Integrated Optical Coherence Tomography (OCT) with Fluorescence Laminar Optical Tomography (FLOT)

51

Chao-Wei Chen and Yu Chen

51.1 Introduction

Multimodal optical imaging techniques offer more comprehensive understanding about the tissue under investigation. The trend of development has been focused on co-registered tomographic imaging and simultaneous anatomy and molecular imaging [1]. Ideally, one modality provides high-resolution structural images, and the other acquires the molecular, biochemical, or metabolic function. Being able to simultaneously acquire such complementary information is critical for clinical diagnosis and therapy. Multimodal imaging has been adopted in clinical settings, including combined PET/CT, SPECT/CT, and PET/MRI systems. Clinical research demonstrates the benefits of combined multimodal imaging technologies for diagnosing and staging of diseases, treatment planning, and monitoring response to therapy.

Furthermore, the synergy has evolved from offering complementary information to refining image reconstruction. For biomedical applications, by interpreting the structural and functional images simultaneously, one is able to improve the diagnostic accuracy which may be not achievable by each individual modality. Anatomically constrained magnetoencephalography (aMEG) combines the spatial resolution of a structural MRI scan with the temporal resolution of the

MEG [2]. Similarly, X-ray-prior-guided diffuse optical tomography (DOT) improved optical contrast of malignancy of breast tumor [3].

Multimodal imaging has been pursued in mesoscopic (millimeter) scale. Pan et al. demonstrated that fluorescence-guided endoscopic optical coherence tomography (OCT) could enhance the efficiency and sensitivity of early bladder cancer diagnosis [4]. In animal model studies, they reported that the specificity of fluorescence detection of transitional cell carcinoma was significantly enhanced by fluorescence-guided OCT (53 % vs. 93 %), and the sensitivity of fluorescence detection also improved by combination with OCT (79 % vs. 100 %) [5]. Tumlinson et al. have developed a combined OCT and laser-induced fluorescence (LIF) spectroscopy imaging catheter for in vivo mouse colon imaging [6, 7]. Recently, combining OCT with reflectance-based fluorescence imaging has been reported by us and others [8, 9].

In this chapter, we focus on the combination of OCT and depth-resolved fluorescence tomography (based on laminar optical tomography, LOT) as a mesoscopically co-registered structural and molecular imaging platform (the red "⇔" in the Fig. 51.1). OCT is primarily based on contrasts from scattering, birefringence, and refractive index variations of the tissue, providing resolution of 1–10 μm and penetration depth of 1–2 mm of tissue microstructures.

Complementarily, LOT has been developed to perform functional imaging with 100 μm resolution and up to 2.5 mm depth [10–16]. LOT is an extension of confocal microscopy by using multiple-displaced-confocal-pinhole design to capture the photons traveling through different depths, and the image is obtained through transport-based reconstruction [10]. Fluorescence LOT (FLOT) additionally provides highly sensitive molecular information through fluorescence contrast agents [17, 18]. The comparable imaging scale and their complementary contrast mechanisms motivate the integration of OCT and FLOT as a multimodality imaging platform to provide tissue structural and molecular information in 3D in millimeter imaging scale. This chapter will describe the theoretical modeling, instrumentation, as well as biomedical applications of this new multimodal imaging modality.

51.2 Combined OCT and FLOT: Instrumentation

A co-registered OCT and line-scan FLOT system was developed in our lab [19, 20]. Figure 51.2 shows the schematic of the multimodal imaging system. The OCT subsystem utilized a wavelength-swept laser as the light source with a spectrum centered at 1,310 nm and bandwidth of 100 nm, thereby providing an axial resolution of 10 μm in the tissue. The laser operated at a sweeping rate of 16 K A-scan/s with an average output power of 12 mW. The output of the swept laser was split into two paths: 3 % was sent to a Mach–Zehnder interferometer (MZI); the remaining 97 % was equally distributed to the sample and reference arms of the OCT Michelson interferometer, which was composed of one circulator and one fiber-optic 50/50 splitter. The light in the sample arm passed through a collimator (C), a pair of galvanometer mirrors (X and Y), and an objective to the tissue. The power on the tissue was 4 mW with a spot size of 15 μm. The reference arm consisted of a dispersion compensation glass (DCG) and a polarization controller (PC). DCG matched the dispersion induced by the optics in the sample arm. The light returned from the sample and reference arms formed the interference signal, which was electronically detected by a balanced detector (BD). The output of BD was discretely sampled by a data acquisition board (DAQ, AlazarTech), which was triggered by the zero-crossings of the MZI fringes. The zero-crossings provided an equally spaced frequency clock, therefore eliminating the need to interpolate/resample the discrete interference signal and increase the speed of data processing. Lastly, discrete Fourier transform rendered the axial profile of the tissue (A-scan) with 2.5 mm imaging depth in 512 pixels. The sensitivity (the minimal detected signal) of the OCT subsystem was 95 dB.

The line-scan FLOT subsystem is shown in the right portion of Fig. 51.2. The excitation source was a continuous wave (CW) laser diode at 670 nm. A cylindrical lens was used to expand the illumination point to a line. Line illumination simplified the scanning mechanism by eliminating the scanning along the illumination dimension. The excitation line sequentially passed through a dichroic mirror (DM-2), galvanometer Y, and another dichroic mirror (DM-1) before illuminating on the tissue. The line illuminated on the tissue was 2.2 mm long in x-direction

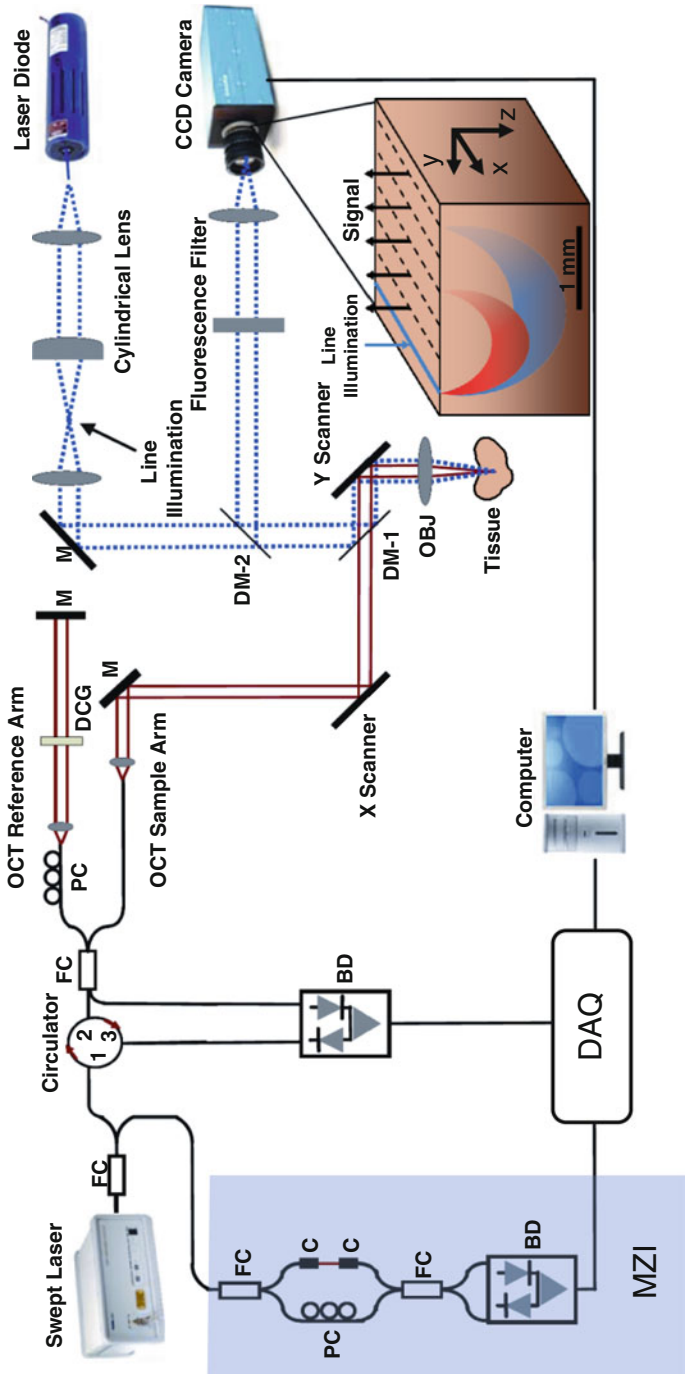

Fig. 51.2 Schematic of the combined OCT and line-scan FLOT system (Reproduced from Ref. [20] with permission © 2010 IEEE)

and 25 μm wide in y-direction. The illumination power was 8 mW. DM-1 integrated the FLOT optical axis and the OCT sample arm. Specifically, DM-1 transmitted the OCT light (at 1,300 nm) and reflected both the FLOT excitation and emission light (<850 nm). DM-2 further separated the excitation reflectance and the fluorescence emission light. The fluorescence light passed a band-pass filter (700 ± 10 nm) to the electron-multiplying CCD (EM-CCD, Cooke Corp.). EM-CCD served as a detector array with one-dimension (orthogonal to the line illumination) pixels collecting the lights with different separations from the illumination spot.

The total acquisition time of this OCT–FLOT co-registered system is 10 s for each 3D volume. For OCT, the beam was scanned in two axes. The fast scanning in x-direction was set at the speed of 25 Hz (x-scan was 2.5 mm wide in 624 pixels), and the slow scanning in y-direction was set at the speed of 0.1 Hz (y-scan was 2.5 mm wide in 256 pixels). For line-scanned FLOT, only scanning in y-direction was needed, therefore the scanning speed was the same as OCT y-scan. EM-CCD totally acquired 256 frames, each of which was exposed 30 ms. The resulting OCT 3D volume size is 624 (x) by 256 (y) by 512 (z) pixels (with voxel size of 4 μm × 10 μm × 4.4 μm, and FLOT image raw data is 501 (x) by 1,024 (y) (2.2 mm × 2.2 mm) by 256 frames. The rate-limiting factors were the FLOT CCD frame rate and the high number of OCT images acquired in the y-dimension. This 10 s acquisition time can be reduced by binning the EM-CCD detector arrays and/or reducing the camera field of view (FOV). If focusing on 2D (xz) cross-section imaging (B-scan) only, it shall be possible to perform real-time FLOT imaging by reading only partial regions of the EM-CCD.

51.3 FLOT Theory and Image Reconstruction

Depth-resolved FLOT image is obtained through image reconstruction process similar to that used in DOT [21]. The fluorescence signal $\mathrm{F}\left(\vec{r_d}, \hat{\Omega}_\mathrm{d}, \vec{r_s}, \hat{\Omega}_s\right)\left(\mathrm{Wm^{-2}sr^{-2}}\right)$ can be expressed as [17, 22]:

$$\mathrm{F}\left(\vec{r_d}, \hat{\Omega}_\mathrm{d}, \vec{r_s}, \hat{\Omega}_s\right) = \sigma_{\mathrm{ex}}\gamma \int \Phi_{ex}\left(\vec{r} - \vec{r_s}; \hat{\Omega}_s\right) C_f\left(\vec{r}\right) \widetilde{\Phi}_{em}\left(\vec{r} - \vec{r_d}; \hat{\Omega}_d\right) d^3\vec{r} \quad (51.1)$$

where $\sigma_{\mathrm{ex}}(\mathrm{m^2})$ is the absorption cross section of the fluorophores at the excitation wavelength, γ(unitless) is the spectral quantum yield of the fluorophore, $\Phi_{ex}\left(\vec{r} - \vec{r_s}; \hat{\Omega}_s\right)\left(\mathrm{Wm^{-2}sr^{-1}}\right)$ is the excitation fluence distribution calculated from the excitation photon radiance from a point source located at $\vec{r_s}$ and at the angle $\hat{\Omega}_s$, $\Phi_{em}\left(\vec{r} - \vec{r_d}; \hat{\Omega}_\mathrm{d}\right)\left(\mathrm{m^{-2}sr^{-1}}\right)$ is the probability density that a photon emitted by a source at position $\vec{r}$ will be detected by a detector located at $\vec{r_d}$ and at the angle $\hat{\Omega}_\mathrm{d}$, and $C_f\left(\vec{r}\right)\left(\mathrm{m^{-3}}\right)$ is the fluorophore concentration at position $\vec{r}$. Equation 51.1 can be discretized into voxels, which yields a matrix equation:

$$\mathrm{F} = JC \quad (51.2)$$

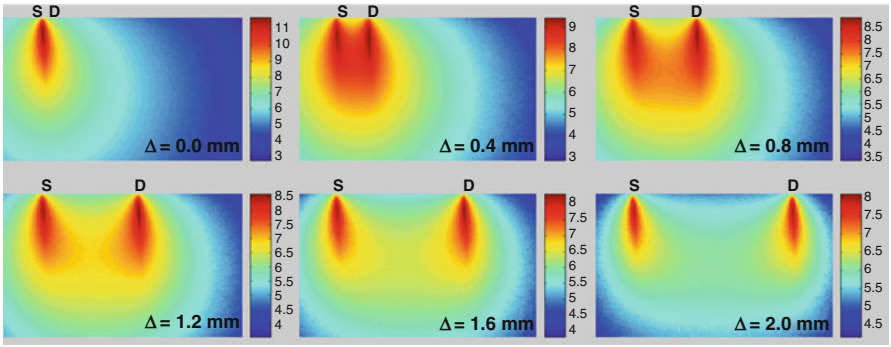

Fig. 51.3 Monte Carlo simulated measurement sensitivity distribution of FLOT measurements (log scale). Tissue geometry was 3 mm (lateral) by 2 mm (depth) with scattering coefficient $\mu_s = 8\ \text{mm}^{-1}$ for excitation and $7\ \text{mm}^{-1}$ for emission ($g = 0.9$) (Reproduced from Ref. [20] with permission © 2010 IEEE)

where F is the fluorescence measurements, C is the spatially distributed fluorophore concentration, and J is the sensitivity matrix that represents the spatial dependence of each measurement to the fluorophore concentration at each voxel. J is expressed as

$$J\left(\vec{r}_d,\vec{r}_s,\vec{r},\hat{\Omega}_s,\hat{\Omega}_\text{d}\right) = \sigma_\text{ex}\gamma\Phi_{ex}\left(\vec{r}-\vec{r}_s;\hat{\Omega}_s\right)\Phi_{em}\left(\vec{r}-\vec{r}_d;\hat{\Omega}_\text{d}\right) \tag{51.3}$$

The sensitivity distribution of FLOT can be calculated using Monte Carlo simulation (see Fig. 51.3). The sensitivity profile varies as the source–detector separation increases as well as the incidence/detection angle. Therefore, depth-dependent information is encoded in the multiple detector measurement and can be recovered through image reconstruction.

Image reconstruction was performed within individual plane (YZ) perpendicular to the illumination line (X). Two main approaches were implemented. First, simultaneous iterative reconstruction technique (SIRT) [23] was used in our phantom experiments and subsurface cancer imaging (Sect. 51.4). The nonnegativity of $C_f\left(\vec{r}\right)$ posts a hard constraint in the reconstruction; in other words, the negative elements will be replaced to zeros after each iteration. Iterations stopped until the change between iterations was <0.1 %. Second, the least square fitting with Tikhonov regularization [11] was used in the engineered tissue imaging (Sect. 51.6). The Tikhonov approach can be expressed as

$$C = \left[J^T J + \lambda^2 S_\text{Max}^2 I\right]^{-1} J^T \text{F} \tag{51.4}$$

where S_Max is the largest singular value in J, superscript $^\text{T}$ stands for transpose operation, and λ is the normalized regularization factor that leverages the signal level and noise level. The criteria of discrepancy principle were implemented to

determine λ, which was typically 3×10^{-4}. Because of explicit inversion, the time of the Tikhonov approach was faster than the SIRT approach. (0.06 s vs. 2 s).

51.4 Results: Phantom Experiments and Subsurface Cancer Imaging

The performance of the OCT–FLOT system was first demonstrated by imaging a tissue phantom, which consisted of a capillary tube with an inner diameter of 110 μm and an outer diameter of 130 μm, suspended in a scattering medium consisting of 2 % Intralipid mixed with Indian ink $\mu_a = 0.2\ \text{mm}^{-1}$, $\mu_s = 7.2\ \text{mm}^{-1}$ at 670 nm, and anisotropy factor $g = 0.9$, similar to those of biological tissues. The tube was filled with 10 μM fluorescent dye Cy5.5.

Figure 51.4 shows the comparison of OCT and FLOT images of a capillary tube phantom. OCT readily images the 3D structure of the tube as shown in Fig. 51.4a. Figure 51.4b shows the comparison of OCT cross-sectional image (YZ) and FLOT image at location "1" denoted in (A). Cross-sectional OCT revealed the capillary tube (indicated by the arrow) with approximately 0.6 mm beneath the surface. FLOT cross-sectional image showed a fluorescence object at the same location, with a slightly larger size due to the relatively larger FLOT resolution compared to OCT. Cross-sectional OCT and FLOT images at location "2" also showed good

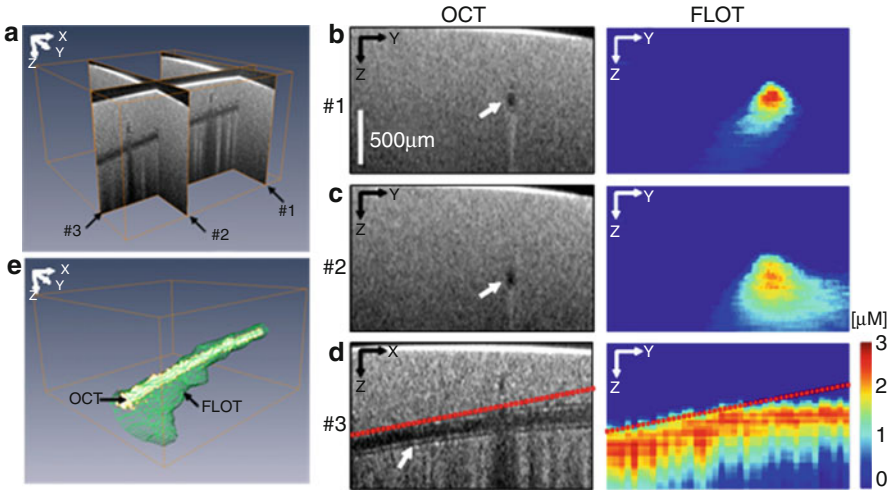

Fig. 51.4 Co-registration of OCT and line-scan FLOT of a capillary tube filled with fluorescence dye. (**a**) 3D OCT imaging showing three representative slices. (**b**) *Left*, OCT image (slice #1) of the capillary tube (*arrow*); *right*, FLOT image reconstruction of the fluorescence object. (**c**) OCT and FLOT images of different position (slice #2). (**d**) OCT and FLOT image (slice #3) reveal the curvature of the capillary tube (two identical *dotted lines* serve as the reference slopes). (**e**) 3D isosurface of FLOT image showed good co-localization with OCT (Reproduced from Ref. [19] with permission © 2009 OSA)

agreement with the tube depth of approximately 0.9 mm (Fig. 51.4c). Compared to (B), the FLOT image for deeper object showed slight enlargement in size. In addition, the peak values were slightly reduced when the object went deeper due to the enlargement of the reconstructed object size. Figure 51.4d shows the OCT cross-sectional image along the tube's longitudinal dimension (XZ). The tube was placed at an angle with respect to the horizontal axis, and slightly bending flat. The FLOT image (XZ) revealed similar contour of the capillary tube as shown by OCT. Also, this image was averaged over a range of 150 μm in y-dimension across the central axis of the tube; therefore, the results indicated nearly constant fluorophore concentration. Here OCT provided the structural information of the phantom, and the FLOT reconstructed image provides the fluorescence dye distribution information. In biomedical applications, FLOT would provide fluorescence-dye-targeted molecular information. Together, the hybrid OCT–FLOT system can be used for concurrent depth-resolved tissue structural and molecular imaging.

Using the same system, an animal model of breast cancer was imaged [20]. A triple negative human breast cancer cell line, MDA-MB-231, originally expanded from a pleural effusion, was obtained from the American Type Culture Collection (ATCC). Plasmid DNA encoding tdTomato (pRSETB-tdTomato) was cloned into the mammalian expression vector pEF-1α-myc/his (Invitrogen, Carlsbad, CA) generating pEF-1α-tdTomato. pEF-1α-tdTomato was stably transfected into MDA-MB-231 cells using the Amaxa Nucleofector II instrument (Amaxa Biosystems, Gaithersburg, MD), followed by fluorescence-activated cell sorting (FACS) of tdTomato-fluorescing cells, and further expansion without antibiotics. Prior to inoculation, MDA-MB-231-tdTomato cells displayed intense tdTomato fluorescence in cell culture as tested with live cell fluorescence microscopy [24].

One hundred thousand to two million MDA-MB-231-tdTomato cells were orthotopically inoculated in the mammary fat pad of anesthetized female athymic nude mice as previously described [25]. Tumor xenografts reached their final experimental size of about 5 mm^3 within 4 weeks. In vivo whole-body fluorescence imaging of MDA-MB-231-tdTomato tumor xenografts was confirmed using a commercially available optical imaging system, the Xenogen IVIS 200 Spectrum (Caliper Life Sciences, Hopkinton, MA) before in vivo OCT–FLOT imaging under anesthesia.

Figure 51.5 shows OCT–FLOT imaging of human breast cancer xenograft model in vivo. Figure 51.5a shows an OCT cross-sectional image of the breast tumor. The high scattering mouse skin layer limited the penetration depth. However, the boundary between the skin and the tumor remained visible (arrow). Figure 51.5b shows the co-registered FLOT image revealing the subcutaneous tumor (which was transfected with red fluorescence protein). Figure 51.5c is the fused OCT–FLOT image which shows the relative position and distribution of tumor regions underneath the skin. Figure 51.5d shows the corresponding histology confirming the presence of tumor. Figure 51.5e shows the OCT cross-sectional image of another region of the breast tumor. The boundary between skin and tumor

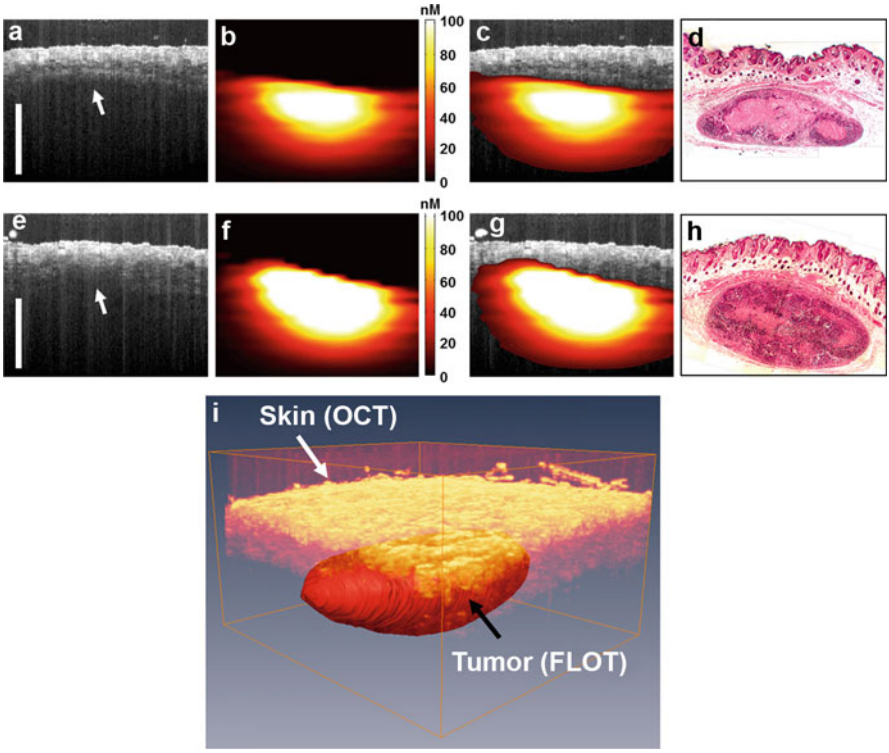

Fig. 51.5 OCT–FLOT of subcutaneous human breast tumor xenograft on mouse model in vivo. Breast cancer cells (MDA-MB-231) were constitutively labeled with tdTomato red fluorescence protein. (**a**) OCT cross-sectional image of breast tumor. Mouse skin layer shows high scattering, and the boundary between skin and tumor is clearly visible (*arrow*). (**b**) Co-registered FLOT image revealing subsurface tumor. (**c**) Fused OCT–FLOT image and (**d**) the corresponding histology. (**e**) OCT cross-sectional image of another region of the breast tumor. The boundary between skin and tumor was less well defined (*arrow*). (**f**) Co-registered FLOT image revealed a larger tumor volume than (**b**). (**g**) Fused OCT–FLOT image. The corresponding histology (**h**) confirmed the larger tumor size than (**d**). (**i**) Subcutaneous breast tumor xenograft in vivo was rendered in 3D. Tumor cells were transfected with red fluorescence protein (*RFP*) and displayed as isosurface of 30 nM of calibration dye Rhodamine 6G. Tumor size: $2.2 \times 2.3 \times 0.9$ mm^3. Bar: 1 mm (Reproduced from Ref. [20] with permission © 2010 IEEE)

was less well defined (arrow) indicating tumor invasion. Figure 51.5f shows the co-registered FLOT image revealing a larger tumor volume than that shown in (B). Figure 51.5g shows the fused OCT–FLOT image. The corresponding histology (h) confirms the larger tumor size than (d). Assuming oval-shaped tumor, FHWM of the long and short axes of the tumor were 2.17×0.92 mm^2 for the smaller tumor region (b) and 2.50×1.11 mm^2 for the larger tumor region (f). The histology findings indicated that the tumor sizes were 2.30×0.83 mm^2 and 2.33×1.25 mm^2, respectively (d, h). These results indicated that FLOT can visualize the difference in subsurface tumor sizes. Figure 51.5i shows the 3D view of mouse skin (from OCT)

and subsurface tumor (from FLOT). This result demonstrates the feasibility of simultaneous morphological and molecular imaging of subsurface tumor in mesoscopic scale using OCT–FLOT.

51.5 Improvement of FLOT Resolution Using Angled Configuration

One of the limitations for our current FLOT system is that the point spread function (PSF) enlarges when the object locates deeper [11, 20]. Our previous measurement (see Fig. 51.4e) indicated that the axial PSF was ~100 to 200 μm at ~0.6 mm depth and increased to ~300 to 400 μm at ~1 mm depth [20]. To overcome this limitation, we investigated the effects of source and detector angles on the imaging performance [26]. Previous work in optical spectroscopy suggests that using angled illumination–collection design (oblique illumination–collection) will enhance the depth selectivity of epithelium tissues [27–31]. The angular degree of freedom in the illumination and detector arms is investigated first using the theoretical analysis and simulation. Then we implemented this design and experimentally demonstrated that angled FLOT (aFLOT) increased the depth selectivity and resolution.

51.5.1 Theoretical Analysis and Simulation

Singular-value analysis (SVA) is a method to evaluate the richness of the content of the sensitivity matrix J by decomposing J into an eigenvalue spectrum and has been demonstrated in the optimization of DOT to achieve a favorable image resolution [32, 33]. SVD of J yields a triplet of matrices: $J = USV^T$. The magnitude of the singular values in S provides a measure of the relative effects of these image-space modes on the detected signal. These singular values are arranged in a magnitude-decreasing order with increasing image-space mode indices. In this study, we used SVA to investigate the optimization of resolution and sensitivity by varying the FLOT source incidence angle and detector detecting angle. For convenience, we studied cases where both angles were equal.

Figure 51.6 shows the sensitivity profiles of FLOT for a representative source–detector pair based on Monte Carlo simulation. Configurations with 0° (top row) and 30° (bottom row) incidence and detection angles showed distinct sensitivity patterns. For each configuration, different scattering coefficients (μ_s = 50, 100, and 150 cm^{-1}) were chosen as the background medium (left to right). The sensitivity map indicates the probability density of photons delivered to each location by the source and captured by the detector. Photon paths were more ballistic for low-scattering medium (μ_s = 50 cm^{-1}) but became more scattered in high-scattering medium (μ_s = 150 cm^{-1}). A set of singular values (SVs) of J are generated for each angle from 0 to 50° with 10° increment and plotted in Fig. 51.7. Figure 51.7a–c corresponds to different background scattering coefficients

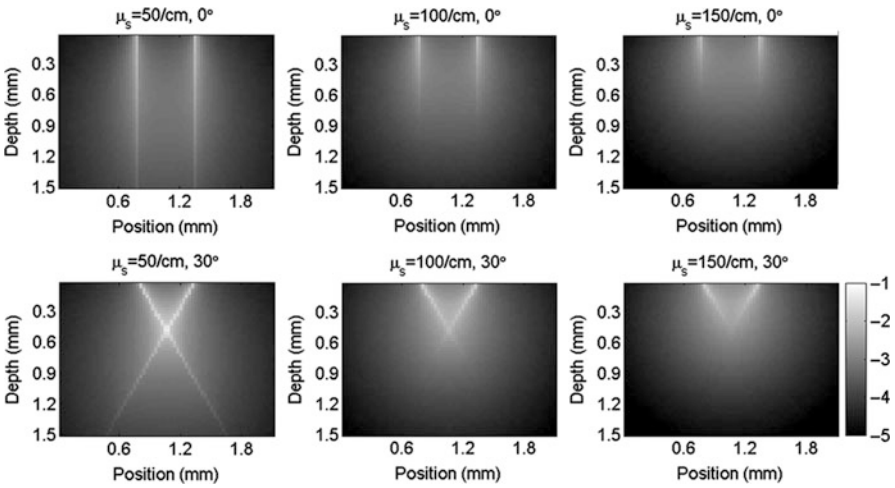

Fig. 51.6 Sensitivity maps (in log10 scale) for source–detector pair with 0° (*top row*) and 30° (*bottom row*) incidence/detection angles. For each configuration, a different scattering coefficient is specified for the medium (*left* to *right*). The sensitivity map indicates the probability density of photons delivered to the location by the source and captured at the location by the detector (Reproduced from Ref. [26] with permission © 2011 World Scientific Publishing Company)

(μ_s = 50, 100, 150 cm^{-1}, respectively). The threshold for the singular-value analysis was set to $10^{-3.6}$ (corresponding to the dynamic range of our EM-CCD detector). The number of SVs above the threshold represented a measure of the useful information contained in that data for image reconstruction. Figure 51.7d plots the number of useful SVs above the threshold for different scattering coefficients. From this figure, 30° configuration had the highest number of useful SVs, especially in low-scattering medium. It also showed that the angular advantage diminishes with increasing background scattering, because photons lose directionality in highly scattering medium, and as a result, both source and detector become more isotropic.

To validate the results from singular-value analysis, we performed image reconstruction of a point object (with unit intensity) under different configurations, using simulated measurement data (with 1.5 % Gaussian noise added). The point spread function along axial (z) direction through the position of a point object was quantified. As expected, axial point spread function (PSF_z) broadened, and its peak intensity decreased as the point object placed deeper. The details of PSF_z were further analyzed using two parameters: (1) the reconstructed peak intensity (or depth sensitivity) and (2) the interquartile range (IQR). IQR represents the range that bounds 50 % area centered around the maximum value under the PSF curve. IQR provides a more stable estimate of spread than FWHM in the presence of long-tail distribution [34]. Figure 51.8a–d shows the PSF_z peak intensity (or depth sensitivity) verses depth for different configurations. In general, at a given depth,

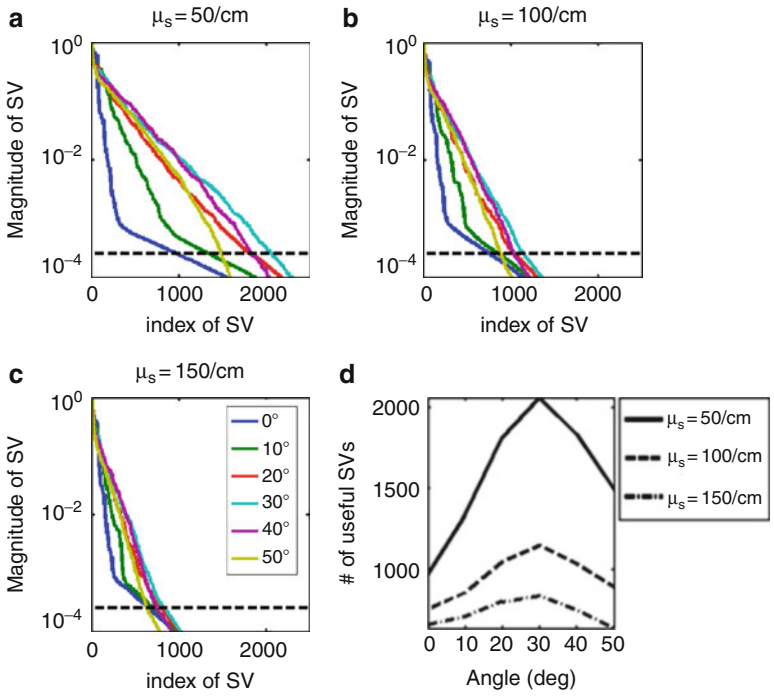

Fig. 51.7 Comparison of singular-value (*SV*) distributions among different incidence/detection angles. For convenience, same incidence and detection angels are specified. (**a**) SV distribution for $\mu_s = 50\,\mathrm{cm}^{-1}$, (**b**) SV distribution for $\mu_s = 100\,\mathrm{cm}^{-1}$, and (**c**) SV distribution for $\mu_s = 150\,\mathrm{cm}^{-1}$. Detection threshold was specified as $10^{-3.6}$ (*dotted horizontal lines* in **a**–**c**). Only SV above the threshold was considered carrying useful information for image reconstruction. (**d**) Plot of the number of SV above the threshold. FLOT arranged in 30° had more useful SVs than other configurations. It also showed the decrease of the angular advantage with increasing scattering (Reproduced from Ref. [26] with permission © 2011 World Scientific Publishing Company)

the 30° configuration had higher peak intensity (sensitivity) than 0° configuration, especially in the shallower depth region. The difference becomes less prominent for high-scattering medium. It is interesting to note that when normalizing these sensitivity curves to mean free path (MFP) ($1/\mu_s$) (i.e., replacing d with $\mu_s d$ in *x*-axis of the plot), only 30° configurations group together, as shown in Fig. 51.8d. The fact that normal configurations were not unified indicates that the underlying mechanisms between angled and normal configurations were different as photons significantly rely on backscattering to travel from source to detector in normal configurations, while the incidence and detection paths overlap in angled configurations. When normalized to MFP, the backscattering factor (as in 0° configuration) might not be linearly scaled.

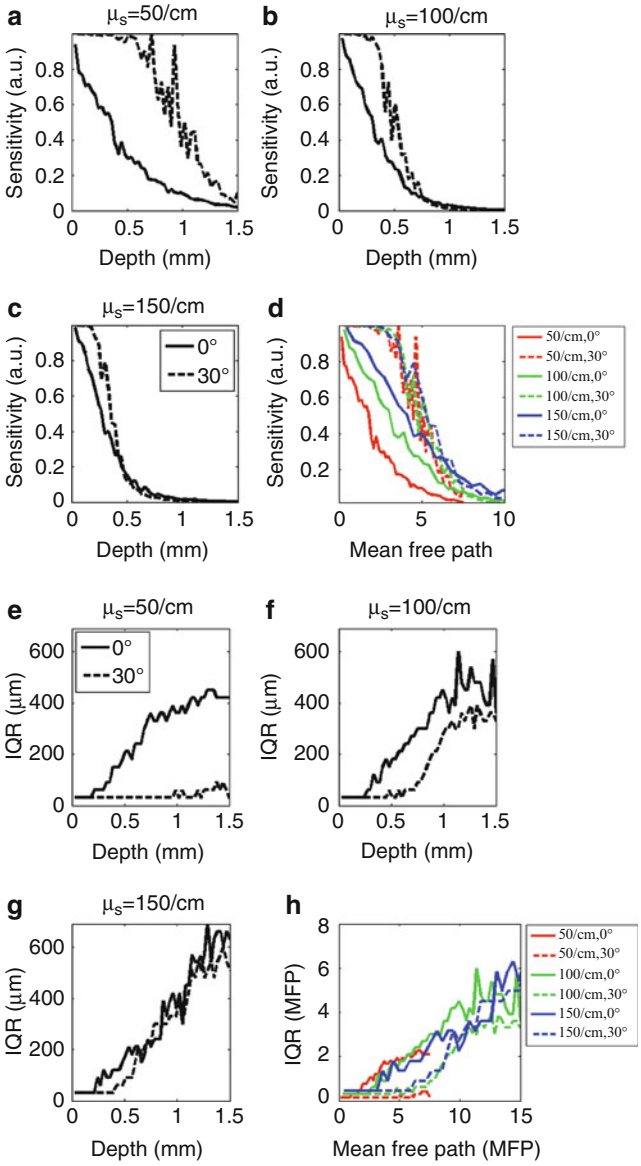

Fig. 51.8 (**a**–**d**) PSFz peak intensity verses depth for different source–detector angle configurations and background scattering. (**e**–**h**) PSFz interquartile range (*IQR*) verses depth for different source–detector angle configurations and background scattering coefficients (Reproduced from Ref. [26] with permission © 2011 World Scientific Publishing Company)

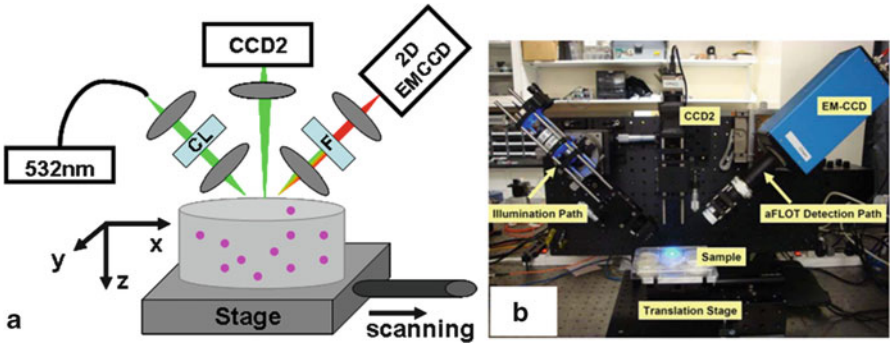

Fig. 51.9 (**a**) Schematic of the aFLOT system. *CL* cylindrical lens, *F* filter. (**b**) Photo of the 45–45° aFLOT system. The illumination–detection arms are arranged at 45° in air (or 30° inside the sample assuming an index of refraction of 1.4)

Figure 51.8e–h plot the IQR of PSF_z verses depth for different configurations. In general 30° configuration had smaller IQR (higher axial resolution) than 0° configuration. Especially, in low-scattering medium, IQR for 30° configuration remained ~30 μm up to 1 mm deep, and remains <100 μm up to 1.5 mm deep. In contrast, IQR for 0° configuration increased rapidly to ~400 μm at 1 mm deep. However, the difference between these two configurations becomes less prominent as background scattering coefficient increased, and as a result, the IQRs for both configurations were almost identical for high-scattering medium. Again, when normalized to MFP as shown in Fig. 51.8h, the grouping of the curves was observed. However, different from the sensitivity, the grouping (unifying) of IQR curves occurred at both normal and angled configurations. This result also indicated that IQR and sensitivity provide inherently different measures.

51.5.2 Experimental Validation

Figure 51.9 shows the schematic diagram and the photo of the angled FLOT system. Similar to our previous FLOT system, the excitation light source was expanded into line-field illumination using a cylindrical lens (CL). An emission filter (F) was placed in the detection axis to select only the fluorescence signal, which was recorded by the 12-bit EM-CCD. Another CCD (CCD2) was placed vertically to record the reflected light distribution to determine the reduced scattering coefficient of the sample using the technique of oblique-incidence reflectometry [35]. When acquiring aFLOT measurement, the translating stage was moved in y-direction (perpendicular to the line illumination along X) with a speed of 50 μm/s. EM-CCD recorded each XY frame with 0.4 s exposure time, and the total recording time was 170 s for one 3D dataset XYT.

Image reconstruction converted each YZ plane (2D) from YT measurements using Tikhonov regularization. In this study, 70 source–detector (SD) pairs with

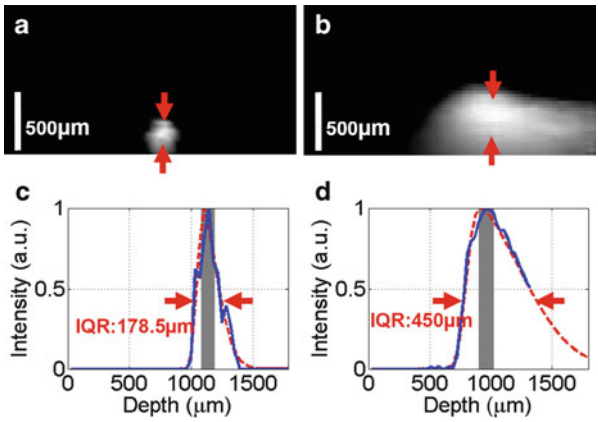

Fig. 51.10 Comparison of aFLOT (**a**, **c**) and conventional FLOT (**b**, **d**). (**a**, **b**) cross-sectional reconstruction; (**c**, **d**) axial profile through the center of the object. Gray area denotes the true dimension of the capillary tube. *IQR* Interquartile range

70 scanning positions were used to determine a single YZ FOV of 3 × 3 mm^2. Local YZ frames were then pieced together longitudinally to form a global FOV in YZ.

We then validated aFLOT imaging experimentally using the capillary tube phantom again. The capillary tube (110 μm in diameter) was filled with 1 μM fluorescent dye Rhodamine 6G and embedded at 1.2 mm deep inside 1 % Intralipid. The excitation wavelength was set to 532 nm and the filter was set to 605 ± 15 nm, based on the spectrum of Rhodamine 6G. Figure 51.10a shows the cross section of the reconstructed capillary tube phantom using aFLOT. The position of the capillary from the reconstructed image (∼1.14 mm) was close to the position independently measured using OCT (∼1.2 mm). As a comparison between angled and conventional FLOT systems, Fig. 51.10b shows the reconstruction using FLOT with normal incidence/detection. Figure 51.10c, d illustrates the central axial profiles of the reconstructed capillary tube shown in Fig. 51.10a, b, respectively. Quantitatively, interquartile range (IQR) was measured and compared. The measured IQR was 178.5 μm for the aFLOT system and was 450 μm for the conventional FLOT. This represents approximately 2.5-fold improvement in axial resolution when using aFLOT.

51.6 Results: Imaging Engineered Tissues

Regenerative medicine has emerged as an important discipline which aims at introducing living cells or functioning tissues to repair injury or replace damaged tissues or organs which lose functions. Optimization of regenerative medicine strategies includes the design of biomaterials, cell-seeding methods, cell-biomaterial interactions, and molecular signaling within the engineered tissue. One challenge is to nondestructively observe and quantify the distribution and migration of seeded cells throughout the bulk scaffold. The development of tissue

engineered products is limited by the lack of laboratory imaging techniques which are capable of nondestructive imaging of the three-dimensional morphology as well as the cell response of a tissue engineering scaffold. The current method for quantifying 3D cell distribution involves fluorescent confocal microscopy imaging of cryosectioned scaffolds followed by digital 3D image recompiling [36]. Although robust, this approach is destructive and time consuming, thereby may become a concern in longitudinal inspection of massive amount of samples.

FLOT (and aFLOT) overcomes the depth limitation of confocal microscopy by using multiple detectors to collect photon traveling through different depths. In this study, we experimentally demonstrated aFLOT imaging of two types of engineered tissues, respectively. Mesenchymal stem cells (MSCs) embedded in homogeneous EH-PEG hydrogels [37], which is low scattering ($\mu_s = 10$ cm^{-1}), was imaged through an incidence/detection angle of 45–45° aFLOT (as shown in Fig. 51.9). In the other experiment, a capillary (100 μm in diameter) containing 1 mM rhodamine 6G was embedded in a heterogeneous macroporous EH-PEG hydrogel [38, 39], which is high scattering ($\mu_s = 110$ cm^{-1}). This phantom was imaged through 45–0° aFLOT. The tomography of capillary was reconstructed and co-registered with that from OCT.

In the first experiment, we used the aFLOT system to image MSC distribution inside a low-scattering, homogeneous EH-PEG hydrogel [37], one common engineered tissue scaffold used for bone regeneration. To mimic cell migration, we controlled the cell-distribution thickness by preparing a bilayer phantom. The bottom layer was pure EH-PEG and was intentionally prepared thick (>6 mm). The top layer was EH-PEG mixed with MSCs (cell density = 10^4–10^5/mL) with thickness of 0.5, 1, 2, and 3 mm. Homogeneous EH-PEG had low scattering as shown in Fig. 51.11a, with typical reduced scattering coefficient of ~1 cm^{-1}, estimated by reflectometry [35]. For reconstruction, Monte Carlo simulation was performed to estimate photon distribution inside homogeneous EH-PEG. Optical properties of EH-PEG, including anisotropy $g = 0.9$, refractive index = 1.33, and absorption coefficient of 0.1 cm^{-1}, were assumed.

Figure 51.11b shows a YZ cross section from stacking of a homogenous EH-PEG phantom with top layer (2-mm thick) containing MSC, and Fig. 51.11c shows that from FLOT reconstruction. Stacking (as used in conventional 3D digital microscopy) provides a blurred yet quick 3D view of the sample due to the weak but nonzero scattering of the sample. FLOT image reconstruction using proper modeling improves the image quality as shown in Fig. 51.11c. Figure 51.11d is the composite 3D reconstruction of the same phantom. The FOV was 6.5 × 7.6 × 2.9 mm^3. Figure 51.11e renders together the phantoms with 0.5, 1, 2, and 3-mm thick MSC distributions on the top layer. Lastly, we show the histogram of stem-cell depth distribution of all four samples. The estimated cell-distribution depths were distinct and consistent with the nominal thickness of each sample during fabrication. One interesting point is that all the cell-distribution patterns peaked at the bottom surface, which may be attributed by

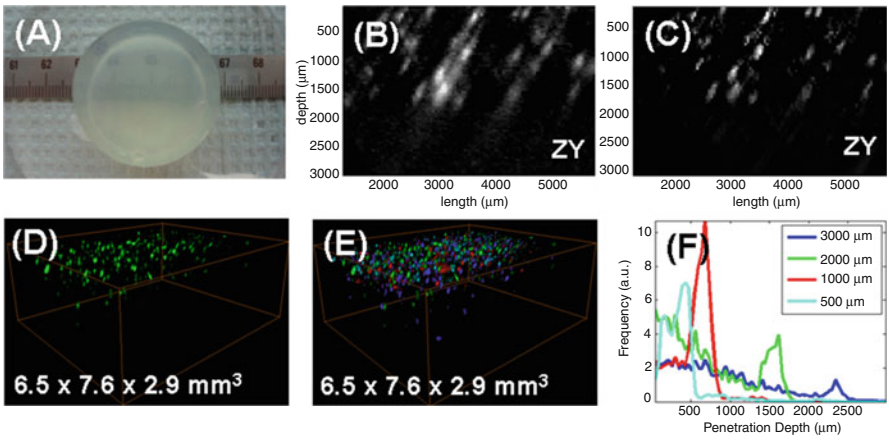

Fig. 51.11 3D aFLOT imaging of EH-PEG hydrogels with stem cells embedded at top layers. (**a**) Photo of a sample. Transparency indicates low scattering. (**b**) Stacking representation of a YZ cross section of the hydrogel with 2-mm thick top layer containing MSC. (**c**) Reconstruction of the same YZ cross section. Image reconstruction through Tikhonov regularization made MSC clearer. (**d**) 3D reconstruction of the same sample. (**e**) Combined view of four samples with different stem-cell-laden layer thickness: 0.5-mm (*cyan*), 1-mm (*red*), 2-mm (*green*), and 3-mm (*blue*). (**f**) Histogram of cell distribution

the condensation of cells or interface reflection. Further research is needed to confirm this finding. In addition, from Fig. 51.8, the detection sensitivity dropped toward deeper region so that the histogram also showed that the peaks declined toward deeper region. In summary, Fig. 51.11 demonstrates that aFLOT can resolve the depth-dependent distribution of cell clusters in the weakly scattering EH-PEG hydrogel.

In the second set of experiments where highly scattering macroporous EH-PEG was of interest, we changed the illumination–detection angles to 45–0° configuration for two reasons. First, we expected that the advantage of the 45–45° configuration diminished as the sample scattering coefficient was higher. Second, the camera could not maintain in focus over a few millimeter FOV if placed at 45°. We embedded a capillary tube (100 μm in diameter) containing 50 μM fluorescent dye indocyanine green (ICG) in a macroporous EH-PEG hydrogel, which was highly scattering at visible wavelength ($\mu_s = 110\ \text{cm}^{-1}$ at 530 nm). The scattering coefficient was reduced at near-infrared (NIR) wavelength ($\mu_s = 50\ \text{cm}^{-1}$ at 780 nm). This phantom was imaged through FLOT with 780 nm excitation. The FLOT tomography of the capillary was reconstructed and co-registered with that from OCT. Figure 51.12a shows the co-registered XZ and YZ cross sections. Figure 51.12b shows 3D FLOT image of the fluorescent capillary co-registered with macroporous EH-PEG hydrogel obtained by OCT. In this experiment, we demonstrated the capability of aFLOT imaging in heterogeneous macroporous scaffolds. These results indicate that OCT–FLOT represents a promising imaging

technique to quantify the depth-resolved fluorophore distribution information in engineered tissue scaffold for investigating cell scaffold cellular and molecular interactions in situ.

51.7 Conclusion

In this chapter, we provided a summary of the instrument and algorithm for combined OCT–FLOT system for biomedical applications. Co-registered OCT morphological and FLOT molecular information can be resolved at millimeter imaging scale, which has strong potential to provide depth-resolved tissue structural and molecular imaging. This unique multimodality platform represents a new multimodal imaging regime that bridges the macroscopic and microscopic imaging regimes. By varying the source incidence and/or detector collection angles, angled FLOT promises to enhance the imaging resolution and depth sensitivity, especially for low-scattering medium. Examples of OCT–FLOT imaging of subsurface tumor and stem-cell-laden hydrogels are presented. OCT–FLOT could be a useful tool for investigating tissue structural and functional relationship in mesoscopic (mm) scales. Future work will focus on the utilization of OCT structural image as the a priori information to improve FLOT reconstruction.

Acknowledgment We acknowledge Dr. David Boas from Massachusetts General Hospital (MGH) for providing the Monte Carlo simulation code (tmcimg), and Drs. Heng Lian (NanYang Technological University, Singapore), Quan Zhang (MGH), and Qianqian Fang (MGH) for technical assistance in modifying the code. We also acknowledge the collaboration with Dr. James Jiang and Alex Cable (Thorlabs, Inc.) on OCT imaging, Drs. Kristine Glunde and Venu Raman (Johns Hopkins University) for breast cancer imaging, and Dr. John Fisher (University of Maryland) on tissue engineering and stem-cell imaging. tissue scattering and absorption, respectively [1–10]. In practice, however, there exist limitations to combining OCT and PA using conventional methods for PA signal acquisition, and thus, there have been relatively few successful demonstrations of a combined approach. Of the multimodal systems that have been presented, one that may offer a solution for translation to clinical use employs an all-optical ultrasonic detection technique based on a Fabry-Perot interferometer (FPI)-based sensor. This chapter chronicles the efforts towards combining PA imaging and OCT, with a focus on a PA tomography (PAT)/OCT system that uses this FPI sensor for all-optical detection.

52.1.1 Photoacoustic Microscopy Versus Tomography

PA signals are generated using the photoacoustic effect: tissue is irradiated with short (typically nanosecond) pulses to create a localized thermal increase in endogenous absorbers such as hemoglobin and melanin or exogenous absorptive contrast agents. Absorption of these pulses leads to an initial pressure distribution, which results in broadband ultrasonic waves that propagate through tissue and any acoustic coupling medium and are detected via a transducer.

The majority of biological tissues are highly scattering, and most biological optical imaging techniques detect ballistically scattered photons and thus cannot penetrate further than one transport mean free path of isotropically scattered photons, or approximately 1 mm in depth [11]. Photon propagation transitions from ballistic to diffusive at one transport mean free path, and techniques that rely on the detection of multiple scattered photons in the diffusive regime, such as diffuse optical tomography (DOT), exhibit higher depth penetration with lower resolution. Photoacoustic techniques, however, allow for higher resolution than DOT because ultrasonic scattering is weaker than optical scattering. Hence, there are two main advantages offered by PA imaging over other optical approaches: the potential to reach higher depths and the possibility to access absorption properties of tissue.

In PA imaging, depth penetration and resolution are scalable. High axial resolution can be attained using an excitation laser with short (e.g., 1–10 ns) pulses and an acoustic detector with a high central frequency and broad bandwidth, and high

lateral resolution can be accomplished with a high numerical aperture lens to focus the excitation beam. An axial resolution of 7.6 μm has recently been demonstrated [12], and submicron lateral resolution has also been presented [13]. While penetration depth increases with lower frequency transducers, spatial resolution suffers with increased depth. Kruger et al. reported imaging of up to 40 mm using a 5 MHz transducer and 800 nm excitation source, but the axial resolution was only 250 μm [14].

Excitation of PA signals via illumination with either a focused or an unfocused light source and detection via focused or unfocused transducers has been accomplished. Though the naming convention varies in the literature, different modes of imaging exist which can generally be defined as follows:

- Optical resolution photoacoustic microscopy (OR-PAM): focused excitation beam. Lateral resolution is defined by the dimensions of the excitation beam and axial resolution is acoustically defined. OR-PAM relies on the detection of ballistic photons, so the maximum penetration depth is ~1mm. The detector can be focused or unfocused.
- Acoustic resolution photoacoustic microscopy (AR-PAM): focused detector. Lateral and axial resolution is acoustically defined. Excitation beam can be focused or unfocused but does not affect spatial resolution.
- Photoacoustic tomography (PAT): wide-field unfocused excitation beam, scanning planar transducer, or array of unfocused transducers that requires the use of reconstruction techniques to obtain an image.

52.1.2 Practical Limitations to Detecting PA Signals with Conventional Ultrasonic Transducers

One of the major constraints in the design of PA systems specifically for combination with OCT is that traditional approaches use scanned detectors or arrays with multiple detection elements so the physical size of the sensor obstructs the optical path required for OCT A-scan acquisition. Single element scanned transducers have been employed, where excitation of tissue occurs via a ring of illumination around the detector, allowing for backward (reflection)-mode detection of PA signals [15]. A problem with this approach, however, is that detector sensitivity scales with active element size, so while OCT acquisition might be possible using a small transducer that does not obstruct the beam, this would be at the expense of sensitive acoustic signal detection. In addition, measurement time using a single element detector is limited by mechanical scanning. While transparent transducer arrays may eventually offer a solution [16] with multiple detection channels allowing rapid acquisition of B-mode images and a transparent window for OCT measurement, further development of these arrays in PA systems is required.

52.1.3 Multimodal PA and OCT Systems

The combination of PA and OCT imaging systems has been presented by multiple groups [2, 3, 7–10, 17]. These systems allow access to both absorption and

scattering information from tissue and also have the potential to be used for functional information (e.g., spectroscopic PA imaging) with high-resolution structural context (from the detection of backscattered light with OCT) in one system [4]. Because published configurations, resolution, speed, and wavelength vary substantially, a summary of the **reported specifications from systems published to date is presented in Table** 52.1.

52.1.3.1 PAM/OCT

Li et al. demonstrated the use of OR-PAM/OCT for evaluating microcirculation in the mouse ear in 2009 [3]. The depth range was estimated to be 1.5 mm for OR-PAM, which was comparable to the 1.8 mm depth for OCT. While this was the first effort to show the feasibility of a multimodal combination with OCT, the transmission (forward) mode configuration required the sample to be very thin. In addition, a mechanically translated objective meant very slow acquisition time (2.5 frames/s), which further limits the application of this configuration. Despite these restrictions, the system was later used to look at neovascularization of a tissue scaffold in anesthetized animals, with the relatively thin mouse ear again used as a model [1].

An effort by Jiao et al. in 2009 looked at the microvasculature of the mouse ear using backward mode detection with an unfocused 15 MHz ultrasound transducer [2]. The authors presented synchronized simultaneous acquisition, though the measurement rate was limited by the excitation pulse repetition rate of the PAM system to 1,024 Hz, whereas a 24 kHz A-scan acquisition would have been possible given their OCT CCD integration time. Liu et al. applied this system for spectroscopic measurements (at 570 nm, 578 nm, 588 nm, and 590 nm) to measure oxygen saturation (sO_2) with a custom-built unfocused 35 MHz needle transducer [4]. They used these sO_2 levels together with Doppler OCT blood flow velocity and total hemoglobin concentration (from laboratory-based blood tests) to measure the metabolic rate in the mouse ear.

52.1.3.2 PAM/OCT for Ophthalmic Applications

Because one of the most common clinical applications of OCT imaging is in ophthalmology, a natural extension of multimodal PAM/OCT imaging is for in vivo retinal imaging. Access to absorption-based contrast could be used to evaluate the retinal pigment epithelium in diseases like age-related macular degeneration, and sO_2 measurements might be used to assess blood vessel status in diabetic retinopathy. Jiao et al. presented a combined PAM/OCT ophthalmoscope system that used an unfocused transducer placed directly on the sclera to acquire preliminary in vivo images of the rat retina at a 93 Hz frame rate (256 A-scans/frame; volumetric image in 2.7 s) [17]. The pulse energy of the excitation laser source was 10 μJ at the output of the laser and estimated to be less than 40 nJ/pulse at the sample. In a study published in 2012 by Song et al., this PAM/OCT system was further extended to include additional modalities like scanning laser ophthalmoscopy and fluorescein angiography and again demonstrated in the rat retina [5]. Despite these preliminary demonstrations in animals, it is unclear whether the pulse energy necessary to generate a PA signal is within the maximum permissible exposure limitation for the human retina.

52.1.3.3 PAM/OCT with a Single Light Source

Using a single light source for PAM excitation and OCT imaging would have several advantages including increased portability and simpler co-registration and synchronization. The first demonstration of a single pulsed light source for PAM/OCT by Zhang et al. (2012) is promising but has some important limitations [7]. Because the same light source and delivery system were used, the images were laterally co-registered. However, the source operates in the visible light range ($\lambda_o = 580$ nm, $\Delta\lambda = 20$ nm), where exposure limits are lower than at near-infrared (NIR) wavelengths and there is shallower penetration into tissue. In addition, the spectrum was very noisy and the quality of the OCT images suffered as a result. The source was also not operated at the maximum pulse repetition rate (30 kHz) but instead at 5 kHz. Considering these factors and the limited source bandwidth and axial resolution, this solution is suboptimal for most biological applications of OCT.

Lee et al. have presented PAM/OCT imaging of black and white human hair using a single nanosecond-pulsed supercontinuum NIR laser source [9]. The output range was 600–1,700 nm, though the spectrometer limited detection to between 650 and 900 nm, with the dominant wavelength band beyond 1,064 nm, making this wavelength range more appropriate for OCT imaging. However, many endogenous molecules that would provide spectroscopic contrast for PA imaging, such as hemoglobin, do not exhibit maximum absorb in this wavelength range. Furthermore, the forward mode configuration for PAM detection would limit any potential in vivo applications to thin samples, and the sample is translated mechanically, limiting the imaging speed.

52.1.3.4 Endoscopic Delivery

A step towards intraoperative PA and OCT imaging was made by Yang et al., who developed a miniaturized probe for endoscopic measurements of PAM/OCT signals along with conventional pulse-echo ultrasound [6]. The excitation pulse repetition rate was 15 Hz, which limited the speed of acquisition, but they presented sequential imaging of ex vivo of ovarian tissues at 740 nm with excitation energy of 1 mJ/pulse. The endoscope had a 5 mm diameter. Xi et al. also recently demonstrated PAM/OCT detection using a smaller endoscopic delivery probe with a diameter of 2.3 mm. Their system consisted of a low-frequency unfocused 10 Hz transducer with time-domain OCT detection at 1 kHz [10]. If scanning speed can be improved, these delivery systems may further extend the clinical utility of multimodal PA/OCT imaging.

52.1.3.5 All-Optical Detection

A major drawback to several of the multimodal approaches presented above – and the reason many of them have only been demonstrated in the mouse ear – is their forward mode detection configuration. Backward mode optical detection methods may eventually offer a more practical alternative with respect to clinical translation.

Noncontact photoacoustic sensing by optically probing tissue has recently been demonstrated [18–24]. These methods optically detect the displacement of tissue that occurs upon an acoustic wave reaching the surface. Especially promising for combination with OCT are approaches that use low-coherence interferometry (LCI) for

acoustic sensing. Wang et al. presented a method for PAM using homodyne LCI detection of surface displacement [24]. This approach, however, is very sensitive to ambient vibrations, which can change the optical path length more than the path length change that is expected from a PA disturbance. To account for this, the authors synchronized acquisition to the point at which the interferometer is most sensitive. One drawback to their approach is that their configuration only allows for combination with time-domain OCT detection, limiting their acquisition speed. The approach by Blatter et al. demonstrated simultaneous PA/OCT imaging using phase-sensitive swept-source OCT, which could potentially be much faster [18]. Currently, however, their implementation is limited to mechanically scanning the sample.

The next section (Sect. 52.2) describes the transduction of PA signals using an optical detection mechanism based on an FPI sensor and its combination with OCT as presented by Zhang et al. in 2011 [25]. To date, this is the only method to have been applied for in vivo human imaging.

52.2 Multimodal All-Optical PAT and OCT Imaging with Fabry-Perot Sensor

Beard and colleagues first described the fundamental principles of backward mode ultrasonic detection using a FPI sensor with an interrogation laser in 2004 [26]. There are multiple advantages associated with this optical approach over conventional sensing techniques for multimodal imaging. The sensor:

- Is interrogated using a laser in backward mode configuration, which means it is not necessary for the sample to be very thin
- Can be designed to have a transmission window that allows for combination with OCT at 1,050 nm

This section describes sensor transduction of ultrasonic signals in the context of one implementation of a PAT system combined with a spectral-domain OCT system at 1,050 nm [8].

52.2.1 Optical PAT Signal Detection Using Fabry-Perot Polymer Film Sensor and Interrogation Laser

The functional unit of the FPI ultrasonic transducer consists of two dielectric optical coatings that form the mirrors of an interferometer and are separated by a polymeric film spacer (Fig. 52.1) [25]. The dielectric coatings are designed to allow for reflection or transmission wavelength bands that are optimized according to application, and the polymeric spacer thickness governs the range of bandwidths to be detected. The FPI is produced on an acrylic substrate that is angled to avoid interference from the interface of the FPI and the substrate surface, and the entire sensor is coated with a layer of Parylene C to protect it from physical damage and prevent water from entering the space between the FPI mirrors.

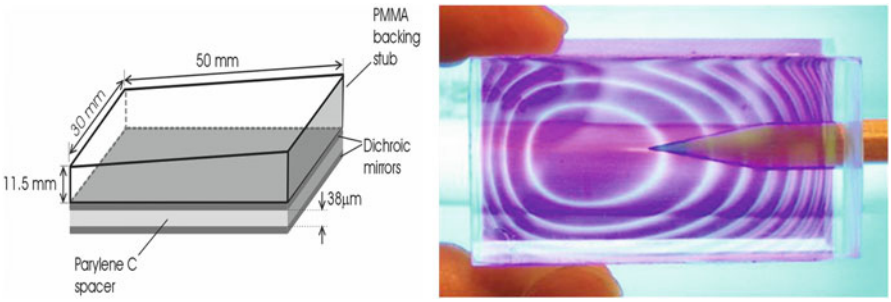

Fig. 52.1 (*Left*) Design of Fabry-Perot sensor; the active component of the sensor consists of a 38 μm polymer film spacer sandwiched between two dichroic mirrors forming an FPI. The sensor is on a wedged backing stub made of PMMA. (*Right*) Photograph of sensor under narrowband visible illumination demonstrating its transparent nature and FPI transmission fringes (Image reproduced with permission from Zhang E et al. [25])

The active side of the transducer is in contact with the sample, coupled with a small amount of water or transparent gel to ensure that acoustic waves propagating from tissue are incident upon it directly without passing through air. Stimulation of a photoacoustic wave is accomplished using nanosecond pulses from an excitation laser coupled into a multimode fiber that delivers unfocused illumination to the sample at a wavelength in which the dielectric coatings of the FPI are transmissive. Signal transduction occurs when an incident acoustic pressure wave changes the thickness of the polymer spacer, leading to a change in reflectivity of the sensor that is probed using a laser. This interrogation laser is a tunable continuous wave laser tuned to a wavelength in which the dielectric coatings are reflective; it is focused on the sensor surface. The laser is scanned in two dimensions across the FPI to allow for the acquisition of volumetric PA signals. Figure 52.2 provides a simplified illustration of the sensor, focused interrogation laser, and excitation light delivery via a multimode fiber.

52.2.1.1 Determining Optimal Bias Wavelength

The wavelength of interrogation that provides the most sensitivity for photoacoustic signal measurement – the optimal bias wavelength, λ_{opt} – varies from location to location on the sensor surface due to differences in thickness of the polymer film spacer that is vacuum-deposited onto the dielectric coatings during fabrication [25]. The main steps for determining λ_{opt} for each location of interest on the sensor can be summarized as follows:

1. Sweep the interrogation laser through a range greater than the free spectral wavelength range of the FPI while recording the reflected optical power with a photodiode; this provides the wavelength-dependent reflectivity interferometer transfer function (ITF), $R(\lambda)$.
2. Fit an Airy function to $R(\lambda)$.
3. Express $R(\lambda)$ as a function of phase and take derivative to obtain normalized phase sensitivity $S(\lambda)$.

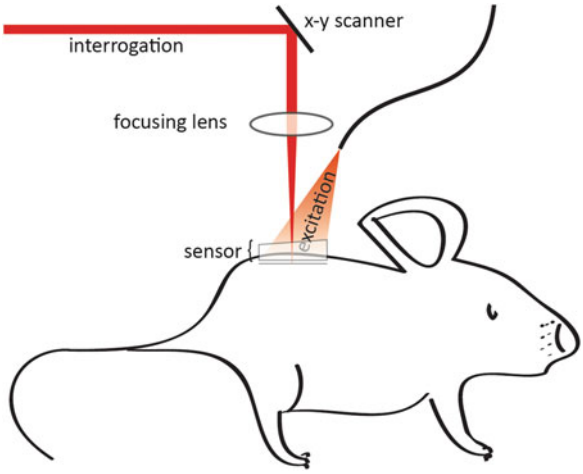

Fig. 52.2 Illustration of FPI sensing: excitation is accomplished via nanosecond-pulsed illumination using a multimode fiber, and the sensor is interrogated using a focused continuous wave laser beam. The sensor is placed in contact with the sample, coupled with a small amount of water or transparent gel so acoustic waves propagating from the sample are not attenuated in air

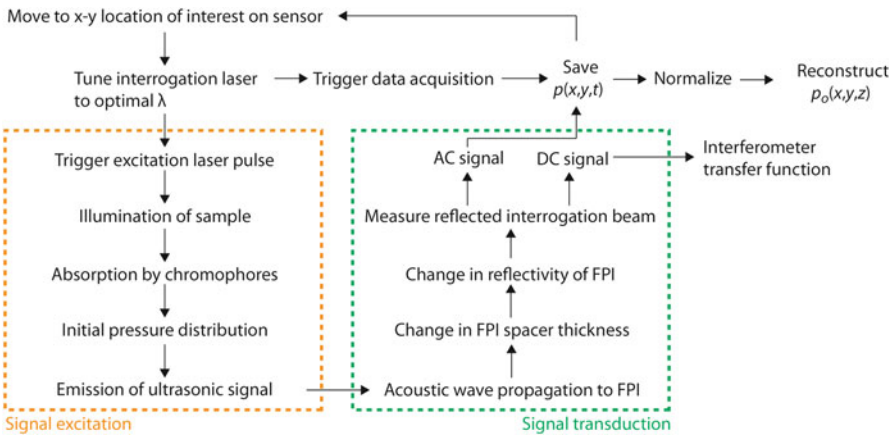

Fig. 52.3 Summary of steps for signal transduction using FPI

4. The maximum derivative of $S(\lambda)$ is considered the optimal bias wavelength (λ_{opt}).
5. Repeat steps 1–4 for every 2D point of interest on sensor.

52.2.1.2 Signal Transduction

The steps for signal excitation and transduction are summarized in Fig. 52.3. First, the interrogation laser is directed to the x-y location of interest on the sensor and tuned to the corresponding λ_{opt} for that location. This triggers both data acquisition and the firing of the excitation laser. Signal excitation results in the emission of broadband ultrasonic signals, which propagate to the FPI, modulating its thickness and, in turn, reflectivity. This change in reflected power is measured using a 50 MHz InGaAs photodiode-transimpedance amplifier that has AC- and DC-coupled output channels.

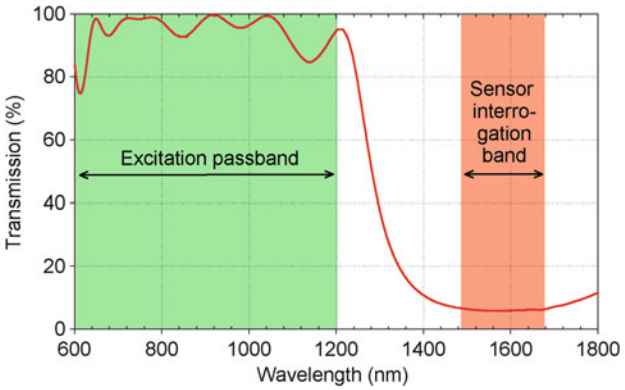

Fig. 52.4 Fabry-Perot sensor transmission characteristics; high transmission is observed between 600 and 1,200 nm for both excitation of photoacoustic signals and transmission of a 1,050 nm OCT source, and high reflectivity is achieved between 1,500 and 1,650 nm, for interrogation of the sensor by a 1,550 nm source (Image reproduced with permission from Zhang E et al. [25])

The DC output is digitized using an 8-bit analog-to-digital card (200 Ks/s); this channel is used to record the reflected optical power for the ITF acquisition as described in Sect. 52.2.1.1. The AC signal is digitized using an oscilloscope (300 MHz) and represents the time-varying optical power modulation that is caused directly by the photoacoustic pressure wave, $p(x,y,t)$. This signal is normalized to account for variations in interrogation laser power by dividing by the corresponding normalized phase sensitivity. Thus, when an acoustic signal modulates the thickness of the FPI, a phase shift is introduced and this is linearly converted to a modulation of optical power using the ITF. Time reversal and k-space reconstruction techniques are used to obtain the initial pressure distribution $p_o(x, y, z)$, which is directly proportional to energy absorbed [27].

52.2.1.3 PAT Sensor, Interrogation Laser, and Excitation Source

The sensor used herein consists of dielectric coatings used to form mirrors with greater than 95 % reflectivity between 1,500 and 1,650 nm and transmit light between 600 and 1,200 nm and a Parylene C spacer thickness of 20 μm to facilitate a frequency response on the order of tens of MHz (Fig. 52.4). The sensor has a -3 dB acoustic bandwidth of 39 MHz, and the free spectral range is 31.4 nm [25]. The reflectivity band was chosen such that a tunable 1,550 nm laser could be used for sensor interrogation. The interrogation laser is a tunable 1,550 nm continuous wave laser with an output range of 1,519–1,630 nm, wavelength resolution of 1 pm, output power of up to 10 mW, and settling time of ~50 ms (Thorlabs ECL5000DT).

The PAT signal excitation laser is a frequency-tripled 355 nm Nd:YAG (Newport Spectra-Physics) pumped optical parametric oscillator (OPO; GWU) with a tunable output range of 410–2,100 nm and wavelength-dependent output pulse energy of 12–36 mJ. The laser has ~8 ns pulses and a pulse repetition rate of 50 Hz. Light from the OPO is coupled into a 1.5-mm diameter multimode fiber and

delivered to tissue through the FPI sensor. Single pulses from the excitation laser are used at each location (no averaging takes place), so the 50 Hz repetition rate limits acquisition time to 20 ms per lateral scan location.

52.2.1.4 PAT Image Reconstruction

In tomographic photoacoustic imaging, signals are recorded as a function of lateral location on the sensor and time of arrival at the surface, $p(x,y,t)$. Thus, the initial pressure distribution, $p_o(x,y,z)$, must be reconstructed. This is accomplished using two different techniques: a fast *k*-space reconstruction algorithm and a slower time reversal approach. The former ignores frequency-dependent acoustic attenuation from soft tissue, while the latter is more computationally expensive but takes attenuation into account. The time reversal approach is thus better when looking at deeper structures, where acoustic waves have higher attenuation before reaching the FPI sensor. Additional details regarding specifics of reconstruction are available in references [27] and [28].

52.2.1.5 Combined PAT/OCT System

A schematic of the combined PAT/OCT system is shown in Fig. 52.5 [8]. As described above and demonstrated in Fig. 52.4, the Fabry-Perot sensor has a transmission band from 600 to 1,200 nm, making it amenable to OCT imaging using a 1,050 nm light source.

The light source used to obtain the OCT images presented in Sects. 52.2.2.1 and 52.2.2.2 is an amplified spontaneous emission (ASE) source (NP Photonics, Tucson, AZ) with a bandwidth of 70 nm and a center wavelength of 1,050 nm [29]. Light from the source is sent through an 80:20 fiber-based beam splitter to a free-space reference arm and to a sample arm that consists of a 2D galvanometer-driven scanner and focusing lens (Fig. 52.5). The OCT sample path is combined with the PAT interrogation path using a dichroic mirror. Backscattered light from the sample and reference arms is detected using a spectrometer in Czerny-Turner configuration and digital line InGaAs array (Goodrich SUI LDH1, Princeton, NJ) with 1,024 pixels at an A-scan sampling rate of 47 kHz. The raw spectral data is inverse Fourier transformed to obtain individual A-scan intensity profiles, and each B-scan consists of 512 A-scans separated by 12 μm. The axial and lateral resolutions of this OCT system are estimated to be 8 and 18 μm, respectively.

Light from the 1,550 nm PAT interrogation laser described in Sect. 52.2.1.3 is directed to the FPI from the source through a circulator and the common optical path (dichroic mirror, galvos, and focusing lens), and reflected light is sampled using the 50 MHz InGaAs photodiode-transimpedance amplifier and digitizing oscilloscope as detailed in Sect. 52.2.1.2. The lateral resolution of this PAT system was previously estimated to be ~66 μm at a depth of 5 mm, and it has an axial resolution of ~20 μm as determined primarily by the bandwidth of the sensor [25].

52.2.1.6 Alignment of PAT and OCT Images

To prevent a strong back reflection from the FPI sensor, which will saturate the InGaAs array, it is necessary to insert a glass wedge between the FPI sensor and

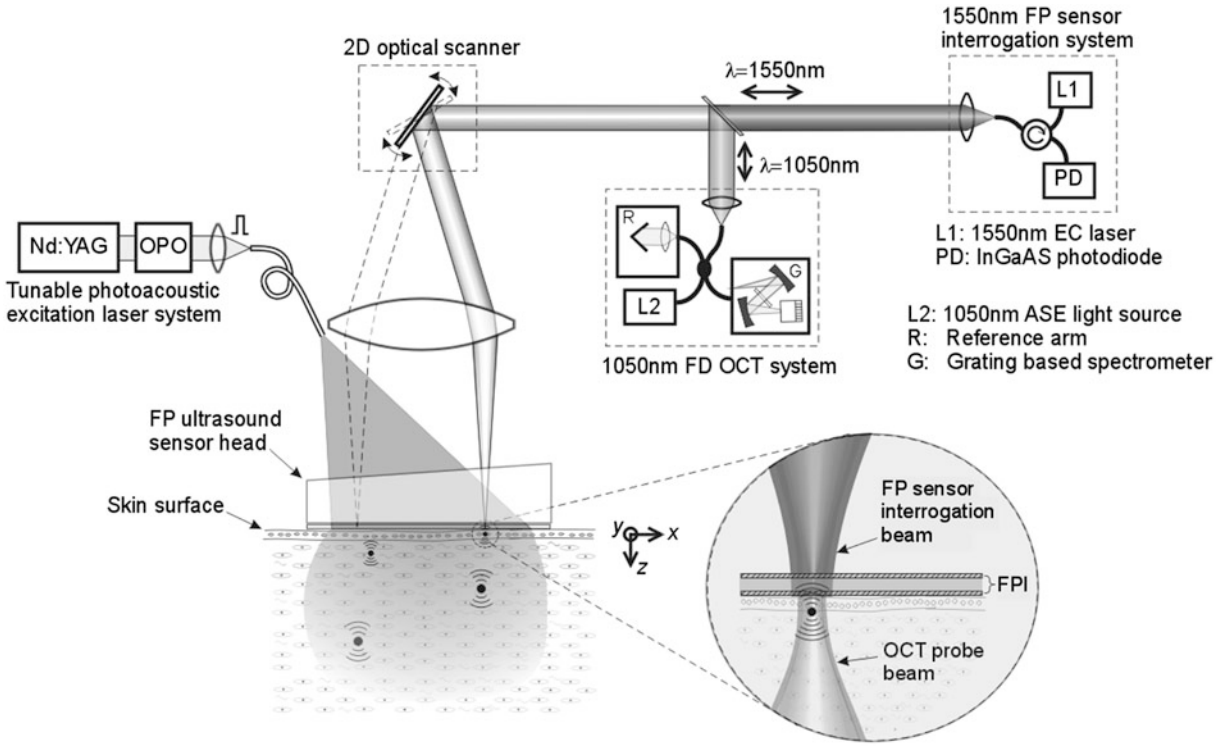

Fig. 52.5 Schematic of multimodal PAT/OCT imaging system. PAT excitation is achieved using a tunable Nd:YAG pumped OPO with nanosecond pulses, and the Fabry-Perot sensor is interrogated using a 1,550 nm laser focused on the interferometer surface. OCT images are acquired using a 1,050 nm source and spectrometer-based frequency domain detection. The beams of the 1,550 nm PAT interrogation laser and 1,050 nm OCT laser are combined using a dichroic mirror, and the same galvanometer-driven mirrors are used for 2D scanning of both systems (Image reproduced with permission from Zhang E et al. [8])

focusing lens while acquiring OCT images. This wedge is not in place when acquiring PAT images, so the PAT and OCT images are offset laterally from one another. A scattering and absorbing grid target is imaged by both modalities to calculate this offset; the offset is used to align images after acquisition. In addition to the lateral offset, there are substantial differences in lateral and axial step size between OCT and PAT images, with PAT images less densely sampled. Thus, PAT images are interpolated prior to registering the images.

52.2.2 Mouse Skin Imaging

One advantage to acquiring OCT and PAT signals from overlapping or identical regions of interest is that OCT gives PAT images context in the form of high-resolution structural information. Similarly, highly absorbing structures that appear as shadows in OCT images (e.g., blood vessels) can be observed with PA imaging.

A combination of PAT/OCT image acquired from the flank of a living anesthetized 5-week-old hairless female mouse placed on the FPI sensor, flank-side down, can be seen in Fig. 52.6. OCT and PAT images were acquired sequentially. Volumetric OCT images were acquired in 24 s and covered a 12.3 mm × 13 mm region with a lateral step size of 12.5 μm between A-scans, with a depth sampling interval equal to the axial resolution ($\Delta z = 6$ μm). PAT volumetric images were obtained in 7 min and covered the same region as OCT images but had a step size of 100 μm between A-scans; an excitation wavelength of 670 nm and a fluence of 14 mJ/cm^2 were used. The PAT axial sampling step size depended on the temporal sampling interval, which in this case was 20 ns. Assuming a speed of sound in tissue of 1,500 m/s, this corresponds to a depth spacing of $\Delta z = 30$ μm. The fast k-space reconstruction algorithm [28] was used to generate the PAT image.

Figure 52.6a shows corresponding single vertical OCT (gray scale) and PAT (red) cross sections. The OCT image provides detailed morphology of the skin including the dermis, panniculus carnosus, hypodermis, and skeletal muscle, while blood vessels are observed in the PAT images. Maximum intensity projections (MIP) from OCT, PAT, and OCT/PAT are presented in Fig. 52.6b–d and clearly show the differences in contrast mechanisms between the two modalities, with blood in vessels being highly absorbing and structures within the skin being highly scattering. Volumetric renderings (Fig. 52.6e–h) further illustrate the absorption-based contrast of PAT and scattering-based contrast of OCT.

52.2.3 Preclinical Imaging of Human Skin

The first demonstration of a combined PAT/OCT system in a human subject in vivo can be seen in Fig. 52.7. The hand of a healthy volunteer was placed on the sensor and held stationary for 4.6 min during the acquisition of a PAT image covering a 14 mm × 14 mm region of the palm with lateral distance of 120 μm between A-scans. As with the mouse imaging, depth sampling again took place in steps of

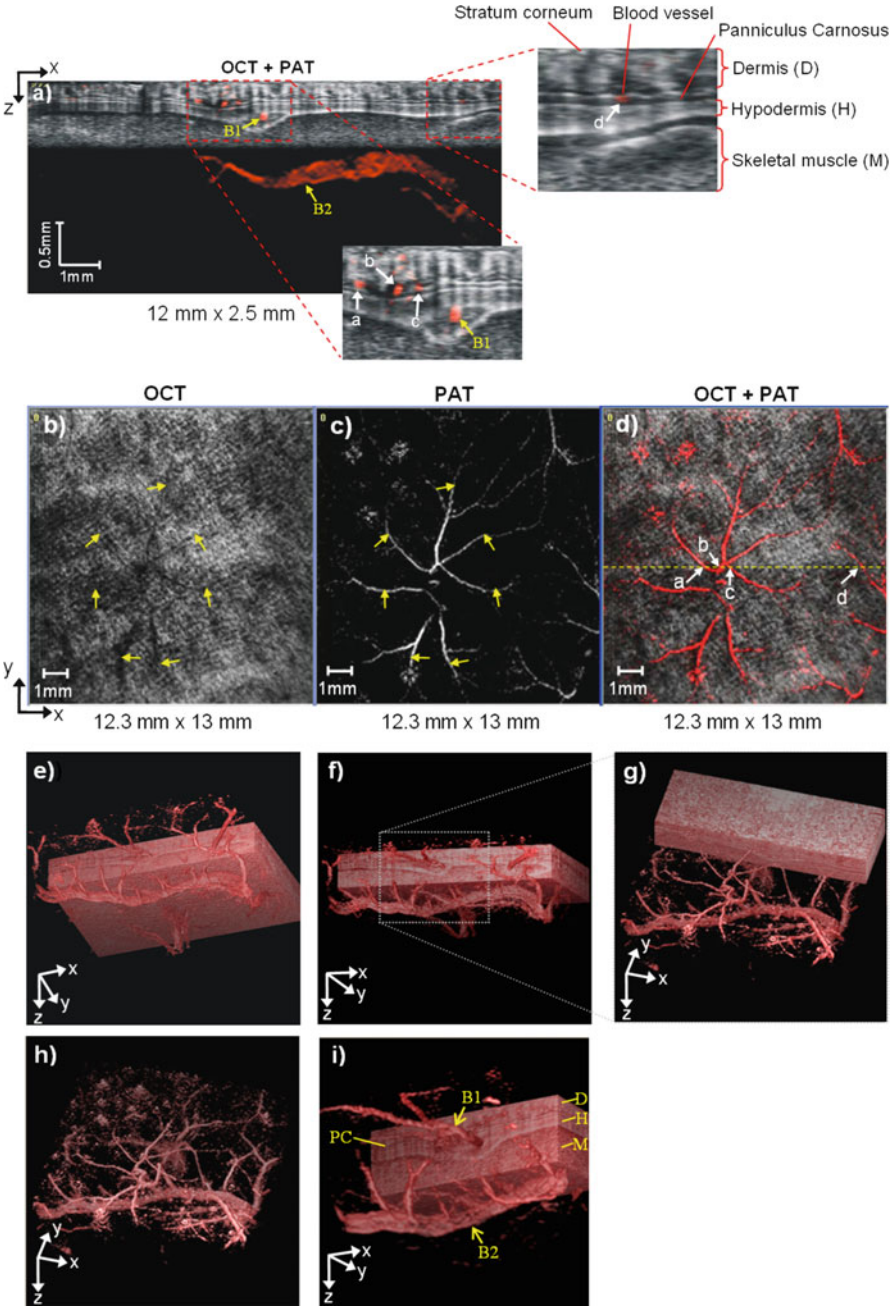

Fig. 52.6 In vivo PAT/OCT images of the mouse skin. (**a**) Fused PAT/OCT cross-sectional vertical (x–z) slice. The OCT image (*gray scale*) shows the layered skin morphology while the PAT image (*red*) shows several superficial blood vessels within the dermis, panniculus carnosus,

$\Delta z = 30$ μm (20 ns sampling interval). The excitation laser was tuned to 672 nm, and a beam diameter of 2 cm and fluence of 14 mJ/cm^2 were used. The PAT image was followed by an OCT image covering an area of 12.8 mm × 12.8 mm in steps of 12.5 μm between A-scans and took a total of 24 s.

A co-registered PAT and OCT cross section is shown in Fig. 52.7a. The stratum corneum, epidermal, and papillary dermal layers are evident in the OCT cross section, while subcutaneous blood vessels and dermal vessels are present in PAT images. Some absorption in the epidermis can be seen in PAT images as well; this is likely caused by melanin – a strong absorber – distributed throughout the layer. As with the mouse images, the OCT and PAT MIPs (Fig. 52.7b–d) demonstrate the difference in contrast mechanisms between the two modalities. Interestingly, many of the vessels that can be discerned using PAT are at a depth greater than the maximum penetration depth of OCT; this is especially clear in the volume renderings (Fig. 52.7e–g).

52.3 Limitations, Future Directions, and Potential Applications

52.3.1 Limitations and Future Directions for FPI PA Sensing

One major limitation to the current implementation of tomographic measurements with the FPI sensor is that imaging time depends on the excitation source. Unfortunately, sources that provide high enough pulse energy at multiple wavelengths for spectroscopic measurements, such as optical parametric oscillators, are expensive and impractical when it comes to large-scale clinical implementation where stable, easy-to-use lasers are necessary. While imaging times on the order of several minutes may be possible in some pathology with cooperative patients, scanning rates on par with OCT sources (e.g., several kHz to MHz) are desirable.

In addition to the prohibitively long PAT scan time, the slow excitation laser makes truly simultaneous imaging difficult. While one solution is to average multiple OCT A-scans in the time it takes to acquire one PAT A-scan, another is to intentionally slow down OCT acquisition to match that of PAT acquisition. Neither of these offers an ideal solution, though, since motion artifacts from the

Fig. 52.6 (continued) hypodermis (*B1*), and the skeletal muscle (*B2*). The lower inset shows an expanded view of the dermis and hypodermis and a cluster of three blood vessels (labeled *a*, *b*, and *c*), which form part of the vascular structure that can be seen in (**b–d**). The upper inset shows an expanded view of the skin layers and a blood vessel (labeled *d*), which can also be seen in (**d**). (**b**) OCT (x–y) MIP image. The *yellow arrows* indicate the location of blood vessels forming a star-shaped vascular structure. (**c**) PAT (x–y) MIP image. (**d**) Fused PAT/OCT (x–y) MIP image. The *horizontal dotted line* indicates the location of the x–z slice depicted in (**a**). The vessels labeled *a–d* correspond to those labeled in the two insets in (**a**). The (x–y) MIPs shown in (**b–d**) were computed over the depth range: $0.24 < z < 0.6$ mm. (**e–h**) Volume rendered representations of fused PAT/OCT image data at different viewing angles with the OCT image successively resected. The rendered image volume is 12 mm × 12 mm × 2 mm. (**i**) Expanded view of (**f**) over a 6 mm × 6 mm × 2 mm volume showing blood vessels *B1* and *B2*, dermis (*D*), panniculus carnosus (*PC*), hypodermis (*H*), and skeletal muscle (*M*) as identified in (**a**) (Image reproduced with permission from Zhang E et al. [8])

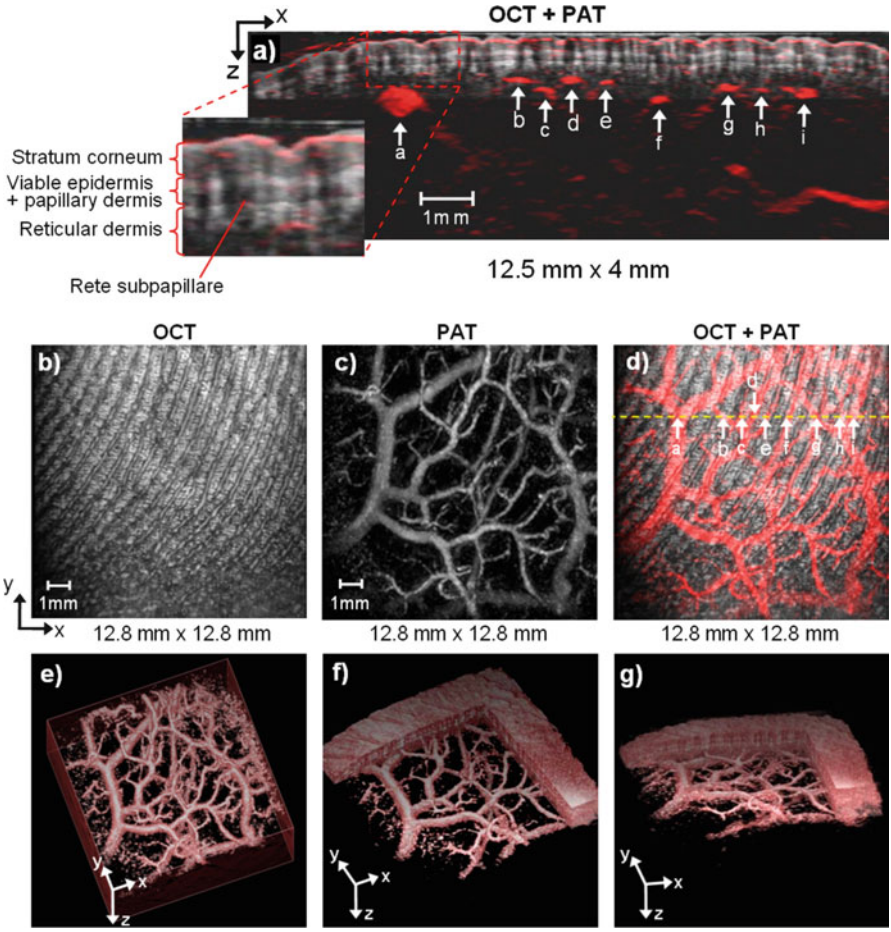

Fig. 52.7 In vivo OCT and PAT images of the human palm. (**a**) Fused PAT/OCT vertical (x–z) slice. (**b**) OCT (x–y) MIP image computed over the depth range $0 < z < 1.2$ mm. (**c**) PAT (x–y) MIP image computed over the depth range $0 < z < 5$ mm. (**d**) Fused PAT/OCT (x–y) MIP image. The *horizontal dotted line* indicates the location of the x–z slice shown in (**a**), with corresponding locations of blood vessels indicated by white arrows. subject could easily result in a distorted/blurred OCT image. Until the speed of PAT excitation sources catches up with that of OCT, an interim solution would be to acquire from multiple points on the FPI surface in parallel using multiple interrogation beams. Another alternative would be to more seamlessly acquire the OCT and PAT images in sequence. This would mean eliminating the glass wedge that is placed on the sensor during OCT scanning, and would be possible if the incident angle of the OCT beam could be offset in the optical path.

Further development of the FPI sensor would also improve its utility in a clinical setting. For example, extending the transmission window below 600 nm would enable higher SNR of PA waves generated from hemoglobin and deoxyhemoglobin. Similarly, extending the transmission window past 1,200 nm would enable OCT imaging with 1,300 nm sources and hence deeper penetration into tissue. Finally, using the FPI sensor with a focused excitation source for microscopy mode imaging to provide comparable resolution and depth range to OCT is a logical next step, since significantly faster light sources are available.

52.3.2 Applications

Multimodal PA/OCT imaging has the potential to impact a broad range of clinical specialties by providing access to absorption-based contrast millimeters to centimeters in depth with 1–2 mm of scattering-based surface structural detail. As demonstrated above, in tomographic mode, deep absorbers can be visualized, while the imaging depths for microscopy mode PA imaging and OCT are comparable. Using endogenous absorbers such as deoxygenated and oxygenated hemoglobin for spectroscopic PA imaging will allow for even better visualization of blood vessels – a feature from which many fields could benefit.

Cancer imaging is an obvious application for this multimodal imaging platform, where hemoglobin would provide endogenous contrast for viewing tumor vasculature and OCT could provide corresponding superficial structural information. This would assist clinicians in planning and performing tumor resection, facilitate longitudinal evaluation of tumor growth, and help determine the effectiveness of treatment. Another endogenous absorber, melanin, could also be exploited for PA contrast in diagnosis and monitoring of melanoma when shorter excitation wavelengths are used.

In ophthalmology, where OCT imaging of the retina is already well established and part of routine clinical care, the addition of PA imaging could provide functional information in addition to structure. Assessment of the status of retinal vessels should improve the diagnosis of diseases such as glaucoma and wet age-related macular degeneration. One major challenge in building a system for retinal use, however, will be delivering enough energy to produce a photoacoustic signal while remaining within safety limitations for the eye.

After endoscopic delivery systems are further refined and tested in vivo, this would extend possible applications of PA/OCT imaging to include intraoperative use. In addition, the ability to access absorption and scattering properties of tissue using a multimodal combination of OCT and PA imaging may be valuable not only in the clinic but for studying preclinical models of disease and evaluating treatment success for novel therapeutic agents. The use of an FPI sensor to monitor tumor vascularization and treatment using PAT has already been demonstrated in animals [30], and the addition of OCT for structural information or even Doppler measurements might improve delineation of tumors for longitudinal monitoring.

Other animal models, such as transgenic zebrafish lines that express absorbing fluorochromes in specific tissue [31], should also be interesting to observe with a combined PA/OCT system.

While OCT has evolved to the point where it is regularly used in clinical practice, the widespread implementation of PA – and therefore multimodal PA/OCT – cannot occur until suitable light sources are developed. Sources for OCT are suitable for clinical application in terms of bandwidth, power, and price, but the same is not true for PA sources. As soon as stable nanosecond-pulsed lasers with high repetition rates and high output energy at multiple wavelengths are available, widespread testing and use of this multimodal platform in both a preclinical and clinical setting should be possible.

53.1 Introduction

53.1.1 Optical Coherence Tomography

Optical coherence tomography (OCT) is a biomedical imaging modality based on the technique of low-coherence interferometry. Although it is usually analogous to ultrasound imaging, the millimeter range echo time delay is too small to be directly measured due to the celerity of light. One uses a broadband light source and the interference between two arms in a low-coherence interferometer, which provides a coherence gate and depth-resolved information. The depth (axial) resolution is inversely proportional to the spectral bandwidth of the light source and ranges from 1 to 15 μm in most OCT systems. The reference arm in an OCT system also provides heterodyne (or homodyne) gain to the weak backscattered light from biological sample, offering OCT the most significant detection sensitivity (i.e., 100–120 dB). The imaging penetration depth of OCT can often reach 2–3 mm in most highly scattering biological tissues when using a near-infrared (NIR) wavelength from 800 to 1,300 nm. In short, OCT fills a gap between the scales of high-frequency ultrasound and confocal microscopy, providing better resolution than the former as well as deeper penetration than the latter.

Recent development in Fourier-domain optical coherence tomography (FD-OCT) technology has significantly improved the imaging speed. It has been reported that an

A-scan rate from tens of kHz to over 1 MHz can be achieved [1–5]. Meanwhile, efforts have been devoted to developing OCT imaging probes to enable imaging of internal organs. Flexible fiber-optically based imaging probes have been integrated with high-speed FD-OCT in a wide range of medical instruments such as endoscopes, catheters, etc., to achieve real-time, even three-dimensional OCT imaging of internal organs [6–12].

53.1.2 Fluorescence

Fluorescence is the process by which light is emitted by a stimulated molecule or fluorophore when the excited electron returns to ground state. This phenomenon has been utilized for many years as a research tool and has evolved to become a standard imaging modality in a variety of fields such as biology, biochemistry, and medicine. Fluorescence can be quantified through various means such as fluorescence excitation and emission spectroscopy, fluorescence lifetime, fluorophore concentration, and quantum yield. These parameters can be sensitive to the local biochemical or physiological environment of the fluorophores and vary between pathologic and normal tissues, offering specific contrast for diagnosis. In addition to a variety of exogenous fluorophores, there are quite a few endogenous fluorophores in biological tissues including nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide (FAD) which are directly related to cellular metabolism, while others are directly related to tissue structures [13].

Fluorophores can be excited by one photon absorption or simultaneous absorption of multiple photons. In case of two-photon excited fluorescence (TPEF) [14], two photons team up within a small time window (attosecond) and excite a molecule. Practically, photons of the same energy are used, though theoretically any combination of photons that provide the necessary energy difference can be used. In order to provide the necessary conditions to enhance the probability of TPEF, photons are usually confined temporally, though the use of pulsed light sources, and spatially, with moderate to high numerical aperture (NA) optics [15]. The fluorescence signal is proportional to the square of the excitation intensity. Thus, TPF effectively occurs within the tight focal volume (corresponding to high excitation photon density), which intrinsically provides depth-resolved information compared to single-photon excited fluorescence.

53.1.3 Complementary Nature of OCT and Fluorescence Imaging

OCT is capable of visualizing micron-scale tissue structural morphologies with the imaging contrast predominantly sensitive to the scattering property of tissues. Fluorescence imaging techniques such as confocal or two-photon excitation fluorescence (TPEF) are able to provide depth-resolved submicron-scale images with the imaging contrast coming from exogenous or endogenous fluorophores, thus providing molecular information which cannot be obtained by OCT. The two complementary

imaging modalities provide important yet different optical information based on unique contrast mechanisms. There is, hence, a strong motivation for developing integrated platforms for performing both OCT and fluorescence imaging. Furthermore, this combination has proven effective in visualizing morphology and fluorophore distribution in several benchtop systems [16–21].

53.2 Instrumentation Design

53.2.1 Dual-Modality OCT and Single-Photon Fluorescence Endoscopy

The instrumentation design of such a dual-modality endoscope and system requires great consideration of several factors such as the method by which light will be combined, separated, and how scanning will be performed endoscopically to conduct real-time imaging. We will address these considerations in the following sections.

In order to simultaneously perform OCT and single-photon fluorescence imaging, we integrated both systems into a dual-modality imaging platform. The integrated imaging platform consists of two modules that are combined in the OCT sample arm through a dual-modal endoscope and several customized fiber-optic components. We will start with the endoscope design and the system-level integration will be discussed later in Sect. 53.2.1.2.

53.2.1.1 Endoscope Design

A few other groups have also designed multimodal imaging catheters [22, 23]; however, here, we will focus primarily on our design. We chose to implement an endoscope based upon a single fiber, since this design benefits from many advantages such as the ability to use the conventional scanning mechanisms (scanning with a proximally located fiber-optic rotary joint or with a distally located miniature motor), along with a pull-back mechanism, to provide 3D volumetric luminal imaging and is still able to maintain an overall compact size of the probe [24].

Some of the associated challenges with a single-fiber design, for example, are how to provide single-mode transmission for OCT wavelengths while providing high-efficiency multimode collection at fluorescence emission wavelengths and how to effectively separate OCT source light and fluorescence excitation light from OCT backscattered light and fluorescence emission light. These requirements were satisfied through the use of a custom dual-clad fiber (DCF) whose dimensions were a 9 μm core, 180 μm large inner cladding, and 200 μm outer cladding. The core of the DCF is able to provide single-mode transmission at OCT wavelengths while guiding fluorescence excitation in low-order mode. During recollection of the signal, the large inner cladding can be utilized to collect more fluorescence emission compared to the much smaller core, while the backscattered OCT light travels through both the core and the inner cladding of the DCF. In this way, we are able to satisfy the requirements of sending and receiving both OCT and fluorescence light to and from the sample.

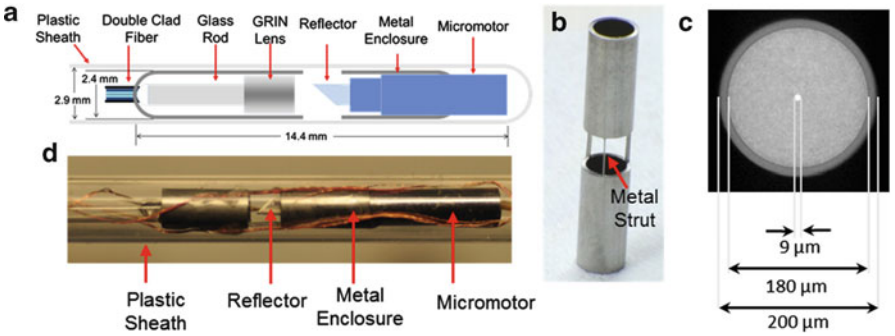

Fig. 53.1 (**a**) Schematic of distal end of the dual-modal endoscope design. (**b**) Photograph of a precision-cut metal enclosure (of an outer diameter 2.4 mm) with minimal beam blockage (i.e., less than 5 %). (**c**) A cross-sectional photograph of the custom dual-clad fiber, with dimensions labeled (9 µm core, 180 µm large inner cladding, and 200 µm outer cladding). (**d**) A photograph of the constructed endoscope of an overall diameter of 2.9 mm including the housing transparent sheath (Figure reprinted with permission from *Biomedical Optics Express*, Optical Society of America)

Though one of the advantages of a single-fiber approach is the ability to implement a traditional scanning mechanism, there are additional considerations for the choice of scanning mechanism due to the use of DCF in the endoscope. In principle, a proximal scanning mechanism such as a fiber-optic rotary joint can be used; however a custom rotary joint with a DCF needs to be fabricated. This approach is challenging because the rotary joint requires extremely precise alignment over a 360° rotation to prevent backscattered OCT light traveling in the inner cladding of the endoscope from being coupled into the single-mode fiber in the interferometer. Due to the different optical path length that OCT backscattered light in the inner cladding will experience from the backscattered light traveling through the core, the OCT image quality would be significantly compromised. Thus, we decided to implement a distally located miniature motor incorporated into the endoscope design with an off-the-shelf 1.9 mm diameter DC micromotor.

The overall endoscope optics design was similar to those published in earlier papers [11, 25, 26]. We used a glass rod after the DCF to expand the beam prior to focusing with a gradient index (GRIN) lens as shown in Fig. 53.1a. The key to this assembly was in the additional care taken to align, center, and stabilize the fiber and lens assembly with the micromotor and microreflector. In order to accomplish this, a custom metal enclosure was fabricated with three windows separated by ultrathin metal struts (~127 µm wide). This metal enclosure, as shown in Fig. 53.1b, provided sufficient mechanical stability while minimizing blockage to the imaging beam (only 5 % of the view blocked over 360°). In addition, the microreflector attached to the micromotor was positioned carefully in the center of the metal enclosure window so that the beam was able to be deflected 90° by the microreflector.

The overall working distance of this endoscope, as defined as the distance between the focal point and the outer surface of the metal enclosure, is governed

by the distance between the GRIN lens and the microreflector. The working distance was measured to be 1.9 mm and the lateral resolution was ~13.7 μm. The distal end of the endoscope has an overall diameter of 2.4 mm with a rigid length of 14.4 mm. Furthermore, for practical use, the entire endoscope was enclosed in an off-the-shelf transparent plastic sheath (outer diameter 2.9 mm) as shown in Fig. 53.1c. We were able to easily adjust the beam focus outside of the transparent sheath by tuning the distance between the microreflector and fiber-lens assembly, and the final beam focus was set at 1.6 mm outside of the sheath.

53.2.1.2 System Design

Thus far, we have discussed the endoscope design that enables the dual-modality OCT and fluorescence imaging; however, some of the challenges in the implementation of this imaging system are in how to combine and separate of light from two individual imaging modalities. The OCT module consists of a swept-source which is a home-built 40 kHz Fourier-domain mode-locking (FDML) fiber laser operating at a center wavelength of 1,305 nm with a 3 dB spectral bandwidth of ~140 nm. The OCT module also includes a Mach-Zehnder interferometer (MZI) to generate a calibration signal and a dual-balanced detector is utilized. The fluorescence imaging module consists of an argon ion laser at 488 nm for excitation and a photomultiplier tube (PMT) for detection.

There are a few methods by which to combine two light sources through free-space optics, a fiber-optic coupler or other fiber-optic devices. Using free-space optics is the most straightforward method, and this method has been widely used in benchtop systems. For endoscopy, this method proves to be bulky with a large footprint and is not portable enough to be used for clinical or animal imaging. For this reason, a fiber-optic approach is favored. In this case, since the OCT backscattered light will go through the coupling device, it is important to maintain a low roundtrip loss. We used a wavelength division multiplexer (WDM) which works at both the near infrared OCT source wavelengths and visible fluorescence excitation wavelengths, shown in Fig. 53.2.

The WDM allowed us to obtain a minimal insertion loss of 0.5 dB for OCT, and although the efficiency of transmitting fluorescence excitation was sub-optimal, we were able to obtain an ~60 % efficiency. This efficiency allowed us to have 3-mW fluorescence excitation light incident on the sample which was sufficient for fluorescence imaging.

The final challenge in the construction of this system lay in how to effectively separate the OCT backscattered light from the fluorescence emission light that are both collected by and transmitted through the endoscope. This posed a great challenge since we opted to implement an entirely fiber-optic platform. Our solution was to use a customized DCF coupler that consists of a single-mode fiber (SMF-28e) port, a multimode fiber port, and a DCF port.

On the forward path (from the source to the sample), the DCF coupler couples the OCT source and excitation source light traveling in the single-mode fiber to the single-mode core of the DCF (with a loss of 0.8 dB and 2.2 dB, respectively). On the return path (from the sample to the detector), the OCT backscattered light and

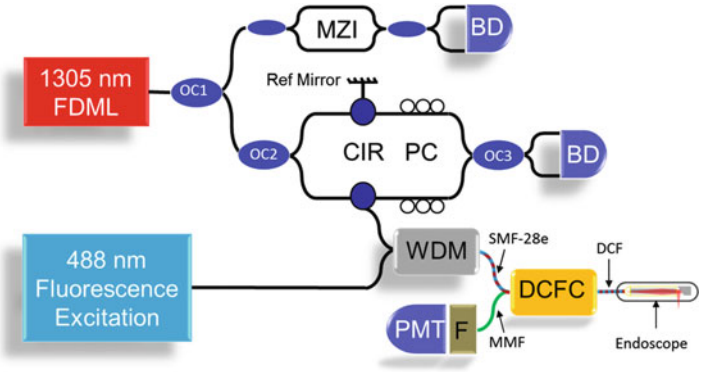

Fig. 53.2 Schematic of the dual-modality system capable of performing endoscopic OCT and fluorescence imaging simultaneously. *FDML* Fourier-domain mode-locking fiber laser, *OC* optical coupler (OC1 95/5, OC2 70/30, OC3 50/50), *MZI* Mach-Zehnder interferometer, *CIR* Circulator, *PC* polarization controller, *BD* balanced detector, *WDM* wavelength division multiplexer, *DCFC* double-clad fiber coupler, *PMT* photomultiplier tube, *F* band-pass filter; *Green*, multimode fiber (*MMF*); *blue*/*red*, double-clad fiber (*DCF*); *black*, single-mode fiber (*SMF*-28e) (Figure reprinted with permission from *Biomedical Optics Express*, Optical Society of America)

fluorescence emission travel through both the core and large inner cladding of the DCF in the endoscope. The DCF coupler allows the light traveling in the core of the DCF to be coupled back into the single-mode fiber port and the light traveling in the inner cladding of the DCF to be separated into the multimode fiber port. In this way, the OCT backscattered light seamlessly returns to the OCT system through fiber optics, where only light at the OCT source wavelengths are able to pass through the circulator and interfere with light from the OCT reference arm. Similarly the fluorescence emission, which travels mostly in the inner cladding of the DCF is coupled into the multimode fiber port and detected by a photomultiplier tube (PMT). Additionally, to avoid any potential leakage of fluorescence excitation light backscattered into the endoscope and transmitted through the inner cladding, band-pass filters were placed before the PMT. Both OCT and fluorescence signals are collected simultaneously during imaging and are digitized, displayed, and stored in a synchronized fashion.

53.2.2 Dual-Modality OCT and Two-Photon Fluorescence Endoscopy

Similar to the OCT and single-photon fluorescence imaging platform, the endoscope is a key component through which simultaneous high-resolution OCT and two-photon fluorescence imaging is performed. Here, an *en face* imaging system is considered for both OCT and two-photon fluorescence. We will start with the endoscope design, followed by the description of the system-level integration.

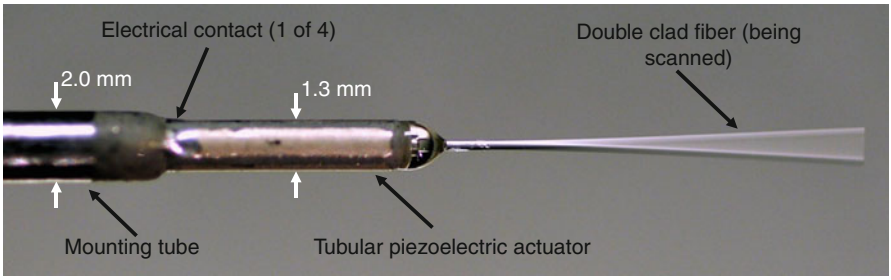

Fig. 53.3 Photograph of 1.3-mm-diameter four-quadrant, tubular piezoelectric actuator mounted on a 2.0-mm-diameter base. The double-clad fiber is threaded through the actuator and is being scanned

53.2.2.1 Endoscope Design

A lateral beam scanning mechanism is required in the endoscope for performing en face OCT and TPF imaging (which is conventionally realized by using galvanometric mirrors in a benchtop system). Here, we adopt our previously developed, piezoelectrically actuated, fiber-optic resonant scanner to achieve rapid lateral beam scanning [7, 27]. Although the movement of the piezoelectric (PZT) actuator is imperceptible, the attached fiber cantilever driven by the PZT actuator at or close to its resonant frequency could generate a large lateral deflection. According to a cantilever beam model, the zeroth-order resonant frequency of a fiber cantilever can be expressed as:

$$f = \frac{3.52}{4\pi}\sqrt{\frac{E}{\rho}}\left(\frac{R}{L^2}\right), \tag{53.1}$$

where E, ρ, R, and L are the Young's modulus, mass density, radius, and the length of the fiber cantilever, respectively. Figure 53.3 shows a photograph of a tubular, four-quadrant monolithic PZT beam scanner with a fiber threaded through the central hole. The overall diameter of the scanner including a housing unit can be as small as 2.0 mm. With an exposed fiber length of about 10 mm, the mechanical resonant frequency of the fiber cantilever of a 125 μm diameter is calculated as ~1 kHz based on Eq. 53.1 that is consistent with experimental results.

Depending on the driving frequency applied on the PZT actuator, either spiral or Lissajous scanning pattern can be achieved at the cantilever tip (as shown in Fig. 53.4). The spiral scan requires two orthogonal driving waveforms of the resonant frequency modulated by a slowly varied amplitude waveform leading to a circular field of view (Fig. 53.4a) [28]. Such a scanning pattern is easy to implement on tubular piezoelectric actuators, and image reconstruction is also quite simple. However, it suffers from nonuniform spatial sampling due to the fact that the tangential velocity of the scan trajectory increases as it moves from the center of the field of view. In practice, this leads to oversampling in the center

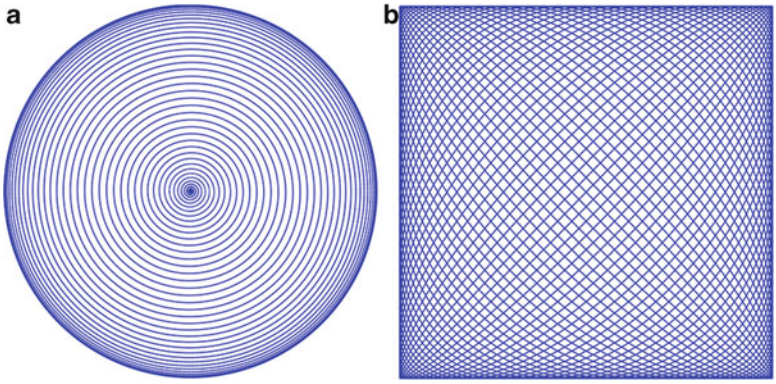

Fig. 53.4 Trajectories of fiber-optic cantilever tip. (**a**) Spiral pattern. (**b**) Lissajous pattern with a frequency ratio of 40:41

and undersampling at the periphery. On the other hand, Lissajous scan can be implemented with two driving waveforms with constant amplitudes but shifted frequencies that are close to the resonant one, leading to a rectangular field of view (Fig. 53.4b) [29]. In order to obtain a closed curve, the frequency ratio must be rational. In practice, the ratio of the two driving waveform frequencies is usually chosen to be close to 1. Although Lissajous scanning provides a better spatial sampling density, the complex trajectory makes reconstruction computationally intensive and sensitive to any perturbation.

Optical fiber is another critical component in the endoscope. Here, a customized double-clad fiber (DCF) was employed. The core diameter of the DCF is ~8 μm, similar to that of the standard single-mode fiber (i.e., SMF-28e®), ensuring both 1,550 nm (the excitation wavelength for TPF) and 1,310 nm (the center wavelength of the OCT light source), can be delivered in single mode through the core, hence achieving small focused spot size on the sample. The inner cladding of the DCF (ϕ175 μm) is able to effectively collect the two-photon fluorescence signal by utilizing its large area and NA. The NA of the DCF core and inner cladding were 0.14/0.12 (at 1,310 nm/1,550 nm) and 0.267 (at 1,550 nm), respectively.

The focusing lens represents a significant challenge in the integrated endoscopic system. The lens needs to have a high NA and low geometric aberrations for obtaining a near diffraction-limited focal spot size. Chromatic aberration should be taken into account due to wavelength difference between OCT, two-photon excitation, and emission wavelengths. In this system, the light from DCF cantilever tip was focused onto the sample by a miniature aspherical compound lens with a maximum NA of 0.8 and a magnification of ~0.22 (along the direction of fiber to sample). A minimal chromatic focal shift of the micro compound lens from the OCT wavelength (1,310 nm) to the two-photon excitation wavelength (1,550 nm) was measured to be ~11 μm.

53.2.2.2 System Design

Figure 53.5 shows the dual-modal system schematic, which integrates the OCT and TPF imaging modalities, capable of performing endoscopic OCT and TPF imaging simultaneously [30]. In the OCT module, the light from a fiber-coupled superluminescent diode of a 13-mW output power with a central wavelength of 1,310 nm and a 3-dB bandwidth of 80 nm was delivered into a Michelson interferometer. In the TPF module, a 1,550 nm passive mode-locked amplified fiber laser was used as the excitation source. The laser generated ultrashort pulses (i.e., ~300 fs with a repetition rate of 42.5 MHz) with a maximum average power of ~155 mW. It operated in the soliton regime so that the laser pulses remain relatively unchanged inside the single-mode fiber (e.g., SMF-28e® or any fiber with the similar dispersion characteristics as SMF-28e®). Therefore, the TPF system does not require any specific dispersion compensation. A high-isolation wavelength division multiplexer (WDM) made of SMF-28e® was placed in the OCT sample arm to combine the 1,310 nm OCT light source with the 1,550 nm TPF excitation laser.

In order to separate the TPF emission and the OCT signal on the return path, a dichroic mirror (DM) was placed between a pair of coupling lenses. A photomultiplier tube (PMT) was used to collect the TPF emission signal reflected from the DM, while the OCT signal transmitted through the DM and was collected via the WDM placed in the OCT sample arm. Although some of the backscattered OCT light from the sample entered the inner cladding of the DCF in the endoscope, the single-mode fiber in the OCT sample arm can filter it out to avoid "ghost" OCT images. In order to perform optical heterodyne detection, an electro-optic modulator was inserted into the reference arm of the OCT module to introduce a beat frequency.

A rapid scanning optical delay line (RSOD) was used both to compensate the dispersion mismatch between the two OCT arms and to select the imaging depth of interest for the en face imaging [31]. A balanced detection scheme was employed in the OCT module to eliminate any DC components and increase the detection dynamic range.

53.3 Results

53.3.1 OCT and Single-Photon Fluorescence Endoscopy

Simultaneous intraluminal OCT and single-photon fluorescence imaging with the dual-modality endoscope was performed in *ex vivo* rabbit esophagus. The tissue was stained with three local injections of 1–2 mL 300 μM aqueous solution of fluorescein sodium from the submucosal side between the lamina propria and muscularis mucosa. The tissue was rinsed with buffered saline afterwards to get rid of excess dye. The endoscope, encased with a transparent plastic tube, was deployed in the esophagus, and volumetric imaging was performed by circumferentially scanning the imaging beam (by the micromotor), while the endoscope was pulled back within the stationary plastic tube.

Figure 53.6a shows a respective 2D circumferential frame depicting simultaneous OCT and fluorescence imaging. The 2D OCT image is shown in grayscale, while the fluorescence intensity is depicted as the overlaid colored annulus.

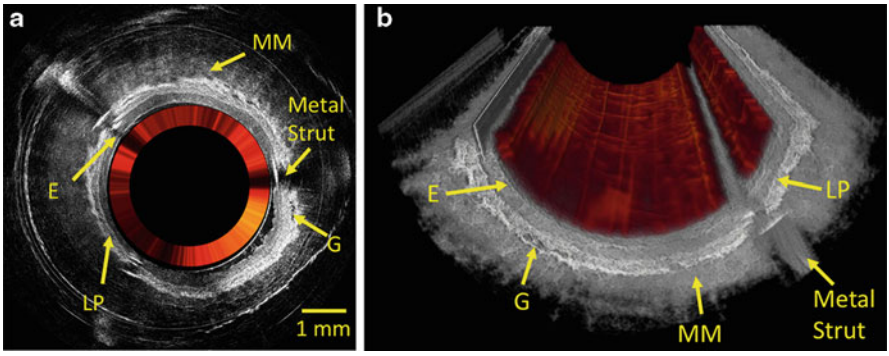

Fig. 53.6 Circumferential scanning and pull back were performed to obtain 3D volumetric OCT images and 2D fluorescence surface map of the esophagus with the dual-modal endoscope. (**a**) Representative 2D cross-sectional OCT image of *ex vivo* rabbit esophagus during one circumferential scan (*grayscale*) with the overlaid inner annulus (*red* hot colormap) of the fluorescence intensity. (**b**) The cut-away view of the 3D OCT volumetric image (*grayscale*) and the 2D fluorescence intensity map inlaid (*red* hot colormap) on top of the OCT image. In both the 2D OCT cross-sectional image and 3D volumetric OCT image the normal layered structures of the esophagus can be clearly visualized, including the epithelium (*E*), lamina propria (*LP*), muscularis mucosa (*MM*), and glands (*G*). The co-registered and simultaneously acquired fluorescence map shows striated structures which are believed to be vasculature. (Figure reprinted with permission from *Biomedical Optics Express*, Optical Society of America)

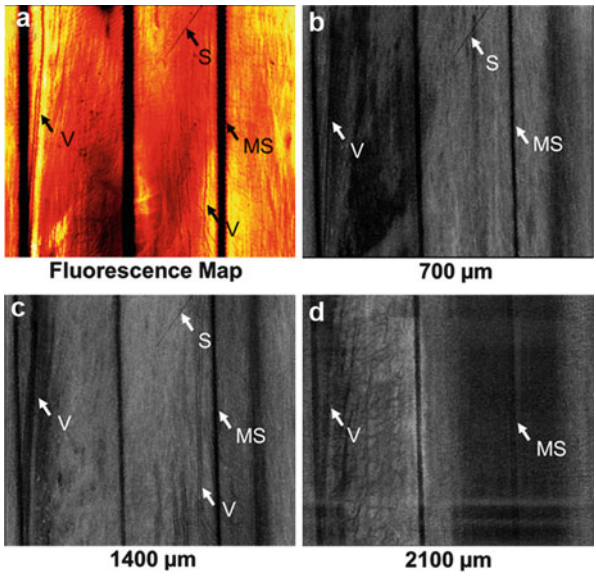

Fig. 53.7 (**a**) Unwrapped 2D Fluorescence image. (**b–d**) Unwrapped OCT images at 700 µm, 1,400 µm, and 2,100 µm depth. The *white arrows* on the OCT images (**b–d**) correspond to the *black arrows* in the fluorescence map (*A*) indicating correlating structures such as vasculature (*V*), suture (*S*), and metal strut (*MS*). The suture was used to provide a registration mark for both OCT and fluorescence intensity images (Figure reprinted with permission from *Biomedical Optics Express*, Optical Society of America)

Similarly Fig. 53.6b shows the cutaway view of the 3D volumetric image with the 3D OCT image shown in grayscale and the 2D fluorescence intensity map inlaid (red hot colormap). The 2D and 3D OCT images are able to visualize normal esophageal structures such as the epithelium, lamina propria, muscularis mucosa, and glands. The inlaid fluorescence images are complementary to the OCT images and display striated structures believed to be the vascular structures of the rabbit esophagus. Furthermore, co-registration and coincidence of the OCT images with the fluorescence intensity images can be seen at three signal poor points which correspond to the metal struts of the metal enclosure.

Imaging was performed with an OCT detection sensitivity of ~108 dB and a penetration depth of 1.7 mm. Both OCT and fluorescence intensity images were acquired simultaneously and were automatically co-registered. In order to demonstrate the correlation between the OCT and fluorescence intensity map, the intraluminal 3D OCT image was flattened into a 2D stack along the imaging depth 700 µm apart and compared with the 2D fluorescence map. Corresponding structures are indicated by the black arrows in the fluorescence map and white arrows in the OCT slices (Fig. 53.7b–d). We visualized a suture (used as a registration mark), striated structures believed to be vasculature and the three signal poor regions corresponding to the metal struts of the metal enclosure.

53.3.2 OCT and Two-Photon Fluorescence Endoscopy

Simultaneous OCT and TPF imaging was performed on both cell culture and *ex vivo* biological tissue. The resolutions were ~2.5 × 10.0 µm (lateral × axial) in air for

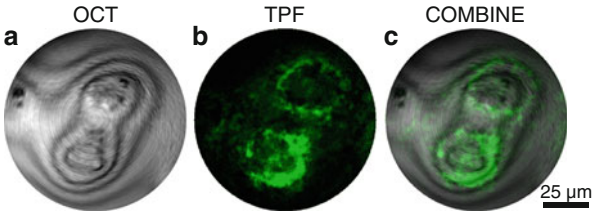

Fig. 53.8 (**a**) OCT and (**b**) TPF images of A431 cancer cells immunostained with anti-EGFR conjugated ICG micelles. (**c**) Superposition of the OCT and TPF images (Figure reprinted with permission from *Optics Letters*, Optical Society of America)

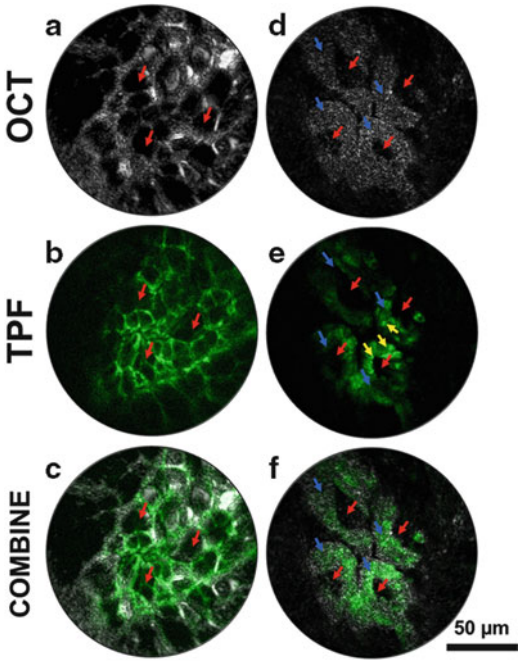

Fig. 53.9 (**a**) OCT, (**b**) TPF and (**c**) superposed images of mouse adipose tissue with local ICG administration. *Red arrow* shown in (**a**) and (**b**) indicates one of the adipocytes visualized under both imaging modalities. (**d**) OCT, (**e**) TPF, and (**f**) superposed images of mouse small intestine tissue with local ICG administration. *Blue arrows* shown in (**d**) and (**e**) indicate villus structures and *red arrows* indicate lacteals. The stronger fluorescence dots indicated by *yellow arrows* shown in (**e**) may be either enterocytes or lymphocytes. Both sets of images show great correlation between two imaging modalities (Figure reprinted with permission from *Optics Letters*, Optical Society of America)

OCT and ~1.2 × 5.7 μm (lateral × axial) for TPF imaging. Imaging was performed through a No. 1 cover glass placed on top of the sample and by a dry micro objective lens of a working distance 200 μm in air. The powers incident on the sample were ~30–50 mW (at 1,550 nm for TPF) and ~4.0 mW (at 1,310 nm for OCT).

Figure 53.8a, b show one set of representative OCT and TPF images of the A431 cancer cells incubated on a coverslip targeted with anti-EGFR conjugated ICG micelles. The superimposed OCT and TPF image is shown in Fig. 53.8c where the whole cell topology can be easily identified with OCT, while the cell membrane is enhanced under ICG TPF imaging. Figure 53.9a, b shows representative OCT and TPF images taken simultaneously from mouse adipose tissue. The overlaid image from the two modalities is shown in Fig. 53.9c, where the OCT and TPF images overlap well, particularly around the cell membranes. Simultaneous OCT and TPF imaging was also performed on mouse small intestine, and the representative OCT and TPF images are shown in Fig. 53.9d, e, respectively. The circular void structures in the OCT image may represent the intestinal villi (indicated by blue arrows) with the lacteals (indicated by red arrows) shown as the areas of lower backscattering on the OCT image. Similar structures were visualized on the TPF image as well. The brighter fluorescent spots (indicated by yellow arrows) on the villi may suggest either the enterocytes or lymphocytes actively absorbed the ICG molecules. The superposed image that is shown in Fig. 53.9f suggested that this endoscopic multimodal imaging platform is able to produce simultaneous imaging even with highly scattering tissues.

53.4 Conclusions

In this chapter, we have discussed the benefits and methodology of how to perform dual-modality OCT and fluorescence imaging endoscopically. The general design considerations were discussed, and key technological challenges and solutions were presented. Some representative images acquired by the dual-modal endoscopy platforms were also presented.

Anterior segment imaging • Corneal pachymetry • Corneal topography • Corneoscleral angle • Crystalline lens • Optical coherence tomography • Tonometry

54.1 Introduction

The anterior segment is the front part of the human eye, which forms the optical system and hence directly impacts vision (Fig. 54.1). It is also the part of the eye that is most exposed to the influences of the external environment. Traumatic or pathological changes in the anterior segment may lead to vision loss and, in some cases, even blindness. Since the eighteenth century, optical instrumentation for measuring and imaging the anterior segment of the human eye has been developing along with modern ophthalmology. Present-day ophthalmic clinics widely use devices such as slitlamp microscopes, gonioscopes, Javal keratometers, and Placido disk-based corneal topographers [1]. Additionally, imaging systems, like rotating Scheimpflug imaging, scanning slit topography, and ultrasound biomicroscopy, are commonly used to obtain quantitative information on the corneal thickness and topography, which may be especially useful for disease diagnosis, precise localization of lesions,

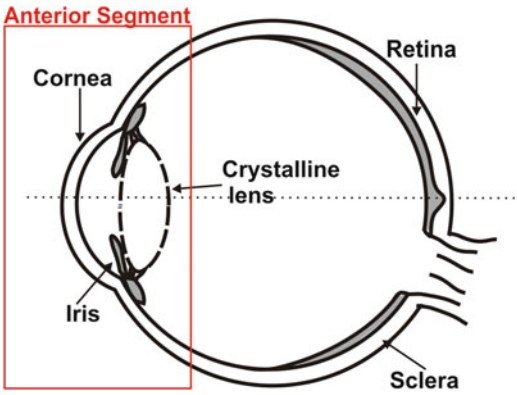

Fig. 54.1 Schematic horizontal section of the human eye

and planning of medical and surgical treatments (especially refractive surgery) [2]. Corneal thickness, contour, and shape of both surfaces can be measured using commercially available systems like Orbscan or Pentacam; however, all currently available technologies suffer from substantial speed limitations.

The optical system of the human eye comprises two optical elements: the cornea and the crystalline lens. The cornea is a quasi-transparent vault-shaped tissue at the front of the eye. It has no blood vessels and is composed of five main layers: epithelium, Bowman's membrane, stroma, Decemet membrane, and endothelium. The cornea provides 85 % of the power refraction, as the larger index of refraction change occurs in the air-cornea interface. The normal cornea is best fit by a prolate conicoid (steeper at the center than along the periphery). The average radius of the anterior corneal surface curvature is 7.87mm and that of the posterior corneal surface is 6.40 $\pm$ 0.28 mm [3]. The average reported corneal conic constants are 0.82 and 0.62 for anterior and posterior surfaces, respectively [3]. The average corneal central thickness is 550 nm [4]. The refractive index changes across layers, with an effective index of refraction of 1.3771 at 598.3 nm [5].

The crystalline lens is a biconvex transparent element that increasingly opacifies with age; it is composed of multiple layers of long fiber cells that originate from the equator and stretch toward the poles of the lens, forming suture patterns at the point where they meet. The lens is covered by an elastic membrane, known as the lens capsule. The anterior and posterior lens surfaces are typically described as having an aspheric prolate shape, with average radii of curvature and conic constants, respectively, of 11.76 mm and -4 for the anterior surface, and 5.96 and -3 for the posterior surface [6]. The typical lens thickness is calculated (in mm) as 2.93 + 0.0236 $\times$ age (in years) [7] in the unaccommodated state. The young crystalline lens can change its shape to focus on near and far objects. The lens capsule is attached via the zonular fibers (mostly around the lens equator) to the ciliary body and ciliary muscle. When the ciliary muscle contracts, the apex of the ciliary body moves toward the lens equator to release tension on the zonular fibers, and the capsule molds the lens into an accommodated form. With accommodation, the lens surfaces become steeper and lens thickness increases. Another interesting optical

feature of the crystalline lens is that the index of refraction is not constant but rather has a gradient distribution (both radially and axially) typically ranking from 1.36 in the nucleus to 1.44 at the surface [8]. The gradient refractive index (GRIN) results in a higher equivalent index (and therefore power) and typically in a more negative spherical aberration in the lens, which compensates for the positive spherical aberration of the cornea. The capability of the lens to shape upon an accommodative effort is lost with age (due to increased stiffness of the lens material). With age, the lens also undergoes shape changes due to its continuous growth throughout life and changes in the GRIN distribution.

In addition to the cornea and the lens, another important element in the anterior segment of the eye is the iris, a thin circular aperture responsible for controlling the diameter of the pupil, and therefore the amount of light entering the eye. Pupil diameter is controlled by ambient illumination, tends to contract upon accommodation of the crystalline lens, can be pharmaceutically controlled, and tends to decrease with aging.

Over the last two decades, there have been several developments in optical technology that have extended our ability to image and evaluate the anterior segment of the human eye. One of the most substantial developments in this field is the application of optical coherence tomography (OCT) to image and quantify morphologic structures of the human eye; this noncontact and noninvasive optical method is very well suited for biomedical applications [9–11]. OCT has found many applications in medicine and clinical practice, primarily because it offers noninvasive and noncontact imaging with relatively high sensitivity; this allows the detection of weakly diffusive, back-reflected light. In OCT applications, the measured thickness of the optically sectioned (coherence-gated) transverse layer is about an order of magnitude thinner than that achievable with scanning laser ophthalmoscopic (SLO) instruments. OCT also offers improved sensitivity due to additional filtering and amplification of the oscillatory interferometric signal. Optical coherence tomography has been most widely applied to retinal imaging [12–15]. This method was initially commercialized by Zeiss with three generations of retinal OCT devices (OCT1, OCT2, and Stratus OCT). Later, another time-domain OCT instrument was introduced to ophthalmology clinics – an en-face OCT/SLO device (OTI) that offers a unique combination of the two abovementioned imaging modalities [16–18]. At that time, it was rare to obtain in vivo three-dimensional images of the entire structure of the eye, primarily due to the physical and technical limitations of the TdOCT method that influenced measurements of time, sensitivity, and resolution.

Introduction of Fourier domain detection in OCT has opened new frontiers in OCT ophthalmic applications. Most importantly, the resultant substantial speed improvement enables rapid image acquisition, helping to reduce artifacts due to patient motion. Thus, it is currently possible to perform high-speed in vivo three-dimensional volumetric imaging over large scales within a reasonable time limit and without reducing system sensitivity [19–22]. Fourier domain OCT (FdOCT) had the additional advantage of making the system sensitivity independent of the axial resolution (i.e., the resolving power of the imaging system in the direction of the propagation of the probing light beam) [14, 21, 23–27]. There are currently

more than seven commercially available FdOCT instruments dedicated for retinal imaging; the functionality of most of them can be extended to cornea imaging, but only in the limited range of 2–3 mm.

The application of OCT to the anterior segment imaging is particularly of interest, since this could potentially provide substantial complementary information regarding the large-scale architecture of the cornea and the crystalline lens, or on small portions of tissue imaged with high spatial resolutions comparable to regular microscopy. The latter could be used for ophthalmic diagnoses, including detailed monitoring of the Bowman's membrane, corneal epithelium, stroma, capsule of the crystalline lens, intraocular lens surface, conjunctiva, or the corneoscleral junction. Meanwhile, large-scale imaging, covering a depth of 6 mm and 12 mm × 12 mm of the transverse range, can provide morphometric parameters, including the corneal thickness and topography, iridocorneal angle, and orientation of intraocular lens [28, 29]. Additionally, remarkable advances in the field of refractive surgery have created requirements for more accurate imaging and measurements of corneal curvature and topography [30]. Three commercially available instruments are exclusively dedicated to diagnoses of the anterior segment; each of them have an imaging light with a 1,300-nm central wavelength, which allows visualization of the whole anterior segment, from limbus to limbus and from the front corneal surface to the posterior surface of the crystalline lens [19]. This spectral bandwidth also ensures improved safety due to the high water absorption of 1,300-nm radiation compared to 800-nm light wavelengths. One of the commercial instruments is the Visante OCT (Carl Zeiss Meditec) and the second is the SlitLamp OCT (Heidelberg Engineering); both use TdOCT. These systems can only collect a couple of thousand A-scans per second; therefore, acquiring an image in a reasonable amount of time allows only a sparse sampling. Quantitative analysis of the cornea can be affected by motion artifacts and imperfections in patient adjustment (in asterisk scan patterns). Substantial improvement of the imaging speed would allow increased sampling density and reduce the influence of motion artifacts, which can be crucial for improved repeatability and accuracy of the corneal topography. The other commercially available OCT device for anterior segment imaging is the SS-1000 Casia (Tomey), the only commercial instrument that uses state-of-the-art technology with swept-source OCT. Unfortunately, this instrument does not exploit the full potential of swept-source OCT, because its imaging speed is 30,000 optical A-scans/s, similar to that of commercially available retinal SOCT devices.

54.2 Technical Advantages and Limitations of Anterior Segment FdOCT Instruments

Compared to retinal imaging, imaging the anterior segment of the human eye requires substantially different measurement conditions and instrumentation. The table in Fig. 54.2 presents the main parameters cited from literature [31–33] that are important for optical imaging of the anterior segment of the human eye; they determine the requirements and limitations in dynamic range, the sensitivity and

Dimensions			Sample	μ_a	μ_s	μ_t	n	D	T	Rd
	Wavelength [nm]	980	Sclera	0.90	27.0	27.9	1.41	1.00	0.32	0.400

Fig. 54.2 Basic optical properties of ocular tissue for 980 nm and 1,310 nm: μ_a, absorption coefficient; μ_s, scattering coefficient; μ_t, extinction coefficient; n, refractive index; D, thickness in mm; T, transmittance; R, diffused reflectance; data collected from Refs. [31–33]

penetration depth of the optical imaging instrument. Careful analysis of these numbers will assist in choosing the optimal wavelength and imaging speed of the device. The most substantial restriction of OCT is the limited penetration depth of the probing light beam in biological tissues. Additionally, the multiple scattering of detected backscattered light substantially reduces the quality of reconstructed images. Therefore, OCT imaging is limited to applications in ocular anatomical structures that weakly scatter light with only a small amount of melanin or hemoglobin. In retinal imaging, the light has to travel through about 2.5 cm of ocular media (mostly through transparent tissues containing water, which strongly absorbs infrared radiation); thus, retinal OCT can only use wavelengths in the optical window of 400–1,100 nm. This limitation does not apply to anterior eye imaging. Typically, light in the near-infrared range ($\lambda = 0.8$–1.3 μm) penetrates well through optically transparent parts of the anterior segment, like the cornea, vitreous, and crystalline lens. However, penetration of the sclera (Fig. 54.2) and iris is still substantially limited. Typically, near-infrared light (700–1,300 nm) penetrates the sclera to a depth of approximately 1 mm. The iris has also low transmittance and high scattering, but it is difficult to determine their absolute values due to high individual variability of the melanin concentration.

The most important challenge in anterior segment imaging is that data must be collected from a much larger volume than for retinal OCT. To obtain all information about the entire corneal architecture, including the corneoscleral junction and the corneal apex, a volume of approximately 15 mm × 15 mm transversally and 5 mm in depth must be scanned. Thus, if a relatively high scanning density is maintained, along with high axial resolution, a substantially greater amount of data will be captured with the acquisition system and stored in the hard drives. For example, three-dimensional reconstruction of the anterior segment with a voxel size of 20 μm × 20 μm × 3 μm and 10-bit analog-to-digital conversion requires collection of 4.5 GB of data. In practice, this information must also be acquired during a short enough time to minimize the negative impact of sample motion; this

concern sets the fundamental speed requirements for the imaging devices to sample at the order of magnitude of gigasamples per second. Such requirements are highly demanding for the state-of-the-art technology, both regarding optical detection with the digitalization and transfer to PC. To meet the abovementioned specifications, an ideal OCT device should run with more than 500,000 A-scans/s to collect high-resolution volumetric data from the entire anterior segment within 1 s.

One feature that makes OCT attractive as a diagnostic tool is that it can perform imaging with resolutions comparable to that of histopathology. Longitudinal (axial) OCT resolution is determined by the central wavelength and spectral bandwidth of light. Another fundamental constraint is the limited lateral resolution, which is related to the finite numerical aperture (NA) of the optical system. This restriction has different effects on imaging, depending on whether OCT is used for imaging the fundus or the anterior segment of the eye. When imaging the retina, the natural optics of the eye limits the available NA and, for beams larger than 2–3 mm, introduces severe distortions of the wavefront, thus substantially degrading the lateral resolution of OCT devices. When imaging the anterior segment of the eye, the restricted optical performance obliges a trade-off between the lateral resolution and the measuring range [34]. Fourier domain OCT systems – those using parallel detection with a spectrometer (SOCT, SdOCT) or serial detection with swept source – have the broadest range of applications. Each type of FdOCT can be optimized for specific applications within the limits of the currently available detector technology and wideband light sources. It has been demonstrated that both types of high-speed FdOCT instruments can provide complementary information about the morphology and architecture of the anterior segment [34, 35].

54.2.1 Parallel Registration by FdOCT Using Spectrometer (SOCT, SdOCT)

Spectral OCT (SOCT) is especially well suited to imaging small portions of anterior segment tissue with high spatial resolutions, comparable to regular microscopy [36]. In fact small software and hardware modifications enable the conversion of a commercially available retinal system into an anterior segment imaging OCT instrument. However, in such case, the ergonomics of commercially available retinal OCT systems is not optimal. This configuration has already been optimized for ultrahigh-resolution retinal OCT imaging at 800 nm in laboratory setups or prototype instruments [19, 37, 38]. One of the examples of such ergonomic prototype device has been developed and introduced by Optopol Technology. Figure 54.3 shows examples of high-quality anterior segment imaging using SOCT Anterius instrument.

Despite limited imaging range of 800 nm high-resolution SOCT instruments, it has been demonstrated that this technology has a potential to become a powerful, noninvasive clinical corneal imaging modality that can enhance diagnosis and surgical treatments. Figure 54.4 shows examples of high-quality corneal imaging using laboratory SOCT instruments, which may be helpful in understanding clinical

pathologic features related to the various corneal diseases including corneal scars and keratitis, bullous keratopathy, epithelial defects, granular corneal dystrophy, and Fuchs endothelial dystrophy [36, 39, 40].

High-resolution SOCT also improves visualization of structures and their relationship to incisional and refractive corneal procedures like penetrating keratoplasty, phacoemulsification, Descemet membrane stripping, endokeratoplasty, corneal implantation for keratoconus, and laser in situ keratomileusis [36, 41]. Figure 54.5 shows examples of high-resolution imaging of cornea after radial keratotomy and penetrating keratoplasty visualizing various postoperative corneal changes like scars, change of the corneal architecture, or the morphology of donor-host corneal junction [36].

In the regular clinical practice, SOCT images of corneal abnormalities may enhance slitlamp biomicroscopic examination, and they can be especially useful in the preoperative and postoperative clinical treatment of patients undergoing cataract surgery. Figure 54.6 shows examples of high-quality and high-resolution imaging of anterior segment showing changes in Descement membrane morphology, corneal incision, intraepithelial vesicles, and posterior capsule opacification – all effects are secondary to the cataract surgery.

Large-scale architecture of the cornea and the crystalline lens can be also imaged using SOCT [34]. However, the SOCT instrument is much less flexible and more demanding than swept-source OCT device. This is mainly because SOCT technique has fundamental and technological limitations in imaging range and sensitivity, especially when the imaged sample has substantial curvature. In such cases, the combination of depth-dependent sensitivity drop-off [19] and fringe washout [42] effects will have a radical negative impact on image quality. Additionally, SOCT setup has limited options for adjusting the axial resolution and measurement range; these parameters depend on the design of the spectrometer and spectral range of the light source. Using a CMOS camera in the spectrometer improves the system's flexibility compared to CCD-based systems. In such a configuration, CMOS sensors usually enable programmable changes of the number of active pixels, which can improve the measurement speed. Unfortunately, reducing the number of active

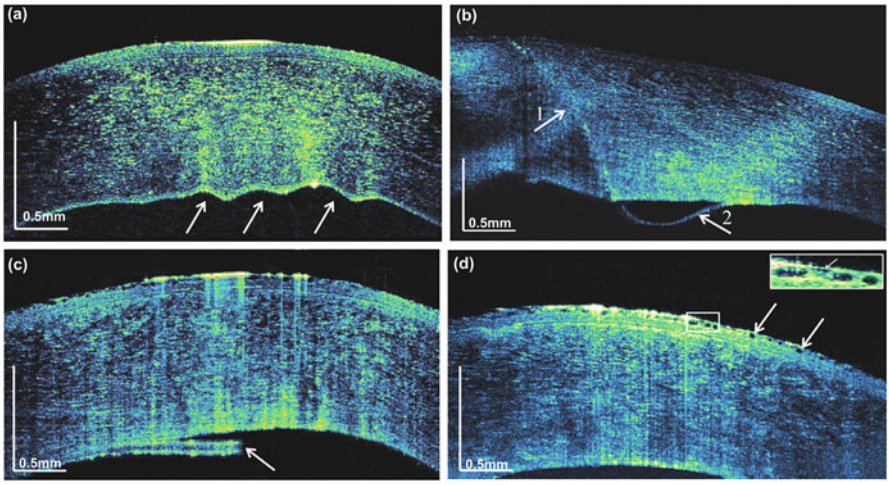

Fig. 54.6 OCT imaging of corneal changes after cataract surgery. (**a**) Folds of Descemet membrane (*arrows*), first day after surgery. (**b**) Corneal incision (*arrow 1*) and detachment of the thin posterior layer of the cornea (*arrow 2*), first day after surgery. (**c**) Partial removal of Descemet membrane (*arrow*), third day after surgery. (**d**) Intraepithelial vesicles caused by edema (*arrows*), third day after surgery; smallest resolved object (insert, *arrow*) is 25 mm wide and 5 mm deep (Image reprinted from B. J. Kaluzny et al., Cornea 25, 960–965, 2006, copyright Lippincott Williams & Wilkins 2006 [36])

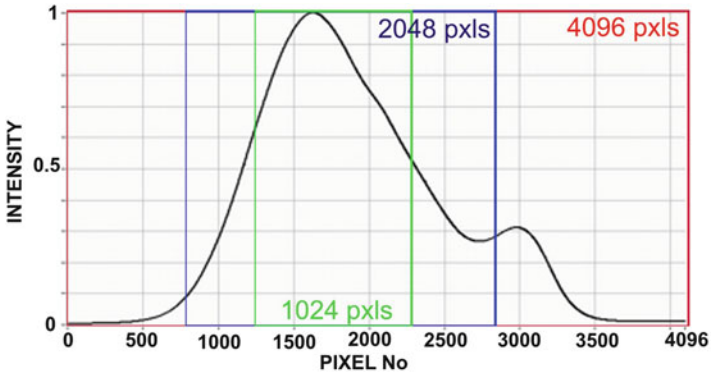
CMOS camera pixels without changing the configuration of the optical elements in the spectrometer results in truncation of the spectrum (Fig. 54.7). Consequently, the axial resolution and sensitivity decrease together with the reduction of pixel number. The last column in the right panel of Fig. 54.7 shows the effective sensitivity values, considering both the shortening of the signal integration time and the truncation of the spectrum.

As presented in [34], even with all of these obstacles, it is possible to obtain high-quality cross-sectional OCT images of the entire cornea with an optimized OCT setup. In this case, high-speed imaging (118,000 A-scans/s) of the cornea and the crystalline lens simultaneously required very careful adjustment of the focal plane of the imaging lens and accurate positioning of the sample in respect to the zero optical path delay (OPD). This procedure helped to compensate the sensitivity roll-off of 20 dB over 5 mm. Figure 54.8 shows OCT images of the healthy eye of the same subject registered for different parameters, including sampling density, registration speed, and position in reference to zero OPD. According to the table in Fig. 54.7, the images were obtained with different sensitivities of 89 dB and 97 dB and axial resolutions 15 μm and 7 μm. Both systems had the same values of transverse resolution Δx (27 μm) and the confocal parameter ς (3.6 mm). Even with the relatively low axial resolution in Fig. 54.8 compared to that from Fig. 54.3, the architecture of the cornea, anterior surface of the lens, and irido-scleral angle are well reconstructed in Fig. 54.8b.



SOCT system parameters for different number of active pixels of the CMOS camera

Number of pixels	Axial resolution [μm]	Sensitivity at T_{exp}= 40us [dB]	Minimum repetition time $T_{rep}^{(min)}$ [μs]	Sensitivity at $T_{rep}^{(min)}$ [dB]
4096	6.9	102	14.2	97.5
2048	8.7	101	7.8	94
1024	15.4	98	4.7	89

Fig. 54.7 Spectrum of the light source used in the spectrometer-based FdOCT system. Areas of interest where the camera has captured 4,096, 2,048, and 1,024 pixels are indicated by *red*, *blue*, and *green rectangles*, respectively. The resolution decreases from 6.9 to 15.4 μm and the sensitivity drops by 4 dB if calculated for a given constant exposure time (T_{exp}) of 40 μs (Image reprinted with permission from OSA, I. Grulkowski, et al., Opt. Express 17, 4842–4858, 2009 [34])

54.2.2 Serial Registration by FdOCT Using Swept-Source Technology (SS-OCT, OFDI)

As mentioned above, an ideal OCT anterior segment imaging system should combine two functionalities: providing high-quality and high-resolution cross-sectional images and having a programmable mode for measuring larger volumes. One of the most important technological advantages of the swept-source OCT setup is more flexibility and robustness in the opto-mechanical design, which can make swept source more advantageous in commercialization. Another important advantage of swept-source OCT device is the substantially lower sensitivity roll-off, which enables more optimal use of the entire measurement range. Moreover, some

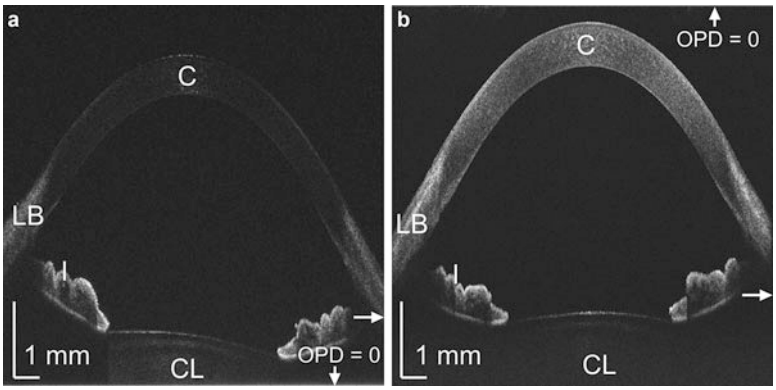


Fig. 54.8 2D OCT imaging of the cornea and anterior chamber using spectrometer-based Fourier detection: (**a**) single-line exposure time, 8.5 μs; repetition rate, ~117,000 A-scans/s; 10,000 × 1,024 pixels; 15 mm and (**b**) single-line exposure time, 53 μs; repetition rate, ~19,000 A-scans/s; 10,000 × 4,096 pixels; 15 mm. Structural elements are visible, including the cornea (*C*), limbus (*LB*), iris (*I*), and crystalline lens (*CL*). Position of zero optical path difference ($OPD = 0$) is indicated. *Horizontal arrows* show the position of the focal plane of the imaging lens (Image reprinted with permission from OSA, I. Grulkowski, et al., Opt. Express 17, 4842–4858, 2009 [34])

swept-source OCT devices are more flexible in the rapid adjustment of axial resolution and measurement range. Operating in different programmable regimes requires controlling the spectral span of light generated by the source; this can be done, for example, by flexible driving of the optical filter in the laser cavity. Unfortunately, not all designs of high-speed tunable light sources enable such control. The three major concepts behind achieving high-speed tuning differ in the method used for wavelength selection inside the laser cavity of the wavelength-swept source: one is based on a fast rotating polygonal mirror [43, 44], another based on a diffraction grating on a mechanically resonant galvo-scanner [45], and the third uses a Fabry-Perot tunable filter (FP-TF) [46, 47]. Only the third solution is able to switch between different modes by changing the amplitude of the FP-TF driving signal: the lower the amplitude of the driving signal, the narrower the wavelength scanning range. In principle, it is possible to choose any value for the axial resolution, limited only by the spectral bandwidth of SOA (highest resolution) or by the laser mode stability (lowest resolution). Gora et al. have demonstrated examples of bimodal operation of swept-source OCT [35]. The high speed of the swept-source OCT system enables high-definition imaging of large volumes, as well as high-accuracy reconstruction of certain portions of the anterior segment morphology, like the irido-scleral angle (Fig. 54.9).

The main limitation in the development of swept-source OCT technology is set by technological problems in developing swept sources for 800 nm and the visible range. Use of shorter optical wavelengths helps in optimization of the system performance in terms of image quality and the resolution. Also the speckle pattern can be reduced more effectively for shorter wavelengths. Finally in swept-source lasers, additional phase jitter can occur since the phase of registered interferometric

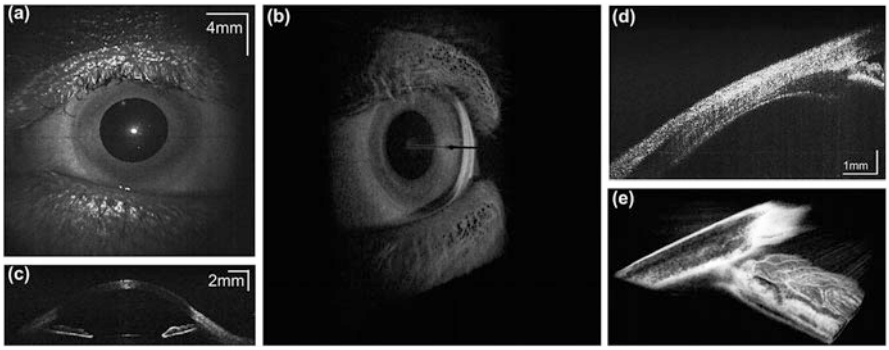

Fig. 54.9 Swept-source OCT imaging of the anterior segment of the human eye in vivo with single-line exposure time of 5 μs. (**a**) En-face view. (**b**) 3D rendering reconstructed from a 1,200 × 300 × 1,024 voxel dataset, with the size of the imaged volume 20 mm × 20 mm × 6 mm. (**c**) Representative cross-sectional image. (**d**) Cross-sectional image of the iridocorneal angle. (**e**) 3D rendering generated from the 3D data set (1,000 × 500 × 1,024 voxels) (Image reprinted with permission from OSA, M. signal is changed by mechanical filtering of optical frequency components in the laser cavity. One of the future challenges is in fast data processing and new algorithms for image processing, which can deliver more reliable and clinically significant information. Also high-speed systems provide huge amount of data which should be managed online.

54.2.3 Main Constrains of Anterior Segment FdOCT Method and Technology

One of the main objectives of high-quality and high-resolution in vivo anterior segment imaging is to achieve accuracy similar to that in microscopy. It is especially important for imaging of Bowman's layer, the epithelial and endothelial tissue layers in the cornea, endothelium, and the capsule of the crystalline lens. However, a careful look at any magnified OCT cross-sectional image reveals that high spatial frequency intensity modulations are superimposed on the reconstructed structure; this modulation is called speckle noise, or a speckle pattern [48]. This "speckle noise" deteriorates OCT image quality and resolution and it occurs always when scattering samples are imaged.

Speckles result from random phases of backscattered light reflected from a rough surface or tissue with scattering structures that are smaller than the focused beam. This stochastic intensity distribution will depend on two factors: irregularities in the imaged tissue and diversity in the phase of detected light. The latter is based on the spectral bandwidth of the light and the NA of the collecting optical system. One important parameter that defines the speckle field is the speckle size. The average speckle spot size will increase with decreases in NA and spectral bandwidth. Thus, the NA of the collecting optics determines the angular range of

scattered light that can be collected by the optical system: the greater the range, the smaller the average speckle size. Similarly, the NA of the device determines the lateral resolution of OCT; increasing NA leads to improved lateral resolution and reduced average speckle size. The electromagnetic field generates a different speckle pattern for each optical frequency component, resulting in additional modulation of the signal as a function of optical wavelength; moreover, after the Fourier transformation is applied, it also causes an intensity modulation in the axial direction. Therefore, two effects – transverse and axial – cause the speckle pattern in cross-sectional OCT images.

One of the main objectives of high-quality OCT imaging with micrometer resolution is to effectively reduce the contrast of speckles. Unfortunately, the presence of speckles is fundamentally related to the formation of the OCT image. In most cases, speckle noise reduction is achieved by averaging multiple images with variable, uncorrelated speckle patterns. Uncorrelated speckle patterns that originate from the same structure can be obtained by tracking speckles in space, over time, or by polarization diversity [49–51]. There are several ways to collect uncorrelated speckle patterns, such as compounding optical frequencies with two incoherent interferometer signals that use two light sources with different central wavelengths [52], applying light with orthogonal polarization states, using a partially spatially coherent light source [53, 54], angular compounding [55–59], inducing mechanical stress to the sample [60], or changing the position of the focusing objective [61]. The most common way of de-correlating the speckle pattern for in vivo imaging is the random spatial compounding method. In this method, a set of two- or three-dimensional images is acquired, with the expectation that the object's natural instability (bulk motion) will cause a small dither in the scanning beam on the object and that this will induce strong variability in the speckle pattern [62–65]. This method has been combined with an eye tracker system in the Spectralis OCT instrument that was brought to the market by Heidelberg Engineering [66]. However, this technique is not fully controlled and can depend on the stability of patient fixation. An eye tracker is used to minimize randomness [67, 68], but the accuracy of this type of device is less than 50 μm [69].

Szkulmowski et al. recently published a study that applied speckle averaging in anterior segment imaging with the spatial compounding technique; this technique is insensitive to sample bulk motion and allows precise control of lateral resolution [70]. The authors used a scanning protocol with a resonant scanner that applied fast beam deflection in the direction perpendicular to the tomogram lateral dimension. This scanning protocol reduced the time interval between the A-scans to be averaged to the repetition interval of the acquisition system. As a result, the averaging algorithm did not require sophisticated data processing to align tomographic images, it is nearly immune to bulk motion in the investigated sample, and it allows precise control of lateral shifts in the scanning beam on the object. The authors also demonstrated a method for optimizing the dithering amplitude using the contrast-to-noise value. Figure 54.10 shows examples of high-resolution and high-quality FdOCT imaging with reduced speckle contrast. Corneal imaging shows a slight change of the imaging contrast within the epithelial layer, forming two layers of

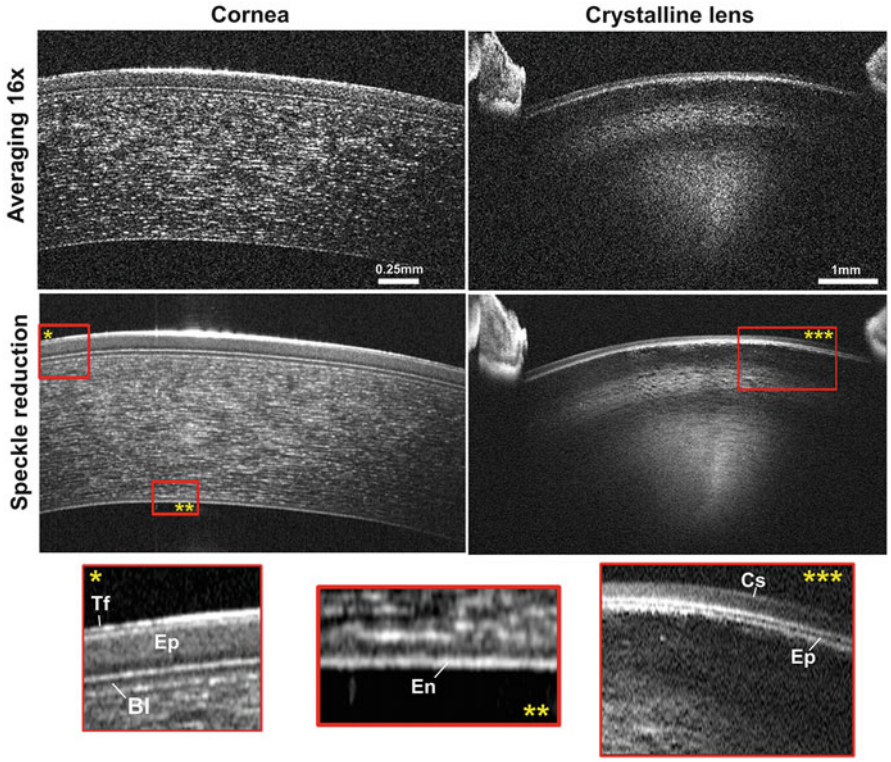

Fig. 54.10 Speckle reduction in OCT images. Axial resolution: 4.2 μm in tissue, imaging range 2.5 mm (cornea) and 7 mm (crystalline lens), imaging speed 200,000 lines/s. Speckle contrast was reduced by precise control of the orthogonal dither of the scanning beam set to 110 um (Image reprinted with permission from OSA, M. Szkulmowski, et al., Opt. Express 20, 1337–1359, 2012 [70])

different reflectivity; the Bowman layer is also visible with reasonable contrast, which is less clearly distinguishable in images without reduced speckle contrast. The reconstruction of the stroma in the posterior section of the cornea reveals a more homogeneous layer close to the endothelium, possibly indicating the presence of Descemet's membrane. It is also possible to distinguish the tear film, probably because the image was taken right after the eye blink, at the moment when the tear film was relatively thick. Speckle reduction also improves cross-sectional imaging of the crystalline lens, where the lens capsule and epithelium are clearly distinguishable. Furthermore, the internal structure of the lens is reconstructed, providing substantial new information about the refractive index distribution within the lens.

This method can only be used for objects with specific morphological symmetry, due to the trade-off between reduced speckle contrast in two dimensions (cross-sectional image) and resolution in the third coordinate (perpendicular to the plane of the cross section). Several technological considerations also limit the construction of highly efficient, high-resolution spectrometers and interferometers.

Ultimately, improved speckle reduction might require the introduction of novel techniques that remain to be discovered. However, there is a high probability that future state-of-the-art OCT technology will be free from speckle noise.

One of the main technological constraints of anterior segment FdOCT is limited axial imaging range. It is mostly caused by a combination of two fundamental technological limitations in Fourier detection scheme: sensitivity roll of due to the limited spectral resolution of the detection system (or instantaneous linewidth in swept source) [19] and additional presence of coherence noise and complex conjugate terms in the FdOCT signal [71]. As it was mentioned before, the sensitivity roll-off may be minimized by using swept-source OCT instruments [72]. However, the second effect is more fundamental and it cannot be solved by a development of better components or a careful design. For relatively thin objects like a retina, it is possible to design OCT instrument to set the total measurement range at least twice larger than the thickness of the measured sample. In such case, there is the possibility of separating the coherence noise components and complex conjugate images from the object's structure reconstruction via a proper selection of the optical path difference between the reference mirror and the first surface of the examined object [12]. However, this procedure may often fail in the case of the anterior segment imaging where measured object has usually significant curvature. In this case, in order to avoid complex conjugate terms and extend the imaging range, it is necessary to introduce a substantial modification to FdOCT technique, which enables to reconstruct complex representation of measured signal and differentiate between complex conjugate signal components. This modified technique is called complex FdOCT [71]. Complex FdOCT technique requires the optical path difference (OPD) between the arms of the OCT interferometer to be varied (either a constant rate or discreet steps synchronized with the detection system) during the acquisition of the interferometric signal. Constant OPD change introduces a carrier frequency for every wavenumber along the time axis. Then an application of two-dimensional Fourier transformation will translate the wavenumber-time space to the depth-velocity space. As a consequence, both complex conjugate images are separated and shifted in opposite directions along v axis. Filtering procedure of negative values of v is equivalent to application of Hilbert Transformation, which in turn provides the complex representation of the real signal. An example of application of a technique of complex conjugate image removal based on the FdOCT using spectrometer has been demonstrated by Grulkowski et al. [45]. Authors demonstrated imaging of the entire anterior segment of the human eye including the cornea, anterior chamber angle, iris, and the entire crystalline lens (Fig. 54.11).

54.3 Application of FDOCT to Ocular Morphometry

OCT allows acquisition of high-resolution images of the anterior segment of the eye. Several diagnostic applications only require visual inspection of the structures and are greatly benefited by the 3D view of the images. However, many cases

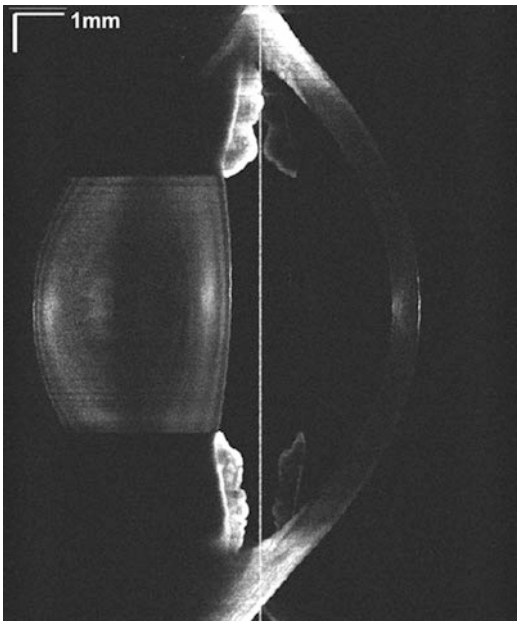

Fig. 54.11 Full-range complex FdOCT image of the entire anterior segment of eye (Image reprinted with permission from OSA, I. Grulkowski, et al., Opt. Express 17, 4842–4858, 2009 [34])

require full quantification of the images, particularly if the images are to be used to guide surgery (e.g., for selection of an intraocular lens to be implanted in cataract or phakic IOL surgery), for identification of candidates for refractive surgery, or for contact lens fitting.

Quantification of OCT images requires image processing algorithms for automatic retrieval of the surfaces and volumes of interest and to correct distortions present in the images. Generally, OCT images are affected by so-called fan distortion [73, 74], which arises from the scanning architecture of the OCT, typically consisting of two physically separated scanning mirrors and resulting in the image of a flat surface not appearing flat (typically with meridional differences in curvature). The amount of fan distortion can be theoretically predicted from the design parameters of the system (focal length of the collimating lens, distance between mirrors, etc.); it can be minimized by hardware, but must be fully corrected by calibrations of the system and software (relying on the computation of the cosine directors of each ray and the correspondence between the instrument coordinates and the local coordinates in space within the object volume) [75]. Correction of fan distortion improves the accuracy of the anterior surface shape reconstruction by 3 % [76]. Anterior segment OCT images are also subject to optical distortion, arising from the fact that objects (posterior cornea, iris, and anterior and posterior lens) are imaged through preceding refracting surfaces. In OCT, it is typically assumed that rays do not bend at the interface, as the optical distances are simply divided by the index of refraction to compute distances. Optical distortion correction is obtained from 3D ray tracing, considering refraction at every interface (subsequently for all surfaces) [77]. Correction of optical distortion improves accuracy of posterior corneal surface reconstruction by 6.2 % and by up to

30 % in reconstruction of the posterior lens shape [78]. Motion artifacts are another potential source of distortion. Decreasing acquisition times have attenuated the impact of subject motion, and motion correction algorithms have also been proposed to compensate for these errors by software [79].

High-resolution high-speed acquisition makes it possible to collect immense amounts of data in a short session. Quantification of these images requires automatic image processing, which allows identification of the structures of interest, correction, and parameterization. Image processing algorithms allow automatic characterization of anterior OCT images and include denoising algorithms, statistical thresholding, volume clustering, multilayer segmentation, axis reference estimates, 3D volume merging, geometrical distance calculation, and surface fitting (sphere, conics, and Zernike polynomials) [76]. Additionally, combining OCT images of the crystalline lens (acquired in vitro in two orientations: with the anterior surface up and the posterior surface up) with global search algorithms allows 3D reconstruction of the GRIN distribution of the crystalline lens [80]. Several studies have evaluated the potential impact of the presence of GRIN on the visualization of the posterior lens surface and its inclusion in optical distortion correction algorithms [81, 82].

Resolution of these challenges has enabled production of quantitative 3D anterior segment imaging (particularly anterior and posterior corneal surface elevation maps), anterior and posterior crystalline lens surface elevation maps, pachymetry, 3D biometry, crystalline lens or intraocular lens alignment in vivo, and crystalline lens GRIN distribution maps in vitro. Applications have been performed in normal eyes [76, 83], in eyes with corneal disease (keratoconus) [30, 83], and after corneal (intrastromal ring segments) [84] and intraocular (IOLs) implants [78].

The above-described methods allow full quantification of the anterior segment of the eye. Figure 54.12 shows a merged image of the cornea, iris, and lens in a normal eye (73 years old) in vivo and the corresponding reconstructed elevation maps for the corneal and lens surfaces. These images also allow estimation of pachymetry, anterior chamber depth, and intraocular lens tilt and decentration.

54.3.1 Corneal Topography

Quantitative analysis of corneal thickness and topography performed by FdOCT instruments has a significant potential in diagnosis of diseases, precise location of lesions, and planning of medical and surgical treatments. Additionally the remarkable advances in the field of refractive surgery have increased requirements for accurate measurements of corneal topography. Currently available systems, like rotating Scheimpflug (Orbscan, Pentacam), scanning slit topography, and ultrasound biomicroscopy are able to provide quantitative information about the corneal architecture [2]. Their main drawback is acquisition speed and limited dynamic range. Additionally the requirement of subjective fixation may always cause uncontrolled translation and rotation of measured cornea in respect to the instrument [85], which in turn may strongly influence the topographical analysis. Anterior segment OCT has significantly larger dynamic range when compared to other

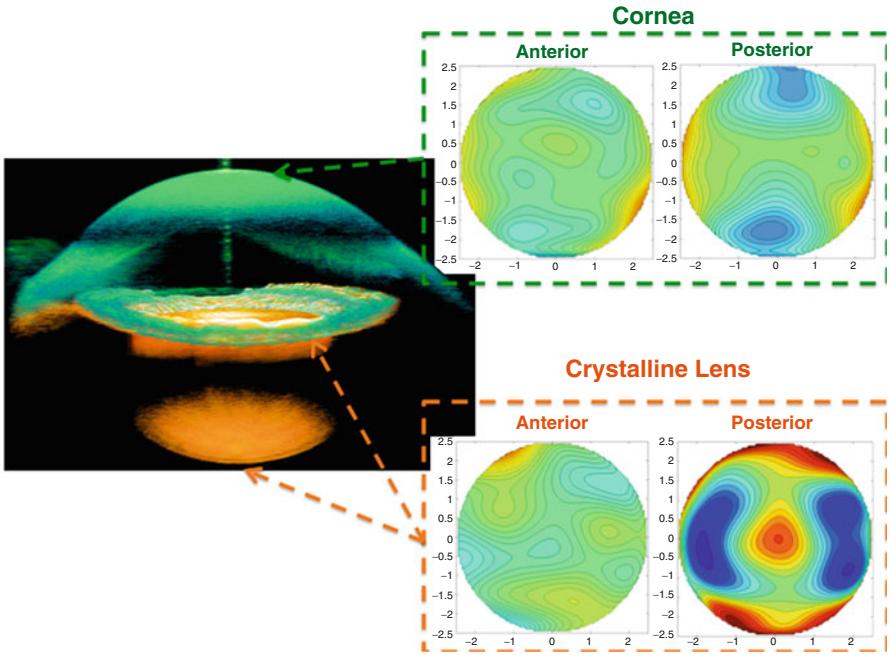

Fig. 54.12 3D full anterior segment in a normal eye, along with quantitative anterior and posterior corneal topographies, and anterior and posterior crystalline lens topography (Image reprinted with permission from OSA, Ortiz et al., Biomedical Optics Express 3, 814–825, 2012 [83])

corneal topographers. It has been already demonstrated that OCT-based anterior corneal topography in normal subjects is comparable (within 2 %) to that obtained using state-of-the-art clinical instruments (Placido disk videokeratoscopy and Scheimpflug images) [30, 76, 78, 83]. In addition, OCT-based corneal topographies show high repeatability (<1 %). Figure 54.13 shows a comparison of anterior corneal topography in a young patient obtained with different instruments and repeated measurements with OCT. The analysis is performed in the form of elevation maps (referred to the best-fitting sphere) as well as radii of curvature and asphericities obtained from biconic fittings.

High-speed OCT instrument with imaging speed of 200,000 A-scans/s. demonstrated by Gora et al. and Karnowski et al. [30, 35] enabled acquiring three-dimensional datasets within 250 ms with sampling density sufficient for quantitative analysis of the anterior segment of the eye [86, 87]. The analysis including reconstruction of corneal topography elevation BFS (best fit sphere) and thickness maps based on a dense raster scan OCT data with reduced number of motion artifacts was demonstrated for eye with a pathology (Fig. 54.14). One of the first demonstrations of high-speed OCT application to quantitative corneal analysis was published by Karnowski et al. [30]. Authors compared corneal topography for three pathologic corneas: keratoconus, a cornea with superficial postinfectious scar, and a cornea 5 months after penetrating keratoplasty. Measurements were performed by FdOCT,

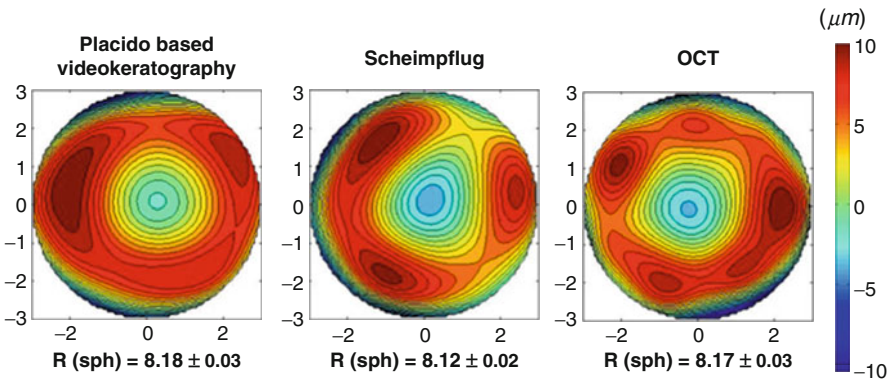

Fig. 54.13 Comparison of anterior corneal surface topography in one normal subject, obtained using commercial corneal topographers (Placido-based videokeratography and Scheimpflug), along with a custom OCT-based OCT (Image reprinted with permission from OSA, Ortiz et al., Biomedical Optics Express **2**, 3232–3247, 2011 [76])

conventional Placido-based topographer (PTC 110, Optopol Technology, Poland), and a rotating Scheimpflug camera (Pentacam HR, Oculus, Germany). Figure 54.14 shows the topographic analysis of a clinically significant keratoconic cornea. Anterior elevation topographies, central keratometry value K1, axis in a flat meridian, posterior corneal topography, and pachymetry were comparable for all instruments. More complicated case of the eye 5 months after penetrating keratoplasty are shown in right panel of Fig. 54.14. In this case, Placido reflections are very distorted. Although only a couple of rings in the center could be partially distinguished and analyzed by the computer, the Placido system provides a curvature map of the entire cornea, even the part that is hidden behind the upper lid. As it might be expected, the differences in central keratometry reading are very large in comparison to Pentacam and FdOCT. Anterior topographies from Pentacam and FdOCT show comparable patterns, but the elevated central island is located slightly higher on the OCT map, resulting in a significant difference in central keratometry readings.

Very practical advantage of morphometric analysis based on OCT data is that one instrument can provide information that was previously only possible to obtain with a few, independent, diagnostic devices. Additionally quantitative analysis of OCT data is usually associated with the reduction of the data dimension, which enables quick assessments of the condition of the ocular structure without requiring a one-by-one study of all cross-sectional images in 3D volumetric set of data.

54.3.2 Architecture of the Crystalline Lens

OCT imaging of the crystalline lens is challenging due to its considerable thickness ranging from 3.5 to 4.8 mm and its high transparency. In contrast to the imaging of the corneoscleral junction, higher diffuse reflectance and less absorption offered by

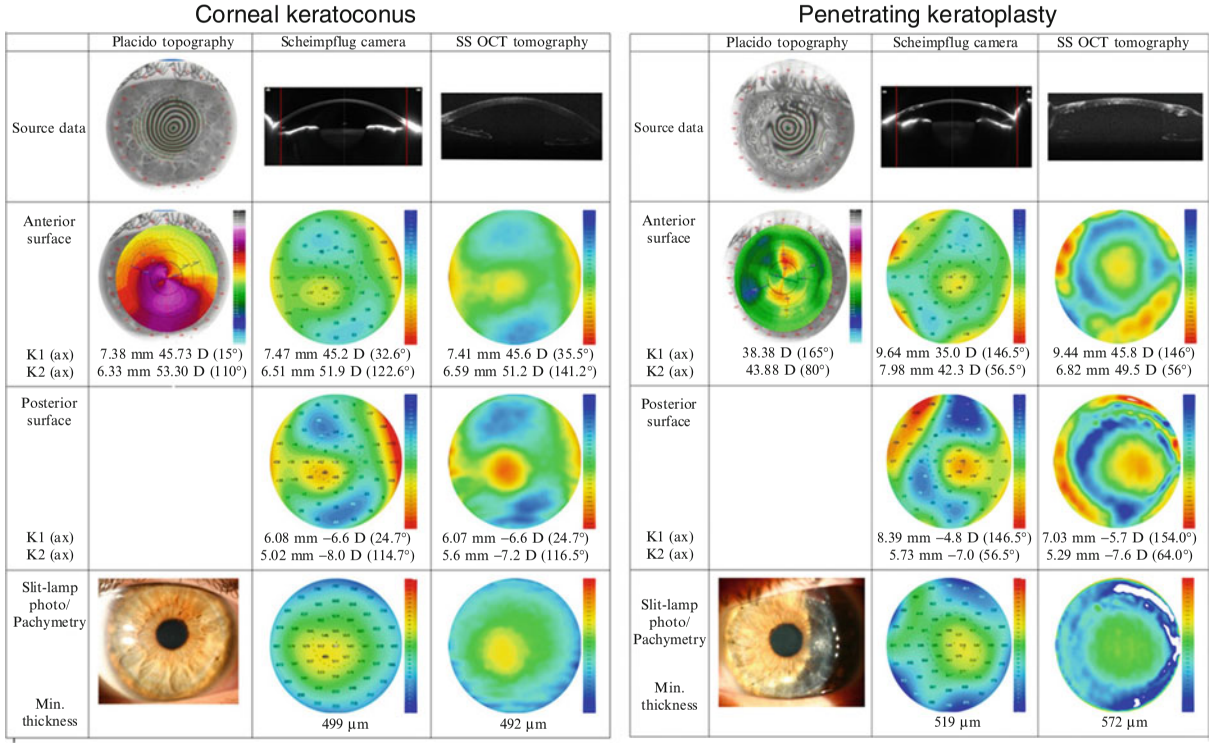

Fig. 54.14 Quantitative analysis of a keratoconic cornea (*left*) and a cornea 5 months after penetrating keratoplasty (*right*) with FdOCT, conventional Placido-based topographer (PTC 110, Optopol Technology, Poland), and a rotating Scheimpflug camera (Pentacam HR, Oculus, Germany). K1, K2 – central keratometry readings. The *red lines* on Scheimpflug images correspond to lateral size of cross-sectional images for FdOCT (Image reprinted with permission from OSA, K. Karnowski, et al., Biomedical Optics Express 9, 2709–2720, 2011 [30])

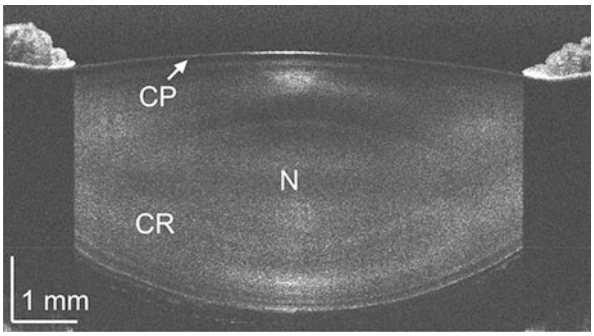

Fig. 54.15 OCT cross-sectional image of the crystalline lens: single-line exposure time 70 μs, transverse scanning density 15,000 A-scans per 9 mm, 4,096 pixels in each A-scan (*CP*, lens capsule; *N*, nucleus; and *CR*, cortex) (Image reprinted with permission from OSA, I. Grulkowski, et al., Opt. Express 17, 4842–4858, 2009 [34])

840 nm can help in visualization of healthy crystalline lenses. Figure 54.15 shows an image of a crystalline lens in a 30-year-old subject obtained with high transverse scanning density (15,000 A-scans in 9 mm). Under these imaging conditions, it is possible to easily distinguish characteristic structures of crystalline lens morphology such as capsule, cortex, and nucleus.

The quantitative OCT allows, for the first time, the obtainment of surface topographies of the crystalline lens (to date, most measurements in vivo have been limited to measurement of radii of curvature, in most cases in a single meridian). The OCT-based estimated lens radii of curvature for the anterior surface (10.27–14.14 mm) and posterior lens surface (6.12–7.54 mm) [84] are in good agreement with those obtained using Scheimpflug or Purkinke imaging – for the unaccommodated state and as a function of accommodation [88]. Besides phakometry, the quantification of full lens surface topography has allowed analyses of high-order terms and potential relationships between surface patterns in the anterior and posterior lens (such as a consistently found cross cylinder). Figure 54.16 shows anterior and posterior crystalline lens surface topographies in one subject (35 years old, unaccommodated state) and repeated measurements for one subject. The analysis is performed both as elevation maps (referred to the best-fitting sphere) and as radii of curvature and asphericities obtained from biconic fittings.

OCT has also enabled, for the first time, estimation of the 3D GRIN distribution in the crystalline lens in vitro. The GRIN is described using a four-variable model, with the index of refraction in the nucleus and in the surface, and meridional variations of the exponential decay. Figure 54.17 shows 2D maps of the GRIN distribution in isolated lenses of different ages (ranging from 6 to 72 years old) [80]. While there is no systematic variation in the values of the refractive index in the nucleus and surface, there is a strong variation in the exponential decay of the index variation, almost parabolic in the youngest eyes, and with a wide plateau in the older lenses.

Another interesting application of high-resolution FdOCT for lens imaging was presented by Kaluzny et al. in 2010 [89]. They demonstrated a unique ability of

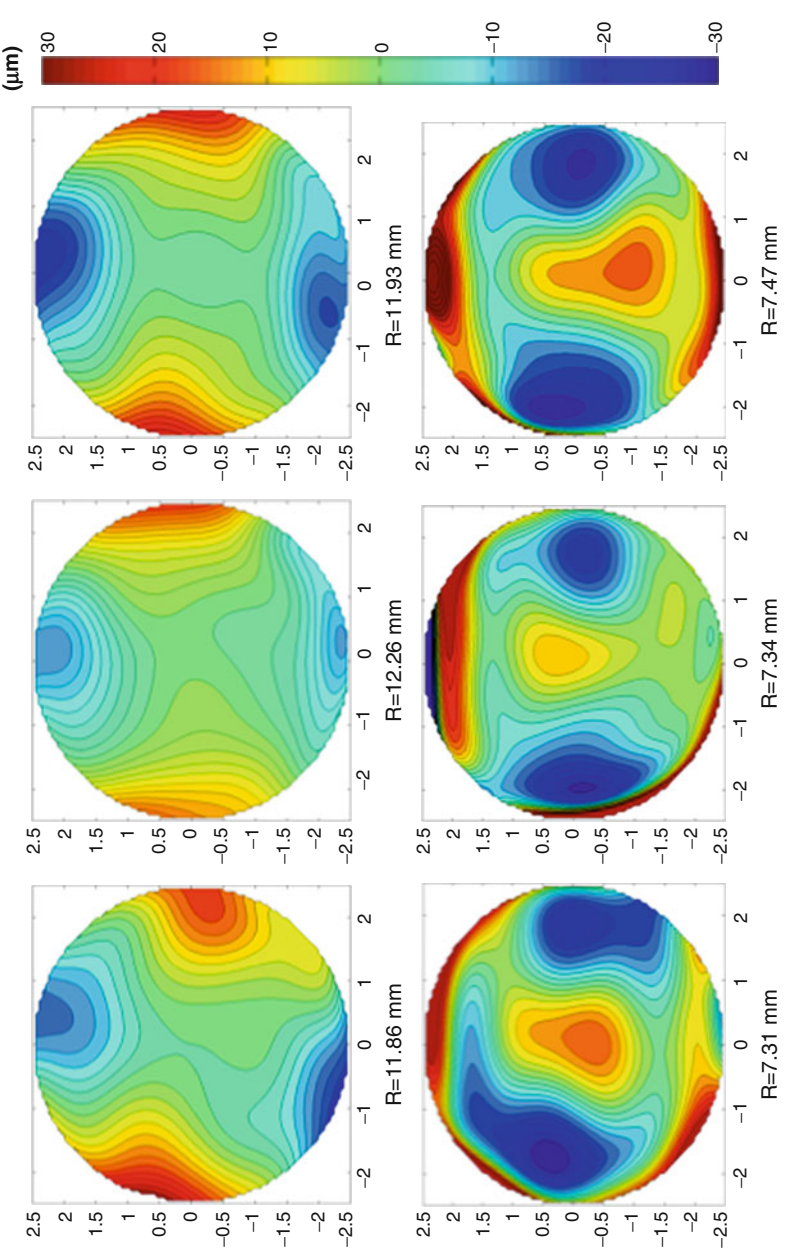

Fig. 54.16 Anterior and posterior crystalline lens topography in a young normal subject (unaccommodated state) (Image reprinted with permission from OSA, S. Ortiz, et al., Biomedical Optics Express 3, 2471–2488, 2012 [84])

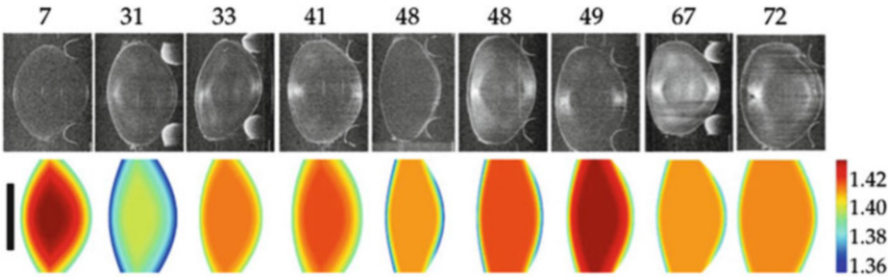

Fig. 54.17 OCT cross sections of human crystalline lenses of different ages (7–72 years old) and reconstructed gradient index of refraction (*GRIN*) distribution

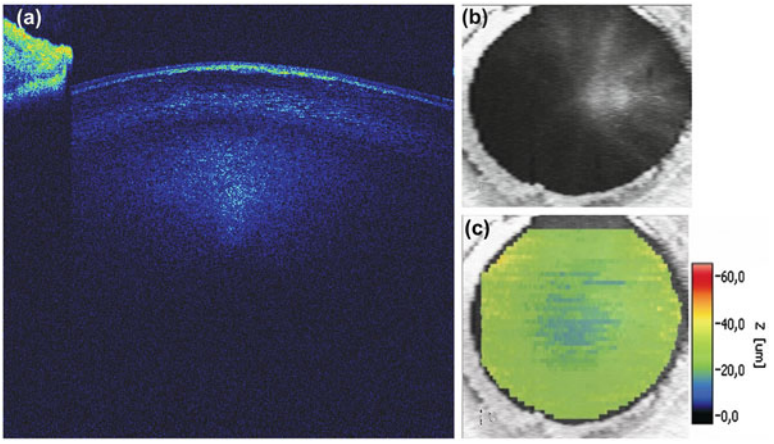

Fig. 54.18 Morphometry of the capsule of crystalline lens. (**a**) Ultrahigh-resolution OCT cross-sectional image of an anterior part of the lens and the pupillary margin of the iris. (**a**) En-face image of the iris and lens surface reconstructed from three-dimensional data. (**b**) Anterior lens capsule thickness map (mm). The area of examination is 7 mm by 7 mm (Image reprinted from B. J. Kaluzny et al., Br J Ophthalmol 94, 275–277 (2010), copyright BMJ group 2010 [89])

FdOCT system using femtosecond laser for precise cross-sectional evaluation of the capsular bag, estimation of its thickness, or visualization of the lens epithelium in vivo [89]. Figure 54.18 shows a high-accuracy thickness map of the anterior capsule of the crystalline lens.

54.4 Real-Time FDOCT Anterior Segment Imaging

The ultrahigh-speed performance offered by the FdOCT technology enables also video-rate monitoring of various dynamic processes in the anterior segment. An example of 3D (three-dimensions and time) imaging is shown in Fig. 54.19, where

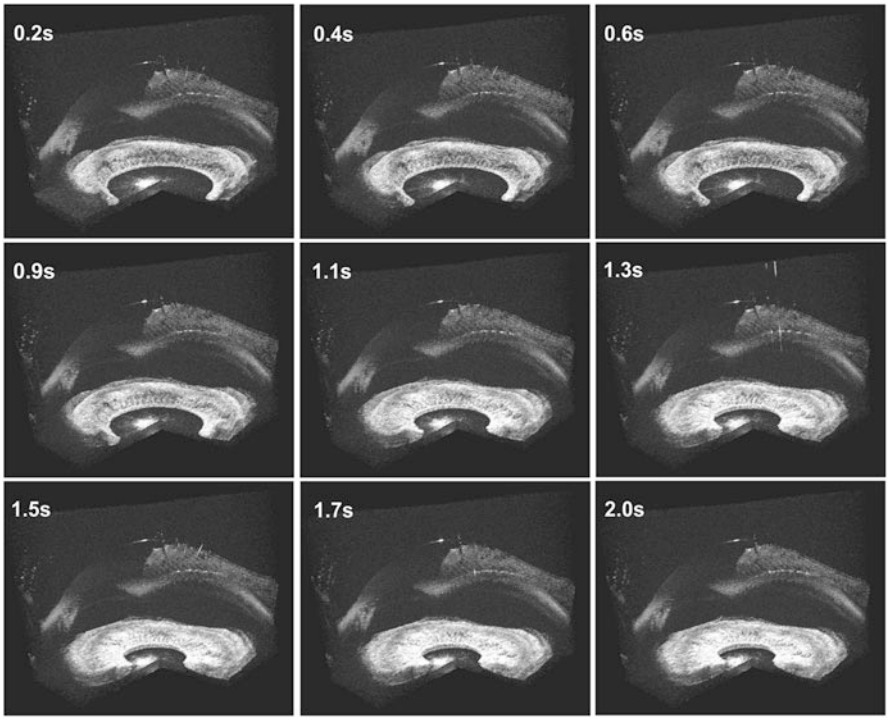

Fig. 54.19 4D OCT imaging using high-speed 800 nm, SOCT instrument: consecutive volume renderings of anterior segment of the human eye during pupillary contraction, volume size 300 × 100 × 1,024 pixels corresponding to 5 mm × 15 mm × 15 mm (Image reprinted with permission from OSA, M. Wojtkowski, Appl Opt 49, D30–61 (2010) [19])

the entire 3D scanning protocol was repeated in time giving real-time volumetric reconstruction of the blinking eye [34, 35]. Another interesting application for tracking dynamic changes in the anterior segment is to observe changes in a cross section of the human crystalline lens during the accommodation process. Grulkowski et al. demonstrated a sequence of nine frames chosen from 80 frames of an OCT movie [34]. The authors claimed that this movie was the first to demonstrate cross-sectional imaging of real-time dynamics of the lens during accommodation [34].

One example of a potential clinical application for high-speed, real-time OCT imaging is the assessment of dynamic processes that occur on the surface of the cornea. As it was demonstrated by Kaluzny et al., such monitoring may help in estimating of contact lens motion induced by blinking and tear film dynamics [90]. An example of a quantitative analysis of the movement of a rigid contact lens after a blink is shown in Fig. 54.20.

Another interesting application of real-time OCT is the assessment of corneal deformation after an air-puff – a concept similar to that used in noncontact tonometry [91].

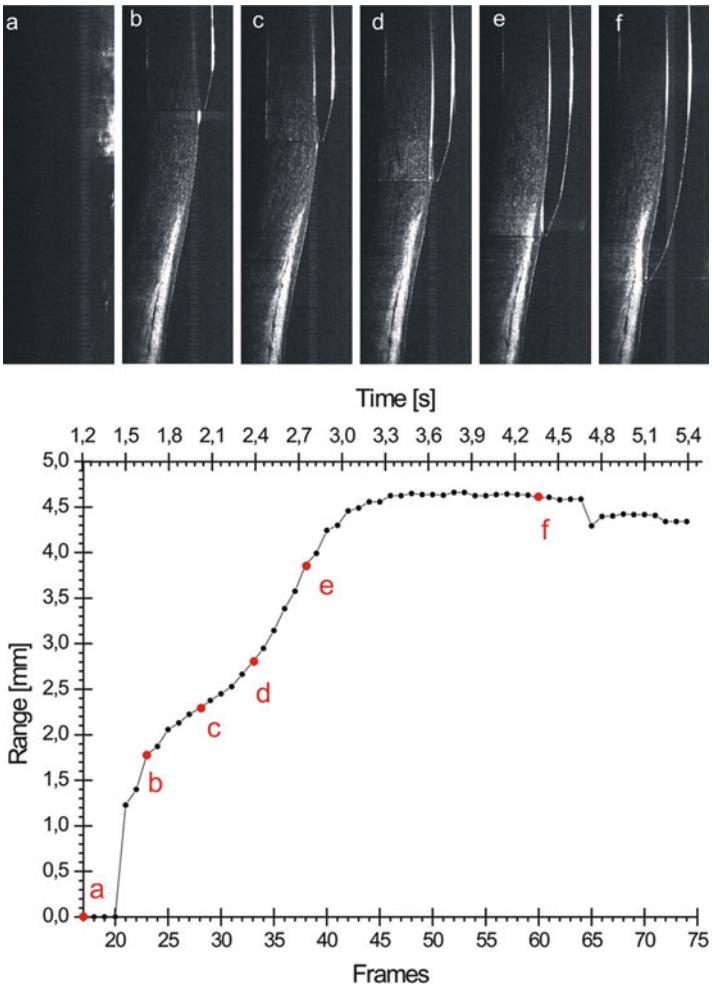

Fig. 54.20 Analysis of the blink-induced vertical movement of a rigid contact lens. *Left*: single frames from a 6-s movie of OCT cross-sectional images. *Right*: plot representing the relative blink-induced movement of the inferior lens edge as a function of frame number and/or time (Image reprinted from B. J. Kaluzny et al., Optom Vis Sci 84, 1104-1109 (2007) [90], copyright American Academy of Optometry 2007)

The geometric properties and integrity of the cornea rely on the mechanical properties of its constituent material. Several corneal diseases – such as keratoconus, which leads to corneal deformation and highly degraded optical quality – result from progressive corneal weakening and thinning. Emerging treatments for keratoconus (such as UV-riboflavin collagen cross-linking) attempt to increase corneal stiffness. Furthermore, several corneal treatments (incisional surgery, corneal laser surgery, and intrastromal implants) can be modulated by the biomechanical properties of the cornea. Our present knowledge of corneal biomechanical properties comes primarily

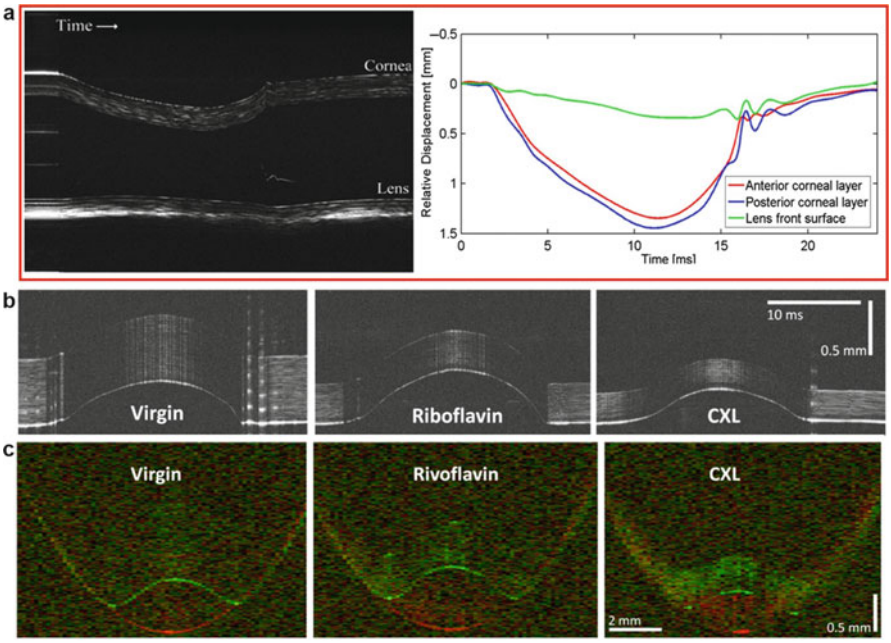

Fig. 54.21 Dynamic OCT imaging of the corneal deformation with an air puff. (**a**) M-scan (1,300 A-scans) showing the surface motion during the measurement along with a plot of a relative displacement of the cornea and lens (Reprinted with permission from OSA, D. Alonso-Caneiro et al. Opt Express 19, 14188–14199 (2011) [91]). (**b**) Deformation of the apex of the cornea as a function of time for the same cornea after application of riboflavin-dextran solution and after collagen cross-linking (CXL). (**c**) Cross-sectional images of a cornea that is undeformed (*red*) and at maximum deformation (*green*) from a corneal deformation sequence. A lower deformation is consistent with increased corneal stiffness. Measurements were performed with constant IOP power (Reprinted with permission from OSA, Dorronsoro et al., Biomedical Optics Express 3, 473–487, 2012 [96])

from lateral extensiometry techniques, corneal button or whole eye inflation, and 2D flap extensiometry performed on in vitro samples [92–94]. Patient diagnosis and predictions of corneal performance following a given corneal treatment require in vivo measurements of corneal biomechanical properties. Promising techniques for such measurements rely on the dynamic measurement of corneal deformation via anterior segment imaging upon air-puff applanation tonometry. A commercial instrument is available for this purpose, which combines Scheimpflug imaging with an air puff [95]. There are recent proposals for new methods based on OCT, which can measure geometrical distortions of cornea with high axial resolution and high speed. The advent of high-speed OCT systems (based on swept sources and spectral OCT systems with a CMOS camera) has enabled the high acquisition speeds required to image the deformation event within an air-pulse duration in the order of milliseconds.

Alonso-Caneiro et al. (2011) reported the acquisition of M-scans (A-scans of the anterior segment at central and peripheral locations as a function of time) during an air-puff event in normal subjects in vivo, using swept-source OCT [91].

The observed corneal deformation tended to increase with drug-induced decrease of intraocular pressure (IOP). Dorronsoro et al. (2012) [96] also reported acquisitions of M-scans, as well as sequences of B-scans during an air-puff event in virgin and treated porcine eyes in vitro, and in a human eye in vivo, using high-speed spectral-source OCT (Fig. 54.21). The porcine eyes were treated with riboflavin-dextran (a photosensitizer used in corneal cross-linking in a highly dehydrating solution) and with UV-riboflavin corneal cross-linking. Measurements were obtained while keeping IOP constant. Corneal deformation is affected by IOP as well as geometric properties of the cornea (particularly corneal thickness). However, substantial differences were found between riboflavin-only and full cross-linking treatments. As corneal geometry was the same before and after UV irradiation, these results indicate a substantial change in the biomechanical properties of the cornea. Corneal deformation is substantially less in the cross-linked corneas, revealing increased corneal stiffness.

Although analyses to date have been limited to the temporal and spatial parameters of corneal deformation (including deformation amplitude, deformation speed, and deformation duration), in the future, the full potential of air-puff OCT will be exploited via combination of the experimental data of corneal deformation with finite element modeling. The possibility of reconstructing corneal biomechanical parameters (such as the elasticity modulus, shear modulus, or viscoelastic time constants) at the individual level will open new avenues for the diagnosis of corneal diseases in which corneal stiffness is compromised, for evaluating the outcomes of procedures that modulate biomechanical corneal properties, and for guiding treatments that rely on corneal biomechanics.

55.1 Background

55.1.1 The Development of Corneal and Anterior Segment OCT Technology

Optical coherence tomography [1] (OCT) was first used clinically for retinal imaging [2]. Most ophthalmologists are now familiar with the applications of OCT in clinical retinal imaging. Not surprisingly, the earliest clinical corneal OCT studies used commercially available retinal scanners such as OCT1, OCT2, or Stratus (Carl Zeiss Meditec, Inc., Dublin, CA) to image the cornea and measure central corneal and sublayer thicknesses [3–10]. However, the initial 840 nm retinal OCT scanners acquires up to 400 axial scans per second. While this is adequate for

Proprietary Interests: David Huang and Yan Li have significant financial interests in Optovue and Carl Zeiss Meditec, companies that may have a commercial interest in the results of this research and technology. Maolong Tang has a significant financial interest in Optovue. These potential conflicts of interest have been reviewed and managed by Oregon Health and Science University.

Financial Support: this study was supported by NIH grants R01 EY018184, a grant from Optovue Inc. and a grant from Research to Prevent Blindness, Inc.

obtaining a spot measurement on the cornea, it is far too slow for mapping the cornea or measuring the width of the anterior chamber.

The need for faster OCT systems and the popularization of corneal refractive surgery at the end of the twentieth century spurred the development of dedicated anterior segment OCT systems. In 2001, Radhakrishnan et al. first reported ocular imaging with a 1,310 nm wavelength OCT system developed in Professor Joseph Izatt's group [11]. The Izatt system featured a high-speed scanning delay line in the reference arm and took advantage of the higher power that can be safely used at the longer wavelength of 1,310 nm to achieve a high acquisition rate of 4,000 axial scans per second.

The scan geometry is one of the important choices to be made in designing anterior segment OCT systems. There are three possible scan geometries: sector, concentric, and rectangular (Fig. 55.1). A sector scan (Fig. 55.1a) sweeps the beam of light in a divergent fan. It is commonly used in ultrasound imaging. Retinal OCT systems employ the sector scan geometry, which matches well to the spherical geometry of the retina. Early anterior segment OCT prototypes also used this geometry, which allows wide scanning with a small objective lens [11]. Retinal scanners can also provide sector scans without additional adaptor lens (Fig. 55.1b). The primary drawback of using sector scans for corneal imaging is that the peripheral cornea reflection is nearly invisible because of the large off-perpendicular incidence angle. The second choice was the concentric scan geometry (Fig. 55.1c). This scan geometry maintains a perpendicular angle of incidence on the cornea. It produces very strong reflections from the boundaries of the cornea and from its internal lamellae (Fig. 55.1d); but unfortunately, these strong reflections obscure features of interest such as the LASIK flap interface or scar. Therefore, the concentric scan is not ideal for anterior eye imaging. Unlike the other two scan geometries, the rectangular scan geometry (Fig. 55.1e) offers the least image distortion. The strong specular reflection at the corneal vertex can offer a very precise central landmark in rectangular scans (Fig. 55.1f). The vertex provides a central reference point that is commonly used in corneal topography and corneal thickness mapping. Stromal details such as the LASIK flap interface can be well visualized in the pericentral and midperipheral cornea. The rectangular scan geometry provides the best contrast for corneal layers and pathologies and also allows wide-field scanning. Thus most anterior segment OCT systems now use this scanning geometry (Fig. 55.2).

Combining the rectangular scan geometry and the 1,310 nm wavelength Izatt anterior segment OCT engine, Professor David Huang collaborated with Professor Izatt's laboratory and developed a practical anterior segment OCT scanner. It can provide angle-to-angle wide-field full-range anterior eye scans (16-mm scan width and up to 8-mm scan depth in air) containing the cornea and the crystalline lens in the same image (Fig. 55.2a). The rectangular scan readily gave accurate biometric measurements such as the anterior chamber depth and width [12]. Later we used an anterior segment OCT prototype system (Carl Zeiss Meditec, Inc., Dublin, CA) with similar performance to map 10-mm diameter corneal thickness (pachymetry) with high repeatability [13].

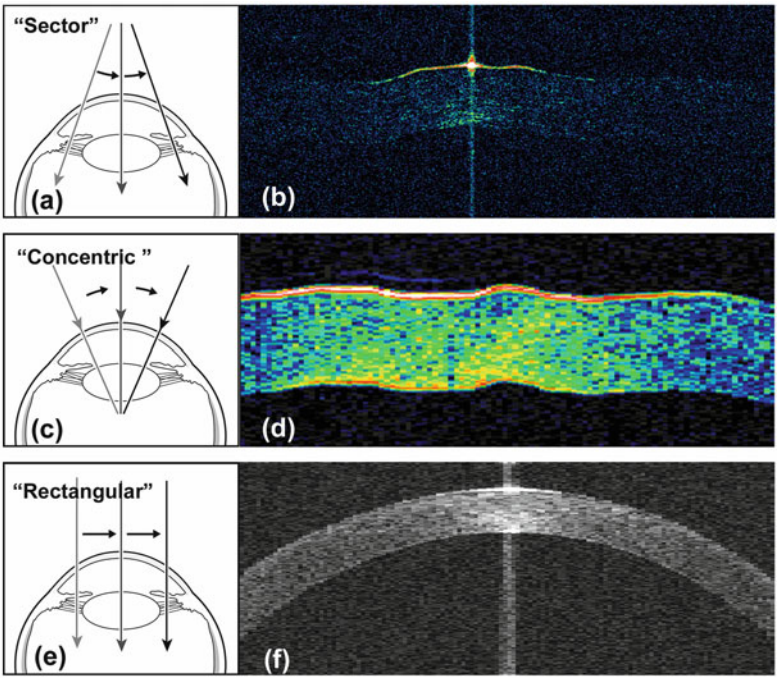

Fig. 55.1 Corneal OCT images obtained with three possible scan geometries. (**a**) Divergent "sector" scan geometry. (**b**) A corneal image taken with a retinal OCT scanner using the sector scan geometry. The scan width was 3 mm. Note weak reflections outside of the central 1 mm and obvious motion artifacts in the corneal contour. (**c**) Concentric or "arc" scan geometry. (**d**) An OCT image taken with an arc-scanning OCT prototype. The scan width was 4 mm. Note the obvious motion artifact. (**e**) "Rectangular" or "telecentric" scan geometry. (**f**) An OCT image taken with the wide-field anterior segment OCT prototype with rectangular scan geometry. The scan width was 10 mm

The original OCT technology is now classified as time-domain OCT, in which the reference mirror is moved through a range of delay, and the resulting inference patterns between the sample and reference beams are processed into an axial scan. The scanning speed in time-domain OCT is limited by having to physically cycle the reference mirror through the delay range. These systems can only collect a few thousands of axial scans per second. At this speed, quantitative corneal shape measurements such as the corneal topography are not possible due to the limited sampling rate and the influence of the eye movement. Luckily, new generation Fourier-domain OCT technology has been developed to speed up image acquisition. In Fourier-domain OCT, the reference mirror is stationary, and the axial scan is generated by Fourier transformation of spectral interference patterns between the sample and reference reflections. Advantages of Fourier-domain OCT include improvements in scanning speed and signal-to-noise ratio that are achieved through elimination of reference mirror movement and simultaneous detection

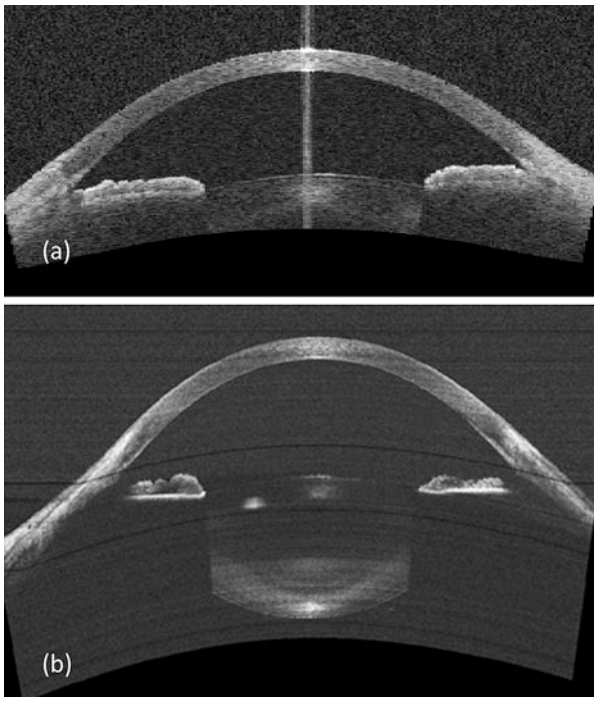

Fig. 55.2 Wide-field anterior eye scans obtained with a time-domain OCT (**a**) and a swept-source OCT (**b**)

of reflections from all layers of the target. There are two main ways of designing and constructing Fourier-domain OCT instruments. The first one is called spectrometer-based (or spectral-domain) OCT, in which the interferometric signal is detected by a spectrometer equipped with a high-speed line scan detector, such as a charge-coupled device (CCD) or complementary metal oxide semiconductor (CMOS) line camera. Spectrometer-based OCT systems capable of 6,700–310,000 axial scans per second were reported [14–16]. The second one is called swept-source OCT, which uses high-speed tunable lasers [17]. Swept-source OCT offers several advantages over spectrometer-based OCT, including reduced fringe washout, lower sensitivity roll-off with imaging depth, and longer imaging range, higher detection efficiencies [18]. The introduction of Fourier domain mode locking (FDML) enabled dramatic increases in sweep speeds by using a long fiber optic delay line in the laser cavity [19]. Anterior segment swept-source OCT instruments with imaging speed of 100,000–400,000 axial scans per second enabled 3D imaging of the entire cornea in 500–125 ms [18, 20, 21].

The increased sensitivity of both Fourier-domain OCT system designs comes at the price of limited usable imaging depth. The symmetric overlapping image artifact in Fourier-domain OCT images, referred to in the literature as the complex conjugate or mirror image artifact, occurs whenever the sample imaging depth spans both positive and negative distances compared with the length of the set

reference path in the Fourier-domain OCT interferometer [22]. Practical 840 nm hybrid retinal/corneal Fourier-domain OCT systems have sufficient speed and sensitivity for anterior segment imaging. However, their maximum imaging depth and width are usually limited to approximately 2 and 6 mm due to scanning optics optimized for retinal imaging. Dedicated Fourier-domain OCT corneal imaging systems allow both high speed and wide field of scan. Extended imaging depth can be achieved using full-depth (complex conjugate ambiguity resolution) or swept-source technology (Fig. 55.2b) [14, 15, 21].

55.1.2 Wavelength Affects Resolution and Penetration

Due to the technological limitations of detectors and accessibility of light sources, three optical frequency windows are commonly used in OCT imaging: centered at 840, 1,050, and 1,310 nm, respectively. An optimal choice of the OCT working wavelength depends on the application of interest. The axial resolution of an OCT system is proportional to the square of the central wavelength and inverse proportional to the bandwidth of the light source. Therefore, the shorter wavelength and broader bandwidth provide better resolution. To achieve maximum axial resolution (1–4 μm), for example, in retinal imaging, a spectral window centered at 840 nm is typically used. To get information from deeper layers with relatively high axial resolution of 6–15 μm, say, imaging of the anterior segment of the human eye, broadband light centered at 1,310 nm can be applied. OCT imaging with the central wavelength of 1,050 nm usually provides medium axial resolution of 4–10 μm [23].

On the other hand, OCT has a limited ability to image through opaque tissue due to signal attenuation by scattering. Scattering is wavelength dependent – the shorter the wavelength, the greater the scattering. In other words, longer wavelength gives deeper penetration. For scattering objects much smaller than infrared wavelength (i.e., collagen fibrils), scattering scales inversely with the fourth power of wavelength (the Raleigh approximation) [24]. Based on this approximate upper limit, the penetration of 1,310 nm light could be as much as six times deeper than that of 840 nm light. Indeed, we observe that 1,050 nm and 1,310 nm OCT is able to penetrate limbal tissue to visualize the scleral spur and angle recess (Fig. 55.3b, c), while 840 nm OCT cannot (Fig. 55.3a).

Moreover, light at the 1,310 nm wavelength is strongly absorbed by water – resulting in a retinal exposure that is less than 7 % of the power incident on the cornea (Fig. 55.4). In contrast, almost the entire 840 nm wavelength light that strikes the eye reaches the retina unabsorbed. Because most 1,310 nm light does not reach the sensitive retinal tissue, much higher power levels can be safely used on the eye. The eye exposure limit set by the American National Standards Institute (ANSI) [25] for extended eye exposure is 15 mW for 1,310 nm wavelength, compared to 0.7 mW for 840 nm wavelength. The ability to use 20 times more power for corneal and anterior segment OCT imaging means that scanning can be performed 20 times faster without sacrificing signal level.

Table 55.1 Commercial OCT systems capable of anterior segment imaging

Manufacturer	Device	Axial resolution (μm)	Wavelength(nm)	Speed (A-scan/second)	Type
Bioptigen	Envisu	3	840	17,000	Fourier domain
Carl Zeiss Meditec	Visante	18	1,310	2,000	Time domain
Carl Zeiss Meditec	Cirrus	5	840	27,000	Fourier domain
Heidelberg	SL-OCT	18	1,310	200	Time domain
Heidelberg	Spectralis	3.9	870	40,000	Fourier domain
Optopol	Copernicus HR	3	850	52,000	Fourier domain
Optovue	RTVue-CAM	5	840	26,000	Fourier domain
Optovue	iVue	5	840	26,000	Fourier domain
Tomey	Casia	10	1,310	30,000	Fourier domain

55.1.3 Commercial Anterior Segment OCT Systems

The first commercial version of anterior segment OCT instruments (Visante and SL-OCT) introduced to the market in 2005/2006 was time-domain OCT systems. Later, Fourier-domain OCT systems (RTVue, Cirrus, Spectralis, Envisu, Casia, etc.) with speeds between 17,000 and 52,000 axial scans per second became available (Table 55.1). All current commercial anterior segment OCT systems operate in the near infrared, at either 840–870 or 1,310 nm. The longer wavelength of 1,310 nm penetrates more deeply through the sclera, limbus, angle, and iris. The shorter wavelength range of 840–850 nm cannot penetrate the sclera or iris, but can offer much higher resolution (Table 55.1). The 1,310 nm systems cannot perform retinal imaging due to water absorption in the vitreous medium. The 840–850 nm OCT systems are generally capable of both anterior segment and retinal imaging. However, the hybrid retina/cornea platforms have limited anterior segment imaging width. To image the entire width and depth of the anterior chamber, dedicated anterior segment scanning optics are necessary (Visante, SL-OCT, Casia, in Table 55.1).

55.2 Diagnostic and Surgical Applications

55.2.1 Mapping of Corneal Thickness

The measurement of corneal thickness (pachymetry) has important diagnostic and surgical applications. Central corneal thickness is routinely used to monitor corneal

edema and endothelial function [26–29], manage ocular hypertension [30, 31], and plan common keratorefractive surgeries such as laser in situ keratomileusis (LASIK) and photorefractive keratectomy (PRK).

Ultrasound pachymetry [32, 33] and several other techniques [34–37] provide only spot measurements, while scanning-slit optical pachymetry [38, 39], very high-frequency ultrasound imaging [40, 41], and optical coherence tomography allow mapping of a wide area of the cornea. Pachymetric mapping provides several advantages over spot measurements. Mapping can reveal abnormal patterns such as keratoconus and pellucid marginal degeneration. It also allows preoperative planning for surgeries that do not primarily concern just the center of the cornea, such as astigmatic keratotomy, intracorneal ring segment implantation, phototherapeutic keratectomy (PTK), and lamellar keratoplasty.

We used a time-domain anterior segment OCT prototype (Carl Zeiss Meditec Inc.) to study corneal thickness mapping [13]. The prototype is similar in performance to Zeiss Visante™ model which was approved by FDA in 2005. It operates at a wavelength of 1,310 nm with a scanning speed of 2000 axial scans per second. The cornea was scanned with 10-mm radial lines on 8 meridians centered on the vertex reflection. Each meridional line consisted of 128 A-scans. The entire scan pattern had 1,024 A-scans and was acquired in approximately 0.5 s. A cross-sectional OCT image is illustrated in Fig. 55.5a.

An automated computer algorithm was developed to locate the anterior and posterior corneal surfaces by identifying the signal peaks at the air–tear film and cornea–aqueous interfaces on each A-scan (Fig. 55.5b).

OCT uses light to probe the eye. The light changes its propagation direction at the interface between air and cornea due to refraction and causes significant distortion in OCT images. Image distortions due to refraction may also occur at other tissue index transition surfaces such as the cornea–aqueous interface. Moreover, OCT records the optical path length that the light travels rather than the physical dimensions. So a "dewarp" algorithm is needed to correct the beam refraction and to transform optical delay into actual physical dimensions (Eq. 55.1).

$$x = \text{Optical path length}/n \tag{55.1}$$

where x is the physical distance, and n is the group index of the medium.

Westphal et al. reported a backward transformation method using Fermat's principle by finding the minimum path to the corrected pixel [42]. They used backward transformation instead of forward transformation because the raw image in their study was distorted by the sector scan geometry, and in turn the incidence angle calculation was difficult. The anterior segment OCT prototype used in our study had a rectangular scan geometry (Fig. 55.1e, f). The normal of the interface and the incidence angle of the beam could be easily defined once the refraction interface is located. Therefore, a forward transformation using Snell's law was used for "dewarping" in our studies [22, 43]. The normal and the incidence angle (θ_1 in Fig. 55.5c) was calculated at each axial scan location (i.e., column of pixels). The beam propagating direction passing the interface was decided by θ_2.

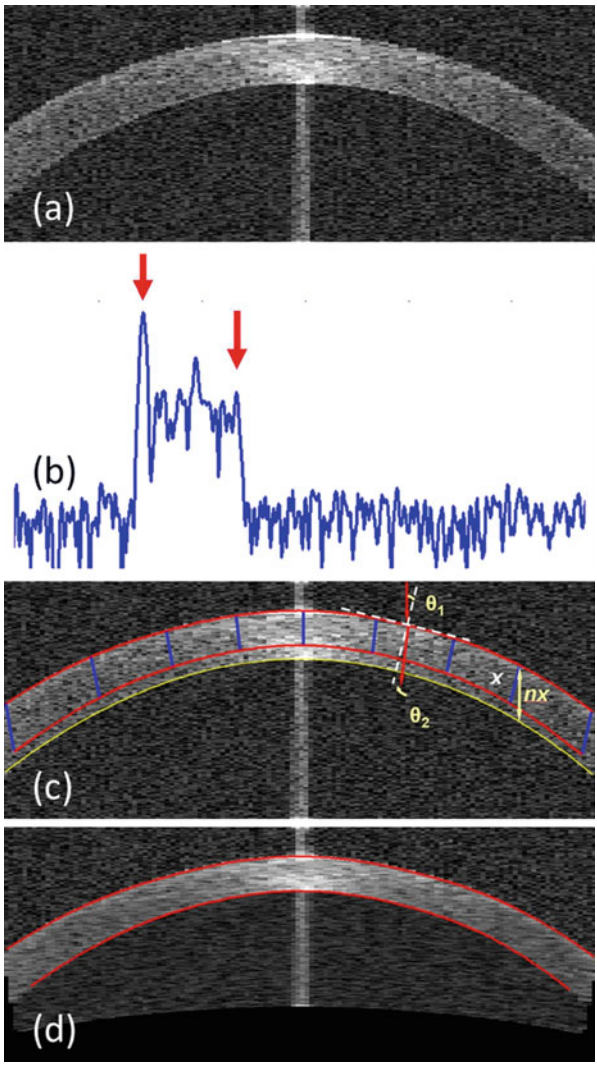

Fig. 55.5 OCT corneal thickness measurement. (**a**) Cross-sectional OCT image on a corneal meridian. (**b**) An OCT axial scan from pericentral cornea plotted on a logarithmic scale. The *arrows* mark the signal peaks at the anterior (*left*) and posterior (*right*) corneal boundaries located by the automated algorithm. (**c**) "Dewarp" to correct the image distortion due to refraction and transition of the corneal group index at the air–corneal interface. The OCT beam reached the cornea with incident angle θ_1 and refracted by angle θ_2. The *yellow double arrowhead line* represents the optical path length *nx* that OCT records. The blue lines indicated the physical distance *x* that the OCT beam travels in tissue. (**d**) Dewarped OCT cross section overlaid with detected corneal boundaries

According to Snell's Law: $n_1 \sin \theta_1 = n_2 \sin \theta_2$
We have

$$\theta_2 = \arcsin\left(\frac{n_1 \sin \theta_1}{n_2}\right) \tag{55.2}$$

where n_1 is the refractive index of the first medium, which equals 1.0 for air; n_2 is the group index of the second medium, which is 1.389 for human cornea (n_{cornea}) at 1.3-μm wavelength [44].

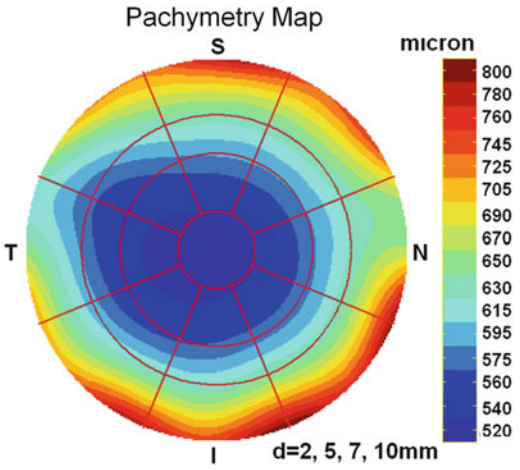

Fig. 55.6 OCT pachymetry (corneal thickness) map

The axial difference between the anterior (red line) and posterior (yellow) corneal surfaces represents the optical path length through cornea (*nx*, denoted by a yellow double-head arrow in Fig. 55.5c). The raw axial scans were then resampled along the refraction directions with a scaling factor of $1/n_{cornea}$. Figure 55.5d showed an example of corneal OCT image after "dewarping."

Corneal thickness was measured from the dewarped image (Fig. 55.5d) as the distance between the anterior and posterior surfaces along lines perpendicular to the anterior surface. A corneal thickness profile was generated from each meridional cross section. The computer algorithm registered the eight corneal cross sections and computed the corneal thickness (pachymetry) map by interpolation. The pachymetry map was presented on a banded color scale (Fig. 55.6). The map was divided into zones and sectors. The sector mean, maximum, and minimum pachymetry measurements within a diameter (D) less than 7 mm were computed. Reproducibility was assessed by the pooled standard deviations of the repeated measurements.

Forty-two eyes of 21 normal subjects were used in our clinical study [13]. The OCT pachymetry mapping and ultrasound central pachymetry (50 MHz CorneoGage 2, Sonogage, Cleveland, OH) were obtained three times on each eye. The average central ($D < 2$ mm) OCT corneal thickness (OCT_{Mean}) was compared with the ultrasound pachymetry. The OCT measurements correlated very well with ultrasound pachymetry (Pearson correlation $r = 0.97$). The Bland–Altman analysis showed that the OCT measurements were slightly thinner than those obtained with ultrasound pachymetry. The difference between the OCT_{Mean} and ultrasound was −6.4 μm (95 % limits of agreement: −23.2 to 10.4 μm). The difference was statistically (t-test, $P < 0.001$) but not clinically significant. Overall, the repeatability of the mean corneal thickness was roughly 2 μm for the three zones within the 7-mm diameter in OCT pachymetry maps.

Our results show that OCT is a reliable method of mapping corneal thickness. In our clinical practice, OCT is now routinely used to screen prospective patients seeking keratorefractive surgery. The thickness map is used to detect thin spots that may indicate keratoconus or pellucid marginal degeneration and to calculate the predicted residual stromal bed thickness after LASIK or PRK. We also track the disease progression in patients with corneal edema (swelling) with OCT. Because the measurement does not require contact, it is more easily tolerated than measurement with an ultrasound probe.

55.2.2 Epithelial Thickness Mapping

The corneal epithelium is the first cellular layer of the human cornea and protects the eye. Accurate and reproducible measurement of corneal epithelial thickness provides important information for assessing corneal remodeling after refractive surgeries such as photorefractive keratectomy and LASIK [45]. Moreover, deviations from normal epithelial thickness could be an early sign of keratoconus [46].

Fourier-domain OCT instruments can provide scan speeds 10–100 times faster than time-domain OCT instruments [47]. The enhanced speeds minimize the effect of eye movements during data acquisition and also allow higher definition imaging due to denser axial scans in the same transverse scan length. The higher scan speed also facilitates frame averaging that suppresses speckle noise. The epithelium–Bowman's layer boundary is a relatively weak interface presented in corneal OCT images.

We used a Fourier-domain OCT (RTVue-CAM, Optovue, Inc.) to investigate automatic epithelial thickness mapping. In this study, we enhanced the epithelial boundary by acquiring five repeated images and averaging them after the registration. The averaged image had higher signal-to-noise ratio than the single frame. Moreover, the Fourier-domain OCT system used in our study had an axial resolution of 5 μm, which is two to three times higher than that of time-domain instruments used in previous studies [48–51]. Not only does the higher resolution and higher speed of Fourier-domain OCT improve image quality, it also makes the automated corneal epithelial thickness mapping possible.

A "Pachymetry + Cpwr" scan pattern (6-mm scan diameter, 8 radials, 1,024 axial scans each, repeated five times) centered at the pupil center was used to map the cornea (Fig. 55.7a). Fourier-domain OCT image data were exported and processed with custom software. For each OCT scan, five repeated radial cross-sectional images on each meridian were registered and averaged (Fig. 55.7b). Next the air–tear interface and the epithelium–Bowman's layer boundary were automatically identified with a computer algorithm by increased signal intensity at corresponding boundaries (Fig. 55.7c, d) [52]. Corneal epithelial thickness was measured as the distance between the air–tear and the epithelium–Bowman's interfaces perpendicular to the anterior surface at the point of measurement. An epithelial thickness profile was generated from each meridional cross section. A 6-mm diameter epithelial thickness map was generated by interpolating epithelial thickness profiles calculated from each meridian.

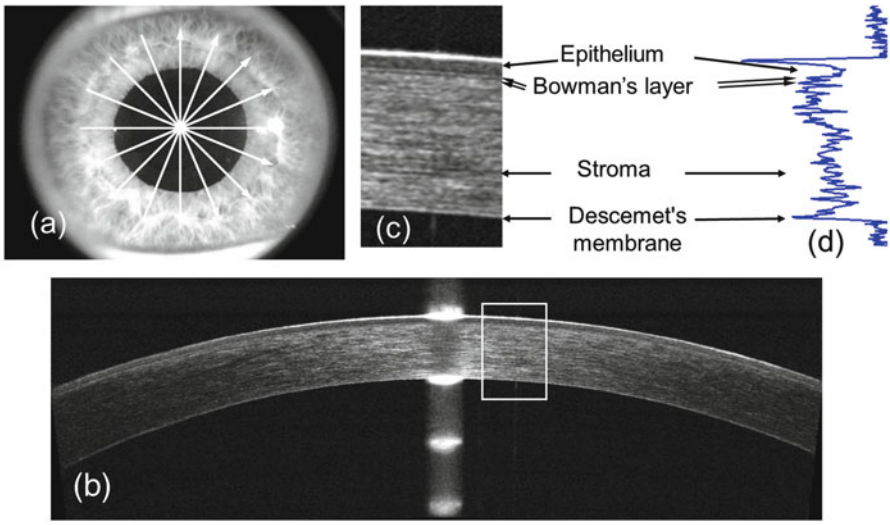

Fig. 55.7 (**a**) The "Pachymetry + Pwr" scan pattern consisted of 8 radial scans. (**b**) A cross-sectional corneal optical coherence tomography (*OCT*) image (average of five repeated frames). (**c**) A magnified section of OCT image shown in (**b**). (**d**) A corneal axial scan

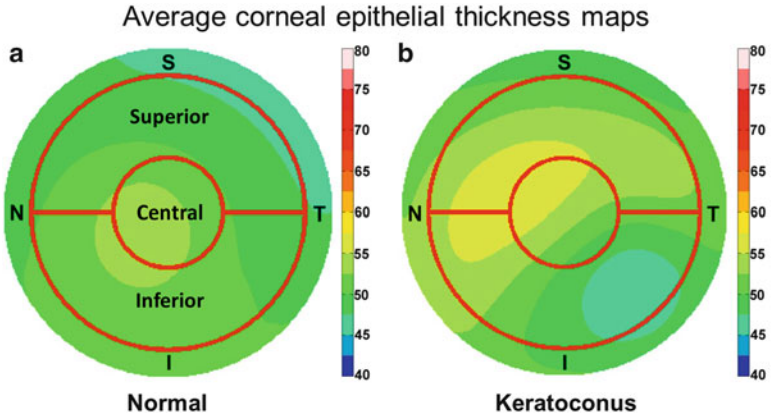

Fig. 55.8 Average epithelial thickness maps of the normal (**a**) and keratoconic (**b**) eyes

Only the central 5-mm diameter map was used for calculating epithelial thickness-based variables. The epithelial thickness map was divided into three zones by diameter and hemispheres: central 2 mm, superior 2–5 mm, and inferior 2–5 mm (Fig. 55.8a).

One hundred and three eyes of 54 normal subjects were involved in this study. Each eye was scanned three times within a single visit. Subjects were repositioned after each OCT scan. The average age of the normal subjects was 46.3 ± 13.4 years

Table 55.2 Cutoff values for optical coherence tomography pachymetric parameters. *I-S* inferior–superior octant difference, *IT-SN* inferotemporal–superonasal octant difference. The diagnostic cutoff threshold is 2.3 standard deviations below normal average (1st percentile of normal distribution). All measurements are made within central 5-mm diameter of the map

Pachymetric parameters	Minimum	Minimum–maximum	I-S	IT-SN
Cutoff (unit: μm)	472	−62	−52	−51

(range 19–65 years). The average steep K was 44.4 ± 1.4 diopter (D) (range 41.0–47.8 D) and the minimum corneal thickness was 529.1 ± 27.5 μm. The repeatability of central, superior, and inferior epithelial thickness measurement was less than 1.0 μm by pooled standard deviation. The average central, superior, and inferior epithelial thicknesses were 52.8 ± 3.9, 49.4 ± 3.8, and 51.2 ± 3.6 μm, respectively. The average epithelial thickness maps of all normal subjects were calculated (Fig. 55.8a). The left eye maps were mirrored to the right eye to calculate the average map of both eyes.

55.2.3 Keratoconus Screening

Keratoconus is the most important contraindication for laser refractive surgeries. Undetected corneal ectatic disorders can result in accelerated, progressive keratectasia and unpredictable visual outcome after LASIK and PRK. Current detection of early stage keratoconus (referred to as *forme fruste* keratoconus or FFK in medical literatures) relies primarily on Placido ring-based corneal topography [53–55]. However, topography does not screen out all eyes at risk [56]. Corneal thinning is a characteristic feature of keratoconus. Studies showed that the OCT pachymetric parameters listed in Table 55.2 are helpful in detecting the keratoconic eccentric focal thinning patterns [57]. If one parameter is abnormal (lower than the cutoff value), the cornea is likely to have keratoconus. If two or more parameters are abnormal, then the eye is very likely to have keratoconus or other ectatic conditions such as pellucid marginal degeneration [58].

The human corneal epithelium covers the surface of the cornea where it protects the eye and plays an important role in maintaining high optical quality. In diseases such as keratoconus, the thickness of the epithelium becomes altered to reduce corneal surface irregularity [46]. Therefore, the presence of an irregular stroma may be less measurable by frontal surface corneal topography. Analyzing the corneal epithelial and stromal thicknesses and shapes separately can facilitate the detection of the disease in its early stage [46, 59, 60]. We also used epithelial map information for keratoconus detection. We conducted a cross-sectional observational study involving 145 eyes from 76 normal subject and 35 keratoconic eyes from 22 patients. We calculated the average epithelial thickness map of keratoconic eyes (Fig. 55.8b) using the method described in Sect. 55.2.2 “epithelial thickness mapping.” Five diagnostic variables, including minimum, superior–inferior (S-I), minimum–maximum (MIN-MAX), map standard deviation (MSD), and pattern standard deviation (PSD), were calculated.

Several corneal epithelial thickness-based variables developed in this study showed good (minimum, AROC = 0.84; MIN-MAX, AROC = 0.88; RMSV, AROC = 0.89) to excellent (PSD, AROC = 1.00) diagnostic power in differentiating keratoconic from normal eyes. By far, PSD was the best variable. With a cutoff value of 0.057, PSD alone gave 100 % specificity and 100 % sensitivity. These variables could be applied to epithelial thickness maps from other imaging systems as well (e.g., very high-frequency ultrasound). Moreover, these variables may be useful for detecting *forme fruste* keratoconus (FFK or subclinical keratoconus). Further studies are needed to evaluate the performance of these variables in FFK detection.

55.2.4 Measuring Corneal Refractive Power

The refractive power of the cornea is determined by the anterior and posterior corneal surfaces. It is commonly measured by manual keratometer or simulated keratometry (Sim-K) from computerized corneal topography systems. Keratometry measures the anterior surface power and extrapolates total corneal power assuming the ratio of anterior and posterior radius is fixed. This assumption, however, leads to measurement error in the corneal power for eyes that have undergone refractive surgeries such as LASIK. Consequently, the calculated corneal power change deviates from the actual refractive change after LASIK.

The wide-field high-speed anterior segment OCT is capable of direct measurement of both anterior and posterior surfaces, thereby avoiding the erroneous assumption. In a study of 32 eyes from 17 LASIK patients, we evaluated the repeatability of OCT-based corneal power measurement by pooled standard deviation [61]. The repeatability is 0.79D for the anterior surface and 0.10D for the posterior surface. The former value is not as good as the conventional corneal topography systems, which usually have repeatability less than 0.25D. The main limitation is most likely the scanning speed. At 2,000 axial scan per second, eye movement during OCT scans still produces noticeable error in corneal power measurement. Nevertheless, if we combine the OCT-measured pachymetry map and anterior corneal topography, the resulting total corneal power can closely track the refractive change after LASIK [61].

55.2.5 LASIK Anatomy

An important use for OCT in LASIK surgery is in measuring the thickness of the flap and the residual stromal bed. In the LASIK procedure (Fig. 55.9), both the flap dissection and the laser treatment weaken the corneal structure. If the remaining stromal bed is less than 250 μm or if the eye has a preexisting condition that has weakened the cornea, there is a high risk of developing keratectasia or progressive focal thinning and bulging forward of the cornea [56]. To avoid this complication, a method is needed to measure the flap and stromal bed thickness [62].

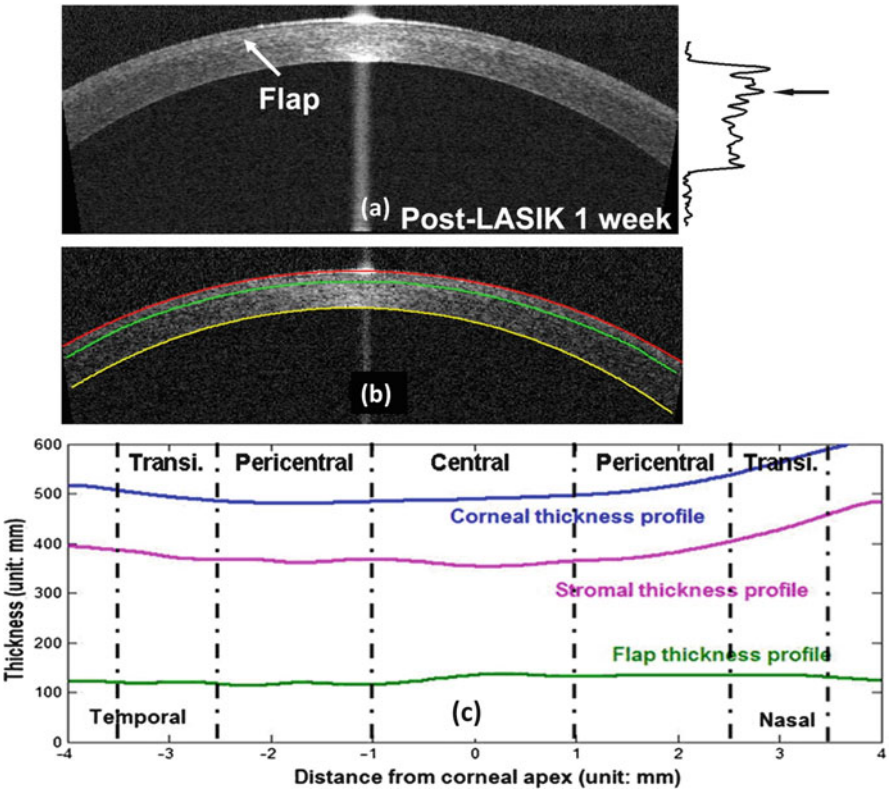

Fig. 55.9 (**a**) A post-LASIK 1 week OCT scan of 1,310 nm time-domain OCT. *Arrows* mark the location of the flap interface. (**b**) Corneal boundaries and flap interface overlaid on the OCT image. (**c**) Corneal, stromal bed, and flap thickness profiles

Currently, LASIK surgeons calculate the residual stromal bed by subtracting the expected flap thickness and ablation depth from the central corneal thickness measured by an ultrasound pachymeter. Some surgeons measure the stromal bed thickness with ultrasound pachymetry intraoperatively and calculate the flap thickness by subtracting the stromal bed thickness from the preoperative corneal thickness [63–71]. This approach has some drawbacks: risk of contamination and hydration change caused by contact of the ultrasound probe with the stromal bed and imprecision of two manually placed measurements. Furthermore, intraoperative ultrasound measurement is not universally practiced. Therefore, measurements of the flap and stromal bed thickness may not be available when needed at a later time for enhancement (repeat laser treatment) planning or complication management.

Optical coherence tomography provides a better solution – a noncontact method that produces high-resolution cross-sectional images from which flap and stromal thickness can be directly measured.

We conducted a longitudinal study to assess the corneal anatomic change after LASIK with the same high-speed anterior segment OCT prototype used in Sect. 55.2.1. Eighteen volunteers seeking refractive surgery participated in this prospective study. The preoperative manifest spherical equivalent (SE) refraction of the 36 eyes ranged from −1.25 to −9.25 diopters (D) (mean, −4.1 ± 2.3 D). The LASIK flap was created with an automated mechanical microkeratome (Hansatome, Bausch & Lomb, Inc., Rochester, NY). The head setting was either 160 μm or 180 μm. Ablations were performed with a scanning spot excimer laser (LADARVision 4000, Alcon Laboratories, Inc., Fort Worth, TX).

The OCT scans were performed preoperatively and at 1 day, 1 week, 3 months, and 6 months postoperatively. The patient cornea was scanned three times at each visit with an 8-mm long horizontal OCT pattern consisting of 512 axial scans. The LASIK flap can be distinguished by increased reflection at the flap interface and increased internal reflectivity (Fig. 55.9a). We developed automated computer algorithms to locate corneal boundaries and the flap interface (Fig. 55.9b). Flap and stromal thickness profiles (Fig. 55.9c) were then calculated. Ultrasound pachymetry was used to measure central corneal thickness before and 3 months after surgery. Residual stromal thickness was recorded during the surgery, both before and after laser ablation. Flap thickness was also calculated from the intraoperative ultrasound measurements.

Postoperative 1 week LASIK flap thickness correlated well with the ultrasound flap thickness (Pearson correlation coefficient $r = 0.81$). The OCT flap thickness was 143 ± 14 μm (mean ± SD, range 119–177) for the 180-μm Hansatome setting and 125 ± 12 (range 101–141) μm for the 160-μm setting. Bland–Altman analysis shows that the OCT measurements were greater than the ultrasound measurements (mean difference: 10.7 μm; 95 % limits of agreement, −8.8 to +30.2 μm). We believe the difference is due to an increase in postoperative flap hydration caused by the release of tensile stress. The repeatability of OCT flap measurement was 5 μm (pooled SD) within the central 5-mm diameter.

In our practice, we now routinely perform OCT imaging of post-LASIK cornea 1 week after the procedure (Fig. 55.10) with a 5-μm resolution Fourier-domain OCT (RTVue-CAM, Optovue, Inc.). The resulting flap thickness measurement is used to monitor the performance of the microkeratome and provide the flap thickness value used to calculate the predicted residual stromal bed thickness for subsequent LASIK patients. If the patient should need a second laser treatment (LASIK enhancement procedure), we also obtain an OCT scan to measure the stromal bed thickness available for laser ablation. We believe these measurements improve the safety of LASIK by preventing excessive laser treatment that could lead to an insufficient residual stromal bed of less than 250 μm.

55.2.6 Corneal Surgery

The ability of infrared light to penetrate through opaque cornea is used to its full advantage in the imaging of corneal scars, dystrophies, and other causes of corneal

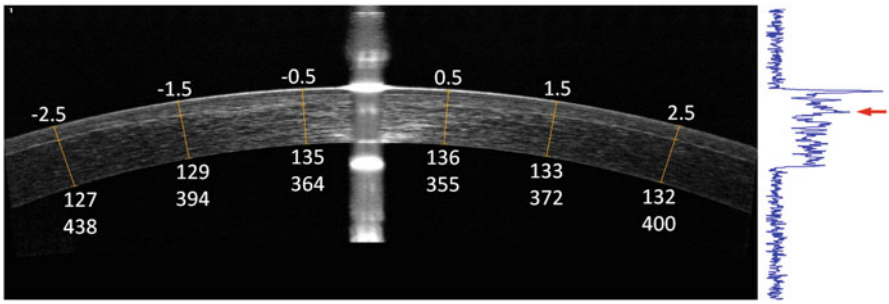

Fig. 55.10 A post-LASIK 1 week OCT scan of 840 nm Fourier-domain OCT. Eight consecutive frames were averaged

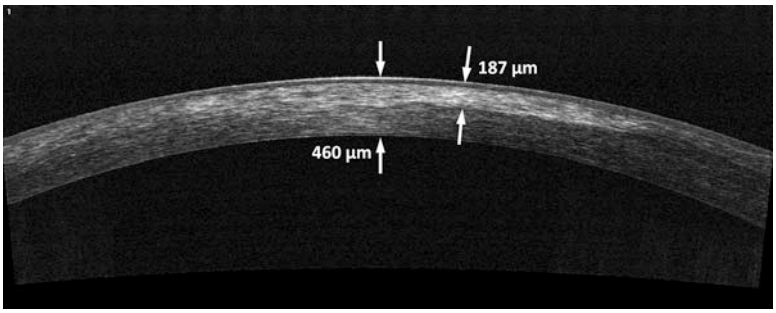

Fig. 55.11 A horizontal OCT of corneal scar with measurements of the corneal thickness and opacity depth

opacity (Fig. 55.11). In a series of 11 eyes with central corneal opacity, we have found that with OCT we were able to accurately measure the corneal thickness and opacity depth, providing useful information for the planning of excimer laser phototherapeutic keratectomy. It is interesting to note that in these cases, the Orbscan II (Bausch & Lomb), a slit-scanning corneal tomography system, significantly underestimated corneal thickness by an average of 157 µm. Thus, the much higher axial resolution of OCT was needed for the measurement of corneal thickness in the presence of corneal opacity.

Intracorneal ring (Intacs®) implantation is an alternative treatment for keratoconus that places two thin plastic ring segments into the stroma. These implants act as passive spacing elements in the midperiphery, shortening the arc length and thereby flattening the central cornea. The rate of complications caused by intracorneal ring is reported to be about 2 % [72]. Many of these complications were associated with shallow placement of the ring segments. Traditional evaluation of ring depth depends on slit-lamp examination by the surgeons. This measure is rough and highly objective. The wide-field anterior segment OCT is capable of imaging a wide area of the cornea and is helpful in better identifying those patients at greater risk of depth-related complications.

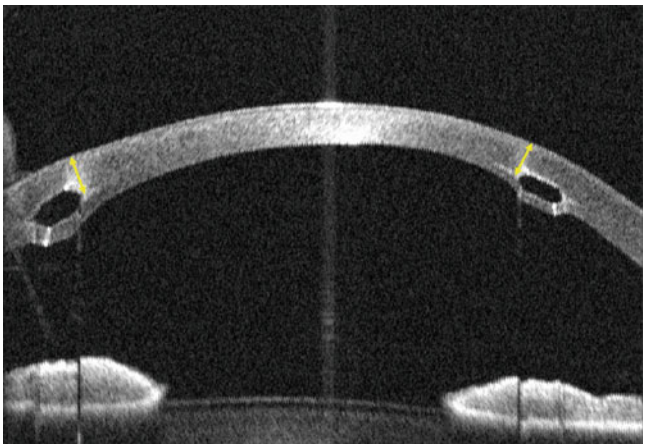

Fig. 55.12 A horizontal OCT scan of an eye after intracorneal ring implantation. The scan length is 12 mm. The segments are 350-μm thick on the left and 250 μm on the right. The depth of ring segment was measured from the inner tip of the ring segment to the anterior corneal surface (*arrows*). It has been recommended that the depth of ring segment is at about 70 % of total corneal thickness to decrease the chance of protrusion

Figure 55.12 is a cross-sectional OCT image of an intracorneal ring along one meridian. This scan can be repeated on different meridians to obtain a quick survey of ring segment depth over 360°. In a case study consisting of four patients who received intracorneal ring implantation, we found the average depth of ring segments was not closely correlated with the surgeons' slit-lamp impressions (r [2] = 0.68) [73]. Shallower segment depth was associated with greater corneal compression anterior to the segment ($p = 0.04$). Some ring segments show progressive shallowing further away from the incision where the segment was inserted. These findings are very useful for interpreting some depth-related complications that occur after intracorneal ring implantation.

Post-keratoplasty glaucoma is a frequent cause of irreversible corneal decompensation and subsequent graft failure [74, 75]. Diagnosis and management of these secondary types of glaucoma is frequently delayed since evaluating the type of glaucoma and measuring intraocular pressure after penetrating keratoplasty can be very challenging. Gonioscopic visualization of the anterior chamber angle is often obstructed by corneal scars, edema, and opacities at the host–recipient interface. Ultrasound biomicroscopy (UBM) is often used to visualize intraocular structures when slit-lamp biomicroscopy is blocked by opacities [76]. One drawback of UBM is the need for an immersion bath to couple the ultrasound from the transducer to the eye, introducing some inconvenience and discomfort. However, OCT imaging provides visualization of anterior segment structures behind an opaque cornea. Figure 55.13 is an OCT image that identified peripheral anterior synechiae as the cause of angle closure.

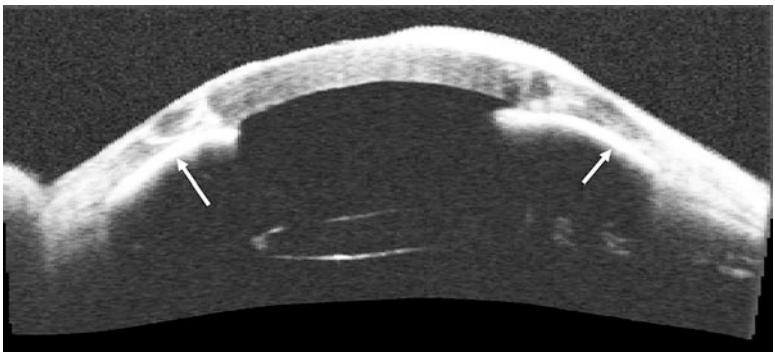

Fig. 55.13 Horizontal wide-field (16 mm) OCT of an eye with an opaque and edematous corneal transplant and elevated intraocular pressure. *Arrows* point to adhesions between the iris and cornea which block the outflow of aqueous fluid from the eye

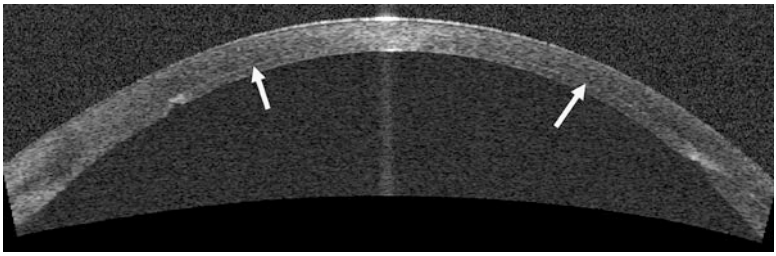

Fig. 55.14 OCT of a cornea after deep lamellar endothelial keratoplasty. The lamellar graft interface (*arrows*) is barely visible. Graft thickness uniformity and size match is excellent in this manually dissected case

Partial thickness corneal transplantation that replaces only the diseased endothelium (endothelial keratoplasty) while retaining the healthy anterior layers is gaining in popularity over full-thickness corneal transplantation (penetrating keratoplasty). It is used to treat corneal edema (swelling) caused by a diseased corneal endothelium. The advantages are fast visual recovery and little disturbance of the optical quality of the cornea (little induced astigmatism), compared to penetrating keratoplasty. Optical coherence tomography is a useful tool for management of post-endothelial keratoplasty patients because of its unique ability to visualize the surgically created layers. Figure 55.14 shows the successful result of one type of endothelial keratoplasty called deep laminar endothelial keratoplasty. The endothelial transplant is visualized as a thin posterior layer that fits well into the space created by the resected diseased endothelium. The edema has resolved, and the corneal thickness has been restored to its normal range. If the transplanted layer did not fully attach or if the edema remains, OCT would be the best modality to visualize the problem.

55.2.7 Assessment of Angle Closure Glaucoma

Angle closure glaucoma is a common cause of visual loss in Asian populations. It occurs in eyes with shallow anterior chambers where the peripheral iris could come forward to block the trabecular meshwork, the normal site of aqueous fluid outflow. Gonioscopy is the current standard for evaluating the anterior chamber angle. In gonioscopy, the physician uses a gonioprism that contacts the cornea to obtain an oblique reflected view of the anterior chamber angle and the trabecular meshwork. Gonioscopy, however, is highly subjective and requires specialized training. Cross-sectional imaging of the anterior chamber angle with either UBM or OCT is easier to interpret. Furthermore, objective quantification of the angle can be obtained from a cross section. Ultrasound biomicroscopy [77] and Scheimpflug photography [78] have been used for quantitative angle evaluation. However, OCT can provide the same detailed angle anatomy, with the further advantage of being noncontact and easy to perform.

Current OCT instruments commonly use 840, 1,050, or 1,310-nm wavelength light. The use of longer wavelength light to image the anterior chamber angle does have advantages: 1,310 and 1,050 nm lights show lower scattering and signal loss in turbid media [18, 79], permitting much better penetration through the limbus and sclera than is possible using shorter wavelengths.

This increased penetration allows 1,310-nm wavelength OCT to accurately measure gross angle morphology and visualize angle structures such as the iris root and scleral spur [11, 80, 81]. As a result, past studies used 1,310-nm OCT systems and developed quantitative angle parameters using scleral spur as the anatomical landmark [82–85]. The axial resolutions of the earlier OCT systems used in the abovementioned studies were limited to 15–20 μm and did not allow reliable identification of smaller angle structures such as the trabecular meshwork and Schwalbe's line. Newer OCT systems capable of producing axial resolutions of 1–5 μm are now available [86, 87]. This marked increase in resolution is due to the combination of broader bandwidth and shorter wavelength.

We used a 1,310-nm wavelength anterior segment OCT to assess the angle width. Images of an open angle and an occludable (narrow) angle are shown in Fig. 55.15. Corneal, scleral, and iris anatomy are visualized in detail. Features in the limbus and angle are clearly shown, including the scleral spur, ciliary body band, angle recess, and iris root. For angle measurements, it is particularly useful that the scleral spur is a highly reflective and easily identified on OCT. To take advantage of the highly contrasted scleral spur, we devised a diagnostic parameter called the trabeculo–iris space area (TISA-X) to quantify the angle opening. We define TISA-X as the aqueous space bounded by a roughly trapezoidal shape between the scleral spur, a point on the corneal endothelium X microns anteromedial from the scleral spur, and the intersections of the anterior iris surface with perpendicular lines drawn from the first two landmarks (Fig. 55.16a). We tested both TISA-500 and TISA-750. The 500-μm figure is anatomically meaningful because the average trabecular meshwork extends approximately 500 μm anteromedially from the scleral spur. The 750-μm figure used a greater portion of the images.

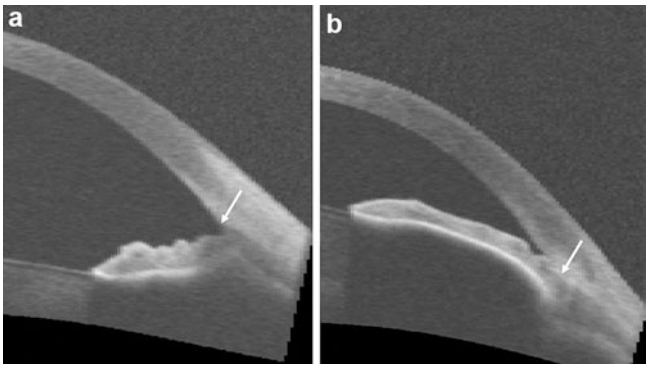

Fig. 55.15 OCT images of (**a**) an open anterior chamber angle and (**b**) an occludable (narrow) anterior chamber angle. *White arrows* indicate scleral spur locations

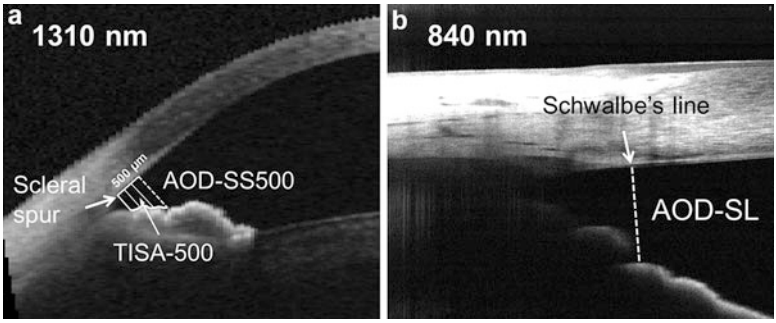

Fig. 55.16 Narrow angle diagnostic parameters of 1,310 nm (**a**) and 840 nm (**b**) OCT systems. AOD-SS500: angle opening distance measured 500 µm away from the scleral spur. TISA-500: trabeculo–iris space area 500 µm from the scleral spur. AOD-SL: angle opening distance at Schwalbe's line

We performed a clinical study to compare OCT and UBM parameters against gonioscopic grading by glaucoma specialists [82]. Thirty-one eyes of 28 subjects were examined. Eight eyes were judged to be occludable by gonioscopy. Subjects underwent OCT and UBM imaging of the nasal and temporal anterior chamber angles. Both OCT and UBM had excellent correlation with gonioscopy in terms of identifying occludable angles. We found that TISA-750 was better than TISA-500 for identifying gonioscopically occludable angles. A cutoff value of 0.12-mm [2] TISA-750 had 100 % sensitivity and 95.7 % specificity. This study showed that OCT is a reproducible method to assess the depth of the anterior chamber angle and validated it against both standard gonioscopy and UBM.

Fourier-domain OCT of 840-nm wavelength showed fine anatomical structures such as Schwalbe's line, trabecular meshwork, and scleral spur (Fig. 55.3a), but provided limited visualization of the angle recess. Schwalbe's line represents the

termination of Descemet's membrane and is approximately 500–750 μm anterior to the scleral spur. The distance between Schwalbe's line and the scleral spur represents the trabecular meshwork and the aqueous humor filtration distance. Schwalbe's line was proposed as an anatomical landmark because it could be consistently identified in 840-nm FD-OCT images. Several research groups recommended measuring angle opening distance at the Schwalbe's line (AOD-SL) for quantitative angle assessment (Fig. 55.16b) [88–90]. Further, AOD-SL has demonstrated good repeatability and strong correlation with gonioscopic grading. In a study reported by Qin et al. [90], 35 glaucoma patients were recruited. Each subject underwent darkroom gonioscopic examination, and a modified Shaffer grade was recorded for each of four quadrants. An occludable angle was defined as Grade 1 or lower in all quadrants. Angle scans were performed under standardized dim illumination conditions (6.6 foot candles) using a Fourier-domain OCT (RTVue-CAM, Optovue, Inc.). Schwalbe's line was visualized in 97.7 % of eyes scanned. Qin et al. also reported good repeatability for AOD-SL measurements with intra-observer coefficients of variation ranging from 9.8 % to 12.0 % and interobserver coefficients of variation ranging from 10.1 % to 13.3 %. Spearman's rho analysis showed strong correlation between AOD-SL measurements and gonioscopic grading with correlation coefficients of 0.80 for nasal angles and 0.81 for temporal angles. The occludable angle AOD-SL measurements ranged from 0 to 350 μm, and the non-occludable angle measurements ranged from 192 to 922 μm. Qin et al. determined a diagnostic cutoff value for occludable angle of 290 μm by performing receiver operating characteristic (ROC) analyses.

Optical coherence tomography is also useful for monitoring the results of treatment for narrow angle [91]. Narrow angle is often caused or exacerbated by a buildup of fluid behind the iris that pushes the peripheral iris forward. The fluid buildup is caused by blockage of fluid flow at the papillary margin due to tight apposition between the iris and the lens. A laser peripheral iridotomy can be performed to create a small hole in the iris as an alternate channel of fluid flow. This allows the iris to fall back and the angle to deepen. The use of OCT allows one to assess whether this procedure is effective.

We believe OCT will become an important tool for detecting narrow angle and monitoring the anatomic results of treatment. Further studies are needed to correlate the OCT measurements and the risk of acute glaucoma attacks due to pupil blockage and the risk of chronic intraocular pressure elevation and glaucoma. The availability of this precise tool for anatomic measurement may allow development of more objective and rational guidelines for treatment in this important class of disease.

55.2.8 Anterior Chamber Biometry and Intraocular Lens Implants

Phakic intraocular lens (IOL) implantation is performed to correct extreme myopia and hyperopia that are beyond the range of corneal procedures such as LASIK and

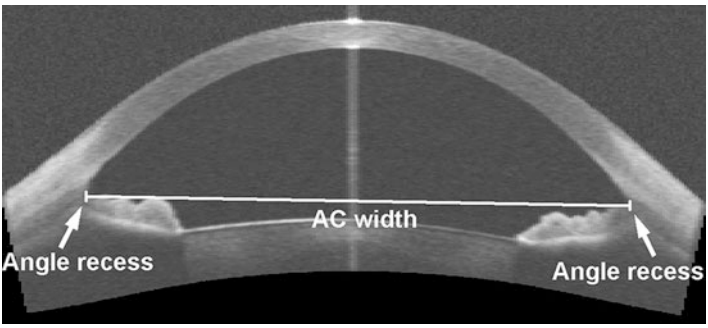

Fig. 55.17 A horizontal OCT scan showing the measurement of the anterior chamber width from angle recess to angle recess (*arrow*)

PRK. They are called "phakic" because the natural lens (phakos) is kept in place, as opposed to IOLs placed after cataract extraction, which are "aphakic" lenses. With the natural lens in place, there is very little room in the eye to add another lens. Thus, the design and fitting of phakic IOLs are more difficult. High-speed anterior segment OCT is able to make precise measurements that aid in the safe insertion of all three types of phakic IOLs now in use.

Anterior chamber width (ACW) measurement is clinically important for sizing angle-supported anterior chamber IOLs. An IOL that is too large can press on the iris root and produce pupil ovalization, while an IOL that is too small can lead to IOL movement, decentration, corneal endothelial damage, and iritis [92]. The traditional method for IOL sizing uses the external corneal diameter (CD), which was assumed to be correlated with the internal anterior chamber width. Typically, the IOL diameter is chosen to be the CD plus a constant such as 1 mm.

Increasing the speed of OCT to 2,000–4,000 axial scans per second allows accurate ACW measurement. For implantation of an angle-supported IOL, the relevant width is measured from angle recess to angle recess across the anterior chamber (Fig. 55.17). We used a wide-field anterior segment OCT system (4,000 axial scans per second) to measure the internal ACW and compared the result to external corneal diameter measurements in 20 normal subjects [12]. The ACW was 12.53 ± 0.47 mm (mean ± standard deviation) and the inter-image repeatability of measurement was 0.13 mm by pooled standard deviation. The difference between ACW and CD was 0.75 ± 0.44 (mean ± SD). Thus the use of OCT could potentially result in a threefold improvement in the precision of IOL fitting.

The iris-supported phakic IOL has been used to correct extreme myopia and hyperopia. Baikoff et al. has demonstrated that OCT is also useful for determining whether there is sufficient clearance between the IOL and the cornea and iris before surgery [93]. A well-fitted iris-supported phakic IOL is shown in Fig. 55.18.

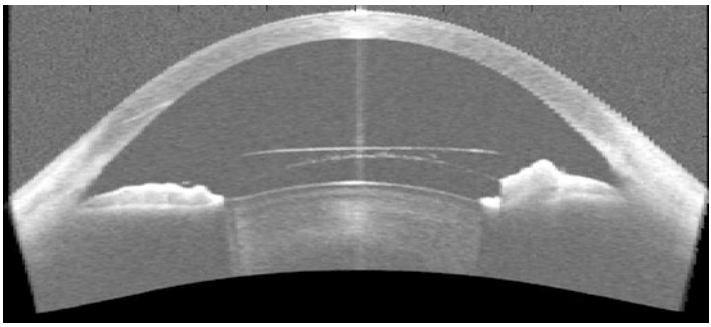

Fig. 55.18 A horizontal OCT scan of a phakic eye with an iris-fixed phakic intraocular lens (*IOL*) implant (Verisyse, AMO, Irvine, CA). There is good clearance of the IOL from the cornea, iris, and the natural lens

Yet a third type of phakic IOL is placed in the posterior chamber, between the iris and the natural lens. Although OCT cannot be used to measure the width of the ciliary sulcus space in the posterior chamber, it is useful to measure the consequence of poor sizing, such as contact with the natural lens (no vaulting) or excessive vaulting that cause chafing of the iris and pigment dispersion [94].

Phakic IOLs provide superior optical quality in the correction of extreme hyperopia and myopia, compared to LASIK. However, long-term safety is a major concern for these relatively new devices. By improving patient selection and IOL sizing, OCT may significantly improve the safety of phakic IOL implantation.

55.2.9 Intraocular Lens Power Calculation

Corneas after refractive surgeries require a method of directly measuring both anterior and posterior corneal power in order to obtain accurate corneal power measurement and intraocular lens (IOL) calculation. Slit-scanning tomography, rotating-slit Scheimpflug camera, and dual-Scheimpflug systems have all been used for this purpose [95–97]. However, the axial resolutions of these devices are between 50 and 100 μm, much lower than the resolution offered by current OCT technology. There have been a number of recent studies showing good repeatability and accuracy when using OCT to measure corneal power [98–100], and OCT is more accurate than other types of corneal tomography when taking measurements in the presence of corneal opacities [101].

The OCT-based IOL formula was published in a recent study [98]. In this study, Corneal power was measured with a Fourier-domain OCT system. Axial length, anterior chamber depth, and automated keratometry were measured with the IOLMaster. An OCT-based IOL formula was developed from these parameters. The formula used an eye model consisting of four optical surfaces: anterior corneal

surface, posterior corneal surface, IOL, and retina. The IOL was modeled as a thin lens. The formula traces the vergence of the light traveling through the eye, starting from the retinal plane to the anterior eye surface to predict refractive outcome after IOL implantation given the IOL model and power.

The OCT-based IOL formula used an eye model consisting of four optical surfaces: anterior corneal surface, posterior corneal surface, IOL, and retina. The IOL was modeled as a thin lens. Light traveled through the first three surfaces and focused on the retina. We traced the vergence of the light beam traveling through the eye, starting from the retinal plane to the anterior eye surface.

At the back of IOL, vergence

$$V_1 = n_2/l_1 \tag{55.3}$$

In front of IOL, vergence

$$V_1' = V_1 - P_1 \tag{55.4}$$

At the back of posterior corneal surface, vergence

$$V_2 = 1/\left(1/V_1' + l_2/n_2\right) \tag{55.5}$$

In front of posterior corneal surface, vergence

$$V_2' = V_2 - P_P \tag{55.6}$$

At the back of anterior corneal surface, vergence

$$V_3 = n_1/\left(n_1/V_2' + \mathrm{CCT}\right) \tag{55.7}$$

In front of anterior corneal surface, vergence

$$V_3' = V_3 - P_A \tag{55.8}$$

Where n_1 = refractive index of cornea, 1.376 is used
n_2 = refractive index of vitreous and aqueous humor, 1.336 is used
l_1 = vitreous length = AL – l_2
l_2 = IOL depth (also called effective lens position, see Eq. 55.10)
P_1 = IOL power

The vergence in front of anterior corneal surface V_3' is the refractive error at the corneal plane. The manifest refraction spherical equivalent (MRSE) at the spectacle plane is

$$\mathrm{MRSE} = 1/\left(1/V_3' + \text{vertex distance}\right) \tag{55.9}$$

A vertex distance of 12 mm was assumed in our calculations. Overall The IOL depth was predicted using a regression-derived formula:
If AL $< = 24.4$ mm:

$$\text{IOL depth} = 0.711 * \text{ACD} + 0.623 * \sqrt{\text{AL}} - 0.25 * P_P + (\text{pACD} - 8.11) \tag{55.10}$$

If AL > 24.4 mm:

$$\text{IOL depth} = 0.711 * \text{ACD} + 0.623 * \sqrt{[\text{AL} - 0.8 * (\text{AL} - 24.4)]} - 0.25 * P_P + (\text{pACD} - 8.11) \tag{55.11}$$

where P_P is posterior corneal power and pACD is the ACD constant, a constant given by the manufacturers to characterize a given lens.

The mean absolute error (MAE) of refractive prediction for OCT-based IOL formula was calculated. A total of 31 eyes of 24 subjects who had uncomplicated cataract surgery with monofocal IOL implantation were enrolled in the two sites. Twenty-two eyes of 16 subjects had previous myopic LVC ranged from −12.46 D to −0.88 D. Nine eyes of eight subjects had previous hyperopic LVC ranged from 0.66D to 5.52D.

For the myopic group, the MAE of OCT-based formula was 0.57 D, and the MAE of Haigis-L was 0.73 D ($p = 0.19$). We also reported a trend toward fewer large prediction errors using OCT, with 18 eyes (82 %) within 1 D of actual refractive outcome, compared with 16 eyes (73 %) within 1 D for Haigis-L. For the hyperopic group, the MAE of OCT-based IOL was 0.26 D, while Haigis-L had an MAE of 0.54 D ($p > 0.05$). There was a trend toward fewer large prediction errors using OCT, with nine eyes (100 %) within 1 D of actual refractive outcome, compared to seven eyes (78 %) within 1 D for Haigis-L. Given these results and the likelihood of future improvements to OCT systems, this technology has a promising future in cataract surgery.

55.2.10 Optical Coherence Tomography in Eye Banking

Eye banks currently employ a number of methods for assessing donor corneal tissue, including penlight exam, specular microscopy, slit-lamp biomicroscopy, medical record review, and family interview [102]. Although these evaluation techniques are largely successful in identifying the contraindications that bar corneas from use in procedures such as penetrating keratoplasty (PK), anterior lamellar keratoplasty (ALK), and endothelial keratoplasty (EK), some eye banks have recently begun adopting Fourier-domain OCT as a way of supplementing their standard procedures for tissue appraisal.

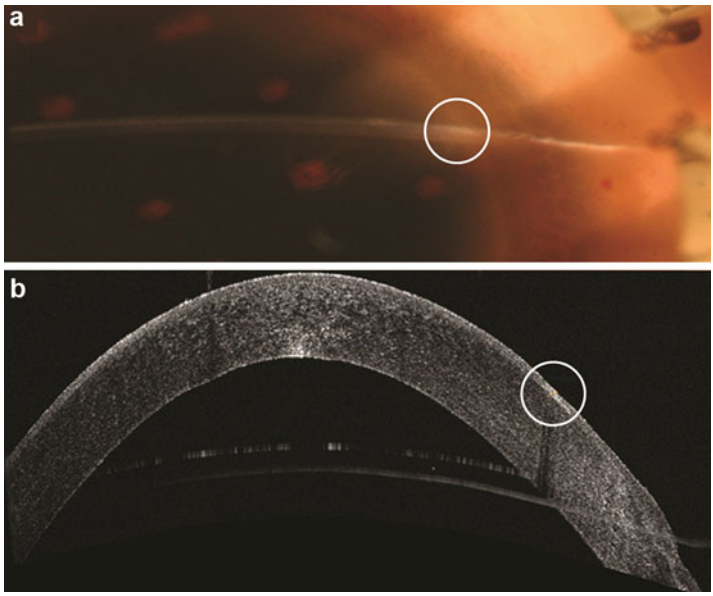

Fig. 55.19 (**a**) Slit-lamp microscopy shows corneal opacity, but its position cannot be determined precisely (*circle*). (**b**) OCT evaluation reveals scarring is actually limited to the corneal epithelium (*circle*)

OCT's unique ability to accurately map corneas over a wide area, and provide precise measurements of stromal opacities while avoiding tissue contamination [101, 103], makes it a potentially valuable instrument for screening donor corneas. This potential is bolstered by the Eye Bank Association of America's (EBAA) 2005 decision to expand the criteria for acceptable tissue: [102] corneas that had been deemed unsuitable for PK because of anterior scarring, central pterygia, or corneal refractive surgeries such as radial keratotomy (RK) are now being effectively used in EK procedures [104, 105]. It is therefore increasingly important that each donor cornea is evaluated both accurately and efficiently in order to make the best use of all available tissue. In an example shown in Fig. 55.19, the slit-lamp examination showed corneal opacity, but its precise position cannot be determined (Fig. 55.19a). However, upon OCT evaluation, it was shown that the cornea contained no stromal scarring, and, with a depth of 82 μm, the opacity was limited to the epithelium (Fig. 55.19b). The tissue was eventually used for EK.

The use of Fourier-domain OCT as an adjunct to standard tissue evaluation methods may provide eye banks with the information necessary to improve their decision-making processes and ensure that no donor cornea is wasted or misused.

55.3 Future Developments

Very high performance anterior segment OCT systems have already been demonstrated in research centers [18, 20, 22, 106–109]. The performance of commercial anterior segment OCT will also improve as the cost of implementation drops and clinical application grows.

With higher speed, three-dimensional visualization becomes possible. Figure 55.20a shows a rendering of a volumetric data set acquired with an ultrahigh speed swept-source OCT operating at 100 kHz for anterior segment imaging. The three-dimensional volume consists of 500 × 500 axial scans covering 16 × 16 mm [2] of the anterior eye. Extended depth imaging has been achieved swept-source technology. As an example, the cross-sectional image in Fig. 55.20b shows the cornea, iris, and entire crystalline lens and spans the entire transverse anterior chamber width, from limbus to limbus.

High-speed imaging also enables more reproducible measurement of the ocular structures. The short time frame of the high-speed measurement reduces the motion artifacts in the image and improves the accuracy of shape and dimension measurements. Several research groups demonstrated corneal topographic measurements with ultrahigh speed anterior segment OCT [20, 106, 107, 109–111]. Karnowski et al. presented corneal topographic maps obtained with a Fourier-domain OCT system operating at 108,000 axial scans per second [106]. They demonstrated good agreement between Fourier-domain OCT-based topographic maps and those obtained with a rotating Scheimpflug imaging and Placido topography (Fig. 55.21).

OCT competes with other imaging methods such as ultrasound imaging, slit-scanning tomography, Placido ring topography, and confocal scanning microscopy. It is unique in its versatility. And as the performance of OCT further improves, it can take over more of the applications currently performed with the other technologies.

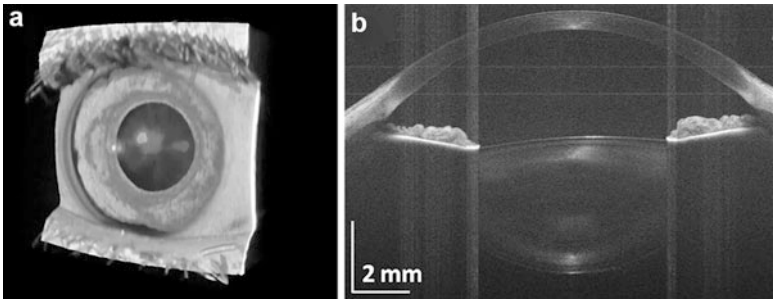

Fig. 55.20 Anterior segment imaging with VCSEL-OCT: (**a**) rendering of the volume, (**b**) central cross-sectional image was averaged by five consecutive B-scans (Reprinted from Grulkowski et al. [107])

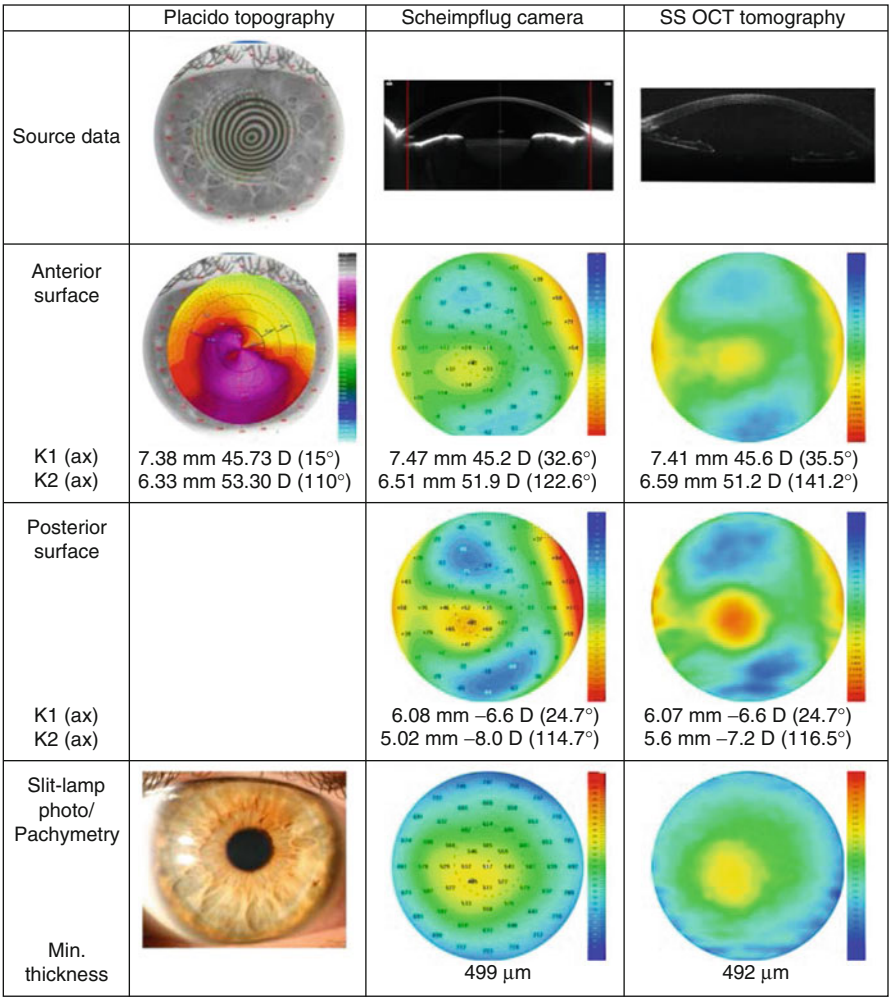

Fig. 55.21 Quantitative evaluation of a keratoconic cornea with high-speed swept-source OCT, rotating Scheimpflug imaging, and Placido topography. K1 and K2 indicate central keratometry readings (Reprinted from Karnowski et al. [106])

Keywords

2D and 3D retinal OCT • optophysiology • retinal OCT in animal models • retinal segmentation • Ultrahigh axial resolution

The eye is essentially transparent, transmitting light with only minimal optical attenuation and scattering providing easy optical access to the anterior segment as well as the retina. For this reason, ophthalmic and especially retinal imaging has been not only the first but also most successful clinical application for optical coherence tomography (OCT). This chapter focuses on the development of OCT technology for retinal imaging. OCT has significantly improved the potential for early diagnosis, understanding of retinal disease pathogenesis, as well as monitoring disease progression and response to therapy. Development of ultrabroad bandwidth light sources and high-speed detection techniques has enabled significant improvements in ophthalmic OCT imaging performance, demonstrating the potential of three-dimensional, ultrahigh-resolution OCT (UHR OCT) to perform noninvasive optical biopsy of the living human retina, i.e., the in vivo visualization of microstructural, intraretinal morphology in situ approaching the resolution of conventional histopathology. Significant improvements in axial resolution *and* speed not only enable three-dimensional rendering of retinal volumes but also high-definition, two-dimensional tomograms, topographic thickness maps of all major intraretinal layers, as well as volumetric quantification of pathologic intraretinal changes. These advances in OCT technology have also been successfully applied in several animal models of retinal

pathologies. The development of light sources emitting at alternative wavelengths, e.g., around ~1,060 nm, not only enabled three-dimensional OCT imaging with enhanced choroidal visualization but also improved OCT performance in cataract patients due to reduced scattering losses in this wavelength region. Adaptive optics using deformable mirror technology, with unique high stroke to correct higher-order ocular aberrations, with specially designed optics to compensate chromatic aberration of the human eye, in combination with three-dimensional UHR OCT, recently enabled in vivo cellular resolution retinal imaging.

New medical imaging technologies can improve the diagnosis and clinical management disease. Furthermore, they can also contribute to a better understanding of disease pathogenesis and, therefore, to the development of novel therapies for disease. Thus, imaging technologies have a significant impact on medical research and clinical practice. For example, A-scan and B-scan ultrasonography are routinely used in ophthalmologic biometry and diagnosis to image and differentiate orbital disease and intraocular anatomy. These ultrasound measurements require physical contact with the eye and typically provide 150 μm longitudinal resolution by using a 10 MHz transducer [1, 2]. High-frequency (50 MHz) ultrasound can achieve axial resolution of 20–30 μm, but its penetration depth is limited to 4 mm because of acoustic attenuation in ocular media [3, 4]. Hence, only the anterior eye segment structures can be imaged with this high resolution. Scanning laser ophthalmoscopy or scanning laser tomography, invented in 1979, represented a major development in ophthalmic fundus imaging [5–7]. A focused laser spot is raster scanned on the retina, while the integrated backscattered light is measured to obtain high-quality, micron-scale, lateral resolution fundus images. Scanning laser ophthalmoscopy provides an *en face* view of the fundus with high transverse resolution and contrast. However, pupil aperture and ocular aberrations limit the axial resolution in the retina to several hundred microns (~300 μm). Axial image resolution has been a key parameter for ophthalmic imaging because of the stratified organization of the retina. In contrast to standard or confocal microscopy, axial and transverse resolution in OCT are decoupled, with the axial determined by the optical bandwidth of the light source and the transverse resolution determined by the focusing of the measurement beam onto the tissue. In this sense, OCT bridges the gap between the high resolution and limited penetration of confocal microscopy and the low resolution and high penetration of ultrasound. These properties make OCT a unique ophthalmic diagnostic modality in which high axial resolution, despite a long depth of focus (field) – a situation encountered with in vivo retinal imaging – can be accomplished. The earliest measurements of one-dimensional, axial information, analogous to ultrasound A-scans, were demonstrated in the mid 1980s [8–10]. OCT, the generation of cross-sectional or two-dimensional images, analogous to ultrasound B-scans, was first demonstrated in 1991 [11]. The first in vivo OCT imaging studies of the human retina were performed in 1993 (cf. Fig. 56.1a, b) [12, 13]. Since that time, OCT has rapidly developed as a noninvasive, medical diagnostic imaging modality that enables in vivo, cross-sectional visualization of the internal microstructure in biological systems (cf. Fig. 56.1c, d) [14–16]. OCT provides images of retinal

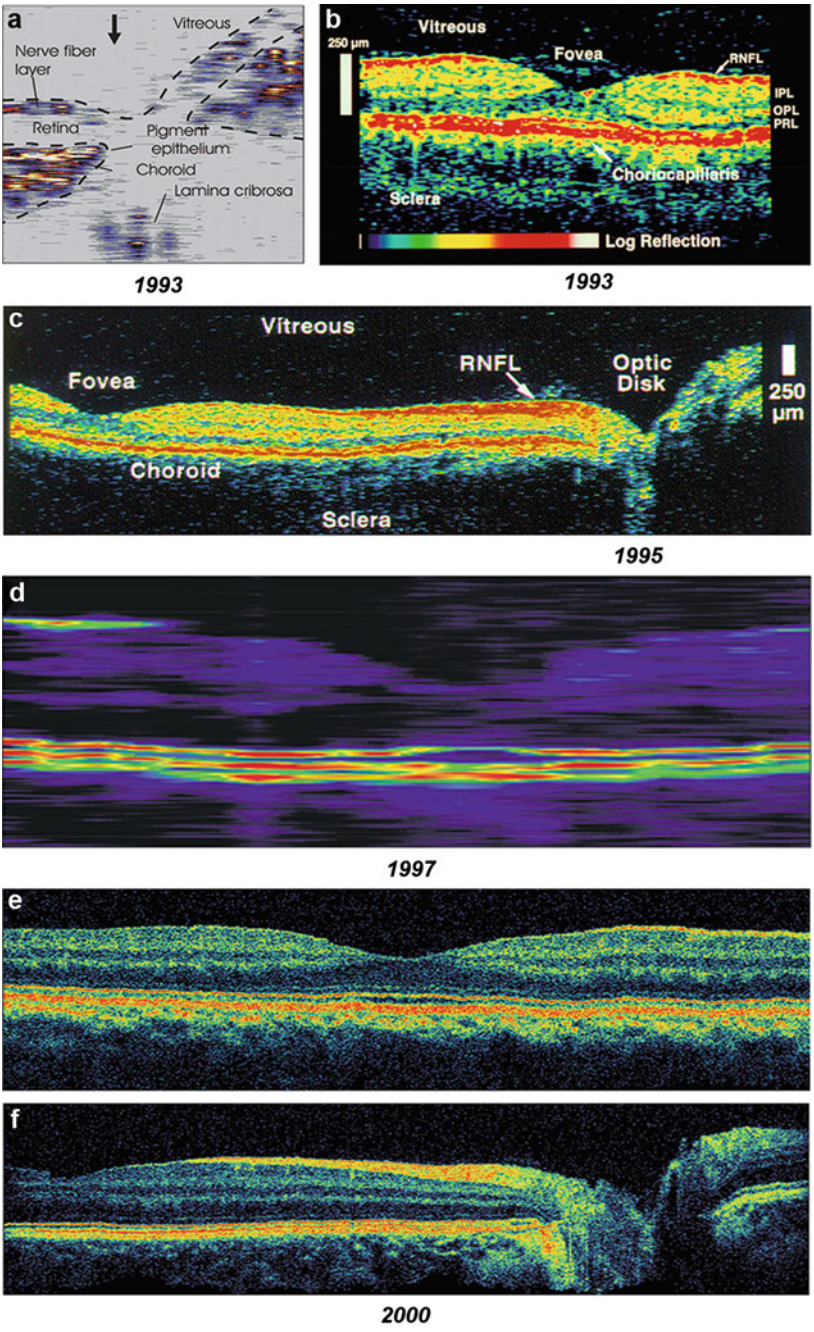

Fig. 56.1 (continued)

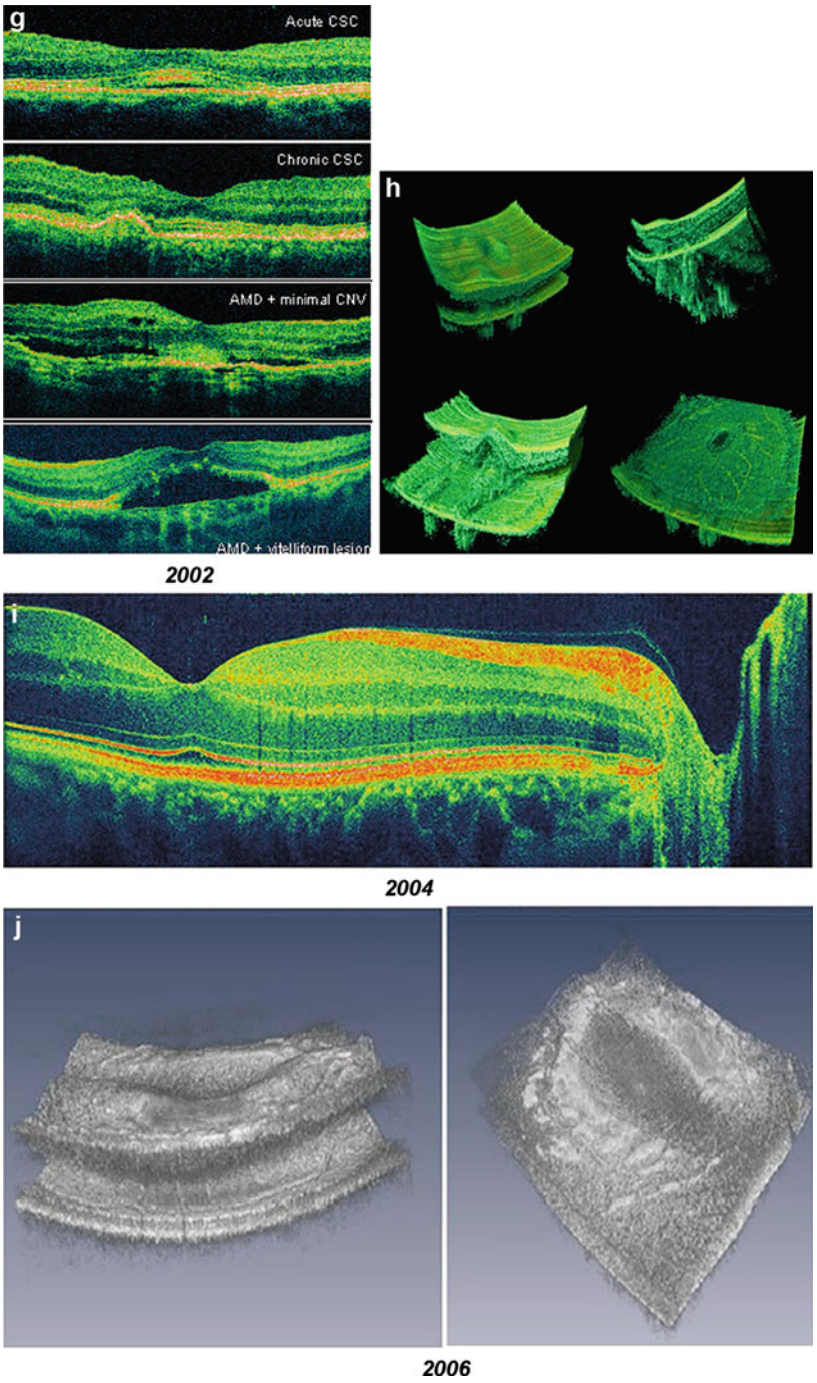

Fig. 56.1 (continued)

structure that cannot be obtained by any other noninvasive diagnostic technique. For these reasons, ophthalmic diagnosis is one of the most clinically developed OCT applications [17–37].

Since its invention, the original concept of OCT has been to enable noninvasive optical biopsy, i.e., the in situ imaging of tissue microstructure with a resolution approaching that of histology, but without the need for tissue excision and post-processing. A critical step towards this goal was the introduction of ultrahigh-resolution OCT (UHR OCT). Improving axial OCT resolution by one order of magnitude from the 10–15 μm to the sub-μm region enabled a noticeably superior visualization of tissue microstructure, e.g., all major intraretinal layers as well as cellular resolution OCT imaging in nontransparent tissue (cf. Fig. 56.1e, f) [38–41]. Since then, UHR OCT technology has been investigated in clinical settings to assess its clinical utility (cf. Fig. 56.1g). Cross-sectional studies in ~1,000 eyes with different pathologies demonstrated unprecedented visualization of all major intraretinal layers and provided important information about the photoreceptor layer [40, 42–50]. These studies demonstrated visualization of photoreceptor layer impairment in macular pathologies, such as macular holes, central serous chorioretinopathy, age-related macular degeneration, foveomacular dystrophies, Stargardt's dystrophy, and retinitis pigmentosa. For the first time, photoreceptor layer loss could be directly correlated with retinal function (visual acuity and microperimetry findings) in patients with Stargardt's dystrophy [43]. Studies also demonstrated the application of UHR OCT to monitor therapy as well as to contribute to a better understanding of disease pathogenesis [42, 44–46]. Advances in photonics technology, including the development of ultrabroad bandwidth and high-speed tunable light sources as well as high-speed detection techniques, have enabled a considerable improvement in the visualization capability of OCT in the last decade, thus establishing it as a state-of-the-art, noninvasive, complementary ophthalmic diagnostic methodology (cf. Fig. 56.1h–j). As a consequence, there have been numerous recent developments of OCT technology and considerable interest in this topic – especially in the field of ophthalmology. Objectively, this is evidenced by a tremendous increase in publications, patents, and companies involved in the field of OCT in recent years. It is noteworthy that about ~50 % of all OCT publications published to date have been in ophthalmic journals, demonstrating the major impact of OCT in this field. Another 25 % have been published in optical journals, reflecting the numerous technical advances that have been accomplished.

Fig. 56.1 Historic development of axial resolution and data acquisition speed in retinal OCT. In vivo retinal OCT imaging with 10–15 μm axial resolution with slow speed (2 Hz and low transverse sampling) (**a**, **b**) and high speed (100 Hz and improved transverse sampling) (**c**); 7–9 μm axial resolution with slow speed (2 Hz and low transverse sampling) (**d**); first in vivo ultrahigh-resolution (2–3 μm) imaging with high speed (160 Hz) of normal subjects (**e**, **f**) and patients (**g**); three-dimensional (**h**) and high-definition (**i**) ultrahigh-resolution (2–3 μm) imaging with 29,000 Hz; ultrahigh-speed (300,000 Hz) and high-resolution (10 μm) 3D retinal imaging at 1,050 nm with enhanced penetration into the choroid (**j**)

56.1 Two-Dimensional Ultrahigh-Resolution OCT Versus Histology: Improved Interpretation of Intraretinal Layers

The development of UHR OCT was a key step toward achieving noninvasive optical biopsy of the human retina, i.e., the visualization of intraretinal morphology in retinal pathologies approaching the level achieved with histopathology. Figure 56.2 depicts an example demonstrating that UHR OCT of a patient with a macular hole can provide similar information as histopathology, shown in a different postmortem eye at a comparable stage of disease.

In order to evaluate the potential of UHR OCT for enhanced visualization of intraretinal structures and to provide an improved basis for the correct interpretation of in vivo ophthalmic 2D UHR OCT tomograms of high clinical relevance, studies have been conducted to compare and correlate 2D UHR OCT cross-sectional images of ex vivo pig [51] and monkey (*Macaca fascicularis*) [52, 53] retinal specimens with histology. Figure 56.3a, b depict in vivo 2D UHR OCT of the foveal and optic disk regions in a nonhuman primate glaucoma model (*cynomolgus monkey*) compared with histology of the same retina at similar location. (This study was conducted in collaboration with Novartis Institutes for Biomedical Research by E. Polska and A. Doelemeyer.) Figure 56.2c, d show a comparison of in vitro ultrahigh-resolution OCT imaging (D) with histology (C) of a macular scan of a monkey retina, demonstrating excellent correlation of the OCT and tissue boundaries and the potential of 2D UHR OCT to visualize all major intraretinal layers. The results of these studies allow the extraction of clinically relevant structural retinal information with in vivo ultrahigh-resolution ophthalmic OCT tomograms and were an important step toward resolving the ambiguities that arose with 2D UHR OCT tomograms in trying to establish the correlation of OCT features with more than ten intraretinal layers.

Despite these studies comparing histology with 2D UHR OCT, it is noteworthy that a comprehensive, reliable delineation of *all* intraretinal layers has not yet been accomplished. The distal part of the retina including the retinal pigment epithelium (RPE), Bruch's membrane, choriocapillaris, and choroid complex remains a particular challenge. Currently, the "last," i.e., most strongest continuous distal signal in UHR OCT tomograms, has been interpreted as being the retinal pigment epithelium (RPE) layer. While literature describing the light-RPE interaction in the near-infrared region around 800 nm would confirm this, the relatively thick (up to 20–30 μm) appearance in UHR OCT tomograms is not consistent with the RPE as a monocellular layer.

Figure 56.4 shows a comparison of in vitro ultrahigh-resolution OCT imaging of a pig retina 2 h *postmortem* acquired with 1.4 μm axial and 3 μm transverse resolutions (B) with the corresponding frozen section imaged by differential interference contrast (DIC) microscopy (G). Fig. 56.4a shows a photograph of the fundus with the major retinal vessels indicating the OCT scan location with a bar. In a series of OCT scans, the initiation of a retinal detachment event was monitored within a time frame of 30 min (cf. Fig. 56.4c–f). Ultrahigh-resolution OCT visualized a focal elevation of the neural retina concomitant with an increase in subretinal

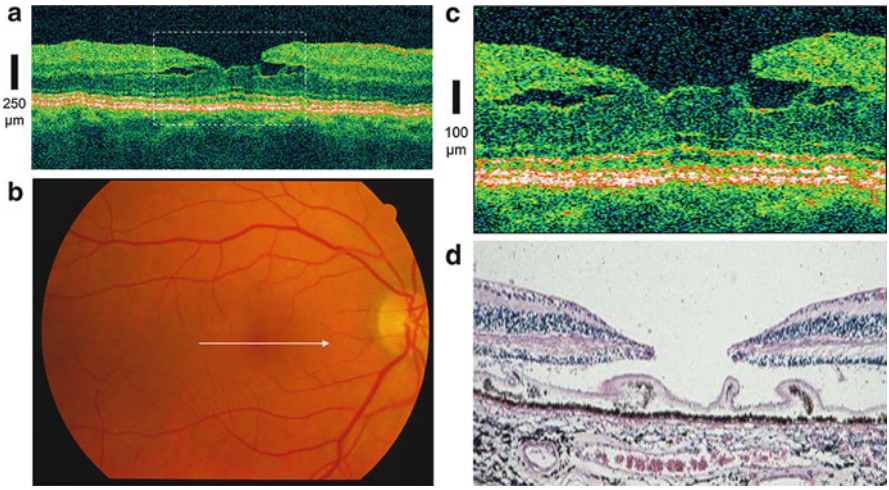

Fig. 56.2 In vivo optical biopsy using ultrahigh-resolution ophthalmic OCT (UHR OCT). UHR OCT of a patient with macular hole (**a**). Fundus photograph (**b**) indicates location of the OCT scan (*white arrow* in **b**). Twofold enlargement (**c**) of the central foveal region (indicated by *dashed white rectangle* in **a**) is compared with histology (**d**) of a different postmortem eye with comparable stage of macular hole (Histology (**d**) was kindly provided by R. Brancato, Italy)

space (cf. Fig. 56.4b, c). Fifteen minutes later, alterations were observed within the monolayered band of the pigment epithelium (PE) signal (cf. Fig. 56.4d). While still continuous, the PE signal appeared triple layered at the initial locus of detachment with a stripe of bright signal framed by two darker bands. After an additional 15 min, all retinal layers were found bent inward and the measurements of their relative thickness (not shown) indicated increased thickness of the proximal retinal layers (cf. Fig. 56.4e). In the PE signal, the bright inclusion increased while the innermost aspect of the signal appeared eroded (cf. Fig. 56.4f). Histological examination of the matching retinal position demonstrated a significantly extended region of detachment (Fig. 56.4g). The pigment epithelium was found to be lesioned at the initial locus of detachment, and fragments of tissue were dislocated into the subretinal lumen (Fig. 56.4g, asterisk).

In addition, the appearance of the RPE and distally adjacent layers, as visualized by in vivo UHR OCT, varies in eyes with different pathologies. Figure 56.5 depicts UHR OCT tomograms of a patient with central serous chorioretinopathy. Figure 56.5c, d show serous retinal detachments (indicated by asterisks), focal pigment epithelium detachments (cf. white arrow in Fig. 56.5d), and a "triple band appearance" (cf. Fig. 56.5c, white arrow) of the photoreceptor/RPE interface. Figure 56.5e–s show a selection of 15 B-scans from 60 that were raster scanned across a $3 \times 3 \times 1$ mm volume. The triple band appearance might be related to the outer tips of the photoreceptors or the anchorage of the outer segments between the RPE cells. Another important issue in the interpretation of UHR OCT tomograms is the ability to visualize Bruch's membrane. The focal feature in the pigment

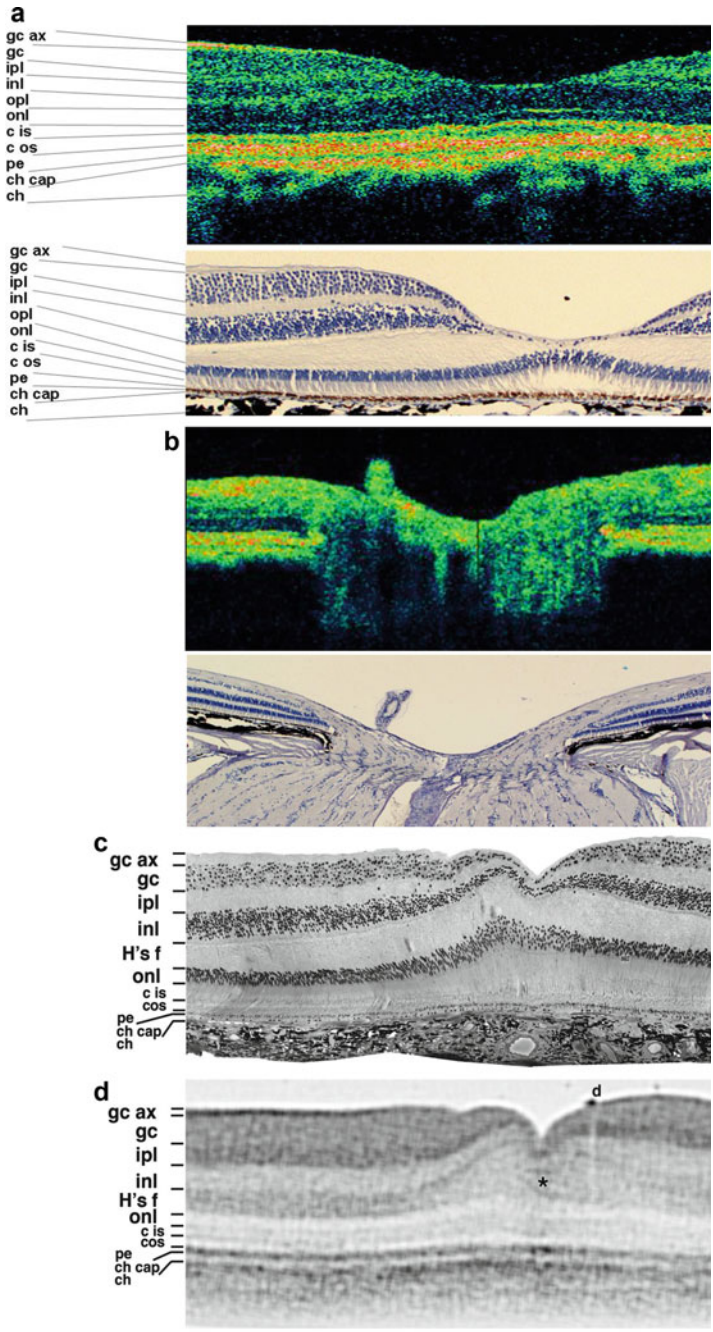

Fig. 56.3 (continued)

epithelium detachment depicted in Figs. 56.5d, f (cf. white arrows) might be interpreted as Bruch's membrane. However, this membrane is strongly attached to the RPE, and it is likely that this membrane is also detached along with the RPE. "Visualization" of Bruch's membrane by OCT is, therefore, problematic. Bruch's membrane thickens with age and is, at most, 5 μm thick in patients in the 75–90-year-old range, as measured histological in postmortem tissue [54, 55]. Since the in vivo UHR OCT axial resolution is at best 2–3 μm at 800 nm, it is not clear that UHR OCT is capable of resolving and visualizing Bruch's membrane. Figure 56.6 depicts representative UHR OCT tomograms of a patient with age-related macular degeneration (A, B) and pigment epithelium detachment (D) with corresponding fluorescent angiography (C) and a fundus photograph indicating the location of the OCT scans (C and E, white arrows). UHR OCT images (A, B, D) more clearly show a thin backscattering layer (yellow arrows) below the RPE layer that is suggestive of Bruch's membrane.

Although state-of-the-art ophthalmic OCT technology enables significantly improved visualization of intraretinal layers, caution is therefore imperative regarding proper interpretation of OCT tomograms, especially of the distal part of the retina, and more comprehensive studies are needed to clarify this issue. Figure 56.7 depicts a state-of-the-art OCT interpretation of intraretinal layers in a high-definition UHR OCT of the optic disk (A) and foveal (B) region of a normal subject. Labeling of intraretinal layers that could be confirmed by clinical investigations using UHR OCT and systematic studies comparing histology with UHR OCT in in vitro animal models are labeled white or black. From the proximal to the distal part of the retina, the nerve fiber layer (cf. Fig. 56.7a, NFL) as well as plexiform layers (cf. Fig. 56.7a, inner (IPL) and outer plexiform (OPL) layer) appear back-reflecting and therefore as a strong signal in the OCT tomogram. The ganglion cell layer (cf. Fig. 56.7a, GCL) and nuclear layer (cf. Fig. 56.7a, inner (INL) and outer nuclear ONL) layer appear less back-reflecting and therefore as a low signal in the OCT tomogram. The external limiting membrane (cf. Fig. 56.7b, ELM), the inner and outer photoreceptor segment (cf. Fig. 56.7b, IS PR, OS PR), as well as the choroid (cf. Fig. 56.7b) are also properly confirmed by literature. Red-labeled layers indicate that caution is imperative and the correct interpretation needs more conclusive studies to confirm correctness. This applies to the internal limiting membrane (cf. Fig. 56.7a, ILM) and the distal part of the retina involving probably the distal tips of the photoreceptors – sometimes also referred to Verhoeff's

Fig. 56.3 Ultrahigh-resolution OCT versus histology. Fig. 56.4 Retinal pigment epithelium appearance in in vitro *UHR OCT*. Photograph of the in vitro fundus showing the papilla and major blood vessels. White bar indicates orientation of the OCT scan (**a**). Time lapse sequence of retinal detachment during in vitro ultrahigh-resolution OCT imaging with 1.4 μm axial ×3 μm transverse resolution. Full OCT image of an area of 0.7 × 2 mm consisting of 14,000 × 2,000 pixels (**d**). Enlarged image portions of the detachment zone covering an area of 0.5 × 0.5 mm consisting of 10,000 × 500 pixels, fast Fourier transform filtered for reduction of radial shadowing effects. Time intervals between these images are 15 min (**c**–**e**). In the aligned micrographs, progressive bending and swelling of tissue are evident. **a** All photoreceptor sublayers have begun to bend proximally resulting in a subretinal lumen. (**b**) The subretinal blebs have significantly increased. Underneath the detachment zone, the *dark* band of signal that corresponds to the pigment epithelium/Bruch's membrane complex is still continuous (*arrowheads*), but locally triple layered, as indicated by a *bright* inclusion. (**c**) The innermost aspect of the triple-banded signal appears interrupted. (**f**) Twofold enlargement of area indicated with *dashed line* in (**e**). Corresponding histological section (**g**). Tissue processing has led to more extended retinal detachment. Debris from the damaged pigment epithelium (*arrow*) is present in the subretinal space (*asterisk*). All scale bars: 50 μm

membrane (cf. Fig. 56.7b), the retinal pigment epithelium including Bruch's membrane (cf. Fig. 56.7b, RPE/BM), as well as choriocapillaris (cf. Fig. 56.7b).

56.2 Two-Dimensional, Clinical Ultrahigh-Resolution OCT

In several clinical feasibility studies [40, 42–50], 2D UHR OCT imaging has been performed using a laboratory prototype as well as a commercially available femtosecond titanium-sapphire laser light sources (INTEGRAL, Femtolasers Produktions GmbH, Austria) that generate bandwidths of 100–175 nm at 800 nm center wavelength [56]. These light sources can support 2–3 μm axial resolution in the retina. OCT imaging was performed with axial scan rates of up to 250 Hz using up to 800 μW incident power in the scanning OCT beam, which is well below the ANSI exposure limit. More than 1,000 eyes with a range of macular diseases, such as macular holes, macular edema, age-related macular degeneration, central serous chorioretinopathy, epiretinal membranes, and detachment of pigment epithelium and sensory retina, were studied. In addition, patients with glaucoma and different hereditary retinal diseases were also imaged. The purpose of these studies was to investigate the clinical feasibility of 2D UHR OCT to visualize and quantify intraretinal morphology changes, especially in the inner (IS PR) and outer segment (OS PR) of the photoreceptor layer in healthy subjects and patients with different macular pathologies.

Figure 56.8 shows a selection of 2D UHR OCT images of the central foveal region in a normal subject and in 11 patients with different retinal pathologies. A significantly better visualization of the extent of photoreceptor impairment in different retinal pathologies was possible, including the ability to distinguish between the inner and outer photoreceptor layers and correlate photoreceptor impairment with visual acuity (shown in Fig. 56.8). These studies demonstrated the potential of 2D UHR OCT to enhance early diagnosis by detecting subtle, early morphological intraretinal changes in a wide range of retinal diseases. Comparative studies using UHR and standard-resolution OCT imaging of different retinal pathologies showed that 2D UHR OCT could be used to guide the interpretation of images from commercial, standard-resolution OCT systems (cf. Figs. 56.9, 56.10, and 56.11). Studies have also demonstrated the application of UHR OCT to monitor therapy as well as to contribute to a better understanding of disease pathogenesis [42, 44–46].

56.3 High-Speed, Ultrahigh-Resolution OCT: Three-Dimensional and High-Definition OCT

UHR OCT imaging was initially based on time domain OCT and, therefore, had a fundamental time-bandwidth trade-off. As a result, operation with ultrahigh resolution required reduced imaging speeds in order to maintain sufficient detection sensitivity. Signal levels could not be increased by increasing light exposure because of the low power levels allowed for in vivo retinal imaging (~600–800 μW at 800 nm). As a consequence of the slow scanning/measurement

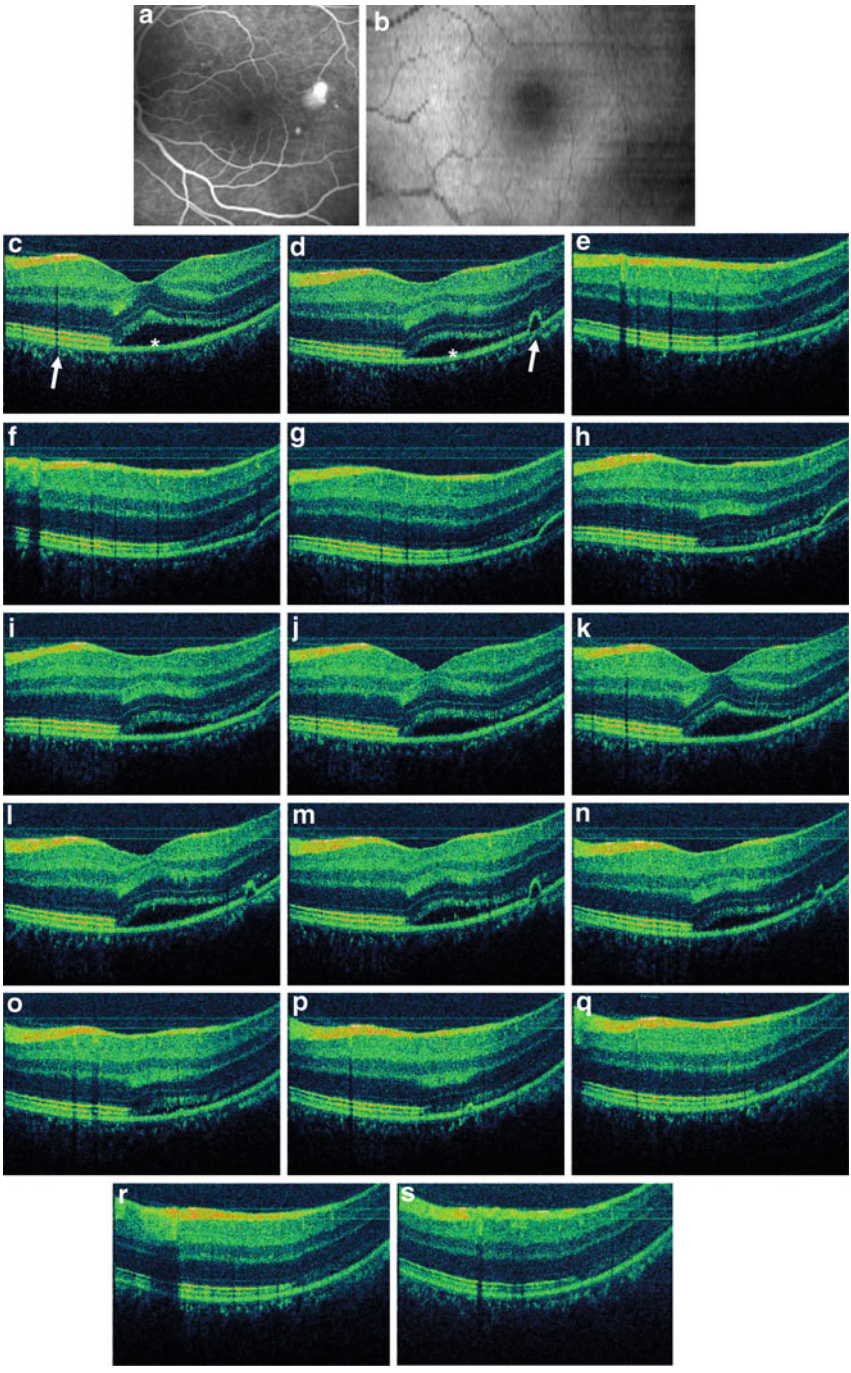

Fig. 56.5 (continued)

time, motion artifacts had to be corrected using post-processing algorithms, and only a limited number of A-scans per B-scan image can be obtained. State-of-the-art, time domain-based OCT systems have been developed to provide high scanning speeds of up to 8 kHz, i.e., 8,000 A -scans per second [57]; however the lower system sensitivity at the faster scanning speeds has prevented their use for retinal imaging. *En face* OCT [58–64] achieves very high imaging speeds by acquiring an *en face* retinal image at a specified depth. These *en face* imaging techniques are described in detail in other chapters.

A powerful alternative to time domain OCT for high-speed imaging is Fourier domain detection techniques where the entire depth-resolved tissue reflectance (A-scan) is obtained simultaneously, thereby removing the need for depth scanning [65–68]. This technique has been referred to in the literature as Fourier domain OCT (FD OCT), spectral domain OCT (SD OCT), swept source OCT (SS OCT), or optical frequency domain imaging (OFDI). This improvement is accomplished either by dispersing the interferometric information in space using a spectrometer setup ("spectral/Fourier domain OCT") or by encoding information in time by tuning a monochromatic light source in combination with a single photodetector ("swept source/Fourier domain OCT" or "optical frequency domain imaging").

The acquisition speed for both approaches – using a spectrometer as a detector or a tunable light source – is mainly limited by the readout rate of the camera which detects the spectrum or by the tuning speed of the light source, respectively. Since the scanning range and electronic detection bandwidth are decoupled, both approaches offer substantial improvements in sensitivity and a dramatic increase in the line rate (A-scan rate) without reducing the sensitivity performance compared with time domain OCT. Although the basic principle of spectral/Fourier domain OCT has been known since 1995 [65], lack of CCD technology and recognition of the sensitivity advantage delayed the experimental and clinical evaluation of this technique for almost a decade. Three groups working independently demonstrated the powerful advantage of this technique for improving data acquisition speed and sensitivity [69–71]. Spectral/Fourier domain OCT using a spectrometer for detection has been shown to enable high-speed [72–74], ultrahigh-resolution [75–77], as well as functional imaging [78, 79].

Despite the sensitivity and speed advantages, OCT using spectral/Fourier domain detection has limitations which are important to note. There is a significant loss of sensitivity and dynamic range as a function of depth, as shown in the tomograms of Fig. 56.12a–c. This effect occurs because of limitations

Fig. 56.5 Retinal pigment epithelium appearance in in vivo UHR OCT. Representative UHR OCT tomograms of a patient with central serous chorioretinopathy. Fluorescence angiogram (**a**) and OCT fundus view (**b**) generated from the UHR OCT A-scans are depicted. UHR OCT visualizes serous retinal detachment (cf. *asterisk* **c**, **d**), focal pigment epithelium detachments (cf. *white arrow* **d**), and "triple band appearance" (cf. *white arrow* **c**) of the photoreceptor/RPE/choriocapillaris/choroid interface. Selection of 15 B-scans from 60 that were raster scanned across a 3 × 3 × 1 mm volume (**e**–**s**)

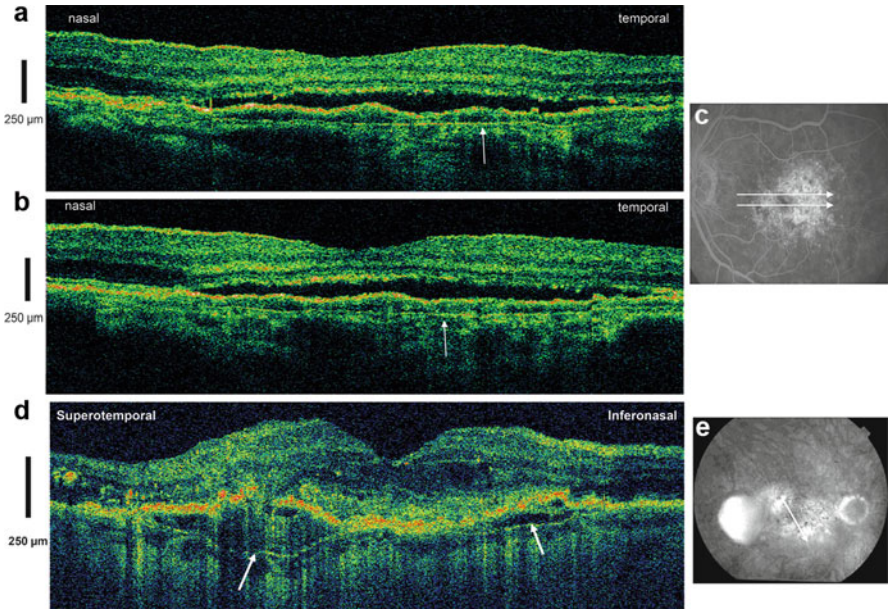

Fig. 56.6 Bruch's membrane appearance in in vivo UHR OCT. Representative UHR OCT tomograms of a patient with age-related macular degeneration (**a**, **b**) and pigment epithelium detachment (**d**) with corresponding fluorescent angiography (**c**) and fundus photo indicating the location of the OCT scans (**c** and **e**, *white arrows*). UHR OCT images (**a**, **b**, **d**) more clearly show a thin backscattering layer (*yellow arrows*) below the RPE layer that is suggestive of Bruch's membrane

in the spectrometer resolution and CCD pixel crosstalk as well as imperfect rescaling and post-processing of the interference signal. By employing new system calibration and signal post-processing techniques using a filter bank approach, this problem can be significantly reduced (cf. Fig. 56.12d–f). Finally, spectral/Fourier detection cannot distinguish echoes from positive and negative delays. This results in artifacts, such as those shown in Fig. 56.12g–k. Overlapping "mirror" images are produced if the tissue moves out of the measurement range. This problem can be solved by using more complex detection methods, which sacrifice scanning speed and/or sensitivity, but effectively double the depth measurement range [80–83].

The ability to achieve significantly higher scanning speeds while maintaining sensitivity is especially advantageous for ophthalmic OCT imaging, due to significant eye motions and the limited amount of power which is applicable according to laser safety standards. Figure 56.13 depicts a normal human optic disk measured by a third-generation, standard-resolution commercial OCT system (StratusOCT, ~10 µm axial resolution, 400 A-scans/s; cf. Fig. 56.13a), a UHR OCT laboratory

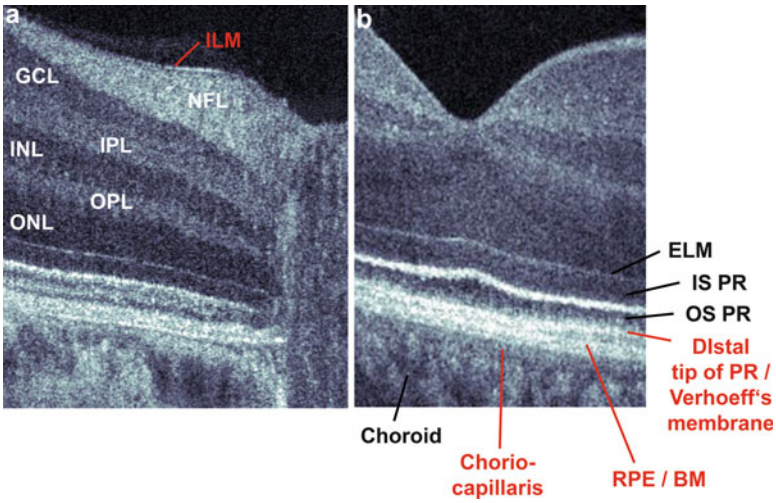

Fig. 56.7 Current state-of-the-art interpretation of intraretinal layers in OCT. High-definition UHR OCT of the optic disk (**a**) and foveal (**b**) region of a normal subject. Labeling of intraretinal layers that were confirmed by numerous previous studies is labeled *white* or *black*. *Red*-labeled layers indicate that interpretation needs additional studies to confirm. Nerve fiber layer (*NFL*), inner (*IPL*) and outer plexiform (*OPL*) layer, ganglion cell layer (*GCL*), inner (*INL*) and outer nuclear (*ONL*) layer, external limiting membrane (*ELM*), inner (*IS PR*) and outer photoreceptor segment (*OS PR*), choroid, internal limiting membrane (*ILM*), distal tips of the photoreceptors sometimes also referred to as Verhoeff's membrane, retinal pigment epithelium including Bruch's membrane (RPE/BM) and choriocapillaris

prototype using time domain detection (~3 μm axial resolution, ~150 A-scans/s; cf. Fig. 56.13b), and a high-speed UHR OCT laboratory prototype using spectral/Fourier domain detection (~3 μm axial resolution, ~25,000 A-scans/s; cf. Fig. 56.13c) [84]. Spectral/Fourier domain detection enables acquisition speeds equivalent to 25 million voxels (three-dimensional volume elements)/s, which is >50 times faster than standard-resolution OCT and >100 times faster than UHR OCT with time domain detection. The significantly higher acquisition speed not only reduces eye motion artifacts in B-scans (thereby preserving the "natural" contour of the posterior segment), but it also enables better delineation of the intraretinal layers because of the higher axial resolution, smaller speckle size, and increase in the number of transverse pixels (A-scans). Higher transverse sampling means that high-definition OCT images can be acquired. High-definition images have more transverse pixels (A-scans) across the same transverse B-scan range. This should not be confused with increased transverse resolution of the OCT image itself. Figures 56.14 and 56.15 depict examples of patients with macular holes comparing high-definition OCT images (cf. Figs. 56.14c and 56.15c) with a 10 mm length in the central foveal, sampled with 10,000 A-scans in 0.6 s [84] with

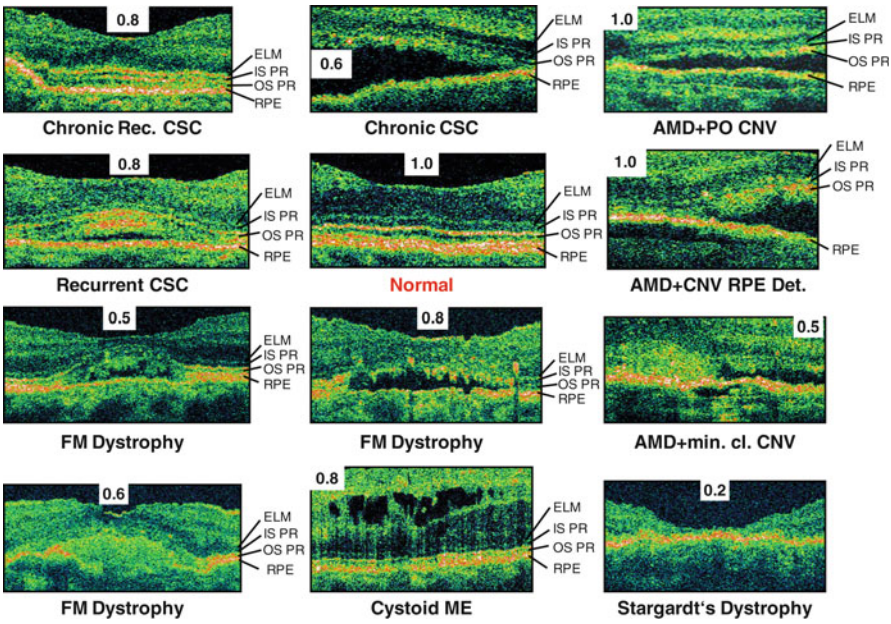

Fig. 56.8 Improved visualization of photoreceptor layer impairment in retinal pathologies using UHR OCT. UHR OCT of the central foveal region focusing on the external limiting membrane (*ELM*), inner (*IS PR*) and outer (*OS PR*) segment of the photoreceptor layer, and retinal pigment epithelium (*RPE*) region in a normal subject (labeled *red*) and 11 patients with different retinal pathologies. a third-generation, standard-resolution commercial OCT system (StratusOCT, cf. Figs. 56.14b and 56.15b) sampled with 512 A-scans in 1.2 s. In Fig. 56.14c, cystic structures associated with the macular hole can be clearly visualized in the inner and outer nuclear layers. The intraretinal layers appear to be normal and external to the hole. By following the IS–OS junction from the parafoveal region to the macular hole, the image shows that the photoreceptor outer segment has lifted away from the normal anatomical position against the RPE, but stays intact and connected to the rest of the retina. Figure 56.15c depicts an example of epiretinal membrane pseudo-hole. Although this appears to be a cyst from the central scan, 3D UHR OCT data confirms that it is a pseudo-hole. The posterior hyaloid is visible and partially detached from the macula. The epiretinal membrane can be seen as well. In general, these membranes can be tracked and visualized in 3D UHR OCT data. Despite big changes of the inner layers, the photoreceptors have not changed much; hence the visual acuity is 20/25. Figure 56.16 shows a high-definition UHR OCT of a patient with macula hole, pre- (cf. Fig. 56.16a) and postoperatively (cf. Fig. 56.16b). Detailed intraretinal morphology can be visualized, especially in the photoreceptor area.

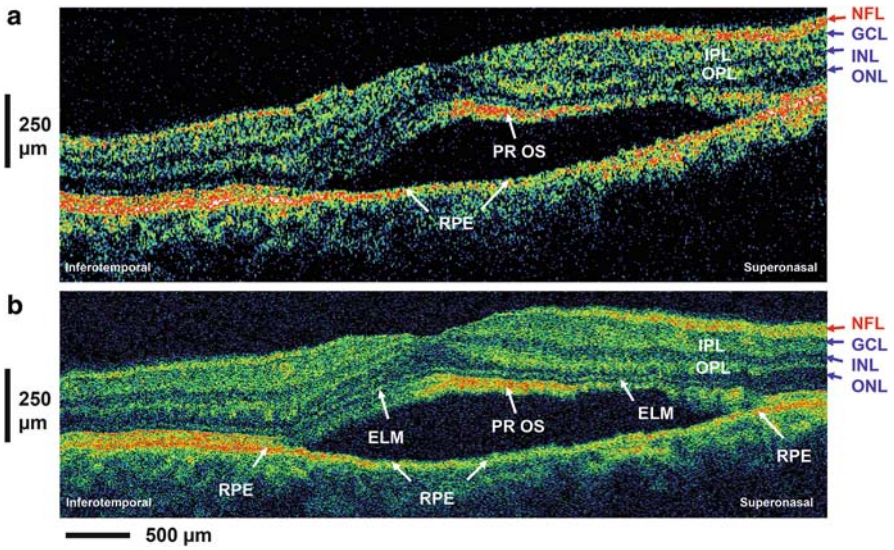

Fig. 56.9 Improved interpretation of commercial OCT using UHR OCT. Standard-resolution OCT (**a**) and ultrahigh-resolution OCT (**b**) image of a patient with central serous chorioretinopathy. Nerve fiber layer (*NFL*), inner (*IPL*) and outer plexiform (*OPL*) layer, ganglion cell layer (*GCL*), inner (*INL*) and outer nuclear (*ONL*) layer, external limiting membrane (*ELM*), outer photoreceptor segment (*PR OS*), retinal pigment epithelium (*RPE*)

Perhaps, the most striking advance associated with the high acquisition speed of OCT with Fourier domain detection is that it enables in vivo three-dimensional, ultrahigh-resolution OCT (3D-OCT). Fourier domain detection techniques enable 50–100 UHR OCT B-scans to be acquired during the time needed to acquire a single UHR OCT B-scan using time domain detection. Hence, a dense raster scan, consisting of multiple, closely spaced planes (B-scans), can be performed to cover a volume of the retina (cf. Fig. 56.17a, b). In analogy to scanning laser ophthalmoscopy measurements, 3D-OCT raster scans a retinal area, but it acquires full morphological information as a function of depth in the region of interest, without the need to scan the depth of focal plane. This measures a three-dimensional volumetric data set similar to that acquired with computed tomography (CT) or magnetic resonance (MR) imaging, but with microscopic resolution. It is possible to generate "fly-throughs" of the B-scans, i.e., a movie (time sequence) of adjacent B-scans using post-processing (cf. Fig. 56.17b). The 3D-OCT data set can also be used to generate tomograms with arbitrary position and orientation, according to the necessary diagnostic needs, such as in ultrahigh-resolution scanning laser ophthalmoscopy (SLO) in *en face* (C-mode) tomograms (cf. Fig. 56.16c). Another clinically important feature of 3D-OCT is that a virtual fundus image, i.e., an OCT fundus image similar to one obtained by standard fundus photography, can be directly generated from 3D-OCT data (cf. Fig. 56.17d). This OCT fundus image is generated by summing the 3D-OCT data set along the axial direction, thus

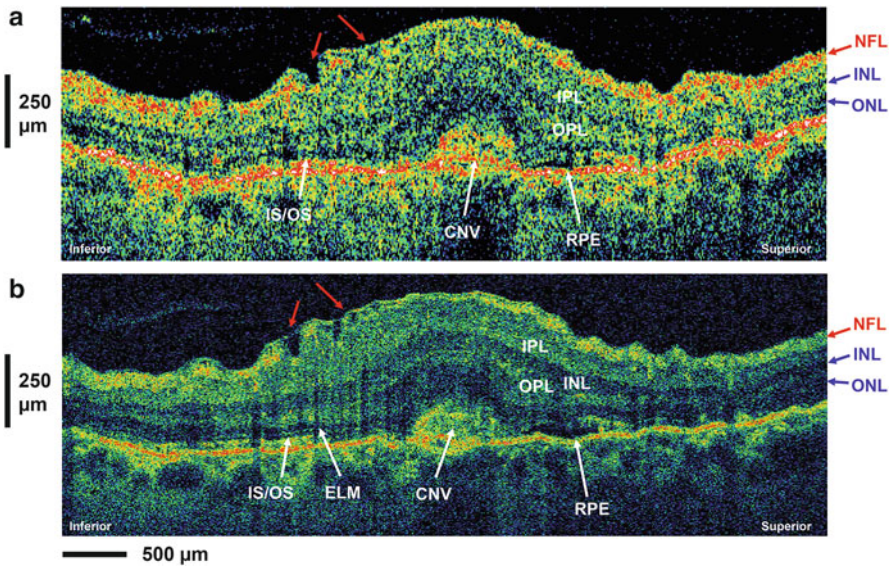

Fig. 56.10 Improved interpretation of standard-resolution commercial OCT using UHR OCT. Standard-resolution OCT (**a**) and ultrahigh-resolution OCT (**b**) image of a patient with choroidal neovascularization (*CNV*). Small irregularities in the NFL and ganglion cell layer with evidence of epiretinal membrane formation can be observed in both images (*red arrows*). Nerve fiber layer (*NFL*), inner (*IPL*) and outer plexiform (*OPL*) layer, inner (*INL*) and outer nuclear (*ONL*) layer, external limiting membrane (*ELM*), junction inner and outer photoreceptor segment (*IS–OS*), retinal pigment epithelium (*RPE*), choroidal neovascularization (*CNV*)

resulting in a pixel brightness value for each axial scan position. The OCT fundus image can be used to precisely and reproducibly register individual OCT tomograms with respect to fundus features.

56.4 Three-Dimensional, Clinical Ultrahigh-Resolution OCT

The first clinical investigations of ultrahigh-resolution 3D-OCT using spectral/Fourier domain detection for imaging retinal pathologies were conducted in several pilot studies [85, 86]. Figure 56.18 shows ultrahigh-resolution 3D-OCT in the foveal region of a normal subject. (Note that the axial dimension is enlarged by a factor of two when compared with the transverse dimensions in order to enable better visualization of the retina.) Figure 56.18a–h show three-dimensional (3D) renderings (software developed in collaboration with C. Glittenberg and S. Binder, Vienna, Austria) of the macular region from different virtual perspectives (cf. Fig. 56.18a–h) depicting the topography of the foveal depression. Three-dimensional rendering enables unprecedented flexibility in viewing, thereby allowing visualization of the retina from any direction, including from the posterior surface (cf. Fig. 56.18e). Figure 56.19 depicts high-definition (A, B) and

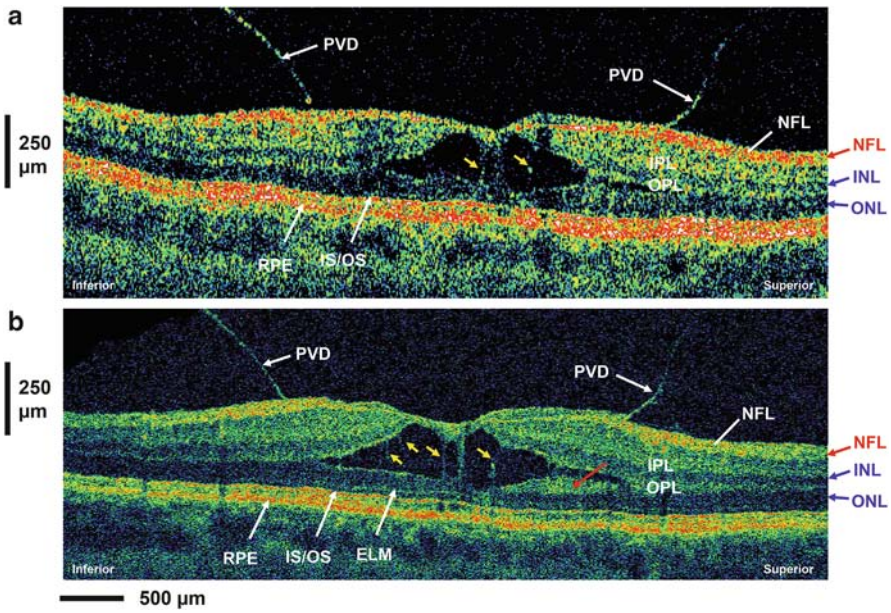

Fig. 56.11 Improved interpretation of standard-resolution commercial OCT using UHR OCT. Standard-resolution OCT (**a**) and ultrahigh-resolution OCT (**b**) image of a patient with vitreomacular traction. Posterior vitreous detachment (*PVD*) can be clearly visualized in both images. Distended structures (*yellow arrows*) spanning the separation in the sensory retina are suggestive of Müller cells. A highly backscattering layer (*red arrow*) adjacent to the ONL might be a portion of the OPL. Nerve fiber layer (*NFL*), inner (*IPL*) and outer plexiform (*OPL*) layer, ganglion cell layer (*GCL*), inner (*INL*) and outer (*ONL*) nuclear layer, external limiting membrane (*ELM*), junction inner and outer photoreceptor segment (*IS–OS*), retinal pigment epithelium (*RPE*)

three-dimensional rendering (C) of a patient with wet, age-related macular degeneration, which is indicated by RPE elevation and a choroidal neovascular membrane (CNV) underneath the RPE. There is fluid between the RPE and elevated photoreceptors. Note the jagged appearance of the photoreceptors where they are elevated. This may be due to photoreceptor disruption or lack of phagocytosis by the RPE, which can cause an elongation of the outer segments. The fluid in the retina looks more highly scattering than the vitreous. In addition, the fluid is more turbid than optically clear serous fluid. This may be due to proteinaceous material or deposits in this region. Figure 56.20 demonstrates 3D UHR OCT in the foveal region of a patient with RPE atrophy. (Note that the axial dimension is enlarged twofold, as compared to the other two dimensions, for better visualization.) The three-dimensional representation of the macular region is presented at different angled views (cf. Fig. 56.20a), thus depicting the pathologically change in the topography of the foveal depression and enabling unprecedented views in which the retina can be observed from any direction, including from below (cf. Fig. 56.20b). Figure 56.19e–h present virtual biopsy/"surgery" using 3D

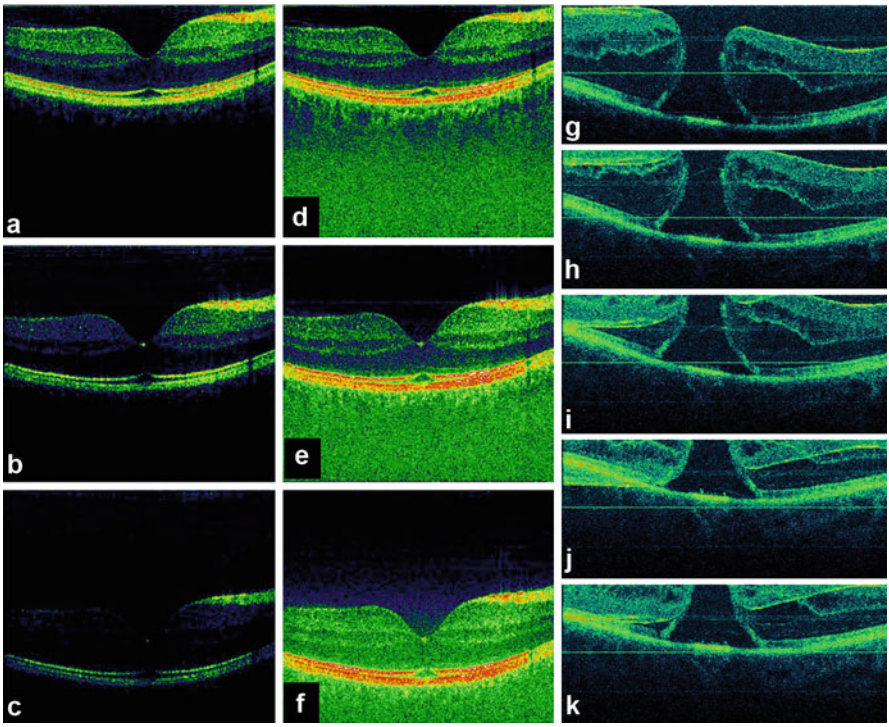

Fig. 56.12 Fundamental problems of three-dimensional UHR OCT (3D-OCT) based on spectral/Fourier domain detection. Depth-dependent sensitivity and dynamic range loss (**a**–**c**). System calibration and signal post-processing compensation for (**d**–**f**); artifacts caused by motion of the tissue/subject out of the measurement range (**g**–**k**). Fourier domain detection cannot distinguish between positive and negative echo delays, and as a consequence, "mirror" artifacts (**h**–**k**) are generated

UHR OCT in combination with 3D data rendering, which allows the user to excise and remove any given layer or part of the retinal volume in order to visualize intraretinal morphology. An important advantage of this method is that it is reversible, since the virtual retina can be reconstructed. Scanning a retinal volume with nearly isotropic (reasonably small equidistant) sampling intervals also avoids the need to decide on the orientation of any line scans that would be required with the time domain OCT. Figure 56.21 shows 3D UHR OCT of both eyes of a patient with a macular hole. The patient's right eye (cf. Fig. 56.21a) shows clear tomographic (cf. Fig. 56.21b) and topographic (cf. Fig. 56.21c) impairments due to the macular hole. The left eye (Fig. 56.21d) was diagnosed as normal with standard diagnostic techniques. By scanning the entire central foveal volume, 3D UHR OCT reduces the risk that retinal features indicating subtle tomographic (cf. Fig. 56.21e) and topographic (cf. Fig. 56.21f) photoreceptor impairment will be missed. Figure 56.22 depicts "virtual biopsy" or "virtual surgery" using ultrahigh-resolution 3D-OCT with 3D data rendering of a patient with macular hole. This virtual biopsy

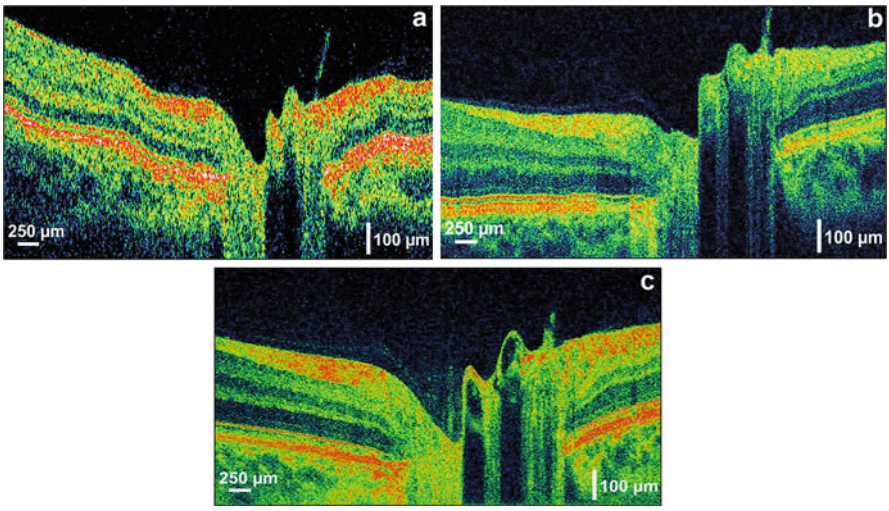

Fig. 56.13 Comparison of ophthalmic OCT technologies. The same human normal optic disk is measured by a third-generation standard-resolution commercial OCT system (**a**) (StratusOCT, ~10 µm axial resolution, 512 A-scans acquired in 1.3 s), UHR OCT performed with a time domain-based laboratory prototype (**b**) ~(3 µm axial resolution, 600 A-scans acquired in 4 s), and UHR OCT performed with spectral/Fourier domain detection (**c**) (~3 µm axial resolution, 2,048 A-scans acquired in 0.08 s). High speed enables motion artifact-free B-scans and significantly better delineation of the stratified appearance of the intraretinal layers

feature allows the investigator to virtually excise and remove any given layer or part of the retinal volume (cf. Fig. 56.22b–j) in order to visualize intraretinal morphology, with the advantage that it is a reversible (cf. Fig. 56.22k–o) procedure.

56.5 Ultrahigh-Resolution OCT in Animal Models

The improved visualization of intraretinal layers provided by ultrahigh-resolution OCT also promises to have significant impact in studies using animal models of retinal pathologies. Animal models, particularly the rodent and monkey, play an important role in studies of retinal diseases, such as age-related macular degeneration, diabetic retinopathy, glaucoma, and myopia [87, 88]. Because OCT is a noninvasive optical imaging modality, it enables longitudinal studies with repeated measurements on the same animal in order to track disease progression. In contrast with the standard techniques of euthanasia and histology, OCT imaging promises to significantly reduce the number of animals required for studies, while providing more complete information on the effects of biological variability between animals. This can enhance the efficiency and reduce the cost of drug discovery and preclinical development.

The earliest studies of ultrahigh-resolution OCT imaging in mouse retinas were performed with an UHR OCT system interfaced to an OCT microscope. Because the

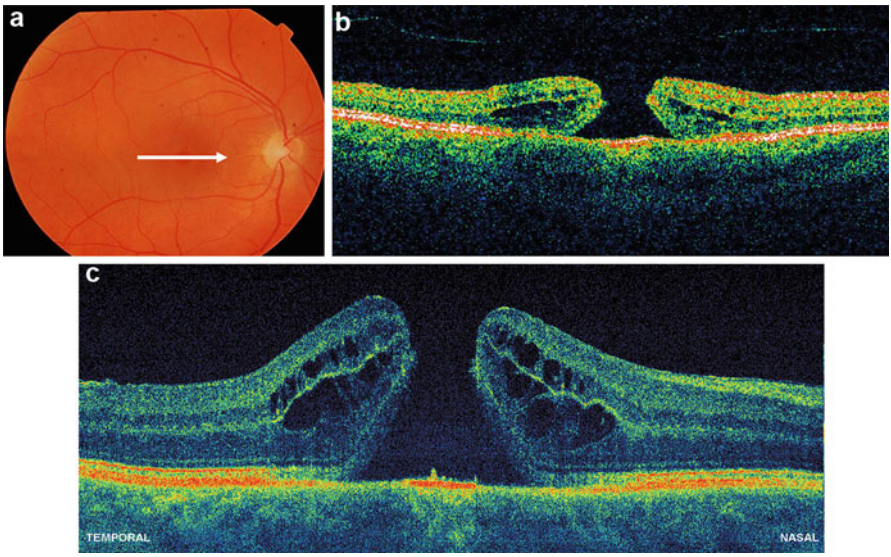

Fig. 56.14 High-definition UHR OCT using high-speed UHR OCT. Fundus photo indicating the location of the OCT scans (**a**). The same patient with macular hole is measured by a standard-resolution commercial OCT system (**b**) (StratusOCT, ~10 μm axial resolution, 512 A-scans acquired in 1.3 s) and high-definition UHR OCT performed with spectral/Fourier domain detection (**c**) (~3 μm axial resolution, 10,000 A-scans acquired in 0.6 s). Significantly improved visualization of intraretinal layers is accomplished due to increased axial OCT resolution and higher transverse sampling density, due to significantly improved data acquisition speed

mouse and rat retinas are thinner than the human retina, ultrahigh resolution is required to visualize intraretinal morphology. The UHR OCT images shown have ~1.5 μm axial image resolutions and were acquired using a broad bandwidth, femtosecond Ti: Sapphire laser light source and time domain detection. Despite the small size of the mouse retina, UHR OCT was able to delineate all major intraretinal layers. Figure 56.23a, b demonstrate UHR OCT imaging of the mouse retinal in comparison to histology. Despite the small dimensions of the mouse retinal, all major retinal layers can be visualized. Figure 56.23c, d depict UHR OCT in a mouse model of retinal degeneration, depicting a comparison of an Rd +/+wild-type mouse (cf. Fig. 56.23c) with an Rd −/− knockout mouse (5 months old; cf. Fig. 56.23d). (This study was performed in collaboration with Dr. Janice Lem from Tufts University School of Medicine and Joel Schuman from University of Pittsburgh Medical Center.) The UHR OCT image shows complete loss of the outer nuclear and outer plexiform layers in the retina of the Rd −/− knockout mouse, which is consistent with the expected pattern of structural degeneration. OCT has the powerful advantage that measurements can be performed over a period of time to longitudinally study disease progression. Figure 56.24 depicts the monitoring of glaucoma progression using in vivo UHR OCT imaging of the optic nerve head in a nonhuman primate glaucoma model (*cynomolgus monkey*). This study was conducted in collaboration with Novartis Institutes for

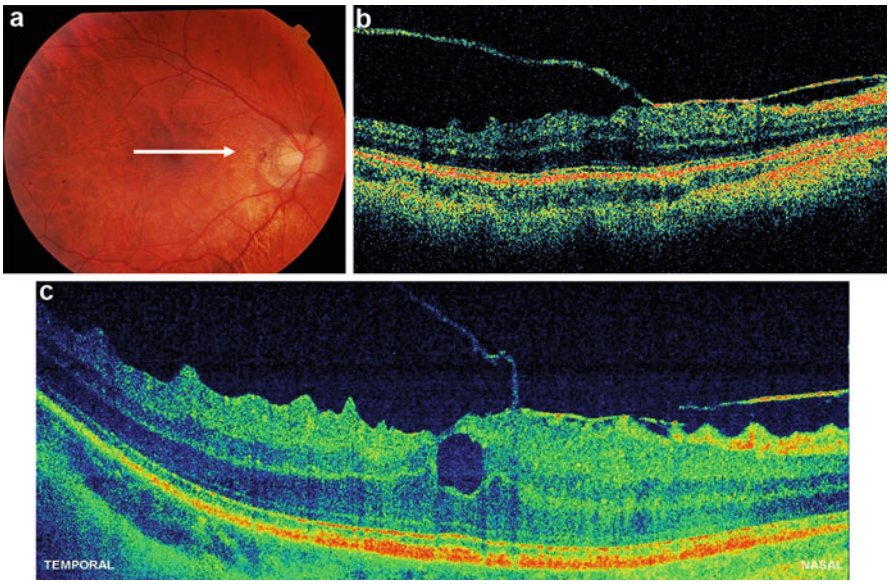

Fig. 56.15 High-definition UHR OCT using high-speed UHR OCT. Fundus photo indicating the location of the OCT scans (**a**). The same patient with a macular pseudo-hole is measured by a standard-resolution commercial OCT system (**b**) (StratusOCT, ~10 μm axial resolution, 512 A-scans acquired in 1.3 s) and high-definition UHR OCT performed with spectral/Fourier domain detection (**c**) (~3 μm axial resolution, 10.000 A-scans acquired in 0.6 s). Significantly improved visualization of intraretinal layers and the epiretinal membrane is accomplished by high-definition UHR OCT

Biomedical Research by E. Polska and A. Doelemeyer. Horizontal, cross-sectional images are depicted at baseline (cf. Fig. 56.24a), 20 days (cf. Fig. 56.24b), 34 days (cf. Fig. 56.24c), 48 days (cf. Fig. 56.24d), and 179 days (cf. Fig. 56.24e) after induction of unilateral ocular hypertension at approximately the same retinal location. The retinal nerve fiber layer in the circumpapillary region is clearly visualized, despite its atrophy due to increased ocular pressure. Furthermore, the cross section of the lamina cribrosa is clearly visualized at baseline (cf. Fig. 56.24a), which might also be used to detect early glaucomatous changes. In the advanced stages, the lamina cribrosa is severely thinned or even absent (cf. Fig. 56.24b–e), and vessels appear prominent, which is caused by significant cupping of the optic nerve head due to increased intraocular pressure (cf. Fig. 56.24f). UHR OCT can visualize the retinal nerve fiber layer (especially its posterior surface), quantify circumpapillary thickness distribution, and provide topographic information on the optical nerve head. Hence, UHR OCT promises to be a powerful technique to track the early stages of this disease in animal models.

With the introduction of spectral/Fourier domain detection, ultrahigh resolution with improved image quality and three-dimensional imaging became available for studies of retinal disease in animal models. Although the instrumentation

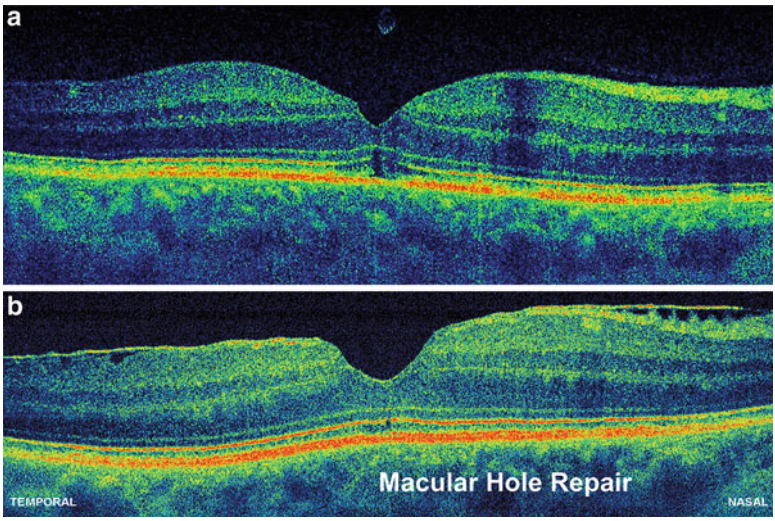

Fig. 56.16 High-definition UHR OCT using high-speed UHR OCT. High-definition UHR OCT performed with spectral/Fourier domain detection (**c**) (~3 μm axial resolution, 10.000 A-scans acquired in 0.6 s) in a patient with macular hole, pre- (**a**) and postoperatively (**b**). Detailed intraretinal morphology can be visualized, especially in the photoreceptor area

requirements are quite different from clinical instruments, many examination protocols and image display techniques that are applicable for clinical imaging in humans can also be applied for small animal imaging. Ultrahigh-resolution 3D-OCT imaging in a normal C57BL6 mouse (left A–E) and Long–Evans rat (right A–E) is depicted in Fig. 56.25. A high-speed (24,000 A-scans/s) OCT system with 2.8 μm axial resolution using a broad bandwidth, multiplexed superluminescent light diode (SLD) light source centered at 900 nm was used for this study [89]. A dense raster scan protocol acquiring 256 images of 512 axial scans each covering a 2.6 × 2.6 mm^2 region with a 10 × 5 μm^2 pixel spacing was used. An OCT fundus image can be generated from the 3D-OCT data (cf. Fig. 56.25a, left and right) and the UHR OCT B-scans precisely registered to fundus features (cf. Fig. 56.25b–d, left and right). All major intraretinal layers could be visualized (cf. Fig. 56.25e, left and right). Figure 56.26 shows a comparison of high-definition OCT images between a normal, young adult Sprague–Dawley (albino) rat and a normal, young adult Long–Evans (pigmented) rat. The inner retinal layers appear similar in both strains. In the Long–Evans rat, the photoreceptors comprise two highly reflective and well-defined bands proximal to the RPE. In the Sprague–Dawley rat, the photoreceptors comprise two highly reflective bands separated by a region of moderate reflectivity. There is increased penetration of the OCT signal to the sclera in the Sprague–Dawley rat, which is consistent with the lack of absorption from pigment in this albino strain.

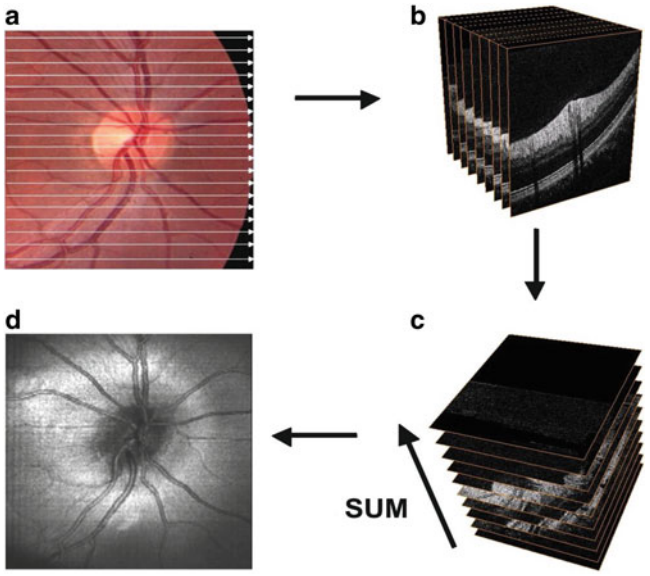

Fig. 56.17 Scanning and post-processing protocols in three-dimensional ultrahigh-resolution OCT. Several planes (B-scans) can be scanned of a whole retinal volume (**a**), resulting in a stack of adjacent B-scans (**b**). The 3D-OCT data set can be summed in the axial direction (**c**) to generate an en face image similar to scanning laser ophthalmoscope in *en face* (C-mode) tomograms (**d**). UHR OCT tomograms can be precisely and reproducibly registered to fundus features. The acquired data of the investigated volume can arbitrarily be cut according to the necessary diagnostic needs, e.g., an ultrahigh-resolution scanning laser ophthalmoscope in *en face* (C-mode) tomograms (**c**). OCT fundus image (**d**), i.e., an OCT view of the fundus similar to one obtained by standard fundus photography, which can be reproduced directly from 3D OCT data. This OCT fundus image is generated by summing the A-scan signal along the axial direction, thereby resulting in a brightness pixel value for each axial scan that can be used to register UHR OCT tomograms directly

56.6 Quantitative Analysis Using Three-Dimensional Ultrahigh-Resolution OCT

Another significant advantage of combining ultrahigh-resolution and high data acquisition speed is that it enables objective, quantitative measurements of intraretinal layers. Quantitative measurement, or morphometry, plays a central role in the early diagnosis of diseases such as glaucoma or diabetic retinopathy and enables objective assessment of progression or response to therapy. The improved axial resolution provided by UHR OCT enables clearer delineation of intraretinal layers. High-speed acquisition enables more sampling points (A-scans at different positions on the fundus), thus increasing coverage of the retina and reducing sampling errors. Data sets with higher numbers of transverse pixels also enable better differentiation of intraretinal layers.

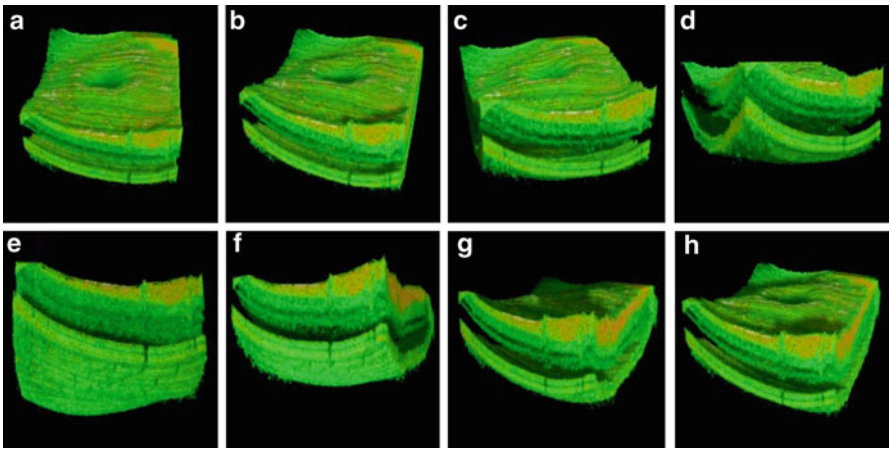

Fig. 56.18 Three-dimensional ultrahigh-resolution OCT of the normal human fovea. Three-dimensional representation (developed in collaboration with C. Glittenberg and S. Binder, Vienna, Austria) of the macular region at different angled views (note that the axial dimension is twofold enlarged compared to the other two dimensions), enabling unprecedented views that allow observation of the retina from any direction, including from below (**e**)

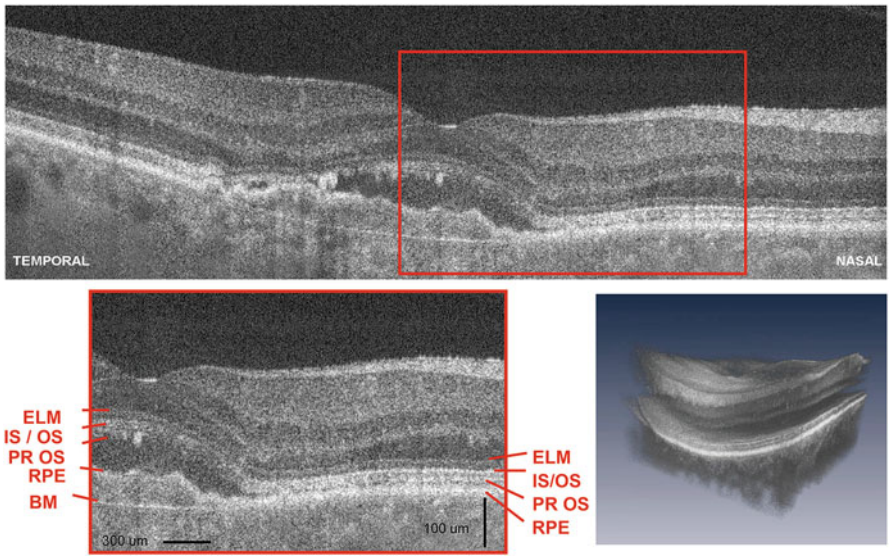

Fig. 56.19 Three-dimensional ultrahigh-resolution OCT of retinal pathologies. High-definition (**a**, **b**) and three-dimensional rendering (**c**) of a patient with wet age-related macular degeneration. Fig. 56.20 Three-dimensional ultrahigh-resolution OCT of retinal pathologies. Three-dimensional UHR OCT enables unprecedented volumetric representation of the macular region of a patient with RPE atrophy at different angled views (**a**) including from below (**b**). Virtual biopsy/"surgery" using 3D UHR OCT (**e**–**h**) allows the user to excise and remove any given layer or part of the retinal volume in order to visualize intraretinal morphology

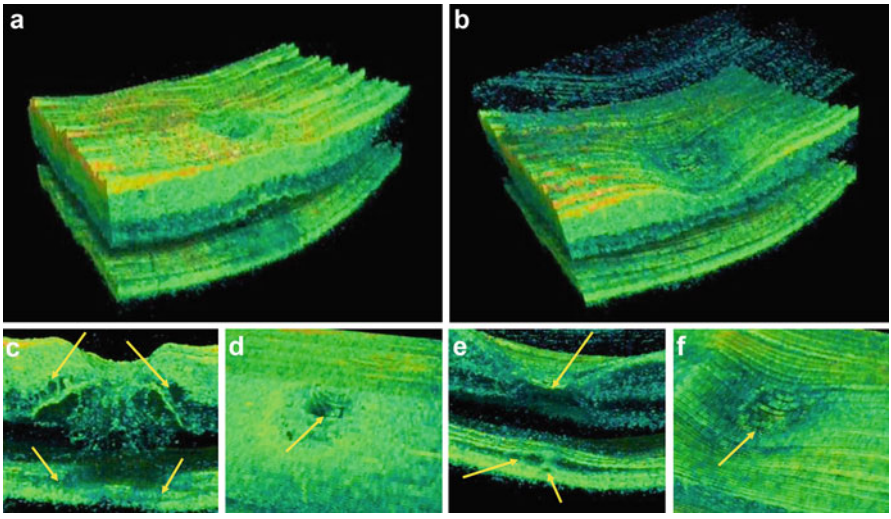

Fig. 56.21 Three-dimensional ultrahigh-resolution OCT of retinal pathologies. Three-dimensional UHR OCT of both eyes of a patient with a macular hole. The patient's right eye (**a**) shows clear tomographic (**b** *arrows* indicate intraretinal cysts (*top arrows*) and photoreceptor impairment (*bottom arrows*)) as well as topographic (**c** *arrow* indicates topographic change of foveal depression)) impairments due to the macular hole. The left eye (**d**) was diagnosed as normal. 3D UHR OCT clearly indicates early, subtle tomographic (**e** *arrows* indicate subtle morphological photoreceptor changes) and topographic (**f**) impairment

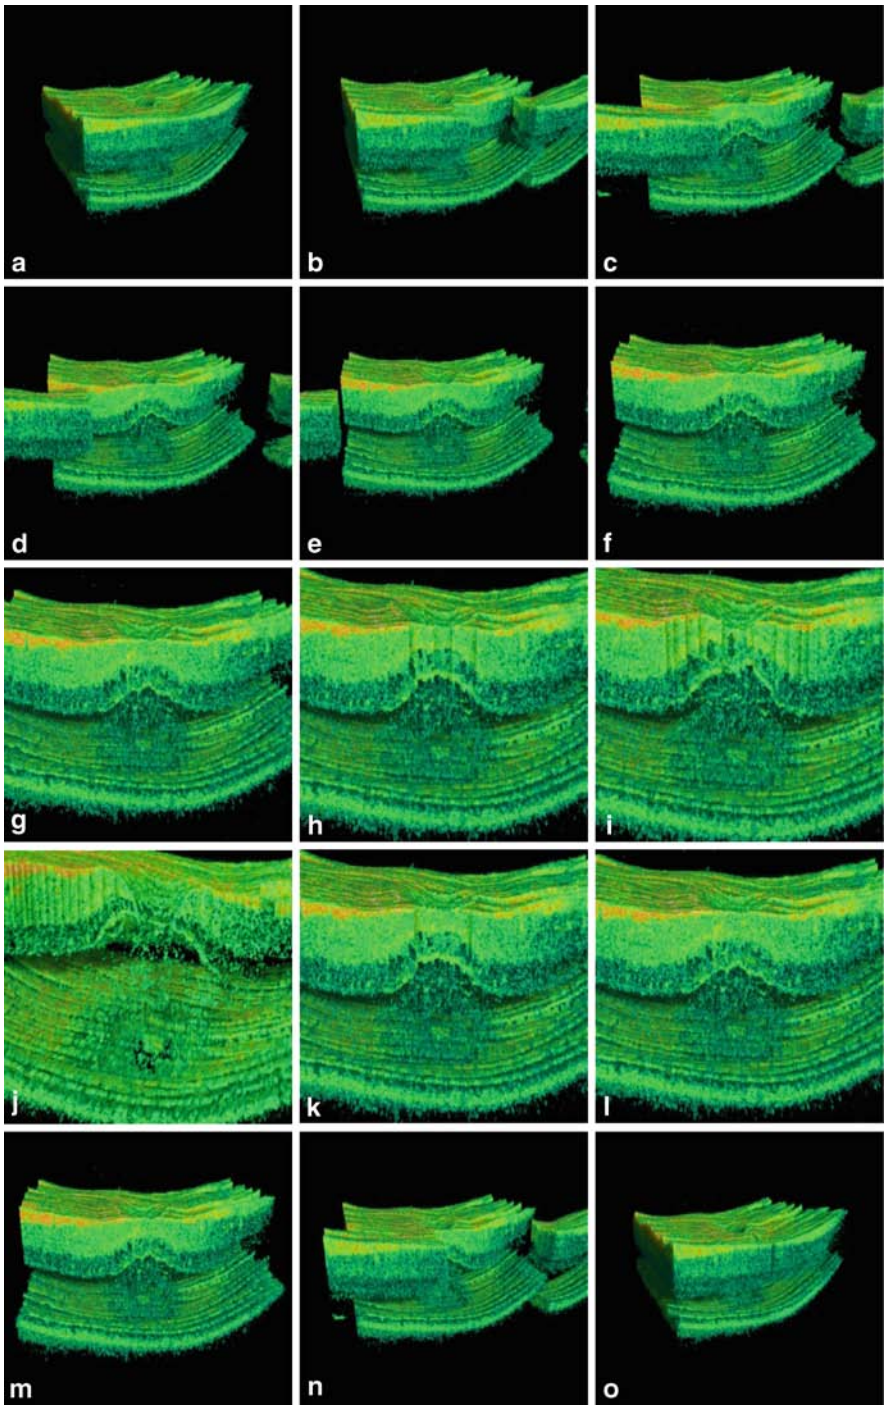

Fig. 56.22 (continued)

Figure 56.27 shows the use of 3D-OCT for the quantitative mapping of intraretinal layer thicknesses in the Long–Evans rat. Figure 56.27a shows an OCT fundus image with a white arrow showing the location of the enlarged cross-sectional image in Fig. 56.27b. Images are segmented, as shown in Fig. 56.27b. Figure 56.27c shows a map of retinal thickness, measured from the vitreoretinal interface to the photoreceptor inner and outer segment (IS–OS) junction, which is overlaid in color on the OCT fundus image. Figure 56.27d shows a map of NFL thickness. Thicknesses were computed by assuming a group refractive index of 1.4. Figure 56.28 shows a rendering of 3D-OCT data from the Long–Evans rat retina. The renderings enhance the NFL striations on the surface of the retina (Fig. 56.28a). Figure 56.28b shows that virtual slices can be created through the 3D data set, thus enabling visualization of 3D-OCT data along arbitrary planes. Figure 56.28c shows a cutaway rendering near the optic nerve head. Renderings can be manipulated in real time to visualize structure.

Three-dimensional UHR OCT can also be used for segmentation and two-dimensional thickness mapping of intraretinal layers from in vivo measurement in human retinas. Figure 56.29a depicts a representative UHR OCT B-scan consisting of 2,048 A-scans from a three-dimensional stack over a $5 \times 5 \times 1\ mm^3$ volume. Segmentation is used to quantify the distance from the junction between the inner and outer photoreceptors to the retinal pigment epithelium, representing the outer segment length of the photoreceptors (cf. Fig. 56.29b); the distance between the external limiting membrane and the retinal pigment epithelium, representing the total photoreceptor length (cf. Fig. 56.29c); and the thickness of the ganglion cell layer and the inner plexiform layer. These quantitative measurements may be important for early glaucoma diagnosis or the diagnosis of age-related macular degeneration (cf. Fig. 56.29d). Figure 56.30 depicts quantitative volumetric analysis of a normal optic disk using three-dimensional UHR OCT. Figure 56.30a illustrates a central, cross-sectional OCT image chosen from the three-dimensional set of 180 horizontal cross sections. Fig. 56.30b shows a three-dimensional (3D) rendering of the entire circumpapillary retinal nerve fiber layer across the entire set of 180 high-speed UHR-OCT images (yellow). Figure 56.30c shows the extracted and rendered nerve fiber layer with clearly visible contour of optic disk and surface profile. Figure 56.30d shows an example of processing the retinal nerve fiber layer, including thickness analysis in arbitrary chosen orthogonal planes. Quantitative volumetric analysis using three-dimensional UHR OCT can also be used to quantitatively monitor therapy. Figure 56.31 demonstrates volumetric analysis of the extent of epiretinal membrane (cf. Fig. 56.31b, d, e, h, j, k, respectively) and the volumetric extent of a macular hole (cf. Fig. 56.31a, c, f, g, i, l, respectively), pre- and postoperatively.

Fig. 56.22 Virtual biopsy or "surgery" of a patient with macular hole using 3D-OCT in combination with data rendering system. This virtual biopsy feature allows the user to excise and remove any given layer or part of the retinal volume (**b–j**) in order to visualize intraretinal morphology inside the tissue with the advantage that it is a reversible (**k–o**) procedure

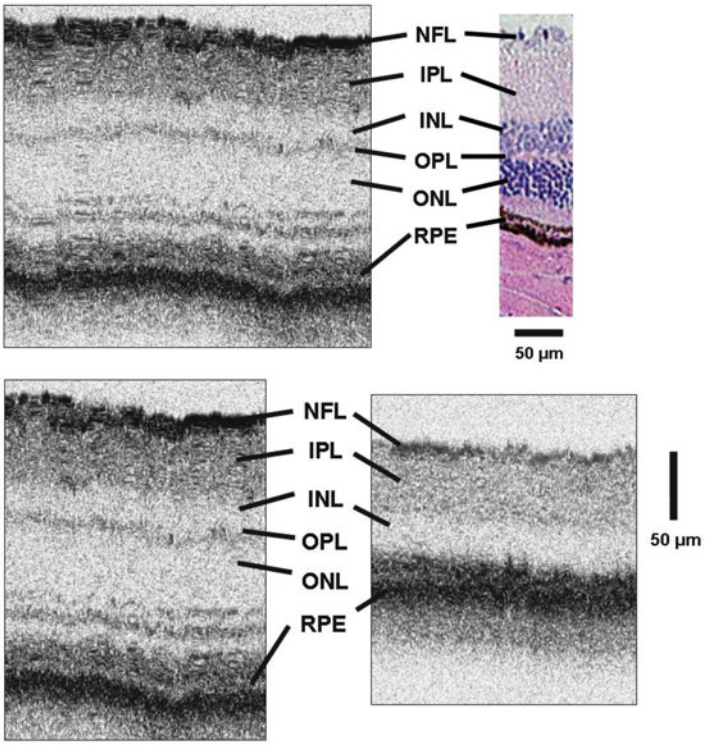

Fig. 56.23 Two-dimensional ultrahigh-resolution OCT in retinal animal models. Comparison of UHR OCT (**a**) with histology (**b**), all major retinal layers can be visualized; UHR OCT in mouse retinal degeneration, an Rd +/+ wild-type mouse (**c**) with an Rd −/− knockout mouse, 5 months old (**d**). UHR OCT is capable of visualizing the complete loss of the outer nuclear and outer plexiform layers in the retina of the Rd −/− knockout mouse (Study was performed in collaboration with S. Bursell, J. Lem, J. Schuman, Boston, USA)

Most attempts to segment OCT images usually build upon layer boundary detection and can yield spurious results, and many approaches have relied upon pre-registration of the tomograms or user input to obtain segmentation [90–92]. Recently automated segmentation algorithms for extracting the layers have been developed based on texture analysis (in collaboration with G. Powell, P. Rosin, D. Marshall, School of Computer Sciences, Cardiff University, UK). Texture analysis tries to identify the individual structure of the layers by their speckle pattern, rather than the boundaries, and might be only one building block of a comprehensive approach. Although speckle holds sub-resolution phase information that should help to identify similar structures, textures in different layers can be very similar, and moreover there are not always distinct boundaries in the speckle patterns between layers. Geometric techniques were also considered, but the nonuniformity of the boundaries between layers makes them difficult to model in a successful and consistent way. To perform effective classification, additional geometric information

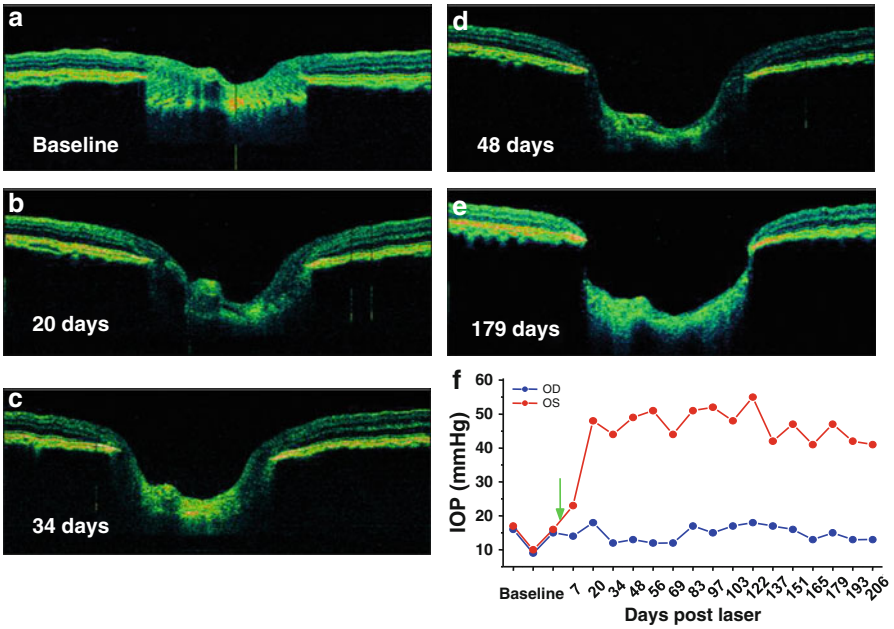

Fig. 56.24 Two-dimensional ultrahigh-resolution OCT in retinal animal models. Monitoring disease progression using in vivo UHR OCT of the optic nerve head in a nonhuman primate glaucoma model, the *cynomolgus monkey*. (This study was conducted in collaboration with Novartis Institutes for Biomedical Research by E. Polska and A. Doelemeyer.) Horizontal OCT images are depicted at baseline (**a**), 20 days (**b**), 34 days (**c**), 48 days (**d**), and 179 days (**e**) after induction of unilateral ocular hypertension. Measured intraocular pressure of test (*red*) and control eye (*blue*, **f**)

must be incorporated, although this is made difficult by the lack of precise and consistent shape of the layer boundaries. Instead, a set of simple local geometric features which have been found to substantially improve the results of using solely texture have been used. In preliminary results, various classifiers were tested and the most suitable classification, in terms of trade-off between accuracy, reliability, and computational efficiency, was to fit Gaussians to the features for each of the layers extracted from the training data. To classify a new (unseen) image, the incoming pixel to this feature space was compared, and through the use of the Mahalanobis distance, the most similar layer for its classification was used.

For the training, 480 images from only three different subjects were used, which were manually segmented by three independent, anatomically skilled operators. This data set was used to build a classifier, as described above. This classifier was then used to automatically segment a 3D volume that consisted of 60 OCT tomograms from a different subject in 2 min on a standard personal computer. Two example cross sections and their corresponding automatic segmentations are shown in Fig. 56.32. Figure 56.32a – (top) depicts a parafoveal cross section, and in Fig. 56.32c (top), a cross section of the fovea centralis is shown. All mayor layers

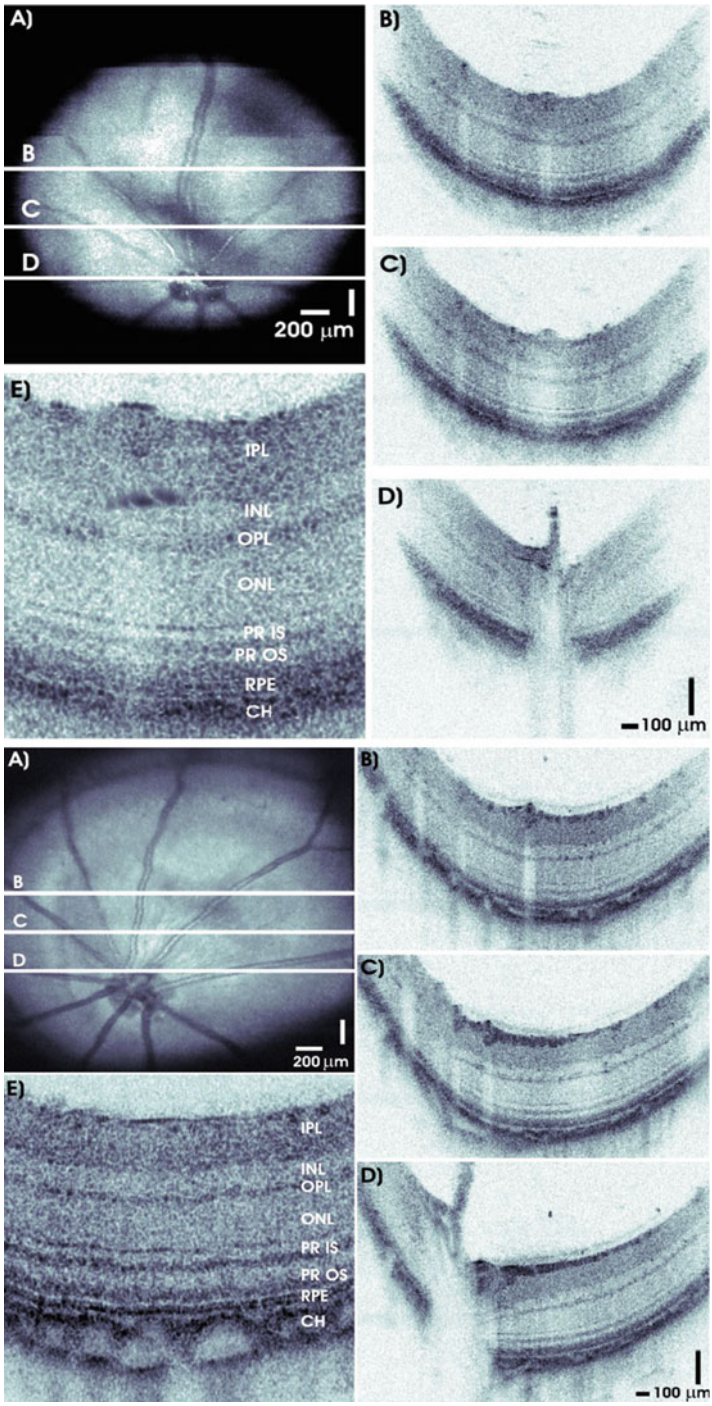

Fig. 56.25 (continued)

are visible and indicated. This includes the nerve fiber layer (NFL), ganglion cell layer and inner plexiform layer (GC/IPL), Henle fiber layer and outer plexiform layer (HF/OPL), outer nuclear layer (ONL), inner segment of photoreceptor layer (IS PR), outer segment of photoreceptor layer (OS PR), and the retinal pigment epithelium (RPE). The segmentation of these layers for the parafoveal tomogram (Fig. 56.32b (top)) and the central foveal tomogram (Fig. 56.32d – (top)) was achieved with reasonable accuracy, taking into account that no manual interaction was required. Thickness maps were then created for each of the eight layers, based on the segmentation results. These thickness maps are shown in Fig. 56.32 (bottom). As expected, GC/IPL (Fig. 56.32b (bottom)) appeared as the thickest layer, followed by NFL (Fig. 56.32c (bottom)) and ONL (Fig. 56.32e (bottom)). The preliminary results show the huge potential of this technique and are likely to improve with further training and fine tuning, as well as by combining standard boundary detection methods.

Assessment of the human retinal nerve fiber layer and retinal thickness at the optical nerve head for novel indicators of glaucoma staging from volumetric images, obtained by high-speed optical coherence tomography, has recently been presented. Three-dimensional UHR OCT at high axial resolution allows for extraction of the full retinal morphology. Analysis of this information helps to deduce pathognomonic parameters that allow for the easy and reliable quantification of disease and therapy progress by comparing true thicknesses in an individual subject. Quantification and localization of the NFL and optic nerve structures have become central to managing patients with glaucoma. There is an urgent need in diagnosis and staging for reliable, objective precursors and markers associated with pathological changes of the ganglion cell layer. Three-dimensional, ultrahigh-resolution optical coherence tomography holds particular promise in this respect, since it enables the volumetric assessment of intraretinal layers, including tomographic data for the retinal nerve fiber layer (RNFL) and optic nerve head (ONH) at the micrometer scale. The resolution advantage, in conjunction with full volumetric sampling, has enabled the development of more informative indices of axonal damage in glaucoma, when compared with the measurements of RNFL thickness and cup-to-disk ratio provided by other devices. In this work, the potential for UHR OCT to enable the combined analysis of tomographic and volumetric data on retinal structure is explored. A novel mapping method was developed, which used the three-dimensional minimal distance (3D-MDM) as the optical correlate of true RNFL thickness around the ONH region, thereby replacing the misleading, projected thickness with its 3D counterpart. Using this information, novel measures

Fig. 56.25 Three-dimensional ultrahigh-resolution OCT in retinal animal models. 3D OCT in a normal C57BL6 mouse (*left*) and a Long–Evans rat (*right*) using a dense raster scan protocol consisting of 256 images of 512 axial scans each, covering a 2.6 mm^2 region resulting in 10 × 5 μm pixel spacing. A fundus image generated from ultrahigh-resolution 3D OCT data (**a**, *left* and *right*) indicates the locations of three selected OCT B-scans (**b**–**d**, *left* and *right*). All major intraretinal layers can be visualized with ultrahigh-resolution OCT (**e**, *left* and *right*)

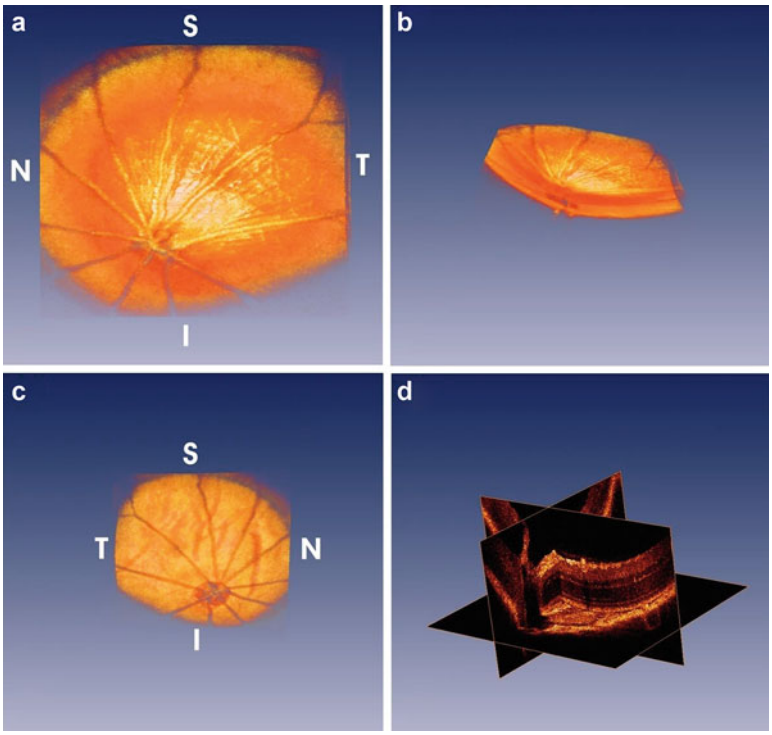

Fig. 56.28 Volumetric rendering using three-dimensional ultrahigh-resolution OCT in retinal animal models: (**a**) A rendering of a normal Long–Evans rat retina. (**b**) It is possible to create virtual slices through 3D-OCT data and view images along arbitrary planes. Cutaway renderings can simultaneously show intraretinal structure and retinal topography (**c**)

of retinal parameters resembling the complex geometrical distortions and features were found in many optic nerve heads. Quantification of three-dimensional surfaces leads to simple, automatically generated parameters to monitor disease progression that can be used to evaluate an individual situation. Preliminary studies found the relation between the cross-sectional areas of the RNFL and the optic nerve to be a useful and sensitive measure of axon loss. For the purposes of this pilot study, data was used from normal subjects and patients with characteristic optic nerve and RNFL changes secondary to glaucoma. Figure 56.33 depicts different mappings of a normal and two different glaucoma stages, based on a volumetric data set obtained by three-dimensional UHR OCT. Figure 56.33a shows fundus images obtained by averaging of the OCT volume across the depth. Figure 56.33b shows the projected and Fig. 56.33c the real thickness of the NFL. Figure 56.33d, e, respectively, depict the region above the optic nerve (black portion) for the full retinal thickness where the projected retinal thickness cannot be defined and give unreliable values that can be extracted. MDMs provide easily interpretable

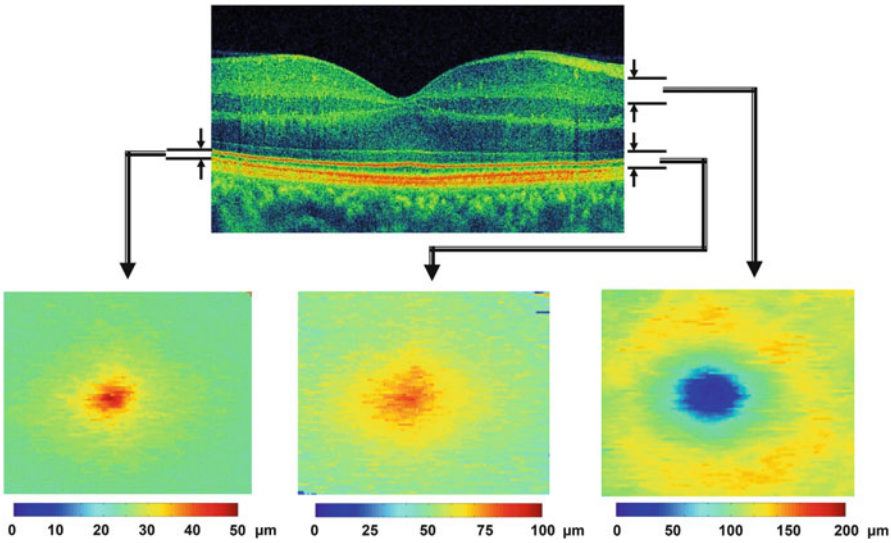

Fig. 56.29 Quantitative mapping of intraretinal layers using three-dimensional UHR OCT in humans: Representative UHR OCT B-scan consisting of 2,048 A-scans from a three-dimensional stack over a $4 \times 4 \times 1$ mm^3 volume (**a**); segmentation of the distance from the junction between the inner and outer photoreceptors to the retinal pigment epithelium, representing the outer segment length of the photoreceptors (**b**); the distance between the external limiting membrane and the retinal pigment epithelium, representing the total photoreceptor length (**c**); and the thickness of the ganglion cell layer and the inner plexiform layer (**d**)

visualization of local retinal thickness and surface roughness. We anticipate that increased imaging speed will allow higher-resolution and isotropic sampling of the ONH and improve the correct estimation of RNFL volumes and areas. The MDM technique appears to be robust and is less sensitive to the confounding effects of ONH tilt when compared to other imaging modalities, e.g., SLO.

56.7 Optophysiology: Depth-Resolved Retinal Physiology

The development of retinal diseases is often accompanied by changes, both in the retinal morphology and physiology. Various imaging modalities, such as fundus photography, ultrasound imaging, and optical coherence tomography (OCT), are commonly used for imaging retinal morphology. Electrophysiological tests, such as electroretinography [93] (ERG), multifocal ERG (mfERG), and electrooculography (EOG), are used for clinical assessment of retinal and pigment epithelial function. These electrophysiological methods allow clinicians to distinguish between diseases of the outer and inner retina and, in the case of multifocal ERG, to map retinal physiology with a modest transverse spatial resolution of $\sim 2^\circ$ ($\sim$600 µm). However, all ERG methods have limited depth selectivity, and currently, there is

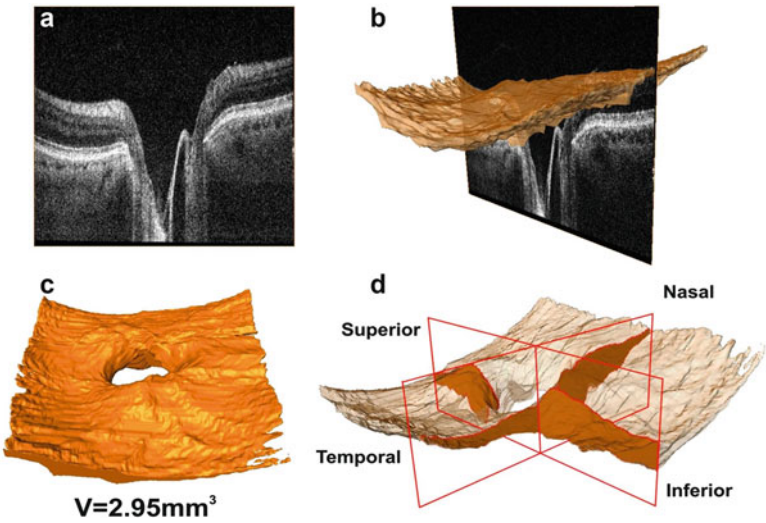

Fig. 56.30 Volumetric analysis of high-speed, ultrahigh-resolution OCT in a normal optic disk. Central, cross-sectional OCT image chosen from the three-dimensional set of 180 horizontal cross sections (**a**); three-dimensional (3D) rendering of the entire circumpapillary retinal nerve fiber layer across the entire set of 180 high-speed UHR OCT images (*yellow*, **b**); extracted and rendered nerve fiber layer with clearly visible contour of optic disk and surface profile (**c**); processing of extracted retinal nerve fiber layer, including thickness analysis in arbitrarily chosen orthogonal planes (**d**)

disagreement about the contributions of various cell populations to the components of mfERG signals. All electrophysiological methods require physical contact between the electrodes and biological tissue, which can result in patient discomfort. In addition, the ERG/EOG techniques are sensitive only to electrical potential changes in the retina and are, therefore, susceptible to any internal or external electrical noise sources.

OCT is sensitive to spatial variations in the optical reflectivity or scattering of tissue associated with local changes in refractive index or structure. Physiological processes that occur on the cellular level, such as membrane depolarization, cell swelling, and altered metabolism, can cause small, but detectable changes in the local optical properties of biological tissue. As an optical technique, OCT is sensitive to any processes that alter the optical reflectivity or scattering. Furthermore, the high sensitivity of OCT ($\sim$100 dB) enables detection of very weak optical signals. Therefore, OCT has great potential for noninvasive probing of tissue physiology.

This first demonstration that UHR OCT can be used for non-contact, high-resolution, spatially resolved probing of the physiological response to light stimulation in the retina was performed in 2006 [94]. To test if UHR OCT was capable of detecting changes in retina reflectivity or scattering triggered by light stimulation, a dark-adapted, living in vitro rabbit retina was exposed to

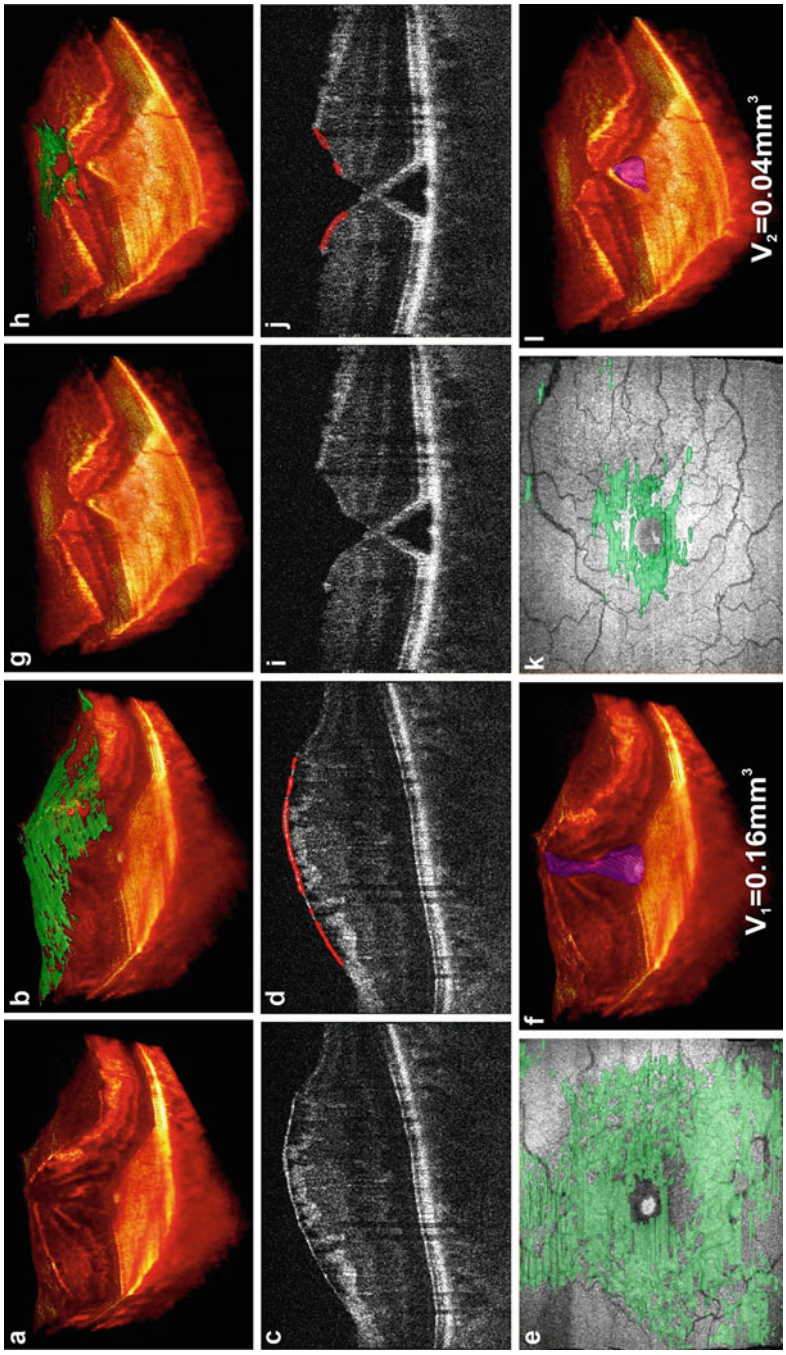

Fig. 56.31 Quantitative volumetric analysis using three-dimensional UHR OCT for quantitative therapy monitoring. a single flash of white light, and UHR OCT data was acquired synchronously with ERG recordings. The OCT light source was a state-of-the-art broadband fiber laser operating at 1,250 nm with a 150 nm bandwidth, yielding a 4–5 µm axial image resolution in the retina. A long wavelength light source was chosen in order to avoid pre-stimulation of the dark-adapted retinas during the optical recordings. This light source is not suitable for in vivo human optophysiology measurements, because this wavelength is absorbed by water and the signal would be attenuated in ocular media.

During the functional experiments, the isolated retinas were stimulated with single, 200 ms long, white-light flashes (cf. Fig. 56.34). The time course of the light stimulus consisted of ∼2–3 s pre-stimulation and 4–6 s post-stimulation periods. Multiple UHR OCT depth reflectivity profiles (A-scans) were acquired at one

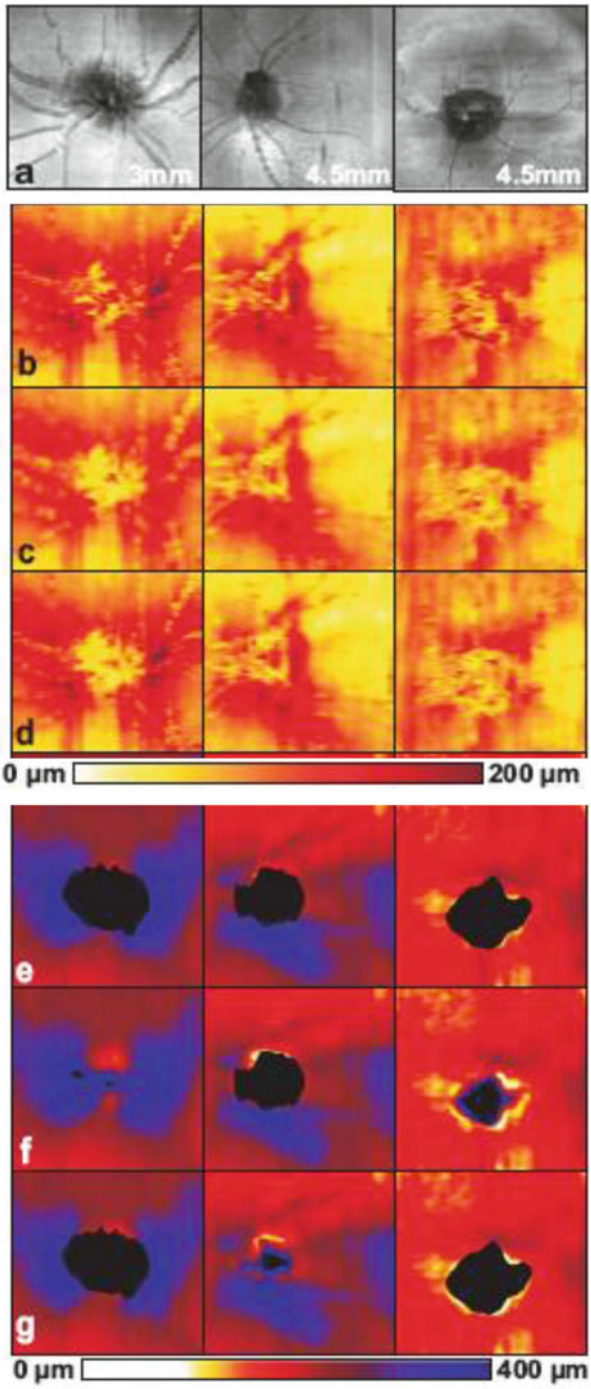

Fig. 56.33 Objective imaging parameters for glaucoma diagnosis using three-dimensional UHR OCT: two-dimensional views of retinal maps for normal (*left* in each row, transversal scanning range, 3 mm) intermediate glaucoma (*middle* in each row 4.5 mm transversal scanning range) and advanced glaucoma (*right* in each row 4.5 mm transverse scanning range). Nerve fiber layer and retinal thickness are color-coded. reconstructed fundus image at 800 nm (**a**), standard mapping of the nerve fiber layer NFL thickness (**b**), minimum distance map (*MDM*) of the NFL calculated for every point on the ILM (**c**), NFL-MDM at the *bottom* of the NFL (**d**), projected retinal thickness map (**e**), retinal thickness MDM measured from the ILM (**f**), and retinal thickness MDM at retinal pigment epithelium (RPE – **g**)

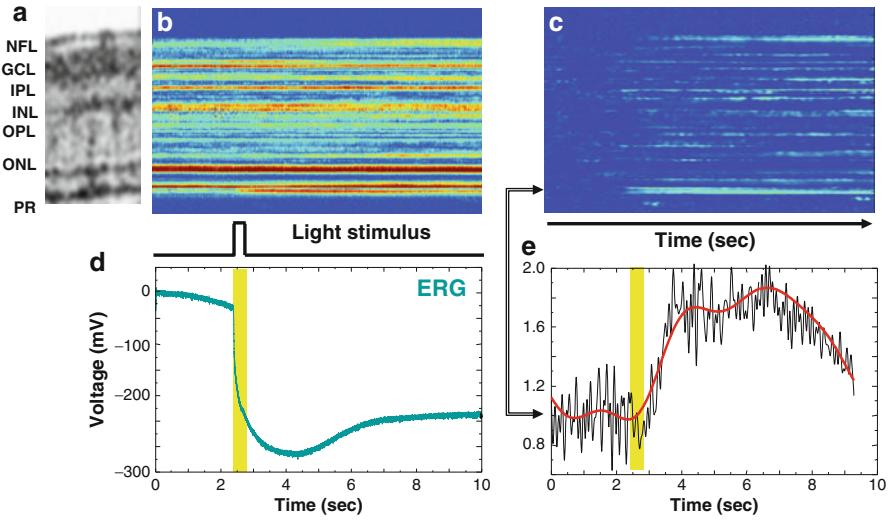

Fig. 56.34 Noninvasive, depth-resolved retinal physiology – in vitro optophysiology using functional OCT. In vitro UHR OCT of the rabbit retina (**a**). Raw (**b**) and differential (**c**, normalized by the background) optophysiological M-scans acquired during single flash stimulation (ERG and stimulus depicted in **d**). The change in the retinal optical backscattering (at a location corresponding to the outer segment of the photoreceptor layer) as a function of time is presented in (**e**), where the *yellow* boxes mark the time duration of the light stimulus

transverse location in the retina, synchronously with ERG recordings. The UHR OCT A-scans were combined to form a two-dimensional, raw data M-scan showing the retina reflectivity profile as a function of time (cf. Fig. 56.34b; procedure similar to M mode scanning in ultrasound imaging). The processing of the optical data involved application of a cross-correlation algorithm to account for any movement of the retina caused by the solution flow, calculation of the optical background (average over the pre-stimulation A-scans of each M-scan), and generation of differential M-scans (cf. Fig. 56.34 $\Delta I/I$, where I is the total optical signal and ΔI is the difference between the total signal and the average optical background determined from the pre-stimulation A-scans) of the raw data M-scans (cf. Fig. 56.34). The effect of fast variations in the optical speckle pattern detected by functional UHR OCT was minimized by applying a time-frequency filtering analysis.

Figure 56.34 shows an OCT retinal image of the rabbit retina (A), demonstrating that UHR OCT is capable of visualizing all major retinal layers. This morphological OCT image, acquired in the vicinity of the location where functional OCT data was recorded, is compared with a representative raw (B) and differential (C) M-scans acquired during single flash stimulation (ERG and stimulus depicted in Fig. 56.34). This comparison is essential to establish the morphological and possibly the physiological origins of any changes in the recorded optical signal, which was observed in the differential M-scan. Figure 56.34 shows a representative single

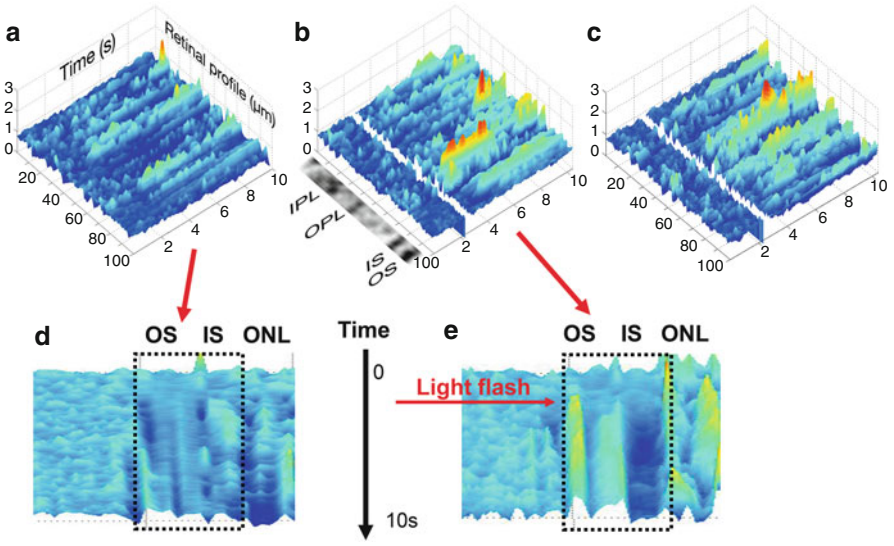

Fig. 56.35 Noninvasive, depth-resolved retinal physiology – in vitro optophysiology using functional OCT. Differential M-scans in 3D for better visualization of the time course and the magnitude of the observed positive and negative optical changes acquired during dark scan (**a**; *DS*), single flash stimulus (**b**; *SF*), and SF + photoreceptor inhibition (**c**). As expected, during DS (no light stimulus) the optical reflectivity of the PR layer did not change significantly with time. In the first and second type of experiments during SF recordings conducted in normal dark-adapted retinas, the reflectivity of the IS and OS of the PR layer exhibited significant negative and positive changes, respectively, after application of the light stimulus. In the case of KCl-inhibited PR function, the optical changes observed in the IS and OS of the PR layer appeared close to the optical background level and showed no correlation to the onset of the light stimulus. Comparison of optophysiological signals in 3D for DS and SF is depicted for more clarity in (**d**, **e**)

flash stimulus differential M-scan. The change in the retina optical backscattering (at a location corresponding to the outer segment of the photoreceptor layer (PR)) as a function of time is presented in Fig. 56.34, where yellow boxes mark the time duration of the light stimulus. The signal exhibits a rapid increase in optical backscattering, beginning simultaneously with the flash and then slowly returning to baseline. Similarly, though opposite in sign, changes are observed in the ERG recording (cf. Fig. 56.34d).

Figure 56.35a–c compare differential M-scans in 3D for better visualization of the time course and the magnitude of the observed positive and negative optical changes acquired during the dark scan (DS, no light stimulus), single flash stimulus (SF), and SF + photoreceptor inhibition. As expected during the dark scan, the optical reflectivity of the PR layer did not change significantly with time. In the first and second type of experiments during single flash stimulus recordings conducted

in normal dark-adapted retinas, the reflectivity of the IS and OS of the PR layer exhibited significant negative and positive changes, respectively, after application of the light stimulus. The onset of the optical signals correlated well with the onset of the light flash. Potassium chloride (KCl) was used to inhibit photoreceptor function, and the optical changes observed in the IS and OS of the PR layer appeared close to the optical background level and showed no correlation to the onset of the light stimulus. The comparison of optophysiological signals in 3D for dark scan and single flash stimulus is also depicted for more clarity in Fig. 56.35e. It is well known from physiology that action potentials induce depolarization in the cell membranes as well as cell size changes that might be detected not only by visualization of morphologic changes using UHR OCT but also by spatially resolved changes in backscattering over time. The exact origin of the optophysiologic signals is still not clear, but it might be related to the dipole reorientation (and, therefore, refractive index changes) at the photoreceptor membrane, light-induced isomerization of rhodopsin in the outer photoreceptor segment, or metabolic changes in the mitochondria of the inner photoreceptor segments.

Noninvasive in vivo functional optical imaging of the intact rat retina was recently demonstrated by using high-speed, UHR OCT with spectral/Fourier domain detection [95]. Imaging was performed with 2.8 μm axial image resolution at a rate of 24,000 A-scans/s in a Long–Evans rat. The advantage of using speed imaging is that it enables signal averaging which reduces the effects of noise from eye motion. A white-light stimulus (1.3 s) was applied to the dark-adapted rat retina, and the average reflectivities from different intraretinal layers were measured as a function of time (cf. Fig. 56.36). During each recording, a 160 × 160 mm^2 (64 × 64 pixels) area of the retina, corresponding to a volume data set, was measured within 162 ms, thus resulting in 6.2 volumes/s acquisition (cf. Fig. 56.36). Figure 56.36 shows an example of a single cross-sectional image. Figure 56.36d is obtained by averaging the photoreceptor outer segment reflectance from one volume. The physiologic noise from the baseline recording had a standard deviation of ∼1 %. A white-light stimulus induced an increase in backscattering of ∼12 %. The spatial distribution of the change in the OCT signal was consistent with an increase in backscatter from the photoreceptor outer segments. This demonstrates the ability to perform functional OCT imaging in the intact retina.

These results are preliminary, but they demonstrate the fundamental concepts of optophysiology. Further research and investigation is required; however, the ultimate goal is to develop an imaging technology that integrates structural and functional imaging at the level of retinal architectural morphology. Signal levels are very small and physiological noise as well as motion artifacts will be complicating factors. However, if these challenges can be overcome, then it will become possible to noninvasively visualize functional activation of the photoreceptors as well as neural transduction through individual retinal layers. Optophysiology remains an ambitious goal, but would have a profound impact on fundamental research as well as clinical diagnosis.

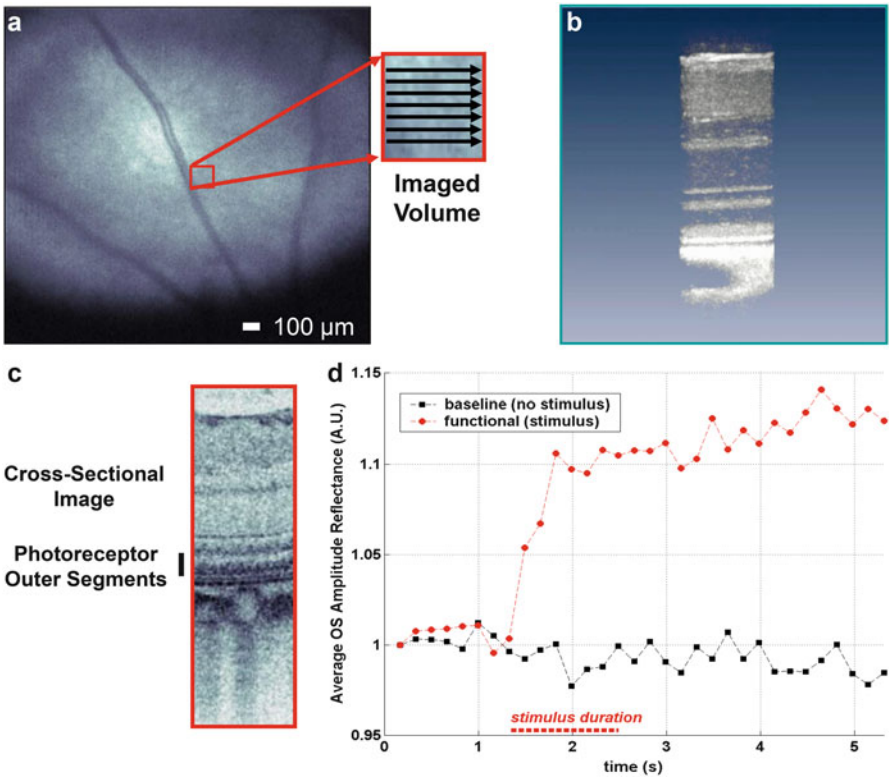

Fig. 56.36 Noninvasive, depth-resolved retinal physiology – in vivo optophysiology using functional OCT in the rat retina. A raster scan pattern is used to measure a volume of the retina as a function of time, each recording is a 160 × 160 µm area (64 × 64 pixels) transverse region, resulting in a 162 ms time resolution and 6.2 volumes/s (**a**). Functional measurements are performed by averaging the photoreceptor outer segment reflectance from one volume versus time (**b**, **c**). The physiologic noise from the baseline recording has a standard deviation of ∼1 %, while a *white*-light stimulus induces an increase in backscattering of ∼12 % (**d**)

56.8 Conclusion

The eye is an essentially transparent medium transmitting light with minimal optical attenuation and scattering and providing easy optical access to the anterior segment as well as the retina. Furthermore, ophthalmology, as a clinical specialty, has historically been open to new optical technologies. There is a wide spectrum of disease that can be diagnosed or monitored using retinal imaging. Therefore, ophthalmology was, and will continue to be, the dominant clinical specialty where new technological developments in OCT are applied.

Modern clinical practice requires the development of techniques to diagnose disease in its early stages, when treatment is most effective and irreversible damage can be prevented or postponed. OCT will play a powerful role in clinical ophthalmology because it enables structural imaging of the retina with resolutions higher than any other noninvasive imaging modality. The development of 3D-OCT imaging dramatically enhances the amount and quality of structural information available, promising to enable the development of a wide range of new markers for disease diagnoses and progression in the future. Diseases such as age-related macular degeneration are currently the subject of intense investigation, both to identify treatment criteria for anti-angiogenesis therapies as well as to identify structural markers that can predict disease progression from dry to wet phases.

High-speed 3D-OCT using spectral/Fourier domain detection methods promises to enable a wide range of new applications that could not have been foreseen in the past. One key issue that has emerged as a challenging, new area of research is how to effectively process and display 3D-OCT data for clinical applications. Modern OCT systems generate massive data sets that are equivalent to hundreds of individual OCT images. Although individual OCT images can be precisely registered to fundus features by using OCT fundus imaging, it is impractical to review all of these cross-sectional images one by one to identify pathology. Intelligent algorithms and image processing methods, therefore, play an increasing role in clinical diagnosis. Image processing for quantitative measurement, or morphometry, will be especially important for clinical applications. These techniques have the powerful advantage of condensing image information into a form that can be compared to populational norms for the diagnosis of disease or monitoring disease progression.

Current commercial OCT instruments have an improved axial image resolution of 5–7 μm, compared with earlier generations of OCT with 8–10 μm resolution. However, commercial instruments still have not reached the level of ultrahigh resolution (2–3 μm), which has been achieved in research prototype instruments. Although broadband superluminescent diode light source technology is improving and yielding better resolutions at lower cost, its price is still prohibitive for widespread clinical use. Furthermore, it is important to point out that spectral/Fourier domain detection has a trade-off between axial resolution and imaging depth. As noted previously, limitations in the size of available CCD line scan cameras mean that achieving 3 μm resolution results in a 1.5 mm imaging depth range. This makes an ultrahigh-resolution OCT instrument sensitive to alignment and difficult to use in general clinical practice. As improved CCD cameras become available and the cost of broadband light source technology continues to decrease, three-dimensional UHR OCT imaging will become increasingly available. Swept source/Fourier domain detection techniques promise to overcome many of the limitations inherent in spectral/Fourier domain detection techniques, but this area of investigation is still in its early stages.

Small animal imaging removes many of the constraints inherent in clinical imaging of human subjects. Therefore, ultrahigh-resolution OCT and AO techniques promise to play an increasingly important role in this area. As noted

previously, OCT enables repeated imaging on the same animal without the need for sacrifice. This capability will dramatically improve the efficiency of drug development and validation, since the role of biological variability is reduced and significantly fewer animals are needed for studies.

Perhaps one of the most promising areas of investigation is functional OCT imaging. Techniques such as Doppler flow, polarization-sensitive OCT (PS OCT), or depth-resolved functional imaging promise to integrate structural and functional information into a single measurement. Many advances in OCT technology, data analysis, and image processing techniques remain to be developed in this area. Functional imaging promises to take OCT to the next level. Doppler OCT enables identification of vasculature, and combined with high-speed 3D-OCT, quantitative mapping of the vascular network should ultimately be possible. Techniques such as PS OCT can provide information about architectural and cellular organization of retinal nerve fibers, whose changes in structure may be the earliest markers of atrophy, before thinning of the nerve fiber layer occurs. Finally, OCT optophysiology promises to enable imaging of neural activation on the level of individual retinal layers and, perhaps ultimately, by combining ultrahigh-resolution and AO OCT techniques, on the level of individual ganglion cells. Much more work must be done, but OCT holds the promise for continuing advances in fundamental research and improvements in clinical care for many years into the future.

OCT Imaging in Glaucoma

57

Jessica E. Nevins, Gadi Wollstein, and Joel S. Schuman

Keywords
Ganglion cell layer • Glaucoma • Macula • Retinal nerve fiber layer (RNFL)

57.1 Glaucoma

Glaucoma is the second leading cause of irreversible blindness worldwide, and estimates put the total number of suspected cases of glaucoma at over 60 million worldwide [1]. The severity of the disease varies among ethnic groups with African-Americans 15 times more likely to be visually impaired and six to eight times more likely to be blinded by glaucoma compared to Caucasians [2, 3].

Glaucoma is characterized by optic neuropathy and progressive loss of retinal ganglion cells (RGCs) and their axons, which comprise the retinal nerve fiber layer (RNFL), with associated visual function loss [1, 4]. The structural loss of the optic nerve head is most easily seen in the superior and inferior poles [5]. Functional loss refers primarily to the presence of a characteristic visual field defect, particularly when locations are clustered and reproducibly present [5]. While the relationship between structure and function is a source of debate, it has been suggested that structural loss often precedes functional loss [6].

57.1.1 Glaucoma Risk Factors and Disease Spectrum

The cause of glaucoma is unknown; however, there are some risk factors associated with the disease. The main risk factor is elevated intraocular pressure (IOP).

DOI 10.1007/978-3-319-06419-2_59

A normal range of IOP is between 10 and 21 mmHg. Other risk factors include, but are not limited to, family history of glaucoma, ethnic background, and older age [7].

Glaucoma is a family of eye diseases, and there are different classifications of the disease with different signs and symptoms. Primary closed-angle glaucoma is characterized by the contact of the iris and trabecular meshwork. This physical contact disrupts the trabecular meshwork from acting out its function, which is to drain the aqueous humor. When the drainage cannot keep up with the production, the pressure in the eye is increased. In some cases, this increase in pressure is rapid and is paired with pain, redness, and reduced vision. However, in other cases, the pressure elevation is gradual and milder, and the patients are asymptomatic. Primary open-angle glaucoma is characterized by an open angle between the iris and the trabecular meshwork with trabecular meshwork blockage at the microscopic level. There are also classifications of glaucoma that are linked to heredity, induced by steroid use, or related to trauma. Glaucoma disease severity is determined depending on how much vision loss has already occurred and the rate at which the vision loss is occurring (also referred to as progression of the disease).

57.2 OCT Background

Because RGC loss cannot be directly detected in a clinical examination, glaucoma diagnosis relies on identification of indirect cues, such as characteristic optic nerve and RNFL changes, along with visual field (VF) abnormalities. Optical coherence tomography (OCT) allows quantifiable observation of the optic nerve and RNFL structures.

57.2.1 OCT Advantages for Glaucoma

There are many advantages to using this technology in imaging the eye for glaucoma evaluation. First, imaging is done in vivo and there is no damage inflicted, allowing repeated scanning of the same area in the same eye, as well as imaging different locations in the same eye. With modern scanning techniques, volumetric scans can be acquired, rather than 2-dimensional cross-sectional data, providing the ophthalmologist with comprehensive information as to the eye morphology. The clinical ability to detect the disease at early stages or identify disease worsening is often challenging because glaucoma is a slowly progressing disease. By providing automated and reproducible quantification of ocular structures, OCT enhances clinical diagnostic performance. However, in the current commercially available devices, there is signal attenuation as the signal's penetration depth increases or when significant media opacities, such as cataracts, are present.

There are two main types of OCT devices currently commercially available – time domain (TD-) and spectral domain (SD-) OCT. Both TD- and SD-OCT devices apply the same basic scientific principles; however, SD-OCT technology has a faster scan rate and improved axial resolution.

Quantification of the peripapillary RNFL has become the most common indicator for clinical glaucoma evaluation [8, 9]. However, the introduction of SD-OCT, with its high resolution and fast scanning speed, has added the quantification of the macular ganglion cell layer as comparative a glaucoma indicator as the RNFL [10–15].

57.3 OCT Scanning Patterns

The fast scanning rate provided by SD-OCT allows flexibility in the types of scan patterns available to be employed. These patterns can vary as a single linear scan, a few parallel linear scans, densely packed parallel linear scans in a raster pattern, circular scans of a predetermined diameter, or a combination of scan patterns, such as linear and circular scans. The following scan protocol descriptions are those often used in glaucoma evaluation and are intended to be general and unspecific to any particular TD- or SD-OCT device.

57.3.1 Linear Scans

The linear scan is composed of sequential axial scans (A-scans) aligned together to create an optical cross section (B-scan) of the structure of interest. The length and density of the A-scans along the line vary among the various commercial devices. The linear scan protocol provides detailed visualization of structures sampled along the scan line, which is most relevant and beneficial for examination of localized damage or for comparison between superior and inferior retinal damage.

The raster scan consists of a series of parallel and equally spaced linear scans [16]. Spacing between the linear scans and length of the linear scans vary among the commercial devices and can be adjusted for some of them. This scanning protocol is mostly used for detailed visualization of the macula or the optic nerve head region.

The radial scan consists of a series of equally spaced linear scans centered through a common point, such as the fovea or optic nerve head center. The number and length of the linear scans vary among devices. This scan allows the acquisition of data from a relatively wide region. However, the sampling is dense closest to the centered point. More interpolation is necessary between lines as distance from the centered point increases. This could lead to a localized small abnormality occurring in the periphery of the scan to be undetected.

57.3.2 Circular Scans

A circular scan is conceptually identical to a linear scan that is bent into a circle. This scan pattern is the most important scan pattern with TD-OCT devices for glaucoma evaluation because its design samples from all retinal nerve fibers approaching the optic nerve head [17]. Three consecutive scans are

automatically acquired after positioning the scan at the desired location, and the average of the three scans is reported. Several SD-OCT devices offer the same scan pattern. Even though the sampling location of the retina is in similar locations for both technologies, TD- and SD-OCT measurements are not interchangeable.

57.3.3 Combination of Linear and Circular Scans

The combination of linear and circular scans is laid out as concentric circles centered on the intersection point of the radial scans. The radial and circular scans are registered along their crossed paths, which leads to dense sampling near the intersection of the radial scans. As the distance from the intersection increases and the spacing between radial scan lines is larger, the concentric circles provide most of the data. A disadvantage to this scan is the eye movement that can occur throughout the period of time between the beginning of the acquisition of the radial scans and the end of the acquisition of the circular scans. This movement degrades the scan registration accuracy. This scan pattern is used for imaging of the optic nerve head region.

57.3.4 Raster Scans

The 3D cube raster is a series of rapid succession captures of adjacent and parallel B-scans. All of the data from the scanning window is acquired, which allows later processing of any desired area or view within the scanning region. Presence of blood vessels and other structural landmarks enables the alignment of scans acquired from multiple visits.

The scanning window can be placed over the macula or the optic nerve head region with the size of the scanning window and the density of the scan lines varying among OCT devices. Some devices acquire isometric scans, in which the distance between sampling points is consistent and pixel size is the same in both x- and y-directions. Other devices acquire unisometric scans, in which the distance between sampling points is different in x- and y-directions, creating a rectangular scanning region. Unisometric scans are beneficial when one direction is more of interest than the other.

3D cube raster scans are the main scanning type used for glaucoma because of the large scanning areas possible in a single scan and the range of post-processing options.

57.3.5 Eye Motion Tracking

Even with increasing scan speeds, eye movement during image acquisition can cause image distortion and impair tissue quantification. Several SD-OCT devices

incorporate eye motion tracking systems that correct for eye movement during image acquisition. Scanning time with functioning eye motion tracking can be significantly extended for patients with much movement, due to the repetition of B-scans upon movement detection.

57.4 Image-Processing Protocols

In addition to advancing imaging protocols, SD-OCT also offers an array of advancing image processing. A few examples are sampling tissue in a desired location within a scanning window or more detailed layer segmentation.

Most devices present the images with a vertical stretch to more easily visualize cross-sectional details. Summing all values along each A-scan creates fundus images, which are also referred to as en face images. These images are 2-dimensional maps from the image window that resemble the appearance of a clinical biomicroscopic examination.

57.4.1 Repeated Scan (Image) Averaging

Repeated scan averaging reduces the noise level and improves the image quality. Averaging is most suitable for linear and radial scans because averaging only slightly increases the scan time duration. Averaging is less convenient for longer duration scan patterns, such as the 3D cube scans. Any further increase in scan duration leads to greater eye movement artifacts, along with other causes of scan quality deterioration. The number of repeats should also be considered because above a certain amount of image averaging, the image quality deteriorates due to small uncorrected movements that lead to smearing of the image.

57.4.2 Segmentation

Segmentation enables differentiation of certain structures in a region of interest. The RNFL in the peripapillary area and retinal layers in the macula are two examples of commonly segmented regions from images of the posterior aspect of the eye. Segmentation is automatically performed through identification of certain landmarks in the signal profile of each A-scan. Segmentation methods enable detection, quantification, and advanced post-processing of abnormalities in certain layers. However, in the presence of severely deformed structures, segmentation might fail because the typical landmarks required for the segmentation are not discernable. Therefore, it is recommended to routinely inspect segmentation performance to ensure validity.

57.4.3 Circumpapillary Retinal Thickness and Retinal Thickness Map

After applying the segmentation analysis on each of the A-scans, RNFL thickness is reported along a circle surrounding the optic nerve head. The thickness profile along the circle is provided in comparison to thickness profiles and measurements derived from a healthy population. This comparison enhances the ability to detect locations with apparent thinning or thickening of the RNFL. The typical circumpapillary RNFL thickness profile is described as a double hump pattern with thicker areas adjacent to the optic nerve head poles and thinner areas in the temporal and nasal aspects. It should be noted that RNFL measurements are not interchangeable among the SD-OCT devices. In addition to the visual representation of the RNFL profile, average thickness measurements are also provided for the entire circle, in quadrants and in smaller sectors. Many of the SD-OCT devices also provide RNFL thickness maps of the entire peripapillary region. This allows detection of abnormalities located outside the sampled circle of the circumpapillary scan used for the visual representation of the RNFL profile. Thickness measurements are compared to thickness values from a healthy population and are reported as a deviation map to highlight the locations of thickness abnormalities.

57.4.4 C-mode

C-mode produces an en face image of selected layers, or a slab, of an image by isolating the reflection to a thin layer of tissue within the B-scans. This method of image processing allows visualization of a selected plane, such as the retinal pigment epithelium, throughout the scanned region.

57.4.5 Progression Analysis

SD-OCT is a candidate to detect structural changes over time because the images provide accurate quantification of ocular structures. There are currently two types of progression analysis commercially used for detecting RNFL thickness loss. One analysis identifies progression at a location where the change is more than the expected variability at the same location in a normative database. The other analysis type is focused on rate of progression, where an eye is marked as progressing when the rate of change using linear regression is outside of the expected RNFL loss rate of a normative database.

57.5 Scanning Locations

Within the eye, there is more than one location that can be imaged to provide information related to glaucoma. At these different locations, certain scan patterns are more useful than others depending on tissue structure and location.

57.5.1 Optic Nerve Head

Various scan patterns are offered among the different SD-OCT devices for imaging the optic nerve head region. The most common patterns are raster scans, radial scans, and the combination of radial and circular scans. The disc margin is traditionally defined as Bruch's membrane opening and is automatically defined for some devices, while other devices require manual definition. The cup is defined by a plane parallel to the plane connecting the disc margin with a fixed offset that varies among the different devices. All devices provide quantification of optic nerve head structure areas, including the disc, rim and cup, as well as the cup to disc ratio.

SD-OCT scanning produces pairs of simultaneous images: one image that is focused more superficially and a mirror image with a deeper focus plane. In all conventional scanning, the first image with the superficial focus is used with the mirror image not being shown. However, in enhanced depth imaging (EDI) the mirror image is used. The deeper focus is useful for imaging structures deep within the optic nerve head, such as the lamina cribrosa. EDI is available with all scan patterns, but at the time of writing this section, it is used for qualitative analysis only.

57.5.2 Macula

Many of the scan patterns (linear, multiple parallel linear, radial, and raster scans) can be used in the macula region with different scan patterns reporting different information. While linear scans are valuable for detailed visualization along the scan line, other scan patterns provide structural information of the entire macula region. All devices are capable of reporting the macular retinal thickness spanning from the inner limiting layer to the photoreceptors or retinal pigment epithelium complex. However, a main reason behind the inability to compare thickness measurement values among devices is the precise layer at the outer retina varies among the SD-OCT devices. In addition to the total retinal thickness, some devices provide thickness measurements in defined sectors.

Advanced segmentation analysis is capable of separately identifying several of the retinal layers. Segmentation is based on identifying typical patterns in the signal profile of each individual A-scan. The utilization of this type of segmentation, as well as the number of individual layers provided, varies by SD-OCT device. There is a balance present between providing as many layers as possible and the robustness of the segmentation analysis. A benefit of this segmentation is the identification and quantification of specific retinal layers, improving the ability to detect structural changes in diseases where certain layers are specifically affected. Glaucoma is an example of such a disease because the ganglion cell layer is prone to the glaucomatous effect, and quantification of this layer individually can improve disease detection. While glaucoma specifically affects the inner retinal layers, a non-glaucoma disease affecting the outer retina can confound the

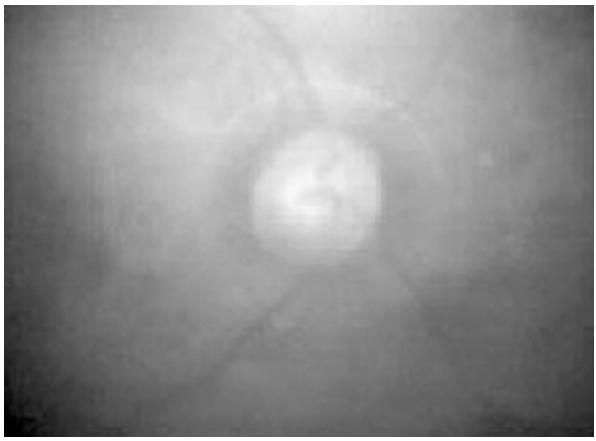

Fig. 57.1 Fast RNFL fundus image

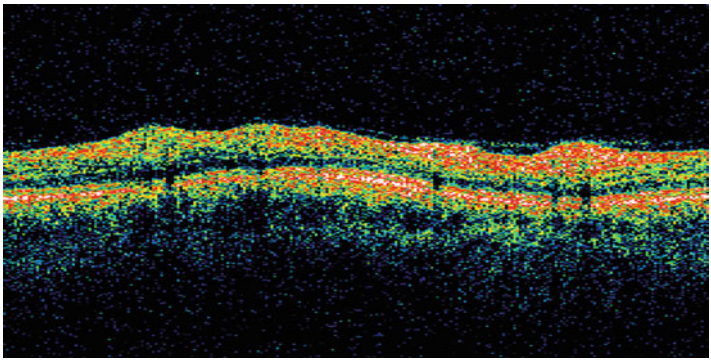

Fig. 57.2 RNFL cross-sectional image

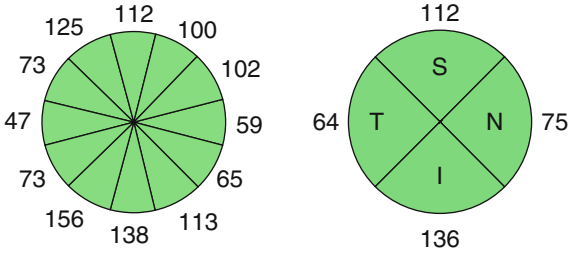

Fig. 57.3 RNFL sectoral thickness analysis

total retinal thickness measurements. In addition to providing quantitative summary parameters of the layers, some devices provide other representations of the data, such as thickness maps of individual layers and deviation maps from a population of healthy individuals.

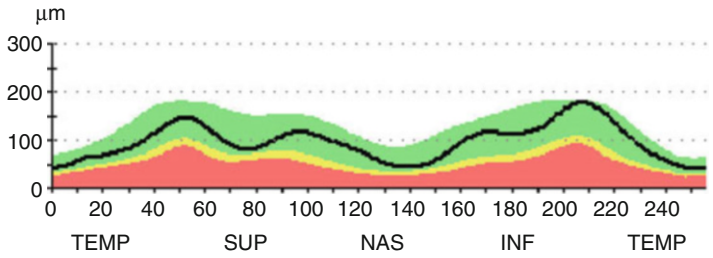

Fig. 57.4 RNFL thickness profile

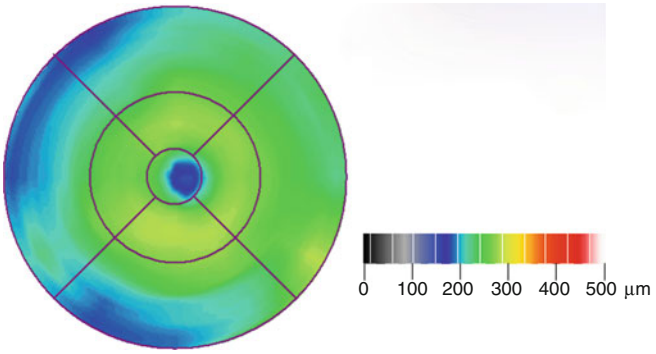

Fig. 57.6 Macula retinal thickness map

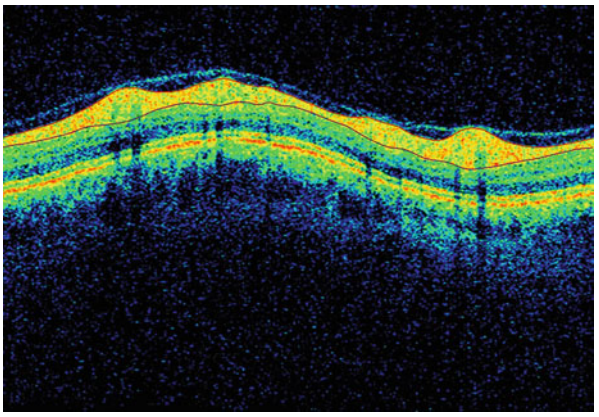

Fig. 57.7 Optic disc cube scan circumpapillary RNFL cross-sectional image

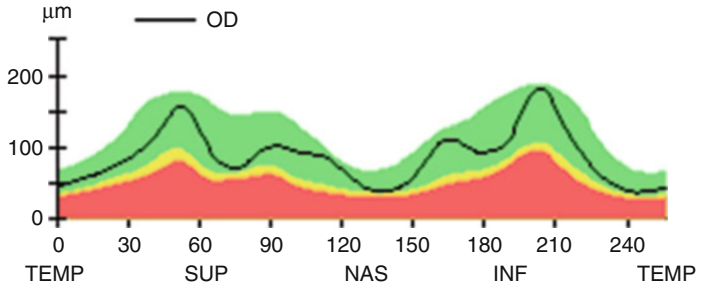

Fig. 57.8 RNFL thickness profile

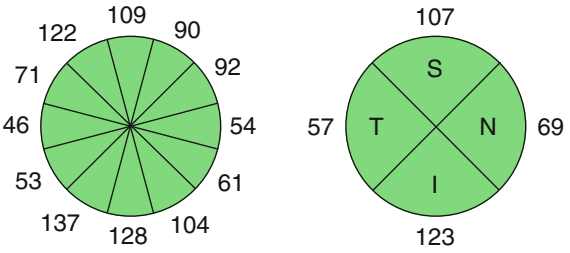

Fig. 57.9 RNFL quadrants and sectors

Another macula feature offered by some devices is C-mode sections. These sections focus on specific planes within the macula. One such example in the macula region is a C-mode section at the retinal pigment epithelium layer that highlights the presence of drusens as irregular "bumps" in the plane.

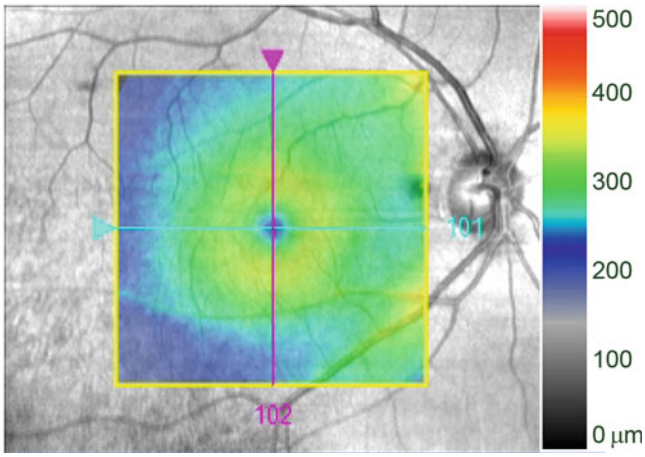

Fig. 57.12 Macula cube thickness analysis on LSO image

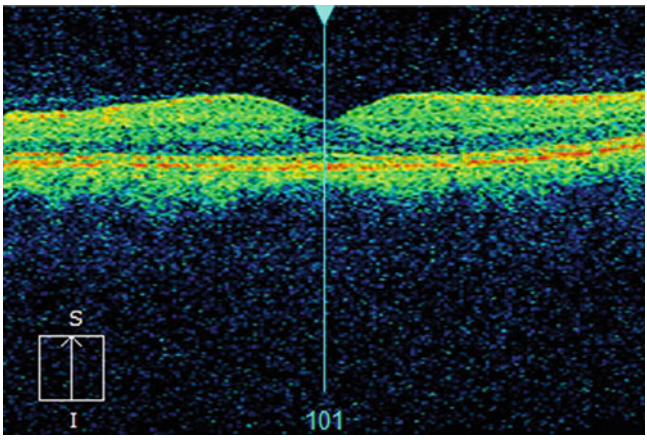

Fig. 57.13 Macula vertical cross-sectional image

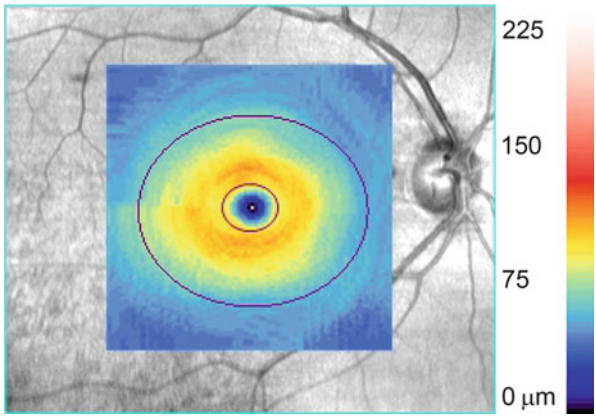

Fig. 57.14 Macula ganglion cell analysis thickness map

57.5.3 Anterior Segment

Anterior segment structures, such as the cornea, iris, and anterior lens, as well as the anterior chamber angle can be visualized with anterior segment OCT scanning. Devices with this scanning capability use a longer wavelength and higher power than typically used in OCT devices. Using a longer wavelength and higher power decreases acquisition time, which reduces the potential for motion artifacts in the scan.

In addition to devices solely for anterior segment imaging, several more conventional SD-OCT devices have the ability to provide anterior segment scanning by employing customized add-on apparatuses.

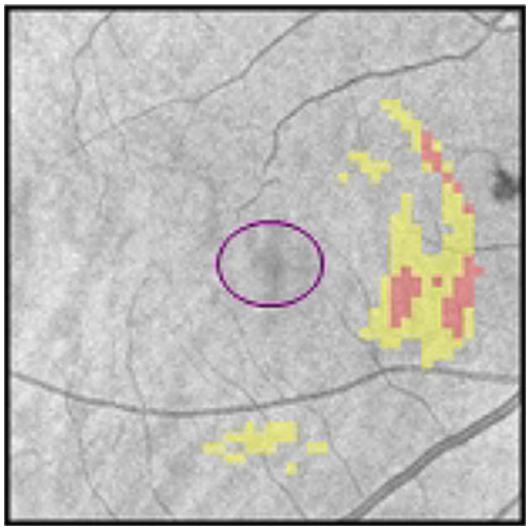

Fig. 57.15 Macula ganglion cell analysis deviation map

Fig. 57.18 Infrared CSLO image of ONH (*Left*) and SD-OCT circle scan around ONH (*Right*)

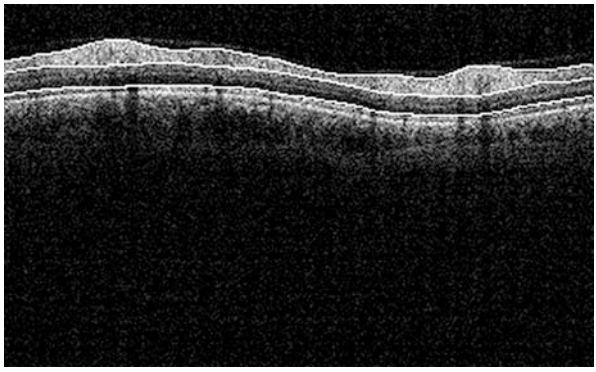

Fig. 57.19 Circumpapillary RNFL cross-sectional image

The quantitative information provided by the devices varies. For glaucoma purposes, the most useful information is the configuration of the anterior chamber angle and the corneal thickness, which has been indicated as a possible glaucoma risk factor. Many devices provide angle quantification, but no consistent parameters are used across the devices.

57.6 Cases

Three cases are provided to show OCT imaging of an eye with no glaucoma disease, an eye with early glaucoma, and an eye with severe glaucoma.

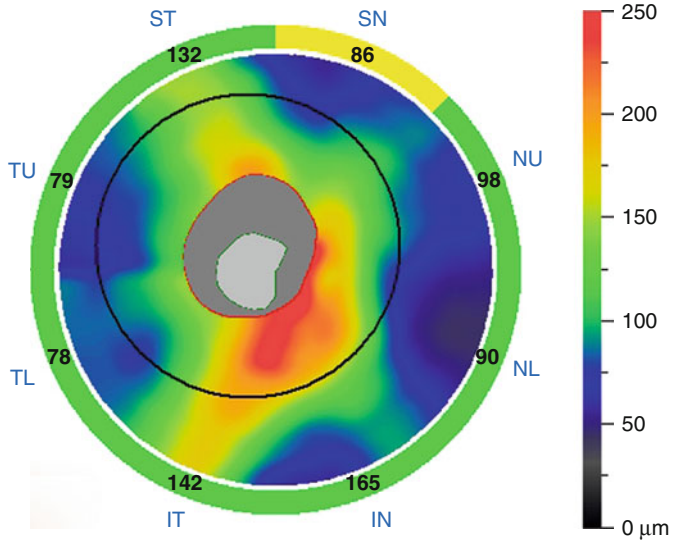

Fig. 57.20 ONH analysis

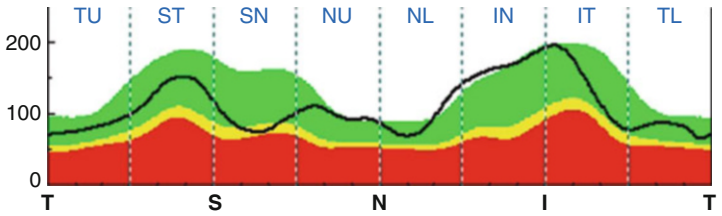

Fig. 57.21 Circumpapillary RNFL thickness analysis

57.6.1 Case 1: Healthy Eye

TD-OCT (Stratus; Carl Zeiss Meditec, Dublin, CA, USA) imaging of a healthy 48-year-old male reveals a normal RNFL thickness (Figs. 57.1, 57.2, 57.3, 57.4, 57.5, and 57.6). The fundus photo (Fig. 57.1) confirms the ONH was correctly centered during scanning. The circumpapillary RNFL cross section (Fig. 57.2), its quantification in sectors and quadrants (Fig. 57.3), and the RNFL thickness profile (Fig. 57.4) show all RNFL thickness measurements are within the normal limits (green background). Figure 57.5 displays the macula cross section with central thinning at the fovea. The macula retinal thickness map (Fig. 57.6) shows the normal retinal thickness with central foveal

thinning surrounded by the perifoveal thickening in a ring (or C) shape with gradual thinning of the retina toward the periphery of the scan.

SD-OCT (Cirrus HD-OCT; Carl Zeiss Meditec, Dublin, CA, USA) imaging of the same healthy eye (Figs. 57.7, 57.8, 57.9, 57.10, 57.11, 57.12, 57.13, 57.14, 57.15, and 57.16) includes this circumpapillary cross section reconstructed from the 3-dimensional scan (Fig. 57.7). The RNFL thickness profile and thickness values of

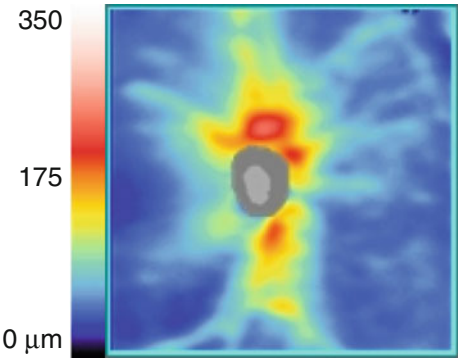

Fig. 57.32 RNFL thickness map

sectors and quadrants (Figs. 57.8 and 57.9) are all within the normal range. The peripapillary RNFL thickness map (Fig. 57.10) demonstrates the normal thickening adjacent to the superior and inferior poles of the optic nerve head with thinning of the RNFL at the nasal and temporal aspects. The en face image of the peripapillary region (Fig. 57.11) shows the sampling location of the circular scan with a diameter of 3.4 mm (purple) along with the automatically defined optic nerve head (black) and cup margins (red). RNFL thickness is compared with population-derived

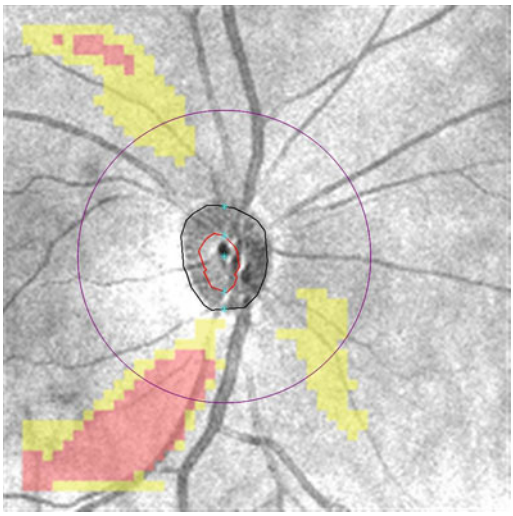

Fig. 57.33 RNFL deviation map on en face image with ONH disc and cup margins

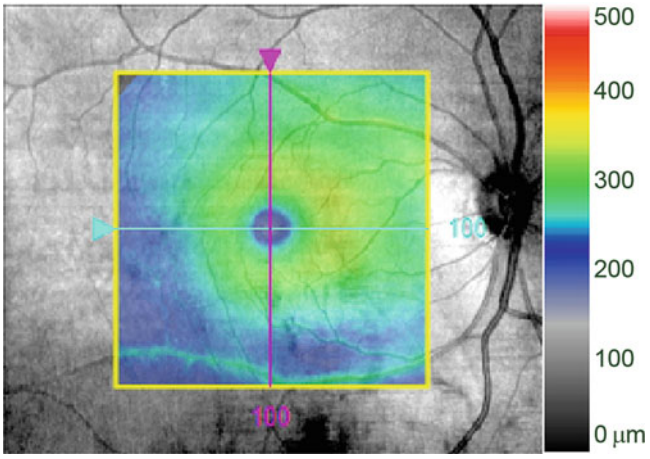

Fig. 57.34 Macula cube thickness analysis on LSO image

thickness measurements, and areas of borderline deviation are marked with yellow coloring. The rim thickness is normal and the yellow spots are minimal far from the disc margin. The thickness map of the macula (Fig. 57.12) and the vertical cross-sectional image (Fig. 57.13) display normal configuration of the macular region. The macular cube ganglion cell analysis (Figs. 57.14, 57.15, and 57.16) shows

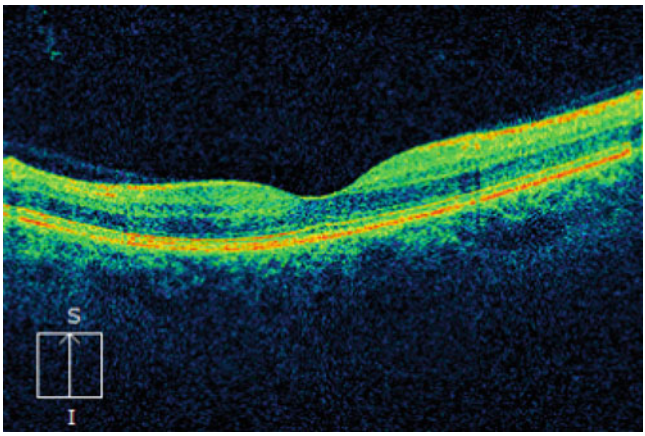

Fig. 57.35 Macula vertical cross-sectional image

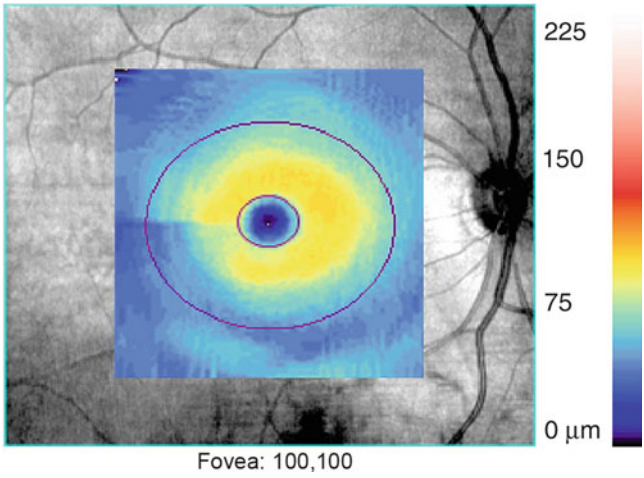

Fig. 57.36 Macula ganglion cell analysis thickness map

normal macula thickness with a localized borderline region at the nasal aspect of the macula by the thickness map (Fig. 57.14), deviation from normal map (Fig. 57.15), and sector measurements (Fig. 57.16). The one yellow sector in Fig. 57.16 corresponds to the few yellow/red spots in Fig. 57.15.

Another SD-OCT device (Spectralis; Heidelberg Engineering, Heidelberg, Germany), employing eye motion tracking and image averaging while scanning the same healthy eye, also shows a normal retinal thickness and ONH cupping with

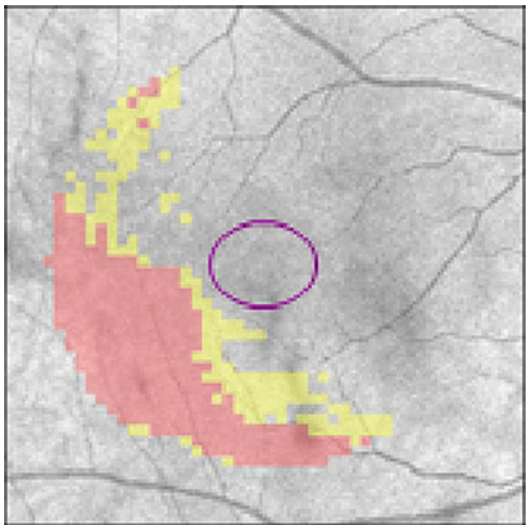

Fig. 57.37 Macula ganglion cell analysis deviation map

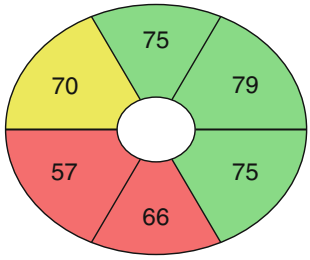

Fig. 57.38 Macula ganglion cell analysis sectors

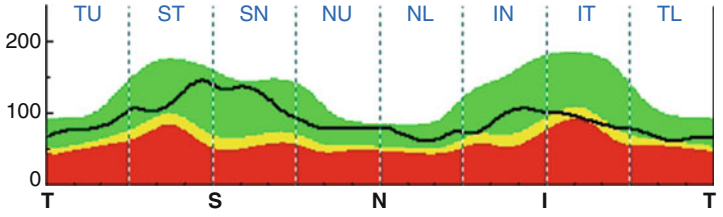

Fig. 57.41 Circumpapillary RNFL thickness analysis

the linear scan (Fig. 57.17) and circular scan (Fig. 57.18). For both scans, the left side of the figure is a scanning laser ophthalmoscopy image overlaid with the OCT scan location (green). Note the highly detailed cross-sectional images.

A third SD-OCT device (RTVue; Optovue, Fremont, CA, USA) also shows a normal RNFL thickness (Figs. 57.19, 57.20, 57.21, 57.22, and 57.23) when scanning the same healthy eye. Figure 57.19 displays the circumpapillary retinal cross section with delineation of the RNFL margins and the retinal pigment epithelium (all white lines). The ONH analysis (Fig. 57.20) provides the thickness map of the peripapillary region surrounded with the ring of sectoral measurements with the comparison with population-derived normal thickness. The RNFL thickness profile around the optic nerve head (Fig. 57.21) shows a normal profile with a small localized superonasal location with borderline RNFL thickness. The macula analysis (Fig. 57.22) indicates thickness values within the normal limits with a vertical cross section (Fig. 57.23) showing similar retinal thickness when comparing corresponding locations superior and inferior to the fovea.

57.6.2 Case 2: Early Glaucoma Eye

The left eye of a 52-year-old female demonstrated RNFL thinning as detected by TD-OCT (Stratus) imaging (Figs. 57.24, 57.25, 57.26, 57.27, and 57.28). Figure 57.24 displays the circumpapillary RNFL cross section. Analysis of the sectors, quadrants, and RNFL thickness profile (Figs. 57.25 and 57.26) shows mostly normal RNFL thickness measurements, except for thinning in the temporal inferior region. The vertical macula cross section shows thinning of the RNFL

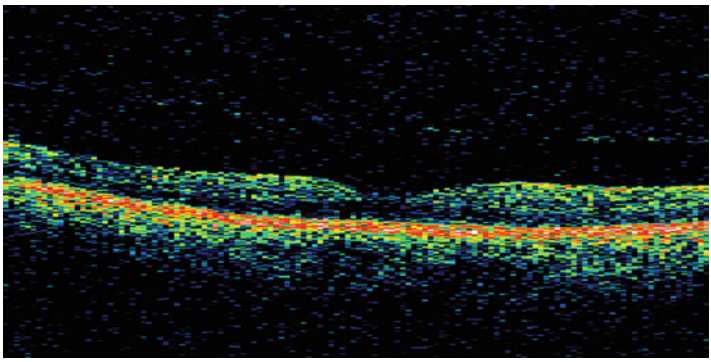

Fig. 57.47 Macula cross-sectional image

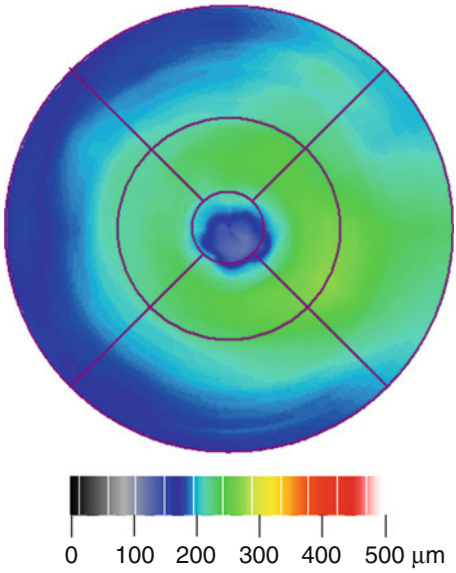

Fig. 57.48 Macula retinal thickness map

layer (upper red band) in the inferior macula (left side of the figure) (Fig. 57.27). The macula retinal thickness map (Fig. 57.28) shows thinning of the inferior macula marked by the blue color with attenuation of the perifoveal thickening in the same region.

SD-OCT (Cirrus, Carl Zeiss Meditec, Dublin, CA, USA) imaging (Figs. 57.29, 57.30, 57.31, 57.32, 57.33, 57.34, 57.35, 57.36, 57.37, and 57.38) of the same eye also reveals a thinning RNFL thickness. Figure 57.29 displays the optic disc cube

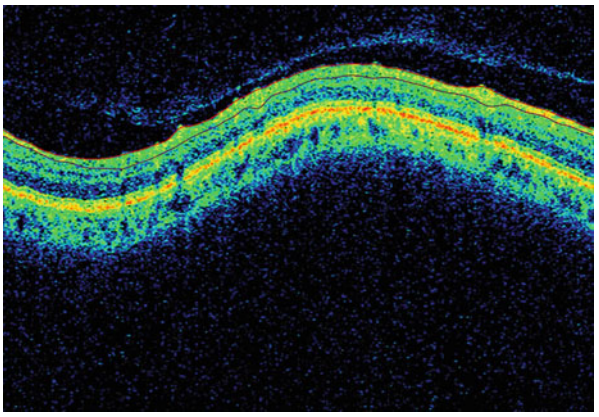

Fig. 57.49 Optic disc cube scan circumpapillary RNFL cross-sectional image

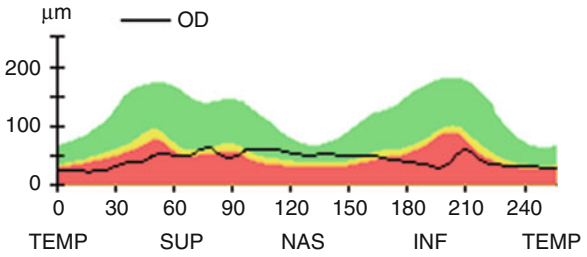

Fig. 57.50 RNFL thickness profile

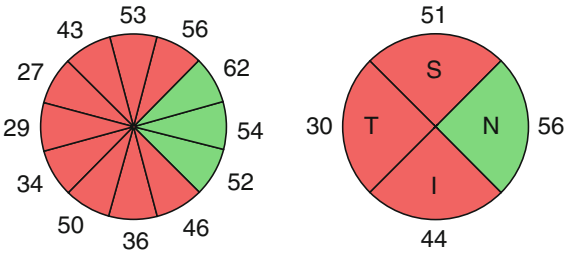

Fig. 57.51 RNFL quadrants and sectors

circumpapillary RNFL cross section. The coloring in the RNFL thickness profile, sectors, and quadrants (Figs. 57.30 and 57.31) indicates thinner RNFL thickness in the temporal inferior region. Thinning of the RNFL is noticeable inferiorly in the peripapillary thickness map (Fig. 57.32). The deviation map (Fig. 57.33) highlights thinning in the temporal inferior region (red and yellow marks). Another region of thinning appears in the temporal superior region that was difficult to identify by assessing the thickness map only. The thickness analysis of the macula (Fig. 57.34) and the vertical cross-sectional image (Fig. 57.35) display the inferior thinning.

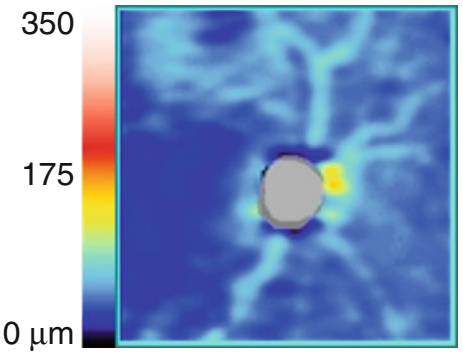

Fig. 57.52 RNFL thickness map

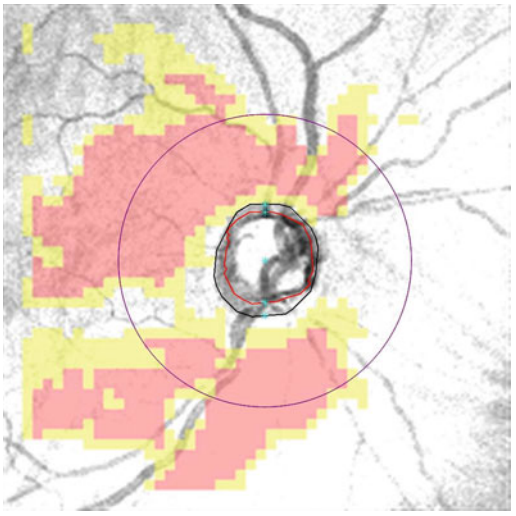

Fig. 57.53 RNFL deviation map on en face image with ONH disc and cup margins

The macular cube ganglion cell analysis (Figs. 57.36, 57.37, and 57.38) shows temporal and inferior thinning by the thickness map (Fig. 57.36), deviation map (Fig. 57.37), and sectors analysis (Figs. 57.38).

Another SD-OCT device (RTVue) also shows a thinner RNFL thickness (Figs. 57.39, 57.40, 57.41, 57.42, and 57.43) in the same eye. Figure 57.39 displays the circumpapillary RNFL cross section. The ONH analysis (Figs. 57.40 and 57.41) indicates thickness values within the normal limits, except for the thinning showed in the temporal inferior region. The macula ganglion cell complex analysis (Fig. 57.42) indicates thinning temporally and inferiorly. Figure 57.43 displays the macula cross line image with marked thinning in the inferior macula.

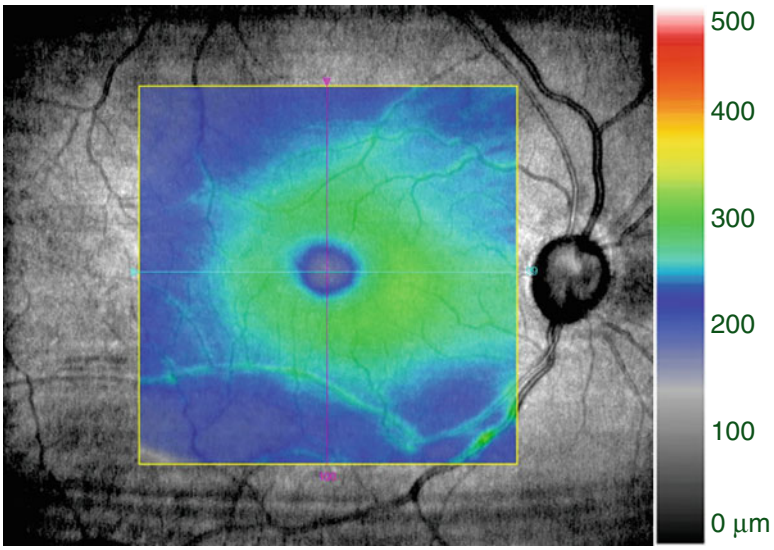

Fig. 57.54 Macula cube thickness analysis on LSO image

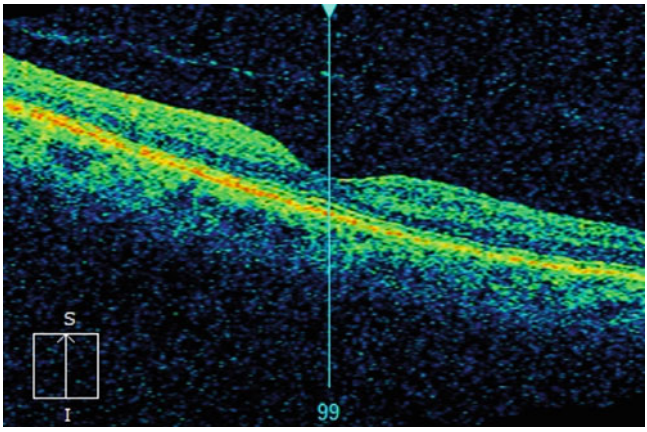

Fig. 57.55 Macula vertical cross-sectional image

57.6.3 Case 3: Severe Glaucoma Eye

The right eye of a 64-year-old female demonstrates severe glaucomatous damage. TD-OCT (Stratus) imaging (Figs. 57.44, 57.45, 57.46, 57.47, and 57.48) reveals thinning RNFL. Figure 57.44 displays the circumpapillary retinal cross section and segmentation of the RNFL with obliteration of both humps. Analysis of the sectors, quadrants, and RNFL thickness profile (Figs. 57.45 and 57.46)

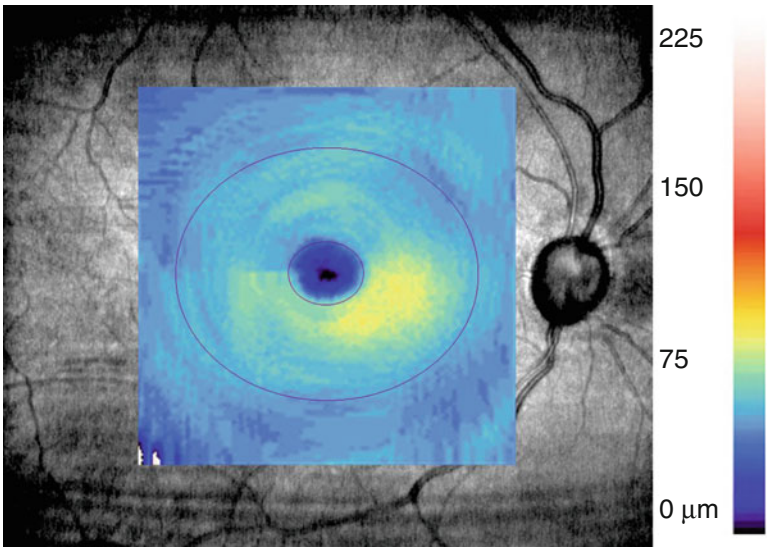

Fig. 57.56 Macula ganglion cell analysis thickness map

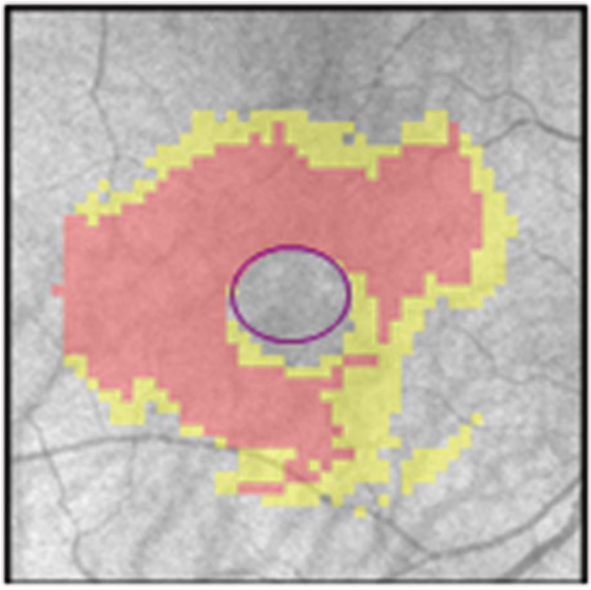

Fig. 57.57 Macula ganglion cell analysis deviation map

shows substantial inferior, superior, and temporal thinning and moderate nasal thinning. Vertical macula cross section demonstrates a total obliteration of the RNFL signal (upper red band) in both superior and inferior macula (Fig. 57.47). The macula retinal thickness map (Fig. 57.48) shows widespread thinning of retinal thickness.

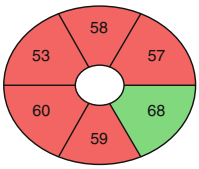

Fig. 57.58 Macula ganglion cell analysis sectors

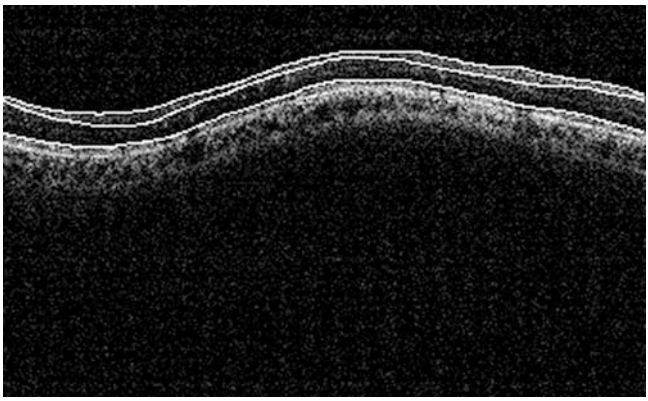

Fig. 57.59 Circumpapillary RNFL cross-sectional image

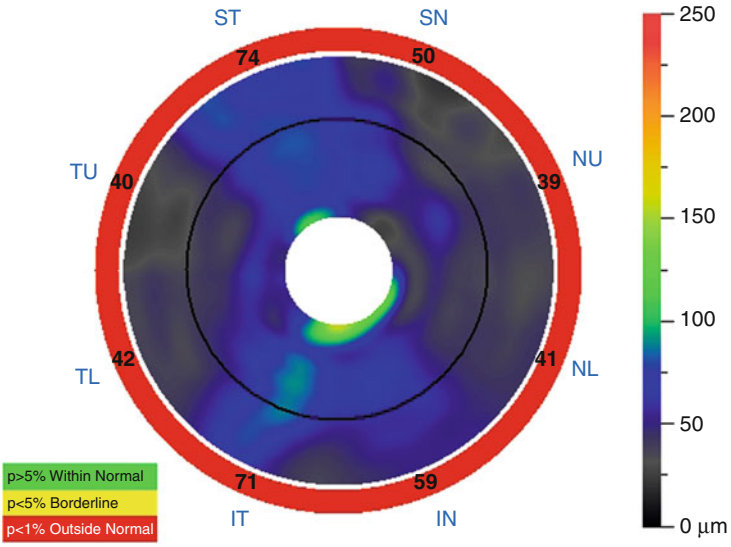

Fig. 57.60 ONH analysis

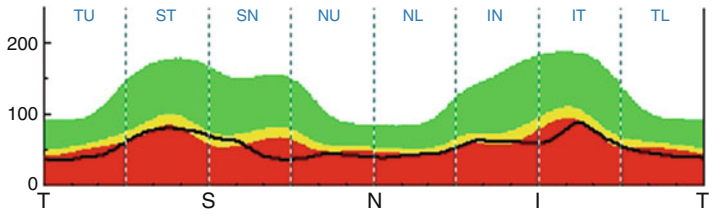

Fig. 57.61 Circumpapillary RNFL thickness analysis

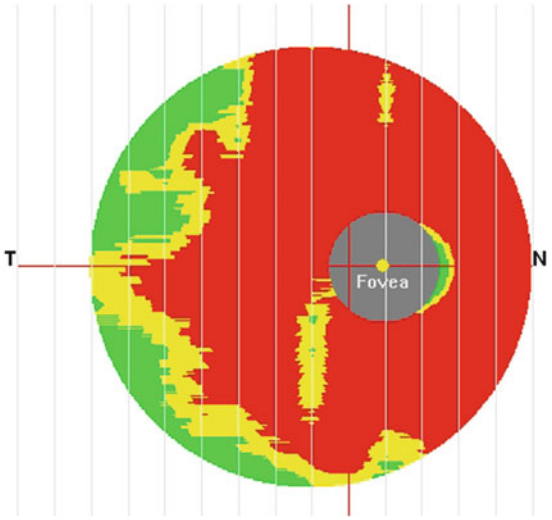

Fig. 57.62 Macula ganglion cell complex thickness significance map

SD-OCT (Cirrus HD-OCT) imaging (Figs. 57.49, 57.50, 57.51, 57.52, 57.53, 57.54, 57.55, 57.56, 57.57, and 57.58) of the same eye also reveals a thinning RNFL thickness. Figure 57.49 displays the optic disc cube derived circumpapillary cross section. The RNFL thickness profile, sectors, and quadrants (Figs. 57.50 and 57.51) indicate severely thinner RNFL thickness inferiorly, superiorly, and temporally. Severe abnormal loss is indicated in the peripapillary RNFL thickness map with total elimination of the typical configuration of thicker RNFL adjacent to the ONH poles (Fig. 57.52). The deviation map shows general enlargement of the ONH cup with neuroretinal thinning and a corresponding thinning of the RNFL (Fig. 57.53). The thickness analysis of the macula (Fig. 57.54) and the vertical cross-sectional image (Fig. 57.55) display marked thinning throughout. The macular cube ganglion cell analysis (Figs. 57.56, 57.57, and 57.58) shows more severe thinning in the superior region with some remaining thickness in the inferior region.

Another SD-OCT device (RTVue, Optovue, Fremont, CA, USA) also shows a thinner RNFL thickness (Figs. 57.59, 57.60, 57.61, 57.62, and 57.63) in the

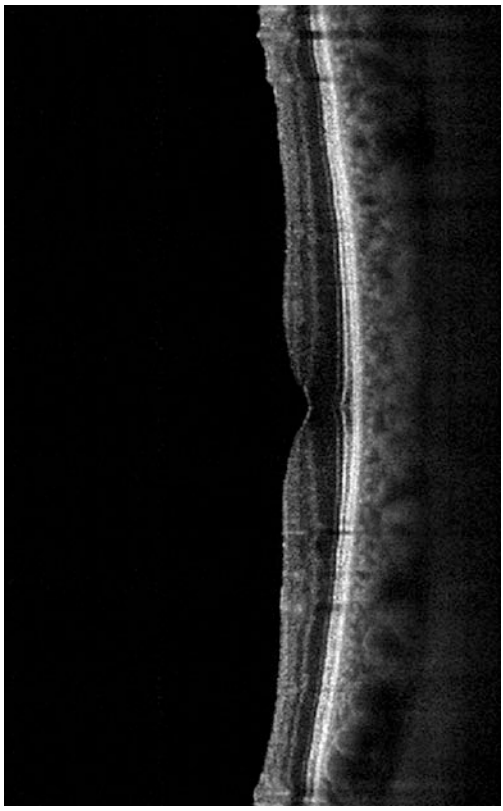

Fig. 57.63 Macula cross line image

same eye. Figure 57.59 displays the circumpapillary RNFL cross section. The ONH analysis (Figs. 57.60 and 57.61) indicates substantial thinning across all sectors. The macula ganglion cell complex analysis (Fig. 57.62) indicates very advanced thinning in the entire macula. Figure 57.63 displays the macular cross line image.

58.1 Introduction

Since its inception in 1991 [1], optical coherence tomography (OCT) imaging has revolutionized diagnostic ophthalmology and become the clinical standard of care for diagnosis of numerous retinal diseases. In this chapter, the emerging application of OCT for real-time, intraoperative diagnostic imaging and visualization of surgical maneuvers is reviewed. Intraoperative OCT provides surgeons with depth visualization in addition to the conventional en face surgical field of

view for both anterior segment eye surgery and vitreoretinal surgery and may facilitate evaluation of surgical procedures. Such advantages may enable OCT as a vital tool during surgical intervention in addition to its well-known diagnostic capabilities.

58.1.1 Benefits of OCT Imaging in Non-ophthalmic Microsurgeries

Microsurgeries are surgical procedures and techniques to manipulate and repair small (micron to millimeter scale) structures, such as small vessels, nerves, membranes, and other tissues. During microsurgery, surgical microscopes are commonly utilized to improve visualization of these small structures. Conventional surgical microscopes provide en face single or dual stereoscopic views of the surgical field, providing only limited perception of the third dimension. Thus, depth, or axial information, must largely be inferred by the surgeon. In addition to stereoscopy, the surgeon may rely on alternative cues such as instrument shadowing or tissue mechanical feedback to determine the depth of surgical tools within the surgical field. With its high-resolution tomographic imaging capabilities, OCT can offer direct visualization of the depth dimension, which may substantially facilitate surgical procedures as well as pre- and postoperative evaluation.

Recognizing such potential advantages, OCT has previously been investigated for use in a variety of non-ophthalmic surgeries [2, 3]. These include OCT guidance of laser ablation of tissue to enable real-time tracking of ablation dynamics and photodynamic therapy [4–6]. OCT has also been utilized to intraoperatively evaluate breast tumor margins. Micron-scale subsurface imaging allowed for more accurate assessment of surgical margins since tissue morphology not apparent in en face views was readily visible in tomographic images [7]. Brain tumors have also been evaluated with high-resolution OCT. A handheld OCT surgical probe was developed to image variations in optical backscatter representing margins between healthy and cancerous tissue. OCT was utilized to demarcate these tumor margins on cadaveric human cerebral cortex, demonstrating its potential for intraoperative use [8].

The feasibility of laparoscopic OCT imaging of endometriosis and ovarian carcinoma has been evaluated. OCT differentiation between pathological and normal tissue was investigated based on tissue morphological changes [9]. Moreover, OCT was utilized to determine if minimally invasive evaluation of gynecologic tissue in human cervical and uterine tissue was feasible [10]. Additionally, intraoperative OCT has been utilized to image human cartilage in normal and osteoarthritic knee joints during open knee surgery. Findings were compared to histology and landmarks identified in OCT correlated with histology. Changes in birefringence, which can serve as an indicator of collagen disorganization in early osteoarthritis, were evident in the OCT images [11]. Furthermore, OCT was utilized to evaluate microsurgical anastomoses of vessels and nerves. An OCT system incorporated into a surgical microscope enabled in vitro imaging of rabbit and human vessels and nerves. Arteries and nerves not visible in the conventional microscope's view were detected in OCT images [12].

58.1.2 Needs and Applications in Ophthalmology

In the modern ophthalmology clinic, OCT routinely enables rapid, noncontact, micrometer-scale visualization of retinal and anterior segment morphology. Translation of the clinical success of OCT into the operating room for better visualization of ophthalmic surgery is emerging as an exciting area of research. The following sections provide a brief review of aspects of anterior segment and vitreoretinal procedures which may particularly benefit from the potential ability of OCT to provide real-time, three-dimensionally resolved feedback to the surgeon.

58.1.2.1 Anterior Segment Surgical Procedures

OCT could potentially provide enhanced visualization of common anterior segment procedures intraoperatively, including keratoplasty (corneal transplantation) and cataract surgery.

In keratoplasty, either part of or the entire pathological cornea is replaced with a healthy, donor cornea. Multiple pathologies are addressed by keratoplasty. These include ectatic disorders resulting in thinned deformed corneas such as in keratoconus and keratoglobus and corneal endothelial decompensation from surgical trauma or genetic conditions resulting in visually disabling swelling of the cornea [13–15]. All of these pathologies result in degradation of visual acuity, necessitating keratoplasty to restore adequate patient vision.

In conventional penetrating keratoplasty, the entire cornea is removed and replaced with a donor cornea. The recovery time for a full corneal transplant can be up to a year, and such procedures are prone to complications such as irregular curvature due to manual suturing with resultant variable suture tension. To mitigate these complications, new surgical techniques have been developed for keratoplasty, including Descemet's stripping endothelial keratoplasty (DSEK) and deep anterior lamellar keratoplasty (DALK) for endothelial and anterior corneal diseases, respectively [16]. The goal of DSEK is to replace only the diseased endothelial layer, the innermost layer of the cornea, rather than the entire cornea. The majority of the cornea (about 95 %) remains untouched [17]. Likewise, in DALK, only the diseased anterior part of the cornea is replaced [18]. During this procedure, the diseased stromal tissue is separated anterior to Descemet's membrane. In contrast to DSEK, only the patient's Descemet's membrane and endothelium are retained; all anterior tissue is replaced by the healthy donor cornea.

For both DSEK and DALK keratoplasty procedures, precise knowledge and control of layer thicknesses throughout the procedure is required for surgical success. The entire cornea is only about 0.5 mm thick centrally, and tissue layers must be dissected and manipulated in both procedures with accuracy of tens of micrometers. Providing micrometer-scale delineation of corneal layers, intrasurgical OCT could dramatically enhance surgical control of these critical parameters which are vital to the success of these ambitious surgical procedures.

Cataract surgery is another commonly performed anterior segment procedure which could potentially benefit from intraoperative OCT guidance. Cataract

surgery is the most frequently performed surgical procedure in the USA; an estimated 20.5 million Americans over the age of 40 have cataract in either eye [19, 20]. Cataracts, defined as opacification or clouding of the lens, can eventually lead to blindness if untreated. The goal of cataract surgery is to replace the clouded lens with an artificial lens to improve visual acuity. Optimizing cataract surgery with image guidance, either by facilitating pre- and postoperative screening or by enabling micron-scale visualization of surgical maneuvers intraoperatively, would have a sizable public health benefit.

In modern small incision cataract surgery, there are important steps to the successful completion of the procedure. After a corneal limbal incision is created, a circular opening approximately 5.5 mm in diameter needs to be created in the anterior lens capsule. The cataractous lens then needs to be separated from the surrounding lens capsule, fragmented with phacoemulsification or femtosecond laser, and aspirated from the eye. The artificial intraocular lens can then be placed in the empty lens capsule. Finally, the corneal incision is verified to be watertight to complete the procedure.

OCT can potentially assist with visualization in each of these critical steps in cataract surgery when using standard phacoemulsification. Further, if the femtosecond laser is used, it could be argued that OCT guidance becomes critical as it provides guidance for the placement of the laser spots [21]. In either case, OCT may provide direct visualization of the corneal incision creation, enabling study of incision type and subsequent performance. OCT could monitor the creation of the anterior capsulotomy to provide guidance on its size. OCT's depth resolution importantly could allow the surgeon to monitor the depth of the phacoemulsification needle or laser spot placement during fragmentation to ensure that the posterior lens capsule is not violated. OCT could image the intraocular lens after insertion to determine its intraoperative orientation. And finally, OCT could be used to directly verify complete closure of the incision along its entire surface to prevent adverse events postoperatively from a leaking incision.

The ability of OCT to provide the axial third dimension to the conventional en face surgical microscope view provides additional and potentially critical information to improve the surgeon's technical precision and the patient's outcome in ocular anterior segment surgeries.

58.1.2.2 Vitreoretinal Surgeries

Vitreoretinal surgery involves critical microsurgical repair of pathologies of the retina and surrounding tissues. In contrast to anterior segment surgery, conventional operating room microscope visualization of retinal surgery requires additional optical accessories to image the retina through the patient's own cornea and lens, which are often of suboptimal quality in the elderly populations most at risk for vitreoretinal pathologies. These additional optical systems further reduce already limited stereopsis. Thus, additional three-dimensionally resolved anatomical information potentially provided by intraoperative OCT is especially promising for improving outcomes in vitreoretinal surgery.

Manipulation and removal of pathological membranes is a common feature of vitreoretinal surgeries which could benefit from intraoperative image guidance. Epiretinal membranes (ERMs) are thin layers of fibrous tissue which can develop on the surface of the retina. If these membranes cause traction, they induce mechanical disturbances leading to vision loss. ERMs can be associated with a variety of pathologies, including retinal detachment, retinal vein occlusions, and uveitis. However, ERMs most commonly develop in patients with no history of other related pathologies. When loss of vision affects the patient's ability to function, vitrectomy (removal of vitreous gel) with membrane peeling may be performed to surgically remove the ERM.

The vitreoretinal surgeon must similarly be equipped to address other pathological membranes. These include the native internal limiting membrane (ILM), in which abnormal tangential traction can prevent surgical closure of a full-thickness macular hole. Patients with proliferative diabetic retinopathy develop fibrovascular membranes in the vitreous cavity and on the retinal surface and may result in complex traction detachments. Retinal detachments due to retinal tears in eyes without diabetes may develop proliferative vitreoretinopathy, which manifests as development of membranes on or below the retinal surface and is a common cause of failure of surgical reattachment.

Microsurgical procedures to remove pathological membranes involve use of a variety of different tools utilized to peel these membranes from the retinal surface, including surgical forceps and membrane scrapers [22]. These membranes are on the order of tens of microns thick and nearly invisible without stains to improve visualization. The surgeon must be able to separate these delicate membranes from the retina with precision and without inducing trauma to the underlying retina. These maneuvers are currently performed under stereo zoom microscopy guidance without any axial information other than stereoscopy and indirect physical cues such as secondary folds of the retina. To provide precise, real-time feedback to surgeons, OCT has begun to be utilized during vitreoretinal surgery by several research groups and companies. In later sections of this chapter, the benefits of applying OCT to visualize different surgical procedures, including ERM and other membrane peeling, are discussed. Specifically, these groups have demonstrated that intraoperative OCT appears to help surgeons delineate pathological from healthy tissue and to help determine the anatomical success of these procedures.

58.2 Current Approaches to Intraoperative Ophthalmic OCT

In this section, we review the three distinct approaches for intraoperative ophthalmic OCT which have been reported to date: external handheld probe OCT (HHOCT), microscope-integrated OCT (MIOCT), and forward-imaging probe OCT. For each case, the relative advantages and disadvantages of the approach are discussed, and imaging examples from published reports on the techniques are provided.

58.2.1 External Handheld Probe Systems

Several research groups have reported on the use of handheld OCT (HHOCT) probes during pauses in ophthalmic surgery, mostly using a commercial HHOCT device from Bioptigen, Inc. (Durham, USA). This product was originally developed for use on animals and for patients such as infants who are unable to sit upright in front of a conventional tabletop OCT scanner [23] and was first suggested for intrasurgical use by Scott et al. [24] and then used in the operating room by Dayani et al. [25] as well as others [26–28]. Ray et al. employed the commercial handheld probe in a rigid holster mounted to the side of the surgical microscope for evaluation of retinal anatomy during macular surgery [29]. In this study, the mounted HHOCT probe was suspended over the eye and moved into position by the use of the microscope's foot pedal-controlled X-Y translation. Intraoperative imaging of the anterior segment using commercial and prototype cart-based systems has also been reported [30, 31]. These studies have demonstrated safe and effective imaging of corneal features at different stages of the procedure. A photograph illustrating the use of the Bioptigen HHOCT system during surgery in freehand mode is shown in Fig. 58.1.

The principal advantage of the intraoperative HHOCT systems used to date in freehand mode is alignment versatility. A well-trained operator, normally the surgeon or an assistant, tilts and translates the probe, wrapped in a clear, sterile, plastic bag, steadily over the patient's eye until good visibility of the retinal tissue is achieved. The freedom and range of tilting over the eye allows the surgeon to explore

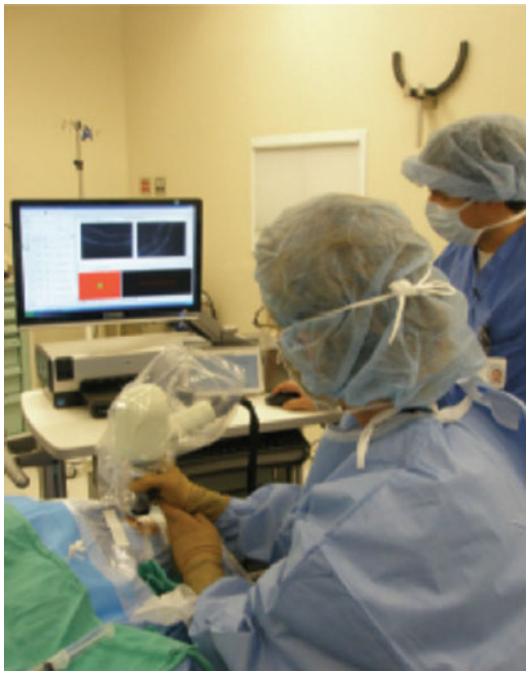

Fig. 58.1 A handheld OCT system in use at a pause in retinal surgery [25]

the retinal area and find the desired features quickly. The freedom of movement is particularly advantageous when the patient has reduced clarity through the pupil, such as with opacification of the lens capsule. The HHOCT used in microscope-mounted mode offers some stability advantage with foot pedal control over the freehand mode, however at the cost of alignment versatility.

The primary disadvantage of intraoperative HHOCT imaging is the unavoidable disruption to the procedure. The surgeon must remove any nonsecure surgical instruments from the eye and remove the operating microscope from the surgical field to bring the handheld probe into position.

Figure 58.2 illustrates HHOCT images taken in freehand mode immediately before and after surgical removal of the retinal ILM layer [25]. Postoperative morphology indicates reduced traction (tension), which is likely important for a favorable surgical outcome. The OCT images clearly demonstrate remnant ILM tissue. Under normal practices, membranes are stained to facilitate their visibility in the surgical microscope. OCT imaging can clearly delineate ILM and the underlying tissue when the ILM is peeled or elevated. Intraoperative HHOCT imaging also demonstrates small hemorrhages caused by instrument manipulation (Fig. 58.2(f)). This additional information may enable the surgeon to better assess whether the extent of peeling or other surgical maneuvers were adequate or whether additional maneuvers would be necessary.

Because intrasurgical HHOCT is based on use of a commercially available product, it has so far likely been used by more investigators and on more patients than the more advanced but still experimental systems described in the next sections. The handheld approach has been shown to be effective at quickly evaluating the morphological changes of the target tissue at various stages during operations and has thus served as a test bed for future development of OCT guidance of intrasurgical procedures.

58.2.2 Microscope-Integrated Systems

To take full advantage of the potential for real-time OCT imaging during surgery and to minimize disruptions required for HHOCT imaging, several groups have reported on OCT systems integrated directly into the optics of the surgical microscope [32–51]. This approach has been termed microscope-mounted (MMOCT) and microscope-integrated (MIOCT) optical coherence tomography. We shall use the latter throughout this review because it better emphasizes the simultaneous operation of both the microscope and OCT systems. The underlying objective for an MIOCT system is to achieve en face and OCT imaging simultaneously without compromising the surgical view.

Integrated OCT designs take advantage of the optical components of the surgical microscope, which are optimized to achieve high-resolution en face imaging under a long working distance objective. This is suitable for manipulations on the surface of the eye, such as for anterior segment procedures. Visualizing the retina is achieved by cancelling or compensating for the power of the patient's anterior optics, either by use of

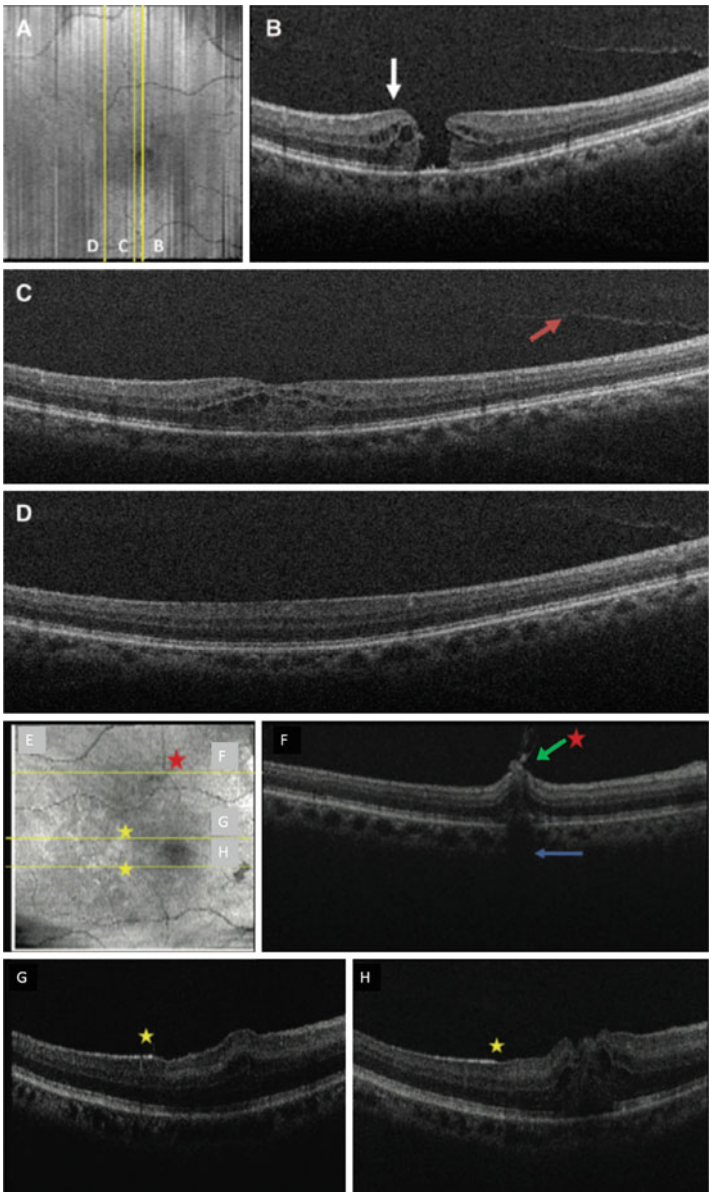

Fig. 58.2 HHOCT images of intraoperatively relevant features on a patient immediately before and after internal limiting membrane peeling [25]. In (**a**–**d**), images from an OCT volume dataset obtained pre-operatively are presented, while post-operative data obtained from the same location is shown in (**e**–**h**). (**a**, **e**) Surface volume projections of the volume datasets with yellow lines indicating positions of the individual B-scans shown following. In (**b**), cystic thickening adjacent to the macular hole is visible. In (**c**–**d**), partial vitreous separation is visible (*red arrow*). In (**f**), the green arrow indicates a pre-retinal hemorrhage corresponding to traumatic retinal hemorrhage caused by membrane peeling (*red star*). The yellow stars in (**g**–**h**) show remnant hyper-reflective ILM tissue

Fig. 58.3 The Duke prototype MIOCT system deployed in the ophthalmic operating room [42]. The surgeon's eyepieces face the camera and the assistant is at the microscope

a flat outer surface lens in contact with the cornea or by reimaging the fundus to an intermediate plane with a positive ophthalmic lens. The latter approach is akin to indirect ophthalmoscopy. Multiple vendors have produced a range of contact lenses and versatile modules that mount the appropriate reimaging optics to the underside of the microscope.

MIOCT systems may combine the OCT beam into the visual path of the microscope either by division of aperture, such as through use of the assistant optical path [44, 45], or by division of wavefront, such as by use of a dichroic beamsplitter [32, 34, 36–43, 46–51]. To take advantage of the above-mentioned methods of viewing the desired field (of either cornea or macula), the OCT beam must optimally match the microscope's normal vergence at the point of insertion, so that the OCT view matches and remains parfocal with the surgeon's view.

A disadvantage of MIOCT systems is that they potentially increase the size, weight, and complexity of the surgical microscope suspended above the patient during surgery. For example, the prototype MIOCT system in current testing by our group at Duke University adds bulk which increases the height of the microscope body (from working lens to surgeon eye pieces). This is primarily due to the fact that these systems are currently experimental prototypes built as add-ons to commercial surgical microscopes. If preliminary testing by research groups is successful, microscope manufacturers could mitigate ergonomic issues by more fully integrating OCT in the design of future microscopes.

A photograph of the Duke prototype MIOCT system in use during surgery is shown in Fig. 58.3. Further details of MIOCT optical design and published results to date are provided below in Sects. 58.3 and 58.4, respectively.

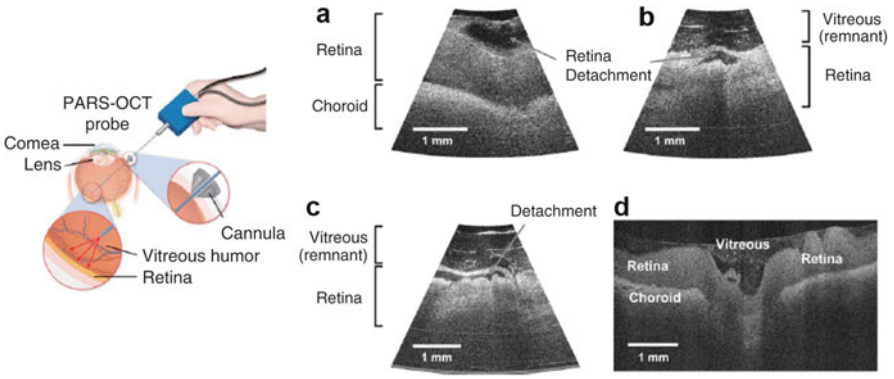

Fig. 58.4 Illustration of the forward-imaging endoscopic probe developed by Han et al. (*left*) and representative B-scans of porcine retinal tissue (*right*) [53]

58.2.3 Intraocular Forward-Imaging Endoscopic OCT Probes

The development of forward-imaging OCT probes was first reported by Boppart et al. early in the history of OCT [52], but they were not initially targeted toward ophthalmic applications. More than a decade later, Han et al. [53] published work on an OCT scanning endoscope integrated into a narrow 21 gauge (810 um diameter) needle for retinal imaging. This design achieved excellent retinal image quality in animal eyes (Fig. 58.4). An unusual feature was the central wavelength of 1,310 nm, which is conventionally used for anterior segment but not retinal imaging because of strong absorption in the vitreous [54]. This issue was circumvented by the fact that the tip of the intraocular endoscopic probe was placed in close proximity to the tissue to be scanned. The working distance of the endoscope was 0.78 mm, leaving little room for vitreal absorption or for much error in hand movement.

One disadvantage of handheld endoscopes for intraocular surgery is the additional need it places on the surgeon for probe manipulation. Typically, one of the surgeon's hands is used for holding an endoilluminator inside the ocular cavity to provide wide-angle illumination, while the second hand controls the tool that is actually manipulating the retinal tissue. Using endoscopic OCT imaging during tissue manipulations may therefore require the illumination to be fixed to a third insertion point in the sclera, such as in chandelier illumination.

Balicki et al. [55] reported an alternate intraocular probe design mounted inside a surgical needle. This effectively combined an OCT scanner with the manipulating surgical tool. However, the probe did not incorporate lateral scanning and thus only performed A-scans directly coaxial with the needle. Generating cross-sectional B-scans by sweeping the tool near the target tissue at a fixed distance by use of this probe was anticipated using robotic assistance, which may become prevalent in the future. This system also incorporated a fast ranging capability feedback to the motorized stage to compensate for patient motion by keeping the instrument tip at a fixed distance from the tissue.

To date, both of these forward-imaging ophthalmic probe systems have only been demonstrated on animal models.

58.3 Microscope-Integrated OCT System Design

In this section, we elaborate on the design and implementation details of MIOCT system hardware and control software, concentrating primarily on the system constructed and tested by our collaborative group at Duke University. We compare and contrast this design to those of other systems known to be under development, to the extent that details of these systems have been reported.

The Duke MIOCT system optical design and performance was first described by Tao et al. in 2010 [34] and the first human intrasurgical results (with the original custom-built OCT engine replaced by a commercial spectral-domain OCT console from Bioptigen, Inc.) were reported by Hahn et al. in 2012 [41, 42, 46]. An MIOCT system developed by Carl Zeiss Meditec (Jena, Germany) has been the subject of several reports by Binder et al. [32, 40]. A group at the University of Lubeck in Germany has developed and reported on a system which has been commercialized by OptoMedical Technologies GmBH (Lubeck, Germany) and Möller-Wedel (Wedel, Germany) [44, 45]. All three of these first-generation MIOCT systems share several similarities. All are based on spectrometer-based spectral-domain OCT engines operating near 850 nm wavelength, with coherence length (corresponding to axial resolution) of approximately 5 μm, and A-scan rates of 20–30 kHz. The principal distinction between first-generation systems appears to be in the sample arm scanner design and surgical microscope interface, which directly influences imaging performance. The Duke and Carl Zeiss systems are shared-objective designs utilizing the principle of division of wavefront, whereas the Möller-Wedel OCT design is based on division of aperture and occupies a separate collection path from the microscope visual optics.

The Duke MIOCT scanner optical design is illustrated in Fig. 58.5, along with a photograph of the scanner attached to a Leica M844 surgical microscope with an Oculus BIOM3 fundus viewing system. In this design, the OCT sample arm scanning beam is coupled into the infinity space directly above the microscope objective lens using a dichroic beamsplitter and aligned with the OCT optical axis midway between the stereo viewing path visual axes [34]. The OCT beam is shaped using a beam expander telescope prior to merging with the microscope visual path in order to achieve the standard lateral OCT resolution (~15 μm) expected by retinal specialists. Thus, the OCT beam aperture in the shared region is larger than either of the stereo view optical apertures, with an associated reduction in depth of field compared to the visual stereo view. Optical design and test performance of the MIOCT unit are also illustrated in Fig. 58.5.

Insertion of the OCT scanning beam in the infinity space of the microscope view provides minimum interference with the operation of microscope components and accessories such as the zoom module, laser filters, camera ports, and assistant eyepieces, all of which are optically upstream from this position. Stacking of

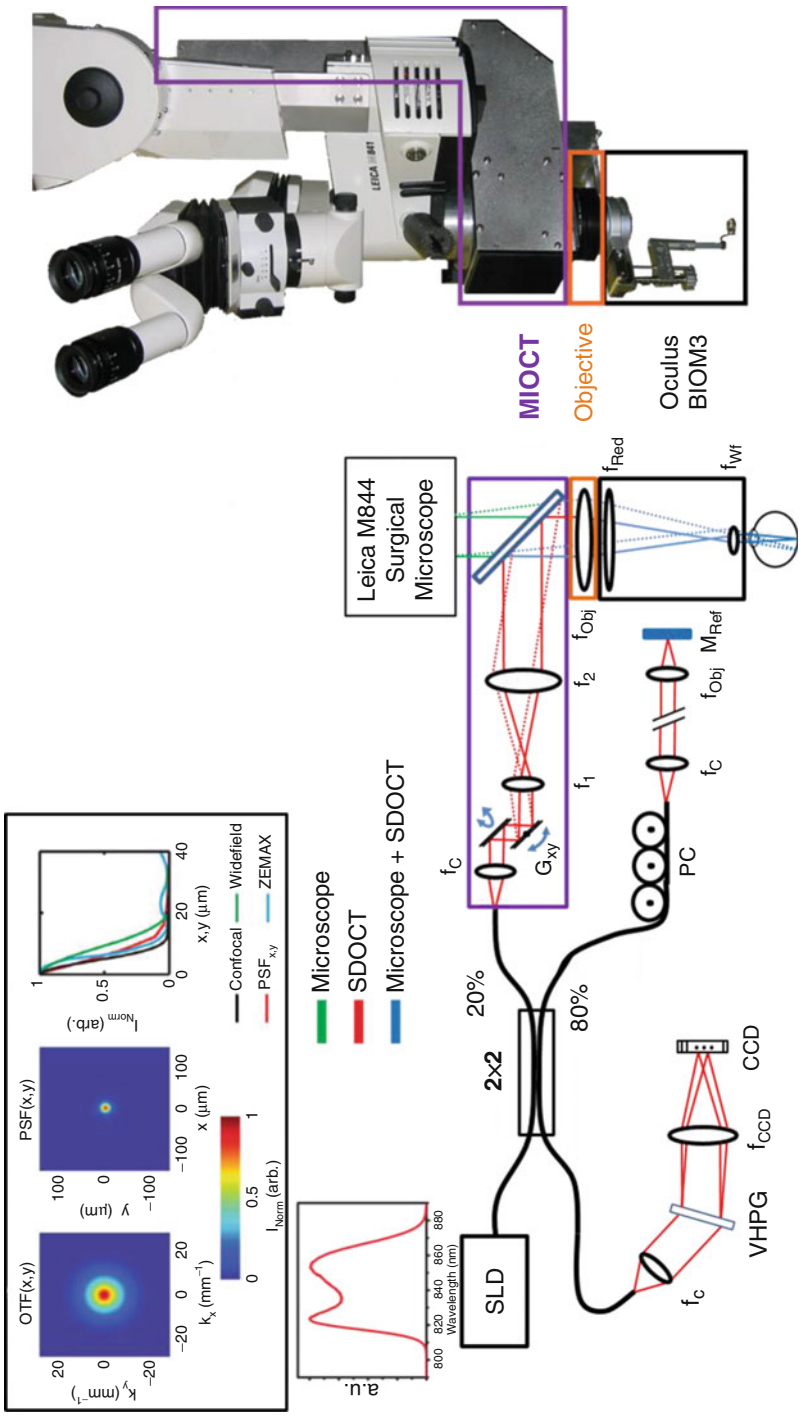

Fig. 58.5 The MIOCT system schematic (*left*) and microscope mounting (*right*) [43], as well as measured and simulated optical performance (inset) [34]

additional components in the infinity space does not alter the microscope resolution; however, care must be taken to avoid reducing the microscope field of view through vignetting, as well as to adjust the internal microscope illumination sources for extraocular and anterior segment work. The added height of the system (approximately 5 in. in the Duke system) can affect the posture of the surgeon and can be mitigated for shorter surgeons by using periscope oculars.

58.3.1 System Features for Managing the Challenging OR Environment

The Duke MIOCT scanner unit was designed as a surgical microscope accessory which is installed and aligned prior to surgery within approximately 10 min. The rest of the MIOCT system (the OCT "engine" and operating software) is a modified commercial spectral-domain OCT unit (from Bioptigen, Inc.) on a wheeled cart which is also brought into the operating room for MIOCT cases, similar to prior intraoperative OCT implementations [7]. All optical and electronic cabling between the OCT engine and the microscope-mounted scanner unit are suspended from the ceiling to avoid any tripping hazard.

Prior to use of the Duke MIOCT system in human surgical cases, extensive operating room evaluations were performed by having experienced anterior segment and retinal surgeons and surgical nurses interact with the MIOCT scanner unit in simulated surgeries. The participants were asked to evaluate how the scanner unit might interact with their normal surgical practices and maneuvers in a series of simulated tasks with defined evaluative assessments. The majority of responses identified no negative impact from having the device within their operating room environment. The overall impression was positive, and 100 % of surgeons and nurses reported that they would consider participating in human intraoperative MIOCT imaging trials [42]. Additional valuable feedback from these sessions, including recommendations on improved routing of the cables and rounding of the device edges, was also obtained to further improve the system.

58.3.2 Dynamic Navigation and Manual/Automated Tracking of Scanning Location

The principal advantage of microscope-integrated OCT scanning, in comparison to handheld systems described previously, is that microscope integration allows for the possibility of live image-based surgical guidance (as opposed to imaging during pauses in surgery). While current-generation clinical spectral-domain OCT systems routinely acquire B-scan images in real time, all available systems require at least several seconds for complete volume imaging of the macula. Even cutting-edge ultra-high speed swept-source OCT systems still cannot image the complete macula in real time in three dimensions with clinically acceptable optical power levels. A promising approach for matching the imaging rate capability of OCT with the

real-time needs of surgical guidance is to implement a feedback-controlled tracking system to align the position of the live OCT B-scan (or a limited set of B-scans which can be acquired quickly) with the position on the macula which is of most immediate interest to the surgeon, such as the tip of the surgical tool in use.

Intraoperative OCT tracking has been implemented on the Duke MIOCT system using both fully automated and semiautomated "manual" tracking approaches (Fig. 58.6) [47–50]. In both approaches, a copy of the video feed from the surgical camera was used as the source of feedback to locate the position of the surgical tool tip (or other feature of interest to the surgeon), in order to direct the OCT scan location to that vicinity. In the automated approach, custom image processing software was developed to automatically locate the tool position and orientation in the video stream. While successful in phantom studies, this software is not yet capable of handling the wide range of illumination conditions in live human surgery. As an interim step, a semiautomated "manual" version of tracking has been implemented which takes advantage of a human observer who can accommodate varying surgical conditions and can also react to instructions from the surgeon. In manual tracking with the Duke MIOCT system, the live surgical view is displayed on a separate tracking computer in custom software operated by a human operator who tracks the mouse cursor to the position of current surgical interest on the macula. The mouse position is translated to a pair-offset voltage signals that are summed with the fast voltage signals controlling the MIOCT lateral scan position. The manual tracking feature has been found to enhance ease of use of the Duke MIOCT system in live human surgery, by improving OCT image placement accuracy and speed of alignment. This capability has led to faster imaging sessions and visualization of instrument-tissue interaction, which was not possible in HHOCT implementations.

58.3.3 Scanning Orientation and Data Visualization

Since OCT volume datasets are acquired quickly in the B-scan direction, and then more slowly in the azimuthal direction, it can be important to choose the scanning direction based on prior knowledge of object motion in the scanning region. For intraoperative OCT imaging, there are many possibilities to orient scanning axes relative to tissue features and/or instrument position and trajectory. As an illustration, in Fig. 58.7, a series of OCT B-scans scans were taken both perpendicular and parallel to a common vitreoretinal surgical tool, the Tano Diamond Dusted Membrane Scraper™ [43]. These images were taken in cadaveric porcine eyes. The relative transmission and shadowing of the tool can be clearly seen, and the contact between the instrument and tissue can be examined easily. For tracking maneuvers, such an orthogonal scan pattern comprised of rapidly sequentially acquired orthogonal scans with their intersection locked to the tool position and their orientation matching the tool axis may be advantageous. Alternative patterns such as a fixed scan on morphologic features may also be desired.

In a busy operating room, the methodology used for displaying the MIOCT data to the surgeon may be nearly as important as the acquisition itself. With the

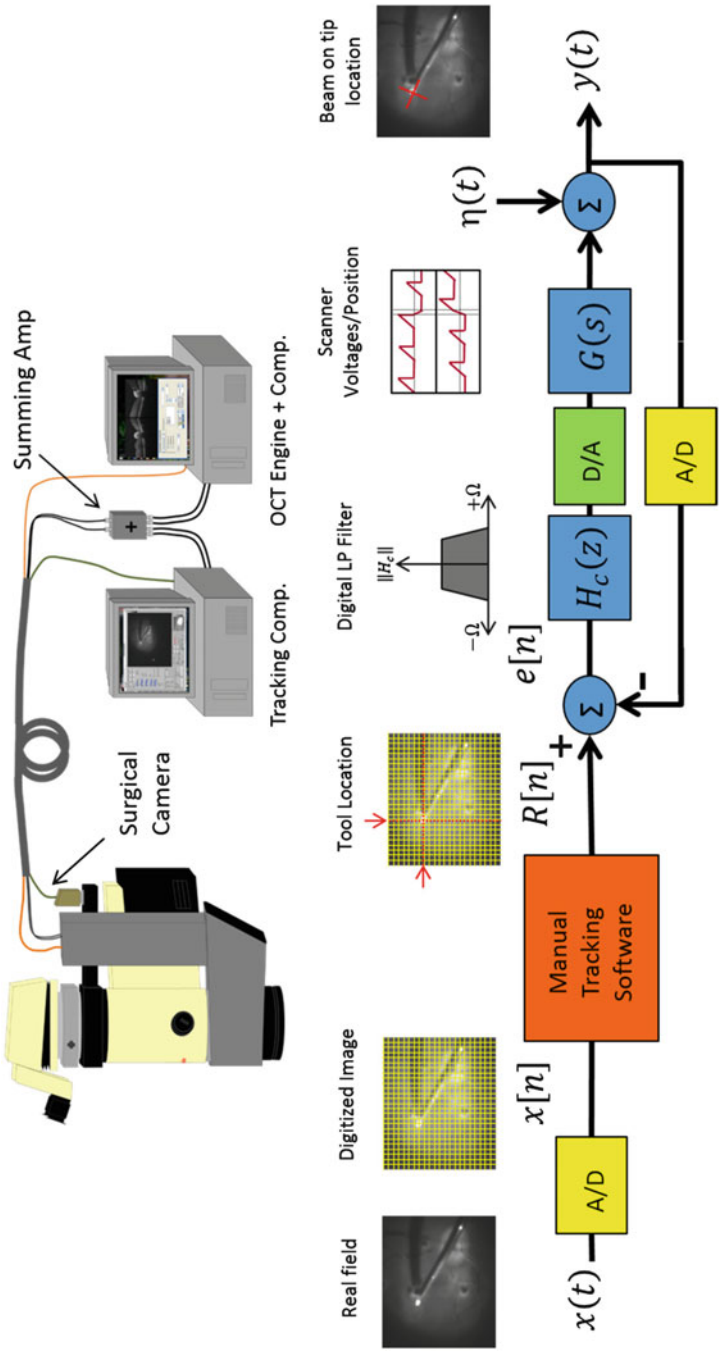

Fig. 58.6 The MIOCT tracking system being used in manual mode [50]. Hardware diagram of tracking and OCT computers (*above*), as well as the control system block diagram (*below*)

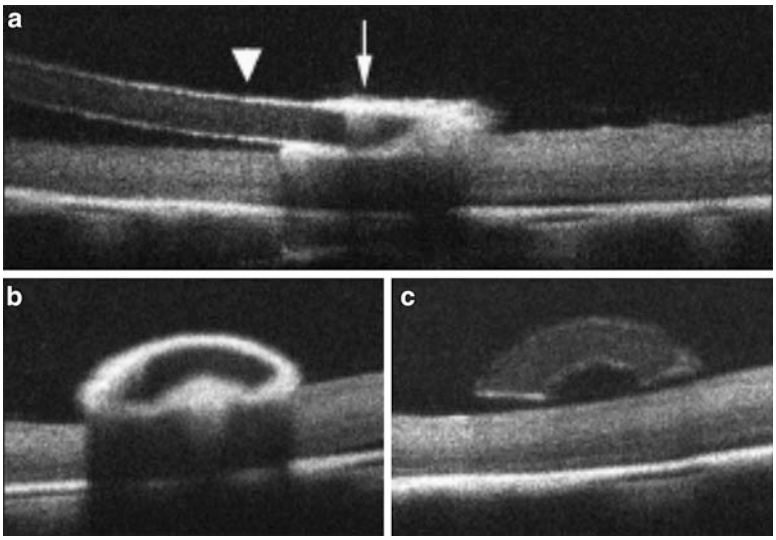

Fig. 58.7 Averaged B-scans of a surgical instrument in contact with a cadaveric porcine retina. (**a**) The view along the instrument axis. (**b**) and (**c**) are perpendicular views of the instrument from the locations at the diamond-dusted tool tip and along the instrument shaft, respectively. The highly scattering diamond-dusted section creates considerable shadowing over the retina, while the silicone shaft creates relatively little

emergence of GPU-based OCT data processing and image rendering [56], there are many options for displaying tomographic data designed to be intuitive to the user. In ultra-high-speed OCT systems (>100,000 A-scans per second) that can capture multiple volumes per second, displaying the entire dataset may be practical. For slower, current-generation systems, it may be better to display multiple registered B-scans in an isometric view. A conceptual example of this is shown in Fig. 58.8, reproduced from Hahn et al. [41], in which two orthogonal B-scans over a surgical tool are overlaid on top of an en face image and projected in a manner representing their relative directions. A likely future direction for MIOCT system development will be integration of such displays into potential "heads-up" displays which enable the surgeon to view live MIOCT image data without removing his or her eyes from the microscope.

58.4 Duke MIOCT Imaging Results

The Duke MIOCT system has been used extensively in human patient studies for both posterior segment (vitreoretinal) and anterior segment (corneal) procedures. In this section, we will review some of the findings that have been reported from studies involving the system at Duke University.

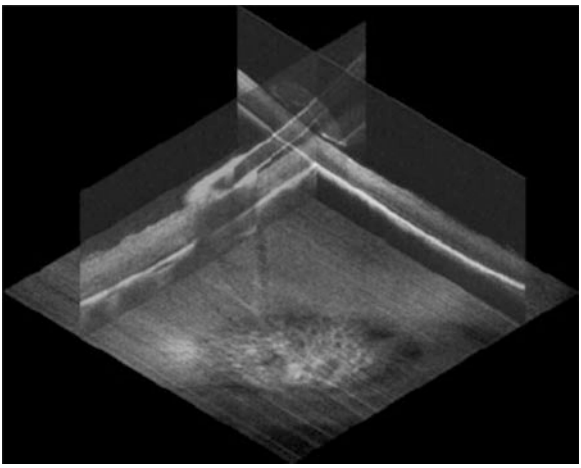

Fig. 58.8 A conceptual live orthogonal B-scan pattern visualization of a surgical instrument intersecting the macula suitable for a potential "heads-up" display [41]

58.4.1 Duke MIOCT Results in Vitreoretinal Procedures

Many vitreoretinal surgical procedures involve the removal of a membrane, such as an epiretinal membrane (ERM) or internal limiting membrane (ILM). These membranes are often difficult to visualize en face, and the surgeon typically uses stains for improved visualization. OCT imaging can often provide improved identification of these membranes, and an early goal for our studies was therefore to use OCT imaging to examine the retina immediately before and after membrane removal. In Fig. 58.9, OCT images taken shortly before and after membrane removal confirm the absence of the membrane following membrane peel.

Another example of verification of postoperative changes in retinal morphology is seen in Fig. 58.10 from Hahn et al. [42]. The patient received surgery to repair a full-thickness macular hole, which is caused by traction along the internal limiting membrane. The image following ILM peel suggests that the tissue near the hole is more relaxed than prior to peeling and therefore that removing the membrane has eased the traction. Remnants of the edge of the uplifted membrane (asterisks), small intraretinal cysts (arrowheads), as well as some subretinal fluid (arrow) are clearly visible. These features would likely not be visible in the en face surgical view and would likely not be present in follow-up imaging of the patient in the days following the procedure.

These data from human vitreoretinal cases demonstrate the ability of MIOCT to take evaluative images of the target tissue at pauses in the surgery and definitively identify changes that would not otherwise be detected. This is very similar to what has already been achieved using HHOCT probes in surgery. The acquisitions, however, were taken with the surgical microscope still in place over the patient creating little delay in the surgical procedure. Also, it allows for the visualization of tools undergoing surgical maneuvers, which will be discussed in Sect. 58.4.1.3.

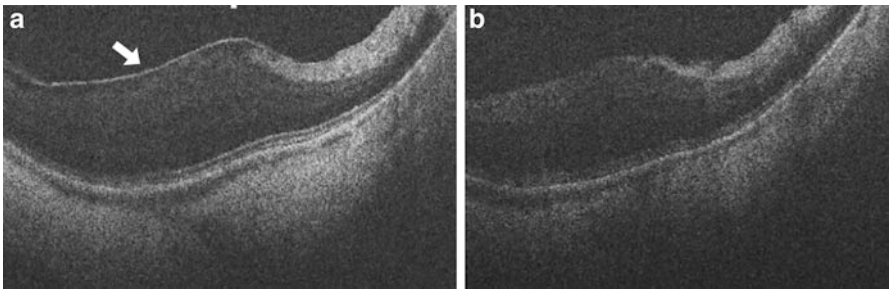

Fig. 58.9 Single B-scans showing a cross section of a diseased retinal directly prior to (**a**) and after (**b**) epiretinal membrane removal [50]. The membrane which is a *bright line* on the surface of the retina (*arrow*) in (**a**) is clearly absent in (**b**)

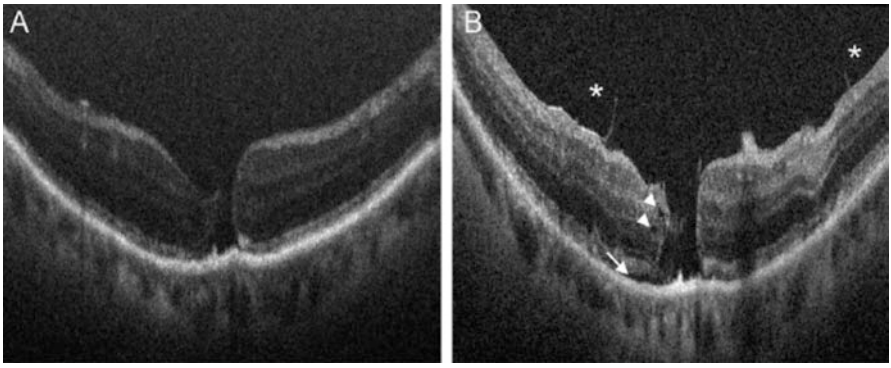

Fig. 58.10 A comparison of averaged B-scan images of the foveal region for a patient undergoing surgery to repair a full-thickness macular hole [42]. The internal limiting membrane was removed to reduce traction in the macula. As compared to the preoperative image in (**a**), the retinal tissue postoperatively in (**b**) appears more relaxed and corrugated, suggesting a reduction of traction. Remnants of uplifted ILM tissue (*asterisks*) as well as intraretinal cysts (*arrowheads*) and mild subretinal fluid (*arrow*) are clearly visible in (**b**) which was taken within minutes of the membrane peel

58.4.2 Duke MIOCT Results in Anterior Segment Procedures

The Duke MIOCT system has also been used to evaluate the state of the cornea in anterior segment procedures such as cataract extraction and DSEK [47]. In cataract surgery, the main incision near the corneal limbus is the entry point for tools to access the anterior chamber and to remove the natural, opacified crystalline lens. The incision does not normally require suturing at the conclusion of the surgery, but a hydration step does ensure the initial closure that then heals during the days following the surgery.

Intraoperative monitoring of the corneal incision at the conclusion of cataract extraction showed initial gaping of the incision which closes with stromal hydration, as illustrated in Fig. 58.11 [47]. Such direct confirmation of wound closure

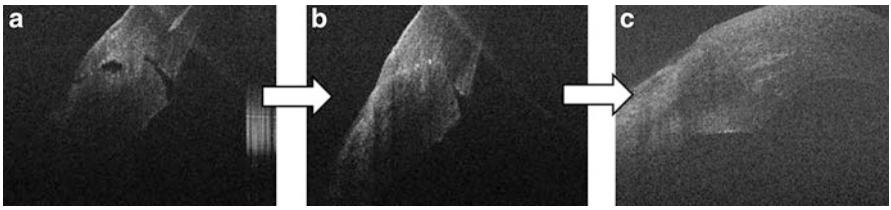

Fig. 58.11 Single B-scan views of the corneal incision wound at the end of cataract surgery before (**a**) and then after (**b**) the hydration closure step and 1 day following the surgery (**c**) [47]

could ensure wound security at the conclusion of the case. The first postoperative visit is typically a day later, and an inadvertently insecure wound could result in devastating introduction of pathological organisms into the eye. In successive cross-sectional B-scans shown in Fig. 58.11, wound opening was initially observed to be gaping (A), then closed by hydration (B), and then remaining closed in follow-up imaging one day after the procedure (C). The follow-up image was taken with a conventional tabletop SDOCT scanner in the clinic.

Dynamic MIOCT imaging of the keratome creating a corneal limbal incision was observed, as shown in Fig. 58.12. In the first frame during insertion (on the *left*), the tool has fully cut through the cornea and in subsequent frames is pushed farther into the anterior chamber. In frames depicting tool removal (on the *right*), the tool is shown backing out of the tissue. The last frame shows the status of the wound immediately after the blade is removed, with the wound mostly closed and some stromal disruption visible, appearing as lengthwise bright streaks that straddle the wound.

MIOCT has been used to monitor graft adherence in DSEK procedures, as illustrated in Fig. 58.13. Here, B-scan images were taken of the patient immediately following the implantation of the donor graft with a supporting air bubble in the anterior chamber. The donor graft was observed to be close to the host cornea, but residual interface fluid was clearly visible. Failure to address this gap intraoperatively would likely result in postoperative graft detachment and additional surgery. A few minutes after the injection of the full air tamponade and additional mechanical maneuvers, MIOCT revealed good apposition of the donor graft and host cornea across the entirety of the visible region.

58.4.3 Visualizing Surgical Tools Inside the Eye

The MIOCT system has clear advantages over intraoperative HHOCT in that it may be used to capture tomograms while surgical tools are maneuvering within the eye. Figure 58.14 shows an en face projection of OCT data captured while a pair of surgical forceps were inside the eye in the mid-vitreous cavity and out of axial range of the OCT B-scans [57]. The effect of the tool shadowing is clear in the representative B-scans which are also shown. This was the first published example of OCT imaging of tools in the eye during human vitreoretinal surgery.

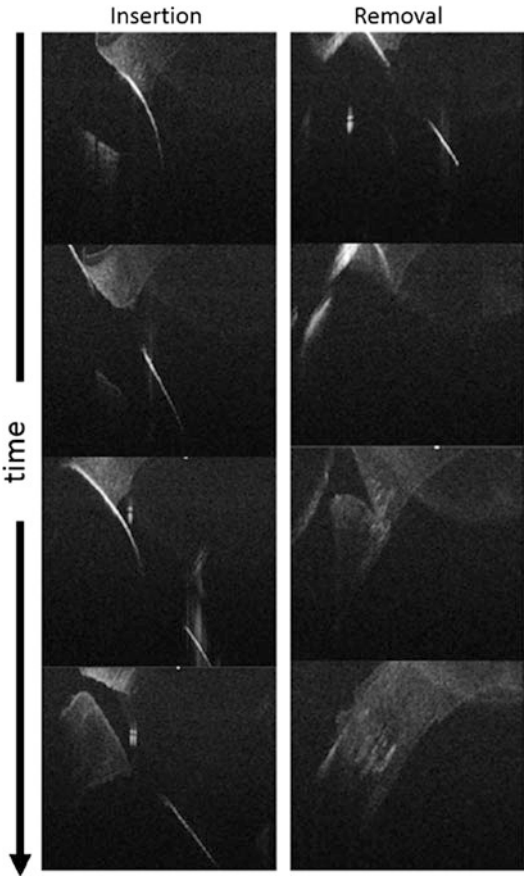

Fig. 58.12 B-scan sequence of corneal incision blade making a cut through the cornea

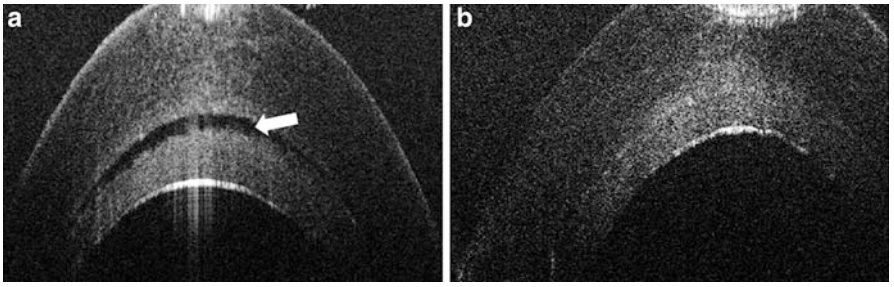

Fig. 58.13 Cross-sectional (single-frame) B-scan of the cornea, showing (**a**) interface fluid (*white arrow*) between the DSEK graft (inferior) and host cornea (superior) and (**b**) successful attachment of the graft to the host cornea [47]

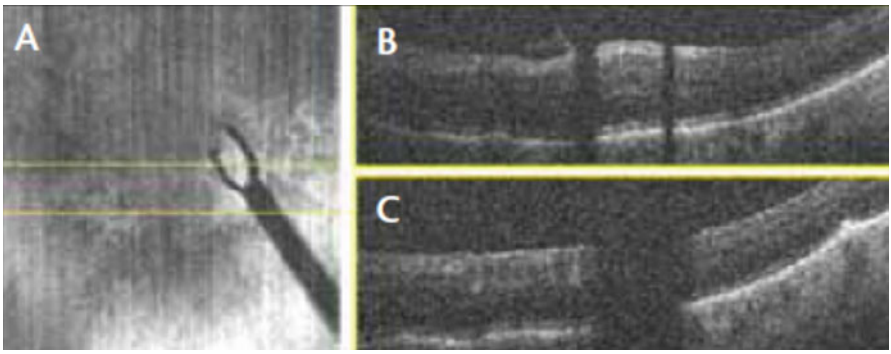

Fig. 58.14 OCT images taken while surgical instruments present in the vitreous cavity [57]. (**a**) A surface volume projection of forceps overlying a human retina and suspended safely in the mid-vitreous cavity. Complete shadowing under the metallic instrument is visible in the corresponding B-scans (**b–c**) at the positions indicated by the *green* and *orange lines* in (**a**)

OCT imaging of tool manipulation of cadaveric porcine model eyes has also been extensively documented by Hahn et al. [41], in which real-time MIOCT imaging of both forceps and membrane scraping tools were presented. The most dramatic of these are shown in Fig. 58.15, in which multiple frames of a linear B-scan sequence are shown. The porcine retina was being brushed by a Tano Diamond Dusted Membrane Scraper™ (Synergetics, O'Fallon, Missouri, USA) instrument from left to right. The sequence in the left column shows an aggressive scrape in which significant deflection of the retinal tissue is obvious. The right column shows a milder brushing motion in which little deflection can be noticed.

58.4.4 Visualizing Tools Despite Artifacts

Another significant advantage of MIOCT over HHOCT is the ability to visualize surgical tools manipulating target tissue. Ehlers et al. have extensively cataloged the appearance of various common vitreoretinal tools as imaged by the MIOCT in cadaveric porcine eyes [36]. OCT images that have tools visible in the frame show evidence of artifacts, either full shadowing (blockage), as can be seen in Figs. 58.14 and 58.15, or distortion of the tissue directly underneath the tool as in Fig. 58.15. Some imaging sessions revealed complex-conjugate reflections that, if misinterpreted, could mislead the surgeon as to the tool's actual location with respect to the tissue.

The distortion of tissue directly beneath a transparent tool or tool portion, such as the silicone shaft of the Tano Diamond Dusted Membrane Scraper™, is subtle but can also cause misinterpretation of the image. This is caused by the small difference in refractive index of the fluid in the ocular cavity and the tool body. Since the axial position of a surface in an OCT tomogram is dependent upon the total optical path

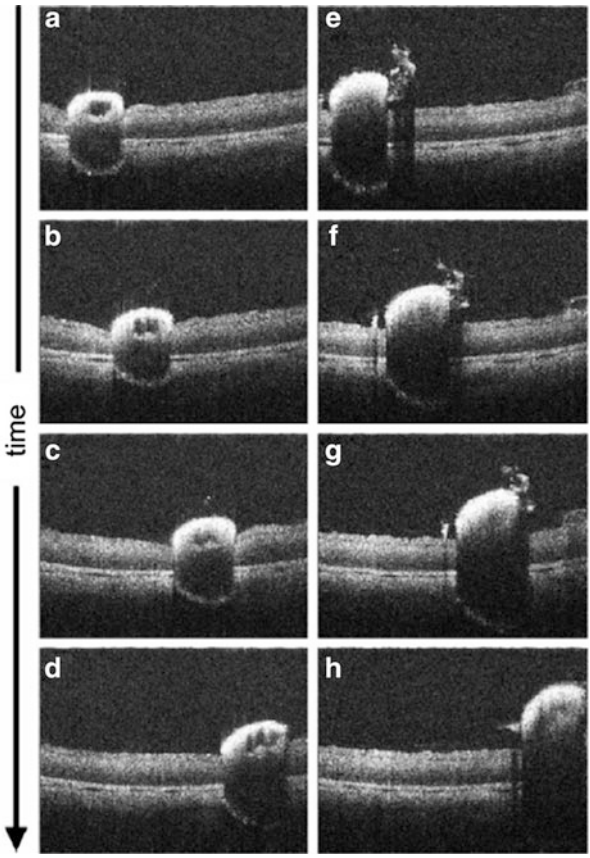

Fig. 58.15 B-scan sequence of the diamond-dusted scraper brushing along a cadaveric porcine retina [41]. (**a**–**d**) show the first example of an aggressive scrape. (**e**–**h**) show a second, milder scraping motion

length of material before it, the appearance of tissues underneath tools could potentially appear deeper than they actually are. As MIOCT becomes increasingly accepted, it is possible that new surgical tools may be specifically designed to minimize such imaging artifacts and to enhance the visibility of tools on OCT images which could also make them easier to track using automated methods.

58.5 Conclusions

Intraoperative ophthalmic OCT is still a relatively new field and several clinical trials are ongoing. Despite this early stage, very exciting results have emerged from research groups using OCT systems in human surgeries. In this chapter, we have reviewed the state of the art of handheld, microscope-integrated, and forward-imaging endoscopic OCT systems that have been used in ophthalmic procedures as well as the design considerations and relevant clinical results of the Duke MIOCT system.

Commercially available HHOCT systems have thus far been the most used in ophthalmic surgeries, while the forward-imaging probes have yet to be used in human subjects. Still, the HHOCT approach has only been adopted by a handful of researchers. It is likely that the other approaches, MIOCT and forward-imaging endoscopic probe OCT, will gain widespread adoption, as they can potentially be used with less interruption of normal surgical practice.

These intraoperative OCT techniques open new opportunities for surgeons to attain enhanced, depth-resolved, real-time visualization of surgery. Increased precision of instrument placement and immediate monitoring of anatomical changes to tissue may lead to better patient outcomes and enable new, more ambitious surgical interventions.

59.1 Introduction

This is a review of a technique for high-resolution imaging of the eye that allows multiple sample sectioning perspectives with different axial resolutions. The technique involves the flying spot approach employed in confocal scanning laser ophthalmoscopy which is extended to OCT imaging via time domain en face fast lateral scanning. The ability of imaging with multiple axial resolutions stimulated the development of the dual en face OCT–confocal imaging technology. Dual imaging also allows various other imaging combinations, such as OCT with confocal microscopy for imaging the eye anterior segment and OCT with fluorescence angiography imaging.

59.2 Different Scanning Procedures

Flying spot imaging systems employ two devices that can scan the target in two mutually orthogonal directions, one axially, the other transversally. Different orientations of the image sectioning plane are possible, depending on the order which

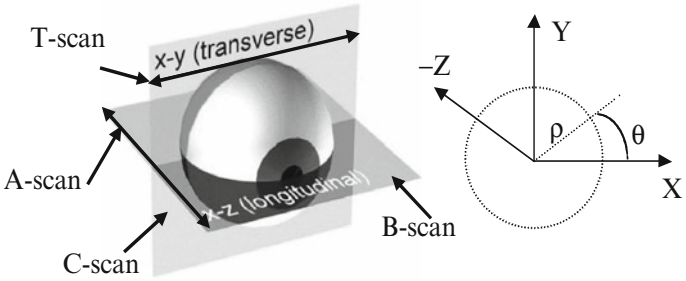

Fig. 59.1 Relative orientation of the axial scan (A-scan), en face scan (T-scan), longitudinal section (B-scan), and en face or transverse section (C-scan) (Reproduced with OSA's permission from [1] and copyright M. Seeger [2])

these devices are operated, scanning rates and the line scan orientation in the raster. The scanning terminology [1, 2] is illustrated in Fig. 59.1.

59.2.1 Flying Spot En Face (T-Scan) OCT

The differences between the longitudinal or axial priority scanning and en face or transverse priority scanning are presented below.

59.2.1.1 A-Scan-Based B-Scan

B-scan OCT images, as the first OCT image generated [3], are analogous to ultrasound B-scans and are obtained by collecting A-scans (Fig. 59.1) at adjacent transverse positions, as shown in Fig. 59.2 (top). The A-scans are one-dimensional sample reflectivity profiles acquired along the depth direction. The transverse scanning is performed in a transverse direction orthogonal to the axial direction (along the X or Y directions or can follow a circular pattern at constant radius ρ in polar coordinates in Fig. 59.1) at a slower pace than A-scanning as illustrated in Fig. 59.2 (top). The majority of reports on time domain OCT [4] in literature refer to this method of operation.

59.2.1.2 T-Scan-Based B-Scan

In this case, the transverse scanners sample the target at a fast rate [5, 6], and each line in the raster is a reflectivity profile in the lateral direction (T-scan) at a given depth in the sample as shown in Fig. 59.2 (middle). Transverse scanning can be performed either parallel to the X- or Y-axes, radially (at a given value of the polar angle θ) or circularly (at a given polar radius ρ). During acquisition of one T-scan, the position of the axial scanner is fixed. The example in Fig. 59.2 (middle) illustrates the generation of a B-scan from adjacent T-scans. In this particular example, the T-scans are parallel to the X-axis, while the axial scanner advances at a slower rate in depth, along the Z-axis.

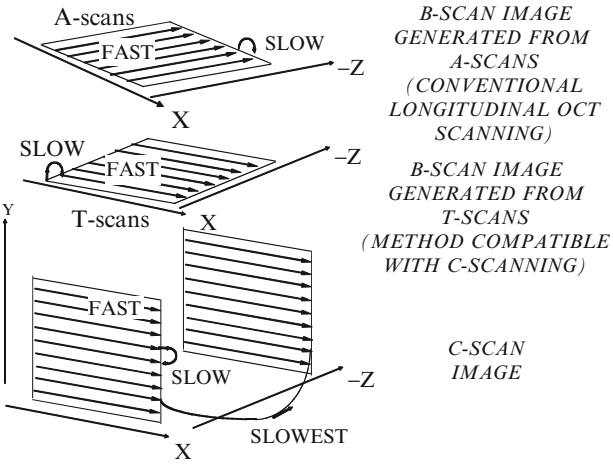

Fig. 59.2 Different modes of operation of the three scanners in a flying spot OCT system. (Reproduced with permission from OSA [19])

59.2.1.3 C-Scan

The OCT T-scanning procedure has a net advantage over OCT A-scanning as it also allows acquisition of C-scans, i.e., of transverse or en face OCT images at a given depth determined by the length of the reference path as illustrated in Fig. 59.2 (bottom). C-scans are transversal sections of the sample made from T-scans, usually performed along the X- or Y-axes, repeated at adjacent locations along the other orthogonal transverse direction (Y, X). The repetition of T-scans along the other transverse coordinate is performed at a slower rate (frame rate) as shown in Fig. 59.2 (bottom). C-scans can be acquired at successive axial positions, either by advancing the optical path difference in the OCT in steps after each complete transverse (XY) scan or continuously at a much slower speed than the frame rate. Such images can be created based on the path modulation introduced by the transversal scanners, as explained above, or by using a phase modulator or a frequency shifter. A fast en face OCT method (T-scan-based OCT method) was reported [7] using a stable high-frequency carrier (40 MHz) generated by use of an acousto-optic modulator and a resonant scanning mirror (4 kHz) for the priority scan (x-direction).

Using a spectral scanning delay line for depth scanning [8], capable of scanning in depth at the same rate as that of transversal scanning, a multimode OCT imaging system was demonstrated [9], capable of producing depth B(A) or en face B(T) cross-sectional images, as well as en face constant depth (C-scan) images. The time required to switch from one regime to the other is limited by the time required to operate the control software. Safety level calculations for maximum optical power allowed to the eye, in retinal imaging, showed that T-scan-based imaging, for lateral sizes larger than 100 pixels, allows at least 4 times more power to be delivered into the eye than in B(A) scan. Here the lateral pixel size is considered

as 10–15 μm. For larger image size, of 500 pixels, even more power could be used in T-scan regime than in the A-scan regime to generate B-scans. This has immediate consequences in terms of signal-to-noise ratio.

59.3 Simultaneous En Face OCT and Confocal Imaging

As T-scans are instrumental in generating both time domain en face OCT scans and confocal images, there are similarities and complementarities between the two imaging principles when applied to imaging the eye:

1. En face OCT images (Fig. 59.1) have the same orientation as standard fundus photographs [10] or confocal scanning laser ophthalmoscopy (SLO) images.
2. In both en face OCT and SLO, the depth scanning (optical path change in case of the OCT and focus change in case of the SLO) is much slower than the T-scan rate (performed at the frame rate).
3. The depth resolution in an SLO is limited by the eye aberrations, while the transversal resolution in OCT is affected by random interference effects from different scattering centers (speckle). Therefore there may be some compensating advantages to combining SLO with OCT technology for retinal imaging.
4. The higher depth resolution of OCT C-scan images tends to make structures in the retina appear more fragmented. In a single C-scan image, tissue features may also appear distorted by tilt making interpretation somehow difficult. However, ophthalmologists have extensive experience with the en face perspective of ocular disease as seen in the SLO images. In order to take advantage of their familiarity with the SLO imaging perspective in the interpretation of the OCT transversal images, it is useful to acquire and display pairs of OCT C-scans and SLO images simultaneously. High-quality SLO images can be used as reference for interpreting retinal C-scan OCT data. Additionally, the integration of confocal imaging in an OCT instrument facilitates the targeting of B-scan OCT acquisition which otherwise would require auxiliary imaging equipment to select the lateral location in the retina to be subsequently imaged with OCT.

59.3.1 OCT/SLO

The combination of confocal imaging and interferometry has already been discussed in microscopy [11], and a comparison between confocal and OCT imaging through scattering media has also been reported [12]. However, (i) the object here is the tissue, which imposes a safety power limit and requires special interface optics, and (ii) the same low coherence source is used for both confocal and interferometer channels with implications in terms of the obtainable signal-to-noise ratio.

A possible configuration combining OCT with confocal microscopy for the eye [13, 14] is shown in Fig. 59.3. Light from a pigtailed superluminescent diode, SLD, is injected into a single-mode directional coupler, DC1. Light in the object arm

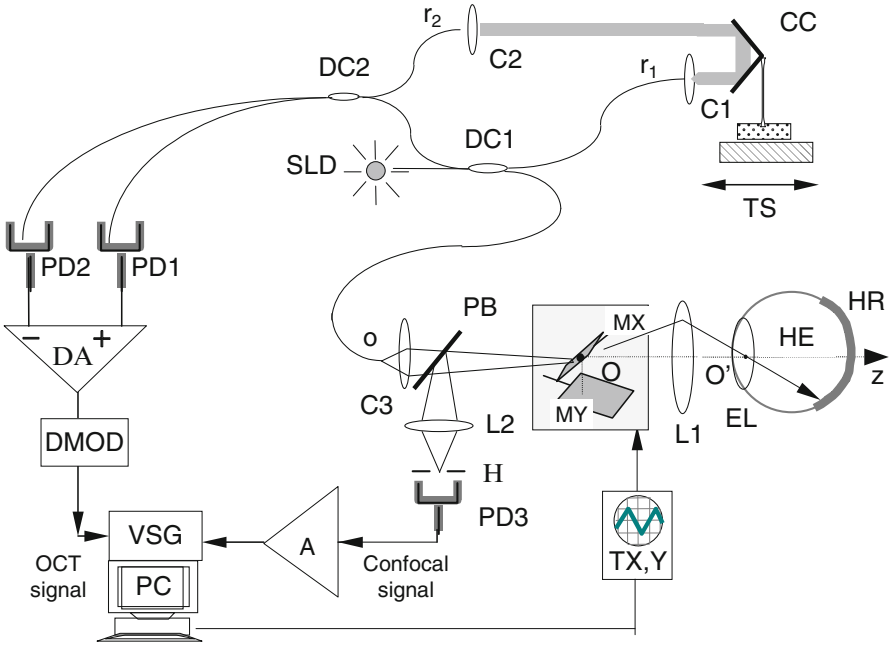

Fig. 59.3 Detailed schematic diagram of the time domain OCT/SLO apparatus using a plate beam splitter to divert light to a confocal receiver. *SLD* superluminescent diode; *C1, C2, C3* microscope objectives; *DC1, DC2* directional couplers; *TS* computer-controlled translation stage; *CC* corner cube; *M1, M2* mirrors; *MX, MY* orthogonal axes galvanometer mirrors; *TX(Y)* ramp generators; *DMOD* demodulation block; *L1* convergent lens; *PD1, PD2* photodetectors; *DA* differential amplifier; *PD3 and A* photodetector and amplifier, respectively, for the confocal receiver; *H* pinhole; *PB* plate beam splitter; *HE* patient's eye; *EL* eye lens; *HR* human retina; *PC* personal computer; *VSG* dual-input variable scan frame grabber (Reproduced by permission of the Institution of Engineering and Technology from [13])

propagates via the microscope objective C3 and plate beam splitter PB to a scanning mirror pair, MX, MY. A lens L1 images the galvanometer scanner aperture onto the eye pupil, EL. The reference beam is directed via microscope objectives C1 and C2 and a corner cube CC to a coupler DC2. The corner cube CC is mounted on a computer-controlled translation stage, TS, used to perform axial scanning. The light back reflected from the retina and transferred via couplers DC1 to DC2 interferes with the reference signal in the coupler DC2. Two silicon pin photodiodes, PD1 and PD2, in a balanced [15] configuration are used to detect the OCT signal, which is then demodulated by the demodulator block, DMOD, whose output is connected to the OCT channel input of the dual input variable scan frame grabber, VSG, controlled by a personal computer, PC.

A separate confocal receiver is built [16]. This consists of a plate beam splitter, PB, which reflects a fraction of the light backscattered by the retina via a focusing lens, L2, and a pinhole, H, to an avalanche photodiode, PD3, whose output is connected to the SLO channel input of VSG.

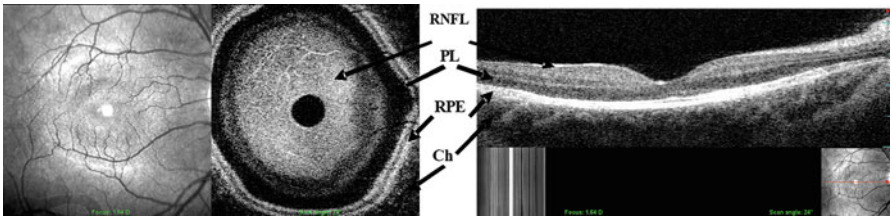

Fig. 59.4 Retinal images acquired with the OCT/confocal system. *Left*: C-scan regime with SLO image left and the OCT image right, collected at the level of the retinal nerve fiber layer, RNFL (which appears as a bright doughnut-shaped region in the center of the image); PL (*dark*): photoreceptor layer; RPE (*bright*): retinal pigment epithelium; Ch (*bright*): choroid. *Right*: B-scan regime with confocal images below, (*left*: simultaneous with the B-scanning and *right*: immediately preceding the B-scan acquisition). Lateral size in all images: 25°; in the B-scan regime image on the right, vertical size in the B-scan OCT image is 2 mm depth measured in air, while in the SLO image left bottom, it corresponds to the acquisition time of the B-scan OCT image, 0.5 s. The lateral variations of the shades in the SLO image indicate lateral movements of the eye during the acquisition. The retinal layers are clearly discernible in the OCT image and bears strong resemblance to histology [54]. (Republished with permission from Springer Science+Business Media, [55])

Ramp generators TX,Y drive the galvanometer scanner mirrors MX and MY and also trigger signal acquisition by the frame grabber.

Retinal images of a healthy eye, provided by the system described above, operating in the B- and C-scan regimes of operation, are shown in Fig. 59.4. In the left, images in the C-scan regime are shown, while in the right, images obtained in the B-scan regime.

59.3.2 En Face Scanning Allows High Transversal Resolution

Due to T-scanning, the B-scan time domain OCT images acquired with the en face method are continuous along the line in the raster, which improves their quality. This is not the case with standard OCT B-scan OCT images generated using fast axial scanning, where the lateral scanning is discrete. Since the scanning direction parallels the anatomic fabric of the retina, connected structures or associations between scattering points in the transverse section are better conserved by transverse scanning. This ultimately ensures the visualization of small lesions above, within, or beneath the retina which might otherwise be chopped up and lost in the reconstruction of the image based on depth priority scanning OCT.

59.3.3 Synergy Between the Channels

The confocal image with its pixel-to-pixel correspondence to the C-scan OCT holds additional value for data acquisition. For small movements, the confocal image can

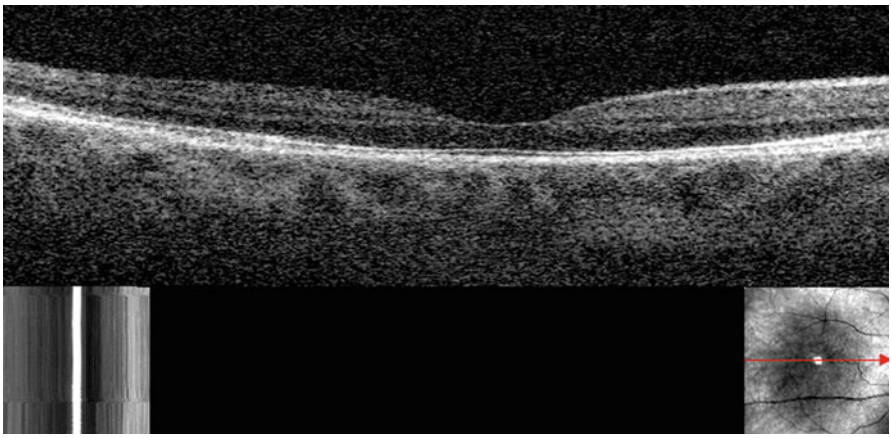

Fig. 59.5 B-scan section of the retina appears slightly elongated due to mild lateral eye movement during the scan. The SLO image in the *lower left* corner shows laterally displaced *vertical* trace pattern due to lateral eye movement during B-scan acquisition. The *lower right* image was collected in the C-scanning regime immediately before initiating the B-scan capture. (Republished with permission from Springer Science+Business Media, [55])

be used to track lateral eye movements between frames and for subsequent transversal alignment of OCT images in a stack of C-scans collected from different depths. In cases of large saccadic eye movements and blinks, the confocal image gives a clear indication of the OCT frames which need to be eliminated from a collected stack. The first artifact-free confocal image in the stack is used as a reference for the aligning procedure.

The SLO image acquired in the B-scanning regime has the appearance of a pattern of parallel vertical traces. Each horizontal line in this image corresponds to a depth position in the OCT B-scan. Lateral eye motion during B-scan acquisition causes lateral deviations of the vertical trace pattern in the SLO image. For example, in Fig. 59.4 right and Fig. 59.5, movements of the eye are indicated by lateral shifts of the traces in the SLO image (lower left box), while the system operates in the B-scan regime. The recorded deviations in the vertical trace pattern in the SLO image can easily be utilized to correct the lateral shift of the lines in the B-scan OCT image (above).

59.3.4 3D Imaging

3D imaging of the retina using SLO [17] is already common in clinical applications. En face sections collected from different depths [18] can be used to construct a 3D profile of the retina which can subsequently aid ophthalmologists in their clinical evaluations. In the same way, an OCT/confocal system can be used for 3D retinal imaging, however, with en face sections as thin as allowed by the source spectral

width. To collect the reflectivity distribution from a volume in the retina, the OCT/confocal system is operated in the C-scan regime collecting en face images at different depths. Ideally, the depth interval between successive frames should be much smaller than the system axial resolution, and the depth change applied only after the entire C-scan image was collected. However, in practice, to speed up the acquisition, the translation stage in Fig. 59.3 is moved continuously, and the depth interval is set slightly larger than the OCT depth resolution [19]. For instance, using 20 μm axial separation between successive OCT C-scans, 60 frames of image pairs from a volume corresponding to a total depth of 1.2 mm in air (sufficient to cover in the axial direction the optic nerve region in the retina) can be acquired in 30 s when operating at 2 Hz frame rate. After acquisition, the images can be aligned transversally using the first confocal image (or the first motion artifact-free confocal image), and the stack of OCT C-scans can be used to construct a 3D OCT volume of the retina [20]. 3D retinal OCT imaging is more convenient than aligning individual OCT C-scans acquired at different depths.

59.3.5 Topography

Topography of the fundus is difficult to perform using A-scan-based B-scans since it requires interpolation in the en face plan [21]. Topographic maps are normally presented from an en face perspective which suggests that stacks of C-scan OCT images could be a natural choice for topography. This procedure was demonstrated in a previous report [22]. Based on en face OCT, topography rendering should be similar to the method using a confocal SLO [23]. Topography of a normal macula is shown in Fig. 59.6 obtained using en face OCT.

59.3.6 New Challenges

New imaging technology brings new perspectives to the clinician, but also brings the requirement for new interpretations of imaging data. En face OCT is no exception to this rule. The higher depth resolution of OCT has the effect of fragmenting the C-scan OCT image [24] in comparison to a SLO image. As the imaging proceeds at a few frames a second, the inherent eye movements may result in significant changes in the size of fragments sampled from the tissue. The fragmentation is especially visible when imaging tissue tilted with respect to the system optical axis. The image on the right in Fig. 59.7 shows the challenges in interpreting and using en face OCT images. First, it is composed of structural features which are discontinuous and unfamiliar in shape.

Second, variations in tissue inclination with respect to the coherence wave surface alter the sampling of structures within the depth in the retina [25], producing novel section orientations with little resemblance to the ophthalmoscopic appearance of the fundus. The bright patches in the OCT image represent the intersection of the surface of optical path difference (OPD) = 0 with the tissue. Due to the

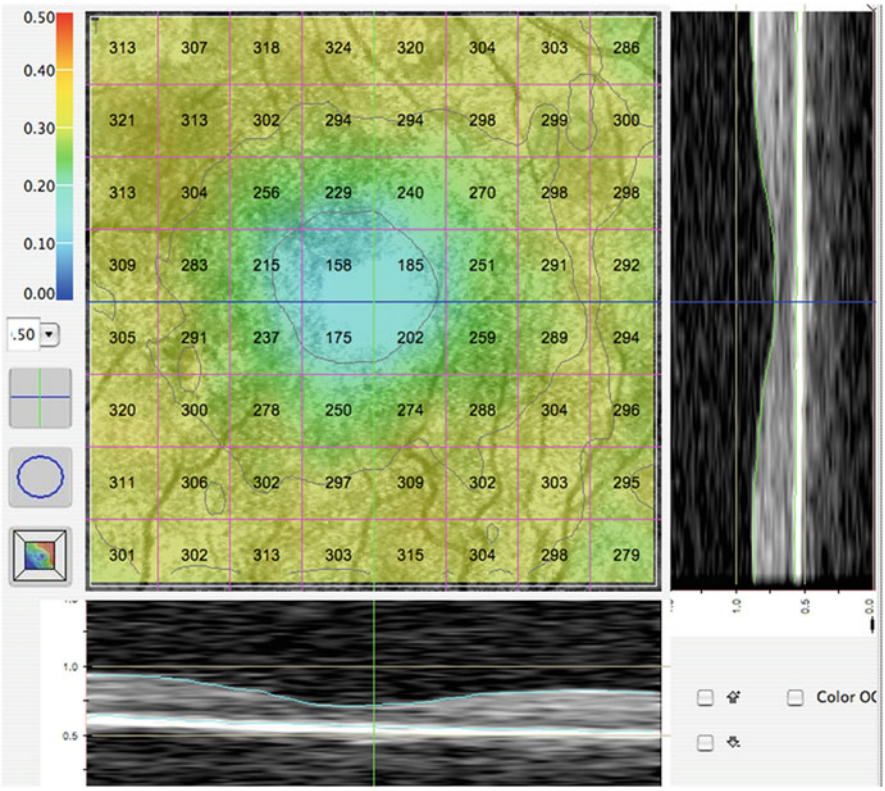

Fig. 59.6 Topographic map of a normal macula. 200 C-scans are aligned according to the vascular pattern with a grid showing the average thickness within each box superimposed on the SLO image. The B-scans below and on the *right side* of the map are reconstructed from the C-scan stack. Their lateral location is indicated by the *green* vertical and aqua horizontal cursors seen on the map. (Republished with permission from Springer Science+Business Media, [55])

specific way in which the retina is scanned, with the fan of rays converging onto the eye pupil, the surface of OPD = 0 is an arc circle with the center at the eye pupil. When we explore the depth, we practically change the radius of the arc. If the arc has a small radius, it may just only intersect the top of the optic nerve or the fovea with the rest of the arc in the aqueous/vitreous. The radius of the arc is increased by extending the length of the reference arm of the interferometer to explore the retina down to the level of the RPE and choroid. The orientation of the retinal tissue at the back of the eye is not perfectly circular, and this complicates the interpretation of the image even further.

Another confounding phenomenon noted is that despite the en face scanning orientation, tilting movements of the eye result in images which display several depths within a single section and may appear like a longitudinal OCT image. These two effects, (i) fragmentation and (ii) depth structures displayed in the C-scan images, are present in a confocal SLO with high depth resolution as well,

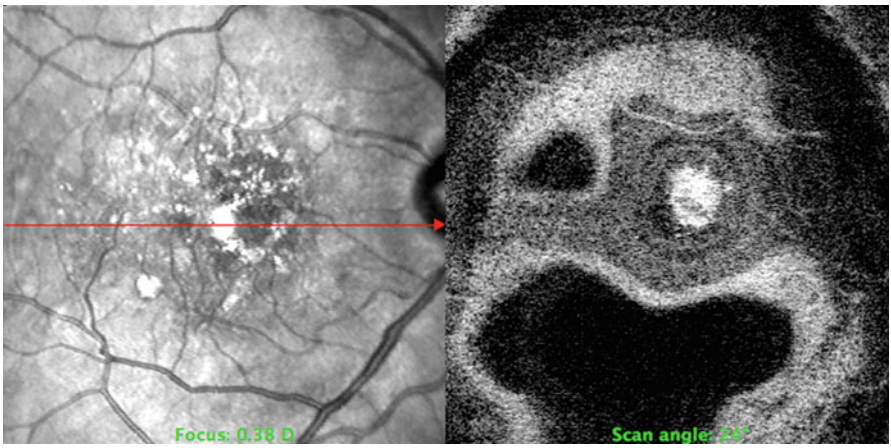

Fig. 59.7 Age-related macular degeneration with drusen and a choroidal neovascular membrane. The SLO image on the *left* demonstrates the superficial appearance lines of pigmentary change and scattered drusen. The OCT C-scan on the *right* demonstrates a tilting of the eye upward so that the image of the vitreous in the lower part of the image appears as a *black* chef's hat surrounded by the highly reflective nerve fiber layer which appears *white*. Beneath the macular drusen lies a serous detachment surrounding a highly reflective white choroidal membrane. (Republished with permission from Springer Science+Business Media, [55])

however, at a scale where they are regularly discarded. In a confocal SLO, the images do not look fragmented, and the depth structure is barely visible due to the coarse depth resolution, ~0.3 mm, comparable to the retinal thickness. Going in and out of focus results in a smooth transition from dark to bright areas in the image. Both problems mentioned above are brought about by the high depth resolution of OCT. We address the fragmentation problem by providing the confocal image, which guides the user, and by collecting many en face images at different depths and subsequently building the 3D profile. The other problem that the en face imaging may also display the depth structure requires further development of the interpretation process.

59.3.7 Clinical Use of the OCT/Ophthalmoscope: Pattern Recognition

Several prototypes of OCT/SLO systems were used to study a variety of clinic pathologies [26] including age-related macular degeneration, central serous retinopathy, macular hole, macular pucker, cystoid macular edema, diabetic maculopathy, and macular trauma. Specific recognizable patterns [27] in the en face OCT images were identified which correlate to a variety of anatomic disease entities. The dual display is particularly helpful to the clinician in correlating the deeper morphology to the surface appearance and facilitating interpretation of the often challenging new images. The subject interface is comprised of a standard chin

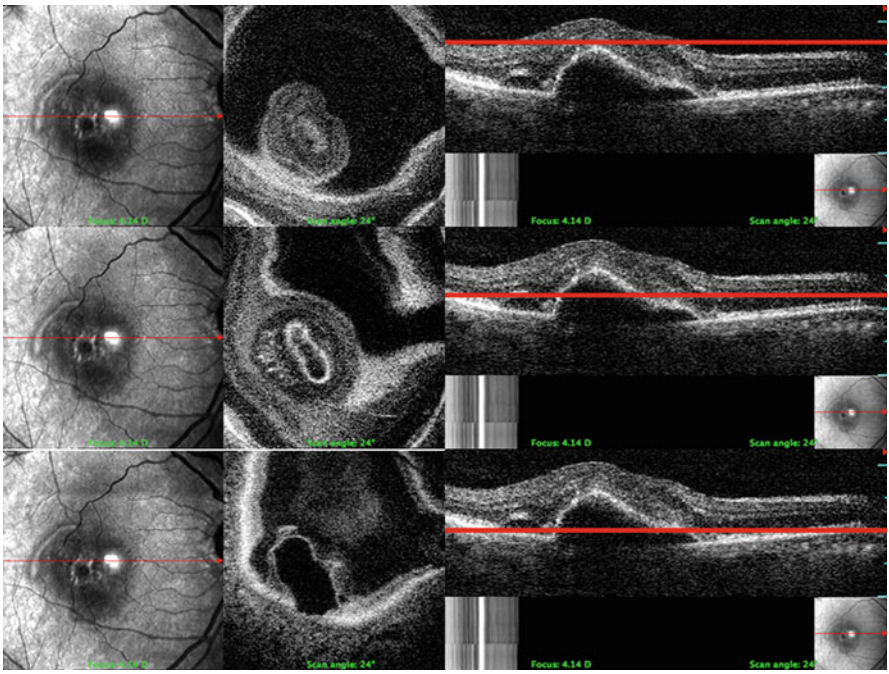

Fig. 59.8 Retinal angiomatous proliferation (RAP). The *top* image set demonstrates a C-scan slice superficial to the retinal pigment epithelial detachment. The small ovoid is the peak of the retinal elevation and is surrounded by a *black circular space* which is the vitreous. The *middle* slice cuts through the pigment epithelial detachment and the intraretinal neovascular complex. In the lowest series of images, the C-scan outlines the base of the pigment epithelial detachment and shows the choroid at the edges. (Republished with permission from Springer Science+Business Media, [55])

rest assembly which provides stability and comfort but allows some movement effects in the images to occur.

Figure 59.8 is a case of retinal angiomatous proliferation (RAP). Three pairs of C-scan OCT and confocal images are shown on the left. Each was taken at different depths as indicated by the lines in the B-scan OCT which was sampled along the line shown in the SLO image. By collecting a stack of OCT/SLO images, the volume of the retinal elevation could be evaluated.

Accurate volume assessment requires collection of a serial stack of C-scans at progressive depths. While the current instrument is equipped with such a feature, we had variable success using it in eyes with pathology due to their limited ability to maintain consistent fixation. We have found another feature of the system more useful, that which allows an easy switch between the two modes, B-scan and C-scan. Successive C-scan cuts viewed in conjunction with selected B-scan images allow the viewer to create a good mental picture of the three-dimensional aspects of the lesion despite the eye movements.

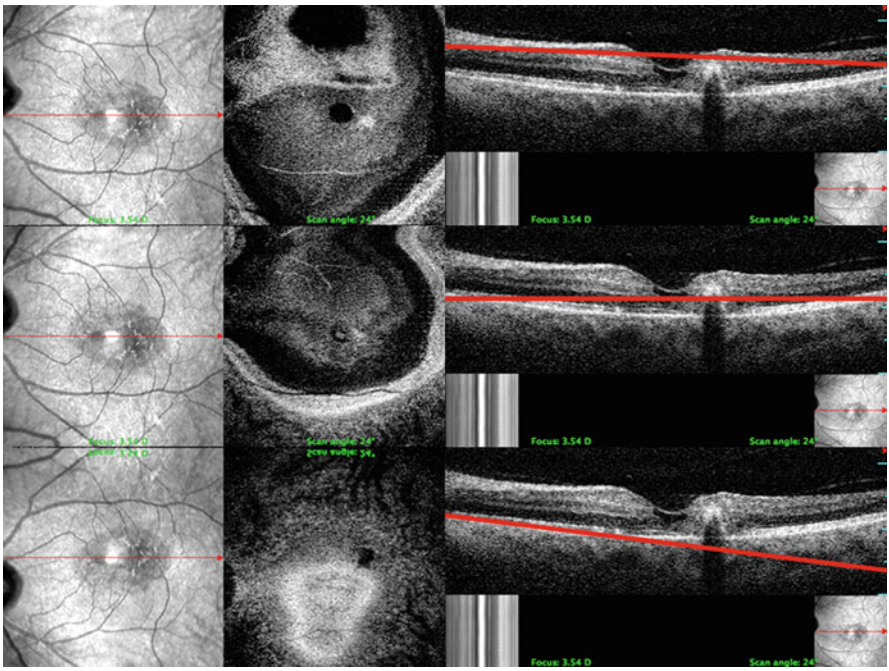

Fig. 59.9 Parafoveal telangiectasia. The lesion is temporal to the foveal depression. A series of confocal images and paired C-scan OCT images taken at different depths are shown. The B-scan OCT on the right of each pair shows the level and angle of the C-scan cut. Note the shadowing beneath the hyperreflective exudative lesion. (Republished with permission from Springer Science+Business Media, [55])

Interpretation of these images requires some careful thought. Due to the inclination of the walls of the thickened retina, the C-scan images often display structures from different depths, as visible in the B-scan OCT images on the right. As such, the C-scan OCT images alone may lead to a wrong interpretation. Comparing them with either of the B-scan image in Fig. 59.8 is helpful in establishing the orientation and the depths of features depicted in individual scans. The images in Fig. 59.8 show the two challenging features of the OCT C-scan imaging: patchy fragmented planes and display of structures from multiple depths for the tilted parts of the tissue. The elongated parts visible in the B-scan OCT images in Fig. 59.8 show up as circles of different intensities in the C-scan images, which indicate different structure in depth due to the discontinuity of optical parameters such as the index of refraction and backscattering coefficient. When we follow the cuts along the straight lines indicated, we can infer the intensity level in the corresponding part of the C-scan OCT image. Evaluating how the radius of the dark circles in Fig. 59.8 varies with depth, the volume of the lesion can be easily inferred.

Similar challenges are presented in the interpretation of the images in Fig. 59.9, a case of parafoveal telangiectasia. Three pairs of C-scan OCT/SLO images

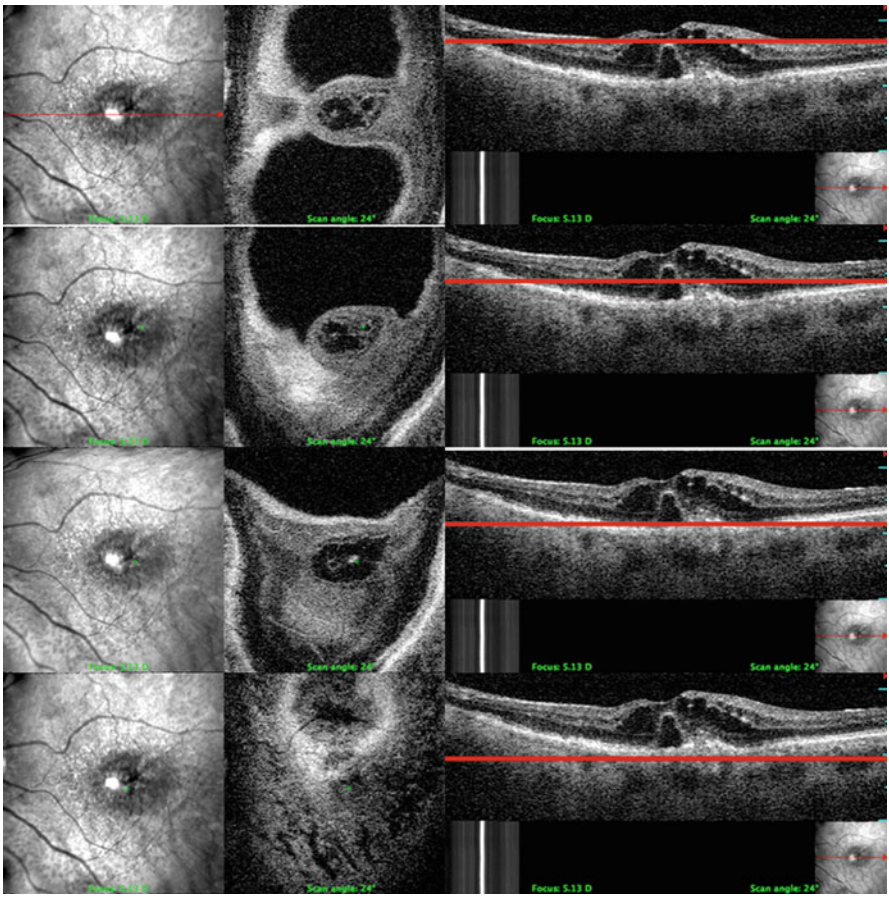

Fig. 59.10 Choroidal neovascular membrane with adjacent RPE detachment and overlying cystoid macular edema. The B-scan OCT images on the right feature *red lines* which indicate the level of the coronal slices. (Republished with permission from Springer Science+Business Media, [55])

acquired at increasing depth positions are shown. For ease in interpretation, the B-scan OCT is displayed on the right-hand side of each OCT/SLO pair. Here, the deepest C-scan OCT image (bottom pair) samples the choroid just touching the RPE. At this level only the shadow of the telangiectatic exudates can be seen. In the first raw, the dark circle in the C-scan is created by slicing through the foveal cone. The C-scan image in the middle raw cuts through the foveal floor which is the roof of an intrafoveal cyst. White edema residues are seen at the edge of the cone. The confocal image in each pair on the left displays the clinical appearance of the surface which reveals limited detail of the underlying pathological features.

Figure 59.10 demonstrates further how C-scan OCT images can enhance the understanding of anatomic relationships between different aspects of pathological

processes that effect complex retinal structure. The images presented are from a case of exudative age-related macular degeneration with a choroidal neovascular membrane [28] and overlying cystoid macular edema. While these two aspects of the lesion can be identified in the cross-sectional aspect of the B-scan OCT, separate C-scan sections reveal a more complete picture at the various interfaces of the components. The transverse direction of scanning is particularly effective at differentiating structures oriented horizontally.

The confocal view of the retina seen in each pair on the left demonstrates a diffusely increased reflex over a thickened central macula. From top to bottom, the image pairs demonstrate progressively deeper C-scan sections with paired B-scans marked with lines indicating the depth. The first section is taken though the inner retina and cuts through multiple perifoveal cysts. The section can be localized to the nerve fiber layer since it is at the same level of the retinal venule, which appears bright in the section. The second section cuts through the lower aspect of the cystic area which is seen surrounding the upper part of the neovascular complex. In this section the venule outline is dark since it is a shadow cast from the layer above. The third section cuts through the center of neovascular complex which appears highly reflective in the image. The bottom section shows the neovascular complex as a cystic area within the RPE bright ring surrounded by darker choroidal vessels.

Another important example of pathology, which demonstrates the clinical utility of the C-scan approach over the simple planar imaging of B-scan OCT, is seen in the case of a macular pucker [29] (Fig. 59.11). The confocal image shows the dragging of retinal blood vessels and loss of clarity characteristic of the epiretinal membranes that distort the macula. The B-scan OCT images have become standard clinical tools for displaying the bunching up of the vitreoretinal interface under the cellophane thin, but contracting blanketing membrane. The difficulty clinicians often encounter in approaching these membranes surgically is in defining their lateral extent in order to plan minimally damaging peeling. The C-scan sections in the pairs in the three raws highlight the tentacle-like extensions of the overlying tissue and help define the thickness and spread of irregularly shaped growth. The C-scan OCT image is patchy and displays fragments of depth structure for the tilted parts of the tissue.

59.3.8 Improved Resolution Using Ultrahigh-Resolution C-Scan Imaging (RR, MV, PG)

59.3.8.1 En Face Ultrahigh-Resolution OCT

Using a broadband light source in a system similar to the first generation of OCT/SLO systems allows for higher-resolution imaging and display of distinctive features. A SLO/en face ultrahigh-resolution (UHR) OCT prototype can acquire B- and C-scan OCT images with an axial resolution of about 3 μm and a lateral resolution around 15 μm. The system is based on a low-cost broadband lighter (Superlum, Russia) with a bandwidth (FWHM) of 150 nm at a central wavelength of 890 nm. Polarization controller paddles are added to input ports of the coupler to match the

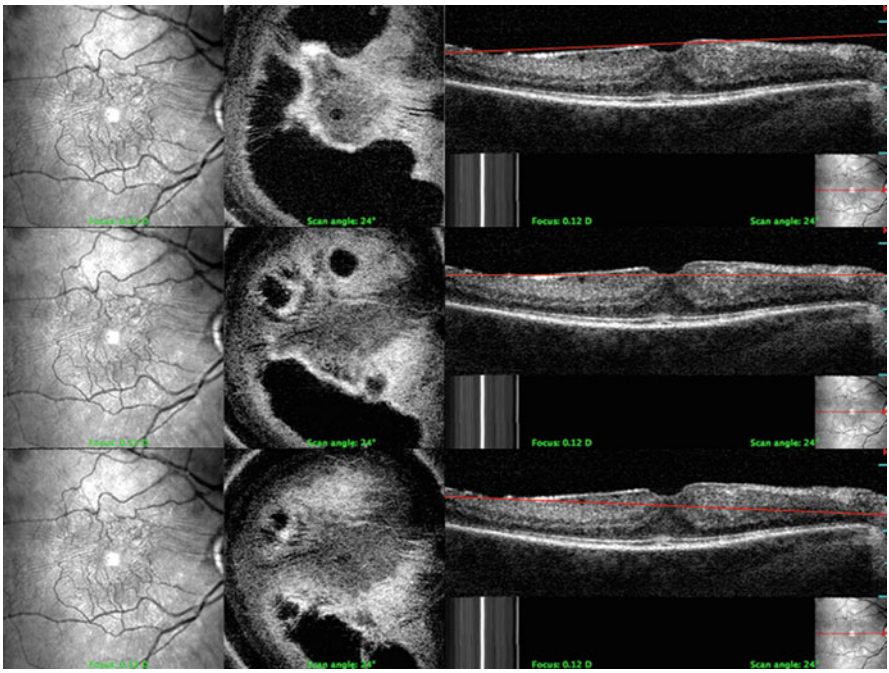

Fig. 59.11 Epiretinal membrane. The C-scan OCT images reveal the extent of the membrane and the presence of multiple cystic formations within the periphery of the membrane. Slight inferior tilting of the eye resulted in capture of irregular oval-shaped areas of vitreous within the three slice pairs shown. B-scan OCT images on the *right* show a *red line* which approximates the level and tilt of the scan angle. (Republished with permission from Springer Science+Business Media, [55])

states of polarization in the reference and sample arm. Dispersion imbalance, introduced by the interface optics and the eye refractive media, is also compensated [30].

UHR-OCT imaging [31, 32] demonstrates enhanced definition of the different retinal layers, the vitreoretinal interface, and the outer retina/RPE/choroid complex, as seen in Figs. 59.12 and 59.13. The latter has been subject to extensive discussion as to the exact interpretation. Averaging of multiple longitudinal scans [33] of the conventional Stratus OCT leads to the finding of three hyperreflective layers in this area, and it was suggested that the innermost layer correlates to the outer retinal segment, the middle layer to the outer retina–RPE interdigitations, and the most outer band to the actual retinal pigment epithelium. Closer examination of UHR-OCT images reported by W. Drexler et al. [32] also seems to show this triple layer. Both B- and C-scan OCT images from the system presented here definitely show this triple layer at the outer borders of the retina/RPE (Fig. 59.12) with a sharp cutoff above the choriocapillary layer.

UHR-OCT imaging substantially facilitates the understanding of the coronal (en face) C-scan OCT images. The improvement in the axial resolution leads to better delineation of the intraretinal layers. Figure 59.13 shows three consecutive

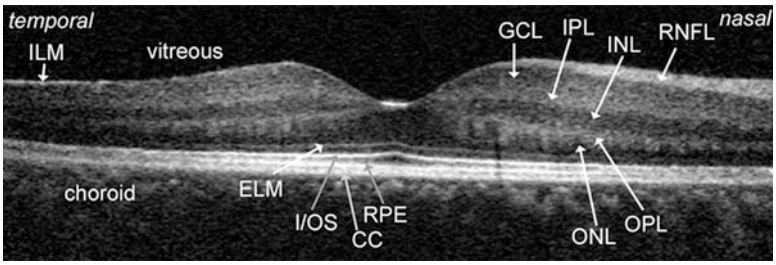

Fig. 59.12 Ultrahigh resolution B-scan OCT. The enhancement of axial resolution clarifies many of the internal retinal layers which are less defined at standard resolutions. This is especially evident in the outer retina where high reflectivity has tended to mask the subtle differences between thin layers. (Republished with permission from Springer Science+Business Media, [55])

C-scan OCT images of a healthy human eye fundus. The first section is taken at the vitreoretinal interface, showing the inner limiting membrane separate from the retinal nerve fiber layer and allowing for distinction of individual nerve fibers within this layer. The second C-scan shows the sharp delineation of the intraretinal layers, which allows for better appreciation and localization of subtle retinal changes within these layers. The third C-scan shows the triple hyperreflective band at the level of the outer retina–RPE junction and the thin external limiting membrane (ELM) layer. Even the external limiting membrane can be appreciated here.

With the improved quality of the B- and C-scan OCT images, it becomes easier to localize retinal pathologies which can be better appreciated. In cases of subtle retinal or subretinal changes, this will help in the diagnostic process. In cases of evident pathology, UHR imaging is not really necessary to make a diagnosis, but will help to better localize pathological change and to further understand the pathophysiology of retinal and choroidal diseases. The two clinical cases which follow demonstrate this further.

In Fig. 59.14, a C-scan OCT image acquired with a UHR-OCT/SLO is shown of a patient with an epiretinal membrane (macular pucker). The subtle folding of the retinal surface caused by this membrane can be clearly appreciated. The detailed pattern of this membrane, showing various points of traction, causes a very peculiar, wavy pattern of folds. This aspect could be compared with that in the B-scan OCT, which shows the epiretinal membrane (ERM) stretched out over the retinal surface and the folding of the retinal nerve fiber layer, but only in a one-dimensional way. The area that the epiretinal membrane covers exact location where it is pulling on the surface is best appreciated in the C-scan mode. Also, such an epiretinal membrane pattern as shown here would not be so evident in the regular OCT/SLO system.

In Fig. 59.15, UHR C-scan OCT images of a patient with a macular hole are shown, in comparison to a C-scan OCT image of the same patient made with the

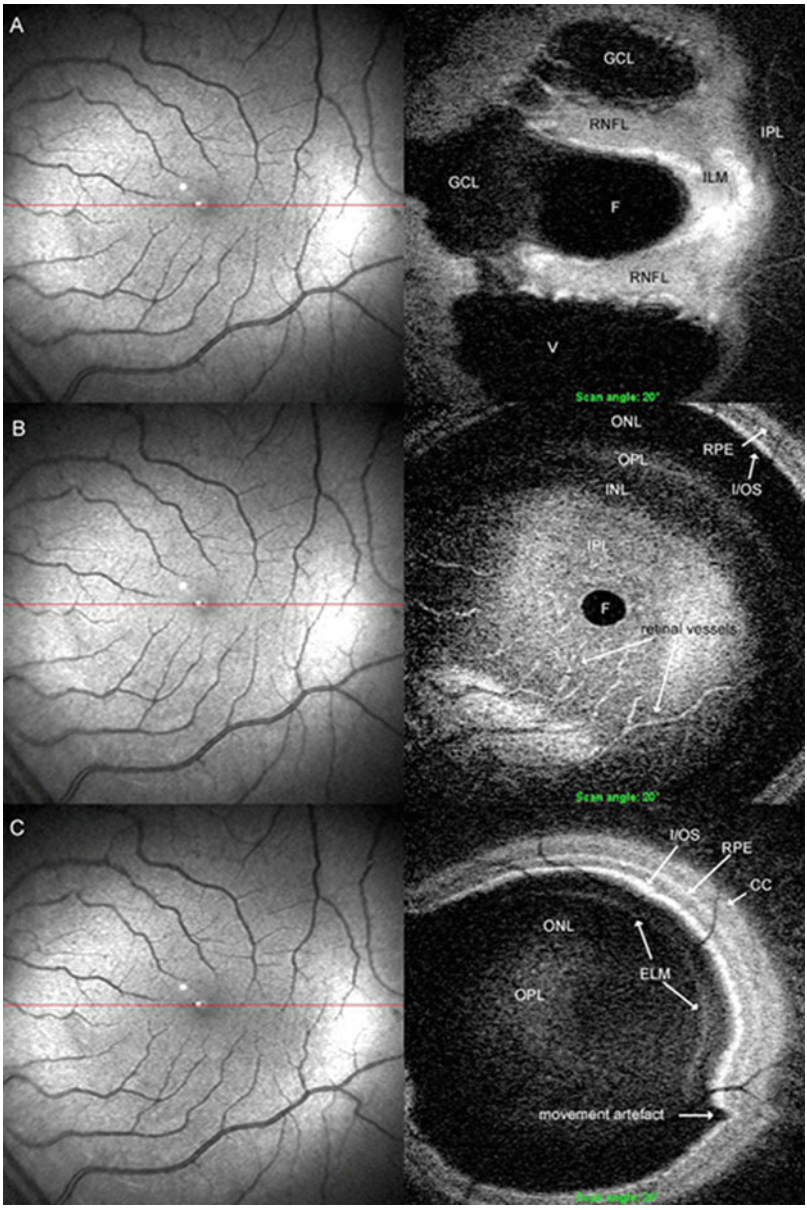

Fig. 59.13 SLO/UHR-C-scan pairs acquired from a healthy eye. (**a**) is the most superficial section demonstrating the patchy variability of depth recorded by transversal planar scanning. Adjacent patches demonstrate distinct features indicative of the layers captured. Pair (**b**) has been captured at a moment when the eye was well centered around fixation. The foveal depression is seen as a *circle* surrounded by concentric rings of successive layers. Pair (**c**) is the deepest image. The OCT reveals some movement with greater detail in the outer retina–RPE–choriocapillaris. (Republished with permission from Springer Science+Business Media, [55])

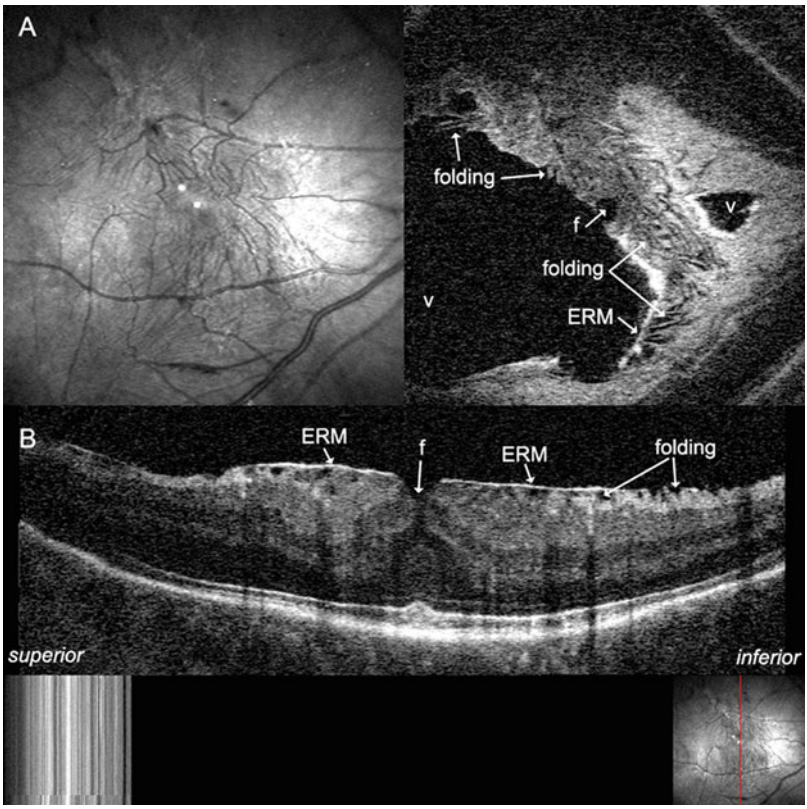

Fig. 59.14 Macular pucker. The SLO image (**a** *left*) displays fine swirling striations on the macular surface. The corresponding C-scan OCT image (**a**-*right*) shows the tilted orientation of the retina, revealing the edge of the macular surface in oblique cross section which highlights the infolding of the surface. The B-scan (**b**) shows the corrugated configuration of the retina due to the epiretinal membrane (ERM) and its effect on the middle layers as well as the surface. (Republished with permission from Springer Science+Business Media, [55])

regular system. The two frames are acquired by the two different systems but at the same level, to prove the more detailed information in the UHR image; the small septa between the cystic changes within the rim of the macular hole can be distinguished, and the lateral borders of these cystic changes are clearly demarcated. In the consecutive C-scan OCT images acquired at the level of the base of the macular hole, RPE irregularities are seen. However, these could also be remnants of the photoreceptor cell bodies that have been pulled out mechanically. These irregularities are also seen in the B-scan OCT image from the UHR system. These changes at the bottom of the hole could not be appreciated in the regular resolution system.

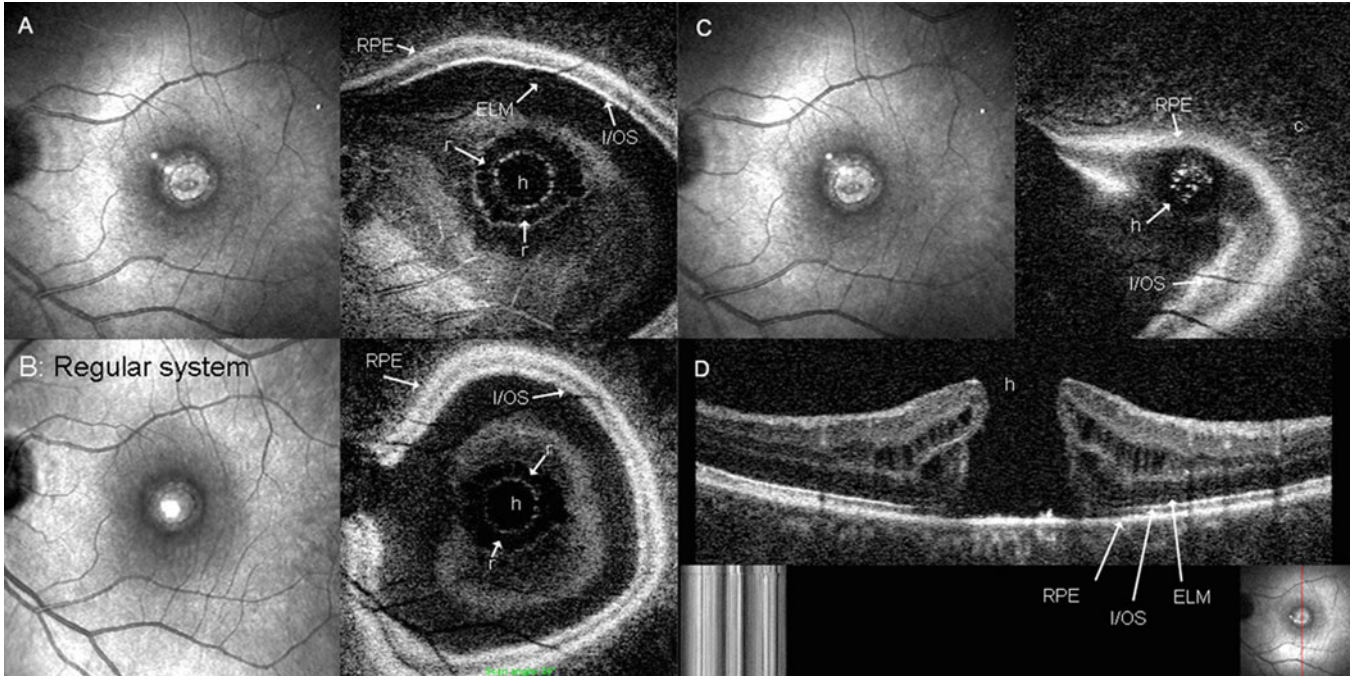

Fig. 59.15 Macular hole. UHR versus standard axial resolution OCT images comparison. Pair (**a**) demonstrates the added detail which is revealed by 3 μm axial resolution versus 10 μm axial resolution of pair (**b**). Pair (**c**) and image D are also UHR and provide details of the base of the hole and the internal retinal cysts more difficult to appreciate at 10 μm resolution. *RPE* retinal pigment epithelium, *ELM* external limiting membrane, *I/OS* inner/outer segment juncture, *h* macular hole. 59.4 Small Size Imaging

Cellular-level imaging has an increasing number of clinical applications as treatment options expand. Measurement of photoreceptor loss or rescue could be very useful in the evaluation of new pharmaceuticals, gene therapies, or stem cell implants. The ability to reliably detect microscopic progression of geographic atrophy could also significantly help shorten clinical trials, limiting prolonged studies of dead-end approaches, saving time, money, and effort. The optics of the eye has been a major limiting factor in achieving lateral resolution capable of detecting cellular boundaries. Cones range in size from 4.0 μm down to 0.5 μm in the foveal center, while rods are typically 2.5 μm in diameter. Adaptive optics [34] is now more used to overcome the eye aberrations, allowing the visualization of the cone mosaic in the living eye. Despite the exceptional resolution of the adaptive optics SLO, its complexity, size, and cost still pose significant barriers to its implementation as a workaday clinical tool. Lower-cost alternative solutions exist, by devising low aberration interface optics and using small angle scanners. At scanned fields reduced to 6.5° or less, it was possible to see clearly defined cone bodies at a location eccentric to the fovea [35, 36]. A clinical prototype, based on a modified commercial Opko-OTI SD-OCT/SLO, was developed by Hathaway and Weitz in 2009 which could exploit this enhanced resolution [37]. Utilizing the integrated OCT/SLO approach presented above, the current prototype allows consistent orientation at different levels of

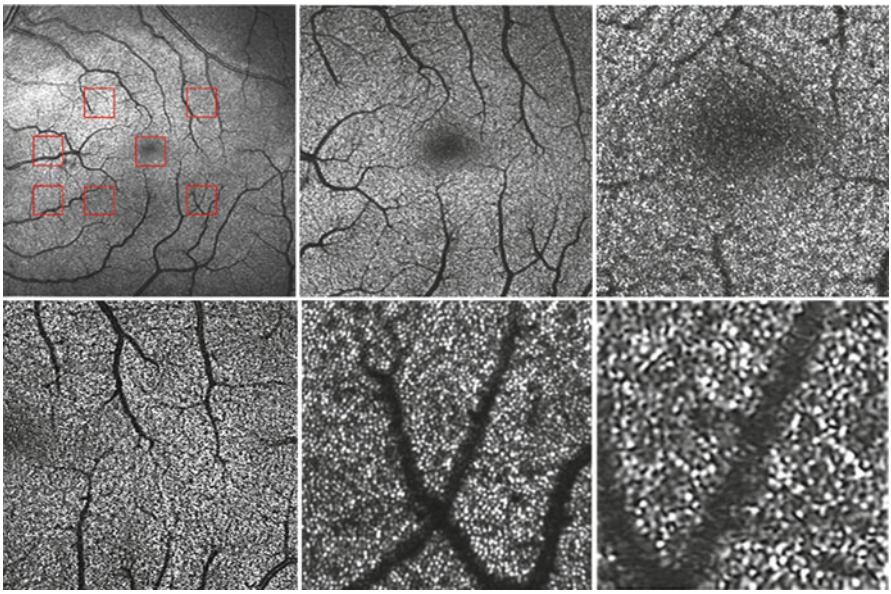

Fig. 59.16 Variable magnification achieved by alteration of scanning laser ophthalmoscope scanning angle. When the scanning resolution of the wide-field image is reduced, the perimacular cone mosaic becomes evident and accessible to post-processing counting algorithms, as shown in the last two images, lateral image size: 0.53 mm and 0.28 mm, respectively

zoom and correlation between OCT cross-sectional features, SLO en face landmarks, and flattened reformatted C-scan OCT slices. Figure 59.3 displays the real-time SLO small size images such obtained (Fig. 59.16).

59.5 Sequential En Face OCT/SLO Imaging

Switching off the reference beam in a configuration as that in Fig. 59.17 removes the high value of photodetected intensity and the noise associated with the high-power reference beam falling on the photodetectors. In this way, the photodetectors can reproduce a noise-free SLO signal. Elimination of the constant terms means that high gain photodetectors such as avalanche photodiodes (APD)s and photomultipliers can be employed, which however need to be swapped for low gain photodetectors such as

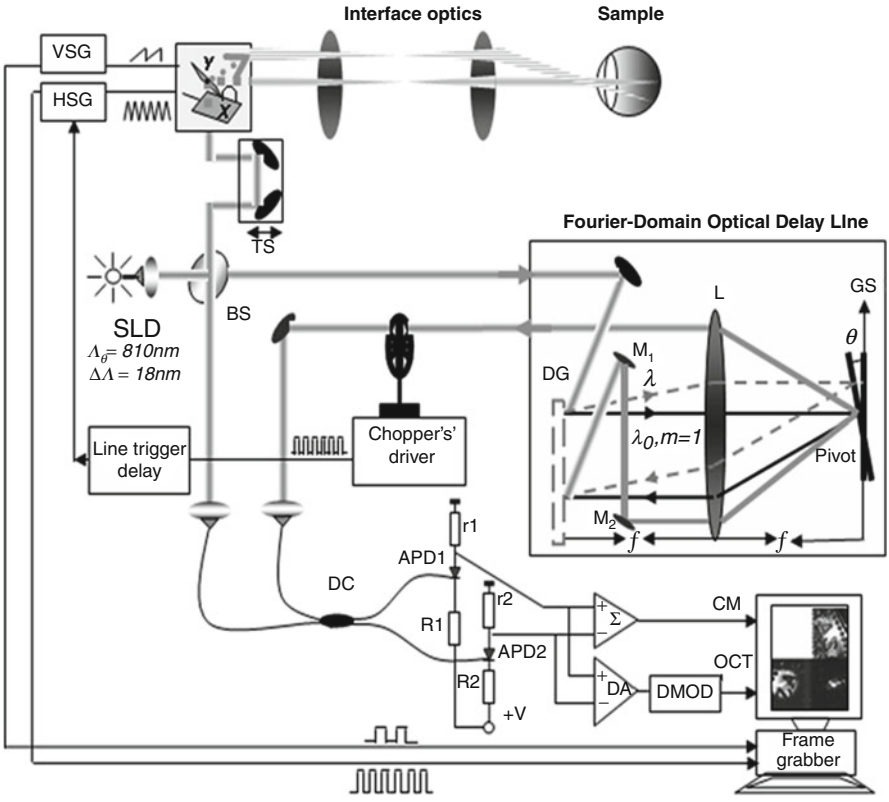

Fig. 59.17 Schematic diagram of the quasi-simultaneous en face OCT/SLO system [40]. *SLD* superluminescent diode (Superlum 361), *BS* beam splitter, *DC* broadband directional coupler, *DG* diffraction grating, M_1 M_2 mirrors, *GS* galvanometer scanner mirror, $APD_{1,2}$ avalanche photodetectors, *VSG* vertical signal generator, *HSG* horizontal signal generator, Σ summing amplifier, *DA* differential amplifier, *DMOD* demodulator block, $R_{1,2}$ ballast resistors, $r_{1,2}$ determine the sensitivity of the photodetection. (Reproduced with SPIE's permission from [39])

pin diode when the reference beam is reinstated on the photodetectors in the OCT regime. A technical solution is presented in [38] where APDs are used in both regimes, and a self-switching APD regime is employed based on the voltage drop on the resistors in series with the APDs. The advantage of such a configuration is its simplicity and also its efficiency in using the whole signal returned from the retina to produce either an OCT or an SLO image, i.e., no splitting of the signal is required.

59.5.1 Quasi-Simultaneous *En Face* OCT/SLO Imaging

Quasi-simultaneous imaging in the two regimes, OCT and CM, is achieved by using a chopper instead of the opaque screen, chopper which is controlled via a synchronization mechanism. This allows line-by-line operation, with a fast switching on the fly between the two regimes of operation, during the raster line of a dual frame image. The sensitivity of the OCT channel is not lowered, since no splitter is required. An additional difficulty was raised by the need to employ avalanche photodetectors (APD) in order to achieve sufficient signal-to-noise ratio in the CM channel. Low noise electronics and optimization of APD voltage combined with the optical power level in the reference beam lead to a signal-to-noise ratio in the OCT regime close to that achieved when using PIN photodetectors.

The system [39], as shown in Fig. 59.17, is based on a two-splitter low coherence hybrid interferometer optimized for broad bandwidth sources. Light from a superluminescent diode (SLD, Superlum, Moscow) centered at 810 nm with an 18 nm bandwidth is launched into the system through a single-mode optical fiber port and then is split by a plate beam splitter, BS, into an object and reference arm. The returned light from both arms is then routed into a second splitter, a broadband single mode directional coupler, DC. In the object arm of the interferometer, a pair of XY galvanometer scanners is employed to direct the beam via the interface optics to the object.

A Fourier-domain optical delay line scheme in the reference arm is employed for dispersion compensation and depth scanning. This works in transmission and exhibits low losses by traversing the diffraction grating only twice [40]. The delay line uses a diffraction grating DG, a lens L, and a tilting mirror GS in a *2f* configuration. The grating disperses a collimated beam, which is then imaged by an achromat lens L at a distance *f* away. A galvanometer scanner, GS, with its pivot located in the other focal plane of the lens, causes a linear phase ramp on the spectrum and redirects the rays back to the DG through L. Here the spectrum is recombined into a collimated beam. The outgoing beam exits the DG at a different point, O', parallel to the incoming beam. The amount of mirror tilt, θ, translates into a group delay for the output beam. This is based on the well-known property of the Fourier theorem that a linear phase in frequency domain corresponds to a group delay in time domain. To eliminate the walk-off, mirrors M_1 and M_2 are used to send the recombined beam back to GS, where the angular tilt is de-scanned.

A chopper (SR540, Stanford Research Systems) is used to square wave modulate the intensity of the reference beam. The chopper is powered by an adjustable voltage power supply, which is set to rotate the chopper at a repetition frequency of 500 Hz. The TTL pulses delivered by the chopper are then fed into a function synthesizer (8116A Pulse/Function Generator, 50 MHz, Hewlett Packard) that outputs a triangle waveform at 500 Hz to drive the line scanner. Mechanical and electric delays in the scanners require adjustment of the correct timing when the reference beam is toggled on and off. A delay is introduced by the block "line trigger delay" in the line delivering the TTL signal to the line frequency generator, and this is adjusted accordingly in order to synchronize the start of ray deflection over the object with the moment of toggling the reference beam power on and off. The chopper's frequency was sufficiently stable not to require any adjustments during the imaging. The frame scanner in the XY pair is driven by a vertical signal generator, VGS, with a sawtooth waveform at 1.5 Hz. The system operates differently during each ramp of the triangle sent to the line scanner. A similar approach was reported for generation of quasi-simultaneous OCT/OCT images with different depth resolutions [41], where a different coherence length source was used during each ramp. Here, the same source is employed, but the regime of operation is toggled from OCT to SLO synchronous with the X scanner.

The system can be used to generate cross-sectional images by using either transverse priority or depth priority scanning, and it is suitable for compensating the dispersion when scanning in depth [42]. However, for the present study we used only T-scans, where the carrier for the image bandwidth was created by the path modulation introduced by the galvanometer scanner determining the line in the final raster [6]. The detection unit employs two avalanche photodetectors, APD1 and APD2 (Mitsubishi PD1002). Essential for the operation regime here is their self-switching [43] depending on the optical power applied and the value of the ballast resistors, r_1 and r_2. Therefore, we have designed a special amplifier board which has allowed adjustment of the ballast resistor values and of the transimpedance in order to optimize the S/N ratio.

The CM signal is provided by the summing amplifier (Σ) where the two photodetected signals collected from resistors *r1* and *r2* are added up. The OCT signal is available at the output of the difference amplifier (DA) after demodulation in the demodulator block (DMOD). A dual-channel variable frame grabber (Bit flow, Raven) is used to display the two images.

Ideally, during the first half ramp applied to the line galvanometer scanner (X), of *1 ms* (ascending slope), the reference beam is on and the system provides the OCT signal (while the CM channel is saturated). During the second half ramp of *1 ms* (descending slope), the reference beam is blocked and the confocal signal is displayed (while the OCT channel provides a distorted CM image). For every line of *2 ms* in the raster, *1 ms* corresponds to the OCT regime and the next to the SLO (CM) regime of operation. Images of the optic nerve area obtained in these two regimes are shown in Fig. 59.18. The delay in producing SLO and OCT images is small, equal to the ramp duration; therefore, images can be considered as quasi-simultaneously obtained. They are however pixel-to-pixel correspondent.

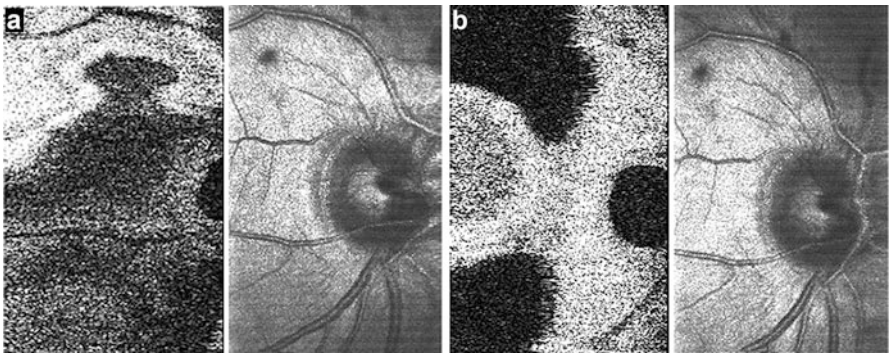

Fig. 59.18 Pairs of quasi-simultaneous C-scan OCT (*top*)/confocal (*bottom*) images of the optic nerve in vivo at different depths in the OCT channel. Image size: 4 mm (*horizontal*) × 7.5 mm (*vertical*). The images here have been cropped from the originals, and the OCT images were horizontally reverted to correspond to the SLO images. (Reproduced with SPIE's permission from [39])

In practice, there is a delay between the signal applied to the transversal scanner and the actual galvo mirror tilt, as well as other delays in the electronics circuitry, which requires correction via the "line trigger delay." The OCT and SLO images captured by the system are mirror-inverted with respect to the median of the frame grabber display window.

59.6 Simultaneous OCT and Fluorescence Angiography of the Retina

The addition of the confocal channel to the OCT channel provides the opportunity to implement all known applications of confocal microscopy with the added advantage of the complementary information provided simultaneously by the OCT channel. The first such application to be developed was infrared fluorescence angiography. A system which can simultaneously produce en face OCT and indocyanine green (ICG) angiographic fluorescence SLO images was designed [44]. The same optical source is used to produce the OCT image and excite the ICG. The system allows the clinician to examine the eye fundus with simultaneous corresponding *coronal* OCT sections and confocal ICG angiograms, displayed side by side. The system also facilitates capture of OCT B-scans by positioning a cursor line anywhere on the ICG image. This feature appears to be especially useful for studying lesions suspected of harboring choroidal neovascular membranes.

Fluorescence angiography using ICG dye [45, 46] is an established technique for studying blood circulation through the choroid of the eye. ICG is a well-tolerated contrast agent and is stimulated by infrared light which has greater penetration and is less phototoxic to the retina than shorter wavelength light [47].

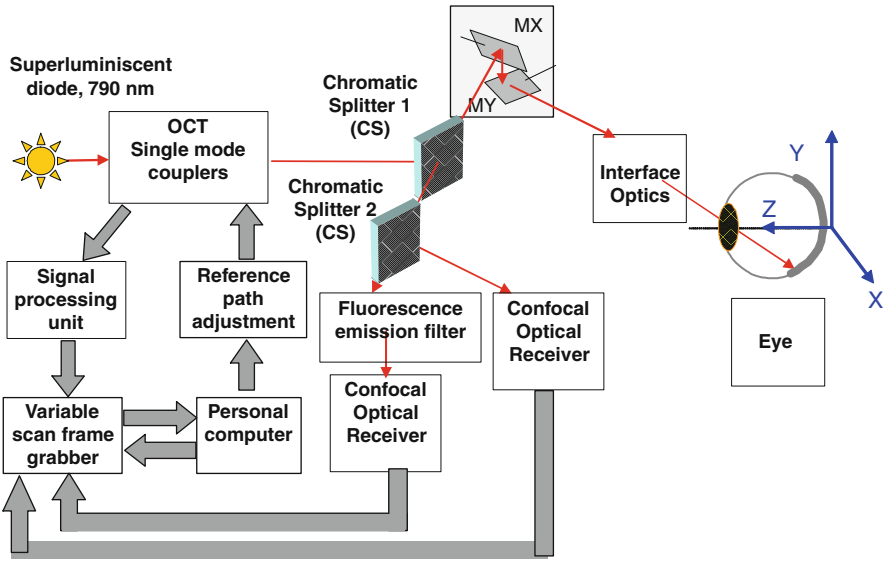

Fig. 59.19 General set-up of the combined OCT/SLO/ICG system. *MX, MY* galvanometer mirrors of the XY scanning pair. (Republished with permission from Springer Science+Business Media, [55])

The instrument, presented in a schematic diagram in Fig. 59.19, is a triple channel OCT/confocal ophthalmoscope/ICG angiographer with versatile scanning and image display capabilities allowing the acquisition of OCT and dual confocal images in B- or C-scan regime of operation. The splitter used in the OCT/SLO configuration [13] to divert some of the light to a separate confocal receiver was replaced by a chromatic splitter, CS [48]. This separates the retina-scattered light at the excitation wavelength, guided into the OCT channel, from the fluorescence signal, which is guided towards the fluorescence confocal receiver. The residual transmission of the chromatic splitter is sufficient to generate an image at the OCT wavelength.

To enhance the contrast of fluorescence in the confocal receiver, a supplementary filter is used in the fluorescence channel to attenuate any excitation band light that gets past CS.

To minimize the distortion of the OCT depth sampling profile (determined by the correlation function of the source), CS is used in transmission by the ICG channel and in reflection by the OCT channel. CS is a cold mirror with a transition wavelength, λ_{tr}, between the excitation band and fluorescence band. Superlum, Moscow, has devised a comparatively powerful SLD for this project, with a 5 mW optical power and $\Delta\lambda = 21$ nm spectral FWHM which gives a depth resolution in the retina of less than 9 μm (considering an index of refraction $n \sim 1.38$).

Following the injection of ICG dye into the patient's bloodstream (5 mg/ml), light from the SLD, guided through to the eye fundus by means of the interface optics, generates on one hand a reflected/backscattered return at the same wavelength (793 nm), which coherently combines with reference light to produce the OCT images, and on the other hand serves to excite fluorescence in any tissue structures containing the ICG dye, such as retinal and choroidal blood vessels. The acquisition of fluorescent images has to proceed rapidly, in less than a minute, due to the fast ICG disappearance rate from the bloodstream of between 18 % and 24 % per minute. Generating OCT, SLO, and ICG images at 2 Hz was found to provide a reasonably good trade-off between the acquisition speed requirement and the quality of the OCT images in terms of their signal-to-noise ratio.

The images in the three channels are displayed simultaneously in a four-up configuration with a fourth channel that overlays the OCT C-scan image on the ICG image. Figure 59.20 shows such images, the SLO (upper left), ICG fluorescence (lower left), OCT (upper right), and overlay channel featuring OCT on ICG (lower right) taken at two different times in the postinjection phase. In 30 s, 60 of such four-up sets of images are acquired, while the depth is explored over a range of typically 1.2 mm in retinal tissue. If the eye has moved considerably during the acquisition and essential parts from the retinal volume are missing, the acquisition can be repeated after the ICG bolus has passed. The pixel-to-pixel correspondence between the three images allows later association of morphologic features between the two images. Generally, just a few correct en face OCT images from the stack collected during the bolus passage are sufficient for subsequent transverse alignment of any other pairs of images. Figure 59.20 presents sets of images from an eye with an occult choroidal neovascular membrane beneath a serous retinal elevation. The confocal fluorescence image on the left in b reveals the location of active leakage within the lesion. Information on the depth-resolved morphology of the retina in these volumes is acquired by switching the system into the B-scan regime.

In these images, blood vessels are well defined in the ICG images while inconsistently revealed within the OCT images. At the same time, the depth resolution in the ICG channel is orders of magnitude lower than the OCT axial resolution, and morphology cannot be assessed accurately. Therefore we believe that such a system will have valuable applications by combining the complementary information supplied by the two channels. Regions of leakage, visible in the ICG image, can be selectively targeted by acquiring B-scan cross sections in the OCT channels as seen in the left hand side of c and in d.

Figure 59.21 further demonstrates this facility in evaluation of a retina of a patient with polypoidal choroidal vasculopathy, a peculiar variant of neovascular macular degeneration. In this case, the ICG angiography reveals a leash of abnormal vessels which originate near the nerve, extend inferotemporally, and terminate with bulbous endings. The accompanying OCT captures the sausage-shaped cuff of fluid surrounding the vessels which accounts

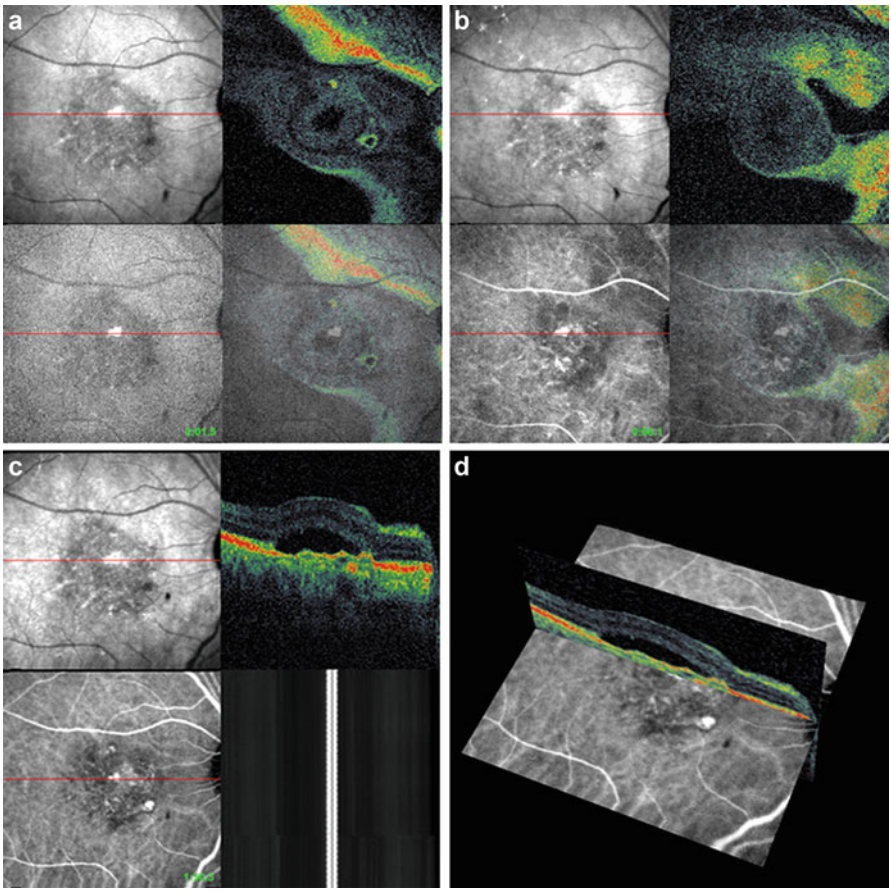

Fig. 59.20 SLO/OCT/ICG image sets acquired from a patient with occult choroidal neovascularization. (**a**) SLO (*upper left*), ICG fluorescence (*lower left*), en face OCT (*upper right*), and OCT/ICG overlay (*lower right*) images of the eye fundus of a patient in the preinjection phase at 1.5 s. (**b**) Same set of channels shown postinjection at 8.5 s. (**c**) SLO (*upper left*), ICG fluorescence (*lower left*), *B-scan* OCT (*upper right*), and confocal lines (*lower right*). The *red line* on the SLO image is the line where the B-scan OCT crossed the coronal slice. The confocal lines in the *lower right* show any movement artifacts during the acquisition of the OCT. 59.7 Anterior Segment En Face OCT

Fast T-scanning followed by slower scanning along a transverse direction or slower depth scanning was also employed to acquire images from the anterior chamber. Continuous examination from the cornea to the lens is not possible using the same

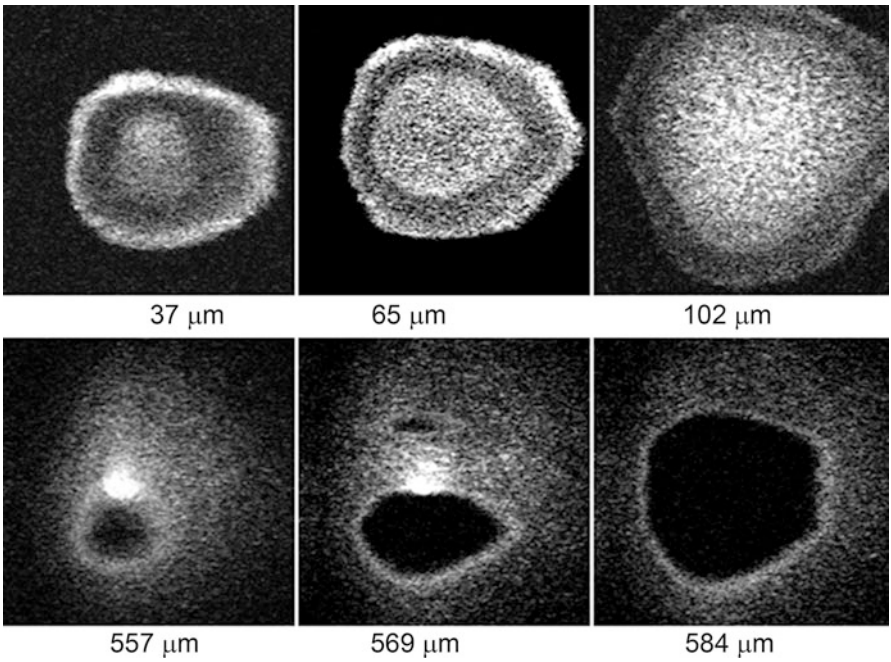

Fig. 59.22 En face OCT images of the cornea, 3 mm × 3 mm. All the depths are measured in air relative to the top of the cornea. (Reproduced with SPIE's permission from [51])

optical design confocal microscope [49]. The reflection from the tear film in front of the epithelium is 2 %. If a confocal instrument is set up to image the lens, then it can be used for imaging the cornea with limited success. The low numerical aperture of the interface optics precludes separation of the different layers in the cornea from the strong reflection at the air–tear film interface. Additionally, by changing the numerical aperture means that the depth resolution at the lens depth is less than that achievable at the cornea. Thirdly, due to the low reflectivity of the transparent tissue in the anterior eye structure, the confocal image exhibits low contrast. OCT addresses all these disadvantages and allows the same depth resolution from the cornea level up to very deep in the anterior chamber [50].

An OCT/confocal instrument was reported for collecting images from the cornea and the anterior chamber [51]. An SLD at 850 nm which delivered 300 μW to the eye was used, depth resolution in the cornea, slightly below 13 μm. To visualize the cornea only, a numerical aperture of the interface optics of 0.1 was used. This gave a transversal resolution of better than 20 μm and a depth of focus of 0.25 mm in both the OCT and confocal channel (the values are larger than those theoretically expected due to aberrations).

The C-scan images in Fig. 59.22 show the multilayer structure of the cornea. The top raw shows sections of the corneal epithelium. The Bowman layer is visible in transverse section, and its separation from the epithelium is transferred to the

distance between the two external and internal circles. The bottom raw displays C-scan images from the endothelium. In order to collect images in the anterior chamber as deep as from the lens, a lower numerical aperture interface optics was used, 0.02. This gives a long depth of focus with the disadvantage that the signal strength is just sufficient to allow visualization of the most important features in the anterior chamber. Figure 59.23 shows a couple of pairs of C-scan images, confocal and OCT, deep in the anterior chamber. The iris and the lens are visible. The images have been collected at a rate of one image pair per second. The images at the top are the confocal images. Scanning deep in the anterior chamber, the iris appears at

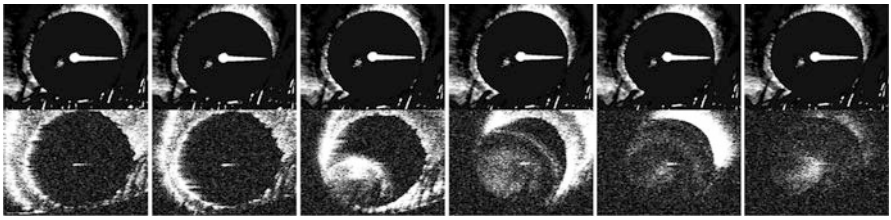

Fig. 59.23 Pairs of confocal (*top*) and OCT (*bottom*) images deep in the anterior chamber. Confocal images show the Purkinje reflections and the iris. Deeper, the lens is seen, offset from the optic axis, around the 3rd Purkinje image. 0.12 mm in air between the pairs. Image size is 6 mm × 6 mm. (Reproduced with SPIE's permission from [52])

The distance to the outer ring reveals the fluid space between the *nipple* on the apex of the cornea and the lens. (**b**) The space between the contact lens and the cornea suggests close

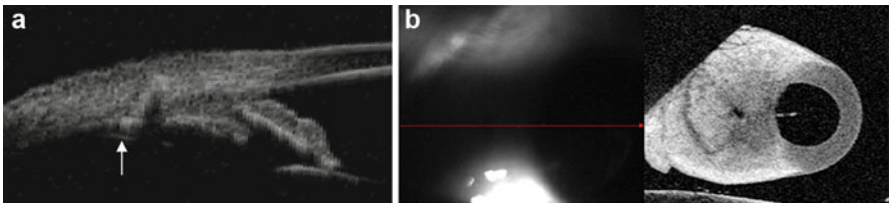

Fig. 59.26 Occult metallic foreign body. (**a**) The cross-sectional OCT demonstrates a small hyperreflective linear object in the sclera; (**b**) the coronal OCT reveals the scleral entry site and track along with linear extent of metallic fragment. (Republished with permission from Springer Science+Business Media, [55])

a depth of 3.5 mm. Clearly visible are the irregularities of the iris rim and the meshwork-like structure of the iris stroma. Then, at a depth of 4 mm, the lens becomes visible. The OCT images underneath show the en face sections around the first Purkinje reflected spot. The offset of the lens from the center of the image indicates how sensitive C-scan imaging is at off-axis orientation in comparison with the B-scan OCT imaging. The Purkinje reflections may be useful in aligning the eye axially, information difficult to handle when generating B-scan OCT images. The first two Purkinje images are visible in the confocal channel in Fig. 59.23.

The clinical value of en face OCT in the anterior segment can be demonstrated with a variety of examples where the pathology in question is so asymmetric that single cross-sectional OCT images are inadequate to image the anatomy. Figure 59.24 shows one such example in an eye with an edematous, opaque cornea and a detachment of Descemet's membrane. The images were taken with a system which incorporates a 1,310 nm source. While the cross-sectional images demonstrate the rumpled dehiscence of the corneal layer, the coronal images provide a much more complete picture of the phenomena.

The advantage of the en face perspective is further demonstrated in a series of images (Fig. 59.25) of a cornea with keratoconus fitted with a rigid gas-permeable contact lens. While the cross-sectional OCT shows the lens well fitted to the cornea, the coronal perspective actually reveals the fine disparity between the peak of the keratoconus *nipple* and the surrounding apex of the cornea.

Coronal imaging also extends to the sclera and may prove useful in detecting small defects such as occult rupture sites created by high-speed foreign bodies. Figure 59.26 shows an example of such a defect which had been covered by reactive swelling of the overlying tissue. While the cross-sectional OCT was able to find the small embedded missile, the en face OCT captured the internal tract and localized the object.

Fig. 59.25 (continued) approximation of curved surfaces in the mid cornea. (**c**) The distance between the lens and the peripheral cornea also suggests a good match between curves. (**d**) Cross-sectional OCT shows the contact lens on the cornea but does not reveal the fine profile of the *nipple*. (Republished with permission from Springer Science+Business Media, [55])

59.8 Conclusions

Simultaneously and quasi-simultaneously acquired real-time en face OCT images paired with confocal ophthalmic images provide unprecedented point-to-point correlation between surface and subsurface anatomy of the tissue. A variety of prototypes for different applications of this technology, including high depth resolution OCT and small size imaging have been reviewed demonstrating the clinical potential of the approach in the posterior segment. Similar technology was also demonstrated for the anterior segment. While the challenges to successful interpretation of these images appear substantial at first, once the clinician is familiarized with this perspective, its value in detecting and localizing occult pathology becomes obvious. The interest for the en face view has been revitalized by the progress in the acquisition speed and reduction in the processing time of spectral domain OCT. Significant volumes of the retinal tissue can now be acquired in a couple of seconds, which, after subsequent software cut, can lead to en face OCT images, however, collected during a time interval marginally longer than the time required by time domain OCT. Combination of spectral domain OCT with SLO is still possible [52] in pixel-to-pixel correspondence in transversal section, similar to the technology presented in this chapter. For large size images of the retina, spectral domain OCT is superior to time domain and determined the current widespread of OCT in imaging the eye. However, other time domain modalities are being developed, to reduce the acquisition time of volumes, based on parallel en face acquisition from several depths [53].

Choroidal OCT

60

Marieh Esmaeelpour and Wolfgang Drexler

In the light of vast evidence, it is well accepted that there is choroidal involvement in the pathogenesis of many ocular diseases of the posterior pole. Histology of choroidal thickness (ChT) has revealed increased ChT correlated with a higher density of vessels in the superficial choroidal layers in open angle glaucoma [1], atrophy to choroidal capillary structure [2], and neovascularization in the choriocapillaris [3, 4] in aging and in age-related macular degeneration. Histological studies investigated biological structures in the eye with comparable high resolution to optical coherence tomography, but these were accompanied by preparation artifacts, shrinkages, and lack of blood supply to sustain vasculature volume [5]. Clinically the choroid is visualized by indocyanine green angiography, the insertion of a dye into the bloodstream that will stain blood vessels, even capillaries. This method shows alterations of choroidal vascular filling time and morphology already in elderly healthy subjects [6]. However, it lacks the third dimension and its use can be toxic and there is a risk of mortality.

Commercial OCTs at 800 nm are clinically used to image the retina and when used for choroidal imaging have a success rate of 74 % for reliably showing choroidal/scleral interface [7]. With the introduction of enhanced depth imaging (EDI) into commercial OCT systems, a new clinical investigation method for the choroid was presented [8]. Applying EDI, commercial OCT devices demonstrate choroidal penetration in scanned volumes only in thin choroids or by limiting imaging to few two-dimensional scans [8–10].

Recent interest in the choroid led a study with 3D-1,060 nm-OCT investigate choroidal thickness confined to central and four peripheral measurement locations in a healthy Japanese population [11]. However, analyzing the measurement at

several image locations neglects the remaining data collected over the entire imaged field. Therefore, a method for mapping choroidal thickness needed to be developed that enabled statistical analysis of the entire imaged volume. The first study of choroidal visualization performance aimed to quantify the complete 3D-1,060 nm-OCT scan with ChT-maps in healthy subjects.

In a study with 34 healthy subjects, three-dimensional (3D) OCT volumes were acquired at 1,060 nm with 15–20 μm transverse resolution, about 7 μm axial resolution and 512 voxel per depth scan. For ChT-maps, a field of 36° × 36° scans with each degree corresponding to ~288 μm [12], centered on the fovea, was used. The OCT volume was averaged in both transversal directions within a field of ~1° to remove speckle and increase sensitivity. Axial ChT was defined as the distance between the center of the peaks originating from the RPE/Bruch's membrane/choriocapillaris (RBC) complex [13] and the choroidal-scleral interface (CSI). For the investigation of the ChT variation throughout the entire field of view, thickness maps were generated based on manual segmentation with segmentation in every 4th tomogram at the RBC complex and the CSI (Fig. 60.1). Two-dimensional ChT-maps, generated by local subtraction of the segmented height profiles were smoothed by transversal filtering, and splining between the slices, followed by a final two-dimensional median filter using a 15 × 15 kernel size. The resulting pixel distance was converted into optical distance using the depth sampling calibration for the 1,060 nm OCT system and further to physiological distance using a group refractive index of $n = 1.4$ (based on the refractive index of blood). This resulted in thickness maps for individual eyes.

For the statistical analysis of mean and variation of the ChT-maps of individual with similar ametropia, all the maps were aligned to each other in respect to the macula and optic nerve position with Matlab software (The MathWorks, Inc., Natick, USA). After correcting for differences in transversal area size with axial eye length (AL), an intensity overlay was introduced to exclude unreliable portions of the images with less than five measurements at one location. The images were evaluated along the depth-scan direction. ChT-maps were grouped by considering the eyes' refraction as myopic ($AL \geq 24.5$ mm, $n = 16$), emmetropic ($24.5 > AL \geq 23.4$ mm, $n = 20$), or hyperopic eyes ($AL < 23.4$ mm, $n = 28$) based on the normal AL variation with refraction and age [14–16]. Groups are described as characteristically myopic (long ALs), emmetropic (mid-length eyes), and hyperopic (short eyes). Mean and SD was obtained to create a compound map of average thickness for these three groups of eyes with color-coded thickness. For illustrating the location and extent of variation in the data sets, the coefficient of variation was found useful to allow comparison of widely different means. The coefficient of variation is expressed in percentage of the standard deviation from the mean.

Central ChT was measured beneath the fovea. Hyperopic eyes had a central ChT of 358 ± 96 μm (mean ± SD) and had the thickest choroid inferiorly but still within a 1,500 μm distance from the center. Emmetropic eyes had a ChT of 341 ± 95 μm, while myopic eyes had the thinnest choroid of the three groups with a central ChT of 213 ± 58 μm ($P < 0.001$, ANOVA, Bonferroni post-hoc testing) and an increase of thickness about 1,500 μm superior to the center (Fig. 60.2). The coefficient of

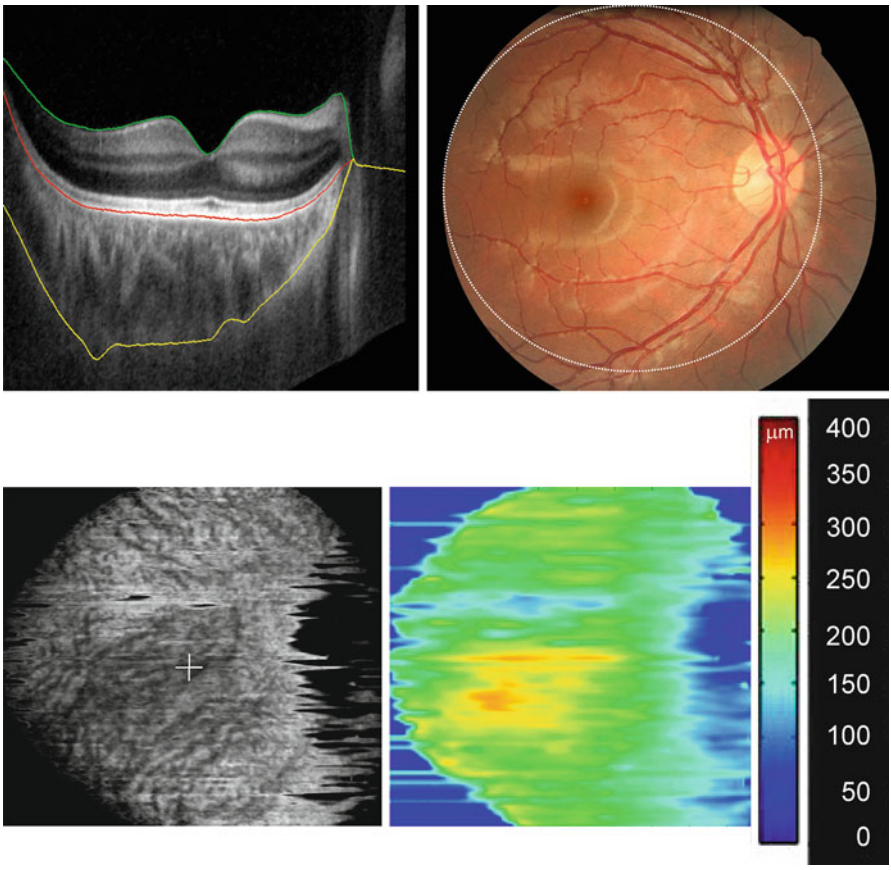

Fig. 60.1 1,060 nm OCT and choroidal thickness map generation in an example of automatic choroidal segmentation (*yellow line* border between sclera and choroid, *red line* RPE-Bruch's membrane/choriocapillaris complex, *green line* retina/vitreous interface). OCT image is taken within the area circled in fundus photograph. Choroid is segmented and averaged shown enface (*lower left image*) Choroidal thickness map generated for a healthy eye (*lower right image*)

variation was lowest in hyperopic eyes being less than 30 % over the majority of the ChT-map area. This study revealed also a decrease of ChT with age at the central and inferior location in eyes with longer ALs typically associated with myopia which is in agreement with the findings of other investigators [8, 11]. The mean of this study was much higher than found in studies with commercial systems (Table 60.1).

The healthy retina with macula and in its center, the fovea, has a structure that is accessible to localized averaged measurement: starting with the fovea centralis as an important measurement point and widening in concentric rings as suggested by the ETDRS study grid [17]. The ETDRS grid lends itself for measuring the choroid within the macula region, since the choroid is a major supplier of the macula and its

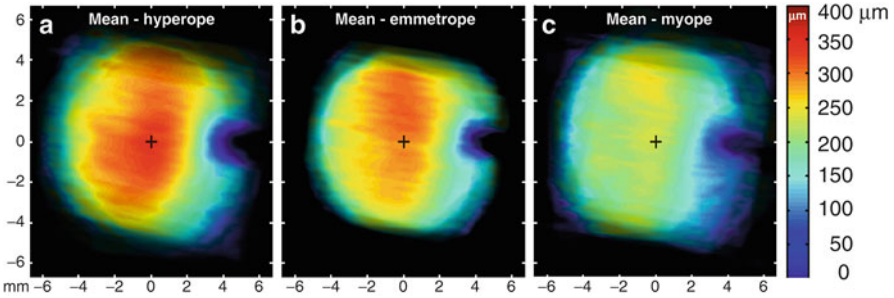

Fig. 60.2 Choroidal thickness maps grouped by axial eye length (*AL*) show a decrease in thickness mean with increasing AL (hyperope: AL<23.4 mm N = 28 eyes, emmetrope: 24.5> AL ≥23.4 mm N = 20 eyes, myope: AL ≥ 24.5 mm N = 16 eyes) [20]

Table 60.1 Choroidal thickness in healthy subjects measured with different OCTs

Investigators	Methods	Central choroidal thickness (mean ± SD)
Manjunath et al. [7]	Commercial OCT at 800 nm	272 ± 81 µm
Margolis and Spaide [8]	Commercial OCT with enhanced depth imaging at 800 nm	287 ± 76 µm
Zhang et al. [31]	Commercial OCT at 800 nm	172.1 (95 % CI 163.7–180.5) µm
Ikuno et al. [11]	Long wavelength OCT at 1 µm	354 ± 111 µm
Esmaeelpour et al. [20]	Long wavelength OCT at 1,060 nm	315 ± 106 µm

measurement is in this region of foremost interest [18]. However, the choroidal structure is unlike the retinal structure mainly a network of vessels with a characteristic segmental structure [19]. Choroidal thickness between the nasal, temporal, superior, and inferior fundus is distributed differently depending on age and AL [20]. Therefore, mapping in a region beyond the macula may allow a superior analysis. However, manual mapping is time consuming even if used only for research data.

60.1 Automatic Choroidal Thickness Segmentation

There are several challenges to automated choroidal segmentation. The first challenge is the low signal-to-noise ratio within the choroid and a washed out and irregular interface to the sclera. That is why previous OCT segmentation algorithms developed for the retina do not perform well with respect to choroidal segmentation requirements. Retinal segmentation algorithms vary depending on the number of layers to be segmented and on their robustness in the presence of speckle, shadows, morphologic irregularities (i.e., vessels, physiologic structural changes at the fovea and optic nerve head), and pathological changes in the tissue. In general most of the

existing approaches tend to be very sensitive to noise or missing data and often rely on well-contrasted boundaries or uniform layer structure. Intensity threshold-based algorithms utilize simple analysis along the depth scan's intensity profiles or find borders by investigating intensity gradients and are frequently confused by missing data, which leads to nonphysiologic results [21–26], thus, making them unsuitable for choroidal segmentation.

The second challenge is not being able to compare OCT images to the choroid itself in vivo for determining the true interface. One can only compare between different imaging modalities. Torzicky et al. segmented automatically in polarization-sensitive (PS) OCT images determining the anterior boundary of the choroid, the RPE, based on depolarization, and the posterior boundary, the CSI, based on the birefringence of the sclera [27]. The exact interface between choroid and sclera became subject to controversy because automatic segmentation of PS OCT images seems to overestimate choroidal thickness when compared to intensity based OCT imaging.

Kajic et al. achieved a robust automated choroid segmentation by using a statistical model that was built upon training data from manual segmentations by human operators [28]. Its advantage is that it can actively learn and determine the segmentation line in a low-signal, noisy environment such as in OCT tomograms in the region of the choroid without having to rely on boundary edge information. Statistical models can reproduce specific patterns of variability in shape and texture by analyzing the variations in shape across the training set. The key step of the statistical model training is the dimensionality reduction of the large set of features from the training data set. This is to enable the computational cost of the optimization method that is used to fit the model to the real data later on. The idea behind this concept is to find statistical dependencies between the produced features and reduce the dimensionality of the space by identifying only a certain number of the most prominent properties in the data set, represented by the most important eigenvectors.

To lower dimensions and to reduce multidimensional data sets for analysis, principal component analysis (PCA) is used. It is the standard vector space transform technique. It operates by calculating the eigenvalue decomposition of a data covariance matrix or singular value decomposition of a data matrix. Ideally, a relatively small number of eigenvectors with greatest eigenvalues can completely describe the original data.

The resulting pixel distance was converted into optical distance using the depth sampling calibration for the 1,060 nm OCT system and further to the anatomical distance. This resulted in thickness maps for individual eyes. Choroidal segmentation performed with a statistical model had as little as 13 % difference to manual segmentation, an error rate computed per tomogram, in a total of 871 tomograms, as a ratio of incorrectly classified pixels and the total layer surface. The reported difference between automated and manual retinal segmentation was comparable to the difference between manual and automated segmentation in the choroid [29]. Interobserver variability, measured by reimaging seven subjects (five healthy and two with dry AMD pathology) and comparing automatic segmentation of subfoveal ChT, ranged between 0 % and 10 % with a median of 1 % difference between the first and the second image [30]. Segmentation proved reliable even in

the presence of low signal (thick choroid), retinal pigment epithelium (RPE) detachments and atrophy, drusen, shadowing, and other artifacts.

Choroidal segmentation developed by other investigators [31] since uses vessel segmentation to identify the lower boundary of the choroid and envelope a surface to the lower vessels segmentation with a thin plate spline (TPS) approach [32]. While the segmentation is working, the main drawback responsible for a high rate of reported non-repeatability seems to be imaging OCT at 800 nm and not achieving the depth penetration needed for imaging the choroid.

60.2 Automatic Segmentation in Pathology

The generation of choroidal thickness maps was developed and applied first for normal healthy subjects to build a normative base. The choroid may be a novel biomarker for the major blinding eye diseases such as age-related macular degeneration and diabetes retinopathy. Statistical analysis using thickness maps in healthy proved practical to isolate areas of thinning or thickening and the extent of thickness alteration with axial eye length beside the classical measurement in the macula center. By illustrating how much a thinner choroid is related to an increasing AL, it becomes obvious that in studies of the choroid pathological eyes need to be matched not only by age but also by AL. Choroidal thickness mapping has also been established for swept source OCT, although segmented manually and investigators suggested applying the grid used by the Early Treatment Diabetic Retinopathy Study (ETDRS) [17] to facilitate reading of thickness values per area [33].

The use of choroidal thickness mapping was extended from healthy subjects to subjects with diabetes type 2 with a range of mild to clinically significant diabetic maculopathy [34]. A significantly lower choroidal thickness than healthy controls ($P < 0.05$) was found. Similarly in subjects with type 1 diabetes, choroidal thickness was reduced when compared to normal healthy subjects (Fig. 60.3) [30]. In type 1 diabetes choroidal thinning was not related to blood glycated hemoglobin or disease duration.

Capillary dropout in eyes with diabetes retinopathy is well documented [2, 35]. With current commercial OCTs, the choriocapillaris is not discernible as it is below the axial resolution of the present 800 and 1,060 nm instruments [36]. The magnitude of choroidal thickness alterations visualized in diabetes studies using thickness maps exceeds possible capillaries change [2, 37]. In both types of diabetes, choroidal thickness change is also present when clinical signs preceding retinopathy such as microaneurisms are not visible in the retina. This may suggest its role in hypoxia-induced injury and ischemia in the retina [38].

Vascular impairment in the choroid is also accounted for ischemia's role in AMD [39, 40]. A preliminary study on subjects with early AMD changes showed a decrease in choroidal thickness [41]. Drusen are deposits below the RPE and their presentation and area are suggested as biomarker for advancing into neovascular AMD [42] and have been associated with choroidal blood flow changes [43]. However, there are no studies with direct association with the choroid below the affected areas.

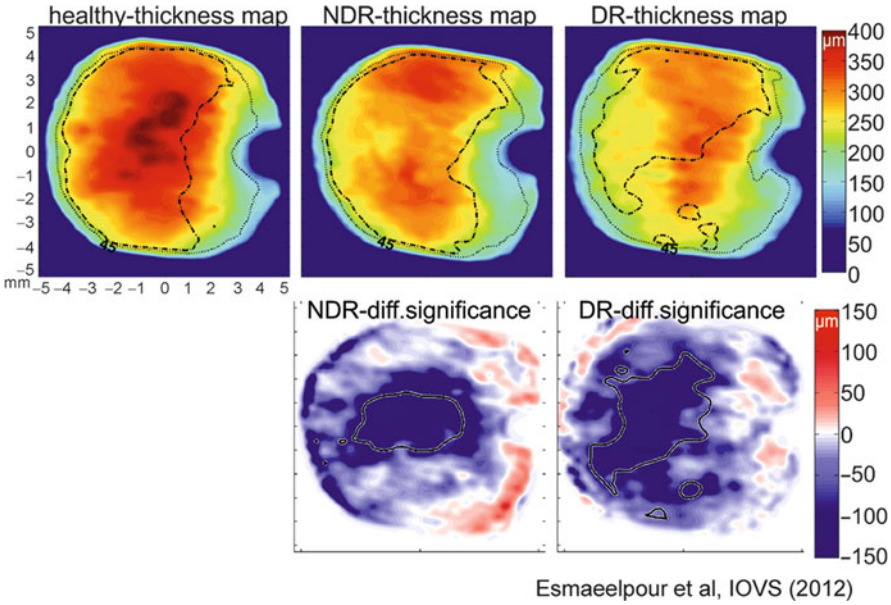

Fig. 60.3 Choroidal thickness and statistical difference contour maps in type 1 diabetes: choroidal thickness maps averaged for two disease stage groups compared with a healthy control group demonstrate that thickness is significantly decreased in NDR and DR group (*NDR* no diabetic retinopathy, *DR* diabetic retinopathy, first row averaged thickness maps with broken contour line representing 30 % variation), *lower row*; difference maps with central area of thinning, contour line represents $P < 0.05$

Another type of deposit associated with AMD are reticular pseudodrusen, which are granular hyper-reflective deposits in the subretinal space [44] suggested to be markers for inflammatory or atrophic vascular changes of the choroidal stroma [45, 46]. Using choroidal thickness mapping in 25 subjects with various types of AMD and pseudodrusen, we found a similarity between the shape of the affected area seen in autofluorescence images and areas with thicker choroid (Fig. 60.4). Thickness map observations show that choroidal areas coinciding with pseudodrusen area are thicker than other choroidal locations [47]. Using choroidal subfoveal thickness to relate to pseudorusen may be misleading as it is more likely to be associated with the severity of AMD rather than pseudodrusen.

Advanced AMD develops rapidly resulting in retinal exudates, with choroidal neovascularization in the choriocapillaris [3, 4], and is associated with functional changes of the choroid measured by laser Doppler [40]. Current treatment modality is intravitreal injection of vascular growth factor inhibitors (anti-VEGF) consisting of three initial injections in a four weekly routine and then treated "as needed" based on clinical findings, optical coherence tomography, and fluorescein angiography. In a current preliminary study, a group of 17 patients that underwent this treatment regime were imaged with 3D-1,060 nm OCT prior to treatment. After the three injections out of this cohort, seven patients were on clinically found

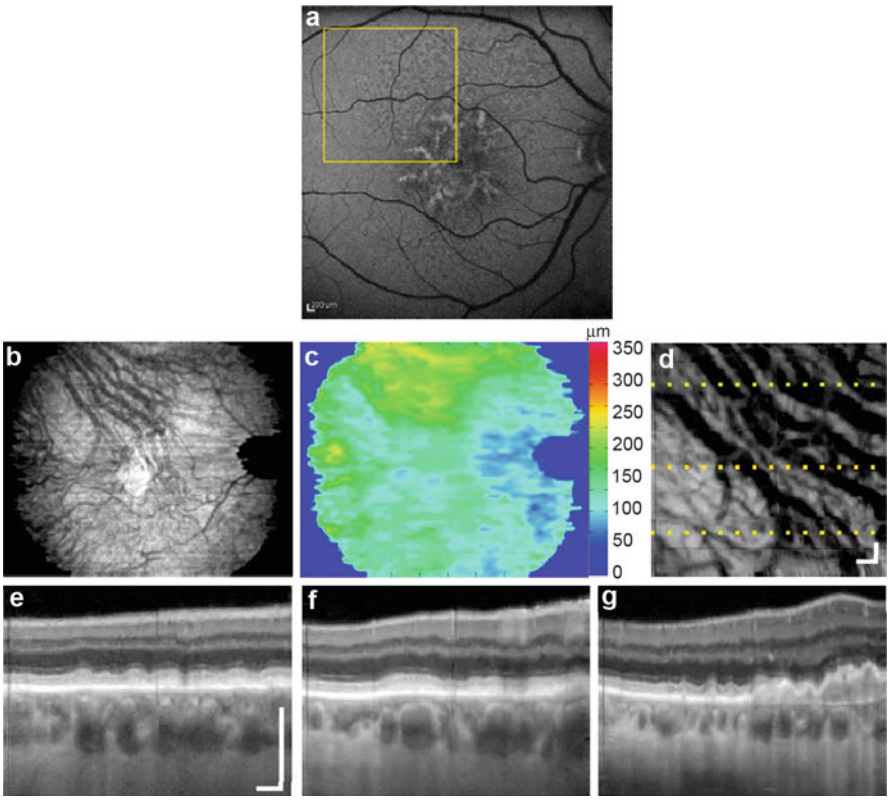

Fig. 60.4 The area where pseudodrusen are most prevalent coincides with the area of greater choroidal thickness. (**a**) Retinal autofluorescence image. (**b**) Enface 1,060 nm OCT image, averaged through the choroid. (**c**) Choroidal thickness map. (**d**) OCT image averaged from the superior temporal macula through the choroid (equal to the area shown in **a** with *lower right* corner ending at the fovea). (**e**–**g**) are tomograms taken at different distances from the fovea showing the distribution of different drusen and underlying choroid. While there is only a layer of large vessels underneath drusen (**g**), middle-size vessels belonging to Sattler's layer appear with an increasing number of pseudodrusen (**e**, **f**) [47]

successfully treated. These had initially a thinner choroid subfoveally than the patients that needed further injections. One eye became dry after five Anti-VEGF injections, while its fellow eye needed further treatment for the active neovascularization (Fig. 60.5). Although the successfully treated eye started with a larger fluid accumulation in the retina when compared to the fellow eye, it had a thinner choroid below the macula. This result may imply that the choroid in the ten non-successfully treated patients was more thickened and hence more affected than in the other patients. It has been postulated that inflammation is part of the pathogenesis of aging and AMD [48] and inflammation may be the reason for thickening in these patients. Another possibility may be fluid leakage not only into the retina but also into the choroid.

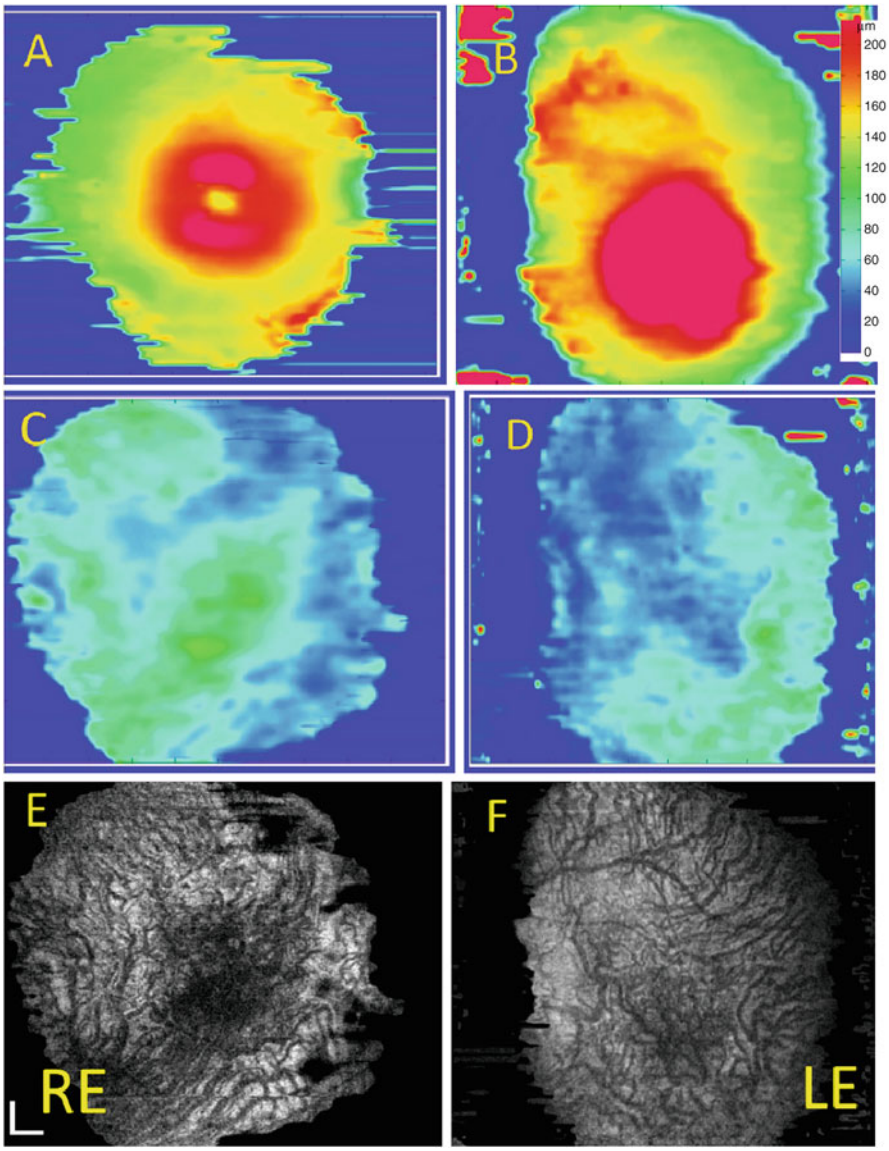

Fig. 60.5 Female subject (77 years old) with CNV type 1 in both eyes. Images were taken before treatment began. Although the right eye retinal thickness map shows a less edematous macular area than in the left retina, the right eye (*RE*) needs further injections, while the left eye (*LE*) was dry after the 5th injection. (**a**, **b**) Retinal thickness maps. (**c**, **d**) Choroidal thickness maps. (**e**, **f**) Enface of the choroidal vessel structure

60.3 Choroidal Vessel Segmentation

Vessel segmentation may provide a more in-depth analysis of choroidal change in ocular diseases. If choroidal vasculature changes with choroidal thickness, the type of change is still largely unknown. Choroidal vasculature has been modelled three dimensionally in vitro by using histology [49] and imagined two dimensionally in vivo by injecting intravitreal dye into the choroid [50]. The latter method is used clinically as it can pinpoint the exact location of activity such as of neovascularization in the choriocapillaries in AMD. It has the disadvantage of being highly invasive, possibly toxic with fatal risk. Alternatively vessels can be recognized noninvasively and in vivo by imaging their blood flow. The extension of OCT with Doppler signals enables in vivo volumetric vascular imaging by locating blood flow within the tissue. Although a good correlation exists between vessel diameter and blood flow velocity in the choroid [51], this type of vessel diameter calculation may underestimate the real diameter. A direct use of OCT choroidal images for vasculature segmentation is preferable as it improves specificity and accuracy of measurements.

Vessel segmentation algorithms used with other imaging modalities such as in MRI and CT rely on relatively high contrast, which allows achieving very high accuracy. Straightforward approaches for edge filtering such as Gabor filters [52] present difficulty when image vessel wall definition is low. Methods that use of seed points [53–55] are prone to segmentation leaks and if manual intervention is needed they are rendered impractical. Artificial intelligence and neural network-based methods require difficult to obtain training sets. Additionally, pixel-based classification algorithms [56] would have difficulty segmenting choroidal vessels based on texture features only. Because OCT background is hard to distinguish from the vessels, Rician distribution background modelling approach [57] encounters the same problem. OCT data intensities such as decreasing signal-to-noise ratio (SNR) with imaging depth, imposes a challenge to more than a hundred algorithms of vessel segmentation techniques, similar to the ones mentioned [58]. For 3D choroidal vessel quantification, a vessel segmentation algorithm is required that scales well with highly noisy data. All of the aforementioned methods require relatively high contrast and rely on various initializations and sequential tracking steps and/or require manual intervention of the operator which is extremely time costly and limited in the case of 3D data by human 2D vision (true 3D data can only be perceived as a 2D projection).

Vessel segmentation of choroidal stroma has been suggested by other investigators. Motaghiannezam et al. demonstrated an algorithm for automated vessel segmentation in three healthy eyes [59], whereas Zhang et al. investigated a cohort of 24 healthy eyes but could not successfully reproduce repeat segmentation in all eyes [31]. Their algorithm identified vessels in the choroidal stroma and assumed the remaining upper choroid to be equivalent to choriocapillaries. Another group of investigators analyzed choroidal vessels in eyes with AMD pathology and thin choroids [60] by pixel intensity without segmenting vessels.

Alternatively, a fully automated, robust vessel segmentation algorithm was developed for choroidal OCT, employing multiscale 3D edge filtering and

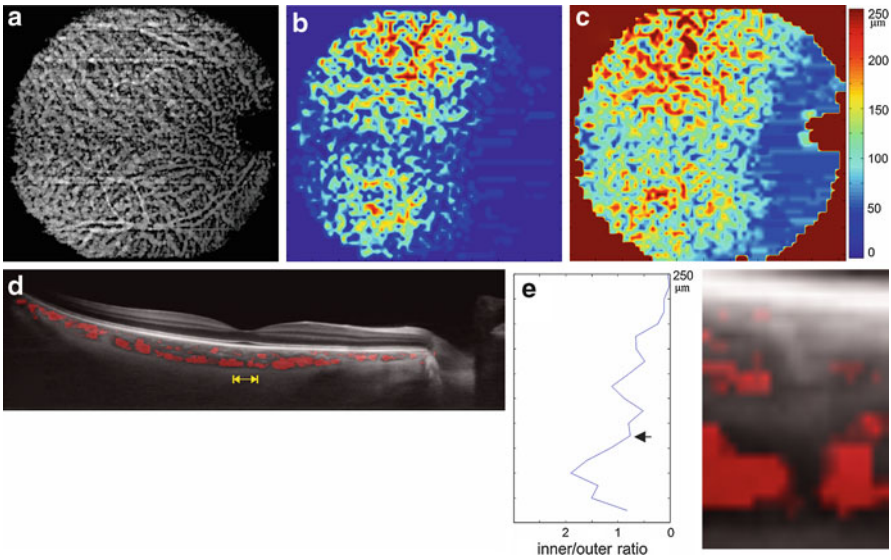

Fig. 60.6 Automatic segmentation of Haller's and Sattler's layer for thickness map generation. (**a**) An enface average of automatically segmented choroidal vessels. Based on diameter thresholding, thickness maps for Sattler's and Haller's layer are generated (**b**, **c**). (**d**) Central tomogram visualizes identified vessel voxels in red. Plot represents inner/outer voxel ratio of a 3D OCT data set with 1° diameter, taken from the location which is marked by *yellow arrows*. (**e**) The *black arrow* marks the border between Sattler's and Haller's layer that was detected based on the largest voxel ration and its local minimum

projection of "probability cones" to determine the vessel "core," even in the tomograms with low SNR. Based on the ideal vessel response after registration and multiscale filtering, with computed depth-related SNR, the vessel core estimate was dilated to quantify the full vessel diameter [61]. The novel algorithm extracts voxels belonging to vessels out of those voxels that belong to tissue (Fig. 60.6). The algorithm performs well when assessing qualitatively by viewing B-scan tomograms in data sets from healthy and patients with retinal pathologies, containing artifacts and extremely low signal due to shadows.

Further, the algorithm differentiates between the number of voxels that belong to outer vessel which have at least one neighboring voxel that is not a vessel voxel and inner voxels that are surrounded by other vessel voxels (Fig. 60.6). They yield themselves to useful statistics of morphological detail of the healthy and diseased choroid. These numbers are related to the distribution of the large and small choroidal vessels. Figure 60.6 shows that the ratio of inner to outer pixels, corresponding to the relative proportion of larger vessels, decreases from the sclera towards the RPE.

Vessel voxels segmented this way have been reproduced in a group of healthy eyes and eyes with dry AMD that were reimaged on a second study day [62]. Choroidal sublayers were segmented according to vessel voxel thresholding and

the coefficients of repeatability for Sattler's and Haller's layers were 35 % and 21 % in ten healthy eyes and 44 % and 31 % in ten AMD eyes, respectively. In representative cases of eyes with AMD and central serous chorioretinopathy, a comparison to vessel images taken with indocyanine green angiography (a dye for visualizing choroidal vessels in 2D field of view) confirmed that segmentation was no artifacts. In fact more vessels were visualized with OCT than with angiography with which vessels were obscured either by choroidal depth or by lesions.

By using inner to outer voxel plots to represent vessel diameter, it was possible to differentiate between Haller's and Sattler's layer. Haller's layer is characterized by large vessel diameter, whereas vessels in Sattler's layer are middle sized before they branch into capillary vessels in the inner choroid. While separating inner and outer choroid vessels within the OCT image allows for visualization of vessel incidence with depth, segmenting choroidal layers allows thickness mapping and may increase sensitivity to pathological changes. Mapping Sattler's and Haller's layer in a healthy normal data base of 40 subjects, it was possible to show that both layers' thicknesses correlate with each other, while paired t-test comparison showed a significant difference and that their thicknesses decrease with larger axial eye length.

61.1 Introduction

The last 20 years have experienced extraordinary advances in optical technology to image noninvasively and at high resolution the posterior segment of the eye. Two of the most impactful technological advancements over this period have arguably been optical coherence tomography (OCT) and adaptive optics (AO). OCT provides unprecedented, micron-scale axial resolution (<3 μm) and sensitivity to detect reflections from essentially any retinal layer, including those that are highly

transparent [1, 2]. OCT has become a standard diagnostic tool for evaluating health of the posterior segment, for example, for macular holes, central serous chorioretinopathy, age-related macular degeneration, macular edema, diabetic retinopathy, and glaucoma.

Unlike OCT, AO is not an imaging modality, but rather a technology that can be used in combination with imaging modalities to improve their performance. AO works by measuring and correcting ocular aberrations at real time. Its benefit is greatest when the pupil is large (>6 mm), which has the added benefit of minimizing the blurring effects caused by diffraction. Correction of ocular imperfections across a large pupil results in unprecedented lateral resolution (2–3 μm), sufficient for resolving individual cells *en face* [3–5]. AO was originally developed for ground-based telescopes to remove atmospheric blur and later incorporated into retinal imaging in the mid-1990s. Since then, AO for the eye has experienced exponential growth resulting in the first textbook devoted to the topic in 2006 [4]. Essentially all facets of AO have undergone substantive development for use with the eye, including its wavefront sensor, wavefront corrector, and control algorithm. In addition, AO has been integrated into a wide range of retina camera architectures to increase their resolution and sensitivity including the three principle types: flood-illuminated ophthalmoscope [3, 6–9], scanning laser ophthalmoscope (SLO) [10–15], and OCT [16–28]. Collectively these have become a valuable suite of imaging tools for vision and clinical research. Individually, each has distinct technical strengths that define the types of fundus imaging applications they are best suited for.

The aim of this chapter is to focus on the latter combination: adaptive optics – optical coherence tomography (AO-OCT). Success of the individual technologies, AO and OCT, has led to considerable effort by several research groups over the last decade to combine them for high-resolution, three-dimensional imaging of the retina. The resulting 3D resolution holds considerable promise to improve the research and clinical utility of OCT: for probing structure and function of the microscopic retina and for earlier detection, more precise diagnosis, and improved treatment monitoring of posterior segment disease.

Several excellent chapters in this book already cover the theoretical and experimental underpinnings of OCT. Thus this chapter focuses on the other key aspects of AO-OCT, especially those important for the design and implementation of AO in OCT systems. With that overriding principle, the chapter is divided into three main parts. First is a summary of our current understanding of the key optical properties of the eye. These properties underlie the motivation for AO-OCT and define the design requirements of AO-OCT systems. This is followed by a discussion of AO technologies and the technical benefits of adding AO to OCT. The second part surveys AO-OCT designs reported in the literature. Unlike flood illumination and SLO modalities that have effectively one principle design configuration, OCT embodies several fundamentally different ones, resulting in a wide variety of AO-OCT systems that have been attempted. The last part reviews some of the latest scientific and clinical uses of this powerful technology and a look to future developments in this rapidly growing field.

61.2 Imaging Properties of the Eye

The eye is unique, unlike any other organ in the body, it represents a complete imaging system including refracting optics (cornea and crystalline lens), aperture (iris), and photosensitive detector (retina/fundus). All of these are of course necessary for the eye to perform its critical function, vision, which it does amazingly well. However, when we purposely reverse the direction of light to view the retina and fundus, for example, examination with OCT, the completeness of the system – in particular the ocular media and iris – is less than ideal. The ocular system imposes severe constraints on how well we can image the back of the eye and the finest microscopic detail we can resolve.

Improved understanding of the optical properties of the eye has enabled AO-OCT to surpass the natural lateral resolution limits imposed by our eyes. This required overcoming the eye's intrinsic monochromatic and chromatic aberrations and minimizing its diffraction effects. Here we summarize the pertinent aspects of each for AO-OCT imaging. Our discussion is limited to the human eye, but it is worth noting that there is growing activity in experimental imaging in animal models using the same technology [29, 30].

61.2.1 Monochromatic Aberrations of the Eye

Monochromatic aberrations of the eye vary spatially across the eye's pupil, vary over time, and vary with field location at the retina. These fundamental properties (spatial, temporal, and field dependence) dictate the performance requirements of AO for effective correction of ocular aberrations and are discussed in order below.

The spatial distribution of ocular aberrations varies considerably among subjects and often does not correspond to the classical aberrations of manufactured optical systems, for example, Seidel aberrations. Instead, Zernike polynomials – orthonormal over circular pupils – are the most popular for representing ocular aberrations [31, 32]. Zernikes are not the most efficient polynomial representation of the eye's aberrations, but are only slightly less compact than the principal modes that derive from a principal components analysis [33, 34]. Zernikes are also mathematically simpler and have well-established properties. The now ubiquitous use of Zernike polynomials is perhaps best reflected by the vision community's establishment and universal acceptance of a single naming convention for the Zernike coefficients and polynomials as described by the OSA/VSIA Standards Taskforce [35].

Today monochromatic aberrations of the eye are well characterized. Detailed measurements of the spatial distribution of wave aberrations for central vision have been made in large populations of normal, healthy adult eyes with large pupils [33, 34, 36], including the pooling of data collected at ten laboratories (2,560 eyes) [37]. More recent studies have also been reported, including a retrospective analysis of 24,000 patients [38], expansion to peripheral aberrations [39, 40], and the effects of age, accommodation, refractive state, refractive surgery, and disease [41–49].

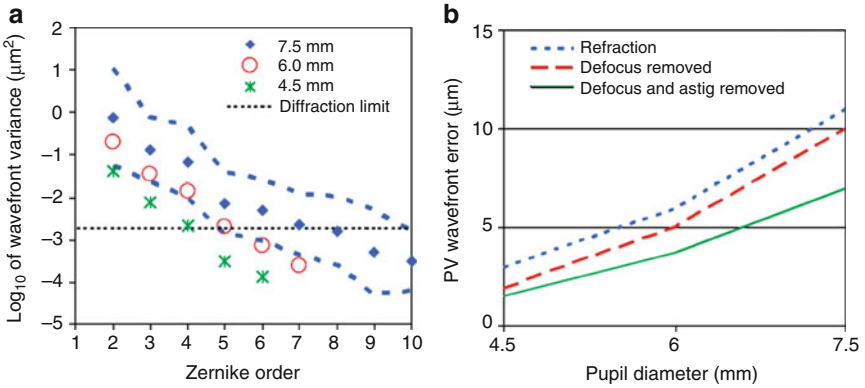

Fig. 61.1 Spatial properties of ocular aberrations in a large population of 100 normal eyes. (**a**) Log_{10} of the wavefront variance after a conventional refraction using trial lenses is plotted as a function of Zernike order and pupil size (4.5, 6.0, and 7.5 mm). *Diamonds* and corresponding *dashed curves* represent the mean and mean ± two times the standard deviation of the log_{10}(wavefront variance), respectively, for a 7.5 mm pupil. *Star* and *open circle* correspond to 4.5 and 6.0 mm pupils. *Thin, horizontal dashed line* corresponds to λ/14 RMS for λ = 0.6 μm. (**b**) PV wavefront error that encompasses 95 % of the population is plotted as a function of pupil diameter. Three second-order states are shown: (i) residual aberrations after a conventional refraction using trial lenses (*short dashed lines*), (ii) all aberrations present with zeroed Zernike defocus (*long dashed lines*), and (iii) all aberrations present with zeroed defocus and astigmatism (*solid lines*) (Reproduced with permission from OSA, Ref. [5])

The spatial characteristics of the ocular aberrations most important for AO are spatial fidelity (frequency composition) and magnitude (peak-to-valley (PV) wavefront error). Both are captured by the Zernike representation – spatial fidelity by the Zernike order and magnitude by the Zernike coefficient – and both are strongly influenced by pupil size. As an example, Fig. 61.1 (left) shows the wavefront variance decomposed by Zernike order for a population of about 100 normal subjects, most in their early twenties [34]. Data points are shown for three pupil sizes, 4.5, 6.0, and 7.5 mm, which span the range over which AO is typically applied to the human eye. For comparison, the maximum physiological pupil size for young subjects is nominally 8 mm. In Fig. 61.1 (left), the power decreases monotonically (approximately linear on a logarithmic scale) with second-order aberrations dominating the total wavefront error. Power also decreases monotonically with decreasing pupil size. The 7.5 mm pupil represents the most demanding condition for AO and requires correction of Zernike polynomials up through at least tenth order to reach diffraction-limited imaging.

Figure 61.1 (right) shows the corresponding PV wavefront error that encompasses 95 % of the population as a function of pupil size (4.5–7.5 mm). Three curves are shown that correspond to three different second-order states (defined in the figure caption). As expected, the PV error increases monotonically with pupil size and is strongly dependent on the second-order state. The PV error for the 7.5 mm pupil ranges from 7 to 11 μm depending on the second-order state.

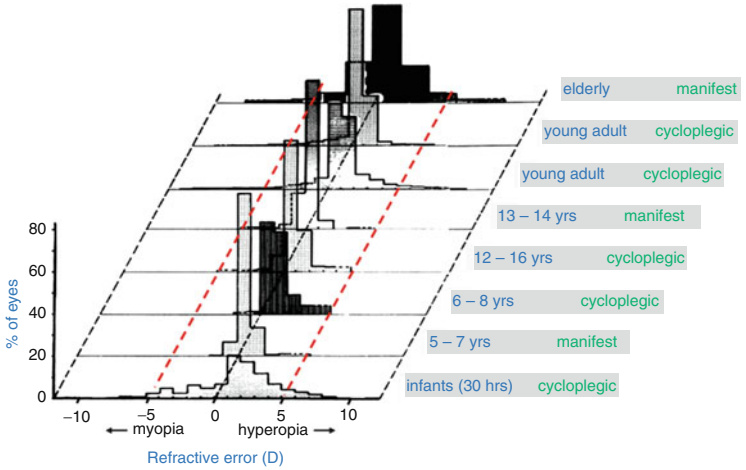

Fig. 61.2 Refractive error distributions sorted by age group and refraction (manifest or cycloplegic) (Graph reproduced and modified with permission from Elsevier, Ref. [50])

The largest error of 11 μm represents the most demanding condition for AO correction. Note that for this study, each subject was meticulously refracted with trial lenses. Typically, AO systems operate under less ideal conditions in which the second-order aberrations are only coarsely corrected or not at all. Under these non-ideal conditions, second-order aberrations can readily surpass the PV error shown in the figure by several times. As such, careful design of an AO system must take into account the anticipated refractive state of the population and the expected manner in which corrective trial and translating lenses and other means are applied in conjunction with AO.

Figure 61.2 provides a sense of the refractive state across eyes, showing cross-sectional refractive error distributions from several studies [50]. The distribution is not simple. It depends on many factors including population, age, education, and refractive state. Based on the figure distributions, a reasonable design goal for AO might be to correct errors up to +/−5 diopters as that covers a large percentage of eyes regardless of the factors shown.

The population measurements in Fig. 61.1 represent essentially static wave aberrations and therefore do not capture the temporal behavior of the ocular media. Two early pivotal studies elucidated the temporal dynamics using a power spectral method and investigated their impact on AO performance [51, 52]. Figure 61.3 (left) shows results from one of these studies, specifically temporal traces of the wavefront error for one subject and a model eye and (right) the corresponding temporal power spectra. As suggested in the figure, temporal fluctuations are found in all of the eye's aberrations, not just defocus, even when the eye's accommodation is paralyzed. In both studies, the reported temporal fluctuations decreased at $f^{-4/3}$, where f is the temporal frequency. This decrease is evident in the temporal power spectrum shown in Fig. 61.3 (right).

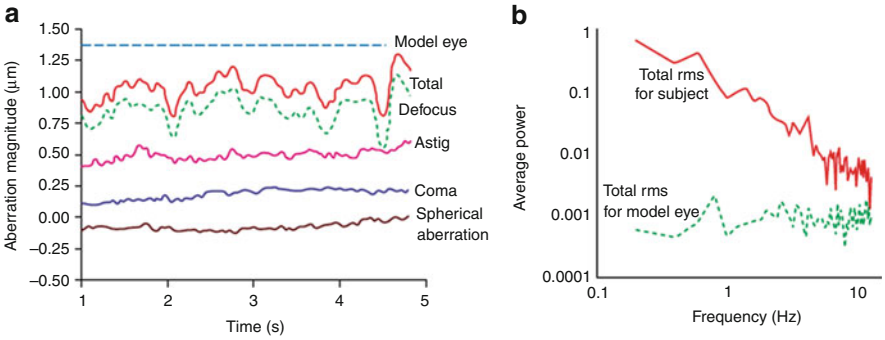

Fig. 61.3 Temporal properties of ocular aberrations [51]. (**a**) Temporal traces of the total RMS wavefront error and Zernike terms: defocus, astigmatism, coma, and spherical aberration for one subject. A trace of the total RMS wavefront error for an artificial eye is also shown and reflects the sensitivity of the instrument. (**b**) Average temporal power spectra are shown for the fluctuations in the total RMS wavefront error for a model eye and one subject whose accommodation was paralyzed. Aberrations were computed for a 4.7 mm pupil size (Reproduced with permission from OSA, Ref. [51])

The vast majority of the aberration power lies below 1–2 Hz, suggesting effective AO correction needs only a temporal bandwidth of a couple Hertz and an AO loop rate roughly 20 times faster.

Finally monochromatic aberrations of the eye also vary with field location at the retina. That is, image quality (or more precisely the point spread function or optical transfer function) at one point on the retina differs from that at another point when sufficiently separated. This difference in image quality stems from the fact that the ocular aberrations originate at the cornea and crystalline lens rather than at the pupil of the eye. Rays originating from different field locations on the retina will therefore take slightly different paths through the ocular media, accumulating different phase delays or equivalently different aberrations. In general there is a local region about any point on the retina in which the path differences are sufficiently small that the ocular aberrations are effectively constant. This region is termed the isoplanatic patch [53]. The diameter of the patch depends on the properties of the eye, but also on the definition of image quality, for example, use of the stringent Maréchal criterion, $\lambda/14$ μm RMS (Strehl ratio = 0.8) yields a narrower isoplanatic diameter than the more relaxed criterion of 1 rad^2 (Strehl ratio = 0.37).

Anecdotal evidence in the AO literature indicates the isoplanatic patch diameter for the human eye is a couple of degrees. Experiments to directly measure the patch size have only recently been conducted. A detailed survey of efforts in this area coupled with a more thorough analysis was published by Bedggood et al. [54]. Figure 61.4 shows a representative result from this study, plotting isoplanatic patch diameter as a function of the residual wavefront RMS at the patch edge. As expected, the patch size increases as the criterion relaxes, i.e., larger residual RMS. As an example, diffraction-limited AO-OCT imaging at 850 nm wavelength requires a wavefront RMS correction of 61 nm or better. Using this as

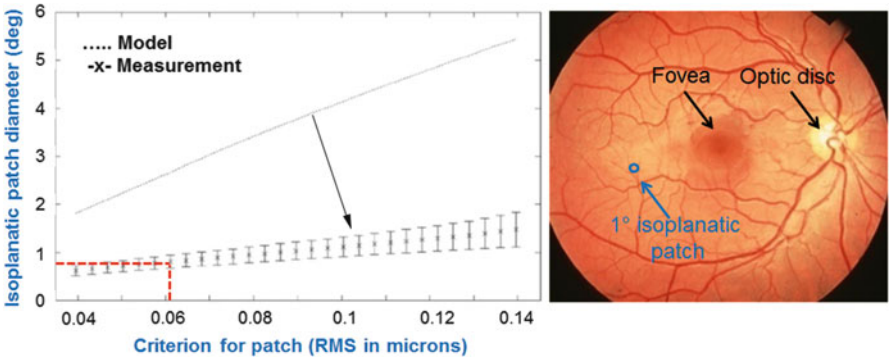

Fig. 61.4 (*left*) Isoplanatic properties of ocular aberrations. Isoplanatic patch diameter is plotted versus residual wavefront RMS at the patch edge after perfect correction of ocular aberrations at the patch center. Data points are average measurements across seven healthy subjects with error bars at ±1 standard deviation. Predicted patch diameter is also shown using the Liou Brennan schematic eye that clearly overestimates the measured diameter by several times [55]. Pupil size for both is 6 mm (Reproduced with permission from SPIE, Ref. [54]). (*right*) A 1° isoplanatic patch is superimposed on a conventional 45° fundus image, illustrating the vast difference in size

a criterion for the residual RMS at the patch edge in Fig. 61.4, the corresponding isoplanatic diameter is predicted to be somewhat less than one degree consistent with anecdotal evidence and other measurements reported in the literature. The narrowness of the isoplanatic patch has severe clinical consequences for AO-OCT as images at the isoplanatic size are substantially smaller than those collected with standard clinical instruments, a point illustrated by Fig. 61.3 (right). Shown is a fundus photograph with a standard 45° field of view and a 1° isoplanatic patch superimposed. While the fundus photograph can be captured in a single flash, AO-OCT performing at the diffraction limit requires tiling of 2,000 1° images – each with its unique AO correction – to cover the same field!

61.2.2 Chromatic Aberrations of the Eye

In addition to monochromatic aberrations, the human eye also suffers from significant chromatic ones (see Fig. 61.5), due primarily to its watery composition whose refractive index varies with wavelength. The longitudinal (LCA) and transverse (TCA) components of the ocular chromatic aberrations have been extensively studied at visible [56] and more recently near-infrared wavelengths up to 1,070 nm [57–59]. LCA and TCA refer to the variation in focus and image size with wavelength, respectively, both effectively blurring the patient's vision or conversely the retinal image. Historically, interest in chromatic aberrations of the eye was driven by their impact on visual performance. This led to the design of numerous achromatizing lenses [60–65], many of which were shown effective at correcting the eye's LCA, which is largely uniform across eyes and insensitive to field angle.

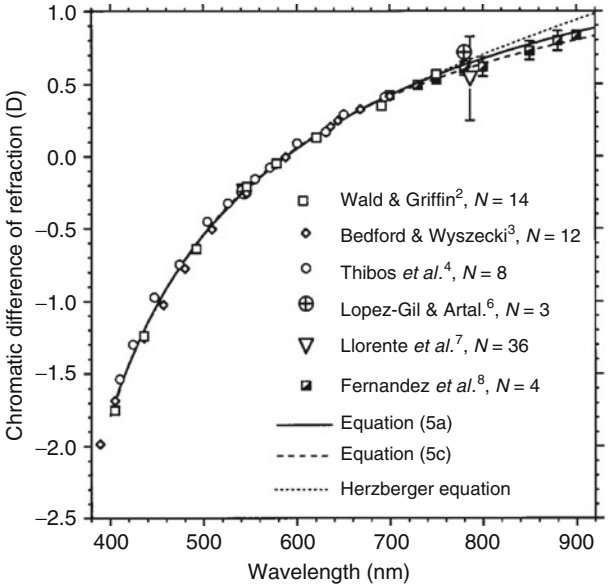

Fig. 61.5 Chromatic difference of refraction from several experimental studies and theoretical models that collective cover the visible spectrum and extend into the near infrared. All data were set to be zero at 590 nm. Close agreement between studies occurs largely because of the relatively small intersubject variation in chromatic aberrations [58]. (Reproduced with permission from OSA, Ref. [58])

In contrast, correcting the eye's TCA has proven significantly more difficult, partly as TCA varies across eyes and is highly sensitive to field angle. In some cases, slight misalignment of the achromatizing lens to the eye was found to substantially increase the TCA, well above that which is intrinsic to the eye. Despite the mixed success of using achromatizing lenses to improve visual performance, its recent use in high-resolution retinal imaging, in particular AO-OCT, has proven beneficial. AO-OCT instruments have several key attributes that reduce the demand on the achromatizing lens. These include a comparatively small field of view, imaging at near-infrared wavelengths, a limiting pupil that is specified by the retina camera rather than the eye, better stabilization of the subject's head, and raster scanning of the retina using galvanometer scanning mirrors.

61.2.3 Image Quality of the Eye

Retinal image quality is degraded not only by aberrations, but also diffraction, which for pupil diameters of less than about 3 mm is actually the largest source of image blur. A pupil about 3 mm in diameter – which is a typical pupil size under bright viewing conditions – generally provides the best optical performance in the

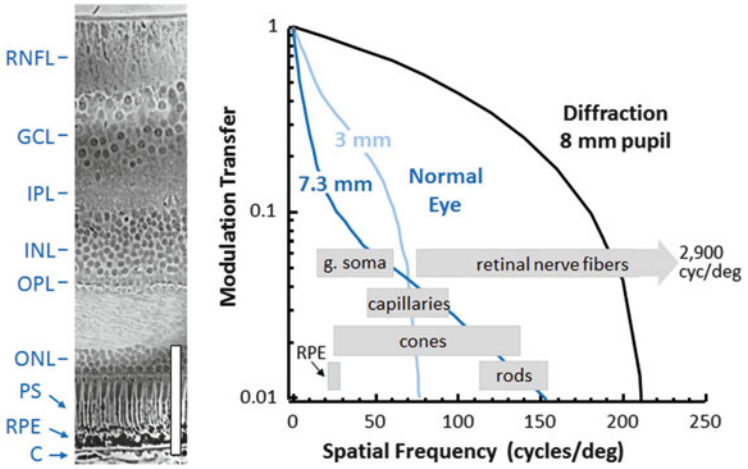

Fig. 61.6 (*left*) Histological cross section of primate retina with labels and scale bar (100 μm) added. (Cross section is reproduced with permission from the Royal Society of London [66].) (*right*) MTF of the eye under normal viewing is shown with pupils that are 3 and 7.3 mm in diameters and with the best refraction achievable using trial lenses averaged across 14 eyes. Also shown is the diffraction-limited MTF for the 8 mm pupil. The area between the normal and diffraction curves represents the range of contrast and spatial frequencies inaccessible with a normal eye, but reachable with AO. Also indicated is the range of fundamental frequencies defining several clinically important cell-sized structures. The ganglion soma (g. soma) range corresponds to sizes in the foveal margin and superior periphery with mean diameters of 11.7 μm (25.6 cyc/deg) and 15.8 μm (19 cyc/deg), respectively [67]. Individual retinal nerve fibers can get as large as 3.9 μm (75 cyc/deg), but the most probable axon diameter is about 0.45 μm (660 cyc/deg) [68]. Retinal capillary diameters are shown for central retina with mean size of 4.9 μm (61.2 cyc/deg) [69]. Cone row-to-row spacing (derived from cone density) is shown for the central +/−15°, averaged over the four meridians [70]. Rod row-to-row spacing is shown for 4.5 and 17° retinal eccentricity, again from histology [70, 71]. RPE spacing is shown for 5–20° in the superior retina [72]. Key: *RNFL* retinal nerve fiber layer, *GCL* ganglion cell layer, *IPL* inner plexiform layer, *INL* inner nuclear layer, *OPL* outer plexiform layer, *ONL* outer nuclear layer, *PS* photoreceptor segments, *RPE* retinal pigment epithelium, *C* choroid

range of spatial frequencies that are important for normal vision. Increasing the pupil size does increase the high-spatial-frequency cutoff, allowing finer details to be discerned, but at the high cost of increasing the deleterious effects of aberrations. Clearly, the very best optical performance would come from correcting all the eye's aberrations across the dilated pupil.

Quantitatively, the effects of diffraction and aberrations on corrected and uncorrected pupils of various diameters are best illustrated by the modulation transfer function (MTF). Figure 61.6 shows the MTF for normal pupils 3 and 7.3 mm in diameter and for a large corrected 8 mm pupil. The large corrected pupil has a higher optical cutoff frequency and an increase in contrast across all spatial frequencies. Peering inward through normal-sized pupils, only large cell bodies (ganglion and retinal pigment epithelium) and the largest cone

photoreceptors and capillaries should be resolved without substantial penalty in contrast due to poor MTF. But with the corrected 8-mm pupil, essentially all cells can be discerned if the cells possess sufficient intrinsic contrast with surrounding tissue. Even some single retinal nerve fibers (ganglion cell axons) should be resolved, although such large caliper fibers are scarce and the most probable diameter is more than three times beyond the 8 mm diffraction limit. Nevertheless at the cellular level, a large corrected pupil is critical for making use of the spatial frequencies that define single cells in the retina.

61.3 Adaptive Optics

An ophthalmic AO system consists of the same principle components as those employed in ground-based telescopes: wavefront sensor, wavefront corrector, and control system. These components are highlighted in the simplified AO schematic of Fig. 61.7 (see figure caption for details). The wavefront sensor and corrector operate in closed loop, and the correction imparted on the wavefront is based on the wavefront sensor measurement. The effectiveness of these components depends fundamentally on their ability to measure, correct, and track ocular monochromatic aberrations, the extent to which depends strongly on the spatial and temporal properties of the aberrations as described in the previous section. General ophthalmic requirements for these (measure, correct, and track) are presented here.

61.3.1 Wavefront Sensor

There is an abundance of optical sensors for wavefront measuring with many representing highly mature devices. These include the Shack-Hartman wavefront sensor (SHWS), shearing interferometer, pyramid sensor, curvature sensor, phase diversity, laser ray tracing, phase-shifting interferometer, and common-path interferometer. While several of these have been applied to the eye and others continue to attract interest, to date almost all operational AO systems for the eye have been constructed using the SHWS. As such, we confine our attention to this sensor type, though much of which will be applicable to the other sensors.

A first-order design of the SHWS entails evaluation of four key properties: (1) spatial sampling, (2) dynamic range, (3) accuracy, and (4) signal to noise. These are set primarily by the characteristics of the lenslet and CCD/CMOS arrays of the sensor, and therefore, selection of these two components is critical. Spatial sampling of the sensor is specified by the number of lenslets that fills the pupil of the eye. The necessary number of lenslets for reliable representation of the ocular aberrations depends on the composition of the ocular aberrations, pupil size of the eye, and to a lesser extent the SH wavelength. A general rule of thumb is that one lenslet is required for every Zernike mode that is to be measured. Based on this, reliable representation up through tenth Zernike order requires at least 63 lenslets that uniformly cover the pupil. In practice, SHWSs routinely sample the pupil with

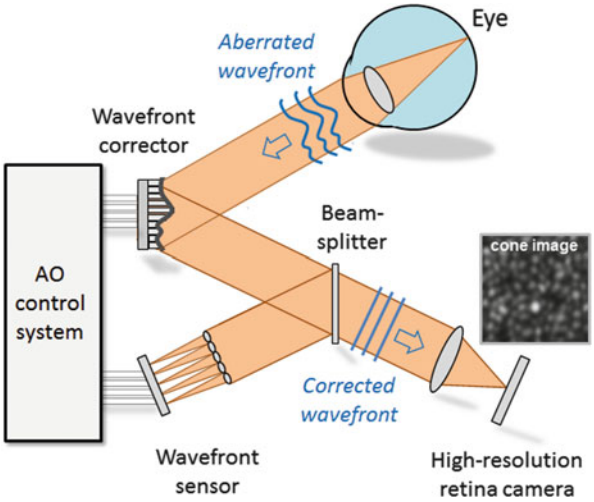

Fig. 61.7 Concept schematic of AO applied to the eye. The wavefront sensor (shown here as a Shack Hartmann implementation) works by measuring the reflection of a light beam that is focused onto the subject's retina. The reflection is distorted as it passes back through the refracting media of the eye. A two-dimensional lenslet array, placed conjugate with the eye's pupil, samples the exiting wavefront forming an array of images of the retinal spot. A CCD or CMOS sensor records the displacement of the spots, from which first local wavefront slopes and then global wavefront shape are determined. Wavefront compensation is realized with a deformable mirror. The mirror lies in a plane conjugate with the subject's pupil and the lenslet array of the SHWS. For retinal imaging, a light source (not shown) illuminates the retina, some of which is reflected out of the eye, reflects from the wavefront corrector, and forms an aerial image at the retina camera

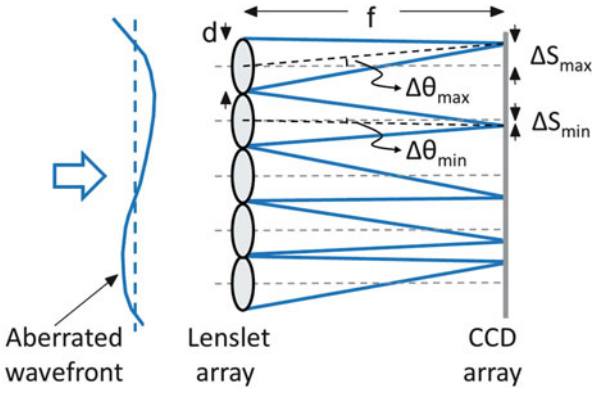

Fig. 61.8 Schematic illustrates the principle operation of the Shack-Hartmann wavefront sensor

much higher density. There is little cost to do so since there is an abundance of light for the sensor. Oversampling makes the measurements more robust (to pupil edge effects, eye motion, drying of the precorneal tear film, and system noise) and applicable to eyes with a wider range of aberrations. Schematic of the SHWS is shown in Fig. 61.8.

Dynamic range refers to the maximum wavefront slope, $\Delta\theta_{max}$, that can be measured by the SHWS. $\Delta\theta_{max}$ is typically expressed as $\Delta S_{max}/f$, where ΔS_{max} is the maximum displacement of the lenslet spot (=lenslet radius) and f the lenslet focal length. Since spherical and cylindrical refractive errors typically consume much of the dynamic range of the sensor, it is often more useful to convert ΔS_{max} to a maximum measurable defocus (diopters), expressed by $D = \Delta\theta_{max}/$ (pupil radius). For example, a lenslet diameter of 0.4 mm and a lenslet focal length of 24 mm give a $\Delta\theta_{max}$ and D of 8.3 mrad and 2.44 diopters, respectively, for a 6.8 mm eye pupil. In general, the dynamic range can be increased by increasing the lenslet diameter, decreasing the lenslet focal length, or decreasing the pupil diameter.

Accuracy refers to the minimum wavefront slope, $\Delta\theta_{min}$, that can be measured by the SHWS. $\Delta\theta_{min}$ is expressed as $\Delta S_{min}/f$, where ΔS_{min} is the minimum detectable displacement of the lenslet spot. ΔS_{min} depends on the pixel size of the SHWS detector, diameter of lenslet spot at the detector (which is a function of the lenslet diameter and focal length), accuracy of the centroiding and thresholding algorithms, and signal to noise of the captured SHWS spot image. In general, sub-pixel accuracy is routinely achieved [73]. While the SHWS parameters can be manipulated to increase accuracy, dynamic range of the sensor also depends on the lenslet diameter and focal length, but inverse of that for accuracy thereby creating a clear trade-off between these two SHWS properties. This trade-off can be partly avoided with smarter centroiding algorithms. For example, cross-correlation techniques have been used to locate centroids of spots outside the conventional search box area. This approach – which is employed in some commercial wavefront sensor systems – substantially increases the dynamic range of the system without loss in accuracy.

Signal to noise of the captured SHWS spot images is limited by the amount of light that can be safely directed into the eye, number of pixels per lenslet focal spot, quantum efficiency of the SHWS detector, and throughput efficiency of the SHWS. Fortunately, ophthalmic AO systems operate under relaxed light requirements, certainly well above the ~100 photons/lenslet needed to close astronomical AO loops. A typical ophthalmic AO system, running at tens of milliseconds exposure time, has at least ~500,000 detected photons/lenslet, this with hundreds of lenslets that sample the pupil. Such high light levels permit use of relatively low quantum efficient CCD and CMOS detectors and tens of pixels that sample the core.

61.3.2 Wavefront Corrector

The effectiveness of AO to correct ocular aberrations has historically been limited by the performance of the wavefront corrector, the most expensive AO component. This device dynamically imparts an ideally conjugate aberration profile onto the incident wavefront, thus canceling the original aberrations.

Wavefront correctors first applied to the eye were developed primarily for compensation of atmospheric turbulence, a common example being macroscopic discrete actuator deformable mirrors (DMs), such as those manufactured by

Xinetics, Inc. [74]. Specifically, their actuator number, stroke, influence function, and speed were tailored to the spatial and temporal properties of the atmosphere [75] rather than that of the eye [33, 34, 51, 52]. Stroke refers to the dynamic range of the corrector and limits the largest wavefront error that can be corrected. Larger stroke provides better correction of large-magnitude aberrations. Actuator number across the eye's pupil and actuator influence function (localized deflection of the mirror surface that results when a single actuator is pushed or pulled) determine the fidelity of the correction. More actuators and a more localized influence provide better correction of high-spatial-frequency aberrations, i.e., aberrations of high order. The dynamic range of these first devices did not match that needed for the eye and provided incomplete compensation of ocular aberrations. Also, their kilohertz response was overkill for the 1–2 Hz fluctuations of the ocular aberrations, and the devices themselves were generally bulky, with large mirror surfaces (∼several centimeters or more) that required long focal length relay optics to magnify the pupil of the eye.

Since then, there have been several extensive theoretical studies that have evaluated the performance of general wavefront corrector classes [76, 77] as well as specific commercial devices [78, 79]. These studies along with empirical evaluations have helped define corrector parameters for eye use, in particular the required actuator stroke, number, and influence function. Other important corrector parameters include temporal response, surface reflectivity for broadband use, corrector diameter, and of course cost.

In recent years, an expanding array of alternative wavefront corrector technologies has flooded the market, replacing the previous small market driven by atmospheric turbulence applications. These new technologies have been a welcome relief, generating a range of commercial devices that span all four major corrector classes: segmented, discrete actuator, bimorph, and membrane wavefront correctors. Figure 61.9 shows representative devices from the four classes that have been applied to the eye. These new devices provide substantially improved corrector performance specifically in the areas needed for ocular applications. Additionally, their small mirror footprint and lower cost are enabling AO technology to jump from the vision research laboratory to the clinic and into turnkey commercial AO ophthalmic cameras.

61.3.3 Control System

The control system performs the critical step of rapidly and repeatedly converting the raw output of the wavefront sensor into voltage commands that shape the corrector surface, i.e., the deformation created by the sum response of the corrector actuators. The control loop takes into account the number, arrangement, and interaction of lenslets and actuators; the influence function and stroke of actuators; temporal response of the AO components; and a desired performance criteria, e.g., minimize the RMS wavefront error. The control loop can be characterized in terms of its spatial and temporal properties.

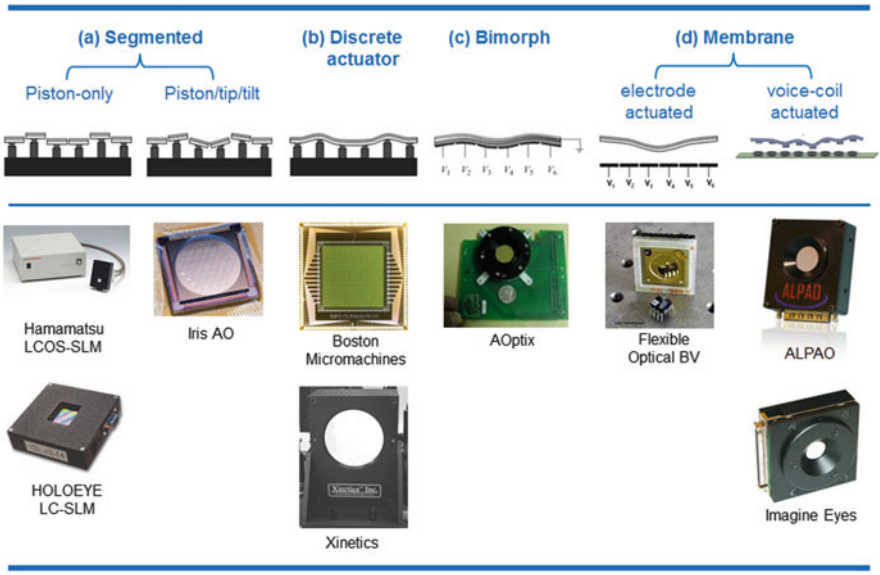

Fig. 61.9 Four main classes of wavefront correctors with specific devices that have been applied to the eye. (**a**) Piston-only segmented correctors consist of an array of small planar mirrors whose axial motion (piston) is independently controlled. Liquid-crystal spatial light modulators control the wavefront in a similar fashion, but use changes in refractive index rather than physical displacement of a mirror surface. Piston/tip/tilt segmented correctors add independent tip and tilt motion to the piston-only correctors. (**b**) Discrete actuator deformable mirrors consist of a continuous, reflective surface and an array of actuators, each capable of producing a local deformation in the surface. (**c**) Bimorph mirrors consist of a layer of piezoelectric material sandwiched between a continuous top electrode and a bottom, patterned electrode array. A top mirrored layer is added to the top continuous electrode. An applied voltage causes a deformation of the top mirrored surface. (**d**) Electrode-actuated membrane mirrors consist of a grounded, flexible, reflective membrane sandwiched between a transparent top electrode and an underlying array of patterned electrodes, each of which is capable of producing a global deformation in the surface. Voice-coil actuated membrane mirrors provide similar global deformation, but realized with miniaturized voice-coil actuators that make no contact with the membrane. Note that photographs of the devices are not shown to scale

Spatial (static) control starts with the layout of lenslets and actuators. Typical AO systems for the eye sample each actuator with two to ten lenslets. This oversampling increases the tolerance to alignment errors and permits detection of all corrector modes. Spatial control of the wavefront corrector using the wavefront sensor is normally realized (based on a linear systems approach) by a multiplication of two matrices, one representing the wavefront sensor output, S, (slope measurements) and the other a reconstructor matrix, A^+, representing the interaction of each actuator with each lenslet (control matrix). This single matrix multiplication,

$$V = A^+ \; S, \tag{61.1}$$

provides the voltages, V, that are applied to the corrector actuators. This approach – commonly referred to as the direct slop method – is fast and efficient. Another common approach is based on modal reconstruction in which wavefront slope measurements are converted to Zernike aberration modes (or other modal set) that in turn are converted to applied voltages. This approach allows explicit control of individual modes, including which ones are sent to the corrector.

Because of the high demand on corrector performance, a recent control strategy has been to distribute the demand across two wavefront correctors using a woofer-tweeter concept. In this arrangement, a large-stroke wavefront corrector (woofer) corrects large-amplitude, low-order aberrations and a high-spatial fidelity wavefront corrector (tweeter) corrects low-magnitude high-fidelity aberrations [25, 80–84]. However, mirror technology is catching up. New voice-coil-actuated membrane deformable mirrors offer both large stroke and relatively high number of actuators and have demonstrated comparable performance to that of woofer-tweeter systems [85].

Spatial properties, however, do not fully characterize the control system as they do not capture the closed-loop performance of AO. Specifically, they neglect the temporal dynamics of the ocular aberrations and the time delays associated with measuring the wavefront slopes and computing and applying the control voltages. Taking into account these temporal effects is critical for optimizing system performance and is accomplished by modeling temporal control as a cascade of transfer functions, each representing an independent component of the system. Details of this process are illustrated in Fig. 61.10 (top) using a block diagram representation of the AO control loop. As an example of the utility of the transfer function approach, Fig. 61.10 (bottom) shows predicted and measured traces of the power rejection magnitude (derived from the transfer functions) for representative AO configurations, one being five times faster than the other. The power rejection magnitude permits determining the cutoff frequency of the AO system, being defined as the frequency at which the power rejection magnitude first reaches 1. For the two configurations in Fig. 61.10, cutoff frequencies occur at 0.5 and 2.0 Hz, with the former consistent with the experimental measurements shown. Note that a cutoff of 0.5 Hz indicates that temporal frequencies below 0.5 Hz are (at least partially) corrected by the system, while those above 0.5 Hz are (at least partially) amplified. Because the vast majority of the aberration power in the eye lies below 1–2 Hz (see Fig. 61.3b), the 2.0 Hz bandwidth AO configuration should be adequately fast and provide improved performance over the 0.5 Hz system.

Finally, it is worth mentioning that there is growing interest in wavefront sensorless control of AO systems for imaging biological structures for which AO cannot establish a reliable wavefront that can be corrected by a wavefront corrector. Bonora et al. have recently published a short review of wavefront sensorless techniques including demonstration of a wavefront sensorless AO-OCT system [86]. Future refinements of this technique, beyond the simple implementation presented in their chapter, should allow its extension to in vivo applications. Interestingly an example of sensorless adaptive optics scanning laser ophthalmoscopy (AO-SLO) for imaging in vivo human retina has been recently presented [87].

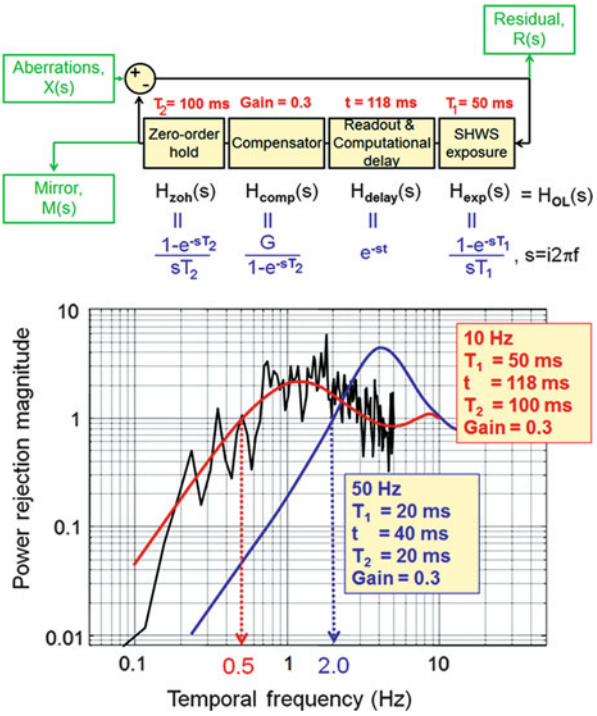

Fig. 61.10 (*top*) Block diagram of the AO system for modeling temporal performance. Input/output parameters $M(s)$, $X(s)$, and $R(s)$ depict the time-varying aberrations of the eye, residual aberrations after correction, and wavefront corrector voltages. For temporal analysis, the AO system is decomposed as a linear cascade of independent transfer functions, in this case the four AO stages that most often limit temporal performance in ophthalmic AO systems: SHWS exposure, sensor readout and computation of V, integral compensator, and finally holding mirror position for one AO loop period. T_1 is the exposure duration of the SHWS detector, T_2 is the sampling period of the AO loop, and t is the total delay to readout the sensor and compute V. (*bottom*) Experimental and theoretical curves for the power rejection magnitude of an ophthalmic AO system. Experimental curve (*jagged, black line*) was obtained on one eye using a gain of 0.3 for a 6.8 mm pupil. The corresponding theoretical curve (*solid, red*) was based on the actual system parameters given in the *leftmost box* on the plot. The second theoretical curve (*blue*) predicts the performance of an AO system that is five times faster. System parameters are given in the *rightmost box*

61.4 Adding AO to OCT

61.4.1 AO Benefits

AO permits access to the full retinal reflection that exits a large pupil of the eye (>6 mm). This translates into three technical benefits for OCT that improve the visualization and detection of microscopic structures in the retina: (1) higher lateral resolution, (2) a smaller lateral speckle size, and (3) higher collection efficiency for

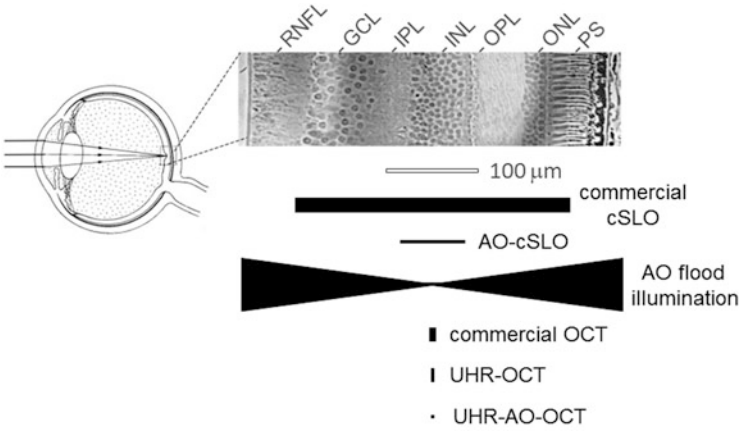

Fig. 61.11 Comparison of (*top*) cell size in a histological cross section of the human retina to (*bottom*) the resolving capability of the major types of retinal imaging modalities with and without AO. The vertical and horizontal dimensions of the *solid black symbols* denote, respectively, the lateral and axial resolution of the instruments. Examples shown include the commercial confocal scanning laser ophthalmoscope (*cSLO*), adaptive optics with confocal scanning laser ophthalmoscope (*AO-cSLO*), adaptive optics flood illumination, commercial OCT, ultrahigh-resolution OCT (*UHR-OCT*), and adaptive optics with ultrahigh-resolution OCT (*AO-UHR-OCT*). See key in Fig. 61.6 for retina labels (Reproduced with permission from The Royal College of Ophthalmologists, Ref. [27])

light backscattered from the retina. Of these three, lateral resolution has received considerably the most attention, but the other two add significant performance value. The benefit of each is discussed below.

The addition of AO typically increases the lateral resolution by approximately six times over commercial OCT. Of course to take advantage of this resolution requires increased A-scan sampling so that the closeness of the individual A-scans does not compromise the improved optical resolution. Current state-of-the-art adaptive optics, ultrahigh-resolution OCT (AO-UHR-OCT) has an isotropic 3D resolution of $2.5 \times 2.5 \times 3\ \mu m^3$ (width × length × depth) in retinal tissue. Two of these three dimensions are governed by conventional optics (diffraction and aberrations), and therefore, the resolution volume is highly sensitive (goes as the square) to AO performance and actually more so than OCT that acts only on a single dimension, depth. Figure 61.11 compares the size of this 3D resolution element of AO-UHR-OCT (smallest black symbol) to that of OCT without AO and to that of two other major imaging modalities – confocal scanning laser ophthalmoscope and flood illumination – with and without AO. As shown, the addition of AO to UHR-OCT or commercial OCT improves the resolution volume by 36 times. Furthermore, AO-UHR-OCT has a resolution volume that is 72 times better than that of commercial OCT, taking into account AO and the two times improvement in axial resolution afforded by the wider source spectrum. In general, AO-UHR-OCT provides the best resolving capability of any of the imaging modalities and the only instrument able to resolve cells in all three dimensions.

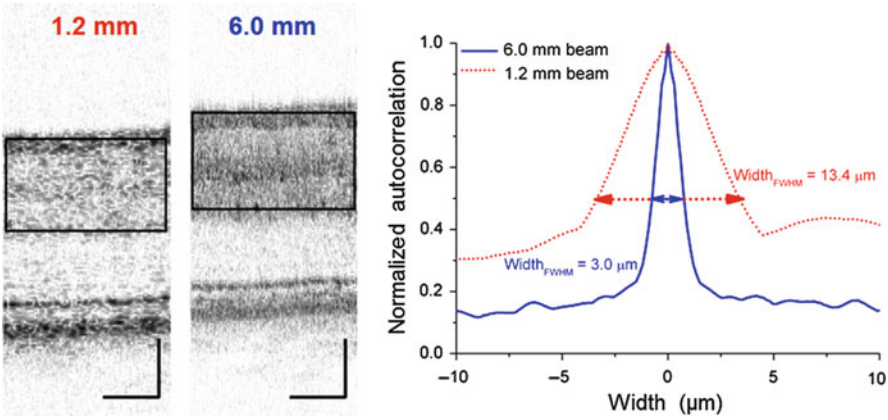

Fig. 61.12 (*left*) B-scans of the same retinal patch taken with the same AO-OCT system, but with 1.2 mm and 6.0 beams. Focus of the AO was near the outer plexiform layer; wavelength was 840 nm. (*right*) The FWHM lateral width of speckle was determined from the width dimension of the two-dimensional autocorrelation of the demarcated area in the B-scans. Only the upper retinal layers were included in the analysis because the autocorrelation algorithm was sensitive to abrupt changes in intensity (Reproduced with permission from OSA, Ref. [88])

The second benefit of AO is reduced lateral speckle size. The interferometric nature of OCT generates high-contrast speckle that permeate the entire OCT image and masks structural details, especially those at the resolution limit of the system. Since lateral speckle size is inversely related to pupil (beam) diameter, the larger pupil size afforded with AO (>6 mm) reduces theoretically the lateral dimension of speckle. For current state-of-the-art UHR-AO-OCT, this corresponds to a reduction of roughly six times and a corresponding speckle volume of 36 times compared to that of standard commercial OCT. Cense et al. [88] confirmed this improvement by a speckle analysis of B-scans acquired 3° from the foveal center. In Fig. 61.12, two examples are given, without (1.2 mm beam) and with (6.0 mm beam) AO. Analyzed over many B-scans, the FWHM lateral speckle diameter was equal to 14 ± 1 μm (1.2 mm beam) and 3.1 ± 0.1 μm (6.0 mm beam), consistent with the calculated FWHM diffraction-limited airy disk sizes of 14 and 3 μm, respectively.

This reduction in speckle size noticeably improves the appearance of the OCT image when magnified as illustrated by the commercial OCT and UHR-AO-OCT examples of Fig. 61.13. At the magnification shown, the B-scan in Fig. 61.13b has a photographic-like quality that shows clear delineation of the various neuronal layers. Speckle appears largely absent and certainly inconsequential for examining the retinal features visible in the image. Magnification necessary to view the microscopic features (see Fig. 61.13c), however, presents a very different view. Speckle and image blur are now obvious artifacts and mask retinal features that would otherwise be present in the image. This is particularly evident by comparing B-scan acquired with commercial system Spectralis (Heidelberg Engineering, Heidelberg Germany) (Fig. 61.13c) to the AO-UHR-OCT B-scan (Fig. 61.13d),

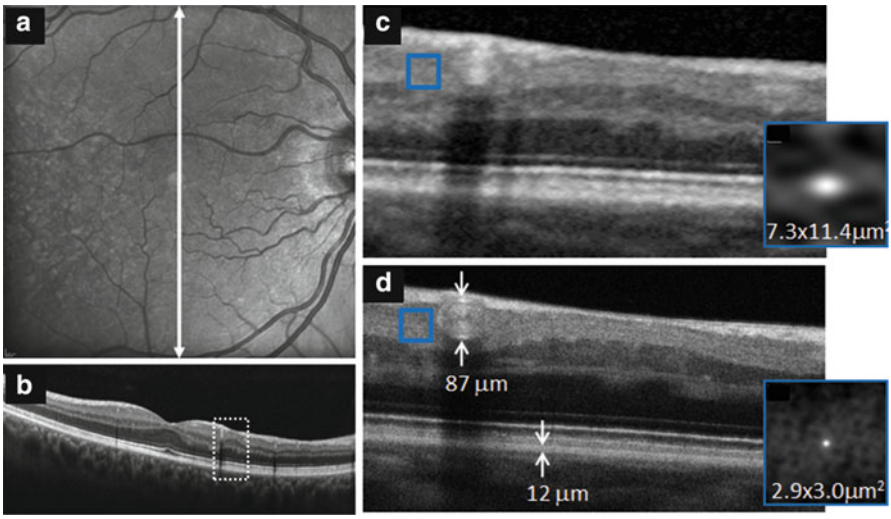

Fig. 61.13 Comparison of fast B-scans acquired of the same patch of retina of a 62-year-old subject with Heidelberg Spectralis and AO-UHR-OCT systems [89]. Spectralis images are shown for (**a**) 20° fundus view and (**b**) vertical B-scan that traverses the fovea. Region highlighted by the *white*, *dashed box* (3° wide) is magnified and displayed in (**c**). The highlighted region crosses an arcuate RNFL defect. AO-UHR-OCT B-scan is shown in (**d**). Both Spectralis and AO-UHR-OCT images are an average of 7 fast B-scans, the UHR-AO-OCT with 0.9 µm spacing. The averaging is consistent with the default averaging mode of the Spectralis system, for a fairer comparison. Insets show the autocorrelation (*gray* scale map) for the region inside the superimposed box in (**c**, **d**), respectively (Reproduced with permission from Elsevier, Ref. [89])

which is of essentially the same patch of retina. Although maximum lateral resolution and structural detail are confined to the depth of focus (~60 µm) that straddles the focal plane (which is at the retinal nerve fiber layer in the figure), speckle is noticeably smaller throughout the entire image. Thus most of the visual difference between the commercial OCT and UHR-AO-OCT B-scans is due to differences in speckle size. Based on the autocorrelation insets, the lateral dimension of speckle is 5× smaller (because of AO) and the axial dimension of speckle roughly 2× smaller (because of UHR-OCT).

A larger pupil and wider spectral light source decrease the lateral and axial dimensions of speckle, but further improvement in AO-OCT image clarity can be gained by reducing contrast of the speckle. Figure 61.14 shows one such example [25]. Because retinal nerve fiber bundles (RNFB) on the local level share the same orientation, averaging of adjacent B-scans (which are orthogonal to the bundle direction) is used to reduce speckle contrast without sacrificing spatial information of the RNFB cross section (width and thickness). Thus bundle clarity is improved as shown in the figure.

The third benefit of adding AO to OCT is the higher collection efficiency for light backscattered from the retina, which translates into higher SNR. In theory a gain of approximately 8–12 dB is expected, based on the difference in pupil

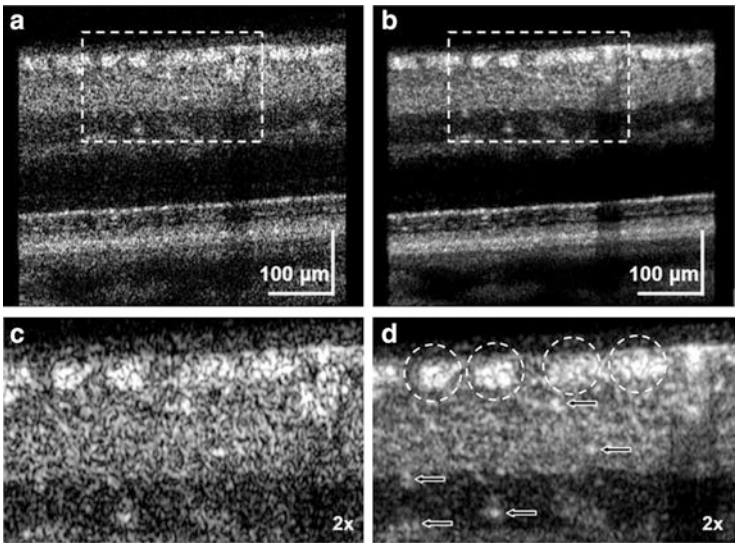

Fig. 61.14 Comparison of (**a**) single and (**b**) averaged B-scans obtained with AO-UHR-OCT system. AO focus was set at inner retina layers at 9° S 4.5° NR eccentricity of healthy 55-year-old volunteer. *Dashed rectangles* in **a** and **b** correspond to the magnified regions shown in **c** and **d**, respectively. Averaging was over ten AO-UHR-OCT frames. *Dashed circles* indicate location of the nerve fiber bundles. *Arrows* indicate location of micro capillaries in the inner retina. Note improved visibility of retinal nerve fiber bundles with averaging (Reproduced with permission from OSA, Ref. [25])

size between conventional OCT and AO-OCT systems and the angular distribution of reflected light expected due to the Stiles-Crawford effect. This effect originates in photoreceptors, typically the brightest layer in the retina and therefore influences SNR [90]. Our measurements approach this theoretical estimate. Specifically, the comparison between measurements taken with the 1.2 mm beam without AO and the 6.0 mm beam with AO (based on Fig. 61.12 setup) demonstrated an increase in dynamic range of at least 4 dB. This number can be further increased by an estimated 4 dB when the AO system is focused at a highly reflective layer, such as the photoreceptor or RPE, as opposed to the inner plexiform layer that was used in the experiment. Adding these numbers, the total gain was 8 dB [88].

61.4.2 AO Disadvantages

AO in OCT is attractive because of the improved resolution, reduced speckle, and increased sensitivity, but these come at a cost. Pragmatic ones include increased system complexity, physical size, and expense. Along with these though are fundamental performance disadvantages, two principle ones being reduced depth of focus, and increased sensitivity to chromatic aberrations, both caused by the larger pupil size.

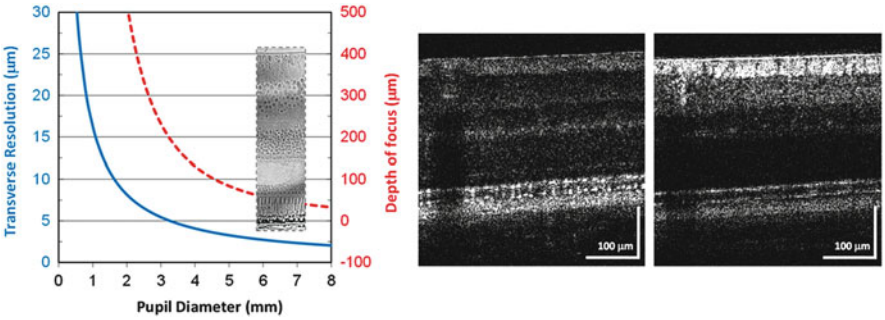

Fig. 61.15 (*left*) Transverse resolution (*solid, blue*) and depth of focus (*dashed, red*) as a function of pupil diameter for an unaberrated eye. Resolution at the focal plane is defined by $1.22\,\lambda f_e/d$, where λ is the wavelength of light (800 nm), f_e is the focal length of the eye (16.7 mm), and d is the pupil diameter. Assuming a Gaussian beam intensity profile, depth of focus is specified as two times the Rayleigh range. (*right*) Example of narrow depth of focus of an AO-UHR-OCT system [89]. B-scans were acquired of the same retinal location with AO focus at the photoreceptor segments (*left*) and retinal nerve fiber bundles (*right*). Shift in focus was 0.4 Diopters, which was generated by the AO wavefront corrector (Reproduced with permission from Elsevier, Ref. [89])

Depth of focus is inversely related to pupil size and trades-off with lateral resolution. Figure 61.15 shows this fundamental trade-off for an unaberrated eye, in this example at a wavelength of 800 nm. Using the pupil sizes in the AO-OCT example of Fig. 61.12, a 1.2 mm pupil provides a transverse resolution of 13.6 μm and a depth of focus of 1.45 mm. The depth of focus exceeds the retinal thickness by several times, making all retinal layers equally in focus, but at inadequate resolution to resolve cells. Increasing the pupil diameter to 6 mm increases the transverse resolution sufficiently for single-cell imaging (2.7 μm), but at the expense of a much narrower depth of focus, just 58 μm. This depth of focus barely covers a single neural layer in the retina (see Fig. 61.15) and thus precludes imaging the full retina thickness simultaneously and necessitates careful focusing of a single layer of interest, for example, photoreceptor segments. Such axial restriction clearly undermines the power of most OCT modalities that rapidly acquire information in depth (A-scans), either simultaneously as in SD-OCT or nearly so as in swept source OCT.

While high lateral resolution and large depth of focus cannot be realized simultaneously with conventional optics, methods to optimize this trade-off are well established in the optics literature albeit showing limited success. These methods are just beginning to be applied to AO-OCT systems [91]. Non-conventional approaches that take advantage of the phase information intrinsic in the OCT image offer considerably more promise. These approaches have been demonstrated to remove focus blur and other aberrations in post-detection, though under well-controlled conditions and specialized samples [92]. While promising, major questions remain as to their robustness to work in living tissue such as the eye.

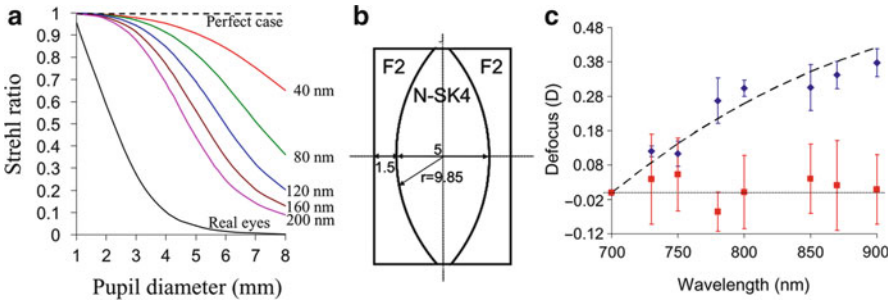

Fig. 61.16 (**a**) Polychromatic Strehl ratio of the human eye computed as a function of pupil diameter at the eye and spectral bandwidth of the imaging light source. *Colored, solid lines* depict perfect correction of ocular monochromatic aberrations, thus image quality is limited by diffraction and chromatic effects. *Black, dashed line* depicts perfect correction of both monochromatic and chromatic aberrations of the eye. *Black, solid line* depicts average of four real eyes with all aberrations present (Reproduced with permission from OSA, Ref. [93]). (**b**) Customized achromatizing lens for correction of ocular chromatic aberrations in the near infrared. (**c**) Chromatic difference of refraction (defocus) in the near infrared with and without the achromatizing lens (*red* and *blue color*, respectively) shown in (**b**). Error bars depict the standard deviation of measurements on five subjects. The *black, dashed line* is the predicted curve for the human eye, the near-infrared portion of that shown in Fig. 61.5. The *dotted line* denotes perfect chromatic correction (Reproduced with permission from OSA, Ref. [96])

Another fundamental performance disadvantage of AO is that it increases the sensitivity of OCT to chromatic aberrations. As discussed in Sect. 61.2.2 and shown in Fig. 61.5, the human eye has significant chromatic aberrations. Recent work by Fernández and Drexler [93] has shown that ocular chromatic aberrations can significantly decrease the detected signal and degrade the lateral resolution of AO-OCT, the extent to which depends strongly on the spectral bandwidth of the OCT source and pupil size. Figure 61.16 illustrates this dependence, plotting Strehl ratio of the eye as a function of pupil diameter (1–8 mm) and spectral bandwidth (40–200 nm). The plot shows image quality monotonically decreases with pupil size and bandwidth. At small pupil sizes typical of conventional OCT (<2 mm), Strehl ratio is negligibly impacted by chromatic aberrations regardless of the bandwidth, even 200 nm. However, at pupil sizes useful for AO (>6 mm), lateral resolution noticeably drops for bandwidths that exceed that of standard OCT (>40 nm). For bandwidths used in UHR-AO-OCT (>100 nm), image quality is predicted to fall below a Strehl of 0.5, this all with perfect AO correction of monochromatic aberrations. Thus given the typical bandwidths of OCT sources, and especially those for UHR-OCT, the benefit of AO correction of monochromatic aberrations is only useful if the chromatic aberrations are corrected too. The present solution is to insert a customized achromatizing lens into the AO-OCT sample arm to provide a fixed correction of the expected average chromatic aberrations in the human eye. Numerous labs have reported such lenses and have demonstrated improvement in image quality [83, 94, 95]. The design of one such lens is shown in Fig. 61.16b; its effectiveness to compensate chromatic aberrations in five subjects is validated in Fig. 61.16c [96].

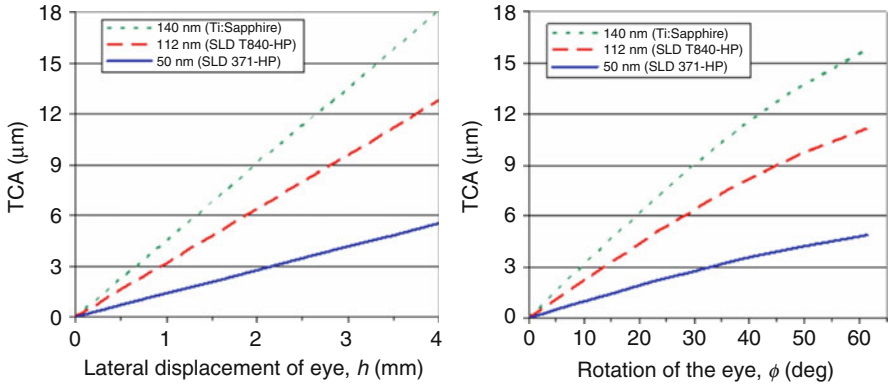

Fig. 61.17 Modeling of TCA as a function of (*left*) lateral misalignment of the eye, *h*, and (*right*) off-axis imaging, φ. (*Left*) TCA is plotted as a function of lateral displacement of the eye's nodal point relative to the optical axis of the retina camera. (*Right*) TCA is plotted as a function of eye rotation (defined as the angle between the camera's optical axis and the eye's achromatic axis). The eye's entrance pupil remains centered on the camera's optical axis, which is a common experimental alignment protocol. Three near-infrared bands were chosen that correspond to specific OCT light sources (Reproduced with permission from OSA, Ref. [25])

Achromatizing lenses are critical for correction of LCA in the eye, but provide no benefit for TCA, which can be substantial and can dilute the benefit of the LCA and AO correction. Zawadzki et al. [25] recently investigated theoretically and experimentally the impact of the eye's LCA and TCA on the performance of high-resolution retina cameras and strategies to minimize them. They determined the extent to which TCA impacts retinal imaging and the conditions under which it can be held at acceptable levels. As discussed in their paper, the two primary contributors of TCA for retinal imaging are (1) errors in the lateral positioning of the eye, *h*, relative to the optical axis of the retina camera and (2) off-axis imaging, φ, i.e., imaging away from the achromatic axis of the eye. Two of their key results are shown in Fig. 61.17. The left plot shows the predicted TCA as a function of lateral displacement of the eye's nodal point from the camera's optical axis. Larger displacements as well as wider source spectra are predicted to generate larger TCA. Use of a pupil camera and bite-bar stage permits accurate positioning of the subject's pupil, likely within about ±0.5 mm. This precision of pupil alignment should be sufficient to keep TCA at acceptable levels. However, clinical use of AO-OCT ultimately means replacing the bite-bar stage with a chin and forehead rest. For these instruments, larger positioning errors are expected.

Figure 61.17 (right) shows the predicted TCA for off-axis imaging when the eye's entrance pupil remains centered on the camera's exit pupil. The figure shows that larger rotations as well as wider source spectra lead to larger TCA. As an example for the SLD T840-HP source (UHR-AO-OCT), the TCA remains below 3.5 µm up to ±16° of rotation. This suggests that the central portion of the retina – from the fovea out to about the optic disk – can be imaged with this source

with relatively small TCA. This interpretation assumes the achromatic axis intersects the retina near the fovea. The 50 nm source will allow even larger rotation ($\pm 39°$), while the 140 nm less ($\pm 11°$). Perhaps of most importance, these predictions represent fundamental limits on the accessibility of the microscopic retina with AO-OCT. The exact numbers will change depending on source spectrum, eye alignment, pupil size, and chromatic aberrations, but hard limits exist and impose serious consequences on imaging performance.

61.5 Examples of AO-OCT Systems

Not surprisingly, development of AO-OCT systems has closely followed advances of the underlying AO and OCT technologies. For AO, these advances have largely been in improved componentry (wavefront sensors and correctors), optical designs (aberration free), and control algorithms that better account for the unique properties of the eye. While considerable AO advances have occurred in these areas, the basic configuration of ophthalmic AO has remained unchanged, being based on the same three components: wavefront sensor, wavefront corrector, and control algorithm.

In contrast, OCT has progressed rapidly along several different design configurations, each taking advantage of different key technologies, especially those for light generation and detection. Major development of these configurations occurred more or less sequentially, and thus AO-OCT development has mirrored these transitions. Over the last nine years, all major OCT design configurations have been demonstrated with AO. AO-OCT combinations include time-domain *en face* (xy) flood-illumination OCT using an areal CCD, time-domain tomographic scanning (xz) ultrahigh-resolution OCT, time-domain *en face* scanning (xy) OCT, high-resolution spectral-domain OCT, ultrahigh-resolution spectral-domain OCT, and more recently swept source OCT.

Regardless of design configuration, AO-OCT performance has been commonly assessed using standard AO and OCT metrics, but ultimately judged by the quality of the retinal image and retinal microstructure that is revealed. Consistent with the rest of the ophthalmic AO field, the retinal cell of choice to assess retinal image quality has been the cone photoreceptor. This is due in part to the cone's high contrast in reflection, regular arrangement that varies predictively with retinal eccentricity and stratified 3D reflectance profile.

Here we present the major AO-OCT design configurations that have been developed, categorized broadly by time-domain and Fourier-domain types. Emphasis is on the first systems reported.

61.5.1 AO with TD-OCT

The first implementations of AO-OCT were based on TD-OCT, the method ubiquitous of OCT up to about 2004. This included a flood-illuminated version based on

an areal CCD [16] and a conventional version based on tomographic scanning (xz) [17]. These first instruments demonstrated the potential of the combined technologies, but fundamental technical limits, primarily in speed, precluded their scientific and clinical use. Nevertheless they represented first steps toward more practical designs that became possible with new OCT methods. The one notable new time-domain method that has been combined with AO and continues to be developed is high-speed transverse scanning TD-OCT (TS-OCT) [22, 24].

Here we briefly describe these first AO-TD-OCT designs based on flood-illumination TD-OCT, tomographic TD-OCT, and transverse-scanning TD-OCT.

61.5.1.1 Flood-Illuminated TD-OCT

The first demonstration of AO-OCT was reported in a conference proceeding a decade ago by Don Miller's laboratory [16] using an *en face* coherence-gated OCT camera. AO consisted of a 37-actuator Xinetics mirror and a SHWS that executed up to 22 measurements and corrections per second across a 6.8 mm pupil. Coherence gating was realized with a free-space Michelson interferometer that employed an areal CCD camera for recording 2D retinal interferograms, with sets of four acquired in less than 7 ms. Axial position of the retina was dynamically tracked using an independent TD-OCT that controlled a voice coil stage. The figure above shows schematic of first AO with flood-illuminated TD-OCT (Fig. 61.18).

Characterization of system performance illustrated the key advantages of parallel detection: no beam scanning and straightforward integration into flood-illuminated AO architecture. The parallel detection scheme demonstrated sufficient sensitivity and resolution for imaging retinal tissue in postmortem [97]. But intrinsic axial motion of the living eye proved challenging for the system's auxiliary TD-OCT tracker and slow readout of the CCD.

61.5.1.2 TD-OCT

The second AO-TD-OCT system was reported by Hermann et al. [17], this one using conventional TD-OCT similar to that in the Zeiss Stratus OCT, but of ultrahigh axial resolution. The system represented collaboration between Wolfgang Drexler's and Pablo Artal's laboratories. The AO system consisted of a 37-actuator OKO DM and a SHWS with separate laser beacon. The design demonstrated clear performance advantages of AO in the living eye and did not suffer from the gating problem of the earlier AO-TD-OCT system. A schematic of their system is shown in the figure above (Fig. 61.19).

Along with clear performance advantages, however, were also clear performance disadvantages. These included the relatively slow OCT acquisition speed and modest performance of the AO system (no active correction during image acquisition and a small pupil size, 3.7 mm). Collectively, these resulted in limited improvement in image quality and considerable degradation from the influence of transverse eye motion [98] that becomes pronounced at high magnification of the retina.

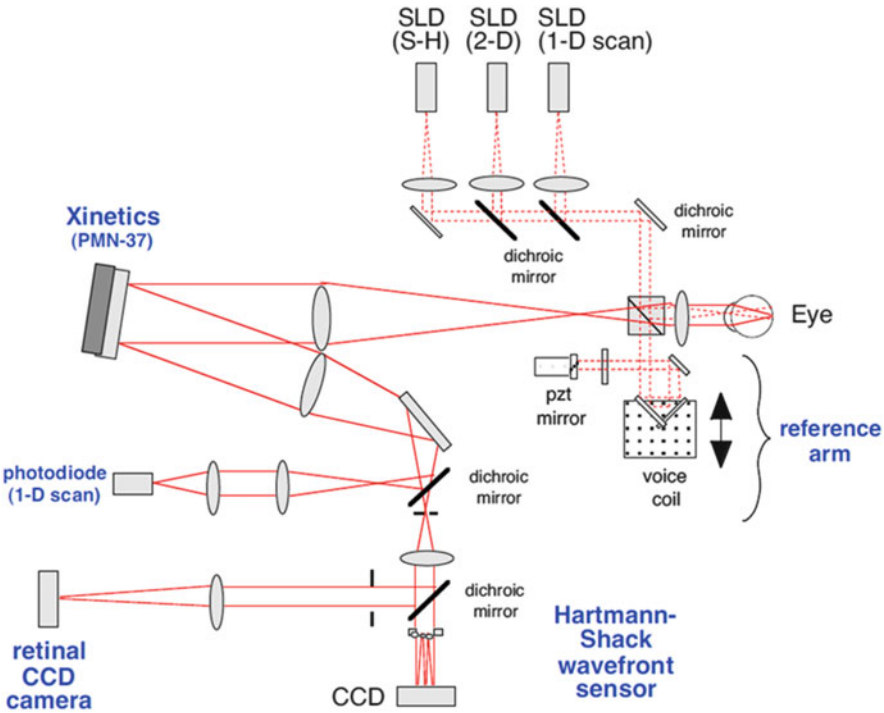

Fig. 61.18 Schematic of the first AO TD-OCT system. It consisted of a flood-illuminated *en face* OCT system (CCD-based) for optical sectioning the retina at 10 μm axial resolution, a 1-D OCT axial scanner for tracking the axial position of the subject's retina, and an AO system (consisting of a Shack Hartmann wavefront sensor and a 37 actuator Xinetics mirror) for measuring and compensating the aberrations of the eye. Separate SLD light sources were employed for each of the three subsystems. A separate incoherent light source for flood illuminating the retina was added to the camera (but is not shown) (Reproduced with permission from SPIE, Ref. [16])

61.5.1.3 Transverse Scanning TD-OCT (TS-OCT)

The more recent combination of AO with transverse scanning OCT (TS-OCT) has resulted in the most effective implementation to date of TD-OCT with AO. In TS-OCT, the "thin" coherence-gated C-scans are recorded at relatively fast speeds (2–27 Hz frame rate), with the higher rates significantly reducing transverse motion artifacts. Other advantages of TS-OCT include direct integration with SLO imaging architectures [99] and implementation of dynamic focus [100]. Adrian Podoleanu's and Chris Dainty's laboratories developed the first TS-OCT system with AO [22]. In their AO-TS-OCT system, the same light source was used for imaging and wavefront sensing. A 37-actuator OKO DM with Badal optometer provided wavefront correction. The acquisition speed of this instrument was 2 Hz/C-scan, which exposed the C-scan images to substantial motion artifacts. The figure above shows schematic of their AO with transverse scanning TD-OCT [22] (Fig. 61.20).

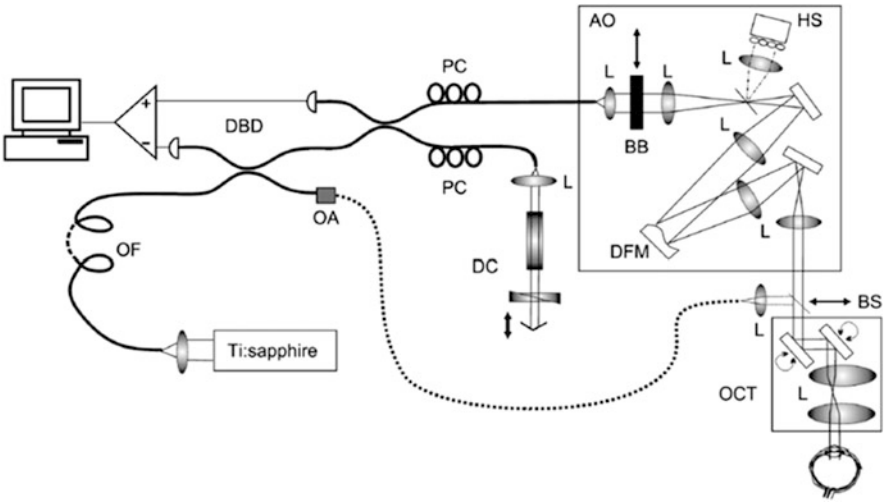

Fig. 61.19 AO UHR OCT system: *DBD* dual balanced detection, *PCs* polarization controllers, *OA* optical attenuator, *OF* 100 m of optical fiber, *DC* dispersion compensation, *L's* achromatic doublet lenses, *BB* removable beam blocker, *DFM* deformable mirror, *BS* removable beam splitter (Reproduced with permission from OSA, Ref. [17])

Much higher C-scan rates were realized with an AO-TS-OCT system developed by Christoph Hitzenberger's and John Werner's laboratories [24]. This system permitted direct comparison of cone photoreceptor images obtained simultaneously with SLO and OCT. The AO system in this AO-TS-OCT system consisted of

a 37-actuator AOptix DM and a SHWS using the same light source as for imaging. Michael Pircher's laboratory from Vienna Medical University has continued working on improved design and data acquisition schemes for transverse scanning TD-OCT systems [101, 102]. These include application of auxiliary spectral domain partial coherence interferometer that tracked and compensated at ~200 Hz for the axial position of the cornea and lens-based AO-SLO system that is compatible with his TD-OCT data acquisition. Today AO-TS-OCT continues to be developed and represents a viable alternative to Fourier-domain-based AO-OCT systems, which are discussed next.

61.5.2 AO with Fourier-Domain OCT

The first reports of AO Fourier-domain OCT (AO-FD-OCT) occurred shortly after major developments in FD-OCT, most notably theoretical and experimental investigations into the substantial sensitivity advantage of FD-OCT over TD-OCT [103–105]. This led to a rapid transition of AO-OCT systems from TD-OCT to FD-OCT. Today, FD-OCT is employed in almost all AO-OCT systems, with spectral-domain OCT (SD-OCT), the principle design configuration, and swept source OCT (SS-OCT) gaining increased interest. Here we present the first examples of AO-FD-OCT based on line-illuminated SD-OCT, scanning spot SD-OCT, and scanning spot SS-OCT.

61.5.2.1 Line-Illuminated Spectral-Domain OCT

First implementation of AO-OCT with FD-OCT was reported by Zhang et al. [18]. A line field (or parallel) SD-OCT system was developed and integrated with an AO system similar to that reported by the same laboratory in their earlier AO-TD-OCT system [16]. The retina was illuminated with a line using a cylindrical lens and the reflectance detected in the Fourier domain using a grating to disperse the line across an areal camera [106, 107]. In this way, the illuminated line resulted in a B-scan image composed of simultaneously recorded A-scans, which greatly reduced the system's sensitivity to eye motion. Figure 61.21 shows a schematic of their system.

Comparison of retinal images captured with and without AO showed clear improvement in image clarity and resolution afforded by the AO. The images also showed for the first time distinguishing features of cone photoreceptors at two depths: the regular spacing of bright spots at the cone inner-segment/outer-segment (IS/OS) junction and the posterior tip of the outer segment (PTOS), also called cone outer-segments tips (COST). Disadvantages of line field SD-OCT were its relatively low (B-scan) duty cycle and lack of a vertical scanner to reposition the B-scan on the retina, both of which prevented volume imaging.

61.5.2.2 Spectral-Domain OCT

Shortly after line-illuminated AO-SD-OCT, two additional AO-SD-OCT systems were reported, both based on conventional xy raster scanning. Raster scanning

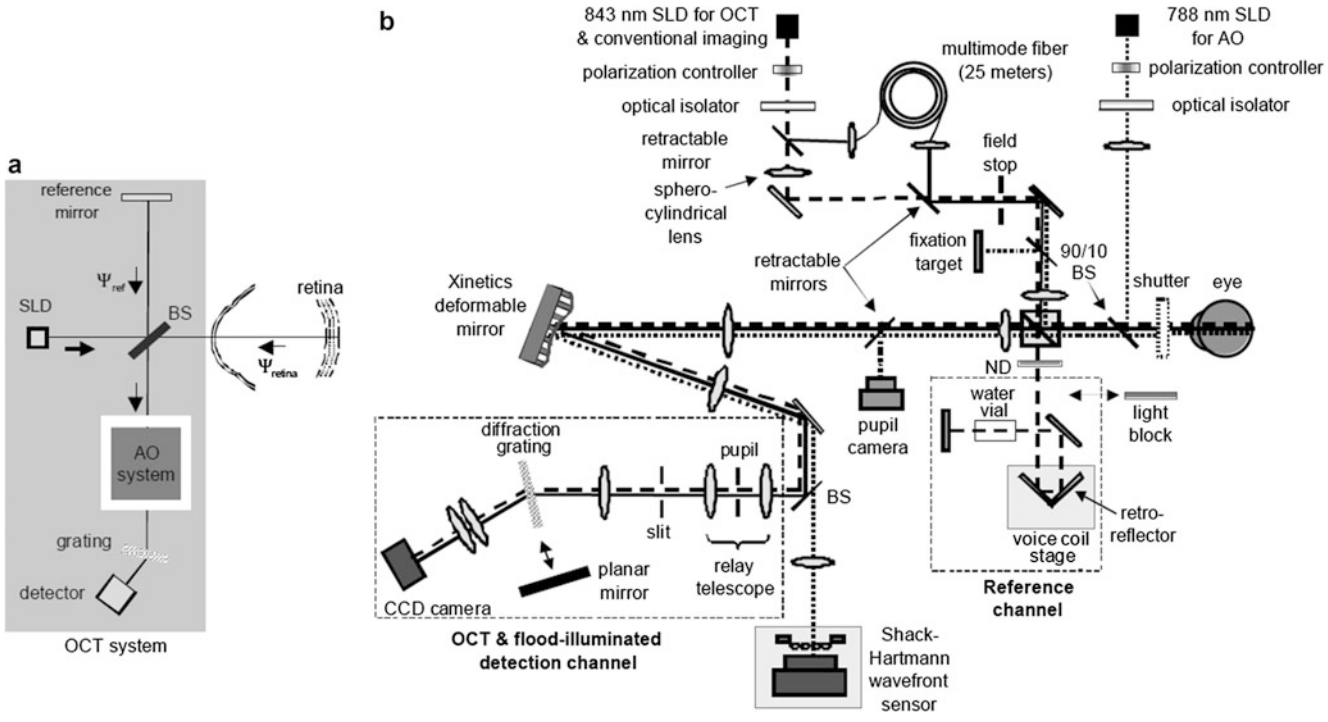

Fig. 61.21 (**a**) Concept layout shows the AO system as part of the SD-OCT detection channel. (**b**) Detailed layout of the AO parallel SD-OCT retina camera. The camera consists of four subsystems. (1) AO system corrects the ocular aberrations using a 788 nm SLD, Shack-Hartmann wavefront sensor, and Xinetics deformable mirror (*short dashed line*). (2) Pupil retro-illumination and fixation channels permit alignment of the subject's eye to the retina camera. (3) Conventional flood illumination is used to validate focusing in the retina and the physical size of microstructures in the retina (*solid line*). (4) Parallel SD-OCT acquires single shot B-scan images of the retina (*long dashed line*) (Reproduced with permission from OSA, Ref. [18])

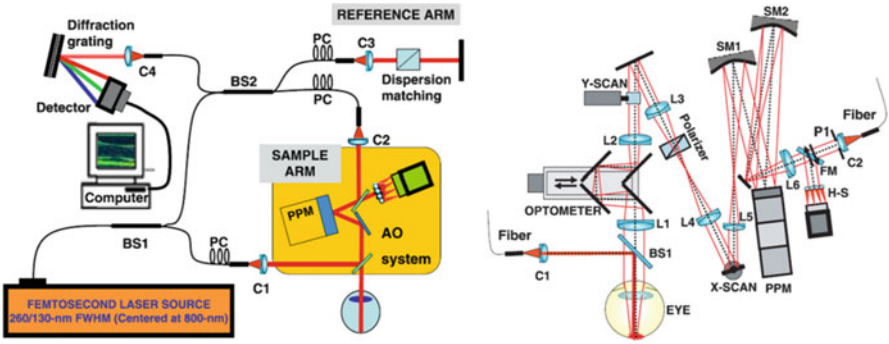

Fig. 61.22 Experimental apparatus. (*Left*): The frequency-domain interferometer incorporates the AO system in the sample arm, performing the aberration correction before the acquisition of the retinal images. An ultra-broad bandwidth laser source is used for retinal illumination. (*Right*): Detailed schematic of the sample arm. The eye's exit pupil is optically conjugate to the two scanning mirrors, the PPM, the H-S wavefront sensor, and the collimator that connects the system to the interferometer, C2. The system incorporates a motorized optometer for correcting defocus independently of the PPM (Reproduced with permission from Elsevier, Ref. [20])

offered considerable flexibility in the scan pattern, including that for volume imaging [19, 20]. The second of the two systems extended the earlier AO-TD-OCT collaborative work of Drexler's and Artal's laboratories [20]. Ocular correction was realized with a high-density liquid-crystal spatial light modulator (LCSLM) in conjunction with a Badal optometer. A separate fiber was used to deliver light for wavefront sensing in "single path" configuration. Figure 61.22 shows schematic of first LCSLM-based AO with raster scanning SD-OCT.

Despite excellent performance of the AO correction as measured by the wavefront sensor (Strehl Ratio ~ 0.95), the AO-OCT images did not demonstrate the same high image quality nor provided the resolution to resolve cone photoreceptors. This led to a detailed analysis and discovery by the authors that the wide spectral bandwidth (130 nm) of their light source exposed the system to significant ocular chromatic blur. This initiated considerable effort in the field to develop customized achromatizing lenses to correct for this effect as described in Sects. 61.4.2 and 5.3 of this review.

The second scanning spot AO-SD-OCT system was developed in Werner's laboratory in collaboration with Joseph Izatt's and Scot Olivier's groups [19]. Their system used the same light source for imaging and wavefront sensing. A large-stroke 37-actuator AOptix DM provided correction. The figure below shows schematic of first DM-based raster scanning AO-SD-OCT system (Fig. 61.23).

As demonstration of AO system performance, authors showed reduced depth of focus in the AO-OCT B-scans compared to that for conventional OCT, the difference is due to the larger numerical aperture of AO-OCT compared to conventional OCT. B-scan images of photoreceptor structure was consistent to that previously reported by Zhang et al. [18]. In addition, the authors reported first AO-OCT images of the 3D

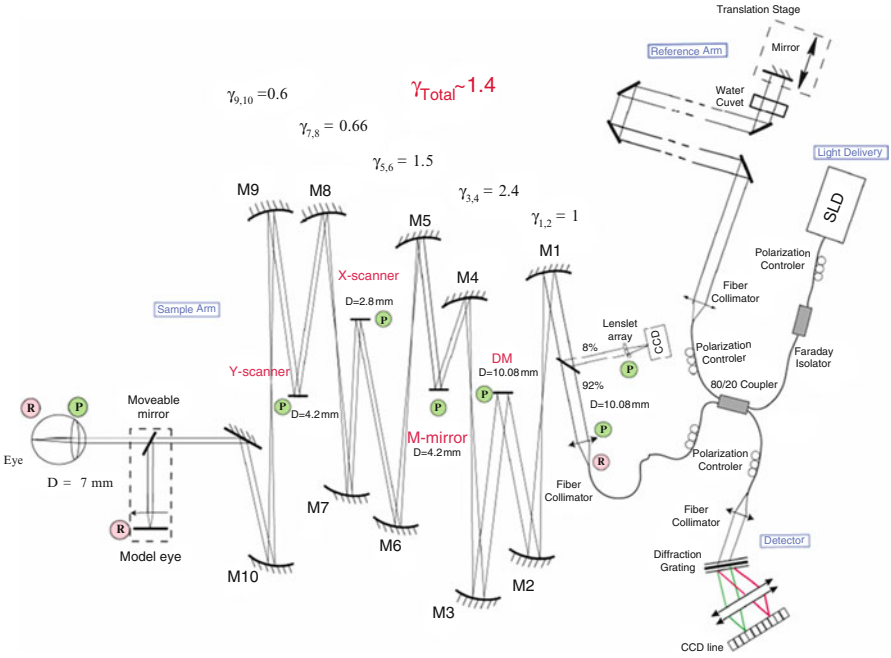

Fig. 61.23 Schematic of UC Davis AO-OCT experimental setup constructed on a standard laboratory optical table occupying 1 × 1 m. The reference arm length is the same as that of the sample arm, but is shown truncated for simplification. architecture of in vivo cone photoreceptors and retinal capillaries. Because of the slow image acquisition (several seconds per volume), however, motion artifacts in transverse direction blurred the visibility of cone photoreceptors in extracted C-scans. Zhang et al. subsequently reported an AO-OCT system that integrated a higher-speed line-scan camera, acquiring A-scans three times faster (75,000 A-scans/s) [21]. The AO system was similar to that described in Zawadzki et al. [19], but a key difference was placement of the AOptix DM on the same side of the scanners as the subject's eye, which provided improved correction of refractive error. The figure below shows schematic of first implementation of AO-SD-OCT with the DM placed on the same side of the xy scanners as the eye (Fig. 61.24).

Imaging at higher speeds and smaller patches of cones increased the volume acquisition rate to 6.7 Hz (150 ms/vol). The high volume rate greatly minimized eye motion artifacts and enabled clear visualization of cone photoreceptor mosaic in *en face*.

These first AO-SD-OCT reports were followed by a large number of developments that targeted improvements in AO-SD-OCT system design and performance and included an expanded list of laboratories pursuing AO-OCT. Improvements continue to be made in essentially all aspects of AO and SD-OCT subsystems, including key components such as system design, OCT light source, OCT detectors,

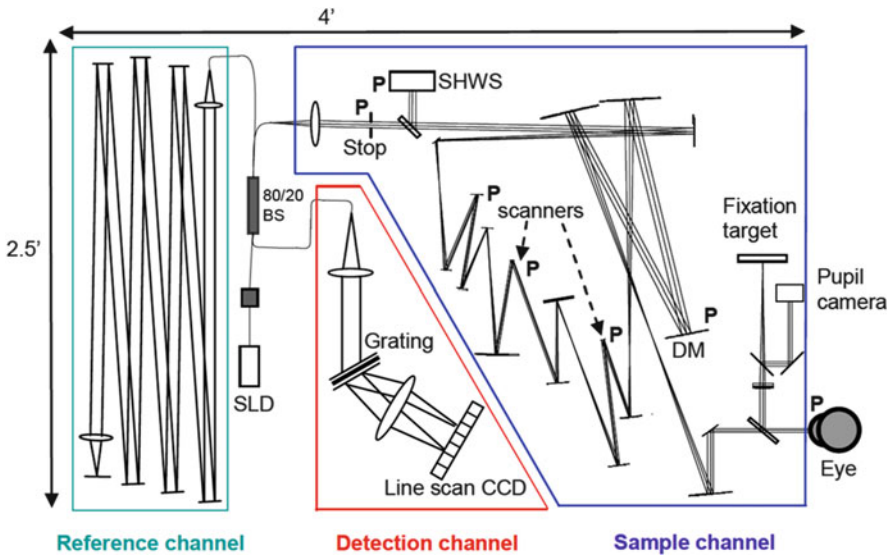

Fig. 61.24 Layout of the AO SD-OCT retina camera. The AO system is integrated into the sample channel. BS, DM, and P refer to the fiber beam splitter, AOptix deformable mirror, and planes that are conjugate to the pupil of the eye, respectively (Reproduced with permission from OSA, Ref. [21])

AO system components, and AO performance evaluation [108] as well as applications of different data acquisition, processing, analysis, and visualization.

A recent AO-OCT system from Yoshiaki Yasuno's laboratory at University of Tsukuba has been used to explore new directions in AO-FD-OCT design (see Fig. 61.25) [109]. In particular, the authors focused on the application of 1 μm imaging window for better visualization of choriocapillaris and choroid. Additional design features included an "off-plain" configuration for reduced system aberrations and a lens-based Badal optometer in "double pass" realized with linear polarizers to block back reflections.

The "off-plain" design follows that employed in AO-SLO systems [110–112], where system lateral resolution was found to significantly improve. More recent AO-OCT systems have extended the "off-plain" concept in ways that provide even further performance improvement and design flexibility [113, 114]. It should be noted that while these recent system developments have occurred largely with SD-OCT systems, the developments are in many cases equally applicable to the other OCT configurations. SD-OCT remains the configuration of choice, but that may change rapidly as the field matures and new technologies develop.

61.5.2.3 Swept Source: OCT

SS-OCT has undergone substantial development in recent years and today represents an attractive alternative to SD-OCT, owing in large part to SS-OCT's higher

imaging speeds and flatter sensitivity roll off with depth. Despite these advantages, however, only a couple of peer-reviewed publications have demonstrated AO-SS-OCT systems. Figure 61.26 shows schematic of first implementation of AO SS-OCT system from Physical Science Inc. [115].

Slow progress in development of AO SS-OCT systems has been due to the restricted spectral range (>1 μm) and bandwidth (modest axial resolution), even among state-of-the-art swept sources. However, swept source technology continues to develop, and sources at shorter wavelengths (~800 nm) and with broader spectral bandwidths will eventually be available. With these advances, SS-OCT may overtake SD-OCT as the configuration of choice for future AO-OCT systems.

61.5.3 Ultrahigh-Resolution AO-OCT (Chromatic Aberration Correction)

As discussed in Sect. 61.4.2, the use of spectrally broad bandwidth light sources for ultrahigh-resolution OCT can substantially degrade lateral resolution owing to the intrinsic chromatic aberrations of the eye. To correct this effect, custom achromatizing lenses are added to the AO-OCT to provide equal but opposite LCA to that of the eye. To this end, the achromatizing lens has been evaluated at two different positions in the AO-OCT sample arm, the corresponding systems of which are presented in Fig. 61.27 [25, 26].

Both achromatizing lens' positions are optically conjugate to the eye pupil plane. In the configuration proposed by Fernández et al., the customized lens occupies a separate pupil plane downstream of the SHWS sensor. In contrast to the configuration proposed by Zawadzki et al., the lens is placed adjacent to the collimating lens of the fiber input thereby taking advantage of an already existing pupil plane and being upstream of the SHWS. Thus main disadvantages of the first configuration are possible back reflections from the achromatizing lens that can create artifacts in the SHWS and need for an additional pupil plane. The main disadvantage of the second configuration is that it corrects the ocular LCA as seen by the WFS only in single pass. Therefore, broadband light sources may require spectral filtering immediately in front of the SHWS or additional post-processing of the SHWS spots in order to avoid wavefront errors caused by chromatic blur of the WFS spots. Given the push to extend AO-UHR-OCT to even higher axial resolution (<2 μm), the impact of chromatic aberrations and how best to correct for it will continue to garner attention.

61.5.4 Multimodal AO-OCT Systems

Combination of OCT with other imaging modalities provides additional, complimentary retinal information, which has proven useful in commercial ophthalmic OCT instruments. Often OCT images are acquired simultaneously with SLO images, the latter used for image registration and navigational purposes. Such multimodal use is also applicable to AO-based imaging systems. One particularly attractive combination is AO-OCT with AO-SLO fluorescent imaging as the two probe fundamentally different cellular mechanisms. Recently, Physical Sciences Inc. (PSI) proposed a multimodal AO-OCT system that included SLO and fluorescent SLO channels as well as a large field of view imager and retinal tracking [29] (Figs. 61.28 and 61.29).

Another example of a multimodal AO-OCT system that includes intensity-based SLO has been recently published by Zawadzki et al. [116]. The authors demonstrated that simultaneously acquired AO-SLO images can be used to extract retinal motion present during AO-OCT imaging and then correct for that motion in post-processing of the AO-OCT data [117]. More examples of retina tracking and motion correction of AO-OCT images can be found in Sect. 61.6.4.

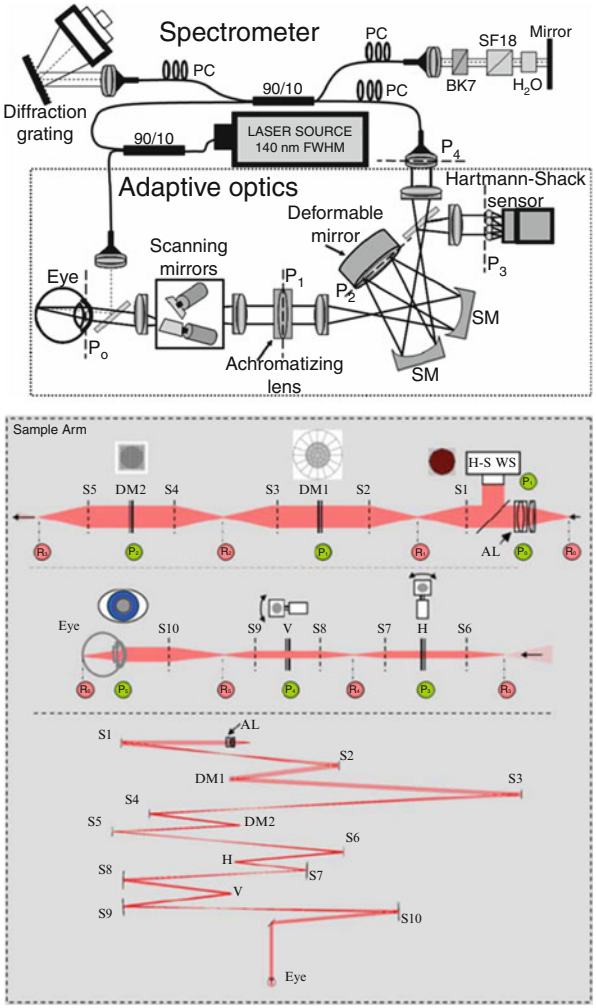

Fig. 61.27 Chromatic aberrations of the eye have been corrected by placement of a customized achromatizing lens at two different positions in the AO-OCT sample arm. These positions are (*top*) between SHWS and the eye and (*bottom*) between fiber collimator and SHWS. (*top*) Experimental system consists of two parts: an AO system (in *dashed lines*) responsible for pancorrection of ocular optical aberrations and a UHROCT system for high-speed retinal imaging. 61.6 Selected Topics on AO-OCT Development

Parallel to the development of AO-OCT along different OCT design configurations, AO-OCT has also progressed rapidly along other engineering fronts. These additions have enabled it to probe more powerfully and accurately structure and function of the cellular retina. Many of these developments mirrored that ongoing in the OCT field, for example, the many methods that take advantage of the complex signal detected by OCT. A few representative developments are described in this section: polarization-sensitive imaging of retinal birefringence, contrast enhancement and quantification of retinal and choroidal blood flow, and phase imaging of photoreceptor growth.

The section ends with a discussion of eye motion artifacts and their correction. This topic represents a fourth engineering front that has been heavily investigated in recent years. Correction of eye motion is applicable to almost any AO-OCT in vivo use because it is almost always present, even in a fixating eye, and leads to distortion and mis-registration in the image. Eye motion is a serious obstacle to effective use of AO-OCT and more problematic than for standard OCT owing to the higher magnification and denser sampling of A-scans. A diverse range of solutions to minimize eye motion artifacts in AO-OCT are currently under investigation and will be summarized here.

61.6.1 Polarization-Sensitive AO-OCT

The polarization state of light carries additional information about the retinal tissue, in particular its birefringence, which is a meridional variation in refractive index

that differentially retards transmitted light polarized along the fast and slow axes of the tissue. Various layers of the retina are well known to alter the polarization state, primary ones being the retinal nerve fiber layer, Henle's fiber layer, and RPE. Change in birefringence has been suggested a sensitive indicator of disease onset, leading to increased clinical attention and the development of ophthalmoscopes with polarization-sensitive detection. In the last decade, polarization-sensitive OCT (PS-OCT) has garnered considerable interest as it enables simultaneous intensity and depth-resolved measurements of the polarization state in the retina [118–121]. PS-OCT, however, is not without limitations, most notably poor lateral resolution owing to the small beam size at the eye (<2 mm) and ocular aberrations as well as large speckle. Collectively, these limit PS-OCT from probing highly localized changes of birefringence that occur on a microscopic level in the retina, for example, variations in birefringence of adjacent retinal nerve fiber bundles. The integration of AO into PS-OCT provides a solution to this problem, allowing access to the full polarization information that exits a large pupil of the eye (>6 mm).

Cense et al. [88] investigated the benefit of AO for PS-OCT measurements. With AO-PS-OCT, they measured the double pass phase retardation per unit depth with values ranging from 0.25°/μm to 0.65°/μm in the birefringent nerve fiber layer 6° from the fovea, with the highest values being noticeably higher than previously reported with PS-OCT. This wide range may reflect local differences in birefringence that are expected to occur between and among RNF bundles and are too fine to be resolved without AO.

Figure 61.30 shows another example that highlights the capability of AO-PS-OCT to detect localized variations in phase retardation. In this case tissue immediately above a 70 μm diameter arterial was found to be extremely birefringent, up to three times more than the adjacent RNFL tissue. The B-scans in the figure show intensity and false color cumulative phase retardation images that were reconstructed from the same AO-PS-OCT data. Location of high (red arrow) and low (blue arrow) birefringent RNFL tissue is indicated in the phase retardation image.

61.6.2 Flow-Contrast Methods in AO-OCT

Flow-contrast methods enhance the visibility of retinal vessels by detecting temporal dynamics in the OCT phase signal that are generated by blood flow. Application of this method to capillary mapping is challenging owing to the small size of the capillaries (5–10 μm) and the little light they reflect. Thus the increased resolution and sensitivity afforded by AO may critically improve detection. One caveate, however, is that the smaller spot size formed at the retina (due to AO) must be properly accounted for in the flow-contrast method. If not, it will exacerbate phase noise and motion distortions and ultimately compromise contrast performance. First use of flow-contrast methods in AO-OCT systems compared intensity and power Doppler-based imaging of capillary beds (see Fig. 61.31) [122]. Results demonstrate enhanced visibility of individual vessels as evident in the figure example.

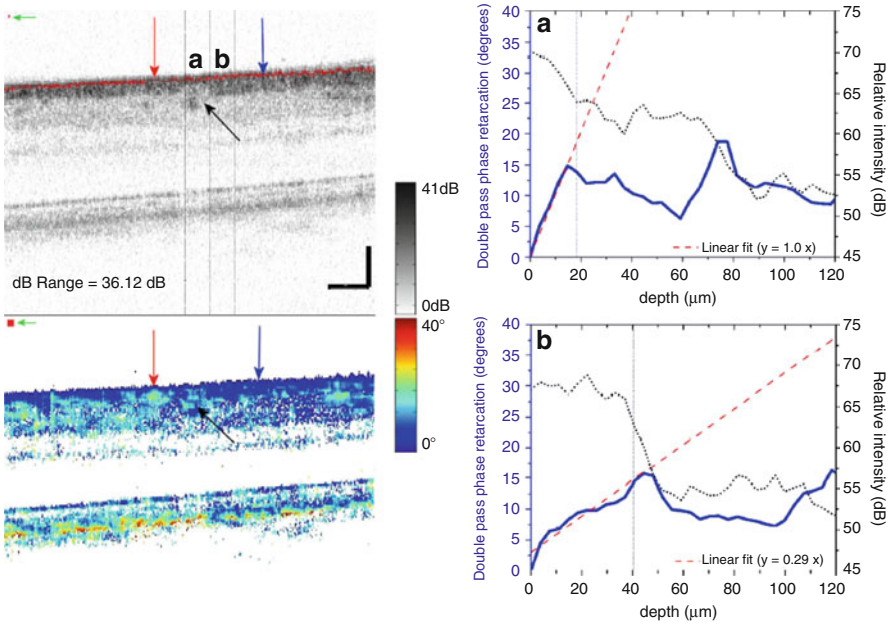

Fig. 61.30 Intensity (*top left*) and cumulative double pass phase retardation (*bottom left*) obtained with AO-PS-OCT. 3° B-scan bisects the nasal/temporal retina with the left and right edges at 4.5° and 7.5° superior of the foveal center, respectively. RNFL birefringence causes the cumulative double pass phase retardation to increase from 0° (*dark blue*) to approximately 30° (*light blue/green*) over a depth of less than 50 μm. The *red* and *blue arrows* point to RNFL regions that exhibit high and low birefringence, respectively. Distance between these regions of extreme RNFL birefringence is just 200 μm. The *black arrow* points to a 70 μm wide small blood vessel that was identified as arterial. Large changes in phase retardation spanning more than 50° is evident in the RPE and is suggestive of rapid changes in fast axis orientation associated with polarization scrambling. In the intensity image, the size of the red block (follow *green arrow*) represents the footprint (width × depth) of the AO-OCT point spread function at the plane of focus as well as the mean speckle size throughout the entire retina. In the DPPR image, the *red block* represents the 14 μm × 14 μm averaging kernel. Data was scaled in the vertical direction assuming an index of refraction of 1.38 and scale bars indicate a length of 100 μm. The two plots on the right show data that encompasses the blood vessel (**a**) and data that was taken next to the vessel (**b**) (Reproduced with permission from OSA, Ref. [88])

61.6.3 Phase-Sensitive AO-OCT for Photoreceptor Imaging

The cone photoreceptor's outer-segment (OS) experiences minute changes in optical path length, both in response to visible stimuli and as a matter of its daily course of renewal and shedding. These changes are of interest to quantify function in healthy cells and assess dysfunction in diseased ones. While intensity-based AO-OCT provides sufficient resolution to distinguish cone photoreceptors in three dimensions, it has not been able to measure cone OS dynamics, whose scale is smaller than UHR OCT's axial resolution of a few microns.

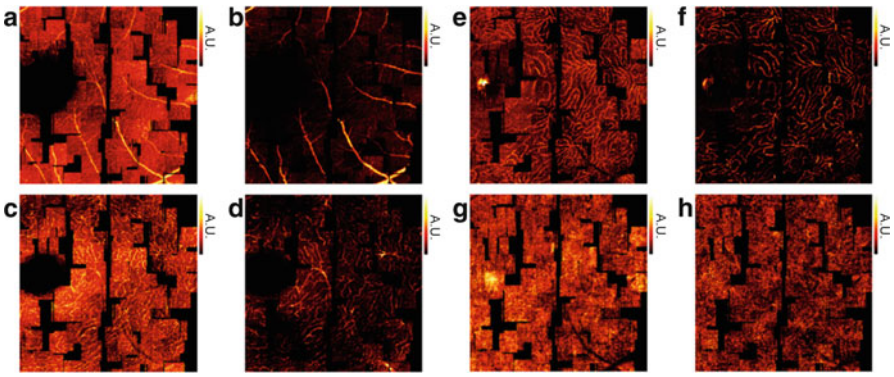

Fig. 61.31 Wide-field *en face* projections of intensity (**a**, **c**, **e**, **g**) and Doppler power (**b**, **d**, **f**, **h**) images at different depths in the retina: GCL and IPL (**a**, **b**), IPL/INL boundary (**c**, **d**), INL/OPL boundary (**e**, **f**), and choriocapillaris (**g**, **h**) (Reproduced with permission from OSA, Ref. [122])

A solution to this problem was presented by Jonnal et al. [123] who took advantage of phase information encoded in the AO-OCT signal. Specifically, they extracted phase differences between the bright reflections that straddle individual cone OSs, thereby effectively converting the OS into a single-cell interferometer. The beauty of this arrangement is that it is immune to axial eye motion (analogous to a common-path interferometer), yet exquisitely sensitive to sub-wavelength changes that occur inside the OS, for example, disk renewal and shedding. As reported, this approach improved the sensitivity of their AO-OCT system to OS length changes by more than an order of magnitude, down to 45 nm, which is slightly thicker than a single OS disk. The figure above shows an example of tracking phase differences between IS/OS and PTOS reflections over time (Fig. 61.32).

61.6.4 Motion Artifact Correction in AO-OCT

Like all in vivo retinal imaging techniques, AO-OCT suffers the effects of involuntary eye movements that occur in all three dimensions and under normal fixation. The resulting image blur and distortion diminish the visibility of retinal structures, especially those at the cellular level, and create real challenges for both laboratory and clinic use. Several approaches to mitigate these effects have been investigated for AO-OCT, in many cases parallel to their development with standard OCT. Principal ones are briefly summarized.

The simplest approach to reduce eye motion artifacts in AO-OCT is to acquire images fast, as with high-speed line-scan cameras in the detection channel of SD-OCT or high-speed swept sources in SS-OCT. Limiting the number of necessary data samples per volume is also beneficial. But neither higher speeds nor smaller volumes eliminate them. In addition, higher speeds require more light to achieve the same SNR and a hard limit exists to the amount of light that can safely

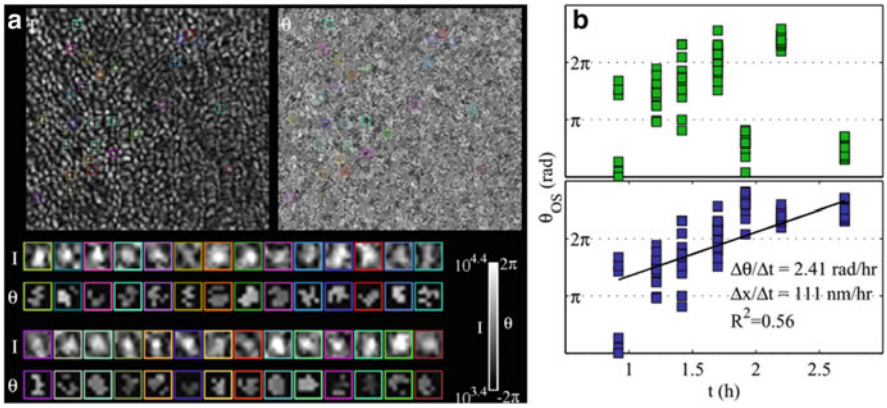

Fig. 61.32 (**a**) Tracking intensity and phase of individual cones over time. (*Upper left*) An *en face* projection of the cone mosaic of a normal subject is shown, constructed by co-adding intensities of IS/OS and PTOS pixels for each A-scan in the volume. *Colored boxes* designate locations of example cones, as they are tracked through the time series. (*Upper right*) An *en face* projection of θ_{OS}, phase difference between IS/OS and PTOS reflections. *Colored boxes* designate locations of the same example cones shown in the intensity projection. Roughly circular patches of correlated phase are visible in the phase projection. (*Bottom*) Views of the example cones shown in the *en face* intensity and phase projections. In each row of box pairs, the top box shows an enlarged view of the intensity projection and the bottom box shows an enlarged view of the phase projection, as indicated by the I and θ symbols at the *left*. In the phase projections, excluded pixels are not shown; correlation among included pixels is visually apparent. In the enlarged phase projections, many cones do not appear circular. The reasons for this are, presumably, eye motion, which often warps the image of the cone, and segmentation errors, which may cause spurious exclusion of A-scans, leading to shape irregularities and discontinuities (**b**) Representative phase changes in a single cone. The temporally wrapped data are shown in the top plot (*green markers*) and temporally unwrapped data shown in the bottom plot (*blue markers*). Linear fit of the unwrapped data reveals an OS elongation of this cone to be 111 nm/h (Reproduced with permission from OSA, Ref. [123])

enter the eye. Thus highly reflecting retinal structures like photoreceptors, RPE, and retinal nerve fiber bundles are the most suitable targets for fast image acquisition systems. Given these constraints, further improvement in motion correction must be found elsewhere.

One area is post-processing. Early attempts (see example in Fig. 61.33) treated each fast B-scan as a rigid body that could be translated in depth and laterally along adjacent B-scans [21, 26]. Due to lack of information along the slow scanning axis, motion artifacts in that dimension could not be corrected. Zawadzki et al. [80] described strategies to optimize this rigid body method for AO-OCT retina volumes.

To remove motion artifacts in both lateral dimensions – a necessity for tracking individual cells over time, for example, cones – required more sophisticated algorithms. Kocaoglu et al. [124] reported a feature-based registration algorithm that split the *en face* projection into strips and then scaled and sheared each strip based on the location of landmark cones. Using this algorithm on acquired movies of cone photoreceptors, motion artifacts were reduced by more than an order of

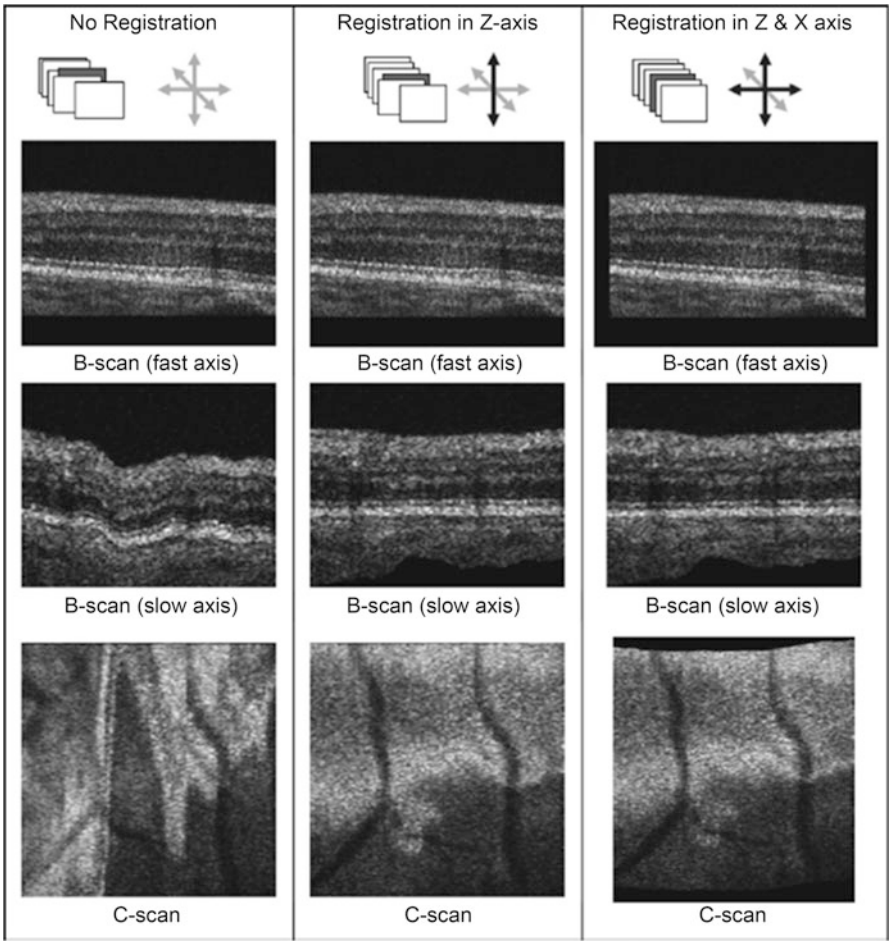

Fig. 61.33 AO-OCT B-scans before and after motion correction with a rigid-body, self-registration algorithm. Different degrees of registration (none, Z-axis, Z and X axis) are shown, their impact illustrated for a representative fast-axis B-scan (*top*), slow-axis B-scan (*middle*), and C-scan (*bottom*). Registered and unregistered axes are denoted by *black* and *gray arrows*, respectively (Reproduced with permission from OSA, Ref. [80])

magnitude, from 15 to 1.3 μm root mean square, the latter sufficient for identifying and tracking cones. More recently, Jonnal et al. [123] developed an algorithm that cross-correlated narrow strips (approximately the width of a single cone) with a reference image to determine local shifts. By combining with axial registration of A-scans, they were able to track individual cone OSs in all three dimensions.

Improvements in motion correction can also be gained with additional hardware, for example, the addition of a separate imaging system dedicated to retina tracking. Multimodal AO-SLO/AO-OCT systems have been developed where fast AO-SLO

frames are acquired simultaneously with OCT B-scans. Tracking algorithms applied to the AO-SLO frames extract retina positions that are used to register AO-OCT B-scans in the volume. First reports of applying this combined AO-SLO/AO-OCT approach have been recently demonstrated [117]. An alternative hardware approach is active tracking [125]. While more hardware intensive, it is attractive as it can compensate for eye motion larger than the imaging field of view and permit repeated imaging of the same patch of retina, both generally not correctable by post-processing.

61.7 Applications of AO-OCT

AO-OCT has been applied to a broad range of scientific and clinical studies of the ocular fundus. Much of the motivation behind these studies has been to determine exactly what can be visualized and what new information can be obtained with AO-OCT, whether in a normal or diseased eye. While much of this work is in the early stages, results to date are encouraging, demonstrating the potential of AO-OCT to study noninvasively retinal structure and function in ways previously not possible. Below we present a brief survey of these main application areas as reported in the literature, categorized by scientific and clinical directions. It should be noted that widespread use of AO-OCT remains a work in progress, largely limited by the complexity and customization of current systems and the need for skilled system operators. As these obstacles fall, AO-OCT will become a more integral, and perhaps indispensable, imaging tool for the scientific and clinical communities.

61.7.1 AO-OCT in Vision Science

Vision is a complex process. While the retina is only one of many components involved, its role is critical, capturing and transducing photons into an electrical signal and providing the first steps of signal processing. Normal vision requires normal function of the retina, and thus the retina has significant scientific interest. Imaging methods that use light to probe, noninvasively, structure and function of the retina have proven highly effective, but proper interpretation of the detected return requires understanding of how light interacts with retinal tissue, that is, the optical properties of the retina. It is in this context that AO-OCT may make its most important contributions to vision science, improving our understanding of cellular-level light-tissue interactions that occur at each layer in the retina and their correlate with cell anatomy and physiology.

61.7.1.1 Optical Biopsy: (Living Histology)

AO-OCT systems have been used to capture volume images of retinal structures that were previously only visible with histology. Of course the lateral resolution of

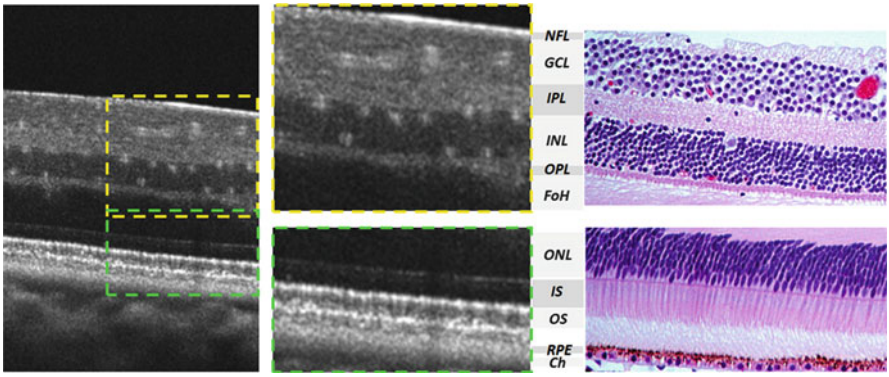

Fig. 61.34 AO-OCT B-scan of the retina compared to histology from light microscopy at a similar retinal location

AO-OCT is ultimately limited by the numerical aperture of the eye, which is notably less than that of light microscopy. But a more important distinction between the two methods is the source of image contrast. Contrast in AO-OCT is the differences in the intensity of backscattered light, which originate from differences in the intrinsic refractive indices of the tissue. For histology, contrast has no refractive index origin. Instead, it is created artificially by impregnating the tissue sample with pigments and fluorescent molecules that are designed to highlight specific organelles and molecules. Thus the two methods produce highly different images of the same tissue (see, for example, Fig. 61.34), and this makes comparison of the two exceedingly difficult.

Figure 61.35 provides an example of the types of retinal microstructures that can be visualized within a given volume of retinal tissue imaged with AO-OCT. The AO-OCT volume is a composite made by re-imaging the same retinal patch, with focus systematically shifted to different depths, in this way preserving the high image quality provided by AO for the retinal layer of interest. Extracted *en face* slices (from top to bottom) are shown of individual RNFBs, microstructures in the ganglion cell layer, retinal capillaries, and outer segments of cone photoreceptors.

The next sections present several scientific examples that have been reported in the literature and make use of AO-OCT for studying targeted layers in the retina. Examples include the photoreceptor mosaic, retinal and choroidal microvasculature, retinal nerve fiber bundles, RPE, Bruchs membrane, and the optic nerve head.

61.7.1.2 Photoreceptor Morphology and Function

Cone photoreceptors have been imaged with a variety of AO-OCT [21, 80] and UHR-AO-OCT configurations [25, 26, 94, 124]. Early studies revealed the reflectance bands observed at the IS/OS junction, and the posterior tips of the OS in standard OCT were actually composed of a regular distribution of punctated

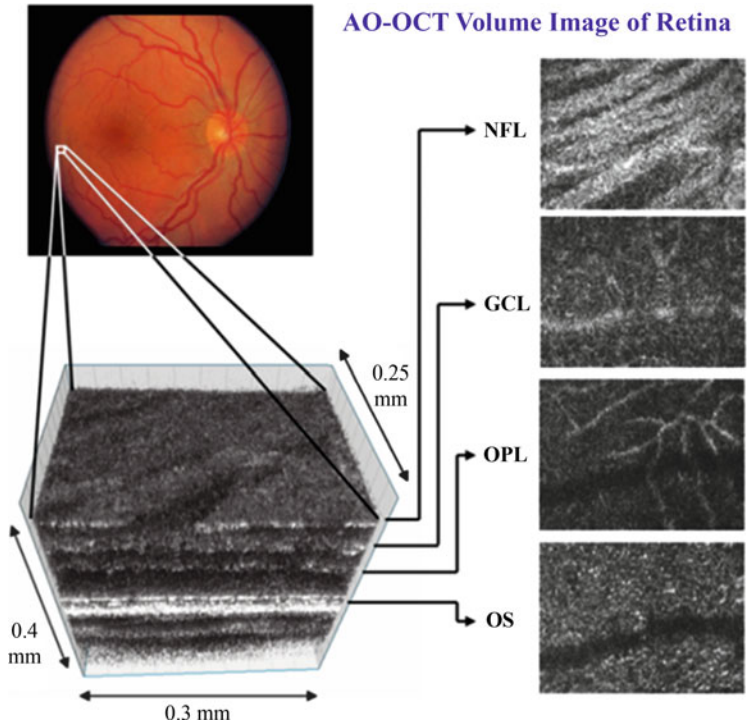

Fig. 61.35 AO-OCT volume of retinal structures acquired over 0.25 × 0.3 mm^2 area at 10° TR eccentricity on a healthy, 32-year-old volunteer. Numerous microscopic structures can be seen in C-scans sectioned at different depths in the volume (*right*). Key: *GCL* ganglion cell layer, *NFL* retinal nerve fiber layer, *OPL* outer plexiform layer, *OS* cone photoreceptor outer segments (Reprinted with permission from SPIE, Ref. [126])

reflections, each originating from a single cone cell. AO-OCT studies further revealed that these punctated reflections were highly correlated between the IS/OS and posterior tip layers, and their spacing was consistent with expected cone spacing. Collectively, these observations give substantive evidence that these reflectance bands occur inside cones and on opposite ends of the cones' outer segments.

More detailed and exhaustive studies of the 3D structure of cones, however, have been slowed by eye motion artifacts that prevent tracking of individual cones across frames of AO-OCT videos. This bottleneck was recently addressed using high-speed image acquisition (up to 200 KHz) to reduce the deleterious effects of eye motion on volumetric images and a novel post-processing registration/dewarping method to further reduce eye motion effects [124]. The combination of the two reduced eye motion to less than a fraction of a cone width. With this level of motion compensation, individual cones were tracked over periods as long

as 10 days. This time duration is more than adequate for studying the physiological processes of disk renewal and phagocytosis at the individual cone level, processes that are known to be disrupted by retinal disease such as age-related macular degeneration (ARMD) and retinitis pigmentosa (RP).

Indeed using post-processing registration and high-speed imaging in conjunction with phase-sensitive AO-OCT (Sect. 61.6.3), sub-resolution changes in the cone outer segment were measured in hundreds of cones over matters of hours. Across all cones, the OS was found to elongate at rates of about 150 nm/h, which is consistent with earlier reports in which renewal was inferred from histology [127, 128] as well as in previous in vivo findings by the same authors using an AO flood-illumination system [129].

In a separate cone length analysis using only intensity of the backscatter, AO-UHR-OCT was shown to be sufficiently sensitive to measure real length differences between individual cones in the same retinal patch and required no more than five measurements of OS length to achieve 95 % confidence. We know of no other imaging modality that can monitor foveal or parafoveal cones over time with comparable resolution in all three dimensions.

With AO-OCT, cones have been resolved as close as 0.25° from the fovea (the most critical area of patient vision), which is the densest packing of cones observed to date with OCT methods. Figure 61.36 shows representative *en face* and cross-sectional views of individual cones acquired with two different high-speed UHR-AO-OCT systems. Note the level of cone detail at the different retinal eccentricities and in both views, for example, the decrease in cone outer-segment length with retinal eccentricity.

61.7.1.3 Retinal and Choroidal Vasculature

AO-OCT systems have proven highly effective at sectioning the various capillary beds of the retina and distinguishing individual capillaries, all based on direct intensity imaging. Numerous reports of such imaging can be found in the AO-OCT literature. Sectioning of the AO-OCT volume at the IPL/INL and OPL/INL layers (with system focus at the same layer) generally provides well-defined networks of capillaries. Figures 61.37 and 61.38 show examples of capillary imaging in two different AO-OCT studies [95, 131]. The first illustrates the extent of the capillary beds by montaging many AO-OCT volumes. The second study investigated the capability of AO-OCT to image the tiny capillaries proximal to the foveal avascular zone. Capillary diameter measurements were found consistent with histology reported in the literature (average, 4.7 μm compared to 5.1 μm) and furthermore supported the view that the vast majority of capillaries in the retina are likely detectable with UHR-AO-OCT, based solely on direct intensity imaging.

To date AO-OCT vascular imaging has been mainly directed at direct intensity imaging of the tiniest of vessels in the retina, for good reason as the benefit of AO is most pronounced for the smallest vessels. However, OCT itself has undergone major development to enhance vessel contrast and quantify flow, the former with flow-contrasting OCT methods and the latter with Doppler OCT [132]; both

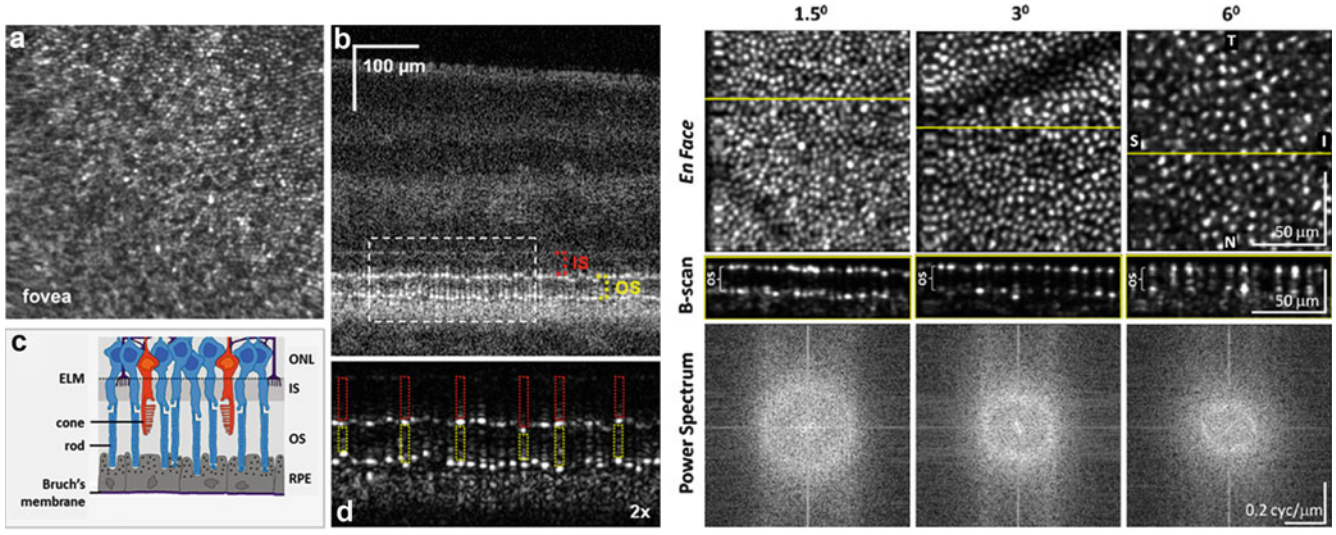

Fig. 61.36 *Left*: Comparison of photoreceptor mosaic imaged with different modalities. (**a**) AO-SLO imaging (linear intensity scale) [130]; (**b**) AO-OCT imaging (logarithmic intensity scale); (**c**) simplified schematic of the cellular structures in outer retina layers; and (**d**) twofold enlargement of the photoreceptor layers (linear intensity scale) from the AO-OCT image (*panel b*). *Dashed red rectangles* show examples of cone photoreceptors ISs. *Dashed yellow rectangles* show examples of cone photoreceptors OSs (Results reproduced with permission from OSA, Ref. [25]). *Right*: (*top row*) AO-OCT cone photoreceptor images of one subject at 1.5°, 3°, and 6° temporal to the fovea. Fig. 61.37 Visualization of the large FOV AO-OCT volume *Left*, view of the volume with co-registered fundus photo *Right*, screenshot from OSA ISP with the slicing plane view of the large FOV AO-OCT volume Note the clear visualization of microcapillaries and foveal avascular zone when altering the location of the slicing plane (Results reproduced with permission from OSA. Ref. [95])

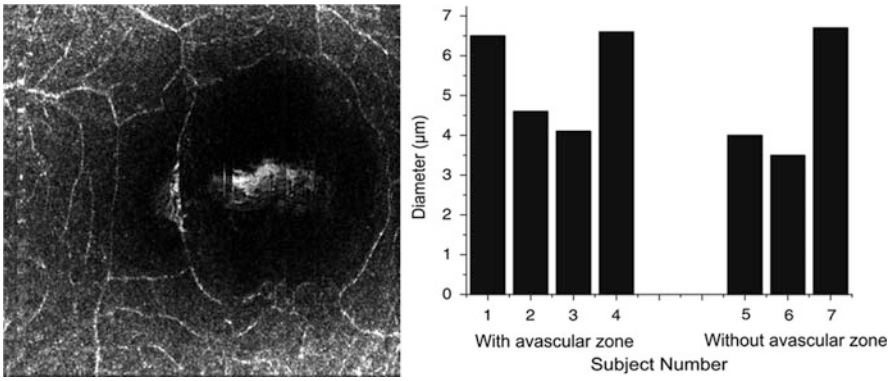

Fig. 61.38 UHR-AO-OCT imaging of the retinal capillaries proximal to the foveal avascular zone. (*left*) *En face* projection (3° × 3°) through the multi-laminar networks of capillaries that define the foveal avascular zone is shown in a normal subject. A well-defined foveal avascular zone is evident. System focus was optimized for vessel clarity. Central bright spot is a residual of the fovea reflex that was not completely removed in post-processing when the capillary subregion was extracted (Results reproduced with permission from *Eye (London, England)*. Ref. [27]). (*right*) Average diameter of retinal capillaries in subjects with and without a foveal avascular zone (*FAZ*). Measurements were taken at the FAZ edge (with) and across fovea (without). The average and SD across all seven subjects is 5.1 ± 1.4 μm, which is consistent with histology (average, ~4.7 μm) (Results reproduced with permission from ARVO. Ref. [131])

methods are described in detail in other chapters. These methods rely on sensing phase or intensity variations created by blood flow and have proven effective for monitoring total retinal blood flow [133] as well as mapping the extensive retinal and choroidal vasculature [134–139]. Both are likely to take on significant roles in

clinical diagnosis. While the integration of AO in either remains largely unexplored, the increased lateral resolution and sensitivity of AO are fundamental and may ultimately improve performance of these methods beyond that of their current form.

61.7.1.4 Retinal Nerve Fiber Layer

AO-OCT imaging represents a potential means to measure cross-sectional RNFB dimensions owing to its micron-level 3D resolution. There have been several observational reports showing the 3D profile of RNFBs in subjects using AO-OCT [25, 83, 94]. Although these early observations are highly encouraging, they were limited to single images acquired on single subjects with no measurements of the RNFB cross section.

More recently, AO-OCT was used to measure the dimensions of RNFBs in five subjects (29–62 years of age; four clinically normal) at the same retinal eccentricities using the same system. Details of the study can be found in Kocaoglu et al. [89]. Taken from this study, Fig. 61.39 (left) plots the average width and thickness of the RNFBs, revealing bundles at the more central location are flatter in cross section, but of similar width. Bundle clarity (individuation) in both cross section and *en face* views was found to vary with subject and retinal location. Interestingly, the overriding determination of bundle clarity was size of the gap between adjacent bundles rather than the size of the bundles themselves. Spacing between adjacent bundles was on the order of a few microns compared to the size of bundles that was on the order of tens of microns. Bundle contrast was also critical for identifying bundles. The reflectance of RNFB tissue was found to be two times brighter (3 dB) than that of the Müller cells that surround the bundles (gaps). This difference provided sufficient contrast to distinguish bundle from gap when resolution allowed.

Repeated imaging of the same bundles over months and years is critical in longitudinal studies, and for detecting and monitoring, for example, slow RNFB changes that occur with progression of disease such as glaucoma. Kocaoglu et al. demonstrated the efficacy of imaging the same bundles 7 months apart, finding width and thickness RNFB measurements at the two time points to be strongly correlated, $p < 0.0005$ (see Fig. 61.39 (right)). In general, results of this study and that of earlier ones suggest that UHR-AO-OCT is capable of measuring the cross-sectional profile of individual bundles even at locations where bundles are increasingly thin (<15 μm) and the same bundles at multiple time points.

61.7.1.5 Retinal Pigment Epitelium, Bruchs Membrane, Choriocapillaris

The RPE is the pigmented cell layer just outside the neurosensory retina that nourishes retinal photoreceptors and is firmly attached to the underlying Bruchs membrane that overlies the choriocapillaris. The RPE is composed of a monolayer of hexagonal cells (RPE cells). The retinal pigment epithelium transports metabolic waste from the photoreceptors across Bruch's membrane to the choroid. Choriocapillaris is a thin layer of the choroid adjacent to Bruch's membrane and consisting

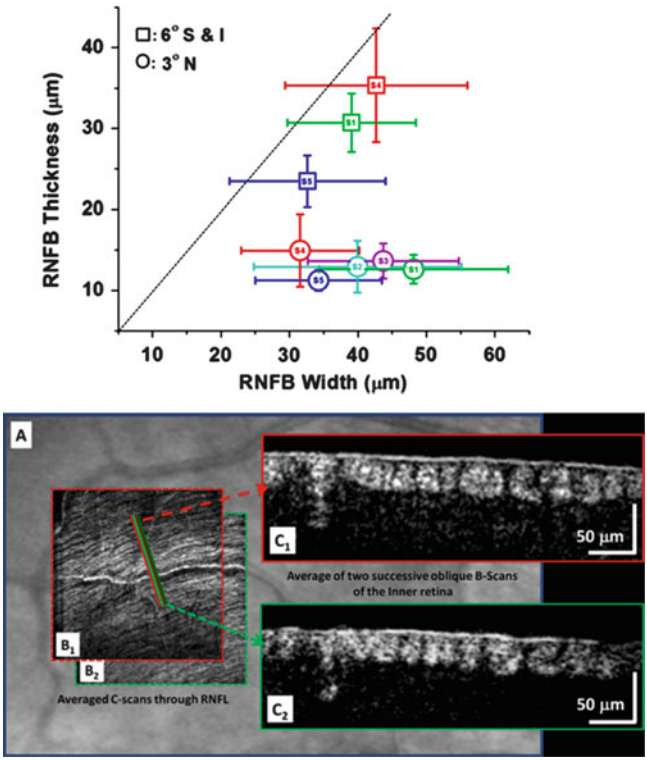

Fig. 61.39 (*left*): Average width and thickness of RNFBs measured at 3° nasal (*N*) and 6° superior (*S*) and inferior (*I*) retinal eccentricities for five subjects. Error bars represent the distribution of RNFB sizes measured at each retinal eccentricity. For reference, the *dashed line* denotes a perfectly circular bundle (width = thickness). (*right*): UHR-AO-OCT images acquired 7 months apart on the same subject. (**a**) Wide-field SLO image facilitated registration of the projected C-scans. (*B1* and *B2*) C-scans averaged through the RNFL reveal the diagonal striation pattern of RNFBs and the presence of retinal vasculature. *Solid lines* denote the first imaging session, *dashed lines* the second. (*C1* and *C2*) Averaged (2), oblique B-scans of the same retinal location (Reproduced with permission from Elsevier, Ref. [89])

of a network of capillaries which supplies nutrients to the retina. These three structures play pivotal role in health of the photoreceptors and the retina placing it in the center of aging and retinal degenerations studies. Therefore, detailed visualization of this complex is very important both in clinical and research settings. Figure 61.40 shows example AO-OCT volumetric visualization of photoreceptor-RPE-choriocapillaris complex [94].

Beside visualization of volumetric cellular morphology of photoreceptor/RPE/choriocapillaris complex, simple averaged AO-OCT B-scans also proved to be helpful in studying these key retinal structures offering details surpassing those available by UHR OCT. Figure 61.41 shows an example of two averaged B-scans

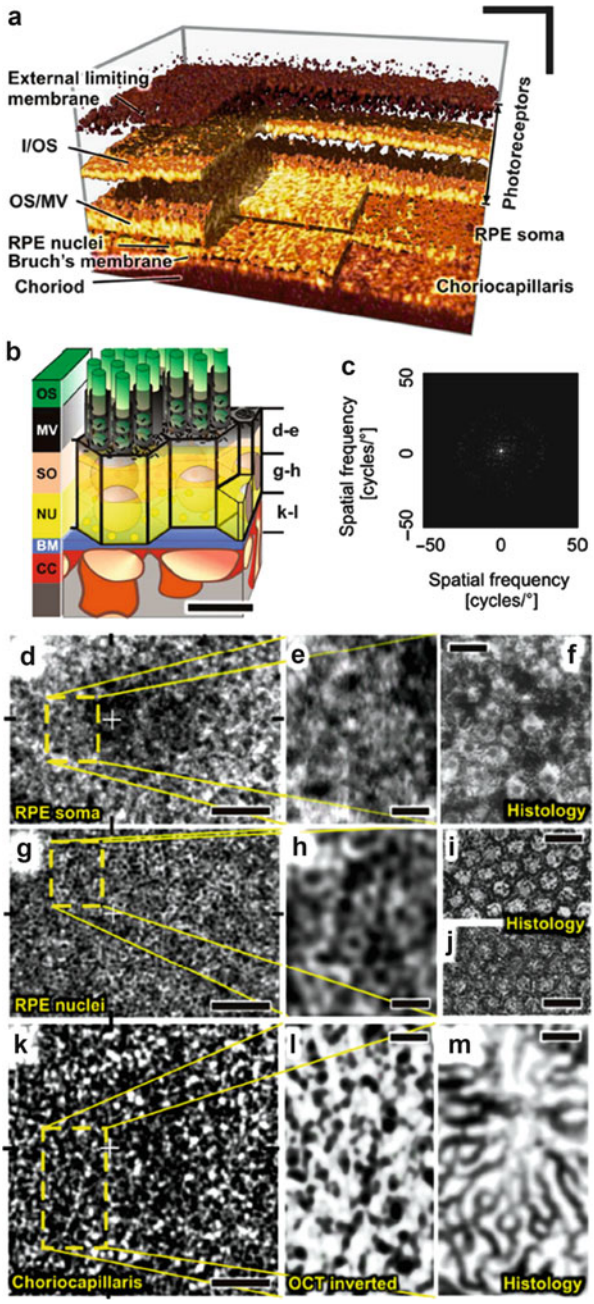

Fig. 61.40 Visualization of foveal retinal pigment epithelium (*RPE*) cells and choriocapillaris. (**a**) 3D rendered OCT volume of a 28-year-old normal male Caucasian retina at the fovea after filtering with ATF. (**b**) Schematic of RPE cell. *OS* outer segments, *MV* microvilli, *SO* inner portion

of outer retina acquired at two retinal eccentricities: fovea and 6° temporal retina (TR) [140]. Such a detailed view of the photoreceptor and RPE bands should allow new studies of these structures.

61.7.1.6 Optic Nerve Head

The optic nerve head (ONH) is part of the fundus where ganglion cell axons exit the eye to form the optic nerve. The optic nerve head is also the entry point for the major blood vessels that supply the retina. Given the importance of the ONH for vision and its susceptibility to disease, most notably glaucoma, the ability to visualize and detect minute changes at the microscopic level in the ONH carry considerable scientific and clinical interest. Figure 61.42 shows examples by two different groups in which AO-OCT was used to image microscopic structures in the ONH [94, 95]. Both studies revealed minute details in the pores formed by the collagenous fibers of the lamina cribrosa, a mesh-like structure which allows nerve fibers and vessels of the optic nerve to pass through the sclera.

However, it is important to mention that AO-enhanced imaging of the ONH is not trivial due to highly scattering and axially extended ONH structures making it difficult to extract reliable wavefront sensor data. Therefore, special attention has to be paid during imaging to AO control to ensure its correct operation. Previously mentioned wavefront sensorless approaches [86] might become a viable alternative in ONH imaging. Additionally, DaeYu et al. have published recently work on extending axial depth range of AO-OCT system by removing complex conjugate artifact in AO-FD-OCT and applying it to ONH imaging [142]. This method allows positioning of the imaged ONH structure near the zero path length difference, where sensitivity of the system is the highest, without possibility of generating mirror complex conjugate artifacts by eye motion or ONH structures extending axially. This feature might be important in future more-automated clinical screening of ONH by AO-OCT.

Fig. 61.40 (continued) of RPE soma, *NU* nuclear (basal) portion of RPE soma, *BM* Bruch's membrane, *CC* choriocapillaris. Also indicated are the levels corresponding to panels (**c–d**, **f–g,** and **j–k**). (**c**) 2D power spectrum of the RPE cell mosaic obtained by averaging of 15 *en face* slices followed by filtering of the resulting power spectrum with BPF4–500. (**d**) Sectioned image at the level of the RPE soma (average of 15 *en face* sections filtered with ATF). At this depth, signal-producing elements are mainly melanin granules inferior to the inner portion of the RPE cell, also magnified in (**e**). (**f**) Histological section from a normal human fovea for comparison. (**g**) Basal RPE exposing structure of the RPE cell mosaic at the level of the cell nuclei (average of 14 *en face* sections the filtered with BPF4–500). (**h**) Enlarged portion of **g** with *yellow circles* enclosing seven hexagonally arranged clusters of RPE cells. (**i–j**) Light micrographs of tangentially sectioned tissue showing an *en face* view of human RPE cells from an 18- and 42-year-old Caucasian male, respectively. (**k**) Sectioned image at the level of the choriocapillaris (averaging of five *en face* sections filtered with ATF). The emerging, structure possibly corresponds to microvessels. (**l**) Inverted and enlarged selected portion of **k**. (**m**) Histology of a human choriocapillaris in alkaline phosphatase preparation. Scale bars: 100 μm for **a**, **d**, **g**, **k**; 20 μm for **e–f**, **h–j**, **l–m** 10 μm for **b**. *White* cross hairs in **d**, **g,** and **k** denote the foveal center (Reproduced with permission from OSA, Ref. [94])

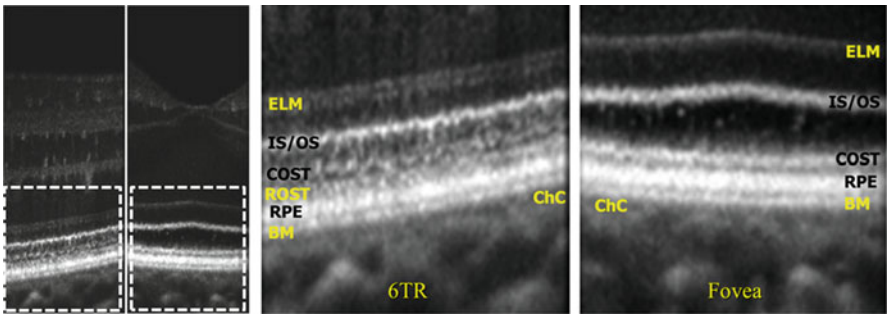

Fig. 61.41 Visualization of outer retina by AO-OCT system. Four outer retinal bands seen on commercial OCT systems can be attributed to the external limiting membrane (*ELM*), the boundary between the inner and outer segments (*IS*/*OS*), end tips of cone photoreceptor outer segments (*COST*), and the retinal pigment epithelium (*RPE*). Additional layers including possible doubling of external limiting membrane (*ELM*), end tips of rod photoreceptor outer segments (*ROST*), Bruch's membrane (*BM*), and choriocapillaris (*CC*) are not visible with current commercial OCT instruments (Reproduced with permission from ISIE/ARVO, Ref. [140])

61.7.2 Clinical Imaging with AO-OCT

This section summarizes key studies that employed AO-OCT to image retinal disease. The clinical potential of AO-OCT lies in its ability to not only diagnose disease early in the process but also improve the monitoring of disease progression and the treatment of disease. It is commonly accepted that minute structural and physiological changes in the disease process precede changes in visual function (visual acuity; contrast sensitivity), often the clinical standard for assessing patient vision. The strategy with AO-OCT then is to capitalize on its micron-scale 3D resolution and high sensitivity to detect these subtle changes. While this direction for AO-OCT is in its infancy, the examples presented here illustrate the potential clinical utility of this imaging technology. Examples include age-related macular degeneration, glaucoma, RNFL defect, retinopathy of prematurity as well as imaging of patients with clinically unexplained vision loss, and color blindness phenotyping.

61.7.2.1 Age-Related Macular Degeneration

ARMD is a leading cause of vision loss among people 50 years of age and older. In its most common form, it gradually destroys the outer retina (photoreceptors, RPE, Bruch's membrane) of the macula, the part that provides sharp vision. Much of the research to date with AO-OCT has focused on this same area, in particular photoreceptors, but in normal healthy eyes. This makes for a natural extension to diseased eyes whose outer retina is affected, for example, with ARMD. Figure 61.43 shows one example, a clinical evaluation of a patient with late-state

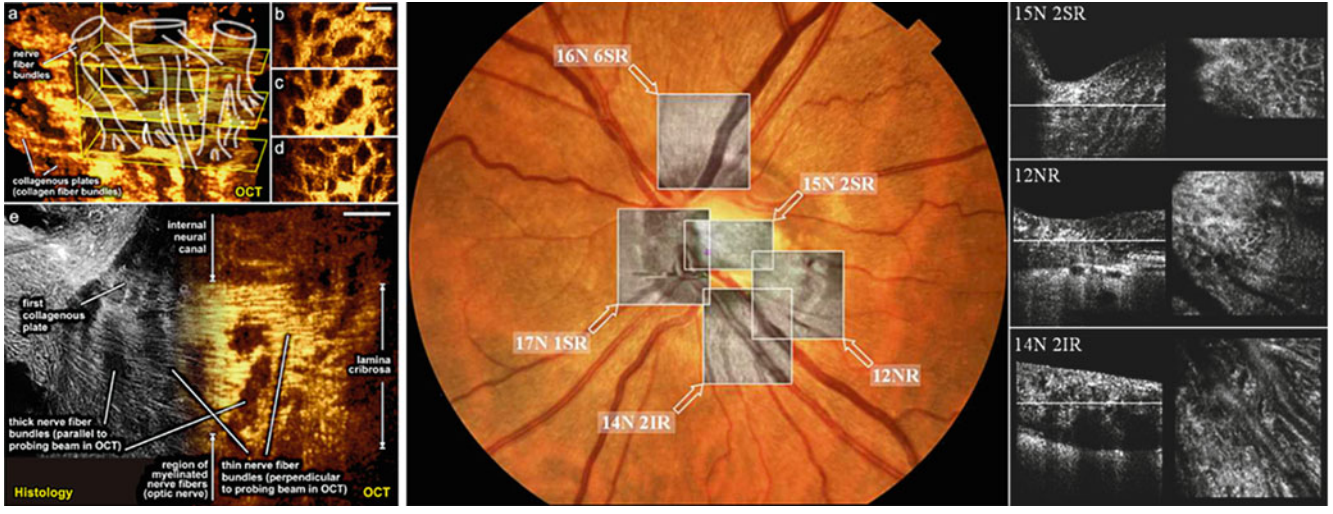

Fig. 61.42 (*left*): Pores and collagenous fibers of the lamina cribrosa (*LC*). **a** 3D rendered volume of the LC (filtered with ATF). **b–d** Single *en face* sections (filtered with ATF) denoted by *yellow rectangles* in **a. e** Lateral section of the LC (*left*) as seen by histology of a human LC (selected portion of Fig. 1 from Kotecha et al. [141]) for comparison with OCT (*right*), obtained after averaging five fast-scan-axis tomograms filtered with ATF. Collagen fiber bundles oriented orthogonal to the probing beam appear bright (Reproduced with permission from OSA, Ref: [94]). (*right*): Visualization of the ONH microscopic structures imaged with AO-OCT. *Left*: screenshot from volume renderer after co-registration of five 3D AO-OCT datasets with fundus photo. *Right*, three AO-OCT volumes shown on the *left*: 15N 2SR (), 12NR, and 14N 2IR *White lines* on the B-scans correspond to the depth of the C-scans reconstructed from the same volume. Multiple microscopic structures including lamina cribrosa and blood vessels are easily recognizable (Reproduced with permission from OSA, Ref. [95])

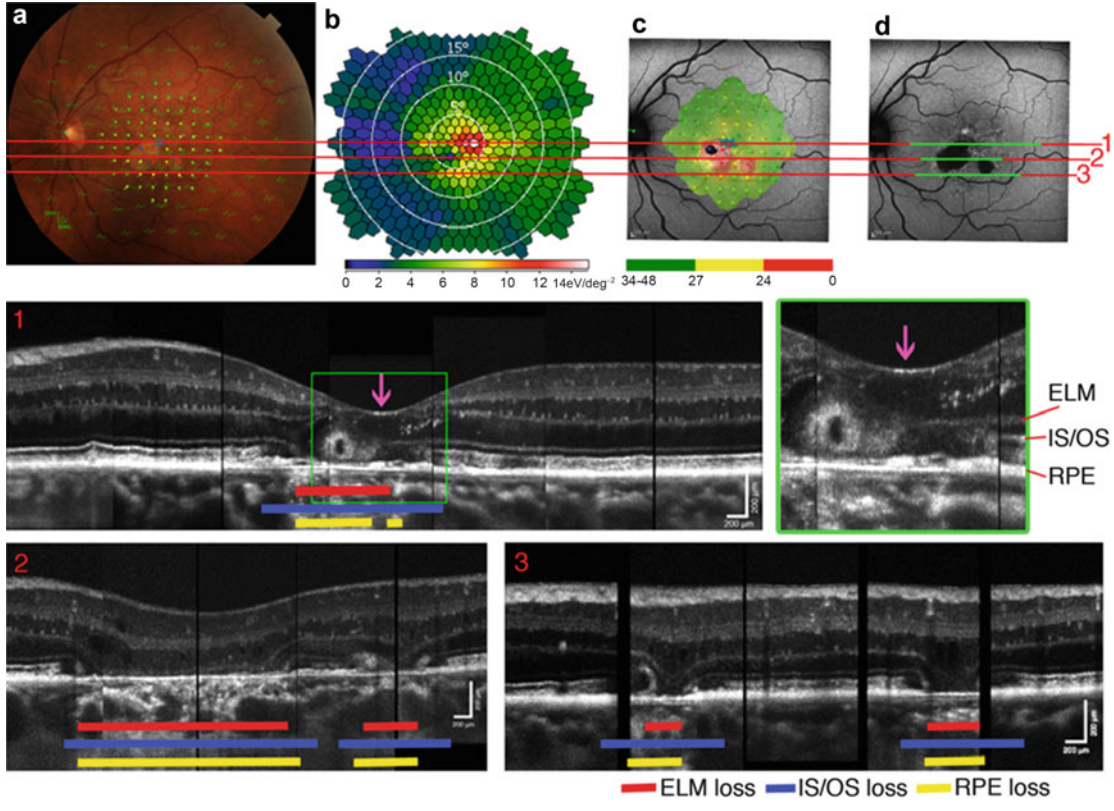

Fig. 61.43 Diagnostic and AO-OCT results from patient with ARMD Geographic Atrophy. *Panel a* is the color fundus photograph (*CF*) with the multifocal electroretinogram (*mfERG*) traces and micro perimetry (*mP*) sensitivity superimposed. *Panel b* shows the mfERG response density map; panel **c** shows the mP

ARMD geographic atrophy (GA) [143]. To help interpret the AO-OCT images, several standard clinical tests (see figure caption) were also collected on the same eye and are shown in the figure.

61.7.2.2 Retinitis Pigmentosa

Retinitis pigmentosa (RP) is an inherited, degenerative eye disease that causes severe vision impairment and often blindness. RP is caused by abnormalities of the photoreceptors (rods and cones) that result in photoreceptor loss accompanied by changes in the RPE. Recent AO-OCT study of RP patient by Považay et al. [144] revealed atrophy in the photoreceptor layer with "drusen-like" appearances especially in the foveal center and significant reduction of cone densities. Results from that study are shown in Fig. 61.44.

61.7.2.3 Glaucomatous and Non-glaucomatous Optic Neuropathies

Optic neuropathy refers to a host of eye diseases that damage the optic nerve. Glaucoma, the most common form of optic neuropathy, can cause excavation of the optic disk along with characteristic loss of visual field due to ganglion cell death. Despite glaucoma being characterized as a disease of the optic disk and inner retina, a detailed look at the outer retina with AO-OCT in a recent study of glaucomatous and non-glaucomatous optical neuropathy patients suggested otherwise [145, 146]. Specifically, AO-based systems including AO-OCT revealed changes in the photoreceptor layer that accompanied the optic neuropathy [147]. Results from that study are shown in Fig. 61.45.

61.7.2.4 RNFL Defect

Early detection of axonal tissue loss is critical for managing diseases that destroy the RNFL such as glaucoma. Axonal tissue loss in the RNFL has been reported to be one of the earliest detectable glaucomatous changes, preceding morphologic changes in optic nerve head and visual field loss [148, 149]. Fundus photography, scanning laser polarimetry, scanning laser ophthalmoscopy, and optical coherence tomography have been used to analyze RNFL loss in glaucomatous eyes [150–153]. Regardless of method, however, none have the necessary lateral and axial resolution to image the cross-sectional profile of individual RNFBs as they traverse the retinal surface. In contrast, AO-OCT has been demonstrated to measure both thickness and width variations of individual RNFBs (see Sect. 61.7.1.4) and to differentiate RNFBs from the radial fibers of Müller

Fig. 61.43 (continued) sensitivity map superimposed on the Fundus Auto Fluorescence (*FAF*), and *panel d* is the FAF. The *three numbered green lines* in *panel d* correspond to the three B-scan montages shown below. The *magenta arrow* in B-scan 1 shows the PRL. The *red*, *blue*, and *yellow bars* on the B-scans correspond to ELM, IS/OS, and RPE loss, respectively. The magnified B-scan section shows remaining RPE that corresponds to the location of the PRL (Reproduced with permission from ARVO, Ref. [143])

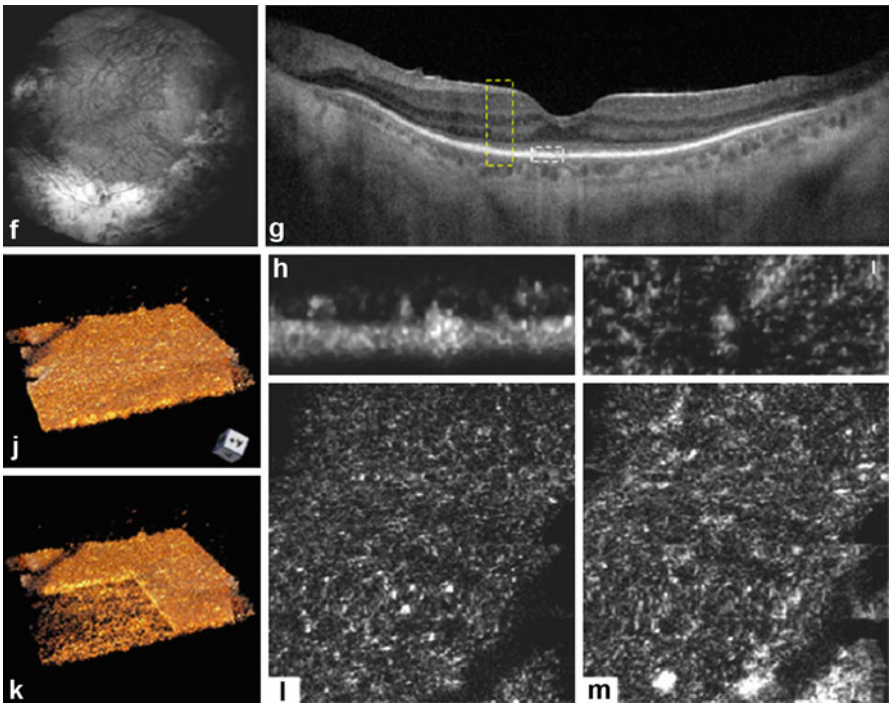

Fig. 61.44 (**f**) *En face* wide field (∼35° × 35°) fundus image of the choroid using 1,060 nm 3D-OCT; (**g**) high definition (2,048 pixel) 1,060 nm 3D-OCT scan over 35°; cellular-resolution retinal imaging using AO OCT: (**h**) cross section and *en face* image (**i**) of s volume at the level of the retinal pigment epithelium; retinal location indicated by *white dashed line* in (**g**); (**j**) volumetric AO OCT at 4° isotropic parafoveal; retinal location indicated by *yellow dashed line* in (**g**); (**k**) volumetric rendering at 4°; (**l**) *en face* images at the level of the inner/outer photoreceptor junction at 6°; (**m**) at the level of the tips of the outer photoreceptors at 6° (**m**) (Reproduced with permission from OSA, Ref. [144])

cells that separate the bundles. This opens the possibility to extend known morphological differences in RNFL thickness between normal, aging, and diseased retinal axonal tissue to morphological differences in RNFB area and volume. While this remains future work, Fig. 61.46 illustrates a rather extreme example, the use of an AO-UHR-OCT system to map an arcuate defect in the RNFL. At the affected location, the area and volume of the individual bundles are clearly reduced almost to the point where the bundles no longer exist [89].

61.7.2.5 Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is a potentially blinding disorder that alters development of the central retina and primarily affects prematurely born babies such as those receiving intensive neonatal care that is thought to be caused by disorganized growth of the retinal vasculature and can lead to complications

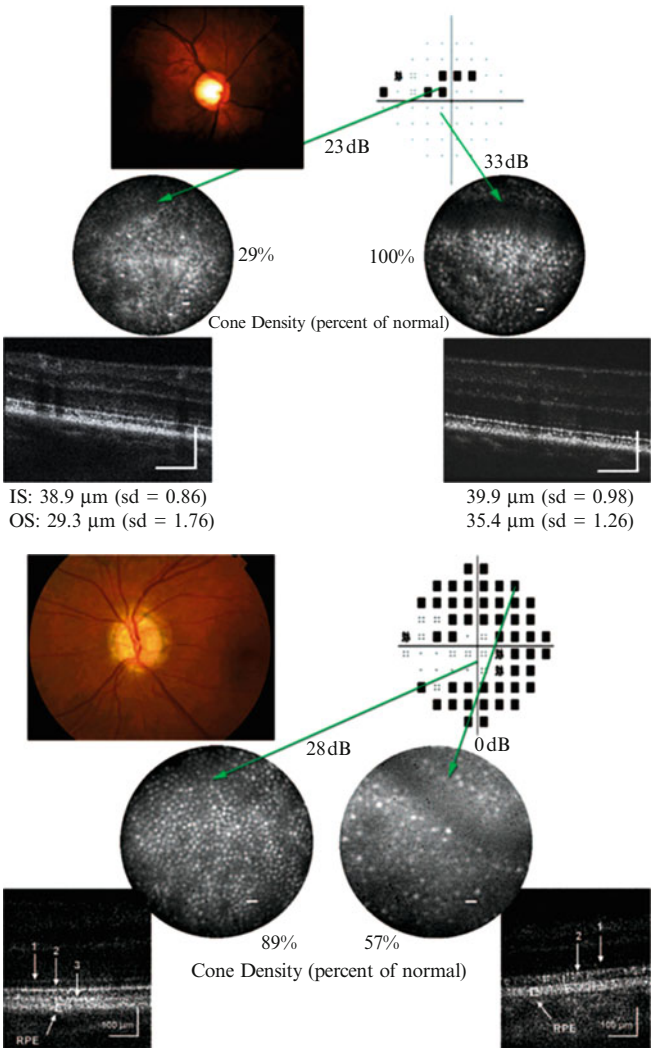

Fig. 61.45 Examination of the (*left*) right and (*right*) left eyes of a 63-year-old patient with primary open-angle glaucoma. For each eye, standard diagnostics included optic disk photography and visual fields (Humphrey Visual Field). Images at select retinal locations were also acquired with AO flood illumination and AO-OCT systems. *Green arrows* show the high-resolution retinal images from areas of higher (*white*/*gray squares*) and lower (*black squares*) visual sensitivity. Below each AO flood image is a corresponding AO-OCT B-scan with focus on the outer retina. Mean length and standard deviation of inner (*IS*) and outer segments (*OS*) are shown below the B-scans. Labels *1*, *2*, and *3* in the AO-OCT images refer to outer limiting membrane, IS/OS junction, and cone photoreceptor outer-segment tips, respectively. Note that the left B-scan (*right eye*) is normal with three visible outer retinal layers and the right (*left eye*) is abnormal with only two visible outer retinal layers. Scale bars for the AO flood illumination and AO-OCT images are 10 and 100 µm, respectively (Reproduced with permission from Nature Publishing Group, Ref. [147])

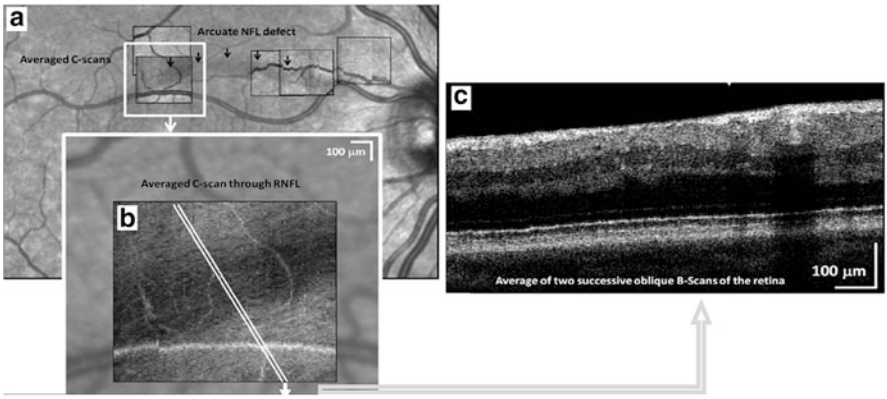

Fig. 61.46 AO-UHR-OCT images of the arcuate RNFL defect in a 62-year-old patient. (**a**) AO-UHR-OCT volumes are laterally registered to the wide-field SLO image using projection C-scans. (**b**) Enlarged view of a C-scan averaged through the RNFL and revealing faint RNFBs traversing diagonally upward from left to right. *Darkened strip* corresponds to the defect area. (**c**) B-scan obtained by averaging two successive oblique B-scans that are approximately perpendicular to the RNFB direction (Reproduced with permission from Elsevier, Ref. [89])

including scarring, retinal detachment, myopia, and amblyopia. While standard clinical methods provide coarse assessment of central retina developments in ROP, the use of AO-OCT in a recent study by Hammer et al. [154] revealed significant differences at the fine structural level, in particular that of the foveal microvasculature. Examples from this study are given in Fig. 61.47, which shows AO-OCT *en face* and cross-sectional views of the fovea of normal and ROP subjects. Absence of a foveal avascular zone is evident in Fig. 61.24 (right: e, g), a hallmark feature of ROP.

61.7.2.6 Unexplained Vision Loss

Unexplained vision loss refers to an apparent visual dysfunction whose cause cannot be determined by standard clinical examination, for example, diagnosis of an abnormality or lesion in the visual pathway. The high sensitivity of AO-OCT to detect subtle changes at the cellular level in retinal tissue offers not only the possibility to localize the source of these changes but also to do so earlier in the process. Figure 61.48 shows two cases where AO-OCT revealed subclinical changes in the foveal morphology [25]. These changes were highly localized to where vision was reduced suggesting the two originate from the same retinal abnormality.

61.7.2.7 Macular Telangiectasia

Idiopathic Juxtafoveal Macular Telangiectasia (MacTel) is a blinding condition of the retina caused by pathologically dilated blood vessels (telangiectasia) near the fovea. Disease progression involves scarring of the retina and accumulation

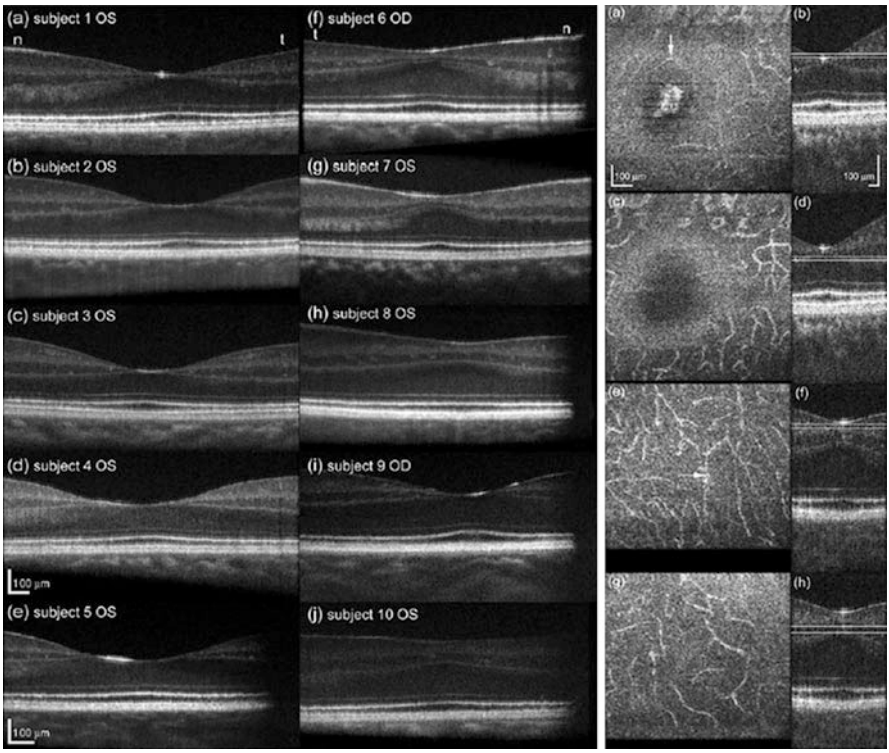

Fig. 61.47 Comparison of fine structures in the fovea of ROP and normal subjects. (*Left*): Composite AO-OCT B-scans from ten eyes: (**a**–**e**) control and (**f**–**j**) ROP subjects. (**d**) Scale bar for (**a**–**d**, **f**–**i**). (**e**) Scale bar for (**e**, **f**). (*Right*): Retinal vasculature in (**a**–**d**) control and (**e**–**h**) ROP subjects. *En face* views (**a**, **c**, **e**, **g**) were created by averaging the axial slices shown between the horizontal lines in the corresponding B-scans (**b**, **d**, **f**, **h**). (**a**, **e**) Vessels in the IPL; (**c**, **h**) vessels in the OPL. Raster scan size is 873 × 873 μm (Reproduced with permission from ARVO, Ref. [154])

of liquid-filled cysts that in turn compromise photoreceptors and can lead to permanent vision loss. In an already mentioned report describing AO-OCT imaging of retinal pathologies, Považay et al. [144] imaged structural changes associated with MacTel. A representative result from their study is shown in Fig. 61.49.

61.7.2.8 In Vivo Phenotyping of Red/Green Color Blindness in 3D

Normal human color vision is trichromatic, being based on three spectrally distinct cone classes. Color vision deficiency is usually manifested by the absence of one of the classes and is usually inherited. Depending on the type of underlying gene mutation, the color deficiency can also be accompanied with retinal disease and dysfunction of photoreceptors. Figure 61.50 shows an example of applying

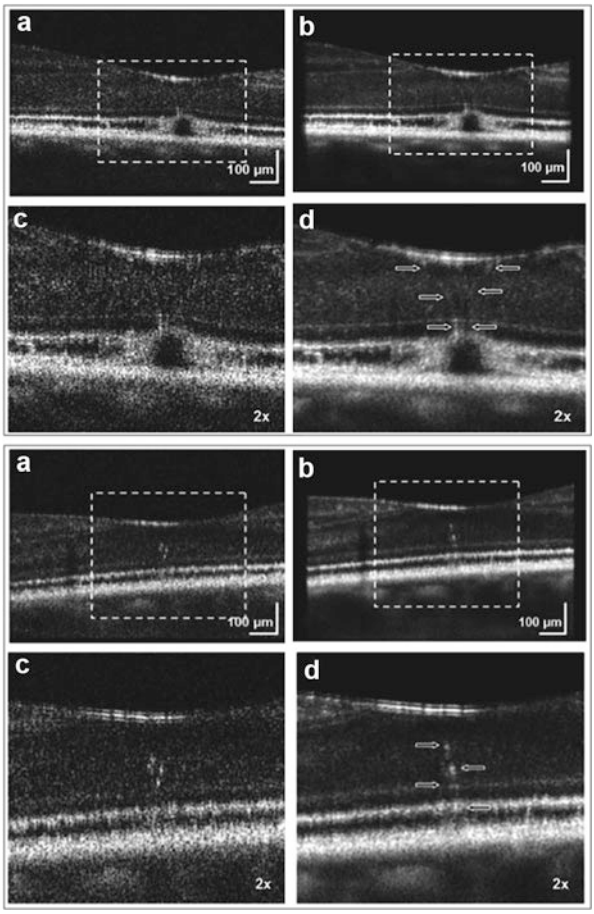

Fig. 61.48 AO-UHR-OCT imaging of two patients, (*left*) one with micro-traction and (*right*) the other with a micro scotoma. (*left*): AO-UHR-OCT images of 65-year-old subject reveal vitreal micro traction in the central fovea. Due to its small size, the traction was misdiagnosed using standard clinical imaging modalities including commercial OCT and fundus photography. *Arrows* indicate probable stress lines. (*right*): AO-UHR-OCT images of 55-year-old subject reveals hyper-reflections (denoted by *arrows*) in the outer nuclear layer near the foveal center and could not be explained using standard clinical imaging modalities (commercial OCT and fundus photography). The location of the hyper-reflections coincided with the micro scotoma, thus suggesting the two are related. For both cases, a single AO-OCT B-scan is shown in (**a**) and an average of ten B-scans in (**b**). Magnified views of the dashed rectangles in (**a**) and (**b**) are shown in (**c**) and (**d**), respectively (Reproduced with permission from OSA, Ref. [25])

AO-OCT to phenotype cone photoreceptors in patients with red/green color deficiency due to a Cys203Arg genetic mutation [94]. Phenotyping in this study involved measuring cone photoreceptor density and segment lengths in both normal and red/green deficient patients.

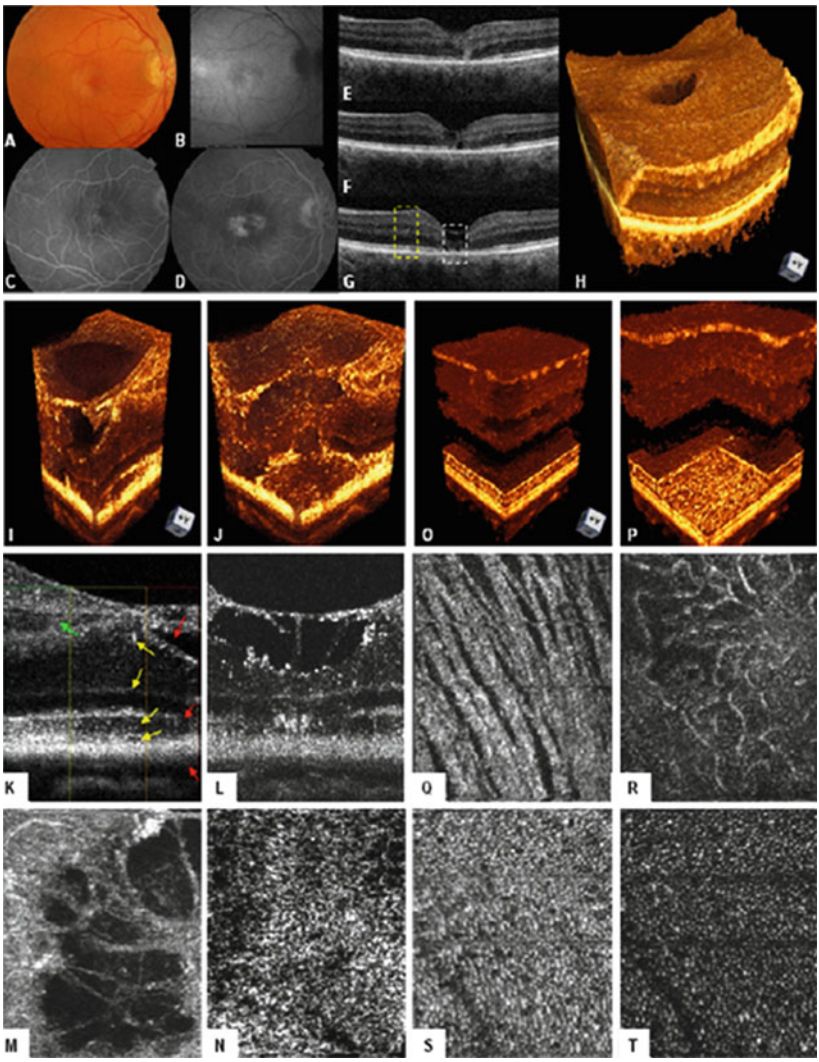

Fig. 61.49 3D-OCT (**e–h**) and AO OCT (**i–t**) at 800 nm of a patient with Type 2 Macular Telangiectasia: (**a**) fundus photo; (**b**) autofluorescence fundus image; **c** fluorescein angiography (early phase); (**d**) fluorescein angiography (late phase); (**e–g**) representative cross section from 3D-OCT, taken from (**h**); (**h**) 3D-OCT at 800 nm over 20° × 20°; cellular-resolution retinal imaging using AO OCT: (**i**) isotropic, volumetric AO OCT at 0°, retinal location indicated by *white dashed line* in (**g**); (**j**) volumetric rendering at 0°; cross sections (**k**, **l**) and *en face* images at the level of the outer nuclear layer (**m**) and retinal pigment epithelium (**n**) at 0°; *arrows* in (**k**) indicate areas of little (*green*), medium (*yellow*) and significant (*red*) impairment; (**o**) isotropic volumetric AO OCT at 6° parafoveal location, retinal location indicated by *yellow dashed line* in (**g**); *en face* images at the level of the nerve fiber bundles at 6° (**q**); capillaries in the inner nuclear layer at 6° (**r**); inner/outer photoreceptor junction at 6° (**s**) and at the level of the tips of the outer photoreceptors at 6° (**t**) (Reproduced with permission from OSA, Ref. [144])

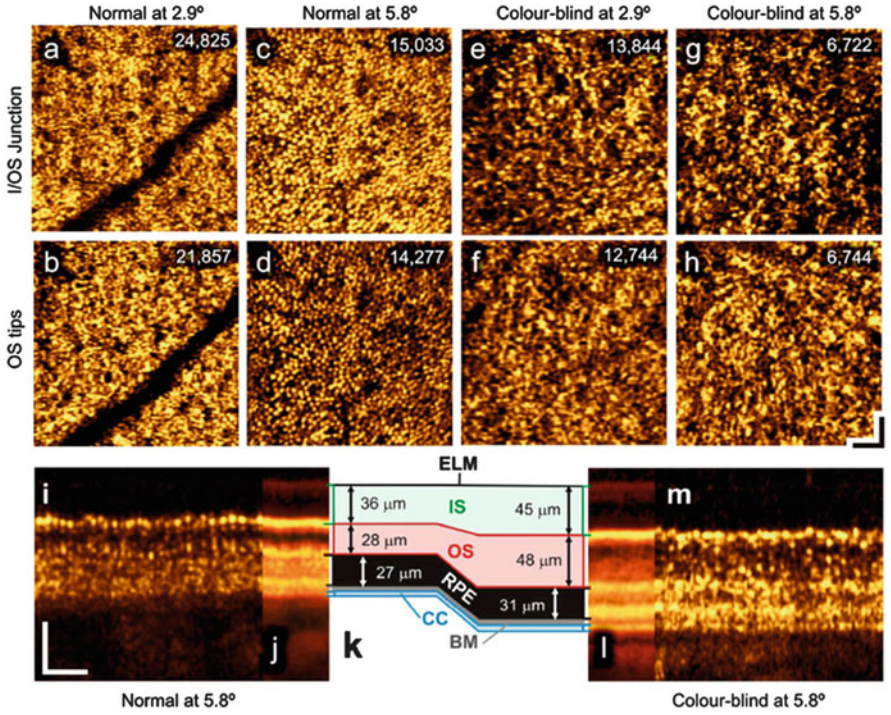

Fig. 61.50 Cellular phenotyping in a normal and *red/green* color-blind patient at 2.9° and 5.8° temporal. (**a**–**h**) *En face* images at the IS/OS and PTOS tips after averaging of 15–22 slices and bandpassed filtered. Photoreceptor densities per mm^2 are indicated at the *top-right corner* of each panel. (**i**–**m**) Comparison of photoreceptor distributions in a normal (**i**–**j**) and color-blind (**l**–**m**) subject at 5.8° temporal. Tomograms obtained by averaging five cross sections filtered with ATF are shown in **i** and **m**, while in **j** and **l**, portions of integrations obtained from 200 fast-scan-axis tomograms filtered with AFT are shown to emphasize transversal cell densities. Layer thicknesses for the IS, OS and RPE are depicted in **k**. Scale bars: 50 μm (Reproduced with permission from ARVO, Ref. [94])

61.8 Conclusions

The last decade has witnessed the creation of powerful high-resolution systems based on AO and OCT to achieve an ambitious goal of cellular-resolution imaging in all three dimensions in the living human eye. Here we presented key aspects of designing and implementing such AO-OCT systems. Particular attention was devoted to the relevant optical properties of the eye that ultimately define these systems, AO componentry and operation tailored for ophthalmic use, and of course use of the latest technologies and methods in OCT for ocular imaging. In less than a decade, AO has been integrated into every major OCT design configuration, many of which we described and compared. Early scientific and clinical studies show exciting potential of AO-OCT to image the microscopic retina and fundus in ways not previously possible with other noninvasive methods. While the

last decade has experienced tremendous advances in AO-OCT, one can only imagine that the next decade will witness even more. Perhaps in the not too distant future, AO-OCT will be ubiquitous in ocular imaging, both in the scientific and clinical communities.

62.1 Introduction

The classical scanning scheme of optical coherence tomography (OCT) [1] is based on A-scans, i.e., the fast scanning direction is the axial direction, perpendicular to the sample surface. This approach can be very sensitive using Fourier-domain OCT because the whole imaging depth can be recorded simultaneously [2]. Most applications target layered structures and require only low or moderate transverse resolution, and therefore, this approach represents the best available choice. However, in some applications, it also has considerable disadvantages: with increasing transverse resolution, the depth of focus (DOF, i.e., the zone of best sharpness) will be limited. Approaching microscopic resolution which lies in the order of a few micrometer results in a decrease of DOF down to a few tens of micrometer. This limits the benefit of FD-OCT in these applications because in order to sharply image the entire volume with a depth of $\sim$1 mm, the recording and stitching of several volumes (with different focal positions) are required. This can be quite time-consuming and the stitching might become problematic. An additional problem in the case of in vivo applications (e.g., retinal imaging) arises from artifacts caused by sample motion which are more pronounced in systems using

high magnifications. Especially microscopic structures that are only visible in the en face, the imaging plane (e.g., cone photoreceptor mosaic) can be heavily distorted even in the case of fast FD-OCT systems.

For these niche applications, transversal scanning (TS) or en face OCT can be an alternative. Here the fast scanning direction is set along the transversal extensions of the sample similar to a confocal scanning microscope. This scanning protocol requires the much less sensitive time domain OCT technique. However, sensitivity can be partly regained in the case of a scattering sample by the increase of the collection efficiency when using higher numerical aperture. Time domain OCT requires the generation of a suitable carrier frequency which deserves some additional consideration in TS-OCT. The first TS-OCT scheme reported generated the carrier frequency by the path length modulation induced by the transversal galvanometer scanners [3], which, however, has the drawback of a varying carrier frequency. We developed an alternate method of carrier frequency generation based on acousto-optic modulators (AOMs) that generate a very stable and adjustable carrier frequency [4]. Originally, this technique has been developed as an alternative for high-speed imaging, and we demonstrated the capability of the method in a variety of applications [5–9]. However, with the discovery of the sensitivity advantage of FD-OCT [2, 10], the original intention became obsolete. Nevertheless, in the case of high transverse resolution imaging, AOM-based TS-OCT has advantageous properties that allow it to compete with FD-OCT in certain applications. Since the transversal priority scanning scheme requires only a slow progression of the coherence gate in axial direction, a dynamic matching of the focal plane with the coherence gate is easily possible, thus allowing high transversal resolution throughout the entire sample depth [11]. This is a clear advantage as compared to classical A-scan-based OCT including FD-OCT where a low depth of focus limits the usable imaging depth. One application requiring high transverse resolution is cellular imaging of the human retina. Because of the permanent eye motion, imaging artifacts are in general a limiting factor when using high magnification. The scanning scheme of TS-OCT minimizes the sensitivity to transverse motion artifacts and allows the recording of basically motion artifact-free OCT images of the retinal photoreceptors in the human eyes in vivo. In this chapter, we present the underlying principle of the AOM-based TS-OCT technology and focus on the application of TS-OCT for retinal high-resolution imaging with and without adaptive optics (AO).

62.2 Carrier Frequency Generation by Acousto-Optic Frequency Shifting

An acoustic wave propagating through an optically transparent medium generates a periodic modulation of the refractive index via the elasto-optic effect. This provides a moving phase grating which can diffract an incident light beam into one or more directions. This phenomenon is known as the acousto-optic diffraction and can be used to modulate the light beam in various ways [12]. To achieve high

diffraction efficiency for a single diffraction order, acousto-optic cells are usually operated in the Bragg regime. In this case, the orientation of the incident light beam with respect to the acoustic wave in the cell is such that the wave vectors fulfill the condition:

$$\mathbf{k}_{\mathrm{d}} = \mathbf{k}_{\mathrm{i}} + \mathbf{k}_{\mathrm{a}}. \tag{62.1}$$

where $\mathbf{k}_{\mathrm{d}}$, $\mathbf{k}_{\mathrm{i}}$, and $\mathbf{k}_{\mathrm{a}}$ are the wave vectors of the diffracted light beam, incident light beam, and acoustic wave, respectively. The frequency of the diffracted light beam ν_{d} is shifted from the frequency of the incident beam ν_{i} by an amount equal to the frequency of the acoustic wave ν_{a}. Depending on the relative orientation of incident light beam and acoustic wave, this frequency shift is upward or downward:

$$\nu_{\mathrm{d}} = \nu_{\mathrm{i}} \pm \nu_{\mathrm{a}}. \tag{62.2}$$

To enable heterodyne detection in an OCT instrument, the frequencies of reference and sample beams have to differ. The amount of this frequency difference is the carrier frequency. This is the frequency that is detected by a photodetector in the detection arm of the low-coherence interferometer in case of path length matching of the two arms.

In the original time domain A-scan-based systems, the frequency of the reference beam is automatically shifted as a result of the Doppler shift caused by the moving reference mirror. In our TS-OCT system, the frequency shift is generated by one or two AOMs placed in the reference arm (placement of the AOMs in the sample arm would also work in principle). If only one AOM is used, the carrier frequency is equal to the acoustic frequency ν_{a} (or $2\nu_{\mathrm{a}}$ if the AOM is passed twice). Since ν_{a} is usually several tens of MHz, the carrier frequency is rather high in this case. On the one hand, this enables very high scanning speeds; however, it requires high-speed detectors and amplifiers which usually have a poorer signal-to-noise ratio (SNR) than slower detectors/amplifiers. For this reason, frequently two AOMs are used. They are operated at slightly different frequencies $\nu_{1\mathrm{a}}$ and $\nu_{\mathrm{a}2}$. One AOM is oriented to upshift the light frequency and the other to downshift the frequency, so that the net frequency shift (and the net carrier frequency) is much lower, on the order of a few 100 kHz to a few MHz, thus enabling the use of slower low-noise detectors/amplifiers.

62.3 Interferometer Setups of SLO/OCT and Dynamic Focusing

In principle different interferometer configurations can be used for AOM-based en face OCT: Michelson and Mach–Zehnder interferometers. However, we discuss the operating principle of such an instrument with reference to a Mach–Zehnder interferometer scheme. This design [13] (c.f. Fig. 62.1) enables balanced detection and incorporates the simultaneous recording of a scanning laser ophthalmoscope (SLO) channel.

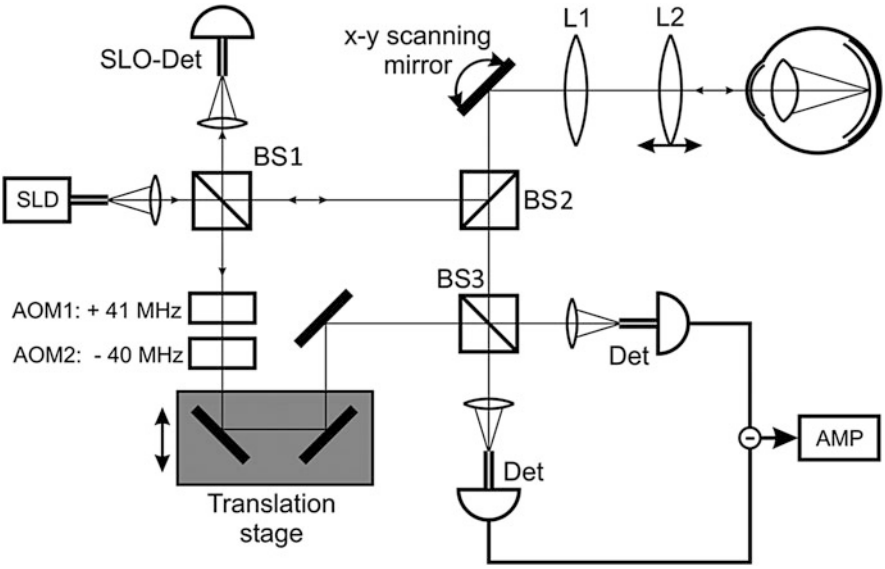

Fig. 62.1 Sketch of AOM-based Mach–Zehnder interferometer for retinal imaging. *AMP* amplifier, *AOM* acousto-optic modulator, *BS* beam splitter, *Det* single-mode fiber pigtailed detector, *L1* and *L2* lenses, *SLD* superluminescent diode, *SLO-Det* scanning laser ophthalmoscope detector (single-mode fiber pigtailed) (Reproduced from Pircher et al. [13] by permission of the Optical Society of America)

A low coherent light source emits a beam of short coherence length, centered at optical frequency ν_0. This beam illuminates the interferometer where it is split by BS1 into two components: a reference beam and a sample beam. The reference beam traverses two AOMs with different frequency shifts (ν_1 and ν_2, resulting in a net light frequency shift of $\Delta\nu$). The angular spreads of the frequency-shifted beams caused by the two oppositely oriented AOMs cancel each other largely. This allows the use of very broadband light sources, thus enabling ultrahigh-resolution TS-OCT [9, 14]. After traversing the AOMs, the beam is reflected at two reference mirrors that are mounted on a translation stage. These act as a variable path delay unit (PDU) that is used to vary the length of the reference path between successive en face scans, thus changing the position of the coherence gate within the sample (in this case the retina). The beam is recombined with the sample beam at the beam splitter that is located at the interferometer exit (BS3). The sample beam traverses another beam splitter (BS2) and is directed to an x–y scanning unit. The telescope located after the scanning unit images the pivot point of the scanners onto the pupil plane of the eye. The last lens of the telescope is mounted on a translation stage that can be simultaneously moved with the change of the coherence gate, thus enabling a simultaneous shift of the focal position with the coherence gate [11]. The light is backscattered from the retina and split into

two parts at the beam splitter BS2. One part is directed to the interferometer entrance where it is partly reflected by BS1 and is coupled into a single-mode fiber. This light is detected by an avalanche photodiode. Although it records part of the light backscattered from the sample, this light is not brought to interference with the reference beam. Therefore, this detector records a simple intensity image from the retina without coherence gating similar to a commonly used SLO [15, 16] detector. As will be discussed later on, this additional signal is essential for alignment, focusing, and post-processing purposes.

The other light part exiting BS2 is directed to the beam splitter at the interferometer exit (BS3) where it is recombined with the reference arm. Light from both exits is coupled into single-mode fibers and is detected by a dual balanced detector. The light-induced electrical signals from both interferometer exits are phase shifted by 180° between each other which enable the dual balanced detection by simply subtracting the two recorded signals before amplification. This procedure reduces source noise and excess noise [17]. In order to allow a pixel to pixel correspondence between SLO and OCT channels, the two OCT detectors have to be confocal to the SLO detector, and the signals are recorded simultaneously using the same data acquisition board.

Subject aligning and data recording are done in the following way. First, the focus is adjusted by moving the last lens and using the information of the SLO channel. Then the PDU is set to place the coherence gate to the location of the cone photoreceptors (junction between inner and outer segments of cones), a location that provides high backscattering signal. Shortly before starting the 3D data recording, the coherence gate and the focus are set deeper into the tissue (within the choroid). The x–y scanner scans the complete x–y plane corresponding to the depth position of the coherence gate (the layer thus scanned is the so-called coherence layer; its thickness is equal to the coherence length). If the sample beam hits a backreflecting or backscattering site within the coherence layer, the backscattered light will interfere with the reference beam. Since sample and reference beams differ in frequency by an amount $\Delta\nu$, the resulting interference signal will oscillate at $\Delta\nu$ (the beat frequency). $\Delta\nu$ constitutes a very stable carrier frequency that can easily be extracted by filtering with a band pass filter centered at $\Delta\nu$. The magnitude of the signal thus extracted is a measure of reflectivity of the sample as a function of the transversal position at the depth defined by the PDU. The signal magnitude is encoded on a grayscale. The signal from the SLO channel is recorded in parallel. However, the depth resolution of this channel is determined by the numerical aperture and the resulting depth of focus. After one en face scan, the PDU and focus settings are changed to move the coherence layer closer to the surface of the sample, and another en face scan is recorded. Step by step, the coherence layer is shifted through the sample. In this way, a 3D data set of a selected region of the sample is recorded. Figure 62.2 illustrates the transversal scanning scheme, as compared to the conventional, A-scan-based scheme, for the case of retinal imaging.

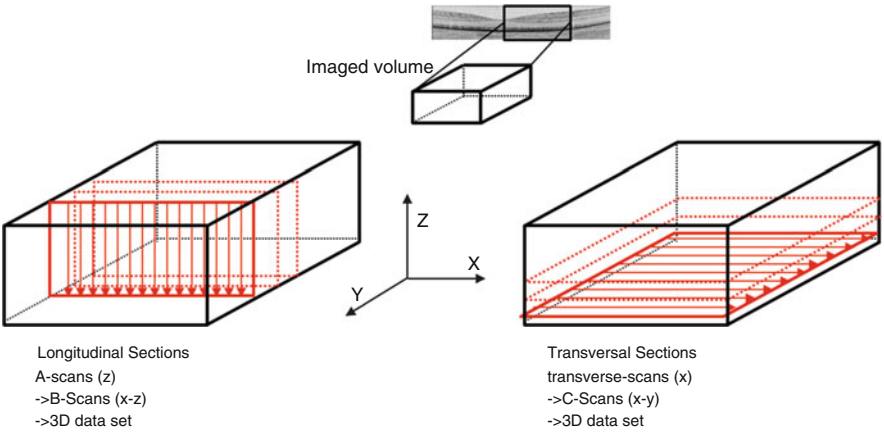

Fig. 62.2 Comparison of conventional longitudinal scan pattern (*left*) and transversal scan pattern (*right*)

62.4 Axial Eye Tracking and Transverse Motion Correction

Imaging the retina in vivo at high magnifications is challenging because of permanent eye motion. This motion will be present in all three dimensions. In FD-OCT axial eye motion is regarded as a minor problem because of the high axial imaging speed. Although axial motion is present in B-scans and in 3D volumes, these artifacts can largely be corrected in post-processing by, e.g., using correlation techniques between different B-scans. On the other hand, transverse motion artifacts can be a limiting factor. To overcome this, either hardware-based transverse eye tracking (2D) [18] has to be implemented or the transverse extension of the imaged volume has to be significantly reduced [19]. The scanning priority in TS-OCT is different; therefore, transverse eye motion can be corrected similar to high-resolution SLO systems in post-processing [20]. Axial eye motion, however, is a limiting factor for 3D measurements and has therefore to be corrected.

Our group introduced a concept for axial eye tracking that is based on an accurate measurement of the corneal apex position. The depth position of the cornea is then used to adapt accordingly the length of the reference arm of the TS-OCT instrument [21]. A sketch of an improved instrument is shown in Fig. 62.3 [22]. The system consists of several parts: the TS-OCT part, a separate FD low-coherence interferometer (LCI) for measuring the corneal apex position, and a part for changing very rapidly the length of the reference arm. The TS-OCT setup is similar to the scheme presented in Fig. 62.1. However, in order to improve the light efficiency within the instrument, additional polarization-sensitive components have been implemented. For details, refer to reference [22]. The LCI is based on a 90:10 fiber splitter and is operated at 1,300 nm with a bandwidth of 55 nm resulting in a depth resolution of ~14 μm. Only 10 % of the light is directed to the sample arm. Via a dichroic mirror, the sample beam is coupled into the sample

[22] by permission of the Optical Society of America)

beam of the TS instrument and is directed to the eye. A collimated beam incident on the cornea is used which is essential in order to minimize influences of transverse motion on the measured apex position [23]. Moreover, only the corneal reflex is detected (no internal structure), resulting in a single OCT signal. Even though the depth resolution of the LCI is moderate, the peak position of the OCT signal can be determined very accurately. Light that is backscattered from the cornea is brought to interference with the light from the reference arm and is detected with a spectrometer. The spectrometer consists of a reflective diffraction grating and an InGaAs line scan camera that can be operated with up to 7 kHz.

While the measurement of the corneal position can be done very fast, the corresponding adaption of the reference arm length can be a limiting factor because of the inertia of the optical components. Even if a high-speed translation stage is used, residual axial eye motion remains [21]. In order to improve the adaption speed, we implemented a technology that is well known from the pre-FD-OCT area: the rapid scanning optical delay line (RSOD) [24]. The RSOD which is placed into the reference arm of the TS-OCT interferometer (c.f. Fig. 62.3) consists of a diffraction grating, a lens, and a galvanometer scanner. The pivot point of the

scanner is adjusted in order to change the group delay only (no additional phase delay is introduced). The improved axial eye motion correction speed ensures that residual correction errors are well below the depth resolution of the system. The tracking system is based on measurement of the corneal position. Hence, it cannot distinguish between axial eye motion and axial eye length changes caused by, e.g., fundus pulsation. However, these length changes are in the order of a few microns [25] and can therefore be neglected.

Using the information from the SLO channel, transverse motion correction can be done in post-processing similar to SLO instruments. For this purpose the cross correlation between each recorded SLO frame with a reference frame (chosen by the user) is calculated, and the frame is shifted according to the displacement from the position of the reference frame. All frames are averaged to produce a new reference frame that should be free of in-frame distortions (provided that the number of averaged frames is sufficiently large). The previous step is repeated using this new reference frame and applying the transformation matrix to the OCT images. Together with axial eye tracking, this procedure allows the recording of 3D volumes of the retina with negligible eye motion artifacts [22]. While the abovementioned procedure is sufficient for imaging without AO assistance, the implementation of AO requires an additional step. In a final step, each frame is divided into several subframes consisting of a certain number of transverse lines. The cross correlation is then performed between each subframe and a reference frame resulting in an improved transverse motion correction, because this procedure partly compensates for in-frame distortions [20].

62.5 High-Resolution Imaging of the Human Retina

It is known from histology that the photoreceptors in the human eye (rods and cones) are arranged in a very regular way resulting in a mosaic pattern [26]. In the fovea, the spot of best vision (in the healthy eye), the cone density and the regularity are highest. The density decreases exponentially with increasing eccentricity from the fovea. While there are no rods present in the fovea, the rod density reaches a maximum at around 12–20° eccentricity from the fovea.

One of the major challenges in retinal imaging using OCT in the past decade was the visualization of the cone mosaic. Using other imaging technologies, it was demonstrated quite early that in healthy eyes with good optics, the correction of low-order aberrations (e.g., defocus and astigmatism) can be sufficient in order to resolve cones in the periphery of the fovea [27]. Unfortunately, the field of view of these initial instruments was limited to a very small patch on the retina. An augmentation of cone visualization capabilities and extending the field of view were achieved with the introduction of adaptive optics (AO) [28–35]. AO corrects a variety of aberrations even of higher orders. Hence, the cone mosaic could be successfully imaged using AO-equipped imaging technologies as flood illumination fundus cameras [36] and SLO [37]. However, the depth resolution of these imaging techniques is rather limited and prevents the visualization of different

interfaces of cone photoreceptors. OCT provides the necessary depth resolution, but its transversal resolution in the retina is commonly restricted by low NA to ~20 μm which is not sufficient to resolve individual cones. The low NA is a compromise between transverse resolution and depth of focus, thus maintaining the transverse resolution over the entire imaging depth (i.e., the retinal thickness).

The first attempt to improve the transverse resolution by combining adaptive optics with OCT has been made in 2003 by the group of D. T. Miller at Indiana University [38]. The approach used full field OCT but faced sensitivity issues when applied in vivo. Later work used AO in an A-scan-based OCT system; however, visualization of individual cones could not be demonstrated with these initial setups [39, 40]. It took another year until transversal structures of a spacing similar to that of photoreceptors could be shown in OCT B-scans using AO-OCT by two different groups [41, 42]. However, both instruments had rather slow 3D imaging capabilities, preventing motion artifact-free 2D imaging of the cone mosaic in the en face imaging plane.

Our group picked up the initial abovementioned idea of cone imaging without using AO assistance. Because TS-OCT has the same scanning protocol as SLO, this technique is ideally suited for recording (nearly) motion artifact-free en face images of the retinal structure. We used the setup shown in Fig. 62.1 for this purpose and demonstrated cone mosaic imaging (in the en face plane) with OCT for the first time [13].

The system employed a moderately wide sampling beam of ~4 mm diameter, enabling transverse resolutions sufficient to resolve the somewhat wider cone spacing at the periphery of the fovea but small enough to avoid excessive ocular aberrations and therefore (in the healthy eye) the necessity of adaptive optics. In addition the standard detection configuration in OCT is already confocal because it is based on using single-mode fibers [43]. The additional confocal SLO detector (also single-mode fiber coupled) operates in parallel to the OCT channel and provides an essential tool for correct subject and focus alignment. After the implementation of faster camera technology or fast swept source OCT technology, the simple concept of moderate sample beam diameter (and confocal arrangement) for cone photoreceptor imaging has been successfully translated to FD-OCT instruments [44–46].

Axial motion artifacts, however, limited the performance of our initial instrument to 2-dimensional imaging (B-scans or C-scans). Full 3D imaging capability was achieved by the implementation of an axial eye tracker [21, 22]. Figure 62.4 shows example images recorded in a healthy subject with a TS-OCT instrument that is equipped with an axial tracker. Figure 62.4a shows a B-scan retrieved from 3D data which demonstrates the capabilities of the axial tracker and the dynamic focus. The images were recorded at ~4° eccentricity from the fovea and cover a volume of 1° (x) × 1° (y) × 500 μm (z). Note that despite the high transverse resolution, the entire depth is imaged sharply which could up to now not be achieved in the retina using FD-OCT. Similar to standard OCT, four distinct posterior layers can be observed. However, there is still some controversy on the labeling of these layers. We strongly favor the following association and provide different evidences for this labeling later on: (1) external limiting membrane (ELM), (2) boundary between inner

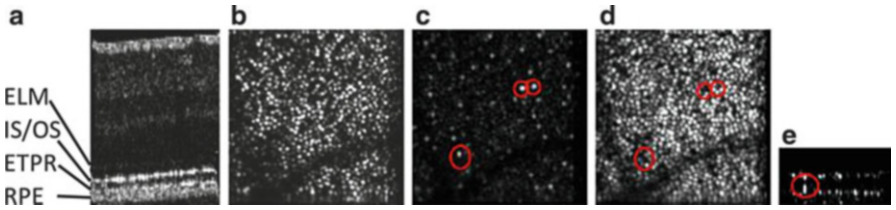

Fig. 62.4 TS-OCT images retrieved from a 3D volume. [22] by permission of the Optical Society of America)

and outer segments of photoreceptors (IS/OS), (3) end tips of photoreceptors (ETPR), and (4) retinal pigment epithelium (RPE). As can be observed in Fig. 62.4b, d, two layers, the IS/OS and ETPR, show a similar cone mosaic pattern as is known from SLO imaging. The appearance in both layers can be explained by the wave guiding properties of the cones [47]. The outermost layer does not show the cone mosaic and appears in general more diffuse than the previous two layers. Using polarization-sensitive OCT, a polarization scrambling was observed from this layer [8, 48, 49]. Data from patients and in vitro measurements showed that melanin is one cause for the polarization scrambling and that the layer can hence be associated with the RPE [50–52].

Interestingly, as is shown in Fig. 62.4c, e, bright reflecting spots (BRSs) within the outer segments of the cones can be observed at some transverse locations. Defects within the cone outer segments could be one possible explanation for these signals. Using a Fourier analysis of the cone mosaic yields Yellott's rings [53], and the radius of each ring is a direct measure of the row to row spacing of the cones. This spacing can be translated into cone density. Figure 62.5a shows the cone density measured at different eccentricities from the fovea for five subjects. The measured densities are in good agreement with values known from histology and show that for four out of five healthy subjects, the cone mosaic could be resolved down to $\sim 2^\circ$ eccentricity from the fovea without the use of adaptive optics. In addition we measured the density of the BRS which shows some kind of maximum at 3–4° eccentricity from the fovea (c.f. Fig. 62.5b).

62.6 Temporal Changes of Human Cone Photoreceptors

The outer segments of cone photoreceptors contain the photopigment and are built up by a stack of densely packed membrane discs. In order to prevent photochemical damage, these outer segment discs are renewed with time [54, 55]. New discs are generated at the IS/OS junction, while at the location of the ETPR, the outermost of these discs is shed followed by phagocytosis of this tissue by the retinal pigment epithelium [56]. The growth rate of the outer segments is known

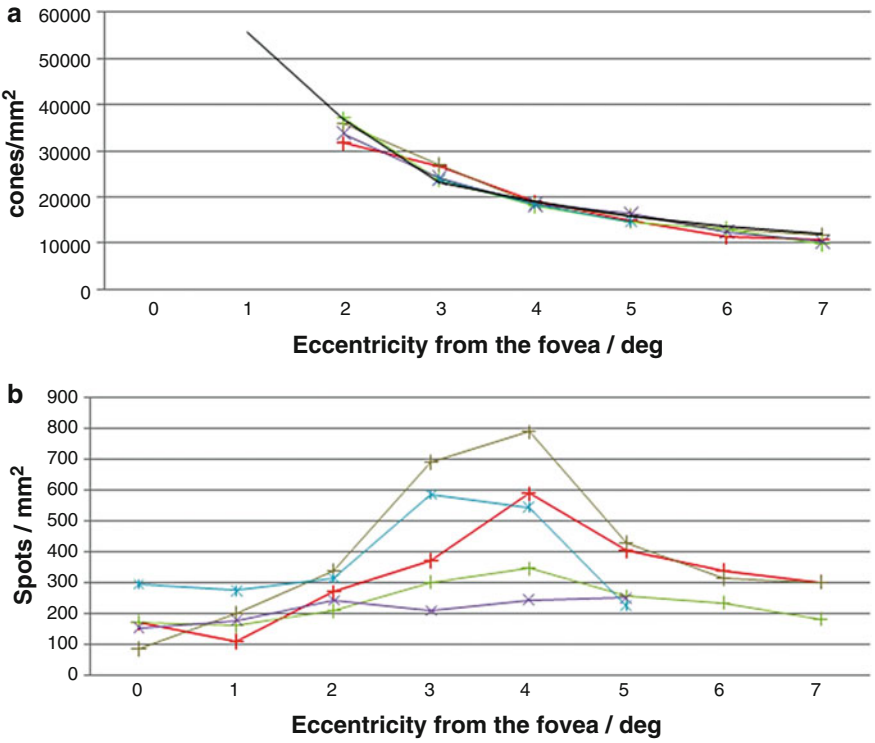

Fig. 62.5 (**a**) Measured cone density of five volunteers at different eccentricities from the fovea (*black line*: data from Ref [26]). (**b**) Measured bright reflections (*BR*) within the cone outer segments at different eccentricities (each color corresponds to a different subject) (Reproduced from Pircher et al. [22] by permission of the Optical Society of America)

from animal experiments and lies in the order of ~100 nm per hour [57, 58]. An investigation of these changes in vivo in humans is quite challenging. Recently, a first approach used a fundus camera equipped with adaptive optics to measure indirectly changes caused by cone renewal [59]. The retina was illuminated with a temporally coherent light source. This leads to interference effects between the signals arising from different depths (e.g., IS/OS and ETPR). Depending on the axial distance between the interfaces, constructive or destructive interference will occur, leading to intensity changes in the observed backscattered light from each cone if the distance between the reflection sites varies with time. With the generation of new discs, the length of the outer segment is changing leading to sinusoidal intensity fluctuations with time (several hours). Note that these length changes are much smaller than 1 μm and can therefore not be observed with standard OCT within a few hours.

TS-OCT has the capability to record high-resolution 3D volumes without noticeable motion artifacts. Hence, the observation of exactly the same location on the retina over time becomes possible. In order to investigate temporal changes

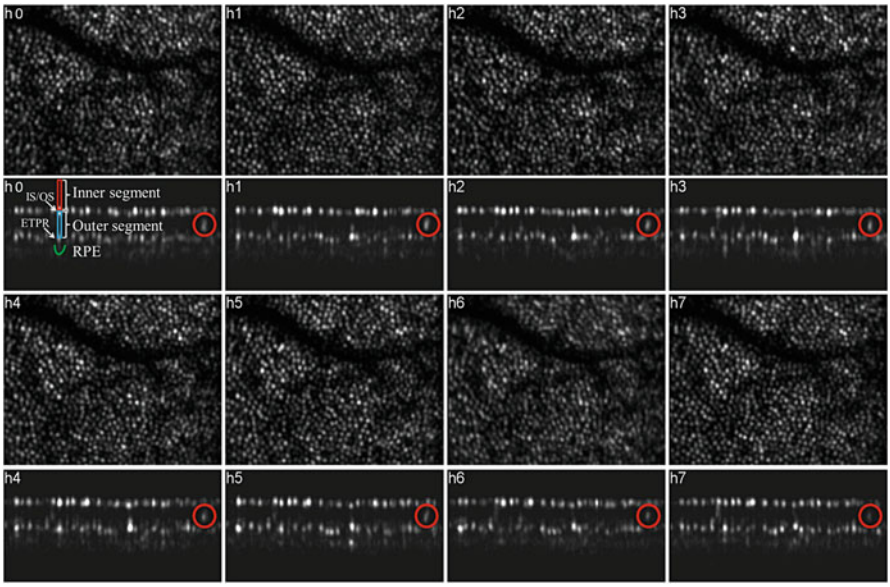

Fig. 62.6 Depth-integrated OCT images (∼0.94° × 0.7°) and representative B-scan images (0.94° × 120 μm) of the cone mosaic recorded over a period of 7 h at the same position. The number in the *upper left* corner indicates the measurement time. *Red circles* mark a bright reflection spot (*BRS*) within the outer segments of the cones. The images demonstrate exact relocation and stability over extended times

caused by the renewal process, we performed measurements over different periods of time [60]. The first period lasted 7 h with ten 3D measurements every hour, while the second period lasted 96 h performing ten 3D measurements every 24 h. Out of the ten measurements at each time point, a minimum of five measurements were averaged in order to minimize influences of subject alignment. Figure 62.6 shows en face images of the cone mosaic recorded within the first measurement period at ∼4° eccentricity as well as an exemplary B-scan at the same location [60]. As can be observed from the images, the residual registration error between the 3D data sets is smaller than the extension of a single cone. In the en face images, intensity fluctuations of individual cones can be observed. The B-scans reveal that both interfaces, the IS/OS junction and the ETPR, show these fluctuations. The depth position of the two layers remains rather constant (i.e., smaller than the detection limit of the system) for each individual cone within 7 h. In addition, the depth position of a BRS (marked with a red circle in Fig. 62.6) stays at the same location. The expected length change by new disc generation for this time period is smaller than 1 μm and hence not detectable with our system. These small changes can only be detected using the phase information of an OCT signal as was recently demonstrated by R. S. Jonnal et al. [61]. The origin of the observed intensity fluctuations is unclear. These cannot be explained by an

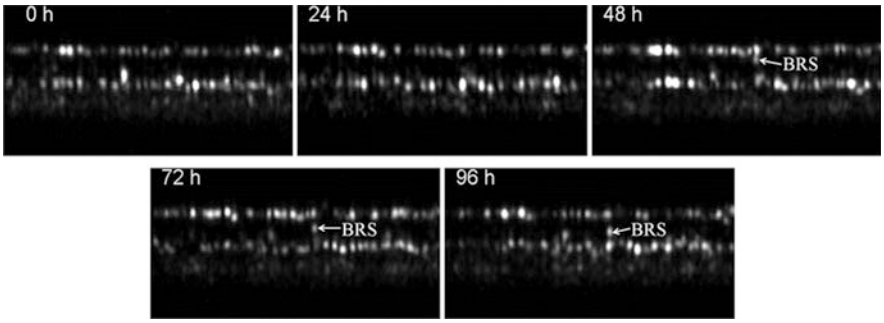

Fig. 62.7 Representative B-scan recorded at the same location over the entire measurement period of 96 h (the number in the *upper left* corner indicates the measurement time) containing a BRS that appears at hour 48. Image extension, ~0.88° × 120 μm^2; retinal eccentricity, ~4° nasal from the fovea) (Reproduced from Pircher et al. [60] by permission of the Optical Society of America)

interference phenomenon as mentioned above observed by the flood illumination system because the TS-OCT instrument uses a low-coherence light source with a coherence length of only ~4 μm in tissue, much smaller than the outer segment length. However, we do believe that the changes may be caused by the generation of new discs at the IS/OS interface.

In order to detect potential length changes with our system, the observation period has to be extended. Figure 62.7 shows exemplary B-scans recorded at the same location within the second measurement period (i.e., 96 h). The intensity fluctuations at the IS/OS and ETPR are more pronounced than in the previous measurement period. In addition changes of the depth position of the ETPR can be observed while the depth position of the IS/OS junction stays constant. These changes are likely caused by the disc shedding process. Depending on the phase within the shedding process, the outer segment length will be shorter (after disc shedding) or longer (right before disc shedding) which is one possible explanation for our observation. Most interestingly, at hour 48, one of the abovementioned BRSs appears shortly below the IS/OS junction and apparently moves in the successive frames toward the ETPR layer. We measured for two healthy volunteers the motion speed of all BRSs and found an average speed of ~110 nm per hour which quite matches the cone renewal speed that is expected from animal experiments and which was measured with other methods [59, 61]. One hypothesis to explain our observation is the following: Cracks or defects in the packing arrangement of the cone outer segment discs give rise to a change in the refractive index and therefore to a strong OCT signal that we observe as BRS. With the generation of new discs at the IS/OS junction, the defect moves together with the surrounding discs slowly toward the ETPR until the discs are finally shed by the RPE. However, in order to support this hypothesis, more measurements are needed.

62.7 Adaptive Optics TS-OCT

Although cone photoreceptors could be resolved with the abovementioned instrument, the visualization is limited to subjects with good eye optics and to eccentricities from the fovea that are larger than ~2°. In order to visualize foveal cones or even rod photoreceptors as was demonstrated recently with AO-SLO instruments [62–64], a further increase of transverse resolution is necessary. This, however, can only be achieved with the implementation of adaptive optics. First, AO-equipped TS-OCT instruments have been presented several years ago [65, 66]. However, both instruments did not incorporate an axial eye tracker which greatly limited their performance. Nevertheless, the cone density from both layers (IS/OS and ETPR) could be measured at different eccentricities from the fovea starting with an eccentricity as close as 0.7° [66].

Based on our experiences with AO-SLO and TS-OCT, we very recently presented the first results obtained with the combination of these two techniques [67]. The sample arm is based on an AO-SLO instrument that uses lenses instead of mirrors for imaging [64]. Figure 62.8 shows en face images of the fovea recorded with the new instrument. Individual foveal cones can be resolved with both imaging modalities which have, up to now, not been demonstrated using OCT. The representative B-scan (Fig. 62.8c) is located at the fovea centralis and shows the elevation of the IS/OS junction due to the longer outer segments' length at this location. Note that the transverse extension is greatly enlarged in comparison to standard OCT images which results in a less pronounced appearance of the elevation. Both layers (IS/OS and ETPR) show the cone mosaic (images not shown here) and therefore the typical discrete spacing of the photoreceptors within the B-scan (as has previously been shown at some eccentricity from the fovea). As is known from standard OCT imaging, the depth separation between ETPR and RPE is less pronounced in this area than at larger eccentricities. Nevertheless, the discrete spacing that appears only within the ETPR and not the RPE allows a differentiation between the two layers in Fig. 62.8c. Although the ELM is visible in Fig. 62.8c, the signal intensity is too weak in order to determine if a similar cone mosaic can be observed from this layer.

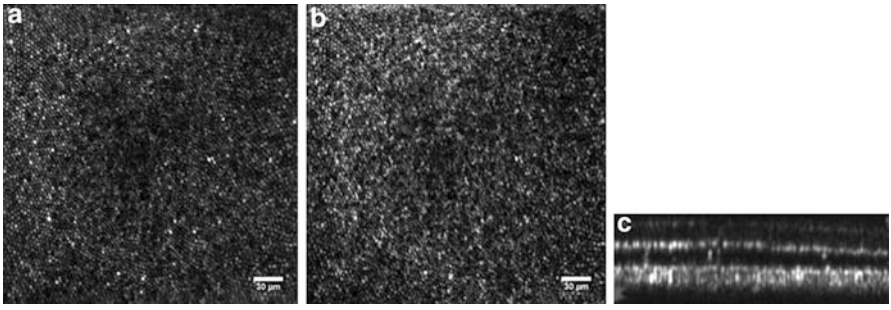

Fig. 62.8 AO-TS-OCT images of foveal cones. (**a**) SLO channel, (**b**) depth-integrated OCT channel (**c**) representative B-scan through the central fovea

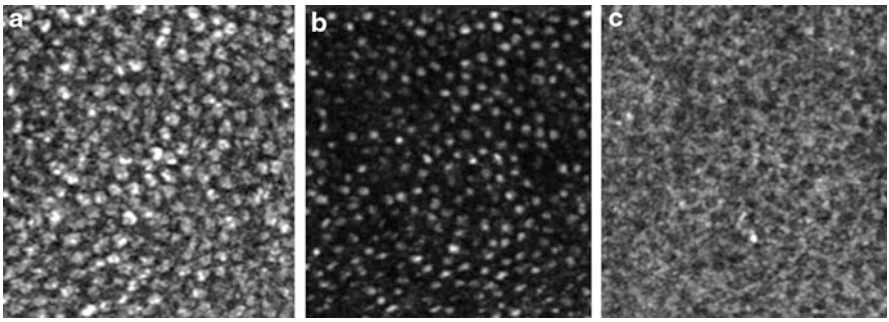

Fig. 62.9 AO-TS-OCT en face images of the cone and rod mosaic. (**a**) IS/OS junction, (**b**) ETPR, (**c**) end tips of rod photoreceptors

At larger eccentricities from the fovea, we expect to observe cones and rods. It is known from histology that the outer segments of rods are slightly longer than that of cones. Although individual rods could be visualized using AO-SLO, the depth resolution of these instruments is insufficient to separate the different interfaces of the outer segments. On the other hand, high-resolution OCT showed the appearance of an additional layer at larger eccentricities from the fovea that was associated with the posterior tips of rods (even though the transverse resolution did not allow for the visualization of individual rods) [68]. We used our AO-TS-OCT instrument to investigate this area with high resolution in all three dimensions. Figure 62.9 shows en face images retrieved at different imaging depths recorded at $\sim 7^{\circ}$ eccentricity from the fovea. Figure 62.9a corresponds to the IS/OS junction. At this layer a signal from both photoreceptor types (cones and rods) is expected. Therefore, we can observe high reflective spots of larger width corresponding to the cones that are surrounded by very small spots corresponding to individual rods. However, the large spots appear somehow speckled, i.e., appear to consist of smaller structures. A similar appearance has been observed with AO-SLO [63]. If we go deeper into the tissue to the location of the ETPR layer (c.f. Fig. 62.9b), we observe only the cone mosaic. Note that within this layer, the individual cones do not show the abovementioned speckled appearance. The measured spacing of the cones corresponds to the expected cone density at this eccentricity. When setting the coherence gate further into the tissue (at the location of the end tips of the rods), a completely different pattern is observed (c.f. Fig. 62.9c). At the locations of the cones, dark patches can be observed that are surrounded by smaller structures which correspond to individual rods.

62.8 Conclusion and Outlook

Although FD-OCT is well suited for a huge variety of different applications, TS-OCT can be beneficial for some niche applications as high-resolution retinal imaging. With the development of even faster FD-OCT setups operating at A-scan

rates in the MHz range, the benefit of greatly reduced transverse motion artifacts could be alleviated (at least for a large field of view [69]). However, these systems provide less sensitivity than standard OCT systems, and for an entirely sharp 3D data set, several recorded volumes have to be stitched together. Moreover, current systems are operated in the 1,050-nm regime which reduces the achievable transverse resolution and probably makes the implementation of AO more complex.

The combination of TS-OCT with AO requires some experimental effort (especially with the implementation of the axial eye tracker), but initial results are quite promising. The implementation of AO correction alleviates the limitation of the previous instrument (only healthy volunteers with good eye optics could be imaged) and enlarges the number of measurable subjects. Nevertheless, the next step must be to investigate the applicability of this technology for patient imaging.

63.1 Introduction

Developing and validating new techniques and methods for small animal imaging is an important research area because there are many small animal models of retinal diseases such as diabetic retinopathy, age-related macular degeneration, and glaucoma [1–6]. Because the retina is a multilayered structure with distinct abnormalities occurring in different intraretinal layers at different stages of disease progression, there is a need for imaging techniques that enable visualization of these layers individually at different time points. Although postmortem histology and ultrastructural analysis can be performed for investigating microscopic changes in the retina in small animal models, this requires sacrificing animals, which makes repeated assessment of the same animal at different time points impossible and increases the number of animals required. Furthermore, some retinal processes such as neurovascular coupling cannot be fully characterized postmortem.

Optical coherence tomography (OCT) for small animal ophthalmic imaging is highly attractive for multiple reasons. OCT has the key advantage that it is noninvasive, so that imaging can be performed repeatedly in the same animals

over time. This can facilitate accurate assessment of longitudinal changes by reducing the effects of biological variability and promises to improve the efficiency of fundamental studies of disease mechanisms or pharmaceutical development. Furthermore, recent advances in OCT technology and new OCT techniques will enable integrated ultrahigh-resolution structural and functional imaging of the retina. In addition, small animal OCT studies can also be an important translational step for developing and validating new technology and methods prior to clinical implementation.

The initial development of ophthalmic OCT imaging techniques in animal models was largely driven by investigation of laser-induced retinal injury in the rabbit and rhesus monkey models in the late 1990s [7–9]. Although there are many other animal models including the ones used for the above experiments, this chapter focuses on murine retinal imaging since it is one of the more widely used species, due to the ease of handling, low cost for maintenance, and availability of transgenic strains. OCT imaging of the murine retina was first demonstrated in mice using time domain OCT in 2001 [10]. Since then, multiple studies investigating rat and mouse models of retinal diseases have been reported using commercial as well as prototype spectral domain OCT systems [11–15]. Readers are advised to search the literature independently for applications of OCT on small animal models of retinal diseases, since there are a large number of studies and this is outside of the scope of this chapter. This chapter focuses on in vivo murine ophthalmic imaging using advanced OCT technology and new OCT techniques. Small animal imaging interface designs will be also discussed, since the human and murine eye sizes are considerably different, which necessitates a different optical scanning design. An overview of structural and functional ophthalmic OCT imaging techniques in small animal models will also be provided.

63.2 Small Animal Imaging Interface

Small animal ophthalmic imaging was historically considered challenging due to the small eye size. However, with a proper imaging interface, imaging can still be performed reliably. Two different types of imaging interfaces have been widely used for small animal imaging.

One approach is to use a telecentric scanning configuration with a thin glass cover slip gently put on the cornea to suppress corneal refraction [16]. Compared to human eyes, in small animals the dilated pupil diameter relative to the size of the eye globe is large. Therefore, a relatively large area on the retina can be scanned using this approach. Eye drops such as hydroxypropyl methylcellulose can be used for corneal hydration as well as maintaining good contact between the cover slip and cornea.

The main advantage of this approach is that the optical design for the imaging interface can be relatively simple since it does not require detailed knowledge about the optics of the murine eye. Commercial microscope objectives can be used to obtain a high transverse resolution <10 μm in air. This scanning configuration can

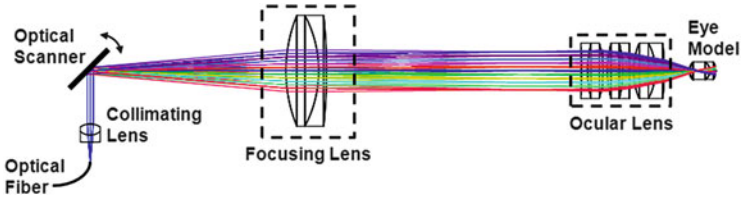

Fig. 63.1 A noncontact, small animal OCT imaging interface with the scan pivot located at the pupil of the murine eye. The imaging interface uses multiple achromatic lenses and a rat eye model based on reference [19]. The collimated beam after the ocular lens is focused on the retina by the optics in the rat eye. For a $1/e^2$ beam diameter of 1.4 mm at the cornea, a spot size of ~15 μm on the retina can be obtained, ignoring aberration from the rat eye. The optical layout was originally generated in the ray-tracing software Zemax and modified

be used for anterior eye as well as whole eye imaging, in which case the cover slip is no longer necessary. However, this approach has several drawbacks for retinal imaging. First, intraocular pressure can be increased due to the extra pressure applied by the cover slip. This can potentially affect ocular hemodynamics as well as the retinal contour for structural imaging. Second, the field of view is limited by the pupil diameter due to the telecentric scanning. The fully dilated pupil diameter is typically ~3 mm in the rat and ~2 mm in the mouse [17, 18]. Residual refraction from the small animal lens and cornea makes the field of view even smaller than the pupil diameter. Although it is possible to move the field of view to a different region on the retina, this typically requires multiple iterations of alignment including readjusting the cover slip, which could be relatively time-consuming.

Another approach is to use a scanning configuration with the scan pivot position located at the pupil as shown in Fig. 63.1, similar to a human retinal imaging interface. In this configuration, the optical beam remains collimated after the ocular lens and is focused on the retina by the optics of the murine eye. Therefore, it is critical to use a correct eye model to achieve optimal performance. Multiple paraxial eye models with radii of curvature, thicknesses, and indices of refraction of different components in the murine eye are available in the literature [17–19], which can be used in a ray-tracing software to simulate and design a small animal imaging interface. Figure 63.1 shows an example of a pivoted scanning imaging interface, using a rat eye model based on reference [19]. According to this eye model, a spot size of ~15 μm on the retina can be obtained for a $1/e^2$ beam diameter of 1.4 mm at the cornea, ignoring aberration from the rat eye. A similar performance can also be expected in the mouse eye.

This pivoted scanning configuration has several advantages. First, there is little to no risk of increasing intraocular pressure since there is no cover slip contact to the cornea required. Second, the scanned area on the retina can be more accurately calibrated using an ideal eye model, which is challenging with telecentric scanning due to the unknown pressure applied by the cover slip on the eye. Third, the field of view is limited by the ocular lens diameter as opposed to the pupil in this case, and it

is possible to move the field of view to the region of interest simply by adjusting the orientation of the murine eye with respect to the optical axis of the imaging interface. However, these optical designs can be more demanding, and different imaging interfaces are required for imaging different animal species due to the structural differences in the eyes.

63.3 Structural Imaging

Although the murine retina is thinner than the human retina, all major retinal layers observed in the human retina can also be found in the murine retina. For small animal imaging, the optic nerve head can be used as a landmark for alignment and imaging since the murine retina does not have a macula.

63.3.1 Ultrahigh-Resolution Retinal Imaging

Ultrahigh-resolution retinal OCT imaging in animals was first demonstrated in pig and monkey eyes ex vivo in 2003 and 2004 using time domain detection techniques in order to establish a comparison of OCT image features with histological findings [20, 21]. In vivo spectral domain ultrahigh-resolution OCT imaging in the murine retina was demonstrated in 2006 [16, 22]. Ultrahigh-resolution OCT imaging in vivo is challenging because any dispersion mismatch between the sample and reference arms results in a broadening of the axial point spread function. Spectral domain OCT has an advantage that the dispersion mismatch can be numerically compensated by using readily accessible phase information in the spectral OCT signal [23, 24], thereby facilitating ultrahigh-resolution retinal imaging.

Figure 63.2 shows a comparison of a representative histology and ultrahigh-resolution OCT image in a Long-Evans rat [16]. The ultrahigh-resolution system had a bandwidth of 145 nm centered at 890 nm, resulting in an axial resolution of ~2.8 μm in tissue. The transverse resolution was ~10 μm in air. The imaging speed was 24,000 A-scans per second. Histology was performed in a sex- and age-matched animal to obtain 7-μm-thick paraffin sections registered to the optic disc. All major retinal layers visible in the human retina can also be observed in the ultrahigh-resolution OCT image of the rat retina with an excellent correspondence to histology. However, a quantitative thickness comparison between histology and OCT images may result in errors since histology tends to generate processing artifacts [20]. The OCT image is displayed in grayscale with brighter pixels corresponding to higher backscattered intensity. Relative backscattered intensities of different intraretinal layers are similar to those observed in the human retina, with the highly backscattering retinal pigment epithelium and relatively less backscattering inner and outer nuclear layers as shown in Fig. 63.2b. It should be noted that the ganglion cell layer cannot be clearly visualized in the OCT image due to speckle and the extremely thin ganglion cell layer thickness in the rat retina.

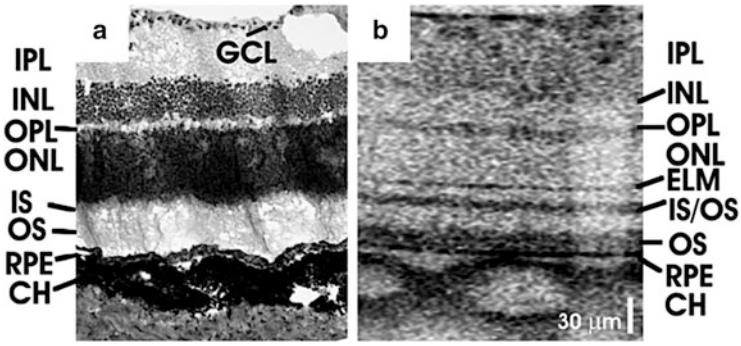

Fig. 63.2 A comparison of a (**a**) representative histology and (**b**) ultrahigh-resolution OCT image in a Long-Evans rat retina near the optic nerve head. *GCL* ganglion cell layer, *IPL* inner plexiform layer, *INL* inner nuclear layer, *OPL* outer plexiform layer, *ONL* outer nuclear layer, *IS* photoreceptor inner segment, *OS* photoreceptor outer segment, *RPE* retinal pigment epithelium, *CH* choroid, *ELM* external limiting membrane, *IS*/*OS* photoreceptor inner and outer segment junction. Scale bar: 30 μm (Image reproduced from Srinivasan et al. [16])

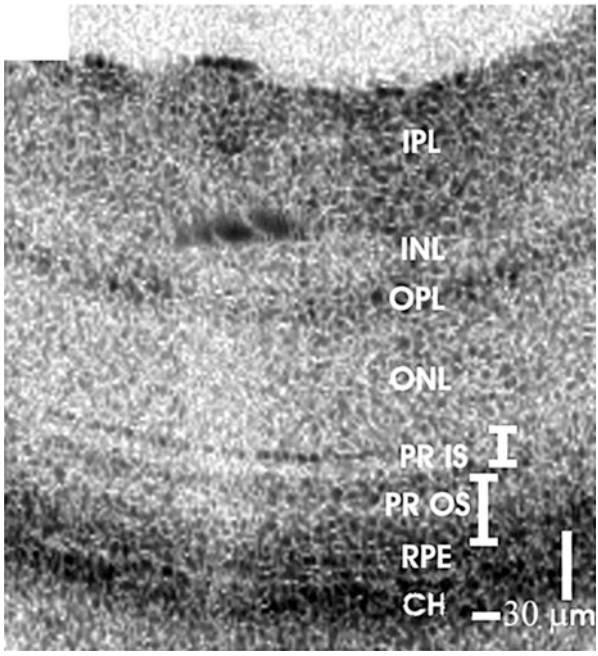

Fig. 63.3 A representative ultrahigh-resolution OCT image from a normal C57BL6 mouse. *IPL* inner plexiform layer, *INL* inner nuclear layer, *OPL* outer plexiform layer, *ONL* outer nuclear layer, *PR IS* photoreceptor inner segment, *PR OS* photoreceptor outer segment, *RPE* retinal pigment epithelium, *CH* choroid (Image reproduced from Srinivasan et al. [16])

Figure 63.3 shows a representative ultrahigh-resolution OCT image from a normal C57BL6 mouse acquired with the same ultrahigh-resolution OCT system [16]. All major intraretinal layers except the ganglion cell layer can be clearly visualized in the mouse retina with ultrahigh-resolution OCT.

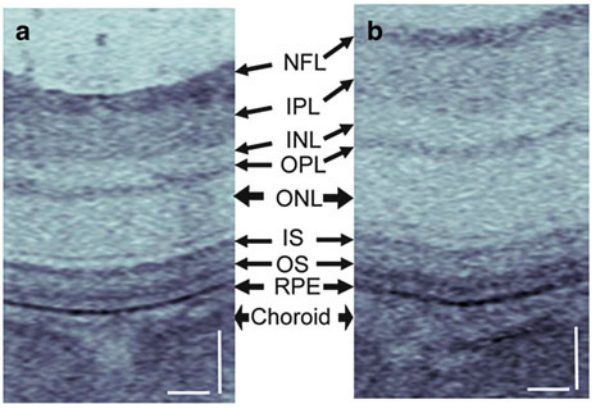

Fig. 63.4 Ultrahigh-resolution OCT can visualize changes in intraretinal layer thickness produced by intravitreal injection of (**a**) saline vehicle control versus (**b**) carbonic anhydrase-I in streptozotocin-induced diabetic rats. Scale bar: 50 μm (Image reproduced from Gao et al. [11])

Figure 63.4 shows an example application of ultrahigh-resolution OCT technology in a rat model of retinal disease using the same OCT system as in Figs. 63.2 and 63.3 [11]. Using ultrahigh-resolution OCT, it was possible to observe retinal edema produced by intravitreal injection of carbonic anhydrase-I, an intracellular enzyme identified in the proliferative diabetic retinopathy vitreous proteome, in a streptozotocin-induced diabetic rat model. The identification of structural changes in early disease or processes such as vascular permeability changes is important because these can serve as surrogate markers for investigating the molecular pathways of disease for the development of new pharmaceuticals.

In addition to increasing the axial resolution using ultrahigh-resolution OCT, it is also possible to increase the transverse resolution in small animal retinal imaging using adaptive optics. Since the numerical aperture available in the murine eye is larger than that in the human eye, the maximum theoretically achievable transverse resolution on the retina with adaptive optics is higher in small animals than in humans [25, 26]. Therefore, combining ultrahigh-resolution OCT and adaptive optics would enable ultrahigh-resolution imaging of the small animal retina in all three dimensions. However, visualization of tissue at the cellular level not only requires ultrahigh axial and transverse resolutions but also high enough contrast between different subcellular organelles, which in histology is provided by difference in staining properties. Although current ultrahigh-resolution OCT technology does not yet enable cellular level visualization, it is still possible to detect morphologic alternations in the intraretinal structure due to retinal diseases, which is a powerful advantage over histology.

63.3.2 Ultrahigh-Speed Retinal Imaging

Ultrahigh-resolution spectral domain OCT system design is more challenging than standard resolution system design because of the broader bandwidth required for

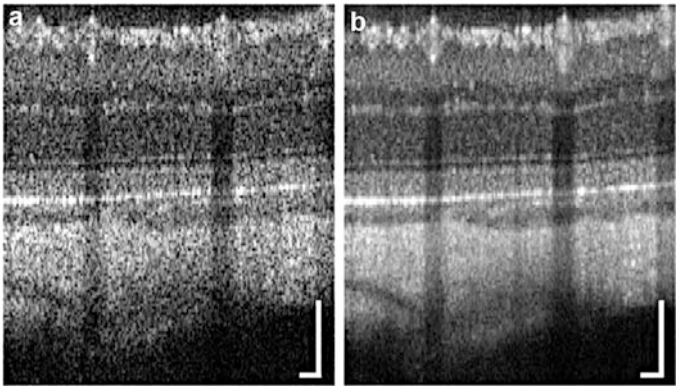

Fig. 63.5 Ultrahigh-speed OCT images extracted from a volumetric data set (**a**) before averaging and (**b**) after averaging six neighboring OCT B-scans. The volumetric data set consisting of 700 × 700 A-scans was acquired from a 1.5 × 1.5-mm^2 area centered at the optic nerve head in a Sprague Dawley rat. The effect of averaging can be clearly seen in terms of speckle reduction and increase in signal-to-noise ratio, which greatly enhances visualization of intraretinal layers. Scale bar: 100 μm

ultrahigh axial resolution. Therefore, many commercial OCT systems currently offer axial resolutions of 5–7 μm in tissue. Recent advances in CCD and CMOS camera technology enabled ultrahigh-speed spectral domain OCT with an imaging speed >200 kHz A-scan rate with a system complexity comparable to commercial spectral OCT systems at slower imaging speeds [27]. While ultrahigh-resolution OCT provides a higher axial resolution and inherently smaller speckle size, ultrahigh-speed imaging enables spatial compounding and image averaging methods to enhance visualization of intraretinal layers in small animals by reducing the effects of speckle.

Figure 63.5 shows OCT images from a normal Sprague Dawley rat. The ultrahigh-speed spectral domain OCT system had an imaging speed of 244,000 A scans per second. The bandwidth of the light source was ∼55 nm centered at 840 nm, yielding an axial resolution of 5.7 μm in tissue. The theoretical spot size on the retina using a standard rat eye model was ∼15 μm. While Fig. 63.5a shows a single OCT B-scan consisting of 700 A-scans, Fig. 63.5b shows an average of six neighboring B-scans uniformly distributed in a thin strip ∼13-μm thick. Note that speckle is dramatically suppressed by averaging multiple neighboring B-scans due to spatial compounding. This comes at the cost of slight reduction in the effective transverse resolution, but enhancement in image quality due to speckle suppression and increased signal-to-noise ratio outweighs the trade-off for most applications. Because Sprague Dawley rats have significantly less pigment in the retinal pigment epithelium and choroid than in Long-Evans rats, OCT images of the Sprague Dawley retina can visualize down to the sclera, which can be useful for applications where choroidal or scleral abnormalities are expected.

It should be noted that ultrahigh resolution and ultrahigh speed are not fundamentally incompatible in spectral domain and swept source OCT. With advances in OCT technology, it will be possible to achieve ultrahigh imaging speeds and ultrahigh axial resolutions simultaneously, thereby combining the advantages of the two techniques in a single OCT system.

63.3.3 Long Wavelength Imaging

In human retinal imaging, absorption of light by water in the anterior eye and vitreous limits the usable wavelength range. Therefore, human retinal OCT imaging typically uses near-infrared (NIR) wavelengths shorter than 900 nm or around 1,060 nm, where absorption of light is negligible or within a transmission window [28]. Unlike wavelengths shorter than 900 nm where ultrahigh-resolution retinal imaging with a broadband NIR light source is feasible, wavelengths around 1,060 nm are at a local minimum in water absorption which has a relatively narrow bandwidth [29], which makes achieving an axial resolution <5 μm in the human retina challenging regardless of the light source bandwidth. In addition human retinal OCT imaging at wavelengths $>1{,}150$ nm is impossible since almost all light is absorbed by the anterior eye and vitreous.

The axial eye length is $\sim$6.1 mm in the rat and $\sim$3.3 mm in the mouse [17, 18], considerably shorter than the axial eye length of $\sim$24 mm in humans. According to the Beer-Lambert law, due to the shorter axial eye lengths, water absorption will be considerably less severe in the murine eye than in the human eye as shown in Fig. 63.6. This implies that retinal OCT imaging using longer wavelengths can be achieved in murine eyes. In both rat and mouse eyes, the water absorption window at $\sim$1,060 nm does not have the same bandwidth limiting effects as in the human eye, making ultrahigh-resolution retinal imaging feasible at these wavelengths in the murine eye. Furthermore, there is a significant transmission through the ocular media even at $\sim$1,300 nm wavelength. Multiple studies have investigated long wavelengths for retinal OCT imaging in the murine eye. The first demonstration of retinal imaging in the mouse eye using time domain OCT utilized wavelengths centered at $\sim$1,280 nm [10]. Spectral domain ultrahigh-resolution retinal imaging at $\sim$1,060 nm wavelengths with an axial resolution <3 μm was demonstrated in the rat eye [30]. Retinal imaging at $\sim$1,310 nm was demonstrated in the rat eye using spectral domain OCT [31].

Using longer wavelengths for small animal OCT imaging may have advantages in small animal models of ocular diseases that develop cataracts and/or other forms of ocular opacity such as vitreous hemorrhage or choroidal neovascularization. Longer wavelengths have reduced scattering, and better visualization of the retina and choroid has been demonstrated in human subjects and patients with cataracts [32, 33]. Ocular opacities caused by blood are also expected to affect the OCT image quality less at longer wavelengths [34].

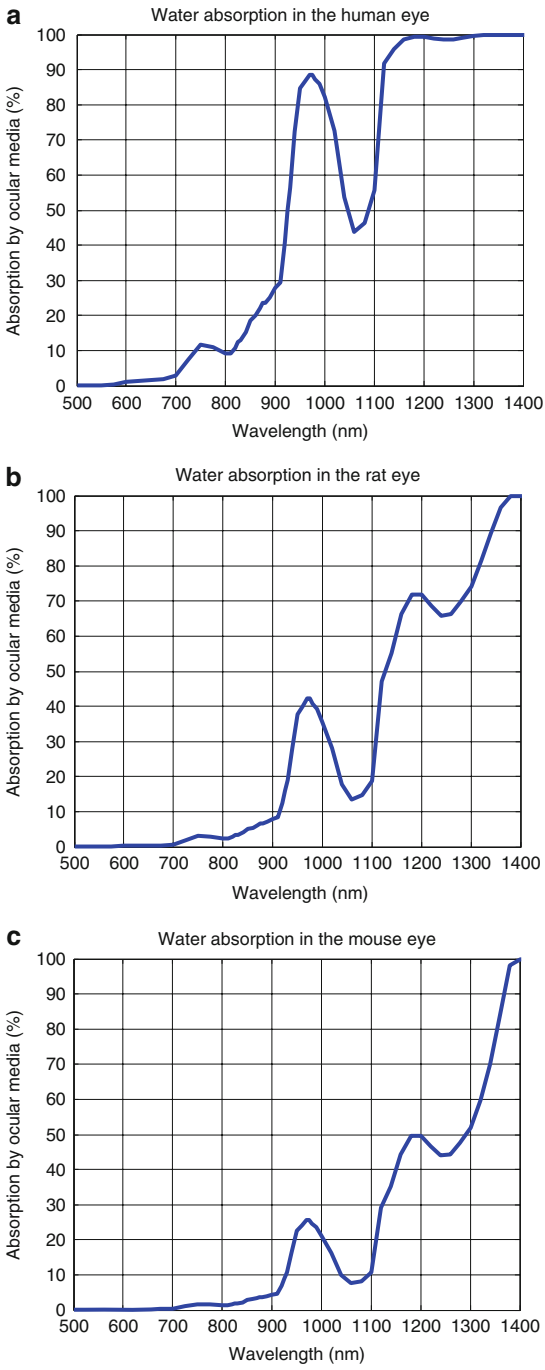

Fig. 63.6 Absorption of light by water as a function of wavelength in (**a**) the human eye, (**b**) the rat eye, and (**c**) the mouse eye. Axial eye lengths of 24, 6.1, and 3.3 mm were assumed for the human, rat, and mouse eyes, respectively. Water absorption coefficients were obtained from Ref. [28]

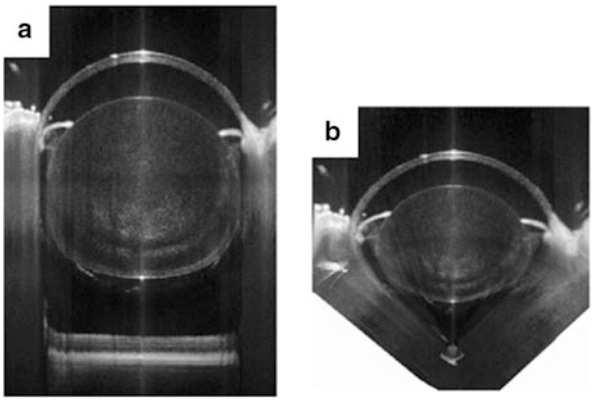

Fig. 63.7 An OCT image of a whole eye of a MF1 mouse (**a**) before refraction correction and (**b**) after refraction correction (Image reproduced from Wang et al. [37])

63.3.4 Whole Eye Imaging

Whole eye imaging using Fourier domain OCT is significantly easier in murine eyes than in human eyes due to the relatively short axial eye lengths in small animals. Although time domain OCT can also be used for whole eye imaging in small animals [35], Fourier domain OCT such as spectral domain or swept source OCT has the advantage that imaging can be performed orders of magnitude faster due to its inherently higher sensitivity. Faster imaging speeds at a given signal-to-noise ratio are advantageous since image averaging can be performed in order to reduce the effects of speckle and increase image quality. Because the numerical aperture of the imaging interface is limited for small animal whole eye imaging due to the relatively long depth of focus required, the signal-to-noise ratio tends to be relatively low for whole eye imaging. Therefore, higher quality images provided by image averaging is essential for better layer visualization and more accurate biometry. Multiple studies have demonstrated whole eye imaging in the mouse and rat eyes using swept source OCT [36–38].

An example of long wavelength ophthalmic OCT imaging in small animals is shown in Fig. 63.7 [37]. The images were acquired with a swept source OCT system using 1,060-nm wavelengths with an imaging speed of 28,000 A-scans per second. The imaging interface was using the telecentric scanning configuration. In order to achieve a sufficient imaging range, a full range OCT imaging algorithm was used, resulting in a total imaging range of 6 mm [39]. High-quality OCT images of mouse eyes were acquired by averaging 50 OCT B-scans with 512 A-scans each. It should be noted that with telecentric scanning, the effective transverse scan range on the retina is essentially limited to a single spot due to optical refraction from the anterior eye. This effect is clearly seen after refractive correction during post-processing as shown in Fig. 63.7b. Regardless, biometric parameters such as axial lengths and radii of curvature of the cornea, anterior chamber, lens, and vitreous can be extracted using whole eye OCT imaging.

63.4 Functional Imaging

In addition to structural imaging, OCT can also be used for functional imaging in the murine retina. In this section, functional imaging techniques such as measurements of intraretinal layer reflectivity in response to light stimuli, retinal blood flow measurements using Doppler OCT, OCT angiography imaging of the retinal capillary network, and spectroscopic OCT imaging will be discussed. Functional imaging can be more demanding than simple structural imaging because it typically requires differential measurements. Ultrahigh-resolution physiology measurements need to detect differential changes in intraretinal layer reflectivities. Doppler OCT requires time differential measurements in the OCT phase. OCT angiography of the retinal capillary network requires mapping of intensity and/or phase changes in time. Spectroscopic OCT measures differential absorption at different wavelengths.

63.4.1 Ultrahigh-Resolution Physiology Measurement

Intrinsic signals from biological tissue detected with optical imaging techniques can be used for measuring neural activity. In the brain, cortical activity can be mapped by imaging intrinsic signals using optical techniques [40]. In the retina, changes in intrinsic optical signals in response to light stimuli have been detected using fundus reflectometry [41, 42]. Although different imaging techniques may measure different types of intrinsic signals, OCT has the advantage that it can detect depth-resolved changes in optical properties of intraretinal layers in response to visual light stimulus. Using time domain OCT, measurement of changes in optical scattering properties activated by visible light was demonstrated ex vivo in the isolated retinae of the frog and rabbit [43, 44]. Figure 63.8 shows an example of ex vivo measurements of backscattered reflectance in the rabbit retina using time domain OCT [44]. As shown in Fig. 63.8d, e, it can be seen that the backscattered reflectance changes in different intraretinal layers due to the visual stimulus.

However, because OCT is a noninvasive imaging technique, it can also be used for in vivo functional measurement of changes in scattering properties of intraretinal layers. In vivo OCT measurement of intrinsic optical signals is challenging because of the small layer thicknesses, speckle, and eye motion. Speckle produces a random spatial fluctuation in backscattered light intensity, which makes quantitation of backscattered reflectivity challenging. Eye motion makes imaging the same location on the retina as a function of time difficult and also introduces noise due to changes in speckle with parasitic eye motion. Ultrahigh-resolution OCT imaging has an advantage that the multilayered retinal structure can be resolved with a $<$3-μm axial resolution. Although the transverse resolution is not as fine as the axial resolution for OCT without adaptive optics, the spatial variation in the retina in the transverse direction is typically significantly less than that in the axial direction. High-speed imaging with spectral domain OCT (as opposed to time domain OCT) enables novel scanning and signal averaging schemes which can reduce the effects of speckle and eye motion.

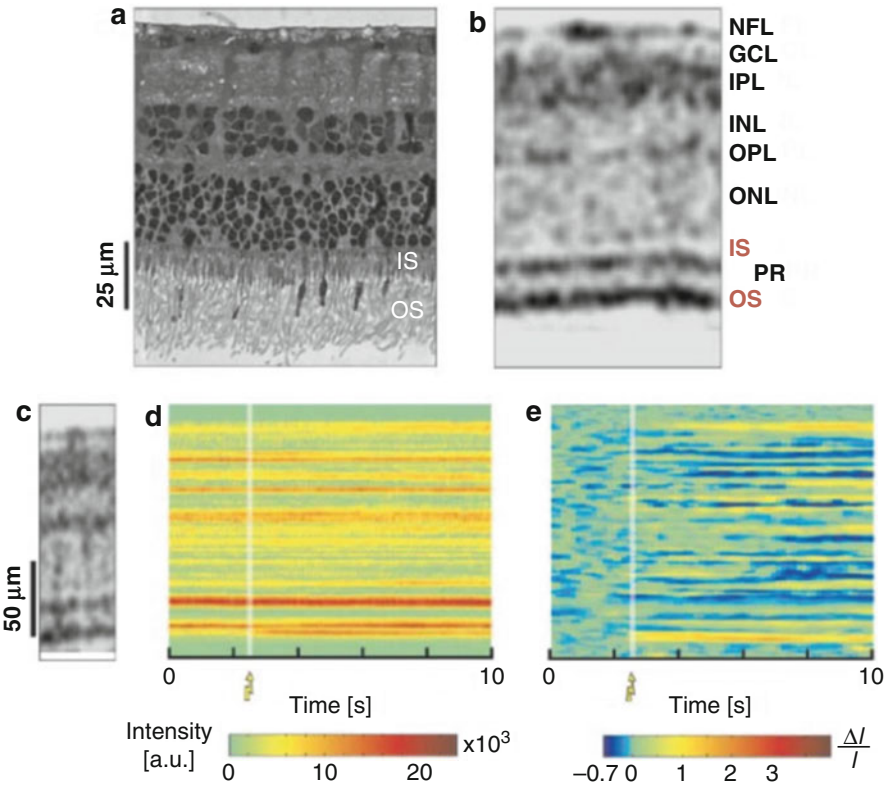

Fig. 63.8 (**a**) A histologic cross section of the rabbit retina compared with (**b**) an ultrahigh-resolution time domain OCT image. (**c**) An example of OCT A-scans repeatedly acquired from the same position on the retina. (**d**) OCT A-scans acquired from the same position before and after visual stimulus. (**e**) Differential OCT A-scans calculated from (**d**) by taking the ratio of the changes in signal intensity relative to baseline and the signal intensity at baseline. The white bar shows the onset and duration of the visual stimulus (Image reproduced from Bizheva et al. [44])

In vivo measurements of functional changes in intrinsic optical signal were first demonstrated in the rat retina using ultrahigh-resolution spectral domain OCT [22]. Measurements were performed in Long-Evans rats, using a high-speed ultrahigh-resolution spectral domain OCT system at 24,000 axial scans per second with a 2.8-µm axial image resolution. Animals were dark adapted before measurements were taken. Because the OCT light source was in the NIR wavelength range, the OCT beam was not visible to the animals. In order to compensate eye motion and reduce speckle, a small area of $160 \times 160\ \mu m^2$ was repeatedly scanned on the retina at a 6.2-Hz volume acquisition rate. Eye motion in the transverse direction was corrected by cross-correlating sequential volumes, and A-scans were aligned in the axial direction with respect to the photoreceptor inner and outer segment junction.

Figure 63.9 shows the results of ultrahigh-resolution functional physiology measurements. Figure 63.9a shows the percent change in amplitude reflectance as

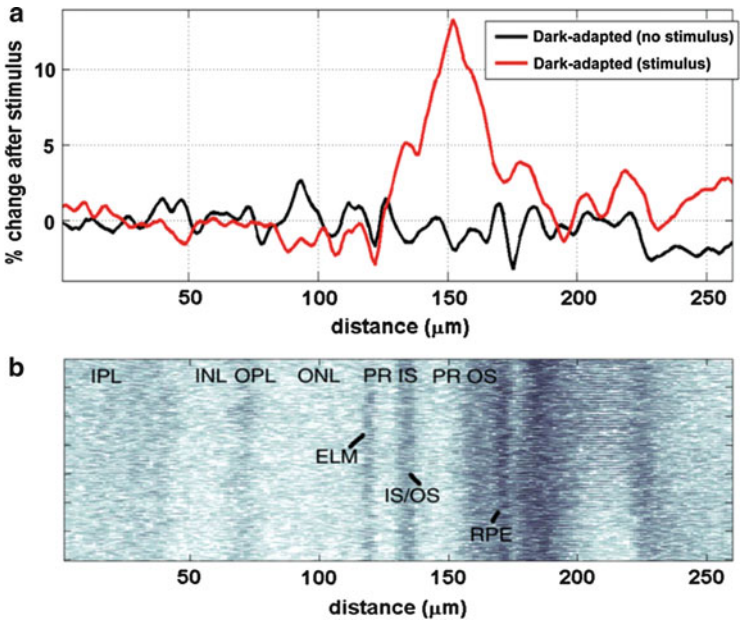

Fig. 63.9 (**a**) Functional OCT measurement showing changes in the backscattered intensity at different depths in the retina before and after visual light stimulus. (**b**) An example showing A-scans from a single volume after aligning with respect to the IS/OS junction, displayed in logarithmic scale for comparison with (**a**). The light stimulus produced an increase in backscattered intensity primarily at the photoreceptor outer segment (Image reproduced from Srinivasan et al. [22])

a function of imaging depth before and after applying a light stimulus on the rat retina with respect to a baseline measurement. Note that the amplitude reflectance was calculated by averaging all A-scans from a single volume after correcting for transverse and axial eye motions in order to reduce speckle. The stimulus resulted in a maximum increase of ~12 % in backscattered amplitude reflectance. Figure 63.9b, which shows all A-scans from a single OCT volume for comparison, indicates that the increase in reflectance was primarily localized to the photoreceptor outer segment.

The volume acquisition rate of 6.2 Hz is rapid enough for visualizing the time course of changes in backscattered amplitude reflectance at the photoreceptor outer segment. Figure 63.10 shows a plot of percent reflectance changes at the photoreceptor outer segment versus time. The standard deviation of reflectance changes in reference to the baseline at the stimulus onset was <1 %, which is significantly smaller than the maximum functionally induced increase in reflectance of ~12 %.

It has to be emphasized that although the increase of ~12 % in amplitude reflectance measured with ultrahigh-resolution OCT is significant, the effect was localized to the photoreceptor outer segment. As can be seen in the OCT image, the photoreceptor outer segment is only a small fraction of the entire retina with

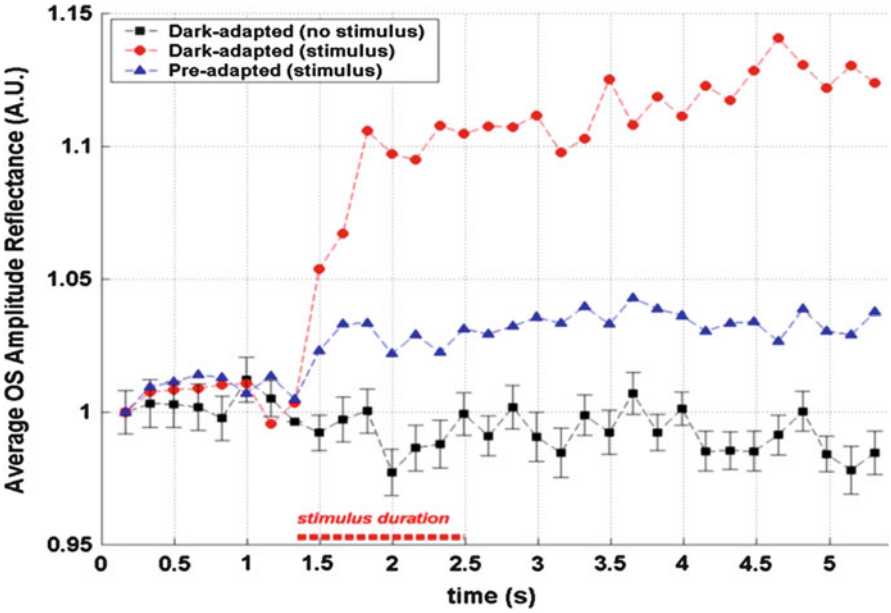

Fig. 63.10 The percent changes in amplitude reflectance at the photoreceptor outer segment at different time points. Each data point is calculated from a single OCT volume. The error bar shows noise (standard deviation of amplitude reflectance values at different time points) of the measurement technique in reference to the amplitude reflectance at the stimulus onset. Stimulus duration is indicated with the *dotted line* at the bottom of the plot (Image reproduced from Srinivasan et al. [22])

relatively weak backscattering when compared to the RPE and RNFL. The photoreceptor outer segment reflectance accounts for only a small fraction of the total reflectance as measured with fundus reflectometry. Therefore, ultrahigh-resolution spectral domain OCT can enable more sensitive measurements compared to other fundus imaging techniques which do not have depth resolution. One disadvantage is relatively slow imaging speeds of current commercial OCT systems for wide field imaging, but advances in OCT imaging techniques are expected to overcome this problem. In vivo optophysiology measurements using optical coherence tomography have also been performed in the chicken retina [45, 46].

63.4.2 Doppler OCT and OCT Angiography

Doppler OCT and OCT angiography are functional extensions of OCT that use repeated scanning protocols to measure flow-induced changes in the OCT signal in time. Spectral domain OCT is especially powerful for Doppler retinal blood flow measurement because spectral domain OCT provides direct access to phase

information required for detecting Doppler shifts [47, 48]. Due to the relatively fast erythrocyte speeds in larger retinal arteries and veins, Doppler OCT of large vessels typically requires sequential A-scans acquired from the same location within a short time interval. This can be achieved by densely oversampling in the transverse direction relative to the OCT beam spot size. In contrast, due to the relatively slow erythrocyte speeds in retinal capillaries, OCT angiography of capillaries typically requires multiple B-scans repeatedly acquired from the same location. The longer time interval between B-scans is used to detect slower flows by mapping time fluctuations in intensity and/or phase on a pixel by pixel basis [49–56]. In this section, applications of these techniques on small animal imaging will be discussed. For small animal imaging, Doppler OCT can be used for measuring pulsatile total retinal blood flow and OCT angiography for visualizing the retinal capillary network in three dimensions. Readers interested in further technical and historical details of these techniques are referred to other relevant chapters in this book for more information.

Doppler OCT for measuring blood flow in individual retinal arteries and veins has been demonstrated in the rat retina [31]. However, these methods require measuring the Doppler angle between the OCT probe beam and blood vessel in individual arteries and veins to calculate blood flow, because Doppler OCT measures the velocity components parallel to the OCT probe beam. With the development of high-speed Fourier domain OCT, en face Doppler OCT measurements became possible [57, 58]. The en face technique measures total blood flow by raster scanning an area that intercepts the blood vessel and summing the axial blood flow velocity components in an en face plane over the blood vessel cross-sectional area. This technique dramatically simplifies the measurement of blood flow because the Doppler angle is not needed. However, high OCT imaging speeds are required because a volumetric OCT data set must be acquired.

Recent advances in OCT technology enabled ultrahigh OCT imaging speeds of $>$100 kHz making en face Doppler OCT measurement of total retinal blood flow possible in the small animal retina. Measuring pulsatile total retinal blood flow in small animals is challenging because of the rapid heart rate. In the normal anesthetized animal, the heart rate is typically 300–400 beats per minute in rats and $>$400 beats per minute in mice, which is $>5\times$ faster than in humans.

Pulsatile total retinal arterial blood flow measurements in rats were demonstrated using an ultrahigh-speed spectral domain OCT system at 244,000 A-scans per second [59]. As shown in Fig. 63.11, major retinal blood vessels emerge out from the central retinal artery located at the optic nerve head. By repeatedly scanning a 200 $\times$ 200-μm area centered at the central retinal artery with 150 $\times$ 25 A-scans, a volume acquisition rate of $\sim$55 Hz can be achieved, fast enough to resolve pulsatile blood flow. For a spot size of $\sim$15 μm, the scan pattern corresponds to an oversampling of $\sim 11\times$ in the fast scan direction, which is sufficient for Doppler imaging.

Figure 63.12 was obtained by calculating total retinal arterial blood flow values for all acquired volumes individually and plotting them as a function of time. Pulsatile total retinal arterial blood flow can be clearly visualized. For comparison,

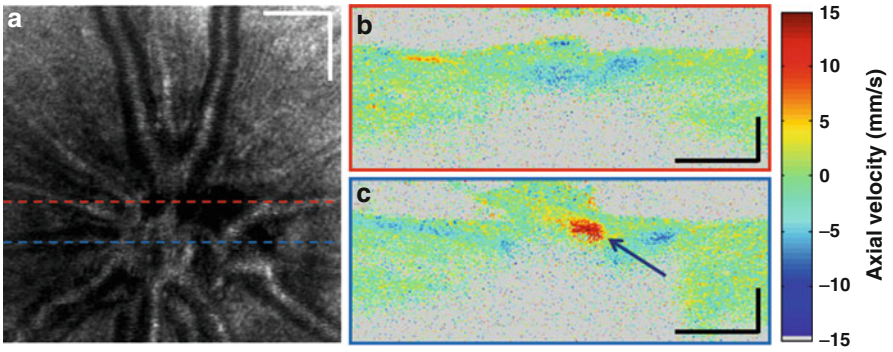

Fig. 63.11 (**a**) An OCT fundus projection image centered at the optic nerve head of a normal rat. (**b**, **c**) Doppler B-scan images acquired from the *red* and *blue dotted lines*. The Doppler images clearly show the location of the central retinal artery (indicated with an *arrow* in (**c**)) relative to the fundus projection image. All scale bars: 100 μm (Images reproduced from Choi et al. [59])

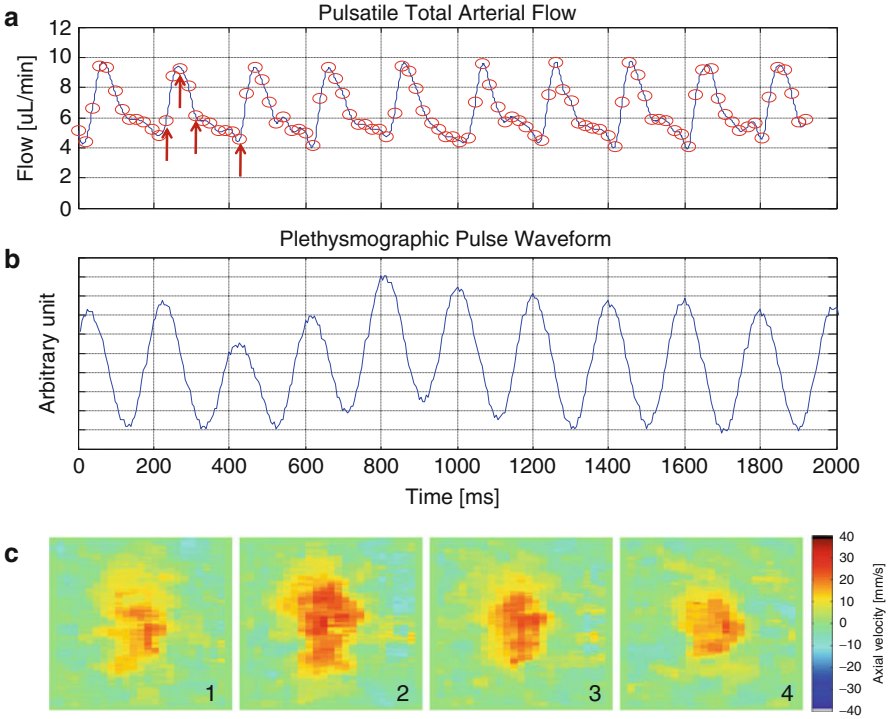

Fig. 63.12 (**a**) Pulsatile total retinal arterial blood flow measured from a normal Sprague Dawley rat. (**b**) Simultaneously acquired plethysmographic waveform. (**c**) En face Doppler images extracted from time points indicated by arrows in (**a**) 200 × 200 μm^2. Time variation in the axial velocity profile corresponding to pulsatility can be clearly visualized (Images reproduced from Choi et al. [59])

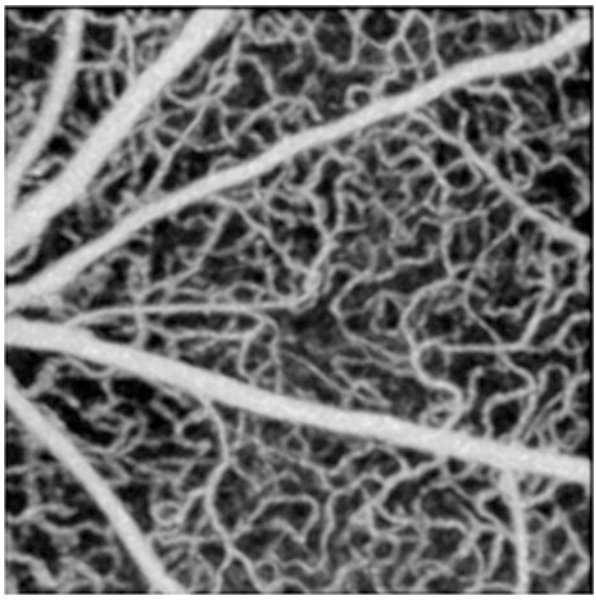

Fig. 63.13 An OCT angiogram acquired from a normal Sprague Dawley rat using speckle variance OCT angiography. 1 × 1 mm^2 field of view

a plethysmographic waveform was simultaneously acquired with a pulse oximeter from a probe attached to the hindlimb footpad of the rat and is shown in Fig. 63.12b. The same instantaneous heart rate can be seen in the blood flow waveform. The en face Doppler images in Fig. 63.12c show blood flow velocity profiles in an en face plane at different time points indicated by arrows in Fig. 63.12a. Pulsatility in the velocity profiles can be clearly visualized.

It is also possible to perform OCT angiography in the murine retina using ultrahigh-speed spectral domain OCT. Because the area of the small animal retina is much smaller than the human retina and the total image acquisition time in anesthetized animals can be significantly longer than in human subjects, data acquisition with high A-scan oversampling is possible and high-quality OCT angiograms can be generated. As an example, Fig. 63.13 shows an en face maximum projection OCT angiogram of a rat retina over a 1 × 1-mm^2 area with 300 × 300 pixels. 300 A-scans were acquired per B-scan at 300 B-scan locations. From each B-scan location, 17 repeated B-scans were acquired, requiring a total of 300 × 300 × 17 A-scans. The example shown performs OCT angiography using speckle variance from the OCT intensity signal, without phase information. Similar techniques using OCT intensity and/ or phase information have been demonstrated by different research groups [49–56], and many other techniques can be applied to visualize the small animal retinal capillary network [31]. OCT angiography has the advantage that it generates a three-dimensional image of the vasculature and because it does not require injected contrast agents, repeated measurements can be easily performed. However, it should be noted that OCT angiography cannot detect vessel leakage which is possible using fluorescein or indocyanine green angiography.

Doppler OCT and OCT angiography can be useful for investigating small animal models of ocular disease where vascular abnormalities are expected during disease progression as well as understanding basic physiology. These techniques have the advantage that they are noninvasive and repeated measurements can be performed on the same animals over time to track disease progression.

63.4.3 Spectroscopic Imaging

Spectroscopic imaging in the murine retina is perhaps one of the more underinvestigated research areas in small animal OCT. Historically, one of the major applications of interest for spectroscopic OCT imaging was noninvasive blood oxygen saturation measurement in the retina [60, 61]. Conventional spectroscopic imaging using fundus cameras has been challenging due to difficulties in calibration from factors such as unknown optical path lengths and effects from chromophores other than oxy- and deoxyhemoglobin in the retina. Spectroscopic OCT, however, can be a promising alternative to spectroscopic fundus imaging because it enables depth-resolved imaging, thereby offering calibrated optical path lengths and isolating parasitic light absorption and scattering from chromophores other than hemoglobin. Despite these advantages, using near-infrared (NIR) wavelengths for measuring blood oxygen saturation with spectroscopic OCT has been difficult since in this wavelength range, hemoglobin absorption is small and scattering dominates absorption [61]. Therefore, OCT using visible light could be advantageous for this application.

Development of supercontinuum light sources provided access to spatially single-mode light, which is necessary for optical fiber-based OCT, in the visible wavelength range with output power sufficient for high signal-to-noise OCT imaging. Recently, visible light OCT utilizing a supercontinuum light source has been demonstrated for retinal blood oxygen saturation measurements in Long-Evans rats [62]. The study demonstrated measurement of oxygen saturation by analyzing the spectrum of backscattered light from the posterior vessel wall. The results were promising in that different blood oxygen saturation levels were observed in retinal arteries and veins as expected, although there were still challenges that needed to be overcome.

One of the advantages of using small animals for developing spectroscopic OCT techniques for blood oxygen saturation measurement is that oxygen saturation can be modulated using an inhaled gas mixture beyond limits that are feasible in human subjects due to safety issues. This can greatly facilitate calibration and validation of new techniques. As with other structural and functional OCT imaging techniques, spectroscopic OCT for retinal blood oximetry can be useful for investigating small animal models of retinal diseases.

Spectroscopic OCT imaging in small animals can also be useful for quantitating the concentration of exogenous dyes or molecular probes introduced by intravitreal or intravenous injection. For example, alterations in retinal vascular permeability, which cannot be directly visualized by structural imaging or OCT angiography, might be visualized with spectroscopic OCT using exogenous dyes. Unlike other

fundus imaging techniques, spectroscopic OCT may provide a more sensitive way to quantify dye concentrations in vivo since it measures depth-resolved backscattered intensity in all three dimensions. Since OCT is an in vivo optical imaging technique, the procedure time can be significantly shorter than performing spectrophotometric analysis on excised retinal tissue, which is a significant advantage for high-throughput small animal studies. Therefore, although it remains largely an underexplored area, spectroscopic OCT imaging may be a powerful technique for quantitative imaging of the small animal retina, especially given developments in exogenous contrast agents and molecular probes.

63.5 Summary

This chapter reviewed key OCT structural and functional imaging techniques that can be applied for small animal retinal imaging. Although this chapter focused on imaging the murine retina, most imaging techniques would also be applicable in other animal models. Designing an optimized small animal imaging interface was reviewed. Structural imaging with ultrahigh-resolution and ultrahigh-speed OCT was discussed. Ultrahigh-resolution imaging may be useful for detecting small focal pathologies, while ultrahigh-speed imaging provides a complimentary way of enhancing image quality. Future advances in OCT technology are expected to combine the advantages of both ultrahigh-resolution and ultrahigh-speed OCT. Several functional OCT imaging techniques such as optophysiology measurement, Doppler OCT blood flow measurement, OCT angiography, and spectroscopic OCT were also briefly reviewed. These functional extensions of OCT promise to provide powerful new approaches for understanding physiology and enable more complete and sensitive characterization of small animal models of retinal diseases. The ability to perform repeated measurements in the same animals is especially important for studies of disease progression or treatment response. The ability to rapidly and quantitatively image surrogate markers of disease should have an impact on both fundamental science and pharmaceutical discovery and development.

64.1 Introduction to Tissue Engineering

As life expectancy increases and mortality rates decrease in the developed world, tissue replacement is frequently required to treat biological wear and tear associated with ageing and accidental damage [1, 2]. Despite the rapid development of modern clinical technologies, the field of medicine faces major challenges in finding solutions for such ageing-linked degeneration, disease, or trauma. Autogenic grafting still remains the gold standard for repair and replacement of tissues and organs.

Viability, immunocompetence, and high incorporation rate are the main advantages of autologous grafting. However, donor site morbidity and the risk of infection and limited availability are the common drawbacks of this procedure. The use of allogeneic tissue or organs offers another option, but the graft immunogenicity and the risk of infection and disease transmission lead to high rates of failure. A third option for repair and replacement of the tissue and organs is the use of a prosthesis made from synthetic materials, which has gained wide acceptance in certain situations, such as orthopedic surgery, where total hip replacement is now a standard practice. The main problem of this technique, however, is premature failure due to lack of biocompatibility. This often leads to a short service time and malfunction of the prosthesis.

Seeking new therapy options has led to the utilization of isolated cells, including stem cells transplantation, instead of tissue or intact organ transplantation. It is reported that transplantation of fetal stem cells and a cell line which can release human ciliary neurotrophic factor (CNTF) have been tested in animal models and human trials to treat Huntington's disease [3]. Delivery of islets from the pancreas has been investigated over a few decades to restore normal blood glucose levels for diabetes patients. It is recognized that enhanced efficiency of cell therapies may be achieved by localization and differentiation of the cells into the correct phenotype in vitro or the generation of matrix with the required quantity and organization in artificial scaffolds before injection or implantation into patients. These investigations have given rise to a new therapy or methodology: tissue engineering.

Over the past decade, tissue engineering has emerged as a promising therapeutic solution in regenerative medicine in the realization of biologically functional implants [4]. Distinct from the aforementioned treatments, tissue engineering conjures up visions of organs built from cellular components in the laboratory until the constructs have reached "maturity," ready to be transplanted into desperately ill patients [5]. In principle, tissue engineering applies engineering approaches to induce specific cells or stem cells to grow into the required tissues in vitro. Synthetic or natural macromolecules are manipulated into a temporary scaffold where cells can be converted into functional tissues. The great advantage of tissue engineering is twofold. First, it has less risk of donor site morbidity because it commonly only involves a small biopsy to obtain a patient's own cell source. Second, the generated tissue is biologically fully functioning and there is no immunogenicity, making the technique equivalent to autologous grafting. Regardless of its short history, tissue engineering promises a bright future when compared with current treatments for the repair and replacement of damaged or diseased tissues.

Developing and repairing tissues and organs in the human body is a highly controlled and well-programmed process consisting of a series of events and steps. Replication and realization of this process in vitro are major challenges for biologists and engineers. To form functional tissues through tissue engineering, three basic elements are required: patient cells or engineered stem cells in a specific quality and quantity, scaffolds with the appropriate biological geometry of the original organ or tissue in which cells can grow and differentiate, and a suitable biochemical and biophysical environment which maintains the physiological conditions for the cells and guides them to deposit the required matrix during development.

64.1.1 Bioreactor (Culture Environment)

A suitable bioreactor is one of the three key elements in tissue engineering. It allows for creation and control of a culture environment that facilitates cell growth and differentiation for successful development of physiologically relevant organs or tissues [6]. Requirements for desired bioreactors are not limited to mimicking this dynamic environment but also include methods for enhancing the microenvironment, which may accelerate cell proliferation and differentiation. Static culture is simple in design and operation, but several studies have revealed that the supply of oxygen and soluble nutrients into the center of three-dimensional (3-D) constructs in in vitro culture is a critical limitation [7]. Also, traditional cell seeding by means of pipettes and relying on gravity as a principle force for cell settlement and subsequent adhesion to the scaffold pores has been questioned because of low efficiency and resulting nonuniformity of cell distribution in the scaffold [8]. To reduce the problems of mass transfer of nutrient and gas exchange, and low efficiency in cell seeding, several types of bioreactors have been designed, such as spinner flasks, rotating wall vessels, and perfusion systems. In fact, a bioreactor is a system optimally designed to simulate the physiological environment for the creation, physical conditioning, and testing of cells, tissues, support structures, and organs in vitro [9].

All bioreactors include methods for the mixing of oxygen and nutrients through the medium and thereby reduce concentration gradients through the thickness of the constructs [10]. Shear forces are usually produced in bioreactors due to the movement of culture media. In addition to shear forces, extra load features can be added to bioreactors for load-bearing tissues. An axial compression force and tensile force have been achieved in some bioreactors [11, 12]. The application of mechanical forces in bioreactors directs cellular activity and maintains cell phenotype in some engineered tissues, for instance, bone and cartilage [13, 14].

64.1.2 Scaffold

The scaffold as a template for seeding cells is a key component in tissue engineering. The three-dimensional scaffold provides the necessary support for cells to proliferate and maintain their differentiation function, and its architecture defines the ultimate shape of the new tissue. The primary task of the scaffold is to act as a temporary matrix for anchoring cells. The requirements of supporting cell growth into functional tissue make it essential for the scaffold to have several unique features. High porosity is a prerequisite, to provide space for the cells to occupy and generate extracellular matrix. The porous structure also facilitates angiogenesis; thus, blood vessels can grow if there is also an adequate supply of oxygen and nutrients to the center of the construct. The ability of the scaffold to degrade in the biological environment via either enzymatic or hydrolytic reactions is another key feature. The elimination rate of the temporary scaffold template should correspond with the rate of tissue turnover, with the goal of having the construct be eventually replaced by a new tissue.

The materials used to fabricate the scaffold are derived either from natural materials, e.g., collagen, chitosan, or from synthetic polymers, mainly from the polyester family. The mechanical parameters and processing properties of these materials can be tailored by molecular weight, crystallinity, and the ratio of comonomers in the copolymers. One unique feature of synthetic polymers is that they can be processed by various methods. In addition, it is possible to combine drug release techniques to fabricate scaffolds which can release modulating molecules such as growth factors, hormones, and ion channel agonists via control release strategies.

64.1.3 Cells

Cells both comprise and generate the building materials for all types of tissues. Not only do they produce signals to control the production of proteins which comprise the matrix, but they also direct the location and organization where the protein synthesis and deposition must occur. There are several considerations in the selection of cells for tissue engineering. In the original definition, a specific mature cell type is used to grow the specific target tissue; for instance, isolated bone cells for bone tissue. The advance in stem cell biology creates another potential cell source: stem cells, either from embryos or from adults. When using stem cells, the major issues are how to culture stem cells while they remain in an undifferentiated state until expansion to the targeted cell number is achieved and how to differentiate the stem cells into a pure and specific cell type. Cell seeding density influences tissue turnover in engineered constructs. Seeding cells into a scaffold at high density has been associated with enhanced tissue formation in 3-D constructs [15]. Too low a seeding density prevents cell-cell interaction. However, the cell number usually is limited by the biopsy size and/or the extent of cell expansion. Therefore, it is often required to seed cells with the highest possible efficiency.

64.2 Current Imaging and Monitoring Techniques

The growth of cells in 3-D scaffolds and the conversion of cells into functional tissues is a long and highly dynamic process. To mimic the body environment, various stimulation conditions have been applied. Monitoring and evaluating cell activities in response to these stimulations and treatments are vital to improve the success rate of tissue formation. However, monitoring and evaluating engineered tissue constructs are much more difficult and complex than for natural tissues due to the presence of scaffold materials and the immature features of the constructs. The full utilization of existing imaging methods and the exploitation of new modalities for monitoring and evaluating engineered constructs are essential to maximize and optimize the functions of the three basic elements in tissue engineering.

There are several key questions to be addressed for the successful development of engineered constructs:

- How do culture conditions (parameters of the bioreactors) affect the activity of the cells within the 3-D scaffold and the final organization of the developed tissue?
- What are the optimal parameters for the scaffold and substrate, and how are they most effectively characterized and evaluated?
- How are the seeded cells distributed spatially within the 3-D scaffolds, and how do they migrate, proliferate, and differentiate within the 3-D scaffold during the lengthy culture period?
- Is it possible to quantify the cell viability and the tissue turnover in the 3-D scaffold in response to various mechanical and biological stimulations?
- How does the implanted tissue evolve and interact with the host environments following transplantation, and how can the efficacy of the treatment be evaluated?

In the tissue engineering field, the existing imaging techniques – light microscopy, confocal microscopy, and micro-CT – are the most widely used tools. In addition, electron microscopy is frequently used on fixed samples to visualize the localization and attachment of single cells with the scaffold.

64.2.1 Light Microscopy and Histology

Light microscopy is a traditional but very powerful tool in the biological field. Various stains and fluorescent dyes can be selected to enhance contrast and to differentiate individual components within a complex biological system. The high resolution, selectable contrast, simple application, and inexpensive use of light microscopy make it an essential technique in every biological laboratory. However, the penetration depth of visible and fluorescent light is very limited. Only thin and transparent samples can be visualized. Inevitably, all tissue or organ samples must be cut into thin sections approximately 3–10 μm thick via conventional paraffin embedding and microtome sectioning or through cryosectioning processing before viewing by light or fluorescent microscopy. These sample preparation methods and histological analysis are not only time-consuming but may also introduce structural artifacts or the loss of some biological or material components because all specimens must be subjected to a dehydration and rehydration cycle. Most importantly, observation by light microscopy is the end-point evaluation and a destructive analysis technique. The same issues arise for transmission and scanning electron microscopy, which is used to further resolve cellular features at the submicron scale. Electron microscopy, too, requires destruction of the sample or specimen for analysis.

64.2.2 Confocal and Two-Photon Microscopy

The emergence of confocal microscopy was a revolution in the microscopy field. By labeling with fluorophores, optically nontransparent specimens with a 3-D

structure could be visualized at high resolution. Up to approximately 100 μm thickness, confocal microscopy can acquire sample images with a focused beam of light and collection of the fluorescent signal via a pinhole aperture that spatially rejects light from out of focus areas of the specimens. Optical sectioning eliminates the requirements of physical sectioning as in histological analysis, enabling the observation of viable cells in the scaffold, and the online measurement of cell activities and tissue turnover.

The drawback of confocal microscopy, however, is the limited penetration depth and the often necessary use of fluorophores. Except for a few engineered tissues, for instance, skin and cornea, the engineered constructs are relatively thick, ranging from a few millimeters to centimeters. The penetration depth in confocal microscopy limits the observation to the surface of the constructs. In addition, to achieve thin optical sectioning, high numerical aperture (NA) optics are frequently required, potentially limiting the working distance between the objective and the tissue surface. The fluorescent labeling may also affect the long-term viability of cells in the constructs.

Fluorescent molecules may absorb two photons simultaneously before emitting light. The use of two-photon excitation has enabled two-photon microscopy. This microscopy technique has advantages over one-photon techniques including efficient background rejection, low photo damage, and enhanced depth discrimination. Using two-photon excitation, where a fluorescent chromophore simultaneously absorbs two incident long-wavelength photons before it fluoresces, can greatly reduce photobleaching [16]. However, the sample penetration depth under this modality is still limited to several hundreds of microns in highly scattering tissue.

64.2.3 Microcomputed Tomography

Microcomputed tomography (μ-CT) is the micron-scale version of X-ray computed tomography used extensively in medical fields. However, instead of keeping the samples or specimens (patients) immobile, the samples in μ-CT are rotated and resolutions as high as 2–10 μm can be realized. Its popularity can be attributed to its ability to provide precise quantitative and qualitative information on the 3-D morphology of specimens. Micro-CT is a nondestructive modality and essentially no additional steps are needed to prepare samples for scanning. However, ionizing X-ray radiation is used, which can affect the viability and health of living specimens. The absorption and contrast ability of X-rays to high-density materials in the biological field are preferential to bone tissue due to the calcium and phosphorus elements. Thus, the best application of μ-CT in tissue engineering is the evaluation of bone cell growth within the scaffold. The degree of mineralization within the 3-D scaffolds can be very clearly delineated [17, 18]. A scaffold made from polymeric materials has low X-ray attenuation, but the contrast of air and polymer is sufficiently high to differentiate them. Therefore, μ-CT has additional applications for the assessment of scaffold architecture, such as pore size, porosity, and pore interconnectivity. Recently, the correlation of strain level around a porous scaffold has been investigated and correlated with the degree of

mineralization of engineered bone within the constructs [19]. The application of micro-CT in tissue engineering is more or less limited to bone tissue generation since other types of tissues lack strong contrast among the components under an X-ray source.

64.3 OCT as an Investigative Tool for Tissue Engineering

The fabrication of thick 3-D tissue constructs has been limited by our ability to visualize the complex cellular dynamics and morphological organizational events occurring deep within these constructs. Therefore, an alternative approach, free from the limitations described above, is highly desirable for successful tissue engineering.

Optical coherence tomography (OCT) [20] has recently emerged as a promising imaging technique, mainly for medical applications. The original development of OCT was for transparent tissues, such as corneal and retinal tissues [21]. Current OCT technology enables nontransparent, soft and hard tissues to be examined in vivo, including the skin [22], gastrointestinal tract [23], nervous systems [24], cartilage [25], and respiratory tract [26], to name only a few. Clearly, the capabilities of OCT provide enormous potential to overcome a number of limitations currently experienced in tissue engineering for monitoring cell growth and morphology within porous scaffolds. In the past decade, the instrumentation of OCT has been continuously investigated and developed. The resolution, the penetration depth, and the functionality of OCT have improved dramatically. Several features in OCT are unique and highly attractive for tissue engineering. Measurements by OCT can be realized online and in a nondestructive manner. The resolution is up to the cellular dimension (0.9–10 μm), and the penetration depth for a nontransparent object can be up to 2 mm, well within the size scale of most complex 3-D engineered tissues.

In this chapter, we discuss the application of OCT to tissue engineering. Imaging examples with OCT and its enabling functions and variants, such as Doppler OCT (DOCT), polarization sensitive OCT, optical coherence microscopy (OCM), etc., are overviewed. For clarity, we arbitrarily divide these imaging examples into separate sections where specific investigations of one of the three main elements in tissue engineering, i.e., bioreactors, scaffolds, and cells, are discussed. Imaging with multimodal microscopes that combine OCT/OCM with other imaging modalities is also introduced, which enables new specific applications in tissue engineering with extended functions and new contrast abilities. The potential of using OCT and multimodal imaging technology for in vivo monitoring of postimplantation dynamics and evaluation of the treatment efficacy is discussed in the last section.

64.3.1 Overview of OCT and Its Functional Variants

Although OCT has a relatively short history since inception, a number of different modes of operation have evolved over the past decade which enable the

visualization and quantification of many different parameters of biological tissue. In addition to standard OCT imaging of cellular and tissue microstructure, functional OCT modes include methods sensitive to flow or tissue movement, birefringence, metabolic states, and biomechanical properties, among others. Operating as both a structural and functional imaging modality, OCT may tackle many different monitoring tasks in tissue engineering.

Time-domain OCT (TD-OCT) was the first version of OCT used widely in the early 1990s [20]. Improvements in the light source, the interferometer design, and the beam delivery system have led to time-domain OCT being widely used to image the microstructures of tissue in clinical trials and the research laboratories. Its simple construction and low cost add merit for its wide application. In the mid-1990s, it was realized that OCT imaging could be performed in the spectral domain (frequency domain OCT, FD-OCT) without the requirement of scanning the optical delays in TD-OCT. Because FD-OCT is achieved without movement of the reference arm, imaging speed is dramatically improved. More importantly, there is a gain in the detection sensitivity and phase stability compared to its counterpart. Such features are very useful for investigating fast dynamic biological systems where speed of data acquisition is vital. Another recent advance in OCT is the development of swept-source OCT (SS-OCT), which is also referred to as time-encoded frequency domain OCT or optical frequency domain imaging (OFDI). In SS-OCT [27], the spectrally resolved interference is recorded based on fast detection of a temporally swept narrow linewidth laser through a broad bandwidth. In addition to improved sensitivity [28], SS-OCT offers much higher imaging speed (up to million A-scans per second [29]), which is enabled by the availability of the stable fast wavelength tuning swept sources, such as the Fourier domain mode-locked laser [30]. Other chapters (► Chaps. 1 "Introduction to OCT," ► 6, "Complex and Coherence-Noise Free Fourier Domain Optical Coherence Tomography," and ► 8, "Complex Conjugate Removal in SS Optical Coherence Tomography") in this book provide specific details on these types of OCT systems.

Combining the Doppler effect with OCT enables the detection of Doppler frequency shifts due to tissue movement or fluid flow, thereby mapping these physiological or functional changes, such as blood flow, to the structural OCT image of the tissue. Thus, Doppler OCT opens another window to detect functional changes, such as abnormal blood flow in the skin or retina, and to track the velocity of moving scatterers within the tissue. In the field of tissue engineering, this has been preliminarily exploited to monitor fluid flow within a construct in a bioreactor [31] or within microfluidic precursors to vascular constructs [32].

The development of high-resolution polarization-sensitive OCT (PS-OCT) has attracted considerable interest since a number of biological tissues have a well-organized matrix, mainly consisting of collagen fibers. The change of the fiber organization, reflected in the spatial distribution of detected birefringence, may indicate disease or abnormality. Thus, PS-OCT can detect structural change in tendon, muscle, or cartilage, depending on the change of birefringence. This technique can also be used to monitor the architecture of newly formed matrix in engineered cartilage and tendon [33, 34].

In addition to providing structural information, or the functional information described above, OCT techniques can be used for extracting spectroscopic information [35–38]. Spectroscopic OCT has been investigated by using appropriate time-frequency analysis. In general, spectroscopic OCT has at least two imaging targets: imaging spectral absorption and spectral scattering. Separation of the two signals can retrieve molecular information either about endogenous molecules or about exogenous contrast agents that provide a more dramatic difference in detected spectral absorption or scattering.

Viewing tissue at the cellular level is a significant challenge for OCT. The highest longitudinal resolution achieved for OCT to date has been obtained by using a state-of-the-art femtosecond Ti:sapphire laser. Using this source, in vivo subcellular imaging with longitudinal resolution of less than 1 μm was demonstrated [39]. Alternatively, the development of full-field optical coherence microscopy (ffOCM) has achieved sub-micrometer resolution using a broadband white-light source [40]. Laser-scanning OCM, which uses high NA objectives to obtain high transverse resolution, has also been demonstrated to be promising for investigation of engineered tissue [41–43].

While OCT has emerged as a promising imaging tool in tissue engineering, it has specific limitations that still need to be considered and addressed. The most predominant one is the low contrast of OCT images, which are normally formed based on the spatial variance of localized refractive index. To improve the contrast of OCT, a few types of exogenous contrast agents, such as microbubbles [44], inert metal nanoparticles [45], microspheres [46], and magnetic nanoparticles [47], among others, have been proposed and demonstrated. Considering the potential side effects of these agents, and the fact that there is normally no organized clearance system in engineered tissue, the use of contrast agents is not preferred. Because of this, the combination of OCT with other imaging modalities, such as fluorescence-based microscopy techniques and nonlinear microscopy, may offer a good option to develop with OCT in tissue engineering. In particular, because OCT can use ultrafast short-pulse laser sources that offer broad spectral bandwidth, such as the common Ti:sapphire laser, integrated microscope systems can be constructed to also perform two-photon excited fluorescence (TPEF) simultaneously [48]. The combination of OCT with multiphoton microscopy (MPM, including TPEF and second harmonic generation (SHG) [49] microscopy) has been exploited for high-resolution imaging of engineered tissue [43, 50]. Moreover, the multimodal imaging system has demonstrated the ability to track cellular dynamics in vivo, showing the potential for investigation and monitoring of the dynamics of cells and engineered tissues following transplantation [51].

64.3.2 OCT Imaging of Bioreactors

Given the complexity of the bioreactor systems for tissue engineering, which involve sophisticated architecture, different types of materials, and dynamic perfusion flow, the observation of developing tissue in bioreactors is nontrivial. Moreover, the growth of an engineered tissue in a bioreactor has specific requirements. For example,

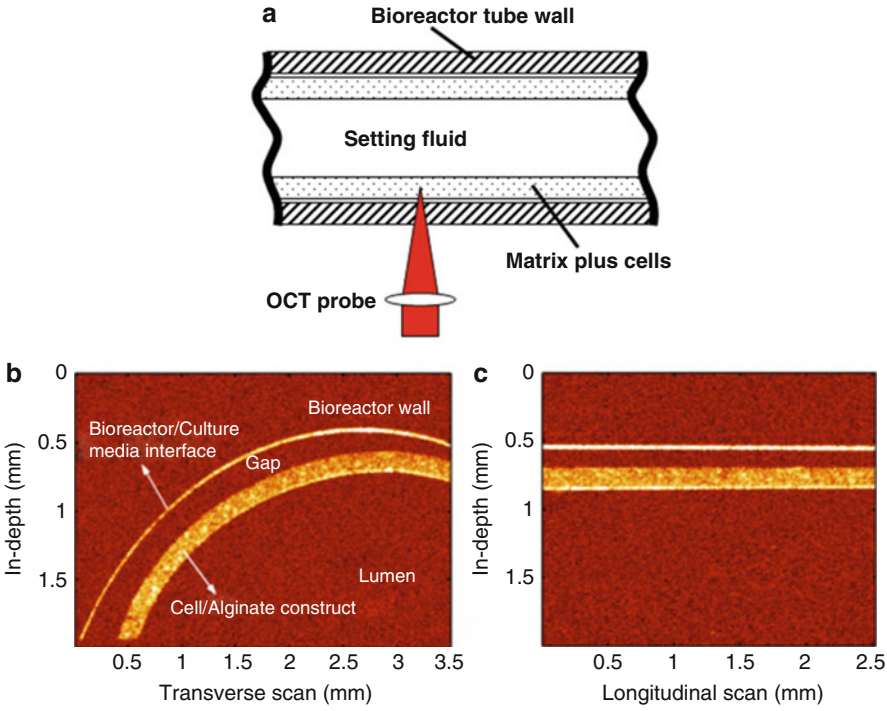

Fig. 64.1 OCT imaging of a bioreactor with its engineered tissue construct. (**a**) Schematic of the bioreactor. (**b**) Transverse and (**c**) longitudinal OCT scan. The *bright pixels* within the construct represent the cells. The outer interface of the bioreactor in OCT image is not shown (Reprinted with permission from [31])

the developing tissue must be bathed in a solution of nutrients at all times, and imaging of tissue should be performed repeatedly without interrupting the development of the tissue. A typical tissue engineering bioreactor, in which the tissue-engineered construct is produced and grown, needs to remain absolutely sterile throughout the weeks to months of operation prior to the harvesting of the living construct for surgical implantation into the patient [52]. During this time, the evolving architecture of the tissue requires constant monitoring in a noninvasive, nondestructive manner and at an acceptable cost.

The nutrients in bioreactors are supplied in the cell or tissue culture medium, which surrounds and perfuses the tissue. This medium typically has a refractive index in the order of 1.34 [53]. Biomedical grade (Food and Drug Administration-approved) plastics have precisely known refractive indices, e.g., Delrin, an acetyl copolymer (Dupont, Wilmington, DE, USA) with a refractive index of 1.48. Given this heterogeneous group of discrete refractive indices in a typical bioreactor, and in the tissue and growth medium, it is possible to obtain OCT images of the bioreactor and the engineered tissue in these culture conditions.

As an example, Fig. 64.1 shows OCT images of a bioreactor within which a hydrogel tube (approx. 4 mm outside diameter by 20 cm in length) with encapsulated mesenchymal stem cells was formed by extruding the cell/alginate solution using a solution of 1 % $CaCl_2$ in 0.9 % saline using a combined fabrication device/bioreactor [31]. From the OCT images, it is evident that the bioreactor contains an inner lining that is composed of living cells within an alginate hydrogel and a distinct inner lumen containing culture medium. The engineered construct is separated from the bioreactor wall by a thin layer of culture medium. In addition, the distribution of the cells within the hydrogel can be visualized, with the cells appearing as bright spots in the OCT images. This appearance is because the cells have relatively high refractive indices compared to that of the hydrogel scaffold, providing the imaging contrast.

64.3.3 OCT Imaging of Scaffold and Substrate

Scaffolds used in tissue engineering act as templates and provide mechanical, chemical, and biological support for tissue regeneration. They are commonly 3-D structures with porous or fibrous degradable structures. The parameters of the scaffold, such as material, pore size, porosity, and pore interconnection, affect the cell activity and cell distribution within the scaffolds. OCT can evaluate and monitor the architecture of the scaffolds and the cellular distribution without sample preparation, which provides instant feedback on the growth and development of the engineered tissue.

Recently, OCT along with appropriate imaging processing algorithms was used to investigate parameters of the porous scaffold, including volume porosity, pore interconnectivity, and pore size [54]. Accurate characterization of these parameters provides valuable feedback for better control of the fabrication conditions. Figure 64.2 shows OCT images of porous hydrogel scaffolds fabricated using the porogen-leaching technique [55] with different formulations. The images are obtained using a swept-source Fourier-domain OCT system (Thorlabs Inc.) with a laser source at 1,300 nm and a broadband spectrum of 100 nm, which provided an axial resolution of 8 μm. The micropores and hydrogels are well resolved in both the cross-sectional and en face images, which also reveal the pore size and density. The color-coded 3-D-labeling images show the interconnectivity of different groups of pores. Based on this information, and assisted with appropriate algorithms, quantitative pore density and interconnectivity can be determined [54].

In order to provide a better nutrient supply to the porous and thick 3-D constructs, the integration of a perfusion method becomes essential in various bioreactors. In addition to a better exchange of nutrients and waste, perfusion generally exerts mechanical stimulation on the engineered tissue, which accelerates the maturation of the constructs. It is essential to attain the information about the relationship between perfusion rate and fluid shear stress in 3-D porous scaffolds and their dependence on the main parameters of the scaffolds such as pore density, pore size, and shape. Potentially, this can be done with DOCT (Doppler optical

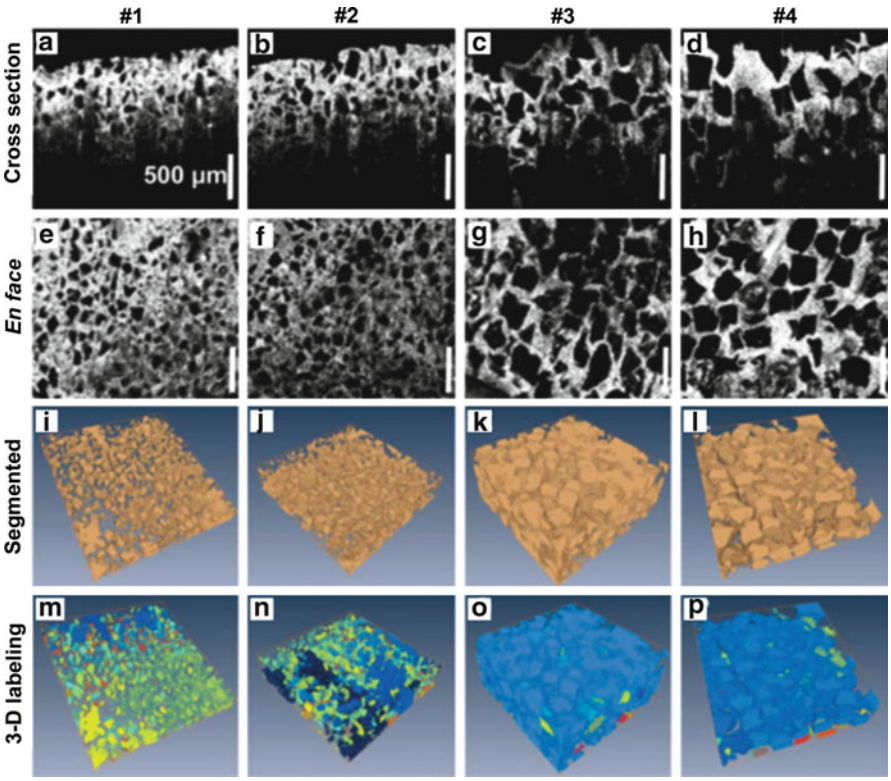

Fig. 64.2 (**a**–**d**) Cross-sectional and (**e**–**h**) en face OCT of scaffolds with different volume porosities. For scaffolds #1–4, the calculated volume porosities are 24.4 % ± 7.5 %, 18.1 % ± 10.3 %, 41.4 % ± 6.0 %, and 39.7 % ± 7.7 %, respectively. En face images are taken at a depth of 100 μm. (**i**–**l**) 3-D observation of the pores segmented from OCT images. (**m**–**p**) 3-D observation of isolated and connected pore groups through the 3-D labeling process. *Different colors* indicate different groups. 3-D images are analyzed using a depth range of 0–300 μm (Reprinted with permission from [54])

coherence tomography), a functional variant of traditional OCT. DOCT uses additional phase information from the complex OCT signals, which can be used to monitor the directions and velocities of moving particles in the backscattered spectrum. It is therefore possible to provide information regarding both the scaffold architecture and local fluid flow through 3-D scaffold, simultaneously.

The shear stress from fluid flow can be directly related to the fluid velocity measured by DOCT:

$$\tau = \mu \frac{\partial v}{\partial n} = \mu \frac{\partial v_z}{\partial z} \cdot \frac{2}{\sin 2\alpha} \left(\mathrm{dyn \cdot cm^{-2}}\right) \tag{64.1}$$

where V is the flow velocity vector and V_z is the component of the velocity in the z direction (probe beam direction) measured by DOCT. This calculation and

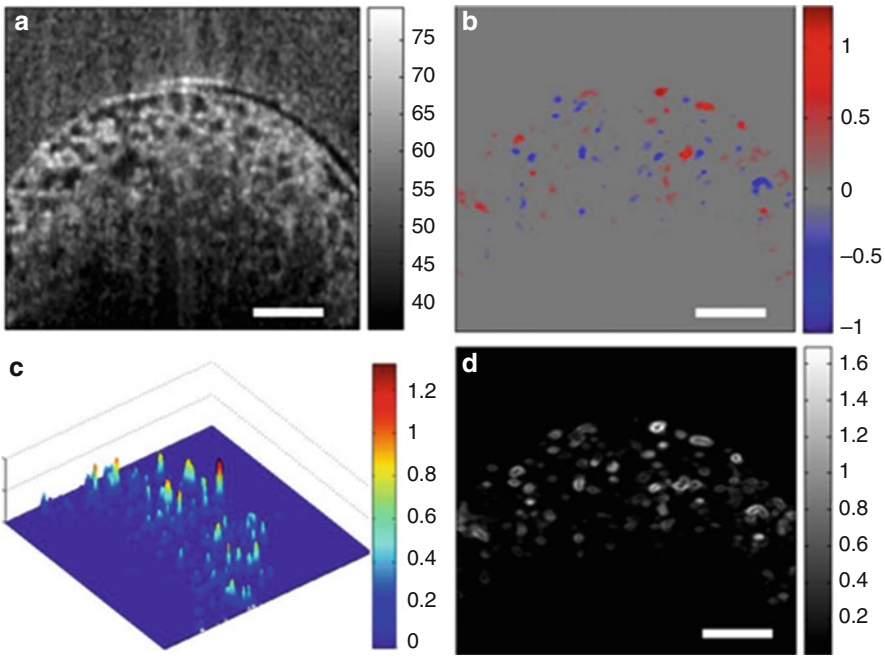

Fig. 64.3 DOCT monitored the fluid flow in a low-porosity chitosan scaffold in situ. Shown are, respectively, (**a**) the microstructural image, (**b**) the bidirectional local fluid flow map, (**c**) the 3-D plot of magnitudes of the flow velocities, and (**d**) the corresponding local shear stress distribution in a typical X-Z section. The units for color bars shown are (**a**) dB, (**b**) mm/s, (**c**) mm/s, and (**d**) dyn/cm^2 respectively. The *white scale bars* indicate 200 μm (Reprinted with permission from [57])

other technical details regarding DOCT can be found in ref. [56] and ▶ Chaps. 42, "Doppler Fourier Domain Optical Coherence Tomography for Label-Free Tissue Angiography" and ▶ 45, "Optical Coherence Tomography in Cancer Imaging" in this book. In addition, since DOCT can provide both the 3-D microstructural morphology and 3-D flow map for each pores in a scaffold, the combination of the structural and flow images permits the direct measurement of porosity and interconnectivity for the porous scaffolds. The porosity is defined as the ratio of total pore volume to total scaffold volume as determined by the OCT structural images, which is typically determined by block image processing.

A typical cross-sectional OCT image of a low-porosity chitosan scaffold (LPCS) with a pore size ranging from 30 to 100 μm is presented in Fig. 64.3a. The chitosan scaffold is fabricated by a freeze-drying technique using a 2 % chitosan solution in acetic acid. The scaffolds, with different porosity and pore size, were obtained by adjusting the freezing rate [58]. A spectral-domain DOCT system, which used a superluminescent diode with a central wavelength of 842 nm and a measured axial resolution of ~7 μm in air, was used to acquire these images. The bidirectional flow velocity map obtained by DOCT is presented in Fig. 64.3b. Both the distributions and the magnitudes of the flow can be seen. The magnitudes of bidirectional

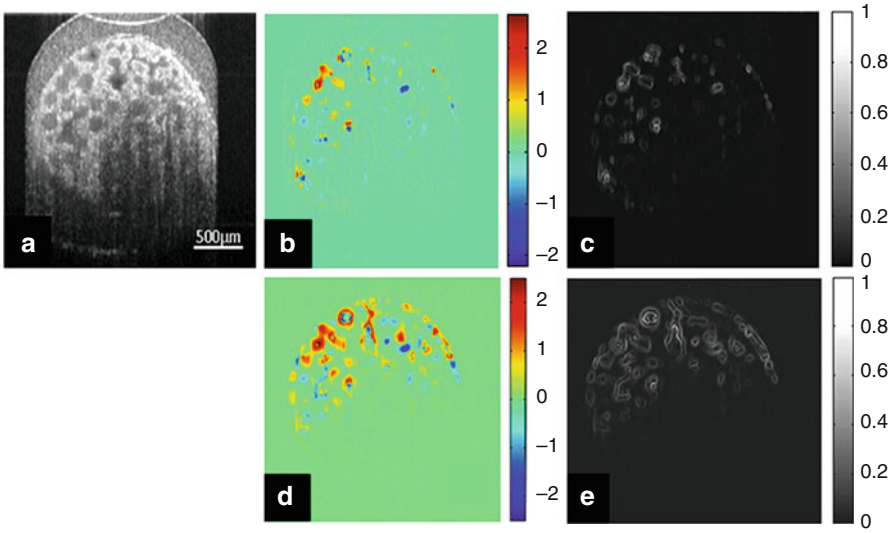

Fig. 64.4 (**a**–**c**) DOCT images for chitosan scaffolds with round-shaped pore structures: (**a**) structural image, (**b**) flow rate, and (**c**) shear stress. (**d**–**e**) DOMAG images of the same scaffolds in (**a**), showing the better resolution of the flow rate (**d**) and shear stress (**e**)

flow velocities were calculated and plotted in Fig. 64.3c. It is seen that there are variations of velocities within pores, indicating a heterogeneous distribution of flow velocity in the porous structures. Although the input flow rate was constant, the local fluid flow in this complex construct varied greatly in both magnitude and direction. Furthermore, the flow in the micropores did not show parabolic distributions. Consequently, the fluid shear stress, as shown in Fig. 64.3d, differed from pore to pore, with values ranging from 0 to 1.65 dyn cm^{-2}. Nevertheless, the maximum fluid shear stress was generally located at the pore walls. Based on the quantitative comparison between the distributions of shear stresses at the pore walls of scaffolds with different porosity, dependence of shear stress on porosity, pore interconnectivity, and shape can also be characterized.

The real flow rate can be further investigated with the technology called as Doppler optical microangiography (DOMAG) [59]. DOMAG combines the phase-resolved technique in DOCT and flow signals from optical microangiography (OMAG), which generates low-noise flow images, reflecting the real flow rate more precisely. Comparison between OMAG and DOCT on the fluid flow measurement in chitosan scaffolds (with round-shaped pore structure) is shown in Fig. 64.4. Figure 64.4a is the structural image of the scaffold. Figure 64.4b, c are from DOCT and Fig. 64.4d, e are from DOMAG for flow rate (d) and shear stress (e), respectively. There are two improvements for these images. First is the higher penetration depth of the image and second is the much clearer flow pattern in each pore using the DOMAG technique, which resulted in more accurate shear stress images (Fig. 64.4e). It is reported that the background noise from a non-flow region

of the scaffold and random noise were imposed onto DOCT flow images, resulting in a difficulty to precisely measure small flow velocity [57, 59]. DOMAG is able to tackle this issue and separate the background flow signals from the background signals, which leads to low-noise images.

In addition, the mechanical properties are important parameters of a scaffold, which affect the development and regeneration of the tissue [60, 61]. The relationship between cell dynamics and the mechanical properties of a scaffold is complex. Cell activities are affected by the mechanical parameters of the environment, but these mechanical properties also have considerable impact on the growth and the behavior of cells. A good understanding and control of this interaction will help us improve regeneration of the desired tissue. Normally, the biomechanical properties of tissues are characterized by elastography. Traditionally, this has been performed with ultrasound or MRI, but recently elastography has been demonstrated in OCT in a technique called optical coherence elastography (OCE). One initial application has been for investigating the biomechanical properties of myocardial tissues [62]. The high resolution and sensitivity of OCE makes it suitable for detecting changes at the cellular level in engineered tissues [62]. As cells seeded in scaffolds proliferate and the engineered tissue develops, the cells increase in number and secrete extracellular matrix. During this process, the biomechanical properties of the engineered tissue will be altered, and these subtle changes can be detected with OCE in a spatially and temporally resolved manner.

Figure 64.5 shows a representative array of structural and OCE images acquired from a 3-D scaffold, with half of the scaffold seeded with cells and the other half serving as a cell-free control. The samples were imaged over a culture time of 10 days, and at each time point, the OCE images were analyzed to generate both displacement and strain maps, which are color coded to indicate regions of higher stiffness. The cell-seeded regions increased significantly in stiffness over the culture period, demonstrating that OCE could be used to measure the stiffness and biomechanical parameters from the engineered tissue in a spatially resolved, nondestructive manner. Related to engineered tissues, OCE was used to image the changing biomechanical properties in the developing *Xenopus laevis* tadpole, which exhibited a more markedly different range of tissue stiffness attributed to organo- and morphogenesis [63]. Much of our understanding of the complex processes in the field of developmental biology (▶ Chap. 67, "Optical Coherence Tomography for Gastrointestinal Endoscopy") can be applied to the field of tissue engineering, where we wish to control the growth and organization of engineered tissues in 3-D and under an array of pharmacological and mechanical stimuli.

64.3.4 OCT Imaging of Cell Dynamics

64.3.4.1 Cell Growth Profiles

In addition to bioreactors and scaffolds, activities of cells in these environments eventually determine the regeneration of the tissue. Because the environmental parameters have a critical influence on cell growth and the deposition of matrix,

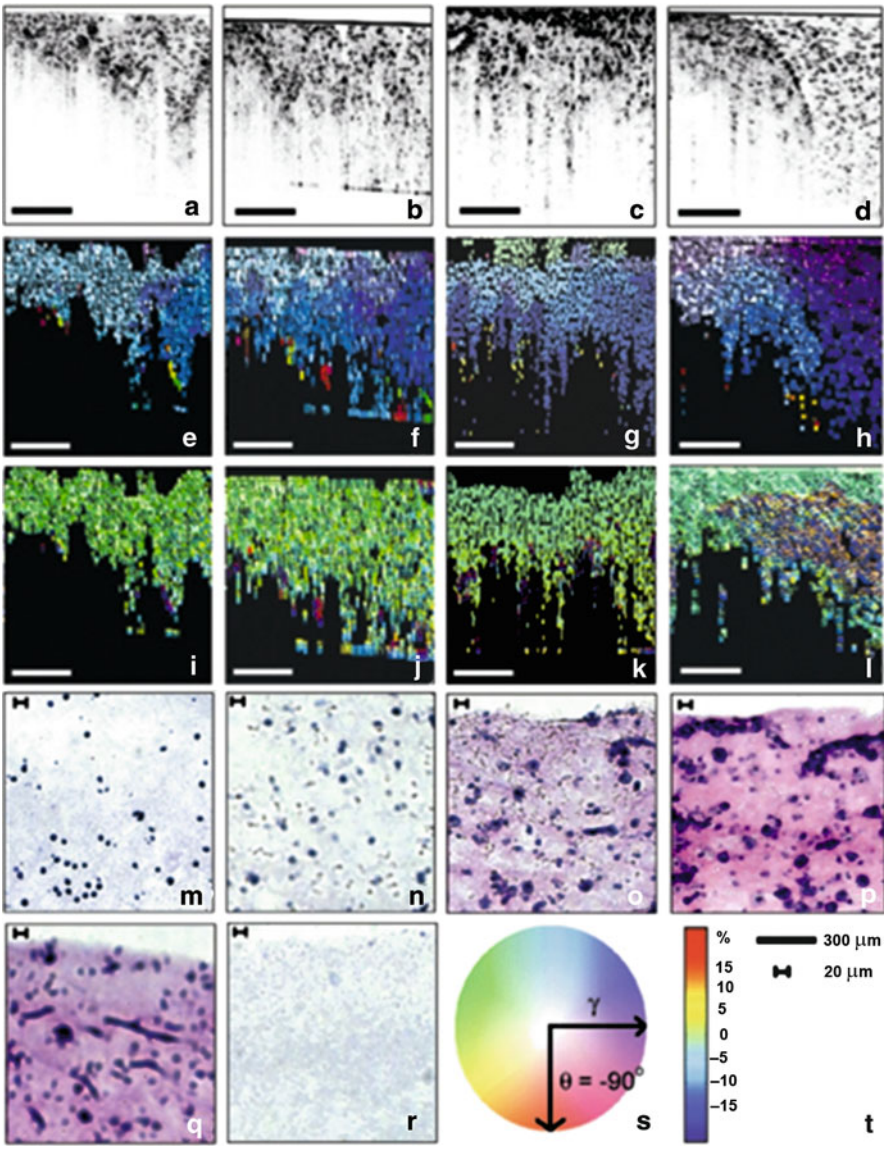

Fig. 64.5 Optical coherence elastography of engineered tissues. (**a**–**d**) Structural OCT images on day 0, 3, 7, and 10, respectively, of the boundary between the cell-seeded region (*left*) and the cell-free region (*right*). Fig. 64.6 Two- and three-dimensional OCT of a cell-seeded porous scaffold. Fibroblast cells were seeded in a chitosan scaffold and imaged at days 1, 3, 5, 7, and 9 (**a**–**e**, respectively) to show cell distribution changes. Initial cell seeding distribution is relatively uniform, but at later days, cells migrated toward surface to form a dense cell layer. Corresponding validating histology (**f**–**j**) is shown, along with 3-D OCT images at days 3, 5, and 7 (**k**–**m**, respectively). *Scale bar* represents 100 μm (Modified figure reprinted with permission from [64])

revealing the cell growth profiles within scaffolds will greatly increase our understanding of how to control culture conditions and optimize growth patterns. OCT has been utilized in this regard [54, 64–68]. Because of the difference in refractive index between cells and scaffolds, which results in the variation of backscattering of light from the different regions, OCT has the appropriate capability to investigate cell dynamics in engineered tissue.

Figure 64.6 shows OCT images, corresponding histology, and 3-D visualization of a fibroblast cell population seeded in a chitosan scaffold and imaged over several days, revealing the cell growth profiles and dynamics. Cells were cultured and imaged at days 1, 3, 5, 7, and 9. Initially, the chitosan scaffold provided very little scattering for OCT, as the index of refraction was similar to the surrounding media. As the seeded fibroblasts populated the scaffold, attached, and deposited extracellular matrix, the more highly backscattering extracellular matrix provided clear OCT signals, and OCT images revealed the porous structures of the scaffold. Interestingly, over time, the initial population of cells that were evenly distributed began to migrate toward the surface of the scaffold, likely in response to limited nutrients and waste exchange at the deeper regions. After 9 days, a high-density cell layer is observed at the surface and confirmed both with 3-D OCT and histological observations [64].

A quantitative measurement of cell growth is shown in Fig. 64.7. An OCT image from a blank poly (lactide) (PLA) scaffold immersed in water is shown in Fig. 64.7a. The scaffold has a 90 % porosity and 250–350 μm pore size. It can be seen that the pore structure is clearly delineated. An imaging depth of around 1.2 mm is achieved, despite the highly scattering nature of the scaffold. The imaging contrast is primarily provided by the difference in refractive indices between the polymer and water. The polymer wall reflects the light to a greater extent, thus appears brighter, while the pore appears as a darker area in the OCT image. Such contrast provides an opportunity to estimate the porosity from the OCT images. Figure 64.7b illustrates the OCT image acquired from a PLA scaffold seeded with MG63 bone cells and cultured for 4 weeks under static conditions. Structural changes are noted as compared to the blank scaffold. The pore size and porosity have decreased significantly, i.e., the darker areas in the images are reduced. From the cell seeding procedure and the expected cell growth profile, the increased brighter areas in the scaffolds are attributed to the cells and the extracellular matrix generated by the cells, increasing the optical scattering properties of the constructs and leading to an increased backscattering of the OCT signals.

The pores within the scaffolds were initially filled with seeded cells. Occupation of pores continued as cells proliferated and differentiated, producing extracellular matrix. Thus, pore size and porosity of scaffolds become dynamic parameters in the culture period, which are closely correlated to cell growth profiles and tissue turnover. It is hypothesized that the quantification of porosity change with culture time and conditions can reveal information about the cell growth profile. A local porosity analysis of scaffolds has been proposed to quantify the porosity change, in which large and continuous defects in scaffolds (i.e., pore size >500 μm) are

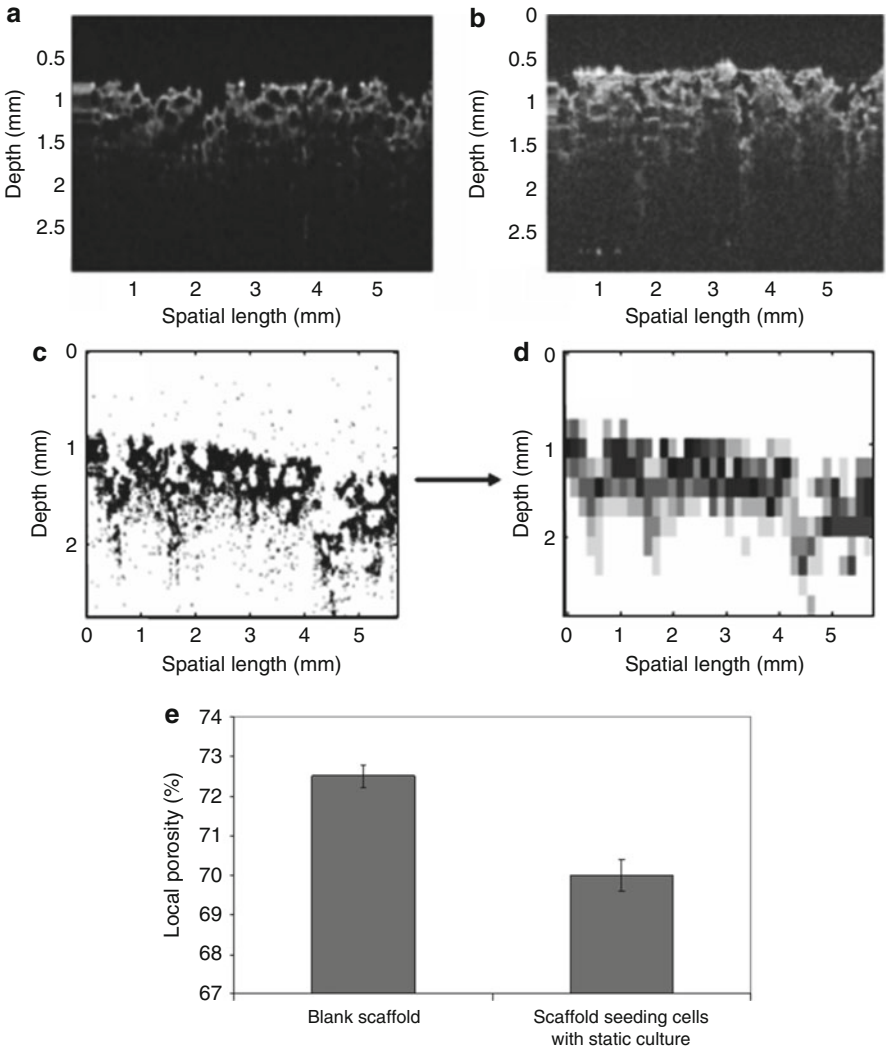

Fig. 64.7 OCT images porous scaffold seeded with cells. (**a**) A blank PLA scaffold and (**b**) a PLA scaffold seeded with MG63 bone cells following static culture for 4 weeks. (**c**, **d**) Accompanying diagrams illustrate an algorithm for calculating local porosity. (**e**) Resulting bar-chart comparison between a blank and seeded scaffold. *The error bars* represent standard deviation (Modified figures reprinted with permission from [56])

excluded. For each OCT scan, a threshold is set to discriminate between true empty pores and the pore walls. After binarization, the local porosity is calculated by a block processing method [56] demonstrated in Fig. 64.7c, d. The difference of porosity with statistical significance between a blank scaffold and cell-seeded scaffold is presented by this calculation method (Fig. 64.7e).

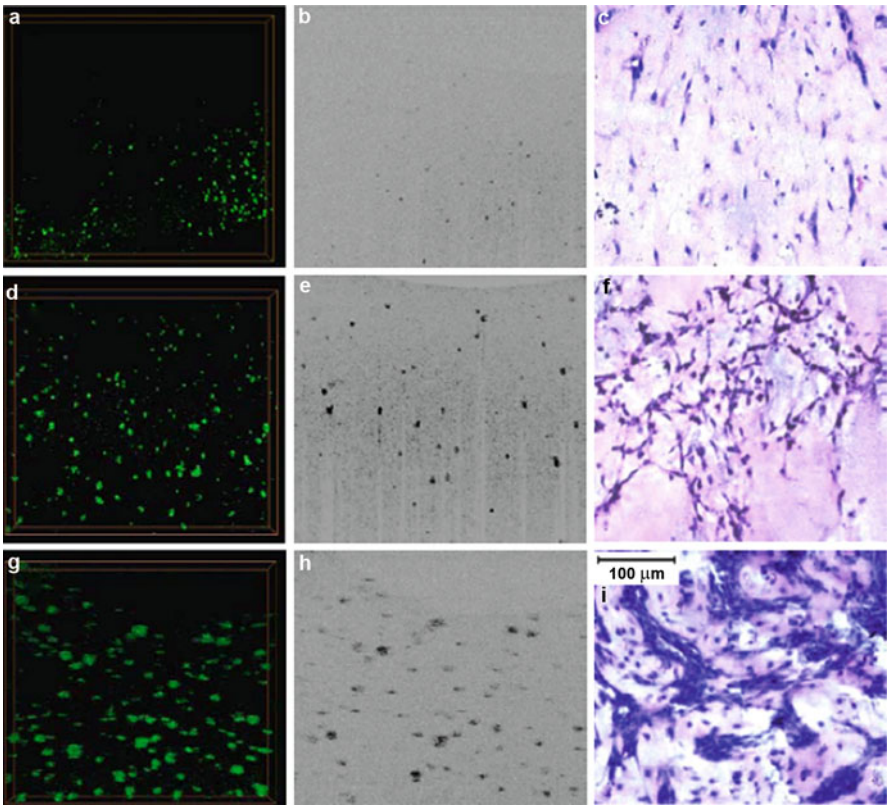

Fig. 64.8 OCT of cell proliferation in 3-D scaffolds. Images were acquired with low (5×10^4 cells) initial cell density. 3-D OCT images (**a**, **d**, **g**) and 2-D (x–z) OCT images (**b**, **e**, **h**) of engineered tissues were acquired on day 0 (**a**–**c**), day 4 (**d**–**f**), and day 8 (**g**–**i**). Histological images stained with H&E (**c**, **f**, **i**) are shown to confirm cell proliferation over time. Scale bar in (**i**) is applicable for all images (Figures reprinted with permission from [69])

64.3.4.2 3-D Cellular Dynamics (Proliferation and Migration)

Our understanding of cell dynamics in 3-D engineered tissues has been limited by our ability to visualize these processes. The use of OCT may play a significant role in tracking these dynamic cellular processes in not only engineered tissues but also for a more basic understanding of fundamental cell behavior. The proliferation patterns of cells within the engineered tissue scaffolds can be monitored, as shown in Fig. 64.8. Three-dimensional OCT imaging shows expanding scattering regions of cells after several days in culture. The increase in scattering is likely the result of both increasing cell numbers in these focal regions but also from the deposition of extracellular matrix secreted by the viable cells.

In addition to cell proliferation, cell migration plays an important role in tissue growth and development. Using repeated OCT imaging over several hours, the

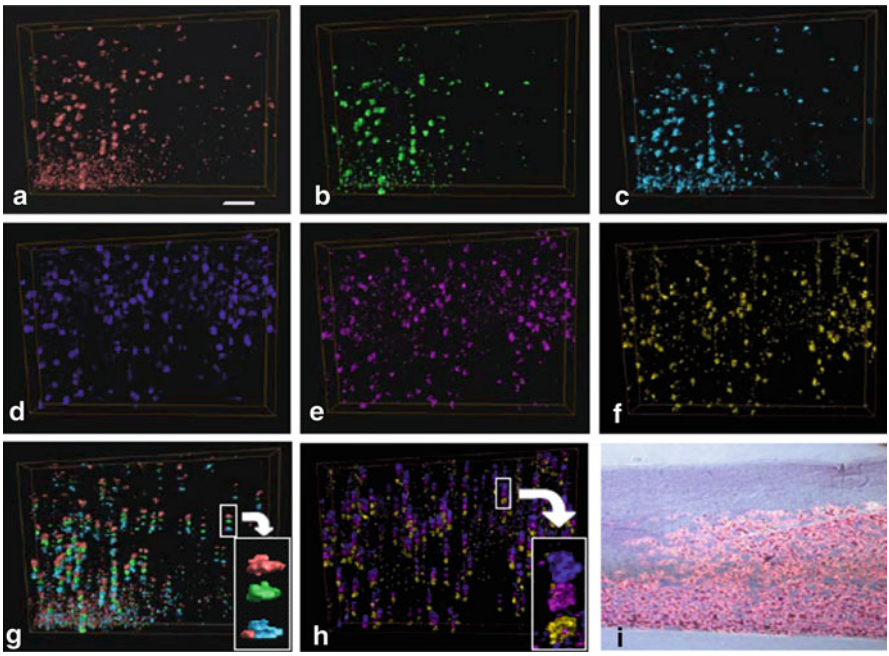

Fig. 64.9 OCT of cell migration. 3-D OCT images demonstrate the migration of macrophages (**a**–**f**). Cells at different points in time are labeled with different colors. The interval time is 40 min between (**a/b**, **b/c**, **d/e**, and **e/f**) and 120 min between (**c/d**). Individual OCT images are merged to form composite images of individual cell migration in 3-D space (**g**, **h**). Composite (**g**) is composed of (**a**–**c**) and composite (**h**) is a composed of (**d**–**f**). Insets in (**g**, **h**) show color-coded single-cell migration. Corresponding histology after the study is shown in (**i**), with macrophages collecting at the bottom. Scale bar is 200 μm (Reprinted image with permission from [69])

migration of macrophage cells was tracked as they moved through a 3-D agarose scaffold in response to a chemoattractant gradient. Images in Fig. 64.9 show the color-coded 3-D spatial position changes over time, with the downward cell migration toward the chemoattractant noted.

A second example of cell migration involves cell invasion through tissues, which is an essential step for tumor cells to metastasize. The invasive behavior of tumor cells in part depends on the cellular factors such as enzymes that enable cells to degrade their matrix components as well as on the characteristics of the extracellular matrix surrounding the cell. Therefore, a good knowledge of the cell-matrix interaction is useful when seeking treatment strategies aimed not only at cell killing but also at inhibition of tumor cell invasion and metastases. OCT offers a potential tool to observe and evaluate this process (Fig. 64.10). A model system with lung tumor cells grown on a collagen gel has been reported as a means to evaluate the tumor cell invasion ability [70]. The lung tumor cells grown on the gel with varying combinations of cell seeding number and collagen gel concentration have been scanned in OCT. It was found that OCT can differentiate cells and the gel.

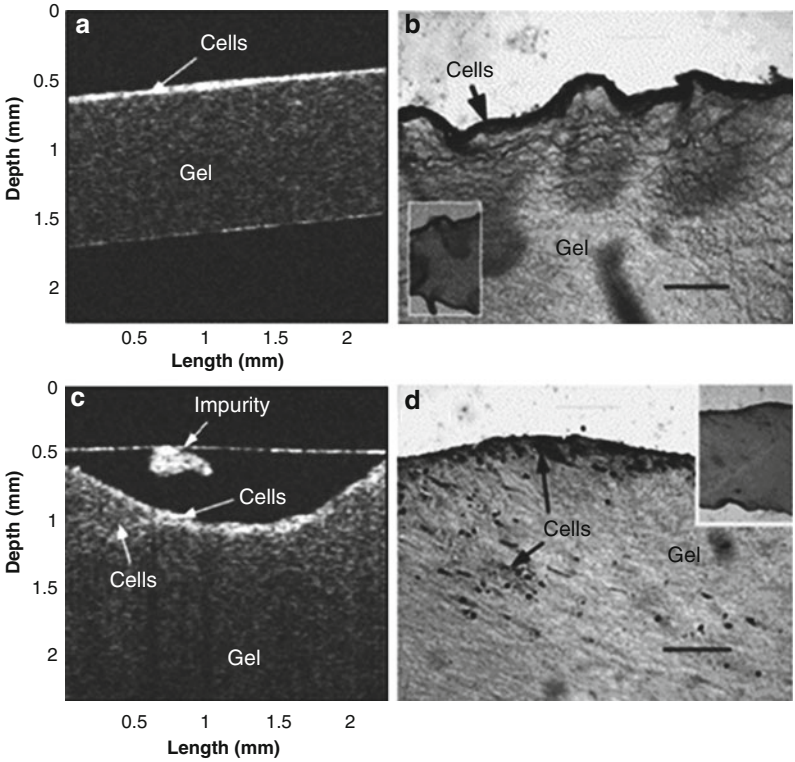

Fig. 64.10 OCT of tumor cell migration. (**a**) OCT image of lung cancer cells seeded on a collagen gel with (**b**) corresponding histological section of the specimen. (**c**) OCT image and (**d**) corresponding histology showing tumor cell invasion into the gel. *Scale bar* represents 100 μm (Reprinted with permission from [70])

With 1×10^6 lung cancer cells seeding on a collagen gel of 2.5 mg/ml concentration, a well-defined two-layer OCT image was obtained: a thin, brighter layer on top of a homogeneous, thick, and darker layer (Fig. 64.10a). The boundary between the layers is sharply delineated. By the nature of the cell seeding procedure, the brighter top layer is ascribed to the cells, while the underlying layer corresponds to the gel. The well-defined two-layer image indicates that there is no cell migration into the gel. However, OCT of the tumor cells seeded on a collagen gel of 1.5 mg/ml concentration invading into the collagen gel can also be visualized and confirmed by histological section images. The OCT images of the tumor cells on the gel reveal invasion, as shown in the image as a brighter diffuse top cellular layer plus additional similarly bright cellular foci infiltrating within the gel layer (Fig. 64.10c). Validation by histological sectioning of the cell and gel complex has drawn the same conclusion, which demonstrates that OCT can become a convenient optical imaging tool to study the dynamic process of tumor cell invasion nondestructively and in real time.

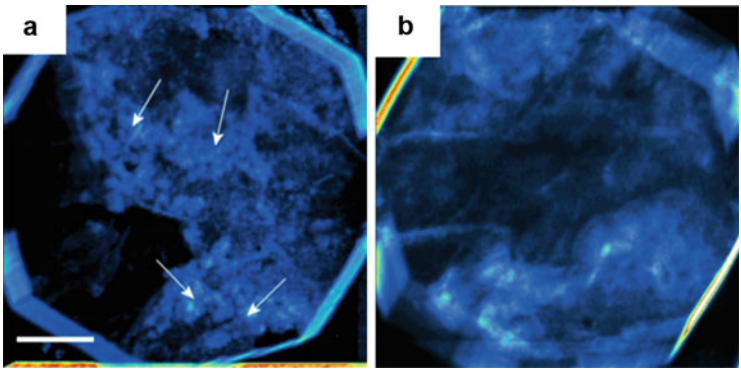

Fig. 64.11 Full-field OCT images of a PLLA scaffold. (**a**) Scaffold seeded with 1×10^6 bone cells and cultured for 1 week, compared with (**b**) that of a blank scaffold. Representative examples of cells are indicated by *arrows*. *Scale bar* represents 50 μm (Modified figures reprinted with permission from [67])

64.3.4.3 Single Cell Identification and Differentiation

We have shown that OCT has the capability to image and monitor cell dynamics in engineered tissue, but only populations or clusters of aggregated cells are resolved. Higher imaging resolutions are needed to visualize single cells and subcellular organelles with OCT. The high-resolution variant of OCT is called optical coherence microscopy (OCM) which uses high NA optics and ultrabroad bandwidth light sources, such as a tungsten lamp, to realize high resolution in 3-D [40], where the axial resolution is governed by the bandwidth of light source, as in conventional OCT, and the transverse resolution is determined by the high NA optics. In contrast to the cross-sectional images of traditional OCT, OCM usually generates images of en face planes, as in confocal or multiphoton microscopy. OCM operates in two modes, i.e., full-field OCM (ffOCM) and scanning OCM. ffOCM has been used to visualize individual pores and cell populations in tissue-engineered constructs. Figure 64.11 provides an example of images acquired with ffOCM where bone cells (1×10^6) were seeded in a PLLA scaffold for 1 week, together with an image from a blank scaffold for comparison [67]. Here several clusters of cells with roughly spherical cell morphology are seen attached to the PLLA scaffold wall in the 3-D microenvironment. Although still in a developmental stage, it is likely that ffOCT could not only offer the ability to visualize small cell populations in 3-D microenvironment as well as their attachment to and interaction with the scaffold wall but also provide informative sensory feedback to optimize scaffold manufacturing.

In scanning OCM, the transverse resolution is improved at the expense of the confocal parameter, and images are acquired in the en face plane by raster scanning the tight focus across the en face plane. Like ffOCM, scanning OCM can image deeper into highly scattering specimens, compared to confocal of multiphoton microscopy, because of the coherence-gated detection that rejects multiply scattered photons.

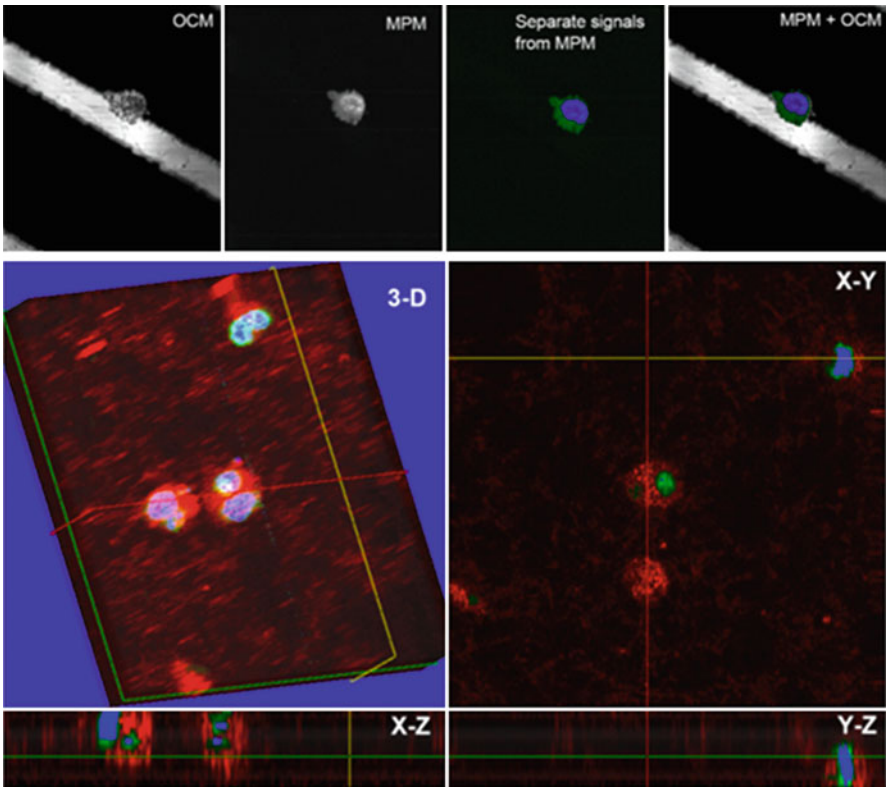

Fig. 64.12 Fibroblasts cultured on a microtextured (grooved) substrate and in a 3-D Matrigel matrix. (*Top row*) Multiple channels of OCM and MPM imaging data reveal information of the cell labeled with GFP and a DNA dye, as well as the unlabeled substrate ridges. (*Bottom images*) Overlaid OCM and MPM images of fibroblast cells in a 3-D scaffold show both structural and functional information (Modified figure used with permission from [42])

An example of cellular imaging with scanning OCM is shown in Fig. 64.12. These images were acquired with a multimodality microscope that combined spectral-domain OCM and multiphoton microscopy, as well as enable other spectroscopic OCM analysis [42, 71]. Two sets of images are shown in Fig. 64.12 that are relevant to tissue engineering. In addition to structural imaging, it is frequently advantageous to collect functional information pertaining to the behavior of the cells or tissue. The multimodality approach can achieve this, as OCM can provide the overall background scattering of not only cells but also the scaffold, while multiphoton microscopy can be used to detect specific labeled proteins or cellular structures and provide functional imaging as these proteins are expressed. A single fibroblast is shown in Fig. 64.12 (top row), attached to the top edge of a microgrooved polymer substrate. This fibroblast has been transfected with green fluorescent protein linked to the expression of vinculin, a cell-adhesion protein. Additionally, this fibroblast was co-labeled with a DNA dye to identify

the nucleus. The OCM image reveals both the cell and the grooved substrate, which provides more spatially relevant information than just the multiphoton image of the cell alone. This multimodality approach enables tracking of singly labeled cells of subcellular features against the background microenvironment. This is most relevant when observing single cells, or small populations of cells in 3-D engineered tissues, as is also shown in Fig. 64.12. Here, several fibroblasts are visualized in 3-D and, because of their 3-D microenvironment, take on a more spherical morphology, as opposed to the elongated spindle-shaped morphology when cultured in 2-D or subjected to external mechanical stimuli. OCM enables tracking of single cells, or small populations of cells in 3-D microenvironments, which will likely extend our basic understanding of cell dynamics in the developing engineered tissues, under different growth conditions and following external mechanical stimuli and under different pharmacological modulators.

In addition, recent efforts have been directed at identifying various cell populations within engineered tissues. While the use of fluorescent or OCT-sensitive contrast agents have been one means of identifying molecules or cells [37, 72, 73], analysis of the spectroscopic OCT signal can possibly provide insight into the spectral-scattering properties of individual cells, possible eliminating the need to add exogenous contrast agents that may either alter the function of the cells or reduce their viability in long-term cultures. Light-scattering spectroscopy has been shown to be sensitive to the size of dominant scatterers such as nuclei [74]. While much of this work has been in the use of wide-field techniques, efforts to use a tightly focused beam for spatially and depth-resolved imaging have been successful [75–77]. The high-numerical aperture optics used in OCM can address the inherent trade-off between high spectral and spatial resolution. By spatially confining the volume from which a spectrally scattered signal is generated, it may be possible to extract more information about the complex types, sizes, and numbers of scatterers [77]. The use of OCM enables this to be done not only in 2-D but also in depth.

Examples of the use of spectroscopic OCT/OCM to utilize the spectral-scattering information from a 2-D culture of cells and from a 3-D agarose scaffold seeded with cells are shown in Fig. 64.13. Wavelength-dependent spectral-scattering plots are shown for locations near the cell center and in the periphery, using a multimodality microscope that combines OCM with multiphoton microscopy [42]. By examining the autocorrelation of the signal from each of these locations, and measuring the full width at 80 % of the magnitude, it may be possible to identify scatterers or enhance contrast within spectroscopic OCT/OCM images [71, 78]. Using structural and spectroscopic OCT, images from 3-D cultures of macrophages or fibroblasts show interesting features. While the structural OCT images appear similar, with cells appearing more as amorphous scattering regions, the spectroscopic OCT images, using the autocorrelation width of the spectrally scattered signal, clear differences are noted between the cell populations. The macrophages exhibit a narrow autocorrelation peak compared to the fibroblasts, likely because the macrophages are more spherical in morphology, compared to the more spindle-shaped morphology of the fibroblasts. It still remains to be determined, however, what cellular components are most significantly affecting the SOCT signal.

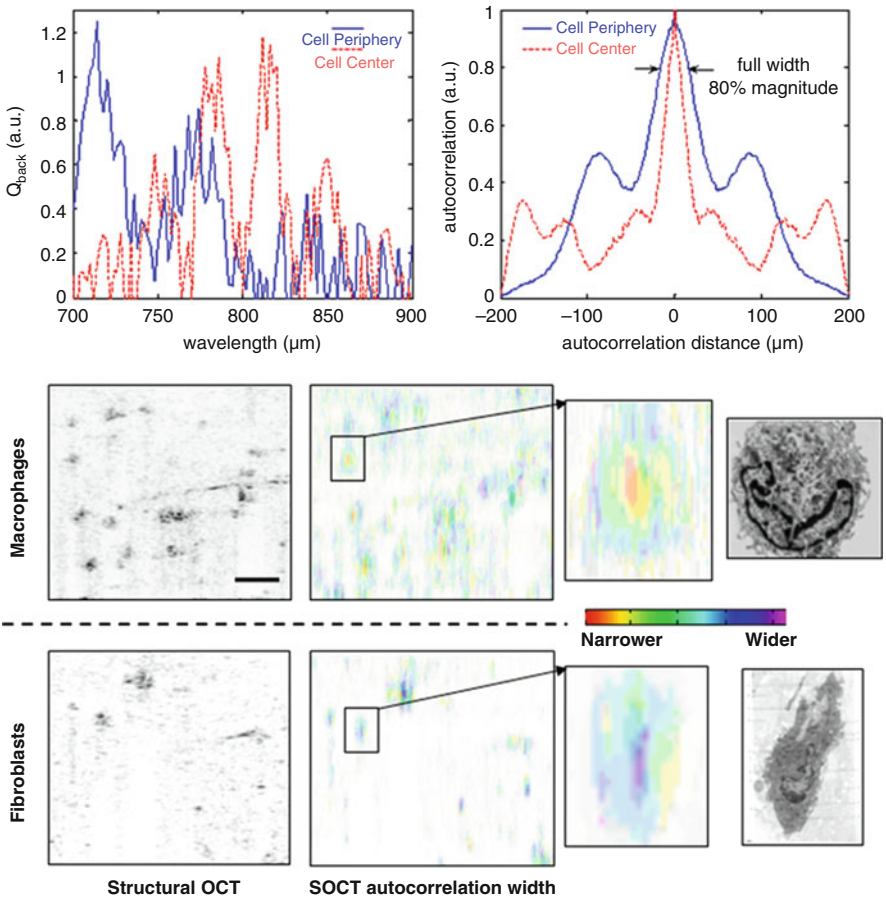

Fig. 64.13 Spectral-scattering data from single cells. (*Top row*) Spectral-scattering data and autocorrelation data from a single cell using spectroscopic spectral-domain OCM. Data was acquired from the cell center (over the nucleus) and from the cell periphery (from the cytoplasm). (*Middle, bottom rows*) Structural and spectroscopic OCT images of macrophages and fibroblasts in a 3-D scaffold. The spectroscopic OCT autocorrelation width may be used to distinguish cell types. *Scale bar* represents 100 μm (Modified figure used with permission from [77])

64.3.4.4 Imaging Cell Behaviors Under Static and Dynamic Growth Conditions

Static culture of constructs has been a simple, traditional, and widely used method. Recently, the use of mechanical stimulation applied during the growth of constructs in culture and in bioreactors has shown to improve cell distribution and enhance the biological and physiological activity of the cells. The remaining challenge is to nondestructively characterize cell activity and cell growth dynamics in response to these stimuli, both quantitatively and qualitatively. On the cellular level, structural OCM data, coupled with more functionally relevant multiphoton imaging of

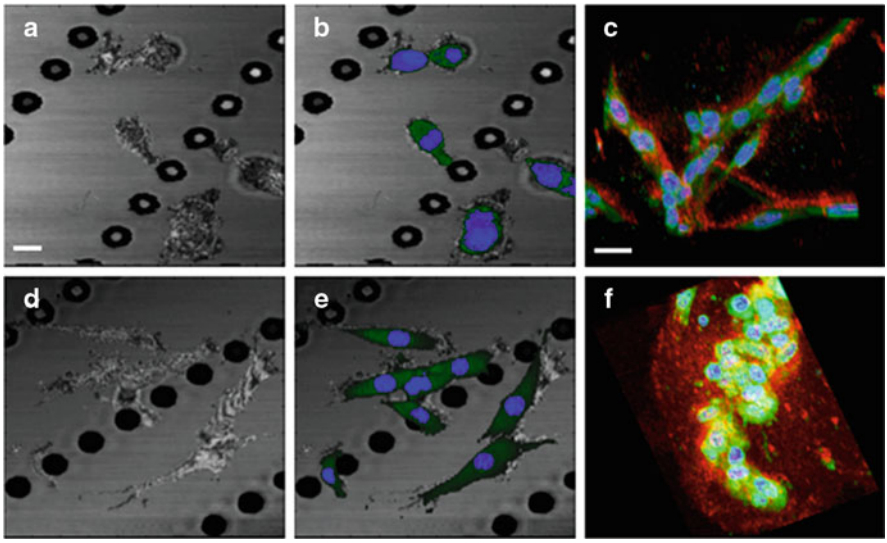

Fig. 64.14 Multimodality imaging of cells under static and dynamic culture conditions. (**a**, **b**, **d**, **e**) Images were acquired with a combined OCM-MPM microscope and represent GFP-vinculin and DNA-labeled fibroblasts on a flexible micro-pegged substrate and, (**c**, **f**) in a flexible 3-D agarose gel. Images were taken under static (**a**–**c**) and dynamic (**d**–**f**) culture conditions and show distinctly different cell morphology and GFP-vinculin expression patterns. *Scale bars* represent 100 μm (Reprinted with permission from [50])

GFP-vinculin expression has been demonstrated [42]. Examples of both micro-topography and 3-D scaffolds are shown in Fig. 64.14. Fibroblasts transfected to expressed GFP with vinculin were seeded on a 2-D topographic poly(dimethyl-siloxane) (PDMS) polymer scaffold comprised of rows of micro-pegs, and in a 3-D agarose scaffold [50]. OCM enabled the visualization of all scattering structures, from both the cells and from the scaffolds. Multiphoton microscopy detected the two-photon fluorescence from GFP-vinculin, which revealed more of the functional behavior of the cells interacting with the scaffold or with other cells. The flexible PDMS scaffold was subsequently amenable to mechanical stimuli by 18-h 5 % cyclic equibiaxial stretching. Similarly, the 3-D agarose gel was subjected to uniaxial mechanical stretching. Following mechanical stimulation, cells in both scaffolds exhibited reorientation along the direction of stretch, as well as a marked increase in GFP-vinculin expression. Further OCM/OCT imaging is possible for extended periods of time, and ongoing efforts are characterizing both the qualitative and quantitative parameters associated with mechanical stimuli.

The effect of static and dynamic growth conditions on cellular behaviors can be semi-quantified based on the OCT image data using the same technique described in section 64.3.4.1, Figure 64.7c–d. A systematical study has been undertaken [56] in which a bone cell-PLA construct was subjected to perfusion culture conditions in a bioreactor in comparison to static culture. The full osteogenesis culture media was flowed continuously through the construct at 0.1 ml/min flow rate for 1 week after

3 weeks of static culture. Compared to the construct which used the same type of scaffold and cell seeding conditions but grown under static cultured for 4 weeks, perfusion culture generates dramatic changes in cell growth profile as manifested by the increased number of closed pores and interconnected structures in the OCT image. By calculating the local porosity based on the OCT images, a statistically significant lower porosity in the perfused construct is demonstrated compared to the construct cultured under static conditions, implying that culture in perfusion conditions improves cell proliferation and tissue turnover. This evaluation derived from the OCT images is consistent with the protein analysis of the constructs in a parallel work [79]. These results demonstrate that OCT is capable of monitoring cell growth profiles under different culture conditions based on its ability to quantify the change of pore architecture in the constructs.

64.3.5 Integrated Imaging Methods

While OCT, OCM, and its many variants such as spectroscopic, polarization, and Doppler analysis provide a wide range of diagnostic information on engineered tissues, further insight can be gained by integrating OCT with other imaging methods. In particular, fluorescence-based and nonlinear imaging modalities can assist OCT with investigation of engineered tissue by providing new contrasts and functional extensions.

The implementation of high numerical-aperture optics in OCM confers many advantages including higher transverse imaging resolution, en face sectioning deep into highly scattering specimens, and potentially higher image contrast due to both the confocal and coherence rejection of out-of-plane photons. OCM has been combined with confocal fluorescent microscopy in a colinear geometry to visualize fluorescently stained osteoblasts and the structure of a microporous polymeric scaffold [80]. The use of multiphoton microscopy confers many advantages for biological imaging including improved resolution, deeper imaging penetration, and less absorption or risk of thermal injury to cells with the use of longer wavelengths of light. It has been recognized that both multiphoton microscopy (MPM) and OCM can utilize the same laser source, such as the commonly used mode-locked titanium:sapphire laser [42, 81]. An example application of multimodal microscope for tissue engineering is shown in Fig. 64.15, where representative images OCM, MPM, and spectroscopic OCM are presented. The images in Fig. 64.15 demonstrate the multimodality approach, where in addition to OCM, spectroscopic OCM analysis methods can reveal the location of strong spectral scatterers (nuclei) in the OCM data (Fig. 64.15b). These findings are validated using multiphoton microscopy of nuclei stained with a fluorescent DNA dye (red) that identifies the spatial position of the nuclei within the cells in this culture.

As another example, a multimodal microscope combining OCM, MPM, and fluorescence lifetime imaging microscopy (FLIM) [82] has also been demonstrated for imaging of engineered tissue [43]. Incorporation of FLIM adds new contrast capabilities, as evident by images of a microporous fibroblast-seeded hydrogel scaffold that were obtained with different modalities (Fig. 64.16). As shown in Fig. 64.16,

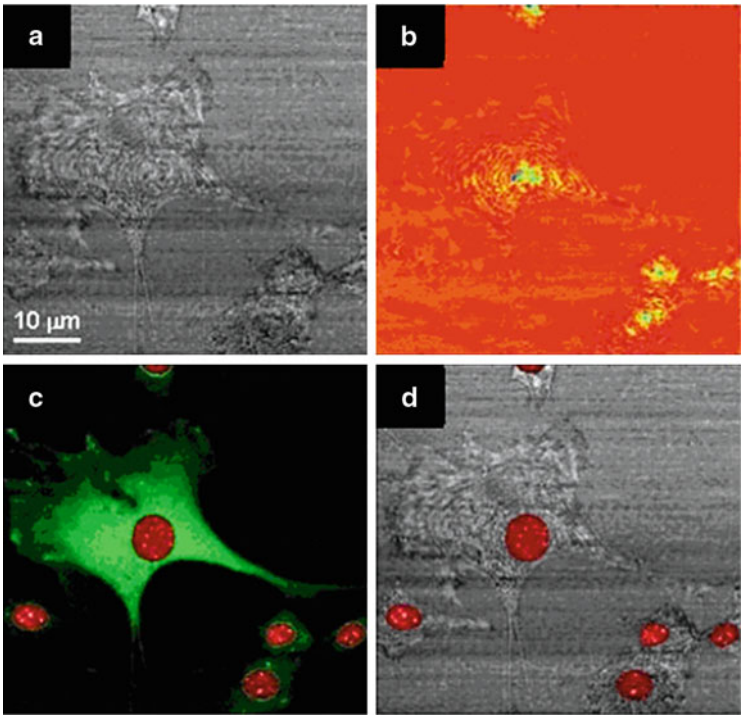

Fig. 64.15 Multimodality microscopy. Images acquired simultaneously from GFP-vinculin and DNA-labeled fibroblasts. (**a**) Spectral-domain OCM. (**b**) Spectroscopic OCM showing regions of strong spectral scattering corresponding to the location of the nuclei. (**c**) MPM with *green* representing the GFP-vinculin and *red* representing the DNA dye. (**d**) Overlay of OCM and the MPM DNA dye signals validating the locations of the nuclei in the cells as detected by spectroscopic OCM (Reprinted with permission from [71])

while the cell morphology and the microporous structure of the hydrogel are clearly differentiated and well observed with both OCM and MPM, they are not well separated in the MPM image, because of the spectral overlap between the autofluorescence from the hydrogel and the autofluorescence from cells. In some cases of fluorescence imaging of engineered tissue, in fact, autofluorescence from the scaffold material may interfere with visualizing the details of the cellular structures, and other contrast mechanisms must be used for better signal separation. FLIM clearly distinguishes the hydrogel from the cells based on the different lifetimes of the two fluorescence emissions, shown as different colors in Fig. 64.16. Additionally, FLIM has been demonstrated for monitoring cellular metabolism based on the lifetime change of autofluorescence from reduced nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide (FAD) [83]. This functional molecular imaging has also been demonstrated with the integrated system, showing its capability to evaluate the health and viability of the developing or mature engineered tissue [43].

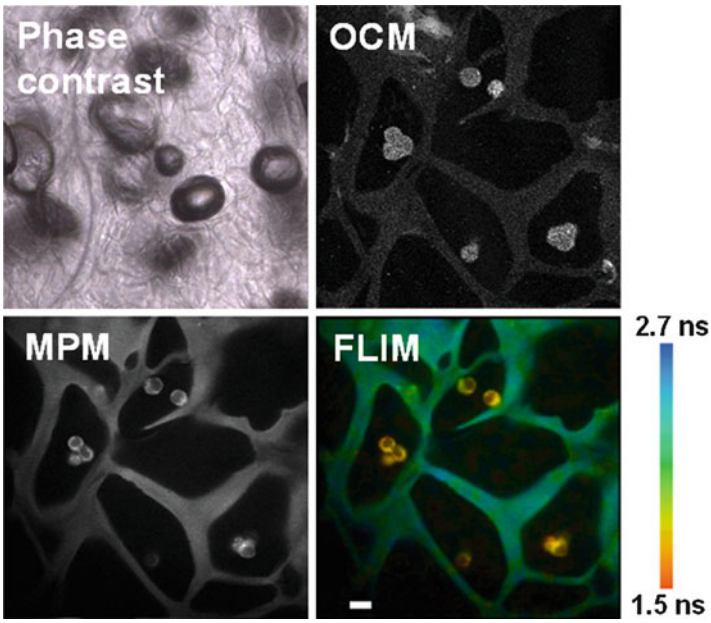

Fig. 64.16 Multimodal images of a microporous 3-D hydrogel scaffold seeded with 3T3 fibroblasts. Representative images are based on phase contrast, OCM, MPM, and FLIM. *Scale bar* represents 20 μm (Reprinted with permission from [43])

64.4 In Vivo Investigation of Post-Implant Cell Dynamics Using OCT

Functional replacement of natural tissues by engineered tissues is the ultimate goal of tissue engineering and regenerative medicine. Posttransplant dynamics and restorative processes have to be investigated and monitored to obtain the necessary information to evaluate the efficacy of treatment. This information will also be used for guiding the control of the culturing conditions to produce physiologically relevant tissues or organs. In this context, a high-resolution, noninvasive imaging tool is highly desired to longitudinally monitor the integration of implanted tissue and the response from the natural tissue at the transplant site. OCT holds promise in this regard. For example, OCT has recently been used to monitor the wound-healing process after implantation of a hydrogel scaffold [84]. As shown in Fig. 64.17, OCT images reveal the structures of wound beds in normal and diabetic mice 7 days after engraftment of hydrogel scaffolds composed of N-carboxyethyl chitosan, oxidized dextran, and hyaluronan. Comparisons between OCT images and their corresponding histological sections demonstrated the unique utility of OCT to unequivocally track the presence of the hydrogel in the wound bed and additionally to discern the morphophysiological transformation of the healing wound covered by the hydrogel scaffold. Generation of granulation tissue and degradation of the

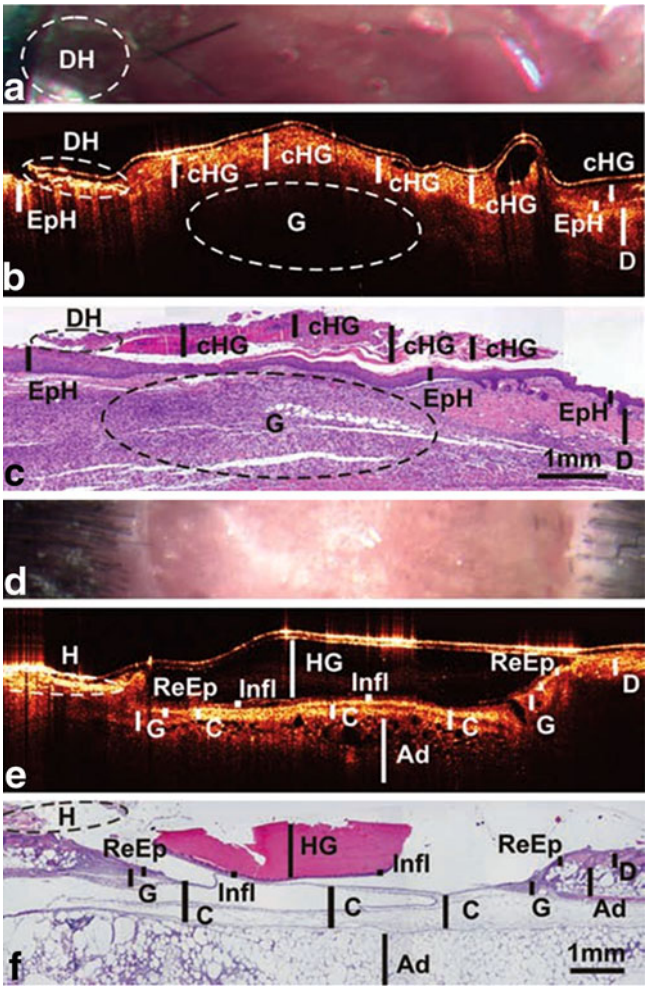

Fig. 64.17 Surface, cross-sectional OCT images, and histological sections of hydrogel implant-assisted wound healing in normal (**a–c**) and diabetic (**d–f**) mice. *D* dermis, *G* granulation tissue, *C* connective tissue, *Infl* inflammatory reaction, *EpH* epidermal hyperplasia, *HG* hydrogel implant, *cHG* cell-infiltrated HG that underwent partial degradation (showing increased scattering), *DH* dehydrated hydrogel implant (ultrahigh scattering), and *H* hair (high scattering). Because of high scattering in cHG, the underlying structures, for example, EpH and granulation tissue, were not detectable in OCT image (**b**) (Reprinted with permission from [84])

hydrogel scaffold is observed in the normal mouse. The formation of granulation and connective tissue and the presence of a non-degraded scaffold in the diabetic mouse are clearly resolved by the OCT images and confirmed with histological images in parallel, showing the capability of using OCT to monitor the morphological changes associated with the wound-healing process.

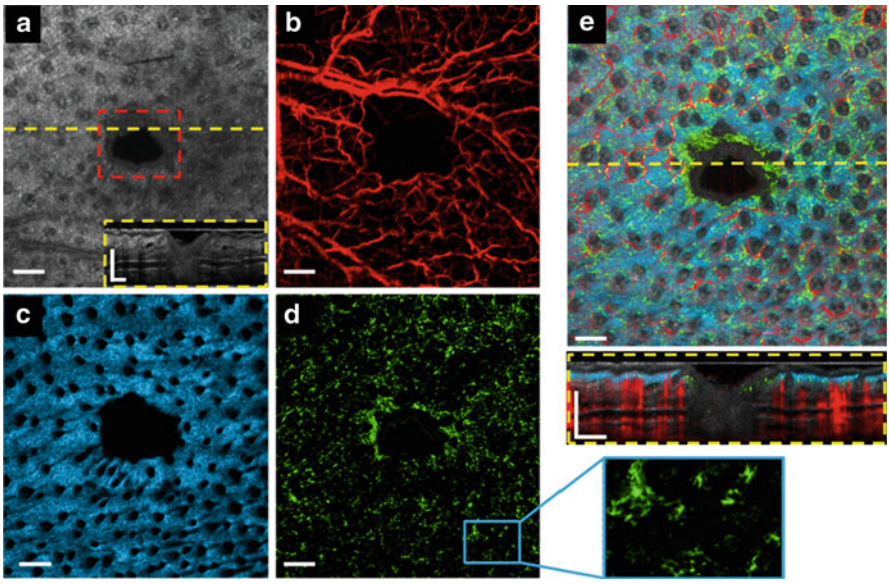

Fig. 64.18 Multimodal imaging of ear skin in a GFP BM-transplanted mouse 10 days following an excisional wound. (**a**) En face structural OCT section showing individual hair follicles and the wound site (*red box*). Cross-sectional image in the inset shows various layers of the skin at the position of the *yellow dashed line*. (**b**) Projection of the OCT phase variance volume along the axial dimension showing the microvascular network. (**c**) Wide-area SHG mosaic of collagen. The central dark region represents the wound, while the hair follicles appear as smaller dark regions. (**d**) Wide-area TPEF mosaic of the GFP expressing BM-derived cells in the skin and a magnified view of individual GFP cells. (**e**) En face image of the four modalities overlaid and cross-sectional view (*bottom*) at the position of the *yellow dashed line*. Scale bars are 250 μm (Reprinted with permission from [51])

As a further advance, the wound-healing process may be better characterized by OCT combined with other intravital imaging modalities. Complementary imaging techniques that have cellular resolution will facilitate the observation of cellular dynamics in detail. One example is shown in Fig. 64.18, which shows multimodal images of a wound bed in bone-marrow (BM)-transplanted GFP-mouse skin obtained with an integrated microscope combining OCT and MPM.

An OCT image is presented in Fig. 64.18a, which visualizes structural features based on the optical scattering properties and, in particular, resolves the different skin layers including the epidermis, dermis, and subcutaneous fat. OCT phase variance [85], which is another functional variant of OCT, provides a view of the microvasculature based on the dynamic motion of blood flow retrieved from the phase variance in OCT data. SHG imaging visualizes the collagen matrix in the dermis of the skin and provides a view of the individual hair follicles, in addition to the collagen reorganization within the wound (Fig. 64.18c). TPEF imaging allows individual BM-derived GFP-expressing cells to be detected in the skin (Fig. 64.18d). The combination of these modalities allows a wide range of complementary

information about living skin to be obtained noninvasively. Overlaying these modalities allows the microenvironments of individual GFP cells to be visualized in three dimensions (Fig. 64.18e). Most importantly, this multimodal imaging combination is noninvasive and does not require the use of exogenous contrast agents, making it suitable for repeated imaging to observe dynamics that occur during skin regeneration. This technology holds the promise for studying the post-engraftment dynamics of cells and tissues, such as in the case of skin wounds and grafts, skin contraction, scarring, vascular network regeneration, collagen deposition, etc., which are important processes associated with wound healing and tissue regeneration.

64.5 Summary

This chapter has explored and reviewed the use of OCT in the field of tissue engineering. Many of the extensions of the OCT technology, including OCM, spectroscopic OCT/OCM, polarization-sensitive OCT, Doppler OCT, and OCE have only further expanded our ability to interrogate engineered tissues. As the field of tissue-engineering transitions from 2-D to 3-D cultures, from static to dynamic growth conditions, and from in vitro to in vivo constructs, it is clear that OCT will offer new investigative methods that will expand our understanding of complex cellular processes and how these contribute to the organization of cells into a functional and physiologically meaningful engineered tissue that would have medical application.

Acknowledgements We wish to thank our many colleagues and collaborators conducting research in this area, and apologize that due to length requirements, we are unable to highlight more results. Some of the recent studies reported in this chapter were supported in part by a grant from the U.S. National Science Foundation (CBET 10-33906, S.A.B.).

65.1 Introduction

The heart of a human fetus begins beating approximately 3 weeks after conception. At this point, the heart is a linear tube. Next, the heart will form first a simple c-shaped loop and then an s-shaped loop before forming the four chambers of the adult heart. This critical process is a complex coordination of many events where small deviations can lead to abnormal development and congenital heart defects (CHDs). Mechanisms of CHDs remain largely unclear despite being the focus of many investigations. Contributing factors of CHDs include single-gene mutations, complex chromosomal rearrangements [1], and environmental agents (e.g., alcohol [2], viral infections [1, 3], hypoxia [4, 5], etc.). Although strong evidence exists to suggest that altered cardiac function can lead to CHDs [6–15], few studies have investigated the influential role of cardiac function and biophysical forces on the development of the cardiovascular system due to a lack of proper in vivo imaging tools. The lack of in vivo imaging instrumentation for early embryos becomes even more dire when one considers the fact that causes of CHDs are most likely multifactorial. For example, if a gene mutation alters molecular signaling and

cardiac function, it is currently not possible to discern if the resultant defects are produced by the altered mechanical function or molecular signaling or a combination. Imaging tools for investigating the live embryonic cardiovascular system early in development would have three major benefits. First, quantifying cardiac function and forces can be a sensitive assay to determine critical time points in the sequence of events leading to CHDs giving clues to the underlying mechanisms. Second, quantifying forces impinging on the cardiovascular system during both normal and abnormal development would enable one to determine the causal relationship between biophysical forces and molecular signaling. Lastly, imaging can be implemented to monitor interventions for improved accuracy and precision.

A suitable in vivo imaging modality for investigating early stage embryonic hearts must have high spatial resolution to resolve the pertinent structures (e.g., endocardium, myocardium, etc.) in the minute heart tube, sufficient depth penetration and field of view to visualize the heart in vivo, and high temporal resolution for real-time imaging. Common animal models utilized for heart development research include avian (e.g., chicken and quail), murine, zebrafish (*Danio rerio*), fruit fly (*Drosophila melanogaster*), and frog (*Xenopus laevis*). Microscopy (e.g., confocal) has the spatial resolution, penetration depth, and temporal resolution for in vivo investigations involving the zebrafish, frog, and fruit fly. Unfortunately, these models do not develop a four-chambered heart and have significant limitations, although they are excellent models for genetic screening. Optical coherence tomography (OCT) has become increasingly popular as a tool for investigating development of the four-chambered heart (avian and murine) [16–18]. Avian and murine hearts develop in a very similar manner to humans. OCT has greater penetration depth (1–2 mm) than microscopy which allows in vivo imaging of the avian and murine heart early in development when the heart is a looping tube. OCT also maintains high enough resolution (2–20 μm) to discern features of the developing heart tube which can be less than a millimeter in length and can achieve high temporal resolution.

Figure 65.1 orients the reader to the anatomical structures of the developing embryo and typical OCT images [19]. Panel A shows a bright-field microscopy image of an early stage quail embryo (stage 14). Arrows designate the inflow and outflow (outflow tract) portion of the heart tube. The green dotted line reveals the location of the OCT cross-sectional image in panel B. From panel B, one can see the three main structures in the developing heart tube. The myocardium forms the exterior of the heart and is only two cell layers thick at the time point shown. The epicardium does not develop until later. The endocardium forms the lumen of the heart tube and is in direct contact with the blood. Finally, the cardiac jelly is a gelatinous material between the endocardium and myocardium and is essential for proper development of the valves and septa. Panels C and D demonstrate the capability of Doppler OCT to perform flow imaging in the outflow tract. The top panel shows forward flow (red), while the bottom panel displays retrograde flow (blue). Doppler OCT offers the ability to measure hemodynamic function and forces in the early embryo heart. The images in Fig. 65.1 demonstrate the potential of OCT to be useful in developmental cardiology studies.

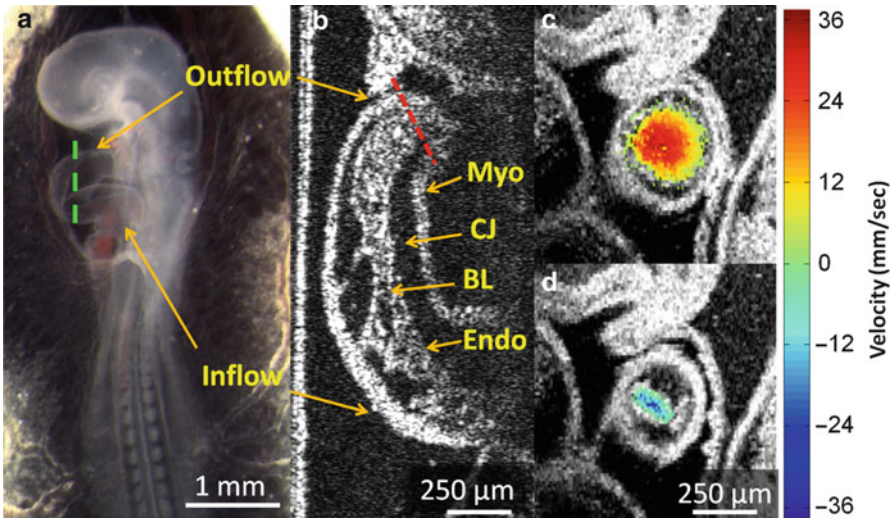

Fig. 65.1 Anatomical structure of the developing embryo. (**a**) displays a quail embryo imaged at 12× magnification. (**b**) shows a B-scan image of the quail embryo heart imaged by OCT. The *green dotted line* approximates the location of the B-scan. OCT allows visualization of all layers in the heart tube (myocardium, cardiac jelly, and endocardium) in both the inflow and outflow regions. (**c**, **d**) Doppler OCT data are overlaid on a structural B-scan of the outflow tract during diastole and systole. The *red dotted line* in B gives the approximate location. The color map is shown to the *right of* the image. *Myo* myocardium, *CJ* cardiac jelly, *BL* blood, *Endo* endocardium

Early demonstrations of imaging the developing heart using OCT demonstrated its ability to visualize cardiac dynamics in one and two spatial dimensions versus time [20–23]. 1-D and 2-D imaging over time opens up the possibility of many exciting experiments. However, biomechanical forces acting upon the heart are often spatially heterogeneous and varying in time. For example, not only does shear stress on the endocardium vary greatly along the length of the heart tube, but certain regions experience oscillatory shear due to regurgitant flow [10]. In order to fully assess complex patterns of biophysical forces, it is necessary to image the beating heart with high spatiotemporal resolution in four dimensions (x, y, z, and time). This is what we refer to as 4-D imaging. Cardiac function and the resultant forces are constantly evolving throughout development. Biomechanical cues are vital for proper growth and maturation. Shear stress on and stretch of the endocardium, strain in the myocardium, and electrical signals have all been implicated as necessary for normal development [6–15]. Also, small deviations in biomechanics can signify that the embryo is developing a CHD. Deciphering the complex spatial and temporal patterns of biomechanical forces acting upon the heart is necessary to fully understand the role of function in the developing embryo.

Numerous solutions over the past several years have demonstrated 4-D OCT imaging of the developing cardiovascular system. This chapter will focus on these solutions and explain their context in the evolution of 4-D OCT imaging. The first sections describe the relevant techniques (prospective gating, direct 4-D imaging,

retrospective gating), while later sections focus on 4-D Doppler imaging and measurements of force implementing 4-D OCT Doppler. Finally, the techniques are summarized, and some possible future directions are discussed.

65.2 Prospective Gating

Cardiac-gated imaging enables the capture of 4-D image data sets by mitigating motion artifacts when the temporal resolution of the system is inadequate for direct 4-D imaging (real-time volumetric imaging). Because cardiac motion is highly repetitive, one can build up a 4-D image set of the beating heart over multiple beats. For prospective gating, a physiological signal is used to trigger data acquisition at specific phases of the cardiac cycle. After several heartbeats, one collects data of the beating volumetric heart by acquiring more data at each cardiac phase with each subsequent heartbeat. Prospective gating has been implemented in several medical imaging modalities found in the clinic including MRI and CT [24, 25].

In 2006 Jenkins et al. used a prospective gating technique to capture 4-D OCT images of beating avian and murine hearts [26]. Because of the difficulties of obtaining a steady physiological trigger signal, the heart was excised and paced as a first step to prove the principle. Specifically, hearts were excised in a Tyrode solution and placed between two platinum plates. A 50 ms electrical pulse both paced the heart and triggered data acquisition. The Tyrode bath was kept at room temperature which lowered the heart rate and enabled pacing at 1 Hz. A time domain OCT system with a bandwidth centered around 1,300 nm acquired data at 4,000 A-scans/s with an axial resolution of 14 μm and a lateral resolution of 10 μm. Sixteen cardiac volumes were captured per heartbeat with imaging of one heart lasting less than 5 min. Chicken embryos were imaged at stage 13, 15, and 20, corresponding to 2–3 days of development, while mouse embryos were imaged on day 13.5. Images were averaged and filtered to reduce noise before correcting the aspect ratio and creating surface renderings of the 4-D structures. Measurements of cardiac volume, ejection fraction, and wall thickness were demonstrated, although some of the measured values probably differ from in vivo measurements made under physiological conditions. This work demonstrated the feasibility of 4-D OCT imaging of a paced, excised heart, but not of the beating heart in an intact, living embryo.

Obtaining ECG signals from patients in the clinic is a simple procedure and can easily be utilized to gate image acquisition. Unfortunately, obtaining a proper ECG signal from an early stage embryo is both difficult and invasive. To overcome this challenge and enable in vivo 4-D imaging, Jenkins et al. designed a prospective gating technique by triggering data acquisition with a laser Doppler velocimetry (LDV) signal [27]. Briefly, a commercial LDV needle probe (Moor Instruments Incorporated, Wilmington, Delaware) was positioned adjacent to a vitelline vessel of a stage 14 quail embryo cultured on the yolk in a Petri dish on a temperature-controlled heating pad (37 °C). The choice of vitelline vessel was not important as long as a strong signal was obtained. The signal was conditioned and then directed

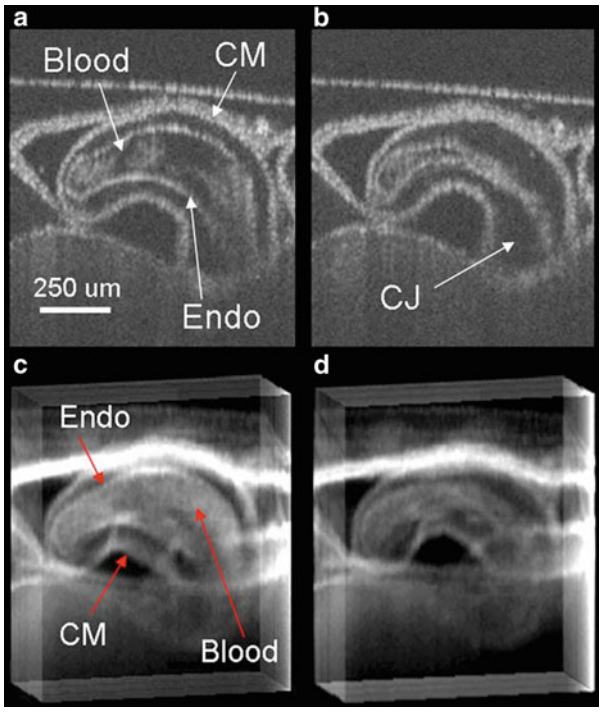

Fig. 65.2 Prospective gating employing a laser Doppler velocimetry (LDV) probe. (**a**) OCT B-scan acquired during diastole cut coronal to the body of the embryo. (**b**) OCT B-scan acquired during systole cut coronal to the body of the embryo. (**c**) Digitally reconstructed radiograph image acquired during diastole. (**d**) Digitally reconstructed radiograph acquired during systole. Digitally reconstructed radiographs project signal intensity along the sagittal orientation. *CM* is the compact myocardium, *endo* is the endocardium, and *CJ* is the cardiac jelly

to a commercial R-wave detector (AccuSync Medical Research Corporation), which produced two triggers: one at the peak of the LDV signal and one at the bottom of the downward slope. Finally, a field programmable gate array (FPGA) received inputs from the R-wave detector and a line-sync from the OCT delay line to produce a frame sync and to control the scanning. The OCT system was identical to the one used in the previous study. Eight heart volumes were collected. Figure 65.2 displays 2-D cross-sections and 3-D volumes (digitally reconstructed radiographs) of a stage 14 quail embryo heart in vivo during systole and diastole. Excellent initial results were demonstrated with prospective OCT gating using LDV, but the requirement of an external signal is a disadvantage relative to direct 4-D imaging and signal-free retrospective gating (which have become feasible using current, high-speed OCT systems) due to decreased set up time. However, prospective gating does require less computation time than retrospective gating which can be advantageous for certain applications.

65.3 Direct 4-D Imaging

Direct 4-D imaging is defined as real-time volumetric imaging without the aid of gating techniques. Until recently, OCT systems were not capable of 4-D imaging of embryo hearts without gating due to insufficient imaging speed, but as speeds have

dramatically increased, 4-D imaging has become feasible with limited spatiotemporal resolution. This step forward is attributed to the paradigm shift to frequency-domain OCT systems and the development of high-speed swept laser sources [28–33]. Details of these developments are presented in other chapters of this book.

Jenkins et al. demonstrated direct 4-D imaging of embryonic quail hearts using a Fourier domain mode-locked (FDML) laser [34]. The high-speed swept source allowed imaging speeds of 100,000 A-scans/s. The axial resolution in tissue was 7 μm, while the lateral resolution was 15 μm. 4-D imaging of stage 14 quail embryos was collected at ten volumes/s (70 × 150 A-lines/volume). Embryos were cultured on a yolk in a Petri dish and imaged on a temperature-controlled plate (37 °C). Because the embryos were not imaged in an incubator, the heart rates were slightly depressed (∼2 Hz), resulting in 4–6 volumes per heartbeat. Several visualization techniques were also demonstrated, including digital reconstructed radiographs, Sobel filtering, and multiplanar reformatting. Figure 65.3 displays the top view of a stage 14 quail embryo heart where a 3-D Sobel mask was applied to the data to bring out the edges of the structures. In 2008, Gargesha et al., using a similar system, demonstrated that volume visualizations applying a 2-D opacity transfer function and image denoising could improve 3-D visualizations and automated segmentation of 4-D data sets [35]. Considering that the maximum wall velocity can reach almost 2 mm/s, a volume must be imaged in 5 ms in order to reduce motion artifact below 10 μm [34]. The authors noted that in order to accurately capture the 3-D motion of the heart tube without gating, faster imaging systems were needed.

Yelin et al. demonstrated 4-D OCT imaging of stage 49 *Xenopus laevis* hearts using a wavelength-swept laser with a polygon scanner-based spectral filter [36]. 54,000 A-scans/s were captured allowing for 20 volumes/s with each volume consisting of 60 × 45 × 256 pixels. The axial resolution was 10 μm in tissue. Embryos were covered by an anesthesia solution and positioned ventral side up on an agar plate. Displacement maps were constructed to show myocardial motion at different phases in the cardiac cycle. Again, although 4-D imaging was demonstrated, meaningful measurements were not possible because of the limited speed of the system.

Direct 4-D OCT imaging is attractive for several reasons which include decreased procedure time, reduced post processing, no increased noise due to abnormal beats, and the ability to capture nonperiodic events like arrhythmias. Over the last several years, FDML lasers have increased OCT imaging speed dramatically including a demonstration of 20 MHz A-line rates [37]. This extraordinary increase can enable direct 4-D imaging with sufficient spatiotemporal sampling (e.g., volumes 2 mm × 1.25 mm transversely in 5 ms) and obviate the need for gating.

Unfortunately, an OCT system this fast is very complex and expensive. Data acquisition and handling are extremely challenging, and adequate commercial DAQ products are not presently available. Real-time data visualization at these rates is also a challenge. Several demonstrations have been reported of real-time 4-D OCT display of tissue structures utilizing graphics processing units (GPU) [38–40].

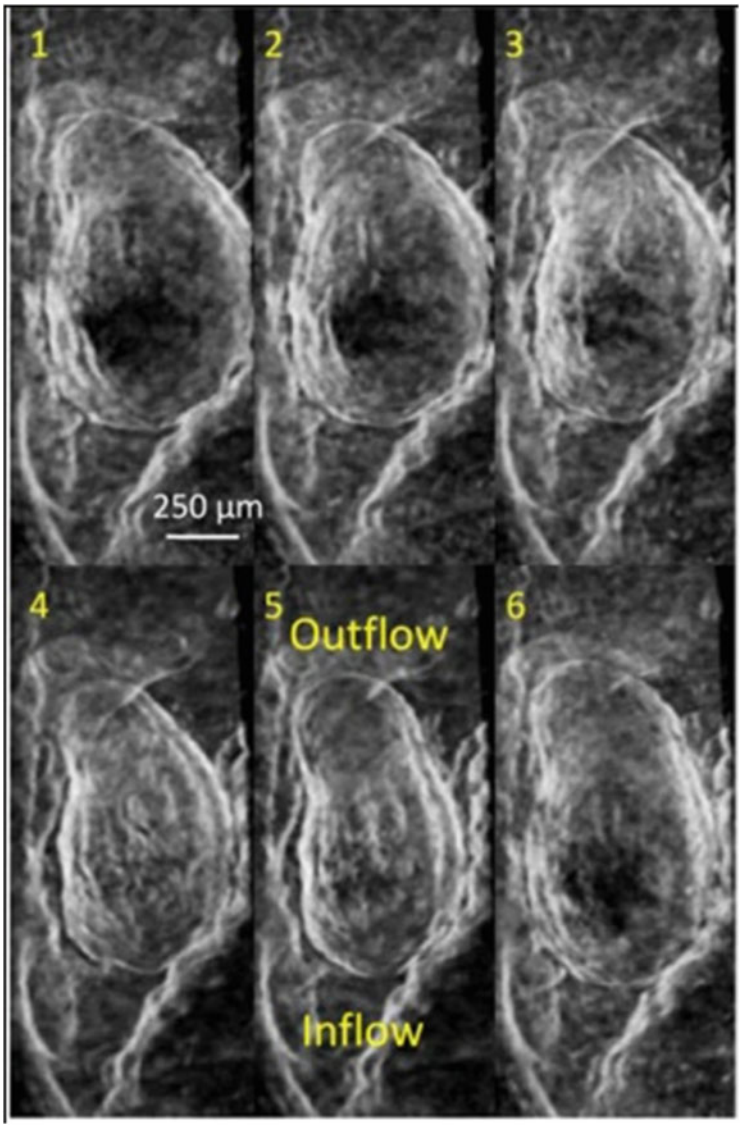

Fig. 65.3 Top view (*ventral*) of a beating stage 14 quail heart (six phases in the cardiac cycle). Data are visualized as an edge-enhanced volume rendering (Data was collected through 4-D direct imaging)

Although these systems need to improve data throughput to visualize the developing embryo heart in a meaningful way, it is likely that new developments in OCT technology and GPUs will enable this in the future.

4-D Doppler OCT imaging will remain difficult without gating. Doppler OCT requires denser spatial sampling than is needed for structural OCT, slowing

imaging speed. Also, because scanning speed dictates the detectable velocity range, capturing 4-D Doppler datasets would be require innovative scanning patterns.

65.4 Retrospective Gating

65.4.1 Signal-Based Retrospective Gating

A signal-based retrospective gating scheme records a physiological signal simultaneously with the image data. Unlike prospective gating where the physiological signal gates data acquisition, here the signal is utilized in a post processing algorithm to parse the data into the appropriate phases of the cardiac cycle creating a 4-D data set. Yazdanfar et al. first demonstrated retrospective gating of a *Xenopus laevis heart* on an OCT system with a scanning rate of 8 A-scans/s [41]. By utilizing the structural OCT signal to determine the number A-scans per heartbeat, the authors obtained five Doppler and structural frames per heartbeat. Building on this first demonstration, Mariampillai et al. implemented a signal-based retrospective gating technique to capture both 4-D structure and Doppler images of stage 51 *Xenopus laevis* hearts [42]. The system comprised two OCT systems; one an adapted commercial swept source OCT system (Thorlabs, SL1325-P16) for imaging and the second a time domain OCT system to capture a Doppler optical cardiogram used as the gating signal. The swept source system had an A-line rate of 16 kHz and was capable of real-time imaging at 25 fps (structural) and 12 fps (Doppler). Briefly, stage 51 *Xenopus laevis* embryos were anesthetized with lidocaine and placed in a shallow V-groove with solution. The time domain OCT system with a rapid scanning optical delay (RSOD) line had an A-line rate of 12.95 kHz. The system recorded from one of the two vessels exiting the heart and operated in M-mode (no scanning). The M-mode Doppler signal was processed, and the mean and standard deviation of the heart rate were calculated from the optical cardiogram, and cardiac cycles with variations below 1.75 standard deviations were kept. Next, the cardiac cycle was separated into equally spaced temporal bins. B-scans acquired from the swept source OCT system were placed into the correct bin by time stamp and reassembled. Finally, 4-D surface reconstructions of both the structure and Doppler images were presented. Signal-based retrospective gating has some promise, but like prospective gating it requires a more complex technical setup and additional setup time between embryos and has lost favor among research groups investigating embryonic cardiac dynamics in favor of signal-free gating.

65.4.2 Image-Based Retrospective Gating

Image-based retrospective gating (or signal-free, i.e., not requiring an external signal) has become the current standard for 4-D OCT imaging in developmental cardiology studies [43–45]. This technique records images continuously, without gating, over

several heart cycles, then rearranges out-of-order data based upon image similarity and obviates the need for extra signals to synchronize data. Although the system complexity is greatly reduced, the gating algorithm requires extra processing time. Gargesha et al. demonstrated 4-D reconstructed imaging of embryonic hearts using an image-based retrospective OCT gating technique by adapting an algorithm originally applied to confocal microscopy images of living zebrafish embryos [44]. The technique consisted of capturing B-scans (500 A-lines) longitudinal to the heart tube at a single location for at least 1.5 heartbeats before translating to a parallel slice 9 μm away. This process was continued until the entire heart was imaged (∼80 slices). The embryos were imaged under physiological conditions by controlling temperature and humidity in an environmental imaging chamber. The scanning orientation was chosen to minimize motion artifacts. The B-scan interval for the system was 4.27 ms. It was previously determined that the maximum error in displacement due to a 5 ms time step was 10 μm [34]. If the first A-scans in the B-scan were captured 5 ms before the last A-scans of the B-scan, there would be a 10 μm displacement error if the velocity of the heart wall was 2 mm/s. Since the maximum wall velocity for stage 14 quail embryo is 2 mm/s, the B-scan interval was fast enough to assume that the motion was frozen during each B-scan.

The gating algorithm consisted of four main steps:

1. Ascertain the period of the heart cycle.
2. Determine relative time shifts between adjacent image slice locations.
3. Establish absolute shifts to align slices with user-selected starting time.
4. Reorder image data.

These steps are similar for all works discussed in this section unless stated otherwise. Before step 1, the data can be decimated to reduce processing time or alternatively can be synchronized based upon a subset of wavelet coefficients from the image [43, 44]. (1) To calculate period of the heart cycle, a string-length minimization method was applied [46, 47]. Image data at each slice location was wrapped into a single cardiac cycle for each guess of the period. An objective function computed the sum of squared differences between temporally adjacent reordered slices and the sum of squared differences between frame times. The period that minimizes the objective function was chosen, and the data were reassembled into one correctly ordered cardiac cycle. The data were then interpolated to create B-scans evenly spaced in time. (2) The sequence of B-scans at each transverse position has a different starting point in the cardiac cycle so the temporal shift between the transverse positions must be determined. The relative shift in time between adjacent transverse positions was determined by maximizing the cross-correlation coefficient between the images as the relative shift was varied. (3) The absolute shift of each slice location was set corresponding to a user-defined reference slice at the middle of the heart tube. The reference shifts were progressively applied to each consecutive slice moving outward from the middle giving an array of correct starting offsets for each slice position. (4) The determined period and absolute shifts were employed to reorder the data. Figure 65.4 shows an example of data obtained with this image-based retrospectively gated OCT imaging method.

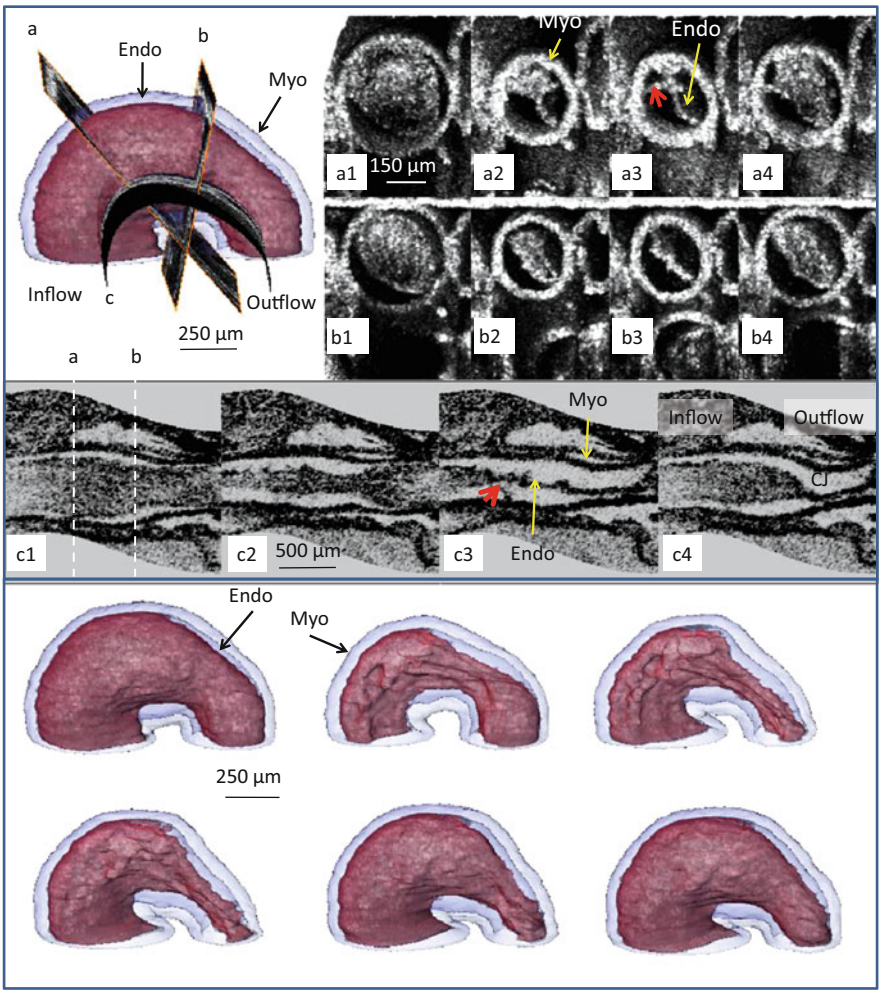

Fig. 65.4 Image-based retrospective gating. Upper *left panel* displays the location of the three slices (**a**, **b**, and **c**) on the 3-D heart. *A1–4* and *B1–4* slices at locations (**a**, **b**) oriented orthogonal to the heart tube at several different time points during the cardiac cycle. *C1–4* illustrates the ability to visualize a curved surface through the center of the length of the heart tube. The locations of slices (**a, b**) are indicated with the *white dashed lines*. The *bottom panel* displays surface renderings as the heart progresses through a cardiac cycle. The endocardium is in *red* and the myocardium in transparent *blue*. *Myo* myocardium, *Endo* endocardium

Gargesha et al. validated the gating algorithm by comparing the retrospectively gated results to directly recorded volumetric imaging of the same samples [44]. Knowing the time delay between slices in the directly imaged volume, the accuracy of the gating algorithm was determined by finding the slices in the directly imaged volume that correlated best with volumes in the gated image set. The maximum

error was 18.7 ms, and the standard deviation of the error was 4.7 ms indicating that the gating algorithm would be capable of producing 200 volumes/s with minimal displacement error (<10 μm). It is likely that this displacement error would increase for OCT systems with slower A-scan rates, and further enhancements in the algorithm would be needed.

Liu et al. demonstrated a similar retrospective gating algorithm to image the outflow tract of stage 18 chicken embryos [45]. A spectral domain OCT system acquired 40 B-scans/s consisting of 250 A-lines. The resolution of the system was 10 μm axial and 16 μm lateral. The eggshell was opened to enable imaging, while temperature and humidity were not controlled and the heart rate was depressed. The Liu algorithm differed from the algorithm described above in several ways. First, instead of maximizing the similarity between adjacent B-scan sequences by varying the relative shift, similarity was maximized between adjacent M-mode images extracted along the same line perpendicular to the B-scans (essentially using one line per image), which increased computational efficiency. To improve accuracy, images were recorded over five cardiac cycles instead of 1.5–2. Furthermore, B-scan slice sequences were transverse to the heart tube. Finally, an extra perpendicular B-scan sequence longitudinal to the outflow tract was utilized to correct the phase lag between adjacent image sequences. Briefly, the phase lag was computed by extracting two M-scans from the sequence of B-scans longitudinal to the outflow tract. By computing the distance between the M-scans and the phase between maximal contractions, the phase lag could be computed. For this measurement, the velocity of the contraction wave was assumed constant in the outflow tract. Reconstructions consisted of 180 volumes per cardiac cycle.

Recently, Happel et al. designed a gating algorithm implementing rotational image acquisition, where each set of B-scan sequences is rotated from one another providing a central A-scan common to all B-scan sequences [48]. The common A-scan was utilized to determine the relative shift between each B-scan sequence. Images were collected with a Thorlabs swept source OCT system (OCS1300SS). Fifty B-scans (>9 images/heartbeat) were acquired in 2.4 s (>5 heartbeats) at every angle (every 2°) at a frame rate of 21 B-scans/s (each B-Scan consisted of 512 A-lines). The axial resolution was 9 μm in tissue, while the lateral resolution was 25 μm. Twenty volumes per cardiac cycle were assembled. Validation was done by acquiring B-scan sequences collected at positions differing from those taken in the 4-D data set and correlating them with the reconstructed data. From Fig. 65.5, one can see that the reconstructed data compares favorably to the validation B-scan sequences.

Larina et al. demonstrated a similar rotational method called sequential turning acquisition and reconstruction (STAR) [49]. The main difference with the STAR method is that it preserves the order of the frames in a single B-scan sequence by applying a nonuniform, elastic registration instead of interleaving the frames from multiple heart cycles. This allows reconstructions even with variations in the heartbeat over a single B-scan sequence and enables the analysis of features with aperiodic motion within each B-scan sequence. One of the advantages of rotational image acquisition includes having a common A-scan in each B-scan sequence

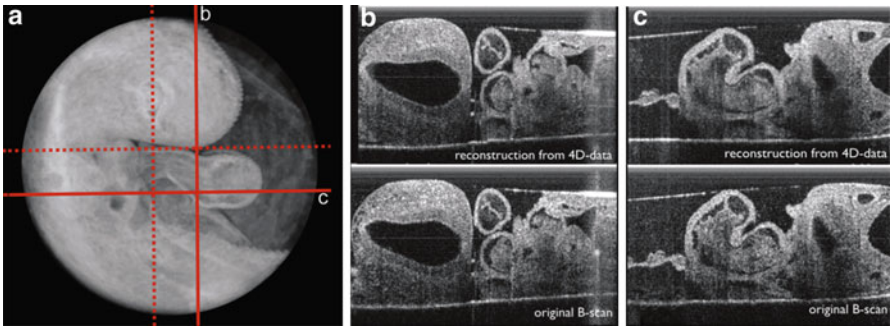

Fig. 65.5 Retrospective gating implementing rotational image acquisition. (**a**) displays a 4-D image set collected with rotational image acquisition. The *red lines* indicate the position of *b* and *c*. (**b**) B-scan from the reconstructed 4-D data looks comparable to a standard B-scan at position *b* taken after the 4-D scan was completed. (**c**) respective images from position *c*

which mitigates the accumulation of registration errors when computing relative shifts across parallel slices. This can be extremely useful when imaging with a slower OCT system. Another advantage is that monitoring the common A-scan during image acquisition can provide feedback on whether the embryo has moved, which would increase image artifacts. A disadvantage of the technique is an increasing voxel size at greater distances from the center.

More recently, Bhat et al. employed two orthogonal sets of parallel OCT slice sequences to produce 4-D images of live cultured mouse and rat embryos [50]. Each orthogonal set was recorded similarly to previous techniques [44]. By acquiring two datasets in perpendicular orientations instead of one, the authors could produce more accurate and self-validating reconstructions by employing similarity between datasets to improve spatiotemporal registration. This technique can eliminate errors that accumulate between adjacent B-scans as one progresses across the field of view. This can be especially useful for slower OCT systems that have greater accumulation errors. Figure 65.6a, c shows the two reconstructed datasets in magenta and green processed independently and together. Figure 65.6b, d illustrates the absolute differences between the two datasets. Clearly, inter-volume synchronization has improved the alignment of the data.

Similar image-based retrospective gating techniques can also be implemented with 2-D + time image data. Applications include reducing noise [51] and increasing the field of view [52].

65.5 4-D Doppler OCT and Shear Stress

Hemodynamics are a crucial regulator of the cardiovascular system during development. As with 4-D structural OCT imaging, 4-D Doppler can allow one to visualize the heterogeneous patterns of biophysical forces impinging on the embryonic heart. As mentioned above, Mariampillai produced the first 4-D Doppler

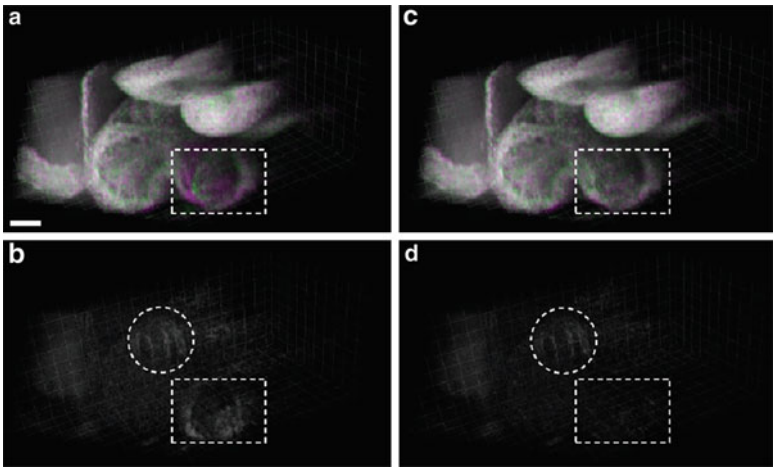

Fig. 65.6 4-D OCT gating employing two orthogonal sets of parallel OCT slice sequences. (**a**) Both orthogonal image sets processed independently. The Y-dataset is false-colored magenta, while the X-dataset is false-colored *green*. When the data from both datasets are in-sync, their colors add up to produce *gray*. (**b**) The absolute difference between the two datasets when processed separately. (**c**) X and Y datasets are synchronized using information from the other dataset. (**d**) The absolute difference between the datasets when both volumes contribute to the synchronization. The *dotted boxes* represent regions that exhibit improved alignment using both volumes for the synchronization. The *dotted circles* show a region in the outflow tract that is mismatched between the X and Y datasets due to sample movement between acquisitions. Scale bar is 100 μm

images of an embryonic *Xenopus laevis* heart [42]. Unfortunately, several issues needed solving before quantitative measurements of blood flow and hemodynamic forces could be extracted from these 4-D data sets. First, blood velocities in the heart cover a large dynamic range. Systems with low A-line rates will have excessive phase wrapping, while imaging fast enough to avoid phase wrapping may lead to lower signal-to-noise ratios especially for slower velocities. Phase wrapping occurs when the phase difference between adjacent A-scans exceeds π. For example, a 2π phase shift would be identical to no shift and cannot be distinguished without additional information. In order to accurately calculate velocities, Doppler data must be unwrapped. Second, Doppler OCT measures relative velocity because it is only sensitive to blood flow in the direction parallel with the OCT beam. Absolute velocities in blood vessels can be quickly determined by scanning the 3-D geometry of the vessel and finding the velocity vector in the direction of the vessel. In a 3-D structure that loops around and is constantly moving (e.g., embryonic heart), determining absolute velocity can be quite challenging.

Ma et al. calculated absolute flow velocity in the outflow tract of a stage 18 chicken embryo [53]. A spectral domain system with an A-line rate of 47 kHz, an axial resolution of 14 μm in air, and a lateral resolution of 16 μm was employed. 4-D data sets were first acquired and then synchronized using the previously

described image-based retrospective gating algorithm [45]. Adjacent A-scans overlapped by 75 % enabling Doppler measurements. To avoid phase wrapping, the phase difference range was shifted from [-π, π] to either [0, 2π] or [−2π, 0] allowing the projection velocity range to be [−24 mm/s, 24 mm/s]. Next the centerline of the outflow tract was determined to find the absolute velocity (velocity vector parallel to the heart tube). First, the volume corresponding to the maximum expansion in the outflow tract was selected. Next, a snake algorithm [54] segmented the myocardial layer at each slice location. The centroids of each segmentation are connected to make up the centerline. The angle between the centerline vector and the vector of the beam propagation enables the calculation of absolute velocity. It is assumed that blood flow is parallel to the centerline and that the direction of blood flow remained parallel to the centerline for the entire cardiac cycle. The errors induced from these assumptions were not determined and may be significant. However, increased accuracy could be achieved by calculating a centerline for multiple phases in the cardiac cycle. Figure 65.7 shows reconstructions of an outflow tract and the computed centerline. The maximum blood flow velocity at the inlet of the outflow tract was 35 mm/s, while at the outlet it was 50 mm/s, the difference owing to tapering of the tube.

In 2010, Jenkins et al. collected 4-D Doppler data to demonstrate several new hemodynamic measurements [55]. An FDML laser-based OCT system with an A-line rate of 117 kHz and an axial and lateral resolution of ∼10 μm was employed. All imaging was performed in an environmental chamber to insure the embryos developed under physiological conditions. 4-D data sets were first acquired and then synchronized using the previously described image-based retrospective gating algorithm [44]. To enable Doppler imaging, the A-scan spacing was 1.3 μm. Doppler data was unwrapped using a Goldstein algorithm [56]. By having access to the entire 4-D Doppler dataset, one could make several new measurements including cardiac output, stroke volume, and shear rate/stress on the endocardium. Also, pulsed Doppler traces could be accurately extracted at the inflow and outflow of the heart tube. Stroke volume and cardiac output were computed utilizing the en face plane obviating the need to determine absolute velocity. One could integrate the Doppler signal spatially in the en face plane across the lumen to yield flow and integrate over time to yield flow per second or per heartbeat. To measure shear rate/stress, an image plane orthogonal to the blood flow was identified, and the velocity gradient near the endocardium was determined. Several assumptions were made to make the shear measurements. First, the blood was assumed to be a Newtonian fluid with a dynamic viscosity of 5 mPa s. Next, it was assumed that the blood flow was laminar and dominated by viscous forces, and finally the blood was assumed to travel parallel to the direction of the heart tube. Hemodynamic measurements were presented for two stage 14 quail embryos. Stroke volumes of 0.04 and 0.038 μL were recorded, while cardiac output was 0.123 and 0.124 μL/s for the two embryos. Maximum shear rate and stress were found in the outflow tract. Maximum shear rate was 1,521 and 1,834 1/s, while maximum shear stress was 7.6 and 9.2 Pa. These measurements are not feasible without 4-D imaging and can hopefully serve as powerful metrics to discern abnormal development.

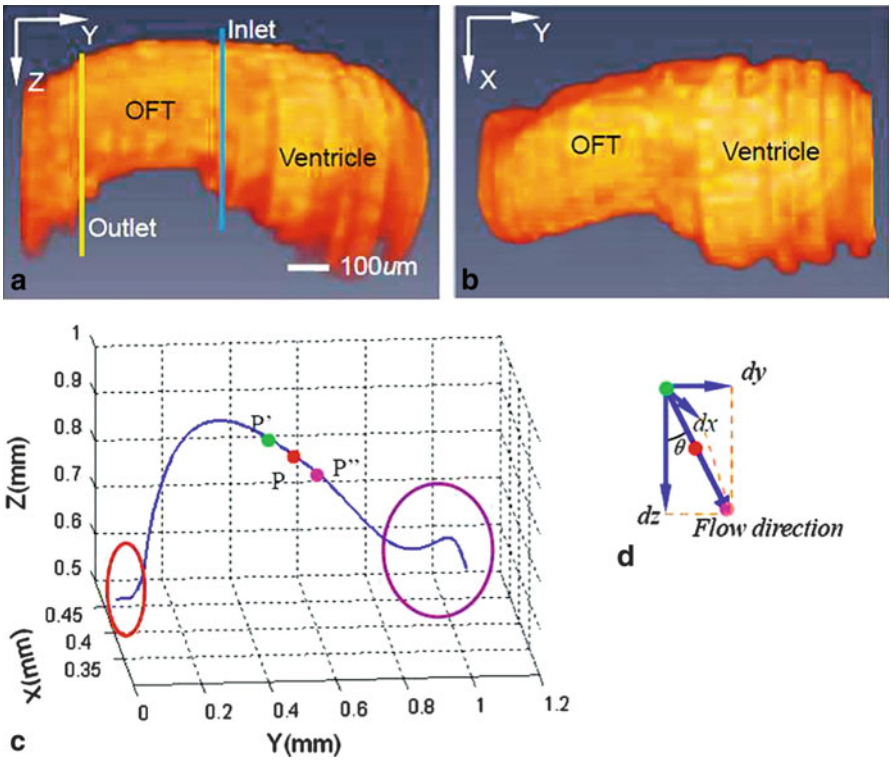

Fig. 65.7 Determining absolute flow in the outflow tract of the chicken embryo. (**a**) Segmentation of the embryonic chick outflow tract walls (*side view*). The *blue line* indicates the inlet, while the *yellow line* indicates the outlet of the outflow tract. (**b**) Top view of segmentation in (**a**). (**c**) Centerline through the heart tube. (**d**) Flow direction is calculated by determining the tangent to the centerline

Recently, Peterson et al. measured shear stress on extended regions of the endocardial surface of an embryonic quail heart over time producing 4-D shear maps [19]. The imaging system employed was described previously [55]. Again, a Goldstein algorithm was employed to unwrap the phase of the Doppler data [56], and the same assumptions for shear stress calculations were made as in [55]. To determine absolute velocity and the velocity gradient normal to the endocardial wall, the endocardium was segmented, and centerlines were calculated for each volume using a TEASAR (tree-structure extraction algorithm for accurate and robust skeletons) algorithm [57]. It was assumed that blood flowed in the direction of the centerline. Tangent lines at each point along the centerline were calculated to determine the velocity direction and estimate absolute blood flow. A surface mesh of the endocardial wall was used to determine the normal vector to the endocardial surface at each location and thereby determine the velocity gradient near the wall. Figure 65.8 shows results from the shear stress algorithm. The pattern of shear stress is heterogeneous and displays the largest stresses on the inner curvature of the

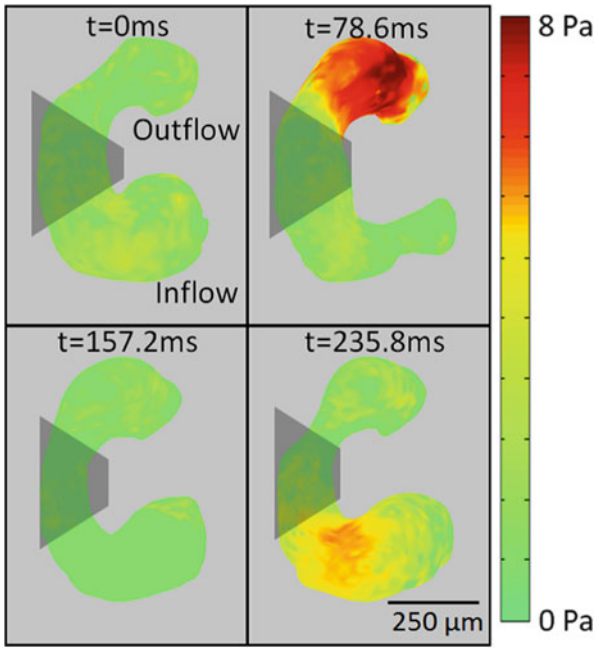

Fig. 65.8 Endocardial shear stress in a quail embryo at four evenly spaced time points during the cardiac cycle, which lasted 367 ms. The shear stress values are color mapped onto the endocardial surface. The shear stress could not be calculated in the *gray* region because flow was nearly perpendicular to the OCT beam

outflow tract. Another prominent region is displayed near the inflow region of the tube. Both regions of higher shear stresses are thought to be where future valves and septa will develop [58]. Recent evidence has shown that shear stress may be important for the development of valves in the zebrafish heart [10]. Future experiments correlating shear stress patterns with molecular expression and subsequent heart development will enable us to understand how altered shear patterns can lead to congenital heart defects.

Liu et al. approximated shear on the endocardium of the outflow tract of a stage 18 chick embryo using a finite element (FE) model of the heart tube (see Fig. 65.9 [17]). 4-D OCT data were utilized to determine the dynamic geometry of the heart tube and the outflow tract (OFT) centerline [59]. Briefly, the OFT centerline was determined from the volume representing the time point when the OFT was most constricted. Five equally spaced cross-sections perpendicular to the OFT centerline were chosen to characterize the geometry and wall dynamics in the model. Pressure measurements at the ventricle and aortic sac using a servo-null micro-pressure system were used for boundary conditions. Unfortunately, it was not possible to record pressure measurements and 4-D OCT images from the same embryo. Ultrasound helped correlate the phase of the pressure waves and OCT data. The model showed that the highest shear levels were located at the inner curvature of the OFT in close proximity to the cardiac cushions. A second study by Liu et al. enhanced the method by improving segmentation of the outflow tract and adding measurements of myocardial wall

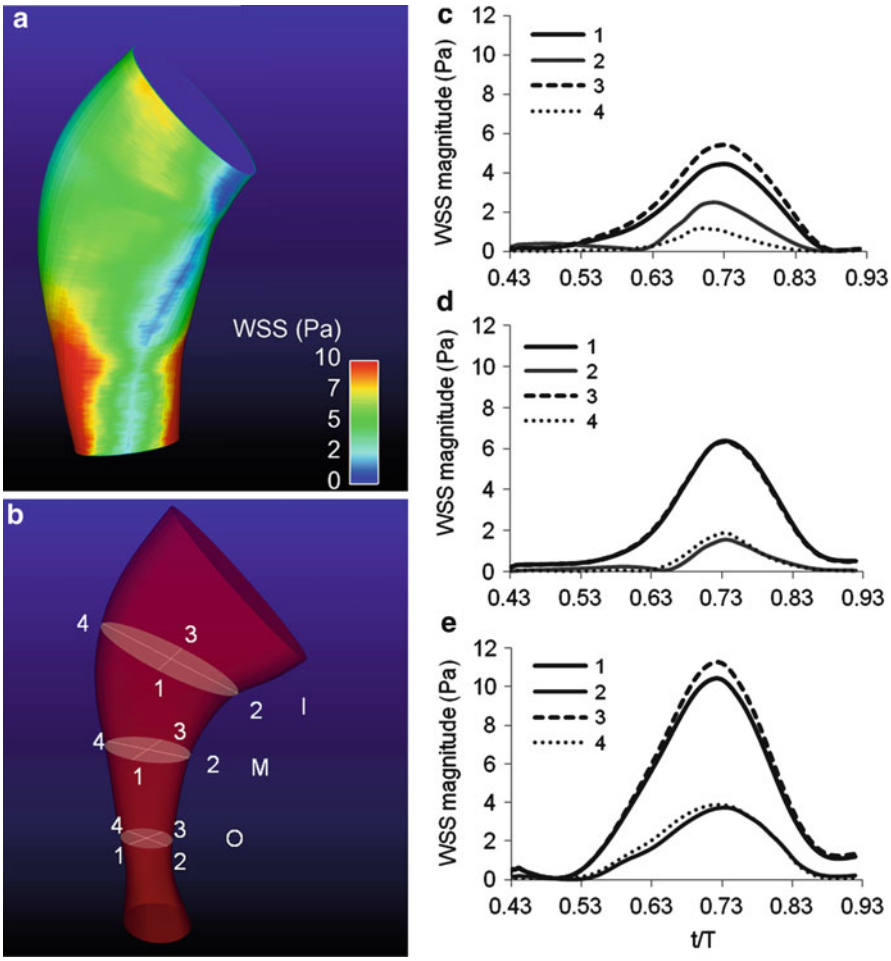

Fig. 65.9 Computing wall shear stress at the outflow tract using computational fluid dynamics. (**a**) Wall shear stress on the outflow tract during the greatest expansion of the tube. (**b**) Outflow tract model displaying cross-sectional planes (*I*, *M*, and *O*) and four points on each plane used for analysis in **c**–**e**. stresses and circumferential strain of the endocardium and myocardium [17]. Myocardial wall stress was estimated using the Laplace law where pressure, radius, and wall thickness are utilized to determine stress. Circumferential strain was estimated by measuring the change in circumference in comparison to the maximum circumference divided by the maximum circumference for the five orthogonal slices. Also, the model was validated by comparing blood velocity obtained from the OCT data along the centerline with blood velocity predicted in the model. It was found that circumferential strain in the myocardium and endocardium decreased distally, and myocardial wall stresses increased distally.

Also, the surface of the cardiac cushions experienced maximal wall shear stresses. Although modeling only approximates the measurements, it can be a useful tool when technology is incapable of obtaining the results.

65.6 Conclusion

Several robust techniques have been developed for 4-D OCT imaging. The first wave of technology development saw the implementation of a varied set of gating techniques. Image-based retrospective gating has now become the standard technique, and research groups are starting to focus on measurements that can be made exclusively with 4-D OCT datasets (e.g., mapping shear stress patterns [19]). Stresses and strains on the myocardium and endocardium are beginning to be measured from OCT images [59–61], and eventually 4-D imaging may allow maps of stress and strain across the entire heart. Also, one can now use these new metrics to differentiate abnormal from normal function. For example, 4-D OCT confirmed slower blood filling in hearts exposed to acute hypoxia [62]. 4-D OCT could become a powerful screening tool early in embryonic development as heart function can be a sensitive gauge of normalcy of cardiogenesis. Ultimately, one would like to utilize 4-D OCT to determine how biophysical forces modulate molecular expression and lead to congenital heart defects. Garita et al. began to correlate the location of mechanotransducing molecules (e.g., fibronectin, tenascin C, α-tubulin, and nonmuscle myosin II) with specific cardiac structures in OCT and optical coherence microscopy (OCM) images [58]. Future work must focus on applying 4-D OCT imaging to help identify signaling pathways that are activated by biophysical forces and which pathways present the biggest threat to developing CHDs.

OCT and Coherence Imaging for the Neurosciences

66

Jonghwan Lee and David A. Boas

66.1 Introduction

The brain plays a central role in most of our life's activity, including consciousness, perception, limb control, emotion, communication, and logical thinking. While the brain has been an intense subject of human interest since the beginning of human history, it is only relatively recently that science and technology has started to unveil the mystery of how the brain works.

The most fundamental building block of the brain is the neuron. Neurons are small cells consisting of a body ($\sim$10 μm in diameter) and projections (typically $>$100 μm). It has two types of projections: axons and dendrites. A neuron accepts electrochemical signal inputs from other neurons through its dendrites, integrates these inputs at its body to determine whether to fire an output signal, and then sends the output through its axon to other neurons. The connections between neurons are called synapses, where an axon meets with a dendrite and electrical signals are transmitted in a chemical way mediated by neurotransmitters. The human brain is an immensely complex system, consisting of about one hundred billion ($\sim 10^{11}$) neurons and one hundred trillion ($\sim 10^{14}$) synapses. These neurons and synapses form a huge neuronal network, and information processing within our brain is accomplished by the complex communications occurring in the network. Therefore, measuring and imaging neuronal activity in the living brain are critical prerequisites for studying how the brain works.

Neuronal activity is based on a difference in the electrical potential across the neuron's membrane due to an imbalance of ionic concentrations (sodium and potassium are more abundant in extracellular and intracellular spaces, respectively).

When a neuron is excited (i.e., depolarized), sodium ions flow into and potassium ions flow out of the neuron across its membrane, weakening the initial ionic unbalance. Since the initial imbalance is important for normal functioning of neurons, neurons have active (ATP-consuming) pumps to draw potassium into and pump sodium out of them, restoring the ionic unbalance. Oxygen and glucose are supplied to meet these metabolic needs for the neuron's active pumping of ions, location by location, moment to moment. The regulated supply of oxygen and glucose is particularly important since the brain has a very limited reserve of these energy substrates. Oxygen and glucose are mainly supplied by cerebral blood flow (CBF). The current paradigm for understanding this brain's energy supply regulation is neurovascular coupling, a range of mechanisms underlying how local neuronal activity adjusts arteriolar tone (and thus local CBF) to meet the spatiotemporally varying metabolic needs. As the brain's blood flow regulation is critical for its normal functioning and thus relates with various brain diseases, neurovascular coupling and the associated hemodynamic responses are important subjects in the neurosciences.

This chapter describes how optical coherence tomography (OCT)-based technologies have advanced in vivo imaging of neuronal and vascular dynamics occurring within the brain cortex. OCT enables μm-resolution and high-speed imaging of tissue structure [1], facilitating a number of basic and clinical studies in ophthalmology [2], cancer biology [3], and neuroscience [4]. In this chapter, we describe OCT-based technologies for μm-resolution imaging of tissue dynamics, especially in the brain cortex of a living animal. First, as CBF plays an important role in normal brain function, we review OCT imaging techniques for quantitative measurement of CBF in the resting-state brain. Traditional Doppler OCT has been used for this purpose, and recently integration of OCT with dynamic light scattering analysis has been suggested. Next, as CBF transiently varies in response to brain activation, this chapter also describes how OCT technologies have advanced imaging of neurovascular coupling and led to novel findings. Dynamic OCT imaging of the brain cortex suggests that the OCT signal spatiotemporally varies in response to brain activation, providing a laminar profile of the response. Furthermore, the high imaging speed and spatial resolution of OCT enables monitoring of blood flow responses not only in arteries and veins but also within the network of capillaries. While these hemodynamic responses occur on the timescale of several seconds, excitation of neurons occurs much faster, on the timescale of milliseconds. Therefore, this chapter will finish by discussing the feasibility of imaging fast neuronal activity with OCT. OCT-based technologies introduced in this chapter, for in vivo imaging of cerebral cortex dynamics ranging from milliseconds to hours, have enabled a range of important new studies of the healthy and diseased brain.

66.2 OCT Imaging of Cerebral Blood Flow Velocity: Steady-State Dynamics

CBF is a physiological quantity that is closely related with healthy brain functions and thereby is important for the study of brain pathophysiology. It has thus far been

measured with various optical methods. Laser Doppler flowmetry is used to measure blood flow at a fixed point [5, 6], and its imaging corollary provides a 2-D map of blood flow [7]. Doppler OCT enables depth-resolved measurement of axial flow velocity with microscopic resolution, resulting in a 3-D map of blood flow [8]. This section describes this application of Doppler OCT to quantitative imaging of CBF. Then, we review a recently proposed method that integrates OCT with dynamic light scattering analysis to measure both the axial and transverse components of CBF velocity.

66.2.1 Doppler OCT Imaging of CBF

Doppler OCT generally repeats A-scans at a fixed position to measure temporal variations in the phase of the OCT signal. The phase variation is approximately linearly dependent on the axial motion of scatterers in the given voxel and thus can be used for quantification of the velocity of scatterer flow [9, 10]. This Doppler OCT measurement of the axial flow velocity can be used to perform absolute measurements of CBF either by estimating vessel angles [11] or by processing volumetric data [12]. In detail, using three-dimensional Doppler OCT and cranial window preparations, Srinivasan et al. introduced a method of absolute flow calculation that does not require explicit knowledge of vessel angles. They showed that OCT estimates of absolute CBF values in rats agree with prior measures by hydrogen clearance, a gold-standard measurement of CBF (Fig. 66.1).

Doppler OCT imaging of CBF displays features characteristic of general blood flow, including conservation along non-branching vascular segments and at branch points [13]. For example, Fig. 66.2 shows how Doppler OCT-measured CBF confirms the conservation of flow at branching vessels. In addition, this study demonstrated that Doppler OCT flow values correlate with hydrogen clearance flow values when both are measured simultaneously. These data validated Doppler OCT as a noninvasive quantitative method to measure tissue perfusion.

66.2.2 Dynamic Light Scattering Optical Coherence Tomography (DLS-OCT)

While Doppler OCT generally measures the axial component of CBF velocity, a recently proposed method integrating OCT with dynamic light scattering (DLS) analysis enables measurement of the transverse component of flow velocity independently of and simultaneously with the axial velocity. This section provides a technical description of the integration, DLS-OCT, and the next section discusses its application to brain cortex imaging. DLS is widely used to quantify the dynamics of scattering particles by analyzing the autocorrelation function of light scattered from the particles, enabling an analysis of the particles' diffusion and/or flow velocity [14–16]. Integration of DLS with OCT will provide μm-resolution 3-D imaging of heterogeneous diffusion and flow but requires a suitable

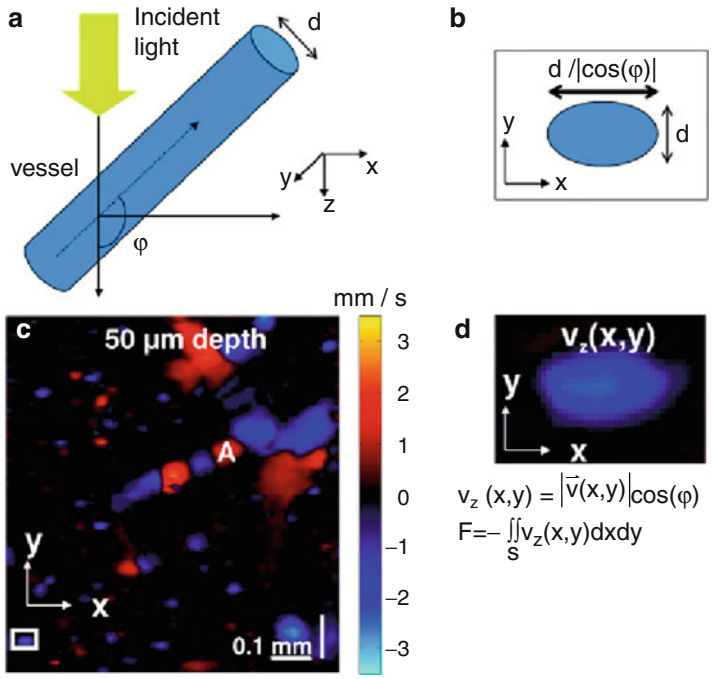

Fig. 66.1 Calculation of CBF from Doppler OCT measurement of the flow velocity. (**a**) Blood vessels can be oriented at any angle φ relative to the incident light. (**b**) The area of the vessel in the en face (*xy*) plane is inversely proportional to cos(φ). (**c**) En face cut at a depth of 50 μm through a 3-D map of the axial velocity (averaged over ten volumes). (**d**) Zoom of a venule showing the axial component of flow velocity over the vessel cross section (upsampled to reduce pixellation). While the area of the vessel in the xy plane is inversely proportional to cos(φ), the axial component of the velocity is proportional to cos(φ). Therefore, the flow F can be obtained from the en face map of the axial velocity, $v_z(x,y)$ (Reprinted from [12] with permission)

DLS theory [17–22] for accurate implementation. Recently, Lee et al. proposed such a DLS theory by deriving the field autocorrelation function directly from the complex-valued OCT signal and validated DLS-OCT measurement of diffusion and flow through phantom experiments [23].

Dynamic OCT imaging of a sample produces four-dimensional (space and time) data of the complex-valued reflectivity, $R(\mathbf{r}, t)$. The field autocorrelation function is obtained as

$$g(\mathbf{r},\tau) = E\left[\frac{\langle R^*(\mathbf{r},t)R(\mathbf{r},t+\tau)\rangle_t}{\langle R^*(\mathbf{r},t)R(\mathbf{r},t)\rangle_t}\right] \tag{66.1}$$

where * denotes the complex conjugate, $< >_t$ indicates an average over time, and $E[\ ]$ means the average over initial positions of the scatterers. When static

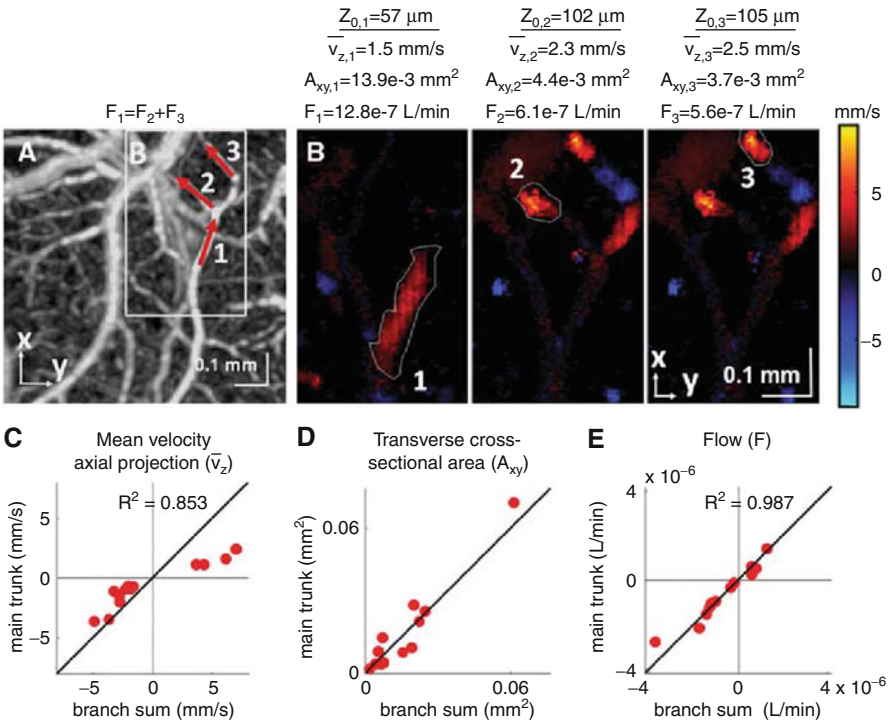

Fig. 66.2 Conservation of Doppler OCT-measured CBF at branch points in a thinned rat skull preparation. (**a**) OCT angiogram showing three locations in a branching vessel. (**b**) En face Doppler OCT images, presenting the axial flow velocity, at two depths corresponding to the main trunk location (*1*) and two branch locations (*2*, *3*) shown in panel A. Plots of mean axial velocity (**c**), transverse cross-sectional area (**d**), and flow (**e**) in the main trunk and summed over branches in 13 branching vessels are shown (Reprinted from [13] with permission)

and moving particles are mixed in the OCT probing volume and the moving particles can exhibit either translational or diffusive motion (Fig. 66.3a), the OCT signal can be expressed by

$$R(t) = \sum_{j=1}^{N_S} e^{-2h^2 r_{Sj}^2} e^{iqz_{Sj}} + \sum_{j=1}^{N_F} e^{-2h^2 r_{Fj}^2(t)} e^{iqz_{Fj}(t)} + \sum_{j=1}^{N_E} e^{-2h^2 r_{Ej}^2(t)} e^{iqz_{Ej}(t)} \qquad (66.2)$$

where q is the representative scattering vector and h is the inverse of voxel size. The scattering cross sections of the particles are considered to be similar. Detailed descriptions of the other quantities and assumptions are given in [23]. The movement of a particle can be expressed by the self-interaction term of the Van Hove space-time correlation function [24], that is, the probability that the particle which was initially at position $\mathbf{r_i}$ at time t_i is found at position $\mathbf{r_f}$ at time t_f, $P_1(\mathbf{r_f}, t_f|\mathbf{r_i}, t_i)$.

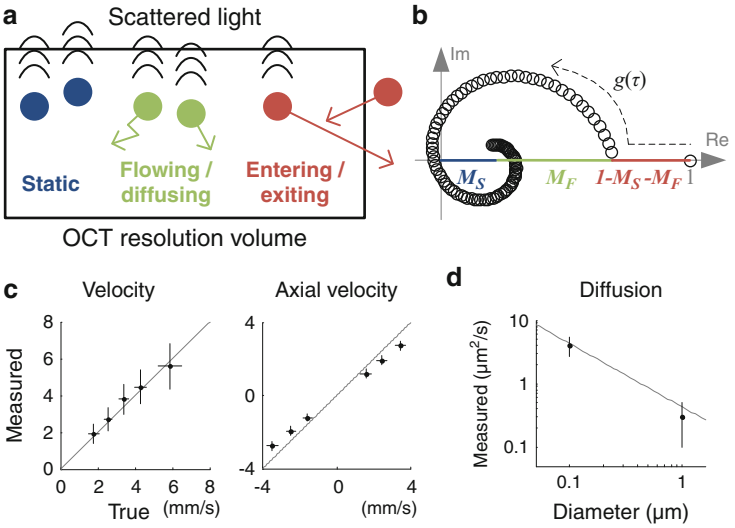

Fig. 66.3 Theory and validation of DLS-OCT. (**a**) Particles within the OCT resolution volume can be categorized into three groups: static, flowing or diffusing, and entering or exiting particles. For clarification, entering/exiting particles enter into or exit out of the voxel during a single measurement time step, resulting in stochastic fluctuations of the OCT signal. (**b**) The general behavior of the field autocorrelation function in the complex plane predicted by DLS-OCT theory. M_S and M_F are approximately proportional to the fractions of static and flowing/diffusing particles, respectively, weighted by their scattering cross sections. It adequately explained the measured ones. (**c**) Phantom validation of DLS-OCT measurement of the flow velocity using a piezoelectrical sample with controlled velocity. The velocity (*left*) means the absolute velocity, $(v_t^2 + v_z^2)^{1/2}$. (**d**) Phantom validation of DLS-OCT measurement of the diffusion coefficient using microsphere samples with different diameters. The *gray line* shows the Einstein-Stroke equation (Reprinted from [23] with permission)

The probability of a particle exhibiting both translational and diffusive motions with the velocity v and the diffusion coefficient D can be formulated by

$$P_1\left(\mathbf{r_f}, t_f | \mathbf{r_i}, t_i\right) = \frac{1}{2\sqrt{\pi D\left(t_f - t_i\right)}} e^{-\frac{\left|\mathbf{r_f} - \mathbf{r_i} - v\left(t_f - t_i\right)\right|^2}{4D\left(t_f - t_i\right)}}. \tag{66.3}$$

Then, the field autocorrelation function of the OCT signal (Eq. 66.2) whose $r_F(t)$ and $z_F(t)$ satisfy Eq. 66.3 was obtained as

$$\begin{aligned} g(\mathbf{r}, \tau) = {} & M_S(\mathbf{r}) + M_F(\mathbf{r})\, e^{-h_t^2 v_t^2(\mathbf{r})\tau^2 - h^2 v_z^2(\mathbf{r})\tau^2} e^{-q^2 D(\mathbf{r})\tau} e^{iq v_z(\mathbf{r})\tau} \\ & + \left[1 - M_S(\mathbf{r}) - M_F(\mathbf{r})\right]\delta(\tau) \end{aligned} \tag{66.4}$$

where $M_S(\mathbf{r})$, $M_F(\mathbf{r})$, $v_t(\mathbf{r})$, $v_z(\mathbf{r})$, and $D(\mathbf{r})$ are the parameters of particle dynamics to be estimated for each position while the others are the parameters given by the

measurement system. M_S is the fraction of the static particles, M_F is the fraction of the moving particles, v_t is the transverse component of the flow velocity, v_z is the axial component, and D is the effective diffusion coefficient quantifying the diffusive motion of particles as in Eq. 66.3. This autocorrelation function adequately explained the general behavior of the experimental measurements (Fig. 66.3b).

Phantom experiments validated DLS-OCT measurement of the flow velocity and diffusion (Fig. 66.3c). For the velocity measurement, a piezoelectrically actuated static sample was used to simulate axial movements of particles while transverse movements were implemented by galvanometric lateral scanning of the OCT beam. The absolute and axial velocities were reliably measured across various true values of the flow velocity and angle. Microsphere samples of 0.1 and 1 μm in diameter were used for validating the diffusion measurement. The measured diffusion coefficient agreed with the theoretical values given by the Einstein-Stokes equation. The diffusion coefficient was estimated to be sufficiently small in the velocity phantom experiment, while the diffusion phantom experiment resulted in negligible velocities. These results confirmed that DLS-OCT can effectively distinguish whether the motion is translational or diffusive and accurately measure either the flow velocity or the diffusion coefficient.

66.2.3 DLS-OCT Imaging of CBF Velocity

Based on the validated DLS-OCT measurement of the flow velocity and diffusion coefficient, DLS-OCT imaging of the living rodent cortex was performed. A-scans were repeated 100 times over ~2 ms at a fixed position, and the position was moved in a raster manner to scan the volume of interest of the cortex. The 4D (space and time) complex-valued field reflectivity of the sample was obtained and then was used to produce the 4D (space and time lag) autocorrelation function data. Analysis of the 4D autocorrelation function data led to 3-D maps of the transverse and axial velocities, the diffusion coefficient, and the coefficient of determination (R^2).

As shown in Fig. 66.4a, the absolute velocity map clearly revealed the structure of the vascular anatomy and cerebral blood flow. The axial velocity map showed the axial component of the flow velocity, which looked very similar to conventional Doppler OCT images (e.g., Fig. 66.1c). The flow direction determined by the axial and transverse velocities agreed with the structural direction of vessels (Fig. 66.4a, right).

When the diffusion map is overlaid with the absolute velocity map (Fig. 66.4b), high-diffusion and low-velocity voxels were observed at the boundary of vessels. Interestingly, the vessel boundaries also exhibited a characteristic low coefficient of determination (Fig. 66.4c). Single-plane images without projection clearly showed the result that the vessel boundaries exhibit high diffusion, low velocity, and low R^2. At the circular cross-sections of the vessels (Fig. 66.4c, blue arrows), high-velocity and high-R^2 blood flow are surrounded by the high-diffusion, low-velocity, and low-R^2 dynamics of the vessel boundaries. In particular, the low R^2 means that

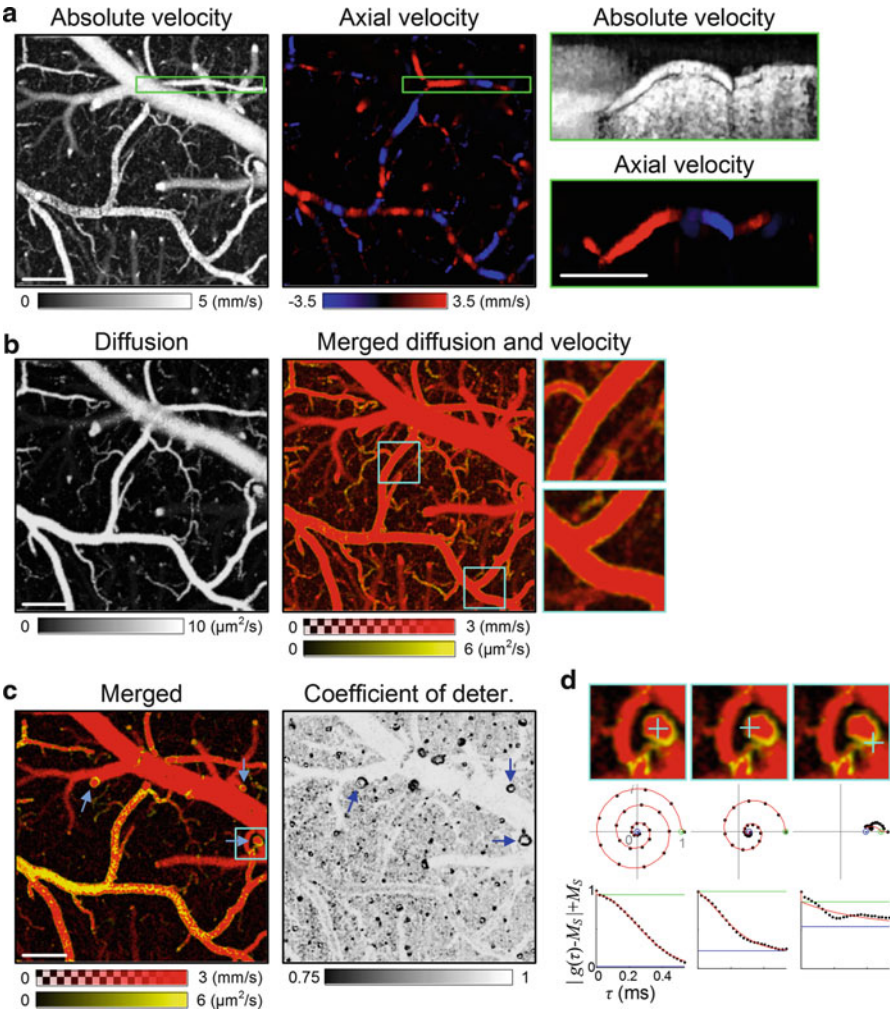

Fig. 66.4 DLS-OCT imaging of the brain cortex in a rat thinned skull preparation. (**a**) The first image presents the maximum projection (MP) of the 3-D map of the absolute velocity along the depth (i.e., en face), and the second image presents the en face signed maximum projection (SMP) of the 3-D map of the axial velocity. The images with the *green* boundary show the MP of absolute velocity and the SMP of the axial velocity along the transverse direction (i.e., cross-sectional) over the volume indicated as the *green box* in the en face images. The SMPs of the axial velocity are presented over the range from $-5/\sqrt{2}$ to $5/\sqrt{2}$ mm/s, where a negative velocity (*blue color*) means that blood flows toward the surface of the cortex. (**b**) The first image presents the en face MP of the 3-D map of the diffusion coefficient. In the second image, the diffusion image (*yellow*) is overlaid with the absolute velocity image (*red*). The 3× magnified images of the *cyan* boxes are presented to clearly show the characteristic dynamics of the vessel boundaries. This merged image is presented with smaller ranges of the velocity and diffusion coefficient for higher contrast. (**c**) Single planes of the merged map and the coefficient of determination map at a depth of 120 μm are presented. (**d**) Examples of the autocorrelation function are presented for three voxels (*cyan crosses*) that are located in the plane indicated as the *cyan box* in (*C*). The *middle*

the motion was neither translational nor diffusive; it might be oscillatory due to the interaction between blood flow and the tension of the vessel walls.

In addition to CBF imaging, DLS-OCT maps revealed another interesting dynamic occurring in the brain cortex. Along with high-NA OCT structural imaging, which identifies neuronal cell bodies in its minimum intensity projection (Fig. 66.5, MinIP; [25]), high-NA DLS-OCT imaging was performed on the cortex. The diffusion map revealed high-diffusion spots in the nonvascular area. They are different from vessel boundaries in that they showed high R^2 whereas the vessel walls exhibited the characteristic low R^2 values. Therefore, another map was introduced to represent diffusion masked with high R^2 ($R^2 > 0.998$, green color in Fig. 66.5). These high-diffusion high-R^2 green spots were morphologically confined when viewed in 3-D, whereas the high diffusion observed at vessel walls extended over a vascular segment. The positions of the green spots were highly correlated with those of neuronal cell bodies. Meanwhile, the green spots generally did not fill the whole area of cell bodies (e.g., Fig. 66.5b). Some of their morphology (e.g., the first three in Fig. 66.5b, where green spots surround a smaller dark sphere), was quite similar to those of intracellular motility in the cytoplasm observed in a high-resolution in vitro imaging study [26]. The mean diffusion as a function of the distance from the nucleic center also showed that the peak diffusion did not locate at the center of cell bodies (Fig. 66.5c). These results on morphology suggest that the green spots are distributed over the space surrounding nuclei, likely in the cytoplasm. Finally, the diffusion coefficient of the spots agrees with those of the motion of intracellular organelles measured in vitro [27–29]. Therefore, the green spots likely represent the diffusion-like movements of intracellular organelles.

66.3 OCT Imaging of Hemodynamic Responses: Second-Timescale Transient Dynamics

As described in the Introduction, when the brain is activated, additional oxygen and glucose should be supplied via increased blood flow in association with spatiotemporally varying metabolic needs. Neurovascular coupling represents the current paradigm for understanding this energy supply regulation of the brain. This current paradigm focuses on how local neuronal activity adjusts arteriolar tone (and thus local CBF) in association with metabolic needs ([30] for review). A number of studies have discovered a range of mechanisms underlying this coupling. Neurotransmitter-mediated signaling from neurons and astrocytes to vascular smooth muscles that dilate and constrict arterioles plays a major role in regulating CBF [31, 32]. When this energy supply regulation does not work, neurons and glia

Fig. 66.4 (continued) row shows the autocorrelation function data (*black dots*) and their fits (*red lines*) in the complex plane, where the estimated M_S and $M_S + M_F$ are presented as the *blue* and *green circles*, respectively. The *bottom row* shows decay of the M_F-terms. The coefficients of determination of these three voxels are $R^2 = 0.999$, 0.988, and 0.647. All scale bars, 100 μm (Reprinted from [23] with permission)

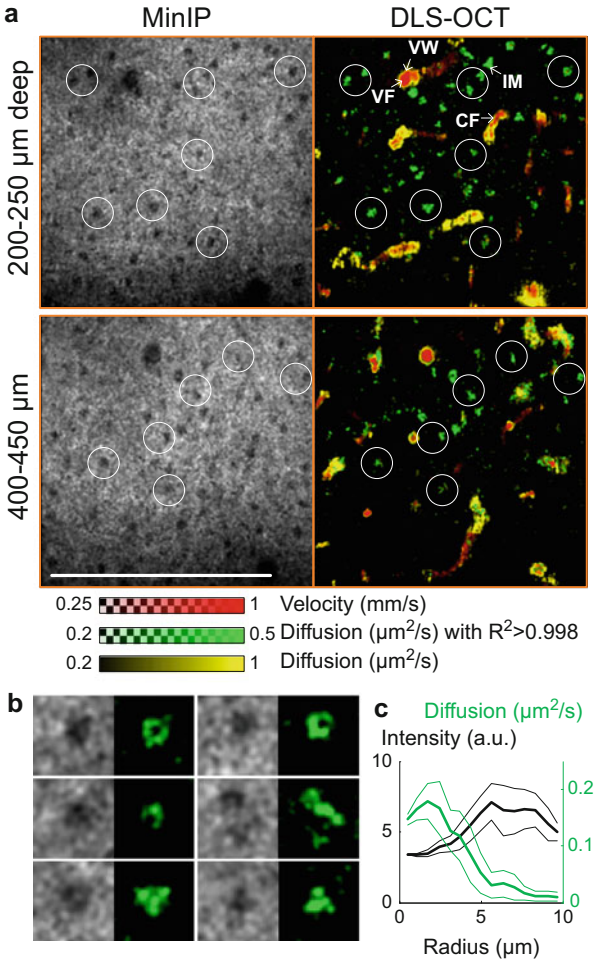

Fig. 66.5 DLS-OCT imaging of neuronal intracellular motility. (**a**) High-NA DLS-OCT imaging of the brain cortex. The velocity and diffusion images (*red* and *yellow*) are superimposed with the map of diffusion with high R^2 (*green*). *White circles* are collocated to visually guide the spatial correlation between the positions of neuronal cell bodies (*dark spots* in MinIP) and neuronal IM (*green spots*). Not all cell bodies are marked. *VF* vessel flow, *CF* capillary flow, and *VW* vessel wall. The small range of the diffusion coefficient is used to increase the image contrast. Scale bar, 200 μm. (**b**) Several examples of neuronal nuclei observed in MinIP and neuronal IM observed in the high-R^2 diffusion map. Image size, 25 × 25 μm, for each. (**c**) The mean intensity (*black*) and diffusion (*green*) as the function of the distance from the nucleic centers ($n = 10$) (Data are presented in mean ± SD) (Reprinted from [94] with permission)

become injured or die. Since such an inadequate supply occurs in various disorders of the brain, understanding the mechanisms is a prerequisite for developing therapies to correct defects in blood flow control occurring in stroke [33], hypertension [34], and Alzheimer's disease [33]. This section describes how OCT can

advance in vivo imaging of neurovascular coupling. This section introduces studies that used OCT for imaging of such neurovascular coupling.

The current paradigm has recently been challenged by the concept that capillaries also contribute to blood flow regulation in response to neuronal activity, so-called neuro-capillary coupling. This concept is supported by recent studies showing that contractile cells called pericytes can control the diameter of capillaries [35], and substances altering the arteriole diameter can contract and relax pericytes as well [36], likely due to alteration of the intracellular Ca^{2+} concentration of pericytes [37]. For example, pericytes (and thus capillaries) constrict in response to noradrenaline and dilate in response to glutamate in brain slices [35]. Extending our knowledge of blood flow dynamics down to the capillary level will be helpful as the capillary bed works as a direct interface through which oxygen and glucose are supplied to the tissue. Regulation of blood flow at the capillary level, however, has been only demonstrated either in vitro or in pathological conditions [38, 39]. Capillary flow regulation in response to neural activation has yet to be demonstrated in vivo under physiological conditions [40], but this is advancing rapidly. Furthermore, there are controversial reports on the in vivo capillary flow responses. Being different from arterioles, capillaries have been reported to exhibit highly heterogeneous responses to neural activation [41, 42] and even nearly stochastic distributions during baseline [43], potentially masking neural activity-induced responses of single capillaries [44].

Due to the nature of capillary flow responses, demonstrating neuro-capillary coupling in vivo requires systematic measurement of blood flow over a reasonably large number of capillaries at the same time. To date, capillary flow responses have been measured by tracking fluorescence-labeled single RBCs with either video microscopy (VM) [43] or two-photon microscopy (TPM) [41, 45]. Those techniques, however, are generally not suitable for the systematic measurement of large numbers of capillaries since they measure the responses over only several capillaries within a single focal plane (VM) or capillary by capillary (TPM). Meanwhile, OCT generally enables a larger imaging volume per time, but the existing OCT-based technologies, including Doppler OCT and DLS-OCT described in the previous section, are still far from achieving the target number of capillaries (>100) with sufficient temporal resolution (~ 1 s) as they require many consecutive scans per position to estimate the flow speed [23, 46, 47]. This section introduces another OCT-based technology for measurement of flow speed and its application to high-speed volumetric imaging of blood flow speed over hundreds of capillaries at the same time.

66.3.1 Slow Changes in the OCT Signal Associated with Neural Activation

Intrinsic optical signal (IOS) generally images oxygenated and deoxygenated hemoglobin concentration at the surface of cortex. Therefore, it can image hemodynamic responses to neural activation while providing two-dimensional,

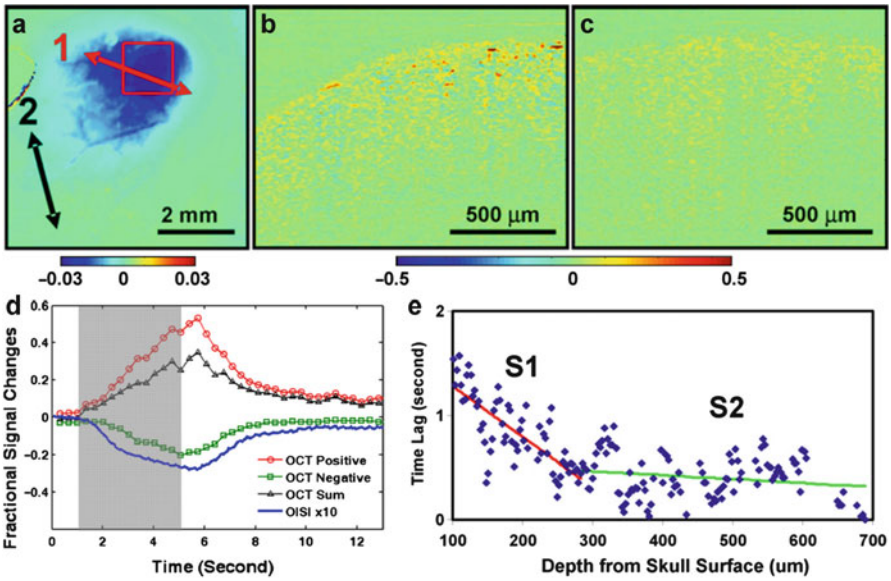

Fig. 66.6 IOS and OCT imaging of brain activation. (**a**) Localization of activation area in IOS imaging. Two OCT scans are denoted by *arrows 1* (*red*) and *2* (*black*). (**b**) Cross-sectional map of fractional changes in the OCT intensity at time window 4–6 s over the activation region denoted by the *arrow 1* during the stimulation of the contralateral forepaw. (**c**) Functional OCT image at time window 4–6 s over the scan denoted by *arrow 2*. (D) Plots of positive, negative, and summation OCT signals at regions with significance level $\alpha < 0.001$. The time course of IOS signal ($\times 10$) is also included to show the temporal correspondence. (**e**) Plot of the averaged time lags at the same depth (from the skull surface) versus the depth. Two distinct regions are indicated by different slopes (*S1* and *S2*) (Reprinted from [48] with permission)

depth-integrated activation maps of brain activity. Whereas general IOS imaging does not provide depth-dependent information of the hemodynamic response, OCT can measure the depth profile of neurovascular coupling. Chen et al. [48] performed IOS imaging to identify an activated region of rat somatosensory cortex during forepaw electrical stimulation and repeated OCT B-scans on the activated and control regions (Fig. 66.6a), resulting in 3-D (x,z,t) OCT data. At every voxel, a temporal fractional change in the OCT intensity signal was obtained with respect to its baseline. This functional OCT signal was significantly larger in the activated region (Figs. 66.6b, c). The mean of the functional OCT signals exhibits time courses similar to that of IOS, with a net positive change that occurs during the activation period (Fig. 66.6d). When the OCT signal is integrated over depth, its lateral profile was highly correlated with that of IOS, supporting that the OCT signals represent hemodynamic responses to neural activation. These OCT signals revealed a laminar profile of hemodynamic responses that a deeper area responds earlier than a superficial area (Fig. 66.6e). This is consistent with the fact that the neuronal activity initiates in the deeper layers of the cortex and then propagates to the superficial cortex. While the neural propagation occurs over only 10's of

milliseconds, the delay in the vascular response is 100's of milliseconds. The greater delay in the vascular response indicates intriguing laminar differences in neurovascular coupling that requires further study. These laminar OCT results were recently elucidated further in [49].

66.3.2 Quantitative OCT Imaging of Hemodynamic Responses

The above study showed OCT signal changes in response to neuronal activity that were similar to the hemodynamic responses measured by IOS imaging, but it remains unclear what mechanisms are driving those OCT signal changes. Srinivasan et al. measured brain activation-evoked changes in blood flow and total hemoglobin in the rat somatosensory cortex [50]. They performed IOS imaging to identify the activated region and chose an OCT scanning line (Fig. 66.7a). Then, Doppler OCT imaging was performed during somatosensory activation for measuring fractional changes in blood flow (Fig. 66.7b for baseline, Fig. 66.7d for flow in the draining vein). In addition, activation-induced changes in the extinction coefficient were measured to estimate dynamics of the total hemoglobin concentration (Fig. 66.7c). Assuming single scattering, the OCT signal profile $R(z,t)$ is determined by the extinction coefficient $\mu_t(t)$ and the backscattering $A(t)$, which are time-varying variables due to brain activation. Using this relation, a least-squares fit was performed to determine $\Delta\mu_t(t)$ as shown in Fig. 66.7d (blue). As a result, the time course of $\Delta\mu_t$ was nearly identical to that of ΔHbT measured by IOS, supporting that the OCT extinction coefficient changes over time were closely related to changes in the total hemoglobin concentration. In contrast, the Doppler OCT-measured flow response showed a faster relaxation than both the ΔHbT and $\Delta\mu_t$ responses, which is consistent with the well-known delayed recovery in cerebral blood volume [51].

66.3.3 Statistical Intensity Variation (SIV) Imaging of Capillary Network Flux

The above study showed that OCT is useful for the measurement of blood flow responses in arteries and veins, but it did not observe responses in individual capillaries. Since cerebral capillaries are known to respond to neural activation in a highly heterogeneous manner, a high-statistical-significance study of capillary responses will require an imaging method that simultaneously monitors changes in blood flow over a sufficient number of capillaries. Existing methods, including video microscopy, two-photon microscopy, Doppler OCT, and DLS-OCT, are not sufficient for this purpose; hence, another OCT-based method is proposed.

The intensity of the OCT signal at a voxel basically represents the amplitude of light backscattered from the voxel. According to the Mie scattering theory, 1-μm wavelength light is supposed to be largely scattered by particles of 0.1–10 μm in diameter. Therefore, we can expect that within capillaries, RBCs (~6.5 μm in

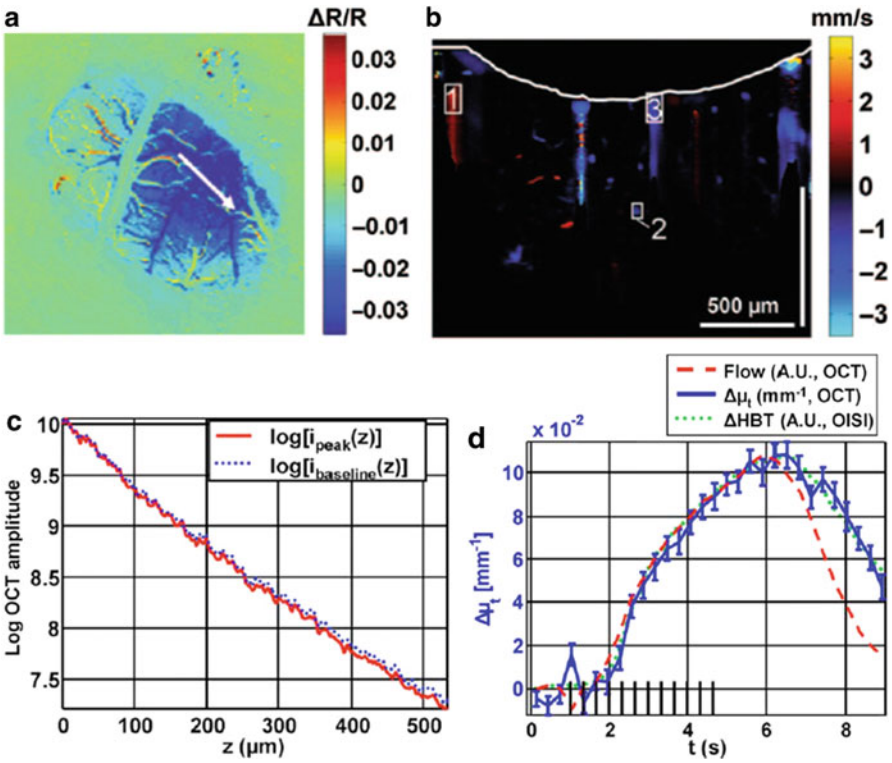

Fig. 66.7 Quantitative OCT imaging of cortical hemodynamic responses. (**a**) Fractional IOS image at peak activation. The OCT scan is shown as the *white arrow*. (**b**) Doppler OCT image at baseline with cortical surface indicated by the *white line*. (**c**) Profile of the natural logarithm of OCT amplitude versus depth, during the baseline (0–1 s, *dotted line*) and peak activation (5–7 s, *solid line*). (**d**) Time courses of $\Delta\mu_t$ measured by OCT (*solid blue*), flow in the draining vein measured by Doppler OCT (*dashed red*), and ΔHbT measured by IOS imaging (*dotted green*) (Reprinted from [50] with permission)

diameter) will result in large OCT signals compared to blood plasma. If this is true, the OCT signal at a given voxel located in a capillary should go up and come back down when an RBC passes. This idea has been validated in that individual RBC passage through a capillary appeared as a peak in the time course of the OCT intensity signal of the voxel located at the capillary center (Fig. 66.8a). This OCT identification of individual RBC passage can be used for quantifying the flow properties of RBCs such as the flux [RBC/s], speed [mm/s], and linear density [RBC/mm]. Although this technique enables us to obtain 3D maps of capillary network flow but is still not fast enough to trace hemodynamic responses, the finding that RBC passage results in OCT intensity variation leads to the possibility of rapid volumetric imaging of capillary network flow via statistical analysis of the intensity variation.

We first defined a metric quantifying the intensity variation between the two consecutive B-scans,

$$SIV(z,x,y) \equiv \frac{E\left[\{I(z,x,t_2;y) - I(z,x,t_1;y)\}^2\right]}{E\left[\frac{1}{2}\{I^2(z,x,t_2;y) + I^2(z,x,t_1;y)\}\right]}$$

where $I(z,x,t_1;y)$ and $I(z,x,t_2;y)$ are the first and second B-scans at a given Y-position, respectively, and $E[]$ denotes ensemble averaging. The ensemble averaging can be implemented by averaging over neighboring voxels and/or repeated volumes. This ensemble averaging will minimize the stochastic speckle effect in the OCT intensity. A single SIV value would not quantify RBC flow properties because the value will depend on the space and time of its acquisition. Instead, if one gathers SIVs in a random manner from a given capillary segment, which is conceptually identical to a random sampling of SIVs from the time course embedding the RBC peaks (Fig. 66.8a, for example), then the mean SIV will increase as the speed increases (i.e., sharper peaks), but it will also increase as the density increases (i.e., more peaks for unit time). Here, numerical simulation and experimental measurements in Fig. 66.8b demonstrated that the mean SIV is linearly dependent of the RBC flux, where (Flux) = (Density) × (Speed).

An example of SIV imaging of the rodent cerebral cortex in the cranial window preparation is shown in Fig. 66.8d. In order to gather SIV values along capillary segment paths, one needs to know the position vectors of each capillary. While there are several methods to do this, Hessian matrix analysis can be used and then the mean SIV for each capillary segment can be converted into the RBC flux. In this way, a 3D flux map over a vectorized capillary network can be obtained (Fig. 66.8e).

As SIV imaging only requires two B-scans per Y position, it enables us to measure the RBC flux over hundreds of capillaries nearly at the same time. Therefore, the technique is suitable for quantifying how the RBC flux varies with functional activation across hundreds of capillaries, overcoming the limitations in the previous measurements owing to the diversity of capillary flow responses. For example, properly splitting the ROI achieved the desired temporal resolution enough to trace fast hemodynamic responses, consequently leading to a temporal series of 20 consecutive SIV volumes with a temporal sampling frequency of 1.3 s ($\Delta T = T_{n+1} - T_n$). This dynamic SIV imaging was performed over an ROI near the center of functional activation in the somatosensory cortex corresponding to forepaw stimulation that was identified with intrinsic optical signal (IOS) imaging (Fig. 66.9b). One of the temporal series of 20 SIV volumes is presented in Fig. 66.9c. About 200 capillary segments were identified, and following data analysis led to a temporal series of 20 capillary network flux maps, one of which is shown in Fig. 66.9d. This means that SIV imaging technique enabled us to trace how the RBC flux varies with activation over hundreds of capillaries (Fig. 66.8e). Some capillaries exhibited early flux increases while some exhibited late increases or even decreases.

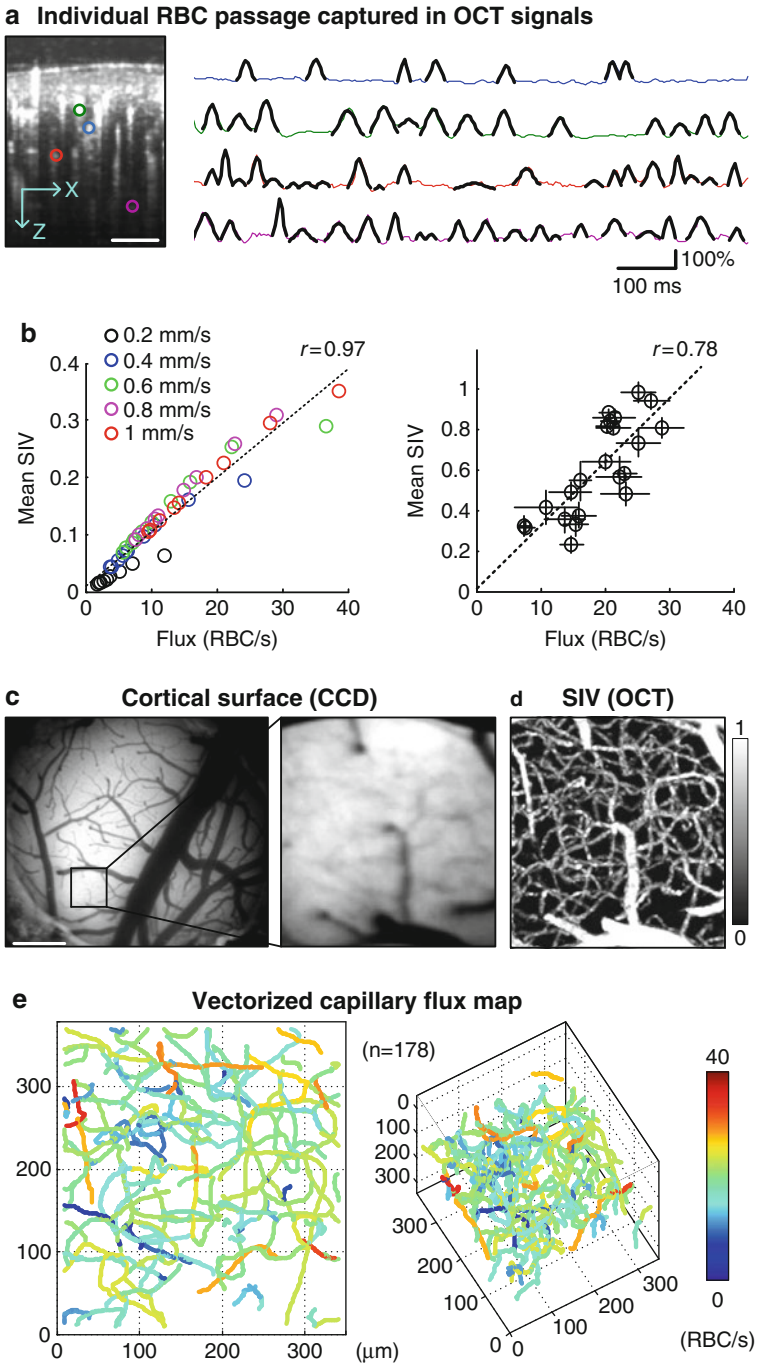

Fig. 66.8 (continued)

66.4 OCT Imaging of Neuronal Activity: Millisecond-Timescale Transient Dynamics

As traditional microelectrode recordings of neural signals can damage brain tissue, noncontact and label-free optical recording of the neural signal (a.k.a., fast optical signal; FOS) has been studied for a long time. Since the original study in 1949 [56], many scientists have demonstrated FOS measurements of neuronal activity in isolated nerves [57–63], cultured neurons [64, 65], retinal tissue [66, 67], live brain slices [68], exposed cortices [69], and the human brain [70–75]. This section describes OCT-based studies extending the FOS measurements into depth-resolved single-cell-resolution in vivo imaging. Despite its potential impact, in vivo imaging of FOS has often been considered controversial and elusive [76]. Our group also reported a failure in detecting FOS in the monkey brain [77]. These difficulties are likely due to the living animal's motion artifacts and the partial volume effect of the lower-resolution imaging methods presently used in vivo. In order to break through these current barriers, we need to further improve motion correction algorithms [78–85] for suppressing cardiac and respiratory motion artifacts from phase-resolved dynamic OCT imaging data; and we need to reduce the partial volume effect. OCT's μm resolution (smaller than single neurons) will clearly minimize the partial volume effect and could be utilized to demonstrate single-cell-resolution imaging of FOS in vivo. This section introduces current progress to overcome these barriers.

66.4.1 Motion Correction for FOS Imaging In Vivo

To improve the sensitivity of in vivo OCT signal to neuronal activity, Lee et al. have proposed motion correction algorithms to suppress cardiac and respiratory motion artifacts from millisecond-scale, phase-resolved dynamic OCT imaging data [86]. They found that, in the regime of their OCT resolution and animal preparation protocol, the animal's cardiac motions cause global phase fluctuations (GPFs, filled triangle in Fig. 66.10a) while the respiratory motions cause bulk image shifts (BISs, empty triangle in Fig. 66.10a). The algorithms were shown to enhance the metric of image stability (e.g., the cross-correlation in Fig. 66.10b), the noise map (Fig. 66.10c), and reduction of phase signal noise (Fig. 66.10d).

Fig. 66.8 SIV imaging of capillary network RBC flux. (**a**) Cross-sectional OCT angiogram of the rodent cerebral cortex (*left*) and RBC passage captured in OCT intensity time courses (*right*). Each *line* presents the time course of relative changes in the OCT intensity at the center of each capillary indicted by the color *circles*. Each peak (*overlaid black* pieces) represents single RBC passage. Scale bar, 100 μm. (**b**) Numerical simulation (*left*) and experimental validation (*right*) of the SIV relation to the RBC flux. Twenty-two capillaries were analyzed in the experimental validation. Data are presented as mean±SD. (**c**) CCD image of the brain cortex through the cranial window. (**d**) *En face* maximum intensity projection (MIP) of the SIV volume data. Ten volumes were averaged. (**e**) 3D flux map of the capillary network (Reprinted from Lee et al. [95] with permission)

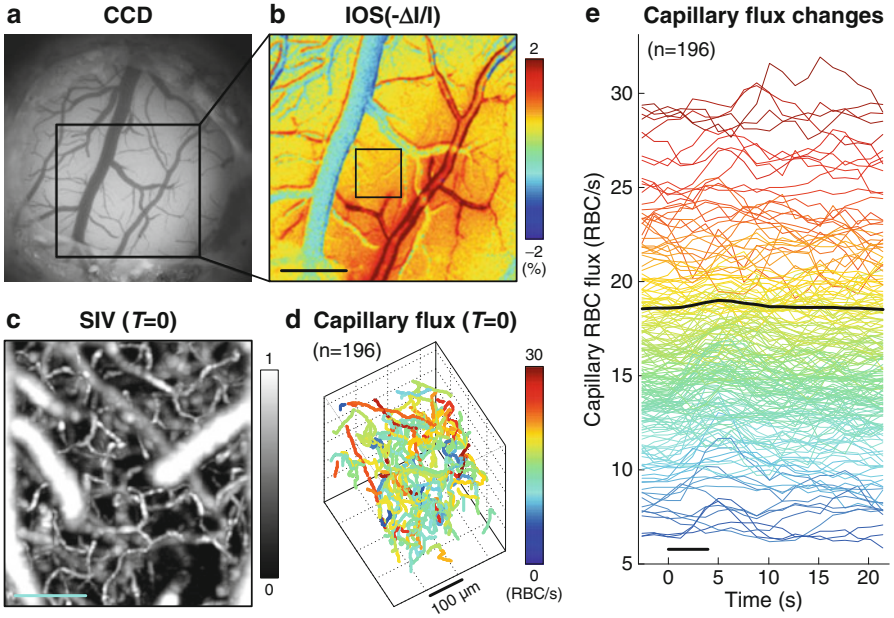

Fig. 66.9 SIV imaging of capillary network flux responses to neural activation. (**a**) A CCD image of the rodent somatosensory cortex. (**b**) IOS imaging of the hemodynamic response of the cortical surface. As we used 570-nm illumination, a decrease in the CCD intensity (*red color*) represents an increase in the blood volume. Scale bar, 500 μm. (**c**) *En face* MIP of SIV at $T=0$ s. A temporal series of 20 SIV volumes like this were obtained. We located the OCT focus at a slightly deeper area to include the capillaries near the neurons of the somatosensory cortex. Scale bar, 100 μm. (**d**) Capillary network flux map at $T=0$ s. A temporal series of 20 flux maps like this were obtained. (**e**) Time courses of RBC flux changes of the 196 capillaries during functional activation. A change in the mean flux averaged across capillaries is presented by the thick black curve. The peak change was 2.2 % and highly significant ($p<10^{-8}$). The black bar in the bottom indicates the duration of forepaw stimulation (3 Hz for $T=0$–4 s) (Reprinted from Lee et al. [95] with permission)

66.4.2 Preliminary Results of In Vivo FOS Imaging of Neuronal Activity

The somatosensory cortical region activated by forepaw stimulation was identified with CCD IOS imaging (Fig. 66.11a). We chose a line (the cross-sectional plane in 3-D) for ms-scale dynamic OCT imaging. From this 3-D (x,z,t) intensity data, we excluded the voxels of vessels and their multiple-scattering shadows by employing a threshold on the baseline noise level. The intensity signals of the surviving voxels were averaged over ten runs of stimulation (3 Hz for 10 s followed by 20 s rest, for each run) and fit with the canonical response function (see caption of Fig. 66.11b for details and example results)

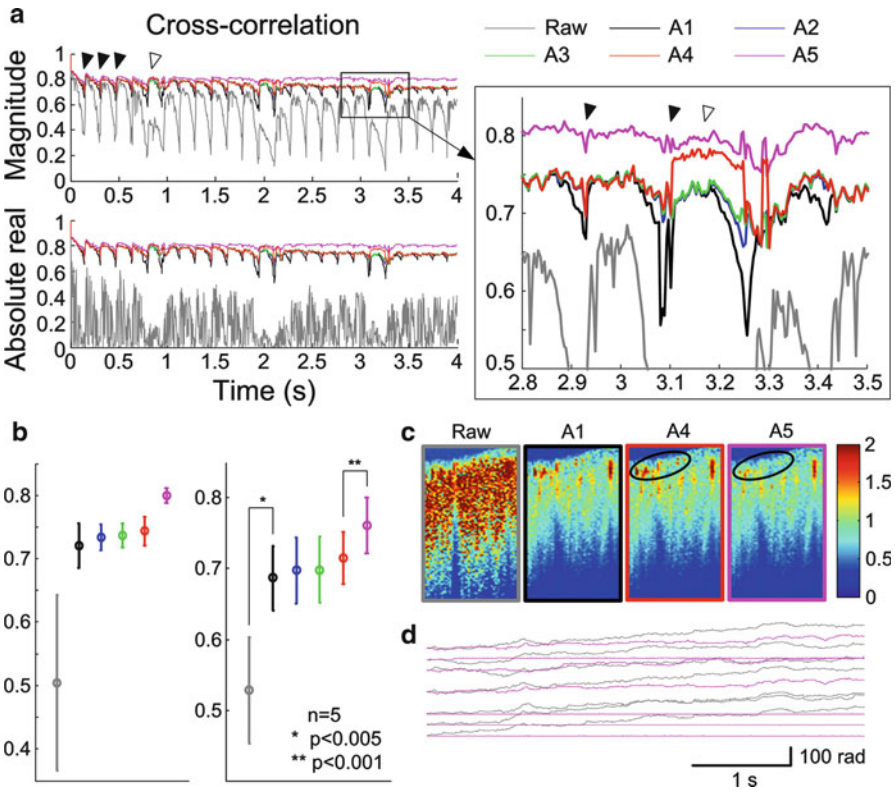

Fig. 66.10 Motion correction for OCT imaging of FOS. (**a**) The cross-correlation of each frame to the first frame is presented as the metric of image stability. The absolute real of the complex-valued cross-correlation (*bottom*) represents the stability of phase signals. The image stability was significantly reduced by either GPFs or BISs. Each color shows the result of different combinations of algorithms (legend). A5 was computationally most expensive but most effective. (**b**) The mean cross-correlation of the later 2 s (*left*). The superior performance of A5 was statistically confirmed across five animals (*right*). (**c**) Noise maps resulted from different combinations of algorithms. A5 was particularly effective in reducing noise at the surface (*black circles*). (**d**) A5 also significantly reduced noise of the OCT phase signals, by more than the two orders of magnitude at many voxels (Reprinted from [86] with permission)

$$f(t) = a(t - t_0)^2 e^{-b(t-t0)} s(t - t_0) \tag{66.7}$$

where a, b, and t_0 are fitting coefficients and $s(t)$ is the step function, which in turn estimated the peak response, $a(2/b)^2 e^{-2}$, peak time, $t_0 + 2/b$, and relaxation time, $1/b$. This fitting estimated each surviving voxel's peak response, peak time, and relaxation time (Fig. 66.11c), which enabled grouping of the various responses by their temporal characteristics (Fig. 66.11d) and revealed a depth profile of the FOSs (Fig. 66.11e).

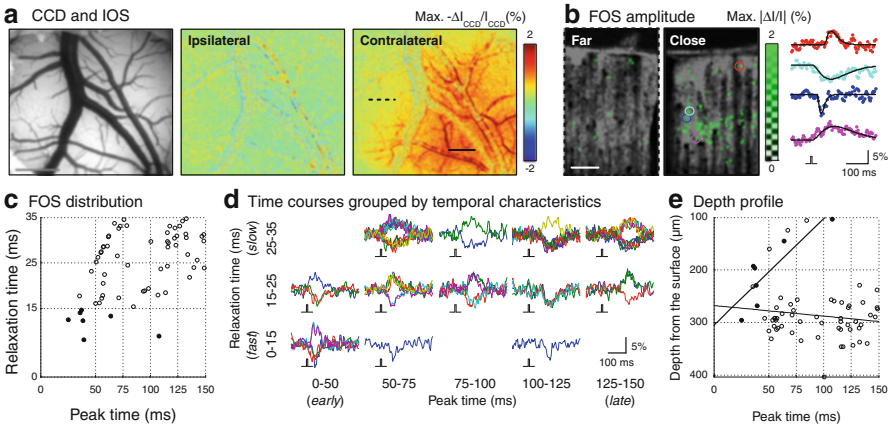

Fig. 66.11 Preliminary results of OCT imaging of FOS. (**a**) CCD imaging of IOS. The signed maximum of the inverted relative change in the CCD intensity ($-\Delta I_{CCD}/I_{CCD}$) is presented (*color images*). The solid and *dotted black lines* indicate the OCT scanning positions close to and far from the AC, respectively. Scale bar, 500 μm. (**b**) Voxels with the baseline std/mean >2 % were excluded. Each surviving voxel's time course was fit with a canonical response function (e.g., right). Only voxels with good fitting ($R^2 > 0.6$) were chosen, and their maximum absolute changes ($|\Delta I/I|$) are presented as *green* on the map of tissue stability (baseline mean/std). Scale bar, 100 μm. (**c**) Distribution of FOS in the peak and relaxation time. (**d**) When grouped by the peak and relaxation time, FOS exhibited highly diverse time courses, from *early fast* to *late slow*. The time courses of *fast* FOS were similar to those of in vitro FOS of action potential. Not all the FOS here would represent neuronal activity; further validation is needed as outlined in the text. Color is random. (**e**) Distribution of FOS in depth and peak time. *Fast* FOS (relaxation time <15 ms) exhibited upward propagation (*filled circles*, $p = 0.015$) while *slow* FOS stayed at depth with varying peak times (*empty circles*). The significance of *fast* versus *slow* FOSs needs further consideration but may relate to action potentials versus synaptic activity

OCT imaging of in vivo FOS of neuronal activity should be validated by showing that (i) the FOS is significantly larger in the ROI close to the activated center (AC) (e.g., Fig. 66.11b) and smaller with ipsilateral stimulation, (ii) its time courses agree with those of in vitro and ex vivo FOSs found in the literature [57, 59, 61, 68, 87], (iii) its laminar and/or temporal structure agrees with well-known characteristics [88], and (iv) it satisfies the five criteria established in [74].

66.5 Summary and Future Direction

This chapter described how OCT-based technologies enable μm-resolution imaging of vascular and neuronal dynamics occurring in the brain cortex of a living animal, leading to novel findings in the neurosciences. First, Doppler OCT is used for quantitative measurement of baseline CBF, an important endpoint in studies of cerebral pathophysiology. We also reviewed the recent integration of OCT with DLS for in vivo imaging of both flow and diffusion of intracellular organelles. Next, we described how CBF responses to brain activation with the time constant of a few

seconds can be measured with OCT. Compared to conventional IOS imaging, OCT provides depth-resolved information of the hemodynamic responses to brain activation. SIV imaging was shown to have potential to enable a systemic study of how the capillary network flow responds to brain activation. Finally, we presented preliminary results supporting the potential of OCT to measure fast optical signals in vivo with millisecond temporal resolution.

DLS-OCT has been shown to measure both the axial and transverse components of CBF velocity (Fig. 66.4), but its applicability to quantitative imaging of capillary flow velocity has yet to be demonstrated. When validated, DLS-OCT imaging could be simultaneously performed with SIV imaging for cross validation. In addition to the CBF imaging, DLS-OCT is likely able to image the diffusion-like motion of intracellular organelles (i.e., intracellular motility, IM). This energy-consuming IM is directly related to and thus can represent cellular metabolism and viability but has been measured only in vitro by existing methods based on fluorescence [89, 90] or DLS [26, 28, 29, 91, 92]. Further validation that the high-diffusion spots revealed in DLS-OCT imaging (Fig. 66.5) really represent IM is needed. Once validated, DLS-OCT will, for instance, be useful for the study of stroke pathology, characterizing the spatio-temporal correlation between reduction in arterial blood flow, associated changes in capillary flow and neuronal viability (IM), and final tissue infarction.

SIV imaging enabled us to monitor RBC flux changes over hundreds of capillaries during activation with ~1 s temporal resolution. This functional study will help reveal how capillary flow responds to neural activation at the network level and with high statistical significance and thus enable us to test the hypothesis that cerebral capillaries may regulate blood flow during brain activation.

OCT-based in vivo FOS imaging of neuronal activity seems promising but still far from robust demonstration. Whereas voxels of vessels were excluded in Fig. 66.11, one may directly identify voxels of neurons using high-NA OCT imaging (e.g., Fig. 66.5a) prior to functional OCT imaging. Also, one can use the phase of the OCT signal which is very sensitive to displacement of scatterers. FOS has been shown to originate from morphological changes in neurons during excitation [93]. When the SNR of the phase signal is not sufficiently high for robust imaging of FOS despite the motion correction (Fig. 66.10d), one may have to employ additional signal processing techniques including wavelet decomposition (WD) and independent component analysis (ICA). WD will help filter out fluctuations with scales other than the known FOS's characteristic time constant. ICA will be performed across, for instance, the 8×8 voxels surrounding a neuron (30×30 μm, 64 channels), filtering out common phase fluctuations due to either residual motion artifact or tissue compression oriented by and propagated from RBC passage in neighboring capillaries.

When demonstrated, FOS imaging technology will be useful for visualizing the microscopic 3-D pattern of neuronal activity propagation in the brain cortex and for pursuing minimally invasive human brain signal recording technology with miniaturized optical systems in the future (potentially enabling ultra-multichannel micro-optode arrays with reconfigurable recording sites in 3-D).

These μm-scale live connection and brain signal recording studies, along with the feasible applications of other OCT-based technologies introduced in this chapter, will enable a range of studies of how the brain works and how it fails in pathological conditions.

Barrett's esophagus • Dysplasia diagnosis • Endoscopic imaging • Image analysis • Optical coherence tomography

67.1 Gastrointestinal Endoscopy Review

Gastroenterology, the study of the human digestive system and the treatment of associated disorders, has promoted and benefitted from the development of endoscopy. Many disorders of the gastrointestinal (GI) tract, cancer in particular, arise within the innermost layer, i.e., the mucosa. Gastroenterologists rely substantially on visual examination of the inner surface with an optical device (i.e., endoscope) and the microscopic interpretation of biopsy samples. However, the conclusive proof of benefit is lacking for some prototypical disorders, such as Barrett's esophagus (BE).

Gastrointestinal mucosae (e.g., of the esophagus, colon, pancreatic duct, bile duct, etc.) consist of three distinct sub-layers: an innermost layer or layers of cells (epithelium), a middle layer of connective tissue (lamina propria), and a layer of muscle cells (muscularis mucosa). The focus of this chapter is cancer that involves or arises in the epithelium. As a gross simplification, the initial step of cancerous

transformation may be genetic mutation(s), followed by the appearance of abnormalities within the epithelial cells and evidence of deviant behavior of these cells, the latter attributes being readily evident by standard histopathology. There is frequently a precancerous stage in which cells are clearly abnormal, but not yet cancerous. In such cases, the descriptive term dysplasia is applied. In general, dysplasia indicates risk that frank cancer will develop if the dysplastic tissue is not treated or removed. Dysplasia is usually subclassified as low grade (LGD) or high grade (HGD); if especially severe but noninvasive, it may be labeled carcinoma in situ. Eventually, the dysplastic cells transform to cancer and may escape the confines of the epithelium, in which case the lesion is termed invasive and is conclusively cancerous. Epithelial cancers may progressively invade the deeper layers of gut wall to adjacent and then distant lymph nodes and to more distant organs. With increasing degree of invasion, the prognosis for the patient worsens. Conversely, the prognosis is usually good if the malignancy is discovered when least invasive, or, optimally, when the process is in a precancerous stage.

Since 1886, the endoscopic diagnosis of pathologic disorders has been based essentially on visual inspection [1]. However, dysplastic epithelium may or may not be recognizable at endoscopy. The most common form of identifiable GI dysplasia is the precancerous (adenomatous) colon polyp. Although polyps can be small, and subtle in appearance, nevertheless the majority can be visualized (and removed) using standard endoscopes. A precursor of the precancerous polyp may be the so-called aberrant crypt focus (ACF) [2–4]. Normally, the epithelial cells lining the colonic crypts have a monotonous, regular appearance. When neoplastic changes occur in the cells comprising the crypts (e.g., enlargement), the crypt takes on an aberrant appearance; groups or patches of such aberrant crypts are termed foci. There is an association between an increase in the density of ACF in the colon and malignancy. Special techniques, such as chromoendoscopy with magnifying endoscopes or OCT (Sect. 67.4), may visualize ACF.

Disorders in which early epithelial dysplastic changes are usually not clearly visible at endoscopy, such as BE, are more challenging. Of the various disorders that increase the risk of cancer, BE is prototypical. In recent decades, the incidence of esophageal adenocarcinoma has increased more rapidly than that of any other malignant neoplasm in the United States [5] and Western Europe [6]. The reason (s) for this are not fully identified, but the increase appears to be related in large part to a corresponding increase in the incidence of BE, an acquired condition which increases the risk of adenocarcinoma at least 30-fold [7–13]. Most patients in whom BE is diagnosed undergo surveillance, which involves the performance of endoscopy at regular intervals. The objective of surveillance is to detect dysplasia or early stage cancer. Subtle morphologic changes in the dysplastic mucosa are sometimes detectable endoscopically, but in the majority of precancerous cases are not discernible within the overall disease process. Thus, the usual surveillance program with these conditions includes obtaining large numbers of biopsies in the hope that extensive tissue sampling will detect the presence of dysplasia and thereby afford the opportunity for treatment prior to the appearance of frank cancer. Because these diseases are chronic, adherence to this surveillance approach dictates that

endoscopic biopsies be obtained at scheduled intervals throughout the life of the patient or until the organ at risk is removed surgically. There is considerable debate regarding the efficacy of surveillance endoscopy because of the lack of randomized trials to support its value. Several studies do suggest the survival advantage of endoscopic surveillance [14–20]. However, in addition to cost and a small risk of complications, the most serious shortcoming is sampling error. Even though large numbers of biopsies are obtained according to standard protocols, the fraction of the mucosal surface sampled is tiny in relation to the overall surface area at risk for cancer, which is often a large segment of the esophagus. Thus, long-term commitment to a costly surveillance technique of uncertain benefit is a difficult clinical decision.

An ability to interrogate the status of the mucosa at endoscopy would be highly desirable for dysplastic changes usually not visible. Endoscopic biopsy interpretation is based on visual assessment of a small sample of mucosa using a microscope. Potentially, the realization of this capability in "real time" at endoscopy could greatly enhance diagnosis. It might reduce the frequency of unnecessary biopsies; perhaps even eventually eliminate the need for biopsies in some cases. The capability of comprehensively examining long segments of GI tubular organ is also attractive to eliminate the sampling error inherent in the current procedure.

The many efforts to improve endoscopic diagnosis, to move beyond reliance on visual inspection alone, have taken numerous directions. These include endoscopic ultrasound (EUS), chromoendoscopy, narrowband imaging (NBI), fluorescence endoscopy, Raman spectroscopy, and confocal endoscopy. Of these, only EUS has become established as a clinical modality. EUS provides an image representation of the tissue layers of the esophageal wall. Thus, EUS can be used to determine the invasiveness (stage) of a tumor. For example, EUS is the most accurate test available for preoperative staging of esophageal cancer [21]. Unfortunately, efforts to utilize EUS to detect high-grade dysplasia (HGD) in Barrett's esophagus have been disappointing [22, 23]. Rather than displaying a white-balanced endoscopic image, NBI adjusts the ratio of red, green, and blue channels to enhance the contrast in mucosal morphology and microvasculature. The morphology and vascular pattern are altered in the transition from intestinal metaplasia to dysplasia [24]. NBI has very high sensitivity and specificity in detecting HGD, but cannot differentiate low-grade dysplasia from non-dysplasia [25, 26]. However, it is believed that the morphologic/microvascular changes are not universally present in all cases [26]. Laser-induced fluorescence (LIF) has been studied most extensively. Fluorescence has been investigated for both endoscopic imaging and point spectroscopy [27–29]. The major obstacle facing LIF for dysplasia diagnosis is a high rate of false-positive diagnosis.

An optical technology that provides an in situ image with a resolution comparable to microscopy would be potentially ideal for endoscopic surveillance of disorders of the gut that confer an increased risk for malignancy. The potential for optical coherence tomography (OCT) in GI tract imaging is apparent. Cross-sectional, or better yet, 3D images in high resolution with detailed microstructure may provide "optical biopsy". It could significantly improve accuracy of biopsies by

demonstrating regions of mucosa with a high probability of harboring dysplasia or occult cancer. In theory, such technology might even obviate the need for biopsies.

67.2 Review of Endoscopic OCT in Esophagus and Colon

Endoscopic OCT (EOCT) has numerous potential applications in the gastrointestinal (GI) tract. The detection of dysplasia and occult malignancy has been a primary goal since early EOCT research efforts. Esophagus and colon have been most extensively studied, which may be attributed to the ease of OCT imaging catheter deployment. Most imaging catheters, especially those used in early studies, are inserted into the accessory channel of the endoscopes. The catheters are semirigid with a fix focal distance and therefore require some inner space for positioning. Esophagus and colon are readily accessible at endoscopy. Positioning the catheter was easily guided to the areas of interest by the video camera. Although imaging of the bile and pancreatic ducts is a logical extension of EOCT, the catheter probe must be smaller and deflected at a considerable angle, sometimes exceeding 90°. Therefore, there are fewer bile and pancreatic duct studies. The following sections will mainly focus on the state-of-the-art EOCT researches in esophagus and colon.

67.2.1 Esophagus

BE studies can be considered prototypical because the current endoscopic methods for the management of this condition are suboptimal. EOCT research has focused substantially on this disorder. The hypothesis has been that dysplastic transformation changes the tissue architecture and optical properties, especially scattering, of the normal mucosa, which can be detected by EOCT. If it can be demonstrated that EOCT accurately diagnoses dysplasia and occult malignancy in BE, its value in clinical gastroenterology is effectively established.

In order to demonstrate the potential for BE diagnosis by EOCT, studies were first conducted to show that EOCT can obtain interpretable images in normal, premalignant, and malignant esophagus [30–40]. The success is attributed to both the high resolution, and the distinct backscattering property of different tissues in the esophageal mucosa. The penetration depth was sufficient compared to the thickness of the mucosa. The potential of "optical biopsy" was investigated by researchers to study whether diagnosis could be made by examining the microstructure in situ. Several clinical trials were then carried out to investigate the feasibility of EOCT to detect specialized intestinal metaplasia for the purpose of BE screening [41, 42], diagnose dysplasia for Barrett's surveillance [43–46], and identify subsquamous Barrett's glands [47]. The diagnostic criteria for detecting abnormality in the epithelium were mainly based on the glandular or layered architecture, surface topology, reflectivity of epithelium, and image penetration depth. Table 67.1 summarizes the performance of a first-generation time-domain EOCT to identify specialized intestinal metaplasia, differentiate non-dysplastic from dysplastic tissue, and differentiate high-grade

Table 67.1 Diagnostic performance of EOCT for esophageal disorder

Disorder	Sensitivity (%)	Specificity (%)
Specialized intestinal metaplasia [42]	81	57–66
Dysplasia [43]	68	82
HGD/carcinoma [44]	83	75

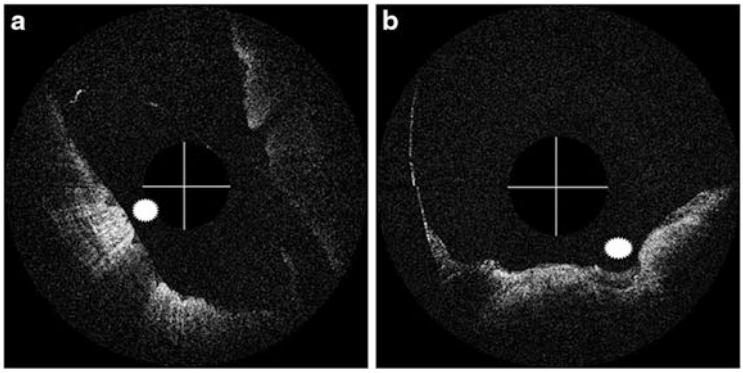

Fig. 67.1 Endoscopic TD-OCT images from a study in dysplasia diagnosis [43]. (**a**) LGD (area marked by *sunburst*). (**b**) HGD (area marked by *sunburst*). Two criteria for diagnosing dysplasia were selected: reduced light scattering and loss of tissue architecture. *Solid lines* are each 2 mm in length

dysplasia (HGD)/carcinoma from low-grade dysplasia (LGD) (Fig. 67.1). Due to significant interobserver variability when diagnosing dysplasia in BE [43], computer-aided diagnosis algorithms were developed to provide a quantitative measurement [45, 46] of dysplasia in BE compared to non-dysplasia in BE. The demonstrated sensitivity of 78–82 % and specificity of 74–90 % could potentially reduce diagnostic variability in classifying dysplasia in BE.

The early EOCT studies above utilized the first-generation EOCT system built in a time-domain configuration. Those early EOCT imaging systems had two major disadvantages: slow imaging speed and small field of view. Therefore, the surface area of mucosa interrogated in any given image was exceedingly small (typically about 6 mm image width by 25 μm slice thickness), making such systems unsuitable for interrogation of large mucosal regions.

One of the latest advances in OCT technology was ultrafast imaging speed, which led to the advent of the second-generation EOCT system. These new EOCT systems benefit from ultrahigh A-scan acquisition rate of Fourier-domain OCT. Miniature catheter probes with centering balloons and more than 10 mm working distance are another key technology which allows for scanning a lumen with a large diameter. New technologies make comprehensive esophageal screening and surveillance possible [48–53]. It was recognized that EOCT imaging could be extended to cover a much larger area of mucosa than that sampled by the conventional biopsy forceps. The aim of eliminating sampling error in current BE

diagnosis procedures has motivated the development the second-generation of EOCT for volumetric esophageal imaging.

The feasibility of this second-generation EOCT was first demonstrated in swine esophagus in vivo [49, 51, 52]. More than three centimeters of esophagus was visualized up to the muscularis externa (smooth muscle) with unparalleled resolution in minutes. 3D reconstruction allows the longitudinal and en face views, in addition to the conventional cross-sectional views. The entire circumference can be scanned with rotary catheter probes when the tissue is expanded with cylindrical balloons. The vasculature in the muscularis mucosa was clearly visualized by extracting the Doppler shift from OCT signal. The impact of the balloon compressing the tissue was questioned [54]. A double-balloon catheter was proposed as an alternative design so that the mucosa to be imaged was not in contact with balloons [52]. A catheter probe without the centering balloon was also demonstrated [55]. This probe achieved higher lateral resolution due to short working distance, with the tradeoff of imaging only a portion of the circumference. Also demonstrated was the feasibility of producing laser ablation marks in live swine using the OCT catheter probe [56]. The ablation site was visualized both in EOCT images and biopsy slides. This technology may be potentially utilized in a clinical setting to precisely correlate EOCT with pathology.

Pilot clinical trials have also been reported [50, 55, 57]. The image acquisition required only minutes to accomplish. No complications have been reported resulting from the imaging procedure. A variety of microscopic features were observed that were consistent with histopathologic findings, including squamous mucosa, intestinal metaplasia with and without dysplasia, Barrett's glands, and esophageal erosion. 3D EOCT has also been investigated as a comprehensive imaging tool to detect residual Barrett's glands after ablation treatments [55, 58]. It may benefit the ablation procedure by reducing the recurrence of Barrett's esophagus and the need for secondary ablation and potentially further increase the complete eradication rate of intestinal metaplasia.

67.2.2 Colon

The early clinical EOCT studies in colonoscopy, similar to early esophageal studies, were limited by the imaging speed and field of view of the first-generation EOCT systems. These studies investigated the backscattering profile of single cross-sectional images. Shen et al. discovered that EOCT demonstrated disruption of the wall structure in the majority (90 %) of patients with Crohn's disease, whereas the disrupted structure was present in significantly fewer cases (16.7 %) of ulcerative colitis [59]. Consolo et al. demonstrated that mucosal backscattering alteration was an effective feature to detect inflammatory bowel disease in colon with sensitivity of 100 % and specificity of 78 % [60]. 3D endomicroscopy of a large area in the colonic wall with high resolution has recently been demonstrated with the advent of the Fourier-domain EOCT technology, enabling the visualization of single crypts [61].

One of the potential clinical applications was to identify ACF, a possible precursor of precancerous polyps. Qi et al. developed an automated algorithm for colonic crypt segmentation and morphologic feature characterization [62]. The algorithm was applied to 3D OCT images obtained from excised human colonic tissues, which demonstrated the potential to differentiate ACF from normal crypts.

67.3 EOCT Key Technologies

State-of-the-art EOCT research focuses substantially on cancer precursor detection in large areas within the GI tract in a clinical setting. Visualizing the tubular organs requires several key technologies. Most of these technologies are developed in the sample arm, making the common OCT configuration usable in the GI tract. The image acquisition has to be fast because the EOCT procedure is expected to be accomplished within minutes. The imaging probe has to be reasonably small and flexible which allows for easy deployment in the lumen of tubular organs. The optical and mechanical design of the catheter directs the probing beam so that the large mucosal area of the tubular organ can be scanned. On the software side, motion artifact correction is required because physiological motion causes artifacts with similar characteristics as nonuniform rotary distortion (NURD). This causes significant misalignment along the longitudinal direction, and the distorted images may diminish the utility of 3D EOCT. Computer-aided diagnosis (CAD) algorithms are also potentially important to assist the challenging tasks of discerning dysplasia and other abnormalities, by providing objective and quantitative interpretation, reducing inter- and intra-observer variability, and speeding image interpretation. 3D EOCT procedures may yield thousands of images per patient. Analysis of these data by the unaided human reader will not be practical.

67.3.1 EOCT System

Currently, swept-source OCT is more often implemented for endoscopic applications than spectral-domain OCT. Currently, commercially available swept laser sources have higher line-scan rates than that of line-scan cameras used for spectrometers for the wavelength of 1,310 nm, which is commonly used in dense tissue imaging. The sensitivity falloff range in a swept-source system is usually more than 6 mm, compared to less than 2 mm in spectral-domain OCT. The complex conjugate artifact can be more easily resolved, e.g., with frequency shifting [63] or other technologies. Swept-source OCT can also be built with all fiber-optic components, without the need to design and maintain a high-speed spectrometer. While SDOCT may potentially have advantages over SSOCT in terms of axial resolution and phase stability, and high-quality EOCT has been implemented in both SSOCT and SDOCT configurations [31, 64, 65], in the foreseeable future, swept-source OCT will likely remain the preferred configuration for gastroenterologic applications.

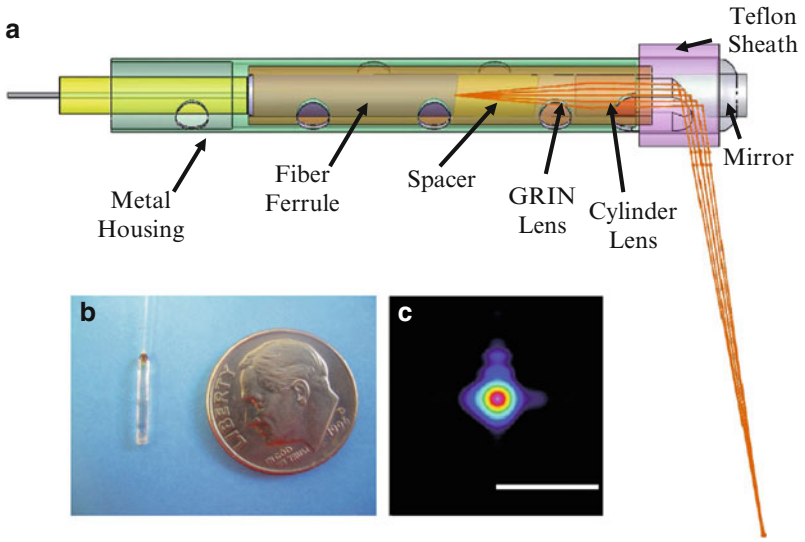

Fig. 67.2 (**a**) The mechanical model of the probe design. (**b**) An assembled fiber-optic probe without metal housing. (**c**) Beam profile measured by a beam analyzer. (Bars: 100 μm)

67.3.2 Miniature Probe

The fiber-optic probe guides the light from the EOCT system to the internal organ, focuses the beam onto the mucosa of the luminal wall, and collects the image-bearing backscattered light. A small outer diameter and short rigid parts are preferred for ease of use, especially when the probe in intended to be introduced through the accessory channel of an endoscope. The side-viewing design is most commonly used. When driven in a helical scanning pattern, the probing beam can scan the inner wall of the tubular organs. The probe may be used with or without a centering balloon, depending on the application and the needed optical performance. Balloon-based probes have long working distances, corresponding to the diameter of the balloon. The probe beam passes through the balloon and is maintained in focus on the entire circumference. They are mostly used for large, straight tubular organs, e.g., esophagus. For a typical (Gaussian) beam, the consequence of a long working distance is a larger beam waist, in other words, lower lateral resolution. Probes without balloons typically have a working distance barely longer than the outer protecting catheter sheath and may therefore be focused to a sharper spot. They are placed directly adjacent to the tissue when imaging, and if the organ has a large diameter, only a portion of the circumference is scanned. Short working distance probes are the better choice for imaging pancreatic/bile duct, which have small lumens, and colon if it is to be imaged in a targeted, rather than comprehensive way.

Figure 67.2a shows an example of a probe design for a balloon catheter [52]. A single-mode fiber was fixed in a ferrule followed by a glass spacer to expand the beam before entering a GRIN lens. A separate cylinder rod lens was attached after

the GRIN lens to correct the astigmatism induced by the protecting sheath. All optical components have polished surfaces angled at 8° to prevent back reflection. The length of the spacer may be selected to result in the desired working distance of the lens group. The lens group and ferrule were assembled in a metal housing. A gold mirror was glued at the tip of the metal housing to deflect the beam by 80° relative the optical axis. The overall numerical aperture of the probe is 0.024. The total outer diameter of the fiber probe, including the metal housing, is 1.7 mm. The rigid tip (medal housing) is about 2 cm long. Figure 67.2b shows the size of an assembled probe without the metal housing. Figure 67.2c shows the lateral beam profile at a 9 mm working distance, as measured by a beam analyzer. The spot had a minimal ellipticity of 0.98 with a FWHM diameter of 33 μm.

In order to perform the helical pattern scanning, a rotary motor and a translational motor were utilized to drive the proximal end of a flexible shaft. The metal housing of the probe was attached to the distal end of the flexible shaft. The flexible shaft can mostly prevent nonuniform rotary distortion (NURD). To further suppress NURD, The position encoder in the rotary motor was used to trigger the OCT A-scan acquisition at equal angular increments.

67.3.3 Balloon Catheter

BA balloon centers a long working distance probe to maintain focus and to stabilize the probe to suppress motion artifacts. The conventional balloon design uses a single balloon, with its two necks attached to the outer sheath using biocompatible epoxy. The imaging probe is placed within the balloon, and the probe beam passes through the balloon and is focused into the adjacent mucosa. It has been shown that catheter pressure on colonic mucosa significantly alters the tissue appearance [66]. This raises the question of whether balloon pressure or contact compresses the mucosa and affects OCT image features that are diagnostic of dysplasia within BE.

Double balloons were proposed as an alternative design [52]. Figure 67.3a illustrates the double-balloon design that allows two imaging schemes to be employed (with and without balloon-tissue contact) to investigate the influence of pressure. For imaging with no balloon-tissue contact, the images were obtained in the gap between the two balloons (labeled beam position (1)). The fiber probe could also be placed within the distal balloon (labeled beam position (2)) to acquire images through the balloon in the conventional way. The length of the gap was well controlled in order to limit the extent of lumen contraction between the balloons and keep the tissue within the axial imaging range. Holes were made in the outer sheath within the balloons so that they were inflated and deflated from the proximal end of the catheter. The outer sheath had an outer diameter of 2.4 mm. The small diameter allowed the catheter to be inserted through the accessory channel of the endoscope (Fig. 67.3b). The deployment and operation of the catheter probe were observed from the camera of the endoscope, so that images were acquired from the esophageal segments of interest (Fig. 67.3c). Figure 67.3d represents a swine esophageal image in anatomic (cross-sectional) view. The diameters of

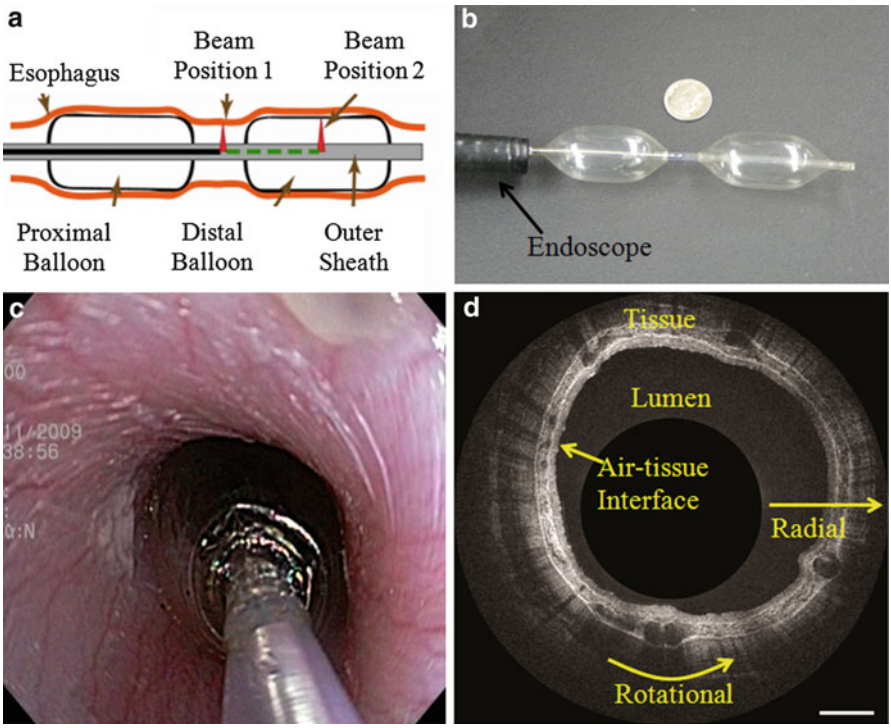

Fig. 67.3 (**a**) Schematic of the double balloon design. The beam can be located between two balloons for imaging without balloon-tissue contact (*solid black line*) or in a balloon for imaging with contact (*dashed green line*). (**b**) The double-balloon catheter (compared with a dime) inserted through the GI endoscope and inflated. (**c**) The deployment of the balloon catheter in swine esophageal observed from the camera of the endoscope. (**d**) A cross-sectional image of swine esophagus in anatomic view (Bar: 1 mm)

the imaged esophagi were around 18 mm, but in order to visualize the tissue structure, the images are displayed with a diameter of about 3 mm.

67.3.4 Motion Artifact Correction

In previous sections, several methods have been introduced for the purpose of motion artifact suppression, i.e., triggering with the encoder in the rotary motor, rotating the probe with a flexible shaft, and stabilizing it with the balloon. However, when imaging living subjects, motion artifact may not be completely suppressed. A study has shown that the motion artifact can be caused by physiological motion, e.g., respiration and heart beating [57]. Figure 67.4a demonstrates an example of motion artifact in the swine esophagus in vivo. Cross-sectional images were acquired for one minute without pulling the probe and stacked in the order of time (time axis). All of the above motion suppression methods were applied.

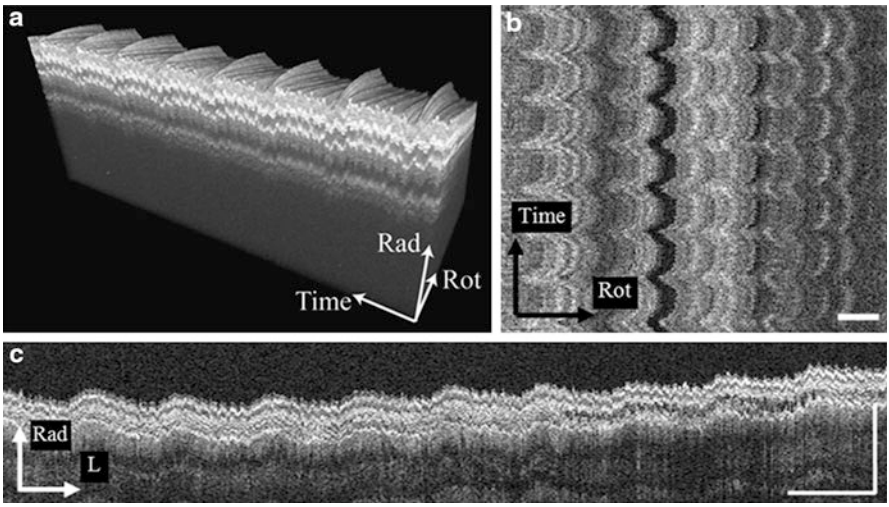

Fig. 67.4 (**a**) 3D reconstruction of swine esophageal images obtained without pulling the probe. The radial-rotational plane should not change over time if there was no motion artifact. (**b**) The en face view of the plane 300 μm deep in (**a**) shows rotational motion. (**c**) The radial-longitudinal view from the 3D reconstruction shows the radial motion (*Rad* radial, *Rot* rotational, *L* longitudinal. Bar: 1 mm)

Ideally without motion, these images should be identical. However, the time-radial plane (Fig. 67.4c) illustrates how the reconstruction is substantially distorted radially. Figure 67.4b is an en face plane extracted from the same volume within the layer of the muscularis mucosa (approximately 300 μm from the mucosal surface). In this view, rotational distortion is clearly observed. Motion artifact along the longitudinal direction (perpendicular to the cross-section) is also prominent. However it cannot be clearly visualized without additional imaging mechanism (i.e., Doppler shift detection [67]). Here, motion artifacts refer to the radial and rotational components if not otherwise specified.

Kang et al. proposed an automatic image registration method to suppress motion artifact during esophageal imaging [57]. Registration started with the detection of esophageal lumen, assuming the air-tissue interface had the highest radial gradient. The detection was formulated as a global optimization problem, which sought a contiguous curve with only one pixel from each A-scan. The summation of the radial gradient value on the curve was a global maximum among all the possible curves. To correct for radial motion, the detected lumen surface was aligned to a circle by translating each A-scan in the radial direction. Local box matching (LBM) was then applied to estimate the rotational motion. LBM matched large regions of interest (ROI) in each image to the previous image by cross-correlation and therefore estimated the bulk rotational motion artifact of the ROIs. Each ROI consisted of a few hundred of A-scans. The rotational position of each individual A-scan was then finely adjusted by considering the bulk motion of the adjacent ROIs in the same cross-sectional image. This method can be categorized as a template

update method in the field of computer vision [68]. In this case, the previous cross-sectional image was the template. Accumulated registration error occurred because LBM did not distinguish tissue motion from the actual variation in the anatomical structure. To visualize the natural tissue structure, the slowly varying components in the motion trace were preserved during the final image reconstruction.

67.3.5 CAD

CAD algorithms have been proposed to analyze colonic crypt morphological patterns [69] and to classify dysplasia in BE [45, 46]. CAD algorithms usually consist of steps including region of interest (ROI) segmentation, feature extraction and selection, and finally classification. It is critical to first identify appropriate and quantifiable target features for computer processing before CAD algorithm development. The straightforward approach is to adopt and quantify the diagnostic criteria established by human expert readers.

EOCT visualizes the 3D structure of the colonic mucosa, which is one of the advantages over other competing colonoscopic imaging technologies, such as high magnification chromoendoscopy. The crypts within aberrant crypt foci (ACF) have larger lumens and are oriented less parallel to each other in three dimension than normal crypts are [70]. Qi et al. proposed to characterize the crypt morphology using 3D image processing to quantify these 3D morphological features [69]. The process was demonstrated using freshly resected segments of colon from patients undergoing surgery to remove cancer. Crypts were first segmented on each en face section of the 3D dataset. Features, such as area of the lumen and density of crypts (counts per square millimeter), were calculated. The centroids of each segmented crypt were then connected to represent the crypt morphological skeleton. Straightness (i.e., a skeletons' spatial linearity) and parallelism (i.e., the similarity of the skeletons' spatial orientation) were computed. All the features were quantified for ACF, normal tissue, and normal-appearing tissue adjacent to cancer (NA). Different feature values were observed between ACF and normal/NA tissue, which may potentially be useful for differentiating abnormal crypts from data acquired in vivo.

CAD algorithms have also been developed to potentially assist in diagnosis of dysplasia in BE [45, 46]. The transformation from normal to dysplastic mucosa in BE includes the size, shape, and density of epithelial nuclei, which affects the tissue attention and backscattering properties. Loss of structure associated with normal histological organization (i.e., homogeneity, layering) has been observed in dysplastic tissue [37, 43, 71]. Some of these previous observations were quantified, such as backscattering coefficient and intensity-based texture parameters, for CAD algorithms. New features, such as the stripe pattern associated with surface topology, were also proposed for CAD algorithms [72, 73]. A stripe pattern was often observed in non-dysplastic tissue and seldom observed in dysplastic tissue. This pattern was quantified by the stripe density and orientation. This method was demonstrated using clinical EOCT images from patients undergoing regularly scheduled BE surveillance, where diagnoses were confirmed by biopsy.

The receiver operating characteristic (ROC) curve of each feature was calculated to select those with best classification accuracy. Principle component analysis was applied to reduce feature redundancy and increase algorithm robustness. Only a few principle components that accounted for the most variance in the feature space were selected as input for the multivariate classification algorithms. Multiple classification methods were compared. In this case, decision tree combined with bootstrapping yielded best classification accuracy. Bootstrapping consisted of construction of multiple classification training sets, each using a randomly selected subset of the EOCT training images. Each training set generated a decision tree, and then each test image was classified by majority voting of those decision trees [45, 46].

67.4 Recent EOCT Imaging Studies

It has been shown that endoscopic OCT (EOCT) can obtain interpretable images of gastrointestinal (GI) mucosal microstructure, differentiate GI mucosal types, and detect abnormality ever since the first-generation time-domain systems [30–40, 59, 74–76]. State-of-the-art EOCT studies in GI tract utilize the second-generation Fourier-domain systems. The aims have been extended to investigate the clinical impact of ultrafast image acquisition, eliminate sampling error, and visualize new diagnostic features, such as buried glands in BE and crypt patterns in colon in vivo.

67.4.1 Animal Studies

Swine esophagus is a commonly used animal model for in vivo studies to demonstrate feasibility of new technology. Kang et al. reported a spectral-domain EOCT system together with double-balloon catheter probe [52]. The fiber probe was rotated at 10 rev/s and pulled back at 2 cm per minute. One centimeter to three centimeter segments of esophagus were imaged. Each cross-sectional frame consisted of 4,700 A-scans. The image resolution was 9 μm, 33 μm, and 33 μm in radial, rotational, and longitudinal directions, respectively. The image voxel size was 4 μm, 11 μm, and 33 μm in the three directions. Swine were sedated, intubated, ventilated, and maintained under anesthesia for the duration of the procedure. During the imaging study, video endoscopy was used to guide the probe deployment and through the endoscope accessory channel and balloon inflation.

Both double-balloon and single-balloon images were obtained from the same esophageal segment (Fig. 67.5) in order to evaluate relative image quality and the effects of the pressure of the balloon on the OCT appearance of the mucosa. Figure 67.5a is a representative cross-sectional image of the swine esophagus without balloon-tissue contact. The same radially compressed visualization method used in Fig. 67.3d is applied here. Tissue layers and structures can be clearly observed, including the squamous epithelium, lamina propria, muscularis mucosa, submucosa, muscularis propria, and blood vessels in the muscularis mucosa.

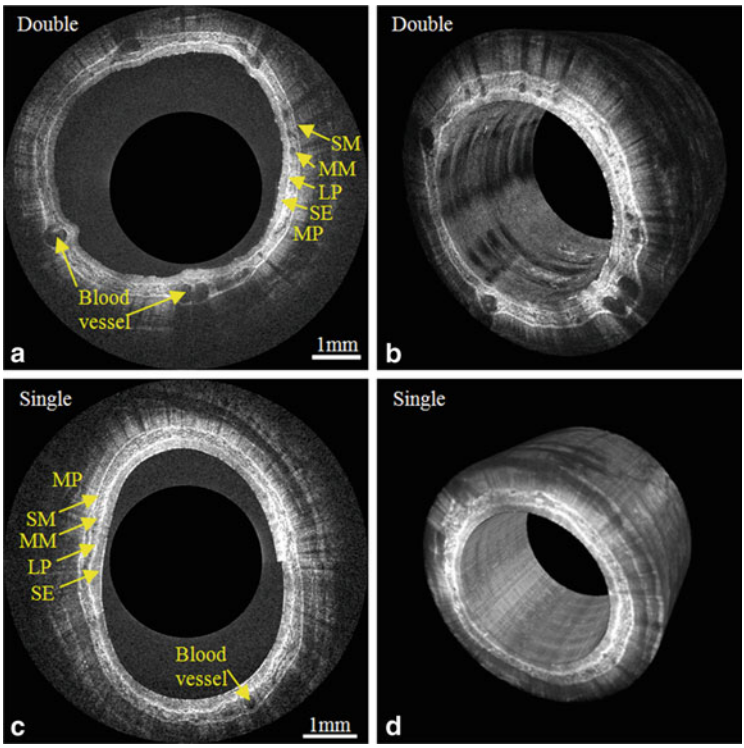

Fig. 67.5 (**a**) A representative cross-sectional image of a swine esophagus with the double-balloon imaging scheme. The layered structure that can be observed includes the squamous epithelium (*SE*), lamina propria (*LP*), muscularis mucosa (*MM*), submucosa (*SM*), and muscularis propria (*MP*). (**b**) 3D reconstruction of a 17 mm long section of swine esophagus obtained with the double-balloon imaging scheme. (**c**) A representative cross-sectional image of the single-balloon imaging scheme. (**d**) 3D reconstruction of 10 mm long segment with single-balloon imaging scheme

The imaging depth exceeds 1 mm. Figure 67.5b shows a 3D reconstruction visualizing a 17 mm long segment obtained within 50 s, using the double-balloon scheme. Figure 67.5c, d show a representative cross-sectional image and the corresponding 3D reconstruction obtained with the single-balloon scheme (10 mm segment obtained within 30 s). The typical layers of the esophagus can also be clearly recognized. The imaging depth in the single-balloon images is greater than that of the double balloon, with multiple layers of muscularis propria visible. However, detailed structure in the muscularis mucosa, especially blood vessels, is more clearly observed in the double-balloon images. The glandular structure and the blood vessels are barely recognized in the single-balloon image. The natural mucosal surface topology is apparent in the double-balloon image, whereas the mucosal surface was compressed and smoothed by the balloon in the single-balloon image. The balloon-flattened surface resulted in more stable illumination and therefore more uniform image brightness. Also, the tissue motion artifact was less

(**b**) The en face view from the original 3D sequence. *Arrows* indicate the position of Fig. 67.4c. (**c**) The registered en face view of (**b**). *Arrows* indicate the position of (**a**). (**d**) The enlarged view of the *dash square* in (**b**). (**e**) The enlarged view of the *dash square* in (**c**). Note the reduced motion artifact and improved contrast in (**c**) and (**e**) compared to (**b**) and (**d**) (*Rad* radial, *L* longitudinal, *Rot* rotational. Bars: 1 mm)

significant with single-balloon imaging due to the balloon support. These observations suggest the need to further investigate the advantages and disadvantages of balloon-tissue contact and pressure, how tissue features of diagnostic significance in BE are altered, and how the changes affect detection of dysplasia in BE.

Figure 67.6 demonstrates the results of correcting the motion artifact caused by physiological movement. Figure 67.6a shows the corrected radial-longitudinal cross sections of Fig. 67.4c. Figure 67.6b, c is the corresponding en face views within the muscularis mucosa layer, uncorrected and corrected, respectively. The yellow arrows indicate the positions of Figs. 67.4c and 67.6a, respectively.

The saw-tooth artifacts in both the radial and rotational directions are corrected and the tissue layers are aligned. The muscularis mucosa has a rich vascular network, which can be visualized more clearly in the corrected en face view. Figure 67.6d, e is enlarged views of the regions indicated in the dashed yellow rectangles in Fig. 67.6b, c, respectively. The motion artifact correction algorithm is able to recover detailed features in Fig. 67.6e which is otherwise obscure in Fig. 67.6d. The corrected images effectively reveal the otherwise distorted microstructure in the esophageal mucosa. Further investigation into the motion trajectories revealed that the frequency components associated with the motion were the fundamental frequencies or higher-order harmonics of respiration and heart beating. Notably, such motion artifacts were not suppressed by increasing the pressure of the balloon to improve stability or other real-time mechanisms [57]. Post-acquisition correction of motion artifact effectively improves the EOCT image quality. Such a correction algorithm is a key component of an EOCT system and may enhance the potential clinical utility.

67.4.2 Clinical Studies

A clinical pilot study was conducted at the University Hospitals Case Medical Center (UHCMC), Cleveland, Ohio, under a protocol approved by the Institutional Review Board of UHCMC. Patients undergoing endoscopic surveillance for BE were eligible for inclusion in the study. Patients with a diagnosis of adenocarcinoma or esophageal stricture were excluded. Informed consent was obtained from each patient.

An initial endoscopic inspection was performed before acquiring OCT images. When a segment of BE (>2 cm in length) was identified, the balloon was inserted through the accessory channel. The balloon was deployed and inflated within the BE segment under endoscopic guidance. 3D volumetric images were obtained by pulling the probe for 1 cm. The balloon pressure was maintained at 100 mmHg. The OCT catheter was extracted after OCT imaging. Biopsies were obtained from four quadrants of the imaged segment for histopathology. The surveillance procedure then continued according to the standard protocol.

67.4.2.1 Normal and Non-Dysplastic Esophagus

Figure 67.7 shows the images of normal esophageal mucosa and non-dysplastic BE from a patient undergoing BE surveillance. The diagnosis was later confirmed by histopathologic examination of a biopsy of the same tissue segment. The EOCT system utilized for the clinical study has a similar configuration as Ref. [52]. Figure 67.7a is a rectangular view of the proximal normal esophagus. The rectangular view displays an unwrapped cross-sectional image before it is transformed into anatomic view (i.e., Fig. 67.4a). The normal esophagus has a stratified squamous epithelium which typically appears in EOCT as a thick layer with consistent thickness and homogeneous intensity. The layered architecture can be clearly visualized, especially the boundary between epithelium and lamina propria. Fibrous, glandular, and vascular structures are apparent beneath the epithelium in

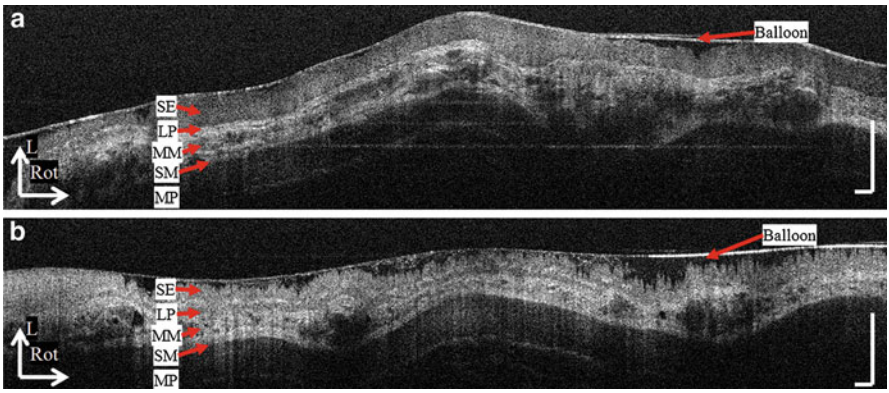

Fig. 67.7 (**a**) Normal esophageal image from a patient undergoing BE surveillance showing distinct layered architecture and homogeneous epithelium. (**b**) Non-dysplastic Barrett's esophageal image. The layers become less distinct with a thinner and irregular epithelium (*SE* squamous epithelium, *LP* lamina propria, *MM* muscularis mucosa, *SM* submucosa, *MP* muscularis propria. Bars: 1 mm in two directions. *Rad* radial, *Rot* rotational)

the lamina propria, muscularis mucosa, and submucosa. The imaging depth is typically more than 1 mm, which allows the visualization of muscularis propria. In non-dysplastic Barrett's esophagus (Fig. 67.7b), the epithelium has higher backscattering and appears less homogeneous, probably due to the transformation from a stratified squamous epithelium to a columnar epithelium associated with specialized intestinal metaplasia. The layered structure is still visible. However, the epithelium is thinner, and the boundary between the epithelium and the lamina propria becomes less distinct.

67.4.2.2 Dysplastic BE

The lack of layered architecture is usually observed in EOCT images of dysplastic esophagus. Figure 67.8 shows images obtained from an esophageal segment where both HGD and normal esophagus existed. Figure 67.8a was obtained from the segment where HGD was later diagnosed. The boundary between epithelium and lamina propria is no longer visible within the entire image. On the other hand, the lamina propria in normal epithelium is clearly identified in Fig. 67.8b, which was obtained from the normal segment. Figure 67.8c, d are the enlarged views of the dashed squares in Fig. 67.8a, b, respectively. Unlike the homogeneous intensity typical in the normal epithelium, the backscattering varies significantly along the dysplastic tissue.

Surface morphology may be a characteristic feature for BE. Figure 67.9 shows the mucosal surface from a patient when both normal and HGD esophagus were imaged. The balloon was not fully expanded in the esophagus, leaving a gap where the tissue surface was visualized. Figure 67.9a obtained from a normal segment has the normal layered structure and homogeneous epithelium. The surface is smooth compared to the fingerlike morphology in the HGD segment (Fig. 67.9b). A 3D reconstruction in the vicinity of Fig. 67.9b is shown in Fig. 67.9c. The raw data was

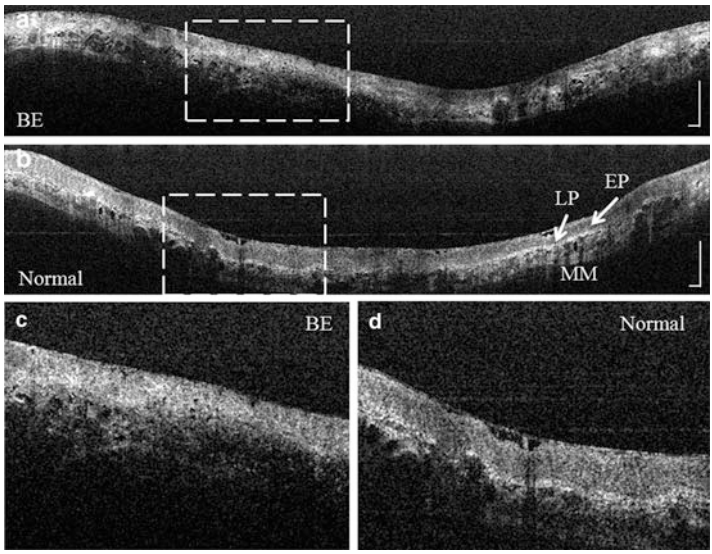

Fig. 67.8 (**a**) Image from an esophageal segment with HGD, where the layered structure can not be identified. (**b**) A cross-sectional image of normal esophagus, where the epithelium (*EP*), lamina propria (*LP*), and muscularis mucosa (*MM*) are clearly identified. (**c**) An enlarged view of the *dashed square* in (**a**). (**d**) An enlarged view of the *dashed square* in (**b**) (Bars: 1 mm in two directions)

first corrected for motion artifact, so that the microstructure in the mucosa was well aligned. The image of the balloon was removed to expose the tissue surface. The irregular pattern in Fig. 67.9b seems to be caused by the elongated folding of the epithelium along the longitudinal direction (indicated by arrows in Fig. 67.9c). Such folding is not observed in normal esophageal mucosa. However, the reason to form the folding is not understood.

Small glandular structures are observed in dysplastic tissue near the tissue surface. Figure 67.10a is an en face view of the 3D reconstruction of Fig. 67.9c showing the mucosa at a depth of 300 μm from the balloon surface. The signal void zone at the top middle of the image is a gap between the tissue surface and the balloon. Yellow arrows indicate representative BE glands. Figure 67.10b is a cross-sectional view from the 3D reconstruction. Its position in Fig. 67.10a is indicated by the red arrows. The corresponding glands are also indicated by yellow arrows. Compared to normal esophageal glands in the muscularis mucosa, these glands are shallower (only a few hundred microns from the tissue surface) and smaller (approximately 100 μm in diameter). These buried Barrett's glands have been observed prior to and post BE ablation treatment [77]. The latter situation suggests that such treatment sometimes fails to eradicate BE completely. The detection of buried Barrett's glands after radio-frequency ablation and cryospray ablation has been demonstrated [58, 78]. The ability to rapidly obtain highly resolved, in-depth images makes EOCT a unique and promising technology for real-time surgery planning and BE eradication assessment. The motion artifact correction algorithm

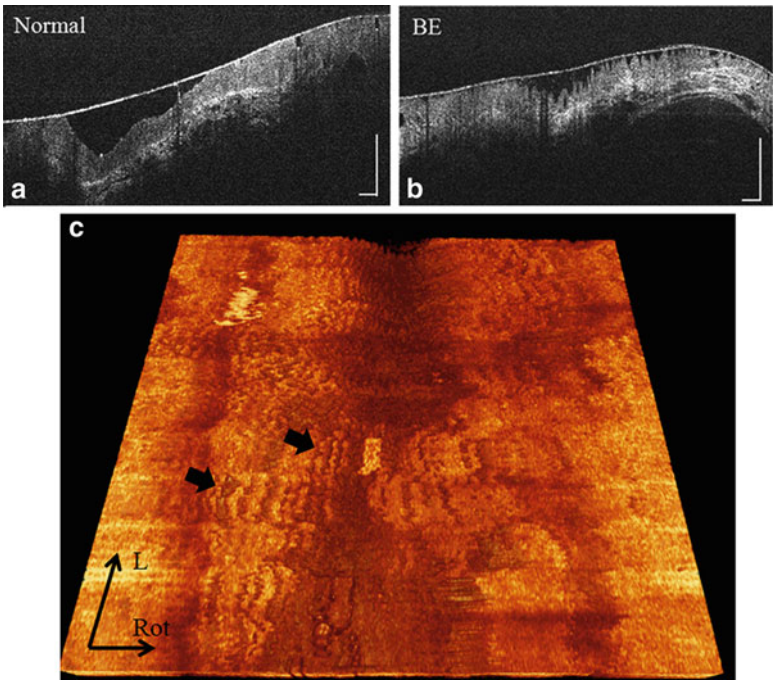

Fig. 67.9 (**a**) A cross-sectional image of the normal esophagus, the balloon was not fully in contact with the tissue. (**b**) A cross-sectional image of dysplastic BE with fingerlike pattern on the surface. (**c**) 3D reconstruction of (**b**) suggests that the fingerlike pattern may be a cross-sectional view of the longitudinal folding (indicated by *arrows*) (Bars: 1 mm in two directions. *L* longitudinal, *Rot* rotational)

described in Sect. 67.3 accurately registered the otherwise mis-aligned small glands in 3D, which may potentially facilitate automated gland counting and analysis.

CAD for Dysplasia Diagnosis

Previously, Qi et al. reported a computer-aided diagnosis (CAD) method for detecting dysplasia and classifying EOCT images of BE in clinical trials [45]. Initial work was further improved to include the use of multiple image frames per examination site [46]. Site-based CAD is possible when 3D esophageal OCT images are available and can potentially be incorporated into future 3D EOCT surveillance. The efficacy of these CAD methods was tested by classifying the examination sites in three ways. First, sites were classified into two categories as non-dysplastic or dysplastic (low grade and high grade). The best classification performance was achieved by using ten frames per site and requiring at least four frames to be positive to classify the site as positive. It yielded sensitivity of 0.78 (95 % CI: 0.54–0.92), specificity of 0.90 (95 % CI: 0.67–0.98), and accuracy was 0.84 (95 % CI: 0.68–0.93). Second, sites were classified into two categories as non-high-grade dysplastic or high-grade dysplastic. The best classification result

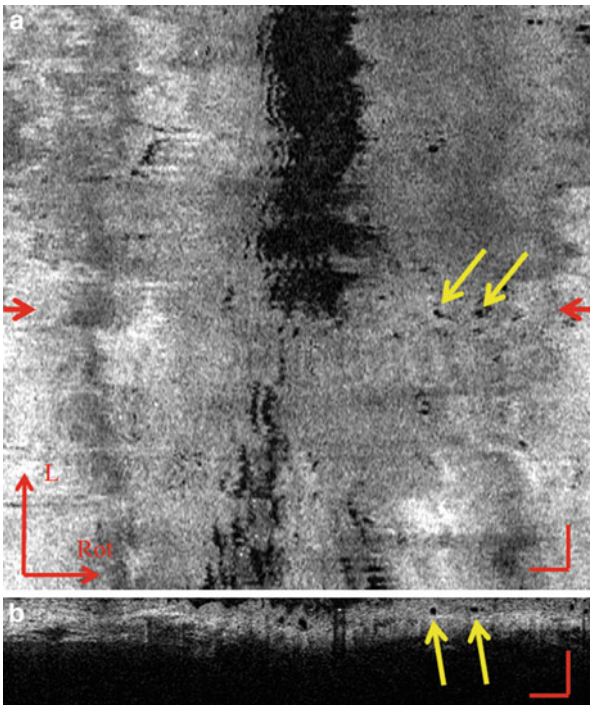

Fig. 67.10 (**a**) An en face view of Fig. 67.9c showing the buried Barrett's glands. (**b**) The corresponding cross-sectional view. The position in (**a**) is indicated by *red arrow*. *Yellow arrows* indicate the buried Barret's glands found in the two views (Bars: 1 mm to two directions. *L* longitudinal, *Rot* rotational)

was obtained by using nine frames per site and requiring two frames to be positive, which yielded sensitivity of 0.67 (95 % CI: 0.46–0.85) and specificity of 1.00 (95 % CI: 0.83–1.00). Third, sites were classified into three categories as non-dysplastic, low-grade dysplastic, or high-grade dysplastic. Using the conservative criteria for multi-image classification, no high-grade dysplastic biopsy sites were misclassified as low-grade or non-dysplastic. Furthermore, no low-grade dysplastic biopsy sites were misclassified as non-dysplastic. However, several non-dysplastic sites and low-grade sites were misclassified as high-grade dysplastic. The use of multiple EOCT images at a single examination location improves classification accuracy over the previous use of a single image. The image analysis presented here should be translatable to 3D comprehensive imaging. Based on these results, it is apparent that CAD has the potential to aid detecting the presence or absence of dysplasia in surveillance of large surface areas of Barrett's mucosa when using EOCT.

67.5 Future Directions

The current status of EOCT can be summarized as feasible, safe, and comprehensive. EOCT has some extremely desirable attributes, namely, rapid imaging speed, large field of view, and a depth of penetration sufficient for detailed imaging of all regions of the GI tract that approaches the degree of resolution offered by

microscopy of ex vivo tissues. Because EOCT systems are portable, compact, relatively inexpensive, and easy to deliver imaging probes, there is no impediment to the widespread implementation of EOCT in clinical practice. Unfortunately, despite these remarkable characteristics, no study to date has conclusively established a clinical application for comprehensive EOCT that is without question superior to existing methods. Moreover, there are a number of competing technologies, with almost no comparative studies of any of these modalities. Given the problems and vagaries of health care, the only thing that insures success is incontrovertible evidence of clinical utility, evidence that is sufficient to justify costs.

Of the numerous potential clinical applications of EOCT, one that may meet the greatest clinical need is the detection of dysplasia. The clinical studies of diagnostic efficacy require histopathology as the gold standard. One remaining technical challenge is to provide biopsy concordance for EOCT images, especially for the commonly used the balloon catheter. EOCT and video endoscopy cannot visualize simultaneously the same esophageal segment when the inflated balloon occludes and compresses the tissue. Ideally, the biopsy should be obtained after EOCT imaging to avoid blood obscuring the image. Suter et al. have proposed to use laser-induced marking of the esophagus, which can be identified during EOCT and later in video endoscopy [56].

Malpositioning of a single rigid balloon near the gastroesophageal junction has also been reported in a clinical setting [50]. Alternative balloon-based and non-balloon-based catheters are a topic of ongoing studies [52, 55, 58].

Assessment of mucosal radio-frequency ablation (RFA) treatment using EOCT has recently drawn attention [58, 79]. Among multiple available BE ablation technologies, RFA results in few serious complications and significantly decreases the rate of progression from HGD to cancer in BE [80]. However, Zhou et al. have showed that most patients have buried Barrett's glands after RFA treatment [58]. These buried glands contain metaplastic cells, from which the risk of cancer development is not known. The abroad acceptance of RFA may bring opportunities for new clinical applications for EOCT, one of which is to identify submucosal glands as an indicator of BE eradication. EOCT is by far the most promising tool to study buried glands.

Because an EOCT system suitable for surveillance of large mucosal areas would generate incredible amounts of data, it is highly improbable that the findings could be interpreted by an endoscopist in real time. Even the interpretation of archived data would be difficult and no doubt prone to error. Thus, it seems certain that computer-assisted image analysis will be needed for applications such as dysplasia diagnosis or buried glands detection.

In summary, endoscopic OCT has shown to have strong potential to become a useful tool in the GI endoscopy clinic. However, for EOCT to become an established routine endoscopic practice in the clinic, further improvements in technology are needed and clinical studies that demonstrate unique and efficacious applications must be carried out.

68.1 Introduction

New gastrointestinal (GI) cancers are expected to affect more than 290,200 new patients and will cause more than 144,570 deaths in the United States in 2013 [1]. When detected and treated early, the 5-year survival rate for colorectal cancer increases by a factor of 1.4 [1]. For esophageal cancer, the rate increases by a factor of 2 [1]. The majority of GI cancers begin as small lesions that are difficult to identify with conventional endoscopy. With resolutions approaching that of histopathology, optical coherence tomography (OCT) is well suited for detecting the changes in tissue microstructure associated with early GI cancers. Since the lesions are not endoscopically apparent, however, it is necessary to survey a relatively large area of the GI tract. Tissue motion is another limiting factor in the GI tract; therefore, in vivo imaging must be performed at extremely high speeds. OCT imaging can be performed using fiber optics and miniaturized lens systems,

enabling endoscopic OCT inside the human body in conjunction with conventional video endoscopy. An OCT probe can be inserted through the working channel of a standard endoscope, thus enabling depth-resolved imaging of tissue microstructure in the GI tract with micron-scale resolution simultaneously with the endoscopic view (Fig. 68.1).

The first demonstration of in vivo endoscopic OCT was performed in 1997 [2]. This study demonstrated OCT imaging of the gastrointestinal and pulmonary tracts in the rabbit using a 1 mm diameter fiber optic catheter and suggested the potential for internal body OCT imaging using noninvasive or minimally invasive devices. Early endoscopic OCT imaging studies of the human gastrointestinal (GI) tract were performed by several groups. Studies were performed in the esophagus and stomach [3–9], small and large intestine [5, 7, 10–12], and bile duct [13, 14]. Barrett's esophagus was clearly differentiated from normal esophageal mucosa, and esophageal adenocarcinoma could also be distinguished from nonneoplastic tissues. Endoscopic OCT was also shown to provide complementary information to endoscopic ultrasound for staging and tumor resection [10, 15]. OCT was demonstrated to detect specialized intestinal metaplasia in Barrett's esophagus patients [16, 17] and transmural inflammation in inflammatory bowel disease patients [12]. OCT was also investigated for differentiating hyperplastic from adenomatous polyps in the colon [11]. Endoscopic OCT studies have shown promise for detection of high-grade dysplasia in Barrett's esophagus. Evans et al. reported a sensitivity of 83 % and specificity of 75 % for detecting high-grade dysplasia and intramucosal carcinoma with blinded scoring of OCT images

from 55 patients [18]. Isenberg et al. reported a sensitivity of 68 % and a specificity of 82 %, with an accuracy of 78 % for the detection of dysplasia from 33 patients with Barrett's esophagus [19]. Using computer-aided tissue classification techniques applied to OCT images, Qi et al. reported a sensitivity of 82 % and specificity of 74 % for identifying dysplasia in 13 patients [20].

With advances in laser light sources, OCT image resolutions approaching a few microns have been achieved [21–27]. Ultrahigh-resolution OCT imaging has reduced speckle size and overall improved image quality [28, 29]. The earliest ultrahigh-resolution endoscopic OCT imaging study in 2004 achieved 4 μm axial image resolution using a femtosecond Cr:Forsterite laser at 1,300 nm and demonstrated endoscopic imaging in vivo in the rabbit gastrointestinal tract [30]. Endoscopic OCT in small animals with even higher, 3.2 μm axial resolution, was demonstrated in the mouse using Ti:Sapphire laser at 800 nm [31, 32]. The first clinical ultrahigh-resolution endoscopic OCT study was performed using a prototype instrument with a Cr:Forsterite laser, surveying a cross section of pathologies including Barrett's esophagus, high-grade dysplasia, and adenocarcinoma [29].

3D-OCT endoscopic imaging became possible using high-speed OCT with Fourier domain detection. Ultrahigh-resolution spectral/Fourier domain endoscopic OCT at 20 kHz axial scan rates with 2.4 μm axial resolution using a Ti:Sapphire laser was demonstrated in the mouse colon [31, 32]. Using swept-source/Fourier domain technologies at 1,300 nm wavelengths, in vivo 3D-OCT volumetric imaging of the porcine esophagus and artery was demonstrated at 10 kHz and 54 kHz axial scan rates in 2006 and 2007, respectively [33, 34]. Using Fourier domain mode locking (FDML) laser technology, record axial scan rates of 100 kHz were achieved and demonstrated for in vivo endoscopic 3D-OCT imaging in the rabbit [35] and human [36–42] gastrointestinal tract with an axial resolution of 7 um. These endoscopic studies demonstrate the impact of advances in OCT imaging technology on endoscopic OCT applications.

Gastroenterology is an especially relevant application for OCT because of the high incidence rates of GI pathologies, the clinical benefits of early detection, and the need for pre- and post-treatment assessment of therapies. In this chapter, we summarize recent advances in endoscopic OCT ranging from technology development, including ultrahigh-resolution OCT, ultrahigh-speed OCT, and endoscopic probe development, as well as clinical applications such as imaging GI pathology and assessment of endoscopic therapies.

68.2 Ultrahigh-Resolution Endoscopic OCT

Image resolution is one of the most critical parameters governing the performance of OCT systems, and therefore achieving ultrahigh image resolutions has been a key objective for endoscopic OCT. The axial image resolution of OCT is inversely proportional to the bandwidth of the light source and in order to achieve ultrahigh resolution, broad bandwidth light sources are required. The majority of previous clinical OCT studies were performed using superluminescent diode (SLD)

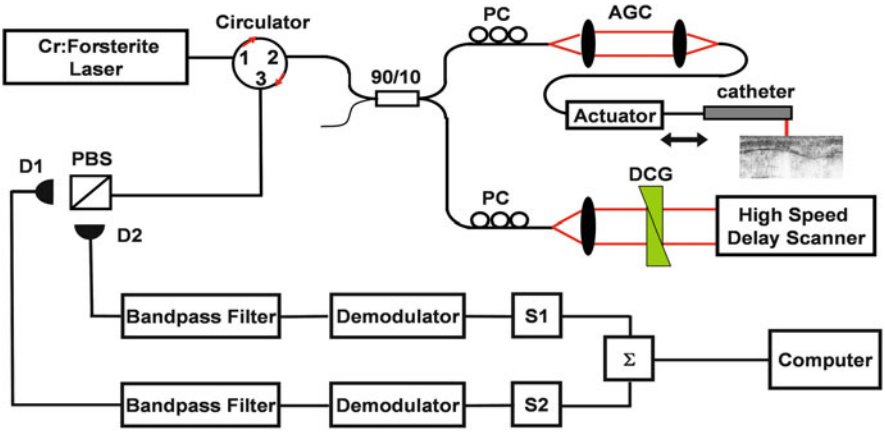

Fig. 68.2 Schematic of an early ultrahigh-resolution (*UHR*) endoscopic OCT system. A broadband Cr:Forsterite laser light source is used to achieve <5 μm axial image resolution. The system used time domain detection and operated at imaging speeds of 3,000 axial scans per second. The system uses a dual circulator interferometer with dual-balanced detection

light sources with axial resolutions of ~10–15 μm. With recent advances in broadband femtosecond lasers, OCT image resolutions in the 2–5 μm range were demonstrated by our group and others [21–27].

Working in collaboration with LightLab Imaging, our group and collaborators developed an ultrahigh resolution endoscopic OCT system by adapting a commercial imaging engine to use an advanced femtosecond Cr4+:Forsterite laser light source (see Fig. 68.2). Although the complexity and cost of femtosecond light sources limits their potential for widespread clinical use, they can provide powerful performance advantages for small-scale validation studies. The system included several innovative features in OCT design to support very broad optical bandwidths necessary to achieve ultrahigh resolutions [30]. The axial resolution was ~3.6 μm in tissue, corresponding to a 3–4× improvement over previous OCT technology. A fiber-optic probe was also developed for endoscopic OCT imaging. The probe was 1.8 mm in diameter and used an optical fiber, micro lens, and microprism which were distally actuated in either a push-pull or rotary motion to generate longitudinal or transverse OCT images at 4 Hz frame rate.

Prior to clinical imaging studies, this technology was validated by performing in vivo imaging of the gastrointestinal and pulmonary tracts of the New Zealand White rabbit, correlating images with histology [30]. Figure 68.3a shows an example in vivo OCT image of the rabbit esophagus and trachea. The tracheal hyaline cartilage (hc) is visible through the esophageal wall, demonstrating the ability to achieve deep image penetration at these long wavelengths. In addition, the structural details of the tracheal mucosa and trachealis muscle are visible. The vacuous region below the tracheal wall at the bottom of the image is the tracheal airway. The corresponding histological section in Fig. 68.3b shows good correlation with the architecture seen in the OCT image. Trichrome staining was used in the histology to enhance delineation of cartilage rings in the trachea.

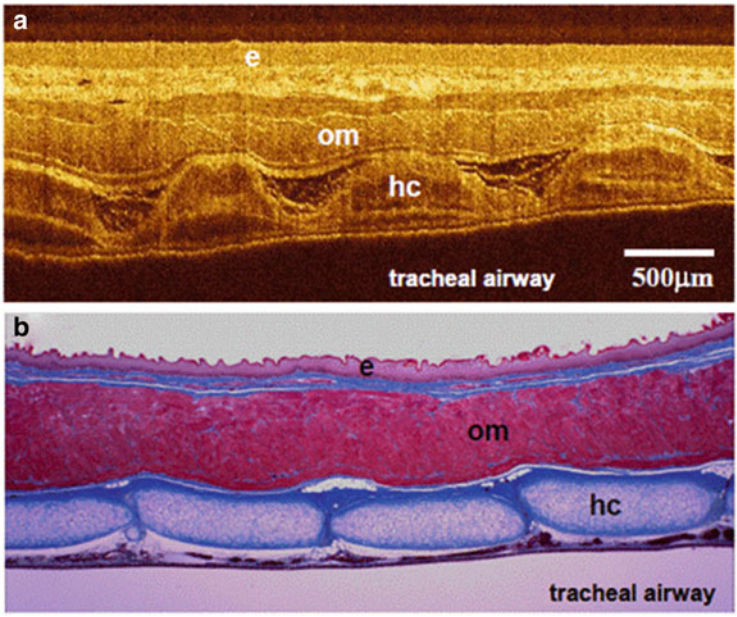

Fig. 68.3 (**a**) In vivo OCT image of the rabbit esophagus and trachea viewed intraluminally from the esophagus and (**b**) corresponding histology with trichrome staining. Tracheal hyaline cartilage (*hc*) between the tracheal mucosa and trachealis muscle is visualized. Note the excellent image quality which can be achieved using a broadband light source and ultrahigh-resolution OCT (From Hertz et al. [30])

Clinical ultrahigh-resolution endoscopic OCT studies were performed at the VA Boston Healthcare System [29]. Patients with previously diagnosed Barrett's esophagus or undergoing elective colonoscopy were recruited from the endoscopy clinic at the VA Medical Center. A total of 112 patients (95 in Barrett's esophagus group and 17 in colonoscopy group) were imaged. Imaging was performed by introducing the OCT probe into the endoscope working channel, providing simultaneous endoscopic and OCT views. Figure 68.4 shows representative ultrahigh-resolution endoscopic OCT images of the human esophagus. Figure 68.4a shows normal squamous epithelium with a characteristic layered architecture, and Fig. 68.4b shows a representative image of Barrett's esophagus. OCT images of Barrett's esophagus show clear differences in architectural morphology compared to normal esophageal squamous mucosa. The layered architecture is replaced by glandular structures, and low-backscattering Barrett's glands are observed in the mucosa with interlaced regions of high-backscattering connective tissue corresponding to the lamina propria. Figure 68.4c shows a representative OCT image of high-grade dysplasia. High-grade dysplasia is characterized by irregular, distorted, and cribriform or villiform glandular architecture and is more heterogeneous than non-dysplastic Barrett's epithelium. Figure 68.4d shows an OCT image of esophageal adenocarcinoma with epithelial disruption and stromal infiltration

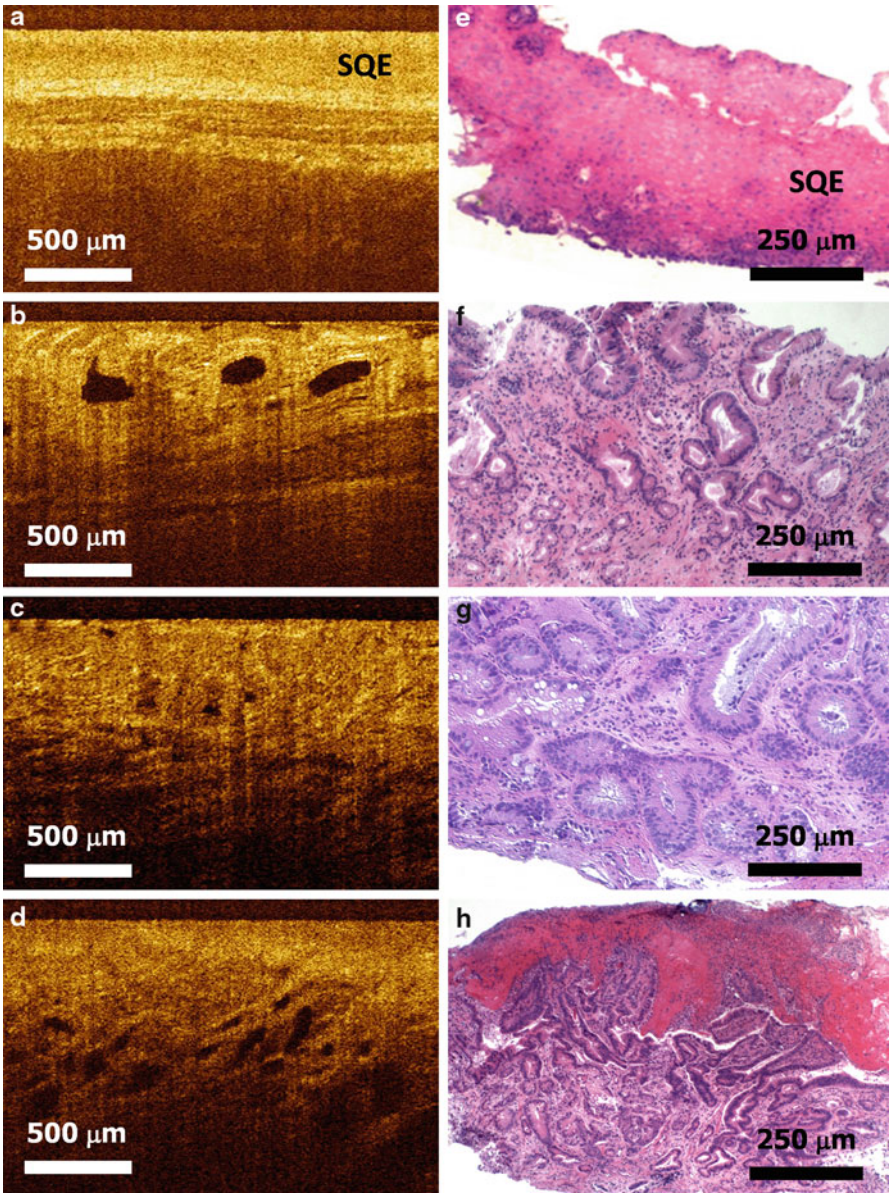

Fig. 68.4 Ultrahigh-resolution endoscopic OCT of esophageal pathology in human subjects. (**a**) Squamous mucosa of normal esophagus. (**b**) Barrett's esophagus. (**c**) High-grade dysplasia. (**d**) Adenocarcinoma. (**e**–**h**) Corresponding pinch biopsy histology to OCT images (From Chen et al. [29])

extending from the superficially ulcerated carcinoma. OCT images show progressive increase in architectural irregularity from Barrett's mucosa to high-grade dysplasia and eventually to adenocarcinoma. Overall, ultrahigh-resolution OCT images showed good correlation with architectural morphology in histology (see Fig. 68.4e–h) [29]. The enhanced image resolution and reduced speckle size enabled ultrahigh-resolution OCT to visualize changes in tissue architectural heterogeneity more clearly than standard resolution OCT; however, imaging speeds were still limited compared with current technologies. In addition, although this study was the first to demonstrate ultrahigh-resolution endoscopic OCT in patients, the limited enrollment and small numbers of dysplasia cases made it difficult to identify OCT image features which could be correlated with histology and used to detect dysplasia.

68.3 Ultrahigh-Speed Endoscopic OCT

Recent advances in Fourier domain detection techniques enable dramatic increases in imaging speed [43–45]. These advances have had a powerful impact across multiple OCT applications ranging from ophthalmology to endoscopy. Ultrahigh speeds are important for enabling broader coverage, which is necessary for the large surface areas in the gastrointestinal tract. Ultrahigh speeds are also critical for 3D endoscopic OCT which requires the acquisition of large volumetric data sets in vivo. Swept-source/Fourier domain detection has achieved the highest imaging speeds to date and is a central focus of current research. Frequency-swept laser sources are a key technology for swept-source/Fourier domain OCT. The repetition rate of the laser sweep and the sweep range determine the OCT imaging axial scan repetition rate and axial resolution, respectively. Early swept lasers used a tunable filter with a diffraction grating and rotating polygon mirror to achieve sweep rates of 15.7–115 kHz with ~10–15 μm axial resolutions [46, 47]. These advances in technology enabled in vivo endoscopic OCT imaging in the porcine esophagus and coronary artery at axial scan rates of 10 kHz and 54 kHz, respectively with ~7 μm image resolution [33, 34].

68.3.1 Ultrahigh-Speed Endoscopic OCT Using FDML Lasers

The development of Fourier domain mode locking (FDML) in 2006 provided a new technique to overcame fundamental limitations in sweep rate of conventional swept lasers, enabling record OCT imaging speeds in multiple applications [35, 48–51]. FDML lasers use a long optical fiber in the laser cavity to store and regenerate the entire frequency sweep, avoiding the need to build up lasing from amplified spontaneous emission as the laser frequency is swept. This enables FDML lasers to achieve sweep rates not attainable using conventional swept lasers and to perform 3D-OCT imaging at unprecedented speeds. Higher acquisition

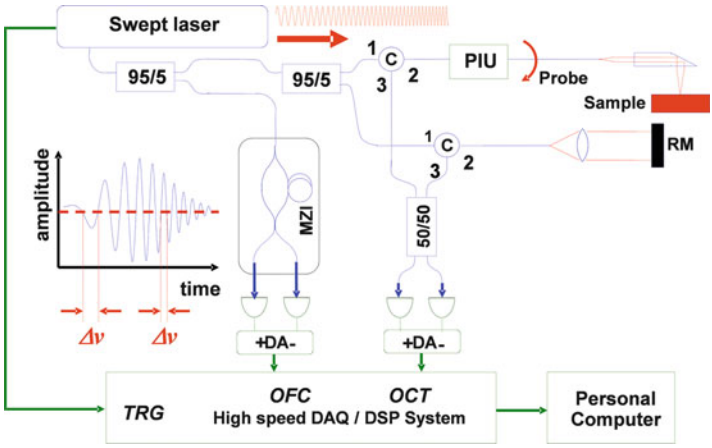

Fig. 68.5 OCT system for ultrahigh-speed endoscopic 3D-OCT imaging. The system uses swept-source/Fourier domain OCT with a high-speed Fourier domain modelocked (FDML) laser. The system uses a dual circulator interferometer with dual-balanced detection. A Mach Zhender interferometer is used to measure the frequency sweep to recalibrate the OCT signal so that it is linear in frequency or wavenumber

speed enables increased field of view, high volumetric sampling densities, and reduced motion artifacts for in vivo 3D-OCT imaging. FDML lasers were used to demonstrate 3D-OCT imaging with record speeds of 370 kHz axial scan rates in 2006 [52]. In addition, FDML lasers have extremely broad tuning ranges of 160 nm at ~1,300 nm wavelengths, supporting axial resolutions of ~5–7 μm in tissue. Swept-source OCT using FDML laser technology enables up to a ~50–100× improvement in speed and up to a ~2–3× improvement in resolution compared with previous time domain OCT technology.

Working in collaboration with LightLab Imaging, our group and collaborators developed a prototype endoscopic OCT instrument using an FDML laser at ~1,310 nm. Figure 68.5 shows a schematic of this system. The system used a dual circulator interferometer geometry for maximum signal collection efficiency combined with a dual-balanced detector. A Mach Zhender interferometer and dual-balanced detector was used to measure the frequency sweep produced by the FDML laser. The Mach Zhender calibration signal is used to recalibrate the OCT signal so that it is linear in the frequency space (k-space) before it is Fourier transformed. The prototype instrument achieved axial scan rates of 100 kHz and 5–7 μm axial resolution in tissue with real-time display and capture capabilities at 50 frames per second. To validate the prototype 3D-OCT system prior to clinical studies in humans, we performed in vivo 3D-OCT endoscopic imaging studies of the rabbit gastrointestinal tract, demonstrating record endoscopic imaging speeds in 2007 [35].

The increased imaging speed enabled a 9 mm segment of colon to be imaged with a high axial scan density in <18 s. Figure 68.6a shows a representative single radial OCT image of the rabbit colon with an inset showing an enlarged view of the

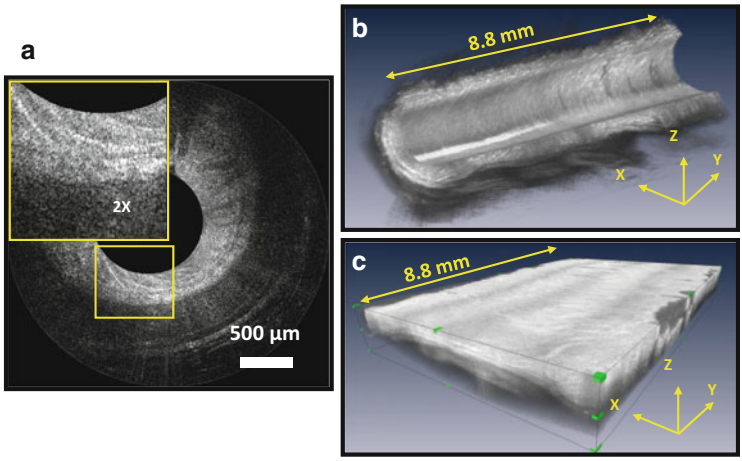

Fig. 68.6 3D-OCT endoscopic imaging at record 100 kHz axial scan rates is enabled by swept-source OCT with FDML laser technology. (**a–c**) 3D-OCT images of rabbit colon in vivo. epithelium. Colonic crypts are clearly distinguishable as dark regions surrounded by bright, filament-like bands of lamina propria. The complete volumetric data set is composed of 885 radial frames, which can be processed and displayed in three dimensions. Figure 68.6b shows a cutaway view of the rendered data set. 3D-OCT data allows virtual manipulation of tissue to facilitate visualization. Figure 68.6c shows a rectangular volume rendering, created by performing a "virtual incision" along the colon and unfolding. In addition, cross-sectional images with arbitrary orientations can be synthesized from the 3D-OCT data set. Figure 68.7a shows a longitudinal (YZ) cross section taken from near the center of the unfolded colon volume. Figure 68.7b shows an average of seven consecutive YZ slices to reduce speckle noise. Figure 68.7c shows an enlarged view of a region of Fig. 68.7b. The cross-sectional OCT correlates well with histology as shown in Fig. 68.7d although the thicknesses of the tissue layers are different in OCT compared to histology due to compression of the in vivo tissue by the imaging probe and changes in tissue from histological processing.

In order to evaluate the performance of ultrahigh-speed endoscopic OCT in clinical settings, we performed studies at the VA Boston Healthcare System [36–42, 53]. Figure 68.8 shows representative images obtained in vivo from the colon of a human subject [36]. Figure 68.8a is an en face image of normal columnar epithelial tissue formed by axial summation of the entire 3D logarithmic data set. Summation over the full axial range reduces speckle noise, while preserving only those image features that persist over significant depths. Macroscale tissue folds are visible in the mucosal surface. A mottled texture is observed due to the presence of a regular, uniform crypt pattern. Crypts are the main glandular structures in the human colon, and changes in crypt size and appearance are associated with the earliest forms of

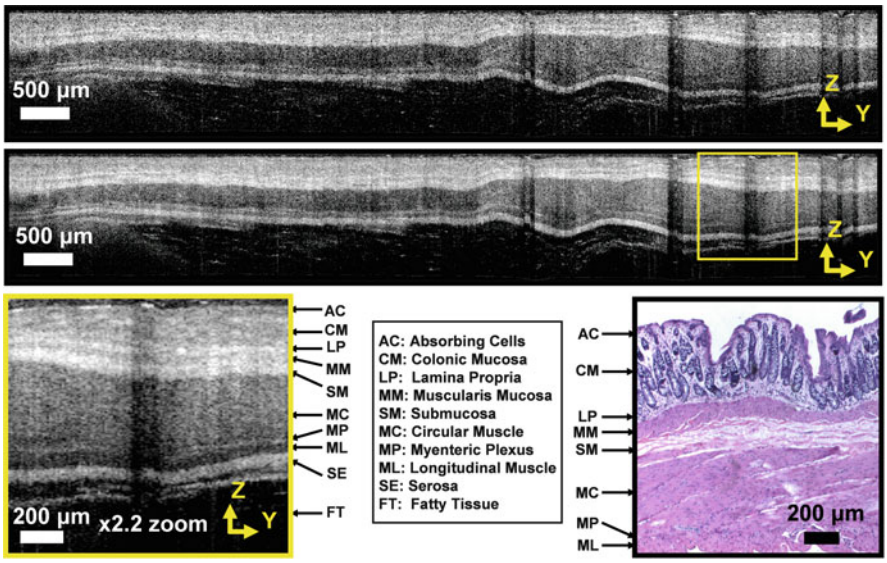

Fig. 68.7 Volumetric 3D-OCT enables the generation of arbitrary cross sections and the use of averaging to improve image quality. (**a**) Single cross-sectional image of rabbit colon in vivo from 3D-OCT data set. (**b**) Average of seven consecutive frames reduces speckle noise. (**c**) Enlarged view shows layered structure of colon. (**d**) Representative histology correlates with OCT images (From Adler et al. [35])

colorectal cancer [54]. The ability to assess the 3D structure of crypts is of potential value for future applications in cancer detection and treatment. Figure 68.8b shows a cross section oriented along the XZ axis, which is the fast rotational axis during data acquisition. Consistent with previous results in ex vivo human tissue [28], optical transmission is increased through the crypt lumens. Figure 68.8c shows a cross-sectional YZ plane, which is the slow pullback axis during data acquisition. Uniform crypt structures are also visible in this plane. Both cross sections were formed by averaging consecutive slices over a 20 µm thickness to reduce speckle noise. Figure 68.8d shows an enlarged region of Fig. 68.8a. The microstructural en face crypt pattern is clearly visualized and is consistent with the representative en face histology image shown in Fig. 68.8e. Figure 68.8f shows a white light video endoscopy image near the OCT imaging site. The mucosa appears regular, and the crypt pattern is difficult to distinguish by conventional endoscopy.

68.3.2 Ultrahigh-Speed Endoscopic OCT Based on VCSEL Wavelength-Swept Light Sources

One of the most significant recent advances in OCT technology has been the development of vertical cavity surface emitting lasers (VCSEL) for swept-source OCT [55, 56]. The VCSEL operates with a single longitudinal mode instead of

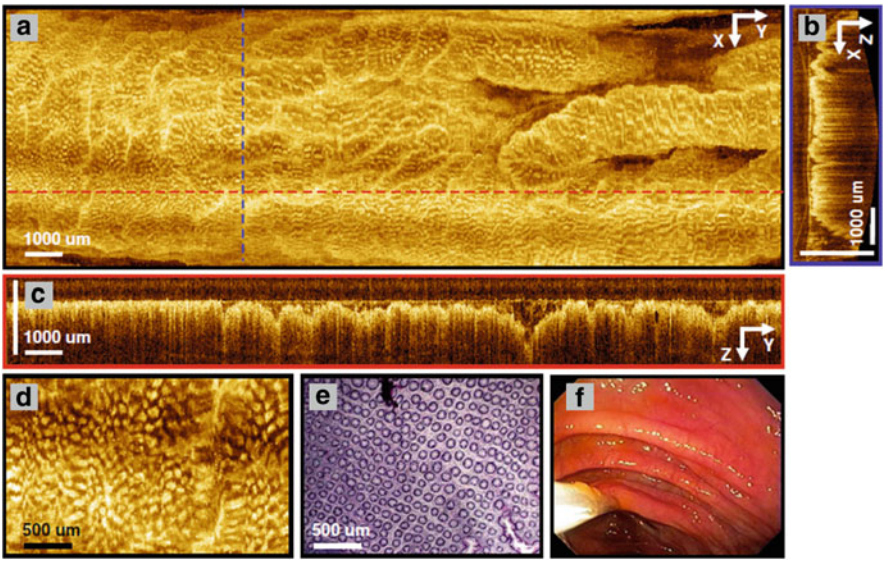

Fig. 68.8 3D-OCT images of columnar epithelial tissue in the human colon. (**a**) En face image constructed by axial summation of the entire data set. *Dashed lines* show locations of cross sections. (**b**) XZ cross section showing typical columnar structure. (**c**) YZ cross section. (**d**) Enlarged view of (**a**), showing en face crypt pattern. (**e**) Representative en face histology of human colon. (**f**) White light video endoscopy image of region analyzed with 3D-OCT (From Adler et al. [36])

multiple modes and therefore has an extremely narrow instantaneous linewidth which enables a long imaging range. The micron-scale cavity length of VCSELs and the rapid MEMS response also enable extremely high imaging speeds. The VCSEL also has the advantage that both the sweep frequency and wavelength tuning range can be adjusted to support multiple operating modes with different speed, resolution, and imaging ranges. These are powerful features which make the VCSEL a promising technology for high-speed and long-range OCT imaging [57]. We developed a micromotor-based catheter with an outer diameter of 3.2 mm for ultrahigh-speed endoscopic OCT using a VCSEL swept source at a 1 MHz axial scan rate [58]. Since this study involves imaging probe technology, further details are described in the next section.

68.4 Endoscopic OCT Probe Technologies

Endoscopic probes are another critical technology for endoscopic OCT. In vivo endoscopic OCT imaging is challenging because fast optical scanning must be implemented inside a miniaturized imaging probe. Many scanning mechanisms have been investigated in catheter-based endoscopic OCT systems, such as proximally actuating a torque cable with a rotating fiber and microprism module at the

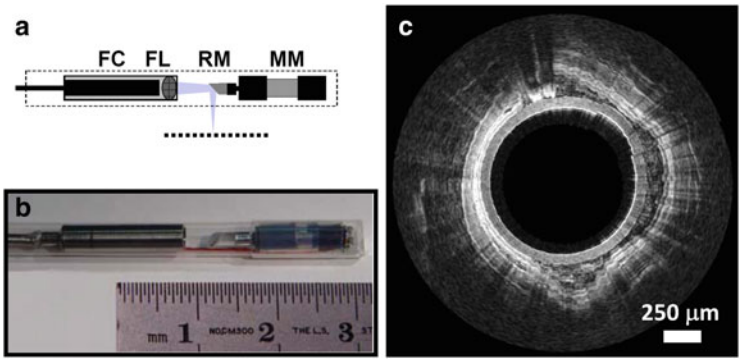

Fig. 68.9 Micromotor probes avoid the need for proximal actuation. (**a**, **b**) Schematic and photo of micromotor probe. (**c**) In vivo OCT image of rabbit esophagus showing normal squamous epithelial structure (From Herz et al. [30])

distal end [2, 34, 35, 59, 60], distally actuating a fiber with a galvanometer [3], distally actuating a fiber with piezoelectric transducer [61–63], and distal beam scanning using microelectromechanical systems (MEMS) [64–67]. Imaging using proximal rotary actuation can cover a large area with a simple probe design and has been used in most endoscopic OCT applications to date. In upper GI imaging, proximal rotary scanning has been combined with inflatable balloons which serve to dilate the esophagus and stabilize the OCT probe at a controlled distance from the lumen. These methods enable dramatic improvements in imaging coverages. However proximal scanning can be unstable because the rotation is translated from the proximal end using a long torque cable to the distal imaging optics. Nonuniform rotation from torsional flexibility and friction over the torque cable length creates artifacts that limit the image quality even if the transverse optical resolution is high. The scanning speed is also limited because the torque cable becomes unstable at rotation speeds higher than a few hundred Hz. By contrast, distal scanning methods using PZT or MEMS-based actuators can provide micron-scale precision scanning because the mechanical motion is not transmitted over a long distance. However distal scanning methods are difficult to implement because the scanner must fit within the catheter.

68.4.1 Endoscopic OCT Probes Based on Micromotor Technologies

Advances in micromotor technology enable distal rotary scanning within small catheter diameters and provide large image areas while maintaining high speed and uniform rotary scanning. OCT micromotor catheters were demonstrated as early as 2004 for ultrahigh-resolution in vivo imaging of the rabbit GI tract [30, 68]. Figure 68.9 shows the schematic and photo of the imaging probe developed by our group [30]. The OCT beam was rotationally scanned by a tilted mirror actuated by a micromotor. The fiber collimator and focusing lens were attached to a cable

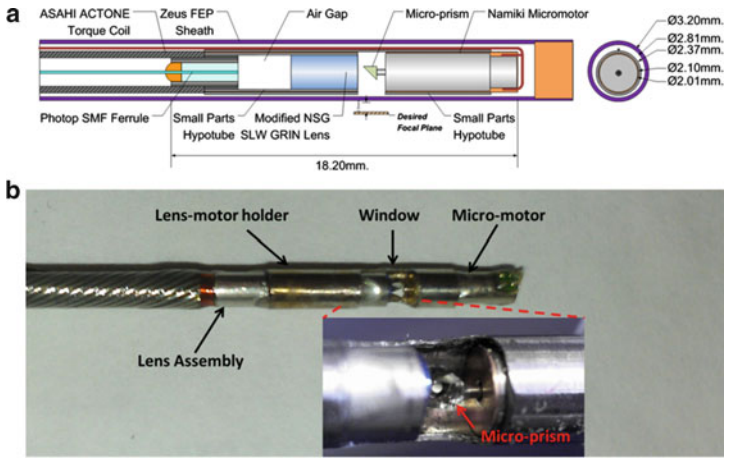

Fig. 68.10 (**a**, **b**) Schematic diagram and photograph of the micromotor probe. The probe sheath has a 3.2 mm outer diameter, and the motor and optics can be pulled back inside the sheath to generate a 3D-OCT spiral scan pattern (From Tsai et al. [58])

that enables the distal focus depth to be adjusted by longitudinally translating the fiber and lens assembly. This enables the probe to be focused on structures at different depths. The assembly fits in a 4.8 mm outer diameter stainless steel housing that is enclosed within a 5 mm outer diameter transparent plastic sheath. In vivo imaging of rabbit esophagus was demonstrated at 2 frames/s with ~3.7 μm axial and ~8 μm transverse resolutions. Esophageal epithelium, lamina propria, and muscular mucosa can be delineated in the OCT image. Other groups have used micromotor-based OCT catheters for endoscopic upper airway imaging, studying smoke-induced injury in animal models with imaging frame rates of 20 fps [69].

Although micromotor can achieve very high rotary scan speeds, early imaging studies were limited to 50 fps acquisition speeds because of the limited axial scan rates which were supported by the OCT imaging system. Using VCSEL swept-source technology described in the previous section, it is possible to achieve ultrahigh-speed endoscopic OCT using a micromotor [58]. Figure 68.10a shows a schematic diagram of a newer version micromotor-based catheter. A microprism was mounted on a 2 mm diameter, 6 mm long micromotor (Namiki Precision, Inc.). The OCT beam was focused by a fiber-GRIN lens assembly, reflected by the rotating microprism and focused outside of the catheter sheath to a spot size of 8 μm in tissue. The motor and GRIN lens were mounted inside a hypotube with a cutaway window that enables imaging over ~70 % of the microprism rotation. A transparent plastic sheath with 2.8 mm inner diameter and 3.2 mm outer diameter was used to house the motor and optics. By pulling back the optical and motor assembly during the rotary image acquisition, a volumetric spiral scanning pattern can be generated. The micromotor drive voltage was less than 5 V and could operate at speeds from 1,200 to 72,000 rpm, corresponding to frame rates from

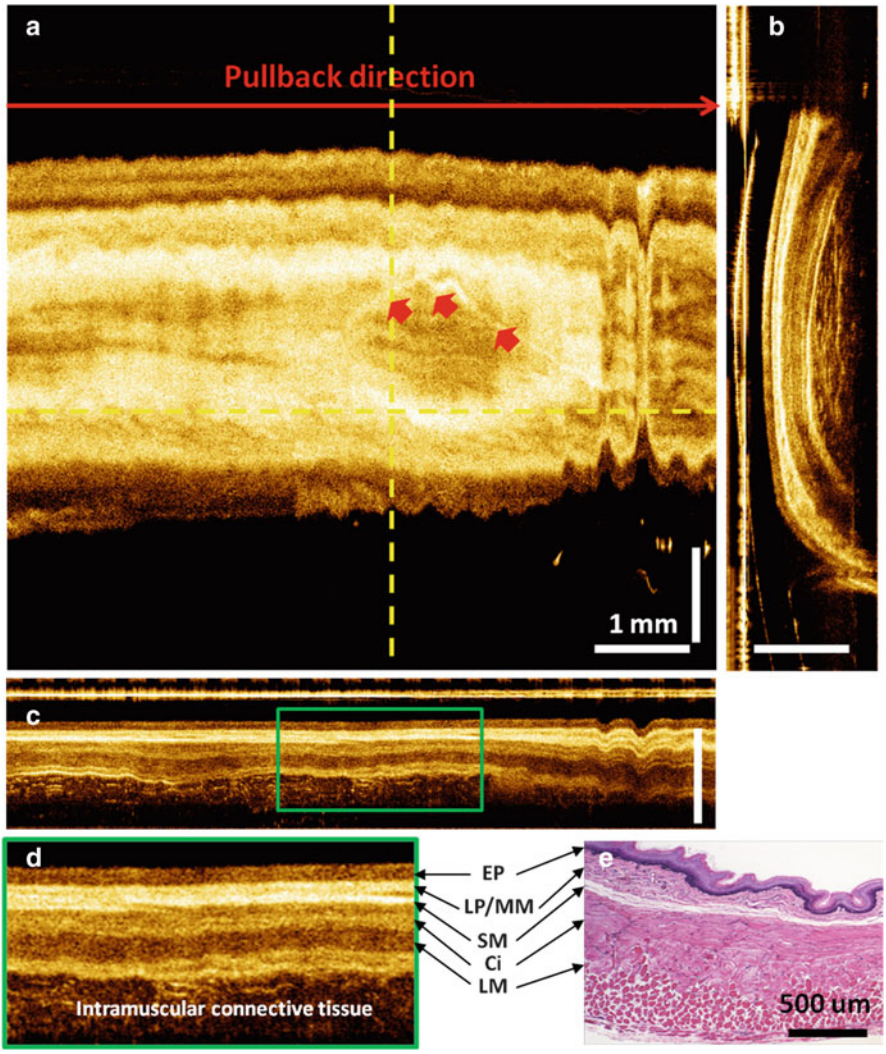

Fig. 68.11 3D-OCT volumetric images from rabbit esophagus in vivo using a micromotor probe and high-speed VCSEL swept-source OCT system. (**a**) En face image of the 3D data set averaged over 15 um at a depth of 150 um. (**b**, **c**) Cross-sectional images in the rotary and pullback directions. (**d**) Zoomed region showing detailed structure. (**e**) Representative histology (From Tsai et al. [58])

20 to 1,200 fps. Figure 68.10b shows a photograph of the micromotor probe. The VCEL light source operated at high 1 MHz axial scan rates and enabled high frame rates with dense sampling.

Figure 68.11 shows a 3D-OCT data set from the rabbit esophagus in vivo. The high-speed micromotor probe combined with the high axial scan rate of the VCSEL

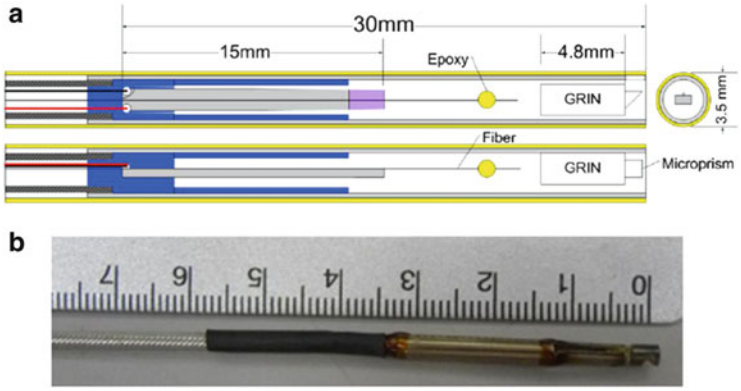

Fig. 68.12 (**a**, **b**) Schematic and photo of the PZT scanning probe. The PZT bender can produce large deflections with a low actuation voltage. 3D-OCT data is obtained by pulling back the actuator and optics from the proximal end of the probe, scanning a raster-like pattern (From Tsai et al. [63])

swept-source OCT enabled 3,000 frames of 2,500 axial scans each to be acquired in 7.5 s (i.e. 400fps), covering a volume size of 7.5 × 7.5 × 1.3 mm (x-y-z). The high axial scan rate enabled dense sampling corresponding to a pixel spacing of 4 × 2.5 × 5.2 um in the x-y-z directions, respectively. The cross-sectional OCT images (Fig. 68.11b–d) show normal esophageal layers including the epithelium (EP), lamina propria/muscularis mucosa (LP/MM), submucosa (SM), circular muscle (Ci), and longitudinal muscle (LM). The OCT images correlate well with representative histology (Fig. 68.11e). The volumetric data set could be processed and displayed in three dimensions. The images shown were generated by averaging three consecutive images perpendicular to the viewing direction in order to reduce speckle. Figure 68.11a, c shows the en face view and cross-sectional view along the pullback direction. The en face view (Fig. 68.11a) is averaged over a depth of 15 um and demonstrates the large field of view that can be achieved. Motion artifacts from cardiac motion are visible in the image. En face images are useful to differentiating features such as vasculature versus glands which can appear similar in isolated cross-sectional images.

68.4.2 Endoscopic OCT Probes Based on PZT Technologies

High-speed endoscopic OCT probes can also be developed using other types of distal actuators such as cantilever PZT scanners [63]. Figure 68.12 shows the schematic diagram of a PZT-based probe design. A tapered 15 mm PZT bender (Piezo Systems, Inc.) was used to scan an optical fiber at its resonance frequency. A drop of epoxy (~40 mg) was placed on the fiber tip to increase the mass and reduce the resonant frequency to ~500 Hz. The fiber tip was angle cleaved at 8° to reduce backreflection. The scanning beam was focused with a GRIN lens objective

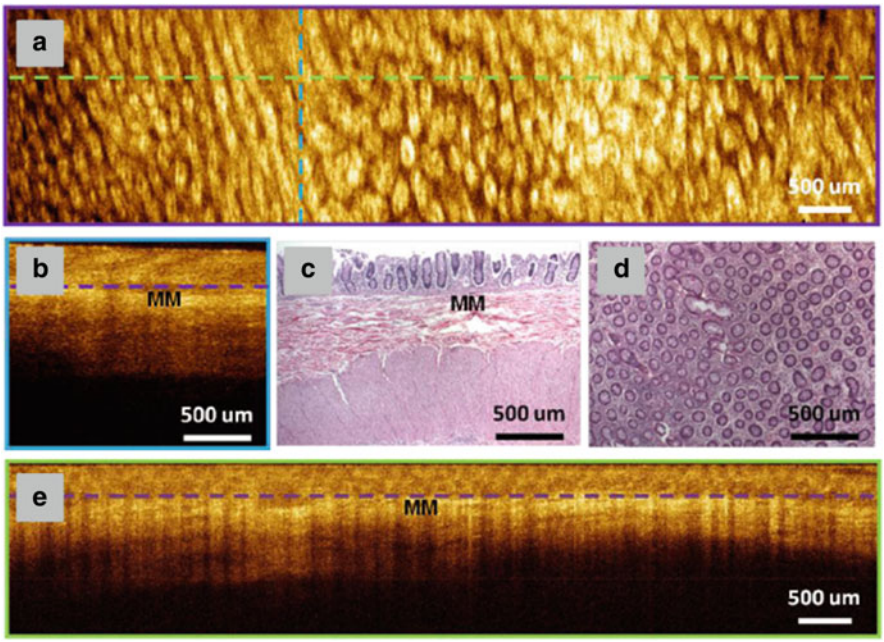

Fig. 68.13 Volumetric 3D-OCT images of a human colon specimen ex vivo. (**a**) En face image at a depth of 350 μm. (**b**) Cross-sectional image along the fast-scan direction. (**c**) Representative cross-sectional histology of the human colon with hematoxylin and eosin stain. (**d**) Representative en face histology of the human colon. (**e**) Cross-sectional image along the pullback direction. *MM* muscularis mucosa (From Tsai et al. [63])

with a microprism glued on distal end to reflect the laser beam. The spot size and scan range could be adjusted by changing the magnification. In this prototype probe, the working distance was set to be 500 μm in tissue, and the focused spot size was 20 μm, corresponding to ~23 μm in tissue. The lateral scanning range was ~2 mm with the PZT bender driven at 10 V (peak to peak) and a frequency of 480 Hz. The PZT bender has the advantage that the actuation voltage is very low. A thin holder mounts the PZT bender on a 2 mm outer diameter torque coil which can be pulled back from the proximal end of the probe. This produces a rater-like scan pattern for acquiring 3D-OCT data. Figure 68.12b shows the photo of the probe. The outer diameter was 3.5 mm with a rigid length of the catheter of ~30 mm.

Imaging was performed in the rabbit GI tract in vivo as well as in human colon specimens ex vivo using an ultrahigh-speed swept-source OCT system with an FDML light source at 480 kHz axial rate with 8 um axial image resolution [63]. Figure 68.13 shows an ex vivo 3D-OCT data set from a freshly excised human colon specimen. Figure 68.13a shows an en face OCT image at a depth of 350 μm averaged over 15 μm depth. Individual crypts in the colon specimen are clearly visualized in the en face plane. Figures 68.13b and e show representative cross-sectional images along the fast-scan and pullback directions, respectively.

Both en face and cross-sectional images show columnar epithelial structure and correlate well with representative histology of human colon in Fig. 68.13c, d.

68.5 Clinical Applications of High-Speed Endoscopic OCT

Endoscopic OCT has been extensively investigated for GI applications by many groups, as described previously. In this section we summarize a representative series of clinical studies performed by our group using endoscopic OCT to visualize GI pathologies [29, 36, 37, 41, 42], as well as to evaluate tissue morphological changes associated with endoscopic therapies [38–40, 53]. These clinical studies were performed at the VA Boston Healthcare System with study protocols approved by the institutional review boards at Massachusetts Institute of Technology, Harvard Medical School, and VA Boston Healthcare System.

68.5.1 Visualizing GI Pathology Using Endoscopic OCT

Barrett's Esophagus: Barrett's esophagus (BE) is a common condition associated with gastroesophageal reflux disease (GERD) where the normal squamous epithelium of the esophagus is replaced by metaplastic columnar epithelium [70, 71]. In the United States, about 5.6 % of the population is affected by BE [72]. Patients with BE have an increased risk of developing esophageal adenocarcinoma, [73] which is a lethal disease with less than 20 % 5-year survival rate. In the past 30 years, the incidence of esophageal adenocarcinoma in white males has increased 300–500 % [74, 75]. Conventional endoscopic imaging lacks sensitivity for detecting high-grade dysplasia, the immediate precursor to esophageal cancer. Therefore, there is considerable interest in developing new imaging techniques which can detect and guide the treatment of dysplasia associated with BE and esophageal cancer.

Using an ultrahigh-speed endoscopic OCT system described in Sect. 68.3, we performed 3D endoscopic OCT imaging in patients with Barrett's esophagus (Fig. 68.14) [37]. Volumetric data sets allow the generation of en face images, thereby enabling precise registration of cross-sectional data with en face features. Projection techniques can be used to selectively display specific depths within the tissue, enhancing image contrast for specific architectural features. Cross-sectional images with arbitrary orientation can also be generated from the 3D data. The en face view (Fig. 68.14a) and cross-sectional views (Fig. 68.14b, c) illustrate the characteristic glandular structures associated with Barrett's esophagus, which can be easily distinguished from the layered structure of the normal esophagus. The enlarged view of glandular structures (Fig. 68.14d) correlates well with the histology of Barrett's esophagus shown in Fig. 68.14e. 3D-OCT endomicroscopy is capable of differentiating glandular and squamous epithelium in vivo. This ability could be important for applications such as the assessment of endoscopic therapies at multiple time points, since it provides an inherent positional registration that is difficult to obtain with isolated cross-sectional OCT images.

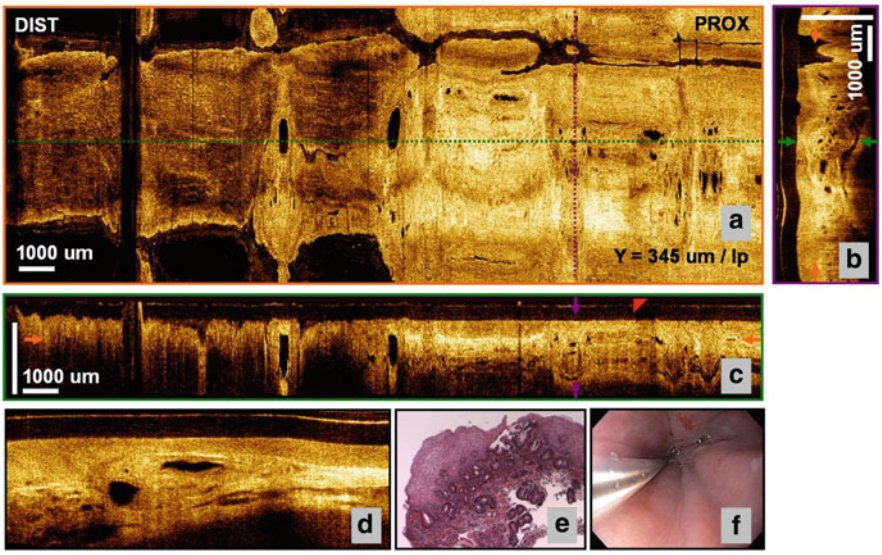

Fig. 68.14 3D-OCT images in Barrett's esophagus. (**a**) En face image constructed by axial summation of a thin slice (~20 um) in the 3D data. (**b**) A cross section in the probe rotary scan direction shows the characteristic glandular structures associated with Barrett's esophagus. (**c**) A cross section along pullback direction also shows glandular structures. (**d**) Zoomed view of cross section. (**e**) Representative histology of Barrett's esophagus. (**f**) White light video endoscopy image of region imaged with 3D-OCT (From Adler et al. [37])

Cervical Inlet Patch: Cervical inlet patch (CIP) is characterized by the presence of heterotopic columnar gastric mucosa in the upper esophagus, most commonly located just below the upper esophageal sphincter (UES). Other sites for heterotopic gastric mucosa have been reported in the duodenum, jejunum, cystic duct, ampulla of Vater, gallbladder, rectum, and the anus, but their etiology and pathologic significance remain unclear [76–80]. The incidence of CIP has been reported to be as low as 1 % and as much as 10 % of endoscopic cases in adult studies [81, 82]. A large autopsy series of 1,000 children demonstrated a CIP prevalence of 4.5 % [83]. During esophagogastroduodenoscopy, the region just below the UES is often quickly traversed after overcoming initial resistance. CIP is usually best seen at the end of an exam when withdrawing the endoscope back through the esophagus and specifically looking for the condition. One study found almost a six- to eightfold increase in the incidence, from 0.3 % to 2.3 %, depending upon the endoscopist's awareness of this entity and thoroughness of examination [84]. Although generally asymptomatic, CIP can present with dysphagia [85], stricture [86], ulcers [87], bleeding [88], or fistula [89].

We have used endoscopic OCT to evaluate epithelial changes in CIP patients compared to normal esophagus, Barrett's esophagus, normal stomach, and duodenum [41, 42]. Figure 68.15 shows white light endoscopy and endoscopic OCT images obtained from a 30-year-old Caucasian patient. As shown in Fig. 68.15a,

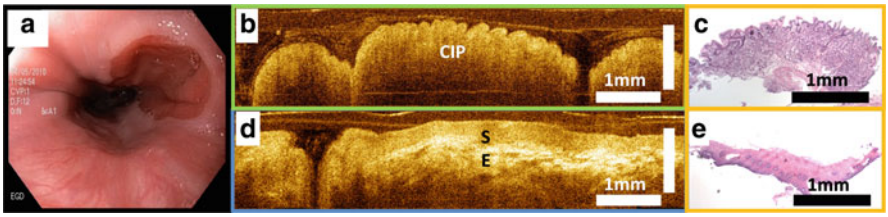

Fig. 68.15 3D-OCT images of cervical inlet patch (*CIP*). (**a**) Endoscopic view of CIP. (**b**) Cross-sectional OCT shows columnar epithelium in CIP. (**c**) Corresponding histology of (**b**). (**d**) Cross-sectional OCT image of normal squamous epithelium of the esophagus. (**e**) Corresponding histology of (**d**) (From Zhou et al. [42])

a pink circular lesion was observed under white light endoscopy in the upper esophagus (spanning 20–22 cm from the incisors) during retraction of the endoscope. Three-dimensional endoscopic OCT images were obtained of the region under direct visualization with white light endoscope by passing the probe through the standard accessory channel. Cross-sectional OCT images along the probe pullback direction clearly demonstrated columnar epithelium in the CIP region (Fig. 68.15b) and the surrounding normal squamous epithelium (Fig. 68.15d), respectively. Biopsies taken from the imaged lesion confirmed the finding of CIP. The OCT features matched representative H&E histology shown in Fig. 68.15c, e.

Ulcerative Colitis: We also performed clinical studies using endoscopic 3D-OCT in the lower gastrointestinal tract [36]. Ulcerative colitis (UC) is a chronic inflammatory condition of the GI tract that produces abscesses, ulcerations, and bleeding. UC affects up to 780,000 individuals in the United States and Canada and is newly diagnosed in 7,000–46,000 individuals per year [1]. UC is associated with a $\sim 5\times$ increase in risk of developing colorectal cancer compared to the general population, with colorectal cancer accounting for one sixth of all deaths in UC patients [90]. Unfortunately, early-stage dysplastic lesions are often flat, diffuse, and multifocal in these individuals [91]. As a result dysplastic lesions are easily obscured by the gross inflammatory background of UC, making early detection extremely challenging. UC represents a disease that can potentially benefit from 3D-OCT endomicroscopy examination for detection of lower GI abnormalities.

Figure 68.16 shows 3D-OCT endomicroscopy images acquired in the rectum near the anal verge of a UC patient. The imaged volume was $8 \times 20 \times 1.6$ mm and was acquired in 20 s. Figure 68.16a shows an en face image formed by axial summation over 20 um at a depth of 350 um below the luminal surface. When compared to normal squamous and columnar mucosa, UC tissue appears highly irregular. Large subsurface voids and bands of hyperscattering, possibly fibrotic tissue, are apparent. A wedge of comparatively normal tissue is visible at the right of the image. Figure 68.16b shows a cross section in the probe rotary scan direction through the region that reveals a regular, layered architecture consistent with anal

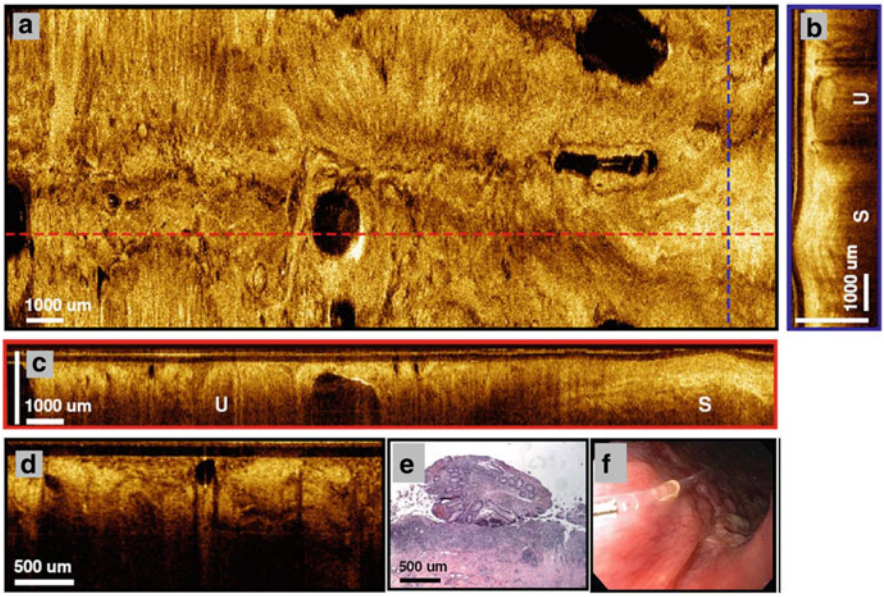

Fig. 68.16 3D-OCT images of ulcerative colitis. (**a**) En face image constructed by summing a 20 um axial section. Large, subsurface voids and ulcerations are present, while the regular crypt pattern is absent. *Dashed lines* show the locations of cross-sectional images. (**b**) A cross section in the probe rotary scan direction contains normal squamous epithelium S and ulcerative colitis U. (**c**) A cross section along the pullback direction shows similar structure. (**d**) Close-up view of the left portion of (**c**) shows disorganized structure and superficial voids. (**e**) Representative histology of UC shows an ulcerative pseudopolyp. (**f**) White light video endoscopy image of UC shows the 3D-OCT probe. The tissue surface is inflamed and ulcerations are visible (From Adler et al. [36])

squamous mucosa. The epithelium is thicker when compared to healthy subjects, possibly resulting from healing in response to prior treatment with anti-inflammatory medications. The ulcerated region exhibits a loss of layered or columnar architecture, superficial edema, and a large subsurface abnormality consistent with submucosal fibrosis. Figure 68.16c shows a longitudinal cross section with UC and normal squamous tissue visible on the left and right sides of the image, respectively. Figure 68.16d shows enlarged regions of Fig. 68.16c. Representative histology of UC in glandular mucosa is shown in Fig. 68.16e. Lymphocytic mucosal infiltration is present along with submucosal fibrosis. Ulceration results in the formation of a pseudopolyp as the epithelium is stripped away to expose the submucosa. Figure 68.16f shows a white light video endoscopy image of a patient with active UC. The mucosa appears red, inflamed, and ulcerative. The 3D-OCT catheter is also shown in position prior to imaging.

These results demonstrate that 3D-OCT can visualize subsurface features associated with inflammation. However the larger challenge is to assess if OCT can detect dysplastic changes associated with UC. However even with advances in imaging speed, OCT still has a small field of view compared with the area of the

lower GI tract. Since dysplastic changes occur focally, and it is impractical to image the lower GI tract at high resolution, OCT must be used in conjunction with a wide field imaging or detection technique which could identify regions of interest for focal high-resolution imaging. Furthermore, it would be necessary to demonstrate in a blinded study that reading OCT images has sufficient sensitivity and specificity to detect dysplasia compared with pinch biopsy and histology. This would require a larger scale clinical study. These types of issues represent some of the ongoing challenges in the development of endoscopic OCT.

68.5.2 Evaluating Therapeutic Response Using Endoscopic OCT

Endoscopic therapies are emerging as preferred treatments for a range of GI diseases due to their shorter recovery time compared with surgery. 3D-OCT endomicroscopy can potentially enhance endoscopic therapies by providing image guidance for optimal treatment planning. 3D-OCT could also be used to monitor therapy and assess healing and recurrence. Finally, 3D-OCT imaging can provide depth-resolved information when excisional biopsy is contraindicated, such as in radiation proctitis, where the risk of bleeding is high.

Radiofrequency Ablation of Barrett's Esophagus: Radiofrequency ablation (RFA) is an emerging endoscopic therapy for treating dysplastic BE [92–96]. Utilizing electrode arrays, RFA catheters deliver radiofrequency energy to the surface of esophageal tissues to ablate dysplastic BE with a low stricture rate [97, 98]. Recent studies have shown that at 1-year follow-up from the initial RFA treatment, complete eradication of dysplasia (CE-D) was achieved in 90.5 % of patients with low-grade dysplasia (LGD) and in 81 % of patients with high-grade dysplasia (HGD) [96]. At 2-year follow-up, CE-D was achieved in 98 % and 93 % of patients with LGD and HGD, respectively [99]. Complete eradication of intestinal metaplasia (CE-IM) was achieved in 93 % of patients with dysplasia after 2 years [99] and in 92 % of patients with non-dysplastic BE (NDBE) at 5-year follow-up [100]. In spite of these promising results, it should also be noted that patients typically require multiple treatment sessions in order to achieve complete eradication of dysplasia or intestinal metaplasia.

After RFA, new squamous epithelium generally replaces previous BE epithelium. However, residual BE glands can become "buried" by the neosquamous epithelium. The subsquamous intestinal metaplasia (SSIM) is not visible by conventional endoscopy, even when supplemented by chromogen or narrow band imaging (NBI). The malignant potential of SSIM is unknown [101–103]; however, SSIM was found in 25 % patients before and in 5 % patients after successful RFA treatment when detected by random biopsies [96]. However, SSIM is likely underappreciated with the current surveillance protocol of four-quadrant random biopsies every 1–2 cm along the area of apparent BE, since the area of neosquamous epithelium is not routinely biopsied in clinical practice. Furthermore, the sampling area ($\sim$1–2 mm^2) and depth [94, 100, 104] of biopsy is limited, even when using large-capacity biopsy forceps.

OCT imaging depth is 1–2 mm in human esophagus, enabling evaluation of tissue morphology underneath the squamous epithelium. The advent of high-speed endoscopic OCT systems [34–36, 60] enables 3D and comprehensive imaging. Since the location of SSIM is unpredictable, the ability of 3D-OCT to perform high-resolution, depth-resolved imaging of large areas holds great potential for identifying and characterizing SSIM before and after ablative therapies. We recently reported a clinical study demonstrating that SSIM can be effectively detected using 3D-OCT in a cohort of 27 patients undergoing RFA treatment [40].

In this section, we summarize clinical OCT studies of RFA treatment response. During the standard endoscopic procedure, the lower one third of the patient's esophagus was first surveyed with high definition white light endoscopy. Then, multiple 3D-OCT data sets were acquired over different quadrants at the gastro-esophageal junction (GEJ). After 3D-OCT imaging, BE regions identified endoscopically were ablated using an RFA catheter (BARRX Halo 90) per standard protocol [96]. Patients received a follow-up endoscopy 6–8 weeks after RFA treatment. If no BE was identified endoscopically, random 4-quadrant pinch biopsies were taken around the GEJ. The patient received additional RFA treatment if intestinal metaplasia (IM) was found based on histology or was followed 1 year later if complete eradication of IM (CE-IM) was achieved.

Figure 68.17a shows representative en face projection OCT images from a patient in the Pre-CE-IM group. Here, columnar epithelium (left) and squamous epithelium (right), as well as the SCJ, can be clearly identified. The location of SSIM is marked as red dots. Cross-sectional OCT images corresponding to the dashed brown and blue lines in Fig. 68.17a is shown in Fig. 68.17b, c, respectively. SSIM, indicated by red arrows, is clustered under the squamous epithelium. Figure 68.17d, e is 3× zoomed views of the SSIM regions shown in Fig. 68.17b, c, respectively. A double-band feature, as also described by other groups [105], can be observed from some SSIM. From the entire patient cohort, SSIM was identified in 72 % (13/18) patients in the Pre-CE-IM group and 63 % (10/16) patients in the Post-CE-IM group using OCT. Furthermore, as shown in Fig. 68.18, the number of SSIM per patient observed in the Post-CE-IM group [7.1 (9.3), mean (standard deviation), median = 5] is significantly lower compared to the number of SSIM per patient observed in the Pre-CE-IM group [34.4(44.6), median = 26.5; $p = 0.02$].

In a related study involving 33 BE patients, we found that the BE thickness measured with OCT prior to RFA is a predictor of RFA treatment response [38]. As shown in Fig. 68.19a, the average BE thickness prior to RFA was significantly thinner for the CE-IM group compared to the Non-CE-IM group (average BE thickness, 257 ± 60 um versus 403 ± 86 um, $p < 0.0001$). Figure 68.19b shows ROC curves using average and maximum BE thickness to predict RFA treatment response. The area under the curve (AUC) was 0.942 ($p < 0.001$) and 0.934 ($p < 0.001$) using the average and maximum BE thickness, respectively. An average BE thickness of 333 um was determined from the ROC curve to achieve the best prediction accuracy. Using this decision threshold, a sensitivity of 92.3 % (12/13), specificity of 85 % (17/20), PPV of 80 %, NPV of 94.4 %, and an accuracy of 87.9 % (29/33) were obtained for predicting RFA treatment response using the

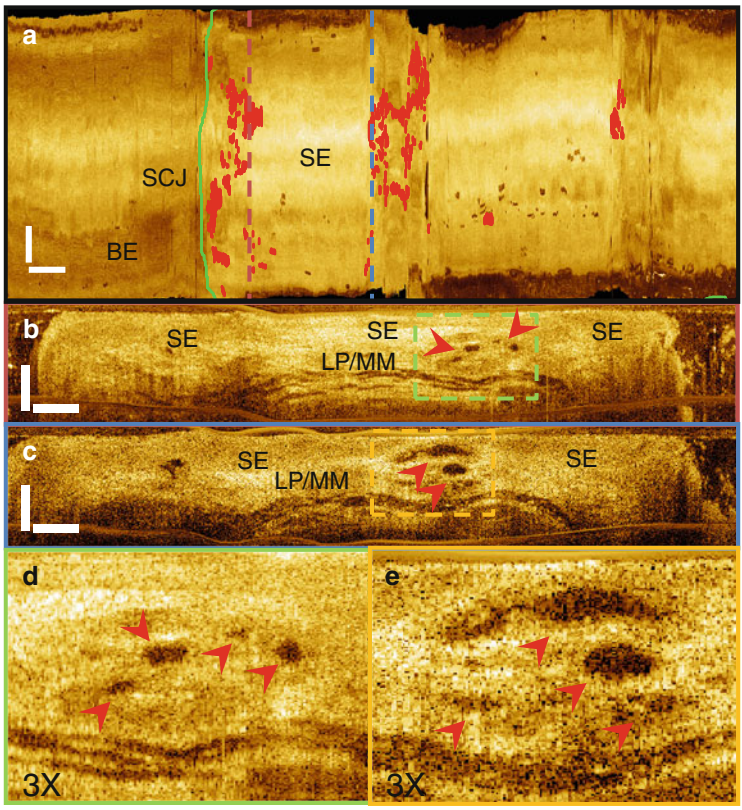

Fig. 68.17 OCT images from a patient in the Pre-CE-IM group. (**a**) En face projection over the full imaging depth of the 3D-OCT data (log OCT signal). The SCJ is marked as a *green line* with columnar epithelium on the left and squamous epithelium on the *right*. Buried glands are marked as *red dots*. (**b**, **c**) Cross-sectional OCT images corresponding to the *dashed brown* and *blue lines* in (**a**). The *red arrows* indicate buried glands. (**d**, **e**) 3× zoomed views of the buried glands regions shown in (**b**, **c**). *SCJ* squamous columnar junction, *BE* Barrett's esophagus, *LP/MM* lamina propria/muscularis mucosa. Scale bars: 1 mm in (**a**), 500 μm in (**b**), and (**c**) (From Zhou et al. [40])

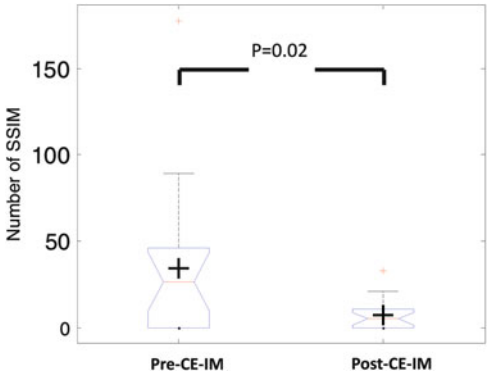

Fig. 68.18 Comparison of the number of buried glands observed per patient in the Pre-CE-IM and Post-CE-IM groups. The number of buried glands per patient was significantly lower in the Post-CE-IM group [7.1(9.3), median = 5] compared to the Pre-CE-IM group [34.4(44.6), median = 26.5; $p = 0.02$] (From Zhou et al. [40])

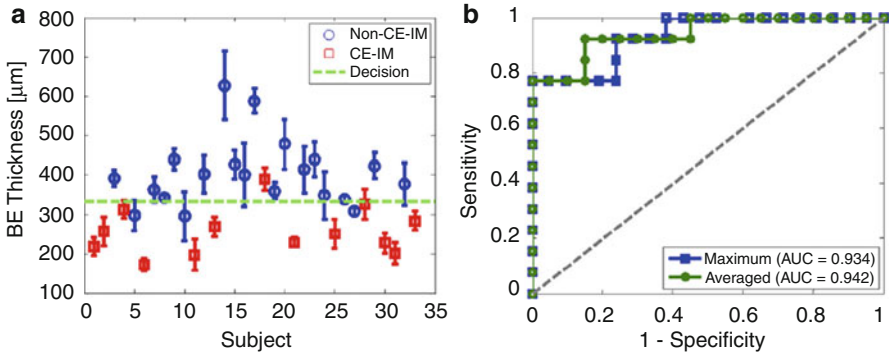

Fig. 68.19 (**a**) Scatter plot of the average Barrett's esophagus (*BE*) epithelium thickness measured by optical coherence tomography. *Blue circles*: non-complete eradication of intestinal metaplasia group. *Red crosses*: complete eradication of intestinal metaplasia group. *Green dotted line*: discrimination threshold at 333 m as determined from the average BE thickness receiver operating characteristic (*ROC*) curve in (**b**). (**b**) ROC curves of treatment response prediction by using average (*green*) and maximum (*blue*) BE thickness. The area under the curve values was 0.942 ($P < .001$) and 0.934 ($P < .001$) by using the average and maximum BE thicknesses, respectively. *BE* Barrett's esophagus, *CE-IM* complete eradication of intestinal metaplasia, *AUC* area under the curve (From Tsai et al. [38])

average BE thickness measured with OCT prior to the RFA treatment. The BE thickness measured with OCT was not correlated with the length of BE ($p = 0.88$) or the number of prior RFA treatments ($p = 0.24$).

The relationship between thickness of BE and RFA treatment response is not surprising because the standard RFA treatment parameters may not be sufficient to ablate the full BE thickness if there are thickness variations. Current RFA treatment protocols do not permit large variations in the treatment parameters, since overtreatment would increase stricture rate. If OCT measurements of BE thickness could be used for treatment planning and dose determination, this may improve the efficacy of RFA. Conversely, OCT might also be used to guide RFA treatment in real time. These approaches are complicated by the fact BE regions in the esophagus are nonuniform and BE thickness may also exhibit inhomogeneity. These inhomogeneities, combined with concerns about strictures which would result from overtreatment, make the development and validation of OCT image planned or image-guided treatment complex and challenging. However, if this problem could be addressed, it would have the potential to significantly reduce the procedural complexity of RFA.

Radiofrequency Ablation of Radiation Proctitis: Radiation proctitis (RP) is a chronic inflammatory condition that causes bleeding, diarrhea, mucous discharge, rectal pain, and fecal incontinence. RP is a common side effect of pelvic radiation therapy, which is often used to treat prostate and cervical cancers. RP affects 5.0–7.5 % of patients who undergo pelvic radiation therapy [106] and therefore is a significant cause of GI morbidity. 3D-OCT imaging was used to assess endoscopic therapy for RP, imaging three RP patients at different time points following

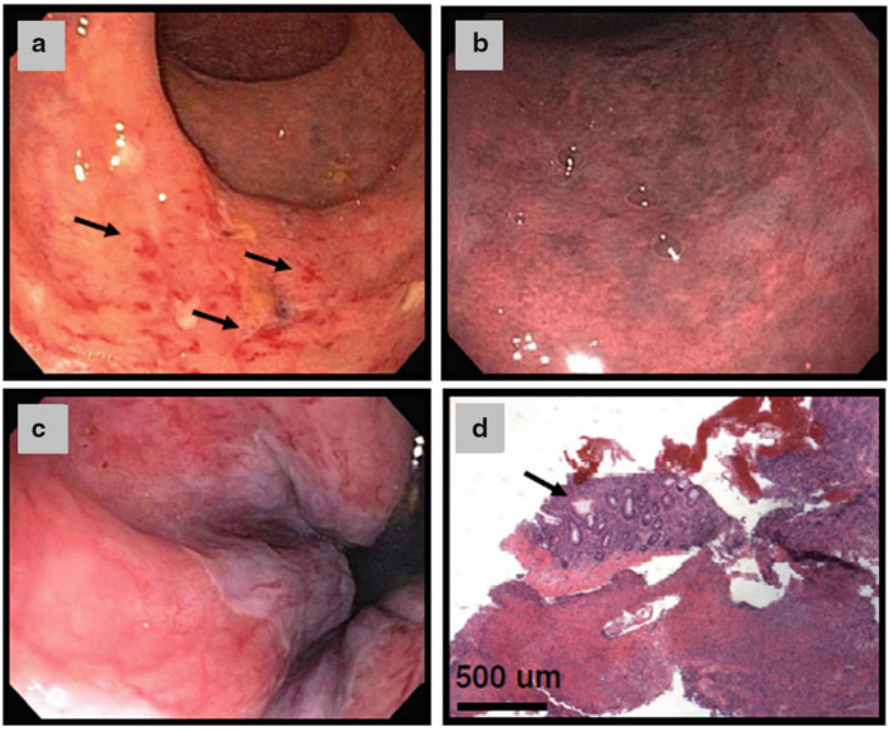

Fig. 68.20 Conventional examination of radiation proctitis. (**a**) White light video endoscopy image of radiation proctitis prior to treatment with radiofrequency ablation. *Arrows* indicate regions of bleeding and ulceration. (**b**) Image 12 months after treatment. (**c**) Image 14 months after treatment. (**d**) Representative cross-sectional histology image of radiation proctitis. *Arrow* indicates a large superficial vessel (From Adler et al. [36])

endoscopic treatment with RFA [36, 53]. Figure 68.20a–c shows white light video endoscopy images from an RP patient prior to treatment and at 12 and 14 months post treatment. Prior to treatment, bleeding vessels and ulcerations are clearly apparent. At 12 months post treatment, the rectal mucosa shows some residual inflammation, but bleeding has markedly decreased. At 14 months post treatment, the rectum appears largely normal. Figure 68.20d shows representative histology of RP, with inflammatory infiltrates and large superficial vessels present. Pinch biopsy was not obtained because it is contraindicated in subjects with RP due to the risk of bleeding. Figure 68.21 shows 3D-OCT images of the same RP volunteer 14 months after the RFA therapy. Figure 68.21a shows an en face image formed by axial summation of a 20 um thick section centered at a depth of 460 sum beneath the luminal surface. This 3D-OCT data was acquired over the dentate line, which is clearly visible as the dividing region between crypt-laden columnar epithelium on the left side of the image and smooth squamous epithelium on the right. There are no large edematous regions, and the subsurface cyst-like structures exhibit less hypointensity with a thicker layer of epithelial tissue on top. Figure 68.21b, c shows

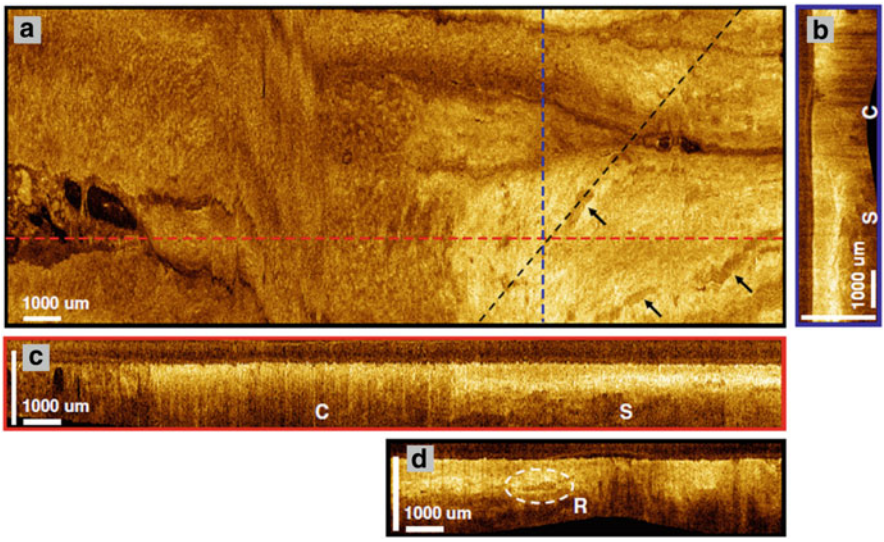

Fig. 68.21 3D-OCT images of radiation proctitis 14 months after treatment. (**a**) 20 um en face summation. Columnar epithelium proximal of the dentate line appears normal. Squamous epithelium is largely normal, with likely former ectatic vessels shown by *arrows*. *Dashed lines* show locations of cross-sectional images. (**b**) A cross section in the probe rotary direction showing regular squamous *S* and columnar *C* epithelium. (**c**) Cross sections in the longitudinal pullback direction showing similar features. (**d**) Arbitrary cross section through the long axis of an ectatic vessel remnant *R* (From Adler et al. [36])

cross-sectional images in the probe rotary scan direction and along the longitudinal direction, respectively, illustrating the transition from normal squamous to normal columnar epithelium. Figure 68.21d shows a virtual image plane oriented parallel to the long axis of one subsurface cyst-like structure. The structure can be easily located by comparing the cross section to the en face view in Fig. 68.21a. These structures may be remnants of the RP inflammation, which are covered in normal squamous epithelium following radiofrequency ablation treatment. 3D-OCT can enable measurement of pathologic structures, suggesting the possibility of quantitative assessment of disease progression, treatment, healing, and recurrence.

68.6 Conclusions

This chapter provided an overview of endoscopic OCT, which emphasizes on ultrahigh resolution and ultrahigh speed imaging technologies, probe technologies, and recent clinical studies which were performed using endoscopic OCT. These OCT technologies and advanced endoscopic imaging probes make it possible to obtain 3D volumetric images of human GI tract with unprecedented imaging resolution and speed. Endoscopic 3D-OCT enables visualization of subsurface

and/or small abnormal GI structures which cannot be seen with standard white light endoscopy. Compared to pinch biopsy, endoscopic OCT provides a 100× or more area of coverage and deeper sampling depth, which could be used to reduce sampling errors associated with pinch biopsy. In addition, real-time in vivo imaging of the GI morphology can be obtained noninvasively using endoscopic OCT, providing instantaneous feedback to the endoscopist. With further development, endoscopic 3D-OCT promises to be a powerful tool for screening GI pathologies and evaluating endoscopic therapies in clinical practices.

69.1 Introduction

Acute myocardial infarction (AMI) is the leading cause of death in the United States and industrialized countries [1, 2]. Research conducted over the past 15 years has demonstrated that several types of minimally or modestly stenotic atherosclerotic plaques, termed vulnerable plaques, are precursors to coronary thrombosis, myocardial ischemia, and sudden cardiac death. Postmortem studies have identified one type of vulnerable plaque, the thin-capped fibroatheroma (TCFA), as the culprit lesion in approximately 80 % of sudden cardiac deaths [3–7]. Over 90 % of TCFAs are found within the most proximal 5.0 cm segment of each of the main coronary arteries (left anterior descending, LAD; left circumflex, LCx; and right coronary artery, RCA) [3, 5].

The TCFA is typically a minimally occlusive plaque characterized histologically by the following features: (1) thin fibrous cap (<65 μm), (2) large lipid pool, and (3) activated macrophages near or within the fibrous cap [3, 5, 7–9]. It is hypothesized that these features predispose TCFAs to rupture in response to biomechanical stresses [10, 11]. Following rupture and the release of procoagulant proteins, such as tissue factor, a substrate for thrombus formation is created, leading to an acute coronary event [12, 13]. While TCFAs are associated with the majority of AMIs, recent autopsy studies have shown that coronary plaques with erosions or superficial calcified nodules may also precipitate thrombosis and sudden occlusion of a coronary artery [3, 5, 14, 15].

Although autopsy studies have been valuable in determining features of culprit plaques, the retrospective nature of these studies limits their ability to quantify the risk of an individual plaque for causing acute coronary thrombosis. For instance, TCFAs are a frequent autopsy finding in asymptomatic or stable patients and are found with equal frequency in culprit and non-culprit arteries in acute coronary syndromes [16]. Moreover, disrupted TCFAs have been found in 10 % of noncardiac deaths [16]. Recent findings of multiple ruptured plaques [17] and increased systemic inflammation in acute patients [18–20] have challenged the notion of a single vulnerable plaque as the precursor for AMI [19, 21, 22]. An improved understanding of the natural history and clinical significance of these lesions would accelerate progress in diagnosis, treatment, and prevention of coronary artery disease (CAD).

An attractive approach to studying the evolution of vulnerable plaques is noninvasive or intracoronary imaging of individual lesions at multiple time points. Unfortunately, the microscopic features that characterize vulnerable plaque are not reliably identified by conventional imaging technologies such as intravascular ultrasound (IVUS) [23–28], computed tomography (CT) [29–32], and magnetic resonance imaging (MRI) [32–35]. While experimental intracoronary imaging modalities, such as integrated backscatter IVUS [36, 37], virtual histology IVUS [38, 39], elastography [32, 40], angioscopy [41–45], near-infrared spectroscopy [46], fluorescence spectroscopy [47–49], Raman spectroscopy [50, 51], and thermography [52, 53], have been investigated for the detection of vulnerable plaque, no method to date has been shown to reliably identify all of the characteristic features of these lesions.

69.2 Optical Coherence Tomography

Intracoronary optical coherence tomography (OCT) is an invasive microscopic imaging technology that has been developed for the identification of vulnerable plaque [54–57]. OCT acquires cross-sectional images of tissue reflectance and, since it may be implemented through an optical fiber probe, it is readily adaptable to coronary catheters [58] for insertion into coronary arteries and circumferential imaging of arterial pathology. The first investigation of vascular optical coherence tomography ex vivo demonstrated the potential of this technique to identify arterial microstructure [59]. Subsequent development of OCT technology enabled image acquisition at rates sufficient for intracoronary imaging in human patients [60–62]. In this chapter, we review studies conducted with this technology at the Massachusetts

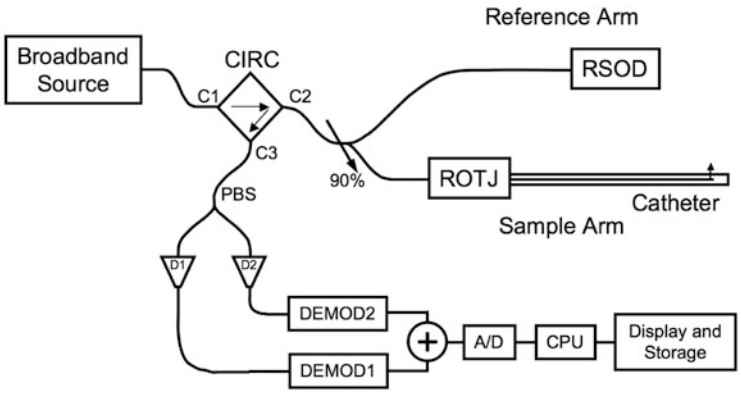

Fig. 69.1 Schematic of the time-domain intracoronary optical coherence tomography system. Polarized, broad bandwidth light passes through a circulator (CIRC, port C1 to port C2) and is split into reference and sample arms via a 10/90 fiber-optic beam splitter. The optical path length (group delay) of the reference arm is scanned by translating the galvanometer of the rapidly scanning optical delay (*RSOD*) line. Sample arm light is coupled into the catheter by a rotating optical junction (*ROTJ*). Light returned from the reference and sample arms is combined at the splitter and transmitted back to the circulator at port C2. The circulator then passes this light through port C3 to a polarizing beam splitter (*PBS*). The two orthogonal polarization states are detected separately by photodiodes D1 and D2. The two signals are demodulated and summed to create the final output signal, which is digitized (A/D) and transferred to the CPU. Detection of the fringe patterns created by sample and reference arm interference allows one radial scan (A-line) to be constructed that maps tissue reflectivity to a given axial or depth location. A cross-sectional image is generated by repeating this process at successive transverse locations on the sample while the ROTJ rotates the internal components of the catheter

General Hospital (MGH). Results from these studies show that a wide variety of microscopic features, including those associated with TCFAs, can be identified by OCT imaging both ex vivo and in living human patients. These findings suggest that this technology will play an important role in improving our understanding of coronary artery disease, guiding local therapy, and decreasing the mortality of AMI.

69.3 Optical Coherence Tomography System

A schematic of the OCT system is shown in Fig. 69.1 [61]. Briefly, the system consisted of a polarization-diverse fiber-optic nonreciprocal interferometer, which operated in the time domain. The light source was centered at 1,300 nm and had a Gaussian spectral full-width-at-half-maximum of 70 nm, providing an axial resolution of approximately 8 μm in tissue. The transverse resolution, determined by the focal spot size produced by the probe, was 25 μm. Group delay scanning at a rate of 2 kHz was conducted by utilizing a phase-control rapidly scanning optical delay (RSOD) in the reference arm [63]. Images (500 pixels transverse $\times$250 pixels axial) were obtained at four frames per second and stored digitally. A custom-built fiber-optic rotary junction was utilized for catheter-based circumferential imaging,

and a galvanometer mirror was used for the free-space experiments [64]. Catheters were constructed by modifying a commercially available 3.0F (950 μm diameter), rapid-exchange IVUS catheter to incorporate a central fiber, a distal gradient index (GRIN) lens, and a deflecting prism, which were rotated to construct a circumferential image [64].

69.4 Ex Vivo Studies

Plaque characterization The first steps in validating this imaging modality were to establish and test the accuracy of objective image criteria for discrimination of atherosclerotic plaque types ex vivo. A total of 357 specimens (162 aortas, 105 carotid bulbs, and 90 coronary arteries) were obtained from 90 cadavers (48 male, 42 female, mean age 74.5 ± 13.25). The specimens were examined fresh, less than 72 h postmortem. Imaging was conducted at physiologic temperature (37 °C). For the training set, 50 cadaver plaques were imaged by OCT and correlated with histology obtained at the imaging site [57]. Registration was accomplished by placing ink marks on the tissue prior to imaging so that both OCT images and histopathology slides contained visibly recognizable reference points. Fibrous plaques were characterized by homogeneous, signal-rich regions, fibrocalcific plaques by signal-poor regions with sharp borders, and lipid-rich plaques by signal-poor regions with diffuse borders (Fig. 69.2). Two blinded readers prospectively applied these criteria to images of the remaining 307 plaques (validation set). Using histopathologic diagnosis as the gold standard, the accuracy of OCT for characterizing plaque type was then determined. These criteria yielded a sensitivity and specificity ranging from 71 % to 79 % and 97 % to 98 % for fibrous plaques, 95–96 % and 97 % for fibrocalcific plaques, and 90 %–94 % and 90–92 % for lipid-rich plaques, respectively (overall agreement, $\kappa = 0.84$). These results demonstrated that objective OCT criteria are highly sensitive and specific for differentiating lipid-rich plaques from other plaque types [57].

Quantification of macrophage content Macrophages are central to the etiology of coronary artery disease [12, 65–67]. Due to the high quantity of intracellular phagolysosomes containing lipid and other cellular debris, we hypothesized that the refractive index contrast provided by the cytoplasm of macrophages would result in a strong optical signal from these cells (Fig. 69.3). Furthermore, since macrophages are typically heterogeneously distributed in atherosclerotic tissue, the spatial variance of OCT signal in plaques with high macrophage content should also be elevated. In order to test this hypothesis, cap macrophage and smooth muscle densities of 27 necrotic core fibroatheromas were quantified by analyzing indirect horseradish immunoperoxidase staining of paraffin-embedded tissue sections incubated with CD68 and smooth muscle actin monoclonal antibodies, respectively [68]. Hematoxylin was the counterstain. Morphometric measurements (single 10×, cross-sectional field) of cell density (% area stained) within a 500 μm (lateral) ×125 μm (axial) region of interest were then compared to the normalized standard deviation (NSD) of the OCT signal intensity at corresponding locations [68].

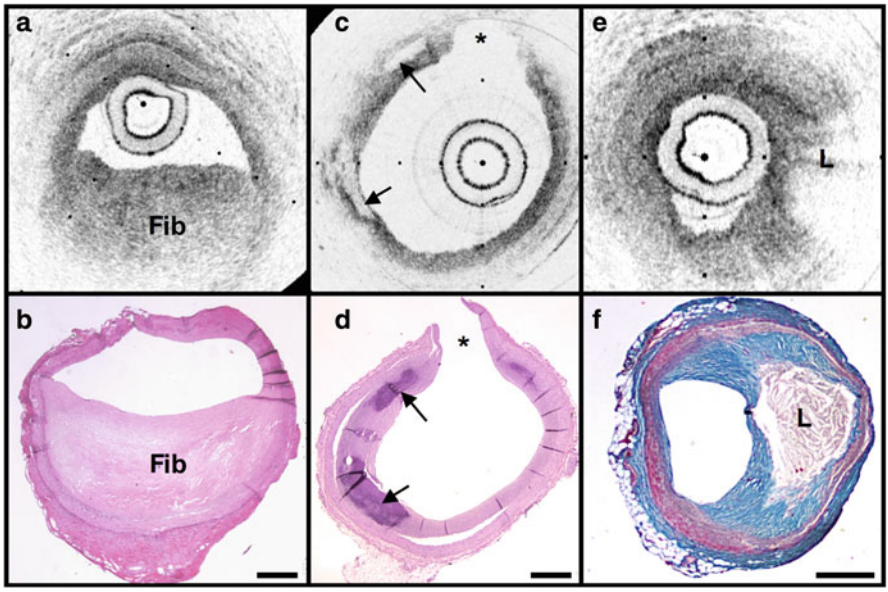

Fig. 69.2 OCT images and corresponding histology for fibrous (**a**, **b**), calcific (**c**, **d**), and lipid-rich (**e**, **f**) plaque types (obtained ex vivo). In fibrous plaques, the OCT signal (*Fib*) is observed to be strong and homogenous. In comparison, both calcific (*arrows*) and lipid-rich regions (*L*) appear as signal-poor regions within the vessel wall. Lipid-rich plaques have diffuse or poorly demarcated borders while the borders of calcific nodules are sharply delineated. (**b**, **d**) Hematoxylin and eosin; (**f**) Masson's trichome; original magnification 40×. Scale bars, tick marks, 500 μm

We found a high degree of positive correlation between OCT and histologic measurements of fibrous cap macrophage density ($r = 0.84$, $p < 0.0001$) and a negative correlation between OCT and histologic measurements of smooth muscle actin density ($r = -0.56$, $p < 0.005$). A range of NSD thresholds (6.15–6.35 %) yielded greater than 90 % sensitivity and specificity for identifying caps containing >10 % CD68 staining. This study demonstrated that the high contrast and resolution of OCT enables the quantification of macrophages within fibrous caps of atherosclerotic plaques. The impact of this finding was significant, as prior to this work there was no established tool that could permit the investigation of these crucial inflammatory cells in patients.

Other plaque features While the previously described studies demonstrated accurate characterization of features associated with TCFAs, OCT is capable of identifying additional plaque components that may be associated with acute coronary events. These features are described below:

Calcific nodules Calcific nodules have been associated with plaque thrombosis in a minority of cases [3, 5]. Calcium by OCT appears as a signal-poor region with a sharp delineation between the nodule and the surrounding tissue (Fig. 69.2c). In our histopathologic study of plaque characterization, we were able to use this criterion to diagnose calcific nodules with 96 % sensitivity and 97 % specificity [57].

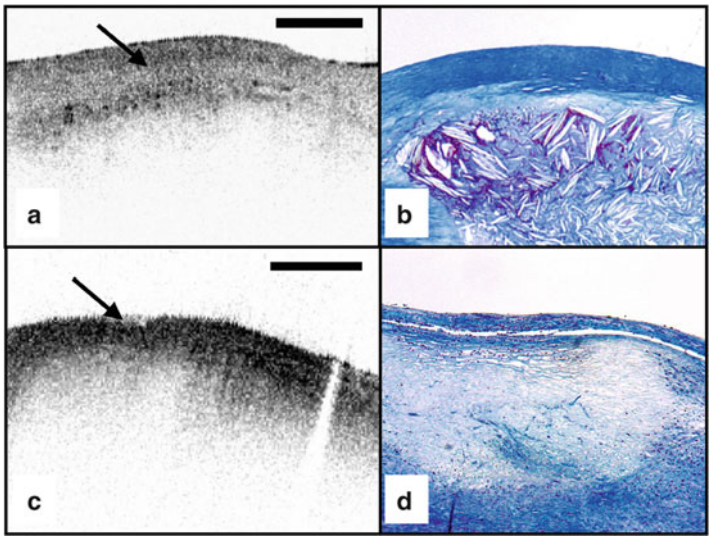

Fig. 69.3 (**a**) OCT image of a fibroatheroma with a low density of macrophages within the fibrous cap (*arrow*) (obtained ex vivo). (**c**) OCT image of a fibroatheroma with a high density of macrophages within the fibrous cap (*arrow*). (**b**, **d**) Histology corresponding to (**a**) and (**c**), respectively; Masson's trichome; original magnification 40×. Scale bars (both OCT and histology), 500 μm

Thrombus Differentiation of thrombus from plaque is critical for accurate plaque characterization. In addition, there is evidence to suggest that thrombus type, platelet-rich versus red blood cell-rich, is an indicator of the flow conditions associated with the thrombus formation and could be an important predictor of the efficacy of thrombolytic therapy [69]. We have conducted a study to correlate histopathologic sections of thrombus with OCT. Our preliminary results suggest that a "red" thrombus (red blood cell-rich) rapidly attenuates the signal in a manner similar to whole blood (Fig. 69.4a). In contrast, a "white" thrombus (platelet-rich) appears to exhibit a homogeneous moderate-strong signal with significantly less attenuation (Fig. 69.4b) [62]. In our experience, both forms of thrombus are usually easily distinguished from the arterial wall proper [70].

Macrophages at the cap-lipid pool border High-resolution cross-sectional optical imaging affords the unique opportunity to study the location of macrophage accumulations within a given plaque cross section. Using our macrophage dataset [68], we found that 84 % of OCT images demonstrated a high signal at the junction between the cap and the lipid pool (Fig. 69.5a, b) when CD68 staining at this interface was greater than 50 %.

Cholesterol crystals Research investigating the biomechanical properties of atherosclerotic plaques has shown that the presence of cholesterol crystals increases the stiffness of lipid pools and, as a result, may decrease the likelihood of plaque rupture [71]. Images of cholesterol crystals demonstrate oriented, linear, highly reflecting structures within the plaques (Fig. 69.5e, f) [72].

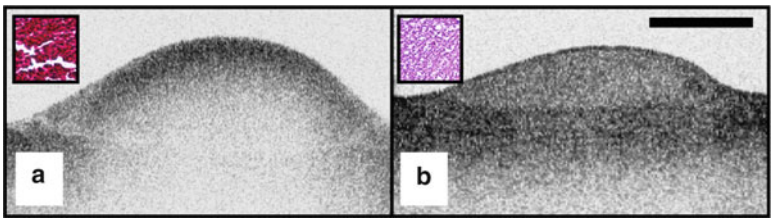

Fig. 69.4 OCT images of red blood cell-rich (**a**) and platelet-rich (**b**) thrombi (obtained ex vivo). The red blood cell-rich thrombus demonstrates high OCT signal attenuation, whereas the platelet-rich thrombus shows a homogeneous scattering signal with relatively little attenuation. Insets depict corresponding histology sections from each thrombus; hematoxylin and eosin; original magnification 40×. Scale bar, 500 μm

Scale bars (both OCT and histology), 250 μm

Neovascularization. Neovascularization in coronary plaque is also considered to relate with plaque vulnerability [73]. Although there is little histopathologic validation of IVOCT for neovascularization, an international community of IVOCT experts believes that the OCT images of neovascularization are identified as small, continuous regions with little or no IVOCT backscattering (presumably due to the removal of blood via flushing), frequently observed over several frames [74].

69.5 Clinical Studies

Histopathologic validation of qualitative and quantitative image criteria ex vivo provided a foundation for interpreting data obtained from living human patients. Between January 2000 and September 2003, a total of 83 patients undergoing routine percutaneous coronary intervention (PCI) were enrolled in a study at

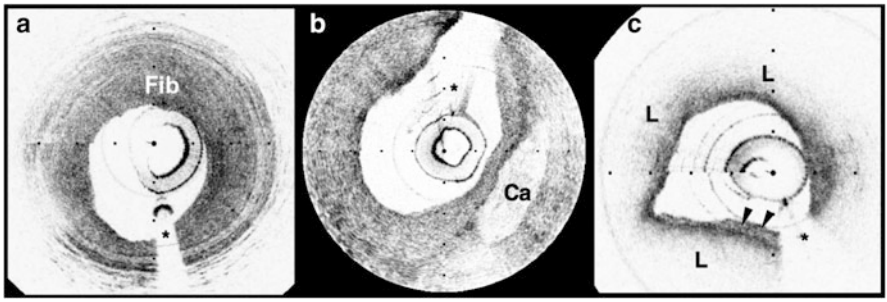

Fig. 69.6 OCT images of coronary plaques acquired from living human patients (obtained in vivo). (**a**) Fibrous plaque (*Fib*); (**b**) calcific nodule (*Ca*); (**c**) TCFA with circumferential lipid pool (*L*) and a region consistent with a platelet-rich thrombus (*arrowheads*). *Guidewire artifacts. Tick marks, 500 μm

the Massachusetts General Hospital (Boston, MA) to investigate the feasibility of intracoronary OCT. Informed consent was obtained for all patients. Imaging was performed in culprit lesions and remote sites with IVUS and OCT pre- and postcoronary intervention [62, 75]. Clear visualization of the arterial wall was accomplished by use of intermittent saline flushes (8–10 cm^3) through the guide catheter. All patients tolerated the procedure well without short- or long-term complications. Images demonstrating detailed arterial microstructure were successfully obtained in all patients studied and in all three major coronary arteries [62, 75]. To compare IVUS and OCT, images were registered by angiographic visualization of the catheter tip, anatomical landmarks, and guide catheter tip location. Summaries of the results from our clinical study are described below:

OCT images obtained in living patients contained the same image features as those obtained ex vivo. All of the characteristics of macrophage-rich TCFAs as well as the additional plaque features described in the previous section were observed in vivo; there were no image features in the clinical data that had not been observed ex vivo (Fig. 69.6) [62]. These observations suggest that image interpretation criteria and algorithms validated ex vivo can also be applied to images obtained from patients.

OCT observations were consistent with IVUS, the current gold standard for intracoronary imaging [62]. Although IVUS is unable to resolve microstructural features associated with vulnerable plaque, it can identify non-atherosclerotic (normal) vessels, large thrombi, calcific deposits, and pronounced arterial disruptions. While unconfirmed, indirect evidence suggests that IVUS may detect large lipid deposits [24]. A study was conducted, comparing 17 OCT-IVUS image pairs obtained from ten patients [62]. In all cases where IVUS identified these characteristics, blinded OCT observations were consistent (Table 69.1). OCT detected additional cases of intimal hyperplasia, thrombus, intimal disruption, and lipid pool not identified by IVUS [62].

Table 69.1 IVUS and OCT findings for corresponding image pairs ($n = 17$)

Feature	A. Identified by *both* OCT and IVUS	B. Identified by OCT *alone*
Intimal hyperplasia	3 (3 patients)	8 (7 patients)
Internal elastic lamina	NE	11 (8 patients)
External elastic lamina	NE	10 (7 patients)
Plaque	17 (10 patients)	0
Fibrous plaque	13 (10 patients)	0
Calcific plaque	4 (4 patients)	0
Echolucent region	2 (2 patients)	2 (2 patients)

Taken from Jang et al. [62]
All features of the vessel wall structure identified by the IVUS reader were seen in the corresponding OCT image (column A). Additional findings by OCT that were not identified by the IVUS reader are enumerated in column B
IVUS intravascular ultrasound, *NE* not evaluated, *OCT* optical coherence tomography

Imaging of culprit lesions demonstrated a higher prevalence of TCFA in patients with acute coronary disease than patients with stable coronary disease [76]. In this analysis, TCFA was defined as a plaque with lipid area $\geq$2 quadrants and cap thickness <65 μm. From a total of 57 patients, 20 presented with AMI, 20 with an acute coronary syndrome (ACS), and 17 with stable angina pectoris (SAP) [77]. TCFAs identified by OCT were found in 13 AMI patients (65 %), 9 with ACS (45 %), and 3 with SAP (18 %) [76]. TCFAs were more prevalent in acute presentations (AMI and ACS) of CAD (55 % versus 18 %, $p = 0.012$) [76]. Plaque disruption was found more frequently in acute CAD (20 % versus 12 %, $p = 0.053$) and calcifications were more frequent in stable disease (41 % versus 12 %, $p = 0.049$) [76]. These findings represent the first observation of presentation-dependent plaque morphology in living human patients and confirm our current knowledge of the relationship between morphology and patient outcome that has been obtained in previous autopsy studies [3–7].

Macrophage content was significantly higher in fibroatheroma caps in patients with acute presentations of CAD versus *caps in patients with SAP* [78, 79]. For this study, we created NSD (macrophage density) images (Fig. 69.7) and analyzed the macrophage distributions in both culprit and remote plaques ($n = 225$) of 49 patients with different clinical syndromes. Macrophage density was found to be significantly higher in the AMI (5.54 ± 1.48 %) and ACS (5.86 ± 2.01 %) groups compared to the SAP group (4.14 ± 1.81 %) ($p < 0.003$) [78, 79].

Both focal and multifocal elevations of macrophage density were associated with severity of clinical presentation [79]. There is great interest in understanding the role of focal versus multifocal plaque features in the pathogenesis of acute coronary thrombosis. The unique ability of OCT to quantify macrophage content and observe the spatial distribution of plaque macrophages provides a valuable tool for investigating this critical question. Supporting the concept of focal risk, sites of plaque rupture demonstrated a greater macrophage density than non-rupture sites (6.95 ± 0.48 %, 5.71 ± 0.37 %; $p = 0.01$) [79]. In addition, macrophage density was significantly higher at the surface (first 50 μm) of culprit plaques in comparison

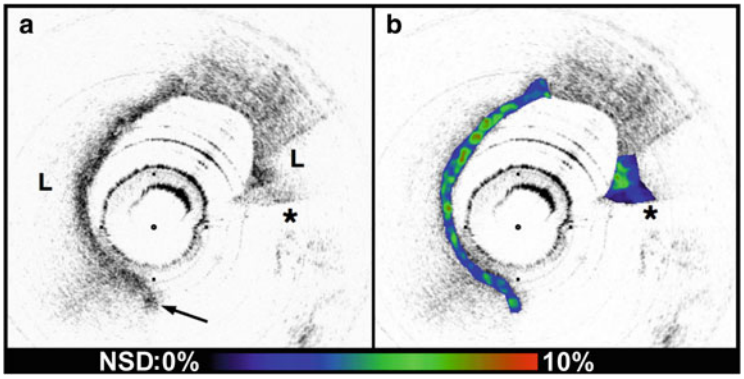

Fig. 69.7 (**a**) Conventional OCT image of a ruptured TCFA obtained from a patient with AMI (obtained in vivo). (**b**) In this image, macrophage density data (*NSD*) from the fibrous cap is displayed using a color look up table. *L* lipid pool, *arrow* intimal disruption, *guidewire artifact. Tick marks, 500 μm

to remote lesions, indicating that superficial macrophages confer a higher risk for developing an acute thrombus [79]. This finding represents a new understanding of the role of macrophages in the pathogenesis of acute coronary disease and may provide an additional parameter to assess individual plaque risk.

We also found evidence in support of the multifocal hypothesis. Macrophage densities at remote sites were correlated with measurements at culprit sites within the same patient ($r = 0.66$; $p = 0.01$) [79]. Fibrous plaques, which are not considered to be high-risk lesions, had a higher macrophage content in patients with acute disease, compared with stable patients ($p = 0.025$) [79]. Taken together, these results suggest that both focal and generalized macrophage distributions play important roles governing the severity of CAD (Table 69.2).

Neointimal hyperplasia and neoatherosclerosis. After these initial demonstrations, OCT has been widely applied for investigating many aspects of coronary artery disease in clinical trials, including evaluation of coronary artery plaque, stent placement, stent strut coverage by neointimal hyperplasia, and stent neoatherosclerosis [80–82]. In general, these studies have shown that IVOCT is capable of detecting plaque rupture, fibrous cap erosion, and intraluminal thrombus, all of which are considered to be vulnerable features of coronary artery disease [80]. Regarding stent-related lesions, OCT could clearly visualize thin neointima and uncovered struts after drug-eluting stent (DES) implantation [81, 82]. IVOCT has also been used to provide information regarding the prognosis of coronary artery disease. One observational IVOCT trial demonstrated that TCFA and neovascularization are independent predictors of luminal progression [83]. Although this result seems to support that the TCFA has the potential to precipitate plaque progression in vivo, whether or not OCT-derived TCFA leads to ACS still remains an open question. A recent pathological study showed that neoatherosclerosis and

Table 69.2 OCT findings from MGH clinical study ($n = 57$). TCFA indicates thin-cap fibroatheroma (lipid ≥2 quadrants + fibrous cap thickness ≤65 μm)

consequent plaque vulnerability can occur even in previously stented lesions after long incubation period [84]. An in vivo OCT observational study revealed that late-phase BMS (>5 years) showed higher incidence of vulnerable atherosclerotic changes, including lipid-laden intima, intimal disruption, and thrombus, than early-phase BMS (<6 months) [85]. Neoatherosclerosis in the stented lesion is currently thought to be an emerging, yet important mechanism of very late stent failure, including thrombosis and restenosis [86, 87].

Limitations of TD-OCT technology for intravascular use. With IVOCT, blood interposed in between the catheter and the arterial wall attenuates the OCT light and signal to the point where only a few hundred microns can be seen through without total degradation of the OCT image quality. Saline purging adequately removes blood from the field, but at the slow frame rates (4–8 fps), intracoronary TD-OCT with saline flushing reduces to a single or few frame cross-sectional measurement. As a result, large area screening of vessel pathology over the entire artery is difficult with this methodology. Proximal balloon occlusion of the coronary artery followed by saline perfusion has been used with good effect [88, 89]. Proximal balloon occlusion is undesirable, however, because of its potential to injure the vessel wall and cause temporary myocardial ischemia.

69.6 Optical Frequency-Domain Imaging

A second-generation form of OCT, termed optical frequency-domain imaging (OFDI) or frequency-domain OCT (FD-OCT), has been developed for clinical use.

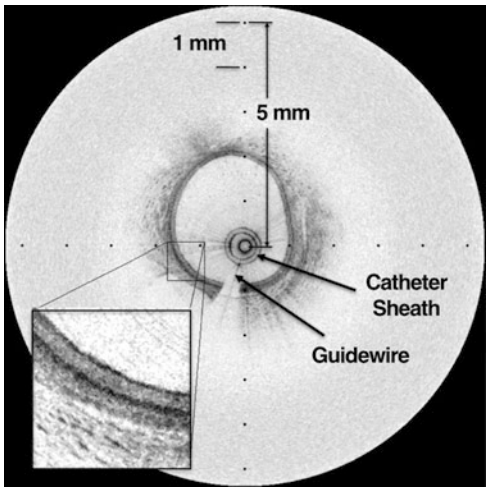

Fig. 69.8 Cross-sectional OFDI image of swine coronary artery, obtained in vivo. Inset shows an expanded view (×3) of coronary wall, demonstrating intima, media, and adventitia. Tick marks, 1 mm

These technologies have now essentially solved intraluminal blood difficulty by imaging and significantly faster than that possible with TD-OCT [90]. The system provides imaging at rates exceeding 100/s and imaging depth ranges greater than 5 mm. In 2006, swine studies were performed to provide a preliminary test of the utility of intracoronary OFDI in vivo and to assess the use of an injector pump (MedRad; Mark IV) for delivering saline through the guide catheter. Multivessel imaging was performed in four swine with several pullbacks per vessel and saline delivery rates ranging from 1 to 4 cm^3/s. In each case, the guide catheter was a seven Fr Cordis BrightTip. For each pullback, the longitudinal length of the vessel over which diagnostic-quality images were obtained was quantified. For all data, the pullback speed was set to 16.2 mm/s corresponding to a longitudinal pitch of 150 μm. A total of 56 pullbacks were performed in four swine: 22 in the RCA, ten in the LAD, and 24 in the circumflex arteries. Clear visualization of the vessels was terminated by either (1) the retraction of the imaging core within the guide catheter (33 of 56 pullbacks), (2) the end of acquisition (11 of 56 pullbacks), or (3) blood reentering the field of view (12 of 56 pullbacks). Including pullbacks in all three arteries, for a saline delivery rate of 4 cm^3/s, the average pullback length was 73 mm (average time = 4.5 s); for 3 cm^3/s, the average length was 52 mm (avg time = 3.2 s); for 2 cm^3/s, the average length was 47 mm (avg time 2.9 s); and for 1 cm^3/s, the average length was 37 mm (2.3 s).

Figure 69.8 shows a cross-sectional image obtained from the OFDI data set, obtained from a swine in vivo. Image quality is at least as good as that obtained from prior-generation OCT systems and the increased ranging depth is evident. Volumetric data from a 4.0-cm coronary artery segment, obtained from a living swine, pre- and post-stenting is shown in Fig. 69.9. Each volumetric dataset was acquired in approximately 3 s [90]. The data was rendered using Osirix 2.2 and viewed

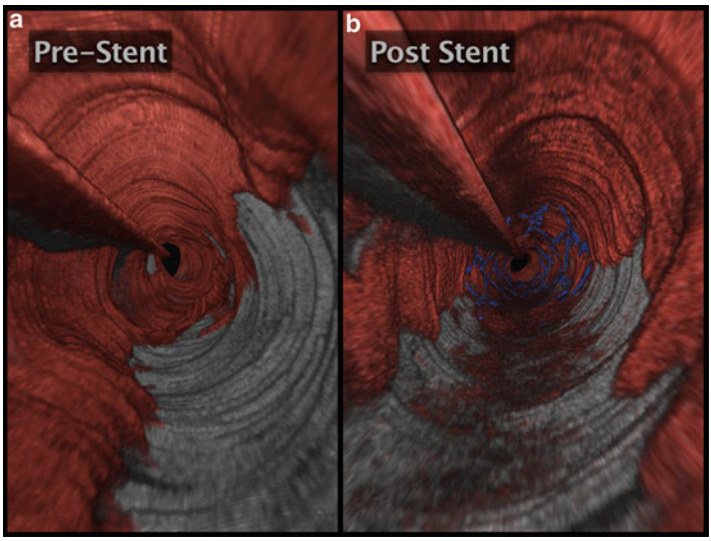

Fig. 69.9 Fly-through views of three-dimensional coronary OFDI images, obtained in vivo following a 3 s nonocclusive saline purge. Intima and media are rendered with a *red color* look up table. Adventitia is *gray* and stent is rendered in *blue*. (**a**) Pre-stent, post balloon angioplasty rendering demonstrates details of the intimal and medial disruption following balloon overinflation. (**b**) Post-stent rendering of same area shows microthrombi adherent to the struts and the exposed adventitia

in flythrough mode. These results demonstrate that blood obscuration during intracoronary imaging can be overcome by a rapid nonocclusive saline purge.

After initial imaging in swine in vivo, a first clinical experience with intracoronary OFDI was reported in 2008, demonstrating first in human application of this technology in three patients undergoing PCI for coronary artery disease [91]. Following catheter placement over the wire, an automated contrast injection was used to inject a nonocclusive lactated Ringers/radiocontrast flush through the guide catheter. Flush rates ranged between 2 and 4 ml/s and automated pullback at 5, 10, and 20 mm/s occurred over a duration that ranged from 3 to 6 s. Figure 69.10 shows three-dimensional images of a right coronary artery (RCA) obtained from a patient who had a history of BMS placement in the proximal RCA 9 s prior and underwent DES placement at another more distal RCA site immediately before OFDI imaging. In this patient, IVOCT enabled the clear visualization of key features within the coronary artery wall, including lipid pool, macrophages, calcifications, and both covered and uncovered stent struts. The high-speed image acquisition of these technologies allowed three-dimensional comprehensive volumetric microscopy to be conducted over very long segments of the coronary artery with less than 20 ml saline flush and rapid helical scanning of the catheter's optics [91]. This methodology of saline/radiocontrast flushing and rapid pullback for image acquisition has now been widely adopted by the IVOCT field.

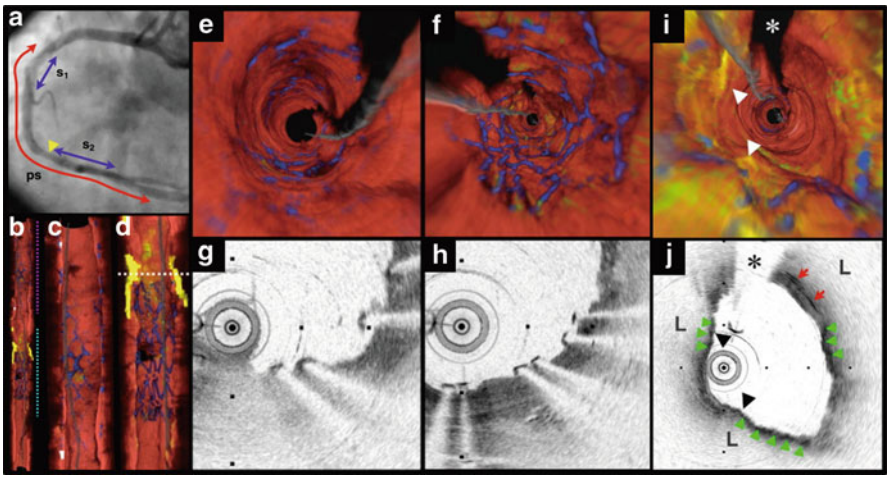

Fig. 69.10 OFDI images of right coronary artery. (**a**) Left anterior oblique angiogram after stent deployment, showing previous (s1, BMS) and current (s2, DES) stents and 7.0-cm optical frequency-domain imaging (OFDI) pullback segment (ps). (**b**) Cutaway view of entire 3-dimensional volume rendered OFDI data set (*top* = proximal; *bottom* = distal). (**c**) Expanded view of segment denoted by magenta *dotted line* in (**b**), showing the BMS. (**d**) Expanded view of segment denoted by cyan *dotted line* in (**b**), showing the DES. *White dotted line* in (**d**) is through a lipid-rich lesion, proximal to the DES. (**e**) Fly-through view (distal-proximal) of the BMS shows covered struts underneath the surface of the artery wall, as well as some struts that appear near the luminal surface. (**f**) Fly-through view (distal-proximal) of the DES demonstrates uncovered struts. (**d** and **h**) OFDI cross-sectional images of the BMS and DES, respectively. The OFDI appearance of the struts is different for the two stents. (**i**) Fly-through view (distal-proximal) demonstrates a circumferential lipid-rich lesion with abundant macrophages, partially covered by the stent. (**j**) An OFDI cross-sectional image obtained at location of *white arrowheads* in (**i**) and *dotted line* in (**d**) shows a circumferential lipid pool (*L*). Thin cap sites (*black arrowheads*) can be identified at multiple locations within the cross-sectional image. Macrophages (*green arrowheads*) and cholesterol crystals (*red arrows*) can also be seen. *Guide wire artifact (Figure and legend taken from Ref [91])

69.7 OFDI in Clinical Use

Now that this imaging technique has been made practical via the advent of second-generation technologies and high-speed imaging, IVOCT is expected to help cardiologists make more informed decisions by providing detailed information about the pathology of the artery wall in vivo, which should improve patient outcome. OCT-guided intervention is currently under investigation to demonstrate such improvement [92–94]. For example, results from a single center registry to evaluate the safety and feasibility of OCT-guided PCI were reported in 2010 [92], concluding that FD-OCT has potential to become a safety guidance tool for PCI. In another retrospective trial, IVOCT disclosed adverse features requiring further intervention in 34.7 % patients and OCT-guided intervention provided a significantly lower risk of cardiac death or myocardial infarction event

compared to angiography-guided intervention [93]. However, because evidence about OCT-guided intervention has not been fully investigated in randomized, controlled trials, further outcome-based studies should be conducted to validate the improvement in patient outcome afforded by IVOCT guidance of interventional procedures.

69.8 Current Challenges and Developments

A recent trend in IVOCT is the combination of IVOCT with other imaging technologies in the same catheter. Recently an integrated OCT ultrasound (US) probing system for intravascular imaging applications has been developed [95]. One of the major limitations of IVOCT is its relatively shallow imaging penetration depth. It is difficult, and sometimes impossible, to evaluate lesions behind lipid and/or macrophages, where OCT signal is highly attenuated at depth [96]. Although the resolution of IVUS is lower than OCT, ultrasound usually can see through the entire coronary artery wall, even for thick atheroma. Therefore, the multimodality application of IVUS and IVOCT could provide both the deep structural information via IVUS as well as the superficial detail of OCT. A miniature integrated OCT and IVUS catheter system already has been tested in in vivo animal model [97]. If commercialized and translated for clinical use, IVOCT-IVUS may become an important tool for coronary artery imaging and interventions. Another multimodality approach is a catheter-based combination of IVOCT and near-infrared fluorescence (NIRF) imaging, a technique that has now been demonstrated in rabbits in vivo [98]. This multimodality technology simultaneously provides images of colocalized molecular and microstructural information. This NIRF-IVOCT device may prove to be a powerful investigational imaging modality and may also have practical clinical implications when molecular fluorescence agents are available for human use.

69.9 Conclusion

To date, optical coherence tomography has had a tangible impact on the quest to understand and identify the vulnerable plaque. It is the only method demonstrated to be capable of measuring all of the microscopic features associated with TCFAs. Our knowledge of the morphology of plaques associated with AMI, previously predicated on retrospective autopsy studies, has now been confirmed in living human patients with this technology. Clinical studies suggest that IVOCT will become important in vivo imaging device for investigating coronary artery disease. Specifically IVOCT should provide better understanding of the vascular response to coronary intervention and eventually be used to guide and improve clinical outcomes. The promise of intracoronary OCT is great, yet these potential benefits must be demonstrated in well-designed, large-scale clinical trials. While there is still much to be done, we anticipate that the unique capabilities of OCT as an

intracoronary imaging device will serve the cardiology community well as it advances to understand, identify, and ultimately treat coronary artery disease and vulnerable plaque.

70.1 Introduction

The potential of optical coherence tomography (OCT) for intravascular imaging and assessing the microstructure of atherosclerosis was suggested already by Huang et al. at the very beginning of OCT [1]. For ophthalmology, the eye provides a natural window for OCT to image the retinal microstructure, and OCT has rapidly become the standard imaging modality to diagnose retinal disease and assess disease progression and response to therapy [1, 2]. Intravascular imaging is more invasive by nature and requires imaging through a catheter probe. This has triggered the development of advanced fiber-optic OCT systems with compact, rotating fiber probes, to image the vessel by circumferentially scanning the luminal wall [3, 4]. In 1998, we established the first cardiac OCT research group at the Massachusetts General Hospital to explore the clinical applications of OCT.

DOI 10.1007/978-3-319-06419-2_72

The first imaging of rabbit aorta was reported by Fujimoto et al. [5], followed by the first swine measurements in vivo by Tearney et al. [6], and finally the first assessment of coronary arteries in patients by Jang et al. [7].

Because of its invasiveness, intravascular imaging is exclusively used in the catheterization laboratory on patients undergoing percutaneous coronary intervention (PCI). Further, because the optical properties of blood are disadvantageous for imaging with OCT, a clearing agent has to be administered to the coronary artery to displace the blood and provide a clear view on the vessel wall. The speed advantage provided by the faster Fourier or spectral domain OCT systems has proved indispensible as it enabled the imaging of longer vessel segments with only a small amount of clearing agent.

These developments have allowed intravascular OCT to be rapidly adopted in clinical research and recently also in clinical practice. With its unprecedented spatial resolution, OCT is a powerful tool to visualize plaque characteristics and help to guide and evaluate vascular response to PCI. OCT is becoming one of the standard modalities to evaluate plaque vulnerability by identifying the presence of lipid content, thin fibrous cap, or macrophage accumulation. Further, after stent implantation, OCT can assess strut apposition and coverage, neointimal hyperplasia, and neoatherosclerosis. In order to provide uniform terminology and standards on the cardiovascular use of OCT and interpretation of the images, a consensus document has been published through an international standardization initiative [8]. Recently, new applications for OCT in intravascular imaging are being explored, such as transplant vasculopathy, monitoring of renal sympathetic ablation, or guiding the crossing of chronic total occlusions.

The scope of this chapter is to highlight the steps taken to bring intravascular OCT from bench to bedside over the last 15 years. We will give a general description of atherosclerosis and its pathophysiology and the specific technical implementation of OCT for intravascular imaging through a fiber-optic probe. The motivation is to provide sufficient medical details to provide a basic introduction to the terminology, principles, and challenges of intracoronary imaging.

70.2 Coronary Artery Disease

Acute cardiac events such as myocardial infarction (MI) and sudden cardiac death (SCD) remain the leading causes of death in the Western world. The underlying cause of these events is atherosclerosis, which consists in the continuous buildup of atherosclerotic plaques in the coronary arteries. The coronary arteries are divided into the right and left branches, which supply the myocardium with blood. The main branch on the right side is the right coronary artery (RCA); the left side has the left main trunk, which divides into two branches, the left anterior descending (LAD) and the left circumflex (LCX). The coronary vessel wall is composed of three layers, respectively, from the *lumen*: *intima*, *media*, and *adventitia*. The *intima* is built of a single layer of endothelial cells, which are in direct contact with the circulating blood. Its subendothelial layer composed of extracellular matrix contains loosely scattered smooth muscle cells. The *intima* is separated from the *media* by the inner elastic *lamina*. The *media* is made of smooth muscle cells densely

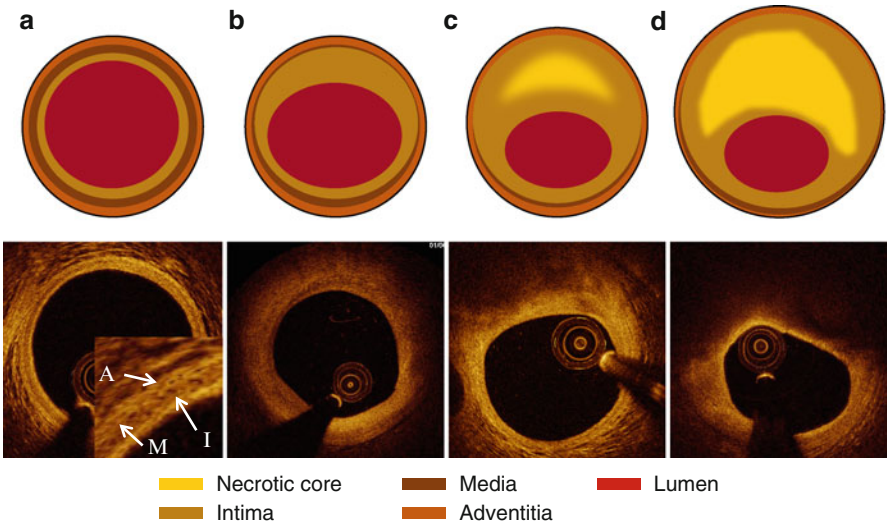

Fig. 70.1 Appearance of atherosclerotic plaque (**a**) The normal coronary artery is structured into intima (*I*), media (*M*), and adventitia (*A*), which are clearly visualized by OCT. (**b**) Pathologic intimal thickening is characterized by the thickening of the intimal layer in the absence of a necrotic core. With the progression of atherosclerosis, the border between intima and media becomes diffuse. (**c**) A fibrous cap atheroma with its typical necrotic core covered by a fibrous cap. **(d)** A thin-cap fibroatheroma is recognized as a rupture-prone plaque and is characterized by a thin fibrous cap overlying a large necrotic core, usually accompanied by inflammation in the fibrous cap and expansive arterial remodeling

packed within a matrix of elastin and collagen. The outer elastic *lamina* separates the *media* from the *adventitia*, which is a layer of connective tissue. Figure 70.1a depicts a schematic representation of the normal vessel and gradual progression of atherosclerosis, together with a corresponding OCT image.

Atherosclerosis is caused by the accumulation of fatty material in the intimal layer of the arteries, accompanied by chronic inflammation. According to the currently accepted view, once monocytes penetrate into the vessel wall, they are taken up by macrophages and become foam cells, which owe their name to their histological appearance. The subsequent signaling cascade eventually results in an advanced lesion with a lipid or necrotic core. The intimal layer that separates the necrotic core from the vessel lumen is usually reinforced by additional collagen and is referred to as the fibrous cap. "Plaque vulnerability"is a term employed to describe the risk of this cap to rupture. Many factors contribute to the mechanical integrity of the fibrous cap, but its thickness is traditionally used as the most obvious indicator of vulnerability, defining lesions with a thin fibrous cap covering a fibroatheroma (TCFA) as most prone to rupture. Figure 70.1b–d displays different presentations of typical atherosclerotic plaques.

A plaque rupture would expose thrombogenic substrates such as von Willebrand factor attracting platelets and fibrin, which results in formation of thrombus. The fate of plaque rupture is determined by three factors: degree of occlusion, duration of occlusion, and the level of preexisting collaterals. When thrombus is

nonocclusive, it may become organized leading to rapid progression of atherosclerosis which is clinically silent. When the lumen is partially occluded, the patient develops unstable angina or myocardial infarction without elevation of the ST segment in the electrocardiogram depending on the duration of occlusion and the level of preexisting collaterals. These events are frequently classified as non-ST elevation acute coronary syndromes (NSTE-ACS). When occlusive thrombus persists for more than 20 min, damage to the myocardium becomes irreversible, manifesting in an ST-elevation (STEMI). Another important underlying mechanism for MI or SCD is plaque erosion, particularly in young women and in smokers. It may be responsible for MI or SCD in up to 30–40 % of cases.

Patients with an acute coronary event are usually treated with antithrombotic medications and frequently by percutaneous coronary intervention (PCI). During PCI, a catheter is introduced through the femoral or radial artery to gain access to the coronary arteries. The goal of the procedure is to reopen the flow-limiting lesion, commonly by balloon angioplasty followed by the placement of stents. Balloon angioplasty is performed by inflating a carefully sized balloon inside the identified artery segment to widen the lumen and reestablish sufficient blood flow. The subsequent placement of a coronary stent, a mesh-like structure placed in the artery with a similar inflating balloon, helps to maintain the gained lumen diameter. The initial use of bare-metal stents (BMS) has frequently caused complications due to neointimal growth within the stent, ultimately resulting in restenosis of the vessel. Drug-eluting stents (DES) reduce this restenosis by releasing drugs that block cell proliferation. Hopes are high that bioabsorbable scaffolds currently under development help to further reduce complications. These scaffolds are eventually fully absorbed and provide a more natural compliant structure that is better accepted by the vessel than the previous metallic stents.

The catheterization laboratory is equipped with a fluoroscope to perform angiography by administration of a radiopaque agent. The contrast agent absorbs the X-Ray irradiation and produces a negative contrast on the angiogram and allows the real-time visualization of the vasculature. Angiography is also the primary diagnostic tool to identify the severity of the lesion in the coronary vasculature. The various catheters have radiopaque markers for visualization on the angiogram. A thin (0.0014″) guide wire is first used to gain access to the coronary arteries. A wide guiding catheter is placed at the ostium. The balloon catheters for angioplasty and stenting, and diagnostic imaging modalities such as OCT or intravascular ultra sound (IVUS), are then advanced over the guide wire into the coronary artery.

70.3 State-of-the-Art Intravascular OCT

Several chapters of this book are dedicated to the thorough discussion of the theory and instrumentation of OCT. In view of this, we only give a short description of the basic principles of OCT but highlight some aspects specific to intracoronary imaging.

Optical coherence tomography (OCT) is a high-resolution imaging modality that generates cross-sectional images of tissue microstructure [1]. It utilizes coherence

gating to select scattering signals from a defined depth within the tissue by interfering the sample light with a known reference signal. The first-generation OCT technology was based on "time domain" detection (TD-OCT). Near-infrared light with a large spectral bandwidth, and corresponding short coherence length, was focused onto the tissue. Combined with the reference signal, only light from the sample depth corresponding to the reference arm length created an interference signal at the detector. Mechanically scanning the reference arm length sequentially retrieved the axial sample reflectivity profile. Dramatic improvements in sensitivity and imaging speed could be achieved by detection in the Fourier domain. This detection scheme is also known as spectral domain OCT, swept source OCT, or optical frequency domain imaging (OFDI). Optical frequency domain imaging operates with a frequency-swept laser source, changing the wavelength as a function of time over the available spectral range [9, 10]. The reference arm is kept at a stationary position, and the interference between the sample and the reference light now creates a signal whose frequency is proportional to the offset of the signal from the reference arm length. Fourier transformation of this recorded fringe signal recovers the axial sample profile with a single wavelength sweep. Because the signal of a single reflecting element in the sample is reconstructed by combining the detected signal of all wavelengths, a large sensitivity advantage results, which was pointed out independently by three different research groups in 2003 [11–13]. This understanding spurred the development of wavelength-swept laser sources and resulted in an impressive decrease in sweep times, resulting in a dramatic improvement of imaging speeds for OCT. This was vital for intracoronary imaging, as the slow imaging time of previous TD-OCT systems required proximal occlusion or continuous flushing with saline or contrast agent (the same agent used for angiography) to displace the blood. The resulting ischemia and limitation on the injected flushing volume restrained the field of view that could be imaged. The increase in imaging speed was essential to achieve imaging of significant segments of the coronary arteries with injection of only a small volume of clearing agent and make intravascular imaging practical.

Figure 70.2 depicts a schematic of a typical intravascular OFDI system. The wavelength-swept laser source operates with repetition rates of 50–200 kHz centered around 1,300 nm and spanning 120–140 nm, resulting in axial resolution in tissue of 6–8 um [14]. The fiber-based interferometer employs fiber circulators for an efficient signal transduction [15] and shifts the reference signal with an acousto-optic modulator to remove depth degeneracy [16]. The sample arm consists of several meters of single-mode fiber, connecting through the rotary junction to the catheter and providing sufficient manipulation range for its operation in a clinical setting. As a result, the polarization state of the light propagating along the fiber is not preserved, and polarization diverse dual-balanced detection is advantageous. The structural OCT signal is obtained by taking the sum of the squared norm of the reconstructed A-line of each channel. This renders the signal independent of the actual polarization state of the light at the detector and makes the tomogram insensitive to catheter motion.

The rotary junction consists of a static collimator on the system side. On the catheter side, a second collimator, which is part of the spinning catheter, couples the

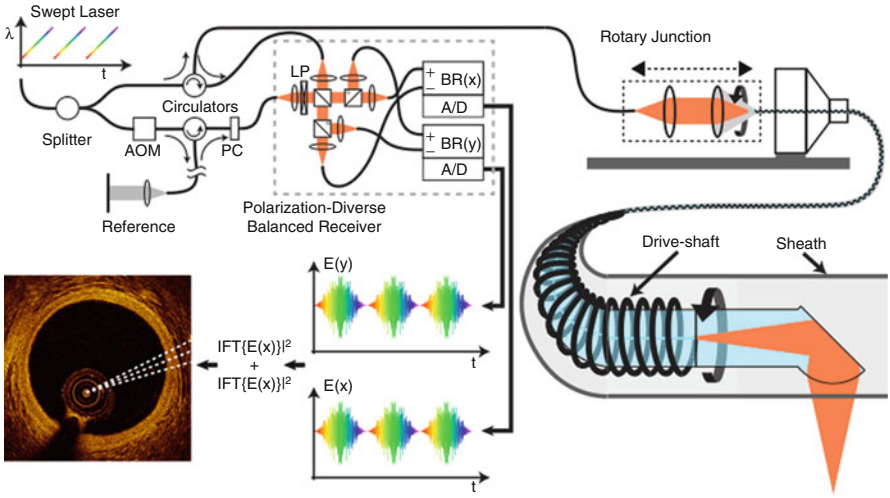

Fig. 70.2 Principle of intravascular optical frequency domain imaging. The fiber-based interferometer is composed of a fiber coupler, splitting the sample and reference light and employs circulators, and acousto-optic modulator (*AOM*) and polarization controller (*PC*) to align the reference light with the linear polarizer (*LP*) at the receiver. *BR* balanced receiver, *A/D* analog to digital conversion. The rotary junction couples light to the rotating fiber probe and can pull back the probe within the static sheath. The tomogram is built up by the sequential depth scans, computed from both polarization channels of the receiver

light into a single-mode fiber, as shown in Fig. 70.2. The fiber-optic probe is at the distal end of this fiber. The probe is composed either of a graded index fiber, followed by a reflecting prism, or an angle-polished ball lens. The ball lens can be fabricated in an integrative way directly at the fiber tip, by heating a carefully sized coreless fiber that was previously spliced to the guiding single-mode fiber, with a fiber-optic splicer, followed by angle polishing. The fiber connecting the collimator and the fiber probe is protected by a coiled driveshaft which transmits the torque for spinning of the catheter and protects the fiber. The assembly of the fiber probe and the driveshaft containing the sample fiber is contained within a sheath, similar to the ones used in IVUS, with a diameter of 2.6 Fr (0.87 mm). The sheath is fabricated from transparent polyethylene at the distal end to enable the sample light to focus through the sheath material onto the vessel wall. The static sheath protects the vasculature from the rotating probe and also enables the pulling back of the fiber probe within this sheath to perform a helical scan pattern on the lumen surface. The focal length of the probe is adjusted to generate a focus of 25–30 μm intensity full width at half maximum at an offset of ∼2 mm from the sheath surface.

The first report of a system similar to this description was given in 2006 by Yun et al. [17]. Current commercial systems operate in a very similar fashion and allow frame rates, containing 512 A-lines per rotation, of up to 158 frames per second, and pullback speeds as high as 40 mm/s.

70.4 Technology Translation and Commercial Development

The success of intravascular OCT as a research tool and its current adoption to clinical practice was largely facilitated by early commercial translation of this technology. The availability of commercial instruments is important for the widespread access of the clinical community to new technology and has helped to gather many of the insights discussed in the following sections.

LightLab Imaging, Inc. introduced the M2 imaging system in Europe already in 2002. This first-generation TD-OCT instrument operated with 15 frames per second (200 axial scans per frame) using saline flushing and occlusion balloons. The later M3 system was introduced in Japan in 2007 and improved imaging speed to 20 frames per second (240 axial scans per frame). The first commercial frequency domain system, the C7XR TM, was introduced in 2010 and achieved imaging speeds of 100 frames per second (500 axial scans per frame). This represented a more than tenfold increase in imaging speed, enabling higher frame rates and an increased axial scan density, improving significantly the image quality. The higher frame rate also resulted in faster pullback speeds, which enabled occlusion-free imaging using injection of contrast to displace the blood. (C8 OPTIS system became available in the United States. We will have a new system within a couple of weeks. Do you want to add it?)

Recently, Terumo Inc. (Tokyo, Japan) has entered the market for intravascular OCT imaging by introducing the Lunawave OFDI system, first in Europe in 2012, and then followed by Japan in 2013. It provides imaging at 158 frames per second and pullback speeds of up to 40 mm/s over a length of 150 mm. These improvements in imaging speeds and system performances facilitate the clinical adoption of intravascular OCT and promise to enable a wide range of clinical studies.

Besides the application for intracoronary imaging, Avinger (Redwood City, CA) has launched an intravascular crossing device with OCT image guidance to corkscrew through chronic total occlusions (CTO) in the peripheral vasculature. From the OCT signal, the clinician can identify the vessel wall and guide the crossing catheter through the lesion without cutting through the vessel wall.

70.5 Ex Vivo Validation Studies

Besides attempting the challenge of in vivo measurements, early studies thoroughly investigated the architectural features that can be visualized with OCT and validated these observations with histology. From a correlation study of 357 atherosclerotic arterial segments from 90 human cadavers, we established the OCT definition of fibrous, fibrocalcific, and lipid-rich plaques (Fig. 70.3). A high sensitivity and specificity (90–98 %) of these criteria and high reproducibility between two observers was demonstrated [18]. Besides plaque characterization, different types of intraluminal thrombus (red thrombus and white thrombus) were reported [19]. Figure 70.4a, b displays an example of a red and a white thrombus.

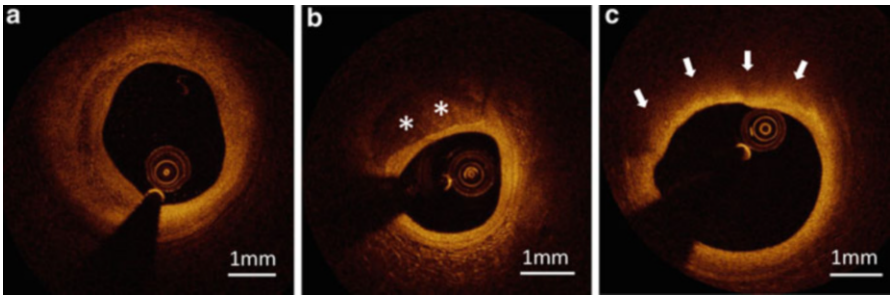

Fig. 70.3 (**a**) Fibrous plaque is characterized by homogeneous, signal-rich regions. (**b**) Fibrocalcific plaques are identified by well-delineated, signal-poor regions with sharp borders (*asterisks*). **(c)** Lipid is characterized by signal-poor regions with diffuse borders (*arrows*)

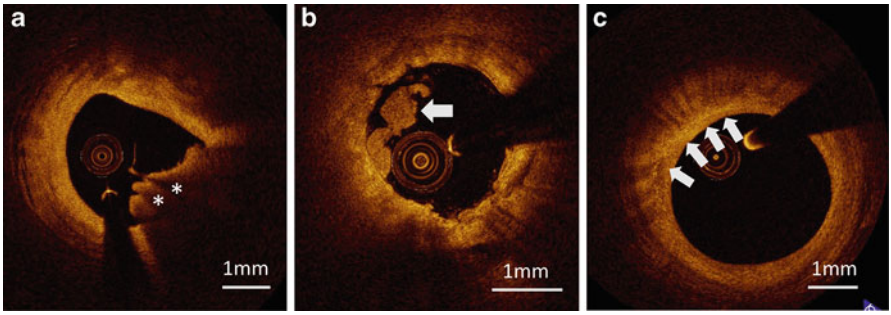

Fig. 70.4 (**a**) Red thrombus is defined as a mass protruding to the lumen, showing high signal intensity on the surface with rapid signal attenuation along depth (*asterisks*). (**b**) White thrombus is a protruding mass showing a lower backscattering signal with low signal attenuation (*arrow*). (**c**) Macrophage accumulation is characterized by increased signal intensity within the plaque, accompanied by heterogeneous backward shadows (*arrows*)

Further, we demonstrated the capability of OCT to visualize macrophage accumulation [20]. The infiltration and accumulation of macrophages is an essential component of vulnerable plaques. The resolution of OCT is insufficient to accurately resolve these macrophages. However, due to their significant uptake of lipids, they approach a size similar to the axial resolution of OCT and comprise a structure with a relatively heterogeneous index of refraction. Normal or fibrous intimal tissue consists of many scattering agents spaced on a sub-resolution scale and results in a homogenously scattering layer with fully developed speckle. The signal from the macrophages, however, is composed of more discrete scattering centers of the macrophage wall and the extracellular matrix but with only little contribution from the intracellular structures. The resulting intensity pattern features a contrast that is sufficiently different from the normal intimal tissue to enable clear identification of regions with macrophages. Frequently, the macrophages also cast a shadow on the underlying tissue. Figure 70.4c shows an

example of macrophage accumulation. Using an adequately normalized standard deviation to quantify macrophage accumulation from the OCT intensity signal within regions of interest in the fibrous cap, a close correlation with the percent area of CD68 positive cells determined by histology was demonstrated [20]. Although the potential of quantifying macrophages by OCT has attracted a significant amount of attention, it is still awaiting more widespread application and should be validated in subsequent studies and with more recent imaging devices.

The superior spatial resolution of OCT is crucial for the measurement of fibrous cap thickness and identification of TCFA. In pathology, TCFA is defined as an advanced atherosclerotic plaque showing a large necrotic core with infiltration of inflammatory cells and a thin overlaying fibrous cap. In an ex vivo histology study, an excellent correlation between OCT and histology-measured fibrous cap thickness ($r = 0.90$) was demonstrated, based on 35 lipid-rich plaques from 102 coronary segments in 38 human cadavers [21]. This makes OCT the only in vivo imaging modality that has been validated with histology to be able to accurately measure fibrous cap thickness.

70.6 First Intravascular Imaging

After promising results from such ex vivo studies and first in vivo animal studies [5, 6], our group at MGH performed the first in-patient study in 2002 [7]. The OCT instrument was a prototype developed at MGH, and the OCT catheter used in this study was constructed using modified 3.2 Fr IVUS catheters (Fig. 70.5). The fiber probe had a miniature gradient index lens and a microprism to focus the optical beam onto the lumen. The bulk system rotary junction allowed a catheter rotation speed of up to 8 rotations per second. The limited image acquisition rate of this TD-OCT system required 8–10 cc of saline to be intermittently flushed through the guiding catheter to displace the blood and clear the view. Both IVUS and intravascular OCT were performed on 17 lesions from ten patients. The comparison demonstrated the potentially superior diagnostic ability of OCT over IVUS for the detection of various plaque components [7].

In a subsequent study, we analyzed the culprit lesions for a broader range of clinical presentations, including patients with STEMI, NSTE-ACS, and stable angina pectoris (SAP) [22]. Out of 69 patients enrolled in the study, sufficient image quality was obtained in 57 patients (20 STEMI, 20 NSTE-ACS, and 17 SAP). TCFA, defined as a plaque with less than 65 μm of fibrous cap thickness and more than 90° of lipid, was more frequently observed in STEMI and NSTE-ACS patients as compared to SAP patients (72 %, 50 %, and 20 %, respectively, $p = 0.012$). Further, the measured fibrous cap thickness was thinner in STEMI and NSTE-ACS patients than in SAP (47.0 μm, 53.8 μm, and 102.6 μm, respectively, $p = 0.034$). This was the first study that demonstrated significant differences in plaque characteristics in vivo depending on the clinical presentation. Moreover, these first in-man studies confirmed the safety and feasibility of intracoronary OCT.

Whereas TD-OCT has been widely used as a research tool for the study of atherosclerosis, its slow imaging speed either required the use of occlusion

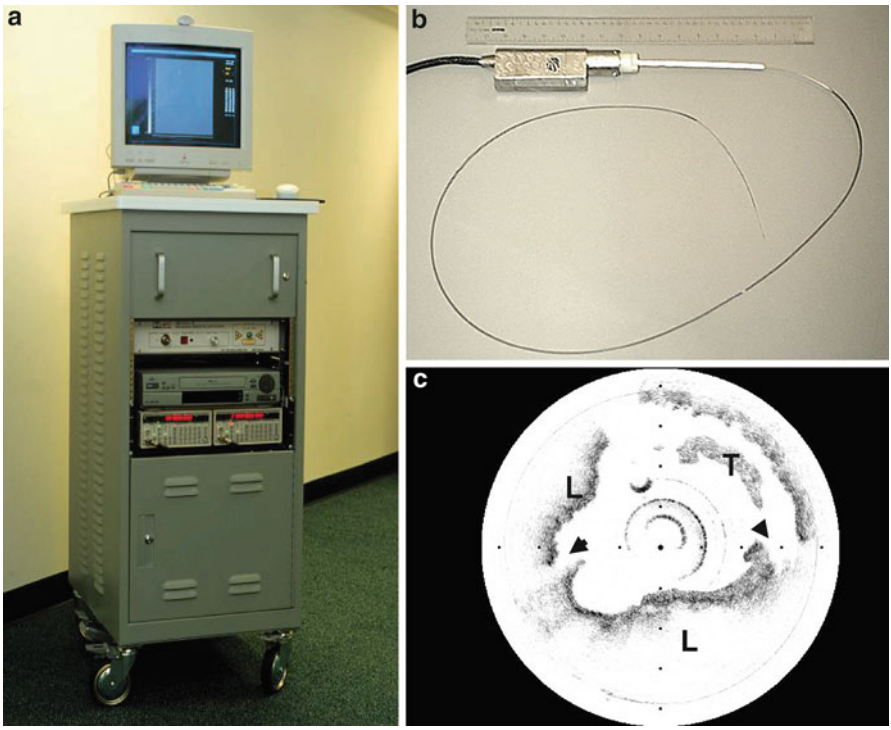

Fig. 70.5 (**a**) Prototype OCT imaging system and (**b**) OCT catheter, used for the first human study. (**c**) OCT visualization of ruptured plaque (*arrowheads*: site of rupture; *T* thrombus, *L* lipid)

balloons, which made the imaging procedure more cumbersome and uncomfortable for the patient, or only permitted the imaging of relatively small sections of the arteries. The advent of the faster spectral domain systems has largely overcome these limitations. We reported the first human in vivo imaging with a spectral domain system in 2008 [23]. The commercial availability of spectral domain systems since 2010 made these advantages also accessible to the wider clinical community and has aided in the ongoing clinical adoption of intravascular OCT.

70.7 Assessment of Coronary Atherosclerosis

In this section we are describing important insights regarding plaque morphology and the pathogenesis of ACS gained by the use of OCT in patients. Previously, clinical imaging modalities such as IVUS, angiography, or computed tomography (CT) lacked sufficient resolution to assess crucial parameters of plaque characteristics. The unprecedented spatial resolution by OCT provided access to decisive plaque features that were correlated extensively with clinical presentation and contributed to clarifying the pathophysiology of coronary atherosclerosis.

Estimating macrophage density by computing the normalized standard deviation in the OCT signal of fibrous and lipid-rich plaques was found to be significantly higher in ACS patients compared to SAP patients [24]. This matches well with the understanding that macrophage accumulation weakens the fibrous cap and hence makes it more prone to rupture [25].

Patients presenting with ACS are known to have lesions with expansive arterial remodeling. The remodeling index is expressed quantitatively by the ratio of the cross-sectional area of the external elastic lamina at the lesion site, with a reference point presenting a more normal vessel appearance. Positive remodeling corresponds to an increased external elastic lamina cross section at the lesion with respect to the reference. Negative remodeling, although less frequent, represents a smaller vessel diameter at the lesion site than at the proximal reference. The remodeling index is a parameter established from IVUS and requires imaging through the entire thickness of the lesion. As such, it is beyond the reach of OCT. In a study where we sequentially imaged with IVUS and OCT [26], we found that TCFA was more frequently observed in lesions with positive remodeling than in those with intermediate or negative remodeling (80 %, 38.5 %, and 5.6 %, respectively, $p < 0.001$). Likewise, the number of lipid quadrants of the lesions correlated positively with the remodeling index [26].

Another factor that is considered to contribute to plaque stability is intra-plaque neovascularization. These blood vessels are shown in OCT images as vesicular structures, or micro-channels, within the plaque. Neovascularization visualized with OCT has been associated with a thin fibrous cap [27], poor responsiveness to statin therapy [28], and plaque progression [29].

The spatial resolution of OCT also enables to study the detailed morphology of fibrous cap disruptions. Tanaka et al. [30] analyzed plaque disruption in 43 patients and compared the features with the exertion level of the patients at the onset of ACS. They found that shoulder-type rupture was more frequent in patients on exertion than those at rest. In another study investigating plaque rupture, STEMI patients were found to suffer more ruptures than patients presenting with NSTE-ACS (70 % vs. 47 %, $p = 0.033$), and cap disruption tended to be directed against the flow in STEMI patients [31].

Cap thickness is generally considered one of the most important predictors of plaque rupture. In a pathological study the minimal fibrous cap thickness was measured in the histological sections of 41 ruptured plaques that had caused sudden cardiac death [32]. The 95th percentile value was found at 65 μm and is the widely accepted threshold for a rupture-prone plaque. Yonetsu et al. [33] performed an assessment of the minimal fibrous cap thickness in an OCT study comparing ruptured with non-ruptured lipid-rich plaques in vivo. A fibrous cap thickness <80 μm was found as the 95th percentile value, which is consistent with expected tissue shrinkage of 10–20 % during histopathologic processing.

Besides the culprit lesion, non-culprit or remote lesions were also studied by OCT. Non-culprit lesions of patients with ACS presented more vulnerable features than remote lesions of patients with SAP: greater lipid amount, thinner fibrous cap thickness, and more neovascularization close to the lumen [34]. These results

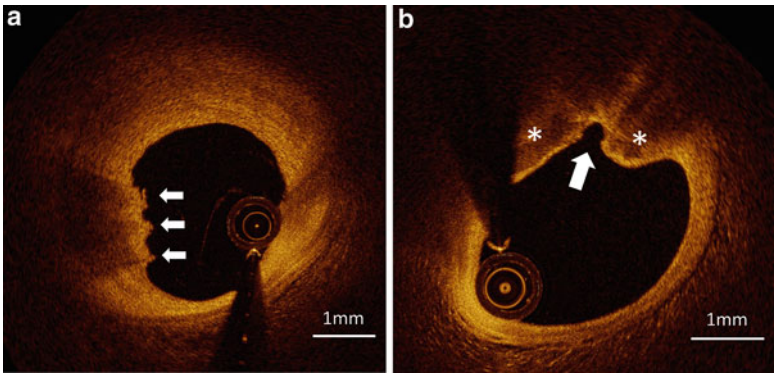

Fig. 70.6 (**a**) Definite erosion is defined as a lesion with thrombus (*arrows*) allowing visualization of the entire underlying intact plaque. (**b**) Calcified nodule is visualized as a lesion with a disrupted fibrous cap (*arrow*) overlying protruding nodular calcium (*asterisks*)

suggested that ACS is a systemic, pan-vascular disease rather than a focal phenomenon of the coronary arteries.

With its ability to precisely assess relevant plaque characteristics, OCT could prove to be ideally suited to evaluate the pathophysiology of ACS [35]. Ruptured plaque is recognized as the primary cause of ACS. However, pathological studies showed that plaque erosion and calcified nodules account for approximately 20 % of sudden cardiac deaths and 25–40 % of acute coronary thrombosis [36–38]. Plaque erosion is defined in pathology as the formation of a thrombus on the surface of a non-ruptured plaque with denudation of the endothelial layer [36]. And a calcified nodule is defined as a calcified plaque with dysfunctional or entirely lacking endothelial layer, resulting in a protruding calcium nodule without fibrous cap [36]. The resolution of OCT is insufficient to detect the presence or absence of the endothelial layer, and the limited image penetration makes it difficult to detect a fibrous plaque behind a massive thrombus [39]. This makes it difficult to apply the pathological definitions directly to OCT. Instead, we proposed an alternative OCT definition of plaque erosion and calcified nodules in collaboration with pathologists. Our definition classifies the culprit lesions of ACS into plaque rupture, calcified nodules, definite erosion, probable erosion, and an unclassified (other) group [40]. Figure 70.6 displays an example of definite erosion and calcified nodules. Using this definition, we analyzed a total of 126 ACS culprit lesions with OCT and found that 55 (44 %) showed plaque rupture, 39 (23 %) OCT-identified erosion (23 definite erosions and 16 probable erosions), and 10 (8 %) OCT-derived calcified nodules. Erosion was found more frequently in younger patients and NSTE-ACS rather than STEMI. This corresponded well with data from pathology, suggesting that the OCT-derived definition of erosion matches well the pathological definition. Taking into account the different mechanisms and patient backgrounds leading to ACS, it would be important to consider different therapeutic strategies for these patients. The current treatment strategy for ACS

patients, and especially STEMI, presumes that coronary thrombosis occurs as an effect of plaque rupture. However, cases caused by erosion or calcified nodules could be treated with antithrombotic agents instead of stenting, because these lesions theoretically have less occlusive plaque underneath the thrombus and thus could be dissolved with antithrombotic therapy.

70.8 Complications with and Response to Stent Implantation

For the assessment of atherosclerosis, OCT has been used primarily as a research tool to improve the understanding of the pathophysiology of ACS. However, OCT offers the possibility to assess a large spectrum of lesion features directly in the catheterization laboratory and could in the future enable a personalization of the therapy and pharmacologic treatment. Still, a substantial amount of clinical evidence to this end is needed. As a tool for assisting in the placement of stents and identifying complications, however, there may exist a more direct path to clinical utility for intravascular OCT [41]. OCT can help in the selection of the appropriate stent length, diameter, and tapering with a pre-procedural pullback. A repeat pullback can then verify the correct placement of the stent and recognize complications that require further intervention.

A wealth of information has been gathered using OCT as a research tool on the vessel response to stent implantation and possible complications. OCT has proven much more sensitive to mechanical complications caused by stent placement onto the vessel wall than IVUS [42, 43]. Tissue protrusion, which includes prolapsed tissue components and intra-stent thrombus, is detectable by OCT in the majority of implanted stents [42, 44, 45]. Stent edge dissection has been found to vary depending on the plaque type at the stent edge, gender, and clinical presentation [46, 47]. Moreover, the presence of lipid pool at the proximal stent edge has been associated with increased risk of postprocedural myocardial infarction [48]. Incomplete apposition is also common immediately after stenting, with an incidence varying from 10 % to 60 % according to underlying plaque characteristics [42, 45]. The stent struts are optically opaque, but their apposition to the vessel wall can be indirectly assessed by taking into account metal and polymer thickness relative to the lumen [49]. Figure 70.7a shows an example of a malapposed stent. Initial studies using repeated OCT examinations reported that most edge dissections and intramural protrusions were resolved at 6–8 months follow-up [43, 50]. Resolution of incomplete stent apposition was found to be dependent on the distance between the strut and lumen [50].

Restenosis within the stent due to excessive neointimal growth was largely resolved with the advent of DES. The initial enthusiasm was tempered with the low but persistent occurrence of late stent thrombosis (LST). OCT was used in a number of studies to examine the coverage and apposition of stents at various time points after implantation to study the vascular response to stent implantation [51–54]. Guagliumi et al. revealed a correlation between the presence of uncovered struts and malapposition with the occurrence of LST [55]. Ideally, the stent

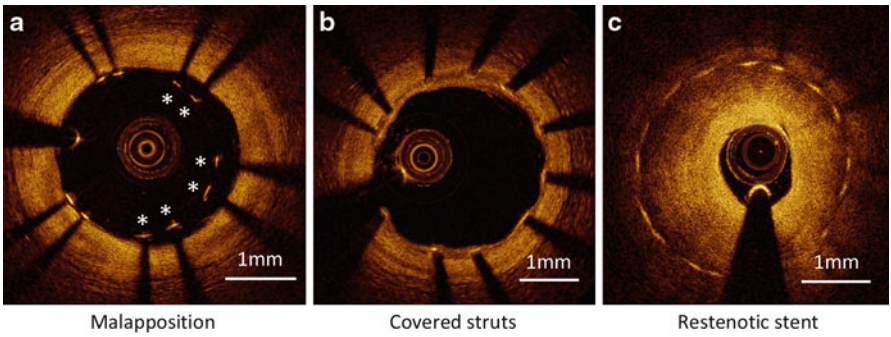

Fig. 70.7 (**a**) Malapposed stent struts are not attached to the lumen wall. (**b**) A covered strut is present if the endothelial layer is visible over the reflection of stent strut. (**c**) In stents with restenosis, various patterns of thick neointimal tissue are visible inside the stent

should be integrated by the host vessel into the intima to obtain a vessel with a re-endothelialized lumen, as visualized in the example in Fig. 70.7b. Whereas a moderate neointimal coverage is desirable, excessive neointimal regrowth would lead to restenosis. Although drastically reduced with the use of DES, this phenomenon still occurs in a small number of patients. OCT has been utilized to evaluate the tissue characteristics of such neointimal hyperplasia and develop a classification into homogenous, heterogeneous, and layered architecture according to the visualization with OCT [56]. Figure 70.7c depicts a stent with significant neointimal regrowth reducing significantly the available lumen cross section.

Atherosclerosis within the neointimal tissue inside the stent presents an alternative potential mechanism for LST. This development of lipid pools and vulnerable atherosclerotic lesions within the stent was termed neoatherosclerosis. It has been investigated by OCT [57] and pathology [58]. Neoatherosclerosis was also observed in DES, especially in patients who presented with ACS caused by in-stent restenosis [59]. We investigated 138 stents with >100 μm neointimal coverage, categorized into early (<9 months), intermediate (9–48 months), and delayed phases (>48 months), to compare the incidence of neoatherosclerosis between BMS and DES. Neoatherosclerosis was more frequent in DES compared to BMS in both the early and intermediate phases, whereas no difference was observed in the delayed phase [60].

Implantation of metallic stents, including BMS and DES, has been the primary mode of PCI for more than two decades. Despite the many remaining challenges, contemporary PCI has a very low incidence of adverse complications. The advent of absorbable scaffolds might help to further alleviate the problems remaining with the vascular response to the "foreign" materials. Such bioabsorbable scaffolds are currently being developed and investigated in clinical trials and become available in some parts of the world [61–64]. OCT is the best available in vivo imaging modality to evaluate the vascular responses to stent implantation and stent resorption and should help us improve clinical practice.

70.9 Future Developments and Other Cardiovascular Applications

In addition to the described applications, intracoronary OCT has also been reported to identify spontaneous coronary dissection [65]. This is a rare but challenging clinical situation, and OCT was shown to improve outcome and patient management. Similarly, OCT was used to investigate cardiac allograft vasculopathy [66], which is one of the major causes of graft failure in heart transplant recipients. This condition is difficult to detect because of the lack of symptoms other than sudden cardiac death. OCT might be able to assist an early diagnosis of this allograft vasculopathy.

Ongoing developments of OCT technology hold promise for further improvements in imaging contrast that could provide additional insight into plaque morphology. Increased spatial resolution generated tomograms with spectacular detail, resolving cellular and subcellular structures, but is challenging to achieve through an imaging catheter [67]. Polarization-sensitive (PS) OCT is an extension of classical OCT and determines the polarization state of the light scattered from the sample [68]. It enables the measure of birefringence, an optical property that is increased in tissue with fibrillar architecture such as collagen. In an early study we demonstrated the potential of PS-OCT to quantify collagen and smooth muscle cell content in aortic plaques [69]. Collagen is the primary extracellular matrix macromolecule that imparts mechanical stability to a plaque and could provide an essential parameter to assess plaque vulnerability in vivo. Translation of PS-OCT to the catheter setting suitable for intracoronary imaging has proved difficult [70], but recent results for managing these challenges are encouraging [71, 72].

Although OCT provides detailed structural imaging with unprecedented spatial resolution, the limited imaging depth is insufficient to quantify plaque burden (cross-sectional vessel area to the outer elastic lamina) and lacks molecular specificity. Combination of OCT with other imaging modalities to combine the strong points of different techniques is currently explored [73]. Combination of near-infrared fluorescence and OCT in a single multimodal catheter has recently been reported [74].

In addition to imaging the coronary arteries, the instrumentation developed for intracoronary imaging is perfectly suitable to assess a wide range of peripheral vessels. Intravascular OCT imaging of the carotid [75], the radial [76], and the infrainguinal artery [77] have been reported.

For the management of resistant hypertension, transcatheter renal sympathetic ablation has been recently proposed as an efficient way to suppress the increased nerve activity associated with hypertension. OCT has been used to investigate and assess the ablation process and may be able to provide new insights on the acute effects of this therapy [78].

OCT may also improve our understanding and management of pulmonary hypertension [79]. We reported the visualization of intimal thickening in patients with pulmonary artery hypertension using OCT [80]. OCT findings could serve as a surrogate of pathological severity and may help improve patient management of pulmonary hypertension.

OCT also attracted interest to guide the crossing of chronic total occlusions [81]. Avinger Inc. (Redwood, CA) has commercialized an OCT system integrating a CTO crossing device and OCT into a single and obtained FDA clearance in 2012.

70.10 Conclusion

OCT has been used for intracoronary imaging for the past 15 years. It served both as a research tool and increasingly also as a clinical instrument. With its high spatial resolution, OCT has enabled to study the microstructure of atherosclerotic plaques and stent implants in human patients with unprecedented detail. OCT has contributed to our understanding of the in vivo pathophysiology of coronary artery disease and has aided in evaluating outcomes after stent implantation. The utility of OCT as a clinical tool to assist PCI has continuously increased thanks to technological innovation and increased imaging speed. Although some studies demonstrated the usefulness of OCT for the guidance of PCI [41] and the prediction of short-term outcomes after PCI [82–84], there is currently no convincing data demonstrating that the use of OCT would improve clinical outcomes. Given the invasiveness of intravascular OCT, it is difficult to conduct a large-scale, long-term, randomized controlled trial to demonstrate evidence-based clinical efficacy of OCT. To address this challenge, the Massachusetts General Hospital (MGH) OCT Registry was created in 2009. This is a multicenter registry of patients undergoing intracoronary OCT imaging for any clinical presentation. Twenty sites across six countries (United States 5, Japan 4, Korea 5, Australia 3, China 2, and Singapore) participate in this registry, which targets 3,000 cases with clinical follow-up of 5 years. We believe that the data accumulated in this registry may be able to answer many of the unsolved questions including the ultimate utility of OCT in the clinical setting. Whereas the merits of OCT as a powerful research tool are unquestioned, the demonstration of improved patient outcome is the goal of any clinical diagnostic tool. This is also a necessity to obtain a reimbursement code for the routine use of intravascular OCT, which then would trigger its widespread application and make it a commercially viable market.

71.1 Why Intravascular Imaging?

The limitations of angiography provide the main motivation for the development of intravascular imaging technologies. To acquire a coronary angiogram, a bolus of radiopaque contrast medium is injected into the target arterial branch via a guide catheter placed in the aortic ostium of the main trunk of the right or left coronary artery. During the injection, a sequence of fluoroscopic X-ray images is recorded. Each image represents an instantaneous two-dimensional projection ('shadowgram') of the beating heart, in which the opacified lumens of the coronary arteries appear as dark structures in a background of weakly attenuating soft tissue. The narrowing of an artery, referred to as a 'stenosis' or 'lesion', can be detected as a sudden reduction in its diameter.

As illustrated in Fig. 71.1, the dimensions of eccentric lesions are susceptible to distortion in single-projection angiograms. Visualization of an artery from inside its lumen overcomes these projection distortions and improves sensitivity to thrombus and other radiolucent structures. A cross-sectional OCT image, like the image shown in Fig. 71.1b, shows the actual shape of the lumen cross section and enables visualization of structures inside the wall of the artery. Although multi-plane coronary angiography systems and multi-detector computed tomography systems are available that can synthesize more accurate cross-sectional views of arterial lumens from multiple projections, these imaging systems are too complicated and time consuming to use routinely for guidance of PCI in real time.

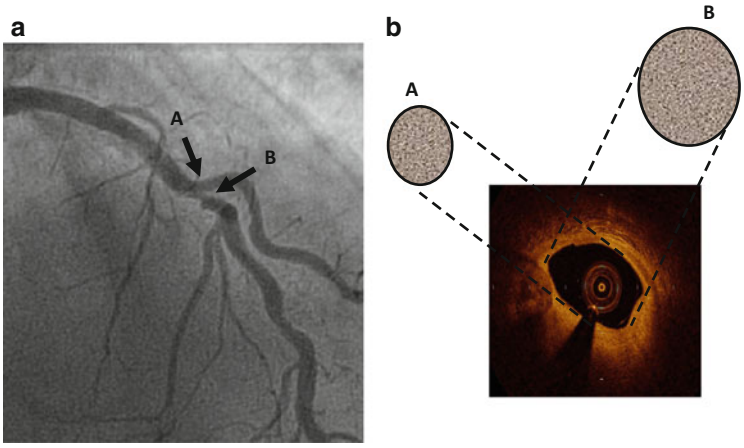

Fig. 71.1 Illustration of the effects of projection angle on angiographic visualization of an eccentric lesion. (**a**) Coronary angiogram of a lesion in the left-anterior descending artery. (**b**) Apparent diameters of the lumen of a cross section of the lesion, viewed from the two projection directions *A* and *B*. The OCT image of the artery shown here shows the actual cross section of the lumen

Length distortion ('foreshortening') is another important limitation of angiography that results from viewing arteries from a single projection angle. Foreshortening occurs when arteries bend sharply in the direction of the X-ray source or detector. To avoid selecting a stent that is too short to cover an entire lesion, the cardiologist must choose the appropriate projection angle for measurement of lesion length. Intravascular OCT and IVUS imaging systems incorporate constant-speed pullback mechanisms to acquire spiral image sequences from which length of lesions can be measured with minimal foreshortening.

Over the years since the first intravascular ultrasound studies were performed in the late 1980s, the importance of assessing the composition and thickness of the plaque prior to treatment of coronary lesions has become increasingly recognized [25]. For the most part, angiography is limited to detecting blood flow alterations caused be narrowing of the vessel lumen. Except for subtle clues that signal the presence of ruptured plaque and thrombus, angiography is blind to structures inside the arterial wall. Therefore, lesions that contain soft, diffusely thickened fibro-fatty tissue or hard calcified tissue are difficult to distinguish by angiography alone. Even arteries with walls distended by thick plaques that are composed of highly thrombotic lipid and cholesterol deposits can remain undetected in routine diagnostic angiograms. Since heavily calcified lesions are often difficult to expand with a balloon and increase the risk of vessel perforations, intravascular imaging technologies that visualize the distribution of superficial calcium in lesions can be valuable for guiding stent implantation. Although composition-specific treatment guidelines have not yet been established, the development of such guidelines continues to be an active area clinical research that has been enabled by advances in intravascular imaging [37].

Better visualization of stented arteries has been another driving force behind the development of intravascular imaging technologies. Stents are not seen clearly enough in standard angiograms to determine reliably whether the struts of an expanded stent contact the wall of the artery over its entire circumference. When a drug-eluting stent is poorly expanded, its effectiveness can be diminished if a portion of the drug elutes into the bloodstream rather than the arterial wall. On the other hand, over-expansion of a stent can cause tears ('dissections') in the arterial wall. Intravascular imaging is used frequently as an adjunct to angiography for optimizing stent expansion and for guiding repair of flow-limiting dissections. In follow-up procedures, intravascular imaging is also employed as a clinical research tool for observing neointimal proliferation, thrombus formation and other biological responses of the arterial wall to different types of stents in different patient populations. These and other applications of OCT are described in greater detail in Sect. 71.4.

71.2 Intravascular OCT Technology

Imaging coronary arteries in the beating heart is a challenging application that places stringent demands on the design and manufacture of intravascular OCT systems. Although these systems have many components in common with other endoscopic OCT systems, a number of application-specific technical features merit closer examination.

71.2.1 Brief History

Since the first in vivo OCT images of coronary arteries were acquired in animal studies in 1999 [9], intravascular OCT has evolved via parallel advances in technology and clinical application (Fig. 71.2). Early work focused on correlating OCT images of different plaque types with histology and IVUS images. An important early milestone was the publication of the results of the first patient study, performed with an OCT system built by researchers at the Massachusetts General Hospital (MGH, Boston, MA, USA) ([17]). At the same time as these patient studies were being carried out, LightLab Imaging, Inc. (Westford, MA, USA) was evaluating the first commercial prototypes of intracoronary OCT systems [10, 13]. Based on time-domain OCT with mechanical path-length scanning mechanisms, this first generation of OCT systems captured cross-sectional images at a line rates of 1,000–2,400 lines/s at frame rates of 5–10 frames/s. Because of their limited image acquisition speeds, early instruments could capture only snapshot images while the blood was cleared from the artery during injection of a bolus of saline or angiographic contrast medium through the guide catheter. During the period 2000–2003, other prototype coronary catheters were developed that incorporated custom flush injection ports for blood clearance and allowed imaging through percutaneous transluminal coronary angioplasty (PTCA) balloons.

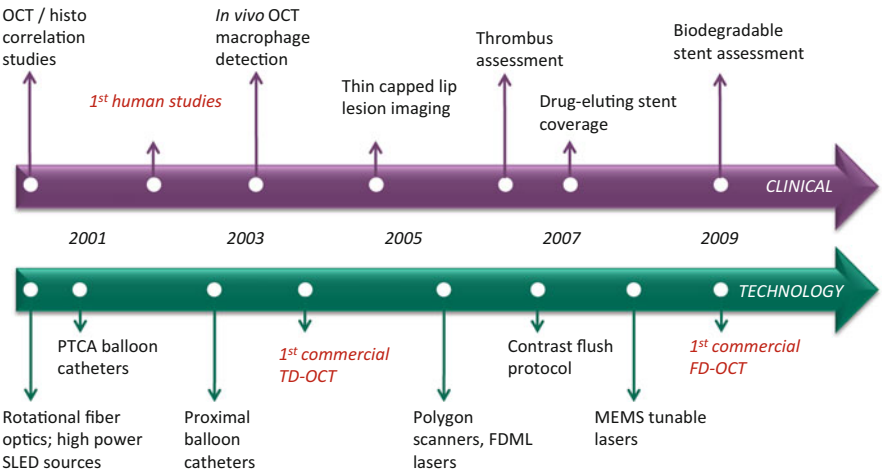

Fig. 71.2 Milestones in intravascular OCT which evolved via parallel advances in technology and clinical application

Nonetheless, the application of coronary OCT was limited to a few clinical research studies until the M2 OCT Imaging System (LightLab Imaging, Inc, Westford, MA; Goodman, Ltd., Nagoya, Japan) was released for sale in Japan and the European Union in 2004. The M2 system utilized an OCT imaging wire (ImageWire^{TM}) inserted through the central lumen of a low-profile occlusion balloon catheter (Helios^{TM}). This catheter delivery system enabled pullback imaging over arterial segments several centimeters long. Approximately 30 s were required to obtain a pullback image over a 3-cm length of artery (Fig. 71.2).

After the commercial release of the LightLab M2 system and its faster (4,800 lines/s; 20 frames/s) successor, the M3 system, the application of OCT expanded rapidly. In particular, the ability of OCT to characterize the various manifestations of atherosclerosis and thrombosis was demonstrated [18, 20, 21]. Results of early OCT studies provided insight into the mechanisms of plaque formation, distribution, and growth, especially in patients suffering from acute coronary syndromes [19, 24]. The high resolution of OCT and its ability to distinguish different plaque types were recognized as potential advantages of OCT in PCI guidance and optimization. OCT also played an important role in understanding the vascular response of arteries to implantation of the first generation of drug-eluting stents, as well as several other novel therapeutic devices introduced in the years between 2002 and 2009 [14, 26].

Although imaging speed had long been seen as the key to achieving more detailed scans of longer vessel segments without inducing ischemia [31], the speed of the M3 OCT system was close to the limit imposed by mechanically scanned time-domain OCT technology. With the development of frequency-domain OCT, a new chapter in intravascular imaging was opened [2]. The first published in vivo study of intracoronary frequency-domain OCT imaging was

performed using a prototype system developed at the Massachusetts General Hospital [49]. Based on a swept-source laser, this system acquired images at 100 frames/s, without loss of resolution, imaging range, or signal-to-noise ratio in comparison with its time-domain predecessors. The first commercially available frequency-domain OCT system (C7XR™, LightLab Imaging/St. Jude Medical, Westford, MA), was introduced in the European Union in 2009 and in the United States in 2010. Based on a swept-source laser, the C7XR™ OCT Imaging System images a 5.4 cm segment of a coronary artery in less than 3 s during the injection of a bolus of angiographic contrast medium. Scheduled to be released in Japan in 2012, but not yet cleared for sale by the US Food and Drug Administration, St. Jude Medical's latest commercial OCT system (ILUMIEN OPTIS™, LightLab Imaging/St. Jude Medical, Westford, MA) captures images of 7.5 cm arterial segments at 180 frames/s. Both of these systems are enabled by the development of rapid contrast injection protocols with software triggering that automatically detects blood clearance. The ILUMIEN OPTIS™ also incorporates wireless pressure-sensing technology for measurement of fractional flow reserve (FFR).

71.2.2 Clinical FD-OCT System

Intravascular FD-OCT systems, such as the C7XR™ and ILUMIEN™, consist of five main modules: an electro-optical engine; a catheter interface device (consisting of a drive motor and optical coupler or 'DOC'); an imaging catheter; a data acquisition and processing system; and a software package for displaying and interacting with the resultant image data. In this section the ILUMIEN is used to illustrate a state-of-the-art clinical system architecture. Although the ILUMIEN system is also capable of performing intravascular pressure measurements using fractional flow reserve (FFR) technology, this section focuses on the OCT sub-system of the ILUMIEN.

A schematic diagram of an electro-optical engine is shown in Fig. 71.3. The engine contains the swept laser, OCT interferometer, and ancillary optics and electronics needed for generating the appropriate data acquisition events. To maximize the delivery of light onto the sample and minimize losses as backscattered light returns from the sample, a dual-circulator design with an asymmetric input split ratio is used for the OCT interferometer. The majority of the light from the swept laser is directed to the OCT interferometer via a fiber-optic splitter S1. A second splitter S2 directs a portion of the light to the sample arm via a first circulator C1 and DOC, and a portion of the light to the reference arm via a second circulator C2 and path-adjustable reference mirror. As the interface between the catheter and the imaging system, the DOC contains a fiber optic rotary coupler mounted to a translation stage. Light from the sample and reference arms is combined in a third splitter S3 and the resulting interference signal is detected by a dual-balanced receiver D1. This interference signal is routed to the analog input of a data acquisition (DAQ) card in a personal computer (PC).

OCT image lines are generated from the digitized interference signal via a fast Fourier transform (FFT). Prior to the FFT operation, the interference signals must be

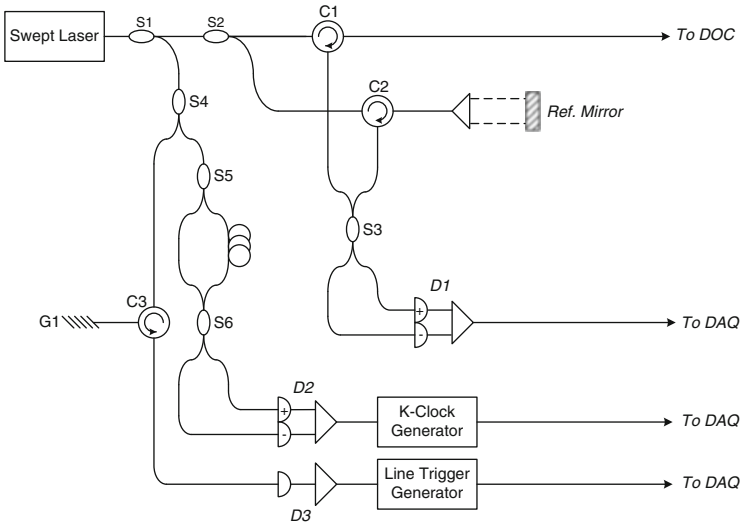

Fig. 71.3 Schematic diagram of the electro-optical engine inside the ILUMIEN OCT imaging system

made linear in optical frequency k with respect to time and must also be parsed into segments corresponding to complete laser sweep cycles. An electronic line trigger, which pulses once per laser sweep, is generated via a fiber Bragg grating G1 attached to a circulator C3 and photodetector D3. The fiber Bragg grating is a narrow-band reflective filter with a reflection peak selected to match the center wavelength of the laser sweep. The resulting line trigger is routed to the trigger input of the DAQ card.

To ensure that the interference signal is sampled at uniformly-spaced optical frequency points, an electronic k-clock is generated from a Mach-Zehnder interferometer (MZI) with a fixed path offset [32]. The MZI consists of two 50/50 optical couplers S5 and S6 with a small relative path offset between the two fibers linking the couplers. The fixed interference pattern generated by the MZI is detected by a dual-balanced receiver D2. Zero crossings of the interference pattern are electronically determined by the k-clock circuit and converted into a digital pulse train, which is subsequently routed to the external clock input of the DAQ card.

A schematic of the distal tip of the DragonFly^{TM} imaging catheter is shown in Fig. 71.4a. The catheter has a 2.7 F (0.9 mm) distal outer diameter and is compatible with 6F (2 mm) guide catheters. A rapid-exchange (Rx) tip design allows delivery of the catheter over conventional 0.014″ intracoronary guidewires. Radiopaque bands demarcate the distal tip of the catheter as well as the approximate position of the imaging lens. A detail of the lens is shown in Fig. 71.4b. The lens is constructed from three segments of optical fiber with tightly controlled lengths are fusion-spliced to one another. A first coreless fiber section acts as a beam expander, allowing the light to fully fill the aperture of a multimode fiber section. The multimode fiber focuses the beam into a second angle-polished coreless section. The fiber-air interface acts as a total internal reflector, directing the beam out the side of the catheter.

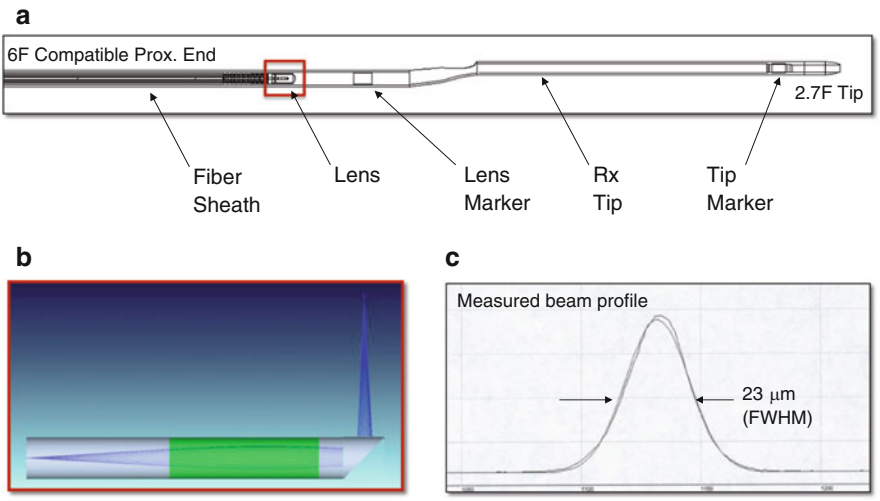

Fig. 71.4 (**a**) Schematic diagram of the distal section of the Dragonfly imaging catheter. (**b**) Detailed schematic of the fused fiber lens. (**c**) Beam profile of a typical fiber lens

Figure 71.4c shows the lateral intensity profile of the beam at the focal plane. A focal spot of 23 um FWHM is obtained at a working distance of approximately 1–2 mm. The catheter is designed to rotate at 100 Hz and pull back at up to 25 mm/s, allowing a 54 mm vessel segment to be imaged in under 3 s. Highly-scattering red blood cells are temporarily cleared from the vessel during the pullback via an intracoronary injection of a viscous fluid, such as iodinated contrast dye used for fluoroscopy, through the guide catheter.

After the OCT data have been acquired, the ILUMIEN software converts the individual image lines into polar frames and displays the data to the user. Figure 71.5 shows a typical screen shot from the ILUMIEN software. The cross-sectional B-mode image representing one rotational frame is displayed in the center of the screen. The longitudinal L-mode image showing a cut through one plane of the pullback is displayed in the bottom of the screen. The axis of the L-mode cut plane is shown as a yellow and blue bar through the middle of the B-mode image. A variety of measurement tools, including length, area, and percent stenosis, can be accessed using the right-hand toolbar. Quantitative measurement values appear in the left-hand information box. Additional visualization modes, such as a 3D rendering and a longitudinal plot of the mean vessel diameter, can also be accessed using a series of checkboxes on the left-hand side of the screen.

71.3 Plaque Characterization

The detailed natural history of atherosclerosis is still an active area of research. Plaques are typically classified by their composition (fibrous, lipid-rich, calcific,

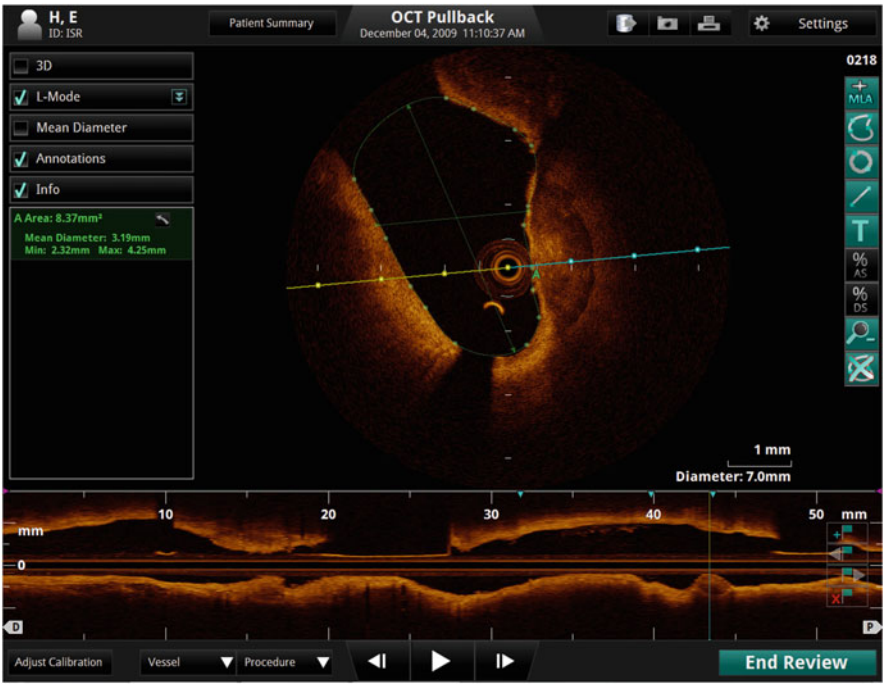

Fig. 71.5 Screen shot of a representative intravascular OCT pullback visualized on the ILUMIEN system software

etc.), as determined by histology. According to the guidelines published by American Heart Association and later revised by Virmani [36, 45], the evolution of plaque can be depicted as a series of complex branching steps, staged roughly according to the age and severity of the plaque (Fig. 71.6). Certain plaques reach a stable size and remain asymptomatic; others grow large enough to encroach on the lumen of the vessel and cause chest pain and other symptoms of myocardial ischemia; still others have thrombogenic properties that cause components of the blood to adhere and form clots. Plaques that thrombose and cause the rapid formation of intravascular blood clots are responsible heart attacks that can be fatal if not treated promptly.

Plaque visualization is important for treatment planning. The first experimental OCT studies were performed on post-mortem samples of excised aortas in mid-90s. In these studies, the salient features of fibroatheroma and fibrocalcific plaques seen in OCT images were first described [5]. In 2002, Yabushita et al. published a qualitative image classification scheme based on correlation of OCT images with histology [48]. Fibrous tissue was identified in OCT images as homogeneously signal-rich regions, calcified tissue as heterogeneous signal-poor regions with sharp borders, and lipid tissue as homogeneously signal-poor regions with diffuse borders. Later, by comparing the OCT images to IVUS images, Jang et al. confirmed that the same criteria were applicable to in vivo OCT images [17]. As intracoronary OCT imaging has become more widespread, additional tissue components have

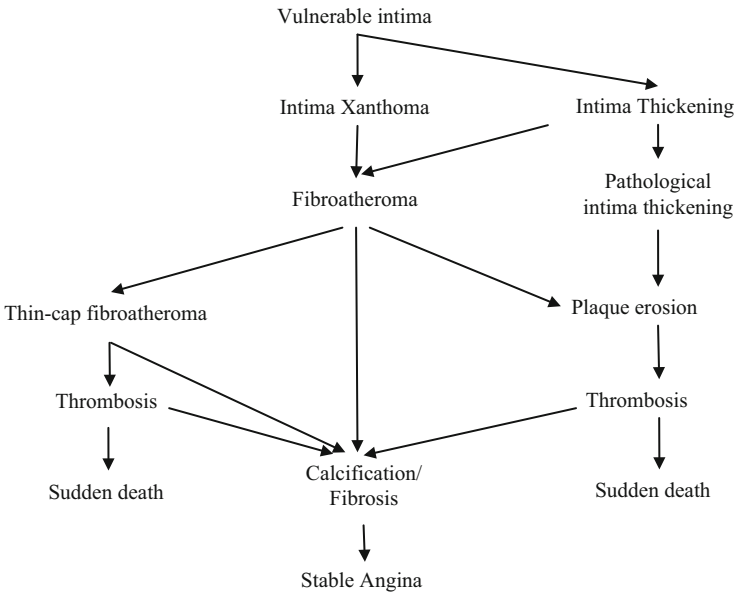

Fig. 71.6 Alternative pathways for progression of atherosclerosis (Adapted from Ref. [45])

been identified. Tearney et al. reported that macrophage foam cells can be detected and quantified with high sensitivity and selectivity by calculating the normalized standard deviation in user-selected regions of interest [40]. Kume et al. reported that red and white thrombus can be distinguished based on their signal-attenuation properties [21], an observation that has been confirmed by subsequent studies [29]. Figure 71.7 shows a few examples of OCT images of different plaque types and their corresponding histology images. The qualitative OCT image features and corresponding bulk optical properties of main coronary artery tissue types are summarized in Table 71.1. An international consensus document (referred to as the Consensus Standard from here on) was recently published to serve as a reference for the interpretation of intravascular OCT images [41].

Although the level of diagnostic accuracy with which coronary lesions and tissue components can be classified based on qualitative criteria alone is quite high, there is still a need for improving tissue-typing accuracy to facilitate real-time decision-making by interventional cardiologists who are less skilled in intravascular image interpretation. In addition, there were some drawbacks to the application of qualitative criteria in the evaluation of certain plaque types, especially lipid-rich plaques. For example, fibrous cap thickness and lipid plaque burden are important variables involved in plaque vulnerability that would benefit from more stringent quantitative measurement criteria. According to the pathology studies, most vulnerable plaques are composed of thin microphage-infiltrated fibrous caps (<65 μm) overlying a large necrotic lipid core [46]. However, although there is a well-delineated border between fibrous cap and the lipid pool in histology, the edge of a diffuse border cannot be

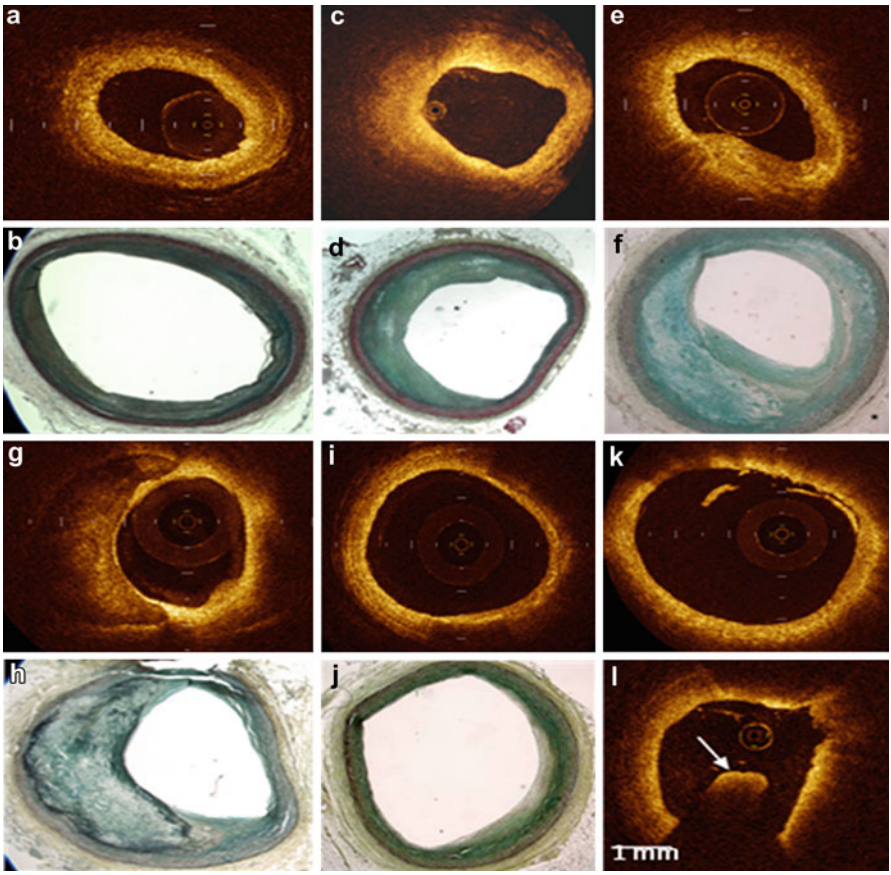

Fig. 71.7 (**a–j**) OCT and corresponding histology for different plaque types: (**a–b**) mostly healthy artery, (**c–d**) fibrotic plaque, (**e–f**) fibroatheroma, (**g–h**) fibrocalcific plaque, (**i–j**) foam cells. (**k**, **l**) OCT image of a *red* and *white* thrombus, respectively

Table 71.1 OCT image features of main coronary artery tissue types

Tissue	Qualitative OCT features
Fibrous tissue	Homogeneous, signal-rich, birefringent
Calcification tissue	Heterogeneous, sharply bordered, signal-poor, low birefringence
Lipid-rich tissue	Signal-rich at the top, high attenuation regions; low birefringence
Red thrombus	Signal-rich at the top, high attenuation region
White thrombus	Signal rich, low attenuation
Macrophage foam cells	Heterogeneous, lumpy, signal rich; very high attenuation, shadowing often evident; low birefringence
Intima	Signal-rich layer near lumen
Media	Signal-poor middle layer
Adventitia	Signal-rich, heterogeneously textured outer layer

defined precisely in OCT by visual inspection. At present, cardiologists must rely on extensive experience and a good physical understanding of OCT images to identify thin-capped fibroatheromas (TCFAs) that are prone to rupture [19, 30].

Both hardware and software approaches have been taken to improve the accuracy and speed of intravascular tissue characterization. Because the collagen fiber bundles and smooth muscle cells tend to be highly organized and anisotropic, these plaque components are more birefringent than lipid and other disorganized plaque components. Consequently, polarization-sensitive OCT has been proposed to increase the image contrast between the fibrous cap and the lipid tissue [11]. Unfortunately, since poorly organized tissue typically is not very birefringent, current methods cannot measure polarization rotation precisely over the short optical paths within the thickness of a thin fibrous cap (<65 μm).

As is the case for any new imaging method, qualitative OCT observations usually have greater utility if they are based on fundamental physical explanations. According to the single-scattering theory, the intensity of OCT signal $I(z)$ of a homogeneous tissue decreases exponentially with depth z, according to

$$I(z) = A(z)\mu_b \exp(-2\mu_t z/n)$$

where $A(z)$ represents the optical capture efficiency of OCT system, μ_b is the backscattering coefficient, μ_t is the total attenuation coefficient, and n is the refractive index. Several investigators have attempted to measure backscattering and attenuation coefficients by imaging post-mortem arteries from the lumen side [23, 43]. Good quantitative correspondence between cross-sectional OCT and histological image data has been difficult to achieve in these studies for several reasons: (1) the imaging depth of OCT in thick plaques is limited; (2) plaques are heterogenous and multi-layered, (3) histological processing distorts or destroys certain tissue components, and (4) precise registration of tissue slices and OCT cross-sections is difficult to maintain in long vessel segments. Xu et al. demonstrated that the optical coefficients could be measured more accurately on transversely sectioned arteries, where each plaque component can be exposed and more easily registered with histology [47]. Figure 71.8 shows the transversely scanned OCT images sectioned at two different depths, the corresponding rotary OCT scanning images, and histology images of representative fibroatheroma and fibrocalcific plaques. While the rotary OCT images were consistent with the previously published qualitative criteria, the transversely scanned OCT images showed that the lipid regions were signal-rich at the top layer, and only became signal-poor at deeper layers as the result of high signal attenuation. The backscattering and attenuation coefficients were determined for calcified tissue ($\mu_b = 4.9 \pm 1.5\ mm^{-1}$, $\mu_t = 5.7 \pm 1.4\ mm^{-1}$), fibrous tissue ($\mu_b = 18.4 \pm 6.4\ mm^{-1}$, $\mu_t = 6.4 \pm 1.2\ mm^{-1}$), and lipid tissue ($\mu_b = 28.1 \pm 8.9\ mm^{-1}$, $\mu_t = 13.7 \pm 4.5\ mm^{-1}$). In later studies similar results were obtained for attenuation coefficients measured from rotary OCT images (healthy vessel wall and intimal thickening: 2–5 mm^{-1}, necrotic core: >10 mm^{-1}, macrophage infiltration: >12 mm^{-1}) [44].

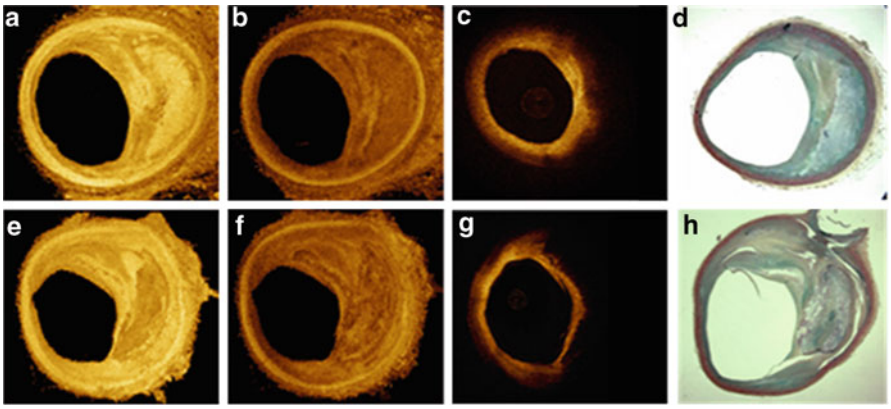

Fig. 71.8 Comparison of transverse OCT images at 50 μm (**a**, **e**) and 500 μm (**b**, **f**) below the surface, with corresponding rotary OCT images (**c**, **g**) and histological sections (**d**, **h**) for a representative fibrolipid plaque (*top row*) and a fibrocalcific plaque (*bottom row*). A consistent intensity mapping was used for **a–c** and **e–g**

Although quantification of intensity-based parameters (attenuation, backscattering, and texture) offers new insights into the interpretation of OCT images, this approach suffers from its own limitations. Similar to birefringence, attenuation is measured by averaging differential measurements over a distance. The minimum distance over which accurate measurements of attenuation can be obtained is typically 10–20 times the axial resolution of the OCT system. Current measurements also require averaging of neighboring scan lines to reduce the effects of speckle noise.

With the advances provided by three-dimensional frequency-domain OCT systems and improved resolution, the potential for rapid and automatic identification of plaque types may be realized in the near future. To achieve this goal, researchers must develop more effective signal acquisition and processing methods that take advantage of both qualitative and quantitative features of different plaque types.

71.4 Clinical Applications

The current clinical applications of intravascular OCT are directly primarily toward improving the safety and efficacy of PCI in patients with complex coronary anatomy or ambiguous lesion morphology. OCT also continues to play an important role in clinical trials of new pharmacological therapies, stents, and other interventional devices. In this section, examples of specific applications are discussed under separate headings.

71.4.1 Stent Planning and Deployment

Since stents are the foremost therapeutic tools of modern interventional cardiology, it is not surprising that guidance and evaluation of coronary stenting

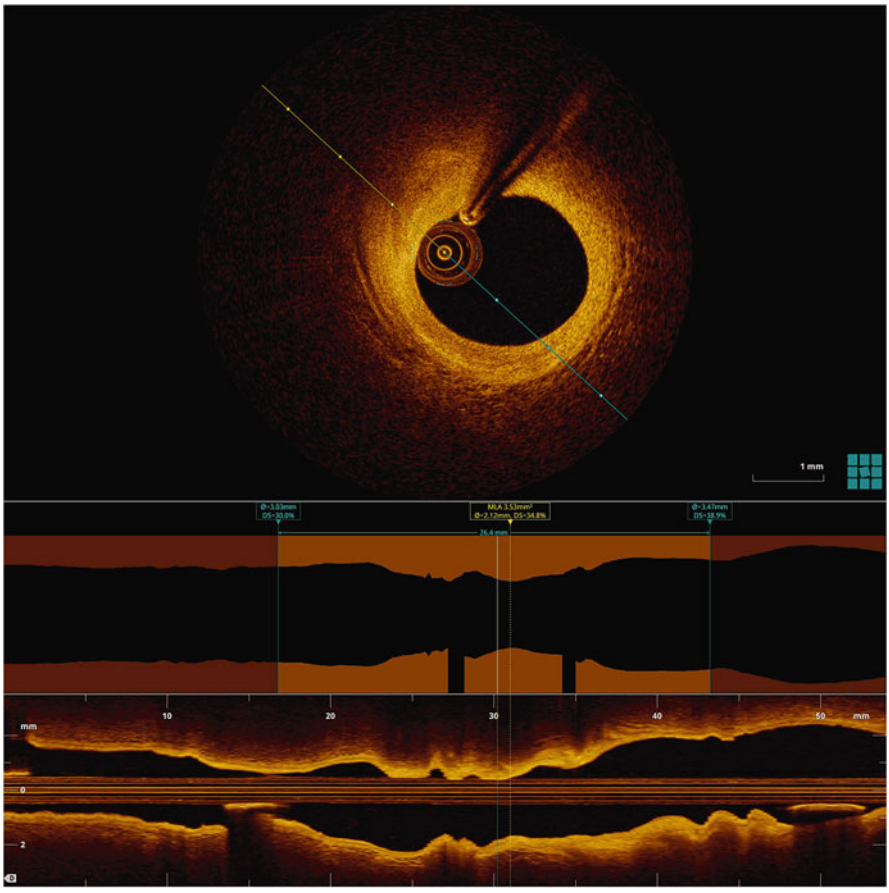

Fig. 71.9 A graphical display panel from the ILUMIEN OPTIS™ OCT imaging system (St. Jude Medical, Westford, MA). The upper panel shows a cross section of an artery at a user-selected frame and the bottom panel shows the longitudinal-mode (L-mode) view of the same artery along a user-selected plane. In the center panel, a computer-generated lumen profile shows the variations in the mean diameter of the artery along its length. The narrowed region of the artery lies within the highlighted region of the lumen profile. The measured values of the areas and diameters of the minimum lumen area and diameter are provided along with measurements at user-selected reference cross sections

procedures have become one of the most important applications of OCT [28, 15]. For optimization of the type and size of a stent before deployment, OCT enables the cardiologist to assess the composition and dimensions of a coronary lesion in three dimensions along its entire length. OCT provides superior contrast and resolution of arterial pathology compared to IVUS [4] and the ability of OCT to measure lumen area with high accuracy facilitates the assessment of lesion severity, especially in arteries with small cross sections [34, 16].

Recently developed software tools for PCI optimization take advantage of the clear delineation of the lumen boundary provided by FD-OCT. Figure 71.9 is an

example of a graphical display panel from an ILUMIEN OPTIS™ intravascular imaging system (St. Jude Medical, Westford, MA) that shows a cross-sectional OCT image of a coronary artery and its corresponding volumetric lumen profile before stenting. Derived from a computer-generated three-dimensional contour of the vessel, the lumen profile shows the mean diameter or area of the vessel lumen along the entire length of the imaged segment of the artery (5.4 cm in this example). In this example the stenosed region of the vessel is highlighted between the blue frame markers. The mean diameter profile facilitates identification of the narrowed vessel cross sections that warrant closer examination. It also provides information about the lengths, diameters, and areas at user-selected cross sections within the stenosed region. This information enables the cardiologist to choose the appropriate stent and to plan strategies for expanding the stent to achieve an optimal vessel profile. Note that, at the time of this writing, the ILUMIEN OPTIS™ system has been cleared for market in Japan only and has not yet been cleared by the US Food and Drug Administration for sale in the United States.

71.4.2 Immediate Post-Stent Assessment

The struts of a properly deployed stent contact the blood vessel along its entire length and expand the narrowed segment in a way that restores its normal tapered contour. Early IVUS studies of bare metal stents found that application of inadequate balloon pressure during stent deployment can lead to incomplete stent expansion and greater rates of target vessel revascularization and restenosis [8]. Incomplete stent apposition of drug-eluting stents has been implicated as one of the factors that contribute to the development of late stent thrombosis, a potentially fatal complication of coronary intervention [6]. Because of its ability to visualize individual stent struts, OCT is a powerful tool for detection and quantification of malapposition [15]. Stent expansion can also be assessed readily with OCT by comparing the stented diameter of the vessel with the diameters of reference segments in which minimal disease is evident.

Figure 71.10 shows examples of OCT images of stented arteries with well-apposed and malapposed struts. Stent measurements with OCT are highly reproducible [12] and separations smaller than 20 μm between the vessel wall and the outer edge of the stent can be discerned [42]. The clinical significance of the mean distance and spatial distribution of malapposition at the time of stent implantation has not yet been defined and is an active area of research.

OCT imaging has been instrumental in the development of optimum deployment techniques for new types of stents, particularly bioabsorbable vascular scaffolds (BVS) and stents designed for treatment of complex bifurcation lesions [1, 27, 33, 39]. Unlike metal stents, polymer BVS are not radiopaque; therefore, their degree of expansion and dissolution over time cannot be seen directly by x-ray fluoroscopy. OCT images the polymer struts clearly and their optical transparency facilitates visualization of the vessel wall through the stent.

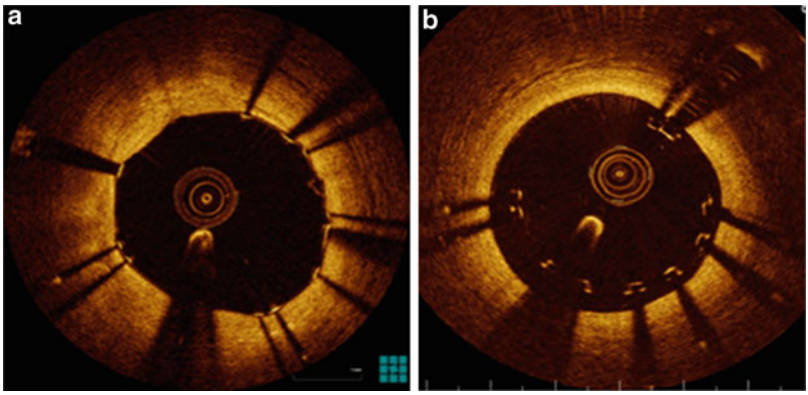

Fig. 71.10 Examples of OCT images of stented coronary arteries. (**a**) Stent with well-apposed struts (**b**) Stent with malapposed struts (5–9 o'clock)

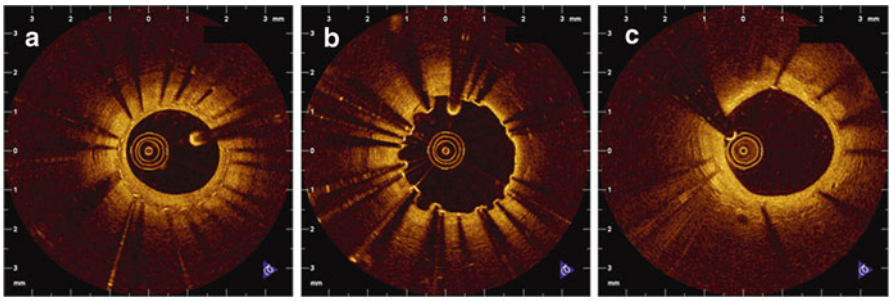

Fig. 71.11 Examples of OCT images of stented coronary arteries at follow-up. Images (**a**, **b**) were acquired from the same stent at two different locations. Image (**c**) was obtained from a stent in a different patient. Note that the variations in the thickness and uniformity of the neointimal growth inside the stent

71.4.3 Follow-Up Stent Assessment

How the artery responds to the implantation of a stent depends not only on the physical construction of the stent and how it is deployed, but also on characteristics of the arterial tissue in which is implanted and the biochemical composition of the circulating blood. The OCT images in Fig. 71.11 give an impression of the wide variety of vascular responses to stent implantation that have been observed during follow-up exams in different patients–and even at different locations in the same artery of an individual patient. Bare metal stents, which were the only type of stent available before the approval of the first drug-eluting stent in Europe in 2002, have relatively high restenosis rates (20–30 %). Because of their lower restenosis rates, drug-eluting stents have become the preferred type of stent for treatment of patients with stable coronary artery disease. The large majority of patients treated with the latest generation of stents do not

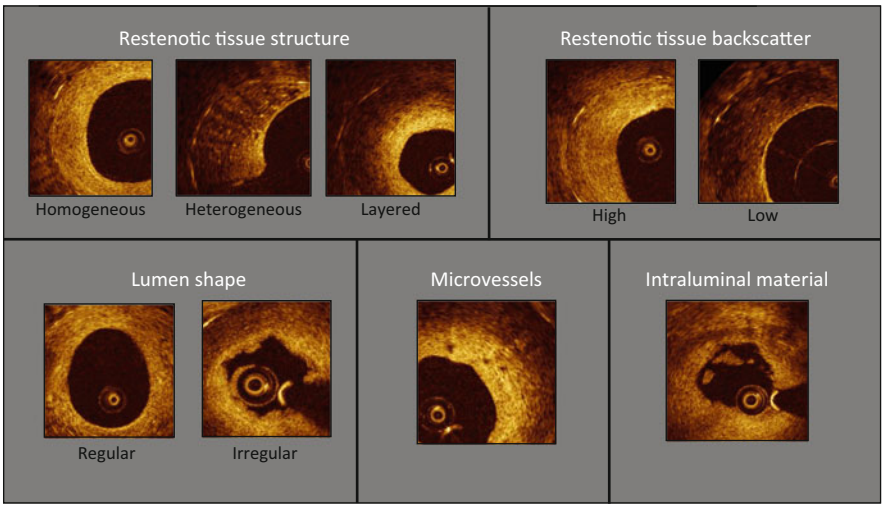

Fig. 71.12 Forms of restenotic tissue coverage on stents, as seen by OCT (Adapted from Ref. [12], with publisher's permission)

experience complications related to the stent that are clinically significant, but a substantial fraction of patients (typically 5–10 %) still undergo revascularization procedures to treat myocardial ischemia or infarction caused by stent restenosis or thrombosis. Although rare (0.5–2 %), stent thrombosis has a particularly high mortality rate (greater than 50 %) [7]. Consequently, identifying the variables that influence stent thrombosis has been a focus of numerous OCT studies.

The tissue that covers drug-eluting stents in asymptomatic patients, which normally remains thin (<200 μm) within 1 year of implantation, is difficult to visualize unambiguously with imaging modalities other than OCT. Stent restenosis is characterized by abnormally thick growth of the tissue inside a stent at angiographic follow-up, for which treatment is warranted if blood flow is compromised. Figure 71.12 illustrates a few of the forms of restenotic tissue coverage that have been documented in OCT studies [12]. Long-term follow-up studies have documented features in OCT images that are associated with late (>12 months) and very late (>36 months) stent thrombosis [36]. Among the goals of these studies is to identify patients at high risk for stent thrombosis so that the cardiologist can select the appropriate type and course of anticoagulant therapy.

71.4.4 Acute Coronary Disease

Intravascular OCT imaging has a number of unique diagnostic capabilities for assessment of culprit lesions in patients suffering from acute coronary syndromes (ACS). The defining symptom of ACS is sudden chest pain, often at rest or with minimal exertion. ACS is usually associated with the intermittent formation of

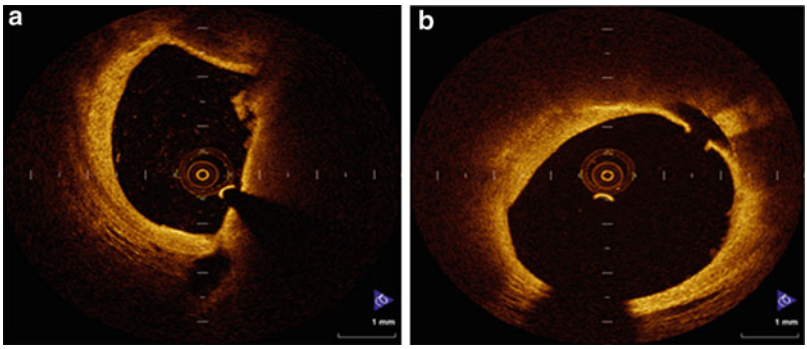

Fig. 71.13 Examples of OCT images of suspected ruptured plaques observed during percutaneous coronary intervention

thrombus that blocks blood flow to the heart muscle. If the blockage is severe, the patient can experience a debilitating – or fatal – myocardial infarction. In the majority of cases, the thrombus-initiating event is the rupture of a vulnerable plaque, which is defined histologically as plaque containing a large lipid core with a thin (<65 um) fibrous cap and an accumulation of macrophages localized within the cap [46]. Numerous studies have been performed to validate OCT's ability to detect thin fibrous caps, macrophages, thrombus, and other features of vulnerable and ruptured plaque [19, 21, 22, 38, 40]. Among the available imaging modalities, OCT may be best modality for detection of these features in vivo [19, 38]. Figure 71.13 show examples of OCT images of suspected ruptured plaques that were acquired from two patients undergoing PCI. Figure 71.13a shows a small mass of thrombus attached to a fissure in a thin fibrous cap (arrow) overlying a highly attenuating eccentric plaque (2–6 o'clock). Figure 71.13b shows a small ruptured plaque in which a void has formed in the intima that exposes the underlying plaque material. The very bright, highly attenuating strips of tissue above the rupture appear to be the remnants of a macrophage-rich cap. Since no in vivo reference standard now exists for direct comparison, the verification of OCT observations relies on correlation with histological findings in autopsy specimens.

The desire to predict which lesions – stented or unstented – will lead to sudden, unexpected cardiac events continues to motivate investigations of the role of OCT in guiding treatment of ACS patients. Demonstration of the diagnostic capabilities of OCT in well-controlled multi-center trials may encourage more effort toward the development of therapies to prevent plaque rupture and thrombosis.

71.5 Future of Intravascular OCT

Although the future of technical progress in any field is difficult to predict, certain trends in medical practice in general and cardiovascular imaging specifically are likely to influence the course of development of intravascular OCT.

1. First, demographics and health care economics will continue to drive demand for lower-cost imaging systems and catheters. Technological improvements that result in higher system performance at correspondingly higher cost that can only be procured by the best-financed research institutions will be eschewed in favor of technologies or manufacturing processes that remove complexity, reduce cost, and thereby extend the reach of OCT into mainstream clinical settings.
2. Second, the increasing workload of interventional cardiologists will require that intravascular imaging systems become increasingly multimodal, automated, and better integrated into the clinical workflow. The demand to combine physiological, morphological, and chemical sensing tools such as FFR, OCT, intravascular ultrasound, and optical spectroscopy on the same hardware platform, or even on the same catheter, is likely to increase. When merged with workhorse angiography X-ray systems, these ancillary technologies can provide the cardiologist with a single set of system controls and displays. To support this integration and ease the burden of interpreting multimodal data, advanced software will need to be developed to provide automated measurements and feature segmentation.
3. Third, an increased focus on evidence-based best clinical practices with links to physician reimbursement will increase the need for large-scale clinical trials to demonstrate the patient outcome benefits of technologies such as OCT. Although this trend is already being observed throughout the medical device industry, OCT and other advanced diagnostic modalities will be particularly challenged given their lack of direct therapeutic effect and increased cost over the default scenario of performing PCI procedures under angiographic guidance only.

72.1 Introduction

Atherosclerosis is one of the major causes of morbidity and mortality in developed countries. The major cause (86 %) of cardiovascular deaths is from heart attacks and the major cause (45 %) of deaths from brain aneurysms is due to less obtrusive plaques known as vulnerable plaques that rupture suddenly and trigger a blood clot or thrombus that blocks blood flow [1–4]. Atherosclerosis is a progressive disease that is characterized by the accumulation of lipids, cholesterol, fibrous constituents, monocytes, and various other inflammatory cells in the arterial wall. These deposits form vascular lesions known as atheromatous plaques, which contain necrotic cores and are separated from the arterial intima by a fibrous cap composed of collagen and smooth muscle cells [4, 5]. Upon plaque maturation, the fibrous caps become thin and increasingly susceptible to tearing, which increases vulnerability to plaque rupture. Rupture of these vulnerable plaques releases inflammatory elements of the necrotic core into the artery, causing thrombosis. This leakage may lead to obstruction of arterial blood flow and angina and/or myocardial infarction, which can be lethal [6]. Atherosclerosis is the single most important contributor to cardiovascular disease-related deaths.

Early detection of plaque lesions is the first and most necessary step towards preventing the lethal consequences of atherosclerosis. Currently, many biomedical imaging techniques aimed at imaging and assessing vulnerable plaques have been reported in literature, including angiography, magnetic resonance imaging (MRI), intravascular ultrasound (IVUS), optical coherence tomography (OCT), intravascular near infrared spectral imaging, intravascular fluorescence imaging, and intravascular photoacoustic tomography (IVPAT) [7–16].

Unfortunately, atherosclerosis exhibits an asymptomatic nature, as vulnerable plaques grow without causing any detrimental side effects until rupturing [4]. Due to this complication, the information provided by a single clinical arterial imaging technique is often insufficient to diagnose vulnerable plaque formation at an early stage. Although the understanding of vulnerable plaques is still at an early stage, previous research based on pathological studies has demonstrated that a plaque's stability is strongly affected by the plaque's morphology and tissue chemical composition [3, 4, 7, 17, 18]. Structurally, the thickness of the fibrous cap is a reliable indicator of plaque vulnerability [7, 19]. Chemically, the intralesion lipid density and the cholesterol content are important parameters that correlate with the vulnerability of the lesion [7, 20, 21]. Therefore, an optimal imaging modality for diagnosis and characterization of plaques should combine high spatial resolution capable of resolving fibrous cap thickness, deep imaging depth capable of assessing plaque burden and vessel remodeling, and molecular sensitivity capable of determining tissue composition and tissue mechanical properties [7].

IVUS and OCT are currently the two most commonly used modalities in the clinic for diagnosing cardiovascular diseases, which allow direct tomographic visualization of cross-sectional images from inside the vessel lumen [7, 22–25]. However, the spatial resolution of IVUS is inadequate to distinguish the microstructure of plaques, especially an accurate thickness of the thin fibrous cap. On the other hand, OCT is a recently developed optical-based technology that can provide real-time, high-resolution, 3-dimensional images with micrometer resolution which is one to two orders better than that of IVUS [24–28]. However, the drawback of OCT is its limited penetration depth, which makes it difficult for OCT to image the complete depth of a large lipid pool. Over the past few years, we have developed an integrated OCT/US imaging probe that enables simultaneous intravascular OCT and intravascular US (IVUS) imaging [29–31]. Integration of intravascular OCT/US is significant because it combines the advantages of the high spatial resolution of OCT and the broad imaging depth of US, which enables quantification of the thickness of both the fibrous cap and plaques. Although each optical probing technique provides access to relevant diagnostic parameters, integration of several modalities is necessary to gather the information required to establish a robust method for early detection of plaque vulnerability.

While the combined IVUS/OCT system can achieve depth penetration and superior resolution, the combined IVUS/OCT system lacks the capability to accurately assess plaque composition and mechanical properties. Several intravascular imaging modalities with molecular sensitivity have been reported.

These include intravascular near infrared spectroscopy (NIRS), Raman, CARS, and fluorescence imaging [9, 17, 21, 32–39]. These imaging modalities use contrast that involve specific molecular electronic and vibrational energy state transitions and therefore can be used to identify tissue composition. Integration of OCT with fluorescence has recently been reported [21, 40].

In addition to structural and chemical composition, tissue mechanical properties provide critical information to assess the vulnerability of plaques [41–45]. The stress in the cap increases with decreasing thickness and increasing macrophage infiltration. High strain locations in the vessel wall indicate the presence of vulnerable plaques [41–44]. We have developed phase-resolved acoustic radiation force optical coherence elastography (PR-ARF-OCE) to image and quantify mechanical properties of vascular tissues [46].

In this chapter, we will review several multimodality intravascular imaging systems including intravascular OCT/US, OCT/fluorescence, and OCT/PR-ARF-OCE.

72.2 Integrated Intravascular OCT/US Imaging

Although the understanding of vulnerable plaques is at an early stage, previous research has demonstrated that thin-cap fibroatheroma (TCFA) accounts for approximately 80 % of all sudden cardiac deaths [18]. TCFAs have been histologically identified with the following pathological features: thin fibrous cap (<65 μm), large lipid pool, and macrophages near or within the fibrous cap [18, 47].

Intravascular ultrasound (IVUS) has been used in the clinic for the diagnosis of atherosclerosis since it permits direct tomographic visualization of cross-sectional images of the vessel wall [22, 48, 49]. IVUS can image more than 5 mm deep inside tissues to cover the full thickness of plaques [50]. However, IVUS resolution is on the order of 50–200 μm, which is not enough to resolve the fibrous cap thickness. OCT is a recently developed optical-based technology that can provide real-time, high-resolution, 3-dimensional images with micrometer resolution which is one to two orders of magnitude better than that of IVUS [24]. OCT images provide details at a higher resolution on the order of 5–20 μm, which can be used to accurately assess the thickness of a plaque fibrous cap. However, OCT has limited imaging depth and cannot quantify the full thickness of the plaque. Therefore, IVUS and OCT provide complementary information that are critical for characterizing TCFA [19, 51]. Recently, Sawada et al. studied the feasibility of the combined use of IVUS and OCT data (images acquired separately) for detecting thin-cap fibroatheroma (TCFA) from 56 patients. The results clearly showed that neither modality alone was sufficient for detecting TCFAs and that the combined use of OCT and IVUS would significantly increase the sensitivity and specificity for detection of TCFAs [19, 52, 53].

Currently, multimodal intracoronary imaging requires introducing separate imaging probes [19]. This practice not only requires a laborious matching procedure for image co-registration and fusion, but it is also time consuming and costly [52, 53].

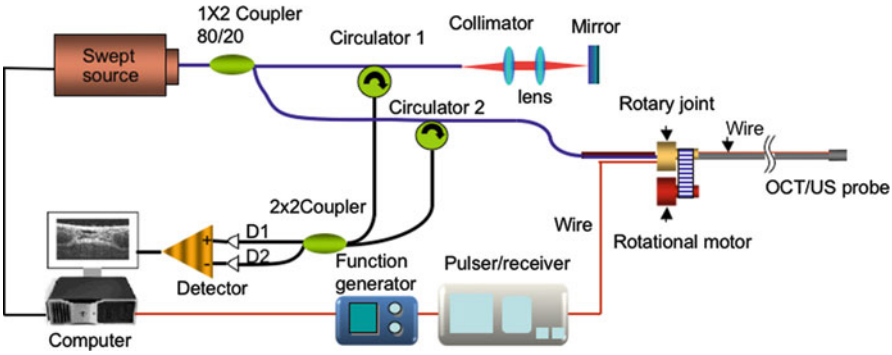

Fig. 72.1 Schematic of US/OCT imaging system with an integrated probe [30]

Therefore, it is significantly advantageous to integrate IVUS/OCT imaging into a single system. Over the past few years, recognizing the complementary nature of OCT and US imaging, we have developed a miniature integrated OCT/US system for intravascular imaging applications [29–31]. Figure 72.1 shows the schematic of the integrated intravascular OCT/US system [29–31]. For the US system, a single sinusoidal wave centered at 50 MHz is generated by a pulser to excite the transducer. The echo signal is received by a broadband receiver. For the OCT system, light from a swept source (1310 nm) is split by an 80/20 1 × 2 coupler. A circulator is used in each arm to redirect backscattered and back-reflected light to the two input ports of a 50/50 2 × 2 coupler for balanced detection. Both US and OCT signals are digitized by a 12-bit data acquisition board. A function generator provides synchronization signals to both the pulser and the data acquisition board [30].

We have designed and developed several different integrated OCT/US probes for intravascular imaging [29–31]. Figure 72.2 shows an integrated probe with a focused ring ultrasound transducer [31]. The homemade 50 MHz focused ring transducer has an effective aperture of 2-mm with a 0.8-mm hole at the center to make room for the OCT probe. The coaxial US and light beams have a common focal length of 4 mm, and both are steered into tissue by a 45° mirror along their pathway. Co-registered rabbit aorta images from the integrated intravascular OCT/US system is shown in Fig. 72.3 [31]. Figure 72.4 shows another design of an integrated OCT/US probe that has an outer diameter of less than 0.7 mm [29]. In vitro OCT and US images of human coronary artery with pathology, as well as in vivo images of vascular tissue in rabbit and porcine animal models, were obtained using this integrated OCT/US probe. Figure 72.5 shows an intravascular OCT/US image from a human coronary artery specimen with a calcified plaque [29]. The plaque can be identified in both OCT and US images. From the OCT image, the plaque cap, as highlighted by the arrow, can be clearly identified due to the high axial resolution and high contrast of OCT. However, the OCT system could not visualize the entire depth features of the vessel wall. On the other

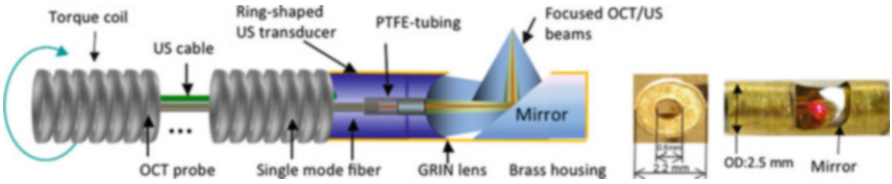

Fig. 72.2 An integrated probe with a focused ring ultrasound transducer [31]

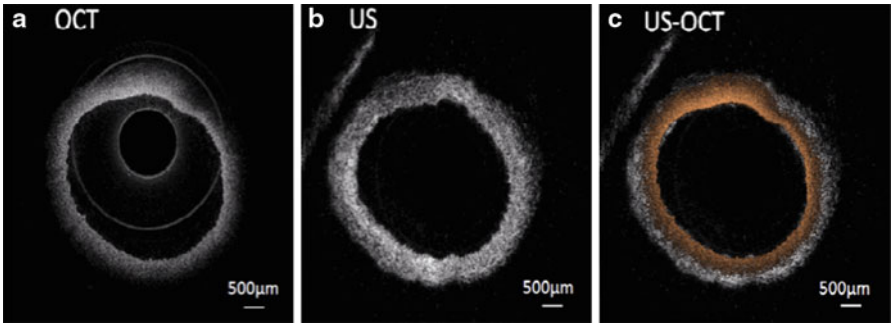

Fig. 72.3 Co-registered rabbit aorta images from an integrated intravascular OCT/US system [31]

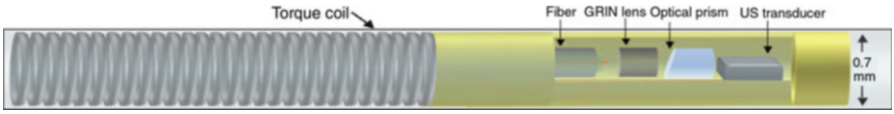

Fig. 72.4 Integrated miniature intravascular OCT-US probe with linear aligned US transducer [29]

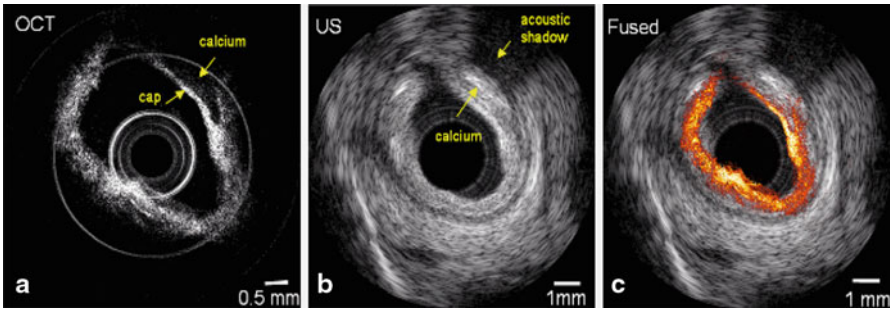

Fig. 72.5 OCT/US images of human coronary artery specimen from an integrated OCT/US system. (**a**) OCT image, (**b**) ultrasound image, (**c**) overlaid OCT/US image [29]

hand, in the US image, the acoustic shadow as pointed by the arrow indicates the location of the plaque and US provides much deeper penetration depth than OCT. However, from the US image, one can hardly distinguish the border between calcium and the surrounding tissue due to inferior resolution of US. We have obtained, to the best of our knowledge, the first in vivo images of vascular tissue in rabbit and porcine animal models using this integrated OCT/US probe [29]. Although further research and development is required to translate this technology to clinical practice, these results clearly demonstrated the potential of the integrated IVUS/OCT system.

72.3 Integrated Intravascular OCT and Fluorescence Imaging

Diagnosis of the latent vulnerability of a plaque lesion relies on both structural and tissue chemical compositions. Although OCT has been used for vulnerable plaque evaluation due to its high resolution, it lacks molecular specificity for identification of tissue composition in plaques. Intravascular fluorescence molecular imaging provides biomolecular information of atherosclerosis inside the blood vessel [21, 54]. It is known that macrophage infiltration affects plaque stability [55]. A fluorescent tagged antibody, such as Annexin V, that targets apoptotic macrophages can provide critical information to determine vulnerability of plaques [56]. In addition, fluorescent lifetime measurement has also been used for the detection of macrophage/foam cell infiltration and discrimination of lipid-rich lesions in atherosclerotic artery [6]. Therefore, an integrated OCT/fluorescence imaging system combining the high spatial resolution of OCT with the molecular sensitivity of fluorescence imaging is capable of resolving both microstructure and biomolecular information at the same time [21, 40].

Integration of intravascular OCT and fluorescence imaging has been reported by a number of groups [21, 40]. The schematic of an integrated swept source OCT-fluorescence system based on a micro motor is shown in Fig. 72.6 [40]. For the OCT system, a swept laser with a center wavelength of 1310 nm, FWHM bandwidth of 100 nm, and output power of 8 mW is used as the light source. The laser beam is split in an 80/20 ratio by a 1 $\times$ 2 coupler, with 80 % of the power directed to the WDM input port then to the combined OCT and fluorescence probe, and 20 % to the reference arm. Two circulators are used in the reference and sample arms, respectively, to redirect backscattered and back-reflected light to the two input ports of a 50/50 2 $\times$ 2 coupler for balanced detection. For the fluorescence imaging system, a continuous-wave (CW) laser diode with a center wavelength of 635 nm and output power of 5 mw is used as the excitation source for fluorescence imaging. A photomultiplier tube (PMT) is used to detect fluorescence emission light. The excitation light and the OCT beam are combined together with a wavelength division multiplexer (WDM coupler 635/1,310). A double-clad fiber (DCF) combiner with one single-mode fiber port, one multimode fiber port, and one DCF port is used to deliver the OCT and fluorescence excitation light beams to the sample and collect the OCT fluorescence signals. The OCT and

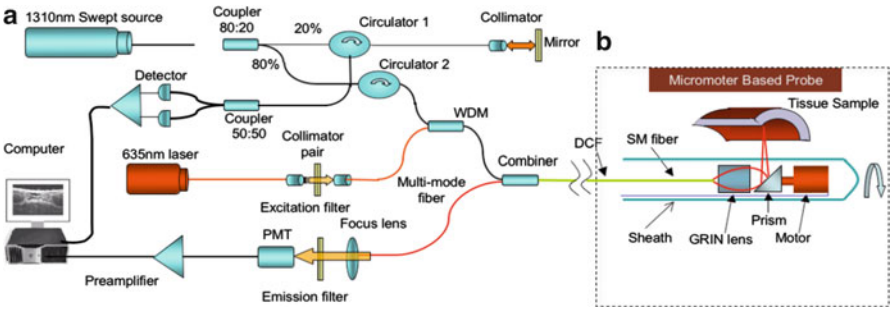

Fig. 72.6 Schematic of the OCT/fluorescence system. *Black line* denotes single-mode fiber (*SMF28*), *red line* denotes multimode fiber, and *blue line* denotes double-clad fiber (*DCF*). (**b**) Intravascular probe based on a DCF combiner. OCT and fluorescence excitation light are transported through the single-mode core of the DCF; the back-reflected fluorescence emission light is collected through the inner cladding of the DCF [40]

fluorescence excitation light are transported through the 8 μm core of the DCF, and the back-reflected fluorescence emission light is collected through the 105 μm inner cladding of the DCF. Subsequently, the backscattered OCT signal from the sample is coupled back through the single-mode fiber port of the combiner and the WDM coupler to the OCT system. Fluorescence emission light backscattered from the sample is coupled back through the multimode fiber port of the combiner and detected by the PMT. The use of a single-mode DCF core to deliver the fluorescence excitation light improves the lateral resolution of the fluorescence image. The schematic diagram of the dual-modality intravascular probe is shown in Fig. 72.6b. A micro motor is used for circumferential scanning of the inner blood vessel wall. This distal scanning design eliminates the disadvantage of unstable vibration and uneven rotational speed in a proximal scanning design and can be applied to more flexible materials without the need of rotational torque transfer [57]. A linear motor outside the endoscope is used to pull back the entire probe to create 3-D helical OCT scanning and to achieve a 2-D superficial fluorescence intensity image. OCT and fluorescence emission signals are digitized by a two-channel, 250 M samples/s 12 bit data acquisition card and transferred to a computer for processing.

We have used integrated OCT/fluorescence to image the aorta of a New Zealand white rabbit. Annexin V conjugated Cy 5.5 was used as the fluorescent contrast to target the plaques and stain the tissue. Annexin V is an antibody that targets apoptotic macrophages which accumulate in the necrotic core, a key characteristic of vulnerable plaques [56]. OCT/fluorescence images from phantom plaques are shown in Fig. 72.7. Figure 72.7a shows the schematic of the two phantom plaques inside the blood vessel wall. Figure 72.7b illustrates the fused fluorescence-OCT image of the model plaques. Figure 72.7c shows the 3-D OCT image and Fig. 72.7d shows that the OCT image of the mimic plaque matches well with the 2-D fluorescence intensity image. This experiment demonstrates that our system is capable of obtaining both OCT and fluorescence intensity signals simultaneously. We can choose different agents to target various molecular factors in vulnerable plaques.

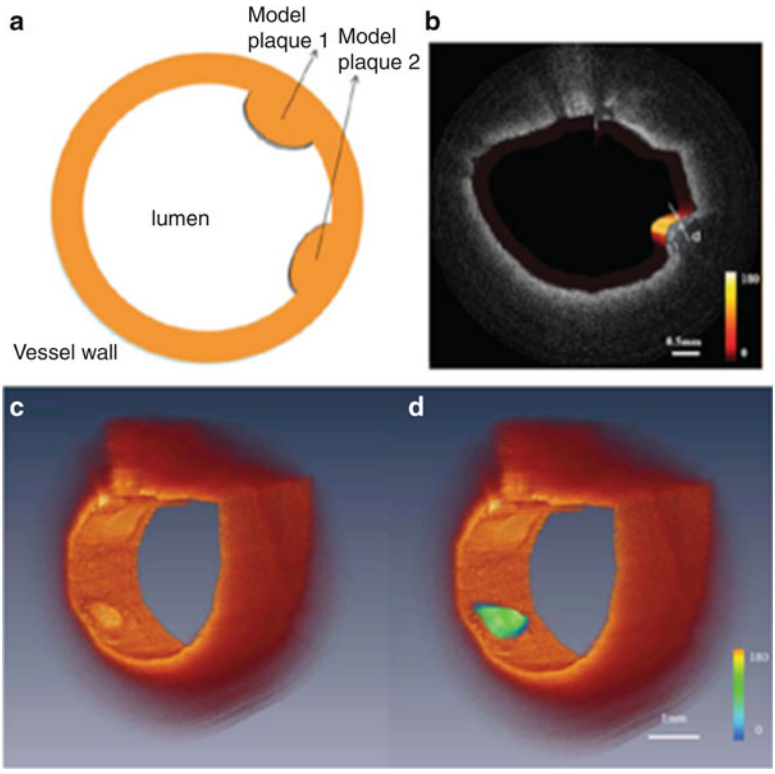

Fig. 72.7 (**a**) Schematic of model plaques, (**b**) fused OCT/fluorescence image of normal rabbit aorta with phantom plaques. The thickness of the plaque cap is around 128 μm as indicated in label (**d**). The color scale in (**b**) shows the relative intensity of the fluorescence signal. (**c**) 3D OCT image and (**d**) combined 3-D OCT/fluorescence image [40]

72.4 Phase-Resolved Acoustic Radiation Force Optical Coherence Elastography (ARF-OCE)

Tissue mechanical properties provide critical information to assess the vulnerability of plaques [41–45]. The stress in the cap increases with decreased thickness and increased macrophage infiltration. High strain locations in the vessel wall indicate the presence of vulnerable plaques [41–44]. Elastography is an imaging technique [58], which measures the local deformation of tissue induced by stress to estimate the strain and stiffness which are directly related to the biomechanical properties. Elastography has become a powerful technique to distinguish healthy and diseased tissues, particularly in cardiovascular research.

Significant progress has been made in developing intravascular ultrasound (IVUS) elastography [42, 59–62]. However, since the dimensions of the structural components of the vulnerable atherosclerotic plaques, such as fibrous caps and

carotid arteries, are on the order of 50–200 μm, the resolution of the IVUS imaging system, which lies in the range of 150–300 μm [63], is not sufficient to resolve the entire structural details of plaques.

Optical coherence elastography (OCE) has a superior micrometer scale resolution and is therefore suitable for imaging subtle mechanical changes in the early stages of disease [64]. Excitation and detection are generally the two prominent characteristics of an OCE system. There are two main categories of OCE with respect to the excitation method: static/quasi-static excitation OCE and dynamic excitation OCE [65, 66]. The former applies compression to the subject statically/quasi-statically and measures the relaxation dynamics, which has limited imaging speed for in vivo imaging. The latter dynamically excites the subject using various waveforms and detects the induced displacement in a gated time window, which enables a much higher imaging speed and makes it possible for in vivo imaging. For the detection system, a phase-resolved OCT system can detect displacements with up to nanometer sensitivity [67]; this is especially important for intravascular imaging as better sensitivity in displacement measurements means reduced force needs to be applied to a vessel wall to quantify tissue mechanical properties. Phase-resolved dynamic OCE has been investigated previously for shear wave propagation detection [68, 69], but this method requires separation of excitation and detection points which limits the speed and spatial resolution. Adaptation of this method is difficult for in vivo real-time 2D and 3D vascular elastography.

We recently developed a phase-resolved ARF-OCE system that uses an acoustic wave to apply pressure to the tissue and uses phase-resolved OCT to evaluate the elastic properties of vascular tissue [46]. The ARF-OCE combines the high-speed excitation of ARF with sub-micrometer/nm detection sensitivity of phase-resolved OCT. This elastography technique allows high-speed and high-resolution point-by-point mapping of local strains in atherosclerotic coronary tissue. Since the mechanical properties of fibrous and fatty plaques are different, PR-ARF-OCE has the potential to differentiate between various plaque components.

Phase-resolved ARF-OCE utilizes chirped acoustic radiation forces to produce excitation along the sample's axial direction and phase-resolved Doppler OCT to measure the vibration of the sample. Figure 72.8 shows imaging of a section of atherosclerotic human coronary artery with phase-resolved ARF-OCE. An OCT intensity image, shown in Fig. 72.8a, provides a general morphological view of the tissue with no obvious evidence of the presence of atherosclerosis. By applying a 500 Hz chirped acoustic radiation force onto the tissue, a strong vibration phase contrast can be clearly imaged using ARF-OCE (Fig. 72.8b). The region indicated by the white arrow in ARF-OCE image is characterized by less vibration and therefore represents less elastic, stiffer tissue such as plaques. The strong vibration representing softer tissue is indicated by yellow arrows. In this ARF-OCE image the stiffer tissue, in this case atherosclerotic plaque, is clearly distinguished from the softer (usually normal) tissue area highlighted by brighter colors. The transition between the plaque and normal region appears blue (indicated by blue arrows) and

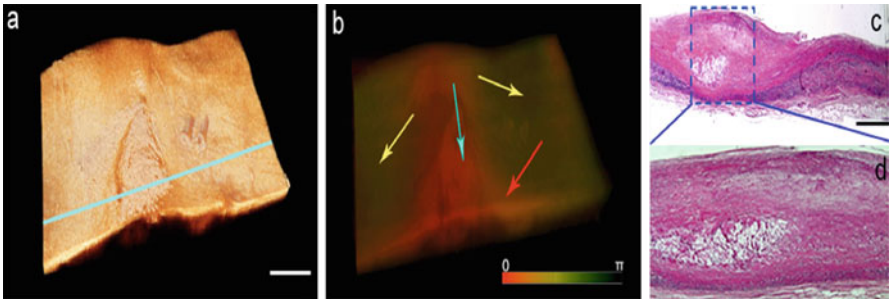

Fig. 72.8 (**a**) OCT structural, (**b**) ARF-OCE phase images of a human cadaver coronary artery under 500-Hz, 350-mV AM modulated excitation; an atherosclerotic lesion was identified as the *red* region corresponding to the *blue box* in (**c**). (**c**) Histological image and (**d**) close-up view of the atherosclerotic lesion. Scale bars: 1 mm [46]

is characterized by intermediate elasticity. This result clearly shows that our ARF-OCE method has great potential to quantitatively characterize mechanical properties of vascular plaques, which may provide critical information towards determining plaque vulnerability.

72.5 Summary

Recent landmark intravascular imaging studies have highlighted the morphological characteristics of high-risk plaques and have generated substantial interest in this area [2, 21, 70–76]. These studies have led to substantial developments in basic science and clinical understanding of plaque stability and progression [77]. They have emphasized the areas requiring further investigation and the urgent need for more intravascular studies [78]. It is particularly important to address functional and compositional aspects of high-risk plaques. Our current knowledge of inflammatory pathways and mechanisms is solely provided by either postmortem specimens of coronary vasculature or circulatory biomarkers. However, the first are not representative of the sequence of events during plaque development, while the later are not representative of the local microenvironment [79]. In vivo imaging, therefore, is of utmost importance despite the fact that it is not currently used for day-to-day clinical practice [80]. It will enable the further understanding of plaque disruption mechanisms and development of strategies for the prevention of acute coronary events, including sudden death.

The clinical need and value for an imaging system that can identify patients with vulnerable plaques at high risk of rupture has been discussed extensively in the literature [7, 81–83] and also highlighted in this year's NIH/NHLBI Working Group Report on Detection of High-risk Atherosclerotic Plaque [80]. Currently there is no imaging system that can reliably determine plaque risk or predict late occlusion after drug-eluting stent placement [7, 82, 84]. Several interventional procedures to treat vulnerable plaques at high risk of rupturing are under clinical

trials [85–87]. The widespread clinical application of these measures requires the improved risk stratification of vulnerable plaques with better predictive power [80, 88]. The ability to detect these vulnerable plaques noninvasively is likely to serve as a powerful stimulus for an increased effort in the development of such therapies [85–87]. This chapter describes integration of intravascular OCT with ultrasound, fluorescence, and elastography. A number of other label-free optical techniques, such as second harmonic generation (SHG) imaging of collagen, two-photon excited fluorescence (TPEF) imaging of elastin, CARS imaging of lipids, and photoacoustic imaging of absorption contrast, have not yet reached the stage of clinical studies but have shown great potential for atherosclerotic research [8–16]. An integrated intravascular imaging modality that can measure structure, chemical composition, and tissue mechanical properties and detect and characterize vulnerable plaques will provide a critically important tool for monitoring the progression of disease and evaluating the efficacy of intervention. The surveillance and early diagnosis of vulnerable lesions will prove to be of the utmost importance in further efforts to tailor therapeutic interventions in patients at risk [89].

Acknowledgments I would like to thank many of our colleagues who have contributed to the intravascular imaging project at UCI Beckman Laser Institute, Department of Medicine Cardiology Division, and Department of Biomedical Engineering, particularly the students and postdoctoral fellows. In addition, I would like to thank my collaborators, Drs. Qifa Zhou and K. Kirk Shung, as well as their students at USC NIH Ultrasonic Transducer Resource Center and Department of Biomedical Engineering, for joint development of miniature ultrasound transducers for the intravascular imaging project. Finally, I also want to acknowledge grants support from the National Institutes of Health (R01EB-10090, R01EY-021529, R01HL-105215, R01HL-125084, and P41EB-015890), Air Force Office of Scientific Research (FA9550-04-0101), and the Beckman Laser Institute Endowment.

Optical coherence tomography • Skin • Dermatology • Skin cancer • Basal cell carcinoma • Non-invasive diagnosis • Optical biopsy

73.1 Introduction

When the first OCT devices were developed in the 1990s, one of the first targets for the researchers was skin [1], simply because it is so easy to access. Even the first primitive devices produced images in which features such as the dermal/epidermal junction (DEJ) and sweat ducts could be easily discerned [2]. However, this early promise imaging skin has taken a long while to bear fruit, while ophthalmic OCT has become mainstream and adopted into the standard of clinical care. Why is this? For OCT to find commercial clinical application in dermatology, it must provide clear benefits to the clinician over and above current clinical practice.

In current practice, the clinician typically diagnoses skin conditions such as cancer in a two-step process: first, "clinical diagnosis" by trained eye, palpitation of the lesion, and use of a handheld liquid-contact magnifier ("dermatoscope") and then if the lesion is considered suspicious, a biopsy is taken: a sample of skin removed, preserved, sliced, and examined by a highly skilled histopathologist. Pathology is a highly developed science, and very detailed information regarding

Disclosures: The author Jon Holmes is an employee of Michelson Diagnostics Ltd., a commercial manufacturer of dermatological OCT instruments for scientific and clinical applications.

the disease can be extracted from study of the tissue structure and cells. The question for the clinician is: why should I use OCT? In ophthalmology, biopsy is not generally a possibility, so OCT provides a clear immediate benefit. For the dermatologist, OCT must provide enough new, accurate information beyond clinical diagnosis, which enables clinically important decisions to be made **without resorting to biopsy**. As it is easy to biopsy skin, and the pathology provides a lot of detail, this is a tough criterion to meet! On the other hand, a biopsy is invasive, needs a topical anesthesia, does not show dynamic changes, leads to scarring, and cannot be repeated at the same site again. It seems that the resolution available with OCT is unlikely to match what is available to the pathologist, but in practice, many clinical decisions do not require this degree of detail. The challenge for the OCT system developer is to provide just enough information for key clinical decisions to be quickly, reliably, and usefully made, in applications where avoiding biopsy is desirable.

Where might avoiding biopsy be useful? A biopsy involves cutting the skin and can therefore leave a scar, which is undesirable to patients for cosmetic reasons, or there may be clinical reasons connected with the patient's age and infirmity, the difficulty of the lesion site, or the patient's clinical history. Some skin conditions are "field" conditions in which a large area of skin is affected with multiple lesions; it is usually impractical to biopsy every one. Biopsy is not ideal for use in conjunction with noninvasive therapies such as topical creams or photodynamic therapy, because the whole point of using these therapies is to avoid cutting the skin and leaving scars. Finally, biopsy is by its nature a "sample" process in which the diagnosis is made of the tissue that is actually removed, and so there is significant risk that the biopsy could actually miss the diseased tissue or even entirely remove it leaving only healthy tissue behind which is nevertheless unnecessarily treated. Biopsy cannot map the edges of a tumor (except by a very time-consuming and laborious procedure called "Mohs micrographic surgery" [3]), so that when the tumor is treated, there is a danger that not all of it is removed, leading to a subsequent recurrence.

In all these cases, OCT imaging has the potential to provide clinical benefits above current practice of clinical diagnosis and biopsy. Efforts to develop suitable technology and validate it are discussed in the sections that follow below. There is a reason to be optimistic, as significant progress has been made in the last 2–3 years on technology and OCT image interpretation, resulting in use of OCT on a routine clinical basis at a few "early adopter" clinics [4].

73.2 Technology

The theory of OCT is described in detail in the first part of this book and to avoid repetition is not repeated here. However, it is instructive to consider certain design decisions that have direct impact on the clinical utility of OCT in dermatology.

73.2.1 Wavelength

Most OCT research in dermatology has been using the 1,300 nm band, which is convenient because of a good compromise between image resolution and depth penetration. At this wavelength, water absorption is restricted, and the scattering coefficient of tissue is such that imaging depths of 1 mm or more can be routinely achieved. In 2007, Carrion and coworkers compared images of excised tissue from animal models at 810 nm, 1,330 nm, and 1,570 nm [4]. They concluded that depth penetration increased with wavelength, but image detail and contrast was greater at shorter wavelengths, and 1,330 nm was a good compromise. In 2010 Drexler and coworkers compared in vivo images of skin, obtained at three wavelengths 800 nm, 1,000 nm, and 1,300 nm [5], and also concluded that 1,300 nm provides greater depth penetration with acceptable image detail and contrast. For most dermatology applications, depth penetration of at least 1 mm is desirable, and most dermatological researchers and OCT equipment manufacturers have preferred 1,300 nm.

73.2.2 Probe Design

There are several factors that are of key consideration in the design of OCT probes for dermatology. These relate both to imaging performance and, crucially, to ease of use in the hands of the dermatologist. Dermatology is a "high-throughput" clinical profession: a typical dermatologist will see literally thousands of patients per year and will meet the patient, examine the lesion, and make a clinical decision (or take a biopsy) in a matter of minutes. Also, nearly all patients come in an outpatient setting and are in the clinic only for a short time. This means that the scan itself must be very quick, otherwise the clinician and the patient will be inconvenienced and will refuse to take the time and trouble. It should also be remembered that patients will also have more than one lesion, and the lesions themselves can be sizeable – several cm diameter is not uncommon – and may require multiple scans to characterize.

Another requirement is that the probe should be easy to handle and lesions can be scanned in any desired location on the patient. Skin cancers are common on sites such as the earlobe, the cleft at the side of the nose, around the ocular depression, and on the eyelid itself. If these sites are not easily scanned, the utility of the scanner will be compromised for the clinician.

This then leads to the following basic requirements for the probe:

- Light, compact, easy to point at awkward locations.
- Scanning process must be quick and straightforward and cover a good portion of the lesion.
- Easy to clean, for hygiene reasons.
- Image resolution quality sufficient to show clinical features of diagnostic interest and with sufficient depth penetration.

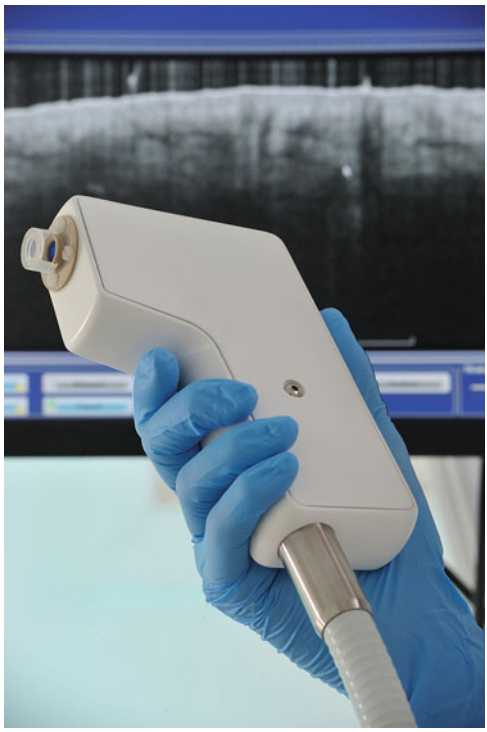

Fig. 73.1 Michelson Diagnostics VivoSight OCT probe

These requirements are to some extent in conflict. For example, high image resolution can be achieved by using a high-NA objective lens, but this reduces the field of view to 1–2 mm, which is often too small in comparison to the lesion diameter for efficient scanning. Also the high-NA lens may also be rather bulky, preventing access to crevices. In addition, the focal depth is reduced, so that it is only possible to scan to 1 mm + by mechanically adjusting the focus during the scan, increasing the time for the scan.

Commercial products have tackled these requirements with varying success. The first OCT product aimed specifically at skin applications was the time-domain OCT scanner "SkinDex" made by ISIS Optronics GmbH [6]. This is no longer available but features in many of the earlier clinical studies. Thorlabs has developed OCT scanners for scientific use based on Fourier-domain OCT [7], and these have been used by many research teams for feasibility studies, although they do not have regulatory clearance for medical use. In 2009 Michelson Diagnostics launched the VivoSight scanner [8] for dermatological applications (Fig. 73.1). This product has CE mark and FDA clearance for medical use and is gaining acceptance for routine clinical use as well as research applications. It has a relatively large field of view (6 mm scan width) and provides real-time images with a resolution of $<$7.5 μm to a depth of over 1 mm, in a compact probe package (Fig. 73.1, 73.2). This enables morphological features to be clearly discerned, but is not sufficient to show cells.

Also available are the Agfa SKINTELL [9], which has CE mark, and LLTech Light-CT [10], which is aimed at scanning excised biopsy samples. They both feature high-NA objective lenses, potentially enabling visualization of more clinical detail, but at the expense of being quite bulky.

The rapid growth of installed commercial scanners will surely lead to growth in the number of research publications supporting a wide variety of clinical applications.

73.2.3 Polarization-Sensitive OCT

An important constituent of skin tissue is collagen, which is highly birefringent. The collagen fibers themselves are very small and difficult to resolve optically unless very high-NA optics is used. Polarization-sensitive OCT has been studied for possible use in managing burns [21], because heat denatures the collagen, and studying dermal response to cosmetic treatments [22]. A difficulty is that the images are quite hard to interpret visually.

73.2.4 Doppler OCT and Speckle Variance OCT

The use of phase-sensitive OCT for detection and quantification of fluid flow, especially blood flow, has been widely studied. The theory of Doppler OCT is discussed in detail elsewhere in this book. For dermatologists, imaging blood flow has many advantages and potential applications. There are many clinical conditions, and treatments for them, in which inflammation occurs resulting in increased blood supply to the affected region. OCT could be of use to monitor the effects of the treatment by showing the reduction in blood flow.

In addition, some conditions result in abnormal blood vessel growth, such as port-wine stains, rosacea, and, perhaps most importantly, tumors. Thus, there is a clear clinical need to image blood vessels. Although these are visible in "ordinary" OCT images as dark streaks and have some diagnostic value, techniques that can highlight areas of flow and even quantify it would have more clinical value.

Doppler OCT is exquisitely sensitive, and some remarkably detailed images of blood vessel structures in skin have been obtained [11]. However, it suffers from two problems. The first of these is that it is almost too sensitive: even the tiniest motion of the subject with respect to the probe produces a huge background signal. The excellent images produced to date have been obtained by "clamping" the probe to the subject, which is not a clinically useful technique. While some work has been done on motion compensation, oversensitivity has so far prevented use of Doppler OCT in practical clinical instruments. A second problem is that by its nature Doppler OCT measures flow parallel to the interrogating beam, which is normally perpendicular to the skin surface, but most blood flow is at 90° to that. In the worst case, only vertically oriented blood vessels can be seen in the image.

More recently, a technique known as speckle variance OCT has been studied [12]. Here, the intensity variance between consecutive images of the same tissue is calculated, the idea being that stationary tissue produces a stationary invariant speckle pattern, whereas blood produces rapid changes. Very impressive images of the "arboreal" blood vessel structures produced by a basal cell carcinoma have recently been produced [13]. However, this approach also suffers from sensitivity to background subject motion, and more work is required. There is also a problem that unlike Doppler OCT, the rate of flow cannot be easily quantified from the speckle variance signal. This may or may not limit its clinical value.

Despite these limitations, it seems inevitable that with further development, blood-flow imaging with OCT will eventually reach the clinic in practical instruments for routine use, and the clinical benefits are potentially huge.

73.2.5 Elastography OCT

Elastographic OCT has also been studied [14, 15]. Here, a mechanical stimulus is applied to the skin and the response in the OCT image observed, for example, by detecting the change or movement in the laser speckle pattern in the image. Researchers claim that it is thereby possible to distinguish regions of the skin that have different Young's modulus, and this may have clinical applications.

73.2.6 Gels and Optical Clearing

Due to differences in the refraction between air and skin, the skin surface reflects at 1,300 nm and so there is typically a large "entrance signal" at the skin/air boundary. This is undesirable, because the bright reflection can wash out surface detail such as the thin stratum corneum, can saturate the detection electronics leading to artifacts, and reduces the "light budget" available for probing deeper into the tissue. There are various approaches to addressing this problem. One approach is to use a contact probe, i.e., the probe has a transparent surface that directly contacts the skin, so that there is no air/skin interface. For this to work well, a fluid such as water or ultrasound gel is typically used to ensure an airtight interface and for refraction index matching, because skin has a similar refraction index of about 1.33 compared to water.

Simply coating the skin with gel also has some benefit in reducing the entrance signal. On the other hand, a gel could modify the skin or confuse the viewer into thinking it is a feature of the skin itself. It remains to be seen whether clinical users feel that use of gel is worth the effort.

Vargas et al. reported that glycerol or other chemicals can have a beneficial effect in improving the depth penetration [16]. This is attributed to hydration of the tissue resulting in index matching. However, the effect takes time to have a useful effect and is unlikely to be adopted in busy dermatology clinics.

73.3 Image Interpretation

Although some features of the skin can be readily discerned such as sweat ducts, dermal/epidermal junction, etc., understanding of the presentation in OCT images of many common clinically important features is still developing and being studied. This is critical in order for the images to be used in the clinic on a routine basis. For example, it must be clearly understood not only how common pathologies such as basal cell carcinoma (BCC) nests present in the images but also similar but benign growths and variations of the most common types such as sclerodermiform BCCs. More generally, the principles behind how and why given tissue types appear as they do must be researched and understood. This is a topic of very active current study.

In general, OCT images reveal tissue morphology, but not details of individual cells (Fig. 73.2). In skin, we observe the following, based on detailed correlation with histology:

Intensity: Some tissue types appear brighter, others darker. Brighter tissue is more strongly scattering. Darker tissue is more weakly scattering and/or absorbing. Collagen-rich scar tissue is often brighter in appearance. In addition, some features like keratosis or calcification can cast shadows on the tissue below them. Blood and lymphatic vessels are usually dark due to the absorption by water.

Layers: Skin is a layered structure and these layers can often be discerned, especially the dermal/epidermal junction. Distortion of layers or damage to or absence of layer junctions can be strongly indicative of disease.

Shapes: Dermatological appendages such as hair follicles and sebaceous glands can be identified by their shape, coupled with intensity. This also applies to diseased tissue. For example, basal cell carcinomas typically present as dark ovoid features with a slightly darker rim, whereas cysts are typically circular with a bright wall. Vessels appear as dark streaks.

Texture: Different tissue types exhibit characteristic textures. Cancerous tissue is usually devoid of texture; healthy tissue is often mottled in appearance. Scar tissue has a swirly appearance.

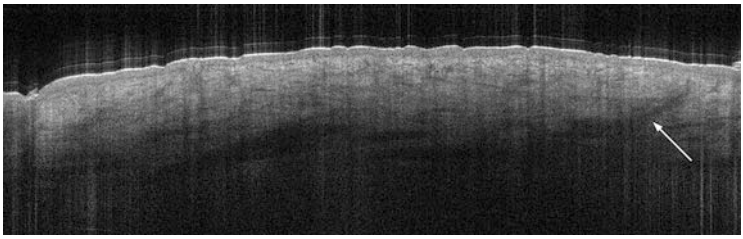

Fig. 73.2 OCT image of healthy skin at the forearm. The first superficial layer is the epidermis. The dermis shows signal poor longish or round structures corresponding to lymphatic and blood vessels. Hair follicles cross the dermis in an oblique way (*arrow*). Image size 6 × 1.9 mm (This and all other images in this chapter were obtained using a VivoSight OCT scanner)

Location: The location of features can also have diagnostic value. Dark streaks suggestive of blood vessels located unusually near the surface and close to an ovoid structure may well indicate a tumor.

These and other indicative features have been documented in an "OCT Manual" published by Michelson Diagnostics with contributions from leading dermatologists and freely available on the Internet [17].

73.4 Applications of OCT in Dermatology

73.4.1 Publications

The availability of practical commercial products with CE and FDA clearance for clinical use is rapidly driving up the publication of research papers in dermatology. Figure 73.3 shows the number of papers referencing "optical coherence tomography" and "skin" indexed by PubMed [18] in a search on 30th December 2013 and categorized by the authors based on choice of publication journal, paper title, and abstract. Papers were categorized as follows:

1. "Technology" papers – the primary subject of the paper is OCT technology itself: engineering, theory, and analysis of the OCT images. These papers are mostly published in technical journals. Only papers that specifically reference skin as the target end user application have been included in the analysis, and papers that merely used skin as a convenient test subject for a new OCT development were excluded.

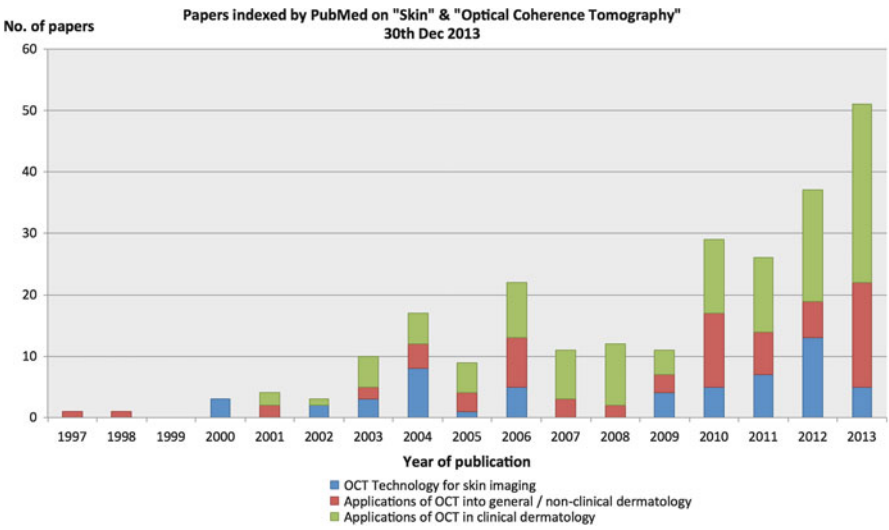

Fig. 73.3 OCT publications in dermatology by year of publication and type

2. General/nonclinical dermatology papers – the primary subject of the paper is the research into skin and skin properties using OCT as a tool. This includes papers studying the structure and properties of normal skin and also nonclinical applications such as cosmetics research and research into drug delivery.
3. Clinical dermatology papers – the primary subject of the paper is research into skin pathology and/or the application of OCT to diagnosis, mapping, or monitoring of treatments of skin pathologies. These papers are all published in clinical journals.

73.4.2 Analysis

In total, 247 papers were indexed since 1997, and the number is continuing to grow at an encouraging rate. This is a larger number than in most other clinical specialties except ophthalmology and cardiovascular (see also ▶ Chap. 84, "OCT Technology Transfer and the OCT Market" by Eric Swanson in this book) and is an indication that OCT is gaining acceptance as a practical and useful imaging modality by dermatologists.

The first papers, published in 1997 and 1998 by Welzel and coworkers, describe the appearance of healthy skin in OCT and show some exemplary images of diseased skin [1, 2]. This was followed by papers in 2000 [19] in which Knuttel and coworkers described the use of OCT to measure skin parameters such as the thickness of the stratum corneum and scattering coefficient of tissue layers. In 2001 enough data had been collected to enable J. Welzel to publish a review paper mentioning potential clinical applications including diagnosis of skin diseases and monitoring of treatment effects [20].

Publications increased gradually in the following years but have increased more sharply since 2010 as dermatologists started applying OCT in more systematic fashion to both clinical and nonclinical applications. These are discussed in more detail below.

73.4.3 Tissue Engineering

Tissue engineering is concerned with the development of artificially grown sections of tissue for use in the repair of damaged human tissue, for example, bone cartilage. In dermatology, one of the main potential applications is repair of wounds, especially diabetic ulcers, which are a huge burden on the world's health resources. OCT has potential use both for noninvasively monitoring the growth of the artificial tissue in the biofactories [21–23] and also, potentially, for monitoring the implanted tissue to assess its viability.

73.4.4 Transdermal Drug Delivery

Pharmaceutical companies are very interested in drug delivery mechanisms as alternatives to hypodermic syringes, for example, patches equipped with hollow microneedles

filled with a drug. The biomechanical interaction of the microneedles with skin tissue is critical to the correct operation of these devices and is an area where OCT can potentially help, by direct real-time imaging needle implantation process. For example, Donnelly and coworkers at University of Belfast have imaged soluble microneedles [24, 25].

73.4.5 Hair and Alopecia

OCT may have application on studying hair abnormalities and causes of alopecia. Bartels and coworkers showed that OCT can be used to noninvasively measure hair shafts on normal and hair affected by alopecia areata with discrimination [26]. Lademann and coworkers also studied the same technique as a method of screening for doping substances [27]. It is possible to image hair follicles, and OCT may prove to be of interest to companies studying hair shaving and hair removal products.

73.4.6 Tattoos

Tattoos are commonly treated with high-power laser pulses. There is potential for OCT to be used to image the tattooed skin pretreatment, in order to assess the depth of the pigment, so that the laser can be adjusted for maximum effect. This has been studied and considered feasible by Morsy and coworkers [28].

73.4.7 Planning and Monitoring Treatment of Vascular Complaints

Skin vascular conditions such as port-wine stains and rosacea are, like tattoos, commonly treated with pulsed laser. There is interest in using OCT to image the blood vessels pretreatment in order to determine their diameter and depth and then to image posttreatment to validate the effects of the laser therapy [29, 30]. As noted above, it is unlikely that these applications will develop into routine clinical procedures before blood-flow imaging based on Doppler or speckle variance OCT is developed in a commercially available product.

73.4.8 Cosmetic Treatments, Skin Ageing and Wrinkles

OCT has attracted some interest from companies developing cosmetic treatments for "rejuvenating" or temporarily ameliorating the apparent effects of skin ageing. 3D OCT can be used to obtain topographic maps of the skin surface with resolution of 10 μm or better. This is higher than is easily available from commercially available alternatives; however, these are much cheaper to buy and also have much larger field of view than is typically available from an OCT instrument. Of more interest is

measurement of epidermal thickness. The epidermis swells when hydrated, reducing wrinkle depth. OCT can be used to accurately measure epidermal thickness over time, thereby offering the researcher a means of quantitatively evaluating both the magnitude of the effect of a cosmetic treatment and how long it lasts.

73.4.9 Actinic Keratosis and Nonmelanoma Skin Cancer

OCT imaging of nonmelanoma skin cancer (NMSC) like squamous-cell carcinoma (SCC) with its precursors actinic keratosis (AK) and Bowen's disease as well as the most common type of NMSC, basal cell carcinoma (BCC), has been intensively studied. NMSC is a very common disease, mainly affecting elderly patients with pale skin complexion and a history of sun exposure. The lifetime risk for NMSC in this group of persons is about 30 %. The diagnosis by the naked eye is not always easy, because there are no marked changes in skin color or appearance. The skin shows in many cases of NMSC only a slight keratosis and induration. Using dermoscopy, more specific signs like "arboreal" vessels in BCC may lead to a correct diagnosis, but for confirmation or distinguishing from inflammatory skin reactions, it is frequently necessary to take a biopsy. Because sun damage is the main risk factor, the lesions start as solitary plaques but evolving within years into a so-called field cancerization where the whole epidermis within a region like the bald head exhibits malignant cells.

There are several alternatives to surgical treatment of NMSC. In AK, topical treatments for single lesions like laser therapy, cryotherapy, and curettage as well as application of diclofenac gel, imiquimod as an immune modulating agent, or photodynamic therapy for field cancerization are efficient. SCC and BCC can be treated as well with imiquimod or photodynamic therapy, but these noninvasive treatments are restricted to superficial lesions because of the limited penetration depth of the drugs. To choose the most suitable therapeutic regime and for control of clearance, it is imperative to determine the diagnosis, the tumor thickness, and the lateral borders of the lesion.

In OCT of AK, the stratum corneum is severely thickened, often with bright parallel lines corresponding to parakeratosis. The dermoepidermal junction can still be defined in in situ lesions with no infiltrative growth (Fig. 73.4). In contrast, SCC exhibits tumor conglomerates, which expand from the epidermis to upper parts of the dermis. The imaging of SCC is often disturbed by signal shadowing caused by hyperkeratosis.

BCC shows very typical findings in OCT (Fig. 73.5): There are sharply demarcated tumor nests with homogenous, epidermis-like signal distribution, deriving from the epidermis and surrounded by a small signal poor rim. This line is caused by scattering differences between palisading keratinocytes at the border of the tumor and the surrounding mucinous stroma. Superficial, nodular, cystic, or fibrotic subtypes of BCC can be distinguished using OCT. The lower border as well as lateral margins can be defined, because the homogenous signal intensity of the tumor differs from the healthy dermis with its irregular distribution of collagen, adnexal structures, and vessels [31–36].

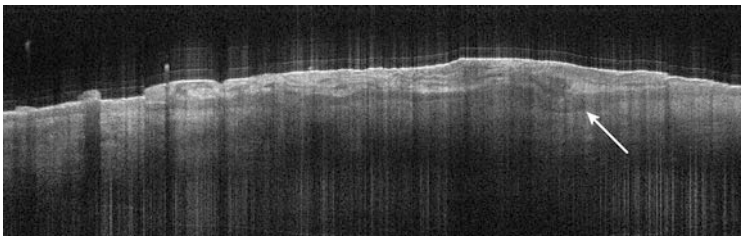

Fig. 73.4 Actinic keratosis at the cheek. The stratum corneum is severely thickened and composed of parallel bright lines. The dermoepidermal border is still detectable (*arrow*), leading to the conclusion that there is no invasive growth. Image size 6 × 1.9 mm

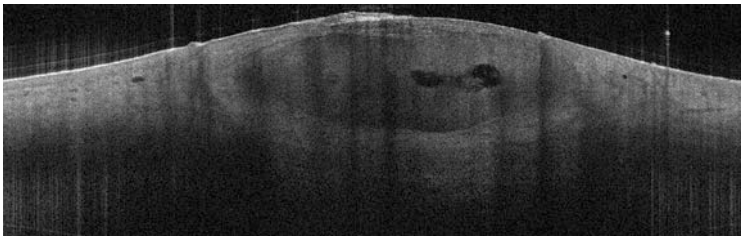

Fig. 73.5 Small nodular basal cell carcinoma at the back with a central cystic degeneration. Image size 6 × 1.9 mm

The capability of OCT to quickly and noninvasively aid the determination of the lesion thickness, lateral extent, and character is of particular value in the management of AK and NMSC. Potential applications of OCT to AK and NMSC include:

- Confirming the clinical diagnosis of BCC without needing to take a biopsy
- Deciding whether an AK lesion has developed into invasive SCC requiring more radical treatment than cryotherapy
- Determining whether a BCC is superficial and therefore will respond to noninvasive therapy or must be treated surgically
- Monitoring the progress and checking the final cure of NMSCs and AKs undergoing noninvasive treatments
- Targeting biopsies to the focal area of tumor
- Assessing the lateral extent of NMSCs prior to surgery

OCT is currently being routinely applied to these applications at a small but growing number of public clinics and commercial practises. In Germany, training courses in OCT image interpretation for professional dermatologists are available. More than 3,000 patients have been scanned by the end of 2013, and the number is set to rise rapidly in 2014 and beyond as the clinical experience, evidence, and the number of users build.

73.4.10 Melanoma Screening and Diagnosis

In principle, melanoma diagnosis is an attractive application for noninvasive optical diagnostic tools such as OCT. It is a fairly common potentially lethal disease and is very difficult to diagnose early, yet early diagnosis is critical for patient survival. Current practice involves visual assessment of pigmented lesions followed by dermoscopy and biopsy of suspicious lesions. The ratio of biopsies to actual diagnosed melanoma is quite high – typically 10:1 or 20:1 – so the burden of "unnecessary" biopsies on the national medical system is severe. Ideally, a noninvasive scan would detect suspicious lesions more effectively than visual techniques.

Unfortunately, this is a challenging task and not necessarily ideally suited to OCT. At the most commonly used imaging wavelength (1,300 nm), melanin is not a strong scatterer, and so it is difficult to pick out melanocytes in the OCT images, let alone identify malignancy. Additionally, the resolution is not high enough to distinguish single cells. Confocal laser microscopy has a higher resolution and is already well established for noninvasive imaging of nevi and malignant melanomas. Initial feasibility studies using OCT for diagnosis of pigmented lesions have not been altogether encouraging. From the point of view of the clinician, the diagnostic capability of OCT depends on whether its capability to image tissue morphology alone (as opposed to cells) has sufficient discriminatory power. In 2007, Gambichler and coworkers studied images from 75 patients with 51 benign nevi (BN) and 40 malignant melanomas (MM) [37]. They identified morphological features of MM not present in BN including marked architectural disarray, diffuse patchy reflectivity of the reticular dermis, and "icicle-shaped" structures. However, for OCT to be adopted into clinical use, these and other features would have to be shown to have high sensitivity and specificity in a large patient cohort.

However, OCT may have a role, for example, to accurately measure the thickness of suspicious lesions (melanomas with invasion below 1 mm depth have much worse prognosis and are treated differently from superficial or "in situ" lesions) as a guide to treatment (Fig. 73.6).

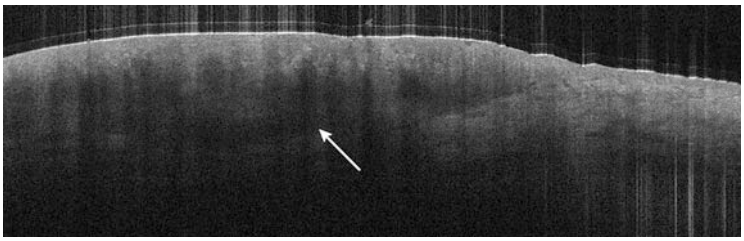

Fig. 73.6 Malignant melanoma at the abdomen. The tumor shows an irregular signal distribution with bright signals. The lower border of the tumor is detectable (*arrow*). Image size 6 × 1.9 mm

73.4.11 Wound Assessment and Monitoring of Healing, Including Trauma and Burns

As mentioned above, polarization-sensitive OCT (PS-OCT) has potential application in assessment of burns. Burn thickness is difficult to assess and is clinically important for the prognosis of the healing process and the decision to treat. If a burn is too deep, the skin will not regrow. In 2008, Todorovic and coworkers developed a PS-OCT probe and tested it by measuring burn thickness on a porcine model and reported excellent agreement with histology [38]. More recently, Kim and coworkers studied PS-OCT scans of two pediatric patients [39]. They reported that superficial burns exhibited the same layered structure as healthy tissue but with more visible vasculature and reduced birefringence and deep burns showed loss of layered structure, absent vasculature, and further reduced birefringence. They concluded that these parameters could be used for noninvasive assessment of burns.

These results are encouraging, although there are some practical issues to consider. Ideally, the OCT probe should not contact the wound, to minimize infection and collateral damage to the healing process. However, imaging without contact to maintain steadiness and adjust the focus distance is not easy. Secondly, serious burns are often large-area effects, and an OCT scan cannot usually capture the whole area of damage, risking an incorrect diagnosis. It therefore remains uncertain whether OCT will compete with other emerging optical techniques [40].

There is also potential for use of OCT to monitor wound healing, by imaging inflammation, by regrowth of the epidermis and the vasculature [41], and with tissue-engineered implants. Wang and coworkers reported use of OCT on a murine model in which OCT was able to delineate the epidermis, the implant, inflammation and reepithelialization, and finally resorption of the implant [42]. The above limitations for burns also apply to this application.

73.4.12 Psoriasis

One of the main symptoms of psoriasis is the development of skin "plaques" with thickened epidermis. In principle, OCT could be used to study the severity of the disease by imaging and measurement of the epidermis (Fig. 73.7). This was studied by Welzel et al. and Morsi et al. [43, 44]. Similar results were reported by Phillips et al. [45]. However, it is not clear whether there is a strong clinical need for this, except perhaps to assist development of the effects of therapies [46].

A potentially exciting application of OCT is in the early assessment and detection of psoriatic arthritis (PsA). PsA is a debilitating disease of the joints that can develop in psoriasis sufferers, and there is currently no test except for the symptoms of joint pain. It is treatable with drugs, but it is highly desirable to detect early to prevent its development and loss of quality of life for the sufferer. A paper by Castillo-Gallego et al. [47] studied the potential for OCT to detect PsA by imaging fingernails of psoriasis sufferers. In their study, 290 fingernails from 17 patients (4 with Ps, 13 with PsA) and 12 healthy controls were imaged and

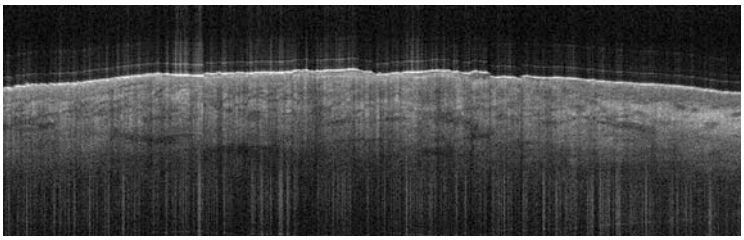

Fig. 73.7 A psoriatic plaque at the chest. The stratum corneum is slightly thickened. The epidermis shows an acanthosis with an irregular border to the dermis, corresponding to papillomatosis. Image size 6 × 1.9 mm

the images assessed in a blinded analysis. They reported good correlation between the blinded assessment of OCT images and clinical assessment. Further work is required to determine if there is predictive value for PsA.

73.4.13 Onychomycosis

Onychomycosis is a very common fungal disease of the nails. It is mainly treated topically and more recently with pulsed thermal laser. It is difficult to distinguish from other conditions such as psoriasis or lichen planus. OCT may have a role in diagnosis and monitoring efficacy of treatment. Abuzahra and coworkers imaged 18 patients of which 10 had fungal nail disease, 2 psoriasis, 1 lichen planus, and 5 controls and reported that OCT detected fungal elements in all 10 afflicted patients via the appearance of highly scattering elongated structures inside the nail plate [48]. This finding was recently confirmed by Nandanan and coworkers [49]. Sattler et al. compared different diagnostic methods for onychomycosis and found OCT to be inferior to confocal microscopy regarding specificity [50].

73.4.14 Scleroderma

Scleroderma is a debilitating autoimmune disease, producing changes in the skin, blood vessels, muscles, and internal organs. Symptoms include changes to the skin. Abignano et al. reported that the OCT images of 66 skin regions in 22 patients showed loss of the hyporeflective epidermal layer and the loss of clear visualization of the epidermal junction and have potential application as a surrogate outcome measure in intervention studies or as predictive of skin involvement in systemic sclerosis [51].

73.4.15 Blood Glucose Monitoring

OCT is just one of many optical techniques that have been studied in relation to blood glucose measurement for the potential application to diabetes patients.

As early as 2002, Larin et al. reported a pilot study, which showed promise [52]. This and subsequent studies attempted to determine changes in blood glucose from the attenuation coefficient of light in skin. The idea is that blood glucose strongly affects this parameter – seen as the "slope" of the OCT signal with depth. These findings were repeated by other groups [53]. Despite these findings, OCT has yet to emerge as a viable technique for blood glucose monitoring, perhaps because of the size of the equipment compared to many other approaches that are being developed.

73.5 Conclusions

The sheer number of different applications of OCT explored by researchers is indicative of the power of the technique. Over the past decade, studies have developed from preliminary exploratory images to systematic and repeatable evaluations of OCT with clearly defined protocols for the diagnosis of diseases and monitoring of treatments. Coupled with this, great advances have been made in the understanding of OCT images. Practical commercial OCT instrument have been launched and obtained regulatory approval.

In a few areas, notably nonmelanoma skin cancer, this has resulted in actual use in dermatology clinics on a routine basis for the benefit of patients and a steady growth in the installed base. We can also expect further developments in the technology of commercial instruments: lighter, smaller probes, blood-flow visualization, and ever higher image resolution. However, it is clear that large-scale systematic multicenter trials will be required to establish OCT more firmly as a standard tool for the practicing dermatologist, and these have yet to be reported in the literature. To the author's knowledge, some of these are already in the pipeline, and we can therefore expect that OCT will be increasingly adopted by dermatologists in the coming years as an essential tool in their armory against skin disease.

There are some other noninvasive imaging methods like confocal laser microscopy and multiphoton tomography, which are competitors to OCT. Both have a higher resolution and are more valuable for diagnosis of pigmented lesions but at the expense of detection depth and field of view. Deeper parts of skin tumors or dermal skin diseases cannot be imaged, which is especially problematic for basal cell carcinomas. Therefore, OCT may be the best technology for diagnosis of nonmelanoma skin cancer and other nonpigmented lesions. Additionally, it may be interesting to combine the methods, i.e. OCT with multiphoton tomography [54] to get both overview and high resolution.

Dental OCT • Oral • Dentistry • Dentin • Enamel • Pulp • Gingival tissue • Tooth decay • Caries • Erosion • Oral mucosa

The oral cavity is a diverse environment that includes oral mucosa, gingival tissues, teeth, and their supporting structures. Oral health is currently evaluated through three main avenues: visual/tactile examination, periodontal probing, and radiographic imaging. After the surfaces are dried with a gentle stream of air, visual examination of the teeth and surrounding soft tissue is completed. Clinicians tactically explore the surface hardness of teeth to detect dental caries while demineralization of the enamel and soft tissue inflammation are characterized by changes in visual characteristics. Probes are also placed between the soft tissue and tooth to assess periodontal health. Radiographs are used to determine the internal structural integrity of the teeth and alveolar bone. Although radiographs are highly sensitive for detecting regions of carious

demineralization and alveolar bone loss, they have several limitations. Since radiographs are two dimensional, precisely locating the position of a carious lesion or osseous defect is impossible. Radiographs cannot distinguish active from inactive disease and cannot identify periodontal disease until after bone loss has occurred. Finally, radiography uses harmful ionizing radiation and provides no information on soft tissue status.

Optical coherence tomography (OCT), a well-known technique for creating noninvasive, high-resolution (<20 μm) images of biological microstructure, has been used in dentistry. In vitro images of porcine dental tissues were first reported in 1998 [1]; subsequently in vivo imaging of human dental tissue proved that OCT could be used as a valuable diagnostic aid for several applications within dental medicine [2, 3]. The goal of dental OCT is to produce in vivo images of oral microstructure that can be used to make qualitative and quantitative assessments of oral tissues. In particular, OCT images depict at high resolution clinically important anatomical features such as the location of the soft tissue attachment, morphological changes in gingival tissue, tooth decay, enamel thickness and decay as well as structural integrity of dental restorations. Because OCT images both the hard and soft tissue structures of the oral cavity at high resolution, it offers the unique capacity to identify dental disease before destructive changes have progressed allowing for earlier intervention than is possible with current diagnostic modalities.

The oral cavity begins at the lips and ends posteriorly at the area of the palatine tonsils. This chapter will focus on the following structures within the oral cavity:

1. The hard dental tissues, i.e., the teeth.
2. The periodontal tissues, i.e., the supporting tissues for the teeth. These include soft tissues, as well as cementum, periodontal ligament, and bone.
3. The oral mucosa, i.e., the lining of the oral cavity.

This section will address all the anatomical structures within the oral cavity that are listed above. A brief review of normal oral structures will be followed by a summary of the pathologies affecting each structure, a discussion of existing diagnostic tools, and an overview of diagnostic usage of OCT in each structure to date. In the final section, the authors present their views on the potential use of OCT in dentistry in the future.

74.1 Hard Dental Tissues

74.1.1 Definition of Dental Hard Tissues

The tooth consists of enamel, dentin, and pulp (Fig. 74.1). The close relationship that exists during the formation of these three tissues is maintained in the structure of the tooth.

74.1.1.1 Enamel

Consisting of 95 % mineral, 1 % water, and 4 % organic material by weight [4], enamel is the hardest structure of the body. The inorganic content of enamel consists of a crystalline calcium phosphate known as hydroxyapatite, which is also found in bone, calcified cartilage, dentin, and cementum. Although the vast

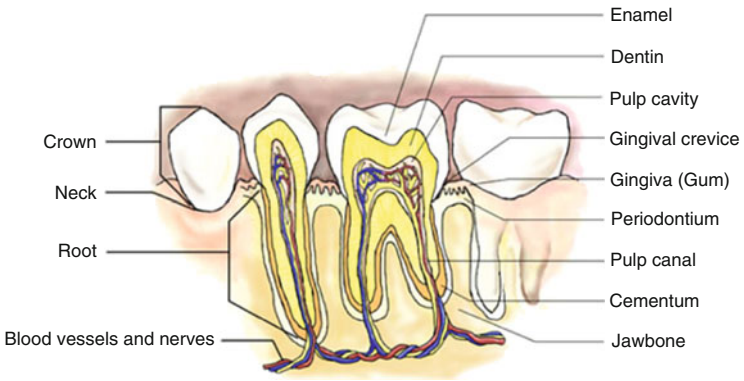

Fig. 74.1 Structure of tooth and periodontium (DeEtte M. DeVille, M.D. AMA atlas of the body: the teeth © Copyright 1999 American Medical Association)

majority of the enamel is occupied by densely packed hydroxyapatite crystals, a fine lacy network of organic material appears between the crystals. The bulk of this organic material is made up of the TRAP (tyrosine-rich amelogenin protein) peptide sequence tightly bound to the hydroxyapatite crystal as well as nonamelogenin proteins [4].

Because of its high mineral content, enamel is extremely hard and brittle. Ground sections of enamel reveal roughly rodlike cylindrical structures 4–6 um in diameter within the enamel, which owe their existence to a highly organized pattern of hydroxyapatite crystal orientation. For the most part, the long axes of the crystals run parallel to the longitudinal axis of the rod. This is particularly true for crystals along the central axis of the rod. Crystals more distant from the central axis, however, flare laterally to an increasing degree as they approach the rod periphery. The interrod region is an area surrounding each rod in which crystals are oriented in a different direction from those constituting the rod [4]. The capacity of OCT to image the orientation of the enamel rods and interrod region is illustrated in Fig. 74.2.

The enamel surface varies with age. In unerupted teeth, it consists of a structureless cuticle 0.5–1.5-um thick [4] overlying a 5-nm thick layer of small loosely packed crystallites interspersed with a few large platelike crystals and cuticular material [4]. This layer merges into the subsurface enamel, where 50-nm crystals are loosely packed. The subsurface layer forms the enamel surface due to rapid loss of the primary cuticle and the surface layer of small crystallites soon after eruption. An organic deposit called the salivary pellicle is present on the tooth surface, usually covered by a layer of dental plaque [4]. The important role of dental plaque in fostering dental decay will be discussed below.

74.1.1.2 Dentin-Pulp Complex

The dentin supports the enamel. The junction between the two tissues is a series of scallops where crystals of enamel and dentin intermix. Dentin and pulp are embryologically, histologically, and functionally the same tissue and are therefore

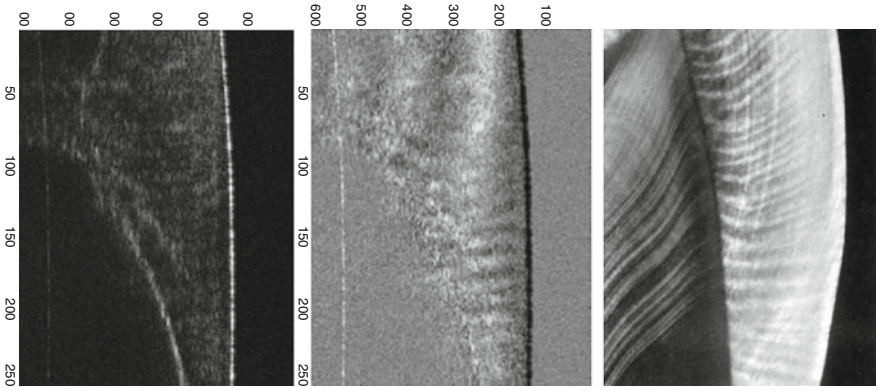

Fig. 74.2 Conventional and polarization-sensitive OCT images and a ground section of a human tooth reveal the superior capacity of polarization-sensitive OCT to image the orientation of the enamel rods and the interrod region. The junction between the enamel and dentin is characterized by a series of scallops where dentin and enamel intermix [6]

considered together here [5]. Mature dentin is, chemically, by weight, approximately 70 % inorganic material, 20 % organic material, and 10 % water (adsorbed onto the surface of the mineral or in interstices between crystals). The main inorganic component is hydroxyapatite; the main organic phase is type 1 collagen with fractional inclusions of glycoproteins, proteoglycans, phosphoproteins, and some plasma proteins. Approximately 56 % of the mineral phase is within the collagen. Due to its inorganic phase, dentin is slightly harder than bone and softer than enamel [5]. Physically, dentin has an elastic quality; it is bound to the enamel at the dentinoenamel junction and covered by cementum in the root of the tooth [5].

Forming the bulk of the tooth, dentin consists of multiple closely packed dentinal tubules traversing its entire thickness and containing the cytoplasmic extensions of odontoblasts that once formed the dentin and now maintain it. The cell bodies of these odontoblasts lie along the inner aspect of the dentin, where they also form the peripheral boundary of the dental pulp [5]. The dental pulp is the soft connective tissue occupying the pulp space in the central area of the tooth, which is divided into the coronal (upper) portion, the pulp chamber, and the lower portion, the root canal. The root canals end at the apical foramen, where the main blood vessels and nerves to the pulp enter and leave the tooth. Through the apical foramen, pathologies can migrate between the pulp and the periodontium [5].

Three types of dentin are recognized in human teeth [5]. The bulk of the tooth consists of primary dentin. The structurally somewhat less regular secondary dentin develops after root formation is complete. Tertiary dentin is produced in reaction to noxious stimuli such as decay or dental procedures and is very heterogeneous in its structure. Viewed microscopically, dentin consists of several structural features. Dentinal tubules are tapered structures approximately 2.5 um in diameter near the pulp, narrowing down to approximately 900 um near the dentinoenamel junction [5]. They extend through the entire thickness of the dentin from the

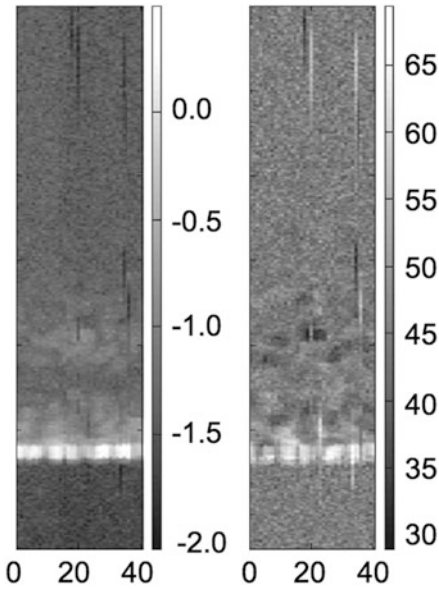

Fig. 74.3 OCT images of a human tooth near the DEJ reveal irregular masses of decreased signal intensity that were 10–20 μm in diameter and consistent with the morphology of interglobular dentin that can be seen in conventional and PS-OCT [6]

dentinoenamel junction to the pulp, following an S-shaped path. At their pulpal end, the tubules are generally thought to contain the process of an odontoblast bathed in dentinal fluid, although there is some uncertainty regarding the exact nature of tubule content [5]. The tubular structure of dentin permits the rapid progression of pathologies and accentuates the pulpal response to dentinal events [5]. It also allows for excellent light propagation into the pulp.

Within the dentinal tubule exits a hypermineralized (40 % more than regular dentin) ring of intratubular dentin causing a progressive reduction and the potential for eventual obliteration of the lumen of the tubule [5]. Exact mechanisms and causes are still uncertain. Intertubular dentin is located between the dentinal tubules and consists of a tightly woven network of type 1 collagen fibrils arranged roughly at right angles to the dentinal tubules, with apatite crystals deposited between and parallel to the fibrils. The ground substance consists of phosphoproteins, proteoglycans, and γ-carboxyglutamate [5]. Interglobular dentin consists of areas of unmineralized or hypomineralized dentin where zones of mineralization have failed to fuse. Here the normal architectural pattern of the tubules remains unchanged, except for the lack of intratubular dentin. The intraglobular dentin can be visualized in PS-OCT images of dentin (Fig. 74.3).

The dental pulp is the soft connective tissue that supports the dentin. Principal cells within the pulp include odontoblasts, undifferentiated mesenchymal cells, fibroblasts, macrophages, and other immunocompetent cells [5]. The major vessels and nerves lie in the central portion of the pulp. The principal collagen fibers of the pulp are type l and type lll collagen [5] in a glycosaminoglycan-, glycoprotein-, and water-containing ground substance.

74.1.2 OCT Imaging of the Hard Dental Tissues

Marked light scattering limits the transmission of visible light at 400–700-nm wavelengths through tooth substance. The relationship between light scattering in enamel and wavelength (λ) is defined as $1/\lambda^3$. At longer wavelengths exceeding 1,500 nm, light absorption by water becomes a limiting factor for the absorption of infrared (IR) light [6–8] Therefore, OCT imaging of the tooth is best performed at wavelengths between 700 and 1,500 nm, with excellent penetration to a depth of 1.5–3 mm. In 2000, Otis et al. demonstrated the superior imaging and penetration of OCT systems using a 1,310-nm vs. 850-nm light source [9].

In 1998, Colston et al. presented the first in vivo optical coherence tomography (OCT) images of dental tissue [1]. The authors presented a dental optical coherence tomography system with a very promising feature – the incorporation of the interferometer sample arm and transverse scanning optics into a handpiece suitable for intraoral use. Examples of use of this imaging system for dentistry illustrated its potential for diagnosis of periodontal disease, detection of caries, and evaluation of dental restorations. The average imaging depth of this system varied from 3 mm in hard tissues to 1.5 mm in soft tissues. Axial resolution was 15 μm (free space). The system had a lateral resolution of 50 μm and an average total lateral scan distance of 12 mm. The total scan time for each image was approximately 45 s. Further studies by this and other groups have clearly demonstrated the effectiveness of OCT for rapid, high-resolution imaging of dental tissues using OCT (please see the appropriate sections below).

Active work in the area of OCT probe development has greatly enhanced the applicability of OCT imaging for dental applications [10–20]. Figure 74.4 shows the schematic diagram and picture of a miniature probe based on a dual axis microelectromechanical system (MEMS) mirror [11]. The MEMS mirror provides high-speed, 2-axis scanning while occupying a very small volume with extremely low power consumption. The dimensions of the MEMS mirror in Fig. 74.4b are 800-mm diameter, and both axes are capable of scanning up to 30° angles at frequencies greater than 3 kHz with good linearity. The packaged probe with an outer diameter 5.0 mm or smaller can be assembled, which is sufficiently compact for dental applications (Fig. 74.4c).

The 2D MEMS probe shown in Fig. 74.4c has been used for in vivo imaging of animal models and human subjects. The representative in vivo 3D images from rabbit and human tissues are shown in Fig. 74.5. These images were acquired employing the FD-OCT system, which provides adequate imaging speed for 3D imaging.

In addition to side-viewing probes based on MEMS, forward-viewing probes based on cantilever-type scanning have been demonstrated by several groups [19–24]. The scanning probes are driven by either PZT, electrostatic, or magnetic force [19–24]. Recently, a forward-view OCT scanning probe based on a fiber-cantilever piezotube scanner was developed by using a semi-resonant scan strategy for a better scan performance (Fig. 74.6a) [20]. A cantilever weight was attached to the fiber cantilever to reduce the resonance frequency down to 63 Hz, well in the desirable range for FD-OCT. By driving the two axes at slightly different

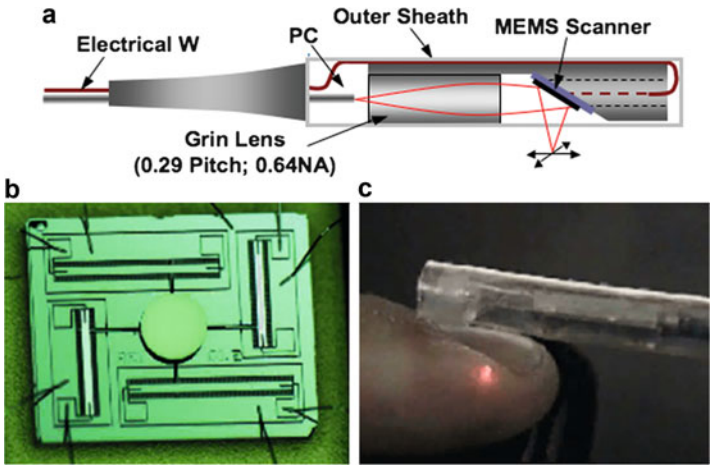

Fig. 74.4 (**a**) Schematic diagram of endoscopic probe; (**b**) photo of a vertical 2-D scanning MEMS based on comb-drive actuator. (**c**) photo of assembled 2-D miniature probe [11]

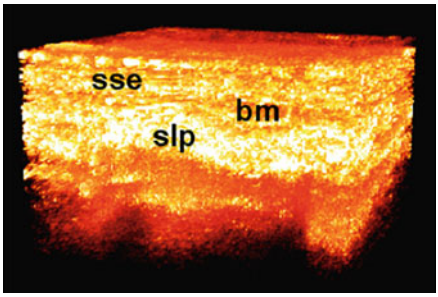

Fig. 74.5 In vivo 3D imaging of true human vocal cord obtained by a FD-OCT system using the 2D MEMS probe. Image size is 1 × 1 × 1.4 mm. Important structures, such as the stratified squamous epithelium (*sse*), basement membrane (*bm*), and superficial lamina propria (*slp*), are clearly visible

frequencies, a low-order Lissajous pattern was obtained for a 2D area scan (Fig. 74.6b). 3D OCT images were successfully acquired in an acquisition time of 1.56 s for a tomogram volume of 2.2 × 2.2 × 2.1 mm^3 (Fig. 74.6c).

These studies demonstrate the capabilities of a miniature probe for 3D OCT imaging. A 3D OCT system employing a high-speed, compact scanner may have the potential to expand the applications of OCT for dental and oral imaging and may revolutionize areas of clinical medicine as well as medical research.

74.1.3 Pathologies of Hard Dental Tissues

74.1.3.1 Decay

The most common pathological condition of the tooth is decay or caries. Cause is a confluence of cariogenic diet and inadequate oral hygiene on a susceptible tooth

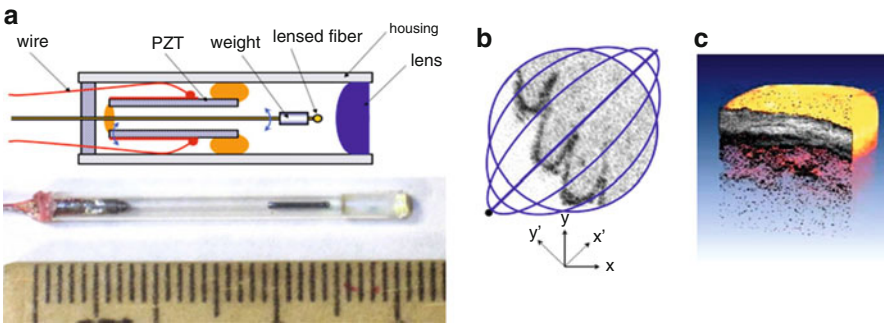

Fig. 74.6 (**a**) Schematic design and picture of the fabricated OCT scanning catheter. The dimensions are given in millimeters; (**b**) schematic Lissajous scan pattern (*blue lines*) in the XY plane laid over an OCT *en face* image; (**c**) the 3D-rendered tomogram [20]

surface. Microorganisms multiply at the tooth surface, forming a layer of plaque. These microorganisms produce lactic and acetic acid, reducing the pH to levels as low as 3.5. At lower pHs, hydroxyapatite becomes increasingly soluble, leading to rapid demineralization and increased porosity and permeability as the calcium bound to the hydroxyapatite is ionized and washed out by the saliva. Decayed or carious lesions usually are associated with a darkening in color. However, some carious enamel lesions appear bright at the surface, especially in their early stages and are thus difficult to detect [25]. An important characteristic of the early carious lesion is that most of the demineralization occurs at the subsurface level, so that a well-mineralized surface zone remains in place for some time. This has an important implication for the early detection of carious lesions, namely, the inability to detect early lesions by clinical visual inspection of the tooth surface alone.

Diagnostic confidence also has significant impact on whether the clinician chooses to initiate further preventive therapy or restorative intervention. When caries reach the dentin, the response is sequential. Frequently at this stage, the enamel is physically still grossly intact, and bacterial invasion has not occurred. However, the lesion has increased the permeability of enamel to acid and other chemical stimuli, which now evoke a response from the dentin-pulp complex such as the deposition of tertiary dentin. Once the enamel cavitates, bacteria reach the dentin surface, and destruction of dentin begins [26].

Current Methods for Diagnosis of Caries

The technologies currently available to dental clinicians for the detection of dental caries have limited sensitivity, and there is controversy surrounding the "gold standard" for caries diagnosis. Detection of pit and fissure caries by all current methods is low. While radiographs reveal approximal lesions with moderate sensitivity and high specificity, occlusal caries are grossly underestimated in radiographic examinations [27–29]. Moreover, the widespread use of fluorides has increased the diagnostic difficulty of pit and fissure caries because enamel remineralization conceals dentinal lesions that continue to progress [29, 30].

Recently, tactile examination with a sharp explorer has been discouraged, since this may produce breakdown of the enamel surface or transfer cariogenic organisms to unaffected sites. Moreover, probing does not increase diagnostic accuracy as compared with visual examination alone [31]. Thus, visual diagnosis has been suggested as the diagnostic method of choice for pit and fissure caries [32, 33]. Trained observers detect small pit and fissure lesions by visual examination with a sensitivity of 0.6 and a specificity of 0.8. This means that 40 % of true dentinal lesions are classified as sound and that 15 % of sound surfaces are classified as diseased. In populations with a low prevalence of caries, the disease usually progresses slowly. Thus, in low prevalence caries populations, traditional diagnostic techniques worked because it is better to err toward false-negative diagnoses than to restore a sound tooth. Limited sensitivity worked in classical operative approaches, because teeth were not restored until caries involvement was significant and then the restoration was extended to include all tooth structure in the vicinity that would be considered "susceptible to caries." Current therapies first employ preventive strategies when lesions are small and the caries risk is low. When the tooth surface is cavitated, caries significantly involve the dentin, or when caries risk is high, the diseased dentin is removed with minimal surrounding tooth structure. For today's dentistry, the sensitivity of traditional diagnostic methods is unacceptable. The materials and operative technology permit placement of small restorations with removal of only the diseased dentin and a minimal amount of sound tooth structure. The success of these minimally invasive operative approaches depends on locating the precise region of active caries and determining with certainty that the remaining tooth structure is caries free [33]. A more precise caries diagnostic method would greatly improve the current standard of dental preventive and restorative care, with a major impact on dental health care delivery [34].

Dentists continue to rely primarily on visual and tactile examination, supported by radiographic data. However, early detection of demineralization and quantification of tooth substance loss using these techniques is extremely difficult, so that dental erosions are usually diagnosed at a relatively advanced stage when substantial irreversible enamel loss has occurred.

OCT Diagnosis of Caries

Studies indicate that OCT is a powerful technique for detecting subsurface changes in the material properties of dental tissues. OCT reliably identifies changes in dentin under sealants and adjacent to the margins of composite restorations. Comparing OCT profiles over time should allow clinicians to quickly detect potential sites of disease progression or monitor the results of remineralization therapy. Most groups have taken one of two approaches to use OCT for the detection and assessment of dental caries, using either conventional time-domain OCT or polarization-sensitive OCT.

Conventional Time-Domain OCT

Amaechi et al. [35] described the quantitative assessment of dental caries using A-scans (depth versus reflectivity curve), B-scans (longitudinal images), and C-scans (transverse images at constant depth). While the B- and C-scans

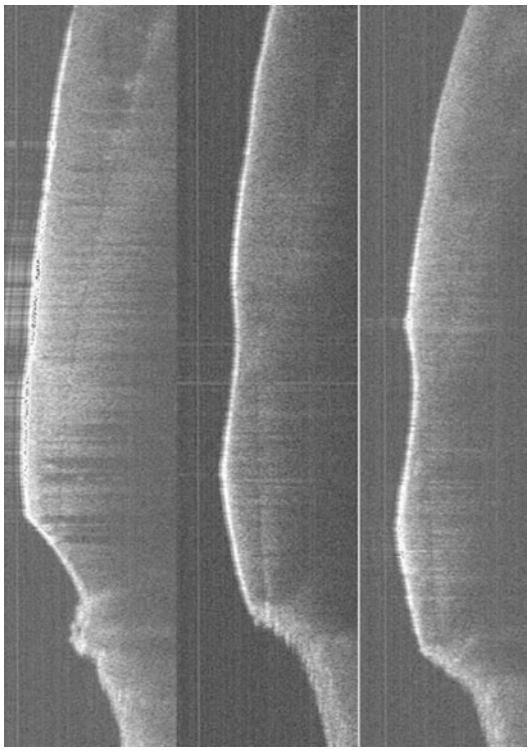

Fig. 74.7 The three OCT images show baseline enamel thickness following two five-minute exposures to a cola beverage (Otis unpublished data)

qualitatively described the lesion detected, the A-scan which showed the depth-resolved reflectivity (dB) of the tooth tissue was used for the quantitative analysis. The percentage reflectivity loss ($R_{\%}$) in demineralized tissue, which related to the amount of mineral loss, increased with greater demineralization time. It was concluded that, using this approach, OCT could quantitatively monitor the mineral changes in a caries lesion on a longitudinal basis. In a later paper, the same group confirmed this correlation using QLF (quantitative light-induced fluorescence) [36].

A novel approach by Ko et al. combined optical coherence tomography (OCT) and Raman spectroscopy to provide morphological information and biochemical specificity for detecting and characterizing incipient carious lesions found in extracted human teeth [37]. OCT imaging of tooth samples demonstrated increased light backscattering intensity at sites of carious lesions as compared to the sound enamel (Fig. 74.7). Using Raman microspectroscopy and fiber-optic-based Raman spectroscopy to characterize the caries further, they demonstrated excellent potential for a new fiber-optic diagnostic tool enabling dentists to identify early caries lesions with greater sensitivity and specificity. In a follow-up study, Sowa et al. compared the caries diagnostic capabilities of the A-scan intensity, the OCT attenuation coefficient as well as the mean and standard deviation of the lognormal fit to the histogram of the A-scan ensemble. The OCT attenuation coefficient showed the highest discriminatory capacity. However, direct analysis of the

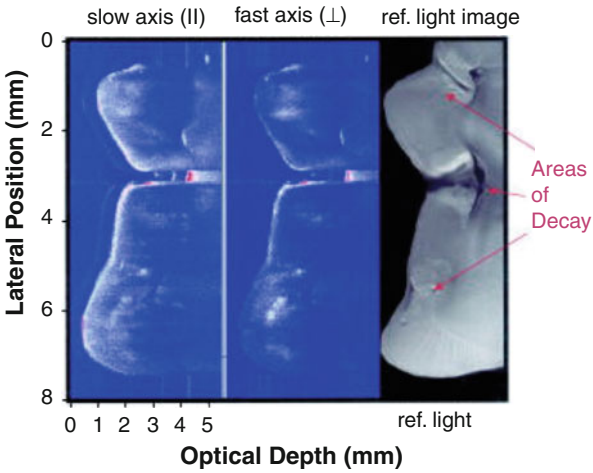

Fig. 74.8 Slow and fast axis OCT scans across the top of a third molar with occlusal decay. The reflected light image of the tooth section is shown on the right for comparison. All three carious areas are resolved in the OCT images with very strong scattering (*red*) in the base of the fissure shown in the *center*. The intensity varies from –40 to 10 dB with intensities of less than –39 dB demarcated in *blue* and those of intensity greater than 5 dB in *red* [43]

A-scans or the histogram of A-scan intensities also showed good diagnostic discrimination [38].

The capability of OCT for early detection and evaluation of root caries was described by Amaechi et al. [39]; its potential for detecting and mapping deficient restorations was also demonstrated by de Mello et al. [40].

Polarization-Sensitive OCT

Birefringence of dentin and enamel provides PS-OCT with a contrast agent useful in indicating pre-carious or carious lesions [31]. PS-OCT can provide additional information related to the mineralization status and/or the scattering properties of the dental materials (Fig. 74.8). Several authors have described the use of PS-OCT for detection and diagnosis of demineralization and dental caries [41–46].

74.1.3.2 Dental Erosion, Attrition, Abrasion, and Cracking

Erosion is defined as the progressive loss of hard dental tissue by chemical processes not involving bacterial action. Repeated or prolonged exposure of teeth to acid leads to selective dissolution of specific components of the tooth surface, with eventual loss of tooth substance, hypersensitivity, caries, functional impairment, and even tooth fracture. The critical pH for enamel dissolution is 5.5. It is estimated up to 80 % of children and over 40 % of adults demonstrate substantial loss of tooth substance, an increasing proportion of which may be related to dental exposure to gastroesophageal reflux disease [47–51]. If enamel demineralization is detected sufficiently early, the enamel can be remineralized before damage becomes irreversible.

Loss by wear of tooth or restoration surface caused by tooth-to-tooth contact during mastication or parafunction is defined as attrition, whereas loss of dental tissue by wear from exogenous substances such as toothbrushes is termed abrasion. Enamel tissue loss is permanent, potentially disfiguring and can be costly and sometimes challenging to repair or mask.

Hairline cracks and fractures in the tooth tend to occur after trauma or excessive loading, especially in older patients. If these remain undetected, they can lead to pain, flawed diagnosis, and inappropriate or failed therapy.

Current Methods for Diagnosis of Dental Erosion, Attrition, Abrasion, and Fracture

The technologies currently available to dentists for the diagnosis of tooth loss include visual inspection and radiography. Diagnosis usually occurs at a relatively advanced stage (1) when substantial enamel loss has occurred, (2) damage is irreversible, and (3) differential etiological diagnosis is very tenuous. Monitoring the effectiveness of remineralizing therapies is not possible with conventional clinical tools. Diagnostic tools for cracks and fractures are limited to visual inspection and probing, neither of which is reliable. Radiographs are seldom useful.

OCT Diagnosis of Dental Erosion, Attrition, Abrasion, and Fracture

Optical coherence tomography (OCT) techniques are well suited to the quantification and imaging of enamel loss [40]. A recent publication described the use of in vivo OCT imaging to determine the effectiveness of a proton pump inhibitor to treat gastroesophageal reflux (GERD) by measuring enamel loss through erosion from OCT images [51]. The study was significant in that researchers were able to identify an association between the medication and a reduced enamel erosion vs. the control (placebo) group after a period of only 4 weeks based on the imaging data (Fig. 74.9). Several studies report on the effectiveness of OCT imaging for detecting tooth fractures and cracks, including hairline cracks in the root surface (Fig. 74.10). OCT imaging gave results compatible to far more expensive micro-CT that uses ionizing radiation. Visual observation was relatively ineffective [52, 53].

74.1.4 Caries Prevention: Fluorides and Sealants

The most common methods of caries prevention include systemic fluoride ingestion during tooth development, topical fluoride application, especially during and directly after tooth eruption, and the use of dental sealants. Typically, sealants are placed over vulnerable areas of the teeth, especially the fissures of erupting permanent teeth, to protect them from demineralization and decay during their first few years in the oral cavity, when they are most vulnerable to demineralization and decay. Early detection of decay under sealants is important to avoid major spread of decay underneath the protective covering.

74.1.5 Diagnosing Sealant and Restoration Integrity

Radiographic evaluation and clinical examinations such as visualization and tactile probing of restoration margins are the less than adequate modalities currently available to clinicians. The capacity of OCT to image dental composite restorations

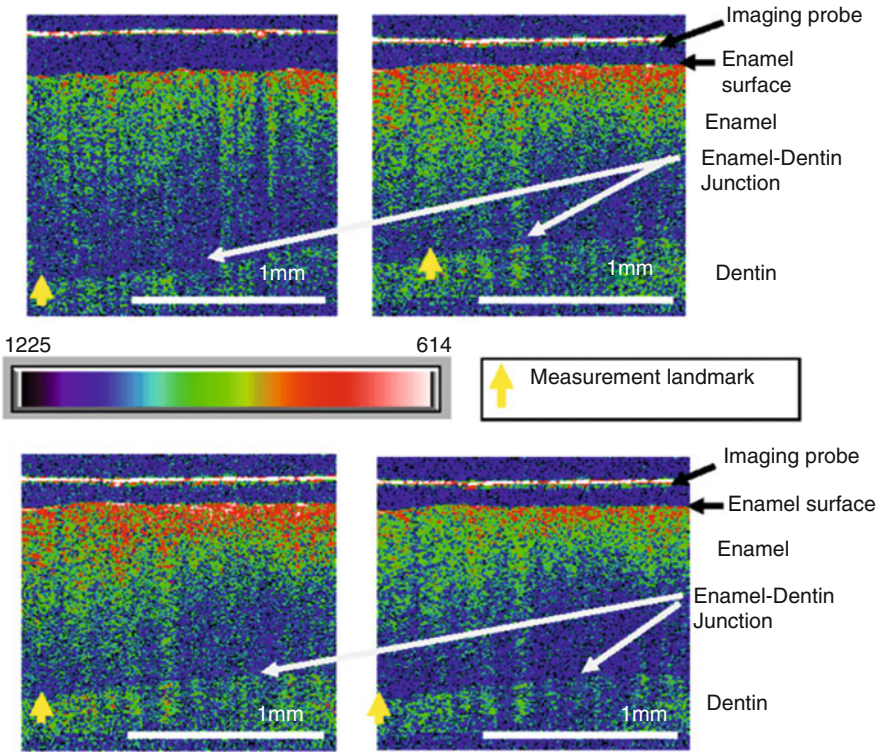

Fig. 74.9 *Above*: In vivo OCT images with pseudo-color superimposition of the same tooth before and after 3-week treatment with placebo. The optical signal near the tooth surface has increased as shown by the greater preponderance of *green* versus *blue*. *Below*: In vivo OCT images with pseudo-color superimposition of the same tooth before and after 3-week treatment with esomeprazole 20 mg bid. The optical signal near the tooth surface has decreased as shown by the reduced preponderance of *red* versus *green* [51]

offers a superior assessment as compared to radiographic imaging [54, 55]. In one study the internal characteristics of facial composite restoration were distinguished, and variations in cavosurface margins accurately identified teeth in restorations with axial cavity depths of 1, 2, and 3 mm. When the teeth were subsequently sectioned, photomicrographs revealed that OCT images depicted with fidelity the composite restorations, dentin-enamel junction (DEJ), and external tooth contours. Minimal spatial distortion of the axial wall was noted in the restorations with axial depths of 1 and 2 mm [56].

OCT has also been shown to identify accurately occlusal sealants and composite restorations [57]. In one study, 21 dentists were asked to interpret OCT images of 9 premolars that were either not restored, contained an occlusal sealant, or were restored with a composite restoration. Following a brief training period, 21 dentists evaluated the OCT images following a randomized blind protocol. The sensitivity

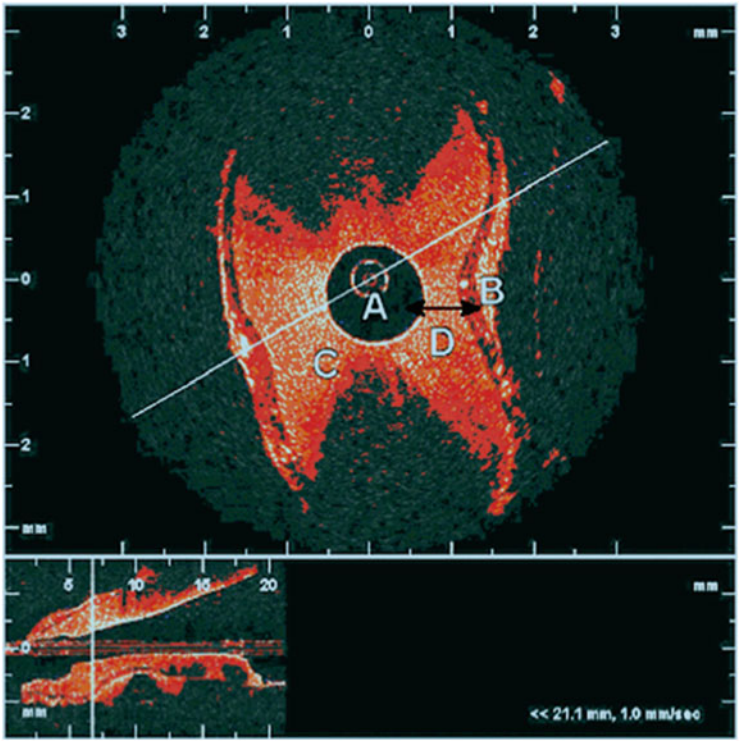

Fig. 74.10 The OCT output at 7 mm from the apex shows a cross-section of a prepared canal. (***A***) The root canal, (***B***) cementum, and (***C***) dentinal tubules. (***D***) "Risk zone" (canal wall 1-mm thick) [52]

of OCT to discriminate composite and sealants was greater than 0.92, while the specificity of discrimination was greater than 0.94. The capacity of OCT to discriminate sealants from non-restored occlusal surfaces was slightly less (sensitivity 0.88; specificity 0.86) but still within a clinically acceptable level. Inter- and intra-rater reliabilities as measured by the kappa statistic also revealed excellent performance by dentists using OCT ($k = 0.82$–1.0). This study also demonstrated that dentists who were previously unfamiliar with OCT images could be trained to interpret the images with a high degree of accuracy.

Not only does OCT detect sealants, it also effectively diagnoses decay underneath sealants. A study by Holtzman et al. evaluating the ability of dentists to detect decay beneath commonly used dental sealants using OCT found that, after 90 min training, dentists were able to detect tooth decay in enamel and under sealants more accurately using OCT than with visual or radiographic examination (Fig. 74.11). Detection using OCT was somewhat better prior to sealant placement than afterward. This effect varied in size depending on the type of sealant used. Radiographic diagnosis was also less accurate after sealant placement. Of the four dental sealants,

Delton provided excellent positive predictive value and the best post-sealant negative predictive values [58].

A paper by Jones et al. described the effective use of polarization-sensitive optical coherence tomography (PS-OCT) to image lesions underneath composite sealants [59]. The polarization-sensitive system, recording images in both the parallel and perpendicular axes, was useful for enhancing the image contrast of the artificial caries and minimizing the interference of the strong reflections at surface interfaces. The artificial lesions could be detected under 750 μm of visibly opaque sealant. Tooth-colored sealants allow deeper imaging depth. The artificial lesions could be detected under 1,000 μm of sealant.

Finally, OCT can be used to assess the internal structure and marginal adaptation of cemented crowns. Cross-sectional images were made in duplicate on the midfacial surface of cemented functional crowns with well-adapted margins and no clinical evidence of recurrent caries. The internal structure and marginal adaptation of porcelain fused to metal crowns were clearly visualized in teeth imaged in vivo. Characteristic image layers that corresponded to incisal and body porcelain were visualized [60].

Using three-dimensional OCT imaging, it is possible to evaluate the structural integrity and wear of composite resin restorations. An OCT contour map of restoration surfaces can be used to quantify volumetric loss or surface changes in a restorative material over time. Wear estimates correlate well with the value as determined by the traditional method of measuring composite wear, the ML scale ($r = 0.86$; $p < 0.05$). OCT images can record changes in the restoration surface that occurred with occlusal function. It was also shown that a region of catastrophic failure not visible clinically or radiographically was detected by OCT [61].

74.2 Periodontal Tissues

Periodontal diseases are a major cause of tooth loss. They are plaque-induced inflammatory disorders that result in the loss of tooth support through the apical migration of connective tissue attachment which results in the resorption of alveolar bone. To establish the diagnosis of periodontitis, it is necessary to detect the loss of connective tissue attachment and alveolar bone [62]. Traditionally, the location of the periodontal attachment has been estimated by mechanically measuring the distance a probe penetrates the soft tissues surrounding the tooth. Attachment level is defined clinically as the distance from a fixed reference point on the tooth (the cementoenamel junction) to the most apical extent of probe penetration. Probing depth is the distance from the gingival margin to the most apical extent of probe penetration. Accurate assessment of probing depth and changes in soft tissue attachment level are critically important in periodontics.

Current methods of periodontal probing use conventional, mechanical, or pressure-sensitive probes. Unfortunately, as a measurement technique, periodontal

probing has several sources of error that make it somewhat imprecise [63]. For example, the extent of probe penetration varies with insertion force [64], inflammatory status of the tissues [65], and diameter of the probe tip [66, 67]. Therefore, under routine clinical conditions, periodontal probes have an average measurement error of approximately ± 1 mm [68]. Examiner variation is a major source of error for conventional probes. Training and calibrating examiners decrease but do not eliminate examiner error. Probing errors also result from patient characteristics, such as anatomical differences in tooth contour, particularly in furcation areas. Probing error varies for different sites within the mouth [69]. Patient discomfort can also result in erroneous measurements [69]. Measurement error limits the ability to identify subtle differences in clinical values, which may be important in early disease detection and intervention. These errors diminish the likelihood of accurately identifying etiological factors correlated with disease progression. Finally, a fundamental limitation is that probing cannot identify disease activity status – which is important, given the cyclical and intermittent nature of periodontal disease activity.

OCT is particularly well suited for periodontal diagnosis, generating ultrahigh resolution cross-sectional images of dental tissues. It has been shown that OCT reliably depicts soft and hard tissue boundaries of the periodontium [70]. Moreover, OCT offers a precision of measurement that is not possible with traditional diagnostic methods. All current periodontal probing methods rely on physical measurements at single points along the tooth surface. To characterize a tooth using current probing methods, points are usually assessed. Thus, all current methods are not only tedious but also assume a direct relationship between these linear point measurements and the area of root surface attachment. OCT, on the other hand, provides rapid, consistent, and reproducible images of the surface topography, pocket morphology, and attachment level that is digitally recorded. These images pinpoint with greater accuracy sites of disease progression. OCT also provides quantitative information regarding the thickness and character of the gingiva, root surface irregularities, and the distribution of subgingival calculus. OCT may delineate changes in the optical properties or structural integrity of the gingival fiber. Comparing OCT images over time should allow clinicians to quickly detect potential sites of disease progression, perhaps even before attachment is lost. OCT images should prove to be extremely valuable in maintaining sites during supportive periodontal therapy. Electronic and visual recording of clinical data avoids subjectivity and transcription error that is associated with current metric techniques [65]. OCT has the capacity to detect disease in the soft tissue early, before bone resorption occurs. When Doppler algorithms are combined with OCT, blood flow can be localized and qualified (Fig. 74.12) offering the exciting potential to distinguish active from non-active periodontitis. Blood flow measurements may

also help elucidate the pathogenesis of periodontitis associated with diabetes and smoking [71, 72].

In a study by Baek et al., the successful use of OCT for monitoring periodontal ligament changes during orthodontic tooth movements was reported in rats [73] (Fig. 74.13). Clinical periodontal probing depth has been shown to correlate well with that measured in OCT images. The midfacial surface of 14 non-restored teeth (1 mandibular and 3 maxillary incisors, 4 maxillary and 6 mandibular premolars) was imaged using a prototype OCT system (1,310-nm wavelength light source, 14 mW, 95 dB dynamic range, 0.46 numerical aperture). Following OCT imaging, probing depths were measured in duplicate using a Michigan 0 probe. Important anatomic features including soft tissue surface contour, gingival crest, periodontal sulcus, and DEJ were identified in OCT images of all of the teeth examined. The cementoenamel junction was identified in 18 of the 28 images; the alveolar bone was presumptively identified in 20 of the 28 images. Probing depth as measured in OCT images was strongly correlated to probing depth as measured by conventional probing measurement ($r = 0.83$; $p < 0.05$). The midfacial surfaces of two restored teeth were imaged (1 maxillary molar, 1 maxillary premolar). Restoration margins and internal restoration contours were visualized and did not interfere with interpretation of OCT images of soft tissue landmarks.

Similarly, an all fiber-optic clinical OCT system was used to obtain 12-mm occlusal-apical OCT images of eight premolars in four healthy volunteers. Images were made in duplicate at the mesial facial line angle. This system employed a 6 mW, 1,310-nm light source and produced images that had an axial resolution of 21 μm. The images of periodontal tissues were similar to those obtained in

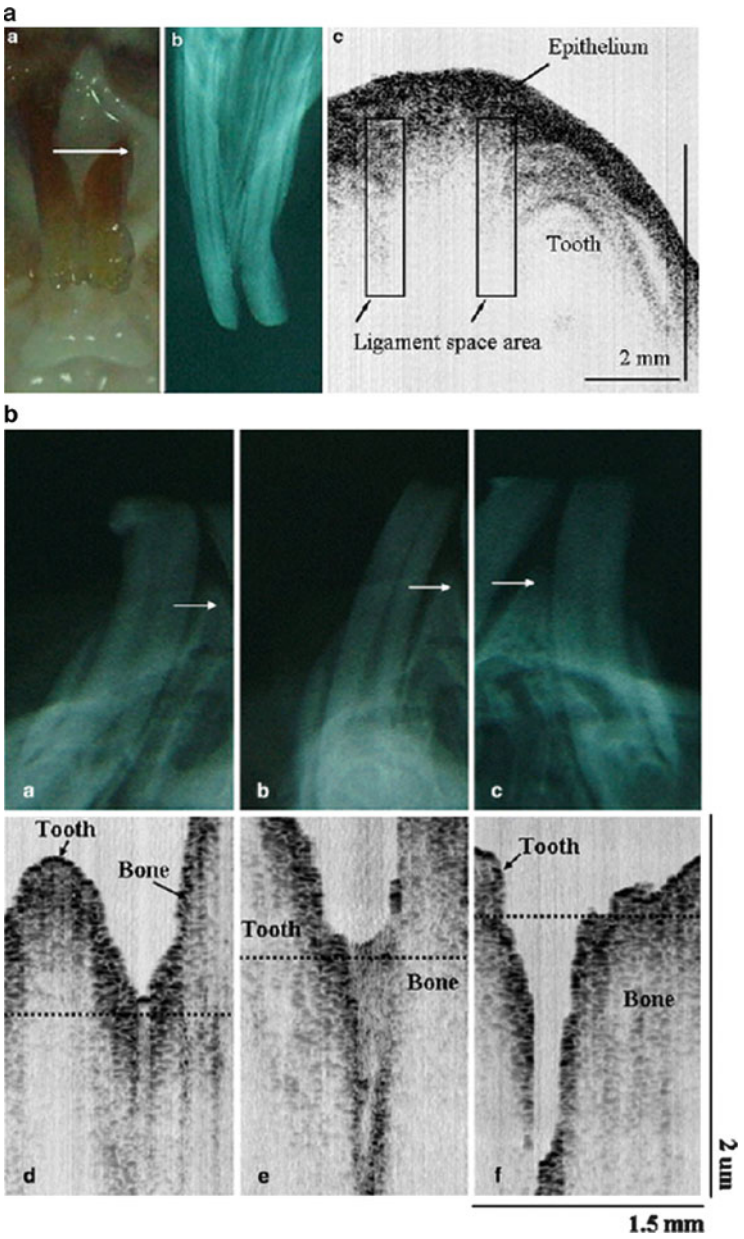

Fig. 74.13 Maxillary anterior tooth of a white rat. (**a**) shows data from the control group to which no orthodontic force was applied: (*a*) optical photograph; (*b*) radiographic image; (*c*) OCT image [73]. (**b**) shows radiographic (*top*) and OCT images (*bottom*) of the maxillary anterior teeth under several orthodontic forces: (*a*, *d*) 5 gf; (*b*, *e*) 10 gf; (*c*, *f*) 30 gf forces, respectively. The two-dimensional OCT image in the *bottom* was taken along the *arrow* direction in each of the *top* (radiographic) figures [73]

previous studies. Characteristic signals representing the sulcus and attached tissues were identified in all images. Premolar sulcular depth as determined from the OCT images ranged from 1.1 to 2.5 and was strongly correlated with probing depth ($r = 0.88$; $p < 0.05$). We defined attached tissues in the OCT images by a uniform signal intensity with no discernable tissue interfaces that extended from the base of the sulcus to the alveolar crest. Measurement of attached tissues in the OCT images ranged from 1.1 to 3.8 mm. The lowest values for attached tissues were found in three teeth with coronal restorations. Signals presumptively identified as the alveolar crest were identified in 60 of the 64 images. The thickness of the gingiva covering the alveolar crest ranged from 0.4 to 1.4 mm. Two teeth had characteristic signals representative of the root surface covered by a thin mucosal tissue; these sites were presumptively identified as fenestration defects. While the OCT images of the root surface are unmistakable, definitive proof of OCT to image fenestration defects requires further investigation. The results of this study, however, convincingly demonstrate capacity of OCT to determine gingival thickness and the shape and contour of the alveolar crest. Visualizing these anatomical features represents a significant contribution to periodontal surgical treatment planning.

74.3 Dental Implants

Endosseous dental implants have been established as a predictable treatment modality for the replacement of missing teeth. While only 2 % of implants fail within the first year, the failure rate rises to 10 % at 5 years and nearly 15 % at 10 years [74, 75]. A successful implant is defined as one that is not mobile and has no peri-implant radiolucencies, no clinical signs of infection, and no discomfort or pain [76–89]. Favorable vertical soft tissue relationships have been demonstrated to be important in the success of dental implants, particularly in maintaining crestal bone height [83]. Peri-implantitis is defined as an inflammatory process affecting the tissues around an osseointegrated implant in function, resulting in progressive loss of supporting bone around the implant [82–84]. The prevalence of peri-implantitis is unknown, although researchers estimate that it ranges from 8 % to as high as 44 % [82–84]. The diagnosis of peri-implantitis is complicated because adequate diagnostic methods to evaluate soft tissues are unavailable and because it is difficult to monitor crestal bone loss around implants. Ideally, implants should lose minimal bone. The implant is at significant risk when more than one-half of the implant height has lost crestal contact [74, 88].

Studies have shown that once peri-implant inflammation is established, it is difficult to eradicate. Unequivocally, any sign of peri-implantitis threatens the longevity of implant restorations and represents a significant health care cost. For these reasons, after implant placement, patients should be examined at regular intervals to evaluate clinical signs and symptoms of peri-implant disease and to receive maintenance therapy [78, 82, 89].

Current implant diagnostic procedures rely on visual estimates of clinical signs of inflammation or single-point physical measurements, such as probing depth.

These techniques lack sufficient sensitivity to detect peri-implantitis at an early stage. Current methods are also subject to high levels of measurement error, and extensive clinical calibration of examiners is required to achieve inter-examiner reliability. The inability to detect problems early jeopardizes effective care. More sensitive tests are needed to understand the causes of late implant failure, to reliably evaluate differences in clinical outcomes between various implant systems, or to evaluate the success of therapeutic interventions for the treatment of peri-implantitis [82, 90].

74.3.1 Expected Improvement of Implant Diagnoses Using OCT

OCT can be used clinically to detect early peri-implantitis with greater sensitivity than current diagnostic methods (Figs. 74.13a, b), with images providing rapid, consistent, and reproducible documentation of peri-implant soft tissue morphology and attachment level. Quantitative information regarding microstructural architecture including the character of the gingiva as well as implant soft tissue relationships is generated. More importantly, OCT identifies the earliest signs of inflammation, so minimal that clinical examination is unlikely to distinguish them. Comparing OCT images over time should prove to be extremely valuable in monitoring health in implant sites during maintenance therapy. Moreover, OCT imaging offers the exciting potential to detect peri-implantitis before significant osseous destruction occurs.

Histological studies in animals have shown that gingival connective tissue forms a scar-like fibrous connective tissue adjacent to titanium implant surfaces, while peri-implantitis is characterized by a disorganized connective tissue containing more vascular elements. Our preliminary data demonstrate that in OCT images of healthy implant sites, collagen appears well organized, and, because of its birefringent nature, it produces a characteristic high OCT signal intensity. OCT images of soft tissue surrounding failing implants are markedly different from images of healthy implant sites and are characterized by linear signal deficits, low-intensity collagen signals, and pronounced increases in vascular elements. To evaluate the feasibility of OCT imaging for implant diagnoses, we conducted preliminary studies in three patients with failing implants. Figure 74.14a demonstrates a 6-mm OCT image made from the midfacial surface of a healthy dental implant site. The peri-implant tissues show no clinical signs of inflammation, and the probing depth measured 1 mm. Figure 74.14b is an OCT image of a plasma-coated IMZ implant. This image illustrates the characteristic findings associated with failing implants, low collagen signal, and increased vascular elements.

OCT will improve clinical evaluation of peri-implant soft tissues and will provide significant advantages over existing diagnostic procedures. Two- or three-dimensional OCT images can depict the topography of the implant sulcus and the relationship of implant soft tissue interfaces. These images can be stored in the patient record and be used to monitor implant health over time. The imaging process is painless, and patient acceptance is far greater than for other dental procedures. Because OCT is noninvasive, it can be performed repeatedly without any risk to the patient.

74.4 Oral Dysplasia and Malignancy

According to the American Cancer Society, 1,220,100 patients were diagnosed with cancer in the year 2000. In the same year, 552,200 persons were expected to succumb to cancer [91]. Despite significant advances in cancer treatment, early detection of oral cancer and its curable precursors remains the best way to ensure patient survival and quality of life. Oral cancer will claim approximately 10,000 lives in the USA this year [92, 93]. Accounting for 96 % of all oral cancers, squamous cell carcinoma is usually preceded by dysplasia presenting as white epithelial lesions on the oral mucosa (leukoplakia). Leukoplakias develop in 1–4 % of the population [94]. Malignant transformation, which is quite unpredictable, occurs in 1–40 % of leukoplakias over 5 years. Dysplastic lesions in the form of erythroplakias carry a risk for malignant conversion of 90 %. Tumor detection is complicated by a tendency toward field cancerization, leading to multicentric lesions [94]. Current techniques require surgical biopsy of lesions, which are often benign, yet they detect malignant change too late. Of all oral cancer cases documented by the National Cancer Institute Surveillance, Epidemiology, and End Results Program, advanced lesions outnumbered localized lesions more than 2:1. Five-year survival rate is 75 % for those with localized disease at diagnosis but only 16 % for those with cancer metastasis [92, 93].

Two basic facts indicate that early detection of oral malignancy should be possible to a far greater extent than is currently seen:

1. ***Oral cancer is predominantly preceded by white or red lesions which are visible to the naked eye and which are often present for a considerable period of time prior to transformation.*** A noninvasive diagnostic modality would permit monitoring of these lesions at regular intervals and detection of transformation and any treatment needs at a very early, relatively harmless stage.

2. ***High-risk populations are clearly defined.*** Tobacco use, alcohol abuse, urban environment, African-American background, poor diet, and frequent exposure to sunlight are primary predisposing factors for oral malignancy [95, 96]. A fast, mobile, relatively inexpensive noninvasive diagnostic modality would permit regular screening for oral lesions and subsequent transformation at an early, relatively harmless stage.

74.4.1 Existing and Emerging Techniques for Oral Diagnosis

1. **Visual examination and biopsy** Oral cancer can be detected by dentists and physicians, but physicians do not routinely inspect their patients for suspicious oral lesions, and dentists are also remiss in the early diagnosis and referral for oral cancer. Since 11 % of dentists and 45 % of physicians do not feel adequately trained to complete an effective oral cancer examination, this results in their failure to examine for oral cancer [96]. The current approach to detecting the transformation of leukoplakia/erythroplakia to squamous cell carcinoma is regular surveillance combined with biopsy or surgical excision. However, visual examination provides very poor diagnostic accuracy, and biopsy techniques are invasive and unsuitable for regular screening of high-risk sectors of the population. Adequate visual identification and biopsy of all such lesions to ensure that they are all recognized and diagnosed are difficult, given the often multifocal nature of oral malignancy [93].
2. **Vital staining** Several studies have investigated the use of vital staining with agents such as Lugol iodine, toluidine blue, and tolonium chloride for detection of oral malignancy. Although the sensitivity of these agents in the hands of experts generally approximates 90 %, specificity of these agents is poor; sensitivity rapidly decreases when this modality is used by nonexperts such as screeners in field units. Extensive clinical experience is necessary to perform these examinations adequately [97–103].
3. **Oral brush cytology** Using cytological examination of "brush biopsy" samples as a noninvasive method of oral diagnosis has been shown to provide moderate sensitivity levels of detection of oral epithelial dysplasia or squamous cell carcinoma (70–90 %) but poor specificity (3–44 %). Thus, this approach is of limited diagnostic value without augmentation by traditional biopsy [103–105].
4. **Photosensitizers** Topical or systemic application of photosensitizers can render pathologic tissues fluorescent when exposed to specific wavelengths of light [106]. While several studies have demonstrated the use of porphyrins as photosensitizers, their accumulation in skin after systemic administration can cause phototoxic reactions upon exposure to sunlight [107, 108]. An alternative approach is to stimulate synthesis of photosensitizing agents in situ with a photoinactive precursor. The photosensitizer protoporphyrin IX (PpIX) is an immediate precursor of heme in the biosynthetic pathway for heme. In certain types of cells and tissues, the rate of PpIX synthesis is determined by the rate of

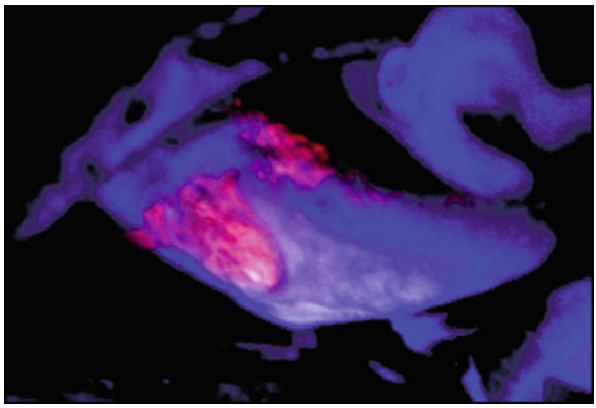

Fig. 74.15 Fluorescence imaging of squamous cell carcinoma of the tongue (*reddish color*) 3 h after topical application of Photofrin® [109]

synthesis of 5-aminolevulinic acid (ALA), which in turn is regulated via a feedback control mechanism governed by the concentration of free heme. The presence of exogenous ALA bypasses the feedback control of this process, inducing the intracellular accumulation of photosensitizing concentrations of PpIX. A selective accumulation of PpIX occurs in areas of increased metabolism such as tumor cells [106]. The resulting tissue-specific photosensitization provides the basis for using ALA-induced PpIX for photodynamic diagnosis and therapy, whereby far lower light doses are used for photodynamic diagnosis. This technique has shown great promise in animal and human studies for head and neck cancers including oral lesions [108–111] (Fig. 74.15). Limitations include the localization of induced fluorescence to the surface layers of the epithelium and the fluorescence caused by common coexisting clinical pathologies such as candidal superinfection, hyperplasia, atrophy, and ulceration.

5. **Spectroscopy** Various types of optical spectroscopy have been investigated to effect a noninvasive, real-time in situ assessment of tissue pathology. All of these methods have one basic principle in common: the optical spectrum of a tissue contains information about the biochemical composition and/or the structure of the tissue which conveys diagnostic information. Malignancy-related biochemical and morphologic changes perturb tissue absorption, fluorescence, and scattering properties. The biochemical information can be obtained by measuring absorption/reflectance, fluorescence, or Raman scattering signals. Structural and morphological information may be obtained by techniques that assess the elastic-scattering properties of tissue [112, 113].

   Reflectance spectroscopy can probe changes in epithelial nuclei that are important in precancer detection, such as mean nuclear diameter, nuclear size distribution, and nuclear refractive index [114]. Applications under investigation include the cervix [115], skin [116], colon [117], oral cavity [114], and esophagus [118].

   Fluorescence spectroscopy can probe changes in epithelial cell metabolism, by assessing mitochondrial fluorophores, and epithelial-stromal

interactions, by assessing the decrease in collagen cross-link fluorescence that occurs with precancer. Areas of application include the cervix, skin, bladder, oral cavity, and esophagus [113, 118–132].

Raman spectroscopy uses laser excitation and the scattering effect is observed in the target tissues. Inelastic scattering results in a frequency shift in the reflected Raman spectra, which are functions of the type of molecules in the sample. Thus, the Raman spectra hold useful information on the different chemical compounds. Raman spectroscopy has been investigated for medical diagnosis applications in general and for the investigation of sites such as the skin, cervix, larynx, esophagus, and colon [115, 119, 133–144].

Significant challenges to the use of diagnostic spectroscopy include the often low signal-to-noise ratio, difficulty in identifying the precise source of signals, data quantification issues, and establishing definitive diagnostic milestones and endpoints. Limited tissue penetration and concerns about mutagenicity when using UV light present further clinical challenges. The abundance of data/information generated in association with our incomplete understanding of the carcinogenesis process render data analysis and interpretation very complex. Many studies have been performed on small numbers of small biopsy samples which do not necessarily translate directly or accurately to the clinical situation.

6. **Optical coherence microscopy** This modality combines the subcellular resolution of confocal microscopy with the increased sensitivity and penetration depth of optical coherence tomography (OCT) to noninvasively acquire details similar to that available in histologic tissue evaluation. Typically, a resolution of 2 μm and a 200- to 500-μm field of view at a penetration depth of up to 600 μm are reported in the literature [145–150]. This suggests that OCM has the potential to image epithelial tissues with the subcellular resolution needed to assess their pathologic state. Challenges include the small field of view, limited penetration depth (although better than confocal reflectance microscopy), and the need for an intraoral probe.
7. **Confocal reflectance microscopy** In vivo confocal imaging resembles histological tissue evaluation, except that three-dimensional subcellular resolution is achieved noninvasively and without stains. In epithelial structure, resolution of 1 μm has been achieved with a 200–400-μm field of view. In skin, where cytoplasmic melanin provides a strong source of backscattering, confocal microscopes have captured morphologic changes in cytologic structure and visualized microvasculature in both basal cell carcinomas and melanomas [151–158]. In amelanotic epithelial tissues, where cell nuclei provide the primary source of reflected light, recent work showed that reflectance confocal imaging of normal and precancerous cervical tissue can characterize nuclear size, nuclear density, and nuclear-to-cytoplasmic ratio without the need for tissue sectioning or staining. In these ex vivo studies, confocal images were used to discriminate high-grade cervical precancers with a sensitivity of 100 % and a specificity of 91 % in a study of 25 samples [159, 160]. Similarly, nuclear-to-cytoplasmic

differences from images of normal and esophageal cancer cells were used to identify cancer with a diagnostic accuracy of 90 % [161]. Confocal imaging of oral mucosa has resolved subcellular detail in the lip and tongue [162] and oral squamous cell carcinoma from multiple sites [163]. While this technology can provide detailed images of tissue architecture and cellular morphology, a very small field of view and limited penetration depth of 250–500 μm considerably reduce the clinical usefulness of this approach.

74.4.2 OCT Diagnosis

Performing studies in the hamster cheek pouch model and in humans, the macroscopic and vascular status of healthy, dysplastic, and malignant oral mucosa has been imaged using in vivo OCT/ODT. Multiple epithelial and subepithelial layers as well as the presence or absence of basement membrane can be visualized. Epithelial invasion during malignant transformation was clearly identified. Blood vessel presence, size, and localization relative to tumor tissue were visible, and blood flow could be quantified [164, 165]. In oral malignancy, small blood vessels were often seen in close proximity to tumor tissue, and using IHC a progressively increased blood vessel count with decreasing level of tumor differentiation was demonstrated [166, 167].

Movement artifacts during OCT registration in human subjects do not appear to be a problem when using the newer, faster imaging systems. As long as patients are seated comfortably in a clinical chair with headrest and neck support, this was not an issue at all, as evidenced by Fig. 74.16. Epithelium, lamina propria, and basement membrane are clearly visible. Structural appearance in the OCT image parallels histological appearance, showing epithelial thickening, loss of stratification in lower epithelial strata, epithelial downgrowth, and presence of basement membrane in dysplastic tissue (Fig. 74.16).

In a clinical study involving 50 patients with leukoplakia or erythroplakia, oral lesions, pre-standardized clinicians were able to diagnose oral lesions from noninvasive in vivo OCT images with approx. 85 % accuracy vs. the gold standard, surgical biopsy, and histopathology [164]. Another study in 73 patients with 78 suspicious oral lesions identified similar levels of diagnostic accuracy [165]. These data demonstrate the excellent capability of in vivo OCT for detecting and diagnosing oral soft tissue pathologies in patients.

74.5 Future Potential

The potential for OCT-based diagnostics in the oral cavity is excellent. The penetration depth of this modality in oral hard and soft tissues is adequate for most dental applications. Ongoing innovations, such as the development of Fourier-domain OCT, which enable up to 100× faster acquisition of 3D OCT images, and of spectral OCT, which provide enhanced imaging contrast, will permit spatially

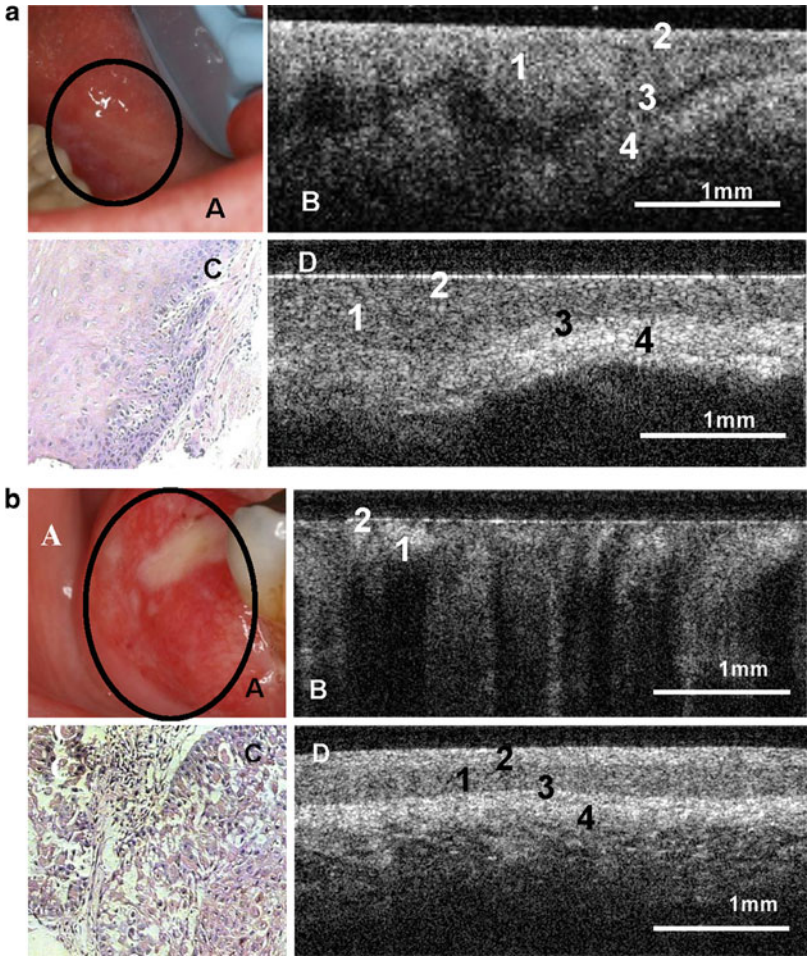

Fig. 74.16 (**a**) Photograph (A), in vivo OCT image (B), and H&E (C) of dysplastic buccal mucosa. In vivo OCT image of normal buccal Mucosa is shown in (D). (**b**) Photograph (A), in vivo OCT image (B), and H&E (C) of alveolar ridge with squamous cell carcinoma. In vivo OCT image of normal alveolar Mucosa is shown in (D). 1-stratified squamous epithelium, 2-keratinized epithelial surface layer, 3-basement membrane, 4-subucosa

resolved detection and quantification of changes within the tissues such as demineralization through their spectroscopic properties. Emerging MEMS-based and 3D techniques are significant factors permitting enhanced speed and effectiveness of the images obtained. Based on the data available to date, direct clinical in vivo imaging shows great potential for improving diagnostic capabilities in the oral cavity for applications ranging from decay, through periodontal disease, to oral malignancy.

Anatomic Optical Coherence Tomography of Upper Airways

75

Anthony Chin Loy, Joseph Jing, Jun Zhang, Yong Wang, Said Elghobashi, Zhongping Chen, and Brian J. F. Wong

75.1 Introduction

The upper airway is a complex and intricate system responsible for respiration, phonation, and deglutition. Obstruction of the upper airways, as in obstructive sleep apnea (OSA), afflicts 12–18 million Americans. Pharyngeal size and shape are important factors in the pathogenesis of OSA. Nocturnal loss in pharyngeal muscular tone combined with high pharyngeal resistance leads to collapse of the airway and periodic partial or complete upper airway obstruction. These episodes, though brief, can lead to significant adverse health outcomes, including cardiac,

neurologic, and metabolic sequelae. Though prevalent in the population, the pathogenesis of OSA is poorly understood. The most common explanation in the literature assumes that OSA is a function of decreased pharyngeal size with concomitant increased pharyngeal resistance. These factors combined with the relaxation of the pharyngeal dilator muscles predispose the pharynx to collapse during sleep.

The three major areas of obstruction are the nose, the palate, and the hypopharynx though it is more likely the combination of two or more of these areas that contribute to OSA. In the Fujita classification, the patterns of obstruction were classified by anatomic location:

1. Type 1: collapse in the retropalatal region only
2. Type 2: collapse in both the retropalatal and retrolingual regions
3. Type 3: collapse in the retrolingual region only

The identification of the area of collapse is needed to direct surgical treatment though this is not often accomplished, and clinical judgment largely dictates the selection of operative approach. Operations and procedures are directed at the most common areas of obstruction. Nasal surgery includes septoplasty, turbinate reduction, and correction of internal and external valve deformities. Nasal surgery rarely corrects OSA by itself, but does allow greater nasal patency for use of Continuous Positive Airway Pressure (CPAP). The most common operation used to treat OSA is the uvulopalatopharyngoplasty (UPPP), which is performed by resecting redundant palatal and pharyngeal tissue. Though it is the most common operation for OSA, the procedure has a widely cited success rate of less than 50 % depending on the severity of disease [1]. Other OSA operations escalate in complexity and address other organs and tissue, but lack of detailed anatomic information on the site or level of obstruction leads to modest improvement in a majority of patients. More aggressive procedures include base of tongue reduction, advancement of the maxilla and mandible to anteriorly displace the base of tongue, suspension of the larynx to the chin, and even tracheostomy.

The failure rate in the surgical treatment OSA stems from a lack of diagnostic information on the site and mechanism of airway collapse. Current diagnostic techniques include magnetic resonance imaging (MRI) and computed tomography (CT), though these studies are not routinely ordered, as MRI and CT are expensive, inconvenient for the patient, generally performed during wakefulness, and in the case of CT necessitate exposure to ionizing radiation. MRI provides great detail of the soft tissue structures of the upper airways while avoiding exposure to ionizing radiation. However, the study is expensive, while the length and noise of the exam may prevent collection of sleep data without sedation. Use of sedatives alters normal physiological control of the pharyngeal musculature and hence limits the utility of this approach in mimicking natural sleep. In regard to young children, sedation is necessary to perform MRI. Computed tomography provides detailed images of bone and soft tissue and is a considerably shorter exam than MRI. However, the exposure to ionizing radiation limits serial examinations over the respiratory cycle, limits the use of multiple exams to document postoperative

changes, and again is applied conservatively in children. Both MRI and CT provide information at a single point in time; they fail to provide volumetric data over the course of the breathing cycle.

More frequently, in-office fiber-optic endoscopy is used to estimate the loci for pharyngeal collapse in the OSA patient. Use of the Mueller maneuver, inhalation against a closed nose and mouth, to identify areas of obstruction is commonly used to better identify surgical treatment targets. The image of the airway through an endoscope is subject to significant distortion due to the wide-angle optics of these instruments. Measurements of airway diameter are thus largely subjective and are dependent on the relative location of the endoscope within the airway [2].

Polysomnography remains the gold standard in the diagnosis of OSA. Polysomnography (e.g., sleep study) is a multiparametric test used in the study of sleep and as a diagnostic tool in sleep medicine. It is an overnight diagnostic test performed during natural sleep that includes electroencephalography; electrooculography; measurement of nasal and oral airflow; electromyography, body, chest, and abdomen position monitors; electrocardiography; and pulse oximetry. Though extensive, it provides only physiological data for diagnosis; it does not provide structural data for treatment [1]. In face of the limitations of current clinically available methods to diagnose OSA, multiple alternative technologies have been proposed as a means to identify the locus of airway obstruction. Sampson's group in Perth developed a long-range optical coherence tomography (LR-OCT) system as a minimally invasive and cost-effective means of acquiring detailed structural data of the upper airway [3, 4]. It is safe for use in patients requiring multiple scans as no ionizing radiation is involved. It allows the physician to acquire serial data sets for the analysis of pre- and postoperative states. The lack of ionizing radiation also makes it safe for extended exposure, and the use of contemporary Fourier-domain technology facilitates rapid data collection with the entire length of an airway scanned in less than 1 min. In LR-OCT, a very small diameter catheter (smaller than conventional endoscopes) is inserted through the nose and into the pharynx. The placement of this imaging probe is similar to the placement of a feeding tube, pH monitor, or fiber-optic endoscope – all of which are routinely placed by physicians in multiple specialties. The probe tip rotates thus acquiring axial images of the pharynx, which can be reconstructed to evolve a structural image of the airway. In this implementation, the technology functions as an optical range finder, and high-resolution anatomic information of the subsurface tissues is not required. LR-OCT provides detailed structural and quantitative data of the upper airway that is not provided by current diagnostic imaging [5]. This information is crucial to the advancement of understanding the pathophysiology of OSA and the application of treatment to specific problem areas of the airway.

Conventional OCT provides detailed three-dimensional tomographic images of tissues with high axial and lateral resolution and beyond ophthalmology has found several uses in the imaging of hollow organs such as the urinary [6], GI [7], and pulmonary systems [8–12] However, the conventional use of OCT in the upper airways for structural imaging is limited due to a scanning range of only a few

millimeters or less. Long-range optical coherence tomography (LR-OCT) works as an optical range finder in circumstances where detailed microanatomic information on the surface is not required. Rather than focusing on microscopic substructure, LR-OCT increases the axial scanning range to image macroscopic anatomy [13]. This application is well suited for imaging the upper airway, where gross images can be used to examine the contours of the airway.

Long-range OCT systems were first described by Leitgeb, who used a phase shifting algorithm in order to double the effective imaging range of conventional OCT. With the increased imaging distance, the system used by Leitgeb also utilized frequency-domain optical coherence tomography to achieve high-speed probing [14]. In Sampson's group the use of LR-OCT in the upper airway is first mentioned in 2003 to measure the area of the human pharynx in patients with sleep apnea. The LR-OCT used at that time had a radial scanning range of 26 mm and a rotation rate of 5 Hz [15]. When first demonstrated by Huang in 1991, OCT was primarily used in ophthalmic imaging. Compared to the systems being used today, OCT was dominated by time-domain imaging. Time-domain imaging is limited by the need to scan through various path lengths in the reference arm in order for the sample arm to be interpreted. In the dynamic upper airway, slow scanning speeds produce motion artifact during the respiratory cycle [16]. In 1995, Fercher described Fourier-domain OCT (FD-OCT), which allowed for high-speed image acquisition (up to 100 times) and a decreased signal-to-noise ratio when compared with time-domain OCT [17]. FD-OCT measures all the optical echoes at once rather than sequentially as in time-domain OCT. This significantly increases sensitivity. Mechanical scanning of the reference path is unnecessary in FD-OCT, increasing the axial scan rate and imaging speed [18]. In recent studies utilizing a time-domain system, a lengthwise scan of the upper airway (12–18 cm) is completed in 12 min [19]. In the following, we describe an LR-OCT system using Fourier domain that is capable of completing a scan of comparable distance of the human airway in under a minute. The increased speed of acquisition decreases motion artifact experienced in previous experiments and negates the need to use respiratory gating to account for changes in the diameter of the airway that would be experienced in slower systems. There has been an increased level of interest in FD-OCT since then with developments improving the quality and speed of the systems. Recent systems employing Fourier-domain locked lasers have shown imaging speeds up to 370,000 axial scans/s, 100 times faster than standard OCT [20].

75.2 Current System

The current system is a catheter-based Fourier-domain optical coherence tomography (Fig. 75.1). Output light from a 1,310-nm swept source laser (26-mW average power, 50-kHz A-scan rate, 102-nm FWHM bandwidth, 5-mm coherence length in air) is split by a 90–10 couple into sample and reference arms, respectively. The reference arm utilizes an acousto-optic modulator (AOM) to generate a carrier

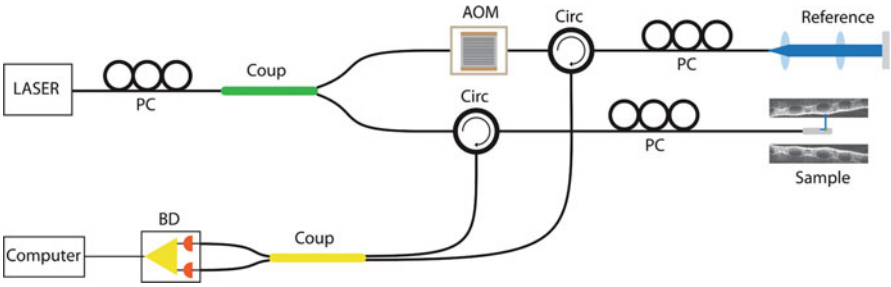

Fig. 75.1 Current long-range OCT system

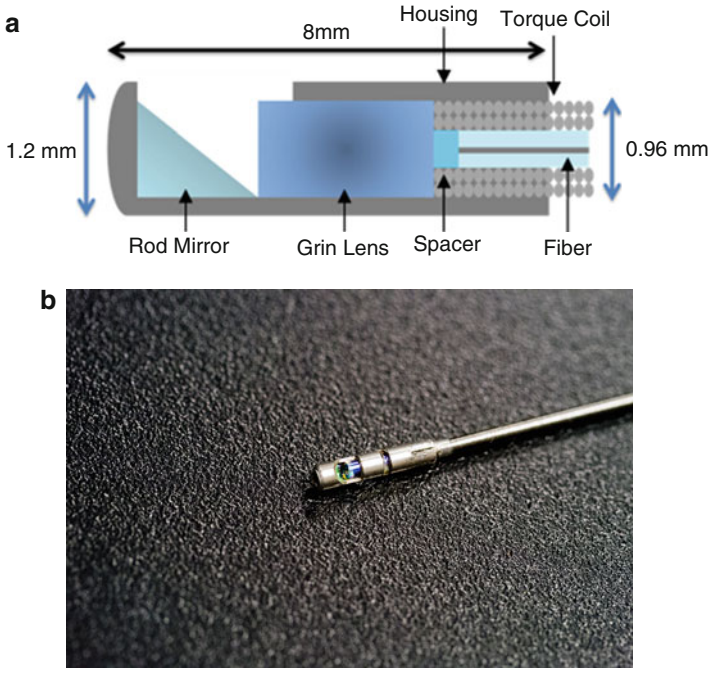

Fig. 75.2 Schematic (**a**) and picture (**b**) of LR-OCT probe

frequency of 150 MHz. No modulator is used in the sample arm to maximize signal and prevent insertion loss typically seen in AOMs. The resulting signal is converted in a voltage signal by a balanced detector and sampled by a 12-bit data acquisition card. Digitizing is performed at a sampling rate of 1 GHz allowing complete coverage of the wavelength sweep in 8192 points to optimize subsequent fast Fourier transform (FFT) calculations. The endoscopic OCT probe (Fig. 75.2) has an outer diameter (OD) of 1.2 mm, smaller than conventional endoscopes currently used in clinics. Rotational scanning is accomplished by using a fiber-optic rotary

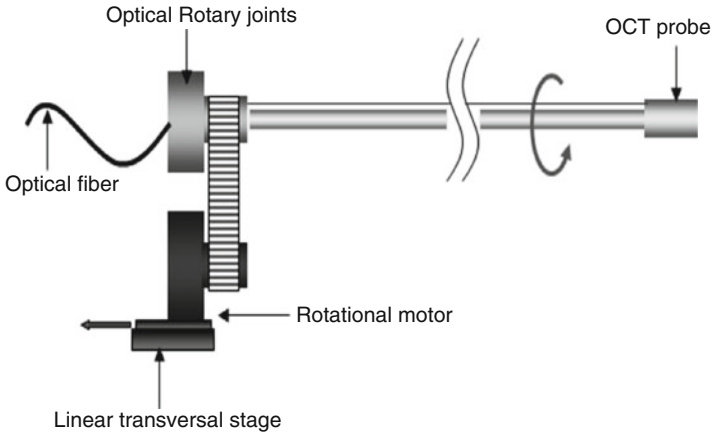

Fig. 75.3 Schematic of external rotational motor and probe

joint coupled with an externally mounted rotational motor. Torque from the motor is translated from the proximal to the distal end of the probe by a triple wound commercially available torque coil (outer diameter, 0.965 mm) (Fig. 75.3). The probe was designed to have an extended working distance of 20 mm. A Gradient Index Rod (GRIN) lens (0.23 pitch, 1-mm OD) combined with a measured spacer made of no-core fiber focuses the light from the probe. The no-core fiber was first spliced and then cleaved to leave a 150-um portion at the end of a standard single mode fiber. UV glue was used to attach fiber and GRIN lens and placed within a custom-designed metal housing. The probe is able to achieve a frame rate of 25 frames per second with each frame having 2,000 A-scans. During imaging, the probe is protected using a fluorinated ethylene propylene (FEP) sheath (OD 1.8 mm) that is first introduced into the airway. A dual motor linear stage was used for linear translation at 0.5 cm/s allowing for helical scanning over 20 cm in the span of 40 s. The axial resolution of the system was 10 μm in tissue and the lateral resolution was 112 μm, which is mainly a trade-off with extending the working distance of the probe.

Acquired OCT data is processed using a modified algorithm [21]. An FFT is first performed to convert the signal into the frequency domain. Multiplication by the Heaviside function isolates the positive frequencies, and an inverse FFT is performed to obtain a complex time-domain signal. A demodulation step removes the carrier frequency from this term and compensates the dispersion cause by the acousto-optic modulator (AOM) by multiplying the negative phase values of a single A-scan obtained when the optical path length difference (OPD) of the reference arm with the AOM and sample arm is zero. The resulting remapped data is linearized in the K-domain via a recalibration step followed by a final FFT to recover the spatial information. Our OCT software package is written entirely

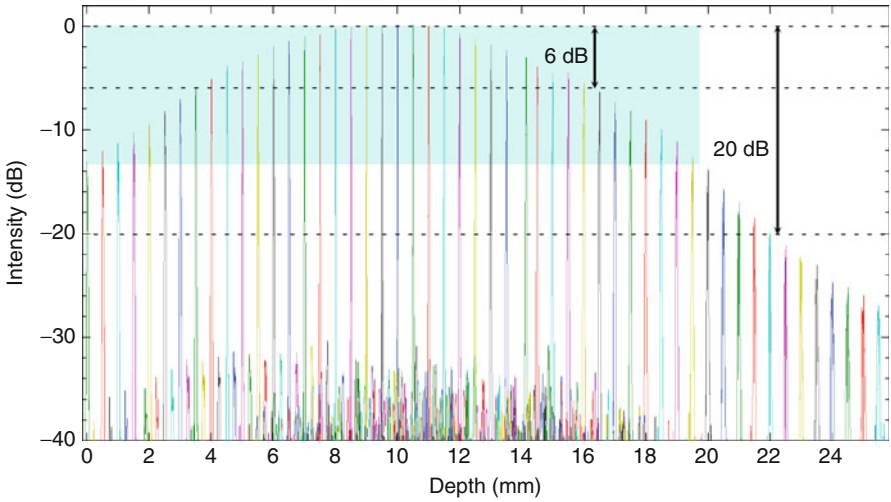

Fig. 75.4 Sensitivity of the current LR-OCT system as a function of depth

in C++ and features a multithreaded design for data acquisition, image processing, and display that allows for maximizing computational throughput. The entire OCT algorithm is processed on a commercial graphical processing unit (GPU) using Nvidia's CUDA package. This allows for frame-by-frame processing with a maximal frame rate of 25 frames per second for a given frame size of 2,000 A-lines.

75.3 Validation

The point spread function (PSF) versus imaging range graph (Fig. 75.4) was acquired by using a partial reflector at various distances and normalizing by the measured power. The system features a 6 dB sensitivity roll off at 12 mm total offset, which is in line with the expected imaging range give the removal of the mirror image.

In order to test the imaging capabilities of our system, a silicone airway was constructed. The airway was selected from a collection of adult CT scans devoid of pathology in the upper airway. The CT scan was loaded into commercial 3D rendering software, Amira, and a Standard Tessellation Language (stl) file was created for use as a model. Using rapid prototyping hardware, a phantom airway was molded in a green silicone matrix to ensure reflective properties compatible with the anatomical optical coherence tomography (aOCT) hardware (Fig. 75.4). The endoscopic LR-OCT probe and FEP sheath was introduced into the model airway in similar fashion to that of an actual research subject.

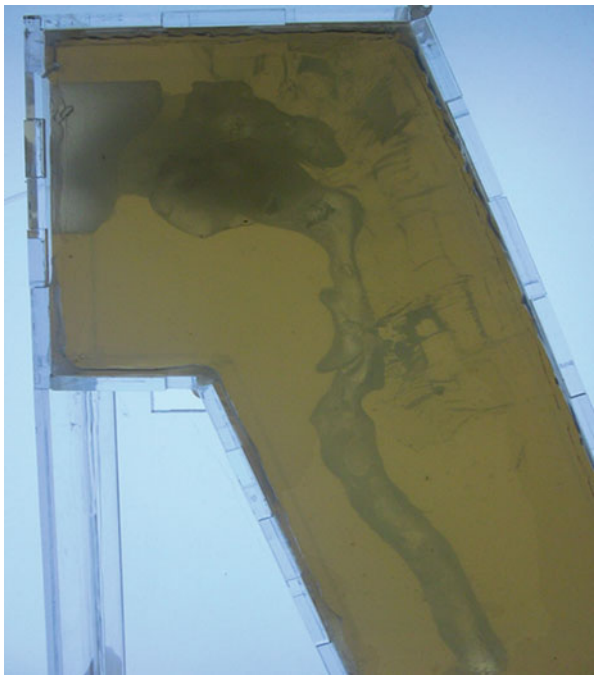

Fig. 75.5 Translucent model of normal phantom airway

A translucent model airway (Fig. 75.5), an exact copy of the green silicone phantom, was constructed to observe the pathway of probe and FEP sheath in the upper airway. A pullback scan of the phantom airway was performed. The resulting OCT data was compared against the original CT scan. As expected, the acquired OCT images are highly correlated with the original CT scan slices (Fig. 75.6).

75.4 In Vivo Human Studies

In vivo human adult imaging has been performed on adult and pediatric subjects. Patients' upper airway was anesthetized using 4 % topical lidocaine administered bilaterally through the nostril; likewise the pharynx was anesthetized with an aerosolized benzocaine. Ten minutes was allowed to elapse in order for the anesthesia to take full effect. The subject was placed into the classical position for in-office fiber-optic endoscopy exam. The FEP sheath was inserted into the anesthetized nostril along the length of the upper airway to the level of the esophagus. FEP tubing was marked as it exited the nostril for repositioning in case movement of the pharynx shifted the probe out of position. The tubing was secured using paper tape attached to the bridge of the nose. The LR-OCT probe was

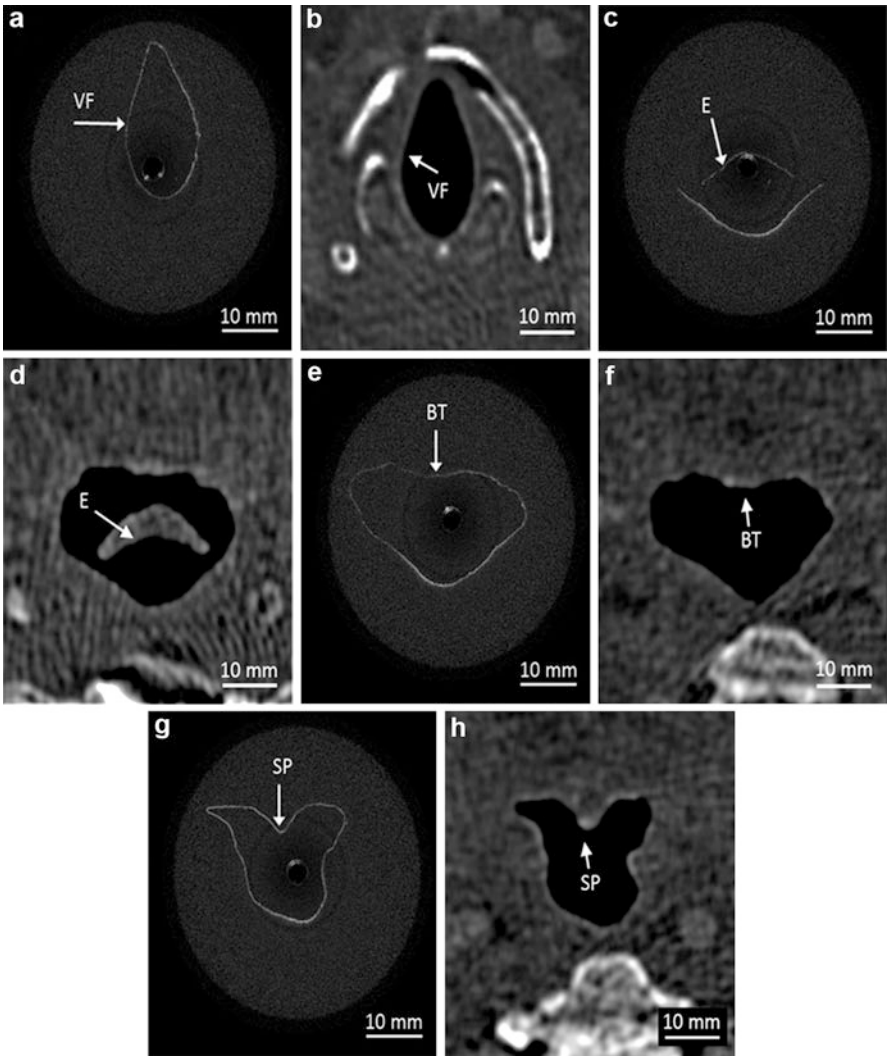

Fig. 75.6 Comparison of OCT images (**a**, **c**, **e**, **g**) in model with normal CT scan (**b**, **d**, **f**, **h**). Vocal folds (*VF*), epiglottis (*E*), base of tongue (*BT*), and soft palate (*SP*)

then advanced down the FEP tubing until resistance was appreciated (signifying the probe has reached the end of the FEP tubing). Placement of the FEP tubing and probe was confirmed using a flexible laryngoscope introduced through the second nostril, after which the laryngoscope was removed. The LR-OCT probe was retracted through the airway at a rate of 0.5 cm per second over a distance ranging from 18 to 23 cm. Multiple sets of images were taken from each subject.

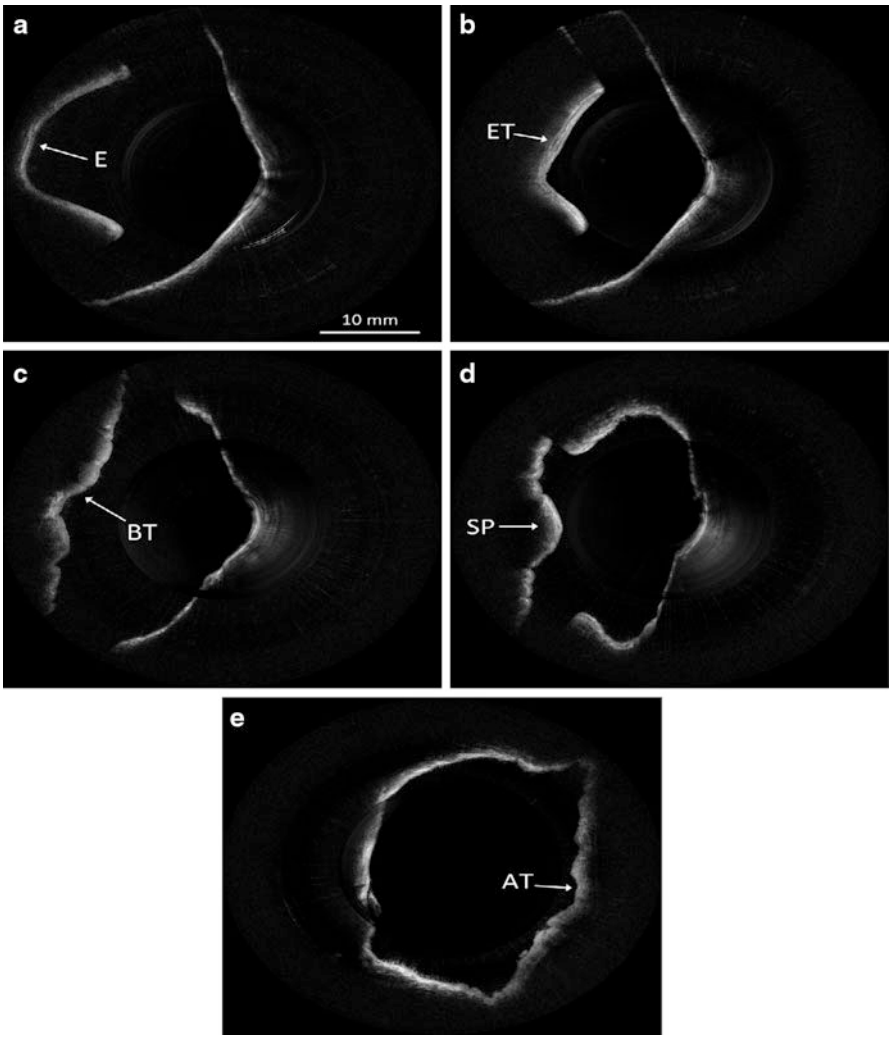

Fig. 75.7 Examples of in vivo LR-OCT images

Examples of acquired OCT data are shown in Fig. 75.7. Each cross-sectional image is 43 × 43 mm. Anatomical structures such as the epiglottis (Fig. 75.7a), base of tongue (Fig. 75.7b) with associated tonsillar tissue, the soft palate and uvula (Fig. 75.7c), and adenoidal tissue (Fig. 75.7d) can be identified by their distinct tissue characteristics. Unlike OCT data acquired in phantom testing, up to 1.5 mm of tissue penetration was achieved and tissue substructure such as the elastic cartilage in the epiglottis can be seen.

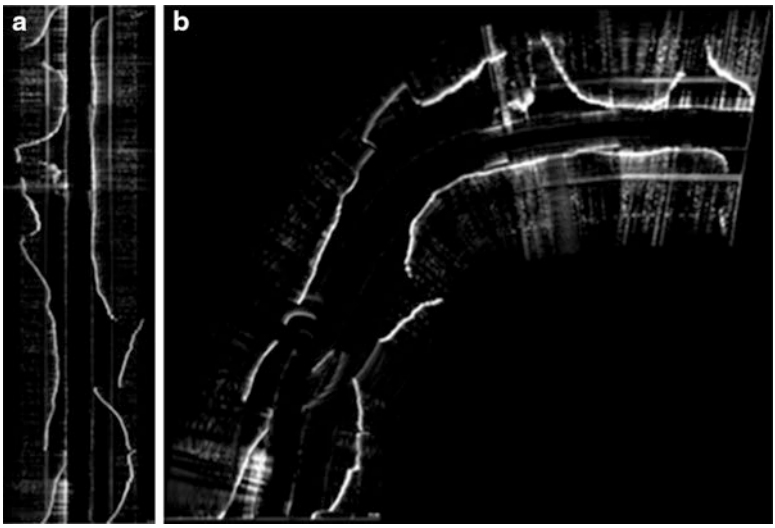

Fig 75.8 (**a**) Stacked LR-OCT data (*sagittal view*) as unprocessed linear data. (**b**) Stacked LR-OCT data (*sagittal view*) after applied bending algorithm

75.5 Image Reconstruction/Rendering

OCT images are loaded into Mimics, a commercially available 3D rendering software. Anatomically, the airway contains many bends, the most exaggerated of which occurs around the area of the soft palate and continues onto the nasal passageways. However, OCT assumes the images are acquired in a linear fashion. Unlike CT or MRI, OCT axial slices deviate from one another in an absolute coordinate system in both X-Y-Z linear displacement and at least 1 angular degree of rotations freedom. Serial OCT images must be transformed to fit along a curved airway and aligned along the "common axis." In order to fashion the linear LR-OCT data to represent the anatomical curve, a custom algorithm is used (Fig. 75.8). Using Cartesian coordinates from a series of CT scans acquired from normal patients. The database contains a variety of subjects, classified by age and sex. The acquired OCT data is matched to a CT scan that most closely correlates patient age and gender. The software creates a bend in sagittal slices of the OCT data creating an image that closely resembles the anatomic curvature. Figure 75.9 displays an example of data collection from a standard CT scan.

The literature has described an OCT probe with integrated magnetic tracking which accurately locates the tip of the OCT probe within the lumen of the airway in 3D space (X, Y, Z coordinates). This configuration can provide patient-specific airway curvatures without the need for third-party software [22]. Commercial magnetic tracking systems are now available in a small form factor (0.56 mm).

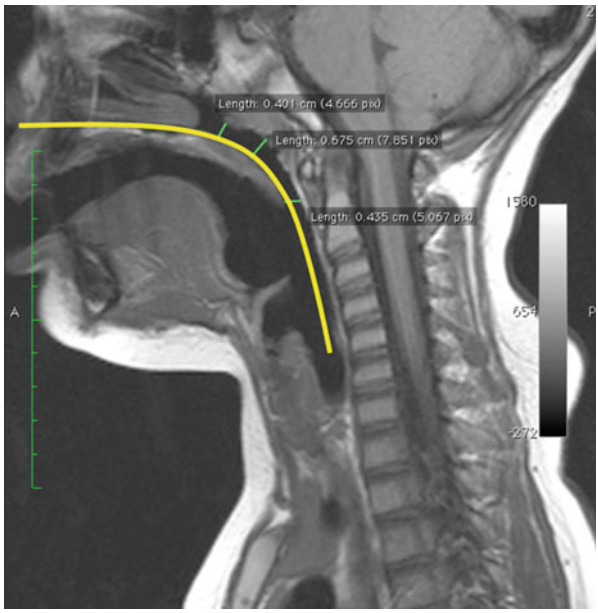

Fig. 75.9 Collection of Cartesian coordinates from normal CT scans for use in custom algorithm

Integration with the existing LR-OCT probe has the limitation of increasing the OD of the probe, necessitating larger outer FEP sheaths, which may lead to increased patient discomfort. However, improvements in the technology may produce smaller tracking beacons that will add negligible bulk to the LR-OCT probe.

After creating the bent upper airway, LR-OCT data is loaded into Mimics 3D rendering software for construction of a volumetric model (Fig. 75.10). Using Mimics, we are able to create accurate 3D renderings of the upper airway that will be used in simulations to visualize flow in normal and obstructed (as in those with OSA) airways. In Mimics, the OCT data is visualized in three planes (axial, sagittal, and coronal). As seen in Fig. 75.7, primarily at the area of the epiglottis, the anterior pharyngeal wall is missing. This is caused by structures (such as the epiglottis) that cannot be penetrated by the infrared light of the LR-OCT probe. This causes a gap in the OCT data, primarily at the level of the vallecula and the anterior pharyngeal wall. During the creation of the volumetric rendering, an individual equipped with endoscopic video data collected at the time of OCT imaging must use intra-frame interpolation and knowledge of anatomy to fill in missing data from the volume. As mentioned before, the epiglottis blocks the area of the anterior pharyngeal wall, which manifests as a gap in the OCT data. In order to compensate for this lack of information, the vallecula (the area between the posterior wall of the epiglottis and the anterior pharyngeal wall) is excluded from the reconstruction. Instead, it is assumed that the epiglottis forms the anterior pharyngeal wall. In simulations of flow based on CT data, the area of the vallecula does not significantly alter the flow within the airway (Fig. 75.11).

75.6 Numerical Simulations and Modeling

Upper airway reconstructions created from Mimics are used to model flow using direct numerical simulation (DNS) via the lattice Boltzmann method (LBM). These flow models can be used to locate areas of possible obstruction. The simulations based on the DNS-LBM have been compared to other DNS methods for several canonical flows with similar results. Simulation of flow in an idealized ETA model geometry is presented in Fig. 75.12. Results of this simulation agree with the experimental images from the smoke array visualization.

Similar to the idealized ETA model, flow through a full upper airway reconstruction of OCT data with the bending algorithm applied (Fig. 75.13) can be visualized. Application of inlet and outlet parameters creates flow, both pressure and velocity, through the model and can be seen at various points within the upper airway (Fig. 75.14a, b).

75.7 Conclusion

The pathophysiology of OSA is not clearly understood although it has been recognized as pathology for greater than 30 years. While polysomnography remains the standard for diagnosis, it only provides insight as to the diagnosis and does not provide anatomical detail for use in corrective surgery. Adjunct studies such as CT and MRI are not routinely used in diagnosis and management of this condition due to high cost, inconvenience, and exposure to potentially harmful radiation [23]. aOCT represents a technology that is ideally suited for use in imaging of the upper airway by being minimally invasive, easily portable, safe during extended imaging sessions, and well tolerated in awake or asleep patients [24]. The ability to simulate flow in accurate three-dimensional reconstructions can provide insight to physicians of individualized areas of obstruction. As it stands, surgical procedures for OSA are given, at best, a 50 % success rate. Localization of problem areas could lead to directed surgery and increased success rates.

aOCT is not without limitation. At certain locations within the upper airway, particularly in the hypopharynx where the epiglottis is located, more anterior tissues obstruct the imaging beam of the aOCT probe from focusing on tissues posterior to the proximal tissue. This creates gaps in axial data slices that must be manually created by correlating endoscopic images and anatomical knowledge to those particular aOCT data slices. An acquired aOCT stack is also assumed to be linear since the acquisition is recorded relative to the catheter and not in three-dimensional space. Though standardized curves extracted from age- and gender-adjusted CT scans can be applied to stacked axial OCT scans, further development of miniature magnetic tracking devices, which do not add additional bulk to aOCT probes, would allow for anatomically accurate curves to be applied to individual patient data.

aOCT has been shown to be comparative with CT for both cross-sectional area and airway structure. It can rapidly image a dynamic airway without exposure to ionizing radiation and can be used as an adjunct to polysomnography or in-office endoscopy with minimal discomfort for the patient. Time-domain systems were limited by slow scanning speeds, lower signal-to-noise ratio, and short imaging distance. Fourier-domain aOCT shows a significant scanning speed boost that is compatible with acute changes in airway structure over the breathing cycle and minimized motion artifact. An increased signal-to-noise ratio maximizes data acquisition and allows for more accurate 3D reconstructions for flow analysis.

In conclusion, imaging of upper airways with diameter of up to 3 cm was achieved in fully cognizant test subjects with minimal discomfort. Compared to an anatomical TD-OCT system, the long-range FD-OCT system not only increases the imaging speed significantly but also enhances the imaging sensitivity to enable visualization of the fine anatomical tissue structure in the airway. Combining this structural information with DNS flow simulations, we can better estimate the site and causes of airway obstruction and better select and design surgery for patients with upper airway resistance.

76.1 Introduction

Advances in pulmonary diagnostics and therapeutics offer a major potential for optical imaging applications both in clinical practice and research settings. Complexities of pulmonary structures and function have restricted widespread OCT investigations and clinical applications, but these will likely be overcome by developments in OCT technology [1]. Some factors that have limited adaptation of OCT into the pulmonary setting in the past have been the shallow depth of penetration, resolution limitations,

relatively slow access times, need to examine large surface areas with numerous branching airways, motion artifacts, as well as a need for development of practical imaging probes to reach the relevant locations in a minimally invasive way. Considerable recent engineering and analytical advances in OCT technology [2–8] have already overcome several of these obstacles and will enable much more extensive investigations into the role for structural and functional pulmonary OCT imaging [1].

There is a wide range of significant clinical pulmonary needs that may be fulfilled by the real-time, high-resolution imaging capabilities of OCT. In a number of these potential pulmonary clinical application areas, the shallow depth of penetration of OCT is adequate enough for the required purposes. For other applications, however, such as defining the depth of penetration of airway tumors or determining airway structural changes in tracheal strictures or malacia, a combination of OCT and high-frequency endobronchial ultrasonography may be more appropriate to visualize the entire central airway wall in cross section [9]. As with any diagnostic or therapeutic clinical tool, the evolution of OCT in pulmonary medicine will be based on knowledge of potential uses, understanding of where the capabilities and limitations meet the clinical needs, and cognizance of areas where OCT is unlikely to be helpful. Many of the initially reported pulmonary OCT studies have focused on areas of highest likelihood for demonstration of success [10–17]. This approach very reasonably demonstrates feasibility and proof of concept, but it must be emphasized that the areas of initial focus and current investigations may not ultimately be the areas of highest beneficial yield in the long-term application of OCT in pulmonary medicine. Evidence suggests, however, that OCT is a promising tool for detection of early airway cancer, facilitating biopsy of peripheral pulmonary nodules, assessing airway remodeling in asthma and chronic obstructive pulmonary disease (COPD), and potentially guiding therapeutic bronchoscopic interventions [1, 18].

76.2 Overview of Pulmonary Anatomy and Physiology: Unique Aspects Relevant to OCT and F-OCT

There are a number of very unique structural and functional components to the pulmonary system relevant to issues of OCT imaging. The major function of the lungs involves gas exchange between the circulatory system and the environment [19]. Anatomically, this requires a very large surface area containing both fine capillaries and alveolar surfaces in close contact for gas exchange. The average adult lung volume is roughly 2–4 l in the resting state (functional residual capacity) [20], with extremely large alveolar surface areas exposed directly to the external environment, providing a potential portal for infection and inhalation injuries. The total alveolar surface area where gas exchange takes place is approximately the size of a tennis court (140 M^2) in an adult [21] (p. 12). The air is conducted into the lungs through the airway system which consists of the upper airway, larynx, trachea, and proximal bronchi. The bronchi rapidly branch in multiple generations like branches on a tree to reach all regions within the lungs [19] (Fig. 76.1). Up to 23 generations of branching occur (Fig. 76.2) [22] to reach the >3 million respiratory bronchioles

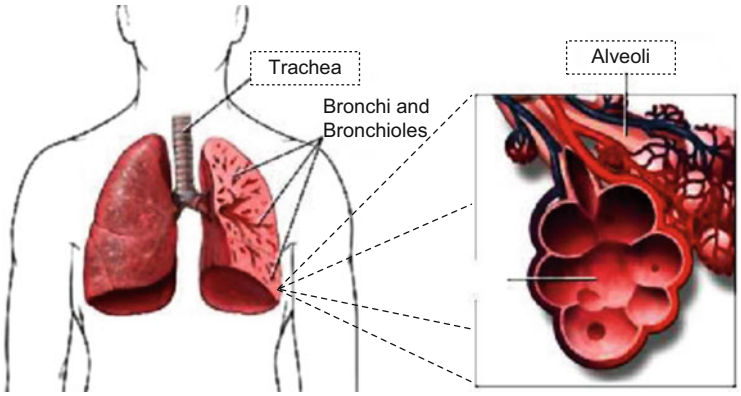

Fig. 76.1 Lungs, airways (including trachea and branching bronchi and bronchioles), and distal alveoli where gas exchange takes place (Modified from http://images.google.com/imgres?imgurl = http://images.webmd.com/images/hw/media65/medical/hw/h5551557.jpg&imgrefurl = http://my.webmd.com/hw/health_guide_atoz/hw141715.asp&h=300&w=460&sz=26&tbnid=jBlE6ZHtW7QJ:&tbnh=81&tbnw=125&hl=en&start=3&prev=/images%3Fq%3Dlungs%2Bairways%26svnum%3D10%26hl%3Den%26lr%3D)

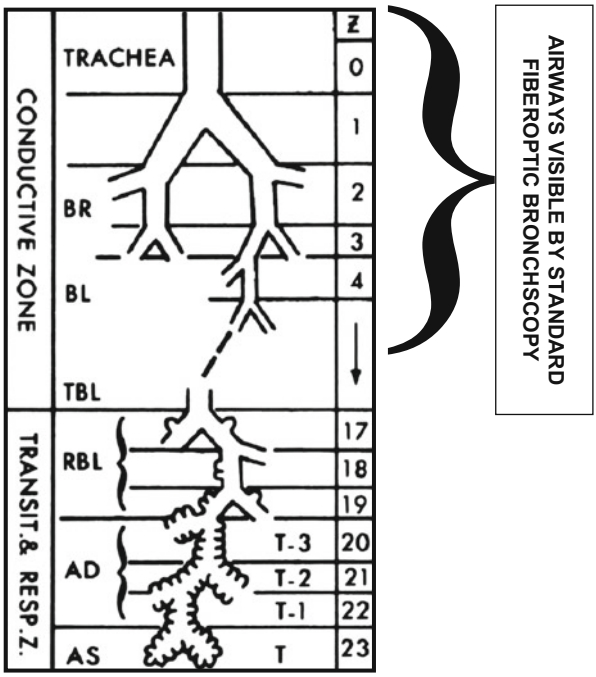

Fig. 76.2 Schematic of airway generations and airway regions accessible for visual examination by flexible fiber-optic bronchoscopy (Modified from Weibel et al. [22])

and alveolar air sacs (generation branches 17–23) [20] (page 6). As the number of branching airway generations increases, their individual luminal diameters decrease in size [19]. Therefore, it is not possible to examine most of the conducting airways within a patient (in contrast, e.g., to the single lumen found in the gastrointestinal tract). Only a few generations of branching can be routinely examined by standard airway endoscopic diagnostic techniques (Fig. 76.2). For more distal airway anatomic examinations, new technologies are needed, along with the ability to guide diagnostic tools to the exact place of interest. This is now possible given the advances in navigational bronchoscopy, a technique that provides a three-dimensional virtual road map and enables a physician to maneuver through multiple branches of the bronchial tree and reach predefined target areas in the lung parenchyma. A significant amount of relevant pathology, however, occurs in the proximal airways, at levels reachable by current bronchoscopic methods, and within areas that can be readily visualized by existing OCT methods. Specifically, OCT can be used for detecting and defining the exact extent of laryngeal and large airway tumors in many cases [23, 24], detecting airway remodeling in asthma and COPD [25], and facilitating understanding of the upper and central airway mechanics in obstructive sleep apnea (OSA), asthma, and COPD [26, 27].

As with any new technology, the exact clinical role for OCT in pulmonary diagnostics and therapeutics will be defined and evolve over time. Anatomic regions of the pulmonary organ system where OCT may be of clinical or research value include the larynx, vocal cords, proximal airways (including trachea with an average of 1.5 cm^2 area and decreasing sized bronchi and bronchioles), smaller gas-exchanging lung structures (including respiratory bronchioles and alveoli of roughly 200–300 μm diameter and 8 μm wall thickness) [20] (Fig. 76.3), and pleural space between the chest wall and lungs (including parenchymal pleura and visceral pleura covering the lung surface) (Fig. 76.4) [15]. In addition, in the pulmonary vascular system including pulmonary arteries, arterioles, more than 300 million alveolar capillary segments (where gas exchange takes place with the blood) [20] (page 13), pulmonary veins, as well as bronchial arteries, capillaries, and veins, OCT may have future applications.

76.3 Standard External Imaging Techniques for Lung and Airway Examination

76.3.1 Chest X-Ray

Chest radiographs are relatively inexpensive, with excellent depth of penetration (the entire thorax can be imaged). Standard chest radiographs are two-dimensional composite shadows of tissue structures, with maximal resolution on the order of millimeters. Digital imaging and subtraction techniques may further improve diagnostic capabilities for chest radiographs and other imaging techniques [28]. Chest radiographs, however, are insensitive for detecting early airway or parenchymal malignancies or structural changes in the airways that can be detected by higher-resolution optical technologies.

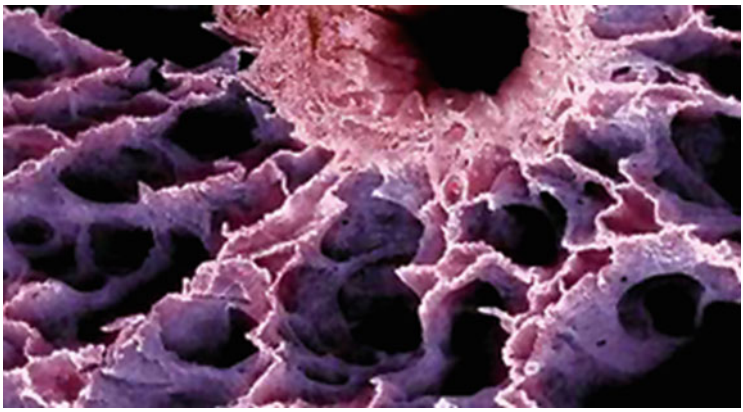

Fig. 76.3 Scanning electron micrograph of bronchiole and distal alveolar structures. Alveoli are approximately 200–300 um in diameter. Fine pulmonary capillary networks perfuse the capillary walls (From http://images.google.com/imgres?imgurl = http://www.visualsunlimited.com/images/watermarked/310/310003.jpg&imgrefurl = http://www.visualsunlimited.com/browse/vu310/vu310003.html&h=251&w=350&sz=28&tbnid=hXOAXFGrrlwJ:&tbnh=83&tbnw=116&hl=en&start=8&prev=/images%3Fq%3Dalveoli%2BSEM%26svnum%3D)

76.3.2 Computed Tomography

High-resolution CT scanning is three-dimensional and also has excellent penetration with resolution on the order of hundreds of microns to millimeters [28–30]. Various reconstruction algorithms can be applied including airway surface renderings for "virtual" "bronchoscopy" [29, 31–33]. However, virtual bronchoscopy is limited in ability to evaluate the mucosal surface of the respiratory tract reliably. Although the overall surface form can be detected, mucosal color, irregularity, or friability cannot be assessed [33]. Studies show that CT imaging detects changes in airway wall thickness in obstructive airway disorders, and these correlate with disease severity and bronchial biopsy measurements of airway wall thickness [34]. However, beyond the fifth airway generation, CT's resolution is inadequate, and in addition, CT cannot detect or measure morphological changes in the airway structured microlayers. These limitations are potentially overcome by optical technologies.

76.3.3 Positron Emission Tomography

Positron emission scanning is relatively low resolution but provides functional information that may be useful in differentiating benign from malignant pathology, particularly in conjunction with CT scanning [35, 36]. PET scanning may be particularly useful for detection of unsuspected metastatic malignant disease in lung cancer patients [35]. As a functional imaging modality, integrated chest PET CT scanning is currently used in diagnostic algorithms for indeterminate pulmonary nodules and staging of cancers.

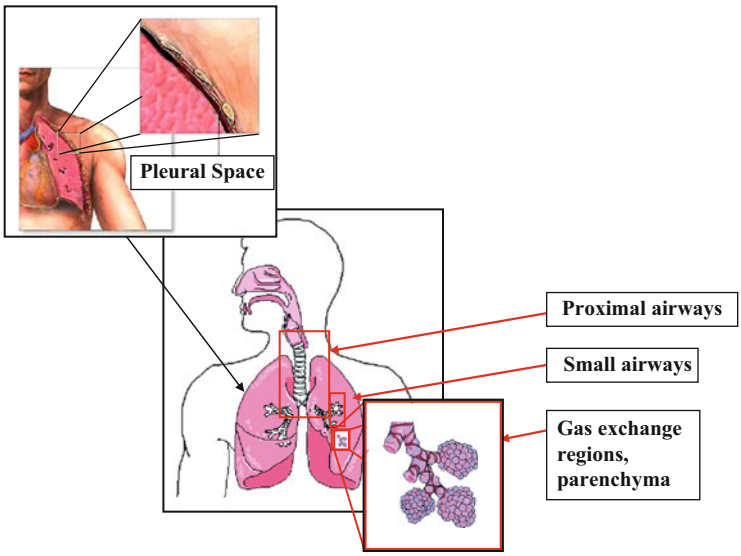

Fig. 76.4 Potential areas for pulmonary OCT clinical and research applications including proximal airways larynx and trachea, bronchi, smaller airways and bronchioles, gas exchanging regions and lung parenchyma, and pleural space (Modified from http://www.smartdraw.com/resources/examples/medical/images/respiratory_full.gif and http://images.google.com/imgres?imgurl = http://www.uscuh.com/CWS/ADAM/Surgery/graphics/Chesttubeinsertion_1.jpg&imgrefurl = http://www.uscuh.com/CWS/ADAM/Surgery/Chesttubeinsertion_1.html&h=320&w=400&sz=13&tbnid=1kw9f2O5YMIJ:&tbnh=96&tbnw=120&hl=en&start=12&prev=/images%3Fq%3Dpleural%2Bspace%26svnum%3D10%26hl%3Den%26lr%3D)

76.3.4 Magnetic Resonance Imaging

MRI imaging is rapidly advancing for thoracic imaging with improvements in acquisition times but is used primarily for mediastinal and proximal vascular structure evaluation in the thorax at this time [28, 30]. MRI is used occasionally in tracheobronchomalacia and for detecting involvement of the chest wall structures by tumor [30, 37]. The depth of penetration is throughout the thorax, and imaging resolution is on the order of millimeters [29].

76.4 Direct Examination Techniques for Airways, Lung Parenchyma, and Pleura

76.4.1 Flexible Bronchoscopy

Flexible bronchoscopy is performed either trans-orally or trans-nasally using flexible endoscopes that are usually at least 100 cm in length and have outer diameters ranging from 3 to 6.5 mm. The bronchoscopes are now commonly

videoendoscopes. The bronchoscopes most commonly have a light source, imaging modality (CCD chip or fiber bundle), and a hollow "working channel" usually ranging from 1.2 to 2.8 mm. Specimens can be obtained including suctioning, saline lavage, brushing, and needle and forceps biopsies (generally of maximal diameter on the order of 1–2.5 mm). The working channels allow the passage of therapeutic instruments (laser, electrocautery, cryotherapy probes) or novel diagnostic tools such as OCT, radial EBUS, or CFM probes. Generally, 3–4 orders of bronchial branching can be directly visualized with standard flexible bronchoscopy, but ultrathin flexible bronchoscopy using flexible scopes of 2–3 mm and working channels of 1 mm allow access to more distal airways and pulmonary abnormalities peripherally situated within the lung parenchyma. The major advantage of flexible bronchoscopy is its versatility. Flexible bronchoscopy can be performed in awake patients with or without moderate sedation. Its use is easily learned, and it enables the operator to reach the distal aspects of branching airways with minimal trauma or patient discomfort. Diagnostic procedures, including those with biopsies, can usually be performed in less than 10 min. Procedures can be performed using topical anesthesia, and bronchoscopy can be done at the patient's bedside or in an outpatient setting. White light bronchoscopy, however, can only image mucosal surfaces. For cancer, for instance, even for visible endobronchial lesions, combined bronchoscopic modalities (brushings, washings, biopsy) result in a diagnostic rate that is less than 100 %, mainly because of sampling errors (biopsies are performed from areas of tumor necrosis, inflammation, or fibrosis). High-magnification bronchoscopy (HMB) provides information of the bronchial mucosa with a maximum magnification of 110 times, thus revealing subepithelial microvessels in the large airways, potentially useful to abnormal vascular networks in the large airway in asthma and lung cancer [38, 39]. HMB, however, is still a surface imaging modality with a resolution of approximately 20 μm. Many pathologic subepithelial vessels have a diameter less than that; in addition, HMB cannot distinguish neovascularization from vasodilation [40].

76.4.2 Rigid Bronchoscopy

Rigid bronchoscopy is usually performed in conjunction with interventional therapeutic procedures. These include laser resection, tumor debulking, silicone and metal stent insertion, or dilatation of benign tracheal or bronchial strictures. Rigid bronchoscopes generally range in size from 5 to 12 mm diameter and 12 to 45 cm in length. Working channels can be as large as 7 mm in addition to the visualization optics. Rigid bronchoscopes can visualize up to four orders of bronchial branching and are primarily focused on proximal airways. Visualization is direct, and resolution is governed by the quality of Hopkins lens rigid telescopes. Airway surface anatomy is visualized with rigid bronchoscopy usually using straight lens telescopes with a digital or other high-grade video camera easily attached to the telescope head. Lateral viewing telescopes of 30, 45, and even 90° can be used, but are infrequently employed today because of the ready availability of the flexible

Fig. 76.5 (*Left*) 12 mm diameter rigid bronchoscope (Bryan Corp, Woburn MA, USA). Note 5 mm rigid telescope, attached digital camera, 3 mm suction catheter placed through sideport and black flexible Racine connector allowing mechanical ventilation and oxygenation. Note 2.8 hollow working channel)

bronchoscope. It is noteworthy that probes or catheters placed through the rigid tube need to be sufficiently firm so that they can be manipulated inside the open tube (Fig. 76.5). This is the case, for example, for existing silicone suction catheters, quartz laser delivery fibers, OCT probes, or radial EBUS (Fig. 76.6). In addition to limitation of white light bronchoscopy, rigid bronchoscopy may restrict the wide application of novel optical technologies in pulmonary medicine because of its limited applications and availability among pulmonologists. Furthermore, the systems can be cumbersome to use in conjunction with dedicated OCT probes, since through a hollow tube, the operator has to accommodate the telescope and the OCT probe and sometimes forceps and laser fibers (Fig. 76.7). This limitation, however, can be potentially overcome by development of integrated WLB-OCT laser systems.

76.4.3 Autofluorescence Bronchoscopy (AFB)

The main rationale for the development of AFB is the fact that WLB is not sensitive enough for detecting abnormalities that are only a few cells thick or below the tissue surface. AFB is based on the hypothesis that differences in epithelial thickness, blood flow, and tissue fluorophore concentration cause abnormal tissues to have diminished red and substantially diminished green fluorescence as compared to normal tissues when exposed to 440–480 nm wavelength blue light excitation (Fig. 76.8); thus, autofluorescence (AF) cannot be seen during conventional WLB as the intensity of fluorescence is very low and is overwhelmed by the reflected and backscattered light. Successful localization of a dysplastic lesion is possible using AFB, whereas WLB is normal. The intensity of green fluorescence is measured, and an abnormally low "green" fluorescent area is identified as a cold spot on a normal green background. The published evidence shows that AFB has a better sensitivity than WLB for detecting intraepithelial lesions [41]. The specificity, however, is low (~60 % vs ~90 % for WLB) due to false-positive

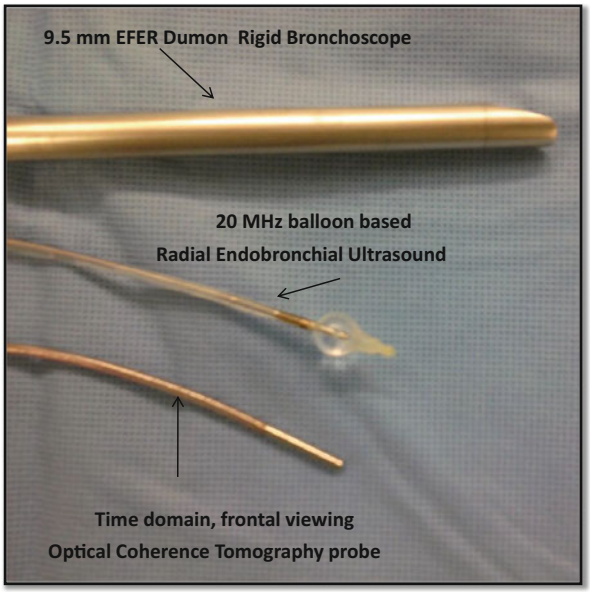

Fig. 76.6 The rigid bronchoscope accommodates a variety of instruments including the telescopes, forceps, suction catheters, laser fibers, as well as optical and ultrasound imaging probes. This is a close view of the 9.5 mm EFER-Dumon rigid bronchoscope, the radial ultrasound probe with its water-filled balloon and the optical coherence tomography probe

fluorescence with inflammation, mucosal gland hyperplasia, and interobserver error. To increase specificity, one may need to obtain information about tissue structure (via OCT or CFM) [24].

76.4.4 Narrow Band Imaging (NBI)

The rationale for development of NBI relies on the fact that malignant and dysplastic lesions are characterized by abnormal angiogenesis which can be detected visually as vessel entanglement and abnormal proliferation within the bronchial mucosa [42]. NBI uses blue light centered at 415 nm and green light centered at 540 nm corresponding to the maximal hemoglobin absorption peaks. The blue light highlights the superficial capillaries, whereas the green light can penetrate deeper and highlight the larger blood vessels in the submucosa (Fig. 76.9). Preliminary studies suggest that NBI can improve detection of dysplasia and CIS compared with WLB [43, 44]. The routine clinical utility of NBI, however, remains unknown as the natural history of the above premalignant lesions is not completely well understood, the indications for NBI have not been well established, and inter- and intra-observer reliability recognizing normal and abnormal NBI images needs to be further defined.

76.4.5 Confocal Endomicroscopy (CEM)

Confocal endomicroscopy (CEM) provides an image of a thin section within a biological sample, where the microscope's objective is replaced by a flexible

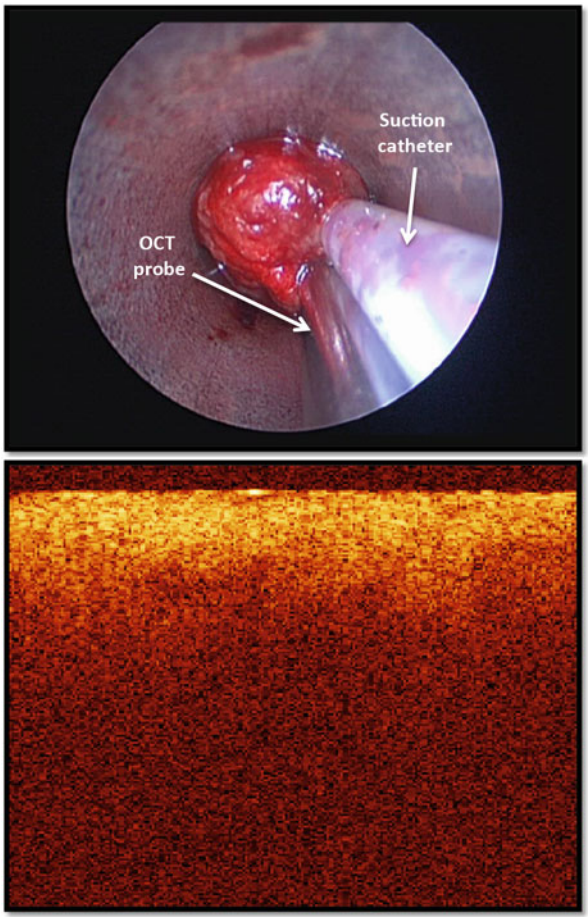

Fig. 76.7 The suction catheter and a time domain forward viewing OCT probe are placed over an endobronchial tumor just before its removal from the airway (*top panel*). The OCT tomogram revealed a pattern of homogeneous light backscattering layer and absence of normal layered microstructures which characterize the normal airway wall (*bottom panel*)

fiber-optic miniprobe [45]. CEM offers spatial resolution down to the submicron range and depth of penetration of approximately 0.5 mm, which should provide sufficient optical information to distinguish benign from early malignant lesions since cellular changes in CIS and dysplasia occur in less than 1 mm in depth, if optical contrast is sufficient. The basement membrane and upper submucosa can be imaged with good quality. Disorganization of the fiber network was seen indicating basement membrane disruption that was observed in the majority of metaplastic and dysplastic samples and all CIS and invasive cancers [45]. CEM has been also investigated in vivo for studying airway remodeling in asthma [46]. While there was no difference in CEM patterns between asthma patients and healthy controls, there was an association between post-bronchodilator FEV_1 % predicted and both histologic and CEM elastic fiber patterns. These findings suggest there may be a structure-function relationship between extracellular matrix in the airway wall

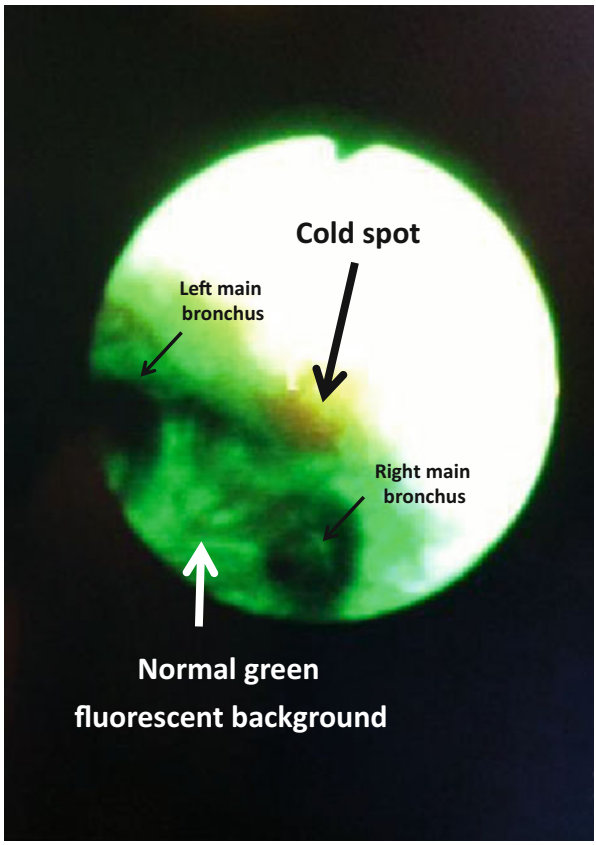

Fig. 76.8 Abnormal tissues have diminished green fluorescence as compared to normal tissues when exposed to 440–480 nm wavelength blue light excitation. The intensity of green fluorescence is measured, and an abnormally low "*green*" fluorescent area is identified as a "*cold spot*" on a normal green background (*arrow*)

and lung function. Because cells do not emit strong autofluorescence with the current commercially available technology, the epithelial cells are not visible. In addition, the fragile epithelium can be scrapped off during the imaging procedure. Studies are needed to evaluate if CEM can distinguish normal from specific abnormalities (dysplasia, inflammation, fibrosis, malignancy), not just normal from abnormal tissues [47]. Furthermore, since the depth of penetration is limited, this technique will likely be appropriate in a multimodality bronchoscopic imaging platform, combining it with technologies able to visualize the cartilage and its potential invasion (i.e., EBUS) and reveal alterations in the airway wall microstructure (i.e., OCT).

76.4.6 Pleuroscopy

Pleuroscopy is a procedure that allows physicians to access to the pleural space. It is also known in the literature as thoracoscopy, medical thoracoscopy,

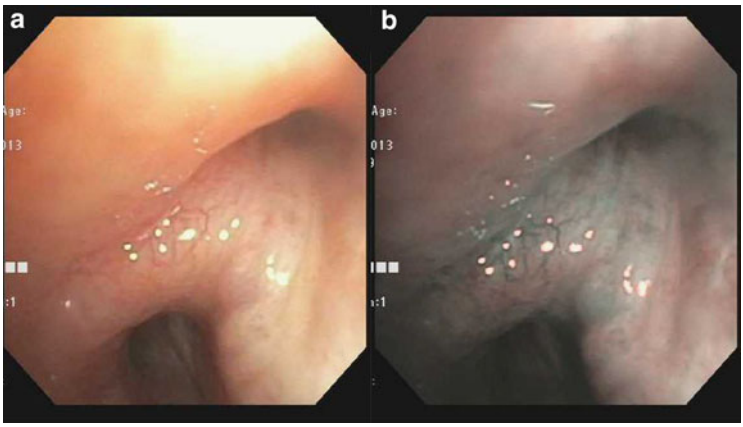

Fig. 76.9 (**a**) White light bronchoscopy at the level of primary right carina (RC1) shows submucosal tumor infiltration. (**b**) Narrow band imaging at the same anatomic site: the blue light highlights the superficial capillaries, whereas the green light can penetrate deeper and highlight the larger blood vessels in the submucosa

or video-assisted thoracic surgery (VATS). In general, however, VATS refers to thoracoscopy performed in the operating room using single-lung ventilation. During medical thoracoscopy, the operator (surgeon or interventional pulmonologist) can perform parietal pleural biopsies, drainage of pleural effusions, and pleurodesis either in an endoscopy suite or operating room. In addition to these procedures, during VATS, thoracic surgeons can also perform lung biopsy, resection of pulmonary nodules or blebs, lobectomy, pneumonectomy, or esophagectomy [48]. Either rigid or flexible instruments can be used for these interventions, but surgeons use mostly rigid instrumentation. Disposable plastic or reusable stainless steel trocars come in different sizes (5–13 mm) and allow the passage of telescopes with different angles of vision (0° for direct viewing and 30–50°) for oblique panoramic viewing of the pleural cavity. In addition, other instruments such as forceps or optical probes can be passed through the trocar inside the thoracic cavity and potentially assist with selection of a biopsy site (Fig. 76.10). The flex-rigid pleuroscope (model LTF 160 or 240; Olympus, Tokyo, Japan) is designed like a bronchoscope with a handle and a shaft of 7 mm outer diameter. The 2.8 mm working channel accommodates forceps, electrosurgical and laser probes, and other accessories (Fig. 76.10). The yield of thoracoscopic parietal pleural biopsy for malignant pleural effusions is 90–100 % [49]. It is possible that the addition of optical technologies will maximize this yield, especially for early-stage mesothelioma, which could resemble pleural inflammation. Overall, however, the limited published clinical evidence available to date does not support the use of autofluorescence or NBI in addition to white light thoracoscopy for the diagnosis of malignant pleural effusion [50, 51].

76.5 Anatomic Regions of the Pulmonary System Amenable to Potential Clinical OCT Applications

76.5.1 Pulmonary Airway Tree

OCT has been demonstrated in a number of studies to acquire images with sufficient contrast and resolution to reliably identify many of the normal architectural features of the airway, parenchyma, and pleura. Deviations from this normal structure such as the loss of the layering of the airway wall, or the visibility of alveoli in the parenchyma, may be indicative of the presence of a pathologic abnormality. The initial reports of OCT in pulmonary medicine involved studies of normal and abnormal tracheal, bronchial, and bronchiolar anatomy in excised tissue specimens [10, 12–14, 52]. The ability of OCT to differentiate epithelial, subepithelial, glandular, cartilaginous, and muscular structures within the trachea of humans and animal models was demonstrated. However, the development and

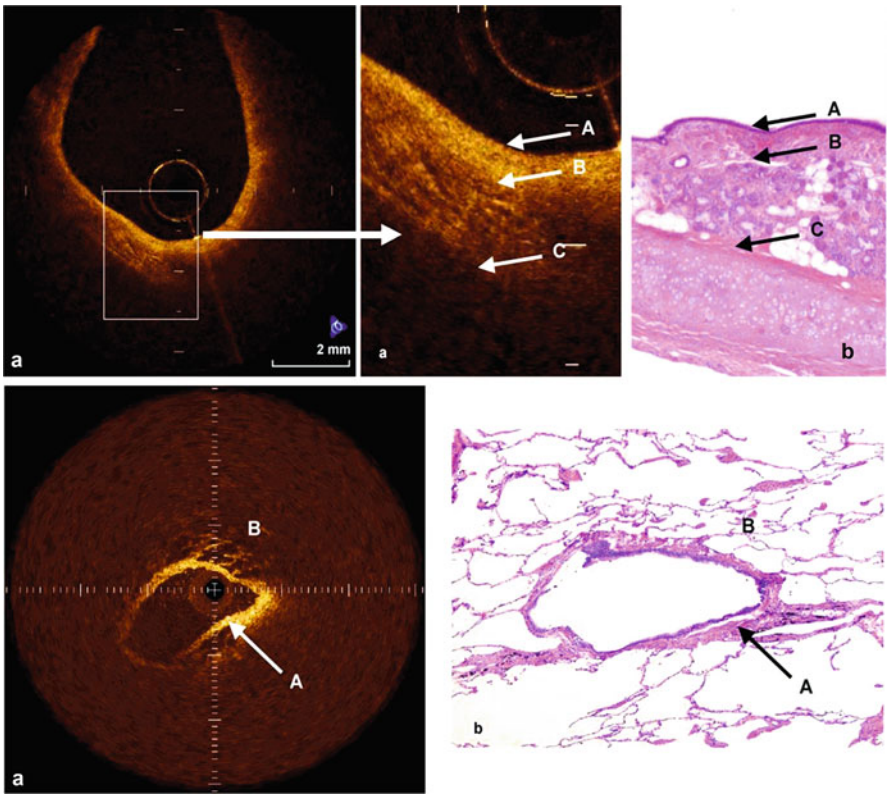

Fig. 76.11 Rotational probe images from human lung specimens compared to corresponding histology from Tsuboi [10]. Images obtained from a SLD laser system (1,300 nm center λ, 70 nm bandwidth). *Top image* shows the OCT image (**a**), and histological finding (**b**), of normal bronchus. The bronchial mucosal and submucosal layer (*A*) appear homogenous in OCT image. The submucosal layer is relatively reflective due to the presence of extracellular matrix. A gap can be seen between the submucosa (*A*) and smooth muscle layer (*B*), and cartilage layer shows much scattering (*C*). Epithelium, mucosa, and cartilage are clearly differentiated, as well as a number of glandular tissues and microvessels by both OCT and histology. (**a**) OCT images, (**b**) histological finding, (*A*) mucosal and submucosal layer, (*B*) smooth muscle layer, (*C*) cartilage. *Bottom* figures show the OCT image (**a**), and histological findings (**b**), of normal peripheral bronchus and alveoli. The uniform bronchial wall (*A*), and the structure of alveoli (*B*), containing air can be observed. (**a**) OCT images, (**b**) histological finding, (*A*) peripheral bronchus, (*B*) alveoli (From [10])

validation of accurate image interpretation criteria to reliably assess OCT images of pulmonary tissues obtained in vivo is a necessary step if OCT is to be adopted in the clinical setting. A number of groups are assessing the close similarity between OCT imaging and standard histologically stained excised specimens (Figs. 76.11, 76.12 and 76.13) [10, 12, 15, 16, 24, 53] and are now beginning to use this information for develop interpretation guidelines (Table 76.1) [53].

These OCT features can be applied to a multitude of benign and malignant processes in the large and small airways. In addition to airway cancer, OCT can be

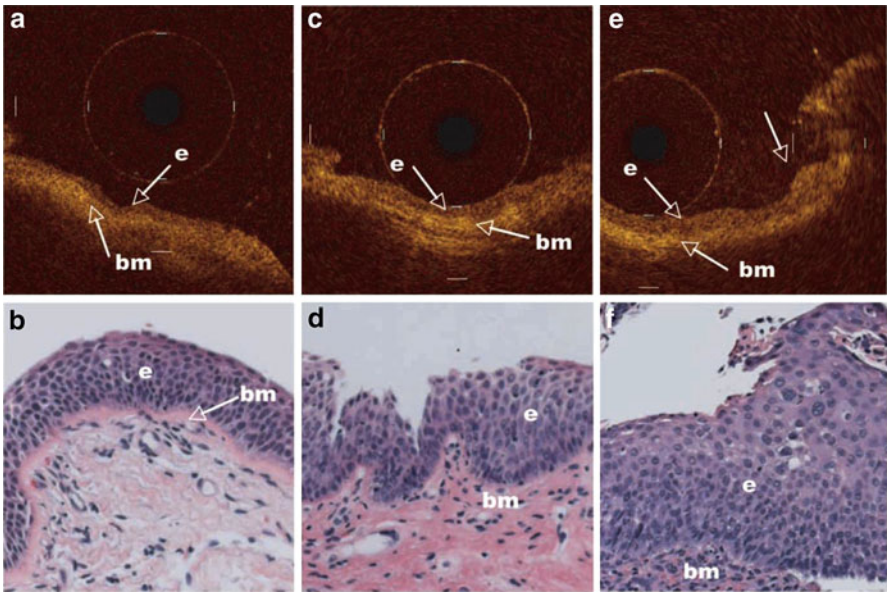

Fig. 76.12 Representative OCT images of an area with mild dysplasia (**a**), moderate dysplasia (**c**), and severe dysplasia (**e**) and corresponding H&E-stained histologic sections (**b**, **d**, and **f**; original magnification, ×20). The nuclei in the epithelium become recognizable as *darker dots* with moderate dysplasia or worse. The *arrow* in the OCT image of the area with severe dysplasia points to the corresponding elevated area in the H&E section (Reprinted with permission from [24])

used to study airway wall thickness and remodeling in asthma, COPD, and bronchiectasis [25, 26]. Long-range OCT applications allow the study of airway compliance and potentially facilitate the identification of flow limiting segments in asthma, COPD, tracheomalacia, and obstructive sleep apnea [54–58]. This is clinically relevant for several reasons: (1) it facilitates airway selection for novel bronchoscopic asthma treatments (bronchial thermoplasty); (2) leads to better understanding of central airway mechanics (elastic properties, dynamic compression) in asthma and COPD; (3) allows measurement of the central airway lumen at normal and stenotic sites, potentially guiding bronchoscopic interventions; and (4) facilitates quantitative evaluation of the upper airway dynamics and localization of the sites of obstruction during polysomnography or continuous positive airway pressure thus potentially guiding surgical interventions for OSA.

76.5.2 Lung Parenchyma

OCT can potentially be used to study focal or diffuse lung parenchymal processes. Current research is limited to ex vivo studies aiming to understand normal and

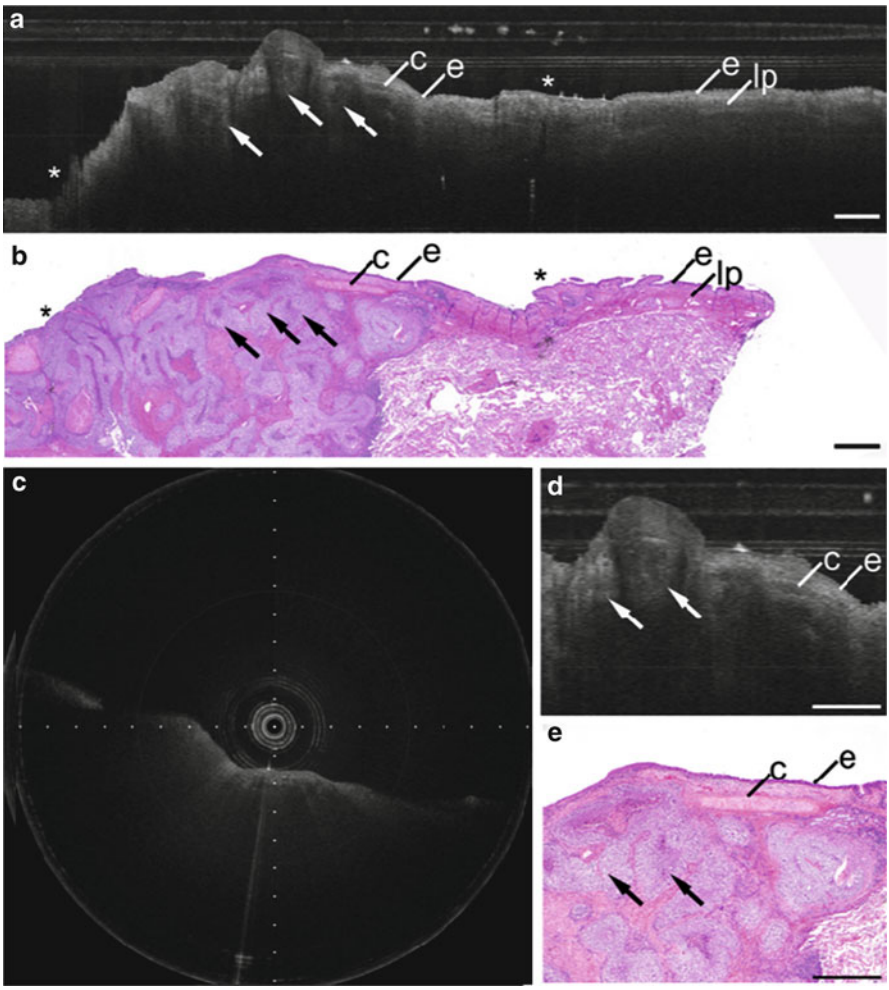

Fig. 76.13 Bronchoscopic catheter-based OCT of squamous cell carcinoma, baseloid type. (**a**) OCT longitudinal section and (**b**) corresponding histology. (**c**) OCT cross section. pathologic alveolar structure and dynamics [1, 59]. Current limitations in clinical applications include technical challenges due to the invasive access to the alveolar space (may require pleuroscopy) and OCT imaging itself of the alveoli due to changes in the refractive index of air, tissue, and mucus (may require liquid filling index matching). Potential clinical applications would likely require a bronchoscopic approach in which the OCT probe is guided to a target previously identified on computed tomography. This is now possible using electromagnetic

Table 76.1 OCT image interpretation features for benign and malignant pulmonary pathology (reprinted with permission [53])

Pathology	Imaging features
Normal	
Airway	Layered architecture, including
	Respiratory epithelium and underlying basement membrane
	Lamina propria
	Cartilaginous rings
Parenchyma	Thin, lattice-like alveolar architecture with signal void spaces
Neoplastic	
Adenocarcinoma	Loss of layered architecture
	Mass with signal heterogeneity with rapid attenuation
	Atypical gland formation
Mucinous adenocarcinoma	Signal intense alveolar wall thickening
	Preserved lattice-like architecture
	Signal poor intra-alveolar mucin
	Homogeneous signal intense tumor-associated scar may be seen
Squamous cell carcinoma, basaloid type	Loss of layered architecture
	Mass with signal heterogeneity with rapid attenuation
	Irregular tumor nests with:
	Signal-intense periphery corresponding to malignant cells
	Signal-poor center corresponding to central necrosis
Salivary gland adenocarcinoma, adenoid cystic carcinoma	Luminal mass protrusion
	Uniform distribution of signal-intense trabeculae
	Small pseudocystic spaces filled with mucin can be seen
	Intact overlying respiratory epithelium may be present
Benign	
Cartilaginous hamartoma	Lobulated mass with well-delineated borders and
	Evenly dispersed, fine-scale regions of high signal intensity
	Background of uniform, moderate signal intensity
Fibrosis	
Usual interstitial fibrosis	Diffuse, signal dense subpleural fibrosis
	Irregularly shaped, signal poor subpleural cysts
Focal mild subpleural fibrosis, idiopathic	Focal, signal dense pleural fibrosis
	Interspersed lattice-like alveoli with mildly thickened alveolar walls

navigation bronchoscopy, which provides a three-dimensional virtual road map that enables a physician to maneuver through multiple branches of the bronchial tree. Once the desired location is achieved, the insertion of a needle probe could allow OCT imaging and biopsy of the desired region (i.e., focal lung mass or alveolar space) [60–62]. In addition, one could gain more information about the basic alveolar dynamics during normal breathing and artificial ventilation [63]. This information could potentially be used to prevent alveolar damage and guide protective lung ventilation strategies in patients with acute respiratory distress syndrome (ARDS), though this is speculative at this time [64].

76.5.3 Pleura

The pleural space is a virtual space between the lungs and their surrounding thoracic structures including the chest wall, mediastinum, and diaphragmatic surface (Fig. 76.4). The pleural space is a site of important thoracic pathology including primary malignancies, metastatic malignancy, fluid collections (benign and malignant), infection, and traumatic and inflammatory conditions. Accurate diagnosis of pleural disease may require open thoracotomy or thoracoscopic examination. Detecting malignancy in the pleural space is essential for proper staging and management of lung cancers. Diagnostic yield from thoracentesis (pleural fluid drainage) is often low. Yield from thoracoscopy is substantially higher. It is uncertain at this time whether OCT will have a role in pleural diagnostics, though it is reasonable to speculate that the ability to obtain high-resolution functional and structural characteristics of pleural spaces and surfaces prior to biopsy would be of potential benefit. This may particularly apply to mesothelioma for which the pleural findings on white light imaging may be nonspecific and deeper pleural biopsies are usually necessary for diagnosis. It is likely that if OCT will have a role in pleural investigations, it will be in a multimodal approach in conjunction with white light thoracoscopy and potentially NBI or AF. OCT may be particularly useful in guiding the site of thoracoscopic biopsy, if studies will confirm that tumor can be distinguished from adjacent nonmalignant findings. Current research in OCT imaging of the pleura is limited to animal studies which demonstrate that fine structures such as the visceral pleura and alveoli were able to be visualized with OCT at high resolution, but it remains to be determined whether OCT is capable of differentiating between benign and malignant pathologies [15, 65].

76.5.4 Pulmonary Vascular Tree

Pulmonary vessels can be accessed for OCT imaging at the time of right heart catheterization. The pulmonary vascular wall changes due to hypertrophy of the intima and media (such as in pulmonary arterial hypertension) or detection of flaps inside the lumen (due to thrombus) can be detected by OCT. This could have diagnostic and consequent therapeutic implications since OCT can potentially

distinguish chronic thromboembolic hypertension from other etiologies [66]. Technically, however, application techniques for OCT imaging of the pulmonary vasculature are not obvious since it may require proximal balloon occlusion and injection of saline or lactated Ringer solution to facilitate penetration of light. These limitations have already been addressed in intracoronary OCT imaging where increases in image acquisition times have negated the need for proximal balloon occlusion and require only a very short saline, lactated Ringers solution, or radiocontrast flush (<10 mL total). Therefore, it is feasible that with further investigation and refinement of imaging techniques, these issues may additionally be overcome in the pulmonary vasculature.

76.6 Pulmonary OCT Imaging Systems and Approaches

76.6.1 Endobronchial

The use of OCT to study the lung in the clinical setting has been predominantly restricted to assessment of airways within the tracheobronchial tree that are accessible with a standard bronchoscope. Endobronchial OCT imaging is typically performed by inserting the OCT catheter through the accessory port of a standard bronchoscope (Fig. 76.14) [10, 24, 53, 67]. Alternative placement of catheters into the more distal airways may be achieved using CT, or fluoroscopic guidance, or by using a guide sheath in conjunction with electromagnetic guidance techniques.

Endobronchial OCT imaging may be performed using a variety of catheter designs. Prior studies have included both circumferential [10, 24, 41, 54] and linear scanning [15, 16] mechanisms, which may be actuated either proximally outside the patient or at the distal tip of the catheter using miniature motors [68] or galvanometric scanners. The designs of both linear and circumferential catheters that are actuated proximally typically consist of an optical inner core encased inside an optically transparent sheath. The primary purpose of the sheath, which is typically single use, is to protect the patient from contact with the reusable inner optical core and to prevent contamination of the optical core with bodily fluids. A common design of the inner optical core consists of a fiber to transmit the OCT signal, coupled to a focusing element which may consist of a gradient index lens [15], ball lens, or other focusing element and a reflecting surface such as a prism to redirect the light to the tissue surface at an angle of approximately 90° to the catheter. The entire optical assembly is encased inside a metal drive shaft to provide added protection to the optical components against breakage and to convey the necessary translational actuation from the proximal end during tissue scanning. The primary difference between linear and circumferential scanning catheters is that the proximal end of circumferential scanning catheters is attached to an optical rotary junction. Together both actuation methods can be used to achieve spiral cross-sectional imaging to capture volumetric images of entire bronchial segments. While many scanning mechanisms may be used to collect OCT images of the airways,

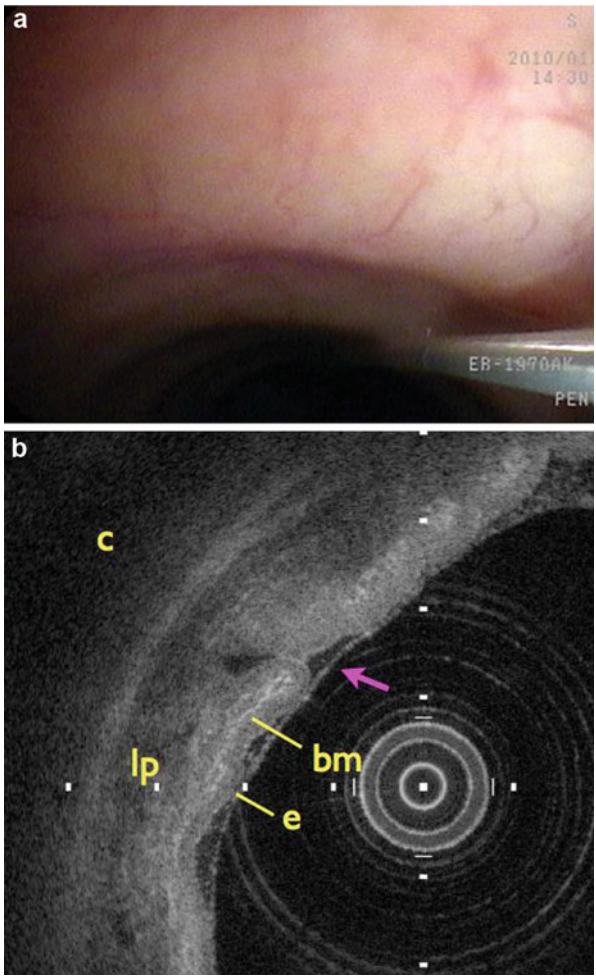

Fig. 76.14 Clinical endobronchial OCT imaging. (**a**) Spiral cross-sectional OCT catheter extending through the accessory port of a standard bronchoscope into the airway lumen. (**b**) Cross-sectional OCT image highlighting the normal layered architecture of the airway wall. *e* epithelium, *bm* basement membrane, *lp* lamina propria, *c* cartilage

circumferential and spiral cross-sectional scanning catheters have been used predominantly for clinical studies in order to acquire complete cross-sectional imaging of the entire airway lumen.

76.6.2 Transbronchial and Transthoracic

In order for OCT to play a future role the evaluation of lung pathology and the guidance of biopsy acquisition, access to regions of the lung that extend beyond the central airways is necessary. This may be through transbronchial approaches where a needle or catheter is passed through the airway wall in order to reach the surrounding parenchyma or through transthoracic approaches where a needle or catheter is passed through the chest wall into the lung. Although no transbronchial

or transthoracic OCT catheters are currently available for clinical use, a number of groups are actively working on the development of these much needed imaging tools.

A number of small diameter rigid OCT needle probes have been developed by research laboratories that may be adapted for transthoracic use [69–73]. In these designs the imaging optics are traditionally housed within the stainless steel hypodermic needles to ensure that the needle probe maintains a small diameter profile to minimize possible tissue damage. To conduct imaging the entire needle is rotated or translated. In many potential clinical applications of transthoracic OCT imaging, it may be useful to obtain biopsy specimens for histopathological analysis prior to imaging. Therefore, one limitation to these OCT needle probes is that it is not possible to obtain tissue specimens for diagnosis through the same imaging needle. Recently, Kuo et al. demonstrated an OCT-guided core-needle biopsy system incorporating a vacuum-assisted rigid breast needle biopsy console, which was modified to accommodate the OCT imaging probe [61]. This work highlights the potential of OCT image guidance for biopsy site selection with rigid needle designs.

Transbronchial OCT imaging requires the development of flexible OCT needle probes that can be passed through the auxiliary channel of the bronchoscope in a similar fashion to standard transbronchial fine-needle aspiration techniques. Tan et al. have developed a narrow diameter flexible OCT catheter that is not only compatible with standard transbronchial needles but additionally facilitates OCT imaging and subsequent tissue sampling through the same needle (Fig. 76.15) [62].

76.6.3 Pleural

Imaging of the lung pleura has been conducted by a number of groups; however, its use has been limited to early preclinical studies. These studies have utilized noncontact benchtop galvanometric scanners [74] and handheld tunable galvanometric probes for use during thoracoscopic surgery [65] to conduct imaging of the pleura and the underlying alveoli. Due to the penetration limitation of OCT, removal of the overlying muscle is necessary to create a thoracic window when using the noncontact galvanometric scanners. These studies have been conducted to both look at the normal pleural and alveolar structure and dynamics and to assess malignancy [65, 74].

76.7 Lung Cancer: Potential Role for OCT

Lung cancer remains the leading cause of cancer death in men and women in the United States. In 2009, for instance, 205,974 people in the United States were diagnosed with lung cancer, and 158,081 people died from it (US Cancer Statistics Working Group. United States Cancer Statistics: 1999–2009 Incidence and Mortality Web-based Report. Atlanta (GA): Department of Health and Human Services,

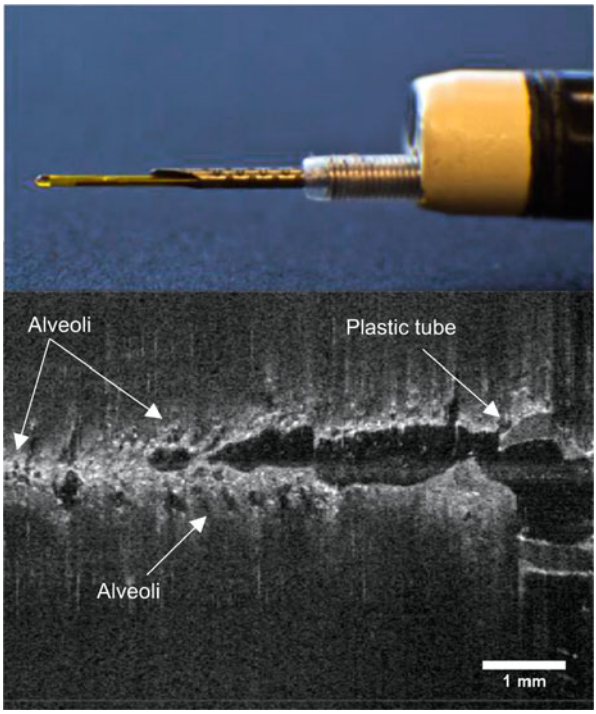

Fig. 76.15 Flexible transbronchial OCT imaging catheter housed within a 21 gauge transbronchial needle that is advanced through the accessory port of a standard flexible bronchoscope. (**b**) Longitudinal reconstruction of an OCT dataset obtained using the transbronchial OCT catheter in (**a**) from an inflated swine lung ex vivo (Modified with permission from [62])

Centers for Disease Control and Prevention, and National Cancer Institute; 2013. Available at: http://www.cdc.gov/uscs). Metastasis from lung cancer is present in over 50–60% of patients at the time of diagnosis [75], and only 40–50 % of patients currently survive for >5 years after curative-intent surgical resection of presumptively local disease. A significant proportion of patients develop local or distant recurrence following attempted curative resection [76, 77].

In addition, only 15 % of lung cancer cases are found at the localized early stage. When lung cancer is detected and diagnosed in an early stage and surgery is possible, the 5-year survival rates can reach 85 % [78] compared to <15 % 5-year survival for later stages (http://ukprc.udy.edu/policynewsletter1-1.pdf). For the vast majority of patients with limited stage non-small cell lung cancer, accurate and complete surgical resection is currently the only potentially curative approach. Accurate staging and assessment of operative margins is important both for cure and to avoid either excessive or inadequate surgical resection. Local recurrence occurs in 5–20 % of patients, depending on the pathologic staging of the tumor. Fifty percent of all recurrences are diagnosed in the first 24 months after presumed curative treatment, demonstrating another shortfall of current diagnostic capabilities. In addition to early detection, better identification of tumor boundaries and subsequent improved resection procedures should potentially lead to reduction in recurrence rates, improved survival, and reduction in inadvertent non-curative surgical procedures. Furthermore, increasingly, lung cancer care is personalized

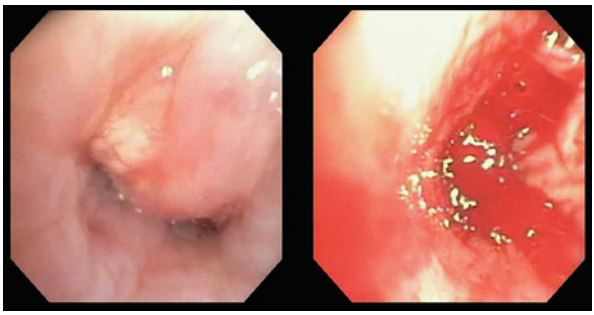

Fig. 76.16 Endobronchial tumor in the bronchus intermedius before (*left panel*) and after biopsy (*right panel*). Before biopsy, the tumor surface is heterogeneous showing areas of prominent vascularity resulting in immediate post biopsy bleeding

based on predictive and prognostic molecular markers. Targeted therapy is the new paradigm in lung cancer management, but this strategy requires sufficient tissue for these molecular analyses to be performed. Thus, it is important to develop improved methods for (1) early detection of endobronchial lung cancer; (2) accurate diagnosis and improved tumor specimen quality and quantity; (3) determination of location, borders, extent, and stage of disease; and (4) diagnostic guidance for peripheral lung nodules. High-resolution OCT imaging may have potential to fulfill some of these needs.

76.7.1 OCT-Guided Biopsy

In a number of endobronchial, peripheral parenchymal lung nodules and pleural malignancies, in which pathophysiologic abnormalities may present at or near airway or pleural surfaces, advances in real-time, high-resolution endoscopy with OCT offer potential to develop the near histologic level endoscopic evaluation capabilities needed for pulmonary and thoracic surgical cancer detection diagnostics. While the majority of lung cancers originate in the periphery, a substantial proportion of tumors (particularly squamous cell cancer) arise in or metastasize to proximal airways, where they may be visualized by current level OCT techniques [10, 15]. In airway diagnosis and treatment, selection of bronchoscopic biopsy sites is prone to sampling errors, and the biopsy procedure may be associated with airway bleeding possibly leading to hypoxemia and hemodynamic instability. This limits the number of biopsies and potential sampling sites, as well as diagnostic accuracy, while it increases risks and expense. Biopsy yield rates vary based on the underlying disease, the patient's ability to tolerate the procedure, and for malignant disease – on the location, depth, appearance, size, extent, cell type, and degrees of vascularity and necrosis. Endobronchial tumors often have regions of fibrosis, vascularity, necrosis, or areas where the tumor is located below the visible airway surface, leading to non-diagnostic endobronchial biopsies, misinterpretation of malignancy borders, or bleeding (Fig. 76.16). Using current white light flexible techniques, the bronchoscopic yield, in terms of diagnostic sensitivity and specificity for endobronchial malignancy, is variable. Rates for diagnosing visible

lesions in patients with endobronchial tumors have been reported between 75 % and 98 %, while non-visualized endobronchial tumors have been diagnosed at rates of 25–65 %. Overall specificity has been reported at 64–96 %, and pathologic diagnostic error rates of 1.5–3 % have been reported [79–92]. For central tumors the maximal diagnostic yield was not achieved until the 4th forceps biopsy, and for peripheral lesions accuracy continued to increase through the 6th forceps biopsy in another study [83]. Thus, improved guidance for airway biopsy would increase yield and decrease risks associated with the large number of biopsies currently necessary for diagnosis. The excellent sensitivity of AF has potential airway cancer screening value, and the usefulness of AF would be dramatically enhanced if methods for more specific optical evaluation of suspicious regions can be added to the sensitive but nonspecific AF screening [15]. In the future, we speculate that multimodality imaging may combine autofluorescence imaging, OCT, endobronchial ultrasound, and confocal endoscopy in various combinations based on clinical application needs, location, and resolution requirements [15, 93]. In this way, OCT may be ideal for early proximal airway malignancy detection when combined with field narrowing AFB modalities discussed previously [24]. In addition, OCT may be of assistance in guiding endobronchial biopsy sites, improving biopsy yield for endobronchial lesions, obtaining more representative specimen for molecular analysis, and reducing complications. Airway tumors are frequently friable, prone to bleeding, with substantial vascularity, as well as containing areas of necrosis and epithelial or fibrotic layers covering the tumor. OCT may be useful in identifying areas of high yield within large mucosal and submucosal tumors of the proximal airways. Submucosal vessels prone to bleeding could potentially be identified by OCT prior to biopsy as well.

In patients with airway cancer, a study of OCT demonstrated tissue structural changes in proximal airways of patients with documented, biopsy-confirmed bronchogenic carcinomas [10]. Whether these findings are specific for malignancy, or whether similar changes may be seen in patients with benign endobronchial pathology, remains to be determined by clinical investigations. This study involved use of a commercial OCT system and flexible fiber-optic rotational probe passed through the working channel of a bronchoscope. Resolution was reported to be 16 μm in axial and lateral directions [10] (Fig. 76.7). The authors examined normal and cancerous proximal airways in vivo and in freshly excised surgical specimens. The findings in the cancerous lesions in five patients are summarized in Table 76.2 (from Tusboi et al. [10]).

The majority of lung cancers, however, are peripheral (i.e., beyond the fourth to fifth generation). This leads investigators to systematically study chest computed tomography (CT) as a screening tool for lung cancer detection. Three randomized controlled studies evaluated the role of low-dose CT scan screening on the rate of death from lung cancer [94, 95]. Only the NLST study had a large number of patients (53,454 vs 4,104 vs 2,811) [94] and found a dramatic 20 % reduction in lung cancer mortality compared to those screened with CXR (RR 0.80, 95 % CI 0.73–0.93, $p = 0.004$). No difference in lung cancer mortality was reported in the DANTE trial ($RR = 0.97$, 95 % CI 0.71–1.32, $p = 0.83$) [19] or the DLSCT study

Table 76.2 OCT findings of central type lung cancer patients

					Normal bronchus			Tumor
No.	Age	Sex	Pathologic type	Location	Layer structure	Alveoli	Uneven distribution	Loss of layer structure
1	60	Male	Squamous	Right B4+5	+	N	+	+
2	56	Male	Squamous	Left B6a	+	+	+	+
3	65	Male	Squamous	Trachea	+	N	+	+
4	68	Male	Squamous	Right B1a	+	N	+	+
5	77	Male	Small	Left upper bronchus	+	+	+	+

+ Detected, *N* not performed

($RR = 1.15$, 95 % CI 0.83–1.61, $p = 0.06$) [23]. The NLST, however, is not only the largest study but also involved longer follow-up (6.5 vs 2.8 and 4.8 years median) and participants at slightly higher risk (30 vs 20 and 20 pack years of smoking for NLST vs DANTE and DLCST, respectively). The current data support a significant reduction in deaths from lung cancer resulting from several rounds of low-dose CT screening of individuals at risk (smokers and former smokers who are aged 55–74 and who have smoked for 30 pack years or more and either continue to smoke or have quit within the past 15 years). However, it is recommended that screening should be done in the settings that can deliver the comprehensive care provided to NLST study participants, which involves among other factors a multidisciplinary program and with a defined intervention algorithm. This is especially relevant for lung cancer screening since the average nodule detection rate is around 20 % but varied from 3–30 % in the randomized controlled studies. Since most studies reported that >90 % of nodules were benign, concerns exist about the potential negative impact on patient safety and health-care costs (i.e., the need for invasive procedures performed for benign disease). It is therefore desirable to obtain a diagnosis in a minimally invasive fashion without compromising a patient's safety. While CT-guided transthoracic needle biopsy and aspiration have an accuracy of 80 % and 95 %, respectively, for confirming lung cancer in peripheral lesions, the complication rates are not insignificant (pneumothorax ~13 %, hemoptysis ~6 %). Therefore, obtaining tissue bronchoscopically could be more cost-effective, especially if lung cancer screening will become standard of care. For peripheral parenchymal lesions, a systematic review showed that the overall sensitivity of conventional bronchoscopy with transbronchial biopsy, brushings, and lavage is 69 %. The sensitivity of all modalities for peripheral lesions less than 2 cm or greater than 2 cm were 0.33 and 0.62, respectively [81].

Electromagnetic navigation bronchoscopy (ENB) allows physicians to navigate through the airways and reach a target lesion in the periphery of the lung. While navigation is successful in 90 % of patients, the diagnostic yield is ~70 % with a pneumothorax rate of 1.5–3 %. The discrepancy between the ability to navigate and obtain a diagnosis is partly related to the fact that ENB guides the bronchoscopist to the lesion, but is not an endoscopic tool. The use of forceps, needles,

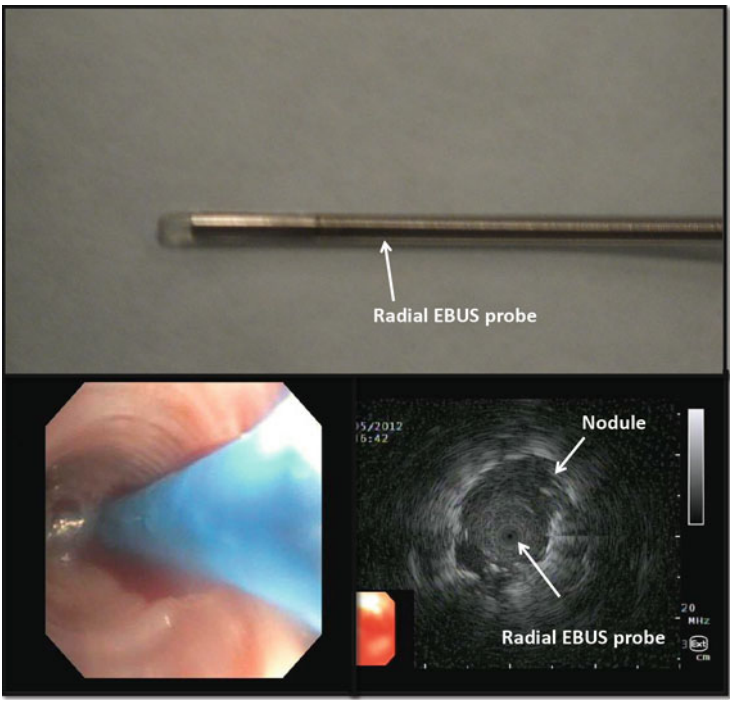

Fig. 76.17 To increase the probability that the biopsy instruments are inside the lesion, the 20 MHz high-frequency radial ultrasound probe (*top panel*) can be inserted through the guide catheter (*bottom left*) and confirm its location within the peripheral lung nodule (*bottom right*)

or brushes to obtain samples usually under fluoroscopy guidance is still necessary. To increase the probability that the instruments are inside the lesion, high-frequency radial probe ultrasound (R-EBUS) can be inserted through the guide catheter and visualize the nodule (Fig. 76.17). Results of studies show that the diagnostic yield of combined R-EBUS with ENB was ~90 %, better than either R-EBUS or ENB alone [96]. With R-EBUS, however, the probe still has to be removed before the sampling instruments are inserted. This could lead to guiding sheath displacement potentially reducing the yield. The development of integrated OCT core-needle biopsy systems can potentially solve this problem [61, 62]. This catheter-based 3-D OCT imaging can be used for real-time image guidance for target tissue localization and imaging of tissue immediately prior to biopsy. In a recent study six readers trained in simple image interpretation criteria were able to successfully differentiate between OCT images of solitary pulmonary nodules and lung parenchyma with a sensitivity and specificity >95 % providing support for the use of OCT-guided biopsy of these lesions [97]. OCT has additionally been demonstrated to differentiate tumor from non-tumor tissues including necrosis, fibrosis, and calcification [98]. Since such OCT images of biopsied ex vivo tumor specimens acquired during core-needle placement correlate with corresponding

histology, these systems can potentially not only localize the lesion but avoid the actual aspiration, specimen retrieval, and processing, if the OCT probe is in the undesirable areas (normal lung tissue, highly vascular or necrotic nodule regions).

76.7.2 OCT Tumor Margin Assessment

During lung cancer resections, despite apparently clean margins based on preoperative and intraoperative evaluations, local airway recurrence rates of 17–26 % after what was thought to be complete resections were reported [99–101]. OCT may have a role in identification of tumor boundaries in the mucosa and submucosa of airways and thus potentially facilitate intraoperative decisions in regard to tumor-free bronchial margins. Determining the proximal and distal boundaries of airway involvement is an important step in staging lung cancer, as well as in determining resectability, operability, extent of resection, and resection margins. Since recurrence at the site of resection must be avoided, preoperative and intraoperative methods for determining the tumor boundaries would be very useful. Accurate clinical diagnosis of endobronchial cancer, and its peripheral margins, is crucial to choosing the correct surgical or medical therapeutic regimen. This is particularly significant when a thoracic resection procedure (tracheal resection, thoracotomy or thoracoscopy with lobectomy, sleeve resection, or pneumonectomy) is being considered with curative intent, and ensuring adequacy of staging and surgical margins around a suspected primary malignant lesion is essential for proper therapy. Identification of unsuspected microinvasion, submucosal spread not visible on the surface, or of small satellite lesions by OCT and AFB could theoretically improve accuracy of biopsy tumor margin assessment, leading to more effective treatment. The role of OCT in such evaluations remains to be determined. However, although OCT may theoretically be very helpful if benign from malignant airway tissue can be readily distinguished, utility may still be limited for detecting tumor margins by the shallow depth of penetration, since deeper level tumor invasion cannot be assessed with current OCT technology. Indeed, the cartilage in the large airway is not entirely visualized in cross section, but this can be done by applying high-frequency endobronchial ultrasonography, method shown to impact treatment decisions in patients with airway cancer [102]. For airway tumors in particular, it is likely that OCT will be used in combination with other modalities. For instance, results of studies show that combination of NBI and AF shows higher sensitivity (93.7 %) and specificity (86.9 %) in the assessment of lung cancer extension when compared to WLB alone [103]. OCT could further improve the specificity for this application of optical technologies.

76.7.3 Optical Biopsy

Some innovators in the development OCT have proposed the concept of “optical biopsy” in which OCT high-resolution imaging may replace current traditional

tissue biopsy methods [104, 105]. While this is a valuable long-term research target, even ultrahigh-resolution OCT imaging is unlikely to replace tissue biopsy for pulmonary diagnostics in the near future. While biopsy specimen examination for histologic appearance may soon be rivaled by ultrahigh-resolution techniques (if endogenous or exogenous contrast is adequate), a range of other information obtained from tissue biopsy may still be unobtainable until considerable scientific advances have been made. For example, special immunologic staining for cellular antigens to characterize tissue origin and define histologic subtypes or infectious agents currently requires excised tissue for staining and/or culture. While it is conceivable that in vivo fluorescent probes with analogous capabilities may someday become available, the broad range of antigen-specific probes necessary will undoubtedly take many years to develop. In addition, malignant cells and many infectious agents are cultured in the laboratory for DNA analysis, metabolites, subtyping, and chemosensitivity or antibiotic sensitivity testing. This is especially relevant now in the treatment of lung cancer, where decisions about prognosis and predictions about response to specific agents are based on molecular markers for which tissue analysis remains necessary.

Thus, the major role for OCT in pulmonary diagnostics will likely include guiding biopsy sites and assessing response to therapeutic interventions in the near term.

76.8 Inhalational Injury

The lung is a unique organ in which internal tissue is exposed to large volumes of external air (greater than 10,000 l/day inhaled and exhaled, with more than 5,700 l/day of blood flowing through the lungs) [21] (page 7), allowing potential exposure to environmental toxins, particulate matter, infectious agents, as well as thermal stresses and smoke. Depending on the nature of the exposure, the predominant injuries may occur in the proximal airways, distal airways, alveoli, or even the pleural space. Some initial investigations have focused on OCT proximal airway exposures. In studies involving pulmonary inhalation-related pathology, OCT was capable of detecting submucosal edema and glandular crowding in a septic inhalation injury airway animal model [16, 106, 107]. In victims of smoke and thermal inhalation, swelling, edema, sloughing, and obstruction of airways are a major cause of morbidity and mortality (Fig. 76.18). It is difficult to determine the extent of airway injury early after smoke and thermal inhalation exposures. Therefore, many patients must be prophylactically intubated in order to assure a patent airway if swelling occurs. OCT has the potential to detect early airway inflammation and progress of airway swelling in a minimally invasive way. In addition, long-range FD OCT may allow not only monitoring of the airway wall thickness but also measurement of the lumen cross-sectional area [57]. Future clinical studies will be needed to determine the value of OCT monitoring in this setting. In addition,

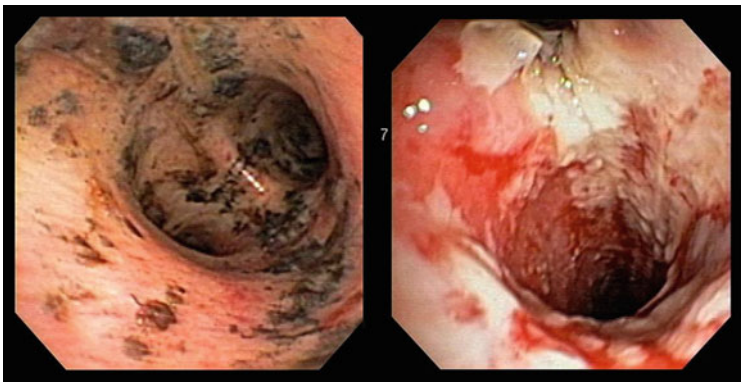

Fig. 76.18 Examples of airway mucosal findings on bronchoscopy in patients with smoke and thermal inhalation injury. Erythema and carbonaceous particulate material can be visualized at earlier stages (*left panel*) followed by edema, mucosal necrosis, sloughing, and obstruction of the airways (*right panel*)

we speculate that OCT may potentially be useful for evaluating submucosal blood flow changes or structural matrix changes using Doppler and polarization-sensitive OCT.

76.9 Asthma

Asthma currently affects over 300 million individuals worldwide, and the prevalence is continually increasing [108]. Approximately 10 % of asthmatics have uncontrolled or poorly controlled symptoms [109], and it is this population that urgently needs improved targeted therapies and management strategies in order to reduce the high morbidity and socioeconomic burden, estimated to be 14.7 billion dollars annually in the United States alone [108]. Asthma refers to individuals with reversible airway obstruction and bronchial hyperresponsiveness. Though classically thought to be a chronic inflammatory disease, studies have recognized groups of individuals with severe asthma in the absence of eosinophils [110, 111]. It is now understood that asthma is not a single disease but is rather a collection of multiple asthma phenotypes [112, 113]. The exact mechanisms behind the pathophysiology of asthma remain uncertain which may be due in part to a lack of available imaging tools with sufficient spatial and temporal resolution to dynamically assess airway structure and function in vivo. OCT has been used to assess airway wall thickness [25] and biomechanical properties [26, 58]. It remains to be seen, however, if OCT will enable the evaluation of all of the hallmark features of asthma including inflammation, remodeling, and hyperresponsiveness. With continued improvements in image resolution to the micron scale, increases in acquisition speed for dynamic imaging, and increases in contrast through Doppler or polarization-sensitive OCT, OCT may become an invaluable tool in assessing asthma.

OCT may be beneficial in improving our understanding of asthma, phenotyping asthma to better match individuals to appropriate therapeutics, guide and monitor response to therapies, and may be useful in guiding critical decision making in the drug development pipeline.

76.10 Commercial Pulmonary Clinical OCT systems

In recent years a number of clinical endoscopic OCT systems have become, or will likely soon become, commercially available including systems by Imalux Corporation [114], St. Jude Medical (Lightlab Imaging) [115], Terumo Corporation [116], Tomophase Corporation [117], Volcano Corporation [118], and NinePoint Medical [119]. At present only Tomophase is focused on the development of systems dedicated for pulmonary use; however, due to the synergy of system and catheter requirements across organ systems, many of the seminal OCT work conducted in the pulmonary space has been performed using commercial and research system designed for intracoronary or gastrointestinal imaging.

76.11 Technological Challenges and Recent Advancements

76.11.1 Multimodality OCT Systems

In many cases a single imaging modality is insufficient to comprehensively investigate pulmonary tissues. Ultimately, multimodality imaging with a variety of methods that may include combinations of endobronchial ultrasound, white light optical imaging, OCT imaging, fluorescence imaging, and fluorescence and non-fluorescence confocal endoscopy may someday be used to optimize the characterization, structure, and function of tissues and to augment or to provide complementary diagnostic information. The fusion of optical imaging technologies, while still in the early stages of development, is currently the focus of many leading research laboratories with investigators conducting preliminary feasibility and proof-of-principle studies evaluating complementary co-registered imaging technologies and developing hybrid systems and catheters. One example includes the recent development of a dual-modality needle probe by Lorenser et al. that enables both fluorescence imaging and simultaneous OCT [120]. The investigators used this multimodality imaging catheter to acquire images of an excised sheep lung following the administration of fluorescein. This dual-modality imaging catheter may be useful in conducting fluorescein angiography of pulmonary vasculature to assess microvascular leakage [121] or for molecular imaging techniques similar to those recently developed for intracoronary imaging [122]. Additional examples of multimodality OCT imaging systems initially developed for cardiovascular applications but with the potential to be adapted to the lung include OCT and fluorescence spectroscopy [123], combined reflectance, fluorescence, Raman spectroscopy [124], OCT and positron detection [125], and OCT and ultrasound [126–128].

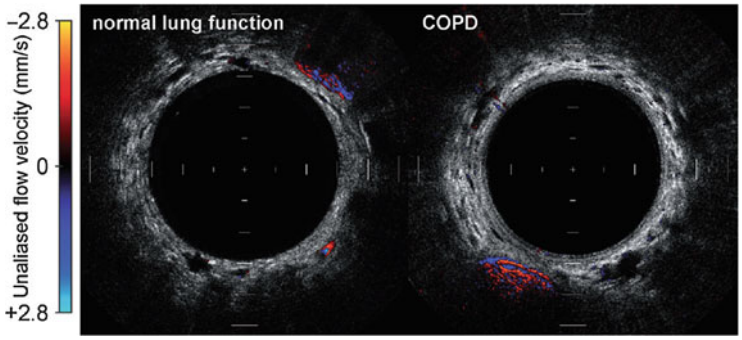

Fig. 76.19 Color Doppler optical coherence tomography images from the airways of (*left*) a subject with normal lung function and (*right*) a subject with moderate COPD, $FEV_1/FVC = 61\ \%$ and $FEV_1 = 60\ \%$ predicted. The detected vasculature using color Doppler OCT imaging (colored) has been overlaid onto the structural OCT images (*gray scale*). Velocity aliasing is apparent from the presence of adjacent positive and negative velocity pixels. Note that the airway remodeling indicated by the airway wall thickening is the COPD subject. Fiducial markers are spaced 0.25 mm apart, assuming air as the imaging medium (Reprinted with permission from [34])

76.11.2 Doppler OCT

In addition to the microstructural information provided by OCT, functional information can be obtained using Doppler OCT [129–131]. Doppler OCT provides a measure of the flow of blood in the microvasculature and in larger vessels. Preliminary studies have demonstrated the use of Doppler OCT to evaluate the pulmonary vasculature in the airways of smokers and healthy volunteers with the goal of identifying changes or remodeling of the vasculature associated with the development of COPD (Fig. 76.19) [34]. With the increase in imaging speed and sensitivity, Doppler OCT has the potential to be a clinically useful imaging tool to assess changes to the pulmonary vasculature in response to various disease processes including tumor angiogenesis and COPD-associated vascular remodeling.

76.11.3 Polarization-Sensitive OCT

Polarization-sensitive OCT is another embodiment of OCT that provides a measure of tissue birefringence by detecting polarization changes in the light returning from the tissue sample being imaged [132]. When light travels through tissues that exhibit form birefringence, orthogonal polarization components of the light will undergo a phase retardation with respect to one another. The degree of phase retardation is dependent on the orientation of the polarization state with respect to the organized linear structures within the tissue, such as collaged fibers and smooth muscle cells [133, 134]. The detected birefringence increases in tissues containing highly organized linear structures. PS-OCT provides complementary image

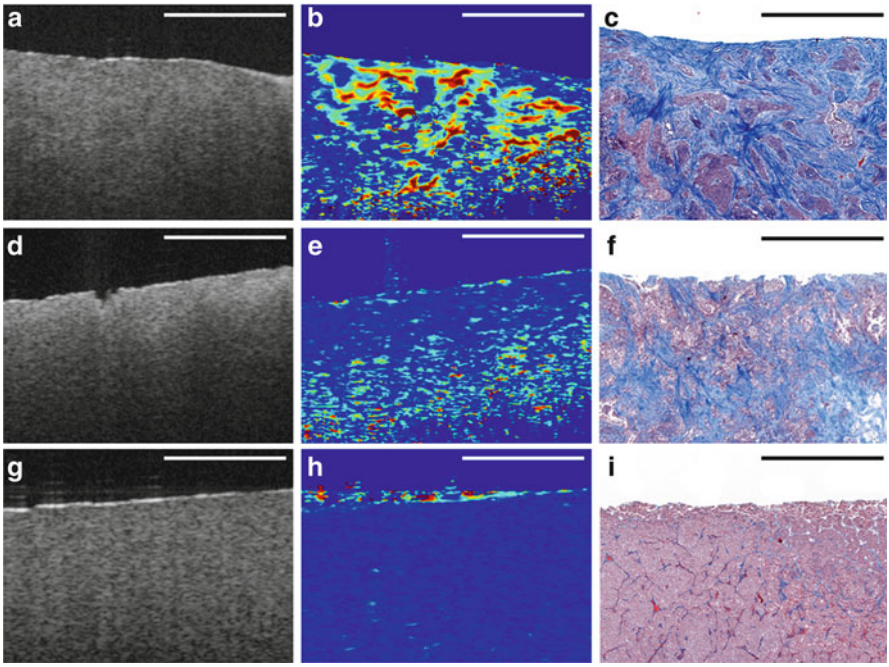

Fig. 76.20 Polarization-sensitive OCT (PS-OCT) of tumor and tumor-associated desmoplasia in ex vivo lung. (**a**) Structural OCT of squamous cell carcinoma with dense desmoplastic fibrosis. (**b**) PS-OCT of squamous cell carcinoma with dense desmoplastic fibrosis, with high birefringence in the fibrotic component. (**c**) Trichrome stain of squamous cell carcinoma with dense desmoplastic fibrosis, displaying deep *blue* staining in areas of dense fibrosis. (**d**) Structural OCT of adenocarcinoma with early desmoplasia. (**e**) PS-OCT of adenocarcinoma with early desmoplasia showing moderate birefringence in the lower half where more organized collagen is present and less birefringence in the upper half where tumor is admixed with young, poorly organized collagen and elastic fibers. (**f**) Trichrome stain confirming more organized desmoplasia in the lower half staining deeper *blue* and less organized desmoplasia in the upper half staining lighter *blue gray*. (**g**) Structural OCT of carcinoid tumor and (**h**). PS-OCT of carcinoid tumor showing little to no birefringence. In both the structural and PS-OCT images, there is a high signal intensity artifact across the surface of the tissue sample. (**i**) Trichrome stain confirming lack of significant collagen with the carcinoid. Scalebars: 1 mm (Reprinted with permission from [98])

information to structural OCT images that may assist in the identification of lung tissues such as the presence of fibrosis or airway smooth muscle.

Recently, Hariri et al. demonstrated in ex vivo lung resections of pulmonary nodules the potential of PS-OCT for guiding biopsy site selection to ensure that diagnostic quality tissue is obtained [98]. Structural OCT can be used to identify normal airway and parenchyma, necrosis, and calcification, but it does not have the necessary contrast to differentiate tumor from non-diagnostic desmoplastic fibrosis. The authors demonstrated that PS-OCT provides additional contrast to the OCT images by detecting a strong birefringence signature in regions of dense desmoplastic fibrosis (Fig. 76.20).

76.11.4 Increased Imaging Speeds

With the current speeds of catheter-based OCT systems, typically in excess of 100 frames per second, motion artifacts in cross-sectional 2D images do not appear to be an issue in the pulmonary imaging. However, when volumetric OCT imaging is required, for example, when imaging bronchial segments spanning multiple airway generations, respiratory and cardiac motion causes longitudinal dithering of the OCT catheter with respect to the bronchial wall. Although still in the early developmental phases, investigators are currently exploring respiratory gating techniques [67], novel scanning and reconstruction patterns [135], and catheter stabilization devices such as wire cage designs to mitigate the longitudinal blurring.

76.11.5 Increased Imaging Resolution

Practical methods for obtaining 1–2 μm resolution are needed for endobronchial diagnostics. The resolution of OCT systems has been steadily increasing over the years, and it is now possible to conduct benchtop imaging on the 1–2 μm scale. Such systems have been used to study mucociliary transport in the normal airway and alterations to this behavior in response to cystic fibrosis or COPD where mucus flow is compromised [136]. However, maintaining this high resolution in catheter-based systems, which are necessary for many in vivo pulmonary imaging applications, remains a technical challenge that needs to be overcome if these systems are to make a real impact in the clinical setting.

76.12 Potential Pulmonary OCT Applications for Future Investigation

As ongoing advances are made in OCT technology and site delivery probe capabilities, many potential areas for pulmonary OCT application can be envisioned. Examples of such applications may include (but would certainly not be limited to) areas listed here in Table 76.3.

76.13 Conclusion

Recent advances in OCT open broad areas of potential applicability for clinical and research applications in pulmonary medicine. Undoubtedly, other applications for OCT in the pulmonary and thoracic clinical arena will be described as OCT technology becomes more advanced and more widely available to researchers and clinicians in the future.

Table 76.3 Potential areas for future clinical and research OCT applications in pulmonary medicine

Providing in situ three-dimensional tomographic images and velocity profiles of blood perfusion in human tracheo-bronchi at discrete spatial locations in either the epithelial or mucosal layers, potentially useful for determining tumor margins as well as for determining remodeling/therapy effects in asthma
Confirm intralesional location of the biopsy and aspiration instruments for peripheral nodules
Guide needles and forceps towards the areas void of necrosis/fibrosis during sampling procedures of the pulmonary nodules
Determining burn/tracheal injury depth and airway lumen cross-sectional area with fast image acquisition systems (long-range FD OCT). This may provide guidance regarding the optimal depth for airway management assessment
Monitoring tracheobronchial tissue perfusion and viability in lung transplants
Monitoring bronchoconstriction and determining smooth muscle mass in asthma before and after therapeutic interventions such as bronchial thermoplasty
Monitoring laser-tissue effects and potentially avoiding normal airway injury during laser treatments of airway lesions
Monitoring the effects of pharmacological intervention on bronchial microcirculation (e.g., effects of vasoactive compounds or inflammatory mediators)
Optimizing oncologic treatment dosimetry by assessing and quantifying alterations in tissue microvascular and matrix structure from external beam irradiation, brachytherapy, or photodynamic therapy (PDT)
Assessing inflammation and hyperemia in chronic bronchitis/bronchiectasis/cystic fibrosis
Pleural space investigations of malignant and inflammatory processes
Examining dynamic structural and functional changes in airways during respiratory cycling

77.1 Introduction: Motivation for OCT Application in Gynecology

Timely and efficient diagnosis of diseases of the female reproductive system is very important from the social viewpoint [1, 2]. Diagnostic efficacy of the existing techniques still needs improvement since malignant neoplasms of the female reproductive system organs are stable leaders among causes of death (over 35.9 %) [3]. Each year, 851.9 thousand genital cancer cases are recorded worldwide [1, 2].

Cervical cancer is among the most common malignant neoplasm in women and the most common cause of death from cancer in young women worldwide. It commonly occurs at the height of women's productive lives often when they

still have young children at home. Yearly, 510,000 new cervical cancer cases are registered worldwide, and of these cases, 288,000 women die, and over 5–6 billion dollars is spent on patient treatment [2].

A decrease in the cervical cancer incidence has occurred in the senior age group, while a significant increase is observed for women in the early reproductive age group (by 2 % yearly, on the average) [4–6]. In the USA, according to the data of the American Oncological Society as of 2002, 47 % of the cervical cancer patients are women up to 35 years old [7]. Cervical cancer in young women has a less favorable prognosis, because it progresses faster, late stage is observed more frequently than in the senior age group, and consequently 5-year survival is lower [7].

Initial risk stratification for cervical neoplasia is performed using screening techniques including Pap smear and HPV (human papilloma virus) testing. The next step for diagnosis is a visual examination of the cervix. The potentially neoplastic lesions can be better visualized using application of acetic acid. The unmagnified examination of the cervix is known as VIA (visual examination with acetic acid), and the magnified examination using low-magnification, long working distance microscope, is known as colposcopy. Both VIA and colposcopy are frequently combined with biopsies. Histopathology evaluation of the biopsies serves as a "gold standard" for diagnosis.

However, the diagnostic efficacy of the visual examination with biopsy is limited. Similar visual abnormalities can be observed for a variety of cervical conditions, benign and malignant, which reduces specificity and positive predictive value. Correct interpretation of colposcopic features requires high skills and long-term clinical experience, which makes colposcopy very subjective and limits interobserver agreement [8–10].

In addition, histological processing of biopsy requires several days or even weeks, which creates several problems. In most cases, treatment decisions cannot be made until histology results are received and reviewed, which requires more visits and increases healthcare cost and patient anxiety. In underdeveloped countries (which account for 80 % of the world's cervical cancer cases), additional visits can be difficult or impractical. Therefore, in many cases a real-time decision should be made without biopsy results, representing a difficult tradeoff between potentially unnecessary treatment because of oversensitive but not specific diagnostics and, alternatively, potentially leaving early and curable cervical cancer untreated which could then grow into a life-threatening condition.

OCT is known to visualize in vivo and noninvasively tissue microstructure with spatial resolution approaching the histologic level and therefore can be expected to guide biopsies and to provide real-time tissue structure information when biopsies are contraindicated or impractical. Although thorough clinical studies are required to determine if OCT can be suitable for this purpose in gynecology in general and for cervical cancer in particular, the early results look encouraging.

The first in vivo OCT images of the uterine cervix were obtained by a Nizhny Novgorod team in 1997 [11]. Later, the clinical feasibility of OCT in gynecology was discussed in a number of papers [12–22]. The papers published by the MIT group in 1999 [23, 24] described the OCT features typical for a normal exocervix

(a sharp, high-contrast interface between stratified squamous epithelium and connective tissue stroma), endocervix (visualization of cervical glands), and endometrium (contrast of glands). It was shown that the possibility to detect neoplastic changes in stratified squamous epithelium by the OCT is associated with the disappearance of the interface between the epithelium and connective tissue. These findings were later confirmed in the studies performed by the CCF group [25, 26] and the University of Texas at Austin [27].

The OCT potential for pelvic organ visualization during laparoscopy was explored in several papers [12, 15, 23, 28, 29]. The Nizhny Novgorod group [15] and the MIT group [29] explored the use of OCT to assess the functional condition of the fallopian tubes in reproductive gynecology. A University of Arizona group, considering four categories of the ovarian conditions (norm, endometriosis, high neoplasia risk, and neoplasia), formulates the OCT features to differentiate between benign and malignant processes [28].

In this chapter, we present a wide spectrum of the OCT studies of different parts of the female reproductive system and demonstrate the potential of the clinical use of a new visualization method in gynecological practice.

77.2 OCT-Colposcopy

77.2.1 Methodology and Patient Selection

During the OCT study of the female reproductive system, 235 patients were enrolled at the Nizhny Novgorod Regional Hospital and Regional Oncology Clinic.

All patients signed the voluntary informed consent. The study was approved by the Ethical Committee for scientific studies with human subjects.

The majority of work was performed on the uterine cervix. Two hundred five patients were enrolled in the cervical OCT study, average age 36.5 years.

The cervical OCT was performed for the patients with:

(i) History of abnormal colposcopic findings
(ii) Abnormal results of Pap smear (ASCUS, LSIL, HSIL)
(iii) Positive HPV test for oncogenic viral type

Exclusion criterion was age under 18.

The breakdown of exocervical conditions is shown in Table 77.1 for the studied group of patients.

77.2.1.1 Uterine Cervix OCT Protocol

The cervical study OCT involved several stages:

- Review of patient history including cytology results
- Visual examination/colposcopy and identification of regions of interest (ROI)
- OCT of identified ROI
- Biopsy of ROI, when clinically appropriate
- Histopathology evaluation of biopsy and comparison with OCT and colposcopic findings

Table 77.1 In vivo OCT study of the female reproductive system

Total studied, $n = 205$				
Normal, $n = 30$ (14.6 %)	Benign pathological conditions, $n = 113$ (55.1 %)	Malignant pathological conditions, $n = 52$ (25.4 %)		Pregnant $n = 10$ (4.9 %)
	Ectopy, $n = 47$	CIN III, $n = 28$	Uterine cervix cancer, $n = 24$	
	Exocervicitis, $n = 28$			
	Endometriosis, $n = 7$			
	Cervical erosion, $n = 10$			
	Leukoplakia, $n = 12$			
	CIN I–II, $n = 19$			

OCT does not require additional preparation of the patient and anesthesia.

During the OCT studies, we used a compact portable OCT system developed and constructed at the Institute of Applied Physics of the Russian Academy of Sciences (Nizhniy Novgorod, Russia). The device received Russian regulatory authority certification for clinical use in August 2005.

The unit has the following technical characteristics:

- Central wavelength 1,300 nm
- Radiation power: not exceeding 6.0 mW
- Spatial resolution: 10–20 μm
- In-depth scanning range – up to 2 mm
- Lateral scanning range 1–2 mm
- Acquisition time for two-dimensional 200 × 200 pixel image: 1.5–2 s

The device is compact and has the following dimensions: 250 × 400 × 450 mm. The weight is 10 kg. All optical and electronic parts of the OCT unit are located inside a console.

The cervical OCT was performed using a detachable, reusable forward-looking OCT probe with an outer diameter 2.7 mm (Fig. 77.1a, b). The probe can be cold disinfected or sterilized. Alternatively, a disposable sterile sheath with an optically transparent membrane (Fig. 77.1b) was used to hold the probe and prevent contamination; in this case the probe was not in direct contact with the patient tissues.

To perform OCT, the probe was applied to the cervical area of interest under the colposcope control. To reduce artifacts related to unintentional movements of the probe and the study object, the distal end of the probe or the sheath membrane was in contact with the tissue.

The obtained images were interpreted directly at the time of the patient examination.

Later, we conducted a comparative analysis of the OCT and histological data. The material obtained by the biopsy, loop electro excision procedure (LEEP), and hysterectomy was subject to histological assessment. The guided biopsy was performed under the colposcopic control immediately after the OCT imaging only when clinically indicated. Cervical histopathology was obtained for 138 out of 205 (67.3 %) patients. The specimen volume and depth were sufficient for identifying the structures in the OCT image with size usually equal to 1.7 × 1.5 mm.

77.2.2 OCT Images of Normal Cervix: Impact of Age and Hormonal Status on the OCT Image

Thirty patients with an unchanged uterine cervix were enrolled in the study. Some of these patients had colposcopy as a stage of preparation for radical hysterectomy. The cervical OCT was performed in vivo during colposcopy 1 day before the surgery. The cervical area to image was chosen at 12 o'clock of a conventional dial, 1 cm from the cervical channel, and the ex vivo imaging was performed of the same area of the fresh surgical specimen, followed by histopathological evaluation.

Figure 77.2 shows typical OCT image (a) and the parallel histology (b) of the unchanged normal cervix. The upper homogeneous layer with moderate signal level corresponds to a stratified squamous epithelium in the histological specimen. The lower, brighter layer in the OCT images corresponds to the connective tissue stroma of the cervical mucosa.

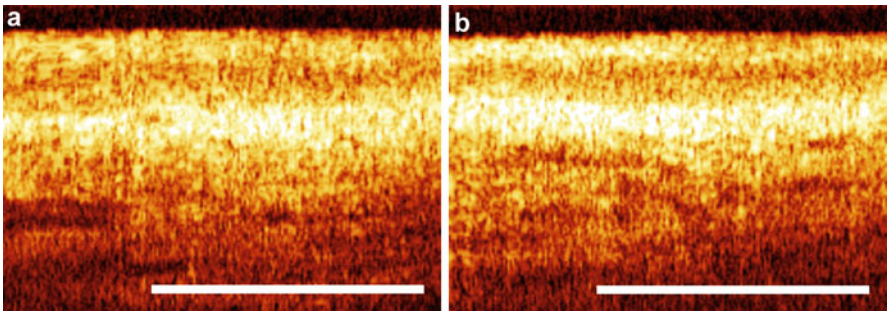

Fig. 77.3 OCT images of the normal cervical mucosa. (**a**) Before application of 5 % acetic acid, (**b**) after application of 5 % acetic acid

The interlayer interface corresponds to the basal membrane location; however, the basal membrane itself is extremely thin (several nanometers) and cannot be directly visualized using light.

After the application of 5 % acetic acid, optical backscattering increases, which is consistent with visual appearance (especially for the acetowhite epithelium) (Fig. 77.3).

We consistently observed a two-layered image with an even, sharp, and continuous interface between the layers as the main sign of the normal exocervical OCT appearance for any age group.

77.2.2.1 OCT Study of the Epithelial Thickness of the Cervical Mucosa

Since the stratified squamous epithelium is well delineated in the normal cervical OCT images, the thickness can be easily measured. This thickness changes significantly depending on the menstrual cycle phase since it is known to be hormonal status dependent. The colpocytological study was performed for ten patients in the group with normal uterine cervix. We used karyopyknotic index (KI) and maturation index (MI) as commonly accepted means to assess hormonal status [30]. Figure 77.4 shows OCT cervical images for two patients in the same age group but with different estrogenic saturation level. For the first patient, 24 years old, the KI on the 24th day of the menstrual cycle was 28 and the MI was 0/44/56, the epithelial thickness was measured 250 μm (Fig. 77.4a) in the OCT image. The second patient, 30 years old, on the 17th day of the menstrual cycle, had KI equal to 0 and MI 0/89/11. Accordingly, the epithelial thickness was 160 μm.

More pronounced differences can be observed between different age groups (Fig. 77.5). Pronounced proliferation with $KI = 32$ and $MI = 0/26/51$ was detected for a 29-year-old patient on the 12th day of the menstrual cycle. In the OCT image (Fig. 77.5a), the epithelial thickness was 275 μm. Epithelial atrophy with $KI = 0$ and $MI = 12/88/0$ was visualized for a 65-year-old patient (Fig. 77.5b) with the epithelial thickness reduced to 100 μm.

Therefore, OCT visualizes and allows objective in vivo measurement of the epithelial thickness variation in the cervical mucosa, including changes related to the hormonal status.

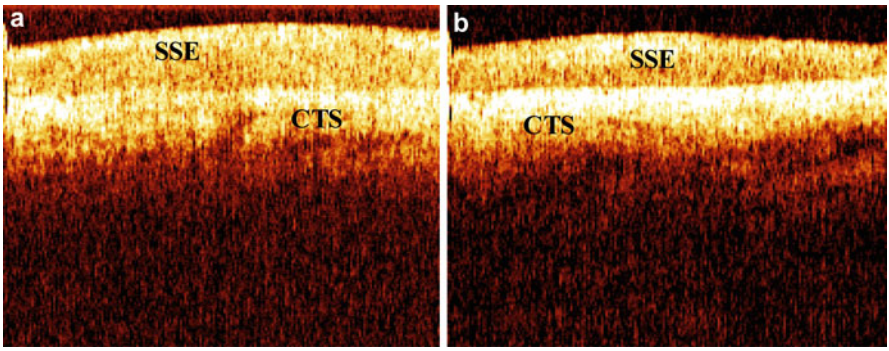

Fig. 77.4 OCT images of the cervical mucosa for two patients in the same age group: (**a**) a 24-year-old patient on the 24th day of the menstrual cycle, KI is 28, MI is 0/44/56, the SSE thickness is 250 μm; (**b**) a 30-year-old patient on the 17th day of the menstrual cycle, KI is 0, MI is 0/89/11, the SSE thickness is 160 μm. *SSE* is a stratified squamous epithelium and *CTS* is the connective tissue stroma

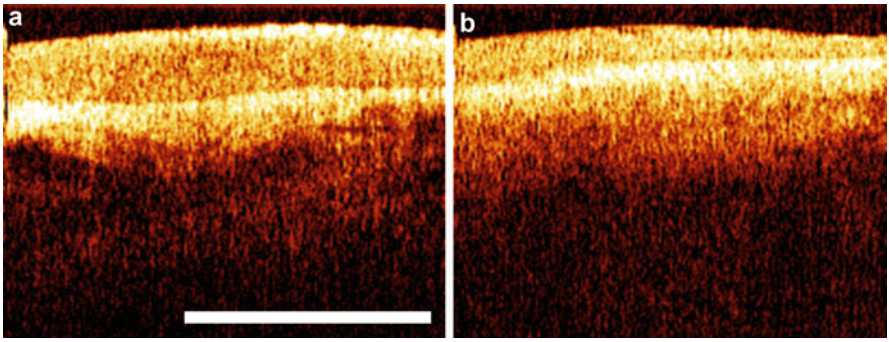

Fig. 77.5 OCT images of the cervical mucosa for two patients in different age groups: (**a**) 29-year-old patient on the 12th day of the menstrual cycle with $KI = 32$ and $MI = 0/26/51$, the SSE thickness is 275 μm, (**b**) 65-year-old, 20 years postmenopausal, $KI = 0$ and $MI = 12/88/0$, the SSE thickness is 100 μm

77.2.3 OCT Images of Benign Processes

77.2.3.1 Ectopy and Metaplasia

The normal cervical OCT appearance serves as a good baseline, and changes of this pattern can be associated with different benign and malignant pathological conditions.

Cervical ectopy (or ectropion) is a very common benign cervical condition. According to the histological data, the stromal base of ectopy is loose, infiltrated by inflammatory cells, and has a papillary shape with formation of crypts. The stromal papillae are covered by a single-row cuboidal epithelium. In the majority

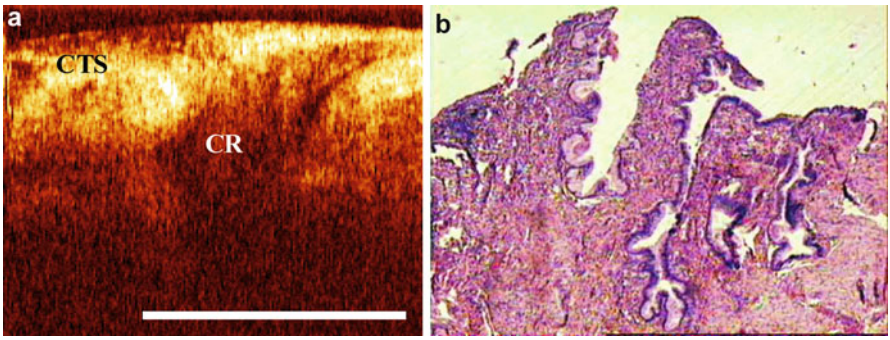

Fig. 77.6 OCT images (**a**) and parallel histology (**b**) of the cervical ectropion. *CTS* is the connective tissue stroma and *CR* is the mucus-filled crypts

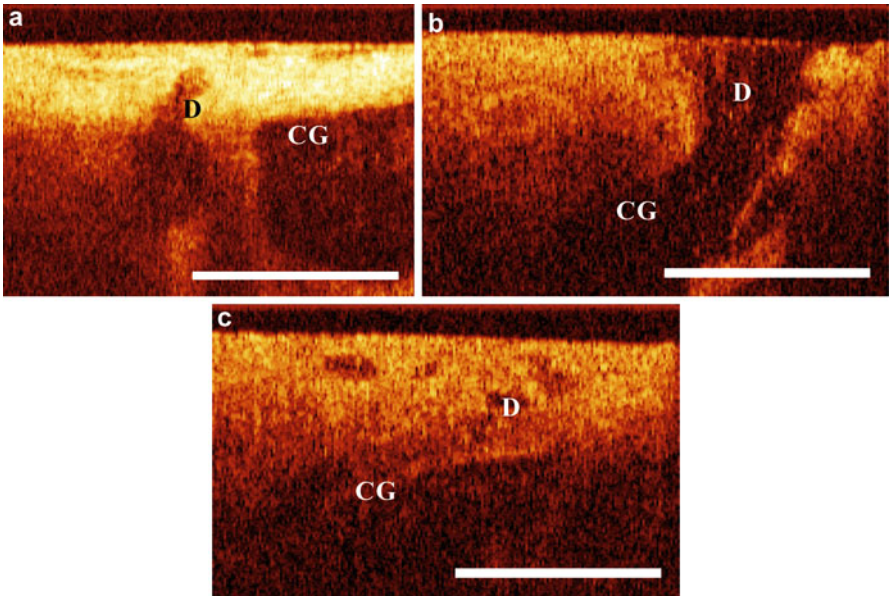

Fig. 77.7 (**a**–**c**) OCT images of structural regeneration elements. *CG* are cervical glands and *D* are the ducts of the cervical glands

of cases, ectropion is visualized in the form of a non-layered structural image (Fig. 77.6a) in which chaotically located various shaped and brightness regions are observed. Comparing OCT images and histology slides, we found that bright (strongly scattering) parts correspond to the CTS, while dark (weakly scattering) parts correspond to the mucus-filled space between the stromal papillas.

The squamous regeneration process is accompanied by formation of structural elements (open ducts and cervical glands). The OCT is capable of visualizing these structures in vivo (Fig. 77.7).

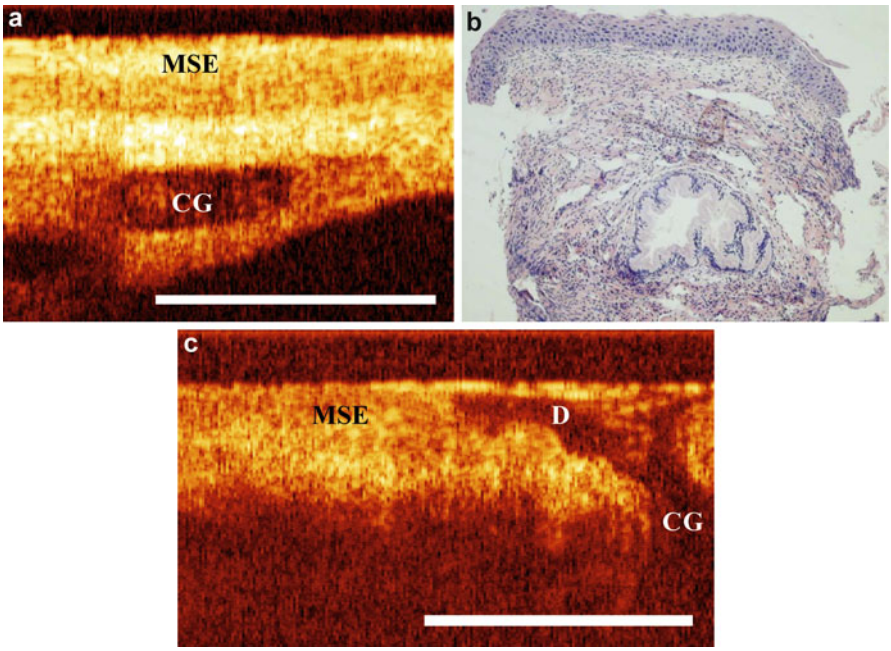

Fig. 77.8 OCT image of mature metaplastic epithelium (**a**, **c**) and parallel histology (**b**). *CG* are the closed cervical glands. *MSE* is the mature squamous epithelium. (**c**) *D* are the ducts of the cervical glands

Once the formation of a mature metaplastic epithelium is completed, the cervical mucosa is visualized as a sharp double-layered image with an even interlayer interface, resembling original squamous epithelium. However, closed cervical glands are seen under that new squamous epithelium (Fig. 77.8), which makes it different from the normal (original) squamous cervical mucosa.

77.2.3.2 Cervicitis

OCT images of inflammatory cervical changes may look different. OCT images still may have a sharp double-layered appearance. However, the contrast between SSE and stroma can be substantially reduced or completely lost. We associate it with the cellular infiltration changing stromal optical properties. In some OCT images, multiple sharp round and/or linear cavities with a low signal level (Fig. 77.9) can be observed. These cavities can be associated with edema and/or cervical glands.

As in normal cervical mucosa, application of acetic acid reduces the stratification contrast and increase brightness of the upper layer (Fig. 77.10).

In some cases, severe inflammation can completely erase the contrast of the epithelium-stromal interface, creating structureless OCT images (Fig. 77.11).

The inflammatory process can be accompanied by epithelial hyperplasia, acanthosis, and papillomatosis, which are visualized as an increase in the upper moderately scattering layer thickness and discontinuous nature of the interlayer interface (Fig. 77.12).

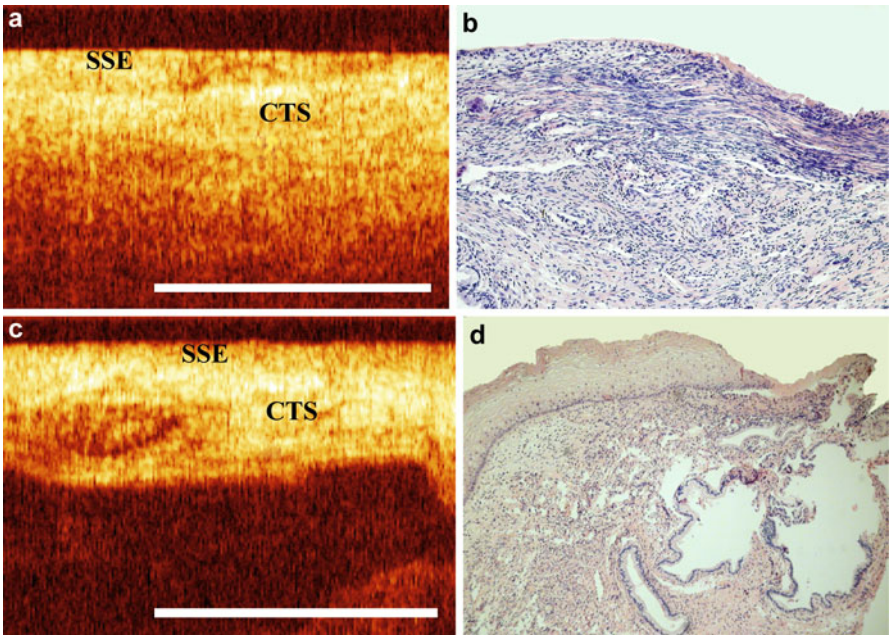

Fig. 77.9 OCT images (**a**, **c**) and histology (**b**, **d**) of the cervical mucosa with cervicitis. *SSE* is the thinned stratified squamous epithelium. *CTS* is the connective tissue stroma

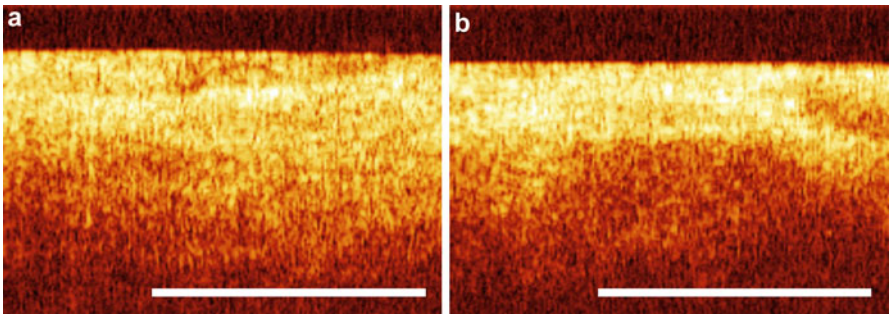

Fig. 77.10 OCT images of the cervicitis. (**a**) Before acetic acid application; (**b**) after the acetic acid application

77.2.3.3 Cervical Leukoplakia

Hyperkeratosis

In the presence of mild hyperkeratosis, the cervical mucosa is still visualized in OCT as a structural layered image (Fig. 77.13). The keratinization is responsible for an increase in the superficial brightness of the image. The interface between the layers could be discontinuous with reduced contrast, because of papillomatosis, which frequently accompanies hyperkeratosis.

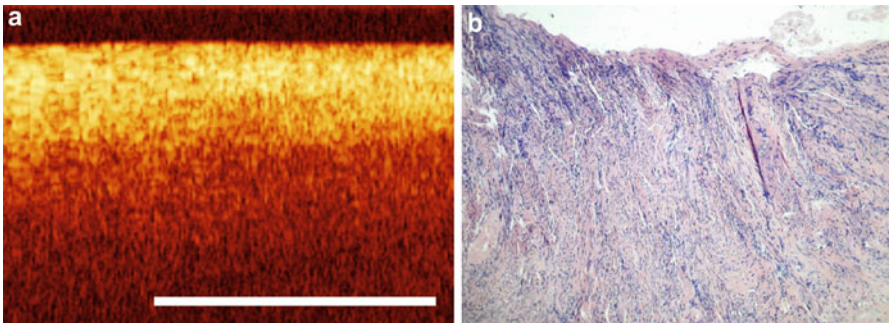

Fig. 77.11 OCT image (**a**) and histology (**b**) of the inflamed cervical mucosa

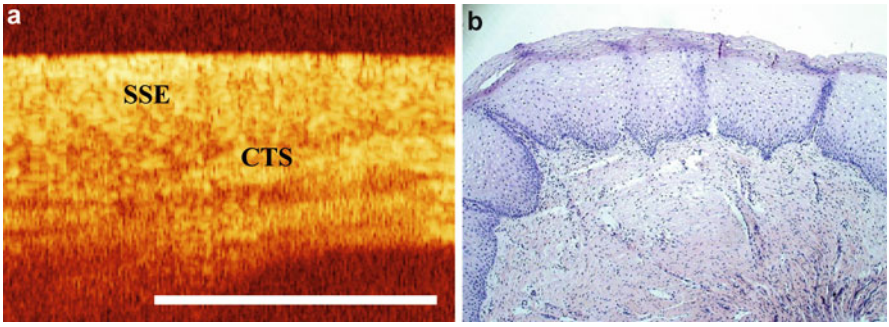

Fig. 77.12 OCT image (**a**) and histology (**b**) of cervical mucosa with inflammatory process of the viral etiology (*HPV*). *SSE* is the hyperplastic stratified squamous epithelium, *CTS* is the connective tissue stroma

77.2.3.4 Cervical Intraepithelial Neoplasia Grade I (CIN I)

CIN I (minimal degree of CIN) tends to regress spontaneously in 70 % of cases. Even if it progresses to CIN II and III and ultimately to the cervical cancer, it is a slow process and can be identified and successfully treated if regular examinations are performed. Therefore, according to the modern guidelines [31, 32], CIN I is considered a benign condition and no immediate treatment is required. CIN I is frequently accompanied by inflammation and appears by OCT to be very similar to inflammation, ranging from normal appearance to homogeneous image (Fig. 77.14a–e).

77.2.3.5 Cervical Intraepithelial Neoplasia Stages II and III (CIN II and III)

With CIN II and III (also known as moderate dysplasia and severe dysplasia/carcinoma in situ), atypical cellular changes involve a larger part of the epithelium. As a result, loss of contrast between epithelium and stroma is observed in the majority of cases (Fig. 77.15a).

In the minority of cases, the stratification can be still seen in the OCT, which could be considered false negative OCT reading for CIN II–III (Fig. 77.15e).

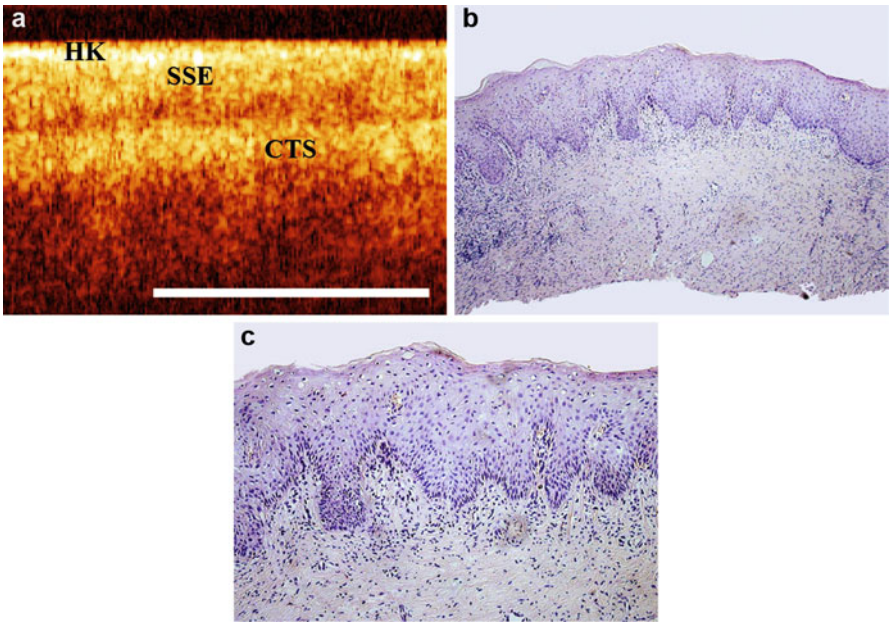

Fig. 77.13 OCT image (**a**) and histology (**b**, **c**) of the cervical mucosa with the mild hyperkeratosis. *HK* is the hyperkeratosis, *SSE* is the stratified squamous epithelium, and *CTS* is the connective tissue stroma

77.2.3.6 Invasive Cervical Cancer

It is natural to expect that invasive cervical cancer completely erases the interface between epithelium and stroma, and in fact, it does happen in the majority of cases (Fig. 77.17). However, in rare cases (Fig. 77.16c) high-contrast stratified OCT image can be observed, even though no appropriate thickness level is seen in the parallel histology. One of the explanations can be the focal nature of the process and difficulties to match precisely the biopsy with OCT imaging location. As stated in [33], "the presence of intact BM surrounding a tumor is not proof that a lesion is not invasive" since cancer can produce its own basement membrane.

We can summarize that a normal exocervical OCT image always has a two-layer image with high contrast between the stratified squamous epithelium and stroma. Benign processes typically preserve this two-layer appearance; however, severe inflammation can substantially reduce the contrast. Neoplastic processes, as a rule, erase the two-layer appearance.

77.2.4 OCT as a Tool to Increase the Efficacy of Visual Cervical Examination

Early feasibility data about cervical OCT obtained by several groups [25, 27, 34] suggests that OCT may be useful to improve the efficacy of visual cervical

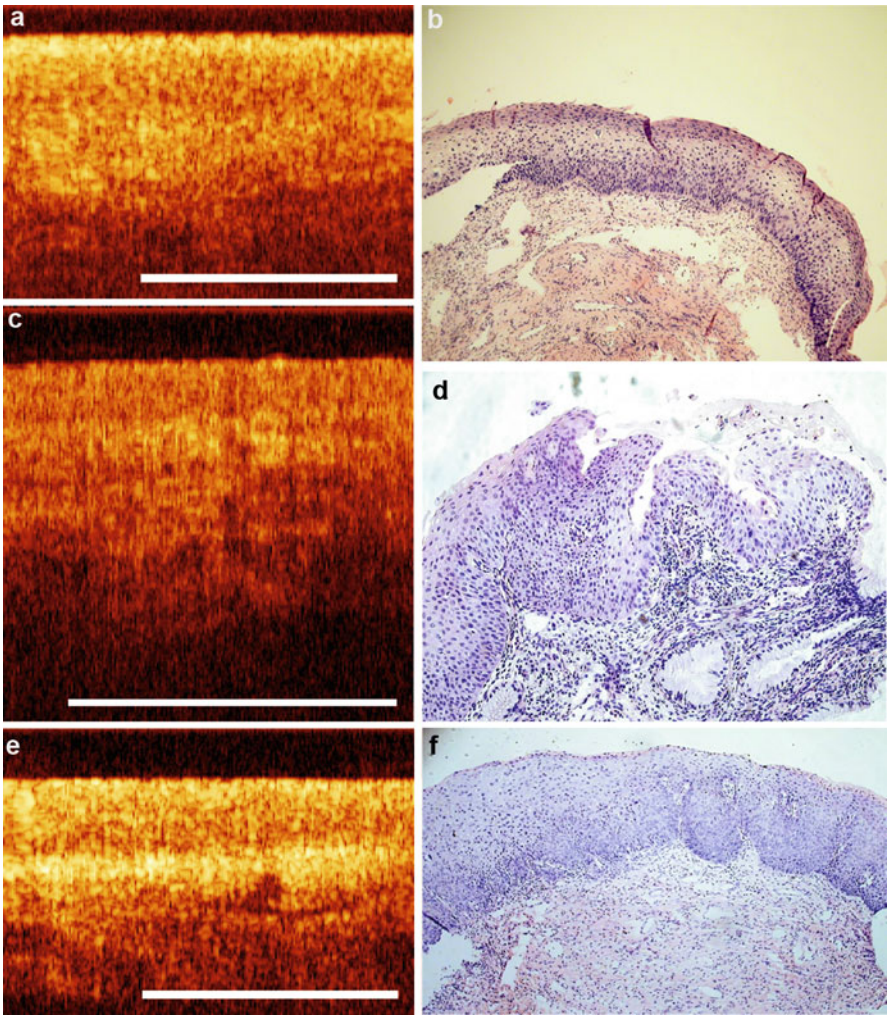

Fig. 77.14 OCT images (**a**, **c**, **e**) and parallel histology (**b**, **d**, **f**) of CIN I

examination – either unmagnified or colposcopic. A clinical trial was done to test this application [35]. The study was designed at the Cleveland Clinic Foundation (CCF) and conducted partially at the CCF and partially at Hospital Maternidad Nuestra Senora de la Altagracia, Santo Domingo, Dominican Republic. The protocol was designed to assess OCT use in two different clinical settings. First, as an aid to cervical cancer screening using unmagnified visual inspection with acetic acid (VIA) in low-resource settings. By increasing the specificity of the examination, this could allow "point of service" diagnosis and treatment without biopsy confirmation. The second setting would be applying OCT to traditional cervical cancer diagnostic programs along with colposcopy and biopsy to increase specificity by directing the biopsies.

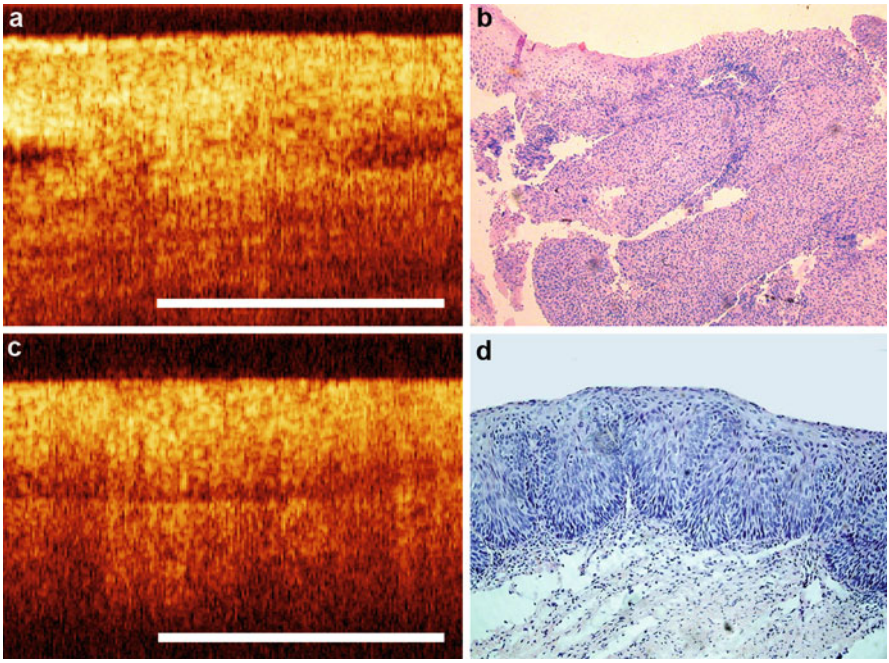

Fig. 77.15 OCT images (**a**, **c**) and parallel histology (**b**, **d**) of the cervical mucosa in the presence of CIN III

77.2.4.1 Materials and Methods

Two hundred twenty patients were enrolled in the study. The inclusion criteria were (a) 18 years of age and older; (b) patients had to sign an informed consent document stating that they understood the investigational nature of the proposed study. Exclusion criteria were: (a) subject was a prisoner; (b) was pregnant, (c) had a prior hysterectomy, (d) or had prior treatment for preinvasive or invasive cervical cancer.

The OCT system used in the study was made by Imalux Corporation (Cleveland OH, USA) and operated at 980 center wavelength, with 45 nm bandwidth and 10 mW source power. It had 25 μm lateral resolution and 11 μm axial resolution (in tissue) and acquired 200 × 200 pixel images in 1 s. A detachable probe with 2.7 mm outer diameter and disposable sheath (Fig. 77.1) was used.

The protocol included five steps:

Step 1 – Unmagnified Visual Inspection using Acetic Acid (VIA). Acetic acid (5 %) was applied to the cervix, and after 1 min VIA was performed. The visual inspection diagnosis was recorded by quadrant.

Step 2 – A digital photograph was taken of the cervix following visual inspection.

Step 3 – Colposcopy. Acetic acid (5 %) was reapplied to the cervix, colposcopy was performed, and observations were recorded by quadrant.

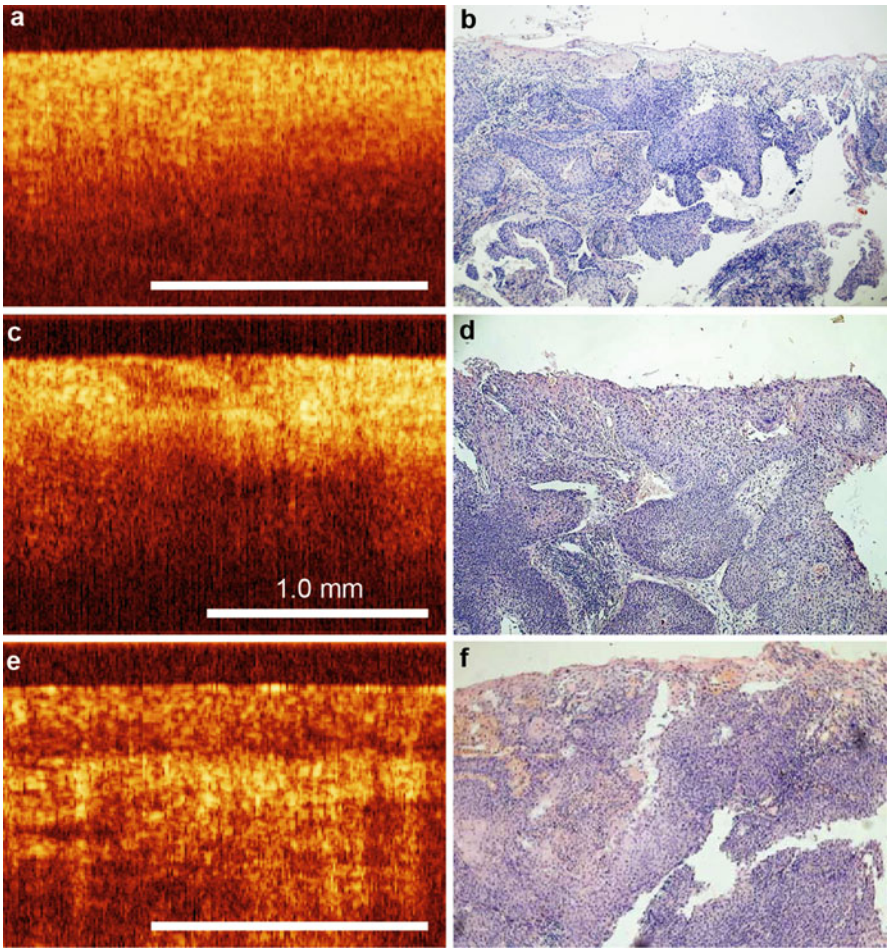

Fig. 77.16 OCT images (**a**, **c**, **e**) and parallel histology (**b**, **d**, **f**) of the cervical mucosa in the presence of invasive cervical carcinoma. Image e represents a rare exception of false negative OCT for invasive carcinoma

Step 4 – Optical coherence tomography. OCT imaging was performed from 2, 4, 8, to 10 o'clock at the squamocolumnar junction (SCJ) as well as any additional abnormal areas found by VIA, Colposcopy, or both VIA and Colposcopy.

Step 5 – Biopsies. Biopsies were taken in each quadrant and appropriately labeled from all VIA, Colposcopic, and VIA and Colposcopic positive areas. In addition, a biopsy was taken from each quadrant at 2, 4, 8, or 10 o'clock at the SJC, matching OCT imaging sites.

After completion of the study protocol, all patients found to have high-grade precancer or true invasive cancer received regular treatment according to standard protocols.

The biopsy material was evaluated by a single histopathologist at the CCF, however a team of gynecologic pathologists at the CCF served as consultants for difficult cases.

Patient information, histopathology and OCT images were then de-identified and coded. Three investigators at CCF interpreted the coded OCT images after all patient examinations had been completed. They each diagnosed the images independently using the following scale: OCT images were graded as *normal* if a well-organized, simple two-layer structure was seen with a sharp interface between the squamous epithelium and the underlying connective tissue, *abnormal* if the tissue was unstructured with, no apparent interface present, and *indeterminate* if irregularities on the images suggested artifacts or physiologic alterations (swelling of the epithelium, edema of the stromal layer or inflammation) and did not meet diagnostic criteria for normal or abnormal.

In order to provide information as to the application of OCT for limited and varying clinical circumstances (i.e. screening, added to VIA, or added to colposcopy), the images were read three separate times for each patient. First, the images were read knowing only the patient's age. Second, they were read with knowledge of the VIA impression by quadrant, and with access to a non-magnified digital image of the cervix. Finally, the OCT images were interpreted with full knowledge of the referral Pap results, the colposcopic diagnosis by quadrant, and viewing a magnified digital photograph of the cervix.

Subsequently, the results of the OCT readings were compared with parallel histopathology. 1,215 OCT images were matched to the final histopathology diagnosis. All statistical processing and data management was performed at the University of North Carolina at Chapel Hill. Histologically, CIN II or greater was considered as positive for neoplasia diagnosis.

Due to the difficulty with patient compliance and patient follow-up, this clinic in the Dominican Republic used very liberal criteria for a colposcopic and/or VIA abnormal area. The per patient sensitivity and specificity of VIA alone was 76 % and 34 % respectively. For VIA with OCT the sensitivity decreased to 53 %, but specificity was nearly doubled to 61 %. If we separate the results for lesions at the SJC, into abnormal areas identified by VIA and those areas interpreted as normal, we will see that on per site basis, OCT had 52 % sensitivity and 64 % specificity in the SJC areas where VIA did not detect any lesions. Therefore we think that OCT has the potential to improve sensitivity of random biopsies in the SCJ area and should be studied prospectively.

For the colposcopy alone, per patient sensitivity/specificity was 39 %/71 % if CIN II colposcopic impression was considered as a positive reading and 93 %/11 % if CIN I colposcopic impression was considered as a positive. The last case is typical in the standard of care because a colposcopic reading of CIN I is associated with a high enough risk of actually having CIN II so a biopsy is recommended. The OCT with colposcopy had sensitivity 46 % and specificity 65 %.

The interobserver agreement was 0.4, which is considered moderate to fair.

Receiver Operating Characteristic (ROC) curves were also generated to access the quality of OCT as a diagnostic test for lesions at the SCJ and lesions distant from

the SCJ. OCT demonstrated to be a fair diagnostic tool (ROC 0.73) adjunctive to VIA and colposcopy in accurately identifying lesions distant from the SCJ.

We envision that in a low-resource setting OCT, directed by VIA, could improve the specificity of the screening examination in detecting CIN II allowing for a single episode of care that includes both diagnosis and treatment without histological confirmation. This "point of care" model for diagnosis and treatment of preinvasive disease would be ideal in areas with a limited health care infrastructure, limited human and financial resources, and with limited ability to have a patient recall system for follow-up care.

In the developed world (moderate to high-resource setting) OCT could be considered in the future perform an "optical biopsy". The optical biopsy would be taken at areas determined to be suspicious by colposcopy allowing for the selection of key areas for biopsy. This could reduce the number of unnecessary biopsies taken, while increasing the number of histologically significant biopsies (true positives). A typical application would be areas of extensive squamous metaplasia (both mature and immature) or determining the margins for a loop electro excision procedure (LEEP) in a young patient with a wide transformation zone.

In this study, the physician acquiring OCT images was unable to see them during the session. We believe that OCT will perform better in a "real-time" setting. In other words, that in order to truly measure the efficacy of OCT combined with visual examination, future clinical studies should include "real-time readings" with OCT. This would reduce the false positives caused by improper positioning at the SCJ, as normal endocervical mucosa looks unstructured in OCT. Furthermore, by reviewing the OCT images during the gynecological examination the clinician will be able to fully integrate the patient history (including Pap smear results), the visual examination before and after acetic acid and the colposcopy impression.

The OCT "optical biopsy" impression could then be compared to the results of histological biopsies taken at the precise area that corresponds to the OCT image. A study with OCT impressions completed in real-time is currently being conducted therefore modeling the use of the OCT as a single episode of care imaging modality.

We believe that OCT could potentially show greatest utility in the management of cervical dysplasia in low-resource settings where a single episode of care is most desirable. The algorithm would be primary screening with VIA and then OCT as the secondary screen for VIA positives. Appropriate treatment or referral would then be based on the OCT and VIA findings.

77.2.4.2 Cross-Polarization OCT: Principles, Device, Results

OCT is an optical interference-based technique and therefore is intrinsically sensitive to the polarization of the backscattered radiation. Nevertheless, for traditional structural OCT polarization sensitivity is often considered as a disturbing factor creating image artifacts. However, light polarization changes in the biotissues can create additional contrast and make OCT more specific. That is why polarization-sensitive OCT (PS-OCT) is one of the known enhancements in the OCT development and subject of intensive studies [36–53].

In particular, PS-OCT can visualize tissue birefringence associated with optical anisotropy in the biotissues, via measurement of phase retardation between polarization components [37, 43, 45, 46, 49, 50] and/or the Stokes parameters [41, 42, 51]. Another phenomenon, the cross-polarization scattering, i.e., the scattering to the orthogonal polarization, can be observed in biotissues independently on birefringence. We call the version of PS-OCT, focusing on comparison between images resulted from cross-polarization and co-polarization scattering of the same biotissue, as cross-polarization OCT (CP-OCT) [47, 52].

In this section, we present some preliminary results obtained using a two-channel portable device for CP-OCT, based on polarization-maintaining (PM) fiber and having an endoscopic OCT probe with 2.7 outer diameter.

77.3 PS-OCT System Design and Performance

The functional diagram of the all-fiber PS-OCT system is shown in Fig. 77.17.

Partially polarized radiation from a superluminescent source with central wavelength $\lambda = 980$ nm is transmitted through Faraday isolator 3 and then through polarizer 4 to increase the polarization degree. Polarization controller 16a is used to optimize power at polarizer output, while the polarization controller 16b is used for selective excitation of one of the polarization modes of PM fiber. For explanation purposes, we assume that a slow polarization mode is excited. Therefore, the radiation in the sample and reference arms in the forward direction of the device has linear polarization state. Radiation backscattered from the biological object has an orthogonal component in addition to the initial polarization, which excites the second polarization mode of the PM fiber in the sample arm. Radiation coming back from the reference arm contains an equal mix of two polarization modes, because of quarter-wave plate located at 22.5° to the initial linear polarization.

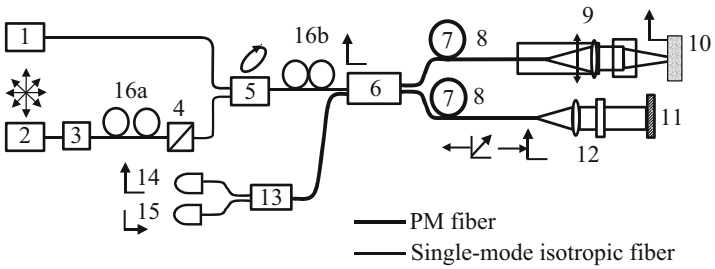

Fig. 77.17 Schematic diagram of the all-fiber PS-OCT system: *1* $\lambda = 630$ nm red aiming laser, *2* $\lambda = 980$ nm superluminescent diode (*SLD*), *3* Faraday isolator, *4* SM fiber polarizer, *5* wave division multiplexer, 6–3 dB PM fiber coupler, *7* piezofiber optical path modulators, *8* PM fiber fixed delay line, *9* endoscopic probe with lateral scanning, *10* sample, *11* reference mirror, *12* quarter-wave plate at 22.5° to PM fiber axes, *13* all-fiber polarization beam splitter, *14*, *15* photoreceivers, *16*a, *16b* polarization controllers

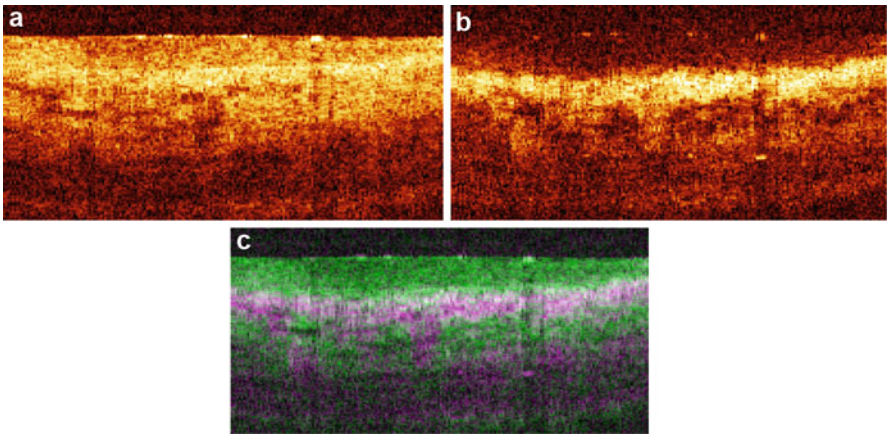

Fig. 77.18 Normal uterine cervix. Patient X. 49 years old. OCT image in parallel (**a**), orthogonal (**b**) polarizations, and simultaneously in two polarizations (**c**)

Waves returned from the signal and reference arms are recombined in the polarization-independent 3 dB coupler [42]. Despite the substantial (several mm) walk-off between slow and fast polarization, the optical path difference between interfering components remains the same, because slow sample polarization interferes only with slow polarization in the reference arm, whereas fast sample polarization interferes only with fast reference polarization. Therefore, the signal in orthogonal polarizations originates simultaneously from the same place of the sample. Then, recombined optical signals in fast and slow polarizations are separated into two detecting channels by a polarization-dependent splitter [50] and then are independently processed by an identical analogue circuitry, digitized, stored, and visualized on a PC display.

Note that Faraday isolator is essential to prevent a strong cross talk between fast and slow channels, associated with the light source reaction to the interference-modulated back-reflected light. With Faraday isolator, this cross talk was suppressed to at least −30 dB level. The use of the all-fiber design allowed us to develop a small-size ($40 \times 40 \times 16$ cm) portable device suitable for clinical studies.

Figures 77.18, 77.19, and 77.20 show three types of the OCT images: in co-polarized (parallel) component, cross-polarized (orthogonal) components, and their mix in complementary colors (green and magenta). Figure 77.18 shows the OCT images of the normal uterine cervix. OCT images of the normal exocervix demonstrate a stratified structure. Parallel OCT component (Fig. 77.18a) is just a regular "structural" image. In orthogonal polarization, the contrast between epithelium and connective tissue stroma is greatly enhanced (Fig. 77.18b) because of different spatial compositions of epithelium and stroma. The main stromal components are the horizontally oriented fibers ensuring substantial depolarization, which creates strong orthogonal OCT signal.

The additional contrast created by PS-OCT can be used to differentiate between OCT images and associated conditions, which look very similar in regular

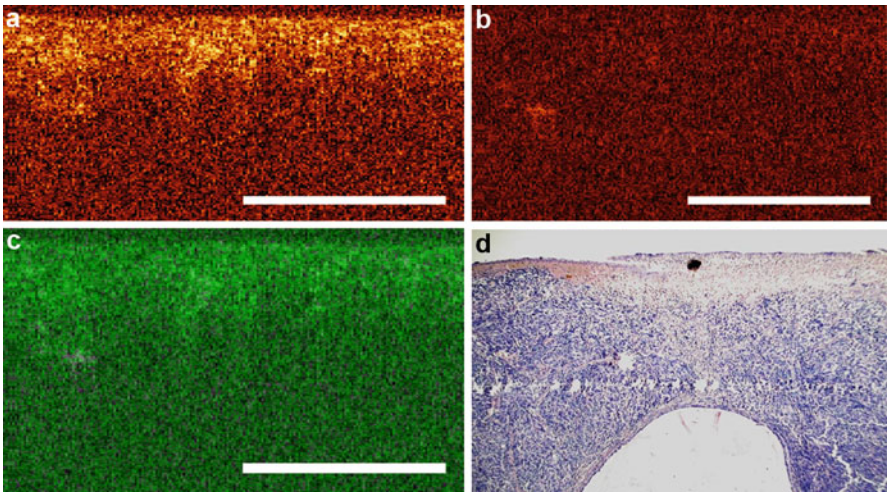

Fig. 77.19 Squamous cell cervical carcinoma. The OCT image in parallel (**a**), orthogonal (**b**) polarizations, and simultaneously in two polarizations (**c**); corresponding histology (**d**)

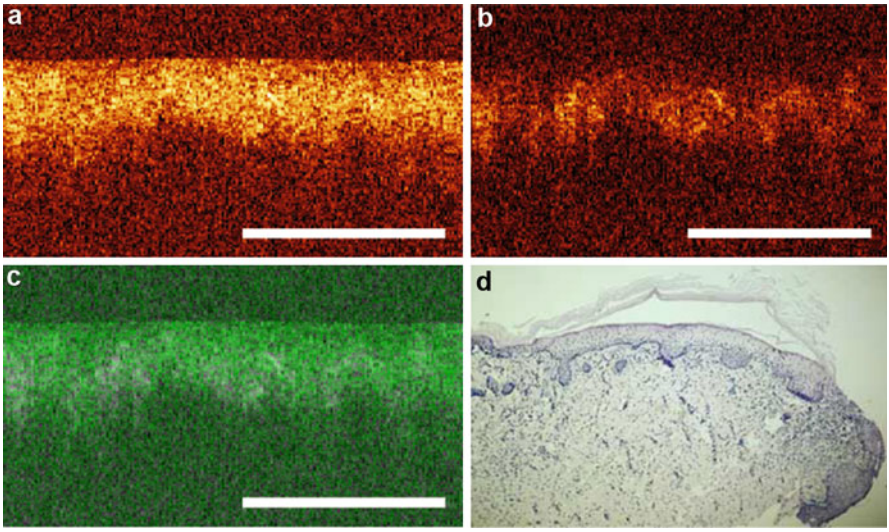

Fig. 77.20 Acetowhite epithelium. OCT image in parallel (**a**), orthogonal (**b**) polarizations, and simultaneously in two polarizations (**c**); histology: leukoplakia

structural OCT. Several illustrating examples are shown in Figs. 77.19 and 77.20. Figure 77.19a demonstrating invasive cervical cancer and Fig. 77.20a, with cervical leukoplakia, show a very similar loss of the layered horizontal structure in parallel polarization in both cases. Therefore, in regular structural OCT the image 43.20a will be interpreted as a malignant condition and will be a false positive.

Table 77.2 Ex vivo OCT endometrial imaging with parallel histopathology

Totally examined, $n = 25$				
Normal endometrium in proliferation phase, $n = 5$	Normal endometrium in secretory phase, $n = 6$	Endometrial atrophy, $n = 4$	Simple endometrial hyperplasia, $n = 6$	Endometrial cancer, $n = 4$

However, in orthogonal polarization leukoplakia looks very different (Fig. 77.20b), because fiber orientation is preserved for the leukoplakia and lost for the cancer.

Therefore, we can expect that additional contrast associated with CP-OCT can potentially increase specificity of OCT, especially for conditions having poor contrast images in parallel polarization.

77.4 OCT-Hysteroscopy

77.4.1 OCT Images of Normal Endometrium, Impact of Age and Hormonal Status

In this section, we show the results of the OCT endometrial ex vivo imaging with parallel histopathology. For this purpose, we conducted a post-hysterectomy OCT study of the surgical material. The uterine wall fragment 1×1 cm^2 was excised from the entire specimen 15–20 min after the hysterectomy. For orientation, two needles were introduced into the specimen around the OCT probe. The scanning line coincided with the direction defined by the needles. Three to five OCT images were acquired from each position of the probe. Then, the specimen with needles was fixed to a cardboard with orientation marks. In histopathology processing, specimen was sliced parallel to the OCT scanning line outlined by the needles.

Twenty-five specimens were included in the OCT study of endometrium, average patient aged 46.8 years. We tried to represent the entire spectrum of the endometrial conditions and all age groups in the sample.

The breakdown of the endometrial conditions is shown in Table 77.2.

77.4.1.1 Results

The endometrium of a woman in the reproductive age in the proliferation phase is visualized in the form of a structureless OCT image (Fig. 77.21).

Histological comparisons show that only the functional endometrial layer is visualized in the OCT images. We believe that in the low-contrast pattern in Fig. 77.21c, areas with brighter signal correspond to the stromal papillas, while the areas with a lower brightness correspond to the glands. In the secretion phase, the OCT image of endometrium is changed (Fig. 77.22): OCT images become stratified.

Comparison with the histology shows that the stratified structure in OCT corresponds to the stromal papilla bent by the OCT probe.

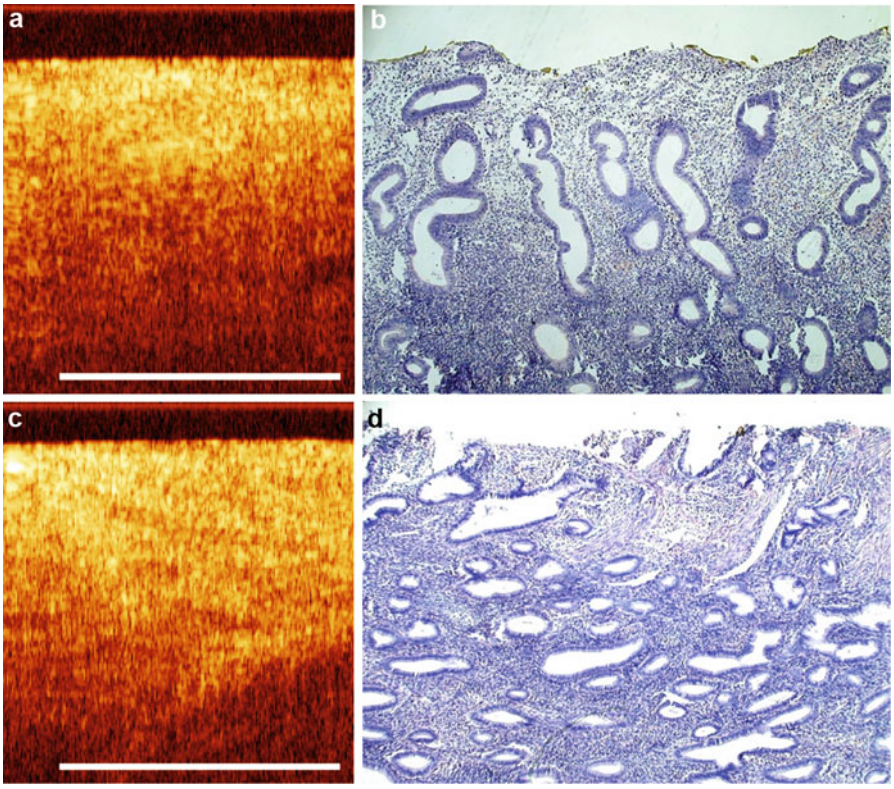

Fig. 77.21 OCT image of normal endometrium (**a**, **c**) in the proliferation phase and parallel histologies (**b**, **d**)

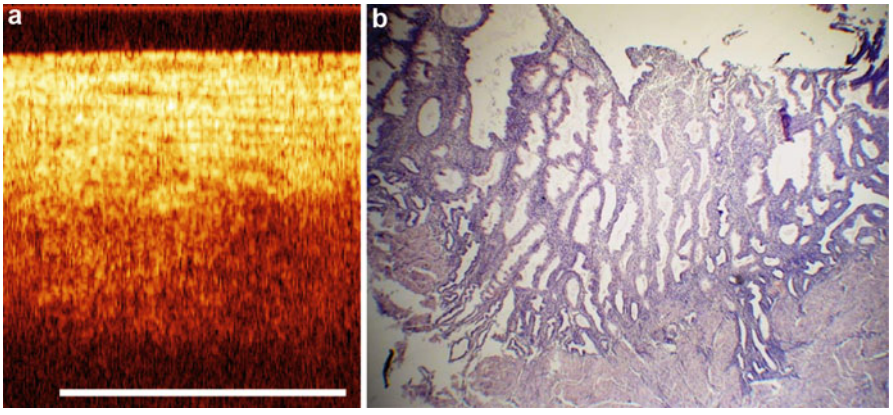

Fig. 77.22 OCT image of normal endometrium in the secretion phase (**a**) and parallel histology (**b**)

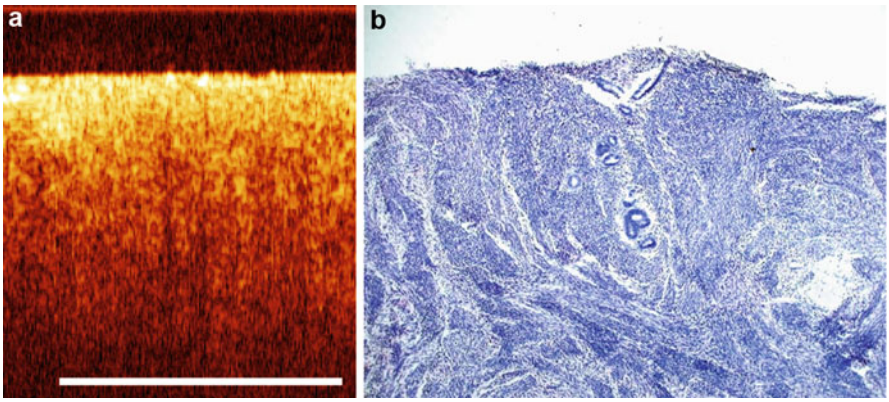

Fig. 77.23 OCT image (**a**) of atrophic endometrium and parallel histology (**b**)

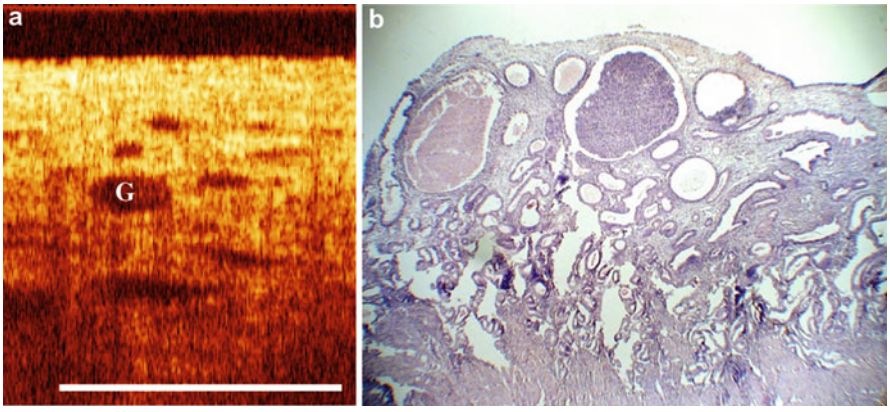

Fig. 77.24 OCT images of the endometrial polyp (**a**) and parallel histology (**b**). *G* glands

In the presence of atrophic changes, endometrium OCT image is structureless (Fig. 77.23).

In an endometrial polyp, OCT can visualize dilated glands, which are represented by round and elongated dark spots (Fig. 77.24).

Endometrial neoplasia looks completely homogeneous in OCT (Fig. 77.25).

In conclusion, endometrial structure makes it challenging for OCT application, because normal endometrium is too thick (up to 1 cm) and image frequently appears homogeneous and unstructured. However, OCT can see some differences, associated with menstrual cycle and with some pathologic conditions. Therefore, future studies could be worthwhile.

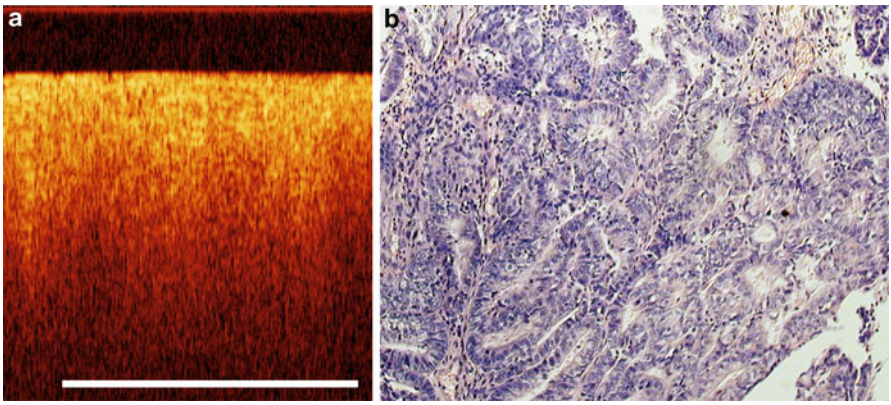

Fig. 77.25 OCT image (**a**) of well-differentiated endometrial adenocarcinoma and parallel histology (**b**)

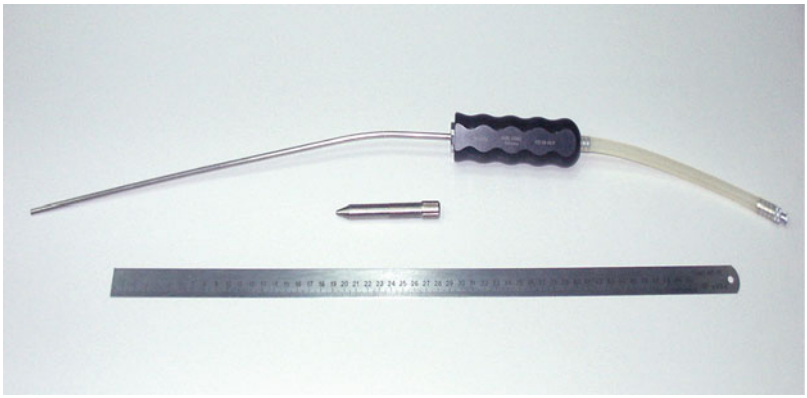

Fig. 77.26 OCT probe laparoscopic holder (*Karl Storz*)

77.5 OCT-Laparoscopy

To study the potential applications for OCT to assess the pelvis organs, we conducted several OCT laparoscopies and obtained OCT images of the uterine body, fallopian tubes, ovaries, and peritoneum of the pelvis. The OCT probe was introduced into the pelvic cavity through an additional trocar using a special rigid holder (Fig. 77.26). The study was performed with five female patients with different gynecological pathologies, when laparoscopy was clinically indicated. Since biopsies were not indicated in these cases, the OCT images were not compared with parallel histological data.

The outer uterine body OCT images have poor contrast (Fig. 77.27).

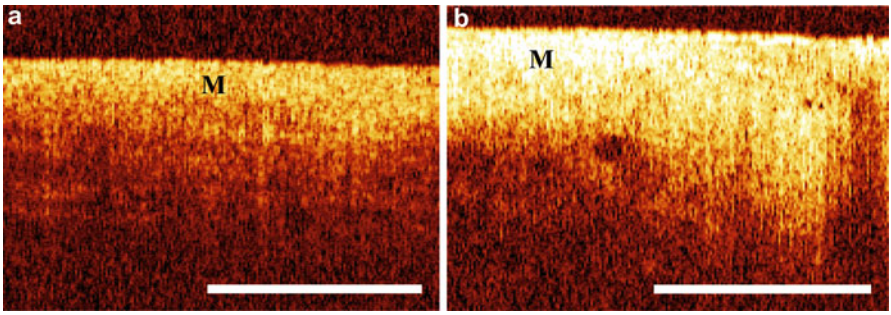

Fig. 77.27 OCT images of the uterine body surface (**a**, **b**). M myometrium

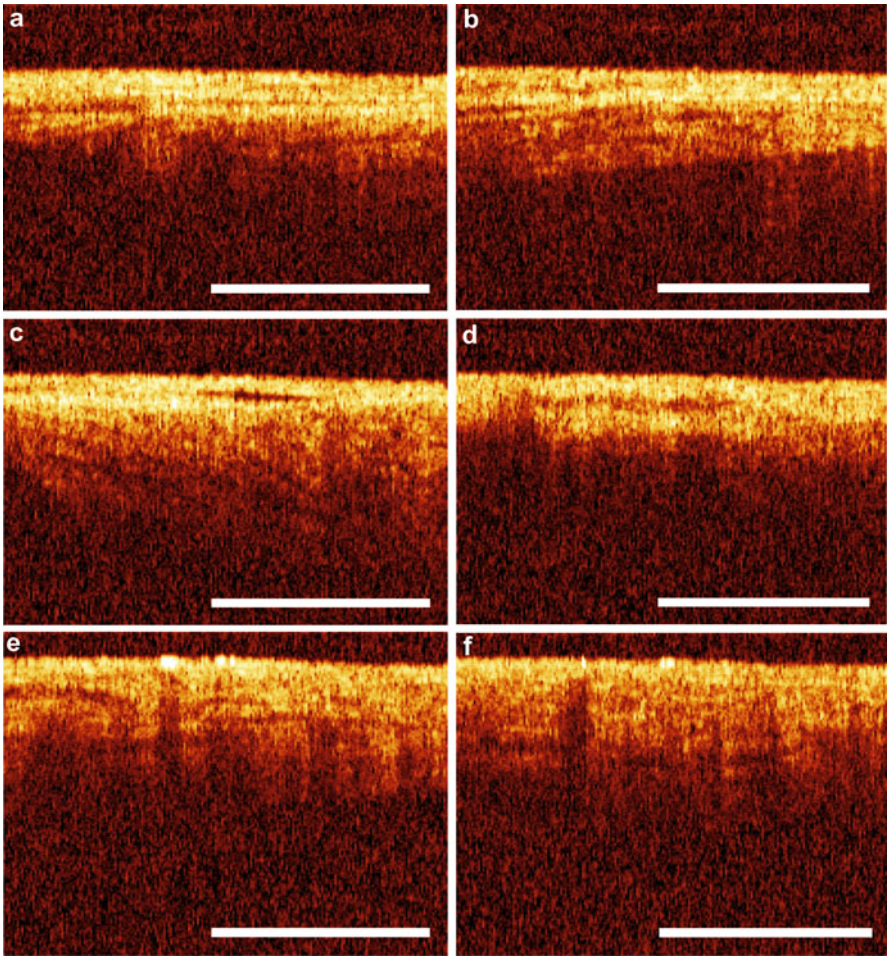

Fig. 77.28 OCT images of a normal fallopian tube wall (**a**–**d**). An OCT image of the fallopian tube with ectopic (fallopian) pregnancy changes (**e**, **f**)

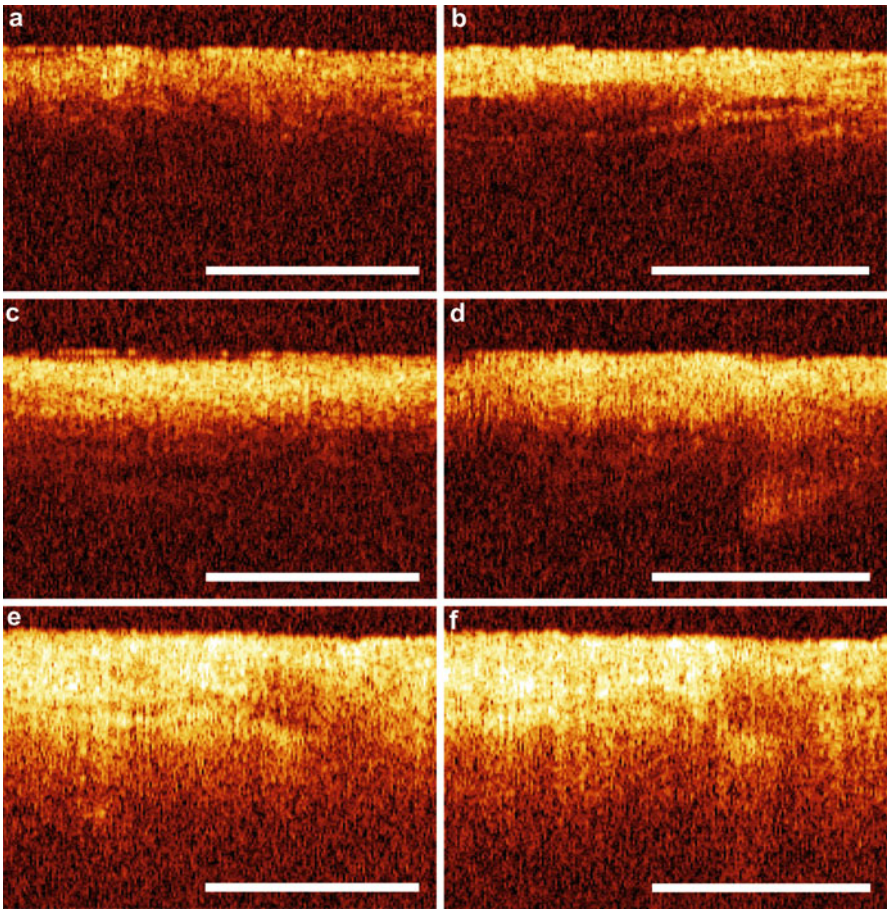

Fig. 77.29 OCT images of the ovaries

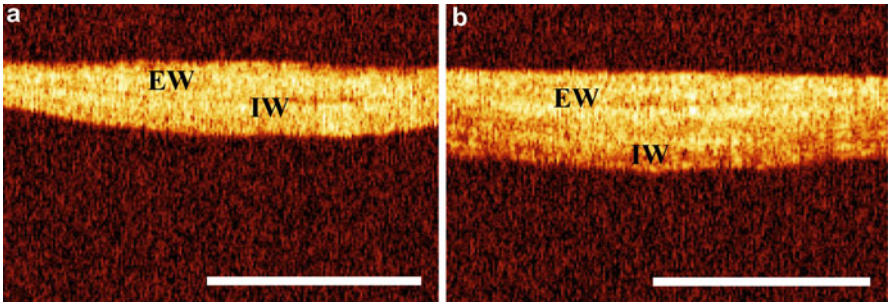

Fig. 77.30 OCT images of the capsule wall of serous cystic adenoma (**a**, **b**). *EW* is the external wall of the ovarian cyst capsule, *IW* is the internal wall of the capsule

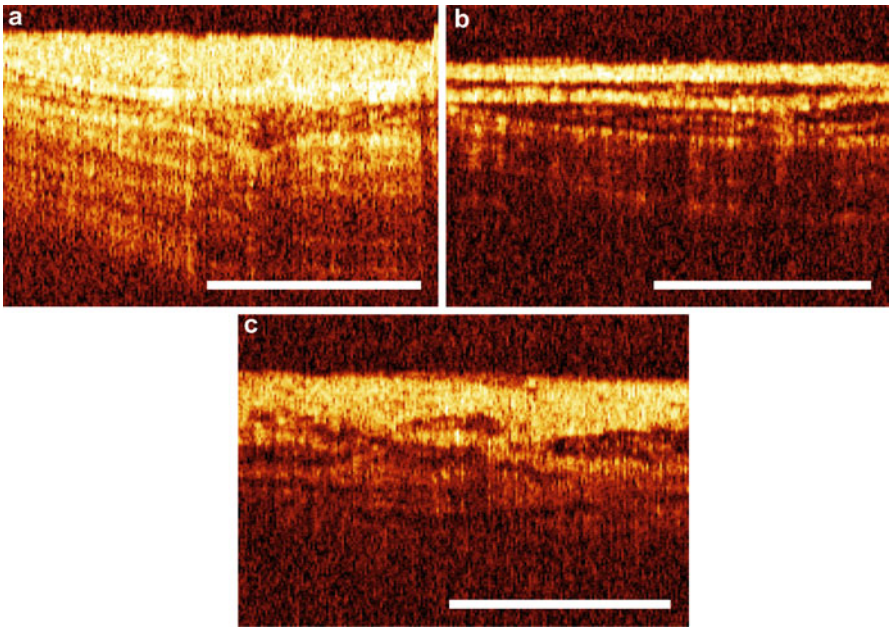

Fig. 77.31 OCT images of the pelvic peritoneum. (**a**) Normal; (**b**) inflammation; (**c**) endometriosis

A normal fallopian tube wall is visualized as a stratified image with sharp intermittent layer interfaces (Fig. 77.28a).

The OCT images of the ovaries (Fig. 77.29) do not show any stratified structure; however, penetration depth may differ significantly. We believe that it is mostly associated with thickness of tunica albuginea. Tunica albuginea is a very strongly scattering connective tissue, so if it is thick enough (0.2 mm or more), then non-scattered light cannot penetrate beyond it. If it is thinner, or more transparent, then follicles and/or a corpus luteum can be seen under the tunica (Fig. 77.29e, f).

Figure 77.30 shows an OCT image of serosal ovarian cystoma. We can see the wall structure and thickness. The image of the wall allowed ruling out noninvasively the papillary growth inside the tumor.

The normal pelvic peritoneum has stratified high-contrast OCT image (Fig. 77.31a).

During an inflammatory process, the OCT image of the peritoneum is changed (Fig. 77.31b), and typical edematous pattern with transparent liquid accumulation can be seen. The endometriosis creates significant changes in the OCT image (Fig. 77.31c): stratification is no longer seen, and irregular dark structures, which we believe correspond to the endometriosis foci, are visualized.

The presented exploratory results show that in vivo OCT images of the pelvic organs have some recognizable patterns, which creates some promise for their clinical use. However, substantial research work has to be further performed to show feasibility of OCT applications in this area.

Endoscopic Optical Coherence Tomography in Urology

78

Yingtian Pan, Wayne Waltzer, and Zhangqun Ye

78.1 Introduction

Clinical statistics has shown a stable prevalence of bladder cancer in recent years, which by far remains among the most common types of malignancy in the USA. With smoking as the most well-established risk factor, bladder cancer is the fourth most common cancer occurrences in male population [1]. In the year of 2014, an estimated 74,690 new cases are expected to occur with estimated 15,880 deaths. Bladder cancer often refers to transitional cell carcinoma (TCC) as it originates primarily from the epithelial cell layer (i.e., urothelium) of the bladder. Unlike prostate-specific antigen (PSA) for prostate cancer screening, there is currently no effective screening technique approved or recommended for the population at average risk [2–5]. As a result, hematuria (i.e., blood in the urine) is often the first clinical symptom of bladder cancer. Fortunately, urinary bladder is more accessible than prostate glands endoscopically; thus cytology following white-light cystoscopy has been the gold standard for current clinical detection of bladder cancer. This is important because bladder cancer if diagnosed prior to muscle invasion (e.g., superficial or at <pT2 stages) is curable by transurethral resection (TUR) following intravesical therapy [6]. Therefore, noninvasive early detection is crucial for the management of bladder cancer patients.

Early diagnosis of TCC, in particular, carcinoma in situ (CIS) of the bladder remains a clinical challenge [7, 8]. Although advanced molecular test such as urine cytology [5, 6], fluorescence in situ hybridization (FISH) [9], and bladder tumor antigen (BTA) [10] may provide high sensitivity and specificity in detecting high-grade TCC, it is insensitive to low-grade TCC, resulting in an overall 28–50 % of

sensitivity. Additionally, as the cancer cells detected in the urine specimen can be from anywhere in the urinary tract, this technique is not capable of locating the cancerous lesions. On the other hand, due to their resolution limitation or other technical imperfection [11], current medical imaging techniques such as intravenous pyelogram (IVP), CAT, MRI, and ultrasound fail to provide useful diagnosis except for large, high-stage invasive bladder tumors. White-light imaging or cystoscopy (i.e., WLI) via direct visual inspection of bladder epithelium (urothelium) is often performed to locate TCC with subsequent TUR of suspicious lesions of the bladder and/or biopsies to verify malignancy. WLI has proven highly efficient for detecting papillary TCC, but it is common clinical scenarios that the bladder of a patient with positive cytology appears unremarkable under cystoscopy and 80–90 % of all preclinical malignancies of bladder CIS (i.e., a type of flat but high-grade aggressive TCC) demonstrate no significant outgrowth [6]. Since current cystoscopy provides no depth resolution, conclusive diagnosis and staging of malignancy relies on random biopsy which may miss nonpapillary TCC (e.g., ~50 % of CIS [6, 7, 12]) and lead to high false-positive rates due to difficulties in differentiating them from benign inflammatory lesions. For the same reason, in the separation of recurrent TCC from benign lesions such as necrosis, scar induced by previous TUR treatments often frustrates the urologists performing surveillance cystoscopy. Clinical surveys reveal [12, 13] that possibly because of inadequate detection by urine cytology and WLI (gold standard), bladder cancer has remained the highest recurrence rate (e.g., ~50 %) among all cancer types and is the most expensive cancer to treat. For instance, ~1.2 million cystoscopies are performed in the USA annually, yet ~40 % of patients with initial superficial TCC ($<$pT2) eventually develop muscle invasive (i.e., $\geq$pT2), life-threatening TCC. Therefore, a more effective imaging technique that can see below the bladder surface at a high resolution to enable early diagnosis is highly desirable for optimizing the management of bladder cancer that may lead to a significant decrease in mortality from this disease.

With the advent of technological advances, a number of emerging optical imaging methods have shown the potential to enhance current cystoscopic procedures for the diagnosis of bladder tumor. For instance, fluorescence cystoscopy using 5-aminolevulinic acid (5ALA) and hypericin has been shown to improve the detection of bladder cancer and CIS in particular [8, 14–16]. Compared with 5ALA, hexaminolevulinate (HAL, e.g., Hexvix® in Europe and Cysview® in the USA) reduces the drug induction time from 4–5 h to 1 h before fluorescence cystoscopy. A recent multicenter clinical study in the EU and USA concluded [15, 17] a considerably improved diagnostic accuracy by comparison to WLI, e.g., up to 30 % more identification of CIS and potentially reduced recurrence rate. Despite some debates regarding its phototoxicity and relatively low diagnostic specificity (e.g., high false-positive rates due to inclusion of benign lesions that are mainly associated with inflammations of the bladder mucosa), the US Food and Drug Administration (FDA) approved Cysview as an adjunct to WLI for the detection of non-muscle-invasive papillary TCC in patients with known or suspected bladder cancer in mid-2010. Narrowband imaging (NBI) as an alternative approach has

been reported [18, 19] to improve the sensitivity for TCC diagnosis by enhancing the contrast of bladder epithelium and subsurface vasculature at different depths (e.g., 415 nm blue light for shallow and 514 nm green light for deep blood vessel visualization). Although NBI also suffers low diagnostic specificity, it circumvents the need for contrast agent (e.g., Hexvix) and thus reduces the associated cost and patient discomfort. Confocal endoscopy and Raman spectroscopy have also been reported to detect bladder cancers by providing subcellular morphology [20, 21] and molecular contrast of cancer cells, respectively. Interestingly, the latter may improve the specificity by discriminating inflammatory tissue and TCC, which remains a common problem of fluorescence and NBI cystoscopy for bladder cancer diagnosis. Noteworthily, in vivo Raman spectroscopy although potentially more objective may have to be combined with or guided by other cystoscopic imaging techniques to provide both high sensitivity and specificity for bladder cancer diagnosis [21, 22].

In contrast to 5ALA fluorescence, NBI and Raman techniques that detect biochemical and molecular features of bladder cancer, optical coherence tomography (OCT) has been applied to imaging the morphological alternations of bladder caused by tumorigenesis [23, 24]. As an emerging optical technique, OCT offers the unique capabilities that enable 2-D and even 3-D cross-sectional imaging of biological tissue such as bladder wall at superb resolution (e.g., 1–10 μm axial resolution) and up to 2 mm of depths, making it a promising imaging technology for detecting various superficial tumors like bladder cancer. Since its first introduction in the early 1990 [25], OCT has been fully developed to the clinical arena (e.g., for routine ophthalmological diagnosis) [26]. In addition to its successful clinical adoption in ophthalmology, there have been active research, development, and clinical studies to explore its applications in diagnosing disorders in many other non-translucent tissues such as dental cavities, vulnerable plaques in coronary vessels, as well as cancers in the skin, oral cavity, bronchus, esophagus, lung, colon, cervix, and urinary bladder [27]. For the majorities of these applications, various miniature OCT probes (e.g., OCT endoscopes) are needed to access internal organs noninvasively or minimally invasively. Recent technological advances that may have significant impacts on in vivo OCT diagnoses of epithelial cancers include the development of laser-scanning probes for endoscopic OCT [27–29], Doppler OCT (DOCT) to permit subsurface vasculatural imaging (e.g., tumor microenvironment) [30–32], and polarization-sensitive OCT [33, 34] and contrast-enhanced OCT [35] to provide more specific diagnosis. Importantly, compared to initial time-domain OCT, spectral-domain OCT and more recent swept-source OCT render in vivo 2-D and even 3-D volumetric OCT imaging of biological tissue in real time and at higher detection sensitivity (i.e., SNR) [36, 37]. On the other hand, ultrahigh-resolution OCT (μOCT) by utilizing ultra-broadband laser (e.g., ultrashort-pulse laser) has been reported to enable in vivo subcellular imaging of biological tissue [38, 39], which may shed some light on its capability for subcellular identification of cancerous cells (e.g., cancer grading). Here, we summarize the technological development and the results from our lab and others on preclinical and clinical studies of OCT for bladder cancer diagnosis.

78.2 Methods

78.2.1 OCT Engines

Like many other OCT groups, the study of our lab on OCT diagnosis of bladder cancer has spanned the transition from early time-domain OCT (TDOCT) to recent spectral-domain OCT (SDOCT). The results presented below include those acquired from both TDOCT and SDOCT engines accordingly. Figure 78.1 depicts the schematic diagram of TDOCT (a) and SDOCT (b) setups.

For TDOCT (a), a pigtailed broadband light source whose power, central wavelength, and FWHM spectral bandwidth are $I_0 = 18$ mw, $\lambda_0 = 1{,}310$ nm, and

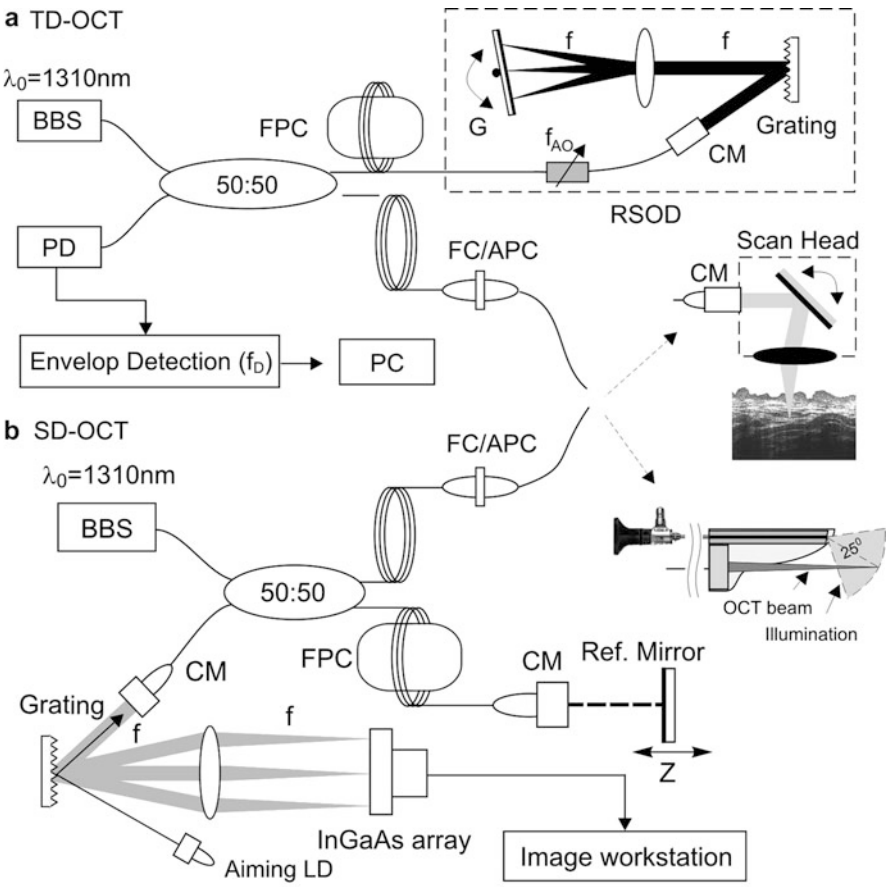

Fig. 78.1 Schematic diagrams of TDOCT and SDOCT setups. (**a**) TD-OCT, (**b**) SD-OCT. BBS: broad band source, *CM* collimator, *FPC* fiber polarization controller, *G* galvanometer scanner, *PD* photo diode, *RSOD* rapid-scanning optical delay line, *AO* differential acousto-optic modulator (e.g., $f_{AO} = 2$ MHz), *LD* aiming *red* or *green* laser diode

$\Delta\lambda = 78$ nm, respectively, is employed to illuminate a fiber-optic Michelson interferometer (e.g., 2×2 fiber-optic coupler) which splits the light equally into the reference and sample arms and recombines the interference in the detection arm. A rapid-scanning grating-lens-based optical delay (RSOD) is used to provide axial scan (A-scan), i.e., to vary optical pathlength delay in the reference arm. As RSOD separates phase and group delays permitting independent control of Doppler frequency shift f_D and bandwidth Δf of the OCT signal, a custom AO modulator is used to provide ultra-stable f_D at 2 MHz (to eliminate f_D drift due to scanning instability) and thus effectively enhance system SNR [40]. The sample arm is connected to either a benchtop scanning probe for ex vivo bladder characterization or a laser-scanning endoscope for in vivo bladder imaging through an FC/APC connector [29]. Typical system specifications are lateral resolution $\Lambda = 12$ μm for benchtop OCT probe and $\Lambda = 16$ μm for OCT endoscope, axial resolution $L_c = 10$ μm (coherence length), SNR ≈ 100 dB, and 2D image rate up to 2–4 fps (limited by the scanning rate $f_G \leq 1$ kHz of RSOD).

For SDOCT (b), the system is illuminated by a broader-band pigtailed source (e.g., $I_0 = 8$ mw, $\lambda_0 = 1{,}300$ nm, $\Delta\lambda = 90$ nm), providing an axial resolution of $L_c \approx 8$ μm. Compared to TDOCT, it employs spectral radar to implement axial scanning, which circumvents the need for mechanical scanning (e.g., RSOD) and thus drastically enhances the A-scan rate to 7.7–92 kHz (limited by the line-scan cameras employed) [41]. In addition, the parallel detection scheme of SDOCT enables it to dramatically improve the system SNR (i.e., by a factor of $N^{1/2}$ enhancement, where N is the pixel number of the spectral graph) [36]. It also allows us to easily couple a red or green aiming laser back into the fiber retrospectively through a diffraction peak (e.g., $m = -1$ order) of the spectral camera to instantaneously trace the region of interest under 2D/3D OCT scans. Typical system specifications are lateral resolution $\Lambda = 10$ μm for benchtop OCT probe and $\Lambda = 12$ μm for OCT endoscope, axial resolution $L_c = 8$ μm, SNR ≈ 112 dB, and 2D image rate up to 8–100 fps (limited by the line-scan camera, $f_{InGaAs} \leq 92$ kHz).

78.2.2 OCT Endoscopes

The combined high resolution and intermediate image depth of OCT have attributed it uniquely attractive for optically guided biopsy to permit noninvasive delineation of epithelium and the underlying morphology to detect epithelial cancers and stage their invasion. However, the development of high-fidelity laser-scanning catheters for EOCT remains a challenge. Endoscopic laser-scanning approaches that have been reported include rotary fiber with 90° microprism [27], coherent fiber bundles or rod lens endoscope [42], PZT-actuated swinging fiber [24], etc. The major engineering challenge lies in the compromise of light coupling efficiency (SNR) and beam quality (focusing capability), light scanning linearity/rate and range (FOV), and catheter size and flexibility. Typically, OCT endoscopes can be categorized to either size-view or front-view EOCT probes. 2-D and even 3-D

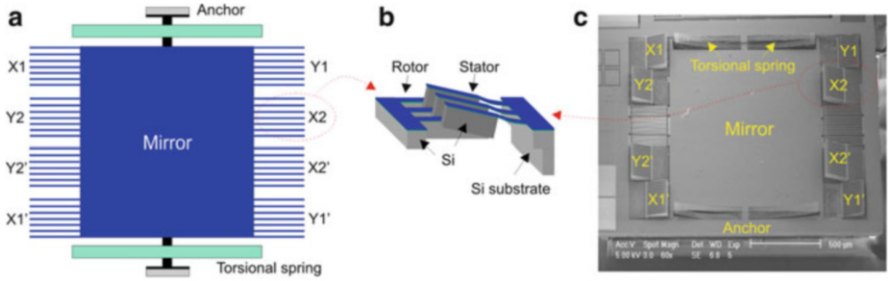

Fig. 78.2 E-ST mirror with curled comb drive. (**a**) Topology of the micromirror; (**b**) sketch of curved comb-drive finger structure, (**c**) scanning electron micrograph (*SEM*). X/Y denotes the comb drives with anchors on the curled/level sides, respectively [46, 54]

side-view EOCT [43] suitable for imaging tubular tissue (e.g., coronary artery, esophagus, colon) has been well developed using a motorized rotary fiber joint or a micro motor together with a push-pull actuator. Front-view EOCT suitable for imaging flat tissue (e.g., oral cavity, cervix, bladder) remains a technical hurdle because it needs to be inserted into the instrument channel (e.g., 16–22Fr) of a conventional endoscope for white-light image guidance [24]. In other words, the challenge is to provide a large FOV with high lateral resolution in a slender catheter. To tackle the challenge, we have developed microelectromechanical systems (MEMS)-based cystoscopic OCT (MEMS COCT) that provides a viable solution to front-view EOCT [29]. MEMS COCT takes advantage of deep reactive-ion-etch (DRIE) CMOS-MEMS mirror technology such as small size, high speed/precision, excellent laser steering capability, and potentially low cost, all of which are crucial for high-performance endoscopic laser scanning [44, 45]. The technique has been dramatically improved to optimize the performances of EOCT (e.g., SNR, resolution, packaging, reliability) [46] and validated in ex vivo and in vivo preclinical studies as well as in vivo clinical study to examine its utility and potential limitations for bladder cancer diagnosis.

Unlike those used for optical switch, MEMS mirrors used for endoscopic applications require large actuation, large size, high linearity, and fast speed. Both electrostatic (E-ST) and electrothermal (E-TH) MEMS mirrors have been developed and tested for endoscopic laser steering. Figure 78.2 exemplifies a sketch and scanning electron micrograph of an E-ST MEMS mirror, illustrating its operating principle. The chip comprises pairs of integrated MEMS z-axis curled comb-drive micro actuators (A, B) fabricated by CMOS micromachining process, allowing for a large angular actuation (C) driven under a bidirectional sweeping voltage on two sides of the mirror. Typical angular actuation (θ) for a 1×1 mm^2 mirror is $\leq 10^\circ$ at $18V_{p\text{-}p}$. The primary advantage of E-ST mirror is of high scanning speed ($\leq$10 kHz) and precision [44].

Figure 78.3 shows an E-TH mirror driven by a bimorph hinge consisting of a stack of Al and SiO_2 thin films embedded with an integrated poly-Si resistor (i.e., an E-TH actuator). Due to residual stress and difference in the thermal expansion

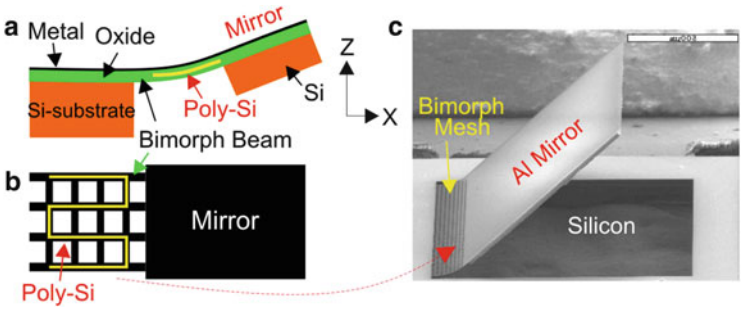

Fig. 78.3 An E-TH mirror with embedded curled poly-Si drive. (**a**) Schematic of an embedded poly-Si beam structure; (**b**) top view with x-axis-oriented poly-Si resistor; (**c**) SEM of a 32° T-TH MEMS mirror (1×1 mm^2 Al-coated mirror) [50, 51, 54]

properties between these two thin layers, the hinge curls up to an initial bending angle (θ_0) above the chip plane and θ varies with the temperature (T) within the bimorph. Thus, the embedded poly-Si resistor acts as the heat source to angularly actuate the mirror, and the actuation range θ can be adjusted by parameters such as the length of the stacked hinge and the differential thermal expansion coefficient between Al and SiO_2. The typical actuation angle attained is $\theta = 17°$, providing a lateral optical scanning over 35° – surpassing the need for endoscopic OCT [29]. The resonant frequency of a 1.2×1.1 mm^2 E-TH mirror is roughly 160–250 Hz, exceeding the speed requirement for 2D COCT. Technical issues encountered in E-TH mirrors, e.g., hysteresis, buckling, and nonlinearity, have been either eliminated or minimized to ensure high-fidelity COCT imaging [45, 47]. The lateral resolution of COCT reaches $\Lambda = 12$–16 μm, which is determined by focal length f (f = 8–10 mm) of the scan lens and beam size ϕ (eventually limited by MEMS mirror size, e.g., 1.2×1.1 mm^2).

Figure 78.4 illustrates the packaging of MEMS-based COCT and the integration to a commercial 22Fr rigid cystoscope via its instrument channel to enable white-light image-guided OCT imaging diagnosis. Despite compromised SNR due to light loss, the first in vivo image result demonstrated the capability of MEMS COCT for delineating the morphology of porcine bladder (a close homologue to human bladder) [22].

78.3 Preclinical Studies

78.3.1 Bladder Morphology Imaged by OCT and Histology

Despite the contrast difference between OCT (backscattering) and histology (H&E stain), Fig. 78.5 shows the morphology of normal human bladder imaged by ex vivo OCT and the corresponding histology, indicating a close correlation for the identifications. For instance, the urothelium (U) is a thin (~110 μm), uniform,

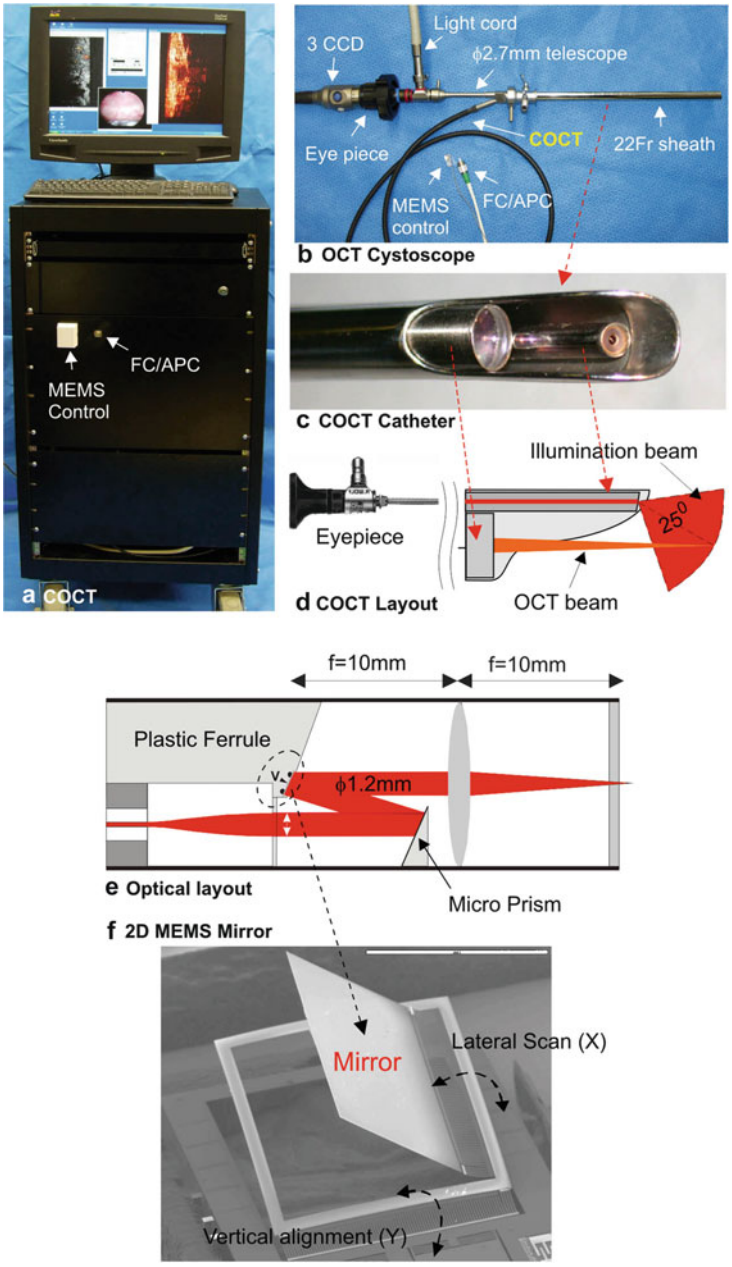

Fig. 78.4 MEMS-based COCT system. (**a**) A picture of the main COCT image station; (**b**) OCT cystoscope that fits in a 22Fr rigid sheath and connects to the main system via fiber/electric cables; (**c**) A picture of an COCT catheter using a ϕ2.7 mm telescope for visual guidance; (**d**) coordination between surface/EOCT scopes; (**e**) optical layout of the COCT catheter; (**f**) an SEM of an MEMS mirror (1.2×1.3 mm^2) [50, 54]

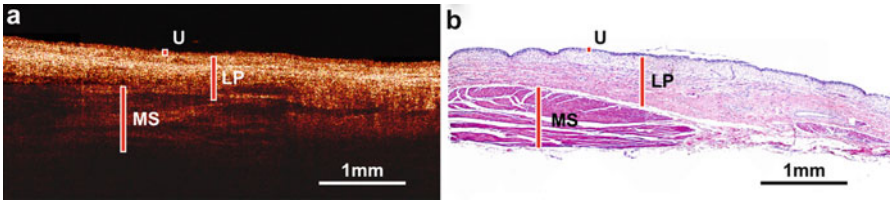

Fig. 78.5 Human bladder under proper stretch imaged by ex vivo OCT and histology, showing close correlations. Three layers in the human bladder wall critical for the diagnosis of bladder cancer prognosis, e.g., urothelium (*U*), lamina propria (*LP*), and the upper muscularis (*MS*), are delineated based on their backscattering differences [57]

and relatively low-scattering superficial layer; lamina propria (LP) is ~550 μm thick and highly scattering and heterogeneous because of compositions of mostly random collagens; the upper muscularis (MS) appears largely bifurcated, likely representing the interfaces between the smooth muscle collagen bundles. This result demonstrates the resolution of OCT to delineate morphological details of human bladder and thus the potential to track their changes (e.g. tumors) so as to determine the level of invasion of early bladder cancers (e.g., to stage TA, T1, flat, or not deeply invasive) toward the bladder wall, while conventional cystoscopy often fails. It is noteworthy that although an issue for in vivo scenario, the ex vivo OCT image contrast of bladder, particularly urothelium, strongly depends on sample preparation (e.g., stretch). As the specimen was refrigerated, most of the hardened muscularis in Fig. 78.5 had to be dissected in order to stretch the bladder for OCT examination.

78.3.2 Animal Bladder Carcinogenesis Imaging

OCT as a new diagnostic imaging modality must undergo throughout a validation process by a clinically proven method (i.e., histology – gold standard for cancer diagnosis) before it can be applied for human studies. In our lab, various animal TCC models have been used to systemically characterize OCT for identifications of the morphological alternations induced by carcinogenesis, which includes (1) female Fischer rats exposed to N-methyl nitrosourea (MNU) – an alkylating agent – to reproducibly induce cystitis, hyperplasia, and neoplasia (i.e., TCC) [23], (2) AY-27 cell instillation to generate multifocal TCCs in rat bladder [48], and (3) SV-40 T transgenic model to develop dysplasia, carcinoma in situ (CIS), and frank TCC in mouse bladder [49]. These protocols allowed us to define the structural and even physiological events that occurred as TCC developed in the urothelium and invaded into the underlying layers to characterize the changes in OCT images.

Figure 78.6 shows the result of ex vivo 3D OCT of rat bladder cancer (by MNU model), in which the 3-D image dataset captured in ~6 s was reconstructed by 32 sequential 2D OCT sections with 80 μm interval. Three hyperplastic lesions and

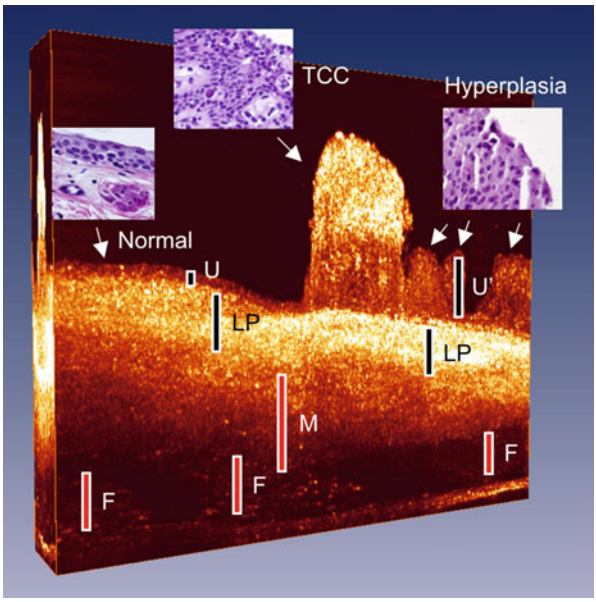

Fig. 78.6 3D OCT of rat bladder ex vivo. Image size: L6 mm × D2.1 mm × 2.5 mm, image acquisition: 6 s. *White/blue dashed circles*: 1 TCC and 3 hyperplastic lesions, respectively [46]

1 TCC (stage Ta) were identified based on their backscattering differences – $V_{U'}/V_U \approx 1.07$ for hyperplasia and $V_{U''}/V_U \approx 1.87$ for TCC – where V_U, $V_{U'}$, and $V_{U''}$ are the averaged backscattering values of normal urothelium, hyperplasia, and neoplasia measured by OCT, respectively. This suggests the potential role of backscattering as a natural biomarker for OCT diagnosis of early urothelial cancer primarily determined by enhanced nuclear-to-cytoplasmic ratio (NC ratio). To further study this effect, optical modeling of nuclear morphology, i.e., NC ratio changes by nuclear size, polarity, and density induced by carcinogenesis, is shown in Fig. 78.7, which collaborates with result in Fig. 78.6. In the modeling, urothelial backscattering coefficient μ_b was calculated using the corresponding histomorphometric data [50].

In addition to diagnosis of TCC, OCT may be further used to detect bladder cancer margins. Figure 78.8 shows that 3D OCT can accurately locate the margins of a large papillary TCC. Panel 1–1′ shows that the bladder wall (e.g., U) was normal except thickened LP with excessive angiogenesis (large blood vessels, BVs). Panel 2–2′ shows the edge to TCC (stage TA) where the interface between slightly thickened urothelium U′ (210 μm) with enhanced backscattering $(V_{U'}/V_U \approx 1.47)$ and the inflammatory LP was clear. Panel 3–3′ shows thick urothelium U″ (~540 μm) with high backscattering $(V_{U''}/V_U \approx 1.78)$. OCT shows the TCC invaded into LP, but the abrupt attenuation induced by high urothelial scattering and absorption of large BVs prevents OCT to separate it from stage T1 or T2. Histology (3–3′) confirms it a T1 TCC and the lateral tumor margin (dashed red circle).

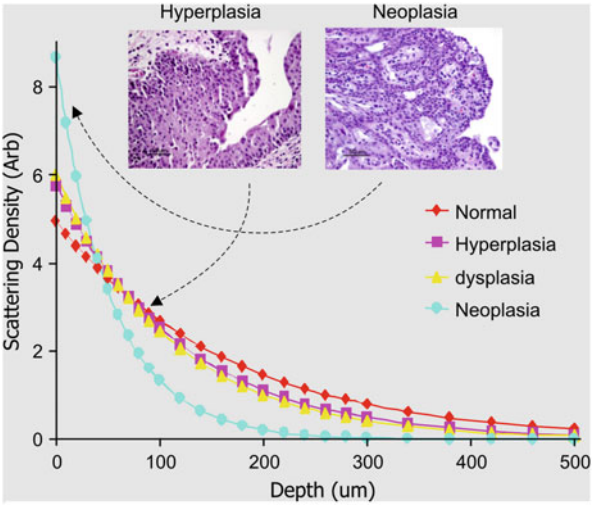

Fig. 78.7 Simulated OCT signals of urothelial backscattering versus depth during carcinogenesis by statistical evaluation of urothelial nuclear density from histological images. Normal, hyperplastic, and early dysplastic epithelia show low backscattering whereas neoplastic epithelium exhibits a ~60 % increase in backscattering [50, 57]

78.3.3 MEMS-Based OCT

In parallel to animal carcinogenesis study, preclinical study on COCT was performed to test its feasibility for clinical human examinations and to provide feedbacks for improving COCT probe design and fabrication. Figure 78.9 compares in vivo 2-D COCT image of porcine bladder (acquired at ~6 fps) and 2-D ex vivo OCT image of almost identical bladder cross section by the benchtop setup. Except a smaller lateral size (2.9 mm vs. 6 mm) and slight decrease (~8 dB) in image SNR due to light coupling loss in the OCT endoscope, COCT enables delineation of the morphology of pig bladder such as U, LP, and MS (identified by the interfaces between large collagen fiber bundles). Figure 78.9 demonstrates technological advances in MEMS-based COCT that allows providing comparable sensitivity and resolution to benchtop OCT; therefore, the results of ex vivo studies including animal TCC studies are potentially transferable to in vivo COCT studies [46].

Additional challenge for in vivo COCT diagnosis of early bladder cancer may include effective image guidance because of large surface areas to be randomly scanned across human bladder. In addition to white light, 5ALA and NBI were tested to assist OCT scans. For instance, Fig. 78.10 compares the results of rat bladder lesions ((a) inflammation, (b) hyperplasia, (c) TCC) with 5ALA fluorescence and 2D COCT, which shows that these two methods compliment each other. Both detected TCC, but the benign lesions false-positively identified by 5ALA fluorescence were corrected by COCT as LP inflammation and hyperplasia (reversible and thus no clinical significance) [48]. This suggests that 5ALA-guided COCT can effectively guide COCT for detecting bladder cancers while reducing the high false-positive rates of 5ALA by OCT to exclude benign lesions [51].

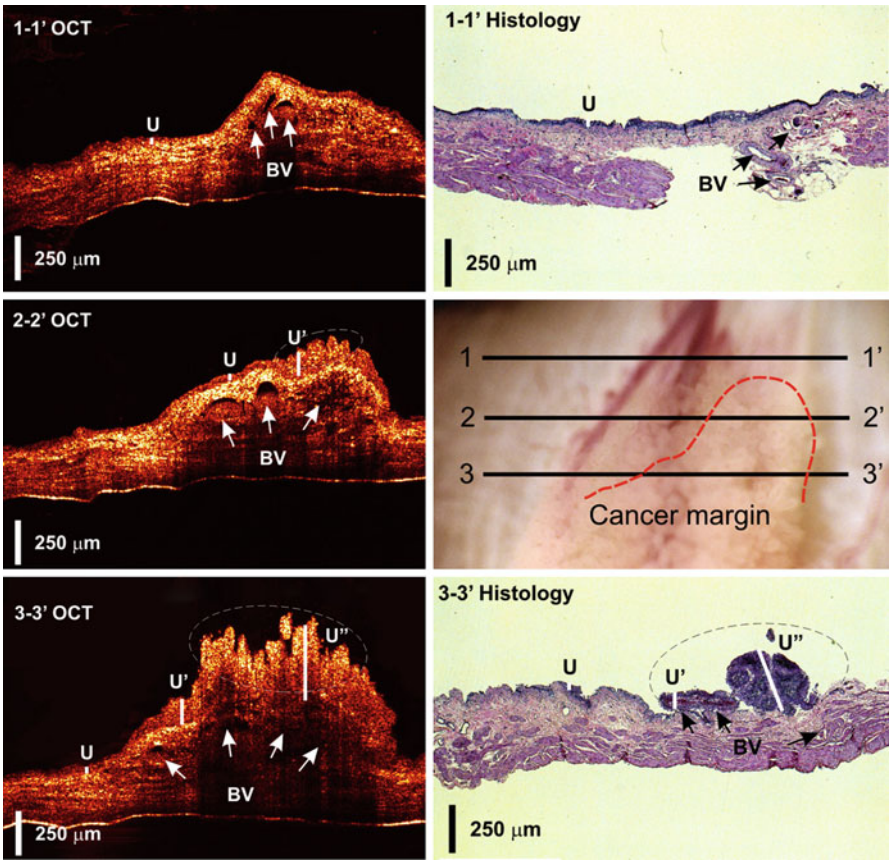

Fig. 78.8 A papillary TCC imaged by OCT and histology. Panels (1–1′) to (3–3′) were OCT sections indicated in the surface image, which covered the transition of morphological changes from "normal" to cancerous bladder areas. Corresponding histological evaluations are presented for 1–1′ and 3–3′ sections. BV: blood vessels (indicated by *arrows*); U, U′: normal and cancerous urothelia, respectively. *White dash-circled* areas: TCCs with drastically increased backscattering. *Red-dashed line*: precise TCC margin. The results demonstrate the potential of OCT for providing accurate precise bladder cancer margins

78.4 In Vivo Clinical Diagnosis

After successful ex vivo validation and in vivo feasibility studies, human studies were initiated in 2005 to examine the utility and potential limitations of COCT on patients suspected of TCC and scheduled to undergo operating-room (OR) cystoscopy. Patient enrollment criteria were those scheduled for transurethral biopsy or resection of bladder tumors. Figure 78.4 shows how MEMS COCT was integrated with conventional WLI for OR diagnosis of bladder tumor (clinical validation). For example, Fig. 78.11 compares the results of WLI,

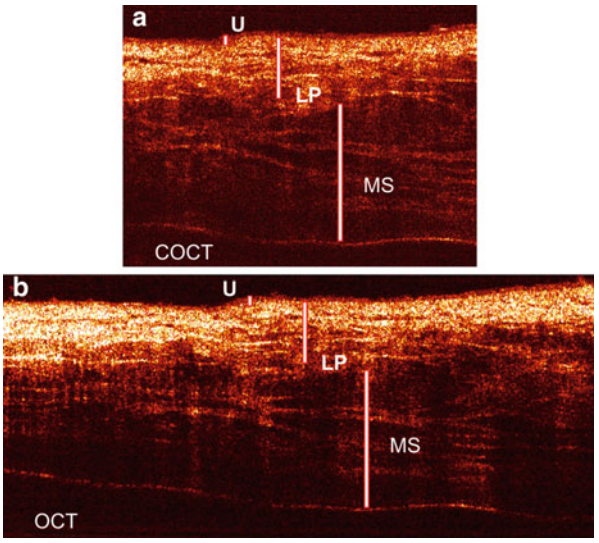

Fig. 78.9 Fresh porcine bladder imaged by COCT (**a**) and benchtop OCT (**b**). Except a slight decrease in SNR in COCT, both clearly delineate bladder morphology from urothelium *U* to muscularis *MS* [46]

COCT, and histology of three OR cases [52]. Panel a is a typical normal human bladder in vivo, which resembles porcine bladder in Fig. 78.9 in that bladder layers such as U, LP, and M were well delineated by COCT and correlated with histology. Panel b and panel c are two typical nonpapillary TCCs, in which lesion b exhibited low urothelial μ_b whereas lesion c exhibited high urothelial μ_b. Interestingly, our clinical data (based on 150 cases) indicated that unlike rat TCC model in Figs. 78.8 and 78.10, most human TCC cases (76 %) exhibited no significant μ_b enhancement; thus COCT diagnosis of TCC solely based on enhanced μ_b is not suitable for human uses. Histomorphometric analyses revealed that TCC c was composed of small but denser nuclei (similar to rat MNU model) which increased μ_b, whereas TCC b was composed of enlarged nuclei (similar to SV40-T CIS model in Fig. 78.15) resulting in minor or no μ_b increase.

On the other hand, it was found that human TCC exhibited increased μ_b heterogeneity which likely resulted from increased architectural variation, e.g., random excessive growth or loss of polarity caused by carcinogenesis. For instance, the COCT signals (black curves) from yellow lines in normal U (a) and in TCC (b) were plotted collaterally with the results (red curves) after speckle reduction, showing that the μ_b heterogeneity as presented by standard deviation were $\sigma = 0.303$ in TCC vs. $\sigma = 0.173$ in normal urothelium, namely, increased 75 %. As a result, the diagnostic criteria of TCC were modified from evaluating enhanced urothelial μ_b to its heterogeneity σ. This approach has been proven effective in the later clinical validation studies. In addition, it has been found that a large FOV is crucial to in vivo image evaluation of urothelial heterogeneity; in this respect, MEMS-based COCT offers unique advantages owing to its large FOV (4.8×2.4 mm^2) and high image fidelity (e.g., SNR) (Fig. 78.12).

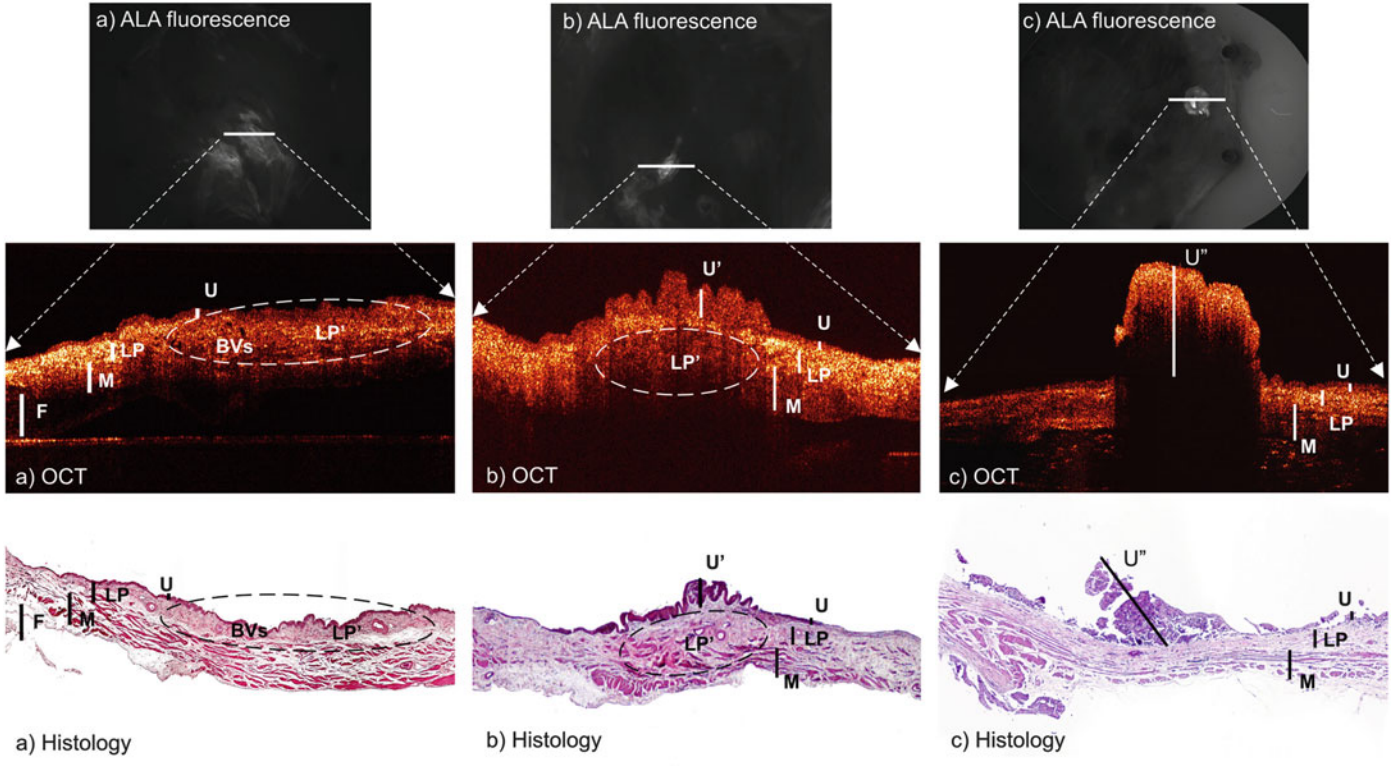

Fig. 78.10 5ALA fluorescence (ϕ30 mm), COCT (4.9 × 2.4 mm^2), and histology of three rat bladders. *U, U′, U″* normal, hyperplastic, neoplastic urothelia, *LP* lamina propria, *M* muscularis, *LP'* inflammatory lesion, *BVs* vasodilatation. Fluorescence detected all three lesions "+" (either benign or malignant), but COCT could differentiate them as (**a**) "−" minor edema (*LP'*), (**b**) "−" hyperplasia (*U′*) with edema (*LP'*), and (**c**) "+" TCC (*U″, pTa*) [48]

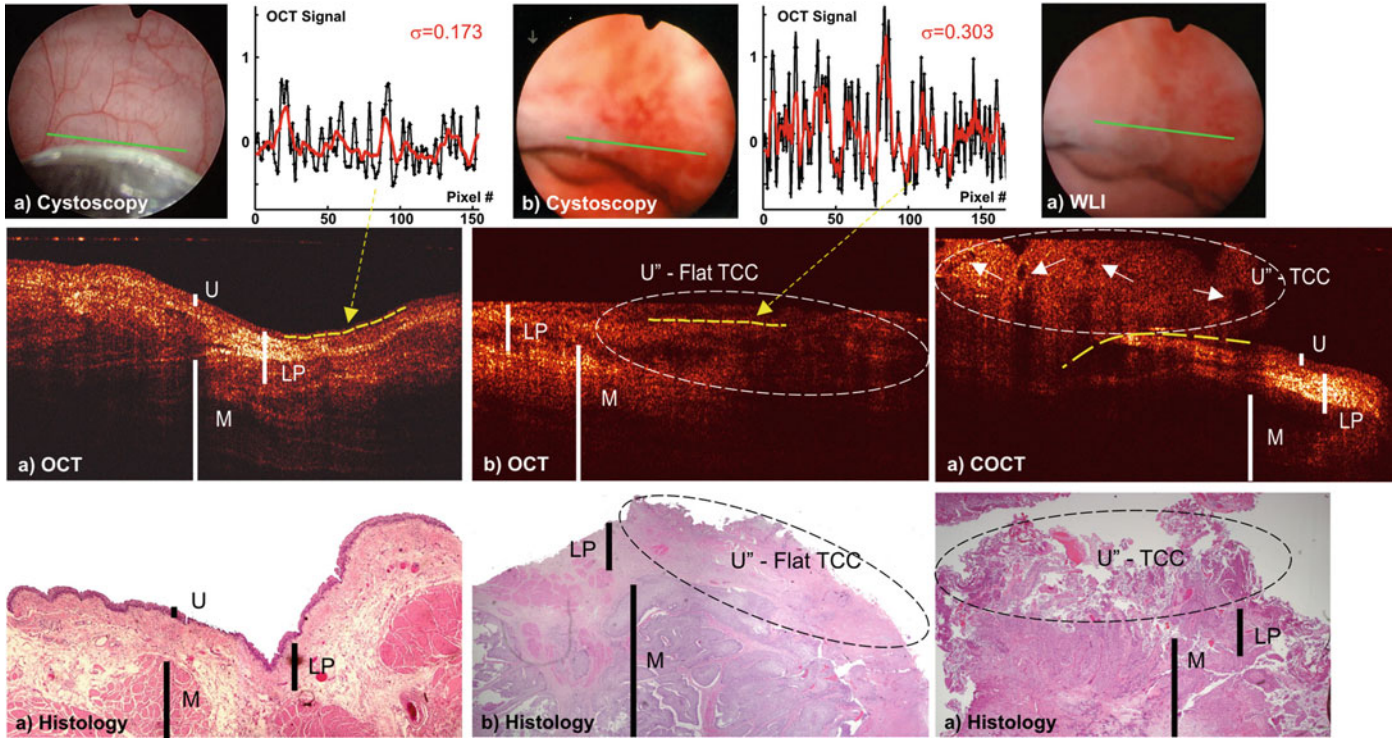

Fig. 78.11 In vivo human bladders imaged by WLI, COCT (4.5 × 2.2 mm^2), and histology. *U*, *U″* normal, nonpapillary TTCs, *N* necrosis. (**a**) normal bladder; (**b**, **c**) nonpapillary TCCs (pT2, LG) with μ_b low in (**b**) and high in (**c**). *Dashed yellow lines*: selected to analyze the original OCT signals (*black curves*) and the urothelial heterogeneity after speckle reduction (*red curves*). Apparently, the μ_b heterogeneity shown as the standard deviation ($\sigma = 0.303$) of *red curves* in TCC (**b**) is 75 % higher than that ($\sigma = 0.173$) in normal urothelium (a), i.e., $\sigma_{TCC}/\sigma_{NR} = 1.752$ [52]

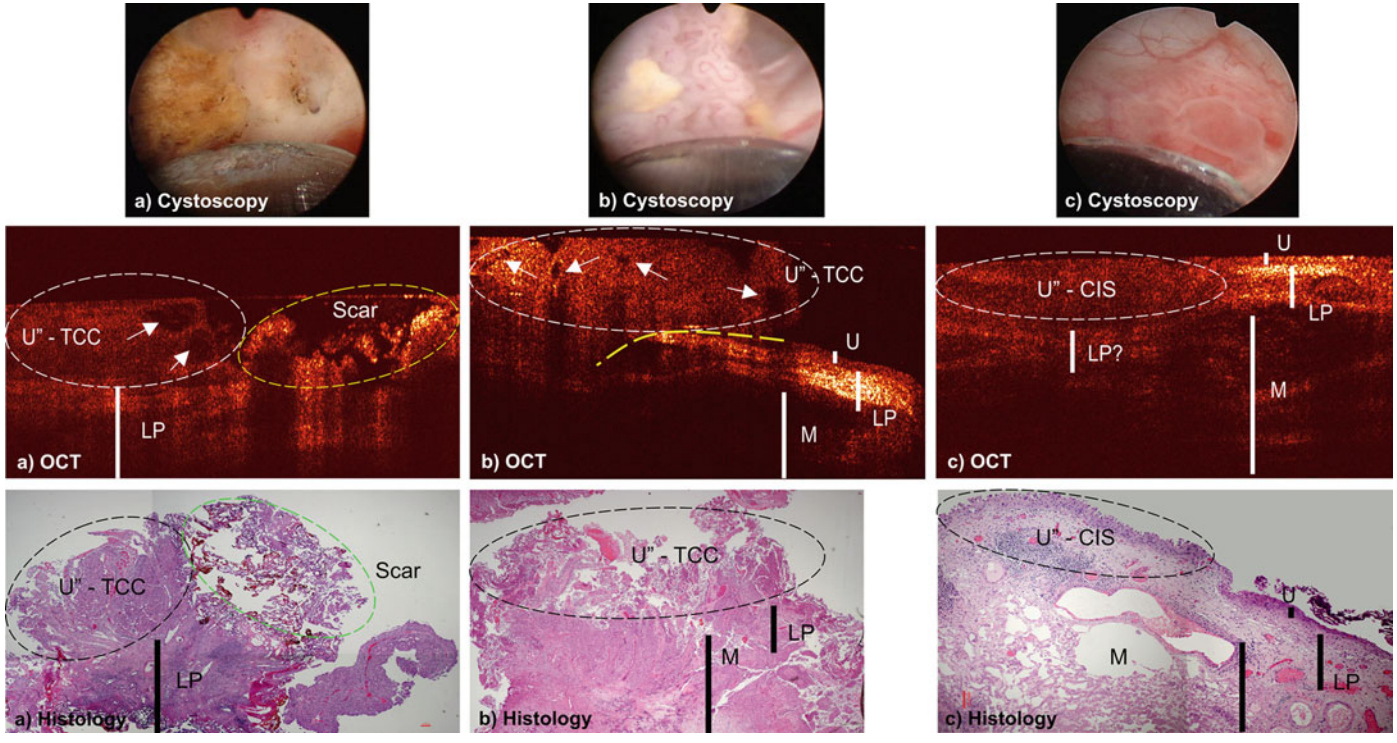

Fig. 78.12 In vivo human bladders imaged by surface image (ϕ30 mm), COCT (4.5 × 2.2 mm^2), and histology. U, U″: normal and papillary TTC or CIS. (**a**) Residual TCC post TURBT (LG), (**b**) papillary TCC (LG), (**c**) CIS. The *yellow line* marks the uncovered tumor margin. Scar, induced by previous TURBT, was differentiated from residual TCC as ultrahigh μ_b with rugged surface. Papillary TCC was identified by enhanced heterogeneity (e.g., honey nests) as pointed by *arrows*. COCT failed to grade CIS, thus unable to differentiate it from low-grade TCC

As TCCs are often associated with other bladder diseases such as inflammation, cystitis, and wounds induced by previous resections, COCT diagnosis of TCC based on morphological changes can be complicated. Figure 78.12 shows a group of three more OR cases to highlight the complexities of clinical diagnoses. For example, prior resections might dramatically alter the architectural "templates" of normal bladder (e.g., U, LP, and M), and detection of residual or recurrent tumor from scar or necrosis remains a major challenge in surveillance cystoscopy, which COCT may play an active role. As shown in panel a, WLI hardly detected any specific difference due to the changes by resections, whereas COCT diagnosed the left lesion as residual TCC based on its papillary features and the right lesion as scar based on its ultrahigh backscattering with very rugged surface topography of scar or necrotic lesions, which was later confirmed by histology. Panel b shows that WLI was able to roughly identify the boundary of papillary TCC, whereas COCT owing to its depth resolution could see through large papillary TCC to precisely locate the lateral cancer margin (dashed yellow line). It is noteworthy that due to reduced image depth within cancerous lesions, staging of TCC by COCT was generally limited to T0, Ta, and T1 without substantive outgrowth. Panel c exemplifies the diagnosis of CIS, i.e., a high-grade, aggressive, and lethal TCC. As the lesion was flat and nonspecific except slightly reddish like an inflammatory lesion under WLI, random biopsies were taken for a conclusive diagnosis. COCT was able to diagnose the lesion as a flat TCC based on enhanced urothelial μ_b heterogeneity with missing U-LP junction. Here, the large FOV was crucial, because it allowed COCT to scan across the transition to adjacent normal bladder to assure that the dashed area was cancerous urothelium. The diagnosis of CIS was confirmed by histology, but COCT was unable to stage the tumor (e.g., low-grade LG or high-grade HG). In his respect, subcellular imaging could provide more accurate diagnosis/grading.

Clinical studies suggest that incomplete transurethral resection (TUR) of bladder tumor may lead to high recurrence rates in current bladder cancer management [12, 13]. Because of large FOV (4.8×2.4 mm^2) of MEMS COCT, multiple COCT scans (e.g., center plus eight edges) on each lesion could be performed to accurately landmark the tumor margin and then overlapped on the surface image to guide TUR. In vivo results in Fig. 78.13 demonstrate the efficacy of COCT for providing accurate tumor margin. Depending on the tumor size, 4–12 scans could provide sufficient coverage of the tumor contour as highlighted by the dark dashed line. Critical importance of this function is to accurately highlight the boundary of a flat TCC or an invasive TCC with coexisting CIS.

Results of clinical statistics based on 176 OR cases (148 patients) are summarized in Table 78.1. Compared with the patient population of office cystoscopy, the OR cases presented here tend to contain more advanced cancers and fall short of control cases, thus resulting in underestimated diagnostic specificity. Meanwhile, the OR cases may likely include more patients with complicated symptoms, e.g., referred due to inconclusive office cystoscopy or surveillance cystoscopy.

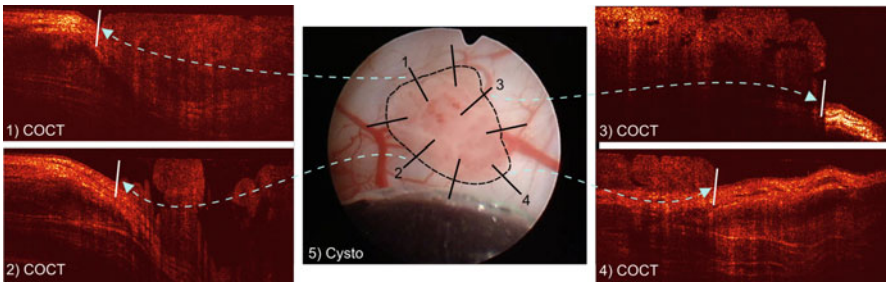

Fig. 78.13 In vivo COCT to landmark the boundary of human TCC (pT1) for accurate image guidance of TUR. A total of eight more COCT scans were performed to locate TCC boundary (*dash line*) of a ϕ13 mm TCC where the *solid dark lines* marked the position of each COCT scan and the *white lines* in each scan were the tumor margins. All eight COCT scans were completed in approximately 98 s by using spectral-domain COCT and then overlapped on the surface image

Table 78.1 Diagnostic sensitivities and specificities of TCC calculated on a per case basis

Methods		OCT		Cyst		Cyto		p-values

Cyst: cystoscopy, *Cyto*: cytology, *N*: total number, *LG*: low grade, *Superficial*: all pTis, and pTa-pT1 tumors. Cytology data for 12 cases were unavailable

[a]Among eight false-negative cases, three were in the retro area (e.g., bladder neck) inaccessible by rigid COCT

The results in Table 1 demonstrate the efficacy of COCT to significantly enhance current clinical methods (e.g., cystoscopy, cytology) for bladder cancer diagnosis ($p < 0.05$). Compared with WLI, the diagnostic sensitivity (SN) and specificity (SP) were increased from $SN_{Cyst} = 75.6$ % and $SP_{Cyst} = 70.2$ % to $SN_{OCT} = 90.3$ % and $SP_{OCT} = 83$ %. If the three cases inaccessible by rigid COCT were excluded, the sensitivity could move up to $SN_{OCT} = 93.7$ %. The related positive and negative predicted values were improved from $PPV_{Cyst} = 68.8$ % and $NPV_{Cyst} = 76.6$ % to $PPV_{OCT} = 82.2$ % and $NPV_{OCT} = 90.7$ %. More detailed data analyses reveal that the major clinical impacts of COCT were on superficial TCC cases (<pT2),

Table 78.2 Diagnostic sensitivities and specificities of CIS calculated on a per lesion basis

Methods	OCT		Cyst		Cyto		p-values		
Tumors	n/N	%	n/N	%	n/N	%	OCT : Cyst	OCT : Cyto	Cyst : Cyto
CIS (pTis)	11/12	**91.7**	5/12	41.7	6/10	60.0	**0.027**	0.135	0.392

in particular, on the CIS cases [52]. Because of limited CIS enrollments and CIS often coexists with TCC, Table 78.1 is replotted on a per lesion basis in Table 78.2. The comparative data indicate that COCT as an optical biopsy tool allowed for significantly enhancing the diagnosis of CIS from $SN_{Cyst} = 41.7\ \%$ to $SN_{OCT} = 91.7\ \%$ ($p = 0.027$).

78.5 Discussion and Future Work

The outcome of our pilot clinical studies demonstrates the potential of MEMS COCT to significantly ($p < 0.05$) enhance current endoscopic procedures for the diagnosis of early superficial bladder cancers, especially CIS, and for detecting residual or recurrent tumors in surveillance cystoscopy following prior TUR and/or intravesical therapy. Based on the results of these OR cases, WLI was able to efficaciously guide COCT for locating suspicious lesions across bladder wall within 10 min; in other words, 5ALA fluorescence-guided COCT, although potentially more effective, may not be absolutely necessary for OR diagnosis of TCC with MEMS COCT. Nevertheless, a number of other limitations and technical issues have been noted, some of which are addressable but some of which are determined by the physical limitations of OCT technology and may need to combine other imaging approaches for viable solutions.

78.5.1 Quantitative Diagnosis of CIS by Subcellular OCT

Although it has been found that the majority of bladder cancers encountered in our clinical studies could be instantaneously diagnosed by direct visual identification of COCT images/movies, image identifications of some lesions (e.g., CIS or residual TCC) were not so straightforward, especially for physicians without OCT training; therefore, approaches to enable more quantitative diagnosis may be desirable for future clinical adoption of COCT.

Apparently, direct measures of nuclear size increase (i.e., NC ratio increase) of urothelial cells will be important for diagnosis of bladder CIS. In this respect, subcellular imaging capability is required, for instance, by subcellular OCT. Although ultrahigh-resolution OCT (μOCT) has been reported to provide subcellular images of relatively larger thus less scattering cells such as mesenchymal cells in African frog tadpole and animal adipocytes [38, 39], μOCT (not optical coherence

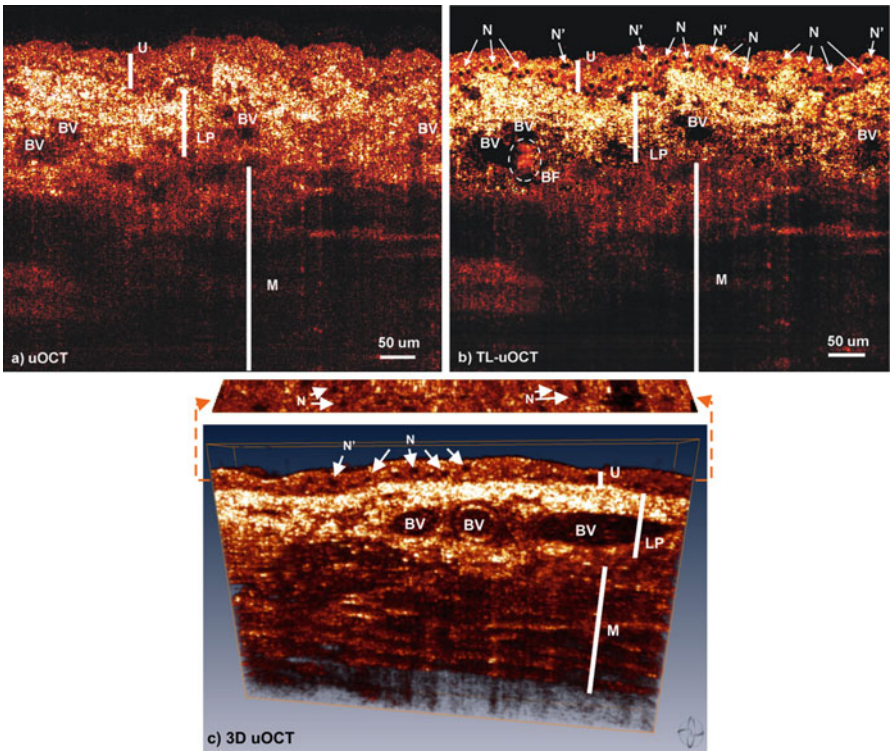

Fig. 78.14 TL-μOCT images of a fresh living normal mouse bladder. (**a**) μOCT (snap shoot) without subcellular details; (**b**) TL-μOCT that uncovers subcellular details; (**c**) 3D TL-μOCT to enable 3D subcellular imaging. A compact Ti:Al_2O_3 laser was used to provide axial resolution of $\Delta z \leq 1.8$ μm and a commercial low-NA achromat (f10 mm/0.25 NA) was used to provide $\Lambda \approx 2.8$ μm lateral resolution [54]

microscopy or OCM primarily by confocal gating rather than coherence gating) of highly scattering mammalian cells such as epithelial cells is hindered by the overwhelming speckle noise and multiple scattering. To solve the problem, we developed time-lapse μOCT (TL-μOCT) which successfully uncovered subcellular details of urothelial cells [53]. TL-μOCT is based on time-lapse averaging to scramble the phase noise of local multiple scattering from intracellular micro-organelles (contributing more to backscattering than nucleus that favors forward scattering) by taking advantage of their micro motion. This method only works for live urothelial cells (because of insufficient micro motion in dead cells or tissue) and the optimal time lapse was 0.7-0.1 s depending on the physiological condition of bladder. Figure 78.14 shows that TL-μOCT was able to uncover subcellular details (e.g., nuclei) of urothelium in living mouse bladder. Importantly, as TL-μOCT only uses a low-NA commercial achromat (f10 mm/NA0.25) to enable subcellular

imaging of urothelium (on focal plane) and architectural imaging of the underlying bladder wall (e.g., LP, M) at up to 700 μm of depths without focal tracking, this technique may be uniquely suitable for endoscopic in vivo optical biopsy to diagnose and grade flat TCC (e.g., CIS) [54].

To validate the utility of TL-μOCT for bladder cancer diagnosis and grading, animal carcinogenesis study was performed and the results are presented in Fig. 78.15. Surprisingly, panel a) shows that the nuclear size ($N \approx 6.7 \pm 1.1\mu m$, $m = 6$) of normal mouse bladder measured by TL-μOCT closely matched the histological counterpart ($N \approx 6.0 \pm 0.8\mu m$, $m = 6$). More interestingly, panel b and panel c further demonstrated the resolution of TL-μOCT to track nuclear enlargement in bladder cancer cells. Apparently, urothelial heterogeneity increases in both lesions reflecting the excessive random growing nature of carcinogenesis, which is consistent with clinical COCT imaging findings. For RAS model b, the measured nuclear size $N' \approx 12.3 \pm 1.6\mu m$ ($m = 10$) measured by TL-μOCT matched $N' \approx 11.4 \pm 1.5\mu m$ ($m = 10$) by histology (LG). For SV-40T model c, $N'' \approx 13.4 \pm 1.3\mu m$ ($m = 10$) measured by TL-μOCT well correlated with $N'' \approx 12.9 \pm 0.9\mu m$($m = 10$) by histology (HG). These results clearly show the potential of TL-μOCT for subcellular image diagnosis and grading of TCC, which is crucial to clinical diagnosis of CIS (high-grade flat TCC). Because of low-NA optics needed for TL-μOCT, this method can be translated into an endoscopic OCT catheter for in vivo diagnosis, and it allows for extended depth of field (e.g., >100 μm for subcellular resolution and >700 μm for OCT imaging) without the need for focal tracking.

78.5.2 Quantitative Diagnosis of CIS by 3D OCT

Although the results presented in Figs. 78.14 and 78.15 demonstrate the capability of TL-μOCT for subcellular image diagnosis and grading of CIS, this technique employs high-cost ultrafast laser which may limit its clinical adoption unless high-power ultra-broadband LED sources will be available in the future. An alternative method for quantitative CIS diagnosis has been developed in our lab by employing 3D OCT.

It is shown in Fig. 78.11 that urothelial heterogeneity (e.g., standard deviation σ of urothelial backscattering μ_b) is increased in TCC and thus used for TCC diagnosis. Mathematically, spatial averaging of μ_b is needed to effectively minimize speckle noise to evaluate the embedded architectural heterogeneity σ. This usually does not pose a problem for 2D OCT by averaging μ_b along the cross section (z-x plane) except for some CIS lesions whose urothelia are too thin (e.g., ~100 μm or even less) to implement effective μ_b averaging for separation between random speckle artifacts and structural heterogeneity (σ). To tackle the challenge, 3D OCT was proposed to enable effective μ_b averaging and thus speckle noise reduction, and transgenic mouse CIS model (SV-40 T) was employed for validation studies. Figure 78.16 shows the results that the subtle textural changes of urothelial

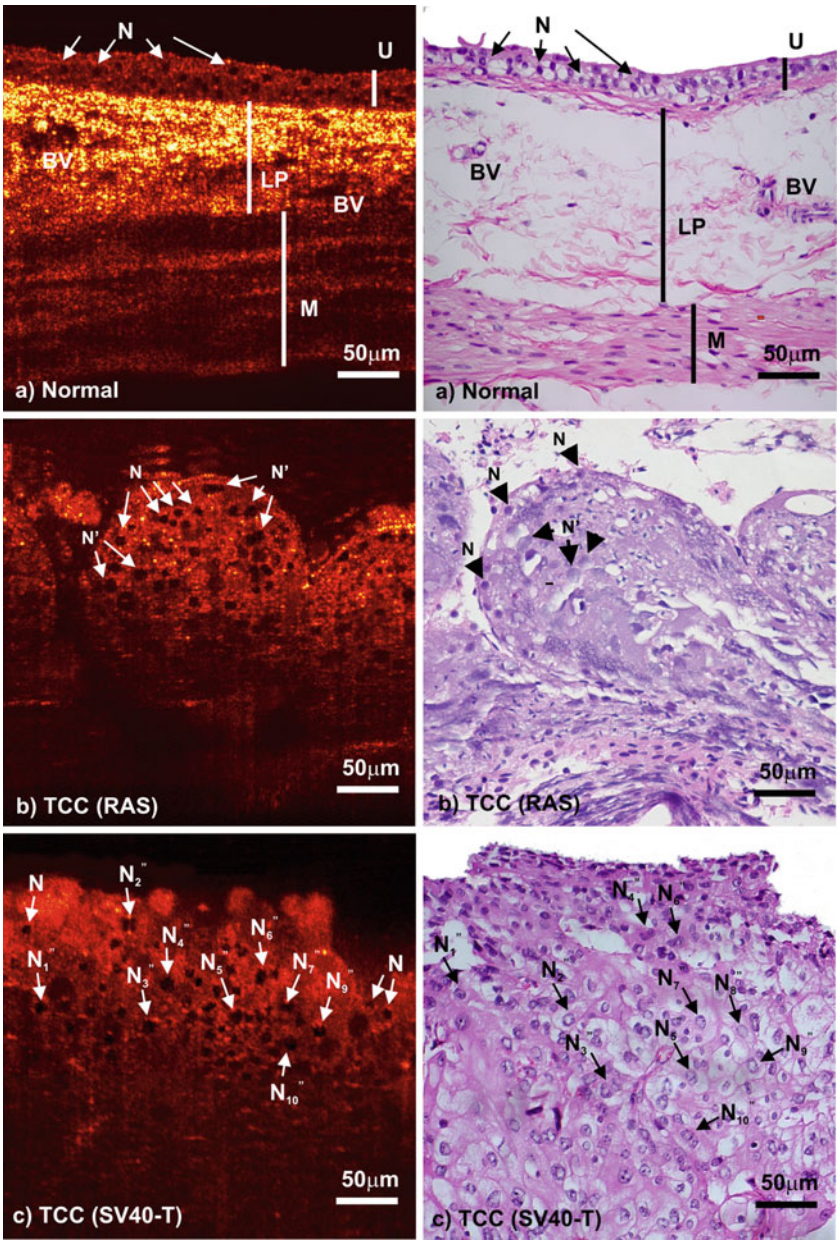

Fig. 78.15 Subcellular images of fresh living mouse bladder with TL-μOCT (time lapse: $\tau \approx 0.7$ s with four-frame average). (**a**) Normal bladder with nuclear size measured by μOCT/histology, N = 6.7 ± 1.1μm/N = 6.0 ± 0.8μm; (**b**) TCC (RAS, LG), N″ = 13.4 ± 1.3μm/N″ = 12.9 ± 0.9μm; (**c**) TCC (SV40-T, HG), N″ = 13.4 ± 1.3μm/N″ = 12.9 ± 0.9μm (based on $N''_i = 1-10$). *U* urothelium, *LP* lamina propria, *M* muscularis, *BV* blood vessel, *N, N', N''* nuclear sizes of normal urothelium, low-grade and high-grade TCCs [53]

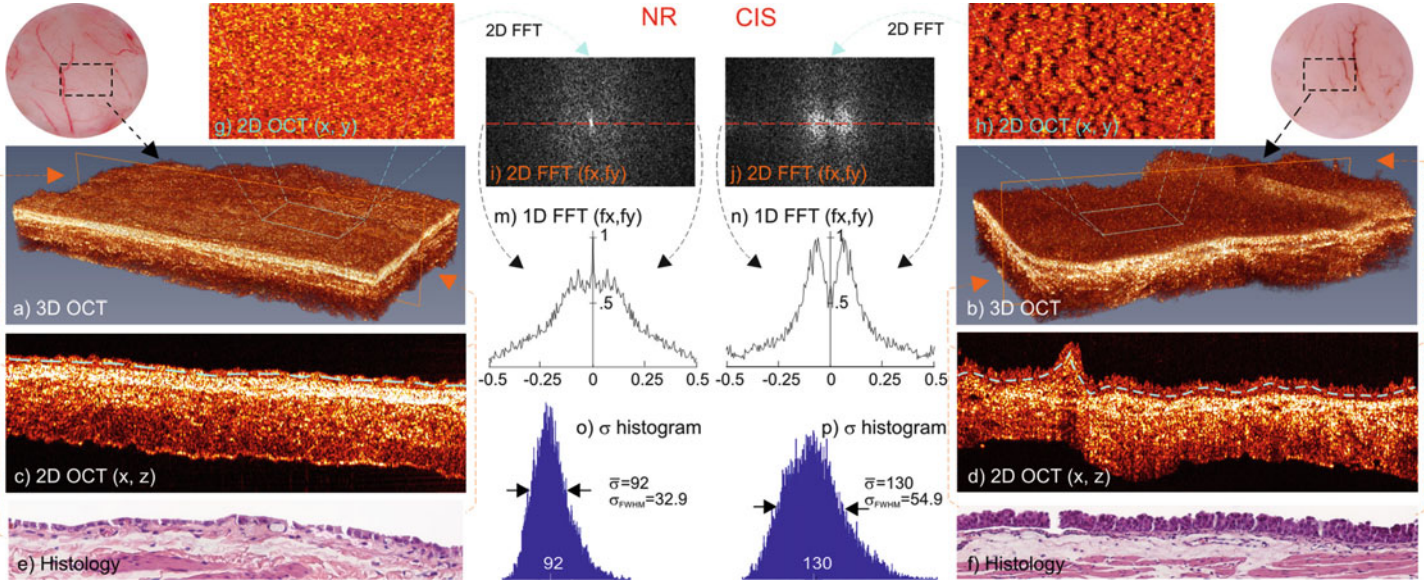

Fig. 78.16 En face standard deviation σ(x,y) of 3D COCT images of mouse bladders. Image size (**g**, **h**): 100 × 200 pixels. σ(x, y) was acquired by first segmenting the bladder surface, averaging first 5 pixels axially, and calculating standard deviation. (*Left*) normal urothelium (*NR*); (*Right*) early CIS (SV-40T) invisible by surface image and not differentiable by 2D OCT. CIS can be separated from NR by their texture difference. Increase in σ and broadening of Δσ-histogram (*o*, *p*) as well as those of 2D/1D FFT (*i*, *j*; *m*, *n*) in CIS reflect urothelial heterogeneity, i.e., 130/92 = 47 % increase in CIS. Without quantitative analysis (FFT or histogram), visual difference of enface OCT (**g**, **h**) btw NR and CIS can be observed [55]

heterogeneity induced by CIS can be readily differentiated by our new 3D OCT algorithm [55]. At such early "stage" of CIS, even pathological diagnosis to differentiate it from dysplasia was difficult. WLI completely failed to identify the lesions; 2D OCT was unable to predict or affirm the diagnosis except identifying a minor urothelial thickening; however, 3D OCT with image processing (e.g., 2D FFT and σ histogram) clearly differentiated it as CIS as a result of more effective 3D speckle reduction to dramatically improve pattern recognition and allow for accurate quantitative analysis. Both 2D FFT and σ histogram showed urothelial heterogeneity (e.g., 47 % increase) in CIS induced by carcinogenesis [56]. As the area needed for en face urothelial averaging is small (e.g., 100 pixels or 200 μm along y-axis), endoscopic adoption can be easily implemented by employing a 2D MEMS mirror for rigid 3D COCT or a rotary fiber probe with a push-pull actuator for flexible 3D COCT developments.

78.5.3 Improving TCC Staging by Combining High-Frequency Ultrasound

In addition to noninvasive early diagnosis (preferably grading) of bladder cancer, staging its invasion into the underlying bladder layers especially into the muscularis (i.e., pT2) is crucial to the management of bladder cancer patients. It is known that the effective penetration depth of OCT imaging (e.g., at $\lambda = 1.3$ μm) is ultimately limited by multiple scattering of biological tissue, which can range from 0.5 to 3 mm depending on tissue type. For urinary bladder, the image depth of OCT is around 1.5–2 mm, which usually allows for imaging the bladder architecture down to the upper part of the muscularis layer (i.e., upper MS). However, large papillary TCCs that outgrow >2 mm over the bladder surface are common clinical cases. Additionally, because of denser tumor vasculature and increased structural heterogeneity, excessive light attenuation in TCC has been common findings, which in turn reduces the effective image depth of OCT in tumor areas. It has been found in our clinical studies that COCT is not suitable for staging large papillary TCC (≥pT1).

To overcome this physical limitation, other medical imaging modalities have been explored, among which high-frequency ultrasound (HFUS) has been found to compliment to OCT to improve TCC staging capability. Interestingly, based on the results of our recent rat TCC validation studies (using AY27 model), that a dual-modality imaging modality combining OCT and HFUS can complement each other: COCT was able to diagnose TCC that HFUS failed due to its limited resolution, whereas HFUS was able to stage TCC to pT2b (muscle invasion) that COCT failed due to its limited imaging depth. Figure 78.17 exemplifies that HFUS mistakenly diagnosed two inflammatory lesions (upper panels) as TCCs which were corrected by OCT as benign lesions, whereas HFUS staged a large TCC (lower panels) as pT2b/T3 that OCT failed to stage due to insufficient imaging depth for solid large cancers like this. This result suggests that a dual-imaging cystoscopic approach that combines COCT and transurethral HFUS will substantially enhance

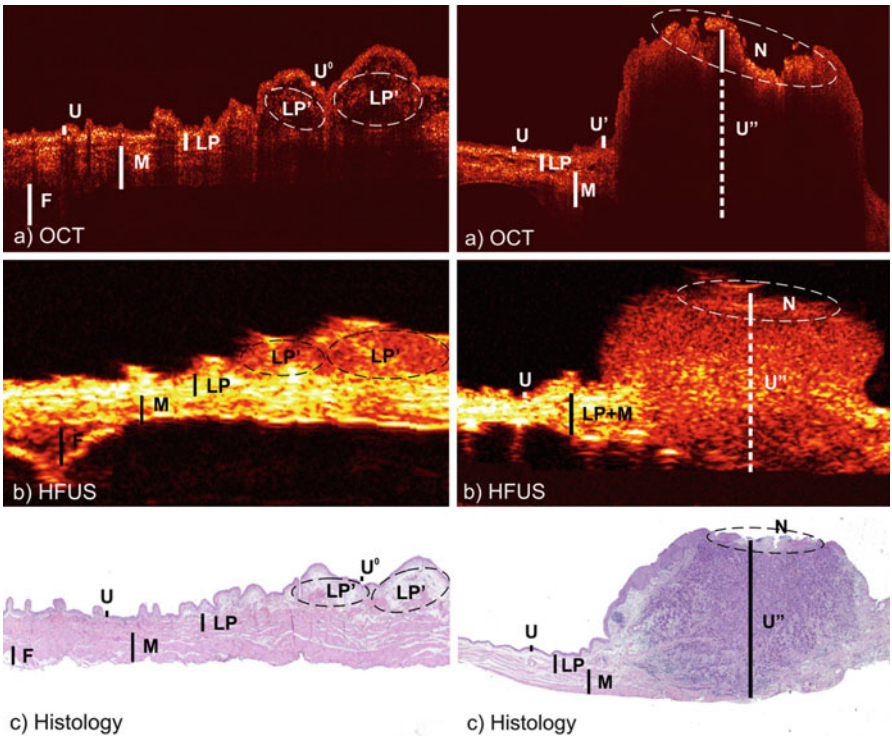

Fig. 78.17 Rat bladders imaged ex vivo by COCT, HFUS, and histology. Image size: 6×2.8 mm^2 (image fusion applied to COCT). (*Upper panels*) Two benign inflammatory lesions misdiagnosed as TCC by HFUS was corrected by COCT; (*Lower panel*) papillary TCC failed to be staged by COCT was determined by HFUS as T2b or T3 tumor. *U, U′, U″* normal urothelium, hyperplasia, TTC, *F* fatty layer, *LP'* inflammatory lesion, *N* necrosis [57]

the diagnosis and staging of bladder cancers. In this respect, studies have been reported that develop combined endoscopic OCT and ultrasound [58].

Acknowledgments Special thanks to the following collaborators who have made important contributions to the presented work: M. Zeidel, MD, and J. Lavelle, MD, in the University of Pittsburgh Medical Center participated in MNU-based rat TCC study; G. Fedder, PhD, in the ECE Department of Carnegie Mellon University and H. K. Xie, PhD, in the ECE Department of University of Florida participated in the MEM mirror development; X. R. Wu, MD, in the New York University Medical Center provided SV-40 T transgenic mouse model; and W. Waltzer, MD, R. Bhalla, MD, F. Darras, MD, Z. Frischer, J. Kim, MD, J. X. Liu, MD, K. Schroyer, MD, and C. W. Du, PhD, in the Stony Brook University Medical Center participated in the clinical studies. T. Q. Xie, PhD, Z. G. Wang, Z. J. Yuan, Z. Wu, PhD, B. Chen, PhD, and H. Keywords

Acute tubular necrosis • Doppler optical coherence tomography • Glomerulus • Kidney transplantation • Optical coherence tomography (OCT) • Renal blood flow • Renal blood flow

End-stage renal disease (ESRD) is associated with both high mortality rates and an enormous economic burden [1]. The preferred treatment option for ESRD that can extend patients' lives and improve their quality of life is kidney transplantation. However, organ shortages continue to pose a major problem in kidney transplantation. Most kidneys for transplantation come from heart-beating cadavers. Although non-heart-beating cadavers represent a potentially large pool of donor kidneys, these kidneys are not often used due to the unknown extent of damage to the renal tubules (i.e., acute tubular necrosis or "ATN") induced by ischemia (i.e., lack of blood flow). Also, ischemic insult suffered by kidneys awaiting transplantation frequently causes ATN that leads to varying degrees of delayed graft function (DGF) after transplantation. Finally, ATN represents a significant risk for eventual graft and patient survival [2, 3] and can be difficult to discern from rejection. In present clinical practice, there is no reliable real-time test to determine

the viability of donor kidneys and whether or not donor kidneys might exhibit ATN. Therefore, there is a critical need for an objective and reliable real-time test to predict ATN to use these organs safely and utilize the donor pool optimally. In this review, we provided preliminary data indicating that OCT can be used to predict the post-transplant function of kidneys used in transplantation.

Previous studies by one of us (Andrews et al.) have shown that the noninvasive microscopic imaging of donor kidneys can be used to determine posttransplant renal function by analyzing the ATN suffered by superficial nephrons [4]. In the past, we have demonstrated that optical coherence tomography (OCT) can be used to image the status of superficial nephrons in a noninvasive fashion and in real time in normal living and insulted rodent kidneys [5, 6]. More recently, clinical trial studies have demonstrated the ability of OCT to image human donor kidneys both prior to and following their transplantation. This imaging was accomplished in a sterile, noninvasive fashion, providing real-time images of superficial renal tubules and glomeruli through the intact connective tissue renal capsule. In addition to evaluating the status of superficial nephrons, we demonstrated the ability of Doppler OCT (DOCT) to evaluate glomerular blood flow [7]. This chapter describes the rationale for imaging donor kidneys with OCT and the studies that have provided the background to support this rationale.

79.1 The Need for a Better Test to Predict Posttransplant Renal Outcome

More than half a million US residents have end-stage renal disease (ESRD), which is associated with high mortality rates (157.3 deaths per 1,000 patient years) and a huge economic burden (more than $30 billion per year) [1]. The treatment options for ESRD include dialysis and kidney transplantation. Transplantation is the preferred option because it promises to extend the patients' lives and also improve their quality of life. Currently, with over 77,500 patients annually waiting for kidney transplants, organ shortages pose a major problem in kidney transplantation. While the vast majority of kidneys used for transplantation are obtained from heart-beating cadavers, many kidneys available for transplant are not utilized because of their unknown status (i.e., from non-heart-beating cadavers, long storage times, etc.). Also, ischemic insult suffered by cadaver kidneys awaiting transplantation frequently causes acute tubular necrosis (ATN) leading to varying degrees of delayed graft function (DGF) after transplantation, which represents a significant risk for eventual graft and patient survival [3], and can be difficult to discern from rejection. The incidence of DGF is estimated to be 15–70 % [8]. Unfortunately, in present clinical practice, there is no reliable test to determine the viability of donor kidneys and whether or not donor kidneys might exhibit DGF. A timely biochemical analysis of kidneys has proven disappointing with no biochemical criteria proving accurate [9]. Therefore, there is a critical need for objective and reliable tests to predict posttransplant outcome to use organs safely and utilize the donor pool optimally.

79.2 Noninvasive Imaging to Predict Posttransplant Renal Outcome

Conventional light microscopy of excision kidney biopsies are not as useful to evaluate kidney pathology as noninvasive imaging procedures because of dramatic destructive artifacts to the kidney tubules associated with such biopsies [10]. In addition, unlike noninvasive imaging procedures, excision biopsies are destructive to kidneys, take time to analyze, and image only small segments of the kidney (i.e., cannot provide global imaging of numerous regions across the kidney surface). Previous studies by one of us (Andrews et al.) have shown that a noninvasive imaging technique termed tandem scanning confocal microscopy (TSCM) could be used to determine the degree of ATN by analyzing the superficial nephrons of living rabbit donor kidneys [4]. Using TSCM, Andrews et al. observed that the histopathological changes (e.g., ATN) of superficial proximal tubules of rabbit kidneys for transplant correlated closely with subsequent posttransplant renal function [11] (see Fig. 79.1). This is not surprising in that the status of superficial proximal convoluted tubules is indicative of the status of proximal convoluted tubules throughout the entire kidney cortex. Other investigators have also used near-infrared confocal microscopy [12] and multiphoton microscopy [13–15] to demonstrate the ability to perform noninvasive imaging of kidney structure and function in animal models. However, the maximum penetration depth associated with these microscopy procedures is limited (about 100 μm for TSCM), which makes it difficult to impossible to nondestructively image the human kidney using the foregoing noninvasive imaging microscopic techniques, especially if it is surrounded by an intact human renal capsule. Indeed, in a previous clinical trial, we found that the limited penetrating ability of TSCM precluded us from imaging human donor kidneys even when an attempt was made to remove the renal capsule [unpublished observations]. Also, conventional bulky systems TSCM are awkward in orientating the kidney specimens and especially difficult when attempting to image the kidney in situ.

79.3 Advantages of Optical Coherence Tomography (OCT) as a Noninvasive Imaging Procedure to Evaluate the Transplant Kidneys

OCT is a rapidly emerging imaging modality that can function as a type of "optical biopsy," providing cross-sectional images of tissue morphology in situ and in real time [16, 17]. OCT is similar to ultrasound imaging, except that it uses the echo delay of light instead of sound to generate images. OCT is safer than X-ray technologies, is much less expensive than MRI devices, and provides higher resolution images than ultrasound. By employing broadband optical light sources, OCT can achieve axial resolutions of 1–10 μm, more than an order of magnitude above that obtainable for high-frequency ultrasound. As a result, OCT can provide very high-resolution images of organs and tissues in a noninvasive manner. This potential

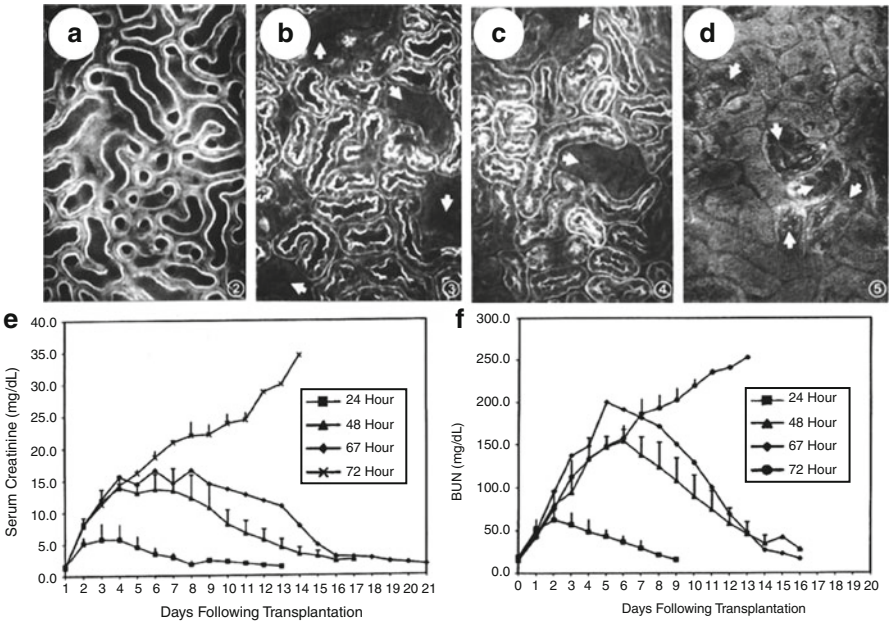

Fig. 79.1 TSCM images of subcapsular proximal convoluted tubules of a rabbit kidney: 1 h (hr) (**a**), 24 h (**b**), 48 h (**c**) and 72 h (**d**) following harvesting. With increasing storage time, TSCM images depict the degeneration of the superficial proximal tubules. Summary of the serum creatinine (*SCr*) (**e**) and blood urea nitrogen (*BUN*) values (**f**) measured at various days posttransplantation. As the storage time increased, the posttransplant SCr and BUN values increased. All the rabbits in the 24-, 48-, and 67-h groups exhibited various degrees of DGF but eventually survived. SCr and BUN returned to normal values. All rabbits in the 72-h group eventually died of uremia (Reproduced from Ref. [11] with permission © 2002 S. Karger AG, Basel)

has been demonstrated in a number of biomedical applications including ophthalmology [18–20], cardiology [21, 22], gastroenterology [23–26], dermatology [27], dentistry [28], urology [29], and gynecology [30], among others. In contrast to other forms of noninvasive light microscopy, OCT can image with longer working distances, with improved penetration depth, and without the need for tissue contact. Not only can it image up to depths of ~1–2 mm in most light-scattering tissues, OCT can also provide three-dimensional images in arbitrary planes. Finally, OCT can be performed using a thin flexible sterile endoscope or catheter [31, 32] or even with a needle [33], enabling ease of use and the possibility of imaging deep within a solid tissue or organ. To make OCT more applicable to the clinical situation, we developed a handheld OCT unit that has proven highly effective in our preliminary clinical trials. OCT has proven especially valuable in studying the living kidney because excisional biopsies are not only invasive, damaging, and can only sample a very small region of the kidney but also produce severe artifacts that are difficult to distinguish from ischemia and other injuries. In preliminary clinical investigations, we have provided evidence demonstrating OCT's capability for imaging intact living human kidney microstructures both ex vivo and in vivo (i.e., following

transplant into patient). Since the morphology of superficial proximal tubules correlates very well with posttransplantation renal function [11], the information obtained by OCT could be useful to evaluate the donor kidney status.

79.4 OCT Studies of the Kidney Using a Rat Model

Initially, we investigated the ability of OCT to provide clinically relevant information using a rat kidney model [5]. Figure 79.2a shows the cross-sectional OCT image of rat renal cortex ex vivo. OCT clearly visualizes the uriniferous tubule lumens that appear as low backscattering (dark regions), while the parenchyma appears as high backscattering (bright regions). Figure 79.2b shows the 3D OCT image that reveals the shape and contour of winding proximal convoluted tubules. Similar patterns are presented in the en face OCT image (planes parallel to the kidney surface) shown in Fig. 79.2c. Renal glomeruli can be visualized (Fig. 79.2d), with a narrow circular space corresponding to Bowman's space. This study demonstrated that OCT has high resolution and sufficient penetration depth to visualize the microstructures in the outer cortex of the rat kidney.

We subsequently studied the capability of using OCT to monitor kidney structural changes in response to ischemic insult in the living rat (i.e., in vivo) [6]. A laparotomy was performed on the anesthetized animal and the living kidneys exposed for in situ observation. We observed the kidneys prior to, during, and following exposure to renal ischemia induced by clamping the renal artery. Again, OCT enabled visualization of the morphology of both uriniferous tubules and renal glomeruli. When renal ischemia was induced, OCT revealed dramatic shrinkage of

tubular lumens due to the swelling of the proximal tubule cells (Fig. 79.3a–c). Total occlusion of the tubule lumens occurred within a minute following onset of ischemia. 3D segmentation provided an estimation of changes in the total tubular volumes in response to ischemia (Fig. 79.3d). Pretreatment with intravenous mannitol (1.0 ml of 25 % mannitol solution) protected the tubules from ischemic-induced swelling. These observations demonstrated that OCT represents an exciting new approach to visualize renal histopathological changes in vivo.

79.5 Noninvasive Imaging of Renal Microcirculation Using Doppler OCT

We have demonstrated that OCT can be used in a Doppler mode (DOCT) to image microvascular blood flow in the kidney [7]. This is an additional parameter to measure following kidney transplantation, in view of studies indicating that blood perfusion may be correlated with both intermediate and long-term graft function [34, 35]. Also, intrarenal hemodynamic abnormalities are thought to be a primary factor associated with the onset and progression of acute injury [36], as well as

diabetic nephropathy [37, 38], and focal segmental glomerulosclerosis (FSGS) [39]. Real-time assessment of renal morphological and hemodynamic changes could therefore help to evaluate the kidney condition and offer valuable information to predict the prognosis of injury or disease, lending to the development of patient-specific management strategies. Currently, there is no sensitive and objective tool for clinical monitoring of renal microcirculatory changes. In the past, renal blood flow (RBF) has been monitored using a number of different imaging modalities including positron emission tomography (PET) [40–45], magnetic resonance angiography (MRA) [46–49], Doppler ultrasound (US) [50–53], and contrast-enhanced ultrasound (CE) [54, 55]. While these techniques allow for noninvasive, wide field-of-view (FOV) imaging, they do not have sufficient resolution to detect changes in renal microcirculation. Optical imaging techniques that have higher resolutions and greater sensitivities could be a more feasible method for monitoring and evaluating microcirculatory changes, especially in an intraoperative setting. Studies using confocal [11, 12, 56] and multiphoton microscopy [13–15] have demonstrated the ability to image kidney microstructure and function (blood flow and filtration rate) in animal glomerular capillaries. However, again the penetration depth has been limited to several hundred microns, and they require the need to administer contrast agents to determine flow. Therefore, using these imaging modalities for human studies pose certain challenges due to the capsule surrounding the human kidney, which can be several hundred microns thick, and the need to inject contrast agents into the patient. OCT and its functional extension DOCT are emerging imaging technologies that have the capacity to provide real-time imaging of tissue in a noninvasive fashion with high resolution near that of conventional histopathology. DOCT can be used to visualize blood flow noninvasively by measuring the Doppler frequency shifts in the OCT interference signal caused by moving scatterers that are label-free, such as red blood cells [57]. DOCT has been used to image and quantify blood flow in vivo for multiple clinical applications including retina [58–61], skin [62–64], and gastrointestinal tract [65], among others.

In a recent study, we investigated the feasibility of DOCT to image kidney microcirculation, specifically, glomerular blood flow. DOCT is able to capture 3D data sets consisting of a series of cross-sectional images in real time, which enables label-free and noninvasive quantification of glomerular blood flow. The kidneys of adult, male Munich-Wistar rats were exposed through laparotomy procedure after being anesthetized. Following exposure of the rat kidney beneath the OCT/DOCT microscope, glomerular blood flow was observed as shown in Fig. 79.4. Figure 79.4a, d, g show en face OCT intensity images revealing the kidney microstructure. Uriniferous tubules are readily identified surrounding the glomerulus, which is the circular structure in the middle of the image surrounded by the crescent-shaped capsular space of Bowman. Figure 79.4b, e, h show corresponding DOCT image from the same plane depicting red blood cell (RBC) velocity in numerous glomerular capillaries. As indicated by the color map, red to yellow represents increasing velocity of blood flow in one direction, while blue to cyan represents increasing velocity of blood flow in the opposite direction. Therefore, the mixture of these colors seen in the DOCT images demonstrates the varying

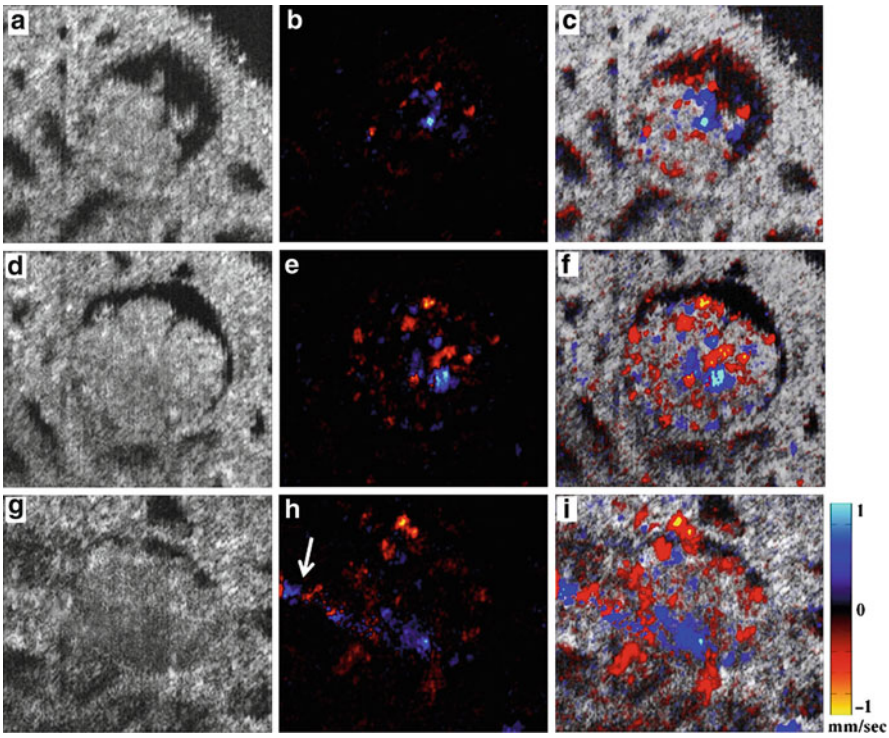

Fig. 79.4 OCT/DOCT imaging of a rat glomerulus. (**a**, **d**, **g**) Represent OCT en face views of single glomerulus. (**b**, **e**, **h**) Represent DOCT en face view of the same imaging plane. (**c**, **f**, **i**) Represent fused OCT/DOCT image showing spatial agreement between the OCT image and the corresponding DOCT image. The three images in each row correspond to the same imaging plane. Depth (**a**–**c**) = 440 μm; (**b**–**f**) = 470 μm; (**g**–**i**) = 545 μm. OCT/DOCT provides virtual sectioning of the glomerulus. The *arrow* in **h** represents the vascular pole (i.e., afferent/efferent arterioles). Image size: 325 × 278 μm (Reproduced from Ref. [7] with permission © 2011 USCAP, Inc)

velocities as well as the convoluted nature of blood flow through the glomerular capillaries. Figure 79.4c, f, i are the fused OCT/DOCT images demonstrating the spatial location of the DOCT signal within the glomerulus.

The effects of acute mannitol and angiotensin II infusion were also observed. DOCT imaging enables real-time monitoring of blood flow changes in three separate physiological states: baseline, following injection of 0.1–0.2 ml mannitol (250 mg/ml), which increases renal blood flow [66–68], and 200 ng/kg body weight angiotensin II [69], which decreases renal blood flow [70–73]. Glomerular blood flow was quantified for the induced physiological states and compared with baseline measurements. Figure 79.5 shows representative glomeruli imaged under each condition. Baseline DOCT is depicted in Fig. 79.5b with mannitol and angiotensin II in Fig. 79.5d, f respectively. After infusion of mannitol, a significant increase in blood flow was observed, and following infusion of angiotensin II,

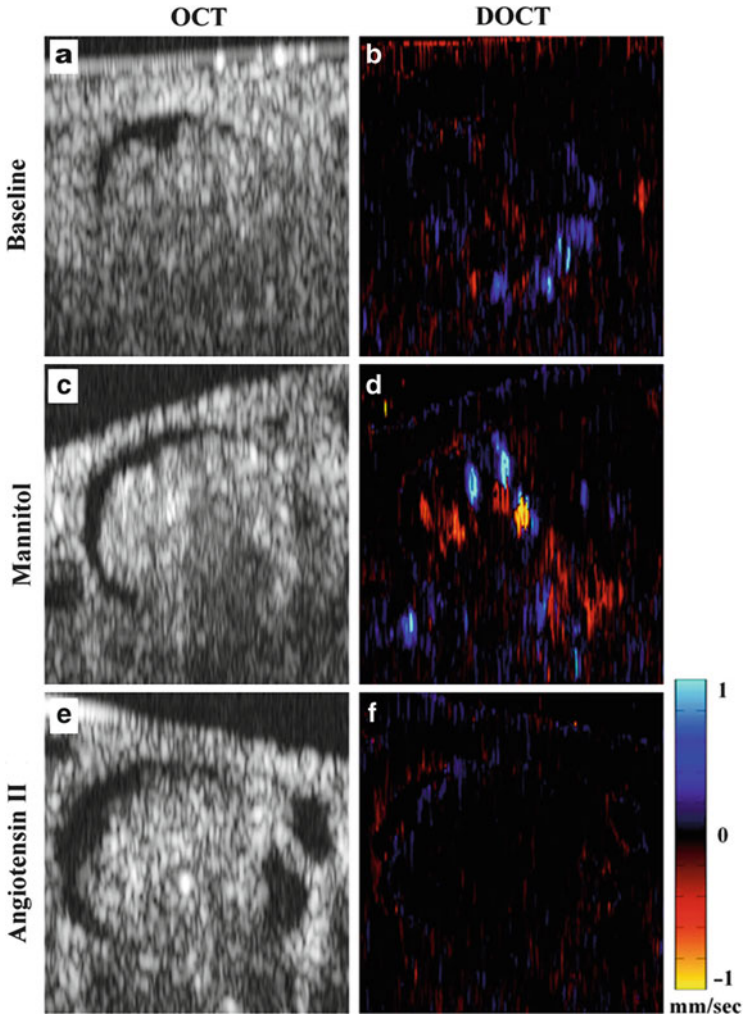

Fig. 79.5 Representative OCT and DOCT images (XZ) from three different physiological states. (**a**–**b**) Baseline, (**c**–**d**) after mannitol, and (**e**–**f**) after angiotensin II. Comparison among the images shows differences in the observed DOCT signal in different glomeruli under altered blood flow conditions. Image size: 294 × 278 μm (Reproduced from Ref. [7] with permission © 2011 USCAP, Inc)

a significant decrease in blood flow was observed. Corresponding OCT images are presented in Fig. 79.5a, c, e for identification of glomerular region in the DOCT images.

3D DOCT data were subsequently analyzed by computing two parameters: cumulative Doppler volume (CDV) and Doppler flow range (DFR). CDV was calculated by summing together the volume of segmented voxels within the glomerular volume containing DOCT signals that were above the background

threshold: CDV $= \sum_{xyz} V(x, y, z)$, where V(x, y, z) is individual voxel volume and the threshold velocity is set to ±0.05 mm/s. Doppler flow was calculated by integrating the DOCT velocity signal over the lateral cross-sectional (en face) area of the segmented DOCT signal at each depth position. Integration over the en face plane eliminates the angle-dependent uncertainty of the Doppler velocity, therefore providing an accurate quantitation of flow as defined by [74] Flow $= \iint_{xy} v_z(x, y, z)dxdy$, where $v_z(x, y, z)$ is the DOCT velocity over the xy segmented DOCT area. DFR was then defined as the flow rate at 99 % area under the curve (AUC) of the 3D flow histogram. Figure 79.6 shows the blood flow histograms of three glomeruli to illustrate differences in blood flow rate and blood volume between the induced physiological states. The aforementioned dynamic changes in blood flow detected under altered physiological conditions demonstrate the real-time imaging capability of DOCT to quantitatively image the kidney microvasculature for transplant graft evaluation.

Figure 79.7a, b shows the DFR and CDV values from seven different physiological states in the same rat. For each state, an average number of $n \approx 4$ glomeruli were analyzed. Both DFR and CDV increase dramatically after injection of mannitol. It is interesting to note that after both the first and second mannitol injection, the DFR and CDV values returned to near-baseline levels during the "recovery" period indicating that the effects of the mannitol were wearing off (∼15–20 min elapsed since injection). Shortly after administering the third mannitol injection to increase blood flow (∼10 min), angiotensin II was injected. This injection of angiotensin II reduced both DFR and CDV dramatically, well below the baseline level. This result demonstrates that DOCT can quantitatively image renal blood flow in vivo, thereby providing valuable diagnostic information for vascular function in addition to structural information from OCT.

These preliminary results using animal models demonstrate that OCT/DOCT can provide valuable information that would be valuable for determining the status of renal transplants.

79.6 OCT Imaging of Human Kidney Microstructure

Figure 79.8 shows the schematic of the high-speed, high-resolution, Fourier-domain OCT system that was used to obtain the first 3D OCT imaging of human kidneys [75]. A wavelength-swept laser light source generating 100-nm bandwidth at 1,310-nm central wavelength was employed, yielding approximately 10-μm axial image resolution in the tissue. The laser used to acquire the preliminary data operates at a sweep rate of 16 kHz, and the real-time imaging was performed at 30 frames per second (video rate). A Michelson interferometer composed of a circulator and a fiber-optic 50/50 splitter was used to generate the OCT interference signal. The reference arm consists of a stationary mirror (M) and a polarization

controller (PC). The light from the sample arm was steered by a pair of galvanometer mirrors (X and Y), then focused by an objective lens onto the sample. The power on the sample was 4 mW with a spot size of 15 µm. The system's sensitivity was 95 dB.

3D OCT volumes ($2.5 \times 2.5 \times 2.5$ mm^3, with $512 \times 512 \times 512$ pixels) were obtained noninvasively from various locations on human kidneys obtained through the Washington Regional Transplant Consortium (WRTC) and preserved (i.e., fixed) with 2 % glutaraldehyde. Figure 79.9 shows a representative cross-sectional OCT image of the human kidney and the corresponding conventional light microscopic histology. Because under normal circumstances the kidney will be surrounded by the renal capsule (i.e., thick layer of dense connective tissue), it is

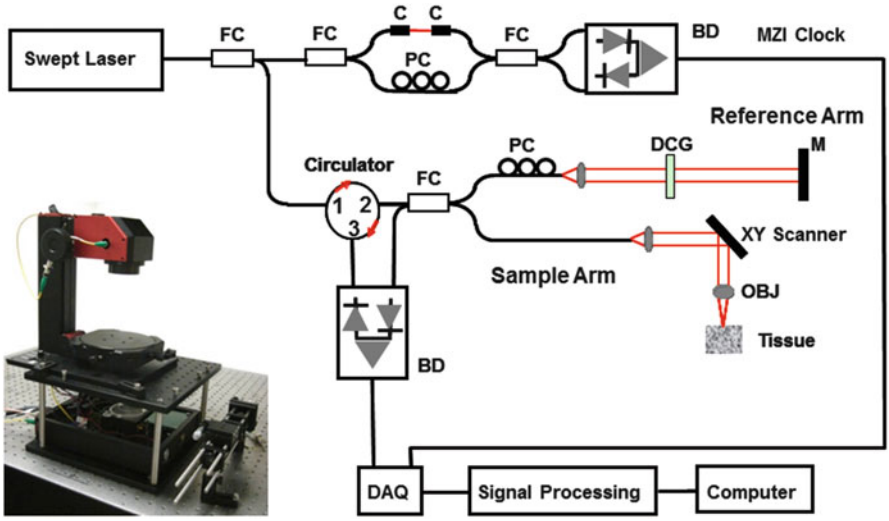

Fig. 79.8 Schematics of the Fourier-domain OCT system used in kidney imaging studies. *Inset* shows the photo of OCT microscope (Reproduced from Ref. [75] with permission © 2009 Optical Society of America)

important to evaluate OCT's capability to image the tissue structures through the renal capsule. Unlike in the previously described TSCM studies (see above), the presence of the renal capsule did not prevent imaging of subcapsular kidney tubules and glomeruli. A corresponding histological image (Fig. 79.9b) shows correlation of the anatomic features observed by OCT with traditional light microscopic histological sections. Renal glomeruli could also be visualized in the upper cortex as light-dense, round-oval capillary tufts and the Bowman's space as a light-lucent area surrounding the tufts (Fig. 79.9c) [76]. These results demonstrated OCT's capability to reveal the histological features in the intact human kidney and underscored its promise for clinical kidney imaging in vivo.

79.7 Clinical Trials of Renal Transplants

In collaboration with Drs. Joseph Melancon and Mathew Cooper, Directors of Kidney and Pancreatic Transplantation at Georgetown University Medical Center (GUMC), we performed clinical imaging of human donor kidneys using OCT prior to transplant (i.e., ex vivo) and OCT/DOCT following transplant (i.e., in vivo) [77]. The study was approved by the IRB and all patients signed consent forms. The IRB approved the OCT as a "nonsignificant" risk to the patients. Figure 79.10 shows the portable OCT unit used in the clinical trial, which consists of a portable cart (holding the computer, laser, optical, and electronic components), a handheld probe containing the objective lens, and a real-time user interface for image display and quantification. A cage

[76] with permission 2010 American Urological Association Education and Research, Inc)

consisting of metallic bars attached to a metallic ring endpiece surrounds the imaging objective lens that makes up the handheld probe. The length of the bars of the cage is adjusted to a proper working distance (i.e., approximately 3 cm.), so that any object place near the ring at the end of the cage is within the correct working distance for imaging (i.e., the cage serves as a spacer for correct working distance). Two issues that were initially encountered in these studies were (1) sterility and (2) keeping the laser beam from being impeded by a buildup of moisture on the glass objective lens. Since the handheld OCT probe is connected to the imaging system by a 6-ft length of cords, the cords were covered with a sterile sleeve, similar to that used for ultrasound imaging with the sterilized handheld probe exposed at the end of the sleeve. This setup worked well for imaging the kidney ex vivo while the donor kidney is being stored in sterile bowl filled with sterile ice (i.e., an ice bath) prior to its transplantation. However, when the sterilized handheld unit is used to image the donor kidneys following their transplant into the patients, temperature differences between the transplanted kidneys warmed by reperfusion of blood and the colder objective lens within the handheld

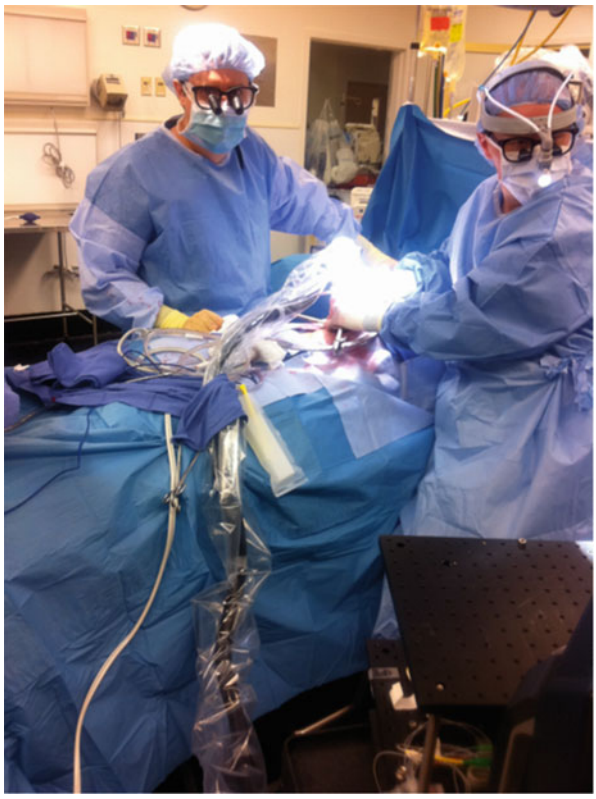

Fig. 79.10 A transplant surgeon holding the sterilized handheld imaging probe over an implanted human donor kidney

probe resulted in a rapid buildup of condensation on the objective lens surface, resulting in a diminished signal. This condensation issue was effectively addressed by covering the entire handheld probe (containing the objective lens) as well as the 6 ft of cords with the sterile camera sleeve. A 1-cm circular hole cut in the end of the sleeve permitted unimpeded passage of the laser signal. The circular hole cut in the sterile sleeve was then covered with sterile, adhesive, transparent "Tegaderm" film (3M Health Care, St. Paul MN). The ultrathin Tegaderm film did not significantly impede the OCT beam and provided a barrier to moisture as well as a sterile interface between the OCT imaging probe and the kidney being imaged. Using this setup, we imaged the harvested donor kidney with the handheld OCT imaging probe (covered by a sterile sleeve and Tegaderm) both while the kidney was being stored in the sterile ice bath prior to its transplantation and in situ, following its reimplantation into the recipient. Imaging the entire surface of the harvested donor kidney ex vivo (i.e., both sides and all poles) took less than several minutes and provided a holistic evaluation of the pretransplant organ. After transplantation and following revascularization of this same donor kidney within the transplant recipient, OCT/DOCT imaging was performed again to detect Doppler flow as well as morphological features of the transplanted kidney. Once transplanted into the patient, only the upper exposed

surface of the kidney was available for imaging. Again, imaging took less than several minutes. This kind of global, noninvasive, real-time histopathological perspective is, of course, not possible when using the invasive, potentially damaging, and artifact-prone procedure of excising renal biopsies. At the Georgetown University Medical Center, kidneys from living donors are protected from ischemia by pretreating the patients with intravenous mannitol (up to 50 g intravenously), flushing the excised kidneys with Viaspan (i.e., also known as the University of Wisconsin solution, or UW solution), and then storage on ice for variable periods of time prior to their transplant. However, Georgetown University Medical Center, as part of the Washington Regional Transplant Consortium/Community, also accepts cadaver kidneys preserved using other procedures including cold storage in Euro-Collins solution and hypothermic pulsatile perfusion preservation.

In our initial studies, we evaluated ten kidneys from living donors and one that was harvested from a heart-beating cadaver. We correlated our data with posttransplant renal function, by analyzing posttransplant serum creatinine levels. Serum creatinine levels are the most universal biological marker for estimating the glomerular filtration with a good prognostic value. In all cases but one, the transplants resulted in a rapid return to normal renal function as reflected by serum creatinine levels (i.e., serum creatinine levels below 1.5 mg/dL). In the one case, however, the serum creatinine remained elevated has not yet (i.e., 6 months later) returned to normal. This kidney had suffered additional normothermic ischemia due to revascularization problems encountered during the implantation procedure. This also was the only donor kidney that revealed no open renal tubules when examined using OCT following its implantation into the recipient. The elevated serum creatinine levels resulted in a biopsy to determine if the elevated serum creatinine levels represented rejection. Histopathological analysis verified that the elevated serum creatinine levels were a result of ischemia rather than rejection. This observation supports our premise that the openness of the uriniferous tubules is a direct reflection of posttransplant renal function. Figure 79.11 shows representative images of in vivo imaging of subsurface kidney structure and function obtained after transplantation. Renal capsule, parenchyma, and uriniferous tubules are clearly visualized. Three to five layers of tubule lumens are visible and open, denoting active renal filtration and a functioning kidney. Also, blood flow within small and large vessels was captured indicating cortical perfusion within the transplant kidney. These results demonstrate the feasibility of OCT/DOCT imaging of the transplant kidney in the OR room during transplantation procedures. Specifically, the OCT/DOCT following grafting shows both the morphological and functional response of the transplant kidney.

Previous studies of donor kidneys from cadavers indicated that the proximal tubules in these kidneys are initially open and then undergo a progressive closing over time during their cold storage (unpublished observations). The openness of these tubules reflects the fact that these cadaver kidneys are flushed with preservative with little or no intervening ischemic time. Intravenous infusion of mannitol will similarly maintain the proximal convoluted tubules of living donor kidneys open and protect them from swelling by acting as an impermeant osmotic agent.

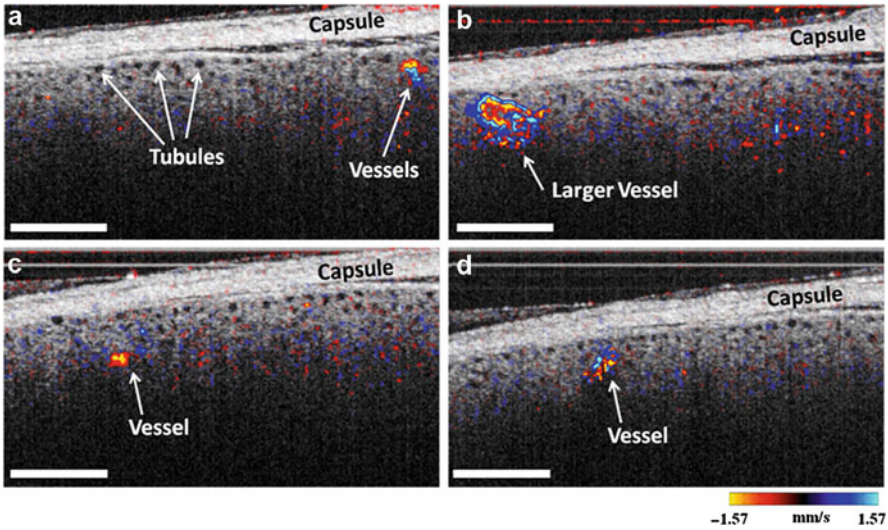

Fig. 79.11 In vivo human kidney showing open tubules and cortical blood flow. Open tubules appear round and relatively uniform across all images. Also, a larger blood vessel is seen in (**b**) against some smaller vessels observed in (**a**, **c**, and **d**). Scale bar = 500 μm, DOCT color map unit = mm/s (Reproduced from Ref. [77] with permission)

In our studies of living human kidney transplants, we found that when the mannitol was infused 30 min prior to harvesting, the proximal convoluted tubules were swollen and the tubule lumens occluded. However, in two donor kidneys that were harvested within 15–10 min following intravenous infusion of mannitol, the proximal tubules remained more open and protected. These two kidneys also demonstrated the fastest return to normal renal function following transplantation as indicated by normal serum creatinine levels within several days instead of a week or more which was seen for the other living donor kidneys. These observations supported our earlier DOCT studies of rat kidneys wherein the effects of the mannitol injection were wearing off ∼15–20 min following injection. While mannitol is believed to have a half-life of 1–2 h, the foregoing observations indicate a need to harvest living donor kidneys within minutes following mannitol infusion. More recently, we expanded these studies to include 14 living donors that received mannitol 15 minutes or less prior to clamping the renal artery (Group A), and 13 living donors that received intravenous mannitol 30 minutes or more before clamping the renal artery (Group B) Again, OCT revealed that this change in timing of manniitol administration (i.e., reducing the timing to 15 minutes or less prior to clamping) protected the human donor proximal tubules from normothermic induced cell swelling. An evaluation of post-transplant recovery of renal function showed that this protection resulted in significantly faster return to normal renal function [78]. This important protocol change is an example of how OCT has provided valuable new clinical insights that improves patient outcomes.

79.8 Image-Processing Algorithms to Quantitatively Assess the Morphometric Parameters of Renal Transplants

Our animal and human studies undertaken thus far have indicated that there are a number of likely morphological parameters that are candidates for algorithm-based image processing to determine posttransplant renal function. One is the mean tubule lumen diameter. Our studies have shown that more open tubules reflect better posttransplant function. Second is the variability in average tubule luminal diameter. The latter may reflect the fact that S1 segments of the proximal convoluted tubules appear to be more sensitive to ischemia than S2 segments as was seen by us in a previous study of ischemic rodent kidneys [79]. However, S2 proximal tubule segments make up the majority of cortical proximal convoluted tubules and the relative role of ATN associated with S1 versus S2 in human kidneys is not yet known. Third is the irregularity in the profiles of the tubule lumens. Irregular profiles in the tubule lumens can result from cellular debris within the lumens (mainly from a disrupted microvillous brush border) lining the tubule lumens as well as from cell swelling. Fourth is the number of open tubules per unit area of cortex (tubular density), and fifth the total tubule luminal space per unit area of cortex. The latter parameter may be the most important because it reflects the overall available filtering surface area in the donor kidney. Together, these foregoing parameters reflect the tubule cell damage resulting from acute tubular necrosis (ATN), which is the main insult resulting in posttransplant renal failure in transplanted donor kidneys. As previously noted, we found that this kind of parameters can predict the extent of ATN in a renal transplant animal model [11]. It should be noted, however, that the data collected in this earlier study were derived from the most superficial proximal convoluted tubules (i.e., one layer deep in the kidney cortex) using TSCM. Using OCT, we are able to see four to five layers or more deep in the human kidney even with an intact renal capsule. Therefore, we are able to image significantly more proximal convoluted tubules than those can be imaged using the aforementioned TSCM imaging. Nevertheless, as previously mentioned, it is important to note that the status of superficial proximal tubule reflects the status of proximal tubules throughout the renal cortex (i.e., including those deeper in the cortex).

The degree of ATN suffered by individual kidneys depends also on a variety of factors including preservation methods and donor background (i.e., age, health, race, weight, etc.). We have previously reported that even the amount of protein in the diet can significantly affect postischemic ATN [80]. Therefore, it is very difficult to predict the degree of ATN suffered by a kidney prior to its transplant without some objective measure. By using OCT, the transplant surgeon can make the most efficient use of available donor kidneys (including the use of kidney from non-heart-beating cadavers), eliminate the possible use of bad donor kidneys, provide a measure of expected posttransplant renal function, and allow better distinction between posttransplant immunological rejection and ischemic-induced acute renal failure. The latter was confirmed in our recent clinical trial data, wherein OCT imaging indicated that there was renal insult to the transplanted kidney (i.e., the tubular lumens were closed following transplant), with this being subsequently verified by

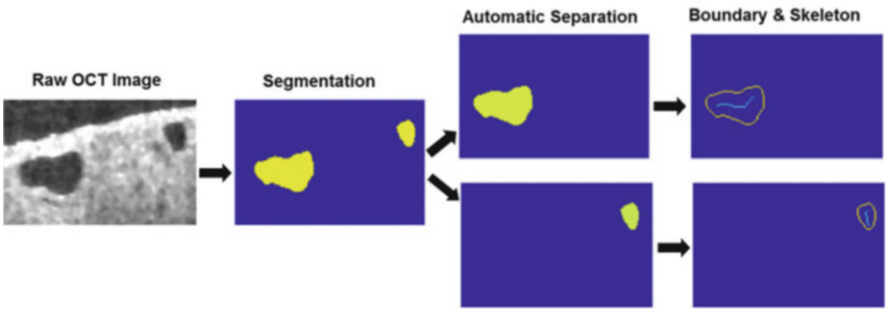

Fig. 79.12 Flowchart of the automatic image-processing algorithm developed by Dr. Chen's Lab, which includes four major steps: (*1*) image segmentation from the raw OCT image; (*2*) automatic region separation and selection; (*3*) finding the boundary and skeleton for each isolated regions to calculate the mean tubular diameter, and (*4*) sum all segmented regions to estimate the tubular volume. Computer-estimated results have been validated with manual measurements (Reproduced from Ref. [75] with permission © 2009 Optical Society of America)

traditional histopathological data showing that post-transplant elevated serum creatinine levels were a result of ischemia rather than rejection.

To provide diagnostic information obtained by 3D OCT, there is a need to develop automatic image-processing methods to quantitatively evaluate kidney morphology. Computer-aided analysis promises to automatically analyze a large volume of data quickly and therefore will be very helpful for providing the clinicians with quantitative diagnostic information in a timely manner and minimizing the inter- and intra-observer errors. With this in mind, we have developed an automatic image-processing algorithm to quantitatively evaluate the imaging parameters of kidney microstructures, such as tubular diameters and density. The algorithm for tubular diameter quantification includes three major steps (see Fig. 79.12): (1) Automatically segment the kidney structures (such as tubules) from the kidney parenchyma using their distinct backscattering intensities; (2) Automatically separate each isolated (not connected) tubular segment by an intelligent image-processing algorithm, which automatically fills each region to its boundary and assigns an index value to every segmented region of interest (ROI). This approach allows different regions be individually selected for further analysis; (3) Quantify the average diameter of each region as follows: the boundary (B) and skeleton (S) of each segmented region are automatically generated using morphological thinning, and the local radius for every pixel (b) on the boundary (B) is calculated by using the shortest distance between the pixel (b) to the skeleton (S), i.e., $Radius(b) = \min\left(\underset{\forall s \in S}{dist.}(b, s)\right)$. The averaged dimension of each region is then calculated by averaging all boundary pixels. In addition, tubular density can be quantified by dividing the sum of the segmented tubular regions by the total renal region (tubules plus parenchyma). Furthermore, DOCT parameters (DFR and CDV) can be quantified using the algorithm described previously.

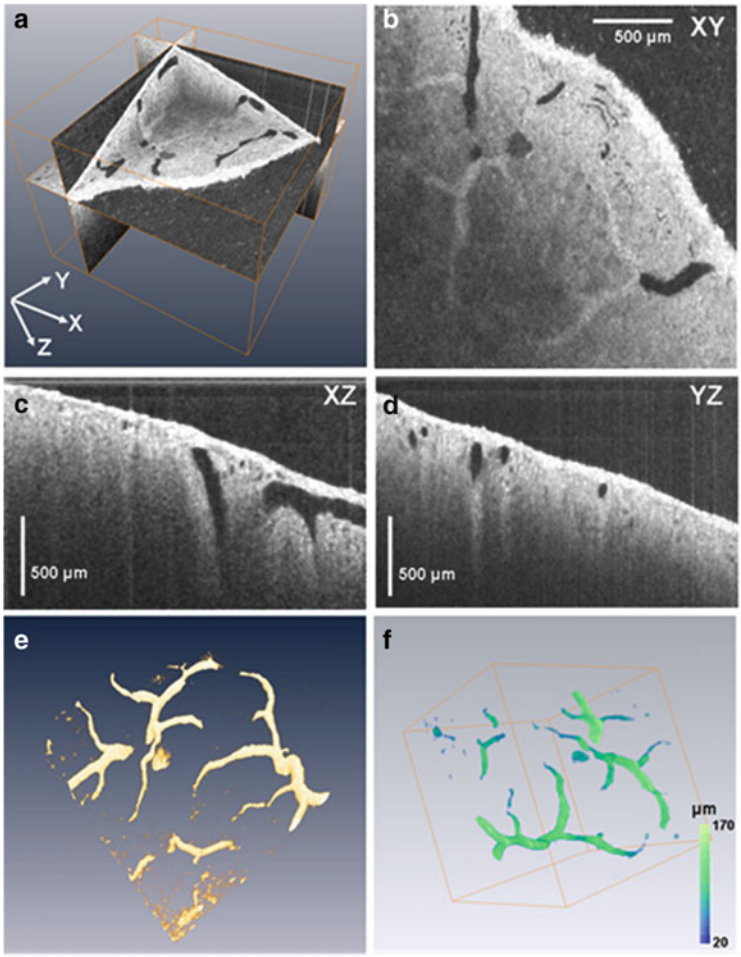

Fig. 79.13 (**a**) 3D cut-through view of the human kidney (case 1). The renal blood vessels as well as the kidney parenchyma are visualized. (**b–d**) Representative OCT images. (**e**) 3D volumetric image of the segmented renal vasculature. (**f**) Automatic quantification of the vessel diameter and color coded on the structural image (Reproduced from Ref. [75] with permission © 2009 Optical Society of America)

Figure 79.13a is the 3D view of one representative ROI (region of interest) in a human kidney ex vivo (case 1). Figure 79.13b–d shows the representative images along the three orthogonal planes (XY, YZ, XZ). Detailed kidney vascular structures can be visualized in all these image planes. Figure 79.13e shows the segmented 3D vascular tree. Figure 79.13f shows the automatic quantification of vascular diameters for different regions, which ranges from 30 to 150 µm. Figure 79.14a is the 3D view of another ROI from a different human kidney ex vivo (case 2). Figure 79.14b–d shows the representative images. Detailed kidney

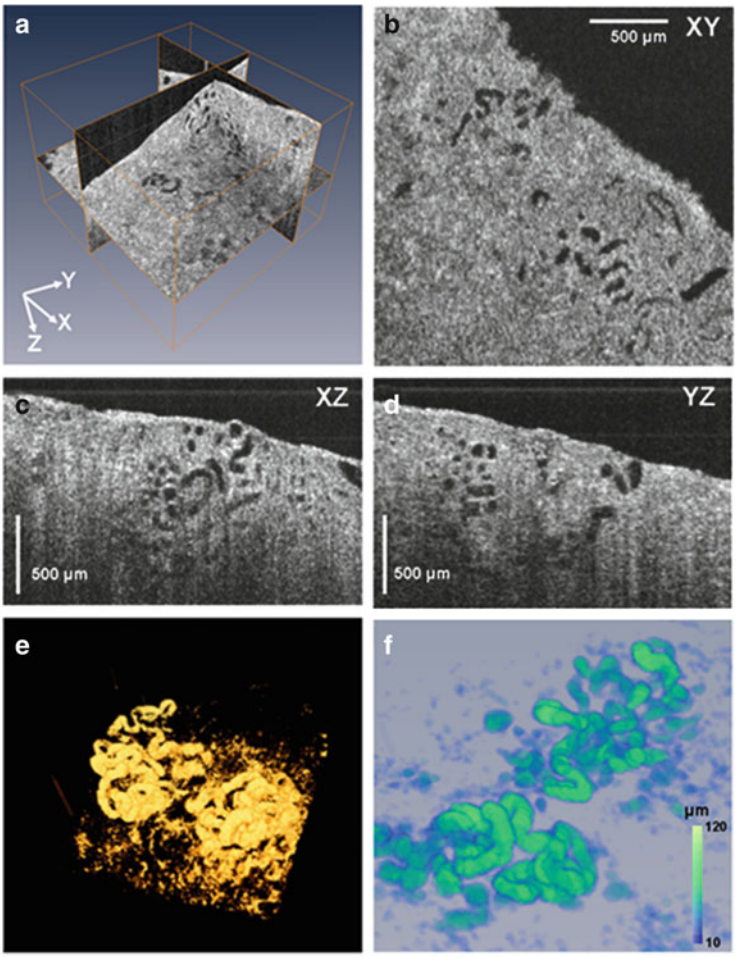

Fig. 79.14 (**a**) 3D cut-through view of the human kidney (case 2). The distended convoluted tubules as well as the kidney parenchyma are visualized. (**b–d**) Representative OCT images. (**e**) 3D image of the segmented distended convoluted tubules. (**f**) Automatic quantification of the tubular diameter (Reproduced from Ref. [75] with permission © 2009 Optical Society of America)

tubular structures can be visualized in all these image planes. OCT shows distended convoluted tubular structure, which is clearly visualized in the segmented 3D view, as shown in Fig. 79.14e, where comprehensive examination of morphological features, such as the tubular curvature and interconnectivity, is possible. Figure 79.14f shows the automatic quantification of tubular diameters for different regions. The distended tubular lumen shows approximately 70–90 µm in diameter. Figure 79.15a is the 3D view of the third example of human kidney ex vivo (case 3). Figure 79.15b–d shows the representative images. Detailed kidney microstructures

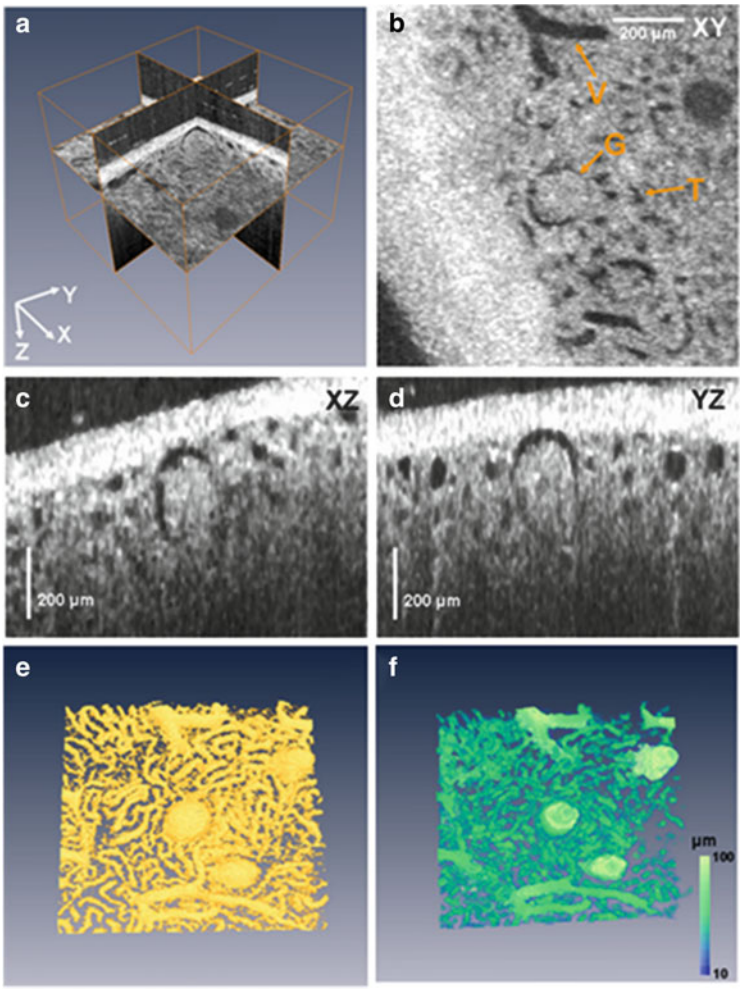

Fig. 79.15 (**a**) 3D cut-through view of the human kidney (case 3). Various renal microstructures including the blood vessels (*V*), uriniferous tubules (*T*), and glomeruli (*G*) are visualized. **b–d** Representative OCT images. **e** 3D view of the segmented renal microstructures. **f** Automatic quantification of the lumen diameter (Reproduced from Ref. [75] with permission © 2009 Optical Society of America)

can be visualized in all these image planes. Figure 79.15e shows the segmented 3D structures. Figure 79.15f shows the automatic quantification of lumen diameters for different regions. The glomeruli are surrounded by an expanded network of uriniferous tubules and blood vessels. The diameters of the glomeruli are measured to be approximately 200 µm. These results show the capability of OCT to visualize and quantify renal microstructures. The quantification accuracy of this procedure has been validated by conventional histological analysis.

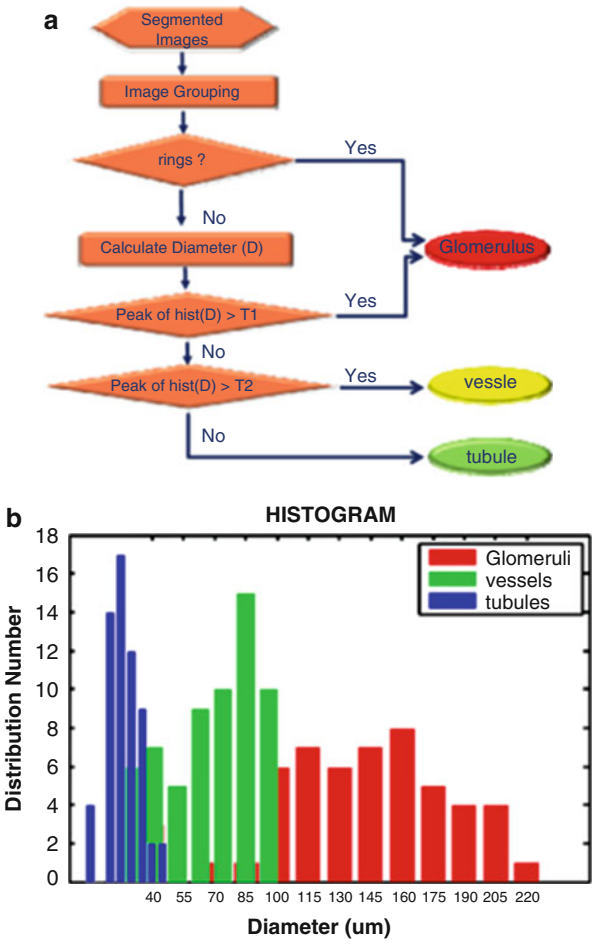

Fig. 79.16 (**a**) Flowchart of the human kidney image classification algorithm. Hist (D) means the histogram of diameter; T1 and T2 are empirical thresholds. (**b**) Histogram depicting the size distribution of kidney structures (glomeruli, blood vessels, and tubules

Additional 3D automated algorithms need to be developed in order to further develop or (1) classify different renal structures such as tubules, glomeruli, and vessels and (2) determine tubular diameters and densities in 3D. Our preliminary image classification algorithm operates on the isolated ROIs of each 3D set of kidney images obtained from OCT segmentation. A flowchart describing the classification algorithm is shown in Fig. 79.16a. Classification of kidney structures is based on each set of spatially interconnected image voxels (groups). We developed a 3D labeling algorithm to automatically identify regions that are spatially connected in 3D [81]. After labeling, label indices can be used to select and extract stereo-isolated groups from the kidney. Each region is a group representing interconnected renal structures.

Figure 79.17a shows the results of the image classification scheme for one representative data set. The three groups of human kidney microstructures are distinguished by different colors. All three classifications are clearly visible

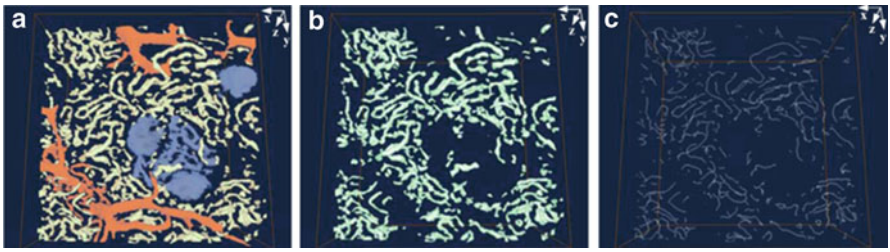

Fig. 79.17 Human kidney image classification and automated tubule analysis. Classification of kidney features is color coded: *green*, glomeruli; *red*, blood vessels; *beige*, tubules. All three classes of microstructures are present within this data set. (**b**) Segmented OCT showing tubular structures only. (**c**) 3D skeletonization of segmented tubules

in Fig. 79.17a, but it is evident that some structures are mislabeled (such as the adjacent uriniferous tubules near the glomeruli). Since the proximal convoluted tubule is physically attached to the glomerulus, this error in group classification is not unexpected. It might be possible to correct this error by using image opening and structure thinning strategies (erosion and dilation) to further separate segmented features in the data set. But, even with the minor misclassification of the juxtaposed tubules, the tubule diameters and density values will not be affected because the glomerulus and the mislabeled tubule will be removed as shown in Fig. 79.17b and will not contribute to the calculations (density = tubular voxels/(tubular voxels + parenchymal voxels), where parenchymal voxels are not including glomeruli and vessel groups. Nonetheless, optimizing the OCT segmentation process will improve image grouping and, thus, the overall classification algorithm. Other more advanced techniques for OCT segmentation, such as marker-controlled watershed segmentation [82], are being studied. Also, it would be useful to employ more advanced image-processing methods to improve classification of groups. Increasing the number of parameters to include the boundary curvature for each group (tubules have high surface curvature radially compared to glomeruli) and the degree of skeleton branching (glomeruli skeleton is more highly branched whereas tubule skeleton branching is minimal) that can be used for criterion will allow better group analysis. Ultimately, the best classification criteria will be based empirically upon which parameters provide the best results and improve the accuracy of the algorithm.

After classification, tubular regions will be selected for further analysis (Fig. 79.17b). Then, 3D skeletonization will be performed on the segmented tubular volume to obtain an interconnected skeleton of the entire tubular network (Fig. 79.17c). The minimum distance between every skeleton element to the 3D boundary of the tubule surface can be computed automatically for the complete volume to yield a distribution of tubule diameters for the entire 3D tubular network. This approach promises to be more accurate than the 2D boundary computation method from the initial algorithm described above. 3D computation does not restrict the boundary of the group to lie only within the current XZ frame where the primary segmented ROI appears but enables the determination of the diameter

along the central axis of the tubule. Furthermore, as automatic image processing for 3D data sets could be time-consuming, graphic processing units (GPUs) can be used to perform parallel computing to accelerate the computational process [83–85].

79.9 Discussions and Conclusions

OCT is a powerful medical imaging technology that can reveal microstructure and blood flow in biological tissue in a noninvasive fashion and in real time. Our preliminary results demonstrate the feasibility of using OCT to assess donor kidney status prior to and immediately following reperfusion by examining tubular morphology and renal blood flow. With ~12-μm axial and ~15-μm transverse resolution and 16-kHz axial scan rate, our OCT system revealed renal tubules and cortical blood vessels in real time during transplantation procedures. 3D imaging is critical to kidney imaging as it not only provides comprehensive volumetric information but also enables integration of DOCT signals over en face plane to quantify flow information correctly [74]. Due to significant motion from the handheld scanner, 3D OCT imaging was not able to be performed in clinical settings with our current image acquisition speed. Higher speed imaging systems (i.e., 55-kHz SS-OCT), however, are now commercially available from Thorlabs, which employ a novel tunable filter technology with a highly efficient laser cavity designed to achieve a broad wavelength tuning range (>120 nm) at high sweep rates. Excellent coherence length (6 mm) is maintained during the high-speed tuning of the swept-source laser, which supports greater OCT imaging depths and higher imaging rates in samples compared to our currently 16-kHz SS-OCT imaging system. 3D OCT volumes with 256 × 256 × 512 pixels can be acquired in ~1 s, thereby reducing the motion artifacts significantly. In addition, Thorlabs recently developed a VCSEL-based swept-source laser running at 760-kHz axial scan rate at 1.3 μm with 100-nm tuning range [86]. Alternatively, Fourier-domain mode-locked (FDML) lasers [87] enable ultrahigh-speed OCT imaging up to MHz A-scan rates [88, 89] and therefore would be an ideal candidate for wide-field kidney imaging. These novel light sources will bring new clinical tools capable of in vivo, volumetric imaging of tissue pathology with an unprecedented axial scan rate.

Motion artifacts might be present during imaging acquisition especially during in vivo imaging. One can stabilize the kidney against the abdominal wall using standard instruments to reduce motion artifacts while imaging. The OCT handheld probe (using the "cage" as a spacer) can also be gently placed on the kidney surface to further minimize motion. Also, the OCT probe can be attached to an articulating arm to reduce the tremor of the surgeons' hand. In addition, cross-correlation algorithms can be applied to correct the motion artifacts [90].

This study demonstrates the feasibility of OCT/DOCT imaging of the human kidney during kidney transplantation. OCT/DOCT imaging results were compared with standard biomarker (serum creatinine) measurements that reflect post-graft

renal function. However, this study is only an initial pilot study. However, the preliminary results of this study suggest that OCT/DOCT is a useful tool in intraoperative monitoring and evaluation of the transplant kidney for predicting post-graft function after ischemia-reperfusion injury. Furthermore, by comparing quantitative imaging parameters with post-graft function, the diagnostic potential of OCT will be investigated. However, this requires additional patient numbers to definitively identify any correlation with graft outcome. In addition, improved diagnostic parameters with 3D imaging will better assist in determining the capacity of OCT to predict post-graft renal function.

Acknowledgments We would like to thank Dr. James Jiang and Alex Cable from Thorlabs Inc. for technical support and Chao-Wei Chen, Dr. Wei Gong, and Dr. Hsing-Wen Wang from University of Maryland for assistance. 80.1 Introduction

80.1.1 Intraoperative Imaging of Cancer Using Optical Techniques

The global incidence of cancer is rising, putting an increasingly heavy burden upon health care. It is estimated that 12.7 million cancer cases and 7.6 million cancer deaths occurred worldwide in 2008 [1]. In 2012, an estimated 1.6 million new cancer cases and 0.5 million cancer deaths will occur in the United States alone [2]. With one out of every four deaths in the United States caused by cancer, the need to effectively detect and treat cancer is one of the most significant

problems faced in health care today. Effective cancer treatment typically depends upon early detection and, for most solid tumors, successful removal of the cancerous tumor tissue via surgical procedures. Difficulties arise when attempting to differentiate between normal and tumor tissue during surgery. Unaided visual examination of the tissue provides only superficial, low-resolution information and often with little visual contrast. Imaging modalities such as ultrasound and positron emission tomography have been developed for intraoperative cancer imaging [3, 4]. Though these modalities are widely used for cancer screening and diagnostics, their use in the operating room is limited by low spatial resolution. Optical imaging provides cellular resolution and numerous forms of contrast mechanisms, allowing for more precise localization of the tumor tissue. It is also relatively inexpensive and highly portable, making it well suited for intraoperative applications.

Many optical imaging modalities have potential for guiding surgical oncology procedures [5, 6]. The majority of these modalities are fluorescence based and require the use of fluorescent-labeled dyes, cells, nanoparticles, or molecular probes [7]. Unfortunately, the use of fluorescent labels introduces issues with bioavailability, specificity, toxicity, and regulatory approval. Therefore, a label-free imaging method would be preferred for surgical imaging. Raman spectroscopy and autofluorescence imaging do not require application of labels or contrast agents and have been proposed for surgical use. Weak signal, high background fluorescence, and complicated probe design have slowed progress toward surgical applications of Raman spectroscopy [8]. Autofluorescence imaging is confounded by uncertain tumor specificity due to the complex biological mechanisms that influence the autofluorescence process [9]. Other label-free methods include wide-field optical spectroscopy which probes the molecular heterogeneity of the tumor environment [10, 11]. The large field-of-view and molecular contrast are advantageous, but the method is dependent upon patient demographics and has markedly lower resolution than many other optical imaging methods.

While each of the above methods may play an important role in cancer imaging, optical coherence tomography (OCT) is currently the most promising solution for real-time, cellular-resolution, label-free structural imaging in biological tissue [12, 13]. Full-field OCT is an alternative to standard scanning OCT and is being explored for in situ use [14]. Further details on full-field OCT can be found in ► Chaps. 25, "Time Domain Full Field Optical Coherence Tomography Microscopy" and ► 26, "Assessment of Breast, Brain and Skin Pathological Tissue Using Full Field OCM".

80.1.2 OCT in Cancer Screening, Guided Biopsy, and Surgical Resection

Cancer screening and detection is typically performed using imaging modalities such as ultrasound, x-ray computed tomography, magnetic resonance imaging, single-photon emission tomography, and positron emission tomography [15]. These modalities have large fields-of-view and high depth penetration making

them well suited for screening applications. However, if a large field-of-view is not necessary, OCT could be used for screening at higher resolutions not possible with other modalities. OCT has already been used to detect cancer in many different applications such as dermatology, endoscopy, colonoscopy, gynecology, and urology, discussed elsewhere in this book.

Despite advances in cancer detection by medical imaging, biopsy followed by histology remains the gold standard for cancer diagnosis. After detection by imaging, tumors are typically sampled using needle biopsy. However, the rate of misdiagnosis for core needle biopsy is disturbingly high [16]. This points to a need for high-resolution guided biopsy, and the recent work on OCT-guided needle biopsy is quite promising [17, 18]. Further information on needle probe imaging can be found in ► Chap. 81, "Optical Coherence Tomography in a Needle Format".

Following detection and diagnosis of cancer, standard treatment involves surgical removal of the tumor. Even when the tumor location has been determined by presurgical imaging, movement of soft tissues over time can make locating and removing the tumor difficult. Using OCT it is possible to image immediately prior to and during resection, providing real-time feedback to the surgeon. One example of this is the imaging of nonmelanoma skin cancer in situ [19, 20]. In one study in particular, OCT was used to demarcate the boundary of a tumor immediately before removal via Mohs surgery [20]. The surgery was then performed in a standard way. Because the tumor extended beyond the area visible on the surface, two stages of resection were required. This suggests that superficial information was insufficient for predicting the extent of the tumor and guiding the resection. In contrast, the OCT images accurately predicted the extent of the tumor due to the ability to identify subsurface margins.

Identification of some tumor margins is even more challenging. Resection of malignant glioma of the brain, for example, does not exhibit a clear brain-tumor interface. Current intraoperative imaging methods such as ultrasound and MRI lack the resolution necessary to detect the ambiguous tumor boundary. As a result, there is only about 30 % correlation between the surgeon's estimate of "complete removal of visible tumor" and "clearance of enhancement on MRI" [21]. This indicates that high-resolution image-guided surgery is necessary. In one study, OCT was used to image ex vivo brain tumors from both a mouse model and human patients [22]. In the mouse model, OCT clearly distinguished between normal tissue, the diffuse tumor edge, and the heterogeneous solid tumor. The results were verified by histology. Glioma tumors typically infiltrate the surrounding brain tissue by migrating along myelinated fiber tracts. Patient survival rate is directly related to the removal of highly invaded tissue. On the other hand, it may be desirable to leave areas of low invasion undisturbed. The ability of OCT to distinguish these areas is a key advantage over existing methods. Imaging was also performed on ex vivo human tissue immediately following excision with similar results to the mouse model.

The first in vivo intraoperative brain study was performed in 2009 [23]. The OCT sample arm was mounted in a flexible arm that enabled noncontact imaging inside the surgical cavity. Both ex vivo and in vivo studies were performed for comparison.

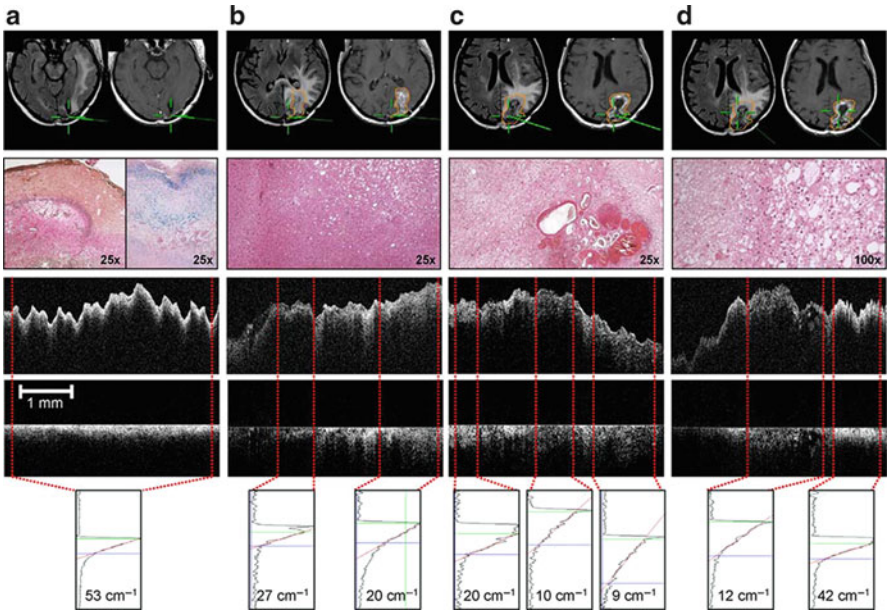

Fig. 80.1 Intraoperative OCT imaging during resection of glioblastoma (WHO grade IV), which recurred after initial surgery and radiation. A pilot laser was used to focus the OCT probe on the target volume. The center of the scan line was registered by the acquisition of marker points using a neuronavigation system. (**a**) Collagen-rich cortical scar: H&E stained (*left*) and with deposition of iron pigmented macrophages (*right*; Berlin blue reaction). (**b**) Microcystic changes within the tumor infiltration zone. (**c**) Highly cellular tumor with vascular proliferations and pleomorphic tumor cells. (**d**) Pleomorphic tumor cells (*right*) and tumor necrosis (*left*) within the center of the tumor (**b**–**d** H&E staining) (From Ref. [23], published by Springer Science+Business Media)

The ex vivo imaging distinguished between normal tissue, tumor infiltrate, solid tumor, and necrosis, verifying results from the previous study. Additionally, the attenuation coefficients were calculated and found to vary according to tissue condition. In vivo imaging was performed on nine patients with a total of 42 imaging sites using a time-domain OCT system. Images were taken from several areas during each surgery. Due to motion during imaging, an automated algorithm was used to detect the surface and realign the OCT A-scans. Figure 80.1 depicts representative results from scarred tissue, tumor infiltrate, solid tumor, and necrotic tissue, respectively. The imaging location, histology, OCT data, realigned OCT data, and attenuation profile are shown for each tissue type. Data from all nine patients was examined by a "blinded" investigator, and each image was evaluated as "normal light attenuation," "loss of normal light attenuation," or "loss of normal light attenuation with a pathological tissue microstructure." Histology slides were evaluated as "no tumor," "diffuse tumor infiltration," and "solid tumor." There was a clear correlation between the OCT and histology results. A total of 12 histological samples were found to have no tumor present. Nine of these were correctly identified as normal by OCT. The remaining 3 were incorrectly identified as

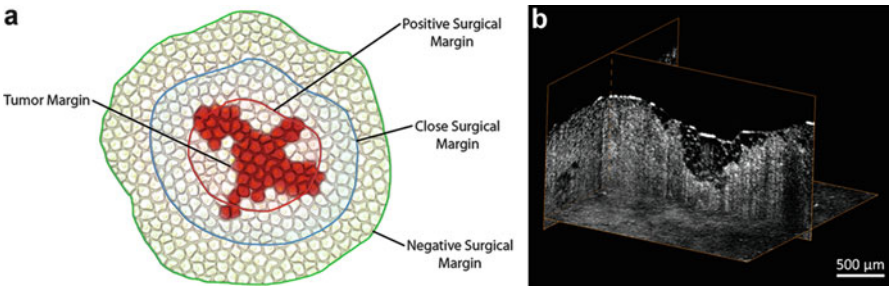

Fig. 80.2 Surgical margins and tumor margins in breast cancer surgery. (**a**) Surgical classification of the tumor margin status depends on the distance of cancer cells from the surface of the resected tissue. If the surgical margin is located along the tumor margin or the tumor cells are found beyond the surgical margin, the surgical margin is considered "positive" (*red line*). A "close" surgical margin (*blue line*) does not have tumor cells within 1 mm or 2 mm from the surgical margin. Otherwise, a surgical margin is considered "negative" (*green line*). The tumor margin follows the edge of the solid tumor itself, and it does not include any metastatic cells that may have migrated away from the primary solid tumor mass (Own work published in SPIE Proceedings, doi:10.1117/12.2040315) [70]. (**b**) Three-dimensional OCT image of a positive margin from an excised human breast tumor mass (Own work unpublished)

loss of normal light attenuation due to micro-hemorrhage of the tissue. Out of 15 diffuse tumor infiltrations, all showed loss of attenuation and 9 showed pathological microstructure. Histological results indicated 15 solid tumors, all of which showed loss of attenuation and pathological microstructure in OCT. Overall, the results indicate that OCT can be used to successfully identify in vivo glioma and the surrounding infiltration, possibly improving the success rate of current surgical procedures.

80.2 Applications in Breast Cancer

80.2.1 Intraoperative Assessment of Tumor Margins: Background

Early cancer detection with x-ray mammography, ultrasound, and MRI allows surgeons in most cases to remove smaller tumors while preserving as much of the normal breast tissue as possible (during lumpectomy procedures). After the surgery, histopathology is performed on the excised tissue to assess the margin status. If the margin contains cancer cells ("positive" margin) or the cancer is present within a certain depth of the resected surface ("close" margin), then the patient is advised to undergo re-excision surgery until a "negative" margin is achieved (Fig. 80.2a). In a survey, 31 % of radiation oncologists defined a close margin as having no cells within 1 mm and an additional 38 % defined it to be no cells within 2 mm of the surface [24]. Since then more studies correlated the width of uninvolved margins to local recurrence of cancer, which has allowed surgeons to use 1 mm to define a "negative" margin and encourage breast conservation surgeries [25, 26].

In a large number of studies, it was found that the margin status was the key predictor of local recurrence of cancer, and positive margins have contributed significantly to a high rate of repeated surgeries [27–38]. A positive margin, with cancer cells on the surface of the resected tissue, occurs in at least 30–35 % of cases, and an additional 10–15 % are classified as close margins [37].

Currently, no real-time intraoperative method exists to rapidly assess the status of lumpectomy margins to determine if additional tissue needs to be removed [39, 40]. None of the investigated techniques, including frozen section analysis, touch prep cytology, specimen radiography, and radiofrequency spectroscopy, satisfy the necessary requirements. Frozen section analysis has a sensitivity of 73 % and a specificity of 98 % compared to paraffin section analysis for breast cancer, but is not widely accepted due to difficulties in performing frozen sections on adipose tissue and increased operating room time (∼20–30 min) [39]. Overall, current histological methods cannot rapidly determine the surgical margin status due to time, cost, and technology limitations. Touch prep cytology with reported sensitivities of 75 % and specificities of 83 % can rapidly assess the entire margin area [41]. However, this technique requires that the tumor cells are present at the surface and that they detach and adhere to the slide for microscopic examination. Touch prep cytology does not provide information about the presence of cancer cells beneath the surface and thus is unable to determine close and negative margins. Surgeons can visualize tumor margins using intraoperative specimen radiography by displaying two-dimensional x-ray projections. Unfortunately, this technique has a rather low sensitivity (49 %) and specificity (73 %) which is primarily due to its inability to identify diffuse microscopic processes, especially where the tumor boundary is poorly defined [42, 43]. Radiofrequency spectroscopy with low sensitivity (71 %) and specificity (68 %), shallow penetration depth (100 μm), and low resolution offers very limited detection within 1–2 mm for margin classification [44].

Among all optical techniques, OCT has the greatest potential for in situ label-free intraoperative margin assessment in breast-conserving surgeries, since it acquires high-resolution images in the same physical range as that used in histological analysis to classify surgical margins as positive, close, or negative (Fig. 80.2b). Figure 80.3 shows some representative OCT images of negative and positive surgical margins obtained ex vivo from resected breast tumors. The observations made by OCT were confirmed by histopathology.

80.2.2 Intraoperative Assessment of Tumor Margins: Results

The first study to demonstrate breast cancer imaging using OCT was conducted using a preclinical rat model [45]. Virgin female rats were injected with carcinogen N-methyl-N-nitrosourea (MNU), leading to the development of invasive mammary tumors. Three-dimensional imaging of the palpable tumors was performed with a time-domain OCT system centered at 800 nm with 2 μm axial and 10 μm transverse resolutions. Healthy mammary tissue was found to have a heterogeneous

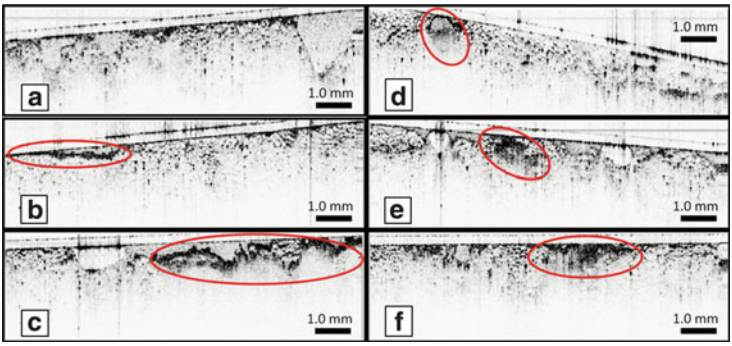

Fig. 80.3 Intraoperative OCT images of resected breast tissue specimens a human patient diagnosed with ductal carcinoma in situ (DCIS). (**a**) OCT of normal tissue was identified by the homogenous pattern of large adipose cells. (**b–d**) Readily identified surgical artifacts are also shown. (**b**) Surface blood appeared as a thin film of scatterers. (**c**) Cauterized tissue exhibited a distinct patch-like appearance. (**d**) Potential duct with a mixed distribution of low- and high-scattering areas. (**e**, **f**) Positive margins contained tumor cells and tissue represented by a highly scattering area that was more heterogeneous and disruptive compared to the surrounding tissue architecture (Adapted from [48])

structure composed of mixed adipose and stroma. In the OCT data, individual adipocytes appeared as segmented oval-shaped objects, while stroma appeared dense and highly scattering. OCT imaging of early-stage tumors revealed thickening and stronger scattering in the ductal morphology, suggesting precancerous changes prior to full tumor invasion. Late-stage solid tumor was identified as dense and highly scattering, similar to the scattering intensity from stroma. Despite this similarity, the morphology of the tumor caused it to appear distinct from the surrounding tissue. While the tumor margin boundary was visible in the 2D representation, 3D visualization facilitated detection of the tumor boundary. Results from this study suggest that while single tumor cells may be challenging to locate, precancerous changes and significant tumor invasion can be detected using OCT.

For OCT to guide surgical procedures, it is necessary to understand how specific histological features appear in OCT images of human breast tissue. To accomplish this goal, a comparison study was conducted between OCT and the corresponding histology sections of human breast tissue [46]. Two-dimensional and three-dimensional spectral-domain OCT imaging was performed at a center wavelength of 1090 nm with 3.5 μm axial and 6 μm transverse resolutions. A total of 119 specimens were imaged from 35 patients covering several pathologies including ductal carcinoma in situ (DCIS), infiltrating tumor, and microcalcifications. Specimen radiography was performed on freshly excised tissue in the pathology lab to guide OCT imaging to suspicious sites. A non-blinded comparison was made between OCT and histology findings. Analysis of healthy tissue revealed clear visualization of adipose, stroma, ducts, and glands. Benign changes including cysts, fibroadenoma, and ductal hyperplasia were also visible. Comparison results for lobular DCIS are shown in Fig. 80.4a. Normal adipose tissue and

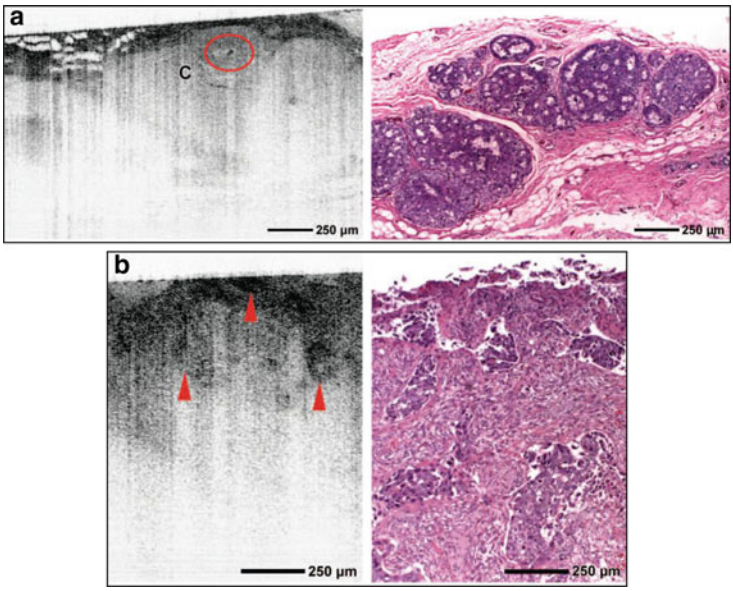

Fig. 80.4 Comparison of tumor features in OCT and histology. (**a**) OCT image and corresponding histology of DCIS lesions in lobules. Tumor cells within lobules appear uniformly low scattering. Dilatation and architectural distortion of the lobules are visible. A microcalcification (*C*, circled area) within the lobules appears highly scattering with pronounced shadowing. (**b**) OCT image and corresponding histology of infiltrating ductal carcinoma. Highly scattering regions (*arrowheads*), which correspond to tongues of invasive cancer, are visible (Adapted from [46], reprinted with permission from Radiological Society of North America)

stroma are visible along the surface of the sample. Enlarged, low-scattering DCIS lobules visibly distort the surrounding structure, and a microcalcification is visible as a small high-scattering area. OCT and histology comparison of invasive ductal carcinoma is shown in Fig. 80.4b. Tumor appears as highly scattering irregular "tongues" which protrude into the desmoplastic stroma. Separate calcifications are also visible. Solid infiltrative ductal carcinoma was also imaged, yet it was difficult to distinguish from stroma due to the highly scattering uniform structure. Results from the comparison study demonstrate that OCT is capable of detecting normal, benign, and malignant tissue structures in the human breast.

A study comparing OCT, optical coherence microscopy (OCM), and histology of breast tissue has shown similar results [47]. An integrated OCT-OCM system was used with 4 μm axial resolution and 14 μm or 2 μm transverse resolution for OCT and OCM, respectively. A total of 34 benign and 10 malignant ex vivo specimens were imaged 2–6 h post resection. A non-blinded comparison of OCT with histology located adipose, stroma, benign lobules and ducts, cysts, and in situ and invasive carcinoma. These results were consistent with previous studies, with the addition of higher-resolution optical scattering data provided by OCM.

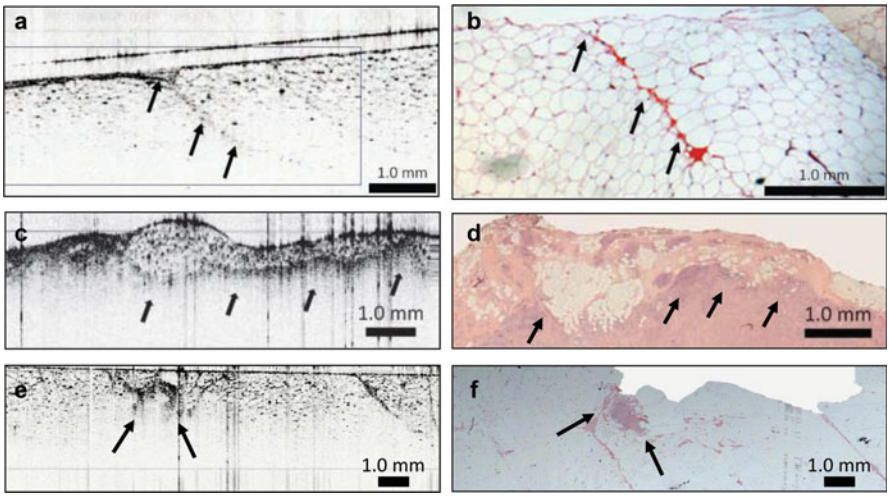

Fig. 80.5 Surgical margins imaged using OCT. (**a**) OCT and (**b**) histology of a negative tumor margin. Adipose cells and microvasculature (*arrows*) are present. (**c**) OCT and (**d**) histology of positive tumor margin. OCT shows a distinct heterogeneously scattering region (*arrows*) with small, highly scattering foci indicative of collections of tumor cells. (**e**) OCT and (**f**) histology of positive tumor margin with an isolated tumor focus (*arrows*) (Adapted from [48])

The first intraoperative OCT breast margin assessment study was published by Nguyen et al. [48]. A portable spectral-domain OCT system was constructed for imaging in the operating room. The system performed 3D imaging at a center wavelength of 1,310 nm with 5.9 μm axial and 35 μm transverse resolutions. A total of 37 patient specimens were imaged immediately following resection. Suspicious areas were located for OCT imaging by visual inspection and palpation. The imaged areas were then marked with surgical ink for correlation with histology. Seventeen of the patient specimens were used as a training set. The training set data included both negative (no tumor present) and positive (tumor present) margins and revealed confounding factors such as pooled blood and cauterized tissue which both appeared highly scattering, mimicking the scattering signature of tumor tissue. When classifying negative and positive margins, these confounding factors must be carefully considered (Fig. 80.3). Highly scattering blood on the tissue surface was easily removed by flushing the tissue with saline. Cauterized tissue was identified as a highly irregular, intensely scattering, and highly attenuating surface that blocked all signals from beneath the cauterized and charred surface. The remaining 20 patient specimens were used to determine the feasibility of tumor margin assessment using OCT. Out of the 20 margins, 11 were diagnosed histologically positive and 9 were diagnosed histologically negative. A blinded analysis of OCT data was performed and compared with histology results. OCT data sets containing tumor cells or tumor tissue were classified as positive, while data sets void of tumor were classified as negative. Representative tumor margins are shown in Fig. 80.5. As expected, tumor cells are identified by high scattering and

heterogeneous structure, in contrast with normal fibroadipose tissue. Comparison of OCT analysis and histology resulted in 100 % specificity and 82 % sensitivity for using OCT to identify positive margins intraoperatively in real time, compared to postoperative assessment of histological tissue sections. This demonstrates that intraoperative breast margin assessment with OCT is feasible and warrants further study.

80.2.3 Intraoperative Assessment of Sentinel Lymph Nodes: Background

Lymph nodes are anatomically distributed along locoregional drainage patterns in the body and function as filters to capture and retain potentially harmful macromolecules and microorganisms and provide a tissue microenvironment to facilitate immunological surveillance of various antigens. Lymph nodes have a well-defined structure with an outer capsule, subcapsular sinus, cortex containing follicles, medullary sinuses, medullary cords, and hilus [49]. The organization of the lymph node is well suited for its filtering role. The lymph enters through the afferent lymphatic vessels into the marginal sinuses, under the capsule, and moves into the medullary sinuses (Fig. 80.6a). The system of sinuses retains the particles, facilitating immune cells in their monitoring functions.

Inactivated (normal) lymph nodes contain a relatively small number of active immune cells. Upon interaction with antigens, lymph nodes became enlarged mainly due to the recruitment and activation of lymphocytes and macrophages involved in the primary immune response. In the case of a metastatic node, in addition to the inflammatory response, there is also the presence of infiltrating and dividing cancer cells. It is well known that cancer cells from the primary metastatic tumor often travel via the lymphatic system and accumulate in the lymph nodes. Most of the lymph from the breasts (80–100 %) drains into the axillary lymph nodes, making them important in the staging of breast cancer. In the past, it was common to remove 10–30 axillary lymph nodes in order to stage disease progression using postoperative histopathological analysis and determine the most appropriate therapeutic treatment. However, removal of lymph nodes can cause disruption of the lymphatic drainage network and obstruction of lymphatic flow, leading to long-term complications such as numbness, sensitivity, and accumulation of lymph fluid or lymphedema. To decrease these postoperative morbidities and complications, most surgeons are now removing only the sentinel lymph nodes (the first nodes collecting the lymph from the tumor site, Fig. 80.6) for biopsy [50]. It was shown in clinical studies that sentinel lymph nodes are sufficient for staging breast cancer and assessment of metastasis [51].

There are several techniques that are currently used to identify and localize lymph nodes before their resection. A radioactive tracer (technetium-99) and a dye (methylene blue) are injected preoperatively near the site of the tumor [50, 52]. They are allowed to circulate, and the sentinel nodes are identified by

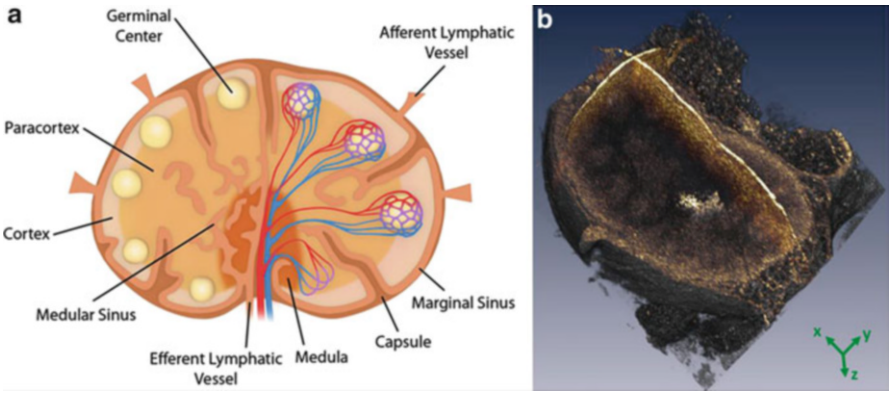

Fig. 80.6 Lymph node anatomy. (**a**) Diagram of a lymph node indicating basic structural components (Own work unpublished). (**b**) Three-dimensional transcapsular OCT of a normal rat lymph node featuring an intact capsule and follicular structures that were distinguishable from the background cortex based on their spheroidal pattern of optical scattering (Adapted from [64], reprinted with kind permission from Springer Science and Business Media)

the color or the level of radioactivity. After resection, lymph nodes are processed and analyzed using standard histological techniques. Fluorescence techniques using near-infrared dye [53, 54] that could provide better localization of the lymph node are also being investigated, but none of the mentioned techniques can provide the assessment of the lymph node status.

Intraoperative techniques currently used for the staging of cancer by assessing lymph nodes require lymph node resection and dissection to expose the internal structure for high-resolution imaging [55, 56] or prolong the surgery. Surgeons often send suspicious nodes for a quick assessment via frozen sections, which could take 20–30 min to perform, increasing the time that the patient is under general anesthesia [57, 40]. Most of the other noninvasive imaging modalities currently used in the clinical setting (x-ray, MRI, CT) can provide information only about the size and general morphology of the lymph nodes [58] and cannot provide any information about the presence of cancer cells in the early stages of metastasis [59, 60]. With a 1–2 mm imaging penetration depth, OCT has a potential for intraoperative in situ imaging of intact lymph node structure and assessment of status, primarily by imaging the capsule and the outer cortex containing the follicles and germinal centers (Fig. 80.6b) [45, 61, 48]. During metastatic progression, cancer cells first infiltrate sentinel lymph nodes in the subcapsular region, and the architectural changes in lymph node morphology all primarily occur in the outer cortex and capsular regions, which are within the imaging depth of OCT [61–65]. In addition, the proliferation of adipocytes in and around the lymph nodes has also been correlated with metastatic involvement, which can be identified and imaged with OCT [71].

80.2.4 Intraoperative Assessment of Sentinel Lymph Nodes: Results

Initial OCT research in lymph node imaging was published in 2005 where three-dimensional time-domain OCT imaging was performed on both rat and human lymph nodes [61]. Many important structures were detected such as the capsule, cortex, sinuses, and follicles. Two freshly excised metastatic human lymph nodes were also imaged and exhibited highly scattering tumorous and necrotic areas. This study demonstrated that although the entire depth of the node cannot be imaged, transcapsular OCT imaging of intact lymph node is still capable of detecting many diagnostically significant features.

To better understand the image characteristics of metastatic node progression, a longitudinal animal study was conducted with imaging performed at several stages of tumor invasion [64]. Rats were injected with mammary tumor cells in the left footpad, forming tumors that metastasized to the popliteal lymph nodes. Injected rats were sacrificed for imaging on days 3, 5, 7, and 9 postinjection. Imaging was performed using a three-dimensional spectral-domain system centered at 800 nm with 2 μm axial and 12 μm transverse resolution, and results were compared to histology. A healthy node from a control animal was imaged on day 0 to serve as a reference point for the following days. The node appeared normal as expected with an intact capsule, low-scattering subcapsular layer, and distinct circular follicle structures. Nodes from injected rats imaged on days 3, 5, 7, and 9 showed increasing levels of inflammation, macrophage invasion, disruption of normal structure, and tumor invasion. En face and cross-sectional OCT images of the day 3, day 7, and day 9 nodes are shown in Fig. 80.7. Nodes resected and imaged on day 3 exhibited mild inflammation which appeared as a loss of distinction between the capsule to subcapsular boundary and an area of low-scattering fluid in the subcapsular area. OCT images from day 5 show increased inflammation in the subcapsular space. Invading macrophages and tumor cells were discovered in the inflammation site by histology. In the day 7 node, low-scattering areas of subcapsular inflammation continued to grow, and the cortex became more homogeneous. Severe inflammation and invasion of macrophages into the node appeared as a large, irregular, low-scattering area. The day 9 node was completely metastatic with little to no original lymph tissue remaining. The OCT image appeared mildly scattering and uniform with few distinguishing features. The knowledge gained in this preclinical longitudinal OCT study can be used as a guide when attempting to stage human lymph node metastases.

More recent studies have imaged normal, reactive, and metastatic human lymph nodes using OCT following surgical resection. In one study, 18 samples were imaged in 3D using time-domain OCT at a central wavelength of 1,320 nm and an isometric resolution of 11 μm [62]. An additional 12 samples were imaged with similar quality using swept-source OCT at 1,325 nm with 12 μm axial and 15 μm transverse resolution. OCT of normal human nodes showed expected nodal structures with adipose tissue surrounding the node. A benign reactive node exhibited normal structure with enlarged germinal centers possibly due to

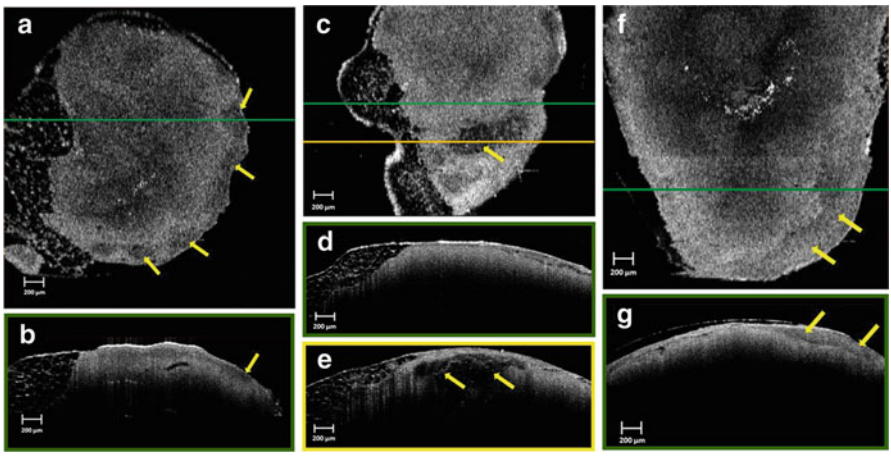

Fig. 80.7 Metastatic progression in lymph nodes. En face (**a**, **c**, **f**) and cross-sectional OCT (**b**, **d**, **e**, **g**) are shown. (**a**, **b**) Rat lymph node imaged on day 3 after injection of cancer cells into the hindlimb footpad. Mild inflammation is observed in the subcapsular region (*arrows*). (**c**–**e**) Rat lymph node imaged on day 7. OCT shows inflammation resulting from invasion of macrophages (*arrows*) and a more homogeneous high-scattering cortex is evident, where follicle structures are no longer visible. (**f**, **g**) Rat lymph node imaged on day 9. OCT shows effacement of node structure and a small area of remaining lymphocytes (*arrows*). In all cases, the *green* and *yellow* frames around the cross-sectional OCT images correspond to the horizontal lines of the same color in the corresponding en face images (Adapted from [64], reprinted with kind permission from Springer Science and Business Media)

an inflammatory response. En face OCT and corresponding histology of two metastatic nodes are shown in Fig. 80.8. Both nodes have been invaded by ductal carcinoma resulting in irregular areas of high optical scattering in the OCT data. In another study, human nodes were imaged using the same system described by Nguyen and colleagues [48]. A total of 17 ex vivo nodes were imaged intraoperatively immediately following resection [63]. Results were similar to those reported above, with inflammation and tumor invasion deteriorating the normal node structure. Representative results are shown in Fig. 80.9. Importantly, of the 30 sentinel nodes resected during this study, 84 % were diagnosed as normal, emphasizing the significant need for in vivo node assessment.

In each of the OCT lymph node studies, normal nodes were clearly distinguished from reactive and highly metastatic nodes. However, differentiating between reactive nodes and newly established metastases remains difficult due to similarities in structure and scattering properties. One possible solution is parametric imaging using the optical attenuation coefficient to provide contrast between various node structures [65, 66]. Future studies are needed to address this issue, as many lymph nodes are reactive due to inflammation from treatment or surgery and may not necessarily contain metastatic infiltrates.

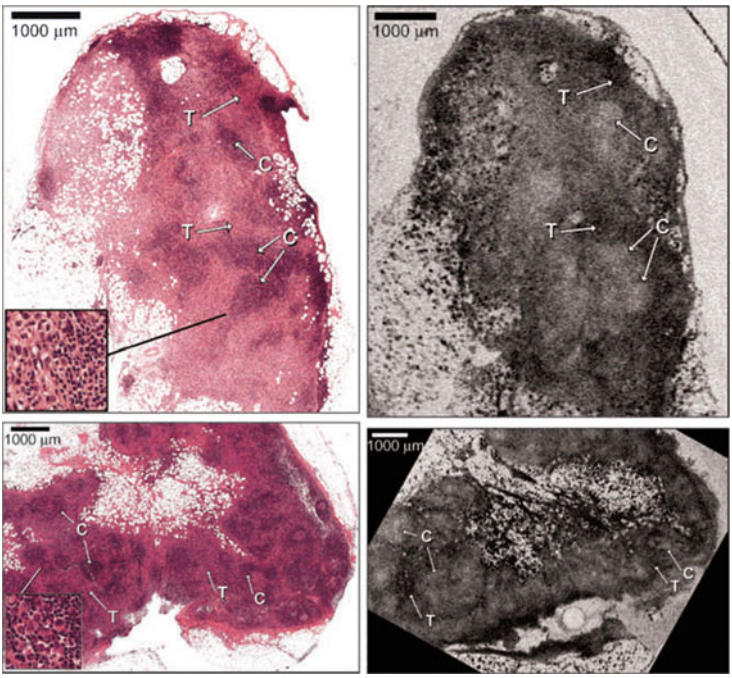

Fig. 80.8 Histology and corresponding OCT images of metastatic human nodes from ductal breast carcinoma. Two different nodes are shown (*top*, *bottom*). Insets in H&E images show the morphology of the metastatic carcinoma at higher magnification. Areas effaced by diffuse sheets of metastatic tumor cells are shown (*T*), as well as areas of uninvolved cortex (*C*) [48, 62]

80.3 Future Outlook

The studies discussed in this chapter have demonstrated that OCT is capable of imaging several tissues of interest in surgical oncology. These results should encourage the development of improved OCT imaging systems and larger clinical studies to demonstrate effectiveness and ease of use suitable for the operating room. While many of the studies presented here imaged tissue ex vivo immediately following resection, in vivo imaging is highly preferred. Imaging in vivo makes it possible to leave healthy tissue intact and also eliminates the confounding artifacts in OCT images associated with surgical removal such as loss of blood and lymphatic circulation and change of shape. To avoid motion artifacts, high-speed scanning is necessary for imaging in vivo. Additionally, processing and visualization of data must be done in near real time for guided surgery to be most effective. Three-dimensional imaging is also preferred over two-dimensional imaging as it provides a more comprehensive view of the tissue. Imaging in 3D can also identify small features such as microcalcifications which may be easily missed in 2D imaging.

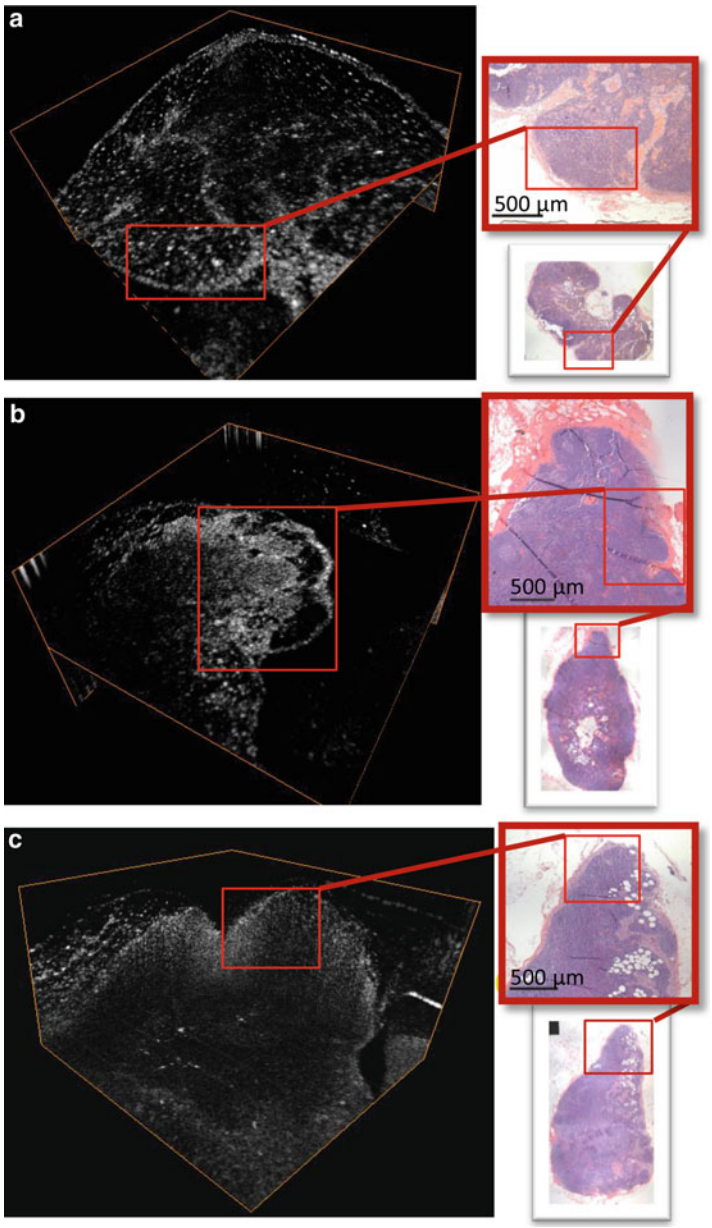

Fig. 80.9 3D OCT and corresponding histology of human lymph nodes. (**a**) Normal human lymph node with distinct capsule and cortex. (**b**) Reactive human lymph node showing inflammatory disturbance of nodal structure. (**c**) Metastatic node exhibiting a loss of distinct nodal structures (Adapted from [63])

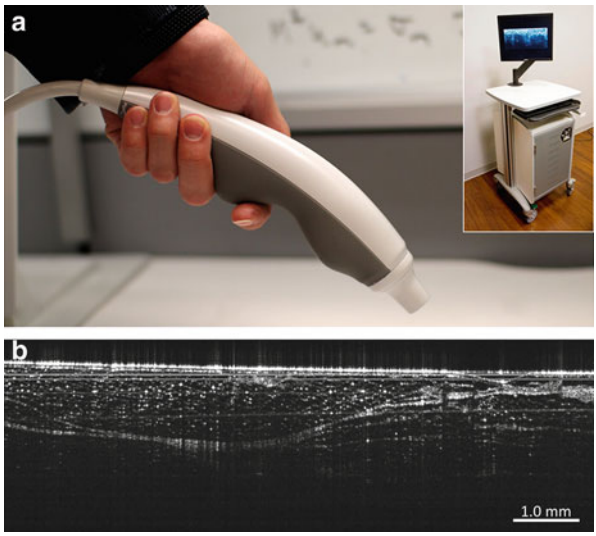

Fig. 80.10 Commercial intraoperative imaging system. (**a**) Handheld probe and portable cart designed for in vivo surgical imaging of breast cancer using interferometric synthetic aperture microscopy (ISAM). (**b**) Real-time ISAM image of normal adipose and parenchymal tissue acquired in vivo within the surgical tumor cavity in a patient undergoing a lumpectomy procedure for breast cancer (Images courtesy of Diagnostic Photonics, Inc.)

The high resolution of OCM provided improved image quality over OCT, demonstrating that increased resolution is a key factor in identifying tissue structures [47]. However, OCM is limited by lower penetration depth and slower acquisition speed than OCT. An alternative may be found in computed imaging methods, such as interferometric synthetic aperture microscopy (ISAM) and computational adaptive optics [67, 68] (see ▶ Chap. 31, "Interferometric Synthetic Aperture Microscopy (ISAM)"). While the resolution may not reach the level of OCM, it is possible to improve resolution throughout the entire imaging range while still acquiring and processing data at high speed. Recently, a handheld ISAM imaging system and probe have been developed as a commercial devices for in vivo breast imaging during surgical procedures. The system and preliminary in vivo data depicting a negative tumor margin are shown in Fig. 80.10. A high-speed OCT/ISAM system can be operated much like a real-time ultrasound imaging system where the probe generating fast 2D cross-sectional images is rapidly moved across tissue surfaces. Or in another configuration, OCT can be integrated into a surgical microscope for intraoperative tumor imaging [69]. Using position information from the surgical microscope and high-speed image processing of the OCT data, the automated system can perform composite 3D imaging over several square centimeters. These new in vivo imaging systems demonstrate that OCT is a highly flexible technology and may be deployed in configurations most well suited for the application.

Preclinical animal studies, human feasibility studies, and the development of suitable OCT hardware have set the stage for OCT to impact the field of surgical oncology. As this technology and target application is commercialized and larger human studies are performed, it is likely that OCT will be found useful in guiding intraoperative procedures.

Acknowledgments We would like to thank our colleagues for their work which contributed to this chapter. We regret that we were unable to include more results from others due to space limitations. A portion of the research presented here was supported in part by grants from the US National Institutes of Health (R01 EB012479 and R01 CA166309, S.A.B.).

81.1 Introduction

OCT has the potential to be used in vivo and in real time, avoiding the need to excise tissue and allowing minimally invasive imaging of disease in situ. The promise of such high-resolution optical imaging has been referred to as an "optical biopsy" [1]. Despite its great potential, OCT imaging has been restricted in clinical applications by its extremely limited imaging depth, typically only 2–3 mm in tissue.

Miniaturized fiber-optic probes for OCT offer the potential to image deep within the body. It is possible to miniaturize the distal scan head and encase it within a medical needle – an OCT needle probe [2], as shown in Fig. 81.1a. The extreme miniaturization of such probes, down to outer diameters of ≈0.3 mm, is made possible by all-fiber distal focusing optics as shown in Fig. 81.1b, where a coreless silica spacer made of no-core fiber (NCF) and a graded-index (GRIN) fiber

microlens have been fusion-spliced directly to the end of the delivery fiber, and a side-deflecting mirror has been realized by angle polishing the fiber tip. A number of promising applications are emerging, including cancer diagnosis [3, 4], pulmonary imaging [5, 6], imaging of the eye [7, 8], and imaging of the brain [9, 10]. The long-term vision of this rapidly evolving field is to create high-speed, handheld OCT needle scanners that allow clinicians to perform real-time in vivo imaging, as illustrated in Fig. 81.1c.

In this chapter, we will review the development and deployment of OCT needle probe technology and examine its use in preclinical and clinical applications.

81.2 Technology

Needle probes replace the sample-arm optics of a conventional OCT scanner. The tasks of the sample-arm optics are to scan and focus the incident light and to collect the weak backscattered light from the sample with high efficiency. Therefore, they define or significantly influence a number of key performance parameters of the OCT system, such as:

- Transverse resolution
- Depth of focus (DOF)
- Sensitivity
- Imaging speed

Losses or backreflections in the sample-arm optics will reduce the system sensitivity, whereas aberrations and alignment errors will negatively impact the transverse resolution and DOF. In a well-designed conventional free-space sample-arm setup consisting of a collimator, galvanometer mirrors, and a compound scan lens, minimal losses and diffraction-limited probe beam quality over the entire field of view can easily be simultaneously achieved using high-quality antireflection-coated optics. In the case of miniaturized sample-arm optics, such as those found in endoscopic or needle probes, the small dimensions and the available fabrication methods often force the probe designer to make trade-offs that negatively impact the performance of the OCT system. Recent advances in probe design and fabrication, however, have shown that needle probes can attain sensitivities and resolution comparable to bulk-optic sample arms [11].

81.2.1 Probe Optics

81.2.1.1 Probe Optics and Output Beam Parameters

The probe optics collimate or focus the diverging beam which is emitted from the single-mode fiber (SMF) of the OCT system and direct it into the sample, as illustrated in Fig. 81.2a. The focusing elements in the probe optics are typically realized using either GRIN optics or refractive optics. GRIN optics can be used either in the form of discrete GRIN rod lenses [12, 2] or in the form of short sections of multimode GRIN fiber that are directly fusion-spliced to the SMF [13–17, 11] in combination with coreless silica spacers made of no-core fiber (NCF). Due to its great importance for fiber probes, the use of GRIN multimode fiber as microlenses will be treated in more detail in Sect. 81.2.1.3. Examples of refractive optics are discrete ball lenses [8] or ball lenses that are directly formed on the end of fiber tips using fusion splicers [18, 12, 6]. Lensed fibers per se are not capable of imaging unless they are combined with some form of scanning mechanism, as will be discussed in Sect. 81.2.2. The most common scanning concept is rotation/pullback scanning in a side-facing configuration using a side-deflecting microreflector, as illustrated in Fig. 81.2a.

This technique has its origins in catheter-based OCT systems [19, 20]. In side-facing configurations, complications due to astigmatism and beam distortion can arise if the beam must exit the needle through a nonplanar output interface (e.g., when an enclosing catheter or transparent casing is used). These issues will be addressed in the discussion of specific probe designs in Sects. 81.2.3 and 81.2.4. While the majority of OCT needle probes have Gaussian or Gaussian-like output beams (practical probes often exhibit beam distortion due to aperture diffraction and aberrations, as will be explained in Sect. 81.2.1.3), it has recently been shown that it is feasible to extend the depth of focus (DOF) of miniaturized fiber-based probes using phase masks [21, 22]. Such advanced probe designs utilizing probe optics with additional wavefront-shaping elements have non-Gaussian output beams that maintain an approximately constant central lobe diameter over a large axial distance in the focal region, as illustrated in Fig. 81.2b.

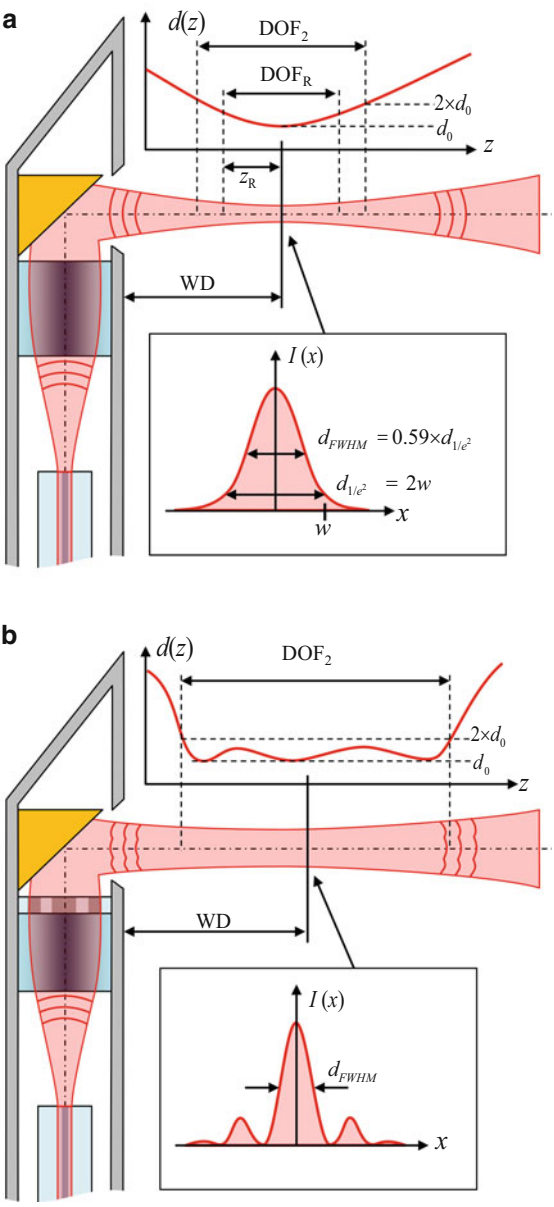

Fig. 81.2 Probe beam parameters. (**a**) Needle probe with a Gaussian output beam, using a GRIN lens which refocuses the beam emitted from the SMF into the sample volume. *WD* working distance, DOF_R depth of focus using the Rayleigh range criterion, DOF_2 depth of focus using the factor-of-two criterion. (**b**) Needle probe with a wavefront-shaped output beam which is generated by a phase mask after the focusing optics. The beam features an extended DOF compared to a Gaussian but its transverse profile has sidelobes

The axial and transverse resolutions of an OCT system are defined as the respective full-width at half-maximum (FWHM) of its three-dimensional (3D) point-spread function (PSF) [23, 24]. While the axial extent of the PSF is largely determined by the coherence length of the light source, the transverse extent of the PSF is determined by the intensity profile of the probe beam. For Gaussian probe

beams, the $1/e^2$ diameter of the beam waist is sometimes quoted as the transverse resolution of the system even though this is not consistent with the widespread use of the FWHM in the axial direction. We prefer to adhere to the FWHM definition of the transverse resolution, which has the additional benefit of yielding more meaningful values for the central lobe diameters of aberrated or non-Gaussian output beams which may have sidelobes or pedestals that exceed relative levels of $1/e^2$. This is very important for the characterization of probe designs that use wavefront-shaping elements, such as phase masks, in order to generate focal regions with an extended DOF, as illustrated in Fig. 81.2b. For an ideal Gaussian profile, the FWHM transverse resolution is given by

$$d_{FWHM} = \sqrt{\frac{\ln(2)}{2}} d_{1/e^2} \approx 0.59 \cdot d_{1/e^2} \approx 0.37 \cdot \frac{\lambda_0}{NA}, \tag{81.1}$$

where λ_0 is the wavelength in vacuum and NA is the numerical aperture. To define the DOF of the OCT imaging system, the double Rayleigh range is often used in the case of ideal Gaussian beams (see, e.g., [25]). The Rayleigh range criterion typically underestimates the perceived useful imaging depth range in OCT because a 40 % (factor of $\sqrt{2}$) change in transverse resolution is hardly visible due to the effects of logarithmic compression of the images and speckle. Similar to the reasoning for choosing the FWHM beam diameters to define the transverse resolution, we prefer to define the DOF as the range over which the FWHM beam diameter stays smaller than twice its minimum value in the focal region. This definition is more robust for numerically evaluating the DOF of probes that have wavefront-shaped output beams, which can have beam diameter variations within the useful imaging depth range that exceed a factor of $\sqrt{2}$, as illustrated in Fig. 81.2b. For an ideal Gaussian beam, the DOF according to the factor-of-two definition is simply a factor of $\sqrt{3}$ larger than the DOF according to the Rayleigh range criterion:

$$\mathrm{DOF}_2 = \sqrt{3} \cdot \mathrm{DOF}_\mathrm{R} = \sqrt{3} \cdot 2 \cdot z_R = \sqrt{3} \cdot 2 \cdot \frac{n\pi w_0^2}{\lambda_0}, \tag{81.2}$$

where n is the sample refractive index and w_0 is the waist radius. We use the subscripts "2" and "R" to denote the DOF according to the factor-of-two or Rayleigh range criteria, respectively.

Another useful parameter for characterizing the output beam quality in the case of aberrated or wavefront-shaped output beams is the Strehl ratio S. The Strehl ratio of an aberrated system is defined as the ratio of its focal spot peak intensity to that of an equivalent diffraction-limited system [26]. Here, it allows the estimation of the penalty in the detected signal level (from a point scatterer) incurred by non-Gaussian output beams that are used to trade off a reduced focal spot intensity for an increased DOF. The Strehl ratio is difficult to obtain from measurements, but it can often be calculated by optical design software (e.g., it can easily be computed for simulated output beams obtained using the beam propagation method [22] which is described in Sect. 81.2.1.3), and therefore, it is mainly used as a figure of merit for optimization and

comparison of probe designs. In the case of a simulated beam with a focal spot peak intensity $\hat{I}$ and total integrated beam power P, the Strehl ratio can be defined as [22]

$$S = \frac{\hat{I}}{\hat{I}_{Gauss}} = \frac{\hat{I}\pi w_{Gauss}^2}{2P}, \tag{81.3}$$

where w_{Gauss} is the $1/e^2$ waist radius of a suitably defined reference Gaussian beam (e.g., an ideal Gaussian beam with the same FWHM focal spot diameter as the simulated beam).

81.2.1.2 ABCD Matrix Modeling

The optical design of micro-optic systems, such as miniaturized fiber-based probes for OCT, cannot generally be performed using the ray-tracing methods used in classical lens design because the approximations of geometrical optics are not satisfied (the size of the wavelength is no longer negligible compared to the dimensions of the optical elements, which means that diffraction effects will have a strong influence). Scalar wave theory is, therefore, required to properly simulate the propagation of the optical field through the optical elements of the probe. While several optical engineering software packages offer such functionality, they tend to be costly and complex to use. A simple but very effective alternative to a numerical scalar wave simulation is paraxial ABCD matrix transformations of Gaussian beams [27, 28]. Since the beam emitted by a SMF can be well approximated by a fundamental Gaussian mode [29], ABCD matrices can be used to calculate its transformation by the optical elements of the probe if these can be described sufficiently well by their paraxial, or first-order, optical properties (i.e., aberrations can be neglected). If no limiting apertures are present in the optics, this formalism fully accounts for diffraction and yields exact results within the regime of validity of the paraxial approximation, as the Gaussian beam is an exact solution of the paraxial wave equation [27]. Most optical beams used for OCT imaging lie well within the paraxial regime, which is a good approximation for beam divergence angles up to $\sim 30°$, corresponding to a numerical aperture of ~ 0.5 [27].

A very convenient feature of the ABCD matrix approach is that the Gaussian beam solution of the paraxial wave equation is separable in x and y, which means that independent complex beam parameters can be assumed in two orthogonal directions and that these can be transformed independently [27].

The ABCD matrix formalism lends itself to implementation in technical computing tools such as Matlab, making it ideal for fast and flexible design calculations. For this reason, ABCD matrix modeling has proven to be a useful framework for basic probe design and analysis [30, 15, 13, 16, 11] and as a simple tool for calculating approximate values for an optical design, which can then be experimentally optimized to yield the desired output beam characteristics. Furthermore, the possibility of working with astigmatic beams allows the study of the effects of astigmatism introduced by curved interfaces and to develop methods for its

compensation [31, 16, 11, 32, 17]. As an example of the usefulness of the ABCD method, we will show in Sect. 81.2.4.1 how it can be used to derive a simple method for astigmatism compensation in needle probes [11] which exploits the "focal shift" effect that occurs when focusing at low Fresnel numbers.

While the ABCD matrix simulation method is a very useful tool for probe design, one must be aware of its limitations. Firstly, the inability to model the effects of aberrations and aperture diffraction can cause it to yield incorrect or inaccurate results in many probe designs using GRIN fiber lenses because of beam distortion resulting from the finite core diameter and nonideal refractive index profiles [22]. Secondly, the ABCD matrix method is limited to probe designs that generate ideal Gaussian output beams, and therefore, it cannot be used to study advanced probe designs incorporating wavefront-shaping elements, such as phase masks or axicons, to generate non-Gaussian or Bessel-like focal regions with an extended DOF [21, 22]. In such cases, a more general wave-optic-based modeling technique such as the beam propagation method is required, as will be explained in the following subsection.

81.2.1.3 Advanced Numerical Modeling Using the Beam Propagation Method

The beam propagation method (BPM) [33] is a numerical technique for simulating wave propagation through inhomogeneous media. It has found widespread application in the simulation of beam propagation through atmospheric turbulence [34] and laser resonators [35], as well as in the analysis of waveguides, including GRIN fibers [36]. We have recently demonstrated its application to the accurate modeling and design of fiber-optic probes using GRIN fiber lenses [22], showing that the BPM can overcome the shortcomings of the ABCD matrix method. The BPM simulation results presented in [22] revealed a number of interesting insights about the aberrations introduced by the deviation of the refractive index profile of the GRIN fiber from the ideal parabolic shape, as well as highlighting the power of this technique for the simulation of advanced probe designs using GRIN phase masks to extend the DOF (see also Sect. 81.2.4.4). The BPM provides the probe designer with a very versatile toolbox covering a broad variety of optical elements. It allows the modeling of free-space propagation, arbitrary GRIN media, arbitrary phase or amplitude masks, and refractive surfaces [37, 21].

Our implementation of the BPM closely follows the one described in [36]. The starting point is the scalar Helmholtz equation in a weakly inhomogeneous medium with a spatially dependent refractive index $n\left(\vec{r}\right)$:

$$\left[\nabla^2 + k\left(\vec{r}\right)^2\right] E = 0, \tag{81.4}$$

where $k\left(\vec{r}\right) = n\left(\vec{r}\right) k_0$ and k_0 denotes the propagation constant in vacuum. In optical fibers, the refractive index variation is on the order of a few percent,

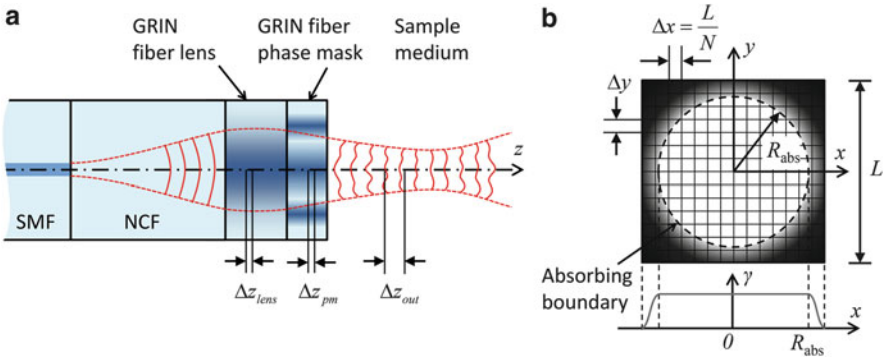

Fig. 81.3 (**a**) Schematic of the BPM simulation geometry for a fiber-optic probe. *SMF* single-mode fiber, *NCF* no-core fiber. (**b**) The $N \times N$ simulation grid with size L and with an absorbing boundary of radius R_{abs} (Figure adapted from [22])

and therefore, the refractive index can be expressed as $n\left(\vec{r}\right) = \overline{n} + \delta n(x, y)$, where $\overline{n}$ is a constant background refractive index (e.g., the index of the silica cladding) and $\delta n(x, y)$ is a small transverse index variation. The scalar field amplitude can be written as $E(x, y, z) = \tilde{u}(x, y, z)\exp\left(-i\overline{k}z\right)$, where $\overline{k} = \overline{n}k_0$ is the propagation constant in the background medium and $\tilde{u}(x, y, z)$ is a complex wave amplitude. For small axial step sizes Δz, an approximate solution to Eq. 81.4 can be written in operator notation:

$$\tilde{u}(x, y, z + \Delta z) \cong \exp\left(\hat{D}\Delta z\right)\exp\left(\tilde{N}\Delta z\right)\tilde{u}(x, y, z), \tag{81.5}$$

where $\hat{D}$ is the diffraction operator in a homogeneous medium with the background refractive index $\overline{n}$ and $\tilde{N}$ is an operator which accounts for the inhomogeneity of the refractive index. We can therefore approximate the propagation in the inhomogeneous medium as a repeated cycle of free-space propagation in a thin slice of homogeneous material of thickness Δz and multiplication of the wavefront with a phase screen $\exp\left(\hat{N}\Delta z\right) = \exp[-ik_0\delta n(x, y)\Delta z]$. For computational efficiency, the diffraction operator is applied in the spatial frequency domain. The simulation geometry is illustrated in Fig. 81.3a. The complex amplitude of the approximately Gaussian beam emitted by the SMF [29] is used as the input field to the BPM simulation, which begins at the NCF/GRIN interface. The field is then numerically propagated through the GRIN fiber lens, through the optional GRIN fiber phase mask, and into the sample medium with BPM step sizes Δz_{lens}, Δz_{pm}, and Δz_{out}, respectively. In the transverse dimensions, the field is sampled on a $N \times N$ Cartesian grid of size L. The criteria that govern the appropriate choice of step size Δz and transverse sampling intervals Δx, Δy are discussed in [22]. In order to prevent large-angle diffracted light from reaching the edges of the grid and causing artifacts in the FFT, we apply an "absorbing boundary" (a two-dimensional (2D) window function) to the field amplitude in the spatial domain at every BPM step as illustrated in Fig. 81.3b.

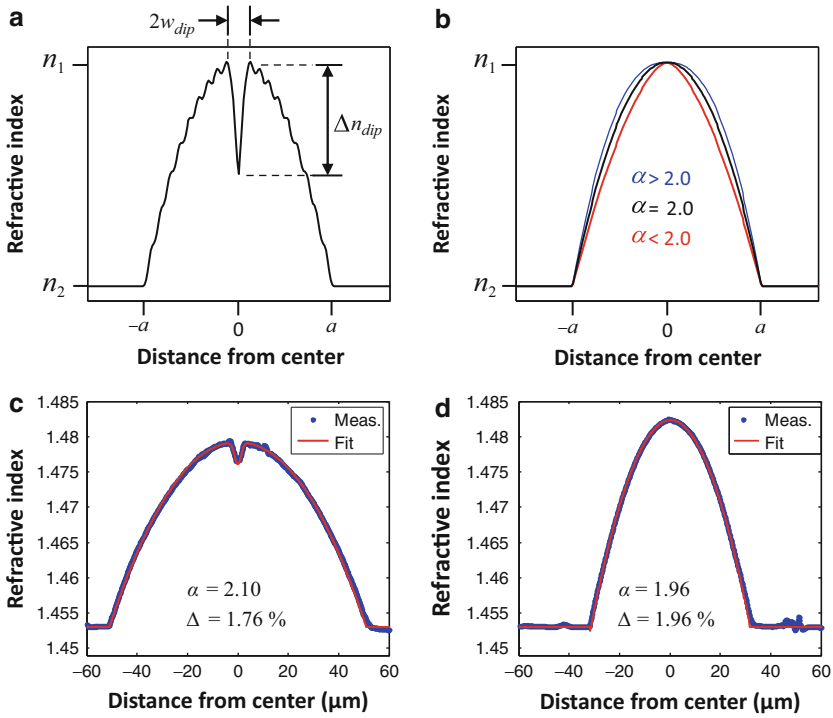

Fig. 81.4 (**a**) Power-law refractive index profile with central dip and ripple. (**b**) Effect of the power-law exponent α on the profile shape. (**c**, **d**) Measured index profiles and power-law fits of commercial GRIN multimode fibers (the cladding index n_2 is set to the refractive index $n = 1.453$ of pure silica at 800 nm). (**c**) 100-μm core-diameter GRIN MMF (100/140 MMF, POFC, Taiwan). (**d**) 62.5-μm core-diameter GRIN MMF (GIF625, Thorlabs, USA) (Figure adapted from [22])

One of the main motivations for using the BPM to simulate fiber-optic probes is that it allows the modeling of realistic GRIN fiber lenses [22]. While the ABCD matrix of a GRIN lens is a highly idealized model representing a perfect square-law medium of infinite transverse extent, the refractive index profiles of real GRIN fibers differ from this ideal in a number of ways, as illustrated in Fig. 81.4a. Firstly, the profile is never a perfect parabola, but it is described by a power-law profile that is truncated at the core radius a of the multimode fiber (MMF):

$$n(r) = \begin{cases} n_1\left[1 - 2\Delta\left(\frac{r}{a}\right)^{\alpha}\right]^{1/2} & r < a \\ n_2 = n_1(1 - 2\Delta)^{1/2} & r \geq a \end{cases} \tag{81.6}$$

where $\Delta = (n_1^2 - n_2^2)/2n_1^2$ is the relative index difference between the core and cladding refractive indices n_1 and n_2 (for small index differences, $\Delta \cong \Delta n/n_1$, where $\Delta n = n_1 - n_2$). The influence of the power-law exponent α on the profile shape is indicated in Fig. 81.4b. Secondly, the profiles of GRIN fibers fabricated using the

modified chemical vapor deposition (MCVD) method exhibit a characteristic central index dip as well as ripples, where the dip results from "burn-off" of dopant during the high-temperature collapse of the preform, and the ripples result from the deposition of a finite number of layers of changing composition in order to approximate the desired power-law shape [38]. Improved preform fabrication methods [14, 39] have led to a new generation of high-bandwidth GRIN MMFs with smooth refractive index profiles which are free of the central index dip that plagues legacy GRIN MMFs. However, these modern high-bandwidth GRIN MMFs are only available with small core diameters of 50 and 62.5 μm, limiting their use to probe designs with relatively low numerical aperture (NA) and short working distance (WD). Furthermore, their index profiles tend to exhibit a more or less pronounced deviation from the ideal parabolic shape that is purposely introduced by the manufacturer in order to minimize pulse broadening in the targeted operating wavelength band [40–42]. Thus, large core-diameter fibers drawn from preforms of such high-bandwidth GRIN MMFs [14] will not necessarily behave as ideal GRIN lenses.

Two example index profiles of commercial GRIN fibers together with their best-fit power-law profiles are shown in Fig. 81.4c and d. Figure 81.4c shows a 100-μm-core-diameter GRIN MMF (100/140 MMF, POFC, Taiwan) which was profiled on an EXFO NR-9200 fiber analyzer at a wavelength of 655 nm. The fiber has an α parameter of 2.1 and a central index dip. We have observed that fiber probes made using this GRIN fiber exhibit significant beam distortions that can be reproduced in BPM simulations [22]. Figure 81.4d shows a 62.5-μm-core-diameter GRIN MMF (GIF625, Thorlabs, USA) which we have used extensively in recent work [16, 11, 43, 32] because probes fabricated using this fiber have exhibited very good Gaussian-like beam quality and shown fairly good agreement with ABCD matrix calculations. This observation is not surprising when one considers the index profile (data provided by Thorlabs), which has a near-parabolic shape with an α parameter of 1.96 and no measurable dip in the center.

A deviation of the refractive index profile from the ideal parabolic shape in a GRIN lens is equivalent to spherical aberration (SA) in a refractive lens, with $\alpha > 2$ producing positive SA and $\alpha < 2$ producing negative SA [22]. This can be seen in Figs. 81.5a and b, which show BPM simulation results of lensed fibers with power-law GRIN profiles that have α parameters of 2.15 and 1.85, respectively (these values are representative of the maximum deviations from the ideal which one may encounter in real GRIN MMFs). The simulated probes consist of SMF with a mode-field diameter of 5 μm at an operating wavelength of 800 nm, with a 275-μm-long section of NCF and a 280-μm-long section of GRIN MMF with a core diameter of 100 μm, $\Delta = 2$ %, and cladding index $n_2 = 1.453$. For an aberration-free GRIN fiber with $\alpha = 2.0$ (or a gradient parameter $g \cong \sqrt{2\Delta/a} = 4\text{mm}^{-1}$), an ABCD matrix simulation yields an ideal Gaussian output beam with a working distance of 390 μm and a $1/e^2$ focal spot diameter of 8.5 μm (FWHM diameter of 5 μm), which is shown for comparison by the dotted curves in the plots of Figs. 81.5a and b (bottom). When the α-parameter of the index profile is "de-tuned" to a value of 2.15 (causing a deformation of the profile shape which is just barely noticeable compared to the ideal

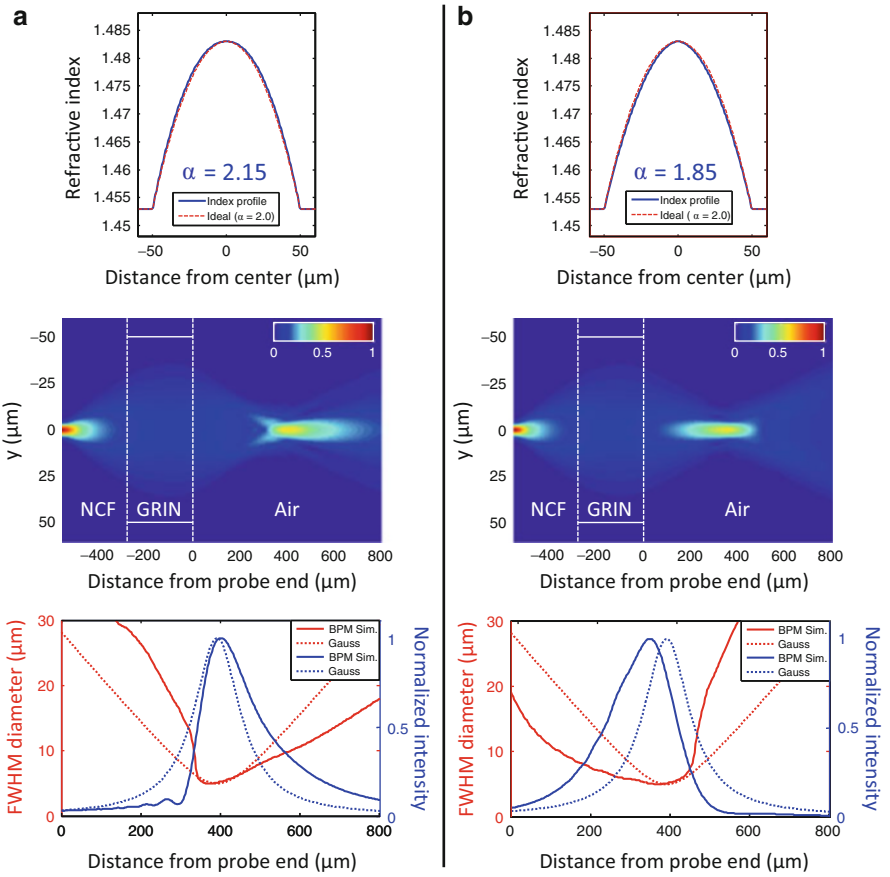

Fig. 81.5 BPM simulation results of lensed fiber probes using GRIN fiber lenses that have nonparabolic refractive index profiles with α parameters of 2.15 (**a**) and 1.85 (**b**). *Top*: refractive index profile of the GRIN fiber compared to an ideal parabolic profile with $\alpha = 2.0$. *Middle*: simulated E-field amplitude in the entire simulated region. *Bottom*: FWHM beam diameter and on-axis intensity of the simulated output beam (*solid lines*) compared to the ideal Gaussian beam that would result in the case of a parabolic profile (*dotted lines*) (Figure adapted from Ref. [22])

parabolic curve in Fig. 81.5a (top)), the focal region takes on an asymmetric shape characteristic of spherical aberration. The focal spot intensity is reduced with a Strehl ratio of $S = 0.77$, while the DOF remains approximately the same as in the aberration-free case. When the α parameter is de-tuned to 1.85, however, the output beam DOF is increased by a factor 1.44 at the cost of only a very slightly reduced Strehl ratio of $S = 0.96$, showing that GRIN profiles with $\alpha < 2.0$ can potentially be used to enhance the DOF of fiber probes.

Using the BPM, we have also investigated the effects of the central index dip and index ripple on the output beam [22]. The results indicate that the detrimental

effects of such anomalies in the index profile are not as serious as one might expect. This can be understood when one recognizes that the dip and the index ripple are aberrations with high spatial frequencies that generate large-angle diffracted waves which, for parameters that are representative of realistic index profiles, carry only a small percentage of the incident beam power and rapidly lose intensity as they propagate away from the probe end due to their strong divergence. By contrast, the majority of the incident beam power remains in an essentially unperturbed component of the wavefront which converges normally to form an almost unaltered focal region with only a minor reduction in Strehl ratio and no significant change in DOF. This is in stark contrast to index profile aberrations with low spatial frequencies, such as nonideal α parameters or systematic deviations from the power-law model, which will have a strong influence on the intensity distribution in the focal region even for very small index profile errors on the order of a few percent [22]. This finding is important for specifying the fabrication tolerances of customized preforms for high-quality GRIN fiber lenses.

Our results show that the BPM enables accurate simulation of fiber probes using a realistic model of the refractive index profile of the GRIN fiber, which is important in the design of high-performance miniaturized fiber-optic probes for OCT. Furthermore, in Sect. 81.2.4.4, we will demonstrate the use of the BPM for studying schemes for extending the DOF of miniaturized fiber probes using GRIN fiber phase masks.

81.2.2 Scan Mechanisms

OCT *imaging*, in the sense that 2D or 3D structural information is obtained, is only possible if the probe beam can be scanned within the sample. In the following, we will give a categorization of scanning probes, based on mechanical and optical principles, which is independent of the technical details of the scan mechanism implementation. This categorization will allow us to gain some insight into the advantages and disadvantages of different classes of currently employed scan mechanisms, and it is general enough to accommodate future developments.

Firstly, probes can be categorized into forward-facing and side-facing types (see Fig. 81.6). Generally, the requirements of the application dictate which of these two is preferable.

Furthermore, probes can be categorized according to their scan mechanisms. There are two main categories of scan mechanisms: beam scanning and probe scanning. The two categories and some of their variations are illustrated in Fig. 81.7. Beam scanning involves a movement of the beam path inside the probe housing, allowing the probe to remain stationary during the scan. Probe scanning, on the other hand, mechanically actuates the entire probe (or a mechanical subcomponent thereof which defines the emitting beam aperture), while the beam path inside the probe is unchanged. Beam scanning probes are more challenging to miniaturize, as they usually require moving parts inside the probe housing. For this reason, probes with submillimeter dimensions generally utilize probe scanning.

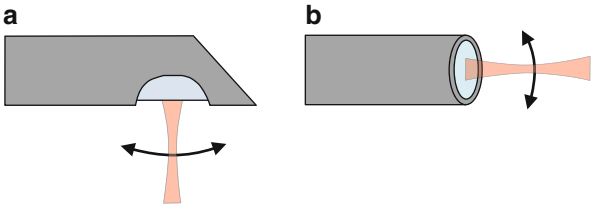

Fig. 81.6 Side-facing (**a**) and forward-facing (**b**) probes. The indicated beam scanning motions in (**a**) and (**b**) are just examples, and a variety of other possibilities exist in both cases

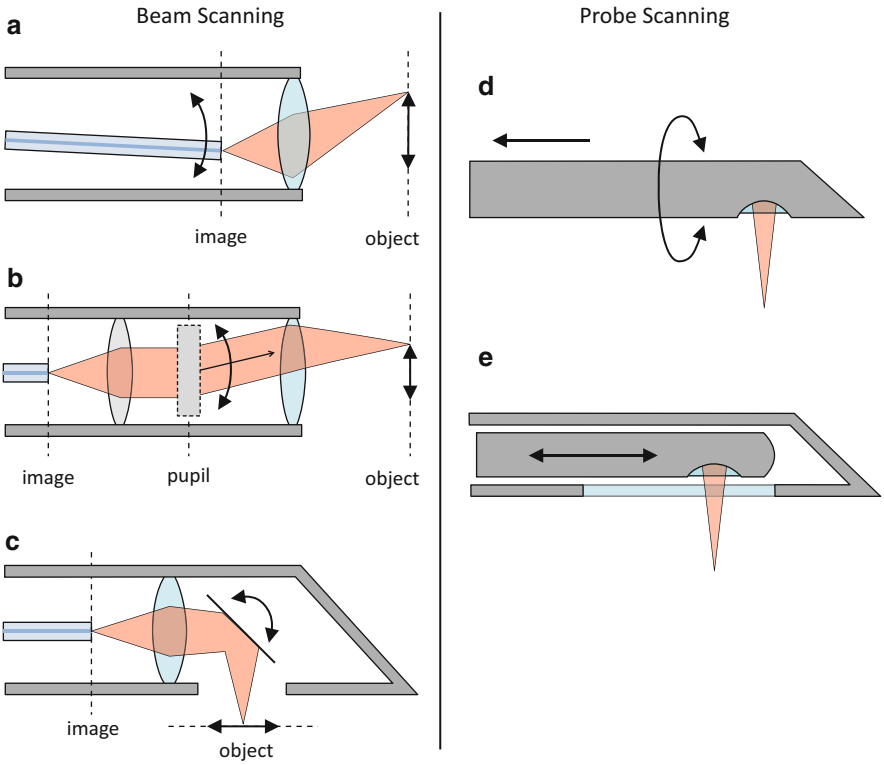

Fig. 81.7 Overview of some basic scan mechanisms, categorized into "beam scanning" and "probe scanning". (**a**) Image-space scanning (using an oscillating fiber tip in this example). (**b**) Pupil scanning. The *dashed grey rectangle* represents a beam deflection mechanism, which can be implemented using various technologies – see text for practical examples. (**c**) Object-space scanning. (**d**) Rotation/pullback scanning. (**e**) Linear-scanning probe inside an outer housing

In beam scanning, the moving beam is projected out of the probe housing into the sample by the probe optics. The probe optics form an imaging system which images scattered light from the sample (the object) onto the sample-arm fiber tip (the image). Using terminology from imaging optics, we can further subdivide beam scanning techniques as "image-space scanning" (Fig. 81.7a), "pupil scanning" (Fig. 81.7b), or "object-space scanning" (Fig. 81.7c). Although Fig. 81.7a, b

shows forward-facing configurations for pupil and image-space scanning, they can in principle also be realized as side-facing types by adding mirrors or prisms to deflect the beam outward at a chosen angle.

Image-space scanning (Fig. 81.7a) can be performed by actuating the tip of the sample-arm fiber. The probe beam focal spot is thereby scanned in the sample over a range, which is determined by the magnification of the probe optics. The concept of image-space scanning has been implemented in endoscopic probe designs using oscillating fiber tips [44], but the miniaturization of these designs to submillimeter diameters has proven to be challenging. Small-diameter forward-facing OCT probes of this type have been reported with outer diameters (ODs) of 2.4 and 2.2 mm using tubular four-quadrant piezoelectric actuators [45] and electrostatic actuators [46], respectively.

Pupil scanning (Fig. 81.7b) involves an angular deflection of the collimated beam in the pupil plane of the imaging optics. This is the principle of conventional beam scanning solutions based on galvanometer mirrors, which are positioned in the back focal plane of the scan lens. Beam deflection mechanisms for pupil-scanning probes have been realized with MEMS mirrors [47] and with counterrotating wedged GRIN lens pairs (paired-angle-rotation scanning, PARS [48]). In pupil-scanning arrangements, MEMS mirror solutions require a folded beam path geometry, resulting in relatively large probe diameters of several millimeters. However, PARS probes have been miniaturized to needle dimensions as small as 21 gauge (21G, OD 0.82 mm) in a forward-facing configuration [7].

Object-space scanning (Fig. 81.7c) sacrifices some of the working distance of the probe optics, but is often used in side-facing miniaturized MEMS mirror probes [49, 50] because the MEMS mirror can conveniently serve as the output beam deflector, which directs the beam sideways out of the probe. Although probes of this type with diameters down to 2.6 mm have been demonstrated [50], MEMS technology does not yet seem to allow miniaturization to submillimeter dimensions at the time of writing and is, therefore, mainly targeted toward endoscopic OCT applications.

An elegant variation of beam scanning involves the use of long and thin GRIN relay rods, which can be inserted into hypodermic needles. By scanning the incident light at the proximal end face of the GRIN relay rod, the relayed and focused beam is scanned in object space at the distal end of the relay. The key advantage of this approach is that the scan mechanism does not need to be miniaturized to the diameter of the needle and can be relocated into a larger-diameter housing to which the needle is attached. Submillimeter diameter needle probes of this kind have been demonstrated for multiphoton and confocal endomicroscopy [51, 52] and OCT [53]. In these needle probes, the GRIN relay rod is an integral part of the distal focusing optics. Depending on the scanning mechanism at the proximal end face of the relay (e.g., by scanning the sample-arm fiber tip [52] or scanning an image of it using a galvanometer mirror and objective lens [53]), they can be classified as either image-space or pupil-scanning types, respectively.

In order to achieve the highest possible degree of miniaturization, probe-scanning techniques (Fig. 81.7d, e) must be used, with the smallest reported probe of this kind

being encased in a 30G needle (0.31 mm OD) [16]. Probe-scanning designs must be side facing in order to enable at least 2D scanning capability. The most widespread approach is the rotation/pullback method of Fig. 81.7d, where B-scans are acquired over one probe rotation and then stacked along the translation direction to generate a 3D image in a similar fashion to endoscopy [20]. An alternative is to perform a fast translation along the probe axis to acquire a 2D image, as illustrated in Fig. 81.7e, and needle probes of this design have been employed in applications that require a fast 2D scan in a plane parallel to the needle axis, such as dynamic imaging of alveoli [5] and Doppler imaging [12, 54].

An interesting new development in the area of probe scanning is to use freehand motion to scan over a region of interest [55, 8, 56]. This approach can be combined with methods to correct for the resulting nonuniformity of the scan motion as well as the misalignment of adjacent A-lines in the OCT image data, either by using feedback control to actively compensate the probe position during the scan [55] or by post-processing of the OCT image data in combination with location data from a position sensor [56].

81.2.3 A Review of Published Needle Probe Designs

In the following subsections, we will give an overview of the technical evolution of OCT needle probes that are capable of acquiring 2D or 3D images via some form of scanning, as described in Sect. 81.2.2. The term "imaging needle," which was coined in [2], is useful because it differentiates such scanning needle designs from "point-sensing" fiber probes that are integrated into needles, typically in a forward-facing configuration. Point-sensing needles measure 1D structural information from A-scans acquired at a stationary position or during needle advancement, and a number of examples have been reported. Sequences of A-scans (M-mode) acquired during needle advancement can be displayed as 2D arrays of depth versus time that allow the successive penetration of tissue layers to be visualized [57] (see also Sect. 81.3.1.2). Alternatively, the relative displacement of scatterers in consecutive A-scans can be analyzed in order to determine the mechanical properties of soft tissue that lies ahead of the needle [58]. Processing of single A-scans acquired with point-sensing needles has been used to obtain localized tissue parameters such as the refractive index [59, 60] or attenuation coefficient [4]. An exhaustive discussion of the technology and applications of point-sensing needles lies outside the scope of this section, and we will, therefore, focus our attention on imaging needles.

81.2.3.1 Side-Facing Rotation/Pullback Imaging Needles

The first demonstrated OCT imaging needle probe [2] was a side-facing design for 2D rotation scanning (see Fig. 81.8a). Even though the distal focusing optics used discrete micro-optical components (a 250-μm diameter GRIN lens and a micro-mirror), it already achieved very compact dimensions with an OD of only 0.41 mm (27G). The use of discrete micro-optics introduces challenges related to precision alignment of components inside the needle shaft, and it requires angled or

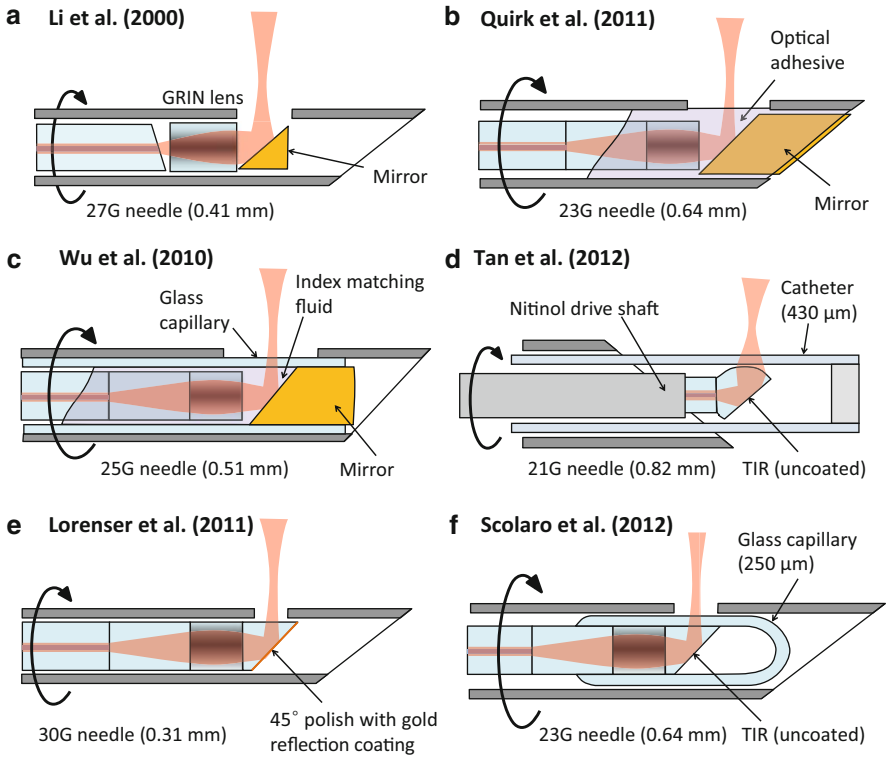

Fig. 81.8 Side-facing needle designs for rotation/pullback scanning. (**a**) The first demonstrated OCT imaging needle probe [2]. (**b**) The first needle probe to generate full 3D OCT data sets using rotation/pullback scanning [61]. (**c**) A capillary-encased design with a robust optical-quality output window that can be flat polished for elimination of astigmatism [17]. (**d**) A catheter-based needle probe for biopsy guidance in lungs [6]. (**e**) The smallest demonstrated OCT imaging needle probe [16]. (**f**) A fully fused capillary-encased needle design capillary-encased needle design with an astigmatism-free output beam and with the highest reported sensitivity [11]

antireflection-coated interfaces in order to avoid backreflections which can introduce image artifacts and reduce the sensitivity. For this reason, many subsequent probe designs were based on "monolithic" all-fiber distal focusing optics using fusion-spliced GRIN fiber lenses or fused ball lenses. The great advantage of such all-fiber probe designs is that they can be fabricated using established fusion splicing technology, which is reproducible and self-aligning. Furthermore, the fusion-spliced optics assembly practically eliminates backreflections from optical interfaces.

Figure 81.8b shows an example of such a design, which was the first OCT needle probe to demonstrate full 3D imaging using combined rotation and pullback [61]. A 23G (0.64 mm OD) side-facing probe was made using a GRIN-lensed fiber which

was embedded together with a side-deflecting mirror in UV-curing optical adhesive. Due to the relatively high refractive index contrast between the GRIN fiber end face and the optical adhesive, this interface can be conveniently employed as the reference reflector in a common-path OCT configuration, as was done in Refs. [61, 3, 43]. A drawback of this design is the lack of mechanical robustness of the optical adhesive surface that forms the interface with the sample medium. Mechanical and chemical wear can degrade the optical quality of this interface, leading to deterioration in the sensitivity and beam quality after prolonged use. Furthermore, the shape of the optical adhesive surface cannot be exactly controlled, leading to some distortion and astigmatism in the output beam [43]. An improved needle probe design with an OD of 0.51 mm (25G) using a flat-polished capillary output window has been demonstrated to address this problem [17] (see Fig. 81.8c). By using index-matching fluid inside the capillary, it was shown that the astigmatism could be almost completely eliminated in this design, and the glass capillary provides a robust optical-quality output window interface, at the cost of a more complex fabrication and assembly process.

An example of an all-fiber probe using a fused ball lens is shown in Fig. 81.8d [6]. This 21G (0.82-mm OD) design uses a polyimide catheter to encase the fiber probe, in order to maintain the refractive power of the ball lens in air and to serve as a protective sheath that allows rotation/pullback scanning of the probe while keeping the needle and catheter stationary. The astigmatism which is introduced by the catheter was partially compensated by the shape of the ball lens, which has different radii of curvature in the sagittal and tangential planes.

Ultrathin needle probes with a diameter of only 0.31 mm (30G) were presented in [16] and [32]. These probes use an all-fiber distal optics design that was initially proposed in a patent covering a variety of ultrathin fiber probes for endoscopy [62], where an angle-polished NCF section that is added after the GRIN lens section is used as the side-deflecting mirror as shown in Fig. 81.8e. The angle-polished probe tip is coated with gold in order to maintain its reflectivity under immersion in fluids. A drawback of this probe design is the astigmatism which the beam acquires as it exits from the side of the fiber cladding, which behaves as a cylindrical lens. However, it was shown in [16] and [32] that the astigmatism is reduced to a tolerable level under the near-index-matched conditions existing when the probe is inserted into tissue. This probe design and some of its recent improvements will be presented in more detail in Sect. 81.2.4.2. A needle-like catheter probe incorporating a similar angle-polished GRIN-lensed fiber was presented in [9] for imaging of brain tissue. The 360-μm OD catheter was delivered via a 24G (0.57-mm OD) needle, and the astigmatism of the probe was compensated using index-matching fluid inside the catheter.

An advanced 23G (0.64-mm OD) needle probe design which uses an angle-polished fiber under total internal reflection (TIR) is shown in Fig. 81.8f [11]. The TIR is maintained under fluid immersion by encasing the angle-polished fiber probe inside a microcapillary which is collapsed and fused onto the fiber. The capillary acts as a robust, well-defined optical window, and its astigmatism is compensated

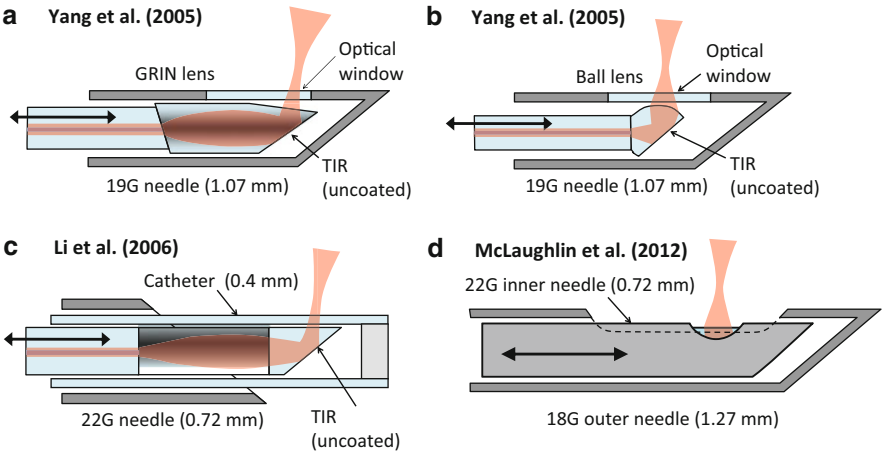

Fig. 81.9 Side-facing linear-scanning needle designs. (**a**, **b**) Early designs employed in the first demonstration of needle-based Doppler imaging [12]. (**c**) Advanced catheter-based design for needle-based Doppler imaging [54]. (**d**) Linear-scanning needle for dynamic lung imaging [5]

using a novel optical design that exploits the focal shift effect [11]. This design achieved the highest reported sensitivity for an OCT needle probe (112 dB) and will be discussed in more detail in Sect. 81.2.4.1.

81.2.3.2 Side-Facing Linear-Scanning Imaging Needles

In contrast to rotation/pullback scanning which combines a fast rotation with a slow linear motion in order to acquire a 3D cylindrical volume, linear-scanning needle probes perform a rapid linear motion along the needle axis in order to generate fast 2D image frames. This can be advantageous for applications where a fast update rate of a large rectangular 2D field of view (FOV) is desirable.

The first linear-scanning OCT needle probes were developed for Doppler imaging and are shown in Fig. 81.9a, b [12]. Two versions were demonstrated, one with an angle-polished GRIN lens and one with an angle-polished ball lens. In both cases, TIR at the angle-polished interface was ensured by sealing the side opening in the 19G (1.1-mm OD) needle with a flat plastic window. These probes allowed imaging at a rate of 1–2 Hz over a linear scan range of ~2.5 mm. In a later version [54], the dimensions of the probe were reduced by using all-fiber probe optics consisting of GRIN fiber and an angle-polished NCF tip section that were enclosed in a protective catheter that was delivered via a 22G (0.72-mm OD) needle as illustrated in Fig. 81.9c.

Another application which requires a fast 2D frame rate over a large FOV is dynamic imaging of lungs, where a 1.27-mm OD (18-G) linear-scanning needle probe was demonstrated [5] (see Fig. 81.9d and also Sect. 81.4.2.3). An inner side-facing needle probe with a similar design to the one shown in Fig. 81.8b was actuated inside the outer 18G needle at a rate of 3 Hz over a linear scan range of ~12 mm.

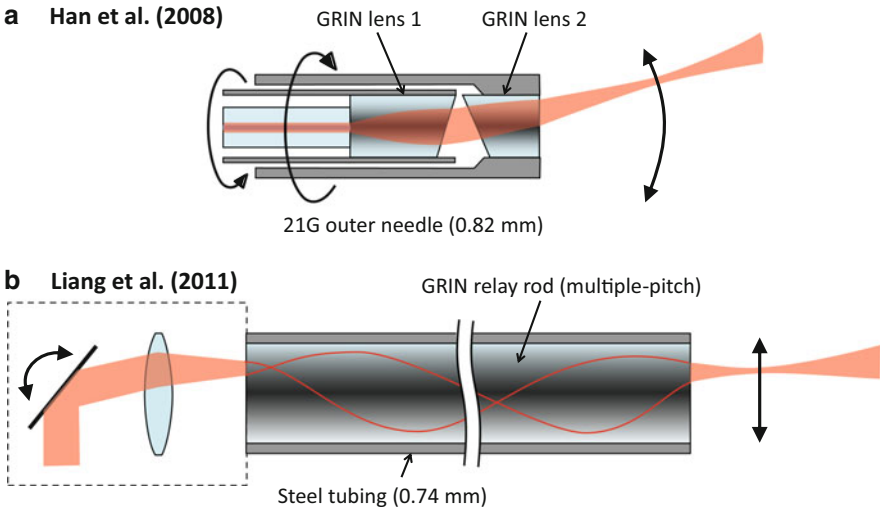

Fig. 81.10 Forward-facing needle probe designs. (**a**) Paired-angle-rotation scanning (*PARS*) needle [7]. (**b**) A design based on a GRIN relay rod, employing proximal scanning via galvanometer mirrors housed in a handpiece (*dashed rectangle*) [53]

81.2.3.3 Forward-Facing Imaging Needles

The mechanical requirements of a sharp needle tip for easy tissue penetration are not straightforward to combine with the optical requirements of a forward-facing imaging system. For this reason, forward-facing imaging needle probes are typically only used for special applications where a blunt front end is acceptable or even desirable.

A forward-facing OCT needle probe concept called paired-angle-rotation scanning (PARS) [48, 7] has been developed for aiding specialized surgical procedures in the eye. As illustrated in Fig. 81.10a, two angled GRIN lenses are mounted in an inner and an outer needle that rotate in opposite directions, causing the output beam to perform a fanlike sweep back and forth on a line trajectory ahead of the needle. The smallest demonstrated probe of this type had an OD of 0.82 mm (21G) [7].

Another application which requires needlelike forward-facing OCT probes is interventional guidance in neurosurgery. Figure 81.10b shows a 0.74-mm OD (slightly larger than 22G) forward-facing needle incorporating a 0.5-mm-diameter, 12-cm-long GRIN relay rod that was proposed for this application [53]. The input beam to the GRIN relay rod was scanned using galvanometer mirrors that were incorporated into a prototype handpiece attached to the needle. The FOV of this probe was a circular region of 0.44-mm diameter, limited by the diameter of the GRIN relay rod. As an alternative to this approach, somewhat larger, forward-facing needle-like probes with outer diameters of ~2 mm have been developed that employ an electrostatically actuated oscillating fiber tip inside the needle shaft [46, 10].

81.2.4 Advanced Needle Probe Designs

81.2.4.1 High-Sensitivity Anastigmatic Imaging Needles

OCT needle imaging systems must achieve optical performance comparable to high-end benchtop systems in order to deliver the image quality that is required for clinical applications. The main source of degraded performance in current side-facing OCT needle probes lies in the optics required for deflecting the beam perpendicular to the needle axis, as they tend to introduce losses and beam distortion. We have recently presented a high-optical-quality OCT needle probe that achieves sensitivity and resolution comparable to conventional free-space OCT sample arms [11]. The probe achieves very low optical losses by utilizing total internal reflection (TIR) from an angle-polished fiber tip, encased in a glass microcapillary, as shown in Figs. 81.11a and b. Fusion of the capillary to the fiber provides a robust, optical-quality output window that minimizes beam distortion. Furthermore, the probe features a novel anastigmatic design, which exploits the "focal shift" phenomenon for focused Gaussian beams to achieve equal working distances (WDs) for both axes.

The anastigmatic design concept can be conveniently analyzed using ABCD matrices [27]. As was outlined in Sect. 81.2.1.2, the Gaussian beams transformed using this formalism are exact wave-optic solutions in the paraxial regime and, therefore, intrinsically exhibit the focal shift which is observed when focusing at low Fresnel numbers [63, 27]. Consider a side-facing probe with a cylindrical output window with radius R as shown in Fig. 81.12a. The refractive indices of the cylindrical output window and the sample are n_1 and n_2, respectively. When the initially circularly symmetric beam is deflected sideways out of the probe, its symmetry is broken by the cylindrical interface with refractive power $\Phi = (n_2 - n_1)/R$ that acts only in the x-axis (we use a sign convention where the radius R is negative for a concave surface, yielding a positive refractive power for $n_2 < n_1$). The output beam therefore becomes astigmatic, with WDs and focal spot diameters that will generally be different in the x- and y-axes, as illustrated in Fig. 81.12a. Directly after the cylindrical interface, the complex output beam parameter [27] in the y-direction is equal to

$$\tilde{q}_{2y} = -WD_y + iz_{Ry}, \tag{81.7}$$

where the minus sign is included to account for the fact that the working distance is a positive number. Inside the probe, directly at the input to the cylindrical interface, the complex beam parameter of the circularly symmetric beam is $\tilde{q}_1 = (n_1/n_2)\tilde{q}_{2y}$. The beam parameter of the output beam in the x-direction is obtained by transforming this beam with the ABCD matrix of the curved interface:

$$\tilde{q}_{2x} = \frac{\tilde{q}_1}{-\frac{\Phi}{n_2}\tilde{q}_1 + \frac{n_1}{n_2}} = \frac{\tilde{q}_{2y}}{-\frac{\Phi}{n_2}\tilde{q}_{2y} + 1}. \tag{81.8}$$

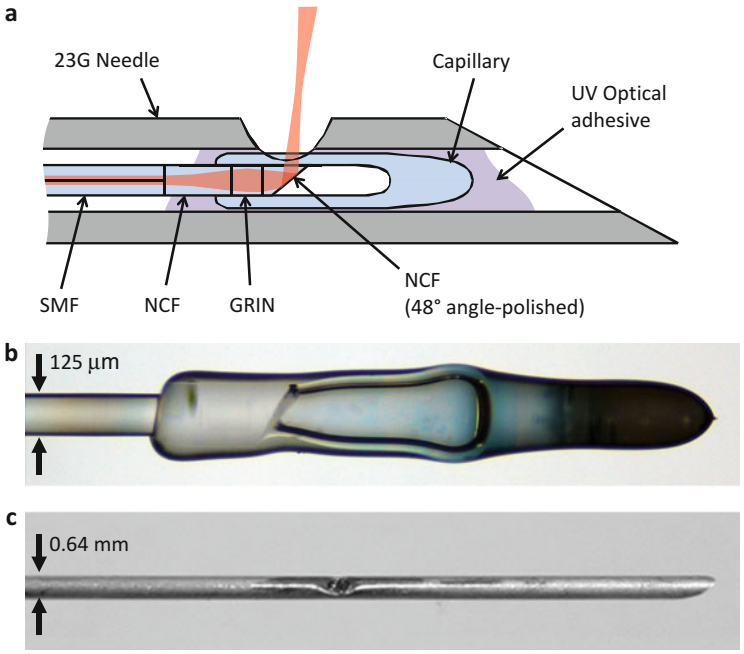

Fig. 81.11 (**a**) Schematic of the anastigmatic TIR imaging needle design. (**b**) Bright-field image of the angle-polished fiber probe encased in a fused glass microcapillary. (**c**) Photo of the fully assembled side-viewing 23G needle (Figure adapted from Ref. [11])

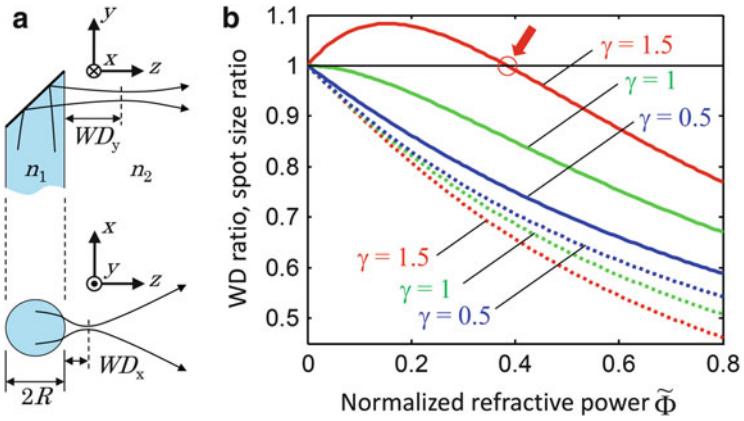

Fig. 81.12 (**a**) Schematic of a side-viewing probe with astigmatism resulting from the curved output window interface. n_1, n_2, refractive indices of output window and sample, respectively; WD_x, WD_y: WD in x and y, respectively; and R, radius of curvature of the output interface. (**b**) Curves illustrating the WD ratio and spot size ratio as a function of the normalized refractive power, obtained by evaluating Eqs. 81.10 and 81.11 for different values of γ. *Solid curves*, WD ratio; *dotted curves*, spot size ratio. The *arrow* indicates the anastigmatic point (Figure adapted from Ref. [11])

If we introduce the dimensionless variables $\widetilde{\Phi} = WD_y\Phi/n_2$ and $\gamma = z_{Ry}/WD_y$, we can write the right-hand side of Eq. 81.8 as

$$\tilde{q}_{2x} = \frac{-WD_y}{\left(1+\widetilde{\Phi}\right)^2 + \gamma^2\widetilde{\Phi}^2}\left[\widetilde{\Phi}\left(1+\gamma^2\right) + 1 - i\gamma\right]. \tag{81.9}$$

After comparing the real and imaginary parts with $\tilde{q}_{2x} = -WD_x + iz_{Rx}$, one obtains the following two dimensionless expressions for the ratios of the WDs and spot sizes in the x- and y-directions [11]:

$$\frac{WD_x}{WD_y} = \frac{1 + (1+\gamma^2)\widetilde{\Phi}}{\left(1+\widetilde{\Phi}\right)^2 + \gamma^2\widetilde{\Phi}^2} \tag{81.10}$$

$$\frac{w_{0x}}{w_{0y}} = \frac{1}{\sqrt{\left(1+\widetilde{\Phi}\right)^2 + \gamma^2\widetilde{\Phi}^2}}. \tag{81.11}$$

The two ratios given by Eqs. 81.10 and 81.11 are plotted in Fig. 81.12b as a function of the normalized refractive power $\widetilde{\Phi}$ for different values of the parameter γ. The curves in Fig. 81.12b can be interpreted as the result of a thought experiment in which a Gaussian beam is transmitted through an initially planar interface between media with the refractive indices n_1 and n_2, coming to a focus with Rayleigh range z_{Ry} at a working distance WD_y (thereby determining the parameter γ). One can then imagine increasing the normalized refractive power $\widetilde{\Phi}$ by "bending" the interface in the x-direction. While the y-direction is unaffected, the WD and focal spot radius of the x-direction begin to deviate from WD_y and w_{0y} with increasing refractive power. For beams with $\gamma > 1$, the WD of the x-direction initially increases and then decreases again, going through an anastigmatic point where the WDs of the two axes are equal (red arrow in Fig. 81.12b).

This seemingly counterintuitive focusing behavior of Gaussian beams within the Rayleigh range is a manifestation of the focal shift effect (the shift between the wave-optic and geometric-optic foci) that occurs at low Fresnel numbers [63]. For a given normalized refractive power $\widetilde{\Phi}$, the optimum γ can be found by setting $WD_x/WD_y = 1$ in Eq. 81.10, yielding

$$\gamma_{opt} = \sqrt{\frac{1+\widetilde{\Phi}}{1-\widetilde{\Phi}}}. \tag{81.12}$$

One can see from Eq. 81.12 that anastigmatic solutions are only possible for $\widetilde{\Phi} < 1$. We can therefore summarize that, for a cylindrical interface with a fixed refractive power Φ, anastigmatic solutions exist under two conditions:

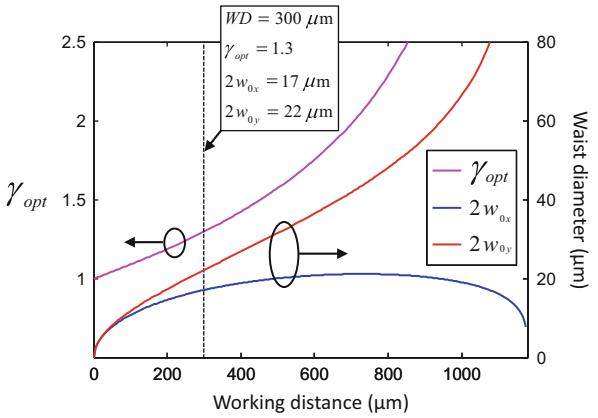

Fig. 81.13 Accessible output beam parameters within the constraints of the anastigmatic solution for a curved interface between a 250-μm-diameter borosilicate glass capillary and water at a wavelength of 1300 nm. The optimum γ parameter that corresponds to the anastigmatic solution is shown by the *magenta curve* (*left axis*). The *red* and *blue curves* show the $1/e^2$ waist diameters of the elliptical focal spot (*right axis*). The *dashed vertical line* indicates the design goal for the anastigmatic TIR needle discussed in the text

- The working distance WD_y of the axis that is unaffected by the cylindrical interface must be smaller than its Rayleigh range z_{Ry}. (This is the condition $\gamma > 1$.)
- The working distance WD_y must be smaller than $WD_{y,\max} = n_2/\Phi$. (This is the condition $\widetilde{\Phi} < 1$.)

We will illustrate the anastigmatic design concept with a numerical example that will lead us to our chosen design for the anastigmatic TIR needle. The starting point was the requirement that the $1/e^2$ focal spot diameter of the probe should be close to 20 μm, which corresponds to an FWHM transverse resolution of 12 μm that is commensurate with the axial resolution of our 1300-nm swept-source (SS) OCT system. Our capillary-encased TIR needle uses a 250-μm-diameter borosilicate microcapillary with a refractive index of $n_1 = 1.46$, and our sample medium is water with $n_2 = 1.32$ at the operating wavelength of 1300 nm. The refractive power Φ is, therefore, 1,120 m^{-1}. The Rayleigh range in water for a 20-μm focal spot diameter is 320 μm. In order to fulfill the requirement $\gamma > 1$ for our desired focal spot diameter, we will aim for a WD of 300 μm, which translates to a normalized refractive power $\widetilde{\Phi}$ of 0.25. From Eq. 81.12, we calculate $\gamma_{opt} = 1.3$, which means that our focal spot diameter in the *y*-direction must be adjusted to 22 μm in order to obtain the anastigmatic solution for the given refractive power and desired working distance of 300 μm. The focal spot is slightly elliptical, with a diameter of 17 μm in the *x*-axis (obtained via Eq. 81.11). Anastigmatic solutions with longer working distances can be obtained at the cost of a stronger ellipticity of the focal spot, as illustrated in Fig. 81.13, which shows the accessible beam parameters as a function of the WD. The dashed vertical line indicates our design goal with a WD of 300 μm.

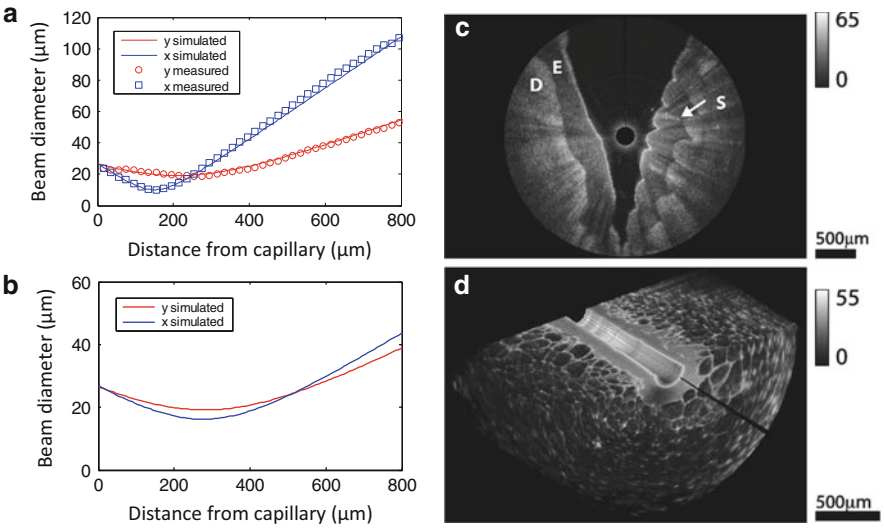

Fig. 81.14 Beam profile characterization and OCT images obtained with the anastigmatic TIR needle probe. (**a**) Measured and simulated beam profiles in air. (**b**) Simulated beam profile in water. (**c**) Radial OCT needle image of the surface of a finger and thumb. *E* epidermis, *D* dermis, *S* sweat duct. (**d**) Cutaway view of a rendered 3D OCT needle image of a cucumber. The needle tract is visible at the center of the volume with its rotation origin marked by the wedge at *lower right*. Colormaps in (**c**) and (**d**) are in dB (Figure adapted from Ref. [11])

Our fabricated anastigmatic TIR needle probe used the above calculation as a guide, and the desired output beam parameters were obtained by iterative optimization of the lengths of the NCF and GRIN fiber sections. As explained in [11], the precise calculation of the anastigmatic solution in our TIR needle is slightly more complex as the refractive index mismatch between the silica fiber claddings ($n = 1.447$), and the borosilicate capillary creates a second (but much weaker) cylindrical interface which must be included in the ABCD matrix calculation. The effect is small, however, and the results of the above calculation are sufficient as a starting value for the experimental optimization of the beam parameters. The measured and simulated output beam parameters in air are shown in Fig. 81.14a. The simulated beam parameters in water are quite close to our desired anastigmatic solution, with almost equal working distances of $WD_x = 270$ µm and $WD_y = 280$ µm and $1/e^2$ focal spot diameters of 16 µm and 19 µm in the x- and y-directions, respectively.

Due to the very low losses introduced by the TIR side-deflecting optics, our fabricated needle probe achieved a record high sensitivity of 112 dB when used in conjunction with the 1300-nm SS-OCT system described in Sect. 81.2.5.3. The good beam quality and high sensitivity of this needle probe yield image quality that is comparable to that obtained with bulk-optic scanning sample arms, as can be seen in the example images in Figs. 81.14c and d.

81.2.4.2 Ultrathin Imaging Needles

To minimize trauma resulting from needle insertion in applications such as imaging of small animals or delicate organs, it is desirable to use very thin needles. The smallest side-facing probe diameters can be achieved with all-fiber distal optics employing an angle-polished fiber tip as a beam deflector. This conceptually simple design poses two substantial challenges. Firstly, the output beam acquires significant astigmatism as it exits the fiber cladding, which acts as a strong cylindrical lens. Secondly, the application of a metallic or dielectric reflective coating to the polished end face is problematic, as the simultaneous coating of the beam output window must be avoided. In [16], we showed that these challenges can be overcome, and we demonstrated an ultrathin all-fiber probe that was encased in a 30G needle (0.31-mm OD), which is the smallest-diameter side-facing needle probe reported in the literature.

The probe was used in conjunction with an 840-nm spectral-domain (SD) OCT system (see Sect. 81.2.5.3) to generate 3D images of lung tissue [16, 5]. An improved, second-generation ultrathin needle was presented in [32], with a range of enhancements in the optical and mechanical properties. The second-generation ultrathin needle was used in conjunction with a 1300-nm SS-OCT system (see Sect. 81.2.5.3) to generate the first 3D needle OCT images of skeletal mouse muscle tissue [32].

The schematic of the ultrathin needle design is shown in Fig. 81.15a. The "monolithic" all-fiber distal focusing optics consist of the usual combination of a NCF spacer and a GRIN fiber lens, but with an additional section of NCF spliced to the end, which is subsequently polished at a 45° angle. A high-reflecting metal coating consisting of a thin chrome adhesion layer and a gold reflection layer is applied to the angle-polished NCF using a thermal vacuum deposition process. In our initial ultrathin needle probe which operated at 840 nm, this metal coating introduced significant absorption losses which represented a large part of the relatively high measured round-trip attenuation γ_P of 10 dB for light returning from a unity reflector placed at the working distance (see Sect. 81.2.5.2). In the second-generation ultrathin needle probe at 1300 nm, the absorption of the metal coating was much lower, leading to a measured round-trip attenuation γ_P of only 2.5 dB.

A fusion-spliced and angle-polished fiber probe, before application of the metal coating, is shown in Fig. 81.15b, and a fully assembled ultrathin 30-G needle probe is shown in Fig. 81.15c. The side opening in the second-generation ultrathin needle depicted in Fig. 81.15c has a diameter of only 140 μm and was drilled by nonthermal ablation with a femtosecond laser in order not to compromise the structural integrity and surface quality of the very thin hypodermic tubing [32].

When the ultrathin needles are inserted into tissue, the immersion in tissue fluids reduces the strong astigmatism introduced by the fiber cladding to a tolerable level, allowing imaging over a range of ~550 μm with FWHM resolution <18 μm in the case of the 840-nm needles [16] and over a range of ~700 μm with FWHM resolution <20 μm in the case of the second-generation 1300-nm needles [32]. The 840-nm needles had a measured sensitivity of 84 dB at 2 μs exposure time. (However, imaging of biological tissue was performed with a longer exposure

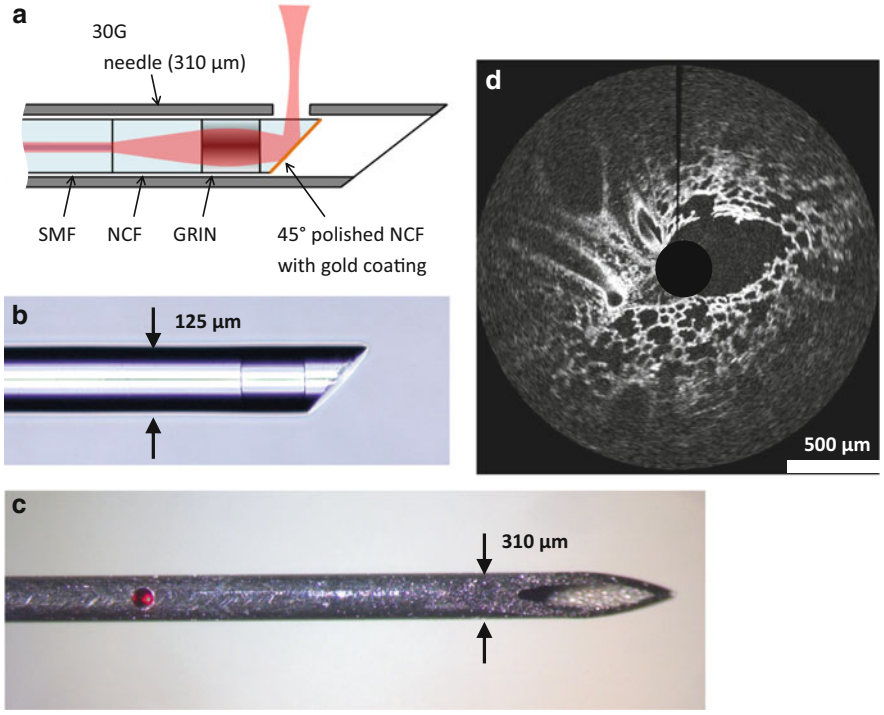

Fig. 81.15 (**a**) Schematic of the ultrathin OCT needle probe design. (**b**) Phase contrast microscope image of the all-fiber distal focusing optics with the angle-polished fiber tip reflector before application of the metal reflection coating. (**c**) A fully assembled 30G ultrathin OCT needle, showing the precision-drilled side opening fabricated by nonthermal ablation with a femtosecond laser. (**d**) Radial OCT image of a saline-inflated rat lung, obtained with the 840-nm ultrathin needle, showing alveoli and several bronchioles (Figure parts adapted from Ref. [32])

time of 13 µs, leading to an expected sensitivity of ~92 dB.) This was sufficient to generate 3D OCT images of lung tissue with good contrast, clearly resolving alveolar structure and bronchioles, as shown in Fig. 81.15d and in Sect. 81.4.2.2. However, attempts at imaging skeletal muscle tissue were unsuccessful using the 840-nm needles, presumably because the sensitivity was not sufficient to detect the relatively weak contrast of myofibers in solid tissue. The 1300-nm needles had a substantially higher measured sensitivity of 108 dB, due to the reduced optical losses of the metal reflection coating and the higher underlying sensitivity of the 1300-nm SS-OCT system compared to the 840-nm SD-OCT system. This enabled us to perform 3D needle OCT imaging of skeletal mouse muscle tissue, showing myofiber structure, tendon, and connective tissue [32].

81.2.4.3 Multimodality Imaging Needles

The diagnostic utility of OCT needle probes can be further enhanced if their capability of generating 3D images of tissue microstructure is combined with

a complementary functional modality such as fluorescence, which provides information about the biochemical composition of the tissue. OCT and fluorescence imaging can be conveniently combined in fiber-based probes using double-clad fiber (DCF) [64], where the core of the DCF guides the single-moded incident and returning long-wavelength OCT signals, as well as the few-moded, short-wavelength fluorescence excitation light. The returning fluorescence signal is efficiently collected by the inner cladding of the DCF due to its high NA and large diameter. This DCF-based combination of OCT and fluorescence imaging was initially demonstrated with bare fiber probes [65, 66]. It was subsequently implemented in endoscopic probes [67, 68] and needle probes [43].

A dual-modality DCF needle probe is shown in Fig. 81.16a [43]. The probe design is very similar to the one shown in Fig. 81.8b, except that DCF is used instead of SMF in a GRIN-lensed fiber that is embedded in UV curing optical adhesive together with a 0.3-mm-diameter mirror inside a 23G (0.64-mm OD) needle. The DCF (SM-9/105/125-20A, Nufern, USA) has a 9-μm core that is single moded over the 1300-nm OCT wavelength band and few moded at the 488-nm fluorescence excitation wavelength (estimated number of modes ~20). The inner and outer cladding diameters are 105 and 125 μm, respectively, with a NA of 0.20. The probe is designed for common-path OCT operation. For this reason, the NCF and GRIN fiber sections that are spliced to the end of the DCF are dimensioned to produce a slightly expanded, collimated output beam that has its beam waist located at the GRIN fiber end face in order to obtain a well-defined backreflection which serves as the OCT reference signal. The calculated −32 dB Fresnel reflection produced by the refractive index contrast between the optical adhesive and the GRIN fiber core has a power level that lies close to the optimum reference arm power for the employed SS-OCT system. The measured backreflection of −34 dB was in good agreement with this expected value. The FWHM output beam diameter in water at 1300 nm stays in the range 12–35 μm over a distance of ~1 mm from the needle. The fluorescence excitation beam at 488 nm has a similar diameter to the OCT beam over the same distance.

The DCF needle probe was connected to a 1300-nm SS-OCT system as shown in Fig. 81.16a. The SS-OCT system (see Sect. 81.2.5.3 and Fig. 81.22 for details) was modified to enable simultaneous fluorescence imaging with 488-nm excitation and detection at >500 nm (e.g., for detecting fluorescein with a peak emission wavelength of ~520 nm). The 488-nm excitation light is injected into the core of the sample-arm SMF via the aiming laser input of the SS-OCT system (see Fig. 81.22). The sample-arm SMF is spliced to a DCF coupler [69, 66] that couples out the returning fluorescence signal from the inner cladding while leaving light in the core unperturbed. The fluorescence signal is detected with a PMT and co-registered with the OCT signal, whereby every OCT A-scan has an associated fluorescence intensity measurement representing the integrated fluorescence collected from that radial direction. The rotation/pullback needle scan, therefore, generates a cylindrical 3D OCT image and a corresponding 2D fluorescence map.

The three frames in Fig. 81.16b–d show a dual-modality image of a sheep lung obtained with the DCF needle probe. Figure 81.16b is a 2D section from the 3D OCT data set, showing the characteristic honeycomb structure of the alveolar

network, as well as two bronchioles (labeled B_1 and B_2) and a vessel (V1). Figure 81.16c shows the corresponding fluorescence image, obtained via a radial projection of the fluorescence map onto the observed plane, with several vessels (labeled V_1, V_2 and V_3) visible as areas of high signal. Figure 81.16d displays the fused data sets. Anatomically, bronchioles are typically accompanied by a parallel vessel, as demonstrated by the bronchiole/vessel pair, B_2 and V_2. Note that V1 presents as a local region of low backscatter in the OCT image, indistinguishable from the bronchioles, whereas the fluorescence information indicates that V1 is most likely a vessel, not a bronchiole.

These early results demonstrate that combined OCT plus fluorescence needle images provide improved tissue differentiation over OCT alone. With the potential to image both autofluorescence and exogenous fluorescence contrast agents, we believe that the further development of dual-modality probe technology will enable clinical applications of OCT in tissues where structural contrast alone is not sufficiently specific.

81.2.4.4 Extending the Depth of Focus

Using state-of-the-art broadband light sources, it is possible to perform OCT imaging with a high axial resolution of a few micrometers. However, it is not straightforward to increase the transverse OCT resolution to similar values without severely compromising the useful depth of focus (DOF) due to the strong divergence of the tightly focused beam. This problem has been addressed in bulk-optic OCT scanners, amongst other means, by generating focal regions with an extended DOF using axicons [71, 25] or pupil phase masks [115]. However, these solutions cannot be directly applied to miniaturized fiber-optic probes because the focal regions of such probes are typically formed in a diffraction regime of low Fresnel number [63] where the optical design methods and approximations used in bulk-optic systems and classical microscopy are no longer valid. (The Fresnel number of an optical system is defined as $N = a^2/(\lambda L)$, where a is the radius of the limiting aperture, λ is the wavelength, and L is the distance from the aperture [26].) As an example, the Fresnel number of a fiber-optic probe with aperture diameter of 100 μm and a WD of 1 mm is ~2 at a wavelength of 1300 nm, whereas the Fresnel numbers of beams focused with bulk-optic lenses or microscope objectives are on the order of 100–1,000. Modeling of low-Fresnel-number systems such as fiber-optic probes requires rigorous wave-optic simulation tools that can calculate the true 3D diffracted field in the focal region. The beam propagation method (BPM) which was presented in Sect. 81.2.1.3 is ideally suited for this task, as it is valid for arbitrary Fresnel numbers [22]. Using the BPM, we have shown that focal regions with extended DOF can still be generated in the low-Fresnel-number regime using GRIN axicons [22] or GRIN phase masks [21]. The concept behind the generation of extended-DOF beams using an axicon is illustrated in Fig. 81.17.

Regardless of its technical realization, the optical functionality of an axicon can be approximated by a phase mask of the form $\exp(ik\,\beta r)$ that transforms an incident plane wavefront into a converging conical wavefront with a characteristic convergence angle β and radial coordinate r. This converging wave field has an effective numerical aperture $NA = n_{out} \sin \beta$, with n_{out} denoting the refractive index of the medium on the output side of the axicon. It forms a diffraction pattern in the region immediately adjacent to the axicon which has a Bessel-like transverse intensity distribution and extends over an axial distance $L \approx a/\tan\beta$ determined by the boundary of the geometrical shadow that results from the finite aperture radius a. Two practical realizations of axicons are shown in Fig. 81.17. The first is the well-known refractive axicon that takes on the form of a conical lens (Fig. 81.17b) [70], and the second realization is a GRIN element with a linear refractive index profile (Fig. 81.17c) [22].

The GRIN axicon has three useful characteristics that make it particularly attractive for fiber-optic probes. Firstly, if it is fabricated in the form of a GRIN fiber, it can simply be added to the end of the fiber probe in the usual manner via fusion splicing without requiring additional manufacturing processes (such as etching, micromachining, or polishing in the case of refractive axicons). Secondly, its NA (which is given by $(n_1 - n_2)t/a$) can be simply tailored by adjusting the length t of the spliced section. Thirdly, its NA is independent of the output medium

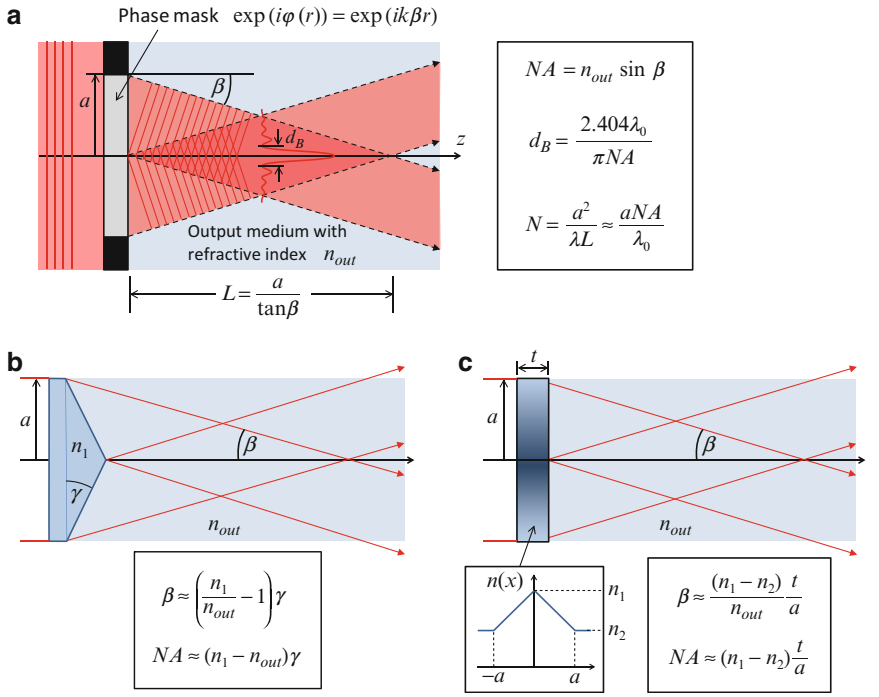

Fig. 81.17 (**a**) Geometry of a generalized axicon and relations for the numerical aperture *NA*, the Bessel beam central lobe diameter d_B, and the Fresnel number *N*. (**b**) Geometry and approximate equations for a refractive axicon. (**c**) Geometry and approximate equations for a GRIN axicon. The equations in (**b**) and (**c**) are valid in the paraxial regime where $\sin\beta \approx \tan\beta \approx \beta$

refractive index, which means that the transverse resolution of the probe remains invariant under immersion in tissue fluids, as opposed to refractive axicons that will suffer a strong reduction of their refractive power.

Figure 81.18 shows the BPM simulation results for a fiber-optic probe using a GRIN fiber axicon at a wavelength of 800 nm [22]. The probe design shown in Fig. 81.18a is based on a standard lensed fiber consisting of NCF and GRIN fiber spliced to SMF, in order to create an expanded and collimated beam with a $1/e^2$ diameter of 66 µm which is used as the input to the 95-µm-long GRIN axicon section with the refractive index profile shown in Fig. 81.18b. Using the analytical equations for a GRIN axicon phase mask from Fig. 81.17c, we calculate the following expected values for the Bessel-like output beam: NA of 0.057, central lobe diameter of 10.7 µm, and an axial range of L = 880 µm (using values of $n_1 = 1.483$, $n_2 = 1.453$, $a = 50$ µm, and $t = 95$ µm). The Fresnel number of this system is 3.6. The output beam E-field amplitude simulated with the BPM is shown in Fig. 81.18c together with the geometrical shadow boundary lines. The simulated beam is in good overall agreement with the approximate analytical values, with a central lobe that has a diameter of ~12 µm and which extends over an axial range

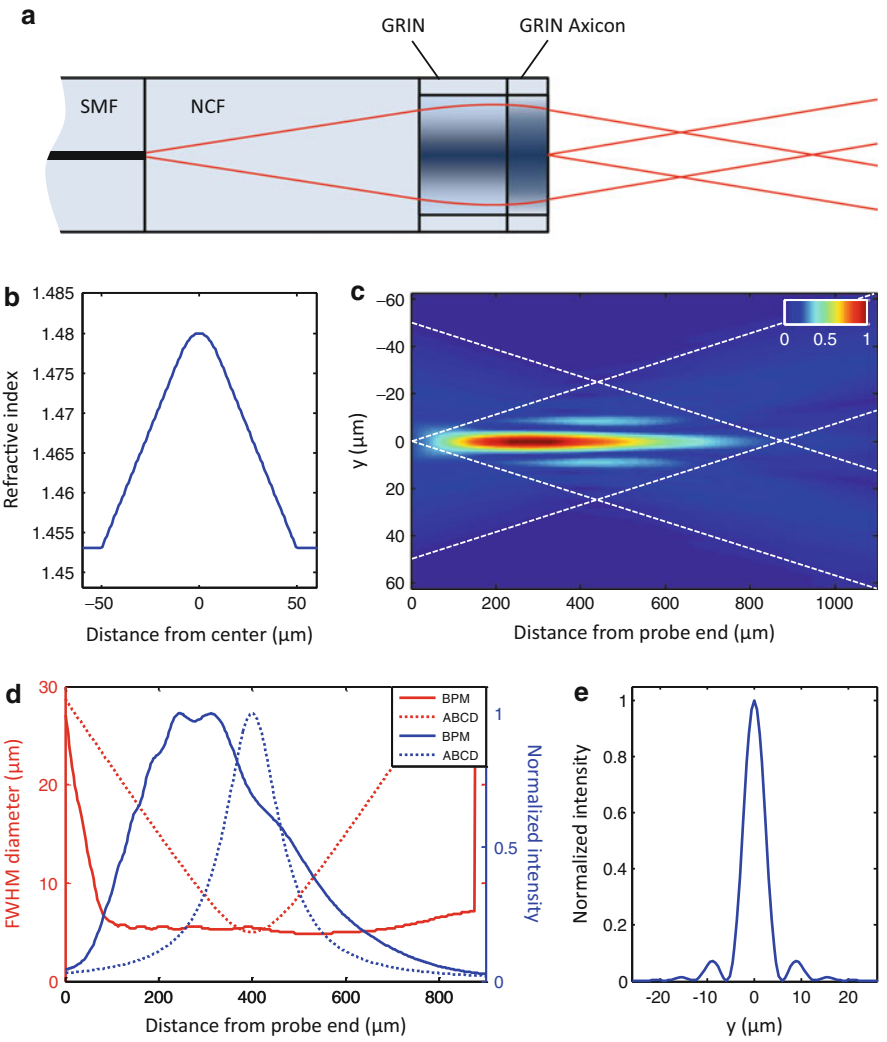

Fig. 81.18 BPM simulation of a fiber probe with extended DOF using an axicon-like GRIN fiber phase mask. (**a**) Schematic of the probe. (**b**) Index profile of the axicon-like GRIN fiber. (**c**) E-field amplitude in the entire simulated region. The *dashed white lines* indicate the boundaries of the geometrical shadow. (**d**) FWHM beam diameter and on-axis intensity of the simulated output beam (*solid lines*) and an ideal Gaussian beam with the same focal spot diameter (*dotted lines*). (**e**) Transverse intensity profile of the Bessel-like beam at ~300 μm from the probe end (Figure adapted from Ref. [22])

of ~800 μm. Figure 81.18d shows the FWHM beam diameter and on-axis intensity as a function of distance from the probe, together with the corresponding curves of a reference Gaussian beam with the same FWHM waist diameter of 5 μm. The transverse intensity profile of the peak at ~300 μm from the probe is shown

in Fig. 81.18e. The useful DOF of this beam will be determined by the acceptable relative intensity of the sidelobes, which gradually increases to 50% of the central lobe intensity at the far end of the DOF. If the full range of ~800 μm is used, we get a DOF gain of 3.3 compared to the reference Gaussian beam, obtained at the cost of a reduced Strehl ratio of 0.56. This example shows that the DOF gain which can be obtained with low-Fresnel-number axicons is significant, but much smaller than in the case of bulk-optic axicons with large Fresnel numbers. The reduced DOF gain comes with the advantage of a much higher central lobe intensity than in the bulk-optic case, because the number of sidelobes in the Bessel-like output field is strongly reduced. Hence, the problem of strong sensitivity penalties that are incurred with bulk-optic axicons [71, 25] is not an issue in the low-Fresnel-number regime [116]. Unfortunately, GRIN fiber axicons are not commercially available at the time of writing, but their fabrication is feasible using existing preform fabrication techniques.

Alternatively, micro-axicons using aspheric refractive surfaces could be used to obtain similar results, but their practical realization will require advanced fabrication techniques. A refractive micro-axicon with <1-mm diameter was demonstrated in [72], showing comparable performance to bulk-optic axicons. Early proof-of-concept work has shown that SMF tips with etched micro-axicons of the type used for near-field microscopy provide some DOF gain compared to a flat-cleaved SMF [73], but the tiny aperture diameter of the SMF core results in extremely short working distances which are much smaller than the fiber radius, making them unsuitable for side-facing scanning probes.

As an alternative approach to custom-made axicon-like structures, we have shown that it is also possible to obtain quite substantial DOF gains of ~2 in miniaturized fiber-optic probes by using very simple phase masks consisting of overfilled sections of conventional (parabolic) GRIN fiber [21]. This extended-DOF (EDOF) concept is shown in Fig. 81.19a. The probe design is again based on a normal lensed fiber using an NCF spacer and GRIN fiber lens section. The phase mask section which is appended after the GRIN lens section consists of GRIN fiber with a core diameter that is smaller than the transverse extent of the beam, as illustrated in Fig. 81.19b. The rays traced in Fig. 81.19a show that the effect of this arrangement can be intuitively understood as a "double-focus" lens, with the small core of the phase mask affecting only the central portion of the beam (see Fig. 81.19b). Using the BPM, the output beam from such an EDOF probe was simulated at a wavelength of 820 nm (see Figs. 81.19c and d). The probe uses GRIN fibers with 100- and 32-μm core diameter for the lens and phase mask sections, respectively. The simulated output beam intensity in water (refractive index $n = 1.33$) is shown in Fig. 81.19c. The FWHM beam diameter and the normalized on-axis intensity are shown in Fig. 81.19d. The minimum FWHM beam diameter is 6 μm, and the DOF is 874 μm. Compared with a reference Gaussian beam of the same minimum FWHM diameter (dotted curves in Fig. 81.19d), a DOF gain of 1.9 is obtained at the cost of a moderate reduction in Strehl ratio ($S = 0.57$).

The practical realization of the EDOF probe design shown in Fig. 81.19a is currently still difficult due to aberrations and imperfections in the refractive index profiles of commercially available GRIN fibers, especially in the case of large core

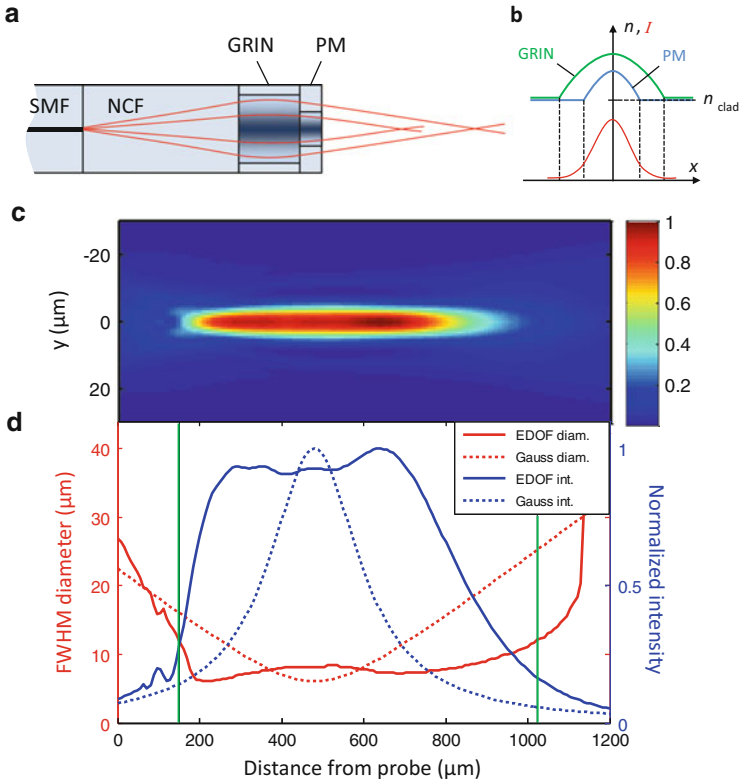

Fig. 81.19 BPM simulation of a fiber probe with extended DOF using a simple phase mask consisting of an overfilled GRIN fiber. (**a**) Schematic of the probe. *PM* phase mask, *SMF* single-mode fiber, *NCF* no-core fiber, *GRIN* graded-index fiber. (**b**) Illustration of the refractive index profiles of the GRIN lens (*green*, *upper line*) and the phase mask (*blue*, *middle line*) relative to the Gaussian beam intensity profile (*red*, *bottom line*): n_{clad}, cladding refractive index. (**c**) Simulated output beam intensity distribution in water. (**d**) Simulated FWHM diameter and normalized on-axis intensity of the output beam in water. The *dotted lines* show the values for an ideal Gaussian beam. The *vertical green lines* indicate the boundaries of the extended DOF (Figure adapted from Ref. [21])

diameters (see Sect. 81.2.1.2). An experimental validation of this concept was, therefore, performed using a slightly modified version of the EDOF probe which used a refractive hemispherical lens in combination with a 50-µm-core-diameter GRIN fiber phase mask. A DOF gain of 1.55 was experimentally demonstrated using this probe, not far from the expected value of ~1.7 that was predicted by the BPM simulation [21]. In order to evaluate the perceived improvement in imaging performance that results from this DOF gain, OCT scans of a lemon sample were acquired with the EDOF probe and also with a conventional lensed fiber probe that had the same transverse resolution. The comparison of the results showed that the increased DOF leads to a visible improvement in the OCT images [21].

In summary, current work on extended-DOF beams for OCT needle imaging is still in the proof-of-concept stage, showing promising early results and highlighting a wide range of interesting opportunities for innovation in the areas of microfabrication and custom GRIN materials.

81.2.5 OCT Needle Imaging Systems

In this section, we will discuss two important points that need to be considered when building an OCT needle imaging system:

- Should the needle probe be operated in a common-path configuration or with a reference arm?
- How will the needle probe affect the sensitivity of the OCT system?

We will also present two examples of spectral-domain (SD) OCT needle imaging systems that were built specifically for clinical use and which have been used extensively in our recent work. While some early work with needle probes was performed with time-domain (TD) OCT systems, practically all current systems employ swept-source or spectrometer-based SD-OCT due to the inherent sensitivity advantage [74]. Hence, we limit our discussion to SD-OCT in this section.

81.2.5.1 Common-Path Versus Separate Reference Arm

In a common-path interferometer configuration, the reference signal is obtained from a well-defined reflection within the probe. In most cases, this will be a strong Fresnel reflection from an interface within the probe optics [75, 43], but alternative designs have been proposed that incorporate a miniaturized beam splitter at the probe tip [76]. Common-path and dual-arm (i.e., with a separate reference arm) interferometer configurations both have advantages and drawbacks that need to be assessed in view of the envisaged application. Figures 81.20a and b shows a SD-OCT system with a needle probe sample arm in a Michelson interferometer configuration (a) and in a common-path (Fizeau) interferometer configuration (b).

The great advantage of the common-path configuration is that it eliminates "down-lead sensitivity" by avoiding issues of polarization or dispersion mismatch between the reference and sample arms, as well as polarization fading due to fiber perturbation during scanning [75]. These characteristics convey a high level of robustness and a quick and easy interchange of probes, which are highly desirable for clinical systems. The main drawback of the common-path configuration is that the reference reflectivity cannot be adjusted during operation and must, therefore, be optimally chosen beforehand. The choice of reference reflectivity, thus, becomes an integral part of the probe design and fabrication process [75, 76, 43]. For this reason, a dual-arm configuration is preferable in research systems, as it allows the user to choose the optimum reference arm power for maximum system sensitivity independently of the zero delay position. However, in this case, numerical dispersion compensation is typically required when using all-fiber needle probes [16], as an air gap and bulk optics in the reference arm cannot be avoided if a certain amount of delay adjustment is desired.

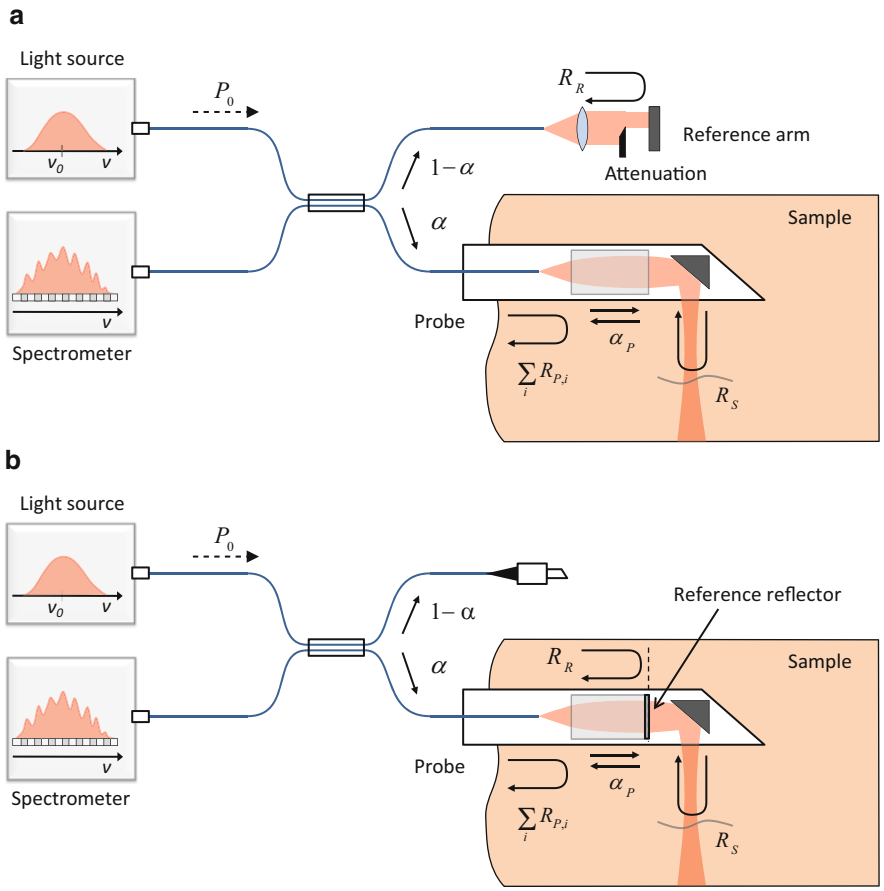

Fig. 81.20 Schematic of fiber-based SD-OCT systems with a needle probe sample arm in (**a**) Michelson and (**b**) common-path (Fizeau) configuration

81.2.5.2 Sensitivity

Needle probes can have a strong impact on the sensitivity of the OCT system due to losses and parasitic backreflections in the distal optics. This is illustrated in Fig. 81.20a, b, where the probe optics introduces a loss α_P as well as backreflections with reflectivities $R_{P,i}$. The loss α_P acts in double pass and is, therefore, better quantified via the round-trip attenuation of the probe $\gamma_P = \alpha_P^2$, which can be measured with a unity reflector placed at the working distance. The signals returning from $R_{P,i}$ are detrimental in two ways. Firstly, they can appear as unwanted structure in the OCT image or generate parasitic "ghost images" of the sample if they are within the imaging depth range (as they are typically situated at negative distances from the zero delay, they also often appear as broadened bands in the image after numerical dispersion compensation). Secondly, even if they are outside the imaging depth range, they will add shot noise and beat noise which

reduce the system sensitivity [77–79]. Fortunately, such backreflections can be kept very low in fusion-spliced all-fiber probes so that needle OCT systems can operate close to the shot-noise limit if the round-trip loss γ_P of the probe is minimized. For SD-OCT (both spectrometer-based or swept-source), the shot-noise-limited sensitivity is given by [74, 80]

$$\sum_{SNL} = \frac{\eta P \gamma_S \tau}{h\nu_0} \tag{81.13}$$

where η is the overall efficiency of the detector (the quantum efficiency of the photodetector in the case of swept-source systems, or the combination of the spectrometer losses and the quantum efficiency of the detector array in spectrometer-based systems), P is the average optical power of the source (in the case of swept-source systems, the mean power during the sweep must be used by applying a correction factor to the average source power which takes into account the sweep duty cycle), γ_S is the fraction of the source power that reaches the detector for the case of a unity reflector in the sample arm (following the notation in [80]), τ is the integration time or sweep duration (for spectrometer-based or swept-source systems, respectively), h is Planck's constant, and ν_0 is the center frequency of the broadband light source. From Eq. 81.13, it is evident that the sensitivity is directly proportional to the round-trip attenuation γ_P of the probe, which is included in γ_S (in the example of Fig. 81.20a, $\gamma_S = \alpha(1-\alpha)\gamma_P$, where α is the power-splitting ratio of the coupler). If parasitic backreflections can be neglected, the parameter γ_P is indicative of the sensitivity loss caused by the needle probe, and it is, therefore, a very useful figure of merit for assessing its optical quality [16, 32].

81.2.5.3 Examples of OCT Needle Imaging Systems

In this section, we give two examples of SD-OCT needle imaging systems that have been used successfully in our recent work.

Figure 81.21 shows a 840-nm spectrometer-based SD-OCT system which we have used extensively for OCT needle imaging, both in common-path [61, 3, 58, 56, 5] and in dual-arm [16, 5] configuration. The source is a superluminescent diode (S-840-B-I-20, Superlum, Ireland) with a center wavelength of 836 nm, an average power of 20 mW, and a bandwidth of 50 nm, yielding an axial resolution in air of 7.6 µm (or 9.3 µm after spectral reshaping [81] of the double-peaked spectrum to a Hann-window profile in order to reduce sidelobes in the axial point-spread function). The spectrometer is a commercial *k*-linear (linear in wavenumber) unit (Hyperion 830 1500, Thorlabs HL AG, Germany) incorporating a high-speed CMOS line scan camera (spL4096-140 km, Basler Vision Techn., Germany). The *k*-linear spectral data eliminates the need for computationally intensive resampling before performing the Fourier transform, allowing a real-time display of the OCT needle scan. The system employs a simple Michelson interferometer using a broadband 50/50 fiber coupler. The reference arm can simply be blocked or disconnected when using common-path needle probes. If the reference arm is

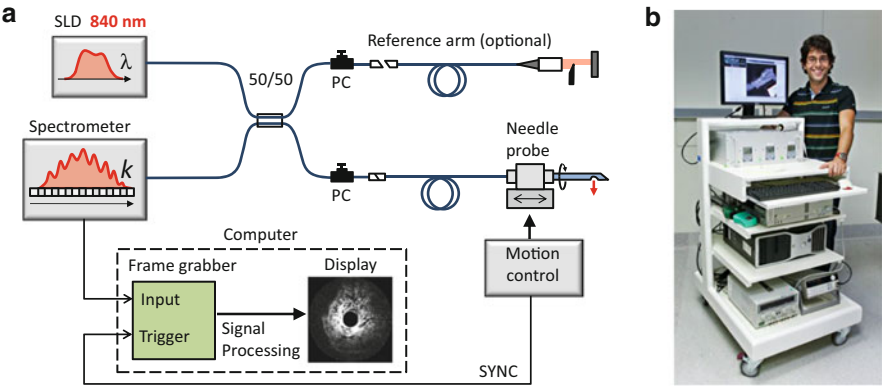

Fig. 81.21 A portable 840-nm SD-OCT needle imaging system. (**a**) System schematic. *SLD* superluminescent diode, *SYNC* synchronization signal from motion control unit, *PC* polarization controller. (**b**) The system shown in (**a**), packaged on a trolley for clinical use

used with needle probes, any air gap in the adjustable delay section must be numerically dispersion compensated in post-processing due to the relatively high material dispersion of silica fiber at 840 nm.

With a bulk-optic galvanometer-scanning sample arm, the measured sensitivity of the system is 100 dB at an exposure time of 36 μs, which is quite close to the theoretical shot-noise limit (104 dB). Using low-loss needle probes, imaging with sensitivities approaching 100 dB is, therefore, feasible with this system.

The synchronization of the OCT data acquisition with the needle scan motion is performed via the trigger input of the frame grabber card, which receives synchronization pulses from the custom-built motion control unit that drives the stepper motors of the rotation/pullback scanning setup.

Figure 81.22 shows a 1300-nm swept-source (SS) OCT system which is being used by our group for OCT needle imaging, both in common-path [43] and in dual-arm [11, 32] configuration. The source is a wavelength-swept laser (Axsun, USA) with an average power of 40 mW, a sweep rate of 50 kHz, and a total sweep range of 100 nm, giving an axial resolution in air of 13 μm (or 21 μm if a Hann window is applied to the spectral data to reduce sidelobes in the axial point-spread function). The source provides a *k*-linear clock output that is generated using a Mach-Zehnder interferometer (MZI) and which is connected to the external clock input of the digitizer card (500 MS/s, 12-bit, model no. ATS9350, Alazar Technologies, Canada). In analogy to the use of *k*-linear spectrometers in SD-OCT systems, this eliminates the need for resampling of the spectral data that is acquired during the wavelength sweep of the laser, allowing real-time display of the OCT scan.

The interferometer configuration of this system was designed to enable the use of balanced detection with common-path needle probes, as well as for allowing easy conversion between dual-arm and common-path operation. When using

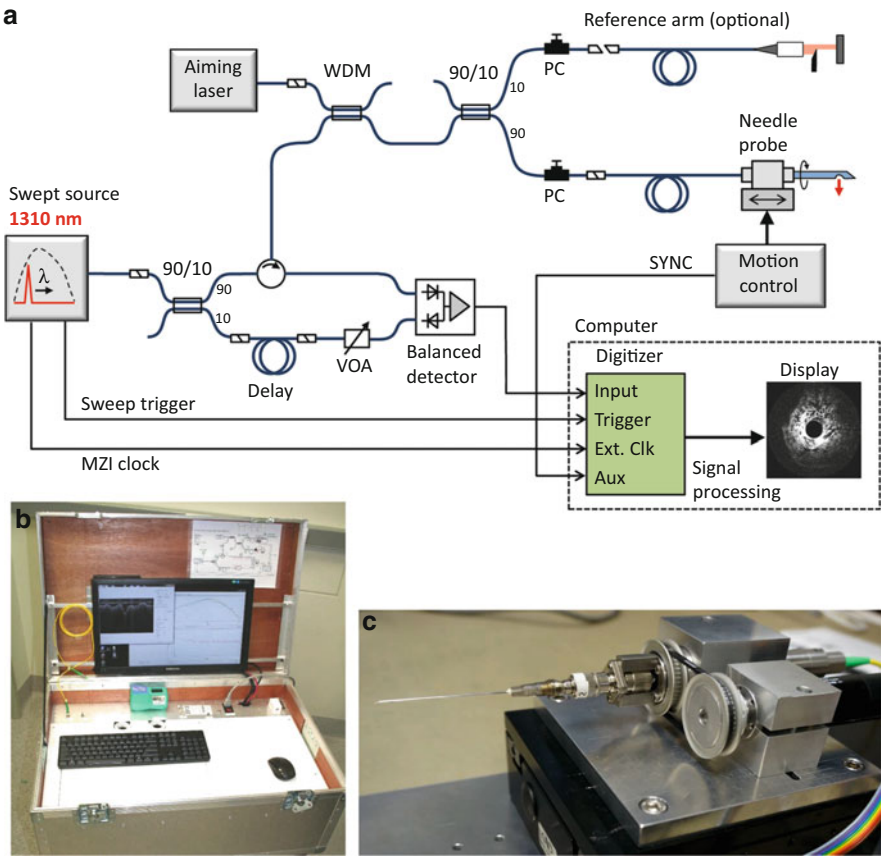

Fig. 81.22 A portable 1300-nm SS-OCT needle imaging system. (**a**) System schematic. *MZI* Mach-Zehnder interferometer, *WDM* wavelength-division multiplexer, *VOA* variable optical attenuator, *SYNC* synchronization signal, *PC* polarization controller (Figure adapted from Ref. [32]). (**b**) The system shown in (**a**), integrated into a rugged carry case for easy portability. (**c**) A prototype motorized rotation/pullback assembly for 3D needle scanning

high-speed wavelength-swept lasers, balanced detection is essential for suppressing the comparatively high relative intensity noise (RIN) of these sources [82]. However, the commonly employed interferometer configurations for balanced detection use a 50/50 coupler before the balanced detector to mix the reference and sample-arm signals [82, 83]. While the 50/50 coupler provides robust "auto-alancing" of the power levels incident on the two inputs of the balanced receiver, it becomes ineffective in common-path operation where the returning sample and reference signals travel in the same fiber.

The interferometer layout in Fig. 81.22a implements a very simple but effective "manual-balancing" variant of balanced detection, which operates as follows. The wavelength-swept laser output signal is split using a 90/10 coupler, with 90%

directed into the interferometer via a circulator and 10% directed to the balanced detector, where it is subtracted from the returning signal from the interferometer after applying a delay which equalizes the optical path lengths from the source to the two balanced detector inputs. The only drawbacks of this arrangement are that it requires a manual adjustment of a variable optical attenuator (VOA) before every measurement in order to balance the incident power levels at the balanced detector, and it does not suppress self-interference signals from parasitic reflections within the interferometer arms (otherwise the common-path signal would also be suppressed). However, the two main benefits of balanced detection are achieved: suppression of RIN and the cancellation of the DC component of the signal (thereby preventing the saturation of the photoreceiver and making optimum use of the dynamic range of the digitizer input). Using this balanced detection method, our system achieves measured sensitivities up to 114 dB with bulk-optic sample arms (the theoretical shot-noise limit is ~117 dB), and this system was used in [11] to demonstrate the highest reported sensitivity from an OCT needle probe (112 dB).

The synchronization of the data acquisition with the needle scan in an SS-OCT system is not as straightforward as in the case of spectrometer-based SD-OCT systems, because the periodic wavelength sweep of the source determines the fundamental timing behavior of the system. In the system shown in Fig. 81.22a, this problem has been solved by using the auxiliary input of the digitizer card for "gating" the sweep trigger signal, whereby the leading edge of a synchronization pulse from the needle motion control unit "arms" the digitizer card so that it acquires an A-scan at the occurrence of the next sweep trigger pulse from the source. All subsequent sweep trigger pulses are ignored until the digitizer is armed again by the next synchronization pulse. This concept is practical if the scan data acquisition rate stays well below the sweep rate of the source, as it obviously results in an unpredictable timing error which has a maximum value equal to the period of the sweep rate (20 μs in the case of our 50-kHz source). This error is negligible for our current prototype needle scanning systems which have data acquisition rates that are one order of magnitude lower than the sweep rate of the source. However, we believe that the demand for short acquisition times in clinical applications will soon lead to high-speed scanning needles that will utilize the full speed potential of modern wavelength-swept lasers.

81.3 Applications of OCT Needle Probes

OCT images recorded with needle probes for the most part represent validations of technical designs rather than forays into specific applications per se. This situation reflects the relative immaturity of needle probe technical development and the relatively small number of groups seeking to advance this field, although both these factors have changed a great deal over the last 2 years. Below, in Sect. 81.3.1, we firstly consider needle probe imaging in animal tissues – from the perspective of simply demonstrating imaging in particular

tissues, as well as of systematic application specifically intended for animals and animal models. In Sect. 81.3.2, we consider such imaging in human tissues and finally discuss limitations and prospects for future applications. In the next section, Sect. 81.4, we present two case studies highlighting the state of the art, one in animals and one in humans.

81.3.1 Needle Probes Demonstrated in Animal Models and Tissues

Needle probes for in vivo applications in animals must typically satisfy more stringent demands on needle size than in human applications, because of the small size of many animal models (e.g., mice, rats). These demands can be met, depending on the application, by not using an outer protective sheath, which also simplifies their fabrication. Below, we consider needle probes applied to animal tissues by tissue constituent and type.

81.3.1.1 Vasculature, Blood, and Blood Flow

In 2005, the first OCT needle probe capable of Doppler measurements was reported. Although rather large, employing a 19G (1.06-mm OD) "echogenic" needle (as employed in interventional radiology: the surface finish provides enhanced visibility under ultrasound), side-viewing linear B-scan imaging was demonstrated in a live rat [12]. The B-scan images featured superimposed Doppler signals and were reported for several anatomical locations. In 2006, an improved 22G version was used to demonstrate the feasibility of monitoring the effects of photodynamic therapy in a rat model of prostate cancer [54]. Microvascular changes in response to the therapy, occurring deep within a tumor mass, were successfully visualized and quantified.

Over the next several years, this research progressed to more extensive studies [84, 85], eventually incorporating high-frequency (40 MHz) ultrasound to guide the needle to the site of the tumor [85], as shown in Fig. 81.23. Although the Doppler flow maps reported in these works displayed only a small portion of the full vascular architecture, they were still very effective in monitoring the reductions in flow over time that resulted from the therapy (see Fig. 81.24). As a result, a relationship was established between the percentage of tumor necrosis post-treatment and the rate of vascular flow reduction [85]. The authors raised the very interesting prospect, yet to be realized, of a clinical role for real-time microvascular monitoring in optimizing photodynamic therapy treatment in individual patients.

More recently, a similar imaging probe with Doppler flow capability based on a forward-looking GRIN rod design in a steel needle of 0.74-mm OD (slightly larger than standard 22G) has been demonstrated [53]. The overall motivation of the research in this case is in the development of surgical guidance tools, primarily for guidance during stereotactic procedures in the brain. Demonstration of in vivo OCT and superimposed Doppler flow imaging (0.44-mm lateral field of view) was reported for insertion in sheep brain and for surface access of rat femoral vessels [53].

(**b**) HFUS side view of the interstitial probe in the tumor mass. (**c**) Corresponding end-on view. (**d**) 3D visualization. The major ticks in the vertical and horizontal scales are 1-mm increments. *White* outlines represent tumor borders (**b**, **c**) (Reproduced with permission from Ref. [85])

81.3.1.2 Brain

The most prominent optical modalities for microscopic imaging in the brain have been one- and two-photon fluorescence microscopy [86], in which GRIN rod lenses have been used to construct bare-glass, high-NA imaging probes for high-resolution microscopy in live rat and mouse brains. Such lenses, with diameters in the range 0.350–1.0 mm and a few tens of millimeters in length, are not sufficiently robust to be used for clinically approved applications in humans without protective sheaths. The main motivation for such probes has been the study of neurological processes and diseases such as cancer and Alzheimer's disease in animal models of the brain [87].

Although OCT does not enjoy the resolution or specific targeting capability of these methods, it has been demonstrated to be capable of motion detection in one dimension [14], detection of blood vessels [53] and anatomical landmarks [88, 57], and surgical guidance and treatment monitoring in the live rat brain [88]. Building on their earlier catheter-based studies of ex vivo human brains [9], the authors of Ref. [88] developed a needle with multifunctional capability, including OCT imaging, wire cutting, and fluid delivery [88]. Simultaneous delivery of a therapeutic agent, monitoring of its delivery and effect on live rat brains, as well as creation and imaging of a focal lesion were very effectively demonstrated (see Fig. 81.25).

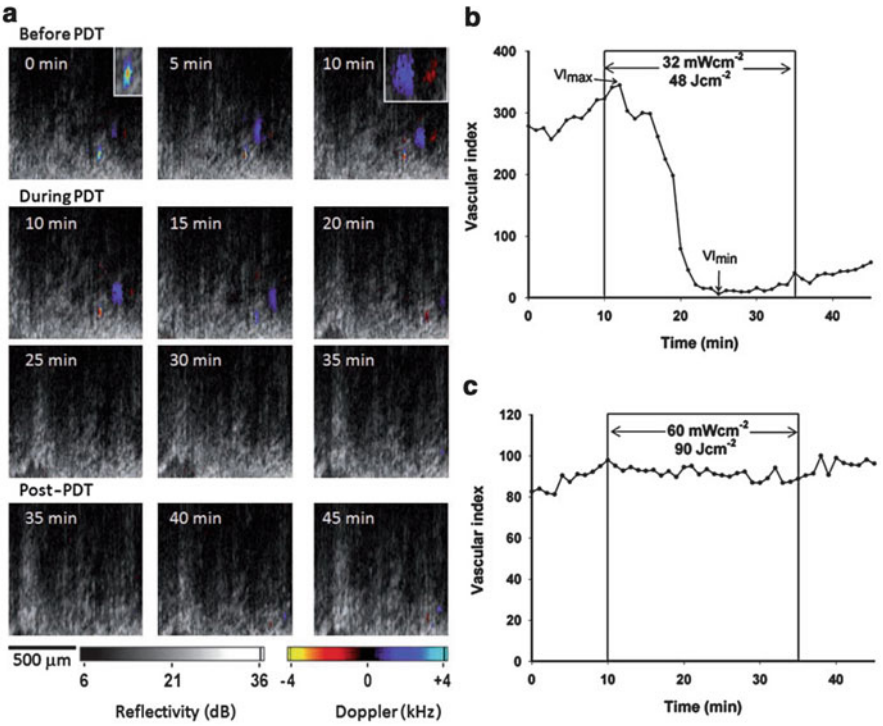

Fig. 81.24 (**a**) Interstitial Doppler OCT imaging sequence of color-Doppler blood flow detection overlaid onto structural OCT images before, during, and post-PDT treatment. The *inserts* show aliasing (0 min) and counter-propagating flow (10 min). (**b**) Vascular index as a function of time in a single animal showing the flow shutdown during PDT light exposure. (**c**) Control animal (light, no photosensitizer) (Reproduced with permission from Ref. [85])

(**b**) Postmortem section of rat brain verifying accuracy of lesion. Hippocampal CA1, CA3, dentate (*d*), and subiculum (*s*) are indicated. Scale bar, 0.5 mm (Reproduced with permission from Ref. [88])

As discussed above, a forward-looking probe developed to explore guidance in brain surgery has shown the feasibility of detection of blood vessels in the sheep brain, although the accompanying OCT images did not show appreciable structure [53]. More recently, with similar motivation, a very small profile 125-μm-diameter bare-glass probe has been used to probe the in vivo rat brain [57]. Two novel elements were the use of a high-precision surgical navigation system to control the probe and, in the absence of B-mode scanning, the presentation of successive A-scans aligned in depth (M-mode). The authors presented evidence capacity to observe the main brain structures, such as the corpus callosum and hippocampus, axon bundles, and the differentiation of gray and white matter [57].

81.3.1.3 Airways and Lungs

The first paper to show full three-dimensional OCT imaging in a needle probe was published by our group [61] using a 23G side-viewing, counterrotated, and translated needle probe to image saline-filled ex vivo sheep lung tissue. This was closely followed by several other works in lung tissues of preterm lambs, rats, and pigs [16, 5]. This work is presented as a case study in Sect. 81.4. Such proof-of-principle imaging of alveoli and associated airway morphology is motivated by the potential to study preclinical models of airway physiology and a range of diseases, with important implications for human disease diagnosis and treatment.

Recently, the use of an OCT needle probe to guide transbronchial needle aspiration, which is the sampling of small amounts of human airway tissue, was proposed. A side-viewing rotating OCT probe of 0.43-mm OD compatible with a 21G transbronchial biopsy needle was demonstrated capable of imaging alveoli in air-filled ex vivo pig lungs (see Fig. 81.26) [6]. The motivation for this research is to confirm the placement of the transbronchial biopsy needle within a peripheral pulmonary lesion prior to biopsy in order to improve the diagnostic yield [89].

81.3.1.4 Eye

The first proposal to use OCT needle probes in the eye was published in 2008 [7]. The motivation was in aiding vitrectomy, the surgical removal of the vitreous humor, which is a required precursor to other surgeries for the treatment of severe eye diseases such as retinal detachment. The success of vitrectomy depends upon the complete local removal of the vitreous humor, which may be difficult to visualize through a fiber-bundle endoscope inserted through an incision into the patient's eye. OCT may provide better visualization because of its inherent sensitivity to scattering and because the probe is able to be placed very close to the retinal surface, thereby maximizing the sensitivity. The novel forward-looking design combining two rotating GRIN rod lenses (see also Sect. 81.2.3.3), first described in 2006 by the same group [48], was improved and incorporated into a 21G needle (0.82-mm OD). Forward-looking radial B-scan segment images (approx. 30°) of the retina of an enucleated porcine eye, with cornea, lens, and vitreous removed, were reported.

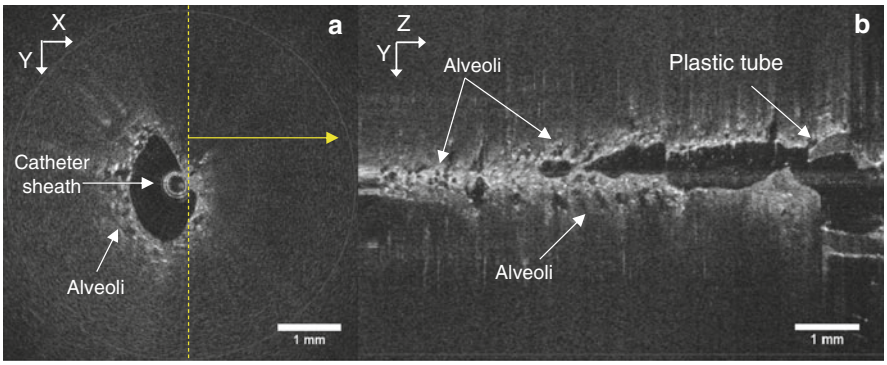

Fig. 81.26 Cross-sectional (**a**) and longitudinal (**b**) OCT images of the inflated pig lung obtained with the imaging needle. (**a**) 5.6-mm circumferential cross-sectional OCT image of lung parenchyma with clear visualization of alveoli. (**b**) An 8.2-mm × 5.6-mm YZ longitudinal reconstruction obtained from the location identified in "a" *(dashed yellow line)* (Reproduced with permission from Ref. [6])

In other work, a handheld OCT system was developed for image-guided intervention during microsurgery. The system is designed not for insertion but for hand scanning of a forward-looking 20G needle probe over a surface. It was demonstrated on ex vivo bovine retina [55].

81.3.1.5 Other Animal Tissues

The first demonstration of an OCT needle probe, reported in 2000 [2], showed an image of muscle tissue acquired in the leg of a live hamster. The 90° segment of a radial B-scan image was taken with a rotating, side-facing 27G needle and showed muscle fascicles (bundles of muscle fibers) and evidence of signal fading induced by birefringence. Still higher resolutions than OCT, capable of revealing sarcomeres at 15-mm depth in bovine muscle tissue, have been demonstrated in fluorescence-based confocal microscopy needle probes, generating en face images at depth in tissue by scanning the proximal end face of a GRIN rod lens [52].

Radial and linear B-scans from needles inserted into various excised animal tissues, including pig spleen and pancreas, and mouse esophagus were presented in [17]. Example B-scan images are shown in Fig. 81.27, reproduced from Ref. [17]. More recently, motivated by core biopsy guidance, images of cat lymphoma wrapped in chicken tissue were reported in [90].

81.3.2 Needle Probes Demonstrated in Human Tissues

Most of the research reported to date on OCT needle probes is motivated by their application in humans for eventual clinical use. Although many catheter-based OCT studies in humans have been reported, no human in vivo OCT imaging needle studies have been reported. Such first-in-human studies are an exciting prospect for

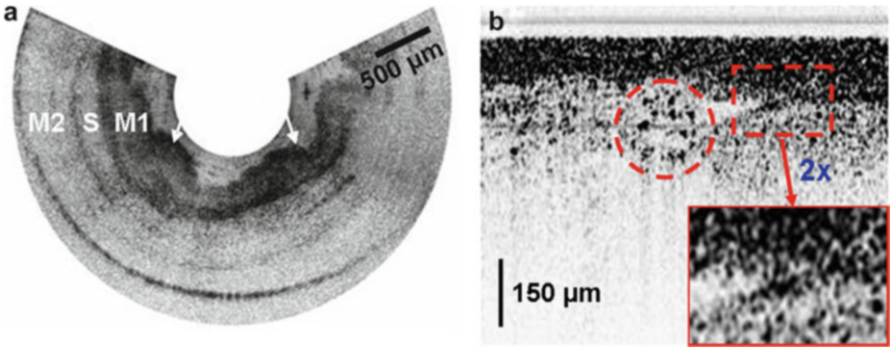

Fig. 81.27 (**a**) Ex vivo OCT radial B-scan segment of fresh mouse esophageal tissue. *M1* mucosa, *S* submucosa, *M2* muscularis. *Arrows* indicate epithelium. (**b**) Ex vivo OCT linear B-scan of fresh pig pancreatic tail. The structure indicated by the *circle* may be related to islets of Langerhans (Reproduced with permission from Ref. [17])

the future. Optical microscopy in humans has been reported, however, in a proof-of-principle image of muscle tissue in vivo by needle-based multiphoton microscopy [91]. Below, we survey reports of needle probe measurements on human tissues.

81.3.2.1 Breast and Lymph Nodes

The first measurements using an OCT needle probe on human tissue (excised breast cancer specimens) were reported in 2005 [4]. The objective was to develop a guide for fine-needle aspiration biopsy, in which smaller quantities of human breast tissue are extracted for diagnosis than for core biopsy. Better guidance is expected to lead to fewer sampling errors, an important consideration in cost and patient convenience when samples are sent off site for histopathological analysis. The 23G probe comprised a bare single-mode fiber, and forward-looking A-scans were recorded from adipose, fibro-glandular, and invasive ductal carcinoma tissues. Subsequently, in 2009, the same group used an improved system on 89 excised tissue samples. The resulting classifier achieved 80% sensitivity and 84% specificity in the correct differentiation of adipose, fibrous, and tumor tissue types [92].

More recently, our group has demonstrated OCT needle probe imaging of breast cancer and associated axillary lymph nodes [3, 93], to be described in detail in the first case study in Sect. 81.4.

81.3.2.2 Brain

In a 2005 study, a LightLab commercial OCT system (St. Jude Medical, MN, USA) was used to image thawed fresh-frozen coronal brain sections. The catheter was inserted into the brain via a 24G hypodermic needle, and pullback scans from the side-viewing, rotating probe were performed. Radial B-scan images showing a range of brain structures were presented, including one from a subject with Creutzfeldt-Jakob disease, as well as a three-dimensional partial reconstruction of a blood vessel in the human putamen. The authors observed that the gray matter–white matter junction

is one structure that OCT can detect with high contrast. This junction can serve as a landmark for guiding deep brain stimulation procedures, such as those developed to treat Parkinson's disease. The authors also pointed to evidence of the detection of vacuoles in Creutzfeldt-Jakob disease and suggested the method may prove useful in other spongiform encephalopathies as a rapid in vivo or ex vivo screening test [9]. The contrast between gray and white matter was subsequently confirmed in research on ex vivo brain slices reported (by substantially the same group) in 2011, in research directed toward the guidance of stereotactic neurosurgery employing a 12-cm-long forward-looking imaging needle with 0.44-mm field of view [53].

81.3.2.3 Skin

No needle probes have been developed for the specific purpose of imaging skin, but a number of incidental examples of images of skin have been reported [17, 55, 11]. Generally, they show inferior quality, in some attribute, to images recorded with non-needle OCT systems. Recently, improved needle systems have begun to evolve (as discussed in Sect. 81.2.4), and thus, Fig. 81.14c above shows a superior recent example of skin imaging with a 23G side-looking counterrotating needle probe in a 3D OCT system with a measured sensitivity of 112 dB [11].

81.3.3 Issues and Perspective on Applications

Most studies reported to date are proof-of-principle, with imaging conducted predominantly in animal tissues. The more advanced applications of OCT needle probes in preclinical imaging are in neuroscience [88], lung morphology [5], and tumor treatment [85] and, in humans, in surgical guidance [53], biopsy guidance [6], and intraoperative tumor margin identification [3].

Key challenges have restricted the advancement of OCT needle probes to date – the difficulty of maintaining high-sensitivity and high-resolution OCT imaging while miniaturizing the probe, the difficulty inherent in many applications of not having available full three-dimensional information, and the difficulty of navigating based only on the needle's inherently limited field of view.

The first challenge has been periodically met in two-dimensional imaging systems [85, 88] and, lately, in three-dimensional systems [11]. It is apparent that this challenge is largely one of good engineering design and realization.

The challenge of the need for three-dimensional imaging in order to address the application need is faced by OCT imaging in general and has seen the wide emergence of three-dimensional imaging systems. Such three-dimensional imaging is in general necessary to create closely corresponding OCT images and histopathology, which is a prerequisite for effective engagement with the pathologists who are essential in interpreting OCT images [94]. Such engagement remains in its infancy.

An important aspect of needle probes is guidance to the correct site for imaging. The use of ultrasound guidance with good effect has been reported by several groups in studies on animal [85] and on human tissues [93]. Magnetic tracking, which provides absolute coordinates, has also been recently used to guide freehand

scanning [56], and surface tracking has been used for noncontact surface imaging needle probes [55]. Most recently, an OCT needle probe has been connected to a stereotactic surgical navigation frame, which provides five-degree-of-freedom stepper motor movement with 1-μm resolution and 30-μm overall accuracy [57].

Many needle scanning systems incorporate precision rotation and translation setups that are cumbersome and do not scan with sufficient speed to make in vivo imaging in humans feasible. However, some systems have already evolved to be well suited for clinical applications [6], and it is very likely that more will soon follow.

The most substantial studies reported to date have been in the assessment of photodynamic therapy in the rat prostate cancer model [85], employing Doppler OCT – a major technical achievement in itself – and the A-scan studies on human breast cancer samples [92]. These latter studies highlight the general difficulty in extracting sufficient information from A-scans to make definitive assessments. The range and promise of these early needle-based studies augurs well for OCT needle probes to make significant clinical impact in the future. Further evidence of this promise is contained in the next section.

81.4 Case Studies

In this section, we explore the potential use of OCT needle probes through two specific case studies: tumor margin assessment in breast cancer and preclinical assessment of lung alveoli.

81.4.1 Breast Cancer

81.4.1.1 Background

Breast cancer is the most commonly diagnosed cancer in women [95], with 235,000 new cases diagnosed each year in the USA alone [96]. The primary treatment for breast cancer is surgery to remove the cancerous tissue. If the tumor is well contained within a small region of tissue, then the patient will often choose to undergo breast-conserving surgery (lumpectomy). Approximately 43% of patients will choose a lumpectomy as their initial surgical treatment [97]. In this procedure, only the tumor is excised, and the remainder of the breast is left intact. If not all malignant tissue is removed, then the patient is likely to suffer a recurrence of the cancer. To reduce this risk, the surgeon removes both the tumor and a margin of additional healthy tissue (tumor margin), typically ∼2–5 mm. Successful surgery relies critically on accurate identification of the edge of the tumor [98].

After surgery, the excised tissue is assessed by a pathologist. Because of the complexities of tissue preparation and the logistics of its examination, it typically takes several days before the pathology results are available to the surgeon. If malignant tissue is found to be too close to the edge of the excised tissue (typically <2 mm), then it is likely that some cancer was left in the patient, and the patient may need to undergo additional surgery. A study of 612 patients found that

approximately one third had poor margins (<5 mm) and one quarter were required to undergo a second surgery [99]. Repeat surgery due to poor margins is both traumatic for the patient and a significant cost to health-care providers.

81.4.1.2 OCT Needle Probes for Margin Assessment

OCT offers the potential for the assessment of tumor margins in fresh tissue, prior to histological evaluation. Scans acquired from the surface of fresh, excised human breast cancer samples have demonstrated visualization of both normal and malignant tissue structures [100–102], and techniques have been proposed to allow automatic differentiation of tissue types [103, 92]. However, intraoperative surgical guidance requires assessment of the tissue prior to excision, where such tissue is significantly beyond the 2–3-mm image penetration depth of OCT.

OCT needle probes offer the potential to image deep below the tissue surface. Figure 81.28 demonstrates an OCT needle probe image of a human breast tumor margin, acquired on a fresh, ex vivo tissue sample. This sample was obtained from a 70-year-old female with a 21-mm, grade 3 invasive ductal carcinoma.

The side-facing probe used here was of the type shown in Fig. 81.8b, encased in a 23G (0.64-mm OD) needle and with a length of 30 mm. The focusing optics yielded a spot with an FWHM transverse resolution of ∼12 μm at a distance of 300 μm from the side window of the needle. The probe was mounted on a motorized rotation/pullback assembly for 3D scanning. It was counterrotated at 2 Hz to acquire 2D radial B-scans consisting of 800 A-scans per 360° rotation, and the pullback step size was 7 μm per rotation. Only clockwise rotations were used to form the 3D OCT data set to minimize artifacts from tissue drag.

The needle probe was interfaced with the 840-nm SD-OCT needle scanning system described in Sect. 81.2.5.3 and operated in a common-path configuration, thereby eliminating "down-lead sensitivity" of the sample arm during scanning (see Sect. 81.2.5.1).

The OCT needle probe was inserted into the tumor and withdrawn while performing rotation/pullback scanning. The reconstruction of the 3D OCT data yielded a dense cylindrical image volume (length 2.36 mm, diameter 1.60 mm, assuming a group refractive index for tissue of $n = 1.4$), with 900 pixels per A-scan and using linear interpolation to compute values for pixels not positioned directly along an A-scan. After imaging, the tissue specimen was fixed in formalin, processed in accordance with standard laboratory procedures, and hematoxylin and eosin (H&E)-stained sections were prepared.

Figure 81.28a shows an image extracted from the 3D OCT data volume. Using in-house visualization software developed in C++, the optimal oblique image slice was extracted to match the H&E-stained histology section, shown in Fig. 81.28b. For this sample, the oblique OCT slice was positioned parallel and adjacent to the needle probe, with the horizontal axis of the image orientated along the direction of needle retraction. Note that each vertical column of the image intersects a different radial B-scan, with the horizontal section through the center of the image being closest to the probe. The reduced signal at the top and bottom of the image corresponds to tissue that is more distant from the needle probe.

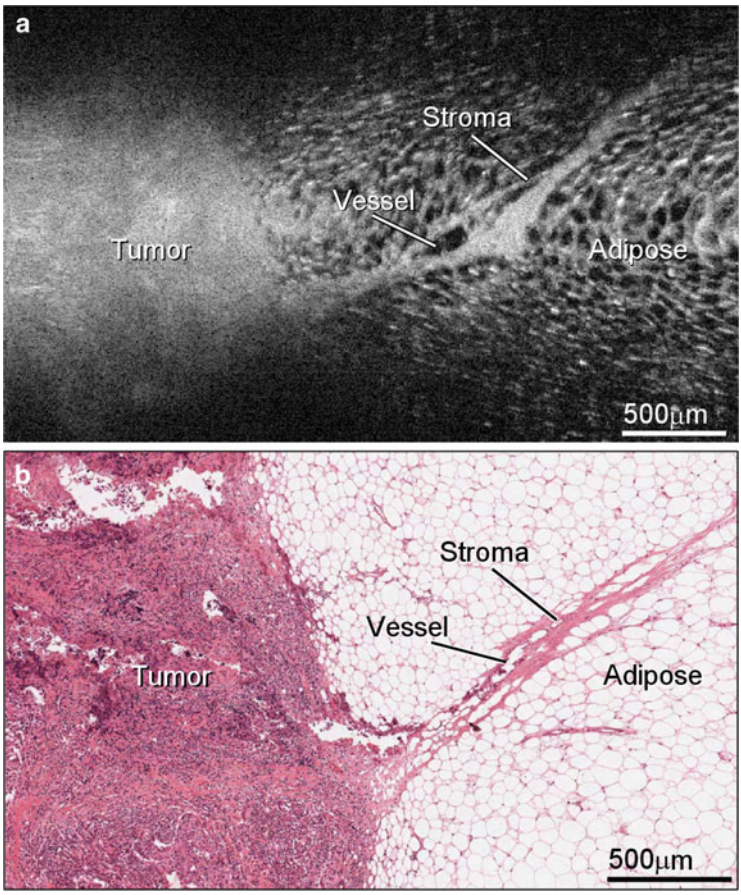

Fig. 81.28 (**a**) Longitudinal reconstructed OCT image of a tumor margin, acquired with a 23G OCT needle probe. The horizontal axis of the image is aligned with the direction of needle retraction during scanning. The imaging plane is positioned adjacent and parallel to the needle (hence the needle is not visible in the image). (**b**) Colocated hematoxylin and eosin (*H&E*)-stained histology (Images adapted from Ref. [3])

Malignant tissue appears as a homogeneous region of high backscatter (light gray), corresponding to invasive carcinoma. A strand of normal fibrous stroma can be seen extending from the area of malignancy, containing a vascular space labeled in both images (vessel). We observe a clear delineation between the dense tumor and the honeycomb structure evident in the surrounding adipose tissue.

Figure 81.29 demonstrates an OCT needle probe inserted under ultrasound guidance into a fresh ex vivo breast tumor specimen. OCT and histology images were acquired on a sample obtained from a 71-year-old female with a 15-mm grade 1 invasive ductal carcinoma. In this case, the 23G (0.64-mm OD) OCT needle probe was inserted through an 18G (1.27-mm OD) guide needle and positioned at the edge of the tumor. The purpose of the guide needle was to indicate the exact location

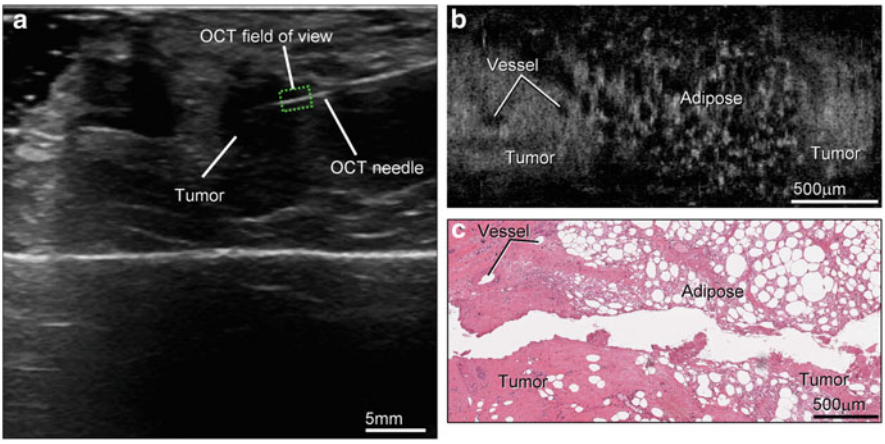

Fig. 81.29 (**a**) Ultrasound guidance of an OCT needle probe during insertion into a breast cancer tumor, showing OCT field of view. (**b**) Longitudinal reconstructed OCT image acquired at boundary of tumor. Horizontal axis of the image is aligned with the direction of needle retraction during scanning. (**C**) Colocated H&E-stained histology (Images adapted from Ref. [93])

scanned for later histological validation; thus, it was left in situ after imaging and the entire sample was fixed in formalin. A slice was obtained along the length of the guide needle, and an H&E-stained section was prepared, as shown in Fig. 81.29c. The optimal matching OCT scan was extracted from the 3D data volume, shown in Fig. 81.29b: a longitudinal image extracted along the direction of needle retraction. Regions of desmoplastic tumor stroma and intervening adipose tissue are visible in both OCT and the histology section. A honeycomb pattern corresponding to the cytoplasmic membranes of individual adipocytes is evident in the OCT. Two vascular structures are also apparent in both OCT and histology images.

We note that the limited field of view of an OCT needle probe scan (typically only 1–2 mm from the needle tip) is insufficient to image an entire tumor margin in a single scan. However, in a clinical scenario, the probe may be inserted multiple times along the planned tumor margin, allowing the clinician to inspect the tissue immediately prior to excision. Such a tool is not intended as a replacement for postoperative histology, but as an intraoperative aid to reduce the incidence of involved tumor margins. Given the large number of lumpectomies performed and the high re-excision rate from involved tumor margins, even a modest improvement in surgical guidance would save thousands of patients each year from an unnecessary second surgery.

81.4.2 Lung Imaging

81.4.2.1 Background

The lungs comprise a network of branching airways, beginning from the larger bronchi extending to the smaller bronchioles, and terminating in a large number of

alveolar sacs. Elastin and collagen fibers within the alveoli walls allow them to expand and contract during respiration, and their walls are interlaced with small capillaries which facilitate gas exchange with the blood. There are a range of diseases which alter the structure and function of the alveoli. Chronic obstructive pulmonary disease [104] is characterized by the destruction of the alveolar walls and the permanent enlargement of these airspaces. In contrast, pulmonary fibrosis [105] presents as a thickening of the alveolar walls caused by fibrotic (scar) tissue with greatly reduced elasticity. These two conditions account for over three quarters of all lung transplants [106].

Imaging of lung tissue has the potential to reveal structural, functional, and anatomical abnormalities that occur during these disease processes. Characterizing the progression of these changes presents new possibilities in the assessment of response to treatment. The heterogeneous nature of these lung diseases makes this problematic in human subjects. However, in the more controlled scenarios of animal disease models, imaging techniques offer the attractive possibility of longitudinal assessment, where the animal may act as its own control subject. In this case study, we show proof-of-principle measurements demonstrating the ability of OCT needle probes to image lung parenchyma in an ex vivo setting.

81.4.2.2 3D OCT Needle Probes to Visualize Alveoli

Ex vivo studies have shown that OCT may be used to image individual alveoli [107, 108] and in vivo OCT imaging using a thoracic window has been demonstrated in both mouse and rabbit models [109–111]. However, such techniques are limited to peripheral lung tissue due to the limited penetration of OCT.

OCT needle probes extend this imaging capability deep into the lung, without the need for excision of tissue. The delicate nature of lung tissue puts additional restrictions on needle diameter to minimize trauma during imaging. In this section, we demonstrate the application of a side-viewing OCT needle probe with an OD of 310 μm. The probe design is described in detail in Sect. 81.2.4.2 and illustrated in Fig. 81.15.

For this case study, imaging was performed on fresh, isolated ex vivo lungs, extracted from a rat model. Adult rats were euthanized by CO_2 inhalation and exsanguinated prior to removal of lung lobes. Following tracheal cannulation, lungs were inflated by a syringe filled with isotonic saline.

Figure 81.30 shows representative OCT images extracted from a 3D needle probe scan. The radial image of Fig. 81.30a was constructed from one full rotation of the probe. The needle hole (labeled n) can be seen at the center of the image, surrounded by alveoli and a small blood vessel (labeled v1) to the left of the image. The alveoli present as small regions of low backscatter (dark gray), delineated by the more highly backscattering alveoli walls (light gray). Figure 81.30b highlights the value of acquiring a 3D pullback scan, showing the relative position of multiple vessels and bronchioles not visible in a single radial image. As with the earlier breast tumor scans, the longitudinal OCT image was extracted from the data volume in a plane parallel and adjacent to the imaging needle. Its location relative

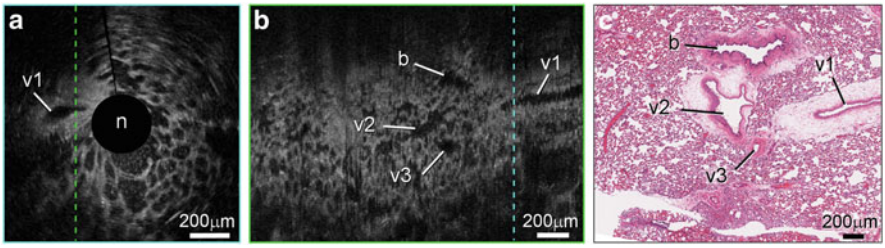

Fig. 81.30 Rat lung images acquired with an OCT needle probe. (**a**) Radial OCT image acquired from one rotation of the probe. *Dashed green vertical line* shows location of the longitudinal image shown in (**b**). (**b**) Longitudinal reconstructed OCT image showing a bronchiole and multiple vessels, with the horizontal axis aligned with the direction of needle retraction. The *dashed cyan vertical line* shows location of the radial B-scan shown in (**a**). (**c**) Corresponding H&E section. *n* needle hole, *b* bronchiole, v1, v2, v3 blood vessels (Images adapted from Ref. [5])

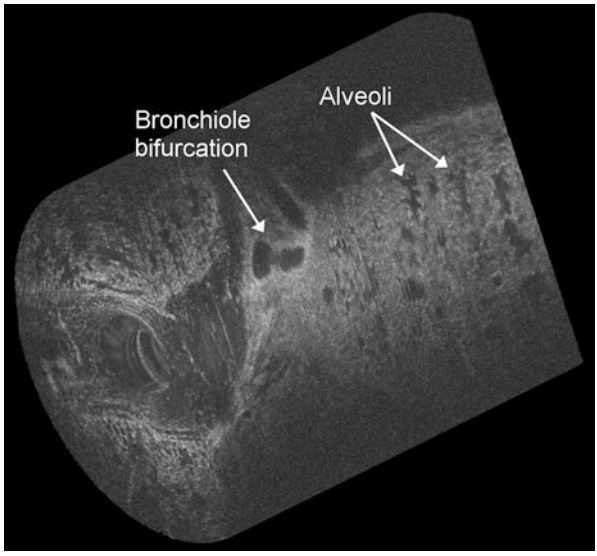

Fig. 81.31 3D visualization of fetal lamb lung. The cylindrical image volume has been sliced along a plane parallel to the needle tract, revealing alveoli and bifurcation of bronchioles. The length of the cylindrical volume is 2 mm and the diameter is 1.66 mm (Image adapted from Ref. [5])

to the radial scan is indicated by the dashed green line in Fig. 81.30a. A bronchiole (labeled b) and three vessels (labeled v1, v2, v3) are visible, showing the correspondence with the colocated H&E-stained histology section in Fig. 81.30c. Orthogonal views of vessel v1 are visible in both radial and longitudinal OCT images (Figs. 81.30a and b).

Using the same experimental setup, images were also acquired from an intact preterm lamb lung containing amniotic fluid. The OCT needle probe was inserted into the freshly dissected lungs and counterrotated over a 2-mm pullback range. Figure 81.31 shows a 3D volume rendering generated from the OCT data set. By manipulating the rendered volume, it is possible to explore the complex

3D structures present in the image data. In this image, a section of the cylindrical data volume has been cropped to reveal the bifurcation of a pair of bronchioles. A video animation of this volume rendering is available as supplementary data in Ref. [5].

Extending from this excised lung model to an in vivo scenario is possible by the insertion of the needle probe through the chest wall. As with transthoracic lung biopsies and fine-needle aspiration biopsies, the use of OCT needle probes carries a risk of pneumothorax, and some tissue trauma will occur. In our measurements, the introduction of the OCT needle probe was found to cause some local trauma to pulmonary structures. The development of small caliber (0.31-mm OD) OCT needle probes, which are significantly smaller than the needles currently used for lung biopsies, is an important step forward in reducing these complications and making in vivo measurements feasible. An alternative approach using a flexible transbronchial OCT needle probe has recently been proposed [6]. This allows insertion of the needle from inside an airway, penetrating out into the surrounding parenchymal tissue, avoiding insertion through the chest wall.

81.4.2.3 Dynamic OCT Needle Probes

OCT needle probes may also be used to acquire dynamic scans of lung tissue. The dynamic probe used in this study was described in Sect. 81.2.3.2 and is illustrated schematically in Fig. 81.9d. In brief, a side-facing, inner imaging needle (0.72-mm OD) was translated back and forth within an enclosing outer needle (1.27-mm OD). This linear motion had a stroke of 12 mm and a rate of 3 Hz. The light beam was emitted through a slit window (length 20 mm) in the outer needle, allowing acquisition of a time sequence of 2D images.

The needle was inserted into a fresh, ex vivo isolated pig lung infused with saline. During imaging, the pressure was cycled between 0- and 20-cm H_20 to simulate cyclical lung inflation and deflation.

Figure 81.32 shows two images acquired during simulated (a) maximum deflation and (b) maximum inflation. The OCT needle probe is positioned along the top of the image, with the light beam orientated downward. The void at the top of the image shows a narrow saline-filled region immediately adjacent to the needle. Figure 81.32c shows the images in (a) and (b) superimposed: maximum deflation (green) and inflation (red), with evidence of both expansion and recruitment of alveoli. A video showing multiple “breath cycles” is available as supplementary data in Ref. [5].

Dynamic OCT acquisitions such as these have the potential to assess viscoelastic properties of lung tissue, by tracking the displacement of parenchymal tissue in response to pressure fluctuations. Comparable measurements have been performed in vivo in an endoscopic setting for human airway compliance [112], and initial measurements have been demonstrated with a needle probe [58], using analysis techniques from optical coherence elastography [113, 114]. Dynamic OCT needle probes present the opportunity to perform such measurements in situ at different locations and depths within the lung, which may be useful in the scenario of lung disease which is inherently heterogeneous.

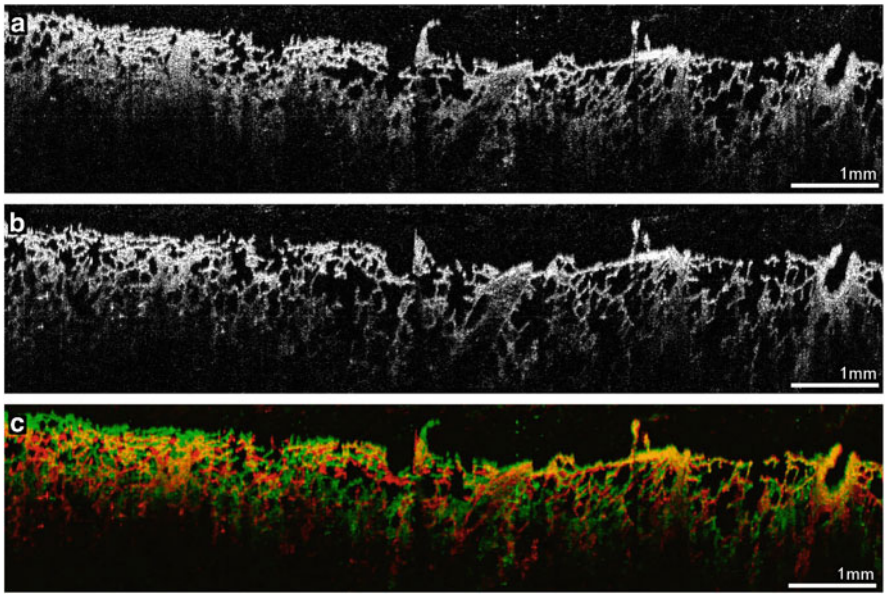

Fig. 81.32 A dynamic sequence of images of a pig lung, showing simulated (**a**) deflation and (**b**) inflation. (**c**) Superimposed images of deflation (*green*) and inflation (*red*) (Image adapted from Ref. [5])

OCT needle probes open new possibilities for the assessment of lung physiology in both health and disease. This case study demonstrates the high level of structural detail visible with an OCT needle probe, allowing visualization of alveoli, bronchioles, and vessels deep within the lung, both statically and dynamically.

81.5 Conclusion

OCT needle probe technology has reached a level of maturity that enables 2D and 3D scanning with image quality comparable to state-of-the-art benchtop systems. Some technical challenges remain, such as increasing the scanning speed or enhancing the depth of focus, but it is very likely that these will be gradually resolved in the medium term with continued engineering advances. We have shown that OCT needle probe technology has opened up a variety of possible application areas where minimally invasive deep-tissue access is required, and the current literature reflects the very promising but still exploratory nature of these investigations. Unlike endoscopic OCT, which has found a commercial foothold in cardiology and gastroenterology, OCT needle probes are still searching for their commercial niche, although some compelling clinical applications such as intraoperative assessment of breast cancer tumor margins or biopsy guidance have already been identified.

Examination of easel paintings • Laser ablation • Leonardo da Vinci • LIBS • Noninvasive examination of artworks • Structural examination

82.1 Introduction

There are certain specific demands of any examination technique that is used for the investigation of artworks. At present, it is usually expected to be noninvasive, which means that it should not interfere with the substance of a historic monument in any way. There are no systematic studies on this matter regarding OCT. However, it is usually assumed that the intensity of the probing infrared beam proclaimed safe for the human retina is also safe for any kind of historic object. Additionally, OCT data collection is fast, and neither object preparation nor use of a sample chamber is necessary. The OCT examination may, therefore, be repeated as many times and in as many places as desired. The alternative to such noninvasive examination is collection of a sample of the structure being examined. The sampled material is then usually embedded in a synthetic resin and the cross section revealed by careful polishing. A specimen prepared in this way is then inspected visually under a microscope, usually with white light illumination or by examination of

UV-excited fluorescence, and cross-sectional photomicrographs are taken. Other methods of examination of samples comprise chemical spot and staining tests [1] or the use of spectroscopic techniques, e.g., micro-Raman [2]. The identification of strata is usually unequivocal, but collecting samples for analysis is always limited by conservation ethics to just a few places, usually where some losses or cracks have occurred. Nevertheless, the samples should be as small as possible. The cross sections obtained are usually of the size of 0.5–1 mm (however, the damage area is prone to be larger than the diameter of the cross section and visible to the naked eye). All these limitations result in the poor representativeness of the sampling technique as compared with noninvasive ones such as OCT.

In contrast with medical applications, where OCT apparatuses are highly specialized and usually designed for specific organs or tissues, in the case of the imaging of artworks, an instrument capable of an inspection of a wide diversity of objects is required. Artworks are composed of various materials and have a broad range of sizes (some paintings have dimensions of a few meters) and different accessibility – for example, restricted access when displayed, either vertically or horizontally; specific storage or display conditions (close humidity and temperature control); and availability for transport. These require a transportable apparatus capable of working on the object without removing it from its permanent installation site. There is no doubt that these requirements can easily be fulfilled by portable OCT systems utilizing fiber optics and compact light sources.

In the context of the diversity of objects, a major limitation of what may be examined with OCT lies in the transparency of their subsurface structures. Sometimes this drawback eliminates whole groups of artworks. In the case of paintings, however, deep examination of usually at least some particular areas may be carried out, thanks to the IR transparency of the pigments used, whereas in other areas, examination is limited just to the transparent varnish layers (if present). Nevertheless, with the increasing sensitivity of modern Fourier Domain instruments, the number of accessible objects is systematically increasing. A good example of this kind is the use of OCT for examination of some, in principle, visible-light-impermeable materials such as sandstone [3]. Apart from the desired high sensitivity, the wavelength used is an important factor to be considered in the choice of OCT instrument for examination of works of art. This subject has been addressed in an early paper by Szkulmowska et al. [4] and later by Liang et al. [5]. The latter report has been expanded lately into a more comprehensive study [6]. The general conclusion from all these contributions is that longer wavelengths offer greater depth of examination. Consequently, in [6], the authors point to 2.2 μm as the most suitable wavelength from the point of view of the transparency of pigments. On the other hand, when compared to those utilizing near-infrared light (750–950 nm), portable OCT instruments working at significantly longer wavelengths ($>$1.3 μm) offer considerably lower axial resolutions. The trade-off between this and depth of examination must always be carefully considered in the context of the desired application. Nevertheless, the present authors generally prefer resolution-priority instruments over transparency-priority systems because, in our opinion, insufficient

resolution eliminates many of the potential applications completely, whereas the lack of transparency may often be compensated by appropriate choice of the areas of examination. Most of the OCT images presented herein were obtained with a portable spectral-domain instrument equipped with a superluminescent source (870 nm central wavelength, 200 nm bandwidth, 0.8 mW at the object) with 3.1 μm axial resolution (in air) and 13 μm lateral resolution.

The convenient feature of many objects of art from the point of view of the applicability of OCT for their examination is their thin-layered subsurface structure. Most of the varnished paintings executed with the traditional technique, as well as polished furniture, stained glass, and many other artifacts, fall into this category. The fact that the axial resolution is commonly two-to-threefold higher than the lateral resolution in typical OCT systems makes this technique especially well suited for differentiation of thin layers in multiply stratified objects.

However, the ultimate feasibility of employing OCT for the examination of a particular piece of artwork can be evaluated only after reviewing the conclusions provided here for the end user (a conservator–restorer, curator, or art historian) to consider. Some examples of this kind of analysis are given in the following sections.

82.2 Overview of Application of the OCT Technique to Examination of Objects of Art

Reports of the application of OCT for examination of artworks [7] have been present in the literature only since 2004 [8–11]. Three major directions were recognized from the very beginning. Most attention has been focused on the examination of subsurface structures of easel paintings, including properties of varnish and glaze layers. A second area of interest is the examination of glass objects: from ancient glass artifacts through stained glass to glaze layers on ceramics. The third group encompasses artworks made of semitransparent mineral gemstones like jades and similar materials. A more detailed review of all of these applications has just recently been published [12].

82.2.1 Application of OCT to Examination of Easel Paintings

Paintings are multilayer structures of varied composition. The straightforward application of OCT is aimed at the examination of the transparent, subsurface layers, decisive for visual appreciation. These typically consist of a transparent varnish layer with semitransparent glazes underneath.

The varnish plays a protective role against the environment and is fundamental for final appreciation [13]. It does not usually scatter light within its structure. Glazes are composed of dyes or pigments embedded in a binder (oil, tempera, or other) at rather low concentration, thus ensuring their partial permeability to visible light. They therefore scatter IR radiation only very moderately. Below the glazes (if present), one or a few layers of opaque paint are present. The bulk of these layers

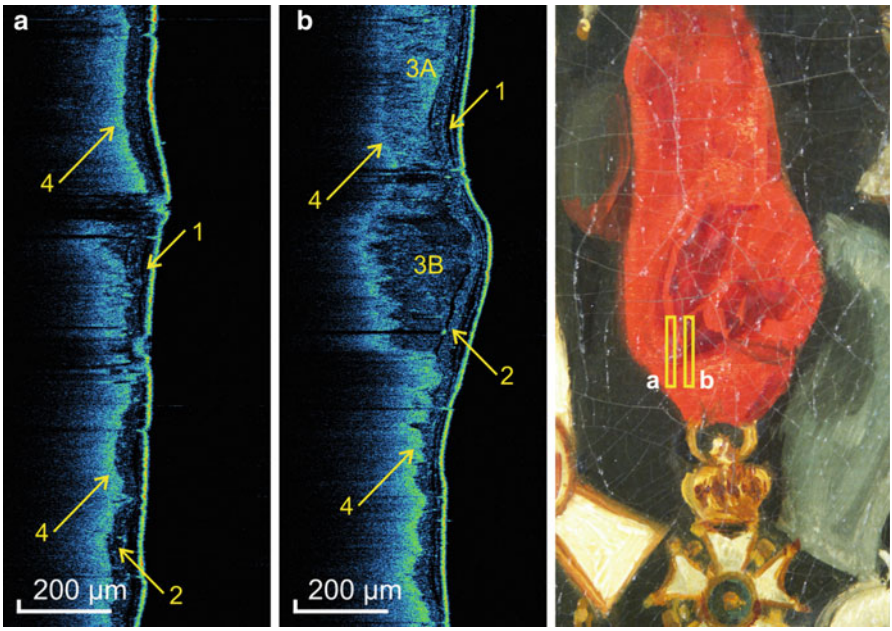

Fig. 82.1 Exemplary results of examination of a painting on canvas (*Portrait of Sir John Wylie* by P. Franck, N., Copernicus University, Toruń); (**a**, **b**) OCT tomograms: from the top, at least three layers of varnish (*1*) and then the glaze layer (*2*) are visible. Below, another thick glaze layer (*3A*, *B*, **b**) on top of the opaque paint layer (*4*) is seen. The depth scale bar is drawn for a medium of $n_R = 1.5$

is usually not accessible to OCT examination because of either high scattering or high absorption. Underneath the paint layers, there is a ground layer acting as an intermediate stratum between the paint and the support – usually a canvas or wood panel.

Easel paintings, especially those executed according to traditional techniques, bearing many layers of semitransparent glazes and of varnish, are usually very rewarding objects for OCT examination. Organic dyes used in glaze layers often have a significant permeability to the probing light. As an example, the results of OCT examinations (Fig. 82.1a, b) of a nineteenth century oil painting on canvas in two areas of the red-order ribbon are given. In this case, up to three layers of varnish (1) are seen on top of a continuous glaze layer (2). In the right-hand-side tomogram (Fig. 82.1b), three different paint layers are seen below it. The bottom one (4) scatters the probing light (770–970 nm) extensively, which thus limits the range of examination. Comparison with the photograph of the area examined allows identification of this layer as a bright red paint responsible for the main tint of the ribbon. Onto this background, subtle shades are added with a darker semitransparent paint (3A, B Fig. 82.1b). This layer reveals a continuous structure. In the upper region (3A) of the tomogram, it has a thickness of 120–150 µm and scatters light moderately. In the center (3B), this layer becomes thicker (up to 200 µm) and more

transparent. This difference in the scattering properties is directly linked with the multilayer painting technique: the intensity of color was obtained by varying the concentration of dye/pigment in the binder. It is worthwhile noting that these semitransparent layers are not present in the left-hand-side tomogram (1a), collected in the close proximity to the former. This demonstrates a common feature of the use of OCT for artwork analysis: to reveal comprehensive information, examination needs to be made in many places, since the structure of the object may vary rapidly and unpredictable over a short distance. Despite the significant amount of information provided by the representative tomogram shown in Fig. 82.1, this figure also illustrates a major drawback of using OCT for examination of artworks: the applicability of the technique is often constrained by the limited permeability of the structure investigated. In the case of paintings, it is very unlikely that support and ground layers will be accessible using this technique.

The OCT examination of varnish and glaze layers of paintings was, from the very beginning, considered an advantageous alternative to sampling. Despite the aforementioned limitations, OCT examination, due to its noninvasiveness and thus the possibility of being performed in as many places as desired, must be regarded as exhibiting improved representativeness [11]. It was early shown [14] that images obtained with OCT are congruent with cross-sectional photomicrographs of the sample taken in the same place after the OCT examination. Latour et al. used full-field OCT microscopy to analyze the structure of pigmented paint layer with superb resolution [15]. The morphology of varnish and glaze layers has been studied to attain a better understanding of the author's technique, as well as of the present state of preservation and of previous alterations and restoration attempts. For instance, the ability of OCT to localize a certain paint layer in relation to the other strata was used to analyze the chronology of historical inscriptions in an eighteenth-century painting, some of which inscriptions were identified as secondary, added during past renovations [16]. By OCT examination, it was possible to link these inscriptions to events from the history of the person portrayed and consequently make properly informed decisions regarding the program for restoration of the painting. In the same account, it was shown that the signature in another painting examined is located between two layers of varnish, so that its execution probably does not coincide with the final stage of the artwork, suggesting forgery.

The ability of OCT to image the top layers of a painting has also been used as a direct aid to the restoration. Preliminary studies by Fontana et al. [16] and Liang et al. [17] revealed the possibility of using OCT to monitor the solvent cleaning of varnish. It has been shown that, with OCT, it is possible to monitor the thickness of the remaining layer of varnish [17] as well as the preservation of the surface of the paint layer underneath [18]. This subject has been further investigated by Iwanicka et al. [19, 20] reporting examples of selective overpaint and varnish removal from historic paintings.

In spite of the fact that the upper layers of paintings are the most popular subject of examinations, in some cases, it has also proved possible to use OCT for examination of underdrawing [11, 18, 21–23] – a preparatory layer often present under the paint layers, used by the artist for the preliminary design of the

composition, sometimes not completely followed in the final result. These are very important features for art historians in studying the evolution of creation of the image. Underdrawings are usually examined with IR cameras, but in that case, the image is blurred by scattering of the illuminating light in the paint layers covering them. When OCT is employed instead, the signal is depth separated by the coherent detection and unwanted signal easily eliminated. The same mechanism can be used to sharpen the image of gold punch marks covered by a thick layer of lacquer [22].

In addition to analysis of the structure, OCT can be used for the tracking of certain destruction processes and thus aid in resolving the state of preservation of the artwork. Delamination of paint layers may be caused by poor adhesion between the layers and/or a mechanical impact. One of the possible causes of poor adhesion, common in the nineteenth century, is the use of canvas with commercial oil primer layers. If this support was used a long time after fabrication, it would have been extremely dry, and if covered with an oil paint layer, the final structure would have become very sensitive to delamination. A second factor – mechanical impact, apart from inflicting surface abrasion – may cause delamination penetrating beyond the perimeter of the area of visible destruction, under the layers in seemingly good condition, and thus be very difficult to detect. This was the case of the oil painting on canvas analyzed by the present authors a few years ago (Fig. 4 in [24]): the delamination was clearly seen to be extending out from the damaged area (varnish loss) and localized between the thick pigmented varnish layer and the glaze.

Similar damage is quite common for a particular painting technique called *Hinterglasmalerei* (reverse painting on glass) [25]. This modality, popular in the folk art of Central Europe (especially in the present south Germany, Poland, Slovakia, and Romania) until the mid-twentieth century, is characterized by employing a sheet of glass as both support and protection for the painting. Since it was designed to be viewed through glass, the details (contour and lights) were painted first, directly onto the glass, followed by glazes and opaque paints. The background layers were added at the end – in this way, the painting process was reversed as compared to classic painting technique. The obvious disadvantage of this method of painting is poor adhesion of the paint to the glass. Thus, extensive delamination is a common destructive phenomenon in these objects. Moreover, the detachments are difficult to examine and evaluated physically, because they are isolated from both sides by being sandwiched between the glass and the paint layer. OCT is here an obvious method of choice because it penetrates well through glass and, due to the high refractive index gradient in such places, is very sensitive to delaminations and blisters [26, 27].

In Fig. 82.2, an exemplary tomogram from a reverse painting on glass is presented, together with a graphic model of the structure. The whole volume of the glass support (6) is visible here, with the probing beam penetrating from the right-hand side (through the glass). Paint layers of different absorbing properties (1, 2, 3) are discernible behind the glass sheet. The adhesion of these layers to the support may be established instantly: in the upper part of the tomogram, the high intensity of light scattered at the inner surface of the glass indicates the existence

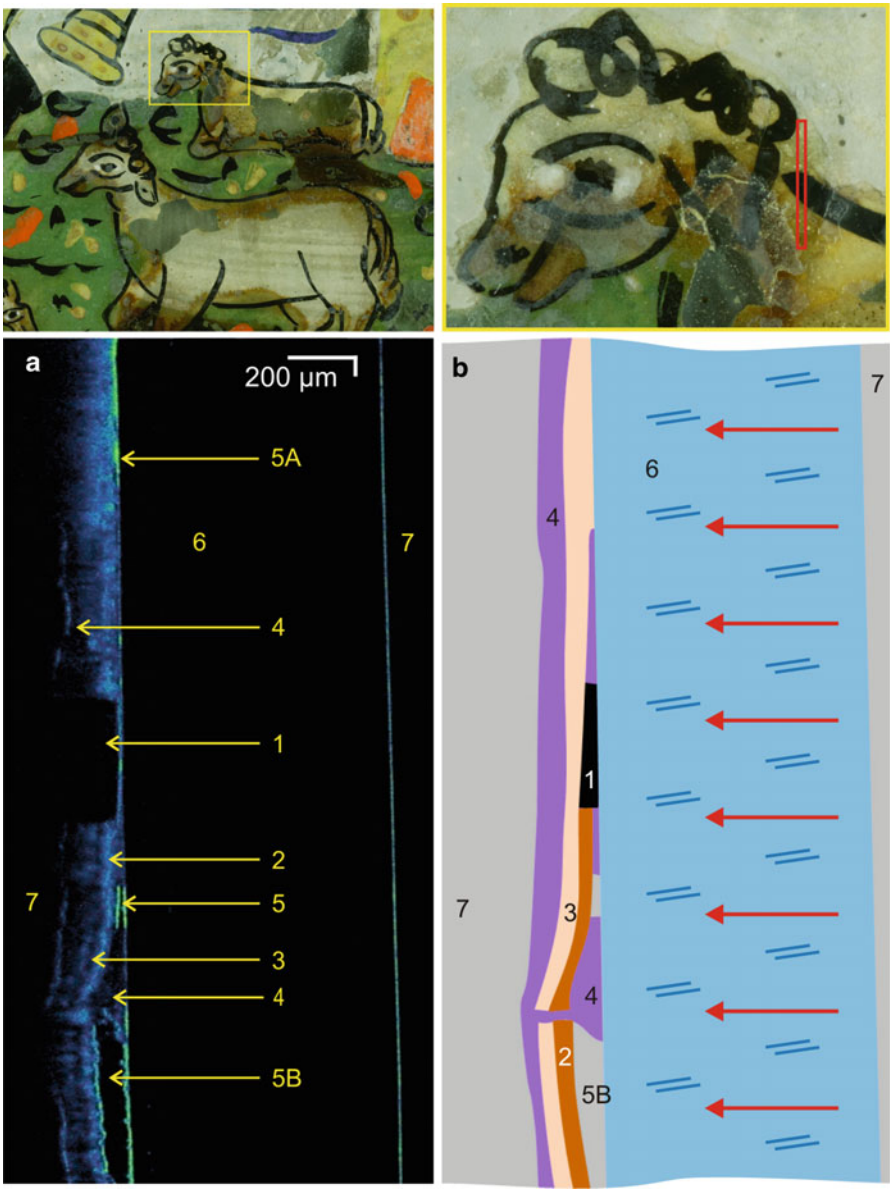

Fig. 82.2 Results of the OCT examination of the reverse painting on glass *St. Wendelin*, nineteenth century, Ethnographic Museum in Toruń, Poland, oil on glass (fragment); (**a**) tomogram obtained in the region indicated by the *red-outlined bar* in the macrophotograph above. The depth scale bar is drawn for a medium of $n_R = 1.5$; (**b**) graphic model of the structure of the painting derived from the OCT data; (*1*) contour (nontransparent paint layer), (*2*) glaze, (*3*) semitransparent paint layer, (*4*) consolidation adhesive, (*5A*) early detachment of paint layer, (*5B*) developed detachment of paint layer, (*6*) glass, and (*7*) air (Photography: W. Grzesik)

merely of a delamination, whereas in the lower part, there is a fully developed blister (5B), partially filled with a consolidation adhesive (4). In the past, there had been some attempts to repair the damage with use of consolidant applied from the back, which was supposed to penetrate through all of the paint layers to eventually fill the voids between glass and paint. As could be detected by OCT, this treatment was not always successful. Moreover, as discovered at other locations in the same object, the consolidant itself had deteriorated with time, losing adhesion to the glass and developing tent-shaped deformations (Fig. 4D in [27]).

In addition to examining the state of preservation, OCT was also used to monitor the consolidation process [19, 28]. In particular, the wetting of glass by consolidant can conveniently be monitored by OCT in real time.

Besides the practical applications of OCT in the examination of paintings, more fundamental studies – on the drying processes of varnishes – were conducted by Liang et al. [21] and continued by Lawman and Liang with combined use of NMR [29] and multi-interface OCT profilometry [30]. In this specific case of a transparent layer of varnish on a glass substrate at both interfaces, the refractive index change is significant and is described by a step function. The OCT A-scan can be approximated by a point-spread function (PSF) in this place. By locally fitting a Gaussian function, the authors were able to localize the interface to a precision ($rms = 55$ nm) two orders of magnitude better than the axial resolution of their instrument (6.5 μm), but only when both interfaces were far enough from each other. In these, and similar studies by Targowski et al. [31], it was confirmed that the ability of varnish to follow the roughness of the paint surface depends mostly on its molecular weight, in accordance with earlier results by de la Rie [13].

82.2.2 Application of OCT to Examination of Historic Glass

There is no doubt that OCT is well suited to the examination of glass objects, since this material is generally transparent. Thus, its internal structure can usually be examined within the whole depth of imaging of the OCT system employed. If the glass object contains structures of different scattering properties, they can be precisely traced with OCT [5, 18, 32, 33].

Apart from examination of structure for inventory purposes, some destructive processes in historic glass may be analyzed with OCT. In the case of stained glass, the advance of atmospheric corrosion [34] is the most important evaluation to carry out in the determination of its state of preservation. This process, caused by the moisture from precipitation at the outer side and condensation at the inner side of the glass sheet, essentially comprises two steps. During the first (called leaching), alkali and alkaline-earth ions are rinsed from the glass and replaced by H^+ or H_3O^+ ions. As a result, a gel layer rich in silica is formed on the surface of the glass. During the second step, water penetrates into this layer, and the glass may be destroyed both chemically and mechanically by freezing if subjected to low enough temperatures. This silica-rich layer may have one of several different optical properties, depending on the glass composition. Usually it has a porous structure

and thus a high-scattering coefficient, although sometimes it is perfectly transparent, but of different refractive index. In both cases, it can be detected with OCT [18, 33, 35]. By contrast with the standard examination technique, SEM–BSE (Scanning Electron Microscopy–Backscattered Electrons), using polished cross sections, no prior preparation of the glass is necessary. In principle, with a portable instrument, it should be possible to examine stained glass without dismounting it from the windows. It is worthwhile noting that the detection of the depth range of the gel layer is usually obstructed by multiple scattering of the OCT probing light within this structure, which is seen as fading tails in the A-scan signal. This disadvantage may be overcome if the other side of the glass is accessible and has not deteriorated: examination through the transparent glass then reveals sharp boundaries to the gel layer [27].

Another kind of historic glass destruction is called crizzling. This is caused by imbalance in the ingredients during their preparation and demonstrates itself as a network of fine cracks at one or both surfaces of the glass piece. When the object is stored under inappropriate environmental conditions, these lesions may develop with time and can eventually lead to the total destruction of the object. The OCT examination of such an artifact [27] revealed that the depth of the cracks on a given side of the glass sheet is uniform but different from that on the other side.

82.2.3 Application of OCT to Examination of Craftsmanship (Musical Instruments, Gemstones, Ceramics)

Lacquer coating on musical instruments is a layer of similar properties to those of varnish on paintings. In both cases, high axial resolution is a decisive factor for successful OCT imaging. Since these coatings are always transparent to visible light, the necessary resolution may well be achieved using OCT with probing light in the visible rather than the infrared range of wavelengths. Latour et al. [36] used red light ($\lambda_{center} = 650$ nm, $\Delta\lambda = 150$ nm) in a full-field time-domain OCT system equipped with a Mirau objective. They presented results of examination of lacquer coating an eighteenth-century Italian violin, preceded by laboratory tests on model samples of flame maple and lacquered wood. They showed, for the first time, evidence of the ability of OCT to reveal the internal structure of the wood (up to 50 μm of optical depth), but some of the conclusions concerning the structure of the coatings on the violin were ambiguous. Another application, encompassing the examination of both painting and craftsmanship, is seen in the imaging of painted enamel on a ceramic tile [18].

Jade art objects of art have been a focus of OCT examination from the very beginning right through to the present. In 2004, Yang et al. [8], using objects from the National Museum of Taiwan, proved that OCT may be used to detect forged archaeological jades, since this semitransparent stone scatters the probing light differently when it has been aged artificially. Natural ageing is a very slow process as compared with the artificial one which is induced by extensive heating. As a result of the latter, counterfeit objects have a more heterogeneous structure

which is possible to differentiate from the more homogeneous, naturally aged one by OCT examination. Similar examples have been reported by Liang et al. [18]. This qualitative conclusion was developed quantitatively by Chang et al. [37], who defined a statistical measure of texture of the OCT image as being a vector in a 6D space composed of three parameters derived from the histogram of the image and three calculated directly from the pixel values of the B-scan. The length of this vector, together with the second parameter representing the translucency of the object, may be used for characterization of various jades, including the detection of fraud. In parallel with this holistic study, details of the structure of jades, in particular the morphology of cracks, have been studied by Yang [38].

Another sort of object for which the use of OCT for examination was noticed early on [9] is the glaze layer on ceramics. Those studies have been continued by other authors [18, 33], focusing on analysis of different phases (and phase boundaries) within the glaze layer [39, 40], the presence and size of air bubbles [40], and the morphology of cracks [38]. The aim of these efforts was to provide a tool useful for identification of the origin, method of production, and thus, in some cases again, recognition of fraud. In the specific case of Egyptian faience, it is possible to distinguish between three ancient production methods by analyzing their cross sections with SEM. In their recent paper, Liang et al. [41] showed that this is also possible noninvasively with OCT operating at 930 nm.

Some attention has also been given to examination of parchment with OCT in the context of its degradation caused by the presence of iron-gall ink. After application, this kind of ink undergoes chemical processes resulting in its change from almost colorless through blue to a final dark brown tint. Simultaneously, acidic components of the ink cause degradation of the support which, in some cases, may eventually lead to the total destruction of the document. Conveniently, radiation of 830 nm is practically not absorbed by this ink. OCT examination is therefore possible also for areas of support covered by the ink and thus most exposed to this degradation factor. Such a study was performed by Góra et al. [42] with utilization of standard as well as polarization-sensitive (PSOCT) techniques. It was shown that OCT of this wavelength is able to image the subsurface structure of parchment with the iron-gall ink thereon, and some evidence of degradation of the parchment was found.

82.2.4 Laser Ablation Control by OCT

Laser ablation of solids is a well-established technique and may be precisely controlled by pulse duration and energy. Therefore, it is used as a fine tool also for the examination and restoration of art objects. In this section, two applications of OCT as a monitoring device of the laser ablation process will be presented. There is no doubt that in both cases, these specific utilizations can be considered only as examples from much wider field of application.

82.2.4.1 Absolute Depth Profiling with LIBS and OCT

Laser-induced breakdown spectroscopy (LIBS, or sometimes LIPS) is a technique of elemental composition analysis by spectral examination of emission from a small plume of plasma generated by the laser pulse. It is mostly used for determination of the composition of metal alloys. The diameter of the crater is usually less than 200 μm, and thus, this technique may be considered as micro-destructive. It is therefore usually regarded as an acceptable method for examination of art objects [43]. Its modality, called LIBS stratigraphy, is especially useful: a tray of pulses is delivered to the same spot on the object, and the ablation crater is created gradually. After each pulse, the plasma spectrum is registered and the intensity of chosen spectral lines determined (Fig. 82.3a). In this way, a depth profile of concentration of a given element may be revealed and eventually associated with a particular layer of the structure examined. A significant drawback of this approach lies in the lack of information about the exact depth of the crater after each pulse. Moreover, for multilayer objects, the ablation rate usually varies from stratum to stratum, and the dependence of depth on the pulse number is not linear. Therefore, for true depth calibration of the concentration profiles, the depth of the crater should be determined noninvasively after each laser pulse. The idea of using OCT for this purpose comes from the group of Sabsabi but, since the US patent [44] and a paper by Dufour et al. [45], has not been further pursued. A similar experiment was previously described by Papazoglou et al. [46] who employed a white light interferometer, similar in principle to a full-field TdOCT system. Amaral et al. [47] have analyzed some historic Brazilian coins using a commercial TdOCT instrument to determine the final depth of the crater after applying the whole train of pulses. To estimate the depth of the crater after each pulse, they assumed a constant ablation rate throughout the whole experiment. Although for metal alloys this seems acceptable, the present authors have shown that this is definitely not the case for paint layers (Fig. 82.3b). In these experiments, performed both on model samples [48] and a historic painting [49], we used spectral-domain OCT instrument after each laser pulse as a fast profilometer. In this way, the combined LIBS/OCT experiment could be performed in a reasonable time and the true depth profile recovered (Fig. 82.3c). Moreover, from changes in ablation rates, the locations of interfaces between strata were determined and confirmed by the analysis of OCT B-scans obtained in the same place. Obviously, such confirmation was possible only within semitransparent strata, whereas the crater depth and ablation rate determinations from the surface profile were feasible throughout. In Fig. 82.3, the first boundary (I/II) can be determined from the OCT B-scan and identified as lying between two layers of varnish, whereas the second boundary (II/III) is clearly visible as a change of the ablation rate (slope of the data in Fig. 82.3b) and is identified from the OCT B-scan as the varnish/opaque paint interface. The third boundary is not visible in OCT imaging as lying within the opaque structure, but can be identified clearly by the increase in strontium concentration. It is worthwhile noting that information about elemental concentration is important for both curators and conservators, as it helps in understanding the painter's technique, in distinguishing between original and non-original areas in the painting, and sometimes in the dating of the artwork.

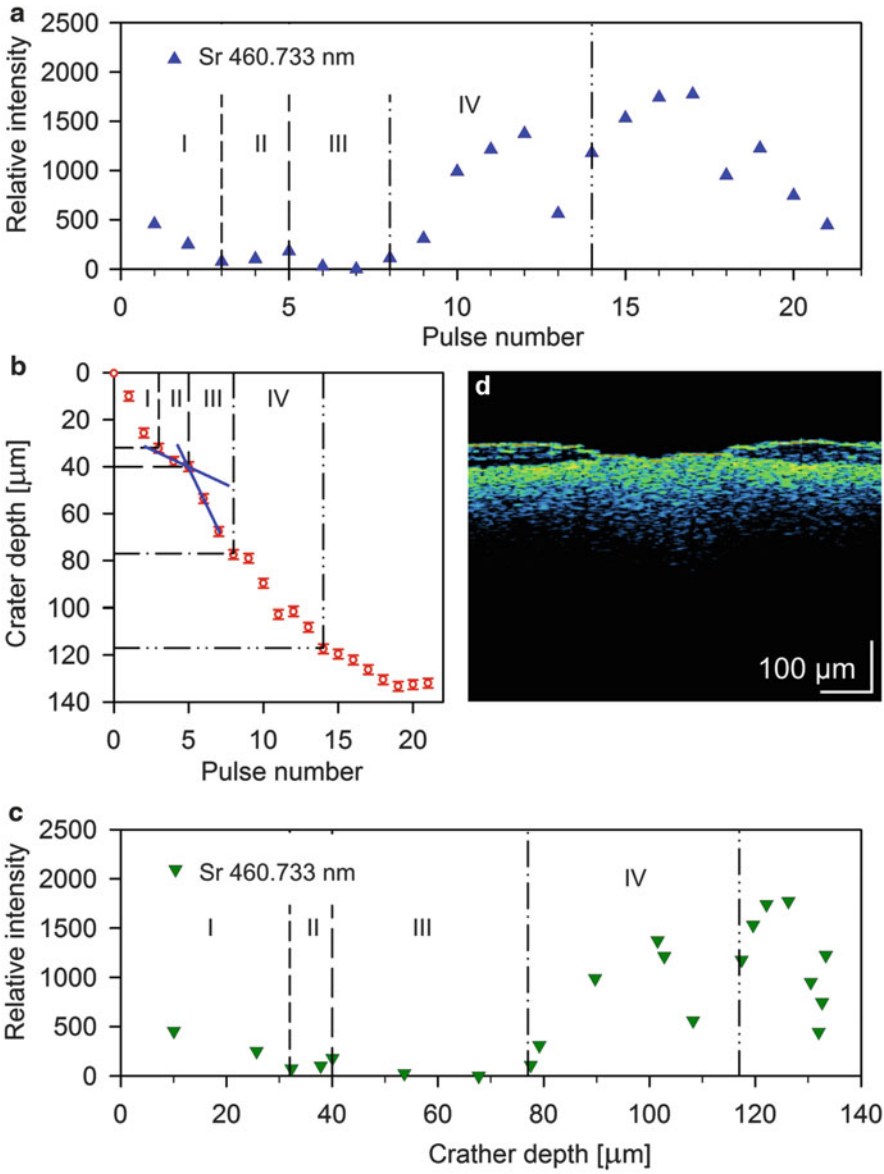

Fig. 82.3 Exemplary result obtained with an LIBS/OCT instrument (Data from [49]); (**a**) depth profile of strontium obtained by LIBS stratigraphy at line 460.733 nm; (**b**) crater depth determined from OCT data – evidence for strata boundary at 40 µm from the change of ablation rate is marked (see text for description of strata I to IV); (**c**) true depth profile determined from LIBC/OCT data; (**d**) OCT cross section after the 4th pulse; the vertical scale bar is drawn for a medium of $n_R = 1.5$

82.2.4.2 Monitoring Varnish Removal with the Use of OCT

Laser ablation paint removal is an interesting and effective alternative to chemical and/or mechanical treatment. It is used, for instance, by the US Navy to remove old paint from aircraft carriers and submarines [50], as well as in aircraft maintenance. In the case of art conservation, it is also a well-established technique for the cleaning of stone and metal sculptures: the operator uses a freehand laser head, and the process is monitored visually. The situation is much more complicated in the case of laser removal of varnish or paint layers from paintings and similar objects [51]. Here, the underlying strata are usually as vulnerable to laser ablation as are the layers to be removed, and very often, in contrast with the abovementioned industrial applications and stone/metal cleaning, it is desirable to leave a thin layer of the stratum, most of which is removed, in order to protect the underlying structure from possible damage. Laser ablation of varnish is thus still in the experimental stages of implementation and is recommended only if the varnish is very difficult to dissolve and remove chemically or if the underlying paint layer is very sensitive to the solvents to be used. In a series of papers [32, 52, 53], the present authors have demonstrated the feasibility of using OCT to monitor the thickness of the remaining layer of varnish. However, the key to real-world application is the ability to monitor this process in real time with OCT. Proof of concept was demonstrated with an SDOCT system capable of the imaging in real time of two frames per second (FPS) comprising two B-scans each made up of 200 A-scans [54, 55]. However, this imaging speed (limited mostly by data-processing capability) is substantially too slow for monitoring ablation performed under realistic conditions. This deficiency can be overcome by very fast data processing with massive parallel calculations on Graphic Processor Units (GPU) [56–58]. That principle, when employed for the setup designed for the laser monitoring of ablation [59], was operating with 6 FPS each comprising four B-scans each made up of 1,000 A-scans, at a speed limited by the acquisition time (40 μs/A-scan). In our opinion, this technology opens the gate to successful practical application of real-time monitoring, but much more work is still needed to ensure an acceptable level of safety for working with unique art objects.

82.3 Exemplary Results of the Examination of Paintings

The following examples come from the mutual research performed by physicists responsible for the instrumentation and art conservators interested in solving real problems emerging from their everyday practice. In the cases presented, OCT aided in the resolution of sequence and of deterioration processes within the secondary layers of paintings. These studies fall into two categories: (1) type, origin, and range of deterioration of historical/contemporary varnishes and (2) sequence, thickness, and continuity of both primary and secondary layers in the areas altered during past renovations.

82.3.1 Resolving Deterioration Processes Within the Varnish Layers

Leonardo da Vinci's monumental unfinished panel painting, *Adoration of the Magi*, was commissioned in 1481 for the main altar in the monastery church of San Donato a Scopeto near Florence. It was abandoned by the painter in 1482 when he went to Milan to work for Ludovico Sforza [60]. This big panel (246 × 243 cm) has been a part of the collection of the Uffizi Gallery in Florence since 1670. Over the last 500 years, it has undergone several treatments, mostly retouching and re-varnishing. OCT examination of the painting was performed in the Opificio delle Pietre Dure (OPD) in Florence, as a part of an extensive multi-instrumental examination.

Among the issues articulated by the conservators was the origin of some discolored vertical areas, not related to the depicted scene, obscuring a full appreciation of the painting. The OCT examination (Fig. 82.4) revealed differences in the structure of the thick upper varnish layer (1) within and outwith the optically altered vertical stripes. The discolored area corresponds to the presence of strong scattering in this varnish layer. The scattering centers are distributed homogeneously in the bulk of the varnish and indicate alteration of its structure. The microcracks which are responsible for this create the effect of blooming of the varnish on a macroscopic scale and are usually caused by exposure to excessive moisture. The vertical orientation of these areas suggests streaks of water running down the surface of the painting at some unidentified past time. OCT examination disclosed the presence, under this bloomed varnish, of a thin and transparent layer of earlier varnish (2), not affected by blooming.

Another task investigated at the suggestion of the conservators was to establish the nature and the cause of some specific local discoloration which had occurred in the eighteenth-century painting *Lady with a bouquet of flowers*. Fifteen years after the last conservation–restoration, white structures started to appear on the surface. The damage was either repeating the craquelure pattern or due to some accidental man-caused abrasion, as suggested by its shape. Microscopic examination (Fig. 82.5c) of the affected regions revealed that the questioned deterioration was limited to the varnish layer alone.

Since it was known that during the previous restoration two layers of dammar varnish of the same kind had been applied, the aim of the OCT examination was to resolve which of them was tending to peel off. This information was crucial to the design of a new conservation program, which was intended to be as minimalistic as possible. If both varnishes were to be removed, the vast amount of inpainting (retouching), carried out in previous conservation efforts to reconstruct lost or deteriorated parts of the work under the varnishes, would probably be destroyed.

As a result of the OCT scanning, it was confirmed that the whitish deterioration was caused by delamination of the varnish (3A in Fig. 82.5a, b), together with some local tenting (3B) and losses (3C). As can clearly be seen from the figure (Fig. 82.5b), the delamination has occurred at the boundary (yellow arrow in Fig. 82.5b) between the thick upper layer of dammar varnish (1) and the thin lower layer. The reason for this phenomenon might be the difference in thickness

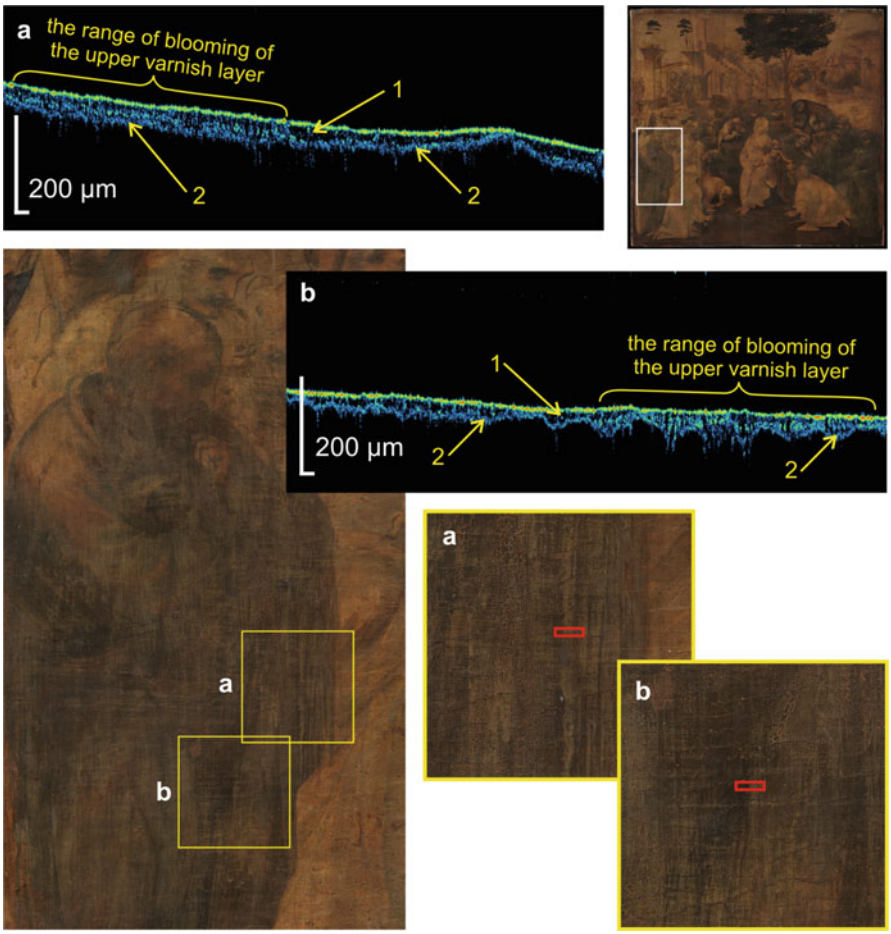

Fig. 82.4 Results of the OCT examination of Leonardo da Vinci's *Adoration of the Magi*, late fifteenth century, oil on wood, Uffizi Gallery, Florence; (**a**, **b**) tomograms obtained in places indicated by *red bars*: (*1*) upper varnish layer, locally bloomed and (*2*) lower varnish layer, transparent. The vertical scale bar is drawn for a medium of $n_R = 1.5$ (Photos: OPD, Florence)

between the two dammar layers. The information obtained provided the basis for deciding on the conservation treatment – in the end, only the upper layer of varnish was removed, with the lower layer left intact to protect the inpainting.

82.3.2 OCT Imaging of Overpainting on Varnish

Overpainting is the addition of secondary paint layers altering and hiding the original composition of a painting. During their lifetime, paintings were treated in this way because of an urge for renovation. However, until the beginning of the

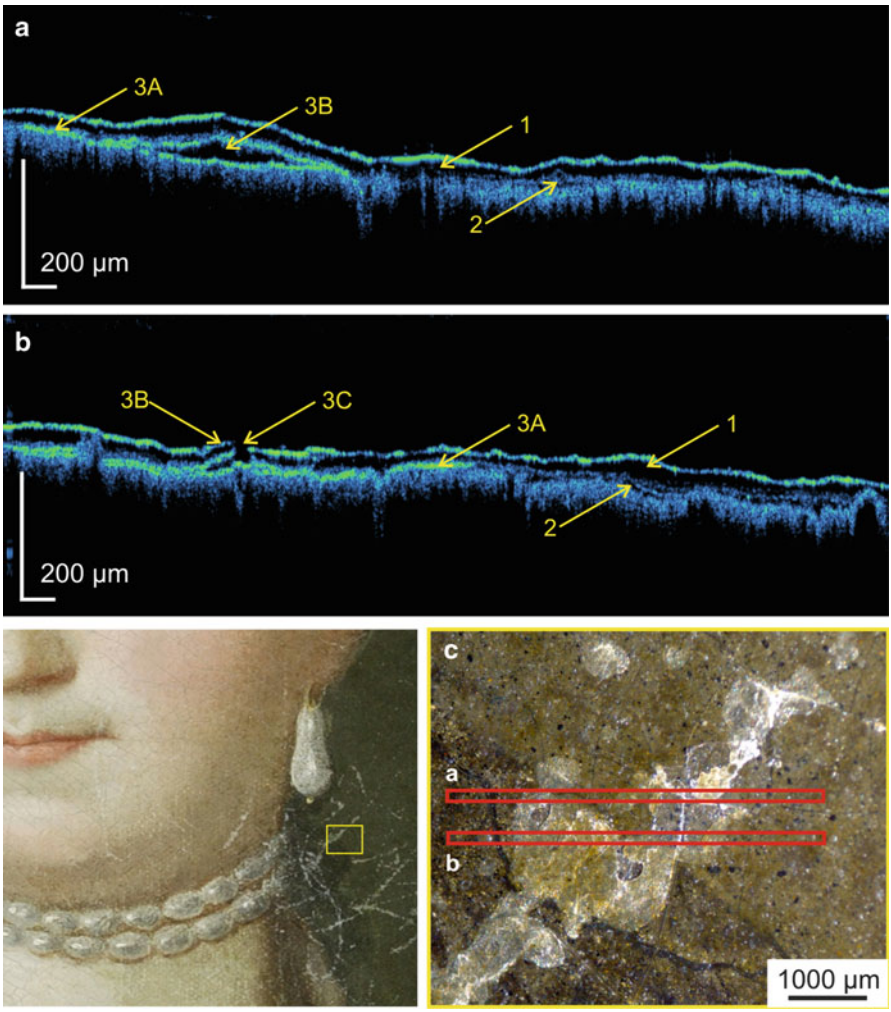

Fig. 82.5 Results of the OCT examination of the painting *Lady with a bouquet of flowers*, eighteenth century, oil on canvas (fragment), District Museum in Chojnice, Poland; (**a**, **b**) tomograms obtained in the places indicated by *red bars* in the microphotography (**c**) of the area examined; (*1*) upper layer of dammar varnish, (*2*) lower layer of dammar varnish, (*3A*) early stage of delamination, (*3B*) local tenting of the scale of the varnish, and (*3C*) loss in varnish caused by the delamination process. The vertical scale bar is drawn for a medium of $n_R = 1.5$ (Photos: E. Ryś, M. Iwanicka)

twentieth century, according to the past doctrines of the aesthetics and renovation of paintings, the original substance of artworks was considered less important than their general visual appreciation. Hence, whole composition areas damaged due to time, environmental factors, mishandling, or improper treatment (e.g., overcleaning) were given new modelling by overpainting. In theory

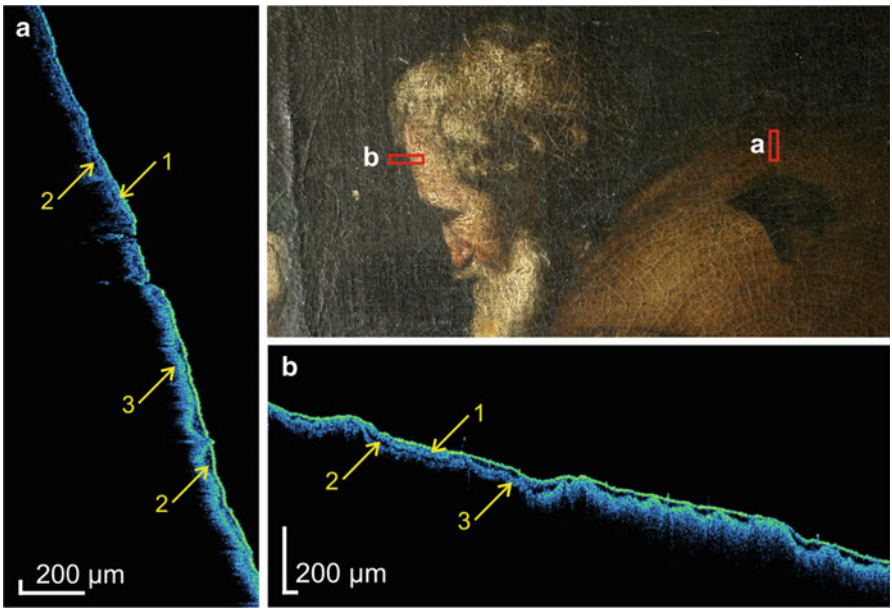

Fig. 82.6 Results of the OCT examination of the painting *Adoration of the shepherds*, after Jusepe de Ribera**,** seventeenth century, oil on canvas (fragment), Franciscan monastery in Pakość, Poland; (**a**, **b**) tomograms obtained in places indicated by red bars in the photograph; (*1*) layer of overpaint, (*2*) varnish, and (*3*) primary paint layer. The in-depth scale bar is drawn for a medium of $n_R = 1.5$ (Photo: M. Dyniec)

overpainting can easily be distinguished and mapped out by means of observation of UV-induced fluorescence of the painting. The secondary layers tend to have fluorescence weaker than the original, more ancient ones. This rule can, however, be misleading in some cases, due to the special properties of certain pigments and the strong fluorescence of some secondary varnishes [61]. For this reason, sampling is usually employed in order to corroborate surmise about the sequence of primary and secondary layers. From the perspective of the conservator, the important issues are not only resolution of the range and thickness of the overpaint but also knowing if there is a layer of varnish in between the primary and secondary paint layers. The existence of such a layer, increasing the safety of the treatment for removal of overpaint, can be naturally established by means of classic sample cross-section analysis. However, only noninvasive examination in many spots can confirm that this varnish layer, if present, is constant in thickness across the area in question.

In the painting *Adoration of the shepherds*, the aforementioned configuration of layers was suspected. OCT scanning at the boundary between the overpainted background area and the figure of St. Joseph revealed the existence of an overpaint, about 40 µm thick (1 in Fig. 82.6), lying on a very thin (about 5 µm) varnish layer (2). The upper surface of the primary paint layer is easily visible in the tomograms presented.

82.3.3 OCT Imaging of Retouching Between Varnishes

Retouching (inpainting) is usually the final stage of the restoration process of a damaged paint layer, performed by the conservators in order to integrate the painting both visually and aesthetically. According to the contemporary theory of conservation, inpainting should be applied only within the actual perimeter of paint loss and should not be laid down directly onto the primary paint layer, so that it can eventually be easily removed if later required. Similar to overpainting, retouching is usually mapped by means of UV-induced fluorescence imaging. However, the practice shows that such identification may be hindered if the retouching lies underneath a layer of varnish of strong UV fluorescence and/or significant thickness.

In the case of *Madonna of the Yarnwinder (Madonna dei Fusi)*, an oil painting attributed to Leonardo da Vinci, some issues regarding the positioning and evaluation of the retouching were clarified on examination by OCT.

Owing to the en face OCT imaging (depth separated by coherent detection), it was possible to establish the sequence of layers in the restored areas, as well as to recover the outline of the retouching and compare it to the contour of actual paint losses. Exemplary slices of such a multilayer structure are shown in Fig. 82.7. In the background area near the Madonna's face, retouching exhibiting strong UV fluorescence is localized (Fig. 82.5d). In the OCT B-scan obtained in that area (Fig. 82.7a), it is mainly retouching between varnish layers (1A, 1B) that are visible (2B). Comparison of the tomogram with the coherence-gate images (Fig. 82.7d, e, f) revealed the existence of two layers of retouching of totally different shape, positioned at different depths within the structure of the painting.

Retouching easily discernible in UV-induced fluorescence lies on the surface of the painting (Fig. 82.7d, coherence-gate depth: 6 μm) and is visible in the OCT tomogram as a thin layer, strongly scattering the probing light (2A in Fig. 82.7a). The layer clearly localized between the varnishes (2B) is the same as that seen in the coherence-gate imaging obtained at a depth of 18 μm (Fig. 82.7e). It is worth noticing the difference in size and shape of this retouching when compared to the superficial one. However, analysis of the range of paint loss (visible in Fig. 82.7f, gate depth: 35 μm) leads to the conclusion that in the region examined, retouching at both depths exceeds the area of the actual loss underneath. At the same level as the paint losses, the texture of the canvas is detectable, imprinted in the paint layer (Fig. 82.7f). This is the result of a former restoration treatment, i.e., transfer of the painting from its support. Since the structure of the contemporary canvas now present in the painting is not consistent with the imprint (as discovered by Fontana et al. by means of 3D conoscopic measurements [62]), it should be assumed that the imprint is the result of a previous transfer.

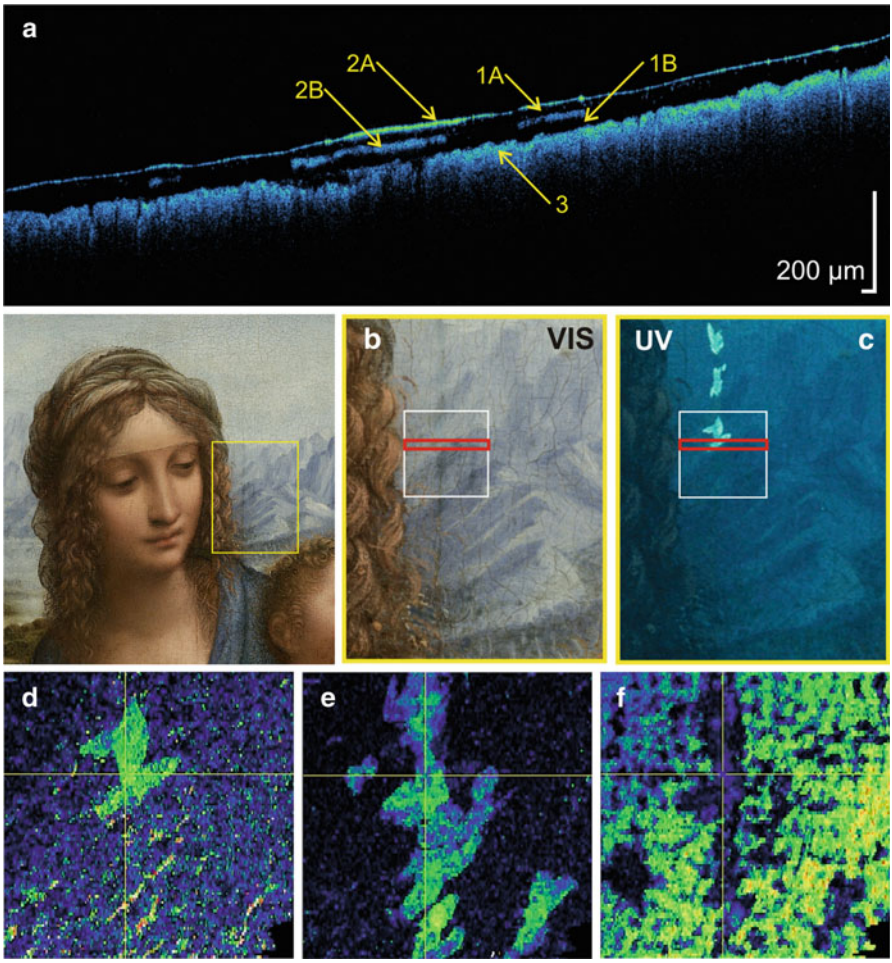

Fig. 82.7 Results of the OCT examination of the painting *Madonna of the Yarnwinder (Madonna dei Fusi)*, attributed to Leonardo da Vinci, early sixteenth century, oil on wood (fragment); (**a**) OCT tomogram obtained in the region indicated by red bars in the photographs (**b**, **c**); (**d**, **e**, **f**) OCT en face images obtained from different depths under the surface (0, 18, 35 µm, respectively). (*1A*, *1B*) varnishes, (*2A*, *2B*) two stages of retouching, and (*3*) primary paint layer. The vertical scale bar is drawn for a medium of $n_R = 1.5$ (photo: OPD, Florence)

Another example of noninvasive evaluation of retouching in the *Madonna of the Yarnwinder* (Fig. 82.8) concerns the area of the background. The OCT B-scan reveals the multilayer structure of the painting in this region, including well-preserved glazes (3) over the paint layers (4, 5). This observation was then confirmed by coherence-gate images, clearly showing that the paint layer is intact (Fig. 82.8c) under the retouching (bright patch in Fig. 82.8b).

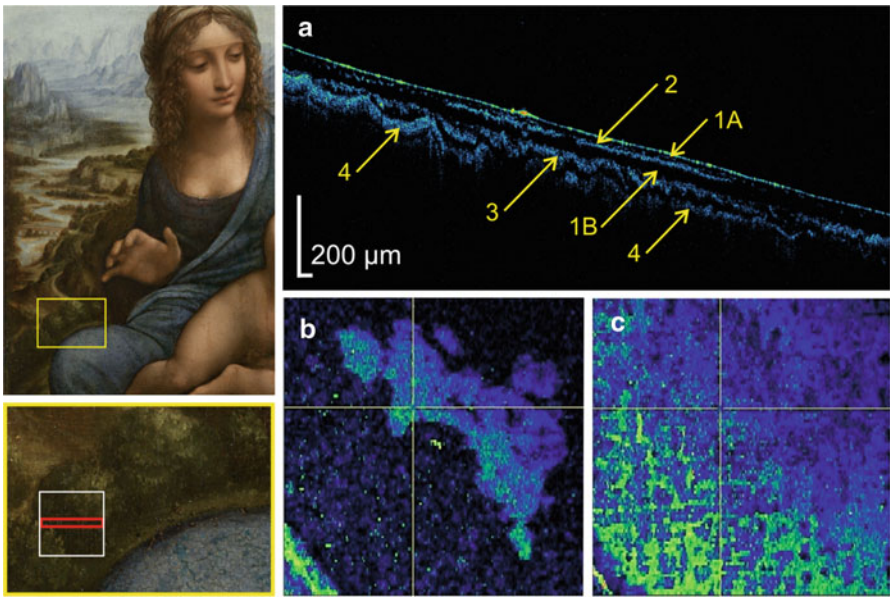

Fig. 82.8 Results of the OCT examination of the painting *Madonna of the Yarnwinder (Madonna dei Fusi)*, attributed to Leonardo da Vinci, early sixteenth century, oil on wood (fragment); (**a**) OCT tomogram obtained in the region indicated by red bars in the photograph; (**b**, **c**) en face images obtained from different depths under the surface (19, 44 μm, respectively). (*1A*, *1B*) varnishes, (*2*) retouching, and (*3*) primary glaze over the paint layer (*4*). The vertical scale bar is drawn for a medium of $n_R = 1.5$ (photo: OPD, Florence)

82.4 Conclusions

In the case of easel paintings executed in the traditional technique, OCT examination aids in resolving the structure of the primary layers (varnishes, glazes, and some semitransparent paint layers) as long as they are transparent enough to near-IR radiation. In our opinion, however, the most useful applications of this noninvasive technique for the practice of conservation are those aimed at the examination of the state of preservation and stage of deterioration, as well as of the range and nature of alterations of the upper layers of the painting, e.g., deteriorated varnishes, glazes, overpainting, and retouching. This advantage of OCT over classic invasive sample analysis arises from the possibility of examining areas large enough to cover boundaries between regions of the painting which differ in color, saturation, glossiness, etc., and therefore are suspected to exhibit some alteration. In such cases, analysis of the continuity of layers over areas of several millimeters helps to resolve complicated issues related to the history of the painting.

As for the examination of other types of artworks, the most promising would again seem to be studies aimed at resolving the structure of the object and its state of preservation.

The examples exhibited in this contribution prove that in the case of some art objects, it is possible to solve conservation issues exclusively by means of noninvasive examination. Optical coherence tomography fully deserves to be considered a fast, and practical, albeit nonuniversal, tool in assisting the conservator both in decisions as to the optimal course to take in the conservation process and in evaluation of its course and the results obtained.

Acknowledgments The results shown in Figs. 82.1 and 82.4, 82.5, 82.6, 82.7, and 82.8 were obtained with an instrument built within the EU Community FP7 Research Infrastructures Programme under the CHARISMA Project (Grant Agreement 228230) and co-funded by the Polish Government. The participation of Anna Szkulmowska, Marcin Sylwestrzak, Ewa A. Kaszewska, Łukasz Ćwikliński, and Maciej Szkulmowski of the Nicolaus Copernicus University in Toruń, Poland, and Jan Marczak, Wojciech Skrzeczanowski, Antoni Rycyk, and Roman Ostrowski of the Military University of Technology in Warsaw, Poland, as well as of Roberto Bellucci of the Opificio delle Pietre Dure, Florence, Italy, is gratefully acknowledged. Authors thank Robert Dale for critical reading of the manuscript.

Nondestructive Material Testing Using OCT

83

D. Stifter

Keywords

Optical coherence tomography • Nondestructive testing • Nondestructive evaluation • Technical materials • Non-biomedical applications

83.1 Introduction

The fact that optical coherence tomography (OCT) provides information on internal structures of scattering tissue in a noninvasive way [1] has led to a broad acceptance of OCT for dedicated biomedical imaging and diagnostics applications. Outside the biomedical field, an irreversible alteration of an object under investigation by the characterization method itself is likewise undesirable, especially in the case that such an object has to be further used with its original state maintained. For this purpose, a variety of so-called nondestructive testing methods is nowadays at hand and to a large extent – depending on the required information which has to be extracted from the sample – successfully applied.

In analogy to the *noninvasiveness* of OCT for biomedical applications, there is obviously a huge potential of OCT to add valuable contributions to *nondestructive testing* and *evaluation* (NDT/NDE) of semitransparent, scattering materials with structural features in the micron scale [2]. Especially the following facts render OCT favorable, usually giving fast and immediate results: (i) no preparatory steps are generally needed for the sample prior the investigation; (ii) no coupling media are required as it is the case, e.g., ultrasound testing; (iii) no special safety precautions have to be taken; and (iv) the achievable resolution is not determined by the sample size, e.g., as in X-ray computed tomography (X-CT).

Within this chapter, the promising potential of OCT for applications in NDT outside the biomedical field is highlighted, focusing on the – to date – investigated material systems, the extracted information of structural or functional character, and presenting dedicated application examples of OCT for NDT.

83.2 Materials Suitable for OCT Investigations

Shortly after the introduction of the OCT method itself [1], the potential of OCT for tasks in NDT was already recognized and demonstrated for bulk polymer and fiber-epoxy composite samples [3] as well as for ceramic structures [4]. However, according to the optical nature and working principle of OCT, usually relying on the detection of back-reflected light in the near-infrared spectral region between 800 and 1,550 nm, there are some restrictions imposed by the materials under test, especially for successful subsurface imaging. In contrast to biomedical applications where the number of types of tissues exhibiting distinctively different optical properties is to a certain extent limited, a quite diverse situation can be found for man-made materials and structures, with wide ranges of different refractive indices (e.g., from ~1.4 to 1.55 for most common polymers to higher than 2 for certain ceramics [5] or even above 3.5 or 4 for selected semiconductors like silicon or germanium) and with strongly varying scattering and absorption properties. In addition, technical structures often exhibit smooth surfaces, interfaces, abrupt phase and material boundaries, as, e.g., in multilayer and composite materials, which can give at first rise to distinctive imaging artifacts caused by strong multiple reflections. Furthermore, distortions of the internal sample geometry in dimensional metrology due to variations in the refractive indices (i.e., optical path lengths versus geometrical path lengths) can likewise be experienced. Consequently, it is often beforehand not clear how OCT will perform for a specific imaging and evaluation task, even if similar materials have already been successfully tested. An instructive example is given in Fig. 83.1 where wedges made from different turbid polymer materials that are commonly used in polymer injection molding were imaged by OCT, once at a center wavelength of 840 nm and once at 1,550 nm [2].

All polymer samples of this study exhibited a similar visual appearance (e.g., level of turbidity), and complementary absorbance measurements in reflection geometry in the visible and near-infrared wavelength region between 500 and 2,500 nm also showed no significant differences between the specimens. Nevertheless, they all performed differently when imaged by OCT. In order to determine the overall penetration depth for the two selected wavelength regions, the polymer wedges were imaged by OCTs which were adjusted to the same sensitivity level. The arrows in Fig. 83.1 represent the level of depth where the backside of the sample is still visible, i.e., simulating a void structure in the polymer bulk. The additional arrows in the 1,550 nm images on the left side are marking for comparison the penetration depth measured at 840 nm. Since light absorption by water is usually of no concern for polymer imaging – a fact which holds true for most technical materials – longer wavelengths are in general more favorable for larger

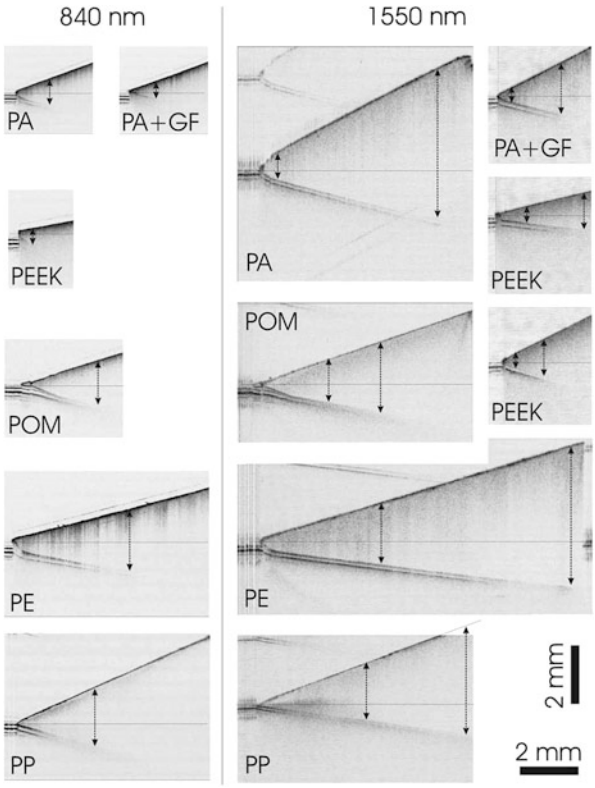

Fig. 83.1 Penetration depth study for various polymer materials, imaged at 840 and 1,550 nm: polyamide (*PA*), polyamide filled with glass fibers (*PA + GF*), polyether ether ketone (*PEEK*), polyoxymethylene (*POM*), polyethylene (*PE*), polypropylene (*PP*) (Reprinted with kind permission from Springer Science + Business Media: Fig. 6 from: D. Stifter, "Beyond biomedicine: a review of alternative applications and developments for optical coherence tomography," Appl. Phys. B, vol. 88, p. 337, © Springer 2007)

imaging depths due to decreased attenuation by scattering [6]. In the example of Fig. 83.1, the scattering behavior is influenced by the different internal morphologies of the polymer samples with crystallites and granular structures of varying length scales. Since the solidification and crystallization behavior of polymer melts is largely dependent on the processing conditions (e.g., temperature, pressure, flow velocity, and shear field gradients in polymer extrusion and injection molding [7]), the situation further complicates, as does the addition of various kinds of fillers (e.g., short glass fibers, talcum, silica, carbon particles, etc.) and pigments to the polymer material, exemplified in Fig. 83.1 for the polyamide (PA) sample filled by 30 wt.% with short glass fibers (GF).

An analogous situation as for the above-presented bulk polymer samples holds true for other material systems. Consequently, for a new envisaged NDT task, a thorough feasibility study for the material or structure of interest will mostly be necessary, although all types of (semi-)transparent media are in principle eligible for OCT imaging. To date, OCT studies have been carried out and reported for a variety of (partly natural) materials, among which can be found:

– Polymers, in the form of bulk material as well as thin films, including paints, organic coatings, layers of adhesives, and bonding agents

– Paper, papyrus, wood, leaves, fruits, and seeds
– Semiconductors
– Metal oxides and corrosion products
– Glass, ceramics, and ceramic glazes
– (Semi-)precious stones and pearls
– ...

The potential applications for OCT multiply when considering composite structures made from the above-listed materials, like glass fiber-reinforced polymer materials with enhanced mechanical properties, micro (opto-)electro-mechanical systems (MEMS, MOEMS) or encapsulated multilayer organic solar cells. A detailed description of already identified applications and results from feasibility studies performed on the above-listed materials and combinations thereof – as reported in literature – is now given in the following.

83.3 Applications of OCT for NDT

In contrast to biomedical OCT imaging, with the diagnostics of retinal diseases being the main driving force for commercial scanners, it has to be stated that no analogous *killer application* could yet be identified for OCT in NDT. However, several material imaging and evaluation studies have been carried out, which already led in some cases even to routine tasks in NDT/NDE with corresponding commercialized OCT scanners and measurement devices.

In this context it is useful to reconsider at first the different types of application areas which take benefit from NDT: the preservation of the original status of a sample is of utmost importance not only in industry, e.g., for the investigation and quality control of final products, but also of products being in an intermediate manufacturing status prior further costly or time-consuming processing steps, most preferably carried out in situ and without introducing additional delay. Likewise, precious or unique objects should also not be altered by the applied investigation method, a task experienced, e.g., in the evaluation of gems and pieces of jewelry, but mostly now emerging in the field of art and cultural heritage conservation [8]. Finally, also for research and development, the nondestructive character of an investigation method is needed, especially if the *same* sample has to be characterized by additional methods in order to learn about complementary properties or if the same sample has to be repeatedly measured in case of time-dependent investigations, like ageing and degradation studies. On shorter time scales, investigations which also can be of destructive nature, as, e.g., mechanical tests, take benefit from continuous nondestructive monitoring in order to study the performance of a single specimen. Summarizing, in the following general situations, NDT methods are indispensable, namely, for:

- (Industrial) quality control of final products (also online)
- Guidance of the production process itself (preferably in situ or online after crucial processing/manufacturing steps), including:

  - Full, 100 % quality control
  - Investigation of small representative areas from each sample
  - Batch inspection by taking samples (off line, on site)
- Evaluation of precious or unique samples like:
  - Precious stones, gems, and pearls (for classification purposes)
  - Art objects for archaeometry, conservation, and detection of forgery
  - Documents, banknotes, etc., for applications concerning security
- Research and development
  - Nondestructive material characterization before or during complementary investigations (e.g., fracture tests), leading also to
  - Repeated measurements on the same sample over time, and including
  - Studies of physical phenomena which are not directly accessible or easily influenced (e.g., flow behavior of liquids)

For the above-listed points, several instructive examples of OCT being successfully applied have been reported and are laid out in the next sections. They are listed according to the category of information obtained from the individual measurements, starting with the evaluation of the pure surface structure, proceeding to thickness measurements of layered systems, to imaging of internal 3D structures and finally leading to the determination of functional information.

83.3.1 Surface Metrology

The principle of white light or low-coherence interferometry (WLI, LCI) was already used in the 1980s for remote sensing of distances in an unambiguous way, e.g., in a point-wise sensing style like standard OCT with fiber optics [9] or by using area sensors for parallel detection [10]. The latter technique, being called coherence probe (CP) imaging, uses a Linnik interferometer in a basically similar setup as full-field (FF) OCT [11] and was immediately introduced for the measurement of surface topographies, with fully automated metrology systems for the inspection of line widths and defects of ***resist structures*** on ***Si wafers*** [12]. Further developments focusing on the profilometry capabilities of this technique soon followed, including a coherence scanning microscope in Michelson configuration [13] or a Mirau correlation microscope [14] with increased stability against vibrations and providing amplitude and phase information for accurate surface measurements as demonstrated on photoresist trenches for ***integrated circuits***. Interestingly, the sectioning capabilities for such CP or correlation microscopes when using medium-to-high numerical aperture (NA) objectives do not solely rely on the temporal coherence properties of the light source (which is mostly also spatially incoherent) but also on the fact that interference can only occur for regions on the sample where the curvature of the wave front matches (correlates with) the one of the reference field [15]. Only, when using such full-field detectors for thicker object structures, the noninterference background image is – compared to conventional OCT – not sufficiently suppressed, which can lead to detector saturation and decreased sensitivity. However, these techniques were most successfully further

developed for the investigation of surfaces, leading to, e.g., scanning white light interferometers (SWLI) which are nowadays routinely used for topography measurements, providing even subnanometer precision on smooth homogenous surfaces by an evaluation of the phase or phase slope information [16]. Equally, dedicated profilometers for rough surfaces have early been reported [17] and applied, e.g., as so-called coherence radar on high aspect ratio features (up to 2 cm deep bore holes with 5 mm in diameter) of ***machined industrial parts*** [18].

Simultaneously to the full-field approaches described above, the point-wise detection scheme of conventional OCT, generally using fiber optics together with spatially coherent sources and exhibiting shot-noise-limited performance, emerged [1]. Here, the detection of weak backscattering features, in contrast to the evaluation of the strongly reflecting air/surface interface, was of prime interest, inspired by the optical low-coherence and coherence-domain reflectometry (OLCR, OCDR) techniques which were originally introduced for the characterization of ***optical waveguide components*** [19, 20] and already used for depth measurements of trench structures in ***memory chips*** [21]. Since both approaches, i.e., full-field CPM vs. conventional point-wise scanning OCT, have their same origin in LCI, OCT is repeatedly subject of surface evaluation studies including ***surface shape*** [22] and ***roughness*** measurements [23]. In this context also efforts in, e.g., providing validated procedures for reliable surface characterization with OCT, which are conform and linked to recognized standards, are essential [24]. However, one has to mention that OCT might not always be the first choice for such surface metrology tasks: especially for easy accessible surfaces with moderately inclined slopes and features, OCT has to compete with other dedicated commercialized surface metrology devices based on techniques like confocal microscopy [25], the above-introduced SWLI, wavelength scanning interferometry (a swept-source (SS) variant of WLI in the Fourier domain (FD)) [26], digital holography [27], or chromatic confocal microscopy (CCM) [28], a principle which relies on chromatic length aberration of specialized lenses to measure distances and results in simple, robust, and cost-effective sensors. These techniques were even further enhanced: e.g., CCM can be combined with the principle of spectral interferometry (SI) – similar to spectral-domain (SD) OCT – to form a hybrid chromatic confocal spectral interferometry (CCSI) sensor for surface metrology of uncooperative surfaces, taking profit from the interferometric gain (like OCT) and from the evaluation of the phase [28]. Nevertheless, OCT systems and dedicated OCT-like sensors were commercialized and are increasingly offered for surface metrology (although such commercial devices are sometimes even not referring to OCT but are just simply called interferometric or topography sensors), with advantageous performance especially for the evaluation of ***high aspect ratio structures***, ***specularly*** or very ***weak reflecting slopes***, and – by using fiber-optic sensor tips or thin needles – for areas which are hard to reach, like the ***interior of bore holes***, ***tubes***, ***and cylinders***.

An example for the topography evaluation of high aspect ratio features is given in Fig. 83.2, with laser-drilled holes, exhibiting an average depth of 1 mm and an average width at mid-depth of 100 μm, in a carbon fiber-reinforced carbon (CFC) composite structure. Such structures are used in the so-called divertor of nuclear

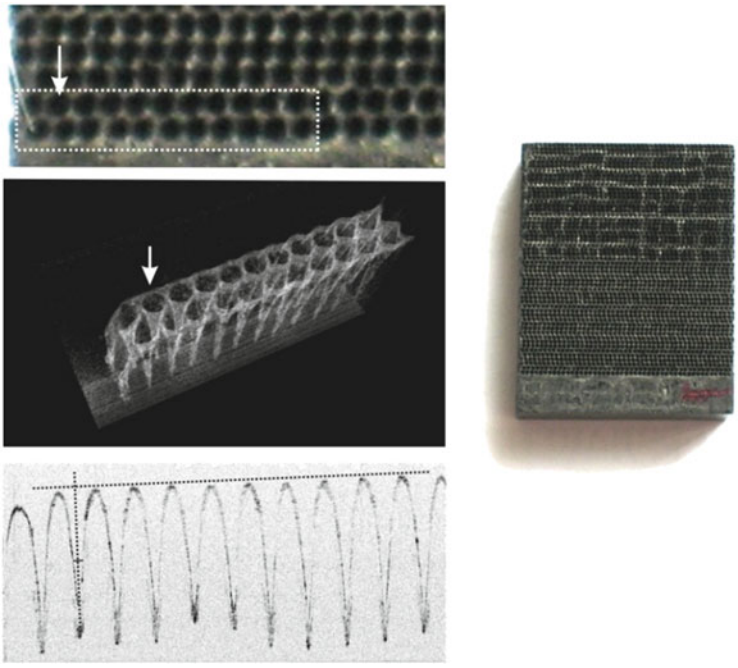

Fig. 83.2 Laser-drilled holes with high aspect ratio in a CFC structure evaluated by OCT. *Top* and *right*: photograph of sample and enlarged surface area indicating the reconstructed volume measured by OCT (*middle*). *Bottom*: cross-section through one row of holes, with an average depth of 1 mm and an average width of 100 µm at mid-depth. (OCT software by M. Wurm, UAR GmbH, Austria), (Sample courtesy of Plansee SE, Austria)

fusion reactors and need efficient cooling, realized by interlocking these structures to a layer of copper. Due to the rough nature of the surface in the inside of the holes (partly caused by exposed fiber ends during machining), the strong inclination, and increased light absorption by carbon, conventional surface metrology tools (like SWLI and confocal microscopy) failed. In contrast, the high sensitivity of OCT ensures that the topography can successfully be traced down to the bottom of the holes. Comparative dimensional measurements on polished sections as well as by X-CT have proven the accuracy of OCT and were leading to a dedicated OCT-based inspection system with automated image evaluation [29].

Further reported examples for surface profilometry with OCT include the shape determination for grinding ***optical lenses*** [30, 31] or surface roughness measurements on ***paper*** [32] and pharmaceutical ***tablets*** [33]. OCT was also used to evaluate the response of surface cracks on an artistic ***painting*** as well as deformations of the canvas during humidity changes [34]. In addition to the examination of ***silicon V-grooves*** [35], ***MEMS*** structures [36] and the determination of shape and deformation of ***semiconductor wafers*** [37], real-time reflectivity and topography measurements of ***integrated circuit*** (IC) structures with FF-OCT [38] and topography measurements of MEMS and ICs from phase maps with SS-FF-OCT [39] were reported.

Modified OCT techniques were used, e.g., to determine the topography of metallic surfaces, like ***ball grid arrays*** or ***electrodes*** with a so-called parallel OCT system [40, 41] where each pixel of the 2D detector array has an own demodulation circuit, or to quantitatively reconstruct surface profiles (like those of ***microlens arrays***) by differential phase-contrast OCT [42].

Finally, it shall be mentioned that the high sensitivity, robustness, and rather long-working distance of such OCT-based sensors and systems render them very suitable for online monitoring during machining/processing as well as for the quality control of moving parts. In the context to the above-presented example of Fig. 83.2, in situ monitoring of ***laser drilling***, ***structuring***, and ***machining*** of materials like ***steel, ceramics***, ***glass***, or ***polymers*** [43–46] even with automatic real-time guidance [47] was reported or – in the field of art diagnostics – the in situ monitoring of laser ablation for removing aged ***varnish layers*** from paintings [48]. Further applications also include OCT/LCI measurements simultaneously performed with laser-induced breakdown spectroscopy (LIBS) for complementary elemental analysis [49, 50]. With respect to surfaces, which are not easily accessible, metering the level of ***liquids*** (e.g., of molten glass in glass melting ovens [51]) or gauging in-line hot float glass [52] shall be mentioned, as well as a study for the in situ determination of the roughness of chemical mechanical ***polishing pads*** for semiconductor wafers which are covered by a wet and slurry containing layer [53]. The last example leads to the application of OCT to provide a profile of a buried/coated surface, as demonstrated for the dynamic monitoring of the drying process of varnish on paint in order to study the formation of surface roughness [54], for analyzing (varnish-covered) imprints of tools which were used for ***gold punch decorations*** as found, e.g., on Renaissance panel paintings [55], as well as for buried topographies of ***printed electronics*** (e.g., radio-frequency antenna) in a comparative study with topography measurements by WLI and contact profilometry [56].

83.3.2 Thickness Evaluation of Layers and Thin Films

The acquisition of profiles from buried surfaces immediately leads to the determination of layer and film thicknesses, a task where OCT has equally to compete with a variety of other optical techniques like with the above-introduced chromatic confocal principle or with (spectroscopic) reflectometry or ellipsometry [57], which are routinely used, e.g., in the semiconductor industry for layers ranging from several hundreds of micron down to (sub-)monolayers. As to the original LCI techniques, one of the first motivation was to use a Michelson interferometer as a remote gauge for distance measurements between two reflecting surfaces [58]. Thickness measurements of ***dielectric layers*** on metal surface by coherence scanning microscopy followed [13], which naturally lead to the extension of WLI for the characterization of layered structures [59], as nowadays routinely used and exemplified, e.g., with SWLI for the evaluation of transparent thin films in ***MEMS*** and ***MOEMS devices*** [60]. In this context, it has to be also noted that an abundance of

variations and modification of the abovementioned LCI and OCT-like methods for surface profilometry and thickness metrology exists. One example is spectrally resolved line-field interferometry, for which a 2D detector as in CPM or FF-OCT is used, but the light is spectrally dispersed in one direction on the detector chip (like in spectral-domain OCT (SD-OCT) using 1D cameras) and a line from the sample is imaged along the other axis. In such a way 1D thickness profiles of transparent thin films on patterned surfaces can be acquired in one shot [61], as it was demonstrated before for pure surface metrology [62, 63].

From these examples, it follows that conventional OCT can also be used as a distance gauge for plane-parallel surfaces/interfaces delimiting transparent and non-scattering materials. In such cases one has to cope with artifacts arising from, e.g., multiple interference [64]; however, the determination of the thickness of single ***semiconductor wafers*** or ***multilayer semiconductor structures***, as demonstrated in [65] for wide band gap materials as GaAsP/GaP heterostructures, is quite straightforward. Also wafers of silicon (with a band gap of ∼1.1 eV) are equally transparent [66] and suitable for thickness measurements when using the 1,300 nm and 1,500 nm wavelength range. Such evaluations are especially important in the context of wafer back grinding and etching to ensure the required uniformity in thickness together with a characterization in terms of flatness and bow/warp, parameters which have to be optimized for a successful 3D integration of (opto-) electronic devices by wafer stacking.

In order to obtain the true geometrical thickness of layers, the refractive index has to be known, as it is usually the case for standard semiconductor materials. If an unknown overlayer is situated on top of a nominally flat substrate (e.g., on a polished wafer surface) and exhibits thickness variations or lateral structuring, the determination of the refractive index is also easily accomplished by evaluating the deviation of the imaged substrate profile from a straight line [67, 68]. In general, however, focus tracking can be used to determine simultaneously with the thickness also the (group) refractive index [69, 70] or phase and group indices, and thickness [71]. The hardening process of UV-cured epoxy was monitored in such a way by detecting variations of the refractive index [72]. Finally, refractive index profiles of graded refractive index rod lens could be determined by iterative fitting of the optical path length calculated by ray tracing [73].

In addition to the examples involving thickness measurements given above, the full potential of OCT is exploited for samples where the type and strength of the reflectivity of the individual surface and interfaces strongly differ, e.g., for a smooth layer on a rough surface or a weakly reflecting coating on top of a mirror-like metallic surface, as well as for complex multilayer structures, and – most important – for layers with embedded scattering features which can obscure the underlying interfaces. In these cases, the conventional measurement approach using SWLI, CCM, confocal microscopy, and related techniques mostly fails and calls for the high sensitivity and depth discrimination capability of OCT. The evaluation of complex and not fully transparent ***multilayer polymer foils*** is consequently one example, where OCT can efficiently contribute, as shown in the example of Fig. 83.3 by using an ultrahigh resolution (UHR) OCT

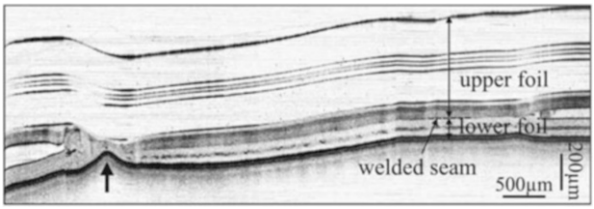

Fig. 83.3 Cross-section of a welded structure from two polymer multilayer foils for thickness evaluation, with a thermally damaged region (indicated by *arrow*) (Reprinted from: K. Wiesauer, M. Pircher, E. Götzinger, S. Bauer, R. Engelke, G. Ahrens, G. Grützner, C. Hitzenberger, and D. Stifter, "En-face scanning optical coherence tomography with ultra-high resolution for material investigation," Opt. Express, vol. 13, p. 1015, 2005, with permission from the Optical Society of America © 2005)

for imaging in the 800 nm wavelength range [67]. The multilayer structure itself consists of two welded foils with a total of 12 individual, partly scattering layers. These individual layers define the mechanical properties and partly represent different gas diffusion barriers, as required for modified atmosphere packaging in the food industry.

With the advent of high speed acquisition by FD-OCT, on-line thickness measurements of such multilayer foils during the production, e.g., by blow film extrusion, can successfully be performed to control the correct dimensions of each layer, by simply using a static point sensor and monitoring a 1D profile of the foil, which is normally moving at a velocity of several tens of meters per minute. Even solutions to cope with the adverse conditions during production, like fluttering of the foils, have been developed: ambiguous mirror terms when the sample crosses the zero optical path delay can be suppressed by, e.g., tailoring the sensitivity profile in SD-OCT with a hardware-based approach and without the need of additional data post-processing [74].

As to the characterization of other layered 2D material systems, the thickness measurement of ***coatings*** on high-quality glossy photo-paper has been shown as well as that – in some cases – imaging through the entire thickness range of some kinds of ***paper sheets*** is possible [75]. However, typically the imaging depth is limited to tens of micrometers for ordinary paper, and a clearing agent (like benzyl alcohol) is needed to detect the backside due to the high scattering properties of the fiber network and the embedded fillers [76].

A similar role of the glossy top coating on paper (beside influencing the printability) plays the ***varnish*** layer on artistic paintings by enhancing the visual appearance and color saturation due to reduced diffuse scattering from the rough paint surface and increased specular reflections (away from the observer's eye) from the smoother varnish surface. A dedicated task in art conservation is the removal of aged varnish, as already pointed out in the above section. Thus, precise knowledge of the thickness as well as information on multiple layers of varnish being potentially present is crucial for a gentle restoration procedure. Similarly to the evaluation of thicknesses and structure of varnish layers [77–80], also ***paint*** layers themselves are

of interest. However, they usually show quite high absorption and decreased penetration caused by scattering, especially in the visible wavelength range. Imaging at longer wavelengths seems preferable, as proven, e.g., in a comparative study using a 820 nm and 1,550 nm OCT system for a variety of different commercially available artist oil paints [81]. In this context, it shall be noted that also the thickness determination of industrial paint layers and multilayer paint systems is a challenging task for OCT [82] (even when confocally enhancing the OCT technique [83]), since such paint structures are usually designed to achieve a high level of opaqueness to efficiently hide the underlying substrate. The addition of diverse, highly scattering filler materials (like, e.g., SiO_2 particles acting as matting agent or wax particles as forming aids) beside the standard pigments render the situation worse, even for thin paint layer thicknesses of around 10–20 μm. Therefore, usually only topmost and rather transparent clear coatings can be monitored, although approaches, e.g., speckle noise reduction by angular compounding, were introduced in order to improve the detection of interfaces of paint layers [84].

Further public reports on thickness measurements include the evaluation of thin (∼1–3 μm) encapsulation/protection layers for ***printed organic electronics***, which are needed to avoid degradation of the devices by exposure to the ambient (oxygen, humidity) [56, 85], the evaluation of roll-to-roll coated polymer ***solar cell*** structures [86]), or of paint layers on ***stained glass*** [79]. Thickness measurements were also performed on glass substrates covered by indium tin oxide (ITO) ***conducting*** **glass** (together with the distribution of refractive index and transmission coefficient) [87] as well as quantitative phase imaging to determine the thickness of structured 300 nm ITO films [88]. Evaluation of thicknesses and defects of ***liquid crystal display*** (LCD) multilayer structures were equally reported [89], as well as the determination of inner gap distances of individual red-green-blue (RGB) LCD pixels, together with an evaluation of spectral information (absorbance of R,G,B pixels), defects, and the cover glass thickness [90].

Other examples of industrially relevant applications for OCT or OCT-like sensors in thickness evaluation encompass the characterization of loudspeaker ***membranes***, of ***skins*** for dry-aged sausages, or of ***adhesive layers*** between stacked sensor structures deposited on glass substrates as well as of thin polymer layers deposited on ***drug-eluting stents***.

On-axis thickness evaluations of multiple ***optical elements*** and whole optical systems were reported [91], as well as a fully developed application for automated ***contact lens*** metrology: the thickness and prism, which is the maximum difference in thickness over the full azimuth at a fixed distance from the edge of the lens, is automatically measured and evaluated using refraction correction and image processing/segmentation [92].

Besides rather planar structures, the evaluation of coating thicknesses and diameter of ***optical fibers*** with FD-OCT was demonstrated [93]. Coating thickness measurements of ***pharmaceutical tablets*** (deposited, e.g., by drum spray coating) prove to be a further promising application [94–96] for OCT and to be more accurate than indirect methods, like measuring the gain in weight or diameter of the tablets. A similar geometry is experienced when determining the thickness of

the so-called nacre layer of ***pearls*** produced by oysters around an artificially inserted nucleus, as demonstrated in [97, 98], leading to automated thickness evaluation [99] and dedicated commercial systems for this task.

83.3.3 Imaging of Inner Structures

Besides focusing solely on the surface and on the thickness of covering layers, imaging of the interior of scattering materials is more in-line with the original motivation of OCT and used in NDT to evaluate and verify inner structures and geometries, which can be introduced in an intended way or represent flaws and defects. Naturally, when measuring the thickness of overlaying (multi-)layers, the simultaneous detection of such embedded features is at hand (and also mentioned in nearly all references from the above section), including defects in ***ITO glass*** [87], structures and defects in ***LCD devices*** [89, 90], bad contact areas between protective coatings and ***printed electronics*** substrates [85], or delaminated and misfolded regions of ***multilayer foil*** structures [100]. Real-time imaging of chip-type ***light-emitting devices*** (LEDs) shall also be mentioned, featuring inspection tasks with respect to correct wire interconnections as well as with respect to the volume and status of the included fluorophore material [101].

In context to the example of ***pearl*** investigations of the above section, hierarchical structures built during the nacre formation [98] and a variety of additional aspects could be determined by means of depth-resolved OCT imaging in order to classify pearls, namely, the distinction between bead-nucleated and non-bead-nucleated ones as well as the identification of the type of nucleus used in the pearl production (e.g., freshwater shell or giant clam nuclei) [102]. These studies were further driven and used to distinguish between different types of pearls and pearl treatments (like bleaching, buffing, coating, filling (with epoxy) or dyeing), also by combining OCT with simultaneously performed laser-induced fluorescence (LIF) measurements [103] as exemplified in Fig. 83.4: besides the nacre thickness, the fine structure of the layer as well as the inner features of the nucleus can be determined and used together with the characteristic spectral fingerprint from LIF for nondestructive pearl evaluation.

Staying with the examples of precious or unique specimens by OCT, the evaluation of ***jade*** objects shall be treated: originally introduced to study the subsurface structure in order to distinguish between naturally whitened and artificially treated ones (i.e., by burning) to detect forgery of ancient jade objects [104], further studies followed, especially in hindsight for the classification of diverse types of jade by evaluating the texture and – due to the high penetration depth of several millimeters – to give a guide for artistic carving (i.e., to avoid internal cracks and non-jade inclusions) [105]. Crack structures (linear ones which are open to the air versus cloudy clusters and networks sealed off from the surface) were further investigated for jade materials and classified in detail (inclination, depth, crack initiation sites, etc.) [106]. In the same study, the investigations were also extended towards the characterization of crack morphologies in (ancient) ***ceramic***

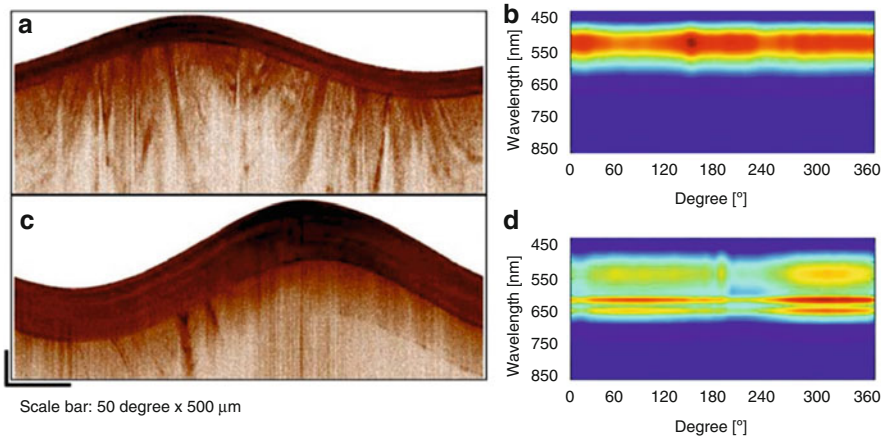

Fig. 83.4 OCT cross-sections (azimuthal scans) of an Akoya (**a**) and Tahitian (**c**) pearl. Corresponding LIF spectra (**b**, **d**) of the pearls simultaneously measured during OCT acquisition (Reprinted after: M. J. Ju, S. J. Lee, Y. Kim, J. G. Shin, H. Y. Kim, Y. Lim, Y. Yasuno, and B. H. Lee, "Multimodal analysis of pearls and pearl treatments by using optical coherence tomography and fluorescence spectroscopy," Opt. Express, vol. 19, p. 6420, 2011, with permission from the Optical Society of America © 2011)

glaze layers. In general, investigations of glaze layers were among the first applications for art diagnosis [34], and especially by studying the subsurface structure, as performed, e.g., in detail on ancient Egyptian faience [107] or Chinese glazes [108], OCT can help to identify the type of ceramics and provide valuable insight to the production techniques formerly used. Similarly, art conservation studies of ***historic glass***, especially for the imaging of corrosion layers on stained glass or the diagnosis for crizzling (i.e., a network of fine cracking caused by an imbalance of the ingredients and reducing the transparency), have been performed [109]. But not only for ancient glasses has OCT proved to be a promising NDT tool: the investigation of laser-induced damage sites in costly large-aperture ***optical components*** has been suggested [110] which could be used in the future to monitor post-processing procedures for damage mitigation [111]. Besides imaging unwanted subsurface features (like cracks and voids induced by laser damage), the verification of intently introduced structures is of interest, as shown for femtosecond laser structuring of ***fused silica*** [112] and ***glass*** with, e.g., an embedded laser-written waveguide coupler [113]. In case that data is written inside a material, OCT can be used for reliable ***data retrieval***, as, e.g., demonstrated with FF-OCT on 3D laser-structured sol-gels [114] or for multilayer optical discs with OCDR [115].

Bulk ***ceramic*** parts and ceramic layers are widely used, e.g., for high-strength hybrid bearings or as thermal barrier coatings protecting blades in gas turbine engines. However, the performance of these materials is crucially dependent on surface and subsurface defects, like cracks in the material itself or delaminations between ceramic layer and substrate, with an early study for subsurface detection of cracks in such scattering ceramic materials, like ***silicon nitride*** given in [4].

The evaluation of layered structures in piezoelectric transducer (***PZT***) composite ceramics and defects in ***silicon carbide*** followed [5, 116] with a detailed study of the geometry of so-called Hertzian cracks in silicon nitride balls as used for bearings [117]. In this context, also a comparative study for optical NDT methods (with confocal microscopy and laser backscatter measurements) on subsurface flaws in silicon nitride ceramics was performed [118]. However, one has to state that due to the high scattering nature of such ceramic materials, the imaging depth is significantly restricted: as an example ***thermal barrier coatings*** (e.g., yttria-stabilized zirconia (YSZ) coatings for gas turbine engines) were evaluated with OCT to find a new inspection method for monitoring their condition and predicting failure (i.e., spallation). Imaging with wavelengths below 1 μm resulted in penetration depths of less than 300 μm but only for electron beam physical vapor deposition (EB-PVD) coatings. In case of air plasma-sprayed coatings [119], which exhibit a far more scattering structure than the columnar one of EB-PVD, the imaging depth is further reduced [120]. Similarly, a limited penetration depth around 260 μm was found even for the 1.3 μm spectral range when imaging ***alumina***-based ceramics which are used, e.g., as inert container material for microfluidic structures: the geometry of embedded channels, cavities, the position of metal stripes (electrodes) and again the detection of defects as well as the thickness determination of covering layers and roughness were the origin of interest in these studies [121, 122]. Additionally, Monte Carlo simulations were performed to predict the performance of OCT for depth-resolved imaging depending upon the optical/scattering parameters of these materials. Finally, in the context of ceramic materials, the evaluation of domain boundaries in ***periodically poled ferroelectrics*** shall be mentioned: the (unwanted) refractive index changes near the anti-parallel domain walls, which are in the order of 10^{-4}, could successfully be traced [123].

Regarding pronounced scattering, the multiple interfaces between fibers and air or between fibers and embedded fillers play a similar role as the grainy and porous structure of most ceramic materials presented above. Consequently, structural imaging of fibrous networks like ***paper*** is also for OCT a challenging task, as already seen for the thickness measurements presented in the prior section. Nevertheless, useful information can be extracted by, e.g., studying larger-scale paper simulation networks; insight on the filler content can be obtained by evaluating the slope of the backscattered depth profile signal [76]; or the degree of paper porosity can be deduced from OCT measurements when compared with Monte Carlo simulations [124]. Similar challenges in coping with scattering have to be met for the characterization of, e.g., electro-spun ***polymer fiber web*** structures [125]. However, when transparent fiber structures are embedded in a homogenous medium, OCT imaging with penetration depths of even several millimeters is easily accomplished (especially at wavelengths around 1,550 nm [126]), with ***glass fiber-reinforced polymer*** (GFRP) composites as prominent examples shown in Fig. 83.5: novel, knitted glass fiber fabrics embedded in an epoxy matrix and exhibiting improved mechanical properties were investigated by ultrahigh resolution (UHR) OCT [127]. In contrast, for ***carbon fiber composites*** (CFCs), usually

Fig. 83.5 3D data sets of knitted GFRP structures (scan areas: (**a**, **b**) 5 × 5 mm^2, (**c**) 3 × 3 mm^2; thickness of displayed stacks: 300 μm) (Reprinted from Comp. Sci. Technol. vol. 67, p. 3051, 2007, K. Wiesauer, M. Pircher, E. Götzinger, C. K. Hitzenberger, R. Oster, and D. Stifter, "Investigation of glass–fibre reinforced polymers by polarisation-sensitive, ultra-high resolution optical coherence tomography: Internal structures, defects and stress", with permission from Elsevier © 2007)

only the surface structure can be evaluated due to the strong absorption of the fibers [100], which is also valid, e.g., for ***carbon nanotubes*** (CNTs) as filler materials in epoxy resin, as shown in a recent study to clarify the effect of plasma treatment on the dispersion of the CNTs in the matrix [128].

Depth-resolved imaging tasks in material research for OCT in the context of the evaluation of GFRPs can be found for the prediction of mechanical properties by acquiring the internal structure but are also concerned with the detection and classification of defects like cracks, kink bands, fiber matrix de-bonding, voids, dry spots, and large-scale delaminated areas [129], as also shown in comparison with other NDT methods like X-CT and confocal microscopy [130]. Equally, the permeability of the fiber structure for infiltration with the liquid epoxy matrix material was predicted by image-processed OCT cross-sections [131]. Concerning the visibility of the glass fiber structure, it has to be noted that there is improved contrast when rather low-refractive-index matrix materials are used [132] and that high resolution or even better UHR-imaging is of advantage when not only whole fiber bundles but individual fibers should be resolved [127]. In the case of short ***fiber-filled polymer composites***, resolving the individual fiber pieces is essential for the determination of the fiber orientation which influences the isotropy of mechanical properties: by advanced image processing algorithms, the fiber orientation was automatically deduced from UHR-FF-OCT images and verified with micro X-CT [133]. Other types of polymer composites are equally promising for OCT imaging due to their translucent nature, with one example of OCT being used to study thermal degradation effects in ***microsphere filled polymers*** [134]. Another task in the development of novel polymer materials, which have to meet increasing performance requirements, e.g., for future automotive applications, is the evaluation of the distribution of different polymer phases in ***polymer blends***, as shown for polypropylene-rubber blends with UHR-OCT, which gave even superior contrast than synchrotron phase-contrast CT [100]. Naturally, when pure ***bulk polymers*** without any additional inclusions are present (see also Fig. 83.1), OCT is very promising for the imaging of the structure of whole injection-molded parts [126], of co-extruded polymer panels [100], or of polymer foams [67].

As example for natural composites, ***wooden specimens*** are worth to be mentioned, with an instructive study given in [135] where the structure of the wood fibers was successfully imaged with a FF-OCT for an eighteenth-century violin below (transparent) ground paint and varnish layers. This application leads us further to the evaluation of other natural materials like the detection of subsurface features in melon ***seeds*** hinting at a virus disease [136], imaging of major structures within tomato seeds [137], or hull thickness determination of lupin seeds by OCT as a novel screening method to classify different genotypes with respect to the de-hulling abilities or nutritional aspects [138]. To study selected aspects of ***food*** can be helpful for quality control (screening of internal defects and rots in onion bulbs [139]) as well as for food engineering and storage, with the evaluation of the microstructure of ***cereals*** (swelling and rehydration behavior when exposed to liquids) and the investigation of lenticels (i.e., pores for gas exchange) and wax layer of ***apples*** as recently introduced examples [140]. Finally, ***protein crystals*** were imaged and the structure compared to those of salt crystals in order to facilitate automated sorting in the future [141].

The successful detection of embedded and hidden structures is also of prime interest with respect to ***security applications***. In order to verify the authenticity of paper representing a certain value (e.g., money, checks, tickets), the reliable identification of characteristic features is essential, as it was done for identifying counterfeit bank notes by retrieving the internal structure of security cash holograms [142]. Likewise, the imaging of security threads embedded in paper has been proven [143] and was developed further towards fast and automatic detection for a transportation speed of the documents up to 1 m/s [144]. In this context, a simple, handheld, and manually operated device was also presented, which enables the detection of visually hidden 2D security features (e.g., a digital image/emblem placed behind a light-scattering medium) [145]. This application is very close to the one involving the evaluation of ***artistic underdrawings*** in paintings (i.e., preliminary sketches of the painting by the artist). This task can be successfully accomplished using OCT with higher contrast and better detail visibility than conventional imaging with an IR camera [78]. An example for this application is given in Fig. 83.6 in which summed voxel projections of the region below the paint layers clearly unveil the underdrawing below the paint [55].

At the end of this section, OCT imaging of structures within ***liquid*** and ***gaseous phases*** are given: applications in this area include the evaluation of vapor bubble formation during laser ablation with ultrahigh speed OCT [146] or the microscopic investigation of the nucleation process of vapor bubbles on heated surfaces (with respect to contact angle, bubble diameter, base diameter) within boiling liquids [147]. Furthermore, the crystallization process of polymer melts in a slit die of an extruder was monitored in situ [148], as well as flow patterns within single microdroplets (seeded with scattering particles) in electrowetting-based microfluidic devices [149], or the flow behavior of fluids within 3D microfluidic mixing structures [150].

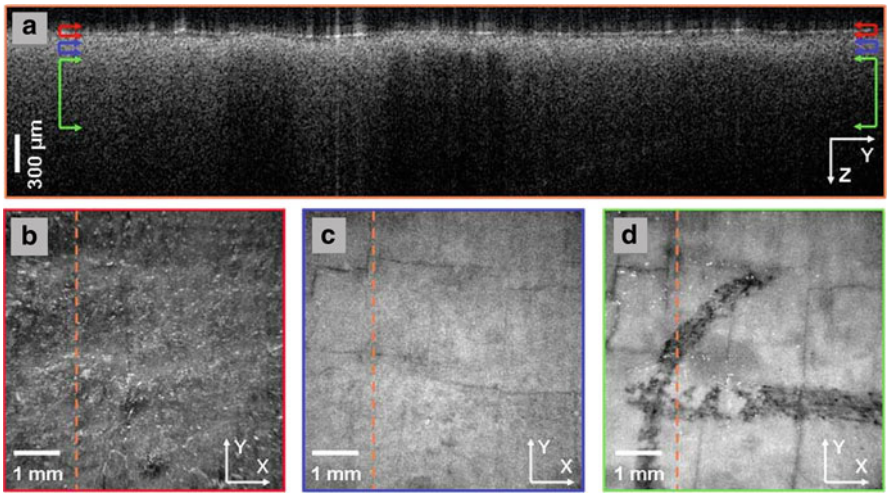

Fig. 83.6 OCT images of underdrawing features in an artistic painting. (**a**) single cross-section with indicated depth regions for the summed voxel projections in (**b**, **c**, and **d**). (**b**): summed voxel projection en face image of varnish layer. **c**: summed voxel projection en face image of paint layer. Jiang, S. Barry, A. E. Cable, R. Huber, and J. G. Fujimoto, "Comparison of three-dimensional optical coherence tomography and high resolution photography for art conservation studies," Opt. Express, vol. 15, p. 15972, 2007, with permission of the Havard Art Museum and the Optical Society of America © 2007)

83.3.4 Modified Contrast and Functional Material Imaging

All information obtained by OCT in the application examples from the above section is in principle of structural nature and originating from relative intensity variations of light back-reflected from spatially separated features. However, already in conventional 2D microscopy different imaging modes have been developed, which allow highlighting specific aspects and extracting additional information from the imaged structures by, e.g., ***modifying the contrast***. In this context, differential phase-contrast microscopy shall be mentioned which gives enhanced contrast in conventional microscopy for transparent, weakly scattering samples and which has been used in combination with OCT to reconstruct profiles and path length distributions within, e.g., microlens arrays [42]. Another example for enhancing contrast of nearly transparent samples in microscopy is dark-field (DF) imaging, which could also be realized for point scanning optical coherence microscopy (OCM) [151]. Likewise, point defects were detected in dielectric multilayer coatings with a FF-OCM variant by measuring at an increased oblique angle to avoid the direct specular back-reflection of the layers (i.e., DF imaging) [152]. Especially when regarding FF-OCM, the whole concept of optical image filtering in the Fourier plane (FP) can even be transferred to the interferometric detection approach

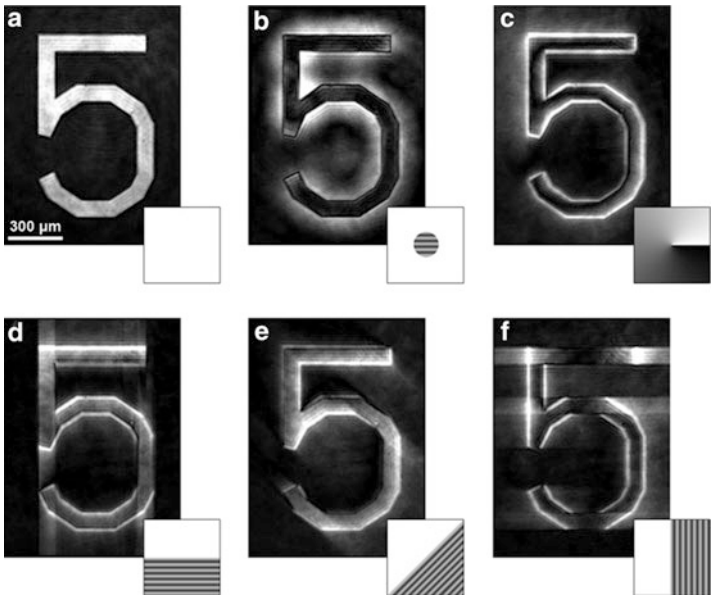

Fig. 83.7 FF-OCM en face images of a test figure taken (**a**) in the bright-field mode, (**b**) dark-field mode, (**c**) with spiral phase contrast, (**d**–**f**) with Schlieren contrast in different directions. The small images in the *lower right* corners represent the (gray-scale encoded) phase delay introduced by the SLM in the FP (Reprinted from: S. E. Schausberger, B. Heise, C. Maurer, S. Bernet, M. Ritsch-Marte, and D. Stifter, "Flexible contrast for low-coherence interference microscopy by Fourier-plane filtering with a spatial light modulator.," Opt. Lett., vol. 35, p. 4154, 2010, with permission from the Optical Society of America © 2010)

of LCI: by using a so-called spatial light modulator (an addressable pixel array for selectively shifting the phase) in the FP, contrast modes like DF, spiral phase contrast (an effective edge filter realized by performing the Hilbert transform in the FP), or Schlieren contrast (enhancing edges in certain orientations) can be realized on the fly, as shown in Fig. 83.7 and proven on layered samples in [153].

The contrast in the above examples is arising from spatial frequencies in the lateral direction. However, it is quite useful to link additional material properties to contrast and – as a final step – to quantitatively determine these properties within the scattering materials. One example is OCT elastography [154] for the evaluation of ***mechanical properties*** by tracking the ***displacement*** of features within the sample, which is subjected to stress, in a spatially resolved way. The displacement can be obtained by cross-correlations of speckle patterns, analogous to conventional digital image correlation (DIC) performed to monitor ***deformations*** on surfaces for full-field strain analysis (FFSA). In case of large deformations, which can lead to uncorrelated speckle patterns between subsequent image frames, the evaluating of the temporal statistical behavior and maps of local dissimilarities of the speckle pattern of OCT cross-sections was shown to mark regions of enhanced plastic

deformation during tensile tests on polymer samples [155], thereby providing complementary information to FFSA data, which was simultaneously taken from the surface [156].

Besides DIC, an established technique to monitor displacement and deformation of surfaces can be found in electronic speckle pattern interferometry (ESPI). In combination with a broadband light source, the principle of ESPI and LCI can also be combined to monitor the deformation of subsurface interfaces within scattering materials, as shown for adhesive-bonded joints [157] or for the layered coating on the famous Chinese terracotta warriors of the First Qin Emperor [158]. Instead of using a broadband source, a wavelength scanning ESPI variant was used in [159] and extended towards the determination of all orthogonal displacement components (3D displacement sensitivity) [160]. In this context, in-plane and out-of-plane displacement measurements was accomplished by, e.g., phase-contrast SD-OCT, as exemplified on a polymer phantom [161].

Besides speckle tracking for small-scale deformations, the evaluation of the Doppler shift is suitable for the evaluation of larger speckle motions as used for OCT elastography [162]. In the same way, ***velocity profiles*** in scattering fluids can effectively be measured by Doppler OCT, as, e.g., demonstrated for the microfluidic mixing devices presented in the above section [150] or for the study on the bubble nucleation process on heated surfaces [147]. Two-phase flow (gas bubbles within liquid) was equally investigated, revealing the velocity profile of toroidal vortices close to the gas-liquid interfaces [163]. Furthermore, imaging of electroosmotic ***flow dynamics*** in microfluidic channels [164] and secondary flow phenomena in curved serpentine mixers [165] were successfully obtained with phase-resolved optical Doppler tomography. Velocity profiles could recently also be directly measured in a rheometer for obtaining a dynamic phase diagram of a polymer solution, indicating so-called linear, shear-banding, and wall-slip regimes as a function of the molecular weight and concentration [166].

Additional contrast and information can also be obtained by evaluating the ***polarization state*** of the back-reflected light, as it was demonstrated for material characterization: parchment degradation by iron gall ink, i.e., the standard writing and drawing ink from the twelfth to the nineteenth century exhibiting corrosive behavior), was studied in this way using polarization-sensitive (PS)-OCT [167]. PS-OCT was also successfully applied to visualize solidified flow patterns and regions under internal stress within injection-molded polymer parts [126]. Especially ***birefringent layers*** in such polymer parts, e.g., caused by a highly oriented polymer morphology which forms close to surface during injection molding due to increased shear forces, can effectively be identified [2, 68] and even monitored in situ during solidification [148]. Furthermore, the ***stress distribution*** within photoresist molds for miniature gear wheels [168] was successfully mapped by transversal UHR-PS-OCT [169]: besides the detection of defects at the substrate-resist interface [67], the PS data could be used to quantitatively determine the amount of residual stress [170], as it was also demonstrated before on bulk polymer samples under mechanical loading [171]. Quantification of stress by PS-OCT was also accomplished for GFRPs under static load with a time-domain PS-OCT [172],

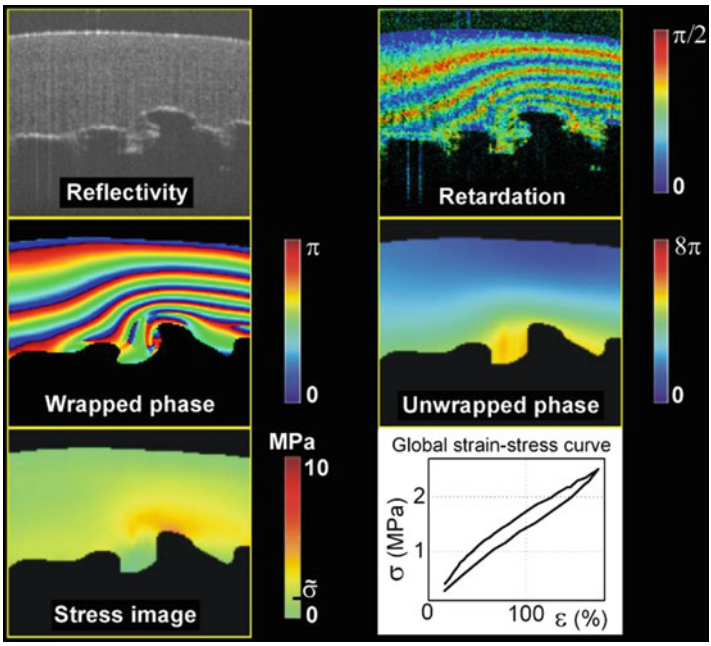

Fig. 83.8 Single-frame excerpt from dynamic SD-PS-OCT recordings of an elastomer test sample (average thickness: 1 mm) under cyclic loading, showing the original reflectivity and retardation images (*top* images, retardation image: *color* encoded), the calculated wrapped and unwrapped phase images (*middle row*), the obtained stress image with indicated average stress obtained from the cross-sectional image (*bottom left*), and the simultaneously measured global strain-stress curve (*bottom right*) (Reprinted from: D. Stifter, E. Leiss-Holzinger, Z. Major, B. Baumann, M. Pircher, E. Götzinger, C. K. Hitzenberger, and B. Heise, "Dynamic optical studies in materials testing with spectral-domain polarization-sensitive optical coherence tomography.," Opt. Express, vol. 18, p. 25712, 2010, with permission from the Optical Society of America © 2010)

as well as with SD-PS-OCT during dynamically performed tensile tests as shown in Fig. 83.8: PS-OCT cross-sections of an irregularly shaped elastomer sample which were evaluated with the help of advanced 2D-image processing and phase unwrapping algorithms yielded spatially and temporally resolved stress maps [173].

Further applications of PS-OCT comprise enhanced defect detection in GFRPs as used for the aerospace industry: composite materials for helicopter rotor blades were evaluated with UHR in this way to resolve individual fibers together with the surrounding strain and thus obtain microscopic information on the early stages of damage formation [127]. An evaluation in terms of the ***degree of polarization uniformity*** of dynamically acquired PS-OCT cross-sections taken from GFRPs during fracture tests led also to the early detection of micro-damage sites, even before large-scale delaminations appeared in the reflectivity images or increased stress-induced birefringence could be observed [173], proving in this way the added value which an additional source of contrast can provide.

83.4 Conclusions and Outlook

Within this chapter, a broad range of applications for OCT in NDT has been recalled, ranging from examples of industrial quality control over classification and authentication tasks to the evaluation of materials in research and development. However, this large variety should not cover the fact that outside the biomedical field, OCT still holds the position of an exotic measurement technique, which is not yet routinely applied to material testing and evaluation. Only in the field of surface, thin film, and multilayer metrology, OCT-like sensors and devices based on LCI already found broad acceptance, which is not surprising since some of these techniques were dedicatedly developed for these purposes, some even before the invention of OCT. For the application of OCT according to its original motivation, i.e., the imaging of structures within scattering media, the situation presents itself in a more ambiguous way. The large variety of materials and sample geometries makes it difficult to employ a standard design of the measurement device or to apply a routine protocol even when considering similar applications. As an example, by changing only one component in a sample structure, the whole evaluation technique might be put into question, e.g., when during further product development an additional layer with stronger scattering characteristics has to be inserted in a multilayer structure. Nevertheless, for all these structures made from a variety of technical and natural materials, valuable ground could already be gained with promising examples highlighted in the above sections.

The future of OCT in material testing will further brighten up, especially when considering the new methodological developments driven by the large (mostly biomedical) scientific OCT community. At the same time, additional impetus is expected when the technique is further refined and supplemented with respect to the specific demands in NDT. Concerning industrial production, this would call, e.g., for automated and instantaneous image acquisition and evaluation/processing/quantification as required for giving direct feedback signals in on-line control of the production. Further advancement will come from modular OCT(-like) sensor systems which can flexibly be tailored to the needs, fully integrated into production lines (hardware and software) and also be used in combination with complementary characterization methods (multimodal analysis).

Similar considerations hold true for evaluation tasks in material development and research. Here, besides investing resources in tailored systems, the use and further development of additional contrasting are especially of interest, giving access to complementary information. In this context, OCT vibrography [174] for the analysis of periodic movements or true (full) color imaging [175] in combination with the evaluation of spectroscopic information [176] (e.g., for substance identification) shall be mentioned. Molecular contrast arising from optical (nonlinear) phenomena leads to second harmonic generation (SHG) OCT, coherent anti-Stokes Raman scattering (CARS) OCT, or pump-probe (PP) OCT [177, 178], representing techniques which might equally prove useful, as exemplified in Fig. 83.9 for combined OCT and SHG-OCT imaging to distinguish zinc corrosion products by using a compact 1,550 nm broadband femtosecond fiber laser as light source.

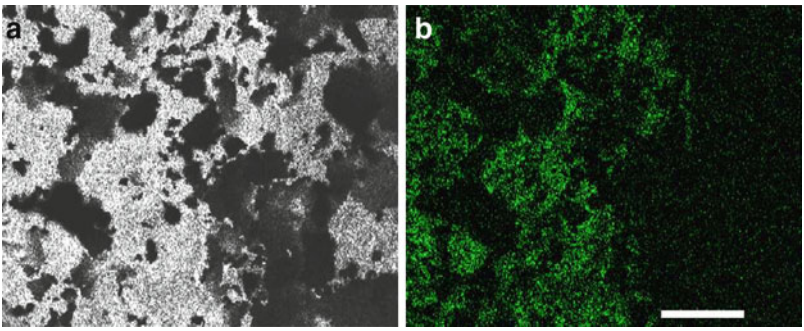

Fig. 83.9 Scanning OCM en face image (**a**) and corresponding SHG-OCM (**b**) image of zinc oxide (*left region*, SHG-active) and hydrozincite-covered surface (*right region*, SHG-inactive, scale bar: 1 mm) (Images by A. Prylepa and D. Stifter, Christian Doppler Laboratory for Microscopic and Spectroscopic Material Characterization, Johannes Kepler University Linz, Austria)

A promising trend for future applications of OCT in NDT is to exploit the extension to other than the usually used wavelength ranges. Ultrathin technical layers could in this way be rendered accessible, as suggested for the soft X-ray and XUV range [179]. Similarly, thick and strongly scattering media would take profit from longer wavelengths, with techniques as principally demonstrated for interferometric THz imaging [180] or for surface metrology in the IR range [181].

Finally, all these recent developments as well as the know-how generated by the applications presented within this chapter will lead – in conjunction with novel photonic components and devices, together with an integration of complementary technologies and a careful reevaluation of formerly presented measurement concepts – to an even stronger sign of life of OCT in the field of NDT.

Commercialization of optical coherence tomography • Entrepreneurship • Optical coherence tomography • Optical coherence tomography market • Technology transfer • Translational medicine

84.1 Introduction

The field of optical coherence tomography (OCT) has blossomed dramatically since the first studies by various researchers around the world began in the late 1980s and early 1990s. Since then cumulatively, there have been dozens of companies created, over a hundred research groups working on or with OCT, over a thousand OCT patents issued, over 10,000 research articles published, tens of millions of patients scanned with OCT, hundreds of millions of venture capital and corporate R&D dollars invested, hundreds of millions of dollars in company acquisitions, and over a billion of dollars of OCT system revenue. Ophthalmic OCT reimbursements for clinical OCT procedures surpassed $1B in 2010 alone! The discovery and development of OCT has had, and will continue to have, a major economic, scientific, and medical impact. For example, OCT has had a tremendous impact on treatments for blinding eye diseases, and there is a patient somewhere in the world undergoing an ophthalmic OCT examination every several seconds. With OCT applications in cardiovascular, gastrointestinal, and other applications advancing, the impact will likely increase.

Eric Swanson is a founder of Advanced Ophthalmic Devices (acquired by Carl Zeiss Meditec), Lightlab Imaging (acquired by St. Jude Medical), and has numerous patents that are licensed to various OCT companies. Mr. Swanson also served on the board of NinePoint Medical Imaging and several other high-tech companies.

The success of OCT is due to an array of factors starting with the underlying interferometric optical principles that enable high sensitivity (quantum limited due to heterodyne local oscillator gain), high-dynamic range (due to electric field detection), high lateral and depth resolution (in a way that partially decouples the two), and relatively low-cost compact systems that can achieve high speed, in situ optical imaging at depths which are clinically relevant to many major diseases and industrial applications. Beyond the physical principles, the success of OCT involves a complex ecosphere involving academics and industry engaging in research and development, publishing papers, filing patents, starting new product lines at existing companies or completely new startup companies, clinical studies, government funding, venture capital, and more. There is a clear pattern of federal dollars, technology/applications development, publications, and patents leading to transfer to for-profit startups or established companies.

Researchers from academics are supported by government funding, tuition, industry, and other means. Part of the satisfaction and responsibility of researchers using government funding is to make an impact in the world. This can be done through a variety of ways, one of which is the commercialization or technology transfer of their research to industry. There are many ways to approach commercialization and technology transfer, several of which will be outlined later in this chapter. Commercialization of new technology into products that are useful and that people will buy is very challenging, especially in the medical diagnostic device market. It's hard to get product development funds; it is hard to recruit top staff; it is hard to develop robust, safe, and manufacturable products; it is hard to get products approved by the various regulatory and reimbursement bodies; it is hard to prove clinical value; it is hard to beat the competition; and it is hard to make a profit that is necessary to keep this flywheel going and workers employed to maintain the current product(s) and start building the next product. All these things and more are required for a successful commercial product. Researchers sometimes believe that demonstrating feasibility in the lab is the biggest step, and the job is 90 % complete. In truth, from a commercialization perspective, it is usually only the first 10 % of the job and 90 % of the work remains to be done. Laboratory demonstrations are the first step in a long road toward commercialization.

This chapter will describe some of the history and factors involved in OCT technology transfer and give a snapshot of the current OCT market. It describes the ecosystem that has surrounded OCT commercial development including the role of government funding, publications, patents, and the role startup and established companies have played in bringing complex new products to clinical practices. It also briefly describes some of the impact of the technology and its future potential.

84.2 Academic Publications

One of the most successful and obvious ways to accelerate the transfer of OCT technology is to publish peer-reviewed journal articles and present research results at conferences. Figure 84.1 shows an example of the dramatic growth

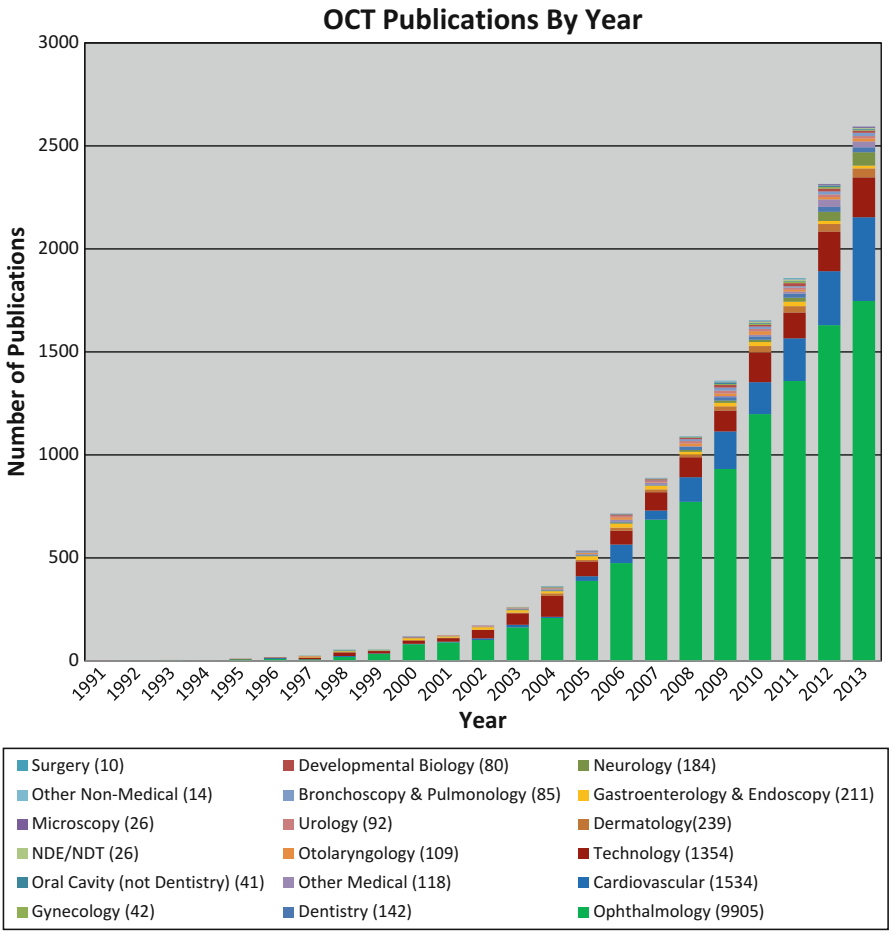

Fig. 84.1 Yearly OCT publications in PubMed categorized by application

in OCT papers since the first "OCT" paper by Huang et al. in 1991. A few things are very obvious, including the dramatic rate of growth of OCT publications (~200 papers/year) and that the publications are dominated by ophthalmology, followed by cardiology, and general technology. The legend below the figure shows the number of cumulative publications by subject area from 1991 to 2013.[1]

[1]In this analysis, only title and abstract were considered. The result is that this data probably underestimates the number of OCT publications but is a good bound. Another limitation is it can be difficult to categorize a publication into a particular subject area, and often publications are in multiple subject areas, and it is often a blurry call if the paper is about fundamental technology or about an application of the technology. Note this data is based on the PubMed database has many good attributes, but there are also limitations in that it doesn't cover every journal, and the number of journals it covers has increased over time.

It is interesting to consider what is driving these publications and the relative breakdown into each subject area. The answer is a combination of fertile and promising research frontiers, availability of government funding, clinical needs and trials, and very importantly, the availability of commercial, regulatory approved OCT products. Certainly, ophthalmic publications would not have grown so dramatically if (1) OCT was not a promising and effective technology for ophthalmology, (2) the NIH National Eye Institute and other government agencies around the word did not provide significant funding, and (3) a commercial company did not produce a reliable and field-able product early on to provide a catalyst for the entire process. These ophthalmic publications are dominated by researchers using commercial instruments, and Zeiss released its first ophthalmic OCT product around 1996 and was the only company making such a product for a good part of a decade – the formative years of this market's development. A similar point is also true for cardiovascular OCT. Cardiovascular/intravascular publications are currently the second largest publication category in OCT. Lightlab (acquired by St. Jude Medical in 2010) obtained its first regulatory approval in 2004. Like Zeiss, Lightlab was almost a decade ahead of other entries into this new market. Examining Fig. 84.1 around the dates of 1996 (2004) shows the start of a big increase in ophthalmic (cardiovascular) publications, in large part, as result of introduction of these new medical products into their respective markets and use by clinicians in clinical settings. These are two clear examples of the power of successful translation of technology from the research environment to the commercial environment. Not only has this resulted in many more publications because clinicians can use fully engineered and approved instruments in their studies and trials, it also dramatically accelerated bringing the technology to patient care (which improved the diagnosis and treatment of blinding ophthalmic diseases and promises similar advances for deadly cardiovascular disease), and it brought financial rewards and market share to the companies that took the business risks and were first to market.

It is interesting to speculate to what extent is publication history a bellwether for future commercial opportunities and are those commercial opportunities subject to the popular trends within funding agencies or are they matched with the best areas for potential impact. Upon examining the data, it seems that funding agencies and subsequent researcher publications do sometimes go off onto dead-end roads, but that those roads usually don't last very long. In addition, as we will see later in this chapter, the number of startup companies and new products from existing companies seem roughly to follow the number of publications. For example, there are several companies in the process of commercializing OCT for new applications such as in the dermatology and gastroenterology markets, the next two highest ranking publication areas in the Fig. 84.1.

84.3 Patents

Patents are obviously another important component of OCT technology transfer and the OCT marketplace in general. Patents play many roles, and the motives to

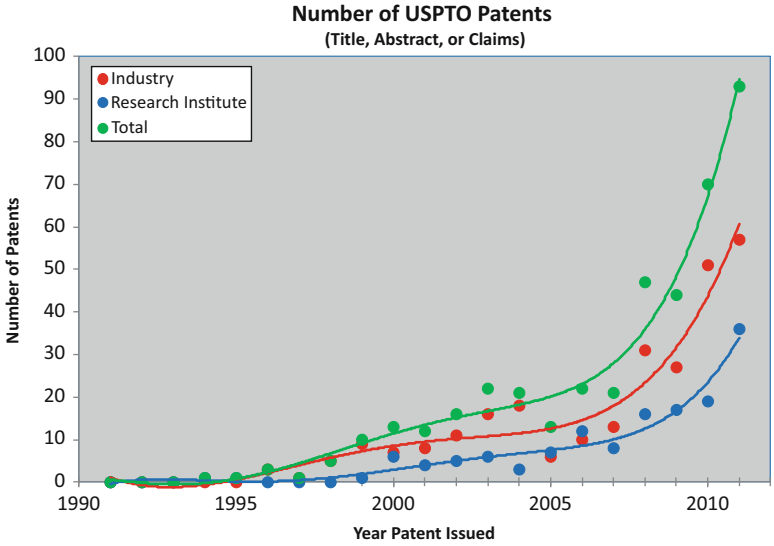

Fig 84.2 Yearly OCT USPTO issued patents

file them are varied. The motive for academics can be either to help enable a startup company the professor or student is involved in or to seek a share in the royalty fees by licensing to a company they are not involved in.[2] Many academics that start companies have licensed patents they authored from their institution, usually under exclusive terms. Exclusive fundamental patents can be a key factor in solidifying equity financing from investors. If a technology is relatively new, patents are especially important because they protect the substantial investment that is necessary to develop and validate the technology. In addition, patents can serve as a historical record of invention, much the way peer-reviewed journal articles do. For example, MIT documented swept source OCT (SS-OCT) systems in most of its earliest OCT patents dating back to 1991, even though the first MIT SS-OCT journal publication was not submitted for publication until 1996. The motives for filing patents in industry are also diverse. Patents can be filed in an effort to provide protection from a competitor entering a market, to ensure that the company has a right to continue to produce, to generate revenue, or for other motives.

Figure 84.2 shows the number of US Patent and Trademark Office (USPTO) patents issued by year that have OCT in the title, abstract, or claims. This Figure shows three curves: the total number of patents, the number of academic patents, and the number of industry patents. It is interesting that even in the early years, industrial patents outpaced university patents. This is, in part, due to the fact that many research institutions do not have the financial resources to file large

[2]In the United States, the Bayh-Dole Act states that universities need to share royalties with the inventor.

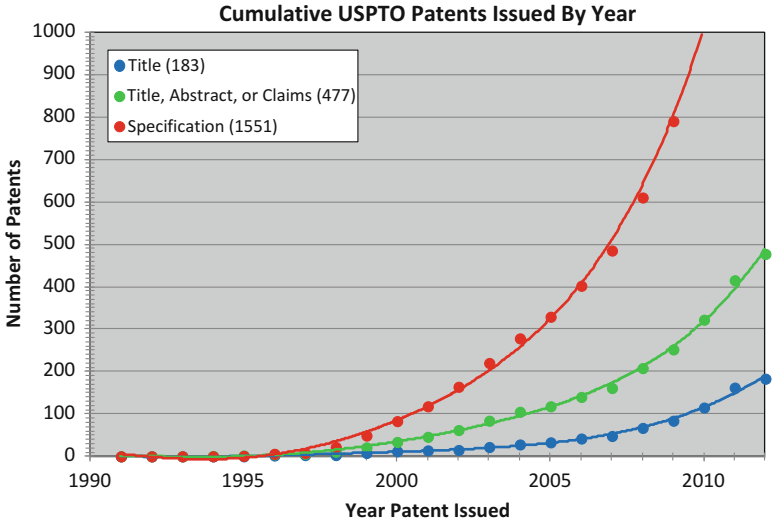

Fig 84.3 Cumulative OCT USPTO issued patents. Cumulative total since 1990 to September 2012 is shown in legend

numbers of patents, and, until recently, publications, research support, and recognition at conferences were key criteria for academic career success. Now, with more emphasis on translation of technology, these criteria may change and result in more academic patents.

Figure 84.3 shows the cumulative number of USPTO patents that have OCT in the title; title, abstract, or claims; and the entire specification. It is clear that the number of issued patents rose initially around 1995, followed by a significant increase around 2007, and there are now over 1,000 issued patents that contain OCT in the specification for the United States and many more patents in Europe and elsewhere. As with publications, it is difficult to determine what an OCT patent is, and there are clearly other patents that do not mention the term OCT, but would impact OCT systems. For example, a patent on a rotary single-mode fiber joint could impact OCT cardiovascular and endoscopic systems, even though it may not mention the word OCT.

Patents are sometimes classified as fundamental or incremental. It is very difficult to get a fundamental patent to issue now that OCT is over 20 years old. In fact, many of the fundamental patents from early years on time-domain OCT, swept source OCT, and full-field OCT systems, scanning techniques, probes, and disposables have expired or are about to expire. Thus, the many of recent patents may represent incremental patents. The role of an individual patent versus a portfolio of patents can be different in an academic setting versus an industrial setting. In an academic setting, patent filings are often focused on more fundamental ideas because it is very costly and risky for a university to develop a large portfolio of patents. Thus, university technology licensing offices will usually not file on incremental ideas. This is also, in part, due to university licensing offices

expecting the licensee companies to file the incremental patents. In industry, a large patent portfolio which may contain many incremental patents can be very important to thwart potential litigation even though it can be hard to place a value on a patent portfolio that is never challenged in court.

Patents can be licensed exclusively or nonexclusively. Licenses to startup companies often are exclusive, whereas licenses to larger companies tend to have a significant fraction of nonexclusive terms [1–3]. In the United States, most university licenses to startups tend to have a combination of fees, equity (1–5 %), and royalties (1–5 %) stakes in startup companies as well as revenue and market due diligence milestones that allow the university to change the licensing terms if the company is not progressing as agreed to in the commercialization process. Often, startup companies and their investors don't want to see precious early company cash going to university licensing offices so they often trade equity for upfront fees. Universities are becoming more stringent about restricting the fields of use to a license grantee in order to avoid situations where a license is given in a field that is never commercially developed. Startup companies and their investors often want exclusivity in the broadest fields of uses, even though this is contrary to the near-term goals of startups which must often focus on a particular market for many years in order to become successful.

It is mainly universities and "patent trolls" that license to industry.[3] Licensing to industry is difficult, and the patent has to be very powerful, as industry has a strong disincentive to give up precious margin (revenue) in the face of market pressures for profitability. Furthermore, while universities typically develop multiple patents in different areas, the vast majority of the licensing revenue is in a very small percentage of their licenses and patents. It is estimated that about one in 200 university patent licenses generate in excess of $1M in any 1 year [3]. At one leading US University between ~85 % of the total royalty and fee income came from the top ~12 patent families. Thus the vast majority of the licensing revenue comes from a small number of big hits. It is probable that a significant fraction of university patents are never licensed at all [1–3]. Patenting law is complex and varies from country to country and over time. For example, US patent law has recently shifted from "first to invent" to "first to file."

Recent trends suggest that patents are playing a more prominent role in the industry. There have been recent major news stories about the increasing value of industrial patent portfolios, particularly in big industries such as wireless where giants such as Apple, Motorola, Google, Microsoft, Samsung, and others are battling for market share [4]. For example, Google bought Motorola Mobility partly for its patent profile for ~$12B in 2011. As another example Apple and Samsung have been embroiled in many patent related lawsuits around the globe, with billions of dollars in damages claimed between them. It seems unlikely in the near term that

[3]Patent troll is a derogatory term for a company that creates or acquires patents and often use what some feel are unsavory tactics against alleged infringers in a manner that is aggressive and often they have no intention to produce any products of their own.

OCT patents will be this litigious, and part of the reason is Apple sells ~$1B in iPhones per week – a long way from OCT sales volumes. In fact, there have only been a very small number of OCT patent battles. But as the revenue stakes increase, so does the likelihood of patent litigation and some of the ugliness of patent trolls and big company tactics being used against small companies [4]. For example, a small startup company is often in no financial position to litigate against an established large competitor, nor are they in a position to fight a competitor litigating against them – even if the apparent legal metrics of the cited patent infringement seem on the side of the small company. Legal battles involving patents can easily exceed $1M and that can be a big chunk of the available cash for small companies.

In summary: patents are important in the OCT technology transfer process and the OCT market in general; patents play a particularly prominent role in startup companies; it is difficult to have a fundamental patent issue after ~25 years of technology development; a significant percentage of university patents are never licensed, the majority of value in university patents comes from a small fraction of the issued patents, and the motives for universities and industry filing patents can be quite different. It is clear that the number of research and industrial sponsored OCT patents is increasing, and this is due to many factors, including the fact that the underlying commercial market is growing, as well as the general high-tech industry-wide increase in the importance of patents.

84.4 Government Funding in OCT

The US government and other governments around the world have been large supporters of funding for research and development in OCT and its applications. This includes funding for basic science and technology as well as applications of the technology including clinical studies and trials. As with journal publications and patents, it is difficult to determine what is OCT funding and even more difficult to track down all the potential sources of OCT government funding around the world. A snapshot of some examples of government funding is shown in Fig. 84.4. This plot contains cumulative funding in OCT for US National Science Foundation (NSF), US National Institutes of Health (NIH), Canada, and the United Kingdom.[4] This data assumes if "Optical Coherence Tomography" is mentioned in the title, abstract, or summary of the grant mentioned, then it was counted as an OCT grant. This data is drawn from a more comprehensive analysis contained in reference [5].

Figure 84.4 illustrates several things, foremost of which is that there has been a steady increase in funding, and in aggregate, this cumulative funding approached $0.5B in the last decade. The actual total could be far in excess of this, approaching

[4]The Canadian data is from the combined Canadian funding from Natural Sciences and Engineering Research Council (NSERC), Canadian Institutes of Health Research (CIHR), and National Cancer Institute of Canada (NCIC). The UK data is combined UK funding from Engineering and Physical Sciences Research Council (EPSRC), Biotechnology and Biological Science Research Council (BBSRC), and Medical Research Council (MRC).

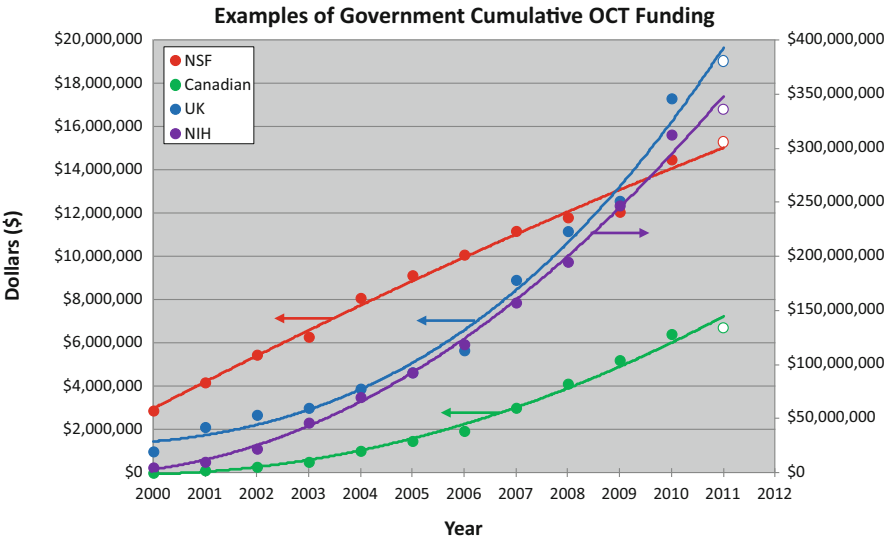

Fig. 84.4 Examples in growth of government funding in OCT. The NSF, Canadian, and UK funding are on the left vertical axis, and the NIH funding vertical axis is on the right. 2011 is a partial year's result

well over $1B since this analysis does not count numerous major sources of OCT funding in the United States, Europe, Japan, Russia, China, and other countries. The majority of funds shown here have come from the NIH, and within the NIH, the National Eye Institute (NEI) has accounted for much of the funding to date [5]. The NEI money has supported ophthalmic clinical studies and clinical trials, which can be expensive. One potential noteworthy trend is that NSF funding appears to be growing at a smaller rate than other sources. This does not bode well for US researchers and industry because NSF funds are better matched to fundamental technology development which is key to future innovation and commercialization.

A question arises as to whether or not this $500M to $1B of worldwide government funding has been effective. Most would say the result is an unqualified success from many metrics. OCT in ophthalmology alone has had over ~100 M procedures, been a major sight saver, created a paradigm shift in ophthalmic practices around the world, generated over $1B in capital equipment sales, generated over $1B in reimbursement in 2010 alone, and created many jobs in the process [5]. With OCT commercialization in other clinical specialties such as cardiovascular, gastroenterology, and oncology, the return on investment and clinical impact on healthcare could continue to be impressive.

It is interesting to speculate about where OCT R&D dollars will come from in the future. In the past, the majority of funding for R&D has come from the government. But with the OCT market approaching ~$0.5B/year it is clear that R&D from industry will begin to play a significant role just as it has in other mature industries such as microprocessors and telecommunications. In the financial

statements of public and private companies, the percentage of revenue spent in R&D can vary from 15 % to 50 % or more. For mature OCT companies with established product lines, the R&D expense number is lower (~15 %), whereas for small startup companies the number can be much higher. Assuming 20 % of a $0.4B market yields an industrial R&D expenditure of ~$80 M/year in 2012. This is about the same level as the yearly US government-sponsored R&D spending in 2012 as seen in Fig. 84.4. Thus, the current government and industry R&D expenditures are roughly of the same magnitude.

This trend does not diminish the importance and necessity of future university research and the government funds that support it. OCT is still an emerging field, and there are large gaps between what industry will fund and the government can fund. Government funding supports new technology development, clinical research, and clinical validation studies. This support continues to be critical and highly leveraged, since industrial funds alone may not support OCT innovation in some of the most new and promising areas for the future.

In summary, the amount of cumulative government spending around the world has exceeded $0.5B, government funding has had a profound effect on the development and commercialization of OCT products, the financial return on this government spending has been outstanding, and continued government support is needed to continue to speed new applications of OCT to market to benefit patient care and commerce. Successful entry of commercial OCT products can accelerate this funding and its positive impact on commerce and clinical care, as is clearly the case in ophthalmology and cardiology.

84.5 Some Examples of Technology Transfer to the Market

Success with technology transfer and the launch of any new product line within a startup company or within an established company is extremely hard. It's difficult and risky to hit all the milestones necessary in the marketplace: to raise funds; recruit and build a team; develop new technology, qualify it, and get regulatory clearances set up manufacturing lines, product support, and quality systems; prove value in clinical studies and clinical trials; get reimbursement; make a profit with the necessary profit margin to reinvest money into supporting existing products and R&D for new products to keep and grow market share; and return profit to the shareholders and keep workers employed. For these reasons, as mentioned previously, academic research is usually only the first 10 % of the job of commercialization, and technology translation often takes much longer and is much harder than expected.

Figure 84.5 (which is similar to that shown in references [6, 7]) shows one qualitative timeline for evolution and phases of a new medical product such as OCT. This suggests that it takes on the order of 3–5 years to design, develop, and qualify a product to enter a new market. Startups have the additional burden during this phase of developing the other aspects of their business (regulatory, sales, marketing, manufacturing, etc.). It then takes another 3–5 years for that product to gain market relevance by, for example, proving efficacy and cost savings though

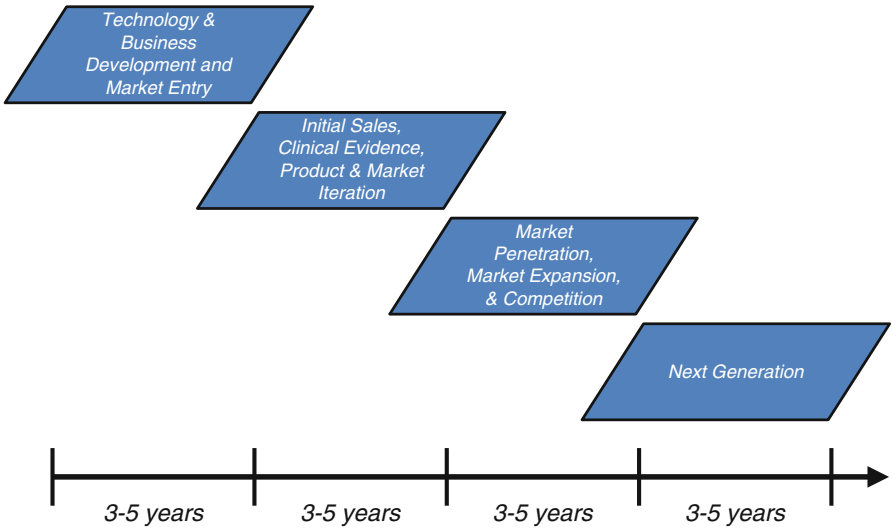

Fig. 84.5 Phases of product evolution ("five-year rule")

clinical studies and clinical trials. Beyond that, it can take another 3–5 years to ramp into significant market penetration, explore and expand into closely related markets, and face competitive pressures. To reach the end of this phase can take 10–15 years. The timeline for additional companies developing a competitive product in a market where a prior product has already received regulatory clearance and some level of market penetration can be, and usually is, much faster than that shown above. The first company often paves the way in regulatory bodies and the market at large. Thus, the second company to enter a new market gets an easier road, but has a disadvantage in the ensuing fight for market share.

Of course not every product falls into this simple phased model, but it is interesting that Advanced Ophthalmic Devices (AOD) and Lightlab Imaging which were among the first OCT companies followed this general pattern. AOD was an OCT startup founded in 1992 out of MIT and acquired by Zeiss in 1994. Lightlab Imaging was also an MIT OCT startup founded in 1998. Lightlab was acquired by Goodman Corporation in 2002 and then acquired by St. Jude Medical in 2010. It is interesting to note that both Zeiss/AOD and St. Jude/Lightlab Imaging led the next significant competitor entry into their respective markets by almost a decade. For both companies, this translated to high risk followed by high reward in obtaining a large market share. Zeiss had shipped ~$100M's in ophthalmic OCT products before a significant scale competitor emerged. St. Jude is currently at ~$100 M/year run rate. Perhaps more important than the profits and market share, the successful transition of the technology had a massive impact in bringing critical diagnostic and research tools to impact clinical care for blinding ophthalmic diseases and deadly cardiovascular disease, accelerating progress by almost a decade.

Figure 84.6 illustrates how OCT in ophthalmology followed the general trend of Fig. 84.5 and further shows the high degree of correlation that makes up this

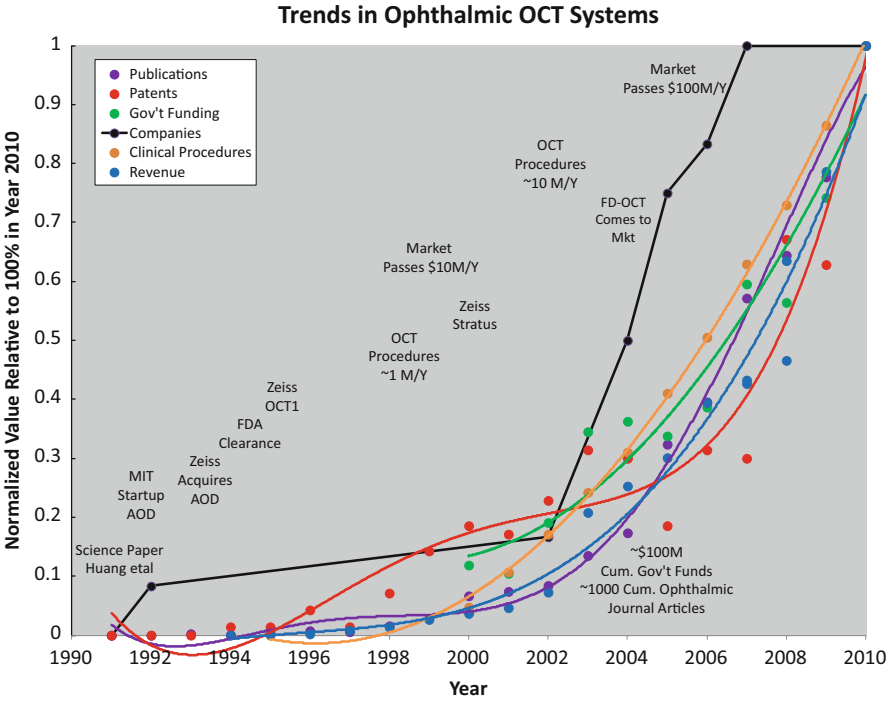

Fig. 84.6 Trends in the ophthalmic OCT system market. (The government funding shown is total NIH funding, but that funding is dominated in this time period by ophthalmology. Similarly, the patents are all OCT patents not just ophthalmology. The clinical procedures are based on Medicare data and were extracted from reference [8].) All the data are normalized to 2010

ecosphere of publications, patents, government funding, companies starting OCT ophthalmic products, clinical ophthalmic procedures (based on CPT code 92135), and revenue for the ophthalmic OCT market. AOD started in 1992, and Zeiss acquired it in 1994 and released its first product in 1996 – 4 years later and within the time period shown in phase 1 of Fig. 84.5. Zeiss shipped ~400 units of its first-generation product (OCT1/2) and gained critical clinical evidence and validation on utility, releasing its second-generation OCT product Stratus in 2002 – 6 years later and within that period shown in phase 2 of Fig. 84.5. There was significant market penetration of Stratus and then around 2007 when Zeiss and several other companies released spectral domain SD-OCT technology – 5 years later and within the time frame shown in phase 3 of Fig. 84.5. It is interesting to note that while commercialization of Fourier domain OCT technology (both SD-OCT and SS-OCT) was a major boost to OCT system utility and capability, the market penetration and clinical utility of TD-OCT had reached a significant level prior to introduction of Fourier domain OCT to the ophthalmic marketplace. While there are now many ophthalmic OCT companies, Zeiss still maintained the largest market share as of 2013.

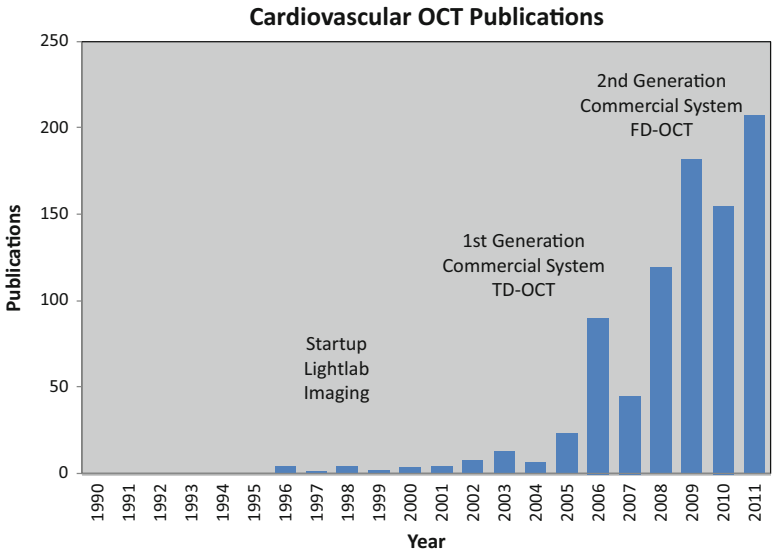

Fig. 84.7 Estimated number of cardiovascular/intravascular OCT publications

Cardiology followed a very similar trajectory as shown in Figs. 84.7 and 84.8. Lightlab Imaging (originally incorporated as Coherent Diagnostic Technology) was founded in 1998 and initially focused on the microscopy and GI markets (for Barrett's esophagus). About a year later, the company changed direction and focused on cardiology. In 2004, Lightlab commercially released its first-generation TD-OCT cardiovascular system in Europe – 6 years later and within the phase 1 shown in Fig. 84.5. By 2005/2006, there were over 1,000 in-man clinical procedures. By 2008, there were approximately 10,000 clinical procedures. Between 2004 and 2009, intravascular OCT gained market relevance – a 5-year period commensurate with phase 2 shown in Fig. 84.5. In 2009, Lightlab released its second-generation swept source/Fourier domain (SS-OCT) cardiovascular product, and in 2013, revenue is estimated to be ~$100M/year, and the number of cumulative clinical procedures has exceeded 100,000. This cardiovascular OCT path was very similar to that experienced in ophthalmology in that it began with a MIT startup company that was eventually acquired by a larger company, a first-generation system paved the way for understanding clinical utility and the market in general, followed by a second-generation system that increased market growth. Also, there was nearly a decade year gap before a scale competitor introduced a product into the marketplace.

Another successful example of OCT technology transfer is Optopol. Optopol was initially distributing ophthalmic equipment and producing devices such as ophthalmic projectors, refraction units, Placido ring corneal topographers, and automated perimeters. Ophthalmic OCT was an attractive market opportunity and for them. Optopol had a leading ophthalmic OCT research group close by, the Nicolaus Copernicus University (NCU). NCU researchers had received significant

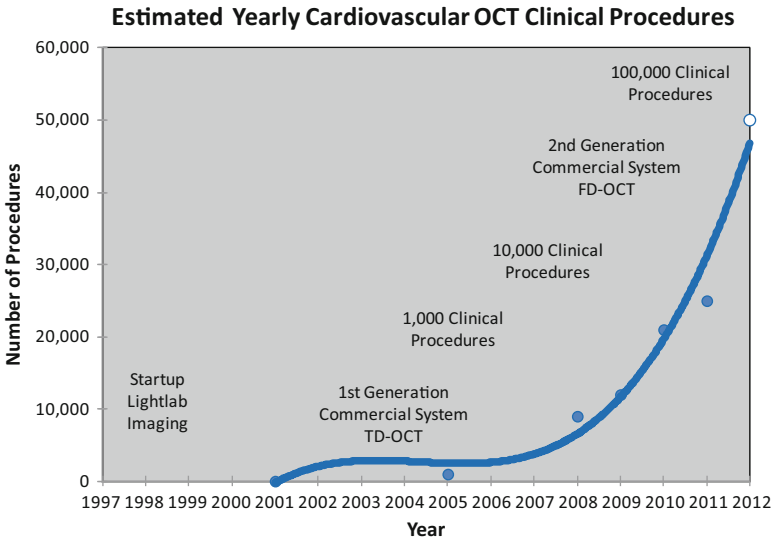

Fig. 84.8 Estimated number of cardiovascular/intravascular OCT clinical procedures. Also shown on chart are cumulative clinical procedures

government funding and had a working SD-OCT clinical prototype. In 2005, an agreement between Optopol and NCU was signed. In addition to transferring technology from NCU to Optopol, the agreement also created an R&D office at NCU. The idea was to create opportunities for jobs in industry for NCU graduate students. In 2009, Canon Inc. acquired Optopol for $94M.

Bioptigen is a different example of an OCT startup. Bioptigen was founded in 2004 and is a supplier of OCT to the preclinical (small animal) and clinical ophthalmology research market, including a handheld SD-OCT product for pediatric ophthalmologists. Bioptigen has strong ties to academic work at Duke University, and Bioptigen is exclusive licensee to patent portfolios from Case Western Reserve University and Duke University. Bioptigen introduced the first commercial ultrahigh resolution UHR SD-OCT system in 2006 and received FDA clearance for the first handheld SD-OCT instrument for ophthalmology in 2012. Government sources played a strong role in funding the company. Initial funding included SBIR grants. Early on, Bioptigen had won in excess of $7M in SBIR awards directly or indirectly in partnership with others, while total equity financing is only $3.8M, none of which came from traditional venture capital. This shows the government can play a big role in both funding research and industrial activities.

There are also examples of highly successful startup companies starting with minimal academic connections and government support. A good example is Optovue. Optovue was founded in ~2004 and was the first to get FDA approval for an ophthalmic SD-OCT system and by 2010 had revenues of ~$50M/year. Optovue was a classic startup company and currently remains privately held. While Optovue interacts closely with academic researchers, the technology transfer

relationship into Optovue was quite different in that it relied heavily on the passion and technical and business expertise of the founder, Jay Wei. He was the lead OCT engineer on the development and release of the early Zeiss OCT products.

There are many other examples of successful technology transfer from universities to startups and established companies (as shown in the Table 84.1). There are also clear examples of companies that have started organically or through association with universities that have not yet been successful from a business perspective. The poor execution is sometimes a combination of bad timing, inexperienced management and/or engineers, insufficient funding, bad choice of markets that didn't develop or are taking a long time to develop, missed milestones, bad luck, or a combination of these and other factors. Even location can be an important factor in the success of a startup. There are several specific regions around the world that have a long track record of fostering startups; these areas have an ingrained startup culture with more risk tolerance and a local economy with access to a talent pool and industrial infrastructure and equity financing (e.g., venture capital) that can be highly beneficial to the success of young companies. These advantages are simply not available in many regions of the world. In startup companies, delays in product development or missed milestones can be deadly, as investors quickly grow impatient and compeition moves on. In large established companies, there is often a bigger financial base and other resources to buffer negative effects. Note that there is a wide range in the amount and types of funding raised by the companies listed in Table 84.1. It ranges from a few million dollars to well over $100M. To bring a successful complex medical device product to market can be quite expensive and is most often well over $10M to hit profitability. The more complex the technology, market, regulatory hurdles, and reimbursement hurdles the higher the number.

84.6 Commercial OCT System Companies

There are ~40 OCT system companies in the market as of mid 2012 in varying stages of maturity.[5] There were even more startups and established companies in stealth mode that have started or are looking to start new OCT related products. There are also several OCT companies that have stated over the past decade and gone out of business or stopped OCT development some of which are listed. Figure 84.9 shows a graph of some of these companies and the approximate time that significant resources were invested in new OCT product development efforts (as of mid 2012). Table 84.1 shows some additional data on these companies including whether their technology initiated as a startup company and/or if there was a strong connection with an academic institution. Some of the data was supplied directly from the companies, and some of the data was estimated where no input was supplied from the company.

[5]There are other OCT companies that currently exist or started in this time period but are not listed here due to their small scale and/or company status or desire to remain confidential.

Table 84.1 Companies with OCT system products in the market or in development

OCT system companies	Academic	Startup	OCT market focus	Comments
AGFA Healthcare			Dermatology systems	Product developments start in 2010. CE Mark 9/5/2011. FDA in process. Technology developed internally
Alcon (LenSx)		Y	Laser technology for cataract surgery that used OCT guidance	LenSx was founded in 2006, was acquired by Alcon for $744 M in 2010. Much of LenSx technology is not focused on OCT. However, OCT being used for laser surgical guidance
Avinger		Y	OCT-guided catheters for chronic total occlusion and atherectomy	Founded 2008. OCT effort started ~2008. OCT product pending FDA clearance (expected Nov 2013)
Bioptigen	Y	Y	Ophthalmic and research OCT systems	Cofounded in 2004 by Dr. Joseph Izatt at Duke University. FDA approval in 2006
Canon (Optopol)	Y	Y	Ophthalmic OCT systems	Optopol founded in 1992, and its OCT effort started in 2005. Canon Medical acquired Optopol for $94 M in 2009. Optopol had strong connections to leading researchers at Nicolaus Copernicus University, and OCT work started at Optopol in 2005 when an agreement with NCU was signed
Carl Zeiss Meditec (AOD)	Y	Y	Ophthalmic OCT systems	Advanced Ophthalmic Devices (AOD) was founded in 1992 by Eric Swanson, Dr. James Fujimoto, and Dr. Carmen Pulifiato at MIT and Harvard Medical School in 1992. Zeiss acquired AOD in 1994. Zeiss developed and released several generation of products: TD-OCT, OCT1/1996, OCT2/2000, Stratus/ 2002, Visante/2005, FD-OCT Cirrus 2007
Colibri Technologies	Y	Y	Cardiovascular OCT	Colibri was founded in 2007 and originated from research conducted at Sunnybrook Health Sciences Centre in Toronto, Canada. Sunnybrook is affiliated with the University of Toronto
Compact Imaging		Y	OEMing compact OCT systems	Founded ~2011. Product in development
Diagnostic Photonics	Y	Y	Surgical-guided OCT systems	Cofounded in 2008 by Dr. Stephen Boppart and Dr. Scott Carney at the University of Illinois at Urbana Champaign

Heidelberg Engineering			Ophthalmic OCT systems	OCT effort started ~2005 when Heidelberg acquired 4optics AG (Lubeck Germany) in 2005. First OCT FDA clearance 2006. 2007 released FD-OCT
Heliotis AG	Y	Y	Microscopy OCT Markets	Heliotis was founded in 2005 and was a spin-off of Swiss Center for Electronics and Microtechnology, a government-sponsored research institution in Switzerland. Shipments ~2007
Imalux	Y	Y	OCT for ENT, gynecology, and urology	Imalux was founded in 2000 by Drs. Felix Feldchtein, Alexander Sergeev, Valentin Gelikonov, and Grigory Gelikonov from the Institute of Applied Physics at the Russian Academy of Sciences. OCT efforts started around 2002. FDA clearance in 2004. Shipments 2005
ISIS Sentronics		Y	Inspection systems: semiconductors, automotive, films, coatings, and medical	ISIS Sentronics GmbH was founded by CEO Dr. Alexander Knüttel in 2006. ISIS Optronics was founded in 1999 and first sales of SkinDex300 in 2000
LLTech	Y	Y	FF-OCT microscopy systems for research and pathology for ex vivo tissue/biopsies assessment	LLTech was cofounded in 2007 by Dr. Claude Boccara and Bertrand Le Conte de Poly at ESPCI Paris Tech University in France and licensed CNRS (National Center for Scientific Research) technology. First OCT funding in 2009. Research market approval 2011 (CE and United States)
MedLumics		Y	OCT systems using integrated optics for cardiology and oral surgery	Founded in 2009. A-round investment in 2011. Company focused on integrated optical photonic circuits to lower size and costs
Michelson Diagnostics		Y	Dermatology market for diagnosis, staging, and monitoring of nonmelanoma skin cancer	Michelson Diagnostics OCT effort started in 2007. Michelson was spun out of an established medium-sized optical engineering company. FDA approval 2010. Shipments 2012
Nidek			Ophthalmic OCT systems	OCT effort started ~2007. 2009 RS-3000 Product Announced
NinePoint Medical	Y	Y	Endoscopic OCT systems for gastroenterology	Founded in 2010 and licensed patents and other IP and receives assistance from the Harvard/MGH. FDA approval 2011. Shipments 2013
Novacam Technologies	Y	Y	3D metrology for industrial and medical markets	Founded in 1997 and OCT systems began in 2004/2006. Novacam works closely with and licensed technology from National Research Council Canada. Shipments ~1999

(*continued*)

Table 84.1 (continued)

OCT system companies	Academic	Startup	OCT market focus	Comments
PhotoniCare	Y	Y	Handheld OCT for otolaryngology and primary care applications	Co-founded in 2013 by Dr. Stephen Boppart and Dr. Ryan Shelton at the University of Illinois at Urbana-Champaign. Product in development
Abbot Medical Optics		Y	Laser cataract surgery systems that used OCT guidance	Abbot Medical Optics acquired Optimedica for $400M in 2013. Optimedica was founded in 2004 and much of the technology was not focused on OCT but on laser surgery. But OCT was integrated to help guide the surgical procedure
OptoMedical Technologies GmbH			Universal OCT camera add-ons for medical imaging	Founded in 2010
Optos (Opko/ Ophthalmic Technologies Inc.)		Y	Ophthalmic OCT systems	Ophthalmic Technologies Incorporated (OTI) founded in ~2002. Acquired by OPKO in 2007 for ~ $15 M. Optos acquire OTI from OPKO in 2011 for ~ $38M. OTI got FDA clearance in 2005, sold in Japan in 2003 via Nidek
Optovue		Y	Ophthalmic OCT systems	Founded in 2004 and was the first to FDA approval for SD-OCT. FDA approval 2006/RTVue, 2010/iVue
Santec			Medical, and nonmedical OCT systems and OEM market	Santec OCT technology R&D started ~2004. Shipments ~2005
Schwind eye-tech-solutions			Refractive and therapeutic corneal surgery	Uses OCT to guide laser surgical ophthalmic procedures. Product release ~2009. Product start ~2007 (estimate). Acquired by Bausch + Lomb in 2012
Shenzhen Moptim Imaging	Y	Y	Ophthalmic and inspection OCT systems	Moptim was founded in 2004 and started in collaboration with Shenzhen Tsinghua University in China. They are currently focused in China market. Chinese regulatory approval ~2009
St. Jude (Lightlab Imaging)	Y	Y	Cardiovascular OCT systems	Founded in 1998 by Eric Swanson, Dr. James Fujimoto, and Dr. Mark Brezinski at MIT as a Joint Venture with Zeiss. Goodman Ltd acquired Lightlab in 2002. St. Jude Medical then acquired Lightlab for $90 M in 2010. TD-OCT 2004/EU, 2006/China, 2007/Japan, FD-OCT 2009/EU, 2010/USA

Technolas Perfect Vision			Refractive and cataract surgical products	Uses OCT to guide laser surgical ophthalmic procedures. Product release ~2011. Product start ~2009 (estimate). Acquired by Bausch + Lomb in 2012
Terumo	Y		Cardiovascular OCT systems	Terumo entered a joint development agreement and licensed numerous patents and other IP and receives assistance from the MGH research in 2004. 2012 European Approval
Thorlabs			Research and OEM market	Thorlabs collaborates with numerous universities; the majority of Thorlabs OCT technology was developed organically around 2004. Shipments ~2005
Tomey		Y	Ophthalmic OCT systems	Tomey is a 40-year old company, and its OCT technology started ~2007. Announced SS-OCT system in 2008
Tomophase		Y	Pulmonary OCT systems	Founded in 2003 (seed) and got A-round in 2005. Founders all came from telecom backgrounds. In April 2014, Tomophase Corp. was acquired by a Chinese company called Winstar, and is now named Tomophase Inc
Topcon Medical Systems	Y		Ophthalmic OCT systems	Topcon Medical Systems OCT effort started 2004. FDA clearance in 2007. Licensing of technology from Tsukuba University, then collaborated during the development
Tornado Spectral Systems		Y	On-chip spectrometers for OCT systems	Founded in 2010 and started OCT in 2011. Developing on-chip spectrometers for OCT applications using photonic integrated circuit technology
Volcano Corporation	Y		Cardiovascular OCT systems. OEMing OCT subsystems through Axsun	Cardiospectra was founded in 2005 by Marc Feldman and Thomas Milner from University of Texas at Austin. Volcano acquired Cardiospectra in 2007 for $63 M for its start in OCT. Volcano also acquired Axsun for its OCT laser technology in 2008 for $21.5 M. In 2013 Volcano announced it was canceling its OCT development and in 2014 Volcano announced it was divesting Axsun Technologies

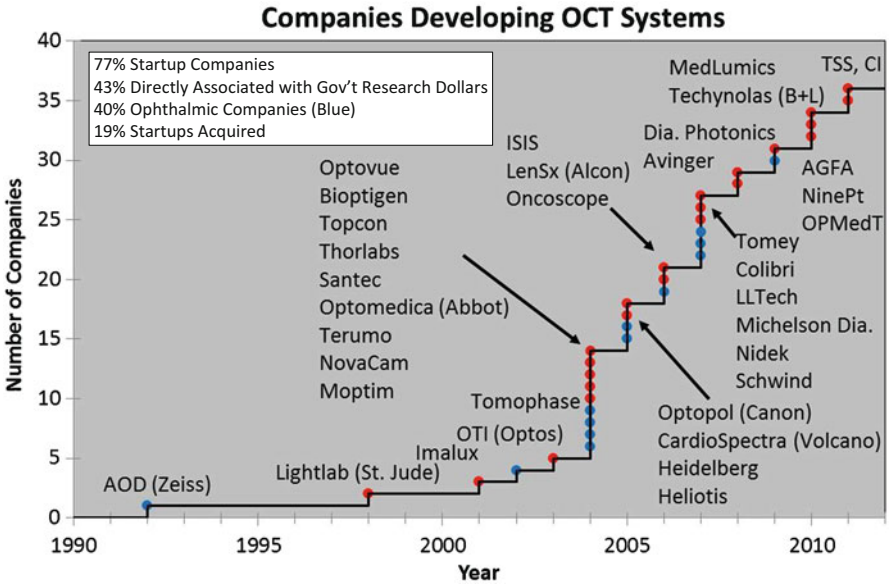

Fig. 84.9 Startups or established companies OCT product development start as of mid 2012

As shown in Fig. 84.9, there was a slow start to OCT system companies. Advanced Ophthalmic Devices, Lightlab Imaging, Imalux, Ophthalmic Technologies Incorporated, and Tomophase were among the first five OCT companies and were all startup companies – a clear testament to the entrepreneurial spirit and power of startups. It is interesting to note that ~75 % of these companies were at one point, startup companies. Additionally, almost one half of these companies owe their start to strong ties with academic institutions that had significant sources of government funding. Of the companies listed, 14 are related to ophthalmology. In the 2005 time frame, there was a lot of activity in new OCT product starts.

Approximately 19 % of the startup companies have been acquired by larger established companies for a total purchase price of ~$300M (not including LenSx, Optimedica, and Technolas which were acquired for large sums but mainly for there non-OCT technology. As of mid 2013, no startup company has gone to the public market for financing.

The end of this chapter shows pictures of some examples of OCT system products in the marketplace.

84.7 OCT Market Size Estimates

It is difficult to get precise data on the worldwide OCT system market. There are many manufacturers, some with direct sales channels and some with sales supported with distributors that have markups; there are a wide variety of models with differing

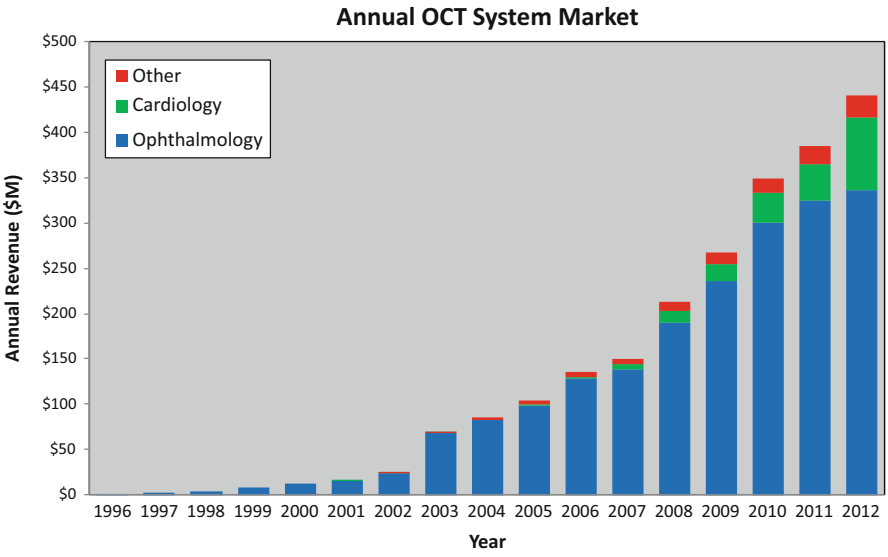

Fig. 84.10 Estimated OCT system annual market size

capabilities and a wide variety of price points. A coarse estimate of the historical OCT system world market is shown in Fig. 84.10. This data was arrived at by a combination of means and represents equipment manufacturers, not end user sales which can often pay higher prices due to distributor costs. While the exact values are subject to some error, one thing is certain: the market has grown dramatically over the past decade and likely exceeded $400M/year in 2012.

It is clear the market has grown dramatically over the past decade and will most likely pass $0.5B in 2013 or shortly thereafter. The majority of the revenue today is clearly from ophthalmology; this is due to the fact that ophthalmology was the first market to be entered, and OCT has proven to be a very powerful tool in ophthalmology, becoming a standard of care. However, cardiovascular OCT is growing rapidly, and many of the startup companies in dermatology, gastroenterology, urology, gynecology, and other markets are just beginning to reach maturity. This should continue to grow the market.

84.7.1 Ophthalmology

As of mid 2012, there are about ten companies in the diagnostic ophthalmology OCT market, plus four more that are using OCT to guide laser surgical procedures in ophthalmic applications. Figure 84.11 shows the estimated growth in total US OCT procedures, the allowed OCT-related Medicare service (based on CPT codes 92132, 92133, 92134, and 92135 used to bill for OCT), and the estimated yearly OCT billing charges [8, 9]. It is impressive that the worldwide OCT billing in 2010

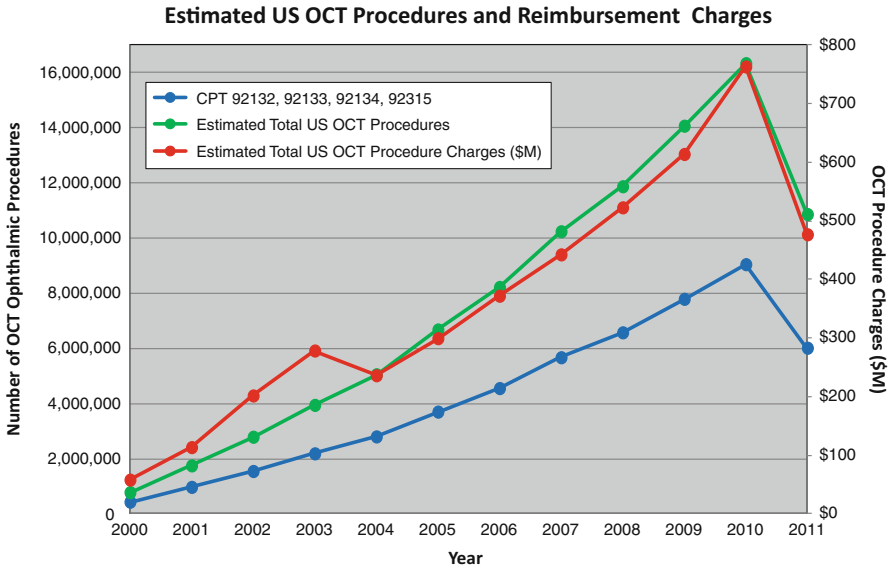

Fig. 84.11 Yearly OCT-related CPT Medicare services, estimated US OCT procedures, and OCT procedure charges

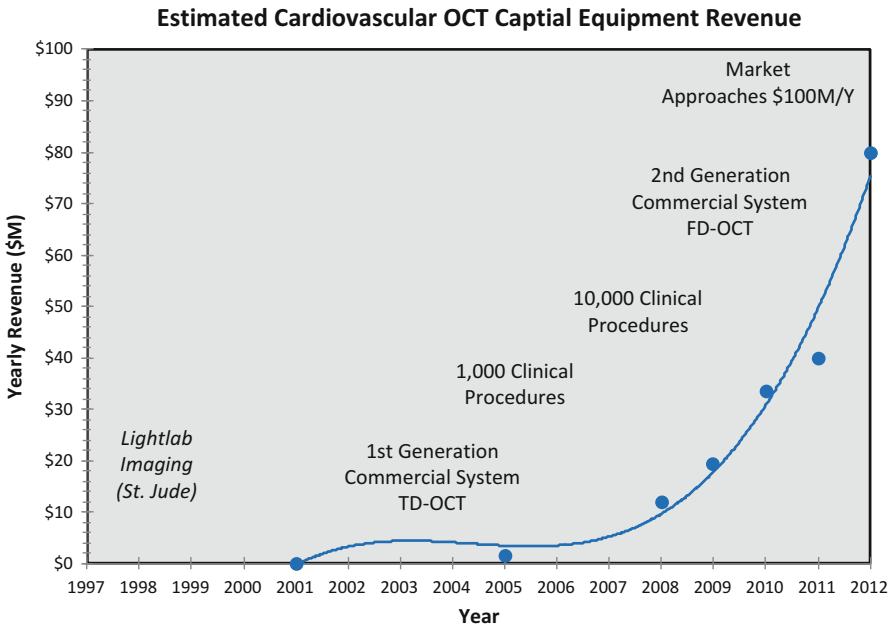

Fig. 84.12 Estimated OCT cardiovascular market

most likely exceeded $1B and was ~$750 M in the United States alone in 2010. This large spending has caught the eye of regulators, who dramatically reduced the Medicare reimbursement allowance in 2011 [8, 9]. This reduction is clearly seen in Fig. 84.11. In 2011 US Medicare policy eliminated CPT code 92135 and split into three new codes: 92132 anterior segment, 92133 optic nerve, and 92134 posterior segment [9]. More relevant in that year, the code was changed from allowing for separate billing of each eye to only allow billing once whether one or two eyes were scanned. Over $100M in reimbursement payments in the United States vanished as a result of this reimbursement change.

This could create a dampening effect on ophthalmic revenue growth. However, there is still a strong opportunity in the optometry market, and much of the developing world still does not have access to any ophthalmic OCT technology. Furthermore, since there is strong clinical evidence that OCT improves clinical outcome, OCT procedures will likely continue to increase and be performed as a standard of care, even though reimbursements have decreased nearly a factor of two. For example, ophthalmologists may perform and bill for fundus photography which has a higher reimbursement, but still do OCT unbilled. Furthermore, even though the OCT Medicare reimbursement rate has dramatically reduced the ROI, it is still attractive for many practices. For example, assuming an ophthalmic OCT instrument costs ~$60k, the blended weighted reimbursement is ~$44, a procedure takes 30 min is used 8 h/day at 100 % utilization yields revenue of ~$200 k/year. Even allowing for costs including technicians taking the exam, doctor reviews, infrastructure, cost of capital, and less than 100 % utilization still yields a very attractive ROI.

It is interesting to estimate the total worldwide ophthalmic OCT procedures. However, there is no readily available data showing the number of worldwide procedures or a reliable breakdown of the US versus international sales of ophthalmic OCT instruments. A coarse assumption is simply to assume the number of world procedures in 2011 was ~2X that of the US procedures. This approach yields a total of worldwide patient procedures in excess of 20M per year and close to one patient per second every day worldwide, a rather amazing achievement for a fairly new technology.

84.7.2 Cardiology

The cardiovascular market segment has been growing rapidly since Lightlab Imaging/St. Jude Medical started shipping its cardiovascular SS-OCT system. The OCT cardiovascular market is expected to continue to grow relative to the intravascular ultrasound (IVUS) market, which is currently around $500M/year. An estimate of the cardiovascular OCT market is shown in Fig. 84.12. It seems likely the market will be ~$100 M/year in 2014, and the market leader is currently St Jude Medical which started shipping commercially in the U.S. in 2010 following the earlier shipments of products by LightLab Imaging in Japan and Europe in 2004.

In 2012, Terumo started shipping its cardiovascular SS-OCT Product in Europe and Japan, and Avinger has introduced an atherectomy catheter that incorporates OCT imaging.

Cardiovascular OCT has been used in clinical research to study mechanisms of coronary artery disease in vivo and to assess percutaneous coronary intervention. But it is uncertain yet to what extent cardiovascular OCT will be adopted into routine clinical practice. Will its usage cap near the IVUS market levels or grow beyond IVUS? The cardiovascular OCT market is already ~25 % of the ophthalmic OCT market. Yet the number of cardiovascular OCT procedures (~50 k) is a small fraction of the number of ophthalmic procedures (~30M). The potential for intravascular OCT to impact patient care and grow market size depends upon whether research demonstrates clear clinical benefits that will lead to indications for intravascular OCT imaging. If such indications are identified, intravascular OCT growth could be dramatic because the number of percutaneous coronary interventional procedures and other intravascular procedures exceeds 1M per year. However, current outcomes in these procedures are relatively good without the use of OCT imaging, and it is unclear as of yet how improved visualization of intravascular structure will improve everyday procedural outcomes. It is also unknown what other functions a future intravascular OCT device, or multimodal device, might provide to further improve outcomes.

There are major research efforts currently underway, such as the Massachusetts General Hospital OCT Registry, to address these important questions and help guide the development and application of the technology in cardiovascular medicine. Important areas for further investigation include the use of OCT to guide percutaneous coronary intervention, including stent selection and deployment, and also the identification of high-risk, vulnerable plaque lesions. The detailed information about coronary plaque morphology provided by OCT may also allow cardiologists to better understand patient risk for future events and therefore modify therapy accordingly.

84.7.3 Other Markets

There are numerous other medical and nonmedical markets for OCT. There are companies developing or already selling OCT and related technology for gastroenterology, dermatology, ENT, urology, gynecology, microscopy, digital pathology, pulmonology, and dentistry, not to mention numerous nonmedical applications such as general purpose research OCT equipment microscopes and NDE/NDT applications. These markets offer growth for the future, but have not yet reached the levels of ophthalmology or cardiology. As of 2012, most of them have not achieved a significant yearly revenue rate in excess of ~$10M/year. In some ways, ophthalmology had an advantage in that it started first as was less invasive and risky and costly to start clinical studies and trials than say cardiology. But commercial efforts are underway in these developing OCT markets, and many of them are very large markets (~$B) where OCT could eventually play an important role.

84.8 Potential Future Trends in OCT

There are many ways OCT could evolve in the future. While details are impossible to predict, it seems a safe bet that both the fundamental technology and its applications will continue to improve and further penetrate existing markets and enter new markets. One exciting technology area where there has been and will continue to be a lot of focus and progress is in software. There are many aspects to this software frontier including the need for efficient algorithms for dealing with collection and real-time processing of extremely large data sets, software for manipulating and visualizing large 3D images, eliminating motion artifacts, and segmentation and feature extraction, as well as development of Doppler, birefringence, and other functional OCT software. Already much of the differentiation in the crowded ophthalmic OCT marketspace is in the software and database front. Its seems clear that for busy clinicians to efficiently deal with what are becoming very large OCT data sets that automated disease detection software will be important software technology area.

Technology for high-performance broadband and tunable light sources will also likely change significantly over the next few years. As of 2012, there are only a few swept source lasers that are commercially available, and this will undoubtedly change in the near future. The design of miniature low-cost scanning probe technology is an area that still seems in its infancy. There are very promising techniques to utilize MEMs, electro-optics, and other approaches to make tiny and low cost scanning medical needle, endoscope, catheter, and guidewire OCT probes. Another very promising area of technology research is integrated photonic circuits (PICs) for lowering the cost and size of OCT imaging engines. While there are a few commercial efforts mainly focused on SD-OCT systems, it seems likely SS-OCT photonic integrated circuits will also play a role in the future, particularly silicon- and InP-based systems where great strides have been made in the telecommunication industry. Such miniaturization and cost reduction offered by multifunction photonic integrated circuits might allow OCT to further penetrate existing markets and to penetrate new cost-sensitive markets such as the optometry market and primary care practice perhaps even low cost and simple enough for home use someday in the distant future. The area of post-optical detection signal/image processing is another exciting research area and includes topics such as synthetic aperture, digital holography, holoscopy, and computational adaptive optics. Such approaches offer many possible advantages such as eliminating need for deformable mirrors in adaptive optics systems and breaking the conventional trade-off between lateral resolution and Rayleigh range.

A factor that comes into play when thinking about future commercial opportunities for OCT component technology such as a new swept source laser, PIC, or similar items is that the current OCT value chain can make it difficult to get a return on an investment for some business plans. For example, the current total yearly market for OCT systems is ~10,000 units. If a startup wants to develop and sell a new laser, it might take between $5M and $50M dollars. If the laser sells in the

marketplace for $1,000, that's a total market size ~$10M and not a very attractive payback opportunity for investors, and no single laser company would own 100 % of the market anyway. If the laser sells for more (e.g., $10k), then there will be pushback from the system vendors selling products into the various medical markets who are facing price competition from competitors and cost pressure from insurers. This can make it difficult for a stand-alone technology company to make good financial progress in supplying the OCT systems market. A partial solution is to find other non-OCT markets for the technology or grow vertically by adding more functionality around the laser to increase the market value of the product. Business climates cycle in and out of time periods where vertical integration is rewarded and when it is not. The other solution is that much of this technology will come out of established multifunction technology companies that sell many components into many markets – and this is the current situation in the OCT marketplace. It is different calculus if a component supplier is shipping into the OCT disposable market due to the large opportunity for reoccurring revenue.

Another exciting future trend for OCT may be in integrating OCT with therapeutic technology. The future of integrating OCT with therapeutic technology seems particularly promising, and companies such as OptiMedica, LenSx, Schwind, Technolas Perfect Vision, Zeiss, Avinger, and others are already working on commercializing. The promise of low cost easy to used OCT screening devices or using OCT to guide therapeutic procedures on a microscopic scale and treating "what you see when you see it" is very appealing. For example, for the large gastroenterology and pulmonary disease management expenditures today, it seems quite possible that in the long term, integrated diagnostic/therapeutic devices could have major market opportunities in these and other areas.

Somewhat similar to integrating OCT with therapeutic technology is multimodality imaging. The future of multimodality diagnostic imaging (e.g., combining OCT and other imaging technology) also seems promising but perhaps faces a few more barriers. On the positive side, the vision of simultaneously getting the best information out of two or more simultaneous diagnostic imaging technologies seems quite attractive. For example, OCT could be used to get 3D morphological microstructural information and fluorescence or Raman or IR technology to get addition molecular or spectroscopic information. Similar comments apply for photoacoustic techniques. On the negative side, the cost of the capital equipment and any associated disposable devices may increase to a point where they are not justified. Other factors such as reimbursement could come into play where, for example, an existing ophthalmic instrument (e.g., fundus camera) and an OCT system could be integrated and prove to be cost-effective for the clinician practice.

Predicting the next medical markets in which OCT will be very successful is more difficult than predicting technology evolution. Figure 84.1 may provide good insight. After ophthalmology and cardiology, the next most published segments include gastroenterology, dermatology, dentistry, neurology, otolaryngology, urology, and pulmonology. Combining this quantitative data with the current availability of commercial approved devices might yield better insight into the next medical

successes. Some of the companies in these spaces are indicated in Table 84.1. They all have significant challenges relative to ophthalmology where from the start there was a clear dearth of technological capability and clear clinical need and a noninvasive procedure and in cardiology where there was an established IVUS technology that could be outperformed in speed and resolution by OCT. There remain large screening, diagnostic, and surgical guidance markets (~$B) where there is a need for improved patient outcomes but the barrier from entrenched products and clinical processes and the technology and economic challenges of the new approaches are significant.

Imaging tools for cancer remains a pressing need in society and a daunting technology challenge. It's made all the more harder because cancer is not one disease. It remains unclear to what extent OCT will provide a key tool to meet this challenge, but there is very promising research work going on in this area including using OCT for cancer margin assessment and to replace or augment current digital pathology tools. It seems highly likely new and novel optical imaging technologies, including OCT, will play a role in future commercial products for fighting cancer. Several existing OCT companies are already focusing on this challenge.

A major factor influencing the future of what medical markets OCT will be successful in will be the current and future health-care cost environment. There are major economic challenges around the world, particularly in the United States, in providing good healthcare while containing health-care cost from escalating to unsustainable levels. In the distant past, a new medical product could more easily be introduced based on improved patient care. Today, it is far more beneficial if a new product significantly lowers costs and improves patient care and to the extent the lowering of costs are clear and beneficial, the better. Further to the extent the cost savings is at the procedure level vs the process level, or at both the better. Reimbursement plays a major factor in the success of medical device companies and their products. It's one thing to get regulatory approval to sell a product, it's yet another to get reimbursement from insurers. In the United States, CPT codes are numbers assigned to every medical task and service provided to a patient. These codes are used by insurers to determine the amount of reimbursement the doctor, nurse, or hospital will receive by the insurer. Even if a generic CPT code can be used for billing or a specific tailored CPT code exists for a procedure, there is still the big step to convince all the major insurers to approve it under the various medical plans and further to convince hospitals to purchase the equipment, and for that, it is highly beneficial that the hospital be able to make a profit, or at a minimum break even, on the cost of purchase and the cost per procedure. Finally as the accumulated reimbursement levels on CPT codes get very large, the regulators may clamp down on the payments as they did in ophthalmology.

Another factor that may influence the future of what medical markets OCT will be successful in could be the changing demographics of society. For example, in some countries, there is the aging of population base, a increase in obesity, and/or dramatic changes in eating habits, the effects of which have not fully played out over time. Such effects could impact what diagnostic tools are needed in the future.

84.9 Summary

The historical growth of commercial OCT has been impressive from the viewpoint of market size, economic impact, and more importantly, for its impact on clinical medicine and patient care. The majority of the commercial efforts have initiated from startup companies – an impressive record and statement to the power of entrepreneurism. Almost half of the current OCT system companies had, or continue to have, strong ties to academic research. Over the past decade, cumulative government funding around the world totaled ~$1B and powered much of this academic and clinical research, which in turn created and powered an ecosystem that enabled startups and new OCT product launches.

While ophthalmology and cardiology are established markets, there remain some wide-open markets for OCT. Research publications (e.g., Table 84.1) may be a good predictor of what markets will be the most successful in the near term. The companies that are first to market face a long challenging process of plowing the field that can take ~10 years. However, they not only can obtain and hold market share for many years but more importantly, can accelerate the translation of research into the clinic by many years, potentially reducing morbidity and mortality.

Now that OCT is nearly 25 years old, the future of technology transfer will undoubtedly begin to change, and industry will play a more prominent role in advancing technology. The nature of how OCT technology is transferred into industry will change, and it is possible startup companies will play a smaller role in the established OCT markets but continue to play a role in new developing markets. It is likely that industrial spending and investment are already reaching levels commensurate with government spending in R&D. This trend happens in many maturing industries. However, this does not obviate the need for continued government funding as it is very clear that the majority of medical markets that could benefit from OCT have not yet been commercialized and remain too risky for significant industrial and venture capital investment. Industry is clearly hesitant to make the large investments needed to develop nonestablished OCT applications, even with the relatively mature technology that may exist today. In order to succeed, a medical diagnostic or interventional device or procedure requires evidence-based data showing improved care and lower costs. This requires multiple clinical studies and trials which is another place where government investment is critical. The return on investment of taxpayers support remains as attractive as it ever was in terms of improved healthcare and quality of life, economic impact, and improved understanding of diseases which will improve diagnosis and treatment even more in the future.

It is exciting to wonder what will be the next big commercial successes for OCT. If its successful expansion continues, OCT will have impacted the world not only in economic and job creation terms and in helping diagnose and treat blinding ophthalmic disease on a routine global basis but also by improving understanding, diagnosis, and treatment of deadly cardiovascular disease and cancer, the #1 and #2 leading causes of death in the industrialized world.

Appendix: Examples of Existing OCT Commercial Products

Below are some representative examples of existing OCT commercial products. There are more OCT system products on the market than those listed here, and several of the companies listed have multiple products.

Cirrus-HD OCT 5000 from Zeiss

Optovue Inc. RTVue and Handheld iVue OCT systems for ophthalmology

Topcon 3DOCT-2000 for ophthalmology

Nidek RS-3000 Advance for Ophthalmology

Heidelberg Engineering Spectralis OCT for ophthalmology

Canon OCT-HS100

Tomey Casia SS-1000 System for ophthalmology

Bioptigen Envisu C2300 SDOCT

Optos SLO/OCT System for Ophthalmology

St. Jude ILUMIEN™ OPTIS™ PCI Optimization System

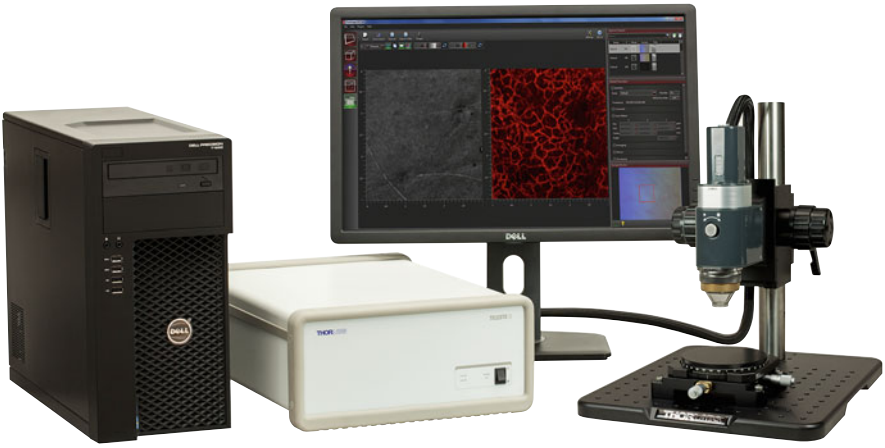
Avinger Inc. Lightbox for guiding chronic total occlusions crossings and atherectomy

Terumo Lunawave Intravascular Imaging Console

Imalux Inc. Product for ENT, gynecology, and urology

Michelson Diagnostics VivoSight Hand-Held Dermatological Scanner

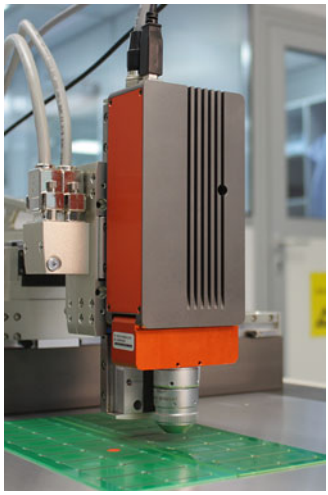
Santec IVS-300 Compact OCT System for research, industrial, biology, and medical applications



Thorlabs Telesto series Spectral Domain OCT System

Agfa HealthCare SKINTELL System for dermatology

LLTech high-resolution 1μm in 3D FF-OCT scanner



Heliotis AG: Ultra-Fast OCT sensor for automated inspection machines

NinePoint Medical Inc. NvisionVLE(tm) Imaging System for endoscopic applications; initial focus on gastroenterology

Abbot Medical Optics OCT Enabled Catalys System for Laser Cataract Surgery. Image courtesy of Abbott Medical Optics, Inc

Tomophase OCTIS Gen2 Console

VICTUS® Femtosecond Laser Platform with 2S-OCT technology

Schwind AMARIS 750S Excimer Laser for laser eye surgery with optional available integrated online pachymetry
