the low pump power end and on the high pump power side 315 nm with 650 mW at 5.4 W pump power with repetition rates ranging between 150 and 200 MHz.

19.3 Cr^{3+}:LiCAF Laser Development

Diode-pumped, mode-locked colquiriite sources have been demonstrated to generate very broad spectra with bandwidth exceeding 150 nm and output powers on the order of tens of mW [4, 35, 36]. The Cr^{3+}:LiCAF laser developed for UHR OCT was pumped by the orthogonally polarized beams from two broad-area laser diodes (Coherent S-670-500C) with 500 mW optical power, each in an elliptical

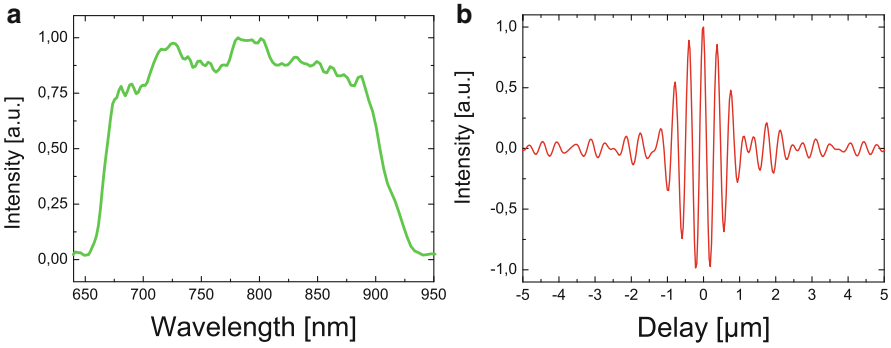

Fig. 19.11 *Ultrabroad bandwidth compact laser source*. Typical output spectrum of 300 nm (FWHM) generated from the compact *excel 100 l* (*1.5 W*) pumped ultrabroad bandwidth all-chirped mirror oscillator with mirrors with enhance bandwidth and reflectance (**a**) and interference signal (**b**) corresponding to the spectrum resulting in a free-space axial resolution of 1.3 μm

multimode beam. The emitter size of the diodes was 1 × 100 μm. Along the fast-diverging axis, the beam was close to diffraction limit, whereas it was multimode along the slow-diverging axis with a beam propagation M^2 factor of 15–18. Along the fast axis direction, a cylindrical fiber-collimating lens reduced the beam divergence. The collimation resulted in an elliptical pump beam with an aspect ratio of slow to fast axis about 4, where the ellipticity did not change as the beam is transformed by spherical optics. As a result of the collimation, the Rayleigh distances in both planes of the beam are equal, and they could be mode-matched simultaneously. The Cr^{3+}:LiCAF laser crystal was 2 mm long and had a nominal 10 % doping concentration that results in an absorption length of 0.7 mm for the pump light. High doping increased the small signal gain in a diode-pumped Cr^{3+}:LiCAF laser, where reabsorption did not affect the laser performance. The Rayleigh range of the pump beam was matched to half the absorption length by focusing the beam to a radius of 30 × 8 μm in the slow and fast axis, respectively. This was accomplished using a telescope consisting of achromatic doublet lenses of 100 mm and 50 mm focal lengths. The absorbed pump power was approximately 850 mW.

A schematic of the laser setup is shown in Fig. 19.12a. The laser was made compact by increasing the repetition rate to 165 MHz and by folding the z-design cavity twice more than previously reported layouts. The resonator eigenmode was focused into the laser crystal by two mirrors with 75 mm radius of curvature. Using this design, the laser size is 20 × 30 cm. The laser, the pump diodes and optics, and the fiber-coupling unit were integrated on a 30 × 60 cm optical board. In continuous-wave operation, the laser emitted up to 90 mW of power through a 0.8 % output coupler. The short absorption length in the highly Cr-doped crystal resulted in a high inversion density leading to strong gain guiding, which enhances the effect of the Kerr lens and the fast saturable absorber action [37]. The strongest Kerr-lensing occurred for resonator settings that are beyond the stability limits of the unpumped resonator without gain guiding. In this way, it was possible to exploit pure soft-aperture Kerr-lens modelocking in this diode-pumped laser, thus resulting

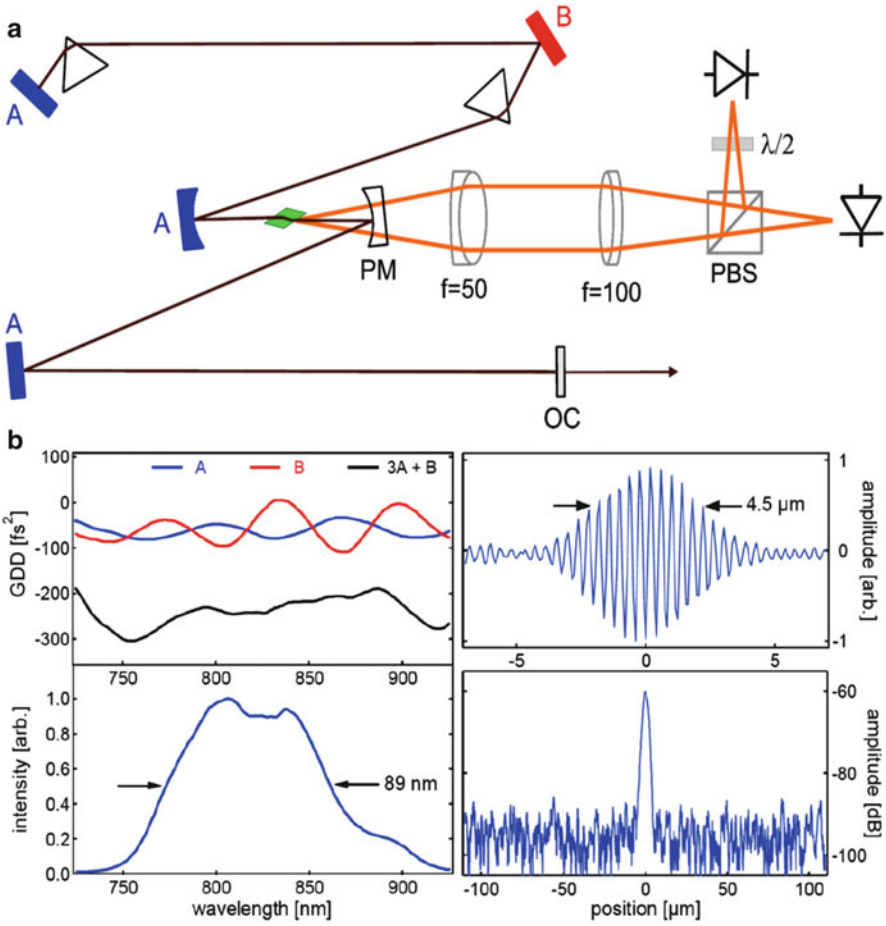

Fig. 19.12 *Broad bandwidth diode-pumped broadband Cr^{3+}:LiCAF laser*. (**a**) Schematic of the laser setup. *Blue* and *red* mirrors A and B are double-chirped mirrors (*DCM*), *PBS* polarizing beam splitter, *OC* output coupler, and *PM* pump mirror, *λ/2* half waveplate. The resolution is 4.5 µm in air, which corresponds to 3.4 µm in biological tissue [36]

in stable pulsed operation. The laser was not self-starting, but mode-locked operation can be started by mechanically perturbing one of the laser mirrors, such as the output coupler. This starting mechanism was similar to that used in Ti:sapphire lasers. The dispersion compensation of the laser was carried out by a combination of double-chirped mirrors (DCMs), generating sufficient negative second-order dispersion, and a fused silica prism sequence for adjusting the second- and third-order dispersion (cf. Fig. 19.12b). Except for the pump mirror and the output coupler, which have low dispersion over the lasing bandwidth, all

mirrors are dispersion-compensating DCMs. The prisms are essential for higher-order dispersion compensation.

The dispersion of the mirrors as measured by white light interferometry is shown in Fig. 19.12b (top left). Mirror A has a dispersion oscillation magnitude of 45 fs^2, whereas oscillations of mirror B have a magnitude of 110 fs^2, with the oscillation out of phase with mirror A's oscillation. The dispersion of a combination of 3:1 reflections on the two different mirror sets is also shown in Fig. 19.12b (top left). Between 750 and 900 nm wavelengths, a near perfect cancellation of dispersion oscillations can be achieved. For practical reasons, 5:2 reflections on mirrors of type A and B are used instead of the optimum 6:2. This combination results in sufficiently flat dispersion characteristics so that broadband emission is obtained with a smooth mode-locked spectrum. The mode-locked spectrum in Fig. 19.12b (bottom left) is centered at 815 nm and has a modulation-free, nearly Gaussian shape with a full width at half maximum bandwidth of 89 nm. The output power of the mode-locked laser is 37 mW. The bandwidth is limited by higher-order dispersion terms of the intracavity prisms. The Cr^{3+}:LiCAF gain bandwidth enables the generation of an output bandwidth of well-above 130 nm. With further optimized DCM designs, which have more accurate dispersion compensation, prismless operation with broader bandwidths is achievable. The interferometric point spread function of the ophthalmic imaging system, shown in Fig. 19.12b top and bottom right, is determined by a calibrated measurement of the reflection from a mirror in the sample arm. The small asymmetry in the point spread function (PSF) is probably the result of wavelength dependence in the split ratio of the fiber couplers. The resolution is 4.5 μm in air, which corresponds to 3.4 μm in tissue.

19.4 Cr^{4+}:Forsterite Laser Development

A self-phase-modulated KLM Cr:forsterite laser has been used for in vivo OCT imaging in nontransparent tissues with 6 μm axial resolution [13]. Recent efforts were focused on developing even broader bandwidth light sources in the 1,300 nm wavelength range permitting OCT micrometer-scale resolution along with up to 2 mm penetration depth. A laser spectrum covering the 1,230–1,580 nm wavelength region with an optical bandwidth of 250 nm (FWHM) was generated directly out of an all-solid-state Cr:forsterite laser [38, 39]. A schematic of the laser is shown in Fig. 19.13a. The laser used a standard z-fold cavity design with 10-cm radius-of-curvature focusing mirrors. The Cr:forsterite crystal was a 5 mm × 5 mm × 5 mm Brewster cut crystal with an absorption coefficient of 2.4 cm^{-1} and was cooled to 263 K. A diode-pumped Nd:YAG laser was used as the pump, along with an optical isolator to prevent feedback. All mirrors in the cavity were double-chirped mirrors, except for the output coupler. To start mode locking, the prisms had to be scanned slightly. The beam path was enclosed by Plexiglas tubes, and the cavity was purged by fried nitrogen to avoid loss and dispersion from the water absorption band at 1.45 μm.

Since Cr:forsterite is a low-gain material, the mirrors must have high reflectivity and low loss. The reflectivity of the DCM's is greater than 0.998 from 1.1 to

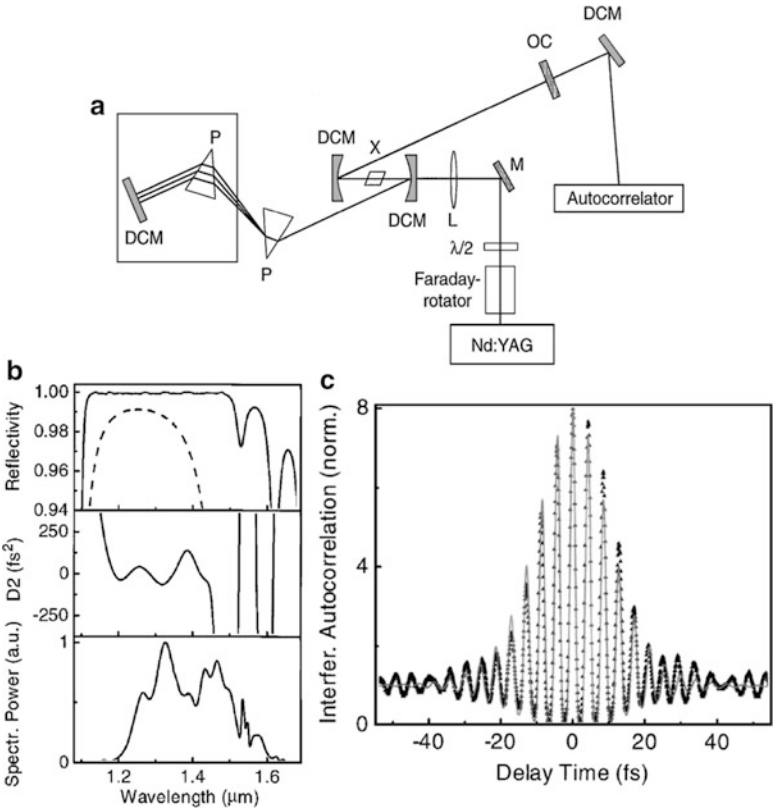

Fig. 19.13 *All-solid-state Cr:forsterite laser*. (**a**) Cr:forsterite laser with double-chirped mirrors (*DCM's*): *P's* PBH71 prisms, *X* crystal, *OC* output-coupling mirror, *L* focusing lens, *M* standard dielectric mirror, and l/2 half waveplate. (c) Interferometric autocorrelation measurement (*triangles*) and sech^2 fit assuming a 14 fs pulse duration [38]

1.5 mm, resulting in a bandwidth of 400 nm, as shown in Fig. 19.13b (top). At shorter wavelengths of <1.10 μm, the reflectivity decreases rapidly, permitting high transmission of the pump beam at 1.064 mm. To increase the gain of the Cr:forsterite, the crystal was cooled to 263 K. The reflectivity of the output-coupling mirror was centered at 1.25 μm and is greater than 0.98 over a 210 nm bandwidth. The pump thresholds for cw operation and Kerr-lens modelocking were 800 mW and 4 W, respectively. At 6 W pump power, the laser had an output power of 80 mW mode-locked and 100 mW cw. Figure 19.13b shows a comparison of the total cavity dispersion (middle) and the laser output spectrum (bottom). The DCM's in combination with the PBH71 prisms balance the dispersion over almost 300 nm. The laser spectrum spans wavelengths from 1,230 to 1,580 nm. The peaks in the output spectrum correspond with regions of net

negative intracavity dispersion caused by the oscillations in the D2 of the DCM's. Figure 19.13c shows an interferometric autocorrelation of the laser output. The pulse duration is 14 fs with a sech^2 fit. This record pulse duration was achieved by use of specially designed DCM's for improved intracavity dispersion compensation in the 1.3 μm wavelength regime.

A compact, broadband prismless Cr^{4+}:forsterite laser was next constructed for use in clinical investigations. The laser was pumped with a compact Nd:YAG fiber laser at 1,064 nm, and the oscillator utilized only double-chirped mirrors to compensate intracavity dispersion. Figure 19.14a presents the system schematic for the laser. An x-cavity design was used for compactness, and the entire laser was

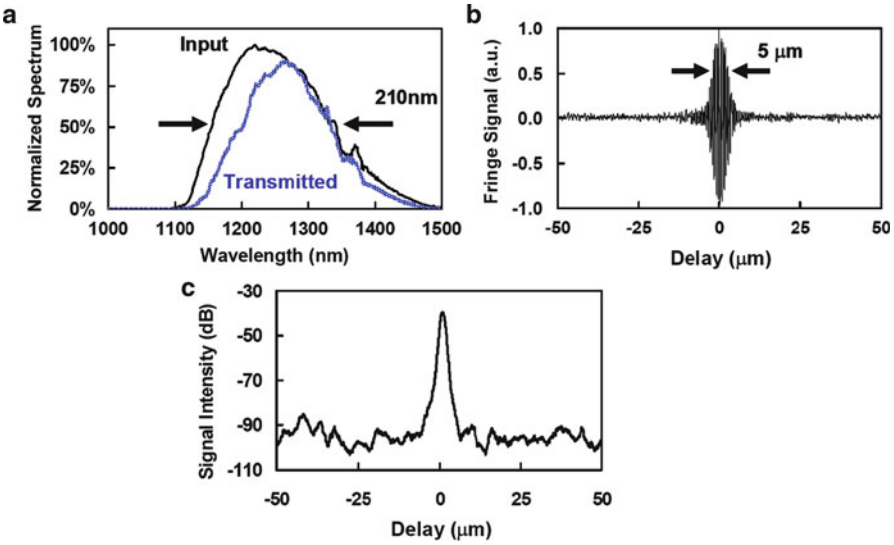

Fig. 19.15 *All-solid-state Cr:forsterite laser for ultrahigh-resolution OCT*. (**a**) Optical bandwidth of the Cr^{4+}:forsterite light source at the input to the OCT system (*black*) and transmitted through to the system (*blue*) enabling a threefold improvement in axial image resolution over standard endoscopic OCT systems using a superluminescent diode light source, (**b**) measured axial resolution of 5 μm in air, corresponding to 3.7 μm resolution in tissue, and (**c**) logarithmic point spread function shows low sidelobes in the point spread function [40]

built on a 40 cm × 60 cm breadboard. To provide optimal bandwidth for OCT imaging, the laser was coupled into a highly nonlinear Germanium-doped fiber, which resulted in spectral broadening to more than 200 nm. Figure 19.14b shows a photograph of the entire laser packaged for use outside the laboratory. The system produced fiber-coupled output power of 50 mW and bandwidth of 210 nm, which resulted in axial image resolution of 3.7 μm and system sensitivities of 102 dB for 10 mW sample power. Figure 19.15a shows the optical spectrum generated by the Cr^{4+}:forsterite laser and nonlinear fiber. Due to bandwidth limitations in the optical circulator, shorter wavelengths were attenuated and the transmitted spectrum was reduced to 150 nm bandwidth (also shown). The measured axial point spread function shown in Fig. 19.15b has a resolution of 5 μm in air, close to the calculated theoretical value of 4.6 μm for the transmitted bandwidth. This corresponds to an axial resolution of ∼3.7 μm in tissue, assuming an index of refraction of ∼1.37, and is a threefold improvement in resolution when compared to previous endoscopic OCT systems. Using the broadband Cr^{4+}:forsterite laser, in vivo ultrahigh-resolution endoscopic imaging of the rabbit gastrointestinal tract was demonstrated [40]. Human clinical investigations in the gastrointestinal tract were subsequently performed using this ultrahigh-resolution OCT system [41]. In a study of patients previously diagnosed with Barrett's esophagus, UHR OCT provided enhanced visualization of tissue architecture in Barrett's, dysplasia, and adenocarcinoma compared to prior standard resolution systems.

19.5 Cr^{4+}:YAG Laser Development

Mode-locked solid-state lasers are capable of generating ultrashort optical pulses with broad spectra and high peak intensities. Cr^{4+}:YAG lasers have the ability to produce such pulses in the wavelength range from 1,300 to 1,600 nm. These lasers operate at room temperature, do not require a vacuum, and have larger gain bandwidths than Er-doped fiber lasers. Ultrafast optical pulses shorter than 20 fs with 400-mW average power at a 110-MHz repetition rate have been generated by a Cr^{4+}:YAG laser with only double-chirped mirrors for dispersion compensation [42]. The corresponding pulse spectrum has a peak intensity at 1,450 nm and extends from 1,310 to 1,500 nm full width at half maximum (FWHM). These pulses, which are believed to be the shortest generated to date from a Cr^{4+}:YAG laser, are only four optical cycles within the FWHM intensity width. Figure 19.16a shows the schematic of the z-fold laser cavity. The laser crystal is 2 cm long with 3 mm diameter Brewster cut rod. Pump light at 1,064 nm with 11 W from a Nd:YVO_4 laser is focused by a 10 cm focal length lens in the crystal. The

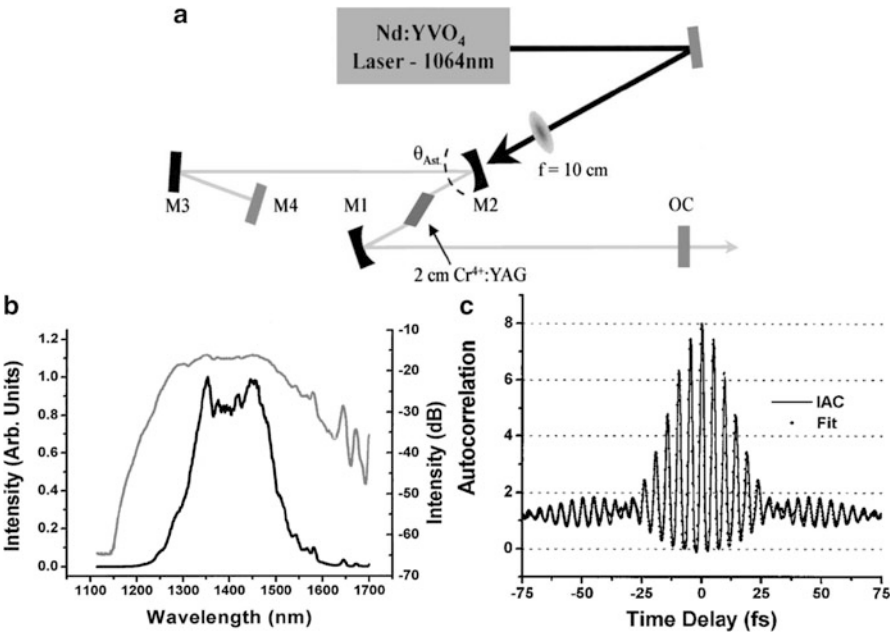

Fig. 19.16 *Broad bandwidth prismless Cr^{4+}:YAG laser*. (**b**) Optical power spectrum of a Cr^{4+}:YAG pulse. The *darker curve* corresponds to a linear scale (left-hand axis) and the *lighter curve* corresponds to a logarithmic scale (right-hand axis). The FWHM is 190 nm, with a peak at 1,450 nm. (**c**) Measured autocorrelation function from an interferometric two-photon absorption autocorrelator (IAC) and fit by a pulse-retrieval algorithm. A pulse width of 19.5 fs is calculated by the pulse-retrieval algorithm, 18.3 fs by assumption of sech-shaped pulses, and 17.0 fs by assumption of Gaussian-shaped pulses [42]

latter one is cooled to 13 °C. All mirrors are double-chirped mirrors except one unchirped quarter-wave-stack high reflector. Mode-locking was initiated by tapping one of the end mirrors. The average power of the 110 MHz pulse train was 200-400 mW, depending on the alignment, for 9 W of absorbed pump. Water vapor in air introduced intracavity GDD and loss through a series of absorption lines from 1,300 to 1,500 nm. To remove this water vapor, the optical path was closed and purged with dry nitrogen gas. An example of the mode-locked pulse spectrum, measured with a calibrated optical spectrum analyzer, is shown on both linear and log scales in Fig. 19.16b. Significant spectrum was present above the noise floor within the wavelength range from 1,140 to 1,700 nm (the optical spectrum analyzer used has a long-wavelength limit of 1,700 nm) and had a full width at half maximum (FWHM) of 190 nm, from 1,310 to 1,500 nm. The spectrum was smooth, with a relatively flat top from 1,340 to 1,470 nm. The output coupler, which rolls off significantly at wavelengths smaller than 1,350 nm, enhanced the output spectrum at shorter wavelengths. The pulse width was measured by fringe-resolved autocorrelation. An autocorrelation trace is shown in Fig. 19.16c. The pulse width is estimated to be 18.3 fs for sech-shaped and 17.0 fs for Gaussian-shaped pulses. The retrieved pulse-intensity envelope had a width of 19.5 fs. A Fourier transform of the optical spectrum, assuming a flat phase profile, indicated a bandwidth-limited pulse width of 17.5 fs.

19.6 Supercontinuum Light Source Development

Spectra far broader than one optical octave can be produced via nonlinear propagation of laser pulses having only moderate energies of a few nJ in microstructured fibers. Photonic crystal fibers enable an emerging class of light sources emitting low time coherence but high space coherent light. Due to the geometry of these fibers, the cross section of the fundamental mode is unusually small, which enhances the peak power and thus nonlinearity [14, 15]. At the same time, the fiber dispersion can be engineered to avoid fast temporal spreading. Hence, photonic crystals offer many extraordinary features as easy dispersion management, single-mode behavior over many wavelengths, and useful nonlinear properties. They can easily be tailored for different needs with spectra at different wavelengths spanning several octaves. These spectral widths would never be accessible directly from a laser oscillator because it exceeds the fluorescence bandwidth of the active ions. Nevertheless, in order to avoid an excessively strong spectral modulation (inherent to the spectral broadening process), only moderated spectral broadening should result from the nonlinear fiber propagation, i.e., the initial bandwidth of the pulses emerging from the oscillator should be as broad as possible. Research in the field of photonic crystals was stimulated by the prediction of a photonic bandgap analogous to electronic bandgaps in semiconductors. Initially, the photonic bandgap was the only guiding mechanism considered for this new class of optical fibers. Now devices can be made by microstructuring and including air holes into the fiber applying the principle of total internal reflection.

19.6.1 Microstructured Fibers

The first demonstration of microstructured fibers (MFs) goes back to the 1970s [43]. Since that time, the technology of MFs has matured tremendously, especially during the last decade. Precise control of the fiber drawing process allows for production of a great variety of complex structures. A typical MF has a 2D cross-sectional structure with a solid pure silica core region providing very low losses at high power and temperature levels. It is surrounded by an array of microscopic air holes running along their entire length. These holes effectively lower the index of refraction, creating a step-index optical fiber and can vary according to the application. The large refractive-index step between silica and air allows light to be concentrated into a very small area, resulting in enhanced nonlinear effects. Moreover, because of the large waveguide contribution to their group-velocity dispersion, MFs can exhibit very unusual chromatic dispersion characteristics. They behave in many ways like standard step-index fibers (which are typically made of germanium-doped raised-index core surrounded by a pure silica cladding), but have a number of advantages.

The mode confinement is introduced by an air-hole structure which contains the beam by the strong index step between the silica core, typically between 1.5 and 4.0 μm, and the silica/air surroundings (size of structure elements is smaller than the guided wavelengths). Designers can manipulate the dispersion characteristics of MFs to create fibers having zero, low, or anomalous dispersion at visible wavelengths. The design flexibility is very large, and the fibers can be manipulated by

- Variation of dispersion
- Arrangement of air holes – many different air hole patterns may be applied
- Size of holes
- Nonlinearities
- Adjusting the effective area of the propagating modes

Although there has been tremendous progress in the fabrication of MFs in the last few years concerning loss, stability, and noise, they are still far away from being comparable with solid-state lasers. High-nonlinearity, air-silica microstructure fibers [14] or tapered fibers [15] have been used to generate an extremely broadband continuum using low energy femtosecond pulses. In the latter approach, a standard single-mode fiber is heated and then lengthened. The light is initially guided inside the fiber core, but in the tapered region, the light propagates through the cladding. As in the air hole fibers, the change of the index of refraction between the light-guiding region, the cladding in the tapered fibers, and the surrounding region, the air, is high. Depending on the cladding diameter, the zero-dispersion wavelength can be shifted. Both the air-hole fiber and the tapered fiber have been studied to find out optimum conditions for broadband continuum generation with minimum noise.

19.6.1.1 Generation of Super Continuum

One of the first applications of MFs has been supercontinuum generation (SC). Supercontinuum is a broadband coherent light source [44] that finds numerous applications in the fields of telecommunication, optical metrology, spectroscopy, and medical imaging. As we will discuss later in detail, the ultrabroad bandwidth

spectrum of a supercontinuum allows for submicron resolution in OCT [45–47]. One crucial point in this supercontinuum generation is the tight confinement. The mode can be confined into a small area, thus enhancing the strength of nonlinear processes that are responsible for supercontinuum generation. Mechanically, robust MFs with extremely small core size down to 1 μm can be fabricated.

Mechanisms leading to supercontinuum generation depend on both the parameters of the input pulses:

- Pulse duration
- Peak power
- Center wavelength

And the parameters of the MF:

- Dispersion profile
- Effective modal area
- Birefringence

These mechanisms include:

- Self-phase modulation (SPM)
- Cross-phase modulation (XPM)
- Four-wave mixing (FWM)
- Stimulated Raman scattering (SRS)

Fiber broadening in highly nonlinear microstructure fiber generating extremely broad bandwidth supercontinuum ranging from the visible to the near infrared by using femtosecond pulses is quite well explored. One reason lies in the waveguide dispersion characteristics of the fibers which shift the zero-dispersion wavelength to shorter wavelengths, and the small core diameters, which provide tight mode confinement. Since there was a rapid development in the design and fabrication of a variety of MFs in the last few years, broad bandwidth light generation from nonlinear optical fibers has also become an attractive method for UHR OCT. High-resolution OCT was achieved by broad bandwidth light generation with a highly nonlinear material-doped optical fiber [48]. Broad bandwidth light was generated at 1.55 μm by stimulated Raman scattering using an erbium-doped fiber [49]. Unfortunately, the generated light exhibited significant white amplitude noise. UHR OCT could be demonstrated achieving 2.5 μm axial resolution using a microstructure fiber [50]. Nevertheless, most of these systems exhibit highly unstable complicated fine structures which are extremely sensitive to the input pulse energy, which results in a poor signal-to-noise ratio (SNR) limiting their application in OCT. The instabilities [51, 52] are due to the fluctuations of the pump source and noise which is amplified during super continuum generation. Recently, it was shown that broad bandwidth light can be generated by coupling a fs Ti:sapphire laser into a single-mode optical fiber [53].

Supercontinuum is the result of a complex interplay of the nonlinear effects described above. The superposition of all these processes leads to its complex spectral shape. Supercontinuum generation by pumping a highly nonlinear fiber with femtosecond laser pulses is only efficient in the vicinity of the zero-dispersion wavelength (ZDW) of the fiber [44, 54] or in the normal dispersion area [55], since high dispersion value tends to limit the magnitude of the nonlinear processes. Supercontinuum generation in the vicinity of the ZDW usually generate very

broad spectra. Since the SC is generated by the excitation of unstable solitons, as described in Genty G., M. Lehtonen, H. Ludvigsen, J. Broeng, and M. Kaivola, *Spectral broadening of femtosecond pulses into continuum radiation in microstructured fibers*, Optics Express, 2002, **10**, 1083–1098, these light sources show large spectral modulation and a lot of noise. The anomalous dispersion region can generate a broad optical spectrum, but a complex interplay of nonlinear effects in this dispersion regime results in instabilities of the supercontinuum generation. Supercontinuum generation in the normal dispersion regime is mainly due to self-phase modulation and therefore creates nice and stable spectra. Investigation showed that the dynamic range of a broad bandwidth light source from a single-mode fiber can be 15 dB higher than with an MF source. No significant intensity noise amplification can be observed in these studies [47]. Nevertheless, SC based on SPM in conventional single-mode fibers generally results in small bandwidths with center wavelengths close to the pump wavelength [42]. Other attempts have been undertaken by pumping a PCF with two closely space ZDWs emitting at 800 nm and 1,300 nm [48, 56]. Although the SC generation of this light source is mainly due to SPM, the spectrum shows spectral modulations. Also a broad bandwidth SC light source with high-power, low-noise, and smooth spectrum centered at 1.15 μm was reported. The SC was generated by SPM using a compact 1.059 μm femtosecond laser pumping a novel photonic crystal fiber, which has a convex dispersion profile with no zero-dispersion wavelength W [50].

In addition, various MFs were employed for the investigation of broadband light generation with different Ti:sapphire oscillators. Light sources based on external broadening using MFs have been developed and utilized for UHR OCT. The fibers varied in terms of length (2–500 mm) and mode field diameter (1–2.4 μm) corresponding to zero-dispersion wavelengths between 650 and 950 nm. In fibers with small core diameter, light can be confined in a small area with high intensity, which increases the nonlinear broadening. Short fibers offered a much smoother spectrum than longer ones. The spectrum seemed to be less modulated, and also the gaps in the spectra could be removed. The stability increased also with the decrease in fiber length, since the bending of the fiber was not so dominant. In general, fibers from Crystal Fiber showed a higher efficiency than Bath fibers. About 800 mW before the objective resulted in 160 mW out of the fiber with 2 μm core diameter.

For all experiments, the laser beam was launched into the different MFs after passing a mirror compressor (cf. Fig. 19.17). Additionally, quarter-wave and/or half waveplates were used to change and adapt the polarization and shape the output spectrum. The focus length of the coupling lens was 3 mm, and the beam diameter was 2 mm before the lens. By matching the numerical aperture of the coupling system with that of the MF, up to 1.2 W linearly polarized pump radiation was launched into the different fibers. The broadband output of light was collimated by a 20× standard microscope objective and a numerical aperture of 0.8. The output spectrum is broadened gradually as the laser intensity increases to a certain threshold. Further increase of the input power only enhances modulations and the fine structure of the output spectrum.

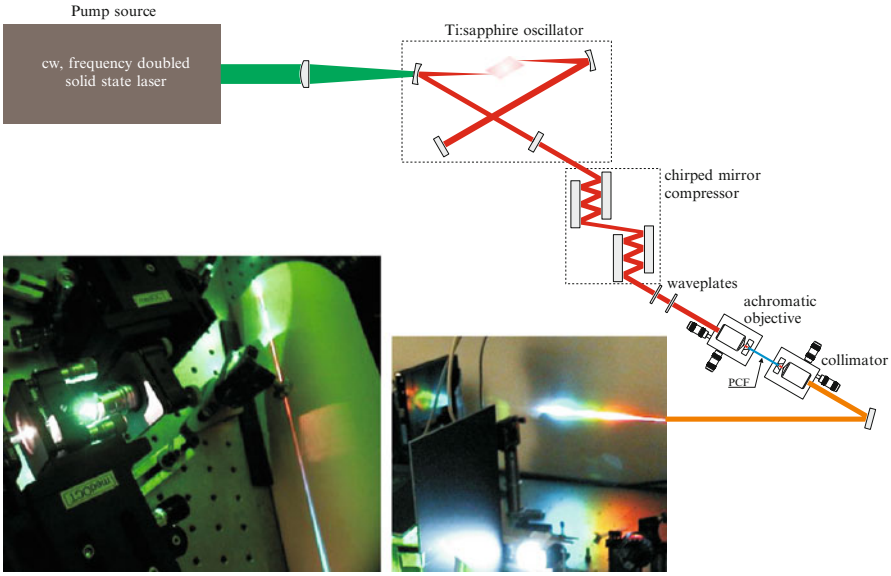

Fig. 19.17 *Supercontinuum light source setup*. The Ti:sapphire laser output is pre-compensated, polarization controlled, and then launched into a microstructured fiber

Different attempts concerning:

1. Ti:sapphire operation at different wavelengths, energies, and pulse durations (bandwidths)
2. Prechirp for precompensation: 16–28 bounces of ultrabroad bandwidth mirrors with $\sim$50 fs^2 GVD per bounce
3. Pair of wedges for fine tuning of the dispersion
4. Linear polarization control with $\lambda/2$ – waveplate
5. Rotational polarization control with $\lambda/4$ – waveplate
6. Achromatic lens or microscope objective as incoupling device
7. Fiber length
8. Core diameter determining the zero-dispersion wavelength
9. Short-/long-wavelength absorptive edge filters – to shape and cut the spectrum

Depending on the different input parameters, spectra in the visible and NIR could be achieved varying in the center frequency, bandwidth, spectral shape, output power, and noise behavior. Nevertheless, several parameters had to be watched very carefully for all these systems, when coupling the light into the microstructured fibers:

1. Exact overlap of the pump focus with the fiber core
2. Maximum energy applied on the fiber surface
3. Clean environment
4. Feedback from the fiber surface to the laser (cleaved angle/faraday rotator)
5. Overlap of the beam divergence at the waist to the acceptance angle of the fiber
6. Dispersion of the fiber and accurate precompensation to prevent pulse broadening and reduction in pulse energy

The setup (cf. Fig. 19.17) provided highly reproducible results (fibers have been used for several weeks without the need of realignment) without protective housing. The objective can be aligned by a 3-D stage with piezo driver (Thorlabs, PI) and actuators (manual, 2 mm; piezo, 150 μm). The influence of the NA of the focusing objective on the throughput was investigated. Several microscope objectives were introduced into the system, and an NA of more than 0.4 seemed to be appropriate for the setup. Even the higher dispersion introduced by the huge amount of glass and the larger chromatic aberrations were less significant than the stronger focusing. Standard microscope objectives with 20–40× magnification could be used as well as highly sophisticated achromatic lenses for fs pulses. Dispersion control should provide shortest pulses in any case and therefore highest energies in the active part of the fiber.

Commercial MFs obviously have a higher destruction threshold, better symmetry, and higher mechanical stability. Additionally, the zero-dispersion wavelength is better reproducible. A reliable quality over the whole fiber is guaranteed. In principle, the commercial fibers showed comparable behavior than the Bath fibers, though the stability was higher. The incident light was precompressed, and the polarization was controlled by half and quarter waveplates. Stable broadening up to 155 nm could be achieved in the yellow. Preliminary results in a free-space OCT system were acquired with a MF (2 μm core diameter, 770 nm ZDW, 4 mm length) with an output power of 24 mW and a SNR of 103 dB. When coupling a 1 W Ti:sapphire laser into the 2 μm or even shorter fiber with a ZDW of 770 nm spectra in the highly interesting 1,050 nm wavelength range (>160 nm bandwidth @ FWHM – in the best case about 250 nm (shorter wavelengths were cut off by a long-wave-pass filter) could be generated. The 22 mW of output power were reduced to ∼4 mW after collimation and recoupling to a 3 m fiber (for connection to the fiber optic OCT system, which is necessary for clinical imaging).

19.6.2 Spectral Broadening in the Visible

Spectral broadening in the visible can be achieved by coupling light from a Ti:sapphire oscillator into a MF with 2.3 μm core diameter and 6 mm length. The state-of-the-art Ti:sapphire pump source has a bandwidth of 120 nm (FWHM) with an average output power of 400 mW emitting sub-10 fs pulses with about 100 MHz repetition rate. By compensation for the positive chirp introduced by the air and the coupling elements with mirror pairs and matching the polarization to the main polarization axis of the fiber a stable, slightly modulated spectrum ranging from 550 to 950 nm can be generated. The SC spanning more than 325 nm (FWHM) with spectral modulations less than 1.5 dB, centered at 725 nm, and providing 27 mW of average output power (cf. Fig. 19.18a) results in 0.5 μm axial OCT resolution in tissue (cf. Fig. 19.18b) [47]. Hence, the spectrum can be successfully broadened by a factor of 3. The total output power from the optical fiber can be as high as 120 mW. The broad bandwidth of this light source also provides access to a spectral region covering the absorption bands of a number of biological

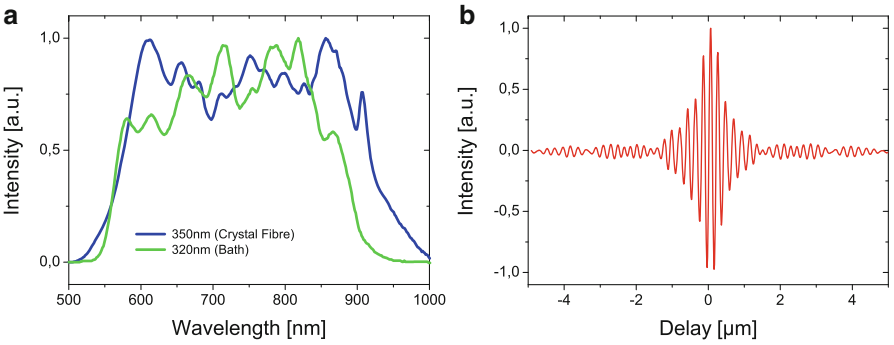

Fig. 19.18 *Supercontinuum light source*. Spectrum of supercontinuum (**a**) generated from a microstructured fiber with sub-µm axial resolution (**b**)

chromophores, thus it has great potential for spectroscopic OCT. This spectral region is interesting because of ultrahigh resolution of the OCT images (sub-µm resolution rather than several microns in the near infrared) with better image contrast as well as stronger absorption of biological chromophores. These three properties are extremely interesting for medical applications, since human cells with common sizes of some micrometers can only be properly investigated with sub-µm resolution for early cancer diagnosis. In addition, intra- and extracellular processes involve changes in optical properties in that special range of the optical spectrum and can be observed in real time, without additional staining.

19.6.3 Simultaneous Spectral Broadening in the Visible and NIR

19.6.3.1 Multiple Wavelengths, Ultrabroad Bandwidth Light Source

In addition to investigations of shorter wavelengths than the pump wavelength around 750–850 nm, also longer wavelengths are required for OCT. Applying 100 fs pulses to long pieces (>1,000 mm) of PCF have resulted in significant, broadening in the infrared wavelength region. For OCT, it is also of major interest if short pulses are also capable to produce light in the NIR at about 1,050 nm. This wavelength region is particularly attractive for ophthalmic OCT imaging due to reduced melanin and hemoglobin absorption in addition to lower scattering properties of biological tissue as compared to standard ophthalmic OCT imaging around 800 nm, which can result in significantly enhanced OCT image penetration below the retinal pigment epithelium into the choroid. Ocular media are still transparent enough in this wavelength region to enable optical access to the posterior pole of the eye. Visualization of subretinal layers have great clinical impact in the early diagnosis of several retinal pathologies, e.g., diabetic retinopathy or age-related macular degeneration. Also bandwidth light sources that cover wavelength regions for which scattering in human tissue decreases, based on SC emission generated by ultrashort pulses in fibers became available. In this study, the application of a source

with central emission wavelengths centered at the water absorption window at 1,060 nm that is utilized for OCT is reported and compared to the penetration properties of a state-of-the-art Ti:sapphire system.

Light sources emitting more than 100 nm bandwidth at full width at half maximum – depending on the central wavelength – are needed to accomplish ultrahigh axial resolution ($\leq$2 μm) OCT. Using full interferometric signal detection, also the spectral information can be extracted. Ultrabroad bandwidth, coherent light sources have enabled UHR OCT, which also gives access to metabolic tissue parameters since these light sources cover spectral regions of several diagnostically important biological chromophores, e.g., melanin or hemoglobin. Thus the combination of UHR OCT with spectroscopy has the potential to perform optical biopsy of biological tissue, i.e., the visualization of tissue morphology at the cellular resolution level, to enhance OCT tomogram contrast as well as to extract quantitative, spatially resolved spectroscopic tissue information over a broad wavelength region at high resolution in a single measurement. A triple band light source can simultaneously access several wavelength regimes for combining the advantages of each wavelength region in one light source and one measurement.

The spectra in the visible and NIR region are generated simultaneously by the means of nonlinear broadening in a MF pumped by a Ti:sapphire laser. The latter one is a commercially available oscillator formed by a standard x-folded resonator that is composed of chirped mirrors and high reflectors for dispersion compensation and pumped by 8 W of a diode-pumped, frequency-doubled Nd:YVO_4 laser. The oscillator provides sub-12 fs pulses with an average power of 1 W at 75 MHz repetition rate. The output spectrum is centered at 800 nm with 120 nm bandwidth at FWHM. According to our previous studies with MFs in combination with sub-20 fs pulses, only short fibers (a few millimeters in length) allow to generate broad spectra in the visible with minimal modulations and low pulse to pulse fluctuations of the spectrum.

Therefore, a 2 mm long fiber with core diameter of 2 μm is used. Since the fabrication process of MFs improved in the recent years, the throughput, the stability, and the noise behavior could be increased a lot. An achromatic objective with $f = 4$ mm and a numerical aperture of NA = 1.0 is used for focusing, providing smooth dispersion with minimal chromatic aberrations in the 700–900 nm wavelength range. Quarter and half waveplates designed for a central wavelength of 780 nm are used to optimize the polarization of the incident beam. Two pairs of chirped mirrors with a total number of 18 bounces are introduced mainly to precompensate the positive dispersion of the focusing objective and provide pulse duration of 14 fs in front of the fiber and 800 mW output power. An achromatic doublet lens designed for low chromatic aberration in the 600–1,000 nm wavelength range with an NA of 0.65 collimates the generated broad bandwidth output of the fiber.

An output spectrum covering the whole wavelength range from 500 to 1,400 nm has been realized in a single MF-based Ti:sapphire laser-pumped light source (cf. Fig. 19.19). The overall output power over the whole wavelength region is 360 mW. The short-wavelength part of the spectrum covers the visible wavelength range from 500 to 700 nm with a bandwidth of 140 nm at FWHM centered at

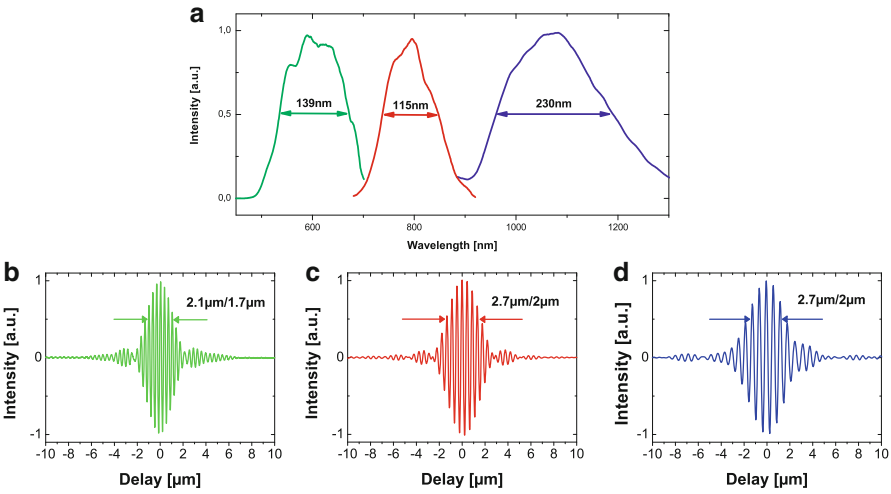

Fig. 19.19 *Multiple wavelengths, broad bandwidth light source*. The three wavelength regions of the light source and the corresponding autocorrelation fringes. Spectrum in *green* is centered at 600 nm achieving 1.7 µm axial resolution, the *red* spectrum is centered at 800 nm with 2 µm axial resolution, and the *blue* spectrum is paced in the so-called water window

602 nm with 40 mW output power. This region is especially interesting for several biological chromophores, i.e., hemoglobin, because the absorption compared to longer wavelength (around 800 nm) is significantly increased by a factor of 10. The central wavelength part spans from 700 to 900 nm at 800 nm with 120 nm bandwidth at FWHM and 160 mW output power. The longer wavelength part covers 950–1,350 nm centered at 1,060 nm with 230 nm bandwidth at FWHM and 35 mW output power. The latter one is the region of the zero-dispersion point of water, the so-called water window. The light source combines the advantages for spectroscopic OCT in the visible and 800 nm wavelength region enhancing the imaging contrast, permitting the differentiation of tissue pathologies by their spectroscopic properties or functional states (e.g., blood oxygenation) with enhanced penetration and cellular level resolution OCT imaging in the NIR region at 800 nm and 1,050 nm in a single optical instrument.

Low-noise broad bandwidth light for optical coherence tomography was also generated by a slightly different approach. A 70 cm long single-mode optical fiber (F-SPV, Newport) with a mode field diameter of 3.2 µm was pumped by a self-mode-locked Ti:sapphire laser [53]. The bandwidth of pump source could be broadened by a factor of 11 enabling a spectral output covering the range from 800 to 1,400 nm. A coherence length of 3.7 µm was achieved. Since the light was broadened by self-phase modulation, no noise amplification could be observed during the broadening process.

Ultrahigh-resolution optical coherence tomography was also demonstrated at 800 nm and 1,300 nm using continuum generation in a single photonic crystal fiber with a parabolic dispersion profile and two closely spaced zero-dispersion

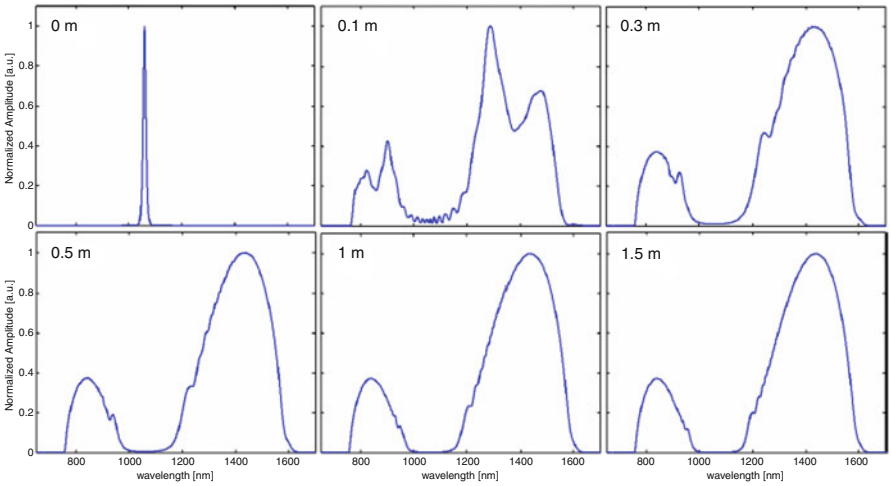

Fig. 19.20 *Numerical simulation for broad bandwidth light source development*. Computer modeling allows advance prediction of experimental results and optimization of nonlinear fiber parameters. Numerical simulations shown here demonstrate generation of dual-wavelength continuum in a photonic crystal fiber with two closely spaced zero-dispersion wavelengths centered at 1,050 nm. Using a pump wavelength of 1,060 nm, nearly complete depletion of the pump is observed along with creation of two high brightness main peaks centered at important OCT imaging wavelengths of 800 nm and 1,300 nm [57]

wavelengths centered around 1,050 nm [56]. The fiber was selected based on numerical simulation results, which demonstrated that relatively smooth spectral shape and sufficient power could be generated at both wavelengths simultaneously using a pump wavelength of 1,060 nm. Figure 19.20 presents the simulated results for spectral evolution as a function of fiber length for a 1,064 nm pump. Nearly complete depletion of the pump wavelength is observed along with creation of two high brightness main peaks centered at 800 nm and 1,300 nm. Results were generated experimentally using ~78 mW average power at 1,064 nm in a 52 MHz, 85 fs pulse train from a compact Nd:Glass oscillator. Continuum processes resulted in a double peak spectrum with >110 nm and 30 mW average power at 800 nm and >150 nm and 48 mW at 1,300 nm. OCT imaging with <5 μm resolution in tissue at 1,300 nm and <3 μm resolution at 800 nm was demonstrated [57]. Figure 19.21a, b compare the point spread function on a linear scale for both wavelengths. At 800 nm, 3.0 μm axial resolution was achieved in air, which for index of refraction in tissue of 1.38 provides ~2.2 μm in tissue. At 1,300 nm, 6.5 μm axial resolution in air provided ~4.7 μm in tissue. Both point spread functions were symmetric and correlate well to the Fourier transform interference bandwidths presented in Fig. 19.21e, f, indicating that dispersion mismatch was minimized. The interference bandwidths indicated that some spectral shaping in the OCT system resulted in reduction of optical bandwidth on the short-wavelength edges of the spectra. Spectral shaping likely resulted from wavelength dependent focusing aberration in the optics as well as some multimode leakage in long optical

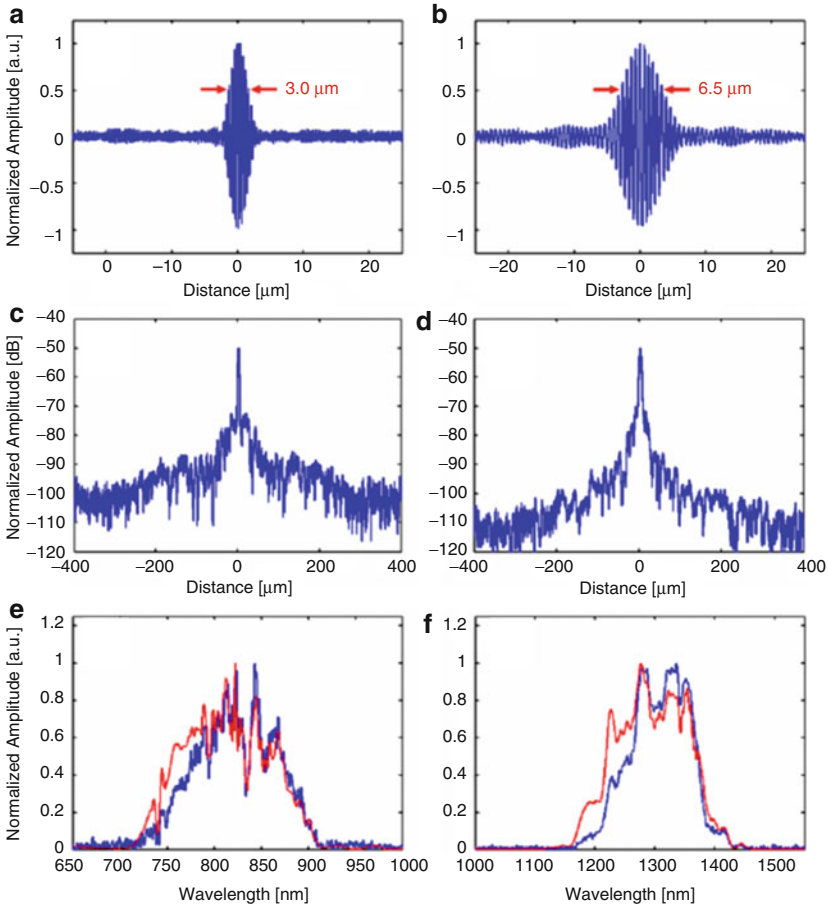

Fig. 19.21 *Dual-wavelength, broad bandwidth light source using a single PCF with parabolic dispersion profile*. Linear (**a**, **b**) and logarithmic (**c**, **d**) point spread functions are shown for both 800 nm (**a**, **c**) and 1,300 nm (**b**, **d**). The Fourier transform of the point spread functions in (**a**, **b**) are shown in *blue* in (**e**, **f**) to indicate the interference bandwidth. They are overlapped with the input source spectra shown in *red* [57]

fibers bringing light to the OCT system setup. Figures 19.21c, d present the logarithmically demodulated output signals for 800 nm and 1,300 nm, respectively. The traces have been normalized and scaled to reflect the 50 dB sample arm attenuation (2.5 OD filter, double pass) used to measure them. At both wavelengths, the sidelobe coherence artifacts on the point spread functions were present at ~25–30 dB. These results correlated well to the expected point spread function obtained by Fourier transforming the input optical bandwidths to the systems indicating that the source of the coherence artefact is the spectral modulation. In general sidelobe levels of 40–50 dB are desirable for OCT imaging.

Dual-band ultrahigh-resolution optical coherence tomography imaging has also been demonstrated simultaneously at 840 nm and 1,230 nm central wavelength using an off-the-shelf turnkey supercontinuum light source [58]. Spectral filtering of the light source emission resulted in a double peak spectrum with average powers exceeding 100 mW and bandwidths exceeding 200 nm for each wavelength band. A free-space OCT setup optimized to support both wavelengths in parallel was introduced. OCT imaging of biological tissue ex vivo and in vivo is demonstrated with axial resolutions measured to be <2 μm and <4 μm at 840 nm and 1,230 nm, respectively. This measuring scheme was used to extract spectroscopic features with outstanding spatial resolution enabling enhanced image contrast.

19.6.4 Spectral Broadening in the NIR

19.6.4.1 Supercontinuum Light Source in the 1,050 nm Region

Ultrahigh-resolution, real-time OCT imaging was demonstrated using a compact femtosecond Nd:Glass laser that is spectrally broadened in a high numerical aperture single-mode fiber [48]. A compact, commercially available diode-pumped femtosecond Nd:Glass laser (High Q Laser Production) generated pulses at 1,064 nm with 100–150 fs duration, 145 mW average power, and 75 MHz repetition rate. The laser employed measured only 53 cm × 20 cm, and even smaller lasers, measuring 18 cm × 10 cm, are now available. The Nd:Glass laser was pumped by two 1 W laser diodes and is soliton mode-locked using a semiconductor saturable absorber mirror (SESAM) for self-starting and intracavity prisms for dispersion compensation. To generate a continuum centered at 1 μm, the femtosecond pulses from the Nd:Glass laser were coupled into a 2 m long commercially available high numerical aperture (NA) single-mode fiber with a 2.75 mm focal length aspheric AR coated lens. The fiber had a germanium-doped core with a 2.5 μm mode field diameter to provide enhanced nonlinear effects. The fiber dispersion was approximately −125 ps/nm/km. Figure 19.22 shows a typical spectrum generated by the high numerical aperture fiber with 100 mW of average output power and a bandwidth of over 220 nm. This bandwidth should yield a theoretical axial resolution of 2.6 μm, as shown by the Fourier transform of the spectrum in Fig. 19.22c. The nearly symmetric broadening of the spectrum is the result of self-phase modulation in the normal, positive dispersion operating regime. A system resolution of <4.0 μm in air was achieved, as depicted in Fig. 19.22b. The difference from the theoretically predicted resolution values may be due to imperfect matching of the dispersion between the arms of the interferometer. Importantly, the relatively smooth spectral shape results in excellent sidelobe suppression on the point spread function, which is shown by the nearly −40 dB peak to sidelobe ratio in the log point spread function of Fig. 19.22d.

A similar approach has been reported using a broad bandwidth continuum light source with high-power, low-noise, and a smooth spectrum centered at 1.15 μm for ultrahigh-resolution optical coherence tomography [59]. The continuum was generated by self-phase modulation using a compact 1.059 μm femtosecond laser pumping

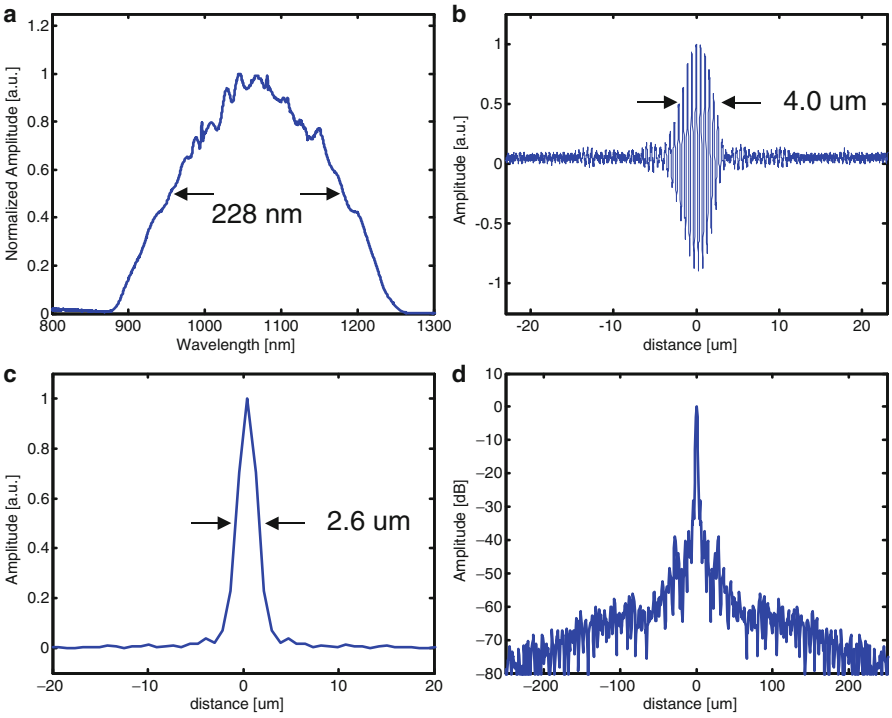

Fig. 19.22 *Broad bandwidth light source based on a compact Nd:Glass laser and a nonlinear fiber*. (**a**) Plot of the optical spectrum of the Nd:Glass laser broadened in the high numerical aperture (*NA*) single-mode fiber. (**b**) Linear point spread function measured in free space. (**c**) Theoretical point spread function computed by Fourier transform of the optical spectrum profile. (**d**) Measured point spread function on a log scale demonstrating excellent peak to sidelobe rejection for high-dynamic-range imaging [48]

a photonic crystal fiber, which had a convex dispersion profile with no zero-dispersion wavelengths. The emission spectrum was redshifted from the pump wavelength, ranges from 800 to 1,300 nm, and resulted in a measured axial resolution of ~2.8 μm in air, suggesting that PCFs with this type of dispersion profile are advantageous for generating SC as a light source for ultrahigh-resolution OCT.

Another supercontinuum source operating at 1.1 μm wavelength has been described accomplishing 372 nm optical bandwidth (FWHM) enabling 1.3 μm axial OCT resolution [45]. The pump source for the PCF was a Kerr-lens mode-locked Ti:sapphire laser. The total output laser power was greater than 700 mW, with a pulse duration of 110 fs and a repetition rate of 76 MHz. The laser output wavelength was 780 nm. The laser beam was then coupled into the PCF after a Faraday isolator to prevent interference of backreflected light. Nitrogen gas was slowly blown onto the coupling part to purge the fiber tip and prevent damage. A λ/2 waveplate after the Faraday isolator was used to adjust the polarization state of the light input to the fiber to optimize the spectrum.

The spectrum of light was broadened as it propagated through the fiber because of self-phase modulation and Raman scattering. The continuum output of light was collimated by a 4.5-mm focal length lens. The spectrum ranged from 800 to 1,430 nm. The total output power from the PCF could be as high as 100 mW, and the remaining power was approximately 50 mW after a long-pass filter.

19.6.4.2 Supercontinuum Light Source in the 1,300 nm–1,500 nm Region

The first development and application of PCF-based supercontinuum sources for UHR OCT was accomplished by launching 100 fs pulses generated by a commercial Kerr-lens mode-locked Ti:sapphire laser (Coherent Mira) pumped by a frequency-doubled Nd:vanadate laser (Spectra-Physics Millennia) into a 1 m length of microstructure fiber [50]. The beam was focused by a 3.5 mm focal length, 0.65 NA best-form lens into the fiber. Dramatic nonlinear effects allowed the generation of an extremely broadband continuum extending from 390 to 1,600 nm in the fiber. The pulse energy in the fiber was only ~2 nJ, corresponding

(**b**) Detected optical spectrum obtained from the Fourier transform of the interferometric signal (**c**). (**c**) Interference fringes recorded by use of an isolated reflection. The FWHM was measured to be 2.5 μm [50]

(**b**) Light source spectrum before spectral shaping. (**c**) Gaussian-like spectrum in the 1,300 nm wavelength range achieved after filtering with WDM coupler. The output power after the coupler is about ~200 mW with a bandwidth of 140 nm at FWHM centered at 1,250 nm. (**d**) Sub-5 µm axial OCT resolution achieved with the Raman light source [51]

to an average power of 150 mW at 75 MHz repetition rate. Since the microstructured fiber was birefringent, a half waveplate was used to adjust the polarization of the light launched into the fiber to optimize the spectral properties of the continuum. The continuum out of the fiber is collimated by a 0.85-N.A. 603 microscope objective and focused by a 10-mm focal length, chromatically corrected, custom-designed 0.3-N.A. lens into the fiber-based OCT system. The spectrum of the light source at the entrance port of the second fiber coupler (cf. Fig. 19.23a) was measured by an optical spectrum analyzer and had a bandwidth of 450 nm centered at 1.2 um. The optimal interferometric signal is shown together with its envelope in Fig. 19.23c. The free-space axial OCT resolution of 2.5 µm was determined by measurement of the FWHM of the envelope. The detected optical spectrum (cf. Fig. 19.23b) was calculated by Fourier transformation of the interferometric signal. The detected spectral bandwidth was reduced to 370 nm. This reduction of the bandwidth occurred on the short-wavelength part of the spectrum and was probably caused by the low sensitivity of the InGaAs photodiodes at wavelengths shorter than 1 µm. In addition, the spectrally nonuniform-coupling ratio of the fiber couplers and the bending loss of the fibers, which are not single

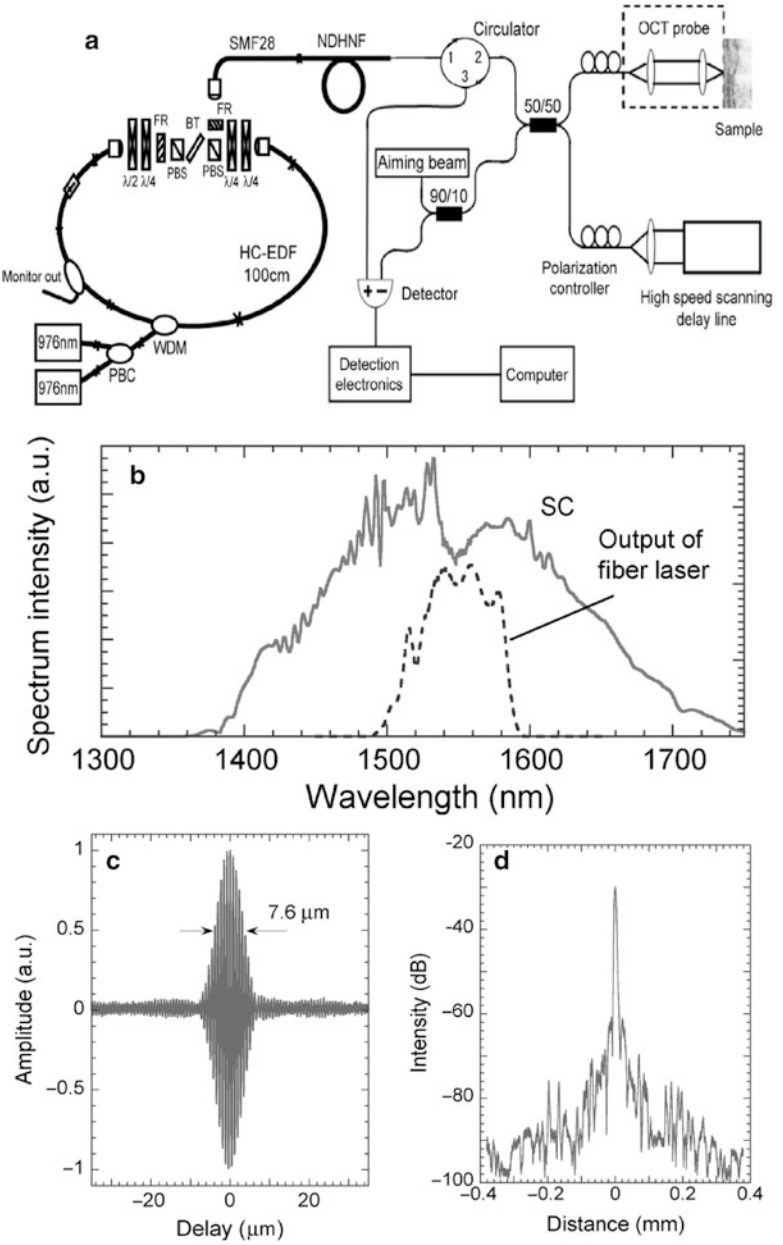

Fig. 19.25 *All-fiber, femtosecond fiber laser continuum at 1,500 nm.* (**a**) Fiber laser schematic. (**b**) Optical spectrum on a linear scale of the output from the fiber laser (*dashed*) and the supercontinuum generated in a high-nonlinearity fiber. (**c**) Interference signal point spread function and (**d**) logarithmically demodulated signal showing an axial resolution of 7.6 μm in air, corresponding to 5.5 μm in tissue [62]

mode for the short-wavelength part of the spectrum, may also cause this reduction in detected bandwidth.

A different approach based on a broadband all-fiber Raman continuum light source in the 1,300 nm region was also described recently using a high-power, continuous-wave, all-fiber pump light source. The turnkey broadband all-fiber Raman continuum light source is based on a 10 W cw, non-polarized, multimode diode-pumped, single-mode Yb-fiber laser directly spliced to an anomalously dispersive microstructure fiber, as shown in Fig. 19.24a. The microstructure fiber is 100 m long, has a dispersion of +35 ps nm^{-1} km^{-1}, a pitch of $\Lambda = 1.72$ µm, and an air-hole diameter of 0.65 µm. Figure 19.24b presents the measured Raman-soliton continuum. It contains 5.5 W of total power and a spectral width of 318 nm (at 20 dB). The spectrum covers the wavelength range from 1,090 to 1,370 nm with a flatness of ± 5 dB and 2.3 W of power. This output was filtered using a special WDM coupler to remove the pump wavelength and to achieve a smooth, Gaussian-like spectrum in the 1,300 nm wavelength range. The output power after the coupler is about ~200 mW with a Gaussian-shaped spectrum with a bandwidth of 140 nm at FWHM centered at 1,250 nm (cf. Fig. 19.24c) enabling sub-5 µm axial OCT resolution at 1,300 nm (Fig. 19.24d) [60, 61].

Real-time, ultrahigh-resolution optical coherence tomography (OCT) was demonstrated in the 1.4 to 1.7-µm wavelength region with a stretched-pulse, passively mode-locked, Er-doped fiber laser and highly nonlinear fiber [62]. The fiber laser, shown in Fig. 19.25a, generated 100 mW, linearly chirped pulses at a 51 MHz repetition rate. The pulses were compressed and then coupled into a normally dispersive, highly nonlinear fiber to generate a low-noise supercontinuum with a 180 nm FWHM bandwidth and 38 mW of output power. Figure 19.25b compares the spectrum of the fiber laser with that after spectral broadening. This light source was stable, compact, and broadband, permitting high-speed, real-time, OCT imaging with axial resolution of ~7.6 µm in air, corresponding to ~5.5 µm in tissue (Fig. 19.25c, d). In vivo high-speed OCT imaging of human skin was demonstrated.

19.7 Conclusion

Ultrabroad bandwidth light source technology has been developed enabling UHR OCT imaging in the visible and near-infrared wavelength region with unprecedented axial resolution. Subcellular structures were resolved with sub-micrometer axial resolution in human cancer and animal ganglion cells at shorter wavelengths, while the different contrast and improved penetration depth with increasing wavelength were demonstrated. Different medical fields such as ophthalmology, dermatology, neurology, gynecology, urology, laryngology, etc. impose various demands to the performance, size, and user-friendliness of UHR OCT systems. Since the OCT axial resolution scales with the center wavelength of the optical source, only relatively small bandwidths are required to achieve micrometer-scale resolution in the visible wavelength range. Here, the image contrast is enhanced due to stronger modulation of the backscattering profile of biological tissue. Major

limitations for UHR OCT in the visible wavelength range are the relatively low image penetration depth as well as the light source stability and inherent noise. Dispersion mismatch which deteriorates the imaging quality is more critical in the visible than in the near-infrared wavelength regime especially compared to 1,060 nm where the zero-dispersion point of water is located. The diversity in fiber-based light sources with respect to center wavelength, bandwidth, and output power makes them extremely attractive for UHR OCT applications. However, their excess noise is higher compared to Kerr-lens mode-locked lasers. It is not easy to find a light source for OCT which fulfills all technical and clinical requirements. On the one hand, there are low-noise, cheap, and nicely shaped SLDs covering a large wavelength range but with limited output power and bandwidth. By multiplexing of these SLDs ultrabroad bandwidth light sources can be generated at the cost of spectral shape and price. Alternatives are solid-state lasers which are capable of nice spectra spanning almost one octave. But these light sources are restricted to the fluorescence bands of the crystals. They have a complex architecture, which makes them expensive and not applicable for widespread industrial use. In the last decade, attempts have been made to make compact and cost-effective solid-state lasers by applying direct diode pumping or integrating of small and cheap pump sources in the optical platform. With this concept, ultrabroad bandwidth light could be generated direct out of a Ti: sapphire laser at reasonable cost with more than 300 nm bandwidth in the 800 nm regime. Nevertheless, they do not prevail the clinical daily routine until now.

MFs have become more and more important in generating ultrabroad bandwidth optical spectra in the visible and near-infrared wavelength range within the last decade. Advances in manufacturing processes allow for reliable operation of these light sources on a daily base. Constant quality is guaranteed from one fiber to the next. The noise behavior has also improved a lot in comparison to first-generation MFs. Especially short fibers and femtosecond pulses as demonstrated exhibit almost no amplification of the noise of the input pulse. OCT tomograms with sensitivities comparable to those acquired with Ti:sapphire lasers or SLDs could be obtained. Analytical treatment and simulation of the broadening process are extremely important to tailor MFs to the demanded wavelength regime and to the required low-noise pump sources. Complex fibers with one, two, or even no zero-dispersion wavelength can be designed and fabricated to fulfill special needs as large optical bandwidth and low noise. If the main broadening process is mainly due to self-phase modulation, no significant noise amplification is noticeable. So it is favorable to suppress all other broadening mechanisms like cross-phase modulation, four-wave mixing, and stimulated Raman scattering which generate a complex fine structure of the spectrum. The development in this direction is far not finished, and there are permanent attempts in this direction. Nevertheless the amplification of the noise especially with longer fibers combined with complex and expensive setups are still limiting factors and/or a handicap for OCT application.

20.1 Introduction

In optical interferometric metrology, the wavelength of light serves as a reference for length. At a given optical wavelength, an interference signal varies as a sinusoidal function of distance with a period equal to the wavelength. Although this approach offers unrivaled precision, the periodic signal results in a 2π ambiguity for measurement of lengths greater than one wavelength. In optical coherence tomography (OCT), one wishes to determine light scattering distances and distribution within a sample, but without the ambiguity. To accomplish this, OCT is based on interferometry using many optical wavelengths, each serving as a "ruler" with different periodicities. OCT traditionally has used broadband light sources providing a wide range of wavelengths, all simultaneously. Alternatively, a tunable light source emitting one wavelength at a time, rapidly swept over a broad spectral range, can also be used to achieve the absolute ranging capability in OCT.

With such a wavelength-swept source, interference signals at individual wavelengths can be measured sequentially with high spectral resolution. This spectrally resolved data acquisition is central to frequency-domain ranging. This method offers significantly higher sensitivity than the time-domain ranging method used in conventional OCT. Furthermore, frequency-domain ranging does not require reference delay scanning and can therefore be applied to increase imaging speed. With a pressing need for high imaging speed in various applications, wavelength-swept sources, particularly rapidly tuned lasers, have developed substantially in recent years and have emerged as important and practical light sources for OCT.

In this chapter, we describe a technical overview of these new emerging light sources. We discuss general specifications of the sources in Sect. 20.2. Section 20.3 is devoted to basic fundamentals of laser and wavelength tuning. In Sect. 20.4, we discuss the principles of various techniques developed to date for high-speed and wide tuning range. Those who are not familiar with the principle of frequency-domain ranging and OCT system instrumentations are encouraged to read ▶ Chap. 7, "Optical Frequency Domain Imaging" before proceeding to the next section.

20.2 General Requirements

This section will review some current key specifications and requirements of swept lasers. The swept laser technology is rapidly progressing, driving and driven by continually expanding applications. Therefore, the following provides general guidelines rather than attempting to define the state of the art.

Output power. In theory [1], the signal-to-noise ratio (SNR) of imaging systems improves indefinitely with sample-arm optical power. In practice, however, various factors limit the dynamic range of SNR. As a result, an optimal power range depends upon the sample and system. For a highly reflecting sample, low sample power would be appropriate to avoid detector saturation ($<$100 μW) and to maximize SNR. The maximum permissible exposure level of the human retina is approximately 700 μW at 800 nm wavelength. Therefore, a source power of 10 mW would be sufficient for ophthalmic applications. Another tissue such as the skin can be exposed to $>$10 mW, so a powerful source with several tens of mW output is desired for deep tissue imaging applications.

Tuning curve. In Fig. 20.1a, a tuning curve shows the output wavelength varying over time. The exemplary curve shows a linear, unidirectional tuning from a short to long wavelength. Some lasers may produce nonlinear or bidirectional tuning curves. In frequency-domain ranging, depth is conjugate to wavenumber, $k = 2\pi/\lambda$. Ideally, the wavenumber, not wavelength, would be tuned linearly over time so that the interference signal can be sampled uniformly, directly Fourier transformed to yield a depth profile. In general, tuning k is nearly always nonlinear, requiring nonuniform sampling or interpolated processing. A highly nonlinear tuning curve is undesirable because it complicates the linearization process and consumes a larger detection bandwidth and sampling rate than is otherwise necessary.

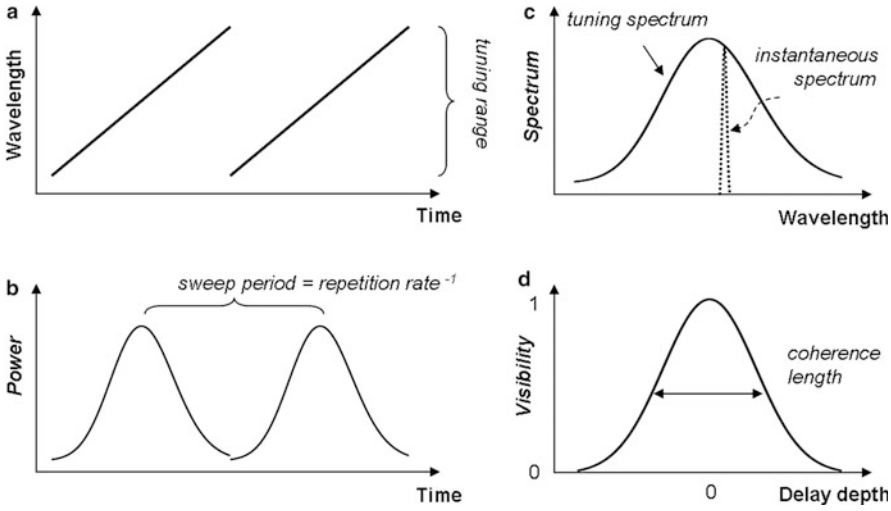

Fig. 20.1 Typical output properties of a swept laser. (**a**) Tuning curve. (**b**) Time trace. (**c**) Spectrum. (**d**) Coherence. The definition of each parameter is described in the text

Sweep repetition rate. Figure 20.1b illustrates an exemplary time trace of laser output power that corresponds to a Gaussian-like tuning spectrum shown in Fig. 20.1c. The sweep repetition rate, a reciprocal of sweep period, determines the A-line acquisition rate in OCT. A higher A-line rate can increase frame rate, reduce motion artifacts, and allow screening over a larger tissue surface in a limited time. For these reasons, A-line rates greater than 20 kHz would be required in most clinical applications. On the other hand, the limited bandwidth and data handling speed of currently available hardware put a practical limit on the maximum achievable A-line rate in a system. Depending on applications and system capability, the sweep repetition rate of a source may need to be between 20 and 200 kHz.

Center wavelength ($\boldsymbol{\lambda_0}$). The optimal center wavelength is somewhat dependent upon the sample and application. Longer wavelengths are less scattered and can penetrate deeper in tissue, but absorption, dominantly by water, has a strong wavelength dependence [2]. In general, there are two distinct spectral windows for imaging. The first window (650–900 nm) is suitable for retinal imaging because of low absorption in vitreous humor. This range can be extended to 1,100 nm where the penetration depth in the retina and choroid is increased. The second window in 1,100–1,360 nm permits even deeper tissue penetration and, therefore, is suitable for most non-ophthalmic imaging. Certainly, other wavelengths, such as visible or beyond 1,500 nm, have potential for specific applications, such as molecular contrast-based imaging or non-biological material with low water concentration.

Tuning range ($\boldsymbol{\Delta\lambda}$). Figure 20.1c depicts an exemplary output spectrum with a truncated Gaussian-like profile, typical of swept lasers. The spectral envelope is related to the point spread function through the Fourier transform, although windowing can be applied in data processing. The tuning range is defined from edge

to edge (full range), at –3 dB (full width at half maximum: FWHM), or at $1/e^2$ level. Assuming a Gaussian spectrum with $1/e^2$ width of $\Delta\lambda$, the axial resolution, defined as the FWHM of point spread function, is given by

$$\Delta z \approx 0.75 \frac{\lambda_0^2}{\Delta\lambda}, \tag{20.1}$$

As numerical examples, a tuning range of $\Delta\lambda = 127$ nm at $\lambda_0 = 1{,}300$ nm yields $\Delta z = 10$ μm; the same resolution is achieved with $\Delta\lambda = 48$ nm at $\lambda_0 = 800$ nm.

Instantaneous linewidth ($\delta\lambda$). The laser emits a narrowband spectrum instantaneously. The finite linewidth of the instantaneous output causes the visibility of interference to decrease with path length difference, as illustrated in Fig. 20.1d. The coherence function is related to the instantaneous spectrum through the Fourier transform, just like the point spread function is to the overall tuning spectral envelope. The coherence length is defined as the optical delay when interference visibility drops to 0.5. This corresponds to a full depth range with visibility greater than >0.5. Because SNR is proportional to the square of the visibility, longer coherence length is required in OCT. The coherence length, z_c, is related to the FWHM instantaneous linewidth, $\delta\lambda$, via

$$z_c \approx 0.44 \frac{\lambda_0^2}{\delta\lambda} \tag{20.2}$$

Most OCT applications require a depth range between 2 and 6 mm. Given that positive and negative depths are indistinguishable in normal OCT, a coherence length of 4–12 mm would be required. As a numerical example, $\delta\lambda = 0.1$ nm at $\lambda_0 = 1{,}300$ nm yields $z_c = 7.4$ mm; the same coherence length is obtained with $\delta\lambda = 0.038$ nm at $\lambda_0 = 800$ nm.

Intensity noise. Intensity fluctuations of laser output, if they have significant frequency components in the signal detection band, can degrade SNR and may produce image artifacts through frequency mixing with signals. Mechanical vibration and noisy pump sources are two primary sources for 1/f-type intensity noise. Mode partition noise or mode beating noise occurs at the fundamental frequency equal to the reciprocal of the cavity roundtrip time or its harmonics. In swept lasers, multiple path interference due to spurious back reflections in intracavity components or the gain chip can cause intensity modulation at frequencies corresponding to path differences. In OCT detection, the total intensity noise should be smaller than shot noise [3], given as $\langle \Delta P_r^2 \rangle < 2\, h\nu\, P_r$ where $\langle \Delta P_r^2 \rangle$ is the time-averaged intensity noise power per a 1 Hz bandwidth, $h\nu$ is a single photon energy (h is Planck's constant), and P_r is the average reference power. The noise power per bandwidth is conveniently characterized with relatively intensity noise (RIN) that is defined as

$$\mathrm{RIN} = \frac{< \Delta P^2 >}{P^2} \left[Hz^{-1} \right] \tag{20.3}$$

Therefore, the shot-noise limit condition is reduced to $\mathrm{RIN} < 2\, h\nu / P_r$. Typically, $P_r = 10$–100 μW, and therefore, RIN $< -135 - -145$ dB/Hz. This is achievable in

swept lasers. The RIN spectrum of a laser output can be measured with a photodiode and an electrical spectrum analyzer. In an OCT system, the effect of the laser RIN can be reduced by 15–30 dB using dual balanced detection.

Output polarization. Single polarization output is ideal. With a dual polarization source, polarization-dependent delay in the interferometer, such as polarization mode dispersion in a circulator, can cause blurry images. Even when the source output is singly polarized, the specific polarization state may vary as a function of wavelength in a swept laser, particularly if the cavity has strong birefringence. This wavelength dependence should be minimized, because it can lead to an intensity modulation through polarization-dependent loss or splitting ratio in the interferometer or probe optics, resulting in image artifacts.

Miscellaneous. A small-sized mechanically durable light source would be highly desirable if it is to be integrated into a compact, portable system for space-limited clinical environment. Long-term reliability and stability are highly desirable for clinical or industrial uses.

20.3 Fundamentals

A laser is an optical oscillator, coined after its underlying physical mechanism: light amplification by the stimulated emission of radiation. Central to laser instrumentation is a gain medium where light is amplified. Another fundamental component is an optical cavity that gives coherent optical feedback for laser oscillation. The optical cavity also provides space to insert other various optical components, such as lenses, nonlinear optical materials, and spectral filters. These intracavity components are used to condition temporal and spectral characteristics of laser light to specific purposes. For example, an intracavity tunable filter is widely used in a tunable laser. In this section, we describe some fundamentals of lasers and their wavelength sweep operation.

20.3.1 Gain Medium

A gain medium that is pumped to reach an electronic population inversion is able to amplify optical energy. Figure 20.2a illustrates this principle with regard to a semiconductor [4]. The valence and conduction bands serve as the ground and excited state. A positive bias is applied to the semiconductor so that injected electrons flow into the conduction band and populate it, whereas holes are created in the valence band. An incoming photon, if its energy is equal to the energy difference between the two bands, can trigger the transition of an excited electron to the valence band, where it is recombined with a matching hole. In this stimulated transition process, the energy difference is radiated optically, resulting in the emission of a new photon that has identical energy, phase, and propagation direction compared with the original photon. This process, called stimulated emission, is the fundamental

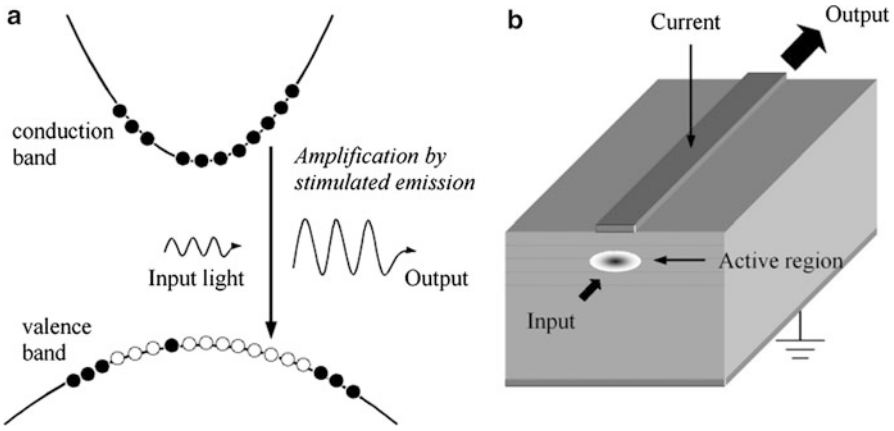

Fig. 20.2 Semiconductor optical amplifier. (**a**) The principle of light amplification in semiconductor. (**b**) A schematic of quantum-well amplifier. Light is guided and amplified in the active region

mechanism for coherent optical amplification. Other types of gain media, such as gas, dyes, crystals, and glass, are based on the same mechanism, although specifics of the transition levels of electrons and pumping methods are different. Gain saturation, or a decrease of gain due to the depletion of population inversion by strong optical intensity, is an intrinsic characteristic of gain media. In typical laser oscillation at the steady state, gain is saturated substantially to a level where the saturated gain is just enough to compensate for the loss in a laser cavity.

20.3.1.1 Semiconductor Optical Amplifier (SOA)

Figure 20.2b shows a schematic of an SOA. SOAs are one of the most widely used gain media for rapidly swept lasers for several reasons. First, the flexibility of semiconductors in making heterogeneous structures offers a wide range of gain center wavelengths. SOAs are typically made from group III–V compound semiconductors such as GaAs/$Al_xGa_{1-x}As$ ($\lambda_0 = 0.75$–0.9 μm) and $In_{1-x}Ga_xAs_{1-y}P_y$/InP ($\lambda_0 = 1.1$–1.6 μm).

Second, an SOA offers high gain with broad bandwidth. This gives a great flexibility in choosing a filter and cavity configuration for wide range and fast tuning. The high gain of an SOA, typically 20–35 dB, comes in part from its waveguide structure that ensures a long active region, typically 300–1,000 μm. Gain bandwidth, depending on the specific semiconductor materials, chip designs, and the inversion level, can be greater than 10 % of the center wavelength.

Third, the gain response time of an SOA is about 250 ps, much shorter than the micro- or millisecond timescale of other gain media, such as a titanium-sapphire and rare-earth-doped fibers. For fast sweep operation, the short gain response time is highly desirable to minimize the intensity noise of the laser output. With a slow gain medium, even a small magnitude of cavity loss modulation associated with

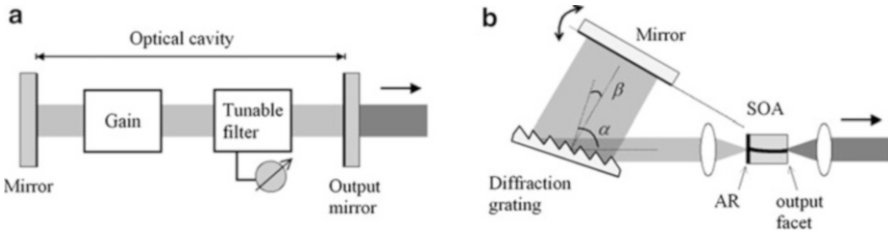

Fig. 20.3 Tunable laser. (**a**) Basic configuration. (**b**) A schematic of typical external-cavity semiconductor tunable laser. *AR* anti-reflection coating, *SOA* semiconductor optical amplifier

filter sweep can interplay resonantly with gain recovery and lead to self Q-switching or relaxation oscillation [5]. For solid-state gain media, this resonance is typically in the frequency range between 1 kHz and 1 MHz, which becomes a serious problem because it may overlap with the signal band used for imaging. A similar type of intensity modulation can arise in a semiconductor laser, but the modulation frequency is in the GHz range, and it can be easily removed electrically without affecting the signals.

20.3.2 Laser Cavity

A laser cavity is a resonator that gives phase-coherent optical feedback for regenerative amplification in the gain medium [5]. A variety of optical materials and components can be incorporated into a cavity to control and condition the characteristics of a laser. By its geometrical shape, a laser cavity can be categorized into a linear, ring, or hybrid (such as sigma) type. In a linear cavity, exemplified in Fig. 20.3a, intracavity light passes through a gain medium and a transmissive filter twice in each round trip. A ring cavity is often made unidirectional, ensured by a magneto-optic isolator with a direction-dependent insertion loss. The unidirectional ring cavity offers a distinct advantage that the backward reflected light from intracavity components is de-coupled from the main beam path and as a result, often produces more stable laser oscillation than a linear cavity. This advantage may not be evident, however, in most rapidly swept lasers that are less sensitive to the spurious feedback due to oscillation of multiple longitudinal modes.

Longitudinal cavity modes are a set of frequency components capable of oscillating resonantly in the cavity. Each mode satisfies the resonance condition that the total optical phase accumulated in one roundtrip propagation is equal to an integer multiple of 2π. The frequency difference between two adjacent modes, or the mode spacing f_m, is given by

$$f_m = 1/\tau = c/L, \tag{20.4}$$

where τ is the total propagation time of cavity roundtrip and L is the total optical length that includes group refractive indices of the cavity.

The laser output is obtained through an output coupler of the cavity. Large output coupling can extract larger optical energy from the cavity, thus resulting in a higher output power, but may decrease the tuning range due to resulting increased cavity loss. An optimum output coupling ratio can be chosen with some trade-off in performance, ranging from a few percent in low-gain lasers, such as a titanium-sapphire laser, to several tens of percents in high-gain lasers, such as a semiconductor or rare-earth-doped fiber laser.

20.3.3 Tunable Laser

Wavelength-tunable lasers have developed considerably since the mid-1960s and are now invaluable light sources for numerous scientific and industrial applications. Figure 20.3a represents a schematic of a tunable laser configuration consisting of a broadband gain media, an optical cavity, and a narrowband tunable filter. To illustrate the basic principle of a tunable laser, let us consider an extended-cavity semiconductor lasers, one of the most versatile and commercially successful tunable sources. Figure 20.3b depicts a representative schematic of the laser. One facet of a semiconductor gain chip serves as a partial reflector and output coupler of a laser cavity. Partial reflectance is normally achieved just by cleaving the facet perpendicular to the optic axis, yielding Fresnel reflection by 26–30 % for typical semiconductor materials. Optical reflection at the other facet of the chip is minimized to <0.001 % by anti-reflection dielectric coating ($R = 0.1$ %) and the curved active waveguide design. At the other end of the cavity, a diffraction grating and a mirror serve as a tunable wavelength selective filter. The angular position of the mirror determines the specific wavelength component that returns to the gain medium via [6]

$$\lambda = p \cdot (\sin\alpha + \sin\beta), \tag{20.5}$$

where p denotes the grating pitch, α is the angle between the grating normal and beam incidence axis, and β is the angle between the grating normal to the diffracted beam as determined by the angular position of the end mirror. The reflected spectrum of the grating filter has a narrowband Gaussian-like profile with a width approximately given by λ/N where N denotes the number of grooves illuminated by the optical beam on the grating.

Figure 20.4a depicts the resulting net-gain profile together with the spectrum of oscillating laser modes. The gain profile has a peak at the wavelength determined by Eq. 20.5. The net roundtrip gain becomes close to one in steady-state laser oscillation. Because of the strong gain discrimination by the filter, only the frequency mode closest to the gain peak is able to oscillate. Single-frequency oscillation offers a very narrow linewidth of <100 kHz and a long coherence length exceeding 10 km, typical of an extended-cavity semiconductor laser.

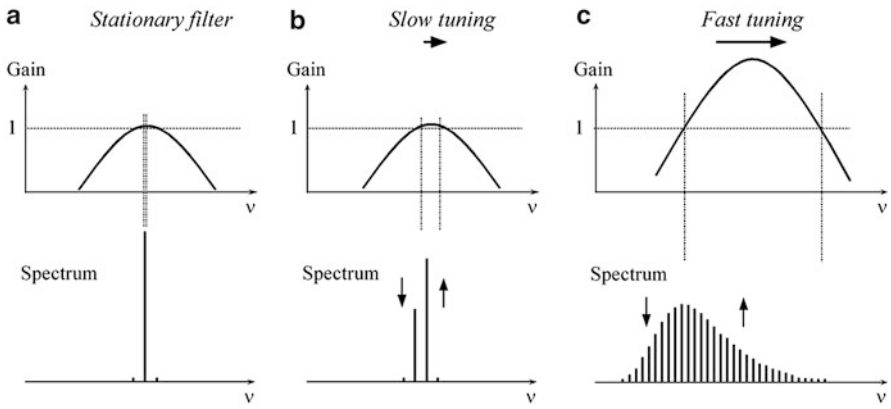

Fig. 20.4 Spectral dynamics in a tunable laser. The net-gain profile and oscillating mode spectrum are illustrated in three distinct cases: (**a**) fixed-wavelength filter and single-frequency oscillation, (**b**) slowly tuned filter and mode hopping, and (**c**) rapidly swept filter and multiple mode oscillation

20.3.4 Sweep Operation

By rotating the end reflector, the gain peak wavelength can be shifted continuously, and the output spectrum can be swept accordingly [7]. Figure 20.4b illustrates this situation in the case of slow adiabatic tuning where steady-state oscillation is reached at any given time. Here, the cavity length is assumed invariant so that the positions of cavity modes are stationary in the frequency domain. Under this condition, as the gain profile is continuously shifted by tuning, the laser spectrum steps from one mode to another – a process called mode hopping.

In some applications such as high-resolution atomic spectroscopy, truly continuous tuning without mode hopping is desirable. The extended-cavity tunable laser shown in Fig. 20.3b offers a simple way to achieve this feature. The underlying idea is to vary the cavity length in conjunction with tuning, such that the frequency of a cavity mode always coincides with the gain peak frequency. This can be achieved by placing the pivot point of the end mirror exactly at the output facet of the gain chip. Using this geometrical arrangement [8], commercial extended-cavity tunable lasers can produce a mode-hop-free sweep over several tens of nanometers. However, their tuning speeds currently are limited to <1 nm/ms, although the technique can work in principle at an arbitrary sweep speed.

Let us now consider high-speed tuning by a scanning filter. The cavity length is assumed invariant. This situation applies to swept lasers with a tuning speed of $>1{,}000$ nm/ms. When the gain profile is tuned so rapidly, it becomes impossible for any single-frequency mode to get amplified enough to reach the full optical power necessary to saturate the gain before the gain peak is shifted away. Then, stable laser

emission is only possible by simultaneously oscillating multiple modes. In this case, the envelope of the multimode spectrum is shifted continuously through the creation of new modes at the leading side of the spectrum and the extinction of modes at the trailing side, as illustrated in Fig. 20.4c. The peak net gain needs to be substantially greater than one in order to allow the new modes to build up. As a result, the peak of the laser spectrum lags behind the center frequency of the filter. It should be noted that the spectral offset and linewidth of the spectrum are dependent upon the magnitude of tuning per roundtrip rather than the absolute tuning speed (e.g., nm/ms) [9]. Therefore, for a given wavelength scan speed, a shorter cavity length can result in narrower output linewidth and higher output power (by reduced filter loss) than longer cavity lengths.

No phase relation would be expected between these multiple oscillating modes if they originated purely from spontaneous emission noise. This is not always the case for a semiconductor laser, because some degree of coherency between modes can be established through nonlinear effects in the gain medium, such as four-wave mixing and self-phase modulation. Although the propagation length in an SOA is short, typically <1 mm, strong nonlinear interactions can be generated efficiently, due to gain saturation and saturation-induced index gratings. Understanding the complicated spectral and temporal dynamics as a result of nonlinear coupling between oscillating modes requires numerical simulations [10]. Nevertheless, a great deal can be learned from the simple time-frequency domain picture, as illustrated in Fig. 20.4c.

A fiber laser is another example where strong nonlinear effects, particularly self-phase modulation, in intracavity optical fibers can generate coupling between oscillating modes. Self-phase modulation generates spectral broadening that provides seeds to newly growing modes under the scanning filter. This coherent process eventually can establish phase locking across the entire oscillating modes and leads to the generation of short pulses. This mechanism, termed sliding-frequency mode locking (SFM) [11], can be an effective method of producing wavelength-swept short pulses.

20.4 Techniques

Over the past few years, swept lasers have advanced rapidly, primarily driven by their applications to OCT. Using rapidly scanned intracavity filters, high wavelength sweep speeds exceeding 1,000 nm/ms have been realized in extended-cavity semiconductor lasers [12–14]. Inherent swept laser dynamics, such as self-frequency shift in semiconductor gain media [10], sliding-frequency mode locking [11], and resonant sweep matched to cavity roundtrip [15], have been used to improve the laser output performance. Furthermore, researchers have used various techniques, including broadband or super-continuum pulse chirping [16, 17], soliton self-frequency shift [18], and dispersive-cavity mode locking [19], to demonstrate an ultrafast sweep speed beyond 1,000 nm/μs at a high repetition rate up to several MHz. Early laser developments focused on 1,300 and 1,550 nm, but wideband high-gain semiconductor chips have become available at 1,060 nm [20]

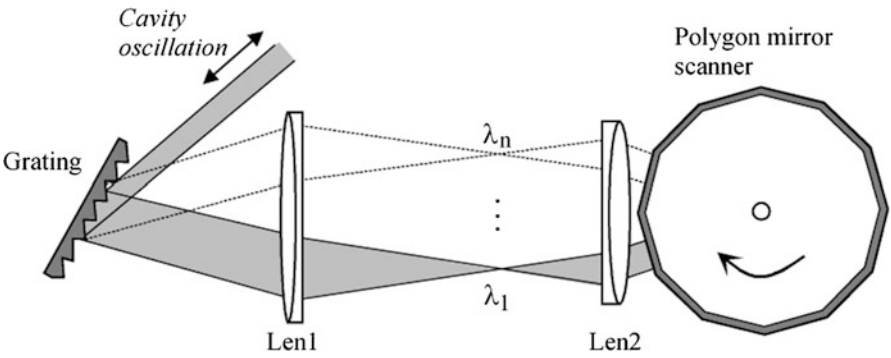

Fig. 20.5 Polygon scanner-based filter. As the polygonal mirror rotates, the center wavelength of narrowband spectrum returning back to the laser cavity is tuned continuously and repeatedly from λ_1 to λ_n

and 850 nm [21], where the output spectra are optimized for specific applications. Visible or infrared wavelengths would also be useful for other applications [22]. In this section, we describe the principles of some of these new technologies for an ultrafast wavelength sweep.

20.4.1 Scanning Filters

Grating and polygonal mirror. A polygon-based scanning filter was one of the first filters that was developed to achieve, simultaneously, a high sweep rate, a wide tuning range, and a narrow linewidth for OCT applications [12]. Figure 20.5 depicts a schematic of the filter, consisting of a diffraction grating, a telescope, and a polygonal mirror scanner. The telescope is constructed with two lenses in an infinite-conjugates configuration, with the grating at the front focal plane of lens 1 and the polygon spin axis at the back focal plane of lens 2. The telescope serves two distinct roles: it converts diverging angular dispersion from the grating into converging angular dispersion after the second lens and it controls the imaged beam size and convergence angle at the polygon. The principle of spectral selection and tuning is similar to that of the grating filter described in Sect. 20.3.3. The beam's orientation, incidence angle, and the rotation direction of the polygon mirror determine the direction of wavelength tuning. The arrangement in Fig. 20.5 produces a unidirectional positive (increasing wavelength) sweep that is advantageous over a negative (decreasing) sweep, because the nonlinear effects in an SOA transfer optical energy toward a long wavelength, resulting in higher output power and narrower linewidth.

The polygon filter can be incorporated into an extended-cavity semiconductor laser. Figure 20.6 shows the output characteristics of one of the first high-speed swept lasers with a 74 nm tuning range and a 16 kHz sweep repetition rate (1,200 nm/ms). The finesse of polygon filter, defined as the ratio of the tuning

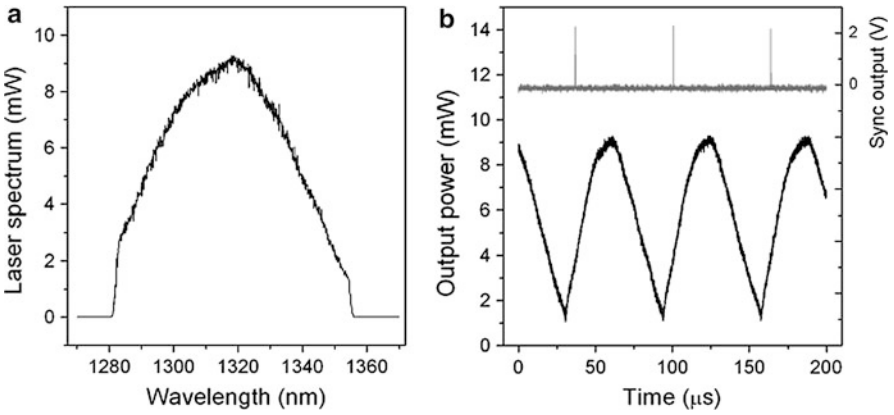

Fig. 20.6 Output characteristics of a polygon-scanned rapidly swept laser [12]. (**a**) Peak-hold spectrum and (**b**) time-domain oscilloscope trace of the laser output

range to the resolution, is typically 300–1,000. The resulting linewidth of the laser output was <0.1 nm, resulting in a coherence length of several mm. Using more optimized filter and cavity designs, much faster tuning rates of 115 kHz and wide ranges over 150 nm have been demonstrated [14]. One of the advantages of the polygon filter is the flexibility in changing varying tuning speed, range, resolution, or wavelength simply by controlling the rotational speed, grating angle, or the magnification of the telescope. A drawback, however, is that the polygonal mirror is a relatively bulky and moving part.

Fabry-Perot tunable etalon. A Fabry-Perot (FP) tunable etalon is constructed with a pair of high reflectivity mirrors separated by a distance that is variable with a piezoelectric actuator. A fiber-based small-mass etalon can be scanned over an entire free spectral range at high sweep repetition rates up to a few tens of kHz quasi-linearly [23] or up to hundreds of kHz using the mechanical resonance of the actuator [24]. The finesse of the etalon filter is determined by the reflectivity of the mirrors and easily can exceed 1,000. The etalon filter's relatively small size is an advantage, but its bidirectional and nonlinear tuning curve is a drawback for OCT applications.

Other filters. The grating filter shown in Fig. 20.3b can be modified to achieve high tuning speed, for example, by mounting the end mirror on a fast rotational actuator [25], such as resonant micro-electro-mechanical system (MEMS). This compact filter is potentially very attractive for commercialization because it can be integrated directly with a semiconductor gain chip to build a cm-scale compact light source. An acousto-optic tunable filter [26] does not have a mechanically moving part. However, currently available devices do not provide sufficiently high spectral resolution, and the tuning speed is typically much less than 100 nm/ms, even with a modest finesse of 100, because of the finite acoustic propagation time. Electro-optic tunable filters would be attractive because of their fast response time and nonmechanical actuation [27], but no practical designs with sufficient finesse have been developed to date.

20.4.2 Resonant Sweep

As briefly discussed in Sect. 20.3.4, intracavity spectral dynamics in a swept filter-based laser are largely affected by the finite buildup time of individual modes. As a result, the output linewidth and power can degrade significantly as the scan speed of the filter increases. One solution to this problem is to make the cavity length as short as possible to minimize the cavity buildup time. In this section, three different approaches are described, that are based on resonant laser dynamics and thereby capable of generating narrowband spectra without resorting to short cavities.

Dispersive mode locking. Active mode locking is a technique to generate short pulses from a laser by actively modulating cavity properties, such as loss, gain, and length (phase). Mode locking [5] occurs efficiently only when the modulation frequency is matched to the fundamental mode spacing frequency, given in Eq. 20.4, or with its harmonics precisely within $<10^{-5}$. Dispersive tuning is a technique applicable to an actively mode-locked laser with a highly dispersive cavity and in which the cavity length varies significantly as a function of wavelength. The resonant mode-locking frequency then becomes highly wavelength dependent. Therefore, a wavelength sweep is achieved by varying the modulation frequency over time. The cavity length and magnitude of dispersion need to be chosen carefully to optimize the output performance. Figure 20.7 illustrates this principle in a fiber-optic semiconductor ring laser employing a high-dispersion fiber. With this configuration, a wide sweep over 100 nm at repetition rates greater than 200 kHz has been demonstrated [19]. Here, harmonic mode locking was achieved by modulating the injection current to the SOA at a carrier frequency of 1 GHz, and the modulation frequency was swept over a couple of MHz corresponding to the amount of cavity dispersion. The electrical control of this technique is an advantage over other mechanical techniques. However, the lack of a direct filtering mechanism tends to make it difficult to obtain stable and narrowband output.

Cavity-resonance sweep. In this technique, the filter tuning period is matched to the cavity roundtrip time or its integer fraction [28]. The result is that a chirped wave is built up and circulates continuously in the cavity. Each wavelength component of this cavity-long chirped light passes the filter in successive roundtrips at the exact times when the filter's center wavelength coincides with the optical wavelength. Figure 20.8 illustrates the basic principle. This operation is reminiscent of active amplitude mode locking, in the sense that a phase relation is established between cavity modes so as to maximize the transmission through the filter (spectral vs. temporal) [15]. Some level of coherence is maintained among successive wavelength sweeps, unlike the previously described non-resonant filter-based techniques where individual sweeps start over from uncorrelated spontaneous emission. Using a resonant FP filter in a km-long fiber-optic cavity, this technique has produced high sweep rates up to 370 kHz with a >100 nm tuning range [29]. The chromatic dispersion of the cavity should be minimized to avoid wavelength walk off between the intracavity light and scanning filter. This resonant technique can

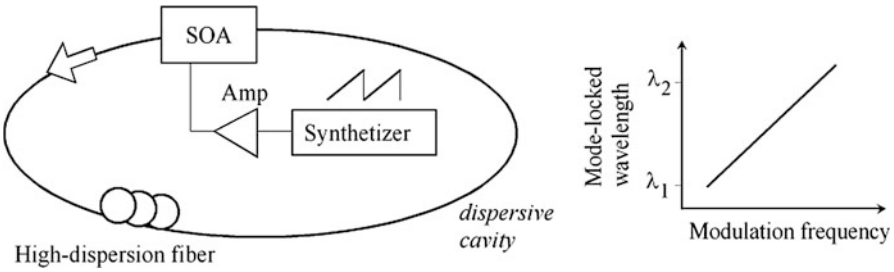

Fig. 20.7 Dispersive tuning in actively mode-locked laser. The output wavelength is tuned by sweeping the gain modulation frequency

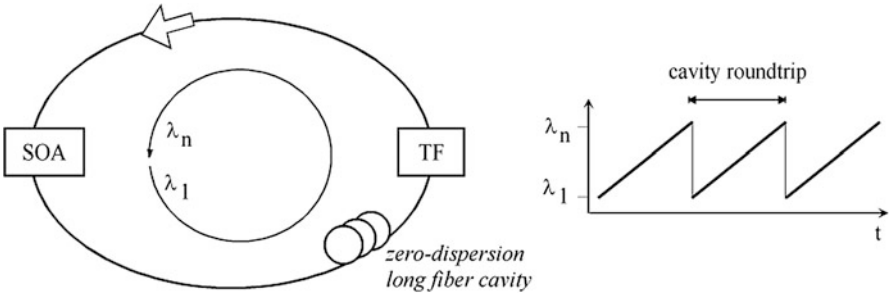

Fig. 20.8 Cavity-resonant sweep. The filter is scanned synchronously with the cavity round trip, resulting in an oscillation of cavity-long chirped pulse(s)

produce narrow linewidths of <0.01 nm, but requires precise sweep frequency control or cavity length stabilization within a precision much less than 10^{-5}, which is difficult to achieve in a km-long fiber cavity.

Frequency shifted feedback. A wavelength-swept operation combined with frequency-shifted feedback can lead to unique output characteristics. Consider a laser having a scanning filter and an acousto-optic frequency shifter in a cavity. On each roundtrip, the laser spectrum is shifted in frequency by f_{FS} and reshaped by a filter with its center frequency shifted by f_{filter} in one cavity roundtrip time. In this case, a simple model predicts that the linewidth of the oscillating laser spectrum is, approximately, proportional to $\delta\lambda \approx b^{2/3}\,|f_{FS} - f_{filter}|^{1/3}$ where b is the filter bandwidth [9]. Figure 20.9 depicts laser spectra of such lasers at three distinct cases. A narrow minimum linewidth is obtained by matching the filter sweep speed to the frequency shift, i.e., $f_{FS} = f_{filter}$. This resonant sweep has been demonstrated in a fiber laser employing an acousto-optic scanning filter. The experimental result in Fig. 20.9d clearly shows the linewidth narrowing at the resonant sweep rate of 270 Hz at which $f_{FS} = f_{filter} = 68$ MHz. This principle is applicable to the rapidly swept semiconductor lasers described in previous sections, but it requires a frequency shifter operating in the GHz range.

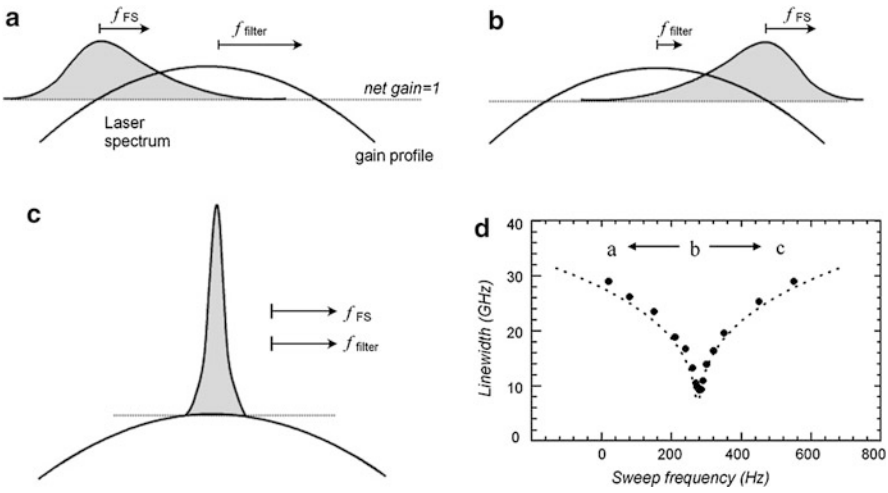

Fig. 20.9 Spectral dynamics in a swept laser with intracavity frequency shift for three cases: (**a**) $f_{filter} > f_{FS}$, (**b**) $f_{filter} < f_{FS}$, and (**c**) $f_{filter} = f_{FS}$. (**d**) Output linewidths (*circles*) of a frequency-shifted-feedback fiber laser [9], measured as a function of filter sweep rate (*dashed line*: numerical simulation)

20.4.3 Sliding Frequency Mode Locking (SFM)

As discussed in Sect. 20.3.4, a large number of cavity modes can oscillate simultaneously in a rapidly swept laser. If each of the modes originated from incoherent spontaneous emission, they would have a random relation with each other and lead to continuous-wave radiation. However, this situation can be completely changed if significant nonlinear broadening is present in the cavity. The nonlinearly generated spectral components can act as coherent seeds for newly developing modes, establish a defined phase relation among the oscillating modes, and, as a result, generate short pulses. This mode-locking mechanism, termed sliding-frequency mode locking (SFM), has been demonstrated in a rare-earth-doped fiber laser using self-phase modulation in optical fibers [11]. Figure 20.10a shows a schematic of the laser with an F-P scanning filter. Its output traces, shown in Fig. 20.10b, show a series of 100-ps pulses at a 12 MHz repetition rate corresponding to the cavity length. Their center wavelengths are scanned over 27 nm at 1,550 nm at a sweep rate of 250 Hz. Short swept pulses with duration of 10 ps to 100 fs may find applications in biomedical imaging based on multiphoton interactions in biological samples or time-resolved spectroscopy.

20.4.4 Stretched Chirped Pulses

In contrast to the laser-based approaches described so far, there are techniques capable of sweeping the wavelength outside a laser cavity. The simplest example is

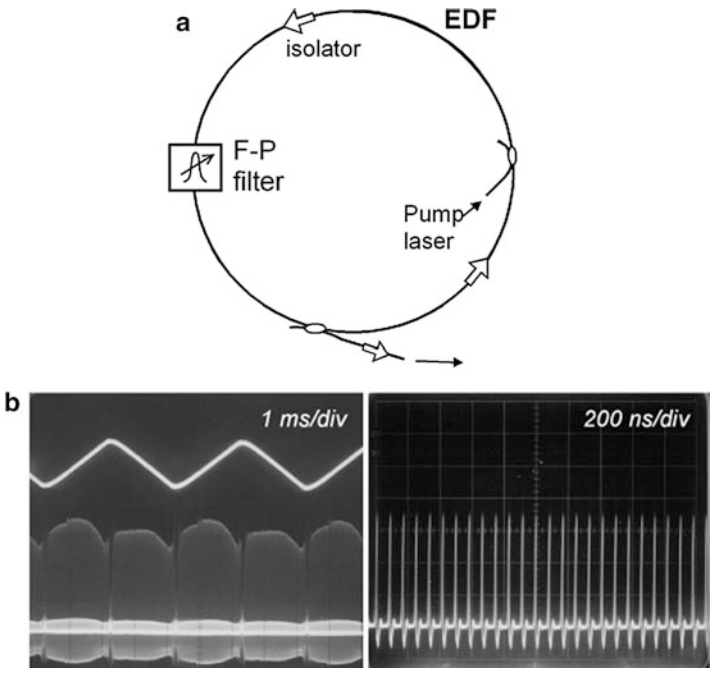

Fig. 20.10 Generation of wavelength-swept pulses. (**a**) Laser configuration. *EDF* erbium-doped fiber. (**b**) Time-domain oscilloscope traces of output pulses [11]

configured with a broadband source and a scanning filter that transmits only a narrowband spectrum of the broadband output at each time during a sweep. Although this approach is inefficient in terms of output power and spectral resolution, its operation is simple and it works with any type of broadband source, such as a super-continuum source. Another example is based on a combination of broadband pulse source and a high-dispersion fiber [30], schematically shown in Fig. 20.11. The light source can be a femtosecond mode-locked laser or sub-nanosecond super-continuum pulse source. The latter has been demonstrated with nonlinear fibers seeded by amplified, nanosecond gain-switched diode laser [17]. The width of each output pulse is stretched to 10–100 ns by a length of highly dispersive fiber. The typical dispersion of such fibers is about 10–100 ps/nm/km. To stretch a short pulse with 100-nm bandwidth to 100 ns, therefore, requires a relatively long fiber length of 10–50 km. The ratio of the initial pulse width to the final stretched value determines the finesse or the ratio of the spectral resolution to the total bandwidth. The repetition rate of the output pulses determines the A-line rate. High A-line rates of several MHz can be achieved easily with this passive tuning technique. The need for a broadband pulse source with low intensity noise and a long length of high-dispersion fiber for a high spectral resolution of <0.05 nm are two potential difficulties of the stretched pulse technique.

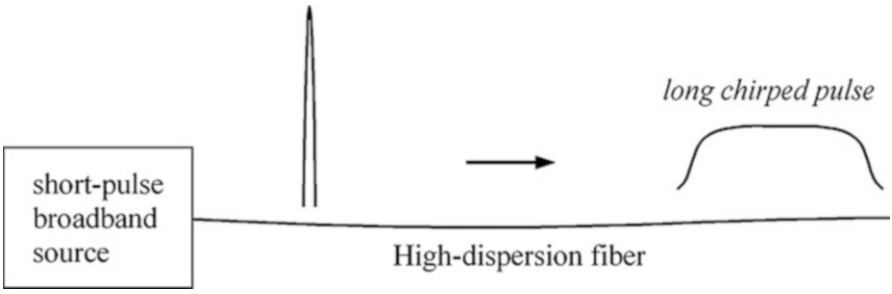

Fig. 20.11 Stretched-pulse swept source. The broadband short pulses from a laser source are stretched to long, typically an order of 100 ns, chirped pulses after propagating through a length of dispersive optical fiber

20.4.5 Wavelength Conversion

Laser-pumped wavelength conversion in nonlinear materials can be used to realize a wavelength-swept source. This section describes two techniques based on parametric conversion and soliton self-frequency shift.

Optical parametric oscillation (**OPO**). In a parametric conversion process in a nonlinear crystal, an intense pump wave is converted to two waves, idler and signal, with different or the same (degenerate) wavelengths. The frequency sum of the output waves is equal to the input wave frequency by phase matching. The efficiency of parametric conversion can be enhanced significantly by using a cavity oscillator resonant to the signal wave. With sufficient pump power, the gain provided by the nonlinear interaction can reach threshold and allow the signal wave to oscillate in the cavity, similarly to conventional laser operation. For a given pump wavelength, the output signal wavelength can be tuned continuously by changing the temperature or orientation of the crystal with respect to the pump beam. Much faster tuning can be achieved by sweeping the pump wavelength. To date, the tuning rate of OPOs has been limited to a few kHz, partly due to a lack of high-power rapidly swept pump lasers [22]. This approach is attractive for generating swept signal waves in the spectral range where conventional laser gain media are not available. Furthermore, a nonlinear optical crystal can be selected or designed such that a small change in pump wavelength leads to a wide tuning of the signal wavelength.

Soliton frequency shift. An optical fiber can support the propagation of soliton pulses through a balance between self-phase modulation and negative chromatic dispersion. When a short soliton pulse propagates through a long distance of optical fiber, stimulated Raman scattering in the optical fiber produces energy transfer within the pulse from short to long wavelength components, causing the pulse's center wavelength to increase constantly with propagation distance. This phenomenon, called soliton self-frequency shift, has been used to build a tunable source [18]. A typical configuration of the source is similar to that in Fig. 20.11, except that the pump source is a fixed-wavelength soliton laser, and the propagation fiber has an

appropriate dispersion and nonlinearity to guide quasi-soliton pulses. The magnitude of soliton frequency shift is sensitive to the input pulse intensity, so the output wavelength can be tuned by modulating the input power of the soliton pulses. A wide tuning range exceeding a few hundreds nm can be obtained easily. However, the need for short soliton pulses, typically with a width of 100–500 fs, makes it challenging to achieve high spectral resolution with this approach.

20.5 Outlook

This chapter covered a variety of techniques for wavelength-swept sources. The recent development of rapidly swept lasers resulted in dramatic improvements in imaging speed of OCT, opening up new applications such as comprehensive three-dimensional imaging in vivo [31]. ▶ Chapter 7, "Optical Frequency Domain Imaging" describes these remarkable advances in OCT technology and applications. We expect that swept laser technology will continue to advance and drive innovations in OCT. For an example, new ideas and engineering will broaden the tuning range to enhance spatial resolution to the cellular or subcellular level. Significant efforts to commercialize high-speed swept lasers have already begun. Compact, low-cost solutions will expedite the commercialization and, eventually, increase the availability and accessibility of swept-laser-based high-speed OCT systems to clinicians. The continuing development in wavelength-swept lasers will also benefit other application areas, including spectrally encoded confocal microscopy [32], sensing [16], and spectroscopy.

21.1 Introduction

In the early to mid-2000s, it became apparent that swept-source optical coherence tomography (SS-OCT) offers significant advantages over both time-domain (TD-OCT) and spectral-domain OCT (SD-OCT). Since that time, significant academic and commercial effort has been focused on developing SS-OCT lasers and sources capable of enabling high-quality SS-OCT imaging. While there are many important components in an SS-OCT system, it can reasonably be argued that the swept source is the most critical as its properties form the basis for most of the major system performance metrics. The detection and data acquisition electronics, together with the source, ultimately define the SS-OCT system performance specifications such as imaging speed, SNR and sensitivity, axial resolution, and imaging depth.

In this chapter, we describe a commercially available 1,060 nm swept-source OCT "engine" developed at Axsun Technologies suitable for ophthalmic and other OCT imaging applications. The engine consists of a swept laser module, control electronics, k-clock, balanced receiver, and data acquisition board which samples on k-clock transitions. The OCT engine provides optical system performance for shot-noise-limited imaging. The engine is designed to simplify construction of OCT imaging systems; the final user provides the optical probe/interface, application

control electronics, computing, and specialized software. Axsun manufactures such optoelectronic swept-source OCT engines for a range of medical imaging applications.

Axsun's 1,060 nm laser with 110 nm tuning range and 100 kHz sweep speed is described in this chapter along with the associated engine electronics. This is just one design point in the Axsun design space; many other swept source and engine configurations are possible and have been realized using the Axsun technology platform. For example, swept sources with various sweep rates, tuning ranges, coherence lengths, and modes of operation have been manufactured in both 1,060 and 1,310 nm wavelength ranges.

This chapter begins with a general description of the Axsun laser design along with a theoretical description of the laser dynamics. Next, we use this theory to explain a recently discovered property of the Axsun swept laser known as coherence revival [12]. We then describe the OCT engine electronics and demonstrate shot-noise-limited performance with sensitivities greater than 103 dB at 1.9 mW sample power. Lastly, we show artifact-free images from both internal testing and Topcon Corporation, a leading supplier of ophthalmic OCT imaging systems.

21.2 Laser Operation

In general, a swept laser consists of a gain medium, a tunable wavelength selection filter, and a laser cavity that supports lasing over the desired wavelength range. The Axsun laser architecture is shown in Fig. 21.1 and contains a reflective MEMS tunable Fabry-Perot filter, a broadband 1,060 nm gain chip, and a fiber reflector that forms the other end of the laser cavity and serves as the output coupler [1]. The filter exhibits a tunable reflection peak due to the filter optical axis tilt with respect to the optical beam [1, 2], and filter tuning is accomplished by changing the drive voltage on the MEMS filter. The MEMS filter can be swept from DC up to several hundred kilohertz depending on the desired repetition rate. The fiber extension brings the equivalent air length of the cavity to 104 mm such that there are a handful of laser cavity modes underneath the filter at all times. The laser is constructed in a hermetically sealed butterfly package with a fiber-optic feed through and exhibits stable polarization due to the strong TE/TM gain asymmetry of the SOA gain chip.

Many rapidly swept lasers exhibit a preference for tuning short to long wavelength [4–6]. They have higher power and are more stable in that direction. This behavior has been attributed to four-wave mixing in the gain medium [6, 7] coupled

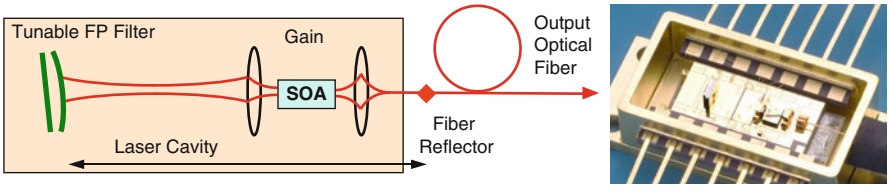

Fig. 21.1 External cavity laser with reflective Fabry-Perot MEMS tunable filter

with the Bogatov effect [8]. Computer simulations have predicted this red tuning behavior and laser pulsation under some conditions [7] and mode locking in some configurations [9]. We have shown both experimentally [3] and theoretically that sweeping the laser rapidly induces passive mode locking in the Axsun laser. Here we describe the basic dynamics of the laser.

Rapidly swept lasers tune too quickly for lasing to build up anew from spontaneous emission at each new wavelength [10]. A nonlinear optical mechanism is required to shift the wavelength of light circulating within the laser cavity to match the wavelength of the filter on successive round trips. In the case of the Axsun laser, a Doppler shift from the moving MEMS filter mirror does part of the job, although it is small compared to the wavelength shift required. Most of the shift comes from self-phase modulation induced by depletion of the gain as the mode-locked pulse travels through the semiconductor gain medium. Gain depletion is accompanied by a rise in refractive index. The coupling between the index and the power gain can be described using the linewidth enhancement factor, α, as

$$\Delta n = -\alpha \frac{\lambda}{4\pi} \Delta g$$

The mode-locking process is illustrated in Fig. 21.2. The SOA becomes optically longer as the pulse travels through, red shifting the light field. The laser does not tune continuously, but rather hops discretely to the next wavelength on each new pulse. The frequency hop for a SOA of length l is

$$\Delta v = -\frac{l}{\lambda} \frac{dn}{dt}$$

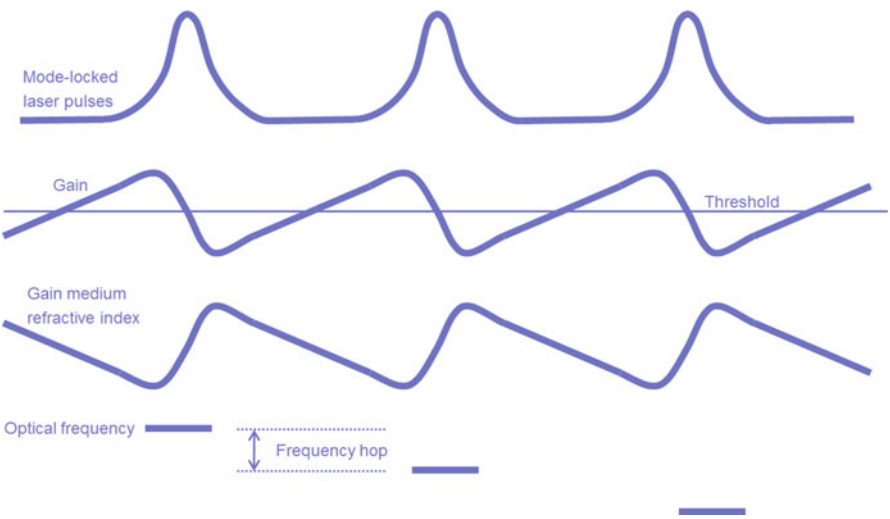

Fig. 21.2 Mode-locking and frequency hopping dynamics of a rapidly swept laser

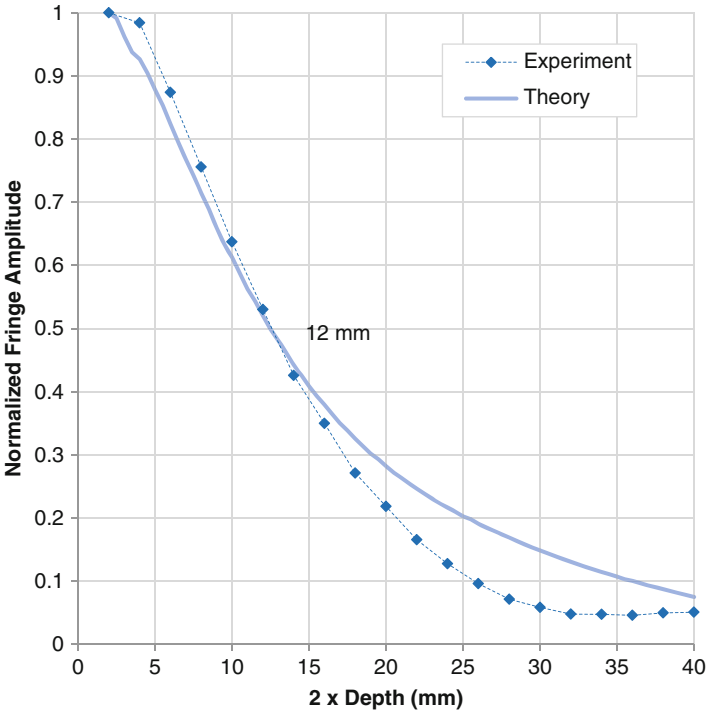

Fig. 21.3 Coherence length measurement compared with mode-locking model calculation

The pulse energy and width determine the magnitude of the frequency hop. The laser operates in this manner because the lowest threshold is obtained when the pulse frequency hops to follow the filter tuning. A feedback mechanism built into the laser dynamics naturally ensures the pulse hops to follow the filter. In the swept steady state, the pulses are tuned slightly to the long wavelength side of the filter and away from the reflection peak. If a pulse gets ahead of the filter (gets too red), it is attenuated by the filter and the lower power ensures the next pulse does not hop as far. Similarly, if a pulse falls behind (gets too blue), it becomes more powerful and catches up with the filter.

The filter line width and sweep rate play a critical role in ensuring proper mode-locking behavior throughout the sweep. The MEMS filter sweep is linearized to provide a nearly constant sweep rate during the tuning cycle. Stable passive mode-locking behavior can be maintained over the 100 nm data collection range of the laser with a total sweep range of 110 nm. This is essential for obtaining low relative intensity noise (RIN) and maintaining clean k-clocks for the optical engine.

We have developed a theory of these rapidly swept lasers, building on the mode-locking work by Haus [11]. This theory describes this mode-locking behavior in detail and can accurately predict a variety of laser characteristics, such as coherence lengths, as indicated in Fig. 21.3 below, and coherence revival properties, as discussed in the next section.

The upper limit of the coherence length of the mode-locked swept laser is determined by the pulse width. Theory predicts considerable chirp to the pulses, reducing the coherence lengths below this upper limit. The coherence length of these lasers is typically 12 mm, which ensures deep imaging capability required for many applications.

21.3 Coherence Revival

The 1,060 nm, 100 kHz laser operates with two pulses traveling in the cavity at once, with the two pulses separated by half the cavity roundtrip time. This can be seen with a high-speed detector and oscilloscope. Normally, an OCT interferometer is set up for short path mismatches, where laser pulses are interfering with themselves. With longer path mismatches, pulses can interfere with their neighbors, leading to the "coherence revival" phenomenon [12]. This behavior is shown in Fig. 21.4. The physical cavity length is 104 mm, but there is also interference at 52 mm due to the double pulsation. A pulse two away is an amplified copy of the first, whereas an adjacent pulse is not. There are two semi-independent pulse trains inside the cavity, leading to a 52 mm coherence function revival that is weaker than the revival at 104 mm.

Coherence revival is important because it can be a source of artifacts in an OCT system. An OCT interferometer needs to be carefully designed so that small stray reflections are not separated by intervals of half-cavity lengths, 52 mm, 104 mm, 156 mm . . . etc., where they can produce artifacts in the OCT image.

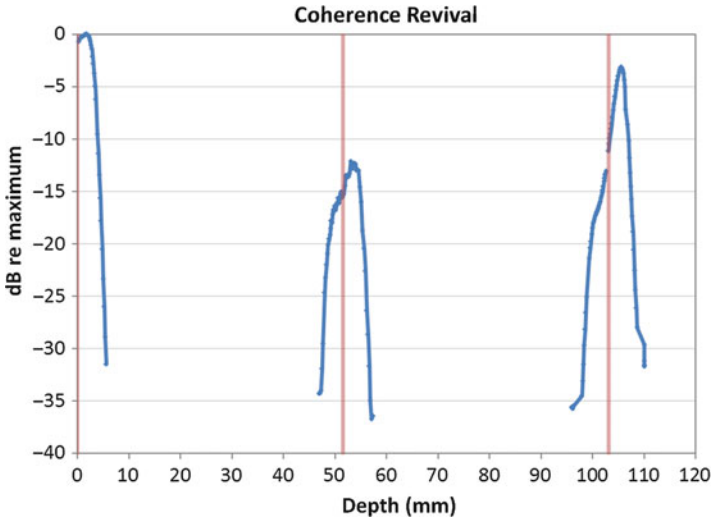

Fig. 21.4 Coherence function of the laser over a wide depth range showing the coherence revival phenomenon. The *red vertical lines* show the depths where the electrical signal frequency is zero. This measurement was made using an engine with a limited detector bandwidth, so the roll off of the curves reflects the detector bandwidth rather than the coherence length of the laser

Coherence revival has also been used to advantage to extend the imaging range of an OCT system [12]. Figure 21.4 shows that the 104 mm peak is displaced from the zero beat location. This means that the signal first goes up with depth before eventually rolling off. The imaging range, which normally is limited by the coherence length, is effectively doubled for this laser when operating at interferometer path mismatches near the 104 mm coherence revival peak. This coherence peak shift is a consequence of the pulse chirp and is a property of this particular laser design. By modifying the cavity design, it is possible to produce sources that do not have this behavior.

21.4 OCT Engine Design

The OCT engine consists of the swept laser module along with control electronics, a calibration k-clock, detection/receiver electronics, and a data acquisition board which samples on k-clock transitions. The engine is designed to simplify construction of OCT imaging systems; the end user provides the optical probe/interface, application control electronics, computing, and specialized software. Figure 21.5 shows a block diagram of the OCT engine.

The laser control board drives the SOA and MEMS tunable filter. The SOA current and filter drives are controlled through a file stored in flash memory. The control file specifies the SOA current and filter voltages as a function of time. In addition, the board contains two optical receivers. The first is for the calibration k-clock. The k-clock serves as an external clock input to the data acquisition (DAQ) board analog to digital (A2D) converter. A balanced receiver detects light from the main OCT imaging interferometer. The balanced receiver output, k-clock, and sweep trigger are differential signals for noise immunity and are run between the boards over SATA cables commonly used for disk drive interfaces.

In swept-source OCT, it is necessary to translate the raw OCT signal from one that is evenly spaced in time to one with data points evenly spaced in optical frequency, or k. This is often done through various software resampling approaches that interpolate the raw OCT signal. The resampling coefficients can be derived at predetermined intervals or on every A-line, depending on the stability of the swept source and the required imaging accuracy. Either way, the raw OCT signal must be resampled during each A-line.

An alternative approach, and the one used in the Axsun OCT engine, is to use a digital k-clock [13, 16]. The k-clock is derived from a fiber-based Mach-Zehnder interferometer (MZI) as shown in Fig. 21.5. As the laser source sweeps across its wavelength tuning range, the MZI receiver has zero-crossings that are evenly spaced in optical frequency. The MZI path length difference must be four times the maximum imaging depth (interference length $= 2 \times$ depth) in order to satisfy the Nyquist sampling limit. This approach speeds up data acquisition by eliminating the computing time for external resampling. However, this approach requires the A2D converter to handle a wide range of k-clock frequencies and duty cycles due to the nonlinear sweep dynamics of the laser.

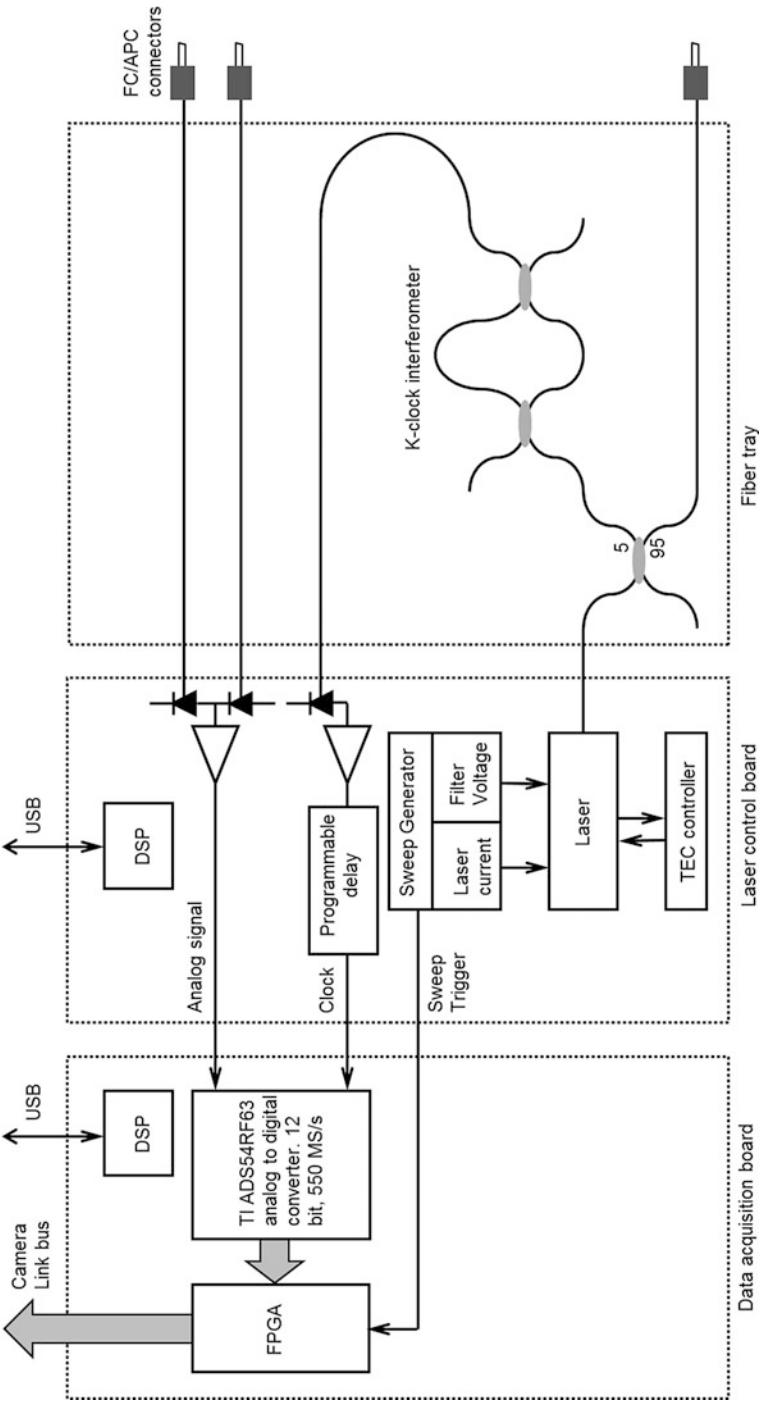

Fig. 21.5 Block diagram of the Axsun OCT engine

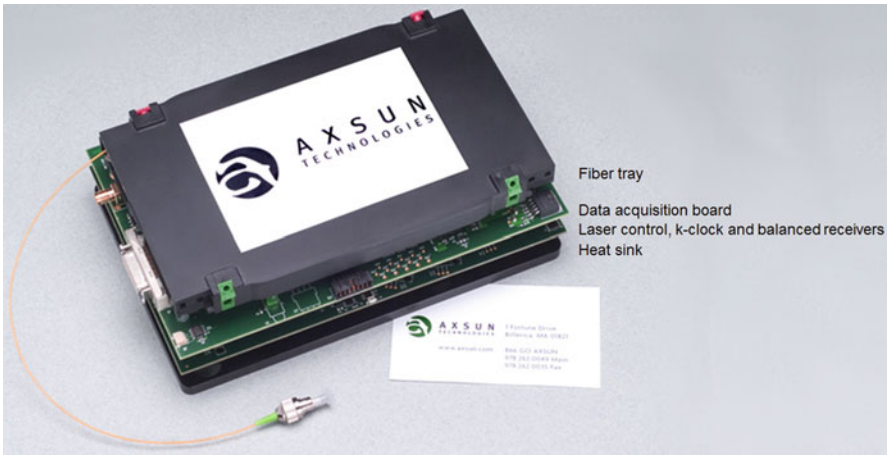

Fig. 21.6 Physical construction of the Axsun OCT engine

The data acquisition card in the Axsun OCT engine utilizes a 12-bit Texas Instruments ADS54RF63 analog to digital (A2D) converter. This chip is very tolerant of varying clock frequencies and duty cycles. Its clock specification is 40–550 MHz. We have verified that the DAQ card performs up to the limits of the chip. The FPGA presents the glue logic between the A2D converter and the Camera Link bus. The Camera Link bus can be set to run at 83.3, 41.7, 20.8, or 10.4 MHz. Two 12-bit samples are issued per clock cycle. There is no on-board data storage, but there is an FIFO buffer that mediates between the incoming variable data rate samples and the fixed rate Camera Link output samples. The engine must fill the FIFO faster than it is emptied and must not issue more samples than can be transferred between sweep trigger pulses. The system described in this chapter runs the Camera Link bus at 83.3 MHz. The laser is swept to keep the k-clock frequency greater than 167 MHz, so the FIFO is never empty. At the 100 kHz sweep rate, it transfers 1,376 out of a maximum of 1,670 samples.

The fiber Mach-Zehnder k-clock interferometer is located in the fiber tray. It is precisely cut and fusion spliced to set the maximum depth (Nyquist fold over distance) to an accuracy of ± 100 μm. Figure 21.6 shows a picture of the OCT engine stack.

Both laser control and DAQ boards can communicate with a personal computer via USB interfaces. A control program, OCTHost, is provided, but customer software can utilize a Windows .NET assembly for custom control.

21.5 System Performance

The Axsun OCT engine described in this chapter is set up for the scan plan in Fig. 21.7. The maximum imaging depth, set by the k-clock interferometer mismatch, is 3.7 mm. The laser sweeps over 110 nm at 100 kHz sweep rate. One thousand three hundred and seventy-six (1,376) samples are acquired, which

Parameter	Min	Value	Max	Units
Maximum scan depth in air		3.7		mm
FSR of clock interferometer		20.26		GHz
Sweep Frequency		100		kHz
Wavelength Range	985.0		1095.0	nm
Optical Frequency Range	273.783		304.358	THz
Data Range in wavelength	989.4		1089.6	nm
Data Range in optical frequency	275.144		302.997	THz
Sweep Range		110.0		nm
Sampled Range		100.2		nm
Maximum possible samples		1509		
Percent bandwidth used		91		%
Selected number of samples		1376		
Pixels in A-scan		688		
Data collection duty cycle		44		%
Estimated Clock Frequency		313		MHz

Window type	Resolution			
	3 dB	10 dB	20dB	Units
Cosine	6.4	11.0	14.6	μm
Hamming	7.0	12.4	16.6	μm
Hann	7.8	13.6	17.8	μm
Dolph-Chebyshev 60 dB	7.8	13.8	18.7	μm
Blackman	8.9	15.7	21.4	μm
Dolph-Chebyshev 80 dB	8.9	15.9	21.8	μm
Dolph-Chebyshev 100 dB	9.9	17.8	24.5	μm

Fig. 21.7 Scan plan for the 1,060 nm OCT engine. *Yellow* cells are inputs to the calculation. The Hann window is used in all of the measurements and calculations presented here

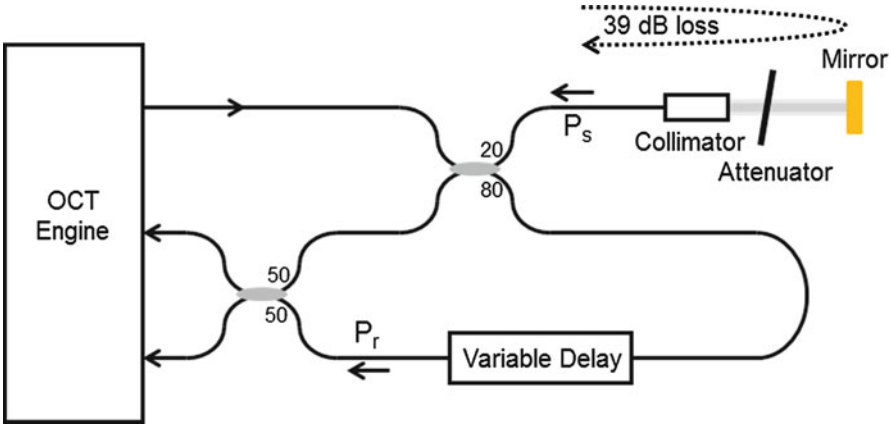

Fig. 21.8 Test interferometer

represents 100 nm of data out of the 110 nm sweep. Although the laser power output is not flat across the sweep, imaging depth resolutions very close to the limits imposed by the pre-FFT window function are obtained. All of the data presented here use a Hann window, though other windows can be chosen to trade resolution for side mode suppression. Calculated theoretical resolutions at 3, 10, and 20 dB from the point spread function peak are listed in the table.

System average output powers exceed 15 mW. The laser control board blanks the laser output power over the nonfunctional retrace portion of the laser frequency sweep. Given the roughly 50 % on/off duty cycle, the imaging power is roughly twice the average. This ensures high SNR while limiting average optical power, which is important, for example, in ophthalmic applications that have strict limits on the average optical power exposure to the eye.

Much of the OCT engine performance testing has been done with an interferometer configured as shown in Fig. 21.8. For imaging experiments, the attenuator and mirror are replaced by a galvo-scanner and imaging lens. Production systems are all tested in an automated test setup for sensitivity, resolution, imaging artifacts, and overall functionality. Most of the data presented here uses the setup of Fig. 21.8.

A calibration table defines the swept laser current and MEMS filter tuning voltage versus time. Each laser frequency sweep is calibrated separately, and a clock analysis similar to that in Fig. 21.9 verifies the calibration. At 100 kHz repetition rate, the filter is being driven well beyond its mechanical resonance, which limits the data collection duty cycle to around 45 % due to the resulting limitations in the linearization of the filter sweep. The red portion of the curves delimits the data collection region which proceeds for 1,376 clock pulses following the trigger. Power is measured with a wide bandwidth photodetector and a 2.5 GHz bandwidth oscilloscope. This is fast enough to see the mode-locked pulses. The wide bandwidth power trace is shown along with a 5 MHz low-pass filtered trace in red. The instantaneous powers are calibrated from an average power measurement made with a power meter.

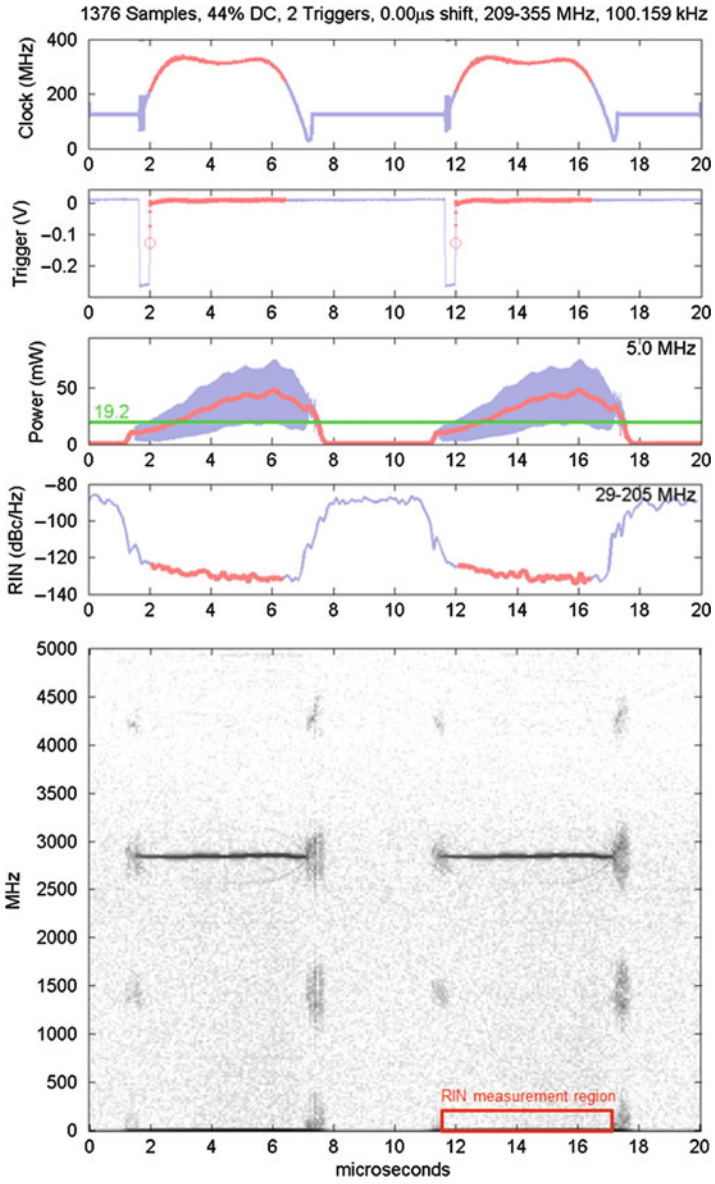

Fig. 21.9 Clock analysis, power, RIN, trigger, spectrogram

An RIN estimate is made from the wide bandwidth power data. It is based on the average noise between 29 and 209 MHz, which is approximately the bandwidth of the balanced receiver. Due to the laser pulsations, there are large RF signals outside this frequency range, but only the signals within the balanced receiver bandwidth are relevant. This high-speed measurement is routinely done to look for laser

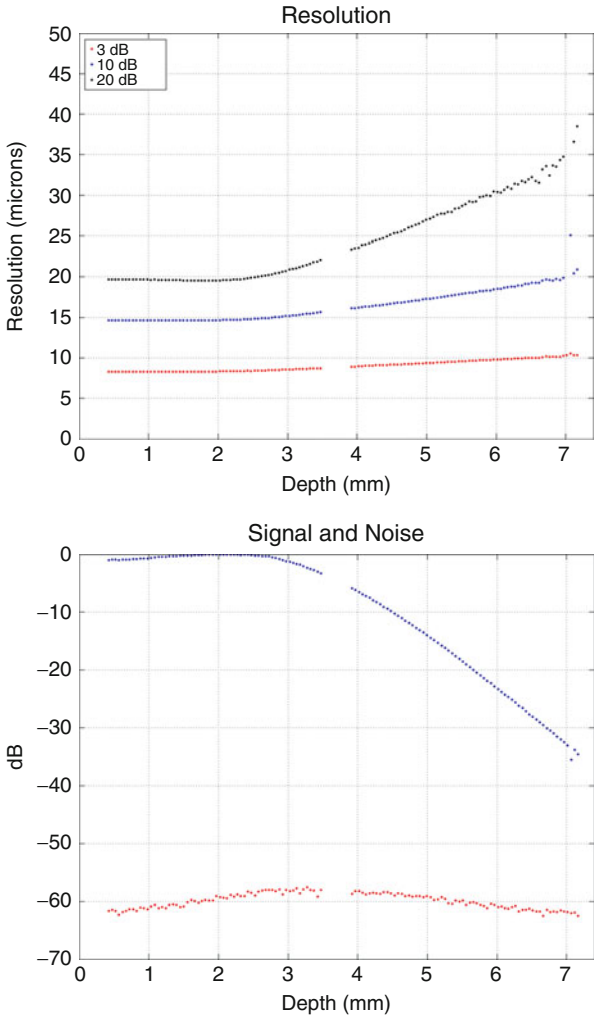

Fig. 21.10 Measured imaging depth resolution at 3, 10, and 20 dB below the point spread function peak. A Hann window was used in processing the data. Conditions: 1.2 mW reference power, 1.9 mW sample power, 46 dB loss. Signal and noise variations with depth are shown in the lower plot

instabilities. However, the RIN is too low to measure accurately by this method and only a rough estimate is obtained. In fact, high-performance telecommunication RIN test sets subtract out receiver noise and calculated shot noise when doing this type of test. Better RIN estimates can be obtained through measurements of system SNR as a function of reference power.

The bottom plot of Fig. 21.9 is a spectrogram of the wide bandwidth detector signal. It shows a strong signal at 2.9 GHz, indicating that the laser is pulsing twice per round trip in a 104 mm cavity. The clean spectrum between DC and 200 MHz indicates low RIN. The time-resolved nature of the spectrogram can reveal local laser instabilities where the laser is not cleanly mode locked.

Resolution and roll off measurements made on our automated test station are shown in Fig. 21.10. Resolution measurements generally match well to the

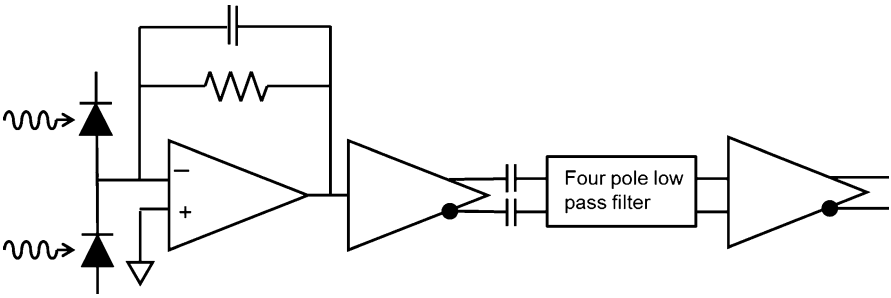

Fig. 21.11 Design of balanced receiver

calculations in the table of Fig. 21.7. These measurements were made through the depth range of 3.7 mm, and the aliased peaks beyond 3.7 mm were also tracked. Second- and third-order numeric dispersion compensation was used [14] and the sign of the compensation was flipped once the 3.7 mm Nyquist point was passed. An error in dispersion compensation broadens the point spread at all depths. It is also important to have the clock and balanced receiver signal time synchronized [15, 16]; otherwise, the resolution degrades with depth. System fiber lengths must be cut properly to achieve this. A programmable clock delay on the laser control board (see Fig. 21.5) can also be used to fine-tune the delay to minimize this effect.

Tracking roll off data past the 3.7 mm Nyquist depth shows the effectiveness of the antialiasing filters, which are located on the balanced receiver and the DAQ boards. The noise plotted is the noise level at the signal depth. It is nearly flat, as expected from shot-noise-limited operation. The test station uses a 1.2 mW reference power for these measurements.

The balanced receiver shown in Fig. 21.11 is a two-stage design followed by a differential output stage that drives the SATA cable connection to the data acquisition board. It has a transimpedance of 16 kohms and a frequency response shown in Fig. 21.12. It is AC coupled with a four-pole low-pass filter for antialiasing. It is thermal-noise limited at low frequency, but the noise is peaked at higher frequencies due to the operational amplifier input noise multiplied by the noise gain of the circuit [17]. This is an expected behavior for this type of receiver and means that the receiver noise is not flat versus depth.

The data acquisition system is another source of noise. The Axsun Camera Link DAQ card utilizes a Texas Instruments ADS54RF63 analog to digital converter. It is a 12 bit pipelined converter rated for a 40–550 MHz clock range. Axsun's own noise measurements with the card are shown in Fig. 21.13. The card is able to meet the ADS54RF63 noise specifications over the rated frequency range, but can also be under- or over-clocked with reduced performance. The converter translates ± 1.1 V differential signals into a 12 bit offset binary code. It achieves $\sigma = 0.9$ count RMS noise over much of its range. That translates to a maximum SNR of 64 dB and an ENOB of 10.4 bits, given the following expressions [18]:

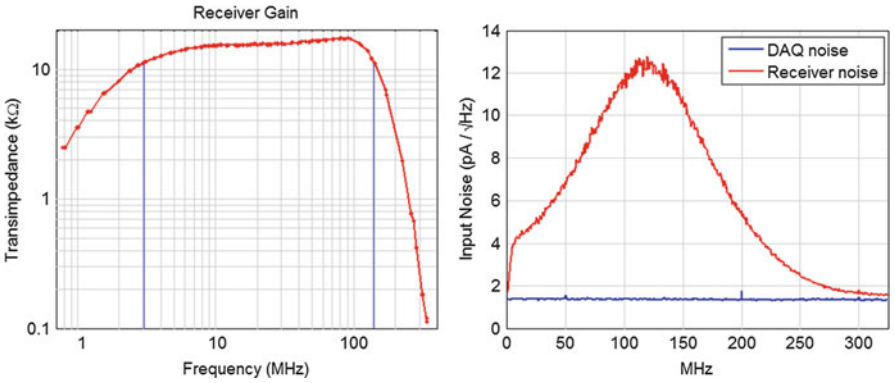

Fig. 21.12 Frequency response data for the balanced receiver. Transimpedance (*left*) and effective input current noise (*right*) are plotted

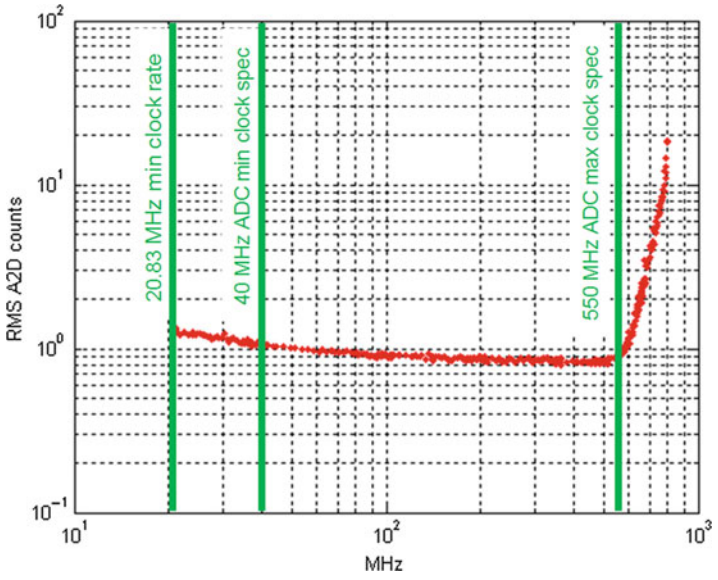

Fig. 21.13 Noise floor of data acquisition board

$$\mathrm{SNR} = \frac{\left(2^{N_{\mathrm{bits}}-1}\right)^2}{2\sigma^2}$$

$$\mathrm{SNR} = 6.02 \cdot \mathrm{ENOB} + 1.76\ \mathrm{dB}$$

Note that the 64 dB converter SNR limit is a broadband limit. FFT processing, which narrows the bandwidth, effectively averages OCT signals to much higher signal-to-noise ratios.

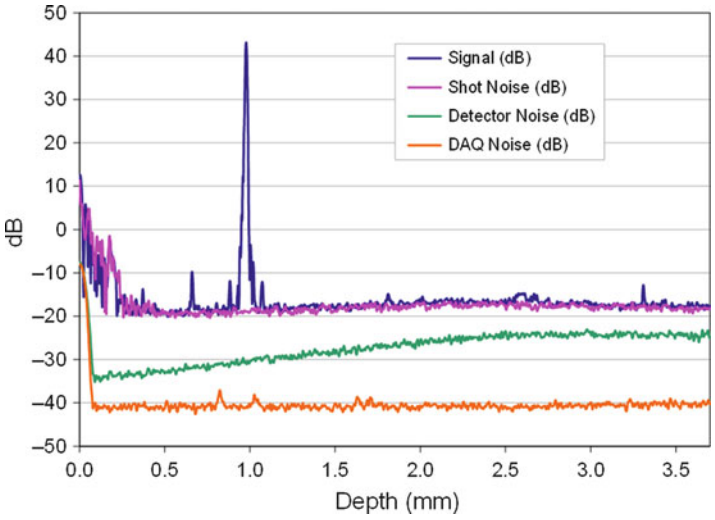

Fig. 21.14 Plot of signal and noise floor components versus depth. Conditions: 2.0 mW reference, 1.8 mW sample power, 39 dB attenuation

Figure 21.14 shows system noises versus depth along with the signal for a fixed reflector at 1 mm depth. It shows that the shot noise limit can be achieved throughout the imaging depth range. The traces are averages of 100 sweeps. Since the phase information is thrown away before averaging, the SNR is the same as for a single sweep, but the hash in the noise floor is reduced to give a better noise estimate. DAQ noise is not a limiting factor because the receiver noise is higher. The receiver noise is also not a limiting factor because the shot noise with 2 mW reference power is much higher. The shot noise is also flat because the transimpedance of the amplifier is flat up to the Nyquist frequency. The receiver noise is not flat, as pointed out earlier, because the noise gain of the receiver circuit is not flat. The useable depth range in this case is about 0.3–3.7 mm.

Figure 21.15 shows how the signal and noise behave as a function of reference power. Around 100 μW the shot noise becomes higher than the receiver noise. At this point the SNR becomes shot noise limited. Note that the SNR does not fall with further increases in reference power as expected from RIN-limited operation. The laser has very low noise. The data shown is limited to 2 mW, as measured on a power meter, which is getting close to the saturation limit of the balanced receiver.

The OCT engine's signal-to-noise behavior is modeled by the following expression, which is similar to that in reference [19]. Reference and sample powers, P_r and P_s, are defined in Fig. 21.8. The digital processing loss is 1.8 dB for a Hann window [20]. We estimate 2.2 dB miscellaneous loss:

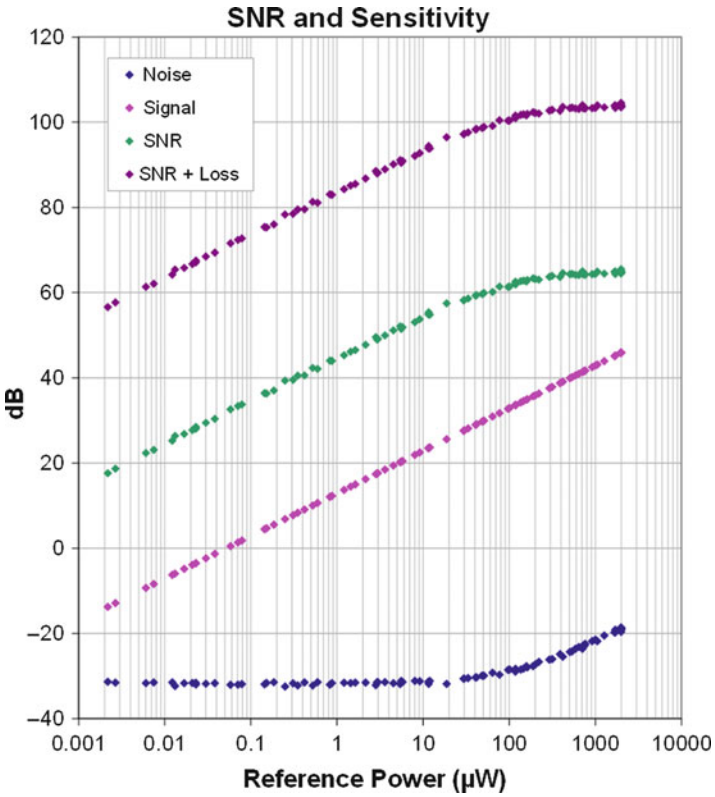

Fig. 21.15 Signal, noise, SNR, sensitivity versus reference power at 1 mm depth and 39 dB loss

$$\mathrm{SNR} = \frac{2\dfrac{T_{\mathrm{Misc}}T_{\mathrm{Coupler}}}{L_{\mathrm{Proc}}}\left(\dfrac{\eta q}{h\nu}\right)^2 P_r P_s}{\left[\left(\dfrac{\eta q}{h\nu}\right)^2 \mathrm{NEP}^2 + 2\dfrac{\eta q^2}{h\nu}P_r + \left(\dfrac{\eta q}{h\nu}\right)^2 \mathrm{RIN}\cdot\mathrm{CMRR}\cdot P_r^2\right]\dfrac{2B}{N}},$$

where

P_r = reference beam power
P_s = sample beam power
η = detector quantum efficiency
q = electronic charge
L_{Proc} = digital processing loss
T_{Coupler} = optical coupler power transmission
T_{Misc} = miscellaneous transmission reductions, such as connector and coupler loss

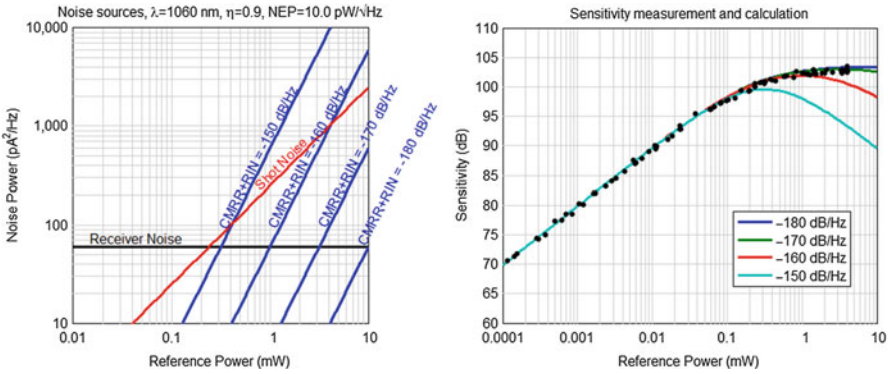

Fig. 21.16 Calculated noise powers (*left*) and comparison of experimental and theoretical sensitivities (*right*)

hν = photon energy
NEP = noise equivalent power of receiver
RIN = relative intensity noise
CMRR = common mode rejection ratio of balanced receiver
B = bandwidth of optical receiver (assumed 1/2 sampling rate)
N = number of samples

As pointed out in the discussion of the RIN measurement in Fig. 21.9, we believe that those numbers are pessimistic for the reasons illustrated in Fig. 21.16. We cannot determine the RIN directly from a measurement of SNR versus reference power, but we can get an estimate of CMRR+RIN (in dB/Hz). The left plot shows the noise floors for several values of CMRR+RIN. For shot noise to dominate, the RIN must be very low, because the CMRR will be poor given that the splitting ratios of fused 1,060 nm 3 dB couplers are not accurate and vary over wavelength. The right-hand plot of Fig. 21.16 shows no decrease in SNR at high reference power. It is likely that CMRR+RIN < -170 dB/Hz. We have not measured our CMRR, but it is probably around 20 dB. That would put the laser RIN in the neighborhood of -150 dB/Hz, much better than we can measure using the methods of Fig. 21.9. The laser has very low noise.

21.6 Images

The OCT engine described above, when coupled with a well-designed imaging interferometer and sample arm probe, is capable of delivering high-speed, high-resolution, high-sensitivity OCT images. The interferometer of Fig. 21.8 is well suited to ophthalmological applications where the average power to the eye is limited. An example image is shown in Fig. 21.17.

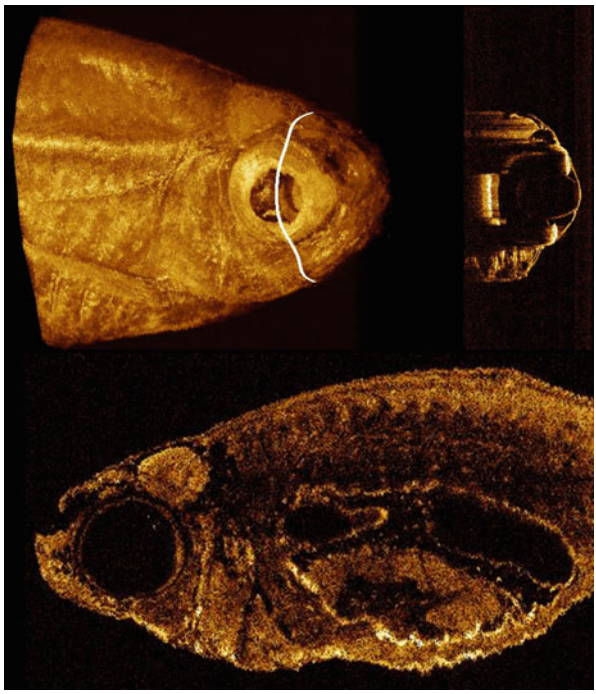

Fig. 21.17 Small aquarium fish imaged in the Axsun Technologies laboratories

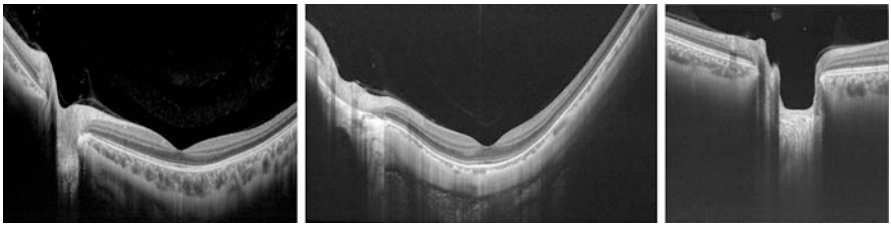

Fig. 21.18 Topcon DRI OCT-1 Atlantis system images of a healthy retina (*left*), a high myopia patient (*center*), and the optic nerve head (*right*) (Images courtesy of Topcon Corporation and Kyoto University)

High-quality retinal images in commercial equipment using the Axsun 1,060 nm OCT engine have also been produced. Figure 21.18 shows retinal images from a Topcon DRI OCT-1 Atlantis system. The 1,060 nm wavelength has several advantages over the current generation of 850 nm imaging systems. Reduced light scattering at longer wavelengths means that 1,060 nm light can penetrate deep into the choroid layer behind the retina. This wavelength also has superior penetration through cataracts. Another advantage is that the light is invisible to the patient, reducing eye motion from the patent's eyes natural tendency to follow the beam. The Axsun OCT engine also sweeps faster than current generation ophthalmic OCT systems and has shot-noise-limited performance, no fixed patterns, and low levels of ghost images.

21.7 Summary

In this chapter we described the design and performance of a 1,060 nm swept laser OCT imaging engine. In addition, we presented a new description of the passive mode-locking behavior of the Axsun swept laser. This deeper understanding of the swept laser dynamics is an important tool for many reasons. It enables modeling and rapid development of new lasers to meet the evolving needs of the OCT academic and commercial communities. In addition, the model allows us to better understand the design tolerance to changes in various key components, which is important for manufacturing these products with low cost.

The laser module, surrounding control and data acquisition electronics, produces an OCT engine that can accelerate commercial OCT system development. An OCT system manufacturer can concentrate on the application, the optical interface and software control. Axsun can provide high-speed shot-noise-limited system performance. This chapter shows one particular engine design useful for medical imaging, but Axsun has the ability to address other imaging and measurement problems with modifications to these systems. In particular, Axsun has both 1,310 and 1,060 nm band swept sources. They can be provided in a variety of sweep speeds, coherence lengths, and modes of operation.

22.1 Background and Introduction

Wavelength-swept light sources are widely recognized as a critical enabling technology for swept source optical coherence tomography (SS-OCT) [1]. This fact has spurred a number of development efforts, employing varying approaches, aimed at creating the ideal SS-OCT tunable laser source. A few wavelength bands have

emerged as most important, including the 1,310 nm band for vascular, skin, and anatomic imaging and the 850 and 1,050 nm bands for ophthalmic imaging. The desired performance parameters of a swept source for SS-OCT include high maximum sweep rate, high output power, variable sweep rate, long dynamic source coherence length, and wide tuning range. High sweep rate is needed for real-time acquisition of large volumetric data sets [2], for reduced sensitivity to patient motion artifacts, and for imaging dynamically varying physiological processes. High output power enhances signal-to-noise and image quality, with 30–60 mW desirable for many 1,310 nm applications and 15–20 mW desirable for many 1,050 nm ophthalmic applications. Variable sweep rates are desirable, since detection bandwidth limits force tradeoffs between imaging range, axial resolution, and imaging speed, depending on the particular biological structure being imaged. Long coherence length is necessary for applications which require a long imaging range such as whole eye imaging and anatomic OCT. Wide tuning range is also critical, because the axial spatial resolution is inversely proportional to the laser tuning range [3].

In response to this diverse and challenging set of requirements, a large number of swept source laser configurations have been investigated in recent years. A comprehensive and up-to-date review of swept source options is found in table I of a recent publication on ophthalmic imaging [4]. It is not the purpose of this chapter to repeat this review, but we mention here briefly two leading swept source options, to illustrate some of the challenges and tradeoffs involved. These two leading candidates are commercial external cavity tunable lasers [5] and Fourier domain mode-locked (FDML) [6] lasers. A commercially available external cavity device at 1,060 nm uses a tunable Fabry-Perot mirror as the reflecting element, providing $\sim$100 nm tuning and axial scan rate up to 100 kHz [5]. Commercial 1,310 nm external cavity devices operating at 50 kHz are also used extensively in cardiovascular imaging. FDML lasers employ a fiber-based ring cavity with a tunable intracavity Fabry-Perot filter, in which the wavelength repetition period of the laser is matched to the round-trip delay time in the external cavity [6]. This allows the laser to operate in quasi-stationary configuration and circumvents the normal speed limitations associated with buildup of amplified spontaneous emission (ASE) to lasing operation [1]. In 2006, an FDML at 1,310 nm demonstrated 290 kHz fundamental axial line rate in conjunction with $>$100 nm tuning [7]. More recently, line rates of 400 kHz have been reported with the FDML [8]. Fiber-optic delay lines and multiple spots have been employed (as could be with other swept sources), to multiplex FDML rates into the multi-MHz range [9, 10].

Both the external cavity laser and FDML are multimode devices, a fact that ultimately limits dynamic coherence length and imaging range. An external cavity laser at 1,060 nm has shown 20 mm dynamic coherence length at 100 kHz operation [5], and the 1,310 nm FDML has shown $>$14 mm at 290 kHz line rate [7]. Both of these results represent impressive advancements over technology available before 2006. Nevertheless, the fact that both lasers operate with a cluster of modes, rather than a single mode, leads to a coherence length that is an order of magnitude or more smaller than single-mode semiconductor lasers. Multimode operation can also increase relative intensity noise (RIN). The FDML has a further limitation that it

must be operated at a fixed rate because of its fixed fiber external cavity length. In short, the external cavity laser and FDML suffer from limited or fixed sweep rate and limited dynamic coherence length due to multimode operation. These limitations are representative of not only these sources but also the majority of other swept sources developed in the last ~15 years [4].

In 2009, Praevium Research and commercial partner Thorlabs began developing a swept source based on amplified microelectromechanical systems tunable vertical-cavity surface-emitting lasers (MEMS-VCSELs). The purpose of this development was to create a truly single-mode swept source for OCT that was capable of variable sweep rates from the kHz range up to the MHz range. MEMS-VCSELs offered a potentially ideal solution to this problem. The short micron scale length of the VCSEL cavity promised single-mode operation and rapid buildup time to lasing [1], and the low mirror mass in previously demonstrated MEMS-VCSELs promised >1 MHz axial line rates [11]. In addition, initial short-cavity designs predicted a longitudinal mode spacing well exceeding 100 nm, suggesting the possibility of mode-hop-free continuous tuning over this range. Linewidths on the order of 3 MHz had been demonstrated in fixed wavelength VCSELs [12], corresponding to a coherence length of tens of meters at 1,310 nm. Previous MEMS-tunable VCSELs had shown larger linewidths up to several hundred MHz, due to additional mechanical chirp contributions associated with the suspended membrane [13], but this linewidth still corresponded to meter scale coherence length or more than an order of magnitude larger than leading competing SS-OCT sources. Lastly, the fully integrated structure of the VCSEL contrasted with the separation of gain and tuning elements present in external cavity lasers, suggesting both cost and performance benefits. By 2009, fixed wavelength VCSELs had established themselves as a low-cost wafer-scale laser technology, and a MEMS-tunable device promised to exploit these same advantages.

MEMS-VCSELs were first conceived in the mid-1990s [14], but development efforts in the field until 2009 were driven primarily by telecommunications [15] and narrow-tuning spectroscopic applications [16, 17]. Application of these devices to SS-OCT therefore posed a large number of uncertainties. As of 2009, no MEMS-VCSELs had been demonstrated at the desired OCT wavelength bands of 1,310 and 1,050 nm, though 1,550 nm devices had undergone advanced development for telecommunications [15]. Secondly, the widest tuning range $\Delta\lambda$ reported for any MEMS-VCSEL at any wavelength was 65 nm at $\lambda = 1{,}550$ nm, corresponding to a fractional wavelength tuning $\Delta\lambda/\lambda$ of 4.2 %. This is equivalent to 55 nm at 1,310 nm, or about half of what competing SS-OCT sources at the time offered. Thirdly, single-mode VCSEL output powers were limited to a few mW, short of the 30–60 mW required for 1,310 nm applications and the 15–20 mW required for 1,050 nm. Semiconductor-based optical amplification promised the required powers, but the quality of imaging obtainable with amplified VCSELs was unknown. Fourthly, although small signal and high-speed tuning had been demonstrated in MEMS-VCSELs [11], high speed in conjunction with wide tuning range had never been reported.

In the last 3 years, these challenges have been addressed through a large multi-disciplinary effort involving Praevium Research, Advanced Optical Microsystems,

Thorlabs, and the OCT Imaging Group at the Massachusetts Institute of Technology (MIT). Praevium Research has taken the lead on VCSEL device design and fabrication. Thorlabs has led manufacturing, packaging, commercialization, OCT imaging validation, and development of supporting electronics. MIT has developed and demonstrated the utility of the VCSEL in new imaging modes and applications. A few results of this effort include the first MEMS-VCSELs at 1,050 nm [18] and 1,310 nm [19]; record tuning ranges of 150 nm at 1,310 nm [19] and 100 nm at 1,050 nm [18]; whole eye imaging, anterior eye imaging, and retinal imaging with 1,050 nm VCSELs [4]; and additional high-quality skin and vascular images with both 1,310 and 1,050 nm VCSELs [20]. Record coherence length >100 mm and axial scan rates up to 1.2 MHz have been demonstrated [20]. Linearized drive waveforms at 200 kHz axial scan rates have also been shown [20].

As a consequence of the results described above, as of 2014, SS-OCT optimized MEMS-VCSELs have reached early commercialization. The sections below describe design, fabrication, and performance of these devices in detail, focusing on the laser source. Detailed discussion of OCT imaging with VCSELs is provided by other chapters of this book.

22.2 Widely Tunable 1,310 nm and 1,050 nm VCSEL Design

22.2.1 Overview of Device Structure

The first 1310 nm MEMS-VCSELs were reported by Praevium and collaborators in mid-2011 [21] and the first 1,050 nm devices in early 2012 [20]. Figure 22.1 illustrates a three-dimensional solid model of a 1,310 nm MEMS-VCSEL. The 1,310 nm epitaxial structure includes a wide-gain bandgap-engineered aluminum indium gallium arsenide (AlInGaAs) multi-quantum well (MQW) active region epitaxially grown on an indium phosphide (InP) substrate and joined by wafer bonding [22] to

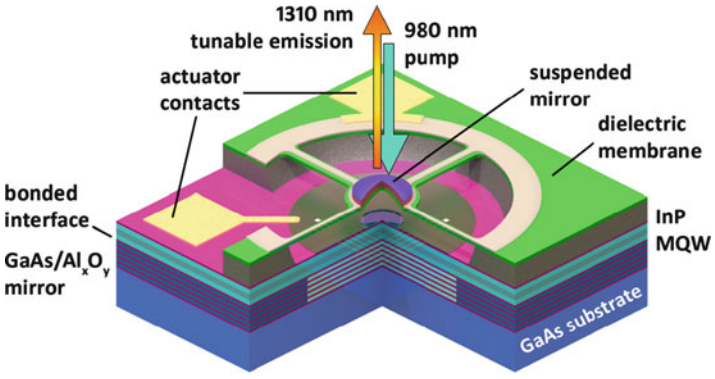

Fig. 22.1 Three-dimensional cutaway view of our 1,310 nm MEMS-VCSEL. InP gain region and GaAs mirror are integrated by wafer bonding. VCSEL is optically pumped at 980 nm (From Ref. [19])

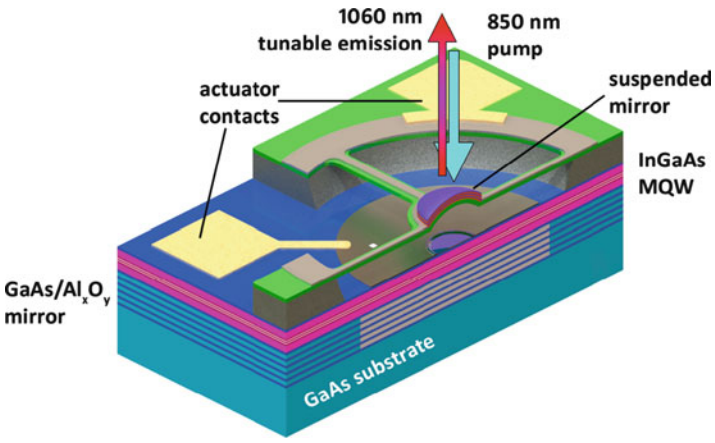

Fig. 22.2 Three-dimensional cutaway view of 1,050 nm MEMS-VCSEL. The structure is grown in one epitaxial step with no wafer bonding. VCSEL is optically pumped at 850 nm (From Ref. [18])

a wideband bottom gallium arsenide (GaAs)-based fully oxidized aluminum oxide (Al_xO_y)-GaAs bottom mirror [23]. Additional metal and dielectric layers on top of this "half-VCSEL" structure complete the optical cavity. This cavity includes a suspended top dielectric mirror, separated from the underlying half-VCSEL structure by an air gap, which can be contracted by electrostatic force as a voltage is applied between the two actuator contacts shown. The VCSEL is optically pumped at 980 nm through the top dielectric mirror, generating tunable 1,310 nm emission, which emerges from the top mirror and is fiber coupled and amplified by a low-noise semiconductor optical amplifier (SOA) before being sent to an OCT system.

Figure 22.2 illustrates a similar view of a 1,050 nm device. Here, the gain region employs compressively strained indium gallium arsenide (InGaAs) quantum wells integrated with a GaAs/Al_xO_y fully oxidized mirror. The structure requires no wafer bonding, since the InGaAs quantum wells are nearly lattice matched to the underlying GaAs and can be integrated by epitaxial growth with the GaAs-based mirror. In this case, the optical pump is at 850 nm, generating tunable 1,050 nm emission.

Implicit in the device structures of Figs. 22.1 and 22.2 are a number of design choices that are critical to obtaining wide tuning range. Below, we briefly describe those choices and the justification for each.

22.2.2 Optical Versus Electrical Pumping

This effort to date has focused on optically rather than electrically pumped devices. Though the ultimate low-cost device will be electrically pumped, optical pumping provides a number of performance advantages over electrical pumping, including enhanced tuning range and spectral purity, for a variety of reasons. First, the absence of electrically active dopants reduces absorption losses and thus reduces threshold gain, enabling lasing over a wider portion of the available gain spectrum.

Second, the absence of resistive heating associated with electrically pumped devices also increases available gain and again promotes wide tuning range. Third, optical pumping eliminates the need for thick intracavity current-spreading layers, which extends the overall cavity length, reducing the cavity free spectral range (FSR) and ultimately limiting the laser tuning range. The widest previously reported MEMS-VCSELs have had tuning range limited by (FSR) [15, 24]. Fourthly, optical pumping simplifies the use of resonant periodic gain structures, which are known to provide a maximal gain enhancement in a VCSEL cavity [25]. Lastly, a single-spatial-mode pump laser provides an optimal overlap between the pump area and the lowest order spatial mode of the VCSEL, which suppresses lasing of unwanted transverse modes. This enables very high side mode suppression ratio (SMSR) of >45 dB to be routinely achieved in properly designed optically pumped devices. This high SMSR has a favorable impact on SS-OCT imaging quality.

We also note that the highest power tunable VCSELs have been demonstrated by optical pumping, achieving an impressive peak power of 14 mW near 1,550 nm [15]. This falls short by a factor of 2–3 from that required for SS-OCT near 1,310 nm but is somewhat close to power levels required for ophthalmic imaging at 1,050 nm. Our design philosophy in this effort is to design the MEMS-VCSEL itself for wide tuning range, enabling improved axial resolution, rather than high output power. We then amplify the VCSEL emission with a semiconductor optical amplifier. The resulting widely tunable, high power emission is used as the source for OCT imaging and has resulted in excellent images, as discussed in Sect. 22.6 below and in additional publications. The previous high power result at 1,550 nm [15], however, suggests that further engineering of 1,050 nm MEMS-VCSELs may remove the need for amplification at this wavelength.

22.2.3 Mirror Design

Wide mirror reflectivity bandwidth is critically important for wide tuning range. A high refractive index contrast mirror with a short optical field penetration depth is also critical to reduce the overall effective cavity thickness and increase the FSR, which further increases tuning range. The fully oxidized mirror shown in Figs. 22.1 and 22.2 satisfies these requirements better than virtually any other mirror, with the possible exception of a hybrid metal/deposited dielectric mirror [24], which we discuss briefly below. Wide bandwidth is also provided by the recently proposed and demonstrated high contrast grating (HCG) [11]. The HCG provides a high reflectivity in a thin single layer structure that has a strong lateral refractive index perturbation. This provides very low mass and high mechanical resonance, but the calculated HCG bandwidth [26] falls short of the fully oxidized mirror, and the ability of the HCG to provide >30 nm tuning in a VCSEL structure remains unproven.

The fully oxidized mirror is realized by starting with an epitaxially grown stack of GaAs/AlAs, etching holes or mesas into the epilayer structure to access the underlying AlAs layers, and exposing the material to a steam atmosphere at elevated temperature [23]. This converts the AlAs layers to Al_xO_y layers with

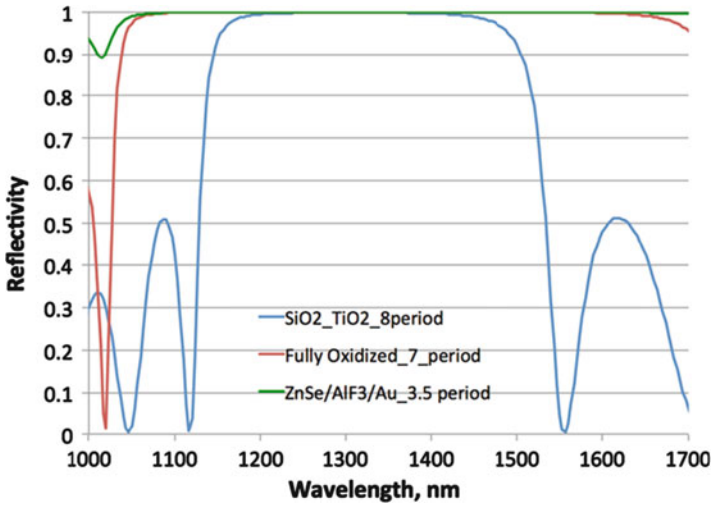

Fig. 22.3 Reflectivity of two candidate back mirrors (*red* and *green*) and one suspended mirror (*blue*)

a refractive index around 1.55, providing a large index contrast relative to the surrounding GaAs layers (index around 3.4). This enables the incorporation of a high reflectivity, wide bandwidth, and short penetration depth end mirror.

The use of the fully oxidized mirror at 1,050 nm is a natural choice, since it can be epitaxially grown with the GaAs gain region. Its use at 1,310 nm is less obvious, since this necessitates wafer bonding an InP-based gain region to a GaAs-based mirror region, as shown in Fig. 22.1. The choice of a heterogeneously integrated material structure stems from the fact that the InP material system provides no easily oxidized material-like AlAs or any other epitaxially grown high-index contrast mirror option [27]. In response to this challenge, previous MEMS-tunable work at 1,550 nm has employed deposited dielectric and/or metal/dielectric mirrors on both sides of the cavity [15, 24]. Similar approaches could be employed at 1,310 nm. Our choice of the wafer-bonded semiconductor mirror is related to mechanical robustness, manufacturability, and ease of handling, relative to a process that requires either backside vias [15] or gold bonding to a transfer substrate [24]. In addition, the transparency of the fully oxidized mirror enables coupling light out at either side of the cavity, to satisfy the needs of a variety of applications, while the metal/dielectric mirror can only function as a back mirror.

Figures 22.3 and 22.4 illustrate the reflectivity of three candidate mirrors for widely tunable MEMS-VCSELs centered at 1,300 nm, neglecting absorption and scattering losses. Reflectivity is calculated with respect to the antireflection (AR)-coated gain medium (i.e., looking from the gain medium outward to the respective mirrors), assuming that the pure dielectric mirror is suspended, and the fully oxidized or hybrid mirror is the fixed back mirror. Both the fully oxidized mirror ($GaAs/Al_xO_y$) and hybrid dielectric/gold mirror ($AlF_3/ZnSe/Au$) show a reflectivity bandwidth between first nulls of about 800 nm. The suspended

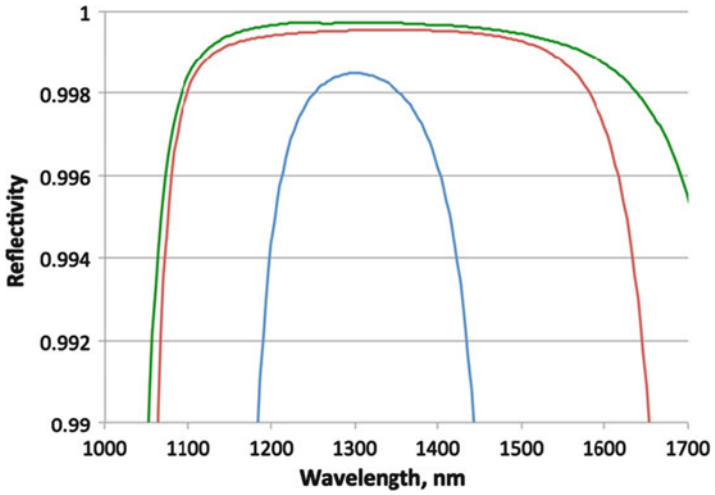

Fig. 22.4 Reflectivity in range > 99 %. Back mirrors (*red* and *green*) provide > 99.9 % over 400 nm. Suspended (*blue*) shows 99.5 % < R < 99.9 % over ~200 nm

dielectric mirror bandwidth between nulls is about half this value. The reflectivity plot of Fig. 22.4 shows the reflectivity spectrum of the same three mirrors over the same wavelength range but only for reflectivity above 99 %. Efficient top-emitting VCSELs require >99.9 % reflectivity on the back mirror. The fully oxidized and the hybrid dielectric/metal mirror both satisfy this requirement over >400 nm, with again the hybrid mirror exhibiting a slightly wider bandwidth. A lower reflectivity pure dielectric mirror, such as the SiO_2/TiO_2 combination calculated in Figs. 22.3 and 22.4, functions as the output coupler. Requirements on this output coupler are somewhat relaxed relative to the back mirror, with a required reflectivity in the range of about 99.5 % < R < 99.9 %. Reflectivity lower than 99.5 % increases the required threshold gain or inhibits wideband lasing, and reflectivity > 99.9 % can compromise output power as very little light is coupled out of the optical cavity. The SiO_2/TiO_2 combination shown in the figure satisfies this requirement over about 200 nm bandwidth, as do other commercially available and robust dielectric coatings such as SiO_2/Ta_2O_5 or SiO_2/Nb_2O_5.

A MEMS-VCSEL employing the dielectric mirror shown in Figs. 22.3 and 22.4 as an output coupler, and either of the back mirrors shown, can be expected to support lasing over 100–200 nm tuning range near 1,310 nm. Similar reflectivity plots can be generated near 1,050 nm and similar conclusions formed. The ultimate limit on tuning then becomes the cavity free spectral range (FSR) or the available gain bandwidth. In previous electrically pumped MEMS-VCSELs, FSR has often limited tuning range. In our optically pumped devices, we have pushed the FSR to 161 nm at 1,310 nm, achieving 150 nm tuning range as discussed below [19]. Achievement of this tuning range requires not only wide mirror bandwidth and large FSR but also proper engineering of the active region. We briefly discuss the active region material design in the next section.

22.2.4 Active Region Material Design

As discussed earlier, MEMS-VCSELs at both 1,050 and 1,310 nm employ compressively strained multi-quantum well (MQW) active regions, since compressive strain provides gain enhancements in quantum well gain for both GaAs-based (1,050 nm) and InP-based (1,310 nm) multi-quantum well active regions [28, 29]. Tensile strain has also been shown to provide superior edge-emitting laser performance for InGaAsP/InP MQW devices [30], but tensile strain enhances transverse magnetic (TM) gain (electric field perpendicular to quantum well plane) rather than transverse electric (TE) gain [29]. Since light propagation is perpendicular to the plane of the quantum well in VCSELs, the electric field will be in the plane of the quantum well and thus compressively strained wells can be employed.

MEMS-VCSELs at 1,050 nm employ InGaAs quantum wells with GaAs barriers as the gain region. This material is known to provide higher gain relative to lattice-matched quantum wells on GaAs [29], and incorporation of indium is necessary to increase the wavelength on GaAs beyond the ~870 nm achievable with lattice-matched materials. Compressively strained InGaAs quantum wells have been used for 980 nm fixed wavelength VCSELs since early in the history of VCSELs [31], and more recently, fixed wavelength devices at 1,100 nm using strained InGaAs quantum wells have also been demonstrated [32]. MEMS-VCSELs at 1,310 nm employ compressively strained AlInGaAs/InP quantum wells. Although the compressively strained InGaAsP/InP quantum wells have a longer history in edge-emitting lasers [30], the AlInGaAs/InP material system has provided superior temperature performance in edge-emitting lasers at 1,310 nm [33]. Other demonstrations in both 1,550 nm fixed wavelength [34] and 1,550 nm MEMS-VCSELs [35] have employed compressively strained AlInGaAs/InP multi-quantum well active regions. For tunable VCSELs, a lesser-known advantage of the AlInGaAs/InP material system is the wider gain spectrum relative to InGaAsP/InP. This width can be obtained by designing quantum wells to have two confined quantum states. State separation is wider in the AlInGaAs/InP material system relative to the InGaAsP/InP system, because of the larger conduction band offset [33], leading to wider gain spectra and higher output powers. This has been demonstrated in superluminescent diodes (SLED) developed by Praevium Research, an example spectrum of which is shown in Fig. 22.5. The InGaAs/GaAs system is also capable of wide dual-quantum state gain spectra, as shown in the SLED spectrum of Fig. 22.6.

22.2.5 MEMS Actuator Design

For SS-OCT operation, the ideal MEMS actuator should have a flat and wide bandwidth frequency response, enabling operation at arbitrary scan rates and linearization of drive waveforms through control of higher frequency dynamics. Note that here we focus exclusively on electrostatic rather than electrothermal [24] actuation, since the latter does not provide speeds appropriate for SS-OCT.

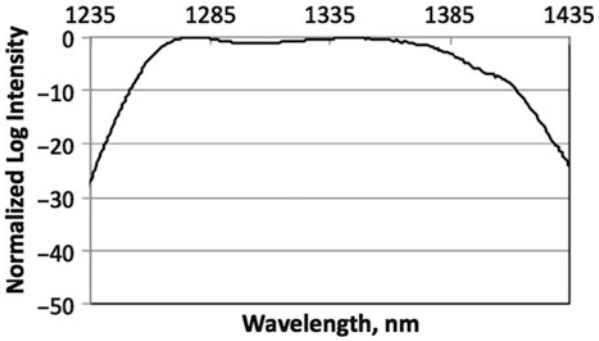

Fig. 22.5 Emission spectrum from a 1,310 nm superluminescent diode (*SLED*) using an AlInGaAs/InP MQW design with two quantum states. Width of SLED spectrum is indicative of width of the gain spectrum

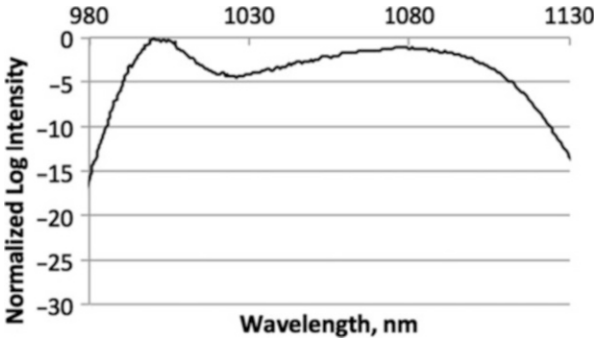

Fig. 22.6 Emission spectrum from 1,050 nm superluminescent diode (*SLED*) using an InGaAs/GaAs QW structure with two quantum states. Width of SLED spectrum is indicative of width of the gain spectrum

Numerous parameters associated with the actuator geometry affect the MEMS-VCSEL tuning frequency response. For the specific geometry of Figs. 22.1 and 22.2, using a central plate with a number of supporting arms, important parameters include the thickness and stress level of the membrane layer, the overall actuator area, the length and width of the supporting arms, the number of arms, the diameter of the central distributed Bragg reflector (DBR) mirror, and the initial air gap. These parameters affect resonant frequency, damping, resulting bandwidth, voltage required for a given wavelength shift, and maximum achievable wavelength span. Many of these factors must be traded off to achieve a commercially viable design. For example, increasing the thickness and stress of the membrane layer increases the resonant frequency but may require impractical voltages to achieve the full tuning range. Increasing the initial air gap thickness increases maximum achievable static deflection, because tuning beyond about one-third of the initial air gap causes electrostatic forces to overwhelm restoring forces, leading to "snapdown" of the actuator [36]. In dynamic operation, the peak voltage can exceed the snapdown voltage as long as the actuation frequency is sufficiently high. Nevertheless, a certain amount of static bias is required on all devices, and avoiding snapdown in electrostatic actuators therefore remains an important design consideration.

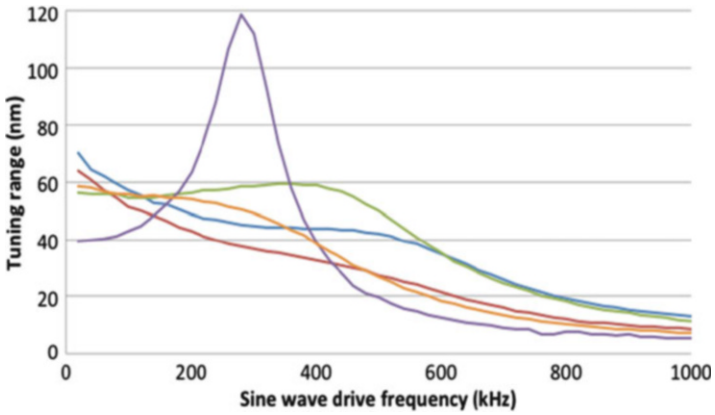

Fig. 22.7 Various frequency responses achieved through modification of the actuator geometry and membrane stress

However, increasing the initial air gap thickness also reduces the free spectral range, which reduces maximum achievable tuning range. Thus, an optimum initial air gap thickness must be chosen.

Diameters of the central DBR mirror and overall actuator area impact performance in a variety of ways. Minimizing DBR diameter increases resonant frequency through reduced mass, but diameter must be larger than the mode size to minimize sidewall scattering losses, accounting for lithographic fabrication tolerances on the alignment between the DBR and the central axis of the cavity. Increasing the overall area of the actuator can either increase or decrease resonant frequency, since increased mass is competing with increased spring stiffness. Lastly, increasing area increases squeeze-film damping through interaction with viscous air [37], which can reduce resonator Q and flatten frequency response, as long as the device is not overdamped.

Figure 22.7 illustrates the range of frequency responses experimentally measured, through variation of the parameters discussed above. As shown, resonant frequencies vary from about ~300 to ~500 kHz, and damping varies from highly under-damped to near critically damped. Peak voltages for full tuning over one FSR (see results in Sect. 22.4 below), for all designs shown, are under 85 V. The flatter responses with 300–500 kHz resonance are preferable for linearizing the wavelength tuning response, as discussed in Sect. 22.5 below. The highest resonance devices have led to record axial line rates of 1.2 MHz [20], when both forward and backward wavelength scans are employed.

The geometry of the MEMS actuator is sufficiently complex that the qualitative tradeoffs discussed above must be accurately modeled using a 3-D finite-element tool such as COMSOL™ to accurately predict frequency response and modal behavior. Finite-element modeling also identifies some subtle features such as the impact of higher order modes on the dynamic response of the actuator. Figure 22.8 illustrates example COMSOL™ modeling of a typical suspended mirror.

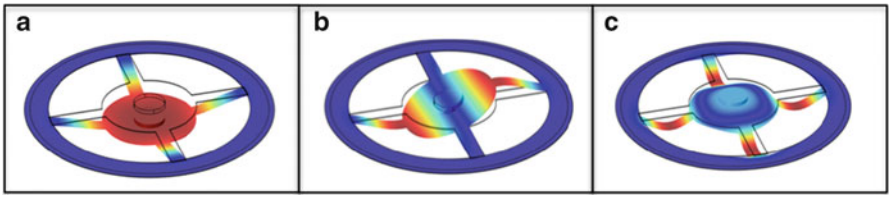

Fig. 22.8 COMSOL™ modeling of the three lowest order modes of a 4-arm actuator, illustrating piston mode (**a**), tilt mode (**b**), and higher order mode with minimal plate motion (**c**)

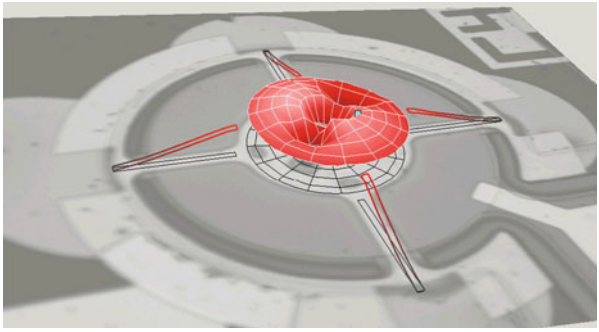

Fig. 22.9 Single frame of laser Doppler vibrometer (*LDV*) animation of actuator motion. Depressions in central plate are artifacts resulting from transparent portions of the membrane. The overall actuator motion is in the primary desired piston mode

The model reveals a lowest order "piston" mode, which is the primary peak seen in the responses of Fig. 22.7, and the motion desired for VCSEL tuning. Additionally shown is an undesirable tilting mode and another undesirable mode corresponding to movement of the actuator arms with minimal movement of the central plate. These higher order modes can be excited by fabrication imperfections or higher drive harmonics used for linearization, but their impact can be minimized by increasing the damping in the structure. Advanced MEMS characterization tools such as laser Doppler vibrometry (LDV) [38, 39] can help visualize actuator movement in real time, correlate with theoretical models, and adjust fabrication methods as necessary to achieve the desired movement. Figure 22.9 illustrates one frame of an LDV movie of actuator motion for a 4-arm device. Depressions in the central plate are measurement artifacts arising from transparent portions of the oscillating membrane. The primary value of the movie from which this frame is constructed is a demonstration that the actuator is moving primarily in the desired "piston mode," rather than in undesirable higher order modes.

22.3 Widely Tunable VCSEL Fabrication

Figures 22.10a–l illustrate key elements of the process flow used to fabricate the device structures illustrated in Figs. 22.1 and 22.2. Many elements of the process flow are derived from previous work [40]. The general process flow is essentially identical for 1,050 and 1,310 nm devices, with the exception that 1,310 nm devices

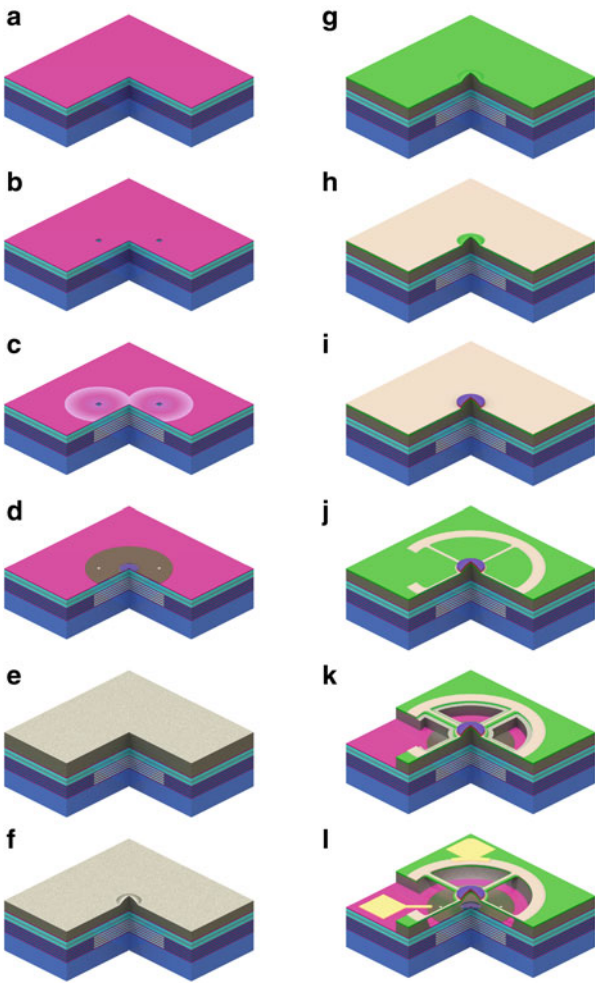

Fig. 22.10 MEMS-VCSEL fabrication. (**a**) Initial structure with gain region (*pink*) on top of the fixed bottom mirror. (**b**) Two etched oxidation vias. (**c**) The oxidized mirror layer region forms a figure 8 around the oxidation vias. (**d**) Deposited bottom contact (*brown disk*) and AR coating (*purple central film*). (**e**) Sacrificial layer (*gray top*) deposited over entire structure. (**f**) Curved surface etched in center of laser aperture. (**g**) Dielectric membrane (*green*) deposited over the entire sample. (**h**) *Tan top* metal deposited over membrane with central opening for light passage. (**i**) Dielectric top mirror (*purple*) deposited and patterned over central device area. (**j**) Actuator pattern wet-etched into *tan top* metal. additionally require wafer bonding to combine the InP-based epitaxial structure with the GaAs/Al_xO_y bottom mirror prior to beginning MEMS-VCSEL fabrication. In addition, thicknesses and composition of epitaxial layers and dielectric films are different for the two wavelengths.

For 1,310 nm devices, the process begins with wafer bonding of an epitaxially grown multi-quantum-well gain region on an InP wafer to an epitaxially grown stack of GaAs/AlAs layers on a GaAs wafer. After bonding, the InP substrate is chemically etched away, leaving an InP gain region integrated on a GaAs substrate. Wafer bonding is a well-known process in which lattice-mismatched semiconductors, such as GaAs and InP, can be joined through application of pressure and heat [41]. Wafer bonding for VCSELs was first demonstrated in the mid-1990s and led to some of the first demonstrations of 1,310 nm fixed wavelength VCSELs [42].

After bonding, 1,310 and 1,050 nm device processing proceeds identically as shown in Fig. 22.10a–l. Figure 22.10a shows the initial epitaxial structure, with gain region integrated on the GaAs/AlAs mirror layers. Figure 22.10b illustrates the formation of two oxidation via holes, which provide access to the underlying mirror layers for a subsequent oxidation step. The etched structure is then exposed to a steam atmosphere at elevated temperature, converting AlAs to AlxOy, creating a high contrast mirror in combination with the high-index GaAs layers. Figure 22.10c illustrates this mirror oxidation step, where the oxidized region expands radially around the etched holes, forming a figure 8 pattern. Deposition of the bottom contact layer proceeds after oxidation, containing an apertured central region with a broadband antireflection (AR) coating (Fig. 22.10d), through which intracavity light will pass into an air gap. Next, a sacrificial layer is deposited (Fig. 22.10e), the thickness of which determines the initial air gap and zero-bias device wavelength. In step (Fig. 22.10f), a curved surface is formed on the sacrificial layer through pattern transfer of a reflowed resist mesa. This curved surface contributes to the formation of a half-symmetric cavity in the final device. Figure 22.10g illustrates deposition of a dielectric membrane layer (green) on the sacrificial layer, followed by deposition of an apertured top actuator contact metal in Fig. 22.10h. The aperture serves to allow passage of light through the structure.

Deposition of the top dielectric DBR proceeds next, followed by etching of a post in the DBR (purple central region) to expose the top contact metal in the field (Fig. 22.10i). Wet chemical etching of the top contact metal creates the desired actuator shape, as shown in Fig. 22.10j. Further dry etching transfers this geometry downward through dielectric and sacrificial layers (Fig. 22.10k). After deposition of top and bottom wire bond pads, chemical undercutting of the sacrificial layer creates the final suspended structure shown in Fig. 22.10l.

22.4 1,310 nm and 1,050 nm VCSEL Static and Dynamic Tuning Results

22.4.1 Section Overview

This section describes the static and dynamic tuning range obtained with various generations of both 1,310 and 1,050 nm MEMS-VCSELs. Section 22.5 discusses additional laser properties relevant to OCT imaging, and Sect. 22.6 shows representative images obtained with these devices. Figure 22.11 illustrates a schematic of the optically pumped MEMS-VCSEL source used for OCT imaging, along with the supporting elements around the VCSEL source. An incoming optical fiber is coupled to the MEMS-VCSEL cavity, delivering incoming pump light at 980 nm for 1,310 nm MEMS-VCSEL operation and at 850 nm for 1050 nm MEMS-VCSEL operation. Isolators protect both the pump lasers and the MEMS-VCSELs from back reflections, ensuring low noise operating and enhancing laser lifetime. The pump fiber also collects the emitted tunable VCSEL radiation, and a subsequent

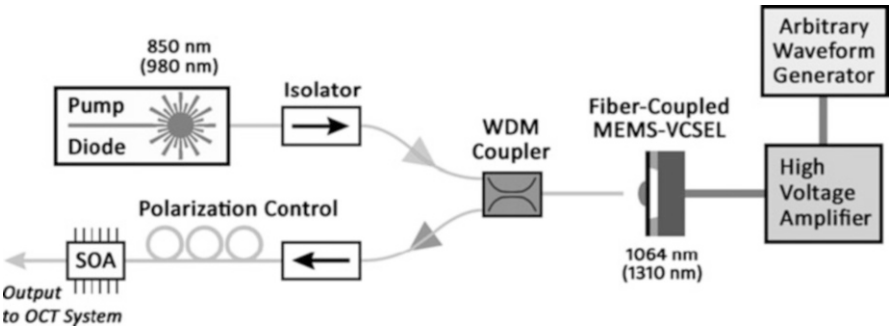

Fig. 22.11 Optically pumped MEMS-VCSEL source, illustrating various supporting elements around VCSEL. Pump laser emission passes through an isolator and WDM coupler before impinging on the VCSEL, which emits into same fiber and is separated to a different optical path by the WDM coupler. VCSEL emission also passes through a second isolator and a polarization controller before being amplified by the semiconductor optical amplifier (*SOA*) and sent to the OCT system. The tuning signal is supplied by an electrically amplified arbitrary waveform generator

WDM coupler separates the incoming pump light from the outgoing MEMS-VCSEL emission, with the latter sent to a semiconductor optical amplifier (SOA). The amplified VCSEL emission (output of the SOA) is sent to the OCT imaging system. As shown, the VCSEL output passes through a fiber polarization controller in order to align the polarization to the preferred orientation for maximum gain through the polarization-dependent SOA. Both pre-amplified and post-amplified VCSEL emissions are sent to an optical spectrum analyzer (not shown) to generate the tuning results below. Both static and high-speed time-dependent tuning voltages are applied via a high-voltage (HV) amplifier, which is driven by an arbitrary waveform generator.

22.4.2 First Generation Commercial 1,310 nm Devices

Our first generation commercial devices based on the structure described in the preceding sections demonstrate >100 nm tuning, with 110 nm being a typical value. Typical fiber-coupled power levels over the tuning range are 0.2–0.8 mW, prior to amplification, using pump power around 10 mW. Absorbed pump power is around half the incident pump power, or about 5 mW. These devices were first reported by Praevium and collaborators in mid 2011 [21]. Figure 22.12 shows these initial fiber-coupled tuning results, demonstrating 110 nm static tuning range with an applied bias of about 85 V. Initial devices also show MEMS resonance frequencies in the 300–400 kHz range with demonstrated axial scan rates of up to 760 kHz and excellent OCT images using amplified VCSEL output.

For commercial devices, the more relevant parameter is not static but dynamic tuning range, since devices will be operated under repetitive scanning at frequencies up to several hundred kHz. Furthermore, since amplification is employed prior

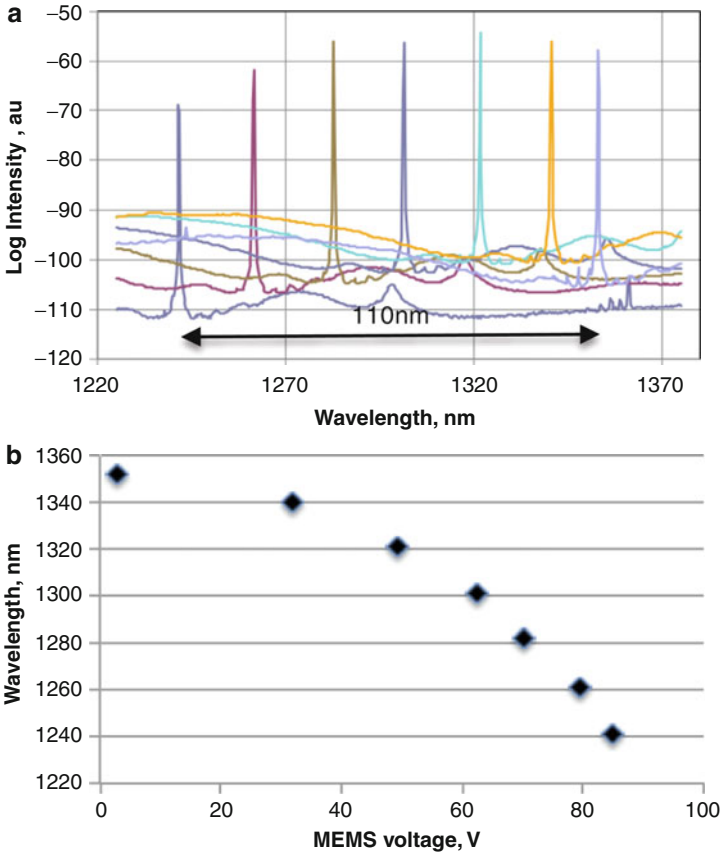

Fig. 22.12 Early tuning results from May 2011. 110 nm tuning (**a**) is achieved with about 85 V applied (**b**)

to OCT imaging, post-amplified dynamic spectral properties are the most critical. Figure 22.13 shows pre- and post-amplified time-averaged optical spectra under dynamic linearized sweeping at 200 kHz axial scan rate, on more recent devices based on a design similar to that used to obtain the results of Fig. 22.12. It is important to note that there is some spectral distortion in the time-averaged spectrum of Fig. 22.13, since the sweep is not perfectly linear and edges of the spectrum are emphasized more strongly as the suspended mirror slows before reversing direction. Nevertheless, Fig. 22.13 illustrates a significant improvement of 3-dB spectral bandwidth after amplification. Current devices show post-amplified 3-dB spectral bandwidth of up to 90 nm. The full tuning range is 110 nm and peak applied voltages are around 65 V. Amplified MEMS-VCSEL powers for these devices are typically >30 mW.

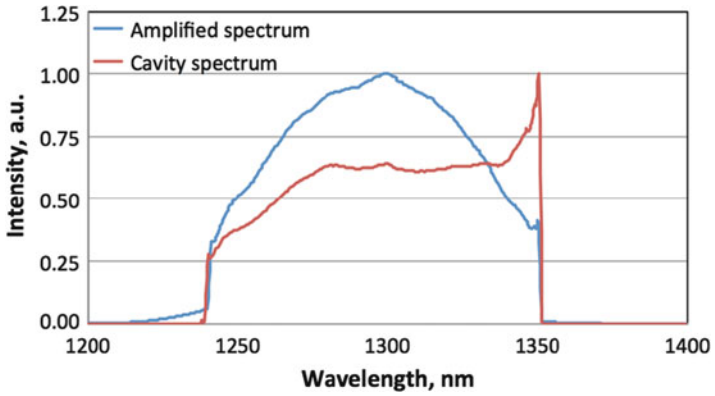

Fig. 22.13 Time-averaged pre-amplified (*red*) and post-amplified (*blue*) optical spectra under linearized wavelength scanning for devices with a design similar to that in Fig. 22.12. The post-amplified FWHM is near 90 nm

22.4.3 Next Generation Ultra-Broadband 1,310 nm Devices

Development progress since the first demonstration of >100 nm in 2011 has enabled expansion of the dynamic tuning range to 150 nm. These advancements have occurred as a result of increasing the cavity free spectral range and further optimization of the gain bandwidth and mirror reflectivity. This tuning range is close to that of the best external cavity lasers used in the research lab, such as the 160 nm reported for the FDML laser [2]. This result is significant, as prior to this demonstration, some questions remained as to the ability of VCSEL-based swept sources to compete with external cavity lasers on tuning range.

Figure 22.14 illustrates both the static and dynamic tuning properties of ultra-broadband VCSELs [19]. In Fig. 22.14a, the optical spectrum at an applied bias of ~12 V is shown as the right-most red spectrum in the figure. This spectrum shows laser emission at 1,372 nm along with a competing mode at 1,211 nm, yielding a 161 nm FSR for these devices. Application of a static voltage up to ~56 V pulls the mode across a stable and continuous static tuning range of 142 nm, illustrated by the overlaid spectra shown in Fig. 22.14a. Higher applied biases enable further tuning to 1,222 nm (covering a 148 nm range), though biases beyond ~56 V exceed the static snapdown voltage of the device. Figure 22.14b shows the theoretical and measured static wavelength as a function of the applied tuning voltage. The green curve of Fig. 22.14a shows the time-averaged optical spectrum under sinusoidal sweeping at 500 kHz, illustrating a 150 nm dynamic tuning range, which is the more relevant parameter for SS-OCT imaging. Note that this 500 kHz sweep rate enables bi-directional scanning at >1 MHz. These 150 nm devices can enable future VCSEL-based SS-OCT systems with improved axial resolution.

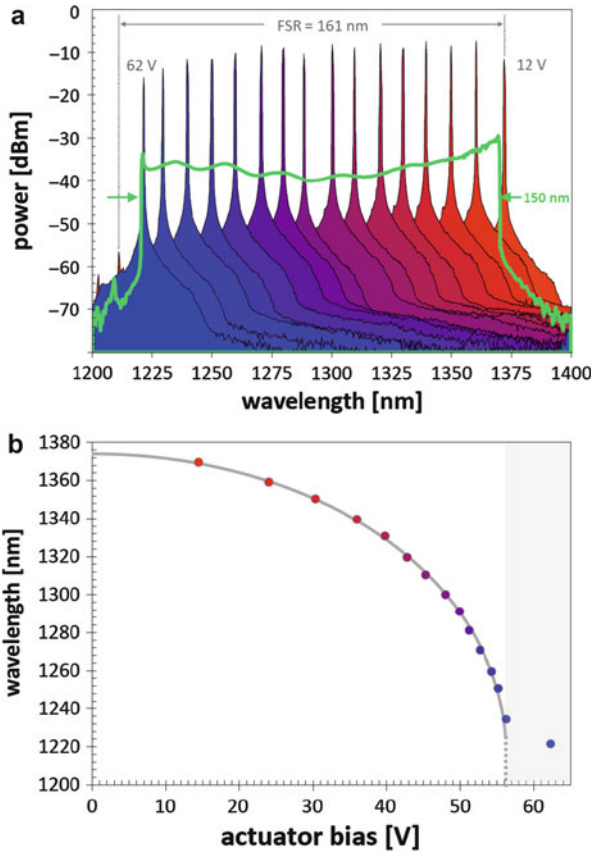

Fig. 22.14 (**a**) Static and dynamic tuning spectra of our ultrawidely tunable 1,310 nm MEMS-VCSEL. The long-wavelength (*red*) spectrum at 1,372 nm exhibits a competing mode at 1,211 nm, illustrating the 161 nm FSR of the cavity. The *green curve* represents the time-averaged spectrum under sinusoidal sweeping at 500 kHz. Both the static and dynamic spectra demonstrate continuous single-transverse and longitudinal mode lasing operation over a 150 nm span. The ripple in the integrated spectrum is due to the residual reflectance of the cleaved delivery fiber. (**b**) Emission wavelength vs. static tuning voltage corresponding to the spectra of (**a**). The shaded region beyond 56 V indicates the unstable regime for the actuator (Data reproduced with permission from Ref. [19])

22.4.4 1,050 nm Devices

The 1,310 nm devices reported first in mid-2011 were followed up by our report of the first 1,050 nm devices for ophthalmic imaging in early 2012 [20]. A subsequent publication [18] described device results in greater detail. Figure 22.2 illustrates the 1,050 nm device structure used for these devices. Figures 22.5a, b illustrate the tuning behavior of recent devices. The zero voltage emission wavelength occurs at 1,006 nm. Application of a small bias causes the device to switch to the longer wavelength mode at ~1,105 nm. Further increases in the applied voltage reduce the emission wavelength to ~1,010 nm before the snapdown instability at approximately 53 V inhibits further static tuning. Figure 22.15a illustrates an overlay of 11 spectra covering the >90 nm static tuning range, demonstrating single longitudinal and transverse mode operation over the entire span. A wavelength range of 100 nm, essentially equal to the free spectral range (FSR) of the cavity, can be accessed by dynamic tuning, as shown by the blue curve in Fig. 22.15a, which represents the time-averaged spectrum under repetitive sinusoidal sweeping at 200 kHz. This dynamic tuning range is, again, the relevant wavelength span for repetitively swept SS-OCT applications.

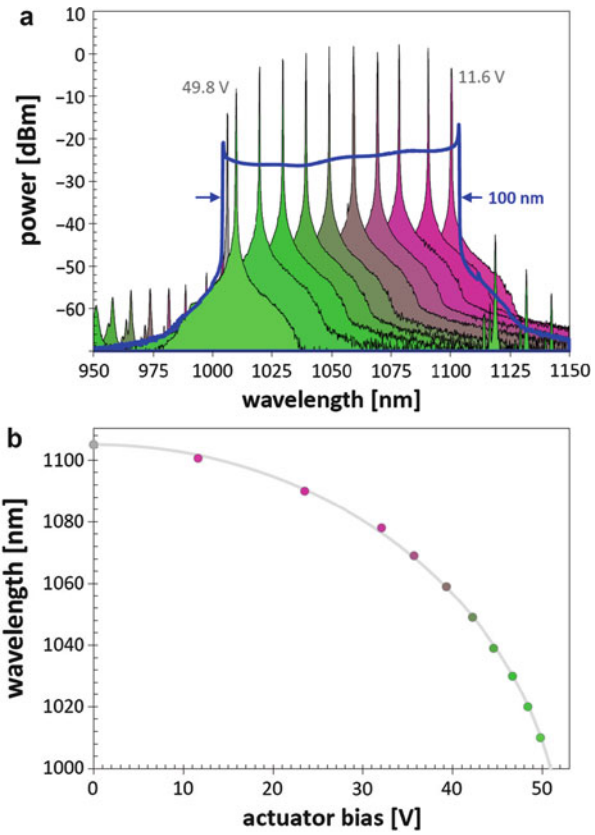

Fig. 22.15 (**a**) Eleven spectra at various actuator biases illustrate a >90 nm static tuning range, while the time-averaged (*blue*) spectrum illustrates a 100 nm dynamic tuning range, under 200 kHz sinusoidal sweeping, covering nearly one FSR. (**b**) Static emission wavelength as a function of the actuator voltage, corresponding to the spectra of (**a**) (Data reproduced with permission from Ref. [18])

The average fiber-coupled output power of 1,050 nm devices under full dynamic tuning is 0.5–1 mW, using pump powers from about 14 to 30 mW. Approximately 50 % of the pump power is absorbed, so absorbed powers are in the range of 7–15 mW. Similar devices have been integrated into ophthalmic imaging systems with collaborators at MIT, using optical amplification as in the 1,310 nm devices to boost the total output power into the ~20 mW range. Ophthalmic images obtained with these devices have demonstrated for the first time anterior eye, retinal, and whole eye imaging in a single SS-OCT instrument [4].

22.5 Additional OCT-Relevant Performance Parameters

22.5.1 Section Overview

The results of Sect. 22.4 demonstrated for the first time the ability of MEMS-VCSELs to access tuning ranges appropriate for SS-OCT at the relevant wavelengths. This demonstration of ~10 % fractional tuning range removed a primary

uncertainty with these devices, since prior to 2011, the maximum demonstrated fractional tuning range was 4.2 % and no MEMS-VCSELs of any sort existed at 1,050 and 1,310 nm. Demonstration of simultaneous high-speed and broadband tuning, at record axial scan rates in the MHz range, was also another significant achievement of these early efforts.

Validation of MEMS-VCSELs for SS-OCT, however, requires demonstration of a number of other stringent criteria not necessarily required for other applications. The ultimate validation of MEMS-VCSEL performance is the quality of OCT images obtained, which is the subject of other chapters of this book and briefly discussed in Sect. 22.6. In this section we touch on dynamic coherence length, transverse mode suppression, polarization stability, output power ripple, scan linearity, and variable speed operation, parameters that have a significant impact on OCT imaging quality.

22.5.2 Dynamic Coherence Length

The single-mode nature of MEMS-VCSELs suggests a very narrow static linewidth and long coherence length in the meter range. The fast cavity dynamics further suggest that this narrow linewidth can be maintained under dynamic operation. This fact is one of the most attractive motivations for applying MEMS-VCSELs in OCT.

Dynamic coherence length in OCT systems is typically measured by evaluating the system sensitivity as a function of imaging depth, as shown in the example measurement of Fig. 22.16. The dynamic coherence length is defined as twice the

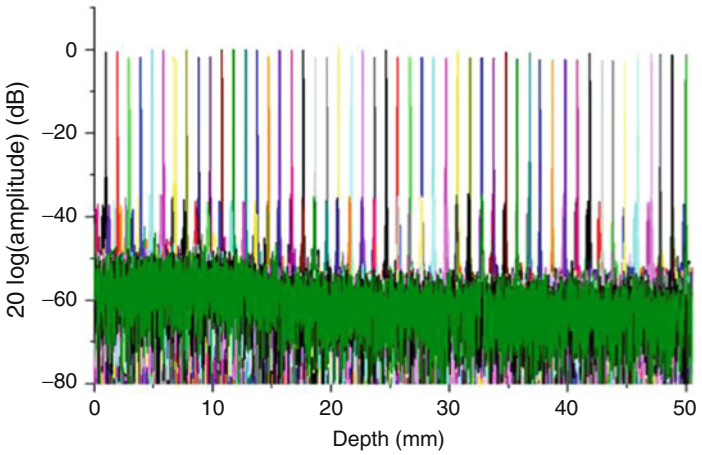

Fig. 22.16 OCT axial point spread function versus imaging depth in air, indicating minimal drop in sensitivity up to 50 mm depth. Measurement performed at 60 kHz uniaxial scan rate. The data shows that the coherence length is $\gg$10 cm. The measurement is detection bandwidth limited, and actual coherence length may be much larger for this device

imaging depth at which the signal sensitivity drops by a factor of 2, since light traverses the imaging depth twice upon reflection before being interfered with the reference beam. The measurement of dynamic coherence length is complicated by the need for increasingly high-speed detection electronics as sweep rate and coherence length is increased. Figure 22.16 shows a measurement using a swept MEMS-VCSEL with a 60 kHz unidirectional scan. As shown, negligible degradation of sensitivity is observed at 50 mm imaging depth in air, corresponding to $\gg$10 cm coherence length. The measurement of Fig. 22.16 remains detection limited, so the measured dynamic MEMS-VCSEL coherence length is even larger than measured. A more recent measurement of coherence length of the 1,060 nm MEMS-VCSEL source using different detection electronics has demonstrated >10 cm at up to 100 kHz axial scan rate [4]. This 10 cm value for 1,060 nm VCSELs compares with the 2 cm reported for a short external cavity 100 kHz swept source at 1,060 nm [5]. The long coherence length in our 1,050 nm MEMS-VCSELs has been validated in whole eye imaging [4]. Most recently, by reducing the axial scan rate and limiting tuning range to stay within the bandwidth of detection electronics, collaborators at MIT have demonstrated dynamic coherence length in excess of 1 m [43].

22.5.3 Transverse Mode Suppression and Output Power Ripple

MEMS-VCSELs, though they are single longitudinal mode devices, can have higher order transverse modes, which can create imaging artifacts. Current devices show >45 dB suppression over the tuning range. A minimum of ~40 dB is required for high-quality imaging, which is a requirement more stringent than many communications applications. The high SMSR in these devices is aided by optical pumping with a single-transverse mode pump beam.

Minimizing periodic output power variation or "ripple" is another critical OCT requirement, since ripple manifests itself as a spurious reflection plane in OCT images. Ripple arises from parasitic reflections in the laser or the package. Considerable development effort has been expended identifying and eliminating sources of ripple. This has resulted in recent commercial devices showing output power ripple values below 0.5 %.

22.5.4 Polarization Stability

Operation in a constant polarization state throughout the tuning range is ideal for commercial OCT-targeted VCSELs. Since our amplified MEMS-VCSELs use polarization-dependent amplification, polarization switching during tuning can lead to power dropouts and severe image degradation. Even in the case of polarization-independent amplification, multiple polarization states can create spectral broadening and degrade dynamic coherence length. The absence of

power dropouts in the amplified spectrum in Fig. 22.13, which used a polarization-dependent amplifier, demonstrates operation of devices in a constant polarization state throughout the tuning range. Another benefit of polarization stability is the ability to make polarization-sensitive OCT measurements [44].

Polarization control in tunable VCSELs has previously been addressed using a sub-wavelength grating [45] or intentionally induced stresses on the VCSEL chip to produce gain anisotropy [15]. Both of these methods have only been demonstrated over a limited tuning range, and suppression of switching in more widely tunable structures can present more challenges. Current state of the art devices show stable polarization over the entire 115 nm range. The factors affecting polarization in these new widely tunable structures are still under investigation, but we believe the combination of an optically pumped approach and internal stresses in the structure arising from local volume shrinkage in the fully oxidized mirror contribute to wideband polarization selection in current devices.

22.5.5 Scan Linearity and Variable Rate Scanning

Commercial OCT systems require linearized wavelength scanning to minimize the required detection bandwidth for a given axial scan rate and given tuning range. The electrostatic actuator used in our MEMS tuning structure is inherently nonlinear, since the suspended mirror displacement varies as the square of the applied voltage. However, the MEMS-VCSEL, like other MEMS-based tunable lasers, can be linearized through drive waveform pre-shaping. A variety of arbitrary drive waveforms have been investigated for scan linearization, and several successful waveforms have been designed. In addition to linearization, another desirable property for commercial OCT systems is the ability of a single source to be swept at a variety of scan rates and tuning ranges. OCT fringe frequency for a given scan rate increases with imaging range and tuning range, requiring faster fringe waveform sampling at long range. It is thus desirable to adjust scan rate and tuning range to tradeoff speed and resolution with depth for different imaging modes in one application with one laser source. Imaging of the human eye provides a good application example. Here, it is desirable to have ultrahigh axial scan rate up to >500 kHz for wide field retinal imaging and a lower axial scan rate of 50 kHz for whole eye imaging [4].

Figure 22.17 illustrates the capacity of a single 1,310 nm MEMS-VCSEL to operate over a wide variety of axial scan rates from 50 kHz to 1 MHz and to be linearized at 50–200 kHz rates. In this figure, the tuning range is held fixed at 115 nm, and a variety of drive waveforms are applied to achieve the desired wavelength trajectories. The top row of the figure illustrates the applied arbitrary waveform and the bottom row the wavelength response with time. The first three columns illustrate linearized scanning, including a unidirectional 100 kHz scan, a bi-directional 100 kHz scan, and a bi-directional 200 kHz scan, respectively. The final column illustrates sinusoidal scanning at 500 kHz, enabling bi-directional scanning at an axial scan rate of 1 MHz axial scan rate. More recent results have

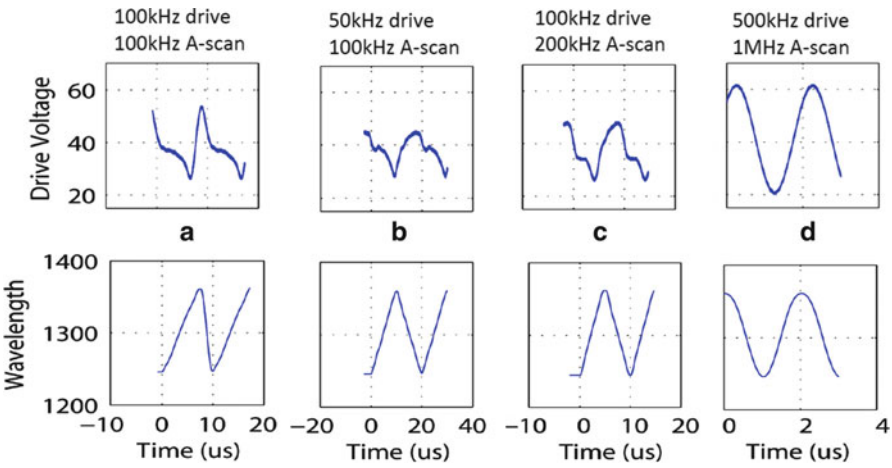

Fig. 22.17 Single VCSEL driven over 115 nm tuning range at a variety of axial scan rates. *Top row* of waveforms shows the applied arbitrary drive waveform, and the *bottom row* shows the measured wavelength response. Labels at *top* indicate the type of scanning achieved, including 100 kHz drive/100 kHz linearized uniaxial scan (**a**), 50 kHz drive/100 kHz linearized bi-directional scan (**b**), 100 kHz drive/200 kHz linearized bi-directional scan (**c**), and 500 kHz drive/1 MHz sinusoidal bi-directional scan (**d**)

extended this maximum axial scan rate to 1.2 MHz [20]. For the lower scan rates, one quantitative measure of linearity is the ratio of maximum slope in the wavelength scan to the ideal linear slope (excluding non-usable edges of the scan). For a sinusoid, this would yield a linearity of 1.57. Most recent linearized 1,310 nm MEMS-VCSELs can be driven to produce a typical linearity between 1.05 and 1.10 at 100 kHz axial scan rates.

22.6 Representative VCSEL-Based SS-OCT Images

The ultimate measure of the MEMS-VCSEL performance in an SS-OCT system is the quality of images produced. Other chapters of this book describe MEMS-VCSEL-based OCT system details and quantify imaging performance with VCSELs, and prior publications have shown a variety of images using 1,050 and 1,310 nm VCSELs operated at a variety of scan rates. These include retinal, anterior eye, and whole eye images using 1,050 nm MEMS-VCSELs at scan rates from 50 to 580 kHz [4] and anterior eye, finger, and leaf images using 1,310 nm MEMS-VCSELs [20].

Figures 22.18a–g show a representative sample of images obtained. Figures 22.18a–c [4] were obtained with a 1,050 nm MEMS-VCSEL-based system operating at 580 kHz axial scan rate. Figure 22.18a illustrates the long dynamic coherence length of the VCSEL in a single image capturing both the anterior eye and the retina. Figure 22.18b shows the volumetric image of the choroidal region from

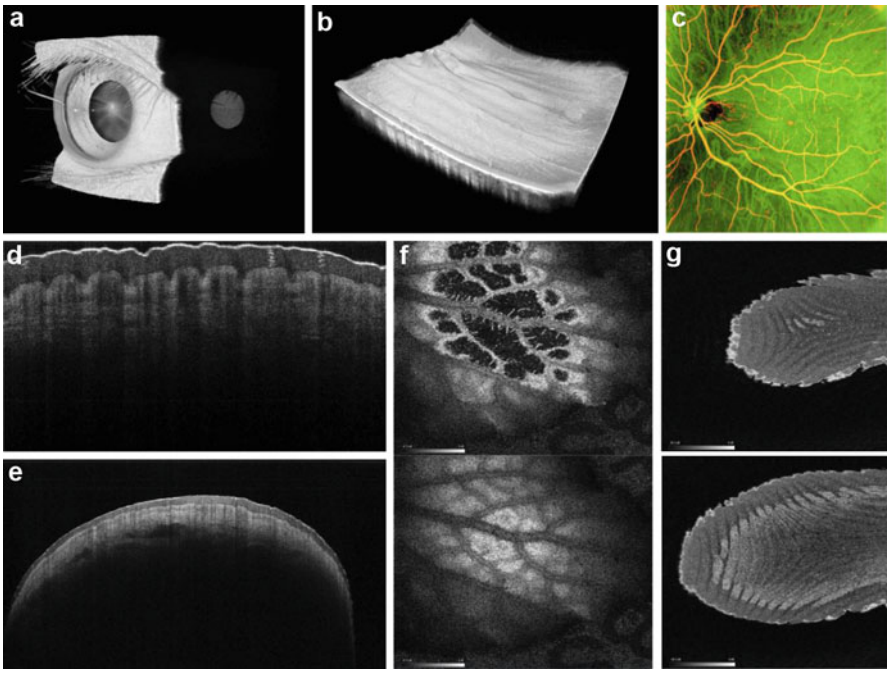

Fig. 22.18 Representative OCT images using 1,050 nm VCSEL (**a**–**c**) and 1,310 nm VCSEL (**d**–**g**). Full eye image showing anterior eye and retina in a single acquisition. (**b**) Volumetric image of choroidal region. (**c**) Choroidal and retinal vasculature superimposed and color coded, from the data of (**b**). (**d**) Finger cross section showing 4,096 axial scans over 5 mm depth at 1 MHz axial scan rate. (**e**) Finger cross section at 60 kHz uniaxial scan, showing blood vessel delineation. (**f**) En face plant leaf images using 300 × 340 axial scans over a field of 6 mm × 6 mm, acquired at 200 kHz axial scan rate. (**g**) OCT en face images of a finger pad consisting of 512 × 512 axial scans over 6.3 mm × 6.3 mm acquired at 400,000 axial scans per second

which the vascular cross section in Fig. 22.18c can be constructed. Figure 22.18c is a color-coded image representing an overlay of both retinal and choroidal vasculature systems and is similar to images obtained using ICG angiography but in a completely noninvasive MEMS-VCSEL-based OCT measurement requiring no injected dyes. Figures 22.18d–g illustrate images obtained with a 1,310 nm MEMS-VCSEL-based SS-OCT system. Figure 22.18d represents a human finger cross section consisting of 4,096 axial scans over 5 mm depth at 1 MHz axial scan rate. Figure 22.18e shows a finger cross section obtained at 60 kHz axial scan rate, showing clear delineation of blood vessels. Figure 22.18f illustrates en face images of a plant leaf using 300 × 340 axial scans over a field of 6 mm × 6 mm, acquired at 200 kHz axial scan rate. Figure 22.18g illustrates 512 × 512 axial scan en face images of a human finger pad over 6.3 × 6.3 mm, acquired at 400 kHz axial scan. The clarity, range, and resolution of these and other images acquired at a variety of scan rates provide the ultimate validation of MEMS-VCSEL technology for SS-OCT.

22.7 Conclusion

MEMS-VCSEL technology advances since 2011 have enabled unique gains in SS-OCT imaging performance, particularly in the achievable imaging speed and imaging range. VCSEL advances include the first demonstration of MEMS-VCSELs at the relevant OCT wavelength windows of 1,050 and 1,310 nm, the first demonstration of >100 nm tuning in MEMS-VCSELs at any wavelength, and the first demonstration of wide tuning in conjunction with several hundred kHz wavelength scanning operation. Integration of these devices into MEMS-VCSEL-based OCT systems has enabled >1 m imaging range, the first whole eye images of the human eye, and a 1.2 MHz axial line rate that is 3× faster than the fundamental un-buffered (no external fiber delays to copy the sweep) speed of the fastest competing swept sources with sensitivity high enough for imaging in vivo and ex-vivo [7, 8]. We note that an impressive 20 MHz axial scan rate has been obtained with the FDML laser using optical buffering and multiple spots [10], and similar approaches could be employed to further extend the axial scan rates of MEMS-VCSELs. The current maximum single-line sweep rate of the MEMS-VCSEL does not appear to be limited by laser dynamics, and higher speeds may be possible by changing MEMS actuator designs to increase mechanical resonance frequency to support higher frequency drive. Ultrahigh sweep rate operation will be especially important for applications which require en face OCT image generation because each en face pixel requires an axial scan. Aside from ophthalmic applications, long imaging range is also important for applications such as intravascular OCT, which requires imaging the entire circumference of arteries irrespective of catheter centration, and anatomic OCT, which involves profiling larger scale structures such as the upper airway.

A further advantage of the MEMS-VCSEL includes wavelength flexibility, and migration of the same technology to other wavelengths from 450 to 2,300 nm appears to be feasible. The recent demonstration of electrical [46] instead of optical pumping for VCSELs promises lower cost and miniaturization. Electrically pumped VCSELs have been demonstrated from wavelengths as short as 460 nm [47] to as long as 2,300 nm [48], suggesting extension of MEMS-VCSEL-based OCT to a wide variety of wavelengths limited only by the availability of semiconductor gain media.

The current tuning range of 150 nm at 1,310 nm is the largest reported for any MEMS-VCSEL and is comparable to the 160 nm reported for the FDML [2]. Further increase of tuning range to ~200 nm may be possible by increasing the number of quantum wells in the gain region, using a wider bandwidth top suspended mirror, and by further increasing the FSR. In addition, it should also be possible to multiplex two or more VCSELs with offset bandwidths in order to obtain increased sweep ranges and improve axial resolutions. Similar multiplexing approaches have been used with superluminescent diode light sources for OCT.

The MEMS-VCSEL continues to enable advances in imaging, including Doppler blood flow imaging [49], high-speed endoscopic imaging [50], hand-held retinal imaging [51], and chorio-capillaris and choroidal microvascular imaging with OCT

angiography [52]. These advances, coupled with lower cost and higher performance of emerging devices, suggest that the coming years may see an expanding array of new OCT applications.

23.1 Introduction

Optical coherence tomography (OCT) [1, 2] is one of the fastest-growing medical imaging procedures. It has undergone three generations; the third and rapidly growing generation produces very high-quality images and to do so requires a swept-laser source at its core [3, 4].

An ideal swept-wavelength laser for OCT is intended to sweep over a wide wavelength range in a perfectly linear-in-frequency manner while maintaining low relative intensity noise (RIN), low side modes, and adequate coherence length—all at a speed that supports the imaging requirements without compromise [5]. A number of approaches have been utilized to build lasers for OCT, including ring lasers [6], grating-based Littman-Metcalf [7–10], MEMS [11–13], polygon mirror [14, 15] pump/VCSEL/MEMS/circulator/SOA [16, 17], crystal deflection [18], FDML [19, 20], DFB arrays [21], and resonant-sine lasers [22–24]. Mechanical movement of the optical filter elements to control the laser wavelength scan has been the basis of all commercial swept lasers, but this movement is often in direct opposition to these image quality goals due to the requisite creation and depletion of momentum and the hysteresis inherent to such mechanical systems. In addition, the resulting relatively long cavity lengths and the many optical elements often results in the cavity instability and vibration instability of typical mechanical systems and the potential for extraneous reflections. Development and implementation of all-semiconductor akinetic laser technology allows these limitations to be overcome.

The term "akinetic" describes absence of movement in a system. An all-semiconductor laser uses an integrated semiconductor optoelectronic design approach without the use of coupling to an external cavity—the only things moving are photons and electrons.

With the advent of akinetic all-semiconductor lasers, these example performance parameters are improved in most categories [25, 26]. The sweep flexibility of the akinetic laser is software driven. The superior line width and spectral performance is a natural outcome of the very short waveguide design. The all-semiconductor construction may allow for further advancements enabling improved OCT imaging and new swept-source OCT (SS-OCT) imaging methodologies.

The semiconductor wafer-scale production nature of the laser also foretells a day in the not-too-distant future where the cost of the laser drops by an order of magnitude [27–29], enabling implementation of OCT to a broader range of imaging and scientific applications [30].

This chapter describes the advantages and compromises of using all-electronic wavelength tuning in conjunction with a semiconductor chip implementation of a swept-wavelength OCT source.

23.2 History of All-Semiconductor Akinetic Lasers

Some of the first work to create a widely tunable all-semiconductor laser was by Professor Larry Coldren at the University of California Santa Barbara [31] in the late 1980s. After some years developing the technology at UCSB [32], Professor Coldren and his team founded the company Agility, which spent over $100 M US to develop widely tunable semiconductor laser technology which is now an indispensable building block for telecommunications [33]. No swept-wavelength products

were developed as a result of this effort, but the widely tunable products went on to dominate the telecommunications market for a long period. Work was being conducted by Syntune [34], Santur [35], and Oclaro [36] on similar semiconductor widely tunable lasers in a similar timeframe.

Professor Kohji Obayashi of Kitasato University did substantial work on adapting single-chip widely tunable lasers for wavelength sweeping. This work produced important results [37–41] and initial OCT images.

Companies such as Smart Fibres [42] were able to develop and commercialize slowly tuning swept lasers utilizing all-semiconductor technology. Additionally, Luna Technologies [43] and AXSUN Technologies [44] similarly adapted semiconductor technology, but these solutions were neither all-semiconductor nor were they akinetic.

Professor Dennis Derickson of California Polytechnic State University had been deeply involved in the development of traditional kinetic swept lasers at HP and then later at Agilent Technologies [45]. Dr. Derickson's work was the first to envision methodologies which would lead to the development and commercialization of all-semiconductor akinetic swept-wavelength lasers [46] with high repetition rates, narrow OCT system point spread functions (PSFs), and long coherence lengths. Working in conjunction with Insight Photonic Solutions, Professor Derickson had a strong role in developing essential techniques and approaches utilized for OCT applications of these akinetic laser designs.

The first commercial swept all-semiconductor akinetic source was developed and commercialized by Insight Photonic Solutions of Boulder, Colorado, USA, in 2012 [25, 26, 47].

Vertical cavity surface emitting laser (VCSEL)-based fixed lasers are all-semiconductor. However, because of the inclusion of a separate pump laser, external circulator, moving microelectromechanical (MEMS) tuning element, and necessary external amplifier with the VCSEL cavity for swept lasers, they do not comprise an all-semiconductor solution, are not akinetic, and will not be considered in this chapter.

23.3 Details of All-Semiconductor Akinetic Swept-Laser Technology

All-semiconductor akinetic laser technology has impacts on most aspects of performance of a swept source OCT system (SS-OCT). A conceptual OCT system diagram is shown in Fig. 23.1. Table 23.1 introduces some of the key performance parameters for the OCT swept source laser of Fig. 23.2 and provides a comparison to other common approaches.

In this section the akinetic laser's performance extant in early 2013 will be explored, and how the performance impacts OCT system performance will be discussed. It is anticipated that capabilities will continue to advance as the all-semiconductor laser design and implementation continues to mature.

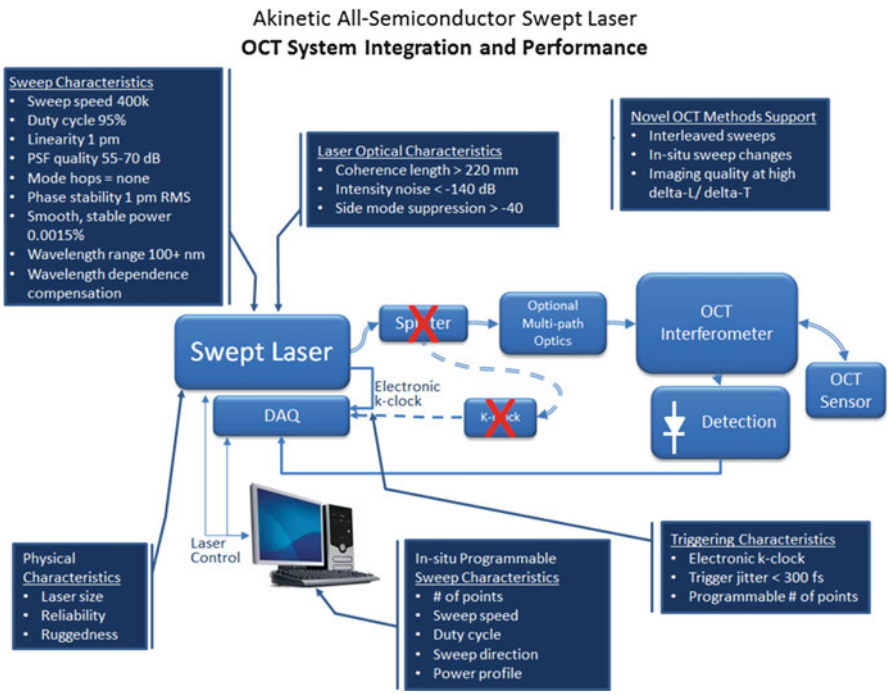

Fig. 23.1 Overall OCT system block diagram with akinetic all-semiconductor laser. Callouts note key system parameters of consideration when utilizing an all-semiconductor akinetic source. An all-semiconductor laser allows for simplification of the OCT system by providing a linear sweep, an electronic k-clock for triggering data acquisition, and programmability of system/laser parameters

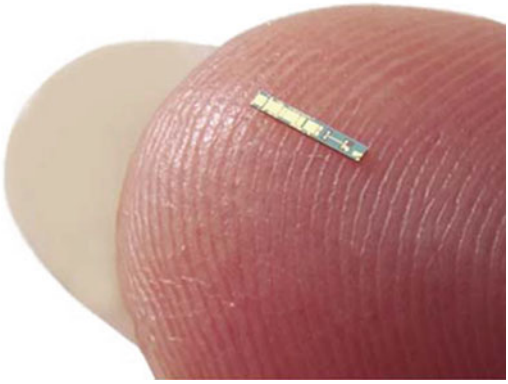

Fig. 23.2 The all-semiconductor akinetic approach promises small, inexpensive swept lasers enabling excellent image quality

Table 23.1 Comparison of characteristics of various swept laser approaches, including akinetic, mechanically tuned external cavity and MEMS-tuned external cavity

Swept laser technology characteristics			
Performance parameter	Akinetic monolithic cavity optoelectronic integrated design	Mechanically tuned external cavity	MEMS-tuned external cavity (micro-electromechanical)
Maximum sweep Repetition rate	Limited by laser diode resistance capacitance time constant product	Limited by mechanical factors and electrical drive interface	Limited by mechanical factors and electrical drive interface
Coherence length and associated spectral line width	Short optical cavity length results in single longitudinal mode operation and long coherence length	Most often multiple longitudinal mode due to long cavity length	Generally smaller cavity length and possible single longitudinal mode operation
Sweep repetition rate adjustability	Continuously adjustable	Typically fixed	Typically fixed
Power output	Moderate	Highly design dependent	Highly design dependent
Sweep to sweep power repeatability	Actively controlled, highly repeatable	Typically determined by gain profile of device	Typically determined by gain profile of device
Size	Diode laser package plus driver electronics	Typically needs to accommodate several packaged devices and interconnections	Typically has several packaged devices and interconnections
Sweep linearity	Controlled by accuracy of tuning tables and software algorithms	Sweep linearity often limited by momentum of mechanical tuning structure	Controlled by accuracy of tuning tables and software algorithms
Sweep drift over time	Controlled by long-term aging of semiconductor active region and internal system recalibration mechanism	Affected by mechanical wear and mechanical flexure aging	Effected by mechanical wear and mechanical flexure aging
Phase stability/ wavelength repeatability	Lack of kinetic movement with all-electronic control supports high repeatability	Mechanical hysteresis and acceleration limit repeatability	Mechanical hysteresis and acceleration and MEMS flexure non-idealities limit repeatability

23.3.1 Coherence Length/Imaging Depth Range

This section addresses achievable coherence length. In a later section on imaging depth range and multipath imaging, the application of longer coherence length on OCT will be investigated.

Long coherence length is a key factor in the following OCT conditions:

- Facilitating deep imaging, (such as anterior eye segment, full axial eye length OCT)

- Allowing for distance variation between the probe and the tissue (such as esophageal and lower GI imaging or in certain OCT-guided surgery applications)
- Enabling advanced OCT measurement techniques, such as superimposed multipath OCT, polarization-sensitive OCT [48], or phase-sensitive OCT [49]
- Accommodating differing length sensors or allowing less expensive sensors that are differing in length

Typical obstacles to long coherence length are finesse of the cavity and time-based shifting of the center wavelength [50]. The all-semiconductor laser cavity is short (~2 mm in length) and monolithically constructed within the semiconductor, minimizing the mechanical variation that might limit coherence length (Fig. 23.3).

The coherence length, z_c, is related to the full-width at half maximum (FWHM) instantaneous line width of a Gaussian profile laser, δλ, via [51].

$$z_c \approx 0.44 \frac{\lambda_0^2}{\delta\lambda} \tag{23.1}$$

The mirror penetration inherent in the all-semiconductor laser's distributed Bragg reflector (DBR)-like structure increases the finesse of the cavity by a factor of approximately nine times, resulting in a narrow line width. The small dimensions of the laser cavity, and the fact that the entire cavity is on a single rigid structure, substantially reduce cavity length variation.

23.3.1.1 Coherence Length Performance

An example coherence length measurement is shown in Fig. 23.4. The measurement shows the point spread function (PSF) as a function of imaging depth range Fig. 23.5.

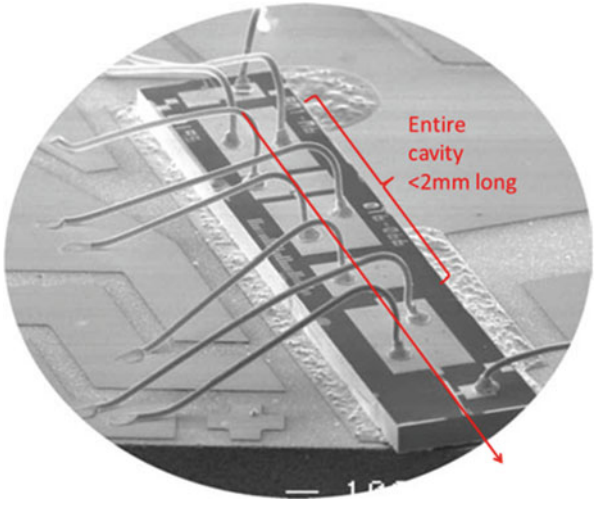

Fig. 23.3 SEM image of the bonded laser chip. The optical path is less than 2 mm long and in a single mechanical part, reducing cavity variation and leading to high coherence length, as well as eliminating the typical inter- and intracavity reflections that can create ghosting with other swept lasers

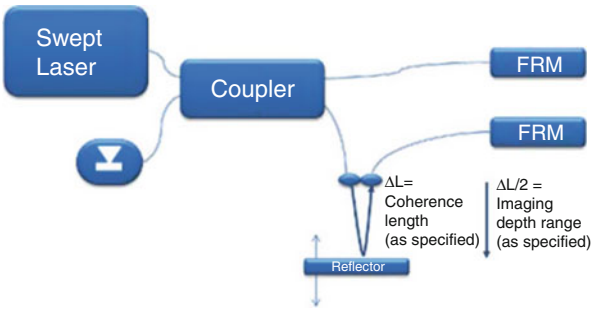

Fig. 23.4 Coherence length test apparatus. The swept wavelength laser is split into two beams with a fiber directional coupler. The two coupler output ports are coupled into Faraday rotation mirrors (FRM to reduce polarization dependency) [52]. One of the two arms consists of a movable reference reflector that allows for path length adjustment in this Michelson interferometer configuration. Finally the reflected beams are added together in the coupler and the combined beam is detected by a photodetector. The interference of the signal in the receiving photodetector is used to analyze coherence length [53]

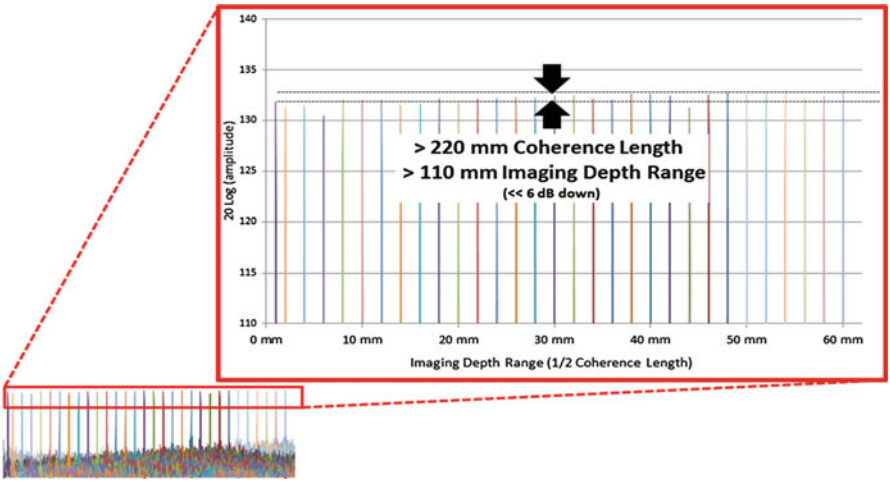

Fig. 23.5 Coherence length test data confirmed at least 220 mm at both 1,310 and 1,550 nm, 8 kHz to at least 320 kHz sweep rate

The PSF drops off very slowly with imaging depth. The resulting coherence length is in excess of 220 mm (~8.6 in., line width of 1.3 GHz, or 7.7 pm line width at 1,310 nm), even at sweep repetition rates up to at least 320 kHz.

The two most common ways to measure coherence length is to look for the −3 dB reduction of the amplitude of interferogram from a fixed reflector or to look for the −6 dB roll-off point of the point spread function (PSF) for the same signal [54, 55].

Another factor that can change coherence length in some lasers is the sweep rate. Typically, a faster sweep rate implies a lower coherence length. Due to the lack of

physical motion, sweep rate has only a weak effect on the coherence length of the all-semiconductor laser. As such, the same coherence length is obtained whether running at 4 k sweeps per second (sps) or to beyond 320 k sps.

23.3.1.2 Coherence Homogeneity in Different Wavelength Portions of the Sweep

Kinetic swept lasers often have a characteristic sweep rate that varies significantly over the duration of the sweep. This change in sweep rate and nonlinearity often leads to the nonhomogeneous coherence length across the sweep. However, no discernible difference in the coherence length at the beginning, middle, or ending portions of the sweep in the akinetic swept laser has been observed.

23.3.1.3 User-Adjusted Coherence Length

User-adjusted coherence length, an upcoming function for the akinetic laser, illustrates a unique characteristic of the laser: it is a software platform allowing detailed control over the laser's behavior. One of the implications of this control is that the coherence length can be adjusted with software. This capability can allow coherence length tuning to reduce unwanted signals in the OCT images caused by multiple reflections [56].

23.3.1.4 Imaging Depth Range Should Be Limited by Nyquist, Not Limited by the Laser

In high-speed systems with all-semiconductor swept lasers, it is increasingly likely that imaging depth range will be constrained by the Nyquist frequency limit of the detection of the interferogram [57] rather than by the long coherence length. One must also ensure that the detection amplifier bandwidth does not further limit the useful imaging depth range. Figure 23.6 shows imaging depth range as a function of sweep repetition rate for a 1,310 nm swept wavelength laser at various sweep conditions. These plots show that the imaging depth is often limited by the sampling rate of the receiver and not the coherence length of the swept laser. For longer coherence lengths at higher speeds, the sweep width is reduced to ensure the return frequencies were below the Nyquist limit.

23.3.2 Sweep Speed

There are a number of reasons that rapid laser sweep speed can be important for OCT. These include the following:

- Reducing blur from movement [58]
- Enabling high-resolution imaging
- Enabling 3D volumetric imaging [59–61]
- Higher time resolution in 4D imaging [62]
- Reducing measurement time needed, thus reducing patient impact

Experimental data shows that moving from any wavelength to an adjacent wavelength with the all-semiconductor laser takes ~2 ns. This measurement was

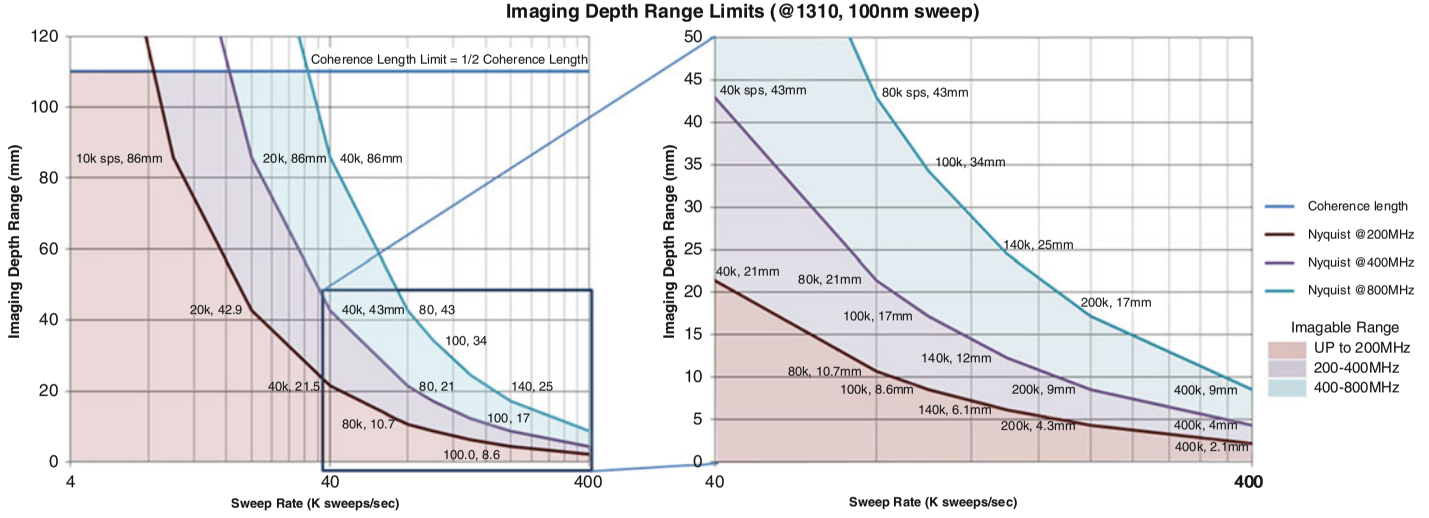

Fig. 23.6 A good laser will allow the imaging range to be limited by Nyquist, not the coherence length of the laser. The charts indicate the maximum imaging depth range due to Nyquist limits at different sweep rates, with curves for different measurement rates (different colored plots). Also shown is the coherence length limit. *Shaded* areas indicate combinations of measurement rate, sweep rate, and imaging depth range that are valid for imaging. The right-hand chart zooms in on short imaging depth range for clarity

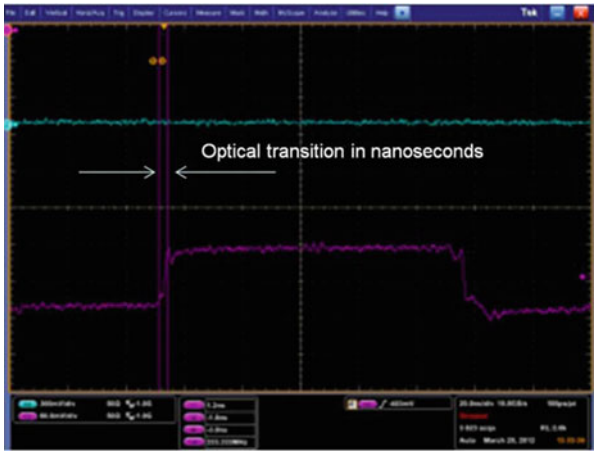

Fig. 23.7 High-speed oscilloscope trace showing full optical transition in <2.5 ns

obtained using a reference interferometer with known free spectral range as a frequency-to-amplitude converter. The resulting photo-detected signal was then measured with a high-speed oscilloscope. The measured time for the wavelength of the laser to change as a result of a step change in the control currents to the laser cavity is shown in Fig. 23.7. An amplitude change in the light transmitted through the interferometer corresponds to a wavelength change in the output of the laser. In the measurement shown, a step change in current occurring over 2.5 ns creates a step change in wavelength in approximately 2.5 ns.

Akinetic laser module designs in early 2013 can drive the laser up to 400,000,000 wavelength points per second. This can yield up to roughly 400,000 A-scans per second with 1,000 points per sweep or 2,000 points at 200,000 sweeps per second. Unlike some mechanically driven lasers, the speed is software controlled. The akinetic laser can be programmed for any speeds over a range from 4,000 to 400,000 sweeps per second. The low repetition rate value of 4,000 sweeps per second is not a fundamental limitation and could be made arbitrarily low.

In lab experiments, all-semiconductor lasers have been demonstrated at 1 million sweeps per second, thus ensuring a growth path with akinetic technology for faster future sweep rates to enable fast, high-resolution 3D imaging. For the longer term, it is believed that the akinetic technology can be pushed to roughly 2 million sweeps per second.

23.3.3 Duty Cycle

The akinetic semiconductor laser's fast tuning from any wavelength to any other wavelength means that the time from the end of a sweep to the beginning of a sweep is short, permitting a high duty cycle with little dead time between sweeps.

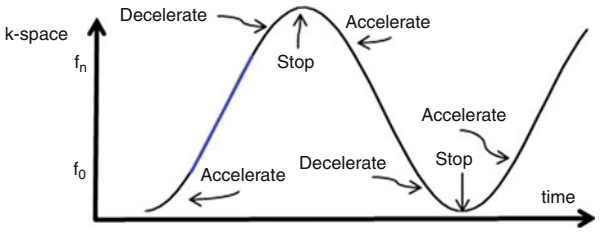

Fig. 23.8 Mechanically tuned lasers transition through accelerate/decelerate cycles, generating and dissipating momentum, that are not pertinent for akinetic lasers

Historically, achieving a sweep with a swept-wavelength laser required generating and dissipating momentum in a mechanical tuning mechanism [25]. Mechanically tuned lasers must start moving from an initial position of a physical tuning actuator, accelerate the actuator (building momentum), maintain the actuator tuning rate for the useful part of the sweep, decelerate the actuator, stop, reaccelerate, and so on (Fig. 23.8).

With some mechanical lasers, portions of this accelerate-decelerate cycle can be expedited but not eliminated [63], resulting in only a portion of the sweep that is actually useful for imaging. In the past, delays in the data acquisition system made this delay inconsequential because it took time to get the data transferred. In today's data acquisition, however, system measurement is virtually continuous. With these streaming-type data acquisition systems, high duty cycle afforded by the all-semiconductor laser increases total throughput and imaging speed (Fig. 23.9).

Because duty cycle is software controlled, it is adjustable. The duty cycle can be set to almost any value from 5 % to 95 %.

23.3.4 Linearity and k-Clock

23.3.4.1 Electronic k-Clock

Linear frequency (k-space) data is a requirement for swept source OCT applications. Mechanically tuned swept lasers often lack sufficient linearity of optical frequency versus time. Thus, most swept lasers require an external optical k-clock for variable-rate clocking of the data acquisition [6, 64] or require a similar k-clock signal that can be analyzed to properly resample the even-in-time data [65–67]. Figure 23.10 illustrates a typical external k-clock block diagram.

The all-semiconductor laser is inherently linear and does not require an external optical k-clock. The laser self-generates an internal electronic k-clock. The laser forces the wavelength to be correct at each of the evenly spaced clock transitions Fig. 23.11. The all-semiconductor laser does not need the extra cost of parts and integration of an optical k-clock and eliminates the challenges frequently associated with the nonuniform triggering that can occur with external optical k-clocks (where zero-level drift creates nonuniformity in the triggering periods and resulting degradation of trigger timing). The result is direct triggering of the data acquisition: No post-acquisition resampling, avoiding the potential of resulting ghosting [68, 69] and reducing computation time.

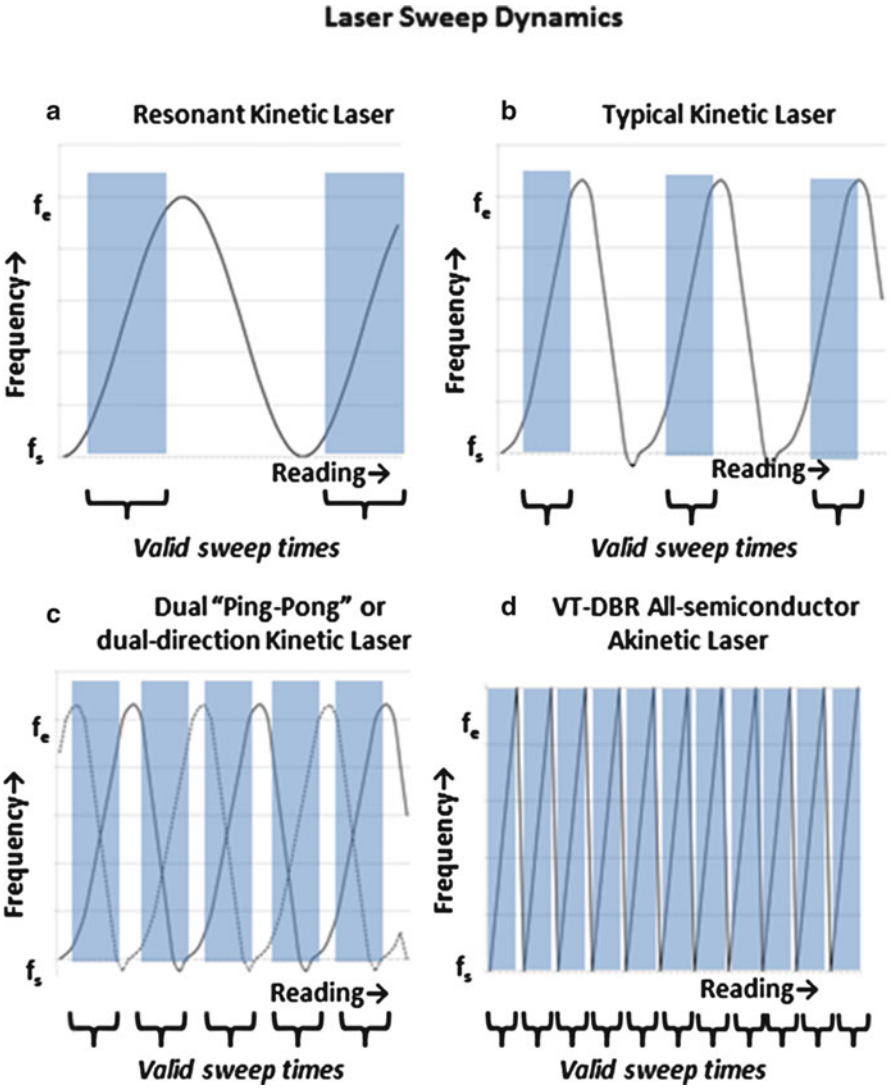

Fig. 23.9 Mechanically tuned lasers must move back from the end of the sweep to get to the beginning, taking time [63]. Akinetic lasers move directly from the end to the beginning, using only nanoseconds

In addition to the electronic k-clock, the akinetic laser also provides a sweep start trigger. This sweep start trigger is always deterministically aligned with the k-clock trigger, providing a pulse at a time just previous to the first valid k-clock, and thus ensuring that the ± 1 clock cycle error [49] that can exist in mechanically swept-laser systems where k-clock and sweep start are not deterministic.

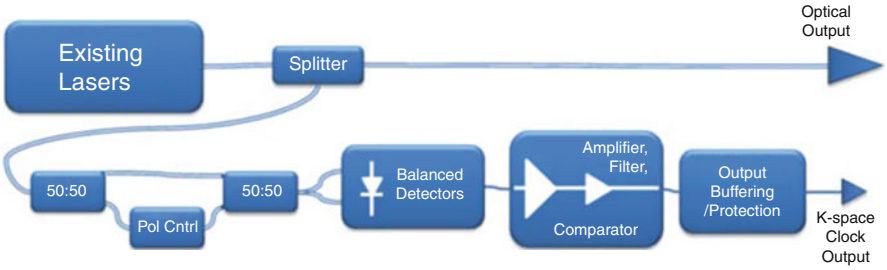

Fig. 23.10 Kinetic lasers generally lack sufficient linearity, requiring either resampling with an external k-clock, or triggering with one, leading to cost, trigger jitter, or the potential of artifacts. The 50:50 couplers and path length delay provides for a Mach-Zehnder filter that provides a repetitive passband filter with equal frequency steps. The interferometer output is detected and processed to provide electrical signal edges to trigger the data acquisition circuitry

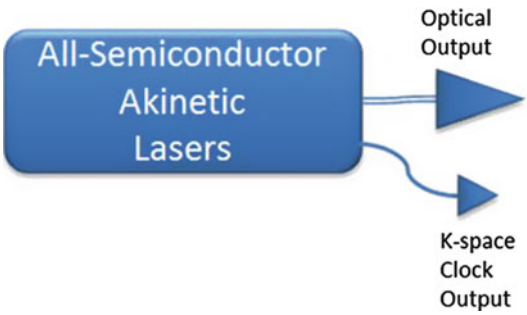

Fig. 23.11 Akinetic lasers can generate an extremely linear sweep, synchronized with an evenly spaced self-generated electronic k-clock. This simplifies receiver design

23.3.4.2 Inherent Linearity

The akinetic laser has typical RMS linearity of 0.0012 % at 200,000 sweeps per second (less than ±1 pm; ±0.2 GHz) and has a linearity span that is typically <±0.002 % (<±2 pm). This linearity produces uniform single-reflection interferograms and results in clean, low-artifact images. Figure 23.12 shows the example output of a Mach-Zehnder interferometer with ~42 GHz free spectral range operating at 1550 nm and Figure 23.13 shows similar performance for a laser operating at 1310 nm. The measurement shows that the spacing between zero crossings is uniform indicating a linear frequency versus time sweep.

23.3.4.3 Equally Spaced, 50 % Duty Cycle Trigger

To achieve high signal-to-noise ratio (SNR) and spurious-free dynamic range (SFDR) as well as the high-speed acquisition rates, most available data acquisition systems require uniform equally spaced 50 % duty cycle triggers. The akinetic laser has equally spaced clock triggers, allowing the system data acquisition hardware to achieve higher SNR. With external optical k-clocks with mechanically tuned lasers, ensuring exactly 50 % duty cycle can be difficult (Fig. 23.14).

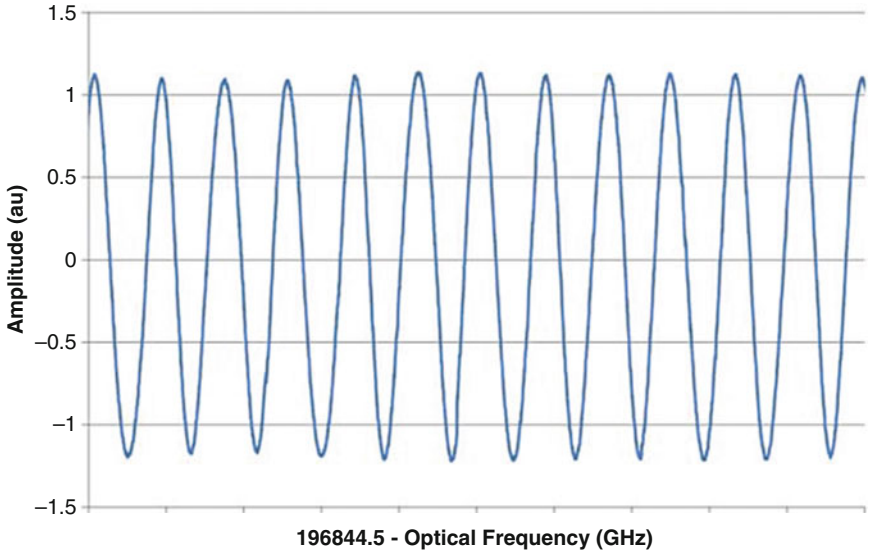

Fig. 23.12 Interferograms do not show the common "accordion" shape typical of mechanically tuned lasers [70]. This image is a short segment of a 1,550 nm laser, operating at 8 k sweeps per second to provide high-resolution interferogram using 400 MHz data acquisition

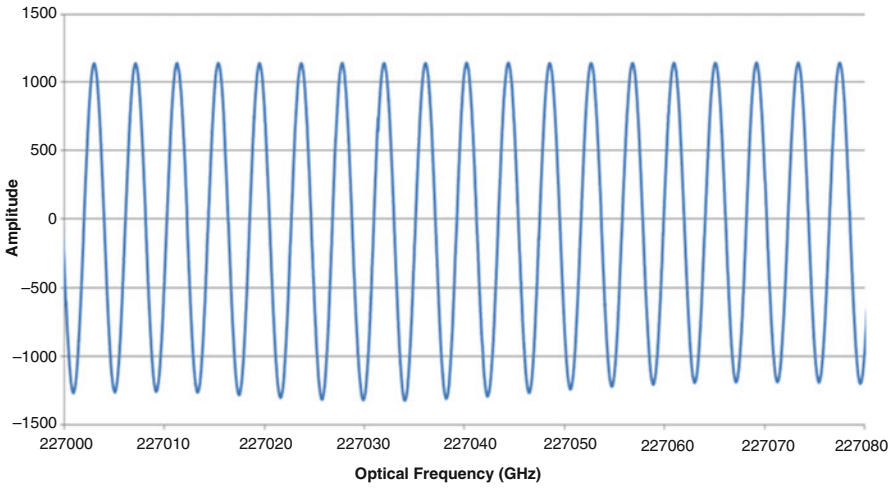

Fig. 23.13 Interferogram at 1,310 nm operating at 8 k sweeps per second to provide high-resolution interferogram using 400 MHz data acquisition

23.3.5 Point Spread Function (PSF) Quality

The axial PSF provides a measure of a fundamental limit on the quality of image possible with a swept laser in an SS-OCT system [4]. The PSF is the power

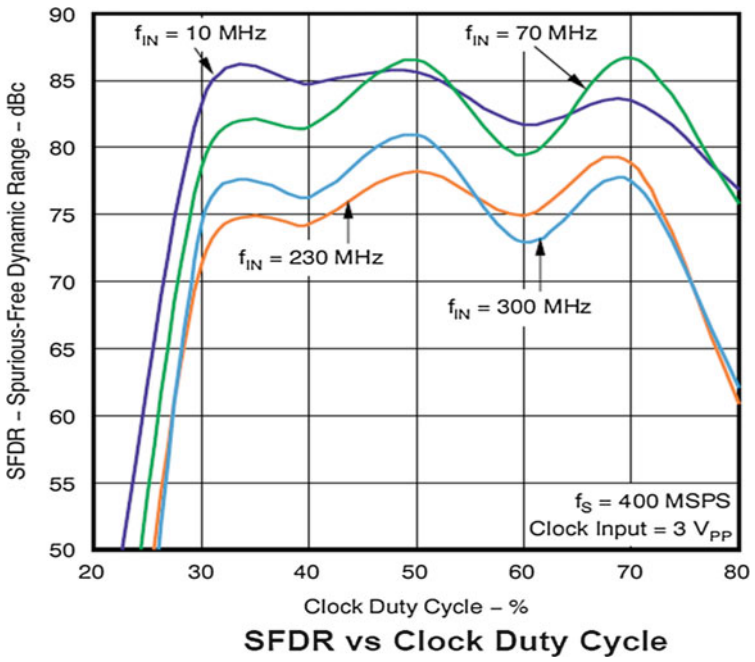

Fig. 23.14 This TI data sheet chart illustrates how a 10 % change in the duty cycle of the clocking can reduce SFDR by almost 10 dB at 300 Mhz [71]

spectrum of the interferogram produced by an OCT interferometer with a single reference reflector. A PSF with low side lobes and low background noise facilitates an image with low artifacts and high contrast and detail. Typical values for the akinetic laser PSF are 45–60 dB to the side lobes and 55–70 dB to the noise floor (defined as the variation of the background), as seen in Fig. 23.15 (the range of values is determined primarily by interferometer characteristics).

The PSF and image quality produced by the all-semiconductor laser will not degrade over time because the laser is constantly re-evaluating its own performance and making small adjustments to its drive signals. Maintaining sweep linearity over time can be a limitation for mechanical tuning lasers, primarily due to mechanical wear and mechanical changes with time and temperature.

23.3.6 Coherence Revival

Coherence revival is the effect where interference fringes are observed in an interferometer illuminated by a light source with a comb-like spectrum not only when the reference and sample arms are matched in delay but also when the two arms are mismatched at periodic intervals. These intervals can be several orders of magnitude longer than the source coherence length [50]. This occurs if a laser is simultaneously oscillating at multiple longitudinal

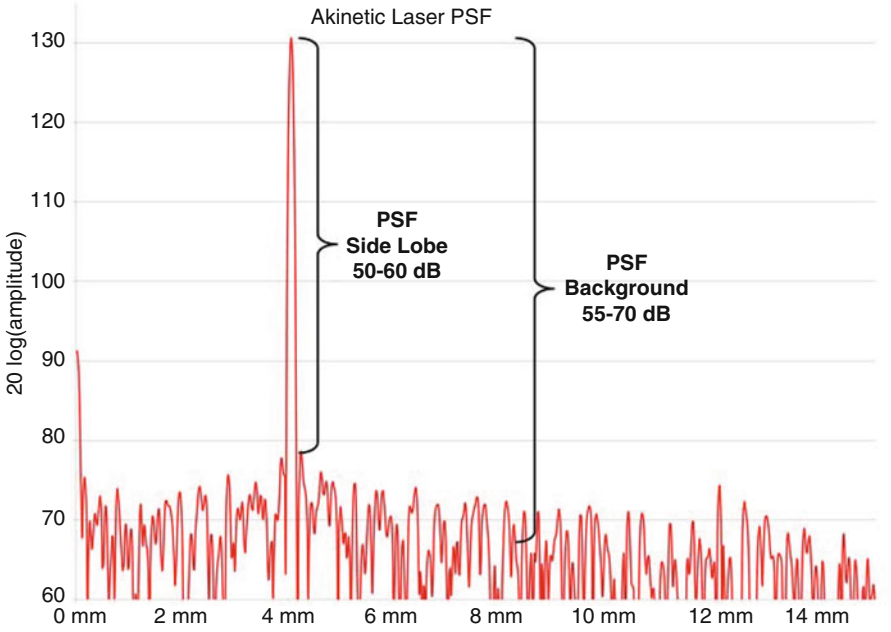

Fig. 23.15 This plot shows the PSF for a 153 kHz sweep. Deep side lobes and low background noise lead to low image artifacts and high image contrast and detail. These are due to the low trigger jitter, linearity, power stability, low RIN, and additional factors

modes of the cavity. The period of the interference fringes is equal to the reciprocal of the mode spacing (which equal to the roundtrip delay of the laser cavity) [50, 72]. These effects can create nonidealities such as ghosting in the OCT image [73].

Because the akinetic swept laser has a single longitudinal mode, the issues with coherence revival in mechanically tuned lasers are largely avoided.

23.3.7 Mode Hops

The all-semiconductor laser uses software control to constantly monitor and ensure that no mode hops occur. Long before the laser could even begin a mode hop, the control optimizes the sweep to ensure optimum side-mode-suppression ratio (SMSR) and guaranteeing no mode hops.

23.3.8 Phase Stability/Wavelength Repeatability

In phase-sensitive OCT applications, such as phase microscopy or Doppler OCT, it is beneficial to have wavelength sweeps of the laser starting at the same

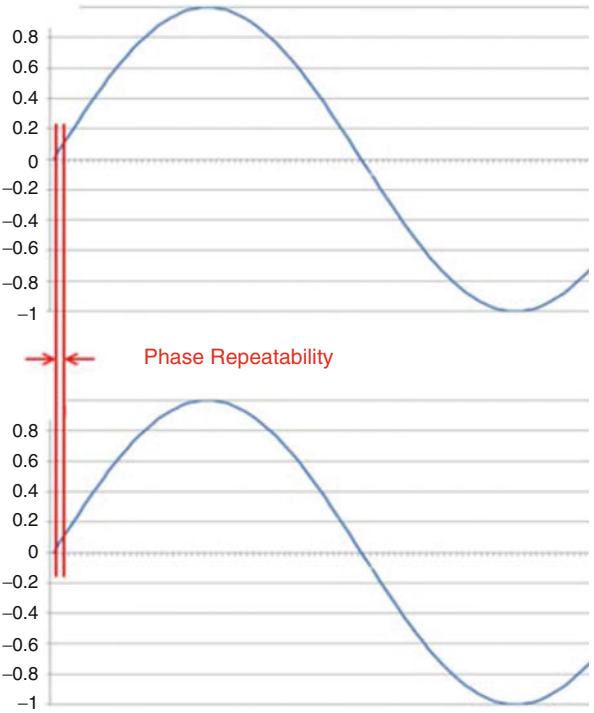

Fig. 23.16 Phase repeatability is typically defined as the repeatability from one sweep to another and is expressed either in picometers repeatability, in milliradians of a specified reflection, or in displacement sensitivity

wavelength and repeat the same wavelengths at all samples in an interferogram (Fig. 23.16). Wavelength repeatability of the laser contributes to phase stability in the resulting interferograms, directly affecting minimum phase sensitivity [49]. Phase sensitivity then determines displacement sensitivity and flow velocity resolution.

Wavelength repeatability of 0.5 pm standard deviation and ±2.5 pm span (peak amplitude) has been confirmed for the all-semiconductor laser. The following charts show the detailed test results (Figs. 23.17 and 23.18).

The displacement sensitivity of a phase-sensitive OCT system is obtained from

$$\delta z = \frac{\delta\phi\ \lambda}{4\pi\ n} + \frac{\delta\lambda}{\lambda} z \tag{23.2}$$

where $\delta\phi$ is the phase uncertainty in the interferogram measurement, $\delta\lambda$ is the wavelength repeatability, z is the nominal path length difference, n is the index of refraction, and λ is the center wavelength. The fundamental phase uncertainty of an OCT system is $1/\sqrt{SNR}$ [75, 76]. To achieve SNR-limited displacement sensitivity, variations in the wavelength repeatability must be minimized as shown in Eq. 23.2. Most phase-resolved OCT systems using mechanical swept sources require the use of a wavelength reference or phase reference to remove the effect of low

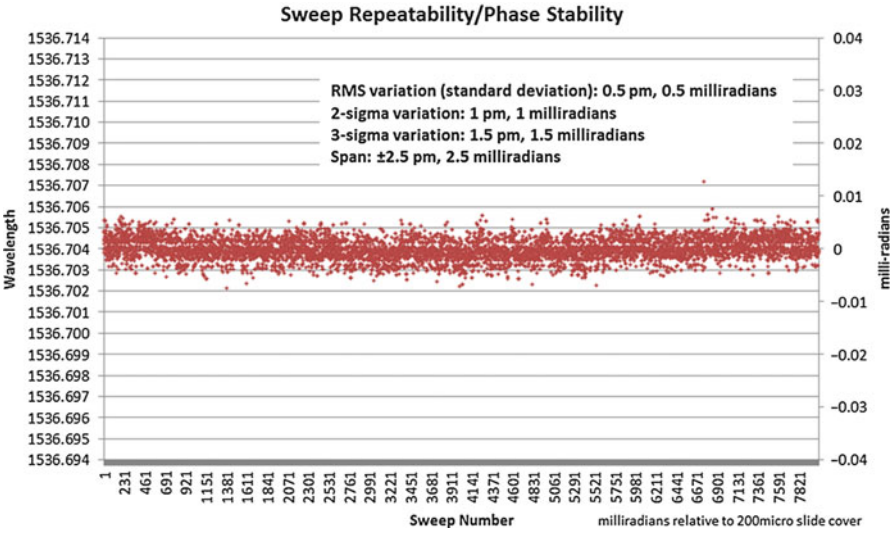

Fig. 23.17 Sweep phase repeatability in nanometers and milliradians. Peak variation is ±2.5 pm; standard deviation is 0.5 pm. A total of 8,040 sweeps were measured over a period of 30 min. Sweep rate was 118 KHz. Test consisted of measuring the wavelength of a feature from an $H^{13}CN$ gas absorption cell at 100 torr [74]. Repeatability was similar at various points along the sweep

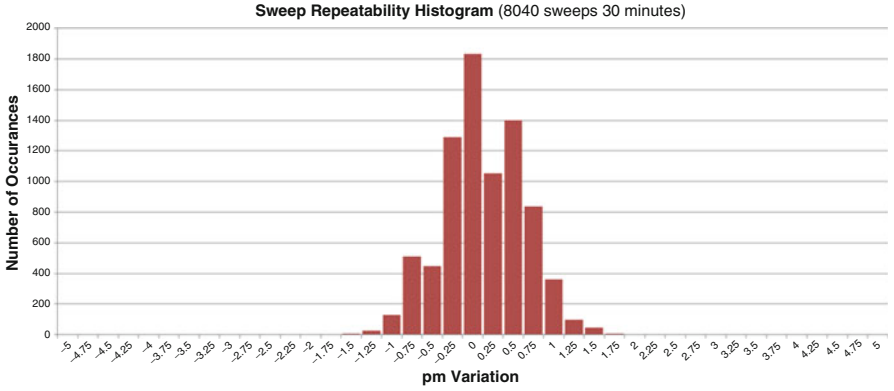

Fig. 23.18 A histogram of akinetic laser sweep wavelength variation in picometers. 0.25 pm is equivalent to 0.25 mrad

wavelength repeatability in sources based on polygon mirrors [49, 77], MEMS cavities [78], or MEMS VCSELs [79].

The predicted performance of the akinetic laser may be calculated in two ways. First, using Eq. 23.2, the measured wavelength repeatability of 0.5 pm and a center wavelength of 1,550 nm, the displacement sensitivity is 65 pm at the thickness of a slide cover of 0.2 mm (650 pm at 2 mm). Alternatively, the wavelength

repeatability term in Eq. 23.2 may be expressed as a depth-dependent phase error, given by

$$\delta\phi = \frac{4\pi\, n\, \delta\lambda\, z}{\lambda^2\, \delta\lambda} \tag{23.3}$$

In air, a wavelength repeatability of 0.5 pm produces a phase error of 0.5 mrad at 0.2 mm (5 mrad at 2 mm). The calculated phase errors for the akinetic laser meet or exceed results obtained from a number of swept-source phase-resolved OCT systems [77–84] without need of a wavelength reference or phase correction methodology [85, 86].

23.3.8.1 Phase Sensitivity Vis-à-Vis Alternatives

Comparing phase sensitivity among different systems with different light sources can be challenging. One typically would like to separate contributions from the source and detector from instabilities in the optics that constitute the interferometer. The most incontrovertible technique for achieving this separation is utilizing the front and back reflection from a glass plate, typically a microscope cover slip, as the reference and sample arm for phase stability analysis of the source and detector. A drawback to this technique is that there is little control over the reference power; hence, the measurement may not be under the appropriate conditions where near shot-noise limited detection may be achieved [87] and precludes the use of balanced detection. Nevertheless, this technique may be used to assess how closely the measured phase stability follows the ideal $1/\sqrt{\text{SNR}}$ relationship.

It is well known that spectrometer-based OCT systems typically have superior phase stability over swept-source-based systems [88] unless measures are taken to compensate for sweep to sweep variations in the swept-laser frequency [79]. This is commonly attributed to the lack of moving parts in spectrometer-based systems. The akinetic swept laser has a similar lack of moving parts; hence, one would expect similar phase stability without any compensation for sweep to sweep variability.

In order to test this conjecture, we have made a direct comparison between a spectrometer-based OCT system at 830 nm (±20 nm) described in detail in [89] with a 1,550 nm (±20 nm) akinetic swept-laser-based system using a glass microscope coverslip (#1,145 μm). The measured standard deviation of the phase noise based upon 10,000 a-lines was 2.28 mrad and 1.4 mrad at 54.8 dB SNR and 57.8 dB SNR for the 830 nm and 1,540 nm systems, respectively. In order to make a fair comparison, we need to ratio these results to the ideal case, i.e., $\sigma = 1/\sqrt{\text{SNR}}$. We can then see that under these conditions the phase noise is 126 % of ideal for the spectrometer-based system and 109 % of ideal for the akinetic swept-laser system. The wavelength repeatability of the akinetic swept laser enables phase stability on par with spectrometer-based systems without introducing compensatory absolute wavelength calibration (via, for instance, fiber Bragg grating).

The following table outlines published data on the phase stability for various laser technologies (note: there has been no effort to control for the different experimental

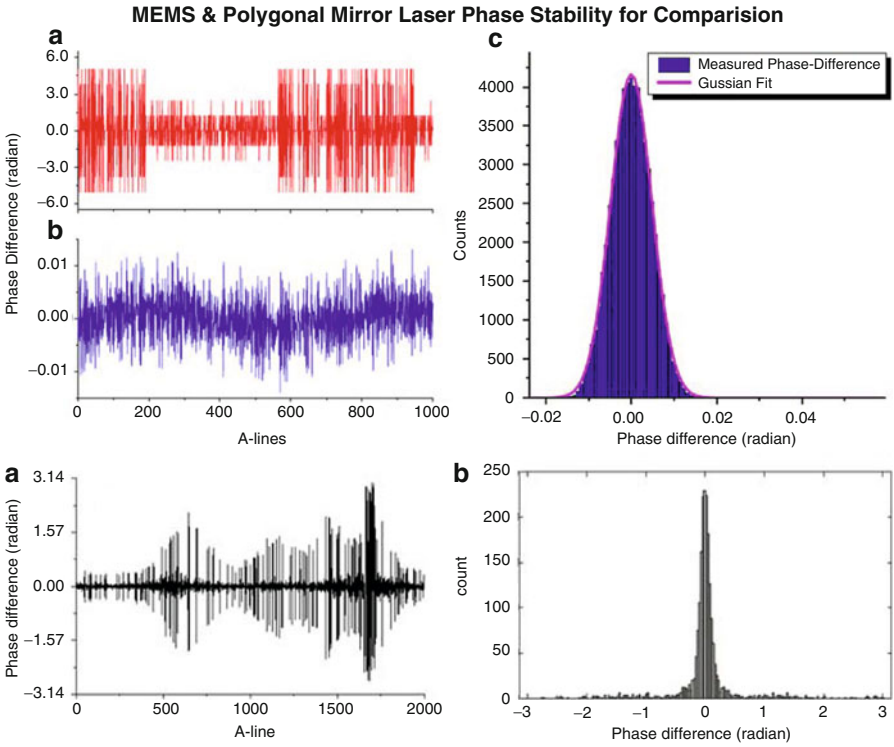

Fig. 23.19 MEMS laser phase stability of ~5,000 mrad peak (*left*) and ~3,000 mrad (*right*) compares to 0.01 mrad for the all-semiconductor akinetic laser. Even the corrected values, in which the researcher added a reference reflection to do corrections, are virtually identical to the uncorrected akinetic laser results (Courtesy of VU University, Amsterdam [78] and Beckman Laser Institute, California [81])

conditions, namely, the signal-to-noise ratio associated with the measurement; hence, ranges have been included where available) (Fig. 23.19 and Table 23.2).

Also pertinent to phase stability is the synchronization between sweep start and the k-clock. In mechanically tuned systems, these signals are typically not deterministic relative to one another, which results in the ±1 clock error issue [49]. Akinetic systems provide an electronic sweep start trigger which is synchronized with the electronic k-clock, eliminating the ±1 clock problem (Fig. 23.20).

23.3.9 Trigger Jitter

Trigger jitter in high-speed OCT systems can represent a key limitation that degrades the SNR [90]. As sweep speed increases, trigger jitter becomes a major factor in SNR and in the resulting image quality [91]. Even small triggering jitter reduces the PSF and image quality.

Table 23.2 Comparisons of phase stability/wavelength repeatability across different lasers [77–83]. Mechanical movement has meant swept-source systems had substantially lower stability. Akinetic lasers achieve results near or better than spectrometers and results much better than mechanically swept lasers

Laser technology	Typical wavelength repeatability	Phase stability (200 μm slide cover)
Akinetic swept laser	0.5 pm std. dev.,	0.5 mrad std. dev.,
	±2.5 pk-pk	2.6 mrad peak to peak
Spectral domain OCT (using spectrometer)	Not applicable	0.32–5.2 mrad std. dev.
		±17 mrad peak to peak
MEMS swept laser	294 pm peak to peak	4.8–3,000 mrad
Polygon mirror swept laser	18–600 pm	32 mrad std. dev.
FDML swept laser		0.76 mrad std. dev.
Crystal-based swept laser		
Littman-Metcalf swept laser	±1– ±20 pm peak to peak typical	
Pump/circulator/MEMS/VCSEL/SOA swept laser	±150 pm peak to peak	1.5 mrad

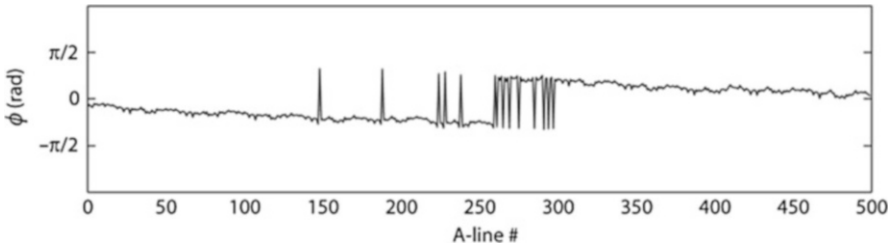

Fig. 23.20 Diagram illustrating the ±1 clock error problem typical with mechanically tuned lasers, where the k-clock and start sweep trigger are not deterministic. The akinetic laser eliminates this problem by providing an electronic start-sweep trigger that is synchronized and deterministic with the k-clock [49]

When utilizing an optical k-clock, it is difficult to achieve better than 18–50 ps jitter due to zero drift and other factors [85]. The akinetic all-semiconductor laser's internal electronic k-clock is designed to minimize trigger jitter and achieves a ±300 fs specification–roughly 10–100 times better than a typical external optical k-clock.

The SNR of a system with analog signal frequency $f_{\text{bandwidth}}$ and jitter $\Delta t_{\text{jitter RMS}}$ is as shown in the following equation [71, 90]:

$$\text{SNR} = \left[\frac{1}{(2\pi)\left(\Delta t_{\text{jitter RMS}}\right)\left(f_{\text{bandwidth}}\right)}\right]^2 \tag{23.4}$$

or expressed in dB

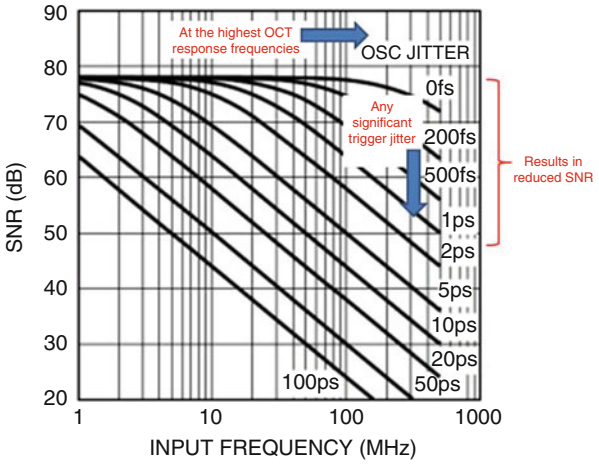

Fig. 23.21 Systematic OCT system SNR reduction with different trigger jitter specification [92]

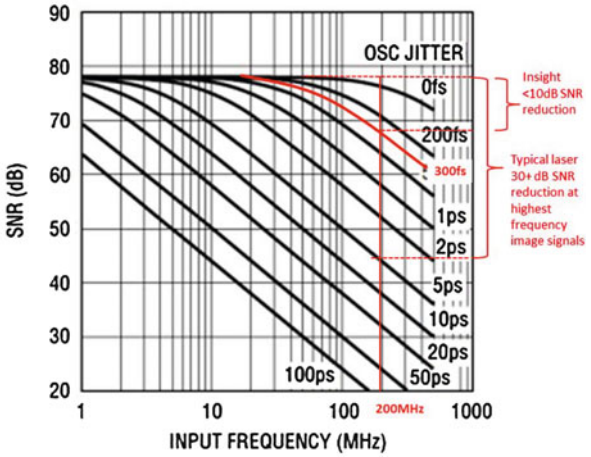

Fig. 23.22 Akinetic lasers can be designed to have low jitter; at 300 fs, SNR is still 65 dB for a 200 MHz signal (Nyquist for 400 MHz acquisition)

$$\mathrm{SNR_{dB}} = -20\log\left(2\pi f_{\mathrm{bandwidth}}\Delta t_{\mathrm{jiter\ RMS}}\right) \tag{23.5}$$

The following generic chart shows the relationship between trigger jitter and SNR [92] (Fig. 23.21).

Trigger jitter can become a significant issue at higher sweep speeds. A 6 mm imaging distance (12 mm round-trip distance) yields a signal of >100 MHz at 200,000 sweeps per second (100 nm width). The following chart shows that a jitter of 5 ps from an optical clock generates a >30 dB SNR reduction (Fig. 23.22).

23.3.10 Smooth, Stable, Controllable Power

The output power character of a sweeping laser can have a significant influence on the performance of an OCT system. Noise can reduce the image quality and sensitivity. Total power can be a limiting factor for penetration depth, and the overall shape of the power profile can limit resolution. In most mechanically tuned lasers, the output power varies substantially during the sweep [3, 5, 6, 11–13, 93], which can create image artifacts and affect the SNR. Precise control of the power profile over the sweep can accomplish the following:

- Smooth output power reduces image artifacts
- Selectable power allows tailoring to gain ranges of the receiver
- Custom profiles allow experimentation with and optimization of the PSF and resolution
- Higher average power across the band
- Flat, strong output power can reduce RIN trade-offs and improve penetration depth

Output power in the all-semiconductor akinetic laser is directly controlled on the chip with the same single-digit nanosecond timing that allows fast wavelength variation. The nominal output power of the laser can be selected from software.

23.3.10.1 Flatness

The all-semiconductor laser has direct control of output power during the sweep. The output power is automatically tailored to the desired output with conformance to ± 0.015 dB or about ± 0.3 % of the signal (Fig. 23.23).

Reduced amplitude variation can directly reduce spurious artifacts in the PSF, reducing ghosting or blurring of the image [94].

The importance of flatness is illustrated by the fact that amplitude variation is not eliminated by balanced detection—only the zero value is corrected [95, 96]. The varying amplitude envelope of other lasers remains in the interferogram, contaminating the image.

23.3.10.2 Selectable Power Profiles

Rather than having to accept the natural output power profile of the laser, the power profile can be selected to optimize image quality and overall system performance. Various research [97] has been inconclusive, with different studies demonstrating advantages of a power profile that is either flat, Gaussian, and cosine tapered Fig. 23.24 or even one with exaggerated power in the beginning and end of the sweep. With an akinetic laser, these and other exotic power profiles may be tried by the user, under program control, for application-specific optimization without any other changes to the system (Fig. 23.25).

Note that for resolution of an OCT image, a Gaussian profile creates a resolution reduction compared to flat top, but FFT artifacts affect the image through the dynamic range. A flat-top profile can be used as an alternative and the resulting interferogram windowed in the time domain for Gaussian or cosine tapered

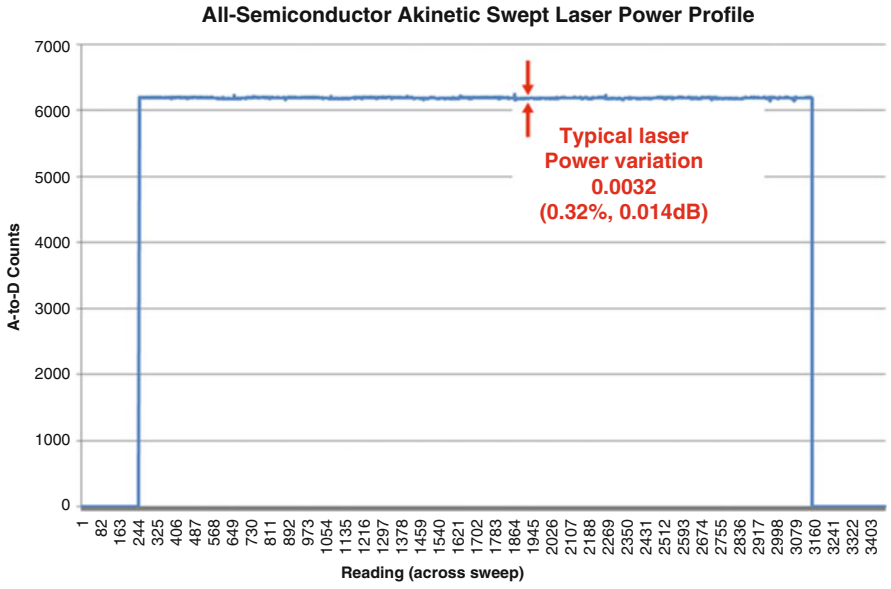

Fig. 23.23 Output power is controlled to ±0.015 dB, reducing power variation-driven image artifacts (Data taken at 108 kHz, 40 nm sweep)

(or other profile), allowing the advantage of the higher measurement SNR of the flat top while avoiding large FFT artifacts.

23.3.10.3 Higher Average Power

While many lasers are specified at peak power [11, 14], the edge-of-band power can be −3 dB, −6 dB, −10 dB, or even −20 dB down from the peak. Power specification for the all-semiconductor laser is flat power over the sweep, potentially yielding substantially higher average power.

23.3.10.4 Sweep Speed Effect on Power

There is no discernible change in output power with sweep speed.

23.3.11 Custom Power Profiles: Wavelength Dependence Compensation and Modulation

To potentially improve the PSF and the resulting image quality, an akinetic laser can auto-level the power profile across wavelength and can automatically preemphasize the optical signal to compensate for wavelength and polarization-dependent losses in the OCT interferometer. This compensation can be applied to the flat top, Gaussian or cosine-tapered profiles.

It is interesting to note that OCT practitioners often do not recognize that the wavelength dependence of the optics can play a strong role in artifact generation

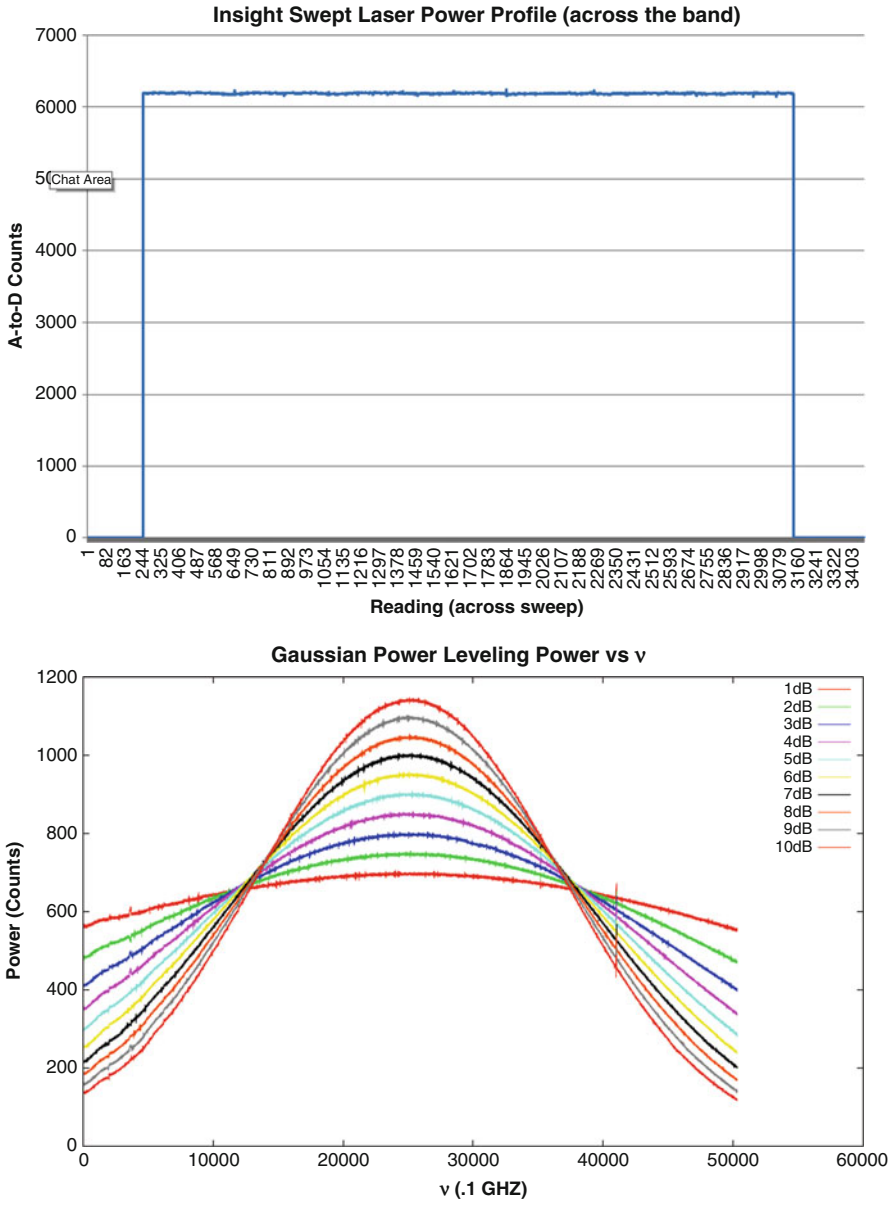

Fig. 23.24 The power profile is user-programmable to flat top, Gaussian, or cosine tapered

because the natural power profile from the mechanical laser is already so nonuniform that the optics wavelength dependency is masked.

In addition to compensating for wavelength dependence, a custom power profile can also be used to superimpose a modulation onto the optical signal amplitude.

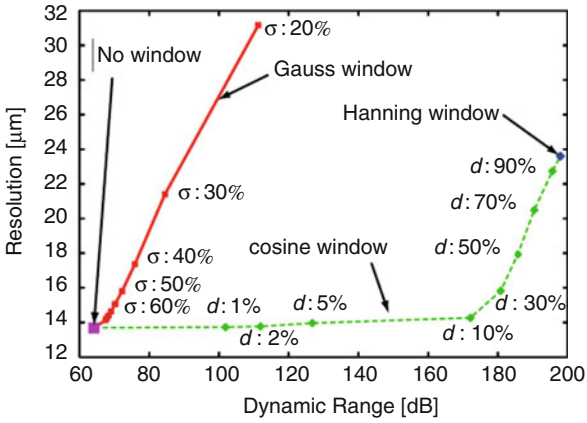

Fig. 23.25 Experimentation with different windows impacts both resolution and dynamic range limits (Chart courtesy Kitasato University [97])

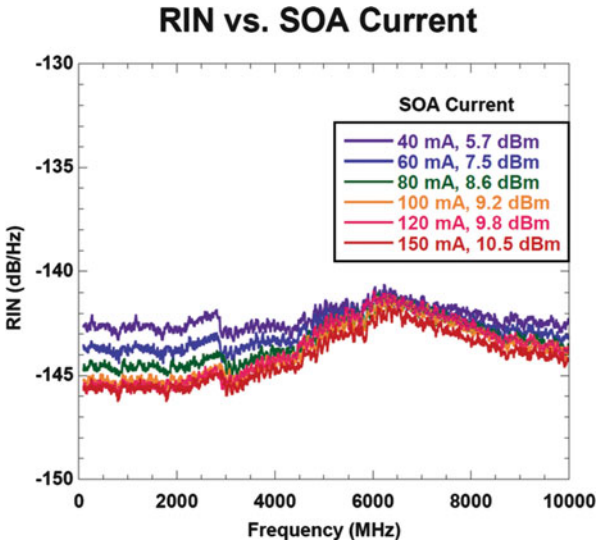

Fig. 23.26 Low RIN (< -140 dB/Hz) contributes to clean PSF and low-noise images

This modulation can be in the form of a sinusoid, a pulse, a repetitive pulse, or any other form of amplitude variation.

23.3.12 Intensity Noise

The static RIN of the laser chip in the all-semiconductor laser is shown in Fig. 23.26. The RIN is less than 140 dB/Hz and tends to be flat through the frequency range of interest to OCT measurements. RIN directly impacts image sensitivity [98, 99].

Integrating the akinetic laser RIN of -140 dB/Hz over a typical maximum 200 MHz bandwidth results in a total integrated 0.14 % noise.

Most OCT imaging systems use balanced detection to reduce the effect of RIN and improve the image sensitivity. Depending on the amount of RIN, the wavelength dependence of the imaging system, and the sensitivity required, sophisticated techniques of spectral balancing or normalization are required [100]. The low RIN of the akinetic laser, combined with the ability to shape the power vs. wavelength profile (see Sect. 23.3.10), should simplify achieving high-sensitivity images.

23.3.13 Side-Mode Suppression

Side-mode-suppression ratio (SMSR) is a measure of the amplitude of the optical side modes of the laser relative to the power of the strongest cavity mode of the laser. Laser side modes can degrade image quality by diminishing edge detail and reducing the sensitivity. The akinetic laser may be tuned such that the amplitudes of competing laser cavity modes are substantially suppressed. Side-mode-suppression ratios of 44–48 dB over the entire tuning range are typical with akinetic laser technology (see Figs. 23.27 and 23.28). By contrast, the mode selectivity of some mechanically tuned laser cavities (Fig. 23.29) may be lower (~30 dB), possibly limited by mechanical alignment tolerances of the laser cavity. The all-electronic control of the akinetic laser cavity allows the laser to operate in a single-longitudinal mode throughout a sweep. Evidence of the favorable SMSR during the sweep is the absence of coherence revivals in the coherence length measurement of Fig. 23.5. Coherence revivals – collapse and restoration of an interferogram – occur when a laser operates in multiple cavity modes [72]. The high dynamic range in PSFs measured with the akinetic laser (Fig. 23.15) also shows that the fringe contrast ratio remains high throughout the tuning range, which is also indicative of single-mode behavior.

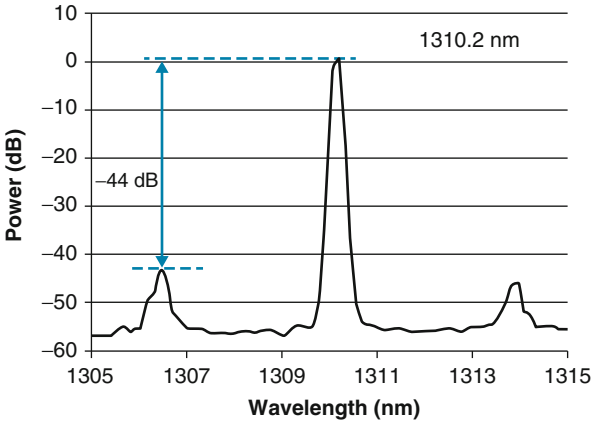

Fig. 23.27 Side modes for the akinetic laser are below −44 dB at 1,310 nm. Typical values for mechanical lasers vary between −15 and −40 dB, with many in the range of −25 to −35 dB

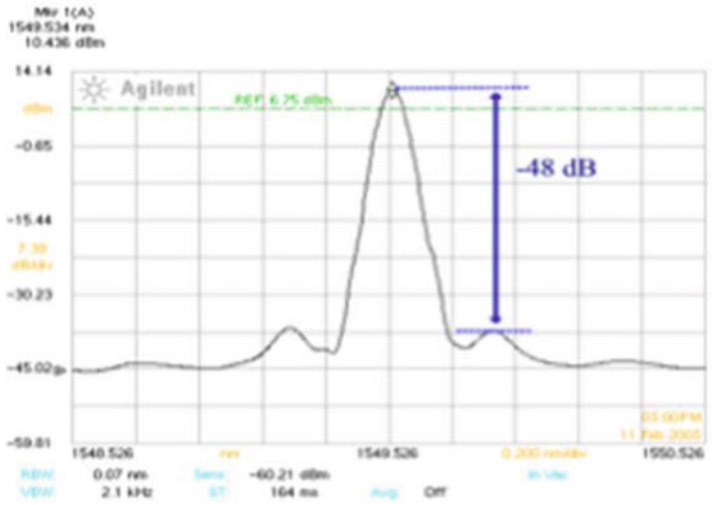

Fig. 23.28 Side-mode suppression at 1,550 nm is under −48 dB

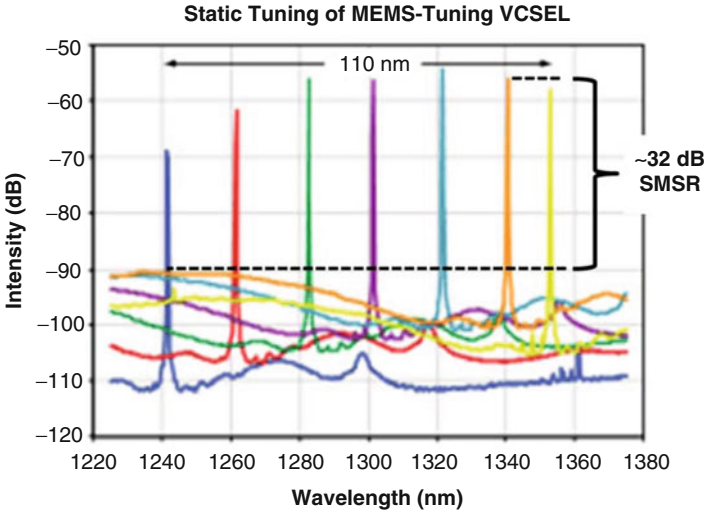

Fig. 23.29 It is not uncommon for other swept laser technologies to exhibit poor side-mode performance. As shown above, the VCSEL/MEMS/pump/circulator/SOA laser exhibits less than 33 dB of side-mode performance [17]

23.3.14 Wavelength Bands and Sweep Range

The initial all-semiconductor swept lasers were developed at 1,310 and 1,550 nm [101, 102]. Over the life of a laser, the center wavelength will only vary by approximately 80 pm based on life-test measurements taken on similar laser devices (Fig. 23.30).

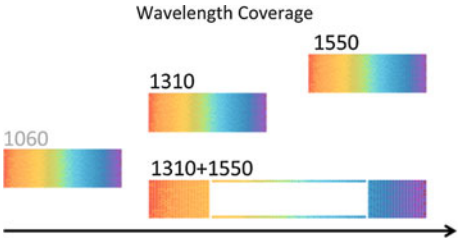

Fig. 23.30 Wavelength bands and sweep width. Dual wavelength band coverage from lower 1,310 to 1,550 nm is also planned

Initial availability of akinetic lasers was 40–50 nm at 1,550 nm, followed by both 100 nm at 1,550 nm and 40–50 nm at 1,310 nm. Full (~100 nm) wavelength coverage at 1,310 nm followed.

At the time of this writing, a consortium of companies is working with Insight Photonic Solutions to migrate the all-semiconductor approach to create a 1,060 nm akinetic swept laser, primarily for ophthalmic imaging applications [103]. The same technology (with a modified substrate) is employed for 1,060 nm. The electronic drive circuitry is identical for 1,310 nm, 1,550 nm, and 1,060 nm. It is also within the bounds of the technology to work with applications at 850 nm and above 1,640 nm. With appropriate frequency doubling, 430 nm may also be attainable.

The all-semiconductor technology will allow production lasers with wavelength coverage of ~140 nm and wider in the future.

23.3.15 Single Longitudinal Mode

The all-semiconductor laser, in contrast to typical mechanical lasers with longer cavity lengths, operates in a single longitudinal mode.

23.3.16 Polarization State Stability

Polarization state stability is critical for polarization-sensitive OCT [48, 104–109], but lack of stability also has negative effects on standard OCT [110].

- Polarization state wobble can impact image clarity and add artifacts through the impact it has on the OCT interferometer.
- Polarization state wobble makes polarization-sensitive OCT much less effective.
- Optional PM output provides flexibility for new avenues for research.

With some mechanically tuned swept lasers, it is common for the polarization state to vary substantially during a sweep [111]. Generally, this "polarization state wobble" is periodic with wavelength, typically with a period of oscillation of a few nanometers [112]. The wobble magnitude and period vary with the individual laser, but wobble of 5–23° is common, and periods from 3 to 7 nm are not unusual (Fig. 23.31).

Because the all-semiconductor akinetic laser is entirely in a single longitudinal mode, the polarization state wobble in the laser itself is very low and has been hard to measure. Optical elements inside and outside the laser cavity can create some wobble,

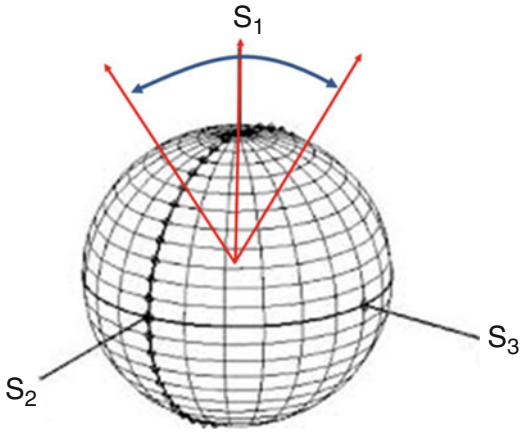

Fig. 23.31 Polarization state wobble is common in mechanical swept lasers and can be between 5 and 23°, creating image artifacts though the polarization dependency of OCT system components

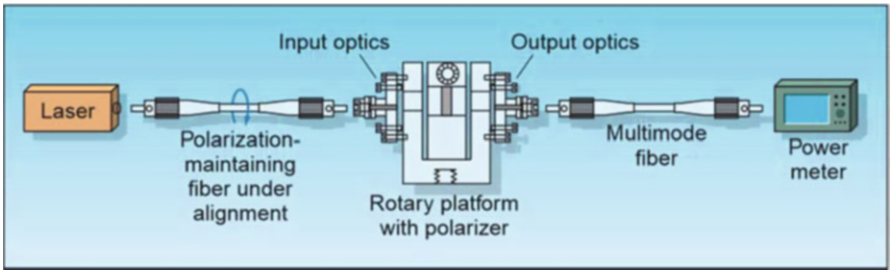

Fig. 23.32 Test configuration to characterize the polarization state wobble of a laser [113]. The polarizer is aligned or anti-aligned with the nominal output polarization of the laser (which can be SM or PM connected). The test shown above will characterize static wobble. To test dynamic inter-sweep wobble, the power meter is replaced with a photoreceiver and an oscilloscope

but the magnitude of such variations is low with the akinetic all-semiconductor approach. Figure 23.32 illustrates the measurement system that is used to characterize polarization state wander in swept lasers.

23.3.17 In-Situ Sweep Programmability

Most lasers can perform at only one speed with a prescribed duty cycle and power profile, and the only way to change the number of points is to change the optical k-clock hardware. With the all-semiconductor laser, each of these parameters is programmed and can be changed from experiment to experiment and imaging run to imaging run (Fig. 23.33).

The following table outlines the programmable parameters of the all-semiconductor laser (Table 23.3):

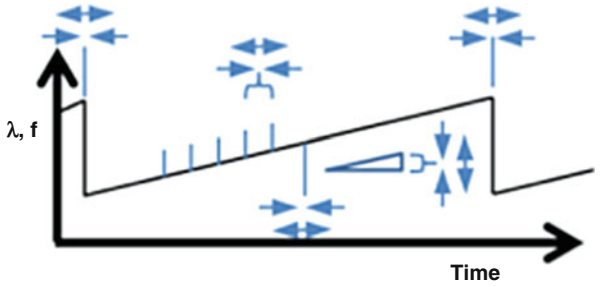

Fig. 23.33 With akinetic all-semiconductor lasers, the number of measurement points, sweep rate, sweep width, center wavelength, coherence length, sweep direction (increasing or decreasing frequency or wavelength), duty cycle, and whether the sweep is linear in frequency or wavelength are all programmable. A command to the laser over Ethernet and the laser uses the new settings for subsequent sweeps

Table 23.3 All-semiconductor, akinetic laser programmable parameters (at time of writing)

Parameter	Typical akinetic all-semiconductor
Programmable duty cycle	Yes: 5–95 %
Programmable sweep width	Yes: 10–140 nm
Programmable number of measurement points	Yes: 1–130,000
Programmable center wavelength	Yes
Programmable coherence length	Yes: 1–40 mm
Programmable sweep power profile	Yes: flat top, Gaussian, user defined
Programmable sweep speed	Yes: 2 k–200 k sweeps per second
Linear sweep parameter	Yes: linear in λ or linear in frequency
Programmable sweep direction	Yes: forward or backward in λ or frequency

Setting sweep parameters is accomplished through Ethernet using simple commands. Changing parameters can be done at any time. It takes a matter of seconds for the change to be fully implemented and the laser ready to run again.

Commands are simple, intuitive strings that control all of the lasers configurable options. As built-in measurement firmware and communications are added to the laser, the data will be available via gigabit Ethernet.

23.3.18 Bidirectional Forward and Backward Sweeps Without PSF Degradation

Probe movement is an issue for some OCT imaging applications and Doppler OCT. Providing interlaced forward and backward linear-in-frequency sweeps facilitates eliminating the effect of probe movement for certain applications.

The sweep linearity of the all-semiconductor laser and the resulting PSF is very nearly the same for forward and backward sweeps.

This was the first of the interlaced sweeps capabilities implemented in the all-semiconductor swept laser (see Sect. 23.3.23 for more discussion).

23.3.19 Imaging at Depth and Multipath Imaging

The coherence length of a swept source defines the maximum depth at which an image can be made (imaging depth range at which the PSF rolls off by 6 dB is one half of the coherence length). More generally, coherence length also sets the limit on the distance difference one can measure over between different arms of an interferometer, which impacts the design of multipath imaging systems and sensors (Fig. 23.34).

23.3.19.1 Imaging at Depth

In a single-path OCT imaging system application, there are a number of factors that can add to the needed coherence length. These are shown in the following equation:

$$\begin{aligned} CL_{\text{Needed}} = 2^{*}\Big(&\text{Depth}_{\text{imaging, desired}} + \Delta L_{\text{sensor-to-tissue movement during imaging}} \\ &+ \Delta L_{\text{sensor-to-sensor varitation}} \\ &+ \Delta L_{\text{sensor-to-tissue distance variation for 2D\&3D beam movement}}\Big) \end{aligned} \tag{23.6}$$

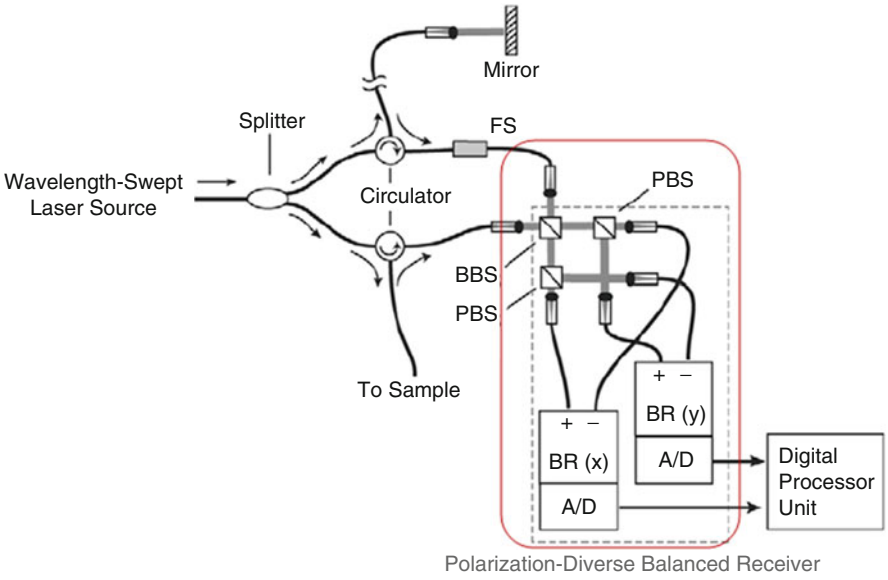

Fig. 23.34 Most existing multipath OCT systems use multiple detectors and data acquisition channels [115]. In some cases, these complications can be avoided by putting the different paths on the same fiber, delayed from one another, using the same detector. This is facilitated by the long coherence length afforded by akinetic lasers

where CL_{Needed} is the needed coherence length; $\text{Depth}_{\text{imaging, desired}}$ is the maximum imaging depth into the tissue; $\Delta L_{\text{sensor-to-tissue movement during imaging}}$ is the amount of movement of the sensor relative to the tissue due to patient movement, or sensor movement; $\Delta L_{\text{sensor-to-sensor varitation}}$ is the variation from one sensor to another, for example, due to fiber length differences; and $\Delta L_{\text{sensor-to-tissue distance - variation for 2D \&3D beam movement}}$ is the variation in the distance from the sensor to the tissue in scanning systems. For example, in endoscopic applications the endoscope is near one side of the esophagus and the light must penetrate the near-side tissue with no distance from the sensor and also penetrate the tissue at the other side of the esophagus 15–20 mm away.

23.3.19.2 Multipath OCT Coherence Requirements

In addition to the coherence requirements above, some approaches to accomplish multipath OCT imaging (i.e., polarization-discriminated OCT) in a single sensor, the effective delay for the multiple paths must be added to the coherence length requirement of the laser. For example, images using two different polarization states can be accomplished by using a polarization beam splitter in the source path and then delaying one of the states before recombining the signals. The measurement can be either polarization discriminating or not; in either case, the FFT is accomplished in the time window associated with each signal. The coherence length must be adequate to accommodate this longer time window, typically slightly over-doubling the coherence length requirement for two simultaneous signals or tripling for three.

Figure 23.43 shows images of a tooth taken at zero path length difference and images taken at 16 mm, 37 mm, and 13 cm (130 mm) path length differences. The similarity of the quality of the images helps illustrate the potential of utilizing the all-semiconductor laser's high coherence length to improve OCT imaging.

23.3.20 Laser Engine Size

- OCT systems can shrink substantially over time.
- Small form factor can enable portable systems.
- Small size can reduce system cost.

The initial size of the akinetic laser was roughly the same size as mechanical lasers [2–7] (Fig. 23.35). The initial development was optimized for performance, not size, leading to approximately 75 % of the volume of the laser package being air.

The first incarnation of the all-semiconductor laser comprised 23 ft^3 of instrumentation and took two lab benches to set up, as shown in Fig. 23.36.

The second incarnation shrank to approximately 7 ft^3. The first commercial unit is 1/8 ft^3. Future reductions in drive electronics and other changes will drive the laser through two major size reductions and lead to a laser about the size of a current smartphone (Fig. 23.37).

Fig. 23.35 Physical form factors for bench use (*left*) and OCT system build-in (*right*)

Fig. 23.36 The first incarnation of the laser comprised 23 ft^3 of space

Fig. 23.37 Laser size is anticipated to drop rapidly, with the laser evolving to be about the size of a smartphone by the end of the decade

23.3.21 Reliability and Ruggedness

Lasers have tended to be higher-mortality elements of an OCT system. Degradation over time of power or PSF leads to degradation in the image quality during the lifetime of an OCT system.

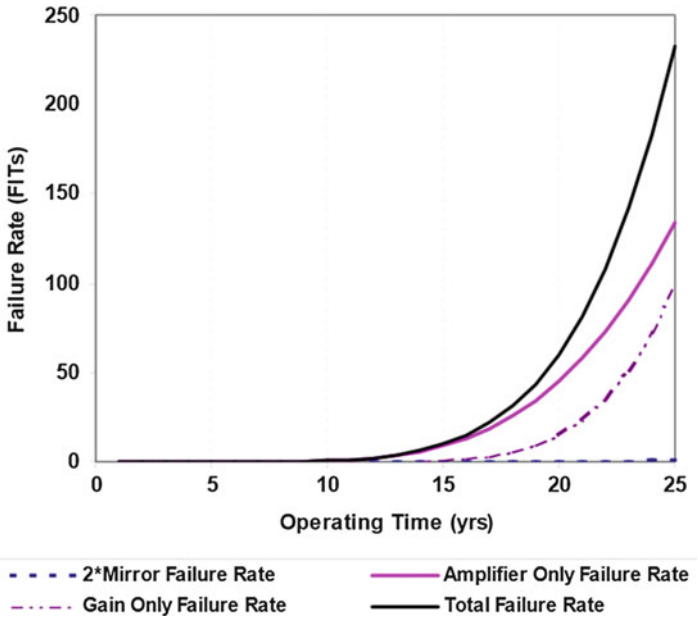

Fig. 23.38 FITs (failures per billion) of the semiconductor are minimal over 10 years and even at 15 years represent less than 20 failures per billion. The laser will likely succumb to a mechanical failure (e.g., connectors) before the laser reaches end of life. The lack of mechanical movement is a major reason for the long mean time to failure (*MTTF*)

The underlying technology that allowed invention of the all-semiconductor laser was originally developed for long-haul telecommunications [116, 117] where components are placed underground or underwater and require reliability over 30 years of operation from −40 °C to +70 °C [118] (Fig. 23.38).

23.3.21.1 Little Power Loss Over Time

Because the entire laser and tuning cavity are all on a single semiconductor chip, the all-semiconductor laser avoids the typical degradation of power over time due to cumulative misalignment losses when many discrete optical components are required [119]. There is a single alignment of fiber to laser within a sealed package, thus minimizing the drop in power over time.

23.3.21.2 Vibration Sensitivity

The same factors that lead to long life and low power loss over time contribute to low vibration sensitivity. The fiber itself is slightly vibration sensitive, but otherwise, the laser is relatively impervious to vibration. This vibration insensitivity applies to both reliability and to performance variation under vibration conditions.

23.3.22 Evolving Capabilities

23.3.22.1 Noncontiguous Sweeps

There have been suggestions that an outsized portion of the information in an OCT sweep is contained in the first and last portions of the sweep. If this concept can be exploited, utilizing the data from only these sections of the sweep may unlock new potential for very fast OCT (Fig. 23.39). Such sweeps can be performance with an akinetic laser without needing to measure faster at lower resolution and reducing the data processing bottlenecks that can exist for high-speed systems.

Since the all-semiconductor laser can produce coherent sweeps in different bands (e.g., 1,310 nm linked to 1,550 nm), implementing noncontinuous sweeps has the potential of creating a wider effective sweep, potentially increasing the resolution.

For a normal OCT sweep,

$$f(t) = f_0 + \frac{df}{dt}\,\Delta t \tag{23.7}$$

However, take two discontinuous segments can be used:

$$f(t) = \begin{cases} f_0 + \dfrac{df}{dt}|_0 \Delta t_0, t_0 < t < t_1 \\ f_1 + \dfrac{df}{dt}|_1 \Delta t_1, t_1 < t < t_n \end{cases} \tag{23.8}$$

23.3.22.2 Custom Wavelength Profiles

It may be that there is some advantage to utilizing a slightly nonlinear sweep to compensate for other system nonidealities. Since the sweep can be created in any increment, predetermined but nonlinear sweeps are possibilities in the future.

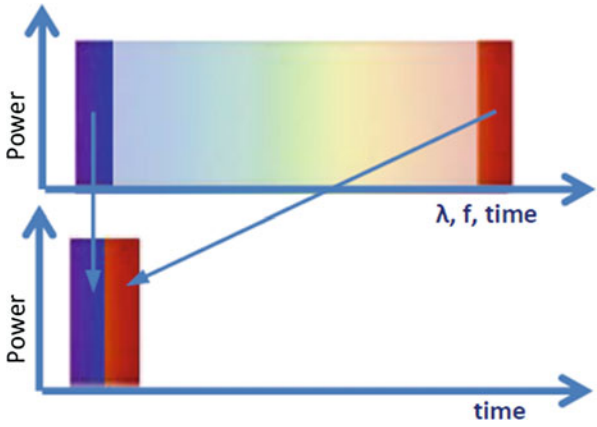

Fig. 23.39 Noncontiguous sweeps may speed imaging and reduce data communication and processing burden with manageable image quality degradation for some applications

23.3.22.3 Simultaneous Multiwavelength Sweeps

Because the all-semiconductor laser generates its own triggers and the wavelength is forced to be accurate at these equally spaced trigger points, the opportunity exists to run simultaneous multiwavelength sweeps. For example, two lasers may be linked to provide simultaneous 1,310 and 1,550 nm band sweeps. Since data from each of these bands provides different and complementary data for the image, combining the results from both bands can give physicians more and better diagnostic information [120–124]. A single fiber optic probe can carry both wavelength bands simultaneously [123, 125], but either time-delay multiplexing or wavelength division multiplexing can be used to separate the bands for data acquisition. In a time-delay multiplexing system, a single detector can be used to acquire both signals. Alternatively, in a wavelength division multiplexing system, dual-channel detection would be used.

23.3.23 Interlaced Sweeps

There is considerable research into new methodologies (Doppler and polarization-sensitive OCT are just two of many) to exploit OCT to derive more information from the tissue [100, 126–128]. The flexibility afforded by a truly software-controlled laser may enable new insights and innovations that were not previously thought possible.

23.3.23.1 Interleaved Coherence Sweeps

There is ongoing research into the potential of using the all-semiconductor laser's ability to interleave sweeps of differing coherence length to achieve advantageous image results, including the potential of speckle reduction and implementation of new analysis techniques.

23.3.23.2 Interlaced Differing Rate Sweeps

Kinetic lasers have limited ability to change sweep rate, while the sweep of the akinetic laser can be changed by the user at any time. In fact, it may be possible to interlace sweeps of differing sweep rates. Sweep repetition rates can be varied by a factor of 20. This capability may facilitate dual high-resolution/high-depth modes with a single laser semi-simultaneously.

23.3.23.3 Interlaced Number of Data Points

The number of data points in a sweep can affect certain characteristics of an image. Because the all-semiconductor laser opens the possibility to running interlaced sweeps with varying numbers of data points, this could help researchers develop ways to reduce more of the nonidealities in an image. With an external k-clock this could be problematic, but it becomes easy with the all-semiconductor laser's internal electronic k-clock.

23.4 OCT Images

Many images were made by various OCT companies over the last 2 years of the akinetic laser's development; however, these images had all been the proprietary property of the companies making the images. This changed in early 2013, when external and independent images were finally made public.

The following images suffer from being made at 1,550 nm and only for 40 nm range, but the resulting image quality from measurements made under these conditions was reasonable nonetheless (Figs. 23.40, 23.41, and 23.42, and 23.43).

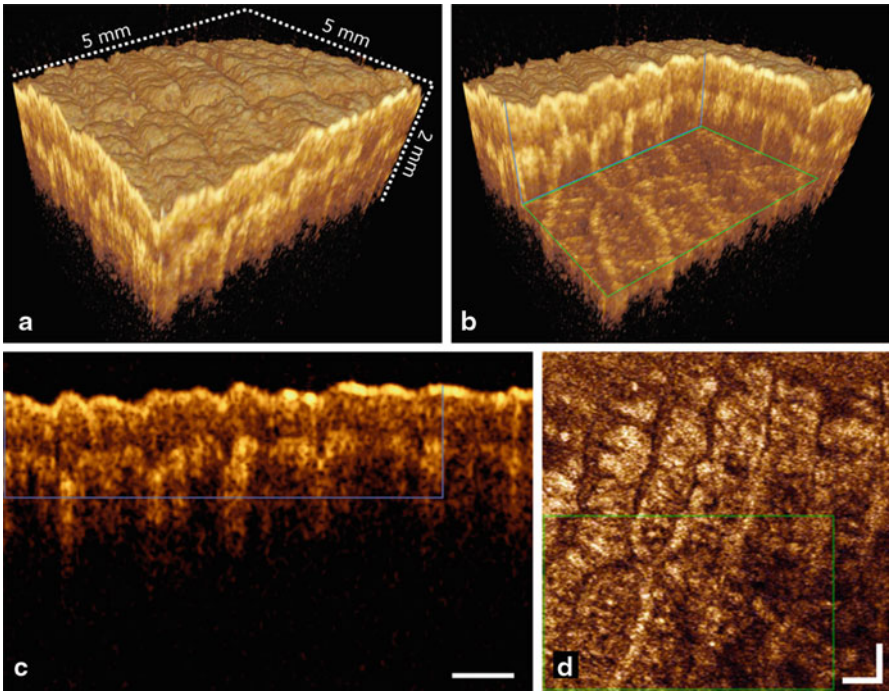

Fig. 23.40 In vivo human skin measurements at 1,550 nm with 20 μm isotropic resolution. (**a**) 3D reconstruction of the data set; (**b**) 3D reconstruction of the dataset with a portion of the data removed to reveal the internal structure of the skin; (**c**) cross-sectional tomography extracted from the 3D dataset, the data enclosed in the overlapped rectangle correspond to equivalent overlapped rectangle (*vertical plane, blue*) in (**b**); and (**d**) en-face view extracted from the 3D dataset, data enclosed in the overlapped rectangle correspond to equivalent overlapped rectangle (*horizontal plane, green*) in (**c**). Acquired volume dimensions were 5 × 5 × 5 mm^3, corresponding to 1,024 × 256 × 180 pixels (width × height × depth). Presented images were cropped along depth (*z*) to report only useful imaging area. *Scale bars* correspond to 0.50 mm (Courtesy Vienna Medical University [114])

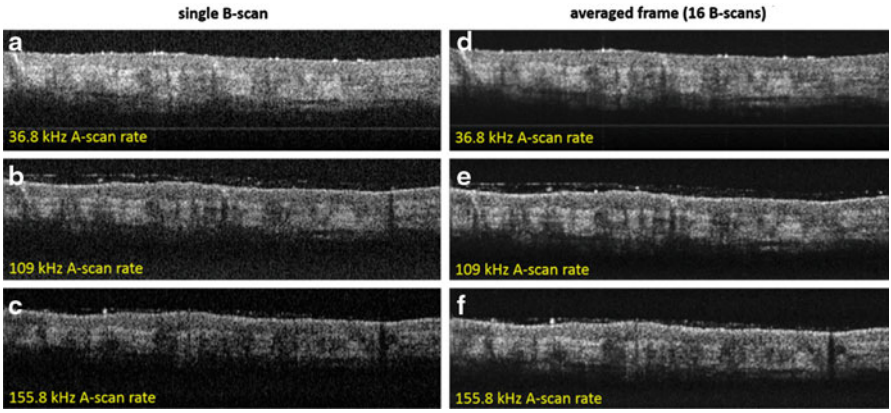

Fig. 23.41 Single-frame and averaged in vivo skin measurements acquired by the same akinetic laser, at different laser sweep rate, under program control. (**a**–**c**) single-frame measurements at 36.8 kHz, 109 kHz, and 155.8 kHz sweep rate, respectively; (**e**–**f**) average of 16 frames (M-scan), sweep rate similar to (**a**–**c**)**,** respectively. During the measurements, the coherence gate was located close to zero delay. Images dynamic range, from a to f, was 25.69, 24.18, 23.91, 35.12, 34.57, and 34.38 dB, respectively. Images area was 5 × 1.7 mm^2, corresponding to 1,024 × 60 pixels (hor. × vert.) (Courtesy Vienna Medical University [114])

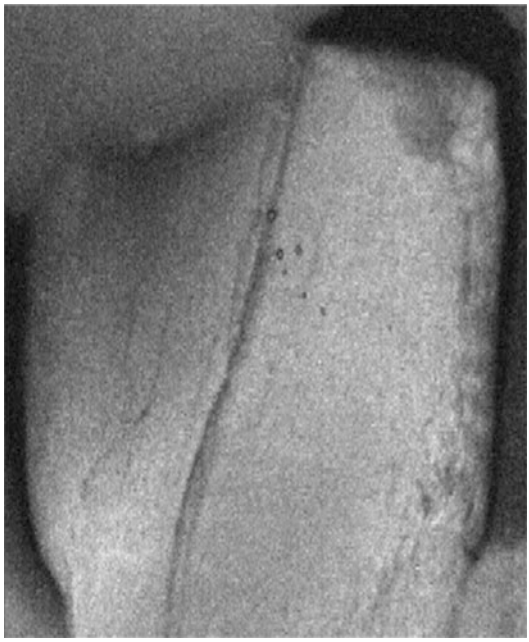

Fig. 23.42 En-face view of a tooth. Size 5 × 6 mm^2 (1,024 h × 256 v) [114]. The same tooth is imaged at different lengths in the subsequent Fig. 23.43

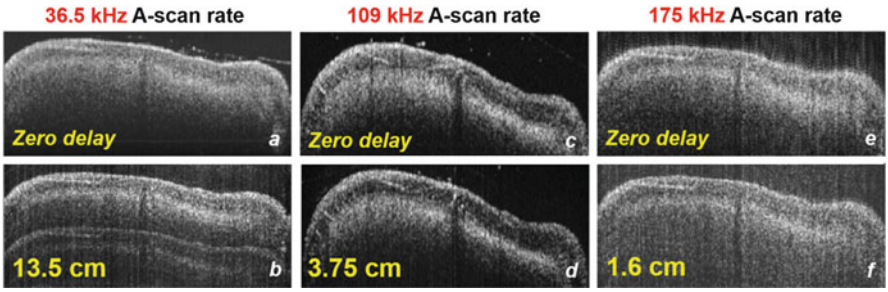

Fig. 23.43 To illustrate deep coherence, images of a tooth (including crack) with zero path length delay and then the same tooth with 16–135 mm of path length delay. Long akinetic laser coherence length may enable new OCT measurement approaches and techniques. Images were generated using 1,550 nm and 40 nm span. Courtesy of Vienna Medical University [114]

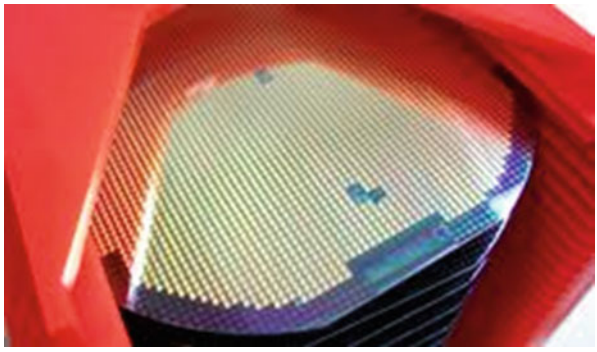

Fig. 23.44 A single wafer contains over 2,500 lasers, which creates a steep cost decline curve with time and volume

23.5 OCT Cost Reduction

Achieving lower cost is critical over time in commercial OCT imaging systems. Typically, the laser is the most expensive part of the OCT system and thus has a big impact on the profitability of OCT system suppliers and on the overall cost of OCT systems and the resulting ability of large markets to gain access to the technology.

Specifically, low pricing can have the following impacts:

- Reduce the development budget.
- Improve margins for OCT system suppliers.
- Allow OCT to penetrate into larger-volume, lower-cost applications.

An all-semiconductor laser can achieve cost advantage because:

- Wafer-scale laser manufacturing assures rapidly declining costs (Fig. 23.44).
- Internal electronics use high-volume telecom parts for continued declines in cost.

The initial cost of the all-semiconductor akinetic laser is near or lower than the cost of other OCT laser solutions. With hundreds of lasers per wafer, the entire laser

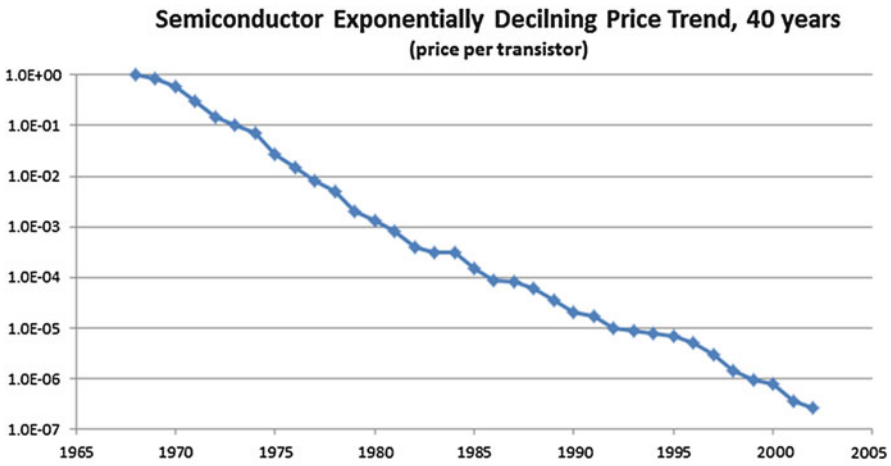

Fig. 23.45 Putting all of a device into semiconductor has been the key to improved performance and order-of-magnitude reductions in cost over time for the last 40 years [27–29]

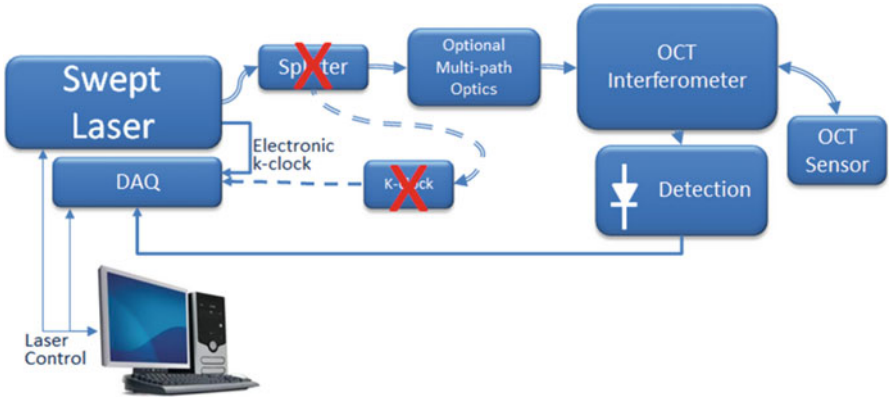

Fig. 23.46 Eliminating a separate k-clock further reduces system cost and assembly complexity

cavity is on the chip. Wafer-scale fabrication results in rapid declines in the cost of such systems [27–29]. The all-semiconductor laser should cost a tenth of existing laser solutions within just a few years (Fig. 23.45).

23.5.1 Reduce System Optics Cost

Because the all-semiconductor laser provides its own electronic k-clock, the system will not need the electronic and optical parts and integration cost of an external optical k-clock (Fig. 23.46).

23.5.2 Integrated High-Speed, High-Resolution Measurement

The all-semiconductor laser has integrated, high-speed, low-noise optical measurements which are used by the laser to ensure that its performance is always optimal. These same measurements can be dual purposed, thus eliminating the need for the additional cost of signal conditioning, analog-to-digital conversion, and related data processing. This can save substantial system cost.

The integrated measurement in the first incarnation of the all-semiconductor laser is 14 bit at 400 MHz, providing intrinsic high-resolution data at high speed, which can result in substantial reductions in overall OCT system cost.

The hardware for the data conversion is already part of the laser. Future versions of these lasers will include the built-in fast communications to transfer the data to the computing system (such as Thunderbolt or USB 3.1).

- Substantially reduce system cost
- Reduce development cost and time
- Reduce system size and complexity
- Provide faster time to market
- Serve as a complete OCT engine; just add the sensor and imaging visualization software
- Improve measurement performance
- Reduce cost of goods, improving margins or reducing price to increase market penetration

23.5.2.1 Dual-Purposed A/D Converter Mean System Cost Savings

The all-semiconductor laser uses high-speed A/D converters internally. The laser can dual-purpose those converters, giving access to data acquisition without much added cost. By adding high-speed 1 GB or 10 GB Ethernet communications and linkage through the built-in digital signal processor (DSP), the laser engine now provides both sourcing and measurement, at an overall system cost savings.

23.5.2.2 One, Two, or Three Converters

A single converter may be all that is necessary for traditional OCT. In multipath OCT applications, such as polarization-sensitive or multiangle or multifocal length, more than one converter can be advantageous (note that for some of these applications, when used with the all-semiconductor laser high coherence length, delay paths may be used to put the signals on a single fiber without the need for multiple converters).

23.5.2.3 14-Bit, 400 MHz High-Resolution Conversion

The quality optical signal and resulting PSF on akinetic lasers can then allow the effective use of higher resolution detection. This higher resolution can provide better image quality, SNR, and conversion at up to 400 MHz (at the time of this writing).

23.5.2.4 On-Board Signal Processing

Since the implementation of an all-semiconductor sweep laser already includes a high-performance field programmable gate array (FPGA), all of the core signal processing (including the FFT and windowing) can be accomplished inside the laser engine, if desired, with little additional cost.

23.6 Akinetic All-semiconductor Technology

23.6.1 Basic Tunable Laser Technology

Light in a tunable laser meets the following condition [129]:

$$m\frac{\lambda}{2} = \overline{n}L \tag{23.9}$$

where m is the mode number, λ is the wavelength, $\overline{n}$ is the effective index of refraction, and L is the effective cavity length.

Cavity-based lasers tune in relative wavelength λ by following the following conditions [129]:

$$\frac{\Delta\lambda}{\lambda} = \frac{\Delta\overline{n}}{n} + \frac{\Delta L}{L} - \frac{\Delta m}{m} \tag{23.10}$$

where $\frac{\Delta\overline{n}}{n}$ is tuned by the net cavity index change, $\frac{\Delta L}{L}$ is tuned by physical length change, and $\frac{\Delta m}{m}$ is tuned by mode selection filter (via index or grating angle).

23.6.2 All-Semiconductor Tuning Technology

The idea for an all-semiconductor tunable laser was first commercialized in the 1990s and 2000s, and over $100 M was spent developing the technology and making the technology manufacturable and reliable for demanding telecom applications. Today, hundreds of thousands of lasers based on this technology are shipped per year and are a mainstay of telecommunications systems worldwide.

The all-semiconductor laser is tuned through changes in the index of refraction of the semiconductor material, which is effected through carrier injection (via current applied to the segment of the semiconductor).

There are five tuning elements in the all-semiconductor swept laser (Fig. 23.47). Tuning occurs when current is applied to a segment of the laser. This current increases the carrier density in a specific region of the device thereby changing the index of refraction of the material. The change in the refractive index changes the effective path length of that specific segment of

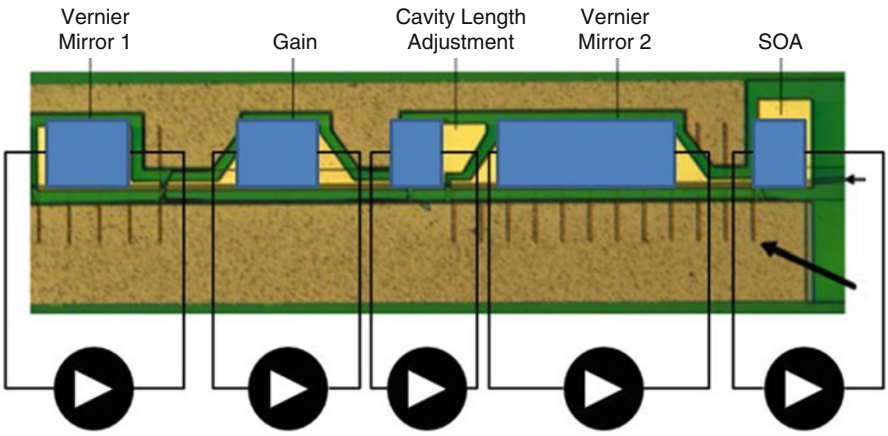

Fig. 23.47 Tuning is effected through changes to the index of refraction of the semiconductor material through carrier injection. This is a cross section of an akinetic all-semiconductor swept wavelength laser design. Each of the five sections of the laser diode is driven by a current source to control the power and wavelength of the laser. The gain section provides the amplification. The Vernier mirror 1 and Vernier mirror 2 provide wavelength-dependent feedback to select the lasing wavelength. The cavity length adjustment allows for small effective changes in the effective path length between the Vernier mirrors for fine wavelength adjustment and single-mode operation. The currents in the Vernier mirrors and cavity length adjustment sections can be coordinated in real time to create an electronically tuned swept wavelength laser. The semiconductor optical amplifier (SOA) boosts the output power of the laser

the laser, permitting precise adjustment of the cavity without moving any of its components.

Two of the tunable segments of the laser are mirror sections (the Vernier mirrors 1 and 2). By applying current and changing the index of the material, the effective mirror spacing is changed. Employing the Vernier-tuning effect, these two mirrors can be used in combination to select any wavelength across the tuning band.

The index change in the semiconductor material is [130]

$$\Delta\eta(N,P,E) = \frac{2ch}{e^2}\, P \int_0^{\infty} \frac{\Delta\alpha(N,P,E')}{E'^2 - E^2}\, dE' \tag{23.11}$$

where c is the speed of light, e is the electron charge, $E = h\omega$ is the photon energy, $\alpha = 4\pi k/\lambda$, and P indicates the principal value of the integral.

The phase section of the all-semiconductor laser is very similar to the mirror sections in that the index changes with the applied current, but instead of tuning a mirror, it is used to fine-tune the overall cavity length. This section is then adjusted in real time as the laser sweeps to ensure that at every point in the sweep, there is no chance of a mode hop.

For many reasons, it is important for the laser to be mode-hop free. Mode hops, or almost instantaneous jumps in wavelength, are a substantial obstacle in obtaining

quality images. In addition, the side-mode suppression is reduced near mode hops, also resulting in a reduction in image quality. In the Vernier-tuned distributed Bragg reflector (VT-DBR) laser, mode hops are avoided by rapidly adjusting the cavity length as the wavelength changes.

In the years since the all-semiconductor laser technology was developed, many groups and individuals around the world have tried to get the laser to sweep linearly over time. Some very capable people have made admirable progress, but none were able to get the laser to rapidly sweep linearly over both time and temperature to the extent required for OCT imaging applications. The first all-semiconductor lasers were built on their efforts.

The key obstacle to linear sweeping is the five different current-driven segments to the laser, each of which has an impact on the wavelength of the laser output. In addition, the temperature of the laser changes the wavelength substantially, and the laser inherently drifts slightly over time. In addition, there are rise and fall times of the signals and slightly differing path lengths for each segment. Compounding this situation, each of the currents has a direct impact on the wavelength through carrier concentration, but there is also an indirect affect on wavelength due to a slight temperature change in the segment. Further complicating this, when the temperature of one segment changes, it will also (with a time constant) change the adjacent segment and then (with a different time constant) change the next adjacent segment, and so on. Every change made to the system also has an effect on all the other variables with differing time constants, and these changes even change the relationship between the other control variables and the wavelength. This represents an imposing problem, indeed.

The first commercial all-semiconductor akinetic laser was developed by Insight Photonic Solutions of Boulder, Colorado, USA [25, 26]. They had spent over 6 years, millions of dollars and utilized the talents of over 35 development scientists and engineers and 20+ top industry technical advisors (including 15 professors and a Nobel Lauriat) to overcome these obstacles. The company claims many patents and patents pending.

23.6.3 Sweeping Tuning Paths

The sweep of the akinetic tunable is designed specifically for use in OCT systems and correlates sweep parameters to accommodate existing data acquisition systems. This includes trigger, clocking, settling times, signal propagation, linearity, and power requirements.

The nature of the VT-DBR laser utilized in swept sources is shown in simplified form in Fig. 23.48.

Tuning consists of the long linear drive current combinations that progress along path 1, then doing the same with path 2, path 3, and so on. The transitions from path to path take single digit nanoseconds.

The laser causes the wavelength at each evenly spaced time as defined by the electronic k-clock output to be correct, providing for linearity.

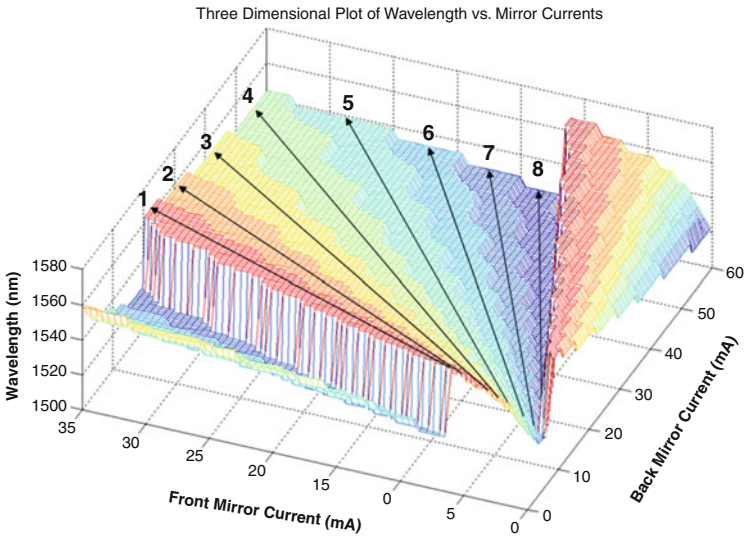

Fig. 23.48 All tuning is handled by the laser control circuitry; initiating a sweep just requires setting a hardware bit or sending a command to initiate the sweep

In the short times between these paths, the laser continues to output exactly evenly spaced-in-time trigger(s) to the data acquisition. After a predefined number of these "hold points," the laser will be back to the next evenly spaced in-frequency point to continue the sweep. The held points are simply removed in software (the laser can be queried for a vector of these hold points) or using a hardware signal ("data valid") which can be sent to the secondary channel of the data acquisition. One data acquisition company has already added this akinetic laser function to their onboard FPGA, eliminating the need for any user programming. Performing this process in software is very fast, as it is a vector function, and LabVIEW VIs are available to make software integration simple.

23.7 Limits of Akinetic All-Semiconductor Technology

Speed. As mentioned previously, maximum laser sweep repetition rate for existing semiconductor lasers and packaging is near 1 M sweeps per second (sps). With reconfigured lasers and packaging, 2 M sps should be attainable. This, though, is likely an upper limit based on today's technology.

Coherence Length. The nonactive coherence length of the all-semiconductor laser is in the 10s of meters. This is substantially higher coherence than the ~200 mm of currently available all-semiconductor lasers. While the nonactive limit may be difficult to achieve, improvement to the existing lasers is likely. In addition, new all-semiconductor topologies promise at least an order-of-magnitude improvement.

Wavelength, Wavelength Range. The materials and processes exist to produce all-semiconductor lasers at 850 nm, 1,060 nm, 1,310 nm, 1,550 nm, and perhaps up to 1,700 nm. Below these wavelengths it is not clear that the processes exist to produce tunable lasers, although frequency multiplication could support lasers in lower wavelength bands. It is believed that the wavelength range of an all-semiconductor system can be extended to roughly 140 nm. While it is possible to extend the range beyond this, cost could become a limiting factor. If the bifurcated wavelength band approach works, the effective range could be further extended. Each new wavelength band requires a semiconductor development, unlike other technologies that can use generally available gain chips. Once developed, chips are very inexpensive and the drive electronics are identical to that of other wavelength bands.

Cost. It seems reasonable to anticipate that the cost of all-semiconductor lasers will trend towards $1,000–2,000 over the next several years. It is not clear that pricing can drop below these levels, but these costs represent a substantial reduction from previous levels.

23.8 Conclusions

The akinetic all-semiconductor technology presents certain unique benefits for optical coherence tomography applications. These capabilities include the ability to perform uniform, linear sweeps while maintaining low RIN, a high SMSR, and sufficient coherence length to permit deep imaging depth range. Due to the novel all-semiconductor design of the akinetic swept laser, these features come without additional cost when compared to traditional mechanical lasers. While the technology is still young (as is OCT in general), akinetic lasers may be able to both respond to the OCT industry's growth and contribute to that growth.

Robert Huber

24.1 Introduction

24.1.1 History of Tunable Lasers and the OCT Challenge

Widely wavelength tunable lasers, i.e., laser where the emission wavelength can be changed in a desired, predefined way by several percent, have been known since the 1960s. For a long time, dye lasers have been the light sources of choice for applications that required wavelength tunable lasers [1, 2]. Later also bulk optics solid state systems, like cw-Ti:sapphire lasers [3, 4] or external cavity semiconductor lasers [5–7], became popular. Depending on their application, tunable lasers are often termed (a) *wavelength agile lasers*, in cases where the application demands fast changes in wavelength to arbitrary positions, (b) *tunable lasers* in cases where the laser is slowly tuned to a wavelength and is stabilized there for a longer time, and (c) *wavelength-swept lasers* in cases where an optical waveform is required that continuously changes wavelength.

In almost all SS-OCT/OFDI applications, ***wavelength-swept lasers*** are required. The wavelength ranges are centered around 800 nm [8, 9] or 1,050 nm [10, 11, 12] for retinal imaging and 1,300 nm [13, 14] or 1,550 nm [15] for highly scattering samples. The most important performance specifications required for OCT significantly differ from the ones typically needed in other tunable laser applications. Today a typical "100^3 performance" of an SS-OCT laser is (a) a wavelength sweep range of $\sim$100 nm, (b) a wavelength sweep repetition rate of $\sim$100 kHz, and (c) an instantaneous linewidth of $\sim$100 pm. The wavelength sweep range determines the axial resolution in OCT, and wider sweep operation results in better axial resolution. The sweep repetition rate directly translates to the OCT A-scan rate of

DOI 10.1007/978-3-319-06419-2_25

the system. The instantaneous linewidth determines the inherent additional system's signal decay over ranging depth often called "sensitivity roll off." Whereas a linewidth below 100 pm has easily been achieved by tunable lasers long before their application to OCT, the combination of the required wide sweep range and fast sweep repetition rate was not available before the year 2000. A sweep operation of 100 nm at a center wavelength of 1 μm corresponds to 10 % relative wavelength tuning, about 30 THz optical frequency. Taking a 100 kHz sweep repetition rate, this is a frequency tuning speed of 3 THz/μs or 3e18 Hz/s.

24.1.2 The Limit of Standard Tunable Lasers: Cavity Buildup Dynamics

A standard tunable laser consists, like all lasers, of (a) a laser gain medium, which can simply be seen as light amplifier which increases the electric field of the incoming light, and (b) a resonator, i.e., the laser cavity, which feeds light from the output of the amplifier back to the input [14]. Resonators are, for example, two mirrors bouncing light forward and backward in a linear geometry or a piece of optical fiber guiding the amplifier output light back to the input. At some point in the resonator, a part of the light is extracted as the laser's output.

To make the laser tunable in wavelength, an additional filter element in the resonator acting as tunable optical bandpass is inserted. This filter transmits only a very narrow wavelength range, in OCT applications typically about 0.1 nm, thereby forcing the laser to operate at wavelengths within this passband (i.e., the transmission window) of the filter. This operation is sketched in Fig. 24.1 [14]. Now to operate a tunable laser as a wavelength-swept light source, the optical bandpass filter is controlled in a way such that it dynamically changes its passband, i.e., the transmitting wavelength window. Such a dynamic tuning causes the laser to operate in a nonstationary regime. This is depicted in Fig. 24.2 [14]. The figure shows the intensity over wavelength. The blue curve is the transmission window of the optical bandpass filter. Within this window, typically several so-called laser modes are active (here: ten red peaks under the blue filter curve). These laser modes are the only "allowed" discrete frequencies set by the laser resonator condition $f_n = n^* c/l$.

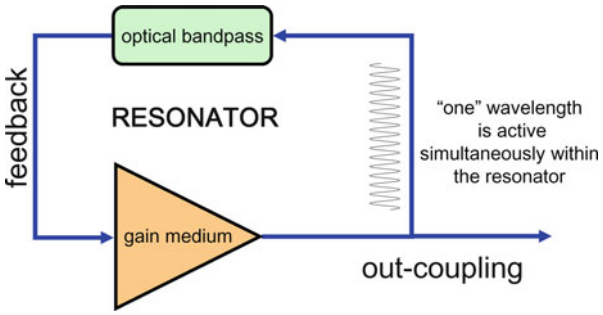

Fig. 24.1 Circuit diagram of a standard tunable laser/swept laser [14, 27]. A laser resonator/oscillator is an optical feedback loop. Inserting a tunable optical bandpass filter enables wavelength tuning [14]

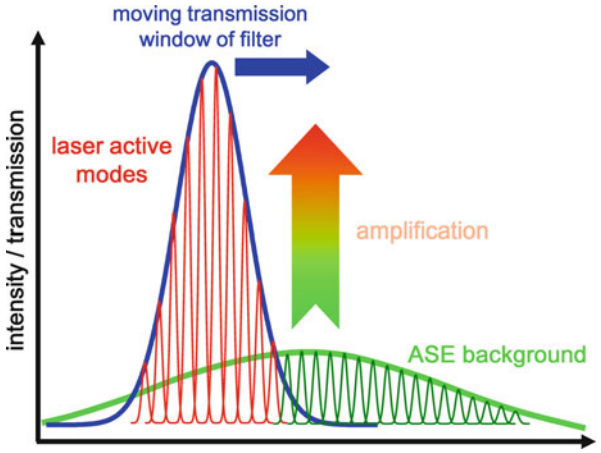

Fig. 24.2 Tunable laser buildup dynamics [14, 27]. The diagram shows the tuning operation of a standard wavelength-swept laser. As the transmission window of the optical bandpass filter (*blue line*) is moved in wavelength, the laser light field (*red lines*, laser modes) has to build up from amplified spontaneous emission (fluorescence) background (*green*). If the filter is tuned too fast, there is not enough time to build up saturated lasing – this effect limits the maximum achievable tuning speed

Where f_n is the *n*th optical frequency, *c* is the speed of light and *l* is the effective optical roundtrip length. Since these laser modes are circulating in the laser cavity and their light is amplified once per roundtrip, they have the highest intensity. The dynamic shift of the filter, indicated by the blue arrow in Fig. 24.2, will lead to increased loss of the active laser light, once the transmission maximum has substantially moved away from the spectral position. At the filter's new wavelength position, where initially there is no strong laser light, the intensity will slowly build up from amplified spontaneous emission (ASE) background by many amplification events in the laser gain medium. ASE is fluorescence that is amplified in the laser gain medium. Since the ASE intensity is typically many orders of magnitude smaller than the laser light intensity, several roundtrips of light in the laser cavity are required to achieve sufficient power. With the fact that light is amplified once per resonator roundtrip, it becomes clear that for fast tuning operation, a short resonator, which provides many roundtrips per second, in combination with a high amplification factor in the gain medium, so that a small number of amplification events are sufficient, is required.

Typical numbers of short cavity lasers are resonator roundtrip lengths of about 0.3 m, yielding ~1 GHz roundtrip frequency and an amplification factor in the gain medium of about a factor of 1,000×. If such a laser should be swept over a 100 nm wavelength range with 100 kHz sweep repetition rate (10 µs sweep repetition time) and a 0.1 nm wide spectral filter is used for tuning, light is only transmitted through the filter for about 0.1 nm/100 nm*10 µs = 10 ns. So light in a 1 GHz (0.3 m length) laser resonator can only perform ~10 roundtrips until it is blocked again. In this

configuration 1000 kHz sweep rate would be the absolute maximum frequency of the laser, since for faster tuning, light wouldn't even be able to finish a single roundtrip before the filter blocks the wavelength again. Strategies to further shorten the laser resonator lead to the problem that the resonator mode spacing, i.e., the optical frequency spacing of the "allowed" laser modes, spreads more and more, leading to a more stepwise, very coarse, and discrete frequency tuning characteristic [16]. The laser jumps from one mode to the next. For OCT application this is a major problem, because the maximum ranging depth of the OCT setup is directly linked to the spectral sampling density. When using classical tunable lasers for SS-OCT, the maximum imaging range cannot be longer than the laser's optical roundtrip length.

Recently, strategies have been demonstrated to solve the problem of the increasing spectral spread (coarse mode hopping operation) of laser modes when reducing the cavity length. One approach, followed in the "akinetic OCT laser source" [17], is to insert an additional active element, a "phase section," which allows to adjust the resonator length such that an "allowed" resonator frequency shifts synchronously with the laser tuning operation. The active synchronization requires complex electronic driving signals and repetitive resetting, blocking the source for ~10 ns every 1 nm tuning.

Another approach to solve the problem of the increasing spectral spread of laser modes when reducing the cavity length is vertical-external-cavity surface-emitting laser (VECSEL) or often just called vertical-cavity surface-emitting laser (VCSEL) [18–25] (▶ Chap. 22, "VCSEL Swept Light Sources", Jayaraman). In these lasers, the laser cavity acts as Fabry-Perot filter with a very wide free spectral range (optical frequency spacing between two laser modes) with the effect that the laser resonator modes are automatically always synchronously tuned to the laser sweep operation. Additionally, light in the laser resonator is Doppler shifted each time it is reflected from the moving laser end mirror; this solves the problem of the repeated buildup of laser light from ASE. The Doppler shift has always the right amount to match and synchronize to the tuning operation. A more detailed description of the intracavity Doppler shift and calculations is given by A. Siegman in the book *Lasers* [26].

24.2 Fourier Domain Mode Locking (FDML)

24.2.1 The Concept

The technique of Fourier domain mode locking (FDML) is one way to overcome the physical limitation of cavity buildup dynamics. The idea behind it is to synchronize the optical roundtrip time of light circulating in the laser cavity with the filter sweep operation period of the optical bandpass [14, 27, 28]. This means one tuning period of the laser takes exactly as long as the light needs to propagate through the laser cavity. In other words, light with a certain wavelength is transmitted through the optical bandpass filter and then propagates through a very long laser cavity, realized by an optical delay line. Meanwhile the optical bandpass filter

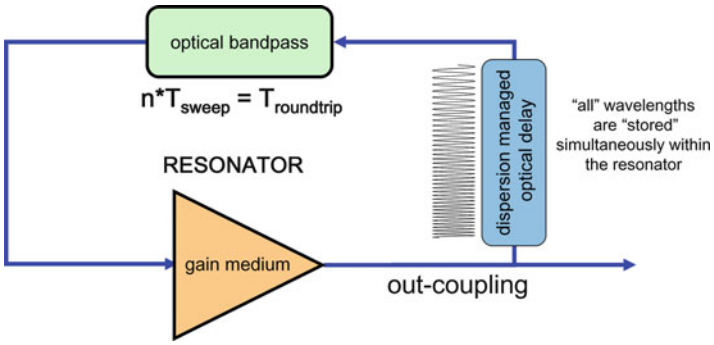

Fig. 24.3 Circuit diagram of an FDML laser [27]. An FDML laser consists of the same elements as a standard tunable laser plus an additional optical delay line (usually a km long fiber spool) to generate the long roundtrip times

is swept over one entire cycle, covering all desired wavelengths, and just when the light arrives back at the filter, the filter transmits this wavelength again, but now already for the next wavelength sweep. This means light does not have to build up from ASE background; it is still there from the last wavelength sweep. In other words, the entire wavelength sweep is optically stored inside the laser cavity. The setup of an FDML laser is identical to a regular swept laser, besides an additional very long optical delay line. Since sweep repetition rates of $f_{sweep} = \sim 100$ kHz require optical path length of $\Delta L = c/f_{sweep} = c/100{,}000\ \text{Hz} = 3$ km, usually a spool of optical single mode fiber is used. To make all wavelength components circulate at the same frequency, the chromatic dispersion of the fiber delay lines has to be compensated. The better the compensation, the higher the number of effective roundtrips of the photons inside the laser and the better the performance of the swept source [29, 30] (Fig. 24.3).

The synchronization condition of FDML operation leads to the effect that the light of a certain wavelength sees the spectral optical bandpass filter always in the same position (see Fig. 24.4, right), whereas in a standard tunable laser, light always is transmitted through a slightly changing filter (see Fig. 24.4, left). The fact the periodic operation makes the filter look "non-tuned" for the light results in a stationary operation of the FDML laser (see Fig. 24.4, right) [36].

24.2.2 Advantages of FDML

The system design and the fact that FDML is a stationary laser operating mode yield many advantages which dramatically improve the performance of the swept laser and, consequently, the OCT system specifications:

1. The high number of effective roundtrips leads to the effect of repetitive spectral filtering (mode competition) making the spectral linewidth of FDML laser much narrower than the one of standard tunable lasers with the same filter

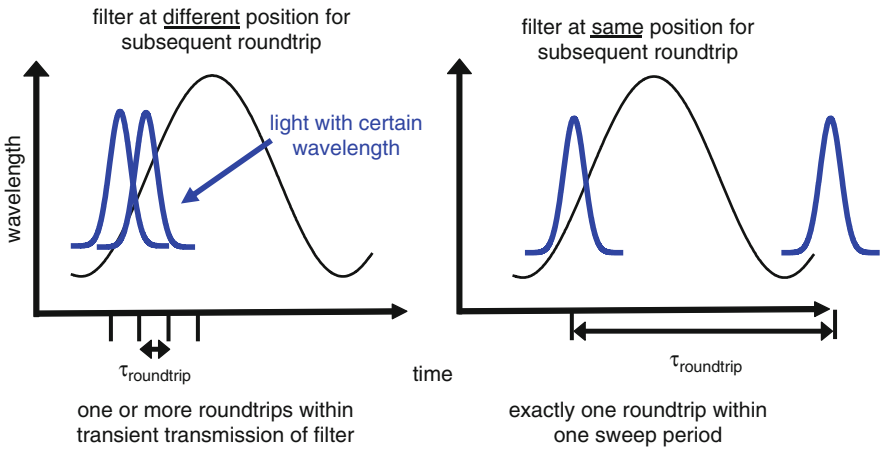

Fig. 24.4 Quasi-stationary filter in FDML operation. *Left*: Nonstationary operation of a standard tunable laser with a sinusoidally driven filter (*black line*). As light of a certain wavelength arrives at the filter after one roundtrip, the filter has changed its spectral position (*black line*). *Right*: In case of FDML the optical roundtrip time is increased so much that when light of a certain wavelength arrives back at the filter after one roundtrip, the periodically driven filter is at exactly the same position (but at the next cycle). This makes FDML a real stationary operation mode

width [27, 29–33]. The narrower linewidth improves the roll-off performance in OCT applications, resulting in a longer ranging depth [29, 30, 34, 35].

2. The fact that the laser light is seeded from the last roundtrip and that FDML is a real stationary laser operating regime reduces the relative intensity noise (RIN) of the laser [29, 32, 33, 36–38], which makes it much easier to design a high-speed OCT system that achieves shot noise-limited sensitivity [39].
3. The good saturation of the laser gain medium enables very high output powers of 100 mW and more, which improves the noise sensitivity in OCT applications where high-power incident on the sample is tolerable [40–43].
4. The separation of laser gain medium and filter element in FDML enables much more flexible system designs compared to VCSEL sources and standard tunable lasers. In both latter cases, the gain medium has to be very short, so typically only semiconductor media can be used. In FDML, almost all groups of laser gain media can be used with length up to meters, such as rare earth-doped fiber amplifiers, nonlinear Raman amplifiers, etc. [44–51]. This enables a much more flexible design of the target wavelengths; improves, as already mentioned, the achievable output power by orders of magnitude; and can dramatically reduce ASE background noise.
5. The high sweep to sweep reproducibility of FDML lasers with respect to their wavelength tuning operation renders hardware clocking in the OCT system unnecessary and reduces system cost [35, 43, 113].
6. Especially at 1,300 and 1,550 nm, FDML lasers are entirely built of standard telecom components [15, 27], which leads to very long lifetimes and high reliability.

24.2.3 The Name FDML and Other Lasers with Resonant Frequency Modulation

24.2.3.1 FDML Compared to Continuous Wave (CW) Lasers and Standard Mode-Locked Lasers

From a viewpoint of physics, FDML lasers are very different from other tunable lasers, because in FDML, the light field of the entire wavelength sweep is optically stored inside the laser resonator. So effectively, a wide range of laser modes is simultaneously active. In comparison, standard wavelength-swept lasers have only one or very few wavelength modes simultaneously active inside the resonator. The situation is sketched in Fig. 24.5. On the left and in the center, the two classical stationary laser operating regimes are shown. On the top is the emitted electric field and on the bottom the corresponding spectrum, which is essentially the squared amplitude of the Fourier transform of the field. A standard narrowband cw laser ideally has a harmonic wave output (Fig. 24.5, left top); the spectrum is a narrow peak (Fig. 24.5, left bottom). A classical mode-locked laser [52], like a femtosecond titanium sapphire laser, has an electric field output representing a train of short pulses (Fig. 24.5, center top), and the corresponding spectrum has a comblike structure with a wide spectral range (Fig. 24.5, center bottom). If this frequency comb is stabilized and the absolute position of each individual comb line is known, a wealth of applications in metrology and sensing can be realized [53]. An FDML laser has an almost constant output power (Fig. 24.5, top right) as the cw laser has;

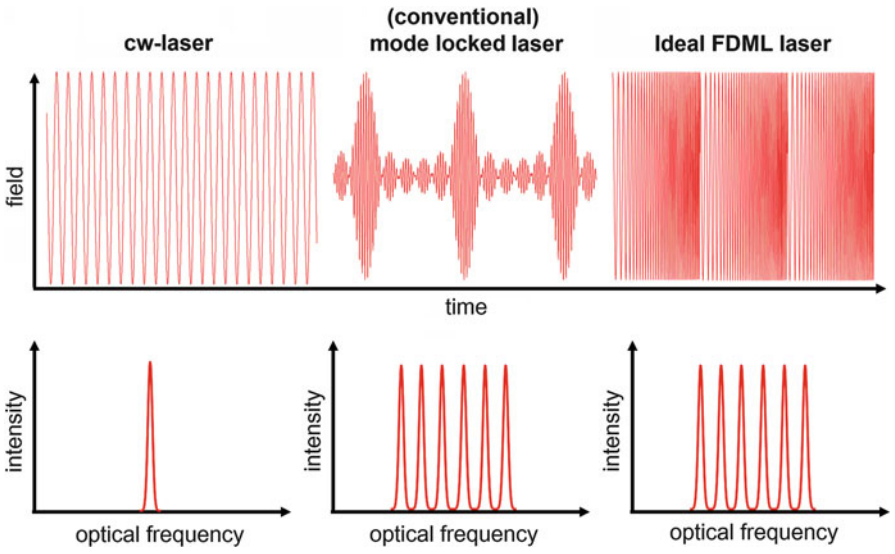

Fig. 24.5 The three stationary laser operating regimes. Electric fields (*top*) and spectra (*bottom*) of (*left*) a narrowband continuous wave (*cw*) laser, (*center*) a standard mode-locked laser, and (*right*) an FDML laser

Table 24.1 Comparison between standard mode locking [52] and FDML [27]. A comparison of the different elements in a standard mode-locked laser and an FDML laser shows that both operating regimes are complementary

	Standard mode locking	FDML
Modulation frequency	Synchronous to roundtrip time	Synchronous to roundtrip time
nature of modulation	Phase/amplitude	Spectrum
	Time domain	*Fourier domain*
Output	Short pulse	Long pulse (sweep)
	Minimum chirp	Maximum chirp
Instantaneous	Broad	Narrow
Phase relation	Fixed (*locked*) phase relation between modes and pulses	Fixed (*locked*), but different, phase relation between modes and pulses

however the output spectrum is broad and has, in the ideal case, a comblike structure. This can be understood, since the FDML wavelength sweep can be considered as highly chirped pulse [54].

Remark: It should be noted that the FDML output is in principle identical to the one of a so-called FM laser; however the experimental setup of both lasers is very different – the FM lasers [55] use ***NO*** filter and the intracavity element, which is a phase modulator, is driven ***OFF*** resonance.

The difference between the standard mode-locked laser and the FDML laser is that the phase of the individual modes with respect to each other is different. It should be noted at this point that currently it seems very difficult to measure the absolute position of the FDML comb line, so it cannot be expected that FDML lasers can be used for the same metrology and sensing applications like standard mode-locked lasers. However, the emission of an FDML laser spans 100 nm or more, proving that many individual modes are simultaneously active.

24.2.3.2 The Name "Fourier Domain Mode Locking"

Table 24.1 shows a comparison of FDML [27] to standard mode-locked lasers [52] which usually generate a train of ultrashort laser pulses. In standard mode-locked lasers, an active (e.g., an acousto-optic modulator) or a passive (e.g., transient Kerr lens, saturable absorber) amplitude or phase modulator modulates the intracavity light field synchronously to the optical roundtrip time. It acts like a shutter which transmits light only over a very short period of time, and only a short electromagnetic wave packet that arrives always at the modulator when the modulator has high transmission or low absorption can continuously circulate in the laser cavity. A time gate or a "time window" is applied. The output is a short pulse with minimum chirp. In FDML a "wavelength window" is applied, also synchronous to the roundtrip time, so it acts in the "Fourier domain" – actually the term "frequency domain" would be more accurate. The FDML output is, as described, a wavelength sweep, which is equivalent to an extremely chirped pulse. This equivalence has been shown by compressing the FDML sweep time [54]. The instantaneous spectrum of a standard mode-locked laser is wide, given by the time

bandwidth limit – in an FDML laser, the instantaneous spectrum is narrow. Because both types of laser emit a train of light fields where each pulse or sweep is a copy of the previous one, there is a more or less pronounced phase relation between the pulses or sweeps. So overall FDML has the same synchronization condition as standard mode-locked lasers; however the modulator does not operate in the time domain but in the Fourier (frequenc<) domain, physical quantities that are short in standard mode locking are long in FDML, and quantities that are wide in standard mode locking are narrow in FDML, so in most parameters the FDML characteristic resembles the Fourier transform of a standard mode-locked laser. FDML is complementary to standard mode locking "linked by Fourier transform."

24.2.3.3 Are the Modes in FDML Laser Locked?

The term mode locking in lasers is used, if there is a certain phase relation between the different cavity modes of the laser. For example, if thermal light or light from an amplified spontaneous emission (ASE) source is transmitted through a comb filter, like a Fabry-Perot, the output has also a comblike structure with multiple peaks, but with no phase relation between the different modes. If the spectrum of the light would be measured at a certain time, it would always contain all wavelength components. To generate a situation like in FDML, where at one certain point in time, only a very narrow range of wavelength can be measured, a phase relation between the different modes is required that generates destructive interference between all components, except the narrow range that is active at one moment in time. So already the fact that FDML lasers emit wavelength-swept light proves a certain phase relation between the different wavelength components.

A similar argument is analog to standard mode-locked lasers. In standard mode locking, the amplitude modulator, a type of "shutter," is operated ideally with a very short duty cycle of, e.g., 1 %. So 99 % of light with an arbitrary phase is absorbed when coupled into the modulator. Now if the modulator is used in a mode-locked laser, where it is driven synchronously to the optical roundtrip time, the cavity modes develop a phase relation amongst each other and almost 100 % of the circulating light field is transmitted. The same is true for typical FDML lasers. The optical bandpass filter has a typical transmission window of about 0,1 nm, and the emission is about 100 nm. If ASE light is coupled into the filter, 99.9 % is back reflected. In FDML operation, we observe at maximum only about ~10 % back reflection, because at each point in time, only modes within the transient spectral filter window interfere constructively.

So already the fact that the FDML laser emits wavelength sweeps and that the intracavity bandpass filter dissipates by orders of magnitude less light than its spectral fill factor proves that there is a certain phase relation between the different modes.

So there is a phase relation between the FDML cavity modes; however, how good this phase relation is, meaning how large the phase jitter between these modes is, is currently investigated. Theoretical models and numerical simulations provide access to the electric field [32, 33, 36–38]. Direct linewidth measurements in

comparison with the theoretical results prove the model of FDML as a stationary operation, because the theoretical models show that FDML lasers continue to operate even without ASE noise. Initially there was a problem numerically simulating FDML operation, because of the wide wavelength sweep range of about 20 THz and the close mode spacing of about 100 kHz which would require an enormous number of simulation points. However, the introduction of a simulation strategy using a sliding reference frame reduced the number of simulation points and enabled successful numerical models describing FDML [32, 33, 36–38].

Very recently, the successfully compression of light from an FDML laser also give access to the internal phase conditions [54]. Simulations with a complementary approach supported by experiments indicate that mainly dispersion in the FDML laser cavity deteriorates the phase relations, i.e., the "mode locking" [56].

24.2.3.4 Other Lasers with Frequency or Phase Modulation

There are other types of lasers that modulate the phase and frequency of the light field inside the laser cavity which are often confused with FDML. However, these lasers are technically very different to FDML. To avoid this confusion, the reader finds some explanations about these different technologies in the following.

FM Mode Locking

FM mode locking [57] is often confused with FDML because of the similar acronym. FM mode locking has been known since the 1970s, and it is used to generate short laser pulses, not wavelength sweeps. FM mode-locked lasers have a phase modulator and not an optical bandpass filter inside their cavity. The phase modulator is driven synchronously to the optical roundtrip time in the cavity. It is often discussed that a more accurate term for FM mode-locked lasers would be "phase mode-locked" lasers. Unlike an FDML laser, an FM mode locking laser does ***NOT*** have a tunable optical bandpass filter.

FM Lasers

An FM laser [55] is a laser with a setup identical to the FM mode-locked laser; however, the phase modulator is driven off resonance. By this strategy, transient wavelength sweeps can be generated. FM lasers generate one wavelength sweep per optical roundtrip time, similar to FDML; however FM lasers don't have an optical bandpass filter and their sweep range is usually limited to a few nm due to the lack of suppression of ASE. Also FM lasers usually exhibit a breathing of the spectrum. Unlike an FDML laser, an FM laser does ***NOT*** have a tunable optical bandpass filter.

Wavelength Tunable Laser with Resonant Frequency Shifting

FDML operation is also often confused with wavelength-swept lasers which incorporate an optical frequency shifter [58]. Such lasers have been demonstrated with sweep repetition rates up to ~1 kHz. The frequency shifter's purpose is to also

overcome the fundamental problem of the required repetitive buildup of lasing during sweep operation. The light inside the cavity is shifted exactly by the amount that is required to compensate the filter tuning operation. In other words, light which is transmitted through the filter is frequency shifted on its way through the cavity, and when it arrives back at the filter, the new wavelength matches exactly the new position of the optical bandpass filter. The problem with this design is that the amount of frequency shift achievable with current devices is hardly more than 1 GHz and it is therefore not sufficient for very fast tuning operation. Unlike an FDML laser, a resonant frequency shifting laser does ***NOT*** synchronize the optical roundtrip time with the filter tuning period of the optical bandpass filter.

Very Rapid Tuning of CW Dye Laser

In 1975 Telle and Tang [28] demonstrated a tunable laser using an electro-optical element acting as a type of optical bandpass filter. The concept of this approach is the same as in FDML; however, no narrowband wavelength filter was applied, and with a tuning range of 2 nm and a linewidth of 0.2 nm at a repetition rate of 100 MHz, this source cannot be used for OCT.

24.3 Milestones in FDML Development

24.3.1 The First Implementation of an FDML Laser

Figure 24.6 shows the first implementation of an FDML laser for OCT in 2005 [59]. The laser is implemented in a ring geometry using a fiber-based resonator. The laser gain medium is a fiber-pigtailed packaged semiconductor optical amplifier (SOA) from Inphenix, Inc. The tunable optical bandpass filter is a Fiber Fabry-Perot Tunable filter (FFP-TF) (Micron Optics, Inc.). A spool with 7 km standard single mode telecom fiber (Corning SMF 28e) provided the optical delay of 34 μs. Figure 24.7 shows the output power of the laser for different values of tuning frequency of the optical bandpass filter. It can be seen that only for a very narrow range of filter drive frequencies $f_{filterdrive}$, the FDML condition $f_{filterdrive} = c/l$ is fulfilled. The resonance has a width of about 7 Hz at a center of 29,015 Hz corresponding to a system finesse of 1/4,000.

As seen in Fig. 24.7, the laser resonator has an optical roundtrip frequency of 29 kHz. Since the Fabry-Perot Tunable filter is preferentially driven sinusoidally at such high speeds, two wavelength sweeps are generated for each drive cycle of the filter. So driving the filter with 29 kHz generates 29,000 forward (shorter to longer wavelength) sweeps and 29,000 backward sweeps per second. For OCT application, 58 kHz line rate is possible.

Obviously this laser can also be driven with higher harmonics, i.e., two or more sweeps are simultaneously active in the FDML laser. The laser has resonances at $2 \times 29 = 58$ kHz, at 3×29 kHz $= 87$ kHz, and so on. In the first demonstration in 2005, up to 290 kHz sweep rate had been demonstrated.

24.3.2 Buffering: Increasing the Sweep Speed by Optical Time Multiplexing

Conceptionally, FDML lasers have no speed limit as long as the intracavity tunable bandpass filter supports the high sweep speeds. It actually turns out that FDML lasers are more stable at higher speed, because the required delay fiber length is shorter for higher frequencies. This reduces thermal drift effects and problems with unstable polarization [29, 60].

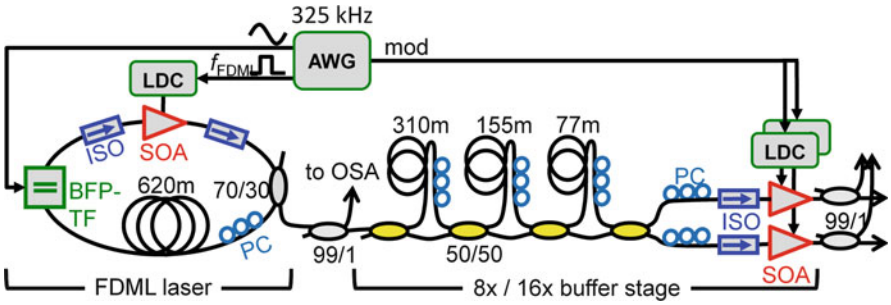

Fig. 24.8 Setup of a 2,600 kHz 8× buffered FDML laser [43]. Example of a buffering setup to multiply the sweep rate. The 2 × 325 kHz FDML is scaled to 2.6 MHz sweep repetition rate. The output is split, a part is delayed, and then the light is recombined

However, the availability of fast tunable optical bandpass filters with the required specifications is limited. The filters should have <0.15 nm passband, >120 nm free spectral range, and >40 dB out of band rejection. Currently, at sweep speeds of more than 100 kHz, only Fabry-Perot filters achieve this type of performance. Custom-built research devices achieve up to 2 × 419 kHz [61], and commercially available devices achieve 2 × 170 kHz (Lambdaquest, Inc.). This is typically the highest mechanical resonance ***frequency*** with sufficient response. However, the achievable tuning ***amplitude*** in these resonances is typically much larger than the lasing range, even larger than one free spectral range. So the total tuning speed measured in nm/μs can be increased by increasing the amplitude.

The technique of sweep buffering [62] can convert excess sweep amplitude to sweep frequency. It is used to convert lower filter sweep frequencies with a high amplitude to high sweep frequencies with lower amplitude. Figure 24.8 shows the setup of an 8× buffered FDML, and Fig. 24.9 shows the concept of sweep buffering in the case of 4× buffering. In the setup in Fig. 24.8, a 325 kHz FFP-TF is used. The filter is driven with such a high amplitude that the duty cycle of one forward sweep is only 12.5 %, and the rest of the time over one entire sweep cycle the SOA is switched off. The sweep output is now coupled into a cascade of splitters and recombiners, each with an additional length of fiber in one arm. The length of this arms is one half, one fourth, and one eight of the cavity length. This leads to multiple copies of the sweep, here 8. After the last coupler, there are two outputs, each with 8 × 325 kHz = 2,600 kHz sweep rate. Figure 24.9 shows the individual steps for a 4× buffered FDML with the steps of overdriving the FFP-TF, generating a short duty cycle, ON-OFF modulation of the SOA, copying and delaying the individual sweeps. It should be noted that sweep buffering is not limited to FDML lasers; it can be applied to all lasers that have excess tuning rate and short duty cycle [63].

The main reason for sweep buffering is to increase the repetition rate of FDML or standard swept lasers [30, 34, 62–71]. However, there are numerous additional advantages of buffering. The most important one is that there is an almost perfect

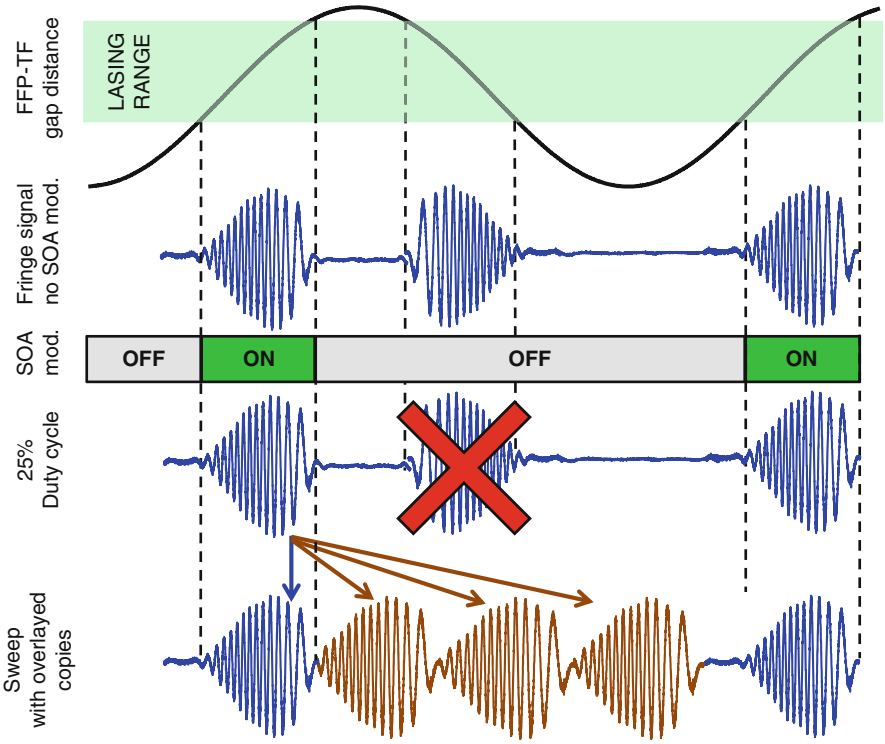

Fig. 24.9 The concept of buffering in case of an FFP-TF [62]. Here the situation for an FFP-TF filter buffering by a factor of 4× is shown. The sweep amplitude is increased to achieve a short duty cycle of the lasing operation, in this case 25 %. The laser gain SOA is switched off over 75 % of the time, and one sweep direction remains. The 75 % gap is filled with copies of the original sweep. The resulting sweeps have a 2× higher sweep rate and are unidirectional and highly linear in optical frequency and groups of four are almost mutually identical

optical phase relation between the different copies of the sweep, making them the ideal source for phase-sensitive and Doppler OCT imaging [68, 69].

Another advantage is that wavelength over time tuning characteristics and also the optical frequency over time tuning characteristics of the light sources' output is usually much more linear than in standard FDML lasers. The reason is that the FFP-TF filter in FDML lasers is usually driven in a mechanical resonance sinusoidally which leads to a very slow tuning operation near the turning points. On one hand, such a huge variation in filter sweep speed is problematic from an engineering viewpoint for an OCT system, because the resulting fringe frequencies span a very wide range of RF frequencies from the photo-receiver. This requires systems with a very flat electronic phase response. On the other hand, the very slow tuning speed at the turning points at a constant exposure level adds up to the total amount of optical power on the sample, but only very few data

points are collected right at the turning points, considering the equidistant optical frequency grid before FFT in SS-OCT/ODFI. This means a lot of energy is put on the sample, but very little information is acquired. So sweep buffering improves linearity which can simplify OCT system design and improve image quality.

A further advantage of sweep buffering is that the polarization state of the different sweeps can be passively controlled. For many PS-OCT applications, a sequence of wavelength sweeps with alternating polarization state is required [72, 73]. This is usually realized by active optical elements with the problem of synchronization, additional differential polarization-dependent group delay, and dispersion. With the technique of sweep buffering, different polarization states can be generated passively [60].

For these reasons, buffering stages are an integral element in many of the most advanced MHz FDML lasers.

24.3.3 The Second-Generation FDML Lasers: Dispersion Compensation

The idea of FDML is to synchronize the optical roundtrip time of light in the laser cavity with the filter tuning period. But this would require that all the different wavelength components of the FDML laser propagate with the same speed. Due to chromatic dispersion in the delay fiber, this is not the case which leads to a more or less pronounced miss synchronization for some wavelengths [29]. The first FDML lasers have been implemented at a center wavelength of ∼1,310 nm. This is the zero dispersion point of standard optical fiber, meaning in a narrow range around 1,310 nm, all wavelengths propagate at the same speed. However, zero dispersion point means only that there is no linear group velocity dispersion (GVD) (i.e., second-order dispersion), so no term measured in ps/(nm*km). However there still is remaining GVD slope measured in ps/(nm^{2}*km). And because typical OCT lasers sweep over a very wide spectral range of 100 nm or more, this has a significant effect on the roundtrip time. Figure 24.10 (left) shows the difference in roundtrip time for the various spectral components in a 100 kHz 1,300 nm FDML laser (2 km fiber).

It can be seen that light with 1,240 nm has a 550 ps longer propagation time through the cavity than light with 1,320 nm. At a roundtrip time of 10 μs, this is a synchronization error of 50 ppm (5e-5) which is small enough that it doesn't affect the output power of the FDML laser. However, it also means that light will not circulate in the FDML cavity forever; after a certain number of roundtrips, the timing offset will be large enough that the light is blocked by the filter. In the shown case, this reduces the number of roundtrips of the intracavity photons in the FDML laser to approximately 12 at the very edges of the spectrum [30]. This negatively affects the instantaneous linewidth of the FDML laser reducing the instantaneous coherence length. For this laser the practical single-sided OCT ranging depth is reduced to about 5 mm, i.e., the OCT depth range over which

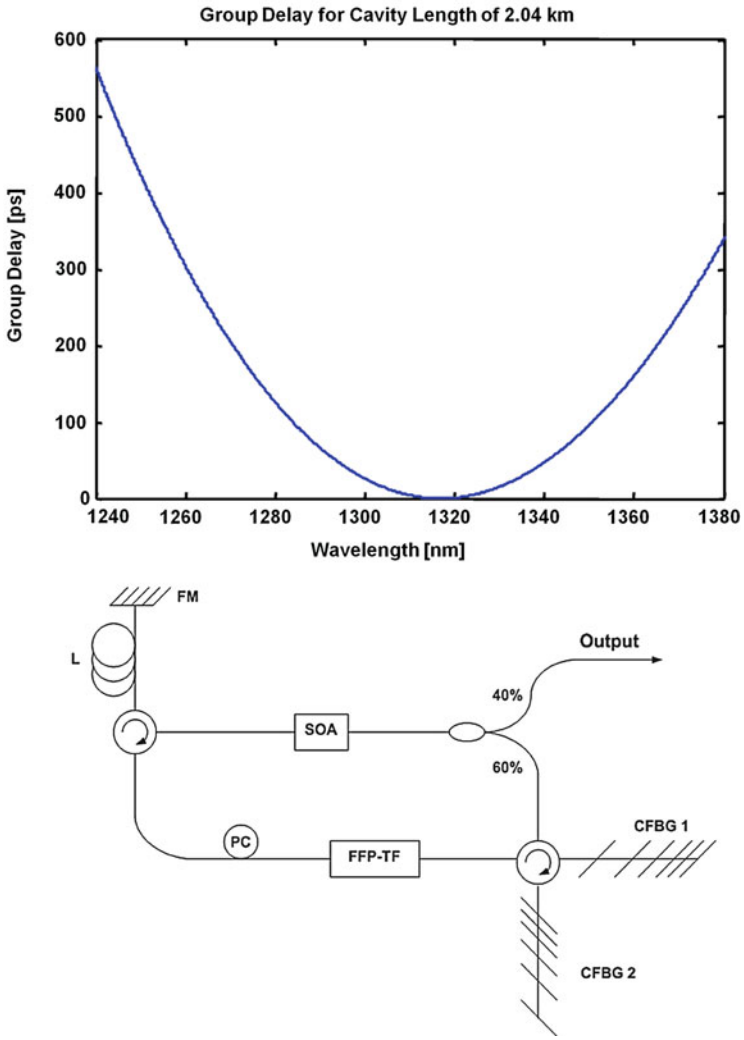

Fig. 24.10 Dispersion in FDML and compensation setup [30]. *Top*: Propagation time difference for the spectral components in a 100 kHz FDML laser cavity [30]. *Bottom*: Setup of an FDML laser with compensated chromatic dispersion. The laser uses two custom-designed chirped fiber Bragg gratings (*cFBG*) from Teraxion, Inc

almost no signal decay can be observed. The effect of chromatic dispersion is even more severe in FDML lasers at 1,050 nm as used for retinal imaging. There the chromatic dispersion of optical fiber has a substantial linear contribution of ∼40 ps/(nm*km).

The solution to this problem is to compensate the intracavity dispersion of the FDML. The different approaches that have successfully been demonstrated are

the use of a wideband zero dispersion photonics crystal fiber [64, 75], the use of a sequence of different fibers to cancel out the dispersion contributions of the individual pieces [29, 76], and most recently the application of chirped fiber Bragg gratings (cFBG) [30, 34, 35]. A cFBG is a piece of fiber with a periodic refractive index modulation where the period changes over length. This way, light with different wavelengths is reflected in different depths yielding a wavelength-dependent propagation time. The cFBGs can now be designed in a way that they exactly compensate the chromatic dispersion of the FDML cavity. Since usually cFBGs are preferred with a monotonic group delay over wavelength, a pair of matched cFBGs is used at 1,320 nm, because the dispersion zero of standard optical fiber leads to a minimum of propagation time. Figure 24.10 (right) shows the setup of a compensated 1,300 nm FDML, and a 4-port circulator is used in the light path to generate the two reflections from the cFBGs. The pair of cFBGs was designed and manufactured by TeraXion, Inc. (Quebec City, Canada). Figure 24.11 (left) shows the group delay of the two cFBGs and the total group delay. Starting from more than 200 ps timing error for the different wavelength components of a 100 nm range, less than 4 ps remain after compensation (Fig. 24.11 right); this is a reduction of more than 50×. The relative timing error of 4 ps compared to the 10 μs tuning period corresponds to a relative error of 400 ppb (4e-7). This value theoretically enables several 1,000 roundtrips of light in the cavity [30].

Because of this higher number, light is effectively filtered more often improving the instantaneous linewidth. The sensitivity roll off is reduced; the OCT system ranging depth improved to more than 10 mm (>21 mm 6 dB coherence length). Figure 24.12 shows the improvement; the point spread functions are plotted over OCT imaging depth. For the non-compensated FDML, a 6 dB roll off over 5 mm is observed. Using dispersion compensation this value is more than doubled. The measurements in Fig. 24.12 may have been limited by the detection electronics rather than by the laser linewidth properties, so the real roll-off performance of this laser can be even much better. This increase in total OCT imaging range is most important for applications in intravascular imaging, where a >5 mm range is usually desired to better image some anatomic features like arterial branches [30].

24.4 Different Variations and Implementations of FDML

Since in FDML both of the critical elements of a tunable laser are separated and because they can have substantial optical path length, FDML allows many different combinations of gain and filter media to specifically tailor them towards the application of interest.

Besides the typical SOA gain medium, FDML lasers has been built with Raman gain for extremely low ASE background noise [51], with rare earth-doped fiber amplifiers [44, 45, 47] for very high output powers, with nonlinear post conversion [77] or optical parametric amplification [47, 48, 78] for very flexible gain regions and with combinations of these different techniques.

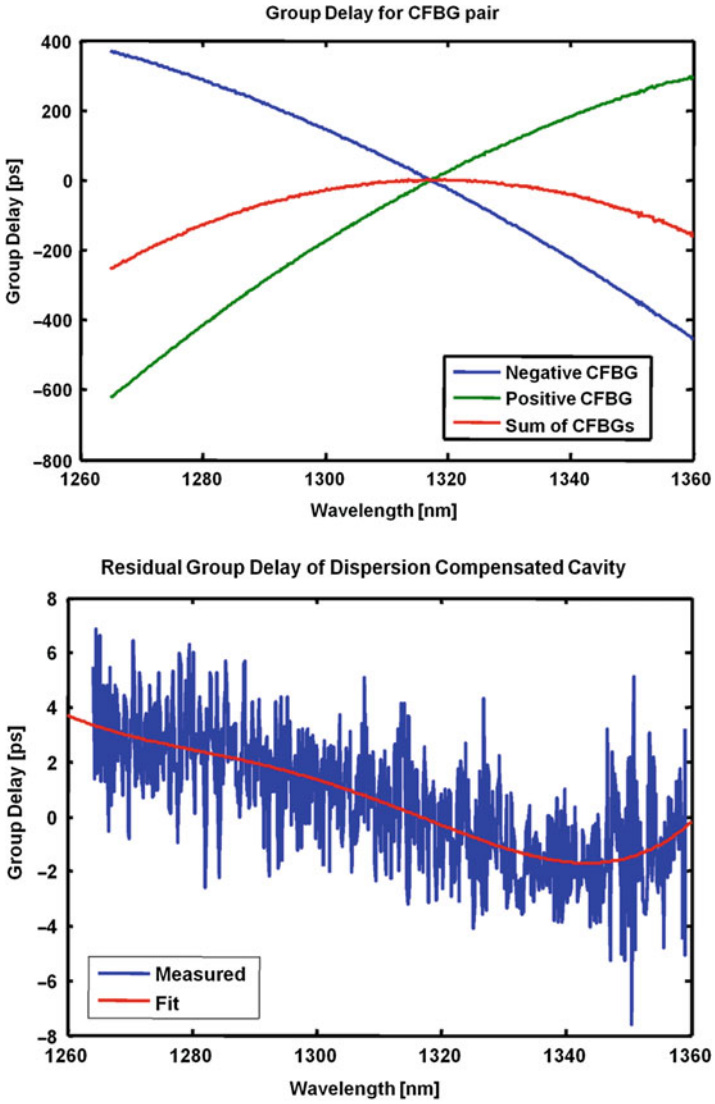

Fig. 24.11 Dispersion compensation with chirped fiber Bragg gratings (*cFBGs*) [30]. *Left*: A combination of two cFBGs can generate a net GVD slope value. *Right*: The dispersion is reduced by almost a factor 50

The tunable filters used for FDML lasers have been limited to very rapidly tunable ones. In most cases Fabry-Perot Tunable filters are used, but also polygon scanner-based systems are possible and have a number of advantages, like inherent unidirectional sweeping and very high-power handling capabilities [79].

Stabilization of FDML operation is usually performed by active or semi-passive mechanisms, solving the problem of drift in FDML.

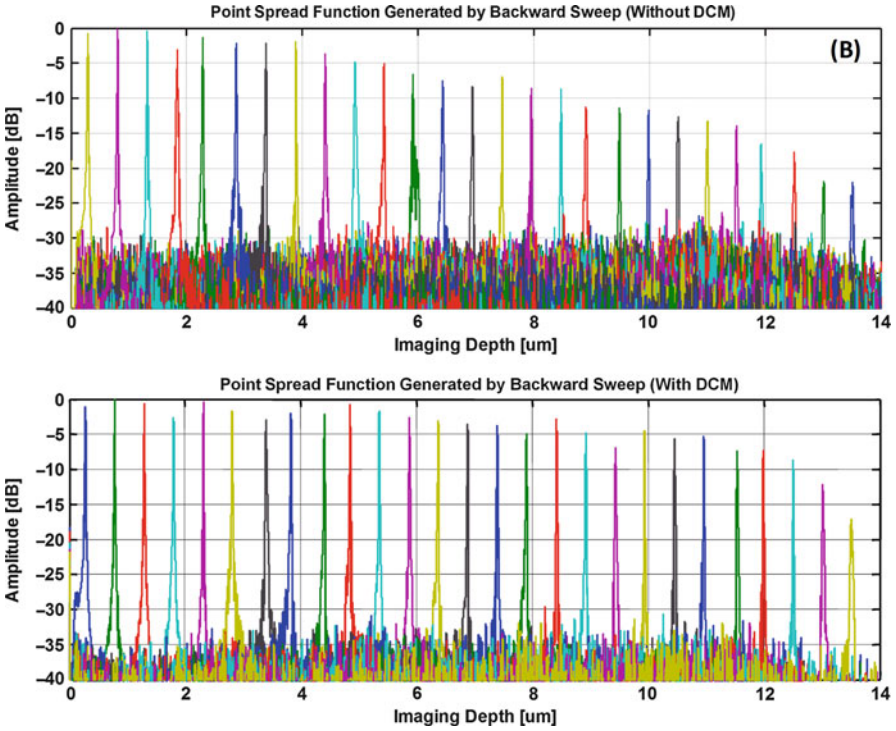

Fig. 24.12 Improved roll-off performance by dispersion compensation [30]. *Top*: Point spread function (*PSF*) over imaging depth for an OCT system using a standard 2 × 100 kHz 1,300 nm FDML laser. A 6 dB signal roll off over 5 mm can be seen. *Bottom*: Roll off for the same laser with additional dispersion compensation – the 6 dB signal roll off is extended to >10 mm

24.4.1 FDML with Raman Gain

Due to their setup with a long length of fiber, FDML lasers offer the ideal starting point for Raman amplification as laser gain process [46, 49–51]. Raman amplification in fibers is widely used, because the small mode field diameter in optical single mode fibers over a very long interaction length compensates for the very small Raman scattering cross section. The advantage of Raman gain is the potentially very flexible range of operating wavelengths and the good noise performance. It has also been used to study the photon life times and loss mechanisms in FDML lasers [51].

24.4.2 FDML with Erbium Fiber Gain

In the 1,550 nm wavelength range, which can also be used for OCT, especially if samples with low water concentration are imaged [15], an erbium-doped fiber amplifier (EDFA) can be used instead of an SOA as gain medium [47, 48]. EDFAs have also

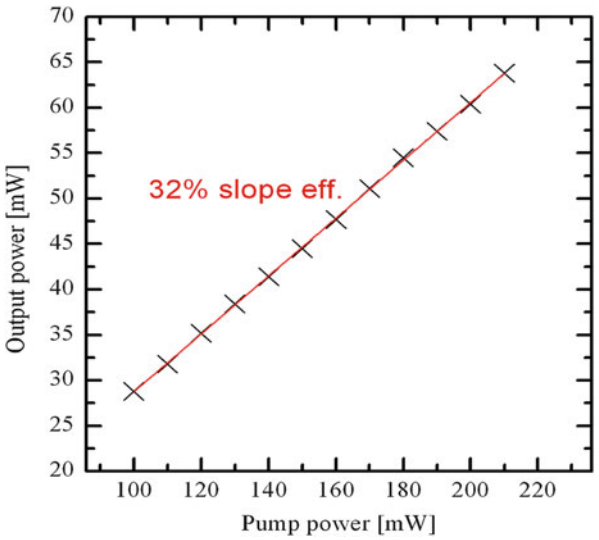

Fig. 24.13 Output power of 1,050 nm FDML using YDFA. The average output power of the FDML can easily exceed 60 mW. At duty cycles of 12.5 % for 8× buffering and a Hanning shaped spectrum, this corresponds to >400 mW peak power of the wavelength sweep

a better noise performance than SOAs, and they can achieve higher output powers. Disadvantages of EDFAs are the smaller amplification bandwidth and the tendency to Q-switch because of the long carrier lifetime of ~20 ms. If EDFAs are used for fast swept lasers and the sweep rate is increased, carrier relaxation oscillations get stronger and high output intensity fluctuations are observed. At some point the laser goes into Q-switching mode emitting a sequence of pulses. Due to the high power of such pulses, they can destroy the intracavity filter.

24.4.3 FDML with Ytterbium Fiber

At 1,050 nm an ytterbium-doped fiber amplifier (YDFA) can be used as amplification element [44–46]. In [45] this was used in combination with an SOA. YDFAs have the advantage of good noise performance and the capabilities for very high-power output. Their gain profile covers an extremely wide wavelength range of much more than 100 nm around 1,050 nm.

The output powers achievable with YDFAs are scalable into the Watt region. Figure 24.13 shows the case for an FDML laser used for retinal imaging. Considering the duty cycle of this laser, the peak power was larger 400 mW. Especially since in the 1,050 nm region swept laser sources often do not exhibit sufficient output power, YDFA-based FDML lasers appear very attractive.

24.4.4 FDML Polygon Scanner Filters

Even though in most cases FDML lasers are built with FFP-TFs, the FDML concept is not linked to a special type of optical bandpass. Leung, Liu, and Mao et al.

demonstrated an FDML laser using a grating filter based on a polygon scanner [40–42, 79]. The advantages of this device are unidirectional scanning operation and very good sweep linearity without buffering.

24.4.5 FDML with Regenerative Mode Locking

One problem of FDML operation, especially if an FFP-TF is used, is the control and automatic stabilization of the wavelength sweep filter. Sweep amplitude, offset, and frequency have to be controlled; thermal drift has to be compensated. Different active control loops have been demonstrated. A very interesting concept is the application of a regenerative mode locking concept [79]. The optical output of the FDML laser is used to control an electronic signal that drives the filter. This way, temperature-dependent changes in the optical roundtrip frequency are automatically compensated for, and the laser always finds the best frequency.

24.5 The Performance of FDML Lasers in Comparison to Other Light Sources

24.5.1 Competing Technologies

At the time of the first introduction in 2005, the performance of FDML lasers was quite unique, and hardly any other technology could achieve the combination of sweep speed, linewidth performance, and spectral sweep range. However, over the last few years, other swept source technologies have been developed that now approach and may even exceed FDML performance in some aspects. In the following sections the state of the art in the year 2013 will be shortly reviewed with respect to performance characteristics of these new sources compared to FDML. Currently there are many promising ideas and concepts for fast wavelength-swept light sources intended for use in OCT, but in several cases, it has not finally been proven, whether these sources can really achieve good imaging performance in biomedical applications [17, 80–82]. So here the focus lies only on three non-FDML techniques and light sources where OCT imaging has already been demonstrated at speeds in excess of 200 kHz, because the high sweep speed performance is the most outstanding characteristics of FDML laser.

The first class of high-speed swept light sources are lasers where the cavity length is reduced so far that the lasing buildup dynamics is fast enough to achieve high-speed tuning. Since this class of sources does not solve the problem of laser buildup dynamics, it can be expected that they are not arbitrarily scalable to higher speeds and probably only several 100 kHz sweep rates are possible, in case other typical OCT performance criteria are maintained. It should be noted that a reduction of the laser resonator cavity length in classic swept laser designs using a separated gain medium and an optical bandpass filter is only possible up to a certain amount. Since the cavity length defines the mode spacing of the laser resonator and this

mode spacing becomes larger as the laser resonator length is decreased, the possible spectral sampling density becomes coarser. In other words, if the cavity length of a linear laser resonator is, e.g., 5 mm, the optical mode spacing of the resonator modes is $\Delta f = c/2\ l = 30$ GHz. At 1,300 nm wavelength, this corresponds to 0.17 nm spectral separation which is, in OCT application, the best achievable spectral sampling density. This corresponds to an OCT imaging range of 2.5 mm. So with a standard laser, it is not possible to build an SS-OCT/OFDI system that has a single-sided ranging depth of more than the laser cavity length. In reality, the laser resonator length is typically chosen significantly longer to avoid beat noise between individual modes. Therefore highly integrated short cavity lasers have the laser end mirror outside the package in the fiber pigtail, resulting in typical cavity roundtrip lengths 30 cm, about 1 GHz optical mode spacing. According to the single roundtrip limit presented in [14], it can be expected that such lasers are limited to $<$300 kHz sweep rate if a 0.05 nm linewidth and 100 nm sweep range are chosen. The problem of discrete mode spacing may theoretically be overcome by advanced variable cavity designs or an active phase section in the laser resonator, as used in telecom applications [17]. However, the laser dynamics at fast sweep operation and the influence on OCT image quality have not been investigated yet. The most prominent examples of fast short cavity lasers are the ones from Oh et al. [63] as research systems and the ones from Axsun technologies [84] and Santec [85]. A more detailed discussion of this laser type can be found in .." reference to Bart Johnson (AXSUN), Bill Ahern chapter in this book.

The second class of successful high-speed tunable lasers are mechanically tunable vertical-external-cavity surface-emitting lasers (VECSEL) (see ▶ Chap. 22, "VCSEL Swept Light Sources"). These devices can achieve very fast tuning operation. It is often argued that the short cavity length of these devices promotes very rapid buildup. However, the most recent results showing meter long coherence lengths, equivalent to $>$10 ns coherence time, are not possible at the typical sweep rate of $>>$1 GHz/ns tuning if lasing is repetitively built up, since this would violate the time bandwidth product. So the reason for the good coherence performance at high tuning speed is that the Doppler shift caused by the reflection of light from the moving end mirror automatically adjusts the wavelength of the light field such that it always matches the resonance condition of the tuned laser cavity. The calculation can be found in [26]. For this reason, VECSELs have also no fundamental tuning speed limit.

The third class of light sources are non-laser sources, i.e., light sources without feedback [86, 93]. A sequence of filters is driven in a way to compensate propagation time effect of light in a pure feedforward configuration. These sources also inherently have no fundamental sweep speed limitation and are amongst the fastest swept sources.

The different sources have various strengths considering the important OCT imaging parameters. Today, sweep speed, achievable axial resolution, and output power are the most important ones. Previously, the instantaneous coherence length, which determines the roll-off performance and the maximum ranging depth of the OCT system, was also of interest. However, today almost all the sources mentioned

Table 24.2 Comparison – imaging speed (single spot)

	1,050 nm	1,300 nm
1. FDML	3,200 kHz [85]	5,200 kHz [43]
2. VCSEL	580 kHz [22]	1,200 kHz [22, 25]
3. ASE swept light source	340 kHz [86]	340 kHz [93]
4. Short cavity (Axsun)	200 kHz [94]	50 [83]

above can achieve more than 20 mm coherence length yielding more than 10 mm single-sided OCT ranging. VECSEL source can achieve even >50 mm. All these values are more than sufficient for almost all classical biomedical OCT applications.

24.5.2 Sweep Speed

One of the most crucial parameters of swept light sources for OCT imaging is the wavelength sweep repetition rate. Since each wavelength sweep results in one OCT A-scan, a faster sweep operation yields a faster OCT system. Today, the fastest swept light sources that have been used for biomedical OCT are FDML lasers, currently with a record speed of 5.2 MHz at 1,300 nm [43] and 3.2 MHz at 1,050 nm [86]. This is more than a factor of 5 faster than the fastest non-FDML source (Table 24.2).

24.5.3 Sweep Range and Axial Resolution

For many OCT applications, the achievable axial resolution is as or even more important than OCT imaging speed [87–90]. Currently and in the midterm future, it seems not likely that fast swept source OCT systems will achieve axial resolution as good as the values demonstrated with ultrahigh-resolution time domain or spectral domain systems [91, 92]. However, the sweep ranges that have been achieved with FDML lasers are still sufficient to allow for ∼3 μm axial resolution in tissue at 1,050 nm and ∼2.5 μm at 1,300 nm wavelength. Also very good values can be achieved with standard short cavity lasers and with the ASE swept light source. VCSEL light source has the inherent problem that the gain medium inside the Fabry-Perot laser resonator sets a lower limit for the cavity length, resulting in a reduced free spectral range and a reduced sweep range. But for many applications the achieved values are still sufficient (Table 24.3).

24.5.4 Output Power

Output power can be a critical parameter for OCT applications, because fast OCT systems require enough intensity on the sample to achieve sufficient signal levels. Usually OCT systems are designed to stay within the limits of a class one laser, but not dramatically below. For retinal imaging at 1,050 nm, up to 1.9 mW is often used and

Table 24.3 Comparison – sweep range and achievable resolution in biomedical OCT applications

	1,050 nm	1,300 nm
1. FDML	120 nm [85]	220 nm [92]
2. Short cavity (Axsun)	100 nm [94]	110 nm [83]
3. VCSEL	85 nm [22]	110 nm [22]
4. ASE swept light source	70 nm [86]	100 nm [93]

Table 24.4 Comparison – max output power

	1,050 nm	1,300 nm
1. FDML	>400 mW [45]	>100 mW [40–42]
2. ASE swept source	>40 mW [86]	>50 mW [93]
3. VCSEL	20 mW [22]	35 mW [25]
4. Short cavity (Axsun)	18 mW [94]	20 mW [83]

for imaging in highly scattering tissue 10 mW or more. Depending on the design of the OCT interferometers and on the inherent losses of the optical components, especially at 1,050 nm, often only 10–50 % of the light source output powers are incident on the sample. So ideally light sources at 1,050 nm should have 4–20 mW, and sources at 1,300 nm should have 20–100 mW. Table 24.4 shows the values for the different sources. The values include setups using an external booster to achieve sufficient power levels. A booster usually does not affect OCT imaging performance too much [14], only in the case of the ASE swept light source [86, 93] that the application of the final amplifier prevented the system from reaching shot noise-limited sensitivity. The good power values in Table 24.4 (Comparison – max output power) for the FDML laser are caused by the good saturation of the system and the high outcoupling value. Typically in FDML about 50 % of the light is extracted and in VECSELs about 0.1 %. The high value for the 1,050 FDML is caused by the application of an intracavity Yb fiber as gain medium, which allows up to Watt-level output.

24.6 OCT Imaging with FDML Lasers

FDML lasers have been applied to many different OCT imaging applications, in most cases because the application demanded fastest imaging speed. The applications range from developmental biology [67] over art conservations studies [114], profilometry with nanometer resolution [68, 69], sensing applications using fiber Bragg gratings [49, 96–100], photothermal imaging [100], deep field OCT imaging with special beam shaping optics [102], functional in vivo OCT imaging [61, 71, 103], ultrawide field retinal imaging [45, 85], intravascular imaging [30, 104], contrast-enhanced imaging with nanoparticles as contrast agents [100], and microangiography with an ultrawide field of view [61] to FDML lasers for noncontact detection of photoacoustic signals [103].

In the following chapter, some examples are chosen which represent some of the unique technical FDML features which, in the specific application, substantially improved the quality of the imaging result.

24.6.1 FDML for Developmental Biology

An early FDML application has been ultrafast OCT in developmental biology [67]. Here, the function and dynamics of the developing quail heart was studied, and the high imaging speed of 100 kHz possible with FDML enabled OCT at 195 frames per second. The resulting high time resolution enabled for the first time the direct detailed observation of the fast contraction phase of the heart. At a reduced line number, volumes with 200 × 60 lines per volume at a rate of 8.3 volumes per second have been acquired. A more detailed description of this application field is presented by Rollins and Jenkins in the "OCT Applications" part of this book in ▶ Chap. 65, "4-D OCT in Developmental Cardiology".

24.6.2 FDML for High-Speed Intravascular Imaging

Intravascular imaging is the second most important field of application in OCT. In 2006, the commercially available system M2 from LightLab Imaging (now a St. Jude Medical subsidiary) exhibited a 3.5 kHz A-scan rate at 15 frames per second. This slow A-scan rate leads to the risk of ischemia due to long pullback times [105], an additional step in the procedure and limited image quality caused by the low number of depth scans acquired during one catheter revolution. In 2006 LightLab Imaging developed their first swept source/OFDI system, which was based on an FDML laser [105].

Table 24.5 summarizes the performance of the LightLab FDML system compared to the pervious time domain M2. Figure 24.14 depicts some imaging results from the year 2006, clearly showing the improved image quality. Recently the potential of a further performance improvement of the LightLab C7XR intravascular FD-OCT system (LightLab Imaging, a St. Jude Medical subsidiary) has been evaluated. For this purpose a second-generation FDML (see Sect. 24.3.3) has been interfaced with the C7XR system and 100 kHz long-range OCT on phantoms was tested [29] (Fig. 24.15). Even though an even higher imaging speed would have been desired, the limitation was the maximum rotation speed of the catheter. with a new catheter, based on a design with a micro motor, the imaging speed could be increased by more than a factor ten. 3200 frames per second have been acquired [104].

24.6.3 FDML for Endomicroscopy

OCT has been extensively applied to gastrointestinal (GI) imaging. Whereas early time domain GI-OCT has usually been limited to single cross sections, the advent of

Table 24.5 LightLab FDML prototype compared to M2 [106]

	FDML-based OCT – prototype	LightLab M2
Line scan rate	45 KHz	3 KHz
Max frame rate	80 f/s (@562 lines/frame)	15.6 f/s (@200 lines/frame)
Scan diameter (in saline)	7 mm	6.8 mm
Signal-to-noise ratio (SNR)	~100 dB	~100 dB
Axial resolution (in tissue)	11–17 µm	15 µm

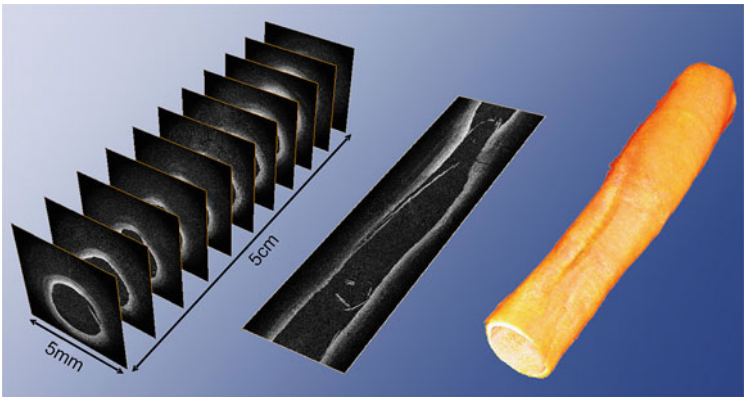

Fig. 24.14 Intravascular images with LightLab FDML prototype in 2006 [102]. Three-dimensional reconstruction of a 5 cm segment of an excised radial artery from a cadaver

fast swept source FD systems [13] enabled the acquisition of large areas as full three-dimensional volumes [106, 107]. Besides the advantage of having a very densely sampled data set, which reduces sampling errors and the probability of missing or overlooking pathology, the 3D volume provides also the possibility of reconstructing an en face visualization in a certain depth, which can be arbitrarily chosen after image acquisition. In combination with a high-resolution flying spot OCT endoscope, this can provide a new class of image representations for improved visualization of tissue morphology. Because an entire 3D data set is reduced to one image, each OCT A-scan yields only one image point. Consequently the A-scan rate has to be high enough, to keep procedure times acceptable.

Figure 24.16 shows endoscopic imaging results of rabbit colon; the data was acquired using an FDML system with 100 kHz line rate and 5 µm axial resolution. The steps of the endomicroscopy approach using OCT are shown. The individual OCT cross sections are fused to one 3D data set, they are flattened, and then a depth section is extracted. The comparison to histology shows that the characteristic crypt structure can clearly be identified in the OCT (Fig. 24.16, bottom).

24.6.4 Buffered FDML for Phase-Sensitive OCT and Photothermal Imaging

In Sect. 24.3.2 the technique of buffering has been described. Buffering splits the output of the swept laser, delays one part of it, and recombines the two sweeps. The main application of buffering is to increase the sweep repetition rate. However, buffered lasers have also a very unique feature considering the stability of the OCT signal fringe phase stability. Usually frequency swept lasers are more prone to phase noise of the detected fringe signal than OCT systems using a spectrometer. This effect is less pronounced in FDML lasers, because each sweep is seeded by the previous one. However the amplification and the transmission through the optical bandpass filter generate some instabilities in the optical field which then cause phase fluctuations in the OCT fringe signal.

Buffered FDML lasers now exhibit a very unique feature, because they always emit, in the case of 2× buffering, pairs of almost identical optical waveforms. Because the FDML output is split and recombined, one of the two sweeps

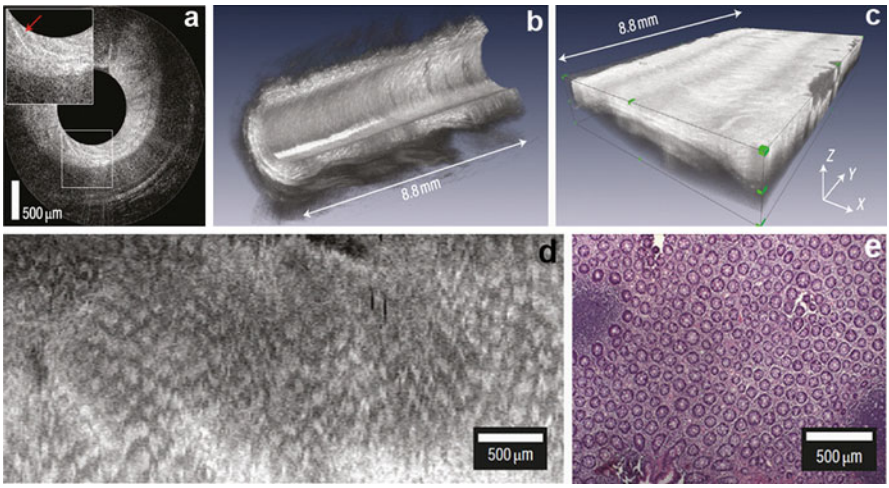

Fig. 24.16 Endomicroscopy of rabbit colon in vivo using FDML [107]. *Top* from *left*: Standard OCT cross section; 3D visualization of whole data set; flattened representation. *Bottom*: En face OCT (*left*) and histology (*right*) correspond well; the crypt structure can clearly be identified in the OCT

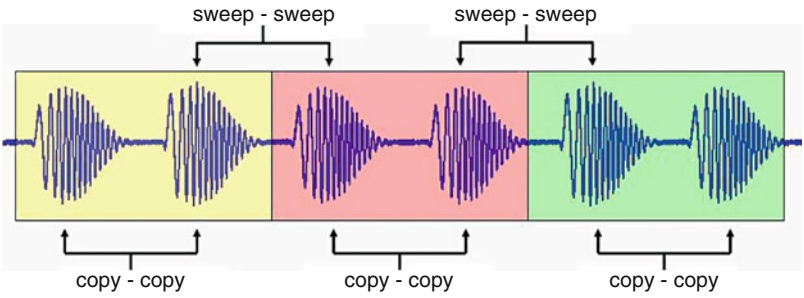

Fig. 24.17 Pairwise coherence of buffered FDML sweeps. FDML lasers with one buffering stage produce output sweeps in groups of two that are virtual optical copies of one another; they exhibit almost no phase noise

simply propagates through some more fiber. Because the fiber is completely passive, the electric field is hardly affected and only very little phase noise is added. A waveform change due to chromatic dispersion can easily be corrected by numerical resampling. The concept is shown in Fig. 24.17. The good coherence between the individual sweeps can now be used for many different phase-sensitive OCT imaging applications.

Figure 24.18 shows two examples of phase-sensitive OCT using a buffered FDML laser. On the left the buffered FDML is used for a phase-sensitive

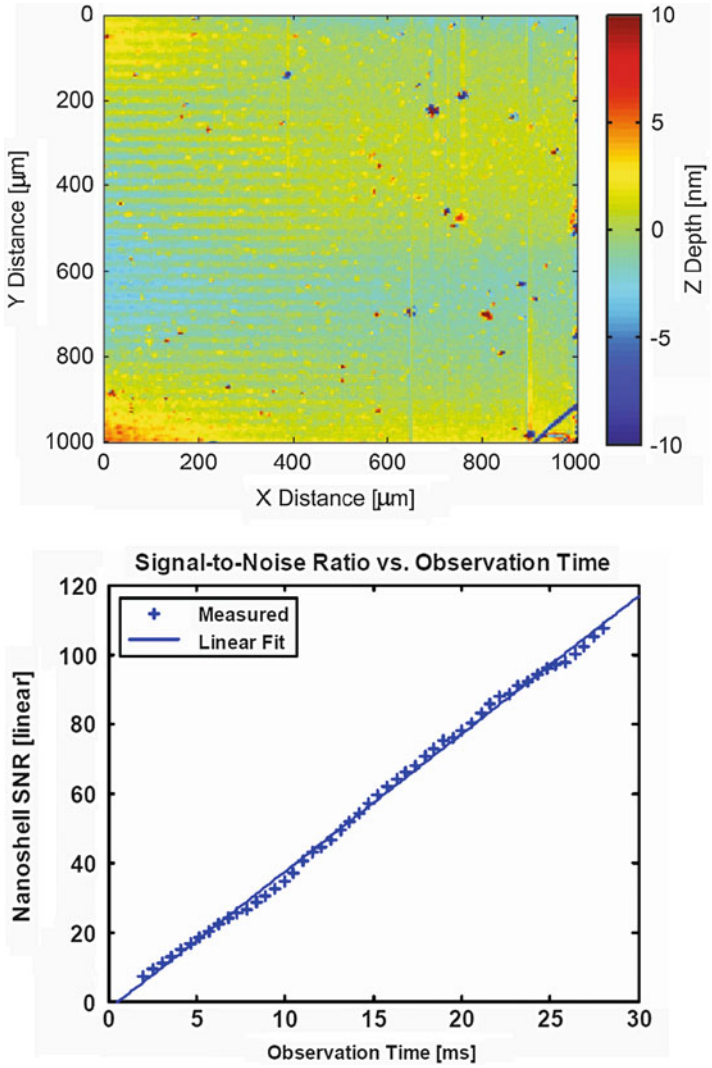

Fig. 24.18 Phase-sensitive OCT using buffered FDML [68, 100]. *Top*: Phase-sensitive profilometry of a glass plate; the overall angle/wedge effect has been subtracted. *Bottom*: Signal to noise achieved with FDML laser in photothermal OCT detection of gold nanoshells with potential use as contrast agent

profilometry OCT application. The image shows the surface of a glass plate with a sub-nanometer resolution (left) and the good signal to noise performance of buffered FDML lasers when used for the phase-sensitive photothermal detection of gold nanoshells as potential future OCT contrast agent (right).
