Suppose there are two images: the fixed image $f_1(x,y)$ and the moving image $f_2(x,y)$ respectively, and the only difference between moving image and fixed image is a translation in spatial domain, which means:

$$f_2(x,y)=f_1(x-x_0,y-y_0) \tag{5}$$

Then the corresponding Fourier transforms of the two images are:

$$\begin{aligned} F_1(\xi,\eta) &= F[f_1(x,y)] \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f_1(x,y)e^{-j2\pi(\xi x+\eta y)}dxdy \end{aligned} \tag{6}$$

$$\begin{aligned} F_2(\xi,\eta) &= F[f_2(x,y)] \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f_2(x,y)e^{-j2\pi(\xi x+\eta y)}dxdy \end{aligned} \tag{7}$$

According to Fourier shift theorem, the Fourier transforms F_1 and F_2 are related by

$$F_2(\xi,\eta)=e^{-j2\pi(\xi x_0+\eta y_0)}F_1(\xi,\eta) \tag{8}$$

Then the normalized cross power spectrum is given by

$$\frac{F_1(\xi,\eta)F_2^*(\xi,\eta)}{|F_1(\xi,\eta)F_2^*(\xi,\eta)|}=e^{-j2\pi(\xi x_0+\eta y_0)} \tag{9}$$

where * indicates the complex conjugate.

By taking inverse Fourier transform, the normalized cross power spectrum in spatial domain is expressed as

$$F^{-1}(e^{-j2\pi(\xi x_0+\eta y_0)})=\delta(x-x_0,y-y_0) \tag{10}$$

Hence, the spatial response of cross power spectrum is a Dirac delta function centered at (x_0,y_0), from which the spatial translation is obtained. As to rotation and scale change, the translation can also be identified if we represent the image in log polar coordinate. Figure 2 shows the stitching results of steel box-girder images.

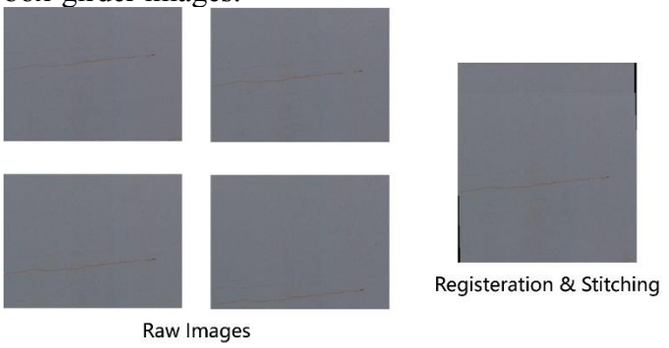

Figure 2 Image stitching result using phase correlation method.

4 DISEASES IDENTIFICATION

Considering the characteristic of the distribution and shapes of surface diseases of steel box-girder, a semantic segmentation deep neural network (DNN) is studied, which can achieve the "end-to-end" disease identification. Based on that, disease identification works are carried out automatically by just feeding a scanning image into the network and then the network will be output a segmentation mask as the result, which presents the diseases position and its class index for each single pixel.

4.1 *Network Architecture*

There are two types segmentation methods, one is called "decoder variants" and another one is "integrating context knowledge". Considering the computing efficiency and facilitating in network training DeepLab architecture (Chen LC et al. 2017), belongs to integrating context knowledge type, is selected.

Figure 3 shows the overall architecture of our segmentation DNN. this network can be divided into four blocks: to down-sample the input image, the first and second blocks are composed of two convolution layers with a max pooling layer behind; the third block is similar to the first and second blocks but the ordinary convolution layers are replaced by atrous convolution layers and pooling layers are discarded; In block 4, an atrous spatial pyramid pooling (ASPP) is used to achieve feature fusion; finally a transpose convolution is added as the last layer to up-sample the resolution reduced feature map and obtain a segmentation mask with the same size as the input image. More details are introduced in followings.

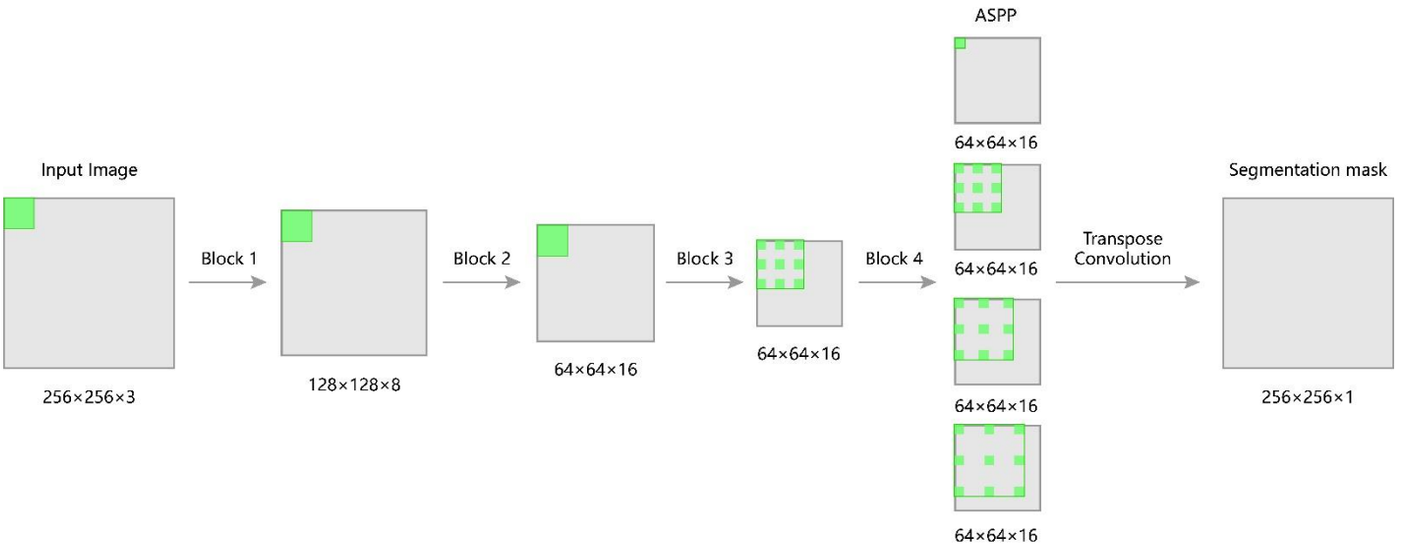

Figure 3 The architecture of segmentation deep neural network.

4.1.1 *Atrous Convolution*

The core of DeepLab network architecture lies in the utilization of atrous convolution (or dilated convolution) instead of ordinary convolution in feature extraction. In comparison with ordinary convolution, a parameter called "dilate rate" is proposed in atrous convolution to perform down-sampling with intervals, as is expressed:

$$I'(x,y)=\sum_{m}\sum_{n} I(x+r\cdot m, y+r\cdot n)K(m,n) \tag{11}$$

where $I'(x,y)$ = output value in (x,y); $I(x+r\cdot m, y+r\cdot n)$ = input value in $(x+r\cdot m, y+r\cdot n)$; $K(m,n)$ = kernel value in (m,n); r = dilate rate.

It can be proved that the atrous convolution result in high resolution feature map contains ordinary convolution result in low resolution, besides the feature map becomes much denser in atrous convolution compared with ordinary convolution. Thus, atrous convolution is applied in our network to keep the resolution of feature map and preserve spatial information to a certain extent.

4.1.2 *ASPP*

There are two variants in DeepLab architecture: DeepLab LargeFOV which lays out convolution layers in cascade and DeepLab ASPP which combines features in multi-scale. The essence of ASPP lies in parallel atrous convolutions with different atrous rates, which is equivalent to construct multi-scale space in feature map. The authors of DeepLab indicate that DeepLab ASPP demonstrates better performance in segmentation task, so DeepLab ASPP architecture is referred in designing our network.

The ASPP block is composed of four layers: the first layer is a linear combination of the input feature map, while in the other three layers atrous convolution is applied parallel with dilate rate of 4, 8 and 16. Each of the layer consists of 16 channels and they are concatenated to achieved a final feature map with 64 channels.

4.1.3 *Network Details*

The size of convolution kernels is fixed as 3×3 in all the convolution layers, and the pooling window size is fixed as 2×2 with non-overlapping to down sample the feature map. As to atrous convolution layer, the dilate rate is set as 2 in block 3 and 4,8,16 in ASPP to construct multi-scale space. The activation functions are fixed as ReLU function in all the convolution layers except the final transpose convolution layer, and sigmoid function is used in the final layer to predict whether a pixel corresponds to disease.

Batch normalization is set before convolution layers, which could modify the original distribution of the input data to accelerate network convergence. The process of batch normalization is shown as follows: firstly, the original distribution is modified with zero mean and unit variance,

$$\hat{x}^{(k)}=\frac{x^{(k)}-\mu_B}{\sqrt{\sigma_B^2+\varepsilon}} \tag{12}$$

where $x^{(k)}$ = the kth sample of the batch; μ_B = the expectation of the batch; σ_B^2 = the variance of the batch; ε = a minimum preventing zero denominator; $\hat{x}^{(k)}$ = the kth modifier sample.

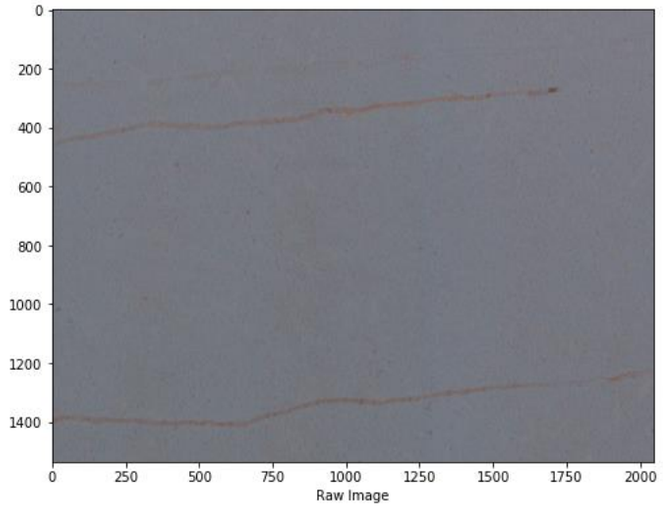
Then, there are two trainable parameters to construct a linear transform of the modified distribution:

$$y^{(k)}=\gamma\hat{x}^{(k)}+\beta \tag{13}$$

where γ, β = trainable parameters; $y^{(k)}$ the kth normalized sample after batch normalization.

Therefore, the original distribution of the input batch is normalized with β mean and γ^2 variance, and these two parameters can be updated in the training process just like other parameters.

In terms of loss function, binary cross-entropy is major component. The loss of each pixel in the output segmentation mask is defined as:



$$J(\theta)=\sum_{i=1}^{m}-y^{(i)}\ln p-(1-y^{(i)})\ln(1-p) \tag{14}$$

where $J(\theta)$ = the loss function; θ = parameters in the segmentation network; $y^{(i)}$ = label of the i th pixel, where 1 indicates disease and 0 indicates non-disease; p = the probability whether the i th pixel corresponds to disease, which is also the output of this pixel in segmentation network.

A regularization term is added to the loss function to prevent overfitting. L2 norm of convolution kernels, biases, etc. are added as regularization and the final loss function is:

$$\begin{aligned}\tilde{J}(\theta) &= J(\theta) + \lambda \|\theta\|_2^2 \\ &= \sum_{i=1}^{m} -y^{(i)} \ln p - (1-y^{(i)}) \ln(1-p) + \frac{\lambda}{2}\theta^T\theta\end{aligned} \tag{15}$$

where $\tilde{J}(\theta)$ = the final loss function; λ = regularization term factor representing the significance of regularization term, and is set to 0.01 by default; $\|\theta\|_2$ = the L2 norm of parameters including convolution kernels, biases, etc.

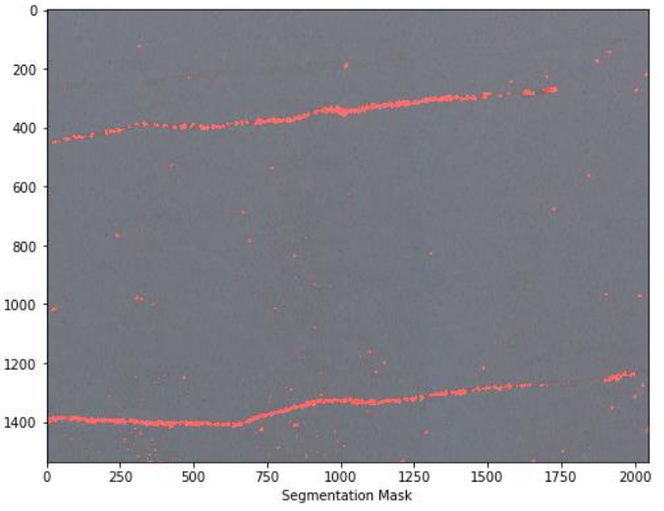


Figure 4 Raw image and segmentation mask.

4.2.2 *Training*

The segmentation network is implemented with TensorFlow framework. Adam algorithm (Kingma DP & Ba J 2014) is applied in training segmentation network to minimize the loss function. The initial learning rate is set as 1×10^{-3}, and the learning rate will be reduced by half when the accuracy in validation set does not drop any more. Only one image with its segmentation mask is trained in one training epoch. All the tasks are performed on a workstation with 16 GB RAM, Intel Xeon E3-1505M v5 @2.80GHz CPU and Nvidia Quadro M2000M GPU. The training process includes 50 epochs, which spends about 10 minutes. The loss curves and learning rate curves in training process are shown in Figure 5 and Figure 6.

4.2 *Network training*

4.2.1 *Dataset*

A training dataset involving Jiangyin bridge disease images is employed in this paper. The dataset contains 100 2048 px × 1536 px images captured at the bottom of girder. The region of corrosion is labeled manually on each single image. The raw image and segmentation mask are shown in Figure 4.

In training processing, to prevent out of memory problem (OOM) in training process, each of the raw images are split to 48 patches with the size of 256 px × 256 px. Thus, the original dataset is extrapolated to 4,800 images for training. This dataset is used for training, validation and testing with the ratio of 8.1:0.9: 1, respectively. which means 3888 images and 432 images are used in training and validation, and finally the other 480 images are used in testing.

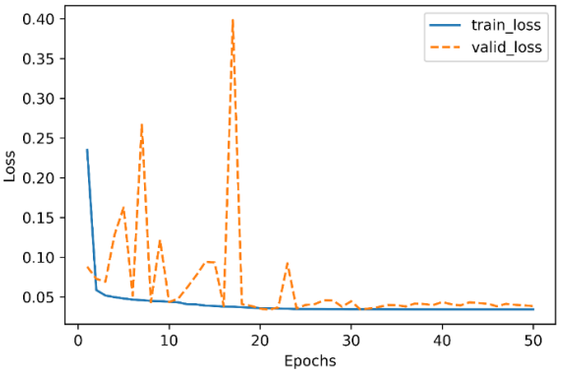

Figure 5 Loss curve.

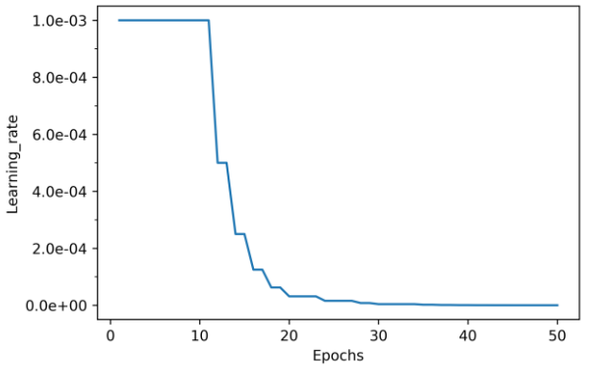

Figure 6 Learning rate curve.

4.2.3 *Validation*

To evaluate the model, precision, recall and accuracy are commonly used. They are defined as :

$$P = \frac{p_{11}}{p_{11} + p_{01}} = \frac{TP}{TP + FP} \tag{16}$$

$$R = \frac{p_{11}}{p_{11} + p_{10}} = \frac{TP}{TP + FN} \tag{17}$$

$$A = \frac{\sum_{i=0}^{1} p_{ii}}{\sum_{i=0}^{1}\sum_{j=0}^{1} p_{ij}} = \frac{TP + TN}{TP + FP + FN + TN} \tag{18}$$

where P = precision; R = recall; A = accuracy; p_{ij} = the number of pixels that belongs to class i but inferred to class j. In other words, p_{11} refers to TP, which is the number of pixels belonging to disease and inferred to disease; p_{10} refers to FN which is the number of pixels belonging to disease but inferred to background; p_{01} refers to FP which is the number of pixels belonging to background but inferred to disease; p_{00} refers to TN which is the number of pixels belonging to background and inferred to background.

With these evaluation indictors, the final binary accuracy, which is the accuracy for binary classification problems, achieves 98.93% on training set and 98.98% on validation set, and their relevant curves are shown in Figure 7.

To obtain the advised threshold value, which also is very important in final application of DNN, precision and recall (PR) curve are illustrated based on testing set, see Figure 8. It shows that it achieves average precision of 82.91% and the classification threshold can be set to 0.5 according to 5% error principle, which means a pixel will be classified as disease if it gets score higher than 0.5 in the final layer, otherwise it will be classified as background.

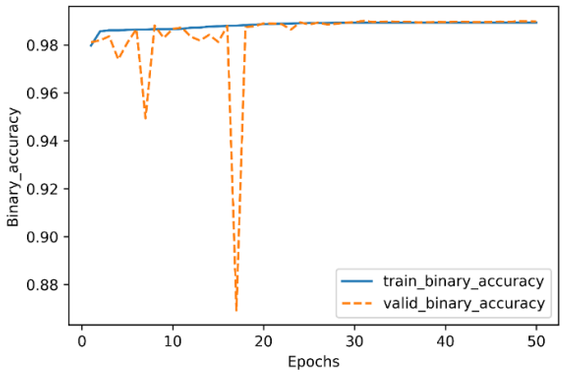

Figure 7 Binary accuracy curve.

We also test our segmentation network on the raw images with resolution of 2048 px × 1536 px, and the testing result shows that the segmentation network could recognize the major part of diseases, as is shown in Figure 9 where TP regions are painted green, FP regions are painted blue and FN regions are painted red.

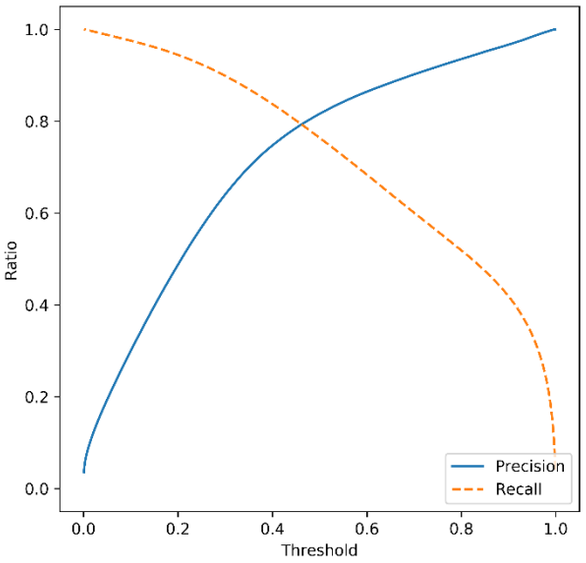

Figure 8 PR curve with threshold.

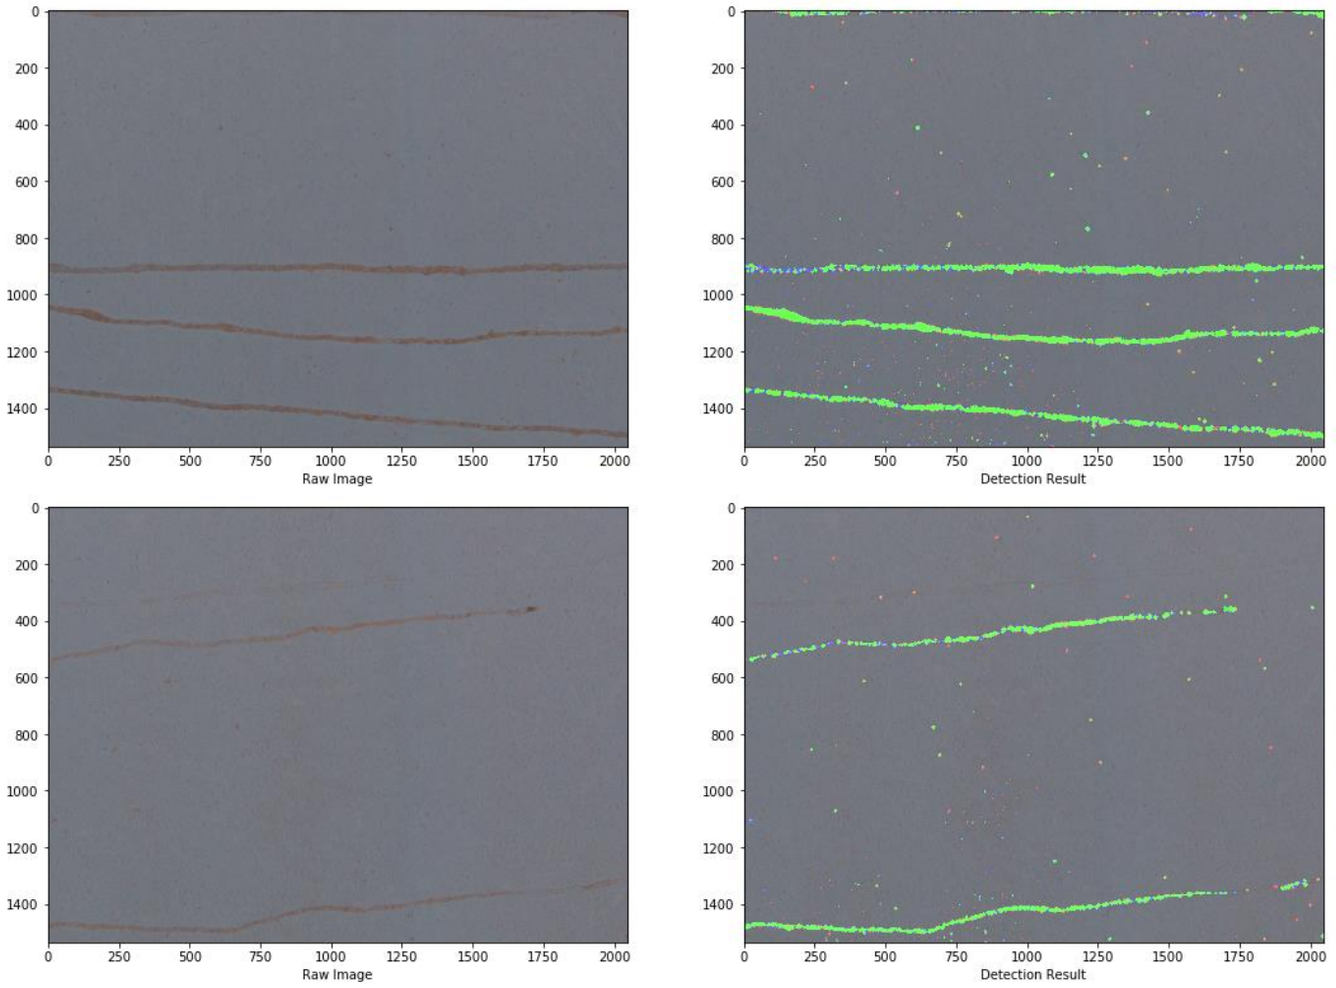

Figure 9 Testing on raw images.

5 EXPERIMENT

5.1 *General information*

The visual inspection system is tested on Jiangyin Bridge to detect surface diseases at the bottom of steel box girder. Jiangyin Bridge is a suspension bridge with a main span of 1,385 meters and 33.8 meters wide deck over the Yangtze River in Jiangsu, China. The hardware system consists of cameras, lens and sliding rails to capture actual images, and the software system consists of image registration program and segmentation network to obtain panoramic image and detect diseases, as pre-mentioned.

Cameras and lens are fixed on the inspection gantry at deck soffit and the layout is shown in Figure 10. The actual view field is measured as 97 cm×69 cm and the scale of view field and image is then calculated as 1: 136.62, which can be converted as one pixel on the image corresponds to 0.47 mm on the bridge. Considering the speed of inspection gantry, the sampling frequency is set as 0.5 fps, meaning that an image is captured per two second.

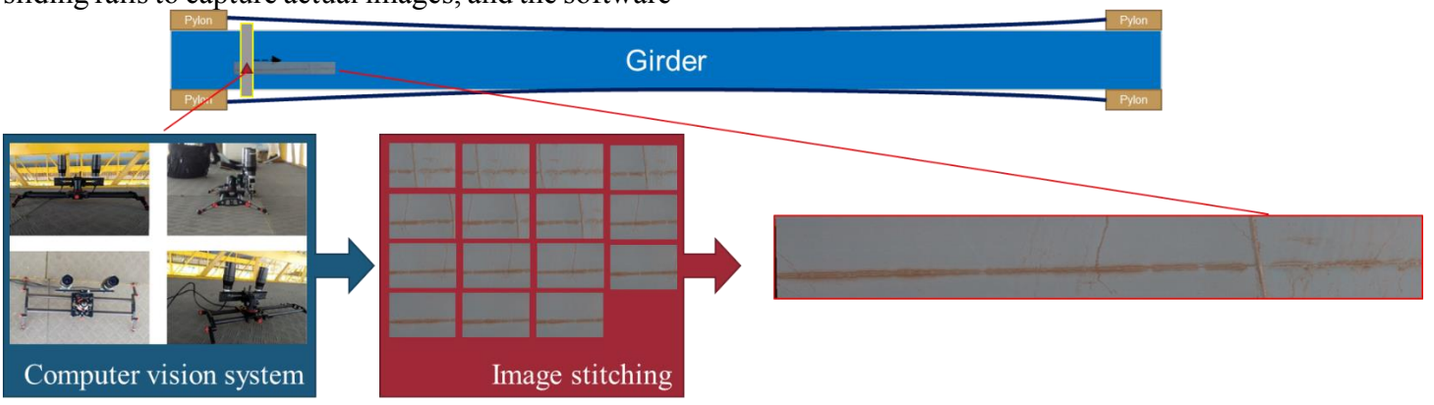

Figure 10 GIS based corrosion inspection management.

5.2 *Segmentation Result*

The segmentation network is applied after image capture. For example, a panorama with resolution of 1816 px ×19832 px is obtained through image stitching and manually cropping, then the panorama is split to 10 patches and fed to segmentation network in case of OOM. The panorama together as well as its segmentation result are shown in Figure 11. The disease area can be easily calculated after the segmentation mask is obtained. In this example, the area of steel disease is 2,607,192 pixels, which corresponds to 0.576 m^2 in total, occupy a 7.24% of the overall inspection region.

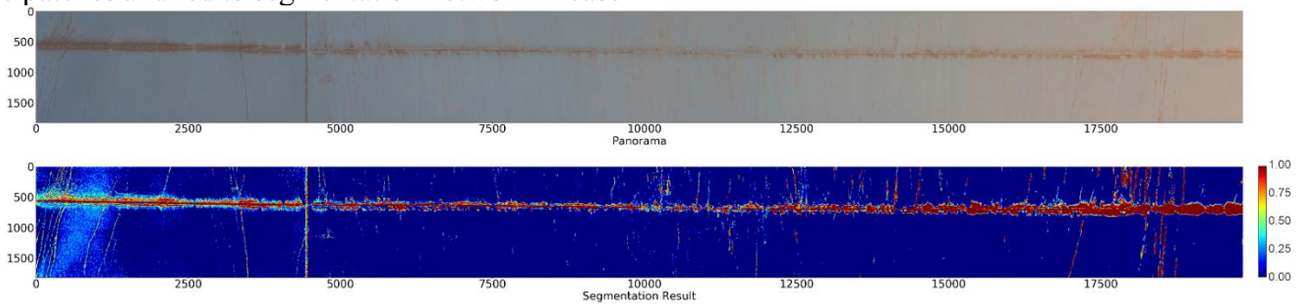

Figure 11 Panorama and segmentation result.

6 CONCLUSION

A novel disease inspection system based on computer vision technology is proposed in this study, and is tested on Jiangyin Bridge to detect surface diseases at the bottom of steel box girder standardized. The inspection system consists of two parts: the hardware system including cameras, lens and sliding rails to capture girder bottom images and software system including image stitching and segmentation network to obtain panorama image and identify diseases, separately. The experiment results indicate that disease identification together with panorama of disease distribution can be realized automatically.

It is believed that the inspection system could provide useful and standardized data for the daily management and maintenance of bridges. In addition, this inspection system can be installed on other platforms to identify diseases in the inaccessible regions for traditional methods, which could improve the level of standardization and extend the application scope of disease inspection to a certain extent.

ABSTRACT: Fibre reinforced polymer (FRP) materials are currently more and more widely applied in structural engineering attributed to the high strength-to-weight ratio and good resistance to environmental attack. Carbon FRP (CFRP) has been demonstrated great potential in fatigue strengthening of defected steel components, because it could help to share the far-field load, to constrain the crack opening, and to reduce the crack propagation rate. The strengthening efficiency relies on the load transfer between steel and CFRP and consequently the interfacial behaviour of CFRP-to-steel joints. Generally, a structural adhesive is adopted to attach CFRP to a steel substrate and it takes one to two weeks to achieve the full strength. However, the potential risk of environmental attack at the curing stage of the adhesive has not been well understood. In this paper, a series of experimental studies on the interfacial behaviour of CFRP-steel double-lap joints were carried out. The specimens were cured in different environmental conditions for two weeks and then statically loaded to failure. The performance of specimens subjected to room condition, salt fog and high relative humidity (RH) was compared. Effects of CFRP material type and surface treatment were also considered. The bond strength was decreased by 2-17% in comparison with the control specimens. Proper silane treatment could help to maintain the integrity of the specimen. This study extends the understanding of the environmental durability of CFRP-to-steel joints and provides some useful suggestions for the strengthening technique.

1 INTRODUCTION

Fatigue damage is a major concern of steel structures and fatigue cracks may emanate from stress concentration zone. Lifecycle management of these infrastructure has been one of the most important issues in the civil engineering community.

Traditionally, these damage is either stopped by hole drilling at the crack tip or replaced by new plate through welding or fastening. These techniques are time-consuming and complex to fix, and the most important, the rehabilitation is still prone to fatigue damage (Zhao & Zhang 2007).

Currently, externally bonding with fibre reinforced polymer (FRP) composite materials have attracted much attention as an alternative in retrofitting of aged infrastructure (Teng et al. 2012, Zhao 2013). For fatigue repair of defected steel structures, extensive studies have been carried out to investigate the fatigue behaviour of initially damaged steel plate strengthened by CFRP overlays (Jones & Civjan 2003, Liu et al. 2009, Yu et al. 2013, 2014, Colombi et al. 2015, Hu et al. 2016). The crack propagation life was significantly prolonged which demonstrated a great potential of CFRP bonding.

Research was also performed on the effectiveness of this strengthening approach applied to steel beams and welded joints (Kim & Harries 2011, Wu et al. 2012, Colombi and Fava 2015, Yu et al. 2015, Yu & Wu 2017).

Most infrastructure endures both service load and environmental attack during their life cycle, and therefore, durability of the CFRP-steel system has become a new concern in recent years (Dawood & Rizkalla 2010, Nguyen et al. 2012, Bai et al. 2014, Borrie et al. 2015). Since the retrofitting scheme relies on load transfer between FRP and substrate, different harsh environmental conditions were selected to investigate their effects on the interfacial bond behaviour and double-lap shear joints were commonly adopted.

Dawood & Rizkalla (2010) tested 44 steel-CFRP double-lap shear joints, among with 30 specimens were exposed to wet/dry cycles in a 5% NaCl solution at a temperature of 38 °C, up to 6 months. Different methods to enhance the bond durability were compared including silane coupling agent, glass fibre layer and a combination of both methods. The results showed that the silane treatment was preferred to improve the bond durability whereas glass

fiber layer was helpful to increase the initial bond strength.

In Nguyen et al. (2012), more complicated environmental conditions were taken into consideration, including, simulated sea-water at 20 °C and 50 °C up to one year, constant and cyclic temperatures with a high level of relative humidity (RH) up to 1000 h. It was demonstrated that simulated sea-water after one year of exposure was more detrimental to both the strength and stiffness of the joints compared to combinations of temperature and humidity for 1000 h of exposure. A prediction model on the degradation was also proposed.

Borrie et al. (2015) presented a study on the combined effect of marine environment and fatigue loading. The CFRP laminate and sheeting patched double-lap shear joints were exposed to a 5% by weight NaCl solution at 20, 40 and 50 °C as well as a certain static tensile load. Afterwards, these specimens were applied by fatigue load for up to 6 million cycles. The residual static strength of the joints witnessed a maximum 28% loss in strength.

To the best knowledge of the authors, there have been limited attempts to perform an experimental study exposed to salt fog to simulate the marine atmosphere which is frequently occurred to steel cross-sea bridges. According to manufactures' datasheet, the structural adhesive Araldite 420 A/B gels in three to four hours at 25 °C and is sufficiently cured to allow handling after 5 hours. 90% of the full strength could be achieved by four to five days and the full strength development takes one to two weeks at room temperature. Currently, the aforementioned research generally first cured the specimens at room condition and then exposed them to aggressive conditions. The effect of environmental exposure during the curing stage of adhesive hasn't been well understood.

This paper presents a series of experimental studies on the performance of CFRP-steel double-lap shear joints. The effect of harsh environment condition on the curing stage was focused and specimens were subjected 5% by weight NaCl fog or 80% RH at 35 °C for two weeks. Normal/high modulus CFRP sheets and normal modulus CFRP laminate were selected. The effect of saline treatment was also carefully checked. Later, all the specimens were statically loaded to failure and the ultimate tensile strength witnessed a reduction of 2-17% in comparison with the normally cured joints.

2 EXPERIMENTAL PROGRAM

The test program was conducted in the Laboratory of Performance Evolution for Engineering Structures at Tongji University, China. A total of 22 specimens were designed and tested, as listed in Table 1.

2.1 *Configuration of test specimens*

Double-lap shear joint specimens shown in Figure 1 were used for the experimental program. Two steel plates with dimensions of 180 × 50 × 5 mm were connected by CFRP materials. A bond length of 100 mm was adopted to ensure the load transfer. The specimen configuration and dimensions were chosen to be similar to those reported in Borrie et al. (2015) for comparison purposes.

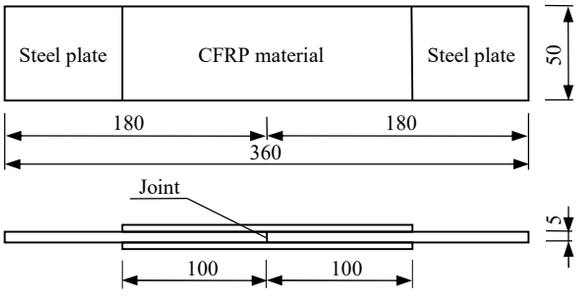

Figure 1. Specimen geometry (dimensions in millimeters, not to scale).

2.2 *Material properties*

The steel plates used in the tests were Q345b (according to Chinese Standard GB 50017-2003). The mechanical properties were determined based on coupon tensile tests. The average yield strength, ultimate tensile strength and Young's modulus were 274.3 MPa, 401.6 MPa and 201 GPa, respectively. The authors realized that the yield strength was much lower than expected. Fortunately, the specimens did not fail due to yield of steel and it was therefore believed that the yield strength had little effect on the experimental program. Different types of CFRP materials were selected for the patching system, i.e., normal modulus CFRP laminate, normal modulus CFRP sheet and high modulus CFRP sheet with a nominal thickness of 1.4 mm, 0.167 mm and 0.217 mm, respectively. Flat coupon tests were also performed to investigate their technical data. The normal modulus CFRP laminate exhibited a Young's modulus of 200.4 GPa, an ultimate tensile strength of 3022.4 MPa, and an ultimate strain of 15081 με, respectively (Yu & Wu 2017). The normal modulus CFRP sheet showed a Young's modulus of 254 GPa, an ultimate tensile strength of 4192 MPa, and an ultimate strain of 1.84% (Wu & Jiang 2013). The high modulus CFRP sheet had a Young's modulus of 532 GPa, an ultimate tensile strength of 2647 MPa, and an ultimate strain of 4976 με. The CFRP materials were bonded to the steel plate by structural adhesive Araldite 420. Its tested Young's modulus, ultimate tensile strength, and ultimate strain were 28.6 MPa, 1901 MPa, and 24000 με, respectively (Fawzia 2007).

2.3 *Specimen preparation*

The steel plate was sandblasted and cleaned by acetone to remove the weak oxidation layer and to expose a chemically active surface. Afterwards, they were lightly bonded together to create a flat and continuous substrate for CFRP application. Araldite 420 was mixed by a weight ratio of 5:2 and laid evenly on the steel substrate and CFRP. The specimens were bonded by one layer of normal modulus CFRP laminate, three layers of normal modulus CFRP sheet, or one layer of high modulus CFRP sheet. The thickness of the bond layer was controlled to be approximately 0.5 mm (Yu & Wu 2017).

Silane treatment has been proven a potential approach to improve the interfacial behaviour between CFRP and steel (Dawood & Rizkalla 2010, Borrie 2016). Four specimens were tried in this experimental program using the glycidoxypropylmethoxysilane supplied by Dow Corning. Two formulas were adopted, i.e., 4% silane by volume with 96% methanol by volume mix (N, representing nonhydrolysed), and 4% silane by volume, 90% methanol by volume and 6% deionised water by volume mix (H, representing hydrolysed). The silane solution was prepared by stirring for 1 hour followed by aging for 20 hours. After brushed by the solution, the steel plates were either aged in room temperature for 1 hour (A, representing ambient temperature) or dried by a hot air stream (80 °C) with dryer for 15 minutes (C, representing hot cured) as suggested by suppliers to achieve a better hydrolytic action. For the specimens with silane treatment, those procedures were taken before application of epoxy and CFRP.

2.4 *Environmental exposure and load condition*

With concern of the effect of curing condition on the bond behaviour of CFRP-steel double-lap shear joints, three different environmental exposure conditions were adopted in the experimental program, i.e., laboratory room condition, an environmental chamber with salt fog generated by 5% by weight NaCl, 35 °C (Figure 2a) and an environmental chamber with a RH of 80%, 35 °C (Figure 2b).

(a) (b)

Figure 2. Environmental chambers: (a) with salt fog, (b) with high humidity.

All the specimens were cured for two weeks since normally the structural adhesive takes two week to achieve the full strength in room condition. Afterwards, they were gripped on both ends and tensioned to failure at a rate of 2 mm/min.

3 EXPERIMENTAL RESULTS AND DISCUSSIONS

Table 1 presents a summary of the test results of all the specimens. The specimen nomenclature is as follows: L = CFRP laminate, 3S = three layers of normal modulus CFRP sheet, 1S = one layer of high modulus CFRP sheet, R = room condition, M = marine atmosphere, i.e., 5% NaCl salt fog and 35 °C, H = 80% RH and 35 °C. Two identical specimens were designed for one scenario to reduce the scatter of the experimental program and the number after the hyphen indicates the number of them. Four specimens with three layers of normal modulus CFRP sheet were intended to examine the performance of silane treatment when subjected to the salt fog, among which, N and H indicate the mixed solutions with and without deionised water, respectively; A and C represent the preparation procedures in room condition and hot air stream, respectively.

Table 1. Experimental program and results.

Specimen	Ultimate tensile strength (kN)
LR-1	95.1
LR-2	98.0
LM-1	90.6
LM-2	89.4
LH-1	94.4
LH-2	86.8
3SR-1	94.8
3SR-2	91.3
3SM-1	90.6
3SM-2	91.7
3SH-1	89.3
3SH-2	91.7
1SR-1	55.1
1SR-2	56.6
1SM-1	44.3
1SM-2	57.4
1SH-1	47.2
1SH-2	45.7
3SMNA	94.1
3SMNC	81.9
3SMHA	93.1
3SMHC	80.2

3.1 *Failure modes*

After two weeks' exposure, obvious corrosion was found in specimens exposed to salt fog while those exposed to high RH witnessed a much slighter corrosion. Figure 3 showed a typical group of cured specimens.

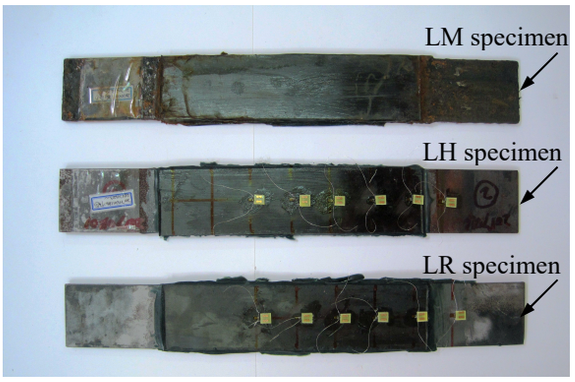

Figure 3. Specimens after environmental exposure.

Specimens with one layer of normal modulus CFRP laminate witnessed adhesion failure between steel and adhesive accompanied by CFRP delamination. Similar failure mode was observed for specimens with three layers of normal modulus CFRP sheet whereas CFRP rupture was found in those with one layer of high modulus CFRP sheet. It is mainly because of the difference of deformability between normal modulus and high modulus CFRP sheet, which is in conformance with the phenomenon reported in Liu et al. (2009). For the specimens with the same patch configuration exposed to different conditions, the failure modes were approximate to each other. With respect to the specimens with silane treatment before CFRP application, similarly, no apparent difference was observed in comparison with un-treated specimens and the specimens all failed with interfacial debonding and CFRP delamination, regardless the zone of delamination was slightly different. Typical failure modes are shown in Figure 4.

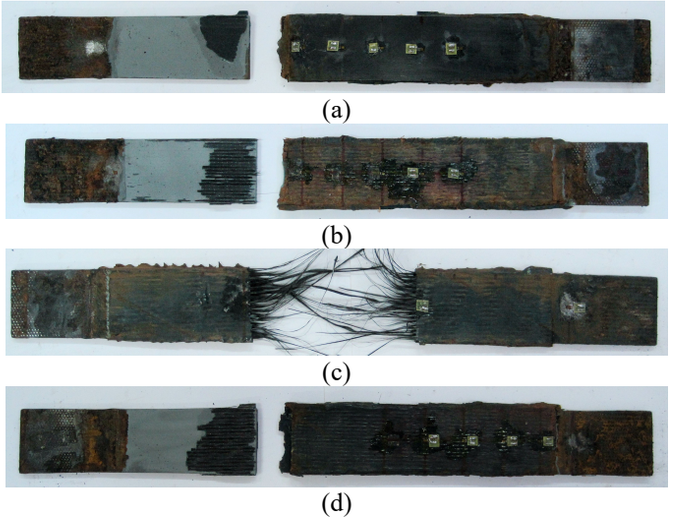

Figure 4. Failure modes: (a) LM-1; (b) 3SM-1; (c) 1SM-1; (d) 3SMNA.

3.2 *Bond strength*

The bond strength ratio defined as the ratio of the average bond strength of two identical specimens to that of the specimens cured at the room condition is displayed in Figure 5. It is shown that the bond strength decreased by 2%-17%. The specimens with three layers of normal modulus CFRP sheet appeared to be the most resilient among the specimens with different patch schemes. Comparing the effects of environmental conditions during the curing stage of structural adhesive, the degradation of specimens with CFRP laminate and normal modulus CFRP sheet was approximately the same when subject to salt fog and 80% RH. However, the specimens with high modulus CFRP sheet seems more vulnerable to high RH condition.

In Borrie et al. (2015), the specimens were first cured at room condition for two weeks and then immersed into sea-water up to six months and fatigue cycles up to 6 million, the bond strengths of the joints generally decreased by 10-15%, and the most severe reductions reached to 20 and 28% occurred to laminate and sheeting specimens respectively. It was therefore implied that the deterioration due to the environmental exposure during the curing stage of structural adhesive was comparable to the long-term attack.

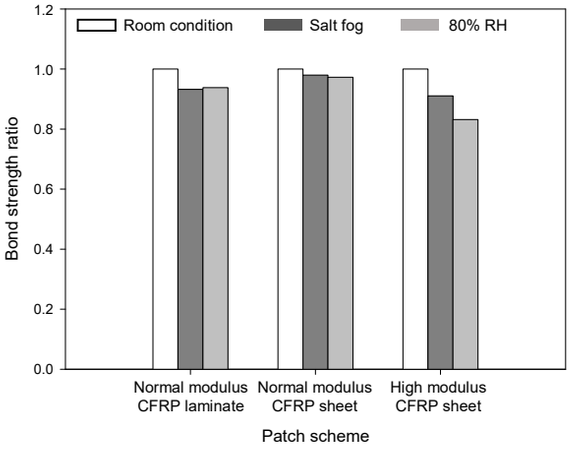

Figure 5. Bond strength ratio.

Figure 6 plots the test results of the specimens with silane treatment as well as the control specimens. It was interesting to find that the procedure of aging in room condition is sufficient to maintain the integrity of the specimen while those dried by the hot air stream which was expected to have a better performance led to an adverse effect. Future research was planned to study the effectiveness of surface treatment.

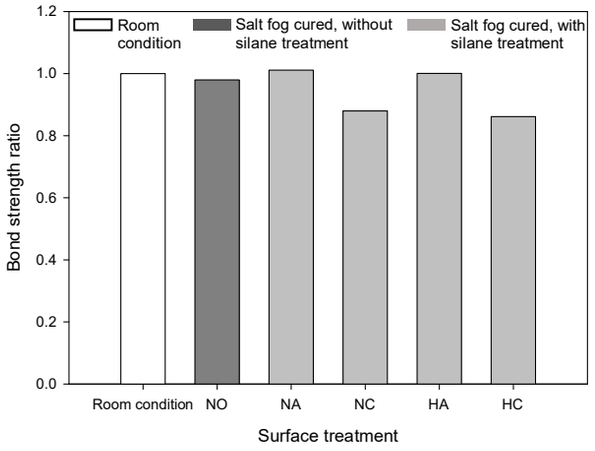

Figure 6. Effect of silane treatment.

4 CONCLUSIONS

This paper presents an experimental study of CFRP-steel double-lap shear joints subjected to environmental exposure at curing stage of structural adhesive. The following is concluded.

After cured in salt fog or high RH for two weeks, bond strengths decreased by 2-17%, which was comparable with the previous study on the effect of long-term exposure.

For specimens with one layer of normal modulus CFRP laminate and three layers of normal modulus sheets, the effects of salt fog and high RH salt did not have an apparent difference. Based on the current test results, the deterioration of the specimens with one layer of high modulus CFRP sheet was the most significant.

Specimens with CFRP laminate and three layers of normal modulus sheets failed with fibre delamination while specimens with one layer of high modulus sheet failed with fibre fracture. The failure mode did not change with the curing condition.

Silane treatment with proper application procedure could be used to improve the interfacial behaviour.

Drilling-Hole Shape for Retarding the Fatigue Crack Propagation

Z.Y. YuanZhou & B.H. Ji & Z.Q. Fu
College of Civil and Transportation Engineering, Hohai University, Nanjing, Jiangsu, P.R. China

ABSTRACT: The study focuses on the drilling hole shape for retarding the crack propagation, on the basis of finite-element method. A lumbar-round hole was proposed, and compared with normal-round hole. The stress concentration factor (SCF) was analyzed, as well as the drilling parameters. The results show that the stress concentration at crack tip can be further decreased when comparing with the normal-round hole. The performance of lumbar-round hole can be further improved by decreasing the radius of arc. When applying the spiral transition curve to design the lumbar-round hole, a better stress distribution can be obtained, resulting in better crack retarding effects.

1 INTRODUCTION

Stop-hole, which is also called drilling-hole, is usually be regarded as a temporary method for preventing crack propagation in mechanical or structural components, such as the orthotropic steel deck (OSD). It is widely applied throughout the steel bridges, due to its excellent structural performance, while it is susceptible to fatigue crack under cyclic traffic load (Ya et al. 2013; Choi & Kim 2009), causing serious damage if left the crack unconcerned. Thus, a proper method should have been conducted before the crack becoming unstable.

When the crack emanates, a high stress concentration area generated near the crack tip, where the stress value may exceed the material yield strength, forming a plastic zone. Some micro-cracks and -holes began to appear with the accumulation of plastic deformation, resulting in crack rapid propagation (Zhu et al 1995). The plastic zone can be removed if drilling holes with a certain size near the crack tip, and the stress concentration can be also reduced, resulting in a delay on crack propagation or stop crack propagation thoroughly. However, the issues that when to drill the hole, what is the drilling size, how is the shape need to be figure out before conducting the drilling-hole method on the operation.

There are numerous on-going research efforts to address these issues. Guo suggested that the proper diameter of drilling-hole should be 0.6 times of the fatigue crack length (Guo et al 2008) by comparing the relationship between crack length and drilling-hole diameter, based on the maximum stress, while other researchers proposed that the diameter of drilling-hole should be 0.4 times of the fatigue crack length (Xiong et al 2016), or about 5.57mm~7.14mm (He et al 2004). The relationship between the drilling-hole diameter and plate thickness were discussed (Ji et al 2016). Though the proper diameter of drilling-hole has not come to an agreement, the similar regulation that the drilling-hole with large diameter has better reduction on stress concentration near crack tip, is confirmed.

Since the stress concentration (Peterson et al 2010) mainly depends on the shape, or structural feature, it can be modified when changing the detail shape parameters. The curvature (Bates et al 1980) is defined as the state of being curved, or the degree to which something is curved. As for the drilling-hole, the reciprocal value of radius equals to the curvature, therefore smaller the curvature is, better stress concentration reduction can be obtained. Fanni M proposed a new crack stop-hole shape, and the analysis results approved that it is better than round hole (Fanni et al 2015). However, it is quite complicated to drill the hole like this type, or even impossible on service structure.

If reducing the curvature continuously to zero, the straight line appears near the hole edge, then the round hole gradually becoming the lumbar-round hole. Therefore, the lumbar-round hole was proposed by considering the curvature reduction. The investigation of lumbar-round hole was carried out in this paper, based on the stress concentration factor by finite-element method (FEM).

2 FINITE-ELEMENT MODEL

2.1 *Model size*

A linear elastic analysis was carried out with the software package ABAQUS, considering the material's young modulus 210 GPa, poisson ratio 0.3. The quarter shell model was established by taking advantages of symmetric model geometry and boundary conditions. The size of whole model was 100mm by 50mm, and the crack length was arranged in the center of the model with 12mm long. The drilling-hole was set at the crack tip, with the diameter 6mm.

Since the drilling-hole may weaken the bearing capacity of the remaining section, the hole shapes with lumbar-round and round are compared under the similar drilling area, as shown in Fig.1. The radius of lumbar-round hole is 2mm, and the horizontal length L is about 2mm.

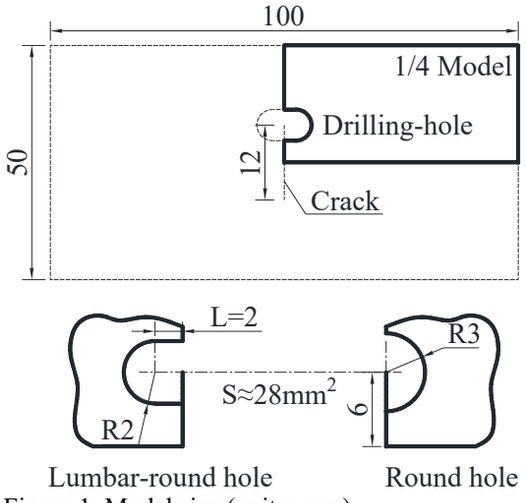

Figure 1. Model size (unite: mm)

2.2 *Modeling details*

Fig.2 shows the modeling details of lumbar-round hole. The tensile stress was applied at the edge the model, with the magnitude of 1MPa. The symmetry boundary was set at the axis both in X and Y direction. In order to deal with the stress concentration, the element type of CPS8 was used in the model, and the minimum mesh size is 0.5mm round the drilling-hole. The parameters of round hole model are the same.

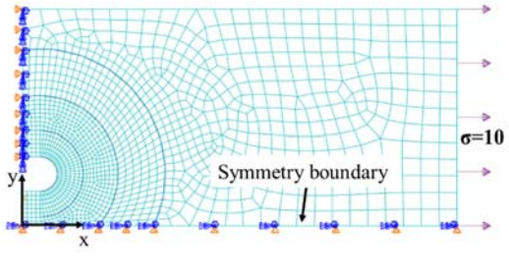

Figure 2. Modeling details of lumbar-round hole

3 RESULTS COMPARING

The stress distribution alone the hole edge was investigated, as shown in Fig.3. It is found that the maximum stress value of lumbar-round hole is a little smaller than that of round hole, and the maximum point is not locate on the crack predicted extension path, i.e. the stress concentration point moves a new location. However, at the predicted extension point (θ=0), the stress value of lumbar-round hole is much lower than that of round hole, due to the reduction on curvature. Therefore, when comparing with the round hole, the lumbar-round hole has better stress distribution.

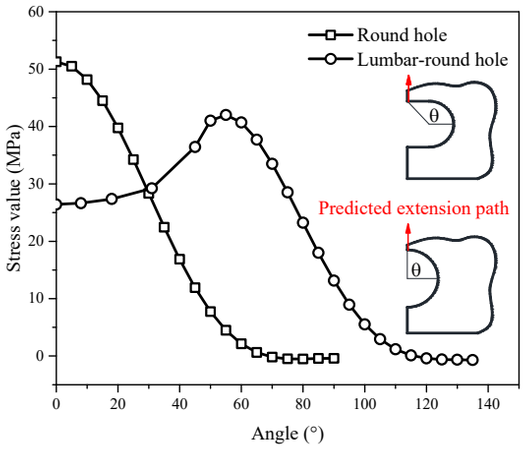

Figure 3. Stress distribution alone the hole edge

The range of effective section will decrease, when drilling a hole near the crack tip, weaken the bearing capacity to an extent. The stress distribution at the remaining bearing section is important for fatigue crack initiation and propagation. Fig.4 shows the stress solution at the remaining section. It turns out that the stress distribution becomes more uniform when using the lumbar-round hole, instead of round hole, while the affected range of stress concentration seems similar. Large stress gradient of round hole can be obtained from the figure, resulting in poor fatigue performance (Montebello et al 2016).

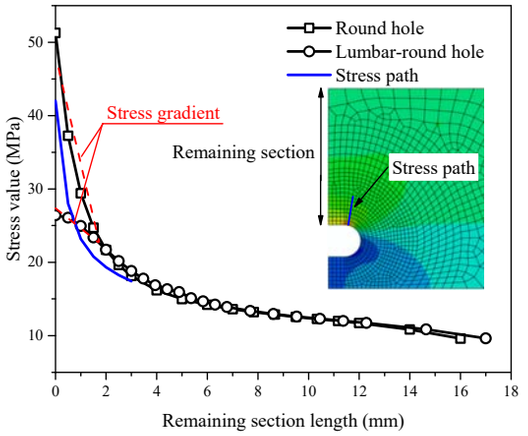

Figure 4. Stress distribution alone the remaining section

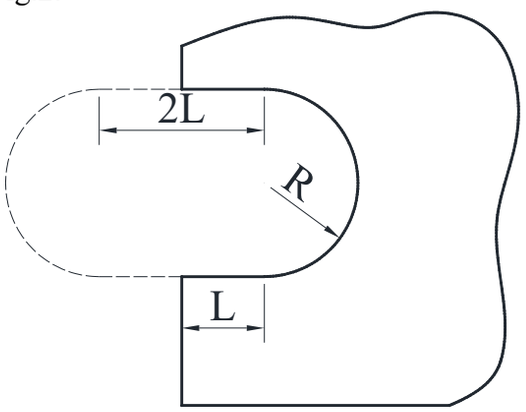
Since the stress concentration appears at the place where the curvature is mutated, the stress distribution along path (the straight line in Fig.4) is also compared. Results show that the stress distribution is similar with the round hole, but the

value is a little smaller. This critical position has potential risk on fatigue cracking.

4 PARAMETERS EFFECT ON LUMBAR-ROUND HOLE

4.1 *Definition parameters*

The parameters of lumbar-round hole consist of two aspects, the horizontal length 2L and the radius R, as shown in Fig.5. Thus, the lumbar-round hole with different parameters can be denoted, for example L2R2 stands for the model described in the Fig.2.



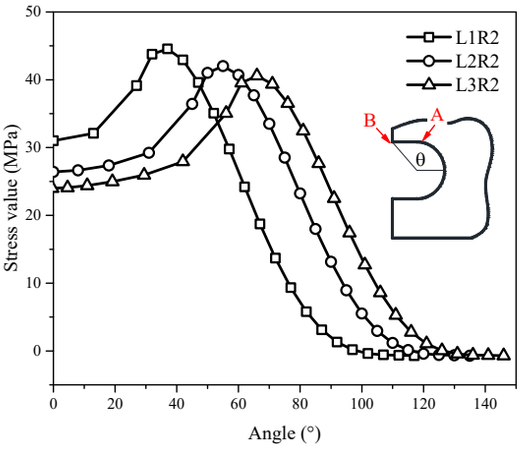


Figure 5. Definition of lumbar-round hole parameters

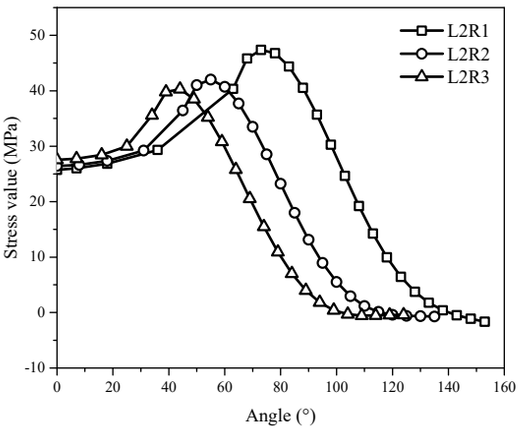
4.2 *Comparison with different parameters*



Regarding the previous model as the reference set, five different cases were calculated by FEM with same load condition, mesh size and element type. Solutions are plotted in the Fig.6. It is found that with the increasing of L, the maximum stress value at critical position (A) decreases, as well as the stress value at position B. However, the decreasing tendency slows down when keeps L increasing. Therefore, excessive increasing the lumbar-round hole length is not suggested, due to the low beneficial for stress reduction.

If changing the radius R, a different stress distribution can be obtained in Fig.6b. With the increasing of R, the maximum stress value at position A decreases, while the stress value at position B seems more stable. Since the curvature equals to the reciprocal value of radius, the curvature thus decreases when increasing the radius R, resulting in lower stress values at position A.

In order to acquire the main influence factors on parameters, the relative stress variation was calculated based on the standard model (L2R2), and the results were shown in Fig.7. It is seen that, the stress variation degree with radius R changes is a little larger than that with L changes, indicating that the radius R may be the main factor influencing the maximum stress around the lumbar-round hole edge. The regulation seems same with the round hole, despite the fact that there is only one parameter for the round hole.

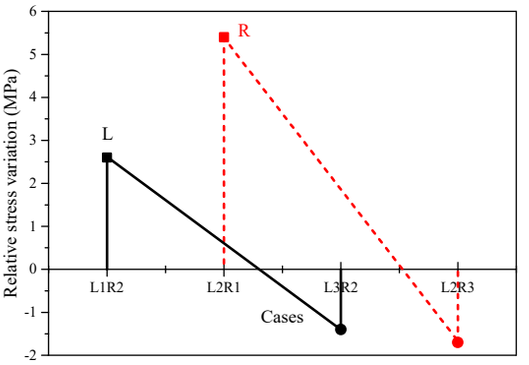

Figure 7. Stress variation degree comparing

5 LUMBAR-ROUND HOLE SHAPE OPTIMIZING

The curvature is mutated at the joint of straight line and curve, resulting in a new stress concentration along the lumbar-round hole. In order to reduce the degree of stress concentration, the spiral transition curve (STC), used in the design of the alignment of road (Yu et al 2011), was considered in the lumbar-round hole shape optimizing. The purpose of using STC is to stabilize the curvature variation, thus resulting in a gentle stress variation. The formulation of STC used for shape optimizing is based on the cubic parabola, shown as follows:

$$y = \frac{1}{6Rl_s}x^3 \qquad (1)$$

where l_s is the length of STC, R is the radius of lumbar-round hole.

The detailed lumbar-round hole shape after optimizing is shown in Fig.8. The STC was added between the straight line and circular curve, resulting a gentle curvature variation.

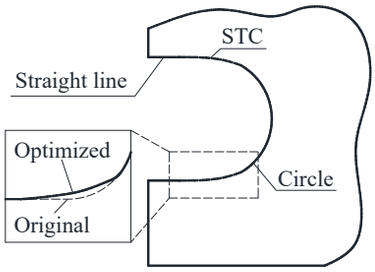

Figure 8. Optimized lumbar-round shape

Fig.9 shows the comparison results after the lumbar-round hole optimized. It is found that the stress peak clipped, when using STC to deal with the mutation of curvature. Meanwhile, the stress values at predicted crack propagation path are almost the same. Therefore, a better stress distribution can be obtained if further optimizing the STC. Although, it is quite difficult to drill the hole when the shape was optimized, it does reflect a fact that proper burnishing to drilled hole is beneficial for stress concentration reduction, resulting in better crack retarding effects.

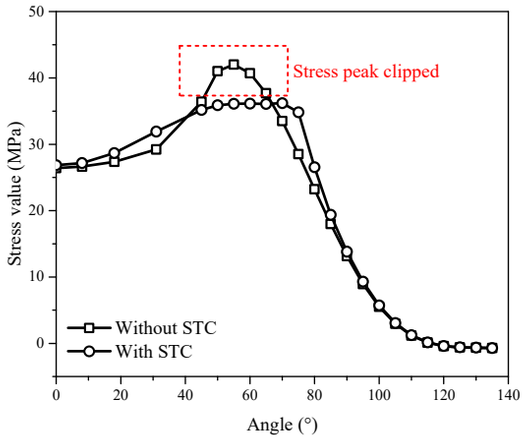

Figure 9. Stress peak reduced by STC

6 CONCLUSIONS

The drilling-hole shape was discussed in the paper, and a lumbar-round hole shape was proposed. The finite-element analysis was carried out to investigate the performance of this shape. The following conclusions may be drawn from this study.

1) The lumbar-round hole has better stress distribution than that of round hole.

2) Increasing the horizontal length and the radius of lumbar-round hole can both beneficial for stress reduction.

3) The lumbar-round hole shape can be further optimized when using the spiral transition curve to deal with the mutation of curvature.

Study on crack stop holes in weld of orthotropic steel bridge decks

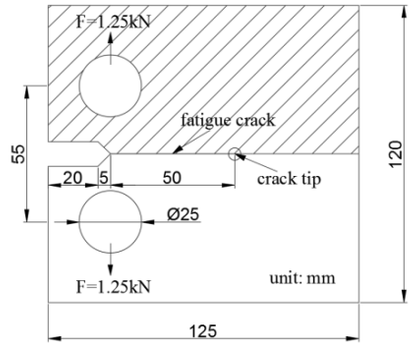
Z.Q. Fu; G.Y. Sun; Y. Yao; B.H. Ji
College of Civil and Transportation Engineering, Hohai University, Nanjing, Jiangsu, P.R. China

ABSTRACT: The technique of drilling stop holes in fillet weld of orthotropic steel bridge decks to arrest fatigue cracking was studied. The stress distribution characteristics at the crack tips were analyzed according to the compact tension model and the local bending model. The variation of stress concentration and gradient were compared to obtain the stress characteristics before and after drilling the holes. Fatigue tests of specimens were also conducted to verify the effects of stop holes. The results shows that drilling a stop hole at the tip of the cracks decreased the stress concentration without changing stress distribution trends while the mean stress of the cracking section increased. The largest stress around the hole appeared at the extending direction of the original crack, which was also the re-cracking position. Stop holes delayed the crack propagation but with no effects on the crack propagation rate of re-cracking.

1. INTRODUCTION

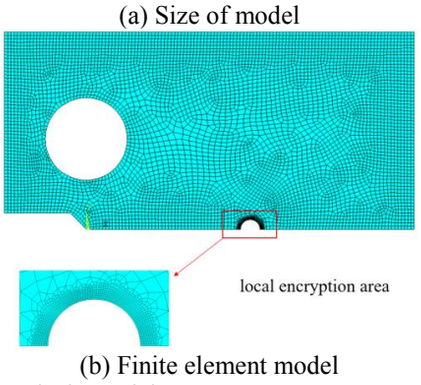
Orthotropic steel bridge decks have been widely used with the advantages in light weight, high ultimate bearing capacity, short construction period and so on(Lu and Li 2014). However, fatigue cracks always occur in the process of bridge operation under the wheel load because of the complex welded structural details and manufacturing defects(Deng *et al*. 2015; Maljaars *et al*. 2013). Some investigation results about bridge collapse shows that fatigue fracture is one of the main reasons(Connor and Fisher 2001). It is difficult to avoid the fatigue cracks of the steel bridge deck because of its structural details and load characteristics. Therefore, fatigue of the steel bridge is paid more attention in the maintenance work. Especially, the crack repair work affects the operation safety of steel bridges. Crack stop holes are a temporary maintenance measure(Choi and Kim 2008), which entail drilling a hole at the crack tip to eliminate the stress concentration, thus the extension of the crack is prevented or postponed and the service life of the structure is prolonged. The crack stop hole is simple to install, and cheap, so it is widely used in the maintenance of metal structures(Makabe, Kaito and Ferdous 2014; Wang *et al*. 2014).

A crack stop hole was verified as having enhanced the fatigue service life of a structure(Wu *et al*. 2010; Crain *et al*. 2010). The effect of hole diameter on the recycled service life of a fatigue crack was also analysed by Song and Shieh.(2004). The effect of hole diameter on crack arrest behaviour was analysed by He, Chen and Du(2004), who proposed a reasonable hole diameter. In addition, the crack arrest behaviour is also influenced by the mechanical behaviour of the structure(Ya, Yamada and Shikawa 2013), as found by (Ayatollahi. Razavi and Chamani 2014; Avatollashi *et al*. 2015), who focused on crack arrest behaviour under pure bending and pure shear. As an accurate location of crack tips was required in crack stop hole design, some scholars proposed that the effects of a single stop hole could be enhanced by improvement of hole shape as well as their arrangement. Fanni *et al*.(2015) simulated a reasonable stop hole shape in view of optimizing the structural stress. The compact tension models were mostly studied for the cracks in both numerical and experiment. However, few researchers studied about the crack stop hole considering the actual steel bridge structure details, especially about the cracking on the fillet welds of bridge decks. Meanwhile, the cycle load of tension and compression stress was adopted mainly.



Nevertheless, the fillet welds of bridge decks were under bending load. The applicability of the results also need more demonstration.

The standard sample recommended by ASTM(American Society for Testing Materials, 2007) and fillet weld in steel bridge deck were adopted in this research to analyse the stress characteristics of crack stop holes. The performance of the stop hole was assessed by stress changes after drilling, which was verified by an experiment involving fatigue cracks on vertical stiffening rib welds in steel bridge deck.



2. ANALYSIS OF THE CT MODEL

2.1 *CT model*

According to the standard samples recommended by ASTM, the compact tension model (CT model) in Fig. 1 was adopted for a finite element model. As the model is symmetrical, only half of the model was analysed. The length of the crack was 50 mm, on the tip of which a crack stop hole was set with a diameter of 6 mm. Coinciding with the centre of the hole, lay the crack tip. The modulus of elasticity E = 206 GPa and Poisson's ratio ν = 0.3; the load F = 1.25 kN; the thickness of the plane t = 5 mm. The singular element was set in the vicinity of the crack tip in the process of mesh generation while the plane quadrilateral element PLANE183 with eight nodes was used in other regions. The mesh size of the model was 5mm globally. Along the diameter of the stop hole, mesh size refined to be 0.25mm in 6mm length.

(a) Size of model

(b) Finite element model

Figure 1. Analysis model

2.2 *Stress around the hole*

The crack usually grows perpendicular to the principal stress and is generated from the position where the local stress concentration is maximized. To obtain the points of local stress concentration, the distribution of stress at the edge of the hole was studied. The major principal stress σ_1 around the edge of the hole was calculated (Fig. 2), so was the slope K of the curve, where 0° was the positive direction of the X-axis.

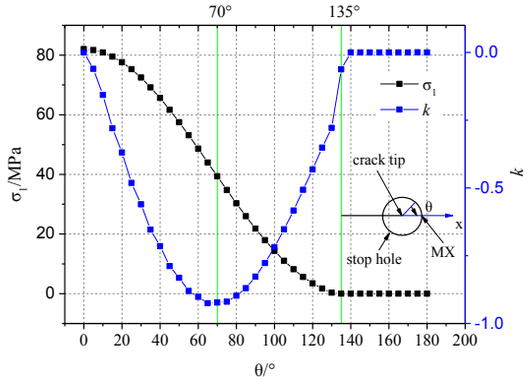


Figure 2. Major principal stress distribution at the edge of a crack stop hole

The distribution of major principal stress in Fig. 2 shows that the major principal stress is symmetrical along the hole wall. It decreases as the angle of the tip ranges from 0° to 135° and remains zero from 135° to 180°. The slope of the curve reaches the minimum at an angle of 70°, which is the inflection point of the curve and the rate of decrease of stress also decelerates. The maximum stress, namely MX, occurs at 0°. New fatigue cracks will generate at 0° under cyclic loading.

The growth path of the crack is obtained according to the stress condition in the vicinity of MX. Stress of Points along the X-axis near MX was shown in Fig. 3: the sample is under tension, the value of stress σ_y in the Y-direction is much the same as that of the major principal stress σ_1 and the value of shear stress τ_{xy} is about zero, while the value of σ_x in the X-direction is between that of σ_y and τ_{xy}. Therefore, the direction of the major principal stress around MX lies along the Y-axis and crack grows along the positive X-axis.

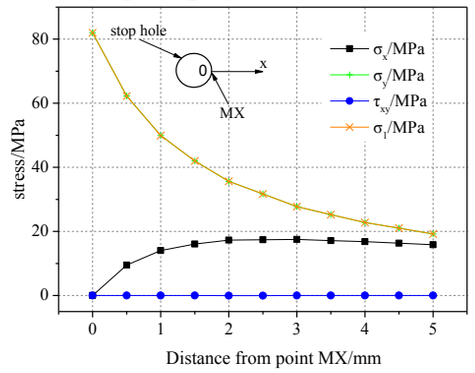

Figure 3. Stress state in the vicinity of a stress concentration

2.3 *Stress gradient*

The influence of stress concentration on the fatigue strength is decided by the fatigue gap coefficient K_f which represents the decline time of fatigue strength, instead of the stress concentration coefficient K_t, showing the increase of peak stress of the gap. Compared with the stress concentration coefficient, the fatigue gap coefficient takes both geometric condition of any gaps and types of material into consideration.

The crack stopping performance of the hole was assessed by K_t and K_f of model. K_t and K_f can be obtained, respectively, by Eqs. (1) and Eqs. (2).

$$K_t = \frac{\sigma_{\max}}{\sigma_{nom}} \tag{1}$$

Where, σ_{max} is the practical maximum stress obtained by calculation; σ_{nom} is the nominal stress obtained by Eqs. (3).

$$K_f = 1 + \frac{K_t - 1}{1 + \left(\frac{c}{\rho}\right)} \tag{2}$$

$$\sigma_{nom} = \frac{2F(2W + L)}{t(W - L)^2} \tag{3}$$

Where, c is a constant related to the material: for steel of type Q345qD, c = 0.45, ρ is the radius of curvature and diameter of the hole, F is the applied load, W is the width of the model, t is the thickness of the model, and L is the length of the crack.

A crack stop hole was set in the path of the crack growth and stress σ_y at the crack tip before, and after, drilling, in the Y-direction, was substituted into (1) as σ_{max}, and the calculated results are shown in Table 1. The stress at MX is only 50 MPa without cracks under the same conditions, while local stress increases to 179.0 MPa, showing remarkable stress concentration at the crack tip. The stress amplitude at MX decreases to 82.0 MPa after drilling: the stress at the crack tip falls by 54.2%, relieving this stress concentration.

Table 1 Comparison of mechanical behavior before and after drilling

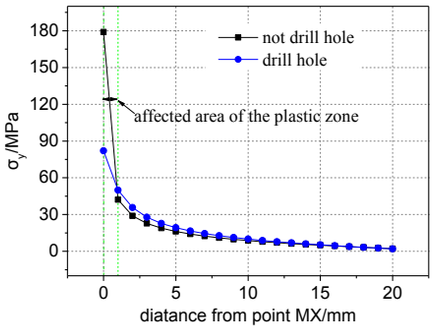
Item	Stress on crack tip/MPa	Stress concentration coefficient K_t	Gap fatigue coefficient K_f
Non-crack	50	/	/
Before drilling	179.0	3.58	3.24
After drilling	82.0	1.64	1.56

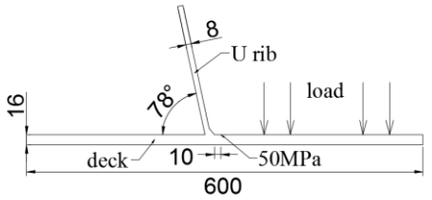
The stress gradient of σ_y before, and after, drilling, in the Y-direction and with crack growth, is shown in Fig. 4: the stress was larger in the vicinity of the crack tip than that at a distance from crack tip and the stress concentration is prominent in the crack tip before drilling. Stress within 1 mm of the crack tip after drilling decrease and the stress concentration is relieved, while the stress 1 mm from the crack tip was slightly larger, showing that crack stop holes eliminate the influence of the plastic zone around a crack tip and result in some stress redistribution. The average stress across the section increases owing to the crack stop hole and all materials work together to bear load. Here, the average stress 1 mm from the crack tip increased from 11.63 MPa to 13.58 MPa, an increase of 16.8%.

3. ANALYSIS OF THE BENDING MODEL

3.1 *Bending model*

The fillet weld of steel deck is one of the most vulnerable details to fatigue cracks under the bending load. The local model of deck and U-rib weld in steel bridge decks is shown in Fig. 5.





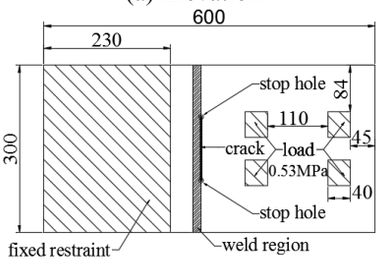


Figure 4. Stress gradient

Q345qD steel was adopted with elastic modulus E = 206GPa, Poisson's ratio υ = 0.3. The model length was 600mm and width was 300mm. The deck thickness was 16mm and U rib thickness was 8mm. Full penetration welding was considered. According to the fatigue test in previous studies by authors, loads of 0.53 MPa were added at the bolt hole positions of the vibration fatigue machine(Fu *et al*. 2017). It caused 50MPa stress at the model center (no crack) with 10mm from the weld toe. All freedom degrees of the area which was 230mm from the

edge were restrained to simulate the fixed end.

(a) Elevation

(b) Plan

Figure 5. Model sizes (Unit: mm)

According to the welding accuracy, the cracks are always not just at the weld toe. Meanwhile considering to the convergence of finite element calculation, the crack was set 0.5mm from the weld toe in the model. The fatigue crack section can be considered to be a semi ellipse(Zeng, Tian and Liao 2016). Therefore, the simulated crack section is shown in Fig. 6, in which a is semi-major axis length and b is semi-minor axis length. The ratio of minor to major axis(b/a) is 0.2 with a=50mm and b=10mm for the model. The endpoints of major axis are crack tips and the curve of crack depth is crack front. The position on the depth curve is indicated by the angle of the radial direction as shown in Fig. 6. It is called position angle in this study. The 0° direction position is located at left crack tip. The angle increases counterclockwise.

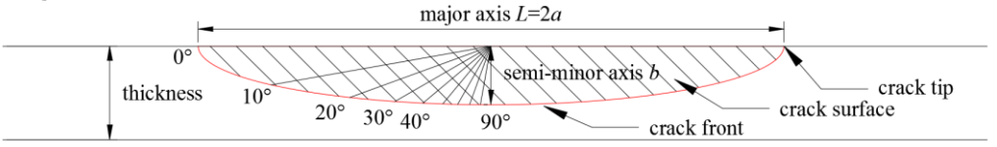

Figure 6. Position angle in crack section

ABAQUS model was built and extended finite element method was used to deal with stress singularity. Elements of C3D8R and C3D10 were adopted. The mesh size of the model was 20mm globally. The mesh size refined to be 0.5mm at the weld. In the width of 20mm out of weld, the 5mm and 10mm mesh sizes were adopted for transition region. Along the crack, mesh size refined to be 1mm in 25mm length range near the crack tips and 2mm at other parts. The position of the stop hole was near the crack tip. The specific positions and parameters were considered according to the analysis condition. The stop holes were formed by Boolean subtraction operation of the cylinder and model without reduction in the division accuracy of mesh sizes. The finite element model is shown in Fig. 7.

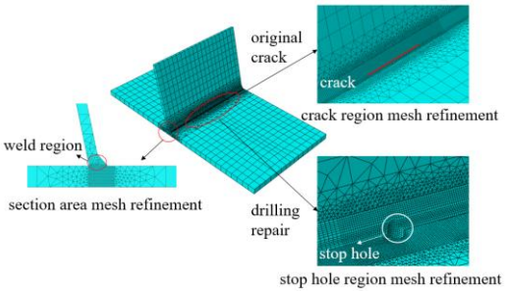

Figure 7. Finite element model

3.2 *Stress distribution*

The surface Mises stress along the crack section was obtained as shown in Fig. 8. As the stress distribution was symmetrical by the medial axis of the model, only half of the curve was drawn. The stresses with or without crack were compared. Due to the crack, obvious stress concentration is appeared at the crack tips. The stress on the crack (L=100mm)is close to 0 because of the releasing after cracking. The crack surface almost has no stress resulting by the stress redistribution. The stress at the crack tip reaches 234.8MPa while the stress at model edge is 44.9MPa. However, the stress distributes without obvious change for the model without crack. The maximum stress is 64.9MPa which located in the center and the stress is 42.3MPa at the two side of model edge. The stress distribution is generally uniform without stress mutations. The stress concentration factor of the crack tip is 3.69 when stress of model without crack is nominal stress.

Fig. 9 is the stress distribution of model with a 100mm crack after drilling stop holes(D=8mm). The center of stop hole locates at the crack tips. Stress on the surface caused by the fracture is small near the crack. The stress concentration

area at the crack tips is removed by the stop holes. However, the maximum stress also appears near the stop hole. It is located at the converge positions of crack and stop hole. The stress concentration is also presented but with a reduction in the peak stress value. In general, the trend of stress distribution is not changed by stop holes.

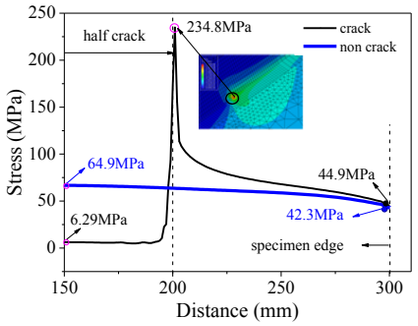

Figure 8. Mises stress along the crack

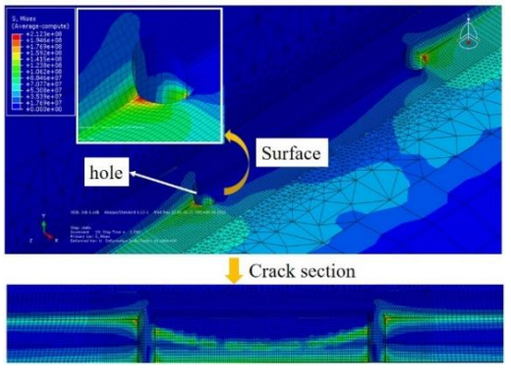

Figure 9. Stress distribution after drilling

The stop hole is a temporary treatment for the crack prevention. The cracks have a possibility to cracking again. Taking the stop hole center as the origin of coordinates, the stress around the stop hole edge is shown in Fig. 10. In the side with crack (90°~270°), the stress is close to 0. The stress in 90°~180° is less than that in 180°~270° because the local stiffness of the weld is greater than that of deck. The maximum stress appears at the extension direction of crack (180°) with a value of 213.0MPa. It is the most probable position to crack again.

4. EXPERIMENTAL VERIFICATION

4.1 *Experiment introduction*

It is hard to simulate fatigue cracks in real conditions on a plate deck, thus a crack stop hole was set in samples featuring a real bridge at full-scale to provide a more favourable reference for real bridge application. The fillet weld connecting the steel bridge deck and its vertical stiffener was adopted: both member sizes and welding technology replicated that of the actual bridge (Fig. 11), i.e., special steel Q345qD and a weld foot of 6 mm for all steel fillet welds were used. Fatigue cracks were obtained by fatigue experiment at an early stage with a crack length on both sides of 30 mm.

Mechanical vibration fatigue testing was used and after fatigue arresting, fatigue loading was carried out. The cyclic loading provided by the apparatus was sinusoidal. The stress amplitude was 120 MPa.

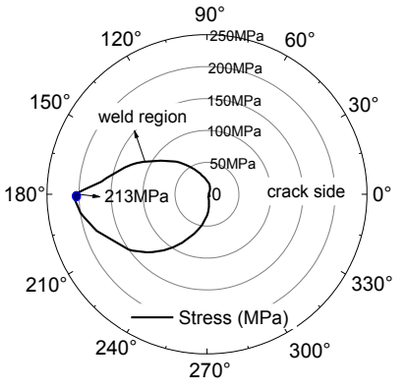

Figure 10. Stress around the hole edge

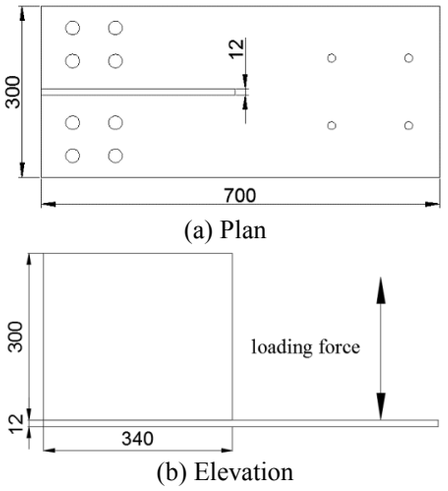

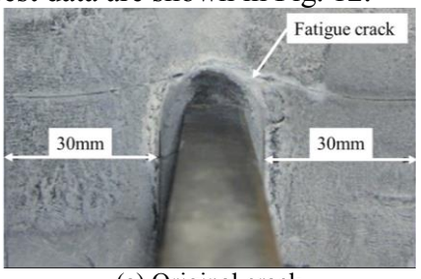

Figure 11. Specimen size(Unit: mm)

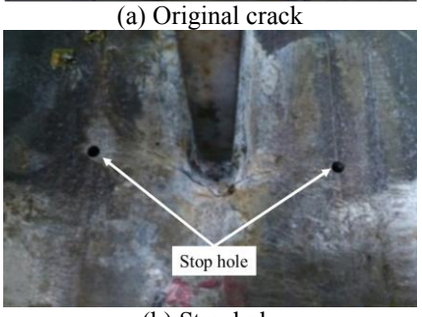

4.2 *Processing of crack arresting*

Crack stop holes with diameters of 0mm(meaning without stop hole), 4mm, 6mm and 8mm were selected for this crack arrest experiment considering the diversity of crack arrest behaviour of different diameters. The four samples were named as SJ1, SJ2, SJ3 and SJ4 in

the order of the hole diameter. As each crack has two tips, the same processing was carried out on them both. Aligning the edge of the hole with the crack tip, the inner wall and edges were polished by round file and sandpaper after drilling. The crack arrest data are shown in Fig. 12.

(a) Original crack

(b) Stop hole

Figure 12. Drilling method

4.3 *Experimental phenomenon and results*

Crack forms of all samples were reflected by magnetic tester after fatigue loading. Fig. 13 shows a cross-sectional view of the sample. Fatigue cracks in samples SJ1 and SJ2 grew at both sides of the crack stop hole while those in samples SJ3 and SJ4 grew at one side of the hole (Fig. 14).

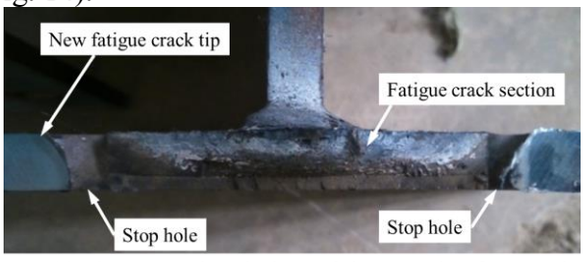

Figure 13. Cross-sectional view of the sample after crack arrest processing

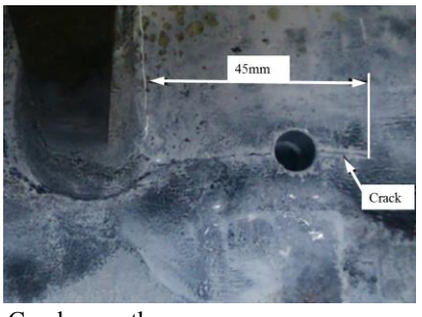

Figure 14. Crack growth

Cycle times for fatigue loading corresponding to regeneration, 5 mm, and 15 mm of crack growth were recorded (Table 2). The total length of crack growth was 45 mm.

Table 2 Loading cyclic times corresponding to growth of cracks(×100 times)

Growth of new crack	SJ1	SJ2	SJ3	SJ4
Regeneration	/	1029	2468	3100
To 5mm-long	/	2921	4237	4968
To 15mm-long	3559	4866	5880	6870

As seen in Table 2, the cyclic times for crack regeneration increased with increasing hole diameter in SJ2, SJ3, and SJ4, thus extending their fatigue life. This verified the conclusion above, i.e., the larger diameter crack stop holes prevented cracks from growing and provided better crack arrest behaviour.

The process of crack growth was divided into two stages: crack growth from regeneration to 5 mm-long, and that from 5 mm-long to 15 mm-long. The growth rate of each stage is shown in Table 3.

Table 3 Crack growth rate in two stages(×10^{-8} m/C)

d_a/d_N	SJ1	SJ2	SJ3	SJ4
The first stage (0-5mm)	-	2.64	2.83	2.68
The second stage(5-10mm)	-	5.14	6.09	5.26
Average	4.21	3.89	4.46	3.97

As seen in Table 3, crack growth rates in both stages were in the 10-8 m/C order of magnitude, namely, a moderate rate. The crack growth rate in the second phase is much larger than that in the first stage. The average rate of crack growth was similar for both stages, i.e., crack stop holes can only prevent cracks from growing, yet have little influence on their growth rate after regeneration.

5. CONCLUSION

The CT model and bending model were adopted in this research to analyse the stress characteristics of crack stop holes. The performance of the stop hole was verified by the fatigue experiment and it could be concluded as following:

(1) Stress in the vicinity of the crack tip after

drilling decreased remarkably and the stress concentration was relieved, while the stress of cracking section was slightly larger, showing that crack stop holes eliminated the influence of the plastic zone around a crack tip and resulted in some stress redistribution.

(2) The stress around the hole edge reached the maximum along the propagation direction of the original crack, which was the initiation cracking again.

(3) The experiment showed that a crack stop hole could prevent cracks from growing and the stop holes with larger diameter provided better crack arrest behaviour. The crack growth rate at later stages was faster than that in the earlier stage after regeneration. Thus a stop hole and its diameter had no influence on crack growth rate.

Fatigue Performance of Hammer-peened Diaphragm-to-rib Welds in Orthotropic Steel Decks

Q.D. Wang, B.H. Ji, Z.Q. Fu
College of Civil and Transportation Engineering, Hohai University, Nanjing, Jiangsu, P.R. China

ABSTRACT: Diaphragm-to-rib welds are easily subjected to fatigue cracking under cyclic traffic loads. To evaluate the effect of hammer peening technique, the simplified finite element model (FEM) of hammer-peened specimen was developed to investigate the local stress variation after hammer peening. The effective stress was also analysed by another simplified FEM. Besides, three local specimens were peened and the subsequent fatigue test was conducted for comparison. The results show that the crack initiation life of hammer-peened specimen is enhanced significantly, while the crack propagation pattern still remains unchanged. Significant compressive stress is induced by hammer peening, and the effective tensile stress under bending load could be decreased effectively, which is beneficial to the fatigue performance of diaphragm-to-rib welds.

1 INTRODUCTION

Orthotropic steel bridge decks (short for OSBDs) has been widely used in long-span cable-supported bridges because of lightweight, excellent stability, high bearing capacity and some other advantages (Fu Z, et al. 2017). However, the structure of OSBDs is complex and main components are welded with each other, which lead to short influence lines of OSBDs and considerable welding residual stress (Kainuma S, et al. 2016). With the increase of services years, the OSBD is easily subjected to fatigue cracking under cyclic traffic load (Xiao Z G, et al. 2008). The stress state near diaphragm-to-rib welds are rather complex because of both in-plane and out-plane deformation, where fatigue cracks are usually found (Choi J H and Kim D H). Fatigue cracks are unavoidable and hard to be detected at its initial stage (Xie, et al.2015) Besides, the detection and repair work of fatigue cracks is expensive (Yamada K, et al. 2015) Therefore, it is meaningful to take measures to improve the local mechanical properties of welded joints, which will also help to reduce the life cycle cost of bridges.

Recently, the methods for improving the mechanical properties of welded joints could be divided into three types: improving the geometric profile of welds, decreasing the welding residual stress and optimizing the structural bearing. Grinding, peening and local strengthening methods are usually adopted thereof (Fisher J W, et al. 2015a). Ultrasonic hammer peening (UHP) and Air hammer peening (AHP) are the main peening methods sharing the similar fundamentals: minor defects of the welds could be eliminated during the impacting process and compressive residual stress will be induced there (Fisher J W et al.1979b; Janosch J J, et all. 1996). For AHP, the compressed air is the source energy of the impacting system. The air pressure of AHP is usually no more than 300 kPa, indicating limited plastic deformation and residual compressive stress (Fisher J W, et al. 2015a). Recently, a new technique called Impact crack-closure Retrofit (ICR) was developed based on AHP, with a much higher air pressure (0.6MPa~0.8MPa) and impacting frequency (Yamada K, et al. 2015). In view of higher impacting energy induced by ICR, the technique was mainly used to retrofit cracked components, and the relative experimental results showed that the fatigue life of cracked specimens was significantly improved after ICR treatment (Zhiyuan Y Z, et al.2016). If the welds are treated by ICR technique before the crack initiation, the fatigue performance might also be improved due to the decrease of effective tensile stress under fatigue load.

Therefore, the simplified ICR process and the out-plane deformation of diaphragm-to-rib welded specimen were both modeled, and the local deformation and stress variation were analysed. Besides, three local diaphragm-to-rib welded specimens were adopted here, and the weld toe near the arc-sharped notch was treated by ICR technique. Then the treated specimens were fatigue tested subsequently using vibrating fatigue test machine. The crack initiation life, crack propagation and stress variation were analysed to evaluate the improvement

in fatigue performance of ICR treated diaphragm-to-rib welds.

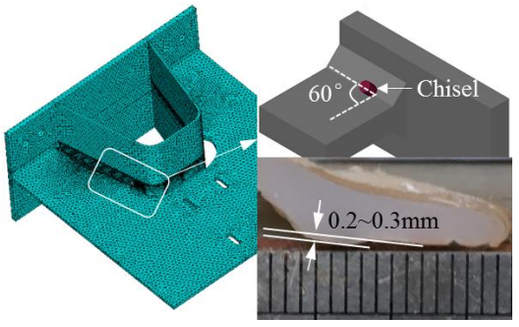
2 FINITE ELEMENT ANALYSIS

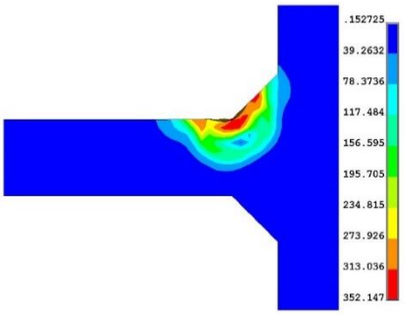
2.1 *Analytical model*

The finite element model was developed by *ANSYS* to analyse the residual stress variation after peening process. Considering that the distribution of residual stress was limited to a small range, a local model was developed for saving time, as shown in Fig.1.

SOLID185-type element was used to simulate both the specimen and the chisel. The model was meshed with a refined mesh size of 1mm. The bilinear kinematic hardening model (BKIN), with a yield strength of 345MPa and a tangent modulus of 0, was adopted. Element types of TARGE170 and CONTA174 were adopted at the surface of chisel and weld respectively. To keep the same boundary conditions with the specimen, nodes at the cut surface between the local and whole model were fixed. The angel between the chisel and the diaphragm was set as 60°.

Displacement-controlled loading was adopted here instead of load-controlled loading. To obtain the displacement of the chisel, preliminary peening was conducted to the diaphragm-to-rib welded specimen, and reverse molding was applied to the peened zone, of which the surface was covered rapidly by hot-melt glue. Then the cold glue was removed and cut into two pieces to measure the peening depth. As the peening depth was 0.2mm~0.3mm, the displacement of the chisel was set as 0.2mm in the model. The peening process was divided into two steps: the pressing and lifting of the chisel. The whole peening process was completed in 0.01s with each step taking 0.005s.





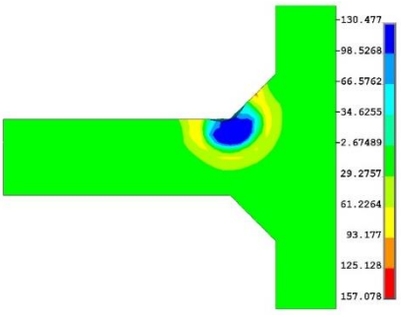


Figure 1. Analytical model

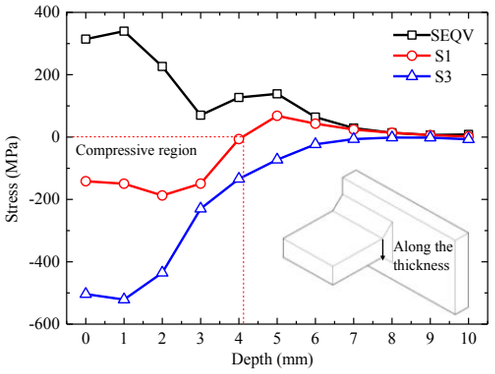
2.2 *Residual stress nephogram*

The nephogram of Mises equivalent stress after peening was shown in Fig.2a, of which the deformation was at its original scale. According to Fig.2a, plastic deformation and significant residual stress was generated in hammer peened zone presenting a radial distribution centred on the weld toe. The maximum residual stress located near the hammer peened surface reaching a value of 352MPa, which indicated that the relevant metal was yield. Because of the plastic deformation, the geometric profile of weld toe was improved, which was beneficial to the local mechanical behavior. The first principle stress near the peening center was compressive and reached a value of -130MPa, which demonstrate that significant residual compressive stress was induced therein.

(a) Mises equivalent stress



(b) The first principle stress

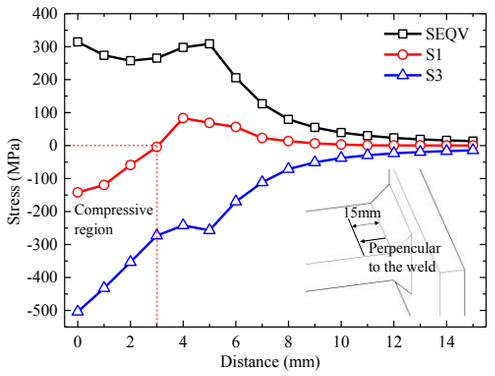


Figure.2 Residual stress nephogram

2.3 *Residual stress variation*

The Mises equivalent stress (SEQV), the first and third principle stress (S1 and S3) in hammer peened region were analysed, as shown in Fig.3. The maximum SEQV was located at the position 1mm under the surface, and the relevant influence depth was about 7mm. S1 was compressive at the weld toe, and became tensile stress while the depth reached 4mm and the distance at the surface exceeded 3mm, which was consistent with the deformation compatibility condition. S1 induced by peening process was about -150MPa at the surface of weld toe indicating the improvement in local mechanical properties therein. It could be assumed that higher residual compressive stress might be generated if the ICR process is improved (e.g. an optimal hammerhead radius is adopted).

3 ANALYSIS OF EFFECTIVE STRESS

3.1 *FE model*

The vibrating fatigue test machine was adopted by the authors' research group to conduct fatigue tests of rib-to-deck welds, diaphragm-to-rib welds and plate edge gusset welds. For diaphragm-to-rib welded specimens, former experimental results showed that the fatigue crack caused by out-plane deformation in the test was similar with the one in real suspension bridges. Therefore, the loading method in the FE model was the same with that in fatigue test as illustrated in Fig.4. The geometric size of the model was given in Fig.5.

In the model, the region near the arc-shaped notch was meshed with a refined mesh size of 1mm (shown in Fig.6), and other regions were meshed with a course mesh size of 6mm. The deck in the model was constraint, and four surface loads of 0.5 N/mm^2 were applied to the model. Other parameters of the model were the same with the former one as illustrated in Section 2.1.

3.2 *Stress concentration*

Significant stress concentration region was located at the junction of diaphragm and diaphragm-to-rib welds near the arc-shaped notch, as shown in Fig.7. It demonstrates that fatigue cracks will initiated therein if cyclic fatigue loads are applied. Fig.8 showed the crack source regions in diaphragm-to-rib welds both in fatigue tests and a suspension bridge in China. It demonstrated that the analytical results were consistent with the experimental results and the actual situation.

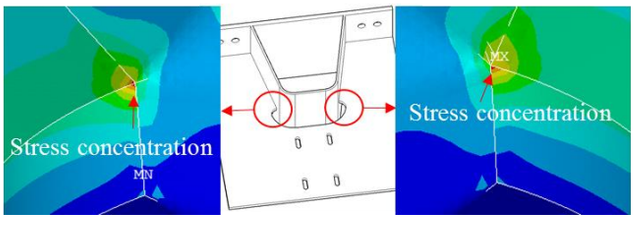

Figure.7 Stress concentration under bearing load

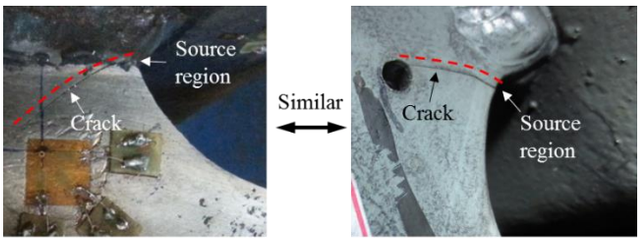

Figure 8. Crack source region of diaphragm-to-rib welds (imaged by the author)

3.3 *Effective stress*

Simulation of peening process was not applied to this model for simplifying. However, superposition principle was adopted here to analyse the effective tensile stress at the weld toe of diaphragm-to-rib welds, where the value of residual compressive stress (-150MPa) was considered. The results were illustrated in Fig.9.

According to Fig.8, the stress amplitude at the junction between the diaphragm-to-rib weld and diaphragm was about 220MPa as the model was subjected to bearing load. However, due to the residual compressive stress induced by peening process, the stress level was decreased by nearly 70%. After hammer peening, the effective stress decreased rapidly and became compressive when the distance was about 2.5mm away from the junction. The effective stress at the surface of junction was only about 60MPa indicating the significant improvement of local mechanical properties.

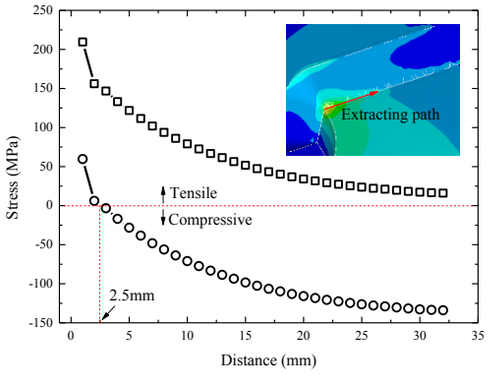

Figure.9 Effective stress

4 EXPERIMENTAL INVESTIGATION

4.1 *Specimen*

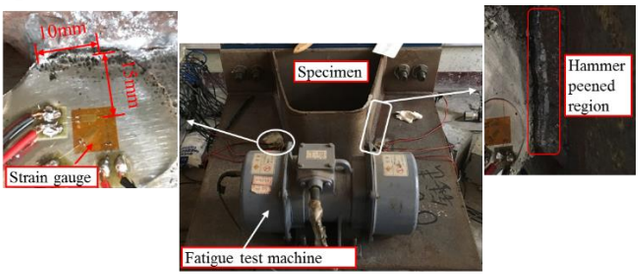
Q345qD was adopted to manufacture the specimens shown in Fig.10. The geometric sizes of the specimen were the same with the FE model (shown in Fig.5), which were also consistent with the geometric sizes in real bridges. All specimens were welded by CO_2 gas metal arc welding technology. Three specimens, labelled S-P-1, S-P-2 and S-NONE-3, were tested. S-P-1 and S-P-2 were hammer peened and subsequent fatigue test was conducted, while S-NONE-3 was fatigue tested without peening. Fig.10 showed the appearance of the specimen.

Figure.10 The appearance of the specimen

4.2 *Test procedure*

Considering that the diaphragm-to-rib welds near the arc-shaped notch were easily subjected to fatigue cracking, peening process was conducted therein before fatigue loading. The hammer peening was performed until obvious plastic deformation was induced at the weld toe.

Vibrating fatigue test machine was used to apply fatigue loads. The loading force was controlled by the vibrating frequency of the machine, which was adjusted according to the strain at the angle of 45 degree. The initial stress amplitude was set as 100MPa in the test, while the relative frequency was 9.32Hz. The experimental details were illustrated in Fig.11.



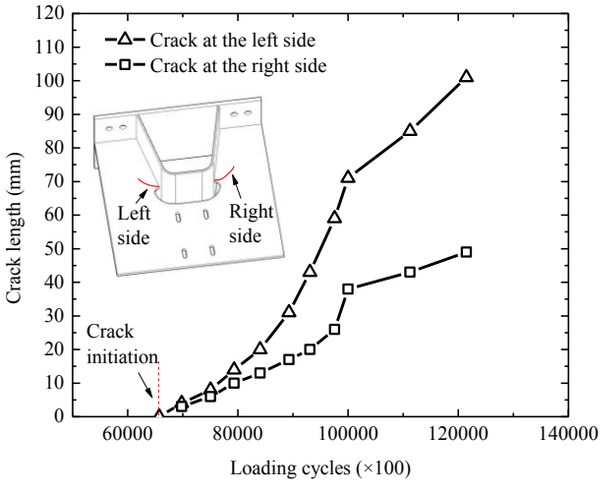


Figure.11 Experimental details

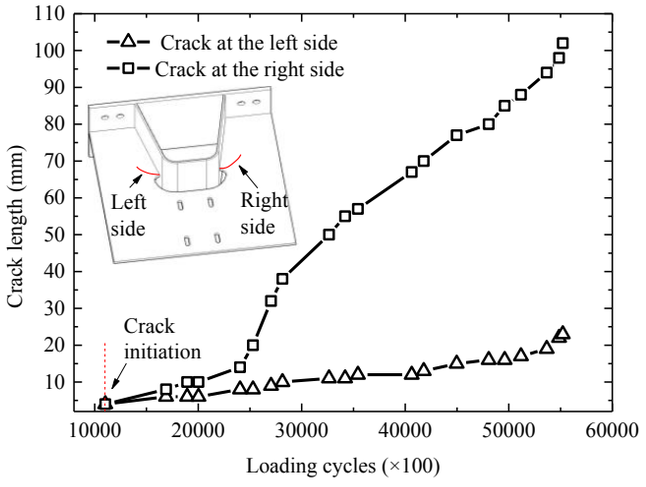
4.3 *Crack propagation*



For diaphragm-to-rib welded specimens, the welds at both sides of the U-shaped rib are easily subjected to cracking. Therefore, the fatigue test was finished once the crack reached a length of 100mm, or the specimen was not cracked with the loading cycles exceeding 10 million times. In the test, S-P-2 was not cracked, while fatigue cracks were both detected at both sides of the U-shaped rib. The source region of the fatigue cracks was the same with the one shown in Fig.8, and propagated at an angle of about 45° along the diaphragm.

Fig.12 showed the crack propagation curves of S-P-1 and S-NONE-3. Even though two cracks

propagated concurrently, the relative propagation rates were different: one propagated rapidly with the other propagated slowly due to the stress release. The crack propagation curves of the two specimens were similar, indicating that the crack propagation pattern of hammer peened specimen remained unchanged. However, the crack initiation life of S-P-1 was about 6.5 million cycles, which was about 10 times higher than that of S-NONE-3 (about 1 million cycles).

(a) S-P-1

(b) S-NONE-3

Figure12. Crack propagation curve

4.4 *Crack initiation life*

The test results of six additional specimens without hammer peening in the former fatigue test conducted by the authors' group was adopted for comparison (labelled from S-C-1 to S-C-6 respectively). The crack initiation life was compared in Fig.13. The crack initiation life of S-NONE-3 was similar with the former test result, which was about 1million loading cycles. However, the crack initiation life of hammer peened specimens was much higher than the one of untreated specimens (6.5million for S-P-1 an0d more than 10million for S-P-2). It demonstrated that the crack initiation life could be significantly enhanced by hammer peening technique.

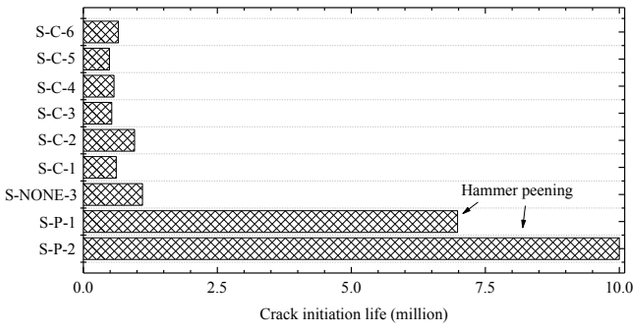


Figure.13 Comparison of crack initiation life

5 CONCLUSIONS

FE models were developed to analyse the residual stress variation induced by ICR process, and the effective stress at the weld near the arc-shaped notch was analysed. Then, the ICR process and the subsequent fatigue test were applied to local specimens to evaluate the effect of peening treatment on the performance of local mechanical properties. The following conclusions may be drawn from this study.

1) Considerable compressive stress was induced by peening process centred on the weld toe, and the effective stress at peened surface was significant decreased.

2) The position of crack source region was not changed after peening process, and the crack propagation path was similar with the one of untreated specimen.

3) The crack initiation life of peened specimens was enhanced by more than six times than that of untreated specimens in the test. It demonstrates that the fatigue performance of diaphragm-to-rib welds could be significantly improved by ICR technique.

Fatigue stress analysis of diaphragm-U-rib welding joints and local optimization

Ye Zhi , Y.X. Wang , H.B. Sun , B.H. Ji
College of Civil and Transportation Engineering, Hohai University, Nanjing, Jiangsu, P.R. China
Jiangsu Yangtze River Bridge Ltd, Jingjiang, Jiangsu, P.R. China

ABSTRACT: To study the fatigue problem of diaphragm-U-rib welding joint and diaphragm arc gap in steel box girder of Yangtze River Bridge, analysis of stress range and service life were carried out on fatigue details mentioned above based on the strain data collected from sensors in real bridge. Meanwhile, in order to improve fatigue behavior of the diaphragm, two new types of diaphragm structure were proposed, including transverse stiffener between major diaphragms and stiffener set on the arc gap. The finite element model of the steel bridge deck was established to analyze influence of the new structure on the fatigue stress. The result shows that the fatigue lives of diaphragm-U-rib weld ending and diaphragm arc web gap are, respectively, 3 years and 10.5 years. The optimized structures proposed in this study can effectively reduce stress range and the possibility of fatigue cracking in these two fatigue details.

1 INTRODUCTION

In recent years, the orthotropic steel bridge deck is widely used for its advantages in low self-weight, rapid construction, good load-carrying capacity. But the complicated structure of the steel deck and welds connecting components lead to the prominent residual stress and stress concentration in critical details, which are vulnerable to fatigue damage and failure under the long-term traffic loading (Cao et al.2015; Li et al.2001). At present, fatigue cracks of various propagations and types have been observed in orthotropic steel bridge deck at home and abroad.

Fatigue cracks propagated from the arc gap in the connection of diaphragm and U-rib is one of the most common cracking types in orthotropic steel bridge deck (Grundy et al.1990; Leendertz et al.1995; Bocchieri et al.1998; Connor et al.2001). The complicated structure results in unfavourable stress in the connection of diaphragm and U-rib (Leendertz et al.1995; Bocchieri et al.1998; Connor et al.2001), and the manual welding is of poor quality during the welding processing considering different welding conditions (taking overhead welding and down-hand welding) and welding sequences. Therefore, residual stress generated from weld is uncertain in the connection of diaphragm and U-rib and fatigue cracks tend to propagate around the arc gap. There are two kinds of cracking types in the diaphragm, including cracks initiated from the diaphragm-U-rib weld ending and the arc gap.

The bridge monitoring was carried out on the cracks initiated from diaphragm-to-rib weld ending and the arc gap of the diaphragm in Jiangyin Yangtze River Bridge. Fatigue life of different details was estimated based on measured data. Besides, two kinds of optimized structures were applied on di aphragm and effects on its fatigue performance were analyzed by the finite element method.

2 REAL BRIDGE LOAD TESTING SCHEME

The fatigue stress monitoring was carried out on the diaphragm measurements under the normal traffic conditions of Jiangyin Yangtze River Bridge. The strain gauge data were sampled at a frequency of 50 Hz for 1-day using the Data Acquisition & Signal Processing system (DASP). The field test was mainly comprised of six stages, namely, measurements arranging, diaphragm polishing, strain gauge sticking, temperature compensating, device debugging and strain testing. The gauges were attached to the ending of the rib-diaphragm weld and arc gap on t he U-rib 6#, which is located on t he slow lane of the downstream direction and 1/4 span of Jiangyin Yangtze River Bridge. It is suggested by IIW that stress at the distance of 1.5t (t is the thickness of deck) from the weld toe was measured as the nominal stress (Hobbacher,2015). The layout of the measurements is shown in Figure1 and Figure2.

（b）M2

Figure3 The strain time curve of measurements (300s)

3 ANANLYSIS OF MEASURED DATA

3.1 *Strain histogram*

Measurement errors are inevitable during the field testing due to the effects of temperature loading, wind loading and various noises. In order to guarantee the reliability of the measured data, the zero drift and signal filtering processing were carried out using the DASP system. Therefore, effects generated from various environment factors were reduced and modified strain histogram curves were extracted under traffic loadings. 300s of strain data were extracted from 24h histogram because of its large volume. Strain changes at the diaphragm-U-rib weld ending and arc gap were shown in Figure3.

The monitoring data show that time periods, namely 9:00~12:00 and 14:00~17:00, are of the most strain cycles, indicating the heavy traffic during these two periods. According to strain histogram curves of diaphragm, strain of the diaphragm-U-rib weld ending changes within 40 με, and strain of diaphragm arc gap changes in a relatively great ranges, mostly within 100 με.

3.2 *Strain spectrum*

The data of stress histogram were obtained through multiplying the strain histogram by the elasticity modulus of steel. Stress of details changing with time can be analyzed according to the stress histogram curves, but fatigue stress spectrums are necessary as the cycles of stress ranges at each levels are still uncertain. By executing the rainflow ananlysis algorithm to the stress histogram data, cycles corresponding to each level of stress ranges were calculated and fatigue stress spectrums were obtained by specifying a resolution of 1.0 MPa for the stress range interval. The stress cycles with amplitudes less than 2.0 MPa were discarded because they had little effect on the results of fatigue life and added extra workload. The stress spectrums of two measurements are shown in Table 1.

Table1 The stress spectrum of measurements

Stress range /MPa	Stress cycles/ N	
	M1	M2
2~3	2914	2400
3~4	530.5	387
4~5	182.5	174
5~6	122.5	113.5
6~7	88.5	52
7~8	73	39
8~9	76.5	31
9~10	72.5	28
10~20	174	93
20~30	58	22
30~40	32	5.5
40~50	15	3
50~60	10	0.5

Table 1 shows that with the increase of stress range, the corresponding stress cycles gradually reduce. The stress range of 2~8MPa accounts for more than 90% of stress cycles, which indicates that low-amplitude cycles are mostly included in stress spectrum of two details. According to the BS5400 specification, the greater stress range will enlarge the initial defects of the component, thus reducing the fatigue limit. As time goes by, the stress range that is lower than fatigue limit of the components can play a part in the accumulation of damage.

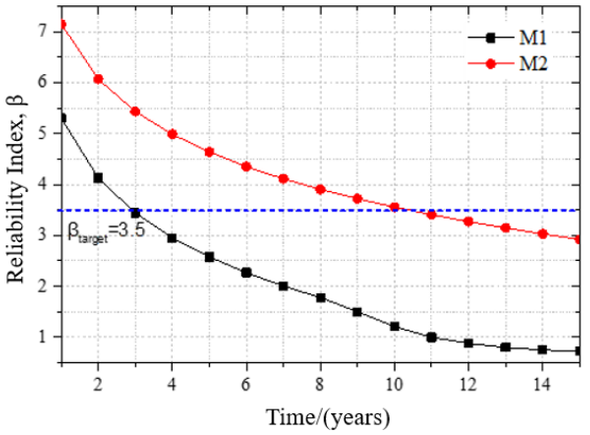
The BS5400 (2009) specification provides the fatigue resistance of classified welded details in steel bridges, in which diaphragm-U-rib weld ending and diaphragm arc gap are classified as level F2 and level B with the fatigue limits of 35MPa and 100MPa respectively. Table 1 shows that the peak stress ranges of M1 and M2 are greater than the fatigue limit, thus M1 and M2 are prone to fatigue damage under the accumulation of vehicle loads.

3.3 *Fatigue reliability*

The equivalent stress ranges of 1-day were calculated and fatigue damage per hour was analyzed based on the fatigue stress spectrum. It's deduced that fatigue damage follows the log-normal distribution. Fatigue reliability of M1 and M2 was calculated by Eq. (1) (Dan M F et al. 2008; Kwon K et al.2010), where D_C=critical damage; D_T =cumulative damage; u=average damage; δ^2 =variance. The target reliability of 3.5, w hich is recommended by the European steel structure association(2010), was adopted with corresponding failure probability is 10^{-4}.

$$\beta = \frac{\ln\left[\frac{u_{D_C}}{u_{D_T}}\left(\frac{1+\delta_{D_T}^2}{1+\delta_{D_C}^2}\right)^{1/2}\right]}{\left[\ln(1+\delta_{D_C}^2)+\ln(1+\delta_{D_T}^2)\right]^{1/2}} \quad (1)$$

Fatigue reliability of M1 and M2 changing with service years was shown in Figure4. The reliability decreases noticeably in the early years but the decline slows down later on. The reliability of M1 is always smaller than that of M2. The reliability index of M2 is estimated as 3.48 in the 10.5 years of service and reliability index of M1 decreases to 3.44 after only 3 years of service, both failing to meet the β_{target}.



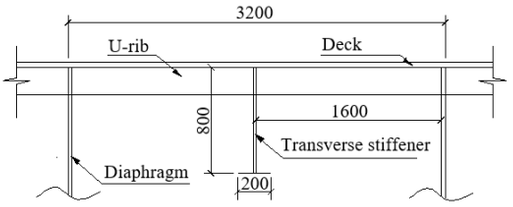


Figure4 Fatigue reliability evaluation of two measurements

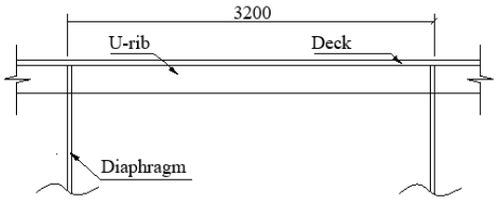
4 ANALYSIS OF OPTIMIZED STRUCTURE



4.1 *Two optimized constructures*

Two forms of optimization were proposed to improve the fatigue problem of diaphragm, namely, setting of the transverse stiffener between diaphragms and stiffener on the arc gap.

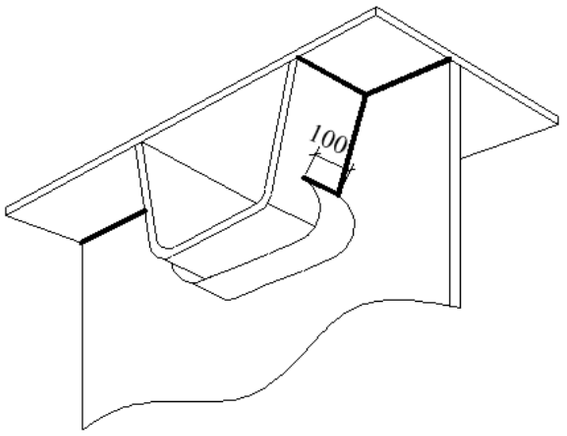
Type 1: Setting of the transverse stiffener between diaphragms (Dan M F et al.2008). There are two kinds of diaphragm setting in the steel box girder nowadays.Taking Ikushi Bridge and Minggang Bridge as examples, the transverse stiffener is set between diaphragms in the steel box girder. For Nanjing Yangtze River Bridge and Humen Bridge (Zhou et al.2004), there's no such structure as setting of the transverse stiffener between diaphragms. Two kinds of diaphragms setting were studied in reference to the former design experience, which were shown in Fig.5. Type1: the space between two diaphragms was 3.2m and transverse stiffener with height of 0.8m and thickness of 0.012m was set between diaphragms. Type2: the space between two diaphragms was 3.2m and there's no transverse stiffener.

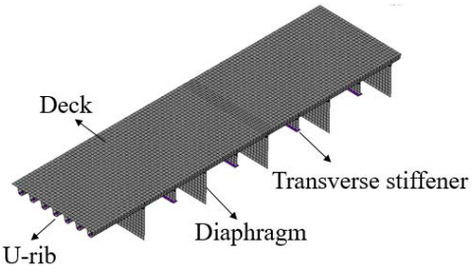
(a) type 1

(b) type 2

Figure5 Two kinds of diaphragms setting

Type 2: Setting of the stiffener on the arc gap. An stiffener sharing the same shape with the arc gap was set and welded with U-rib. The stiffener was perpendicular to diaphragm and the width on bot h sides of the U-rib were 100mm, which was shown in Fig.6.





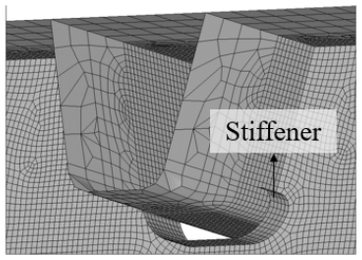


Figure6 Setting stiffener on the arc gap

4.2 *Finite element model and loading*

Seven U-ribs were fitted in the transverse direction and five diaphragm distances were adopted in the longitudinal direction to reduce the influence of boundary conditions on the stress value in calculating area. The total length of the model is 16000mm and space between diaphragms is 3200mm. The width of the model is 3900mm, the space between U-rib is 600mm and the size of U-rib is 300mm×280mm×8mm. The thickness of deck and diaphragm were 16mm and 12mm respectively. The local model was simulated by Shell63 elements. The bilinear kinematic hardening plasticity model was adopted. The elastic modulus E of steel is 2.0×10^5MPa and the poisson ratio is 0.3. T he finite element models of two optimized structures were adjusted on the basic model, as shown in Fig.7.

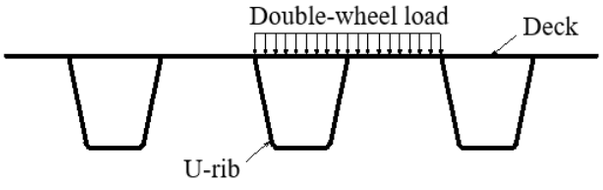
(a) model with transverse stiffener

(b) model with stiffener on the arc gap

Figure7 Finite element model of two optimized structures

Stress increment caused by change of geometrical shape was only considered in the calculation of the nominal stress. The weld and partial penetration gap could be overlooked and the rough grid size was acceptable for FEM analysis. Therefore, the nominal stress method was adopted for fatigue assessment of the diaphragm-U-rib weld ending and the arc gap (Hobbacher A et al.2016; Martinsson J et al.2005; Yamada K et al.2008).

In order to calculate stress ranges of fatigue measurements, the double-wheel loading was applied on the local model of steel bridge deck. According to General Specifications for Design of Highway Bridges and Culverts(in Chinese), the acting length of the double wheel was 0.6m and 0.2m respectively along the transverse and longitudinal direction, and the wheel loading was 70kN. The stress influence line was calculated by moving area loading on the local steel bridge model. The transverse layout of the loading was shown in Fig.8.



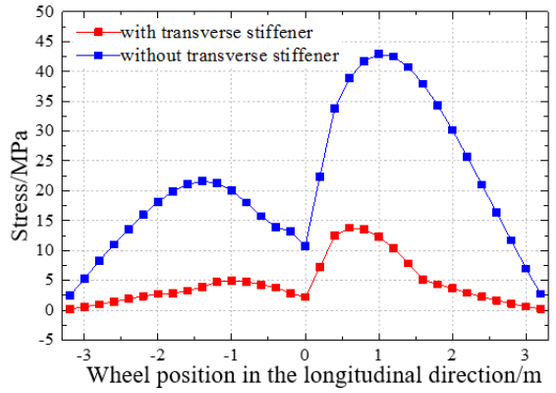


Figure8 The position of wheel loading

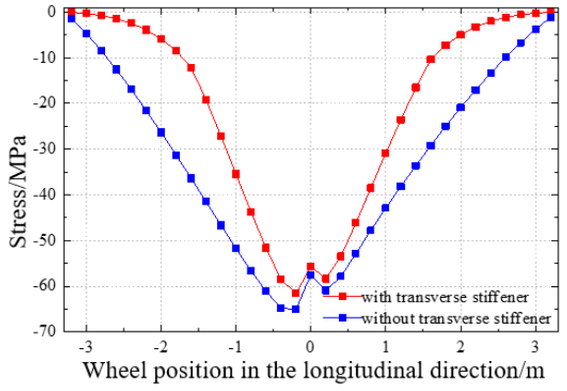


4.3 *Analysis of calculation results*

The stress influence line of two measurements, with the transverse stiffener setting between diaphragms was shown in Fig.9. Stress of critical M1 and M2 is noticeably declined. The maximum tensile stress of diaphragm-U-rib weld ending are reduced by 67%, having the specific value decreases from approximately 32.33MPa to 10.40MPa. Likewise, maximum tensile stress of the arc gap are reduced by 5%, having the specific value decreased from

approximately 65.05MPa to 61.58 MPa. The setting of transverse stiffener leads to greater decline in stress of diaphragm-U-rib weld ending than that of the arc gap, indicating diaphragm-U-rib weld ending is more susceptible to the transverse stiffener. The decrease of the tensile stress of diaphragm-U-rib weld ending can effectively reduce the possibility of fatigue cracking. By the stress influence line of two measurements, stress of diaphragm-U-rib weld ending shows barely no changes and compressive stress of diaphragm arc gap increases gradually before arrival of wheels on the transverse stiffener. When the wheels cross transverse stiffener, stress of diaphragm-U-rib weld ending changes in great amplitude and compressive stress of diaphragm arc gap increases linearly. This is because loadings transferred from the deck are shared by the diaphragm and transverse stiffener after the setting of the transverse stiffener between diaphragms.

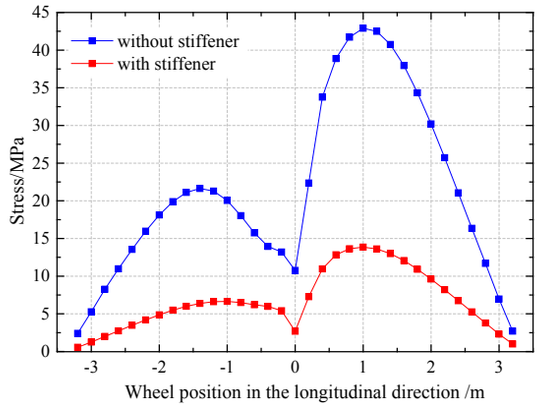
(a) diaphragm-U-rib weld ending

(b) arc gap of the diaphragm

Figure9 Stress influence line of fatigue details

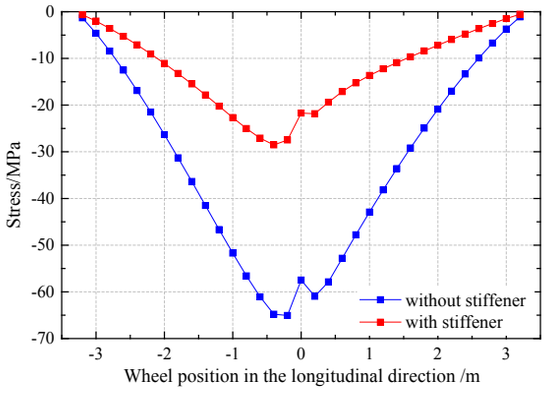
The stress influence line of two fatigue details in the bridge deck is equivalent to the stress histogram under vehicle loadings, The stress range and cyclic number were calculated by using the rainflow analysis algorithm. The Miner's cumulative damage rule, as shown in Eq. (2), was applied to calculate stress ranges corresponding to one stress cycle(AASHTO 1990; Miner MA et al.1945). where σ_{eq}= equivalent stress range; n_i= cycles corresponding to σ_i; N_T= the total cyclic numbers of all the stress cycles ; m= the slope of the *S-N* curve, for most of the fatigue details, m=3.

$$\sigma_{eq}=\sum\left[a_i\sigma_i^m\right]^{\frac{1}{m}}=\left[\frac{1}{N_T}\sum n_i\sigma_i^m\right]^{\frac{1}{m}} \quad (2)$$



The transverse stiffener was set between diaphragms and the equivalent stress ranges of these two measurements were shown in Table2. The transverse stiffener exerts no effects on stress ranges of the arc gap, which decreases less than 4% after the setting of transverse stiffener. The stress ranges of diaphragm-U-rib weld ending are susceptible to the transverse stiffener and reduces by 66%, having the specific value decreased from approximately 32.33MPa to 10.85MPa.

Table 2. Stress range of details with the transverse stiffener



Forms	Stress range/MPa	
	U-rib - diaphragm weld ending	arc gap of the diaphragm
with transverse stiffener	10.85	48.81
without transverse stiffener	32.33	50.40

According to the stress analysis of two measurements, setting of the transverse stiffener between the diaphragms can effectively decrease stress ranges and the maximum tensile stress and compressive stress are reduced to different degrees. Therefore, setting of the transverse stiffener not only improves fatigue performance of diaphragm, but also reduces the possibility of fatigue cracking.

The stress influence line of two details with the stiffener setting on the arc gap was shown in Fig.10. The maximum tensile stress of diaphragm-U-rib weld ending are reduced by 67%, having the specific value decreased from approximately 42.89MPa to 13.85MPa. Likewise, maximum tensile stress of the arc gap are reduced by 58%, having the specific value decreased from approximately 65.05MPa to 27.47 MPa. This is mainly because the bending and torsional deformation of the U-rib are restrained by the shear force and bending moment of weld connecting the U-rib and diaphragm. The shear force and bending moment reach the maximum on the arc gap. Therefore, the stiffener not only improves the flexural rigidity of arc gap, but also improves its fatigue performance.

(a) diaphragm-U-rib weld ending

(b) arc gap of the diaphragm

Figure10 Stress influence line of fatigue details

The equivalent stress range with the setting of stiffener on the arc gap was calculated according to the aforementioned method and the results were shown in Table 3. The maximum tensile stress of diaphragm-U-rib weld ending are reduced by 67%, having the specific value decreased from approximately 32.33MPa to 10.40MPa. Likewise, maximum tensile stress of the arc gap are reduced by 45%, having the specific value decreased from approximately 50.40MPa to 27.50 MPa. The stress ranges of diaphragm-U-rib weld ending and arc gap are both susceptible to the stiffener setting on the arc gap. Therefore, setting of the stiffener on the arc gap can improve the fatigue performance of diaphragm as the stress range is one of the main factors of steel structure failure.

Table 3. Stress range of details with stiffener on the arc gap

Form	Stress range/MPa	
	U-rib - diaphragm weld ending	arc gap of the diaphragm
With stiffener on the arc gap	32.33	50.40
Without stiffener on the arc gap	10.40	27.50

5 CONCLUSIONS

1) The reliability index of arc gap was estimated as 3.48 in the 10.5 years of service and reliability index of diaphragm-U-rib weld ending decreased to 3.44 after only 3 years of service, both failing to meet the target reliability index.
2) Setting of the transverse stiffener between the diaphragms could effectively decrease stress ranges of two details. The stress ranges of diaphragm-U-rib weld ending were more susceptible to the optimized structure and declined more than that of the arc gap.
3) Setting of the stiffener on the arc gap decreased stress ranges of the diaphragm-U-rib weld ending and arc gap, thus reducing the possibility of fatigue cracking.

ABSTRACT: Concrete-Filled Steel Tube (CFST) structures have been widely applied in civil infrastructures. The grouting compactness in the steel tube will seriously influence the loading capacity and structural behavior for the CFST structures. In this paper, the electro-mechanical impedance technique was developed to monitor the grouting compactness of CFST arch bridges. In the study, a small-scale steel tube specimen was fabricated to simulate the actual CFST arch bridge structure, all the experimental results demonstrated that the developed method can clearly reveal the structural changes during the grouting in the steel tube, and can be used to monitor the grouting process and detect the occurrence of debonding disease in real-time.

1 INTRODUCTION

Due to their distinguish advantages, such as high load-carrying capability, perfect ductility, convenience and economy in construction, Concrete-Filled Steel Tube (CFST) structures, which combine the advantages of both steel and concrete, have been widely applied in infrastructure construction. Figure 1 presents the applications of the CFST in two arch bridges. In practical applications, the steady cooperative work between the concrete and steel materials in the tube is crucial to guarantee the structural safety during its service period. However, the incomplete grouting of CFST structures during its construction period, may induce the debonding between the concrete core and the steel tube, and will seriously influence the load-carrying ability, reduce the structural integrity, and leave a serious threaten to the vehicle and pedestrian (Su, 2009). Figure 2 presents the detection photos of the surface deformation of the steel tube because of the incomplete grouting of CFST structure.

(a) (b)

Figure 1. The arch bridges using concrete-filled steel tube (a) The first bridge of Yangzi river in Hejiang county (Xhf0293, 2014), (b) Taiping lake bridge in Anhui province (He, 2014).

In order to deal with this problem, some routine detection methods had been applied in actual bridges to detect this defect on the tube, such as the drilled core specimen (Lu et al., 2011), artificial knocking (Chen, 2011), ultrasonic detection (Liu, 2004) and etc. However, these techniques still face a lot of challenges, especially involve the manual inspections, for example, it is always inconvenient or difficult for the workers to reach to the detection region of the bridges, besides, the inspection results usually strongly depend on the worker's experience. On the other hand, for drilled core specimen method, it is inevitable to induce the second artificial damage for the test structure, and may help the disease development. Therefore, developing a new Non Destructive Testing (NDT) technique for the CFST structures to detect the debonding disease in real time, is very necessary and meaningful.

Figure 2. Tube surface deformation caused by incomplete grouting

Electro-mechanical impedance (EMI) technique, which utilizes high-frequency signal as the structural excitation sources, presents great potential for structural health monitoring (Liang et al., 2016a, Liang et al., 2016b). At the same time, the distinguish advantages of piezoceramic materials, such as wide bandwidth, dual sensing and actuation abilities, and availability in different size and shapes, also make the EMI-based method an attractive technique to damage diagnose. The basic idea of this technique is to use high frequency vibrations to locally monitor the desired structure for finding any structural damage especially at the incipient stage. Physical changes in the host structure cause changes in the structural mechanical impedance, which may induce changes in the electrical impedance of the surface bonded PZT patch of the structure. Lots of researcher have successfully applied this technique to monitor the structural health condition, including an aircraft structure (Chaudhry et al., 1995), a massive steel bridge joint (Ayres et al., 1996), complex precision parts (Park et al., 1999), and several applications under significant varying-temperature condition (Park et al., 2000).

In this paper, the electro-mechanical impedance technique was employed here to monitor and detect the grouting process and the quality of grouting compactness of the steel tube. At the beginning, the theoretical description of the EMI technique is briefly introduced, then a small-scale steel tube was designed and fabricated to simulate the real CFST arch bridge structure. A distributive sensor network, including eight piezoceramic patches, was developed in the specimen. The specimen was grouted through a reserved grouting hole in four stages, and each stage extended three days for cement hydration. For each stage, the eight patches will be connected with a high precious impedance analyzer to acquire the electrical impedance, and then the acquired signals in different location under different stages will be compared and analyzed. Finally, all the experimental results demonstrate that the EMI-based method can effectively detect the occurrence of the debonding disease and evaluate the compactness quality of the CFST arch bridge.

2 DETECTION PRINCIPLE

2.1 *Electro-mechanical impedance*

The electro-mechanical coupling of piezoelectric (PZT) actuator/sensor patch is the key for the impedance-based qualitative health monitoring technique. This technique was first proposed by Liang (Liang, 1997) and subsequently developed by other researchers (Ayres et al., 1999, Park and Inman, 2007). The coupling effect of the EMI for a system with a PZT patch and a host structure can be conceptually investigated by using an idealized 1D electro-mechanical system, as shown in Figure 3. From the figure, a PZT is bonded to the surface of the structure by adhesive, and is considered as a thin bar that vibrating axially due to an applied alternating voltage. Thus, the integrated electro-mechanical system may be electrically represented by an electrical impedance which is affected by the dynamics of the PZT and the host structure.

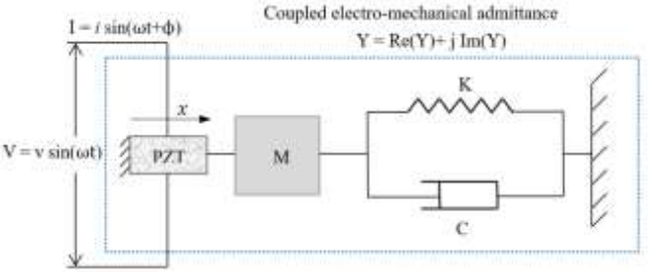

Figure 3. 1D electro-mechanical impedance system (Liang et al. 2016b)

From the figure, assuming the mechanical impedance of PZT patch Z_A is defined as the ratio of a harmonic input voltage $V(\omega)$ at an angular frequency ω to the current response $I(\omega)$ in frequency domain. Similarly, the mechanical impedance of the host structure that is idealized as a SDOF system, can be represented by Z_S and is defined as the ratio of a harmonic excitation force $F_0(\omega)$ at an angular frequency ω to the velocity response $\dot{x}(\omega)$ in frequency domain.

Thus, the solution of the wave equation for the PZT bar that is connected to the structure leads to the following equation for a frequency-denpent electrical admittance:

$$Y(\omega) = j\omega \frac{wl}{h}\left[\frac{Z_A(\omega)}{Z_A(\omega)+Z_S(\omega)}\frac{d_{31}^2 \bar{Y}_{11}^E \tan(\kappa l)}{\kappa l} + \bar{\varepsilon}_{33}^T - d_{31}^2 \bar{Y}_{11}^E\right] \quad (1)$$

where ω is the angular frequency of the driving voltage; $Y(\omega)$ is the electrical admittance (inverse of impedance) of the PZT patch at angular frequency ω, κ is a wave number ($=\omega/c_t^E$); c_t^E is a wave velocity ($=\sqrt{\bar{Y}_{11}^E/\rho}$); ρ is density; Z_A and Z_s are the mechanical impedance of the PZT and the host structure, respectively; w, l and h are the width, length and thickness of the PZT transducer, respectively; $\bar{Y}_{11}^E = Y_{11}^E(1+\eta j)$ is the complex Young's modulus of the PZT transducer at zero electric field; d_{31} is the coupling piezoelectric constant between the z and x direction at zeros stress; $\bar{\varepsilon}_{33}^E = \varepsilon_{33}^E(1-\delta j)$ is the complex dielectric constant at zero stress along the z direction, η and δ are the mechanical loss factor and dielectric loss factor.

From the equation, it indicates that electrical impedance of the PZT patch is directly related to the mechanical impedance of the host structure. Therefore, the EMI technique can be employed to identify the structural diseases, including the grouting compactness changes and the debonding defect of the concrete-filled steel tube for arch bridge.

2.2 *Grouting compactness and debonding detection using the EMI technique*

In this study, the impedance technique was employed to monitor the grouting compactness and detect the occurrence of debonding disease of the CFST structure. The PZT patch was bonded on the outside surface of the steel tube, and then connected with a high precious impedance analyzer, thus the electrical impedance signal of the PZT patch can be acquired in real-time.

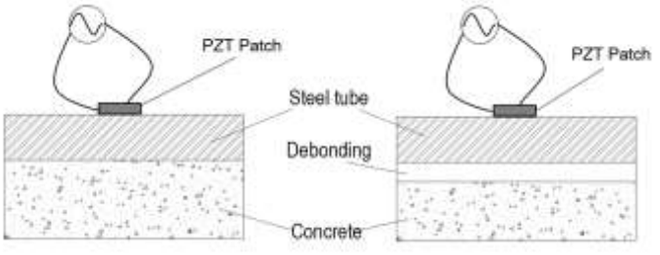

Figure 4. Principle of impedance-based debonding detection for CFST structure

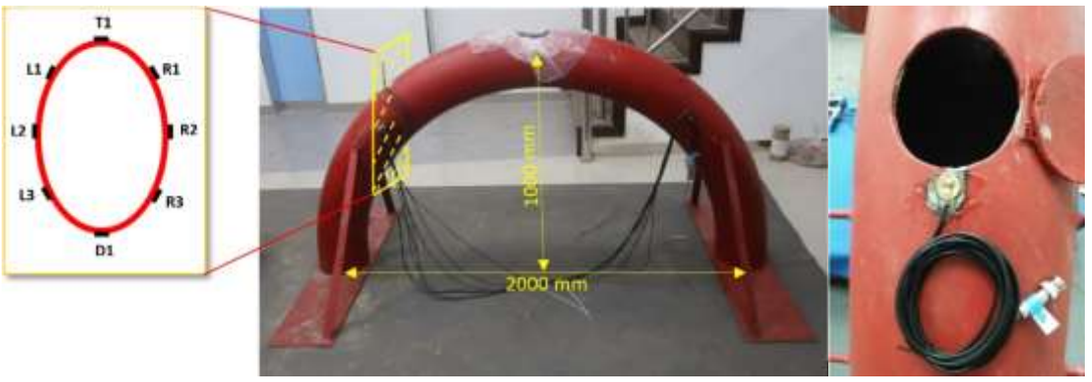
As shown in Figure 4, when grouting is incomplete during its construction, a debonding occurs between the core concrete and the outside steel tube. This disease induces the structural physical characteristic change, including the local stiffness decrease, dampling ratio variation and etc. Therefore, following the description of EMI technique in last section, this structural physical parameters changes will influence the mechanical impedance of structure, and then induce the variation of the electrical impedance of the PZT patch. Thus, by acquiring the electrical impedance of the PZT patch, the health condition of the structure can be monitored, and the debonding disease of the steel tube can also be identified by monitoring and analyzing the variation of the impedance signal acquired from the surface bonded PZT patches.

2.3 *Compactness monitoring index*

After the electrical impedance signals of the PZT sensors were acquired under different grouting compactness conditions, in order to conveniently compare and analyze these signals, a monitoring index was proposed here to monitor the compactness of the steel tube, and diagnose if there is a debonding occurrence. The monitoring index is given as



$$I_{RMSD} = \sqrt{\frac{\sum_{i=1}^{N}\left(Y(\omega_i) - Y_0(\omega_i)\right)^2}{\sum_{i=1}^{N}\left(Y_0(\omega_i)\right)^2}} \quad (2)$$

where $Y(\omega_i)$ is the admittance signature at the ith measurement point, and $Y_0(\omega_i)$ is baseline (empty condition) admittance signature at the ith measurement point, N is the total measurement points in a signature. As the structural compactness monitoring index indicates, when the current structural status is close to its empty condition $Y(\omega_i)$, and the IRMSD is close to 0.

3. EXPERIMENTAL SETUP AND PROCEDURES

3.1 *Specimen and sensor location*

In order to verify the effectiveness of proposed method in this paper, a small-scale steel tube specimen was designed and fabricated, as shown in Figure 5. The construction material of the steel tube is Steel Q235. The diameter of the tube is 200 mm, and three holes with the diameter of 150 mm were reserved on the tube for grouting in the test, as shown in Figure 5(b). In the study, eight PZT patches were bonded on the outside surface of the steel tube along the vertical section near one of the reversed holes, as shown in Figure 5(a), in which, two PZT patches located on the top and down side denoted as T1 and D1, respectively, and three patches locate on left side, denotes as L1-L3, and three are right, denoted as R1-R3.

(a) (b)

Figure 5. Specimen (a) the small-scale steel tube specimen and sensor location (b) the reserved grouting hole and the PZT patch

3.2 *Experimental setup and procedures*

In the experiment, a high precious impedance analyzer was connected to the bonded PZT patch using a BNC line, and it was then connected to a laptop with supporting software to control the signal acquisition and the following data analysis, as shown in Figure 6. When the test is beginning, the left side of the steel tube specimen was grouted through the grouting hole by four times, as shown in Figure 7. The grouting cement is C40 which is a typical type of construction concrete. Shortly after grouting, compaction was performed by tapping a rubber mallet at the exterior of the steel tube. In each grouting stage, the impedance signal was acquired for each PZT patch by using the impedance analyzer, then these signals were compared and analyzed by the processing terminal. It should be noted that the each grouting stage holds for three days and the measurements conducted at the 3rd day of each grouting stage.

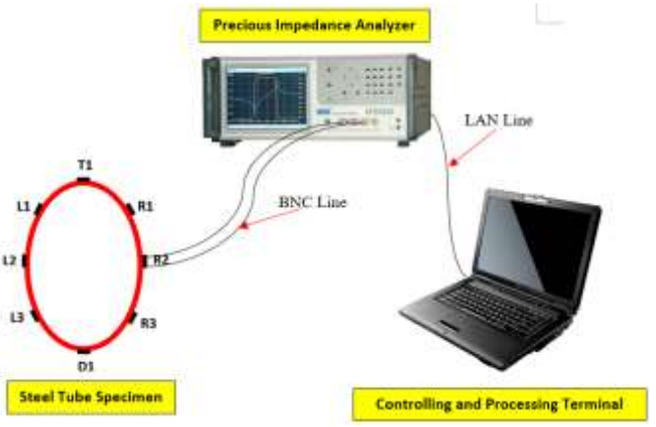


Figure 6. Experimental setup

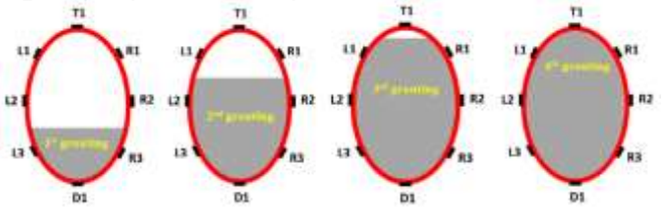

Figure 7. Four times grouting for the steel tube

4. TEST RESULTS AND ANALYSIS

4.1 *The acquired impedance signals*

In the study, the electrical admittance signal was acquired by the impedance analyzer with a frequency range from 300 kHz to 500 kHz. Even though both the real and imaginary admittances were measured, only the real admittance measurements were analyzed and presented in the following analysis due to the fact that the real admittance has a large interaction with the structure than the imaginary admittance (Ayres et al., 1999, Park and Inman, 2007). Because of the space limitation, only the electrical admittance signal acquired by the top sensor was presented and analyzed in the following study, as shown in Figure 8.

From the figure, it is clear that with the increase of the concrete grouting into the steel tube, the real part of the acquired admittance signals have an obvious increase compared to the signal acquired under the empty condition. This phenomenon may be explained by the increase of grouting compactness of the specimen during the experiment. Thus, the structural mechanical parameters change, including the local stiffness and damping ratio, and finally induce the variation of the structural mechanical impedance, which can be caught by the changes of the electrical impedance acquired by the PZT patch on the specimen.

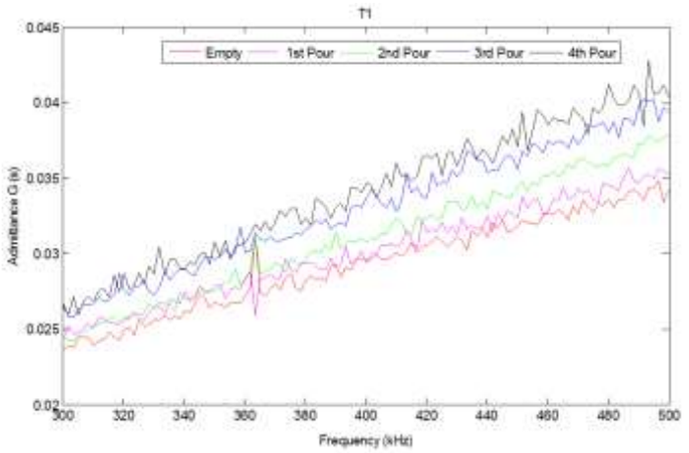

Figure 8. Admittance (real part) versus frequency chart for top PZT patch

4.2 *Impedance-based compactness monitoring index*

In order to clearly quantify the variation of the admittance signal acquired under four different pour conditions, a compactness monitoring index, was employed here to evaluate the grouting compactness and detect the debonding occurrence. The final calculation results was shown in Figure 9. From the figure, it is clear that with the increase of the concrete grouting, i.e. from empty to 4th pouring, the RMSD index increases monotonously, which demonstrates that the developed impedance-based method can effectively monitor the concrete grouting process during the construction, and accurately diagnose the debonding disease between the core concrete and the outside steel tube.

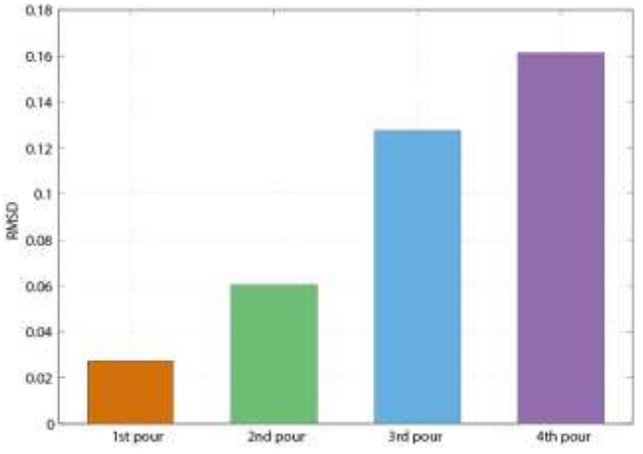

Figure 9. Admittance-based debonding index for the top PZT patch

5. CONCLUSIONS

In this paper, an electro-mechanical impedance based technique combining with piezoceramic transducers, was developed to monitor the grouting process during the structure construction, at the same time, to detect the occurrence of the debonding disease between the core concrete and the outside steel tube for Concrete-Filled Steel Tube (CFST) structures. In order to validate the effectiveness of the developed method, a small-scale steel tube specimen was designed and fabricated in the laboratory, and then eight PZT patches were attached along the outside steel section in the selected location. During the test, concrete was filled the steel tube through the reversed hole on the specimen by four times. For each pouring, the eight PZT sensors were successively connected with a higher impedance analyzer to acquire the electrical admittance of the sensors bonded on the specimen in different location. Then, all the acquired admittance signals were compared and analyzed with the one acquired in the empty condition. Finally, all the test results demonstrated that the developed method can monitor and evaluate the cement grouting process effectively, and also has the ability to evaluate the compactness severity and detect the occurrence of the debonding for the specimen.

Study on soil-steel bridge response during backfilling

T. Maleska & D. Beben
Opole University of Technology, Opole, Poland

ABSTRACT: The paper presents the results of the numerical study and field testing of shell steel structure under backfilling. For these purposes a soil-steel bridge with span of 17.67 m and height of 6.05 m was chosen. The steel shell is made of corrugated steel plate of thickness 0.007 m and has a corrugation depth of 0.14 m and pitch 0.38 m. The assembled shell structure was backfilled with soil layers of thickness ranging from 0.2–0.3 m, which were then properly compacted (min. $I_D = 0.97$). Numerical analysis was conducted using the DIANA program based on finite element method. The assumptions of computational 3*D* model of shell structure with linear interface layer are also described. The corrugated steel plate elements are defined by shell-type elements as an elastic-plastic material and the backfill will be modelled using the non-linear elastic hyperbolic Duncan-Chang model. The highest axial force and stresses in the shell structure observed on additional ribs near the supports and at 1/4 height of shell. Maximum axial forces and stresses were compressive. The greatest bending moments are also compressive and they occurred at the additional ribs (at the 1/4 of height) and at shell crown. The maximum displacements situated near the shell crown and at the end of structure. The displacements obtained from the measurements and finite element analysis are generally quite close to each other. The maximum strains were observed near the support of shell and at 1/3 of shell height. The calculated values are smaller than those obtained from the field test (maximum differences were ca. 20%).

1 INTRODUCTION

Corrugated steel plate (CSP) structures are used to build engineering objects for many years around the world. In Europe, this type of structures began the more popular over the 80s and in the following years saw rapid growth of further investments with the use of corrugated sheets. The reasons for such a rapid increase in the number of structure made from CSP are: (i) the simplicity of construction, (ii) relatively low construction costs, (iii) short construction period and (iv) small expenditure related to maintenance of the object. Soil-steel bridges usually have a span in the range of 3 to 25 m, and they are used to construct bridges, culverts, railway passes, etc. (Machelski 2008).

The durability of soil-steel bridges determines the resistance of the steel to corrosion, which is related to: (i) the abrasion of the inner part due to the rapid flow of water, (ii) the salinity of the water flowing from the road and (iii) the strength and aggressiveness of the backfill. Due to the character of the behaviour of soil-steel bridges, the procedures related to the design as well as selection and execution of backfill are very important issues for the proper and safe operation of the entire structure. This is especially valid during the backfilling process (compaction of the backfill). Suitable backfill characteristics, such as density index, aggregate grain size, density intensity, thickness of compacted layers, backfill range, type of soil and soil cover height are the basic elements affecting the strength of the soil-steel bridges. In addition, the following have to be checked: (i) the weight of the moving equipment near the structure, (ii) the size of the structure deformations during the backfilling, and (iii) the tightening of the connecting bolts.

Strict observance to the technological regime and control of construction processes as well as the application of appropriate enforcement procedures is required. Even a good designed structure can be damaged as a result of an incorrect compaction procedure, the use of unsuitable backfill, lack of appropriate equipment, and lack of control the structure during backfilling (Janusz & Madaj 2009)

So far, attempts have been made to analyse the impact of backfilling for soil-steel bridge (Pittino & Gosler 2006, Manko & Beben 2005). It was found that during the backfilling, the displacements and the bending moments exceeds the maximal values, especially in the initial layers of backfilling of the CSP structure. Koruszewicz & Kunecki (2011) analysed

the backfill densities in the laboratory conditions and the obtained results were compared with the numerical ones. The differences between the laboratory and the numerical results were at the level of 16%, which can be considered an acceptable error. Sanaeiha et al. 2017 present a field test of a soil–steel bridge during backfilling. The case study involved a CSP that was stiffened by concrete rings. The test results show that both maximum deflection and the maximum bending moment occurred at the crown when the soil reached the crown level. Conversely, the maximum axial force occurred at the bottom of the arch when the soil reached its maximum level above the arch. Influence of backfill quality and RC relieving slab on soil-steel bridges was analysed by Beben (2017) and Beben & Stryczek (2016), respectively.

The design of this type of structure has also been verified according to the applicable standards, where the various soil cover heights (in the range of 0.45–1.5 m) were considered (Elshimi et al. 2011). Significant differences of bending moments were observed up to 70% between the values obtained using the Canadian standard (CHBDC 2006) and the measured ones. These results were also compared with finite element analysis (FEA). The difference between the FEA and the measured values was a few percent. Bayoglu Flener (2010) analysed the Canadian standard in comparison to the FEA, but the height backfill over the shell crown was in the range of 2.5–4.08 m. Significant discrepancies were observed, which reached over 50%. Brachaman et al. (2012) investigated the influence of manner of CSP modelling (orthotropic and corrugated). The obtained results were compared to the measured values. The received results show that the difference between the simplified model (orthotropic steel plate) and the result obtained in the tests differs by few percent (for displacements – 4%, and for strains – 13%). The highest discrepancies amounting to 40% occurred in bending moments. 2*D* numerical studies of soil-steel bridge during backfilling were presented also by Beben (2012) and Taleb & Moore (1999). The results are quite reasonable, however they are not show the behaviour of whole structure.

Figure 1. Side view of soil-steel bridge during backfilling.

Some design methods, such as Sundquist-Pettersson (2014) and CHBDC (2006) allow calculating the maximum internal forces in these structures also during the backfilling process. However, these methods give appropriate results for the bridges with small spans up to 8.0 m. Additionally, Bayoglu Flener (2010) received conservative results using these design methods in comparison to experiments. Taking into account these experiences it was decided to focus elaborating an own finite element model, which do not include conservative safety factors and too preservative approach for modelling the interaction between steel shell and backfill. This paper analysed the soil-steel bridge with a large span (almost 18 m) during the backfilling (Fig. 1). Backfilling process is one of the most important stages in this type of structures due to the bridge safety. The obtained results were verified with test values received during the construction of the analysed object. The obtained results can be helpful for designers and practitioners.

2 DESCRIPTION OF THE SOIL-STEEL BRIDGE

The analysed soil-steel bridge constitutes the overpass for animals. The structure have a span of 17.67 m, and vertical height of 6.05 m (Fig. 2). The shell structure was made from corrugated steel plate with depth of 0.14 m, pitch of 0.38 m and plate thickness of 0.007 m. The corrugated sheets were joined together on the span using the high strength bolts. The CSP structure is based on two massive footing with a base width of 4.00 m and a length of 57.83 m, made of C25/30 concrete. The CSP shell is reinforced using additional ribs of the same corrugated plates in an axial spacing of 1.524 m. Additional ribs consist of two wave over the entire length of the bridge (Fig. 2a). The interior of the ribs was filled with concrete mix without bars after backfilling process, therefore it was not included in the numerical analysis.

The length of shell structure at the top is 40.39 m, while the lower part of the structure is 53.83 m. The assembled shell structure was backfilled with soil layers of thickness ranging from 0.2–0.3 m, which were then compacted (I_D = 0.97). The basic dimensions of the soil-steel bridge are shown in Figure 2. The predicted soil cover depth at the shell crown is 1.80 m, which makes it possible to plant various types of vegetation. Such backfill depth also results in a good damping of the shell structure and a reduction of the noise level coming from the vehicles ride under the bridge. Both ends of the shell structure (the inlet and outlet sides) were secured and reinforced using the RC collars with dimension of 0.40 × 0.60 m.

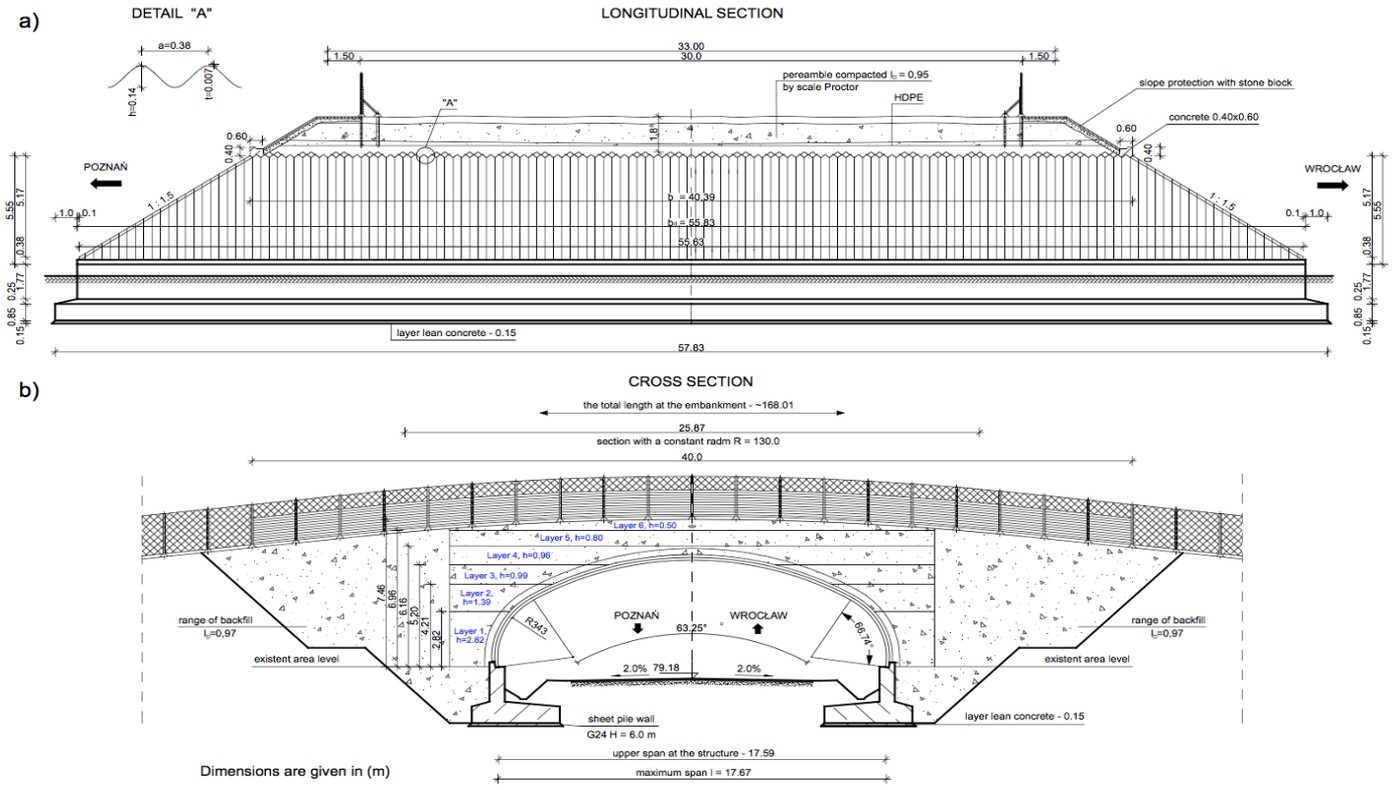

Figure 2. Soil-steel bridge: a) longitudinal section, and b) cross-section with analysed backfill heights.

3 NUMERICAL MODEL DESCRIPTION

3.1 *General remarks*

For the numerical analysis of the soil-steel bridge, a DIANA program was used (DIANA FEA 2017). This program is based on finite element method (FEM). The bridge was modelled as a 3*D* object using shell curved elements (Q24IF) for shell structure and solid elements (HX24L) for soil (backfill) medium. Figure 3 shows the numerical model in DIANA.

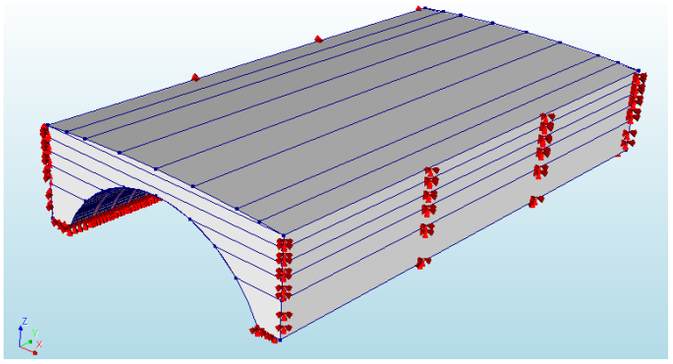

Figure 3. Numerical model created in DIANA.

Table 1 and Figure 2b present the thicknesses and weight of backfill for what the numerical analysis and field measurements were conducted.

Table 1. Weight and thickness of backfill layers.

Layers number	Thickness* (m)	Weight * (kN/m^2)
1	2.82	57.8
2	4.21	86.3
3	5.20	106.6
4	6.16	126.3
5	6.96	142.7
6	7.46	153.0

* - thickness of backfill is counted from top level of foundation (please see Fig. 2b).

3.2 *Material characteristics*

For the numerical analyses following material were used:

- backfill was modelled as solid element (HX24L) with Duncan-Chang nonlinear elastic hyperbolic model with material density of 2050 kg/m^2, Young's modulus of 1e^8 N/m^2, Poisson ration of 0.2, angle of internal friction of 39^o, dilation angle of 5^o, cohesion of 3000 N, unloading-reloading stiffness E_{ur} = 1000 N/m^2, failure ratio R_f = 0.7, reference pressure P_{ref} = 101350 N/m^2, exponent for backbone curve n = 1.1, exponent for unloading reloading curve m = 0.25, minimum tangential stiffness of backbone curve $E_{t.min}$ = 1200 N/m^3, and minimum compressive stress 350 N/m^2,
- steel plate was described as shell element (Q24IF), elastic-plastic model with density of 7850 kg/m^3, Young's modulus of 205e^9 N/m^2,

Poisson ratio of 0.3, the yield strength of steel of $235e^6$ N/m^2, plate thickness of 0.007 m, cross section area of $8.867e^{-6}$ m^2, and moment of inertia of $2.189745e^{-5}$ m^4,

- connections of the backfill and steel shell structure were made by using an interface as automatic interface by applied function "Coulomb friction" with rigidity of $1e^8$ N/m^3, angle of internal friction of 39º, dilation angle of 5º, and cohesion of 3000 N,
- boundary conditions were assumed as non-transferable supports on all boundary walls of the soil and support of the shell walls for x, y, z directions (Fig. 3),
- quadratic finite elements with dimension of 0.5×0.5 m for flat shell and backfill were applied.

The corrugated steel plate of the shell structure was modelled as shell elements using variable material characteristic plates. An orthotropic shell (Fig. 4) was used to calculate the equivalent parameters such as:

- equivalent thickness of plate:

$$t_{equ.} = \sqrt{12(1-\nu^2)\frac{I}{A}}, \tag{1}$$

where I = moment of inertia; A = cross-sectional area; ν = Poisson ratio ($\nu = \nu_x = 0.3$),

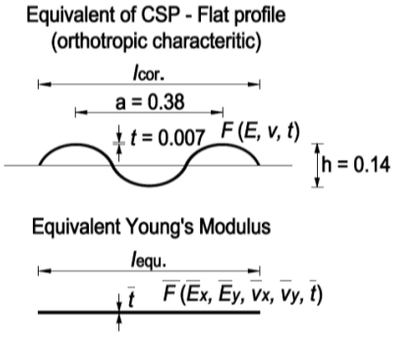

Figure 4. Orthotropic characteristics of flat plates used in numerical model of shell (dimensions are given in m).

- equivalent elastic modulus of material (Young modulus) in circumferential direction of shell thickness of plate:

$$E_{x\,equ.} = E\frac{A}{a\,t_{equ.}}, \tag{2}$$

where a = a pitch of corrugation,

- equivalent elastic shear modulus:

$$E_{y\,equ.} = E\left(\frac{t}{t_{equ.}}\right)^3, \tag{3}$$

- equivalent Poisson ratio:

$$\nu_{equ.} = \nu\frac{E_{y\,equ.}}{E_{x\ equ.}}. \tag{4}$$

4 EXPERIMENTAL TESTING

Four Leica self-levelling levels with a reading accuracy of 0.01 m were used for the displacement measurements of shell structure during backfilling. Due to the relatively long shell structure (about 60 m), four measuring stations were set up (Fig. 5). So, such approach allowed that each measuring point was controlled by at least two independent measuring instruments.

Three transverse cross-sections and four longitudinal cross-sections were selected to provide accurate information about the displacements of the CSP

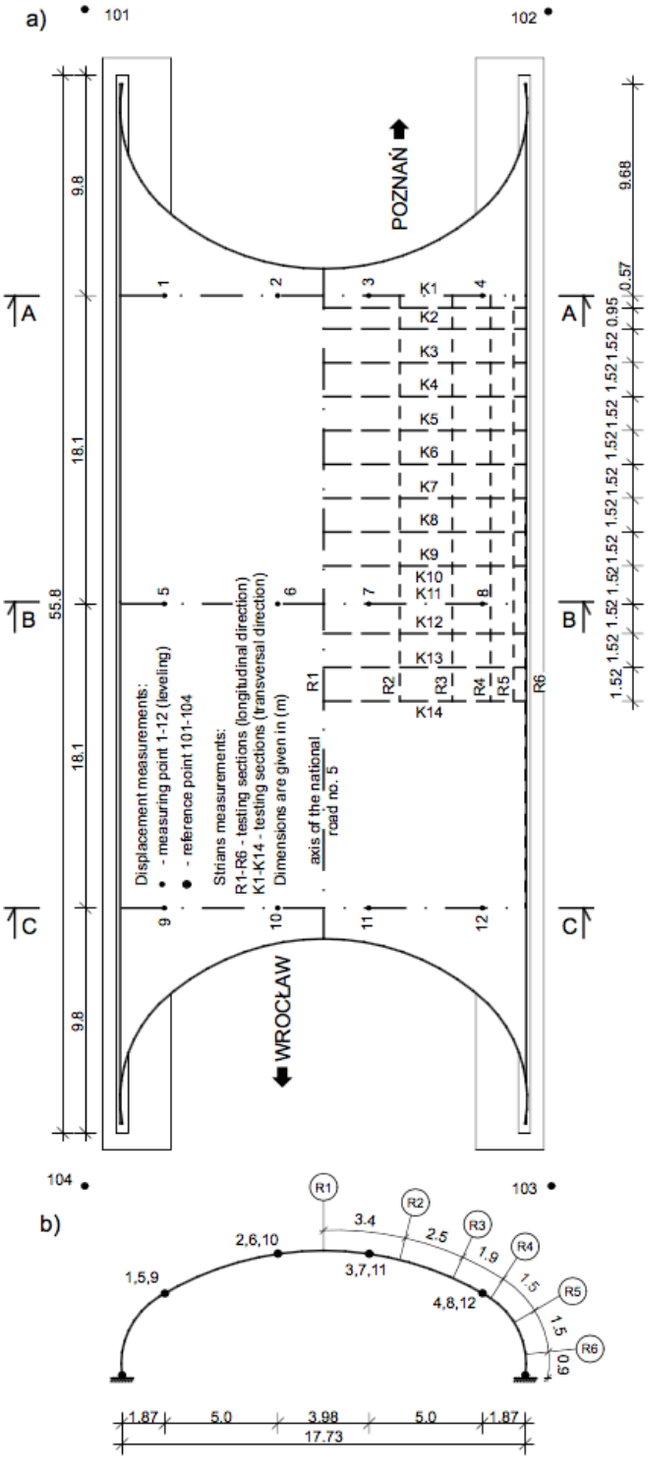

Figure 5. Location of measurement points and testing sections.

shell structure (Fig. 5). Measurement points were stabilized from the bottom of the shell structure to allow for the exact way to make the measurements.

Measurements of the height network of bench marks # 101, 102, 103 and 104 were performed by geometric levelling in the main and return direction. An assessment of the constancy of the bench marks was also conducted. Displacement and strain measurements were executed between 18.00 and 22.00, i.e. after completion of all building work on the facility to obtain actual deformation of the shell structure after full day loading and compacting of the backfill around the structure. The testing was started with the output measurements, i.e. the analysis of the state of the structure before loading (without backfill) to obtain the so-called measurement base (comparative). Vertical displacements of the examined points were calculated on the basis of changes in altitude differences.

Additionally, in selected points and sections of CSP shell structure, the strains were measured (Fig. 5). In cross-section, six testing points (R1-R6) were predicted (only on the half of shell – due to the symmetric of structure). In longitudinal section fourteen testing sections (K1-K14) were chosen (to half of the structure). The strain gauges were located at the top and bottom of the corrugation of basic shell structure and additionally on the reinforcing ribs.

5 ANALYSIS OF RESULTS

Analysis of results at this stage of construction of soil-steel bridges is very important, i.e. taking into account that the steel shell structure was first uploaded by the backfill and technological equipment (roller, vibratory plates). The measurements were carried out after compaction of each of the analysed backfill layers. Therefore, the direct impact of forces coming from the vibration plates has been omitted in calculations. However, some influence of these equipment's exists. Performing a thorough analysis of the state of displacement and internal forces in the CSP structure allows us to determine the strength and behaviour of the thin steel shell structure. Additionally, the first phase of cooperation between the backfill and steel shell can be also evaluated.

It has been observed that the values of the vertical displacements obtained in most cases are similar to the measured ones during backfilling process (Table 2). The highest displacements in the numerical program were obtained for the case of backfill layer # 6, where the maximum value was 21.3 mm (Fig. 6a), near the measurement points # 2, 3, 10 and 11 (end of shell structure).

Slightly smaller displacement (18.6 mm) occurred in the middle of the shell length in the vicinity of measurement points # 6 and # 7. The smallest calculated displacements from the numerical calculations for the backfill layer # 6 occurred at the lower part of

Table 2. Maximum displacements (mm) of CSP structure obtained from testing and numerical analysis.

shell (the measuring points # 1, 4, 5, 8, 9, and 12) and it was 2.6 mm (Table 2).

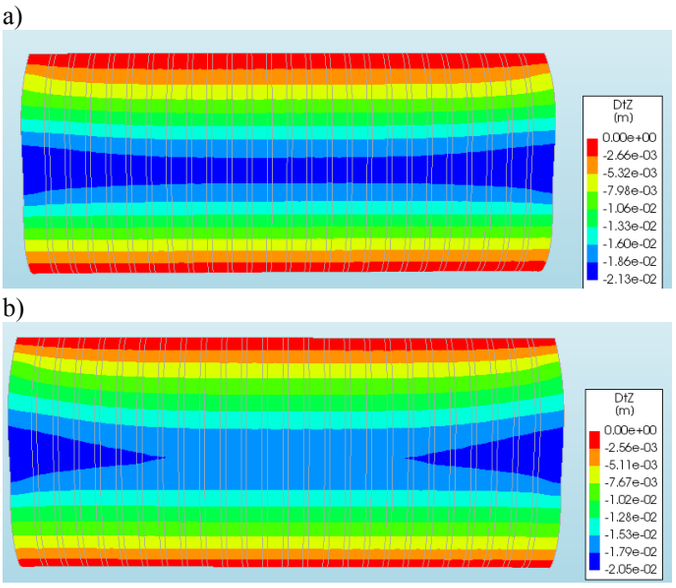

Figure 6. Maximum displacement of CSP shell structure from backfilling of layers: a) # 6, and b) # 5.

However, the largest measured displacements amounted to 29 mm and it was located at measurement point # 11, located at one end of the CSP shell structure. In the adjacent measurement point # 10 the displacement was 20 mm. In the numerical analysis for points # 11 and # 10, the displacements were at the level of 20.5 mm (Fig. 6b), which constitutes of 71% and 102.5% of measured ones for points # 11 and # 10, respectively. The same calculated values were obtained in opposite points # 2 and # 3. They are 158% higher and 85% lower than the measured value. In the middle of shell structure, the displacements do not exceed 19.0 mm. The greatest discrepancies between numerical and measured values were observed in case of backfill layer # 3, where the difference in displacements were 377%, i.e. the calculated displacements were strongly higher than measured ones. Generally, the smallest displacements were observed during loading of backfill layer # 1. They are no exceed 6.5 mm at the measuring points # 2, 3, 10, and 11 as well as at points located in the middle of span, i.e. # 6 and # 7. All displacements of shell structure are presented in Table 2.

It was also observed that the largest axial forces Nxx obtained from the numerical analysis were caused by backfill layer # 5 and they amounted to –3336 kN/m (Fig. 7). They were observed on additional ribs near the supports and 1/4 height of shell. The backfill depth was on level of the crown of the shell structure. During backfilling of the layer # 6 (over the crown shell) the axial forces Nxx were smaller and equalled to –2656 kN/m, which represents 80% value of axial force from layer # 5. In the remaining backfill layers (# 1–4), the axial forces were strongly reduced. For example, the first analysed backfill layer caused that the axial forces in the shell structure were on the level of –1088 kN/m. It constitutes only 33% of the axial force from layer # 5. The remaining maximum axial forces are shown in Table 3. It should be also mentioned that all maximum axial forces are compressive.

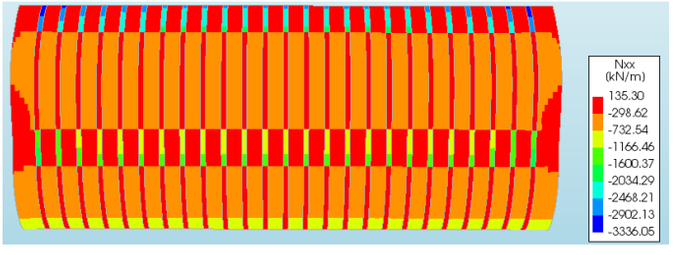

Figure 7. Maximum axial forces in shell structure during backfilling of layer # 5.

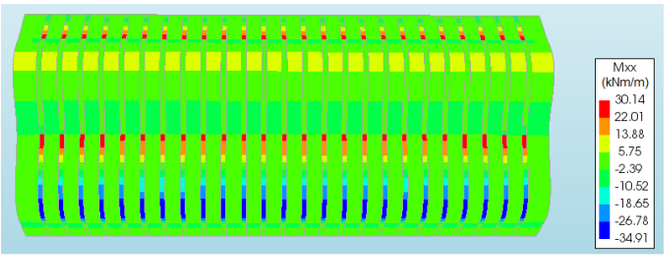
The highest bending moment amounted to Mxx = –34.91 kNm/m and it was observed during compacting backfill layer # 1 (Fig. 8). The maximum bending moments occurred at the additional ribs (at the 1/4 of its height) and the a little smaller values (ca. 31 kNm/m) at the shell crown. It means that at the beginning of the backfilling process the top of shell structure lifts up. Bending moments during backfilling of backfill layer # 5 do not exceed –29 kNm/m (Fig. 9a) which represents ca. 80% of the bending moment caused by backfill layer # 1. After completion of backfilling process (layer # 6 – Fig. 9b) the bending moments decrease to the level of –22 kNm/m which constitutes ca. 62% of the bending moment caused by first analysed backfill. The smallest bending moment occurred during backfilling of layers # 2–4, and they are not exceed –16 kNm/m. The difference between these layers was a few percent. Maximum results of bending moments are shown in Table 3.



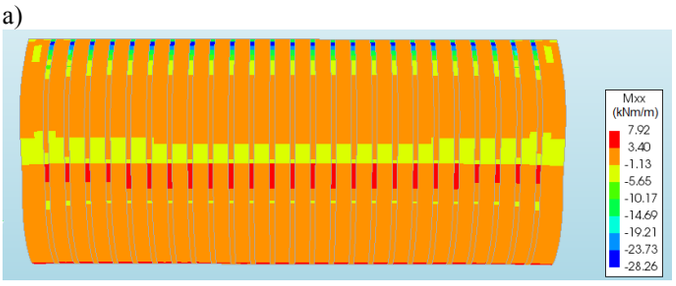


Figure 8. Maximum bending moments in shell structure caused by backfill layer # 1.

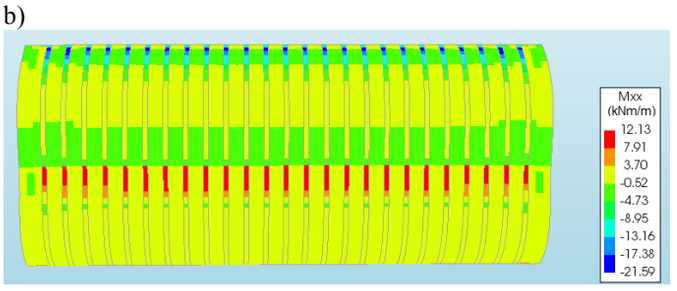
Table 3. Maximum results of axial forces, bending moments and stresses.

Backfill layers:	Axial forces Nxx (kN/m)	Bending moments Mxx (kNm/m)	Stresses Szz (MPa)
1	–1088	–34.91	–6.70
2	–1324	–11.26	–4.50
3	–1491.7	15.57	–5.67
4	–2037	–15.9	–7.58
5	–3336	–28.26	–11.20
6	–2656	–21.59	–10.10

a)

b)



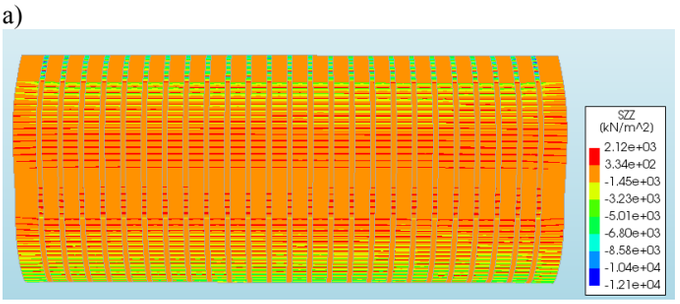


Figure 9. Maximum bending moments in shell structure during backfilling of layers: a) # 5 and b) # 6.

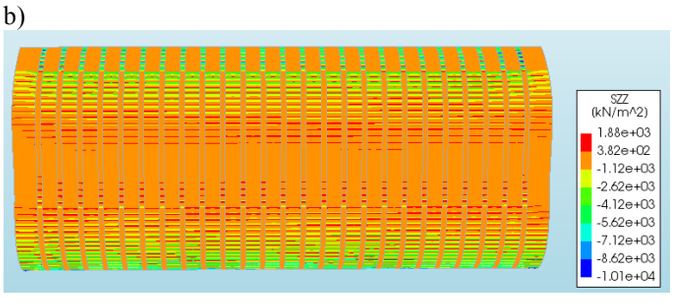
The highest stresses occurred similarly as the axial forces during compacting the backfill layer # 5 (Fig. 10a). Maximum values amounted to –11.20 MPa and they were located at additional ribs near the supports and at 1/4 height of shell. After finish of backfilling process (layer # 6), the stresses were slightly reduced (–10.10 MPa) and they were observed at in the quarter points (Fig. 10b). It is worth underlined that first three analysed backfill layers did not strongly affect on the level of stresses in the shell structure. The maximum stresses do not exceed –8 MPa during backfilling of these layers. It should be also added that all stresses are compressive and generally increases together with the backfill height (with except of layers # 2 and # 6). Maximum stresses of the shell structure are shown in Table 3.

a)

b)



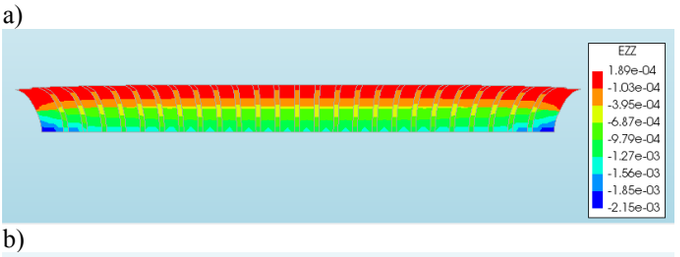


Figure 10. Maximum stresses in shell structure during backfilling of layers: a) # 5 and b) # 6.

Table 4. Maximum strains in shell structure obtained from numerical calculations and measurements.

Number of backfill layer:	Strains (10^{-6})		Differences (%)
	Calculation	Field test	
1	–709	–854	20.5
2	–818	–950	16.1
3	–908	–1005	10.7
4	–1220	–1359	11.4
5	–2150	–2256	4.9
6	–1590	–1690	6.3

It was also noted that the maximum strains in the CSP shell occurred during backfilling the layer # 5 (Fig. 11). Very similar strain maps of the shell structure were obtained for backfill layer # 6 (Fig. 12), while the values were a little smaller than those received from backfill # 5. In both cases, maximum values were observed near the support of shell and at 1/3 of shell height. The maximum strains obtained from numerical calculations and measurements are presented in Table 4. It should be underlined that the calculated values in all cases of backfill loading are smaller than those obtained from field test. However, they were occurred at the same sections of the shell structure. The largest differences were observed in the first backfill layer and they were about 20%. In the remaining layers, the differences were between a few and a dozen percent. This can be caused by some construction works, which had to done (not stopped during testing), for example the movement of vibratory plates.

6 CONCLUSION

Taking into account the numerical analysis and experimental tests, carried out on the soil-steel bridge during backfilling process the following general conclusions can be drawn:

– the highest axial force and stresses in the CSP shell structure occurred during backfilling of layer # 5 (backfill height was on the level of shell

crown). Maximum axial force was –3336 kN/m and highest stress was at the level of –11.20 MPa. They were observed on additional ribs near the supports and at 1/4 height of shell. Maximum axial forces and stresses were compressive.

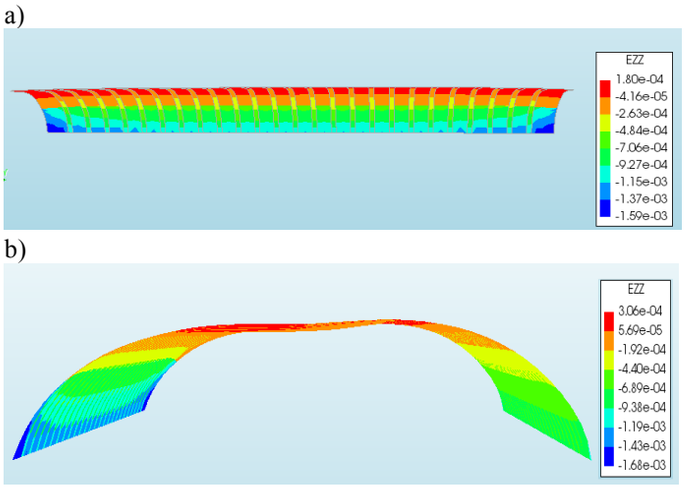

Figure 12. Maximum strains of CSP shell after completion of backfilling process (layer # 6) in section: a) longitudinal, and b) transversal.

– the greatest bending moments were caused by compaction of backfill layer # 1 (–34.91 kNm/m). In the results of the lateral soil pressure, the top of CSP shell structure lifts up. The maximum compressive bending moments occurred at the additional ribs (at the 1/4 of their height) and at shell crown.
– the maximum measured and calculated displacements were 29 mm and 20.5 mm, respectively. They were situated at the point # 11 (near the shell crown and at the end of structure). Generally, the highest displacements were observed at the structure ends during backfilling of layers # 5 and # 6 (shell was completely backfilled). The displacements obtained from the measurements and finite element analysis are generally quite close to each other.
– the maximum calculated and measured strains occurred during backfilling of the layer # 5 and they were observed near the support of shell and at 1/3 of shell height. The calculated strains in all cases of backfill loading are smaller than those obtained from the field test (maximum differences were ca. 20%). This can be caused by some construction works, which had to be carried out (works has not been stopped during testing), for example, the movement of vibratory plates.
– the observed differences between calculations and measurements would be probably smaller for more density of finite element mesh. At this stage of analysis, there was no need for the greater density of the finite elements because the obtained results are quite reasonable.

To provide more general conclusions, further analyses are needed for this type of structure. These analyses should be included the various type of backfill, various corrugation profiles, and modelling of the shell without using the additional stiffening ribs.

ABSTRACT: This paper describes an experimental study on retrofitting web-gap regions in steel girder bridges. The retrofit aims at reducing the stress concentrations at the intersection of connection plates and the web which can potentially be where distortion induced fatigue cracking initiates. In this study, a laboratory investigation was performed on a small-scale steel bridge bay under displacement-control vertical loading to simulate the differential deflection between two girders in actual bridges. A new method to retrofit the web-gap is proposed by modifying the existing slot-method by connecting the connection plate and web with steel angles on either side of the connection plate. The performance of the newly-developed retrofit technique, called the slot-angle technique, is compared with existing retrofit techniques. Results showed that the newly-developed slot-angle technique has significant potential for effectively reducing the stress concentrations in the web-gap region which by moving the location of the initial stress concentrations and potentially redistributing those stresses over a wider area.

1 INTRODUCTION

The design specification for steel bridges built in the United States prior to the mid-1980s discouraged welding of connection plates (CPs) to the tension flange to avoid cracking issues due to primary longitudinal stresses (Jajich and Schultz, 2003, Khalil et al., 1998).

The resulting flexible connection resulted in reducing the torsional resistance of bridge girder webs leading to stress concentrations in the unstiffened web-gap under out-of-plane forces. In many cases, these stress concentrations led to distortion-induced fatigue cracking after only a limited number of cycles. Several experimental studies (Hartman et al., 2013, Alemdar et al., 2013) and field-test measurements (Shifferaw and Fanous, 2013, Connor and Fisher, 2006, Tarries, 2002, Khalil et al., 1998) have been conducted to investigate distortion-induced fatigue cracking and to propose effective repair measures. However, selection of an appropriate repair strategy is complicated and depends on many factors (Alavi et al., 2017). A previous study (Lindquist et al., 2015) elaborated on one such case where girders developed web-gap cracking shortly after completion of a comprehensive seismic repair which consisted of replacing existing "K"-type diaphragms with much stiffer ×-type diaphragms. This repair resulted in increasing the web-gap stresses above the constant amplitude fatigue threshold (CAFT) and led to significant cracking (Motaleb et al., 2016). The current study shows that stresses in these regions can be mitigated with additional retrofit measures prior to the development of distortion-induced fatigue cracks. This paper examines the effectiveness of this newly developed web-gap retrofit method by comparing stresses with two existing and popular retrofit techniques.

This paper presents laboratory test results of three beams utilizing different web-gap retrofit techniques. The testing was performed on a small-scale steel bridge bay by applying a vertical displacement to the free end of a cross-frame diaphragm to simulate the differential deflection between two adjacent girders in bridges.

2 RETROFIT MEASURES

There are two retrofit options frequently used to reduce stress in web-gap regions including (1) increasing the stiffness of the web-gap region by providing a positive attachment between the CP and the longitudinal girder flanges, or (2) increasing the flexibility of the web-gap region in order to reduce the concentration of stresses. In this study, variations of these common retrofit techniques, along with an innovative strategy, are compared to measure effectiveness in reducing stress concentrations in the web-gap region.

The proposed retrofit technique consisted of a slot and an angle section connecting the disconnected

part of the CP to the web to reduce stresses by softening the web-gap region as well as distributing lateral forces, transferred by cross-frames, over a wider area of the web (slot-angle retrofit). This technique can be implemented to upgrade existing slot repairs that failed to sufficiently address distortion-induced fatigue cracking in the web-gap region. Two other common retrofit methods are also considered in this study so that the effectiveness of the newly developed technique can be compared with the most popular techniques. The first retrofit strategy provided a positive connection between the CP and the girder flange (referred to as the top-angle retrofit). The second retrofit created an 89-mm (3.5-in.) slot where approximately one-sixth of the CP depth is cut from the web (slot-retrofit) thereby softening the web-gap. The slot was created by cutting the stiffener while still providing enough room for handling the grinder. Thus, there was a thin part of stiffener (about 0.25 in.) that remained on the girder web. Figures 1 through 4 show the retrofit measures investigated in this paper. The main advantage of the slot-angle technique over top-angle option is that traffic interruption and lane closures are not necessary for implementation.

Fig. 1 – Instrumentation of Control beam

Fig. 2 – Instrumentation of Top-angle retrofit

Fig. 3 – Instrumentation of Slot retrofit

Fig. 4 – Instrumentation of Slot-angle retrofit

3 EXPERIMENTAL PROGRAM

A small steel bridge prototype consisting of a 1-m [3-ft] long standard hot-rolled W24×55 girder connected to a 0.2-m (8-in) thick 3.05 m × 2.13 m (10 ft. × 7 ft.) concrete deck was used for testing. The cross-frame consisted of 2 L2×2×¼ angles connected to a CP through a welded gusset plate, as shown in Figure 5.

The bottom flange of the beam was fixed to the deck using twelve A325 12.7 mm (5/8 in.) diameter structural bolts to simulate an inverse steel-concrete composite beam, as shown in Figure 6. The load was applied with a portable gantry crane used to apply a tension force through a load cell to the free end of the diaphragm. The loading system was intended to approximately simulate the differential deflection between two girders in actual bridges by applying a differential upward vertical displacement. All specimens were subjected to a deflection of approximately 20.3 mm (0.8 in). The system remained intact during the tests while the retrofit measures were implemented.

Fig. 5 – Test setup

Fig. 6 – Inverted steel-concrete beam

4 STRAIN GAGES LAYOUT

A total of eight strain gages were attached to the girder to measure the strain in this experimental study based on the predicted strain concentration locations before and after implementing the retrofit methods. A schematic view of the strain gage layout is shown in Figs. 7 and 8. The control beam was instrumented with three strain gages while gages 2 and 3 recorded the strains that originated 12.7 mm (0.5 in.) and 19.1 mm (0.75 in.) left of the stiffener where it intersects the web, as shown in Fig.7. Strain gage "a" was positioned on the opposite side of the stiffener 5.08 mm (0.2 in.) from the stiffener.

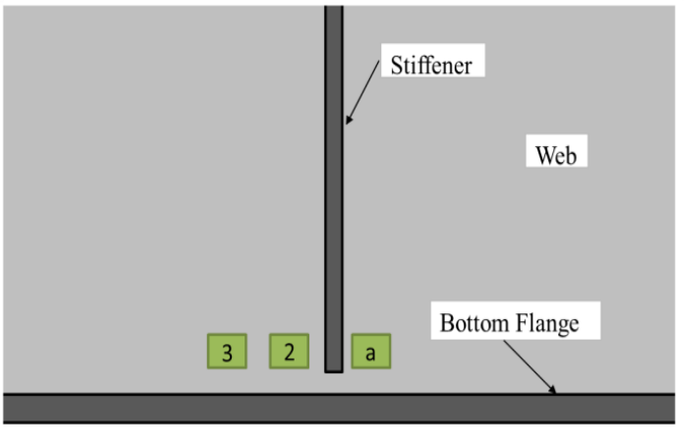

Fig. 7 – Starin gage layouts for control beam and top-angle retrofit

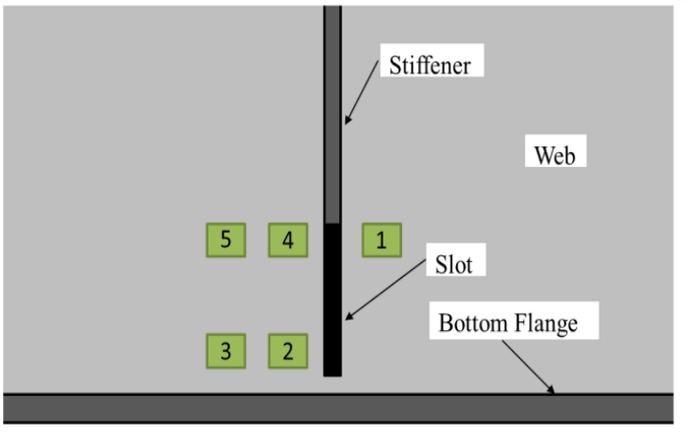

Fig. 8 – Strain gage layouts for slot retrofit and slot-angle retrofit method

5 EXPERIMENTAL RESULTS

Each strain gage provided three values for strain in three directions which was converted to a principal stress for each rosette gage. The principal strain was converted to stress using Hooke's law and a steel elastic modulus of 29,000 ksi. Each test was repeated three times to ensure consistency, and the results for each test are summarized in Table 1. The stresses reported in this table correspond to the strain readings for the control and retrofitted beams under a 20.3 mm (0.8 in.) differential deflection. Various reductions in the elastic stresses were observed with respect to the control beam which varied between 14.8% and 62.0%. An L2×2×1/8 angle was first used to connect the CP to the flange using two bolts on each leg. The top-angle option showed the lowest reduction among the investigated options as it decreased the stresses from 14.8% to 16.8%. The slot technique reduced the stress in the original web-gap region by 62.0% and stress at the new CP-web intersection did not exceed 100 MPa (14.5 ksi) – far below the stress range in the control beam. The slot-angle retrofit method experienced 137 MPa (19.8 ksi) which corresponds to a 44.4% reduction compared to the control.

Table 1 – Laboratory test results

Web-gap stress (MPa) corresponding to 20.3 mm (0.8 in.) deflection							
Gase#	Control	Top-angle (units)	Reduction (%)	Slot	Reduction (%)	Slot -angle	Reduction (%)
a	272	226	***-16.8***				
1				88.3		43.5	
2	246	203	***-17.4***	93.8	***-62.0***	137	***-44.4***
3	206	175	***-14.8***	86.9	***-57.8***	123	***-40.4***
4				100		60.3	
5				95.1		61.1	
Distortion $x10^{-3}$ (mm)	40.6	115		11.8		28.7	

6 CONCLUSIONS

In this study, a method to retrofit web-gap distortion and upgrade existing retrofits was introduced. The effectiveness of the proposed technique is compared with two other common retrofit techniques. This study was based on structural tests performed on a small portion of a bridge designed to simulate the actual condition presented in the field. The slot retrofit option removed the stress concentrations from the CP ending and introduced new stress concentrations at the slot termination, while in terms of the magnitude, the highest stresses are not as large as for the control beam. On the other hand, results from the newly-developed slot-angle technique has significant potential for effectively reducing stress concentrations in the web-gap region by eliminating the location of initial stress concentrations and potentially redistributing those stresses over a wider area. The slot-angle method does not require disruption to the concrete deck and consequently does not disrupte traffic flow. This technique can also be used to upgrade slot retrofits already implemented if they are ineffective.

Investigation of live load deflection limit for steel cable stayed and suspension bridges

E.-S. Hwang & D.-Y. Kim
Kyung Hee University, Yongin, Korea
K.J. Park
Department of Structural Engineering, Yooshin Engineering Corporation, Korea

ABSTRACT: Sea-crossing bridges connect islands to secure the sea and road traffic in the area. For the construction of sea-crossing bridges, bridge engineers should plan to secure the safety of large ships passing under the bridge. In particular, clearance of cable-stayed bridges and suspension bridges is determined considering the height of the ship master from the surface of the water, the trim of the ship, the psychological free space, the tide height, and live load deflection. Of these, bridge engineers should calculate the deflection of bridges by live loads. The purpose of this study is to investigate the suitability of live load deflection limit for cable-stayed and suspension bridges over main span length of 200m. For the design of long span cable stayed and suspension bridges, limitations are L/400 and L/350 respectively in the Korean Bridge Design Code (2010) and Korean Bridge Design Code (LSD) (MLIT, 2015). Saadeghvaziri (2012) also suggested deflection limit based on natural frequency, acceleration limit of 0.5 m/s^2 and vehicle speed. In this study, the theoretical analysis of Yi Sun-Sin grand bridge (suspension bridge, main span length=1,545m) and Young-Hung grand bridge (cable stayed bridge, main span length=240m) were carried out and compared with these limits. The results of the study on the limitation of live load deflection are expected to be useful reference for the design, the proper planning and deflection review of the long span bridges around the world.

1 INTRODUCTION

1.1 *Backgrounds and objective of this study*

Sea-crossing bridges are being constructed to connect islands to secure the sea and road traffic in the area. They are also being constructed for the purpose of bypassing the center of a complex port city. For the construction of sea crossing bridges, bridge engineers should plan the vertical profile to secure the safety of large ships passing under the bridge. Clearance of cable-stayed bridges and suspension bridges is determined considering the height of the ship master from the surface of the water, the trim of the ship, the psychological free space, the tide height, and live load deflection, as shown in Figure 1.

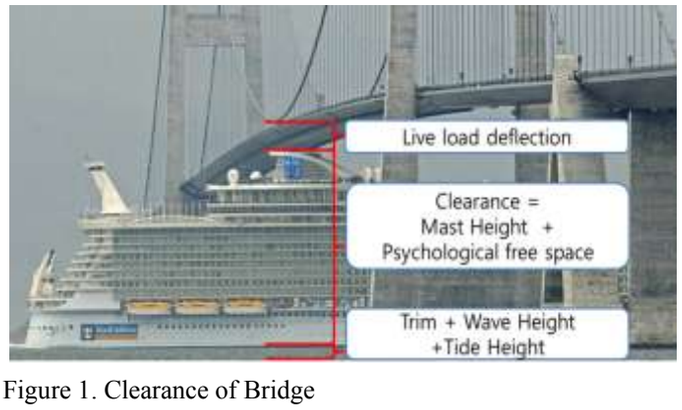

Figure 1. Clearance of Bridge

In line with the worldwide trend of constructing longer and slender bridges, limiting live load deflection becomes more important issue for the safety and serviceability of bridges. In design codes for long span bridges, there is no consensus on the deflection or vibration criteria even though L/400 and L/350 are specified in Korean Bridge Design Code (LSD) (MLIT, 2015), respectively for cable stayed and suspension bridges.

On Oct. 26, 2014, traffic on the Yi Sun-Sin Grand Bridge, a suspension bridge located in Korea, was controlled due to the civil complaint against the vibration of the bridge. Later, it was found out that the amplitude of the vertical acceleration was increased by 20 to 30% and the frequency of the vibration was changed from 0.1171 Hz (the 1st vertical mode) to 0.3173 Hz (the 4th vertical symmetrical mode). The deflection was not increased. the vibration was related with the changes of the relations between displacement amplitude and natural frequency.

The purpose of this study is to investigate the suitability of live load deflection limit for cable-stayed and suspension bridges over main span length of 200m. Since the new live load model is adopted in Korea Bridge Design Code (Limit State Design) (MLIT, 2015), it is necessary to make a comparison between old live load model (DB24, DL24) in Korea

Bridge Design Code (MLTM, 2010) and new live load model (KL-510) in Korea Bridge Design Code (Limit State Design)(MLIT, 2015). Results are compared with deflection limit in the code and equation proposed by Saadeghvaziri. For this study, two long span bridges (a suspension bridge with the main span length of 1,545m and a cable stayed bridge with the main span length of 240m) are analyzed.

1.2 *Literature review*

In this section, the design criteria in various codes, human comfort criteria and previous researches on deflection and/or vibration serviceability are reviewed.

1.2.1 *Deflection Limits in Design Codes*

Deflection limits for road bridges were first introduced by AASHTO for the purpose of controlling the vibration using the span ratio. However, these limits were found to have insufficient technical foundations (ASCE, 1958). In order to supplement such technical inefficiency, the Ontario Highway Bridge Design Code (OHBDC, 1983) and the Canadian Code (CSA, 1990) adjusted deflection limits based on the natural frequency. However, these criteria are specifically for short to medium span bridges and cannot be applied to long span bridges. Korea Bridge Design Code (Limit State Design) (MLIT, 2015) describes the optional deflection limit for short to medium span bridges as 1/800~1/1200 of the bridge spans. The deflections are calculated as the larger value of standard truck load only and the combination of 25% of the standard truck load and the standard lane load. In the commentary of the code, the limits of the span ratio are 1/400 for cable-stayed bridges, 1/350 for suspension bridges, and 1/600 for other types of bridges.

1.2.2 *Human comfort criteria and other studies on vibration assessment*

Diverse studies have been carried out across the world on displacement and vibration in order to ensure vibration serviceability. In 1931, Reiher and Meister(1931) suggested a vibration response curve following the natural frequency. Postlethwaite(1944) suggested acceleration limits of 0.03g for a natural frequency level below 1Hz. Acceleration and displacement amplitude limits dictated by the natural frequency were studied by Goldman(1948) and by Wright and Green(1964). Wright and Walker(1971) proposed a new design method that defined the acceleration limits as 100 in/sec^2 based on reflecting the static deflection, the natural frequency, and vehicle speed. Recently Barker (2011) developed an approximate relationship based on a graph of the "Approximate & Actual Deflection vs. 1st Natural Frequency Log-Log Axis" as a way of supplementing the deflection limitation of OHBDC, which does not include any formulas. Saadeghvaziri et al. (2012) suggested deflection limit standards calculated based on the natural frequency in terms of a formula that defines the relationship between speed coefficient, deflection, and acceleration. Their formula was found to generate similar values to the deflection limits for bridge span ratios of 1/1000 suggested by AASHTO.

Most studies of vibration serviceability for long span bridges are limited to deflection and vibration limits, which require displacement and acceleration vibration amplitudes calculated during lab tests or structural analysis. There are not a sufficient number of experimental studies on the vibration serviceability of bridges that have frequencies below 1Hz like steel cable-stayed bridge (Hwang et al., 2014).

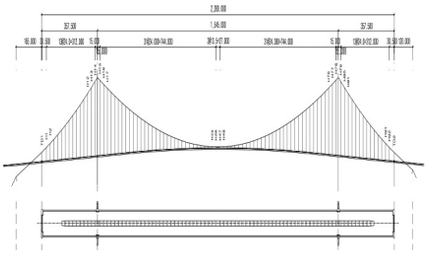
2 EXAMPLE BRIDGES

2.1 *Yi Sun-Sin Grand Bridge*

For the purpose of this study, two steel cable bridge are selected for the analysis. Yi Sun-Sin Grand Bridge is the longest suspension bridge in Korea with the main span length of 1,545 m. It connects Gwangyang city to Yeosu Industrial Complex. It has steel decks and steel box girders as shown in Figure 2(a). The longitudinal cross section of Yi Sun-Sin Grand Bridge is shown in Figure 2(b). The box girder cross section of Yi Sun-Sin Grand Bridge is shown in Figure 2(c).

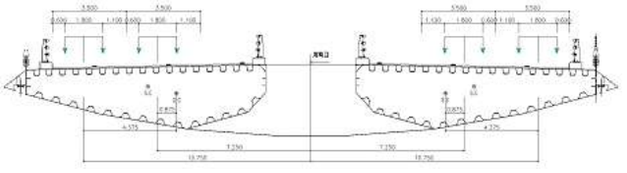
2.2 *Young-Hung Grand Bridge*

Another bridge is Young-Hung Grand Bridge which is a cable-stayed bridge with the main span length of 240m, as shown in Figure 3(a). This bridge connects YoungHung island with SunJae island that is part of Incheon City. The longitudinal cross section of Young-Hung Grand Bridge is shown in Figure 3(b). The box girder cross section of Young-Hung Grand Bridge is shown in Figure 3(c).



3 STRUCTURAL MODELING AND ANALYSIS

3.1 *Structural modeling of example bridges*



Structural analysis was carried out to examine deflection limits for example bridges.

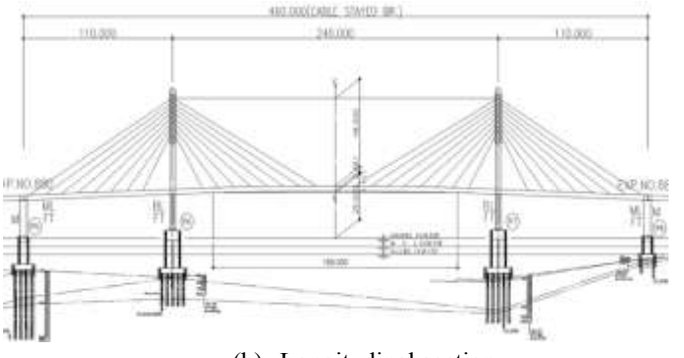
(a) Yi Sun-Sin Grand Bridge (Suspension Bridge)

(b) Longitudinal section

(c) Cross section

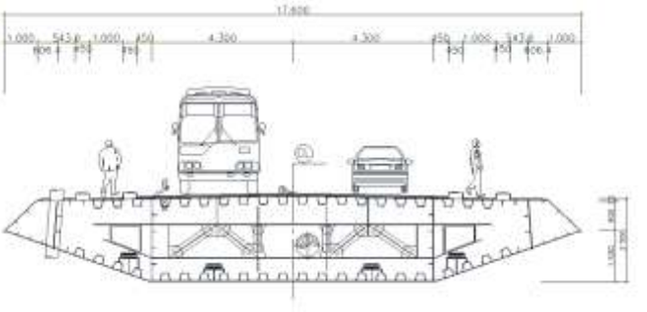
Figure 2. Example Suspension Bridge

Yi Sun-Sin Grand Bridge is modeled by RM Bridge V8i, as shown in Figure 4(a). Young-Hung grand bridge is modeled by MIDAS CIVIL 2012 LSD V300, The FE model for structural analysis of the test bridge was composed of 274 nodes and 248 elements as shown in Figure 4(b). The steel girders and steel pylons are modelled with beam elements, and cable is modelled with truss (tension only) elements.



3.2 *Live load model*

Live load model for the calculation of deflection of the bridges includes DB24/DL24 model in Korea Bridge Design Code (MLTM, 2010), as shown in Figure 5(a) and (b). KL-510 model in Korea Bridge Design Code (Limit State Design) (MLIT, 2015), are shown in Figure 5(c) and (d).



In DB/DL model, design deflections are selected as the larger deflection of DB24 and DL24. For long span bridges, DL24 usually produce larger deflection.

(a) Young-Hung Grand Bridge (Cable-Stayed Bridge)

(b) Longitudinal section

(c) Cross section

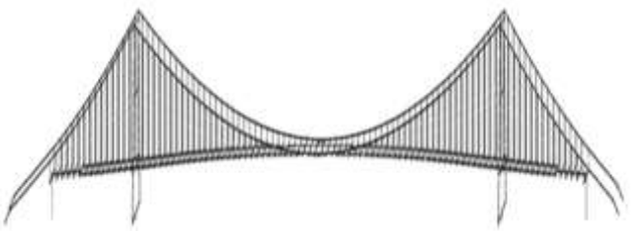


Figure 3. Example Cable-Stayed Bridge

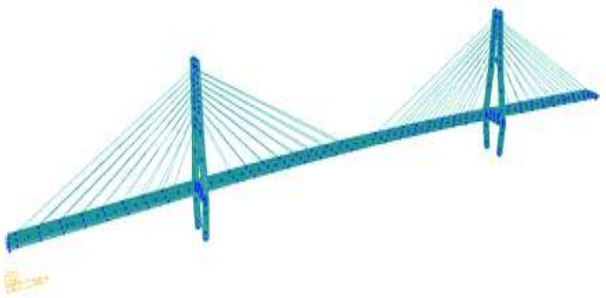
In KL-510 model, design deflections are selected as the larger deflection of KL-510 standard truck load and standard lane load combined with 25% of standard truck load.



4 ANALYSIS RESULTS AND COMPARISON

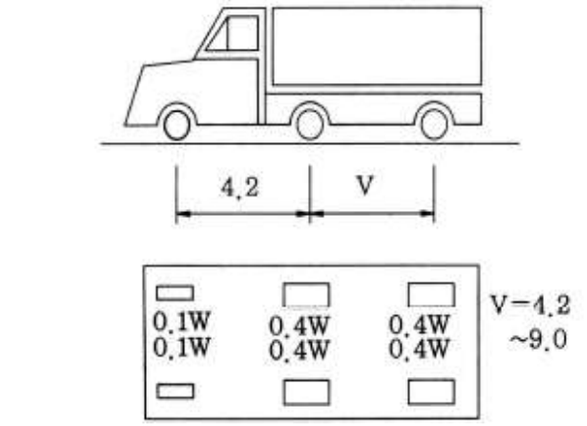
4.1 *Deflections*

Deflections for the long span cable bridges are calculated based on the influence line of the bridge. Figure 6 shows the influence line for deflection at midspan of the main span. The maximum deflections at each section of Yi Sun-Sin grand bridge by DL24 and KL-510 model is shown in Figure 7. As shown in the figure, the maximum deflection does not occur at midspan.

(a)FE model of Yi Sun-Sin grand bridge

(b) FE model of Young-Hung grand bridge

Figure 4. FE model of example bridges



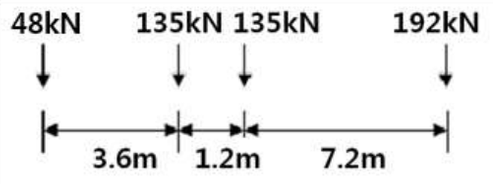
For example, in case of Yi Sun-Sin grand bridge, maximum deflection of center span is 3.448 m but deflection at midspan of center span is 2.759 m. Maximum deflections at center span of each bridge by two design live load models are shown in Table 1.

For Yi Sun-Sin grand bridge, maximum deflections at center span are 3.877 m by DL24 and 3.448 m by KL-510. For Young Hung grand bridge, deflections at midspan are 0.302 m by DL24 and 0.242 m by KL-510. Deflections by KL-510 shows smaller values than by DL24.

4.2 *Natural frequencies*

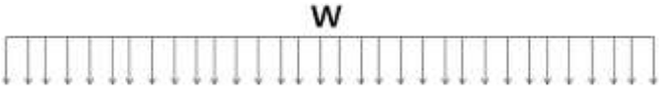
From the structural modeling, natural frequencies of each bridge are also calculated. Figure 8 shows the mode shapes of the first vertical natural frequency. The first natural frequency of the vertical mode is 0.113Hz and 0.435Hz for Yi Sun-Sin Grand Bridge and Young Hung Grand Bridge, respectively. Natural frequency of the bridge is an important parameter since some code (CSA, 2000) specify the dynamic load allowance or impact factors as the function of the natural frequency. ISO2631-2(1989) and some other passenger comfort criteria specify the displacement or acceleration limit as the function of the natural frequency also.

Some researchers (Saadeghvaziri (2012), Irwin(1978)) suggested the deflection/vibration limit as the function of the natural frequency of the bridge. In this study, the criteria suggested by Saadeghvaziri are used and explained below.



W=240kN

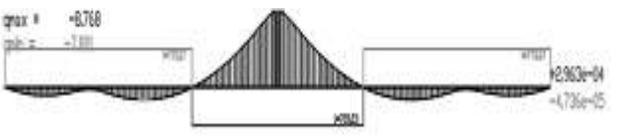
(a) DB24 truck load



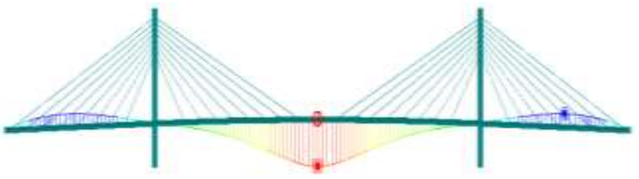
W=12.7kN/m, Ps=156kN, Pm=108kN

(b) DL24 lane load

(c) KL-510 Standard truck load



L≤60m; W=12.7 (kN/m),



L>60m; $W=12.7\times(\frac{60}{L})^{0.10}$ (kN/m), L=Span length

(d) KL-510 Standard lane load

Figure 5. Live load models

(b) Young Hung grand bridge (Park & Hwang, 2016)

Figure 8. Mode shape corresponding to the first vertical natural mode

4.3 *Comparison with deflection limit*

Deflection limits in Korean codes are L/400 and L/350 for cable-stayed and suspension bridges, respectively. Another deflection limits are proposed by Saadeghvaziri (2012), as shown in Eq. (1) and Eq. (2).

$$\delta_{limit} = \frac{A_{max}}{(2\pi f)^2 \times 1.2\alpha} \quad (1)$$

$$\alpha = V/2Lf \quad (2)$$

In this equation, A_{max}, the acceleration limits of the girder are 0.5 m/s^2 and 1.0 m/s^2. The design speed(V) are 60km/h, 80km/h, 100km/h. α is the speed coefficient as shown in Eq. (2), L is main span length, and f is the primary natural frequency for vertical direction. Deflection limits proposed by Saadeghvaziri (2012) of Yi Sun- Sin grand bridge is shown in Figure9 and Table 1. Deflection limits proposed by Saadeghvaziri (2012) of Young-Hung grand bridge is shown in Figure10 and Table 2.

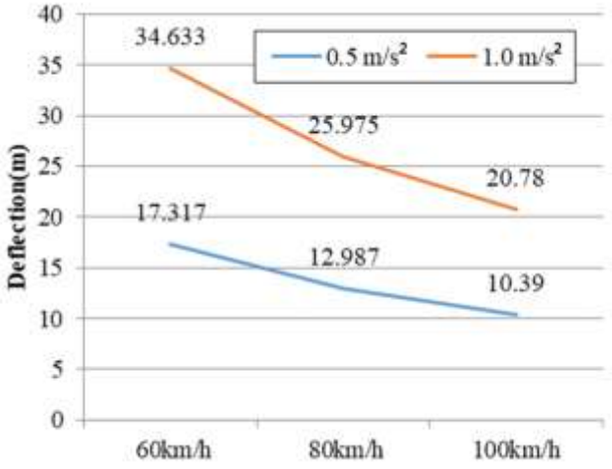

Figure 9. Deflection limits proposed by Saadeghvaziri (2012) of Yi Sun- Sin grand bridge

Table 1. Deflection limits proposed by Saadeghvaziri (2012) of Yi Sun- Sin grand bridge

A_{max}	0.5 m/s^2	1.0 m/s^2
Deflection under 60km/h (m)	17.317	34.633
Deflection under 80km/h (m)	12.987	25.975
Deflection under 100km/h (m)	10.390	20.780

Both Yi Sun- Sin grand bridge and Young-Hung grand bridge are designed as 0.5 m/s^2 with 60km/h. By the equation, deflection limits proposed by Saadeghvaziri (2012) on 0.5 m/s^2 with 60km/h for Yi Sun-Sin and Young Hung grand bridge are 17.317m and 0.699m, respectively and are shown in Table 3.

Calculated deflections and design limits are summarized in Table 3 and Figure 11 for both example bridges. Deflections by both live load model satisfy all limit or criteria. However, deflection limit by Saadeghvaziri is very large compared to other criteria and this criterion may not be suitable for very long span bridges.

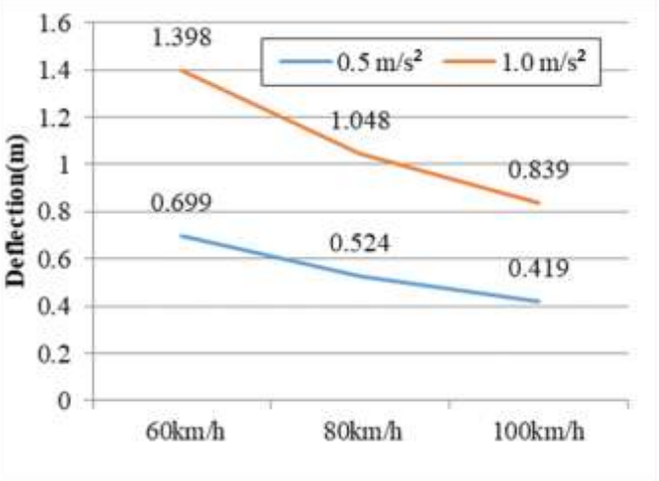

Figure 10. Deflection limits proposed by Saadeghvaziri (2012) of Young-Hung grand bridge

Table 2. Deflection limits proposed by Saadeghvaziri (2012) of Young-Hung grand bridge

A_{max}	0.5 m/s^2	1.0 m/s^2
Deflection under 60km/h (m)	0.699	1.398
Deflection under 80km/h (m)	0.524	1.048
Deflection under 100km/h (m)	0.419	0.839

Table 3. Natural Frequency and Live Load Deflection of example bridges

Bridge	Yi Sun- Sin grand bridge	Young-Hung grand bridge
Structural type	Suspension bridge	Cable-Stayed bridge
Main Span Length(m)	1,545	240
First Vertical Natural Frequency (Hz)	0.113	0.435
Deflection by DL24 (m)	3.877	0.302
Deflection by KL-510 (m)	3.448	0.242
Deflection limit in the code (m)	4.414 (L/350)	0.600 (L/400)
Deflection limit proposed by Saadeghvaziri under 0.5 m/s^2 with 60km/h(m)	17.317	0.699

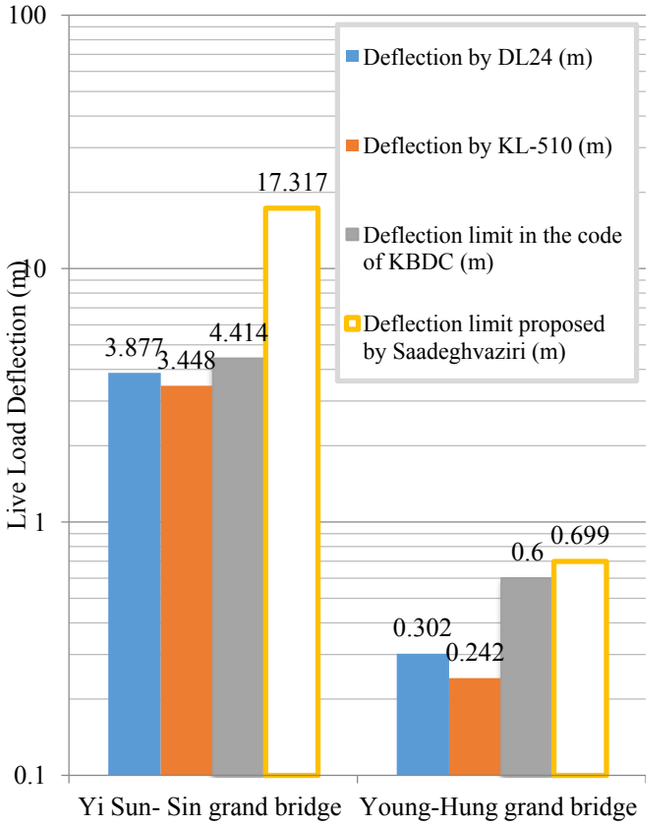

Figure 11. Comparison of Live load deflection and limitation of live load

Table 4. Ratio of Deflection limit proposed by Saadeghvaziri for Yi Sun-Sin grand bridge

Bridge	Yi Sun- Sin grand bridge	Ratio of Deflection limit proposed by Saadeghvaziri
Deflection by DL24 (m)	3.877	22.4%
Deflection by KL-510 (m)	3.448	19.9%
Deflection limit in the code (m)	4.414 (L/350)	25.5%
Deflection limit proposed by Saadeghvaziri under 0.5 m/s^2 with 60km/h(m)	17.317	100.0%

Table 5. Ratio of Deflection limit proposed by Saadeghvaziri for Young-Hung grand bridge

Bridge	Young-Hung grand bridge	Ratio of Deflection limit proposed by Saadeghvaziri
Deflection by DL24 (m)	0.302	43.2%
Deflection by KL-510 (m)	0.242	34.6%
Deflection limit in the code (m)	0.600 (L/400)	85.8%
Deflection limit proposed by Saadeghvaziri under 0.5 m/s^2 with 60km/h(m)	0.699	100.0%

4.4 *Ratio of the deflection limit proposed equation*

Ratio of deflection limit proposed by Saadeghvaziri on Yi Sun-Sin grand bridge for Deflection by DL24, Deflection by KL-510 and Deflection limit in the code are 22.4%, 19.9% and 25.5%, respectively and are shown in Table 4.

Ratio of deflection limit proposed by Saadeghvaziri on Young-Hung grand bridge for Deflection by DL24, Deflection by KL-510 and Deflection limit in the code are 43.2%, 34.6% and 85.8%, respectively and are shown in Table 5.

Deflection limit are proposed by Saadeghvaziri (2012) may not be suitable for very long span bridges like Yi Sun Sin grand bridge.

5 CONCLUSION

Deflection of the sea-crossing bridges by live loads is very important since it controls the clearance and the overall elevation of the bridge. It also controls the passenger or pedestrian comfort criteria. In this study, the theoretical analysis of long span suspension and cable stayed bridge are performed to investigate the live load deflection limit specified in the code. Two live load models (DL24 and KL-510) are used. Other deflection limit based on the natural frequency is also investigated. Following conclusions can be made based on results of this study:

1) For example bridges, deflection by live load model satisfies deflection limit specified in the code, which is the function of the span length.

2) Deflections by two live load models, namely DL24 and KL-510, show similar values but KL-510 gives smaller deflections.

3) The example bridges satisfy deflection limits suggested by Saadeghvaziri, which is based on the natural frequency of the bridge. This limit shows larger limits than the code values, but for very long span bridge such as Yi Sun-Sin grand bridge, the limit is too generous.

Further researches are required to find the optimum deflection or vibration criteria for long span bridge and their effects on bridge clearance and elevation. Also many other long span bridges should be considered in the analysis.

ABSTRACT: Fatigue cracking in steel highway bridges presents major safety and maintenance concerns for bridge owners: if bridges are not regularly inspected and maintained, fatigue cracks can lead to structural failure. It is of key importance to detect and assess fatigue crack activity in steel bridges in a timely and holistic manner. This study presents a novel strain sensing technology for fatigue crack monitoring based on soft elastomeric capacitors (SECs). SECs are inexpensive, easy to fabricate, highly stretchable, and mechanically robust capacitance-based strain gauges. Additionally, SECs are a highly-scalable technology, capable of monitoring deformations over a much larger area than can be achieved with traditional metal foil strain gauges. This characteristic enables SECs to be applied over and around entire fatigue details in steel bridges to detect, localize, and monitor fatigue cracks. Here, we first review previous experimental work using the SEC as a crack monitoring device for in-plane fatigue crack detection on small-scale compact, C(T), specimens. Then, we extend the SEC technology for sensing fatigue damage in a large-scale structural surface through dense SEC arrays. An effective data visualization method is proposed to convert a fatigue damage feature, termed crack growth index (*CGI*), from individual SECs to a 2-dimensional *CGI* map, which depicts the fatigue damage over a large-scale area. It is possible to monitor fatigue damage evolution by observing the change in intensity in *CGI* maps during the fatigue test. The effectiveness of this approach was validated through an experimental test on a bridge girder-to-cross-frame connection subjected to out-of-plane fatigue loading. Overall, the results of this study indicate that the SEC technology has great potential for detecting and monitoring fatigue crack growth in practical applications.

1 INTRODUCTION

Fatigue cracking in steel highway bridges presents major safety and maintenance concerns for bridge owners. If bridges are not regularly inspected and maintained, fatigue cracks can lead to structural failure. According to a recently released report by the American Society of Civil Engineering (ASCE) in 2017 (ASCE 2017), 9.1% of the 614,387 bridges in the United States are structurally deficient. Significant maintenance or retrofitting can be expected to be required for these bridges due to deterioration or damage occurring in load-carrying structural members. Currently, bridge owners in the United States such as state departments of transportation (DOTs) generally rely on visual inspections at typical two-year intervals (Phares et al. 2001). However, due to variations in inspector interpretation of inspection results, objective evaluations of fatigue cracks are not guaranteed (Zhao & Haldar 1996).

Many advanced sensing technologies have been proposed for detecting and/or monitoring fatigue cracks in domains of both structural health monitoring (SHM) and non-destructive evaluation (NDE) over the past decades. Examples include: piezoelectric actuators (Ihn & Chang 2004), lamb wave (Staszewski et al. 2007), digital image correlation (DIC) technology (Poncelet et al. 2010), machine vision method (Kong & Li 2018), laser lock-in thermography (An et al. 2014), impulse response method (Keller el al. 2017), and others. However, these methods may require extensive efforts in sensor deployment, human operation, and signal processing, which may present significant practical challenges for detecting and monitoring fatigue cracks in steel bridges.

Recently, novel large-scale strain sensing technologies have shown potential as a cost-effective solution for monitoring structural damage. Sharing the same feature of large-scale sensing, several types of sensors have been reported in the literature including: resistance-based sensing sheets (Yao & Glisic 2015), carbon nanotube-based sensors (Kang et al. 2014), antenna sensors (Mohammad & Huang 2010), and soft elastomeric capacitors (SECs) (Laflamme et al. 2012). In particular, the SEC technology, previously developed by the authors, is a large-scale flexible strain gauge, capable of sensing up to 20% strain (Laflamme et al. 2013) over a large area (e.g. typical research on the SEC used 63.5 mm by 63.5 mm area sensors). The SEC is mechanically-robust and suitable for long-term monitoring. Our previous research established a numerical method to predict the SEC's response under fatigue crack growth (Kong et al. 2016), and experimentally validated the SEC's performance for sensing in-plane fatigue cracks on small-scale compact, C(T), specimens (Kong et al. 2017b, Kharroub et al. 2017a, Kong et al. 2017b).2015).

To extend the SEC fatigue sensing technology from small-scale specimens to realistic large-scale structural components, a challenge must be overcome: detecting fatigue cracks over a large fatigue-susceptible region without prior knowledge of the locations of crack initiation and propagation paths. One solution is to deploy multiple SECs in the form of dense sensor arrays over a structural surface to greatly increase the chance of capturing fatigue damage over the large area.

In this article, we describe a deployment of dense SEC arrays on a bridge girder-to-cross-frame connection subjected to out-of-plane distortion induced fatigue in the girder web gap regions (the region near the web to flange connection, when the connection plate is not attached to the flange). Fatigue damage in web gap regions commonly exists in many aged steel bridges in the United States, and hence are of primary concern to state DOTs. A sensing algorithm was formulated to extract fatigue damage feature, termed crack growth index (*CGI*), from each individual SEC in the sensor arrays. Then a data visualization method is created to convert the extracted *CGIs* into a 2-dimensional *CGI* map, depicting the fatigue damage over a large structural surface. More importantly, the fatigue crack growth can be identified through monitoring the change in intensity from a series of *CGI* maps during the fatigue test. The results in this article form the basis for applying the SEC technology in field sensing of fatigue cracks in steel bridges.

The rest of this article is organized as follows: Section 2 begins with an introduction of the SEC technology and its sensing principle, followed by a review of previous SEC-based experimental work on in-plane fatigue crack detection; Section 3 describes the experimental methodology and test setup, the algorithm for constructing the *CGI* map, and the test procedure; Section 4 summarizes conclusions.

2. BACKGROUND

2.1 Soft elastomeric capacitor

The sensing principle of the SEC has been reported in Laflamme et al. (2012). A brief summary is provided here. Shown in Figure 1*a*, the SEC is a flexible capacitor comprised of a dielectric layer sandwiched between two conductive layers. Equation 1 describes the SEC's sensing principle, where C is the capacitance of the SEC; ε_0 and ε_r are the permittivity of air and the dielectric, respectively; l, w and h are the length, width, and thickness of the SEC as denoted in Figure 1*b*.

The SEC can serve as a large-area strain gauge (Figure 1*a*). Variations in surface strains on the monitored structure induce changes in the geometric dimensions of the SEC (i.e. l, w, and h), leading to a capacitance change C of the SEC according to Equation 1. The capacitance C can be measured through two copper tapes attached on the top and bottom conductive layers (Figure 1*b*). A photograph of the SEC is shown in Figure 1*c*.

$$C = \frac{\varepsilon_0 \varepsilon_r l w}{h} \tag{1}$$

2.2 SEC-based in-plane fatigue crack detection

Use of the SEC for detecting in-plane fatigue cracks has been previously investigated in Kong et al. (2017a, 2017b). A brief summary of the experimental results is described here. Figure 2 shows the test setup using a steel compact, C(T), specimen. The dimensions of the specimen are presented in Figure 2*e* where the thickness of the specimen is 6.35 mm. As shown in Figure 2*b*, the C(T) specimen was installed in a closed-loop servo-hydraulic universal test frame (Instron model 1334) via two clevises. Two adhesive measuring tapes were attached to the specimen for visually identifying the crack growth. On the other side of the specimen, an SEC was adhered using JB-weld epoxy (Figure 2*d*). An off-the-shelf DAQ system (ACAM PCAP02) was used to collect capacitance data from the SEC, as shown in Figure 2*a* and 2*e*.

Both the applied load and the SEC's response were collected during the test as the crack propagated to different lengths, visually identified using the adhesive measuring tapes. Then, the fatigue damage features, termed the crack growth index (*CGI*), were extracted from the measurements as a robust indicator of crack growth. As demonstrated in Figure 3, an increasing trend of *CGI* was observed when the crack propagated. This indicates that as a single sensing unit, the SEC can detect and monitor the fatigue crack growth in a small-scale specimen. More discussions on this test including the loading protocol can be found in Kong et al. (2017b).

3. METHODOLOGY

This section introduces the test setup, test procedure, and the approach used to extract fatigue damage over a large-scale structural area using dense SEC arrays. Due to space limitations, the test procedure for the top portion of the connection (the top web gap) is presented in this section.

3.1 Test setup

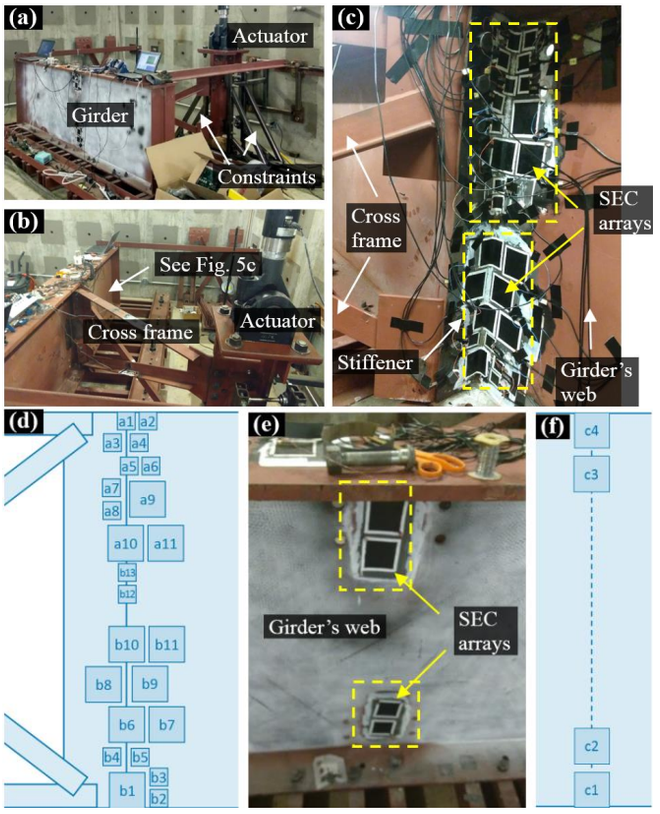

Figure 4. (a) Exterior view of the test model; (b) interior view of the test model; (c) SEC arrays and (d) sensor layout at the interior side of the connection; and (e) SEC arrays and (f) sensor layout at the exterior side of the connection.

The test setup includes three components: 1) the test model; 2) the loading system; and 3) dense SEC arrays. The test model is a bridge girder-to-cross-frame connection as shown in Figure 4*a* and 4*b*. The bridge girder was mounted upside-down on the floor and a cross frame was connected to the girder through a connection plate as shown in Figure 4*c*. The connection plate was only welded to the girder web while the top and bottom of the connection plate were not attached to the flanges. This configuration mimics typical connection details in many aged steel bridges in the United States. Detailed discussion on this connection detail can be found in Yu et al. (2017). By testing the girder upside-down, the restraint offered to the bottom flange by the laboratory strong floor simulated the restraint provided to the top flange of a bridge girder by the laterally-stiff deck.

Cyclic fatigue loading was applied through the actuator attached at the far end of the cross frame (Figure 4*a* and 4*b*). Load cycles were applied at a frequency of 0.5 Hz with a load range of -4.9 kN to 4.9 kN. To prevent out-of-plane movement of the cross frame when applying the load cycles, additional lateral constraints were added so that only vertical movement would occur at the cross frame, as illustrated in Figure 4*a*.

Figure 4*c* shows the arrangement of the dense SEC arrays at the top and bottom web gaps, where two sizes of SECs were used, including large SECs (63.5 x 63.5 mm), and small SECs (25.4 x 25.4 mm). A total of 24 SECs were deployed over the interior side of the connection. On the exterior side of the connection, 4 SECs were attached in the top and bottom web gaps, respectively (Figure 4*e*). Figure 4*d* and 4*f* show the layout and the sensor labels for the SEC arrays.

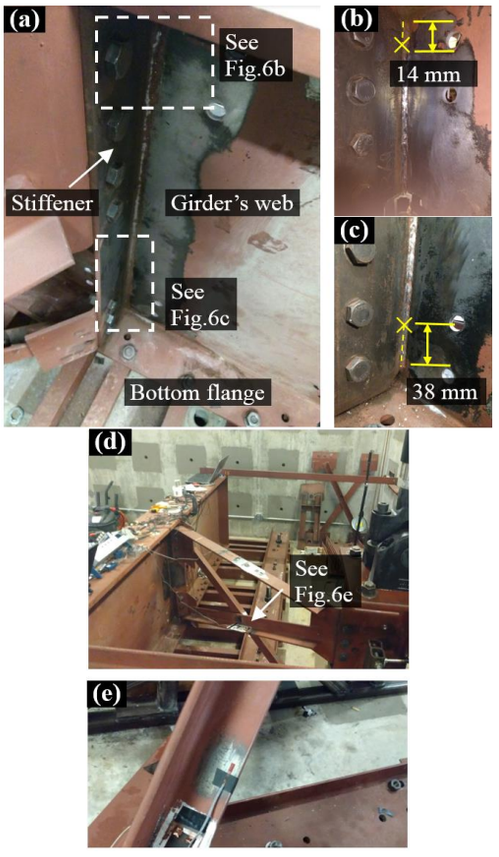

Figure 5. (a) Test model prior to sensor deployment; (b) an existing fatigue crack at the top web gap; (c) an existing fatigue crack at the bottom web gap; (d) and (e) a strain gauge was deployed on a diagonal member of the cross frame.

Prior to installation of the SEC arrays, the test model had been loaded with 2.7 million cycles using a load range of 0 to 11.2 kN. Two out-of-plane fatigue cracks had generated between the connection plate and web as shown in Figure 5*a*, *b*, and *c*. The top

fatigue crack was approximately 14 mm (Figure 5*b*) long, while the bottom fatigue crack was about 38 mm (Figure 5*c*) long. The tips of the fatigue cracks are denoted using a yellow "x" in Figure 5*b* and *c*.

In field applications, the load magnitudes caused by traffic may not be always known. One solution to deal with this challenge is to deploy strain gauges along the load path to indirectly infer the magnitude of loads. Because distortion-induced fatigue cracks are driven by differential vertical movements between two adjacent girders, strains in the cross frame members are proportional to the external load. For this reason, a foil strain gauge was deployed on a diagonal member of the cross frame to indirectly capture the applied load as shown in Figure 5*d* and *e*.

3.2 Test procedure

During the test, 71,000 new cycles were applied to the test model and eight datasets were collected when the cycle count reached 0; 15,000; 21,500; 30,000; 43,100; 53,800; 64,900; and 71,000 cycles; respectively. After 71,000 cycles, SEC a1 was removed to closely inspect the propagated crack. As shown in Figure 6*a*, the length of the fatigue crack was 14 mm at the beginning of the test prior to the installation of the SEC arrays. When the test was completed, the crack had propagated to its new length of 42 mm, indicating that the fatigue crack propagated within the eight data collection intervals.

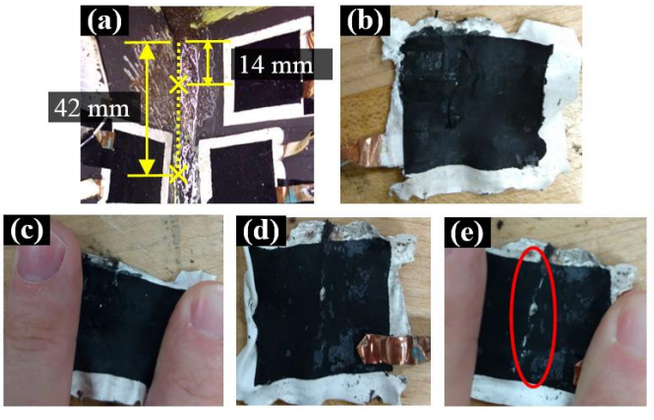

Figure 6. (a) The fatigue crack grew from 14 mm to 42 mm during the test; (b) front side of the SEC a1; (c) front side of the SEC a1 under stretching; (d) back side of the SEC a1; and (e) back side of the SEC a1 under stretching.

3.3 Fatigue damage features

The authors previously established a robust algorithm for extracting fatigue damage features, termed the crack growth index (*CGI*), described in Kong et al. (2017b) based on a single SEC applied on a small-scale C(T) specimen. Here, we have extended this algorithm for extracting the fatigue damage feature in dense SEC arrays. As illustrated in Figure 7, first the short-time measurements of capacitance C from the SEC and strain ε from the strain gauge (Figure 5*e*) were collected. Then, the peak-to-peak amplitude of strain measurement, denoted as Amp_ε, was obtained. The peak-to-peak amplitude of the capacitance measurement is challenging to directly identify in the time-series signal due to high noise content. Thus, the power spectral density (PSD) is proposed, where the peak of the PSD curves $Peak_C$ would indicate the peak-to-peak magnitudes in the time-series signals of capacitance C. Next, the *CGI* was established by computing the square root of $peak_C$ over Amp_ε.

The *CGI* is a normalized strain indicator under fatigue cracking. If the crack propagates into the SEC, the SEC can directly capture the crack growth by showing an increasing *CGI*. On the other hand, if the crack propagates but does not grow into the SEC, the SEC functions as a large area strain gauge to monitor the strain field migration caused by crack propagation.

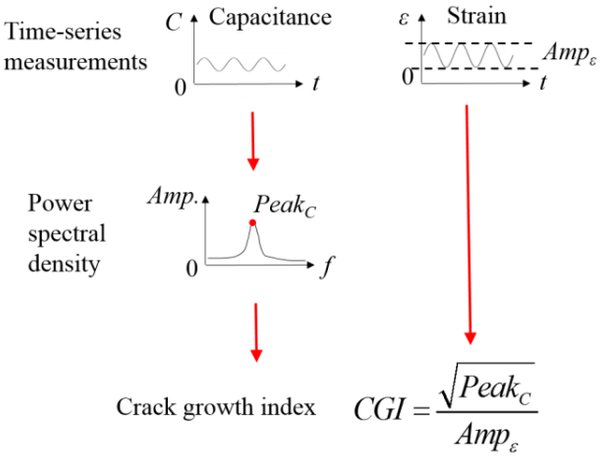

Figure 7. Fatigue damage sensing algorithm based on CGI from a single SEC.

Utilizing the procedure in Figure 7, the *CGIs* of all the SECs deployed over a large fatigue-susceptible region were computed. Figure 8*a* shows an example of *CGIs* computed from the 11 SECs in the top web gap of the connection. Linear interpolation was applied to these *CGIs* over the spatial dimensions x and y (denoted in Figure 8*a*) to create a 3D *CGI* surface as shown in Figure 8*b*. Essentially, the 3D *CGI* surface is a matrix containing the interpolated *CGIs* within the red-dashed zone in Figure 8*a*. Next,

the 3D *CGI* surface was presented in terms of a 2D image, termed the *CGI* map, in Figure 8*c*. The intensity of each pixel (x, y) in the CGI map is an interpolated *CGI*. The *CGI* map offers a clear presentation of the spatial distribution of *CGI* and serves as the basis for fatigue damage sensing using dense SEC arrays.

Finally, by periodically collecting short-time measurements from the monitored structure under the fatigue load cycles, a series of *CGI* maps was constructed through the above procedure. If the fatigue crack did not propagate during the data collection intervals, the corresponding *CGI* maps would exhibit similar spatial intensities. Conversely, if the fatigue crack grew during the data collection intervals, it would result in changes to the intensity distribution of the CGI map.

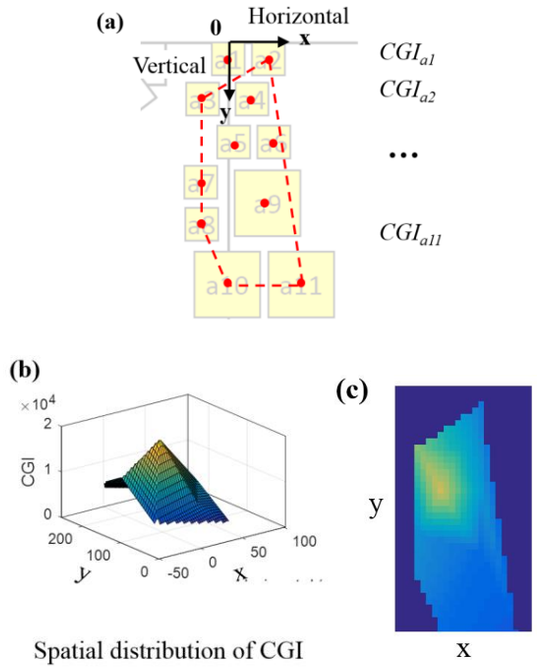

Figure 8. Construction of the *CGI* map.

4. RESULTS AND DISCUSSIONS

This section provides the test results and discussions. Results from the top web gap of the connection are discussed.

4.1 CGIs of single SECs

Following the *CGI* extraction algorithm presented in Section 3.2, the CGI responses of SEC arrays on the top of the connection are shown in Figure 9. Generally, SEC a1 exhibited the largest CGI response in the top web-gap region. This is because SEC a1 was deployed directly over the existing fatigue crack. The out-of-plane distortion-induced fatigue crack provoked a significant change in capacitance in this particular SEC. In addition, a significant increase of CGI was observed in SEC a10 at approximately 60,000 cycles.

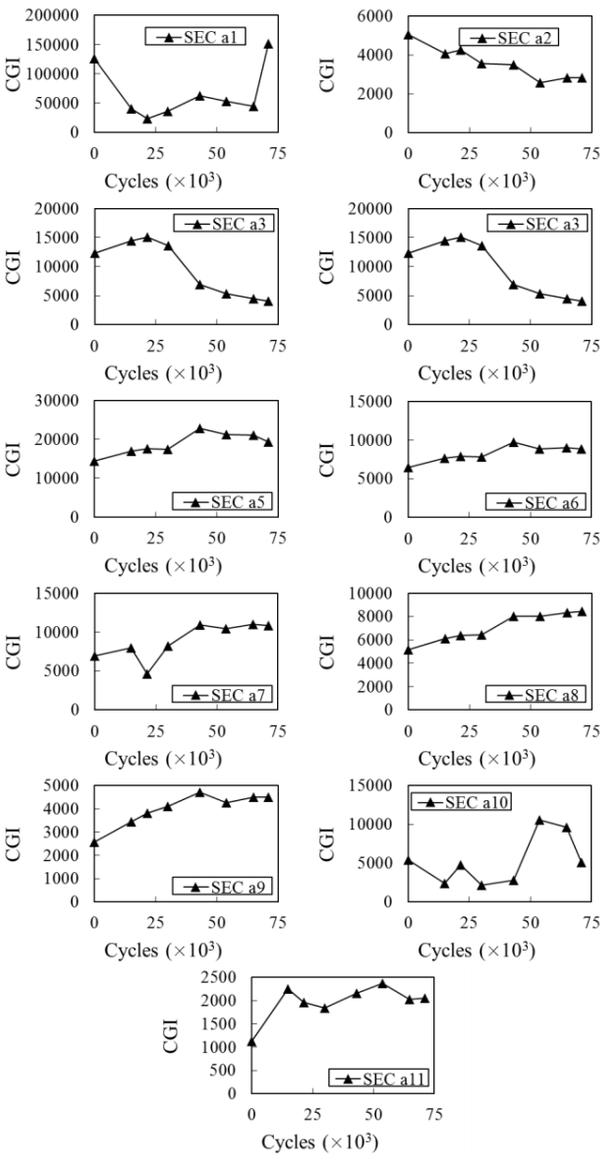

Figure 9. CGI response of the SEC arrays on the top region of the connection. The sensor numbers are shown in legends.

Figure 10 shows the CGIs of all the top web-gap SECs except SEC a1 and a10. By correlating the CGI changes with the spatial distribution of the SEC arrays (Figure 4*d*), some observations can be made as follows: 1) during the crack propagation as shown in Figure 6*a*, the concentrated strain field migrated

along with the crack tip. In particular, the strain level continuously dropped along the two sides of the crack path due to stress relief. As a result, decreasing trends in *CGIs* were observed for SEC a2, a3, and a4; 2) crack growth provoked increased strain levels in the sensor that covered the crack, leading to increasing trends for *CGIs* at SEC a5, a6, a7, a8, and a9. Interestingly, the above phenomenon became clearer between 30,000 cycles and 40,000 cycles, as highlighted in the black dashed block in Figure 10, indicating a period of significant crack growth.

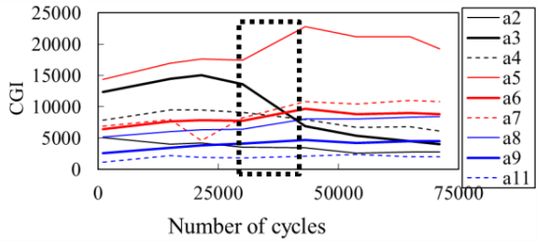

Figure 10. Comparison of CGIs in SEC a2 to a9, and a11.

4.2 CGIs maps

Utilizing the method proposed in Figure 8a, the *CGI* responses of the SEC arrays were used to further construct *CGI* maps. Figure 11 shows the spatial distribution of the *CGIs* obtained by linearly interpolating all the *CGIs* from the SEC arrays in the top web gap of the connection. The results clearly show the distribution of *CGI* magnitudes of the SEC array, enabling a clear depiction of the fatigue damage over a large area. As shown in the figure, as the number of load cycles increased, the fatigue crack grew causing the shape of the *CGI* surface to change. Monitoring such changes enables detection of the fatigue damage. Briefly, the largest *CGI* magnitude was observed near x=0 mm and y=100 mm, which is the location of SEC a5. The same information could also be obtained through Figure 10. In addition, the *CGI* maps show changes in intensity as the cycle count increased. The local region around SEC a5 (x=0 mm, y=100 mm) gradually became brighter (more intense) from 0 to 30,000 cycles, as shown in the first row in Figure 12. Then the intensity was significantly increased when the test reached 43,100 cycles, indicating significant fatigue crack growth in this particular interval.

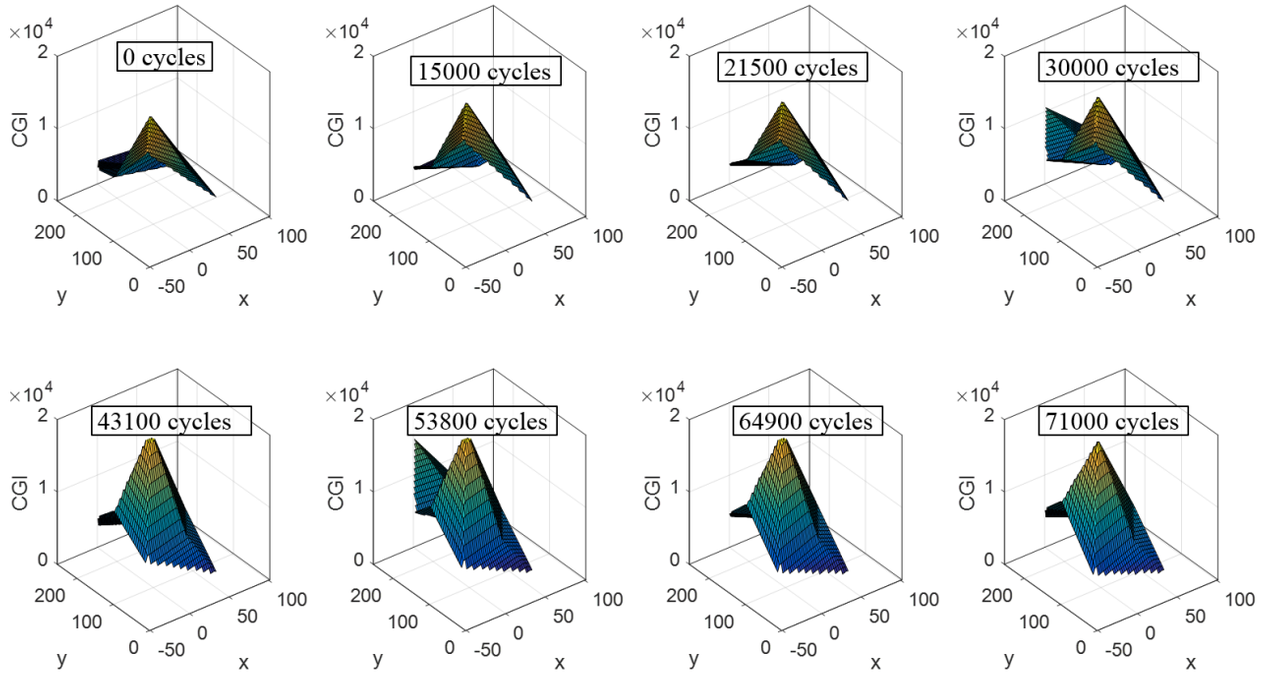

Figure 11. Spatial distribution of CGIs with different load cycles.

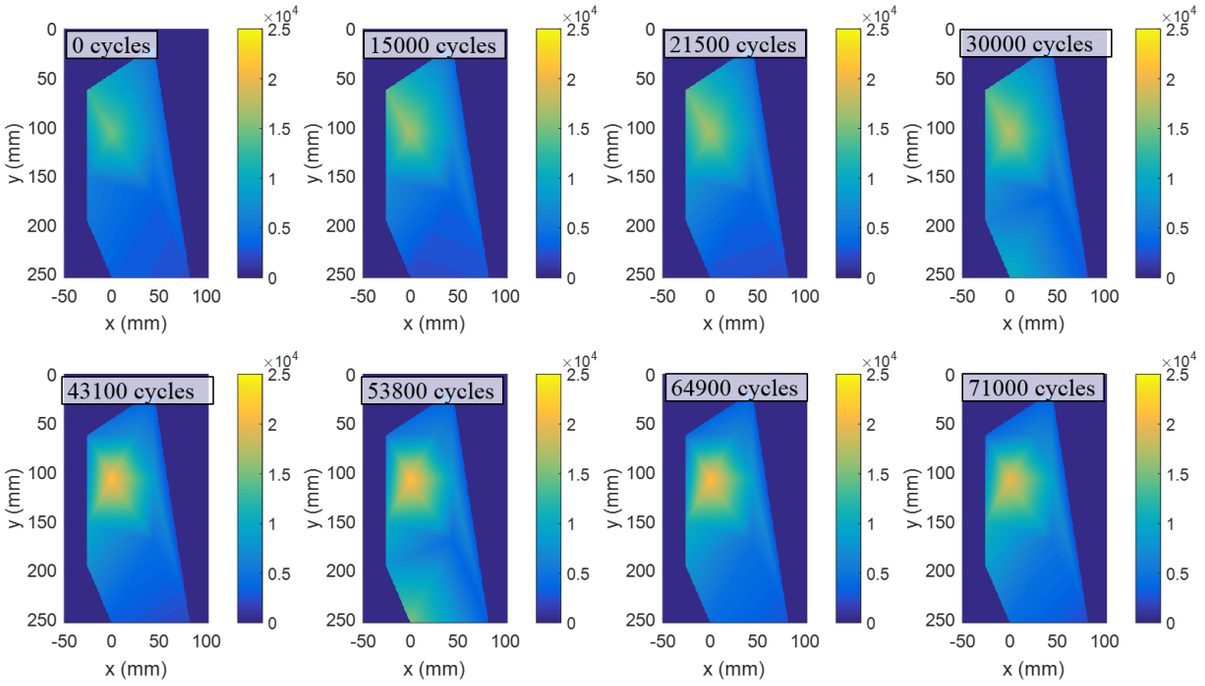

Figure 12. CGIs maps with different load cycles.

5. CONCLUSION

In this paper, we proposed strain-based dense sensor arrays to monitor fatigue cracks over large structural surfaces. The strain sensing technology, termed soft elastomeric capacitor (SEC), is a large-area flexible strain gauge, serving as the basic sensing unit in this study. A fatigue damage feature extraction algorithm was established based on the SEC arrays, through which the development of fatigue damage can be visualized with *CGI* maps. By observing the changing pattern of intensities in the *CGI* maps, the fatigue damage occurring in a large structural surface can be monitored. The effectiveness of this approach has been validated through an experimental test using a large-scale steel girder-to-cross-frame connection. The success of the proposed *CGI* map concept will serve as the enabling tool for field applications of the SEC technology for sensing fatigue damage in steel bridges.

Fatigue Assessment of Concrete Girder Bridges Based on Traffic Information

P. J. Zhang, C. S. Wang, Q. Wang, L. Duan
Engineering Research Center for Large Highway Structure Safety of Ministry of Education, College of Highways, Chang'an University, Xi'an, China

ABSTRACT: With the increasing of traffic volume and carrying capacity of vehicles, fatigue failure of concrete girder becomes the one of the most serious problem. A better way to evaluate the fatigue performance of concrete girder bridges is using existing information instead of taking field test. As the main load fatigue load of concrete girder bridges, vehicle load affects the fatigue life of concrete bridges significantly. Traffic information can be changed into fatigue load when bridge information is known. So a process is proposed to evaluate the fatigue performance of concrete girder bridges by using traffic information. An assessment method contains five parts including gathering vehicle load information, setting up fatigue load model, calculating stress spectrum, correcting the calculated stress spectrum and doing fatigue life calculation is proposed. To verify the effectiveness of the method, a small box girder bride is chosen as the case bridge. The weigh in motion system (WIM) and manual counting were used under the real traffic conditions. And in order to give the correction factor, dynamic strain monitoring data was taken to provide comparative results.

1 INTRODUCTION

Concrete girder bridges are the most widely used bridge style around the world. Before 1970, fatigue problems were rarely found in concrete girder bridges because of allowable stress design method adopted in earlier design specifications, smaller design load, and the lower material stress. With the development of social economy, the traffic volume and gross vehicle weights of trucks are increasing continuously. Thus, concrete bridges are subject to serious fatigue problems(Wang et al. 2012, Feng et al. 2003 Aggarwal et al. 2015). Combined with the environmental corrosion impact, concrete material aging and mechanical behaviour deterioration appear gradually. These all leads to reduction of strength and fatigue damage accumulation of reinforcing and prestressing steel (Akgül & Frangopol. 2004, Sarveswaran et al. 2000, Darmawan & Stewart 2007). But existing standards and specifications rarely focused on it. The common practice is taking long term monitoring and using measured stress spectrum to calculate fatigue life for concrete bridge, which is costly and time-consuming. To solve this question, it will require a method that uses fatigue load model to reduce the complexity and expense of fatigue evaluation.

Fatigue load model has been researched a lot for evaluating fatigue performance conveniently and economically, and most of the researches are for steel bridges. The fatigue load includes measured load spectrum, standard load spectrum and standard fatigue load model. The measured load spectrum data obtained from actual traffic volume statistics are complex and cumbersome, and are generally simplified to standard load spectrum. Based on this, a standard fatigue load model with universal applicability is established. The currently research on the fatigue load model mainly taken overall bridge structure as the research object (Wang et al. 2005, Zhou et al. 2010, Zong et al. 2013). Taken a vulnerable detail in the steel bridge deck of Hong Kong Zhuhai Macao Bridge as the research object, and adopted the traffic statistics data of Humen bridge and Lantau link, Bu and his collaborators have established the four axle fatigue load model with total weight 300kN (Bu et al. 2014). Based on the dynamic weighing data of Guizhou Baling Bridge within one week, Sun Xiuya has established three kinds of axle load spectra suitable for the steel bridge deck (Sun et al. 2014). Due to the difference between various fatigue stress behaviors of steel deck, the fatigue load model established with someone detail may not be suitable for other details, and the adaptability of fatigue load model only established with few data samples still need to be verified. Standards and specifications also give the suggested models for fatigue evaluation. Based on British highway traffic load information, a four axle standard fatigue load model with total weight 320kN was proposed by British BS5400 standard (BS 5400-2: 2006

2006); the four axle standard fatigue load model with total weight 480kN was adopted by Eurocode (BS EN 1993-1-9: 2005 2005); the three axle standard fatigue load model with total weight 325kN was recommended by AASHTO code (AASHTO LRFD 2010); and the four axle standard fatigue load model with total weight 480kN was suggested in China latest specification for highway steel bridge design implementation (JTG D64-2015 2015), the vehicle type and axle load of which is consistent with the European Eurocode 3.

For concrete girder bridges, most of standard and specification only give a stress limit for fatigue design. And little researchers focus on the fatigue load models of concrete bridges. Although from some fatigue load model researches of steel bridges can be used in fatigue assessment for concrete girder bridges, the structure un-symmetry, existing structural damage and other factors can lead to an incorrect consequence because measured stress amplitude may have difference from the calculated stress amplitude which uses fatigue load model.

In this paper, the proposed assessment method contains five parts including gathering vehicle load information, setting up fatigue load model, calculating stress spectrum, correcting the calculated stress spectrum and doing fatigue life calculation. A small box girder bride is chosen to calculate the fatigue life. The weigh in motion system (WIM) and manual counting were used under the real traffic conditions. And to verify the effectiveness of the proposed method and give the correction factor, dynamic strain monitoring data was taken to provide comparative results.

2 ASSESSMENT METHOD USING TRAFFIC INFORMATION

For steel bridges, using fatigue load model to evaluate fatigue life is a common practice. But for concrete, most of standard and specification only give a stress limit for fatigue design.

It is much convenient and economical to use fatigue load model when calculate fatigue life. So, the method to be proposed is a way to using fatigue load model. Similarly to the establishment of fatigue load model for steel bridges, the procedures for calculating fatigue load model for concrete girder bridges contain two main steps which are collecting vehicle load information and calculating fatigue load model by using equivalent damage theory.

However, structure un-symmetry and existing structural damage will lead to bigger stress amplitude than that of ideal model. This will result in a wrong consequence. That means the original stress which calculated by fatigue load model needs a correction factor. The correction factors for calibrating the calculated stress spectrum can be obtained through statistical vehicle information or field test of bridges. After that, fatigue life evaluation can be carried out. The whole

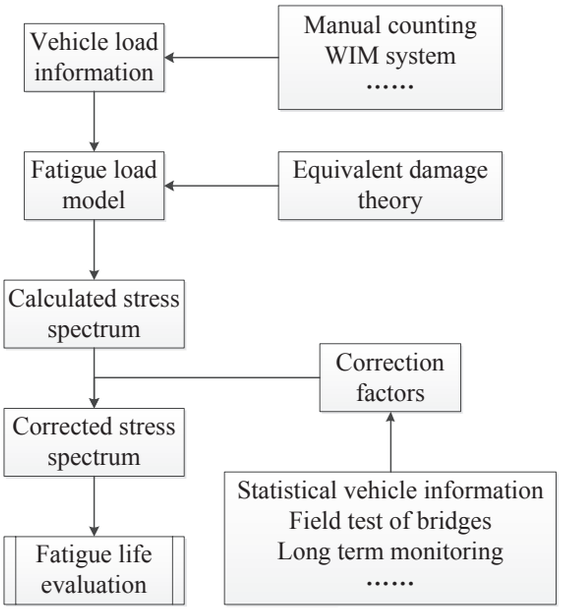

Figure 1. Assessment method using traffic information

3.1 *Information of Case Bridges*

Shown in Figure 1, a small box girder bridge which located in Shaanxi Province (China) was chosen as case study bridges. Traffic information was gathered and long-term stress monitoring was adopted for the three bridges. Information of three bridges is listed in Table. 1.

Table 1. Information of case bridges

Section form	Span layout	Structure type	Steel bar grade
Small box girder bridge	4×30m+4×30m	Continue bridge	d=16mm; f_y=335MPa

Figure 1. External view of case bridges

3.2 *Vehicle Load Information*

Before taking the observation of traffic information, it is necessary to classify the vehicle types. Figure 2 shows the various types of vehicles: 'a' and 'b' are 2 axle vehicles; 'c' to 'g' are 2, 3, 4, 5 and 6 axle trucks respectively. Also, two ways to gather traffic information are shown as 'h' and 'i' which 'h' is WIM system and 'i' is manual collection of traffic information. WIM system is the system that can collect the information such as vehicle types, axle numbers, gross weight, axle distance and so on. By using manual counting, manual collection is a method collecting vehicle types, driving directions and loading condition. Considering the features of the two methods and the field situation, observations using the two methods were carried out at different observation site. Based on the two ways above, vehicle information of three case bridges in this paper were gathered as follows.

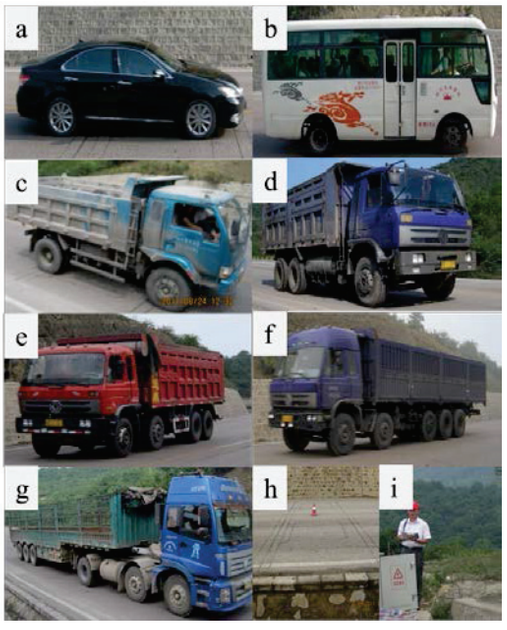

Figure 2. Different types of vehicles and WIM system

For the small box girder bridge, observation was carried out from Aug. 22nd to Sep. 22nd in 2011. Taken the vehicle data gathered from WIM system as case sample, the values of occupation ratio of different types of vehicles are shown in Figure 3. It can be seen that the largest number of vehicles is trucks for both uplink and downlink. Compared with the hollow slab girder bridge, the main type of trucks is 4-axle truck which occupies over a quarter of all kinds of vehicles.

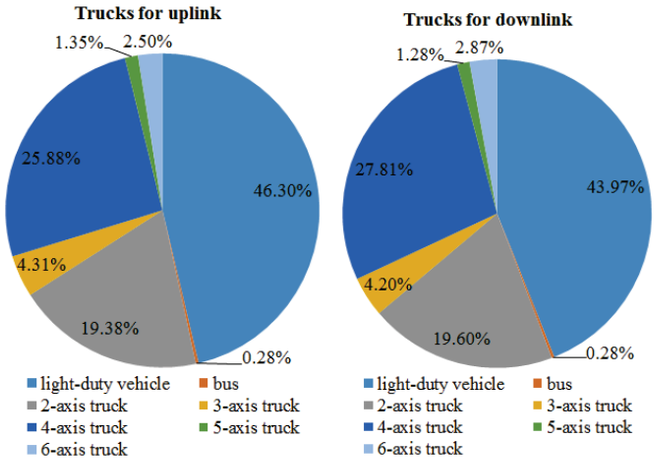

Figure 3. Occupation ratio of different types of vehicles for small box girder bridge

Based on the statistical analysis of measured data, the daily average value, variation coefficient, maximum and minimum values were obtained. As shown in Table 2, take the seven-day vehicle information of the small box girder bridge as an example, the variation coefficient of vehicle types in this measuring point is relatively large, which was above 1.0. The results showed that the vehicle load discreteness was larger, the vehicle type was various, and the load weight was difference. While the average values and variation coefficient of vehicle load in each day showed that there were little difference on the average values and variation coefficients of daily vehicle load. It suggested that the traffic load was stable in short term and can represent the situation of vehicle load in a period of time.

Table 2. Seven-day vehicle information of the case small box girder bridge

Date	Vehicle number	Gross weight	Maximum weight	Minimum weight	Average weight	Variation coefficient
		ton	ton	ton	ton	
2011-8-24	595	4368.17	53.40	0.66	7.34	1.01
2011-8-25	919	6113.17	37.90	0.27	6.65	1.00

2011-8-28	928	6775.04	63.20	0.36	7.30	1.13
2011-8-29	908	7949.81	53.80	0.17	8.76	1.11
2011-8-30	808	5232.90	58.30	0.34	6.48	1.26

3.3 *Fatigue Load Model*

Because the vehicle types are various and the gross weight of single vehicle has big range of variation. It is necessary to set up a fatigue load model by using vehicle load information. Common practice is:
1) Using the Equation (1), merge the vehicles which have same axle numbers into a submodel.

$$W_{ej} = \left[\sum\left(f_i W_{ij}^m\right)\right]^{\frac{1}{m}} \tag{1}$$

where f_i is the relative frequency of *i*th vehicle in same vehicle class; W_{ij} is the *j*th axle weight (axle distance) of *i*th vehicle; W_{ej} is the *j*th equivalent axle weight (equivalent axle distance) for the corresponding submodel; *m* is the slop of the S-N curve.
2) Based on equivalent damage assumption, the equivalent axle weight can be calculated for each submodel as Equation (2) and Equation (3);

$$\alpha = \frac{W_S}{W_B} \tag{2}$$

where α is the correction factor of the axle weight; is W_S the axle weight of the fatigue load model, W_B is the axle weight of the submodel.

$$\alpha = \frac{\left(\frac{n_T \Delta\sigma_T}{N_T n_B'}\right)^{\frac{1}{m}}}{\Delta\sigma_B} \tag{3}$$

where n_B' is the number of the stress cycles which caused by one submodel; n_T is the number of the stress cycles which caused by one fatigue load model; $\Delta\sigma_T$ is the sum of the equivalent stress amplitude; $\Delta\sigma_B$ is the equivalent stress amplitude caused by submodel.

3) Chose the main truck type as the basic model of the fatigue load model;
4) Using the sum of equivalent axle weight of each submodel, the equivalent gross weight of fatigue load model can be obtained through.

According to the vehicle information of the case small box girder bridge, the following conclusions were summarized:

(1) Trucks made up the largest proportion of all vehicles; 4-axle truck accounted for the largest proportion in all trucks, which was the basic model of the fatigue load model.

(2) Impact of light-duty vehicles such as sedan car and small agricultural machinery should be ignored because the lighter weight cause little fatigue damage.

(3) Through the dynamic strain monitoring test on the part of bridge, we found that when the vehicles (including buses and trucks) were passing, the stress curve usually occurred two peaks, which was the structure response of two axle groups in the front and in the back of vehicles.

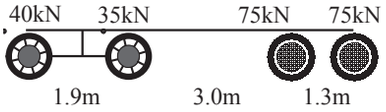

Figure 4. Diagram of fatigue load model of the case small box girder bridge

Based on the gathered data and the dimensional details, the four axle truck was recommended as the fatigue load model in this place, and the values of axle weight and wheelbase truck were averaged and rounded according to the data provided by the manufacturer of truck and the measured data, the values were. The suggested fatigue vehicle load model as shown in Figure 4:

4 FATIGUE ASSESSMENT FOR CASE BRIDGES

For case small box girder bridge, validation of equivalent stress was carried out firstly. By using the influence lines, the fatigue load model was loaded on the structure and its equivalent force amplitude was calculated, and compared with the stress produced by the actual traffic flow which was gathered from WIM system. The vehicle driving direction for the case small box girder bridge was divided into two directions, namely uplink direction and downlink direction.

Table 3. The stress amplitude comparison between fatigue vehicle and actual vehicle

Stress amplitude	Number of stress cycles	
	Loaded by fatigue load model	Loaded by measured vehicle axle weight
MPa	*n*	*n*
1	580	1444
2	33	109
3	36	93
4	49	210
5	679	22
6	40	4
7	20	7
8	20	16
9	10	8
10	\	13
11	\	7
12	\	3

The measured data showed that in the measured strain data of the case bridge girders, the stress of external girders is larger than the internal girders.

And because the bridge was a continue girder, the critical steel bar was in the 0.4L section of side span than the other parts of the bridge. Therefore, the 0.4L section of side span was selected as the control section. And the steel bar in the bottom plate of the control section was chosen as the critical member which needs to be assessed. Through influence line, the fatigue load model and the measured vehicle load were loaded to the structure to calculate the equivalent force amplitude, and the results were compared and showed in Table 3.

Ideally, the equivalent stress amplitude which caused by fatigue load model should be same with the equivalent stress amplitude which caused by actual vehicle. However, round-off error from each steps cause a little deviation as Table 4 shows. But the result still shows good agreement with expected the equivalent stress amplitude.

Table 4. The equivalent stress amplitude loaded by fatigue load Model and actual vehicle

Load type	Equivalent stress amplitude MPa	Ratio of Fatigue load model to actual vehicle
Fatigue load model	4.88	1.03
Actual vehicle	4.74	

In order to valid the effectiveness of the method, the long term stress monitoring for critical part of the case bridge was conducted for the case small box girder bridge. The strain measurement point layout as shown in Figure 5.

Diameter of critical steel bars in the bottom plate is 16mm, and specification of prestressing steel at the measured position is 4×15.2. The layout of steel bar and prestressing steel are shown in Figure 6.

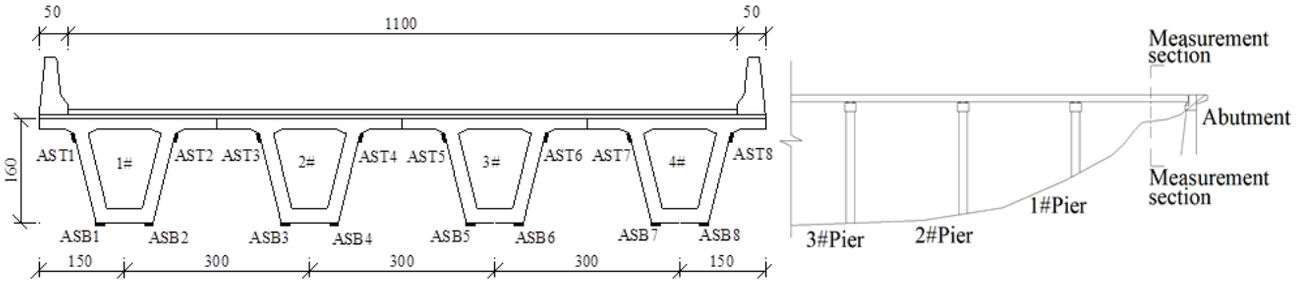

Figure 5. The measuring points layout at side span 0.4L cross section (unit: cm)

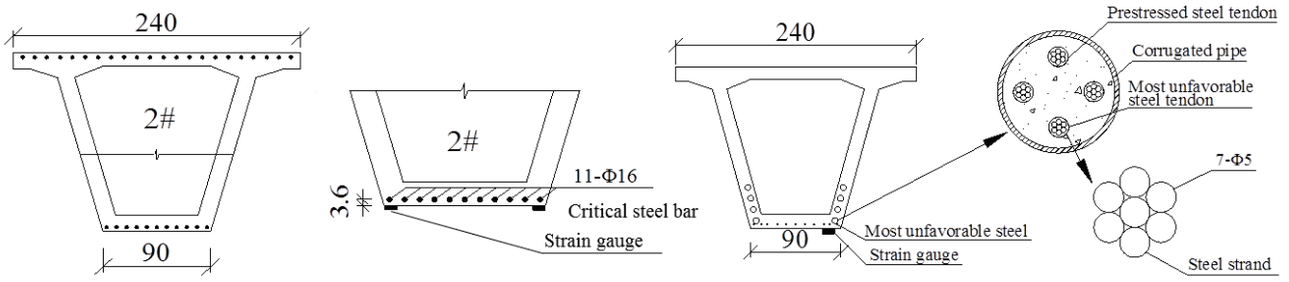

Figure 6. The layout of critical steel bar and prestressing steel at side span 0.4l cross section (unit: cm)

In the field monitoring, the maximum internal force section is selected, and the longitudinal strain gauges were arranged on the surface of the bottom plate of the box girder. Based on the plane cross-section assumption, the strain of critical steel bar and most unfavorable prestressing steel can be calculated by using the measured strain. The stress spectrum of the steel bar is obtained by the rain flow counting method. According to Eurocode[28], the detail category of steel bar is close to level 100 for normal steel bar.

In the measured stress data, the test point which had larger accumulated damage was selected as the evaluation object. After comparing, the measuring points with maximum cumulative damage at the most unfavorable section is selected, that is, the measure point of ASB3. The stress spectrum of ASB3 is shown in Table 5.

Neglect the stress which is in stress level 0~2MPa where has lots of noise and has no effects on fatigue life calculation. Based on plane section computational assumption, the stress spectrums for both steel bar and prestressing steel were obtained. By comparing the stress amplitude of the two spectrums, prestressing steel and steel bar were both in low stress

level. So, for convenience, only chose steel bar as calculation object.

Table 5. The stress spectrum of measure point ASB3

Stress amplitude	Number of cycles	Stress amplitude	Number of cycles
MPa	*n*	MPa	*n*
0<S≤2	/	24<S≤26	18
2<S≤4	4868	26<S≤28	12
4<S≤6	390	28<S≤30	15
6<S≤8	457	30<S≤32	13

18<S≤20	59	42<S≤44	3
20<S≤22	39	44<S≤46	0
22<S≤24	25	46<S≤48	1

Linear cumulative damage theory is the most widely used to assess fatigue performance. Considering the high randomness of fatigue damage initiation position and shape, linear cumulative damage theory is adopted in this paper. According to linear fatigue cumulative damage theory, damage caused by one cycle is presented as Equation (4).

$$D = \frac{1}{N} \tag{4}$$

where N means cycles within the action of stress amplitude level S. Under the effect of constant amplitude stress, the fatigue damage caused by n cycles is as Equation (5).

$$D = \frac{n}{N} \tag{5}$$

Under the effect of variable amplitude stress S_i of n_i cycles, the fatigue damage is as Equation (6).

$$D = \sum_i D_i = \sum_i \frac{n_i}{N_i} \tag{6}$$

where N_i is cycle within the action of stress amplitude level S_i until failure.

Based on above analysis, during the monitoring period, actual stress amplitude $\Delta\sigma_i$ and cycles are obtained and the fatigue accumulation damage can be calculated by Equation (7).

$$D_T = \sum_i \frac{n_i}{N_i} \tag{7}$$

Fatigue life Y of structure can be calculated by Equation (8).

$$Y = \frac{D_{cr}}{D_T} \times T \tag{8}$$

where D_{cr} is critical fatigue damage, T is monitoring time and D_T is fatigue damage during time T. Previous experiments show that, under random loading, D_{cr} is around 1, so the value of D_{cr} is taken as 1.

The fatigue damage within the monitoring duration is 4.256×10-6 and the monitoring duration is 21-day long. So, based on the measured stress spectrum, the fatigue life is calculated as follow:

$$Y = \frac{21}{4.256\times10^{-6}\times365} = 13518 \quad \text{years} \tag{9}$$

As mentioned above, the real structure is different from the ideal model. Structure un-symmetry and existing structural damage will lead to bigger stress amplitude than that of ideal model. According to the fatigue load model calculated in Section 3.3, the stress spectrum corresponding to the fatigue load model is smaller than the measured stress spectrum. So, it is required correct the stress spectrum which was obtained by loading fatigue load model, and amplify the stress range into a reasonable scale.

Take measure point ASB3 as the research object, the stress spectrum of the probability distribution fitting field monitoring of bridge, the mixed Gauss model is simulated, the distribution function as shown Equation (10) and the fitting curve as shown in Figure 7.

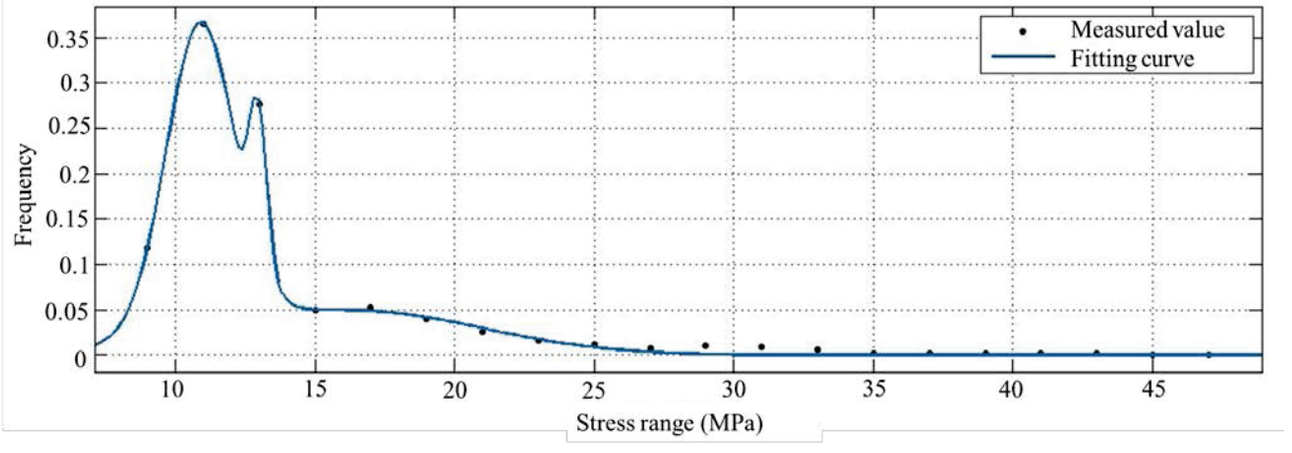

Figure 7. Fitting curve for the frequency of measured stress spectrum

$$f_f(\sigma) = 0.1613\exp\left\{-\left[(\sigma-12.96)/0.4393\right]^2\right\} + 0.009794\exp\left\{-\left[(\sigma-11.17)/3.557\right]^2\right\} + 0.3334\exp\left\{-\left[(\sigma-10.89)/1.713\right]^2\right\} + 0.04838\exp\left\{-\left[(\sigma-16.46)/6.483\right]^2\right\} \quad (10)$$

where f_f is probability density function of the measured stress spectrum.

Considering the possible overloading in the actual operation of the bridge, the upper limit of the stress amplitude is taken as the upper cut-off frequency when the integral value of the frequency distribution function is 0.9. Therefore, the equivalent stress amplitude of the fatigue car model is modified as Equation (11):

$$\sigma_c = (\sigma_{\varepsilon-\mathrm{sd}} \cdot \mu) \cdot \left[\frac{\sigma_{0.9\mathrm{f-max}}}{(\sigma_{\mathrm{s\text{-}max}} \cdot \mu)}\right] \quad (11)$$

where σ_c is the corrected equivalent stress amplitude; $\sigma_{\varepsilon-\mathrm{sd}}$ is the equivalent stress amplitude which was calculated by fatigue load model; $\sigma_{0.9\mathrm{f-max}}$ is the maximum stress of the measured stress spectrum when the upper cut-off frequency equals to 90%. $\sigma_{\mathrm{s\text{-}max}}$ is the maximum stress amplitude of the measured stress spectrum; μ is the impact factor.

Through calculation, the corrected equivalent stress amplitude is calculated as:

$$\sigma_c = 4.88 \times \left(\frac{18.66}{12}\right) = 7.588 \quad \mathrm{MPa} \quad (12)$$

Similarly, the corresponding number of stress cycles also need to be zoomed on account of the relationship between actual traffic flow and simulation loading. The number of stress cycles corresponding to corrected equivalent stress amplitude was calculated as 637097 times. Thus, fatigue life of the case small box girder bridge was calculated as follow:

$$Y = \frac{21}{4.499 \times 10^{-6} \times 365} = 12787 \quad \mathrm{years} \quad (13)$$

The calculated fatigue life of the fatigue load model calculated by Equation (7) is close to the calculated fatigue life which is 13518 years based on the measured stress spectrum as Equation (4). And the result using fatigue load model reaches 94.6% of the fatigue life using the measured value. Furthermore, because it is smaller than the fatigue life calculated by measured stress spectrum, it is a safe result.

At the same time it can be seen that the parameter and variables are sensitive to load and structure factors. For instance, $\sigma_{0.9\mathrm{f-max}}$ and $\sigma_{\mathrm{s\text{-}max}}$ are easily affected by traffic volume, structure type of bridge, pavement roughness and some other factors. Taking these factors into account, every bridge should have its own scaling factor. This paper only gives the calculating example of the case small box girder bridge.

5 CONCLUSIONS

An assessment method that uses traffic information to evaluate fatigue life was proposed. And it was applied for a case small box girder bridge. Based on the results and analysis of the measured and calculated data, conclusions can be drawn as follows:

(1) The assessment method of fatigue life evaluation for concrete girder bridge was established. The method needs traffic information and correction factor.

(2) Compared with the equivalent damage that calculated by WIM data, fatigue damage calculated by fatigue load model has error due to round-off error, however, the error was small which did not affect the result of fatigue life calculation.

(3) Structure un-symmetry and existing structural damage will lead to bigger stress amplitude than that of ideal model, which needs a correction factor to scale the stress amplitude calculated by fatigue load model.

(4) Using the proposed method, the fatigue life calculated by using corrected stress spectrum show good agreement with fatigue life calculated by using measured stress spectrum.

(5) Because the features of each concrete girder bridges are different, the scaling factors using proposed method are not likely to be the same. The regularity of the factors still needs to be analyzed.

ABSTRACT: This paper presents load models for quantifying the effect of historical rail traffic on the remaining fatigue life of riveted bridges in the UK. Three types of load models, based on realistic trains, accounting for differences in rail traffic composition, are developed and subsequently used for investigating their effect on the accumulation of fatigue damage in typical old metallic bridge structures. The overall findings show that the increase within train axle loads from 1900 to 2010 is the main attributor to the significant increase in fatigue damage caused from the modern trains compared to the residual fatigue damage from the historic trains. These findings are particularly relevant to the majority of existing metallic rail bridges on the rail network, which are known to have a span length less than 10 m. These findings show the importance of considering the effects of historical loading for more reliable fatigue assessment purposes, leading towards more efficient planning of bridge maintenance and renewal programmes.

1 INTRODUCTION

A vast number of the existing metallic bridges in the British railway network, as well as many parts of Europe and North America, are either wrought iron or early mild steel riveted bridges. According to the Sustainable Bridges European Demography, out of the 47,000 metallic railway bridges in Europe, approximately 12,000 of these are made of wrought-iron (Bell, 2007). About 30% of the metallic bridges are exceeding 100 years of age. These existing bridges can be considered as fatigue sensitive structures as they significantly precede any design methodology that is inclusive of fatigue damaging effects. Although fatigue has been studied for over 100 years, the explicit inclusion of fatigue effects within the performance of bridges has only occurred since the 1970s in the UK (BS5400, 1980). During the last few decades, there have been significant amounts of research carried out on understanding and quantifying the fatigue behaviour of riveted bridges (Akesson, 1994; Al-Emrani, 2005; Al-Emrani and Kliger, 2003; Imam, 2006; Imam *et al*., 2008; 2012; Righiniotis *et al*., 2008). These investigations provided valuable insight by identifying, both experimentally as well as numerically, the factors that affect their fatigue performance and the modes of initiation and propagation of fatigue damage in this type of bridges.

A fundamental part of keeping the existing railway network operating without having to replace existing structures, unless absolutely necessary, is to be able to accurately calculate their performance. In the case of metallic bridge structures, fatigue is one of the critical elements to the performance of the structure, especially as the only live loading experienced by these is train loading which, inherently by its nature, is one of the most fatigue damaging types of loading process. However, unlike other fatigue damaging live loading, for example wind loading or highway loading, rail loading can be accurately predicted and modelled, as it is a controlled process. The axle loads are known for all train types on the network and an estimation of the frequency of trains over a particular structure is possible; therefore, a reasonably accurate method can be used to gauge the fatigue damage within the bridge member being considered.

One of the key steps during fatigue analysis of bridge structures is the prediction of load effects; it is well known that fatigue damage is highly sensitive to the stress range estimates. Accurate estimation of the remaining fatigue life of old metallic bridges, considering a safe life approach, is highly dependent on the accurate prediction of the past, current and future damage accumulation. This is, in turn, reliant on accurate estimation of the load effects caused by railway traffic in each of these periods. The codes of practice for fatigue design and assessment often provide good information regarding modern (current-day) train loading and traffic. However, they lack information and guidance about historical (past) rail

traffic which is essential for quantifying the fraction of fatigue damage that has already accumulated in existing bridges. There is limited literature that considers the variation between historic (1900s) and modern train loading trends and the effects this has upon these old metallic bridge structures.

This paper concentrates on the fatigue effects due to these variations in train loading upon riveted plate girder bridges with the aim of understanding the differing effects of historic to modern train loading. The aim of this study is to identify where the majority of the fatigue damage originates in old metallic bridges to allow a greater accuracy of fatigue analysis and therefore enable more accurate prediction of their remaining fatigue life. To this end, examples of historical train load models are reviewed first and a novel load model that captures variations in rail traffic composition from passenger-dominated to freight-dominated is developed. The load model, which is based on realistic trains, is used on a number of typical case-study bridge structural models to investigate the effects of historical loading on the fatigue damage of old metallic bridges and identify other parameters that affect fatigue behaviour.

2 HISTORICAL RAIL TRAFFIC MODELS

For historic railway bridges that have not been designed for fatigue, to assume that they have been subjected to modern train loading since their initial construction, circa 1900, is an extremely conservative method to be using, considering how sensitive fatigue damage is to small variations within the load trends. On the other hand, neglecting completely the effects of historical rail traffic on their fatigue behaviour is likely to overestimate their remaining fatigue life. This demonstrates that there is a genuine requirement to provide a standardised historical train load model for the purposes of more reliable fatigue assessment.

A detailed history of the train locomotive development and the significant changes of the freight wagons and passenger coaches over time are presented by Hayward (2010; 2013). The 1960s saw the introduction of fuel tanker bogie wagons weighing 100 tons loaded. These were followed by 100-ton mineral tipper wagons and coal hopper bogie wagons. Presently, modern freight trains typically induce 25-ton repetitive axle loads which have considerably increased outside the bounds of the historical design envelope, potentially having serious implications on the fatigue performance of the existing bridges in the rail network.

A practical way of considering the cumulative effect of historical loading on bridge structures has been suggested by Akesson (1994). According to his method, the amount of damage that historical trains have caused to date can be estimated by transforming the freight tonnage amount per year into a number of equivalent freight train passages over the bridge. This approach provides a simplified conservative way of quantifying the fatigue damage based on a known statistical tonnage per year, without taking into account the variation in train layouts or axle spacings that have occurred during the lifetime of the bridge. However, in many cases, axle weights and spacings, rather than train frequencies, can be the governing factors that control the remaining fatigue life of bridges.

A past traffic load model is suggested by the International Union of Railways (UIC, 1988). The model is divided into six different time periods and each period is represented by a number of representative trains for passenger and freight traffic, including their daily frequency. This load model has been used for the fatigue assessment of a real case study metallic railway bridge in Italy where it was shown that the fatigue damage produced by the historical trains is not insignificant (Pipinato *et al*., 2012).

One of the few load models that have been developed in the past to capture historical rail traffic and its effect on the fatigue damage of old metallic bridges is the one proposed by Imam and Righiniotis (2010). The basis of this model, which has been developed in collaboration with Network Rail based on realistic train configurations, was taken from BS5400: Part 10 (BS5400, 1980) which includes the modern train load models. BS5400 defines three variations of fatigue loading, light, medium and heavy which correlate to passenger-only lines, mixed passenger and freight lines and dedicated freight lines, respectively, and provides details about the types and frequencies of the trains to be used in each model. The load model developed by Imam and Righiniotis (2010) is divided into three distinct periods between 1900 and 1970 and considers the medium traffic variation only. It has been developed from the number of trains per year of the medium traffic variation suggested in BS5400. As opposed to the model developed by Akesson (1994), this historical load model not only takes into account changes in train frequencies over time but it also captures changes in axle loads as well as axle spacings.

In this paper, this model is further extended allowing it to be used for passenger-only and freight dedicated lines corresponding to light and heavy fatigue loading conditions according to BS5400. For example, a bridge which is located on a freight route that has been used to transport heavy freight such us iron ore or coal is likely to have experienced heavy traffic type; on the other hand, a bridge which is located in the vicinity of a city centre is more likely to have experienced passenger traffic only.

There is a distinct difference between the haulage capacity of modern and historical freight trains. For example, the freight train defined in the load model

developed by Imam and Righiniotis (2010) for the period 1900-1920 has a capacity of 570 tonnes whereas the modern heavy freight train (No 7) has a capacity of 1,120 tonnes. Due to this difference in tonnage the formation of the heavy historical train load model has been based on the tonnage per train rather than the frequency of trains per year. The modern total tonnage has been divided by the haulage capacity of the historic freight train to calculate the frequency of historic freight trains required to haul the tonnage annually. The tonnage hauled per year for each historic period has been proportionally adjusted against the modern tonnage provided in BS5400 using historic freight data (Coucher *et al*., 2008; IMechE, 2009; Leach, 2002; Whiteing, 2003). The heavy historical train load model is presented in Figure 1.

The light historic train load model, unlike the heavy model, is not created from the annual tonnage of trains as the weight of passenger coaches have not changed significantly through the periods (Hayward, 2010; 2013). The light model is created by considering the amount of coaches required per year to move the volume of passengers. This is proportionally adjusted from the known historic passenger volume data (Coucher *et al*., 2008) against BS5400 (1980) to back calculate the annual train frequency required for each period. The historic passenger volume data that has been used to create the adjusted weighting for each historical period has been obtained from (Coucher *et al*., 2008). The light historical train load model is presented in Figure 2. The layout of all the historical trains shown in Figures 1 and 2 can be found in Imam (2006) and Imam *et al*. (2006). The layouts of the modern trains for the period 1970- can be found in BS5400 (1980). All the load models developed in this paper are based on realistic train configurations.

Period	Traffic Type	Locomotive Type	Wagon Axle Weight	No of Wagons	Train speed	Annual Frequency
1900-1920	F	0-6-0 Superheater Freight Engine	2×8 t	30	30mph	48,421
1920-1940	F	0-6-0 Superheater Freight Engine	2×10 t	40	40mph	45,505
1940-1970	F	2-8-0 Freight Engine	2×10 t	40	40mph	48,825
1970-	F	Mixed freight (BS5400 no 9)	2×7, 4×20, 6×20 t	12	120 km/h	4,821
	F	Heavy Freight Train (BS5400 no 7)	4×25 t	10	120 km/h	7,232
	F	Heavy Freight Train (BS5400 no 8)	2×25 t	20	120 km/h	15,845

Figure 1. Heavy traffic historical and modern train load model.

3 FATIGUE ASSESSMENT

Historically, within the rail network, there were a few typical bridge designs that were commonly used for their construction. In general, these can be categorised by the span length of the bridge. Short span bridges consist mainly of either masonry arches or plate girder bridges. For medium span bridges, truss girders or plate girder arches were preferred, with plate girder arches and large box section bridges being preferred for longer spans (Hayward, 2010; 2013). The majority of the bridges on the rail network have a span around or less than 10 m (Hayward, 2010; 2013; Imam, 2006) and are of plate girder construction. For example, about 45% of the metallic bridges in Europe have a span less than 10 m (Bell, 2007). Of the metallic bridge types used, the truss girder bridges and box section bridges are less fatigue sensitive in terms of their main truss members due to their long span lengths; the dead load dominates a high percentage of the available capacity and therefore reduces the fluctuating live load stress range on those elements. On the other hand, plate girder bridges and stringers and cross-girders of truss bridges work in bending and therefore sections see high fluctuating tensile stresses as the live load dominates the available capacity due to the shorter span length. As a consequence, short span plate girder bridges can be considered as the most fatigue sensitive bridge type on the railway network.

Period	Traffic Type	Locomotive Type	Wagon Axle Weight	No of Wagons	Train speed	Annual Frequency
1900-1920	P	4-4-0 Passenger Engine	4×8 t	30	50 mph	41,163
	LS	0-4-4 Tank Engine	4×8 t	8	30 mph	82,326
1920-1940	P	4-6-0 Superheated Mixed Traffic Engine	4×9 t	12	60 mph	58,888
	LS	0-4-4 Tank Engine	4×8 t	4	30 mph	44,165
1940-1970	P	4-6-0 Superheated Mixed Traffic Engine	4×9 t	15	70 mph	44,217
	LS	0-4-4 Tank Engine	4×8 t	6	40 mph	41,454
1970-	F	Steel Train (BS5400 no 1)	6×18.5 t	15	80 km/h	752
	P	Electric multiple unit (BS5400 no 2)	4×10 t	8	145 km/h	14,516
	LS	Southern region suburban (BS5400 no 3)	9.5, 11 & 13 t	12	145 km/h	23,546
	LS	Southern region suburban (BS5400 no 4)	9.5, 11 & 13 t	6	145 km/h	47,093
	P	Diesel Hauled Passenger Train (no 5)	4×10 t	12	160 km/h	4,500
	P	Electric Hauled Passenger Train (no 6)	4×10 t	12	160 km/h	2,360

Figure 2. Light traffic historical and modern train load model

For the purposes of comparing the effect of varying historical loading on fatigue, single span riveted plate girder bridges are considered in this paper. These comprise of two girders with equal load share supporting a single track via a simple ballasted troughing deck. For the analysis of the main girders a standard bridge set consisting of 17 bridges has been created to represent riveted plate girder bridges with spans ranging from 4 m to 20 m in one metre increments. These bridges are based on a standard cross section layout; a simply supported bridge with a trough deck supporting ballast and single track, connected to two plate girders as shown in Figure 3.

The parameters that are being investigated in this paper in terms of their influence on the fatigue behaviour of these bridges are:

- The axle spacing of the trains and the bridge span length.
- The differences between the modern and historical trains within the train load models.

- The variance created between the three train load models, light, medium and heavy.
- The comparison between wrought iron and mild steel riveted bridges.
- The year of construction of the bridge

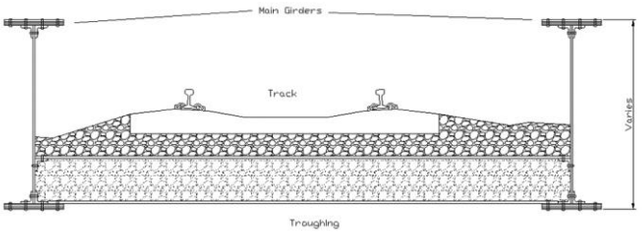

Figure 3. Standard bridge set cross-section at midspan.

To ensure the analyses are representative, each bridge has been designed from the working stress limit of 77.5 MPa for wrought iron and 100 MPa for mild steel, which were typical values employed circa 1900s for design (Fitzmaurice, 1895). Live loading is based on the equivalent uniform distributed load (EUDL) curve design model defined in (Hayward, 2010; 2013). The bridges have been designed so that the combination of live load stress and total dead load stress sums to the working stress limit (Fitzmaurice, 1895; Hayward, 2010; 2013). This method may provide higher utilisation within the main girders than existing bridges. However, the aim of the analyses is to find correlation within the results from the bridges rather than explicitly quantifying the fatigue failure point of these bridges.

The design process is based on only varying the strength of the main girders between each bridge. As the span length increases the bending moment due to the total dead and live load will also increase. To ensure that the combined maximum total dead load and live stress on the main girder at midspan equals to the working stress limit for each span length, the strength of the girder must increase. Therefore, an iterative process has been used to calculate the strength of the girder. The combined live and total dead load stress is equated to the working stress limit by iterating through standard riveted girder section sizes (Fitzmaurice, 1895).

The DAFs for each train and for each span are taken into account within the assessment procedure by multiplying the DAFs obtained from (Network Rail, 2006) with the static stresses obtained from the bridge analysis. An overview of the effect of dynamic amplification on fatigue damage of metallic bridges and the range of values expected in such bridges can be found in Imam *et al*. (2006).

The standard bridge set is assessed for fatigue damage occurring within the bottom flange detail of the main girder at the location of the rivet holes. This detail is classified as Class D according to BS5400: Part 10 (BS5400, 1980). The analysis of the bridge set is carried out by developing a structural model of each bridge within the finite element program, STRAP 2010. These models comprise of line (beam) elements to represent the bridge members with each element having a representative section and material property. Linear static analysis was carried out to extract the stress histories resulting from the passages of the trains over each bridge span. An influence table for the bending moment at the midspan due to a unit load traversing across the bridge representing one train axle has been obtained from the analysis; these have then been combined through the superposition rule to produce the train stress histories. These are then converted into stress range histograms through rainflow counting and are used for the calculation of fatigue damage. The fatigue damage is estimated through the Miner Rule (Miner, 1945), which forms the basis of a major part of fatigue assessment codes worldwide, including the UK fatigue assessment code for metallic railway bridges (Network Rail, 2006) which is used in this paper.

For the purposes of the fatigue damage calculations, the fatigue limit has not be considered and all stress ranges, even below the fatigue limit, have been assumed to contribute to fatigue damage accumulation, which is a conservative assumption.

4 RESULTS AND DISCUSSION

4.1 *Effect of train axle spacing*

It can be expected that there is a fatigue damage relationship between the span length of the bridge and the axle spacing of the train. Key trends can be identified within the layout of the train axles and the critical effects these trends have upon fatigue damage. The locomotive engines make up only a small percentage of the total axles within an entire train. The engine and tender axles are typically between 1.5 m and 3 m spacing and generally are the heaviest loaded axles. Due to this close axle spacing the engine loading often acts as a uniformly distributed load rather than individual axles. For this reason, the engine locomotive produces only one stress cycle per train journey, which predominantly is the single largest stress range within the load spectrum for that train, as can be seen in Figure 4.

For both the historical and modern trains within the train load model, the passenger train represents a key identifiable axle trend. The passenger coach is formed of four axles, two axle pairs at either end of the coach. The axles within the pairs are spaced 1.5 m to 3 m apart and between 1 m and 3 m from the end couplers of the coach. The central spacing between the axle pairs is between 11.5 m and 13 m. This creates four axles evenly spaced between 1.5 m to 3 m then a significant gap of between 11.5 m and 13 m before the next set of four closely spaced axle. Similarly to the engine and tender trend, the axles of

the coaches are closely grouped together and do not cause large stress range amplitudes themselves. However, the increased spacing between the axle groups will cause large stress range amplitudes caused by the full loading and complete unloading of the bridge.

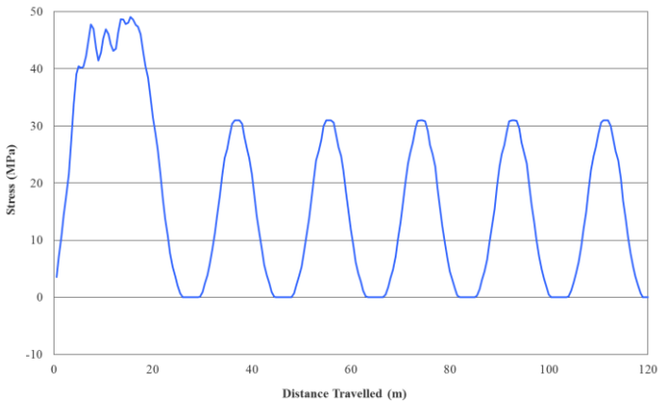

Figure 4. Stress history in main girder for passenger train 1900-1920.

Figure 4 shows the stress history obtained from the passage of the 1900-1920 passenger train over the 9 m span standard bridge and provides examples of the axle trends described above. The first stress cycle from 0 m to 30 m represents the engine and the front of the first coach travelling over the bridge. Each stress cycle of the evenly spaced equal amplitude stress cycles from 30 m to 160 m represents the grouping of the four coach axles. The four meters of zero stress between each coach cycle represents the difference between the central coach axle spacing and the span length which, in this case, is equal to four metres (13 minus 9).

In addition to the passenger coach axle trend, the effects of the freight train No 7 wagon can be added. This wagon represents the 100 tonne coal and mineral wagon used since the 1970s (Hayward, 2010; 2013). The axle spacing for these wagons falls within the bounds discussed above. The axle loads for these wagons are approximately double the axle loads of the passenger coaches, causing significantly greater fatigue damage than the equivalent coach.

The final key axle trend identified represents the historic freight wagons and the modern freight train No 8 wagons, which have short wagon length. The historic freight wagons consist of two axles spaced at 3 m with 2 m spacing between adjoining wagon axles. This trend extends to 5.5 m spacing between wagon axles and 3.5 m between adjoining wagon axles for the modern freight train No 8 wagons. The historic freight wagons produce the smallest amplitude stress fluctuations of all the trains and, for most bridges, can be treated as a uniformly distributed load for fatigue assessments. For longer span bridges over 17 m the modern freight wagon can also be considered as a uniformly distributed load for fatigue assessments. However, for spans under 10 m, the axle spacing to span length ratio becomes critical to the scale of the fatigue damage that the freight train No 8 wagons causes. Figure 5 shows the stress histories for the freight train No 8 wagon on three varying spans less than 10 m in length. The variance within the amplitude of the stress cycles between the span lengths is critical to the change in fatigue damage between the spans.

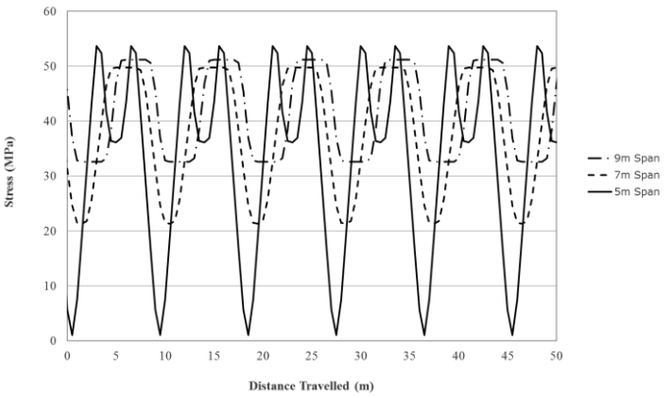

Figure 5. Stress histories of freight train No 8 wagons for different spans.

4.2 *Comparisons between modern and historic trains*

Comparison of the fatigue damage between the historic and modern train types has been carried out using the standard bridge set. Figure 6 shows the total fatigue damage caused from the historic trains against the modern trains within the medium traffic load model. The historic trains are representative of the period from 1900 to 1970 and account for all the fatigue damage within this period; the modern trains represent fatigue damage from 1970 onwards until the present. The results in Figure 6 and all subsequent figures have been normalised to the highest peak point in order to identify the trends and relative differences between the different types of loading rather than providing an explicit estimate of the fatigue damage.

The results in Figure 6 show that for bridges around 100 years old that have been subjected to medium traffic conditions, modern trains cause the majority of the fatigue damage for bridge spans ranging between 4 m and 14 m. In particular, fatigue damage in bridge spans under 9 m can be seen to be heavily dominated by modern trains which demonstrates the criticality of short span bridges being particularly fatigue sensitive to modern train loads (Hayward, 2010; 2013). For bridge spans greater than 14 m, historic trains can be seen to produce the highest proportion of the fatigue damage. For example, for a 9 m bridge, approximately 70% of the fatigue damage can be attributed to modern loading and the remaining 30% to historical trains. On the other hand, for a 16 m bridge, approximately 60% of

the damage is attributed to historical trains whereas the remaining 40% to modern rail traffic.

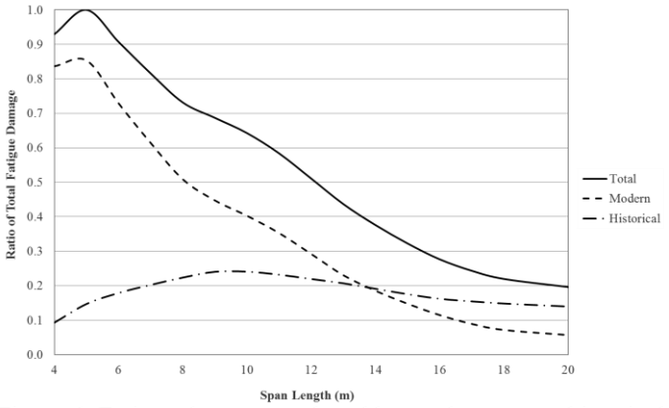

Figure 6. Fatigue damage produced by modern versus historical loading.

The variables that create this distinct difference in fatigue damage between modern and historic trains are:

- The length of service for each train type.
- The physical length of the trains i.e. the number of wagons/coaches.
- The engine locomotive axle loads.
- The wagon and coach axle loads.
- The annual frequency of the train types.
- The train speeds which affect the applied dynamic amplification factor.
- The type of axle grouping trains within each period (short axle spacing versus long axle spacing).

To understand which trains cause the most fatigue damage for particular span lengths, the critical variables have been removed to create a standardised train set for comparison. The standardised variables across this train set are:

- The train length; the train consists of the engine and five trailing units only.
- A period of one year for all trains has been used for the comparison.
- 10,000 trains per year for each train type has been assumed.
- The remaining variables have been left independent for each train type.

As can be seen in Figure 7, the standardised train results show that, for span lengths less than 10m, the modern trains BS5400 No 1 to 8 cause significantly greater fatigue damage than their historical counterparts. Between span lengths of 10 m and 18 m the modern trains, excluding the BS5400 No 7 freight train, cause relatively similar fatigue damage to the historic trains with both sets having a slow linear change between span lengths. BS5400 No 7 and 8 freight trains have the greatest axle load of 25 tonnes per axle for all the trailing unit types (BS5400, 1980). All other units range between eight and thirteen tonnes per axle. The damaging effect of these high axle loads can be seen within the results in Figure 7. The increased magnitude of axle load within the modern freight trains creates similarly increased stress ranges within the bridge spans of the same spacing magnitude. However, the relationship between stress range and fatigue damage is cubed or higher, therefore any increase in stress range is vastly magnified for the corresponding fatigue damage.

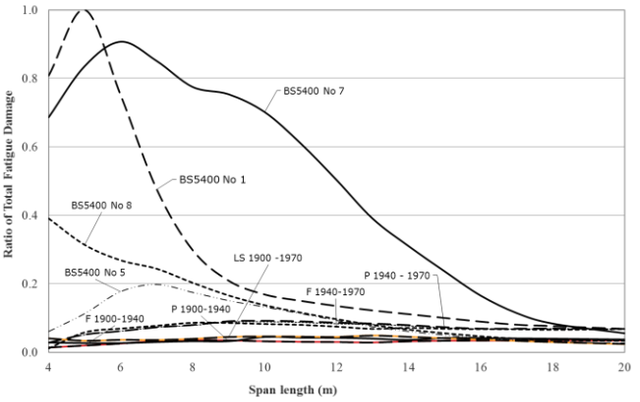

Figure 7. Individual train fatigue damage for the standardised train set.

4.3 *Light, medium and heavy historic load models*

The light and heavy train load models presented in Figures 1 and 2 have been developed based on the modern load models within BS5400: Part 10 (BS5400, 1980), which represent bridges that solely see either passenger trains or freight trains respectively. A bridge subjected to the light train load model could be representative of a bridge located just outside one of the main London terminus stations and would only ever see passenger trains. On the other hand, a bridge located outside a busy freight terminal, away from a major city, would only be subjected to the heavy freight train load model.

The difference between the light and the heavy traffic load models can be seen in Figure 8 which shows the fatigue damage for all three models (medium, light and heavy traffic). The light load model consists solely of large axle spacing trains. The significant increase in fatigue damage caused by the historic trains with respect to the damage caused by the modern trains, in comparison to the medium train load model is created due to the much higher frequency of the extremely damaging passenger locomotive engine. For example, for the 6 m span bridge the locomotive engine causes 33% of the total damage from the historic passenger train, whereas for the 18 m span bridge the percentage contribution increases to 82% of the total damage by the passenger train.

The results from the heavy train load model have a high correlation with the medium train load model, showing that the freight trains predominantly create the fatigue damage with the medium train load model.

It should be noted that the load models suggested in this paper are based on representative UK rail traffic. However, comparison of the train suggest here with other historical load models, such as the one suggested by UIC (1988), displays similarities in terms of the evolution of the axle loads over time and the configuration of the trains. The historical traffic experienced by bridges located in different parts of the railway network is likely to be different; for example, an old railway bridge that is located close to a coal/iron mine is likely to have experienced heavier historical loads due to freight trains as compared to a typical bridge located on a main passenger route, where traffic may be more passenger-dominated. The proposed load models with the light and heavy variations can be representative of upper and lower bounds of fatigue damage originating from historical trains. Obviously, in the availability of detailed historical traffic data for a specific region, further detailed traffic load models can be developed.

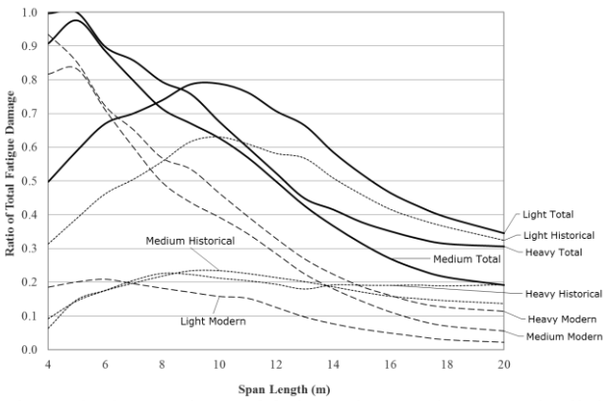

Figure 8. Comparison of fatigue damage between the light, medium and heavy traffic load models.

4.4 *Wrought-iron vs mild steel riveted bridges*

It is known that during the mid-19th century the Board of Trade imposed design strength limits upon the use of wrought iron of 77.5 MPa within tension members and additionally a limit to mild steel in tension of 100 MPa two decades later (Fitzmaurice, 1895; Hayward, 2010; 2013). The implication from these design limits is the additional strength of mild steel, which creates a lighter design than the equivalent wrought iron bridges, therefore having a higher maximum live load limit and increased equivalent amplitude of stress cycles due to trains travelling across the structure. This increased stress range would, under the same fatigue detail, produce significantly more fatigue damage for the steel bridges than the wrought iron counterparts.

However, the fatigue detail categories vary for riveted plate girders in steel compared to wrought iron. BS5400 Class D (BS5400, 1980) is suggested for the former whereas a separate classification exists for wrought iron girders (Network Rail, 2006).

Another standard bridge set has been created so that both steel and wrought iron bridges are represented; the steel and wrought iron bridge sets have been designed to the same working stress method (Fitzmaurice, 1895; Hayward, 2010; 2013). From comparing the fatigue damage results for both bridge material types, it can be seen in Figure 9 that the reduction in stress cycle amplitude between the steel and wrought iron bridges is more significant than the increased fatigue category sensitivity of the wrought iron. The early mild steel riveted plate girder bridges are between 15% to 30% more fatigue sensitive across the span range than the equivalent wrought iron riveted plate girder bridges.

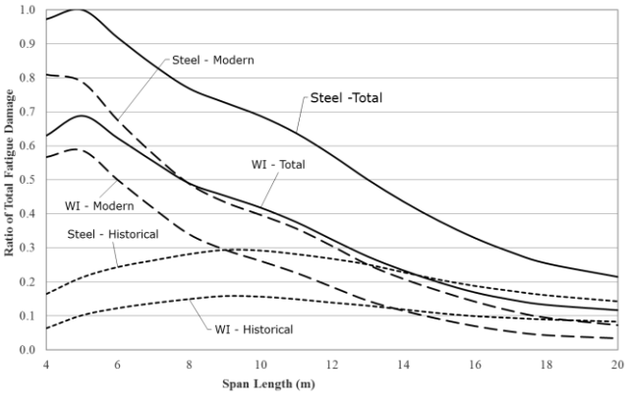

Figure 9. Comparison of fatigue damage between steel and wrought iron bridges.

4.5 *Comparison of bridges between 1900 and 1940*

A comparison of the fatigue damage for the standard bridge sets constructed between 1900 to 1940 is shown in Figure 10. For comparison purposes, the fatigue damage produced solely by the modern (1970-) trains is also presented. The historic load models for each bridge era have been created by excluding any fatigue damage from trains representing earlier periods. It can be seen from that figure that as the standard bridge sets become younger, the modern trains increasingly dominate the proportion of fatigue damage caused. For any riveted plate girder bridge constructed in wrought iron or steel up to 1940, modern train loads based on the medium train load model dominate the fatigue performance of short and medium span bridges.

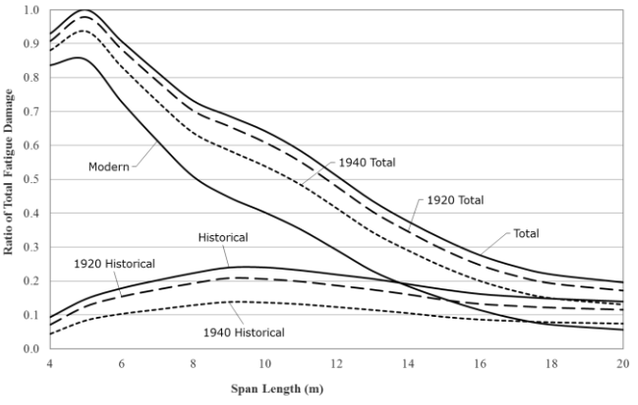

Figure 10. Comparison of bridges constructed between 1900-1940.

5 CONCLUSIONS

This paper focused on fatigue effects due to the variations in train loading over time upon riveted plate girder bridges, with the aim of understanding the differing fatigue effects of historic to modern train loading. Three historical load model variations, accounting for passenger-dominated, freight-dominated and combined railway lines have been proposed. These were then applied to a set of typical riveted plate girder bridges to investigate trends on fatigue loading. The parameters that have been investigated were the type of the trains passing over the bridge, the bridge span, the material of the bridge (mild steel vs. wrought iron) and the date of construction of the bridge.

The results show that, for the majority of existing riveted plate girder bridges, which have been constructed circa 1900, the modern trains from 1970 to 2010 cause the majority of the fatigue damage for bridge spans less than 14 m in length, as compared to the historical trains from 1900 to 1970. The fundamental effect of increasing axle loads over time was observed to override the other identified effects of variation in train frequency, train length and loading lifetime. The results presented in this paper can be easily used during fatigue assessment in identifying and quantifying the significance of historic loading on fatigue damage accumulation for different bridge spans. Obviously, the configuration as well as the intensity of historical rail traffic will can vary in different railway lines (routes) where some routes can be more freight-dominated, whereas other routes can be more passenger-dominated. Nevertheless, the results presented in this paper show that, in some cases, the effect of historical traffic may not be insignificant.

Comparison between wrought iron and mild steel main girders has shown that due to the increased strength found within early mild steel compared to wrought iron, higher fatigue damage is accumulated within the steel girders compared to an equivalent wrought iron detail. This increased fatigue sensitivity of steel riveted plated girders varies from 20% for the short span bridges to 10% for the longer span riveted bridges. Furthermore, by investigating the influence of the year of construction of the bridge it was found that the younger a riveted plate girder bridge is, the more dominant the effect of the modern trains becomes on the overall fatigue damage caused.

Multi-Objective Optimum Service Life Bridge Management Based on Fatigue Damage Detection

Sunyong Kim
Wonkwang University, Iksan, South Korea
Dan M. Frangopol
Lehigh University, Bethlehem, PA, USA

ABSTRACT: This paper deals with the inspection planning for service life management of deteriorating bridges based on efficient multi-objective optimization. The damage detection based-objectives presented in this paper are (a) minimizing the expected fatigue damage detection delay, (b) minimizing the probability of fatigue failure, (c) maximizing the expected extended service life, and (d) minimizing the expected total life-cycle cost. The effect of fatigue damage detection on the probability of failure, service life extension, and life-cycle cost is considered. Using the objective reduction approach, the effects of adding or removing particular objectives among these four on the Pareto front are investigated, and the redundant objectives, which have no effect on the Pareto front, are identified. By removing the redundant objectives, the efficiency in decision making and visualization of the multi-objective optimization for inspection planning are improved.

1 INTRODUCTION

Damage detection and identification are the first phase to ensure the structural safety and extend the service life of deteriorating bridges (NCHRP 2006). During the last few decades, the techniques associated with damage detection and identification have been extensively developed (Frangopol 2011, Frangopol et al. 2011, Frangopol & Soliman 2016). However, due to the uncertainties associated with the damage initiation and propagation prediction, and damage detection, damage may not be detected on time (Mohanty et al. 2009, Kwon & Frangopol 2011). Therefore, inspection plans have to be applied at uniform or non-uniform time intervals (Frangopol et al 1997). Inspection plans can be established through single or multi-objective optimization (Kabir et al. 2014). It has been known that the increase of the number of objectives to be optimized simultaneously can lead to more rational and well-balanced solutions (Deb 2001, Arora 2012). However, more effort is required for computation to find the Pareto solutions, visualization of these solutions, and decision making to select the well balanced solution (Deb 2001, Brockhoff & Zitzler 2007, Saxena et al. 2013, Jaimes et al. 2014).

Recently, the optimum inspection planning based on four objectives was investigated for deteriorating reinforced concrete structures by Kim & Frangopol (2017a). Based on this study, the five objectives for the optimum structural health monitoring planning were developed, and applied to a fatigue-sensitive ship hull structure in Kim and Frangopol (2017b). However, the multi-objective optimum inspection planning for a steel bridge under fatigue needs to be investigated considering the correlation among the objectives based on damage detection.

This paper deals with the inspection planning for service life bridge management based on fatigue damage detection. The objectives considered are (a) minimizing the fatigue damage detection delay, (b) minimizing the probability of fatigue failure, (c) maximizing the extended service life, and (d) minimizing the expected total life-cycle cost. They are formulated considering the effect of damage detection on probability of failure, service life extension, and life-cycle cost. Using the objective reduction approach, the effect of adding or removing particular objectives among these four on the Pareto front are investigated, and the redundant objectives, which have no effect on the Pareto front, are identified. By removing the redundant objectives, the efficiency in decision making and visualization of the multi-objective optimization for NDT planning are improved.

2 DAMAGE DETECTION-BASED OBJECTIVES

Service life management of deteriorating structures should be based on multi-objective optimization. The formulation of the objectives for fatigue management intervention considers the damage initiation and propagation prediction, probability of damage

detection, service life prediction, and cost estimation (Kim et al 2013).

2.1 *Fatigue damage detection delay*

When the time t_{oc} for damage to occur is deterministic, and the damage is detected at time t_{de}, the damage detection delay t_{dl} is $t_{de} - t_{oc}$. However, due to the uncertainties associated with damage occurrence/propagation and the inspection methods, damage detection delay cannot be estimated deterministically. The expected fatigue damage detection delay $E(t_{dl})$ is expressed as (Kim & Frangopol 2011a)

$$E\left(t_{dl}\right) = \sum_{i=1}^{N_{in}} \left[\int_{t_{in,i-1}}^{t_{in}} t_{dl,i} \cdot f_T\left(t\right) dt \right] \quad (1)$$

where N_{in} = number of inspections; $t_{in,i}$ = ith inspection time; $t_{dl,i}$ = damage detection delay when the damage occurs between $t_{in,i-1}$ and $t_{in,i}$; and $f_T(t)$ = probability density function (PDF) of the damage occurrence time. The optimum inspection planning can be based on the minimization of the expected damage detection delay. Improvement of inspection quality and increase of number of inspections can result in reduction of the expected damage detection delay (Kim & Frangopol 2011a).

2.2 *Probability of fatigue failure based on damage detection*

Fatigue cracks have to be detected and repaired before reaching critical sizes to reduce the probability of failure and extend the service life. The time-based safety margin can be expressed as the difference between the time associated with the occurrence of the critical crack size t_{cr} and damage detection time t_{de} (Kim & Frangopol 2011b). By treating t_{cr} and t_{de} as random variables, the probability of fatigue failure P_{fail} is defined as

$$P_{fail} = P\left(t_{cr} < t_{de}\right) \quad (2)$$

The optimum inspection planning can be based on minimizing the probability of fatigue failure. Increasing the number of inspections and/or improving inspection quality results in reduction of the probability of failure (Kim & Frangopol 2011b).

2.3 *Extended service life*

The service life can be extended through the timely and appropriate maintenance actions, which have to be applied after damage detection and identification. The formulation of the extended service life is based on the decision tree, where the relation among damage detection, maintenance and service life extension is addressed. The extended service life $t_{sv,ex}$ is expressed as (Kim et al. 2013)

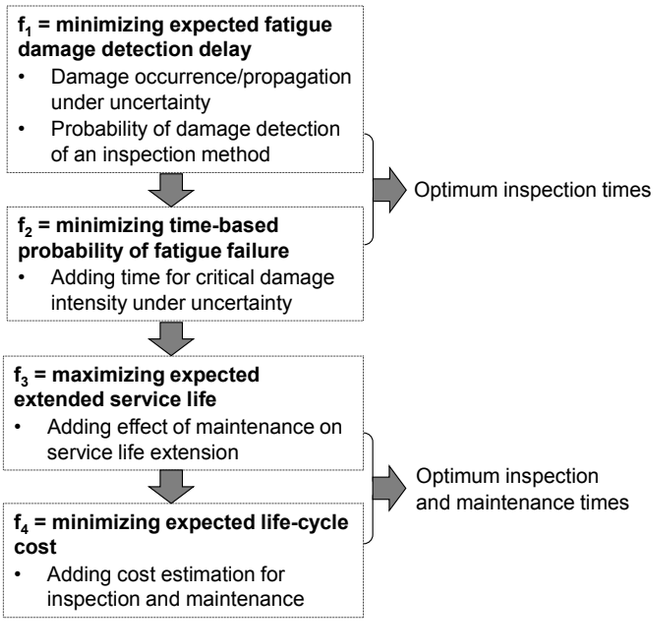

Figure 1. Required estimation for the formulation of objectives f_1, f_2, f_3 and f_4.

$$t_{sv,ex} = t_{sv,o} \quad \text{for } t_{in} > t_{sv,o} \quad (3a)$$

$$t_{sv,ex} = \left(1 - P_{in}\right) \cdot t_{sv,o} + P_{in} \cdot \left(t_{sv,o} + t_{ex}\right) \quad \text{for } t_{in} > t_{sv,o} \quad (3b)$$

where $t_{sv,o}$ = initial service life; P_{in} = probability of damage detection; and t_{ex} = extended service life. The service life extension t_{ex} in Eq. (3b) depends on the type of maintenance. The maintenance type is determined based on the degree of damage (Kim et al 2013). It should be noted that late inspection (i.e. $t_{in} > t_{sv,o}$) or no damage detection (i.e. $1 - P_{in}$) results in no service life extension (i.e. $t_{ex} = 0$) as indicated in Eq. (3).

2.4 *Expected life-cycle cost*

Damage detection and maintenance to reduce the probability of failure and extend the service life are generally cost related. In order to consider direct and indirect costs of deteriorating structures, and establish the optimum inspection and maintenance plans, life-cycle cost analysis has to be applied (Frangopol et al 1997). The expected life-cycle cost C_{lc} during the predefined service life of a deteriorating structure is expressed as (Frangopol et al. 1997, Wallbank et al. 1999, NCHRP 2003)

$$C_{lc} = C_{ma} + P_{fail} \cdot C_{fa} \quad (4)$$

where C_{ma} is the cost for inspection and maintenance, and C_{fa} is the monetary loss induced by the structural failure.

3 ESTIMATION OF RELATION AMONG OBJECTIVES

In this paper, the optimum service life management is based on four objectives of (a) f_1 = minimizing the fatigue damage detection delay (see Eq. (1)), (b) f_2 = minimizing the probability of fatigue failure (see Eq. (2)), (c) f_3 = maximizing the extended service life (see Eq. (3)), and (d) f_4 = minimizing the expected total life-cycle cost (see Eq. (4)). As shown in Figure 1, the formulations of the objectives f_1, f_2, f_3 and f_4 includes estimating the probabilistic damage occurrence and propagation, and probability of damage detection of an inspection method. Therefore, the objectives may be correlated.

In order to quantify the linear relationship between the objectives f_i and f_j, the Pearson's coefficient of correlation ρ (f_i, f_j) is computed as (Ang & Tang 2007)

$$\rho_p\left(f_i, f_j\right) = \frac{E\left[\left\{f_i(\mathbf{x}) - E\left[f_i(\mathbf{x})\right]\right\} \cdot \left\{f_j(\mathbf{x}) - E\left[f_j(\mathbf{x})\right]\right\}\right]}{\sigma_i \cdot \sigma_j} \quad (5)$$

where $\mathbf{x}$ is the vector of the design variables, and σ_i and σ_j are the standard deviations of the objective values of f_i and f_j in the design space, respectively. The monotone relation between the objectives f_i and f_j is represented by the Spearman's coefficient correlation as (Myers et al. 2003)

$$\rho_s\left(f_i, f_j\right) = 1 - \frac{6\sum_{i=1}^{n} d_i^2}{n\left(n^2 - 1\right)} \quad (6)$$

where n = number of values of objective f_i or f_j in the design space; and d_i = difference between the ranks of objective values of f_i and f_j.

Furthermore, the relation among objectives can be represented by using the dominance relation-based objective reduction approach. If and only if $\forall f_a \in \Omega_R : f_a(\mathbf{x_1}) \leq f_a(\mathbf{x_2})$, a solution $\mathbf{x_1}$ dominates another solution $\mathbf{x_2}$ for $\Omega_R \subseteq \Omega_O$, where Ω_R and Ω_O are the reduced and original objective sets, respectively. $\forall f_a \in \Omega_R$ denotes any objective f_a of Ω_R. The purpose of this approach is to investigate the dominance relation among the objective values, and the change of the Pareto front by removing a particular objective. Finally, the redundant and essential objectives are identified. The dominance relation is represented by the normalized degree of conflict γ_{nm} ranging from 0 (non-conflict) to 1 (full-conflict). γ_{nm} between Ω_R and Ω_O equal to zero indicates that there is no change in the dominance relation and Pareto front when the original objective set Ω_O is replaced by the reduced objective set Ω_R. Detailed information on this approach is available (Brockhoff & Zitzler 2006, 2007).

4 ILLUSTRATIVE EXAMPLE

The approach presented is applied to an existing highway bridge, which is the I-64 bridge over the Kanawha River in West Virginia, USA, and was opened for traffic in 1974 (Connor & Fisher 2001). This application focuses on the gap between the bottom flange and the end of the transverse connecting plate as shown in Figure 2. The fatigue propagation under uncertainty is predicted based on the information provided in Soliman et al (2013). In this illustrative example, it is assumed that (a) the ultrasonic inspection method is applied to detect the fatigue crack, (b) the initial condition before cracking occurred is expected by applying the maintenance such as cutting out and re-fabricating parts of elements, and (c) the cost for each inspection and maintenance and monetary loss due to the structural failure are \$65000 and \$100000, respectively.

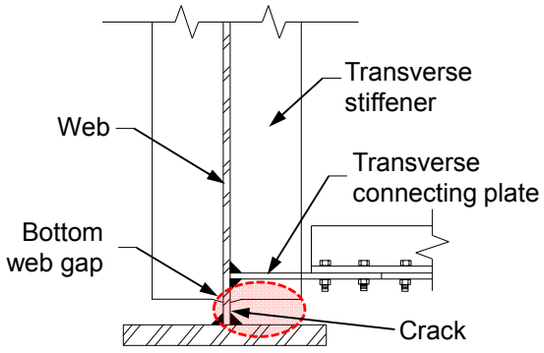

Figure 2. Fatigue sensitive detail of steel bridge (adapted from (Soliman et al 2013)).

Table 1. Correlation coefficients among the objectives $E(t_{dl})$, P_{fail}, $E(t_{sv,ex})$ and C_{lc} for N_{in} = 2.

		$E(t_{dl})$	P_{fail}	$E(t_{sv,ex})$	C_{lc}
Pearson's coefficient of correlation ρ_p	$E(t_{dl})$	1	0.991	0.423	-0.004
	P_{fail}	0.991	1	0.403	-0.001
	$E(t_{sv,ex})$	0.423	0.403	1	-0.694
	C_{lc}	-0.004	-0.001	-0.694	1
		$E(t_{dl})$	P_{fail}	$E(t_{sv,ex})$	C_{lc}
Spearman's coefficient of correlation ρ_s	$E(t_{dl})$	1	0.989	0.119	0.348
	P_{fail}	0.989	1	0.068	0.374
	$E(t_{sv,ex})$	0.119	0.068	1	-0.727
	C_{lc}	0.348	0.374	-0.727	1

The coefficient of correlation between the expected damage detection delay $E(t_{dl})$ and probability of failure P_{fail} is the largest (i.e., $\rho_p = \rho_s = 0.99$) as indicated in Table 1. Figure 3 illustrates this relation for two inspections N_{in} = 2. Since $E(t_{dl})$ and P_{fail} are highly correlated, $E(t_{dl})$ or P_{fail} may be redundant (Kim & Frangopol 2017a).

The multi-objective optimization formulation using the objectives f_1 to f_4 for a given number of inspections N_{in} is

$$\textit{Find } \boldsymbol{t_{in}} = \{t_{in,1},\ t_{in,2}, \ldots t_{in,Nin}\} \tag{7a}$$

$$\textit{for } f_1 = \text{minimizing } E(t_{dl}), \tag{7b}$$
$$f_2 = \text{minimizing } P_{fail},$$
$$f_3 = \text{maximizing } E(t_{sv,ex}),$$
$$f_4 = \text{minimizing } C_{lc}$$

$$\textit{subject to } 1 \text{ year} \leq t_{in,i} - t_{in,i-1} \leq 20 \text{ years} \tag{7c}$$

where $\boldsymbol{t_{in}}$ is the vector consisting of the design variables of inspection times. In order to solve the multi-objective optimization problem defined in Eq. (7), the genetic algorithm provided in MATLAB R2016b (MathWork 2016) is used. The Pareto solution set obtained from the multi-objective optimization problem is used to compute the normalized degree of conflict γ_{nm} between the original objective set.

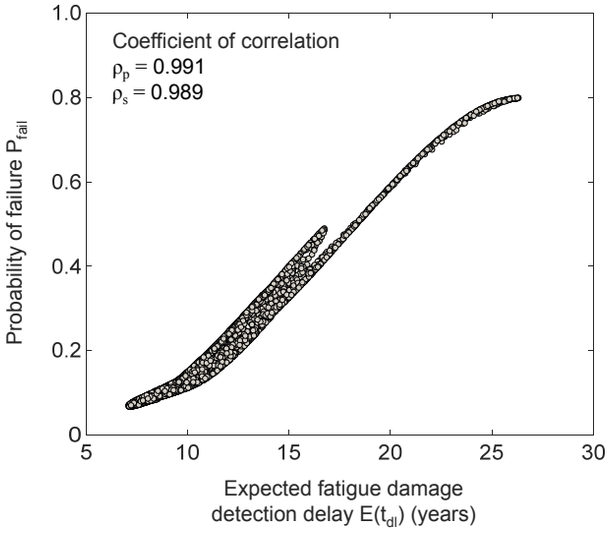

Figure 3. Relation between $E(t_{dl})$ and P_{fail} for $N_{in} = 2$.

Table 2. Normalized degree of conflict γ_{nm} between original objective set $\Omega_O = \{f_1, f_2, f_3, f_4\}$ and reduced objective set Ω_R.

Reduced objective set Ω_R	$N_{in} = 1$	$N_{in} = 2$
$\{f_1, f_3\}$	0.001	0.992
$\{f_2, f_3\}$	0.0	0.992
$\{f_2, f_4\}$	1.0	1.0
$\{f_3, f_4\}$	0.001	0.953
$\{f_1, f_2, f_3\}$	0.0	0.992
$\{f_1, f_3, f_4\}$	0.001	0.001
$\{f_2, f_3, f_4\}$	0.0	0.038

The representative γ_{nm} for the number of inspection N_{in} =1 and 2 is presented in Table 2. Figure 4 compares the Pareto solution sets of the original objective set $\Omega_O = \{f_1, f_2, f_3, f_4\}$ and reduced objective sets $\Omega_R = \{f_2, f_3\}$, $\{f_1, f_2, f_3\}$ and $\{f_2, f_3, f_4\}$ for N_{in} =

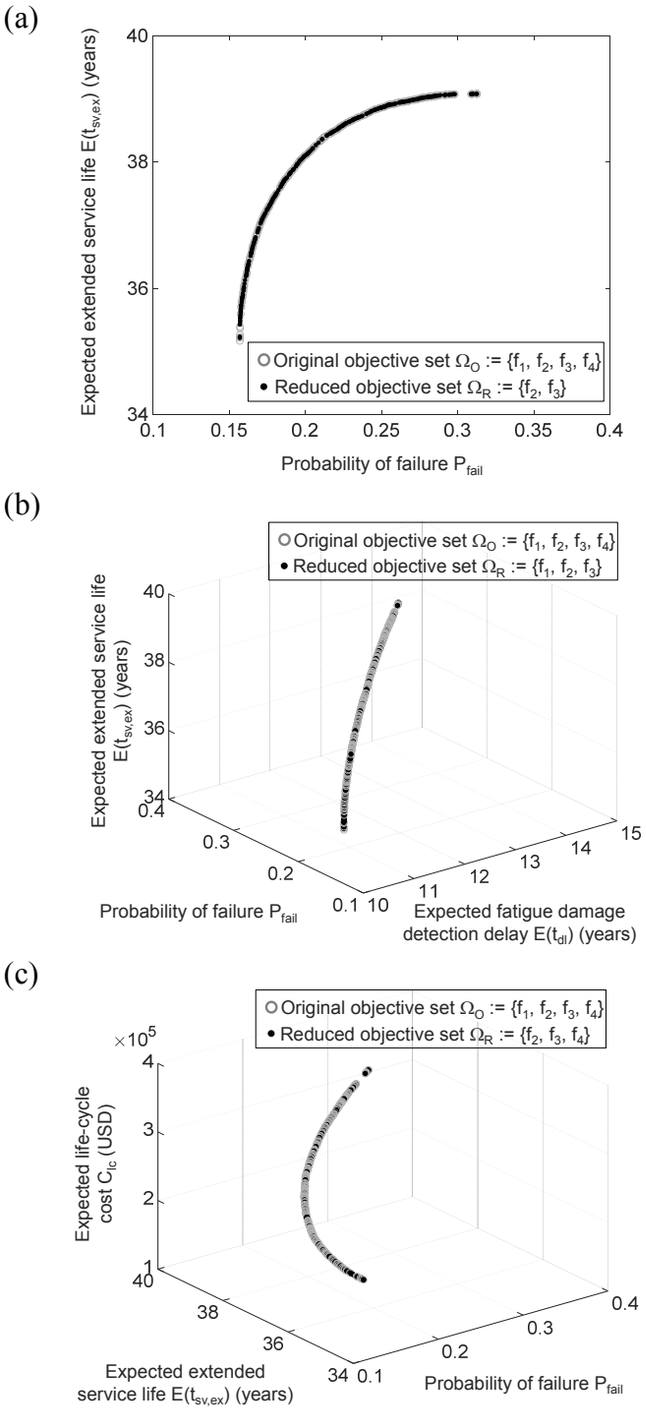

Figure 4. Pareto solution sets for $\gamma_{nm} = 0$ and $N_{in} = 1$: (a) $\Omega_R = \{f_2, f_3\}$; (b) $\Omega_R = \{f_1, f_2, f_3\}$; (c) $\Omega_R = \{f_2, f_3, f_4\}$.

1. From Fig. 3, it can be seen that the reduced objective sets $\Omega_R = \{f_2, f_3\}$, $\{f_1, f_2, f_3\}$ and $\{f_2, f_3, f_4\}$ result in the identical Pareto set with the one of Ω_O, since γ_{nm} is equal to zero. $\Omega_R = \{f_2, f_3\}$ associated with the minimum number of objectives is the essential objective set, and f_1 and f_4 are redundant.

For $N_{in} = 2$, the comparison between the Pareto-solution sets of Ω_O and $\Omega_R := \{f_1, f_3, f_4\}$ is illustrated in Figure 5. Since γ_{nm} between these objective sets is approximately zero (i.e. $\gamma_{nm} = 0.001$), the Pareto front of Ω_O is similar to that of $\Omega_R := \{f_1, f_3, f_4\}$. For this reason, it can be concluded that the objective set $\{f_1, f_3, f_4\}$ is the essential objective set, and is used

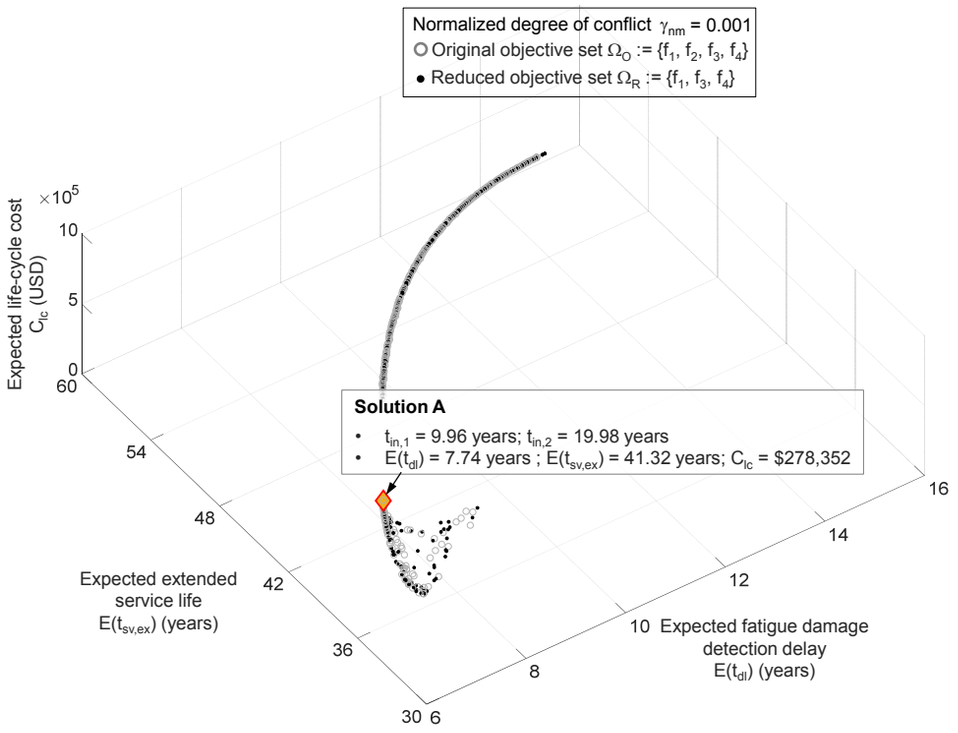

Figure 5. Pareto solution sets of Ω_O = {f_1, f_2, f_3, f_4} and Ω_R = {f_1, f_3, f_4}.

for optimum inspection planning instead of using all the four objectives f_1 to f_4. The solution A in Figure 5 requires two inspections applied at time $t_{in,1}$ = 9.96 years and $t_{in,2}$ = 19.98 years, and the associated $E(t_{dl})$, $E(t_{sv,ex})$ and C_{lc} are 7.74 years, 41.32 years, and $278352, respectively.

5 CONCLUSIONS

This paper presents the damage detection–based objectives including minimizing the expected fatigue damage detection delay, minimizing the probability of fatigue failure, maximizing the expected extended service life, and minimizing the expected life-cycle cost. These objectives are used for multi-objective optimum service life management of deteriorating highway bridges under fatigue. The correlations among the four objectives are investigated. In order to identify the redundant and essential objectives, the dominance relation-based objective reduction approach is used. The approach proposed is applied to a highway bridge under fatigue. The approach can be extended to include system reliability, redundancy, sensitivity, and lifetime maintenance (Frangopol 1985, Frangopol & Nakib 1991, Frangopol & Estes 1997, Onoufriou & Frangopol 2002, Okasha & Frangopol 2009).

Probabilistic fatigue life prediction employing an advanced crack propagation model

Y.-J. Lee, J.H. Lee & S. Lee
Ulsan National Institute of Science and Technology (UNIST), Ulsan, Republic of Korea

ABSTRACT: Steel railway bridges are exposed to repeated train loads that often result in fatigue failure. As critical nodes of a transportation network, railway bridges should be designed and maintained to prevent fatigue failure for a predetermined period of time. However, as this would mandate accurate prediction of the fatigue life of railway bridges, the various sources of uncertainty associated with aging bridges, train loads, and the environment considerably complicate this task. In addition, for accurate fatigue life prediction, it is necessary to introduce an appropriate model for crack propagation. Although various studies have been conducted to predict the probabilistic fatigue life of steel railway bridges, many of them are based on a relatively simple model of crack propagation that assumes zero minimum stress and constant loading amplitude, thereby limiting the application scope and reducing the result accuracy. Thus, in this study, a new probabilistic method employing an advanced crack propagation model is proposed for the fatigue life prediction of steel railway bridges. A series of formulations are derived from an advanced crack propagation model such that probabilistic fatigue failure probability can be calculated through reliability analysis using the derived formulations as limit-state functions. Additionally, the formulations are derived such that the model can handle variable amplitude loading, which is the most common loading pattern for railway bridges. To demonstrate the proposed method, it is applied to a numerical example of a steel railway bridge, and the effects of an advanced crack propagation model and various loading amplitudes on bridge fatigue life is discussed through a parametric study.

1 INTRODUCTION

Railway bridges, which play an important role in the daily lives of numerous people, are known to be highly susceptible to fatigue failure. Many structural systems are subjected to the risk of fatigue-induced failure as due to repeated loading over their life cycle; consequently, this is an important safety concern for railway bridges. Thus, it is essential that fatigue life is accurately predicted such that an effective bridge design and maintenance plan can be developed. However, this is not an easy task, as there are various sources of uncertainty associated with aging bridges, train loads, and environmental conditions. Moreover, it is also necessary to introduce an appropriate model for crack propagation.

Two approaches are commonly employed for the fatigue damage evaluation and life prediction of bridge structures. The first approach is the traditional stress-life (S-N) curve method in which the relationship between the constant-amplitude stress range, S, and the number of cycles to failure, N, is determined via appropriate fatigue experiments and described by an S-N curve. In this approach, the Palmgren-Miner linear damage hypothesis, which is also referred to as Miner's rule (Miner 1945), extends this approach to variable amplitude loadings. The second approach is the fracture mechanics approach, which is primarily dedicated to exploring the features and disciplines of crack initiation and growth, while also considering the stress field at the crack tip.

These two approaches are generally applied in sequence, with the S-N curve method being implemented first at the bridge design stage, or for the preliminary evaluation of fatigue life; the fracture mechanics approach is subsequently used to refine the crack-based assessment of remaining fatigue life, or to promote effective inspection and maintenance strategy-related decision-making (Chryssanthopoulos & Righiniotis 2006). However, the S-N curve can only be obtained via experimentation, and is limited in its ability to estimate the probabilistic bridge life as based on the current condition of a bridge.

Alternatively, the fracture mechanics approach is often applied to predict the propagation life as based on an initial crack or defect. More specifically, linear elastic fracture mechanics (LEFM)-based methods relate the growth of an initial crack of a certain size

to the number of fatigue cycles. To date, there has been many investigations into fracture mechanics-based bridge fatigue condition assessment. For example, Fisher (1984) illustrated more than 25 case studies on fatigue crack phenomena in steel bridges using the fracture mechanics approach and other theories. Agerskov and Nielsen (1999) investigated fatigue damage accumulation in steel bridges under the condition of random loading and determined the fatigue life of welded joints in steel highway bridges by carrying out fracture mechanics analysis. By using an LEFM model to predict crack growth, MacDougall et al. (2006) quantified the effects of successive passages of a steel-sprung vehicle and an air-sprung vehicle, respectively, on the differences between the fatigue lives of a short-span bridge and a medium-span bridge. Using experimental data obtained via the structural components of Kinuura Bridge, and LEFM-based theoretical predictions, Xiao et al. (2006) found that the lack of 2–3-mm penetration zones resulted in the low fatigue strength of butt-welded joints. Imam et al. (2008) proposed a probabilistic fatigue assessment methodology for riveted railway bridges, and subsequently applied this method to predict the fatigue occurring in a typical short-span riveted railway bridge in the UK by using train loading data. Similarly, Park et al. (2005), Zhao et al. (1994), and Madsen (1983) used a fracture mechanics approach to estimate the fatigue reliability of bridges. Additionally, Lukić & Cremona (2001) proposed a crack growth model for the probabilistic assessment of steel components damaged by fatigue, and applied the results to a typical steel bridge.

Although there are numerous studies proposing models for fatigue failure prediction of railway bridge components, many of the studies focused on probabilistic fatigue life implement a relatively simple model of crack propagation that assumes zero minimum stress and constant loading amplitude, and thereby limits the application scope and reduces the result accuracy. Thus, in this study, a new probabilistic method implementing an advanced crack propagation model is proposed for the fatigue life prediction of steel railway bridges. The proposed method entails derivation of a series of formulations that allows the model to appropriately manage non-zero minimum stress and variable amplitude loading. To validate the method, it is applied to a numerical model of a railway bridge, and the fatigue life of the bridge is subsequently evaluated.

2 PROPOSED METHODOLOGY

In a structural reliability problem, the failure probability calculation requires construction of an appropriate limit-state function, which represents the failure event of interest as an analytical function of random variables (RVs) and deterministic parameters (Agerskov & Nielsen 1999, Xiao et al. 2006). As was mentioned in Section 1, many researchers have developed various S-N-based or LEFM-based methods for the fatigue reliability analysis of bridges. A widely used LEFM-based numerical model for crack propagation is the Paris equation (Lee & Cho 2016, Lee et al. 2017). Building on this equation, Lee and Cho (2016) and Lee and Song (2014) derived a series of formulations to estimate the structural risk of fatigue-induced failure. However, because the formulations are based on the Paris equation (Paris and Erdogan 1963), which assumes zero minimum stress and constant-amplitude loads, they cannot be practically applied to a railway bridge, as non-zero minimum stress and variable amplitude loading is the realistic pattern generated by train traffic. Therefore, in this study, the limit-state functions proposed by Lee and Cho (2016) and Lee and Song (2014) are modified to enable practical application as a method to evaluate the fatigue life of a railway bridge.

First, consider the following Walker equation (Dowling et al. 2009):

$$\frac{da}{dN} = C_0 \left(\frac{\Delta K}{(1-R)^{1-\gamma}} \right)^{m_0} \tag{1}$$

where a denotes the crack length, N denotes the number of loading cycles, C, m, and γ are the material properties, R is the stress ratio, and ΔK is the range of the stress intensity factor. The stress ratio R is defined by the ratio of the minimum stress σ_{min} to the maximum stress σ_{max} of the cyclic load.

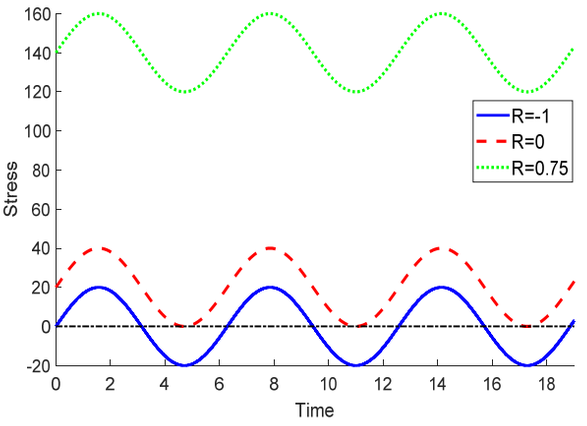

Figure 1. Cyclic loading for various values of R

Figure 1 shows cyclic load examples for different values of R (i.e., −1, 0, 0.75). R = −1 represents a load in both compression and tension. Alternatively, tension loading is dominant when R is zero, which represents a special case; under these conditions, the Walker equation is equivalent to the Paris equation, which yields a widely-known model of crack propagation. In addition, if the ratio of live load (i.e., train

load) to dead load (i.e., self-weight) is 1/3, the stress ratio R becomes 0.75, and the bridge will experience an oscillating stress such as that illustrated in green in Figure 1.

In Equation (1), the stress intensity factor range ΔK can be estimated via Newman's approximation (Newman and Raju 1981):

$$\Delta K = \Delta S \cdot Y(a) \cdot \sqrt{\pi a} \tag{2}$$

where ΔS denotes the stress amplitude and $Y(a)$ is the geometry function, which is a dimensionless parameter that varies according to the crack geometry. The following equation can be obtained by substituting Equation (2) into Equation (1):

$$\frac{1}{\left[Y(a)\sqrt{\pi a}\right]^{m_0}} da = C_0 \left(\frac{\Delta S}{\left(1-R\right)^{1-\gamma}} \right)^{m_0} dN \tag{3}$$

If the load amplitude is constant, Equation (3) can be developed into an equation for the fatigue life evaluation of a structure, as has been described by Lee and Song (2014) and Lee and Cho (2016). However, when a train passes over a bridge, the stress experienced by a structural member has been confirmed to oscillate, thereby enabling the use of the formulations devised for constant amplitude loading.

The rainflow cycle counting algorithm (Nieslony 2009) is commonly used to handle such variable amplitude loading and assess the fatigue life of structures, particularly in the field of mechanical engineering. Generally, the algorithm extracts cycles from the load, stress, or strain history as obtained via measurement or simulation results. Then, several cycles and half-cycles with varying amplitude and mean values are obtained subsequent to cycle counting. Because this counting algorithm implements a fatigue damage accumulation hypothesis (e.g., Paris equation and Miner's rule), it offers the advantage of enabling theoretical computation of the expected fatigue life under random loading conditions (Nieslony 2009).

The stress amplitude ΔS_i and the corresponding number of cycles and stress ratios n_i and R_i are used for the integration of Equation (3) from the initial condition to the current time point, thereby providing the following relationship between the current crack length and the time duration as follows:

$$\begin{aligned} &\int_{a^0}^{a} \frac{1}{\left[Y(a)\sqrt{\pi a}\right]^{m_0}} da \\ &= C_0 \cdot \nu_0 \cdot T \cdot \sum_{i=1}^{N_{amp}} \left[n_i \left(\frac{\Delta S_i}{\left(1-R_i\right)^{1-\gamma}} \right)^{m_0} \right] \end{aligned} \tag{4}$$

where a^0 is the initial crack length, ν_0 is the frequency of train loading, T is the time duration, and N_{amp} is the total number of stress amplitude values. If a crack failure is assumed to occur when the crack length exceeds the critical crack length a^c, the time required for crack growth from a^0 to a^c, T, is expressed as follows:

$$T = \frac{1}{C_0 \nu_0 \sum_{i=1}^{N_{amp}} \left[n_i \left(\frac{\Delta S_i}{\left(1-R_i\right)^{1-\gamma}} \right)^{m_0} \right]} \int_{a^0}^{a^c} \frac{1}{\left[Y(a)\sqrt{\pi a}\right]^{m_0}} da \tag{5}$$

The limit-state function for the failure of the j-th structural member within a given time interval $[0, T_s]$ is expressed via the following equation:

$$g(\mathbf{X}) = T_j^0 - T_s = \frac{\int_{a^0}^{a^c} \frac{1}{\left[Y(a)\sqrt{\pi a}\right]^{m_0}} da}{C_0 \nu_0 \sum_{i=1}^{N_{amp}} \left[n_i \left(\frac{\Delta S_i}{\left(1-R_i\right)^{1-\gamma}} \right)^{m_0} \right]} - T_s \tag{6}$$

where $\mathbf{X}$ denotes the vector of random variables, and T_j^0 is the time to fatigue failure of the j-th structural member. In structural reliability problems, $g(\mathbf{X}) \leq 0$ typically indicates the occurrence of a failure event.

Multiple considerations must be considered if a railway bridge is considered to be a structural system comprising multiple structural members. First, the failure of the bridge system should be expressed by a Boolean function of the failure events of individual members; to obtain such a function, system reliability analysis is required. Thus, in this study, a bridge is considered to fail if any of its members experience fatigue failure; the probability of this system event, P_{sys}, is described as

$$P_{sys} = P\left[\bigcup_{j=1}^{N_{mem}} \left(T_j^0 < T_s \right) \right] \tag{7}$$

Reliability analyses need to be performed to calculate fatigue failure probabilities by using these formulations (i.e., Equation (6) at a component level and Equation (7) at a system level). Therefore, among numerous methods developed to date for reliability analysis, the first-order reliability method (FORM) and second-order reliability method (SORM) (Der Kiureghian 2005) are implemented in this study to perform component reliability analysis. As a computational platform, FERUM (Finite Element Reliability Using MATLAB; Sudret and Der Kiureghian 2000), which is a reliability software package developed at the University of California, Berkeley, was modified and then introduced to perform reliability analysis. Secondly, for a structural system comprising multiple structural members, a failure event must be expressed as a system event; this requires system reliability analysis (SRA). In

this study, because it is assumed that the railway bridge system fails if any of its structural members fail, a multivariate normal integral method (Genz 1992), which enables us to efficiently and accurately calculate the probabilities of large-size parallel systems, is employed to calculate the system probability.

3 NUMERICAL EXAMPLE

3.1 *Numerical example of a steel railway bridge*

The proposed method of fatigue life estimation is tested by applying it to a simple numerical example shown in Figure 2. The bridge is assumed to be 95 m long, 21 m tall, 10 m wide, and made of A36 American Society for Testing and Materials (ASTM) steel.

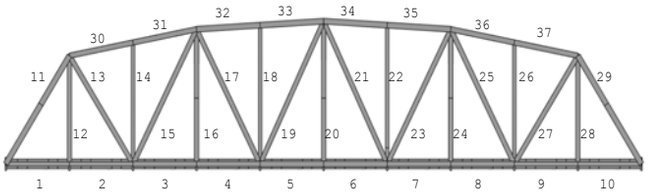

Figure 2. Steel railway bridge example

When a test train, which is assumed to be an ordinary American Amtrack train, passes over the bridge, the axial stresses of the members can be analyzed via dynamic analysis. The results reveal that the following five members, as is labeled in Figure 2, yield the highest stress values (in decreasing order of maximum stress): Members 13, 27, 8, 6, and 7. Table 1 respectively lists the maximum stresses of the five members induced by the train load. It can be seen that the stress levels of Members 13 and 27 are significantly higher than those of the other members. Thus, for further analysis, how the stress changed over time was examined. Figure 3 shows the stresses of Members 13 and 27 as a train passed over the bridge.

Table 1. Maximum stress values of the five structural members with the overall highest stress values.

Member No.	13	27	8	6	7
Maximum stress (MPa)	32.82	32.48	21.26	20.73	20.73

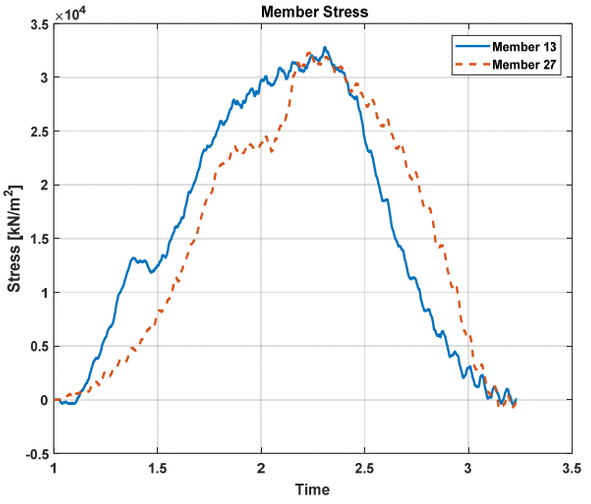

Figure 3. Stress history for Members 13 and 27

Next, the rainflow counting algorithm is applied to the stress responses of the five selected members. The rainflow cycle counting algorithm is widely used for the fatigue life assessment of machine components or structures under the condition of variable amplitude loading. Although the algorithm typically extracts cycles by using the load, stress, or strain history obtained via measurement or simulation, in this study, a code for rainflow counting developed by Nieslony (2009) is used and applied to the simulated results using the model developed by Kim et al. (2016) to obtain the number of amplitudes and cycles. The data are then used to calculate failure probability via Equation (6).

Here, the stress ratio R in Equations (1) and (6) can be determined as based on the ratio of the maximum live load to the dead load; this facilitates consideration of the effects of the mean stress on the fatigue life evaluation of the bridge. In this example, for the sake of simplicity, the ratio R is assumed as 0.75, which represents the ratio of the dead load to the total load (i.e., both the dead and live loads). This means that the live load is one-third of the dead load. In addition, a parametric study implementing various values of R is conducted to investigate the effects of the mean stress on bridge fatigue life.

3.2 *Random variables and deterministic parameters*

In this study, the applied statistical properties of random variables are determined as based on a comprehensive literature review (Lee & Cho 2016, Lee & Song 2014, Moan & Song 2000, Tada et al. 2000, Yazdani & Albrecht 1989, Lee & Song 2012); the means, coefficients of variation (c.o.v.s), and distribution types of the random variables are summarized in Table 2. Although each of the random variables in this numerical case study is assumed to be normally, lognormally, or exponentially distributed, other dis-

tributions, such as Gumbel and Weibull distributions, can also be applied if they more accurately represent the uncertainty of a random variable. This variety of distributions is possible because the proposed method employs FERUM, which ensures reliability for up to a total of 16 different probability distributions, including normal, lognormal, exponential, Gumbel, and Weibull distributions.

In this example, only C is considered as a random variable, and m, and γ are respectively assumed to be 3.344 and 0.7352, as determined subsequent to a comprehensive literature review.

Table 2. Statistical properties of random variables (RVs).

RVs	Mean	c.o.v.	Distribution type	# of RVs
C	1.537×10^{-12} m/cycle/ (MPa·mm)^m	0.2258	Lognormal	5
a^0 (mm)	0.11 mm	1.0	Exponential	5
I	1.0	0.1	Lognormal	1

(#: number)

Statistical independence is assumed for all random variables except the following: (1) values of the Paris equation parameter C for the ten members (correlation coefficient: 0.6), and (2) initial crack lengths (a^0) in the ten members (correlation coefficient: 0.6). Because the correlation coefficients in these cases are unknown, they are initially assumed to be 0.6; this indicates that the five members have been manufactured by the same manufacturer, and thus have material properties that are highly correlated.

In addition, the following deterministic parameters are used: L-bracket width (b) = 650 mm, critical crack length (a^c) = 12.7 or 19.05 mm, and average train traffic = 20 per day. For the geometric function $Y(a)$ in Equation (2), the following function for I-beams is applied as based on the findings of Tada et al. (2000).

$$Y(a) = 1.122 - 0.231\left(\frac{a}{b}\right) + 10.550\left(\frac{a}{b}\right)^2 - 21.710\left(\frac{a}{b}\right)^3 + 30.382\left(\frac{a}{b}\right)^4 \quad (7)$$

4 ANALYSIS RESULTS

Figure 4 shows the reliability indices at various periods throughout the service life for the five selected members. Overall, the reliability indices for the bridge decrease as the time of service increases; this means that the probability of failure increases with increased bridge use.

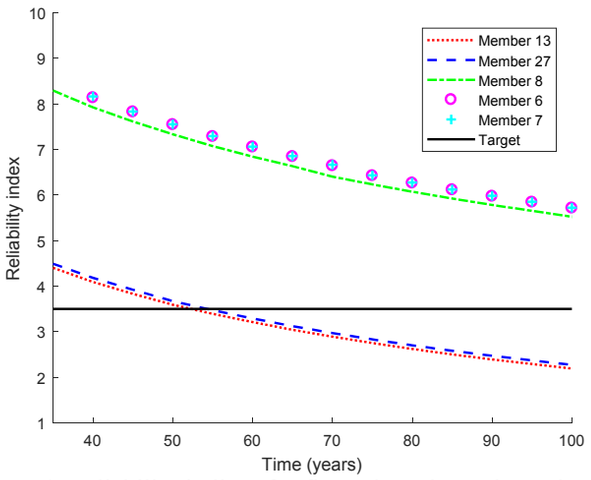

Figure 4. Reliability indices for five selected members obtained via proposed method (R = 3/4).

The American Association of State Highway and Transportation Officials (AASHTO) Bridge Design Code recommends a target reliability index of 3.5, which equates to a failure probability of 2.33×10^{-4}, (Lee & Cho 2016, Lee et al. 2017). The fatigue lives of the five selected members are estimated using this target reliability index as a reference (Target line in Figure 5). Accordingly, the fatigue lives of Members 13 and 27 are evaluated as 52.3 and 54.3 years, respectively, whereas the fatigue lives of the other members are estimated to exceed 100 years. As was mentioned in Section 3.1, this difference is primarily attributed to the significantly higher stress levels of Members 13 and 27 relative to the other members. Because Members 13 and 27 have the shortest fatigue life, only the analysis results of these two members are hereafter presented.

By considering the 0.6 correlation coefficient value for the Walker equation parameters and initial crack lengths of the five members, and the target reliability index of 3.5, the fatigue life of this bridge system is evaluated as 70.7 years.

In this manner, the fatigue lives at component and system levels can be estimated for different values of R. In this study, the R values for parametric analysis are 0, 2/3, 3/4, 4/5, and 5/6. The corresponding analysis results are shown in Figure 5, and the associated fatigue lives are summarized in Table 3. It is observed from the table that the fatigue lives of the members and the railway bridge system decrease significantly as R increases.

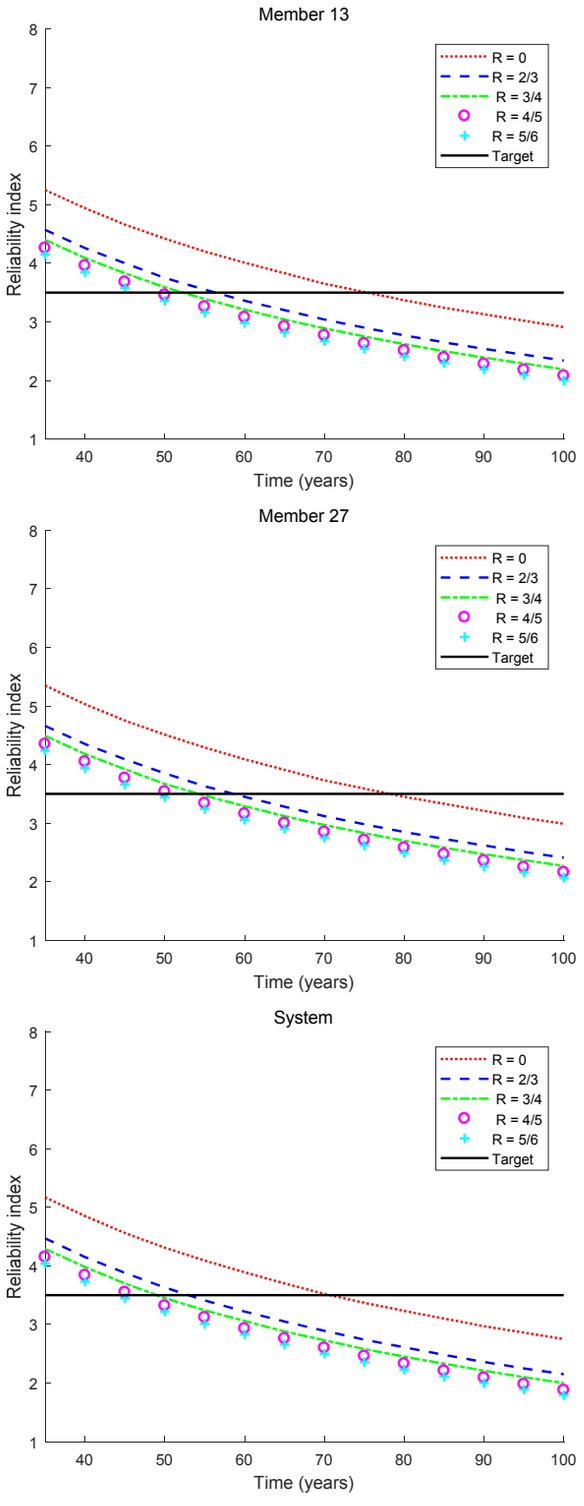

Figure 5. Reliability indices for two selected members and the entire system, as derived via the proposed method.

Table 3. Proposed method results: fatigue lives of two selected members and entire system.

	Fatigue life (years)		
	Member 13	Member 27	System
$R = 0$	75.4	78.2	70.7
$R = 2/3$	56.3	58.6	53.0
$R = 3/4$	52.3	54.3	49.0
$R = 4/5$	49.1	51.0	46.1
$R = 5/6$	46.8	48.6	44.1

5 CONCLUSIONS

This study presents a new probabilistic method employing an advanced crack propagation model to be applied for the fatigue life prediction of steel railway bridges. Specifically, to overcome the limitations of previous studies and accurately predict the fatigue life of a steel railway bridge, an advanced crack propagation model that is able to account for non-zero minimum stress and variable amplitude loading is implemented. A series of formulations are derived via the advanced crack propagation model such that probabilistic fatigue failure probability can be calculated via reliability analysis by implementing the formulations as limit-state functions. To validate the proposed method, it is applied to a numerical model of a steel railway bridge, and the corresponding results are analyzed via reliability indices and fatigue life evaluations. Consequently, the proposed method is shown to accurately estimate the fatigue life of a steel railway bridge. Furthermore, it has been confirmed that the fatigue life decreases with increasing mean stress, and that the proposed method is able to quantify the effects of mean stress on fatigue life.

Development of Calibration Factor for Fatigue Assessment

J. Y. Park & H.K. Kim

Institute of Construction and Environmental Engineering, Seoul National University, Seoul, South Korea

ABSTRACT: Based on linear elastic fracture mechanic (LEFM), stress cycles non-contributing crack growth from stress range spectrum is truncated for fatigue assessment. Calibration which make fatigue life N_c representing total applied stress cycle to failure instead of stress cycle contributing crack growth is considered for realistic fatigue assessment. Effectiveness of truncation and calibration is identified through actual fatigue reliability assessment case using weigh in motion measurement data. The result shows importance of considering stress spectrum truncation and calibration for N_c simultaneously for realistic fatigue reliability assessment.

1 INTRODUCTION

In linear elastic fracture mechanic (LEFM), crack growth can be divided by three phase. Phase I is non-propagation stage which fatigue crack cannot propagate under stress intensity factor (SIF) ranges below fatigue crack propagation threshold (ΔK_{th}). Phase II is linearized propagation stage which fatigue crack propagation rate and SIF in log-log scale (Paris & Erdogan, 1963). Phase III is fracture stage which fatigue crack propagate to a critical crack size. In welded details, propagation life only exist due to large initial crack and can be estimated from linearized propagation stage of phase II although fatigue life is generally defined as sum of initiation and propagation life of crack.

SIF at the crack tip which is essential factor for crack growth can be defined by applied stress range, crack length or depth and correction factors. Therefore, only stress ranges over ΔK_{th} are contributed to crack growth and stress ranges below ΔK_{th} are neglected for fatigue crack growth as shown in Figure 1. This concept is similarly applied to bridge evaluation procedure through S-N approach as shown in Figure 2. S-N curves defined for fatigue details consists of finite and infinite life regimes. In order to estimate finite fatigue life using S-N approach, stress ranges in a stress range histogram below half of constant amplitude fatigue threshold (CAFT/2) should be truncated not to underestimate the fatigue life(AASHTO, 2013).

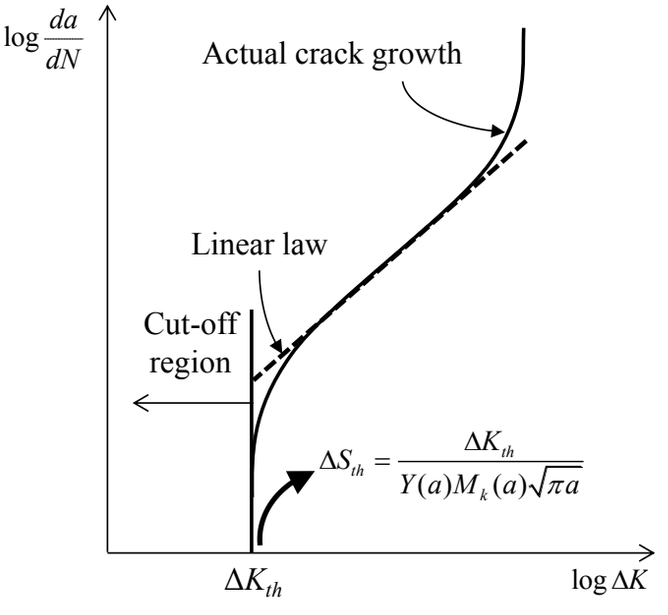

Figure 1. Fatigue crack growth model in LFEM

Therefore, it is important to truncate stress cycles non-contributing crack growth from stress range histogram for realistic fatigue assessment. Moreover, it must be considered that the threshold of stress ranges (ΔS_{th}) contributing crack growth changes according to crack grows. When this is not considered, fatigue life can be underestimated since every stress cycle is effectively applied to crack growth.

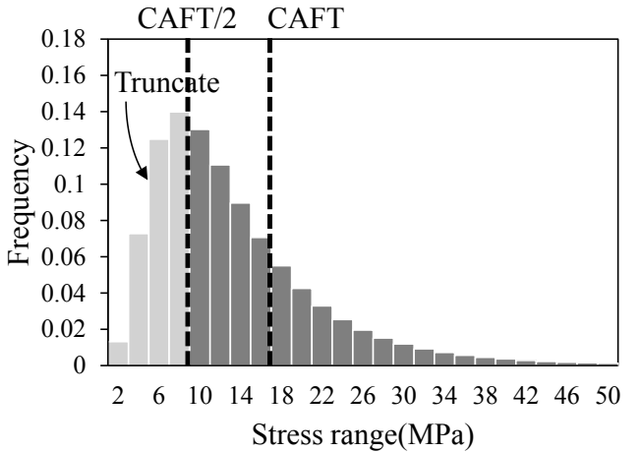

Figure 2. Stress range truncation in S-N approach

Fatigue reliability analysis is performed using stress spectrum itself. Otherwise, each stress blocks should be considered separately for the fatigue analysis. Whole spectrum is represented by effective stress range and reliability analysis is performed using first order reliability analysis (FORM).

Fatigue limit state is consisted by expected fatigue life and current fatigue life. Expected fatigue life can be represented by stress cycles to failure, N_c. Current fatigue life can be represented by number of applied stress cycles at the time of evaluation, $N(t)$. Since only stress ranges over ΔK_{th} contribute to crack propagation, N_c only includes stress cycles contributing crack growth. The stress cycles which contribute to crack growth will be called "contributing stress cycles". $N(t)$ is usually estimated by traffic information, weigh in motion (WIM) data and so on, which includes both contributing and non-contributing stress cycles. In order to eliminate difference between N_c and $N(t)$, calibration should be applied to N_c or $N(t)$. It may be reasonable to calibrate N_c because it is difficult to separate contributing stress cycles in $N(t)$ without identifying exact history of crack growth and traffic information.

In this paper, stress spectrum truncation and calibration for N_c is proposed for fatigue reliability assessment using FORM. Effectiveness is identified through case study of actual bridge assessment.

2 PROPOSED PROCEDURE FOR FATIGUE RELIABILITY ASSESSMENT

2.1 *Fatigue assessment based on LEFM*

A linearized crack growth model proposed by Paris & Erdogan (1963) is utilized for fatigue crack growth in Equation (1).

$$\frac{da}{dN} = \begin{cases} 0 & for\ \Delta K < \Delta K_{th} \\ C(\Delta K)^m & for\ \Delta K_{th} \le \Delta K \end{cases} \tag{1}$$

where a is fatigue crack depth, N is number of applied stress cycles, da/dN is fatigue crack growth rate, C and m are material parameters in Paris' law, ΔK is range of stress intensity factor at the crack tip and ΔK_{th} is fatigue crack propagation threshold.

Since crack growth in depth direction is considered, stress intensity factor is only calculated at the deepest point of crack as shown in Figure 3. Range of SIF could be calculated by:

$$\Delta K = Y(a) \cdot F_g(a) \cdot S_r \cdot \sqrt{\pi a} \tag{2}$$

where $Y(a)$ is geometry correction factor which is function of the aspect ratio of crack and size and geometry of detail, $F_g(a)$ is stress gradient correction factor which considers the stress distribution through thickness and S_r is applied nominal stress range.

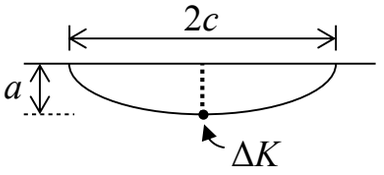

Figure 3. Semi-elliptical surface crack and location of maximum ΔK

Since stress intensity factor is function of crack size and stress range, threshold of the stress range, $S_{r,th}$, changes as the crack grows. Effective stress range, S_{re}, also changes as:

$$S_{r,th}(a) = \frac{\Delta K_{th}}{Y(a) \cdot F_g(a) \cdot \sqrt{\pi a}} \tag{3}$$

$$S_{re}^m = \frac{\int_{S_{r,th}(a)}^{S_{r,\max}} S_r^m f_S(S_r) dS_r}{\int_{S_{r,th}(a)}^{S_{r,\max}} f_S(S_r) dS_r} \tag{4}$$

where f_S is stress range spectrum and $S_{r,max}$ is maximum stress range.

In order to calculate the effective stress range which changes as crack growth, $S_{r,max}$, $S_{r,th}$ should be determined. In this paper, $S_{r,max}$ is determined as measured maximum value of WIM data. $S_{r,th}$ is determined by fatigue crack propagation threshold ΔK_{th} and crack size (a) according to crack growth as Equation (3).

Expected stress cycles to failure can be obtained by integrating the crack growth rate as

$$\begin{aligned} N_c &= \int_{a_0}^{a_c} \frac{1}{C \cdot (\Delta K)^m} da \\ &= \int_{a_0}^{a_c} \frac{1}{C \cdot \left(Y(a) \cdot F_g(a) \cdot S_{re} \cdot \sqrt{\pi a} \right)^m} da \end{aligned} \tag{5}$$

where a_0 is the initial crack depth, a_c is predefined critical crack depth. Expected stress cycles to failure is calculated using effective stress range for general variable amplitude loading condition.

2.2 *Calibration factor for N_c*

When expected fatigue life, N_c, is estimated by LEFM considering effective stress, fatigue life only includes contributing stress cycles. On the other hand, $N(t)$ includes of contributing and non-contributing stress cycles since $N(t)$ usually estimated by WIM data or counting truck traffic or counting stress cycles at fatigue details. In order to make N_c representing total applied stress cycle to failure instead of contributing stress cycle, calibration factor (Ω) is applied to crack growth rate and then calibrated stress cycle to failure can be obtained as

$$\Omega(a) = \frac{N_t(a)}{N_e(a)} = \frac{1}{\int_{S_{r,th(a)}}^{S_{r,\max}} f_S(S_r)dS_r} \tag{6}$$

$$\begin{aligned} \overline{N_c} &= \int_{a_0}^{a_c} \frac{1}{C(\Delta K)^m} \cdot \Omega(a)\, da \\ &= \int_{a_0}^{a_c} \left[\frac{1}{C \cdot (\Delta K)^m \cdot \int_{S_{r,th(a)}}^{S_{r,\max}} f_S(S_r)dS_r} \right] da \end{aligned} \tag{7}$$

where N_e is contributing stress cycles in stress spectrum, N_t is total applied stress cycles including both contributing and non-contributing stress cycles in stress spectrum.

3 CASE STUDY: FATIGUE EVALUATION ON ACTUAL BRIDGE

3.1 *Fatigue detail*

Investigated bridge is part of a test road of the expressway in Korea, which is composite box girder bridge. Among the fatigue details of the bridge, fillet-welded connection of gusset plate to girder web plate classified as AASHTO Fatigue Category E is evaluated, shown in Figure 4. Detail information of the bridge can be referred to Park & Kim (2014).

Semi-elliptical surface crack is assumed and then geometry correction factor, Y, is referred to Newman & Raju (1981) as

$$Y(a) = \left[M_1 + M_2 \left(\frac{a}{t}\right)^2 + M_3 \left(\frac{a}{t}\right)^4 \right] \frac{g f_\phi f_w}{\sqrt{Q}} \tag{8}$$

where t is thickness of web plate, Q is shape factor for elliptical crack, f_φ is angular function, f_w is finite-width correction factor. f_φ and g is one when crack growth in depth direction is considered. Stress gradient correction factor, F_g, for investigated fatigue detail is referred to Norris & Fisher (1981) as

$$F_g = \frac{SCF}{1 + 0.88a^{0.576}} \tag{9}$$

where SCF is stress concentration factor which varies between 5.5 and 7.0, 7.0 is applied in this assessment.

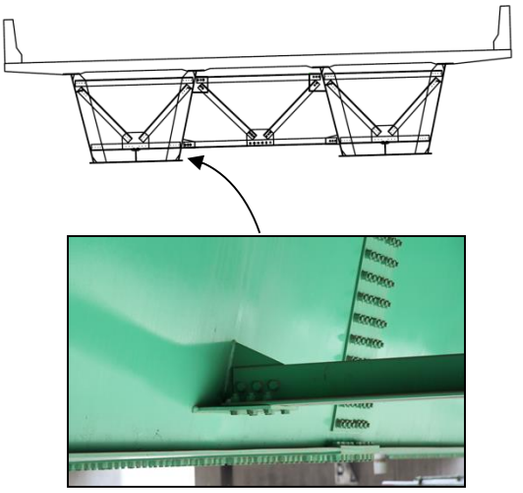

Figure 4. Investigated fatigue detail

3.2 *Probabilistic variables and assumptions*

Crack-related variable, material-related variables and uncertainty of loading condition is considered for fatigue reliability assessment. Detailed information of variables utilized for reliability analysis is shown in Table 1.

Table 1. Probabilistic variables.

Variables	Distribution	Mean	COV
Initial crack depth[1], a_0 (mm)	Lognormal	0.125	0.36
Critical crack depth, a_c (mm)	Deterministic	12	-
Aspect ratio[2], a/c	Lognormal	0.39	0.41
Material constant[3], m	Deterministic	3.1	-
Material constant[3], ln$C$	Normal	-29.84	0.02
Crack propagation threshold[4], (MPa-m$^{1/2}$)	Lognormal	140	0.4
Load effect uncertainty factor[5]	Normal	1.0	0.20

1) Referred to Engesvik & Moan (1983)
2) Referred to Yamada et al. (1989)
3) Referred to BSI (2015)
4) Referred to JCSS (2011)
5) Referred to Hwang et al. (2013)

3.3 *Determining stress spectrum*

Truck weight is measured by weigh in motion (WIM) study and then Truck weight histograms are converted to stress range histogram using result of dynamic loading tests performed in investigated bridge. Stress range spectrum can be fitted with

stress range histogram. In order to determine suitable stress spectrum based on histogram, Lognormal, Weibull, Gaussian mixture model (GMM) and so on are utilized. Each distribution model is evaluated through root mean square error (RMSE) with histogram and fatigue life estimation. As a result, GMM with three components are well fitted than other distributions. Therefore, GMM which reflect the global shape of histogram is considered as representative distribution.

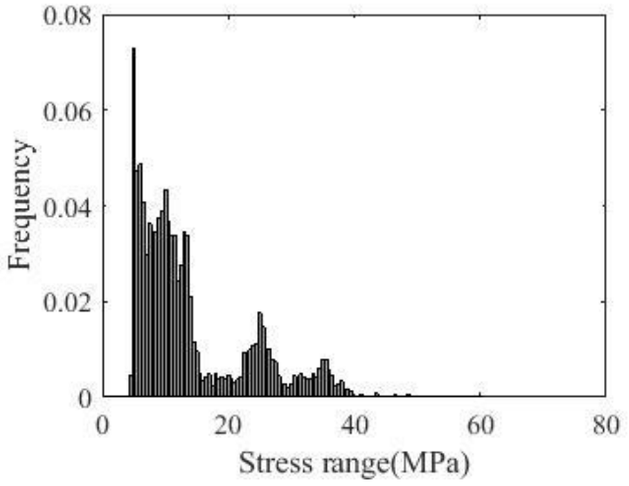

Figure 5. Stress range histogram based on measured truck weight

4 RESULTS

Three analysis cases were compared to identify the effect of stress spectrum truncation and calibration factor. Case 1 is performed without considering stress spectrum truncation, which assume that all stress cycles are effectively applied to crack growth. Case 2 is performed with stress spectrum truncation. Case 3 is performed with stress spectrum truncation and calibration factor simultaneously.

Table 2. Mean fatigue life of investigated detail.

Case	Mean fatigue life (year)
1:W/o truncation	72
2:W/ truncation	20
3:W/ truncation and calibration	96

Table 2 shows the mean fatigue life which represent the zero of reliability index. When stress spectrum truncation is not applied, mean fatigue life is underestimated than Case 3 since all of region in stress spectrum is effectively applied to crack growth from initial crack stage. When only stress spectrum truncation is applied, mean fatigue life is considerably underestimated than Case 3 since very few stress cycles only effectively applied to crack growth are considered as fatigue life. Therefore, stress spectrum truncation and calibration should be considered simultaneously for reasonable assessment.

5 CONCLUSIONS

Procedure for fatigue assessment considering stress spectrum truncation and calibration for N_c is proposed. When stress spectrum truncation and calibration is not considered, fatigue life and reliability can be underestimated. For realistic fatigue reliability analysis, stress spectrum truncation and calibration for crack growth rate should be applied to assessment simultaneously.

Fatigue assessment of deteriorated steel bridge members considering corrosion

Y.C. Park
Institute of Construction and Environmental Engineering, Seoul National University, Seoul, Republic of Korea

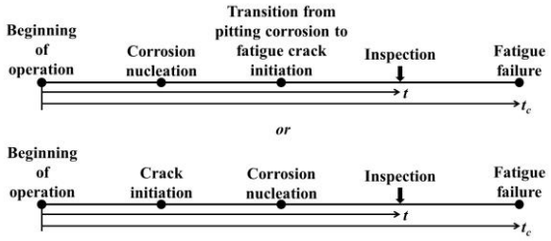
L.S. An & H.K. Kim
Department of Civil and Environmental Engineering, Seoul National University, Seoul, Republic of Korea

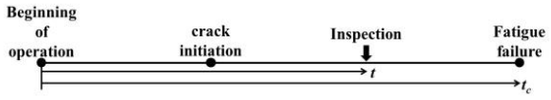
ABSTRACT: Fatigue crack and corrosion are two significant factors which could affect fatigue performance of steel bridge members. In this study, a reliability based assessment procedure for determining remaining fatigue life is proposed. Both fatigue crack propagation and progress of corrosion are simultaneously considered for the assessment. Three scenarios simulating progress of steel bridge deterioration are established and fatigue assessment was performed accordingly. As corrosion progresses, stress concentration effect around the corroded area increases and may cause fatigue crack initiation. By utilizing stress-strain approach and linear elastic fracture mechanics, pit depth threshold which can be transformed as fatigue crack is determined. To develop relation between pit depth threshold and fatigue crack initiation, an equation estimating the stress concentration factor for corrosion pit is formulated by parametric study based on finite element analysis Proposed fatigue assessment method could establish reliability based deterioration levels, which may lead to reasonable and efficient maintenance strategy.

1 INTRODUCTION

Bridge assessment is significant for maintenance of deteriorated steel bridge. Initial step for assessing steel bridge is inspection of each member. Condition assessment of the steel bridge could be conducted based on the inspection results. Various bridge assessment manuals and guidelines have been published from North America, Europe and other countries. However, most of them recommends quantitative evaluation rather than qualitative evaluation. For example, in *AASHTO Bridge Element Inspection Guide Manual*, inspector's judgment dominates the structural member's rating (AASHTO 2010). *Ontario Structure Inspection Manual* provides quantitative criteria for corrosion, but does not suggest criteria for crack (Ontario Ministry of Transportation 2000). Korea Infrastructure Safety & Technology Corporation (KISTEC 2012) categorizes levels of steel elements into five steps (A to E) to evaluate deterioration of steel bridges (Table 1). Categorizing deterioration level of steel members is conducted based on measuring data, i.e. crack length, uncoated and corroded area or section loss due to corrosion. However, ranges of the damages were somehow determined without any rational judgement.

This study developed preliminary study for reliability-based fatigue life assessment for deteriorated steel bridge member. Realistic scenarios which indicate results of inspection were established and case studies were conducted.





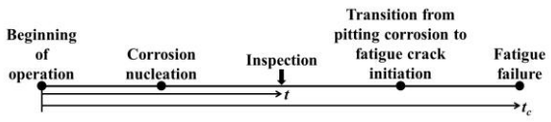


Table 1. Categories of Deteriorations for Steel Member (KISTEC 2012)

Level	Types of Deteriorations	
	Corrosion	Crack
A	-None	-None
B	-Uncoated area<10% -Corroded area<2%	-Local crack in secondary member
C	-Uncoated area>10% -2%<Corroded area<10%	-Large crack in secondary member -Local crack in primary member
D	-Corroded area<10% -Section loss<10%	-Large crack in primary member
E	-Section loss>10%	-Large crack in primary member (>20% of its depth)

2 DETERIORATION SCENARIOS OF STEEL MEMBERS

Following Table 1, corrosion and fatigue crack are considered to develop the fatigue assessment procedure. When inspecting crack and corrosion, three scenarios of inspection results can be assumed. Since this study only focuses on fatigue assessment, corrosion failure is not considered. The deterioration scenarios are established based on the inspection results and presented in Table 2.

Table 2. Fatigue Life Assessment Scenarios based on Inspection Results

Scenarios	Expected Time Line
I	
II	
III	

Detail information of each scenarios is following:

• Scenario I: This scenario represents the case that both fatigue crack and corrosion pit are found at the same location. If both fatigue crack and corrosion exist simultaneously, fatigue crack dominates fatigue life of the member. According to Kondo (1989), corrosion does not proceed if fatigue crack is initiated from corrosion. Therefore, although it is unknown that which deterioration among corrosion and crack occurred earlier, it is reasonable that the member will be failed due to fatigue crack.

• Scenario II: This scenario represents the cases when fatigue crack is found only.

• Scenario III: This scenario represents the cases when corrosion is found only. In this case, fatigue crack was transformed from corrosion pit.

3 ESTABLISHING FATIGUE LIMIT STATE

As per the scenarios, both corrosion and fatigue crack propagation should be considered for defining fatigue limit state. The parameter which commonly represent both fatigue crack propagation and corrosion is time. Therefore, fatigue limit state function is defined in terms of time as shown in Equation 1

$$g = t_c - t \tag{1}$$

where, t_c and t denote expected fatigue life of steel member and years of operation, respectively.

3.1 *Scenario I and Scenario II*

Fatigue limit state is defined based on crack propagation for Scenarios I and II. Although corrosion is also found in the case of Scenario I, fatigue crack is related with fatigue failure directly and it dominates fatigue failure. Thus, the limit state function of these two scenarios is founded based on linear elastic fracture mechanics (LEFM) concept using Paris' Law (Paris & Erdogan 1963).

$$\frac{da}{dN} = C\left(\Delta K\right)^m \tag{2}$$

where, a and N indicate fatigue crack length and the number of cycles, respectively. C and m are material coefficients. ΔK is stress intensity factor range at the crack tip. It can be calculated as follows.

$$\Delta K = Y\left(a\right) S_{re} \sqrt{a\pi} \tag{3}$$

where, Y and S_{re} denote correction factor and equivalent stress range, respectively.

If initial crack length (a_0) and critical crack length (a_c) are determined, expected number of cycles to fatigue failure (N_f) can be calculated by integrating Equation 3 as follows.

$$N_f = \int_{a_0}^{a_c} \frac{da}{C\left(\Delta K\right)^m} \tag{4}$$

Since the fatigue limit state is defined in terms of time, the number of cycles has to be converted into time divided by average daily stress cycles (*ADSC,* cycles/day). Finally, fatigue limit state function for Scenario I and II can be set as follows.

$$g = t_c - t = \int_{a_0}^{a_c} \frac{da}{C \cdot \Delta K^m \cdot 365 \cdot ADSC} - t \tag{5}$$

3.2 *Scenario III*

This scenario represents the case only corrosion was found from the inspection. Stress concentration effect due to corrosion pit and micro-cracks around the pit could initiate fatigue crack under repeated loading. Therefore, possibility of initiating fatigue crack could become larger as corrosion pit grows. According to Kondo (1989), corrosion pit stops growing when fatigue crack initiated from the pit. The maximum size of corrosion pit, which may initiate fatigue crack is defined as pit depth threshold (d_{th}).

Expected life of steel member, t_c should include expected time to form corrosion nucleation (t_0), required time for growing corrosion pit to pit depth threshold (t_{cg}) and required time to failure by fatigue crack propagation (t_{cg}). Accordingly, fatigue limit state function for Scenario III is defined as follows.

$$g = t_c - t = t_0 + t_{cg} + t_{cp} - t \tag{6}$$

The first part of this scenario (t_0) is not well understood yet, because it depends on factors such as electrolytes, loads, materials (Shi & Mahadevan 2001). Therefore, the first part, t_0, is assumed as a random variable.

Pit depth threshold is determined by estimating fatigue threshold proposed by Roy & Fisher (2005). It was developed based on the stress-strain approach suggested by Smith et al. (1970). Roy & Fisher's

study successfully estimated maximum stress range which may not initiate fatigue crack under constant stress range for UIT treated welded cover plate connection. The result of this study was adopted by Park (2015) and applied to estimate fatigue threshold for various tube-to-transverse plate welded connection. In order to find pit depth threshold, the critical condition which may initiate fatigue crack is defined as per stress-strain approach (Equation 7).

$$\sqrt{(\sigma_{\max}\sigma_a)} = \sqrt{(\sigma_a+\sigma_0)\sigma_a} = \frac{F_u}{2} \tag{7}$$

where, σ_{max}, σ_a, σ_0 and F_u denote maximum stress, stress amplitude, mean stress and ultimate strength of steel, respectively. Stress concentration effects around corrosion pit can be reflected by utilizing fatigue notch factor (K_f) which is the function of stress concentration factor (K_t), material parameter (a) and pit radius (d). Thus, stress concentration factor developed by corrosion pit should be applied. Cerit et al. (2009) proposed a stress concentration factor for corrosion pit, but it could not be applied because the pit depth considered for this study was too small. Thus, stress concentration factor for corrosion pit is developed by a parametric study based on finite element analysis for various pit sizes. Result of the parametric study is shown in Figure 1.

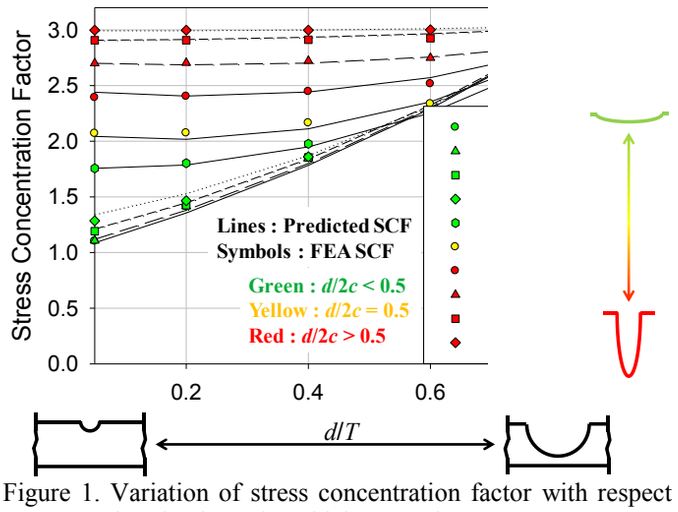

Figure 1. Variation of stress concentration factor with respect to penetration depth to plate thickness ratio.

Finally, pit depth threshold could be obtained by solving Equation 8.

$$1+\frac{K_t-1}{1+\frac{a}{d}} = \sqrt{\frac{F_u^{\,2}}{4(S_a+S_0)S_a}} \tag{8}$$

where, S_a and S_0 are nominal stress amplitude and mean stress, respectively.

Komp (1987) proposed a corrosion growth model, which corrosion growth can be determined against time.

$$t_{c,cg} = \left(\frac{d_{th}}{p}\right)^{\frac{1}{q}} \tag{9}$$

where, p and q are environmental parameters.

For fatigue crack growth, pit depth threhold can be considered as an initial crack length. Finally, fatigue limit state function for Scenario III is defined as follows.

$$\begin{aligned} g &= t_c - t = t_0 + t_{cg} + t_{cp} - t \\ &= t_0 + \left(\frac{d_{th}}{p}\right)^{\frac{1}{q}} + \int_{d_{th}}^{a_c} \frac{da}{C\cdot\Delta K^m \cdot 365\cdot ADSC} - t \end{aligned} \tag{10}$$

4 CASE STUDY

Case study is conducted for existing 80 year-old bridge by applying the fatigue assessment procedure suggested in this study. Actual measurement of stress range for fatigue critical detail is used for reliability analysis. The fatigue critical detail was fillet-welded cover plate welded connection at the bottom of main girder. AASHTO fatigue detail category of cover plate detail is E′, which is the lowest among other welded details in the bridge.

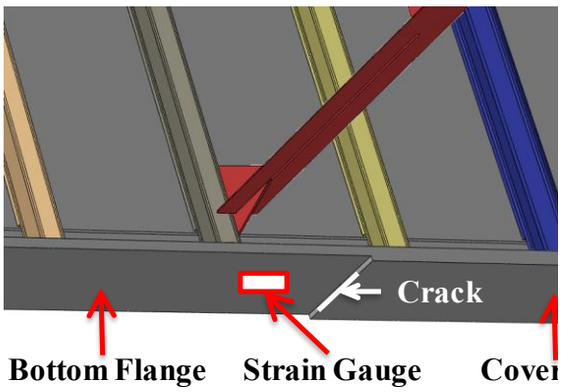

Figure 2. Case study: the location of a fatigue crack.

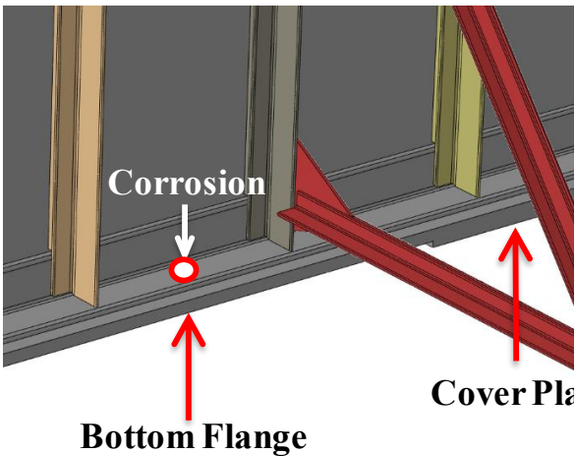

Figure 3. Case study: the location of a pit corrosion.

First-order reliability method (FORM) is utilized for the reliability analysis. Variables used for the reliability analysis are presented in Table 3.

Result of fatigue reliability analysis for Scenarios I and II is shown in Figure 4. Reliability indices decrease from approximately 5.0 to 2.0 for the operation time (t) from 10 to 100 years. The trend of the reliability indices shows a sharper decrease at the early years of operation than the later years of operation.

Results of fatigue reliability analysis for scenario III is shown in Figure 5. Time to corrosion nucleation (t_0) is considered for reliability analysis. It was assumed as a random variable due to a lack of information about the phenomenon. Even though coefficient of variance (COV) is changed from 0.01 to 0.95, reliability indices do not show significant discrepancies. It indicates that the time to corrosion nucleation does not have significant influence on fatigue failure of scenario III.

Table 3. Variables used for a case study.

Variable	Mean	C. O. V.	Type	Reference
T (mm)	51	-	Deterministic	Girder flange thickness
F_u (MPa)	400	-	Deterministic	Ultimate strength of steel
S_0 (MPa)	145	-	Deterministic	Actual measurement

q	0.593	0.4	Lognormal	

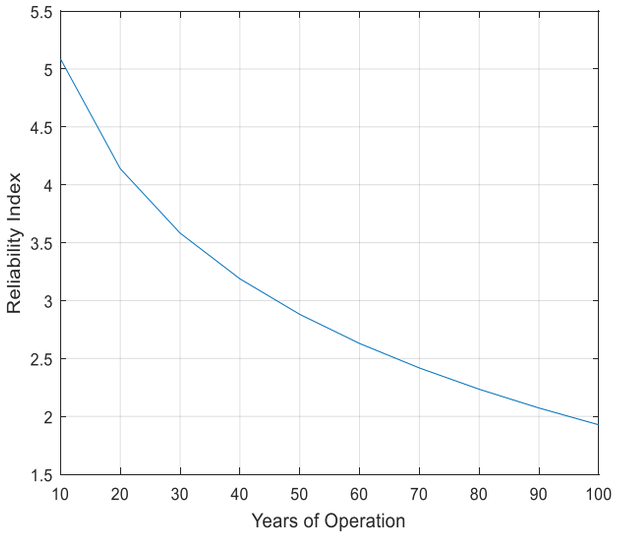

Figure 4. Reliability index for Scenario I and Scenario II.

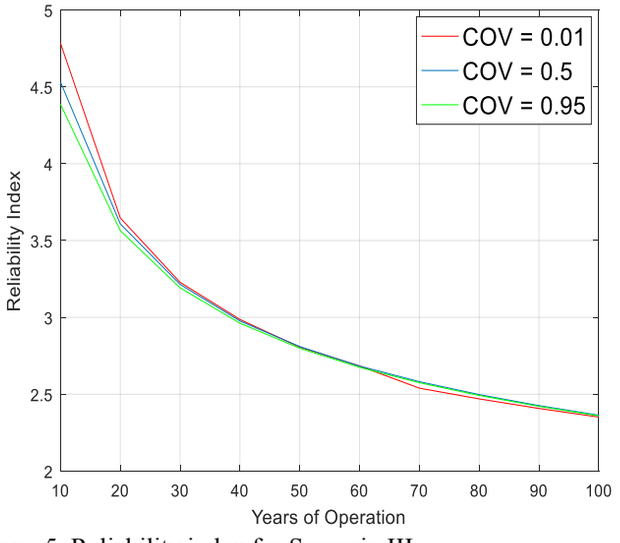

Figure 5. Reliability index for Scenario III.

5 CONCLUSIONS

As a preliminary study for developing reasonable guideline for evaluating deteriorated steel bridge member, fatigue reliability assessment procedures were studied. Since fatigue crack propagation corrosion are the two major damages of deteriorated steel members, fatigue limit state functions which reflects corrosion and crack propagations simultaneously are developed. Stress-strain approach is used to determine a limit penetration depth of a corrosion pit. Case studies were conducted to verify effectiveness of proposed assessment procedure.

Reliability Analysis of Steel Bridges under Propagating Fatigue Cracks

H. Ali & M. Soliman
School of Civil and Environmental Engineering; Oklahoma State University, Stillwater, Oklahoma, USA

ABSTRACT: Fatigue is one of the major factors that may influence the safety of civil and marine structures. The presence of significant uncertainties related to loads, geometry, and material properties affects our ability to reliably predict the time-dependent performance of structures under fatigue deterioration. Probabilistic approaches can aid in predicting the time-dependent performance of structures under fatigue deterioration considering uncertainties. Moreover, reliability and risk-based management techniques can be used to predict the safe service life of fatigue sensitive structures, plan for their future inspections and support the decision-making process regarding maintenance and repair actions. This paper applies a probabilistic approach to quantify the reliability of a box-girder bridge against fatigue failure. The approach establishes a relationship between the maximum live load that can be sustained and the crack size. This relationship is next used to compute the time-variant bridge reliability against fatigue failure. The approach is applied to an existing steel box-girder bridge.

1 INTRODUCTION

Fatigue damage poses a significant threat to the integrity and safety of steel structures. This damage can lead to significant risks if overlooked during regular bridge inspection and maintenance activities. Fatigue cracks can occur at regions of high stress concentrations in a structural member subjected to load fluctuations. These stress concentrations are inherently present in a member due to the presence of initial imperfections induced during manufacturing and fabrication or due to residual stresses occurring in the heat affected zones during welding (Osgood 1954). The stress fluctuations under working loads causes plastic deformations at the crack tip (Lu and Liu 2010). In case of bridges, the stresses due to regular traffic loads at the fatigue critical details causes the initially microscopic imperfections to grow into macroscopic cracks which start to propagate at greater rates. These growing cracks can cause structural failure if not repaired on time (Han and Ramulu 2005). The increase in truck weights and traffic volume over time can lead to accelerated crack growth. Under time-variant increasing demand and diminishing capacity (see Figure 1), the service life and optimum maintenance and repair activities can be established based on reliability analysis.

The AASHTO code (AASHTO 2008) outlines the S-N (stress-life) curve approach for designing bridge components to minimize fatigue damage. In this approach, different structural configurations (i.e., details) are grouped based on their fatigue resistance into several categories each with its own stress-life relationship. These generalized curves are most commonly used in the design phase to predict the safe fatigue life. However, this method cannot be used to study the state of the crack at any point during the

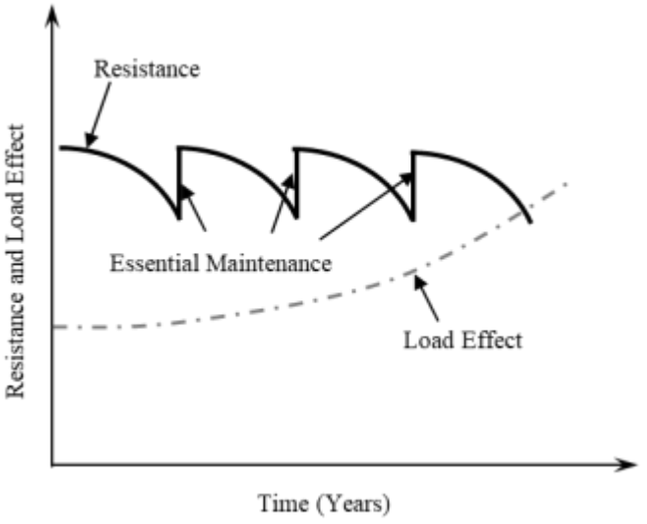

Figure 1. Load effect and resistance of bridge over time with maintenance actions

service life of the structure. Such problems can be solved by utilizing approaches based on the linear elastic fracture mechanics (LEFM). This approach can predict the crack growth against the number of cycles or time given the geometry and stress conditions at the investigated detail. LEFM is used in this paper to predict the crack growth in box-girder bridges. The bridge reliability considering fatigue crack growth is quantified by combining LEFM with information on the loads acting on the bridge during its service life.

Numerous research studies have been conducted on the prediction of crack growth in steel structures. McMillan and Pelloux (1967) experimentally investigated the growth of cracks under random and pseudo-random loadings. Their work has since served as a basis for research on random fatigue loading and crack growth. Lu and Liu (2010) developed a method for predicting the cycle-by-cycle crack growth over any timescale and over any crack length. Their model can analyze fatigue problems under variable amplitude loading. Mahmoud and Dexter (2005) investigated the crack growth behavior in stiffened panels under flexure loading. Cheung and Li (2003) performed probabilistic analysis using LEFM crack growth model and obtained the reliability of welds in steel bridges.

Kim et al. (2013) used LEFM to establish the optimum inspection and maintenance schedules of fatigue prone details in ship structures. Soliman et al. (2013) also used LEFM in a probabilistic model that can establish optimum inspection plans for bridges with multiple fatigue critical details. Finally, Soliman et al. (2016) proposed an approach based on LEFM for establishing the optimum inspection, monitoring, and maintenance times and types for fatigue critical locations. However, these probabilistic studies did not cover the overall reliability of the structural system against failure due to cracks, but rather, they focused on establishing the reliability with respect to the crack reaching a critical size.

In this paper, a probabilistic approach is proposed to quantify the bridge reliability considering global flexure failure under the presence of cracks. The crack growth is predicted using an LEFM model which considers the effect of residual stresses and provides the probabilistic descriptors of the crack size along the service life of the bridge. A finite element (FE) model of the structural system is constructed and used to find the live load carrying capacity of the bridge considering the loss of stiffness due to the growing cracks. Finally, a performance function is established to quantify the bridge reliability against global flexure failure under growing cracks. The approach is illustrated on an existing box-girder bridge.

2 CRACK GROWTH MODEL

The linear elastic fracture mechanics encompasses the stresses and their effects around a crack. The stress acting at the vicinity of the crack tip are expressed in terms of the stress intensity factor as

$$K = Y(a) \cdot S \cdot \sqrt{\pi \cdot a} \tag{1}$$

where K is the stress intensity factor, S is the stress, a is the crack size, and $Y(a)$ is the geometry correction factor which accounts for finite width or thickness, stress gradients, surface cracks, and crack shape (Fisher and Martz 1984).

Paris and Erdogan (1963) developed a relationship between the crack growth rate and stress range of the intensity factor as

$$\frac{da}{dN} = C \cdot (\Delta K)^m \tag{2}$$

where N is the number of cycles, C and m are material dependent parameters, and

$$\Delta K = \Delta S \cdot \sqrt{\pi \cdot a} \tag{3}$$

in which ΔS is the stress range.

Hence, the number of cycles required for the crack to grow from an initial crack size a_0 to a size a_c (i.e., critical crack size) is

$$N = \frac{1}{C \cdot \Delta S^m} \cdot \int_{a_0}^{a_c} \frac{1}{(Y(a) \cdot \sqrt{\pi \cdot a})^m} da \quad (4)$$

Each of the parameters in Equation (4) can be considered as a random variable with its own probabilistic distribution; therefore, the crack growth problem should be performed using probabilistic analysis in order to account for uncertainties associated with these input parameters (Cheung and Li 2003).

2.1 *Crack Growth in Stiffened Panels*

In stiffened bridge box girders, the crack growth is restricted compared to unstiffened plates, due to the presence of the longitudinal stiffeners. The crack growth in stiffened panels has been studied for stiffened box girders and a model to obtain the stress intensity factor accounting for the effects of stiffener restraint and residual stresses has been established in Dexter and Pilarski (2000). This approach is adopted in this paper to predict the crack growth in a bridge box girder with longitudinal stiffeners.

In welded box girders, the residual stresses play an important part in the crack growth. If the crack is in a zone with residual compressive stresses, the crack would require higher stresses (or larger number of cycles) to grow; whereas in case of tensile residual stresses, the crack growth would be rapid.

The stress intensity factor for the crack growth in a stiffened panel with stiffener restraint effect and residual stress effect is given by Dexter and Pilarski (2000)

$$K_{total} = 1 + K_1 + K_2 + K_{residual} \quad (5)$$

where $K_1 = f_1 \sigma \sqrt{\pi a}$ and $K_2 = f_2 \sigma \sqrt{\pi a}$ are stress intensity factors due to stiffener restraint, f_1 and f_2 are stiffener restraint coefficients and $K_{residual} = \frac{2}{\pi} \sqrt{\pi a} \int_0^a \frac{\sigma_{res}(x)}{\sqrt{a^2 - x^2}} dx$ is the residual stress intensity factor (Dexter and Pilarski 2000).

By combining Equation (5) and (4), the number of cycles required for a crack to grow from an initial crack size a_0 to a given crack size in the stiffened panel a_f can be established.

3 BRIDGE CAPACITY AND RELIABILITY PREDICTION

Due to the growing cracks, the flexural stiffness of the bridge box girder will decrease. This reduction can be quantified by computing the reduced live load carrying capacity of the box girder under the presence of the growing cracks. In this paper, the bridge resistance at time t is computed as the HL-93 loading (AASHTO 2008) multiplied by a factor $LLM(t)$, which results in the load that causes bridge collapse or large deflections to occur. In this paper, this deflection limit is assumed to be 0.0075L following the recommended values in Ghosn et al. (2010). Accordingly, the probability of failure can be represented as (Okasha and Frangopol 2010)

$$P_f(t) = \mathrm{P}[LLM(t) < LL(t)] \quad (6)$$

where $LLM(t)$ is the live load multiplier representing the resistance and $LL(t)$ is the expected normalized maximum live-load effect acting on the structure within the appropriate time t.

The input parameters required to establish the relationship between the live load multiplier and the crack size is obtained through executing finite element (FE) analysis of the investigated bridge. An iterative process has been established to quantify the maximum live load that could be placed on the bridge before it reaches the limiting deflection for a given crack size.

In order to estimate the time-variant probability of failure and reliability, the expected normalized live load $LL(t)$ can be computed using extreme value statistics as outlined in (Frangopol et al. 1997). This model is based on available truck survey data performed by the Ontario Ministry of Transportation which covered 10,000 trucks (Nowak 1993). The model can provide the distribution of the maximum truck loads with respect to time. The time-variant increasing rate of occurrence of these maximum loads can also be established following the approach proposed by the National Cooperative Highway Research Program Report 538 (NCHRP 2005).

Given the uncertainties associated with the different crack growth model input parameters (Rolfe and Barsom 1977; Connor and Fisher 2001), Monte Carlo simulation is used to establish the probabilistic distribution of the time required to reach a certain

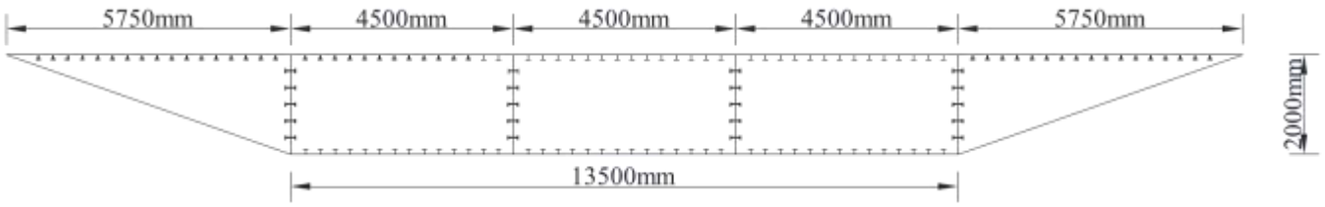

Figure 2. Bridge section

crack size, and subsequently, the time required to reach a certain live load capacity. The probability of failure can be used next to quantify the reliability using Equation (7) as shown in Figure 7.

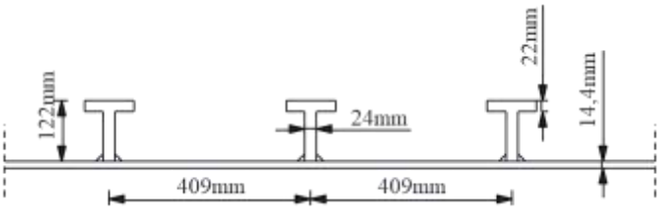
$$\beta(t) = \Phi^{-1}[1 - P_f(t)] \quad (7)$$

Where Φ is the CDF of normal distribution.

4 ILLUSTRATIVE EXAMPLE

A three-lane steel box girder bridge, the Xianyue Road Bridge in Xaimen City, China, is selected as the case study in this paper. The superstructure of the bridge is a 25m wide thin walled box girder consisting of two 45m long spans. The cross-section has three box cells and two external lenticular cells shaped cantilever extensions as shown in Figure 2. Since the lenticular cells do not play a significant role in the load resisting mechanism of the bridge (Zhang et al. 2010), they were replaced in this study by triangular cells for simplicity. Figure 3 shows the details of the longitudinal stiffeners of the box girder.

The FE model (Figure 4) of the bridge is constructed using non-linear finite element code SAP2000® v.19 (SAP2000 2016). The FE model provides the bridge deflections and live load multipliers for different crack sizes. The model was developed for one span of the bridge assuming pinned support conditions. The model is constructed using a combination of shell and frame elements. The flanges and webs of the box girder are modelled as shell elements and the longitudinal stiffeners are modelled as frame elements.



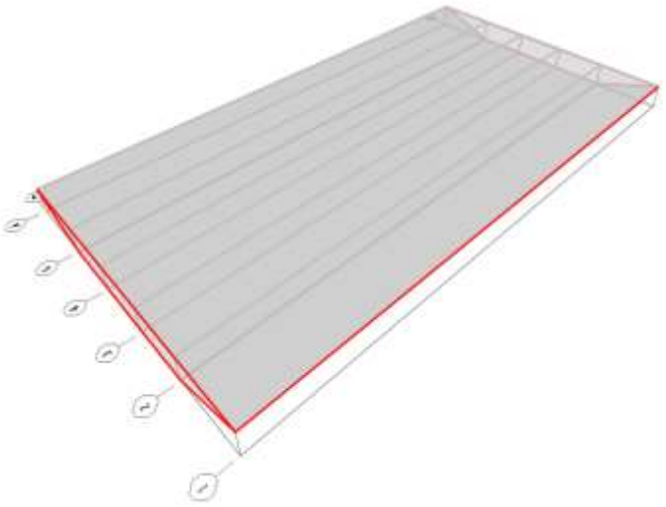


Figure 3. Stiffener Detail

The AASHTO HL-93 (AASHTO 2008) loading, consisting of a distributed lane load and a standard truck, was placed on the bridge to obtain the largest deflection at mid-span. Next the live load is increased incrementally until the established deflection limit is reached.

Figure 4. FEM model of bridge

4.1 *Probabilistic Crack Growth Analysis*

A transversal crack is initiated and propagated in the lower flange of the box girder. The initial crack size is assumed 400 mm and the crack propagation is studied up to crack size of 4200 mm. The values of material constants C and m are considered as 9.5×10^{-12} and 3 respectively. The number of cycles is assumed a random variable with mean 3500 and coefficient of variation of 0.1. The maximum and minimum stress values are obtained from the finite element model under dead load and total loads. The probabilistic crack growth profile is established using Monte Carlo simulation based on Equations (4) and (5) and shown in Figure 5.

For each crack size, the live load multiplier required to reach a deflection of 337.5 mm (i.e., 0.0075L) is computed using the non-linear finite element analysis. Accordingly, a probabilistic time-variant live load multiplier can be established as

shown in Figure 6. By setting the reliability threshold, optimum maintenance and repair times can be identified as the time to reach the reliability threshold.

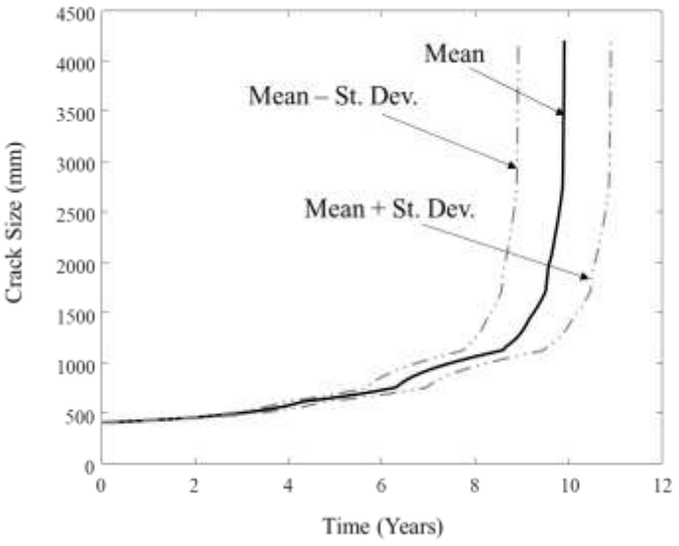

Figure 5. Probabilistic crack growth profile through stiffened panel

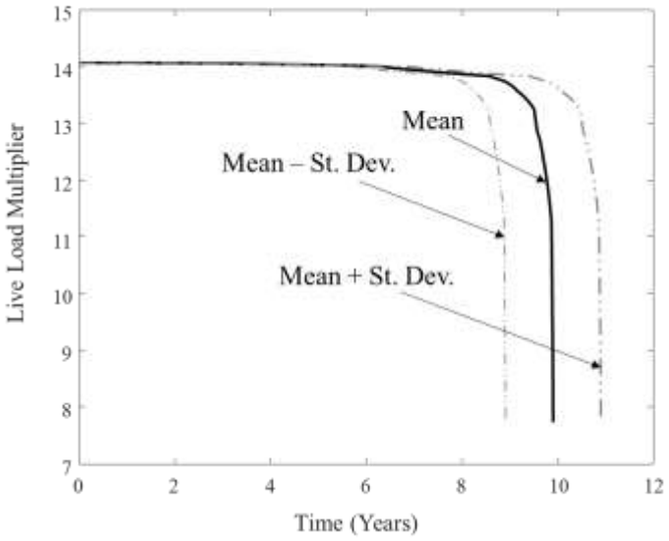

Figure 6. Change in live load multiplier with time due to crack growth

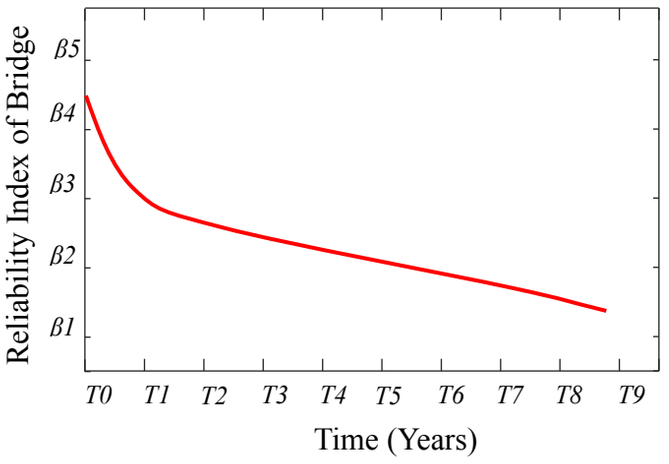

Figure 7. Time variant bridge reliability under growing cracks

This live load multiplier combined with information on time-variant live loads acting on the bridge can be used to establish the probability of failure representing the probability the actual live load will exceed the live-load capacity of the bridge. This is shown conceptually in Figure 7.

5 CONCLUSIONS

This paper presented an approach for establishing the time-variant global reliability profile of bridges considering the reduction in resistance due to fatigue cracks. The approach employs LEFM to establish the crack growth profile and integrates it into a finite element model to quantify the maximum live load that can be applied to the bridge until a certain deflection limit is reached. The maximum live loads are quantified as a function of the number of cycles (or time).

The approach is proven efficient in considering ductile failure due the reduction of the cross-sectional resistance. However, more analysis is required to include failure modes associated with uncontrolled crack growth. This can be performed using the failure assessment diagram as outlined in the guide to methods for assessing the acceptability of flaws in metallic structures (British Standard 2005).

ABSTRACT: The numerous welded joints on orthotropic steel deck lead to high probability to the emerge of fatigue cracks. Numerical simulation based on linear elastic fracture mechanics has been proven to be effective on reproducing the crack growth process. When put into practice on actual projects, however, its accuracy and feasibility are largely dependent on features in various scales. This paper presents a non-concurrent multiscale method on investigating the crack on orthotropic steel decks. According to the fatigue test, the rib-to-deck weld toe crack that penetrates the deck plate was addressed, and the key factors were the crack shape and size, especially for the shallow and long early-stage cracks. Therefore, a two-dimensional local model of rib-to-deck weld toe crack was built using extended finite element method, by which the stress intensity factors for early-stage cracks can be calculated. Based on the similar concept of nominal stress, it can be easily linked to the macroscopic model, and forms a non-concurrent multiscale method that enables to simulate the crack growth at rib-to-deck weld toe. As a result, a detailed analysis on different stages in crack growth rate curve were given with respect to Paris law, implying the influences from welding process on early-stage fatigue cracks. The results will benefit the fatigue assessment and life estimation of orthotropic steel decks, and may further be introduced to the maintenance work by combining with inspections.

1 INTRODUCTION

As a common structural type in steel bridge, the orthotropic steel deck (OSD) is favored for its mechanical efficiency in terms of load carrying capacity per unit weight. Whilst its fatigue performance is always the issue, as it is one of the most-reported structures that suffer from fatigue problems. According to previous studies (Fisher 1970, Wolchuk 1990, de Jong 2004), the most fatigue-prone areas of OSDs are the welded joints and adjacent areas. Experimental and numerical studies were conducted on this issue (Kolstein 2007; Sim & Uang 2012; Xiao et al. 2008; Aygül et al. 2012). These studies were mainly based on the stress-life relations that overlook the exact crack growth in the fatigue process. With respect to that, the introduction of linear elastic fracture mechanics will provide a way to further investigate the fatigue problem on OSDs (Kiss & Dunai 2012, Nagy et al. 2015). In addition, this kind of method is capable of evaluating the remaining life of OSDs, in case the fatigue-oriented inspection was given.

Nevertheless, since the initial cracks in welded joints are tiny when compared with the structure size, the multiscale problem is one of the biggest concerns when focusing on the fatigue crack growth on OSDs. For multiscale problems, two kinds of models, i.e. the concurrent model and the non-concurrent (or hierarchical) one, were usually adopted (Li et al. 2009, Sumi & Inoue 2011, Silani et al. 2014). Generally speaking, the concurrent model may obtain results with higher accuracy. But on the issue of fatigue on large-scale engineering works, the concurrent model is quite difficult to put into practice as it requires to solve various scale simultaneously. Therefore, the non-concurrent model seems to be a better option, since the trivial coupling effects between the cracked part and the whole model can be neglected.

This paper presented a multiscale study with respect to the fatigue test that reveals the crack growth behavior on rib-to-deck welded joint of OSDs. The multiscale method was established in a non-concurrent way and obtained the crack growth rate (CGR) curve. For the final step, different stages of the fatigue process of the rib-to-deck welded joint of OSDs were addressed and analyzed.

2 FATIGUE TEST

As the most convincing way, the fatigue test is always the first option for fatigue studies. Kolstein (2007) summarized 245 fatigue tests on rib-to-deck welded joints of OSDs, and the stress-life relations were obtained and compared with the S-N curves in Eurocode. However, the information about the crack growth process in these fatigue tests is limited. Hence, a fatigue test designed with respect to that was conducted. A brief introduction is given in this

section, and more details can be found in (Nagy et al. 2017).

2.1 *Test scheme*

Given the scatter results from the fatigue tests in previous studies, it is preferred that the test can be repeated as many times as possible. In that case, fatigue test on small-scale specimens is a good option for cost concerns. The designed test specimen was, therefore, consisted of one trapezoidal stiffener and the deck plate, as shown in Figure 1. It was simply supported at the distance between longitudinal stiffeners, i.e. 300mm, to the concerned welded joint, and fixed at the distance of 150 mm to the welded joint on the other side. The load was a line load applied at the distance of 70 mm to the left of the welded joint. The length of the specimen is 370 mm. According to the common way of OSD production, the test specimens were welded by submerged arc welding (SAW).

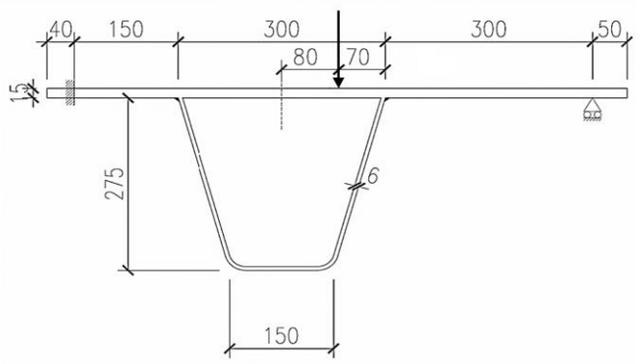

Figure 1 Test specimen and boundary conditions (unit in mm)

To understand the fatigue crack growth, the beach mark on the fracture face offers a simple way to trace the entire process. The only concern is that according to some of the fatigue tests on OSDs (Ya et al. 2011, Kainuma et al. 2016), the obtained beach marks were either with limited quantities, or can hardly be identified visually. Hence, it was planned to apply the loading sequences designed for this fatigue test specifically, which can help to produce clear beach marks on the fracture face.

The loading sequences consisted of two parts, i.e. the base cycles and beach mark cycles. The beach mark cycles were designed following the principle that the maximum load equals to the base cycle to prevent the effect of overload retardation. Whilst the minimum load, noted as $P_{beachmark}$, will determine the load range ratio between beach mark cycles and base cycles, which is about 0.2~0.4 in this test.

2.2 *Test results*

In total eleven specimens were tested, among which nine specimens were designed to produce beach marks. The exceptions were Specimen 2 which did not apply beach mark cycles, and Specimen 8 which stopped after more than 1.5 million cycles as no sign of failure occurred. The summary of the applied loads and the cycles till failure for all test specimens were given in Table 1.

By this fatigue test, results show that the crack initiation at the weld toe was predominant in every specimen. The cracks propagated vertically towards the top face of deck plate and longitudinally followed the weld toe strictly.

Table 1 Summary of loading conditions and fatigue cycles on test specimens

No.	P_{max} (kN)	P_{min} (kN)	$P_{beachmark}$ (kN)	R	N_{base}	$N_{beachmark}$

11	30	-30	-18	-1	101 394	148 871

2.3 *Crack growth process analysis*

The beach marks were observed with naked eyes in the first place. One of the test specimens with most beach marks on its fracture face was Specimen 10, as shown in Figure 2, which is also analyzed as the typical case hereinafter. Clearly, only a few beach marks can be observed on such a global view. The first few beach marks can only be identified from magnified local view from scanning electron microscope (SEM) and/or stereo microscope. According to the beach marks, it can be addressed that the shape of a single crack was basically semi-elliptical.

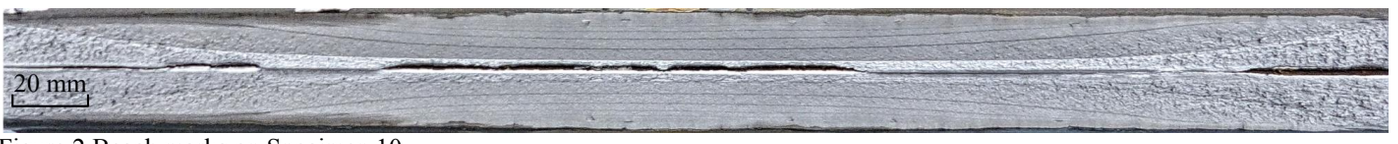

Figure 2 Beach marks on Specimen 10

The size of the semi-elliptical cracks was measured afterwards. The crack depth *a* with respect to the fatigue cycle numbers *N* was given in Figure 3. Table 2 further presented the elliptical long axis length, namely the half crack length *c*, and the aspect ratio *a/c* for Specimen 10. The results show that the crack is quite long and shallow in the beginning, and grows mainly in the depth direction as the aspect ratio gets larger.

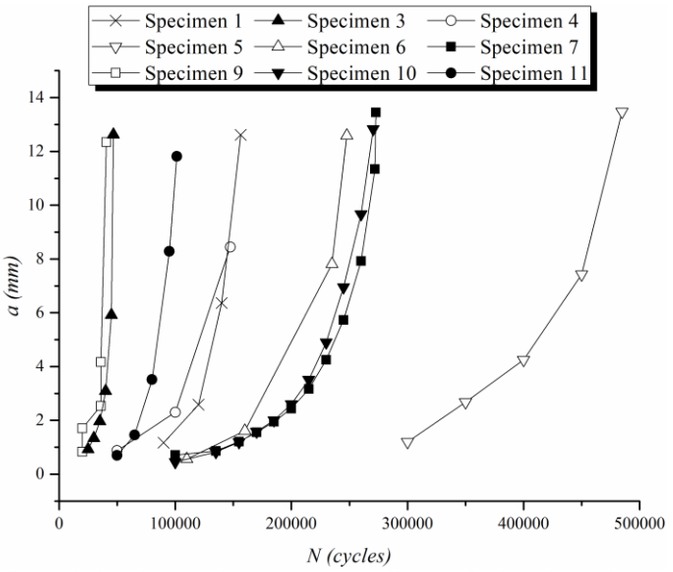

Figure 3 Crack growth process according to the beach marks

Table 2 Crack sizes on Specimen 10 according to the beach marks

Beach mark	N	*a* (mm)	*c* (mm)	*a/c*
0*	0	0.288	93.6	0.003

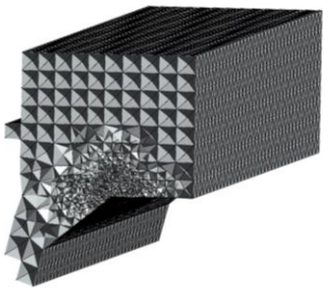
3 NON-CONCURRENT MULTISCALE STUDY BASED ON BEACH MARKS



3.1 *Macroscopic model*

With respect to the fatigue test setup, a macroscopic model was firstly built in finite element software SAMCEF, as shown in Figure 4a). The element type used was solid element, and the total number of elements was 144 966. The supportive system was modeled as the test scheme, which means to fix the deformation on all directions on the left, and the deformation on the longitudinal and vertical directions on the simple-supported line.

With the eXtended Finite Element Method (XFEM) module in SAMCEF, a user-defined XFEM domain that contains a crack can be defined in the model, and the mesh around the crack will be refined in an adaptive way to generate elements that are fine enough to calculate the stress intensity factors (SIFs) along the crack front. Ideally, it is possible to verify or reproduce the fatigue process in the test based on all beach marks. Nevertheless, the computations were too heavy to conduct for small cracks in early stages. The main reason could be attributed to the shallow and long crack shape, which requires an enormous number of elements in the XFEM domain.

Figure 4b) presents the refined mesh of the XFEM domain for a semi-elliptical crack with the depth of 2mm and length of 128.4 mm, in accordance with the 5th beach mark on Specimen 10. It can be seen that the element shape is converted into tetrahedra for adaptive refinement first, and the region around the crack, especially the crack front, is refined. It added 107 910 elements to the model, and pushed the total element number to more than 250 000. However, for an initial crack with a depth smaller than 0.3 mm and a length more than 90 mm, the density of the elements would be too high to achieve. Since the XFEM has already provided the advantage by allowing the crack body to intersect the elements, the refinement of the mesh is only determined by the requirement of calculating stress field around the crack front. It means that the mesh around the crack cannot be optimized anymore.

a) Macroscopic model

b) XFEM domain for the 5th beach mark of Specimen 10
Figure 4 Cracked model in SAMCEF

All the beach marks were tested to calculate with the macroscopic model, and it turns to be feasible for those with the depths larger than 1.5mm only. For

smaller cracks, it is, therefore, necessary to build a multiscale way.

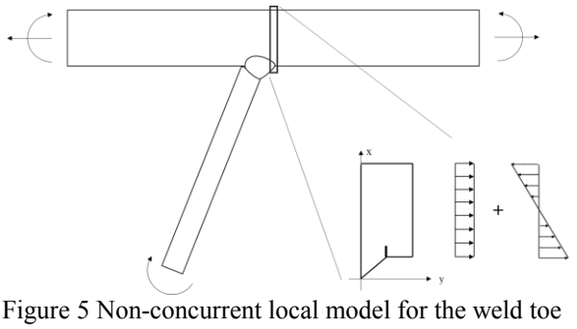
3.2 *Local model*

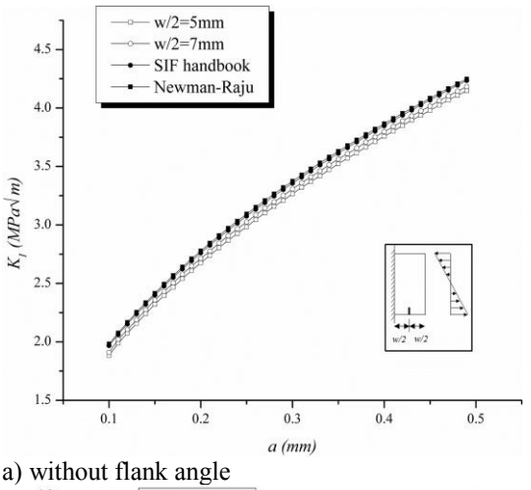
This model was built focusing on the early-stage cracks with the depth smaller than 1.5mm. As the aspect ratios for these cracks were quite small, the crack length was much larger than the depth, which means the stress field for the crack front could be approximated by plane strain assumption in two-dimensions. On the other hand, a two-dimensional model is also the only feasible way with the current computational ability, as the macroscopic model in SAMCEF has almost reached its limit.

An XFEM program coded in MATLAB was adopted to build the two-dimensional model in plane strain status, as shown in Figure 5. It was built for the weld toe region, and the geometry was determined with respect to the full thickness of the deck plate and the weld toe flank angle.

As a local model, the boundary conditions should be in accordance with the global model, i.e. the macroscopic one. Normally, the displacement-based sub-model could give a relatively accurate solution. However, the sub-model is kind of a refined model that zooms into the macroscopic one, which requires the exact same geometry. As in two-dimensions, the boundary displacements can comply with only one section of the three-dimensional model, and this essential difference could lead to inevitable errors. In that case, the stress boundary conditions were applied to this local model instead of the displacement boundary conditions. The bending/membrane stresses were applied on the right edge of the model, while full fixations were used on the left edge. But it should be noted that, in most cases, the membrane stresses were so small that can be ignored (Wang et al. 2017), and only the bending stresses were applied.

The stress to be applied should be far away enough to the weld toe, which makes it more or less similar to the nominal stress. Two benchmarks were given to validate this local model by comparing the Mode-I SIFs. To be comparable with the results obtained by stress intensity factor handbook (Murakami & Hasebe 2001) and Newman-Raju Equation (Newman & Raju 1981), it was built without considering the flank angle first, as shown in Figure 6a). As long as the distance between the crack and boundary, namely the half width of the local model *w/2*, is large enough, the adopted boundary conditions agreed with previous studies that using nominal stress. In case that the flank angle is considered, this distance should be further verified, since the flank angle itself will lead to stress concentration. Therefore, a set of local models with the flank angle equals 40 degrees and various values of *w/2* were built to calculate and compare the SIFs, as shown in Figure 6b). The SIFs obtained by *w/2* larger than 5mm are quite close, indicating the small error using this model.





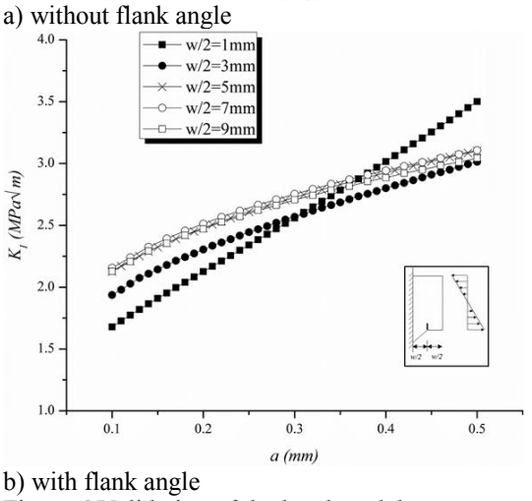


Figure 5 Non-concurrent local model for the weld toe

a) without flank angle

b) with flank angle

Figure 6 Validation of the local model

On the other hand, the stress to be applied should also be free from the influence of the growth of early-stage cracks, so that the local model could be easily linked to the macroscopic one, and this non-concurrent method will be applicable on this issue. According to the strain ranges measured on Specimen 10 (see Table 3), it can be addressed that early-stage cracks (till the 4th beach mark) will hardly affect the strain ranges if *w/2* is larger than 7mm. With consideration of both requirements and computational abilities, *w/2* was set to be 8 mm. Hence, the size of the local model was 16 × 15mm. The element size of 20 μm was adopted, leading to more than 600,000 elements in the local model. The applied

bending stress on the local model was 172.21MPa, provided by the non-cracked macroscopic model.

Table 3 The reductions of strain range at different strain gauges

w/2 (mm)	$\Delta\varepsilon_1$ (με)	$\Delta\varepsilon_2$ (με)	$\Delta\varepsilon_3$ (με)	$\Delta\varepsilon_4$ (με)	$(\Delta\varepsilon_4-\Delta\varepsilon_1)/\Delta\varepsilon_1$
3	981	862	738	610	-37.80%
5	980	934	881	818	-16.53%
7	984	967	943	914	-7.19%

11	758	753	746	737	-2.75%

* $\Delta\varepsilon_i$ is the average value of the strain ranges before the *i*-th beach mark

3.3 *Results*

The results were verified in the first place by comparing the SIFs for three cracks, i.e. S10BM4, S7BM4, S6BM2, that are possible to solve by both the SAMCEF model and the local model, as given in Table 4. The S10BM4, for example, refers to the 4th beach mark identified on Specimen 10, and so on. Clearly, the results from the local model are slightly smaller with acceptable errors.

Table 4 Verification of results obtained by the local model

Beach mark	Crack dimensions		K (MPa·√m)		
	a (mm)	*c* (mm)	Local model	SAMCEF model	diff.
S10BM4	1.578	123.5	13.81	14.31	-3.52%
S7BM4	1.551	123.2	13.74	14.15	-2.90%
S6BM2	1.611	147.5	15.70	16.26	-3.46%

Eventually, the macroscopic SAMCEF model combined with the local model was applied to obtain the SIFs for cracks indicated by beach marks, as shown in Table 5. It should be noted that the crack growth rate can only be achieved by the distance between two beach marks and the cycles, and thus is an average value for one period. Therefore, the SIF for each beach mark cannot be used directly for the CGR curve. Instead, a representative SIF range for one period is required. As the Paris law indicated, the CGR changes with SIF range in power law, and therefore a linearity can be expected when taking the logarithm of them,

$$log_{10}(\frac{\Delta a}{\Delta N})_i = log_{10}C + m log_{10}\overline{\Delta K_i} \quad (1)$$

where *i* refers to the period before the *i*-th beach mark; *C* is the Paris constant and *m* is the Paris exponent; $\overline{\Delta K_i}$ is the representative SIF range for this period. Being a linearity, it is easy to get $\overline{\Delta K_i}$ as follows,

$$log_{10}\overline{\Delta K_i} = (log_{10}\Delta K_{i-1} + log_{10}\Delta K_i)/2 \quad (2)$$

where ΔK_i is the SIF range for the *i*-th beach mark. Accordingly, the CGRs and the corresponding SIF ranges were given in Table 5. Consequently, the relationship between CGR and the SIF range can be drawn for Specimen 10 in logarithm coordinates, as shown in Figure 7.

Table 5 Summary of calculation on specimens

Beach mark	K (MPa·√m)	$\Delta a/\Delta N$ (m/cycle)	$\overline{\Delta K}$ (MPa·√m)
0	8.89	-	-
1	9.87	1.628E-09	9.37
2	11.46	1.069E-08	10.64
3	12.67	1.815E-08	12.05
4	14.31	2.600E-08	13.23
5	15.57	2.827E-08	14.66
6	17.23	3.993E-08	16.38
7	19.65	6.087E-08	18.40
8	23.24	9.240E-08	21.37
9	28.57	1.368E-07	25.77
10	34.60	1.807E-07	31.44
11	32.85	3.001E-07	33.71

In accordance with Paris law, the entire progress of crack growth is generally described by three stages: I) threshold region; II) Paris region; III) stable tearing crack growth region. However, one interesting observation in Figure 7 is that there exists a slight reduction in Stage II, which makes a "pit" on the curve. Thus two sub-stages could be addressed, named as Stage II-a and Stage II-b hereinafter. The stages of crack growth can then be elaborated as follows.

Stage I: the initial crack stage, in which the crack growth rate is low but increases sharply. In this stage, microscopic and mesoscopic heterogeneities will affect the crack growth. From the test results, this stage lasts till the crack goes to the depth about 0.5 mm.

Stage II-a: the transition stage, in which the increment of CGR, i.e. the slope of the curve, slows down gradually. In the meantime, the uncertainty induced by the microscopic and mesoscopic heterogeneities still affect the CGR. In the end of this stage, as the crack (around 2-mm-depth) is getting further away from the heat-affected zone, the reduction of CGR can be identified on the curve instead of a smooth transition to the next one.

Stage II-b: the stable crack propagation stage. The classical Paris law is expected to be applicable, and the uncertainty induced by the heat-affected zone fades in this stage.

Stage III: the unstable crack propagation stage.

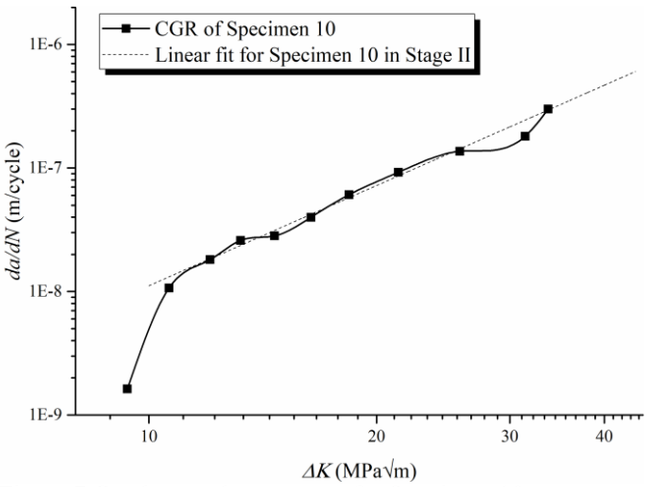

Figure 7 Crack growth rate curve for Specimen 10

4 CONCLUSIONS

This paper established a multiscale method that enables to compute the SIFs in a numerical way with respect to the fatigue test. Firstly, the crack growth process was traced using beach mark method in the test, and then the corresponding SIFs should be calculated with respect to the crack shape and size. The three-dimensional macroscopic model built in SAMCEF was proved to not applicable on the early-stage cracks due to computational ability limits. Hence, a two-dimensional local model was built and linked to the macroscopic one using a non-concurrent way. The applicability and the accuracy were validated by comparing with previous studies and with the SAMCEF model. Afterwards, the SIFs for the whole crack growth process can be obtained. As a result, different stages of crack growth can be addressed, which are basically follows the Paris law. However, part of Stage II seemed to have fluctuations of CGRs, which could be the effect induced by the heat-affected zone or weld defects in welded joints. The results will benefit the fatigue assessment and the maintenance work for OSDs when combining with inspections. But due to the limited data points in Stage I and Stage II-a, future research is still needed as the majority of fatigue life will be spent on these stages.

Numerical Fracture Mechanics Analysis of Distortion-Induced Fatigue in Steel Bridges

C. S. Wang, B. Cui, N.X. Ma, L. Duan, Y.Z. Wang
Engineering Research Center for Large Highway Structure Safety of Ministry of Education, College of Highways, Chang'an University, Xi'an, China

ABSTRACT: Aimed to study the propagation mechanism of steel bridge distortion-induced fatigue cracks, a finite element model was built to calculate the residual stresses by simulating the entire welding process of the horizontal-gusset-plate web gap detail. Numerical fracture mechanical models were built based on eXtended Finite Element Method to analyze the crack propagation behavior. The results of the welding process show that there are large residual tensile stresses at stiffener-to-web weld toes, which are close to the yield stress. Static numerical fracture mechanical analysis results show that the crack propagation modes are greatly affected by initial propagation angles, and the crack mode is Mode I leading mixed cracks of Mode I, II and III. Dynamic numerical fracture mechanical analysis shows that the detail is in the state of tension under the test loading. When the residual stress was introduced, the numerical fatigue crack propagation form is consistent with the fatigue test results, and the fatigue crack growth rate is faster.

1 INTRODUCTION

Steel bridges have been widely adopted by the countries all over the world. However, because of combined action of many factors like inadequate consideration about fatigue problems in design phase, low quality of welding and the objective existence of overloaded vehicles, steel bridges have high stress level, more times stress cycle under the action of axle load of vehicles, and the fatigue crack problems are relatively outstanding (Wang et al. 2015, 2017a). Fatigue of steel bridges can be divided into two categories: loading induced fatigue and distortion induced fatigue. Loading induced fatigue only needs to calculate the internal stress of steel girders under the action of fatigue loads, so that the design and analysis of the fatigue resistance can be carried out. However, distortion-induced fatigue has no direct relation with loads but depends on local out-of-plane distortions in key details. Research from American scholars shows that about 90% of fatigue cracks in steel bridges are caused by out-of-plane distortions (Connor & Fisher 2006).

Many researches for steel bridge web gap distortion-induced fatigue have been carried out by scholars. In 1987, a large number of actual bridge tests by Fisher, et al. (1987) show that the size of web gaps is an important factor that influences the distortion in web gaps and stress at corresponding welding details. In 2006, Berglund, et al. (2006) analyzed factors which have influence on stress distribution and size in web gaps affected by out-of-plane distortion, and they found that web gap sizes and bridge spans have great influence on the stress at gaps of webs, while the other factors have less influence. Hassel, et al. (2013) established a large number of 3D finite element models, and analyzed the influence on distortion-induced fatigue in steel bridges by factors like oblique angle, lateral brace spacing, transverse brace shape, brace stiffness and loading position, and the results show that the stiffness of the cross bracing and the shape of the cross brace have important influences on web gaps. From 2010 to 2016, Wang, et al. analyzed web gap distortion-induced fatigue in different kinds of bridges; steel bridge web gap distortion-induced full-scale fatigue tests were carried out, and the distortion-induced detail fatigue strength was determined based on hot-spot stress method; effective cold maintenance for web gap distortion-induced fatigue crack details were carried out (Wang & Cheng 2010, Cheng 2010, Yan 2013, Cheng 2013, Wei 2014, Sun 2015, Wang et al. 2017b). Researchers commonly use fatigue tests and theoretical analysis to study the fatigue performance and fatigue design of steel bridge web gap distortion-induced details. The results of fatigue tests with large dispersion and high test cost cannot meet the engineering demands of fatigue design and maintenance. Therefore, new technological approaches should be explored to study the distortion-induced fatigue behavior.

In this paper which is based on linear elastic fracture mechanics (LEFM) theory and extended finite element (XFEM) technique, numerical fracture mechanics models of the horizontal-gusset-plate web gap detail were established by ABAQUS software platform, and the welding residual stress field was introduced, then the web gap distortion-induced fatigue crack mechanism and propagation law were revealed, which can give theory and technology support to fatigue performance research, fatigue design and maintenance of steel bridges.

2 NUMERICAL METHOD FOR SIMULATION OF FATIGUE CRACK GROWTH

2.1 *Calculating stress intensity factors using the interaction integral method*

In the extended finite element method, the basic principle is that the extension function is introduced in the conventional finite element displacement model to reflect the discontinuity, and the level set function is used to track the crack surface (Moës et al. 1999). The extended finite element displacement function can be expressed as follows:

$$u(x)=\sum_{\mathrm{I}\in K}N_{\mathrm{I}}(x)\left[u_{\mathrm{I}}+\underbrace{H(x)a_{\mathrm{I}}}_{\mathrm{I}\in K_{\Gamma}}+\underbrace{\sum_{\alpha=1}^{4}F_{\alpha}(x)b_{\mathrm{I}}^{\alpha}}_{\mathrm{I}\in K_{\Lambda}}\right] \tag{1}$$

where u_{I} is continuous node displacement vector, a_{I} is improved degree of freedom passed by cracks, b_{I}^{α} is improved degree of freedom in crack-tip, K is collection of every discrete node, K_{Γ} is collection of elements and nodes passed by cracks, K_{Λ} is collection of elements and nodes on crack-tip, $H(x)$ is jump function which represent discontinuous displacement field of cracks, and its expression is:

$$H(x)=\begin{cases}1 & (x-x^{*})n\geq 0\\ -1 & (x-x^{*})n<0\end{cases} \tag{2}$$

where x is Gauss point，x^{*} is x point's projection in nearest point from the crack, n is unit exterior normal vector.

$F_{\alpha}(x)$ in formula (1) is a progressive function to describe crack-tip displacement, and it includes following 4 base functions:

$$F_{\alpha}(x)=\left[\sqrt{r}\sin\frac{\theta}{2},\sqrt{r}\cos\frac{\theta}{2},\sqrt{r}\sin\theta\cos\frac{\theta}{2},\sqrt{r}\cos\theta\sin\frac{\theta}{2}\right];\quad \alpha=1\sim 4 \tag{3}$$

Where (r,θ) is polar coordinate of crack-tip. The governing equations of the extended finite element method are derived based on the virtual work principle, and the total stiffness matrix and load matrix are obtained. Finally, the nodal displacements are solved. When solving the stiffness matrix, Gauss integral method is generally used for the conventional elements; for elements with cracks, usually, these units in the crack edge are taken to the boundary, and it is divided into many sub-elements, then each sub-element will be integrated and summed respectively.

2.2 *The achievement of crack propagation in ABAQUS*

When fatigue crack propagation is being simulated under the iterative action of cycle loading, the Paris formula expressed by ABAQUS is as follows (Paris 1963):

$$\frac{\mathrm{d}a}{\mathrm{d}N}=c_1\left(\Delta G\right)^{c_2} \tag{4}$$

where c_1, c_2 are material parameters, ΔG is strain energy release rate, a is crack length, N is time of cycles; when the crack tip meets $G_{\mathrm{th}}<\Delta G<G_{\mathrm{pl}}$, cracks begin to grow, G_{th} is threshold value of energy release rate, G_{pl} is upper limit value of energy release rate.

When dynamic crack propagation is being simulated by ABAQUS, the use of crack tip asymptotic function is given up, and jump function is only used. After N cycles, the crack propagation direction is determined by the maximum shear stress criterion according to the stress state of the element at the front edge of the crack tip. It is assumed that the jth element in crack tip front edge cracks completely in the crack propagation direction, the virtual crack propagation length is identified according to the shape of the element, strain energy release rate is calculated using virtual crack closure technique (VCCT), then the cycle value ΔN_{j} is calculated according to the formula (4), so the fracture element is the element with the minimum required number of cycles, where $\Delta N_{\min}=\min(\Delta N_{\mathrm{j}})$, finally, the cycle times and the crack length are updated and it can be in next cycle.

3 STATIC NUMERICAL FRACTURE MECHANICS ANALYSIS OF WEB GAP DISTORTION-INDUCED FATIGUE CRACKS

3.1 *Finite element model*

In this paper, using ABAQUS finite element analysis software, based on XFEM, multi-scale static crack analysis models of the horizontal gusset plate web gap details in the full-scale fatigue test specimens were established. The specimens were made of steel plate girder 600mm segments including flanges, webs, and stiffeners. The size of flanges (L×W×H) is 600×300×24mm, and the size of webs (L×W×H) is 600×870×8mm. Among them, the size of the stiffener (L×W×H) is 870×120×6mm, and the size of horizontal gusset plates (L×W×H) is 360×230×10mm, and the width of rectangle digging holes is 86mm, and the size of correspondingly nominal web gaps is 40mm. The diagram of the specimen is shown in Figure 1.

Using mutil-scale modeling method, the finite element model including 3 levels which are segmental

steel plate girder shell model, solid sub-model, and block model with cracks. The local shell model is modeled by shell elements S4R; solid sub-model

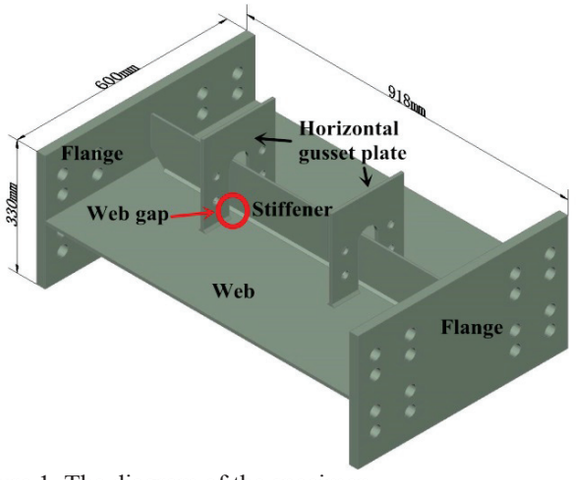

Figure 1. The diagram of the specimen

is modeled by solid elements C3D8R; the block model with cracks is modeled by elements introducing enrichment function. “Shell-solid” coupling restraint is used between segmental shell model and solid sub-model; “binding” restraint is used between solid sub-model and block element with cracks. The shape of cracks is semi-ellipse and $a_0/2c_0$=1mm/3mm. Special treatment is used to make the elements of the block with cracks well divided, and the first 15 fracture parameter values of the crack tip were outputted, and values after numerical values were stable were treated as corresponding fracture parameters. According to the test condition, nodal concentrated forces were exerted in totally 4 bolt hole positions on 2 horizontal gusset plates, and the direction is down; the resultant force of the applied load is 30KN, and the individual concentrated force should be 3.75KN. The finite element model and the mesh generation are shown in Figure 2.

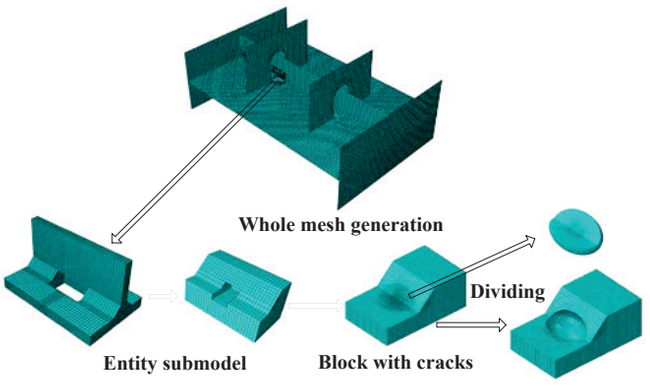

Figure 2. Finite element models and mesh generations

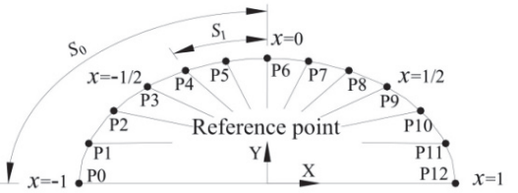
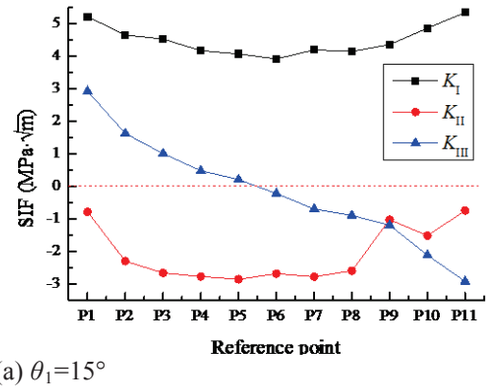
3.2 *Stress intensity factor analysis*

Because the initial defects in the manufacturing process of the steel plates are random, the initial propagation angle of the crack is also random. This paper adopted different initial expansion angles to analyze its impact on the cracking mode. Due to the mesh generation of the critical details, namely the locations of the cracks, is denser, the number of XFEM points are larger at the crack front. In order to obtain a more stable crack fracture parameter, the 15 line integral paths are chosen to output it. This section selects 13 reference points (P0 ~ P12) of the crack propagation front to describe the crack front position. The reference points divide the arc length of the semi-elliptical arc into 12 equal parts, and the ratio of the elliptical arc length (S_1) of the reference point to P6 and 1/4 elliptical arc length (S_0) represents the reference point position (x=S_1/S_0).The numerical value of x of the left side and the right side are equal, and the sign is opposite, as shown in Figure 3.





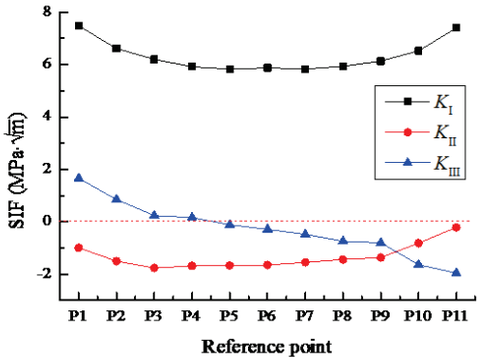


Figure 3. Position of crack propagation stage reference points

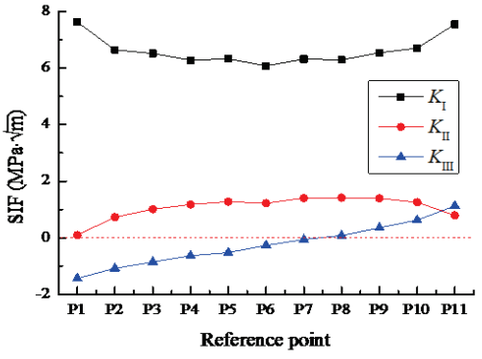
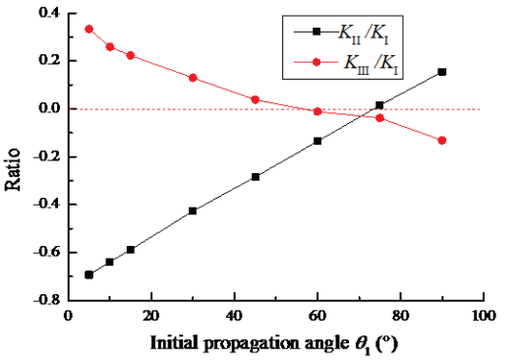


Fatigue cracks were set in advance at the location where the typical horizontal gusset plate web gap fatigue cracks are easy to form. In this section, the initial expansion angle θ_1 is selected to be 15 °, 45 ° and 90 °, so as to obtain the curve, as shown in Figure 4.

(a) θ_1=15°

(b) θ_1=45°



(c) θ_1=90°

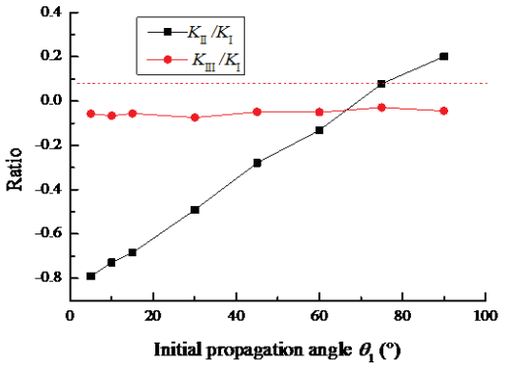


Figure 4. Position of crack propagation stage reference points

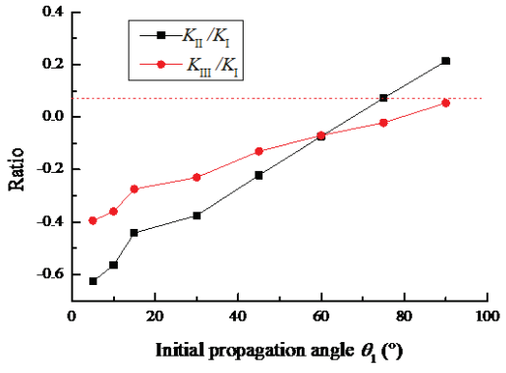
Figure 4 shows that the values of K_I of the reference point positions are larger than that of K_{II} and K_{III} of different initial propagation angles. The distribution curve of the value of K_I is concave along the crack front reference points. K_I of the reference point positions that is close to the two ends of the long axis is larger. And the distribution curve of K_{II} gradually changes from negative concave curve to positive convex curve with the increase of θ_1. The slope of the distribution curve of the value of K_{III} converts from positive to negative with the increase of θ_1, and the K_{III} near P6 is approximately zero. As for different initial propagation angle θ_1, both K_{II} and K_{III} occupy certain proportions, indicating that the crack at this point is a combination of Mode I, Mode II, and Mode III cracks, which is predominant Mode I.



Three representative reference points are selected according to the variation of stress intensity factor values along the crack front at different initial expansion angles, namely P3, P6, and P9. The effect of initial propagation angles on the cracking modes of fatigue cracks was analyzed based on the proportions of K_I, K_{II}, and K_{III}, as shown in Figure 5.

(a) P3

(b) P6

(c) P9

Figure 5. K_{II}/K_I and K_{III}/K_I of different initial propagation angles

Figure 5 shows that the K_{II}/K_I distribution curve of P3, P6 and P9 is approximately linear and the slope is positive. And its value is close to zero when the initial propagation angle θ_1 near 70°. During the process of the initial propagation angle θ_1 increases from 0 ° to 90 °, the proportion of K_{II}/K_I increases. The K_{III}/K_I distribution curve at P6 is always small. The K_{III}/K_I distribution curve decreases at P3 and increases at P9 as the initial expansion angle θ_1 increases from 0 ° to 90 °. Therefore, the initial propagation angle θ_1 has a great influence on the initial

crack propagation mode. In general, the proportions of K_{II}/K_I and K_{III}/K_I decrease at first and then increase. And the effects of the Mode II and Mode III cracks at different initial propagation angle cannot be ignored.

4 WELDING RESIDUAL STRESS ANALYSIS OF DISTORTION-INDUCED FATIGUE DETAILS

Residual stress is considered to be an important factor influencing the fatigue cracking in the weld zone of steel bridges. There is a large residual stress in the weld zone, and even reach to the yield strength of the material. In this paper, simulation analysis of residual stress of welds in steel bridge web gap details was carried out to prepare for the numerical fracture mechanics analysis of fatigue mechanism in steel bridge web gap details.

4.1 *Finite element model of welding analysis*

The stress field produced in welding process involves the nonlinear problems of material, geometry nonlinearity, and the heating source is also highly concentrated and inputted into welding component instantly. Because of the complexity of welding thermo-mechanical coupling behavior, at the same time, in order to simulate accurately, nonlinear transient problems based on the incremental theory is used in the numerical simulation of welding. In this paper, a sequentially coupled thermal analysis method is used to analyze the residual stress. Based on ABAQUS software platform, the horizontal gusset plate web gap detail joint weld is established (Fig.6).

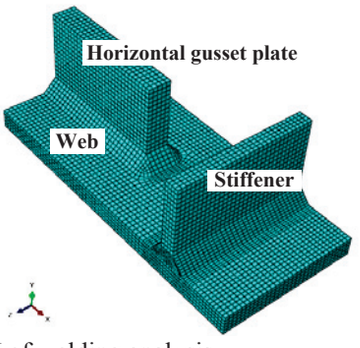


Figure 6. FEM of welding analysis

The length of stiffener in residual stress analysis model in horizontal gusset plate web gap fatigue detail is 60mm, and the length in the direction of horizontal gusset plate is 130mm. There are 20986 elements and 25536 nodes. DC3D8 eight node linear hexahedron elements are used in the thermal analysis, and heat transfer transient analysis steps are used in analysis steps. C3D8R eight node linear hexahedron elements are used in the thermo-mechanical analysis, and static-general analysis steps are used in analysis steps. No boundary condition was performed in the thermal analysis; in order to avoid inaccuracy caused by too many welding constraints and to guarantee the convergence in the model calculation, the boundary conditions should be exerted as little as possible according to actual welding conditions.

At present, the thermal physical and thermal mechanical parameters of steel are not complete. According to the value in the research from Zhao & Wu (2012), and some data were modified, mechanical parameters of Q345 steel are shown in Figure 7. Three kinds of heat transfer form (heat conduction, heat convection, and heat radiation) are considered. Heat convection and heat radiation areas are divided into the area below the CO_2 nozzle, the gas flow area and the cooling zone. The parameters of thermal transmission were referred from the paper of Zheng et al. (2007). The radiation Stefan-Boltzmann constant is 5.67×10^{-8}W/(m$^2\cdot$°C^4), and the absolute zero is -273.15°C.

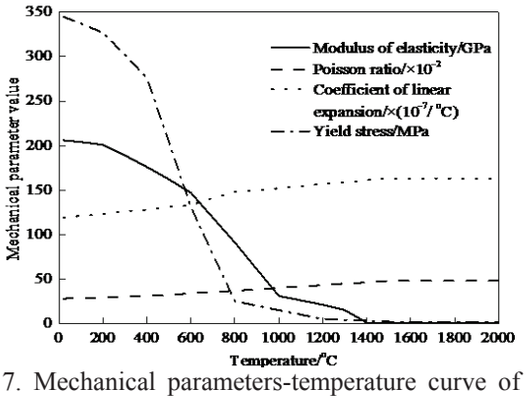

Figure 7. Mechanical parameters-temperature curve of Q345 steel

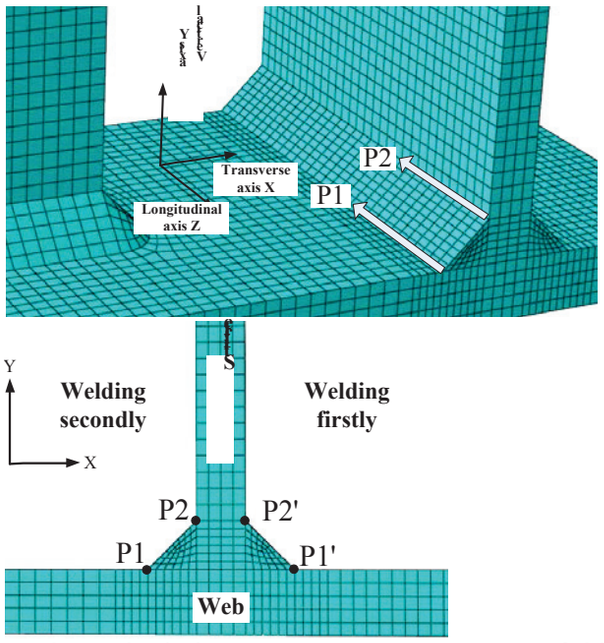
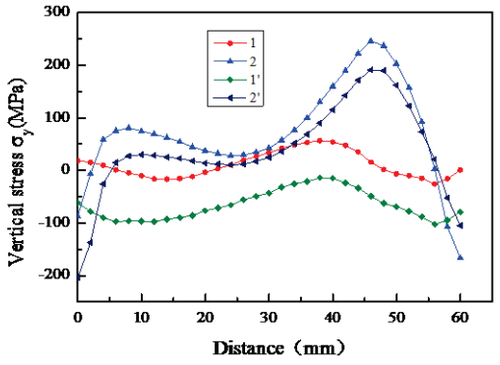
4.2 *Welding residual stress analysis*

Figure 8 shows routes P1 (P1'), P2 (P2') to extract residual stress in the flange to web welding area. Figure 9 shows distribution curves of transverse and vertical residual stress in the direction of welding seam. As can be seen from figures: (1) the residual stress changes largely in arc and arc blowout stages, and the transition in the middle is gentle; (2) residual stress located in the weld toe in web side is large, and the residual stress in the weld toe in the stiffener side is smaller; (3) residual tensile stress nearby the center of the direction of weld length, meanwhile, under the action of experimental load, stiffener to web end weld toe is mainly in cyclic tension, so fatigue cracks in this detail are easy to initiate and propagate.





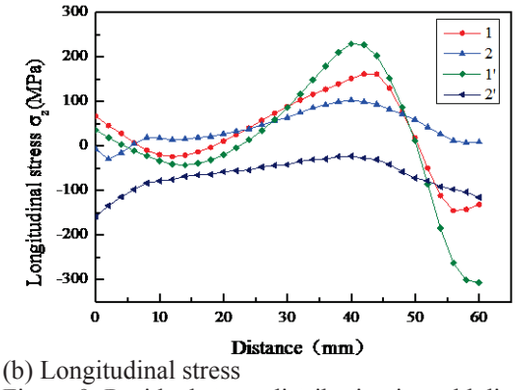


Figure 8. Mechanical parameters-temperature curve of Q345 steel

(a) Vertical stress

(b) Longitudinal stress

Figure 9. Residual stress distribution in weld direction

Figure 10 shows the residual tensile stress distribution curve in the vertical weld direction of horizontal gusset plate to web (route P3 and P3'). As is shown in Figure 10, residual tensile stress close to horizontal gusset plate to web weld toe area is large, and is close to the yield strength of steel. As the distance with the weld increases, the residual tensile stress decreases gradually.

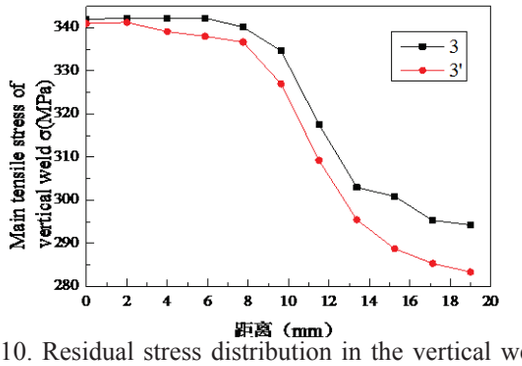

Figure 10. Residual stress distribution in the vertical weld direction

Figure 11 shows the residual stress distribution curve on the web in horizontal gusset plate to stiffener gap (route P4). As is shown in Figure 11, large residual main tensile stress is located in the position close to horizontal gusset plate to web end weld toe in horizontal gusset plate web gap, and is close to the yield strength of steel. Residual tensile stress decreases rapidly within 15mm distance of this weld toe, and the residual tensile stress increases in a position close to stiffener to web weld toe. Because of the action of testing loads, horizontal gusset plate to web weld toe endure compressive stress, so cracks cannot initiate in this position easily. However, stiffener to web weld toe endure cyclic tensile stress under testing loads, and the damage continues to accumulate, so fatigue cracks can initiate and propagate easily.

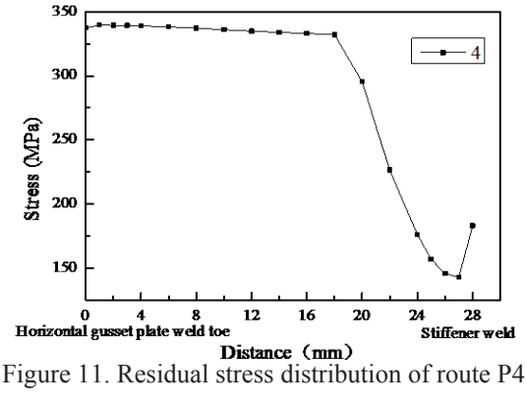

Figure 11. Residual stress distribution of route P4

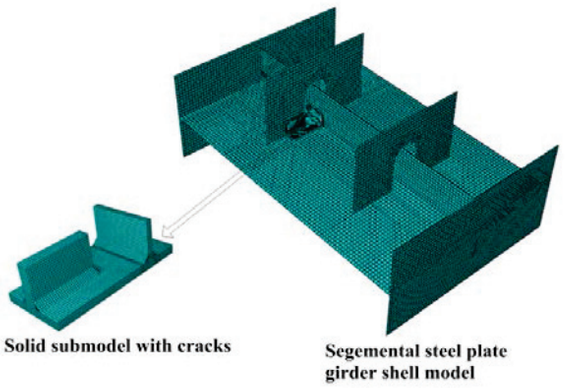
5 CRACK PROPAGATION BEHAVIOR ANALYSIS OF DISTORTION-INDUCED FATIGUE

5.1 *Finite element model*

As is shown in Figure 12 is the finite element analysis model for the web gap fatigue detail of horizontal gusset plate considering residual stress field. The model consists of 2 sections: segmental steel plate girder shell model and local solid sub-model. The introduction of the residual stress field needs three steps: firstly, the welding temperature field is obtained by welding thermal analysis of the local solid

sub-model; secondly, the welding temperature field results are introduced into the welding thermal stress analysis model of the local solid, and the welding residual stress field is obtained; thirdly, the welding residual stress field is introduced into the dynamic crack growth analysis model.



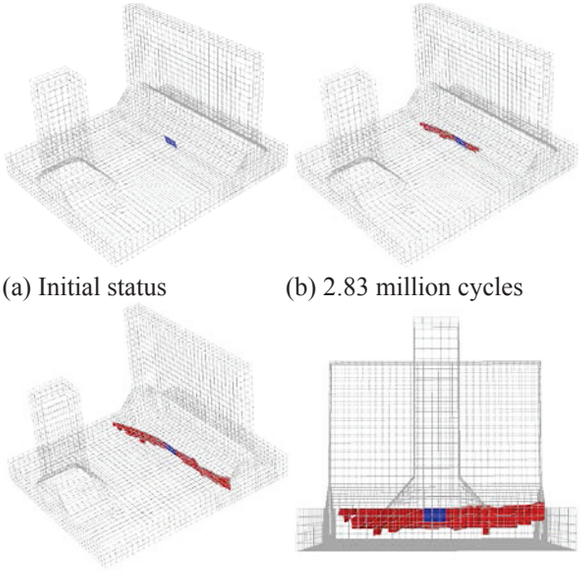


Figure 12. The finite element model with the introduction of residual stress field

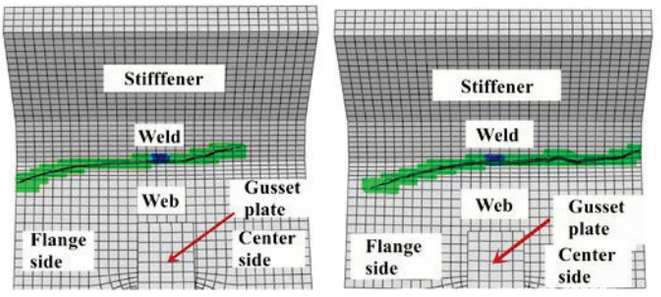
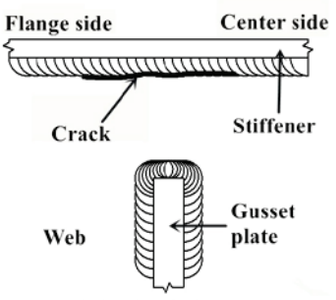
5.2 *Dynamic fatigue crack propagation simulation*

The initial crack size of stiffener end weld toe position is assumed as $a_0/2c_0$=2mm/6mm, and the propagation behavior of the fatigue crack is shown in Figure 13. The crack propagates along the direction of weld toe to both sides of the horizontal gusset plate. Crack propagation in both sides of the horizontal gusset plate has a lesser difference, which coincides with the fatigue test.



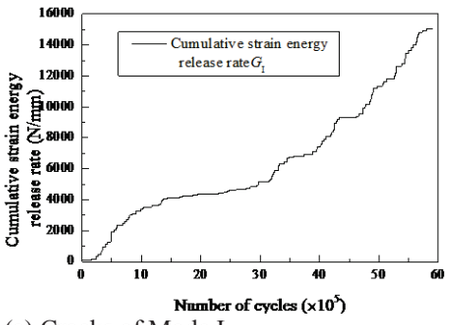
(a) Initial status (b) 2.83 million cycles



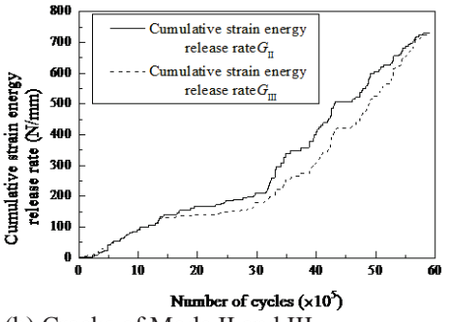
(c) 5.91 million cycles

Figure 13. Dynamic fatigue crack propagation in stiffener end weld toe

Figure 14 shows the comparison between fatigue test results and numerical analysis results for the surface crack forms of the web with and without considering residual stress. As is shown in Figure 14a is the crack form without considering residual stress after the action of 9.03 million cycles, and the long axis of the crack propagates from 6mm to 47mm; as is shown in Figure 14b is the crack form considering residual stress after the action of 591 million cycles, and the long axis of the crack propagates from 6mm to 58mm. Therefore, the existence of residual stress can influence the form of crack propagation, meanwhile, because of the larger residual tensile stress, under the same load amplitude, the crack propagation rate is faster.



(a) Without the residual stress (b) With the residual stress



(c) Crack in the fatigue test specimen

Figure 14. Comparison of crack propagation

As is shown in Figure 15 is cumulative strain energy release rates G_{I}, G_{II} and G_{III} in crack propagation process with the consideration of residual stress. Obviously, cracks of Mode I are dominant, meanwhile, cracks of Mode II and III are similar. After conversion, $K_{\mathrm{II}}/K_{\mathrm{I}}$ and $K_{\mathrm{III}}/K_{\mathrm{I}}$ are both about 0.22, which is larger than the value without considering residual stress, and forms of cumulative strain energy release rates are different, which indicates that the influence of Mode II and III cracks increases and crack propagation forms have difference with the consideration of residual stress. Crack propagation form reflected by the cumulative strain energy release rate curve is basically consistent with the results obtained by static crack analysis, which is that cracks at the end of the stiffener web weld toes are Mode I leading mixed mode cracks of Modes I, II and III.

(a) Cracks of Mode I

(b) Cracks of Mode II and III

Figure 15. Cumulative strain energy release rate of crack propagation

6 CONCLUSION

Typical cracks at stiffener to web weld toe in the horizontal gusset plate to stiffener web gap detail are Mode I leading mixed mode cracks of Modes I, II and III. When fracture mechanics is used for analysis and assessment, cracks of Modes II and III cannot be ignored.

Great residual tensile stress exists at stiffener to web weld toe in the horizontal gusset plate to stiffener web gap detail, and the value is reach to the yield strength of steel; the residual tensile stress is one of the major factors that control the fatigue crack initiation and propagation form in such details.

After considering the influence of residual tensile stress, crack propagation form in the dynamic crack propagation analysis model of the horizontal gusset plate to stiffener web gap is similar to the fatigue test results. The rate of crack propagation increases because of the existence of residual tensile stress, and the influence of residual tensile stress cannot be ignored when analysis and assessment of steel bridge web gap distortion-induced fatigue behavior.

Fatigue life assessment of reinforced concrete bridges from monitoring data

P. Junges

ABSTRACT: The majority of Brazilian bridges are made of reinforced concrete with spans smaller than 50 m. These bridges are reaching their design service life and, thus, have already been submitted to the passage of millions of vehicles. Furthermore, there have been an increase in the load traffic and in the number of trucks in the highways. Trucks with up to nine axles are usually seen nowadays. As a result, fatigue assessment is needed to ensure safety. Therefore, two reinforced concrete bridges were monitored with time intervals in order to assess their structural safety. The monitoring lasted 120 days in each structure. In this paper, the signals acquired at the midspan of the girders during the monitoring were used to assess the fatigue life of the bridges. Equivalent stresses were calculated from stress bin histograms for several variable amplitude fatigue limits (VAFL). In order to estimate the life cycle, it was used the tension-life (S-N) approach, using S-N curves from international standards. Moreover, it was considered a linear accumulation damage through the Palmgren-Miner rule with the counting of stress cycles given by the Rainflow method. Uncertainties about maximum stresses and bridge degradation were taken into account in a simplified way based on international standards recommendations. It is concluded that the consideration of VAFL value between 10% to 33% of the constant amplitude fatigue limit (CAFL) would better describe the actual state of conservation of the evaluated bridges. Also, it is not expected that fatigue will be the failure mechanism of these bridges.

1 INTRODUCTION

The majority of Brazilian bridges have been built in the last century, and thus, are reaching their service lives. They are typically 50 m long reinforced concrete bridges. For these small span bridges, live loads due to traffic are the ones that bring in stresses with larger amplitudes.

The normal traffic usually induces cyclical stresses below the resistance stresses of the bridge materials. Nonetheless, a large number of repetitions of these cyclical stresses may lead to failure of a structural component by fatigue.

In addition, the traffic on the highways has changed significantly in the past decades. There has been an increase in the number of trucks and in the load traffic. Trucks with up to nine axles are usually seen nowadays.

Consequently, the bridges have been submitted to the passage of millions of vehicles which are constantly increasing their gross weight. Thus, these structures have already supported a large number of stress cycles, and even stress cycles that were not taken into account during the design. Hence, it is necessary to perform a fatigue assessment in order to ensure their actual safety level.

Although fatigue assessment is often done for steel bridges, several researches have addressed this assessment to reinforced concrete bridges (Schläfli & Brühwiler 1998, Higgins et al. 2006, Kumpoopong & Herabat 2010, Forrest et al. 2010, Sasaki et al. 2010, Zanuy et al. 2011, Junges et al. 2016).

The estimation of the remaining fatigue life is usually deterministic, using stress-service life approaches supported by S-N curves given by international standards together with a particular damage accumulation rule. The stress ranges applied are obtained from numerical models with the use of design traffic loads, which may or may not represent the reality of the current traffic.

To improve this approach, some researchers have been using traffic data from weigh-in-motion (WIM) measurements (Wang et al. 2005, Sasaki et al. 2010, Guo et al. 2012, Zhang & Cai 2012) while others have continuously monitored bridges for some period of time (Higgins et al. 2006, Zhou 2006, Kwon & Frangopol 2010, Junges et al. 2016).

To perform more accurate evaluations, it is of the utmost importance the use of real data in order to correctly characterize the actual structural behavior of the bridge. Consequently, it has become more common to use Bridge weight-in-motion (B-WIM)

techniques to verify traffic loads and to evaluate the structural safety of bridges (Žnidarič & Lavrič 2010, Junges et. al. 2017).

In this study, a B-WIM system was used to acquire strain data due to traffic load yielding the stress ranges supported by two bridges. These stress ranges were then used to evaluate the bridge service life to fatigue. This evaluation was performed solely for the reinforcing bars, thus assuming that fatigue failure in concrete is unlikely (Schläfli & Brühwiler 1998). Service life was estimated based on the S-N curves provided by the Eurocode 2 (2004). Uncertainties about maximum stresses and bridge degradation were taken into account in a simplified way based on Eurocode 2 (2004) and AASHTO LRFD (2014) recommendations.

2 FATIGUE ASSESSMENT

2.1 *Fatigue analysis based on S-N curves*

An S-N curve (Figure 1) relates the nominal stress required to cause a fatigue failure after some number of cycles. This curve is derived from experimental tests on specimens subjected to harmonic loads at different amplitudes.

As can be seen in Figure 1, when plotted in a log-log graph, the S-N curve shows a bi-linear typical behavior. The initial linear part of the curve is described by Basquin's equation, provided in Equation (1), relating the number of cycles to failure.

$$S_a = A(N)^m \tag{1}$$

where A represents the linear coefficient of a S-N curve, m is the slope of the curve in a log-log scale, and N_f is the number of cycles to failure.

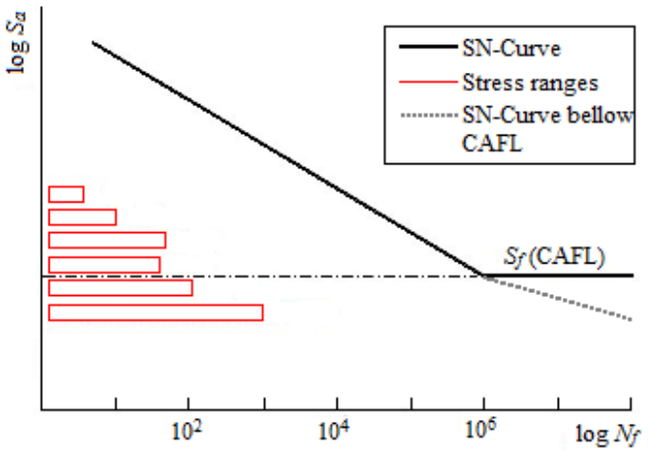

Figure 1. Typical S-N Curve.

Unlike the harmonic loads used to build an S-N curve, traffic loading on bridges leads to variable amplitude stresses. Thus, it is necessary to consider a cumulative damage model in order to take into account the damage derived from cycles at different amplitudes.

Fatemi & Yang (1998) have analyzed several cumulative damage models and concluded that there is no model that is widely accepted. The most popular model is the Palmgren-Miner model. It does not consider sequence effect and damage accumulation, being regarded as independent of the stress level.

This model evaluates total damage as the sum of damage given at each stress level, as indicated by Equation (2).

$$D = \sum n.d_i = \sum_{i=1}^{k} \frac{n}{N_{f,i}} \tag{2}$$

where D is the total damage in the structure; n is the number of cycles accumulated at a stress level S_i; di is the individual damage due to stress level S_i; k is the number of stress cycles analyzed; $N_{f,i}$ is the average number of cycles to failure at stress level S_i.

The lack of consideration of sequence effects is one great disadvantage of the Palmgren-Miner damage model. As a result, when stress levels below the fatigue limit S_f, also known as constant amplitude fatigue limit (CAFL), are applied, there is no damage caused. This may be true when harmonic loads are applied. However, when variable amplitude loading is applied, cycles with amplitudes greater than the fatigue limit may induce the initiation of cracking. Subsequent cycles, even at lower amplitudes, may propagate such cracks leading to damage (Schijve, 2003).

One possibility to reduce this disadvantage is to extrapolate the S-N curve to values below the fatigue limit. In this case, stress levels below CAFL would be considered in the damage model (Figure 1). This consideration is adopted by several international standards, such as the Eurocode 2 (2004). Usually, the slope of the line bellow CAFL is proportional to the slope of the original S-N curve (Schijve 2003).

However, not all cycles below CAFL have to be taken into consideration. In fact, it is necessary to define a variable amplitude fatigue limit (VAFL), below which the cycles will not propagate the fatigue crack. Usually the VAFL is defined as a percentage of CAFL. Zhou (2006), Kwon & Frangopol (2010), and Guo et al. (2012) present values of 25%, 33% e 50% applied to evaluate fatigue of steel bridges. Junges et al. (2016) used the same values to evaluate fatigue in a reinforced concrete bridge. In the present study, VAFL values varying between 1% and 50% are considered, as can be seen on Table 1. This table gives the corresponding stress levels considering the CAFL indicated by Eurocode 2.

Table 1. VAFL used in the analysis

CAFL (Eurocode 2)	162.50 MPa
CAFL (Medium stress)	79.01 MPa
VAFL (% CAFL)	VAFL (MPa)
1	0.79
2	1.58
3	2.37
4	3.16
5	3.95
10	7.90
15	11.85
20	15.80
25	19.75
30	23.70
33	26.07
35	27.65
40	31.60
45	35.55
50	39.50
60	47.40
70	55.30
80	63.20
90	71.10
100	79.01

As Table 1 presents, the VAFL values are calculated using the CAFL corrected by the mean stress value. Stephens et al. (2011) recommend to correct the stress amplitude values depending on the mean stress value, so the non-stationary state of stresses are taken into account. One possibility to correct the stress levels is to use the Goodman method, as introduced in Equation (3).

$$\frac{S_a}{S_f} + \frac{S_m}{S_u} = 1 \tag{3}$$

where S_a is the stress semi amplitude; S_f is the fatigue limit stress; S_m is the mean stress; and S_u is the ultimate strength.

Each VAFL value shown in Table 1 leads to a different stress histogram. From these histograms it is possible to calculate an equivalent stress range (S_{re}) as presented in Equation (4).

$$S_{re} = \left[\sum \frac{n_i}{N} S_{ri}{}^{m} \right]^{\frac{1}{m}} \tag{4}$$

where S_{re} is the equivalent stress range; S_{ri} is the predefined stress range bin; n_i is the number of observations in the predefined stress range; N is the total number of cycles; and m is the angular coefficient of the S-N curve above CAFL.

Even though several researchers have been using Equation (4) (Higgins et al. 2006, Zhou 2006, Kwon & Frangopol 2010, Guo et al. 2012, Zhang & Cai 2012), this equation ignores the second slope and the stress cycles below CAFL. It only takes into account the first slope of the S-N curve, above CAFL. To overcome this, the stress cycles above and below CAFL can be treated separately, as given in Equation (5).

$$S_{re} = \left[\left(\sum_{S \geq CAFL} \frac{n_i}{N_1} S_{ri}{}^{m_1} \right)^{\frac{1}{m_1}} \frac{N_1}{N_T} \right] + \left[\left(\sum_{S < CAFL} \frac{n_i}{N_2} S_{ri}{}^{m_2} \right)^{\frac{1}{m_2}} \frac{N_2}{N_T} \right] \tag{5}$$

where S_{re} is the equivalent stress range; S_{ri} is the predefined stress range bin; n_i is the number of observations in the predefined stress range; N_1 is the total number of cycles above CAFL; N_2 is the total number of cycles below CAFL; N_T is the total number of cycles (N_1+N_2); and m_1 and m_2 are the angular coefficient of the S-N curve, above and below CAFL respectively.

Equation (5) takes into account the stress cycle amplitude and the amount of cycles above and below CAFL to calculate the equivalent stress range.

The non-stationary nature of the resultant stresses also makes difficult to easily count the cycles of each stress level. Therefore, a specific algorithm, such as the rainflow-counting algorithm, must be used (ASTM E1049-85, 2011). This algorithm was developed to take into consideration slow, as well as fast stress variations, forming pairs of maximum and minimum values (Johannesson, 1999).

3 PROPOSED METHOD

The two bridges analyzed in the present study, were monitored by a Bridge Weigh-in-motion (BWIM) system in order to evaluate their structural safety. The strain data acquired during the monitoring are used here to evaluate the service life related to fatigue failure of the reinforcing steel of bridge girders (Schläfli & Brüwiler 1998, Zanuy, Alabajar & Fuente 2009).

The B-WIM system transducers were mounted on the inner surface, close to the mid span of the girders. As pointed out by Zanuy et al. (2011) and Higgins et al. (2013), the tension stiffening effects decreases as the number of cycles increases. Accordingly, the girder section must be considered as a pure cracked section.

The evaluation of service life due to fatigue is performed by the S-N approach with VAFL varying as displayed on Table 1. The rainflow counting algorithm, and the Goodman method are also used to consider the non-stationary state of stress as provided by Equation (3). Finally, the equivalent stress range (S_{re}) is calculated for each VAFL using Equantion (5). The service life, in years, is estimated considering damage due to each stress cycle together with the average daily number of cycles, as given by Equation (6).

$$Y = \frac{1}{365 \times ADC \times D_C} \quad (6)$$

where Y is the service life to fatigue in years; ADC is the average number of cycles per day; D_C is the damage due to one cycle for the equivalent stress range. Stress range

During the monitoring period, maximum stress range is unlikely to be captured. Therefore, AASHTO LRFD Bridge Design Specifications (2014) assume that the maximum stress range is twice the effective stress range. In addition, it is expected that reinforced concrete structures lose stiffness due to degradation, especially when subjected to corrosion. Thus, Eurocode 2 (2004) permits the extrapolation of the S-N curve below CAFL using the same slope coefficient as the one above CAFL. This way, bridge degradation is taken into account in a simplified way. These two considerations (maximum stress range and degradation due to corrosion) are used in the present study.

4 APPLICATIONS

The bridges assessed in the current study are located at highway BR-153, between the cities of Uruaçu and Porangatu in the state of Goiás. This highway is subjected to a significant heavy trucks traffic.

Among the several bridges in this portion of BR-153, the Lambari and Itinguijada bridges were chosen since their location permits easy access to inspection, as well as to mount B-WIM transducers. Also, the girders of Lambari Bridge exhibit some cracking and exposed corroded reinforced steel, while Itinguijada Bridge seems to be in good conditions.

For both bridges, the design drawings were not available. Then, the reinforcing steel area was estimated from Brazilian standard at the expected time of construction (NB 1, 1960), together with information gathered during bridge inspection.

4.1 *Lambari Bridge*

4.1.1 *Description of the bridge*

Lambari Bridge is composed of four main simple supported girders; with main span around 15 m and two unsupported spans at each end, which leads to 22.5 m girder length. There are, also, five transverse beams, one in the mid-span, two over the piers and two others at the free ends of the girders. More details of the structure can be seen on Figures 2 to 5.

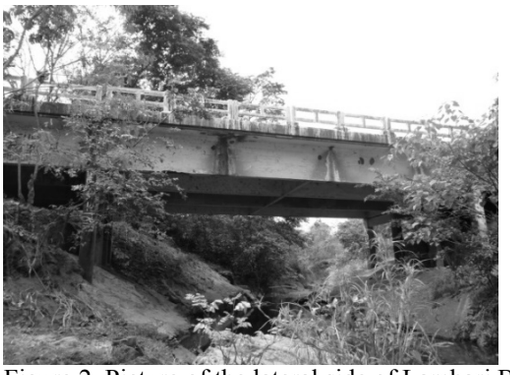

Figure 2. Picture of the lateral side of Lambari Bridge.

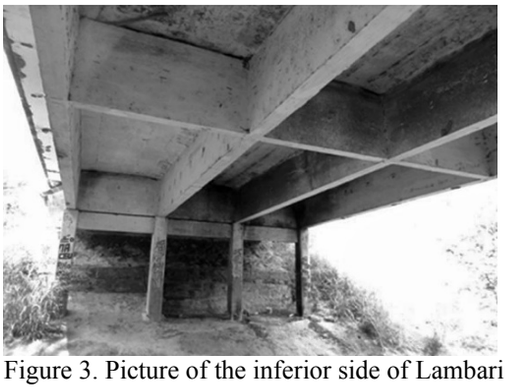

Figure 3. Picture of the inferior side of Lambari Bridge.

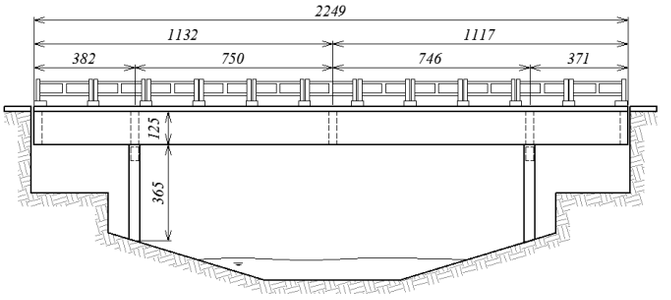

Figure 4. Side view of Lambari Bridge (in cm).

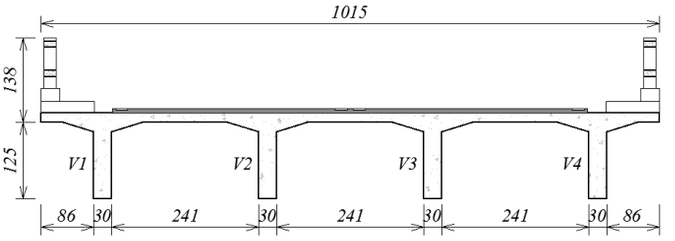

Figure 5. Lambari Bridge transversal section at mid-span (in cm).

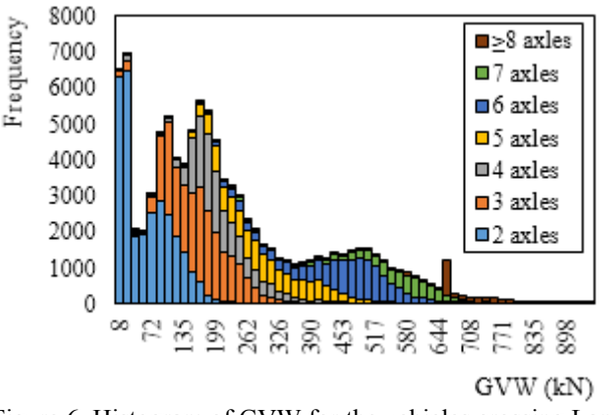

Figure 6. Histogram of GVW for the vehicles crossing Lambari Bridge during the monitoring period.

Lambari Bridge was monitored between November of 2013 and January of 2014, for a total of 42 days. The B-WIM transducers were placed on the bottom surface of the girders near to the mid-span in order to evaluate the bending moments of the bridge. During the monitoring time, more than 100,000 vehicles crossed the bridge. Figure 6 illustrates a histogram of gross vehicle weight (GVW) of these vehicles. As can be seen in this figure, vehicles up to 326 kN are the majority. However, vehicles heavier than the Brazilian design live load (450 kN) sum 15%.

4.1.2 *Results of expected service life to fatigue*

Figure 7 depicts an example of the obtained histograms of stress ranges of the four girders. As can be seen, the great concentration of cycles in low stress ranges makes important the adequate choice of the VAFL values to be used in the analysis. This figure also emphasizes that girders V2 and V3 were the most demanded, with almost the same number of stress cycles.

Nevertheless, the damage suffered by girder V3 is quite higher than the damage of girder V2, as can be seen in Figure 8. This figure shows the equivalent stress ranges with its respective number of cycles for each VAFL cut-off levels. Damage is evaluated by the distance between dots and the thick line (S-N Curve). In this way, girder V2 has roughly the same damage as girder V4, which has half number of cycles.

According to Figure 8, girder V3 is the most damaged and, if traffic is constant for all service life, it will be the first one to fail. Accordingly, the service life of Lambari Bridge will be limited by girder V3. Table 2 brings the estimated service life of Lambari Bridge for each VAFL cut-off value considering the stress ranges histograms as measured.

In order to take into account the effect of maximum stresses and bridge degradation, the stress ranges histograms were multiplied by a factor of 2 (AASHTO, 2014) and the second slope of the S-N Curve, below CAFL, was taken as the first one (Eurocode 2, 2004). Therefore, Table 3 presents the results of estimated service life for Lambari Bridge considering the worst case scenario.

Figure 8, Table 2 and Table 3 establish that below a certain level, there is no improvement in the estimation of service life in spite of a larger number of cycles. In fact, as the equivalent stress range decreases, it matches the inclination of the S-N curve and the number of cycles does not matter anymore. For the worst case scenario of Lambari Bridge, the VAFL value below which this happens is VAFL45. Thus, it can be said that the service life of this bridge is 53 years.

4.2 *Itinguijada Bridge*

4.2.1 *Description of the bridge*

The superstructure of Itinguijada Bridge is formed by two girders, simple supported on four circular columns, with a mid-span of about 20 m and two unsupported spans at each end, which give girders of 29.70 m long. There are five transverse beams. Figures 7 to 10 display more details of this structure.

Itinguijada Bridge was monitored between September and November of 2016, for a total of 68 days. The B-WIM transducers were placed on the bottom surface of the girders near to the mid-span in order to evaluate the bending moments of the bridge. During the monitoring time, more than 150,000 vehicles crossed the bridge. Figure 13 reveals a histogram of gross vehicle weight (GVW) of these vehicles. This figure indicates a great concentration of vehicles with GVW between 70 and 370 kN. Furthermore, around 14% of the total vehicles are heavier than 450 kN (live load for Brazilian standards).

4.2.2 *Results of expected service life to fatigue*

Figure 14 depicts an example of the obtained histograms of stress ranges of the two girders of Itinguijada Bridge. Similarly to Lambari Bridge, there is a great concentration of cycles in low stress ranges, which makes important the adequate choice of the VAFL values. It is easily seen that girder V1 was the

most required during the monitoring, as can be also seen in Figure 15. This figure exhibits the equivalent stress ranges with its respective number of cycles for each VAFL cut-off levels.

Considering that the service life of Itinguijada Bridge will be limited by girder V1, Table 4 brings the estimated service life of this bridge for each VAFL cut-off value considering the stress ranges histograms as measured.

Bridge degradation and the effect of maximum stresses were also taken into account as said before. The stress ranges histograms were multiplied by a factor of 2 (AASHTO, 2014) and the second slope of the S-N Curve, below CAFL, was taken as the first one (Eurocode 2, 2004). Thus, Table 5 exhibits the results of estimated service life for Itinguijada Bridge considering this worst-case scenario.

In Figure 15, differently from Figure 8, one cannot see a clear difference between the slope of the equivalent stress range points. This happens because of the low levels of stress that Itinguijada Bridge is subjected. In spite of that, in Tables 4 and 5 is possible to identify the cut-off limit.

For the worst case scenario of Itinguijada Bridge, the VAFL value below which the slope of the points matches the slope of the S-N curve, and the number of cycles does not matter anymore, is VAFL10. Thus, it can be said that the service life of this bridge is 5511 years. Therefore, it is considered that Itinguijada Bridge has infinite fatigue life.

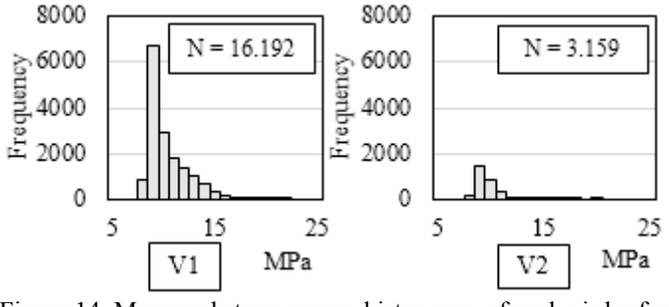

Figure 14. Measured stress ranges histograms of each girder for VAFL10 cut-off level for Itinguijada Bridge.

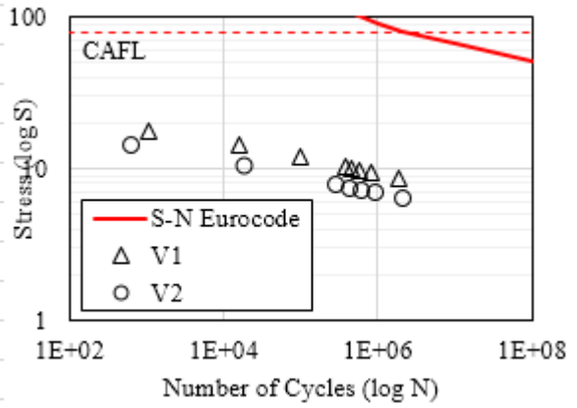

Figure 15. Equivalent stress range and number of cycles for each VAFL level for Itinguijada Bridge.

5 CONCLUSIONS

In the present study, the fatigue service life of two simple supported short-span reinforced concrete bridges were evaluated. The equivalent stress ranges used were calculated from monitoring data given by a BWIM system.

The proposed method estimates the service life due to fatigue using S-N curves offered by international standards, with the correction of medium stress, and equivalent stress ranges produced by actual traffic conditions calculated in a novel way. This analysis was performed for several VAFL cut-off values in order to identify which one would be more suited to evaluate those bridges. The main conclusions are:

- The extension of the S-N curve below CAFL must be considered for cycled loading. Without an adequate VAFL cut-off level, the calculated service life would be quite optimistic;

- VAFL between 25 to 33% of CAFL, normally used in the literature, can give a good and conservative estimative of the service life when degradation and maximum stresses are taken into account;
- From the results of both bridges, it is expected infinite fatigue life for bridges with estimated life above 100 years when VAFL50 cut-off level and the worst-case scenario are considered.

The results obtained in the current study contribute to the state-of-the art of fatigue in reinforced concrete bridges. However, they are not definitive.

The assumptions made regarding maximum stress range and bridge degradation, are conservative. They do not describe perfectly the effects of degradation and traffic conditions.

Although the period of monitoring was quite long, it was not long enough to characterize the seasonal nature of traffic. Hence, it is not possible to state that the actual traffic was well-defined. In addition, it cannot be stated that the traffic will remain the same over the next years. Therefore, a better model should include an expected increase in traffic.

All these aforementioned issues may be addressed by a reliability model, which considers all the problem variables as random.

ACKNOWELEGMENTS

The authors would like to express their gratitude to the Brazilian National Department of Infrastructure (DNIT) for having financially supported such research.

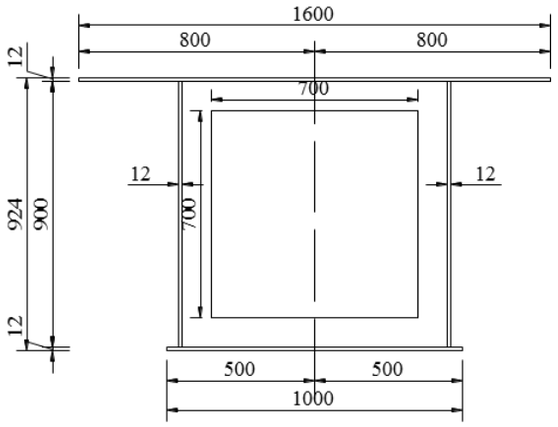
ABSTRACT: Steel structures have been generally exposed atmospheric corrosion environments such as humidity, temperature, airborne salt from the sea and chemical components in regional areas etc. to function as structural members of infrastructures. These atmospheric corrosion environments have naturally generate the corrosion problem of steel structures based on oxidational characteristics of structural steel materials. Therefore, it is important to measure the corrosion environment and condition for steel structure. In this study, thus, corrosion environment and condition were examined using atmospheric corrosion monitoring sensors, monitoring steel plate(MSP) and environmental data as temperature, humidity etc. Then compare corrosivity grade was calculated and compared to use basic data for proposing mean corrosion depth estimation method depending on structural members using monitoring data.

1. INTRODUCTION

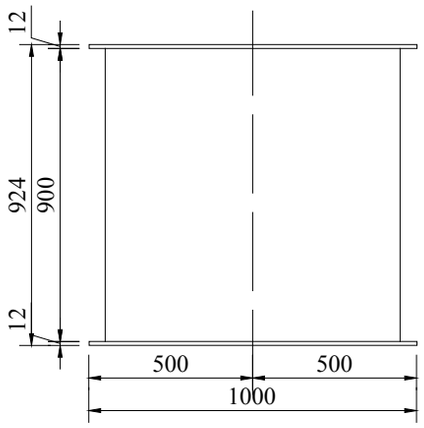
1.1 Research outline

In various infrastructures, steel members have been generally used as main structural element to resist or transmit the service load and forces. These steel structural members can be easily damaged and failure by corrosion and fatigue phenomena related to their maintenance process for their service periods. For fatigue problem of steel structure, many studies and reviews were reported and researched for its failure mechanism and related causes. For corrosion problem of steel structure, however related studies and researches have been limited up to now. Corrosion problem of steel structures could be related to environmental conditions as wet time, sedimentation of chloride etc. affected by installed and structural locations of steel structural members. Thus, different corrosion problems and rates can be occurred in the same structure. Therefore, it is useful to examine corrosion environment of steel structures depending on its installed environmental characteristics to estimate corrosion rate of steel structure. For steel bridges, however, it is difficult to examine the corrosion environment for each bridge member of steel bridges determined by structural shape using general corrosion test method, since its installed condition and structural condition. In this study, therefore, corrosion condition and environment of each structural direction were measured for test steel box structure similar to real steel box bridge from corrosion monitoring sensors and monitoring steel plate (MSP) to estimate corrosion rate instead of typical carrion tests.



1.2 Research objectives

In this study, corrosion condition and environment were examined depending on structural characteristics of steel box from corrosion monitoring sensors and monitoring steel plates. To examine corrosion environments, atmospheric corrosion monitoring sensors were used as corrosion environmental monitoring sensors (Shinohara. 2015). This sensor data will be used to compare the difference between structural direction in the same structure. And monitoring steel plate (MSP) was additionally installed to examine each corrosion conditions and its weight loss level and mean corrosion depth were measured according to installed environment of each monitoring steel plate (Kainuma at al. 2013, 2014). For monitoring steel plate (MSP), carbon steel and weathering steel were used to compare corrosion level and condition under same corrosion environment and structural characteristics, since corrosion rate can be main design factor in steel bridges. Additionally, temperature and humidity, precipitation were also compared to confirm the corrosivity grade. From these corrosion environment condition monitoring method and MSP monitoring, corrosion environment was examined depending on structural direction of steel box member.



2. TEST METHOD

2.1 Test specimen

To examine the corrosion environment effect depending on structural direction in same structure, steel box specimen was fabricated with 900mm height, 1,000mm width and 1,000mm length. To make the similar corrosive environment of steel box bridge, its upper flange of the steel box specimen was fabricated with 1,600mm. Figure 1 shows the dimensions of the steel box specimens used in this study. These steel box specimens were installed to south and north direction in the steel frame with 900mm height. Figure 2 shows the test steel box specimens, attached monitoring sensors and attached monitoring steel plates (MSP) in the exposure test.

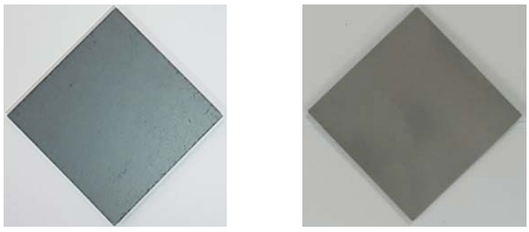
(b) Side view of test steel box

Figure 1. Dimension of exposed test steel box specimen.

(a) Test set up for atmospheric exposure test



(b) Front view of test set-up

Figure 2. Exposure test set-up.

2.2 Monitoring steel plate (MSP)

The monitoring steel plate (MSP) used in this study was manufactured with a height of 60mm, a width of 60mm, and a thickness of 3mm, and carbon steel(SM490A) and weathering steel(SM490AW) were used (KS D 3515. 2016; JIS G 3114. 2008). Before attaching the monitoring steel plate to the structure, SSPC SP 10 standard was applied and surface treatment was performed to remove foreign substances such as mill scale on the surface of steel and to form a uniform corrosion product. Figure 3 shows the monitoring steel plate before and after the surface treatment. Double-sided tape for industrial was used to install the monitoring steel plate in the bottom of the monitoring steel plate. In order to equalize the corrosion rate of the actual structure and the monitoring steel, a heat conduction sheet was also attached to the bottom of the steel.

(a) Before surface treatment (b) After surface treatment
Figure 3. Before and after surface treatment.

2.3 Atmospheric corrosion environment sensor

The atmospheric corrosion monitoring sensor with the characteristic of generating galvanic currents between dissimilar metals (Fe/Ag) was used. Figure 4 shows the mechanism of galvanic cell of the atmospheric corrosion monitoring sensor. As shown in Fig. 4, double metal layers were placed on the surface of the sensor, it measures the galvanic current between Fe and Ag when a water film is formed on the sensor surface. From measured corrosion current, the corrosion environment and thus the corrosion rate of the steel can be evaluated (Cheng et al 1997). Figure 5 shows the atmospheric corrosion monitoring sensor.

For raining atmospheric corrosion environment, the amount of electric charge output from the atmospheric corrosion monitoring sensor can be highly generated. For evaluating the corrosion rate of steel using atmospheric corrosion monitoring sensor, its highly generated electric charge output results should be considered. Thus, in order to obtain the correlation between the mean corrosion depth of the steel and the sensor output, it is necessary to convert the amount of electric charge measured by the atmospheric corrosion monitoring sensor in consideration of the influence of rainfall (Kainuma at al. 2010; Shinohara at al. 2005).

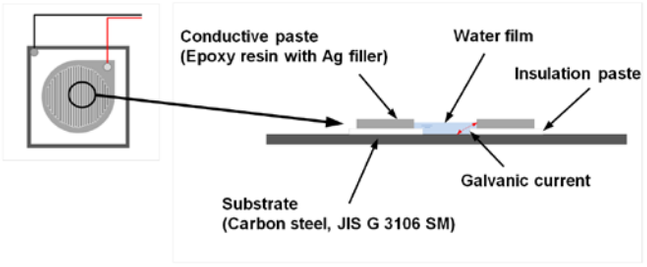


Figure 4. Mechanism of galvanic cell.

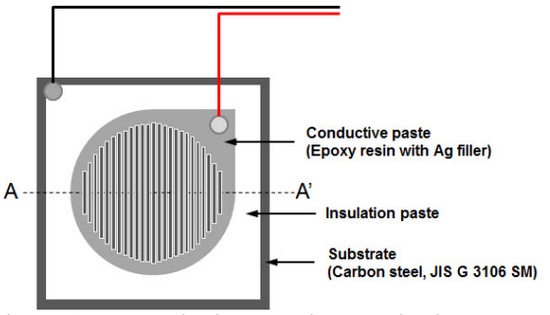

Figure 5. Atmospheric corrosion monitoring sensor schematic diagram.

2.4 Corrosivity grade

For general steel and alloy steel, corrosion grade is defined as following factors such as time of wetness (τ) by relative humidity, pollution by sulfur dioxide (SO_2) (P) and salinity of the atmosphere (S) in ISO 9223. For each corrosion factors, atmospheric corrosivity is defined as the ability to cause corrosion in a given corrosion system. Time of wetness is defined as time during which the steel surface is covered by the liquid film of the electrolyte and the absorbability. For pollution grade, it is also defined as calculated grades based on quantitative measurements of certain chemically active substances, corrosive gases or suspended particles in the atmosphere (both natural and artificial results) different from the normal components of the atmosphere. Wetness of steel surface is caused by various factors such as dew, rainfall, melting snow and high humidity. Thus, time of wetness is classified as Table 1 in ISO 9223 (ISO 9223. 2003).

Table 1. Classification of time of wetness (Tow) (ISO 9223. 2003).

Grade	Time of wetness (Tow)	
	h/a(hour/year)	%
$\tau 1$	$\tau \leq 10$	$\tau \leq 0.1$
$\tau 2$	$10 < \tau \leq 250$	$0.1 < \tau \leq 3$
$\tau 3$	$250 < \tau \leq 2{,}500$	$3 < \tau \leq 30$
$\tau 4$	$2{,}500 < \tau \leq 5{,}500$	$30 < \tau \leq 60$
$\tau 5$	$5{,}500 < \tau$	$60 < \tau$

The pollution grade assessed by sulfur dioxide and salinity in the atmosphere can be affected by atmospheric condition such as rural, urban, industrial and marine environments. In case of sulfur dioxide, its grade is divided into four classes (from P_0 to P_3) according to its deposition rate and concentration. The rate of SO_2 is P_d, and the concentration of SO_2 is represented by Pc. Table 2 shows the pollution classification by sulfur-containing substances. In case of salinity generated in the marine atmosphere, airborne salt developed from seawater evaporation can accelerate the corrosion of the nearby steel structure. Therefore, it is necessary to evaluate the atmospheric salinity. Table 3 shows the pollution clas-

sification by amount of salt under atmospheric (ISO 9223. 2003).

Table 2. Pollution classification by sulfur-containing substances (ISO 9223. 2003).

Attachment rate of SO_2	Concentration of SO_2 μg/m3	Grade
$P_d \leq 10$	$P_c \leq 12$	P_0
$10 < P_d \leq 35$	$12 < P_c \leq 40$	P_1
$35 < P_d \leq 80$	$40 < P_c \leq 90$	P_2
$80 < P_d \leq 200$	$90 < P_c \leq 250$	P_3

Table 3. Pollution classification by amount of salt under atmospheric (ISO 9223. 2003).

Attachment rate of Chloride mg/($m^2 \cdot$ d)	Grade
$S \leq 3$	S_0
$3 < S \leq 60$	S_1
$60 < S \leq 300$	S_2
$300 < S \leq 1{,}500$	S_3

The corrosivity grade of steel exposed to the atmospheric environment can be evaluated according to the ISO 9223. It is a method to estimate the corrosive grade by measuring its weight loss from corrosion and its thickness reduction. Table 4 shows the criteria for measuring and reducing the weight loss of the corrosion tested steel and the criteria for measuring the reduction in the thickness of the steel. It is classified as C1 ~ C5, with a very low corrosion rate for C1, a low corrosion rate for C2, a normal corrosion rate for C3, a high corrosion rate for C4, and a very high corrosion rate for C5.

Table 4. Corrosion rate for initial 1 year exposure (ISO 9223. 2003).

Corrosivity Grade	Corrosion rate of carbon steel(γ_{corr})
	Carbon steel
C1	$\gamma_{corr} \leq 10$ [g/(m2·a)] $\gamma_{corr} \leq 1.3$ [μm/a]
C2	$10 < \gamma_{corr} \leq 200$ [g/(m2·a)] $1.3 < \gamma_{corr} \leq 2.5$ [μm/a]
C3	$200 < \gamma_{corr} \leq 400$ [g/(m2·a)] $25 < \gamma_{corr} \leq 50$ [μm/a]
C4	$400 < \gamma_{corr} \leq 650$ [g/(m2·a)] $50 < \gamma_{corr} \leq 80$ [μm/a]
C5	$650 < \gamma_{corr} \leq 1{,}500$ [g/(m2·a)] $80 < \gamma_{corr} \leq 200$ [μm/a]

3. EXPOSURE TEST RESULTS

From atmospheric corrosion expose test of steel box structure, corrosion rate and corrosion condition of carbon steel and weathering steel were examined depending on structural direction as south and north of steel box structure. Atmospheric corrosion expose tests were conducted for six months. From atmospheric corrosion monitoring sensors and monitoring steel plate (MSP), corrosion environments and weight loss rate were measured and mean corrosion depth etc. were calculated. And also there results were explained related to corrosivity grade depending on structural direction of test steel box.

3.1 Visual inspection results

To evaluate corroded condition of each monitoring steel plate (MSP) installed on the structural direction of steel box. Firstly, visual inspection of each monitoring steel plate was conducted such as rust examination through surface color change. In this study, color of rust was examined by its installed direction and exposed test period, since several test specimens were attached depending on direction and location of test steel box. Figure 5 s hows tested monitoring steel plates. When comparing initial specimen and six months specimen, it can be confirmed that monitoring steel plate exposed to the atmospheric environment has corroded on the plate surface due to repetition of the wet state depending on each installed corrosion environment due to increase in the exposure test periods as shown in Figure 5.

From visual inspection for monitoring steel plates, the rust color of every monitoring steel plate gradually becomes yellowish brown depending on the increase in the exposure test periods. This color is similar to the color of α-FeOOH (Goethite) among the components of rust which determines rust. The characteristics of goethite are chemically stable among the rust formed from general atmospheric corrosion environment, it is inactive rust with low possibility of corrosion because it is difficult to dissolve oxidized Fe^{3+} ions due to low solubility. Thus, it is considered that this atmospheric corrosion environment is likely to form a relatively stable rust layer.

(b) North (Start)

(c) South (Six months)

(d) North (Six months)

Figure 5. Surface condition of test steel box and MSP.

3.2 Evaluation of corrosion rate of monitoring steel plate (MSP)

The measured values of the weight of the monitoring steel plate in the south direction and the north direction were obtained and the mean corrosion depth was calculated using the weight loss method. Figure 6 and 7 shows the weight loss and mean corrosion depth. From Fig. 7, the weight loss and mean corrosion depth of north direction is greater than those of south direction. And also, it shows that the different weight loss and mean corrosion depth depending on the steel type; carbon steel and weathering steel. In results was obtained from six months exposure tests, therefore it can be more clearly evaluated after long-term measurement.

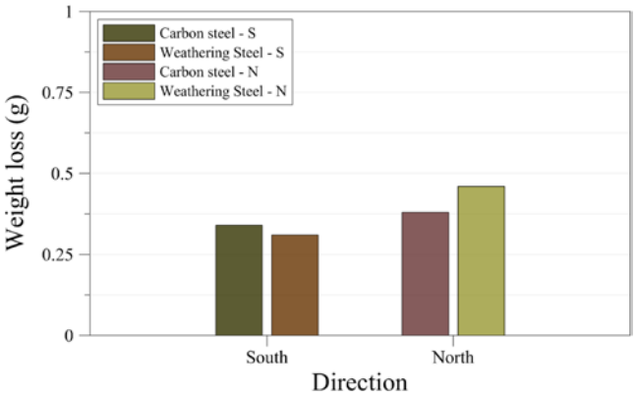

Figure 6. Weight loss – structural direction of the test period.

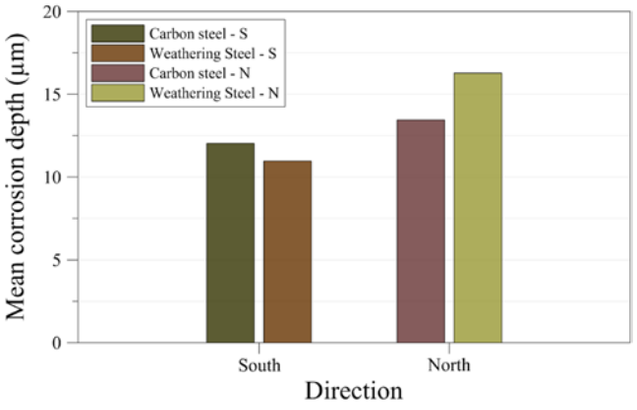

Figure 7. Mean corrosion depth – structural direction of the test period.

3.3 Assessment of corrosivity grade by weight loss method

According to ISO-9223 (Corrosion of metals and alloys - corrosivity of atmospheres - classification), from Fig. 6 and 7, corrosivity of atmospheres were evaluated as C2 in the south direction and C3 in the north direction. Table 5 summarized the annual corrosion rate conversion results and corrosivity grades for each tested direction.

Table 5. Result according to the ISO-9223 – corrosion of metals and alloys – corrosivity of atmospheres – classification

Steel	Mean corrosion depth (μm)	Annual corrosion rate g/(m2·a)	Annual corrosion rate (μm/a)
Carbon steel-S	12.03	188.89	24.06
Carbon steel-N	13.45	211.11	26.89

Corrosivity grade			
Carbon steel-S	C2	Carbon steel-N	C3
Weathering steel-S	C2	Weathering steel-N	C3

3.4 Corrosivity grade from test results

To identify atmospheric corrosion environmental grades based on atmospheric corrosion environmental data, temperature and humidity data of the exposed test region were taken from meteorological office for exposure test periods (17.01.12~17.07.12). Figure 8 and Table 6 summarized monthly mean temperature and humidity in the exposed test region. From these atmospheric corrosion environmental data, time of wetness (τ) was calculated as 22.50% for over 80% humidity with over 0℃ temperature. The concentration of sulfur dioxide (μg / m3) and the deposition rate of chloride (mdd) were obtained from "Air Korea" internet site which provides information on the atmospheric environment. (http://www.airkorea.or.kr/index). Table 7 summarized the classified corrosion grade and corrosivity grade of the atmosphere for this exposed condition due to time of wetness and pollution according to ISO-9223. As shown in Table 7, this atmospheric corrosive grade was evaluated as C2 or C3 from combining the classified grades and this result is similar to those of atmospheric corrosivity calculated using the weight loss method.

3.5 Evaluation of corrosion environment through atmospheric corrosion monitoring sensor

The atmospheric corrosion monitoring sensors were attached to the south and north direction of the web along the monitoring steel plates in the steel box specimens. Figure 9 shows the measured corrosion current. Table 8 summarized the measured atmospheric corrosion monitoring sensor data. As shown in Figure 9, the amount of electric charge was gradually increased depending on exposure test period. For installed direction, the amount of electric charge in the north direction was higher than that of the south direction. Figure 10, shows the difference in the amount of electric charge in the south and

north direction of the web. From these results, it can be considered that corrosion environment is different and affected depending on s tructural direction of steel box.

4. CONCLUSION

This study dealt with relative corrosion condition and environment of each structural direction for a steel box structure using corrosion monitoring sensors and monitoring steel plates (MSP). For this purpose, the daily mean current achieved from atmosphere corrosion sensor affected by corrosion environment was measured. And weight loss and mean corrosion depth of MSP were calculated according to installed environment of each structural direction. Additionally, corrosivity grade of tested region was evaluated using environmental data. Thus, these results were compared to estimate corrosion condition and corrosion environment. For this test region and structural direction was evaluated as C2 or C3 corrosivity grade. It can be confirm the corrosion condition is different depending on structural member and direction. This result can be explained from atmosphere corrosion sensor data. This comparison and measured data can be used to propose mean corrosion depth estimation method depending on structural members or direction etc. from correlation between rate of corrosion and amount of the daily average electricity in the future.

ABSTRACT: This present a series of bridge condition assessment methods using innovative nondestructive testing tech-niques (i.e. microwave interferometry radar IBIS-S and 3D optical measurement system ARAMIS). Using a timber bridge in Australia as a case study (i.e. Eltham Rail Trestle Bridge), it demonstrates that IBIS-S can ef-fectively capture the dynamic behaviour of the bridge under train loading, such as natural frequencies, maxi-mum vertical and horizontal displacements, while ARAMIS optical measurement system has the capability for accurately measuring the deformation of the critical members of the bridge.

.

1 INTRODUCTION

There are around 29,000 timber bridges in Australia with most over fifty years old (Samali, Li, Dackermann, & Choi, 2011). Some are still being used to carry heavy traffic loads (e.g., train loading). Consequently, ageing bridges and the induced dynamic effects caused by the passage of trains could accelerate the structural deterioration of the bridges, ultimately the reduced service life of the bridges (Moreu et al., 2015; Terry Wipf, Ritter, & Wood, 2000). Thus, the development of innovative methods for condition monitoring of bridges becomes critical important.

1.1 *Monitor the dynamic behaviour of the bridges*

Traditional measuring devices for dynamic behaviour of bridges (e.g., accelerometer) may be limited the bridge accessibility, time and budgets (Gentile, 2010). Other monitoring devices i.e. laser sensor, also have limitation in detecting the overall deformation of a bridge and are very sensitive to enviromental conditions (Pieraccini et al., 2007). When full-field monitoring real-time dynamic behaviour of bridges is required, the recent advanced IBIS-S radar interferometry technique provides a solution.

A typical IBIS-S system primarily consists of three parts: a sensor module, a user control PC and a power supply unit. The sensor module consists of two horn antennas and is supported by a rotating head tripod, sends and receives the electromagnetic waves. The data acquisition and interpretation are handled by a laptop which is connected to the sensors (IDS, 2013).

The IBIS-S radar sensor is designed for remote monitoring of structural vibrations from a distance up to 1km with high accuracy. Vibration frequencies can be measured as high as 100 Hz. In operational condition, the radar is suitable for measuring displacement of a structure with accuracy better than 0.1mm, a range resolution of 0.5m and a sampling rate up to 200Hz.

The performance of IBIS-S radar sensor technology is founded on the combined use of the interferometry technique and the stepped-frequency continuous wave technique (SF-CW). While SF-CW detects the positions of different target points in the range direction, the interferometry technique provides the displacement of each target point by analysing the back-scattered electromagnetic waves reflected by the targets at different time points. Detail of these techniques can be found in (Kafle et al., 2017; Maizuar, Zhang, Miramini, Mendis, & Thompson, 2017; Zhang, Maizuar, Mendis, Duffield, & Thompson, 2016). It should be noted that IBIS-S technique enables a measurement of the line-of-sight displacement or the radial displacement of structures. Once the radial displacement has been obtained, the actual displacement of the measured points can be easily calculated by applying a simple geometric projection.

1.2 *Monitor the deformation profile of the bridge members*

The deformation of bridge structural members (e.g., column) has conventionally been measured using strain gauges. However, the use of these devices generally consists of localized measurements since only at preselected points information and in one direction could be obtained (Schmidt, Tyson, & Galanulis, 2003). Further, the quality of measurement essentially depends on the contact surface of a structure and its accuracy could be greatly affected by changing environmental conditions (Motra, Hildebrand, & Dimmig-Osburg, 2014). When a full-field non-contact deformation measurement profile is required, the non-contact 3D optical measurement (e.g., ARAMIS) system has the capability of capturing the time-dependent deformation profile of critical bridge members. This technique allows unique non-contact measurements of 3D deformations and analyzes the displacement and strain fields through 3D digital image correlation methods (DIC). It is robust technique which enables large data capturing and accurate model validation (Miramini, Zhang, Richardson, Mendis, & Ebeling, 2016; Zhang et al., 2017).

The ARAMIS system consists of a pair of digital CCD cameras (1280 x 1024 pixels) with a 3D resolution of around 3.0μm, specimen lightings, laser pointer, tripod, data acquisition box and a laptop PC installed with commercial ARAMIS software package. While the digital CCD cameras capture the images of an object from different angles when the object is subject to external loading, the time-dependent deformation of the object is obtained through image processing using ARAMIS post-processing software (GOM, 2017).

2 CASE STUDY

The IBIS-S and ARAMIS described in the Sections 1.1 and 1.2 were implemented to monitor the structural performance of Melbourne's only wooden Eltham Rail Trestle Bridge in Australia. The Eltham bridge is one of few timber heritage bridges in Australia that are still providing train service for Melbourne's metropolitan electric railway network. This timber bridge was built in 1902 with a length of approximately 200m and is possibly the longest curved wooden bridge for commuter railway in the southern hemisphere (VHD, 2005).

The IBIS-S radar sensors were configured to a horizontal distance of 5.2m and a height (h) of 3m with a distance resolution of 0.75m and a sampling frequency of 100Hz (Figure 1). Simultaneously, the deformation of a timber column of the bridge was measured using ARAMIS system, the selected column areas for deformation analysis were approximately 1.5m above ground level with measurement area was set to be 100×75mm, and camera lens were located 810mm from measurement surface (Figure 2).

Figure 1. Monitoring dynamic behaviour of bridge using IBIS-S

Figure 2. Monitoring deformation of timber column using ARAMIS

3 RESULTS AND DISCUSSION

3.1 *Dynamic behaviour of the bridge captured by IBIS-S*

The quality of the electromagnetic signals captured by IBIS-S can be obtained from the range profile of the test scenario as shown in Figure 3. P2 indicates the target measurement point while P1 and P3 are the neighbourhood of the target point. It can be seen that peaks with a good electromagnetic reflectivity (*i.e.,* SNR over 50dB) can be used as measurement points.

Figure 4 shows the vertical displacement time history of the bridge girder resulting from a passing

train. The results show that the observed maximum vertical displacement was around 10mm.

As shown in Figure 5 the natural frequency is identified using the displacement spectrum data analysis in frequency domain by a peak point at 4.6 Hz. This result is consistent with other previous studies (T Wipf, Wood, Phares, Ritter, & Bigelow, 2004). It also indicates that the bridge is in good condition.

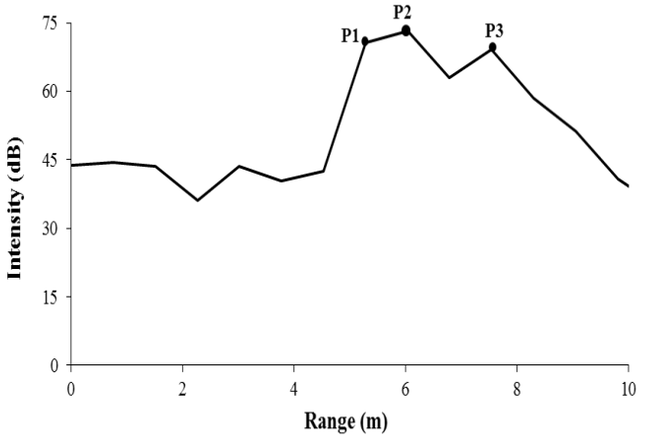

Figure 3. Range profile of the bridge

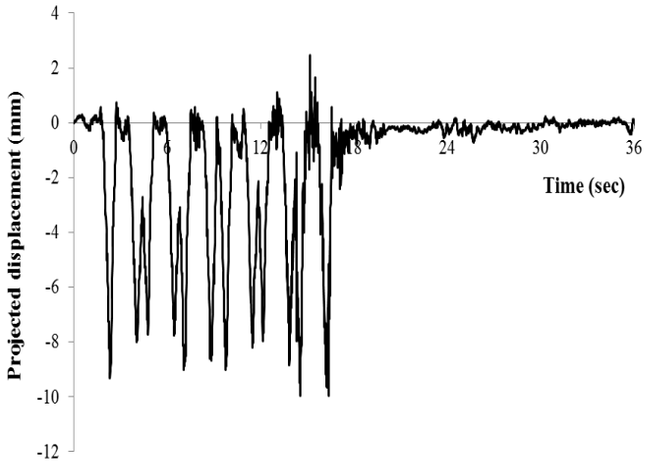

Figure 4. Displacement time history of a bridge girder

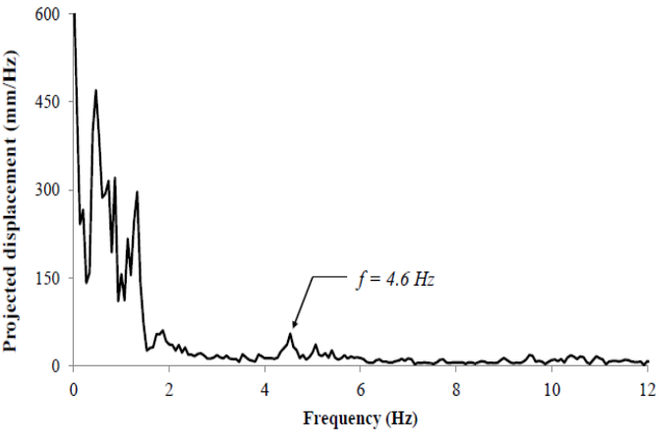

Figure 5. Natural frequency of the bridge

3.2 *Deformation of bridge member captured by ARAMIS*

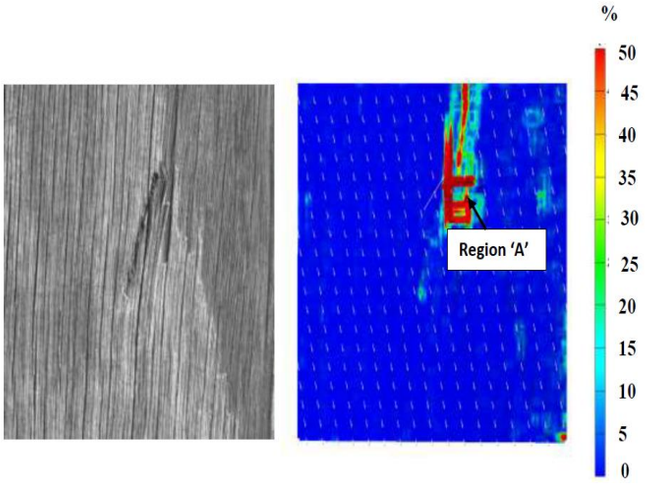

Figure 6. Surface of a timber column and von Mises strain distribution in region 'A'

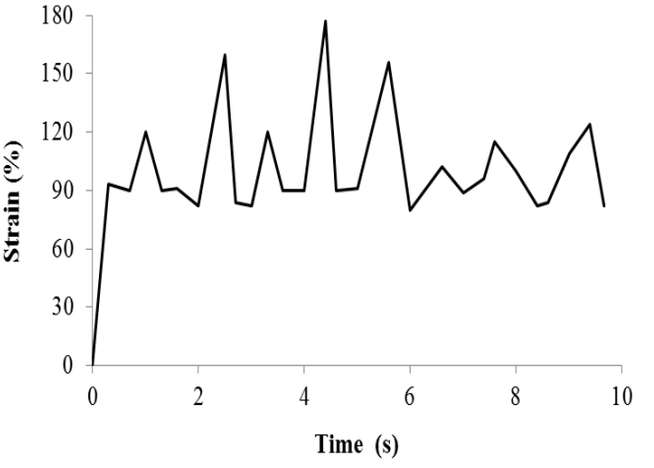

Figure 7. Time-dependent Von Mises strain in region 'A'

The von Mises strain distribution and the image of the column surface with a region of defect 'A' are illustrated in Figure 6. The results show that, under train loading, the strain in most area of column surface is relatively small (around 5%), and there is a strain concentration in the region of defect (i.e. region 'A'). It also demonstrates that, under a passing train, the maximum strain and vertical displacement in the defect region of the column surface (region 'A') could reach larger than 177% (Figure 7) and 0.7mm (Figure 8), respectively. The results also show that ARAMIS has the capability in capturing the column surface strain with a region of defect demonstrating its potential use for bridge structural health monitoring and assessment.

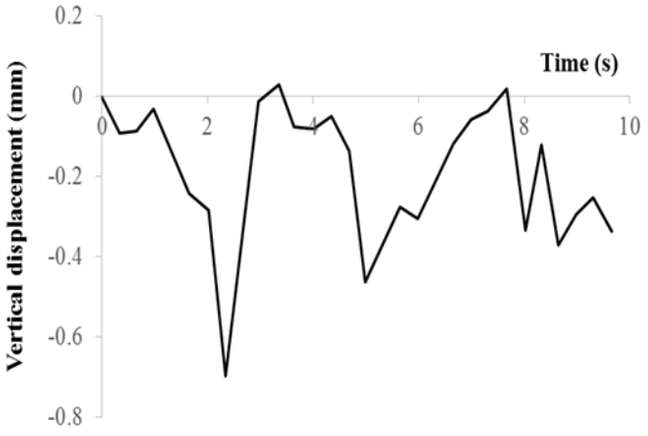

Figure 8. Time dependent vertical displacement in region 'A'

4 CONCLUSION

A structural monitoring of timber bridges under train loading using the recent advanced non-destructive testing (NDT) involving interferometric radar IBIS-S and ARAMIS optical measurement system was performed. The results of the study demonstrate that IBIS-S can effectively capture the dynamic behaviour of the bridge under train loading such as its natural frequency, maximum vertical and horizontal displacements. In addition, it shows that the 3D ARAMIS optical measurement system has the capability for assessing the structural performance of the critical members of the bridge (e.g., column) caused by a passing train, particularly in the region with surface defect.

Fatigue life assessment of damaged steel strands

Y.C. Park
Institute of Construction and Environmental Engineering, Seoul National University, Seoul, Republic of Korea

S.M. Yoo, C.Y. Kim & M.S. Park
Myongji University, Yong-in-si, Gyung-gi-do, Republic of Korea

ABSTRACT: Fatigue assessment was conducted for damaged strands collected from corroded tendons to evaluate their structural safety and serviceability. Fatigue test was conducted for the nominal stress range of 190 MPa and maximum nominal stress of 1100 MPa. All corroded strand specimens could not satisfy two million stress cycles recommended by Eurocode. Five specimens were tested under 70 MPa stress range which was known to be actual stress range in tendons under live load. Except one specimen, all of them were fractured and had fatigue lives lower than seven million stress cycles. On the other hand, the specimen without defect did not developed fatigue crack. It was observed that remaining fatigue life of corroded strand does not have any correlation with the size of corroded section. The lowest fatigue life was found from the least corroded strand.

1 INTRODUCTION

One of the external tendon of a pre-stressed concrete box girder bridge in Seoul, Korea was failed in 2016 (Figure 1). It was the first tendon failure in Korean history. As per in-depth investigation of the failure, it was found that corrosion of steel strands in the tendon was the major reason of the failure. Accordingly, other tendons were also inspected. Many tendons in the same section where the failure was found were also corroded. The reasons of the corrosion were investigated and those were:

1) Air vents were located underneath the bridge deck and those were not properly sealed or damaged. From the opened air vents, water with high level of chloride infiltrated. Abnormally higher moisture and chloride contents were found from the grout under the air vents.

2) Transverse and longitudinal gradients of the bridge deck was very low at the failure location which were almost close to zero degree. The low gradients caused drainage problem and could accelerated corrosion.

3) Large void was found at the saddle of the tendons, which were located underneath the damaged air vents.

4) Although the bridge was inspected regularly, only visual inspection was conducted. Any deterioration inside of the tendon could not be inspected by visual inspection.

Figure 1. Photograph of the failed external tendon.

Once the preliminary inspection was completed, all the external tendons in the bridge were inspected and many corroded tendons were found. As a result, serviceability of the corroded tendon was concerned and the fatigue tests for the corroded tendons were conducted.

2 EXPERIMENTAL STUDIES

2.1 *Description of fatigue tests*

Corroded strand specimens for fatigue testing was obtained from the tendon which had been in service. After the in-depth investigation was completed,

owner of the bridge decided to replace corroded tendons. Twelve strands having 1 m length were collected from the replaced tendons. Corroded strands with various section loss were collected. (Figure 2). Configuration of the corrosion was various such as pitting corrosion and wide surface corrosion. In order to prevent breaking wire in the wedge or the boundary of the wedge, it was intended to place corroded part at the center of the specimen.

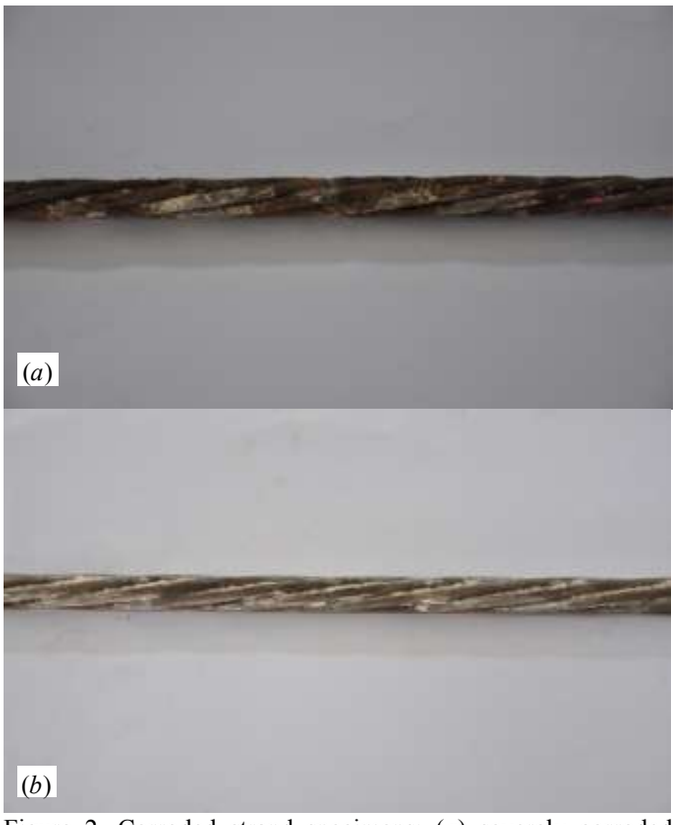

Figure 2. Corroded strand specimens: (*a*) severely corroded strands; and (*b*) less corroded strands.

Fatigue test were conducted at the multi-direction testing facility in the Hybrid Structural Testing Center (HYSTEC) in Myongji University, Korea. Two grips were fabricated to hold the wedges and connect to the foundation block and actuator, respectively. The loads were applied using 50 tone hydraulic actuator as shown in Figure 3.

Fatigue test was conducted under constant amplitude sinusoidal loading. The test was load controlled and load and displacement were recorded.

As per Eurocode (1994), post-tensioning strands should achieve two million stress cycles under nominal maximum stress of 0.7 GUTS (guaranteed ultimate tensile strength) and nominal stress range of 190 MPa, which are equivalent to respectively 1300 MPa and 190 MPa for the strands having GUTS of 1860 MPa. The nominal stress range of 190 MPa is much higher than the actual stress range in tendons develops by heavy trucks (Lee 2015). However, the maximum stress range was set to 1100 MPa, because the first specimen was broken at the corroded section while it was loaded to the maximum stress. Loading frequency was varied between 10 to 14 Hz depending on the responses from the specimens. Testing was continued until at least one wire fail due to fatigue crack (ASTM 2016).

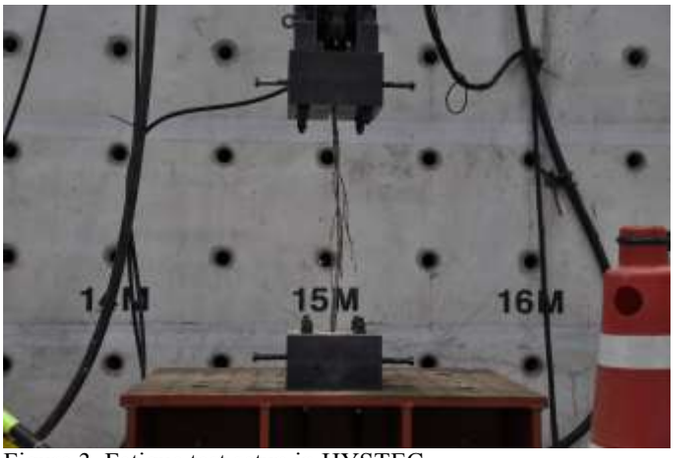

Figure 3. Fatigue test setup in HYSTEC.

2.2 *Fatigue test results*

Three specimens were failed while the specimens were loaded to the maximum stress range. Thus, only nine specimens were valid for fatigue testing. One specimen developed fatigue crack inside of the wedge, so that the results of the specimen was excluded from the test results. The wires in some specimens were broken multiple times during testing. Initial wire fracture was verified by the record of displacement and number of cycles. As it is shown in Figure 4, sudden drop in displacement was recorded when a wire was fractured. In this case, fatigue life of the specimen was determined at the time of the drop.

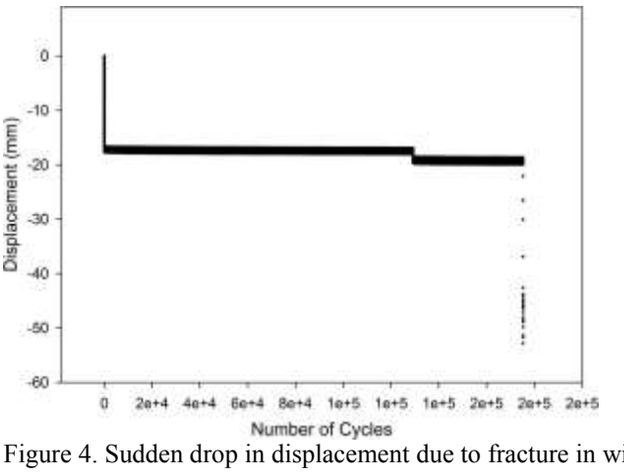

Figure 4. Sudden drop in displacement due to fracture in wires.

After the test was completed, fracture surfaces of the specimens were carefully observed. It was found that all specimens developed fatigue cracking at the corroded section. None of the center wire was frac-

tured and only outer wires developed fatigue cracks. Fatigue lives of the corroded strands were ranged between 0.13 to 0.52 million cycles, which could not achieve the requirement of two million cycles at the stress range of 190 MPa.

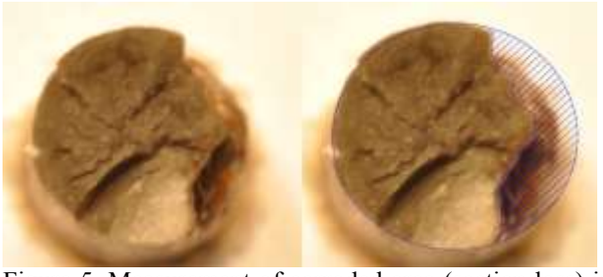

Figure 5. Measurement of corroded area (section loss) in fractured surface.

Section losses in wires were measured from the fracture surfaces. The wires which did not develop fatigue crack were cut at the section where fatigue crack was found. Sections of each wire were photographed to measure corroded area in the fractured section using AutoCAD. The section loss was defined by the ratio of corroded area and non-corroded area of strand. Section loss of fatigue tested specimens were in range of 7.7% and 33.2%. For the specimens which fracture during static loading, section loss was 39.6% or higher. Photograph of fractured section demonstrates section loss due to corrosion, fatigue crack surface and tensile fracture surface (Figure 5). Gray shiny surface presents fatigue crack surface. On the other hand, dark rough and wrinkled surface presents tensile fracture surface, which is generally shown from the tensile fractured surface of high strength steel. Fatigue crack initiated from the bottom side of the corroded surface and propagated towards left. None of the specimens developed fatigue cracking initiated from non-corroded surface.

3 DISCUSSION OF TEST RESULTS

The S-N plot of the fatigue test results are presented in Figure 6, along with the fatigue design curves from the *AASHTO LRFD Bridge Design Specification*s (AASHTO 2012) and design curve suggested by Paulson et al. (1983). The fatigue test results are plotted against nominal stress, which was computed based on non-corroded section of a strand.

Fatigue life of corroded strands distributed between AASHTO Fatigue Category B and D, which was much lower than target fatigue life of two million cycles. The fatigue lives are also lower than Paulson et al.'s design curve. Therefore, corroded strand could cause fatigue problem during service.

Fatigue test results always demonstrate spread due to inconsistent distribution of micro-discontinuities, residual stress or notch severity. However, the spread in the test results is larger than other connection details. It may be because applied stresses of each strand at the cracked section were diverse due to difference in remaining section. Variability in the configuration of corroded surface could also develop different stress concentration, which may change stress condition.

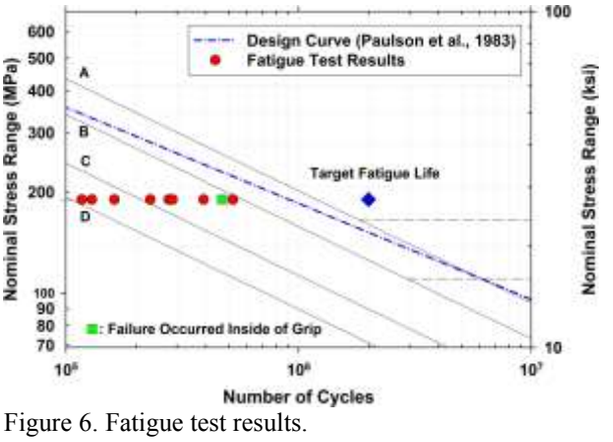

Figure 6. Fatigue test results.

To verify influence of section loss in fatigue performance, fatigue test results are plotted with respect to section loss in Figure 7. Comparison shows that specimens having larger section loss demonstrate less fatigue life, but distinct trend is not shown. Minimum and maximum fatigue lives exhibited by the specimens having section loss of 13.1% and 7.7%, respectively. Range of section loss of the specimens having fatigue lives less than 0.2 million cycles was from 13.1% to 33.2%. Therefore, little section loss could make large difference in fatigue life. It may be concluded that strands having large section loss definitely exhibit low fatigue life, whereas little section loss could exhibit low fatigue life as well.

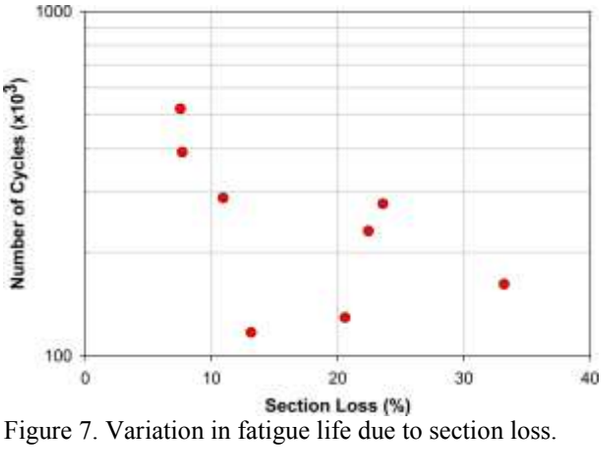

Figure 7. Variation in fatigue life due to section loss.

4 CONCLUSTIONS

The fatigue test results demonstrated that corroded strands exhibit low fatigue life and could not satisfy required fatigue resistance of two million stress cycles recommended by Eurocode. Irrespective to the section loss due to corrosion, fatigue life could significantly less once strand was corroded.

Dynamic analysis of scissors-type of deployable pedestrian bridge under earthquake

Y. Chikahiro, S. Zenzai & S. Shigeru
Shinshu University, Nagano, Japan

I. Ario
Hiroshima University, Higahi-Hiroshima, Japan

ABSTRACT

In recent years, the world has seen several types of natural disasters that have caused many critical situations in the lives of people by damage of an infrastructure. It is important to rebuild the damaged traffic routes immediately in such serious situations in order to facilitate quick relief and restoration activities.

This paper presents a dynamic analysis of new type of emergency bridge, called Mobile Bridge, which can be quickly constructed in case of damage after a natural disaster. The concept of the bridge is based on the application of a scissors mechanism, which enables its rapid deployment. During the deployment phase, the bridge is supported only at one end resulting in cantilever boundary conditions. Once deployed, the bridge has two supports hence the deployed, second condition is the simply supported beam case, where the supports have horizontal and vertical displacement constraint. After finishing construction, the pedestrian bridge is set on the upper decks aligned at the line of top hinges. Up to now, the authors have constructed several types of the experimental Mobile Bridges for pedestrian and vehicle loading. In the case of deployable structures as well as the static analysis of different configurations of expansion, it is important to investigate dynamic behavior of the system. The high compliance and flexibility of the scissors-type bridge may influence the comfort and safety of users in case of heavy dynamic loads such as human induced impacts, wind gusts, or earthquakes.

The presented research deals with fundamental numerical results to clear dynamics of the Mobile Bridge based on the experimental pedestrian bridge. From the point of using the Mobile Bridge in disaster area, it is needed to clear dynamic behavior. Therefore numerical simulation included both eigenvalue and seismic response analysis with model validation. From these results, it was possible to estimate basic mechanical characteristics of dynamic properties of the bridge. The conducted research allows for better and safer design of the structure of the Mobile Bridge.

A Dynamic System Identification of the Ha'penny Footbridge

ABSTRACT: The Ha'penny Footbridge is a historic cast iron structure in Dublin City Centre and a well-known Irish landmark. The main objective of this research was to establish a comprehensive picture of the dynamic behaviour of the bridge. This information and the associated model could then be used in future structural health monitoring (SHM) and damage detection, with the aim to aid in the structure's preservation and prolong its serviceability. The methodology of this study began with the creation of a preliminary finite element (FE) model using the computational software MATLAB (The MathWorks Inc). This model was designed to assess the free-vibrational response of the structure in three dimensions from first principles, including its natural frequencies and mode shapes. The modes obtained from this preliminary analysis were then used to assist an operational modal analysis (OMA), carried out using strain gauges fitted to the structure. The results of this analysis were used in order to update and calibrate the FE model. The result of this research and experimentation was an accurate representation of the bridge within acceptable limits. The FE model developed using MATLAB was found to have improved accuracy when compared to a previous model created using a FE software package in 2001. The calculated damping ratios of the structure were found to be low and so the installation of a permanent SHM system was recommended. In addition, it was recommended that the structure be fitted with an increased number of strain gauges to allow for strain measurements to be gathered in multiple directions.

1 INTRODUCTION

1.1 *Introduction*

The continuous development of high-performance building materials has led to an increasingly common trend towards the design of lighter and more flexible bridge structures. This is especially true in the design of pedestrian bridges, which are typically more slender due to lower loading requirements and typically shorter spans. With this low stiffness and mass comes reduced natural frequencies and hence, a higher probability of resonant vibrations during service. Excessive vibrations can lead to serviceability failure, in that the bridge may be rendered unsuitable for use by the public, or in ultimate failure due to fatigue and related damage. A lack of understanding of the modal identity of pedestrian structures can result in serious consequences, as was seen in the excessive movement of the London Millennium Footbridge shortly after it's opening in 2000 (Dallard et al., 2001). This widely-publicised failure incited an increased interest in the study of lateral excitations and responses, where previous research had primarily been focused on vertical movement.

The need for a comprehensive understanding of dynamic behaviour is not only applicable to modern designs, but also to historic structures. This is especially true in the case of bridges, where increasing populations and associated changes in loading patterns are altering the operational excitation. Previous examples of dynamic investigations into historic structures can be found in Gentile and Gallino (2008) and Gentile and Saisi (2013). From these, it is clear that knowledge of the dynamic systems of these structures is essential to their preservation. From this literature, as well as studies carried out in Altunişik et al. (2011), Bayraktar et al. (2009), Barton et al. (2011) and Hu et al. (2012), it can be seen that the dynamic system identification (DSI) and establishment of SHM systems in structures may be powerful tools. These tools, often used in conjunction with FE models, can allow for the identification of areas of weakness and developing damage within the structure. Over time, this may lead to improved efficiency in the repair of the structure in question and may ultimately prevent collapse.

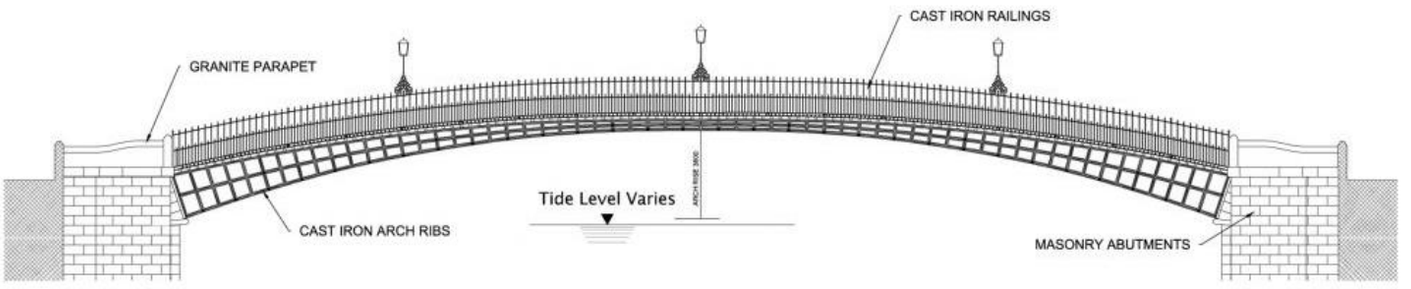

Figure 1. Side elevation of the Ha'penny Bridge (Dublin City Council, 2017a)

1.2 *The Ha'penny Bridge: History and Background*

The Ha'penny Bridge (officially known as the Liffey Bridge) is a landmark structure spanning the Liffey River and is one of the defining features of Dublin, Ireland. The footbridge was erected in 1816, currently making it over 200 years old. It is a cast iron bridge which was originally built as an alternative to a ferry which connected the North and South sides of the city. Its name is derived from the half-penny (ha'penny) toll which was required in order to cross. The bridge was designed by John Windsor with iron cast in the Coalbrookdale Foundry in England (Dublin City Council, 2017a). At the time of its opening, the bridge catered to a city of a much smaller size and had just 450 pedestrians crossing the bridge daily. In recent times, this has increased to an estimated average of 30,000 per day (Dublin City Council, 2017b). This exemplifies the level to of change in the amount and pattern of loading that the bridge has experienced within its lifetime.

The bridge has the form of an elliptical arch which spans 42.8m with a width of 3.6m. The arch has a 3.35m rise above high water at the centre-span. It was constructed in 6 individual sections, each separated by a cast iron diaphragm plate. The main arch structure of the bridge consists of three longitudinal ribs of cruciform section, one at each side of the bridge's width and one running along the centre-width. The ribs consist of three longitudinal chords with vertical members at intervals, creating a grid-like pattern. The three ribs are connected by a series of transverse and bracing members. The transverse members of the arch consist of cast iron tubes that contain tension rods which are believed to be of wrought iron. Figure 1 shows the geometry of the structure in elevation.

In the late 1990's, Dublin City Council (DCC) commissioned a complete renovation of the bridge from Mott MacDonald Consulting Engineers. This included a structural assessment, the renewal of existing bridge members and the replacement of certain members which were deemed beyond repair. In addition, the timber decking of the original design was replaced with stiffened steel and covered with an epoxy coating. Although there was some replacement of structural members, 98% of the original cast iron was re-used. The results of the structural investigation were published in (Mott McDonald Consulting Engineers, 2001) and the bridge was re-opened in December 2001.

The aforementioned structural investigation of the footbridge comprised of a theoretical dynamic analysis but did not include any experimental analysis to support it. This was also carried out before the completion of the renovation and so only considered the bridge structure as it existed previously. Additionally, there were a number of assumptions made about the geometry of the structure which may not necessarily hold true. For example, it was assumed that the bridge is completely straight in plan and is fully symmetrical about its longitudinal axis and its mid-span. These assumptions may be more likely in the event of a modern footbridge, however the age of the structure and the technology at the time of construction must be considered. Hence it was decided that these assumptions may not readily be made. It is also worth noting that the previous model took into account vertical displacements only, disregarding the fact that the bridge is free to move in three dimensions. The negative consequences of such assumptions were seen in events such as the excessive lateral movement of the London Millennium Bridge (Dallard et al., 2001) under pedestrian loading, as previously referenced. Overall, the consideration that this previous model may not be entirely reliable is one which must be explored.

2 METHODOLOGY

The methods used in this study consisted of the development of a preliminary FE model in MATLAB, followed by the use of this model's results to determine the optimum sensor locations on the bridge. The bridge was then instrumented before testing of the bridge response under ambient loading. The resulting response signals were processed and interpreted and finally the modal responses were used to calibrate and update the original MATLAB model.

2.1 *Finite Element Model*

The Ha'penny Bridge structure is a relatively complex arch structure, typical of cast iron bridges of its time. The structure consists of a large number of members oriented in the lateral, longitudinal, vertical and diagonal directions. Given the level of interactivity between members and the individual impact of each member on the stiffness properties of the bridge, it would be considered a vast oversimplification to model the structure as a single degree of freedom system. As the objective of this research was to provide an accurate representation of the bridge, it was necessary to discretise the structure into a multi-degree of freedom (MDOF) system allowing for free movement in three dimensions.

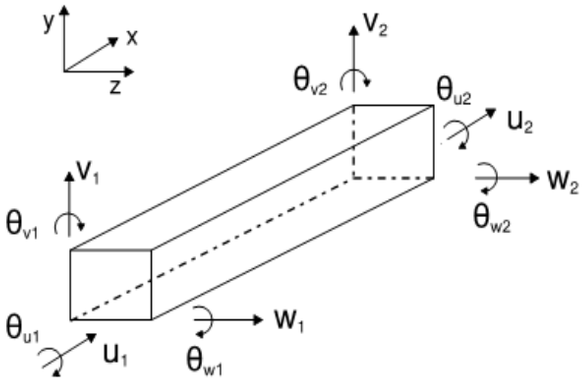

Figure 2. DOF of a space frame element

Keeping this in mind, the elements chosen for use in the model were space frame elements. Space frame elements may be considered as a combination of truss and beam elements which are capable of resisting forces in both the axial direction and directions perpendicular to the longitudinal axis of the bar (Quek and Liu, 2003). They are two-noded elements with six DOF at each node, three translational in the x, y and z directions, and three rotational about the x, y and z axes (Fig. 2). Hence each individual element has a total of twelve DOF before the introduction of boundary conditions. In this FE model, a single space frame element was used to represent each member of the structure.

The MATLAB program represented the structure as a MDOF system in free vibration. This was done using the equation of motion as shown in Equation 1 where *M*, *C* and *K* are the mass, damping and stiffness matrices of the system, *u* is the displacement and *F(t)* is a force vector at time *t*.

$$M\ddot{u} + C\dot{u} + Ku = F(t) \tag{1}$$

Assuming free vibration, it was possible to set the damping and applied forces to zero, giving Equation 2. Harmonic motion was then assumed giving Equation 3, where $q_n(t)$ is a vector of the modal coordinates for mode *n* at a time *t* and is a function of the natural circular frequency ω_n, and φ_n is the deflected shape. Hence Equations 2-3 can be simplified into Equation 4 which is known as the Characteristic Equation of the system and is a conventional eigenvalue problem.

$$M\ddot{u} + Ku = 0 \tag{2}$$

$$u(t) = q_n(t)\phi_n \tag{3}$$

$$(K - \omega_n^2 M)\phi_n = 0 \tag{4}$$

Solving this problem returns a set of eigenvalues, which are representative of the squares of the natural circular frequencies, and a set of eigenvectors which represent the mode shapes of the structure.

2.2 *Experimental Methods*

The chosen form of experimentation for this research was testing under ambient vibration. In this case, the ambient loading experienced by the bridge was predominantly due to pedestrian traffic. It was acknowledged that this form of loading would be the least disruptive to the general public and would also minimise the risk of damage to the structure. In addition, testing the bridge under operational conditions requires a lower amount of specialized equipment than in the case of free or forced vibration testing.

The chosen instrumentation for this operational modal analysis (OMA) was strain gauges. There are a number of reasons why these gauges were chosen. Firstly, the aesthetics of the bridge had to be considered. Given that this historic bridge is one which is frequently visited by tourists, the fitting of more bulky instruments such as accelerometers may be considered an eyesore. Strain gauges, on the other hand, are much smaller and more discrete instruments. The chosen gauges were FLA-5-11 gauges from TML. An additional consideration is the difference in cost between these gauges and other forms of instrumentation. They are a much cheaper alternative to accelerometers and require no calibration.

2.3 *Bridge Instrumentation and Testing*

The FE model was a necessary tool in determining appropriate locations for the strain gauges. A preliminary analysis of the structure using the FE model returned the mode shapes as shown in Figure 3. From these, it can be seen that the maximum displacement in modes 1 and 2 are at mid span, and for 3 and 4 are at the quarter spans. Hence instrumenting these areas would provide the most effective results.

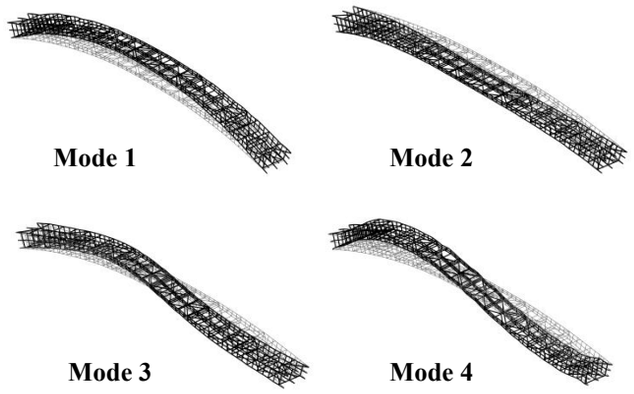

Figure 3. Mode shapes 1-4 from the preliminary MATLAB model – lighter colour indicates original shape

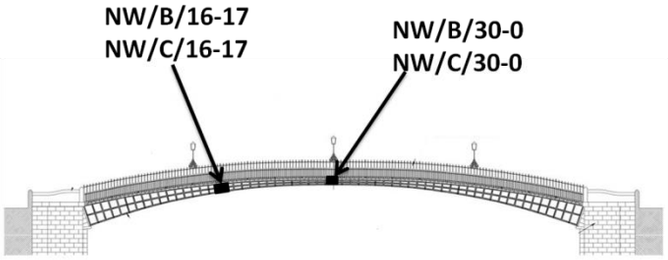

Figure 4. Western elevation of the footbridge with arrows indicating strain gauge locations (two gauges at each location). Modified from (Dublin City Council, 2017a)

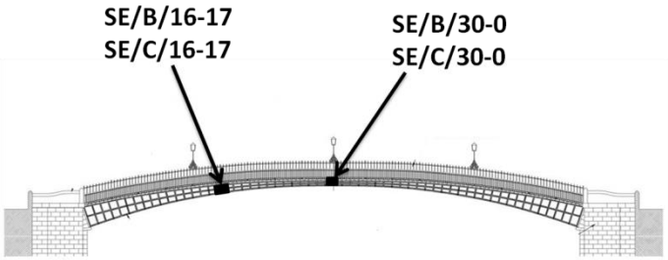

Figure 5. Eastern elevation of the footbridge with arrows indicating strain gauge locations (two gauges at each location). Modified from (Dublin City Council, 2017a)

The gauges were attached to the bridge at the Northern quarter span on the Western elevation, the Southern quarter span on the Eastern elevation, and at mid-span on both elevations. There were 8 sensors in total. They were oriented along the longitudinal axis and were attached to the bottom and middle chord members of the longitudinal arch ribs (Figs. 4-5).

The bridge was instrumented on the 14th March 2017. The gauges were attached to the top surface of the members. They were weatherproofed using buthyl rubber tape and sprayed with white paint to make them more aesthetically discrete. Testing occurred on the 27th March 2017. The test was carried out using a Vishay MicroMeasurements data logger with StrainSmart logging software (Micro Measurements). The loading applied to the structure consisted of the free and random movement of pedestrians over the bridge under normal conditions. The readings were taken over a 15 minute (900s) period at a sampling rate of 100Hz, resulting in a total of 900,000 test samples.

3 RESULTS

The resulting raw signals from the operational testing were obtained and recorded. Each sensor was named in accordance to a coordinate-based naming system developed for the purpose of this study. No data was read for the sensor SE/C/30-0 due to wiring issues during testing. However it was assumed that this member, which was the bottom chord member at mid-span on the Eastern elevation, had similar behavior to the middle chord member in the same area. This assumption was made based on the behavioural similarities seen between the middle and bottom chord sensors in all other locations.

Although the sensors were roughly zeroed before the recording of data, it was noticed that certain signals had their mean above or below zero. Also, evidence of noise and zero drift could clearly be seen in the raw signals. Thus it was necessary to apply a post-processing algorithm in order to reduce distortion and error caused by these issues. A Fast Fourier Transform (FFT) was also included in this algorithm and implemented in order to convert the signals from the time domain to the frequency domain. This process is summarized in the flow chart in Figure 6.

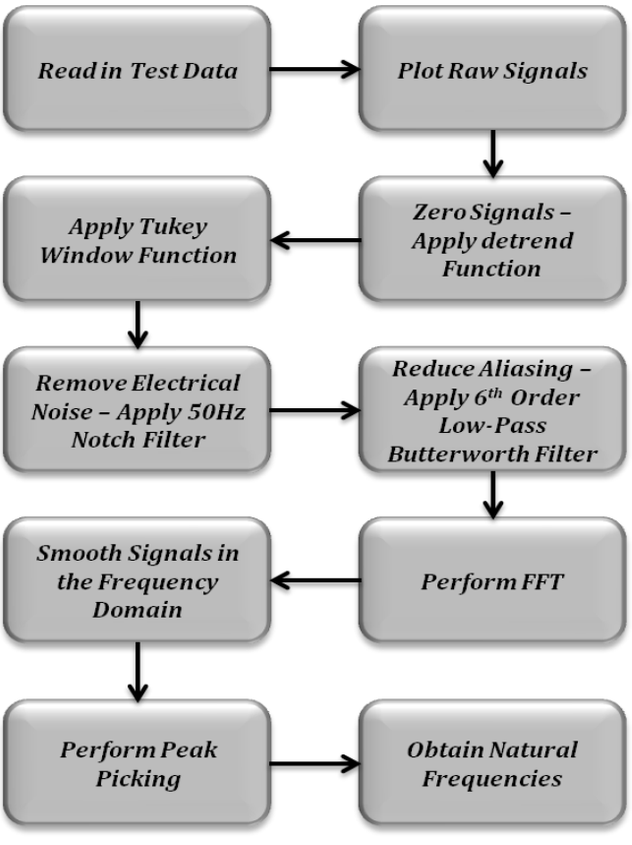

Figure 6. Post-processing procedure adopted for the raw input data signals

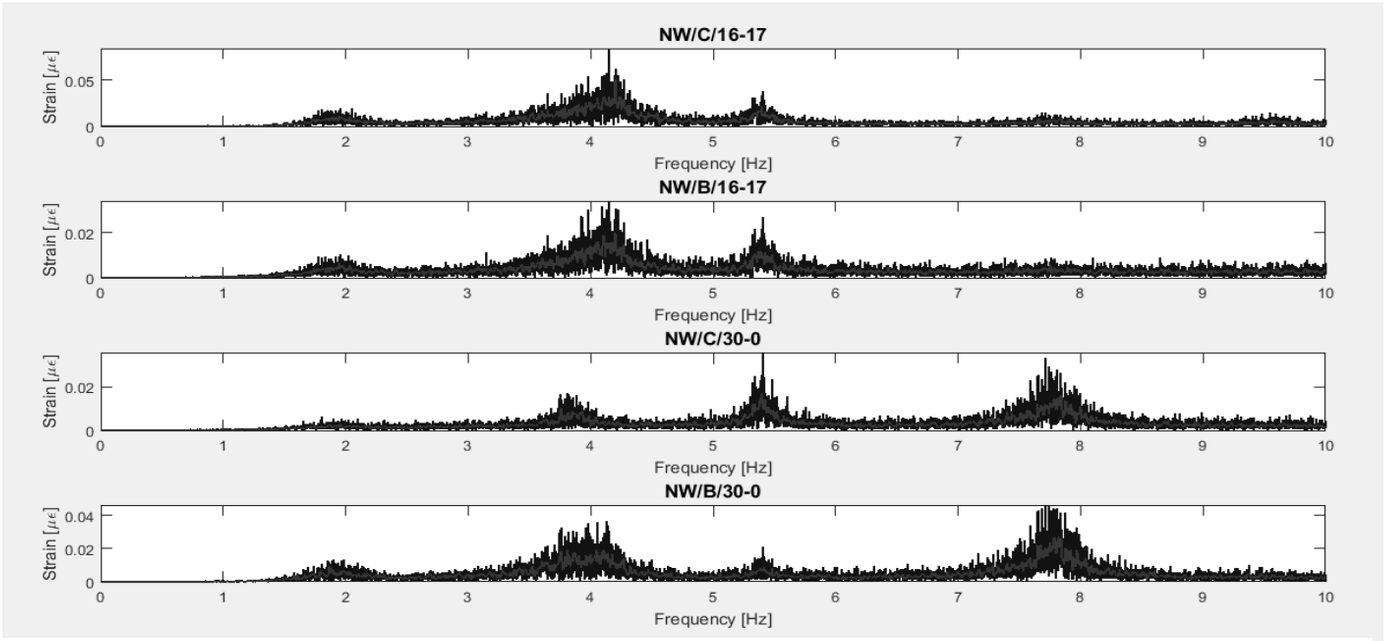

Figure 7. Frequency spectra from sensors on the North Western side of the bridge

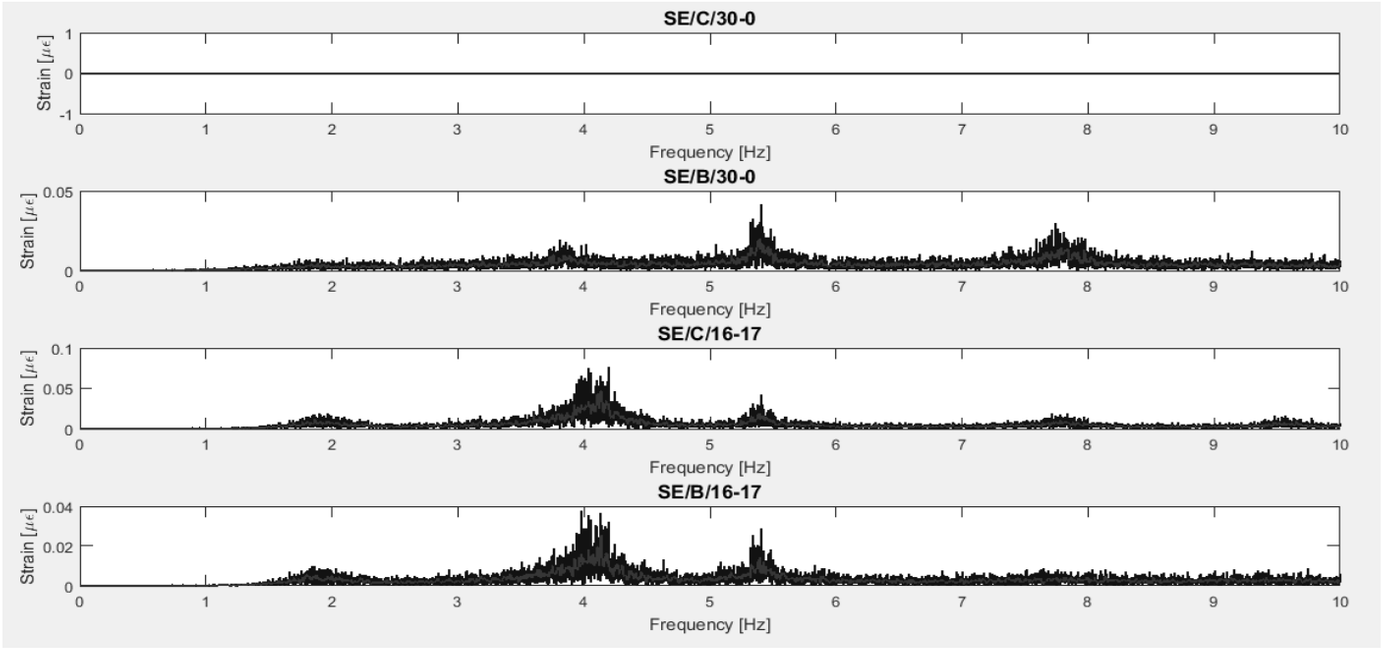

Figure 8. Frequency spectra from sensors on the South Eastern side of the bridge

Table 1. Comparison of experimental and MATLAB model frequencies

Mode	Experimental (Hz)	MATLAB (Hz)	Error (Hz)	Error (%)
1	1.92	4.5916	2.67	139.15
2	4.11	5.8503	1.74	42.34
3	5.41	8.5428	3.13	57.91
4	7.78	9.2503	1.47	18.90
		Average:	2.25	64.57

The values in Table 1 show quite a large discrepancy between the experimental frequencies and the frequencies obtained from the preliminary MATLAB model. The percentage error of 64.57% is high and must be reduced in the model calibration stage.

The damping ratios (ξ) of the bridge were calculated using the Half-Power Bandwidth method as shown in Equations 5-6. The results are shown in Table 2 (Donnelly, 2017).

$$D = \frac{D_{max}}{\sqrt{2}} \tag{5}$$

$$\xi = \frac{f_2 - f_1}{f_2 + f_1} \tag{6}$$

where D_{max} is the amplitude of the signal at a peak point (i.e. at a natural frequency of the signal) and $f_{1,2}$ are the frequencies at which a horizontal

line from the *D* value on the Y-axis would cross the peak.

Table 2. Damping ratios calculated from experimental data

Sensor No.	Damping Ratio Mode 1 (%)	Damping Ratio Mode 2 (%)	Damping Ratio Mode 3 (%)	Damping Ratio Mode 4 (%)
NW/C/16-17	0.23	0.17	0.03	-
NW/B/16-17	0.19	0.21	0.02	-
SE/C/16-17	0.21	0.13	0.05	-
SE/B/16-17	0.27	0.11	0.03	0.07
NW/C/30-0	-	0.22	0.04	0.02
NW/B/30-0	0.24	0.19	0.03	0.05
SE/C/30-0	N/A	N/A	N/A	N/A
SE/B/30-0	-	0.13	0.03	0.06
Average:	0.23%	0.17%	0.03%	0.05%

Damping ratios could not be calculated for some of the sensors as these modes did not appear in the frequency spectra of these gauges. This is possibly due to proximity to local minima. These damping ratios are very low and may be cause for concern regarding the health of the bridge. Typical damping ratios for metal footbridges sit at around 0.4% (Bachmann, 1995). Lower damping ratios imply that the structure will take longer to return to its undeformed state after vibration. This means that the bridge members are more susceptible to fatigue and related damage.

4 MODEL UPDATING

The results of the OMA as shown in the previous section imply that the natural frequencies of the MATLAB model need to be reduced significantly in order to represent the bridge structure more accurately. Basic knowledge of dynamic theory dictates that natural frequency is inversely proportional to mass and directly proportional to stiffness. Therefore, a reduction in natural frequency would come about through a decrease in stiffness and/or an increased structural mass. As there was a high level of uncertainty initially regarding the material properties of the cast iron used in the bridge, the Young's modulus (E) and the density (ρ) of the iron were considered the most significant sources of uncertainty in the model. Additional uncertainty lay in the definition of boundary conditions at connections. It was also considered that the original decision to neglect the non-structural members was a simplification that could lead to inaccuracy.

The original estimation for the E value of the material was 90GPa with an estimated ρ value of 7200 kg/m^3. The boundaries at connections were considered perfectly rigid in all restricted directions and the influence of non-structural elements (e.g. lights, railings, decking) was ignored. Thus, the calibration of the model involved the adaptation of the material and boundary parameters and the consideration of non-structural elements. The decided method for the consideration of the mass of the non-structural elements was through the introduction of an equivalent density. This density was calculated based on mass

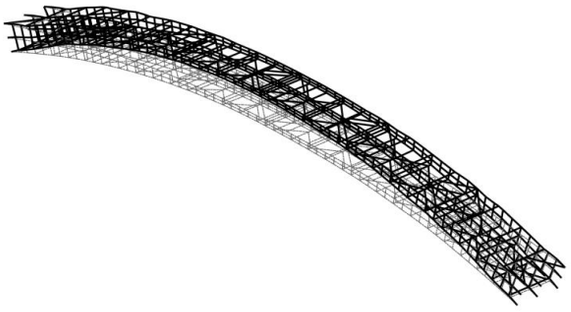

Figure 9. Mode Shape 1 - calibrated MATLAB model

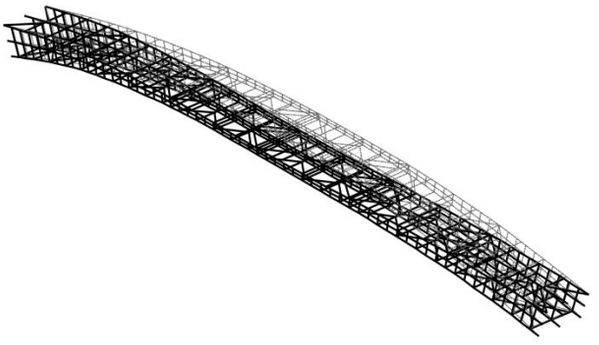

Figure 10. Mode Shape 2 - calibrated MATLAB model

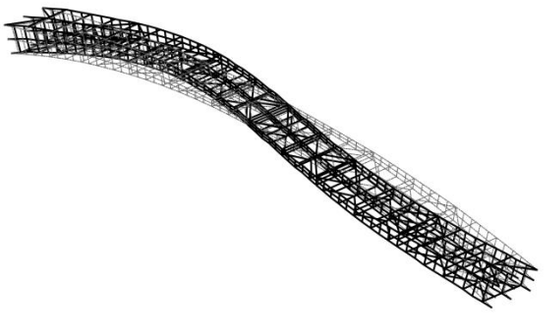

Figure 11. Mode Shape 3 - calibrated MATLAB model

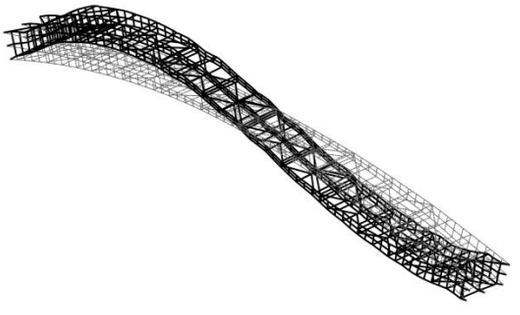

Figure 12. Mode Shape 4 - calibrated MATLAB model

estimations and was applied over each element in the model. Firstly, the total mass of the structural elements (m_{NS}) was roughly calculated using elevations and sections obtained from Dublin City Council. The total volume (v_S) and mass (m_S) of the structural elements was then calculated from the model and all of these parameters were combined in Equation 7 to find the equivalent density of the structure (ρ_{eq}).

$$\rho_{eq} = \frac{m_{NS}+m_S}{v_S} \quad (7)$$

Using information about the railings and deck geometries obtained in Mott McDonald Consulting Engineers (2001) and Dublin City Council (2017a), an estimated non-structural mass of $17x10^3$ kg was obtained (Donnelly, 2017). The total weight and volume of the structural members were found to be $44.4x10^3$ kg and $6m^3$, respectively, assuming a maximum cast iron density of 7400 kg/m^3 (Angus, 2013). This resulted in an equivalent density of 10,500 kg/m^3 to be applied to all structural members in the model. The E modulus was obtained with a criterion of minimum averaged error between the obtained and the observed frequencies of the first 4 vibration modes, resulting in 83 GPa, an appropriate reduction within the range stated in Angus (2013). Finally, previously-defined boundaries which were considered to be perfectly rigid pins were allowed some rotation to account for loosened bolts or connections which are not perfectly flush. Results from the updated model are shown in Figures 9-12 and Table 3 (Donnelly, 2017).

Table 3. Comparison of experimental (Exp.), updated model and 2001 model frequencies

Mode	Exp. (Hz)	MATLAB (Hz)	Error (Hz)	Error (%)	2001 Model (Hz)	Error (%)
1	1.92	3.64	1.72	89.58	3.194	66.35
2	4.11	4.64	0.53	12.90	3.385	-17.64
3	5.41	6.76	1.35	24.95	3.629	-32.92
4	7.78	7.33	-0.45	-5.78	-	-
		Average:	1.01	33.30		38.97

It can be seen in Table 3 that the average percentage error between the experimental and MATLAB frequencies was reduced from 64.57% to just 33.3%. The average total error was reduced from 2.25Hz to just 1.01Hz. The previous dynamic model of the bridge carried out in 2001 (Mott McDonald Consulting Engineers, 2001) had an average percentage error of approximately 38.97%. Thus it is clear that the updated MATLAB model is more accurate.

Another point worth noting is the difference in interval sizes between the modes in the MATLAB model and the 2001 model. The 2001 model shows very closely spaced modes of vibration, however the MATLAB model contains very distinct and separate modes. In this respect, it could be argued that the calibrated MATLAB model is significantly more accurate than the 2001 model, given that the results of experimentation on the bridge also show distinctly spaced modes of vibration.

5 CONCLUSION

5.1 *Conclusions*

The conclusions of this research may be summarised as in the bullet points below:

- The FE model developed in MATLAB was proven to be effective at estimating the natural frequencies of the Ha'penny Bridge structure within a reasonable error range.
- The updating of the FE model led to a decrease in the percentage error from 64.57% to 33.3% and a decrease in the average total error from 2.25Hz to 1.01Hz.
- The most significant error in the preliminary MATLAB model was in the first mode, where the actual value was 1.92 Hz. This unusually low frequency value could suggest damage in the bridge structure. Alternatively, this frequency could represent the frequency of the walking load as described in Bachmann (1995). This will be investigated through further study.
- The updated FE model was proven to have a lower average error than the previous model developed in 2001.
- The updated FE model was shown to better represent the frequency intervals between modes than the 2001 model.
- The use of strain gauges was found to be effective in obtaining the natural frequencies of the bridge.
- The evaluation of the mode shapes from the experimental data was considered inconclusive due to a high amount of uncertainty caused by the strain gauge placement along a single axis.
- The damping ratios of the structure were found to be very low and were significantly below average for a metal footbridge.

As outlined in the above points, the calibrated MATLAB model was shown to represent the dynamic bridge system in a more accurate way than the 2001 model. Knowledge of the correct modal frequencies, shapes and damping ratios, in conjunction with an accurate bridge model, can be essential in prolonging the service life of footbridges such as this one.

The previous model was created using a software package in an industry setting. The use of analysis software such as in this case is common within industry due to time constraints and practicality issues. However, the outcome of this study should serve as a warning as regards the level of accuracy of the results returned. This is especially true in the modeling of historic bridges, where often there was no consideration of dynamics during the structure's design stage. Therefore, it is common that recent models have no older point of comparison. Additionally, historic structures often have a high level of uncertainty associated with their material properties due to less accurate testing procedures and quality control issues at the time of construction, as well as due to degradation of materials over time. This leaves models at risk of significant errors unless calibrated against experimental data.

5.2 *Future Recommendations*

It is strongly suggested that further study should be carried out into the dynamic system of the Ha'penny Bridge in the future. In this future research, it is recommended that an increased amount of instrumentation be fitted to the bridge. This will allow for a fuller picture of the bridge's dynamic response to be obtained. If possible, it would be ideal to orient gauges along the three axes of the bridge (longitudinal, vertical and transverse), possibly through the use of rosette strain gauges. This would allow for the principal stresses in members to be calculated, as well as removing the ambiguity regarding mode shapes that was apparent in this study. The ability to confirm the mode shapes of the structure may serve to further validate the MATLAB model.

From a long-term perspective, it is recommended that a permanent SHM system is fitted to the bridge. The low damping ratios calculated in this study imply that the bridge has a lower capacity to prevent excessive oscillation than it should have. In addition, the significantly low frequency for the first mode could signify damage. The severity of these issues is heightened due to the age of the bridge and the brittle nature of cast iron. Further monitoring of the bridge may give more insight into practical damping measures which may be implemented in order to preserve the structure and maintain its serviceability for years to come. In addition, initial signs of failure or damage may be detected more quickly and effectively, allowing for repair and maintenance.

ACKNOWLEDGEMENT

This study was supported by Dublin City Council and the Department of Civil, Structural and Environmental Engineering in Trinity College Dublin.

Parameter identification of a biodynamic walking model for human-structure interaction

A. Firus & J. Schneider & H. Berthold & M. Albinger

Institute of Sport Science
Technische Universität Darmstadt, Darmstadt, Germany

ABSTRACT: To account for the human-structure interaction during walking on flexible structures, a pedestrian is typically represented by an equivalent single degree of freedom (SDOF) system moving over the structure at a constant speed together with an external force. The latter corresponds to the force exerted by a pedestrian when walking on a rigid structure while the SDOF system is responsible for modifying the force at the contact point in order to account for the human-structure-interaction (HSI). This contribution presents a novel method for experimental identification of the SDOF parameters (stiffness and damping), which is based on a combined analysis of biomechanical and structural measurements. All the investigations were performed on an experimental pedestrian bridge, which was instrumented with biomechanical force plates, a 3D motion capture system as well as several sensors for the acquisition of the structural responses. Since both structural and biomechanical responses were recorded simultaneously, an accurate comparison between the measurements and the results of the structural analysis is allowed.

1 INTRODUCTION

The human-structure interaction (HSI) effect usually occurs in case of walking on lightweight and slender structures, which are prone to an excessive level of vibration. However, the interaction is usually neglected by common methods for the numerical analysis of pedestrian induced vibrations, which typically consider the walking pedestrian as a time dependent load moving over the structure at a constant speed (Fig.1a). In many cases this simplified approach leads to an overestimation of the structural responses (Caprani and Ahmadi 2016, Živanović 2015, Van Nimmen et al. 2017). In order to improve the accuracy of structural simulations, several coupled human-structure systems were developed in the last decades. They represent the human body as a mechanical model with equivalent dynamic parameters, i.e. mass, stiffness and damping. The complexity of the models varies from a simplified representation of the pedestrian by its moving mass (Fig. 1b) towards more realistic assumptions such as a single degree of freedom (SDOF) system (Fig. 1c) or even bipedal energy based spring-mass-dampers systems (Qin et al. 2013, Fig. 1d). An extensive overview over different approaches for prediction of structural responses with consideration of the HSI is given by Shahabpoor et al. (2016).

One of the main issues of the common HSI models is represented by the lack of systematic experimental validation of the dynamic model parameters for pedestrians walking on flexible structures, which are likely to differ from the parameters determined during walking on a rigid surface (Živanović 2015). Silva and Pimentel (2011) and Toso et al. (2016) performed experimental studies on identification of stiffness and damping for an equivalent SDOF system of a walking pedestrian. These studies are based on the correlation between the acceleration of the human body at the waist level and the ground reaction forces (GRF) recorded during periodic activities. However, the GRF considered there are taken from literature or measured using force plates installed on a rigid structure.

This contribution proposes a novel method for the identification of human body dynamic parameters, which considers pedestrian locomotion on a flexible structure. The investigations were performed on an experimental pedestrian bridge instrumented with biomechanical force plates, a 3D motion capture system as well as several sensors for the acquisition of the structural responses. The synchronous measurement

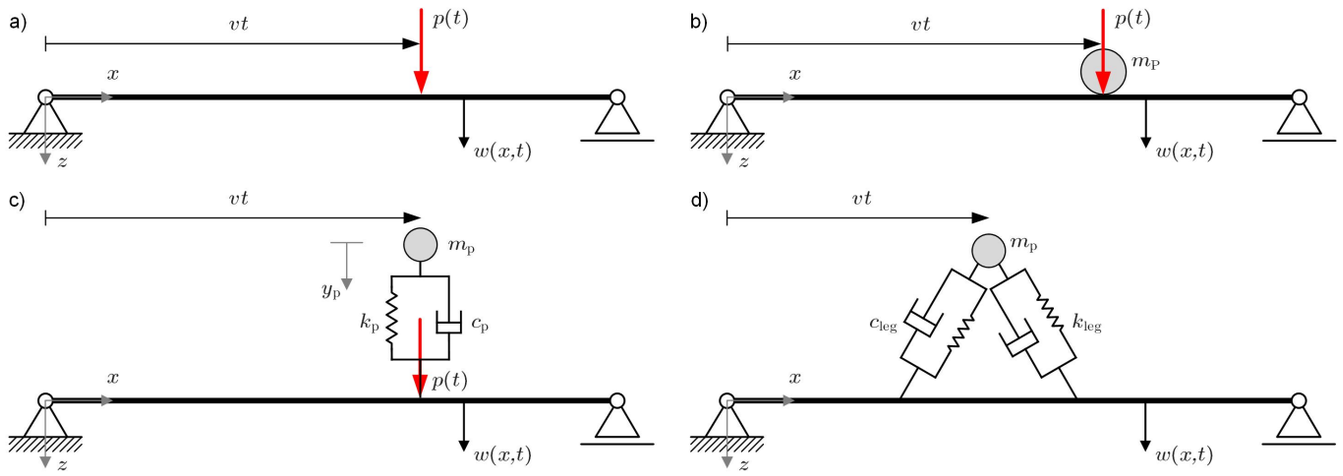

Figure 1: Mechanical models for prediction of pedestrian induced vibrations: a) moving force; b) moving mass; c) single degree of freedom system (SDOF); d) bipedal model

of both structural and biomechanical responses also allows an accurate comparison between the measurements and the structural analysis.

2 FORMULATION OF THE PROBLEM

2.1 *Background*

The vertical ground reaction force of a pedestrian walking on a rigid surface can be determined by means of the second Newton's law of motion as a sum of the inertial forces of all body segments (Racic et al. 2009):

$$p_{\mathrm{b}}(t) = \sum_{i=1}^{n_{\mathrm{s}}} m_i \cdot (\ddot{y}_{\mathrm{b},i}(t) + \mathrm{g}) \tag{1}$$

m_i denotes the mass and $\ddot{y}_{\mathrm{b},i}$ the acceleration (relative to the rigid surface) of the centre of mass (COM) of the i-th out of n_{s} body segments while the gravitational acceleration is depicted by the term g.

The contact force exerted by a pedestrian walking on a rigid floor is equal to the ground reaction force $p_{\mathrm{b}}(t)$ and is thus solely dependent on the body weight and step frequency of the pedestrian. In contrast to this, the contact force $p_{\mathrm{p}}(t)$ induced by a walking pedestrian in an oscillating structure is additionally affected by the interaction effects between the pedestrian and the structure. It can be expressed as a sum of the ground reaction force induced on the rigid ground $p_{\mathrm{b}}(t)$ and an interaction force term $p_{\mathrm{h}}(t)$, according to Equation 2:

$$p_{\mathrm{p}}(t) = p_{\mathrm{b}}(t) + p_{\mathrm{h}}(t) \tag{2}$$

It is to be mentioned that Equation 2 is valid only under the assumption that the walking behaviour of the pedestrian is not affected by vibrations of the underlying structure. In case of the walking on rigid structures it is assumed that $p_{\mathrm{h}}(t) = 0$, which leads to $p_{\mathrm{p}}(t) = p_{\mathrm{b}}(t)$.

Considering a human body consisting of n_{s} body segments, Equation 2 yields (Van Nimmen et al. 2016):

$$p_{\mathrm{p}}(t) = \underbrace{\sum_{i=1}^{n_{\mathrm{s}}} m_i \cdot (\ddot{y}_{\mathrm{b},i}(t) + \mathrm{g})}_{p_{\mathrm{b}}(t)} + \underbrace{\sum_{i=1}^{n_{\mathrm{s}}} m_i \cdot \ddot{y}_{\mathrm{h},i}(t)}_{p_{\mathrm{h}}(t)} \tag{3}$$

where

$$\ddot{y}_{\mathrm{h},i}(t) = \ddot{y}_{\mathrm{p},i}(t) - \ddot{y}_{\mathrm{b},i}(t) \tag{4}$$

describes the additional COM acceleration of the i-th body segment which occurs due to the interaction between the pedestrian and the structure, whereas $\ddot{y}_{\mathrm{p},i}(t)$ represents the total acceleration of the i-th body segment when walking on a flexible structure. Furthermore, the corresponding (interaction) COM displacement of the i-th body segment relative to the contact point on the flexible structure is defined as:

$$y_{\mathrm{rel},i}(t) = y_{\mathrm{h},i}(t) - w(t) \tag{5}$$

where $w(t)$ depicts the displacement of the structure at the contact point.

The numerical approach considered in this investigation describes the pedestrian by a SDOF model (Fig. 1c) system which crosses the structure together with an external force induced at the contact point between the SDOF system and the structure. The external force corresponds to the ground reaction force induced by a pedestrian while walking on a rigid structure ($p_{\mathrm{b}}(t)$ in Equation 2), while the SDOF system serves for modifying the force $p_{\mathrm{p}}(t)$ at the contact point in order to account for the HSI. This effect occurs due to the spring and damping forces generated by the relative movement between the mass m_{p} and the contact point, which are comprised by the term $p_{\mathrm{h}}(t)$ in Equation 2. As the SDOF comprises the whole body mass at a single point m_{p}, corresponding to the COM of the body, Equation 3 reads:

$$p_{\mathrm{p}}(t) = p_{\mathrm{b}}(t) + m_{\mathrm{p}} \cdot \ddot{y}_{\mathrm{h}}(t) \tag{6}$$

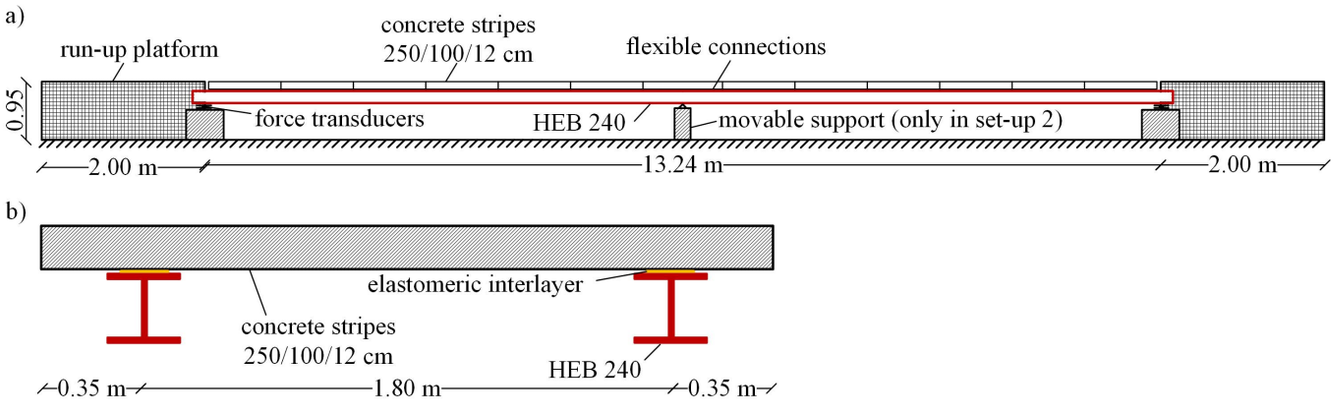

Figure 2: Experimental pedestrian bridge: a) side view; b) cross section

Expressing the equilibrium of the SDOF, Equation 6 can be written as:

$$p_{\mathrm{p}}(t) = p_{\mathrm{b}}(t) - k_{\mathrm{p}} \cdot y_{\mathrm{rel}}(t) - c_{\mathrm{p}} \cdot \dot{y}_{\mathrm{rel}}(t) \tag{7}$$

k_{p} and c_{p} represent the stiffness and the damping of the SDOF system. Their experimental identification is discussed in the following sections.

2.2 *Methodology*

In order to identify the unknown parameters k_{p} and c_{p} in Equation 7, the difference between the contact force of a pedestrian walking on a rigid structure and the corresponding contact force on a flexible structure is expressed as:

$$\Delta p(t) = p_{\mathrm{b}}(t) - p_{\mathrm{p}}(t) \tag{8}$$

$\Delta p(t)$ is considered to occur due to the interaction effects between the subject and the structure. Introducing Equation 8 in Equation 7, the following expression is obtained:

$$\Delta p(t) = k_{\mathrm{p}} \cdot y_{\mathrm{rel}}(t) + c_{\mathrm{p}} \cdot \dot{y}_{\mathrm{rel}}(t) \tag{9}$$

By time discretisation of Equation 9, the following Equation system is formulated (Lipfert et al. 2012):

$$\begin{bmatrix} \Delta p(t_1) \\ \Delta p(t_2) \\ \vdots \\ \Delta p(t_n) \end{bmatrix} = \begin{bmatrix} y_{\mathrm{rel}}(t_1) & \dot{y}_{\mathrm{rel}}(t_1) \\ y_{\mathrm{rel}}(t_2) & \dot{y}_{\mathrm{rel}}(t_2) \\ \vdots & \vdots \\ y_{\mathrm{rel}}(t_n) & \dot{y}_{\mathrm{rel}}(t_n) \end{bmatrix} \cdot \begin{bmatrix} k_{\mathrm{p}} \\ c_{\mathrm{p}} \end{bmatrix} \tag{10}$$

It can be solved using the unconstrained least-squares method in order to identify the unknown vector $[k_{\mathrm{p}} \quad c_{\mathrm{p}}]^{\mathrm{T}}$. However, $\Delta p(t_i)$, $y_{\mathrm{rel}}(t_i)$ and $\dot{y}_{\mathrm{rel}}(t_i)$ have to be determined through experimental investigations.

3 EXPERIMENTAL INVESTIGATIONS

3.1 *Experimental pedestrian bridge*

The experiments were carried out on an experimental footbridge (HUMVIB-Bridge), located on the campus of TU Darmstadt. The supporting structure consists of two longitudinal simply supported steel beams (steel type S235JR) with a span of 13.24 m and a cross section HEB 240 (Fig. 2). In order the keep the natural frequency in a range excitable by pedestrian walking, a contribution of the deck plate to the global stiffness of the system had to be avoided. Hence a deck plate consisting of 13 precast reinforced concrete stripes (250 x 100 x 12 cm) was installed. The concrete stripes only contribute to the structural dynamic behaviour as additional mass. Moreover, the use of concrete stripes reduces the uncertainties in numerical analysis, since the influences from the scattering of the concrete material parameters are also avoided. The gap between the stripes is 2 cm. It is small enough to secure a safe locomotion of the subjects (without tripping) but large enough to avoid a contribution of the concrete to the global stiffness of the structure. The concrete elements are deployed on the steel beams using a thin elastomeric interlayer (t=5 mm) in order to prevent slipping between the steel and concrete components.

The total mass of the experimental pedestrian bridge of 12 tons leads to a fundamental frequency of the structure of 2.03 Hz, confirmed also by experimental investigations. The corresponding modal damping ratio was identified to be 0.3 %.

Furthermore, an additional movable support was planned, in order to allow a flexibility of the structural system for further research topics, e.g. investigations of stiffer and higher frequent structures.

3.2 *Measurement set-up*

Since the solution of the least squares problem formulated in Equation 10 requires both information regarding the body kinematics and the structural behaviour, a combination of experimental methods for structural analysis and biomechanics is needed. The measurement set-up is shown in Figure 3. Moreover, the body kinematics and the forces induced at the contact point are required both for walking on a rigid and on a flexible structure. Therefore the investigations included the following structural configurations:

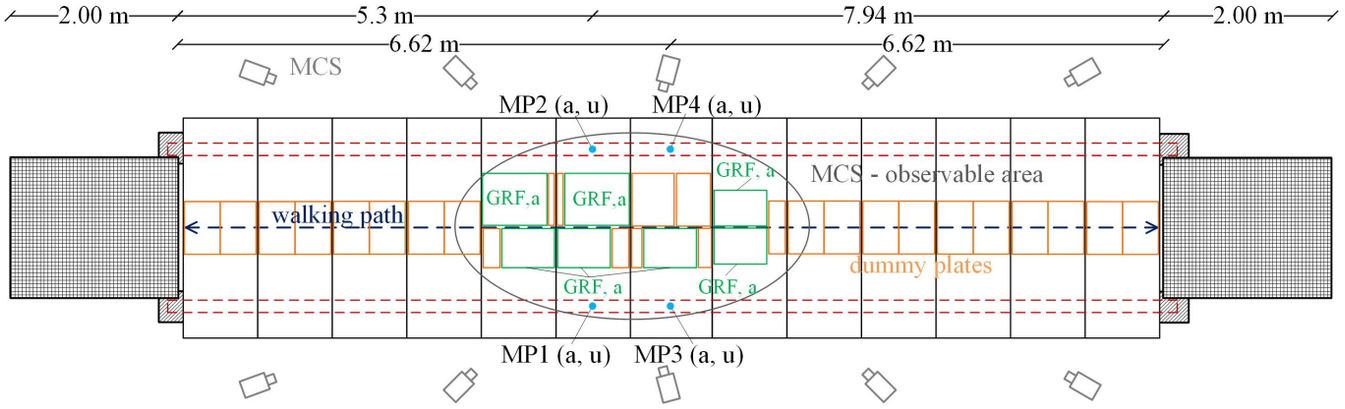

Figure 3: Measurement set-up

- set-up 1: simply supported beam, denoted in the following as ”flexible structure”;
- set-up 2: continuous beam, denoted in the following as the ”rigid structure”. In this configuration the additional movable support was installed at the midpoint, in the vicinity of the force plates.

So far, the investigation focused on analysing the scenario of single pedestrians walking over the structure. A total number of six subjects (four males and two females) aged 29.7 $\pm$ 8.4 years with a body mass of 71.6 $\pm$ 6.9 kg were investigated. Each of them performed eight trials in each structural configuration, whereas they were asked to walk over the bridge along the predefined walking path (s. Fig. 3) with a the prescribed frequency of 2 Hz (controlled by metronome beats).

The structural responses in vertical direction were recorded using 1D seismic accelerometers (PCB-TLD393B04) and linear variable displacement transducers (HBM 1-WA/50MM-L). The relevant locations for this investigation are shown in Figure 3. The only processing applied to the signals from the structural measurements is a low pass filter with a cut-off frequency of 35 Hz. The same frequency content was used as well in the numerical analysis.

The acquisition of the forces exerted by the walking pedestrians on the structure employed five force plates of type KISTLER 9260AA6 (600 x 500 x 50 mm) and two force plates KISTLER 9287CA (900 x 600 x 100 mm) with a mass of 8.6 and 25 kg, respectively (Kistler 2017). They were installed on the concrete stripes, around the midpoint of the bridge (Fig. 3) so that a number of up to four steps could be recorded during the trials. In order to level the walking path (due to different heights of the force plates), dummy plates were installed on all the other concrete elements along the walking path. This secures proper conditions for natural gait behaviour and reduces the tripping hazard of the subjects. It is to be noted, that the measurement accuracy of the force plates might be affected by vibrations of the structure they are installed on (Werkle et al. 2016). Therefore the force plate signals recorded during walking on the flexible structures have

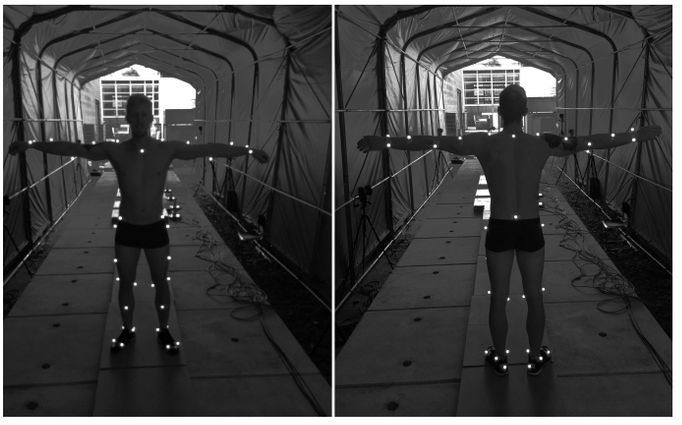

Figure 4: Typical marker instrumentation of a subject: front view and back view

to be processed by subtracting the inertial forces generated by the accelerations of the force plate mass. This leads to the necessity of acceleration measurement at the location point of each force plate. Furthermore it should be noted that the force plates present (in case of proper installation) natural frequencies of about 200 Hz (9260AA6) and 500 Hz (9287CA) (Kistler 2017). Therefore it is presumed that internal vibrations of the force plates and relative vibrations of the force plates with respect to the bridge surface can be excluded.

The human body kinematics was recorded using a *Qualisys*® motion capture system. It includes ten infrared cameras which focused on the location area of the seven force plates, in order to assure a proper correlation between the force signals and the body kinematics data. The time-dependent 3D position for a number of 41 reflective markers placed on the subject body (Fig. 4) was recorded in every trial at a high sampling rate. Additional markers were installed at the corners of the force plates in order to record the displacement $w(t)$ of the contact point. It should be noted that the infrared cameras are very sensitive to changes in light conditions. Hence the bridge, which is situated outside, had to be covered by a tent during the investigations (s. Fig. 4).

The kinematic data was processed using a low pass filter with a cut-off frequency of 12 Hz. An anthro-

pometric model was then used to calculate the COM (Winter 2009). The displacements of the COM in the rigid and flexible configuration ($y_{\mathrm{b}}(t_i)$ and $y_{\mathrm{p}}(t_i)$) were subsequently employed together with the displacement of the contact point $w(t_i)$ for determination of the matrix entries $y_{\mathrm{rel}}(t_i)$ in Equation 10 according to Equations 4 and 5. The COM velocities $\dot{y}_{\mathrm{rel}}(t_i)$ were calculated by numerical differentiation of the relative displacement vector.

4 RESULTS

4.1 *Experimental results*

In the following, the procedure of parameter identification will be illustrated by reference to the results of the first (male) subject, aged 47, with a body mass of 69 kg. For now, the four steps recorded will be analysed separately, whereas a "step" is defined in the following as a period from one minimum to the next minimum of the force resulting by superimposing the data from the left and right foot (Fig. 5).

The ground reaction force difference $\Delta p(t)$ has to be determined by subtracting the force signal recorded in the flexible configuration from the force time history recorded on the rigid structure (s. Equation 8). However, the two structural configurations were investigated independently and are thus not correlated with respect to their time vectors. In order to overcome this issue, a Fourier approximation in the phase angle form was computed according to Equation 11 for every step in each configuration as average from all the eight trials.

$$p(t) = G + \sum_{i=1}^{5} G \cdot \alpha_i \cdot \sin(2 \cdot \pi \cdot i \cdot f_{\mathrm{s}} \cdot t - \varphi_i) \quad (11)$$

Herein α_i and φ_i represent the Fourier coefficients and the corresponding phase shift of the i-th harmonic. f_{s} depicts the step frequency and G is the subject weight. The Fourier approximations were subsequently synchronised in time for each of the four steps.

Figure 5 shows typical Fourier approximations of the forces measured during the investigations on the stiff and on the flexible structure as well as the corresponding difference. The results shown were recorded for the first subject. The difference $\Delta p(t)$ is considered to occur due to the human structure interaction and has to be compensated within the structural analysis by the SDOF system. As expected, a general trend of higher GRF maxima in the rigid configuration could be noticed for all the subjects investigated. This effect arises presumably as a consequence of the interaction effects.

Due to the uncorrelated measurements in the rigid and flexible configuration, also the COM time histories had to be represented by equivalent Fourier series

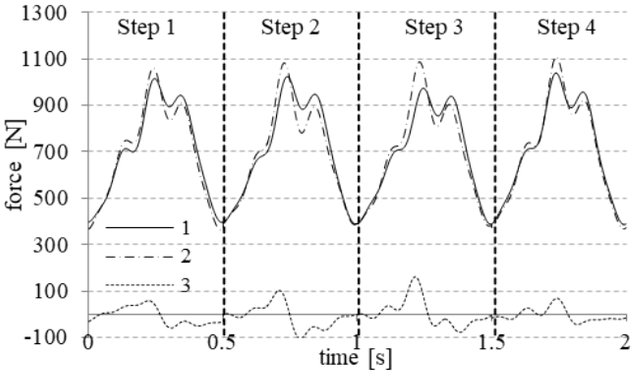

Figure 5: Fourier approximation of the GRF (subject 01): 1 - exerted by the subject on the flexible structure $p_{\mathrm{p}}(t)$, 2 - induced on the rigid structure $p_{\mathrm{b}}(t)$ and 3 - the corresponding difference $\Delta p(t)$

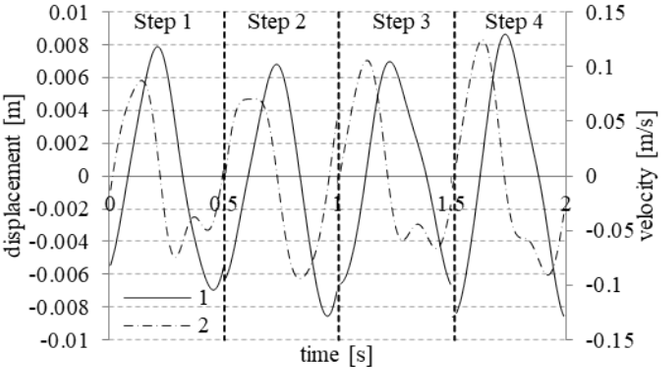

Figure 6: COM relative time histories used in the optimisation process for the subject 01: 1 - displacement $y_{\mathrm{rel}}(t)$, 2 - velocity $\dot{y}_{\mathrm{rel}}(t)$

(including five harmonics), as average from all the trials. Figure 6 illustrates exemplarily the relative displacement and relative velocity time histories ($y_{\mathrm{rel}}(t)$ and $\dot{y}_{\mathrm{rel}}(t)$) determined from measurements according to Equations 4 and 5 for the subject 01.

After introducing the contact force difference $\Delta p(t)$ (Fig. 5) and the COM relative motion quantities $y_{\mathrm{rel}}(t)$ and $\dot{y}_{\mathrm{rel}}(t)$ (Fig. 6) of subject 01 in Equation 10, the stiffness constants and damping coefficients shown in table 1 were determined by solving the unconstrained least squares problem. The results reveal a rather high intra subject variability. A statistical analysis over the four steps leads to average values of k_{p}=4001 N/m and c_{p}=358 Ns/m. The corresponding standard deviations amount to 1980 N/m and 200 Ns/m which represent about 50% of the average values.

It is to be mentioned that the optimisation was performed only in one step over the whole time window. Therefore it is expected that the reconstructed force difference using the parameters from table 1 and Equation 10 matches the measured time history only to a limited extent. This effect ist clearly illustrated

Table 1: Human body parameters of Subject 01:

Parameter	Step 1	Step 2	Step 3	Step 4
k_{p} [N/m]	4691	2425	6495	2392
c_{p} [Ns/m]	286	599	417	128

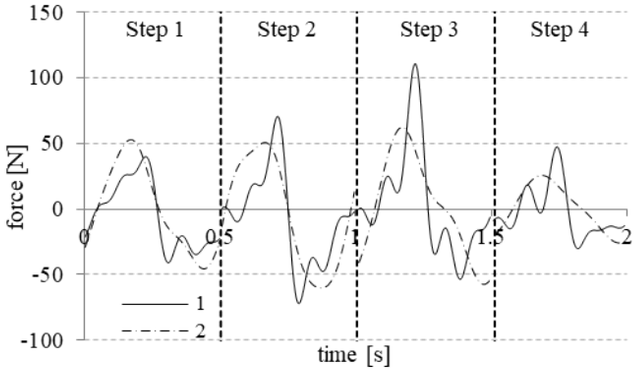

Figure 7: Ground reaction force difference (subject 01): 1 - measured, 2 - reconstructed by introduction of the optimised parameters k_p und c_p (table 1) in Equation 10

in Figure 7. An improvement of the method would be represented by determination of time dependent parameters (Firus et al. 2017).

4.2 *Structural analysis*

Since both structural and biomechanical responses were recorded simultaneously, it was possible to check the influence of the optimised parameters in the numerical model. The structure was modelled using a beam formulation in modal coordinates. The mechanical HSI model used within the investigation is represented in Figure 1c. It represents a SDOF system travelling over the bridge at a constant speed, together with a harminic force $p(t)$, which represents the forced induced by a pedestrian on a rigid structure, as measured in gait laboratories using force plates or instrumented treadmills (Racic et al. 2009). The SDOF system serves for modifying the contact force induced when walking on the flexible structure, in order to account for HSI. For a detailed presentation of the formulation of the coupled system human-bridge implemented within the present investigations, it is referred to Caprani and Ahmadi 2016. The equilibrium equations of motion were integrated using the time-stepping method of Newmark (Werkle 2008).

Figure 8 shows the acceleration time histories computed at the midspan of the structure for the subject 01 using the moving force (MF) and the interaction (SDOF) approaches. For the SDOF representation of the human body, the average parameters k_p=4001 N/m und c_p=358 Ns/m determined from table 1 were considered, while the force adopted in the MF model represents the average force (Fourier approximated) measured for subject 01 in the rigid configuration. In order to facilitate the comparison, the figure also includes a typical acceleration time history measured at midspan (MP4). Figure 8 reveals, as expected, that the moving force approach results in higher accelerations than the SDOF model. In this case, a difference of about 13% occured. It is obvious that the MF model significantly overestimates the measured result. The MF maximal acceleration of 1.35 m/s^2 lies about 16% above the average measured result of 1.16 m/s^2

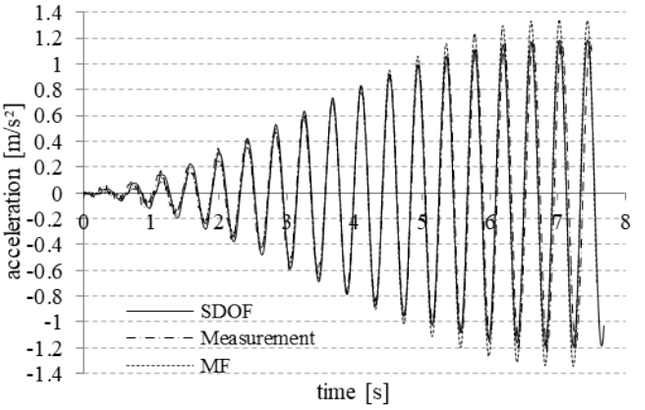

Figure 8: Measured and computed acceleration time histories at midspan of the bridge for a subject walking with a step frequency of 2 Hz

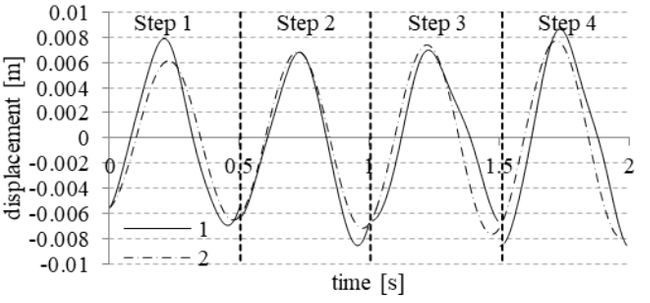

Figure 9: COM relative displacement time history $y_\mathrm{rel}(t)$ for subject 01: 1 - determined from measurements; 2 - computed using the SDOF approach

(from eight trials). However, the results of computations using the SDOF mechanical model generated a maximal acceleration of 1.19 m/s^2 and revealed thus a very good match with the measured result.

A further check of the results' quality was performed by comparing the computational relative displacement of m_p and the simulated force induced by the SDOF into the structure with the corresponding results determined from the measurements. Figure 9 and Figure 10 show satisfactory matches for both the order of magnitude and the time history trends between the computed quantities and the measured results. However, some remarkable differences can be noticed, especially in the case of the force comparison. They occur most likely due to the assumption of constant parameters k_p and c_p as average values from all the steps.

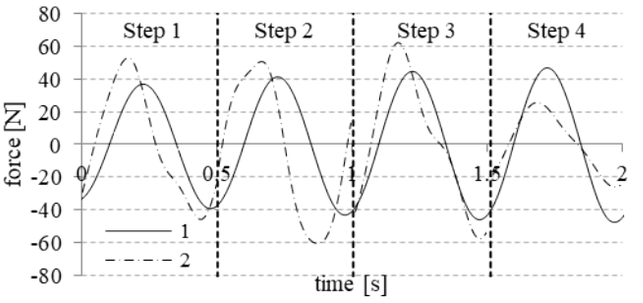

Figure 10: force time history exerted by the SDOF on the structure: 1 - computed using the SDOF approach and 2 - estimated using Equation 10 and the optimised parameters determined from measurements

Table 2: Stifness constants damping coefficients of the SDOF system determined for a pedestrian walking on a flexible structure

Parameter	Subject 01	Subject 02	Subject 03	Subject 04	Subject 05	Subject 06
k_p [N/m]	4001 $\pm$ 1980	4970 $\pm$ 1769	6436 $\pm$ 3302	13999 $\pm$ 2477	5732 $\pm$ 1479	7801 $\pm$ 2113
c_p [Ns/m]	358 $\pm$ 200	608 $\pm$ 286	108 $\pm$ 93	639 $\pm$ 577	289 $\pm$ 114	500 $\pm$ 201

The procedure described above was employed for the analysis of the data from all the six subjects investigated. The results are given in table 2.

Since no direct correlation between the values of the stiffness and damping coefficients to the step number (one to four) could be found, only the average values of the four steps and the corresponding standard deviations are included. Analysing the standard deviations of all the subjects, it is clear that the intra-subject scattering has a similar (rather high) level of magnitude as observed for the first subject. Considering the data from all the subjects, the average stiffness and damping are determined to 7157 $\pm$ 3592 N/m and 417 $\pm$ 204 Ns/m. They lead to natural frequencies of the SDOF system between 1 and 2 Hz. These values are situated at the lower bound of the parameter ranges given in the literature (Shahabpoor et al. 2016).

5 CONCLUSIONS

This work focuses on the experimental identification of the parameters of an SDOF system representing a pedestrian walking on a flexible structure. The SDOF can be used for consideration of human-structure interaction effects within the numerical analysis of pedestrian induced vibrations. A novel method for parameter identification was proposed. It is based on a combination of experimental methods for structural and biomechanical analysis and implies measurements both on a rigid and on a flexible structure. The investigations performed on six subjects revealed average values of 7157 $\pm$ 3592 N/m for the stiffness constant and 417 $\pm$ 204 Ns/m for the damping coefficient, based on four steps analysed for each of the eight trials per subject. These values lie at the lower bound of the ranges specified in the literature and lead to natural frequency of the human body between 1 and 2 Hz. The scattering of the results was found to be rather large (standard deviation around 50%) for both intra-subject and inter-subject analyses. So far, no clear correlation between the different steps could be found.

Furthermore, the authors would like to highlight the importance of the cooperation between civil engineering and sport science on this topic. This facilitates a better understanding of the adaptation mechanisms of the human body walking on flexible structures and can lead to significant improvements of the vibration serviceability guidelines, which should include reliable models for considering the human-structure interaction effects.

ACKNOWLEDGEMENTS

The scientific discussions on this topic with Katrien Van Nimmen and Peter Van Den Broeck are greatly acknowledged.

ABSTRACT: For slender footbridges, the dynamic response to human-induced loading needs to be verified in a vibration serviceability assessment. The assessment is commonly based on a simplified load model and relying on the nominal values of the modal parameters of the structure as predicted by a finite element model. Often, resonance with a single mode is considered and a reduction factor rates the risk for resonance with that mode. For a reliable response prediction, uncertainties in the modal parameters of the structure must be dealt with, however. If the vibration levels exceed a predefined comfort criterion, a Tuned Mass Damper (TMD) can be installed. In this contribution, a robust vibration serviceability assessment is proposed. Different levels of uncertainty are introduced to account for the effect of uncertainties in the modal parameters resulting in a multi-interval assessment. Realistic loading scenarios are implemented using detailed simulations considering variability of the pedestrian walking characteristics. The contribution of multiple modes is considered and the instantaneous peak acceleration is retained and tested to criteria for vibration comfort. The procedure is illustrated for a slender footbridge. First, the response is evaluated for different levels of uncertainty. Second, the procedure is applied in the design of a TMD by tuning its mass, stiffness and damping constants such that an effective reduction of the vibration levels is ensured. The advantage of the robust interval-based approach is that it allows understanding how the uncertainties in the modal parameters of the structure affect the response prediction. Besides, the method investigates the trade-off between the TMD parameters and its robustness against uncertainties in the modal parameters. The level of uncertainty can be determined based on a monitored or assumed range of variations of the modal parameters of the structure.

1 INTRODUCTION

Slender structures such as footbridges are often characterised by low natural frequencies that may lie in the range of human-induced loading. As these light structures are generally also lightly damped, they are sensitive to human-induced excitation. A vibration serviceability assessment is therefore required to evaluate the dynamic response of the footbridge to human-induced loading.

Frequently used procedures for the assessment have been presented by guidelines such as Sétra (2006) and HiVoSS (2008). For these simplified methods, the load induced by number of randomly distributed pedestrians N is translated to an equivalent load induced by N_{eq}, equally distributed and perfectly synchronised pedestrians. Resonance conditions between one mode of the structure and the first or second harmonic component of the walking load are considered. A reduction factor is included for frequencies which significantly deviate from the expected loading frequencies. However, for footbridges, multiple modes are often excited simultaneously all contributing to the response. Besides, more detailed load models also consider two other important aspects: human-human interaction (HHI) and human-structure interaction (HSI) (Venuti et al. 2016). HHI models describe the synchronisation among pedestrians. In general, for a higher pedestrian density, the synchronisation rate increases resulting in a decrease of the average walking velocity and average step frequency. The relation proposed by Weidmann (1993) is widely applied to link the pedestrian density and average walking speed. Recently, it was investigated that HSI con-

siderably affects the response as well. In vertical direction, the added damping due to the pedestrian bodies must be considered (Van Nimmen et al. 2016, Caprani and Ahmadi 2016, Salyards and Noss 2014). In (Van Nimmen et al. 2017), it was found that the effective damping due to the pedestrians is significantly higher than the modal damping of the empty structure.

As the vibration serviceability assessment strongly depends on a good knowledge of the modal parameters, it is recommended to account for the effect of uncertainties in that modal parameters. The natural frequency and modes can be calculated by a finite element model (FEM) while the modal damping can be estimated based on experience with similar structures such as the values proposed in Sétra (2006) and HiVoSS (2008). Relatively small variations of the nominal values of the modal parameters may lead to large discrepancies in the predicted response, however. In Van Nimmen et al. (2014), it was found that natural frequencies predicted by a detailed FEM of a structure may be up to 10% off from the actual measured values. Also large variations of the modal damping depending on the acceleration amplitude are reported in Avci (2016). Up to now, this uncertainty in the modal parameters of the structure is not accounted for in any of the conventional methods for the response prediction and evaluation of footbridges.

Therefore, this paper proposes an approach for the robust vibration serviceability assessment of footbridges. Both the effect of uncertainties in the modal parameters of the structure and the stochastic nature of the load are accounted for. Different levels of uncertainty are considered to account for the effect of uncertain modal parameters resulting in a multi-interval approach. Based on state-of-the-art load models such as Venuti et al. (2016), Li et al. (2010) and Van Nimmen et al. (2016), the stochastic nature of the load is considered by simulating multiple realistic walking scenarios accounting for variability of the walking characteristics of the pedestrians. HSI effects following Van Nimmen et al. (2017) and HHI effects according to Weidmann (1993) and Venuti and Bruno (2007) are accounted for. The robust assessment then consists of an evaluation of the range of calculated instantaneous peak response.

The outline of the paper is as follows. First, the strategy of the robust vibration serviceability assessment is presented (section 2). Second, in section 3, the procedure is applied to a case study where also a TMD design is discussed by solving an optimisation problem where constraints for vibration serviceability are imposed. Finally, in section 4, a number of conclusions are drawn summarising the advantages of the presented approach.

2 METHODOLOGY FOR ROBUST RESPONSE PREDICTION

In the robust vibration serviceability assessment, both uncertainties in the modal parameters of the structure and the stochastic nature of the loads are considered. The section is organised as follows. First, the methodology to deal with uncertainties in modal parameters is discussed. Second, a summary of the state-of-the-art load models is given. Third, it is given how to extract the instantaneous peak acceleration and to perform the multi-interval assessment.

2.1 *Uncertain modal parameters*

To deal with uncertainties in the natural frequency and modal damping of the structure, a multi-interval approach is proposed which allows assessing the sensitivity of the vibration serviceability assessment to a change in the modal parameters of the structure (Lievens et al. 2016). A multiplication factor β which is modelled as a convex fuzzy number is used to characterise the uncertainty and its value lies in an interval between its minimal value $\beta^{-}(\alpha)$ and maximal value $\beta^{+}(\alpha)$ depending on the value of the membership function (situated between 0 and 1) corresponding to different levels of uncertainty α. The boundaries of these intervals increase linearly for a higher level of uncertainty.

Here, β_{f_j} and β_{ξ_j} are defined to account for uncertainty in the nominal value of the natural frequency f_j and modal damping ξ_j, respectively, of mode j. The interval bounds for the multiplication factor of the natural frequency corresponds to 10% deviation on the nominal value of the natural frequency (Van Nimmen et al. 2014) for the largest level of uncertainty ($\alpha = 0$). The nominal values of the natural frequency correspond to the case with no uncertainty ($\alpha = 1$). Uncertainty in the modal damping is modelled similarly although in this case a wider range of 0.5 to 1.5 times the nominal value is considered. The membership functions of the multiplication factors are visualised in figure 1(a) for the uncertain natural frequency and in figure 1(b) for the uncertain modal damping. These intervals will be considered for the natural frequency and modal damping in all further analyses in the paper. Since these input parameters are modelled as fuzzy numbers, the output variable (response) is also a fuzzy number.

For structures where the contribution of multiple modes is considered, it is assumed that the uncertainties affect the natural frequency of all modes in an identical way ($\beta_{f_j} = \beta_f$). A similar approach is assumed for the modal damping ($\beta_{\xi_j} = \beta_\xi$). Therefore, the assumption is made that the same level of uncertainty α holds for both the natural frequency and modal damping simultaneously.

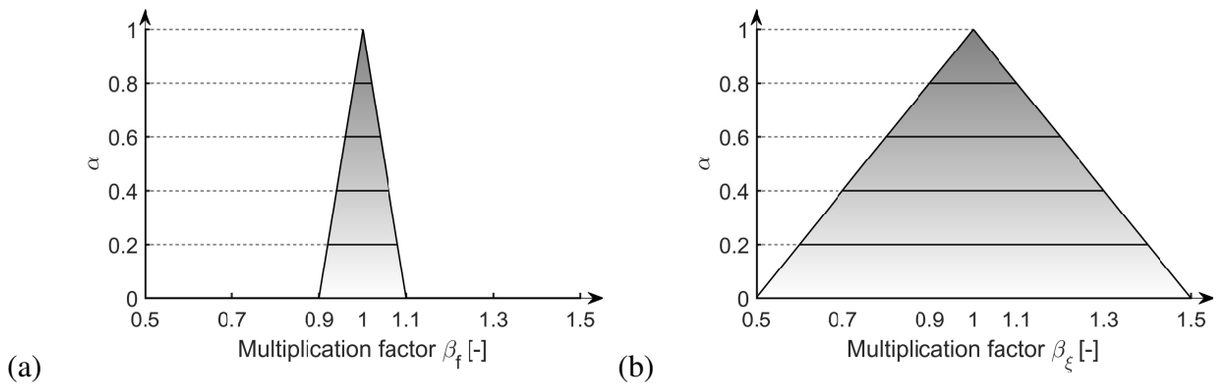

Figure 1: Multi-interval approach for the multiplication factor at different levels of uncertainty α for (a) natural frequency and (b) modal damping.

2.2 *Stochastic nature of human-induced loading*

The model considered in this paper is based on the advanced state-of-the-art load models in Venuti et al. (2016) and Van Nimmen et al. (2016). This section describes how these models are used, for both the single pedestrian walking force and the crowd-induced force model. It is also indicated how the HHI- and HSI-effects are implemented.

2.2.1 *Single pedestrian force*

The pedestrian's walking force of a single footstep is written as a summation of harmonic components as:

$$\frac{F(t)}{G} = \sum_{n=1}^{5} A_n(f_s)\sin(\frac{\pi n}{T_c}t) \quad \text{for} \quad 0 \leq t \leq T_c \qquad (1)$$

with $F(t)$ the force [N] of one single footstep at time t, G the weight of the pedestrian [N], $A_n(f_s)$ the Fourier coefficient of the n-th harmonic component of the generalised load model as a function of the step frequency f_s [Hz] and T_c [s] the contact period between foot and ground. The model given by Li et al. (2010) is used to calculate the walking force in vertical direction, specifying the values of $A_n(f_s)$. The contact time according to Li et al. is found as $T_c = T_s/0.76$ with $T_s = 1/f_s$. By considering a continuous sequence of forces alternatingly induced by left and right foot and respecting the contact time, the step-by-step force is derived.

2.2.2 *Crowd model and induced force*

To develop the model for a moving crowd, a large number of pedestrians must be considered which are each characterised by their trajectory, weight G, step frequency f_s and walking speed v_s. Here, a continuous uni-directional pedestrian flow is assumed. The walking paths of the individual pedestrians are straight lines in the longitudinal direction of the bridge. The weight $G = 700$ N of each pedestrian is equal for all pedestrians. Two important aspects must be considered: interaction among pedestrians and interaction between structure and pedestrians.

Multiple pedestrian densities are considered in the assessment, going from low densities (0.2 pers./m^2) to a high occupancy (1.5 pers./m^2). For densities higher than 0.7 pers./m^2, free movement of the pedestrians is restricted resulting in a decrease of the overall walking speed v_s. The relation between the pedestrian speed and density d [pers./m^2] is given in Weidmann (1993) and Venuti and Bruno (2007) as following:

$$v_s = \bar{v}_s \left(1 - \exp\left[-\gamma\left(\frac{1}{d} - \frac{1}{d_{\text{jam}}}\right)\right]\right) \qquad (2)$$

with $\bar{v}_s$ the average free walking speed, γ a fitting coefficient accounting for the travel purpose and d_{jam} the jam density, i.e. the maximal possible density at the structure corresponding to a null speed flow. d_{jam} generally ranges between 5 and 6 pers./m^2 (Venuti and Bruno 2007). Based on equation (2), the pedestrian speed v_s is found as a function of the density. An expression relating the average step frequency $\bar{f}_s$ of the pedestrians at a specific density and the walking speed v_s was derived from a large set of data from tests in the laboratory (Bertram and Ruina 2001) and is given by Venuti and Bruno (2007) as follows:

$$\bar{f}_s = 2.93v_s - 1.59v_s^2 + 0.35v_s^3 \qquad (3)$$

Five different pedestrian densities d are considered in this paper. The average walking speed and step frequency for the considered densities are shown in figure 2. Therefore, following parameters are used in eq. (2): an average free walking speed of $\bar{v}_s = 1.34$ m/s, the coefficient for travel purpose $\gamma = 1.913$ and the jam density $d_{\text{jam}} = 5.4$ pers./m^2 (Weidmann 1993).

The step frequencies of the pedestrians are sampled from a zero-truncated Gaussian distribution $f_s \sim \mathcal{N}(\mu_{f_s}, \sigma_{f_s})$ with μ_{f_s} the mean value and σ_{f_s} the standard deviation of the step frequency. In nominal conditions, μ_{f_s} equals the value as obtained from equation (3). The value for σ_{f_s} depends on the pedestrian density. For low densities (d <1 pers./m^2), 0.10 Hz is assumed in this paper for σ_{f_s} (Butz et al. 2008). For higher densities ($d \geq$1 pers./m^2), the free movement of the pedestrians is restricted resulting in a decrease of the average speed and mean step frequency

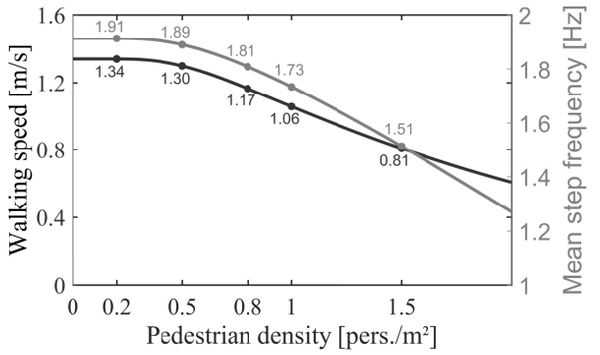

Figure 2: Relation between pedestrian density d and walking speed v_s [m/s] (dark) and between pedestrian density d and average step frequency $\bar{f}_s$ [Hz] (light).

$\bar{f}_s$. Furthermore, a higher level of synchronisation is found resulting in a decreased value of σ_{f_s} (0.05 Hz) (Butz et al. 2008). For all pedestrians, the same walking speed is considered, determined by the pedestrian density (equation (2) and figure 2). At each time step, the longitudinal position of each pedestrian on the footbridge is calculated based on the walking speed. Their lateral position is sampled from a uniform distribution covering the width of the bridge. In the simulations, the arrival times of the individual pedestrians are sampled from a Poisson distribution (Živanović 2012). The total modal load of the flow is then found as the superposition of the modal load of the individual pedestrians, respecting the arrival times. In figure 3, an example is given of the spatial distribution of the single step forces of a sample of walking pedestrians during an arbitrary time interval $[t_{i,k}, t_{i,k} + T_{c,k}]$ with $t_{i,k}$ the time of the i-th start point of one single footstep in the flow simulation of pedestrian k and $T_{c,k}$ the contact time of the footstep of the k-th pedestrian.

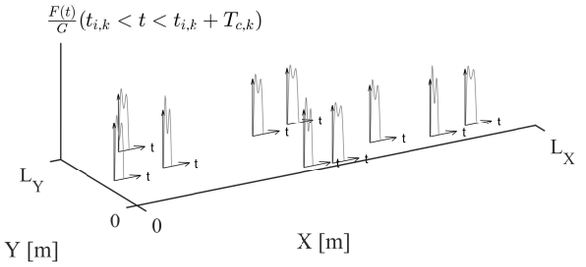

Figure 3: Spatial distribution of single step forces of randomly distributed pedestrians with different characteristics during a time interval $[t_{i,k}, t_{i,k} + T_{c,k}]$ with $t_{i,k}$ the time of the i-th start point of one single footstep in the simulation of pedestrian k and $T_{c,k}$ the contact time of the footstep of the k-th pedestrian.

No active interaction is assumed, implying that the internal driving forces of the pedestrians remain unaltered when walking on the vibrating footbridge. Then, the interaction force between the pedestrian and the footbridge is formulated as the sum of the ground reaction force on a rigid surface and a term resulting from the interaction between the footbridge and the human body as a mechanical system. Following the pseudo moving crowd model of Van Nimmen et al. (2017), the forces move step-by-step while the SDOFs, representing the human bodies, are distributed uniformly over the bridge deck on fixed positions. The parameters of the SDOFs match those of persons assuming a walking posture. To account for inter-subject variability of the human-body parameters, the natural frequency is sampled from $f_H = \mathcal{N}(3.25, 0.32)$ [Hz] and the damping from $\xi_H = \mathcal{N}(0.30, 0.05)$ [-] (Matsumoto and Griffin 1998, Matsumoto and Griffin 2003). The pseudo moving crowd model gives results which deviate at most 5% from a model where the SDOFs move with the loads for all densities of 0.2 pers./m^2 and higher since the model accounts for the actual spatial distribution of the pedestrians (Van Nimmen et al. 2017).

2.3 *Response calculation and evaluation*

The time history of the modal load of the entire flow is constructed as discussed in section 2.2.2 for each mode contributing to the response. Then, a discrete-time state-space model is used to compute the acceleration response of the generated flow. The instantaneous peak value of the bridge acceleration in a time interval with length T, is calculated to statistically characterise the response. The mean value $\mu_{\ddot{u}_{\max}(T)}$ and standard deviation $\sigma_{\ddot{u}_{\max}(T)}$ of the instantaneous peak response are calculated according to (Davenport 1964, Der Kiureghian 1980, Preumont 1985, Piccardo and Tubino 2012) based on the power spectral density (PSD) function of the acceleration time history. In Lievens et al. (2016), this methodology is verified for the prediction of human-induced vibrations. The length of the time window T is here set to twice the time a single pedestrian needs to cross the footbridge T_{cross} as proposed in (Živanović 2012, Association Française de Génie Civil, Sétra/AFGC 2006, Research Fund for Coal and Steel 2008) and the 95th percentile of the instantaneous peak value $\ddot{u}_{95}$ is calculated, here approximated as $\mu_{\ddot{u}_{\max}(T)} + 2\sigma_{\ddot{u}_{\max}(T)}$.

To account for variability on the average walking frequency, an interval for μ_{f_s} is defined as follows:

$$\mu_{f_s} \in [\bar{f}_s(d) - 0.1, \bar{f}_s(d) + 0.1] \tag{4}$$

The interval width of 0.2 Hz for μ_{f_s} is found by evaluating eq. (3) for almost all values of v_s assuming $\sigma_{v_s} = 0.2$ m/s (Živanović 2012). Continuous flows of pedestrians are then composed for each pedestrian density and for each value of μ_{f_s} in the interval as described before, with the following pedestrian characteristics: $f_s \sim \mathcal{N}(\mu_{f_s}, \sigma_{f_s})$ (see section 2.2.2).

The multi-interval analysis then consists of evaluating a range of calculated response. At each level α, the relevant statistical quantity of the response $\ddot{u}_{\max}(d, \alpha)$ for a density d then is expressed as:

$$\ddot{u}_{\max}(d, \alpha) = \max_{\beta_f(\alpha), \beta_\xi(\alpha), \mu_{f_s}(d)} (\ddot{u}_{95}) \tag{5}$$

Similarly, the minimal instantaneous peak value $\ddot{u}_{\min}(d, \alpha)$ is extracted obtaining a range for the instantaneous peak value at level α that can be compared to criteria for vibration comfort from Sétra (2006).

3 APPLICATION

3.1 *The Phénix footbridge*

The Phénix footbridge is a slender construction situated nearby the railway station of Charleroi (Belgium). The construction has a single span of 38.25 m and a width of 13.35 m and a wooden deck is constituted by the steel frame. A neoprene bearing at each corner supports the structure. A detailed description of the footbridge is given in Lievens et al. (2016). In figure 4, the modal parameters of the first three modes are summarised as calculated by the FEM. A modal damping ratio of 0.4% for each mode shape is assumed based on Sétra (2006) and HiVoSS (2008).

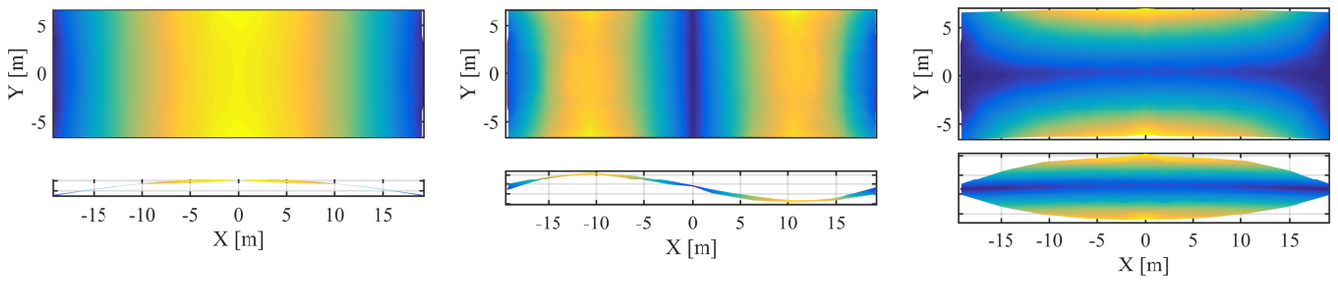
3.2 *Vibration serviceability assessment*

The response is calculated following the methodology from section 2. Simulations are performed for the different pedestrian densities considered in this paper accounting for variability on the average step frequency μ_{f_s} and for uncertainties in the modal characteristics as defined by multiple values of the multiplication factors β_f and β_ξ. The response is evaluated by calculating the mean value and standard deviation of the instantaneous peak value in a time window of $2 \times \frac{38.25 \text{ m}}{1.34 \text{ m/s}} \approx 57$ s. A fixed discretisation of 0.01 Hz is considered for the interval of the average step frequency (eq. (4)) while the intervals of the multiplication factors β_f and β_ξ were discretised with a fixed number of 21 uniformly distributed values.

Figure 5 shows the results of the vibration serviceability assessment for the Phénix footbridge as a function of the level of uncertainty in the modal parameters α for each pedestrian density. The overall maximum vertical response at the bridge deck is evaluated. The level $\alpha = 1$ represents the possible acceleration levels considering variability in the loading only while for higher levels of uncertainty, the minimal and maximal possible value of the instantaneous peak acceleration account for both variability in the loading and uncertain modal parameters. It is clearly illustrated in figure 5 how a wider range of uncertainties in the modal parameters leads to a larger interval of the instantaneous peak response.

The values of the instantaneous peak acceleration for $\alpha = 1$ and the average value of μ_{f_s} for each pedestrian density are indicated with cross points. The value of the calculated response remains rather constant for densities up to 1.0 pers./m^2 and strongly increases for the highest density.

The levels for vibration comfort according to Sétra (2006) are also indicated on figure 5: maximal, medium or minimal. At the level $\alpha = 1$, a medium level for vibration comfort is predicted for most of the pedestrian densities (0.2-1 pers./m^2) and a minimal level is predicted for the highest density. When the effect of uncertainty in the natural frequency and modal damping is considered, it is found that, for some values of the parameters, the level of comfort becomes minimal for all densities.



The reduction in the walking speed for increasing pedestrian density drives the values of the step frequency closer to the natural frequency of the first mode in this particular case. Then, resonance is more likely to occur. Especially, for the densities up to 1 pers./m^2, the effect of uncertainty is large since the risk for resonance is very small at nominal conditions of the flow. For a density of 1.5 pers./m^2, the risk for resonance with the first mode is already high in the nominal case. For a better understanding of the results from figure 5, information about the shifted value of the natural frequency and the average value of μ_{f_s} (figure 2) must be simultaneously considered.

To support this interpretation, the PSD function for accelerations is plotted for two pedestrian densities (0.2 and 1.5 pers./m^2) in figure 6 considering the nominal values of the modal parameters and the nominal conditions for the flow. For low pedestrian densities, the added mass of the pedestrians hardly affects the value of the natural frequency (1.65 Hz, first small peak). A second peak at ± 1.9 Hz represents the first harmonic component of the walking load. The rather small range of accelerations at nominal conditions (0.2 pers./m^2, figure 5) is due to the low risk for resonance between the natural frequency of 1.65 Hz and the possible values of f_s at that density. If the effect of uncertainties in the natural frequency is accounted for, the risk for resonance between the range of μ_{f_s} and the uncertain value of the natural frequency $\beta_f \times \pm 1.65$ Hz strongly increases. On the contrary, for high densities, the value of the natural frequency of the footbridge is significantly affected by the pedestrians and is close to the values of μ_{f_s} in the range 1.51 ± 0.1 Hz (first peak around ± 1.5 Hz). At nominal conditions, resonance is likely to occur between the decreased value of the natural frequency and values of μ_{f_s} in the range 1.51 ± 0.1 Hz. The effect of uncertainties in the natural frequency is rather small since at nominal conditions, the loading frequency could already coincide with the natural frequency (resonance conditions), resulting in a worst case situation. Other peaks in the PSD represent the higher harmonic components of the load or the contribution of other modes.

3.3 *TMD design and reassessment*

3.3.1 *TMD parameter tuning*

According to the results from figure 5, vibration comfort can not be guaranteed, and the installation of a TMD is opted to reduce the vibration levels. The

(a) mode 1 ($f_1 = 1.65$ Hz, $\xi_1 = 0.4$ %, $m_1 = 126.9$ ton)

(b) mode 2 ($f_2 = 5.22$ Hz, $\xi_2 = 0.4$ %, $m_2 = 100.2$ ton)

(c) mode 3 ($f_3 = 6.15$ Hz, $\xi_3 = 0.4$ %, $m_3 = 21.5$ ton)

Figure 4: Top and side view of the first three modes of the Phénix footbridge as calculated by the FEM: (a) 1st bending mode, (b) 2nd bending mode, (c) 1st torsional mode.

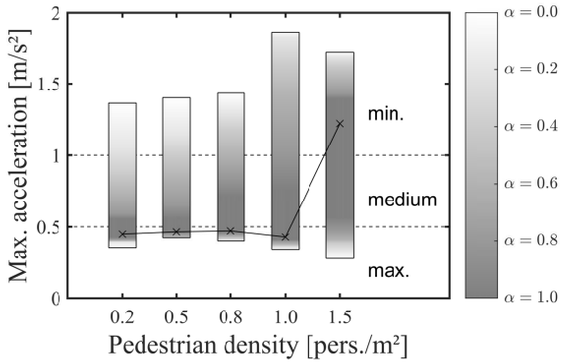


Figure 5: Robust vibration serviceability assessment for the Phénix footbridge: possible range of the instantaneous peak response accounting for variability of the load and for uncertain modal parameters of the structure, indicated by increasing levels of uncertainty in the natural frequency and modal damping (dark to light) and indication of the response in nominal situation (–×–). Comfort criteria according to Sétra (2006).

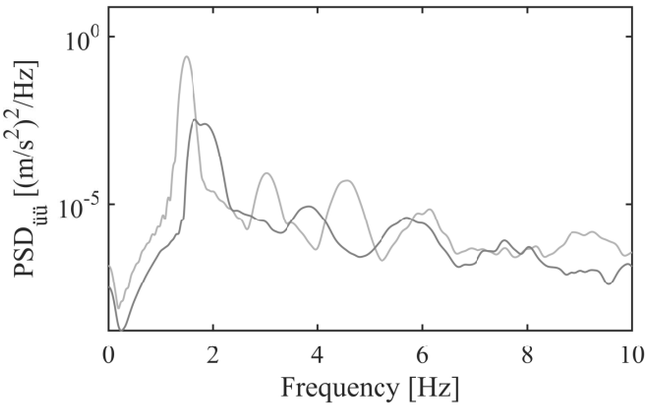

Figure 6: PSD of the acceleration response at mid span for $d = 0.2$ pers./m^2 (dark) and $d = 1.5$ pers./m^2 (light) with $\beta_f = 1$, $\beta_\xi = 1$ and $\mu_{f_s} = \bar{f}_s(d)$.

TMD mass m_{TMD}, stiffness k_{TMD} and damping c_{TMD} are tuned by solving an optimisation problem. The aim is to minimise the cost of the TMD while meeting vibration serviceability criteria. Therefore, the total mass of the TMD m_{TMD} is taken as a measure of its cost. Criteria for vibration serviceability are added as constraints to ensure an acceptable probability of exceeding a threshold for vibration comfort $\ddot{u}_{\text{comfort}}$. The TMD parameter tuning problem then is formulated as follows:

$$\begin{aligned} &\underset{m_{\text{TMD}},k_{\text{TMD}},c_{\text{TMD}}}{\text{minimise}} \quad m_{\text{TMD}} \\ &\text{subject to} \quad \mu_{\ddot{u}_{\max}(T)} + 2\sigma_{\ddot{u}_{\max}(T)} \leq \ddot{u}_{\text{comfort}} \\ &\qquad\qquad \forall\beta_f(\alpha), \forall\beta_\xi(\alpha), \forall\mu_{\text{fs}} \end{aligned} \tag{6}$$

In this case, the limit for vertical vibrations is $\ddot{u}_{\text{comfort}} = 1$ m/s^2 corresponding to a medium level of vibration comfort. The location of the TMD corresponds to the mid span of the footbridge at the antinode of mode 1. The working direction is vertical.

A non-linear constraint is implemented for all combinations of possible values of the mean step frequency of the flow μ_{f_s}, and all possible values in the intervals of the multiplication factor of the uncertain frequency β_f and modal damping β_ξ at the level α.

The proposed methodology allows to investigate the trade-off between the cost of the TMD and the level of robustness, i.e. for what deviations from the nominal values of the modal parameters vibration serviceability is still guaranteed. To illustrate the trade-off, the problem for the Phénix footbridge is solved twice. First, it is assumed that no information is available about variations or uncertainties in the modal parameters, for instance in design stage. In this case, the largest level of uncertainties in the modal parameters is considered ($\alpha = 0$). This allows estimating the TMD required when there is insufficient time for designing and installing the TMD based on measurements in between the construction of the bridge and before it is put into service. When measurements can be performed after construction, only seasonal variations of the modal parameters need to be accounted for. In this case, a higher α-level can be opted leading to a smaller TMD mass and a more cost-effective design. Here, the problem is solved for $\alpha = 0.6$. The trade-off thus encompasses the total cost, containing the cost for measurements and/or TMD units, and the timing of the design process.

The optimisation problem defined in eq. (6) is solved using a gradient based method with an interior-

point approach for handling the constraints (*fmincon* function in Matlab (The Mathworks, Inc. 2015)).

3.3.2 *Results and discussion*

The solution of the optimisation problem from equation (6) (TMD constants) for the two considered values of α is summarised in table 1. A lower TMD mass and damping are found for the design at a lower level of uncertainty ($\alpha = 0.6$). From the optimisation routine, it is found that the frequency of the TMD is close to the natural frequency of the first mode of the footbridge in the range between $\beta_f^-(\alpha) \times 1.65$ Hz and $\beta_f^+(\alpha) \times 1.65$ Hz, as was expected for the given position. In table 1, the values of the TMD parameters are also given in dimensionless terms considering the nominal values of the modal mass and natural frequency of the first mode. Besides, following parameters are also given: the TMD frequency $f_{\text{TMD}} = \frac{1}{2\pi}\sqrt{\frac{k_{\text{TMD}}}{m_{\text{TMD}}}}$, the mass ratio $\mu_{\text{TMD}} = \frac{m_{\text{TMD}}}{m_{j,\text{ver}}}$, frequency ratio $\rho_{\text{TMD}} = \frac{f_{\text{TMD}}}{f_j}$ and damping ratio $\xi_{\text{TMD}} = \frac{c_{\text{TMD}}}{4\pi m_{\text{TMD}} f_{\text{TMD}}}$ with j the number of the mode to which the TMD is tuned to (here $j = 1$) and $m_{j,\text{ver}}$ the corresponding modal mass considering the mass-normalised vertical modal displacement at the location of the TMD.

	$\alpha = 0.0$	$\alpha = 0.6$
m_{TMD} [kg]	1266.7	651.6
k_{TMD} [N/m]	126994.1	59917.4
c_{TMD} [Ns/m]	2025.2	796.1
f_{TMD} [Hz]	1.59	1.53
μ_{TMD} [%]	0.94	0.49
ρ_{TMD} [-]	0.96	0.92
ξ_{TMD} [%]	7.98	6.37

Table 1: Optimised values of the parameters of the TMD for the two considered values of the parameter α.

The entire vibration serviceability is now repeated for the footbridge with TMD, considering the optimised TMD parameters. The results of the analyses are summarised in figure 7. For all pedestrian densities, a strong reduction of the response is found compared to the results from figure 5. For a pedestrian density of 1 and 1.5 pers./m^2 and a TMD design at $\alpha = 0$, the maximal predicted acceleration equals 1 m/s^2, satisfying the design constraint (figure 7-left intervals). Similar, for the TMD designed for $\alpha = 0.6$, the maximal predicted acceleration equals 1 m/s^2 at the level $\alpha = 0.6$ (figure 7-right intervals). For higher levels of uncertainty, the medium comfort level is not met for all densities considered. For both designs, the constraint for vibration serviceability are only active for the pedestrian densities of 1 and 1.5 pers./m^2. The assessment considering nominal values ($\alpha = 1$) results in the smallest range of accelerations since only the effect of variability of the loading is present. That range is also visible in figure 7. For higher levels of uncertainty, a wider range of calculated vibration levels is found. An indication is also given for the peak response at nominal conditions.

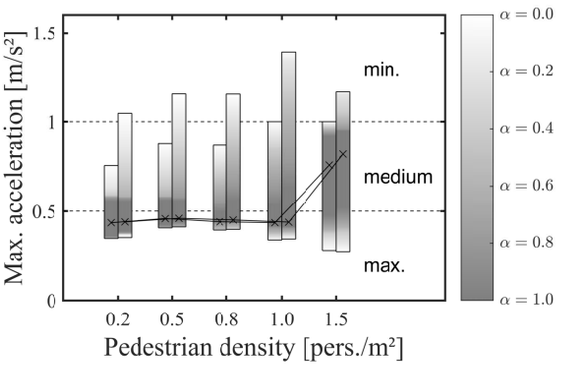

Figure 7: Robust vibration serviceability assessment for the Phénix footbridge equipped with TMD with parameters as summarised in table 1: TMD designed at (left) $\alpha = 0$, (right) $\alpha = 0.6$. Possible range of the instantaneous peak response accounting for variability in the load and for uncertain modal parameters of the structure, indicated by increasing levels of uncertainty in natural frequency and modal damping (dark to light) and indication of the response at nominal conditions (–×–). Comfort criteria according to Sétra (2006).

The power spectral density function of the acceleration response for the structure equipped with TMD is given in figure 8. Compared to the results from figure 6, the peak value of the PSD for $d = 1.5$ pers./m^2 has decreased while for $d = 0.2$ pers./m^2, the value remains constant. This means that the response for the higher density is more influenced by the TMD than for the lower pedestrian density.

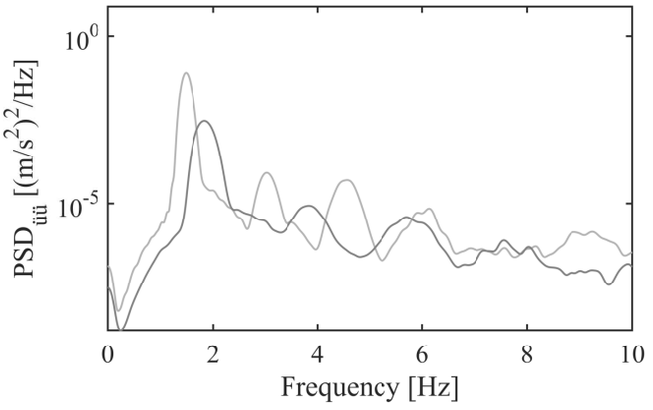

Figure 8: PSD of the acceleration response at mid span for $d = 0.2$ pers./m^2 (dark) and $d = 1.5$ pers./m^2 (light) with $\beta_f = 1$, $\beta_\xi = 1$ and $\mu_{f_s} = \bar{f}_s(d)$ for the footbridge with TMD tuned at $\alpha = 0.0$.

4 CONCLUSIONS

A strategy is proposed to account for the effect of uncertainties in the modal parameters of the structure and for variability of the loading in the vibration serviceability assessment of footbridges subject to human-induced loading. Therefore, different levels of uncertainty are introduced for the modal parameters leading to a multi-interval assessment. The width

of the intervals determines the robustness of the assessment resulting in a range for the calculated acceleration levels. An advanced load model which accounts for variability of the walking load is used by simulating continuous flows of pedestrians. Human-structure interaction effects are also accounted for.

The proposed multi-interval assessment is illustrated for the response prediction of the Phénix footbridge showing how the predicted vibration levels were affected by the effect of uncertainties. Next, the robust design of a TMD is considered. Its parameters are tuned by solving an optimisation problem minimising the total mass. Design constraints are added to satisfy criteria for vibration comfort. It is found that for a decreasing range of uncertainty in the modal parameters of the footbridge, the TMD mass required to satisfy the design constraints also decreases without violating the design constraints illustrating the trade-off between cost and robustness.

The proposed methodology has two advantages compared to other approaches. First, by accounting for variability in the walking load and for uncertainties in the modal parameters, a range of values for the instantaneous peak acceleration is found, rather than one single value, which is compared to a threshold for vibration comfort. Second, the sensitivity of the response and the TMD performance to the required degree of robustness (level of uncertainty) can be investigated. In that way, the multilevel approach allows to investigate the trade-off between the total cost of the TMD and the level of uncertainty.

ABSTRACT: The Modal Assurance Criterion (MAC) is the most widely used indicator to correlate mode shapes. However, it is recognized that the single index nature of the MAC is insufficient to detect localized differences in mode shapes. Mode shapes of structures made from Glass fibre-reinforced polymer (GFRP) can exhibit localized features. Consequently, model updating process of GFRP structures may not be optimal with the MAC. This paper proposes a shape-descriptor–based model updating procedure using Tchebichef Moment Descriptors (TMDs) for improved model updating of GFRP structures. Shape descriptors are advantageous in describing mode shape features at a range of fidelities, and so are well suited for use in model updating procedures. The proposed model updating framework is implemented on a benchmark GFRP footbridge which exhibit localized differences in mode shapes. The method is validated using a simulated model updating of the footbridge. A combination of shape descriptors and natural frequencies for the updating objective yield the most improved numerical model. The updating results suggest that the proposed method is an improvement for model updating of GFRP structures.

1 INTRODUCTION

Finite element (FE) analysis is a powerful tool for numerical analysis of building structures. Due to modelling simplifications and uncertainties, discrepancies often arise between FE predicted results and experimental measurements. A process termed 'model updating' is therefore frequently carried out on FE models to improve accuracy of numerical predictions. In structural dynamics, mode shapes are generally used for model updating, along with frequencies. Mode shapes between numerical and experimental models are typically compared using correlation indicators.

The most widely used indicator is the modal assurance criterion (MAC). Since it was first presented by Allemang (1982), it has been used extensively to correlate mode shapes in model updating. The MAC indicates the degree of consistency between two mode shapes using values between 0 (indicates no correlation) and 1 (perfect correlation). The main advantage of the MAC is that it is a single number. However, a single number is unable to reveal extended information regarding differences between two mode shapes. Localized differences could be easily missed using the MAC.

In structural dynamics, the term 'mode localization' refers to vibration confinement, i.e. where the magnitude of a specific part of the free vibrational mode is large relative to the rest of the mode (Kim & Lee, 1998). To graphically illustrate the concept of localized mode shapes, the example of a plate disc from Wang, Mottershead & Mares (2009a) is shown in Figure 1. The first mode shapes of the plate with and without an added mass are given in Figure 1a and 1b respectively. From here one can observe that the mode shape ordinate opposite the location of the added mass is significantly larger than the remaining ordinates.

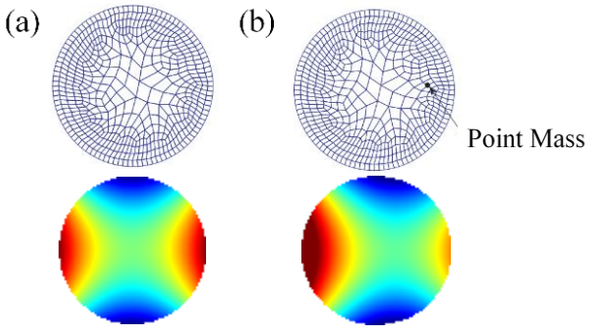

Figure 1. Localization of mode shape due to added mass in (b) compared with (a) (after (Wang, et al., 2009a)).

Structures made-wholly from glass fibre-reinforced polymer (GFRP) can exhibit localized mode shapes (Zivanovic, et al., 2014). Consequently, their behavior deviates from that idealized. This deviation can originate from (1) manufacture: randomness in GFRP material properties associated with the fibre-matrix built-up (Bank, 1993), and; (2) fabrication: the connection methods of GFRP structural members (either bolted or adhesive). Consequently, model updating of GFRP structures using the single number of the MAC may not be optimal. Indeed, as will be seen, this issue was found in the recently-constructed Monash GFRP Footbridge (Ngan, et al., 2016). Therefore, an alternative to the MAC is needed for model updating of GFRP structures.

Since mode shapes are images, they can be classified based on its features of the shape represented. To this end, descriptors or indices can be used to indicating resemblance of features in the mode shapes. These shape descriptors can then be used to compare

mode shapes, simply by correlating paired shape descriptors. Since there are generally more than one shape descriptor for a given mode shape, mode shapes can be correlated using two or more descriptor terms, unlike the single index of the MAC. Consequently, this approach can reveal significantly more information about mode shape differences for model updating. Application of shape descriptors in model updating has been pioneered by Wang, Mottershead and their team (Wang, Mottershead & Mares 2009a, b, Wang, Mottershead, Ihle, et al, 2011, Wang, Mottershead, Sebestian, et al, 2011, Wang, et al, 2013)

The presented work is a model updating framework based on Tchebichef moment descriptors (TMDs) that was previously studied by Wang et al (2011). In this study, the model updating framework is proposed for model updating of GFRP structures. The work demonstrates the benefits of using the finer sensitivity of shape descriptors on a laboratory GFRP footbridge. This paper informs on the effectiveness of the proposed framework for GFRP structures.

2 MODEL UPDATING FRAMEWORK

Model updating is an iterative method which uses the sensitivity of model responses to each parameter in order to optimize model parameters. The method has been well-described by Friswell and Mottershead (Frisswell & Mottershead, 1995). The presented framework uses Tchebichef shape features i.e. TMDs to correlate mode shapes for updating.

2.1 *Tchebichef moment descriptors*

TMDs are derived from Tchebichef polynomials that inherit orthogonal properties (El-ghazai, et al., 2009) (Mukundan , et al., 2001). This property yields orthogonal shape features, which are highly efficient and advantageous in classifying mode shape features (Wang, et al., 2011) (El-ghazai, et al., 2009). The nth discrete Tchebichef polynomial, $t_n(x)$ up to order of N is defined as (Mukundan , et al., 2001):

$$t_n(x) = (1-N)_n \, {}_3F_2(-n,-x,1+n;1,1-N;1) \tag{1}$$

where x is the discrete pixel position in the x direction of a quadrilateral image; ${}_3F_2$ is the generalized hypergeometric function given as:

$${}_3F_2(a_1,a_2,a_3;b_1,b_2;z) = \sum_{k=0}^{\infty} \frac{(a_1)_k (a_2)_k (a_3)_k}{(b_1)_k (b_2)_k} \frac{z^k}{k!} \tag{2}$$

where $(a)_k$ is the Pochhammer symbol or rising factorial, k defined as:

$$(a)_k = a(a+1)(a+2)\cdots(a+k-1) \tag{3}$$

The Tchebichef polynomials of Equation (1) requires scaling because the value of $t_n(x)$ grows as N^n (Mukundan , et al., 2001). Therefore, a scaled Tchebichef polynomial is defined as

$$\tilde{t}_n(x) = \frac{t_n(x)}{\beta(n,N)} \tag{4}$$

where $\beta(n,N)$ is the scaling constant independent of x with definition outlined in (Mukundan , et al., 2001). The two-dimensional TMDs of an intensity function of a mode shape image, $f(x,y)$ can be obtained as the product of two discrete Tchebichef polynomial given by:

$$T_{nm} = \sum_{x=0}^{N_x-1} \sum_{y=0}^{N_y-1} \tilde{t}_n(x) \tilde{t}_m(y) f(x,y) \tag{5}$$

where N_x and N_y are the total number of image pixel in the x and y dimensions of the image in which the scaled Tchebichef polynomials is calculated, and n and m denote the Tchebichef polynomials of the x and y dimension respectively.

2.2 *Sensitivity Analysis*

In each iterative updating step, the sensitivities of the ith FE model outputs (e.g. TMDs and natural frequencies) $\mathbf{R}$, to changes in the jth FE model parameters, $\mathbf{P}$ (e.g. mass density, stiffness), are computed. For consistency of units between different parameters and outputs, a normalized sensitivity matrix is considered. The increment of parameters and difference in outputs are divided by the initial parameter values and initial outputs respectively. The normalized sensitivity matrix $\mathbf{S}$ (of dimension $i \times j$) is calculated for iteration k as (Frisswell & Mottershead, 1995):

$$\mathbf{S}_k = \left[S_{ij} \right] = \left[R_{ii} \right]^{-1} \left| \frac{\delta \mathbf{R}_i}{\delta \mathbf{P}_j} \right| \left[P_{jj} \right] \tag{6}$$

where $\delta\mathbf{R}$ is the difference in measureable outputs of the FE model due to an increment in model parameters $\delta\mathbf{P}$, for response i, and parameter j. R_{ii} and P_{jj} are diagonal, square matrix holding the initial output and parameter values respectively.

The iterative model updating function is based on the sensitivity matrix, and is given as (Anon., 2015)

$$\theta_{k+1} = \theta_k + \left[S_k^T S_k \right]^{-1} S_k^T \left(\mathbf{R}_m - \mathbf{R}_k \right) \tag{7}$$

where $\boldsymbol{\theta}_k$ and $\boldsymbol{\theta}_{k+1}$ are vectors containing the FE model parameters of the current and next iteration steps; $\mathbf{R}_m$ is the measured (target) metric and $\mathbf{R}_k$ is the output metric from the current iterative step. The final parameters are found when the Euclidian norm difference of the output metrics between increments is sufficiently small (taken here as < 1%)

$$\varepsilon = \left\| \frac{(\mathbf{R}_m - \mathbf{R}_k)}{\mathbf{R}_k} \right\| \leq 0.01 \tag{8}$$

The metrics $\mathbf{R}_m$ and $\mathbf{R}_k$ contains the TMDs and natural frequencies of the experimental and FE model respectively.

3 TEST STRUCTURE

The Monash University pultruded GFRP Footbridge is 9 m long and 1.5 m wide. It was constructed in 2016 for the study of human-induced vibration. The results of experimental modal analyses and numerical modelling details are given in this section.

3.1 *Description of footbridge*

The deck of the footbridge is a sandwich panel made from pultruded GFRP box sections incorporated between two GFRP flat sheets as shown in Figure 2. The orthotropic deck is supported on two pultruded FRP I-beam girders, spanning about 8.8 m. All components in the footbridge are joined together using adhesive bonding to ensure full composite action. No bolted connections or steel components are used. Bi-directional fibre orientations for flat sheets, box section and I-beam girders were adopted to maximize strength and stiffness in both transverse and longitudinal directions (Figure 2). The footbridge has a mass per unit length of 92.56 kg/m.

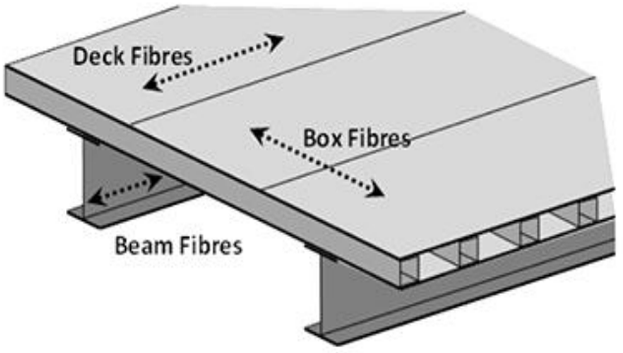

Figure 2. Fibre orientation of pultruded sections

3.2 *Experimental Modal Analysis*

Experimental modal analysis (EMA) was carried out to identify the modal properties of the footbridge. The footbridge was instrumented using 10 accelerometers (sensitivity of 10^4 mV/g) on measurement grids which are shown in Figure 3 and Figure 4.

The footbridge was excited using an electrodynamic APS 118 shaker (known as shaker test). The shaker was placed at the location shown in Figure 3 to ensure excitation of majority vibrational modes. Following this, a second EMA test was conducted using an impact hammer to excite the structure. A following roving hammer test was carried out by repeatedly hitting the hammer at each accelerometer position in Figure 4 while simultaneously acquiring responses. The acquired acceleration data was processed in MACEC (Reynders, et al., 2014), a well-known system identification program. Frequency response functions (FRFs) were obtained from the experimental data to extract natural frequencies and mode shapes of the footbridge.

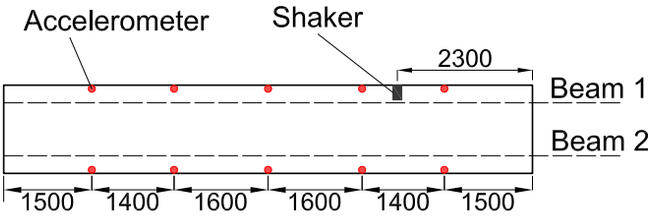

Figure 3. Measurement grid for shaker tests

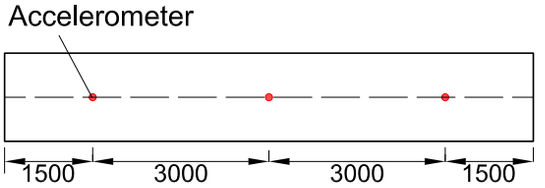

Figure 4. Measurement grid for impact hammer tests.

3.3 *Numerical Modelling*

An FE model of the footbridge was developed in LUSAS software. All components of the footbridge including flat panels, box sections, and bottom I-beam girders are modelled using 8-node quadrilateral shell elements (QTS8). This shell element has six degrees of freedom at each node: translation in nodal x, y, and z directions and also rotation about nodal x, y, and z axes.

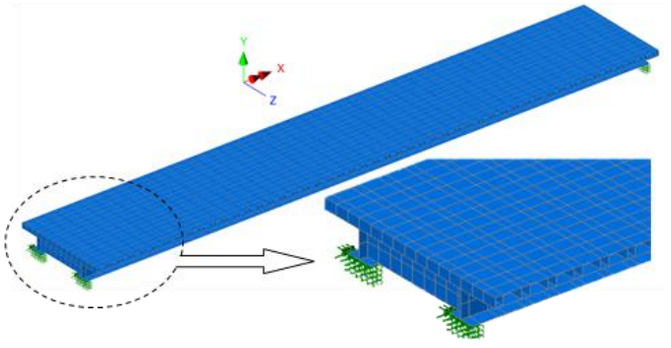

Figure 5. The 3-D FE model of the GFRP footbridge.

Orthotropic material properties for GFRP are incorporated in the FE model. The orthotropic shell elements in each respective component are orientated according to the fibre directions in the actual footbridge (Figure 2). Spring-supported boundary conditions are considered for the four load cells supporting each end of the I-beams. Left end supports are constrained in all three directions (x, y and z). At the right end, the support configuration allows free displacement in the longitudinal (x-axis) direction.

3.4 *Modal Results*

The modal properties identified from both shaker test and impact hammer test of the EMA are summarized in Table 1. Eigenvalue analysis is carried out to extract the modal properties i.e. natural frequencies and mode shapes of the first six modes of vibration from the FE model. The natural frequencies from the FE model and shaker test are summarized in Table 2, and the MAC values are given. The mode shapes from experimental and FE model are given in Figure 6 and Figure 7 respectively.

Table 1. Comparison between natural frequencies from shaker test and impact test.

	Natural Frequencies (Hz)		
Mode	Shaker Test	Hammer test	Difference (%)
1	5.86	6.17	5.3
2	10.02	-	-
3	18.14	19.60	8.1
4	20.60	-	-
5	25.60	-	-
6	37.54	38.30	2.0

Table 2. Summary of natural frequencies from shaker test and FE model.

	Experimental Shaker testing		FE model		
Mode	Nat. Freq.(Hz)	Damping ξ (%)	Nat. Freq. (Hz)	NFD[1] (%)	MAC
1	5.86	0.59	5.95	1.5	0.98
2	10.02	0.96	9.62	4.0	0.97
3	18.14	0.61	20.27	11.7	0.98
4	20.60	1.65	23.87	15.9	0.64
5	25.60	1.33	28.85	12.7	0.66
6	37.54	0.92	39.52	5.3	0.85

[1] Natural frequency difference

3.5 *Discussion*

From the results, it can be observed that the ordering of FE mode shapes is identical to the experimental mode shapes. This is expected since the footbridge is built to closely resemble the FE model; for example, with no additional railings and covers. Natural frequencies obtained from shaker tests are uniformly lower than from the hammer test.

The results suggest that the maximum displacements of the experimental mode shapes (shaded red in Figure 6) exhibit some localized features. Since the footbridge structure is globally symmetric, it is intuitive that the maximum displacement of the experimental mode shape should be symmetric. This is true in FE mode shapes (Figure 7). These observations are most likely explained by mass loading of the shaker. Since the shaker mass is relatively close to the mass of the footbridge (mass ratio of 1:17), it contributed mass to the vibrating system, possibly leading to the observed localization of the mode shape's peak.

To examine if the localized feature of mode shape is due to mass loading effect of the shaker, five experimental modal analyses were conducted. In each test, the shaker position was varied as shown in Figure 8. The first mode shape obtained for each test is overlaid in Figure 8. Shaker position 1 corresponds to the initial shaker position as given in Figure 3.

As can be seen in Figure 8, the peaks of most mode shapes (shaker positions 1 to 5) are localized, most notably towards the north edge of the footbridge. This feature, most notably for test positions 1 to 5, is most severe for positions 1 and 4. It is certainly likely that due to the bridge's light weight, the high relative mass of the shaker influences the vibrating system.

Interestingly, as the shaker is placed towards the south edge (location 5 and 6 in Figure 8) the localized effect reduces and eventually balances out at position 6. Seemingly, the shaker mass is balancing out some asymmetry of structural stiffness, since the mass of the overall system is constant for each test. Thus, it appears that there is a reduced longitudinal stiffness along the footbridge, most notably along beam 1 (Figure 3).

The MAC values for the modes of vibration are given in Table 2. As can be seen, the MAC for the first three modes suggest high consistency between the FE model and experimental results, with high MAC values (more than 0.9) despite the presence of the localized feature in mode shapes. This highlights the inability of the MAC to indicate the localized feature of mode shapes. As such, model updating procedures based on MAC would fail to capture the seeming reduced stiffness of beam 1, but would instead lead to a more global scaling that would improve MAC a little.

4 APPLICATION OF THE FRAMEWORK

The model updating framework outlined earlier is now carried out to improve the structural representation of the FE model, i.e. capture the reduced longitudinal stiffness and natural frequency prediction.

For the GFRP footbridge, accurate structural behavior representation from the FE model is needed for subsequent analysis, e.g. transient analysis. Furthermore, accurate representations of the first three modes of vibration are needed due to the characteristics of these natural frequencies to human walking. To give an example, the first natural frequency was found to coincide with the third harmonic of walking frequencies (Ngan, et al., 2016). Therefore, the model updating considers the dynamic properties of the first three modes of vibration. The mode shapes (TMDs) and natural frequencies are selected as the target output metrics of the updating process (i.e. $\mathbf{R}_m$ and $\mathbf{R}_k$ of Equation 7).

Two updating processes are conducted. (Denoted as Case 1 and Case 2). Each case considers different output metrics for updating. For Case 1 the updating only consider the mode shape's TMDs while Case 2 consider both TMDs and natural frequencies.

The model updating and TMD algorithm is carried out in MATLAB. A Visual Basic (VB) program was written to carry out inter-Object-Communication (COM) between MATLAB and the FE software, LUSAS. The key processes in this model updating are outlined in this section.

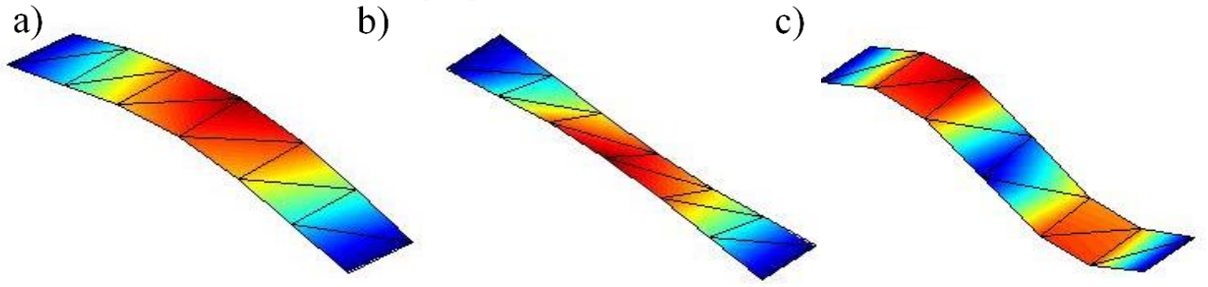

Figure 6. First three modes of vibration obtained from shaker test: (a) f = 5.86 Hz, (b) f = 10.02, (c) f = 18.14 Hz.

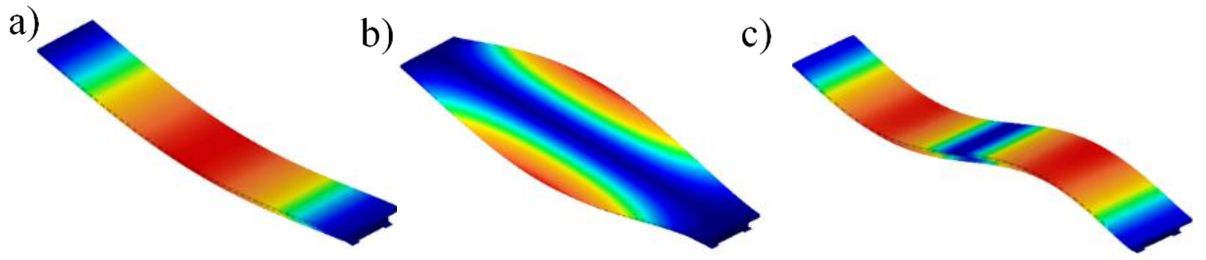

Figure 7. First three modes of vibration from FE model (a) f = 5.95 Hz, (b) f = 9.62 Hz, (c) f = 20.27 Hz.

4.1 *FE Model parameterization*

The results from the five experimental modal analyses suggest an imbalanced longitudinal stiffness that is balanced out by the mass loading of the shaker. Since the longitudinal stiffness is mainly contributed by the I-beam girders, the imbalanced stiffness must originate from properties related to the I-beams. Two possible explanations for this are: (1) poor bond quality between the I-beam girder and deck, resulting in a lack of composite action, or; (2) different material properties of the two longitudinal I-beams, perhaps due to different manufacturing runs of the sections. Both potential causes can be represented as a lowered elastic modulus for the affected beam; i.e. beam 1 in Figure 3.

To capture the effect of a differing elastic modulus of some of the GFRP components, the bridge is parameterized into three regions: the longitudinal elastic modulus of each I-beam (denoted as E_{beam1} and E_{beam2}), and the deck components (denoted as E_{deck}).

To correlate the shaker test results, the shaker mass is introduced in the FE model. A non-structural mass is implemented to represent the 52 kg shaker mass on the deck of the FE model similar to position 1 in Figure 8). The natural frequencies of the FE model after modelling of the shaker mass are summarized in Table 3 following the presentation of the updating results.

4.2 *Mode shape image interpolation*

In previous works (Wang, Mottershead, Ihle, et al 2011), full-field measurement of mode shapes are obtained through 3-D scanning vibrometers. Full-field measurements provide finer resolution of mode shape information compared to traditional spatially-discrete measurements from accelerometers. In turn, the use of TMDs on full-field mode shapes are more prevalent. Nevertheless, in this work only discrete measurements were taken at the grid points noted in Figure 3.

Due to the lack of full-field measurements, the full-field experimental mode shapes are interpolated from the discrete measurement points (accelerometers). This is conducted by first representing the pixels correspond to position of discrete measured points as the equivalent image intensity. Image intensity is represented by a greyscale with black (pixel value of 0) representing global minimum and white representing global maximum (pixel value of 1) of a mode shape. Then, the pixels of the remainder (un-measured region) of the mode shape image are obtained using spline interpolation of the discrete measured pixels, which preserves shape smoothness resulting in a continuous mode shape field. This is important for the comparison with FE mode shapes which are smooth continuous mode shapes generated from LUSAS.

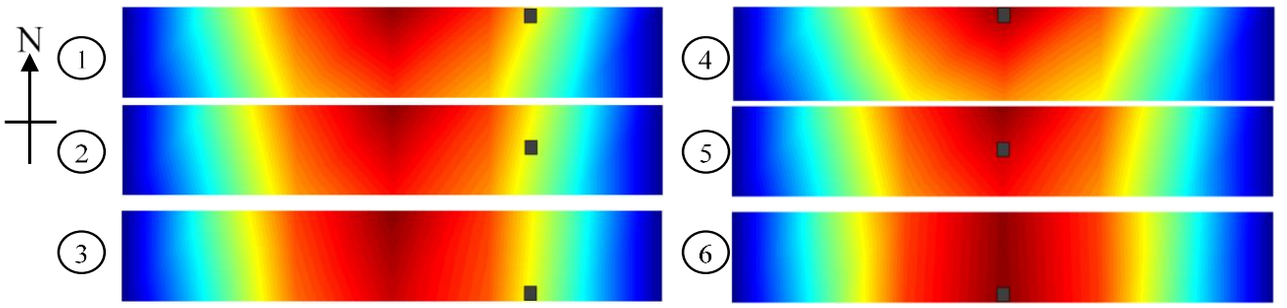

Figure 8. Top view of first vertical mode shape from EMA for each considered shaker position (Grey box denotes the shaker) (Not to scale). Position 1 was the initial shaker position.

4.3 *Tchebichef shape features of mode shapes*

To describe the features of mode shapes, top views of both FE and experimental mode shapes (similar to Figure 8) are obtained. These are then each decomposed into 30 Tchebichef moment descriptors. The first seven are shown in Figure 9

The TMD decomposition results, showing the magnitude of each TMD, for the first three FE mode shapes are given in Figure 10 as an example. As can be seen, several TMDs for each mode shape are significant. For example, mode 1 is predominantly the 6th Tchebichef feature (TMD 6 in Figure 9). More importantly, the localized feature of the modes can be detected through the TMDs, which is not possible using the MAC. Similar to Wang, Mottershead, Ihle, et al (2011), the dominant TMDs can be selected to perform model updating. In this study, the first six maximum TMDs are selected.

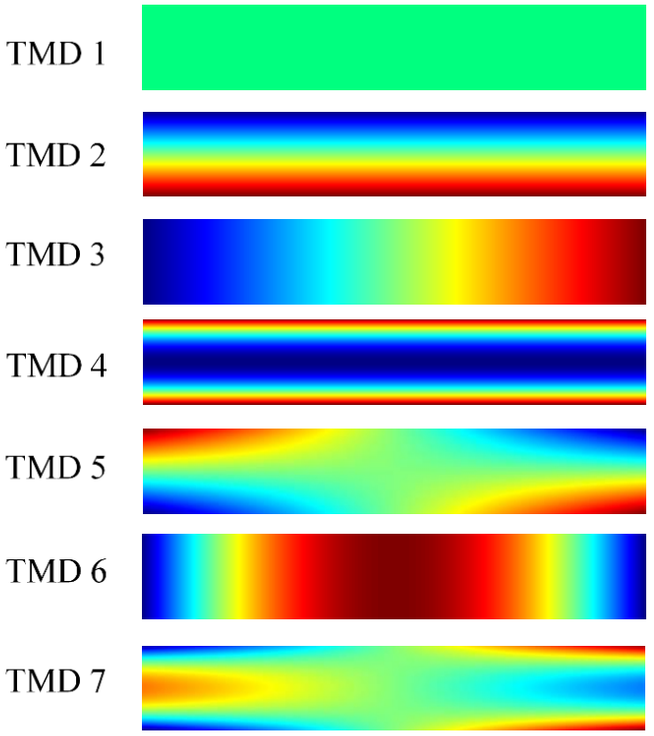

Figure 9. Example Tchebichef Moment Descriptors.

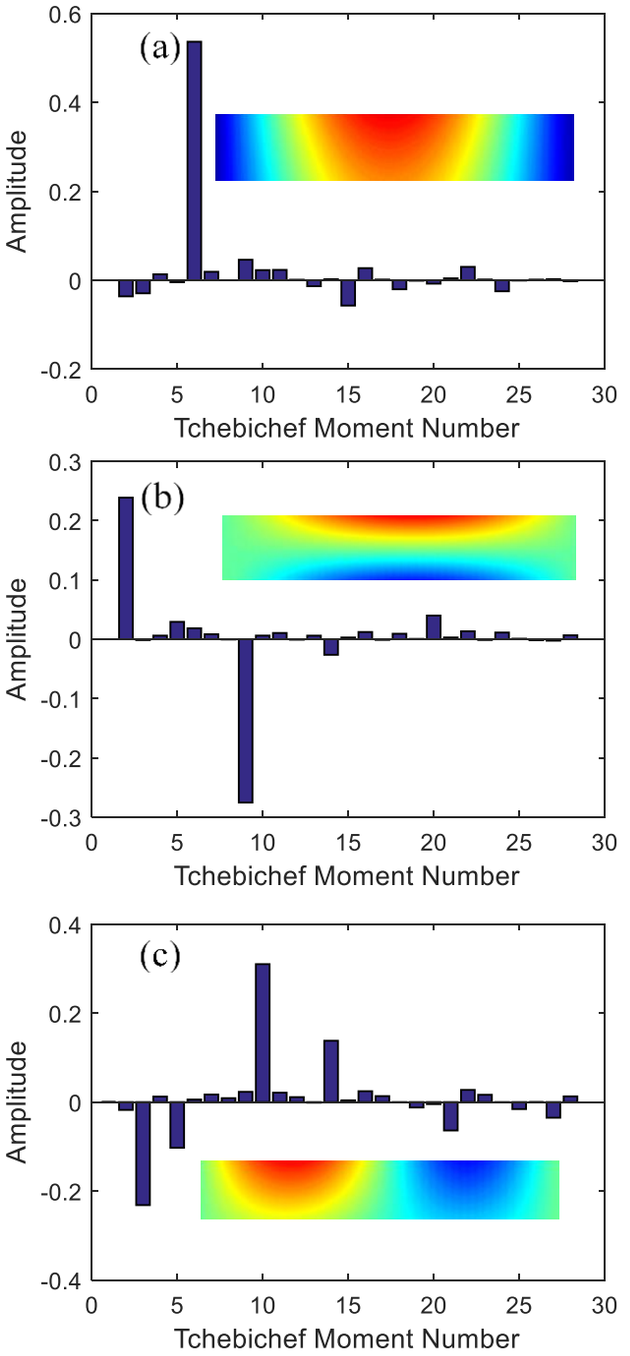

Figure 10. TMDs of FE mode shapes: a) first b) second and c) third mode.

It should be noted that the magnitudes of TMDs between experimental and FE mode shapes are different. This is because mode shapes are generated from different source, i.e. FE mode shapes from LUSAS

and the experimental mode shapes from MATLAB have different image intensity and size. To resolve this for comparison in model updating, the TMD amplitudes from each source are normalized (Wang, Mottershead, Ihle, et al 2011).

4.4 *Validation of framework*

To validate the model updating framework, a simulated model updating is conducted. The simulated updating aims to reproduce a known reduced stiffness by pre-defining a lowered elastic modulus for the model parameters. For this, a set of TMDs (similar to Figure 10) were obtained using values for parameters E_{beam1} and E_{beam2} as 15 GPa and 24 GPa respectively. The starting values of parameters E_{beam1} and E_{beam2} are 22 GPa and 24 GPa respectively. The parameter updating histories of the simulated updating is shown in Figure 11. It is observed that the parameter converges to the prescribed solutions within eight iterations. Consequently, the proposed model updating framework is verified as being applicable for the closely-related experimental specimen.

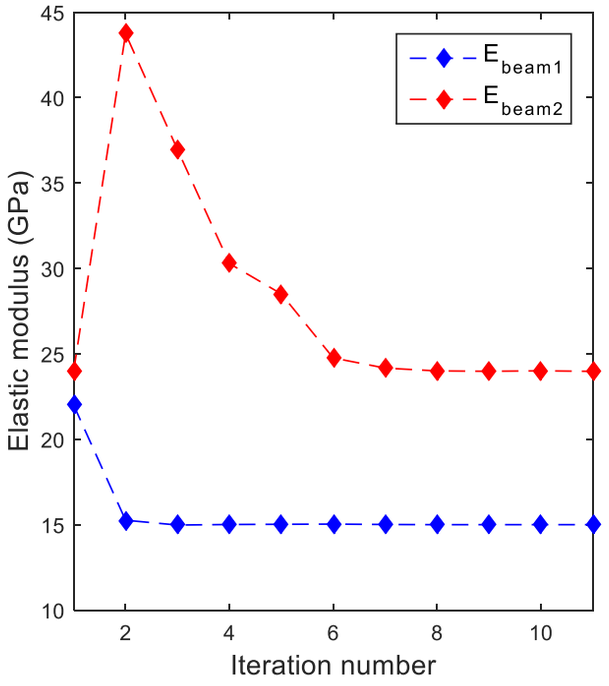

Figure 11. Model parameter updating history - simulated case.

5 RESULTS AND DISCUSSION

The results of the two model updating cases as mentioned previously are given. In both cases, the starting values for E_{beam1} and E_{beam2} are 22 GPa and 24 GPa respectively.

For Case 1 (using TMDs only), the parameter updating histories is shown in Figure 12. The parameters E_{beam1} and E_{beam2} converged to values of 20.3 GPa and 25.9 GPa respectively.

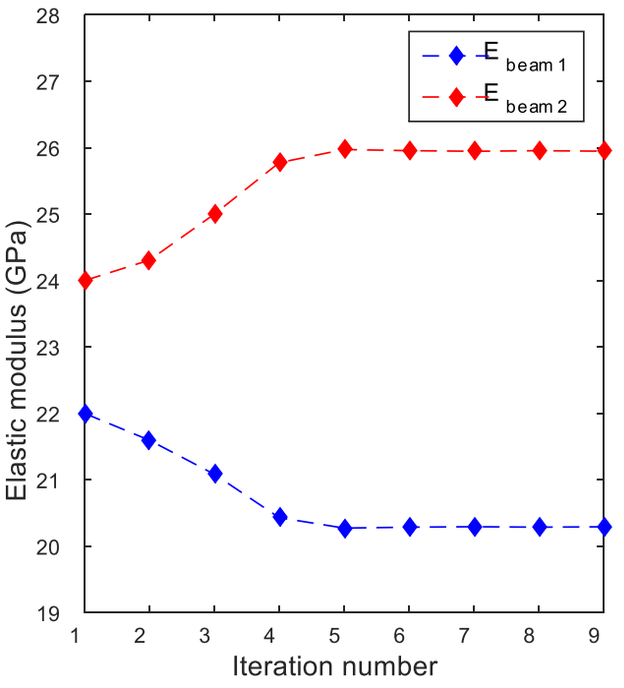

Figure 12. Parameter updating history of Case 1

For Case 2 (using both natural frequencies and TMDs), the parameter updating histories are shown in Figure 13. The values of parameters E_{beam1} and E_{beam2} converged to 30.6 GPa and 42.5 GPa respectively.

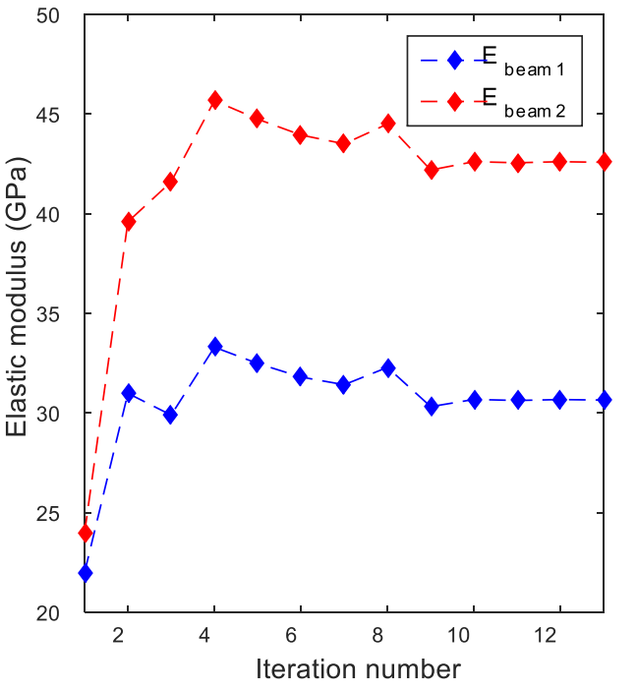

Figure 13. Parameter updating history of Case 2

5.1 *Comparison of Updated FE models*

The natural frequencies extracted from the updated models of both cases are summarized in Table 3. The results show that the updated model from Case 2 gives better natural frequency prediction than Case 1. This is intuitive since natural frequencies are included in the model updating objective. However, the changes in parameter values of Case 2 are physically

not meaningful. The variation of parameters E_{beam1} and E_{beam2} are too significant and are beyond physical range of GFRP material properties (i.e. ±20% from Ye, et al (1995)). This suggests possible modelling uncertainties in the FE model which are not considered in the model updating. Consequently, the values of parameters E_{beam1} and E_{beam2} are updated to physically non-meaningful values to compensate for natural frequencies objectives.

Table 3. Comparison of natural frequencies

		FE model	Updated FE model	
Mode	Experimental	Initial[1]	Case 1	Case 2
1	5.86	5.29	5.35	5.99
2	10.02	9.23	9.28	9.71
3	18.14	16.68	16.85	18.81
4	20.60	20.83	21.02	22.71
5	25.60	23.99	24.17	25.78

1: After shaker mass incorporated

Indeed, the results from Case 1 and 2 indicate a reduced longitudinal stiffness which can be caused by several factors such as imperfect bonding connection or GFRP material properties. Despite the exclusion of natural frequencies in Case 1, the model updating nonetheless improves the structural representation of the FE model.

6 CONCLUSION

This paper considers a model updating framework which correlates mode shape features using TMDs. The TMDs can discriminate shape features of the mode shapes, most notably localized shape features that is not possible using a traditional scalar indicator, i.e. the MAC. The experimental results of the GFRP footbridge suggest the existence of reduced stiffness of the I-beam girders. Consequently, this results in localized mode shapes in the footbridge. The proposed model updating framework is implemented to improve the natural frequency correlation and structural behavior representation of the FE model, i.e. reduced structural stiffness.

Full-field measurements give two-dimensional mode shape information at a fine resolution. As such, the TMDs from full-field mode shapes are more prevalent. However, in this study, approximated mode shapes are used in place of full-field measurements. A useful outcome of this work is that TMDs coupled with approximated mode shape measurements provide superior information to traditional scalar mode shape estimators (e.g. the MAC). The updating results show that the suggested model updating framework can update the FE models in a meaningful way using approximated mode shapes. Further work should be carried out to investigate the performance of the model updating framework on approximated mode shape against full-field measurements. Nonetheless, it is instructive that the updating results show the capability of the TMD-based model updating to be an improvement on traditional model updating processes for GFRP structures. As such, this form of model updating should find good use in examining GFRP structures in the field.

Vibration Serviceability Assessment of a Multi-Span Footbridge

J.W. Ngan, C. Caprani
Department of Civil engineering, Monash University, Melbourne Australia

A. de Lacy
WSP Australia Pty Limited

ABSTRACT: Footbridge designs are becoming ever more innovative and creative. This can result in footbridges with structural forms that are complicated and slender, and so potentially lively. Serviceability problems due to excessive vibrations have been reported in many recent footbridges. Further, current vibration serviceability approaches can be overly-conservative resulting in unattractive changes to designs. This paper evaluates the vibration serviceability of a multi-span footbridge (denoted as NB Bridge) using a novel approach. The NB Bridge is modelled as a 1-D beam model using finite elements (FE) method. This model is calibrated against a complete 3-D structural model of the bridge using model updating techniques. Moving loads are applied to the bridge model to simulate crossing of random (1) single pedestrian, and (2) pedestrian crowds. Vibration serviceability is evaluated using current guidelines, namely the European Guideline HiVoss (2008) and French Guideline Setra (2006), both of which are commonly applied in practice. This paper therefore illustrates this 1-D finite element beam modelling approach for vibration serviceability assessment of footbridges with similar complexity.

1 INTRODUCTION

1.1 *Background*

The advancement of engineering technology and greater understanding of construction materials have led to footbridges that are longer, lighter, and more aesthetically pleasing. Some of these footbridges can be quite slender, potentially leading to serviceability problems due to excessive vibrations. This usually occurs when the natural frequencies of the structure are within harmonic range of pedestrian pacing frequencies. Moreover, vibrations can be further amplified when large crowds crossing the structure are in sync with one another. Over the last decade or so, numerous vibration serviceability problems in footbridges have been reported, including some well-known cases such as the Millennium Bridge, London (Dallard, et al., 2001), the T-bridge, Japan (Fujino , et al., 1993) and the Pont du Solferino, Paris (Danbon & Grillaud, 2005). For most footbridges with vibration serviceability problems, pedestrian loads are usually the main source of loading leading to vibrations. Consequently, this has drawn much research attention on developing reliable techniques to better predict human-induced vibrations in footbridges.

To predict human-induced vibrations, dynamic forces of pedestrians can be modelled analytically as time-varying forces acting on footbridges (Živanović, et al., 2005). This state-of-the-practice approach has been commonly adopted and has received much research attention. Consequently, design guidelines and codes have also adopted the moving force approach to define design procedures (Caprani & Ahmadi, 2016). For example, this approach has been adopted in the European guideline HiVoss (2008) and French guideline Setra (2006). However, there is lack of moving force validation for different footbridge designs, particularly for new innovative footbridge designs. As a result, current guidelines may result in overly conservative vibration predictions. This may result in unattractive footbridge design changes or costly vibration control solutions to satisfy vibration serviceability needs. With increasing pressure for more aesthetically pleasing footbridges, the need to understand the applicability of the moving force approach for vibration serviceability of innovative footbridge designs is becoming increasingly important. However, works to update this knowledge are still limited. This is important for the vibration assessment of new footbridges, particularly for landmark bridges.

The work presented here evaluates the vibration serviceability of a proposed multi-span footbridge (denoted the NB Bridge) using a combined approach. The work is based on a finite element moving force modelling approach, and uses model updating to facilitate the use of a simple beam model of the structure. The work here is instructive for the performance of the current state-of-the-art on vibration serviceability for different footbridges and crowd considerations.

1.2 *The NB Bridge Structure*

The NB Bridge is a 270 m long cable-stayed footbridge (Figure 2). The superstructure of the bridge is a concrete-steel composite deck supported by steel girders on each side. The bridge has three spans: two cable-supported spans and a middle span between the mid-river piers. The longest cable-stayed span has a length of 126 m and is supported by 5 cables as shown in Figure 2a.The width of the bridge deck is 5 m and

widens at the middle span from 5 m to 15 m (Figure 2). The deck of the NB Bridge has a mass of 4150 kg/m for the narrower deck and 10240 kg/m for the wider deck. The calculated bending stiffness, *EI* of the composite section for the 5 m width deck is 1.248×10^{10} N m^2.

2 NUMERICAL MODELLING

2.1 *Basis*

The complex form of the NB Bridge (Figure 2) needs a three-dimensional (3-D) finite element model to accurately capture the global behavior, incorporating cable pre-stress and mast structure for example. This model is developed in commercial FE software, which does not have the capability to represent moving force crowd models. For this, an in-house 1-D beam model is used with the moving force crowd model. The key challenge then, is to replicate the dynamic behavior of the full 3-D model within the 1-D beam model. This challenge is met using model updating to match natural frequencies and mode shapes between the models by tuning key parameters of the 1-D beam model. By doing so, the complexity of the 3-D model is then inherent in the 1-D beam model.

It is acknowledge that some commercial FE software has the capability to export FE model properties into a general format which can be used by other FE software, avoiding the need for the model updating process. However, to date, the in-house 1-D beam model is yet to have the capability to utilize general formats of FE models from other software. Therefore, the aforementioned model updating approach is adopted in this study.

2.2 *3-D Finite Element Model*

Figure 1 shows the 3-D model of the NB Bridge. The deck is modelled using 1-D beam elements with end releases and offsets as appropriate to reflect the intended deck cross-sections. 2-D shell elements are considered across the deck to model the stiffness associated with the concrete deck. Mast structure is modelled using 1-D beam elements of tapering cross-sections. The cables are modelled as linear-elastic 1-D beam elements of equivalent axial stiffness anchored at both sides of the deck. The mass of the 3-D model reflects the self-weight, super-imposed dead loads, and a reduced live load equivalent to a pedestrian density of 0.5 ped/m^2.

2.3 *Initial 1-D Finite Element Beam Model*

In the in-house 1-D beam model, the deck of the NB Bridge is modelled using 141 Euler-Bernoulli beam elements which have Hermitian interpolation shape functions and two degrees-of-freedom per node (vertical translation and rotational about node). Nodes of the 1-D beam model are located at feature points (bridge points in Figure 2a). The element sizes are approximately 2 m, spaced evenly between the feature points. The mast piers (blue lines in Figure 2) of the NB Bridge are not considered in the 1-D beam model, but their effects are implicitly included by the model calibration. The beam model has lumped mass assumed. Equivalent beam properties (bending stiffness and mass) are implemented to define the mass and stiffness matrices of the beam elements.

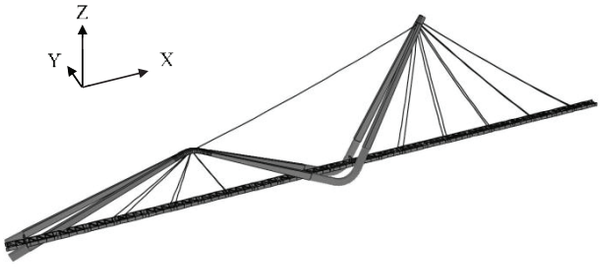

Figure 1. 3-D FE model of the NB Bridge.

The cable supports are modelled as additional vertical spring stiffness at corresponding vertical nodal degree-of-freedoms in the beam model (Figure 2). This additional stiffness is a representative surrogate to model the effect of the cables in the 1-D beam model. Modelling of cable support stiffness is initially taken as 1×10^6 N/m for all cables. The damping ratio of the NB Bridge is taken as 0.5% for the first two modes, this is based on bridge damping ratios reviewed by Heinemayer et al. (2009) for footbridges with similar complexity. Rayleigh damping is assumed thereafter to obtain the damping matrix.

2.4 *Single pedestrian Modelling*

Pedestrian induced forces are represented by the moving force model which is a periodic force represented by a Fourier series (Bachmann, et al., 1995):

$$G(t) = W \sum_{k=0}^{r} \eta_k \cos(2\pi k f_p + \varphi_k) \quad (1)$$

where $W = m_p g$, m_p is the mass of pedestrian, f_p is the pacing frequency, r is the number of harmonics, η_k and ϕ_k are the dynamic load factor (DLF) and phase angle respectively. Reasonably, it is assumed that the moving pedestrian force maintains contact with the beam surface throughout the crossing (i.e. continuous contact force). The number of harmonics, DLFs and phase properties varies between different authors.

This work considers Young's DLFs for up to four contributing harmonics (Young, 2001). The phase angle for each harmonic is taken as uniformly random in the interval 0 - 2π.

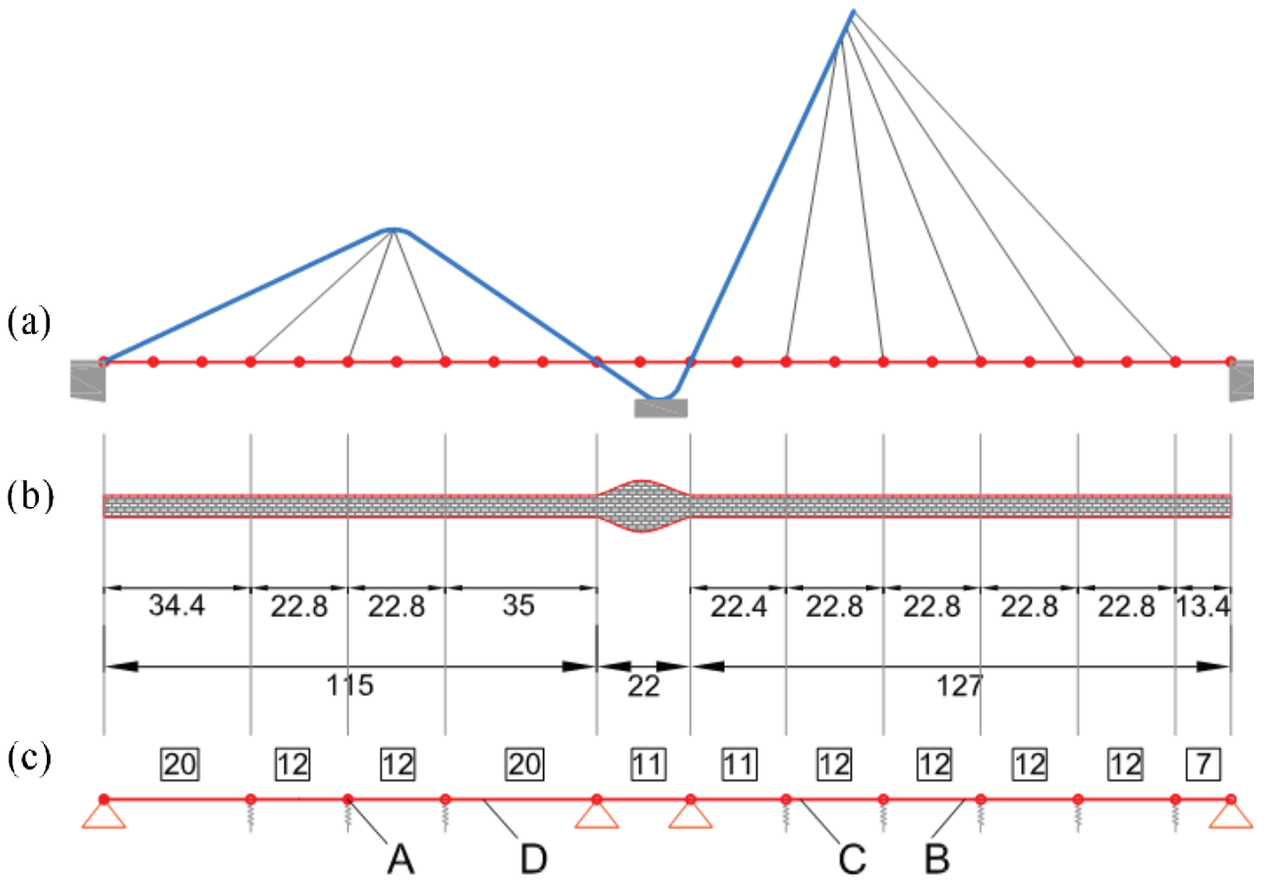

Figure 2. The NB Bridge: (a) elevation, showing points used for defining the mode shapes from the 3-D model (red dots); (b) plan view of deck, with key dimensions; (c) 1-D finite element beam model showing rigid supports and cable spring stiffness supports along with the number of Euler-Bernoulli elements used in each sub-section in boxes.

As a constant pedestrian velocity, v is assumed, the position of the moving pedestrian force at time t in Equation (1) is distributed to adjacent nodes of beam elements according to a global shape function. As will be required later, the global shape function is given with respect to velocity and time:

$$\mathbf{N}(vt) = \{0_{1\times4} \ldots \mathbf{N}^j(vt) \ldots 0_{1\times4}\} \tag{2}$$

where $\mathbf{N}^j$ is the Hermite shape function for the jth element for which the pedestrian force is located (Caprani & Ahmadi, 2016). When the pedestrian moves off the structure, this shape function becomes zero. The equations of motion are therefore written as:

$$\mathbf{M}\ddot{\mathbf{d}} + \mathbf{C}\dot{\mathbf{d}} + \mathbf{K}\mathbf{d} = \mathbf{N}^T(vt)G(t) \tag{3}$$

where $\mathbf{d}$, $\dot{\mathbf{d}}$ and $\ddot{\mathbf{d}}$ are the vectors of displacement, velocity, and acceleration; $\mathbf{M}$, $\mathbf{C}$, $\mathbf{K}$ are the mass, damping, and stiffness matrices of the beam model respectively. Transient solutions from equation (3) are obtained using Newmark-β integration.

In this work, random characteristics for pedestrians are generated using different distributions for pedestrian walking parameters. Pedestrian's pacing frequency, f_p is considered as normally distributed with mean and standard deviation of 1.96 Hz and 0.21 Hz respectively (within normal range of walking frequencies of 1.8 – 2.2 Hz (Živanović, et al., 2005)). The pedestrian mass, m_p is represented by a log-normal distribution with mean and standard deviation of 73.85 kg and 15.68 kg respectively (Portier, et al., 2007). The step length is taken to be normally distributed with mean and standard deviation of 0.66 m (Barela & Duarte, 2008) and 0.066 m (coefficient of variation of 10%) (Caprani, et al., 2012). Pedestrian velocity, v is obtained from the product of step length and pacing frequency.

Worth noting, is that the moving force model does not consider any mass or stiffness interaction between moving pedestrian and bridge structure (Živanović, et al., 2005; Caprani, et al., 2012).

2.5 *Crowd Modelling*

The forces on the NB Bridge due to a crowd at any point in time is taken as the superposition of individual pedestrian forces from Equation (1). The equation of motion of a crowd loading is simply an extension of Equation (2), considering the forces imparted by each pedestrian:

$$\mathbf{M}\ddot{\mathbf{d}} + \mathbf{C}\dot{\mathbf{d}} + \mathbf{K}\mathbf{d} = \sum_{i=1}^{n} \mathbf{N}_i^T(v_i t)G_i(t) \tag{4}$$

in which $\mathbf{N}_i(v_i t)$ is the global shape function vector calculated for the position of ith pedestrian at time t. Other variables are as defined previously.

The characteristics of each pedestrian in the crowd are generated as described previously. Different crowd densities have been considered in the literature (Bachmann & Ammann, 1987). A crowd density of 0.5 ped/m^2 (following Setra (2006)) is considered to represent a medium crowding scenario. The total number of pedestrians in the crowd is calculated by taking products of crowd density with crowd length and width. The crowd length and width are taken as 500 m and 5 m respectively, so that the bridge will be wholly covered for a time, even allowing for random walking speeds. This corresponds to 1250 pedestrians in total. An exponential distribution with mean of 0.56 m is used to describe the intervals of pedestrian arrival (Caprani, et al., 2012). The velocity of each pedestrian is determined from their individual step length and pacing frequencies. In this simulation, pedestrians with different velocities are free to overtake each other. Crowd synchronization effects (i.e. instances where two or more pedestrians have the same pacing frequency) is considered in the crowd modelling, similar to Colin & Ahmadi (2016). For this work, a synchronization level of 20% (following Fujino et al. (1993)) is considered for all crowd simulations, (i.e. at most 20% of pedestrian forces on the bridge model at any time instance will have their pacing frequencies be in-sync).

3 MODEL CALIBRATION PROCEDURE

As noted earlier, the dynamic properties of the NB Bridge from the 1-D beam model are calibrated against those obtained from a full three-dimensional finite element model of the NB Bridge (referred to as 3-D model). Specifically, the natural frequencies and mode shapes are matched to those of the 3-D model. For comparison of mode shapes, the mode shape vertical displacements from the 3-D model are extracted at positions along the centerline of the deck, identified as red points in Figure 2a. It is acknowledged that use of even a calibrated 1-D modelling app roach retains yet some approximations. Nevertheless, once a reasonably conservative serviceability criterion is adopted, the results are meaningful for a crowd vibration serviceability assessment.

3.1 *Initial dynamic properties*

Figure 3 shows the dynamic properties i.e. natural frequencies and mode shapes of the first four modes of vibration from the initial 1-D beam model and 3-D model with the mode shapes overlaid on each other. Interestingly the sequence of mode shapes are in good agreement with those of the 3-D model. However, large differences in natural frequencies are observed, with the 1-D beam model under-predicting the natural frequencies. Further, mode shape displacements are not well-correlated for some modes. The Modal Assurance Criterion (MAC) (Allemang & Brown, 1982) is calculated for the mode shapes and are summarized in Table 2 following the calibration procedure.

The large errors in dynamic properties from the initial 1-D model are expected of course, and due to the unknown spring stiffnesses required to match the effects of the cables, pre-stress, and mast behaviors. Initially, the uniform spring stiffness value (1×10^6 N/m) defined for all cable supports clearly needs to be updated to properly capture the 3-D model behavior.

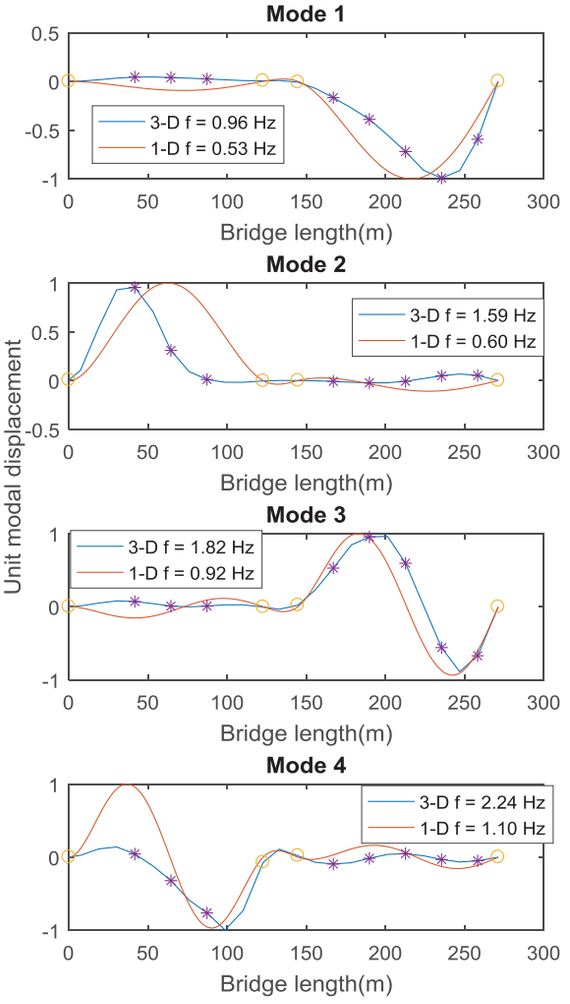

Figure 3. Comparison of modal properties from Initial 1-D beam model and 3-D beam model (* denote cable supports, o denote pier supports).

3.2 *Model updating*

The large difference between dynamic properties from both models are reconciled through finite element model updating (Frisswell & Mottershead, 1995). In structural dynamics, model updating is an iterative method which uses the sensitivity of model responses to each parameter to optimize model parameters until a good agreement of dynamic (modal) properties is achieved. Model updating procedures

have been well-described by Friswell and Mottershead (Frisswell & Mottershead, 1995) and can be found summarized in past papers (Živanović, et al., 2007). Therefore, details on model updating are not outlined in this paper.

In each iterative updating step, the sensitivities of the *i*th FE model outputs, **R**, to changes in the *j*th input parameters, **P** (e.g. mode shape, and natural frequencies), are computed. For consistency of units between different parameters and outputs, a normalized sensitivity matrix is considered. The normalized sensitivity matrix **S** (of dimension $i \times j$) is calculated for iteration k as (Frisswell & Mottershead, 1995):

$$\mathbf{S}_k = \left[S_{ij}\right] = \left[R_{ii}\right]^{-1} \left[\frac{\delta \mathbf{R}_i}{\delta \mathbf{P}_j}\right] \left[P_{jj}\right] \tag{5}$$

where $\delta\mathbf{R}$ is the difference in measureable outputs of the FE model due to an increment in model parameters $\delta\mathbf{P}$, for response i, and parameter j. R_{ii} and P_{jj} are diagonal, square matrix holding the initial output and parameter values respectively.

For this work, the 1-D beam model is updated using the dynamic properties of the first four modes of vibration. The dynamic properties i.e. natural frequencies and mode shapes (MAC) from the 3-D model are taken as the target properties for updating. The 8 cable spring stiffness in the 1-D beam model are selected to be optimize during the updating process.

3.3 *Updated dynamic properties*

The updated cable stiffness are given in Table 1. The modal properties of the updated 1-D beam model are given in Table 2, along with a comparison to those of the initial 1-D beam model and 3-D model.

Table 1. Spring stiffness parameter changes.

Cable	Initial ($\times 10^6$ N/m)	Updated ($\times 10^6$ N/m)
1	1	9.18
2	1	11.8
3	1	34.5
4	1	21.0
5	1	11.9
6	1	4.56
7	1	2.49
8	1	16.3

The results show that the updated 1-D beam model overall produce improved natural frequencies, in good agreement with the natural frequencies from the 3-D model. The MAC values improved significantly (> 0.9) from the initial model, showing that the updated 1-D beam model produces quite accurate mode shapes (compared to the 3-D model). From Figure 4, it is evident that the mode shapes are in far better agreement than the initial 1-D beam model. As such, the model updating procedure is demonstrated to be feasible for tuning a 1-D model to represent more complex 3-D behavior, at least in one direction, as is considered for this work (vertical).

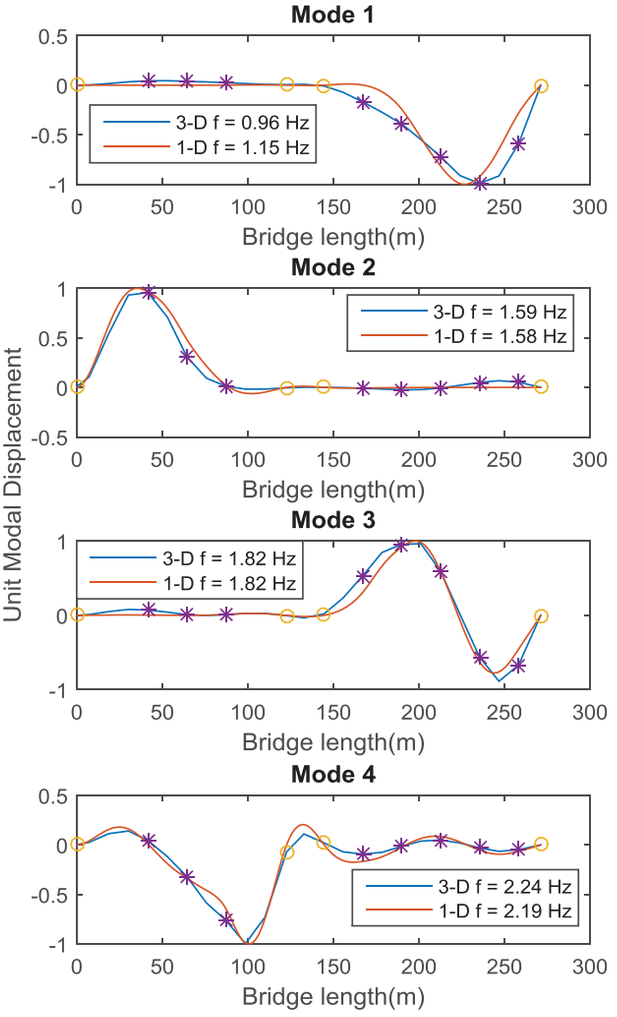

Figure 4. Comparison of modal properties from Updated 1-D beam model and 3-D beam model (* denote cable supports, o denote pier supports).

Table 2. Comparison of natural frequencies from models.

	3-D	Initial 1-D			Updated 1-D		
Mode	Hz	Hz	NFD %	MAC	Hz	NFD %	MAC
1	0.96	0.53	44.8	0.86	1.15	-19.8	0.96
2	1.59	0.60	62.2	0.49	1.58	0.6	0.99
3	1.82	0.92	49.5	0.79	1.82	0.0	0.96
4	2.24	1.10	50.9	0.48	2.19	2.2	0.95
5	2.31	1.71	26.0	0.86	2.25	2.6	0.94
6	2.71	1.98	26.9	0.84	2.50	7.7	0.96
7	3.20	2.86	10.6	0.93	3.45	-7.8	0.95
8	3.52	3.22	8.5	0.94	3.54	-0.5	0.93
9	4.49	4.32	3.8	0.81	4.63	-3.1	0.84
10	5.44	4.83	11.2	0.74	5.32	2.2	0.74

NFD%: Natural frequency difference.

From Table 2, the first updated natural frequency error is found to be outstanding (10% greater than all other natural frequency difference), suggesting that tuning vertical spring stiffnesses may be insufficient to match this natural frequency. This also suggest that

there are other parameters in the 3-D model that influences the first mode, which could not be considered in the 1-D beam model. Such parameters can be related to mast pier effect for example. Nevertheless, this error is justifiable since the first natural frequency is less likely to result significant resonance from pedestrians (i.e. not within range of walking frequencies).

4 VIBRATION SERVICEABILITY ASSESSMENT

Following the calibration process, the moving force analysis is performed on the updated 1-D beam model to obtain vibration responses due to single pedestrian and crowds, modelled as described earlier.

4.1 *Considered vibration responses*

Acceleration responses are the common measures for vibration responses. In this work, only the vertical acceleration responses is of interest. This is taken as the 1-s root-mean-squared (RMS) acceleration of the 1-D beam model. The metric for any particular scenario (single pedestrian or crowd) is taken as the maximum 1-s RMS value of that response over the duration of the scenario. Four locations of this response are considered, as given in Table 3.

The selection of output locations is justified as follows. Clearly, the accelerations at the mid-spans of the two cable spans are relevant (points A and B in Figure 2c). Two more points are considered also though. Several modes of vibration from the 1-D beam model, most notably modes 3 and 4 coincide with normal range of walking frequencies (1.8- 2.2 Hz). This suggests that pedestrian walking may have a significant resonance at these modes. Therefore, the locations of the maximum modal ordinates of modes 3 and 4 are also selected (C and D in Figure 2c).

Table 3. Considered vibration response locations.

Point	Description
A	Mid-span of left cable supported span
B	Mid-span of right cable supported span
C	Maximum modal displacement of mode 3
D	Maximum modal displacement of mode 4

4.2 *Evaluation of vibration serviceability*

Maximum acceleration limits are recommended in codes and design guidelines. The predicted vibration responses of the NB Bridge are evaluated against those of the European guideline HiVoss (2008) and French Setra (2006) guideline. For structures with first natural frequency less than 5 Hz, the acceleration limits for maximum and mean comfort level are 0.5 m/s^2 and 1 m/s^2 respectively.

4.3 *Random Single Pedestrian Response*

Figure 5 illustrates the acceleration time history at point A of the NB Bridge to a single pedestrian traversing the structure. A total of 1000 single pedestrian simulations are conducted using the random characteristics mentioned previously. The distributions of the 1000 maximum RMS responses for the four points of interest are given in Figure 7. The characteristic responses are defined as the 95 percentile value of the distributions and are also given in Figure 7.

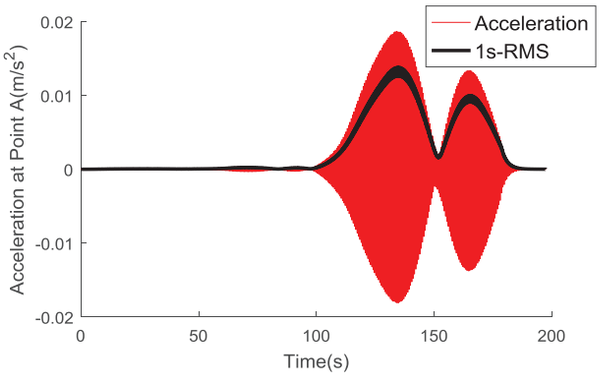

Figure 5. Acceleration time history and 1-s RMS at point A for bridge subjected to a single pedestrian.

4.4 *Random Crowd Loading Response*

A total of 100 crowd simulations are performed. Each of the 1250 pedestrians in a crowd are generated with random crowd characteristics. Figure 6 shows the acceleration time response history of the NB Bridge at Point A for a sample random crowd. The distributions of the 100 maximum RMS responses for all four points considered are also given in Figure 8. Also shown again are the 95 percentile values of the distribution, along with the mean and maximum comfort limits earlier.

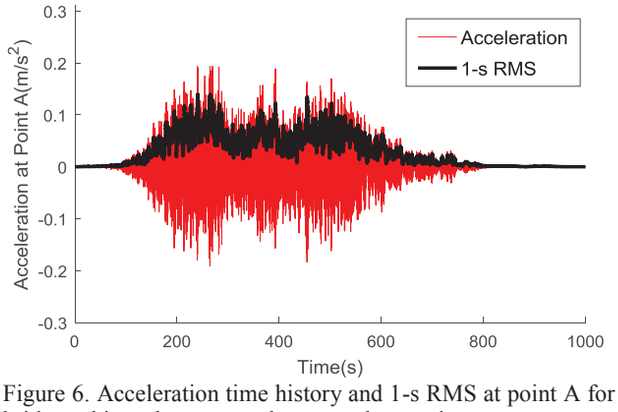

Figure 6. Acceleration time history and 1-s RMS at point A for bridge subjected to one random crowd scenario.

4.5 *Discussion*

From the preceding results, it is clear that for single pedestrians, the characteristic responses are well below the limit for maximum comfort. Of note, Point A

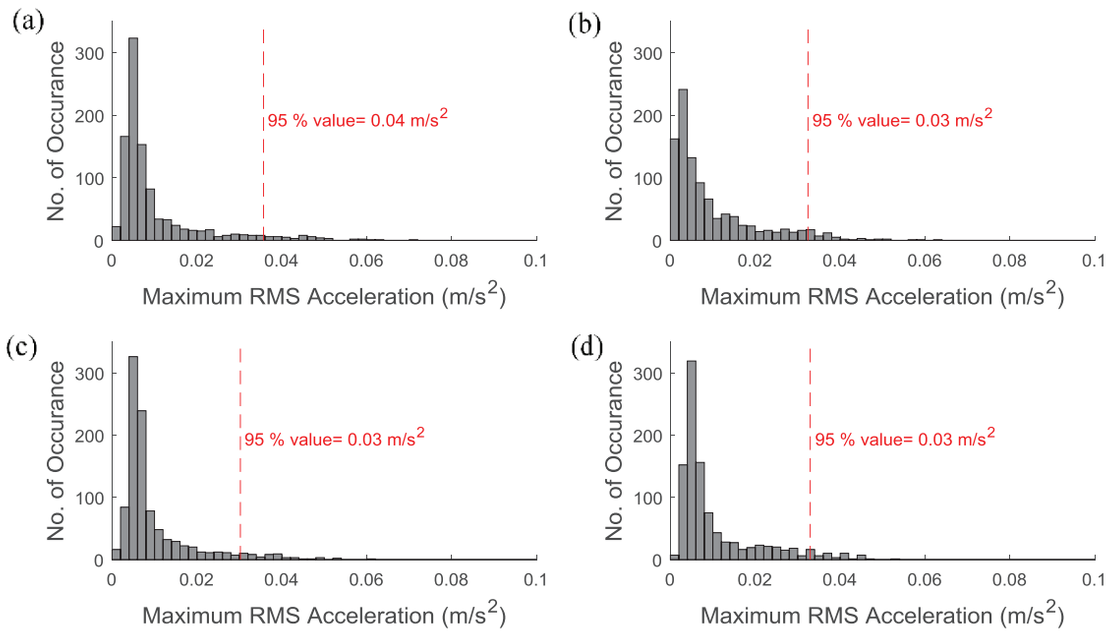

Figure 7. Histograms of 1-s RMS acceleration responses under random single pedestrians at: a) Point A; b) Point B; c) Point C, and; d) Point D.

has the highest characteristic response for single pedestrians. In contrast to the single pedestrian results, for the random crowds, Point B is found to have the highest response. It is interesting that the histogram of responses for Point B has two peaks (bi-modal distribution), suggesting that there exists a loading topology that offers a severe response. This seems to occur mainly when the maximum crowd density is located fully along the span, along with a maximum number of synchronized pedestrians. All single pedestrian responses are well below maximum comfort limit. Similarly, the characteristic crowd responses for points A and C. The critical responses occur for points B and D, with characteristic responses being between the maximum and mean comfort levels. Interesting one crowd response was above mean comfort level for Point B.

Notably, the critical response locations under crowd loading are not readily identified using the single pedestrian results (Point A), nor just by identifying the maximum span (Point B). Instead, the dynamic behavior (frequency of mode 4 leading to Point D) should also be considered when assessing likely critical response locations

5 SUMMARY & CONCLUSIONS

5.1 *Summary*

This work proposes a methodology to assess the vibration serviceability of a bridge with complex form using state-of-the-art crowd modelling. A calibrated 1-D modelling approach of the NB Bridge is considered to allow efficient simulations of pedestrian crowd crossings. The dynamic properties of the NB Bridge from the 1-D beam model are calibrated against those from a full 3-D model using model updating. Following the calibration, the simulations of pedestrian crossing are conducted using moving force models. Moving force model is applied onto the 1-D beam model to simulate random single pedestrians and random crowd loading. Maximum RMS acceleration responses along key locations of the NB Bridge are obtained. Histograms of these responses are established and the 95-percetile values found. These are compared with limits imposed by HiVoss and Setra guideline. Since all characteristic maximum RMS accelerations are well below the 1 m/s^2 limit imposed by HiVoss (2008) and Setra (2006), the footbridge is deemed acceptable in terms of vibration serviceability.

5.2 *Conclusions*

The approach presented here allows for improved vibration serviceability assessment of complex structural forms. Suitably accurate 1-D model representation of footbridges with complex structural forms can be obtained through calibration with detailed 3-D models using model updating. Such simpler 1-D models can then be used in a more advanced vibration serviceability assessment algorithm, as is done here. This work is therefore suitable for engineering practice to allow efficient modelling and vibration predictions of footbridges with similar complexity.

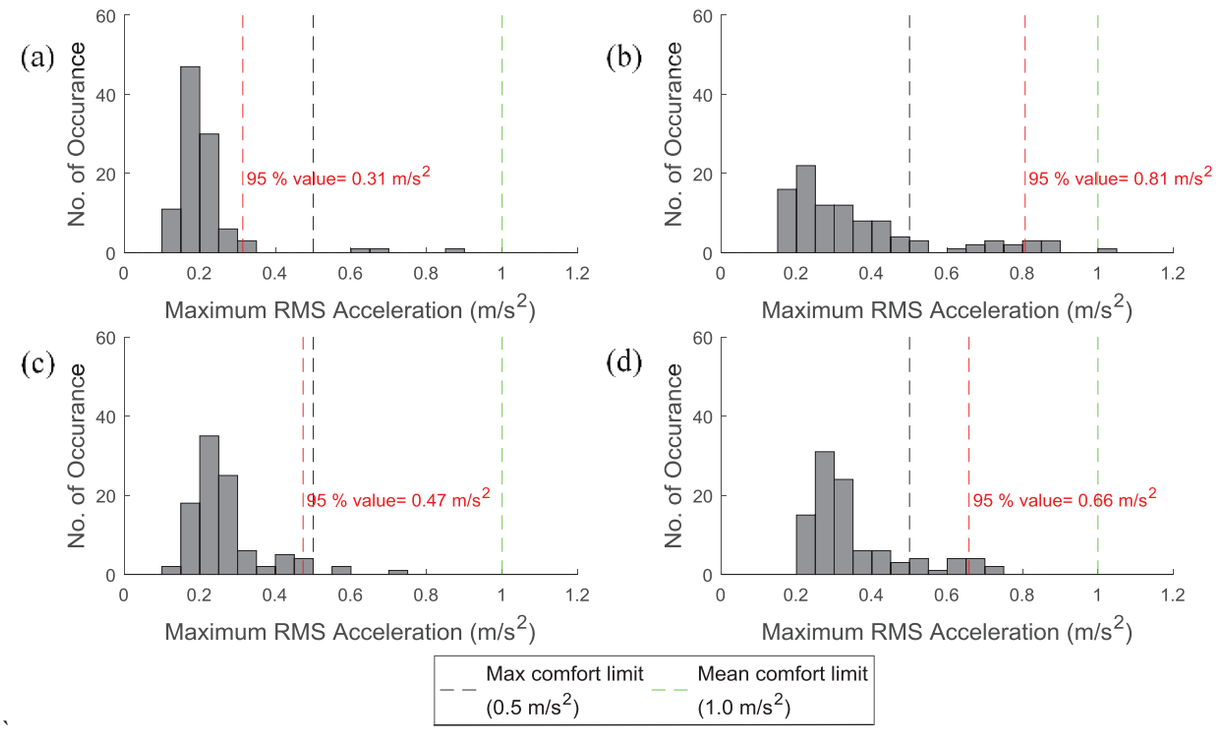

Figure 8. Histograms of 1-s RMS acceleration responses under random crowds at: a) Point A; b) Point B; c) Point C, and; d) Point D.

Although the method developed here uses advanced modelling of crowds and moving force presentation of the pedestrian imparted forces, it should be recalled that the present simulation does not consider the influences of mass damping and stiffness of humans on the overall bridge system dynamic properties. This leaves the possibility that the accelerations due to the simulated crowd could even be less. Nevertheless, it is possible, as suggested in Setra (2006), that the mass of the bridge model is adjusted to include the crowd, to represent these effects on the system's dynamic properties. However, conservatively, this approach is not taken here and the performance is yet found to be acceptable.

A study of pedestrian evacuation on bridge sidewalk by simulation method

Z.R. Jin, X. Ruan & Y. Li
Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: Pedestrian evacuation has become an important issue of operation safety for bridges nowadays. In this paper, cellular automata are discussed and illustrated as the foundation for evacuation simulation. Floor field model, as a combination of updating rules, is then integrated into cellular automata for updating the position of each pedestrian. To consider the effect of coordinators in pedestrian flow, a state transition rule is proposed to account for the variation of pedestrian's moving strategy. By the model, evacuation time of different spans of bridges with various sidewalk widths is obtained through simulation, which indicates that a wider sidewalk is necessary for the longer bridge to further decrease the evacuation time. The effect of emergent blocking of the bridge on the evacuation time is also investigated. Furthermore, the position of coordinators is optimized to reduce the evacuation time to the maximum extent.

1 INSTRUCTION

Long bridges are usually designed specifically for the use of automobile passing or train passing, or both. However, sidewalks would be sometimes designed as well for maximizing the function of this structure. In most cases, given the safety concern, the sidewalk which enables the passing of pedestrian or non-motor vehicle is separated from the main motor vehicle lanes. This measure, in another aspect, may trigger the evacuation problems due to the fact that the sidewalk for evacuation is relatively narrow while the exit of the sidewalk is located at the very end of the bridge. In some scenarios, a sidewalk is also built as an auxiliary component for sightseeing. When the arches of a bridge are also accessible for the recreational purpose, e.g., Sydney Harbor Bridge (Fig 1), the issue of pedestrian evacuation becomes much more noteworthy. Hence, the safe evacuation for long bridges with sidewalk needs an inspection to evaluate whether a certain geometry layout of the sidewalk is appropriate for the pedestrian evacuation under some emergency.

a

Many methods have been proposed to address the problem of evacuation. At the micro level, models are established on the continuous or discrete basis. Herein, cellular automata (CA) functions in a spatial and temporal discrete system (Von Neumann & Burks 1966). When used for evacuation simulation,

it updates pedestrians' positions synchronously according to the local environment and the pre-defined local rules. Through the iteration of applying local rules to each cell, the flow of pedestrian is emulated. Based on CA model, several updating rules have been proposed in previous studies to tackle different aspects of evacuation problems. The floor field CA model is widely utilized to evaluate the evacuation behaviors for a variety of structure layouts. Many improvements have been made on floor field CA model to incorporate some certain scenarios where the pedestrians may behave distinctly from the common sense, e.g., group behavior(Lu et al. 2016) and evacuation from the fire(Zheng et al. 2011) or smoke(Yuan & Tan 2011). However, few applications of floor field CA model is adopted in the scenarios of the evacuation on bridge sidewalks, whose geometric feature are quite distinct due to long span but small width.

Thus, in this paper, the conventional floor field CA model is modified to fit for the evacuation simulation of the sidewalks in long span bridges. The evacuation time is compared among different widths of sidewalk for the given spans of bridges. Also, the adverse effect caused by the local blocking due to the emergency like fire or explosion is discussed on the basis of further simulation. Finally, to improve the efficiency of the evacuation process, two coordinators are allocated along the span of the bridge. Their influence is reflected based on the state transition rules of pedestrian, which is proposed for the first time. The optimal positions of coordinators are investigated on the premise of the evacuation time obtained from the simulation.

The rest of this paper is organized in the following pattern. The next section is aimed to present a brief introduction of the floor field CA model and the state transition rules for the consideration of coordinator's influence. The framework of simulation will be articulated in section 3. Then in section 4, the application of the modified floor field for the evaluation of sidewalk evacuation problem is conducted, and the foregoing topics are discussed based on the output of simulations. For conclusion, in section 5 the observations of this work are summarized, and the further applications of floor field CA for evaluation on the evacuation problem in bridge sidewalk are suggested.

2 THE MODIFIED FLOOR FIELD CA

2.1 *Physical environment of basic CA model*

In the basic CA model, the finite and continuous evacuation plane is divided into some cells with lattice of certain sizes. These cells have well-defined boundaries, and the states of this cells are finite. In the problem of evacuation simulation, each cell is occupied by obstacles, e.g., walls or barricades, by a pedestrian, or just empty. The information like each pedestrian's moving parameters and obstacle's occupation parameters is stored in the relevant cell, which serves as the input for the subsequent updating of pedestrians. In this work, Von Neumann neighborhood is adopted as Figure 2, where the current position of a pedestrian is at the center of the neighborhood. Under this constraint, the moving range of a pedestrian for a time step would be in the four directions, i.e. up, down, left and right. Pedestrians update their position synchronously at each time step, based on the beforehand defined local rules, its current state and the environment which is formed by the nearby pedestrians and the obstacles. During the updating process, the moving parameters of each pedestrian are transferred from the previous cell to the target cell as shown in Figure 3, which mimics the movement of the pedestrians in real time. In the relatively dense pedestrian flow, a typical spatial occupation of a pedestrian can be set as a square area whose side length is 0.5m . Therefore, the size of each cell is set to be 0.5m ×0.5m in this application, and each cell can only be occupied by a single pedestrian. At each time step, a pedestrian is required to move only one cell from the current position or stay still.

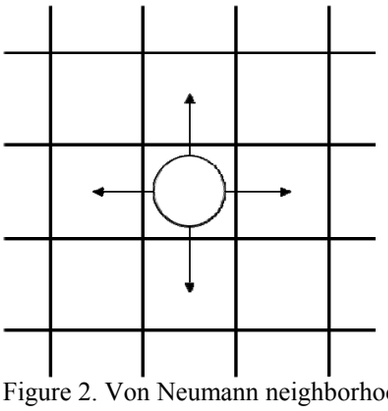

Figure 2. Von Neumann neighborhood

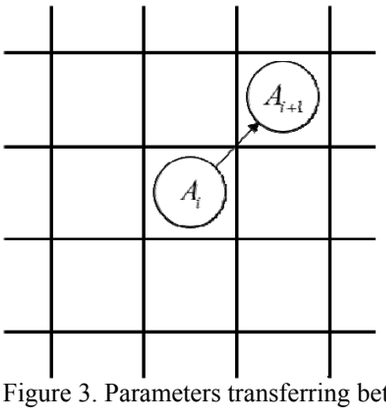

Figure 3. Parameters transferring between cells

2.2 *A detailed introduction of floor field CA model*

The floor field CA model is constructed at the micro level and the pedestrians are allowed to move in the neighborhood at each time step in accordance with the dynamic probability calculated by the pre-defined local rules. In the first place, the floor field CA was inspired by the chemotaxis phenomenon that commonly exists in nature(Kirchner & Schadschneider 2002). As a typical floor field CA model, two kinds of floor field are combined to present an interactive updating scheme that enables the variations of transition probability and further determines the movement of a pedestrian. The static field S and the dynamic field D will facilitate the pedestrians to be more likely to move in the direction where the field values are higher.

The static field S represents the pedestrian's ability to find the most favorable way to egress, which is determined by the shortest routine to get to the exit. The nearer one cell is to the exit, the more attractive this cell will be to a certain pedestrian, in terms of the evacuation process. The dynamic field D stands for pedestrian's behavior of following others when evacuating, the certain values of dynamic field D illustrate the virtual trace left by the pedestrian flow. In this sense, the chemotaxis phenomenon is correlated to show that people tend to follow the trace, i.e., the herding behavior.

The first proposed calculation method of static field S is based on the absolute distance to the exit(Kirchner & Schadschneider 2002). In applications of floor field CA to the evacuation simulations of long bridge sidewalks, the powers to the natural base are too large for practical calculation. To deal with it, the distance difference is adopted here to measure the attractiveness of the cells in the neighborhood, which is stated in the literature(Zheng et al. 2011). The static field S is constant throughout the entire evacuation process and is not influenced by the presence of any pedestrian. Conversely, the dynamic field D is time-dependent and will always change following the rules of diffusion and decay. At each time step, the dynamic field D of a cell from which a pedestrian moves out will increase by one. And the dynamic field D will decay with probability δ and diffuse with probability α to one of its neighboring cells(Kirchner & Schadschneider 2002). In addition to the original paper that proposed the floor field CA model, the inertial field is added later to take into account the fact that pedestrians are likely to keep their moving direction while evacuating(Nishinari et al. 2004).

In the Von Neumann neighborhood as depicted in Figure 1, the transition probability of the pedestrian is obtained through Equation 1 below:

$$p_{ij} = N \exp\left(k_S S_{ij}\right) \exp\left(k_D D_{ij}\right) p_I(i,j) I_{ij} \left(1 - n_{ij}\right) \xi_{ij} \qquad (1)$$

where

$$p_I(i,j) = \begin{cases} \exp(k_I) & \text{if } cell(i,j) \text{ accords with the direction} \\ 1 & else \end{cases}$$

$$n_{ij} = \begin{cases} 0 & \text{if } cell(i,j) \text{ is not occupied by another pedestrian} \\ 1 & \text{else} \end{cases}$$

$$\xi_{ij} = \begin{cases} 0 & \text{if } cell(i,j) \text{is forbidden by obstacles} \\ 1 & \text{else} \end{cases}$$

To make sure that the summation of transition probability equals to 1, the normalization item is added in as Equation 2:

$$N = \left[\sum \exp\left(k_S S_{ij}\right) \exp\left(k_D D_{ij}\right) p_I(i,j) \left(1 - n_{ij}\right) \xi_{ij}\right]^{-1} \qquad (2)$$

Where k_S, k_D and k_I are sensitivity parameters used to determine the weights of S_{ij}, D_{ij} and $P_I(i,j)$, respectively.

2.3 *Pedestrian contraction at a wide exit*

According to the observations of the previous studies of floor field CA model, it is noteworthy that the pedestrian will form an unusual array at the exit when the width of the exit is relatively large, which is a common situation in the bridge sidewalk. This phenomenon can not accord with what is happening in reality and is mainly attributed to the underlying updating rule that each pedestrian longs for the shortest path to egress. In this scenario, the pedestrian on both sides of the exit will always choose the side cells at the exit and crowd around it struggling to get out. This problem was noticed by (Nishinari et al. 2004) first, and he caught the inspiration from hydrodynamics to called this effect as the contraction. By merely weighting more the cells near the center of a wide exit owing to the contraction, the static field S is modified accordingly. After this modification, the status of crowding array on both sides of an exit is obviously mitigated. Whereas, the cells far from the center of exit are not fully utilized during evacuation. In this work, a discounting parameter is proposed to shrink the distance between the inner cells and the cells near the center of an exit while still incorporating the static field influence of the lateral cells of an exit. This process is explained by Equation 3:

$$L_D(i,j) = \beta L_O(i,j) \qquad (3)$$

where $L_O(i,j)$ is the original distance between the inner cells and the cells at the exit; β is the discount factor that equals to 1 for the exit cells farthest from the center and a certain value for the exit cell at the center. And for the cell in between, β changes linearly. Then $L_D(i,j)$ is adopted as the input for the static field S determination.

As described in Figure 4a and Figure 4b (the geometry of the evacuation space is only chosen for visualization concern), if $\beta = 0.8$ for the cell at the center of an exit, the previous crowding at both sides of the exits is remarkably downsized and a conventional phenomenon of arching emerges again, which means that the simulation is more realistic.

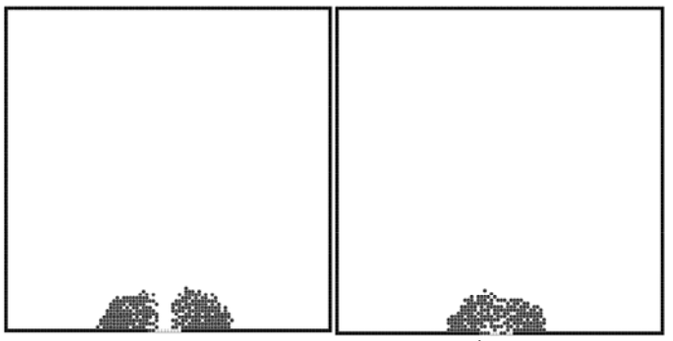

Figure 4 (a) Pedestrian distribution at the exit without considering contraction (b) Pedestrian distribution at the exit when $\beta = 0.8$

2.4 *Coordinator's influence and state transition*

As well known, when the width of a sidewalk is small and the evacuating path is long, the influence of the oscillation in pedestrian flow on the ultimate evacuation time will be obvious. If the pedestrian flow is kept more ordered, the evacuation time may me reduced to some extent. Since the dynamic field D represents the herding behavior of the pedestrians which leads to the deviation from the shortest path for evacuation, a large D will hinder the smooth process of evacuation. With this in mind, if a coordinator is allocated along the span in the process of evacuation, he is supposed to prevent the pedestrians getting into chaos, and mathematically, the dynamic field will get decreased within a certain range of the coordinator.

Here we set k_D in a range of [k_{Dmin}, k_{Dmax}], where the min value lessens the herding behavior of pedestrians and accordingly reduces the oscillation in pedestrian flow; the max value is the original k_D of all the inner cells, which will entail a high probability of oscillation. The variation of k_D is based on the relative distance between the cells and the coordinators, which is shown in Equation 4:

$$k_D = \begin{cases} k_{D\min} + \left(\dfrac{L_C}{L_E}\right)^2 \left(k_{D\max} - k_{D\min}\right) & L_C \le L_E \\ k_{D\max} & L_C > L_E \end{cases} \quad (4)$$

where L_C is the relative distance between a certain cell and its closest coordinator; L_E is the coordinator's effective range.

This variation of k_D ensures that a state transition of the pedestrian takes on around the coordinators. The variation pattern is illustrated in Figure 5. It is clear that when a pedestrian is close to a coordinator, the latter's influence decreases slowly. While when a pedestrian is getting far from the coordinator, the coordinator's influence for an ordered evacuation diminishes rapidly until k_D equals to the original value k_{Dmax}.

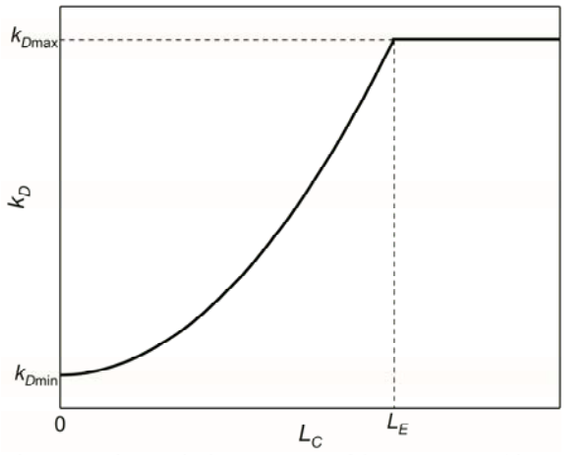

Figure 5 The variation pattern of k_D versus L_C (the state transition rule)

3 FRAMEWORK OF SIMULATION

The bridge sidewalks from which the pedestrians evacuate from is discretized into cells based on the aforementioned cell size. Initially, each cell would be either empty or occupied by the wall or a pedestrian at most. For each of the pedestrians, the next action could be moving to one of the neighboring cells or stay still following the transition probabilities calculated at each time step based on Equation 1 All of the pedestrians will choose their target cells for the next time step synchronously. Only one of the pedestrians will be randomly selected to move into the target cell while the other stay at current cells, in case that a confliction happens when several pedestrians share the same target cell.

The detailed framework for conducting an evacuation simulation on a long bridge sidewalk is elaborated as follows:

Step 1: Initialize a series of pedestrian and then populate them into the bridge sidewalk with random positions.

Step 2: Calculate the static field S of each cell with contraction effect considered. The static field S remains constant in the following simulation.

Step 3: Obtain the transition probabilities from Equation 1. Different values of k_D are derived from Equation 4 when the coordinator's influence is taken into account. Then the pedestrian will randomly de-

termine the target cells referring to the current transition probabilities.

Step 4: Deal with the conflict scenario if necessary.

Step 5: Update the dynamic field floor D for this time step according to the decay and diffusion rules mentioned before. The values of the dynamic field D at all the cells are initialized as zeros and are time-dependent throughout the simulation process.

Step 6: Iterate from Step 1 to Step 4 until all of the pedestrians have evacuated from the bridge sidewalk.

For the sake of a better visualization, an example of evacuation process simulated by the proposed model is present in Figure 6.

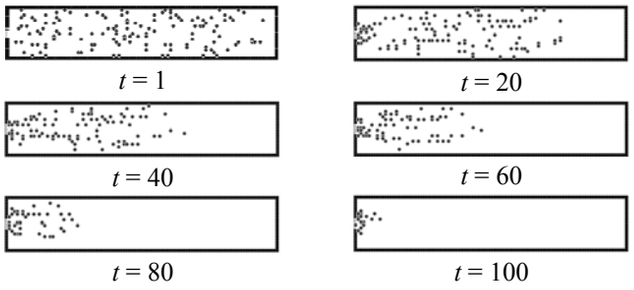

Figure 6 The evacuation process (unit: time step)

4 SIMULATION AND ANALYSIS

4.1 *Parameters setting*

The input parameters are list below for evacuation simulations using the floor field CA, and the disordered pedestrian flow is emulated by this combination of parameters(Kirchner & Schadschneider 2002): $k_S = 4$, $k_{Dmin} = 0$, $k_{Dmax} = 2$, $k_I = 0.2$, $\alpha = 0.3$, $\delta = 0.3$, $\beta = 0.8$, the cell size is 0.5m×0.5m.

4.2 *Influence of sidewalk width*

The width of a sidewalk is studied with respect to the appropriate width for a certain span of the bridge. The geometric layout of the bridge sidewalk is described in Figure 7. The bridge spans are 100, 300, 500, 700 and 900 (unit: m) while the widths of sidewalks are 1.0, 1.5, 2.0, 2.5 (units: m) in this comparative analysis. The practical layouts of bridge sidewalk in China have been consulted before the adoption of these widths. The number of pedestrians for each span of the bridges is calculated on the hypothesis that the people density is 0.6 (unit: person/m^2) when the width of the sidewalk is 2.0m. Thus, the initial pedestrian numbers are 120, 360, 600, 840 and 1080 (units: person) for the previously defined spans, respectively. In all, there are 20 groups of simulation scenarios and the evacuation time of each group is the average over 24 simulation runs.

Figure 7 The geometric layout of the bridge sidewalk

The evacuation time information of different sidewalk widths for a certain bridge span is illustrated in Figure 8. For the sake of comparison, the decrease percentages of evacuation time are calculated with the sidewalk width of 1m as the benchmark. Three different kinds of variation patterns can be discerned from Figure 8:

For the bridge sidewalk of 100m, the evacuation time decreases rapidly when the width of sidewalk begins to ramp up. However, a decline in decrease percentage is observed when the width reaches 2.5m. This is mainly due to the fact that a sidewalk width of 2.0m is enough for a smooth evacuation. Further increase in sidewalk width cannot improve the evacuation efficiency but may boost the probability of an oscillation since pedestrians may walk more freely than before. This oscillation may exert an adverse effect on the overall evacuation process.

For the bridge sidewalk of 300m and 500m, the evacuation time decreases with the increase in sidewalk width. And after the sidewalk width reaches 2.0, the evacuation time keeps stable approximately, which means that a width of 2.0m is proper for the evacuation of these volumes of pedestrians when the bridge spans are 300m and 500m.

For the bridge sidewalk of 700m and 900m, the evacuation time keeps decreasing along with the sidewalk getting wider. Even though the sidewalk width has arrived at 2.5m, there is still a potential that the evacuation time will be further decreased.

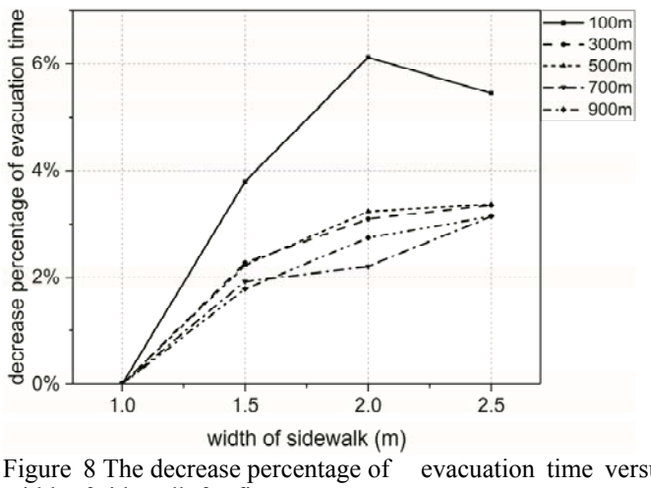

Figure 8 The decrease percentage of evacuation time versus width of sidewalk for five spans

4.3 *Influence of local blocking*

To investigate the outcome of emergency, e.g., fire and explosion, different blocking positions along the bridge span are set to evaluate the increase in evacuation time. The bridge span of 500m is chosen to be evacuation space. The blocking positions include one of the exits, 1/8, 1/4, 3/8 of the span, and the middle of the span, as depicted in Figure 9. The pedestrians on both sides of the blocking can not transverse to the other side. Accordingly, the static field S at each cell should be calculated based on the distance to its accessible exit.

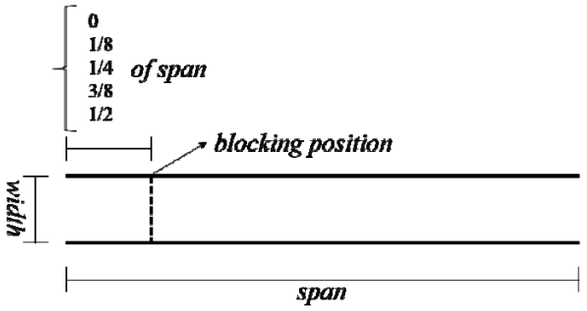

Figure 9 The blocking positions on the bridge sidewalk

The evacuation time information of different sidewalk widths for a certain blocking position is shown in Figure 10. And the evacuation benchmarks for each sidewalk width are the values of no-blocking scenarios for 500m span analyzed in Section 4.2. In Figure 10, the increase percentages of evacuation time are presented. It is straightforward that the variation of sidewalk width has little influence on the increase percentages of the evacuation time for the same blocking position. Nevertheless, the blocking caused by an emergency does increase the evacuation time to some extent, and increase percentage can accord well with the distance between the exit and the pedestrian farthest from it. This result confirms that under this people density and sidewalk width layouts, the overall evacuation time changes linearly with the distance that the farthest pedestrian is going to transverse to reach the exit.

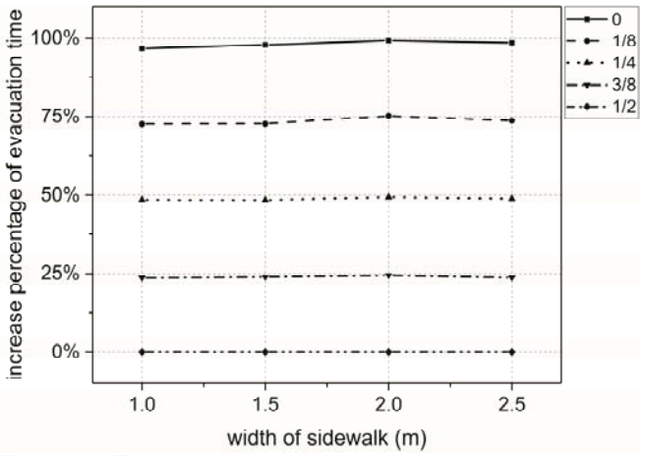

Figure 10 The increase percentage of evacuation time versus width of sidewalk for five blocking positions

4.4 *Influence of coordinators and the position optimization*

In this work, in a bid to improve the evacuation efficiency, the concept of coordinator is proposed to keep a certain range of bridge sidewalk more ordered than original state. The method of such intention is to decrease the values of k_D, as detailed previously. The positions of coordinators include one of the exit, 1/8, 1/4, 3/8 of the span, and the middle of the span, as depicted in Figure 11. In consideration of simplicity, only two coordinators are allocated symmetrically on both sides of the mid-span. (Except for the mid-span scenario, where only one coordinator is allocated.) The L_E is set as 100 (unit: cell) for all the scenarios. Based on the positions of coordinators and the value of L_E, if the span is less than 500m, there will be an overlap of effective range for different scenarios, making things too complicated for discerning the variation. Therefore, only bridge spans of 500m, 700m and 900m are discussed in this topic.

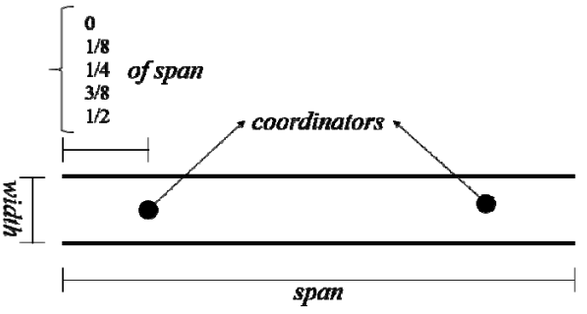

Figure 11 The positions of coordinators on the bridge sidewalk

The evacuation time information of different positions of coordinators for a certain bridge span is shown in Figure 12. The evacuation time without coordinators from Section 4.2 is chosen as the

benchmark for comparison. In Figure 12, the decrease percentages of evacuation time are presented. According to the data in Figure 7, when the bridge spans are 700m and 900m, the nearer coordinators are to the exit, the more evacuation time get decreased. Whereas, for bridge span of 500m, the 1/8 of the span is the optimal position for the allocation of coordinators. Moreover, the influence of the coordinators is more salient for the bridge span of 700m than that for the bridge span of 500m and 900m, when the coordinators are allocated at the same positions of the span.

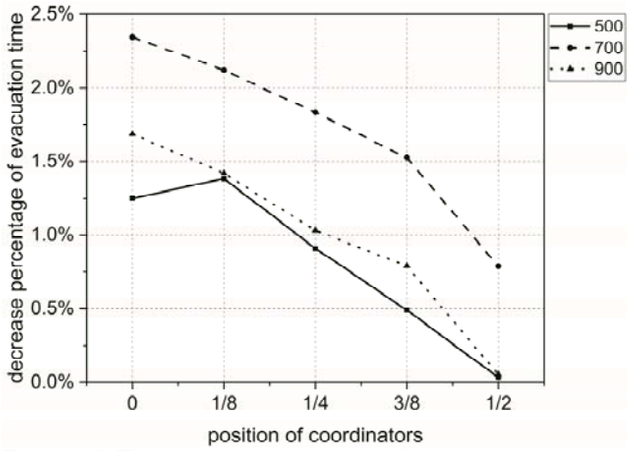

Figure 12 The decrease percentage of evacuation time versus position of coordinators for three spans

5 CONCLUSION

This paper introduces the floor field CA model to study the pedestrian evacuation bridge sidewalks. The floor field CA model is modified based on the geometric features of evacuation space: the method of the static field *S* calculation is chosen specifically for computational ease; the pedestrian contraction at the exit is modeled properly for a more realistic crowd simulation when the width of an exit is large. Furthermore, the concept of coordinators is proposed to enhance the evacuation efficiency, by introducing the state transition controlled by the values of k_D. On the basis of the previous simulations and discussions, the following conclusions are drawn:

- The widths of the bridge sidewalks do influence the overall evacuation time. And for fixed people density, the variations of evacuation time versus sidewalk widths show three distinct patterns among five spans of bridges. When the pedestrian flow is disordered for small span (100m), simply increasing width will not decrease the evacuation time monotonously. For large span (700m and 900m), the width of 2.5m can be further increased to get a higher evacuation efficiency.
- The variation of width of sidewalk has little influence on the evacuation time when some positions are blocked. And the evacuation time only depends linearly on the farthest distance between a pedestrian and the exit under the people density and sidewalk layout specified in the context.
- The coordinators allocated along the span do have a positive effect on the evacuation efficiency. Generally, the nearer the coordinators to the exit, the more obvious efficiency enhancement will be.

We do recognize that there still exist some limitations for a deep analysis of evacuation time on the bridge sidewalk in this work. The number of pedestrians for a certain bridge span is fixed for comparison ease. And the coordinator's effective range is not studied in a sensitivity analysis due to space limitation. For the further study, the people density can be changed to gain more insight into the variation patterns evacuation time. The coordinator's effective range should be discussed or calibrated against the in-situ test to obtain a more comprehensive understanding of its mechanism. In a nutshell, this work only provides a basic idea on the study of the width of long bridge sidewalk for evacuation's concern.

Uncertainty propagation in serviceability assessment of footbridges

F. Tubino, L. Pagnini & G. Piccardo
University of Genoa, Genoa, Italy

ABSTRACT: The paper deals with the propagation of uncertainties inherent to structural and loading parameters on the serviceability assessment of footbridges. Based on the equivalent spectral model, the standard deviation and maximum value of the footbridge acceleration are expressed as a function of the probability distribution of the step frequency and of the modal properties of the footbridge. The assessment of the propagation of uncertainties in the characterization of such parameters is carried out using the Taylor expansion method. The results are discussed and compared with conventional verifications, based on deterministic evaluations.

1 INTRODUCTION

Modern footbridges can be very sensitive to human-induced vibrations and their serviceability assessment is a central issue in their design. Recent guidelines provide straightforward procedures to deal with their serviceability analyses, based on simplified expressions of pedestrian-induced forces. Dealing with multi-person traffic, a uniformly distributed resonant equivalent load is commonly provided by guidelines and a deterministic estimate of the maximum acceleration is thus obtained, to be compared with suitable serviceability limits (e.g. SETRA 2006). The Equivalent Spectral Model is an alternative loading model that allows estimating the maximum footbridge acceleration as a function of the probabilistic distribution of step frequency (Piccardo & Tubino 2012). Assuming deterministic values for the structural dynamic parameters (modal mass, natural frequency and damping ratio) and for the loading parameters (dynamic loading factor, pedestrian weight and pedestrian step frequency distribution), a deterministic estimate of the maximum footbridge acceleration is obtained. Since, however, the estimate of several structural and loading parameters is uncertain, the serviceability assessment should consider this randomness.

This paper discusses the propagation of uncertainties in both the structural and the loading parameters on the serviceability assessment of footbridges. Based on the Taylor series expansion technique (e.g., Pagnini 2010), the uncertain parameters having large influence on the maximum acceleration are identified. The proposed procedure is then applied to a case study. Results are discussed and compared with conventional verifications, based on deterministic evaluations.

2 SERVICEABILITY ASSESSMENT OF FOOTBRIDGES

Vibration serviceability assessment of footbridges is commonly carried out through simplified procedures (SETRA 2006, ISO10137 2007, BSI 2008, HIVOSS 2009), based on equivalent loading for pedestrian groups modelled as a resonant harmonic load, whose amplitude is defined as a function of the expected pedestrian density. The equivalent loading expressions are based on numerical simulations of the forces exerted by pedestrian groups, modelling the single pedestrian loading as a moving harmonic with a frequency distribution according to a Gaussian function having a mean value coincident with the natural frequency of the footbridge.

The Equivalent Spectral Model (ESM, Piccardo & Tubino 2012) allows estimating the standard deviation of the footbridge acceleration and its maximum expected value as functions of the harmonic content of the loading and structural parameters characterizing the dynamic behavior of the structure. It is based on the following expression for the power spectral density function of the j-th modal force:

$$S_{F_j}(\omega) = \frac{N_p}{4}(\alpha_m G_m)^2 \, p_\Omega(\omega) \tag{1}$$

where N_p is the number of pedestrians, α_m and G_m are, respectively, the mean value of the dynamic

loading factor and of the weight of pedestrians, $p_\Omega(\omega)$ is the probability density function of the step frequency of pedestrians, assumed as normal:

$$p_\Omega(\omega) = \frac{1}{\sigma_\omega \sqrt{2\pi}} \exp\left[-\frac{(\omega - \omega_{pm})^2}{2\sigma_\omega^2} \right] \quad (2)$$

ω_{pm} and σ_ω being the mean value and the standard deviation of the step circular frequency, respectively.

Based on the ESM, the standard deviation of the footbridge acceleration in terms of the j-th modal principal coordinate p_j can be expressed as follows:

$$\sigma_{\ddot{p}_j} = \sqrt{\frac{\pi \omega_j}{4 M_j^2 \xi_j} S_{F_j}(\omega_j)} \quad (3)$$

where ω_j, M_j, ξ_j are, respectively, the footbridge natural circular frequency, the modal mass and the damping ratio of mode j.

The expected value of the maximum acceleration can be then estimated as follows:

$$\ddot{p}_{j\max} = g_{\ddot{p}_j} \sigma_{\ddot{p}_j} \quad (4)$$

where $g_{\ddot{p}_j}$ is the peak factor, which can be estimated according to the Davenport formulation (Tubino & Piccardo 2016) as:

$$g_{\ddot{p}_j} = \sqrt{2\ln\left(2\nu_{\ddot{p}_j}\tilde{T}\right)} + \frac{0.5772}{\sqrt{2\ln\left(2\nu_{\ddot{p}_j}\tilde{T}\right)}}$$
$$\nu_{\ddot{p}_j} = \frac{1}{2\pi} \quad \tilde{T} = N\frac{\omega_j L}{c_m} \quad N = 10 \quad (5)$$

L being the span length. In the following, a simplified assumption is made, and the mean walking velocity c_m (m/s) is assumed as proportional to the mean step frequency n_{pm} (Hz), as usual in practice (see, e.g., FIB 2005) being $n_{pm}=\omega_{pm}/2\pi$:

$$c_m\,(\mathrm{m/s}) = 0.9 n_{pm} \quad (6)$$

3 ANALYSIS OF UNCERTAINTIES

The estimate of footbridges' serviceability is affected by the uncertainty of the parameters characterizing both loading and structural properties.

In the following Sections, a synthetic bibliographic analysis of uncertainties affecting the characterization of pedestrian loading (Section 3.1) and structural modal properties (Section 3.2) is proposed.

3.1 *Pedestrian loading*

Pedestrian loading (Eq. (1)) is defined as a function of the number of pedestrians N_p, of the mean value of the dynamic loading factor α_m and pedestrians' weight G_m and of the parameters defining the probability distribution of the step frequency of pedestrians (i.e., mean value ω_{pm} and standard deviation σ_ω). The number of pedestrians N_p can be assumed as a deterministic design requirement, set by the owner of the structure taking into account its location. Dealing with the other loading parameters, the literature is not very rich in information about α_m and G_m, while a certain amount of data are available concerning the statistical distribution of the step frequency, commonly assumed as normal. Table 1 reports results of experimental data available in the literature dealing with the probability distribution of step frequencies, including mean value n_{pm}, standard deviation σ_{np} and coefficient of variation $V_{np}= \sigma_{np} /n_{pm}$. The number of persons N_p on which these values are determined is also reported.

3.2 *Structural properties of the footbridge*

The structural parameters affecting the dynamic response are the structural modal mass M_j, natural circular frequency ω_j and damping ratio ξ_j. The modal mass can be evaluated with a certain degree of accuracy. Fundamental frequency can be either estimated on the basis of experimental measurements on the structure investigated or by a finite element model, once the mass and the stiffness matrices are known. For some types of structures, the a priori estimate can be very uncertain (e.g., buildings for the presence of masonry and secondary elements). Concerning footbridges, estimates obtained from finite element models may be affected by limited errors due to the modelling of structural restrains and/or secondary elements, which can cause a discrepancy between the numerical prediction and the actual value. Zivanovic et al. (2006) and Van Nimmen et al. (2014, 2016) reported a discrepancy between measured natural frequencies and numerically predicted ones for a large number of footbridges (Table 2). Uncertainties might also arise from environmental effects (e.g., temperature variation). Possible variation of the natural frequency due to these actions has been reported, e.g., by Moser & Moaveni (2011), and by Hu, Caetano & Cunha (2013) (Table 3).

Table 2. Variation of footbridge natural frequency (measured vs FEM model) (Zivanovic et al. 2006, Van Nimmen et al. 2014, 2016).

Table 3. Variation of natural frequency of footbridges due to temperature effects (Moser & Moaveni 2011, Hu, Caetano & Cunha 2013).

Bridge	Mean (Hz)	Min (Hz)	Max (Hz)
Dowling Hall	4.68	4.61	4.81
FEUP Campus	0.979	0.906	1.056

Damping is one of the most uncertain quantity. It is the result of dissipation mechanisms involving the soil and foundation, the structure and the aerodynamics. It can be subjected to large variations according to the level of structural displacement and to the wind velocity. Reliable estimates can only be obtained from experimental measurements on the existing structure; however, the damping value may still be affected by uncertainties concerning the measurements and the technique adopted for its identification. Usually, recourse is made to empirical models calibrated on collections of measurements obtained on structures of similar typology. SETRA (2006) recommends assuming a value for first modal damping ratio according to the structural typology (Table 4).

Table 4. Damping ratio (SETRA 2006)

Type	ξ_1 (%)
Reinforced concrete	1.3
Pre-stressed concrete	1
Mixed	0.6
Steel	0.4
Timber	1

HIVOSS (2009) provides minimum and average values for damping ratio according to construction material (Table 5).

Table 5. Damping ratio (HIVOSS 2009)

Type	ξ_1 min (%)	ξ_1 average (%)
Reinforced concrete	0.8	1.3
Pre-stressed concrete	0.5	0.6
Composite steel concrete	0.3	0.6
Steel	0.2	0.4
Timber	1	1.5
Stress ribbon	0.7	1

Different values can be found in the literature concerning experimental measurements on real footbridges (e.g. Zivanovic et al 2006, Zivanovic et al 2010, Moser & Moaveni 2011, Hu, Caetano & Cunha 2013, Van Nimmen et al. 2014, 2016, Tubino et al. 2016). Table 6 summarizes some of the recent data available in the literature specifying the corresponding structural typology. It should be noticed that the experimental damping ratios of the fundamental mode of vibration reported in Table 6 are not always related to a vertical flexural mode; the scattering of values in Table 6 could also be related to the different nature of the fundamental modes.

4 UNCERTAINTY PROPAGATION

Many procedures allow propagating the uncertainties (e.g., Kareem 1987, Solari 1996). In this paper, Taylor Series Expansion (TSE) is adopted. After recalling the analytical formulation (Section 4.1), in Section 4.2 TSE is applied to footbridge serviceability assessment.

4.1 *Analytical formulation*

Let R be a quantity representative of the response of a structural system. Let us consider an adequate model of the structural behavior which estimates the response R; it is a function of a set of parameters listed by a vector $\mathbf{x}=\{x_1, x_2,..x_n\}^T$. As the evaluation of these quantities is affected by uncertainties, the errors inherent their estimate propagate over R.

TSE expands the original function R around the mean value of $\mathbf{x}$, i.e. $\mathbf{x}_m=\{x_{1m}, x_{2m},..x_{nm}\}^T$:

$$R(\mathbf{x}) \simeq R(\mathbf{x}_m) + \sum_{i=1}^{n} (x_i - x_{mi}) \frac{\partial R}{\partial x_i}(\mathbf{x}_m) + ... \quad (7)$$

Applying statistical operators to Eq. (7), one obtains the mean value R_m and its variance σ^2_R as functions of the statistical moments of $\mathbf{x}$:

$$\begin{aligned} R_m &\simeq R(\mathbf{x}_m) \\ \sigma^2_R &\simeq \nabla^T R(\mathbf{x}_m) \mathbf{C}_X \nabla R(\mathbf{x}_m) \end{aligned} \quad (8)$$

where $\nabla R = \left\{ \frac{\partial R}{\partial x_1} \quad \frac{\partial R}{\partial x_2} \quad \cdots \quad \frac{\partial R}{\partial x_n} \right\}^{\mathrm{T}}$ stands for the gradient of R and $\mathbf{C_X}$ is the covariance matrix of $\mathbf{x}$.

When the covariance among different random parameters can be neglected (i.e. considering $\mathbf{C_X}$ as a diagonal matrix), the second Eq. (8) reduces to:

$$\sigma_R^2 \simeq \sum_{i=1}^{n} \left(\frac{\partial R}{\partial x_i}(\mathbf{x}_m) \right)^2 \sigma_{xi}^2 \tag{9}$$

Thus the coefficient of variation of the response quantity R, $V_R=\sigma_R/R_m$, may be expressed as follows:

$$V_R^2 \simeq \sum_{i=1}^{n} V_{Ri}^2; \quad V_{Ri} = c_{xi} V_{xi}, \quad c_{xi} = \frac{\partial R}{\partial x_i}(\mathbf{x}_m) \frac{x_{mi}}{R_m} \tag{10}$$

where V_{Ri} is the variation coefficient of R related to the sole uncertainty in the i-th parameter x_i; $V_{xi}=\sigma_{xi}/x_{mi}$ represents the variation coefficient of the random parameter x_i; c_{xi} are propagation coefficients defining the influence of the i-th uncertain parameter on the variation coefficient of R.

TSE is particularly suitable when $R(\mathbf{x})$ is described by an analytical model. In this case, the procedure can be implemented through symbolic calculation tools, giving rise to closed-form solutions. However, when $R(\mathbf{x})$ is a non-linear function and the uncertainties are very large, TSE evaluation loses precision.

4.2 *Application to footbridges' serviceability assessment*

Dealing with footbridge serviceability assessment, the response quantities of interest are the standard deviation of the modal acceleration and its maximum value (thus, $R=\sigma_{\ddot{p}j}$ or $R=\ddot{p}_{j\max}$). The vector of random parameters is defined as follows:

$$\mathbf{x} = \left\{ V_{\omega_p} \quad \alpha_m \quad G_m \quad \tilde{\omega}_j \quad \xi_j \quad M_j \right\}^T \tag{11}$$

where $\tilde{\omega}_j = \omega_j / \omega_{pm}$ and $V_{\omega p} = \sigma_\omega / \omega_{pm}$ is the coefficient of variation of ω_p.

Considering the standard deviation of the acceleration as the response quantity of interest, $R=\sigma_{\ddot{p}_j}$ and assuming that the random parameters are uncorrelated, the coefficient of variation of R may be expressed through Eq. (10). The propagation coefficients c_{xi} are given by:

$$\begin{aligned}
&c_{x1} = c_{V_{\omega p}} = -\frac{1}{2}\left[1 - \frac{1}{V_{\omega p}^2}\left(\tilde{\omega}_j^2 - 1 \right)^2 \right]\Bigg|_{\mathbf{x}_m}; \\
&c_{x2} = c_{\alpha m} = 1; \qquad c_{x3} = c_{Gm} = 1; \\
&c_{x4} = c_{\tilde{\omega}_j} = \frac{1}{2}\left[1 - \frac{1}{V_{\omega p}^2}\left(\tilde{\omega}_j^2 - \tilde{\omega}_j \right) \right]\Bigg|_{\mathbf{x}_m}; \\
&c_{x5} = c_{\xi_j} = -\frac{1}{2}; \qquad c_{x6} = c_{M_j} = -1
\end{aligned} \tag{12}$$

where $\bullet|_{\mathbf{x}_m}$ means quantities calculated in the mean values of the parameters.

Eq. (12) clearly shows that the propagation on $\sigma_{\ddot{p}_j}$ of the structural damping ratio, of the modal mass, of the dynamic loading factor and of pedestrian weight are independent on the other random parameters. The contributions related to the ratio between the footbridge natural frequency and the average pedestrian step frequency and to the coefficient of variation of pedestrian frequency are instead dependent on their mean values. Indicatively, when $\tilde{\omega}_j = 1$, $c_{\tilde{\omega}_j} = -c_{V\omega p} = 0.5$.

The maximum response $\ddot{p}_{j\max}$ is related to $\sigma_{\ddot{p}_j}$ through the peak coefficient which is only ruled by $\tilde{\omega}_j$ in the proposed formulation. Therefore, the related propagation coefficients are the ones listed in Eq. (12), except from the one related to $\tilde{\omega}_j$, referred to as $c'_{\tilde{\omega}j}$:

$$c'_{\tilde{\omega}j} = \frac{1}{\Upsilon}\left(\frac{\Upsilon - 1}{\Upsilon + 1} \right) + c_{\tilde{\omega}j}; \quad \Upsilon = 2\,ln\left(\frac{L}{4.5}\tilde{\omega}_j \right) \tag{13}$$

being $c_{\tilde{\omega}j}$ the value given by the second of Eqs. (12). In the usual values of L, $c'_{\tilde{\omega}j} \approx c_{\tilde{\omega}j}$.

5 APPLICATION TO A CASE STUDY

The proposed procedure is applied to a real footbridge in Milan (Figure 1) that was the object of extensive full-scale experiments carried out to assess the dynamic characteristics and the vibration level induced by pedestrians.

The structure is made by a steel depressed double hinged arc. The main span length is L = 60 m; ω_1 =13.6 rad/s and ξ_1 = 0.005 have been measured during the experimental tests. Moreover, the following nominal values can be assumed: M_1 = 51000 kg; G_m = 600 N, α_m = 0.4 (Tubino et al. 2016). From Table 1, it is assumed ω_{pm}=12.55 rad/s $V_{\omega p}$ =0.08. The analysis is carried out investigating the contribution of the first mode to the structural response, i.e. j=1.

Figure 1. Footbridge crossing Viale De Gasperi in Milan (Italy).

At first, a preliminary sensitivity analysis is carried out in order to detect the parameters mainly affecting footbridge serviceability (Section 5.1), then the propagation coefficients are analyzed (Section 5.2). Finally, uncertainty propagation is performed in Section 5.3, where results are also compared with conventional verifications.

5.1 *Preliminary sensitivity analysis*

Figure 2 reports a preliminary sensitivity analysis of the structural response carried out assuming N_p=50. The variation of $\sigma_{\ddot{p}_1}$ varying each investigated parameter around its nominal value is plotted. The diagrams highlight the prominent role of the quantity $\tilde{\omega}_1$, pointing out that possible differences between the actual value of the frequency ratio and the value assumed as nominal quantity give rise to large differences in the estimate of the structural response. Especially, it shows that possible overestimates of $\tilde{\omega}_1$, i.e. possible overestimates of the natural frequency of the footbridge and underestimates of the pedestrian loading frequency, lead to underestimate the structural response and therefore to non-conservative evaluations.

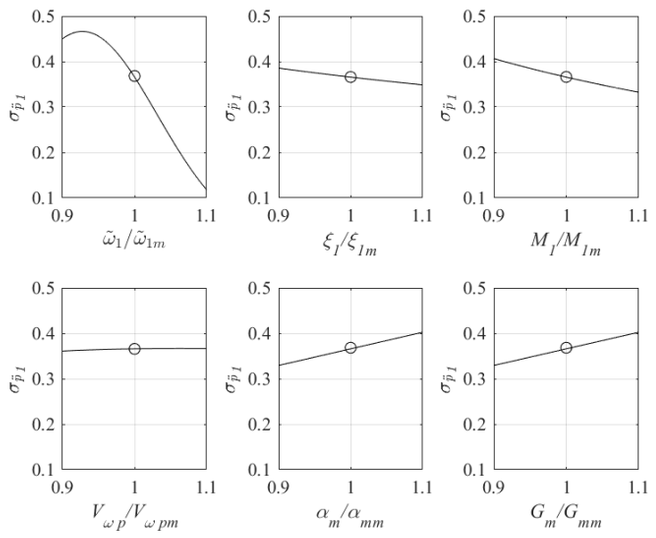

Figure 2. Response quantity $\sigma_{\ddot{p}_1}$ varying the input parameters. The circle indicates the estimate in the nominal value.

5.2 *Propagation coefficients*

Figure 3 plots the propagation coefficients in Eq. (12), solid line, and in Eq. (13), dashed line, as functions of $\tilde{\omega}_1$. The mean values of the parameters are assumed equal to the nominal value. Figure 4 shows a parametric diagram of $c_{\tilde{\omega}_1}$, $c'_{\tilde{\omega}_1}$ and $c_{V\omega p}$ for different values of $V_{\omega p}$. In both diagrams, the dashed vertical line indicates the nominal value of $\tilde{\omega}_1$.

Coherently with Figure 2, the diagrams show the prominent role of $\tilde{\omega}_1$, which is characterized by the largest propagation coefficient (in modulus) in the range of the nominal value of the parameters investigated, i.e. $\tilde{\omega}_1$=1.085, $V_{\omega p}$=0.08. It can also be noted that such coefficient becomes smaller than the others in resonant conditions, around $\tilde{\omega}_1$=1; it increases again for $\tilde{\omega}_1$<1. Especially, this trend is particularly marked when $V_{\omega p}$ is small, i.e. when the range of variation of the step frequency of the pedestrians is small.

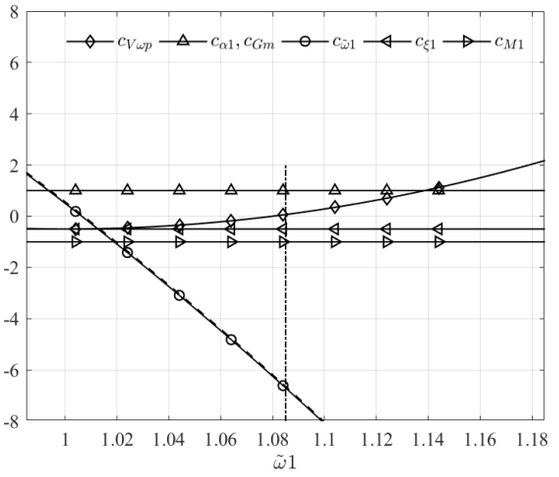

Figure 3. Propagation coefficients for the response quantity $\sigma_{\ddot{p}1}$ and $\ddot{p}_{1\max}$

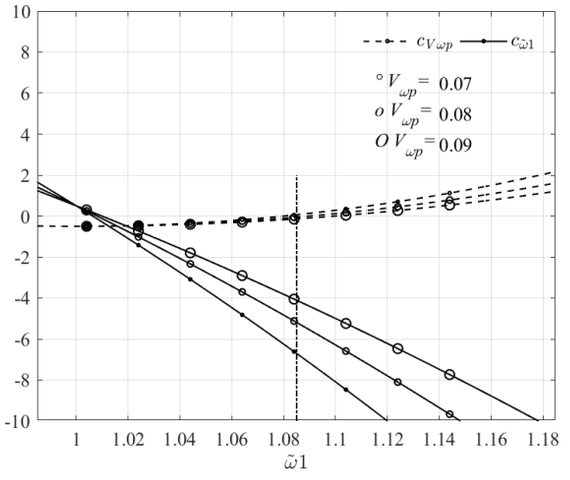

Figure 4. Variation of the propagation coefficients with $\tilde{\omega}_1$ and $V_{\omega p}$. The vertical line reports the mean value of $\tilde{\omega}_1$

5.3 *Uncertainty propagation analysis and comparison with conventional verifications*

The uncertainty propagation is carried out considering the actual scattering in the parameters in the application of the ESM described in Section 2. The mean value of the parameters is assumed equal to the nominal values. Concerning the pedestrian load parameters, the coefficient of variation of $V_{\omega p}$ is assumed 0.16 (see Table 1). Given the lack of information, the coefficient of variation for α_m and G_m is assumed 0.1. Concerning structural parameters, and taking into account the scattering related to both ω_1 and ω_{pm} (Table 1-3), the coefficient of variation of $\tilde{\omega}_1$ is assumed 0.1; the coefficient of variation of damping ratio ξ_1 is assumed 0.3; the coefficient of variation of the modal mass is assumed 0.05.

The propagation of uncertainties is carried out by Eq. (10) and Eq. (12) which account both for the role of each parameter in the analytical expression of the response and for the uncertainty inherent in the parameters. Table 7 summarizes the results obtained for the response quantity $\sigma_{\ddot{p}1}$; each row considers the related parameter as uncertain and assumes the nominal values of others. Results obtained on the peak value are essentially the same, being the values of the propagation coefficients c_{xi} almost coincident.

Table 7. Uncertainty propagation on the response standard deviation by TSE

x_i	V_{xi}	c_{xi}	V_{Ri}
$V_{\omega p}$	0.16	-0.065	0.09
α_m	0.1	1	0.1
G_m	0.1	1	0.1
$\tilde{\omega}_1$	0.1	-6.7	0.67
ξ_1	0.3	-0.5	0.15
M_1	0.05	-1	0.05

Values reported in Table 7 show that errors in the estimate of the involved frequencies, of the structure and the pedestrian loading, represent the main sources of uncertainties in the evaluation of the structural response. In this case, notwithstanding the prediction of this quantity is characterized by limited uncertainty, it affects the response evaluation according to a propagation factor larger than 5. Its prediction should require therefore a large effort in order to reduce errors in the prediction of the dynamic response.

Among the other structural parameters involved, it can be noted that the large scattering concerning damping evaluation is rather mitigated by the related propagation coefficient. The uncertainty in the modal mass is very small, however it propagates straight forward on the response.

Concerning the other dynamic loading parameters (coefficient of variation of the step frequency, average dynamic loading factor and average pedestrian weight), they all have comparable effect on the uncertainty of the response, providing a variation which is negligible if compared with the one provided by the uncertainty in the non-dimensional frequency characterization.

As a final remark, it should be noticed that the coefficient of variation of the response, taking into account the uncertainty in all the parameters (assumed as uncorrelated) is obtained applying Eq. (10) and it is given by $V_R = 0.71$.

A comparison with results provided by conventional verifications can be finally carried out.

SETRA (2006) provides the equivalent uniformly-distributed resonant loading per-unit-length:

$$f(t) = \frac{10.8\sqrt{\xi_j N_p}\,\alpha_m G_m \cos(\omega_j t)}{L} \tag{14}$$

Considering a sinusoidal mode shape, the modal load is given by:

$$F_j(t) = \frac{2\times 10.8\sqrt{\xi_j N_p}\,\alpha_m G_m \cos(\omega_j t)}{\pi} \tag{15}$$

The maximum acceleration $\ddot{p}^S_{j\max}$ provided by this standard loading condition is:

$$\ddot{p}^S_{j\max} = \frac{10.8\sqrt{\xi_j N_p}\,\alpha_m G_m}{\pi M_j \xi_j} \tag{16}$$

Table 8 reports the nominal values of the maximum footbridge acceleration obtained applying the ESM and the standard loading condition suggested by SETRA (2006). The number of pedestrians is assumed as N_p=50. A suitable interval of variation of the footbridge maximum acceleration provided by ESM taking into account the propagation of uncertainties is also reported ($R_m(1\pm V_R)$).

It can be noted that the conventional verification based on Eq. (16) provides a conservative estimate of the maximum footbridge acceleration if compared with the mean value provided by the equivalent spectral model, Eq. (4). However, taking into account for the randomness of the involved parameters, the response spread up to such an extent, so that results based on conventional evaluations turn out to be no longer representative of the actual response. Especially, within the range of variation obtained by the application of ESM, they can result non-conservative, providing unsafe evaluations.

Table 8. Comparison between conventional verification and uncertainty propagation results

	SETRA	ESM R_m	$R_m(1\pm V_R)$
$\ddot{p}_{j_{max}}$ (m/s^2)	1.61	1.45	0.42-2.48

6 CONCLUSIONS

In this paper, the propagation of uncertainties inherent to structural and loading parameters on the serviceability assessment of footbridges has been analyzed through the Taylor Series Expansion method. The joint analysis of the uncertainties of the loading parameters reported in the literature and of the propagation coefficients has allowed to identify the main parameters causing uncertainty in footbridges' serviceability assessment.

The application to a real case study has highlighted the determinant role of the frequency ratio (i.e. the ratio between the footbridge natural frequency and the mean pedestrian step frequency). Dealing with the specific case analyzed, it has been shown that conventional verifications based on equivalent uniformly distributed resonant load, are conservative with respect to estimates supplied by the Equivalent Spectral Model based on the nominal values of the

parameters. However, considering the large uncertainties inherent the estimate of the involved parameters, conventional estimates can lead to non-conservative evaluations.

It should be finally remarked that experimental measurements (Zivanovic 2012, Van Nimmen et al. 2014b) demonstrate that human-structure interaction could significantly affect human-induced vibrations of footbridges. This aspect, that has been neglected in the present paper, constitutes an additional source of uncertainty for the definition of the dynamic properties of the coupled pedestrians-footbridge system (Tubino 2018).

ABSTRACT: The vibration serviceability assessment of footbridges exposed to high density crowds is often imperative for the design. Due to the lack of representative operational loading data, current models for crowd-induced loading remain unvalidated. This lack of data can partly be ascribed to the fact that the existing techniques to directly register human-induced loading are infeasible to apply for a high-density crowd. Instead, this contribution is taking a first step towards the indirect measurement of crowd-induced loading by identifying the individual walking trajectories of a high-density crowd from video footage. A unique case study of a footbridge exposed to real pedestrian traffic with a density of 1 person/m^2 is presented. Based on the collected video footage, the detection of each individual pedestrian in the crowd is obtained by employing an image segmentation algorithm. Next, each detection is associated to the corresponding track by using a motion-based prediction model. Subsequently, the obtained tracks are converted to world coordinates using two different setups: mono and stereo vision. The accuracy of the identified tracks is investigated. Finally, the flow characteristics are analyzed. The error propagation of measurement noise of the detection was observed to result in an accuracy in an order of magnitude of centimeters for the stereo-vision setup. Also, the error was found to be nearly constant for the entire bridge deck. In case of the single-view setup, the maximum error is higher than the stereo setup, especially for oblique viewing angles. A track obtained by mono-vision conversion has nearly the same accuracy as a track obtained by stereo vision provided that the true height of each pedestrian is accounted for. The identified mean walking velocity in the crowd is found to be in agreement with a widely-applied speed-density model in literature.

1 INTRODUCTION

As materials nowadays are ever stronger, structures become more slender and therefore more prone to dynamic excitation. In case a structure is designed for human occupants (e.g. grandstand, footbridges, ...), this trend is further stimulated by the relatively small service load. As a consequence the structural design of such structures is often governed by the vibration serviceability requirements. Although an accurate description of the human-induced load is indispensable to make a reliable prediction of the dynamic performance of a structure, designers are forced to rely on simplified force models. These models are based on unvalidated assumptions and neglect several important phenomena, such as the interaction between the crowd and the structure (Venuti and Bruno 2009). The main reason that current load models are unvalidated is the absence of well-documented full-scale operational loading data. However, this data is the only way forward for a further development of reliable load models that describe crowd-induced loading (Živanović 2012).

This absence can partly be ascribed to the fact that classical techniques to directly register human-induced loading are impractical to be applied for high-density crowds, involving a large number of participants. While these techniques have proven their

competence for laboratory or small-scale applications (Racic et al. 2010, Dang and Živanović 2015), upscaling these techniques is infeasible due to practical and/or economical reasons. Promising alternatives to register the crowd-induced loading are inverse force identification techniques (Van Nimmen et al. 2016), or indirect force characterizing techniques (Van Nimmen et al. 2014, Racic et al. 2010). The latter method characterizes the crowd-induced force by combining the 2D position of each pedestrian in the crowd with the participant's 3D body motion, more specifically the time-variant step frequency.

The pedestrians' trajectories can be obtained from video footage through the application of tracking algorithms on video footage of the pedestrians on the footbridge. The challenge of tracking people based on video frames has already received large attention in the literature. However, several challenges remain present, especially for high density crowds (Nguyen et al. 2016). The main developments in this domain are established within the context of video surveillance (Wang et al. 2014) or automotive safety applications (Gerónimo et al. 2010). Typically, these algorithms aim for a semantic understanding of the video footage. As a consequence, the conversion of the obtained tracks to world coordinates and, more importantly, the related accuracy of those world coordinates has not been investigated. This conversion and the quantification of the accuracy is indispensable for structural dynamical purposes.

This contribution presents a methodology to determine the trajectories of each pedestrian in a high density crowd on a footbridge, expressed in world coordinates. The methodology is illustrated by the application on a high-density crowd on a footbridge.

The outline of the paper is as follows. First, in Section 2 the footbridge structure is presented. Section 3 introduces the methodology for determining the pedestrians' tracks based on video footage, while Section 4 presents the methodology to convert the obtained tracks to world coordinates. In Section 5 the accuracy of the obtained tracks is analyzed and discussed. Section 6 presents the results of the applied methodology. Finally, Section 7 summarizes the main conclusions.

2 THE WAALSE KROOK SOUTH FOOTBRIDGE

The Waalse Krook South footbridge is a steel pedestrian and bicycle bridge with a single span of 23 m and a width of 6.8 m, designed by Couse & Goris architects in a collaboration with TV RCR Aranda Pigem Vilalta Architects (see also Figure 1). The bridge deck is composed of a two-way ribbed steel-concrete composite plate (2 cm steel, 12 cm concrete). The bridge deck is supported by two neoprene bearings on one side, and two steel columns on the other side.

Figure 1: The Waalse Krook South footbridge.

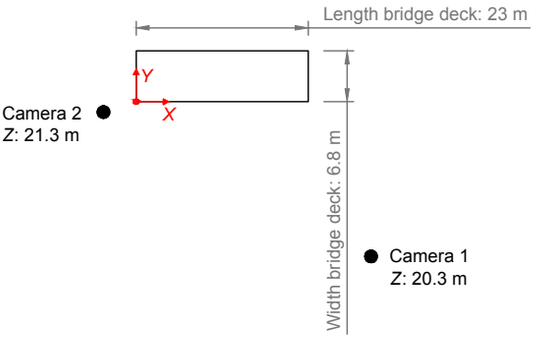

Figure 2: Schematic plan view of the bridge, camera positions and definition of the global axes X and Y. The axis Z coincides with the vertical direction.

2.1 *Camera setup*

Two stationary cameras are used to capture the motion of the pedestrians on the bridge deck. The position of camera 1 (outdoors, Nikon D3300) and camera 2 (indoors, Canon XA25) is given in Figure 2. The resolution of both cameras is 1920x1080p. The framerate is respectively 24 fps and 25 fps. A snapshot of the field of view of both cameras is shown in Figure 4. The area of the bridge deck in the snapshot of camera 1 is 5.11×10^5 pix^2 and for camera 2 is 5.04×10^5pix^2. This results respectively in an average ground sampling distance of 17.5 mm/pix and 17.4 mm/pix.

2.2 *Experimental program*

The experimental study considered 142 pedestrians walking on the bridge deck. This corresponds to a pedestrian density of approximately 1 persons/m^2. Prior to the experiment, the height and body mass of each participant was measured. The pedestrians were distributed over the entire bridge deck and were asked to walk at a self-selected speed. The total test duration was 10 minutes.

3 PEDESTRIAN DETECTION AND TRACKING

Determining the trajectories of each pedestrian in a crowd is a three-step process: (1) the detection of each pedestrian in each frame, (2) the association of each

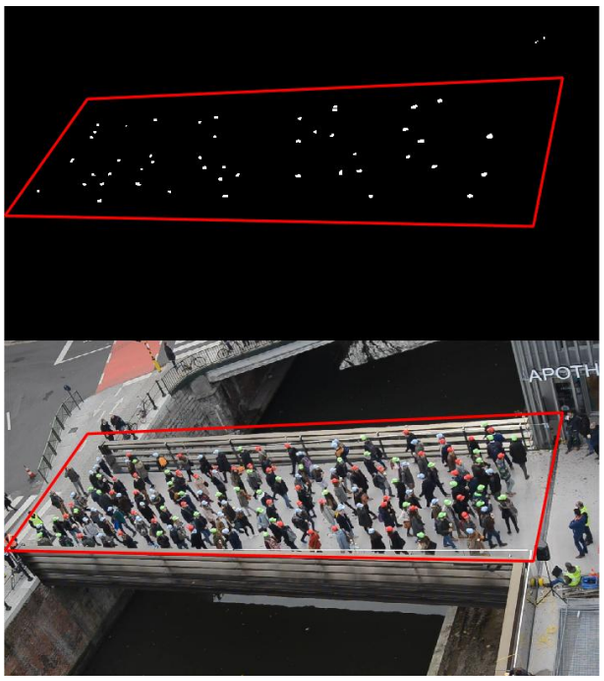

Figure 3: Example of a detection mask of blue colored hats on the bridge deck.

detection to its corresponding track and (3) the conversion of image coordinates to world coordinates.

The pedestrians can be tracked with one camera i.e. a mono-vision setup or multiple cameras i.e. a stereo-vision setup.

For the implementation of the methodology outlined in this section, various functions of the Computer Vision System Toolbox from Matlab R2016b™ are used (The MathWorks Inc. 2013).

3.1 *Detection*

Tracking a large number of pedestrians in video images requires stable, robust and scalable algorithms. Over time, many techniques have been developed for human detection in video footage. Typically, these techniques employ machine learning techniques (Girshick et al. 2014). The methods are effective for their intended purposes (e.g. video surveillance, face recognition etc.). However, for the detection of humans in large-density crowds the algorithms often become unstable due to the fact that parts of the body are occluded. Also, the computational cost of techniques based on machine learning is high.

In the present experimental study, a color segmenting technique is used. Each pedestrians was equipped with a colored hat in order to facilitate the detection. The method segments each pixel of the frame in two categories: detections of the colored hat of a pedestrian and the background. This approach has the main advantage that only the head of the pedestrian is detected, which enhances the accuracy of the obtained track. In addition, the robustness of the algorithm is not susceptible to occlusion of (parts of) the participant's body, provided that the viewing angle of the camera is not too oblique.

Three colors were used for the hats: red, blue and green. The colors were chosen in such a way that no overlap exists with the colors of the background in the RGB color-space. Next, 20 frames involving a varying illumination are used as training frames from which the pixels corresponding to the colored hats are selected. Mean and standard deviation of the resulting color vector are calculated. A 95% confidence volume in the RGB color-space is determined, assuming a multivariate normal distribution for each color vector. Subsequently, a detection mask is obtained for each frame by segmenting each pixel in the frame according to the obtained 95% confidence volumes of the colored hats. Finally, the detection of the hats is done by selecting the blob areas on the mask that exceed a user-defined area. In the present work, only blob areas larger than 12 pixels are retained. Other blob areas are considered as noise. An example of a detection mask is shown in Figure 3.

3.2 *Tracking*

Since there are several pedestrians, and thus multiple tracks, the data association problem is a multi-object tracking problem. A Kalman filter is used as a motion-based estimation model to predict the location of each pedestrian in the next frame. As a result of the relative high frame rate of the cameras, the frame-by-frame walking speed of the pedestrian only changes slightly. For this reason the motion model of the Kalman filter is configured with a constant velocity. The velocity in the motion model of the current frame is estimated as the average velocity of the past 5 frames. Both measurement and model noise are assumed to have a standard deviation of 3 pixels, invariant of the direction. The motivation for this assumption is given in Section 5.

The approach of using a Kalman filter has two advantages. First, the location of a track in the consecutive frame is estimated, which is subsequently used to determine the likelihood that a certain detection corresponds to a track. The association problem is solved by applying the James Munkres' variant of the Hungarian assignment algorithm (Munkres 1957). The second advantage of the Kalman filter is that an estimate can be made of a track's location when no measurement of that track is found in the next frame(s), e.g. due to occlusion. This allows to pick up a track when it becomes visible once more after several occluded frames.

4 CONVERSION FROM IMAGE COORDINATES TO WORLD COORDINATES

The identified tracks are obtained in one ore more image planes. However, further analysis is performed in world coordinates, so a conversion is required.

4.1 *Camera model*

The camera model that is used in the present work is the standard pinhole camera model. This section briefly discusses the used camera model. For a detailed description the reader is referred to (Hartley and Zisserman 2003).

The pinhole model describes the relation between world points $\mathbf{M} = [X, Y, Z, W]^{\mathrm{T}}$ and the image points $\mathbf{m} = [x, y, w]^{\mathrm{T}}$ in homogeneous coordinates. In case of Euclidean coordinates the last component i.e. W or w equals 1. The projection is described by equation (1) where $\simeq$ means "equal up to a non-zero scale factor":

$$\mathbf{m} \simeq \mathbf{PM} \tag{1}$$

$$\mathbf{m} \simeq \mathbf{K}[\mathbf{R}^T | -\mathbf{R}^T\mathbf{t}]\mathbf{M} \tag{2}$$

with $\mathbf{K}$ the matrix describing the intrinsic parameters of the camera:

$$\mathbf{K} = \begin{bmatrix} \alpha_{\mathrm{x}} & s & u_{\mathrm{x}} \\ 0 & \alpha_{\mathrm{y}} & u_{\mathrm{y}} \\ 0 & 0 & 1 \end{bmatrix} \tag{3}$$

with α_{x} and α_{y} the focal length, expressed in pixels, s the skew and u_{x} and u_{y} the location of the principal point, expressed in pixel coordinates. As digital cameras do not posses any skew, it holds that $s = 0$.

$\mathbf{R}$ and $\mathbf{t}$ are a 3×3 matrix and 3×1 vector describing the orientation and position of the camera in world coordinates respectively. The matrix $\mathbf{P}$ is a 3×4 matrix and is called the projection matrix.

Equation (1) is a linear equation and is an idealization of the actual projection mechanism of real-life cameras. The linear model does not capture radial or tangential distortion effects, typically present in such cameras.

As the influence of tangential distortion is usually much smaller than radial distortion, only the latter effect is taken into account. The effect is modeled with a polynomial function that describes the relation of the distorted and undistorted coordinates in the focal plane. As a consequence, the relation between the image point $\mathbf{m}$ and the world point $\mathbf{M}$ becomes non-linear and is denoted with by the vector function F:

$$\mathbf{m} = F(\mathbf{x}, \mathbf{M}) \tag{4}$$

With $\mathbf{x}$ being the camera parameter vector that contains all the relevant parameters of the camera model.

4.2 *Camera calibration*

The camera parameter vector $\mathbf{x}$ can be obtained by camera calibration. Several techniques exist for this calibration. In this work the methodology presented in (Triggs et al. 2000) is used. In this methodology the cameras are calibrated using correspondence points which were measured on the image planes (image coordinates) and on the bridge deck, the bridge railing and 1.7 m above the bridge deck (world coordinates). The 3D location of the world points was measured reflectorless with a total station, yielding accuracies of 2 mm + 2 ppm root mean square. Figure 4 shows the location of these correspondence points. The points are non-coplanar and scattered over the volume of the bridge deck, as this is the region of interest for the pedestrian detection.

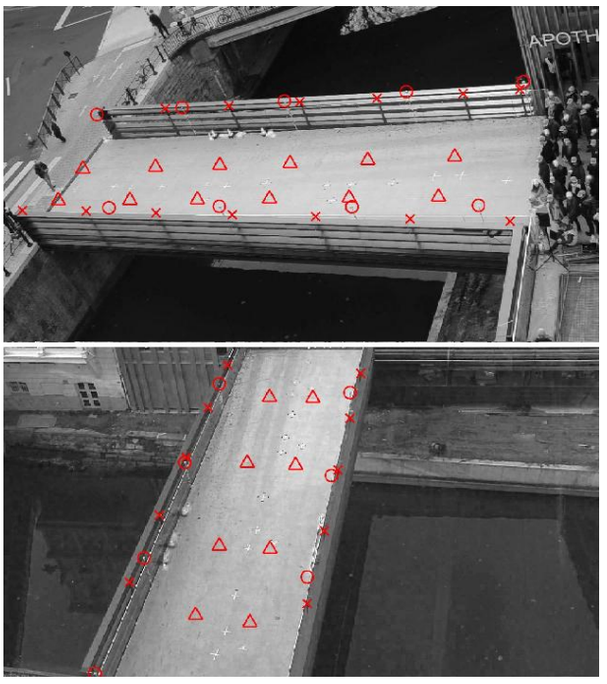

Figure 4: Snapshot of camera 1 (top) and camera 2 (bottom). Correspondence points used for calibration are situated on the bridge deck (△), the bridge railing (X) and on points 1.7m above the bridge deck (O).

For a given camera parameter vector $\mathbf{x}$ the reprojection error $\boldsymbol{\epsilon}$ is defined as $\boldsymbol{\epsilon} = \mathbf{m}_{\mathrm{c}} - \tilde{\mathbf{m}}_{\mathrm{c}}$, with $\mathbf{m}_c$ the image coordinates of the correspondence points and $\tilde{\mathbf{m}}_c$ the estimated image points obtained as $\tilde{\mathbf{m}} = F(\mathbf{x}, \mathbf{M})$.

The camera parameter vector $\mathbf{x}$ is estimated in such a way that the squared sum of the reprojection errors (i.e. $\boldsymbol{\epsilon}^{\mathrm{T}}\boldsymbol{\epsilon}$) is minimized. The calibration procedure yields camera parameter vectors for which the mean reprojection error is 0.60 pix and 0.91 pix for camera 1 and 2 respectively. This is considered to be sufficiently accurate for the envisaged purpose.

4.3 *Transformation of image coordinates to world coordinates*

In this paragraph two different approaches to retrieve 3D information about the pedestrians are discussed. First, the 3D position is determined using a multi-view setup. Second, the 3D position of the pedestrians is determined from a single view, using a planar homography.

4.3.1 *Retrieving the 3D position using stereo vision: triangulation*

When the projection matrices of both cameras $\mathbf{P}_1$ and $\mathbf{P}_2$ are known, the 3D information of a point $\mathbf{M}$ can be retrieved if the point is visible in both cameras i.e. $\mathbf{m}_1$ and $\mathbf{m}_2$.

The point $\mathbf{M}$ is the point for which the following holds:

$$\begin{cases} \mathbf{m}_1 &= \mathbf{P}_1\mathbf{M} \\ \mathbf{m}_2 &= \mathbf{P}_2\mathbf{M} \end{cases} \tag{5}$$

Since some measurement noise is always present, no exact solution for $\mathbf{M}$ exists. Therefore, $\mathbf{M}$ is found in such a way the the true reprojection error $\sum_{i=1}^{2} D(\mathbf{P}_\mathrm{i}\mathbf{M}, \mathbf{m}_i)$ is minimized. The practical procedure is described in (Moons et al. 2010).

4.3.2 *Retrieving the 3D position using single view geometry: homography*

Although 3D information is typically obtained from multiple 2D images, there are ways to obtain 3D information of points based on a single image. However, in this case one or more assumptions are to be made as a single view is mathematically insufficient to retrieve 3D information about an object.

In the present work a planar homography is used to obtain the 3D information about an object detected in a single frame. The homography describes the linear transformation of a 2D point. As such it can describe the transformation of a point in one plane to a corresponding point in another plane. In this case, the first plane is the (undistorted) image plane while the second plane π is defined as the horizontal plane 1.7m above the bridge deck.

It is assumed that the participants' heads coincide with the plane π. The consequences of this assumption will be investigated in paragraph 5.

The homography $\mathbf{H}_\pi$ is a 3×3 matrix and is defined as the relationship between the image coordinates $[x, y, w]^\mathrm{T}$ and the world coordinates $[X, Y, W]^\mathrm{T}$:

$$\mathbf{m}\begin{bmatrix} x \\ y \\ w \end{bmatrix} \simeq \mathbf{H}_\pi \begin{bmatrix} X \\ Y \\ W \end{bmatrix} = \begin{bmatrix} h_{11} & h_{12} & h_{13} \\ h_{21} & h_{22} & h_{23} \\ h_{31} & h_{32} & h_{33} \end{bmatrix} \begin{bmatrix} X \\ Y \\ W \end{bmatrix} \tag{6}$$

where the world coordinates are only expressed in terms of X and Y as the plane is horizontal.

The relationship between image coordinates and world coordinates is also described by equation (1). As it is assumed that each detection lies on the plane π, it holds that $Z = 1.7$m. This relation and equation (6) are substituted in equation (1). Rearranging yields the components of the homography matrix homography matrix $\mathbf{H}_\pi$.

Finally, the world coordinates $\mathbf{M}$ are calculated based on the detected image coordinates $\mathbf{m}$ by applying the inverse homography:

$$\begin{bmatrix} X \\ Y \\ W \end{bmatrix} \simeq \mathbf{H}_\pi^{-1}\mathbf{m} \tag{7}$$

5 ACCURACY OF THE IDENTIFIED TRACKS

In this paragraph the accuracy of the determined tracks is investigated. First, the measurement noise of the detection is discussed. Second, the accuracy of the stereo-vision setup is assessed. Third, the accuracy of the single-view setup is evaluated. Finally, a comparison is made between the tracks determined with the stereo and the mono-vision setup.

5.1 *Measurement noise of the detection*

Assume a certain participant in the test. The center of gravity of the colored hat on the image plan is denoted as $\mathbf{q} = [x_\mathrm{q}, y_\mathrm{q}]^\mathrm{T}$.

The measurement of this point is denoted as $\tilde{\mathbf{q}} = [\tilde{x}_\mathrm{q}, \tilde{y}_\mathrm{q}]^\mathrm{T}$.

It is assumed that the components of $\tilde{\mathbf{q}}$ are normally distributed around the components of the real center of gravity $\mathbf{q}$:

$$\tilde{x}_\mathrm{q} \sim \mathcal{N}(x_q, \sigma_{x_\mathrm{q}}^2) \tag{8}$$

$$\tilde{y}_\mathrm{q} \sim \mathcal{N}(y_q, \sigma_{y_\mathrm{q}}^2) \tag{9}$$

Furthermore it is assumed that the variation is the same in x and y direction (i.e. $\sigma_{x_\mathrm{q}} = \sigma_{y_\mathrm{q}}$) and that the measurement noise in both directions is independent. Hence, the joint probability density function (PDF) reads:

$$f_{\tilde{x}_\mathrm{q}\tilde{y}_\mathrm{q}}(x, y) = f_{\tilde{x}_\mathrm{q}}(x) f_{\tilde{y}_\mathrm{q}}(y) \tag{10}$$

The standard deviation $\sigma_{x_\mathrm{q}} = \sigma_{y_\mathrm{q}}$ is assumed to be 3 pixels. The border of the 95% confidence area of the corresponding joint PDF $f_{\tilde{x}_\mathrm{q}\tilde{y}_\mathrm{q}}$ is a circle with center $\mathbf{q}$ and a radius of 6 pixels. The 95% confidence area comprises the hat of the participant, see Figure 5.

The point in world coordinates which corresponds to the point(s) $\mathbf{q}$ is denoted as $\mathbf{Q} = [X_\mathrm{Q}, Y_\mathrm{Q}]^\mathrm{T}$. The world point which corresponds to the measured point(s) $\tilde{\mathbf{q}}$ has a probabilistic distribution as well and is denoted with $\tilde{\mathbf{Q}} = [\tilde{X}_\mathrm{Q}, \tilde{Y}_\mathrm{Q}]^\mathrm{T}$.

5.2 *Accuracy of the mono-vision setup*

In case $\mathbf{Q}_\pi$ is obtained by a single view, $\tilde{\mathbf{Q}}_\pi$ can be obtained by change of stochastic variables since the relation between $\mathbf{q}$ and $\mathbf{Q}_\pi$ is invertible. This relation is described by a planar homography and is given by equation (6). The point $\mathbf{Q}_\pi$ has the index π as it is

Figure 5: Detection of a person on the bridge deck. Dot: real center of gravity, $\mathbf{q} = [390\text{pix}, 370\text{pix}]^{\text{T}}$. Line: boundary of 95% confidence area of the measured center of gravity $\tilde{\mathbf{q}}$.

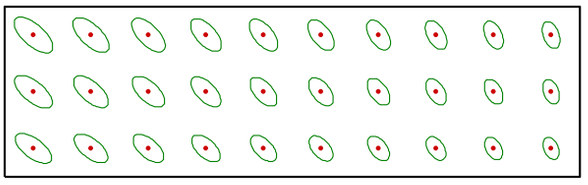

Figure 6: Boundaries of 95% confidence areas (lines) for different locations $\mathbf{Q}$ (dots) on the bridge deck. Confidence areas are rescaled with a factor 3 around the center of gravity of each confidence area.

assumed that this point lies on the plane π i.e. the assumption that was made when defining the homography $\mathbf{H}_\pi$. In this paragraph camera 1 is considered.

The components of an image coordinate $\mathbf{q}$ can be written as a functional of the coordinate $\mathbf{Q}_\pi$:

$$x_{\text{q}} = v_1(X_{\pi,\text{Q}}, Y_{\pi,\text{Q}}) \tag{11}$$

$$y_{\text{q}} = v_2(X_{\pi,\text{Q}}, Y_{\pi,\text{Q}}) \tag{12}$$

The joint PDF of $(\tilde{X}_{\pi,\text{Q}}, \tilde{Y}_{\pi,\text{Q}})$ is obtained through change of stochastic variables and is given by:

$$g_{\tilde{X}_\text{Q}\tilde{Y}_\text{Q}}(X_\pi, Y_\pi) = |J| f_{\tilde{x}_\text{q}\tilde{y}_\text{q}}\left[v_1(X_\pi, Y_\pi), v_2(X_\pi, Y_\pi)\right] \tag{13}$$

With J the Jacobian defined by:

$$J = \begin{bmatrix} \frac{\partial v_1(X_{\pi,Q}, Y_{\pi,Q})}{\partial X_\pi} & \frac{\partial v_1(X_{\pi,Q}, Y_{\pi,Q})}{\partial Y_\pi} \\ \frac{\partial v_2(X_{\pi,Q}, Y_{\pi,Q})}{\partial X_\pi} & \frac{\partial v_2(X_{\pi,Q}, Y_{\pi,Q})}{\partial Y_\pi} \end{bmatrix} \tag{14}$$

The 95% confidence area of $g_{\tilde{X}_{\pi,\text{Q}}\tilde{Y}_{\pi,\text{Q}}}$ is depicted in Figure 6 for different locations $\mathbf{Q}$ on the bridge deck.

Next, the maximum error e_{mono} is calculated as the maximum distance between the point if no error occurred (which corresponds in this case with the mean value $(X_{\pi,Q}, Y_{\pi,Q})$ and the boundary of the 95% confidence area. The maximum measurement error for every possible location $\mathbf{Q}$ on the bridge deck is shown in Figure 7.

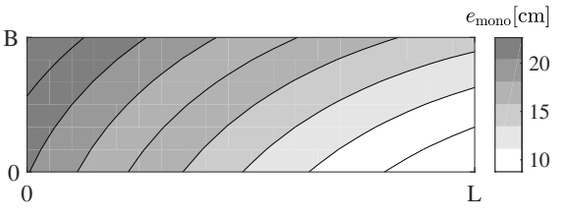

Figure 7: Maximum measurement error of a mono setup e_{mono} for every possible location of $\mathbf{Q}$ on the bridge deck.

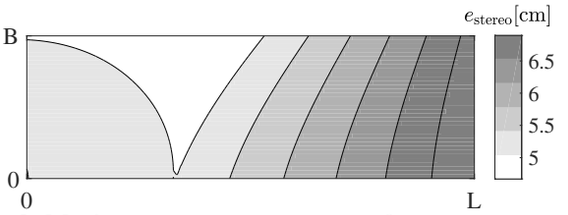

Figure 8: Maximum measurement error of a stereo setup e_{stereo} for every possible location of $\mathbf{Q}$ on the bridge deck.

The result shows that the maximum error as a result of the measurement error is 25 cm, in the North-West corner of the bridge deck. The lowest error is found in the South-East corner of the bridge deck. The error increases with the obliqueness of the viewing angle of the camera.

5.3 *Accuracy of the stereo-vision system*

Since the equations that describe the relation between the image points on two planes, $\mathbf{q}_1$ and $\mathbf{q}_2$, and the corresponding point in world coordinates $\mathbf{Q}$ are not invertible, a simplified approach is taken to evaluate the accuracy of the stereo-vision system.

A point $\mathbf{Q}$ is considered which lies on the bridge deck. The corresponding image coordinates of the different cameras $\mathbf{q}_1$ and $\mathbf{q}_2$ are calculated using equation (4). Next, one of the image points is translated by 6 pixels (the radius of the 95% confidence area of $\tilde{\mathbf{q}}$) in the $\pm x$ or $\pm y$ direction, i.e. 4 possible locations for the measured point $\tilde{\mathbf{q}}$ are considered. Then, the corresponding 3D location $\tilde{\mathbf{Q}}_i$ is obtained by using the procedure explained in paragraph 4.3.1, with one image point translated 6 pixels and one image point not shifted. This is done for both image points. Finally, the horizontal error $e_{\text{stereo},i}$ is defined as the horizontal distance between $\tilde{\mathbf{Q}}_i$ and $\mathbf{Q}$ and is calculated for all 8 possible combinations. The final error e_{stereo} is obtained as $\max_i(e_{\text{stereo},i})$.

Figure 8 depicts the maximum measurement noise for every possible location of $\mathbf{Q}$ on the bridge deck. From this figure it can be observed that the measurement error is low (order of magnitude 6 cm) and that the measurement error is nearly constant for every location of $\mathbf{Q}$ on the bridge deck.

5.4 *Comparison of mono versus stereo vision*

A comparison is made between the tracks determined by triangulation (stereo vision) and the tracks determined using a homography (mono vision) for 40

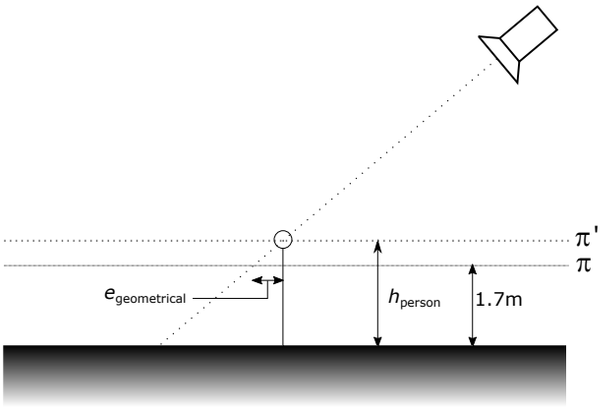

Figure 9: A geometrical error occurs when using a homography if a person's height is higher or lower than 1.7 m (i.e. the height of the reference plane π).

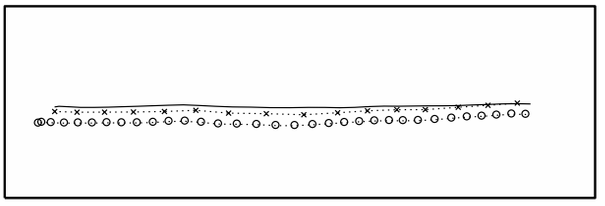

Figure 10: Part of a track of a person with a height of 1.55 m. Tracks calculated by triangulation (solid line), homography (dashed line with marker O) and homography with the reference plane translated to take into account the height of the person (dashed line with marker X). The relative horizontal distances of the dashed lines with respect to the solid line are rescaled with a factor 3.

pedestrians. The latter considers two different calculation methods: (1) the height is not explicitly taken into account (and assumed to be 1.7 m) and (2) the height of the pedestrian is taken into account by translating the plane π with a distance $(h_{\text{person}} - 1.7\text{m})$. The horizontal geometrical error increases as $|h_{\text{person}} - 1.7\text{m}|$ increases and as camera becomes more oblique, see also Figure 9 and 10.

The comparison considers pedestrians crossing the bridge a single time. The error for each frame is calculated as the difference in horizontal distance of the track using a homography relative to the track determined by triangulation. Next, the root mean square error (RMSE) is calculated for each track.

Figure 11 depicts the RMSE of the tracks determined by mono versus stereo vision. In this graph it can clearly be seen that the RMSE of the tracks increases with $|h_{\text{person}} - 1.7\text{m}|$ in case the height of the person is not taken into account, reaching RMSE values higher than 0.30 m. On the other hand, taking into consideration the height of the person results in an average RMSE of 0.04 m, independent of the person's height.

6 RESULTS OF THE VISION-BASED METHODOLOGY

Figure 12 shows a typical result of the obtained track of a pedestrian based on the vision-based methodology and its corresponding velocity. The figure shows

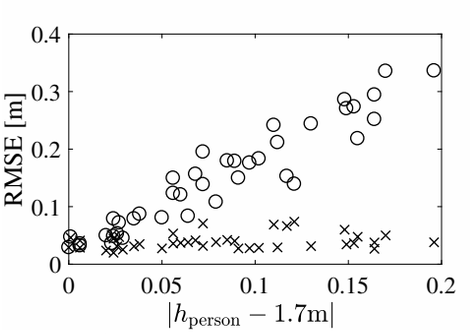

Figure 11: RMSE of tracks determined by using a homography relative to the tracks obtained by stereo conversion as a function of the quantity $|h_{\text{person}} - 1.7\text{m}|$: height of the pedestrian not taken into account (O) and height explicitly taken into account (X).

that the walking velocity varies over time, which is a result of the fact that (1) pedestrians have to deviate from a straight line to avoid collision with other pedestrians causing them to change route and speed and (2) the current case study involved lower speeds when turning on either side of the bridge due to local congestions.

The pedestrians turn in a zone of approximately 2 meter at the end of the bridge decks. These zones are indicated in gray in Figure 6. Since these parts of the track are an artificial situation, they are omitted in further analysis.

Figure 13 shows the distribution of the average walking velocities of the pedestrians during the test. The figure shows that the mean walking velocity is 0.96 m/s. The walking speed is also be predicted using an average speed-density relation, as proposed in (Weidmann 1993). Based on this relation, an average walking velocity of 1.05 m/s is predicted for a crowd density of 1 person/m^2. The comparison shows that the measured walking velocity is 9% lower than the predicted velocity. This may be ascribed tho the fact the predicted velocity in (Weidmann 1993) considers an unidirectional flow, whereas the real situation is bidirectional. In (Weidmann 1993) the reduction of speed is estimated to be about 4-9% in case of an equal flow in both directions. This estimate is in agreement with the observed mean velocity.

7 CONCLUSIONS

A methodology is presented to track the pedestrians in a high-density crowd based on camera footage. By taking the appropriate measures prior to the start of the experiment, the presented algorithm is capable to determine the trajectories of each pedestrian.

The effect of error propagation of measurement noise of the detections was investigated. In case of the stereo setup, the final error has an order of magnitude of 6 cm and is nearly constant over the bridge deck. In case of a mono-vision setup, the maximum error is 25 cm in the North-West corner of the bridge. The error increases as the obliqueness of the camera increases.

A mono-view conversion of the identified tracks is compared to a stereo view transformation. Using

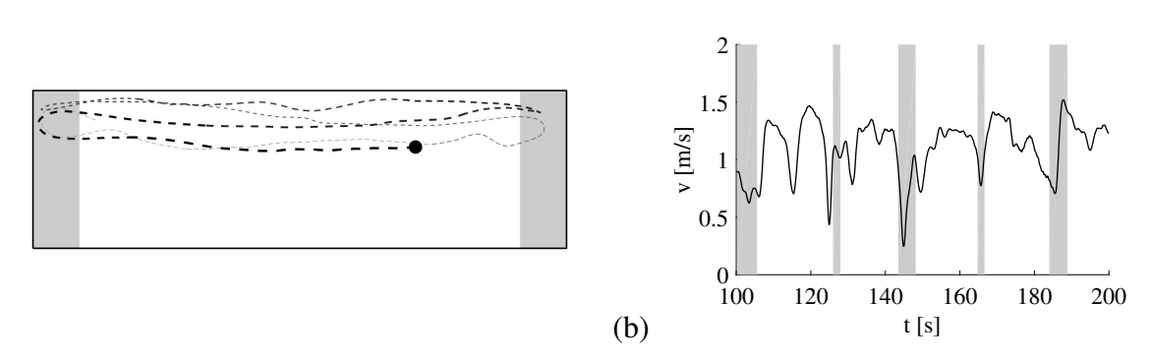

Figure 12: Example of the result of the vision-based methodology. (a) Trajectory of a pedestrian between 100s and 200s. The gray hue indicates the location on the bridge deck where the longitudinal component of the distance to the border is less than 2 m. (b) Corresponding velocity of the pedestrian. The gray background indicates the time slots when the longitudinal component of the distance of the pedestrian to the border is less than 2 m.

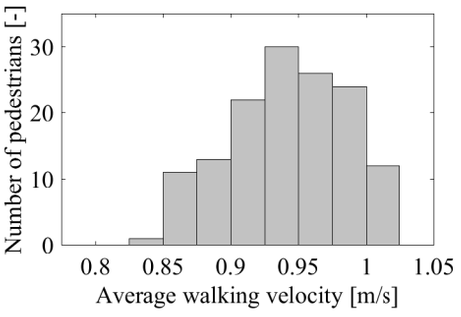

Figure 13: Distribution of the average walking velocities of the pedestrians during the test.

a homography yields RMSE's up till 0.35 m, especially for persons whose height is remarkably higher or lower than the height of the reference plane. By taking into account the height of the pedestrian, the RMSE can be mitigated to 0.04 m.

The proposed pedestrian-tracking methodology is applied to a case study with a high-density crowd of 1 person/m^2. A comparison of the measured mean walking velocity compared to the velocity predicted by a well-known speed-density model in literature, indicates that the measured velocity is in good agreement with the predicted velocity.

ABSTRACT: The further development and improvement of prediction models for crowd-induced vibrations of footbridges requires detailed information on representative operational loading data. This paper uses an inverse method to estimate the parameters that govern human-structure interaction from the resulting structural response. The parameters of interest concern the dynamic characteristics of a single-degree-of-freedom (SDOF) system, applied to describe the mechanical interaction between the pedestrian and the structure. The parameter estimation procedure assumes that the dynamic behaviour of the emtpy structure and the distribution of step frequencies in the crowd are known. The dynamic characteristics of the SDOF model are estimated by minimizing the discrepancy between the observed and the simulated power spectral density of the structural response.
The proposed approach is applied to a real footbridge. First, the operational modal characteristics of the empty structure are identif ed and used to calibrate the f nite element model of the structure. Second, the structural response induced by a pedestrian density of 1 persons$/\mathrm{m}^2$ is observed. The corresponding non-resonant response is used to estimate the distribution of step frequencies in the crowd. Finally, the parameter estimation procedure is applied and a reasonable estimate of the dynamic characteristics of the SDOF model is obtained.

1 INTRODUCTION

Prone to human-induced vibrations, the dynamic performance of footbridges under crowd-induced loading is often imperative for the design. Although the force exerted by a pedestrian on a perfectly rigid laboratory f oor is well known (Racić et al. 2009), the mechanical interaction between the human body of the pedestrian and the supporting structure (human-structure interaction, HSI) is not (Georgakis and Ingólfsson 2014, Tubino and Piccardo 2016). However, the latter is expected to have a signif cant impact on the structural response to pedestrian excitation, in particular for high pedestrian densities (Kasperski 2014, Busca et al. 2014, Bocian et al. 2013, Pedersen 2015).

In the low-frequency range of interest for vibration serviceability (0-10 Hz), the dynamic behaviour of the human body in vertical direction for a person standing still, resembles that of a highly damped single-degree-of-freedom (SDOF) system for which the natural frequency ($2.7 < f_{\mathrm{H}} < 7.0$ Hz) and damping ratio ($20 < \xi_{\mathrm{H}} < 60$ %) largely depend on the body posture (Matsumoto and Griff n 1998, Matsumoto and Griff n 2003, Van Nimmen et al. 2017a). Based on these observations, the pedestrian excitation is often modeled as the superposition of the force exerted by a pedestrian on a rigid f oor and a mechanical interaction term which depends on the dynamic properties of both the human body and the footbridge (Alexander 2006, Van Nimmen et al. 2017a, Shahabpoor et al. 2016, Venuti et al. 2016). However, the SDOF system is an approximation of the human body of a pedestrian and these assumptions should be validated and its model parameters calibrated based on in-f eld observations involving walking persons (Van Nimmen et al. 2017a, Tubino and Piccardo 2016).

This contribution applies the parameter estimation

procedure proposed in (Van Nimmen et al. 2017b) to estimate the dynamic characteristics of the SDOF interaction model from the (measured) response of the supporting structure. The methodology assumes that the dynamic behaviour of the emtpy structure and the distribution of step frequencies in the crowd are known and uses the measured structural response induced by pedestrians as input. In the present contribution, this methodology is applied to a real footbridge. The dynamic behaviour of the empty footbridge is experimentally identif ed and applied to calibrate the f nite element model of the structure. Next, the structural response induced by a high pedestrian density is observed. The distribution of step frequencies in the crowd is derived from the corresponding non-resonant structural response. Finally, the parameter estimation procedure is applied to estimate the dynamic characteristics of the SDOF interaction model from the full-scale observations.

The outline of this paper is as follows. First, the coupled crowd-structure model is introduced (Section 2). Second, the parameter estimation problem is formulated (Section 3). Third, the approach is applied to full-scale data collected on a real footbridge (Section 4). The conclusions are summarized in Section 5.

2 COUPLED CROWD-STRUCTURE MODEL

Pedestrians in a crowd are active systems for which the walking behaviour is controlled by an internal driving term. The pedestrian and the supporting structure (e.g. the footbridge) are considered as two linear subsystems coupled at a single contact point. In this way, the contact force not only depends on the internal driving term of the pedestrian but also on the dynamic properties of both subsystems (Van Nimmen et al. 2017a, Shahabpoor et al. 2016).

A modally reduced system is derived from the linear dynamic f nite element (FE) model of the supporting structure. The governing equations of motion in modal coordinates read:

$$\ddot{\mathbf{z}}(t) + \mathbf{\Gamma}\dot{\mathbf{z}}(t) + \mathbf{\Omega}^2\mathbf{z}(t) = \mathbf{\Phi}^\top \mathbf{p}(t) = \mathbf{\Phi}^\top \mathbf{S}_\mathbf{p}(t)\mathbf{p}_\mathbf{p}(t) \quad (1)$$

with $\mathbf{z}(t) \in \mathbb{R}^{n_m}$ the modal coordinate vector, n_m the number of modes retained in the modally reduced system, $\Omega^2 \in \mathbb{R}^{n_m \times n_m}$ a diagonal matrix containing the square of the natural frequencies $\omega_j = 2\pi f_j$ in rad/s, $\Gamma \in \mathbb{R}^{n_m \times n_m}$ a diagonal matrix containing the terms $2\xi_j\omega_j$ with ξ_j $[-]$ the modal damping ratios, $\mathbf{\Phi} \in \mathbb{R}^{n_{\text{DOF}} \times n_m}$ a matrix which has the mass-normalised mode shapes $\boldsymbol{\phi}_j$ as columns, $\mathbf{\Phi}^\top\mathbf{p}(t)$ the modal projection of the external forces $\mathbf{p}(t) \in \mathbb{R}^{n_{\text{DOF}}}$ with n_{DOF} the number of degrees of freedom (DOF) of the FE model. The vector of the forces $\mathbf{p}(t)$ contains the contact force(s) between the bridge and the n_{H} pedestrian(s). For each pedestrian, the contact is reduced to a single point representing at the same time the left and the right foot. The time history of the n_{H} contact forces $p_{\text{p}}(t)$ are collected as rows in the force vector $\mathbf{p}_\mathbf{p}(t) \in \mathbb{R}^{n_{\text{H}}}$. Using the selection matrix $\mathbf{S}_\mathbf{p}(t) \in \mathbb{R}^{n_{\text{DOF}} \times n_{\text{H}}}$, the forces are transfered to the corresponding DOFs of the FE model of the structure.

At this point, the key assumption is made that the walking behaviour of the pedestrian is not affected by the vibrating surface, i.e. the internal driving term of the pedestrian is identical to the one in case of a rigid supporting system. Assuming a *f xed-driver term* allows the body motion and, hence, the contact force of a pedestrian $p_{\text{p}}(t)$, to be decomposed in a term resulting from the driving term $p_{\text{F}}(t)$ and a term resulting from the interaction between the pedestrian and the supporting structure $p_{\text{H}}(t)$:

$$p_{\text{p}}(t) = p_{\text{F}}(t) + p_{\text{H}}(t) \quad (2)$$

For a perfectly rigid f oor, thus without interaction ($p_{\text{H}}(t) = 0$), the contact force equals the ground reaction forces (GRFs) as registered by the force plates or an instrumented treadmill f xed to a rigid laboratory f oor ($p_{\text{p}}(t) = p_{\text{F}}(t)$) (Racić et al. 2009). When a large number of pedestrians is involved, these force terms are governed by (imperfectly known) parameters characterizing inter- and intra-person variabilities (Racić et al. 2009, Caprani et al. 2012). Given the fact that the focus is on the resulting structural response, a number of reasonable simplifying assumptions can be made. The comprehensive numerical analysis performed by Tubino et al. (Tubino and Piccardo 2016) shows that the statistical distribution of the walking speed and the pedestrian weight have a negligible inf uence on the dynamic response of the structure. Therefore, all pedestrians are assumed to have the same weight and walking speed v_s [m/s]. The latter is def ned in terms of the pedestrian density d [pedestrians/m^2] (Bruno and Venuti 2009). The walking trajectories are straight lines parallel to the longitudinal axis of the bridge deck. The arrival times are assumed to follow a Poisson distribution (Živanović 2012). The step frequencies are assumed to follow a Gaussian distribution ($f_s = \mathcal{N}(\mu_{f_s}, \sigma_{f_s})$ [Hz]) (Association Française de Génie Civil, Sétra/AFGC 2006). Together, the pedestrian's step frequency f_s and weight G characterise the vertical walking load $p_{\text{F}}(t)$, described in this study by a probabilistic single-person force model that accounts for intra-person variabilities (Živanović et al. 2007). This load model accounts for the f rst f ve main and intermediate harmonics of the walking load as well as for the narrow-band nature of the force around each (sub-)harmonic.

When the supporting structure is f exible, the contact force $p_{\text{p}}(t)$ in addition depends on the interaction between the two subsystems. The interaction term $p_{\text{H}}(t)$ in Eq. (2), can be further elaborated based on the mechanical properties of the SDOF system representing the human body (Matsumoto and Griff n 2003,

Van Nimmen et al. 2017a):

$$p_{\mathrm{p}}(t) = p_{\mathrm{F}}(t) - m_{\mathrm{H0}}\ddot{u}(t) + c_{\mathrm{H1}}\left[\dot{u}_{\mathrm{H1}}(t) - \dot{u}(t)\right] + k_{\mathrm{H1}}\left[u_{\mathrm{H1}}(t) - u(t)\right] \quad (3)$$

with m_{H1} the sprung mass, m_{H0} the unsprung mass, k_{H1} and c_{H1} the spring and damping element, $m_{\mathrm{H}} = m_{\mathrm{H1}} + m_{\mathrm{H0}}$ and $u_{\mathrm{H1}}(t)$ and $u(t)$ the displacements of the mass m_{H1} and the bridge at the contact point, respectively. The mechanical properties of the interaction model (m_{H0}, m_{H}, k_{H1} and c_{H1}) are assumed identical for all pedestrians.

3 PARAMETER ESTIMATION PROBLEM

The parameter estimation procedure detailed in this section, is borrowed from (Van Nimmen et al. 2017b).

The objective is to identify the parameters that determine the effect of HSI on the resulting structural response: the dynamic characteristics of the linear mechanical systems representing the pedestrians in the crowd. It is assumed that the structural response induced by the pedestrians and the dynamic behaviour of the emtpy structure are known. The former requires vibration measurements on the structure during operation. The latter can be predicted using a f nite element model or identif ed directly from experimental vibration data using system identif cation techniques (Peeters and De Roeck 1999, Reynders and De Roeck 2008). In addition to the dynamic behaviour of the empty structure and the HSI-effects, the structural response also depends on the total *f xed-driver term* induced by the crowd. To limit the number of variables in the parameter estimation problem, it is assumed that the following a-priori information on this *f xed-driver term* is available: the distribution of step frequencies ($f_s = \mathcal{N}(\mu_{f_s}, \sigma_{f_s})$ [Hz]). The latter can be derived from empirical relations (Bruno and Venuti 2009), e.g. as a function of the pedestrian density (see Section 2) and/or, preferably, be based on additional information collected in situ.

In (Van Nimmen et al. 2017b) it is shown that when a suff ciently long duration of the structural response induced by a certain pedestrian density is considered, the statistical effect of the remaining unknown stochastic parameters, i.e. the effect of the randomness in the f xed-driver term, on the PSD of the resulting structural response can be averaged out. The randomness of the f xed-driving term results from the arrival times and the intra-person variabilities (see Section 2). As these parameters are much more diff cult to identify experimentally, it is a great advantage to be able to average out their statistical effect.

Next, an optimisation problem is formulated where the objective function measures the difference between the PSD of the experimentally observed ($\tilde{\mathbf{G}}_{\ddot{u}}$) and the numerically simulated ($\mathbf{G}_{\ddot{u}}$) structural response within a frequency range def ned by a lower (ω_{l} [rad/s]) and upper bound (ω_{u} [rad/s]). For now, it is assumed that the structural response is observed in a single output location. The residuals are computed at discrete frequencies ω_k [rad/s]: $\omega_k = \omega_{\mathrm{l}} + k\Delta\omega$ for $k = 0, ..., N$, with $N + 1 = (\omega_{\mathrm{u}} - \omega_{\mathrm{l}})/\Delta\omega + 1$ the number of samples and $\Delta\omega$ the selected frequency resolution. The decision variables in this optimisation problem are the natural frequency f_{H1} and the modal damping ratio ξ_{H1} of the selected linear mechanical system (see Section 2). These parameters are assumed identical for the different persons on the structure and are subject to the following physical constraints: $f_{\mathrm{H1}} > 0$ and $\xi_{\mathrm{H1}} > 0$. The problem, subject to 2 inequality constraints, is formulated in standard form:

Figure 1: The Waalse Krook South footbridge.

$$\underset{f_{\mathrm{H1}},\, \xi_{\mathrm{H1}}}{\text{minimise}} \quad \frac{\| \tilde{\mathbf{G}}_{\ddot{u}} - \mathbf{G}_{\ddot{u}}(f_{\mathrm{H1}}, \xi_{\mathrm{H1}}) \|_2^2}{\| \tilde{\mathbf{G}}_{\ddot{u}} \|_2^2} \quad (4)$$

$$\text{subject to} \quad f_{\mathrm{H1}} > 0 \quad (5)$$

$$\xi_{\mathrm{H1}} > 0 \quad (6)$$

and can be categorised as a nonlinear programming problem due to the nature of the objective function (Nocedal and Wright 2006). The inequality constrained optimisation problem is solved using the lsqnonlin-solver (MATLAB (MATLAB 2015)) by means of the trust-region-ref ective algorithm.

Based on a numerical verif cation example, it is shown in (Van Nimmen et al. 2017b) that the above proposed methodology allows to estimate both the natural frequency and the modal damping ratio of the SDOF model. The results also suggest that as the structural response is predominantly sensitive to the natural frequency of the interaction model, the corresponding estimation uncertainty is low.

4 APPLICATION TO FULL-SCALE DATA

4.1 *Waalse Krook South Footbridge*

The Waalse Krook South footbridge is a steel pedestrian and bicycle bridge with a single span of 25 m and a width of 6 m, designed by Couse & Goris architects in a collaboration with TV RCR Aranda Pigem

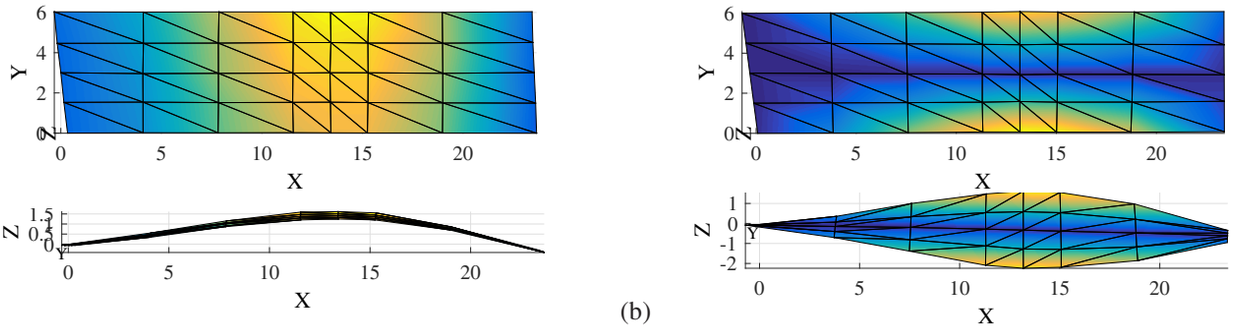

Figure 2: The operational modal parameters of the two modes identif ed for the empty footbridge: (a, left) 3.30Hz, 0.86% and (b, right) 4.14Hz, 0.25%.

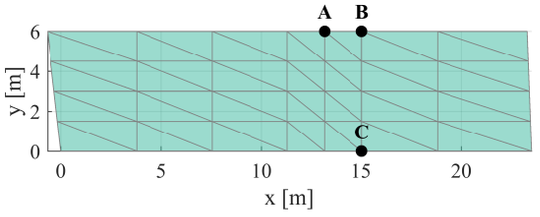

Figure 3: The measurement locations A, B and C on the bridge deck.

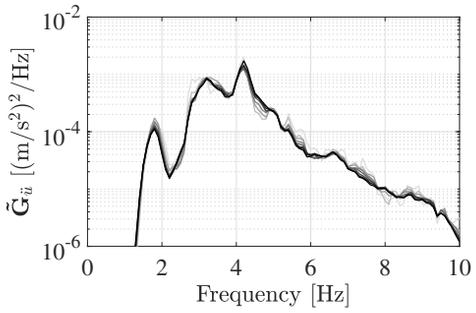
Vilalta Architects (Figure 1). The bridge deck is composed of a two-way ribbed steel-concrete composite plate. The bridge deck is supported by two neoprene bearings on one side, and two steel columns on the other side.

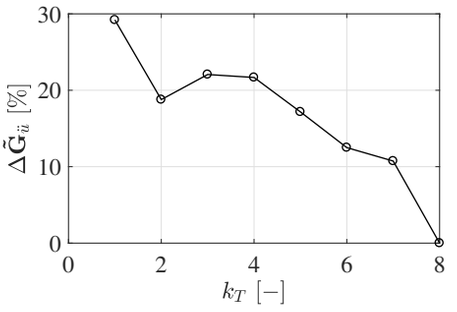
An operational modal analysis is performed for the empty footbridge. The vibration data was collected using tri-axial accelerometers (GeoSIG GMS-18) for a total of 40 grid-points. The output-only data have been processed using the reference-based covariance-driven stochastic subspace identif cation (SSI-cov) algorithm (Peeters and De Roeck 1999, Reynders and De Roeck 2008). Two modes with a frequency up to 5.5 Hz are identif ed (see Figure 2): a vertical bending mode and a torsional mode.

A detailed f nite element (FE) model is developed according to the architectural drawings using the FE software ANSYS. The FE model consists of Timoshenko beam elements for the supporting columns and the ribs of the bridge deck, and a regular mesh of 4-node shell elements (Mindlin-Reissner theory) for the steel-concrete composite bridge deck. By tuning the translational stiffness of the neoprene supports, an optimal agreement is obtained with the experimentally identif ed natural frequencies and mode shapes: for both modes, the relative frequency deviation is limited to 2% and the corresponding MAC-values are high (>0.95).



In the following, the numerical simulations are performed based on the experimentally identif ed natural frequencies and modal damping ratios, and the mass-normalized mode shapes of the calibrated FE model. All modes with a natural frequency below 20 Hz are taken into account. Unless stated otherwise, the simulated and measured structural response are both low-pass f ltered with a cut-off frequency of 10 Hz.

4.2 *Full-scale observations*



A full-scale measurement campaign was carried out considering a pedestrian density of 1 persons/m^2. Different types of human excitation were considered: (1) standing still (duration 5 minutes), (2) free walking (duration 10 minutes) and (3) synchronized walking whereby a metronome was used to aim for resonance between the second harmonic of the walking load and the fundamental or second natural frequency of the footbridge (duration 5 minutes). The short test durations were imposed by practical limitations. During these tests, the vertical structural response was registered at 3 locations on the bridge deck, corresponding to the anti-nodes of the f rst and second mode of the footbridge (f gures 2 and 3).

The test of interest in the present study involves free walking. Based on the preliminary data analysis, a time frame of 8 minutes ref ecting the stationary response of the structure, is selected. The structural response is low-pass f ltered with a cut-off frequency of 10 Hz. The PSD of the structural response is calculated considering $n_T = 8$ [-] consecutive time windows of length $T = 60$ s, with 50% overlap. In Figure 4 the convergence of the PSD is f rst analysed by evaluation for an increasing number k_T of consecutive time windows of length T. Analogously to the formulation of the objective function in Section 3, the convergence error ($\Delta \mathbf{G}_{\ddot{u},k_T}$) is def ned as the discrepancy between the PSD calculated considering k_T ($\mathbf{G}_{\ddot{u},k_T}$) and the total of $n_T = 8$ ($\mathbf{G}_{\ddot{u},n_T}$) consecutive time windows. This Figure 4 shows that as a result of the relative short measurement duration of 8 minutes, a convergence error of approximately 10% remains which, in turn, will inevitably result in an error on the results of the parameter estimation procedure.

The dominant contributions around 3.3 Hz and 4.1 Hz in Figure 5 show that the pedestrians mainly excite the fundamental and the second mode of the footbridge. In addition, the structural response is characterized by clear contributions around 1.8 Hz. These contributions ref ect the non-resonant excitation by the fundamental harmonic of the walking load. The aim is now to use this observation to derive information on the distribution of step frequencies in the crowd. To do so, the structural response is f rst low-pass f ltered with a cut-off frequency of 2.3 Hz such

(a)

(b)

Figure 4: (a) The PSD of the structural response induced by a pedestrian density $d = 1.0$ pedestrians/m^2 measured at the location A indicated in Figure 3 calculated for an increasing number k_T of consecutive time windows of length $T = 60$ s, for $k_T = 1$ (white) up to $k_T = 8$ (black) and (b) corresponding convergence error $\Delta\tilde{\mathbf{G}}_{\ddot{u}}$.

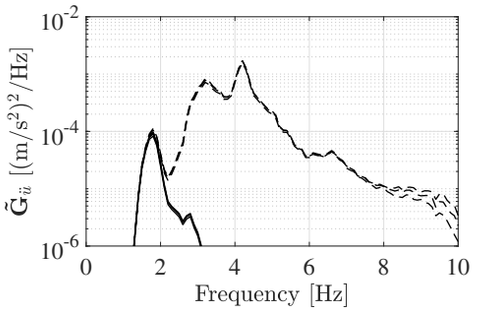


Figure 5: The PSD of the structural response induced by a pedestrian density $d = 1.0$ pedestrians/m^2 measured at the locations indicated in Figure 3: low-pass f ltered with a cut-off frequency of 10 Hz (dashed) and 2.3 Hz (solid).

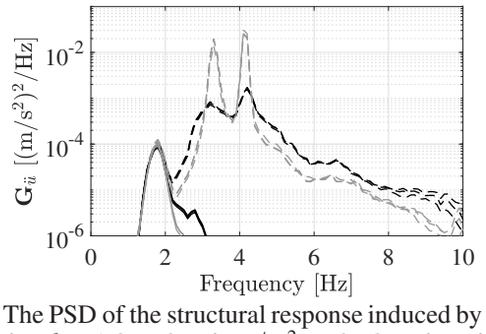

Figure 6: The PSD of the structural response induced by a pedestrian density $d = 1.0$ pedestrians/m^2 at the locations indicated in Figure 3: low-pass f ltered with a cut-off frequency of 10 Hz (dashed) and 2.3 Hz (solid), measured (black) and simulated without HSI (grey).

that the inf uence of the dynamic modes of the structure is minimised. Figure 5 shows that in this way, the contribution of the fundamental harmonic of the walking load to the PSD of the structural response is isolated and is in fact hardly inf uenced by the dynamic contribution of the modes of the footbridge. Second, it is in addition assumed that this contribution is not inf uenced by HSI, an assumption that is reasonable based on the observations made in (Van Nimmen et al. 2017a). Based on this assumption and by minimizing the difference between the PSD of the measured and simulated structural response low-pass-f ltered at 2.3 Hz, the following distribution of step frequencies in the crowd is f tted: $\mathcal{N}(1.68, 0.13)$ Hz. At this point, the simulations are performed without HSI, i.e. with $p_{\text{p}}(t) = p_{\text{F}}(t)$ (see also Section 2). Figure 6 shows that based on this f tted distribution of step frequencies, a good agreement is found between the PSD of the measured and simulated structural response for frequencies below 2.3 Hz. Figure 6 also shows that for frequencies higher than 2.3 Hz, and in particular for frequencies close to the fundamental and second natural frequency of the footbridge, signif cant differences are observed between the PSD of the measured and simulated structural response. It is reasonable to assume that these differences are largely due to HSI that is disregarded in these simulations.

4.3 *Parameter estimation*

Finally, the objective is to estimate the parameters governing HSI using the full-scale observations detailed in Section 4.2. To this end, the parameter estimation problem formulated in Section 3 is solved. The structural response is simulated using the coupled crowd-structure model introduced in Section 2. The dynamic behaviour of the structure (Section 4.1) and the PSD of the structural response and the distribution of step frequencies in the crowd (Section 4.2) are used as input. The following solution is obtained:

$$f_{\text{H1}} = 3.10\text{Hz}$$

$$\xi_{\text{H1}} = 0.25\% \tag{7}$$

Figure 7 shows that in this way a reasonable f t is obtained between the simulated and measured PSD of the structural response. The agreement has signif cantly improved around the contribution of the fundamental and second mode of the footbridge. These results corroborate recent f ndings in the literature (Shahabpoor et al. 2016, Van Nimmen et al. 2017a). Although the present application illustrates the potential of the proposed procedure, a considerable level of uncertainty remains due to (small) modelling errors and the limited duration of the experimental observations.

To illustrate the effect of HSI on the vibration serviceability for the Waalse Krook footbridge, Figure 8 shows a typical time history of the structural response simulated with and without HSI for a window of 8 minutes. This f gure illustrates that although the maximum vibration levels are in both cases below the limit for maximum vibration comfort (0.5 m/s^2 (Association Française de Génie Civil, Sétra/AFGC 2006)),

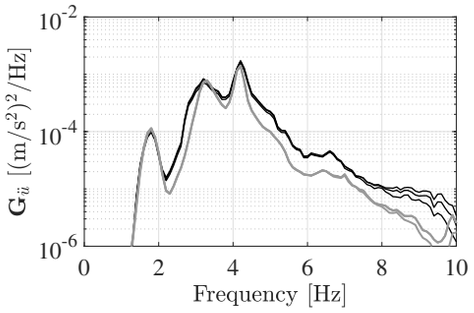

Figure 7: The PSD of the structural response induced by a pedestrian density $d = 1.0$ pedestrians$/\mathrm{m}^2$ at the locations indicated in Figure 3: measured (black) and simulated with HSI (grey).

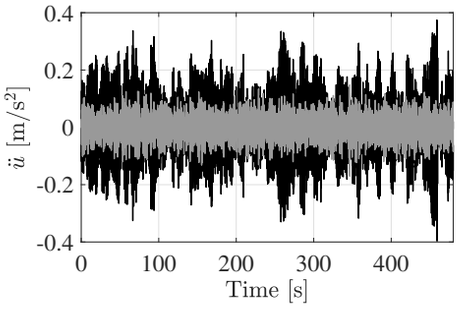

Figure 8: Typical time history of the acceleration levels at location A, simulated without (black) and with HSI (grey).

the maximum structural response is almost 3 times lower when HSI is accounted for.

5 CONCLUSIONS

In this contribution, an inverse method is applied to estimate the parameters that govern the effect of HSI from the measured response of the supporting structure. The parameters of interest concern the dynamic characteristics of a SDOF model, applied to describe the interaction between a linear mechanical system representing the human body (SDOF system) and the supporting structure. The parameter estimation procedure assumes that the dynamic behaviour of the empty structure and the distribution of step frequencies in the crowd are known. By minimizing a cost function that measures the discrepancy between the observed and the simulated PSD of the structural response, the dynamic characteristics of the considered SDOF interaction model are estimated.

The proposed approach is applied to a real footbridge. Full-scale testing involved (1) ambient excitation and (2) the excitation by a pedestrian density of 1 persons$/\mathrm{m}^2$. The ambient vibrations are applied to identify the operational modal characteristics of the empty structure and are subsequently applied to calibrate the f nite element model of the structure. Next, for the load case involving pedestrian excitation, the distribution of step frequencies in the crowd is estimated from the corresponding non-resonant structural response. Finally, the proposed parameter estimation procedure is applied and an estimate of 3.10 Hz and 0.25% is obtained for the natural frequency and damping ratio of the SDOF model, respectively. These results corroborate recent f ndings in the literature. Although the present application illustrates the potential of the proposed procedure, a considerable level of uncertainty remains due to (small) modelling errors and the limited duration of the experimental observations.

Comparison between structure- and crowd-based mitigation strategies on vibrating footbridges

F. Venuti

ABSTRACT: Due to their lightweight, slenderness and extremely low structural damping, footbridges may often be prone to vibrations under human-induced excitation. As a consequence, structural control devices, mainly TMDs, have been installed before or after the footbridge opening to mitigate excessive vibrations under pedestrian dynamic loading. The aim of this study is to explore an alternative approach towards the mitigation of human-induced vertical vibrations: instead of acting on the structure, the novel approach acts on the source of excitation, that is, the crowd flow. Bearing in mind the dependence of the step frequency on the walking velocity, which in turn depends on the crowd density, a strategy based on the modification of the crowd flow along the footbridge, through the proper location of obstacles on the deck, is proposed. The crowd-based strategy can be quickly implemented, either as a permanent (e.g., benches or light poles) or an emergency temporary measure (e.g., Jersey barriers), and is expected to be cheaper than structure-based alternatives. The study is carried out by means of numerical simulations. Crowd dynamics simulations are performed through the commercial software Mass Motion, which is based on a microscopic model of crowd dynamics. The generated pedestrian trajectories and velocities are then used to build the force signals, that are subsequently applied on a 1DOF structure model to calculate the vertical response. The effectiveness of the proposed crowd-based mitigation strategy is then evaluated on an ideal footbridge and finally compared with the one of a linear viscoelastic TMD, the latter designed to meet vertical vibration serviceability requirements.

1 INTRODUCTION

Footbridges are very often lightweight and slender structures with extremely low structural damping. For this reason, they are prone to vibrations under dynamic loadings, in particular under human-induced excitation. In the last fifteen years, an increasing number of cases has been reported where mitigation measures had to be installed before or after the footbridge opening to reduce excessive human-induced vibrations (e.g, Dallard et al. 2001, Dziuba et al. 2001, Caetano et al. 2010, Tubino et al. 2016).

Because increasing structural mass or stiffness implies high costs and undesired aesthetic impact, mitigation measures on footbridges generally consist in adding supplemental damping devices, such as viscous dampers (Dallard et al. 2001) and friction dampers (Law et al. 2004). A similar purpose can be accomplished by transferring most of the structural vibration energy to an attached Tuned Mass Damper (TMD), which, in its simplest form, is composed of an auxiliary mass-spring-dashpot passive system dissipating the energy away by vibrating out of phase with the structural motion (Housner et al. 1997). TMDs have been widely applied on real-life bridges for response control against wind-induced loads, primarily (Soong and Dargush 1997), yet successful applications on pedestrian bridges exist wherein TMD is used to mitigate either vertical or horizontal human-induced vibrations (Dallard et al. 2001, Dziuba et al. 2001, Brownjohn et al. 2004, Caetano et al. 2010). Unlike buildings, for which TMDs with high mass ratios are recently receiving considerable attention (De Angelis et al. 2012, Reggio and De Angelis 2015), technical reasons cause the TMD mass in bridges to be typically below few percent (1%-5%) of the structural mass. This limitation may possibly jeopardize in practice the effectivess of the control device as well as its robustness against detuning effects derived from structural nonlinearities or uncertainties.

An alternative approach to vibration mitigation on footbridges has been first suggested by Carroll et al. (2012) and subsequently investigated by Venuti and Bruno (2013) for the case of lateral vibrations due to Synchronous Lateral Excitation. According to this approach, the reduction of the structural response can be obtained by acting on the source of excitation, i.e. on the crowd flow, in analogy to what is done to reduce wind-induced vibrations on tall buildings (Kareem and Kijewski 1999) or long-span bridges (Sarwar and Ishihara 2010). Carroll et al. (2012) suggested the installation of temporary barriers along the footbridge path, while Venuti and Bruno (2013) investigated a strategy of crowd flow control based on the smooth widening/narrowing of the walkway width along the footbridge span. In both cases, the aim is to modify the distribution of the crowd density and, as a consequence, of the walking velocity and step frequency, i.e. modify the dynamic load exerted by the pedestrians. Both proposals require a modelling approach quite different from the one usually adopted and prescribed by codes and guidelines. In fact, the pedestrians are intelligent agents, whose behaviour is influenced by the interactions with the surrounding pedestrians and environment according to specific rules. Therefore, crowd models should be used to properly describe the pedestrian walking behaviour.

The aim of this study is to systematically explore the effectivess of crowd-based mitigation strategies on the reduction of footbridge vibrations. Specifically, the proposed strategy is based on the control of crowd flow by means of obstacles located along the footbridge span. In this paper, the very first results are presented in the case of footbridges crossed by unidirectional pedestrian traffic and with vertical vibrations. In order to emphasise similarities and differences with well established structural control strategies, comparisons with an optimally designed linear viscoelastic TMD are finally made.

The paper develops as follows. Section 2 presents the adopted modelling approach; Section 3 describes the benchmark footbridge adopted as case study; Section 4 is devoted to the design of crowd- and structure-based retrofitting measures; in Section 5 the results of the numerical simulations are illustrated and comparisons between the two mitigation strategies are discussed; in Section 6, conclusions and research perspectives are outlined.

2 MODELLING APPROACH

The study is carried out by means of numerical simulations and the following modelling assumptions are made:

a1. even though it is widely accepted that Human-Structure-Interaction (HSI) occurs when pedestrians walk on a flexible structure, there is still great uncertainty about how to model HSI (Shahabpoor et al. 2017). Therefore, HSI is neglected in this study. This choice is justified by two main reasons: on the one hand, this allows to better focus on the effects of the crowd flow on the structural response, without introducing further sources of uncertainty; on the other hand, modelling HSI still belongs to the research field, while codes and guidelines neglect its effects;

a2. the obstacles placed along the footbridge span to achieve the crowd flow control are modelled as purely geometrical constraints, not affecting the mass, stiffness and damping properties of the footbridge.

Figure 1 illustrates a scheme of the adopted modelling approach, whose details are provided below.

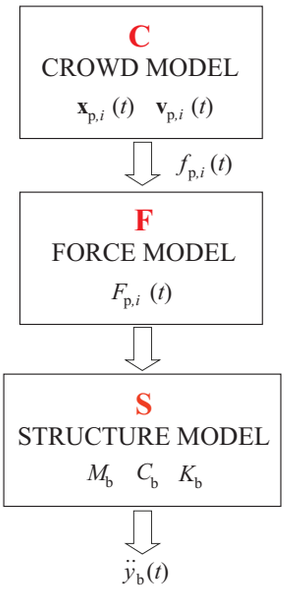

Figure 1: Scheme of the modelling approach

2.1 *Crowd model*

Simulations of crowd flow are performed through the commercial software Mass Motion v. 8.5 (Oasys Ltd. 2017), which is based on a microscopic model of crowd dynamics derived, as a modified version, from the Social Force Model first proposed by Helbing and Molnár (1995). In such a model, each individual pedestrian is described as an agent, whose goal is to reach her final destination walking at her desired velocity. Desired velocities v_{des} are randomly assigned to the pedestrians from a Normal distribution, with mean 1.34 m/s and standard deviation (std) 0.26 m/s (Buchmueller and Weidmann 2006). While walking, each agent is subjected to a set of forces that modify her desired velocity on the basis of the interaction with neighbouring pedestrians and the environment (walls, obstacles, etc.). The interested reader is referred to Helbing and Molnár (1995) and Oasys Ltd. (2017) for a detailed description of the mathematical and numerical framework.

Crowd flow simulations result in trajectory $\mathbf{x}_{\mathrm{p},i}(t) = [x_{\mathrm{p},,i}, z_{\mathrm{p},,i}]$ and velocity $\mathbf{v}_{\mathrm{p},i}(t) = [v_{x\mathrm{p},,i}, v_{z\mathrm{p},,i}]$ for each i-th pedestrian along time t, where x and z are the longitudinal and the transverse footbridge axis, respectively.

2.2 *Force model*

Trajectory $\mathbf{x}_{\mathrm{p},i}(t)$ and velocity $\mathbf{v}_{\mathrm{p},i}(t)$ are then used to build the moving time-varying force $F_{\mathrm{p},i}(t)$ exerted by the i-th pedestrian on the footbridge.

The continuous force model of Young (2001) is assumed as reference, where $F_{\mathrm{p},i}(t)$ is described by a sum of n Fourier harmonic components:

$$F_{\mathrm{p},i} = G_{\mathrm{p},i} + \sum_{j=1}^{n} G_{\mathrm{p},i}\, DLF_j \sin\left(2\pi j f_{\mathrm{p},i}\, t - \theta_j\right), \quad (1)$$

where: $G_{\mathrm{p},i} = m_{\mathrm{p},i}\, g$ is the pedestrian weight, being $m_{\mathrm{p},i}$ the pedestrian mass and g the gravity acceleration; $f_{\mathrm{p},i}$ is the pedestrian step frequency; DLF_j and θ_j are, respectively, the Dynamic Load Factor and phase shift of the j-th contributing harmonic.

With respect to the model of Young, here the pedestrian step frequency $f_{\mathrm{p},i}$ is not constant in time, being calculated as a function of the walking velocity $v_{\mathrm{p},i}(t)$ according to the relation proposed by Venuti and Bruno (2007):

$$f_{\mathrm{p},i}(t) = 2.93 v_{\mathrm{p},i}(t) - 1.59 v_{\mathrm{p},i}^2(t) + 0.35 v_{\mathrm{p},i}^3(t). \quad (2)$$

In this study, only the first contributing harmonic is considered in (1). Its DLF_1 is expressed as a function of $f_{\mathrm{p},i}$ (Young 2001), and this dependence causes DLF_1 to be time-variant as well:

$$DLF_1(t) = 0.41(f_{\mathrm{p},i}(t) - 0.95) \leq 0.56. \quad (3)$$

Note that the time-variant pedestrian characteristics are assumed to vary in time continuously and not on a step-by-step basis.

Mass $m_{\mathrm{p},i}$ is randomly assigned to each pedestrian from a Normal distribution with mean 75 kg and std 15 kg (Zivanovic 2012).

This model allows to account for both inter-subject and intra-subject variability of human load.

2.3 *Structure model*

The footbridge is modelled as a Single Degree of Freedom (SDOF) system, representing a structural vertical vibration mode of interest, whose dynamics is governed by the well-known equation of motion:

$$M_{\mathrm{b}}\ddot{y}_{\mathrm{b}} + C_{\mathrm{b}}\dot{y}_b + K_{\mathrm{b}} y_{\mathrm{b}} = F, \quad (4)$$

where $y_{\mathrm{b}}(t)$ is the displacement response at the antinode, the overdot indicating differentiation with respect to time t; M_{b}, C_{b} and K_{b} are the modal mass, damping and stiffness of the footbridge, respectively; $F(t) = \sum_{i=1}^{N} F_{\mathrm{p},i}(t)\, \Phi\left(x_{\mathrm{p},i}(t)\right)$ is the modal force, being N the number of pedestrians walking on the footbridge at time t, $\Phi(x)$ the unity-normalised modal shape of the structure. The contribution of the pedestrian modal mass is neglected according to assumption a1.

3 DESCRIPTION OF THE BENCHMARK FOOTBRIDGE

Numerical simulations are performed on a benchmark footbridge, whose dimensional and dynamic properties are summarised in Table 1 and Figure 2. A sinusoidal modal shape function $\Phi = \sin(\pi x/L)$ is assumed for the first vertical mode.

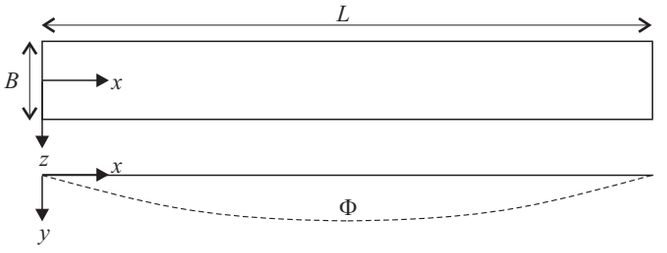

Figure 2: Schematic plan and side view of the footbridge

Table 1: Properties of the benchmark footbridge

L [m]	B [m]	m_{b} [kg/m]	f_{b} [Hz]	ζ_{b} [-]
100	3	1500	1.8	0.005

In order to set the pedestrian traffic condition (i.e. the incoming pedestrian density) that is likely to induce the highest acceleration response on the footbridge, a parametric study is carried out with Mass Motion (MM). Ten simulations of crowd dynamics are performed by increasing the incoming pedestrian density ρ in the range [0.1, 1] ped/m^2. In each simulation, N_{tot} pedestrians have been generated at the footbridge entrance over a time T. Arrival times in MM are randomly generated according to a uniform distribution. The time T is set equal to 10 times the average crossing time $T_1 = L/v_{\mathrm{m}}$, where v_{m} is the mean walking velocity, initially estimated as a function of the crowd density according to the Weidmann (W) fundamental law (Buchmueller and Weidmann 2006):

$$v_{\mathrm{m,W}} = 1.34\left\{1 - \exp\left[-1.913\left(\frac{1}{\rho} - \frac{1}{5.4}\right)\right]\right\}. \quad (5)$$

Hence, the total number of pedestrians N_{tot} that enter the footbridge is equal to $10\rho LB$.

For each simulation, both average density and velocity are calculated over a time period T_{full} corresponding to full occupancy of the footbridge. The latter has been derived by excluding the initial and final time periods corresponding to pedestrians populating and leaving the bridge, respectively. The lower

and upper boundaries of T_{full} have been determined as the first and last time instant when N_{m} pedestrians are on the footbridge, being $N_{\text{m}} = \rho LB$. Results are reported in Figure 3. Simulations of crowd dynamics were run twice, since the velocities obtained with MM are lower than those predicted through Eq. 5. Therefore, a second run was necessary to tune the time T in order to obtain the expected average density on the footbridge (white circles in Fig. 3). Figure 3 also plots the frequency ratio $f_{\text{r}} = f_{\text{p,m}}/f_{\text{b}}$, where the mean step frequency $f_{\text{p,m}}$ is obtained as a function of $v_{\text{m,MM}}$ through Eq. 2.

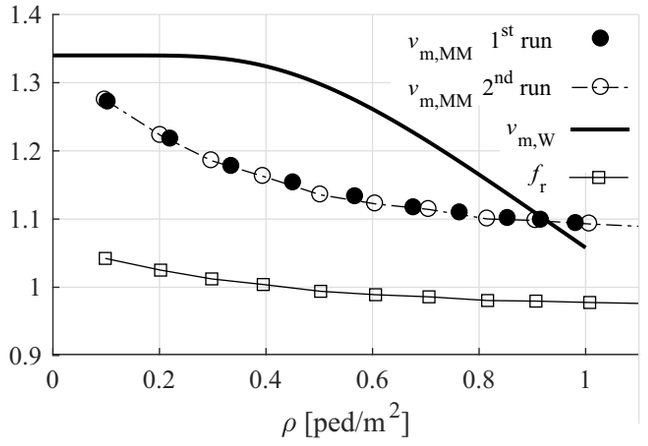

Figure 3: Mean walking velocity v_{m} [m/s] and dimensionless frequency ratio f_{r} vs ρ

The crowd density corresponding to the f_r value closest to unit, i.e. $\rho = 0.4$ ped/m^2, is selected as the worst case scenario for the following simulations.

4 DESIGN OF MITIGATION STRATEGIES

4.1 *Crowd-based strategies*

Crowd flow control strategies have been proposed in the fields of applied mathematics and transportation engineering. The control of the crowd flow, e.g., in evacuation scenarios, is often obtained by means of punctual obstacles, such as columns, located in strategic positions, in order to force the crowd flow to follow certain patterns and avoid the formation of jams or to ease the evacuation (Helbing et al. 2002, Helbing et al. 2005).

Taking inspiration from the above cited literature, the proposed strategy of crowd flow control is based on the location of obstacles along the footbridge path. The obstacles can be intended either as permanent (e.g., benches or light poles) or as emergency temporary measure (e.g., Jersey barriers). In the second case, they can be easily and quickly installed whenever the footbridge is expected to be crossed by a crowd density which could induce vibrations above the comfort limits.

Two different types of obstacle layout are investigated (Figure 4):

- obstacles located along the footbridge longitudinal axis in order to force lane separation (LS);
- obstacles located along the footbridge lateral edges in order to obtain bottlenecks (BN), i.e. local narrowing of the footbridge width.

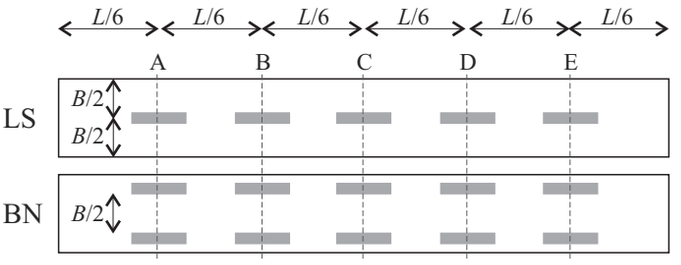

Figure 4: Scheme of the investigated obstacle layouts

Each obstacle have dimensions $l = L/10$ and $b = B/10$. Table 2 summarises the number of obstacles and their position for each investigated layout; layout 0 represents the uncontrolled configuration of the footbridge.

Table 2: List of the investigated obstacle layouts

Layout	Type	n°	Position
0	-	-	-
1	LS	1	C
2	LS	3	B-C-D
3	LS	5	A-B-C-D-E
4	LS	2	B-C
5	LS	2	B-D
6	BN	2	C
7	BN	6	B-C-D
8	BN	10	A-B-C-D-E
9	BN	6	A-C-E
10	BN	6	A-B-C

4.2 *Structure-based strategy*

To control the dynamic response of the footbridge in the first symmetric vertical mode, a linear viscoelastic TMD is considered to be installed where the relevant modal shape function $\Phi(x)$ attains its maximum, i.e., at the footbridge's mid-span.

Assuming the modal shape to be set to unity at the TMD location, $\Phi(L/2) = 1$, a generalised SDOF structure - TMD system (Figure 5) can be introduced, whose equations of motion are written as:

$$\ddot{y}_{\text{b}} + 2\zeta_{\text{b}}\omega_{\text{b}}\dot{y}_{\text{b}} + \omega_{\text{b}}^2 y_{\text{b}} = \frac{F}{M_{\text{b}}} + \frac{u}{M_{\text{b}}},$$

$$\mu\ddot{y}_{\text{d}} = -\frac{u}{M_{\text{b}}}, \tag{6}$$

$$\frac{u}{M_{\text{b}}} = 2\mu\zeta_{\text{d}}\alpha\omega_{\text{b}}(\dot{y}_{\text{d}} - \dot{y}_{\text{b}}) + \mu\alpha^2\omega_{\text{b}}^2(y_{\text{d}} - y_{\text{b}}).$$

In Equations 6, $y_{\mathrm{b}}(t)$ and $y_{\mathrm{d}}(t)$ are the vertical displacements of the footbridge's mid-span section and of the TMD, respectively; M_b is the modal mass of the footbridge; $F(t)$ is the modal input force acting on the footbridge, as defined in Section 2.3; $u(t)$ is the force exerted by the TMD on the mid-span section of the footbridge. Furthermore, the following parameters are defined: ω_{b} and ζ_{b} are the uncoupled modal frequency and damping ratio of the footbridge; $\zeta_{\mathrm{d}} = c_d/(2\sqrt{k_d\, m_d})$ is the uncoupled damping ratio of TMD; $\mu = m_{\mathrm{d}}/M_{\mathrm{b}}$ and $\alpha = \omega_{\mathrm{d}}/\omega_{\mathrm{b}}$ are the mass ratio and the frequency ratio of the generalised SDOF structure-TMD system, denoting with $\omega_{\mathrm{d}} = \sqrt{k_{\mathrm{d}}/m_{\mathrm{d}}}$ the uncoupled natural frequency of TMD.

Within the set of five parameters that govern the response of the generalised SDOF structure - TMD system, modal properties $\omega_{\mathrm{b}} = 11.31$ rad/s and $\zeta_{\mathrm{b}} = 0.005$ are known data of the footbridge (see Table 2), mass ratio $\mu = 0.01$ is set out as a customary value in pedestrian bridges, while frequency ratio α and damping ratio ζ_{d} are the design parameters of the TMD, to be determined on the basis of an optimisation criterion. Following Warburton (1982), who considered a random white noise force applied to the undamped SDOF structure and minimised the variance of its displacement response, the optimal values of the TMD design parameters are determined accordingly as:

$$\alpha_{\mathrm{opt}} = \frac{\sqrt{1+\frac{\mu}{2}}}{1+\mu} = 0.9926,$$
$$\zeta_{\mathrm{opt}} = \sqrt{\frac{\mu(1+\frac{3}{4}\mu)}{4(1+\frac{\mu}{2})(1+\mu)}} = 0.0498. \tag{7}$$

Regarding the applicability of Warburton parameters (7) to the case under consideration, it may be observed, on the one hand, that pedestrian traffic is not accurately represented by a white noise input; on the other hand, that the minimisation of the displacement response is not a suitable optimisation criterion when the design objective is to control the acceleration response. Recent numerical investigations conducted by Tubino and Piccardo (2015), however, have demonstrated that Warburton parameters lead to a control performance comparable to the one obtained by maximising, under normal unrestricted pedestrian traffic, the TMD efficiency in reducing the acceleration response.

5 RESULTS

This section presents the results of the computational simulations performed on the benchmark footbridge without and with mitigation measures. For each layout, the response was simulated 20 times and peak values of the acceleration were extracted from each time history and averaged across the 20 simulations.

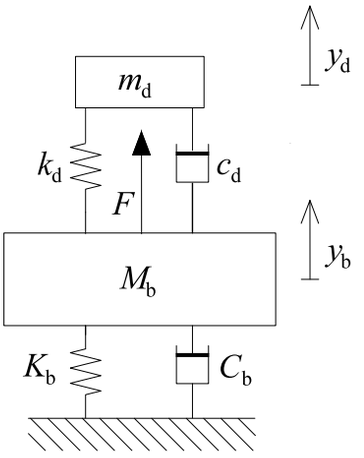

Figure 5: Mechanical model of the generalised SDOF structure - TMD system.

The statistical reliability was checked by calculating mean and std of the crowd density and walking velocity and peak acceleration on the footbridge during T_{full} and averaging their values over increasing number of simulations. The relative error in average estimation between successive simulations n and $n+1$ falls below 0.5 % for both statistics of crowd density and velocity and below 1 % for peak acceleration when $n > 15$.

5.1 *Footbridge uncontrolled response*

Figure 6 illustrates the time histories of the number of pedestrians/crowd density on the footbridge and of the acceleration response for one of the 20 simulations. The average peak acceleration $a_{\mathrm{peak},0}$ during the period of full occupancy equals 1.2 m/s^2. Therefore it exceeds the upper limit of minimum comfort (1 m/s^2) according to the Sétra/AFGC (2006) guideline by 20%.

Figure 7 plots the probability density function (PDF) of moduli v of actual velocity and v_{des} of desired velocity, as obtained with MM for one of the 20 simulations. It can be observed that the distribution of actual velocities follows a normal distribution with lower mean (1.15 m/s) and std (0.21 m/s) with respect to desired velocities. This is expected, since desired velocities correspond to unconstrained pedestrian behaviour (i.e., a pedestrian walking alone, that is, ρ=0), while, in the presence of a higher crowd density, mean walking velocity decreases and std decreases as well (Butz et al. 2008). Step frequencies, calculated as a function of walking velocities, also follow a normal distribution with mean 1.79 Hz and std 0.15 Hz.

5.2 *Footbridge controlled response*

The effectiveness of each mitigation measure is evaluated by calculating the ratio between the controlled and the uncontrolled average peak acceleration :

$$r_{a,j} = a_{\mathrm{peak},j}/a_{\mathrm{peak},0} \quad \text{for } j = 1, 3, \ldots, 11. \tag{8}$$

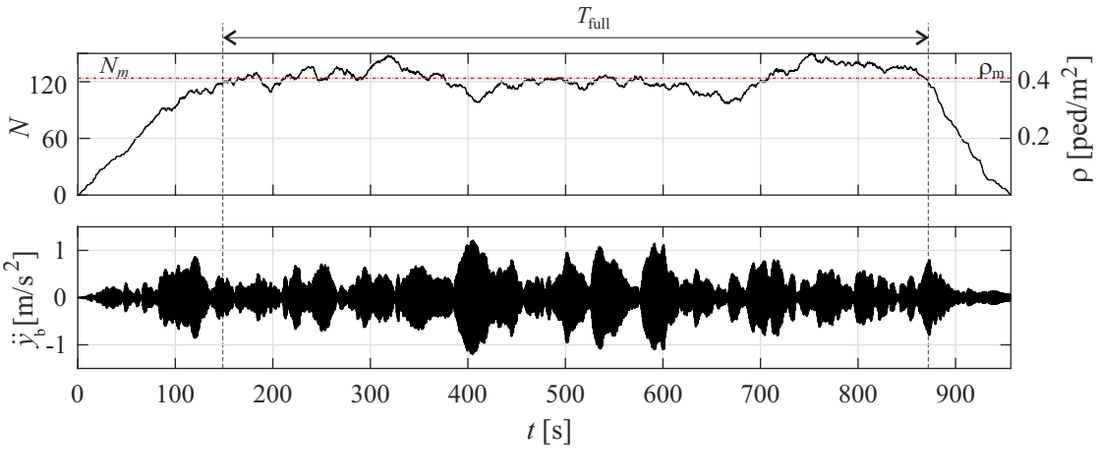

Figure 6: Example of time history of the number of pedestrians, pedestrian density and acceleration response

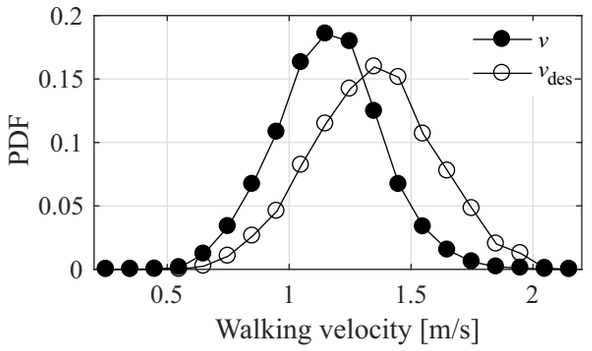

Figure 7: Example of PDF of actual and desired walking velocities

Figure 8 plots the obtained acceleration ratio for each mitigation layout. As a reference, the Sétra/AFGC (2006) upper limit of minimum comfort, normalised with respect to $a_{\text{peak},0}$, is reported as a dashed horizontal line.

Regarding the crowd-based mitigation strategies, BN layouts are, in general, more effective than the LS ones in reducing the peak acceleration response: maximum reduction amounts to 31% in BN layout 8, while it is limited to 11% in LS layout 2. This difference can be explained by looking at the distribution of crowd density, which is locally increased due to the obstacle placement. As a consequence of this density increase, the frequency ratio f_{r} decreases and moves away from the resonance condition (see Figure 3). Figure 9 illustrates the distribution of crowd density, averaged over T_{full}, for layout 0, LS layout 2 and BN layout 7: it becomes apparent that the density increase is much higher in the BN case, since the obstacle location causes a higher local reduction of the footbridge width.

Considering the structure-based mitigation strategy (layout 11), the optimised linear viscoelastic TMD is able to reduce the average peak acceleration by 60%. Even though the effectiveness of TMD in reducing the structural response is higher, it should be noted that the two mitigation strategies are not directly comparable. In fact, the TMD is designed according to an optimum criterion, which is not the case for the presented crowd-based mitigation strategy. Moreover, the two strategies have been compared from a quantitative point of view, but other factors should be considered when chosing the mitigation approach to be adopted. For instance, the crowd-based mitigation strategy presents some advantages, with respect to the structure-based counterpart: it can be adopted as temporary measure, since it can be quickly installed and removed; its design, installation and maintenance costs as expected to be lower; different obstacle layouts can be adopted on the basis of the traffic condition that is expected to cross the footbridge.

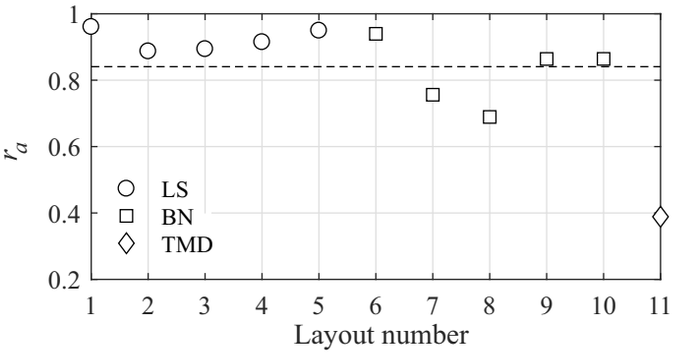

Figure 8: Peak acceleration ratio for each mitigation layout

6 CONCLUSIONS

In this paper, an alternative approach to the mitigation of human-induced vibrations on footbridges has been proposed. The approach is based on the crowd-flow control by means of obstacles located along the footbridge span. This strategy allows to act on the source of excitation instead of acting on the structure.

The proposed strategy has been applied to a benchmark footbridge crossed by unidirectional traffic and subject to uncomfortable vertical vibrations under human loading. Different layouts of obstacle placement have been investigated, in order to determine the most effective one in reducing the peak vertical acceleration. The maximum reduction, amounting to 31%, has

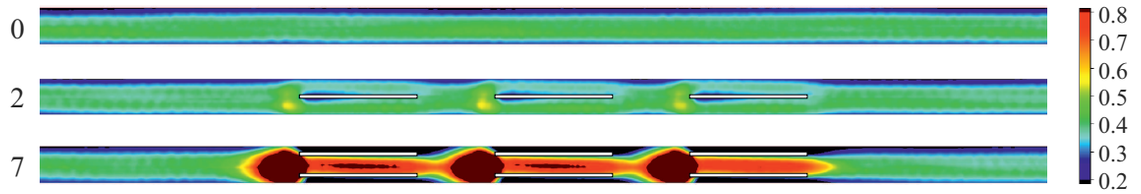

Figure 9: Example of crowd density distribution averaged over T_{full} for layouts 0, 2 and 7.

been obtained when the obstacles are placed to create local bottlenecks along the footbridge. The effect of locally reducing the footbridge width results, in fact, in a local increase of the crowd density and in a consequent, favourable shift of the pedestrian input frequency away from the resonance condition.

The control performance obtained through the proposed crowd-based mitigation strategy has been measured against the one achieved by way of a linear viscoelastic TMD, which is a structure-based mitigation strategy widespread, nowadays, in pedestrian bridges. Although the effectiveness of TMD seems to be higher, it has to be noted that a mere quantitative comparison in terms of control performance between the two mitigation strategies may be misleading, given their irreducible differences as to design, installation and maintenance costs. Moreover, the crowd-based mitigation strategy can be designed not only as a permanent solution (e.g., through the installation of benches or light poles) but, more interestingly, as an emergency temporary measure (e.g., through the placement of Jersey barriers). In both cases, the obstacle placement is supposed to slightly modify the footbridge dynamic properties.

The proposed crowd-based mitigation strategies, even if demonstrated only for a simple case study, could have good potential and is worth to be further investigated. A possible critical issue lies in the fact that the main effect of the obstacle placement is to locally increase the crowd density. If the incoming crowd density is quite high, this could lead to possible congestions, with consequent onset of panic conditions and increase in the time needed to cross the facility. Moreover, HSI should be taken into account to have a reliable estimate of the structural response. These aspects will be investigated in the next development of this study.

Dynamic Study of Yangtze River Bridge at Chongqing-Lichuan Railway

K.J. Chen & Y.P. Zeng & *S.X. Chen*
China Railway ErYuan Engineering Group Co.Ltd, ChenDu, China

ABSTRACT: Hanjiatuo Yangtze River Bridge is a railway steel truss girder cable-stayed bridge with span arrangement of (81+135+432+135+81) m. As a double track railway bridge for mixed passenger and freight traffic, it is the largest bridge in the world with less weight relatively and it is easily affected by dynamic effects. In this paper, firstly, the restraint system between the pylons and girder is studied under the consideration of braking force and seismic response. For this long span structure, a control system consisting of a novel velocity based locking device with self-control panel and a viscous damper is presented to control the braking force-induced vibration and seismic response respectively. Then, a scaled steel truss girder section model is tested in the wind tunnel laboratory, with additional dynamic loads acting on the bridge including dynamic interactions from the vehicles. The vortex-induced vibration under low wind speed is discovered in the test, for which a segmented deflector is creatively proposed to suppress the vibration.

1 PROJECT OVERVIEW

Hanjiatuo Yangtze River Bridge is a steel truss cable-stayed bridge over the Yangtze River at Chongqing-Lichuan Railway, located at Fuling District, Chongqing Province, China. The bridge ranks among the longest cable-stayed bridges in the world in the year 2013, with the span of (81+135+432 +135+81) m.

It is a double-track railway bridge for mixed passenger and freight, with the train speed of 200 km/h. The spacing between two tracks is 4.4 m, and the designing load is CR-live loading.

2 PROTOTYPE

As shown in Figure 1, a semi-floating system is adopted in the main bridge, with pylon-pier fixed and pylon –girder detached.

Two parallel N-shape steel trusses are used for the girder, with a spacing of 18m. The height of the truss is 14m, and the panel length 13.5m. The steel box girder is chosen for upper and lower chords with the slab thickness of 50mm, and monolithic joint welding method is adopted. On top of the orthotropic steel bridge deck is the concrete ballast slab with the thickness of 15cm. The material for both the truss and deck is Steel Q3701qD.

The pylon is a single column shape in longitudinal direction and designed in vase pattern (fold line H shape) in transverse direction. The cross section of the pylon and cross-girder is hollow rectangular. Except for the lower cross-girder and upper pylon which are pre-stressed, other components reinforced concrete structure using C50 concrete. The height of P10 and P11 is 182.5m and 187.5m respectively.

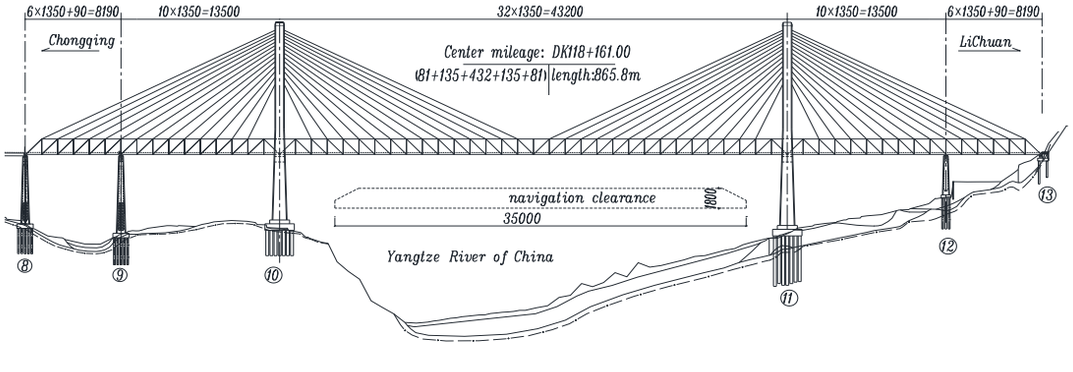

Figure 1. Overall layout of Hanjiatuo Yangtze River Bridge.

The 56 pairs of stay cables using galvanized high strength steel wire bundle constitute double parallel fan-shaped planes. The spacing of the cable on the pylon is 2.5~4m, and the spacing on the girder is 13.5m. In order to reduce the hinge effect at the anchoring point, the anchorage device at the girder side is designed to spherical hinge.

3 PYLON-GIRDER CONSTRAINT SYSTEM

For large span cable-stayed railway bridge, an appropriate pylon-girder constraint system should satisfy three demands: (1) the girder can slide and retract freely under temperature loading; (2) the pylon can restrain excessive movement of the girder under living and braking force to ensure the driving safety; (3) the system can reduce the seismic response, and guarantee the constraint system and structure not damaged as well, under earthquake striking.

Based on these demands, a semi-floating system is utilized instead of fixed bearing in longitudinal direction, leading the girder retracting freely under temperature loading. However, compared with highway cable-stayed bridge, the living load has a large effect on cable-stayed railway bridge, especially the braking force and traction force. Therefore, the braking/traction force should be well controlled as well as the seismic force. Considering the differences in aspects of quantity and property between these forces, a control system consisting of a novel velocity based locking device with self-control panel and a viscous damper is introduced to control the vehicle-induced vibration and seismic response respectively.

3.1 *Seismic force control*

The seismic force can be controlled by using hydraulic viscous damper which can increase the damping in the structure. So, the force transmission relationship between the pylon and girder is modified and the seismic response of the structure is reduced consequently. The constitutive relation of the hydraulic viscous damper is shown as follow:

$$F=CV^{\alpha} \tag{1}$$

Where, F denotes the damping force, C is the damping factor, V is the relative velocity of the damper, α represents the velocity index.

Based on Equation (1), theoretical resistance force of the damper is close to zero when the deformation is slow, such as temperature induced deformation, while the force is increasing under seismic force because of large relative velocity between the pylon and girder. In this circumstance, the longitudinal movement is restrained at the joint of pylon and girder by the dampers and the seismic response is also reduced.

Since the damping parameters have great influence on the restraint effect, a numerical model is built to analyze the seismic responses at different c andαvalue, and the main results are shown in Figure 2~5 (Chen 2010, 2011,2012).

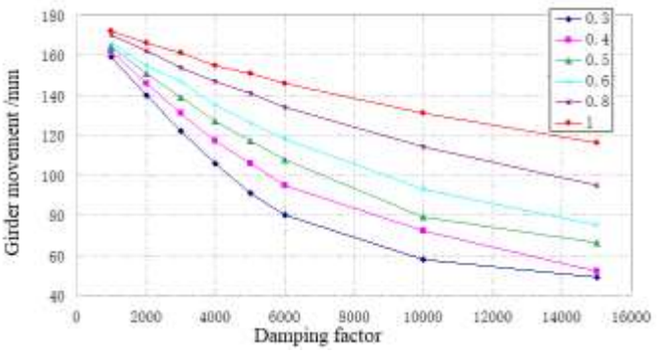

Figure 2. Effect of damping factor on girder movement.

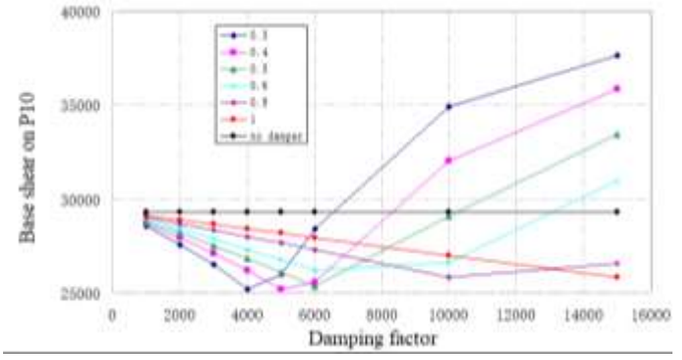

Figure 3. Effect of damping factor on base shear on P10.

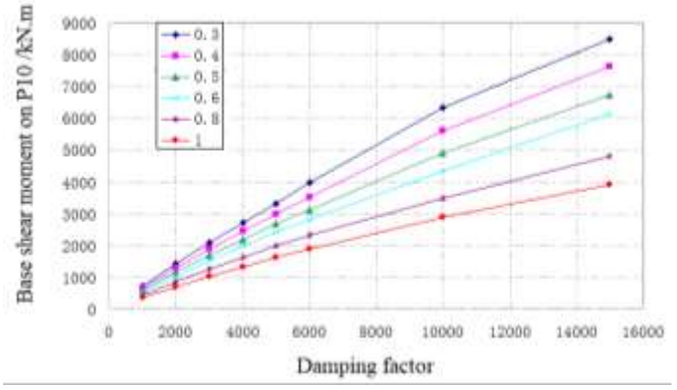

Figure 4. Effect of damping factor on base moment on P10.

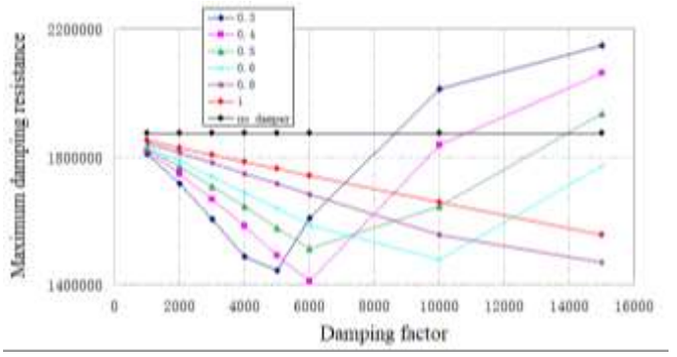

Figure 5. Effect of damping factor on the maximum resistant force in the damper.

It can be seen in Figure 2 that as C increases and α decreases, the beam displacement decreases, which means the damping effect is enhanced. But, for the economical viewpoint, the fabrication cost is increasing with the tonnage and stroke being improved. As for the base shear and moment, when C value is small, the damping effect is improved with α decreasing. However, when C becomes larger, an inflexion point arises.

Hence, for this bridge, the damping factor C is designed to be 4000KN(s/m) and α to be 0.4, which can result to reduction rate of 62.1%, 14.8% and 19.2% for displacement, base shear and base moment respectively.

3.2 *Braking force control*

Given that the braking force is much smaller compared with seismic force, the corresponding pylon-girder relative displacement and damping force is smaller according to Equation (1). So, the effectiveness of the damper is limited for the vibration response caused by braking and living forces. Therefore, a novel velocity locking device with self-control panel is proposed.

The velocity threshold for this device is 0.15mm/s, i.e. when the relative velocity surpasses 0.15mm/s, the locking device starts to work, acting as a rod with large stiffness between the pylon and girder. In this way, the braking force-induced vibration can be greatly controlled (see Figure 6). Under temperature loading, the relative displacement speed between the pylon and girder is lower than the threshold, hence the girder can still retract freely without thermal secondary force. Under seismic force, however, this device might be easily destroyed because of its large stiffness and low damping. In another hand, to pursue large designing strength, the cost will be raised and the moment and shear in the pylon will increase tremendously. Hence, a control panel is added on common locking device, i.e. when the earthquake induced force in the device is larger than 2300 KN, the locking device will deactivate and the damper starts to function. After the earthquake, the locking device can be reset allowing the traffic recovery.

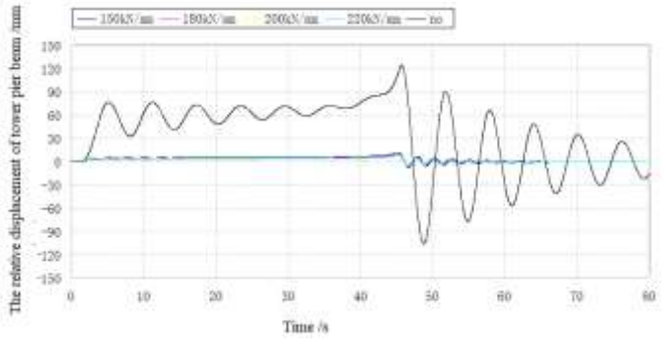

Figure 6. The controlling effect of locking device to girder displacement under barking force.

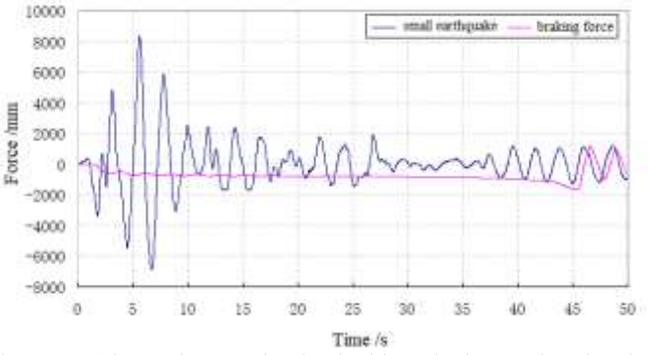

Figure 7. The resistance in the locking device under the designed earthquake and braking force (the blue curve corresponds to earthquake induced resistance).

4 KEY TECHNOLOGY FOR WIND RESISTANCE OF STEEL TRUSS GIRDER

In this part, the wind resistance performance is discussed in detail, including the vortex-induced vibration, buffeting and wind-rain induced vibration of the cables, through wind tunnel test, numerical modeling and theoretical analysis also. Herein, only the vortex-induced vibration is presented with the corresponding vibration control method.

4.1 *Wind tunnel test of section model*

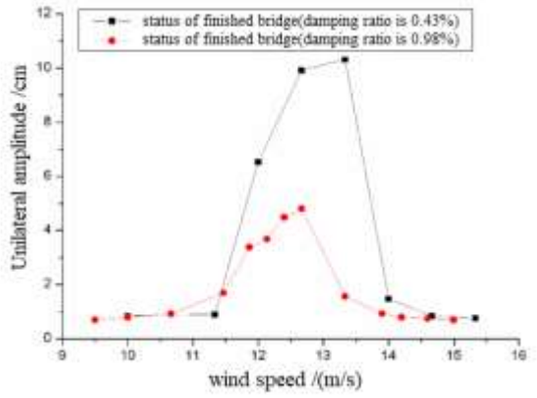
In wind tunnel test, two models with geometric scale ratio of 1:45.77 and 1:19.74 are utilized with damping ratio about 0.43%. Angle values α=0°,+3°,-3°,+5°,-5°are tested on full-bridge state and construction state, and the results are compared afterwards.

It is noted that, at full-bridge state, the vertical vortex vibration occurs forα=-3° and -5°, especially forα=-5°the maximum vibration amplitude on one side reaching 110mm with wind speed of 13m/s. At the largest single-cantilever state, the vertical vortex vibration occurs forα=-3° and -5° again, and the maximum vibration amplitude on one side reaches 42mm with wind speed of 13.2m/s when α=-5°. For each incidence angle, there is no torsion vortex vibration at both full-bridge and construction states.

When the vertical damping ratio increases to 0.98%, there still appears obvious vertical vortex vibration, but the amplitude is decreasing. For α=-5°, the amplitude on one side is 49mm and the lock-in wind velocity region does not largely change.

The resistance in the locking deivce under the designed earthquake and braking force (the blue curve corresponds to earthquake induced resistance)

Figure 8. Section model in wind tunnel test.



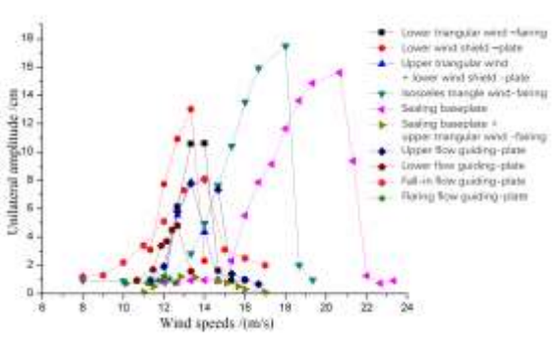


Figure 9. Vortex-excited vibration at full-bridge state (incidence angle α=-5°).

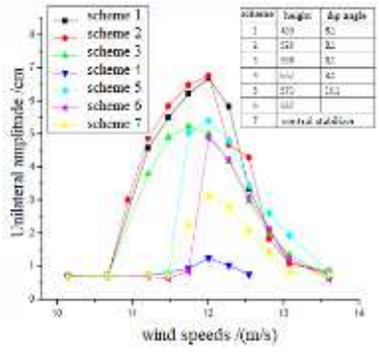
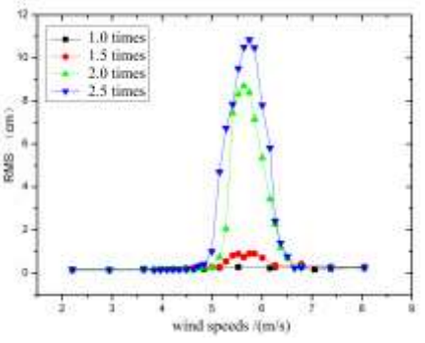
4.2 *Vortex-excited vibration control method*



In order to control the vortex-excited vibration, experiments for ten models are conducted, which are (1)lower triangle wind fairing, (2) lower wind shields, (3) upper triangle wind fairing and lower wind shields, (4) isosceles triangle wind fairings, (5)sealing the bottom of girder, (6) sealing the bottom of girder and upper triangle wind faring, (7) upper baffle plate, (8) lower baffle plate, (9) introverted baffle plate, (10) external baffle plate.

Figure 10(a) shows the results for each controlling method in wind tunnel test. Amongst all the methods, No.6 and No.10 are the most effective, which can totally eliminate the vertical vortex-induced vibration. However, taking into account the aspects of fabrication, maintenance and structural details, method (10) is recommended.



Based on the baffle plate method, other7 optimized plans are tested to discuss the influence of suspension point height and inclination angle of the deflector on vortex-induced vibration. The results are presented in Figure 10(b). It can be seen that Plan 4 is the most effective one with suspension height of 0.6m and inclination angle 5.5, and the amplitude of vortex-induced vibration is about 1.4cm.

(a) effect of each method

(b) optimization of hanging point and inclination angle

(c) optimization of segment distance

Figure 10. Research process of eliminating the vortex-induced vibration.

Theoretically speaking, for sectional baffle plate, the vortex frequencies are different between the adjacent girders, which will lead to the vibration reduction much easier. Therefore, segment distance is discussed. The results show in Figure 10(c) that, the most effective arrangement is the one with segment spacing equal the length of the plate. It can also be seen that, the elimination effect is decreasing obviously when the spacing is larger than 1.5 times the plate length. Thus, taking into account fabrication, material consumption and additional loading generally, the arrangement with spacing equal the plate length (see Figure 11) is adopted in the end.

Figure 11. Sectional baffle plates (before and after installation).

5 RESEARCH ON WIND-VEHICLE-BRIDGE COUPLED VIBRATION

Wind-vehicle-bridge coupled vibration system is a time-varying system under double stochastic excitation, i.e. rail roughness and fluctuating wind, includ-

ing bridge-vehicle interaction, wind-vehicle interaction and wind-bridge interaction. In this paper, wind tunnel test is first carried out to obtain the aerodynamic coefficients of vehicle (CRH2 train, full-load train and no-load train) and bridge, and also to obtain the flutter derivatives under different wind attack angles. Four loading cases are considered, i.e. no vehicle on the bridge, vehicle on the windward side, vehicle on leeward side and vehicles on both sides. For each loading case, six average wind speed values, e.g. 10m/s、15m/s、17m/s、20m/s、25m/s、30m/s, are utilized as subcases. The results show that, the vehicle-bridge aerodynamic interference is significant and therefore, it should be taken into account in vibration calculation.

In analytical study, the fluctuating wind field is simplified to transverse and longitudinal distributed 1D multi-variants random wind field, which is further simulated using spectral method along the bridge at uniformly-spaced distance. After extracting the aerodynamic data from wind tunnel test, the vibration of wind-vehicle-bridge coupled system is analyzed with CRH2 Train under three loading cases, i.e. vehicle on the windward side, vehicle on leeward side and vehicles on both sides. Subsequently, the response of the train and bridge is obtained (Chen 2011, Zhang 2012, Li 2013), and the results indicate that:

(1) For bridge structure: in each case, the deflection span ratio, acceleration and rotation angle of the bridge can all meet the requirements. The responses are increasing with the train speed and wind speed increasing, in transverse, longitudinal and rotational directions.

(2) For train: the dominant response is when the train is on the windward side or on both sides. The derailment coefficient and horizontal wheel force can meet safety requirements. The result shows that the response of the train increases as the train speed rises up, and the train acceleration will exceed the limit when the wind speed reaches high value. Hence, wind speed and train speed for one-train and double-train running should be controlled and the standard is illustrated in Table 1 and Table 2.

Table 1. Wind and train speed standard with one train running.

Average wind velocity (Va)	Instantaneous wind velocity (Vi)	Train velocity
Va≤17 m/s	Vi≤25 m/s	Designed train speed 200km/h
17<Va≤20 m/s	25<Vi≤30 m/s	≤110 km/h
Va＞20 m/s	Vi＞30 m/s	Close rail transit

Table 2. Wind and train speed standard with double-train running.

Average wind velocity (Va)	Instantaneous wind velocity (Vi)	Train velocity
Va≤15 m/s	Vi≤22 m/s	Designed train speed200km/h
15<Va≤17 m/s	22<Vi≤25 m/s	≤160 km/h
17<Va≤20 m/s	25<Vi≤30 m/s	≤90 km/h
Va＞20 m/s	Vi＞30 m/s	Close rail transit

6 CONCLUSIONS

Hanjiatuo Yangtze River Bridge at Chongqing-Lichuan Railway is a long span structure with notable dynamic effect. Based on this bridge, the study on the long span cable-stayed railway bridge is carried out, and several key technologies are proposed and solved. The bridge starts serving at the end of 2013 and works well in nearly 4 years of operating, which verifies the effect and reliability of the research results. The research results are of a great importance in contributing to the development and application of railway cable-stayed bridges in the future.

Bridge Engineering Department, Civil Engineering School, Southwest Jiaotong University, Chengdu, Sichuan Province, China.

ABSTRACT: With the advancement in technology, the need for an effectual health monitoring of structures, specially the long span cable stayed bridges have increased the quest for a continuous monitoring of these cable stayed bridges so that, an accurate and reliable data is collected from these sophisticated instruments installed at these bridges and then analyzed in a very effective way. Therefore in this paper the FIR and IIR filter are introduce one by one, to the dynamic data obtained from real life cable stayed bridge. Then the reconstructed signal obtained after performing the filtering was used for the continuous modal parameters identification such as Frequency and Damping Ratio using the improved Data Driven Stochastic Subspace Identification (DATA-SSI). For this purpose the real life data has been collected form Sutong cable stayed Bridge, and the proposed technique was applied to this real life data. The results shows that the proposed method gives better results and the modal parameters obtained by this technique are more accurate and consistent and provides better representation of real life bridge health monitoring.

1 INTRODUCTION

In recent years bridge health monitoring is emerging as a new field and the monitoring campaigns of long span bridges are becoming more common day by day Wenzel (2009). In order to develop a more reliable and efficient monitoring system at these long span cable stayed bridges to continuously monitor its structural performances we need a noise free signal data, which is mostly required for a reliable data base for the accurate data analysis (Cross et al. 2013). Generally in cable stayed bridges the vibration responses are obtained using centralized data acquisition with wired sensors, however these wired sensors have proven to be difficult in case of dense deployment on large structures such as long span cable stayed bridges (Wu et al. 2013), with the advancement in technology these wired sensors are replaced by wireless sensors because the performance of these wireless sensors are better than the traditional wired sensors, Shi and Cattani (2012). Lynch and Loh (2006) reviewed almost 150 papers on wireless sensors for structure health monitoring. Also about the performance of wireless sensors the recent studies carried out by (Jang et al. 2010, Cho et al. 2010, Nitta at al. 2005, Gao at al. 2006, Rice and Spencer (2009), Tanner at al. 2003) shows very good performance of wireless sensors on large scale infrastructure such as cable stayed bridges. These wireless sensors then transmit the data to the central computer for further detail data analysis. The key challenge in transmitting these signals from the sensors to the central computer is the contamination of these signal with unwanted noise, which may cause the results obtained from these data analysis as false and misleading, thus creating false alarms for the structural safety and may distort the whole bridge monitoring system. Therefore some efficient and effective techniques are required to avoid these problems, for this purpose the introduction of filters such as FIR and IIR will be an effective approach to deal with such type of problem in order to extract the modal parameters such as Natural frequency, Damping ratio and Mode shape from the sensors data very efficiently and accurately, because it is very important for the assessment of structural performance and for the calibration of the analytical design methods (Cho et al. 2004).

Filtering and parameter estimation are closely related to each other, because in general the information is carried out in a number of signal parameter but in reality the observation collected from any structure in the form of signal contains noise by Arce (2005), therefore filtering the unrequired noise and accurate estimation of the modal parameter is becoming more and more important in recent years specially for the monitoring of long span cable stayed bridge, because the FIR and IIR are not use

before in modal parameter identification of long span cable stayed bridges. Therefore for the first time an attempt is made to introduce these filters in bridge health monitoring for better and accurate estimation of modal parameters such as Natural Frequency, Damping Ratio and Mode Shape.

Ambient excitation method specially in bridge engineering to identify the structural modal parameters in time or frequency domain is getting more and more importance. In order to extract these operational modal parameters a number of stochastic identification techniques have been developed in the past, but among them the stochastic subspace identification (SSI) is very effective and multivariate identification technique. The SSI algorithm is an advanced technique for performing operational modal parameter identification (Lin et al. 2013). SSI uses the ambient vibration response data to identify the system model by linear algebraic manipulations Shan and Li (2009). The SSI consist of two methods, i) Data Driven Stochastic subspace identification (DATA-SSI) and, ii) Covariance Driven Stochastic subspace identification (CO-SSI). The DATA-SSI method perform better than the CO-SSI because the identification starts directly from the raw time series, instead of using the covariance matrices, thus making the identification process more fast and effective and consumes less time in its processing as compare to the CO-SSI. Overschee and Moor (1996), (Bassville etal. 2007), (Weng et al. 2008), Bonyapinyo and Janesupasaeree (2010) studied the applications of DATA-SSI, but they directly identified the modal parameter and does not treat the data using any type of filter, thus the results obtained by them were not very accurate, because of the inclusion of noise in the data analysis. Therefore in this paper first data treatment has been done using filters such as FIR and IIR, then the DATA-SSI is adopted because of its inherent advantages of less computational time, stability and robustness (Bonyapinyo et al. 2006). Another major problem with DATA-SSI is, it's an offline method and can only be used for a fix batch of data, hence cannot be used in on online fashion, (Goethals et al. 2006) come up with sliding window technique, but it was proved not to be so effective, secondly it was not applied to some real life data for continuous modal parameter identification and also there were no discussion and information about the mode shape. Therefore some improvements are made in DATA-SSI in this paper, to identify the continuous modal parameter such as frequency, damping ratio and mode shape.

2 FILTERS

Filtering is the most commonly used technique in digital Signal Processing (DSP) Shenoi (2006), but to the knowledge of the Author it is never tried in bridge health monitoring. Filtering is the most commonly used technique in digital Signal Processing (DSP) Shenoi (2006), but to the knowledge of the Author it is never tried in bridge health monitoring. Therefore it is a first attempt to use these filters for signal processing from the dynamic data obtained from the accelerometers installed at a long span cable stayed bridge. The basic phenomenon of introducing filters in the dynamic analysis of cable stayed bridge is to remove the unwanted frequencies and the noise. In science and engineering noise is consider as the disturbance, especially the random noise and thus reduces the clarity of signals Wu and Huang (2005). As the collected data from the sensors $\mathrm{d(t)}$, consist of the true signal $\mathrm{s(t)}$ and noise $\mathrm{n(t)}$, hence it can be written as:

$$\mathrm{d(t)} = s(t) + n(t) \tag{1}$$

Since noise is obliquitous and depicts highly undesirable and dreaded part of any data, therefore most of the data analyst design some techniques to remove the unwanted noise and extract the true information from the true signals collected from the sensors data Wu and Huang (2005). In order to carry out the above process effectively FIR and IIR were introduced and then the filter designing of each of them were carried out to match our collected data, so that the dynamic modal parameter identification should be carried out effectively and efficiently and provides the true and accurate assessment of the long span cable stayed bridge.

2.1 Vibrations

The Finite Impulse Response (FIR) filters are linear discrete-time filters having high filter order, stable and characterized by their impulse responses. Therefore an impulse response can have either a finite or infinite duration. A finite impulse response $\mathrm{h(n)}$ having its non-zero values over a finite time interval and zero and even beyond that interval, thus its finite impulse response can be written as Lai (2003):

$$\mathrm{h(n)} = \{ h_0, h_1, h_2, \cdots, h_N, 0,0,0, \cdots \} \tag{2}$$

In addition it also contain non-zero values in the interval, $0 \leq \mathrm{n} \leq \mathrm{N}$. Thus it is referred as a FIR or system order N. Therefore an N^{th} order FIR filter has an impulse response with a length of $(\mathrm{N}+1)$ samples, where h_0, h_1 etc. are the filter coefficients, filter weights and filter tap coefficient. In case of FIR filter the output sequence is related to the input and the impulse response of the filter by convolution sum and can be expressed as Lai (2003).

$$y(n) = \sum_{m=0}^{M} x(m)\, h(n-m) \quad (3)$$

This equation shows the non-recursive nature of the FIR filter, because the output samples is only dependent on "N" input for N^{th} order filter, thus the summation on the right hand side is a convolution between x(n) and h(n), also called the impulse response of the filter. Since the discontinuity are more in frequency domain, therefore to cope up with the frequency response we need a window which tapper off smoothly rather than a rectangular window in order to reduce the ripple effect, therefore hamming window is selected in this paper, because its performs better as compare to the other rectangular window. Hamming window can be mathematically expressed as:

$$\omega(n) = 0.54 - 0.46\cos\left(\frac{2\pi n}{N-1}\right) \quad (4)$$

Where $n = 0,1,\ldots,N-1$ and the above equation defines the window samples as already shifted (indices from 0 to N−1).

2.2 IIR filters

Infinite Impulse Response (IIR) filter are having impulse responses that are infinite in the duration, thus it is opposite to the FIR filters. As IIR filters are recursive, therefore the relationship between input and output is expressed as:

$$y(n) = -\sum_{k=0}^{N} a(k)\, y(n-k) + \sum_{k=0}^{M} b(k)\, x(n-k) \quad (5)$$

Rearranging the above equation in linear difference equation form and can be rewritten as:

$$\sum_{k=0}^{N} a(k)\, y(n-k) = \sum_{k=0}^{M} b(k)\, x(n-k) \quad (6)$$

With $a(0) = 1$, we can write the above equation as:

$$\sum_{k=1}^{N} a(k)\, [z^{-k}\, y(n)] = \sum_{k=0}^{M} b(k)\, [z^{-k}\, x(n)] \quad (7)$$

Where z^{-1} is the unit delay function of one sample and can be expressed as: $z^{-k}\, x(n) = x(n-k)$

Thus a transfer function in the form of "z" can be expressed as:

$$H(z) = \frac{y(n)}{x(n)} = \frac{\sum_{k=0}^{M} b(k)\, z^{-k}}{\sum_{k=0}^{N} a(k)\, z^{-k}} \quad (8)$$

The ratio of the two polynomials can be expressed as:

$$H(z) = \frac{b(0)+b(1)z^{-1}+\cdots+b(M)z^{-M}}{1+a(1)z^{-1}+a(2)z^{-2}+\cdots+a(N)z^{-N}} \quad (9)$$

In this paper Butterworth function is used and its magnitude squared function for the nth order can be expressed as Lai (2003):

$$|H(\omega)|^2 = \frac{1}{1+C\omega^{2n}} \quad (10)$$

Where "C" is the constant which determine the transition of "ω" between pass band and the stop band to occurs. For normalized Butterworth filter, this point is at $\omega = 1$ and thus $C = 1$, therefore we also called it as cut off frequency. But the response at both $\omega = 0$ and $\omega = \infty$ are completely horizontal, thus we can say at such frequency the response is ideal.

3 DATA DRIVEN STOCHASTIC SUBSPACE IDENTIFICATION

3.1 Numerical modelling

The ambient excitation of a dynamic system of a bridge structure under classical formulation can be expressed as:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = fv(t) \quad (11)$$

Where “m” is the mass, “c” is the damping coefficient and “k” is the stiffness, $\ddot{x}(t)$, $\dot{x}(t)$ and $x(t)$ are the acceleration, speed and displacement vector at time instant t respectively. "f" is the input matrix of the force excitation and ν(t) is the input vector at time instant t.

Now considering the discrete form, DATA-SSI method performs the identification of the modal parameters using the state space model by the following equations:

$$x_{k+1} = A.x_k + \omega_k + 1 \quad , \quad y_k = C.x_k + \nu_k \quad (12)$$

Where $x_k$is the discrete time state vector at time instant k, y_k is a vector with the sampled outputs, A and C are the discrete state and output matrix respectively and ω_{k+1}, v_k are state noise and modelling in accuracies vectors respectively.

3.2 Data driven stochastic subspace identification algorithms

The data driven stochastic subspace identification (DATA-SSI) techniques utilizes Projection matrix created from the Hankel matrix as compare to the covariance driven stochastic subspace identification (CO-SSI). Secondly the calculation needs less memory due to the Projection method, even though this makes the principle of the method a little bit more complex, but still it is more efficient as compare to CO-SSI.

In case of DATA-SSI the number of block rows and columns in the Hankel matrix plays a very important role and thus the influence on the identification process is very prominent, the block columns

must be larger than the block rows, and the rows are generally multiplied with the number of sensors, so the column number of the Hankel matrix in case of DATA-SSI is larger as compare to COSSI method. The given Hankel matrix in case of DATA-SSI can be determined from the output data, computing the projection matrix of the row space of future into the row space of the past. In general using RQ decomposition on the Hankel matrix to calculate two projection matrices P_i, P_{i+1}, the Hankel matrix can be expressed as:

$$\text{Hankel} = \begin{bmatrix} y_0 & y_1 & y_2 & \cdots \\ y_1 & y_2 & y_3 & \cdots \\ y_2 & y_3 & y_4 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} = \begin{bmatrix} y_p \\ y_f \end{bmatrix} \tag{13}$$

After performing the RQ Decomposition, it can be written as:

$$\text{Hankel} = RQ = \begin{bmatrix} R_{11} & 0 & 0 & 0 \\ R_{21} & R_{22} & 0 & 0 \\ R_{31} & R_{32} & R_{33} & 0 \\ R_{41} & R_{42} & R_{43} & R_{44} \end{bmatrix} \begin{bmatrix} Q_{11} \\ Q_{12} \\ Q_{13} \\ Q_{14} \end{bmatrix} \tag{14}$$

$$P_i = \begin{bmatrix} R_{31} & R_{32} \\ R_{41} & R_{42} \end{bmatrix} \begin{bmatrix} Q_{11} \\ Q_{12} \end{bmatrix} \tag{15}$$

$$P_{i+1} = \begin{bmatrix} R_{41} & R_{42} & R_{43} \end{bmatrix} \begin{bmatrix} Q_{11} \\ Q_{12} \\ Q_{13} \end{bmatrix} \tag{16}$$

In order to get the observability matrix O_i. Singular value decomposition is performed on the projection matrix P_i to get:

$$P_i = USV^T = \begin{bmatrix} U_1 & U_2 \end{bmatrix} \begin{bmatrix} S_1 & 0 \\ 0 & S_2 = 0 \end{bmatrix} \begin{bmatrix} V_1^T \\ V_2^T \end{bmatrix} \tag{17}$$

$$P_i = O_i X_i = \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{i-1} \end{bmatrix} \begin{bmatrix} x_i & x_{i+1} & \cdots & x_{i+j-1} \end{bmatrix} \tag{18}$$

$$O_i = U_1 S_1^{1/2} \tag{19}$$

Then eliminating the last block row of O_i in order to get O_{i+1}. Then we obtained the two Kalman Filtered states matrices x_i, x_{i+1}, based on the Kalman filtered state estimation, by using the observability matrices and the projection matrices.

$$x_i = O_i^{-1} P_i, \quad x_{i+1} = O_{i-1}^{-1} P_{i+1} \tag{20}$$

Hence the system matrix A can be written as follow:

$$A = x_{i+1} x_i^{-1} \tag{21}$$

Then using the last block row output data matrix $y_{i/li}$ and multiply the inverse Kalman filtered state matrix x_i to get the system matrix C and thus it can be written as:

$$C = y_{i/li} x_i^{-1} \tag{22}$$

Therefore the eigenvalue and the eigenvector can be obtained by eigenvalue decomposition on the system matrix A and can be written as:

$$A = \psi \Lambda \psi^{-1} \tag{23}$$

3.3 Modal parameter identification

After calculating these matrices the next step is to identify the modal parameters. The model parameters can be obtained by choose the suitable order, a suitable order of the system depends on the suitable date of the singular value decomposition on the projection matrix P_i in order to plot the singular value figure to decide the order. Then the diagonal matrix with n dimensions can be written as:

$$\Lambda = diag[\mu_i] \tag{24}$$

Where the matrix Λ is composed of the complex eigenvalue μ_i, and the relation between the eigenvalues of matrix A and systematic one is given as:

$$\lambda_i = \frac{\ln \mu_i}{\Delta t} \tag{25}$$

Where the eigenvalue of the system is λ_i, with sampling time interval of Δt. The relation between the systematic eigenvalues and λ_i and systematic intrinsic frequency ω_i and the systematic damping ratio ξ_i is given as:

$$\lambda_i, \overline{\lambda_i} = \xi_i \omega_i \pm j\omega_i \sqrt{1 - \xi_i^2} \tag{26}$$

Hence the frequency, the damping ratio and mode shape can be found from the equations given below:

$$f_i = \frac{\sqrt{|\lambda_i|}}{2\pi} \tag{27}$$

$$\zeta_i = \frac{-\lambda_i + \overline{\lambda_i}}{2\sqrt{\lambda_i \overline{\lambda_i}}} \tag{28}$$

$$\phi_i = C\psi_i \tag{29}$$

The schematic diagram of the whole process of the modal parameter identification is shown below:

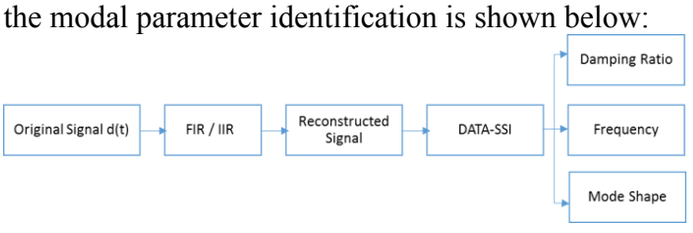

Figure 1. Modal parameters identification process

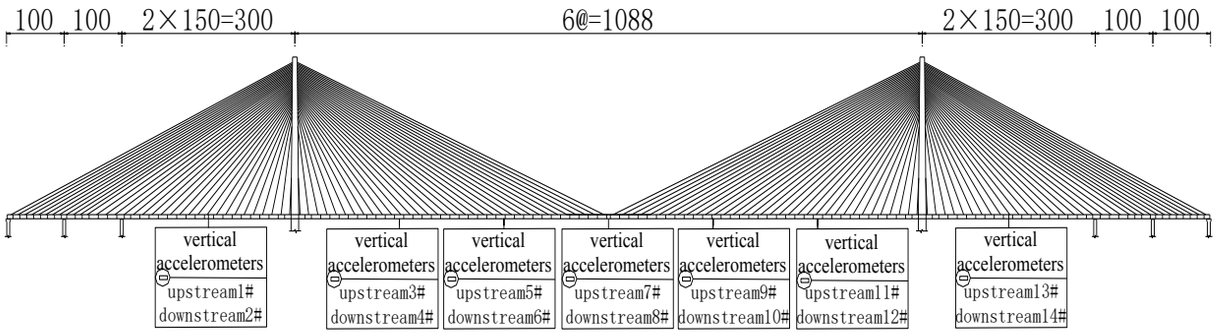

Figure 2. Layout of accelerometer on main girder (Unit:m)

3.4 Sliding window technique

Now giving a finite set of hankel matrix $\widehat{Y_0}$ ... $\widehat{Y_{2i}}$ and a finite dimensional estimate, then $\hat{O}$ for O can be found by SVD of $\hat{H}$, now it can be expressed as:

$$\hat{H} = \begin{bmatrix} \hat{Y}_0 & \hat{Y}_1 & \cdots & \hat{Y}_i \\ \hat{Y}_1 & \hat{Y}_2 & \cdots & \hat{Y}_{i+1} \\ \vdots & \vdots & \ddots & \vdots \\ \hat{Y}_i & \hat{Y}_{i+1} & \cdots & \hat{Y}_{2i} \end{bmatrix} \tag{30}$$

Generally DATA-SSI method process the data in one batch, hence it cannot be used as an online health monitoring technique, therefore a new method called sliding window technique is adopted to make the DATA-SSI a continuous online modal parameter identification process. For this purpose the new Hankel matrix must be adopted, which can be written as:

$$y_k^+ \equiv \begin{bmatrix} y_{k-i+1} \\ y_{k-i+2} \\ \cdots \\ y_k \end{bmatrix}, y_k^{-T} \equiv \begin{bmatrix} y_{k-i}^T & y_{k-i-1}^T & \cdots & y_{k-2i+1}^T \end{bmatrix} \tag{31}$$

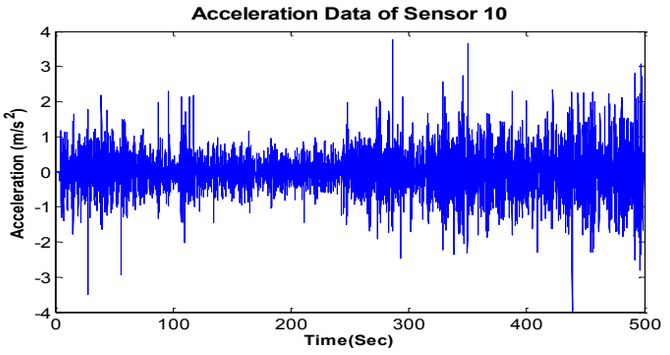
Where y_k^+ and y_k^{-T} are the output measurements vectors and "i" is the number of block rows, therefore new Hankel matrix $\hat{H}$ can be written as:

$$\hat{H} = \frac{1}{p}\sum_{k=i}^{N} y_k^+ y_k^{-T} \tag{32}$$

Where k is ranging over the entire set of data and p is an optional normalization parameter and the length of the Hankel matrix is N. Finally the sliding window technique is applied to the already filter data. The new data is incorporated into $\hat{H}$ at the same rate as the old data is removed. Thus it can be expressed as:

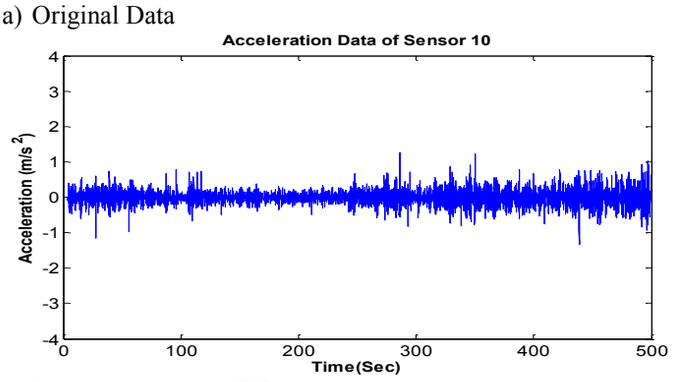
$$\hat{H}_{N+1} = \hat{H}_N + y_{N+1-i}^+ (y_{N+1-i}^-)^T - y_i^+ y_i^{-T} \tag{33}$$

Where all the manipulations of $\hat{H}$ amount to update of the form



$$\hat{H}_{t+1} = \hat{H}_t + y_{t+1}^+ y_{t+1}^{-T} \tag{34}$$

4 RESULTS AND DISCUSSION

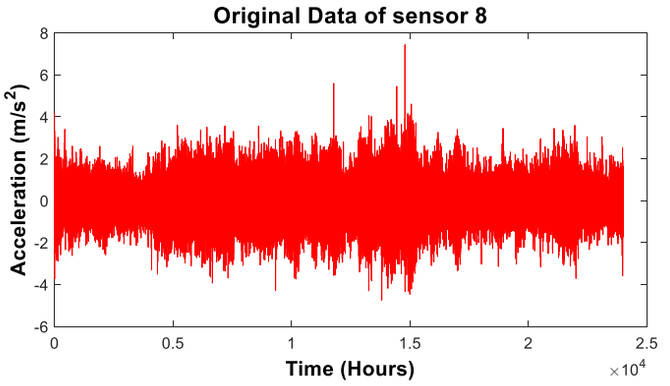


Sutong bridge is one of the longest spanning cable-stayed bridge is taken as a case study. It is located on Yangtze River and connecting the cities Suzhou and Nantong. The bridge is a seven span double pylon and double cable plane steel box girder cabled-stayed bridge having a main span of 1088m, the overall arrangement of span is 100+100+300+1088+300+100+100 = 2088m. In order to identify the modal parameters of Sutong bridge, the data collected from Sutong bridge was first filtered by using the FIR and IIR filters, then DATA-SSI algorithm is adopted based on MATLAB to get the required results.

4.1 FIR filtering of sutong bridge

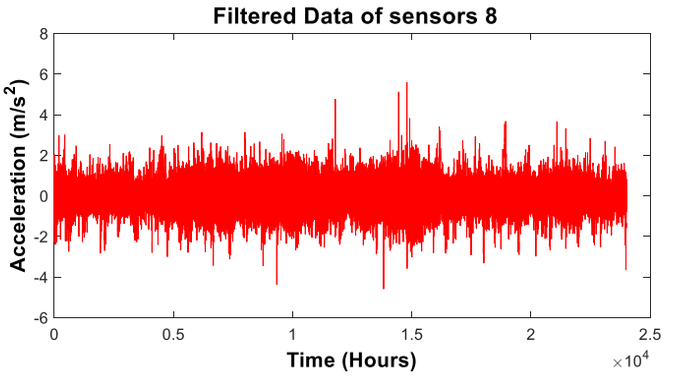
In order to carry out the FIR filtering on the data collected from Sutong Bridge using MATLAB, each of the 14 sensors are filtered one by one, but due to space limitation only few of them are shown below:

a) Original Data



b) Improved by using FIR

Figure 3. FIR filtering of sensor # 10 data



The results in Figure 3 shows that the filter works very effectively and the acceleration trend is very regular and compact after using the FIR filter as compare to without filtering the data. In Figure 3(a) it can be seen very clearly that the peaks are more pronounced as compare to the Figure 3(b), means that the filter works properly and have removed the unwanted noise very effectively and have made the data regular and compact.

4.2 IIR filtering of sutong bridge

Similarly in order to carry out the IIR filtering on the data collected from Sutong Bridge using MATLAB, each of the 14 sensors are filtered one by one, but due to space limitation only few of them are shown below:

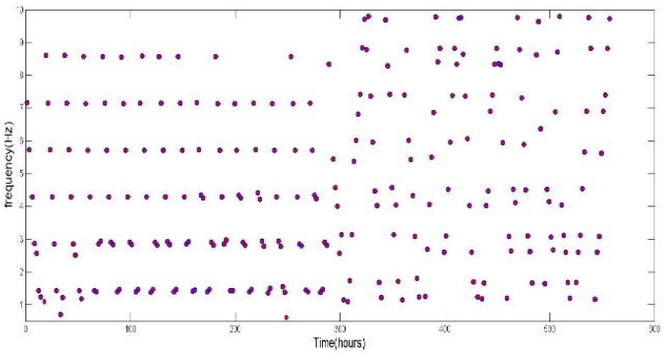
a) Original Data

b) Improved by using IIR

Figure 4. IIR filtering of sensor # 8 data

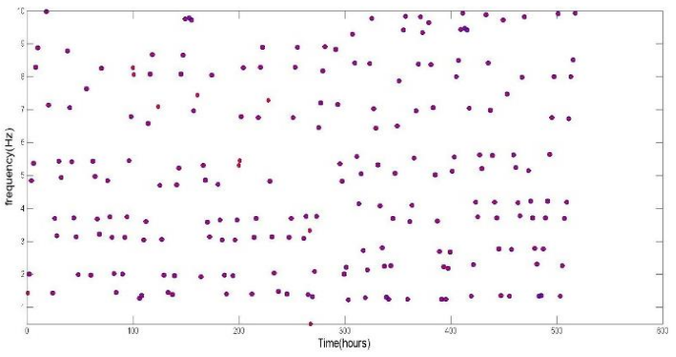
The results in Figure 4 shows that the filter works very effectively. After using the FIR filter the acceleration trend is very regular and compact as compare to without using the IIR filter. Figure 4(a) depicts that the peaks are more pronounced as compare to the Figure 4(b), means that the filter works properly and have removed the unwanted noise very effectively and have made the data regular and compact.

4.3 Modal parameter identification of sutong bridge



In order to identify the continuous modal parameters data was collected from Sutong bridge for a period of 1 month form 01-07-2011 to 31-07-2011. This was collected from 14 vertical accelerometer sensors installed at the bridge. The layout of the vertical accelerometer sensors are shown in Figure 2. The sensor details are shown in Table 1, whereas the sampling frequency is 20Hz. In our study we have only used the data obtained from the 14 vertical accelerometer sensors installed at the Sutong Bridge. The data was first processed by using the FIR and IIR filters one by one on the already collected data from the Sutong bridge, then the reconstructed signal obtained after performing the filtering is used to identify the modal parameters such as frequency and damping ratio using the DATA-SSI technique.

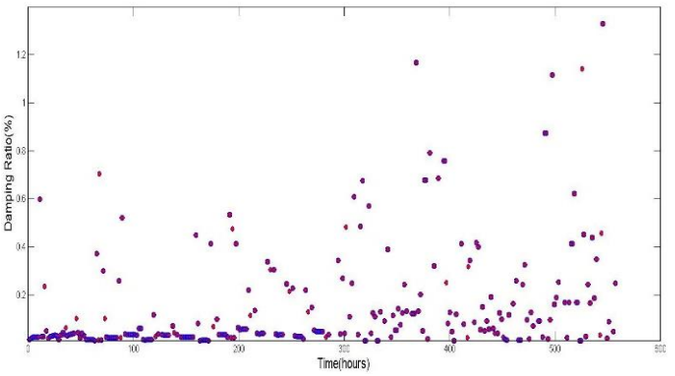
Table 1 Vertical accelerometer sensor's detail



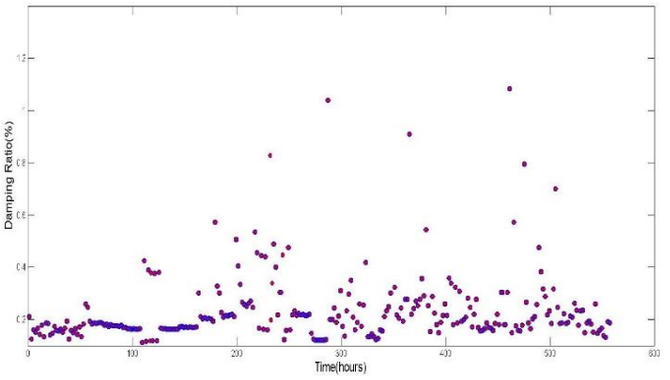
Vertical Accelerometer Numbering			
S/no	Vertical	S/no	Vertical
1	ZD020102	8	ZD050102
2	ZD020104	9	ZD050104
3	ZD030100	10	ZD050200
4	ZD030102	11	ZD050202
5	ZD030104	12	ZD050204
6	ZD030106	13	ZD070100
7	ZD050100	14	ZD070102

Figure 5 shows the frequency estimates obtained by using MATLAB. The frequency trend in Figure 5(b) as compare to Figure 5(a) is more compact and regular. The frequency band specially at frequency 1.5 to 2Hz, 3 to 3.7Hz and 4.7 to 5.4Hz is more pro-

nounced and compact and a regular trend can be seen from left to right in Figure 5(b), thus showing that the results obtained are very good after performing the FIR filtering, because after the introduction of filter the frequency trend become regular as can be seen clearly in Figure 5(b). It can also be deduced from the results obtained in Figure 5(b) that the vertical sensor's data is more robust in terms of vibration, because in cable stayed bridge the vibration are more, thus the results shows an accurate representation of the real life conditions. Figure 6 shows the Damping ratios obtained from the vertical sensors using MATLAB, with and without using the FIR filter, the results obtained shows that the damping ratio is not more than 0.1 to 0.6%. The Chinese specification for cable stayed bridge specified the maximum limits for damping ratio between 1%-2%. In our case the results obtained are within the limits, specially for the Figure 6(b) because it shows the real life representation of cable stayed bridge as compare to Figure 6(a), because in Figure 6(a) most of the damping ratios is around zero, which is not a true representation of cable stayed bridge, thus validates the proposed method.



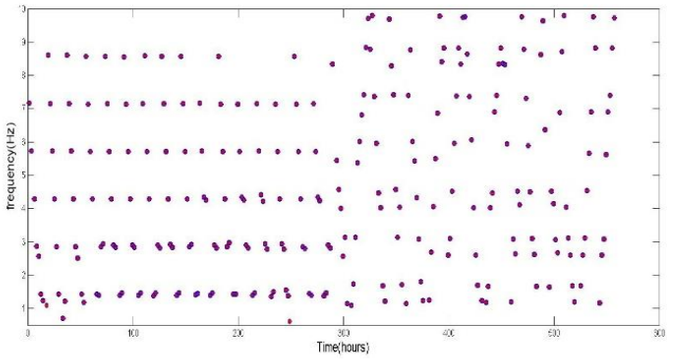
a) Original Data



b) After using FIR filter

Figure 5. Frequency estimates before and after using the FIR filter

a) Original Data



b) After using FIR filter

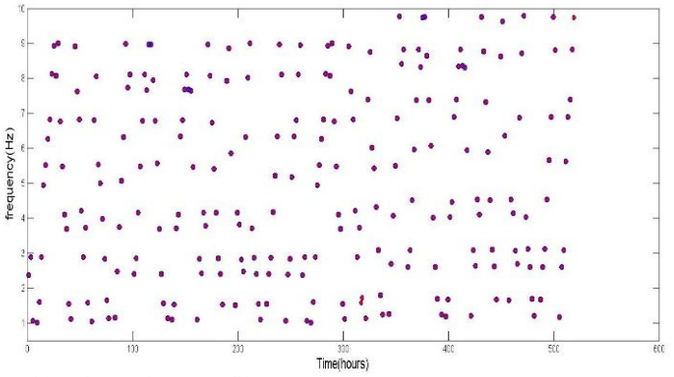


Figure 6. Damping estimates before and after using the FIR filter

Figure 7 shows the frequency estimates obtained by using MATLAB. The frequency trend in Figure 7(b) as compare to Figure 7(a) is more compact, regular and the extracted frequencies band from left to right is more regular. The frequency band specially at frequency 1 to 1.5Hz, 2.5 to 3Hz and 3.7 to 4Hz is more pronounced and compact and a regular trend can be seen from left to right in Figure 7(b), thus showing that the results obtained are very good after performing the IIR filtering, because after the introduction of filter the frequency trend become regular as can be seen clearly in Figure 7(b). It can also be deduced from the results obtained in Figure 7(b) that the vertical sensor's data is more robust in terms of vibration, because in cable stayed bridge the vibration are more, thus the results shows an accurate representation of the real life conditions. Figure 8 shows the Damping ratios obtained from the vertical sensors using MATLAB, with and without using the IIR filter, the results obtained shows that most of the damping ratio is between 0.1 to 0.3% and is not more than 1.2%. The Chinese specification for cable stayed bridge specified the maximum limits for damping ratio between 1%-2%. In our case the results obtained are within the limits, specially for the Figure 8(b) because it shows the real life representation of cable stayed bridge as compare to Figure 8(a), because in Figure 8(a) most of the

damping ratios is around zero, which is not a true representation of cable stayed bridge, thus validates the proposed method.

5 CONCLUSION

In this paper first the data is collected from Sutong bridge, a long span cable stayed bridge, then the data is filtered so that the noise and disturbance is removed from the data by using the FIR and IIR filters one by one. Then the reconstructed signal obtained after performing the filtering was used for the continuous modal parameter identification. Finally to get the continuous modal parameters DATA-SSI was engaged for the continuous modal parameter identification, because DATA-SSI is robust, accurate and consumes less time in data processing, with only problem of processing the data in one batch, hence sliding window technique was used to make it more suitable to be used for the continuous modal parameter identification. The above technique combines the advantages of two methods i.e. the filtering technique to remove the unwanted noise and secondly the continuous monitoring by employing the DATA-SSI. The modal parameters such as frequency and damping ratio obtained from the above used technique are very effective, robust and can provide more useful information about the real life bridge health monitoring.

ABSTRACT: In the past, phenomenon of a bridge being washed away because of a typhoon, a heavy rain in the rainy season, a localised torrential rain, a tsunami and other floo disasters have been observed several times. Hence, new technology and science to restore bridges that have been washed away or damaged are facing an increasing demand. Using the latest technical developments in light structures, the post-buckling response of a thin cylindrical shell is reviewed herein similar to the concept of Origami. This engineering idea is very useful when applied to deployable bridge systems with a rapid construction method. The folding bridge design takes inspiration from the folding skills of Origami, where the scissors mechanism is understood and applied. This study presents a new type of bridge based on the folding idea of Origami and the multi-folding microstructure. The developed bridge system for providing relief after natural disasters is then reviewed by performing a field test in a real river.

1 INTRODUCTION

Globally, natural disasters come in many different forms, including earthquakes, floods tsunamis and landslides. Japan has a long history of devastating disasters, which killed thousands of people and severely devastated both the infrastructure of urbanised areas and transport links. The Great Hanshin Awaji earthquake occurred in 1995, destroying numerous buildings and civil engineering structures. In 2017, the region around Tohoku is still recovering from the 2011 earthquake and tsunami. Figure 1 shows several traffi infrastructures damaged by typhoons and earthquakes in Hokkaido, Tohoku and Kagoshima. Natural disasters can occur anywhere in the world and pose a threat to people in communities, where they will strike. A range of infrastructures will be damaged as an aftermath of a natural disaster. However, it is the rapid repair of any affected bridge or the installation of temporary bridges that is significantl beneficial Repairing all infrastructures is important, but very little improvement will be achieved if any bridge link is remains not passable. Having a bridge link allows for a two-way transport (e.g. evacuation and delivery of aid to local communities).

Urgency, risks, and hazards are present within disaster zones. If a prefabricated bridge is to be used as a temporary structure, it takes a significan time before it reaches a usable state (i.e. typically over a week). This will result in a delayed access of heavy machinery and emergency vehicles needed in a disaster zone to affected regions, consequently resulting to delayed recovery work. In other scenarios, where an emergency bridge is needed, necessary personnel (e.g. pro-

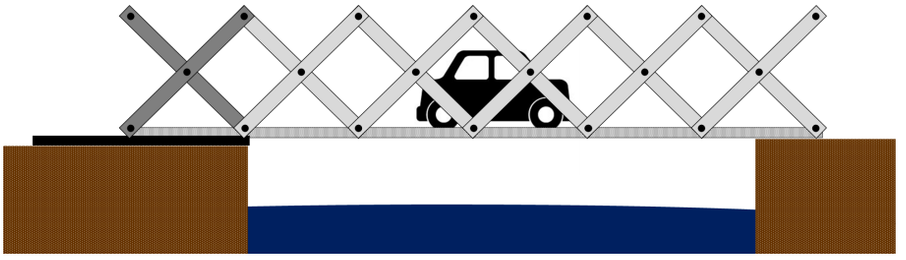

Figure 2: New concept of a scissor bridge based on Origami-folding idea.

fessional engineers) may not be available to construct them. Secondary hazards caused by localised damage would also possibly impede any rescue operations. These situations raise the important issue of selecting the critical activities to be performed in the immediate aftermath of a natural disaster.

In developing a deployable or folding bridge, the fundamental behaviour of the basic mechanisms for the buckling of a thin cylindrical shell under torsional loading must be considered and reviewed from a post-buckling perspective. Deflection are extensively considered in a large deflectio range to the point that the shell is allowed to fold to a fla two-dimensional form in a mechanism reminiscent of a deployable structure. Critical and initial post-buckling effects are explored herein through the concepts of energy minimisation and hidden symmetries. A truss element program is employed for comparison with the fina large-deflectio folded shape. As buckling develops, the mode shape must change to accommodate both the symmetry-breaking aspects of the predominately inward deflectio and the rotation of the peak and valley lines of the buckle pattern necessary to accommodate the geometry of the fina folded shape.

The concept behind the structure is inspired by two different forms of structural design techniques: Origami, which is the art of paper folding, and scissor mechanism, which is a principle using linked supports in a cross 'X'-shaped pattern as a basic unit in a structural system. The firs author thought that if a bridge can fold like the cellular post-buckling of Origami to be a beautiful pattern with a compact size, it would be very useful for the rapidly recovering bridge in Figure 2. A novel structural system that utilises both techniques is proposed herein specificall for constructing a bridge used to provide aid relief for displaced people in times of need and emergency situations. A scissor structure is employed using an Origami-inspired de-

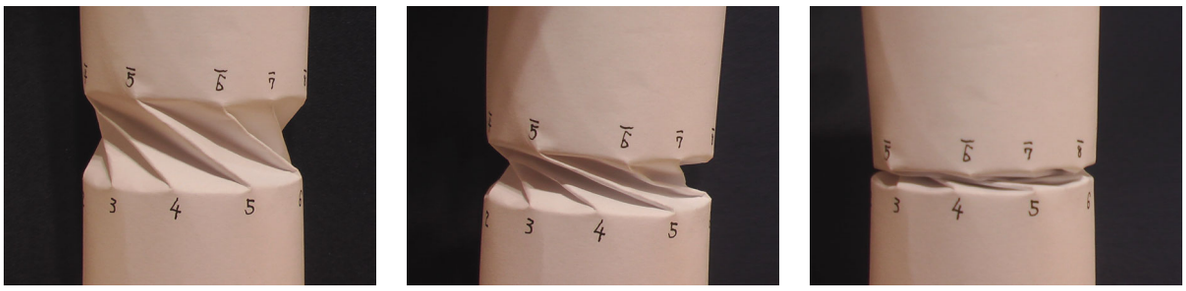
ployment mechanics to create a foldable/deployable and movable bridge and show that constructing a bridge using a folding mechanism based on the academic science of Origami is useful. Hence, a deeper understanding of the essence of an 'Origami-inspired more useful industrial deployable bridge' is advisable.

In the fiel of bridge engineering, several studies have discussed the merits of modular bridges by Thomas and Sia (2013) and the use of lightweight materials (e.g. fibre-reinforce plastic) by Sedlacek (2003) or air tubes by Luchsinger (2004). These propositions allow for the rapid construction of bridges. However, various problems regarding the creation of large construction yards and the use of heavy industrial machinery remain. Any rescue technology should have a low level of complexity and a high degree of resilience to enable its deployment even by unqualifie personnel. Hence, we propose herein a new type of foldable and deployable bridge traded as the 'mobile bridge' (MB) (Japan patent no. 2006-037668 2012; PCT WO2015/193930A1 2015, including European patents). The MB can be quickly deployed and folded because of the scissor mechanism [1] that allows for a highly efficien construction and an easy transportation. The idea for this new bridge was based on the academic studies on post-buckling using the Origami fundamentals of Hunt and Ario (2005) and Pawlowski et al. (2013).

Previous studies (Ario et al., 2017; BBC News, 2015; Web exclusives on ASCE, 2015; Adachi et al., 2017; Chikahiro et al., 2017) evaluated the mechanism and the design concept of the MB through a numerical finit element analysis, followed by a fundamental static loading test using a small experimental bridge. The current research reviews the fiel testing of the latest MB in a real river and its fundamental experimental and numerical results using a full-scale experimental MB.

2 MB BASED ON ORIGAMI AND MULTI-FOLDING TECHNOLOGY

2.1 *Utilising the art of Origami in the fiel structural engineering*



Buckling is recognized as one of the fundamental problems of elastic stability because of its signifi cance in the engineering design of, for example, a thin circular cylindrical shell under torsion and/or axial compression will experience a sudden reduction in stiffness at the onset of buckling. The two contrasting loading situations exhibit quite different characteristics of load/deflectio response as deformation continues into the large-deflectio range. While the former initially results in a highly unstable response followed by restabilization as it settles into a localized form of the well-known YOSHIMURA(1951) pattern (or, it is called "diamond pattern" deformation), the latter forms similar but oblique shapes which are capable of folding entirely in the axial direction without significan in-plane stretching. Figure 3 shows the development of these folds in a paper specimen twisted between two inner plastic mandrels. Following an initial buckling stage that involves both bending and membrane (in-plane) stretching, a pattern resembling an Origami type mechanism is generated. Such folding is prevented in the axially loaded problem which has YOSHIMURA pattern due to the significan stretching occurring at the restabilization stage. The framed core of the buckling pattern resembles a part of the pantographic-lift machine which is available to lift up and down a mechanically expanding/folding system along the vertical direction. Folding without stretching is undoubtedly of considerable interest in the fiel of deployable structures.

2.2 *Post-buckling problem using Origami techniques*

Cellular buckling of a cylinder made by origami, although extremely useful in engineering, is one of the worst issues in structural designing. The instability of a structure under a compressive stress such as buckling becomes an important problem. In the post-buckling theory, there is an opportunity in the cylindrical shell structure built using origami to study the compression buckling by which its symmetry is broken. As the cylinder is twisted, akin to a wet towel squeezed dry, periodic oblique wrinkles in the paper appear at buckling (it appears as a local periodic buckling pattern and this is a type of the multiple bifurcation buckling phenomenon called "cellular buckling"). In the world of Origami, this wrinkle pattern is called a Kresling-pattern, and was introduced by the French origami creator, Kresling(2001). An experiment relevant to this is the post-buckling experiment of the cylindrical shell structure of YAMAKI(1976).

The fundamental behaviour is generally not well understood. However the symmetry of the mode such as the number of waves and its angle of the wrinkles, and an angle variation, should be considered in determining the reason of folding (two or more compression buckling modes should appear in a multiple-singular point) of the energy equilibrium between the bending moment and the in-plane force in the test specimen. Hence, this problem would essentially become difficult The firs author worked thus nonlinear problem and observed deeply this phenomena by using this origami idea for the analysis comparison model, and applied it to the post-buckling theory of YAMAKI. The author fought desperately every day to determine the solution for the problem via geometric observation and reappearance calculation of the

[1] Although the upper and lower chords are the main elements that resist sectional forces in an ordinary truss bridge, the MB lacks chords but can be transported and constructed quickly using a scissor mechanism.

(a) (b) (c)

Figure 3: The foldable cylinder based on twist buckling of a paper roll in Hunt & Ario(2005).

method by which it was folded.

The firs author of this work discovered an important mechanism from the Kresling pattern according to which the truss was built, and its application to lightweight deployment structure has been proposed in this scientifi observation and approach. This was a turning point because most designers and engineers of structural engineering have to ensure that there is no occurrence of instability from buckling behaviour for a structure. However, we think that it is so useful to expand the deployable structure by using the minimum force based on the principle of the minimum energy with this initiated deformation of Kresling pattern in nature. So it is important to avoid buckling in structural design but it does become an aspect for the design of lighter deployable structures for space engineering if this Origami type buckling considered here becomes a useful mechanism when the folding lines from the deformed shell of Origami's post-buckling are considered. We realized that this idea is revolutionary using an engineering method from traditional Origami skills. We could obtain a new concept of engineering design by using Origami which adds to modern phenomenology. So, Origami engineering, can be considered a new construction concept. We believe that this method may become one of the solutions for many problems when solving with innovation and engineering values. This opportunity in the academic study became a turning point of research of Hunt & Ario(2005).

2.3 *Creation of Deployable Bridge based on Origami and Post-Buckling Theory*

In October 2004, the Chuetsu earthquake occurred in Niigata, Japan, following which we investigated the damaged infrastructures in the disaster zone. It is impossible for damaged infrastructure such as railway, bridges, and roads to be used at the time of a disaster. Thus, human efforts are required for the restoration tools to be involved quickly. However, these are very scarce. Moreover, the restoration technique in a distressed area, whether it is inside and/or outside the country, has to be repeatedly applied, and the necessity for a temporary bridge serving as a restoration tool has been realized. Joint research of the structural instability problem of the buckling theory of a multiple-folding micro-structure and the multiple singular points of the diamond truss model of a multilayered pantograph mechanism was conducted with a professor of Polish Academy of Sciences.

2.4 *Trigger of MB development*

The firs author found the deployable structure of the pantograph and a rapid restoration method, which is often used in the elastic expansion of a child's toy played, and related them to the problem of the previously discussed compression buckling. He envisaged an innovative possibility of utilizing the bridge and proposed that the deployable structure could be effectively used if a bridge could be folded similar to that of Origami creations. Although it seems similar to the accordion-like gate of a house, this expanding system in the construction site needs more stiffness in order to design a real bridge for transmitting structural loading. It is necessary for the minimum control force to expand and fold the whole mechanism. Our design is a new concept for the design of a bridge mechanism and selecting the most suitable structural members, using the principle of minimum energy of the post-buckling problem theory along with Origami folding skill and ideas. And we have two another approaches; one is based on the concept of the multiple folding microstructures theory and the other one is based on the concept of topological optimisation method using computing finit element method. Hence, it is realised that it is possible to build up the multi-folding type of bridge based on a principle of the minimum energy like the buckling pattern of Origami. Lightness and strength of the part are important parameters, and the dynamic equilibrium, structural stability, and appropriate structural form are essential considerations. The authors realistically chose the materials with a specifi tensile strength, equilibrium state of the stiffness, and structural stable conditions.

However, technical skill is required to apply the strategy which makes a primary member convergent. Although it is safe to improve the higher stiffness and the stronger bridge and reduce the number of the bridge parts, to ease the stress concentration in the bottom configuratio where the analysis and design

Figure 4: Tests of foldable, movable and deployable bridge “Mobile bridge (MB0)” at November 2009.

are currently of a high-quality, we thought it was possible because of a specification Alternatively, when structural instability is well-controlled, it is possible to form the basis for the ability to fold a bridge effi ciently.

However, we have to firs understand the “Ori” (meaning folding) structure which is an unsolved academic problem, involving questions such as the method to fold and how to fold while maintaining the strength of the bridge. The mechanics of the classical post-buckling behaviour is in the territory of undeveloped dynamics in spite of the product called “Ori-Tatami” (it means multi-folding), which is a specialty of Japan. For a particular efficien collapse, The firs author has mathematically determined a multiple peculiar point (a rip of symmetry and multiple structural instability hide potentially). However, there is a high-risk in the case of a heavy construction such as a bridge structure that is sensibly usually evaded, but it is compound by the use of the structurally unstable pantograph mechanism and expanded the parts of the deck slab and the chord members from Origami idea. Thus, the whole system can be developed in terms of multiple structural stability by combining the most suitable and smart structural concept. The development structures are called “Deployable Structures” and often used in applications in the fiel of space engineering. But the deployable structure on the ground is influence by gravity, and its condition becomes generally more severe than in zero gravity space. I perceived that one could not generally understand that it was designed for such conditions, and the embodiment of the mechanical principle in the bridge was entrusted as a prototype shown in figur 4, while the construction was delegated to a manufacturing unit in Hiroshima university to conduct experiments in the limited budget. The manufacturing accuracy has also completed a prototype in the early stage in less than three months thanks to a highly skillful technical staff at Hiroshima University. This concept of a new bridge was created from Origami and it means people pray “Let us build up the peace in the world be like a bridge between countries or people.”

2.5 *Deployable structure*

The scissors mechanism in its most basic form consists of two linear elements joined at their centres by a pivot providing a hinge-connection. In the fully deployed state, the two members are in the shape of the character ‘X’, creating the deployed single scissor unit. This basic scissor unit is connected to the next unit by two hinges. The structure is deployable and has a large ratio of length change from the fully extended state to the folded state. In the non-deployed or compact state the structure can be easily transported or stored for future reuse. Pinero(1965), an architect from Spain, has presented the concept of a scissor type mechanism. He applied this idea to a deployable roof structure and obtained a patent in 1961. After this successful application, Zeigler(1976) and Escring(1989) focused on the geometric layout design of the scissor units and proposed deployable domes

using mechanisms. Recently, Hahawa & Saitoh et al.(2001) has analysed the strength and stability of scissor structures reinforced with a string system. Indeed, scissor type structures are being increasingly used in a wide range in the mechanical and space engineering field Glisic. Our current study for the MB plays an important role as an innovative product in the bridge engineering field The scissors mechanism enables the MB to be constructed and easily transported because of the compact preassembly configuration. These fundamental concepts of the design of the MB result in the following advantages:

1. The MB uses patented technologies (2012)& (2015) based on the scissors mechanism for deploying an emergency bridge system set within a modular design and incorporating deck-boards.

2. The MB is a compact transportable bridge system, *robotic bridge*, which is suitable for transportation on a car trailer or lorry.

3. The MB system has a completely novel design and offers extraordinary performance without requiring assembly of the block type using the trussed structures approach.

In addition, the MB can be deployed in a wide range of areas, not only during emergency situations, but also in normal operations. For example, many existing old bridges are in a poor technical state owing to improper maintenance or overloading. Smaller bridges are available to operate the scissors type of bridge using the MB, which is quick serving as a temporary bridge. This provides the advantage of movable bridges to act as a temporary bridge quickly and easily without interrupting traffi and increasing further damage to the existing bridge.

3 DESIGN OF MOBILE BRIDGE VER. 4.0

The MB has a scissor-like structure that is connected to the main structural members to form an 'X' shape; this enables expansion and contraction while retaining strength. The idea for this new bridge was developed from the academic studies on buckling based on Origami (Japanese traditional paper craft), which has attracted the attention of researchers in space engineering and other fields

The manufacturers developed MB version 4.0 (MB4.0) as a type of robotic bridge by improving its mobility and functionality and decreasing its weight. Therefore, MB4.0 has become more transportable and easier to set up at temporary construction sites without any foundation construction or crane operations. As a result, it is also less expensive.

MB4.0 is the fastest, largest, strongest, and lightest expanding scissoring bridge of the world. In addition, it is the fastest to set up. Because the bridge and its lanes are expanded simultaneously, the bridge is ready for use by traffi as soon as it is fully expanded. From the arrival of MB4.0 on site to its full expansion only takes approximately one hour. The actual extension time is only f ve minutes only. This is especially important for time-sensitive situations during a disaster.

The developers state that "from this testing of a new bridge concept, the next generation of bridge technology reaches a new stage in the fiel of bridge engineering. It is possible to use a real deployable and smart bridge with a scissors type bridge system using this structural theory."

3.1 *First test of MB4.0 for taking over a river*

We review the release of the firs test of the full-scale, novel scissors-like bridge structure MB4.0 Ario et al. (2017), Adachi et al. (2017), Chikahiro et al. (2017). The developers at the Institute of Engineering at the Hiroshima University conducted a fiel test in conditions resembling the real situations of bridge deployment. The test of the MB4.0 over a real river, called the Hongo river, demonstrated its capability for practical use on 24th April 2015 in Fukuyama, Japan. The width of the river was surveyed as about 17.1m and it was accessible before bridge construction.

During the test, MB4.0 arrived on one side of the river carried by a heavy trailer. This bridge system is equipped with an out-rigger system which enables the automatic removal from the transport trailer after connecting to a hydraulic pump. In the next step, the bridge, which is transported in the horizontal position, is rotated by 90° to the pre-deployment state. The expansion process can be easily controlled and it took only f ve minutes for the bridge to be fully deployed. The MB4.0 reached the other side of the Hongo river safely without any technical problems and was operated by a very limited technical crew, as shown in fig ure 5. The total time from the arrival of the MB4.0 on-site to its full expansion was approximately one hour. No work, including preparation of foundations for the other side of the river, was conducted during the test. The deployment of the bridge also did not involve the use of a crane or any other construction machine, which are typically involved in such situations. This is particularly important in time-sensitive situations characteristic of disasters.

In the current research, we developed the MB4.0 as a type of robotic bridge by improving its mobility and functionality and decreasing its weight. Thus, the MB4.0 has become more transportable and easier to set up at temporary construction sites without any foundation, construction, or heavy machine operations. As a result, it is also much more cost efficient The current model, the MB4.0, has a length of about 20 m and a height of 2 m, as listed in Table 1. The main structural members of the bridge are made of extruded aluminium alloy, while the frame of the hy-

draulic deployment system is constructed from steel SS400.

4 CONCLUSIONS

This study presents a new deployable and/or folding bridge design with a scissor structure based on post-buckling theory for a cylindrical shell using the Origami skill in the engineering field We applied the design to a full-scale MB4.0 with integrated lower deck boards and a fiel experiment related to crossing a real river in Japan. After demonstrating the structural safety of the bridge, we performed a fundamental numerical simulation and an experimental test to investigate the MB4.0 dynamics. The results lead to the following conclusions:

1. The development of a full-scale scissor-type bridge for three vehicles was successful, and its on-site usability was demonstrated based on the fiel experiment over a real river.

2. During the test, the constructing bridge was completed within 1 hour (the expanding bridge was taken for only 5 minutes) without any work performed on the foundations. Vehicles were then able to easily travel across it. The deployment was safely achieved with very little human involvement and without any problems such as those encountered in robot bridge.

3. This new bridge type has the fl xibility and improved mobility of a function; hence, it is a very useful emergency bridge without any foundation or construction.

Various numerical models were designed to provide the basis for the development of new methods for structural reinforcement and vibration suppression. The conducted research allows for a better and safer MB to be designed.

Rational decision-support system for selecting bridge construction alternatives

U. B. Attanayake & H.M. Aktan
Western Michigan University, Kalamazoo, Michigan, United States of America

ABSTRACT: The bridge rehabilitation/replacement with conventional construction (CC) methods impacts motorized and non-motorized traffic mobility for a duration that extends from months to years. Accelerated Bridge Construction (ABC) concepts and methods are developed to reduce mobility impact time. ABC methods include prefabricated bridge elements and systems (PBES), slide-in bridge construction (SIBC), and self-propelled modular transporter (SPMT) moves. At present, highway agency policies have been establish to require evaluating every bridge site's suitability for implementing ABC methods. Since the ABC is not the solution for every site, highway agencies are demanding a robust and rational process to be implemented during network level and project level scoping to identify the most preferable construction methods for selected sites. A hybrid multi-criteria decision-support model was developed and presented in this paper. The model was developed using the Analytical Hierarchy Process (AHP) and accommodates quantitative as well as qualitative parameters identified through literature synthesis including post-construction and lessons learned reports and years of ABC experience of the authors. The quantitative parameters are customized based on the region specific data as well as the site-specific data. However, the qualitative parameters are judged based on the experience/knowledge from experts. The model has the ability to include additional qualitative parameters, contingent to project manager's discretion. Further, the model incorporates a hybrid approach of integrating the region specific data, the site-specific data, and the experience/knowledge from experts to automatically perform AHP steps with reduced user input.

1 INTRODUCTION

When bridges are replaced using conventional construction (CC) methods, motorized and non-motorized traffic mobility is impacted for a duration that extends from months to years creating difficulties and safety issues to the stakeholders. Accelerated Bridge Construction (ABC) concepts and techniques are designed to reduce mobility impact time. ABC methods include prefabricated bridge elements and systems (PBES), slide-in bridge construction (SIBC), and self-propelled modular transporter (SPMT) moves. Since the ABC is not appropriate for every site, highway agencies need a robust and rational process to be implemented during network level and project level scoping to identify the optimal construction methods for selected sites. As an example, the Michigan Department of Transportation (MDOT) evaluates every bridge project during the scoping process for ABC potential. In 2013, Aktan and Attanayake (2013) developed a multi-criteria decision-support framework to comparatively assess conventional construction (CC) vs. ABC. The framework was customized for implementation in Michigan and supplemented with a guided software program titled *Michigan Accelerated Bridge Construction Decision-support (Mi-ABCD) tool*. The software was developed using Microsoft Excel and Visual Basic for Applications (VBA) scripts. In the 2013 version of Mi-ABCD, the ABC only encompasses prefabricated bridge elements and systems (PBES) construction.

Recent ABC technologies, such as slide-in bridge construction (SPMT) and self-propelled modular transporter (SIBC) moves, are being increasingly implemented throughout the U.S. In Michigan, SIBC was implemented in three pilot projects involving four bridge replacements. Aktan et al. (2014) and Aktan and Attanayake (2015) present details of two projects, US-131 over 3-Mile Road and M-50 over I-96. Ridvanoglu et al. (2017) presents details of the other project, M-100 over the Canadian National (CN) railroad. To address the need of assessing four bridge construction/replacement methods (CC, PBES,

SPMT, and SIBC) for a site, the decision-support framework developed by Aktan and Attanayake (2013) was extended. Aktan and Attanayake (2015) present the updated scoping framework and the associated guidelines for its implementation. Later, Aktan and Attanayke (2017) updated the software to comparatively assess all four bridge construction/replacement methods. This article presents an overview of the software features, data structure, output formats, and implementation recommendations.

2 MATHEMATICAL FRAMEWORK IMPLEMENTED IN THE TOOL

2.1 *Significance of AHP in Evaluating Bridge Construction Methods*

The Analytical Hierarchy Process (AHP) was developed by Saaty (1980) for comparing a set of decision alternatives. AHP involves representing the complex problem in terms of parameters, and establishing a hierarchy. In the hierarchy, the top level includes the objective, the middle level includes the parameters that affect the objective, and the bottom level includes the decision alternatives that can be implemented to achieve the objective. The parameters in the hierarchy are subjected to pair-wise comparisons using an ordinal scale between 1 and 9. Where 1 represents equal importance and 9 represents extreme diverging importance between parameters. The decision alternatives are evaluated with respect to each parameter by the pair-wise comparison process. The pair-wise comparisons develop the AHP matrices. The priority vectors for the matrices are calculated and subjected to AHP synthesis in order to obtain normalized priorities for the decision alternatives (Saaty 1980).

Each AHP matrix is a unit positive reciprocal matrix, where the diagonal elements are unity and the lower triangular elements are reciprocal of the corresponding upper triangular elements. In an ideal consistent matrix if $a_{ij} > a_{ik}$ for all j and k, i.e., if one row dominates another row, the priority of the i^{th} element is greater than the priority of the k^{th} element. The measure of inconsistency in the AHP pair-wise comparison matrix is represented by a consistency ratio (CR). A CR of 0.10 or less is considered acceptable for the pair-wise comparison matrices, and normalized column-row averaging method is implemented to calculate the normalized preference rating for the variables in the matrix. However, increased number of parameters in a pair-wise comparison matrix may lead to inconsistencies requiring repeating the pair-wise comparisons (Saaty, 1980). A theoretically sound approach to manage inconsistency in a pair-wise comparison matrix is to take large powers of the matrix that enables transforming the complex order among the matrix elements to a linear order (Saaty, 2001). This process is utilized in several computing algorithms to calculate the Eigenvectors of a matrix, such as Mathcad Hessenberg form coupled with QR Decomposition algorithm. The algorithm uses the procedure of balancing with an order of N^2 that substantially improves the accuracy of an inadequately balanced matrix (Press et al. 1992). Using such algorithms to calculate Eigenvector associated with principal Eigenvalue of a matrix, leads to normalized preferences for the variables in the matrix (Saaty, 2001). This approach is an improvement over the normalized column-row averaging method and eliminates the need for repeating the pair-wise comparisons.

AHP provides the ability to group the parameters into several levels, such as categorizing the parameters into major-parameters and associated sub-parameters. This categorization enables us to identify not only the optimal decision alternative, but also the major-parameters that highly influence the problem and the decision. Therefore, specific to evaluation of bridge construction methods, a 4-level hierarchy is typically established for the AHP such that the top level includes the objective, the second level includes the major-parameters, the third level includes the sub-parameters, and the bottom level includes the decision alternatives. The key part of the hierarchy consists of major-parameters, sub-parameters, and decision alternatives. For this specific case, the AHP pair-wise comparisons are performed between (1) major-parameters, (2) sub-parameters under respective major-parameter, and (3) decision alternatives and each sub-parameter. This process results in three sets of AHP matrices for calculating normalized preferences for the major-parameters and the decision alternatives.

2.2 *Hybrid Methodology*

A methodology was developed considering the limitations in the available decision-making models for bridge projects and lessons learned from past ABC projects, in order to accomplish the following objectives:

- Warrant the decision-making for bridge projects with site specific data.
- Eliminate the apprehension with pair-wise comparison of parameters and associated consistency control.
- Simplify users' input and enable incorporating user judgment based on their experience.

As shown in Figure 1, the qualitative as well as quantitative parameters are included, along with the hybrid AHP. The AHP hierarchy consists of major-parameters, sub-parameters, and decision alternatives. The quantitative parameters have numerical values either assigned or calculated during the project planning stages. The quantitative parameters are incorporated in the decision-making based on project specific data (i.e., site-specific data, traffic data, life-cycle cost data), and general data for a state or a region (i.e., common site characteristics and economic indicators). On the other hand, the qualitative parameters are incorporated in the decision-making based on preference from users. The preferences of users are termed as preference ratings on an ordinal scale. The methodology implements Ordinal Scale Ratings (OSRs) ranging from 1 to 9 to form AHP pair-wise comparison matrices; thus, eliminating the pair-wise comparison step. The OSRs provide a uniform measure for quantitative and qualitative parameters, and enable the decision makers to provide preference for qualitative parameters based on past project experiences. Incorporating OSRs rather than pair-wise comparisons, the AHP is described as "hybrid."

The methodology includes a process wherein the OSRs of the quantitative parameters are calculated based on project specific data, and general data for a state or region. The OSRs for quantitative parameters represent interval data, i.e., the OSRs from 1 to 9 are equally split into range of values for respective quantitative parameter. For the qualitative parameters, the judgments from users are obtained as preference ratings that represent the OSRs. In this case, the OSRs represent ordinal data, i.e., the difference between 8 and 9 OSRs is not necessarily the same as difference between 5 and 6 OSRs.

3 Mi-ABCD TOOL

3.1 *Sample Popup Menus and Datasheet*

The VBA's Graphical User Interface (GUI) forms are utilized to interact with the user. These forms are termed as *Pop-up Menus* (Figure 2a and b), and the Excel sheets that are customized for user input are termed as *Datasheets* (Figure 2c). The main features of the *pop-up menu* are to provide (1) Command buttons, (2) Dropdown menus, (3) Tabs, (4) Text fields, (5) Check boxes, and (6) an Additional information button ( ) (Figure 2-a and b). The most commonly used features are the *command buttons* and *dropdown menus*. The primary features of a *datasheet* are (1) Command buttons, (2) Dropdown menus, and (3) Data input fields.

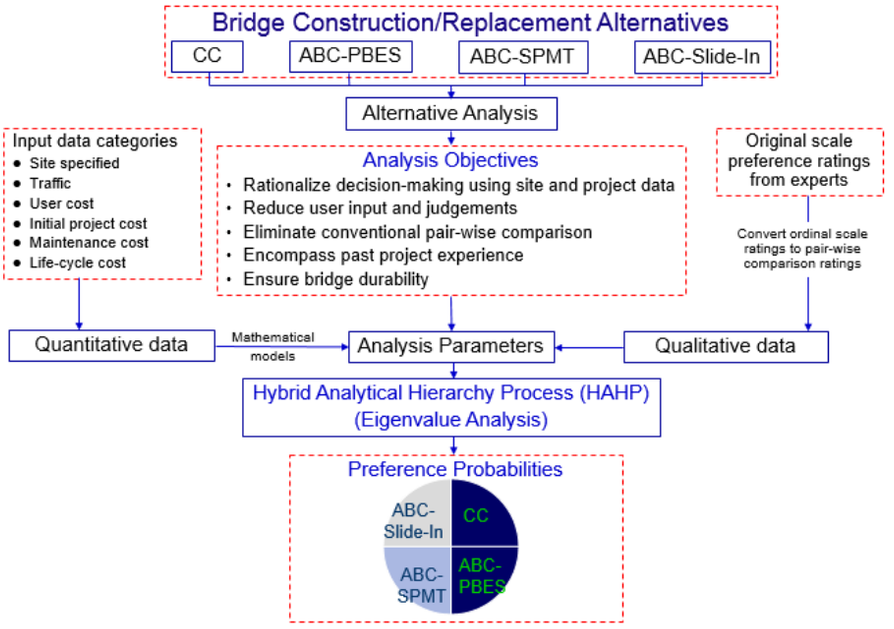

Figure 1: The methodology implemented in the decision-support tool

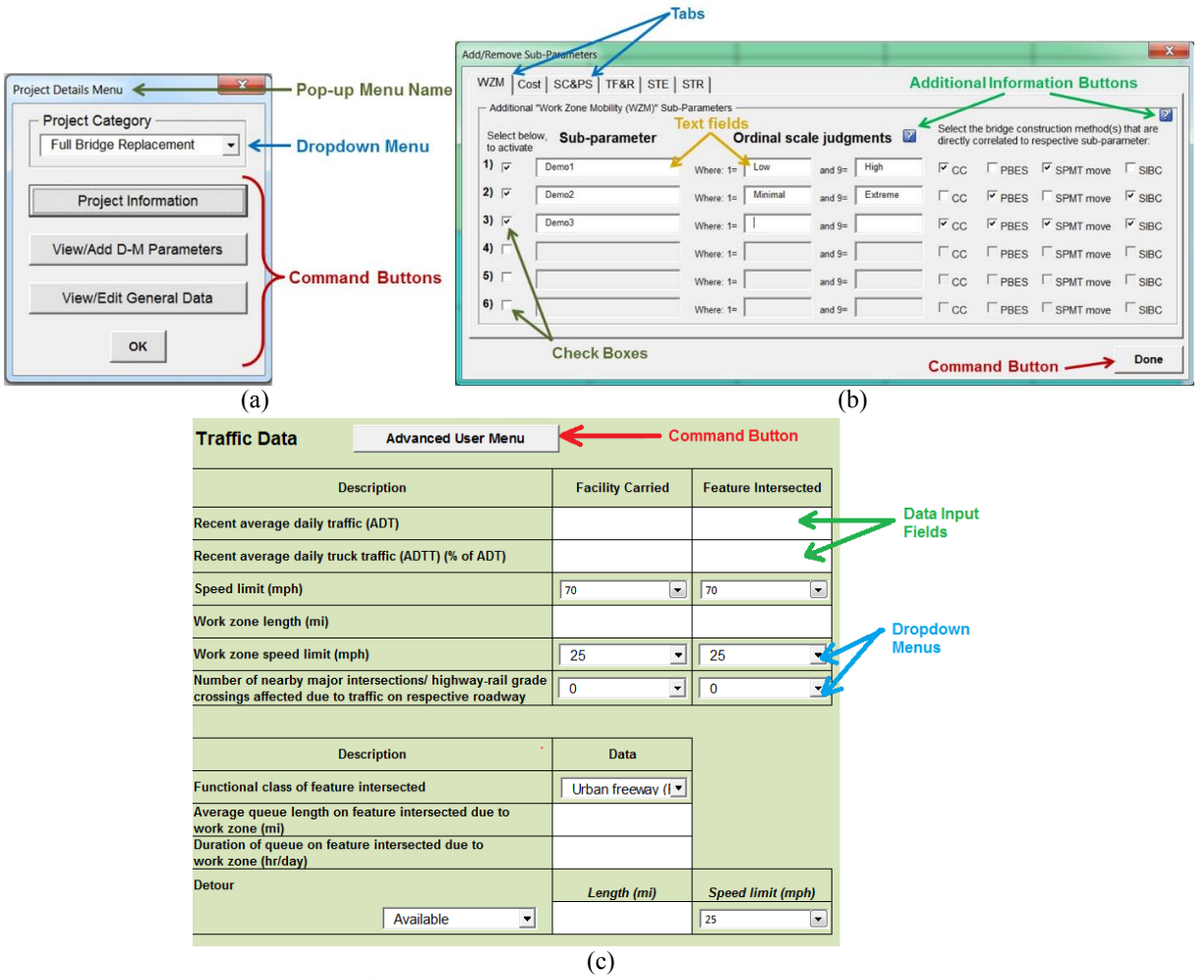

Figure 2: Sample popup menus and datasheet

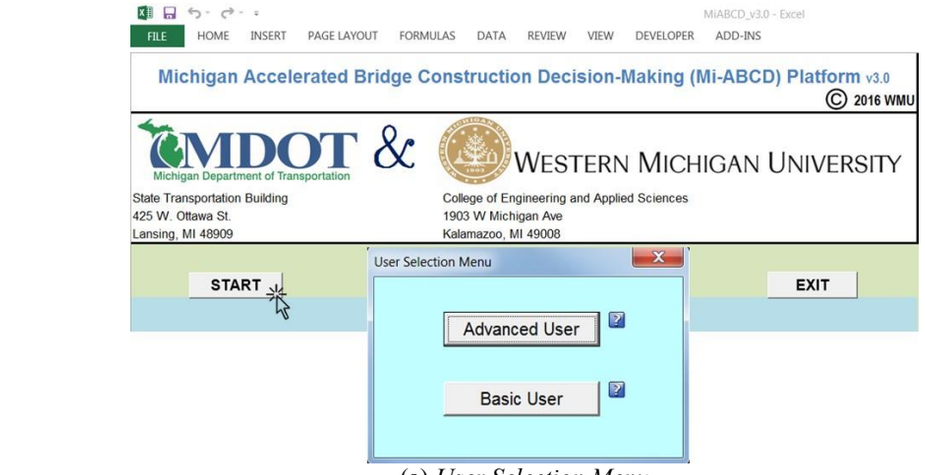
3.2 *User Menus*

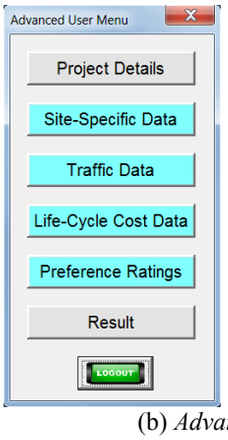
Data entry screens are for two types of users: (1) the *Advanced User* and (2) the *Basic User* (Figure 3a). The *Advanced User* is often a project manager who is familiar with the project specifics such as site-specific data, cost estimates, traffic data, and construction methodologies. The *Advanced User* enters and edits *Project Details, Site-Specific Data, Traffic Data, Life-Cycle Cost Data, and Preference Ratings*. Finally, the *Advanced User* also executes data analysis and view *Results*. The *Advanced User Menu* (Figure 3b) contains command buttons for entering and editing data, data analysis, and viewing results. In order to execute the analysis process, the *Advanced User* must complete all the steps before any *Basic User* is allowed.

The *Basic User* is generally on the project team, and enters the preference ratings for qualitative parameters based on their experience on recent bridge projects. The *Basic User* can view *Project Information,* enter *Preference Ratings,* execute data analysis, and view *Results* (Figure 3c). One of the advanced features in this software is that it allows the *Basic User* to describe reasoning in the text boxes on the *Preference Ratings* datasheet. The subsequent users can view the comments, but preference ratings of previous users are concealed.

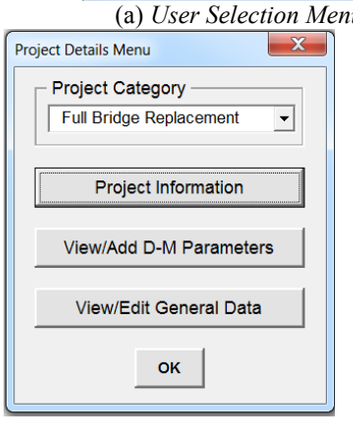


3.3 *Data Entry using the Advanced User Menu*

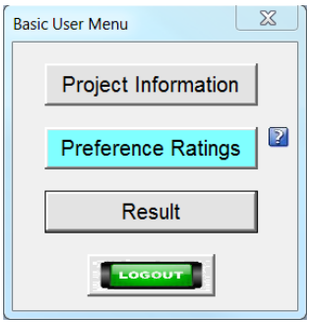
First, the *Advanced User* selects *Project Details* menu to access *Project Categor*y, *Project Information*, *View/Add D-M Parameters*, and *View/Edit General* data using *Project Details Menu* (Figure 3b). *Project Information* page allows specifying the *Evaluation options* and providing an image of the site and a description. The project description may include the project location, surrounding businesses and stakeholders, and any critical aspects that the project manager considers useful to the *Basic Users*. The *Evaluation options* includes the following:



1) CC vs. PBES vs. SPMT move vs. SIBC
2) CC vs. PBES
3) PBES vs. SPMT move vs. SIBC
4) SPMT move vs. SIBC.



Note that the *Advanced User* selects the evaluation option based on the availability of staging area. For example, if staging area is unavailable for a project, evaluation options may be limited to CC vs. PBES. Next, the *Advanced User* can access *View/Add D-M*



Parameters (Figure 3b), and review them or, if needed, add new parameters. The default decision-making parameters are grouped under major-parameters, sub-parameters, and secondary-level sub-parameters. Apart from the default sub-parameters, *Advanced User* can add up to six additional sub-parameters under each major parameter. Thus, a total of 36 (i.e., 6×6) additional sub-parameters can be incorporated in the decision-making process.

(a) *User Selection Menu*

(b) *Advanced User Menu* options (c) *Basic User Menu*

Figure 3: User menus

3.3.1 *General Data*

The *View/Edit General Data* command button opens the *General Data* datasheet. This datasheet includes a majority of the data needed for the workings of Mi-ABCD tool and the AHP evaluation of bridge construction methods (Aktan and Attanayake 2013; Aktan and Attanayake 2015). A majority of the data in the *General Data* datasheet will remain the same for a region and for a period of time. The *Advanced User* can modify the following data in the *General Data* datasheet. The following categories are included under the *General Data*:

1) County jobs multiplier.
2) Range for specialty equipment procuring distance.
3) Options for clustered bridge replacement projects.
4) Range for allowable ground bearing pressure.
5) Speed limit options.
6) Peak hour factors for roadway functional class.
7) Detour length.
8) User cost data.
9) Utility relocation cost.
10) Costs related to SPMT move.
11) Costs related to SIBC.
12) Correlation of decision-making parameters with bridge construction methods.

3.3.2 *Site-Specific Data*

The *Site-Specific Data* command button on the *Advanced User Menu* opens the *Site-Specific Data* datasheet. The data required for this datasheet is obtained from the layout of the project site, data from corridor planning process, and preliminary design of the proposed bridge.

3.3.3 *Traffic Data*

The *Traffic Data* command button on the *Advanced User Menu* opens the *Traffic Data* datasheet. Data from the corridor planning process and preliminary traffic study at the site are required for completing the datasheet.

3.3.4 *Cost Data*

The *Cost Data* command button on the *Advanced User Menu* opens the *Cost Data* datasheet. The data in this datasheet is related to the bridge construction methods. The project manager(s) needs to identify the cost estimates for the respective bridge construction method prior to entering the data. The following cost data categories are listed in the *Cost Data* datasheet:

1) The *cost of upgrading detour* is applicable only if the required detour duration is more than 14 days, and is added to the maintenance of traffic (MOT) cost.
2) The *specialty contractor cost for SIBC* is estimated based on the contractor availability and qualifications.
3) The *initial construction cost* deals with the cost of superstructure and substructure, excluding the maintenance of traffic cost, specialty contractor and equipment cost. .
4) The *repair activity cost* needs to include all of the costs associated with the repair of structure constructed using the respective bridge construction method.
5) The *average duration between the repair activities* data is not yet available for ABC projects. It is reasonable to assume that for ABC this duration is longer than CC. Accuracy of this estimate will improve once performance data of large number of ABC projects are available.
6) The *disposal cost or salvage value* for each bridge construction method is calculated considering the respective residual life of the structure with respect to life-cycle cost analysis period. Life expectancy of bridge with each construction method can be different. The life expectancy of the structure with CC is the basis for life-cycle cost analysis period. For service life expectancy greater that CC, *disposal cost or salvage value* will be negative.

3.3.5 *Preference Ratings*

The *Preference Ratings* command button on both the *Advanced User Menu* and the *Basic User Menu* opens the *Preference Ratings* datasheet. The qualitative judgments are assigned in the form of preference ratings on an ordinal scale of 1 to 9. Preference ratings are categorized into three groups: *Cost Preference Ratings*, *Site-Specific Preference Ratings*, and *Bridge Construction Method-Specific Ratings*. Under these three categories, a total of 35 ordinal scale ratings are provided by a user.

3.4 *Evaluation of Results*

The *Result* command on the *Advanced User Menu* or *Basic User Menu* displays the analysis results. The results are displayed in the following four formats:

1) Two pie charts showing the *Upper Bound Rating Result* and *Lower Bound Rating Result* of the bridge construction methods being evaluated (Figure 4 - top left). The pie charts show upper and lower bound ranges from the preference ratings of multiple users. With only one user the *Lower Bound Rating Result* will display equal value for the bridge construction methods.
2) A line chart showing the *Normalized preferences for major-parameters* from multiple users with different line types and colors representing each user (Figure 4 - top right).
3) A bar chart showing the *Normalized preferences for bridge construction methods* of multiple users (Figure 4 - bottom). Each bar is stacked with six different colors representing the contribution from six major-parameters: (i) Work Zone Mobility (WZM), (ii) Cost, (iii) Seasonal Constraints and Project Schedule (SC&PS), (iv) Technical Feasibility and Risk (TF&R), (v) Site Considerations (STE), and (vi) Structure Considerations (STR).

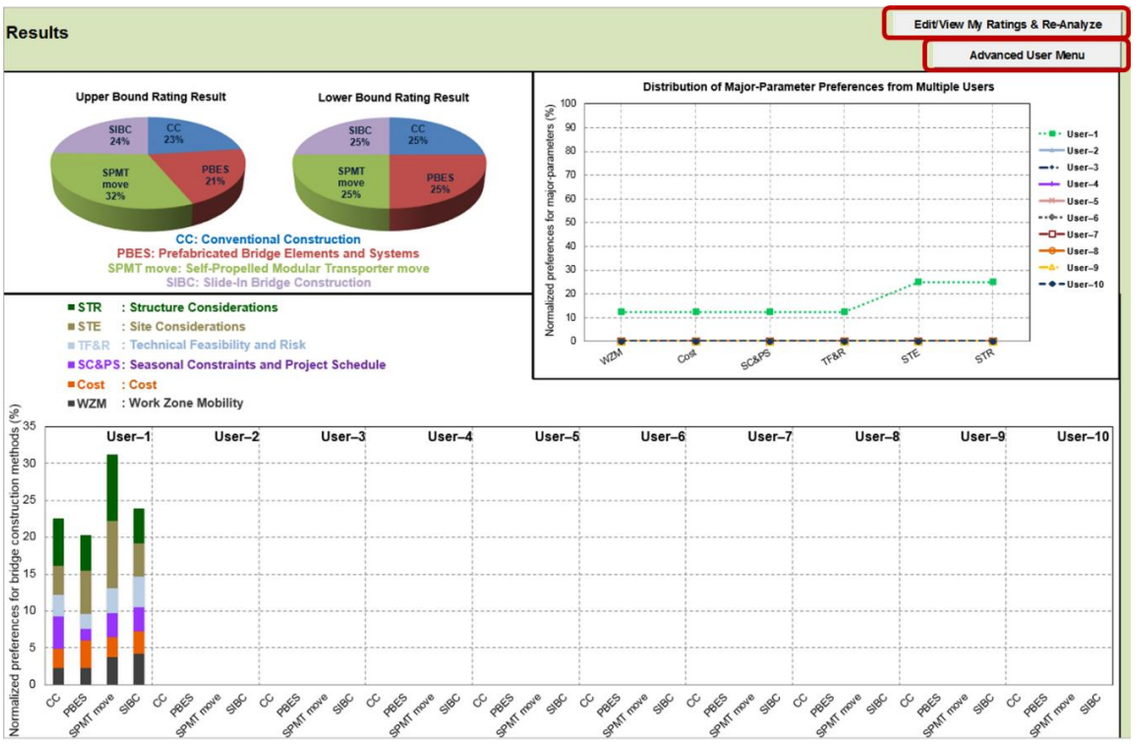


Figure 4: Results in chart format

4 SUMMARY, CONCLUSIONS, AND RECOMMENDATIONS

The policy statement developed by highway agencies requires the project selection to be based on the feasibility of ABC. If ABC is not justified for a project, a rationale is required. A multi-criteria decision-support framework to comparatively assess CC versus ABC, and a guided software program titled *Michigan Accelerated Bridge Construction Decision-support* (Mi-ABCD) tool were developed.

The specific conclusions related to the Mi-ABCD tool are as follows:

1. The tool is designed to evaluate CC, PBES, SPMT, and SIBC or any subset.
2. The tool incorporated a knowledge-base that consists of *General Data*. The general data does not require frequent changes and is extensively used during the computation process.
3. The *Advanced User* can display ratings from all the users and the associated comments. This allows the project team in a committee setting to review all the ratings and rationales provided by the users and deliberate over the results.
4. The *Advanced User* can *Remove All Ordinal Scale Ratings and Comments* and input a new set of ratings generated during the deliberation process to evaluate the results of the collective effort.
5. Project managers are expected to input best estimates for initial cost categories such as initial construction cost. In a future version, the cost data derived from completed projects can be incorporated into the knowledge-base as general data to minimize user input requirements.
6. Service life and maintenance frequency of bridges constructed using PBES, SIBC, or SPMT moves are estimated for life-cycle cost calculation. In a future version, the performance data needs to be incorporated into the knowledge-base as general data to minimize user input requirements.

4.1 *Recommended Mi-ABCD Tool Implementation Process*

1) For a particular project, the *Advanced User* first completes the datasheets for *Project Details, Site-Specific Data*, *Traffic Data*, and *Cost Data*. *Advanced User* can assign preference ratings, perform analysis, and view results.
2) To allow for *Basic User* data entry, the *Advanced User* must *Logout* and forward the saved file to the *Basic User*(s) sequentially for their entry of preference ratings and associated comments.
3) For the next *Basic User* to access the *Preference Ratings* datasheet as a "New User," the

current user must *Logout* after entering preference ratings, performing analysis, and viewing the results.

4) Finally, the *Advanced User* reviews the results using all the *Basic User* ratings, and deliberate at a meeting to develop the final decision on the construction method for the selected site. If needed, the *Advanced User* is privileged to *Delete All Ordinal Scale Ratings and Comments* and input a new set of ratings generated during the deliberation process to evaluate the results of the collective effort.

ACKNOWLEDGEMENTS

Standardizing Lateral Bridge Slide Design

U. B. Attanayake & H.M. Aktan
Western Michigan University, Kalamazoo, Michigan, United States of America

ABSTRACT: Accelerated Bridge Construction (ABC) methods such as prefabricated bridge elements and systems (PBES), slide-in bridge construction (SIBC), and self-propelled modular transporter (SPMT) moves are designed to reduce mobility impact time. In Michigan, USA, four bridges were replaced using SIBC, also described as the lateral slide. The Michigan projects, a large volume of lateral slide project documentation in the Federal Highway Administration (FHWA) repository, and resources available through state departments of transportation (DOTs) were reviewed and the successes, difficulties, and activities were documented and analyzed. Additionally, instrumentation and monitoring as well as refined finite element (FE) simulations of two slides completed in Michigan were performed to calculate structural effects of the slide and investigate the sources and effect of the difficulties. Design procedures, considerations, and limitations were formulated based on the findings from the completed projects and from FE simulation results. The final product of this work described in this article is a step-by-step process to standardize bridge slide activities and designs.

1 INTRODUCTION

Accelerated Bridge Construction (ABC) requires innovative planning, design, and materials to reduce onsite construction time with safety and cost efficiency constraints (Culmo 2011). ABC is implemented to reduce adverse mobility impacts of conventional construction (CC). Slide-In Bridge Construction (SIBC) is an ABC method where the new superstructure is constructed adjacent to the existing bridge on a temporary structure and moved in place with a sliding and an actuating system. SIBC provides opportunity to maintain traffic on the existing bridge during construction of a new superstructure parallel to the in-service bridge. After completion of the new superstructure, traffic can be shifted and maintained on the new superstructure while preparing the site and substructure at the final alignment. The new superstructure is moved into final alignment by a lateral slide. Typically, the maximum traffic impact duration during the SIBC is between 24 to 48 hours (SHRP2 2017).

Bridge slide operation requires additional activities compared to conventional construction. The additional activities include (i) a temporary structure designed and constructed to support a new superstructure during construction and lateral slide, (ii) a sliding system to provide interaction surfaces and a path during slide, and (iii) an actuating system to provide forces for initiating and maintaining bridge slide.

During the 2014-2015 period, three SIBC projects (the US-131 over 3 Mile Road, the M-50 over I-96 , and the M-100 over the CN railroad) were contracted and completed by the Michigan Department of Transportation (MDOT). These SIBC projects were monitored and activities, successes, and difficulties were documented and analyzed. Finite element (FE) simulations of the US-131 over 3 Mile Road and the M-100 over the CN railroad were performed to calculate structural and other effects of the slide to understand the sources and effects of the difficulties. Finding of SIBC monitoring and FE simulation activities are documented in Aktan and Attanayake 2017; Ridvanoglu et al. 2017; Mohammed et al. 2016; Aktan and Attanayake 2015; Aktan et al. 2015.

Twenty-eight (28) completed SIBC projects were reviewed, and data was compiled on SIBC components and design parameters, temporary structure design, sequence of operations, and constructability. Each SIBC implementation has been unique so far. Uncertainties include slide properties contributing to friction between surfaces, pushing and pulling force levels, and monitoring and controlling the force levels. The standardization purpose is to develop repeatable procedures for SIBC.

2 SLIDING SYSTEMS

A bridge sliding system, in most cases, consists of *Teflon* pads or rollers and an actuating system. Additional components are integrated into a slide mechanism to control the transverse and vertical movement of the superstructure.

2.1 *Sliding System Parameters and Design Considerations*

The weight of the superstructure and all the components and attachments above the sliding surface (W) act normal to the sliding surface. With the friction

coefficient of the sliding surface, weight controls the magnitude of the required sliding forces.

When neoprene pads *Teflon* and stainless steel shoes are used, bearing pressure (σ_B) is calculated as the ratio between vertical load at each sliding shoe and the contact area of a shoe. A uniform pressure distribution can be assumed for design. The number of shoes and the size of each shoe is based on the allowable pressure on the neoprene bearing pads. Typical values of interface pressure range from 0.5 ksi to 2 ksi (Aktan and Attanayake 2015).

Sliding system design requires static and kinetic friction assumption. Typical static friction values used in earlier projects range from 5% to 10% (Aktan and Attanayake 2015). Kinetic friction is a function of sliding velocity (v_s). The sliding velocity is not constant throughout the slide; however, a value needs to be assumed to estimate kinetic friction coefficient. In addition to the sliding velocity, kinetic friction is also a function of normal stress at the sliding surface (σ_B), *Teflon* composition, temporary sliding shoe surface roughness, surface treatment (lubrication applied at the interface), temperature, and the angle between the surface polishing of steel and the *Teflon* (Hwang et al. 1990). Even though a large number of parameters affect the kinetic friction coefficient, at least the bearing pressure and sliding velocity need to be considered in order to estimate a value. Kinetic friction estimates in earlier projects range from 3% to 5% (Aktan and Attanayake 2015).

Sliding force (S_F) is the sum of all frictional forces developed at the sliding surface. It is a function of weight and coefficient of friction. Since kinetic friction is a function of bearing pressure and velocity, sliding force is also a function of those parameters.

Sliding bearings are designed considering horizontal forces and vertical stress. Bearing deformation should be minimized. Deformations may change the contact area which, in turn, affects the bearing pressure, coefficient of friction, and consequently the sliding force. In order to accommodate the surface unevenness of the sliding girder, steel reinforced neoprene pads with *Teflon* should be used instead of a single *Teflon* layer. Dimpled *Teflon* is preferred to retain the lubricant on the sliding surface.

When rollers are used, manufacturer data sheets provide the maximum load capacity for their products. Based on the load capacity and the contact area, the maximum roller pressure (σ_R) can be calculated. The sliding track bearing capacity needs to be checked against the roller pressure. Hence, roller selection primarily depends on the allowable bearing capacity of the sliding track surface. This allows specifying the appropriate number of rollers to distribute the structure weight. The friction coefficient (μ) of typically used rollers for bridge slides is less than 5% (Aktan and Attanayake 2017). Static and kinetic friction coefficients are the same for rollers.

Vertical jacking is required when rollers or temporary *Teflon* pads are used. The number of jacking locations and the capacity of jacks are required. Generally, jacks are placed between each girder. Non-uniform load distribution due to deck overhang and safety barriers needs to be taken in to consideration. The superstructure needs to be analyzed under jacking loads to check the maximum stresses developed at the deck surface. Also, bearing stresses and the use of stiffeners at support locations need to be evaluated.

Transverse movement tolerance (t_T) defines allowable movement in a transverse direction. Tolerances are defined based on a specified sliding system and the project requirements. Movement in a transverse direction at the level defined by the tolerances will develop transverse forces (R_F) between transverse restraints and guides.

3 ACTUATING SYSTEM

A hydraulic operation system and hydraulic actuators are components of the actuating system that generates and delivers the required force to initiate and maintain a slide. Hydraulic operation system components include a reservoir, pump, and a hydraulic pressure control unit. Hydraulic cylinders and prestressing jacks are two available actuators utilized in many completed SIBC projects. Each actuator includes specific components and considerations to provide forces to initiate and maintain slide as well as to monitor movements.

Hydraulic fluid stored in the reservoir is pumped into the actuator during extension stroke and drained during a retraction. Pressure is monitored through a power control unit to control the displacement of the stroke. Pressure regulated and servo controlled units are available as pressure control systems. Pressure regulated units are capable of controlling hydraulic pressure manually (Searcy et al. 2012), whereas servo controlled systems monitor displacements through sensors and automatically calibrate applied pressure to adjust the movement (Anderson and Trankler 1991). Servo controlled systems can be used to maintain the bridge superstructure alignment because equal stroke is maintained between actuators by synchronizing measured displacements through the adjustment of actuating forces.

Hydraulic cylinders are primarily used for pushing the superstructure. Hydraulic cylinders with

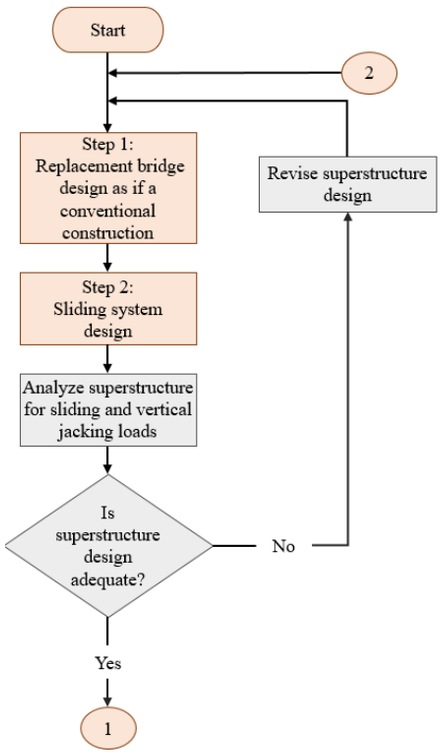
pushing and pulling capabilities are very useful when the sliding structure needs to be retracted due to jamming or other reasons. Another alternative is the hydraulic prestressing jacks. A rod is connected to a superstructure and extended though the jack that is mounted against a stationary reaction frame. As the jack pulls the cable, the superstructure is moved towards the reaction frame. Also, a prestressing jack can be mounted against the sliding superstructure with one of the pulling rods connected to a reaction frame. This configuration allows pushing of the structure to the final alignment. The sliding operation is discrete, and the distance moved during each discrete event depends on the stroke length limitation.

3.1 *Design Considerations and Parameters*

The following is a list of parameters that need to be considered during the actuating system selection and design of the sliding operation:

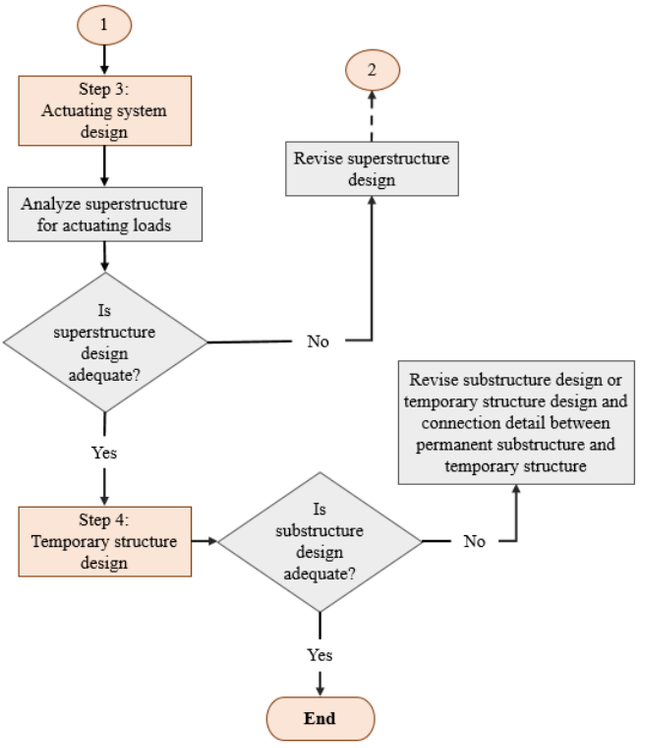
- Actuating force (A_F) is the total force applied by an actuator to the superstructure. An actuating force that is slightly greater than the sliding force is adequate to maintain a slide because sliding can be initiated and maintained with low acceleration. The difference between an actuating force and a sliding force is defined as the net force (N_F).
- Actuator capacity (C) is the maximum force capacity. It should be larger than the estimated actuating force in order to compensate for the potential increase in sliding force. Capacities of actuators used in completed projects range from 30T to 110T.
- Actuator stroke length (S_L) defines the maximum length that a structure is pushed or pulled during each discrete slide event. Stroke length of actuators used in already implemented projects ranges from 2 in. to 48 in.
- Actuator jerk (j) is the rate of change of the acceleration and deceleration of the actuator (ramp up and ramp down durations). Sudden increases in acceleration result in greater reaction forces than sliding forces because of the dynamic response of the temporary structure.
- Reservoir volume and pump capacity of the hydraulic operation system should be sufficient to provide required sliding velocities and actuating forces.
- The connection between the hydraulic cylinder piston and the sliding track requires detailed design consideration. Connection points should be provided with tolerances to provide flexibility in attaching the cylinder to the sliding track. In addition, a swivel connection is most appropriate between the cylinder piston and the superstructure to prevent load transfer to the superstructure, except in the sliding direction.
- Prestressing jacks require a stationary reaction frame. A temporary structure can include the reaction frame, or part of the permanent substructure can be utilized as a reaction frame.

4 STANDARDIZING SIBC DESIGN



Design procedures, considerations, and limitations are formulated based on the findings from the reviewed and monitored projects as well as from FE simulations. A set of flowcharts depicting an overview and design of SIBC, a sliding system, and an actuating system were developed.

4.1 *Overview of SIBC Design*



SIBC includes four primary design activities encompassing the design of the replacement bridge, sliding system, actuating system, and temporary structure (Figure 1). The process starts with the design of a replacement bridge as if the bridge will be constructed by conventional methods. At this stage, the loads from the bridge slide are not taken into consideration. Next, a sliding system is designed, and the superstructure design is checked against sliding loads and modified if necessary. The actuating system design is performed following the sliding system design. The superstructure is checked again for sliding loads. The final step is the temporary structure design under sliding loads.

4.1.1 *Sliding System Design Procedure*

The sliding system design process is depicted in Figure 2, Figure 3, and Figure 4. A typical sliding mechanism can be specified using either *Teflon* or rollers. Hence, the first step in a sliding system design is the selection of a slide mechanism. Based on past project experience and numerical simulation results, it is suggested to maintain a transverse movement tolerance of, at the most, 1 in. for *Teflon* and 0.1 in. for rollers. If *Teflon* is specified, the design process depicted in Figure 3 is followed. For rollers, the process shown in Figure 4 is followed.

(a) Step 1 and Step 2

(b) Step 3 and Step 4

Figure 1: An overview of SIBC design

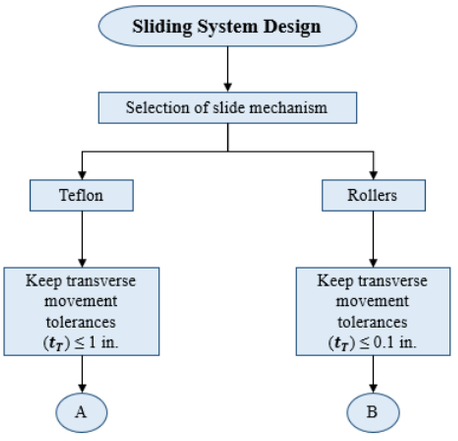


Figure 2: Sliding system design procedure

4.1.1.1 Design Procedure for a System with Sliding Shoes and Bearing Pads with *Teflon*

The design procedure is described in Figure 3. Weight of the superstructure is calculated after completing Design Step 1 in Figure 1. The number of sliding shoes and the size of a shoe are determined so that the bearing pressure on each shoe is maintained between 0.5 ksi and 2 ksi. Even though bearing pressure can be calculated based on the area under the sliding shoe, it can vary based on the changing contact area during slide. Contact area is affected by deformations of the sliding track because of the differential stiffness of the temporary structure. In previous projects, designers often used 1 ksi bearing pressure. As discussed in Aktan and Attanayake (2015), the friction coefficient decreases with increasing bearing pressure. However, for typical *Teflon* pads, the friction developed at the sliding surface with the above stated bearing pressure range is lower than the typical values used for a bridge slide design. Lubrication is often used to reduce friction between sliding surfaces. Hence, dimpled *Teflon* surfaces are recommended, as they can hold lubrication on the surface during slide.

The coefficient of friction is a function of sliding velocity. According to the data presented in Aktan and Attanayake (2015), for a velocity up to 0.1 in/s with a surface roughness of 2 micro inches and a bearing pressure range of 0.5 ksi to 2 ksi, the friction coefficient remains less than 5%. The maximum sliding velocities in the range of 0.07 in/s and 0.4 in/s have been recorded from past projects (Aktan and Attanayake 2015). When designing the sliding shoe and bearings, it is recommended to assume a reasonable sliding velocity using the data presented in Aktan and Attanayake (2015). The coefficient of friction is used for the sliding force calculation and bearing design. The breakaway friction coefficient for initiating the slide is the highest. Due to the lack of field data for quantification, 10% static and 5% kinetic friction coefficients are assumed. It is recommended to use these friction coefficients until more refined data is available from future implementations. Once the bearing pressure and the slid-

ing force is calculated, the sliding bearing is designed. If the bridge is moved on permanent bearings, the design needs to be evaluated against the permanent bearing design requirements based on the governing specifications. If the bridge is moved on temporary bearings, vertical jacking is required. It is recommended to specify the number of jacks, locations, and the capacity of each jack to minimize the differential movement of the bridge superstructure and thus, to minimize concrete cracking potential. Further, the superstructure design needs to be evaluated for the vertical jacking forces and deformation tolerances.

The typical practice is to construct the replacement bridge superstructure on sliding bearings and route traffic over the new superstructure on a temporary structure while preparing the site for bridge replacement. This requires checking the bearing design against the permanent bearing design requirements. Hence, irrespective of whether the bridge is to be moved on permanent bearings or not, the sliding bearing design needs to be evaluated against the permanent bearing design requirements.

4.1.1.2 Design Procedure for a Sliding System with Rollers

The primary steps of the design procedure are shown in Figure 4. The first step is to determine the number of roller assembly units needed for the slide. Here, each unit is referred to as an assembly because it consists of many rollers connected to form a chain of single rollers assembled with top and side plates. For multigirder bridges, the typical practice is to place one unit under each girder end. Once the number of units is decided, the next step is to calculate the load carried by each unit (P). Total weight of the bridge superstructure is acquired after completing Design Step 1, as shown in Figure 1. Knowing the total weight and bridge configuration, the load acting on each unit can be calculated. It is reasonable to assume that the load acting on each unit is equally distributed amongst the number of rollers in contact with the slide track. Only a limited number of discrete rollers in a chain is in contact with the slide track at a given position. The geometric dimension of roller units that can carry the load calculated in the previous step can be established using the technical specifications from the manufacturers/suppliers. A candidate roller assembly can then be selected based on the dimensions of the roller assembly and sliding track dimensions. Sliding track material properties required for calculations include the modulus of elasticity (E_T), Poisson's ratio (ν_T), and yield strength (fy_T). The next step in the design process is to acquire the design parameters from the technical specifications provided by the roller manufacturer. The design parameters are the number of rollers in contact with the track (n), radius of a single roller (R_R), contact length of a roller (L_R), and the elasticity modulus (E_R) and Poisson's ratio (ν_R) of the roller material.

The maximum normal stress (σ_{max}) acting on the sliding track can be calculated using the Hertz's formula (Eq. 1) (Hearn 1997). The current practice is to use an allowable stress design with a safety factor of 2. If the allowable stress limits are not satisfied, the designer has two options – select a roller assembly for reevaluation or increase the number of roller units selected to support the bridge superstructure. Once the allowable stress limits are satisfied, the sliding track deflection is calculated based on the support structure configuration and the loads. Rollers are installed just before the bridge slide and removed following the slide. As a result, vertical jacking is inevitable and requires calculating the number, location, and capacity of these jacks. In order to maintain superstructure alignment during slide and to control "racking", guide rollers need to be incorporated into the roller units located under the fascia girders. A coefficient of friction of 5% is used for the slide force calculation.

$$\sigma_{max} = 0.591\sqrt{\frac{P}{R_R L_R E'}} \qquad (1)$$

where,

$$E' = \frac{1-\upsilon_R^2}{E_R} + \frac{1-\upsilon_T^2}{E_T} \qquad (2)$$

When needed, the width of the roller contact area can be calculated using the following equation:

$$b = 2.152\sqrt{\frac{P\,E' R_R}{L_R}} \qquad (3)$$

Hertz's formula incorporates several simplified assumptions (Stachowiak and Batchelor 2014). Assuming a frictionless surface, the maximum shear stress (τ_{max}) is equal to one third of σ_{max} and is located at a distance of *0.393b* below the sliding surface of the track. When the bridge superstructure is supported on rollers, friction is present at the sliding tack surface reacting to the sliding or the tendency to slide. When friction is present and other assumptions are violated, the stress state becomes highly complicated. However, the stress calculated using Hertz's formula can still be used for design. As stated by Hearn (1997), the use of Hertz's formula is justified under static or very low rolling operations where failure normally arises as a result of excessive plastic flow which produces indentation to the surface.

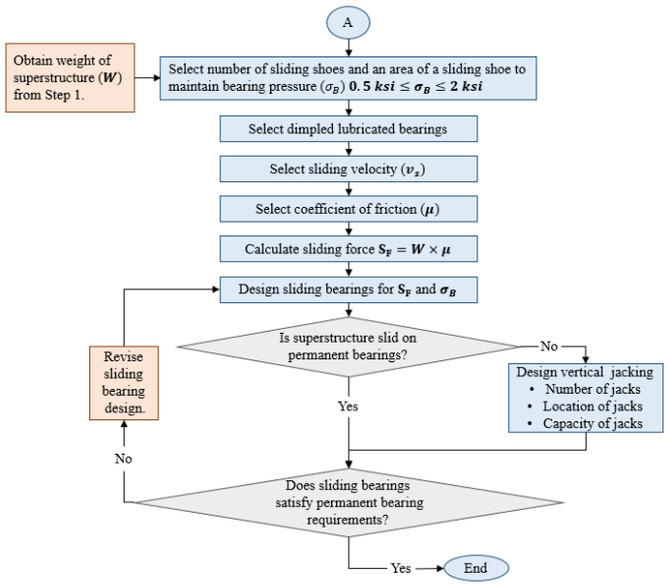

Figure 3: Sliding shoe and *Teflon* bearing pad design procedure

4.1.2 *Actuating System Design Procedure*

The design procedure is shown in Figure 5 and Figure 6. As the first step, a hydraulic operation system is specified. Actuating force capacity is a function of the sliding force and bridge superstructure acceleration and weight. Sliding force is calculated during the sliding system design. Superstructure weight has been previously calculated. Superstructure acceleration data is not widely available. Aktan and Attanayake (2017) recorded a maximum of 0.2%g acceleration in the sliding direction with the slide performed using rollers. Since the acceleration data for a slide using slide bearings has not been reported, the use of 0.2%g as peak superstructure acceleration is reasonable. In order to have adequate capacity to initiate the slide, the actuator needs to have 25% additional capacity in excess of the calculated required force. A maximum actuator capacity should be limited to 150% of the required capacity in order to have better control during a slide. Once the actuator force capacity is determined, the next step is to specify an appropriate stroke length. Different stroke lengths ranging from 2 in. to 48 in. have been used during completed slide projects. Having a short stroke length slows sliding operations due to frequent resets to the hydraulic actuator positions. Long strokes require additional alignment controls to reduce the potential for racking and jamming. Specifying a stroke length that is in between 20 in. and 40 in. is suggested. With limited slide monitoring and actuator control, it is suggested to specify a stroke length closer to the lower bound. With a longer stroke length, it is recommended to perform the slide using advanced slide monitoring systems such as servo controlled hydraulic actuators. Next, the hydraulic oil reservoir volume and pump capacity is specified based on the required force and stroke length. A sufficiently large hydraulic oil reservoir capacity needs to be maintained to control oil temperature.

Actuating the mechanism selection procedure is described in Figure 6. The use of a hydraulic actuator with pulling and pushing capabilities or a prestressing jack with pulling capability are the two alternatives suggested.

The hydraulic actuator requires having reactive and pushing connections at the sliding track and the superstructure, respectively. An actuator casing saddle with holes and pins, or ears, are two connection types used in many completed SIBC projects as reactive connections. It is important to provide a sufficient number of connection points with appropriate tolerances in both connection types to reduce delays while retracting the actuator at each slide cycle. A pushing connection is the connection between the actuator and superstructure where all the actuating loads are transferred to the superstructure. A swivel connection needs to be used for the pushing connection in order to assure load transfer alignment to the sliding direction.

A stationary reaction frame is needed when prestressing jacks are used for pulling or pushing a bridge. Depending on site conditions or the selected temporary and permanent structure types, temporary structure, permanent abutment wingwalls, backwalls, or even the superstructure itself can be used as a reaction frame. High strength steel tendons are used with prestressing jacks. Tendon elongation and relaxation need to be properly accounted for in order to minimize jerky movements and racking of the superstructure.

Servo controlled and pressure regulated mechanisms are available. It is strongly recommended to utilize a servo controlled mechanism to minimize the potential for jamming and superstructure racking due to the unequal friction on sliding surfaces. This is especially important with unguided sliding systems. The use of prestressing jacks creates additional risks because of tendon elongation and relaxation. Therefore, a servo controlled mechanism with synchronized and computerized monitoring and control capabilities is recommended.

5 SUMMARY, CONCLUSIONS, AND RECOMMENDATIONS

Standardized procedures for the design and component selection of lateral bridge slide activities are described. Flowcharts provided describe primary design considerations and compatible components for lateral bridge slide. The following conclusions are derived based on the developed standard procedures presented in this paper:

1. A replacement bridge can be designed as if it is to be constructed conventionally when SIBC is specified for the project. Even though SIBC will not require significant changes to the bridge design, the superstructure and substructure should be checked under SIBC loads.
2. A sliding system design includes a slide mechanism selection with options for *Teflon* with steel sliding shoes or rollers with sliding tracks. The design of the vertical jacking components is also included in a sliding system if temporary sliding bearings or rollers are used as a sliding mechanism. The use of *Teflon* requires the design of neoprene bearings with a *Teflon* surface and sliding shoes, while rollers are selected from manufactured products having the required capacity. Transverse movement tolerances, bearing pressure under sliding shoes, sliding velocity, coefficient of friction, and sliding force are estimated at this stage based on the specified and designed components.
3. Actuating system design includes a hydraulic operation system and an actuating mechanism selection including options of hydraulic actuators and prestressing jacks. A hydraulic operation system includes the design of stroke length, estimating actuating force and actuator capacity based on the sliding force calculated in the sliding system design, hydraulic pump reservoir volume, and pump capacity.
4. Hydraulic cylinders require reactive and pushing connections which may have a significant impact on slide quality and speed. On the other hand, prestressing jacks require a stationary reaction frame design.
5. Servo controlled and pressure regulated control mechanisms are available. Even though a force control mechanism can be specified with the hydraulic actuators, servo controlled pressure regulated control is strongly recommended to improve the quality of monitoring and to reduce the problems created from unequal friction at sliding tracks.

ABSTRACT: There is strong demand for construction innovations that facilitate rapid reconstruction of existing, degraded infrastructure. Robust solutions are needed so that infrastructure can uninterruptedly serve as the backbone of a modern economy. Given that the U.S. roadway network is largely built out, heavy demand focuses on in-service reconstruction with maintenance-free solutions. A significant advancement has been the push toward prefabrication of an ever-greater proportion of a bridge's structure, thus allowing for changes to the project critical path and increases in component quality. The move toward prefabrication has occurred concurrently with the move toward the use of advanced materials and detailing practices for the connections between prefabricated bridge components. The research conducted at the Turner-Fairbank Highway Research Center has been a key part of these advancements which are allowing higher quality bridges to be quickly constructed with the expectation of longer, uninterrupted service.

1 INTRODUCTION

Management of a bridge inventory inherently includes recognizing when major maintenance actions need to be taken and encouraging rehabilitation solutions that will deliver substantially improved performance. The fact that roadway networks commonly operate at capacity means that temporary restriction or removal of network nodes (i.e., bridges) can result in major impacts on the local and regional economy. Bridge owners need rehabilitation solutions that can be implemented in short timeframes and will provide robust performance for durations longer than can be achieved using common past construction practices. In essence, spending months to replace a bridge only to have it deteriorate within decades is not acceptable.

Bridge decks operate in an extremely aggressive environment. A common reinforced concrete bridge deck acts as both the plate that transmits loads into the structure and as the roof of the structure itself. A review of deck inspections of bridges across the USA demonstrates that the combined effect of environmental stressors and truck wheel loadings accelerates the degradation of the deck. Decks in regions with freezing temperatures, deicer application, and heavy traffic deteriorate faster. Those same roadways whose 24/7 service is ensured year round through heavy salt application are forced out of service too frequently for rehabilitation.

On the positive side, bridge decks often protect bridge superstructures and substructures leading to a situation where only the bridge deck needs to be replaced. This has led to the recognition that rapid redecking of bridges could provide major advantages to owners and users alike.

In the USA, bridge decks are commonly 20 to 24 cm thick and are reinforced by two orthogonal mats of 16 mm or 19 mm diameter reinforcing bars. Decks are commonly cast in place using conventional portland cement concrete.

The common construction methods of bridge decks pose a problem. The weather conditions for casting a large thin slab of concrete are rarely ideal, particularly when the construction schedule is constrained and opportunity for delay is limited. Any number of factors, including mix shrinkage tendency, consolidation, rate of water evaporation from the placed concrete, and superstructure restraint, can cause the deck to crack and thus expose reinforcing bars. The concrete itself may also be susceptible to environmental degradation, such as freeze-thaw distress, due to the mix design not sufficiently controlling the air content.

For these reasons and the fact that forming and casting a deck takes a significant amount of effort, there is a strong movement toward prefabrication of bridge decks. Precast concrete bridge decks have similar overall design as compared to conventionally constructed bridge decks, but they inherently require the creation of field-installed connections between

the precast pieces and from the precast pieces to the underlying superstructure elements. These connections need to perform at least as well as the precast components, lest the connections become the weak link necessitating further rehabilitation of the structure.

In the USA the use of precast bridge decks has been ongoing for decades. Early precast decks often relied on pretensioned deck panels that were post-tensioned together through unreinforced shear keys. This deck system was expected to perform well due to the compressive forces inherent in the deck; however, the complexity of the fabrication and construction proved to be a major challenge. The connections also sometimes underperformed, leading to deterioration of post-tensioning tendons and potential loss of precompression.

More recently there has been a trend toward the use of concrete deck panels with reinforced connections, such as shown in Figure 1 where the inset shows the overlapping hairpin bar reinforced connection. These types of precast decks generally do not require any pre- or post-tensioning, although pre-tensioning of the piece may be implemented to address excessive handling stresses. The factory cast concrete panels can be of high quality due to the tight controls that can be implemented in this fabrication environment. The primary challenge is with the complexity of the connections between the panels and from the panels to the girders. In order to create reinforced connections that transmit stresses from both mats of reinforcement between panels, the connection details have tended to become quite complex with sophisticated, expensive reinforcement details. Headed bars, hairpin bars, lacer bars, and even embedded steel sleeves have been used in an effort to reduce the size of traditional lap splice rebar connections. These solutions have often resulted in high costs for precast components and delayed construction operations when tolerances and fit-up issues arise in the field.

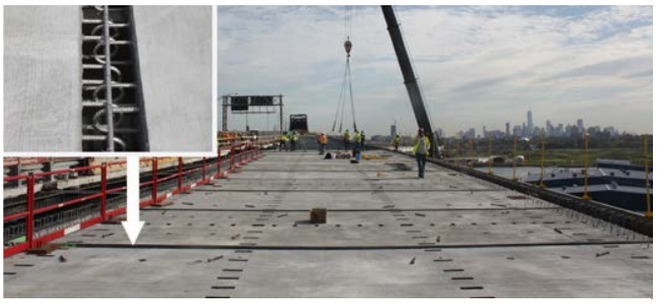

Figure 1. Precast deck panel installation on a bridge near New York City.

Also, the concept of inducing connection performance through reinforcement detailing without carefully considering the field-cast grout or concrete has sometimes led to the deployment of materials whose durability and resiliency pales compared to the precast components which compose the majority of the bridge deck area.

An emerging solution to these challenges is the use of advanced cementitious materials, including ultra-high performance concrete (UHPC). Over the past decade UHPC has proven to be a viable solution, having been deployed in field-cast connections between prefabricated components in nearly 200 bridges across the USA and Canada (Fig. 2). The enhanced mechanical and durability properties of UHPC allow for simpler connection details (Fig. 3), less expensive precast components, easier construction, and better overall system performance. Further discussion of key connection detail considerations and the advantages of using UHPC for these connections is provided in the following sections.

Figure 2. Bridges using UHPC in North America.

Figure 3. Simple, robust connection designed for use with UHPC.

2 DURABILITY OF MATERIALS

The durability of the materials used in a bridge deck is a foremost concern as it is central to ensuring overall system durability. Durability of cementitious composites is commonly measured in relation to the permeability of the material, based on the recognition that reduced permeation correlates with extended times prior to aggressors degrading the material.

The porosity and the degree of connectedness of the porosity will influence the permeability of the

cementitious material. One of the methods used to assess permeability is referred to as the Rapid Chloride Penetration Test (RCPT), which monitors the current flow through a 50 mm slice of concrete exposed to a NaCl solution (ASTM C1202). As the solution penetrates into the material, the current flow increases. The flow of current through the specimen is monitored for a period of six hours to determine a total amount of charged passed. This technique has been used to rank a wide range of cementitious materials for nearly the last three decades, and different performance classes have been established based upon the total charge passed over six hours, with the lower amount of charge corresponding to a less permeable, more durable material (Whiting 1981, ASTM C1202 2017).

Results from RCPT, shown in Fig. 4, indicate performance of the most common parent material used in prefabricated component bridge systems. The first of these materials is a concrete typical of that used in a precast facility. It is a concrete made with ordinary portland cement, a water-cement ratio of 0.35, and consists of 30 % paste, by volume. The other materials are examples of a commercial available cementitious grout and a UHPC that were mixed in accordance with manufacturer's requirements.

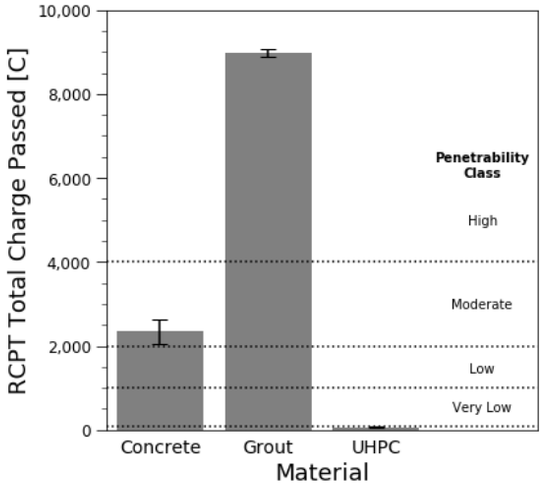

Figure 4. RCPT results indicating large penetration into the cementitious grouts and minimal penetration into UHPC.

The RCPT results (Fig. 4) indicate that the concrete as a low to moderate penetration and the UHPC has negligible penetration, while the grout material is highly penetrable. The superior performance of UHPC is attributed to the near elimination of capillary porosity and tortuous nature of the pore network (Graybeal and Tanesi 2007).

While the RCPT provides a somewhat qualitative estimate of the resistance to chloride penetration, more quantitative comparisons can be done by comparing chloride ion diffusion coefficients. This paper presents results of the apparent chloride ion diffusion coefficient determined from electrical resistivity as discussed in literature (Snyder 2001, Spragg et al. 2016). The apparent chloride ion diffusion coefficient (D) is inversely proportional to an estimated time to corrosion initiation, and can be used to quantify impacts on service life. Specifically, as the apparent diffusion coefficient decreases, the amount of time before corrosion begins increases. Values of D shown in Table 1 are similar to the results observed with RCPT, in that grout materials are more permeable than typical precast concrete and UHPC. These values can be used with life-cycle estimation equations, such as Fick's second law, which are detailed elsewhere (Weiss et al. 2017).

Table 1. Chloride ion diffusion coefficients (D) for typical materials used in precast systems.

Material	D [10^{-13} m^2/sec]
Concrete	180
Grout	500
UHPC	4

In addition to the penetration of chlorides, the ingress of water can lead to durability problems with cementitious materials. Most readily, is the expansion of water as it transitions from its fluid phase to its solid phase, i.e. water to ice. This can lead to stresses that build up and lead to cracking and scaling. The resistance to freeze thaw can be assessed using a ASTM C666 (2015), a method that subjects the materials to freeze/thaw cycles and monitors relative dynamic modulus. Dynamic modulus is a measure of stiffness, and as materials develop damage during freeze/thaw cycles the stiffness degrades and the material will break apart, ultimately demonstrating complete failure. The results are presented relative to the initial dynamic modulus which is measured before any freeze/thaw cycles are incurred (STP 169D, 2006). While not readily usable in service-life calculations, the performance in this test demonstrates resistance to freeze/thaw aggressors and provides relativistic performance between materials.

Figure 5 illustrates relative modulus degradation during freeze/thaw cycles for typical materials used in closure pours (Swenty and Graybeal 2013). The magnesium phosphate grout exhibited a very rapid loss in stiffness, suggesting that it would not perform well in a wet environment prone to freeze/thaw cycles. The other materials, a cementitious grout, an epoxy grout, and a UHPC, demonstrated a relative dynamic modulus of at least 90 %, even after 600 freeze/thaw cycles.

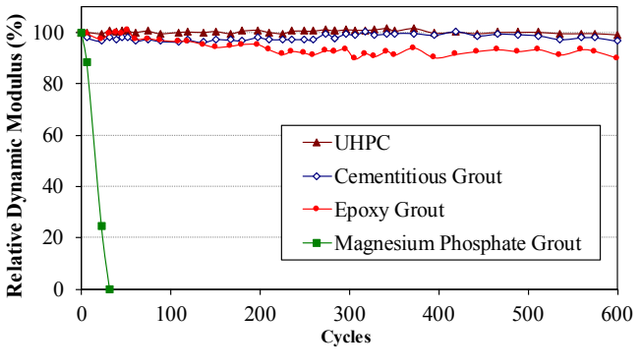

Figure 5. Freeze/thaw testing results of materials commonly used in closure pours. From Swenty and Graybeal (2013).

3 DIMENSIONAL STABILITY OF MATERIALS

A bridge deck is a restrained two-dimensional element. If the field-cast materials composing the bridge deck express dimensional instability, the expansion or contraction will be restrained by the rest of the system. Concretes and other portland cement-based materials naturally express shrinkage as they transform from a fresh state into a hardened state. Proper mix design can mitigate some shrinkage effects, as can proper curing of the concrete.

Shrinkage is a significant concern in the construction of conventional concrete bridge decks; often these decks will express regularly spaced shrinkage cracks within their first year in service. The use of precast deck panels eliminates these cracks, but raises the possibility of similarly detrimental cracks forming in the field cast connection filler should it express too much shrinkage as it cures. This is one of the primary reasons why bridge owners often require the use of non-shrink grouts in field cast deck level connections. In the USA, the common test method for qualifying these types of grouts is ASTM C1107 (2014). Unfortunately, experience has shown that grouts passing the C1107 thresholds can still exhibit significant shrinkage and their usage in precast system connections often results in shrinkage cracks within the grouts and at the interfaces with the precast pieces.

An extensive research study was performed by De la Varga et al. to evaluate the dimensional stability properties (i.e., expansion and shrinkage) of a set commercially-available grout-like materials (2015). It was observed that the test methods used for evaluating dimensional stability described in ASTM C1107 consider several parameters simultaneously (e.g., chemical expansion and shrinkage, autogenous and plastic shrinkage, etc.), thus providing a qualitative approach that is only useful for comparative purposes. The results showed that most of the grouts evaluated seemed to perform well in terms of dimensional stability when tested in accordance with ASTM C1107 (see Table 2). However, separate testing to specifically assess autogenous and drying deformations via ASTM C1698 (2014) and ASTM C157 (2017) demonstrated that ASTM C1107 is not necessarily an appropriate means to capture the full range of critical dimensional stability behaviors, especially for the most-commonly used non-shrink cementitious grouts (Figure 6). The amount of drying shrinkage shown in Figure 6 is starkly different from the results observed for these same materials according to ASTM C1107 as reported in Table 2.

Table 2. ASTM C1107 results indicating that many grouts can qualify as "non-shrink" by expressing minimal gross height change at specific time intervals.

	Average height change of hardened grout at a given age (%)*				
Grout	1 day	3 days	7 days	14 days	28 days
NSCG1**	-1.2	-1.2	-1.2	-1.2	-1.2
NSCG2	0.0	0.0	0.0	0.0	0.0
NSCG3	0.0	0.0	0.0	0.0	-0.1
NSCG4	0.0	0.0	0.0	0.0	0.0
UHPC	-0.4	-0.4	-0.4	-0.4	-0.4

* Maximum and minimum allowed by ASTM C1107 is 0.3 and 0.0 %, respectively.
** "NSCG" stands for Non-Shrink Cementitious Grout

4 INTERFACE BOND

The use of prefabricated bridge decks includes acceptance of the fact that the deck will include multiple cold joints, two at each side of every connection. These interfaces must express good bond or else the deck will quickly experience stresses or shrinkage that will result in debonding, reflective cracking through any overlay, and leakage. Interface bond has two key elements: the tendency of the field cast material to bond and the tendency of the substrate to accept the bond. If both are present and appropriate then the bond at the interface may approach the tensile strength of the weaker of the two bonded materials.

Substrate bondability of concrete is driven by a combination of macrotexture and microtexture. A more "open" (or rougher) surface is preferred as this allows for interstitial spaces and a greatly increased surface area to which the field cast material can bond. Various techniques for roughening the concrete surface are commonly deployed, including hydro-demolition, scarification, sandblasting, and aggregate exposure using in-form retarders (ICRI Committee 310 2013), though some of these are not practical for precast component connections with extending connectors. Different degrees of roughness can be obtained depending on the technique selected; however, some of them are recognized to also cause some local damage to the concrete surface, thus affecting the bond performance. Figure 7 compares the bond strength of a cementitious grout and a UHPC when bonded to concrete substrates with different degrees of roughness. It is interesting to note that while increasing the surface roughness resulted in increased bond strengths for a cementitious grout, this was not the case for the UHPC material, where 90% of the bond strength achieved with a high roughness level could be obtained with a minimum (low) surface preparation.

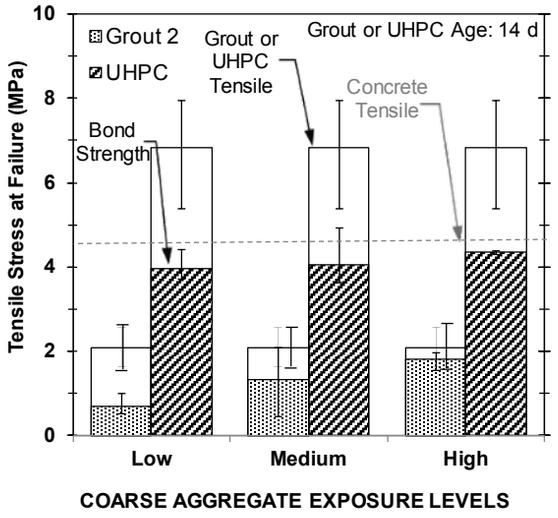

Figure 7. Tensile bond strength of a cementitious grout and an UHPC when different roughness levels are applied to the concrete slab (de la Varga et al. 2017a).

Field cast material bondability is driven by a combination of the rheological properties of the material and the material's tendency to create microscopic chemical bonds across the interface with the precast concrete substrate. Therefore, changes in the mixture design can purposely be made to provide the appropriate rheological and reactivity properties of the material.

Along the lines of favoring the proper reactivity of the field cast material, a low-cost strategy has been widely accepted in the concrete construction community: the provision of interface moisture at the concrete surface prior to the grout pour. Theoretically, when a fresh cementitious material is cast upon a dry concrete substrate the latter may demand mix water from the former. That is, water may be forced to migrate from the freshly-cast material to the dry substrate (Lukovic and Ye 2016). Migration of water could cause development of internal stresses at the interface and higher porosity in the field cast grout due to the loss of water required for hydration. Thus, water migration could be mitigated if additional moisture was present at the interface prior to placement of the fresh material (Bentz 2016). Extensive research has been carried out on this particular topic (Shearrer at al 2015, Beushausen 2015, Beushausen et al 2017). An example is provided in Figure 8, where the tensile bond strength of two cementitious grouts and a UHPC cast atop a concrete substrate with two different moisture conditions are compared. "SSD" corresponds to a moisture state known as "saturated surface dried".

Independent of the properties of the two materials being bonded, other means can be used in the field to guarantee a good bond. These include the use of bonding agents and ensuring the cleanliness of the precast concrete surface.

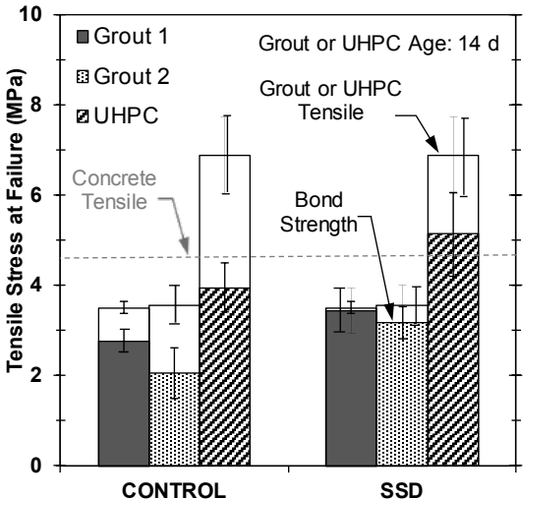

Figure 8. Effect of the substrate moisture condition on the tensile bond strength of two cementitious grouts and an UHPC (De la Varga et al. 2017b).

5 PERMEABILITY AT INTERFACE

The discussion of prefabricated bridge deck permeability is not complete without consideration of the permeability along the two dimensional bonded interfaces. Of specific concern is the vertical interface between the concrete of the precast element and the field-cast closure pour material. This vertical interface is exposed to chlorides from deicing operations and water, and the reaction products that create the chemical bond between the substrate and the field cast material may express different permeability than the parent materials. If the permeability is particularly large then these locations could be weak links in the durability of the system. Research investigating

this topic is currently underway with results anticipated in 2018.

6 REBAR DEVELOPMENT LENGTH

A key aspect of simplifying the detailing of deck level connection between precast components is recognizing that the field-cast material itself can affect the design. Common practice has always relied on overlapping and interlacing reinforcements to transfer forces, and smaller connections tended to become ever more heavily reinforced. Through the use of heavily fiber reinforced cementitious composites, it is possible to shift some of the stress transfer burden onto the field-cast material. The dense microreinforcement inherent in UHPC, along with the increased tensile capacity of the material, changes the tensile response of the material such that it can sustain tensile loads beyond cracking. Therefore, UHPC can provide significantly enhanced confinement around embedded reinforcements and can thus shorten the development length of these bars.

Extensive research conducted by Yuan and Graybeal (2014, 2015) and by Haber and Graybeal (2018) showed that bar sizes commonly used in bridge decks could develop the yield strength of the bar when embedded as little as eight bar diameters (d_b) into UHPC, assuming that sufficient cover concrete is provided. Key findings from these studies are discussed herein.

The bond strength between UHPC and embedded steel reinforcement was evaluated using the direct tension pull-out test set-up shown in Figure 10. This set-up was developed to simulate the tension-tension lap-splice configurations typically encountered in prefabricated bridge deck connections. Test specimens were created by casting UHPC strips atop a precast concrete slab. The precast slab had a series of protruding M25 Grade 420 bars which were centered along the length of the strips. Test bars were positioned to achieved the desired test parameters: embedment length (l_d), lap-splice length (l_s), clear spacing between bars (s), and clear cover (c). Other test variables included different commerially available UHPC-class materials, different reinforcement types and sizes, different fiber volume fractions (V_f), and different compressive strengths of UHPC.

Figure 11 depicts the relationship between the average peak bar stress in the bar prior to failure ($f_{s,max}$) and the embedment length for the three different reinforcing bar types, uncoated (Gr. 420), epoxy-coated (Gr. 420) and high-strength (Gr. 830); here, the clear cover, bar spacing, UHPC type and fiber volume (2%), and UHPC compressive strength were approximately constant. It can be observed that increasing the embedment length of a reinforcing bar increases the bar stress at bond failure and the relationship between the bar stress and the bonded length is nearly linear. This relationship is similar to that observed in normal-strength concrete, but is not typically observed in high-strength concretes. Thus, the observed linear relationship between bond strength and embedment length implies that the behavior attributed to traditional high-strength concretes may not be present in UHPC, potentially due to the enhanced pre- and post-cracking tensile response of the UHPC.

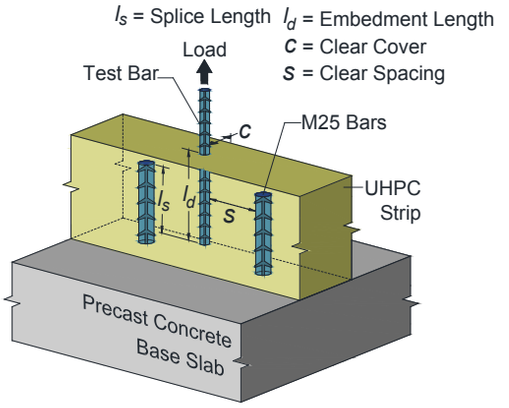

Figure 10. Direct tension pull-out set-up used for embedment length testing.

Other key findings were related to bar spacing and clear cover. As the bars spacing gets large, stress transfer from the loaded bars to the adjacent bars becomes less effective and more load must be carried by the UHPC thus reducing bond strength. On the other hand, when adjacent bars are in close proximity, load transfer also becomes less effective likely due reduced confinement of the bars by the UHPC. As it relates to side cover, bond strength between UHPC and embedded reinforcement tends to increase with increasing side cover; this is similar to conventional concrete.

An important question commonly posed by designers, related to bond of UHPC to reinforcement is "what is an approximate fiber volume fraction?" UHPC mix optimization can result in more efficient structural systems. Figure 12 depicts the relationship between the peak bar stress (normalized by the square root of the compressive strength of UHPC) and the fiber volume fraction when all other parameters are held approximately constant. The data reflects five different commercially available UHPC-class materials: U-A through U-E. This result indicates that increasing V_f results in enhanced confinement of the embedded bars when subjected to direct tension which increases bond strength. These results would also indicate that connections employing UHPCs with fiber volume fractions less that $V_f = 2\%$ may result in reduced ductility at the ultimate limit state.

In summary, the significant reduction in embedment length as compared to conventional cementitious materials leads to the opportunity to create small, simply reinforced connections with only ex-

tended bar stubs emanating from each adjoining precast deck panel. The data from the aforementioned studies was used to develop design guidance for bridge engineers and bridge owners interested in levering the innovative properties of UHPC to create simplified, yet robust connections. The design guidance is available in document published by FHWA (Graybeal 2014).

7 SHEAR CONNECTIONS

The structural connection of precast deck panels to the underlying bridge girders is both critical to the structural performance of the bridge and complicated by the traditional need to have steel shear connectors passing between the girder and the deck. In order to ensure appropriate structural performance, structural design specifications define a maximum connector spacing. This spacing requirement often drives the detailing of the precast deck panel to include blockout through which the connectors will pass or be placed. The constructability challenges with this type of system are significant.

As with the deck level connections discussed previously, the use of heavily fiber reinforced cementitious composites can also allow for a redesign of these deck-to-girder connections. By using the rheological and mechanical properties of the field-cast material to the advantage of the connection, the configurations of the connectors on the girder and on the deck can be simplified. This allows the precast deck panel to be fabricated more cost effectively and it allows the field assembly of the deck panel to occur more easily.

Details such as those shown in Figure 13 have been tested and found to be capable of providing appropriate performance. Further information can be found in Graybeal (2012) and Haber et al. (2017).

8 CONCLUSIONS

Bridge deck rehabilitation is a major part of any bridge management program. Having rehabilitation solutions that afford both better performance and a shortened construction timeframe is advantageous. Recent advancements in concrete, including the emergence of UHPC as a competent, practical material, has created new opportunities to address specific design and construction challenges.

There are many considerations that come into play when designing and detailing precast bridge decks. As discussed herein, consideration of critical material- and structural-scale parameters can lead to the development of innovative bridge construction solutions. The properties of UHPC address many of the shortcomings of traditional bridge decking and redecking operations. The overall process of using a prefabricated deck system addresses the timelines inherent in traditional cast-in-place deck construction and the commonly encountered issues with early age deck cracking. Precast deck panels, when designed for use with UHPC connections, can be easier to fabricate and easier to install than traditional deck panels. The UHPC connections offer greater durability and a system whose weak links have been addressed. As evidenced by the owners across the USA that are moving to demonstrate, integrate, then institutionalize UHPC connections technology into their bridge construction programs, this concept offers real advantages that address longstanding shortcomings in the bridge sector.

CME Engineering, East Hartford, CT USA

ABSTRACT: Slide-In Bridge Construction (SIBC) has been used in Accelerated Bridge Construction (ABC) for the past decade. SIBC is carried out using bearing pads consisting of polytetrafluoroethylene (PTFE), and stainless and carbon steel surfaces.

Appropriate coefficients of friction (COFs) had not been determined for the use of SIBC in temporary applications. In this study, COF values in SIBC with variable surface roughness, lubrication type, and contact pressure were determined through experiments. Among three tested surfaces, the rough rolled stainless steel, as well as the carbon steel, produced COF values much higher than those resulting from the stainless ones with a #2B surface. Dry (no lubrication) and graphite lubrication resulted in high friction values, whereas the soap, grease, and oil had low friction values. Additionally, four different applied pressures were investigated. These experimental test results give additional insight into the application of sliding bearings in the field of slide-in bridge construction.

1 INTRODUCTION

1.1 *Sliding Bearings*

Bridges are vital elements of the United States transportation grid. With an average bridge age of 42 years, many bridges are on the verge of needing repairs or replacement (Infrastructure Card, 2017). Bridge construction can be time-consuming. Traffic delays and congestion that happen during construction impose extra cost on transportation agencies and passengers. According to Culmo (2011), Accelerated Bridge Construction (ABC) methods are defined as construction "that uses innovative planning, design, materials, and construction methods in a safe and cost-effective manner to reduce the onsite construction time that occurs when building new bridges or replacing and rehabilitating existing bridges." Using ABC methods reduces traffic impact and onsite construction time and increases the safety and construction quality. Common strategies in ABC are Prefabricated Bridge Elements and Systems (PBES), Geosynthetic-Reinforced Soil-integrated Bridge Systems (GRS-IBS), and Slide-In Bridge Construction (SIBC). ABC strategies are gaining popularity among state Departments of Transportation (DOTs). A survey in 2015 indicated that of the 31 states that responded to the survey, 16 have completed 6 or more ABC projects(Ofili, 2015).

One practical ABC method is Slide-In Bridge Construction (SIBC). The SIBC implementation guide states that using SIBC in a project to replace an existing bridge enhances the safety, reduces the construction time, reduces mobility impact, cuts project costs, and increases the quality of construction (FHWA 2013). The superstructure for the new bridge is constructed adjacent to the existing bridge so that during construction of the new bridge, the existing one can continue to be in service. The new bridge is built or assembled on top of tracks used to slide the structure into place once the existing one is removed. Typical bridge replacements can shut down traffic for anywhere from a couple of months to over a year. SIBC, on the other hand, generally allows the road to be open to traffic during the full construction period other than for a couple days or weeks.

The method used to slide the newly constructed bridge on the sliding track and into place typically uses sliding bridge bearings that have two flat sliding surfaces which have low coefficient of friction (COF) values when used together. The surfaces used for the sliding bearings include a polymer called Poly-Tetra-Fluoro-Ethylene (PTFE) and stainless or carbon steel. Use of PTFE and stainless steel interfaces in bridge bearings has been a common practice since around the 1960's, mainly for permanent use to allow movement due to prestress shortening,

shrinkage, creep, or seismic activities. These movements can also be caused by change in live loads, temperature, misalignments, and camber (Caltrans 1994). Using the bearings for SIBC is a short term use and has not been investigated nor specified before.

SIBC is an emerging area in the realm of bridge construction and transportation. Iowa DOT held a workshop to introduce ABC and SIBC to engineers (Iowa DOT, 2009). The Wisconsin DOT sponsored the University of Washington to conduct tests for determining COFs between several different stainless-steel finishes and a PTFE coated surface (Taylor and Stanton 2010). The purpose of this study was to provide the Wisconsin DOT with the results in a clear and straightforward way and to be implemented by the bureau of structures for bridge design. Since stainless steel polished to a #8 finish is more expensive and can be more difficult to obtain than other finishes, #2B rolled finish and rough as-rolled finish stainless steel was tested and then compared to the results of #8 polished stainless steel. The investigated parameters in determining COFs were surface finish, contact pressure, and sliding speed slide path. The COF for the #8 m irror finish increased as the slide path increased, whereas for the #2B rolled finish it stayed constant, and for the rough as-rolled finish it decreased. Based on the tests that were conducted, an equation was developed to help predict the friction coefficient as a function of the surface finish, the contact pressure, the sliding speed, and the slide path. After all of the tests were completed and the results were analyzed, it was determined that stainless steel with a #2B surface finish was an appropriate alternative to a #8 mirror finish in terms of COFs. The findings of this study were later inserted into the Wisconsin DOT bridge manual. This manual recognizes two slide-in methodologies using hydraulic rams as the bridge slides on a smooth surface and PTFE coated elastomeric bearing pads or using rollers instead of sliding pads and winches in place of a hydraulic ram (Wisconsin DOT, 2013).

The Strategic Highway Research Program 2 (SHRP2) has created an addendum for rapid bridge renewal called "ABC Toolkit on Lateral Slides". In this document, the applicability of using the SIBC, design considerations, and key components in implementation were discussed (SHRP2, 2013). FHWA published the guide for SIBC developed by Utah DOT and the Michael Baker Corporation (FHWA, 2013). The SIBC guide was designed to demonstrate the advantages of using SIBC and show how it can be implemented by state and local agencies (FHWA, 2013). One year after the manual publication, Michigan DOT initiated a workshop (Aktan et al. 2014). In the Michigan DOT workshop, static and dynamic COFs were discussed. In addition, the implementation of the COF values by Michigan DOT, in order to select required jacking hydraulics to move the bridge, was also explained.

2 TEST PARAMETERS

2.1 *Investigation*

The main goal of using bridge bearings in SIBC is to reduce the required force to push or pull a bridge across the slide track and into its final resting place. This force is governed by the amount of friction between the sliding surfaces which depends on several parameters. Similar to the study performed by Stanton, (2010), in this study, the following parameters were investigated to determine the surface COFs: surface roughness of the mating material which the PTFE slides on, lubrication used between PTFE and the mating surface (e.g. stainless steel), and contact pressure of the PTFE pads in contact with the mating surface.

2.2 *Surface Roughness*

Three mating surfaces were investigated in the laboratory testing. When using PTFE bearings for permanent bridge bearing applications, AASHTO specifies the mating surface to be stainless steel with a #8 mirror finish (AASHTO 2014). Although AASHTO recommends #8 mirror finish stainless for permanent bearing applications, for this study three mating surfaces were tested, namely, #2B stainless, #1 stainless, and hot rolled carbon steel surface. The resulting COF values for these surfaces are reported.

2.3 *Lubrication*

Four lubrications were investigated in the laboratory study. It is common practice to use lubrication in conjunction with dimpled PTFE pads to reduce the friction for PTFE sliding bearings. Small concave dimples are drilled out of the PTFE pads so that there is a place for the lubricant to be retained. Four lubricants were studied: common dish soap, grease, oil, and graphite. In addition, tests were also performed with no lubrication for reference (referred to as "dry" tests).

2.4 *Contact Pressure*

As the contact pressure between the PTFE and the mating surface increases, the COF decreases. Extensive testing was done for the NCHRP Report 432, High-Load Multi Rotational Bridge Bearings (NCHRP, 1999) where the researchers proposed that the COF decreases linearly as the contact pressure increases for pressures less than 21 MPa, and as the pressure increases into higher pressures the COF remains fairly constant. Considering this, the follow-

ing four pressures were investigated: 11 MPa, 21 MPa, 31 MPa, and 55 MPa.

3 TEST SETUP

3.1 *Laboratory Testing*

The tests were carried out in the System, Material, and Structural Health (SMASH) lab at Utah State University (USU). The testing was done during the winter months where the lab temperature was maintained at 15 °C to 18 °C.

3.2 *Test Setup*

The SMASH lab has a reaction frame to which the test setup was mounted. Figure 1 is a schematic drawing of the test setup. Two vertical rams were used to simulate the vertical load caused by the weight of a bridge by applying a load to a spreader beam, which pushed down and sandwiched the PTFE pads. Once this vertical load was applied, the horizontal actuator was used to slide the specimens back and forth with the only resistance being the friction between the PTFE pads and the mating surface. Load cells were placed between the vertical rams and the spreader beam to measure the vertical load for each ram. In order to prevent eccentric loading on the vertical rams or the load cells, spherical bearings were used. These were placed just under the load cells and on top of the spreader beam. Figure 2 shows the actual lab test setup. The horizontal actuator (shown on the right in this figure) is a servo hydraulic ram. This actuator has a built-in load cell to measure the horizontal load needed to slide the specimens. It also has built in sensors that measured the horizontal displacement, the speed, and the number of cycles continuously during the testing.

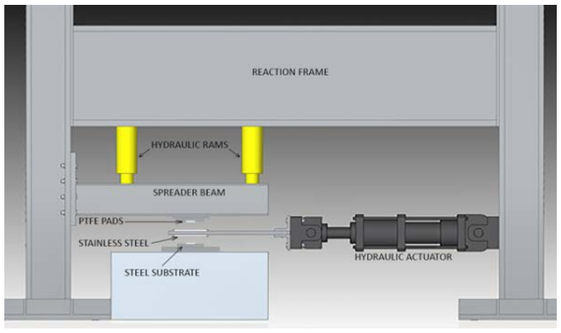

Figure 1. General test setup (schematic)

When using sliding bearings in a bridge slide, the PTFE bearing pads are placed on a track with the PTFE surface facing up. There is a mating surface slide shoe on the underside of the superstructure of the bridge that slides across the PTFE bearings. However, with the setup in the lab, two PTFE pads and two mating surface plates were used in order for the system to work properly and not have any extra resistance from the use of a roller or some other type of setup.

Figure 2. General test setup (actual)

Initially the plan was to attach the PTFE pads to the steel tongue and push them back and forth sliding along the stainless steel plates, which would create an eccentric loading on the pads as they slid from one end of the stroke to the other. To avoid this eccentricity, it was decided to keep the pads stationary by attaching them to the spreader beam above and the concrete block. Then, the mating surface plates were attached to both sides of the steel tongue and slid back and forth. Figure 3 shows how the mating surface plates and PTFE were attached and sandwiched together. The steel substrates, used to confine and hold the PTFE, were tack welded to the spreader beam and large plates below on the concrete block. The friction between the large steel plates and the concrete block was always higher than the friction between the PTFE pads and mating surface, which kept the base plate from sliding on top of the concrete block.

Figure 3. Test setup showing PTFE pads attached to steel substrates, and stainless steel sheets attached to steel tongue

4 TEST RESULTS

4.1 *Data Acquisition and Data Processing*

Two data acquisition units were used to collect the data. The MTS ram had its own system set up to it, and the two vertical rams were hooked up to a separate system. The vertical data acquisition only measured the vertical force for both vertical rams and time. The MTS data acquisition was set up to measure the horizontal forces, horizontal displacement, cycle count, and time at 100 samples per second.

The sliding speed was set to be constant at 254 mm/min. The ram was set to push the samples back and forth ± 25.4 mm, corresponding to a stroke of 51 mm. In order to produce a sliding speed, the MTS actuator was programed to run a ramp waveform instead of a s inewave or square wave. As the ram reached the end of the stroke, it switched directions and started moving the other way. When this change in direction happened, the force required to push the ram spiked higher due to the static friction. Figure 4 shows a graph of the horizontal force on the y-axis and displacement on the x-axis. This graph shows all 101 cycles for the test. The highest spike in force on the left hand side was the static friction for the first cycle. The force decreased suddenly after the first cycle, and then slowly continued to decrease as the cycles (or slide path) increased. It is easier to see the trend of the force decreasing over time when the cycles are spread out on a force versus time plot. Figure 5 shows the first 12 cycles of a test. The static friction was the highest on the first cycle, and then decreased slowly for each progressing cycle.

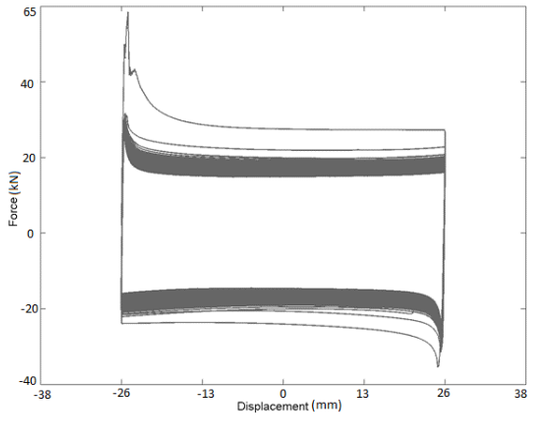

Figure 4 Typical graph of force versus displacement for all 101 cycles

COF is calculated using the following:

$$COF = F/(2 \times N) \quad (1)$$

where N is the normal force based on the contact pressure and F is the horizontal force and the two accounts for the two sliding surfaces in the test setup. When the COF is plotted, as shown in Figure 4, it looks much like the last plot of force vs time but with different values.

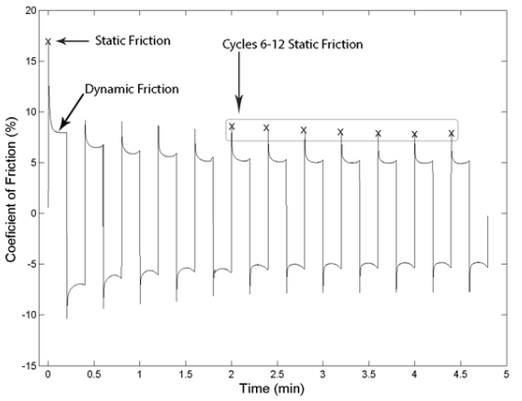

Figure 5 Typical plot of the coefficient of friction versus time (cycles 1-12)

The static friction is the amount of friction that keeps an object from moving. Dynamic friction is the friction present once the object is in motion. The dynamic friction is always lower than the static friction, therefore, the static friction values were critical and the focus of this study. In each test, COF values correspond to cycles one through 12, and cycle 101 was recorded.

After the testing was complete, the COF values were determined using equation (1). Table 1 shows the acronyms used in this paper to describe the performed tests.

Table 1 Acronyms used in test codes to identify parameters used for each test

Term	Description
2B	Stainless steel a #2B surface finish
RR	Stainless steel with a #1 surface finish, rough rolled (RR)
CS	Carbon steel
D	Dry test
Sp	Lubricant Soap
Grs	Lubricant Grease
Oil	Lubricant Oil
Gph	Lubricant Graphite

Static COF values for the performed tests are shown in Table 2. Note that not all the possible cases were tested.

Table 2 Static COF values (cycles: 1, mean of 6-12, and 101)

Roughness	**2B**			**RR**			**CS**		
Cycle	1	6-12	101	1	6-12	101	1	6-12	101
	11 MPa (contact pressure)

Sp	1.44	0.88	1.26	-	-	-	-	-	-
Grs	0.67	0.32	0.47	-	-	-	-	-	-
Oil	0.90	0.46	0.47	-	-	-	-	-	-

4.2 *Dry Tests*

Dry tests were performed using #2B and #1 stainless steel. No dry tests were performed on the carbon steel. Figure 6 shows typical dry tests that used the smaller #2B stainless steel sheets.

Figure 6. Dry test which used dimpled PTFE

4.3 *Soap*

A grocery store available dish soap was applied to both the PTFE pads and the stainless steel or steel plates. Dimpled PTFE pads were used for all of the soap tests. Figure 7 shows a typical picture of how much soap was applied to the PTFE and Stainless steel or steel.

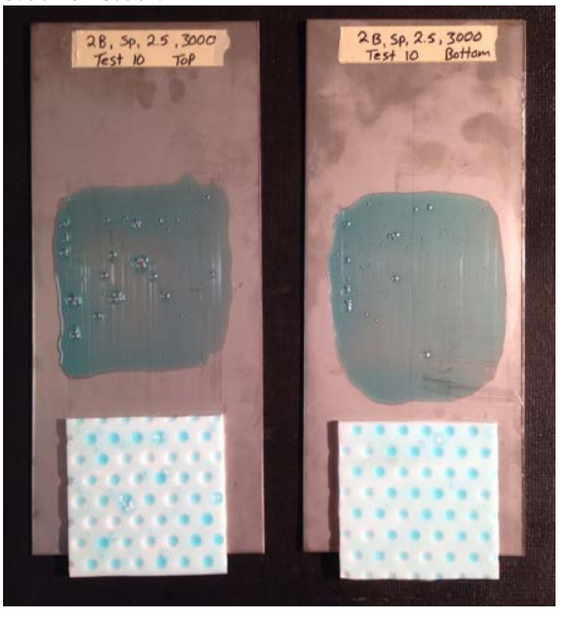

Figure 7 Typical soap test. Shows how much soap was applied to the sliding surfaces

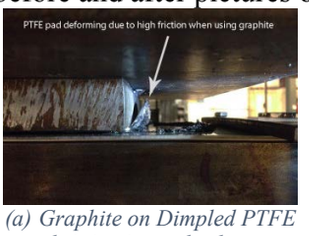
4.4 *Grease*

Dimpled PTFE pads were used for all of the grease tests. A thick layer of grease was applied to the PTFE pads so that all of the dimples were filled and there was an even layer of grease on the pad. A layer of grease was also applied to the stainless steel

and carbon steel plates. Figure 8 shows the before and after picture for one of the grease tests. Even though the majority of the grease would get pushed off to the side, the sliding surfaces stayed lubricated throughout the tests.

Figure 8. Typical grease test. Grease was applied to PTFE pads and stainless steel or steel plates.

4.5 *Oil*



The type of oil used for the testing was 10W-40 automotive engine oil. An adequate layer of oil was applied to the specimens and the tests seemed to stay well lubricated throughout the testing. Figure 9 shows a typical oil test.

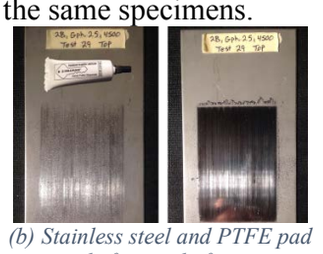


Figure 9. Typical Oil test. Shows oil on PTFE and stainless steel before testing

4.6 *Graphite*

For the graphite tests, standard tubes of powdered graphite were used. Both the PTFE and the stainless steel were coated with the graphite. Only two tests were done with graphite due to its poor performance as a lubricant. The first graphite test was performed using excessive amounts of graphite on the pad to compensate for losses and high COF values were observed. This led the PTFE pads to deform significantly (Figure 10a). It was suspected that there was too much graphite put on the test specimens and that using smooth PTFE instead of dimpled would possibly give better results. For the next graphite test that was performed, smooth PTFE pads were used instead of dimpled, and only a light even coating of graphite was applied to see whether COF values would decrease. Figure 10b is a picture of the stainless steel and PTFE pad used on top. This shows the before and after pictures of the same specimens.

(a) Graphite on Dimpled PTFE pad sitting in steel substrate

(b) Stainless steel and PTFE pad before and after

Figure 10. Graphite test

4.7 *Future Work*

Additional testing and analysis is recommended in order to more fully populate the expected friction values for various surfaces and lubricants. The effects of temperature are also of interest.

5 CONCLUSION

In this study, three parameters influencing the coefficient of friction (COF) for sliding bearings, which use PTFE-Steel sliding interfaces, were investigated. This research focused on testing the effects each of these parameters have when using PTFE sliding bearings for Slide-In-Bridge Construction (SIBC). The tested parameters were: (1) Surface Roughness, (2) Lubrication, and (3) Contact Pressure.

5.1 *Surface Roughness*

There were three surfaces roughness tested: stainless steel with a #2B surface roughness (2B), rough rolled stainless steel that has a #1 surface roughness (RR), and standard carbon steel (CS) which is readily available at construction sites. As expected, the #2B stainless steel resulted in lower COF values than the rough rolled stainless steel, followed by the carbon steel.

5.2 *Lubricants*

The lubrications that were tested were standard liquid dish soap, dielectric silicone grease (SAE-AS8660), automotive motor oil (10W-40 viscosity), powdered graphite, and dry tests. The dry tests and graphite tests had very high friction values, whereas

the soap, grease, and oil all resulted in low and comparable friction values.

5.3 *Contact Pressure*

It has been well documented by other researchers that as contact pressures increase, the COF values typically decrease when using PTFE bearing pads. The testing for this project produced results that agree with this pattern.

Dynamic Effects Caused by SPMT Bridge Transport

ABSTRACT: This paper studies the dynamic effects of Self Propelled Modular Transporter (SMPT) movement for the purposes of Accelerated Bridge Construction. First, accelerometers were attached to a SPMT and different motion cases were simulated in three loading conditions. For the out-of-plane direction, driving the SPMT over rough terrain provided the Peak Platform Acceleration (PPA) while start-and-stop motion was controlling for the in-plane direction. In the out-of-plane, accelerations were related to SPMT transport speed. The in-plane accelerations were not affected by the speed of the SPMT, but were affected by the ability of the operator to perform a smooth braking operation. Out-of-plane accelerations can be reduced by limiting the SPMT speed; however, in-plane accelerations may need to be reduced because some level of damage is likely acceptable to the falsework in a similar manner currently used for AASHTO LRFD earthquake design. The SPMT movement had a larger impact on the system as the total weight of the system decreased, both in out-of-plane and in-plane directions.

1 INRODUCTION

Bridges are vital elements of the United Stated transportation grid. With average age of 42 years, more bridges are on the verge of repair and replacement (Infrastructure Card, 2017). Bridge construction can be time-consuming so traffic delays and congestions that happen during the construction impose extra cost on the transportation agencies and passengers. According to Culmo (2011), Accelerated Bridge Construction (ABC) methods are defined as construction "that uses innovative planning, design, materials, and construction methods in a safe and cost-effective manner to reduce the onsite construction time that occurs when building new bridges or replacing and rehabilitating existing bridges." Using ABC methods reduces impact on mobility and onsite construction time, and increases the safety and construction quality. Common strategies in ABC are Prefabricated Bridge Elements and Systems (PBES), Geosynthetic-Reinforced Soil-integrated Bridge System (GRS-IBS), and Slide-In Bridge Construction (SIBC). ABC strategies are gaining popularity among state Departments of Transportation (DOT). A survey in 2015 indicated that 16 out of 31 states' that responded used ABC for 6 or more past projects(Ofili, 2015). ABC has five categories including structure placement methods which can be performed using Self Propelled Modular Transporters (SPMTs). According to the Federal Highway Administration, a SPMT is "a combination of multi-axle platforms operated through a state-of-the-art computer-controlled system that is capable of pivoting 360 degrees as needed to lift, carry, and set very large and heavy loads of many types" (FHWA, 2017). Using SPMTs reduces traffic disruption, speed-up the construction process, improves the quality of construction, and provide more options for constrictors (FHWA, 2007). SPMTs were introduced to the bridge industry in 2008 and are mainly used to transport superheavy bridges from a prefabrication site to their final position. Each SPMT module can be attached to the other modules for moving very large structures, forming a combination of multi-axle platforms operated by computer interface (Bellon 2017).

The bridge transportation process falls in the temporary works category which usually is performed and designed by contractors. SPMTs move at a walking speed, but the dynamic forces applied to the cargo during the transportation, especially in an emergency situation, can be an issue. Sudden stops, turns, and rotations can occur during transport and there is currently limited guidance for this in design. These dynamic forces are typically the responsibility of the contractor and the design engineer. To investigate the dynamic effects of SPMT movement to the bridge and falsework, the authors conducted a series of experiments.

2 EXPERIMENT

2.1 *Direction of Accelerations*

The maximum acceleration can happen in three directions in a 2-D plane, i.e. SPMT platform, longitudinal, transverse, and vertical. Therefore, to get the full acceleration field at any location on the platform, three accelerometers are required. On the other hand, the acceleration profile may change in different locations of the platform. Thus, three locations were instrumented, front and back on the platform, and middle on t he weights. Each accelerometer was mounted magnetically to measure one of three principle directions. Positive longitudinal is defined as the forward direction of the SPMT. Positive transverse is defined as perpendicular to the longitudinal direction on the platform plane, using the right hand rule with positive vertical defined as opposite of gravity (i.e. up). The direction of each sensor is shown in Table 1. The sensor placements and clusters are shown in Figure 1. Data acquisition system and sensors were made by Bridge Diagnostics Incorporated (BDI).

Table 1. Accelerometer's placement on the SPMT

Position	Accelerometer	Direction
	A2130	Longitudinal
Cluster 1	A2131	Transverse
	A2132	Vertical
	A2133	Longitudinal
Cluster 2	A2089	Transverse
	A2090	Vertical
	A1036	Longitudinal
Cluster 3	A1035	Transverse
	A2087	Vertical

2.2 *Load Cases*

During this experiment, the weights shown in Figure 2 were used to replicate the weight of a bridge superstructure. The vehicle was loaded with two stacks of crane counter weights: nine steel plates on one side and eight on t he other side. Each individual plate weighed 50 kN (Figure 2). Additionally, a steel platform on which the weights were placed weighed 150 kN, thus the total load on the SPMT was 10,000 kN. In the case shown in Figure 2, the SPMT carried 50% of its capacity which is referred to as the heavy load case. Four and five steel plates were removed from the SPMT to simulate medium load case. The medium load case was when the SPMT carried 5,000 kN or 25% of its capacity. After removing all steel weights, the total weight on the SPMT was only 150 kN which was 7.5% of its total capacity, which was called the light load case.

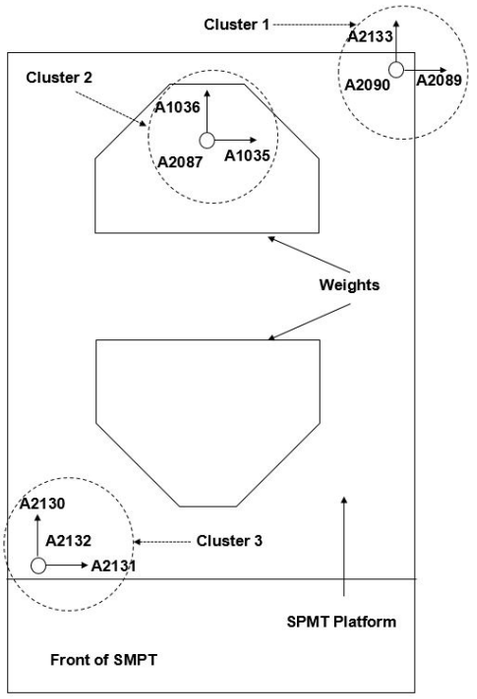

Figure 1 Schematic plan view of the sensor's placement

Figure 2. The steel weights on SPMT (heavy load case)

2.3 *Motion Cases*

The following scenarios, referred to as motion cases, were defined and investigated to cover all possible extreme events during the cargo transport:

- "Start and Stop" (SS): A sudden brake or a rapid take off can cause considerable longitudinal accelerations. This scenario is considered the most common event and can occur several times during one carriage, although typically not to the extreme.
- "Up and Down" (UD): Bouncing of the vehicle can cause significant acceleration in vertical direction. This may occur during raising or lowering of the cargo into place.

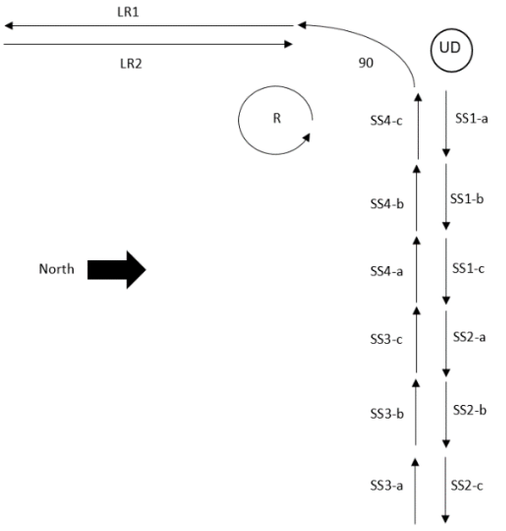
- "90 Degree Turn" (90): Turning while moving a bridge superstructure on the road can create both longitudinal and transverse accelerations.
- "Long Run" (LR): During a transport, it is possible to encounter uneven ground or the weight of the loaded SPMT can create uneven ground in poorly prepared roadbed. This motion case is characterized by a long run of road unevenness with locations of well and poorly compacted soil, causing significant vertical accelerations.
- "Rotation" (R): SPMTs can rotate 360 degrees causing accelerations in horizontal directions.

For each load case, defined in section 2.2, all the above motion cases where carried out. A schematic drawing of all performed tests is shown in Figure 3. As seen, in each load case, one UD, one R, one 90, two LRs, and four SSs were carried out. In addition, each SS motion case included three sudden start and stops.

2.4 *Peak Platform Accelerations*

After the test, the data was post-processed to obtain the Peak Platform Accelerations (PPA) in each direction and in each motion case. Table 2 shows the recorded PPAs in each direction for all clusters and load cases. In addition, the critical motion case in which a certain PPA was recorded was also identified. As the cargo weight decreased, the platform experienced greater accelerations. The maximum accelerations were similar between motion and load cases. The largest difference was observed in the transverse directions for the R motion which was likely affected by the evenness of the driving surface. The SS motion case was critical motion for the in-plane accelerations by imposing maximum accelerations in all sensors and all load cases. For transverse direction maximum accelerations occurred during the LR motion case for all load cases in three clusters expect in cluster 2 in medium load case. The SS motion case created the largest vertical accelerations as well, however it is unclear if they would be present in a series of linked SPMTs transporting a large bridge.

Figure 4 shows the time history graphs for critical cases identified in Table 2 in each cluster of sensors. As seen in the graphs, the longitudinal accelerations were considerably greater than transverse ones. The maximum longitudinal accelerations were also consistent with the SS motion case; therefore, the SS motion case can be used to represent the maximum in-plane accelerations. The SS motion was also the dominant motion case for the out-of-plane direction.



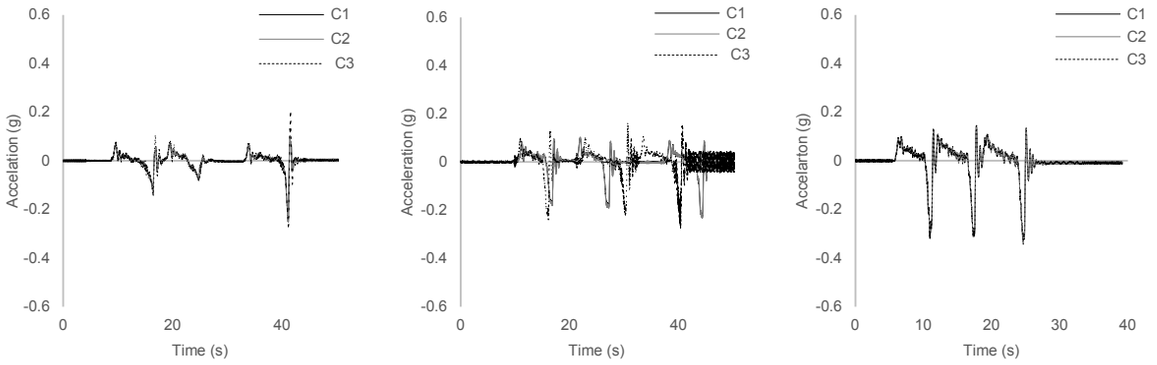


Figure 2 The schematic layout of the tests for each load case

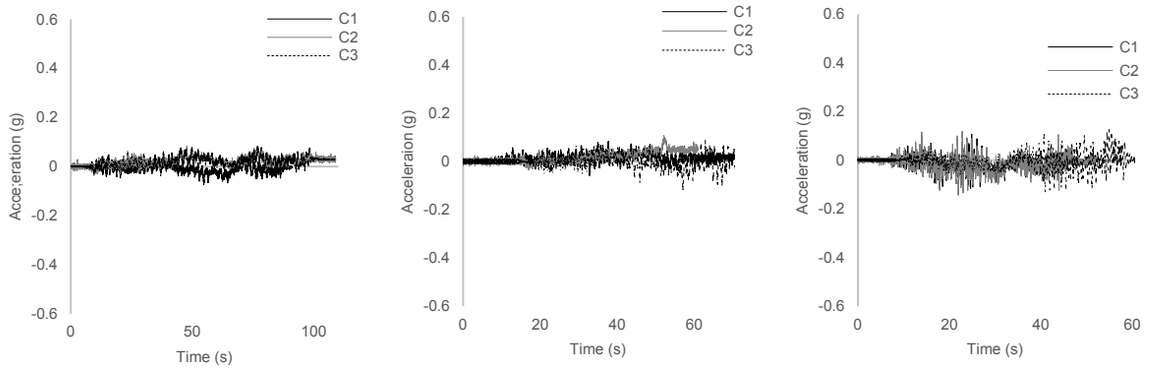
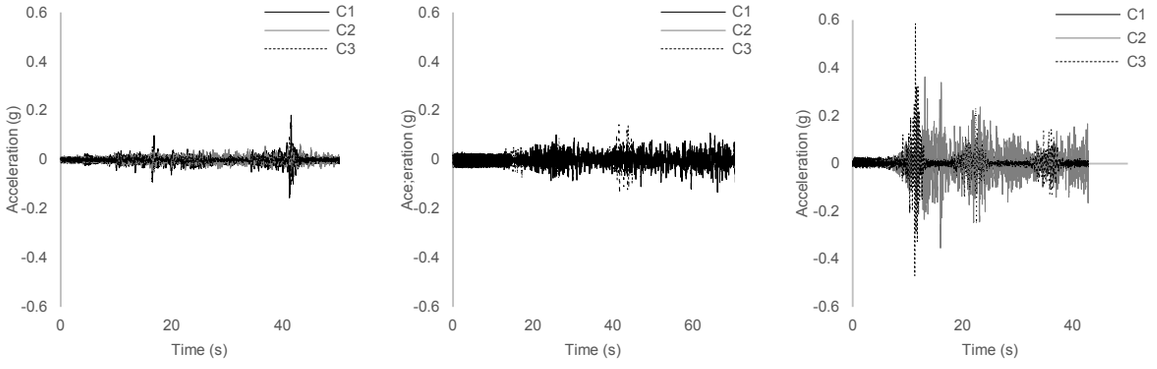


Maximum out-of-plane accelerations were considerably higher in the SS motion than any other. However, this is somewhat misleading because of the rotation of the platform during the starting and stopping maneuver. During a stop, vertical accelerations were generated by the rotation of the platform about some point between the center of the platform and the back axle, due to the heavy power pack attachment. During a large bridge move it was assumed that more than one SPMT will be linked, whether directly attached or through the attachment of the falsework and bridge assembly. By linking the SPMTs this rotation was assumed to be restrained significantly so only the in-plane readings from the Start and Stop Motion Case should be considered for design values. Maximum out-of-plane accelerations during the LR motion were caused by the velocity of the SPMT navigating uneven ground. For this reason, the out-of-plane accelerations from the LR motion were considered critical to design. Maximum longitudinal accelerations were significant in the LR motion, but rarely controlling simply based on the maximum measured accelerations. The maximum vertical accelerations during the LR motion is shown in Table 3. The time history graphs associated with the out-of-plane PPA is shown in Figure 5.

Table 2 Recorded PPAs in each direction for all clusters



Cluster	Principle Direction	PPA (g)			Critical Motion

3 CONCLUSION

In this paper, the dynamic response of a loaded SPMT with 7.5%, 25, and 50% of its capacity was investigated during several common motion cases. It was found that traveling a long stretch of uneven ground was critical for the out-of-plane (vertical) direction (the Long Run) and rapid decelerations were critical for the in-plane (horizontal) direction (the Start and Stop). Transverse accelerations were found to not be critical for the in-plane direction. Increasing the payload of the SPMT decreased the measured accelerations significantly. Acceleration data was recorded from the platform in various locations during these motions.

The following conclusions can be made based on the testing and analysis of SPMT dynamic loads:

- Out-of-plane accelerations were controlled by the LR motion;
- Out-of-plane accelerations were related to SPMT transport speed;
- In-plane accelerations were controlled by the longitudinal direction of the SS motion.
- In-plane accelerations were not affected by the speed of the SPMT, but were affected by the ability of the operator to perform a braking operation;
- Transverse accelerations were considerably lower than the longitudinal accelerations, therefore longitudinal accelerations were considered the controlling case for the in-plane direction;
- Significant reductions in the PPA values were observed as payload increased. Contractors are recommended to use large loads, with respect to SMPT capacity, to reduce design forces;

ABSTRACT: The deteriorations of highway bridge concrete slabs constructed during the high economic growth period have become apparent. One of the efficient maintenance measures is to replace these slabs into new slabs. However, there is an obstacle that renewal work causes heavy traffic due to lane regulation for the replacing slabs. In addition, design standard has been revised due to increasing live load. Therefore, we need to develop new lighter slabs which has adequate strength for current standard, and develop efficient construction methods. From these reasons, in order to develop the precast panels using Ultra high strength fiber reinforced concrete (hereafter UFC) that are lighter than existing concrete slabs and the new connection system using perfobond strip shear connector between panels and steel girders, following several experiments were conducted. In this research, the behavior and durability of new panels and the connection systems were discussed.

1 INTRODUCTION

In Japan, a lot of infrastructures were drastically constructed from the high economic growth period of 1965. However, currently those constructions have been aging. In regard to the maintenance measures, replacement seemed to be an efficient measure instead of reinforcing and repairing structures. Particularly, bridge slabs have been simply deteriorating over time, in addition they have been suffering fatigue damage due to the repeated load caused by traffic of overload vehicles and increasing volumes. Therefore, the deterioration became apparent. In this research, we discussed a new slab replacement system for efficient renewal construction.

The age of most existing damaged slabs is over 40 years. Design standards of construction bridges have been revised by the change of the load regulation. The new slabs designed based on current standards are usually heavier and thicker than the existing slabs which are designed based on previous standards. If new replacing slabs are designed on current standards, the increase in weight of new superstructures causes reinforcement of substructures. Furthermore, traffic regulations during the replacing construction seems to cause heavy traffic congestion around the construction area. To overcome these problems, it is necessary to develop lightweight slabs in order to minimize effects on substructures and rapid replacement method in order to keep traffic safety and smooth. In this study, the structure of new precast panels and the new connections between panels and girders were developed. The behavior and durability of the new slab system were verified by experiments results.

2 THE STRUCTURE OF NEW PRECAST SLAB

A developed slab was designed for a single-span, 30 m long and 8.2 m wide, bridge as a replacement for an existing bridge at Tokyo Metropolitan Expressway. The type of superstructures was steel plate girders bridge, composed of three main girders with concrete slabs. Both existing slabs and new slabs were connected to the existing girders rigidly, and they behaved as composite girders.

The new structure was designed on the basis of Japanese Specification of Highway Bridges (Japan Road Association 2012) and UFC Guideline (Japan society of Civil Engineers 2004) (Fig. 1).

In order to make new slabs lighter, the ultra high strength fiber reinforced concrete (hereafter UFC) was used. The slabs had transverse and longitudinal ribs at the bottom of flat slabs. Pre-stressed concrete steel strands (hereafter PC strands) and pre-stressed concrete steel bars (hereafter PC bars) were also installed in those ribs.

UFC has compressive strengths of above 180 MPa, tensile strength of above 8 MPa, young modulus 50 N/mm^2. It contains 2% volume steel fiber reinforcement that is 15 mm long and no coarse aggregate. Its water-cementitious material ratio is less than 0.2.

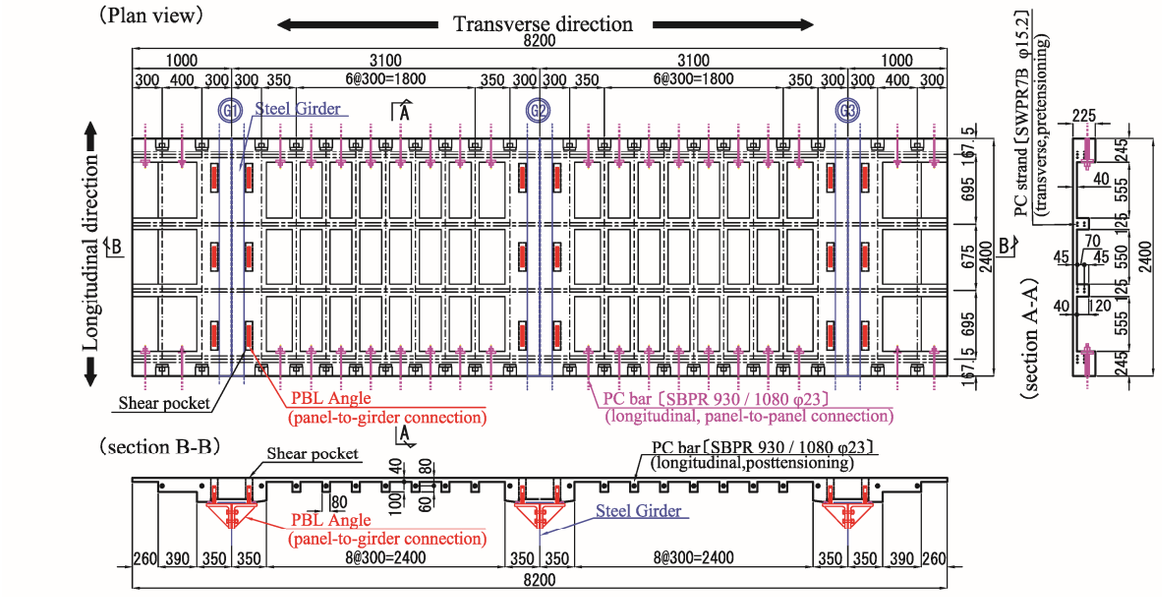

Fig. 1 dimensions of precast UFC panel

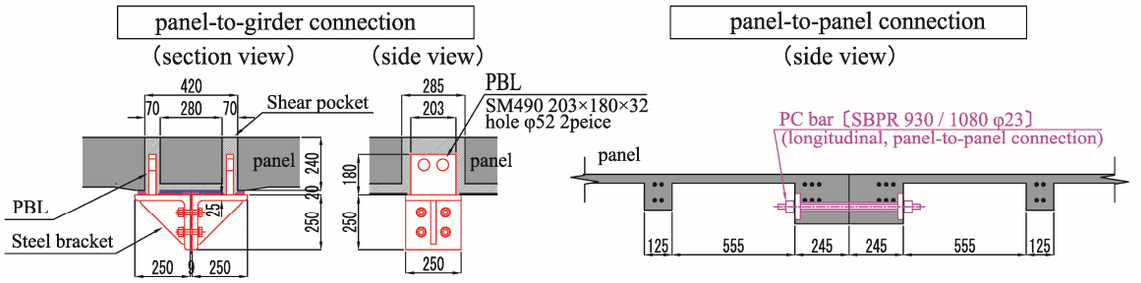

Fig. 2 detail of connections

The precast UFC panel was totally 225 mm thick and consisted of a 40 mm thick slab plates cast integrally with 120, 100 mm depth concrete ribs spanning in transverse, longitudinal direction in general section, respectively. In addition, the ribs were 185 mm depth at the part of panel-to-panel connection and panel-to-girder connection.

PC bars were SBPR 930/1080 (in Japanese Standards) (φ 23 mm), one PC bar was placed in every longitudinal rib and stressed by posttension method. PC strands was SWPR 7B (in Japanese Standards) (φ 15.2 mm), and 4 strands were placed in inner 2 ribs and 6 strands were placed in both outer ribs in transverse direction. All transverse PC strands were stressed by pretension method.

In actual construction, the precast UFC panels are fabricated by short line match casting method in precast concrete plants, shipped to jobsites, and placed on the girders. Then panel-to-panel and panel-to-girder connection are carried out (Fig. 2). The panel-to-panel connections are connected by tensioning with short PC bars (SBPR 930/1080φ, 23 mm).

In conventional method, the shear connectors of the panel-to-girder connections were set up on girders after removing the existing slabs. The method was not efficient in the point of rapid construction because a series of works was continuously conducted on girders, for example, cleaning the top flange of girder, welding studs on the flanges, installing new slabs. In order to accelerate these site work, the panel-to-girder connections using perfobond strip shear connector (hereafter PBL) was developed (Fig. 2). PBLs are combined with the fabricated steel brackets by welding (hereafter PBL angle). PBL angles are installed on the web of girders with bolts prior to setting panels. After setting panels, PBLs are placed in shear pockets of panels. The space in shear pockets and between panels and girders are quickly filled with shrinkage-compensating mortar as filling material. The new connection had no rebar in the hole of PBLs.

The depth of these UFC panels designed in this study was 144 mm in average, and the weight of the panels was lighter about 30% than precast conventional pre-stressed concrete slabs designed based on current specification.

3 PUSH-OUT TEST FOR THE PANEL-TO-GIRDER CONNECTION

3.1 *Objectives of test*

The new connection using PBL angles was applied to the panel-to-girder connection. Moreover, in Japan, the shear capacity of PBL was regulated except for the end-bearing effect (Japan society of Civil Engineers 2014). Thus, those experiments aimed to verify the shear capacity by the new connection and the effectiveness of concrete end bearing.

3.2 *Test variables and material properties*

Figure 3 shows the dimensions of the specimen. PBL had a thickness of 32 mm, a height of 180 mm, and a length of 203 mm. Shear pockets had a width of 70 mm, a height of 210 mm, and a length of 285 mm.

In order to assess the shear capacity by the new connection and the effectiveness of concrete end bearing, two test cases were conducted. One case (case 2: full resistance), the shear capacity was due to the full resistance including dowel action and end bearing. The other case (case 1: no end bearing), the shear capacity was due to all resistance except for end bearing. (Fig. 3).

For material properties of UFC, the compressive strength, tensile strength, splitting tensile strength, modulus of elasticity were determined with 100 × 200 mm cylinders. For the one of shrinkage-compensating mortar, the compressive strength was determined with 50 × 100 mm cylinders (Table 1).

Table 1. Material properties at time of test initiation

	UFC panel	Mortar
Compressive strength (N/mm^2)	218.0	63.2
Tensile strength (N/mm^2)	14.0	-
Splitting tensile strength (N/mm^2)	9.1	-
Modulus of elasticity (kN/mm^2)	53.0	-
		PBL
Yield strength (N/mm^2)		357
Tensile strength (N/mm^2)		533

3.3 *Test method*

Taking actual construction in a jobsite, panels and panel-to-girder connections were cast in horizontal position. After that, the two panels were put in vertical position, two girders were connected with splice plates and bolts.

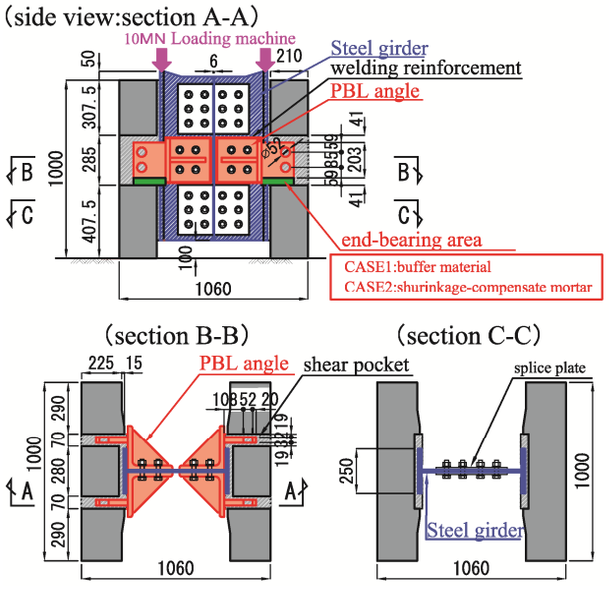

Fig. 3 the dimensions of specimen

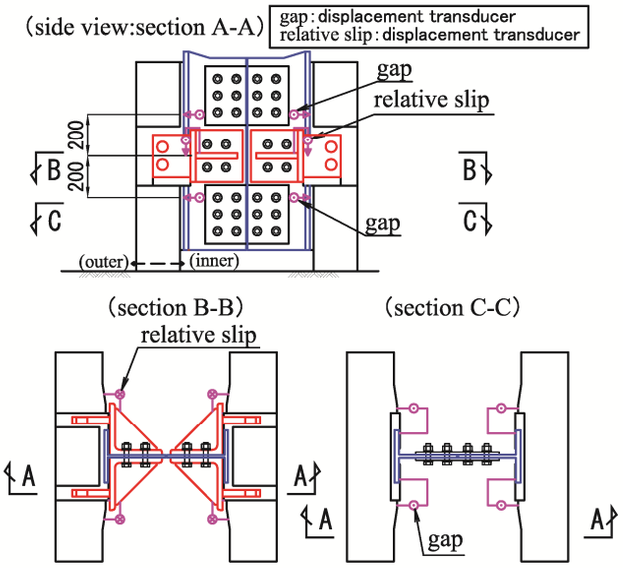

Fig. 4 the instruments

Loading method was as follows. The specimens were loaded cyclically by displacement control. This displacement presented the relative vertical slip between panels and PBL angles. The specimens were loaded and unload repeatedly every 0.2 mm until 1.0 mm, every 0.5 mm until 4.0 mm in the above relative slip. After the slip was over 4.0 mm, the specimens were loaded until failure.

The measurements of the tests were the value of load, the relative slip between girders and panels, and the horizontal gap of panels and girders (Fig. 4). The slips and the gaps were measured with displacement transducers.

3.4 *results*

The failure mode of the case 1, few cracks were observed on the surface of panels and pockets at the ultimate load. On the other hand, in the case 2, cracks were found out apparently. The two main cracks developed from the bottom edges of the PBL downward to expand a distance between each other.

Figure 5 shows shear force vs. relative slip between panels and girders. The slip presented the average value of 4 points. Y axis shows the shear force per a pair of PBLs, which was half magnitude of the load. For the target bridge, the equivalent of the design shear force owing to service load was 310 kN for a pair of PBLs. In contrast, the maximum shear forces measured were 668 kN (safety factor: 2.15) for case 1, 1281 kN (safety factor: 4.13) for case 2. In the case 1, the safety factor was less than that regulated by Japanese specification (Japan society of Civil Engineers 2014), which is more than 3.0.

In the case 1, the shear force increased initially with increasing slip. After the shear force reached a maximum (668 kN) at 1.43 mm of the slip, after that the shear force decreased gradually as the slip increased abruptly. Then, the shear force increased

gradually again and finally reached 553 kN at 10 mm of the slip. When the shear force was 310 kN that corresponds to the designed service state, no damage to the specimens was observed.

In order to ignore end bearing, buffer materials with a thickness of 41 mm were set under the PBLs in the pockets. Therefore, the bottom of PBLs did not reach the surface of pockets. So, dowel in the holes of PBLs resisted initially the shear force, and after cracks around dowel were generated, the resistance against sliding in the both interfaces of the crack maintained to resist partly the shear force.

On the other hand, in the case 2, when the shear force was 310 kN that corresponds to the designed service state, no damage to the specimens was observed same as case 1. Moreover, the shear force increased as the slip increased up to 10 mm of the slip. As shear force was increasing, PBL angle was also deforming. When the slip reached 10 mm, the deformation was very large and loading was stopped.

Figure 6 shows Shear force vs. horizontal gap between panel and girders. The gap presented each average of measurements of upper or lower side in the one side. In the both case, the gap of upper side was larger than that of lower side. It seemed that PBL angles were twisting inward.

According to several studies, when the types of experiments were conducted, the large rotation of slabs caused to make wrong estimate the shear capacity (Takahashi et al. 2015). Then, in the case 2, Figure 7 shows a picture of cutting surface in the side of PBL.

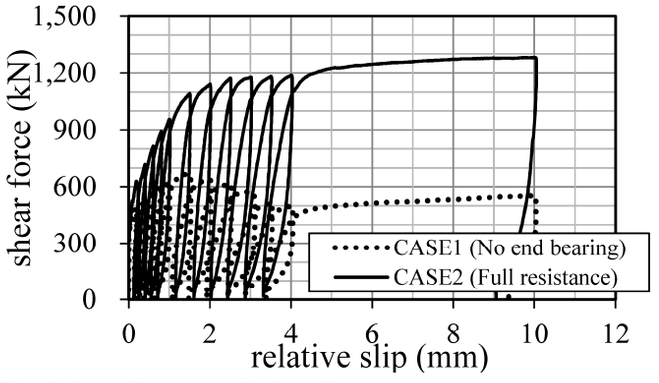

Fig. 5 shear force vs. relative slip

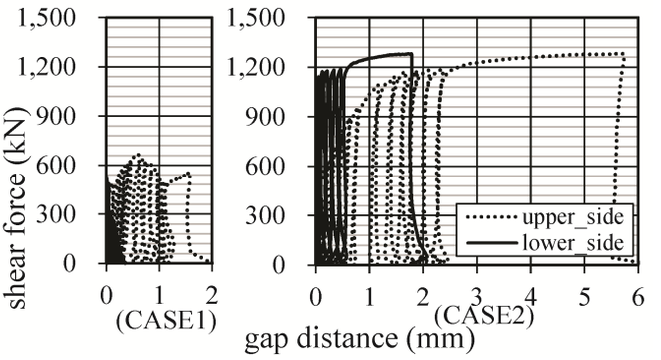

Fig. 6 Shear force vs. relative horizontal gap

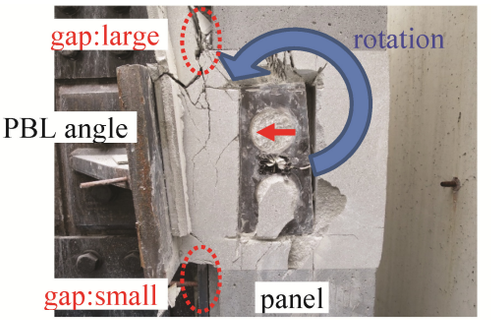

Fig. 7 cut section around PBL (case 2)

The upper hole in PBLs moved largely inside by rolling and the dowel in the hole was shear-fractured horizontally. However, the lower hole in PBL hardly moved, the dowel in the hole was not shear-fractured. In contrast, in the case 1, PBLs moved downward and the dowels in both holes were shear-fractured vertically. The panels remained nearly normal to the foundation in the both case. Judging from the above shear-fractured states of dowels, the deformation of PBL angles, and the states of panels, the results given by this experiment seems to be proper for the shear capacity.

3.5 *Comparison of test results and previous prediction*

In current specifications in Japan (Japan society of Civil Engineers 2014), concrete was used as filling material in pockets. Moreover, the proposed equation for shear capacity with PBL in Japan was based on the results of experiments without the effect of end bearing. Equation (1) was used when the hole of PBL was without a transverse rebar.

$$V_{psud} = 1.60 \cdot d^2 \cdot f'_{cd}/\gamma_b \qquad (1)$$

With $35\text{mm} \leqq d \leqq 90\text{mm}$, $12\text{mm} \leqq t \leqq 22\text{mm}$, $24\text{N/mm}^2 \leqq f'_{cd} \leqq 57\text{N/mm}^2$

where V_{psud} is the shear capacity at the hole (N), d is the diameter of the hole (mm), f'_{cd} is the compressive concrete strength (MPa), t is the thickness of the plate (mm), and γ_b is the member factor (=1.0).

According to Equation (1), the shear capacity of a pair of PBL was 1,094 kN.

On the other hand, there were many equations for shear capacity with PBL suggested by other researchers. For example, there were the equations suggested by Oguejiofor and Hosain (1994) and by Ahn et al. (2010). Most equations for shear capacity contained not only dowel action in the hole but also end-bearing effect. The equations were assumed that filling material in the shear pockets was concrete.

In this study, the new connection had twin PBLs. Then the results were compared with shear capacity that was calculated based on the equation for twin

PBLs suggested by Ahn et al. (2010). That was given by Equation following.

$$Q = 2.76h_{sc}t_{sc}f_{ck} + 1.06A_{tr}f_y + 3.32n\pi(d/2)\sqrt{f_{ck}} \quad (2)$$

where Q is the shear capacity at the shear connector (N), f_{ck} is the compressive concrete strength (MPa), A_{tr} is the area of the transverse rebar in the hole (mm^2), f_y is the yield strength of the transverse rebar (MPa), n is the number of holes, d is the diameter of the hole (mm), h_{sc} is the height of the plate (mm), and t_{sc} is the thickness of the plate (mm).

According to Equation (2), the shear capacity of a pair of PBL was 1,675 kN.

In Japan, PBLs were often used for connections between corrugated steel web and concrete slabs in pre-stressed concrete bridges. In this case, end bearing was not estimated because the steel plate of PBLs were continuous and there were no end-bearing zone. So end-bearing effect of PBL was not probably estimated for shear capacity. However, in terms of the new connections, since PBLs were set intermittently along girders, the end bearing seemed to be effective as other researchers suggested.

The shear capacity results (case 1), (case 2) obtained by experiments were compared to the shear capacity estimated by Equation (1), Equation (2), respectively.

The ratio of the experimental results to the estimated value were in the range of 0.6 to 0.8.

The causes of the shear-capacity reduction were probably not only that several parameters in the equation were out of the application range but also that shrinkage-compensating mortar used as a filling material, which had a few of aggregate interlock without coarse aggregate.

In each comparison, the differences between experimental results and estimated values were about 400 kN. If the main cause was lack of aggregate interlock, it was understood easily that the differences in the both case were almost same.

These results show that the end bearing acts effectively from the structure of the new connection. From the result of the case 2, the shear capacity of the new connection satisfies the safety factor regulated by above Japanese specification.

The connection proposed in this study should be expected the contribution of end-bearing effect of PBLs, and it should be expected that Japanese specification adopts that design. Moreover, for tight space between girders and panels, shrinkage-compensating mortar can be used effectively as a filling material. Therefore, it is necessary to investigate for the shear capacity of PBLs with shrinkage-compensating mortar.

4 FATIGUE DURABILITY TEST BY USING WHEEL RUNNING MACHINE

4.1 *objectives of test*

Bridge slabs was suffering the cyclic load of driving vehicles, and they were finally damaged by punching shear. Therefore, high fatigue durability was required for bridge slabs. In this study, in order to demonstrate the fatigue durability of the proposed precast UFC panels, fatigue durability test was conducted by using wheel running machine.

4.2 *Test variables and material properties*

The specimen consisted of two fabricated UFC precast blocks (2490 by 2800 by 225 mm, 1810 by 2800 by 225 mm). Their blocks were connected integrally by a line of transverse connection (Fig. 8).

The dimensions of specimens were based on the proposed UFC panel. The whole outer ribs which supported the specimen and connection area between two blocks were 225 mm thick. The inner area consisted of 40 mm thick slab cast integrally with 120 ,100 mm deep ribs spanning in transverse, longitudinal direction, respectively.

The amount of pre-stressing was determined based on the design of the precast UFC panel and introduced by posttension method.

Both blocks were fabricated by match casting method. After adhesive bonds are applied to their interfaces, which were connected at the next step, the blocks were placed facing each other. After that, they were pulled up each other and stressed by tensioning PC bar (SBPR 930/1080, (In Japanese Standard) φ 23mm) for the connection.

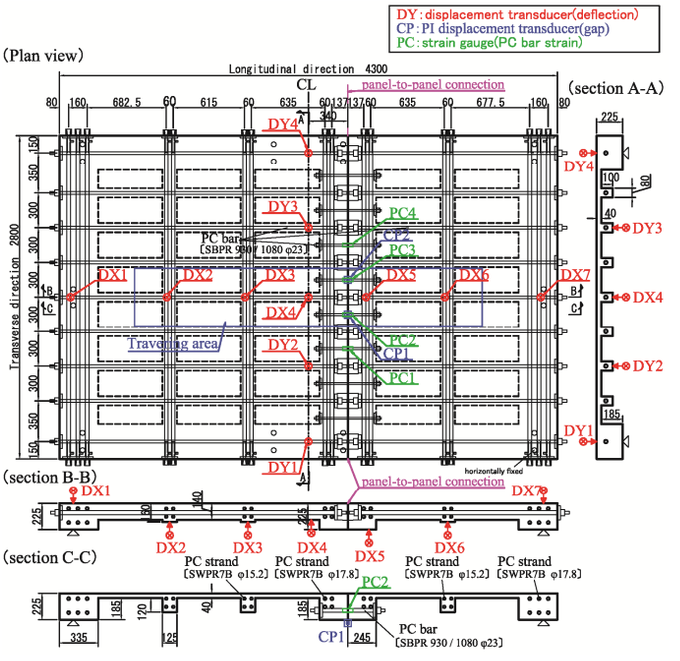

Fig. 8 the dimensions and measurements of specimen

For this experiment, the compressive strength, tensile strength, splitting tensile strength, modulus of elasticity were determined with 100 × 200 mm cylinders (Table 2).

Table 2. Material properties at time of test initiation

	UFC block	
Compressive strength (N/mm^2)	215.0	
Tensile strength (N/mm^2)	15.3	
Splitting tensile strength (N/mm^2)	11.7	
Modulus of elasticity (kN/mm^2)	52.1	
	PC strand	PC bar
Yield strength (N/mm^2)	1,027	1,795
Tensile strength (N/mm^2)	1,145	1,946

4.3 *test method*

The Wheel Running Machine had the steel wheel which was 320 mm wide and 750 mm in diameter, and the wheel was moved by crank mechanism and the traveling distance was 3,000 mm and 20 rpm (40 times loading per minute). the maximum load in vertical direction was 400 kN (Fig. 9).

Based on the loading program that conducted by Ministry of Land, Infrastructure and Transport in Japan (National institute for land and Infrastructure management 2002), fatigue durability test was performed for the specimen. In order to accelerate the loading experiment, the initial load was set as 157 kN, after that, the load was increased step by step. These loads were bigger than the live load (98 kN) specified for bridge design. Moreover, Static load test was conducted every 20,000 cycles. For static test, the loads at the stages were applied at the center of the specimen (Fig. 10).

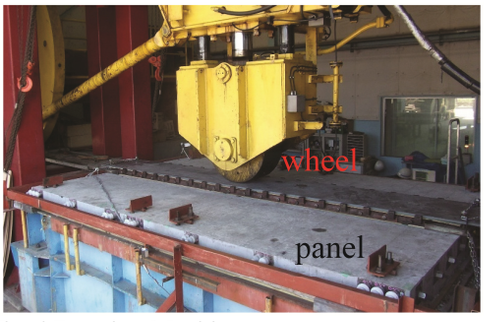

Fig. 9 Wheel Running Machine

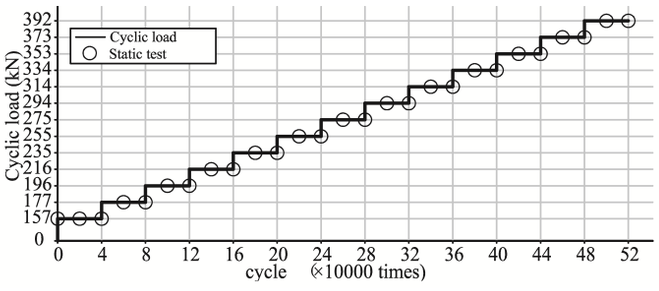

Fig. 10 cyclic program

The specimen was simply supported by pin with span length of 2,500 mm in longitudinal direction, and elastically supported by steel beam with span length of 3,900 mm in transverse direction.

The measurements of the test were the value of load, the vertical deflections in longitudinal and transverse direction, the horizontal gap, and the strain of PC bar for connection (Fig. 8). Vertical deflections, horizontal gaps, strains of the PC bar were measured with displacement transducers, PI displacement transducer, strain gauge, respectively.

4.4 *Results*

The development of cracking at the bottom of specimen was as follows. At 80,000 cycles of load (176.4 kN), cracks were found out at first at the bottom of two ribs in transverse direction. Next, with increasing cycles, cracks in the lower surface were gradually widening and propagating at transverse ribs, and then cracks were generating and developing in longitudinal ribs. Particularly, the range between DX2 (refer to Fig. 8) and DX3 was largely damaged. After that, at 447,500 cycles of load (372.8 kN), the vertical deflection at DX3 was developing drastically and the moving machine stopped owing to the limit of vertical deflection, which was set for 15 mm. Followed by, the state of upper and lower surface of the specimen was observed and it was determined that the specimen was critically damaged by punching shear.

After this loading test, all cracks were observed, and the specimen was cut in order to investigate the internal state (Fig. 11). In upper surface, the center point of the punching shear was about 850 mm away from the left side of specimen above the loading line and the cave-in on the upper surface was the range of 700 mm in diameter. In addition, several cracks were generated nearly horizontally in cut section of 40 mm thick slab. This was because the load was moving and shear cracks developed almost horizontally.

Figure 12 shows the distribution of deflections in two directions. These data of deflections were obtained by static load test. The distribution of vertical deflections in transverse direction had an approximately bilaterally symmetrical with respect to the center of the specimen. In contrast, in the similar distribution in longitudinal direction, the deflection of DX5 was slightly smaller than that of DX3 because the point of DX5 was located on the panel-to-panel connection, and transverse ribs close to DX5 have higher stiffness compared with the transverse rib close to DX3. Excluding that, until 400,000 cycles, the distribution had an approximately bilaterally-symmetrical with respect to the center of specimen, too. However, at 447,500 cycles, the deflection of DX2 developed drastically and became roughly

equivalent to that of DX4. This also indicated that punching shear failure was generated around DX2.

Figure 13 shows load vs. gap distance. The gap between precast panels increased slightly with increasing load. However, the gap was approximately 0.02 mm and very small even at the time of punching shear failure. Moreover, by unloading, that was almost closed again.

Figure 14 shows load vs. strain of PC bar. The strain of PC bar for connection remained nearly constant in spite of loading and unloading at all stages and hardly changed. Thus, though several cracks were generated around connection, pre-stressing effectively at interface until the failure and the function of the panel-to-panel connection seemed to be sufficient.

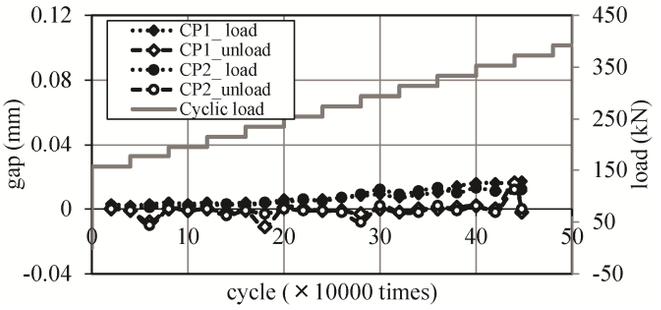

Fig. 13 load vs. gap distance

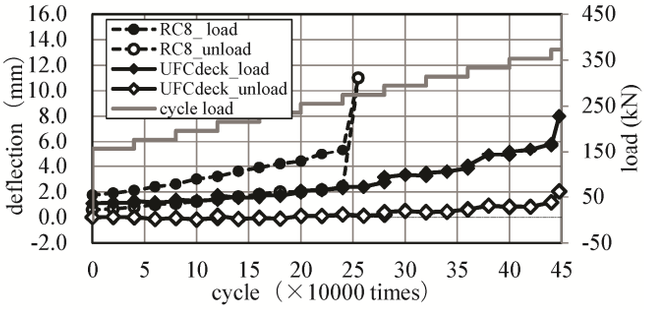

Fig. 14 load vs. strain of PC bar

4.5 *Fatigue durability*

It was recognized in Japan that bridge decks that designed on the basis of Specifications for highway bridge (Japan Road Association 1996) had commonly sufficient fatigue durability. For the typical specimen (hereafter RC8) designed based on the above specification, fatigue durability test was conducted by using wheel running machine. In this test, the same loading program was applied and RC8 was damaged due to punching shear failure. The results reported that the number of cyclic load was 255,600 (maximum load 274.7 kN). Figure 15 shows the change of vertical deflection at the center of specimen (DX4) compared with the result of RC8. The result demonstrated that the vertical deflections and the speed of increase in the deflection of UFC panel are much smaller than those of RC8. Though UFC slab is thin and has small cross-sectional shape due to structure with ribs compared with RC8 which was 250 mm thick and had a rectangular cross section, it is expressed that UFC panel has more fatigue durability than RC8.

Followed by, from the number of cyclic load at their failure, fatigue durability for each slab could be compared. For the comparison, their traveling cycles

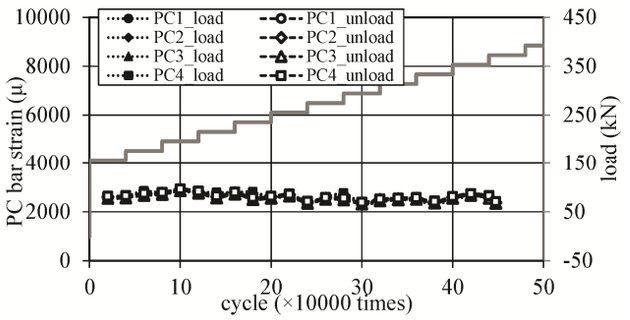

Fig. 15 deflection with experimental cycle

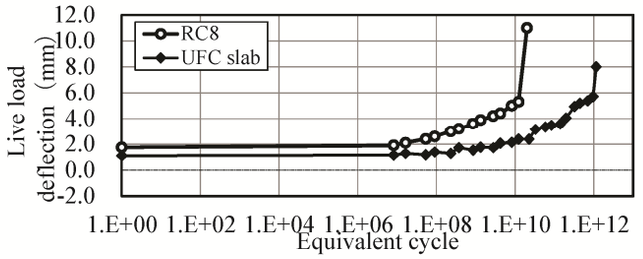

Fig. 16 deflection with equivalent cycle

were converted to equivalent cycles with regard to 98 kN load-level by using Miner's law (Matsui 1991) as,

$$N_{eq} = \sum (P_i/P_o)^m \cdot n_i \quad (3)$$

where, N_{eq} is an equivalent traveling cycle, P_o is the base referential load (98 kN), n_i is the traveling cycles with load P_i, and m is the inverse of the gradient of S-N curve (=12.76).

Figure 16 shows the vertical deflection vs. the equivalent traveling cycles. The punching shear failure of UFC panel occurred at 447.5 thousand cycles (113.9 billion equivalent cycles). By contrast, the punching shear failure of RC8 occurred at 255.6 thousand cycles (2.0 billion equivalent cycles).
Therefore, UFC panel has fatigue durability approximately 57 times as much as RC8.

5 CONCLUSION

5.1 *Push-out test for the panel-to-girder connection*

For the new panel-to-girder connection, two push-out tests were conducted on condition that filling material around shear connectors was shrinkage-compensating mortar. The test variables were whether or not buffer materials were installed under PBLs in the shear pocket of UFC panel.

From the results of the both case, for the shear capacity including end-bearing effect was larger than that without end-bearing effect. Moreover, the former and the latter were 4.13, 2.15 times as large as the shear force designed on service state, respectively. Since Japanese specification applied the shear resistance of PBL to the equation ignoring concrete end bearing and it was necessary that safety factor was more than 3.0, the latter was out of range. However, it is structurally clear that the end bearing of PBL in the new connection system acts efficiently from experimental result and the comparison with the shear resistance on the basis of the equation suggested by Ahn et al. (2010). As a result, the shear capacity of the new connection satisfies the safety factor regulated by Japanese specification (Japan society of Civil Engineers 2014).

If shrinkage-compensating mortar is used as filling material, the shear capacity decreases due to lack of aggregate interlock.

5.2 *Fatigue durability test by using wheel running machine*

In this study, fatigue durability test by using wheel running machine was conducted for the specimen with a transverse connection. The specimen was critically damaged by punching shear at 447,500 cycles of load (372.8 kN). Compared with RC8 which had commonly sufficient fatigue durability in Japan, the deflection at the center of specimen in this study was smaller than that of RC8. Moreover, these traveling cycle are converted to equivalent cycles with regard to 98 kN load-level. As a result, the precast UFC panel with transverse connection has fatigue durability approximately 57 times as much as RC8.

Thus, the precast UFC deck is efficient for replacement.

An advanced technique for the analysis of box girder bridge superstructures

K. Kashefi
Arup, Adelaide, SA 5000

A. H. Sheikh
The University of Adelaide, Adelaide, SA 5005

ABSTRACT: An efficient modeling technique has been proposed to predict the behavior of thin-walled steel box-girders subjected to dynamic loading. In the proposed technique the general three-dimensional (3D) equations used for accurate representation of the structural deformation of these complex beam-like slender structures are decoupled into a two-dimensional (2D) cross-sectional problem and a one-dimensional (1D) beam problem through decomposition of the 3D strain field. The 2D cross-sectional problem is solved by a 2D finite element analysis considering in-plane as well as out-of-plane warping displacements of the beam section. The 1D beam problem is solved by a 1D beam finite element analysis and the results obtained are utilized to recover 3D stress, strain and displacement fields accurately. Numerical examples of thin walled box girders are solved using the proposed approach to show its performance. The comparison between the results obtained by the proposed method and detailed 3D finite element analyses highlights the accuracy as well as computational efficiency of the proposed method.

1 INTROUCTIONS

Box girder bridges are practically thin-walled beams having closed or combination of closed and open sections. The behavior of these structures under an arbitrary loading scenario is quite complex which is primarily due to the cross-sectional warping (out-of-plane warping) and the distortion of the sections (in-plane warping). A detailed 3D finite element (FE) analysis can predict the behavior of these structures accurately. However, considering the large number of elements and nodes involved with this approach it will require a large amount of computational resources which can be very expensive and not always available. Moreover, a significant amount of time and effort is required to create such detailed finite element models. This is inconvenient at, e.g., the preliminary design stage when the analysis is typically performed a large number of times while the design is being modified and improved.

The other extreme is to analyze these structures as one-dimensional beams. While this will make the analysis highly efficient computationally, models based on conventional beam theories such as Euler-Bernoulli hypothesis cannot predict the behavior of these structures accurately because they cannot capture the local deformations in the form of warping and other effects. For instance, Euler-Bernoulli beam theory does not consider the effect of shear deformation which is incorporated in Timoshenko's beam theory but this theory cannot capture the effect of warping deformations. Saint-Venant considered the effect of warping due to torsion which is absent in the above theories but this theory can only account for the unconstrained out-of-plane warping. The effects of shear deformations are still missing in the theory. An improved representation of the deformation of thin-walled beams is proposed by Vlasov (1961) to accommodate constrained warping (out-of-plane warping) but it cannot capture the distortion (in-plane warping) effects of the beam section (Dvorkin (1989)). A number of researchers (e.g. Bauld and Tzeng (1984), Chandra et. al. (1990), Lee (2005) and Sheikh and Thomsen (2008)) used Vlasov's theory and made some advancement. However, these theories require prior knowledge of the pattern of warping displacements which can change from one case to another. Subsequently, the effect of distortion in thin-walled box girders has been studied by few researchers (e.g. Razaqpur and Li (1991,1994) and Kermani and Waldron (1993)). These studies led to a better understanding of the behavior of thin-walled box girders which can have significant distortion. However, these techniques for modelling the distortion are based on ad-hoc assumptions and thus cannot be used in general cases.

In order to develop an accurate beam model for representing more realistic behavior of these structures, it is necessary to extract the exact potential

energy expression without any simplifying assumption that can eliminate important contributions. In this context, beam sectional analysis which was first proposed by Giavotto et al. (1983) and subsequently extended and employed by other researchers (e.g. Borri and Merlini (1986), Ghiringhelli and Mantegazza (1994) and Blasques (2014)) seems to be very attractive. In this approach, the complete 3D elasticity problem defining the actual behavior of beam-like structures is decomposed to a two-dimensional (2D) beam cross-sectional analysis and a one-dimensional (1D) beam analysis without any ad hoc assumptions. The method only assumes that the cross-sectional dimensions are small compared to the beam length which is true for medium to long-span bridge structures. The 2D beam sectional analysis is carried out using a 2D finite element discretization of the cross section where the effects of in- and out-of-plane warping deformations are considered. The 2D finite element analysis generates an accurate constitutive matrix (or stiffness matrix) of the beam cross-section which correctly accounts for the coupling between the different modes of deformation. This cross-section stiffness matrix is then used in the 1D beam analysis which can be carried out using a standard 1D beam finite element model. The cross section forces and moments obtained in the 1D beam analysis together with the warping solutions provided by 2D cross-sectional analysis, are used to obtain the warping displacements and finally to recover the detailed 3D stress and displacement fields in the cross section. The computational efficiency of this approach is remarkable in terms of the prediction of the 3D response of beam like structures.

In this paper, an efficient technique for obtaining the dynamic response of steel box girder bridges is developed where the cross-sectional analysis is based on an implementation of the theory given by Giavotto et al. (1983). Using the proposed method free vibration analysis as well as forced vibration analysis are investigated under time varying and instantaneous loads. The effect of damping is also incorporated following the concept of Raleigh damping (Clough (1975)). A computer code is developed to implement the 2D sectional analysis, 1D beam analysis as well as the recovery of the beam 3D response. Numerical examples of free and forced vibration response of box girder bridges are then solved by the proposed technique. The obtained results are compared with those obtained from the detailed 3D finite element analysis of these structures. The results highlight the accuracy and computational efficiency of the proposed method.

2 MATHEMATICAL FORMULATION

A brief overview of the methodology proposed by the authors is given in this section. For more detailed explanation on formulation refer to the other published work of the authors (Kashefi et al (2015)). The formulation is based on the assumption that the beam like structure has a slender geometry and does not have any abrupt variation of the cross-sectional geometry and material properties. Material remains linear elastic and the formulation considers small deformation theory.

2.1 *2D sectional analysis*

Figure 1 shows a typical beam like structure where the Cartesian coordinate axis (x-y-z) is used as the reference system which passes through the geometrical center of cross section. The displacement vector at an arbitrary point of a beam section $\{u\}$ can be divided into two components as

$$\{u\} = \{v\} + \{w\} \tag{1}$$

where $\{v\}$ is the displacement vector due to translations and rotations of the section without having any distortions and $\{w\}$ is due to the generalised 3D warping of the beam section. The first component of the displacement vector $\{v\}$ can be expressed in terms of translations $\{U\} = [U_x \quad U_y \quad U_z]^T$ and rotations $\{\theta\} = [\theta_x \quad \theta_y \quad \theta_z]^T$ of the section as

$$\{v\} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & -y \\ 0 & 1 & 0 & 0 & 0 & x \\ 0 & 0 & 1 & y & -x & 0 \end{bmatrix} \begin{Bmatrix} \{U\} \\ \{\theta\} \end{Bmatrix} = [H]\{\Delta\}. \tag{2}$$

For the warping displacements, the beam section is discretized with 2D finite elements which help to express the displacements as

$$\{w\} = [N]\,\{d\} \tag{3}$$

where $\{d\}$ contains the nodal parameters of w_x, w_y and w_z and $[N]$ is their interpolation function.

The 3D stress-strain relationship is written as

$$\{\sigma\} = [D]\,\{\varepsilon\} \tag{4}$$

where the stress and strain vectors are arranged as $\{\sigma\} = [\sigma_x \quad \sigma_y \quad \tau_{xy} \quad \tau_{xz} \quad \tau_{yz} \quad \sigma_z]^T$ and $\{\varepsilon\} = [\varepsilon_x \quad \varepsilon_y \quad \gamma_{xy} \quad \gamma_{xz} \quad \gamma_{yz} \quad \varepsilon_z]^T$, respectively and $[D]$ is the corresponding constitutive matrix.

The stress resultants ($\{P\} = [\{F\}^T \quad \{M\}^T]^T$) at a section of the beam consist of three forces ($\{F\} = [F_x \quad F_y \quad F_z]^T$) and three moments ($\{M\} = [M_x \quad M_y \quad M_z]^T$) which are produced by the last three components of the stress vector $\{\tau\} = [\tau_{xz} \quad \tau_{yz} \quad \sigma_z]^T$ treated as tractions acting on the beam section having an area of A. These stress resultants can be obtained as

$$\{P\} = \int [H]^T \{\tau\} dA. \tag{5}$$

The strain vector can be now expressed in terms of derivatives of the displacements where the derivatives with respect to x and y (sectional coordinates) are separated from the derivatives with respect to z (axial coordinate) as

$$\{\varepsilon\} = [\partial_{xy}]\{u\} + [S]\{u\}_{,z} \tag{6}$$

Equations (1) to (3) are substituted in the above equation which leads to

$$\begin{aligned}\{\varepsilon\} = {} & [\partial_{xy}][H]\{\Delta\} + [S][H]\{\Delta\}_{,z} + \\ & [\partial_{xy}][N]\{d\} + [S][N]\{d\}_{,z}\end{aligned} . \tag{7}$$

As $[\partial_{xy}][H]$ in the above equation can be written as $[S][H][T]$ where $[T]$ is a 6x6 square matrix having all elements zero except $T(1,5) = -1$ and $T(2,4) = 1$, the strain vector can be rewritten as

$$\{\varepsilon\} = [S][H]\{\Psi\} + [B]\{d\} + [S][N]\{d\}_{,z} \tag{8}$$

where $\{\Psi\}$ is the sectional strain vector consisting of two shear strains, one axial strain, two curvatures and one torsional strain. The sectional strain vector can simply be expressed as

$$\{\Psi\} = [T]\{\Delta\} + \{\Delta\}_{,z} . \tag{9}$$

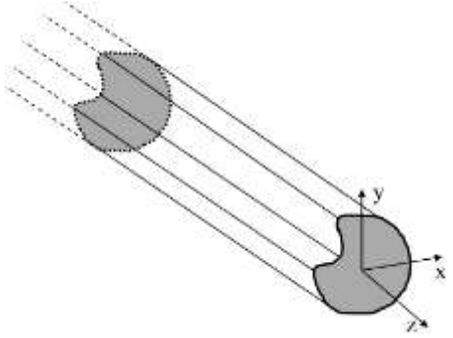

Figure 1. A typical beam like structure with reference coordinate system

2.2 *Equilibrium equations*

Now the virtual work principle ($\delta W_i = \delta W_e$) will be applied to get equilibrium equations of the beam section. For this purpose, a small element of the beam in the form of a small slice having a length of dz is taken. Assuming no variation of stresses and strains within the small length dz (along z), the internal virtual work can be written as

$$\delta W_i = dz \int \delta\{\varepsilon\}^T \{\sigma\} dA . \tag{10}$$

The external virtual work will be caused by the stresses or tractions $\{\tau\}$ acting on the two cross-sections of the slice and δW_e can be written as

$$\begin{aligned}\delta W_e = {} & \left[\int \delta\{u\}^T \{\tau\} dA + \frac{\partial}{\partial z}\left(\int \delta\{u\}^T \{\tau\} dA \right) dz \right]_{\text{at } (z+dz)} \\ & + \left[- \int \delta\{u\}^T \{\tau\} dA \right]_{\text{at } z} \\ = {} & \frac{\partial}{\partial z}\left(\int \delta\{u\}^T \{\tau\} dA \right) dz = dz\left(\int \delta\{u\}_{,z}^T \{\tau\} dA + \int \delta\{u\}^T \{\tau\}_{,z} dA \right)\end{aligned}$$

. (11)

So the final form of the virtual work can be written as

$$\int \delta\{u\}_{,z}^T \{\tau\} dA + \int \delta\{u\}^T \{\tau\}_{,z} dA = \int \delta\{\varepsilon\}^T \{\sigma\} dA \tag{12}$$

After substitution of Equations (1) to (5) and Equations. (8) to (9) in the above equation, the final form of equations will be:

$$\begin{aligned}& [A]\{d\}_{,zz} + \left([C] - [C]^T\right)\{d\}_{,z} + \\ & [E]\{\Psi\}_{,z} - [L]\{d\} - [M]\{\Psi\} = 0\end{aligned} \tag{13}$$

$$[E]^T \{d\}_{,z} + [M]^T \{d\} + [R]\{\Psi\} = \{P\} \tag{14}$$

where $[A] = \int [N]^T [S]^T [D][S][N] dA$,

$[C] = \int [N]^T [S]^T [D][B] dA$, $[E] = \int [N]^T [S]^T [D][S][H] dA$,

$[L] = \int [B]^T [D][B] dA$, $[M] = \int [B]^T [D][S][H] dA$,

$[R] = \int [H]^T [S]^T [D][S][H] dA$, $\{Q\} = \int [N]^T \{\tau\} dA$ and

$\{Q\}_{,z} = \int [N]^T \{\tau\}_{,z} dA$.

2.3 *Constraints*

It should be noted that the solution of above equations cannot be found unless suitable constraints are imposed. This is due to the use of $\{v\}$ (Equation (2)) in addition to $\{w\}$ (Equation (3)) to define the displacements of a point within the beam section. Actually, $\{w\}$ could be used to define the total displacement vector $\{u\}$ through the 2D finite element approximation but $\{w\}$ is used only for the warping displacements and $\{v\}$ is used in addition to define $\{u\}$. In the present case, the number of constraints is six as $\{v\}$ is defined in terms of $\{\Delta\}$ (Equation. (2)) which has six components. The constraints can be defined on the basis that the warping displacements should not contribute towards any translation or rotation of the beam section.

2.4 *Cross sectional stiffness and mass matrix*

Utilizing constraints in Equations (13) and (14) and the virtual work, the stiffness matrix of the beam section can be obtained as

$$[K_s]=[F_s]^{-1}=\left(\begin{bmatrix}[X_1]\\ [X_2]\\ [Y_1]\end{bmatrix}^T\begin{bmatrix}[L] & [C] & [M]\\ [C]^T & [A] & [E]\\ [M]^T & [E]^T & [R]\end{bmatrix}\begin{bmatrix}[X_1] & [X_2] & [Y_1]\end{bmatrix}\right)^{-1} \tag{15}$$

where $[X_1]$, $[X_2]$, $[Y_1]$ and $[Y_2]$ are linear operators that consist of constants (Kashefi et. al. (2015)).

This way the stiffness matrix of the section is defined accurately and can account for any geometrical and material coupling such as for composite structures.

Simliar to the cross-sectional stiffness matrix, we need to derive the cross-sectional mass matrix which will be utilised to derive the mass matrix of the beam elements. Using Equations. (1) and (2), the components of acceleration at a generic point of the section may be expressed as $\{\ddot{v}\}=\begin{bmatrix}\ddot{v}_x & \ddot{v}_y & \ddot{v}_z\end{bmatrix}^T=[H]\{\ddot{\Delta}\}$ where the effect of warping is neglected. Taking a slice of beam section of unit length (dz =1), the inertia forces of an element of small volume $dv = dxdy = dA$ (as dz =1) can be written using the above expression for the acceleration vector as $\{f^i\}=\rho dA\{\ddot{v}\}=\rho dA[H]\{\ddot{\Delta}\}$ where ρ is material density. Similar to Equation (5), the resultant inertial forces consist of three forces and three moments can be obtained by integrating the element inertia forces over the cross-sectional as follows.

$$\begin{aligned}\{F^i\}&=\int_A[H]^T\{f^i\}=\left(\int_A\rho[H]^T[H]dA\right)\{\ddot{\Delta}\}\\ &=[M_s]\{\ddot{\Delta}\}\end{aligned} \tag{16}$$

where $M_s=\begin{bmatrix}m & 0 & 0 & 0 & 0 & 0\\ 0 & m & 0 & 0 & 0 & 0\\ 0 & 0 & m & 0 & 0 & 0\\ 0 & 0 & 0 & I_{xx} & -I_{xy} & 0\\ 0 & 0 & 0 & -I_{xy} & I_{yy} & 0\\ 0 & 0 & 0 & 0 & 0 & I_{xx}+I_{yy}\end{bmatrix}$

In the above equation, m is the mass per unit length of the box girder whereas the other terms are corresponding to the different components of rotary inertia due to cross-sectional rotations which can be written as follows,

$$\begin{aligned}&m=\int_A\rho dA,\\ &I_{xx}=\int_A y^2\rho dA, I_{yy}=\int_A x^2\rho dA,\ I_{xy}=\int_A xy\rho dA\end{aligned} \tag{17}$$

2.5 *One dimensional dynamic analysis and three dimensional stress/strain recovery*

After calculating the sectional stiffness and mass matrix, the 1D beam finite element analysis needs to be carried out. A C^0 continuous displacement based isoparametric formulation is adopted for the derivation of these three-node elements considering bi-axial bending, bi-axial shear, torsion and axial deformations. According to isoparametric formulation, all the field variables are interpolated in terms of their nodal values in an identical manner. Sectional stiffness matrix $[K_s]$ (Equation (15)) is used to derive beam element stiffness matrix $[K_e]$ as

$$[K_e]=\int[B_z]^T[K_s][B_z]dz \tag{18}$$

In a similar manner, the mass matrix of an element can be derived and it can be expressed as

$$[M_e]=\int[N_z]^T[M_s][N_z]dz \tag{19}$$

The integrations found in Equations (18) and (19) are carried out numerically following the Gauss quadrature technique, where a full integration rule is applied and field consistent technique is used to stabilize the strain field.

The stiffness matrix and mass matrix for all elements are obtained and assembled together to form the global stiffness matrix [K_g] and mass matrix [M_g] of the structure.

In order to form the damping matrix [C_g] of the structure, Rayleigh technique (1896) is used which expresses the damping matrix in terms of stiffness and mass matrixes as

$$[C_g]=\alpha[M_g]+\beta[K_g] \tag{20}$$

where α and β are the Rayleigh constants, which are determined by solving the following simultaneous equations

$$\begin{Bmatrix}\alpha\\ \beta\end{Bmatrix}=2\frac{\omega_n\omega_m}{\omega_n^2-\omega_m^2}\begin{bmatrix}\omega_n & -\omega_m\\ -1 & 1\\ \hline \omega_n & \omega_m\end{bmatrix}\begin{Bmatrix}\xi_m\\ \xi_n\end{Bmatrix}. \tag{21}$$

In the above equation, ξ_m and ξ_n are the damping ratios corresponding to two modes of vibration (m and n) which can be obtained from experimental measurement (Thompson (2002)). ω_m and ω_n are the

corresponding frequencies of vibration which can be obtained from the free vibration analysis of the structure. Once the above matrixes and the global load vector $\{F_g(t)\}$ are obtained, the governing equation for free and forced vibration response of the structure can be expressed as the followings:

Undamped free vibration:

$$[K_g]\{\delta\}+[M_g]\{\ddot{\delta}\}=0 \tag{22}$$

Dynamic response:

$$[K_g]\{\delta\}+[C_g]\{\dot{\delta}\}+[M_g]\{\ddot{\delta}\}=\{F_g(t)\} \tag{23}$$

Equation (22) gives an eigenvalue problem which is solved by the simultaneous iteration technique of Corr and Jennings (1976) to calculate the natural frequencies of vibration, ω. The time integration method following Newmark beta (Bathe (2006)) is used to solve Equation (23) for the time history response of displacement, velocity and acceleration vectors.

Once the nodal displacement vector is obtained from the 1D finite element analysis, it can be utilized to evaluate the generalized strain vector $\{\Psi\}$, the cross section force and moment vectors, $\{P\}=[K_s]\{\Psi\}$, at any desirable section of the beam at any time (t). Based on $\{P\}$, the 3D displacements and stresses can be recovered using Equations (8) and (4).

3 NUMERICAL RESULTS AND DISCUSSION

A computer program is developed in FORTRAN to implement the proposed method for the static and dynamic (free and forced vibration) analysis of beams having different thin-walled cross-sections which are commonly found in bridge decks. The material properties used in the examples are that of steel with elastic modulus E = 200 GPa, Poisson ratio ν = 0.3 and the mass density ρ = 7948.89 kg/m^3.

3.1 *Single cell box girder-Cross sectional analysis*

A 20m long cantilever beam having a thin-walled cross-section as shown in Figure 2 is studied in this section.

For the sectional analysis, which is the initial step of static or dynamic response analyses, a 2D finite element analysis using eight-node quadratic isoparametric elements is carried out. The sectional analysis is carried out for different mesh sizes. Results show that a mesh consisting of 240 elements (corresponding to 3606 degrees of freedom (DOF)) is sufficient to have a converged solution. The non zero components of the sectional stiffness matrix predicted by the present approach are presented in Table 1, where K_{11} and K_{22} are transverse shear stiffness components corresponding to x and y axes, respectively, K_{33} is the extensional stiffness component, K_{44} and K_{55} are bending stiffness components corresponding to x and y axes, respectively, and K_{66} is torsional stiffness component. The sectional stiffness matrix is also calculated using the conventional beam theory and values are included in Table 1. A significant difference is observed between the values of transverse shear and torsional stiffness components of the thin-walled beam predicted by these two approaches. Moreover, the off-diagonal components of the cross-sectional stiffness matrix, which are due to shear-torsion and bending-extension couplings (K_{16} and K_{34}, respectively) cannot be captured by classical beam theories. The cross-sectional stiffness components evaluated by the proposed approach are the most accurate and this is verified by using these stiffness values in the 1D beam analysis for accurately predicting the static and dynamic responses of the girder.

3.1.1 Dynamic response due to a suddenly applied load

In this section, the dynamic response of the girder under an instantaneously applied load ($F_y = -1.0\,kN$) at its free end is investigated. The element discretization and mesh details for the sectional analysis are the same as in the previous section. For the validation of the present results, the girder is also analyzed using the finite element software ABAQUS having 20-node quadratic hexahedral solid elements (C3D20). A total number of 12800 solid elements is used corresponding to 269760 Degrees of Freedom (DOF) (almost 75 times more than the DOF required in analysis of the same structure by the proposed approach) are used where the aspect ratio of an element is maintained as 1×2×2 (thickness× breadth ×length) in order to ensure a reliable and converged solution. Before undertaking the dynamic analysis of the girder using time integration method, the free vibration analysis of the structure is carried out by the proposed technique to obtain frequencies of vibration (ω_1 = 19.067 rad/s; ω_2 = 28.954 rad/s) which are required for the evaluation of damping ratios. In order to ensure that the frequency values calculated by the proposed method are accurate, these are also determined from a detailed 3D finite element analysis of the girder using ABAQUS (ω_1 = 19.108 rad/s; ω_2 = 28.90 rad/s) which shows a difference of less than 0.2%.

The forced vibration analysis of the girder is carried out using the proposed approach as well as a detailed 3D finite element (FE) model (ABAQUS) and the dynamic response of the structure is captured for a period of 1.2 sec. The time history diagrams for the deflection (u_y) at two points (A and E) on the free end cross section (Figure 2) obtained by the proposed method as well as the 3D FE analysis are presented in Figures 3-4. The time history responses for normal stress (σ_{zz}) at two points (A and D) obtained by the proposed method and 3D FE model are presented in Figures 5-6. As can be seen from these figures, the results predicted by the presented model are in very good agreement with those produced by the 3D FE analysis.

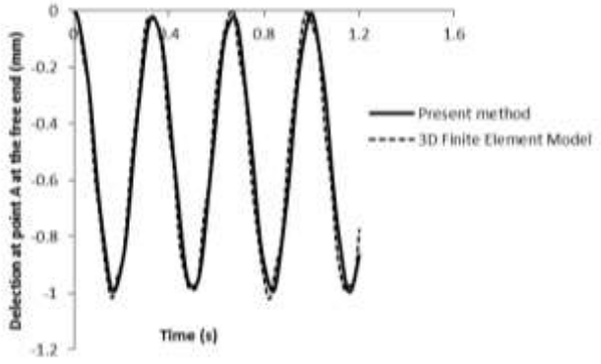

Figure 3. Time history of the deflection at point A (uy mm) of the free end section (Figure 2)

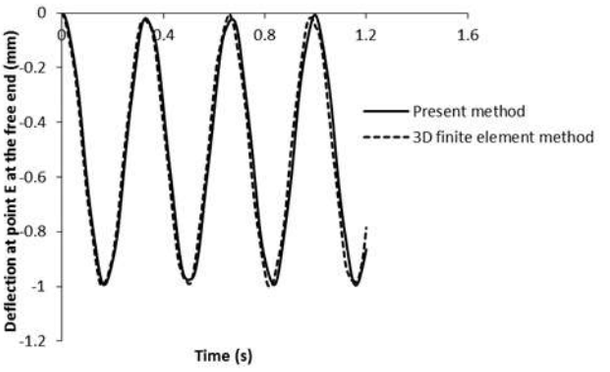

Figure 4. Time history of the deflection at point E (uy mm) of the free end section (Figure 2)

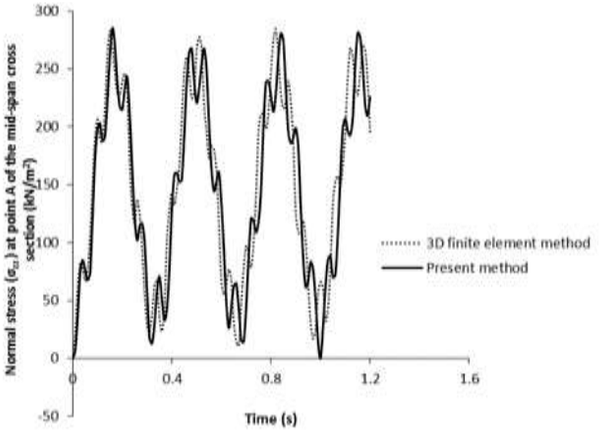

Figure 5. Time history of the normal stress (σzz kN/m2) at point A of the mid-span section (Figure 2)

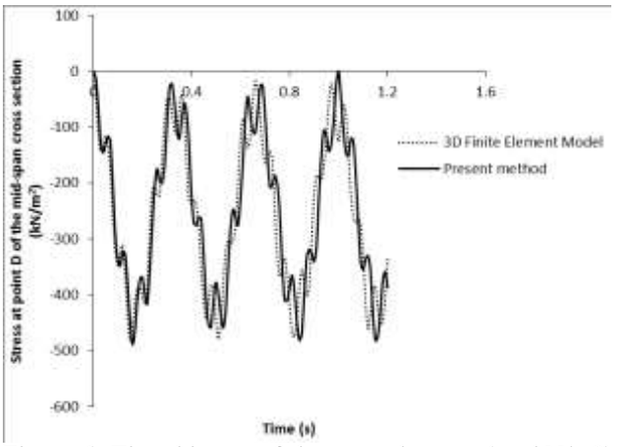

Figure 6. Time history of the normal stress (σ_{zz} kN/m2) at point D of the mid-span section (Figure 2)

As the effect of damping is not considered in the previous analysis, the structure is reanalyzed exactly in a similar manner taking damping ratio of 2% and 4% in order to show the effect of damping on the structural response. The time history diagrams for the deflection at point A on the free end section of this girder obtained from these two models are presented for a period of 2.5 sec in Figure 7. The amplitude of deflection is found to be reduced with the increase of damping ratios as expected.

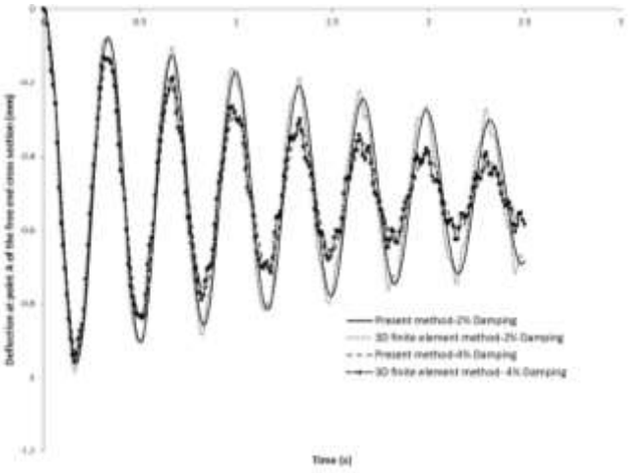

Figure 7. Time history of the deflection at point A (uy mm) of the free end section (Figure 2) considering damping

3.2 *Dynamic response of the two-cell box girder due to a time-varying load Two-cell box girder*

This section considers a 20 m long cantilever two-cell box girder as shown in Figure 8. The converged solution for cross-sectional analysis of this girder is obtained with 202 eight-node quadratic elements (DOF: 3021) .

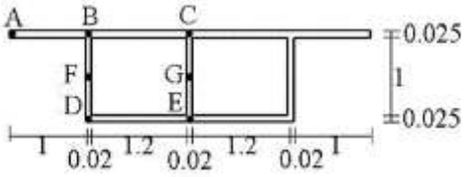

Figure 8-Two-cell box girder (dimensions are in m)

The dynamic response of this girder due to a time-varying load in the form of a triangular pulse (Figure 9) acting at the free end of the girder is predicted by the proposed method and the 3D FE analysis. For this purpose the 1D beam analysis of this girder is implemented using 15 three-node beam elements (DOF: 186). The 3D FE analysis is also performed for the validation of the present results using 20-node quadratic hexahedral solid elements (C3D20). A total number of 20800 solid elements (DOF = 435351; almost 145 times more than the DOF required for the proposed approach) are used where the aspect ratio of an element is maintained as 1×2×2. The time history for the deflection (u_y) at point A of the free end section is obtained using both 3D FE model and the present method. The results are plotted in Figure 10. The time histories for the normal stress (σ_{zz}) of points C and D at the mid-span section are illustrated in Figures 11-12 for both approaches. The results obtained by the present method are in very good agreement with those obtained by the 3D FE model.

4 CONCLUDING REMARKS

An innovative modelling technique is presented for dynamic analysis of thin-walled box girder bridge structures. The dynamic analysis includes free and forced vibration analyses under time varying and instantaneous loads. The capability of the proposed method is comparable to that of a detailed 3D FE model whereas the computational efficiency of the method is very high compared to 3D FE analysis (e.g. almost 150 times fewer DOFs). The method decomposes the full 3D equations defining the behaviour of any beam-like slender structure into a 2D cross-sectional problem and a 1D beam problem, which are solved by using a 2D plane FE model and 1D beam FE model, respectively. This decomposition actually helps the present approach to be computationally efficient. On the other hand, the accuracy of the solution is not affected as the method does not adopt any major assumptions unlike most of existing beam theories. From 2D analysis, a cross-sectional stiffness is obtained which can account for all of the geometrical couplings found in multi-cell bridge girders. Apart from the usual displacements due to translations and rotations of the section, the 2D sectional analysis also includes 3D warping displacements consisting of out-of-plane warping of the section as well as in-plane warping i.e., sectional distortion. This is while, it is very challenging to incorporate warping displacements properly in a beam theory. Once the cross-sectional stiffness matrix is evaluated using the 2D finite element analysis, it can be used in the 1D beam analysis for static, free vibration, forced vibration or any other type of structural analysis. Therefore, this method can provide a very useful analysis tool which can specifically be used in the preliminary design of these structures when the designer needs to understand the contribution of different parameters to the overall response of the structure.

In order to demonstrate the performance of the proposed method, numerical examples of thin-walled box girders have been solved and the results produced by this method have been compared with those generated from the detailed 3D FE analysis of these structures. The results produced by these two approaches are found to have very good correlations. Based on the above observation, the proposed method is highly recommended for the analysis and design of thin-walled box girder bridge structures.

ABSTRACT: In a staggered erected cable-stayed bridge made of concrete, time-dependent phenomena (such as creep or shrinkage) effects might play an important role in both its geometry and its stress state. In fact, because of these phenomena, stays will indeed lose force and higher bending moments will appear in the structure. To compensate these effects, one or two re-stressing operations are traditionally planned during the life time of long span cable- stayed bridges made of concrete. These re-stressing operations might be technologically challenging and always imply additional costs. To guarantee that allowable stresses and deflections are not exceeded during erection, a number of simulation methods are presented in the literature. Some of these methods, concretely those based on a backward simulation approach, fail addressing the effects of the time-dependent phenomena. To simulate these effects, methods based on the forward simulation approach are traditionally followed. Nevertheless, the main trade-off of these algorithms is that their computation is based on complex iterative processes that make simulation more time consuming. Furthermore, these methods are not able to avoid the need of additional re-stressing operations in service to prevent the effects of the time-dependent phenomena. To fill all these gaps, a new simulation algorithm, the Forward-Direct Algorithm (*FDA*), is formally presented in this paper to simulate the construction process of cable-stayed bridges including the time-dependent phenomena effects. This algorithm takes advantage of the unstressed length of the stays concept to carry out a computationally efficient simulation based on an innovative direct simulation approach. The major advantage of this algorithm is the fact that the prestressing operations during construction can be defined to avoid the need of additional re-tensioning operations in service. To illustrate the creep and shrinkage effects, the proposed algorithm is applied to a real cable-stayed bridge. This tool also can be used by the designer or the contractor for construction control of the strand by strand tensioning technique.

1 INTRODUCTION

Most cable-stayed footbridges are built on temporary supports (Menn 1986). In this erection method, the bridge superstructure is first erected on a set of temporary and permanent supports. Then, during the tensioning process of the stayed cables, the loads counterbalanced by the temporary supports are successively transmitted to the stay system. At the end of this tensioning process, a target geometry or stress state, known as the Objective Service Stage (*OSS*) (Hassan et al 2012) is achieved.

Cable-stayed bridges are extremely redundant and the effect of tensioning one cable has the effect of changing the stresses of the already installed cables. In order to achieve the *OSS* at the end of the construction process careful simulations are required. In fact, many researchers and practitioners have stated the importance of this simulation (Janjic et al. 2003). The traditional method to simulate the construction process of cable-stayed bridges is to start at the *OSS* and dismantle the structure. Several authors have proposed methods based on this "backward" approach both for the temporary supports (Lozano-Galant et al 2012a), and the cantilever erection method (Behin and Murray 1992, Wang et al. 2004). The primary challenge of this simulation is the difficulty to model any modification in the bridge design and/or in its tensioning strategy. To overcome these problems, a forward simulation, which follows the actual erection sequence on site was proposed for the temporary supports (Lozano-Galant et al 2012a) and the cantilever method (Wang et al 2004). Most of the simulation methods presented in the literature assume that any construction stage can be obtained by deactivating or activating group of elements, loads or boundary conditions from the following or the preceding construction stages. This hypothesis assumes that the construction process can be simulated by linear superposition of stages. Other works (Lozano-Galant et al. 2013) proposed a direct approach that avoided the need of this superposition of

stages. These procedures increased computational efficiency.

The main algorithms presented in the literature for the simulation of the temporary supports erection method are as follows: Backward Algorithm (BA) (Lozano-Galant et al. 2012a), Forward Algorithm (FA) (Lozano-Galant et al. 2012b) and Direct Algorithm (DA) (Lozano-Galant et al 2013). The main characteristics of each of these simulation methods are summarized in Table 1. This table includes the simulation direction (backwards, forwards or direct), the application or not of the superposition of stages principle (abbreviated in tale as Sup.), the use of a Local (LIP) or an Overall (OIP) Iterative Process, and if the simulation includes or not the effects of the Time-Dependent Phenomena (TDP).

Table 1. Characteristics of the simulation algorithms for the temporary supports erection method

Algorithms	Direction	Sup	LIP / OIP	TDP
BA	Backward	✔	✔ / ✘	✘
FA	Forward	✔	✔ / ✔	✘
DA	Direct	✘	✔ / ✘	✘

Analysis of Table 1 shows that any of the methods presented in the literature enables the simulation of the time-dependent phenomena. In order to fill this gap, this paper presents a method, the Forward Direct Algorithm, *FDA*, to simulate the construction process of cable-stayed bridges built on temporary supports including the effects of the time-dependent phenomena. This algorithm also enables the simulation of the stresses in the strand-by-strand tensioning technique. In the following section, the strand by strand tensioning technique is first described and then the simulation proposed by the *FDA* is summarized.

2 STRAND BY STRAND TENSIONING TECHNIQUE

Due to flexibility of cable-stayed bridges, the tension of individual strands of a stay cable does not remain constant as it varies during the stressing operation of each strand. To ensure the uniformity of forces in all strands of a stay cable at the end of the stressing operation, several patented methods might be used.

The stressing of multi-strand stay cable (Fig. 1.A) with a mono-strand jack might be carried by the following steps: (1) The first strand is fixed to one of the anchorages, and its other end is threaded into the other anchorage, and then cut and stressed to a calculated force, which takes into account the foreseen deformation of the structure. (2) The first strand is not yet wedged into the anchorage block, but wedged in a special single anchoring device provided with a load cell that gives a permanent reading of this force. (3) The second strand is then installed in a similar manner, cut and stressed. Then, the stressing is carried out with a mono-strand jack equipped with a load cell identical to the one indicating the force of the first strand. (4) As the second strand is stressed, the force of the first strand decreases, and the stressing operation is stopped when the readings of the two cells are identical. The second strand is then anchored in the permanent anchor block. At this point the first two strands are equally stressed. This process is carried out automatically by adequate software developed by the prestressing company. (5) The third strand is then installed and stressed until its force reaches the reading of the first strand (which decreases jointly with the force of the second strand). When the same forces are reached, the three strands are identically stressed.

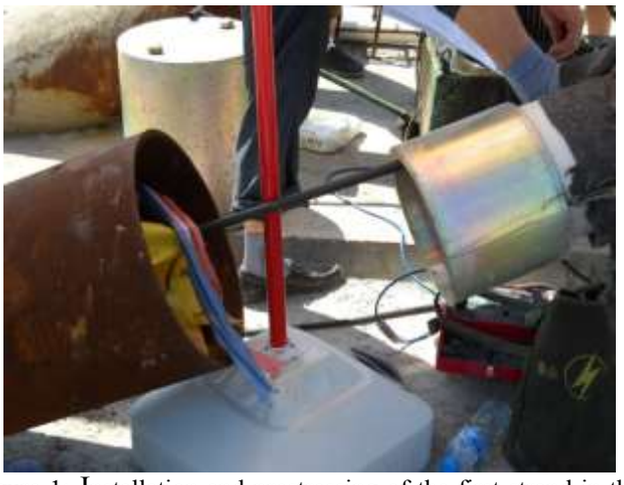

Figure 1: Installation and prestressing of the first strand in the strand by strand tensioning technique.

A linear approximation of the evolution of the strand forces in the strand-by strand tensioning process is presented in SETRA (2001). This analysis includes the stiffness of the structure into the stay cable-direction. The results of this approximation are close to the actual variation of tension on site for stay cables with a high number of strands.

3 SIMULATION OF THE CONSTRUCTION PROCESS

The simulation algorithms of cable-stayed bridges have to assure the achievement of the *OSS* by an adequate tensioning process. This process describes the tensioning operations to be introduced by the jack on site to transfer the load from the temporary supports to the stay cable system. The tensioning process plays an important role in the structural behavior of the structure both during construction and in service.

Usually stay cable system of cable-stayed bridges is prestressed on two tensioning operations. The

forces in the first operation are usually defined directly by the designer as a percentage, usually ranging between the 70% and 85%, of the prestressing forces in the *OSS*. Unfortunately, the calculation of the forces in the second prestressing operation is not straightforward, as it must take into account the effects of all the preceding and subsequent tensioning operations and time-dependent phenomena. In order to carry out this simulation, an algorithm, the Forward Direct Algorithm (*FDA*) is presented in this section. This procedure takes advantage of the unstressed length of the stays concept to avoid the need of an overall iterative process. Furthermore, the *FDA* enables the calculation of the stresses in the first strand obtained by the strand-by-strand tensioning technique.

In this section, the main hypotheses of the *FDA* are first explained in detail. Secondly, the unstressed length concept of the cables and its simulation in the *OSS* are described. Then, a procedure to include the effects of the time-depend phenomena into the strains in the OSS is presented. Finally, the simulation of the first and the last tensioning operations are summarized.

3.1 *Hypotheses*

The main hypotheses of the *FDA* are: (1) This algorithm is applied to the temporary supports erection method. (2) The simulation of the *FDA* is carried out according to the actual construction sequence (forward simulation). This modeling direction enables the simulation of the time-dependent phenomena effects. (3) The superposition of stages principle is used to simulate changes during construction in the structural system (e.g. placement of the stays), loads (e.g. stay prestressing) or boundary conditions. (4) A Local Iterative Process is used to simulate the lifting of the temporary supports produced by a tensioning operation or by the time-dependent phenomena effects. (5) Stay forces are simulated by imposed strains on the stays. (6) The *FDA* does not require separate models to calculate the evolution of stresses in the strands when the strand by strand tensioning technique is used. (7) The construction process is defined to achieve the *OSS*. (8) The simulation of the first prestressing operation differs from that of the last one. For this reason, each simulation is described separately in the following subsections. (9) The temporary supports are removed when the deck is lifted at its location. (10) At the end of the first tensioning operation all the loads are transferred to the stay system (in this way, during the last tensioning operation the structural system remains constant and without temporary supports). (11) To avoid the requirement of an overall iterative process, the prestressing of the last tensioning operation is based on the unstressed length concept. (12) The effects of the time-dependent phenomena (such as creep or shrinkage) are simulated by adding *Auxiliary Models* with amplified curvatures and axial strains in concrete elements. (13) To avoid excessive computation times, the increments of time in creep and shrinkage simulation vary from 1 to 360 days.

3.2 *Unstressed Length of the cables*

A length-based adjustment is sometimes used to introduce the tensioning of the stays on site. In this procedure the stays are made to accurately measure a so called unstressed or neutral length of a stay, L_0 (SETRA 2001). This is the length of a given cable when it has not axial stress or strain. This length is measured when the cable rests horizontally on a support that counterbalances the effects of its own self weight. L_0 is an intrinsic parameter that is independent of the conditions to which the stay is subjected on site.

This procedure is especially interesting for cable-stayed footbridges with prefabricated cables. In this case, the stay is then stressed on site from L_0 until its ends occupy the position of the anchorages in the deformed geometry, and the stressed length L_S is achieved. This is equivalent of introducing an imposed strain ε in the stay. With ΔL_n being the increment of length in the *nth* stay, the value of this strain can be calculated as presented in the following equation.

$$\varepsilon = \frac{\Delta L}{L_0} = \frac{L - L_s}{L_0} \tag{1}$$

According to (SETRA 2001) ε presents values close to -0.003. These parameters have been used to simulate the structural behaviour of cable-stayed bridges (see. e.g. (Janjic et. al 2001). In this paper, these strains are proposed to be used to simulate of the construction process of cable-stayed bridges. To do so, the *FDA* assumes that extending a L_0-length stay on site to get a given force F produces the same effect that shortening an L-length stay in the computer model to get such force. This is valid when the same stressed length L_S and the same axial force are obtained by both procedures. The shortening in the computer model might be simulated by mean of a unitary strain in the *OSS*, ε_{OSS}, which is related with the force F, the Young's Modulus of the cable material E, the cross sectional area of the stay A, L, L_0 and L_S by the following equation:

$$L_s = L_0 - \left(1 + \frac{F}{EA}\right) = L - \left(1 - \varepsilon_{OSS} + \frac{F}{EA}\right) \tag{2}$$

Using the strains ε_{OSS} enables a direct simulation of the construction process that does not require the application of the superposition of stages. Strains ε_{OSS} might be calculated by the procedure defined in the following section.

3.3 *Objective Service Stage (OSS)*

The *OSS* can be characterized by a set of stay forces. Some of the main criteria used to define these forces in the *OSS* are summarized in (Jorquera et al. 2016). Between these methods, is remarkable the Rigidly Continuous Beam Criterion (Lazar et al. 1972). In this method the stay forces are defined by projecting, into the stays direction, the vertical reaction of an equivalent continuous beam (in which the anchorages of the stay cables at the deck are replaced by supports).

Once defined the stay forces of all the stay cables in the *OSS*, they can be clustered into a vector $\{N_{OSS}\}$. These forces can be obtained by the sum of a passive, $\{N_P\}$, and an active state, $\{N_A\}$, as presented in Equation 4. The former vector includes the passive stay forces produced when the Target Load, *TL*, is applied into the structure and the latter one includes the effect of the prestressing of the stays.

$$\{N_{OSS}\} = \{N_P\} + \{N_A\} = \{N_P\} + [\Delta N]\{\varepsilon_{OSS}\} \quad (3)$$

The active state is simulated in the computer software by introducing imposed strains, ε_{OSS}, into the stays. The vector of imposed strains, $\{\varepsilon_{OSS}\}$, must be calculated taking into account the stiffness of all the structure. To do so, an Influence Matrix, $[\Delta N]$ that includes the effect in term of stay forces of the prestressing of every single stay in the rest of stays is required. The only unknown of Equation 4 is $\{\varepsilon_{OSS}\}$ and it can be directly defined by the following equation:

$$\{\varepsilon_{OSS}\} = [\Delta N]^{-1}(\{N_{OSS}\} - \{N_P\}) \quad (4)$$

in which $[\Delta N]^{-1}$ is the inverse of $[\Delta N]$.

3.4 *Including the time-dependent phenomena into the OSS*

Creep and shrinkage might play an important role in the structural behavior of concrete cable-stayed bridges. In fact, they change the stress state of the structure over time. Nevertheless, these phenomena are rarely included into the definition of the *OSS* due to a number of uncertainties (e.g. in the construction process).

In order to include time-dependent phenoemena effects $\{\varepsilon_{OSS}\}$ might be replaced by an alternative vector $\{\varepsilon_t\}$. This new vector can be used to simulate the construction process of cable-stayed bridges.

Assuming that every stay cable is prestressed in two operations, $\{\varepsilon_t\}$ includes the strains to be introduced into the last tensioning operation of each stay at their respective prestressing times. In those cases where the structural system is defined to remain invariable during the last tensioning operation, that is to say when all temporary supports are lifted in the first *N* tensioning operations, $\{\varepsilon_t\}$ can be calculated by modifying Equation (4) as follows:

$$\{\varepsilon_t\} = [\Delta N^{tT}]^{-1}(\{N_{OSS,tT}\} - \{N_{K-N,tT}\}) \quad (4)$$

in which $[\Delta N^{tT}]^{-1}$ is the inverse of an influence matrix in terms of increments of stay forces in the last tensioning operations, $\{N_{K-N,tT}\}$ is a vector that includes the stay cable forces after the first tensioning operations and $\{N_{OSS,tT}\}$ is the vector of target forces in the *OSS*.

A detail calculation of this equation can be found in Lozano-Galant et al. 2014 and Lozano-Galant and Turmo 2014.

3.5 *Simulation of the first tensioning operation*

The stay forces in the first tensioning operation assure that allowable stresses and deflections are not exceeded. In the *FDA*, these forces are defined to assure also the lifting of all the temporary supports. In this way, the structural scheme of the completed structure remains constant in the last tensioning operation.

The simulation of the first tensioning operation is summarized as follows: (1) The superstructure is staggered erected. (2) The effects of each stay prestressing are successively included. In this simulation, each stay prestressing is modeled by adding *Auxiliary Models*. The active forces of the stay cables are calculated to achieve the target force defined by the designer. (3) After each stay prestressing, the vertical reactions of the temporary supports are evaluated. If any temporary support is lifted, a Local Iterative Process is used to define an adequate structural system. A detailed explanation of this process can be found in (Lozano-Galant et al 2013).

3.6 *Simulation of the last tensioning operation*

The last tensioning operation assures the achievement of the *OSS*. The simulation of the stay prestressing is not as straightforward as in the case of the first tensioning operation. For this reason, in most of the algorithms based on a forward simulation, an Overall Iterative Process is required to assure the achievement of the *OSS* (see (Lozano-Galant et al. 2012b)). In this process, the deviations between the simulated model and the pursued state are successively corrected by updating certain parameters.

As in the case of the Direct Algorithm, *DA* (Lozano-Galant et al. 2013), the *FDA* uses the set of imposed strains at target time calculated in Equation (5) to avoid the need of the Overall Iterative Process and to include the effects of the time-dependent phenomena in the *OSS*.

4 EXAMPLE OF APPLICATION

To evaluate the proposed analysis, the *FDA* is applied in this section. First, the main characteristics of the cable-stayed bridge are described together with the tensioning process. Then, the obtained results are presented. To evaluate the creep and shrinkage effects throughout the Model-Code is used.

4.1 *Description*

The cable-stayed bridge is erected on 11 temporary supports placed every 15 m as described in Fig. 2.

The model of the structure includes a concrete pylon 55 m high, a 180 m long concrete deck and N=19 stay cables. Each stay cable is composed by 50 strands and they are arranged in a fan symmetric form and uniformly anchored every 9 m along the deck. The self-weight of the bridge deck, g_1, the dead load, g_2, and the Target Load, TL, are 135, 70.5 and 202.5 kN/m, respectively. In service, the structure includes a live load of 80 kN/m.

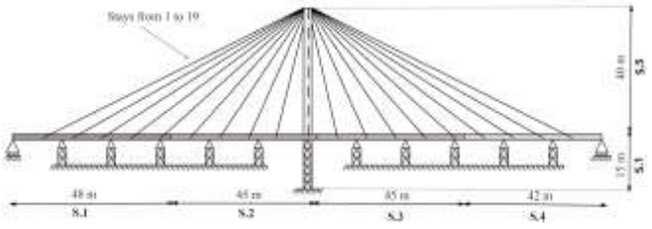

Figure 2: Geometry of the analysed cable-stayed bridge.

The superstructure is evolutionary erected by five construction stages (named from *S.1* to *S.5*). The length of the different segments of each of these stages are described in Fig. 2. The construction process is initiated at 28 days and each stage requires 12 days.

The *FEM* of the bridge consists of 360 elements for the deck, 110 for the pylon and 19 for the stay cables. The Area, A, Young's modulus, E, and the Inertia, I, of the different elements are summarized in Table 2.

The stay cables are prestressed in two operations. During the first prestressing operation, the stays are installed and prestressed to the 80% of their final force. These forces are presented in Figure 3.

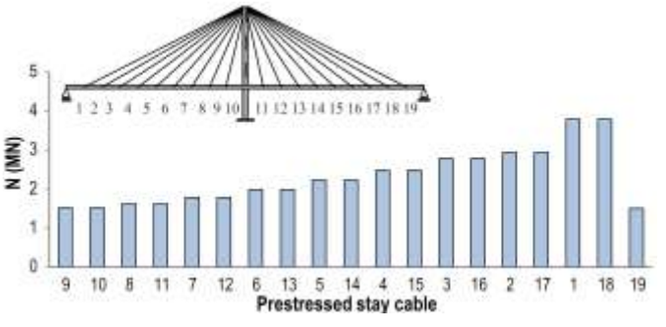

Figure 3. Axial forces in the first tensioning operation.

Table 2. Geometric properties of the bridge elements.

	A [m^2]	E [MPa	I [m^4]
Deck	5.4000	33500	4.2
Pylon	8.5400	33500	14.4
Stays	0.0072	195000	0.9

For the second prestressing operation the vector $\{\varepsilon_t\}$ is used. To include the effects of the time-dependent phenomena into this vector, the procedure described in Lozano-Galant et al. (2014) is used. The stays are prestressed from 88 to 107 days for the first tensioning operation and from 110 to 130 days for the second one. After both tensioning operations, the dead load (70.5 kN/m) is added.

The stay cables in the *OSS* are defined by the rigidly continuous beam criterion (Lazar and Nazmy 1972). The Target time, t_T, to achieve the *OSS* is defined at 130 days. Analyses were carried out until the age of 10000 days.

4.2 *Results*

In this section, the main results of the simulation by the *FDA* are summarized. Fig. 4 presents the axial forces at the second tensioning operation. This figure shows how the asymmetry of the construction process affects the tensioning process.

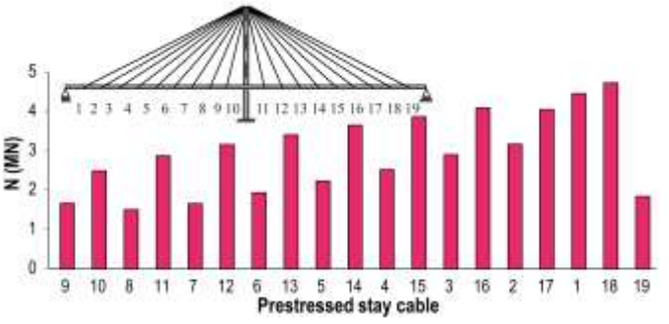

Figure 4: Axial forces in the second tensioning process.

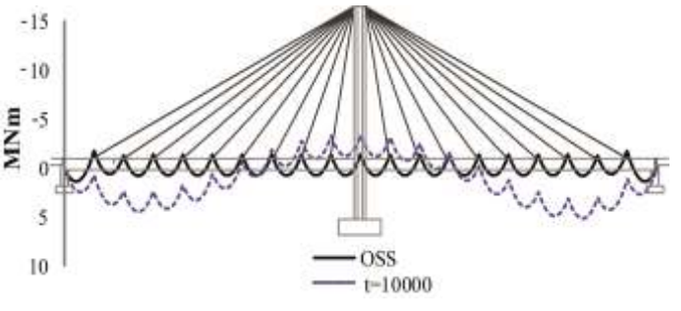
The deck bending moments in the *OSS* (at 130 days) and at 10000 days are presented in Figure 5.



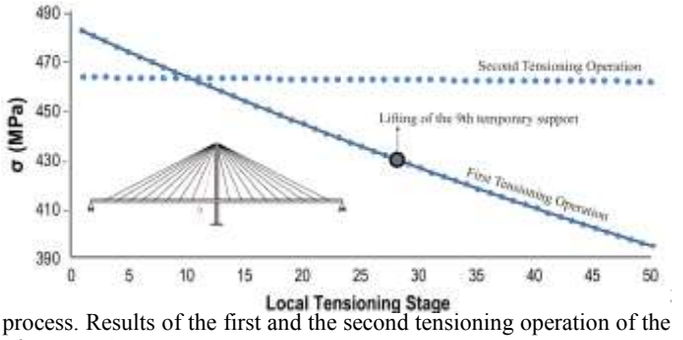


Figure 5: Bending moment diagrams at the end of the construction process at 130 and 10000 days.

The analysis of Figure 5 shows how the target behaviour is only achieved at certain time. The designer can choose what is more economical: using additional tensioning operations in service to correct these effects or avoiding these additional tensioning operations by taking into account these effects during the calculations done in the design process. If this last choice is done, stay forces can be incremented and deck and towers can be pre-cambered to mitigate the effects of the time-dependent phenomena.

With the *FDA*, the stresses in the strands of the stays can be easily calculated without the need of separate models, even when the strand-by-strand tensioning technique is used.

The fifty strands forming each stay are successively introduced into the structure and prestressed. The strain that is needed to achieve in the full stay the desired axial force is successively applied into each of the strands when placed to simulate its tensioning. In the model, when a new strand is introduced and prestressed the axial forces of all placed strands are modified. At the end of the stage, when all the strands are placed and prestressed all the forces in the strands are equal and the force of the stay matches the target value.

Fig. 6 shows the stress in the first strand of the *9th* stay in the first prestressing operation throughout the strand-by-strand tensioning technique. In this construction stage, the structural system consists of the set of the temporary and permanent supports. When the first strand is placed, a certain stress is obtained. Then, as new strands are successively introduced into the structure, the stress of the first placed strand is successively reduced. When all the strands have been placed and prestressed, the stress of the first strand is reduced 84.3 MPa respect to its value when first prestressed. This implies a prestressing loss of the first strand of 20.2%. When the *28th* strand is introduced and prestressed, highlighted in Fig.6, the axial force introduced into the stay is such that is able to unload the temporary support under the stay cable. Therefore, the structural system of the bridge changes as the unloaded temporary support is removed from the model. In the following stages, the stays will be re-stressed, using the strand-by-strand tensioning technique. In order to do so, the imposed strain in the strands when they were first prestressed is successively changed to the one that corresponds with the stage where the strands are being re-stressed.

process. Results of the first and the second tensioning operation of the 9th stay cable.

Fig 6 also shows the stress in the first re-stressed strand of the *9th* stay in the *35th* construction stage. As all the stays were placed and the temporary supports were unloaded and removed from the model in the preceding construction stages. This structural system remains constant throughout the re-stressing stage. When all the strands have been re-stressed, the stress of the first strand is reduced 1.70 MPa respect to its value when re-stressed. The increment of axial force along the re-stressed stage is 12.5 kN, which is the 5.2 % of that axial force introduced by the jack.

The comparison of the reduction percentages of the stress in the first strand obtained in the *1st* and the *35th* construction stages showed that lower reductions of stress were calculated when the stay is re-stressed. This can be explained by the fact that in the re-stressing stage the axial force introduced by the jack is lower as well the structural system of the bridge is stiffer as all the stays were placed in the preceding stages.

5 CONCLUSIONS

This paper presents the first algorithm, the Forward-Direct Algorithm (*FDA*), to include the effect of the time-dependent phenomena into the simulation of cable-stayed bridges built on temporary supports. This algorithm includes the following assumptions: (1) Forward simulation approach, (2) Application of the superposition of stages principle. (3) The Objective Service Stage (*OSS*) is defined in terms of axial forces in the stay cables to achieve the behavior of a continuous beam in the deck. (4) All temporary supports are removed before the last re-tensioning operation. (5) Stay cable forces are simulated by imposed strains.

The main innovation of the *FDA* consists of introducing the time-dependent phenomena effects into the unstressed length of the stays concept to calculate the prestressing strains to be introduced during the last re-tensioning operation. The application of the unstressed length concept has major advantages during the simulation (as the achievement of the *OSS* can be assured without any overall iterative process)

and during service (as time-dependent phenomena effects might be considered during erection).

To validate the results of the *FDA*, a cable-stayed bridge is analyzed. The results of this example showed the important role of time-dependent phenomena in cable-stayed bridges. A detailed analysis of the optimum time to define the *OSS* will be addressed in the future.

Design of Pergola Structures for High Speed Rail Bridges

A.P. Ranasinghe
Jacobs Engineering, New York, USA
E.G. Honarvar
Jacobs Engineering, New York, USA

ABSTRACT:

Pergola structures also known as elevated slab structures are used in rail bridges where the rail alignment crosses over features such as roads and rail tracks at very large skews. These structures have become quite useful and popular in high speed rail projects where the track alignment is such that the avoidance of large skews is not possible. A pergola structure consists of two lines of several multi-span frames spanning the features crossed. In each multi-span continuous frame, standard precast pre-tensioned concrete (PC/PS) wide flange girders or for shorter spans PC/PS box girders placed in the transverse direction support a concrete deck slab that carries the guide way. The transverse girders are supported by two longitudinal reinforced concrete or post-tensioned edge beams. Each edge beam is supported by single columns through a pinned connection or a bearing. In this paper, the design requirements of track structure interaction analysis required in high speed rail structures are explained. Also steps taken to design the pergola structures in order to comply with the tight design criteria are discussed. Design details such as the edge beams, joints between pergola frames and transitions from pergola structures to other superstructure types are provided.

1 INRODUCTION

Pergola structures also known as elevated slab structures are used in rail bridges where the rail alignment crosses over features such as roads and rail tracks at very large skews. These structures have become quite useful and popular in high speed rail projects where the track alignment is such that the avoidance of large skews is not possible.

A pergola structure consists of two lines of several multi-span frames spanning the features crossed. In each multi-span continuous frame, standard precast pre-tensioned concrete (PC/PS) wide flange girders or for shorter spans PC/PS box girders placed in the transverse direction support a concrete deck slab that carries the guide way. The transverse PC/PS wide flange girders or PC/PS box girders are supported by two longitudinal reinforced concrete or post-tensioned edge beams. Each edge beam is supported by single columns through a pinned connection or a disk bearing.

In this paper, the design requirements of track structure interaction analysis required in high speed rail structures such as deflection, frequency, and acceleration are explained. Also steps taken to design the pergola structures in order to comply with the tight design criteria are discussed. Design details such as the edge beams, joints between pergola frames, transverse girder supports, and transitions from pergola structures to other superstructure types are provided. These design details provided can be quite useful in the construction, operation, and maintenance of Pergola Structures used in High Speed Rail Bridges.

Figure 1 shows a typical Pergola Structure with Box Girder Approach Structures.

Figure1. A Typical Pergola Structure with Box Girder Approach Structures

2 PERGOLA MODEL

The superstructure of pergola frames, including the deck and transverse PC/PS girders can be idealized in the FEM using a Grillage Model, as exhibited in Figure 2. In the Grillage Model, a grid of transverse and longitudinal beam elements characterizes the concrete deck slab. The columns and drilled shafts are modeled using beam elements placed at the center of gravity of these structural components.

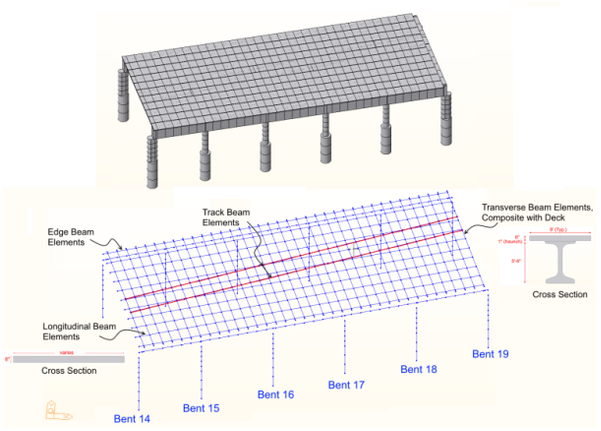

Figure 2. Finite Element Model of the Pergola Structure

The details of the Grillage Model are shown in Figure 2. In the transverse direction, the grillage members coincide with the centerlines of transverse PC/PS girders. The stiffness of transverse beam elements accounts for the composite action between the girder and deck. The deck slab behavior in the longitudinal direction is captured by placing longitudinal beam elements (cross beams) at appropriate spacing. The longitudinal beams are the same as the deck with zero weight.

In order to perform live load analysis, dummy beam elements with an infinitesimal stiffness and zero weight are employed to model track path along the bridge.

Soil-structure interaction was modeled using p-y curves along the drilled shafts.

3 TRACK STRUCTURE INTERACTION

Track Structure Interaction (TSI) Analysis is necessary to limit deformations and acceleration of Track Structure Interaction critical structures subjected to high-speed moving trains. To this end, the TSI analysis shall conform to the following design requirements: frequency analysis recommendations, track-serviceability limits, rail-structure interaction limits, and dynamic structural analysis limits.

3.1 *Frequency Analysis*

Using the Eigenvalue analysis in the FEM, the natural frequency of the primary modes of deformation of the Pergola Structure is determined. The calculated frequencies in the vertical, transverse, and torsional direction are compared to the corresponding values recommended by the design criteria to ensure well-proportioned structures and minimize resonance effects. For the pergola section, as the transverse span length is the dominant mode, the frequency limits were determined using the transverse span length.

3.2 *Track Serviceability Analysis*

The primary objective of the serviceability analysis is to limit track displacements due to structural deformations. The deformation limits are based on maintenance requirements, passenger comfort, and track safety standards. The vertical and transverse deflection limits are determined as a function of span length. However, the definition of the span length is unclear when a bridge frame consists of both transverse and longitudinal spans, as does the pergola section. Therefore, these limits are calculated for both of the minimum longitudinal and transverse span length of the pergola frames. Using the longitudinal span lengths result in the smaller defection limits compared to the limits calculated based on the transverse span lengths for the pergola frames. Since the deck is directly supported by the transverse girders, it is deemed more reasonable to define the deflection limits using the transverse span length rather than using the longitudinal span length.

In addition to vertical deflections, the rotation limits about transverse and longitudinal axis, relative vertical and transverse displacement at expansion joints, and the deck twist are checked.

3.3 *Rail Structure Interaction (RSI) Analysis*

Railway bridges and continuous welded rail constantly impart forces on each other due to their distinct responses to the applied loads. The structure loads, which are transferred to and from the rails through fasteners, increase the probability of rail fracture. Therefore, the values of relative displacements between two adjacent frames at expansion joints and rail axial stresses are evaluated using RSI analysis. The calculated values shall be lower than the limits specified by the design criteria to minimize the probability of rail fracture.

The RSI analysis will be performed using the Rail-Track Analysis Model available in the Midas Civil software, which is incorporated into the FEM described earlier. In RSI analysis, the specific construction method and construction sequence in addition to time-dependent deformations caused by prestressing, creep, and shrinkage will be considered.

The interaction between the rail on the bridge and the adjacent rail on the embankment is captured by ample rail extension to the embankments beyond the abutments. The rail extensions terminate at a perfectly plastic longitudinal spring supports. Force accumulation in this spring will be examined to validate the length of rail extension and must remain less than 39.7 kips typically.

The interaction between the rails and superstructure is represented by coupling springs along the length of the model (superstructure and embankment). Throughout the entirety of the FEM, springs representing the tie fasteners will be spaced at a maximum of 10 ft. Tie fastener spacing is assumed to be 27 in. across all project structures. Linear springs are used to account for the vertical and lateral stiffness, while bi-linear spring represents the longitudinal stiffness. The bi-linear longitudinal restraint accounts for force accumulation and displacement in the rail fasteners before rail slip occurs. Typical values for the longitudinal restraint is 1.37 kips per foot of track (unloaded) and 2.7 kips per foot of track (loaded) for non-ballasted track at the yield displacement of 0.02 in.

After completing the RSI analysis, if the relative displacement and axial stress limits given in the design criteria could not be met at the expansion joints, alternatives to connect and reinforce adjacent joint interfaces would be explored. As a commonly used alternative, longitudinal dowels or steel pipes may be used at the joint interfaces to reduce relative displacements and axial stresses, thereby satisfying RSI analysis requirements. The longitudinal dowels or steel pipes would allow for relative rotation about transverse axis and displacement in the longitudinal and vertical direction, but restrain the remaining degrees of freedom.

3.4 Dynamic Structural Analysis

Dynamic structural analysis is performed to assess the interaction between the bridge and all potential high speed rolling stock options and limit vertical deck acceleration. In particular, the occurrence of maximum dynamic amplification effects due to resonance is investigated by comparing the bridge's natural vertical frequency and the frequency of axle loading.

3.4.1 *Resonance and Cancellation Speeds*

The FEM is used to determine what vehicle speeds correspond to both resonance and vibration cancellation. If the resonance speed is close to the vehicle operating speed and substantial deflections occur, an alteration of the superstructure properties may be necessary.

3.4.2 *Determination of Vertical Impact Factor*

Using the dynamic analysis, dynamic live load vertical deflection, shear, and moment will be determined. The vertical impact factor imposed by the high-speed trainset is then calculated by comparing ratios of each dynamic load response with the corresponding static response. The maximum ratio will be the vertical impact factor used for the high-speed rail vehicle live load.

3.4.3 *Vertical Deck Acceleration*

The vertical deck acceleration limit is in place to ensure safety and passenger comfort. Typically for non-ballasted track bridges, the maximum deck acceleration is limited to 16.1 ft/s2(0.5g).

4 DESIGN ISSUS

4.1 *Design Issues Related to RSI*

Some of the step taken in order to comply with the tight design criteria for deflection, frequency, and acceleration to design the pergola structures are as follows:

4.1.1 *Reducing the Deflections*

The For high speed rail the live load deflection limit for passenger comfort and track maintenance is very stringent. The span to live load deflection ratio for this can be as high as 3500. The deflection can be reduced by using deeper girders and reducing the girder spacing. However, lighter girders are preferred as an increased superstructure mass can have an adverse effect on the natural frequency.

4.1.2 *Increasing the Natural Frequency*

The natural frequency can be increased by increasing the depth and the concrete strength of the girders.

4.1.3 *Reducing the Deck Acceleration*

The deck acceleration can be reduced by taking advantage of the composite action between the guideway and the deck. Figure 3 shows the guideway and the deck that will act together compositely.

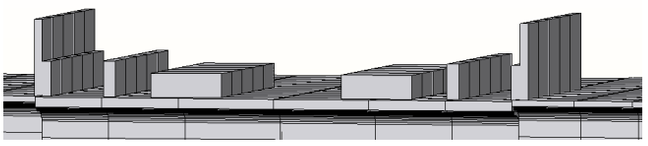

Figure 3. Typical Section of the Guideway and the Deck

4.2 *Other Design and Construction Issues*

Some design and construction issues are as follows:

4.2.1 *Edge Beam Support Condition*

In some pergola designs, the edge beam is supported on the pergola column directly. They are connected together with a small vertical steel I-beam. There are concerns however, that the concrete around the I-beam tends to crack over the years. The use of disk bearings placed on the pergola columns to support the edge beams is considered an expensive, yet a better solution. Figure 4 shows a disk bearing supporting an edge beam.

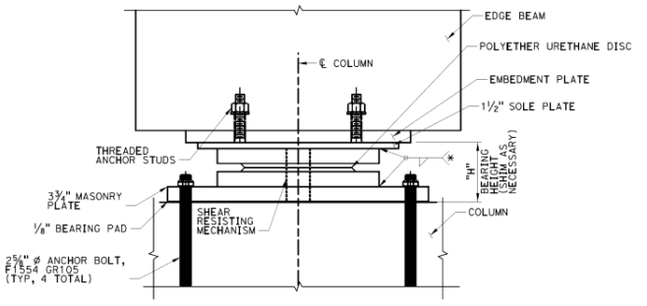

Figure 4. A Disk Bearing Supporting the Edge Beam

4.2.2 *Transverse Girder Connection to the Edge Beam*

Since the transverse girders are pre-stressed concrete girders, they are connected to the edge beams as simply supported. Figure 5 shows the typical interior girder elevation with the connection of the girder to the edge beam.

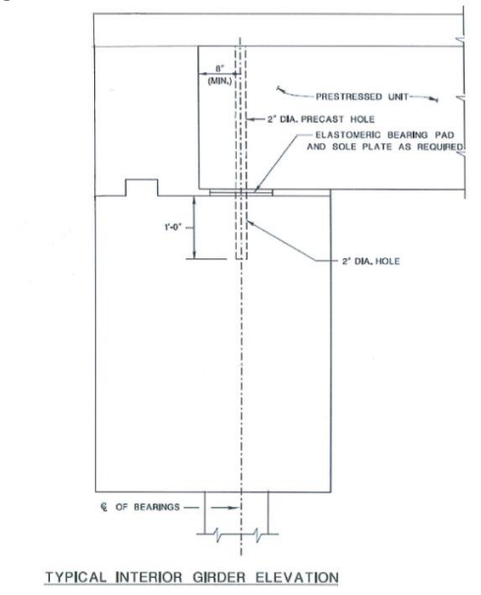

Figure 5. Girder Connection to the Edge Beam

4.2.3 *Joints between Pergola Frames*

The joints between the pergola frames should transfer no moments and should allow the pergola frames to move in the longitudinal direction independently. Figure 6 shows a pipe type connection and a link type connection. The pipe type connection is hard to build and cost effective but its long term performance is questionable. A link type connection is expensive but its long term performance is better than a pipe connection.

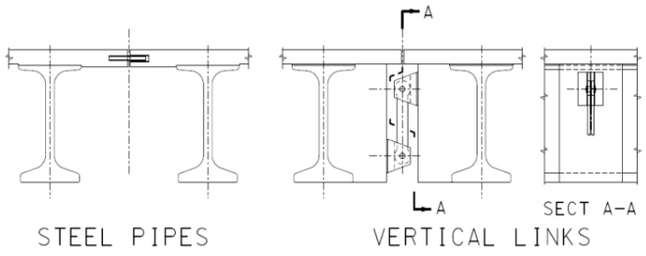

Figure 6. Connections between Pergola Frames

4.2.4 *Transition from Pergola Section to Approaches*

When there are right-of-way limitations, or utility conflicts the two edge beams of a pergola frame may not be of the same length. This often happens at the pergola frames near the approaches. In situations like this, if the approaches are box beams the box beam is cantilevered from the edge beam thus maintaining the continuity of the guideway. Figure 7 shows the transition of the pergola section to a box beam approach.

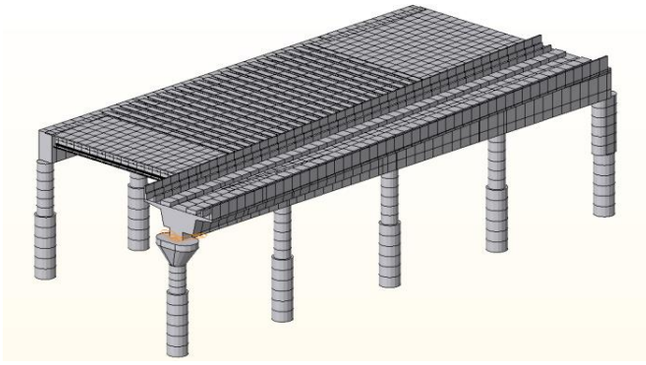

Figure 7. Transition from Pergola Section to Approaches

5. CONCLUSIONS

The methods suggested in this paper will help the designer to comply with the tight design criteria required for high speed rail bridges. Also, the additional design details provided will be very useful in the construction, operation, and maintenance of pergola structures used in high speed rail bridges.

How new performance based contracts add value in maintenance contracts

J. D. van der Walt
Assistant Lecturer, University of Canterbury, New Zealand

Dr. E. Scheepbouwer
Director Construction Management Programme, University of Canterbury, New Zealand

ABSTRACT: Public agencies in charge of maintaining highways and bridges walk a fine line between cost and quality. Recently the New Zealand Transport Agency (NZTA) has adopted many changes in their procurement methods to obtain greater value for money. The new Network Outcomes Contracts (NOC) have been set up to invest where needed and give more control to the agency. This research investigates how the use of the NOC contracts influenced the quality of the assets and whether this resulted in value creation or not. It is concluded that NOC contracts take a more long-term vision approach. However, some assets were arguably kept at too high level of service; a situation that allows present reduction in expenditure. In this paper, qualitative data have been used to identify lessons learned to date. This can assist agencies and contractors in their continued drive to improve outcome based contracts, creating value in the long term.

1 INTRODUCTION

As highway agencies are accountable to the public, delivering value has become an important issue politically. Maintenance regimes from highway agencies inevitably balance the cost of maintenance against the level of service. After years of operating performance based arrangements, the agency has opted for a change towards Network Outcome Contracts (NOC). Both contracts are applicable for the maintenance of highway assets (Zietlow, 2005). The former Performance-Specified Maintenance Contracts (PSMC) used a, '*best for asset'* approach. Contractors were reimbursed for performed work, but carried the majority of the risk. Over the years this approach has led to an increase in the level of service. Higher levels of service do not intrinsically translate to increased value, and recently the NZTA has opted to change towards an arrangement that focused more on providing value. Its goal was to decrease the cost while maintaining the quality of their assets. This paper discusses the differences between both methods with regards to the strategic goals of NZTA, how these goals are achieved and what concerns have been raised. Both PSMCs and NOCs will be discussed after which details on the new approach will be provided.

1.1 *Objective*

Aim: Investigate how the use of the NOCs influence the asset quality and whether this constitutes value creation over previous methods.

Scope:

- This will be a qualitative study as there is limited long term data available due to the recent implementation of NOCs.
- The focus is on experts in the industry who have had first-hand experience with NOCs.
- This study includes expert parties from client (transport agency), consultant, contractors and sub-contractors.

This study has been conducted in New Zealand, therefore is limited to the New Zealand context. However, the results can serve as an indication to other nations with similar contractual arrangements.

1.2 *Literature Review*

There are several business models that have been used in the past. The traditional equipment-based service model is centred on reimbursement of work and materials to meet standards. Cost of labour, equipment, maintenance and consultation for activities on highways and bridges were traditionally billed as a lump sum, once the activity was completed (Wheel, 2000).

Another approach is the cost-plus model. In this case a customer is provided with a detailed structure of prices for equipment, labour and consultation. Both parties agree on a fixed profit percentage to be added to the actual costs (Kim, Cohen, & Netessine, 2007).

Various types of performance-based contracts have been used for several decades in many European and Australasian countries (DeWitt et al., 2005). These contracts aim to refocus the industry, to measure performance instead of specification compliance (Mike Manion & Tighe, 2007).

Performance-specified maintenance contracting (PSMC) and its potential application to the international market has been extensively discussed by Gransberg et al. (Gransberg, Scheepbouwer, & Tighe, 2010). The traditional PSMC moves the focus from '*minimize cost*' to '*maximize value*'. The evolution of this produced the hybrid PSMC. This contract lets the owner hold control of the design contract, however allows the contractor to give significant input through Early Contractor Involvement (ECI) (Zietlow, 2004). This contract allows the contractor to offer alternatives that the design consultant can warrant (Porter, 2001).

Maintenance alliance contracts are normally reserved for the maintenance of large public works. Primarily, it is a way to share risks for major transport arteries on dedicated networks. Alliances have taken up many of the principles introduced by PSMC including working to deliver maximised value and ECI (Botha & Scheepbouwer, 2015; Scheepbouwer & Gransberg, 2014).

Outcome based contracts as a new business model has been increasingly discussed within the commercial and academic world (Ng, Ding, & Yip, 2013; Wirtz, Pistoia, Ullrich, & Göttel, 2016). The need for effective new business models are driven by three key components:

1) Value drivers are often an important factor for organizations. Therefore, when a change in value drivers is present, a need is created to change business model.
2) When value drivers are changed an organization's performance during this time is highly scrutinised to see if key outcomes are compromised.
3) Change in value drivers can result in partnerships changing, requiring new innovative agreements to be reached.

Outcome based contracts have evolved from these principles to focus on the holistic outcomes of assets rather than the resources required for a single asset (Lee & Barrett, 2003). Outcome Based contracts have the following goals:

1) Align both parties to the outcomes of a product or service.
2) Shift shared risk back to the client, increasing responsibility of the client.
3) A party that can attain best outcome results from both interior and exterior connections and collaborations, is more able to exceed expectations.(Ng et al., 2013)

Outcome based contracts draw from the classical approaches and trends seen in recent years. Moving the contractor closer to the client. Outcome based contracts also change the focus from *'value of asset'* to *'value of network'* perspective.

1.3 *Network Outcomes Contracts with Asset Management*

The introduction of NOCs was the conclusion of a process that was initiated by the need to find ways to reduce cost (a change in value drivers). The New Zealand Transport Agency undertook three years of investigation to meet this demand. NZTA identified multiple opportunities. Firstly, the NZTA identified that more work needs to be conducted by the agency instead of handing this off to an external supplier. This is particularly important in the fields of decision making and customer service. Secondly, move away from a risk adverse management culture therefore taking on more shared risk in the contract. This could result in reduced cost. Thirdly, introduce better methods to estimate Net Present Value as the current system was not applied consistently. Finally, investigate new methods to understand the risk of flat budgets limiting the amount of renewals undertaken. Following this investigation, the NZTA after considerable consultation introduced the NOC system to implement these changes (M. Manion, nd).

1.4 *Changes to Managing Assets*

At its core, the NOC is an outcome based contract and pursues a quality outcome. The NOC does not specify the methods of how the outcome is achieved, but does specify the performance measures to show that a quality outcome has been reached. Outcome based contracts have drawn from traditional performance based, alliances and hybrid contracts with a change of focus. The contractor retains the risk of the supply chain to build/maintain quality assets. The method of how the contractors establishes the cost for achieving a quality outcome is up to them (NZTA, 2015).

From the literature review and contract documents the following key elements will change in how assets are managed. Firstly, NOCs payment contain both measure and value and lump sum components. Secondly, the contractor is responsible for

managing the general condition of the asset, so that it remains serviceable and safe. The contractor must estimate the amount and type of repairs and approximate the cost of delivering them to the specified performance measures in the contract. Thirdly, the contractor must make provisions to achieve these performance measures in a lump sum component. Failing to provide the required level of performance will result in a financial penalty. However, suppliers who manage renewals investment below a target quantity are rewarded (M. Manion, nd; NZTA, 2015).

Like in previous methods, contactors are still able to seek variations to rates if quantities differ substantially from those listed in the schedule of prices. This is if they can sufficiently demonstrate a material effect from the quantity change. It is then up to the contractor to show that quantity has changed and that this has had a material effect, otherwise the rates as tendered remain for the increase of quantity (NZTA, 2015).

2 METHODOLOGY

The methodology of this research has consisted of gathering and analysing literature on the challenges faced and decisions made by NZTA. As well as this, an in-depth document study of the NOC has been completed to understand the methods and reasoning.

There is limited long-term maintenance data available on the NOC contracts due to their recent introduction, therefore this study instead will focus on a qualitative approach through structured interviews. Standardised questions were prepared which focused on key aspects of NOCs and the assessment of value. Interviews with representatives from the delivery teams, clients, contractors and other persons of interest were conducted. Results from these interviews have given insight on how the industry perceives the value of NOCs as well as insight into the operational character of the procurement system. Their expert opinion will form the basis of the results in this paper. This study surveyed from the sub categories in Table 1.

Table 1.Table showing subcategories of parties interviewed

	Client (Agency)	*Consultants*	*Contractor*	*Sub-contractor*
# of experts interviewed	3	3	3	2

3 RESULTS AND ANALYSIS

In this section, the opinions of the different parties will be stated. Each section contains a table that captures the opinions of the consulted experts with a continued discussion of the points. At the end of this section the results will be summarized.

3.1 *Client's Point of View*

The client's argument from the start has been around cost savings. From discussion with client representatives, NOC contracts aim to force contractors to be more effective in their management programs as the new contract will significantly limit maintenance funds. The contractor must offset this change with a smarter strategic maintenance strategy. The focus has been to prove value, as previous systems in place did not achieve the desired result. Before maintenance is allowed the contractor must comply with new more rigorous specifications to demonstrate value.

Table 2. Client, showing key factors that drive value and potential issues from the implementation of NOC in New Zealand.

Factors driving value for the Client (NZTA)	*Potential issues for the client (NZTA)*
• *Reduce cost* • *Results are more in line with desired outcomes* • *Increased co-operation* • *Drive strategic forward work planning* • *Sustainably of the industry is increased* • *Better understanding of customer behaviour* • *Performance measures drive quality* • *KPI and KRA show improvement* • *Upskill the industry* • *Industry adapting to holistic focus* • *Change in business model for the industry*	• Increased risk to the client • Require large increase in personnel • Potentially higher cost due to outsourcing and limited numbers of sub-contractors • Increased dissatisfaction from the public • Some performance measures are not realistic or effective in driving value and requires further work • Large amounts of resources required to implement NOCs • Communication with the public

The NZTA recognises that the implementation of the NOC will take time. Relevant staff and personnel must be retrained to work effectively with the new contract. Much effort has been put into establishing clarification of new terms in the contract.

An important part of the NOC is the inclusion of a clause specifying that a large proportion of work must be conducted by sub-contractors. This forces a substantial amount of funds back into the community and stimulates small business growth.

Large contractors are using their learnings from earlier contracts to minimise first year difficulties with NOC contracts. This shows the industry adapting to the new environment.

NOCs in South Canterbury, New Zealand show great improvement. They have moved from poor to outstanding due to more rigorous reporting and

communication. In general, the NZTA is reporting steady state or improvement in key areas.

NZTA reports that it has gained a better understanding of customer behaviour, and this has led to an improvement in efficiency. For example, more regular litter collection has been implemented outside of fast food restaurants. Another example includes more regularly cleaning graffiti from bridges. Both examples resulting in visually cleaner assets.

Looking ahead, NZTA representatives noted that NZTA is moving its focus from implementation to delivery and performance of the NOC contracts. This requires auditing that has not been well-established. Auditing this type of contract has presented several difficulties which they are working through currently.

3.2 *Contractors' Point of View*

Due to the decrease in funds and reduced control by the contractor, there is speculation within the construction industry that these changes will result in reduced level of service over time. Therefore, this could result in the inevitable rise of maintenance cost in the far future.

Severe weather events can result in the contractor losing a significant amount of income because of unexpected maintenance. This can put pressure on an already streamlined lump sum budget. With extreme weather events set to increase in the coming years this may not be a once off issue.

Meeting performance levels under extreme financial pressure is difficult. If contactors do not meet these levels of performance they are then also financially punished.

If certain assets are maintained to too high a standard, it can result in NPV issues for the rest of the network. Contactors must be careful in spending available funds as they are required to prove a network performance outcome.

Contractors speculated that some of the KPIs & KRAs require excessive resources which does not result in value. Contractors are pleased that NZTA has recognised this and are working on reforming the KRA & KPI framework.

All contracts agree that the NOC has put more pressure on their forward work program. They have been forced to innovate, especially to justify in terms of value. Contractors are forced to operate a much leaner program only conducting work that is absolutely necessary. An example of this is the heavy reliance on the ratio of defects over area to justify NPV.

To implement the new framework, the contract requires multiple parties to communicate from the NZTA. Previously contractors generally have had to deal with one point of call, instead now with the NOC framework, contractors are required to communicate with four and above personnel from the agency. Some contractors have indicated that this communication process is slowing performance and is not driving value.

Table 3. Contractor, showing key factors that drive value and potential issues from the implementation of NOC contracts in New Zealand.

Factors driving value for the primary Contractor	*Potential issues for the primary Contractor*
• *Decreased maintenance cost.* • *Longer contact period roughly 7 years. Allows for forward work planning and investment.* • *Larger area contracts* • *Increased in quality of work delivered* • *Requires the contractor to innovate to remain competitive* • *Potential gain if performance criteria are reached* • *Multiple parties are available from the NZTA when problem arise* • *Drives the industry forward as everyone is working for outcomes* • *Driver collaboration between client, consultant, contractor and sub-contractor* • *Drives sustainability of the industry* • *Drives better educational resources to train external industry*	• Reduced monetary value can appear as a potential loss of profit • Anxiety that less spending and less control by the contractor will result in a potential decreased level of service • Scope creep can become a real issue • Financial penalties if the contractor does not meet criteria • Events outside of the contractors control could significantly influence losses and gains • Lump sum portion of the bid requires extreme foresight, this can result in cost overruns and low margins • More communication is needed with different parties in the NZTA slowing progress and hindering performance • Contractors can be punished for keeping the asset in elevated condition. The rest of the network may be neglected • This might not be the best model for the public • Sub-contractors are, "hit and miss" in terms of quality and performance • Increased risk when using sub-contractors • Uncertainty of how handover will occur after the end date of the contract

Contractors must revolutionize the systems they use. Great efforts and resources are being invested into further development of techniques to preserve asset life for a low cost. An example of this is the 1st Signs approach to maintenance (M. Manion, nd).

Cooperation between the agency, contractor and subcontractor has become vital to success under the NOC contracts. The inclusion of a high proportion of subcontractors in the NOC has forced the principle contractor to increase H&S and environmental training to minimise risk.

3.3 *Consultants' Point of View*

Some consultants are expecting reduced quantity of work as NZTA is conducting much of the decision making and consumer service in house. NZTA has recently hired many new staff to support these contracts. Contractors have also taken a large proportion of the responsibility from the consultants.
Consultants, have been asked by contractors to develop methods and systems to support these new contracts.

There was a push from contractors to allow them to exclude consultants and allow much of the work to be completed in house. The NZTA disagreed as this would not provide value in terms of sustainability of the industry. Therefore consultant-contractor partnerships are still present, preserving some work for the consultant. The consultant has now moved to take up a supportive role for the primary contractor.

Table 4: Consultant, showing key factors that drive value and potential issues from the implementation of NOC in New Zealand.

Factors driving value for the Consultant	*Potential issues for the Consultant*
• *Consultant – contractor partnerships are still maintained* • *Higher standards of H&S, auditing and reporting* • *New need for engineering development and research* • *Quality work*	• Reduced decision-making work for the consultant • Loss of capability in the industry through consolidation • Increase of quality of work but a potential decrease of level of service

Consultants believe that there has been a loss of capability of the industry through consolidation caused by the formation of NOCs.

3.4 *Sub-contractors' Point of View*

The requirement of a high proportion of sub-contracted work in the NOC has led to the general unavailability of sub-contractors. This is particularly the case for local councils as the larger contracts offered by the primary contractor of the NOC are more appealing. This has led to councils struggling to find suitable sub-contractors to complete work. There has also been an increase in the average bid price due to the lack of competition in some cases. This could be a possible temporary side effect as more sub-contractors move into this space and restore competition. The sub-contractors reported that their business model has not changed under the new NOC contract, 'business as usual'.

Sub-contractors have reported that much more rigorous training is available to conduct work, especially in the areas of health and safety, environmental impact and forward work programming.

Table 5: Sub-contractors, showing key factors that drive value and potential issues from the implementation of NOC in New Zealand.

Factors driving value for the sub-contractor	*Potential issues for the sub-contractor*
• *Increased sub-contractor involvement* • *Increased amount of work given to sub-contractors* • *Increase training of sub-contractor staff* • *Possible gap in the industry for the formation of smaller contracting businesses* • *Higher standards of sub-contractor training* • *Taking on more diverse tasks*	• Sub-contractor's quality and standards and training differ greatly • Speciality sub-contractors could see number of jobs decrease • Lack of sub-contractor competition therefor increasing bid price for client

3.5 *Comparison and Discussion*

The introduction of the NOC contracts has been relatively well received by contractors, consultants and sub-contractors. It became clear that the previous contracting methods were not achieving the desired outcome for the NZTA. This need was driven originally by the financial crisis to reduce costs but has developed into a change that the industry needed. Over multiple years of consultation the NOC contract was introduced. Contractors and consultants felt that this contract has been long in the pipeline and they have had sufficient time to be consulted.
From the results, it was evident that NOC has clearly driven the industry in the direction that the agency wanted. This is evident by contractors reporting significant pressure on managing their forward work program with large oversight from the agency. Contractors have also felt the impact from the new value requirements. They have reported that it has become much more difficult to justify maintenance, driving value.

The NOC has introduced significant changes in communication and reporting. Results have shown that communication has driven value from the agency's point of view. However, contractors have insisted that communicating with multiple agency representatives have slowed down progress and is hindering value creation.

The consultants' view is that the primary contractor was previously not exposed to the agencies demands. Previously it was the consultant's job to act as an intermediary. With the NOC, the link between contractor and client has been narrowed exposing the contractor to more agency points of call.

Table 6. Comparison of opinions from the four affected parties: client, contractor, consultant and sub-contractor

NOC Driver (Client)	Principal Contractor	Consultant	Sub-contractor
Pervious method not producing ideal outcome	*Agree*	*Agree*	*Indifferent*
Need for change to NOC	*Agree*	*Agree*	*Agree*
Enhanced communication requirements drive value	*Does not agree, can slow down processes*	*Agree*	*Can slow down progress*
Performance measures leads to improved procedures and quality work	*Mostly*	*Mostly*	*Agree*
Reduce cost while maintaining current LoS	*Does not agree*	*Does not agree*	*Indifferent*
Enhance sustainability of the construction industry	*Agree, More training*	*Agree*	*Increase in the number of jobs*
Communicated changes with the public	*Does not agree, improvement needed*	*Does not agree, improvement needed*	*Indifferent*
Impact to business	*Large impact to procedures and business model*	*Loss of work*	*Increase of work*
NOC is an enhanced contracting method for the foreseeable future to boost value	*Agree, requires further review from Agency*	*Agree, requires further review from Agency*	*Agree*

The NOC has had the largest impact on the client and contractor, whereas the consultant and sub-contractor has felt less of its effects. The contractor has had to invest large amounts of resources into training and personnel to deal with the new terms of the NOC contact. This has also been the case for the agency. The consultant has moved to a supporting role and the sub-contractor has seen a significant increase in the amount of work as a direct result of the implemented NOCs.

The intention of the NOC to upskill and grow the larger construction industry appears to be working. The results from this paper suggest that the primary contractor is investing a significant amount of resources into the training of sub-contractors. The sub-contractors have reported that this training was improving their performance in key areas.

Some contractors are apprehensive that less spending and reduced control by the contractor will result in a decreased level of service compared to previous methods. It is the contactors' impression that NZTA has recognized this. Some contractors believe that changes in level of service due to NOC should have been better communicated with the public.

The intention of the agency was to decrease cost while maintaining quality. The implementation of strict performance measures was intended to achieve this. Some contractors and clients argue that this has resulted in an increased quality of work completed. However reduced funding could result in a decreased level of service provided to the public overall. There is speculation within the industry as to whether the current form of the NOC is of best value to the public.

Although the results of the paper show many potential issues, most parties interviewed agree that these issues can be mitigated or resolved with further implementation changes. NZTA has shown they are willing to listen to criticism and make changes. An example of this is where contractors criticised the current KPI and KRA framework used in the NOC. NZTA has responded and is currently re-evaluating the framework. All parties seem to agree that this change in procurement method is to the benefit of the client and will drive value.

4 CONCLUSIONS

Transport agencies are under increasing pressure to reduce cost and provide value for the taxpayer. In New Zealand, NZTA is under pressure from the Ministry of Transportation to reduce maintenance cost. However, maintaining assets is a balance of cost and quality. NZTA must find methods to retain quality in the face of cost savings. NZTA has introduced Network Outcome Contracts in a response to this pressure. These contracts fundamentally change how maintenance is completed in New Zealand. NZTA is taking onboard much of the decision-making process previously outsourced to consultants. The industry is optimistic about the implementation of NOCs. Overall affected parties agree that NOCs are the way forward for the industry. However, the industry is anxious that less spending and less control by the contractor will result in reduced levels of service over time. The industry also fears that possible short-term cost savings could result in long term cost. However, the industry agrees that with continued review the NOC will be a very successful framework for value driven maintenance compared to the previous method. This is echoed by the NZTA, where continuous auditing is now the main driver to improve the performance of these newly introduced contracts. The ideal outcome is a balance

between minimum investment in quality by the asset owners and minimum required repair needed by the maintaining party. As time goes on, an increasing amount of quantitative data will become available. Further research is required to ensure that value is continuously improved for the client and the taxpayer.

Design method for scissors-type bridges

Y. Hama, I. Ario and K. Adachi
Department of Civil & Environmental Engineering
Hiroshima University, Higashihiroshima, Japan

ABSTRACT: Many natural disasters destroy infrastructure such as roads and bridges. It therefore becomes essential to restore them to serve as a refuge and help disaster victims. Several emergency bridges are often used for the restoration of these lifelines. We propose "Mobile Bridge" based on the concept of origami engineering as an emergency bridge that is smarter than existing emergency bridges. In this paper, the concept of influenc line diagrams into design of scissors structure is introduced for the firs time. This result revealed the basics of a design of SCI having the scissors structure that acted the moving load including a vehicle and a person. In addition, the rational reinforcement method of a bridge with a scissors structure and superiority is considered, as opposed to the double Warren truss structure that is used as a current emergency bridge and scissors structure.

1 INTRODUCTION

The damage and destruction to social infrastructure by natural disasters, such as earthquakes, floods landslides and tsunamis, are serious problems in disaster prevention for the inhabitants of a stricken area. In particular, many bridges were damaged by a typhoon No.10 in Hokkaido (shown in figur 1). There are assembling block type of temporal bridge (shown in figur 2(a)) to serve as lifelines after a disaster has occurred. However, they are not based on the design concept of an urgent bridge that can be used quickly to save lives at the stricken area. So we need to develop a new bridge of rescue type to survive victims. In other words, We have to consider how to rebuild damaged infrastructure and how to build a new type of rescue system which can be implemented quickly because time is very important when trying to save lives after an emergency. From a previous study on the optimization structure and deployable structure of bridges by Holnicki-Szulc et al. (2003) and Ario et al. (2006, 2010), we propose a new type of movable and deployable emergency bridge called Mobile Bridge (MB) (shown in figur 2(b)) by Ario et al. (2006) and Chikahiro et al. (2012). This bridge does not need assembling work because it is based on the scissors structure (SCI) consisting of the framework structure of the form 'X' by Ario (2013). A temporary bridge of the double Warren truss structure (DWT) exists in the typical assembling bridge. Two different bridges vary in a cross-linking process, but they become the structures that are apparently similar by equipping the reinforcing members in MB. Therefore, the firs purpose of this study is to confir whether the reinforced SCI can exhibit a greater proof stress than the DWT. The influenc line of the main posture used for the design of the bridge and design load are used for comparing the sectional force in both structures. The second purpose is to build the MB design method using the influenc line suitable for a moving load. As a design concept toward a bridge that is both lightweight and strong, we confir the superiority of MB, compared to a DWT, as the emergency bridge with an SCI.

2 ANALYSIS OF INFLUENCE LINES FOR LOADS

SCI is compared with DWT using each sectional force. The design methods for the sectional force of DWT and SCI are explained in the following paragraph.

2.1 *Influenc line analysis of DWT*

As a truss structure similar to SCI, a model of DWT is shown in figur 3 and explained. The form of DWT is similar to SCI. However, it is a different structural element in terms of structural mechanics. DWT consists only of axial forces (shown in figur 4). In contrast, SCI consists of an axial force, a shearing force, and bending moment. Because it is a statically indeterminate structure, its sectional force is calculated by using the nodal point method and the unit load method. In each nodal point of four corners and the

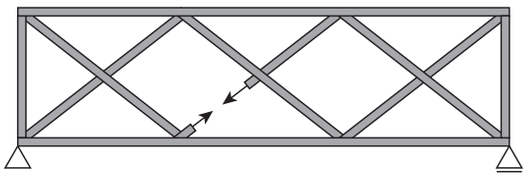

Figure 1: Collapsed bridges by natural disaster in Hokkaido (2016)

(b) Scissors type of bridge (MB2.0)

(c) Structural model of (DWT)

(d) Structural model of (SCI)

Figure 2: Double Warren truss (DWT) and scissors type of bridge (SCI)

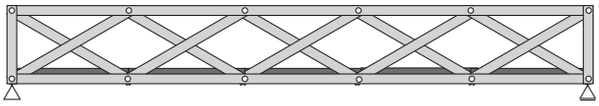

Figure 3: A bridge model of the Double Warren truss (DWT) (5 units)

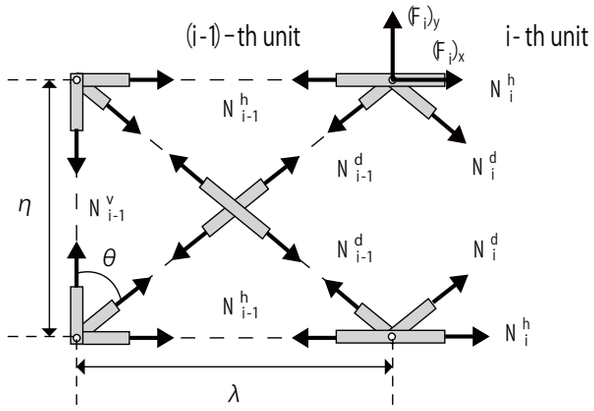

Figure 4: Sectional forces in an units of DWT

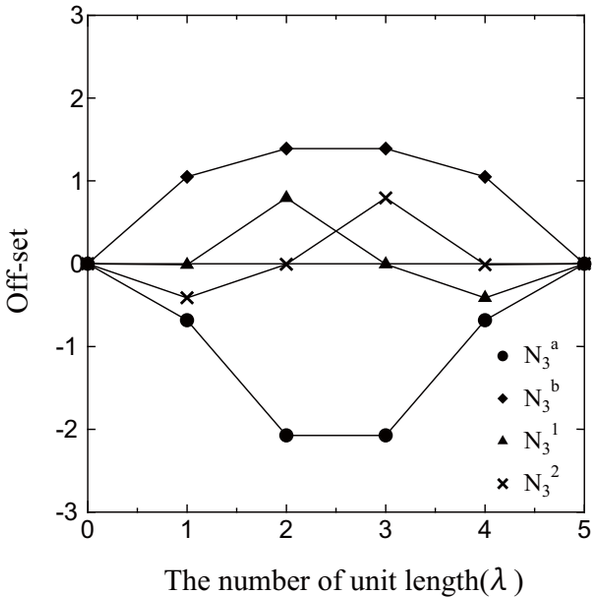

Figure 5: Influenc Line of axial force of 3rd unit (DWT)

pivot of each unit, the equilibrium equations are given by equations (1) and (2). In determining an influenc line, we take into account sectional forces when the unit load ($(F_i)_y = -1$) acts as nodal point external force as offset of influenc line. All influenc line diagrams of each sectional force are obtained by moving the unit load distance λ and repeating the calculation.

$$\begin{bmatrix} 1 & \cos\theta & 0 \\ 0 & \sin\theta & 1 \end{bmatrix} \begin{Bmatrix} N_i^v \\ N_i^j \\ N_i^h \end{Bmatrix} = - \begin{Bmatrix} \pm(F_i)_y \\ (F_i)_x \end{Bmatrix} \tag{1}$$

$$\begin{bmatrix} \cos\theta & \cos\theta & 0 & 0 \\ -\sin\theta & \sin\theta & -1 & 1 \end{bmatrix} \begin{Bmatrix} N_{i-1}^j \\ N_i^j \\ N_{i-1}^h \\ N_i^h \end{Bmatrix} = - \begin{Bmatrix} \pm(F_i)_y \\ (F_i)_x \end{Bmatrix} \tag{2}$$

Here, these letters have the following meanings: i, the number of units; v, vertical member; h, horizontal member; d, diagonal member; and F, nodal point external force. As an example, four influenc lines of the axial force of the members in the third unit of a DWT with f ve units are shown in figur 5. This fig ure shows that the maximum compression axial force occurs in the upper chord member and the maximum tension axial force occurs in the bottom chord member when a downward load acts.

2.2 *Influenc line analysis of SCI*

It is necessary for the nodal forces of the whole SCI structure to be calculated as the firs stage in calculating the sectional forces of SCI. The equilibrium equations of the nodal force and the condition equations of the combination region are given by equations (3) and (4).

$$L_d \boldsymbol{b}_i^L + R_d \boldsymbol{b}_i^R + \boldsymbol{b}_i^C = \boldsymbol{0} \tag{3}$$

$$\boldsymbol{b}_i^R + \boldsymbol{b}_{i+1}^L = \boldsymbol{P}_i \tag{4}$$

Here,

$$L_d = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ -\eta & \lambda & 0 & 0 \\ 0 & 0 & \eta & \lambda \end{pmatrix},$$

$$R_d = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & \eta & -\lambda \\ -\eta & -\lambda & 0 & 0 \end{pmatrix},$$

$$\boldsymbol{b}_i^* = \{(B_i^*)_x, (B_i^*)_y, (A_i^*)_x, (A_i^*)_y\}^{\mathrm{T}}, * = \{L, R\}$$

$$\boldsymbol{b}_i^C = \{(C_i)_x, (C_i)_y, 0, 0\}^{\mathrm{T}}$$

$$\boldsymbol{P}_i = \left\{(P_i^B)_x, (P_i^B)_y, (P_i^A)_x, (P_i^A)_y\right\}^{\mathrm{T}}$$

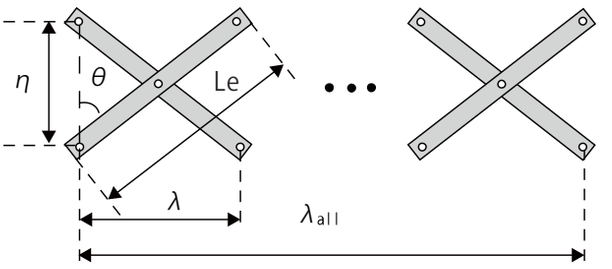

Figure 6: A bridge model of the scissors structure

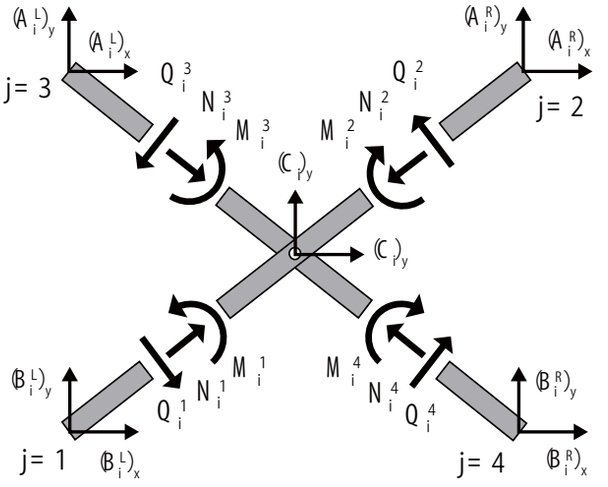

Figure 7: Sectional forces in an unit of SCI

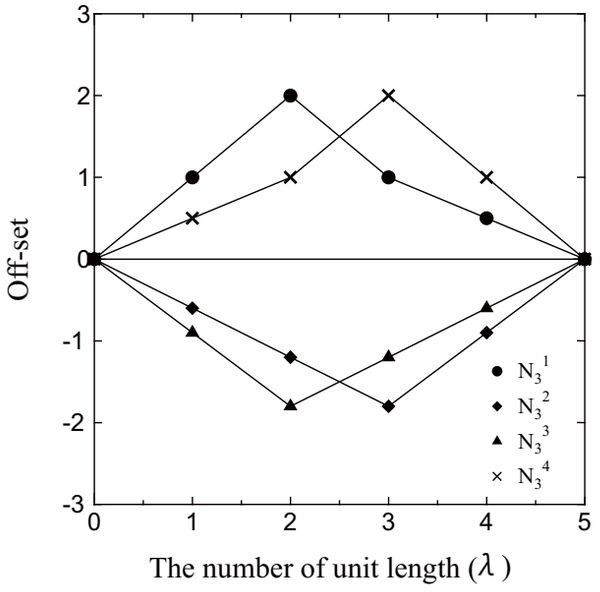
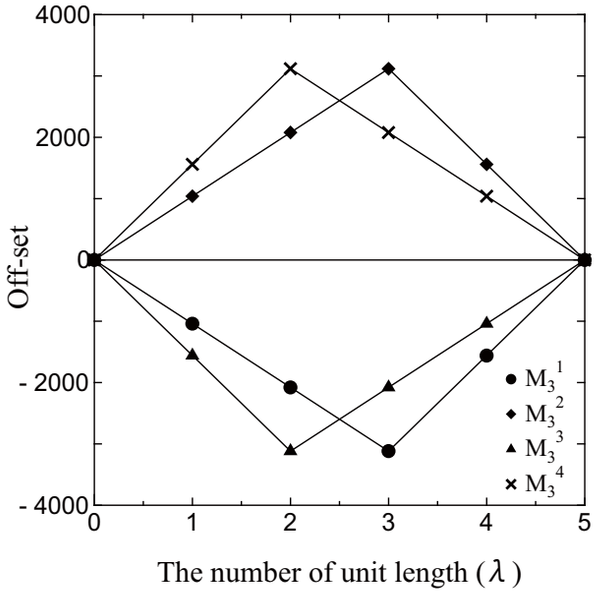


The definition of other letters are similar to DWT and are shown in figur 6. These formulas are derived from the equilibrium equations of nodal forces in the horizontal and vertical directions, as well as the bending moment around the centre point C in a scissors member. Overall, the nodal forces are calculated from equations (3) and (4). In the $i-$th scissors structure, the nodal forces and sectional forces are define as shown in figur 7. The sectional forces of the members such as the axial force, shear force and bending moment are calculated by coordinate transformation to the member direction using equations (5) - (7).

$$N_i^j = \pm(O_i^*)_x \sin\theta \pm (O_i^*)_y \cos\theta \tag{5}$$



$$Q_i^j = \pm(O_i^*)_x \cos\theta \pm (O_i^*)_y \sin\theta \tag{6}$$

$$M_i^j = \{\pm(O_i^*)_x \cos\theta \pm (O_i^*)_y \sin\theta\}\,\chi, \quad 0 \le \chi \le L_e/2 \tag{7}$$

Here, these letters symbols have the following meanings. N, axial force; Q, shear force; M, bending moment; and O, representing A or B. The validity of this calculation method was already verifie by comparison with experiments of the a prototype and full-scale MB by Chikahiro et al.(2012) and Ario et al.(2014). The influenc lines are calculated by the acting of a unit load ($(P_i^B)_y = -1$), just as in a DWT. As an example, influenc lines of the axial force and bending moment of the members of the third unit in an SCI with f ve units simply supported are shown in figur

(a) Axial forces

(b) Bending moments

Figure 8: Influenc Line of sectional force of 3rd unit (SCI)

8 (L_e =6000mm, θ=60°). These figure show that a maximum sectional force occurs when a point load acts on the position at a distance 2λ or 3λ from the left supporting point. In addition, it is clear that bending moment, depending on the length of the member, is much higher than the axial force.

3 THE REINFORCEMENT METHOD OF SCI

The stiffness of SCI is low because of its high fl xibility. For this reason, it is necessary to raise the stiffness of the bridge by inserting a reinforcing member when the large load is assumed. If a number of the reinforcing members are required for larger loads, it is possible to set this because this is a module type that depends on the capacity of traffi loads. The sectional forces of reinforced SCI are calculated by the combination of the method introduced in a foregoing paragraph and the unit load method.

Table 1: Calculation conditions of SCI

Section	h400 × b60 × t19.7
height (mm)	400
width (mm)	600
thinness (mm)	19.7
length of main member(mm)	6000
length of reinforcing member(mm)	λ
material	SS400
Yonung's modulus (MPa)	206
specifi gravity	7.85
boundary condition	simple support

3.1 *Confirmatio of reinforcement effect*

The effect of the strut reinforcement of SCI has been examined since last year by Adachi et al.(2016). In this analysis, a rational reinforcement method is examined by the stress calculation of the real main posture design using the influenc line diagrams. For the purpose of reducing the maximum stress of SCI after expanding, some partial reinforcement patterns that changed place and the number of the horizontal reinforcing chord members that are equipped are made. The section of main member and reinforcing member are assumed to be a section like real MB with 400mm in height, 60mm in width and thinness 19.7mm. and only dead load is acted as the load conditions to compare. It then becomes clear that the member of the central unit of the whole SCI system has the maximum relationship stress. For this reason, the position of a reinforcing member is decided in the central unit of the model having f ve units. We pay attention to the maximum edge stress where a reinforcement effect was examined. The pattern having a lower horizontal member was confirme when few reinforcements were used. However, a large reduction in the maximum edge stress of the centre unit was confirme in a pattern having an upper horizontal member and both side horizontal members. For this reason, the stress-relaxation of the whole SCI is enabled by giving a similar reinforcement to the 2nd, 3rd, and 4th units, which produce maximum bending stresses. A pattern having three reinforing members is named pattern A and shown in figur 9. A pattern having six reinforcing members is named pattern B and shown in fig ure 10. The maximum edge stress is reduced by approximately 73% in the central unit, by approximately 72% in the 2nd and 4th units of pattern A, contrary to SCI which does not exhibit reinforcement by using reinforcing members. The maximum edge stress is reduced by approximately 97% in the central unit of pattern B, and by approximately 91% in 2nd and 4th units.

3.2 *Comparison between SCI and DWT*

In this section, We examine superiority of the SCI except the mobility by comparing the strength of DWT which are used as emergency bridge and SCI. We use

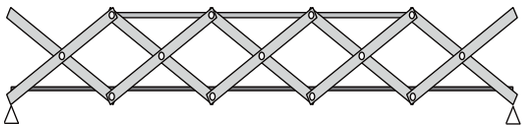


Figure 9: A reinforced model of SCI as a pattern A

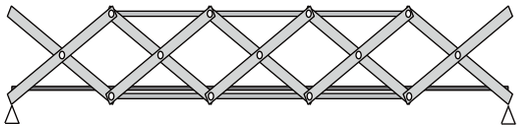

Figure 10: A reinforced model of SCI as a pattern B

the strength of the maximum distributed load strength per unit weight of the bridge as an index in comparing pattern A and pattern B with DWT. Live loads and dead loads are loaded like figure11 The maximum distributed load strength is equal to load when yielding or buckling occurs. The section of the DWT was decided so that its weight became almost same as that of reinforced SCI. The results of the comparison are given in table 2. It shows that both reinforcement patterns obtain the values that are bigger than DWT.

4 CONCLUSIONS

The main result of this structural analysis was the introduction of the concept of influenc line diagrams into the design of scissors structures for the firs time. This result revealed the basics of a design of SCI having the scissors structure that acted on a moving load, including both a vehicle and a person. Several points that were deduced by this analysis are summarized as follows.

1. Based on the equilibrium equations and the displacement conformity condition equations of the scissors structure, we developed the design method using the influenc line diagram for a live load design of SCI.

2. Using the program of the influenc lines, we analysed reinforcement methods and clarifie the rational reinforcement method.

3. As a comparison between the stresses of DWT and SCI, it was shown that SCI can have strength per unit weight that is bigger than DWT by reinforcement. In other words, SCI is effective structure and it is the more suitable as emergency bridge.

Table 2: Properties of SCI reinforced patterns and DWT

	Weight(kN)	Strength(kN/m^2)	index
Pattern A	58	21	0.36
Pattern B	78	57	0.73
DWT	65	10	0.15

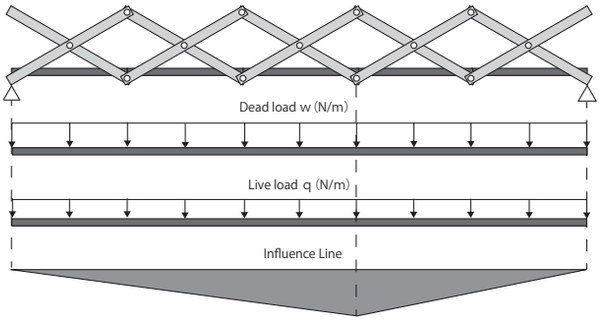

Figure 11: Section forces using the infuruence line under live and dead loading

ACKNOWLEDGEMENT

This research has been supported by the Bilateral Programs between Japan Society for the Promotion of Science (JSPS) and Polish Academy of Sciences (PAN) in 2016 - 2018.

G. Palamà
MS Candidate in Civil Engineering, Politecnico di Milano, Milano, Italy

ABSTRACT: The work aims to investigating the effect of vehicle-bridge interaction (VBI) on a Submerged Floating Tunnel (SFT), a novel type of bridge still at the feasibility study phase. The case study is a prototype SFT designed to cross the Messina's Strait, in Italy. Tethers guarantee the static equilibrium of the SFT subjected to Archimede's forces and, due to their length, behave in a non-linear way. The VBI coupled problem is solved through an uncoupled iterative procedure, where bridge and crossing vehicle are analyzed separately for the whole duration of the time history: the vehicle is subjected, on its wheels, to roughness and bridge motion and the bridge is subjected to vehicle's contact forces. The ANSYS code performs the non-linear analyses of the bridge, while a research code integrates the vehicle equation of motion and handles the data exchange between the two codes. The numerical procedure achieve convergence in a few iterations. Results show that the effect of crossing vehicle do not propagate on the tunnel, affecting only the nearby tethers.

1 INTRODUCTION

Natural dynamic excitations arising from earthquake, waves and currents affect the design of floating tunnels. At a lower level, the dynamic interaction tunnel-travelling vehicle is to be considered for fatigue and serviceability conditions. Due to transit of heavy vehicles, the tunnel response is coupled with that of the vehicle. The road roughness plays a role also.

The parametric oscillation of the anchoring tethers, induced by the motion of the tunnel, has been the subject of recurring studies. A suitable model for these oscillations is that of Mathieu's equation. A time-varying tension force arises in the anchoring system when dynamic loads, such as regular waves or possibly moving vehicles, act on the tunnel body. Sato et al. (2004) studied the possibility of the occurrence of unstable motions considering the arrangement of the mooring system lines, the effect of viscous damping, of quadratic damping and of external forces on the parametric excitation.

In a Mathieu type of instability, the growth of the oscillation amplitude is related to a parametric resonance in which the variation of the parameters must occur at twice the natural frequency of the system. This was verified, among others, in relation to submerged floating tunnels (SFTs), in (Sun 2011) where it was found that the displacement and velocity root mean square responses of tethers reach the peak if the circular frequency of the tube doubled that of tether. The authors pointed out, however, that owing to the damping force of water, the responses of the anchoring tethers decrease more rapidly compared with the tethers in air.

Parametric excitation of the tethers due to the wave motion has been more recently also studied in (Cantero et al. 2016), where the authors studied the frequent design situation of moored SFTs parametrically excited by long period waves. In this study, the authors included the contribution of multiple modes of vibration, and adopted the harmonic balance method to assess the amplitude of vibrations, arriving at discussing the validity of using stability charts for the design of mooring lines. A similar parametric excitation can be induced by moving vehicles inside the tunnel. The exciting force is due to the moving mass and weight of the vehicles and to their motion activated by both the motion of the tunnel and the asperities of the road.

Although less studied, a handful of works is available in the literature about this problem. The effect of moving loads on moored floating structures has been studied at different levels of detail e.g. by (Fleischer, and Park 2004, Tariverdilo et al. 2011, Zhang et al. 2016). Typically, several simplifying hypotheses are adopted in these studies, regarding both the structure and the way the moving vehicle is represented. In the

last study cited, as an example, the SFT was simplified as an elastically supported beam with springs and dampers at each end to represent the mooring system. According to the results of that numerical study, the vertical stiffness of the mooring system has a significant effect on suppressing the SFT displacements, and consideration should be given to the velocity and weight of vehicles during the design process of a SFT.

A similar, equally recent, study (Liang and Jiang 2016), adopted a simple model for the moving vehicle (the one-fourth vehicle model with two degrees of freedom: sprung mass and unsprung mass) while it retained an approximate modelling of the tunnel. This was simplified as an Euler-Bernoulli beam with two simple supported ends, while the anchoring system was modelled through spring elements to simulate the theters. For a 100 m long section, the influence of road roughness on traffic loads was studied within the finite element software ANSYS (Ansys 2017). Traffic was modelled as two approaching vehicles (speed 80 km/h, weight 20 kN) finding that it accounts for $1/10^{th}$ of the displacement due to 20m long waves having height 0.3 m, for a tunnel with positive buoyancy ratio 1.4 and 100 m depth of sea-bead. However, no details are given on how the roughness of the pavement was implemented in the ANSYS model or on the solution of the coupled vehicle-structure dynamic interaction problem.

The integration of the equations of motion of the coupled system composed of tunnel and moving vehicles, taking into account the roughness, poses computational problems connected to the time-varying nature of the structural matrices. One possible solution strategy relies on a forced uncoupling of the coupled equations, with a separate integration of the two systems (Feriani et al. 2008). At contact points, the bridge is subjected to the forces transmitted by the vehicle that, in turn, is subjected to an imposed motion at the wheels due to combined effect of roughness and bridge motion. An iteration process to restore equilibrium and compatibility at the system interface completes the uncoupled solution strategy. The iteration can be performed either within each single time step (STS) or on the whole time history (WTH) (Feriani et al. 2011). The two iterative procedures turned out to be equivalent, producing the same results (Maneo 2016).

The aim of this work is to analyze the vehicle-bridge interaction (VBI) for the SFT using the WTH procedure. The peculiar nature of the structure at study, subjected to hydrostatic and hydrodynamic forces, and characterized by a geometric non-linear behavior of the anchoring systems, requires the adoption of a sophisticated commercial code as ANSYS for a correct structural analysis. In this work the WTH procedure, derived for the case of structural linear behavior, is extended to a nonlinear system. The iterative procedure relies on ANSYS for the solution of the structural system and on an ad-hoc research code, named INTER, to integrate the equation of motion. Also, INTER handles the data exchange between the two systems and governs the iterative process.

The case study, a prototype tunnel crossing Messina' strait, is presented in Section 2. The vehicle and roughness model are described in Section 3. Section 4 presents the rationale for the derivation of the coupled equation of motion and the uncoupled solution strategy. Numerical results, in Section 5, show the positive performance of the iterative approach. Conclusions address the positive outcomes of this work and the need for further studies.

2 THE PROTOTYPE SUBMERGED FLOATING TUNNEL

The model structure to study the effects of vehicle-structure interaction is a design proposal devised for the Messina Strait crossing, in Italy. The crossing is 4680 m long and the maximum depth of the sea-bead is about 350 m. A side view of the tunnel is depicted in Figure 1.

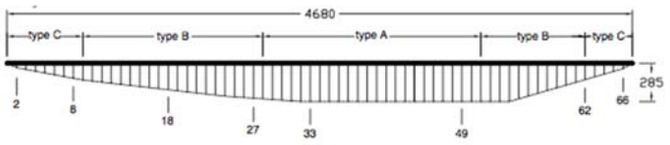

Figure 1. Lateral view of the SFT at study.

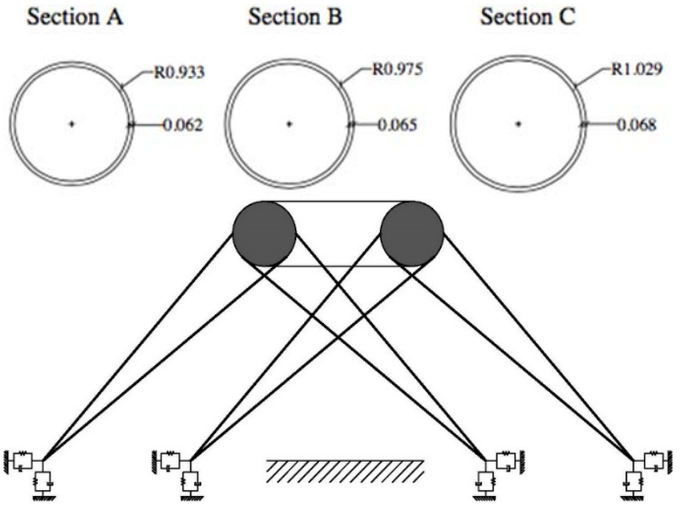

Figure 2. Cross-section of tunnels and tethers and tethers layout.

The general layout of the SFT comprises a double tube configuration with two straight independent tunnels located at a centreline distance of 40 m, connected at a distance of 480 m by escape routes introduced for safety reasons. The escape routes make the

tunnels behave as the chords of a Vierendeel beam in the horizontal plane and couple the response of the tubes due to their torsional stiffness, in the vertical plane. Further details on the design philosophy can be found in a companion paper (Perotti et al. 2018).

Each tube of the tunnel is independently anchored to the seabed (see Figure 2), replicating an anchoring scheme that demonstrated a good performance in previous studies (Shi 2013, Oregioni & Triaca 2016, Di Pilato et a. 2008) where the anchor bars were exploited in non-linear material behaviour range during strong earthquakes. Since the anchoring elements are hollow tubes, of different diameters and thickness along the length of the tunnel (see Figure 2), their buoyancy counteract their slenderness, contributing to achieve a straighter configuration in service, thus minimizing geometrical non-linear effects. Passive control devices are introduced at the tunnel-shore interfaces to limit the axial forces in the tunnel.

The first natural periods and frequencies, along with a classification of the modal shapes, are reported in Table 1 for the modes that involve mainly a global movement of the tunnels. Due to the coupling between the tunnels, also torsional modes are present. Local modes of the tethers are in the range between 0.185 and 0.324 Hz.

Mode	Type of mode	Freq. [Hz]	Period [s]
1	First Longitudinal vibration mode	0.157	6.369
2	Second Longitudinal vibration mode	0.337	2.967
3	First torsional vibration mode	0.443	2.257
4	Second torsional vibration mode	0.517	1.934
5	Third longitudinal vibration mode	0.534	1.872
6	First transversal vibration mode	0.559	1.789
7	First vertical vibration mode	0.561	1.782
8	Second vertical vibration mode	0.565	1.769
9	Second transversal vibration mode	0.565	1.769

Table 1. Global natural modes of the SFT under study.

3 MODELS ADOPTED

In the following the models for the vehicles and the road roughness are summarized. Among the possible models, a plane vehicle model is adopted (Green & Cebon 1994), consistently with the FE discretization of the tunnel. A 3D model could have been adopted as well. Many mathematical relations are proposed in the literature to describe the Power Spectral Density (PSD) of the roughness profile. This preliminary study adopts the one proposed by Eurocode 1. It must be underlined that the iterative procedure is not restricted to the models described here.

3.1 *Vehicle*

The 2D ½ vehicle model in Figure 3 has two axles, two contact points constrained to the road, and four degrees of freedom (dofs). The first two describe the vertical motion of the unsprung masses m_1 and m_2, the third is the vertical displacement of the body mass M and the fourth describes the pitch. The total mass adopted in the analyses is 40 t. The center of gravity *G* of the body mass M is located in the middle of the mass itself (a_1=a_2=1 m). The (damped) natural frequencies of the four modes are 1.59, 3.18, 23.89 and 23.91 Hz, respectively. The first mode is a "pitching" mode, the second one is a "surge" mode, with the three masses oscillating in phase.

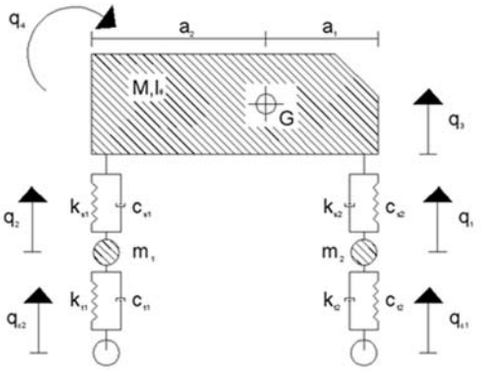

Figure 3. 2D Vehicle model from Green & Cebon (1994).

3.2 *Roughness*

The longitudinal roughness profile adopted in the analyses is generated by assigning random phases to amplitudes respecting the Power Spectral Density function defined in the Annex B of Eurocode1 (EN 1991-2. 2003). This power spectrum is defined by a straight line in a logarithmic plot, in accordance with ISO 8608:

$$\Phi(\Omega) = \Phi(\Omega_0)\left(\frac{\Omega}{\Omega_0}\right)^{-n} \quad (1)$$

In Eurocode 1, the parameters of the power spectrum were derived to describe different road quality scenarios. Pavements are subdivided in classes, from A to E, of descending quality. The class A pavements correspond to a newly paved highway, while a very good to good pavement belongs to class (A-B), the border between A and B. For this class, adopted for the tunnel roads, the reference cyclic frequency Ω_0 (rad m^{-1}) in Equation 1 is equal to 2. The value of the spectrum at the reference frequency. $\Phi(\Omega_0)$ (m^3 rad^{-1}) is 1. Finally, the parameter *n* is equal to 2.

4 EQUATION OF MOTION AND UNCOUPLED SOLUTION STRATEGY

The VBI coupled problem is solved by deriving the coupled equation of motion and subsequently devising an uncoupled iterative solution procedure. In this way bridge and crossing vehicle are analyzed separately: the vehicle is subjected, on its wheels, to roughness and bridge motion and the bridge is subjected to vehicle's contact forces.
The equations of motion are written under the following hypotheses:

- The vehicles travel at constant speed and along a straight line parallel to the tunnel axis;
- The horizontal motion of the vehicles is known and decoupled from the vertical one;
- The contact area between the generic tire of the vehicle and the road surface is reduced to a massless point;
- The contact between the wheel and the paving is perfect;
- Contact forces have only a vertical component.

Under the above assumptions and using the Lagrange's equations it is possible to define mathematically the problem of vehicle-structure interaction with a system of ordinary differential equations:

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{q}_k}\right)+\frac{\partial V}{\partial q_k}+\frac{\partial D}{\partial \dot{q}_k}=0 \qquad k=1,\ldots,n_{dof} \qquad (2)$$

In Equation (2), T is the total kinetic energy of the system composed of the tunnel and the crossing vehicles, V is the potential energy of the same system and D is the dissipation function that accounts for energy dissipation due to both the tunnel motion and the vehicle masses motion. The equation of motion obtained in this way describes the coupled behavior of the vehicle and of the structure.

The mass matrix of the coupled system is uncoupled, due to the assumption of massless contact points. The system of equations can be decoupled by moving to the right-hand side the terms coupling the motion of the structure and of the vehicles, as well as the time-dependent terms. In this way, coupling terms become, for each system, forcing terms.

The forcing term acting on the structure is a function of the static forces, of the floating forces and of three physically different terms:

- the first is given by the displacements and the velocities of the roughness profile, modified to include the static deflection of the bridge;
- the second depends on the displacements and the velocities of the contact points (in motion since the structure is in motion);
- the third is due to the motion of the vehicles.

The forcing term that acts on vehicles depends on the surface roughness, as well as on the displacements and the velocity of the contact points.

The separate equations of motion of the vehicles and of the tunnel cannot be solved independently, because the displacements of the structure contribute to the forcing term in the motion of the vehicles. Vice versa, the moving contact forces that the vehicles transmit excite the structure (Feriani et al. 2008). However, the two coupled systems can be resolved through an iterative procedure. In this work, the procedure named Whole Time History (WTH) is adopted. The general flow chart for the case at study is reported in Figure 4.

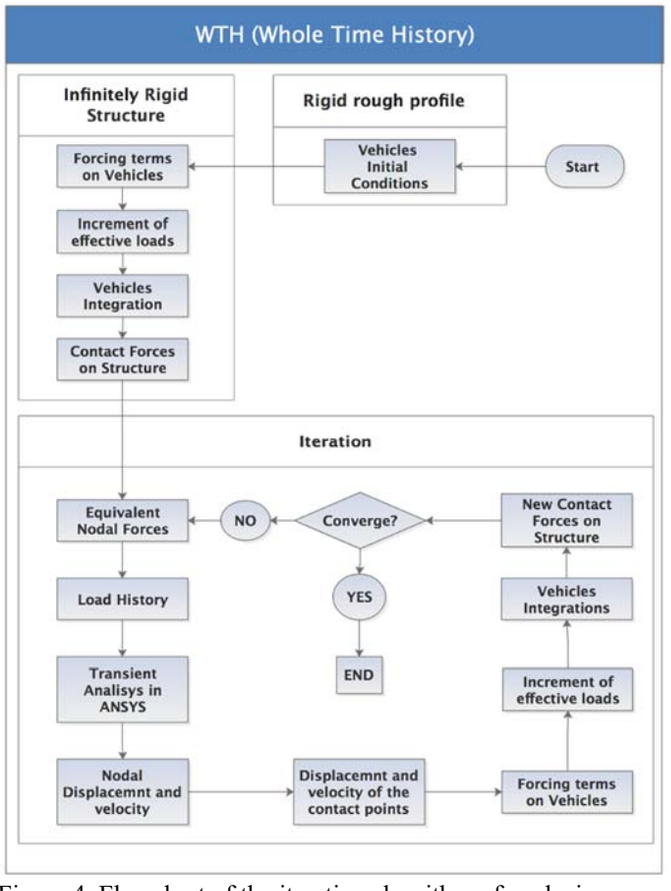

Figure 4. Flowchart of the iterative algorithm of analysis.

As the name suggests, the WTH procedure iterates throughout the entire time-history. First, the vehicles transit over a rigid roughness profile sufficiently long to eliminate the effect of their initial conditions of motion. Then, at each cycle, vehicles are repositioned at the beginning of the tunnel and the integration is repeated considering as forcing term the contact forces arising from the bridge motion obtained in the previous iteration. The ANSYS code performs the

non-linear analyses of the bridge, while the research code INTER integrates the vehicle and handles the data exchange with ANSYS.

At the first iteration, the vehicles moves on the structure that is considered as infinitely rigid. The INTER Code calculates the increase in the effective loads of the vehicles, which at this iteration depend only on the surface roughness or on initial disturbances such as bumps. Subsequently, INTER solves the equations of vehicle motion with the Newmark method (Newmark 1959) and calculates the contact forces to be transmitted to the bridge for each time step. Since contact points, in general, do not coincide with mesh nodes, contact forces are transformed into equivalent nodal loads (vertical forces and moments) on the tunnel model. Proper shape functions are used to this aim. On the tunnel, the equivalent nodal loads act only on the nodes directly loaded by the moving vehicle (named "useful nodes"). Thus, the code INTER generates a load history, including the entire tunnel crossing. transmits the load history to ANSYS which performs the transient analysis and transmits back to INTER the time history of the motion (vertical displacements, rotations and related first time derivatives) of the useful nodes. From these data, the INTER Code calculates (vertical) displacements and velocities of the contact points using the same shape functions previously adopted to compute nodal forces. Then, a new increment of the effective loads is computed, the equation of motion of the vehicles are integrated again and a new set of contact forces is determined.

The convergence criterion is written in terms of contact forces. For the i^{th} vehicle and at each time step k, the difference vector $\boldsymbol{R}$ is calculated between the value of the force at iteration j and that derived from the previous iteration. The mean square error, accounting for the N_t time steps of the whole time history, is normalized according to the weight of the vehicle along the whole integration domain:

$$err_i = \frac{1}{W_i}\sqrt{\frac{\sum_{k=1}^{N_t}\left(R_{i,k}^{j}\right)^2}{N_t}} \leq tol \qquad (3)$$

If the error in any vehicle wheel is less than a prefixed tolerance *tol*, the procedure ends, otherwise a new iteration is performed, transmitting to ANSYS the updated set of contact forces. On the base of the experience by the authors also in analyses considering up to 20 vehicles, the numerical procedure usually achieves convergence in a few iterations.

5 NUMERICAL ANALYSES

The procedure WTH and its implementation on the two codes, ANSYS and INTER, were validated by comparison with a closed form solution (Fryba 1972). A simply supported beam (15m long, cross-section 0.4×0.4m) is crossed by a moving load F=9.81kN traveling at 10, 20 and 30 m/s respectively. Figure 6 depicts the results in terms of time history of the vertical mid-span displacement for the case of 20 m/s. The agreement between numerical and closed form solution is excellent.

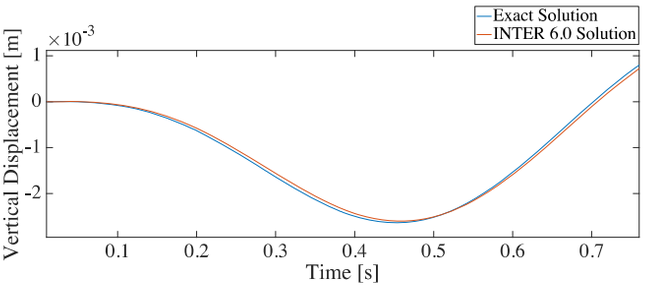

Figure 6. Test beam. Closed-form vs numerical solution, vertical mid-span displacement.

The results of the numerical analysis of a traffic induced vibrations on the SFT for the Messina Strait concern the traffic model depicted in Figure 6. This comprises two vehicles entering the two tunnels from opposite directions, and travelling with constant velocity of 20 m/s (72km/h). Two different roughness profiles are adopted for each tunnel. A bump at each tunnel entrance simulates the presence of the joints at the two ends. An integration time step of 0.1s is adopted, sufficient to integrate the tunnel, to maintain the time necessary for each analysis in 40 hours.

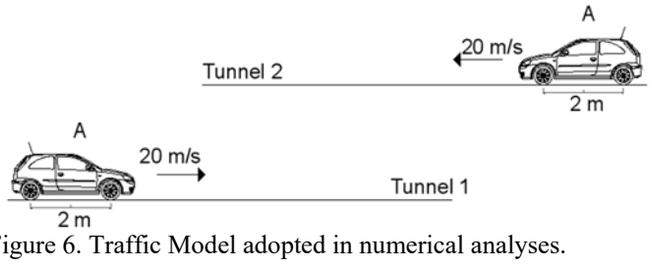

Figure 6. Traffic Model adopted in numerical analyses.

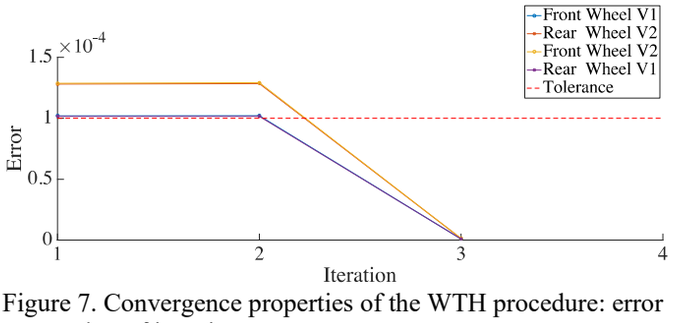

Figure 7. Convergence properties of the WTH procedure: error vs. number of iterations.

Figure 7 depicts the error measure in Equation 3 versus the number of iterations, for the front and rear

wheel of both vehicles. For the structure at study, only three iterations suffice to eliminate the error, and thus to enforce both equilibrium and compatibility throughout the entire time history between the structure and the vehicles in the VBI problem.

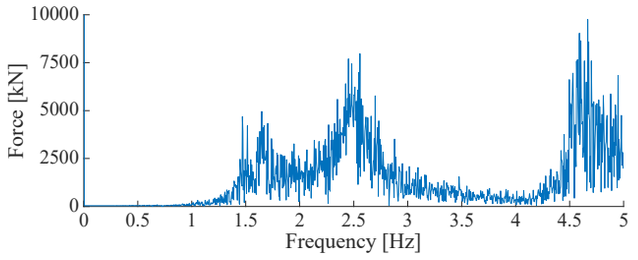

Figure 8. Contact force of front wheel - Vehicle 1: Fourier Spectrum

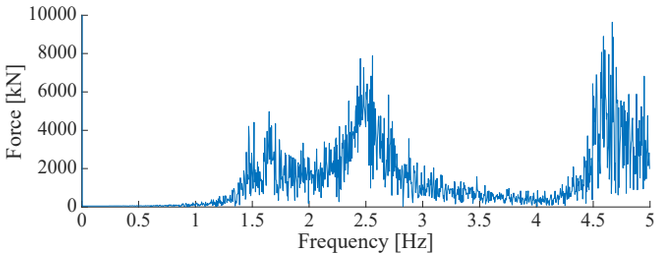

Figure 9. Contact force of rear wheel - Vehicle 1: Fourier Spectrum

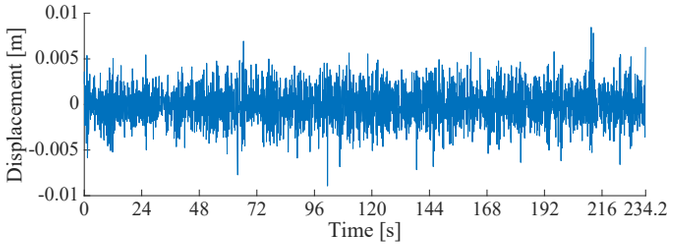

Figure 10. Vehicle 1, displacement of DOF#3: time history

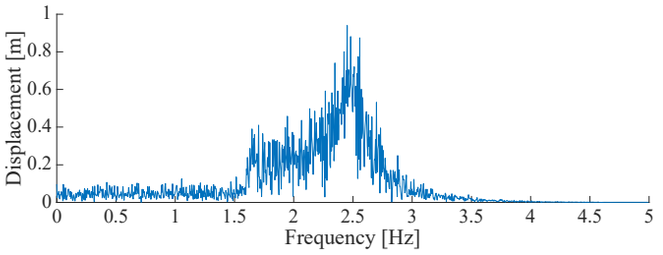

Figure 11. Vehicle 1, displacement of DOF#3: Fourier Spectrum

Figures 8 and 9 depict the frequency content of the contact forces for the front and rear wheel of Vehicle 1 respectively. The results for the two wheels are very close and similar to those of Vehicle 2. The wide frequency content of the force reflects the properties of the roughness profile adopted in the analysis. Figure 10 depicts the time history of the displacement of dof #3 in the vehicle model in Figure 3, corresponding to the vertical displacement of the mass M in the same figure. The smooth finishing of the road, and the small displacements of the structure lead to a limited motion of this mass, in the order of 5-8 mm.

Figure 11 shows the frequency content of the motion in Figure 10. The natural frequencies of the vehicle are 1.59, 3.18, 23.89 and 23.91 Hz respectively, while that of the structure are much lower (see Table 1). In Figures 8 and 9, and in Figure 11, the amplification of the response due to the resonance with the first mode of the vehicle, at 1.59 Hz, can be clearly appreciated, as well as resonances at 2.5 and 4.7 Hz, that are under further scrutiny to identify the structural modes, or the physical or numerical cause, they relates to. The resonance at 2.5 Hz is evident also in the vehicle response (Figure 10), while that at 4.7 Hz is evident only in the contact forces (Figures 8 and 9).

Finally, Figure 12 depicts the variation in the axial force in a reference tether (tether # 20, located 1908 m away from the tunnel end). As it can be appreciated, the variation due to a single vehicle is rather small, and is located around the time instant when the vehicle approaches the tether. A similar result is found for all the tethers. Thus, for this traffic model, the result shows that the effect of crossing vehicles do not propagate on the tunnel, and only affects the tethers nearby the vehicle position. This finding is consistent with the very small values of the vertical displacement of the tunnel, not reported here for the sake of brevity.

A small contribution, however, can be found at a previous time instant also. This corresponds to the instant when the vehicle travelling in the opposite direction overpasses the nearby transverse connection between the two tunnels. This finding highlights that traffic load will excite also torsional modes due to the tunnel and connection arrangements.

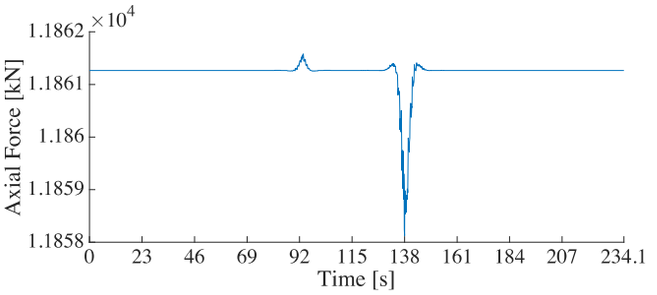

Figure 12. Axial force in tether n. 20, 1908 m away from the end of tunnel 2

6 CONCLUSIONS

This paper investigates the effect of VBI in a SFT proposal for the Messina Strait crossing, in Italy. The problem is tackled through the adoption of an uncoupled iterative solution strategy (WTH), based on the complete derivation of the coupled equation of motion.

In this work, the WTH procedure has been implemented in the research code INTER in such a way that the non-linear analysis of the structure relies on the commercial code ANSYS. A few tests on a simply supported beam validated the code implementation and the adoption of the procedure, by means of the comparison with a closed form solution. The extension to a nonlinear structure did not show any problem, apart from the need of a very high computing time. In fact, at each time step, ANSYS takes into account the geometric nonlinearities of tethers and iterates to find the equilibrium solution of the SFT. Thus, the solution strategy based on an uncoupled formulation of the equation of motion associated with an iteration process proved to be successfully, requiring a small number of iterations to achieve convergence with a very strict tolerance. It can be concluded that this work establishes a framework for investigating the most important aspects of VBI problem. Among these, we quote the vibration levels of the tunnel, which are of utmost importance for comfort and psychological acceptance of the SFT infrastructure, and the oscillations of the anchoring elements, important from the viewpoint of maintenance and durability.

From the computational point of view, further studies will concern the complete implementation of the iterative procedure, including also the vehicle model, with the mechanical APDL language of ANSYS. In addition, the adoption of the STS procedure that enforces equilibrium and compatibility at each time step could be investigated. Seen the heavy request of computing time, it would be interesting to analyze the effect of neglecting tethers nonlinearities on the outcome of the procedure.

The paper presents and discusses some preliminary results, concerning the transit of a single vehicle in each tunnel. Results show that the effect of crossing vehicles do not propagate on the tunnel, affecting the nearby tethers only. Undergoing studies show that the same situation holds for larger number of vehicles, when the spacing between two subsequent vehicles is of the order of 150-200 m, a reasonable value for safety reasons. The traffic effect on the motion of the tethers due to parametric excitation appears mild, but this aspect need to be further analyzed. In this respect, more severe load conditions can be considered, including crossing trains and the superposition with hydrodynamic loads due to waves and currents.

Maximum stresses in mooring lines during parametric excitation

D. Cantero & A. Rønnquist
Norwegian University of Science and Technology NTNU, Trondheim, Norway

ABSTRACT: The ferry links crossing the fjords along the west coast of Norway are going to be replaced by fixed links. Among the proposed solutions is the construction of Submerged Floating Tunnels (SFT). A mooring system should be used to restrain the movements of these floating structures. Long period waves, such as swell waves, parametrically excite the system and might result in excessive vibrations in the cable. Relevant literature have extensively analyzed the lateral motions during parametric resonance. However, it is unclear how parametric excitation affects the stresses along the mooring line. The existing studies investigating the actual stresses developed during such violent situations are limited. Additional studies are deemed necessary for the safe design of this crucial element in SFT. Maximum tension and bending moments might vary in magnitude and location during parametric resonance. Thus, this paper investigates the maximum total stresses along the tether due to the combination of both spatial- and time-varying forces. The aim of this paper is to assess the necessity of using the stability charts for the design of mooring lines with respect to safe levels of cable stresses. This is achieved through the numerical analysis of a submerged cable model using Abaqus. Cable vibrations, forces and stresses are analyzed and compared for a range of amplitudes and frequencies of the support motions.

1 INTRODUCTION

As part of the E39 ferry-free project (Vegvesen 2012), the National Roads Authority (NRA) in Norway is planning to build floating suspension bridges and submerged floating tunnels. Because of their location (near the end of the fjords and next to the sea), they are exposed to sea states with wind waves and swell. In particular, swells have a long period and can last for several hours with effects that decrease linearly with water depth. Therefore, these constructions require mooring systems to hold them in place and to resist any imposed motion. Taut mooring systems made of steel tubes have been proposed, similar to those used in Tension-Leg Platforms (TLP) (Aage et al. 2000). These tension pipes or tethers have large dimensions and high pretension levels. The environmental loads on the bridge towers or the submerged tunnel lead to varying tension levels and imposed motions on the tether that define a parametrically excited system.

Under certain circumstances, parametric excitation leads to parametric resonance, which is an unstable situation that produces excessive lateral motions on the tether. For instance, under a harmonic imposed motion of the upper support with a frequency twice the fundamental frequency of the tether. That 2:1 frequency ratio is generally called the principal parametric resonance. Parametric excitation has been extensively studied before. In particular, when considering the particularities of submerged risers and immersed slender structures, good literature reviews on the instabilities of such structures can be found in (Franzini & Mazzilli 2015, Lei et al. 2013).

As indicated in (Cantero et al. 2017), the publications that have studied parametric excitation of cables mainly focus on lateral motion only, giving little or no attention to other load effects such as tension and bending moment values. For this reason, in (Cantero et al. 2017), the authors focus on the tension values reached during parametric excitation, concluding that additional dynamic effects on tension are very small. Now, this paper extends that thorough analysis to evaluate also the effects of parametric resonance on bending moments along the tether. This is achieved by numerical simulations with Abaqus (Abaqus 2011). In particular, some relevant case studies are investigated in detail. Maximum bending moments and tension values are compared by means of maximum sectional stress levels in terms of steel utilisation. Then multiple parametric studies are presented to evaluate the influence of different boundary conditions, excitation frequencies and excitation amplitudes.

2 NUMERICAL MODEL

The tether of a mooring system is modelled as a submerged beam and the wave-induced motion is represented as a sinusoidal imposed vertical displacement of the upper beam support. The beam is modelled considering rotational stiffness (k_r) at the ends. A schematic representation of the model is given in Figure 1. The model has been developed in ABAQUS (Abaqus 2011) using 40 beam elements (B21), including nonlinear geometric effects. The drag and added mass contributions of the hydrodynamic effect are included with the Morison equation. The beam, of total length L, is assumed to have an initial pretension T_0. The vertical motion of the upper support is prescribed to a harmonic motion with amplitude A and frequency f. Table 1 shows the additional model properties required and the particular values used in this study.

Drag coefficient	C_D	1.5	-

3 PARAMETRIC RESONANCE OF A DRY TETHER

This section investigates the response of a dry tether, i.e. without considering any hydrodynamic effects. The results highlight the importance of the instabilities produced by parametric excitation. In particular, the tether presented in Section 2, considering fixed rotational supports, is excited with an imposed support motion with twice the tether's fundamental frequency (2:1 frequency ratio). Figure 2a shows the time-history of the mid-span lateral displacements, featuring a maximum of 4.47 m, while the amplitude of the upper support motion is only 0.10 m. Similar beating-like behavior during parametric resonance have also been reported in (Lilien & Da Costa 1994), amongst others. However, other load effects have only rarely been investigated and additional analysis are required.

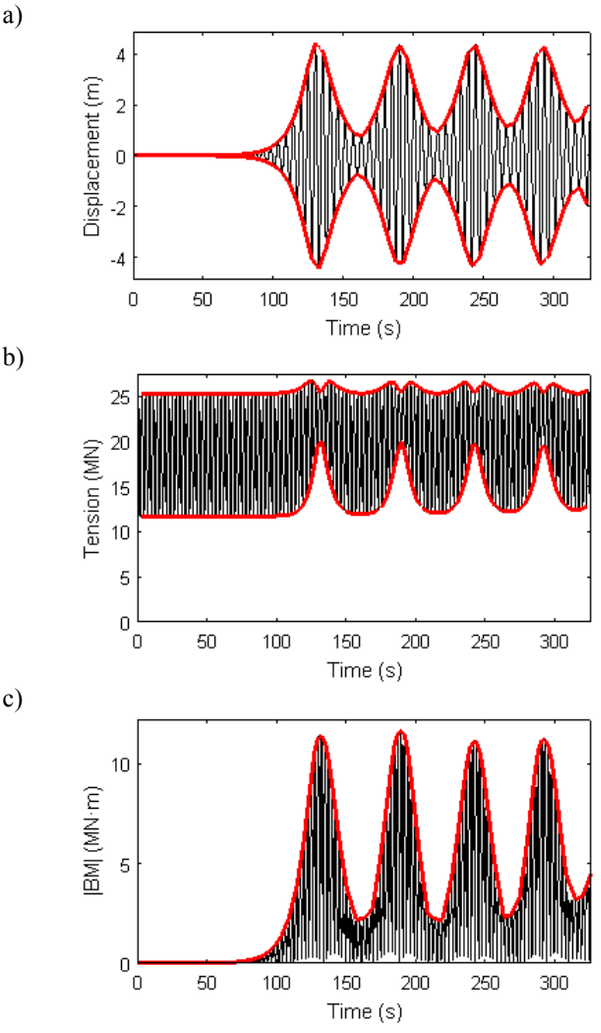

Figure 2. Tether responses under parametric resonance; a) Mid-span displacements; b) Mid-span tension values; c) Support Bending Moment in absolute value (Red lines = envelopes)

Figure 2b shows the time-history of the axial forces during parametric resonance. The tension values vary around the initial prestress tension and oscillate mainly because of the shortening and stretching of the tether length due to the imposed motion. The parametric resonance produces some small changes to the tension values. When larger lateral motions are observed (e.g. 130 s in Figure 2b), one can see an increase in tension values (both maximum and min-

imum) in Figure 2b. In any case, tension values never decrease and thus avoiding the risk of a temporarily slack tether. On the other hand, the maximum bending moment values on the tether clearly depend on the stability of the system as can be seen in Figure 2c. There is a clear increase in bending moment associated to an increase in the curvature of the deformed shape, which is directly related to the larger lateral motions observed during parametric resonance.

In order to compare both load effects, namely tension and bending moment, it is necessary to define them in terms of section stresses. Normalization of the maximum section stresses over steel's yield strength gives the utilisation of the material. Utilisation values greater than one indicate yielding of steel. When calculating utilisation values separately for each load effect, the total utilisation is the sum of all. Figure 3 shows the evolution in time of the utilisation for each load effect for the dry tether during parametric resonance. The results show that, while the tension utilisation remains approximately constant, the utilisation for bending moments varies significantly and is often greater than that of tension. Note that utilisation calculations are based on the envelopes of the load effects, shown in red in Figure 2.

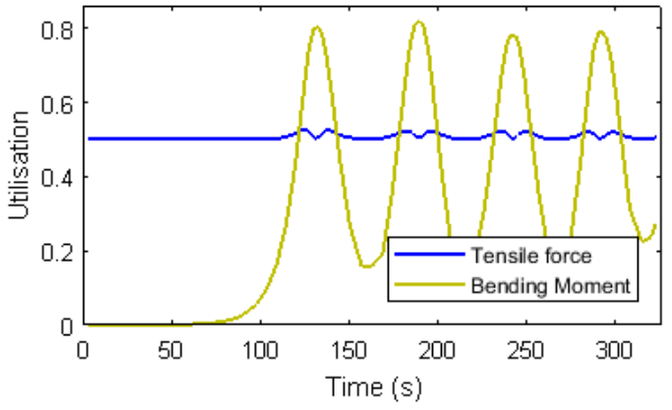

Figure 3. Utilisation of steel for a dry tether during parametric resonance

4 SUBMERGED TETHER

4.1 *Effect of hydrodynamic contribution*

Hydrodynamic effects, such as drag force and added mass, are the greatest contributors to the damping of the system. Parametric resonance of a submerged tether can still occur, but the stresses and responses differ significantly due to the higher energy dissipation. This becomes very clear when analyzing the same tether and support motion as in Section 3. Figure 4 shows the temporal evolution of the utilisation, now including the hydrodynamic effects. The utilisation for tensile forces remains practically constant and is of similar magnitude as for the dry tether case (Figure 3). Whereas the bending moment utilisation grows when the system arrives at the parametric instability, which occurs approximately after 140 s. However, the maximum bending moment values and so the associated maximum utilisation value is only a fraction of that observed in previous section. While the maximum bending moment utilisation for the dry case (Figure 3) is 0.82, for the submerged case it is barely 0.10. Therefore, these results confirm that the submerged tether can also become unstable after sufficiently long excitation period. However, the effects of parametric instability are considerably smaller when including the hydrodynamic effects.

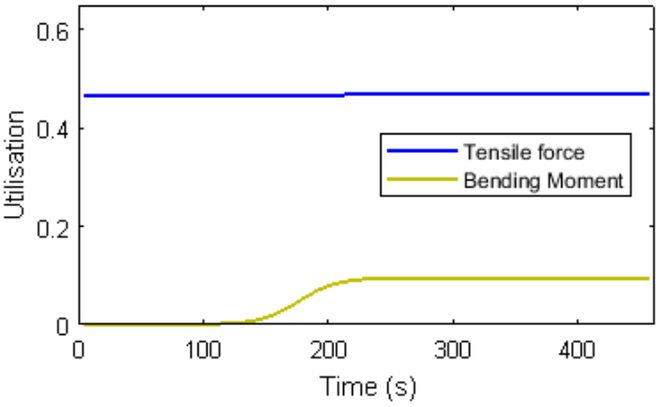

Figure 4. Utilisation of steel for a submerged tether during parametric resonance

4.2 *Effect of boundary condition*

The particular technological solution used to fasten the tether to the floating structure and to the seabed will determine the tether's behavior at those locations. In other words, boundary conditions of the tether are system dependent. When numerically modelling that system, it is very important to choose the correct properties of the boundary conditions. The possibilities range between free-to-rotate supports to fully restrained rotations. Therefore, this section investigates the effect of rotational stiffness (k_r) at the boundary conditions of the tether model. Figure 5 shows the fundamental frequency of the tether for various values of rotation stiffness. As expected, the stiffer the support, the higher the frequency.

Even though the frequencies change only slightly, the structural behavior changes significantly. This is particularly pronounced for bending moments. Figure 6 shows the bending moment diagram along the tether during parametric resonance. The tethers are excited with an imposed motion with a 2:1 frequency ratio. Because the tether's fundamental frequency varies (Figure 5), the excitation frequency is different depending on the rotational stiffness considered. Three particular rotational stiffness values are considered, which correspond to the cases marked with red dots in Figure 5. If the supports are free to rotate, the maximum bending moment is located at midspan and there is no moment at the supports (Fig-

ure 5a). However, as soon as the rotational stiffness increases more bending moments appear at the support (Figure 5b). If the rotations are fully restrained, the bending moment diagrams are dominated by the moments near the supports (Figure 5c). However, not only the location of the maximum is of interest, it is also important to note the difference in bending moment magnitudes for each case. While for the free-to-rotate case the maximum is 0.15 MN·m (Figure 5a), for the fully restrained rotation case the maximum bending moment is 1.35 MN·m (Figure 5c). For the considered tether and depending on the rotational stiffness, the maximum bending moment can be up to one order of magnitude greater.

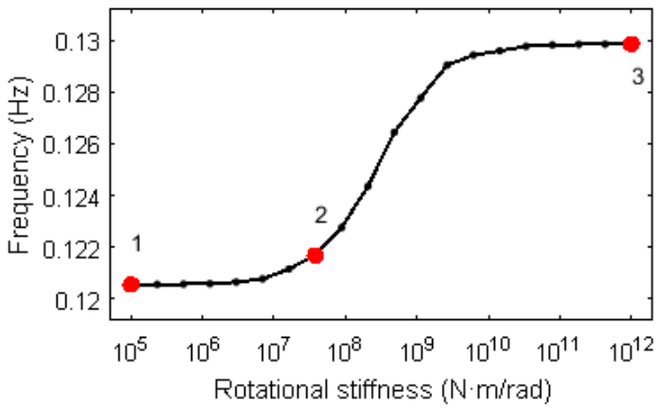

Figure 5. Tether's fundamental frequency for different rotational stiffness

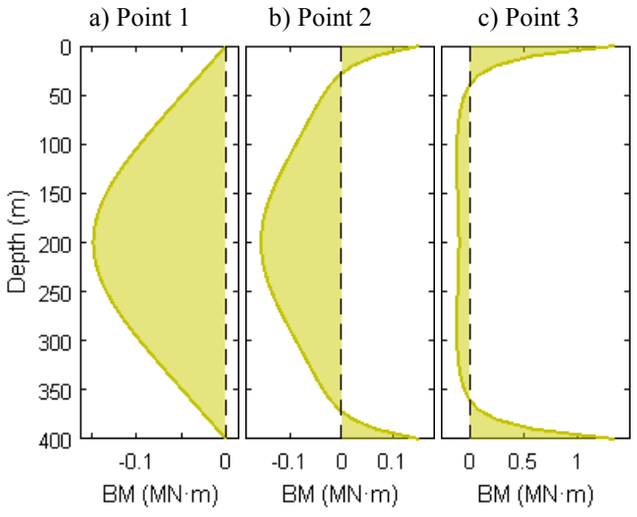

Figure 6. Bending moment diagram along the tether during parametric resonance for various rotation stiffness: a) Low stiffness (≡ free to rotate); b) Intermediate stiffness; c) High stiffness (≡ restrained rotations)

Figure 7 shows the corresponding maximum utilisation obtained during parametric resonance for each considered value of rotational stiffness. The utilisation due to tension is in practice constant, whereas for bending moment it is highest for the case with (effectively) fixed rotational supports. Therefore, to assume a high rotational stiffness is conservative and will give the highest (worst) utilisation values. A tether that allows for some rotation at the support can indeed become unstable by reaching parametric resonance, but the maximum stresses will be smaller than for the case with fully restrained rotations.

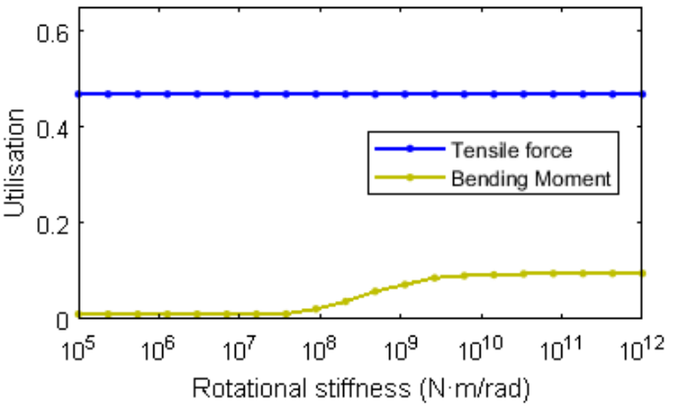

Figure 7. Maximum utilisation of steel for a submerged tether during parametric resonance for different rotational stiffness

4.3 *Support motion: Amplitude and frequency variation*

The imposed support motion, directly related to the wave loading, can vary in amplitude and frequency. It is common to represent the system's stability for any amplitude-frequency combination in graphical form using stability maps or Strutt diagrams. The limits between stable and unstable regions are delimited by the transition curves. The regions grouping all unstable solutions are often called instability tongues. Figure 8 shows the stability map for the tether under consideration in this study. To generate this figure, 1320 separate simulations were necessary, each considering 120 cycles of imposed motion. Each simulated case is represented with a dot in Figure 8. Small black docks indicate that the corresponding amplitude-frequency combination results in a stable response of the submerged tether. Whereas, large red dots indicate that the system is unstable, in other words, that it has reached parametric resonance.

Figure 8 also displays the theoretical transition curves based on the analytical expressions derived in (Cantero et al. 2017). This formulation gives the transition curves for a dry tether with internal damping. No analytical solution exist that includes hydrodynamic effects. For this reason, an internal damping of 10% is used to approximate the energy dissipation effects of the submerged case. This formulation provides a set of transition curves for each mode of vibration considered. Figure 8 shows as gray areas the instability tongues of the first three modes. The agreement between numerical and analytical results is acceptable.

This stability map shows that reasonably small amplitudes of support motions can lead to important unstable tether responses. Furthermore, the greater

the amplitude of the support motion is, the more frequencies there are that result in unstable motions.

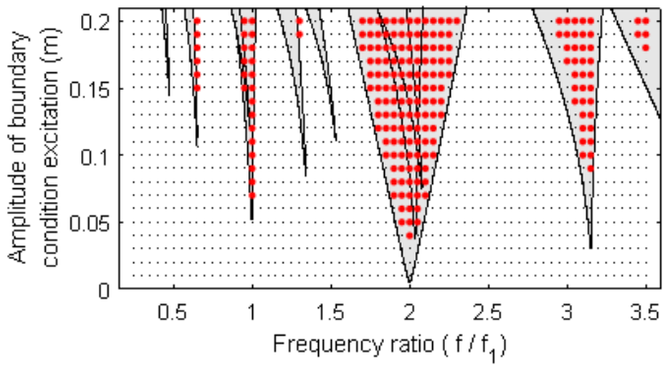

Figure 8. Stability map for submerged tether (stable = small black dot, unstable = large red dot) and theoretical instability tongues (see Appendix) associated to tether's 1st mode (Blue), 2nd mode (Green) and 3rd (Red) mode

As it is customary, the stability criteria to generate the Strutt diagram in Figure 8 is based on the values of lateral displacements of the tether. However, it is interesting to investigate the effect of the system's stability on other load effects for the same amplitude-frequency combinations. Figure 9 shows the maximum utilisation values due tension. It clearly shows a steady increase of the utilization with the amplitude of the support motion regardless of the particular excitation frequency. The effect of the system's stability is barely visible.

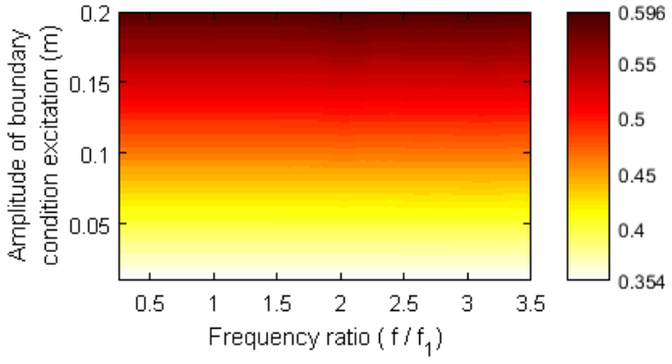

Figure 9. Maximum utilisation of steel due to tension

On the other hand, the maximum utilisation due to bending moments, shown in Figure 10, is strongly related to the stability of the system. The same instability tongues observed for lateral displacements (Figure 8) can be observed on the bending moment utilisation values (Figure 10). However, the magnitude of the utilisation values due to bending moment is rather small compared to those due to tension.

5 CONCLUSION

This document has investigated the effect of parametric excitation on the response of taut mooring lines. It extended existing studies in order to analyze other load effects that are generally not investigated. In particular, this study focused on maximum tension values and bending moments along the tether length. In order to compare both load effects, the results are expressed in terms of sectional stress values and normalized by the yield strength of the material, which gives the utilisation of steel. First, parametric resonance is investigated for the case of a dry tether. The instability produces significant dynamic effects that translate into large variations of bending moment utilisation. Then, the same tether is studied including the hydrodynamic effects. Larger energy dissipation mechanisms reduce the effect of parametric resonance. Tension utilisation is practically not influenced by the instability, whereas bending moments show only a moderate increase. Furthermore, the study of the influence of rotational stiffness at the supports has shown that the fully restrained rotational support leads to the highest stresses and is thus regarded as conservative. Finally, the analysis of multiple amplitude-frequency combinations for the support motion produced the stability diagram for the considered tether. With respect to the axial forces, the simulations confirm that the tension utilisation is practically independent of the systems stability and that it is directly proportional to the tethers elongation due to the imposed support motion. As for the bending moments, the system's stability clearly influences the results, obtaining larger utilisation values at the instability tongues. However, the magnitude of the utilisation values due to bending moment is rather small compared to those due to tension.

ABSTRACT: With both the development in construction technology of offshore engineering and the ever growing demand for transportation to cross the waterways, submerged floating tunnel (SFT) attracts more and more attention. As an innovative structure, SFT represents much more advantages in comparison with the traditional structures in a long distance waterway crossing. The focus of this paper is to provide an overview of fundamental design aspects of SFT in the light of existing research and design reports. In particular, case studies adopting different cross-sections, various structural materials, support systems, structural connections, under diverse imposed loads, are presented. In addition to this, issues about the fabrication and erection processes, ventilation and evacuation plans are also summarized. The main aim behind the work presented herein is to provide a concise source of information to researchers working in this domain of engineering.

1 GENERAL BACKGROUND

The first idea of Submerged floating tunnels (SFT) dates back the beginning of 1900 (Hakkart, 1996) in Norway. An earliest milestone is the proposal for the Messina Strait Crossing (Italy), by Alan Grant in 1969 (A.N.C.E. 1971, Faggiano et al. 2001, Fig. 1). During time in Europe several opportunities of international cooperation on this subject have allowed a huge progress, starting from the earlier Forum of European National Highway Research Laboratories, involving the Norwegian Public Roads Administration with the Danish Road Institute and the Italian Company Ponte di Archimede S.p.A (FEHRL, 1996), up to the recent SIJLAB Sino-Italian joint laboratory, which consolidated the interest of China with the participation of the Institute of Mechanics of the Chinese Academy of Science to the joint venture linking the Italian Company Ponte di Archimede S.p.A, the University of Naples Federico II and the Polytechnic University of Milan, for the design of the first prototype of Submerged Floating tunnel (Mazzolani et al., 2008). The attention to SFTs is also testified by the dedicated international conference dedicated international conferences. The first one, namely "Submerged Floating Tunnels", was held in 1996 in Sandnes (Norway). Recently, in the last years, two international symposia on Archimedes bridges (ISAB2010) and on Submerged Floating Tunnels and Underwater Tunnel Structures (SUFTUS2016) were held in China, in Qiandao Lake and in Chongqing respectively.

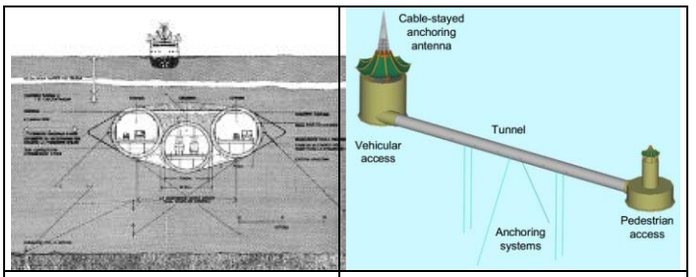

Figure 1. The Archimede bridge: a) Alan Grant, 1969; b) SIJLAB prototype, 2008. (Mazzolani et al. 2010)

Several feasibility studies have been carried out worldwide, the geographical distribution is shown in Figure 2. They are in Italy (Faggiano et al. 2001), in United States (Felch et al. 2001), in China, Jintang Strait (Mazzolani et al. 2002), Qiandao Lake (Mazzolani et al. 2008), Qiongzhou strait (Jiang et al. 2018), in Japan (Kanie, 2010), in Indonesia (Wahyuni et al. 2009), in South Korea (Seo et al. 2015) and in Mexico (Faggiano et al. 2016). The SFT idea has been also taken into consideration for Lugano Lake in Switzerland, the Gibraltar Strait and in Malta.

Based on existing projects, as well as research reports, this article summarizes the structural features of SFT and provides an overview of the main design issues. Specifically, the design options for cross section, materials, anchorages, structural connections

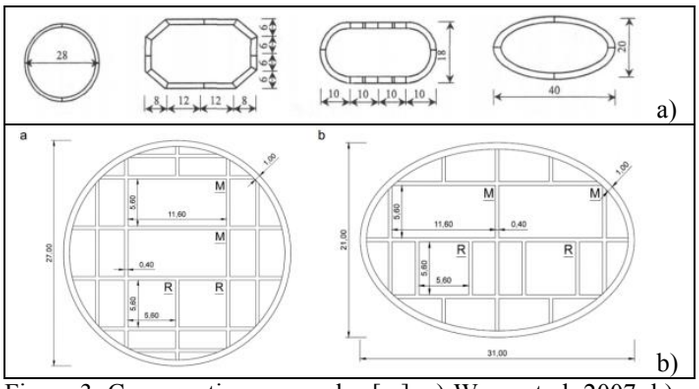
and loads are described. This overview provides pros and cons of the solutions adopted and therefore is a useful reference for future developments of the SFT.

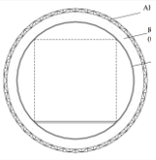
Figure 2. Geographical map of SFT proposals worldwide

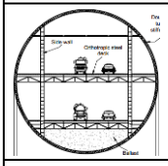
2 MAIN STRUCTURAL FEATURES

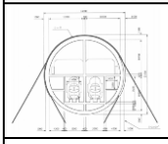
2.1 *Cross-section*

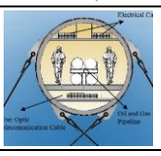
The cross section size and the internal arrangement of the SFT are determined by static and functional requirements, such as buoyancy ratio (such as buoyancy over weight ratio, BWR), strength and stiffness properties, water-tightening, size of infrastructures. Elongated (elliptical, polygonal) shapes guarantee the best behavior against hydrodynamic actions induced by waves and currents (Wang et al, 2007; Mandara et al, 2016), similarly to the case of emerged bridges that should resist the aerodynamic actions by wind (Fig. 3). The main features of cross-sections proposed in literature are summarized in Table 1.

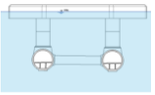












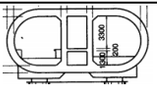


Figure 3. Cross sections examples [m]: a) Wang et al. 2007; b) Mandara et al. 2016

External walls of the tunnel must resist the hydrostatic pressure and eventual collisions from both internal and external sides, besides they should assure watertighting. In some cases a sandwich structure is proposed, where the external layer is a reticular spatial aluminum structure, conceived to absorb the impact by sinking objects and also to guarantee a high durability in the aggressive marine environment thanks to the peculiarity of the material aluminium.

Table 1. Cross-sections data sheet

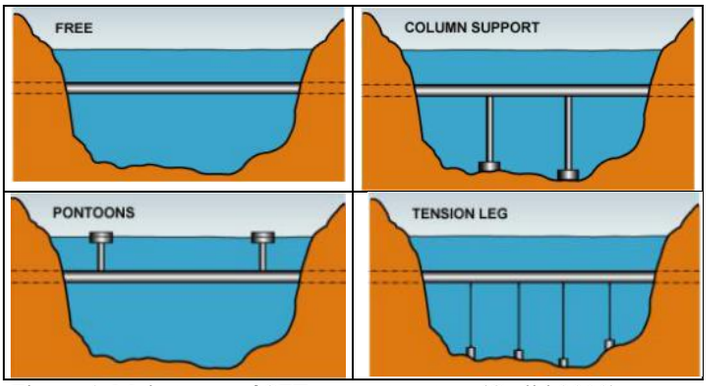
Shape	Case study	Size	Function	Structural features
Single circular	Qiandao Lake, China (Mazzolani et al. 2008)			
		Φ: out 3.55m; in 2.50m	Motorway	"Sandwich" configuration exploiting good mechanical performance for each material.
	Messina Strait, Italy (Martire et al. 2009)			
		Φ: out 19.3m; in 18.6m	Motorway, Railway	Outer double steel tubes with stiffening ribs and inner steel walls and plates.
	Funka Bay, Japan (Kanie 2010)			
		Φ: 24m	Motorway, Railway	Upper layer for motorway and lower layer for railway, large BWR.
	Indonesia (Budiman et al. 2016)			
		Φ: 3-5m	Pedestrian way, Pipeline	Steel wall plate welded on circle frame and coated to prevent corrosion.
Multi circular	Sognefjord, Norway (Fjeld et al. 2012)			
		Φ: out 12.6m; in 11.0m	Motorway	Effective in resisting current loads and suppressing long-period resonance.
	Messina Strait, Italy (Alan Grant 1969)			
		Φ: out 12.3m; in 10.5m	Motorway, Railway	Compose of three single circles, outer steel shell to keep stable.
Rectangular	Oinaoshi, Japan (Kanie 2010)			
		Width: 5.7m; Height: 13.6m	Motorway, Pedestrian way	Include two-lane road with pedestrian walk, cross-section with fixed pile support.
	Baja California, Mexico (Faggiano *et al.* 2016)			
		Width: 32m; Height: 12m	Motorway	"Ad hoc" triangular shaped lateral steel wings for improving dynamic behavior.
Elliptical	South Sea of Korea, South Korea (Seo et al. 2015)			
		Width: 15.1m; Height: 13.5m	Railway	Suitable for accommodating railways and evacuation.
Oval	Osaka Bay, Japan (Sakurai 1996)			
		Width: 13.6m; Height: 6.2m	Railway	Double-track railway, central tunnel for ventilation and maintenance
Polygonal	Jintang Strait, China (Mazzolani et al. 2002)			
		Width: 27.9m; Height: 12.1m	Motorway	High residual buoyancy, inner cells designed for functional equipment and evacuation.

The appropriate strength and stiffness is then provided by the composite steel concrete circular structure.

In many cases, the tunnel is provided with perimetral cells, which can serve as either watertight compartments, protecting the transport lines from accidental partial flooding in case of out or inside collisions, or ballast compartments, for regulating the buoyancy ratio, or escape routes.

2.2 *Support system*

Four main types of support systems are taken into consideration, such as: free tunnel, column support, pontoons and tension leg, as shown in Figure 4 (Østlid 2010). The selection of support system depends on many factors, such as location, surroundings, destination of use, type of soil, water environment.



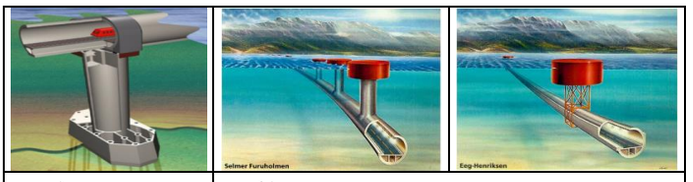


Figure 4. Main types of SFT support system (Østlid 2010)

Free system has no anchoring at all except at landfalls, it is independent of water depth. Obviously, the length of SFT with free support is limited.

Column support system could be employed for negative residual buoyancy (i.e. the buoyancy is lower than the self-weight). The water depth plays an important role in this case, it determining the piers height and therefore influencing the stability. Foundation of piers also specifically requires good geological condition of seabed, in order to keep pears in position (Fig. 5a, Haugerud et al. 2001).

a) b)

Figure 5. a) Column supports for Lugano Lake (Haugerud et al.2001); b) Pontoon for SFT proposal in Norway (Østlid 2010)

Pontoon system is independent of water depth, besides it is sensitive to wind, waves, currents and possible ships collision at the water surface (Fig. 5.b, Østlid 2010). Design should provide that the structure still survive in case of one pontoon lost. Furthermore, the pontoons must be placed for guaranteeing enough clearance for the navigation requirements.

Tension legs can be adopted for positive residual buoyancy (i.e. the buoyancy is greater than the self-weight). These are usually conceived as a series of cables groups, distributed along the tunnel axis with different configurations in the tunnel cross-section plane (Fig. 6, Yan et al. 2015).

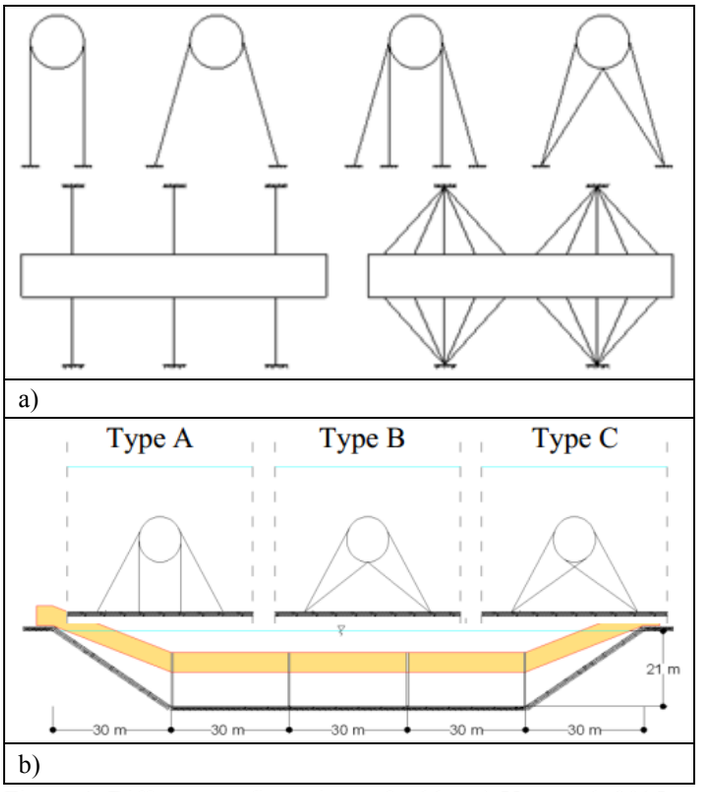

Figure 6. Different configurations of cables a) Yan et al. 2015, b) Wahyuni et al. 2009

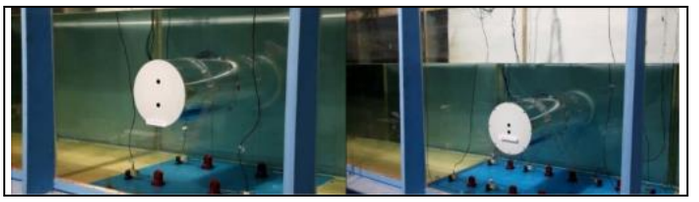
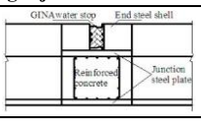
Wahyuni et al. (2009) examined different configuration of anchoring cables, showed that Type C tension legs arrangement (Fig. 6b) has a better structural behavior in terms of stress and displacement, what has been also confirmed by Cifuentes et al. (2015) which carried out experimental test on small scale specimen equipped with both inclined and vertical mooring system (Fig. 7).





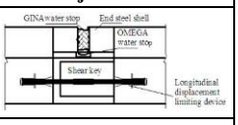


Figure 7. Experimental set up by Cifuentes et al. 2015

The effect of the anchorage configuration on the dynamic behavior of the STs has been investigated by Faggiano et al. (2001), Mazzolani et al. (2008), Martire et al. (2009, 2010, 2012). Specifically, Mooring cables behavior and modelling aspects are investigated by Cantero et al. (2016),

2.3 *Joints*

SFT is made up of pre-fabricated modules assembled in situ. The design of joints between inter-modules should conform to several requirements, such as water tightness, strength and stiffness, durability, workability, maintenance. They should guarantee the continuity between the module therefore they should realize full strength connections.
Zhang et al. (2010) discussed about two types of joints realizing a rigid and a flexible conditions. Main features are described in Table 2. However flexible joints, even though they are easier to realize and then less expensive, are not suitable.

Table 2. Features for rigid joint and flexible joint. (Zhang et al. 2010)

Features	**Rigid joint**	**Flexible joint**
Structural composition		
	End steel shell, GINA water stop, junction steel plate and reinforced concrete	End steel shell, GINA water stop, OMEGA water stop, shear key, longitudinal displacement limiting device
Construction	Long period and great difficulty	Convenient construction
Cost	Cheap	Expensive
Applicable position	End joint	Intermediate joint

The inter-modular joints for the Qiandao Lake SFT prototype (Mazzolani et al. 2010) are essentially bolted connections, designed for being set up and assembled when the modules are already submerged. At the external aluminum layer, a rubber ring crushed between the modules guarantees the water tightening of the connection. A sliding rubber ring is placed between steel and aluminum elements, in order to allow relative displacements due to thermal variations (Fig. 8).

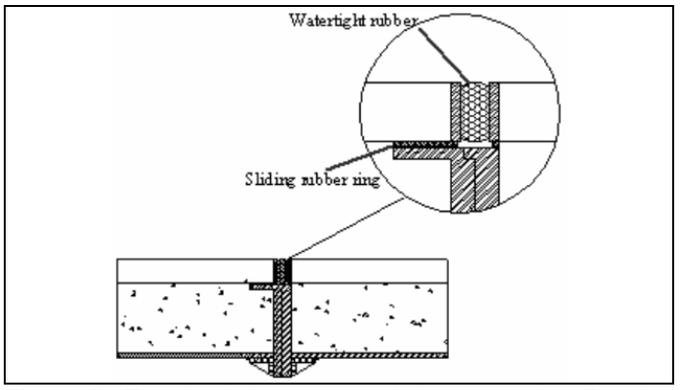

Figure 8. Detail of the inter-modular joints for Qiandao Lake SFT prototype (Mazzolani et al. 2010)

2.4 *Shore connections*

The connection of the SFT to the shore requires appropriate interface elements to couple the flexible tunnel in the water with the much more rigid shore infrastructure. This connection should be able to restrain tube movements, without any unsustainable increase in stresses. Furthermore, the connections must be watertight. A landfall tunnel realizes the transition between the SFT and the shore infrastructure. The latter can be either a tunnel bored in the ground or a special access structure, leading through ramps to the surface transportation ways.

This is the case for example of the SFT prototype for Qiandao Lake crossing in China (Mazzolani et al. 2007), which has the following features: at one end the access structure is conceived for allowing the vehicular and pedestrian access, it involves helicoidal ramp inside, at the other end only the pedestrian access is allowed. The access structures are completed by roofs, whose structural features are inspired to the Chinese traditional architecture (Fig. 9).

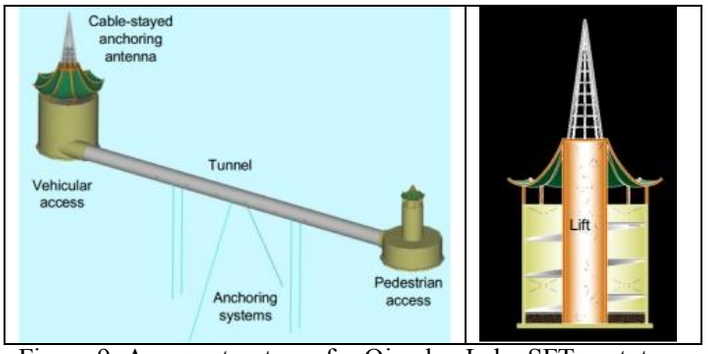

Figure 9. Access structures for Qiandao Lake SFT prototype (Mazzolani et al. 2007)

Another example is developed for the SFT proposal for crossing the Baja California in Mexico (Fig. 10). In this case, helicoidal ramps are provided at the tunnel ends at the shores with the purpose to reduce the length of tunnel, allowing a rapid connection to the surface transportation ways (Faggiano et al. 2016).

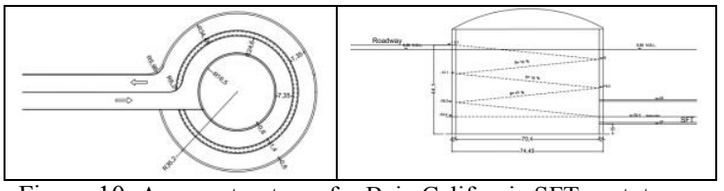

Figure 10. Access structures for Baja California SFT prototype (Faggiano et al. 2016)

2.5 *Material*

The selection of the materials applied for SFT must correspond to the planned structural and functional performances, taking account of several factors such as the resistance to the marine environment, fabrication, assembly and maintenance issues, time needed for the supply, cost and so on, further to strength and stiffness.

Suitable materials for the tunnel tube are steel, concrete, aluminum and rubber foam (Fehrl, 1996). Main related feature are reported in Table 3.

Suitable material for cables is steel for steel pipes or strands, but also synthetic fiber ropes, like CFRP (Lin et al, 2016), are proposed for application in marine environment. They should guarantee high tensile strength and resistance to corrosion and fatigue. Some features for different type of cables are reported in Table 4.

Table 3. Characteristics of different materials for the tunnel tube

Materials	Advantages	Disadvantages
Steel	Good mechanical properties; Good resistance to fatigue and abrasion; Good workability and weldability; Large strength-to-weight ratio.	Low resistance to corrosion; Low performance of welded connections with respect to fatigue Low resistance to fire.
Concrete	Good resistance to the corrosion in marine environment; Good resistance to abrasion; Good resistance to fire and high temperatures; Possibility to be cast to realize complex shapes; Low cost.	Negligible resistance to tensile stresses.
Aluminum alloys	Wide range of strength; Good workability; High resistance to marine corrosion; High resilience.	Poor resistance to fire; Low stiffness compared to steel; Low specific weight compared to steel; High cost.
Rubber foam	Extremely light weight Dissipation of the energy transmitted by external impacts	Poor resistance to fire and high temperature

Table 4. Characteristics of different types of cables for SFT (Lin et al. 2016)

Types	Advantages and characteristics	Defects
Steel pipe	Rigid rope Large bending stiffness, subjected to pressure	Heavy mass, small elasticity, worse workability, low tensile stiffness,
Steel strand or parallel steel strings	Flexible rope High tensile strength	Low resistance to corrosion and abrasion
Aramid strands	Light flexible rope Good resistance to corrosion and abrasion, low density	Low stiffness, low resistance to fatigue

3 LOADS

The "*permanent loads*" on a SFT are self-weight of the various structural and non-structural component, buoyancy and hydro-static pressure.

The buoyancy-weight ratio (BWR) is a key design parameter. It defines the relationship between self-weight and buoyancy of the structure. Common values range between 1.2-1.5, mediating the requirements of limiting design tensile stress and increasing the stiffness and stability of the cables. Hong et al. (2016) investigated the relationship between buoyancy-weight ratio (BWR), inclined mooring angle (IMA) and slack-taut performance (STP) under the wave actions (Fig. 11).

It is apparent from Figure 11 that the tether STP is sensitive to the both BWR and IMA of SFT. The effect by these two factors are coupled. For small IMA (close to 0), the slackening of cables is unabled to occur except for the small BWR. For large BWR a narrow range of IMA, around 10^{o}, can give rise to snap force, the snap IMA range becomes wider as BWR decreases. For BWR as small as 1.1, slackening always occurs.

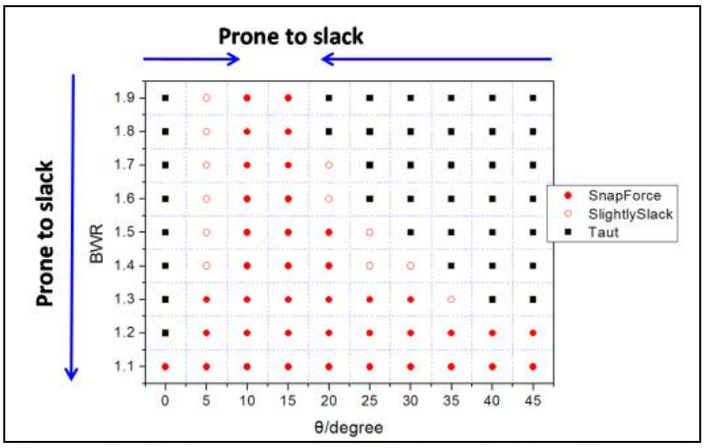

Figure 11. Slack-taut map of SFT (wave height: 12 m, and wave period: 15 s) (Hong et al. 2016)

The "*functional loads*" are associated with the passage of cars, trucks, trains and/or pedestrians, according to the destination of use of the SFT. Several studies have been carried out on the dynamic behavior of the tunnel under traffic loads (Tariverdilo et al, 2011; Dong et al, 2016), showing how an increase of the cable stiffness can lead to an improvement in the dynamic response of the tunnel system. According to the comparisons among different simulation methods, the moving vibration load is proved to be more appropriate for simulating the traffic load in SFT (Liang et al, 2017).

The "*accidental loads*" are related to emergency situations, such as fires, explosions, flood, infiltration, landslides, collisions (referring to floating object, boat wreck, submarines). Several studies have been carried out, testing the response under the action of fire loads (Ingason et al. 2013, Fig. 12.a) or explosions (Seo et al. 2013, Fig. 12.b) of the tunnel equipped with various safety systems. Figure 12.a presents the longitudinal ventilation system which is designed for SFT to create a longitudinal flow to prevent the smoke back-layering produced by the fire (Ingason et al. 2013). Figure 12.b shows the simulation of an explosion in a SFT through a simplified model of a simply supported beam with elastic springs subjected to impulse pressure.

The "*environmental loads*" are associated to currents, waves, tides, tsunamis, earthquakes, thermal variations, encrustations produced from underwater organisms. In particular, researches emphasize currents, waves and earthquake, which mainly affect the dynamic behavior of the SFT.

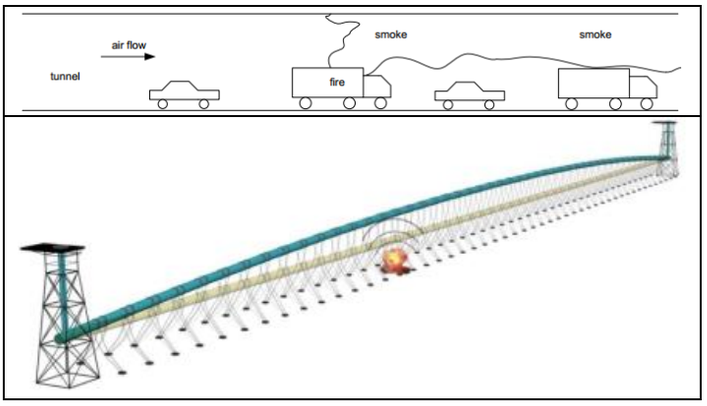

Figure 12. a) Fire ventilation in a tunnel with longitudinal ventilation (Ingason et al. 2013); b) SFT attacked by underwater explosion (Seo et al. 2013)

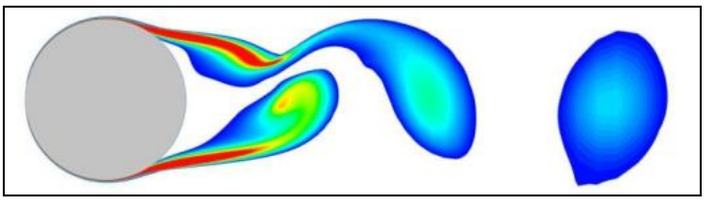
The tunnel being immersed in the water interacts with the water, both in static condition, through buoyancy, and in dynamic condition, it being affected by the surrounding water mass in movement, which give rise to an additional damping and inertia. Moreover vortex shedding can occur, at an extent depending on the shape of the cross section. The flow is unable to follow all along the surface of the structure, then it separates from the surface itself, creating a vortex which causes a local increase in rotational velocity. Higher flow velocity yields a reduction in dynamic pressure, which creates an attraction force by the vortex on the structure. The position of the separation point alternates between the top and bottom of the cylinder, and creates a vortex street, as illustrated in Figure 13 (Fjeld et al, 2012). Fluid-structure interaction for SFTs has been also recently investigated by Ge et al. (2010), Xiang and Zhang (2013) and Mandara et al. (2016).



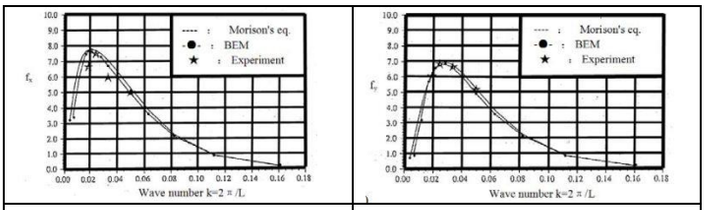


Figure 13. Vortex Street behind a circular cylinder (Fjeld et al. 2012)

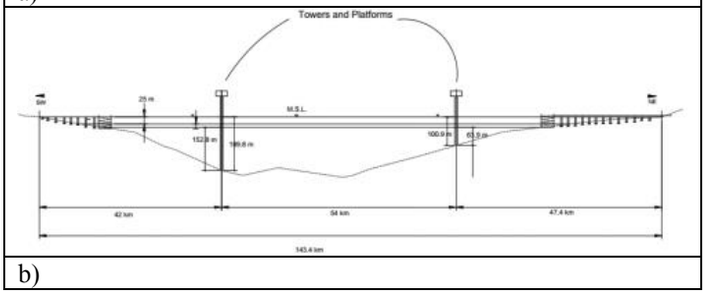
With regards to the wave force model, Kunisu (2010) applied both the Boundary Element Method (BEM) and the Morison's equation Eq. (1), which estimate both drag and inertial forces, comparing the results with the experimental evidence.

a) b)

Figure 14. Estimation of wave force by different methods a) transverse and b) vertical directions (Kunisu 2010).



A satisfactory approximation is achieved. With regards to seism, SFTs seem to be particularly suitable in high seismicity zones, due to large transversal flexibility and to the beneficial effect of the water-structure interaction, giving rise to a reduction of the earthquake input energy on the tunnel. Deep studies on the seismic behavior of SFTs have being carried out in Italy by Di Pilato et al. (2008), Fogazzi and Perotti (2000), Martire et al. (2009, 2010, 2012), Martinelli et al (2011, 2016) aiming in all at characterizing the structural behaviour of SFTs during severe seismic events, estimating the performance of the different structural configurations, investigating the influence of the crossing length on the seismic response of SFTs, comparing the structural response to multisupport excitations, studying the characteristics of vertical ground motion propagation into water and its effects on the SFT seismic response.

4 VENTILATION AND EVACUATION

SFT is a closed structure and located underwater, hence lighting and ventilation are key issue, as well as the escape access for emergency in case of any accidents. For long structures, evacuation towers are set along the tunnel (Fig. 15), as proposed by Seo et al. (2015, Fig. 15a) and Faggiano et al. (2016, Fig. 15b).

a)

b)

Figure 15. Evacuation tower and platform for long SFT a) in South Korea (Seo et al. 2015), b) in Baja California, Mexico (Faggiano et al. 2016)

Towers are equipped with a top platform, for helicopter take-off and landing for facing emergency rescue, the towers are also designed for several services, including ventilation and tourism.

5 FABRICATION AND ERECTION

Indications to erection procedures can be found with reference to the SFT prototype in Qiandao Lake (Mazzolani et al. 2010), where all the construction phases including fabrication of the tunnel modular unit (Fig. 16) have been studied. To this specific concern, it is worth to note that the circular cross section has a sandwich structures. The internal steel tube and the external aluminum tube are preliminary realized, then they are used as a formwork for the concrete casting.

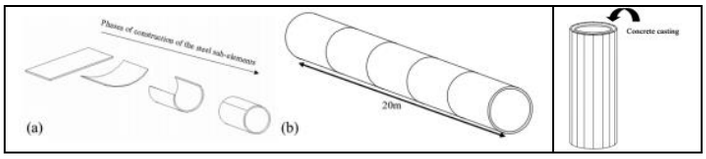


Figure 16. Fabrication of SFT modules (Mazzolani et al. 2010)

Fjeld et al. (2012) described the procedure of construction and installation in the feasibility study related to the Sognefjord crossing. The procedure mainly consist of the following steps: construction of elements, tow to assembly site, temporary mooring at assembly site, jointing of tunnel sections, landfalls, installation of SFT, installation of pontoons.

6 CONCLUSIVE REMARKS

In this paper, main structural features of SFT are briefly summarized with reference to existing researches. They are mainly related to cross-section, support systems, connections, materials, loads.

Also aspects like lighting, ventilation, evacuation, as well as the procedure of fabrication and erection are mentioned, they being very important for SFT design.

So far, the achievements of SFT are based on the theoretical studies, numerical simulation and experimental investigations. Nevertheless this structural type can benefit of the huge experience in the field of tunnels and off shore structures, from which SFT differentiates for the peculiar dynamic behavior. However to this concern some similarities can be found with aerial bridges.

Nowadays the state of knowledge is preparatory to the challenging realization of the first submerged floating tunnel.

ABSTRACT: The anchor foundation of submerged floating tunnel has great influence on the safety and stability of the submerged floating tunnel. At present, there are few researches on the quantitative analysis method of anchor foundation of submerged floating tunnel. In this paper, a method of numerical simulation using ABAQUS finite element analysis software is put forward for the bucket anchor foundation of submerged floating tunnel. This method can conveniently and quantitatively analyze the uplift capacity of bucket anchor foundation of submerged floating tunnels in complicated geological and topographical conditions. Moreover, we compared the experimental data of entity model with the numerical simulation results to verify the feasibility of the finite element numerical simulation method.

1 MAIN TEXT

Submerged floating tunnel (SFT) is a new type of traffic across the water. It is characterized by not being buried under the river bed, nor on the river bed, but a closed structure suspended in the water.Due to the characteristics of the SFT, the anchorage foundation meeting the uplift requirements is the necessary guarantee for the safe passage of the SFT.

The length of the SFT is very long, and it spans a wide range of sea area, so that the geological terrain around the anchor foundation is very complex, and the soil environment of the anchor foundation is different. Therefore, an analytical method for quantitatively analysing the anchored foundations of the SFT plays an important role in the study of stability and safety of the anchored foundations of the SFT.

We have already made a study of the entity model experiment to the bucket foundation of the SFT. In this paper, we will establish the three-dimensional model by ABAQUS finite element analysis software according to the experiment of the entity model, and set up the soil parameters, for example, elastic modulus, Poisson's ratio, Moore -- Kulun plastic modulus and uplift load etc. to achieve quantitative analysis. Then the numerical simulation results are obtained by software analysis and calculation. In order to verify the feasibility of the finite element quantitative analysis method, the numerical simulation results are compared with the experimental results of the entity model. The text should fit exactly into the type area of 187 × 272 mm (7.36" × 10.71"). For correct settings of margins in the Page Setup dialog box (File menu) see Table 1.

2 BRIEF INTRODUCTION OF FINITE ELEMENT ANALYSIS SOFTWARE

The finite element analysis is mainly modeled by ABAQUS. ABAQUS is one of the most advanced large-scale finite element analysis software in the world, which has extensive simulation performance. It has numerous unit model, material model, analysis procedure and so on, so it can be used to analyze the various problems in various field, such as solid mechanics, rock mechanics and structural mechanics, especially to solve complicated problems and nonlinear problems. It is because of the excellent analytical ability and the reliability of analog complex systems of ABAQUS that it has been widely used in industry and research of various countries. The main advantages of ABAUS are as follow. First, it is powerful and convenient to use. In most simulations, even highly nonlinear problems, the user only needs to provide some engineering data, such as structural geometry, material properties, boundary conditions and load conditions. Second, nonlinear analysis is powerful. In nonlinear analysis, it can automatically select the corresponding load increment and convergence speed. It can not only select the appropriate parameters, but also adjust the

fax: +86-022-27405816.
E-mail address: shilunfeng@126.com(Shilun Feng)

parameters continuously to ensure the accurate solution in the analysis process. Third, it has a rich library of unit libraries and material models.

3 FINITE ELEMENT NUMERICAL SIMULATION

3.1 *The numerical mode*

We use ABAQUS to build the finite element model, which mainly includes the simulation of the bucket foundation and test soil. The bucket foundation is modeled on the 2# bucket in the previous model experiment, and the specific dimensions are given in Table1. The length of the test soil is about 6 times the diameter of the bucket foundation, and the depth is about 5 times the height of the bucket foundation. By trial calculation, such a region can basically eliminate the influence of the boundary effect on the calculation results.

Table1. The 2# bucket foundation size

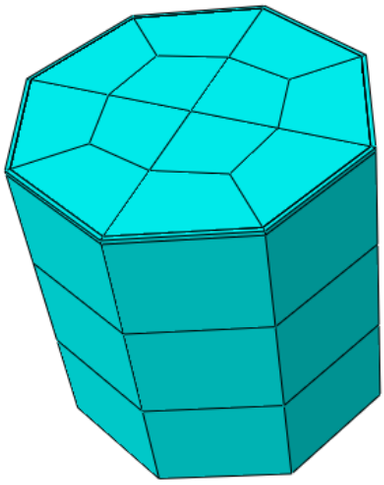
Material	Characteristics of the bucket foundations			
	Mass /kg	Wall thickness /mm	Diameter /mm	Height /mm
Iron	3.77	3	220	220

In the process of modeling, we considered the following basic assumptions:

1. The test soil layer is shallow, so the simulated soil is not layered and adopts the same parameters;

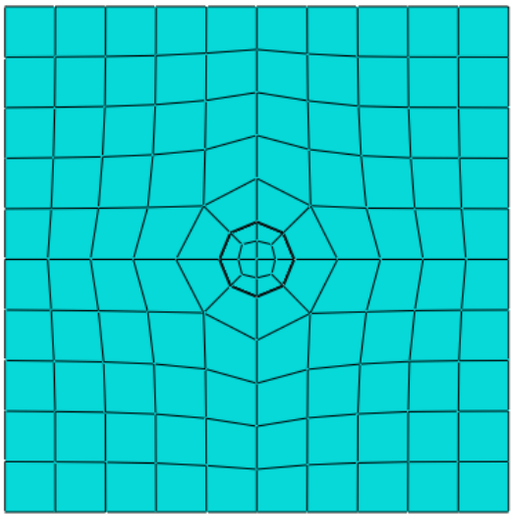
2. The construction step is adopted to simulate the whole process of the experiment, which mainly considers the spatial displacement changes regardless of the time effect;

3. We will mainly simulate bucket foundation and test soil, and simplify simulation of the bucket foundations without consideration of detail changes. The force applied during the test is replaced by load, and no longer simulate other test instruments.



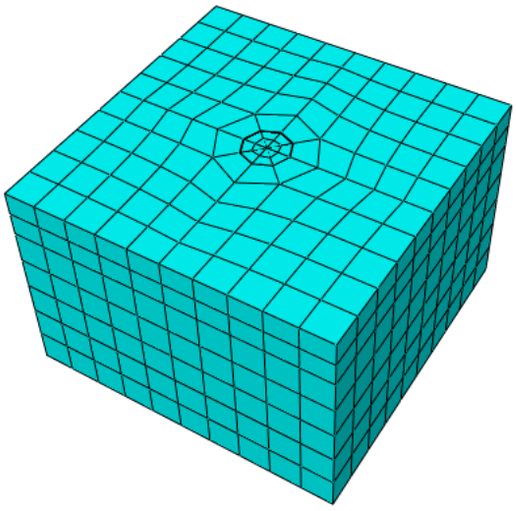
The overall model is modeled by taking the center of the bucket foundation as the coordinate origin and the deepest point of the soil layer as the Z axis 0 point. Both the bucket foundation and the test soil are modeled with a solid homogeneous model. The specific material parameters are shown below.

(1) Bucket foundation

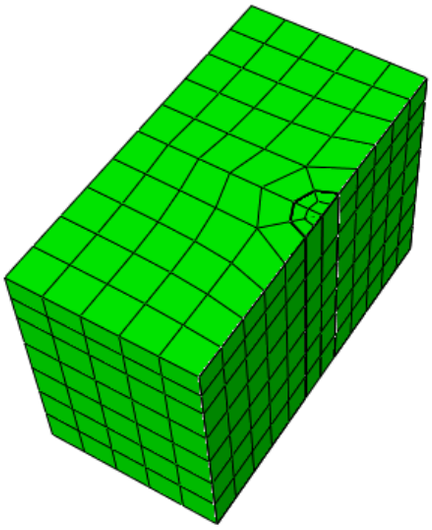


The diameter of the bucket foundation is 220mm, the barrel height is 220mm, and the barrel wall thickness is 3mm. A linear elastic constitutive model is adopted for the barrel structure. The density is 7850kg/m^3, and the elastic modulus are 2.5×10^4 MPa and Poisson's ratio is 0.26. The completed finite element model is shown in Figure 1.(a).

(2) Test soil



The basic dimensions of the test soil are: 1.5m long, 1.5m wide and 1m deep. The test soil type are cohesive soil and sandy soil. The density of cohesive soil is 1950kg/m^3, the elastic modulus is 58MPa, the Poisson's ratio is 0.42, the friction angle is 20°, and the cohesive force is 20kPa. And the density of sandy soil is 1050kg/m^3, the elastic modulus is 67.5MPa, the Poisson's ratio is 0.42, the friction angle is 25°, and the cohesive force is 0kPa. The complete finite element model is shown in Figure 1.(b)~Figure 1.(d).



(a) bucket foundation;

(b) bucket foundation top view;

(c) bucket foundation isometric side view;

(d) bucket foundation profile;

Figure 1. finite element model: (a) bucket foundation; (b) top view; (c) isometric side view; (d) profile.

3.2 *Boundary conditions*

In the whole calculation model, the displacement boundary condition is adopted. The top surface of the whole model is a free boundary surface, the bottom surface is completely fixed to limit the displacement, and the plane displacement is restrained around.

The interaction between the bucket foundation and the soil is finite slip contact, and it's friction coefficient is 0.35.

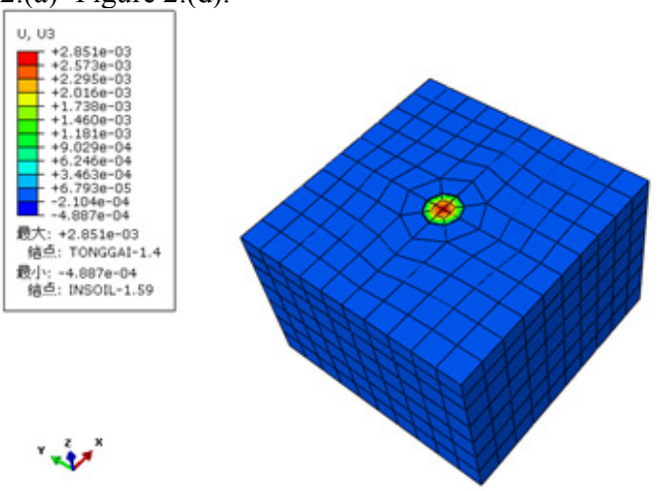
3.3 *Model loading*

Model loading is mainly divided into two steps:

(1) Initial geostress balance

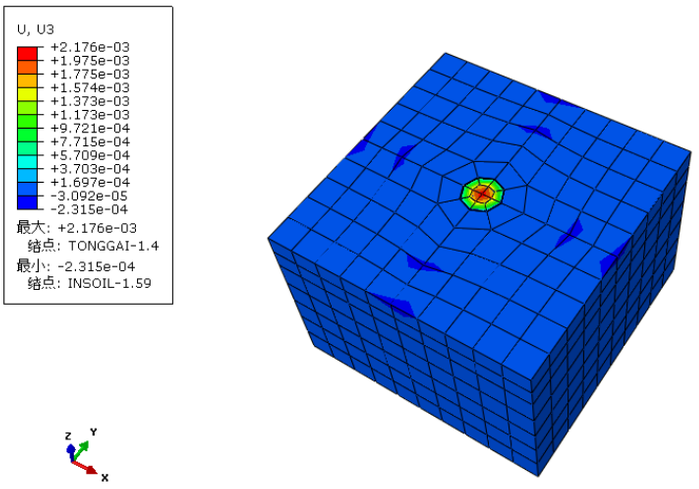
The geostress field is considered in terms of gravity stress field. First, the initial self-weight stress field is established. The test soil for static treatment, and the soil will sink under self-weight, so when the uplift process of the bucket foundation is simulated by finite element method, the initial geostress must be balanced in order to reach the initial state of natural soil layer. Therefore, the first stage of the numerical simulation is the geostress equilibrium stage. At this stage, ABAQUS will calculate the displacement field and stress field of the soil under the action of gravity, eliminate the settlement displacement and construct the initial geostress field.

(2) Uplift loading



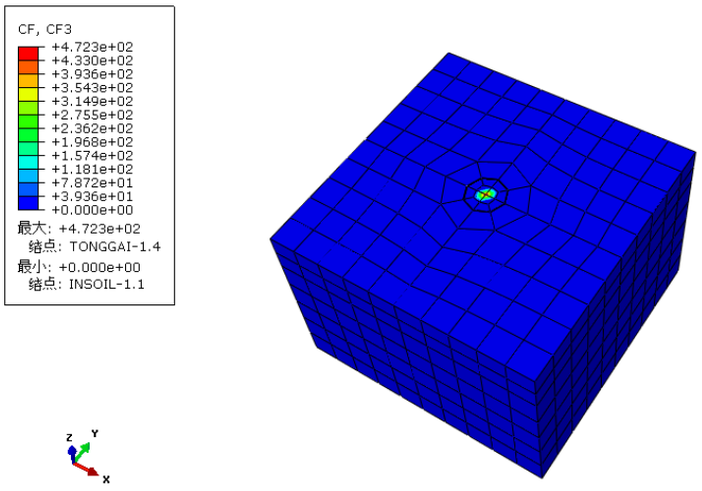
After removing the settlement displacement, the uplift load is applied to the bucket foundation with reference to the previous test loading force. First, the middle of the barrel is taken as the action point, and then the vertical concentrated force is applied at the action point. The loading force values of the test are shown in Table2.

Table2. Loading force

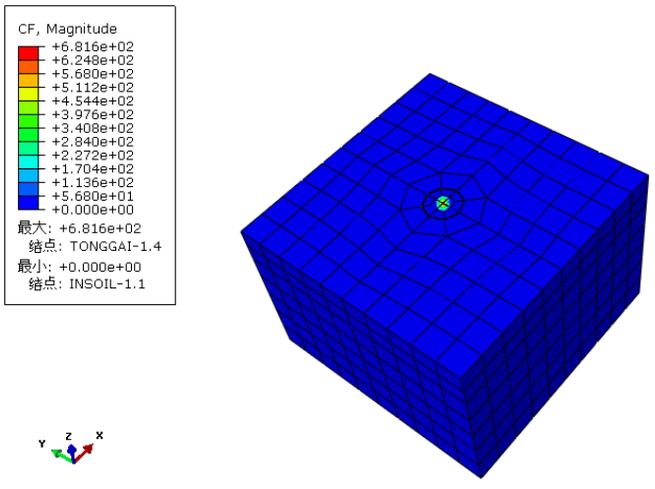


Test soil	Loading force	Action point
Cohesive soil	750	Center of barrel values
Sandy soil	500	Center of barrel values

3.4 *Result*

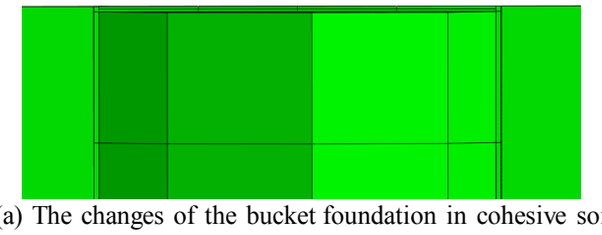


Through the software calculation, we can get the displacement contour and force— displacement curve after the model is loaded. The loading force is greater than the ultimate uplift capacity of the bucket foundation which we get from the previous test. So, as the loading force increase, when the loading force is greater than the ultimate uplift capacity of the bucket foundation, the bucket foundation will be pulled out, and a large shift will occur in the process of simulation, then the software calculation will diverge and eventually interrupt the calculation. Therefore, it can be considered that the force acting on the bucket foundation is the ultimate bearing capacity of the bucket foundation when the software calculation is interrupted. The displacement contour and the concentrated force contour of the 2# bucket foundation in the cohesive soil and sandy soil simulated test are shown in Figure 2.(a)~Figure 2.(d).

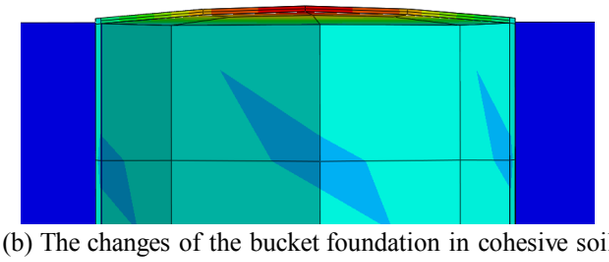


(a) The displacement contour of the cohesive soil;

(b) The displacement contour of the sandy soil;

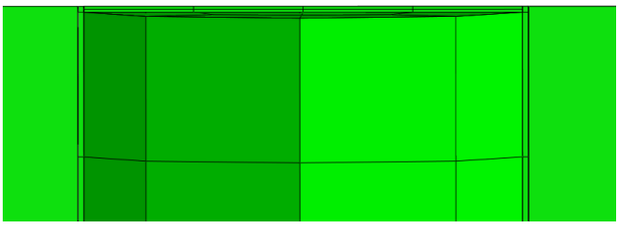


(c) The concentrated force contour of the cohesive soil;

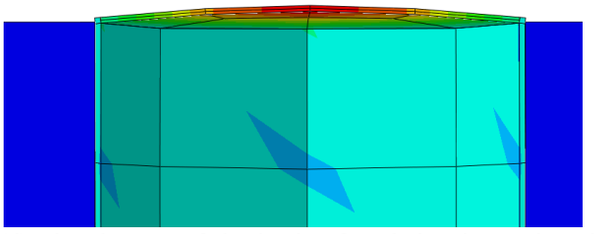


(d) The concentrated force contour of the sandy soil.

Figure 2. contour of simulation results: (a) The displacement contour of the cohesive soil; (b) The displacement contour of the sandy soil; (c) The concentrated force contour of the cohesive soil; (d) The concentrated force contour of the sandy soil.



The bucket foundation will displace after loading, which is shown in Figure 3.(a)~Figure 3.(d).



(a) The changes of the bucket foundation in cohesive soil: before loading;

(b) The changes of the bucket foundation in cohesive soil: after loading.

(c) The changes of the bucket foundation in sandy soil: before loading;

(d) The changes of the bucket foundation in sandy soil: after loading.

Figure 3. The changes of the bucket foundation in cohesive soil: (a) before loading; (b) after loading. The changes of the bucket foundation in sandy soil: (c) before loading; (d) after loading.

Through the software calculation and analysis, we also can get the force-displacement curve of the 2# bucket foundation in cohesive soil simulated test, which is shown in Figure 4~Figure 5.

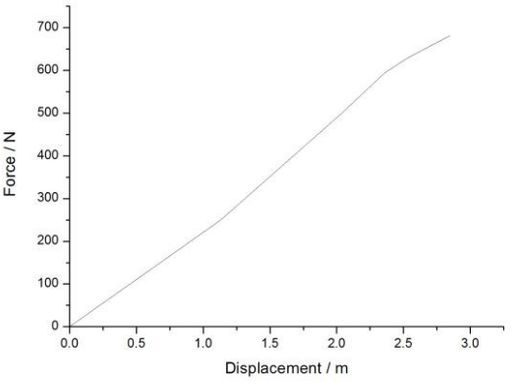


Figure 4. the force— displacement curve of 2# bucket foundation in cohesive soil simulated test

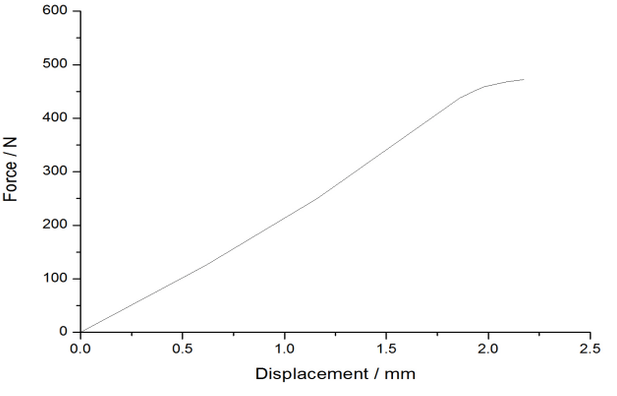

Figure 5. the force— displacement curve of 2# bucket foundation in sandy soil simulated test

4 RESULT COMPARISON

In the previous entity model experiments, we obtained the uplift load—displacement curve of the 2# bucket foundation in cohesive soil and sandy soil test shown in Figure 6~Figure 7.

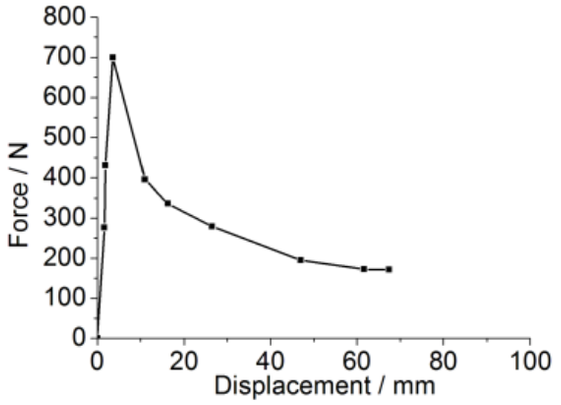

Figure 6. the uplift load—displacement curve of the 2# bucket foundation in the cohesive soil.

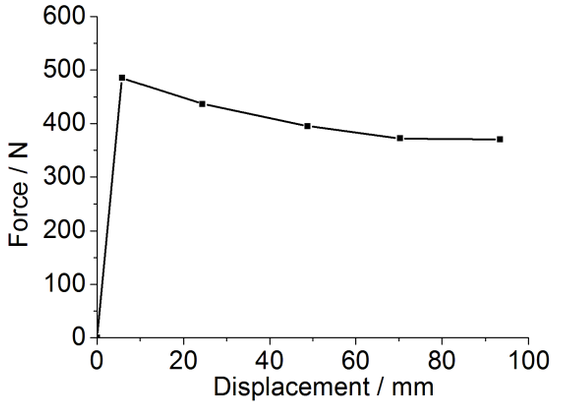

Figure 7. the uplift load—displacement curve of the 2# bucket foundation in the sandy soil.

Through the finite element software ABAQUS analysis, we got the results of numerical simulation. Compared the numerical simulation results with the previous experimental results, we got the contrast result given in Table3~ Table4.

Table3. Comparison of uplift test and numerical simulation of the bucket foundation in the cohesive soil.

Test cohesive soil	Uplift displacement s/mm	Uplift bearing capacity f/N
Model test	3.56	700.12
Numerical simulation	2.85	681.60
Error	-	2.65%

Table4. Comparison of uplift test and numerical simulation of the bucket foundation in the sandy soil.

Test cohesive soil	Uplift displacement s/mm	Uplift bearing capacity f/N
Model test	3.80	485.12
Numerical simulation	2.17	472.30
Error	-	2.64%

By comparing the data in the table, the error of the test result and the simulation result is below 3%, therefore, we believe that the numerical simulation method in this paper for calculating the uplift capacity of the bucket foundation is feasible.

5 CONCLUSIONS

In this paper, the numerical analysis of uplift capacity test of the bucket foundation is carried out. We use ABAQUS software to simulate the uplift test of the bucket foundation in the cohesive soil and the sandy soil. Finally, in the numerical simulation results, the force—displacement curve of the test is obtained, moreover, according to the curve, the ultimate uplift bearing capacity of the bucket foundation is also obtained. By comparing the numerical simulation results and the experimental results, it is proved that the proposed finite element method in this paper is feasible for quantitative analysis of ultimate uplift capacity of the bucket foundation.

Feasibility Study on a Submerged Floating Tunnel for the Qiongzhou Strait in China

B. Jiang, B. Liang
College of Civil Engineering, Chongqing Jiaotong University, Chongqing, P.R. China
B. Faggiano, G. Iovane, F.M. Mazzolani
Department of Structures for Engineering and Architecture, University of Naples Federico II, Naples, Italy

ABSTRACT: Currently, one of the challenging tasks for the structural engineering is to construct a waterway crossing for the Qiongzhou Strait in the south of China. This project has also gained significant attention from researchers in academia. The study presented herein is centered on providing a feasible solution for accomplishing the above mentioned task. Initially, different alternative locations, judged on the basis of the environmental constraints, are studied. Then a comparison between various structural solutions, such as suspension bridge, submarine tunnel and SFT, presents the SFT as a suitable alternative for Qiongzhou Strait waterway crossing due to distinctive advantages, like, among others, shorter distance, lower cost, less impact on environment and navigation, etc. Based on the appropriate conception for cross sections, support systems, materials, joints and connection, a numerical FE model is developed by means of the software ANSYS/Fluent. The SFT structural behavior is analyzed under the influence of different environmental loading conditions, varying the wave heights and lengths, current velocities and water depths, which are typical in Qiongzhou Strait. The numerical results reveal that the proposed SFT solution performs safely even under extreme weather conditions.

1 INTRODUCTION

In the last two decades, several proposals for waterway crossing have been carried out in China due to the demand of traffic and the development of civil engineering technology, such as the crossings of Bohai Strait, Taiwan Strait and Qiongzhou Strait. Moreover, the successful experiences of waterway projects as Hangzhou Bay Bridge, Qingdao Jiaozhou Bay Submarine Tunnel, Xiamen Xiang'an Submarine Tunnel and Hong Kong-Zhuhai-Macau Bridge have greatly increased the enthusiasm and confidence to investing and realizing further projects.

In particular, the Qiongzhou Strait is located in the south of China, between Leizhou Peninsula and Hainan Island. Since 1980s, the local government started to investigate the feasibility for a Qiongzhou Strait waterway crossing and relevant research about this topic still keeps going even up to now. Tan et al. (2001) investigated the possibility to construct an undersea tunnel by means of the shield method, the investment estimation was made too. Mai et al. (2003) discussed the feasibility of a SFT in view of collecting a great amount of meteorological, hydrological, sea conditions and geological data and analyzing the present research situation. Li et al. (2009) studied the option of a cable-stayed submerged floating tunnel, whose feasibility was discussed from the aspects of construction technology, economic index and environmental protection. Yan et al. (2015) listed various layouts of tethers for the submerged floating tunnel and made a comparison of differences among the types and layouts respectively, then provided several proposals for SFT schemes. Wu et al. (2016) analyzed the advantages of SFT in the aspects of nature conservation, construction cost, operation risk with respect to other bridge solutions, also discussing the key technology problems for the selection of a SFT type.

In this article, at first the environmental conditions of Qiongzhou Strait are presented, with reference to the geological nature of the subsoil, weather and marine states. Possible alternatives of locations for crossing are discussed accordingly. Then the main characteristics of different type of structural solutions, like aerial bridges, submarine tunnel and submerged floating tunnel (SFT) are analyzed. As a result of the comparison, a central pattern has been judged as the most convenient for crossing the strait and the SFT solution as providing the best performances for the Qiongzhou Strait waterway crossing. Furthermore, a SFT proposal has been defined, by characterizing the main basic aspects. A FE numerical model has been then set up and hydrodynamic

analyses carried out for investigating the structural behavior.

2 SITE CONDITIONS IN QIONGZHOU STRAIT

2.1 *Geological and weather conditions*

The Qiongzhou Strait is one of the largest three straits in China. The length is about 80 km from east to west and the width ranges from 18 km to 35.5 km (29.5 km on average) from north to south. The seabed is generally wide and deep, with the water depth ranging from 80 m to 120 m along the central axis. In addition, scarps with a maximum height of 70m and a maximum slope angle of 22°-24° are located on the south and north shores (Tan et al. 2001).

Fractures are the major geological structure. The Qiongzhou Strait consists of several groups of fractures: the East-West fracture, the North-East fracture and the North-West fracture. The submarine strata are mainly sedimentary formed in the Tertiary and Quaternary Periods. The upper layer is filled with sludge, sandy clay or silt, while thick-bedded clay and silty sand are distributed on the bottom layer with thickness of hundreds meters.

According to statistics, about thirty-one earthquakes of magnitude above 4.75, from year of 1400 to 1995, have occurred in this area, among them ten ruinous earthquakes, nine of which are over 6.0 in magnitude. The most serious earthquake occurred in Qiongshan in the year of 1605 with a magnitude of 7.5. Two 6.1 magnitude earthquakes occurred in the Northern Gulf in December 1994 and January 1995, respectively. All of them are shallow earthquakes with the majority depth of focus ranging from 5 km to 20 km. All these indicate that the southeast coastal area tends to enter a period of active earthquakes. Besides, there is no records about volcano in this area.

The Qiongzhou Strait is located in a tropical area which is subject to the tropical monsoon climate. The average annual temperature is 24℃, the rainy season is from May to October and the average annual precipitation is more than 1500ml. Every year, the period from May to November is a typhoon season. Every year, in particular, there are more than 5 days in September when the wind force is stronger than Level 8 (Wind speed: 17.2-20.8 m/s). Besides, there are more than 24 days on average every year with dense fog.

2.2 *Location proposals*

According to careful investigations and evaluations, several proposals of locations for waterway crossing in Qiongzhou Strait are put forward by Yan et al. (2015) and Wu et al. (2016): the east line, the central line, and the west line, as shown in Figure 1.

The East Line is characterized by the complex topography, large water depth and high risk of earthquakes. Because the connection point of this line on Hainan Island is far away from Haikou, the capital city of Hainan Province, this line is inconsistent with the development requirements of this city. It would bring more disadvantages than advantages to Haikou and even the whole Hainan Island if constructed as proposed.

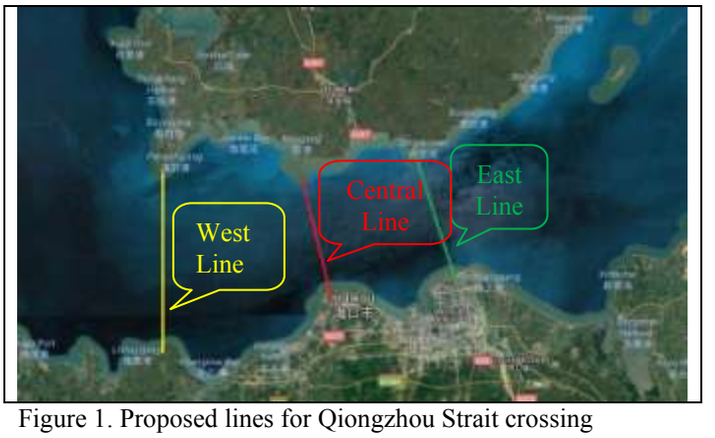

Figure 1. Proposed lines for Qiongzhou Strait crossing

The Central Line is a short waterway crossing distance, connected conveniently with the existing highways and railways at both shores. The main advantages of this line include low investment for the projects, shorter travel time, and low operation cost. Therefore, it can well meet the requirements of the city planning. However, the maximum water depth is 88 m.

The West Line, compared with the other lines, is characterized by a more flat seabed, with the maximum water depth equal to just 55 m, but the length of the waterway crossing is larger. It is farther away from the existing highways and railways at both shores, so the investment for the project would increase. In addition, this line has to avoid crossing the nature reserve located in this area, which may cause more obstacles in construction.

Among these three lines, the central line is the most appropriate location for the waterway crossing due to its shorter distance and better geological conditions compared with the others. Therefore the central line is selected in this article, as a consequence the studies hereafter are based on this location.

3 FEASIBILITY OF DIFFERENT CROSSING SOLUTIONS IN QIONGZHOU STRAIT

3.1 *General items*

The complexity of the design issues for traditional technological solutions, like either suspension and cable-stayed bridges or immersed and underground tunnels, increases as the distance to be covered grows up, so that the crossing of long span waterways can be, in many cases, very difficult and some-

times impossible for such traditional systems. The necessity to find alternative technical solutions rises. A Submerged Floating Tunnel (SFT) is an innovative underwater structure, applied for waterway crossing in particular case of long distances and has many features that make it advantageous compared to traditional structural types, allowing to solve some problems.

Hereafter main aspects for every bridge types are depicted and compared each other.

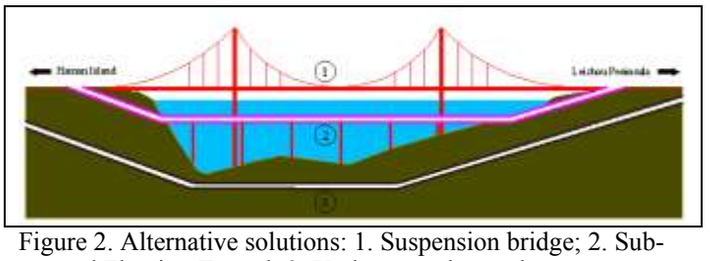

Figure 2. Alternative solutions: 1. Suspension bridge; 2. Submerged Floating Tunnel; 3. Underground tunnel

3.2 *Suspension and cable stayed bridges*

At present, the longest span of suspension bridges is found in the Akashi Bridge, whose main span reaches 1991 m. China has reached experience in construction of long-span bridges, such as the Zhoushan Xihoumen Bridge (1650 m, 2009), the Runyang Yangtze River Bridge (1490 m, 2005) and the Jiangyin Yangtze River Bridge (1385 m, 1999). The hydrological, meteorological, geological and navigational conditions of the Qiongzhou Strait are complicated and therefore it is difficult to construct a bridge in the large-depth zone. In the central line location aforementioned, the construction of a multiple spans bridge with a single span over 1000m could be feasible. By means of modern construction technology, the foundations and piers of long-span bridge can be constructed successful (Zhang, 2016). Compared with tunnels, the vehicles running on the bridge have undoubtedly much comfortable travel conditions, as lighting, ventilation, vision, and so on. As the same lower expense for the bridge operation are required, also for easier maintenance service. On the other hand, the central line is around 20km in length. If the bridge is designed with single spans of about 1000 m, about 20 piers and related foundations are needed, involving high cost. Conversely, the extension of the length of single spans gives rise to increasing height of the main tower of the bridge. For this reason, the design and construction of the foundation would become very hard.

Moreover, the Qiongzhou Strait is a busy sea crossing. For this reason, the piers of the bridge would impact on the ships navigation. In addition, the distance from the deck to the water surface would limit big ships from crossing the strait. Moreover, the tall main tower resulting from the long-span bridge would affect flights.

Because the bridge is directly exposed to the natural environment, the traffic would be affected largely by weather conditions. In case of strong wind, heavy fog, or other inclement weather situations, the safety of vehicles would be reduced inevitably, or what's worse, the traffic would be interrupted.

3.3 *Underground and immersed tunnels*

Over the past years, the world has seen great improvements in the technology of submarine tunnel design and construction. Several submarine tunnels have been completed in the past decades, such as the Seikan Tunnel (Japan, 1988) and the Channel Tunnel (Great Britain-France, 1994). In China, researchers have also obtained experiences from some subsea tunnel projects, such as the Xiamen Xiang'an Subsea Tunnel (2010) and the Qingdao Jiaozhou Bay Tunnel (2011). At present, the longest roadway immersed tunnel project is the Hong Kong-Zhuhai-Macao Bridge. The construction has been completed and the tunnel will be opened for public use before July 2018. Taking advantage of the design and construction experiences gained from China and foreign countries, an underground or immersed tunnel for crossing Qiongzhou Strait could be feasible. Compared with an aerial bridge, a submarine tunnel can assures the continuity of the vehicle travel, it being not influenced by the weather conditions. Moreover, it has far less impact in service on the environment. However, at the central pattern in the strait, the maximum water depth is around 85 m. Therefore, according to the construction experiences of existing submarine tunnels, the buried depth of such a submarine tunnel in this location would be over 100 meters. In order to meet the slope requirement, the submarine tunnel should be then extended to land with a very long distance. It is estimated that the minimum distance of the submarine tunnel would reach 30 km, what involve a high increment of the cost of construction.

A submarine tunnel needs to meet higher requirements for geological conditions. Due to some uncertainty factors that could exist in the construction it would result in large investment, high risks and a long construction period.

Due to the presence of fractures, landslide and water gushing accidents could almost inevitably occur during the construction and operation. Moreover in service, the cost on lighting, ventilation and maintenance would be higher than those of a bridge. As previously mentioned, the Qiongzhou Strait is located in a seismic region, so the subsea tunnel would suffer catastrophic damages in case of an earthquake. Once a disaster happens, the water flow into with high pressure through possible failures. As a consequence, the tunnel could never be repaired.

3.4 *Submerged Floating Tunnel (SFT)*

From Figure 2, it is evident that the length of the submerged floating tunnel is shorter as respect to subsea tunnel, the slope being reduced. Therefore the SFT has less influence on the surroundings. The lower length is of course also favourable for escapeing in case of accidents. The distance between the SFT and the water surface can guarantee the security of navigation. The unit cost of the SFT is constant, whereas the cost of the suspension bridge and the submarine tunnel increase rapidly as the span increases (Faggiano et al., 2010).

SFT is also a convenient solutions in seismic areas due to both the structural deformability and the damping effect of water, with a consequent reductions of the seismic effects.

So far, no SFT project has been constructed yet, even though several detailed studies have been carried out (Mazzolani et al. 2008, Jiang et al. 2017). In this case, the lack of specific construction experience is bridged by the consolidated experiences in the construction of subsea tunnels and off shore structures counterparts.

4 THE SFT PROPOSAL FOR QIONGZHOU STRAIT WATERWAY CROSSING

4.1 *General aspects*

Compared with a bridge or a submarine tunnel, SFT is the most suitable solution for the Qiongzhou Strait waterway crossing due to its distinctive advantages, such as, among others, shorter distance, lower cost, less impact on environment and navigation.

The Qiongzhou Strait is a busy shipping way. In order to satisfy the requirement of navigation space for big vessels and reduce the impact from the water surface wave, the clearance depth between the water surface and the submerged floating tunnel is proposed to be 30 m (Xiang et al. 2017).

Based on the geological condition of the central line and the navigation clearance requirement, the longitudinal profile for the proposed SFT is shown in Figure 3.

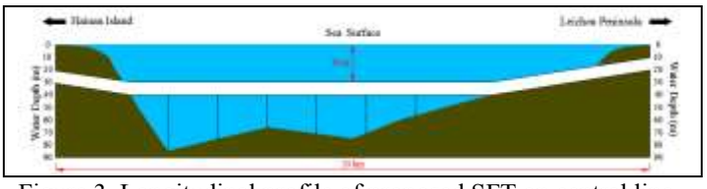

Figure 3. Longitudinal profile of proposed SFT on central line

4.2 *Cross-section*

The proposed reinforced concrete polygonal cross-section is illustrated in Figure 4.

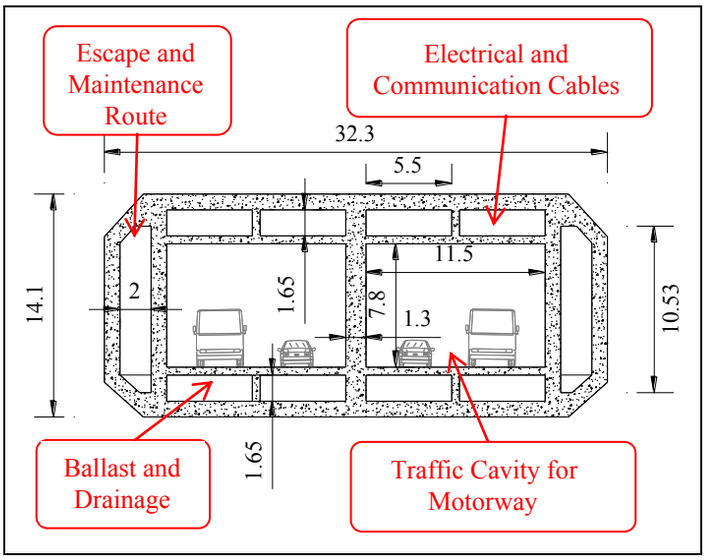

Figure 4. Proposed polygonal Cross-section [m]

For the Qiongzhou strait crossing, only the motorway traffic is considered. The elongated polygonal shape is selected joining a good performance in terms of hydrodynamic behavior, space exploitation, workability. As a counterbalance the streamlined external shape requires more accuracies and thus causes more difficulties to the construction technology.

The clearance space requirements for traffic lanes are defined according to the Code for Design of Road Tunnel (JTG D70-2004, in Chinese). Overall sizes are 14.1 x 32.3 m. Main walls have 1.0 m thickness (1.3 m the central wall), the other walls have 0.5 m thickness.

Reinforced concrete is widely used in maritime structures and particularly recommended when a large structural weight is required to stabilize the structure. It should provide the required structural strength and stiffness, as well as the weight needed to counteract the tunnel buoyancy.

4.3 *Support systems*

Among all the possible support systems of the SFT, free tunnel and pontoons are not suitable for the long distance and busy navigation in the Qiongzhou Strait. In addition, with the various fractures distributed at the seabed, column support is not an appropriate solution. Based on the geological condition of the Qiongzhou Strait, steel cable support is a reasonable alternative for the SFT, commonly proposed for several SFT prototypes (Wahyuni et al. 2009, Mazzolani et al. 2010, Seo et al. 2015, Faggiano et al. 2016).

In order to control the displacement induced by the environmental loads, either in the horizontal or vertical directions, the inclined configuration of four cables (0.3 m diameter) into a group is adopted, as shown in Figure 5.

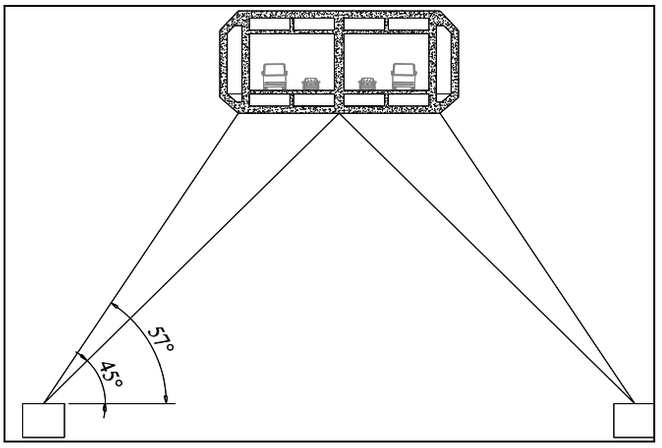

Figure 5. Proposed inclined configuration of cables

4.4 *Joints and connections*

The inter-module joints and the shore connections play a significant role in the whole SFT structure.

In general, the inter-module joints must guarantee the continuity of the structure. The SFT can be subjected to significant displacements and rotations in the longitudinal bending planes. In addition, the axial displacements are allowable at the terminal joints due to thermal variations and triaxial rotations (Martire, 2010). Therefore rigid joint are necessary. Also requirements of tightness, workability and durability should be satisfied.

The connection between the SFT and the shore involves appropriate interface transition elements to couple the flexible water tunnel with the rigid tunnel bored underground (Faggiano et al. 2016), also guaranteeing watertighting. In particular, the Qiongzhou Strait is located in seismic area, so the risk of submarine landslides needs additional attention.

Moreover, the longitudinal gradients of the bored tunnel should be opportunely fixed, taking account that the SFT should keep straight on the longitudinal direction and that the length of the bored tunnel is closely related to the cost of the entire project, therefore it should be limited as possible. The longitudinal gradients of a bored tunnel are proposed to range from 0.3% to 3%, according to the regulations specified in different codes, as shown in Table 1 (Zhang et al. 2013),

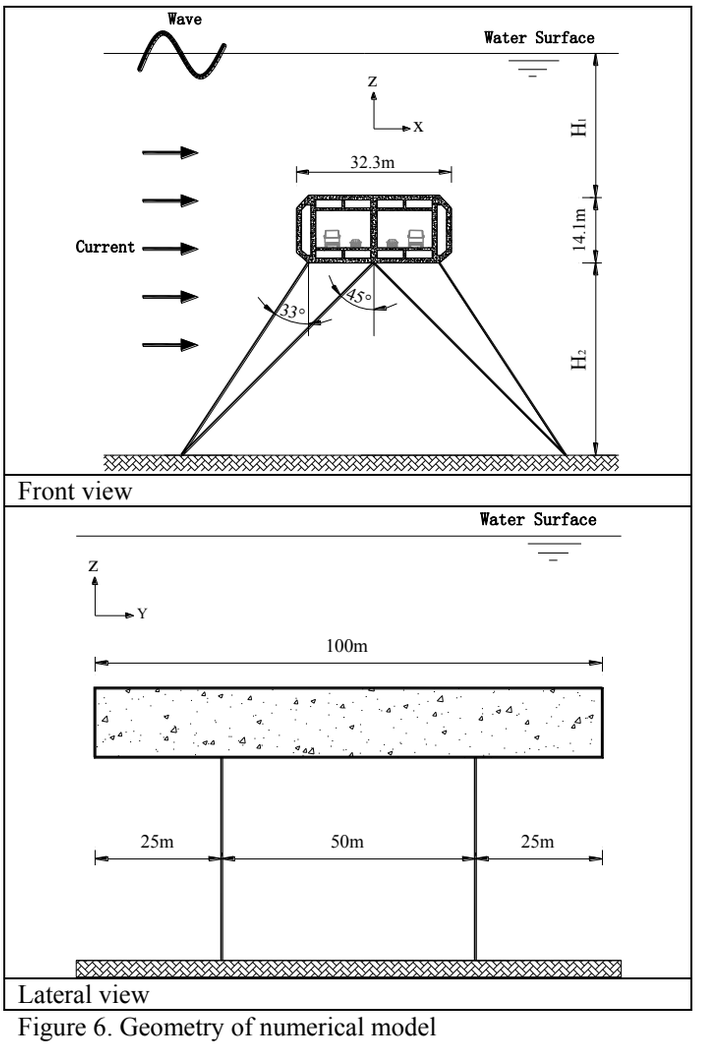
Table 1. Regulations for tunnel longitudinal gradients (Zhang et al. 2013)

Country	Code	Tunnel longitudinal gradient
P.R China	MOT. JTG D70-2004 Code for design of road tunnel	0.3%-3%, maximum 4% depending on traffic conditions
European Union	DIRECTIVE 2004/54/EC	> 5% normal, [3-5%] assistant measures > 3% no extra measures
USA	FHWA Road Tunnel	> 3%-4%
UK	Design code for Road and Bridge	> 6% depending on traffic and ventilation requirements
Norway	NPRA Motorway Tunnel	6%-8% normal
Sweden	VV Tunnel 2004	> 5% normal < 5% for short distance permitted by experts
The Netherlands	SATO	> 4% design speed 90 km/h > 3% design speed 120 km/h

5 NUMERICAL ANALYSIS

A Finite Element numerical model is implemented by means of the software ANSYS Workbench and Fluent in order to perform a preliminary rough evaluation of the structural performance of the SFT assumed against hydrodynamic loads. The model in fact represents just a short tube 100 m long. Therefore only displacement and rotation along the longitudinal direction Z are restrained at both ends of the tube. Spherical hinges have been assumed at both ends of the cables.

The model geometry is given in Figure 6. The material properties are given in Table 2.



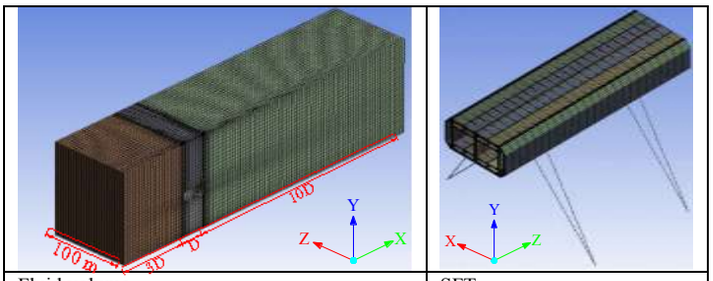


Figure 6. Geometry of numerical model

Table 2. Material properties

Properties	Materials	
	Concrete	Steel
Density	2500 Kg/m^3	7850 Kg/m^3
Elastic modules	32x10^3 MPa	201x10^3 MPa
Strength	35 MPa	1860 MPa

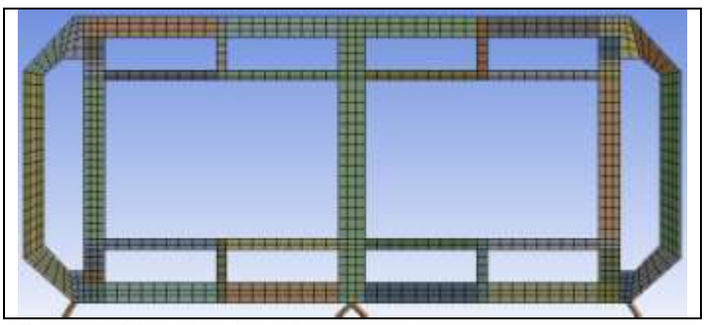
The fluid model is calculated first in Fluent, then the result data are transferred to ANSYS Workbench for Transient Structural Dynamic calculation. In order to reproduce the full turbulent phenomenon, the distance from the inlet upstream side has been assumed equal to 3D (D width of the polygonal section = 32.3 m), a distance of 10D has been set downstream the tunnel. The width along direction Z is set to 100 m, as the length of the tube. The depth of H_2 varies depending on the location of the proposed SFT. The hexahedron finite elements are applied for meshing the both the fluid and the tube, as shown in Figure 7. The cables are modeled as beam element.

For the sake of simplifying the calculation of the fluid model, the Airy wave and RNG viscous mode are applied for simulating the wave and turbulence, respectively, while the current is assumed as steady flow.

Fluid volume | SFT

Figure 7. Mesh scheme of numerical model

An appropriate mesh size for the model is very important for calculation accuracy. The mesh size of the fluid volume is 4.0 m. For the tube model, the mesh size ranges from 0.2 m to 4.0 m, depends on different zones due to its irregular shape, as shown in Figure 8.



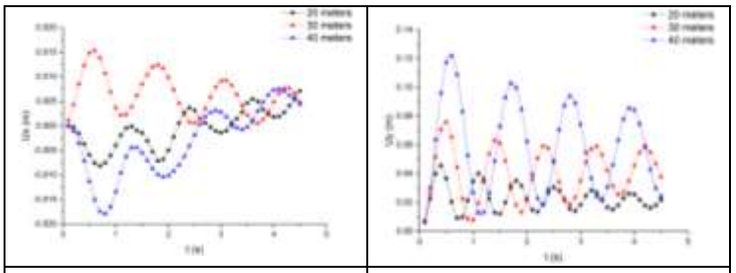


Figure 8. Mesh detailed of cross-section plane

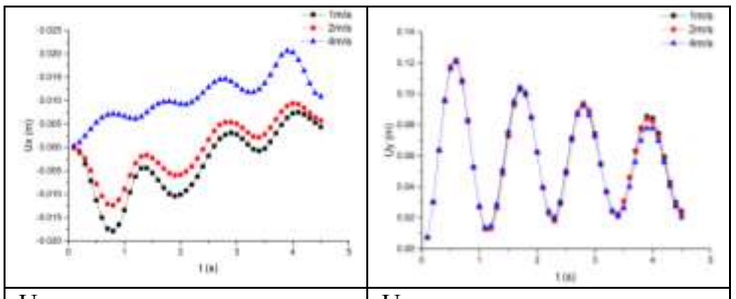
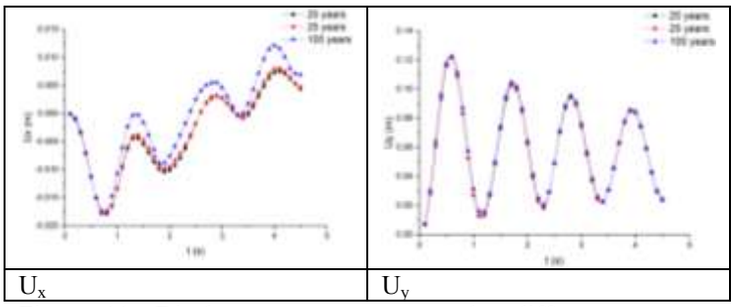
Current, wave and traffic loads are considered in the model. Assumed parameters for current and wave loads as given in Table 3. Only motorway traffic loads are considered. According to the Chinese code (MOT. JTG D70-2004 Code for design of road tunnels), the traffic loads are defined as distributed loads of 10.1 kN/m^2 and arranged fully on the internal pavement.

Table 3. Analysis parameters assumed



Water depth (Fig. 7)		
H_1= 30m	H_2= 40, 30, 20 m according to different geological seabed conditions	
Extreme wave	according to monitored data in Qiongzhou Strait	
Return period [years]	Height	Length
20	7m	115.11m
25	7.3m	119.45m
100	8.6	137.38
Current velocities	1.0 m/s, 2.0m/s, 4.0 m/s	

The U_x and U_y displacements at the tube mid-span are presented in Figures 9-11 with varying water depths, current velocities and waves. Because the limit speed of vehicle in the tunnel is 80 km/h, the figures only show the results within 4.5 s which equals to the time that the vehicle crossing the 100 m tube with limit speed.



U_x | U_y

Figure 9. Displacement responses under different water depths H_2 (wave height: 7.0 m, current velocity: 1.0 m/s)

U_x | U_y

Figure 10. Displacement response under different current velocities (H_2:40 m, Wave height: 7.0 m)

U_x | U_y

Figure 11. Displacement responses under different waves (H_2:40 m, current velocity: 1.0 m/s)

In Figure 9, the maximum displacement values for H_2=40 m are U_x = 0.18 m, U_y = 0.12 m. The amplitudes of U_x and U_y are all reduced as far as H_2 depth decrease, as the wave effect is lower.

In Figure 10, for current velocity equal to 4.0 m/s, the maximum amplitude of U_x rises to 0.20 m. It is

apparent that the current velocity influences U_x, but it has a slight effect on U_y.

In Figure 11, the maximum displacement values are U_x = 0.18 m, U_y = 0.12 m. U_x and U_y don't have large changes while wave parameters change.

In general, the maximum U_x is 0.2 0m, the maximum U_y is 0.12 m. These displacement responses are acceptable relative to the size of structure. In addition, the maximum calculation stresses in the tunnel structure and cable are 18.52 MPa and 1025 MPa, respectively. They are all smaller than the defined strengths of materials in the model.

The results prove that the proposed SFT structure is safe even under extreme weather condition, whatever in the view of displacement and stress.

6 CONCLUSIVE REMARKS

This article presents the preliminary feasibility studies on a Submerged Floating Tunnel (SFT) for the Qiongzhou Strait waterway crossing.

Compared with proposed east line and west line for Qiongzhou Strait waterway crossing, the central line is an appropriate location because of its geological and weather conditions. On the other hand, the SFT is a better solution compared with bridge and submarine tunnel, due to its distinctive advantages, such as shorter distance, lower cost, less impact on the environment and navigation, etc.

A polygonal cross-section, the inclined cable support system, the rigid inter-module joints are selected for aforementioned aspects respectively.

By means of the Finite Element numerical software ANSYS Workbench and Fluent, the displacement responses at the SFT mid-span are analyzed, for different water depth, current velocity and wave parameters. The results reveal that the displacement response of proposed SFT is acceptable relative to the size of structure, even under extreme weather conditions. In addition, the calculation stresses in the tunnel structure and cables are all smaller than the strengths of related materials.

In conclusion, the SFT solution is feasible for Qiongzhou Strait waterway crossing according to the previous studies about location, design aspects and numerical analysis. This article aims to render the Qiongzhou Strait waterway crossing into reality. If the SFT solution is adopted by the decision maker for Qiongzhou Strait, it will be a revolutionary event of civil engineering in the world, and will also be considered the realization of a common dream of all SFT researchers.

ABSTRACT: The situation of Submerged Floating Tunnel (SFT) subjected to various loads is complicated, it would be more complex if involving traffic loads. In order to find the appropriate method to simulate the traffic loads in SFT, the simulated formula of traffic loads is carried out in this paper. This formula borrows the experiences from the researches of traffic loads for roadway and railway, several influence factors are taken into account in the formula, such as static loads, road roughness, velocity of vehicle and external incentive loads. Then this paper investigates the characteristics of simulated traffic loads and the impacts on dynamic response of SFT structure due to different simulation of traffic loads. The results reveal that the simulation which proposed in this paper is more reasonable to calculate the traffic loads of SFT in a certain extent.

1 INSTRUCTIONS

Submerged Floating Tunnel (SFT) has several advantages, like shorter length, better economy, more friendly environment (Xiang et al. 2016), compared with other traditional waterway crossing structure (such as suspension bridge, tunnel, etc.) , which has attracted more and more academic and social attention in recent years. In the related researches of SFT, the internal traffic load must be taken into account as well as the reasonable form of traffic load simulation. Concerning the simulation method of SFT's internal traffic load, several related researches has been conducted already by the domestic and foreign scholars. Perotti et al. (2010) proposed that the simulation method of SFT can take references from the bridge traffic researches, because the SFT structure is similar to the closed underwater bridge and the studies of bridge traffic load is relatively mature. Martire (2010) used the constant uniform load to simulate the traffic load in SFT, according to the European standard (Env 1991-3, traffic loads on bridges) method in the study of bridge traffic load. Tariverdilo et al. (2011) simulated the traffic load in SFT as moving concentrated load along the tube longitudinal direction, on the basis of the simulation to study the dynamic response of SFT; Dong et al. (2016) simplified the traffic load in SFT as a series of equidistant and concentrated load, then studied the influence on SFT's dynamic response from the tension leg vertical stiffness, the value of traffic load and the vehicular gap; In the existing studies, the internal traffic load of SFT mainly simulated as uniform load or concentrated load, but the dynamic properties of traffic load are not fully considered.

In this paper, the traffic load of SFT is simulated as moving vibrant load, the fluctuation and periodicity of traffic load are considered, meanwhile considering the influence of the wave and current which belong to the external excitation loads. By means of the proposed traffic load simulation and numerical calculation, the variation law of traffic load is analyzed. In addition, the influence of different traffic load simulation methods on the vibration displacement response of SFT is also studied contrastively.

2 INFLUENCE FACTORS AND SIMULATION FORMULA OF TRAFFIC LOADS

2.1 *Simulated factors of traffic loads*

The traffic load is a random load, its motion and size vary randomly. In the existing studies of highway and railway traffic load, the traffic load is often simulated as vibrant load, therefore the traffic load of SFT is proposed as the moving vibrant load in this paper. The moving vibrant load is a kind of dynamic load with a certain frequency and amplitude, it can better reflect the dynamic characteristics of vehicles, it also can simulate the different traffic volumes and

different axle loads of vehicles by changing the vibration law.

In the aspect of railway traffic load research, Liang et al. (2006) propose that the railway traffic load could be simulated with an exciting force function, which corresponding to the vertical wheel rail force that appears mainly in the low frequency range (0.5-10Hz), the intermediate frequency range (30-60Hz) and the high frequency range (100-400Hz). The interaction force between wheel and rail is simulated by the excitation force which reflects irregularity, additional dynamic load and rail corrugation effect, it is shown in Equation 1.

$$F(t) = P_0 + P_1 \sin \omega_1 t + P_2 \sin \omega_2 t + P_3 \sin \omega_3 t \quad (1)$$

Where P_0 is the wheel static load, P_1, P2, P_3 are the amplitudes of the vibration load corresponding the vibration frequency of the rail ω_1, ω_2, ω_3 respectively.

$$P_i = M_0 a_i \omega_i^2 \quad (2)$$

Where M_0 is the unsprung mass, a_i is the height of the geometric irregularity corresponding to the different circular frequencies of vibration, it reflects the road condition. ω_i is the circular frequency of vibration.

$$\omega_i = 2\pi v_t / L_i \quad (3)$$

Where v_t is the velocity of train, L_i is the wavelength of geometric irregularity curve.

In the aspect of highway traffic load research, the simulation is simpler than railway traffic load. Zhang et al. (2001) used a simple force similar to the excitation form that can reflect its periodic characteristics and geometric irregularities to express vehicle loads approximately.

$$F(t) = P_0 + P \sin(\omega t) \quad (4)$$

Where P_0 is the wheel static load, P is the amplitude of vibrant load, only the traffic dynamic load, which caused by the road irregularity, is considered.

$$P = M_0 a \omega^2 \quad (5)$$

Where M_0 is the unsprung mass, a_i is the height of the geometric irregularity, it reflects the road condition. ω is the circular frequency of vibration.

$$\omega = 2\pi v_c / L \quad (6)$$

Where v_c is the velocity of vehicle, L is the wavelength of geometric curve.

According to the aforementioned simulation methods of railway and highway traffic load, it can be found that the simulated factors of traffic load mainly include: wheel static load, geometric irregularity of rail surface or road surface, velocity of vehicle, construction of vehicle (unsprung etc.).While studying the traffic load of SFT, the external excitation load (wave and current) should be considered except the above factors.

2.2 *Formula of traffic load*

On the basis of above analysis, the formula of moving vibrant load could been concluded for railway or roadway. In this paper, only the traffic of roadway is considered, the proposed formula of traffic load is given as Equation 7.

$$F(t) = P_0 + M_0 \cdot A_1 \cdot \omega_1^2 \cdot \sin(\omega_1 t) + M_0 \cdot A_2 \cdot \omega_2^2 \cdot \sin(\omega_2 t) \quad (7)$$

Where P_0 is the wheel static load, M_0 is the unsprung mass, A_1 is the road roughness, and it reflects the road condition. A_2 is the vertical vibration displacement of SFT structure caused by wave and current, it reflects the influence from external excitation load.

ω_1 is the circular frequency of vehicle vibration caused by road roughness:

$$\omega_1 = 2\pi v_c / L \quad (8)$$

Where v_c is the velocity of vehicle, L is the wavelength of geometric curve, equals to the length of vehicle.

ω_2 is the circular frequency of vehicle vibration induced by wave and current, it equals to the frequency induced by vortex vibration.

$$\omega_2 = \omega_s = 2\pi S_r v_f / D \quad (9)$$

Where Sr is the Strouhal number, usually equals to 0.2 (Qin et al. 2010). vf is the velocity of current. D is the section width of tube.

The simulation expression is based on the existing traffic load calculation formula, the particularity of the environment of SFT is considered, and the influence of external excitation load (wave and current action) is added.

3 NUMERICAL SIMULATION AND ANALYSIS

3.1 *Numerical model*

In view of the fact that there is no SFT project in the world, this paper refers to the existing design data and research results worldwide (Mazzolani et al. 2008, Kanie 2010, Seo et al. 2015, Faggiano et al. 2016), the proposed SFT model is built as shown in Figure 1.

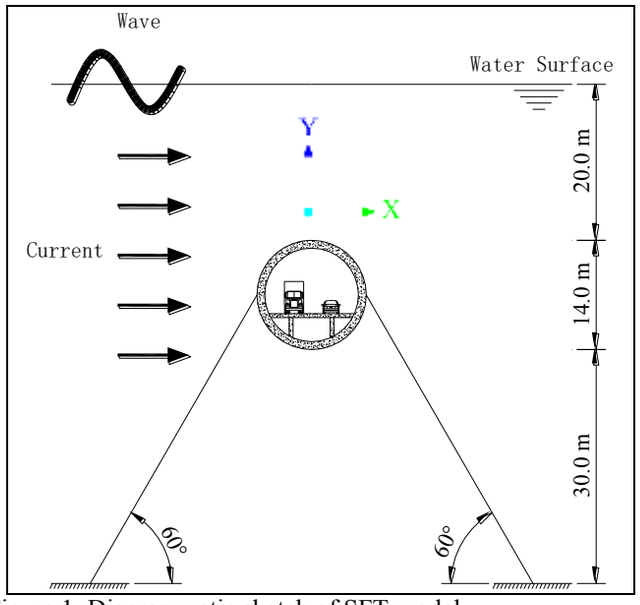

Figure 1. Diagrammatic sketch of SFT model

In this model, circular cross-section and inclined cable support system are selected for SFT. The circular cross-section consist of external shell and internal cavities, the upper cavity is designed for roadway traffic and the lower cavities are designed for ballast and functional equipment. In this paper, only one segment of the tunnel (100 m) is selected for calculation. There are two groups of inclined cables which arranged at the two ends of tunnel. The water depth is also assumed in Figure 1.

About the materials, the reinforced concrete and steel strand are adopted for tunnel and cables, respectively. The basic parameters for the model are given in Table 1.

Table 1. Fundamental parameters of SFT for numerical simulation

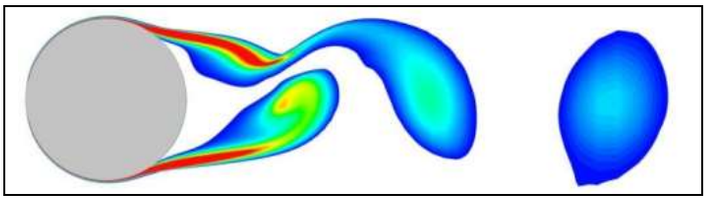
Properties	Unit	Value
Inner diameter of tube	m	12
External diameter of tube	m	14
Equivalent density of tube	kg/m^3	2500
Elastic modules of tube	GPa	32
Density of cable	kg/m^3	7850
Elastic modules of cable	GPa	201
Diameter of cable	m	0.3
Density of current	kg/m^3	1028

Based on aforementioned assumptions and parameters, another important factor BWR (Buoyance Weight Ratio) is calculated for 1.40.

As shown in Figure 1, current, wave and traffic loads are considered in the model. Current is assumed as steady flow, the velocity of current is defined for 1.0 m/s. Wave is assumed as airy linear wave, the properties of slight sea are adopted (Wave height: 1.0 m; Wave length: 13.0 m).

In order to study the differences of traffic load simulation method, three different types of traffic loads are selected: fixed distributed load, moving concentrated load and moving vibrant load. The fixed distributed load is arranged fully on the internal pavement, the moving concentrated load or moving vibrant load is assumed as distributed load applied in a small area. This area simulates the wheel of vehicle moving from one end to another end of tunnel. The parameters of traffic load is given in Table 2.

Table 2. Parameters of traffic load



Parameters	Unit	Value
Static wheel load	kN	20
Unsprung mass	N · s^2/m	120
Length of vehicle	m	6
Road roughness	m	0.002
Velocity of vehicle	km/h	80

According to the China current highway tunnel design code MOT. JTG D70-2004 Code for design of road tunnel, the limit speed of vehicle in tunnel is 80 km/h, therefore the duration is 4.5s when the vehicle crossing the 100m tunnel. Only the results within 4.5s are presented.

The numerical simulation is implemented by means of the finite element analysis software ANSYS Workbench and Fluent. The fluid model with current and wave loads is calculated in Fluent at first, then the fluid result data could be transmitted directly to Workbench. The Transient Dynamic analysis is completed in Workbench. Finally, the dynamic response of tunnel structure can be obtained.

3.2 *Characteristics of traffic load*

Vortex shedding occurs because the flow is unable to follow along the surface of the structure and separates from the surface. This flow separation creates a vortex which causes a local increase in rotational velocity. Higher flow velocity yields a reduction in dynamic pressure, which creates an attraction force by the vortex on the structure. The position of the separation point alternates between the top and bottom of the cylinder, and creates a vortex street, as illustrated in Figure 2. (Fjeld et al, 2012)

Figure 2. Vortex Street behind a circular cylinder (Fjeld et al. 2012)

The transverse (Direction X) and vertical (Direction Y) displacements of tunnel structure induced by vortex should be calculated at first, in order to confirm the parameter A_2 in Equation 7. The point on mid-span is selected as the structural check point.

Only wave and current loads are considered in the first calculation, the traffic load is ignored. The results are shown in Figure 3.

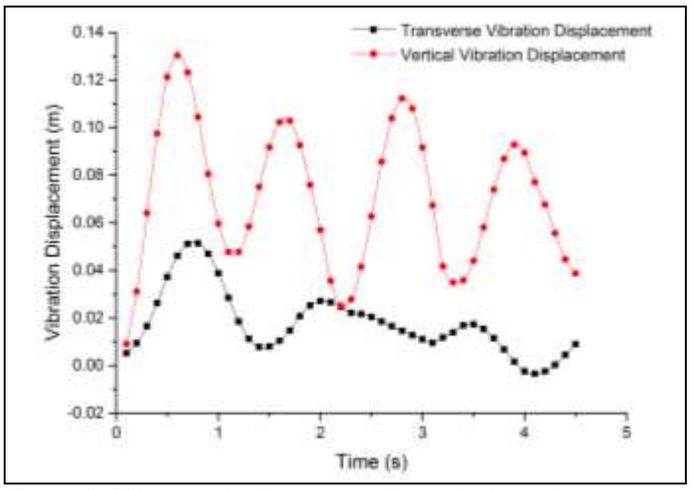


Figure 3. Vibration displacements of tunnel tube under wave and current loads

From the Figure 3, the amplitude of vertical vibration displacement is obviously larger and more regular than the transverse vibration displacement. Considering the aspect of safety, the maximum value (0.13 m) of the vertical vibration displacement is regarded as the influence value of the external excitation load A_2 (Equation 7) on the traffic load. The simulated traffic load as shown in Figure 4.

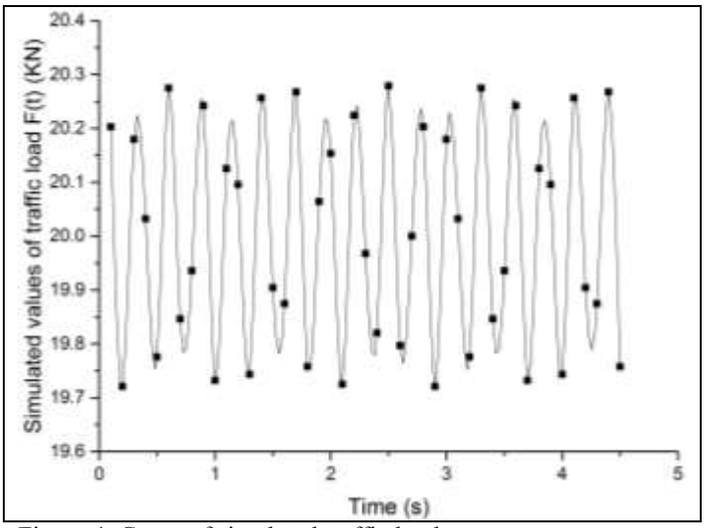

Figure 4. Curve of simulated traffic loads

From the Figure 4, the simulated value curve of traffic load has variable frequency and amplitude with time changes. It has a certain periodicity and this is consistent with the characteristics of the vibrant load. The wheel static load P_0 is 20 kN, therefore the simulated value curve fluctuates at 20kN. Moreover, the amplitude of the fluctuation curve deviates from the static load means the part of dynamic load in the traffic load, while the amplitude is larger, the proportion of dynamic load is greater.

3.3 *Comparative analysis of traffic load*

In order to study the rationality of traffic load simulation method, three different types of simulation methods are selected: fixed distributed load, moving concentrated load and moving vibrant load. Under the combined action of wave and current, the influence of different traffic load simulation methods on the vibration displacement response of SFT is compared and analyzed, and the change of vibration displacement in the mid-span of structure is observed as shown in Figure 5 and Figure 6.

The values of fixed distributed load and moving concentrated load are 20 kN, the moving load is calculated by using the previous simulation results, and the speed of moving load is 80 km/h. Because the traffic load is too small compare with wave and flow force, only the increment of vibration displacement is analyzed after adding different traffic loads, on the basis of the SFT structure without traffic load, as shown in Figure 5 and Figure 6.

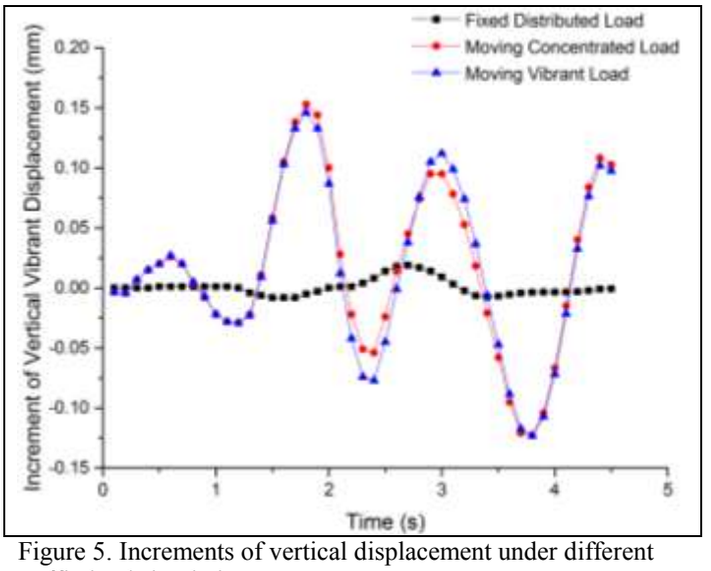

Figure 5. Increments of vertical displacement under different traffic load simulations

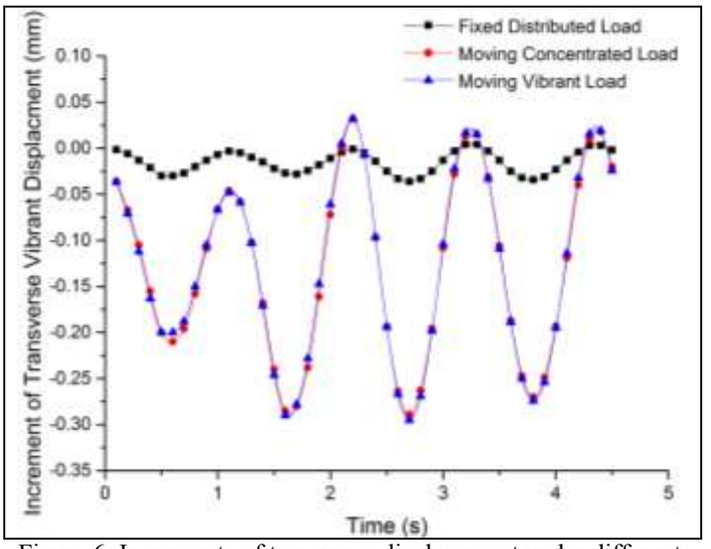

Figure 6. Increments of transverse displacement under different traffic load simulations

From Figure 5 and Figure 6, the increments of tunnel structural displacement under different simulation methods of traffic load are all slight. However, the amplitude of displacement variation of moving concentrated load and moving vibrant load is relatively larger than that of fixed distributed load.

The influence of the fixed distributed load on the vibration displacement of SFT is relatively slight, because it can be regarded as a part of dead load, equals to static load. The effects of moving concentrated load and moving vibrant load on the structural vibration displacement are very similar. The increments of longitudinal and transverse vibration displacement on mid-span appear relatively large regular fluctuation, as the traffic load moving from one end to opposite end. According to the foregoing analysis, moving vibrant load has additional dynamic load compare with moving concentrated load. The proportion of dynamic load is small in the moving vibrant load, hence the amplitude of vibration displacement is slightly larger in the calculation results of moving vibrant load. On the other hand, it also shows that moving vibrant load can real reflect the influence of dynamic load on structural vibration displacement response.

4 CONCLUSIONS

(1) The simulation method of traffic load in SFT should not only considers the factors such as wheel static load , road roughness, velocity of vehicle, but also the influence of the external excitation loads should be taken into account. The combined force of wave and current is the main component of external exciting load.

(2) The proposed simulation formula of moving vibrant load in SFT considers various influence factors. The traffic load is calculated with the volatility, in accordance with the characteristics of vibration load and traffic load.

(3) The influences of various simulation methods of traffic load on the structural vibration displacement response are different. The fixed distributed load equals to static load, has little effect. The effects of moving concentrated load and moving vibrant load are very similar, they all appear relatively large regular fluctuation on the mid-span. However, the moving vibrant load is more reasonable and realistic to reflect the influence of dynamic load on structural vibration displacement response.

(4) The numerical formulation and method are only evaluated by means of the numerical simulations in this paper, it should be evidenced by the experimental tests in the future studies.

Submerged Floating Tunnels under Seismic and Seaquake Loadings

Luca Martinelli
Politecnico di Milano, Dep. of Civil and Environmental Engineering,
P.zza L. da Vinci 32, 20133 Milano, Italy

ABSTRACT: Submerged Floating Tunnels (SFTs), also named Archimedes Bridges, are a promising alternative to cross a water body. SFTs are normally designed with positive buoyancy, and are held floating underwater by a mooring system anchored at the seabed. In the case of an earthquake, SFTs will have to withstand both the effects of ground motion at the supports as well as the so-called "seaquake" loading. This last is due to the transmission through water of compressive waves originated by the seabed motion. The studies on seaquakes are contrasting with respect to the effects of the compressibility of the soil below the seabed. In this light, this paper extends the model for generating seaquake effects, set-up by the research group, by including this aspect. A first comparison of the loading due to seaquake with and without the presence of a compressible soil layer is carried out for a significant prototype structure.

1 INTRODUCTION

Submerged Floating Tunnels (SFTs), also named Archimedes Bridges, are a promising alternative to cross a water body, efficiently connecting the shores while having a very low impact on the landscape. SFTs lend themselves naturally to the crossing of large body of water due to inherent modularization of the structure, which allows to reach dimensions in plan of the order also of some kilometers.
Most of the SFTs design proposal have been drafted assuming the SFT is under positive buoyancy and is kept floating underwater by a mooring system, that is anchored to the seabed.

Depending on the type of mooring systems, SFTs can be restrained at several positions along their length (Fig. 1) and, in the case of an earthquake, will have to withstand both the effects of ground motion at the anchoring positions of the mooring system, and the so-called "seaquake" loading (Fig. 2).

This last loading term is due to the transmission through water of compression waves originated at the seabed due to the seabed motion, and works as a hydrodynamic pressure due to the compression waves. This phenomenon is important for SFTs since it can significantly contribute to the loading of the SFT main tunnel, of the anchor elements and the foundations.

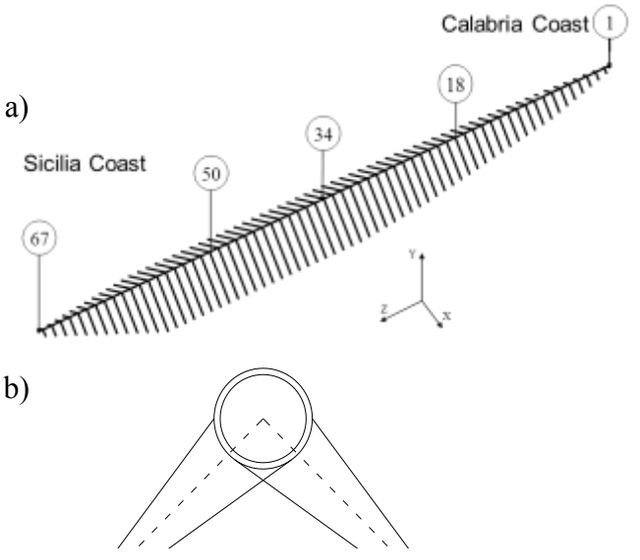

Figure 1. Scheme of the SFT proposed for the Messina Strait crossing (Italy); span 4680 m, maximum depth 350 m. (a) General view, (b) cross-section.

While the study on the dynamic response of SFTs subjected to environmental actions has made significant progress in the last years, seaquakes related research received less attention. Some studies on the effects of seaquakes, however, are nevertheless available in the literature, or their results can be of use also for SFTs (Crouse & Quilter 1991, Boore &, Smith 1999, Martire et al. 2010, Martinelli et al 2010,

2011, Shi et al. 2012, Shi & Martinelli 2013, Li et al. 2015, Lee et al. 2016), but are contrasting with respect to the effect of the compressibility of the last soil strata beneath the seabed on the motion of the water.

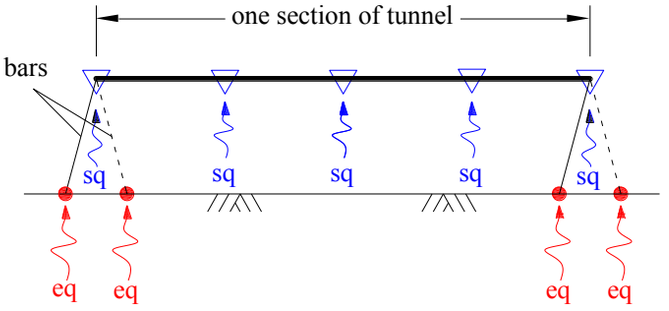

Figure 2. Schematics for a SFT under earthquake ("eq") and seaquake motion ("sq").

In this light, this paper extends the model for generating seaquake effects set-up by the research group (Martinelli et al 2010, 2011, Shi et al. 2012, Shi & Martinelli 2013) by including the compressibility of the last soil strata beneath the seabed and compares the theoretical result in the case of seabed corresponding to the bedrock to those when a flexible soil layer is interposed between the water and the bedrock.

The target structure for this exercise is the SFT in Figure 1, proposed for the Messina Strait crossing (Italy). This SFT spans 4680 m, has a maximum depth of the seabed of about 350 m while the tunnel of the SFT is located about 40 m below the surface.

2 FORCES ACTING ON SUBMERGED FLOATING TUNNELS DUE TO SEAQUAKES

The term seaquake denotes the transmission of compressive fluid waves from the sea bottom which moves under seismic conditions.

The detailed numerical simulation of the seaquake phenomenon involves complex studies related to wave propagation and fluid-structure interaction. Simplified approaches, appropriate at the design stage, rely on a representation of the seaquake loading on the tunnel by using the Morison equation (Equation 1), to represent the forces on a moving body in oscillatory fluid flow (Chakrabarti 1987):

$$f = \frac{1}{2} C_D \rho D |u - \dot{x}|(u - \dot{x}) + \\ + C_M \rho \frac{\pi}{4} D^2 (\dot{u} - \ddot{x}) + \rho \frac{\pi}{4} D^2 \ddot{x} \quad (1)$$

or, alternatively:

$$f = \frac{1}{2} C_D \rho D |u - \dot{x}|(u - \dot{x}) + \\ + C_A \rho \frac{\pi}{4} D^2 (\dot{u} - \ddot{x}) + \rho \frac{\pi}{4} D^2 \dot{u} \quad (2)$$

where C_D, C_M are the drag coefficient and inertia coefficient, respectively, C_A is the added mass coefficient, ρ is the water density, D is a relevant dimension in the cross-section (typically the cylinder's diameter), u, $\dot{u}$ are the instantaneous water particle velocity and acceleration (here the one of a water particle ideally located at the center of tunnel), $\dot{x}$, $\ddot{x}$ are structure velocity and acceleration, $u - \dot{x}$, $\dot{u} - \ddot{x}$ are the relative velocity and acceleration. Adoption of Morison equation is justified for the elements of a SFT on the base of the elements' characteristic dimensions and expected wavelength of the waves.

For the application of Equation 1, when seaquake effects are introduced, both the motion at the supports (denoted as "eq" in Fig.2) and the motion of water itself (denoted as "sq" in Fig.2) contribute to create the hydrodynamic pressure acting on the SFT's main tube and elements of the anchoring system.

A simplified model, which derives the motion of the water from a mono-dimensional wave propagation equation, has been adopted by the research group in previous works. This will be presented in the following.

3 SEAQUAKE INDUCED WATER VELOCITY AND ACCELERATION

When the ground below the seabed is excited by vertical seismic waves, as schematically depicted in Figure 2, it is possible to derive the vertical seaquake-induced motion of the water upon application of the linearized one-dimensional wave propagation equation, with the following assumptions and simplification (see Shi 2013 and also, e.g., Hamamoto 1995):

1. the hydrodynamic pressure due to the seaquake is associated with the water-transmitted seismic vibration from the sea bed to the floating structure, neglecting the scattered waves due the structure presence (i.e. the hydrodynamic pressure is related to incident waves);

2. the sea water is assumed as inviscid, incompressible and the velocity field is irrotational;

3. the water velocity (seaquake's velocity) at the seabed is the same as the vertical ground velocity (earthquake's velocity) at the same point;

4. the vertical ground motion of the water will be described in the frequency domain.

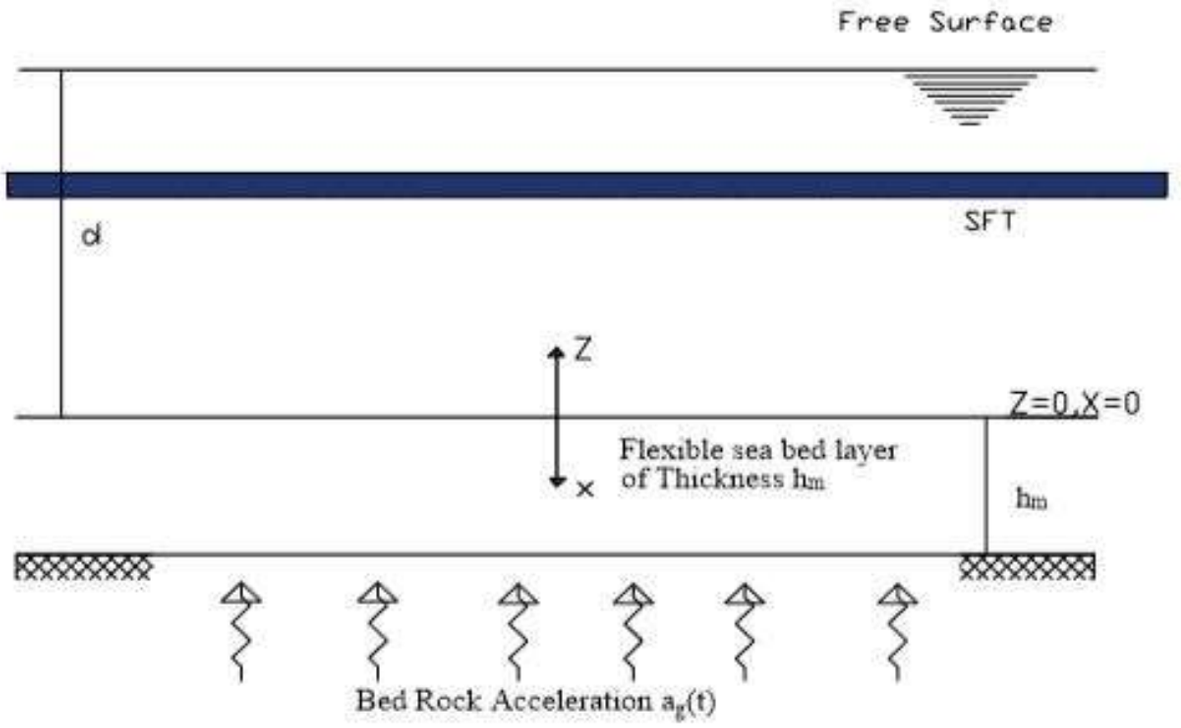

Figure 3. Schematics for definition of seaquake motion in water when a flexible soil layer is located between the water and the bedrock.

Thanks to the abovementioned hypotheses and simplification, the vertical component u of the water velocity (seaquake velocity) at a point in the water domain is given by the gradient of the scalar velocity potential function:

$$v = \nabla\phi = \frac{\partial\phi}{\partial z} \tag{3}$$

The velocity potential function, in turn, must satisfy the Helmholtz equation:

$$\nabla^2\phi = \frac{1}{c^2}\frac{\partial^2\phi}{\partial t^2} \tag{4}$$

where: ϕ is the velocity potential function of incident waves, ∇^2 is the Laplace operator and c is the acoustic wave velocity in water (herein assumed as 1560 m/s).

With reference to Figure 3, the boundary conditions for Equation 4 are the free surface and seabed one described in the following.

3.1 *Free surface boundary condition*

Assuming that the height of the waves, that will eventually ensue at the free surface, is small compared to the wavelength, a linearized free surface boundary condition can be adopted.

Including both the static requirement (pressure is constant across the free surface interface: $p = p_{atm}$, with p_{atm} the atmospheric pressure and p the pressure in water at the free surface) and the kinematic requirement (once a particle is on the free surface, it will remain there), this can be stated as:

$$\frac{\partial\phi}{\partial z} + \frac{1}{g}\frac{\partial^2\phi}{\partial t^2} = 0 \quad \text{at} \quad z = d \tag{5}$$

3.2 *Sea bed boundary condition*

The boundary condition at the seabed is that the motion of the water will follow there that of the ground:

$$\frac{\partial\phi}{\partial z} = \frac{\partial U_g(t)}{\partial t} \quad \text{at} \quad z = 0 \tag{6}$$

In Equation 6, g is the gravity acceleration, d the depth of the seabed, $U_g(t)$ the vertical ground displacement at the seabed ($x = 0$).

The seaquake acceleration can then be found as the derivative of the velocity:

$$\dot{v} = \frac{\partial v}{\partial t} \tag{7}$$

3.3 *Velocity Potential for seaquake*

With the previous assumptions and boundary conditions, assuming the motion at the seabed is harmonic with circular frequency ω and acceleration $a_g\, e^{i\omega t}$, the following holds:

$$\frac{d^2U_g(t)}{dt^2} = a_g e^{i\omega t} \tag{8}$$

and the velocity potential function takes the form (see Shi 2013, Hamamoto 1995):

$$\phi = \frac{cg\cos\left(\frac{(d-z)\omega}{c}\right)}{\omega\left(c\omega^3\cos\left(\frac{d\omega}{c}\right)+g\omega^2\sin\left(\frac{d\omega}{c}\right)\right)}a_g e^{i\omega t} + \\ -\frac{c^2\omega\sin\left(\frac{(d-z)\omega}{c}\right)}{\omega\left(c\omega^3\cos\left(\frac{d\omega}{c}\right)+g\omega^2\sin\left(\frac{d\omega}{c}\right)\right)}a_g e^{i\omega t} \tag{9}$$

4 DEDUCTION OF THE VELOCITY POTENTIAL FUNCTION FOR A SEAQUAKE AND FLEXIBLE SEABED

In the case of a flexible soil layer beneath the seabed, the vertical propagation of compression waves in the water is derived from the study of the linear viscoelastic system shown in Figure 3.

The system consists of a horizontal layer which extend to infinity in the horizontal direction and has the bedrock below. The layer is homogenous and isotropic and is characterized by the thickness, h_m, mass density, ρ_s, shear modulus, and damping factor, β.

The 1D wave propagation through the soil layer is the solution of the following Equation:

$$\frac{\partial^2 u}{\partial x^2} = \frac{1}{\alpha^2}\frac{\partial^2 u}{\partial t^2} \tag{10}$$

Where the velocity of propagation of the wave α, is: $\alpha = ((\lambda + 2\mu)/\rho_s\,)\text{^}(1/2)$, ρ_s is the density of the soil, μ and λ are the Lame's constants of the soil, defining its mechanical characteristics.

4.1 *Boundary conditions for the Seaquake wave equation*

In the following we will denote with u the ground displacement in the soil layer, with $a_s(t) = a_s\, e^{i\omega t}$ the bedrock acceleration, assumed as sinusoidal of circular frequency ω, with ρ_w the density of water, with ϕ the velocity potential function, with $E^* = (\lambda + 2\mu) + i\omega\,\eta$ the complex elasticity modulus for the soil layer, with $\eta = 2\beta\,(2\mu + \lambda)/\omega$ the viscosity constant of the soil layer, with β the damping ratio of the soil, and we will define k_s as:

$$k_s = \frac{\rho_s\omega^2}{E^*} \tag{11}$$

Taking into account the different positive directions shown in Figure 3 for the axes z and x, respectively used for describing the motion in the water and in the soil layer, the boundary conditions for Equation 10 can be listed as in the following.

4.1.1 *Compliance of ground layer and bedrock motion*

The compatibility of the ground motion with the one at the bedrock can be stated as:

$$a_s e^{i\omega t} + \frac{\partial^2 u}{\partial t^2} = 0 \quad at \quad x = h_m \tag{12}$$

where $a_s(t) = a_s\, e^{i\omega t}$ is the bedrock acceleration.

4.1.2 *Compliance of water and soil layer motion*

The compatibility of ground velocity with the water velocity can be stated as:

$$\frac{\partial u}{\partial t} + \frac{\partial \phi}{\partial z} = 0 \quad at \quad x = 0,\, z = 0 \tag{13}$$

where it has been accounted that the ground velocity is equal to the water velocity at the interface of water and soil layer, but the two have opposite positive directions.

4.1.3 *Equilibrium Equation at the interface of water and soil layer*

The equilibrium equation at the interface between water and the soil layer can be stated as:

$$\frac{\rho_s\left(\frac{\partial u}{\partial x}\right)\omega^2}{k_s{}^2}-\rho_w\frac{\partial\phi}{\partial t}=0\quad at\quad x=0,z=0 \tag{14}$$

where it has been accounted that the ground velocity and water velocity have opposite positive directions.

4.1.4 *Velocity Potential for water*

The solution of the PDE in Equation 10, with the listed boundary conditions, can be found in closed form in term of the velocity potential as:

$$\phi=\frac{-e^{i\omega t}2a_g e^{ik_s x}Mcg\cos\left(\frac{(d-z)\omega}{c}\right)}{Q}+ \\ -\frac{-e^{i\omega t}2a_g e^{ik_s x}Mc^2\omega\sin\left(\frac{(d-z)\omega}{c}\right)}{Q} \tag{15}$$

Where the constants Q, M, N, P are:

$$Q=\omega\left(N\omega\sin\left(\frac{d\omega}{c}\right)+P\cos\left(\frac{d\omega}{c}\right)\right)\cdot \\ \cdot\left(g\omega^2\sin\left(\frac{d\omega}{c}\right)+c\omega^3\cos\left(\frac{d\omega}{c}\right)\right) \tag{16}$$

$$M=g\rho_s\omega^2\sin\left(\frac{d\omega}{c}\right)+c\rho_s\omega^3\cos\left(\frac{d\omega}{c}\right) \tag{17}$$

$$N=\left(c^2k_s e^{2ik_s x}-c^2k_s\right)\rho_w+ \\ +\left(-ige^{2ik_s x}-ig\right)\rho_s \tag{18}$$

$$P=\left(-ice^{2ik_s x}-ic\right)\rho_s\omega^2+ \\ +\left(ck_s g-cgk_s e^{2ik_s x}\right)\rho_w \tag{19}$$

4.2 *Seaquake velocity and acceleration*

Once the Velocity Potential function is known, the water velocity can be obtained again by Equation 3 and form this, by derivation, the water acceleration.

5 COMPARISON OF RESULTS OF WATER VELOCITY WITH AND WITHOUT FLEXIBLE SOIL LAYER

In the following the results with and without the presence of a flexible soil layer will be presented in terms of transfer functions from known acceleration (typically the one at the bedrock) and velocity of the water at a selected depth (typically the depth of the tunnel).

The mechanical parameters for the soil layer have been taken from (Li et al. 2015) and are listed in Table 1. The depth of the water is compatible with the maximum one for the SFT in Figure 1 (325 m), the depth of the tunnel is 40 m below sea level. Water has no damping. The flexible soil layer is h = 30 m thick, the damping for the soil layer is 5% relative to the critical.

Table 1. Soil data for flexible soil layer.

Name	Type	l	m	ρ_s
		Pa	Pa	kg/m^3
G5	Soft Clay	1.6 x 10^7	1.4400 x 10^8	1600

The tunnel in Figure 1 had (Shi 2013) the first longitudinal vibration mode at 0.196 Hz, the second longitudinal mode at 0.391 Hz, the first transversal vibration mode at 0.580 Hz, the first vertical vibration mode at 0.580 Hz, the second transversal vibration mode 0.585 Hz, the second vertical vibration mode 0.585 Hz. The mooring system had the following natural frequencies of the local modes: first symmetric bending vibration mode 0.0616 Hz, first anti-symmetric bending vibration mode 0.0616 Hz, second bending vibration mode 0.1393 Hz, third bending vibration mode 0.2446 Hz. In the analyses, the range of frequencies up to 12 Hz will be studied.

The theoretical value of the resonance frequency of the water column is $f = c/4d$ = 1.2 Hz with c = 1560 m/s, while that of the soil layer is $f = V_p/4h$ = 2.76 Hz with V_p = 331.66 m/s.

Figure 4 reports the modulus of the transfer function from the acceleration at the seabed to water velocity at the tunnel position, this is practically the same as the modulus of transfer function from the bedrock acceleration to velocity of water at tunnel position without the flexible soil layer. Figure 5 depicts the modulus of the transfer function from bedrock acceleration to the water velocity at the depth of the tunnel, while Figure 6 that of transfer function from the bedrock acceleration to the water acceleration at the same location. Finally Figure 7 and 8 depicts the transfer function from the bedrock to the seabed respectively in the case of presence of the water layer and absence of the same (outcropping).

Figure 4 is characterized by the resonance peaks of the water layer, set at the odd multiples of the base resonance frequency of 1.2 Hz.

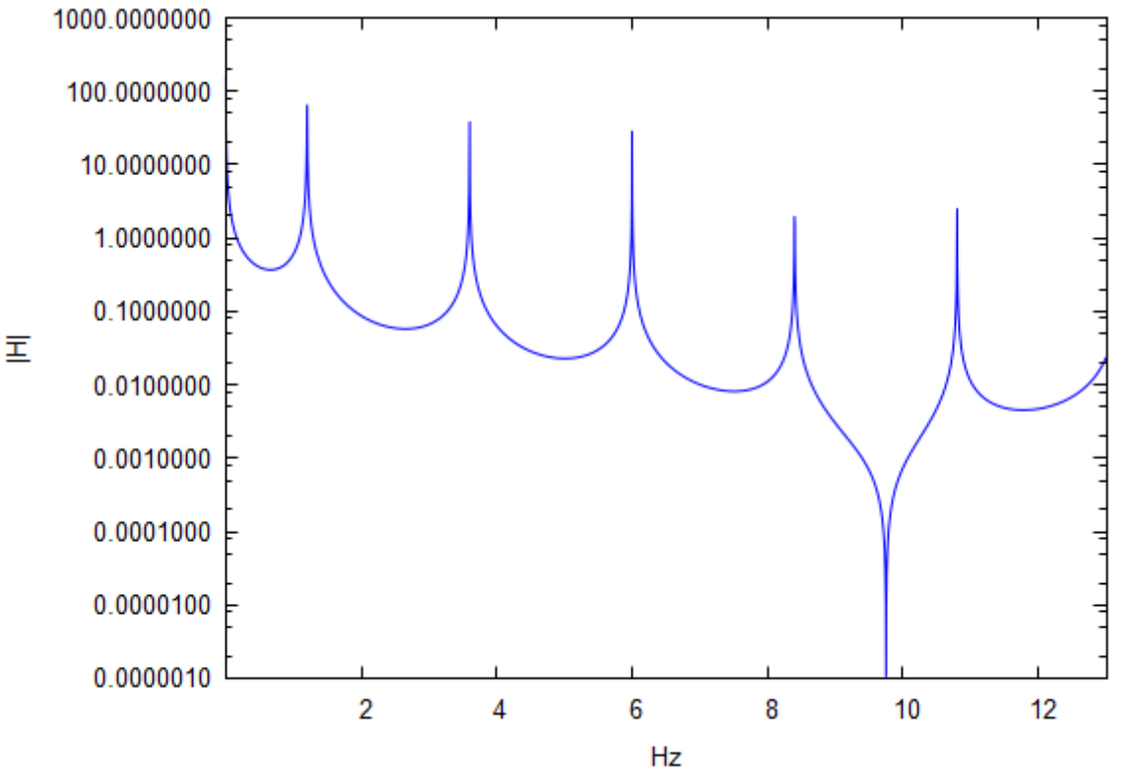

Figure 4. Modulus of the transfer function from the seabed acceleration to velocity of water at tunnel position

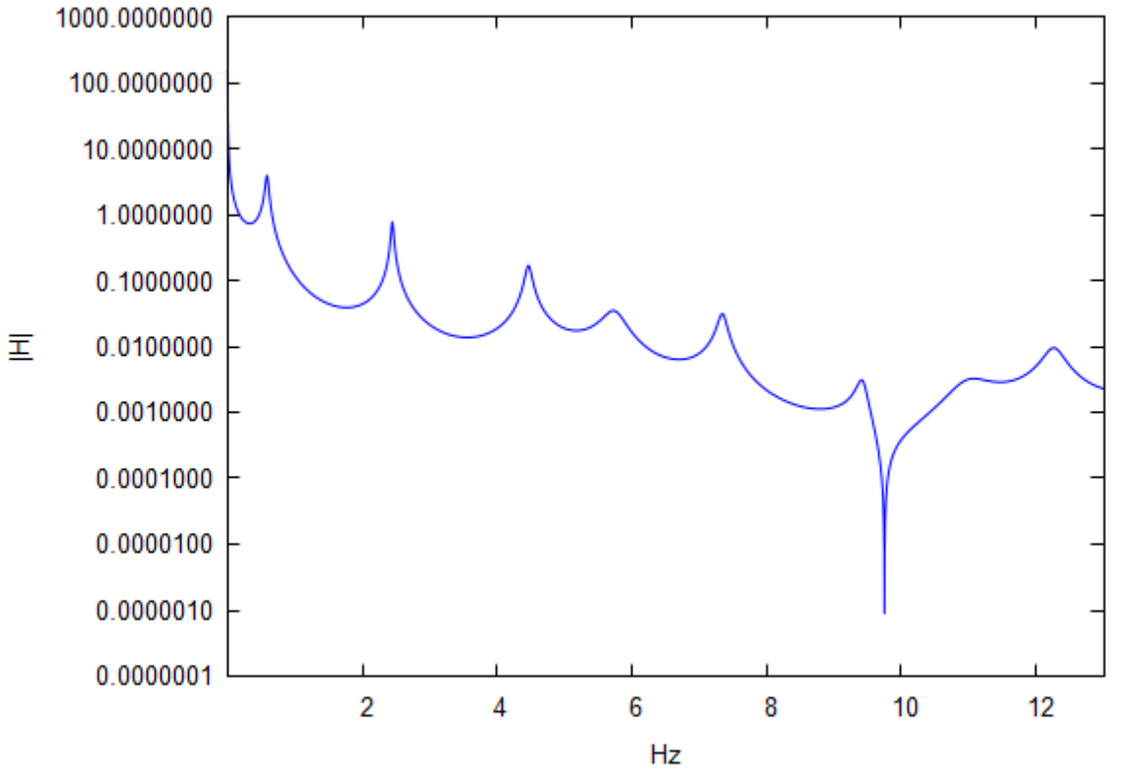

Figure 5. Modulus of the transfer function from bedrock acceleration to velocity of water at tunnel position.

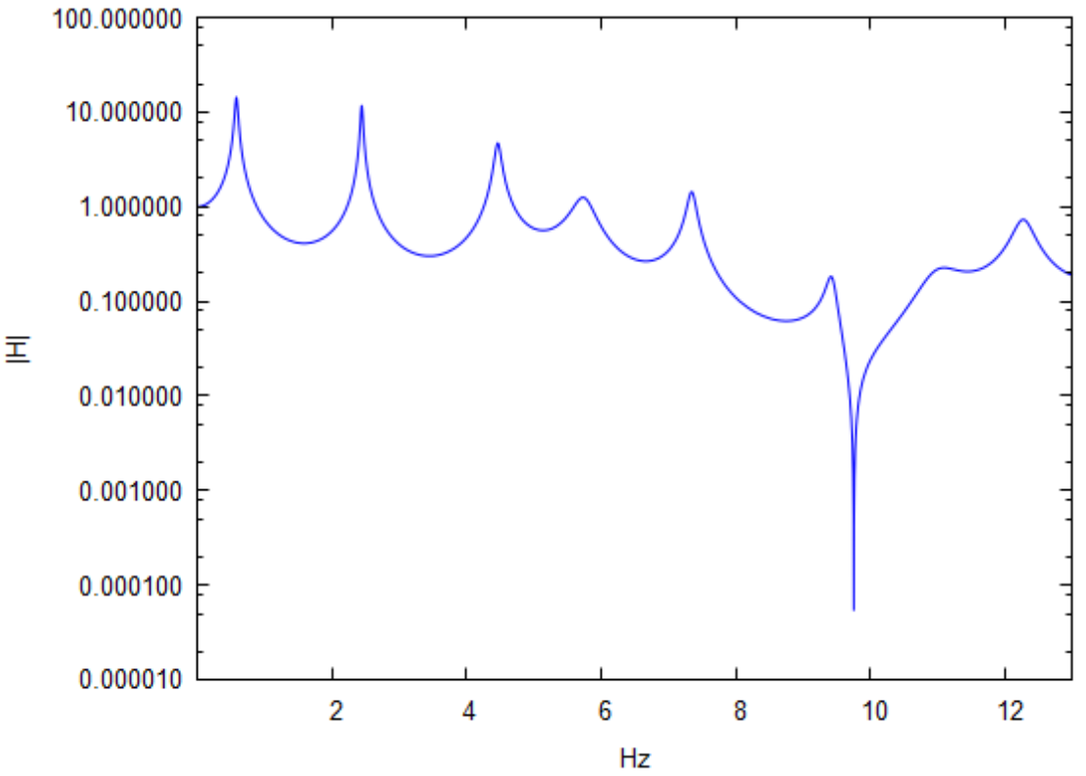

Figure 6. Modulus of the transfer function from bedrock acceleration to acceleration of water at tunnel position.

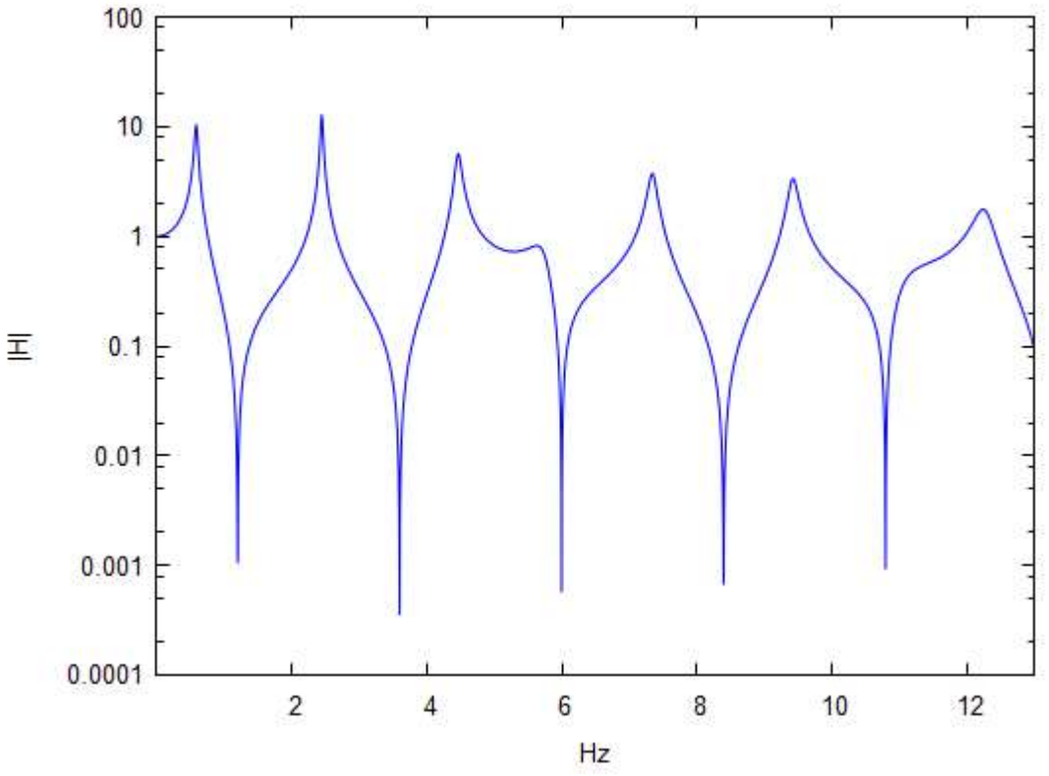

Figure 7. Modulus of the transfer function from bedrock acceleration to seabed acceleration.

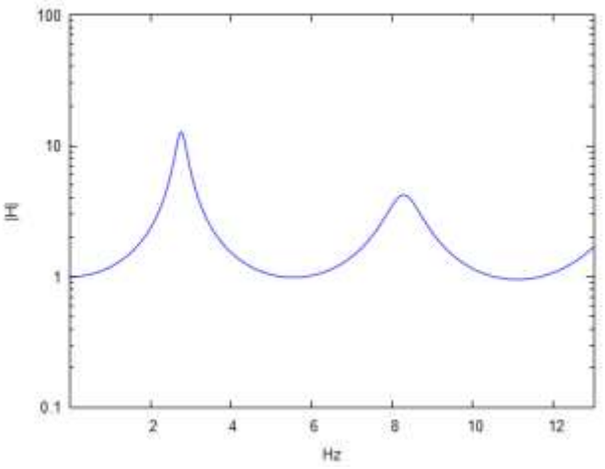

Figure 8. Modulus of the transfer function from bedrock acceleration to seabed acceleration when the water layer is not present, or very thin (0.1m).

By comparing Figure 5 to Figure 4 it is possible to appreciate the effect of the soil layer. This acts as a filter, that widens and reduces the resonance peaks, that get also shifted to lower frequencies. The de-amplification is more important for the higher harmonics of the base frequency.

By comparing instead Figure 7 and Figure 8 it is possible to appreciate the effect of the water layer on the seabed acceleration. In Figure 7 the peaks are at the odd multiples of 2.76 Hz, and while the water layer actually de-amplifies the ground motion at the frequencies of the odd multiples of 1.2 Hz, it amplifies the response at other frequencies (e.g. the peak below 1 Hz and the one in between 2 and 4 Hz).

6 CONCLUSIONS

In this initial work, the transfer function between the bedrock acceleration and the water velocity has been recomputed in closed form including the effect of a deformable soil layer. The effects of the water layer are of a de-amplification of the motion of the seabed at the resonance frequencies of the water layer, as it was also found by others authors, but contrary to what reported in several research works, an amplification effect has been found as well between each de-amplified frequency. The analysis of the effect of the soil layer in terms of the force given by Morison equation is ongoing.

SFTs under dynamic loads: new design issues and numerical simulation

F. Perotti, F. Foti, L. Martinelli & M. Tomasin
Department of Civil and Environmental Engineering, Politecnico di Milano, Italy

ABSTRACT: In the paper some recent developments of the design trends in the field of seabed anchored Submerged Floating Tunnels are reviewed; the focus is on the implications on the anticipated dynamic behavior of the tunnel and on its numerical simulation. The design needs here considered are mainly of two types; the first is the necessity to cope with more stringent fire regulations. The second is the consideration of partial-flooding loading conditions, which was neglected in older designs according to the "no water ingress" principle. Both needs lead to the introduction, in the conceptual design, of the twin-tube solution, where two tunnels run parallel and are interconnected in order to allow fire escape. In addition, partial or total flooding of one of the two is considered, while the other can deliver sufficient buoyancy to avoid collapse. This evolution, along with the recent design activity performed within the E-39 Norwegian project, requires, in the writers' opinion, a review of the fundamental design choices, with a twofold purpose: first, to "classify" available options in view of coping with environmental loading scenarios (seismicity, wind waves, currents, naval and road/rail traffic, etc.) of different severity. Second, to discuss the various design configurations in view of the predictability of their structural behavior, especially under dynamic actions, this being a very delicate aspect for a never-built construction. Within this context, scope of the paper is to address the basic aspect of the SFT conceptual design along with the experimental and/or numerical procedures for simulating the dynamic behavior of the SFT under extreme environmental conditions. An example is finally given, illustrating some typical modelling options in relation to a SFT solution for the Messina Strait crossing, with particular reference to seismic response and seismic-induced hydrodynamic loading.

1 INTRODUCTION

Though a first realization is still missing, the Submerged Floating Tunnel is deemed to be a competitive option for crossing sea straits, fjords, alpine lakes and waterways in general (Ahrens 1996, Faggiano et al 2005, Østlid 2010, Ingerslev 2010). This is, first of all, for environmental reasons related to the small, or virtually zero, visual impact of the infrastructure and to the small occupation of surface land. Secondly, because among the various crossing solutions, the SFT should be the one less prone to interruption/limitation of its operability due to adverse weather conditions, this being of utmost importance when public transportation is involved.

On the contrary, adverse psychological reasons come from the novelty of the approach; in this light, a prototype installation was proposed some years ago within an international project (SIJLAB 2007). The prototype was intended as an icebreaker providing considerable insight into some design, construction and installation issues and acting as a real-size lab for some years, before becoming a mere tourism attraction. The prototype was thoroughly designed but never built, though remaining, in this writers' opinion, a necessary step towards the installation of the first "real" SFT.

After some years from SIJLAB it seems to be high time for reviewing some of the basic ideas and conceptual design options that were at the basis of the research activity performed in the late 90s and in the first decade of the new millennium, also in view of some emerging facts and situations; first of all, and on the "supply" side, the augmented capabilities of the scientific community to face complex physical experiments and numerical simulations. Secondly, by the "demand" point of view, the considerable pressure exerted by new initiatives; first of all, the E39 coastal highway project (NPRA 2011) involving the crossing of eight major fjords, today operated by ferries, and envisaging the adoption of a SFT for crossing the Bjørnafjord (NPRA 2014).

In this light some general considerations and remarks will be summarized in the present paper; the point of view will be unavoidably affected by two fundamental facts regarding the authors. The first is

their prevailing interest in matters related to structural dynamics, these being recognized as extremely important for the structural design of a SFT, but obviously sharing this importance with other aspects. The second is the "European" point of view on the topic, unavoidably biased by the two main drivers to the research performed, in the EC countries in the last decades (FEHRL 1996), i.e. the Messina Strait crossing in Italy and the already mentioned activity related to Norway projects. These can be regarded as paradigmatic cases; the Messina case due to the harshness of its environmental loading conditions for marine structures (earthquakes, tsunamis, wind waves, currents, naval traffic, etc.). In addition, for the absolute necessity to support a high speed railway, this resulting in rather strict performance criteria, also in terms of continuous operability.

Environmental loads are substantially less severe in Norwegian fjords, where seismic hazard is negligible and the sea conditions benefit from the shielding effect provided by the system of islands contouring the north coast. As an additional "relief", no railway track is anticipated to run parallel to E39. On the other hand, fjord conditions are often extreme in terms of sea depth, making the tunnel anchorage at the seabed unfeasible and pushing towards other design solutions (surface pontoons, …) which are outside the scope of this paper.

Under these premises, the following sections will be first devoted to review conceptual design criteria and basic options and then to summarize open issues related to testing, simulation and analysis supporting structural design of seabed anchored SFTs.

2 CONCEPTUAL DESIGN

2.1 *Tunnel and anchoring system*

The main features of the overall tunnel design will be here reviewed, with reference to the case of seabed anchored tunnels. The discussion doesn't pretend to be exhaustive, but rather to address aspects and criteria which has been investigated and/or debated within this research group.

2.1.1 *General arrangement*

The interconnected twin-tunnel arrangement (Figure 1) is the solution adopted in the most recent design proposals. In fact, it can satisfy two basic requirements: the first one is to provide safe escape in case of fires or other type of accidents occurring in one of the tunnels. The second is related to the "partial flooding" condition, which was not introduced in the earlier designs, but is considered in the most recent proposals; in such situation the flooded tunnel can benefit from the support of the other.

On structural grounds, connecting the two tunnels enhances their performance in terms of lateral stiffness, even though it makes the shore connection more complex; a possible solution, in this respect, could be to make the two tunnels come closer and merge when approaching the shore.

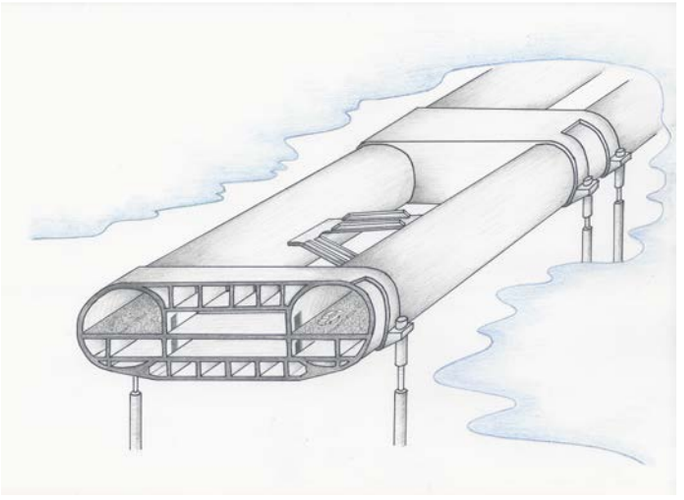

Figure 1. Twin-tunnel SFT

It can be noted that fire escape requirements result in what we could define as a "minimal" structural coupling between the tubes, with connection spacing up to 500 m. The type or "degree" of connection can obey to very different structural goals and criteria, also related to the strategy for seabed connection (see 2.1.3).

Finally, clearance above the tunnels is dictated by local regulations and ship traffic and by the benefits in term of reduction of wave loading; typical values are in the 20-30 m range.

2.1.2 *Plan layout*

The essential choice is here between a straight or curved tunnel. The second option obviously benefits of the arch effect resulting in largely increased stiffness; appears to be almost mandatory for long SFTs suspended to pontoons. For seabed anchored tunnels, the curved solution allows for vertical tethers layout.

On the other hand, coupling between axial and transverse behavior leads to a most problematic design of end connections. It can be regarded as non-advisable if strong seismic actions must be resisted and in all cases in which an anticipated variation of distance between the shores must be accommodated.

In the straight tunnel case, transverse stiffness can be provided by tethers inclined in the plane orthogonal to the tunnel axis. When longitudinal stiffness is considered, different options can be considered; the first is the adoption of double-inclination tethers. The second is to rely on the restraint offered by the tunnel end connections: here the introduction of dissipation devices should be carefully considered, in order to mitigate the dynamic behavior both in operation and in seismic conditions and to limit axial forces developing in the tunnel.

Within such context, the restraining system should be able to accommodate slow variations in the crossing length.

2.1.3 *Anchoring elements type and layout*

Two basic types of elements have been considered in SFT design; cables and tubular sections. The latter is deemed to be preferable for inclined long elements, since can benefit from buoyancy in order to avoid catenary effects, which unavoidably penalize serviceability performance.

For single-tube tunnels a typical layout of the anchor bars is the one in Figure 2, ensuring adequate lateral and torsional support

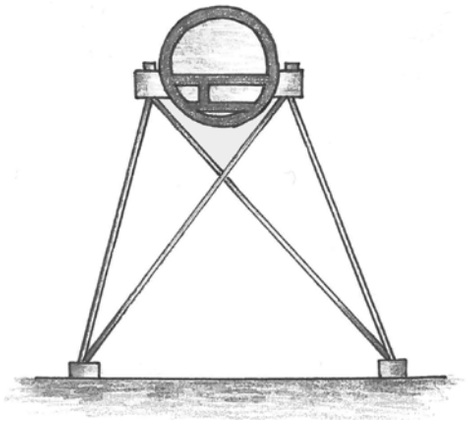

Figure 2. Typical layout of anchor bars for single-tube tunnels.

For a twin-tube system, the tethers arrangement is affected by the criterion adopted for connection between the tubes; for "densely" interconnected tunnels, an anchorage system can be introduced at all connections, so that the scheme of Figure 2 can be simply extended to the coupled tubes (Figure 3).

If the spacing between the connections is large, i.e. dictated only by fire escape requirements, each tube can be independently anchored to the seabed (Figure 4). A suitable plan layout must be devised, in this case, to avoid interference.

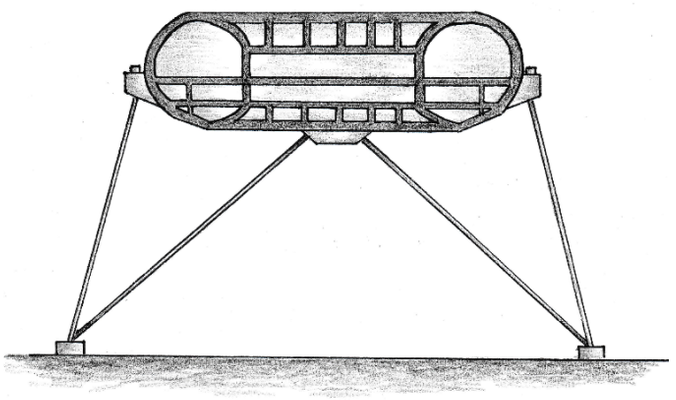

Figure 3. Layout of anchor bars for twin-tube systems with dense interconnection

When design criteria for tethers are to be established, a debated issue is whether they must be always tensioned in design conditions or they can go slack under extreme loading, typically under ULS seismic actions. It is in this writers' opinion that when severe design seismic loads are to be resisted very high buoyancy-to-weight (BtW) ratios are necessary to meet the first criterion, resulting in excessive tension loads on the foundation; on the other hand, it has been shown that in the Messina Strait case, the adoption of a BtW ratio of about 1.3 led to an acceptable dynamic response of the anchor bars, even though the "no compression" criterion was not satisfied (Fogazzi & Perotti 2000, Di Pilato et al 2008, Feriani et al 2008)).

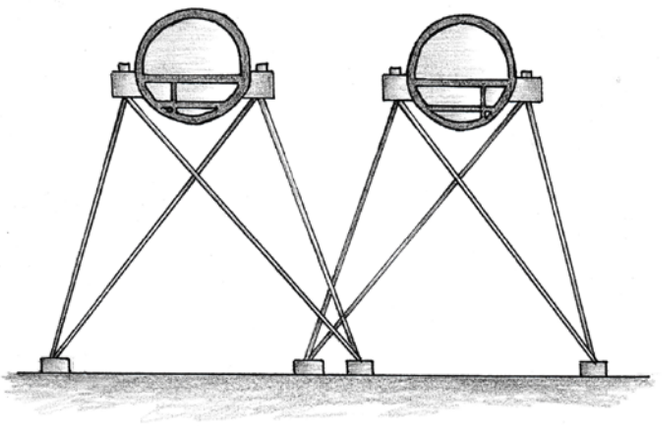

Figure 4. Layout of anchor bars for twin-tube systems with independent tethering

2.1.4 *Section shape and separation*

Circular hollow sections at a centerline distance of 30-40 m are currently proposed within the E39 project; this choice should be confirmed by studies regarding the hydrodynamic behavior, with special attention to galloping instability and to high-Reynolds regimes.

2.2 *Loading conditions*

Partial-flooding loading conditions have been introduced in recent proposals for SFTs, along with stricter fire-resistance provisions, thus resulting in the above quoted new design trends. Note that flooding is not necessarily related to sea water entering the tunnel, i.e. to loss of its integrity or tightness, but more likely to malfunctioning of internal water ballast systems.

Most loading conditions for SFTs are typical of tunnels, bridges and other road infrastructures. Some scenarios, however, are related to the particular location of the structure, such as the impact of sinking objects or the occurrence of an external explosion.

2.3 *Reparability*

The intrinsic modular structure of the SFT and its consequent stability in "incomplete" configuration should be exploited by considering, at the design stage, the possibility of replacing a damaged module. Note that the capacity of resisting partial flooding loading conditions and reparability are of utmost importance when issues regarding insurance policies for the infrastructure are considered.

3 ANALYSIS, TESTING AND SIMULATION

In this section some issues related to the experimental activity, both numerical and physical, supporting the SFT design process will be reviewed. Following a brief review of general modelling issues, the topics will be grouped according to the most relevant loading scenarios.

3.1 *General modelling issues*

As a general remark, it can be observed that the following considerations apply to loading conditions mostly involving "global" loading patterns (earthquakes, wind waves, current, traffic, etc).

3.1.1 *Structural modelling*

Based on the above consideration, structural modelling can be largely based on the introduction of beam elements for modelling the tunnels and to beam or cable elements for capturing the response of the tethering bars. A special attention must be devoted to the latter, whose dynamic behavior is prone to develop large transverse displacements, though essentially remaining within the small deformation range. In such conditions, the co-rotational formulation (Di Pilato et al 2008, Foti et al 2015, 2017), has proven to be effective for modelling the response of slender beams and cables; the formulation can incorporate refined material models (Foti 2016, Foti & Martinelli 2016, Foti et al 2016). These can capture important effects related to cable behavior, such as internal damping and fatigue behavior in zones of high curvature.

3.1.2 *Soil-structure interaction*

Simplified models, based upon the hypothesis of rigid mat foundations, can be applied to model the global structural behavior, both for the case of surface foundations and for pile groups. Piles have been often introduced in the design in order to resist tension forces developing in extreme conditions.

3.2 *Response to seismic actions*

Earthquake actions are transmitted to offshore structures of this type through two different mechanisms, either directly in terms of motion transmitted to the foundations or via hydrodynamic forces which develop due to the motion of the water surrounding the structure.

3.2.1 *General model for ground motion*

Given the structure size, the input ground motion must be defined also in terms of spatial variation; to this aim, stochastic models are available in the literature, usually defined in terms of direct and cross spectral densities. Starting from these models, artificial generation of time histories of free-field ground motion can be performed, characterizing the ground shaking at the seabed anchoring points and, more generally, along the tunnel axis.

3.2.2 *Ground-transmitted seismic excitation*

Based on the general ground motion model (see 3.2.1), the seismic excitation directly transmitted to the structure by the ground motion must take account of kinematic interaction. In this respect, effects due to the structure plan size must be introduced, to account for both the dimension of the foundation at a single anchoring section, and for the distance between the foundations (see Tomasin et al 2017).

3.2.3 *Water-transmitted seismic excitation*

Two different phenomena are relevant for a SFT. The first is the so called *seaquake* and is due to the vertical motion of the seabed under the tunnel; this motion is responsible for the transmission of vertically propagating compression waves. These waves interact with the tunnel by developing significant forces; to model these forces simplified approaches have been proposed, based on the free-field motion at the seabed, as specified by the general model (section 3.2.1) and on the solution of the 1D wave equation (see section 4.2).

A second hydrodynamic excitation mechanism can be due to *tsunami waves*. A wave of this type is originated where the fault rupture intersects the seabed; it propagates at a very high speed, with very long period and wavelength. Approaching the coast, the shoaling effects makes the wavelength and period become smaller and the height larger, often resulting in a dramatic run-up over the coast.

According to simple 2D models, the tsunami excitation doesn't appear to be critical for offshore structures, even though they are located on rather shallow waters. Special attention, however, should be devoted to structures under strong 3D effects. A typical situation is the one of a tsunami wave approaching the Messina Strait from South, thus undergoing the 3D effect due to the simultaneous reduction of the depth and width of the sea basin.

3.3 *Response to wave and current loading*

3.3.1 *Effect of wind waves*

Given the usual depth of a typical SFT, wind wave loading is often not deemed to be a critical issue among extreme environmental interactions.

Nevertheless, the topic has been addressed in many research works (see, for example Di Pilato et al 2008, Hong & Fe 2010) due to the severity of the wave scenario anticipated, as a typical example, in the Messina Strait and due to the consideration that the spectrum of large wind waves tends to match the frequency content of the transverse oscillations of long tethering elements.

To the aim of analyzing the effect of severe conditions, wave fields can be artificially simulated starting from a spectral density function describing the sea elevation at a point and a directional spreading function to account for the propagation of wave trains at different angles. Global wave kinematics can be derived based on the most suitable wave theory. Given the large wavelength of extreme waves, the Morison approach can be usually adopted to simulate wave-structure interaction. No linearization of the drag force has to be performed, since time domain step-by-step response must be performed anyway to represent geometrical non-linearity due to large oscillations of the tethers.

A similar approach can be adopted for extreme waves due to swells.

Different simulation criteria have to be introduced if wave loading need to be checked in serviceability conditions, along with traffic loading, for investigating fatigue and comfort issues. In such situation, given the small oscillation context linearized structural behavior can be assumed; on the other hand, for small waves diffraction effects cannot be neglected. The latter can be introduced as well via a linearized (potential) approach, resulting in frequency dependent hydrodynamic effects; accordingly, direct frequency domain analysis can be performed to evaluate the system response.

3.3.2 *Vortex induced vibration (VIV)*

The VIV issue is one of the most critical for the dynamic response of SFTs, especially in relation to fatigue effects. Two main problem arise; the first is that the transverse oscillations of long tethers can show natural frequencies of the order of the Strohual frequencies, so that lock-in conditions can occur.

The second problem lies in the values the of Reynolds numbers characterizing the current flow around both the tunnel and the tethering elements; these values are clearly outside the subcritical range, to which most of practical models and approaches refer. Note that, in this writers' opinion, global modelling of the SFT response to VIV excitation is necessary to capture coupling effects among VIV and other phenomena occurring at low frequencies, such as: transverse oscillations of tethering elements, longitudinal oscillations of the tunnel and structural response to long-period waves. On computational grounds, global modelling obviously requires simplified representation of the VIV phenomenon with special attention to lock-in behavior; the fluid oscillator model, in this respect, seems to represent the most suitable modelling tool. A question arises whether this approach, currently used in the subcritical regime, can be extended to the postcritical range.

VIV at high Reynolds numbers has recently received the attention of several research groups. In (Belloli et al 2015) the results of an extensive experimental campaign in the wind tunnel are shown and commented. High Reynolds numbers are here reached also exploiting surface roughness of a large diameter cylinder; both aerodynamic and aeroelastic tests are described. Even though the Reynolds number increase due to roughness cannot be precisely defined, the results clearly shown that VIV takes places as well in the postcritical range, showing similar features as detected in subcritical conditions. This allows for optimistic considerations about the possibility of adopting, and calibrating, fluid oscillator models for high Reynolds number VIV simulation.

3.4 *Response to traffic loads*

Dynamic behavior under vehicle-structure and train-structure interaction must be checked. Given the intrinsic time-dependent properties of the coupled vehicle-structure system, the simulation must be carried on by step-by-step analysis in the time domain; a promising option, in this respect, is represented by decoupled procures (see, for example Palamà 2017) in which the vehicle and structural system are separately integrated, and convergence is monitored on the global response. This allows for adopting different procedures for the two systems. In train-structure analysis, for example, non-linear effects in track-wheel interaction can be captured, though maintaining linearity in the response of the tunnel model.

3.5 *Response to accidents and intentional attacks*

Internal impacts, fires and explosions can be treated according to load models which are common in tunnel engineering. In setting simulation procedures and performance criteria, however, the location in water must be carefully taken into account.

A difficult situation arises when the case is considered of an external explosion, occurring in the water in proximity of the tunnel. The issue is new in tunnel engineering and simulation must face extremely complex phenomena. However, depth charges are sadly common in military operations against submarines, so that a vast literature on the topic is available and could be exploited if required.

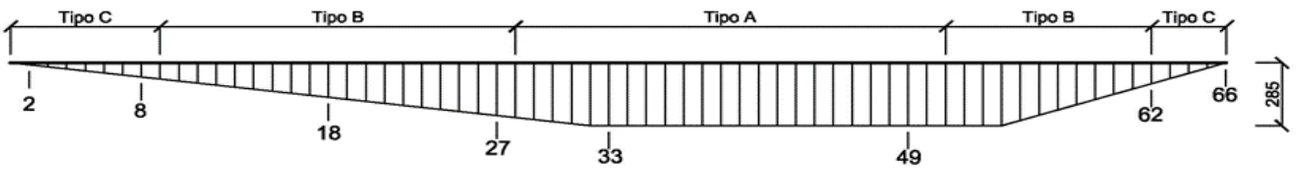

Figure 5. Side view of the model, showing the anchoring sections and the seabed profile, and organization of the mooring system (dimension in meters).

4 A CASE STUDY

A recent MS thesis supervised by one of the authors (Oregioni & Triaca 2016) deals with the Messina crossing and the seaquake effects.

4.1 *Description of the structure*

A general side view of the model, devised for the Messina crossing, is depicted in Figure 5. The model is based on one of the proposals for the crossing (see Bruschi et al 1990), modified in order to account for the more recent design trends.

In this light, a double tube configuration is addressed, in which escape routes connect the tunnels at a distance of about 500 m creating, on structural grounds, a Vierendeel beam acting in the horizoe. The anchoring system is of independent type, as shown in Figure 6, while the anchor bars show non-linear material behavior. Passive control devices are introduced at the tunnel-shore interfaces to limit both the axial forces in the tunnel and the longitudinal displacements in seismic conditions.

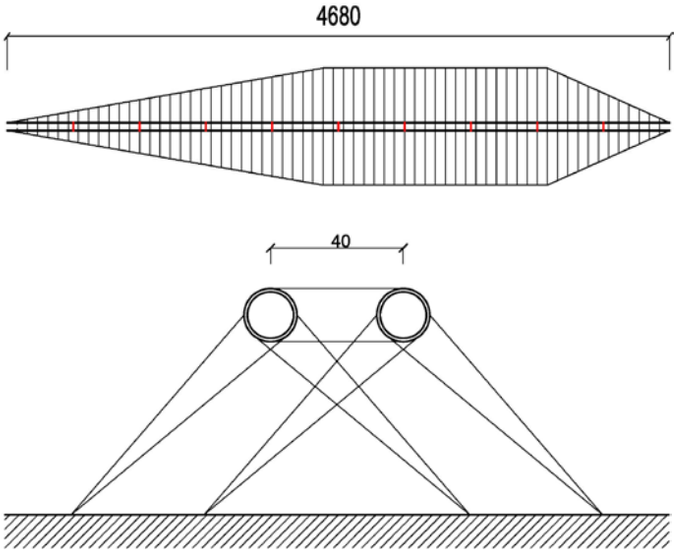

Figure 6. Top view of the model, showing the anchoring sections and the seabed profile, and organization of the mooring system (dimension in meters).

Each tube has a composite steel–concrete cross-section (Figure 7) and is assumed to behave elastically due to water tightness requirements. The anchor bars, which are assumed to have non-linear material behavior, are of three different sizes (Type A, B, C in Figure 5 and 7) depending on the seabed depth.

Since there is yet no specific normative on SFTs, appropriate rules from other fields have been adapted. In the case of the escape routes for fire or flooding, the distance has been set to 468 m to comply with EN 2004/54/CE, originally drafted for tunnels. This (paragraph 2.3.8) requires that the distance between emergency exit need to be less than 500m.

4.2 *Seaquake*

In the work (Oregioni & Triaca 2016), seaquake effects are introduced through the hydrodynamic pressure waves associated to the water motion due to the vertical oscillation of the seabed.

The water motion is assumed as that of a vibrating fluid column excited by the seismic motion of the seabed. It is computed in linearized form, at the depth of the SFT tunnel, from potential theory (Hamamoto 1995); the velocity potential is deduced from the wave equation (Shi & Martinelli, 2013) considering as boundary conditions the compatibility with the vertical seabed motion and the free surface condition.

Due to the non-linearity inherent to the SFTs behavior (both geometrical and mechanical), seaquake effects are accounted for in time domain. A realization of seismic vertical accelerations at the seabed according to the procedure in (Martinelli et al. 2010, 2011) is used to compute the vertical acceleration at the position of the nodes for which the seaquake related forces need to be computed. The force on the SFT elements due to the oscillatory flow caused by the seaquake is modeled adopting Morison's equation. The relative velocity of the SFT with respect to the water is used in computing drag forces.

Note that a more recent MS thesis work (Hemanth Kumar 2017), which is also the subject of the parallel paper (Martinelli 2018, submitted) was entirely devoted to seaquake modelling. Here the amplification effects on the water motion was studied

also considering a flexible soil layer interposed between the bedrock and the seabed.

4.3 *Main results*

The main results of the first study are that structural response under violent seismic actions is improved by admitting plasticization of the anchoring bars. These exceed the yield stress not only near the shores, where this was expected due to the "end effect" and to the smaller length of the bars, but also at a quarter and midspan. Seaquake shows a major effect on the response in the vertical plane. Longitudinal dissipation devices at the tunnel-shore interface are efficient in controlling the axial internal forces in the tunnels.

The problem of shear and bending moments developing in the tunnel close to the shore connections, anyway, deserves attention at the research and design level; different solutions pursuing a mitigation of the effects could be devised either by adopting a "denser" pattern for the anchoring system approaching the tunnel ends, or by introducing dissipation devices also in the vertical and lateral directions.

Finally, internal forces obtained in the case of three flooded compartments are higher than those due to seaquake and the asymmetry of the loading (one tube only is flooded) causes high torque actions. The most critical situation was found at the tunnels midspan.

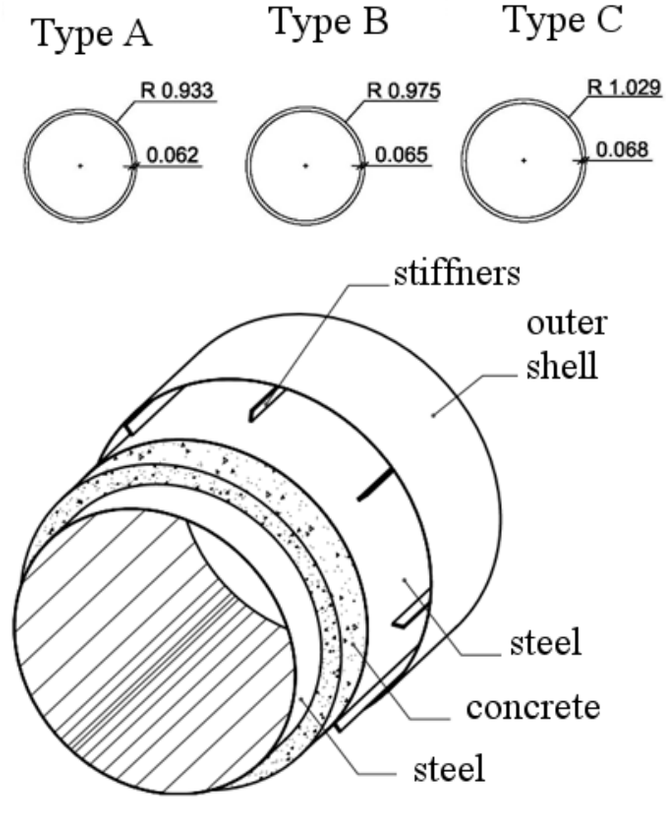

Figure 7. Type A, B, C of the anchoring bars cross-sections and composition of tubes cross-section (dimensions in meters).

5 CONCLUSIONS

In the paper, some general issues regarding the design and analysis of seabed anchored SFTs have been reviewed and discussed, trying to identify unresolved design issues and/or aspects of the SFT structural behavior needing a further research effort. Among these, and with reference to the twin-tunnel design solution, we can quote the following:

- end connection to the shores, especially in relation to seismic design,
- optimization of the distance between the connections,
- optimization of the distance between the tunnels,
- design for partial flooding conditions,
- replacement of damaged modules,
- 3D effects in tsunami loading of strait crossings,
- VIV modelling at high Reynolds numbers,
- train-SFT dynamic interaction,
- effect of an external explosion.

Finally, some recent activity performed by the research group has been summarized, focusing on the seismic behavior of twin-tube SFTs and on the seaquake excitation mechanism. Some results obtained in studying partial-flooding loading conditions are also commented.

An Experimental Study on Bending Behavior of Composite Hollow RC in Submerged Floating Tunnel (SFT)

J.H. Seo, D.H. Won &W.S. Park
Coastal Engineering Division, Korea Institute of Ocean Science and Technology, Bus

ABSTRACT: In case of a submerged floating tunnel (SFT), which is difficult to cast in-site underwater construction, it is modularized on land and then assembled them in the field. So, it is influential to investigate the structural performance of the joints between the modules. A concept of the steel composite hollow in SFT which stably maintains the joints has been proposed by applying prestressing method to resist various external loads. In this study, the bending behavior of module joints in a steel composite hollow tunnel was experimentally analyzed to evaluate the safety for the bending deformation which is dominant in SFT. Test results show that there is a difference at the module joint portion in the performance depending on whether or not the inner steel tube is connected. As a result, in the design of the module joint, depending on the purpose of SFT, it is possible to consider both methods which is allowing the ductility behavior of internal tube and controlling the tight connection. And, the failure criterion of the bending behavior of the module joint can be selected as the maximum load or deformation limit.

1 INSTRUCTION

1.1 *Outline of SFT*

SFT (Submerged Floating Tunnel) is a tunnel installed in the water and can be described as underwater bridges. There are various linking means for water-spanning structures; a general suspension bridge, an immersed tunnel, an underwater tunnel, and a SFT refers to an installed tunnel between a sea level and a seabed surface. It is commonly called Submerged Floating Tunnel (SFT), also called a suspended tunnel or Archimedes bridge. A SFT comes into the spotlight as an alternative technology for creating practical space with the introduction of eco-friendly concept.

The supporting methods of these SFTs are classified with to its own weight and buoyancy (Figure. 1). When the buoyancy is greater than the self-weight (W<B), there is a method of using a taut mooring system such as a tension leg. When the self-weight is larger than the buoyancy (W>B), either an additional buoyant pontoon or a way using the supporting piers on the seabed is used to equalize the total weight and buoyancy. And by corresponding the weight with buoyancy (W=B), there is also a way not to provide a separate support structure or mooring system.

These methods require the appropriate selection depending on each marine environment. Of the various marine environment, SFT can be useful in that it can directly connect the underground road network. That is it is feasible for a low slope since it has the lowest connecting section in comparison with other water-spanning structure types. In the intercontinental connection with deep water and long transversal distance, it means to secure economic feasibility.

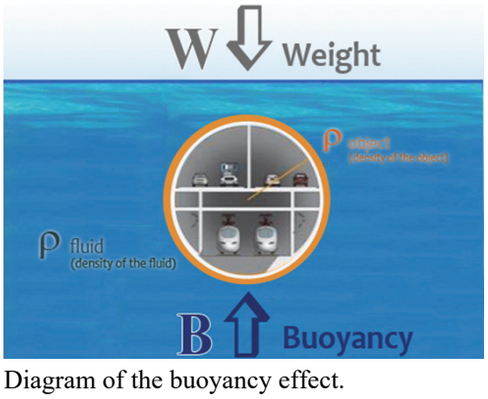

Figure 1 Diagram of the buoyancy effect.

Many countries have studied about SFT with these many advantages. Typical examples of research include Høgsfjord crossing in Norway, Messina Straits crossing in Italy, Lake Lugano crossing in Switzerland, and Northern Japan Exchange Axis, Funka Bay crossing connecting Hokkaido and Honshu in Japan, and in China, there is conducted a research in collaboration with Italy on the Archimedes Bridge Prototype in Qiandao Lake (Mazzolani et al., 2010; Park et al., 2012). Especially, in the Norwe-

gian coast, there are more than a thousand fjords with deep water and long transversal distance, and researches on SFT were conducted early on. As a part of the project "Coastal Highway Route E39", Norway's Public Roads Administration (NPRA) has an ambitious plan to solve the problem by building the world's first floating submerged tunnel system about 30 meters (100 ft) underwater beneath the Søgnefjord (Duan, 2014).

1.2 *Joint of composite hollow RC in SFT*

Since the SFT is difficult to cast in-site underwater construction, it is considered to be the most reasonable construction method using the module fabrication which move it from the coast to the field site using the ship. The joint structure that connects each module of the SFT must be capable to perform appropriate functions such as water tightness, transmission of force, flexibility, etc. while also reasonably performing the joining of each module.
This joint structure can be divided into a continuous joint that is tight connected each module according to the stiffness of the joint. And this joint structure not only applies to the connection between the SFT modules, but also refers to the module and the ventilating tower, and the connection with the ground as a final joint. Therefore, it is required to develop a new type module considering rapid construction, stability, and economical feasibility. This study focuses on the joint structure between the SFT modules.

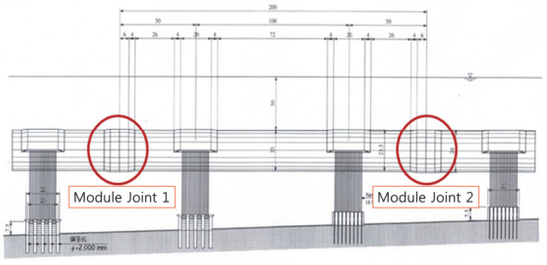

Figure 2 Side view of SFT

In case of Qiandao crossing in China, Funka Bay crossing in Japan, as well as the Busan-Geoje Fixed Links Immersed tunnel in Korea and Dutch immersion tunnel having the similar structures, the module joint methods to stably keep the concrete joints vulnerable to tensile are proposed as shown in Figure 2 and Figure 3. Fist of all, cross-section of SFT is applied steel composite hollow RC section under member. This section has inner tube, it has good ductility and strength (Han et al, 2008). In this research, this section applied SFT's section.
The joint of module composite hollow RC column need to solve connection method between concrete and steel tube, respectively. This connection method has been proposed. The connection of concrete has different connection method another module connection type which is arch post tension method because in-site construction is impossible. As shown Fig. 3, prestress tendon can be give initial stress in SFT. It is very good method for SFT. In this reason, this arch post-tension method is suggested. For connecting method of steel tube, high tension bolts are applied as shown Fig. 3. It already suggested method like as steel bridges design and construction method. Using a Gina profile and an Omega profile, they form the primary and secondary shield skirts, and provide prestressing with a coupler and a steel PC tendon (Mazzolani et al., 2010; Zhang, et al., 2010). And the empty space was applied by using mortar. Many countries have proposed various types of module joints for SFT, but none have actually been constructed yet.

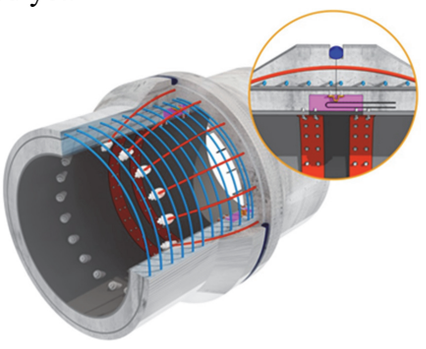

Figure 3. Module joint of composite hollow RC SFT.

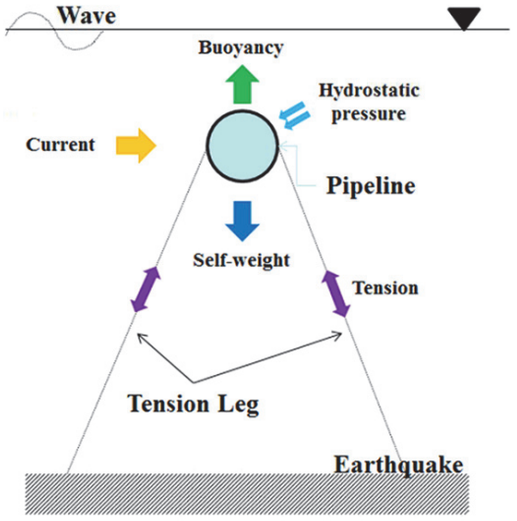
Figure 3 shows the Gina and Omega profiles installing outer and inner respectively to completely block the water. In order to improve the structural stability of the module joint, it is necessary to connect the longitudinal steel rebar, the inner steel tube and the concrete. Therefore, the arched prestressing method is applied to bond the concrete with the longitudinal rebar. At this time, the thickness of the outside of cross section was increased to reduce the curvature and the stress concentration of the arched PC tendons introduced for tensile force. In additional, a rebar connection to improve the connection performance of the concrete was installed to be made up the intersection when both modules are jointed. The mortar is injected into this joint, and in case of the inner tube, it is installed through bolting or welding to enable complete joint.
The loads acting on the module joints in SFT (Figure 4) have various external loading conditions such as hydrostatic waves, seismic loads, especially, in case of an earthquake, the tensile force should be examined since the axial force is generated. The bending deformation expected to have a dominant influence among bending and torsion, axial tensile and compressive forces, this is an important factor for safety of SFT by generating tensile and compressive forces on tunnel walls. Therefore, it is required to design a joint in SFT that can be able to appropriately resist the horizontal and vertical shear force.
The module joint used in this study is based on the cross section of composite hollow in SFT proposed by Han et al. (2013). As shown in Figure 4, the tun-

nel length per module was set to 200 m and is assumed that it is moored by two mooring devices.



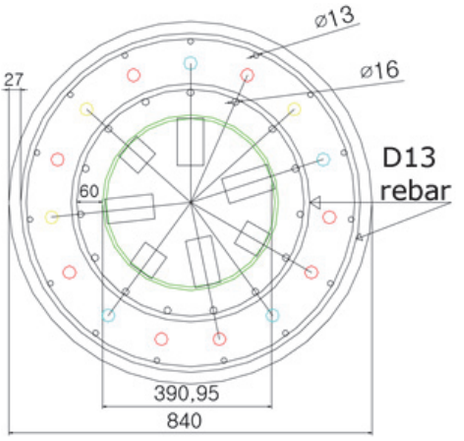


Figure 4. Various loads acting on the module.

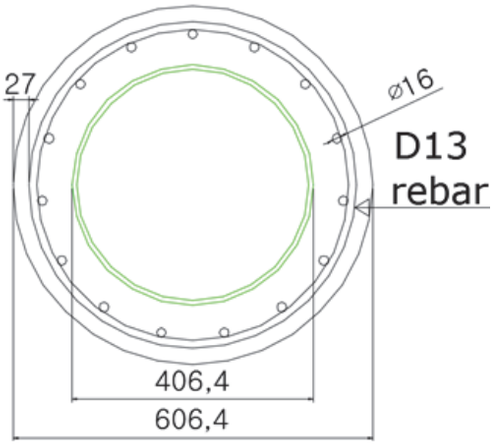
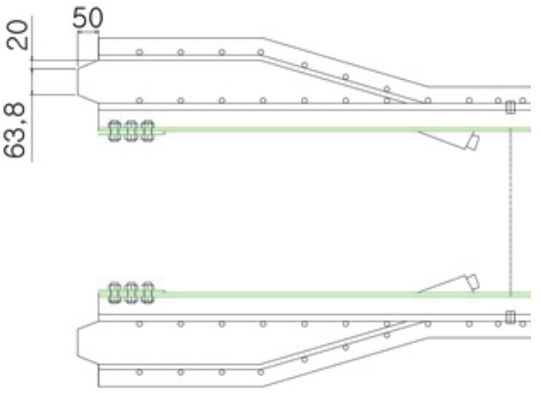
This paper performed an experimental study for bending behavior of the module joint assuming that would be subjected to axial load. Test variable is connection type of inner steel tube. The main objective of this study is to evaluate the failure mode and bending behavior of the module joint of composite hollow RC in SFT using the proposed prestressing method.



2 TEST PROGRAM

2.1 *Experimental Model*



To verify the bending strength of joints between steel-composite hollow RC modules in SFT, Specimens were designed and manufactured as shown in Figure 5 and Figure 6. The total length (L) of the specimen is 7 m, connecting two modules of 3.5 m. Figure 5 shows design details of the test modules. This model is scale reduction model (1/100). This model designed by design code with the pre-stressed concrete. Variables studied in the test program are the presence or absence of the inner steel tube in PART A, and two specimens were manufactured for each connection type of inner steel tube. One specimen was bolted to an inner tube having 7.5 mm thickness (Figure 6), and another specimen was left unconnected and simulated with a hinged structure.

(b) Top plate (c) Bottom plate

Figure 6. High tension bolt for connection plate (units: mm)

Figure 7~8 show the production process of test specimens, which were fabricated by assembling the reinforcing bars to the molded specimens, attaching the gauges, pouring concrete into the tunnels and demolded. For specimen with bolting inner tube, at first, the inner steel tube was welded. Then the longitudinal steel bars were bonded using a coupler, then the lateral steel bars were bonded, and concrete was filled. After the two modular portions (PART B) were placed the concrete, post-tensioning was performed on the PART A which is the joint portion.

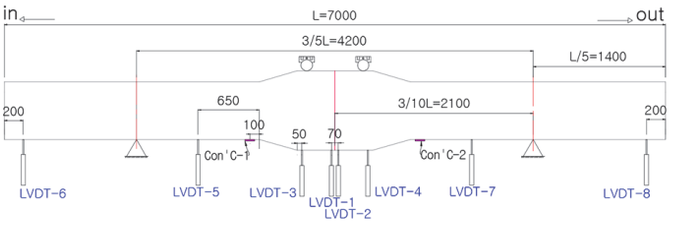

Figure 7. Molding and assembly.

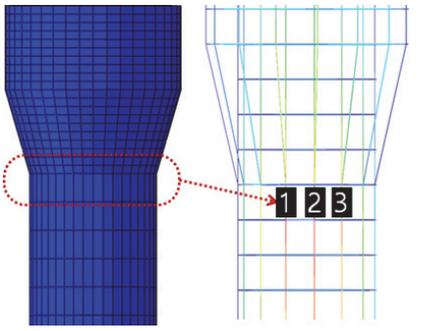

Figure 8. Pouring and demolding.

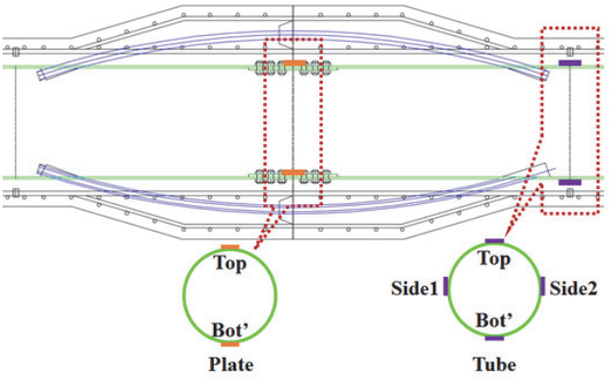
2.2 *Test Method*



In order to evaluate the bending performance of the manufactured specimen, we refer to the bending strength test method of the pretensioned spun high strength concrete piles, F 4306 (KS, 1988). The deformation of specimen was investigated using four displacement gages (LVDTs) and twenty-four strain gage. To measure deflection, a displacement gages were installed at the lower part of the test specimen where four LVDTs #1 ~ #4 in front of PART, and other half LVDTs #5 ~ #8 were installed in front of the two modules on PART B (Figure 9(a)). And, to investigate the strain of steel reinforcement bars, the strain gauges were attached at the end of the welded section where the thickness was increased to reduce the stress concentration.

(a) Installation of LVDTs

(b) Strain gages for rebar

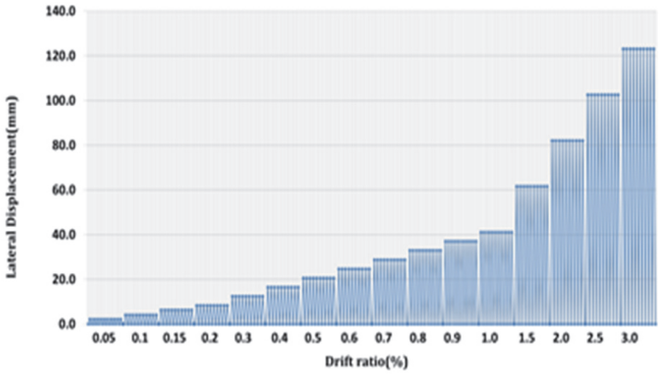
(c) Strain gages for inner tube

(d) Setting the specimen

Figure 9. LVDTs & strain gages (units: mm)

As shown in Figure 9(b), six strain gages were installed at longitudinal reinforcement bars with load-direction (Top-1, 2, 3) and opposite direction (Bottom-1, 2, 3). In addition, to investigate the bending behavior against axial tension and compression, the four gauges were set to the outside of inner tube in four directions (Tube Top, Tube Bottom, and Tube Side 1, 2) respectively. In the event of bolting case of the inner tube among the two specimens, there was the supplemental connecting steel plate at the center of the span, and two gauge were attached to the upper and lower parts and named Plate Top and Plate Bottom (Figure 9(c)). In addition, strain gauges (Con'C-1, Con'C-2) for measuring the concrete strain were similarly attached to the end of the tapered section of the joint in the opposite direction. Here, Con'C-1 means that it is installed in the inner direction (in) corresponding to the left side in Figure 9(a) and Con'C-2 indicates that of the opposite direction (out).

In this experiment, the displacement control method is applied by the loading control method using the actuator of 200 tonf. The test speed is shown in Figure 10, as the deformation amount of specimen increases, the joint speed is increased from 0.15 mm/s to 1 mm/s. The actuator is located at the center of the span where the joint part is placed. The acting load was based on the measurement value by the actuator.



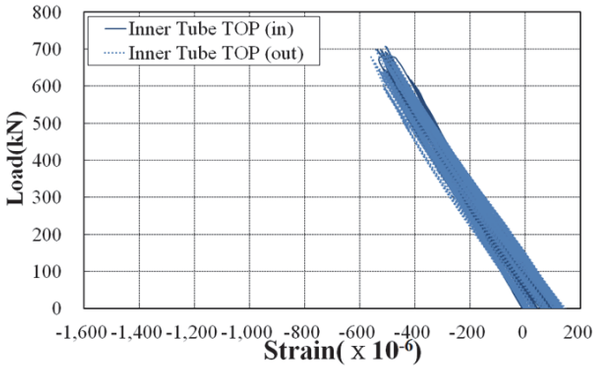


Figure 10. Half cycle low fatigue loading (10cycle/step).

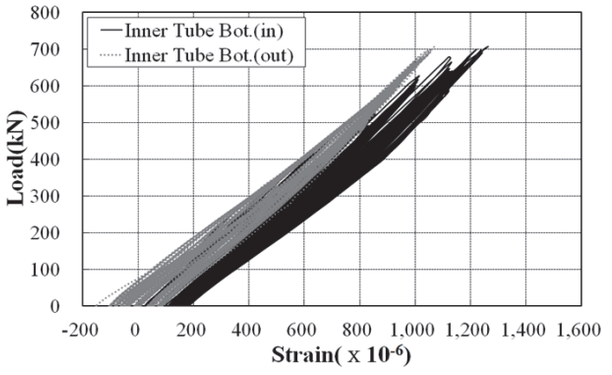
3 BENDING BEHAVIOR OF MODULE JOINT



The cross section of the composite hollow in SFT does feature in which the longitudinal reinforcing steel and the inner tube are connected by the PC tendon, and the concrete surrounds the outer wall. In case of the acting load is applied on more than the performance of PC tendon with the prestressing, the inner tube is responsible for the safety of the structure. The safety criteria for evaluating the bending behavior of these modular joints depend on the application of the tunnel. There are two methods for ultimate strength calculation to determine the strength evaluation of the joint. One method is determining as the maximum load of the load-displacement curve, and another is determined as the deformation limit based on the deformation of the joint (Zhao, 2013). In this section, the bending behavior of module joints are analyzed and compared according to the presence or absence of the internal tube connection

3.1 *Test Result*

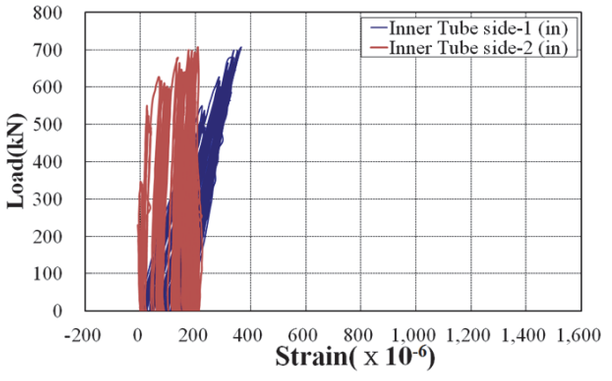


Figure 11 and Figure 12 show the results for the specimen which the inner tube is not connected. The strains obtained from the gauge (Tube Top, Bottom, Side 1, 2) attached to the inner tube (Figure 11) show that compressive force is generated at the upper part and tensile force is applied at the lower part as the loading rate increases, the bending behavior can be determined symmetrically without the torsional effect.

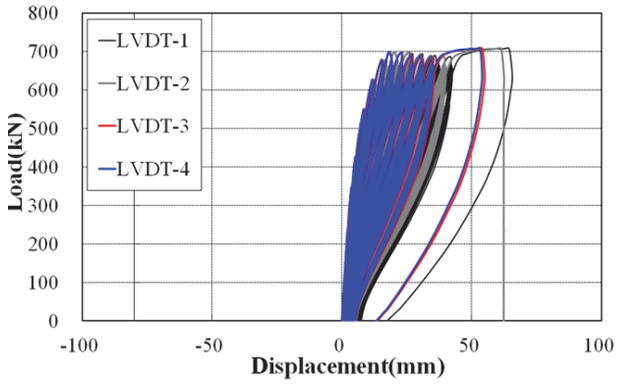
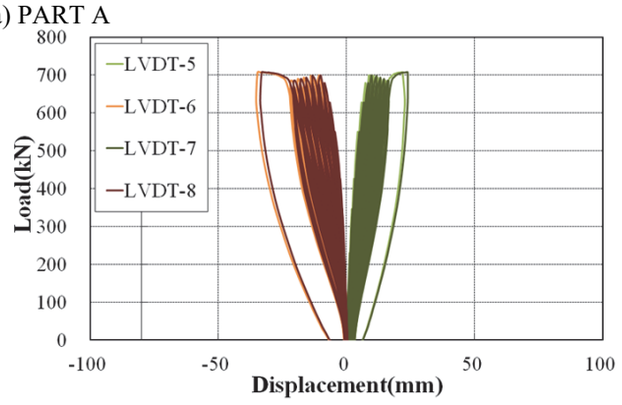
(a) Tube: Top



(b) Tube: Bottom



(c) Tube: Side

Figure 11. Strain curves of the specimen without inner tube connection.

Next, in the load displacement curve (Figure 12) of the specimen without inner tube connection, the maximum tensile displacement of about 60 mm occurred in the joints at PART A (LVDT 1 ~ 4), and the deformation of the close part to the center was larger. Also, it was confirmed that the maximum compressive displacement at PART B (LVDT 6, 8) was about 35 mm. It can be seen that the deformation of specimen which the inner tube is connected has larger bending deflection in both the tension and compression portion than that of without inner tube connection. It can be means that the resistance performance by the inner tube exhibits in the above section of acting load having the prestressing by the PC tendon in the tensile portion which is the opposite direction of loading.

(a) PART A

(b) PART B

Figure 12. Load-Displacement curves the specimen with connected inner tube

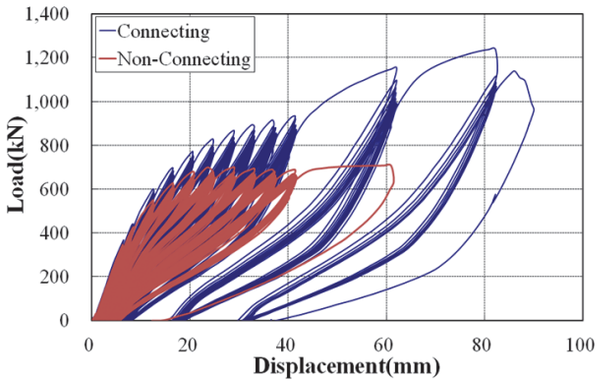


Figure 13. Comparison of performance of inner tube with the specimens.

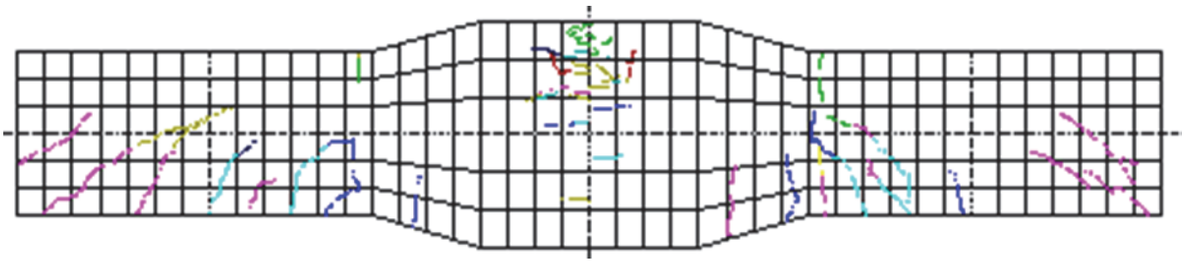
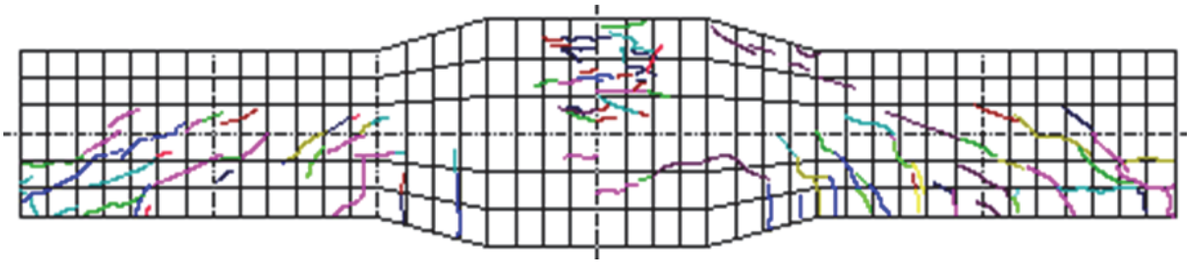


In order to compare the resistance performance by the inner tube, Figure 13 describes the load-displacement history curve. In case of the specimen (red solid line) without the inner connection, the maximum strength is 700 kN, whereas the specimen (blue solid line) with the inner connection by bolting has a maximum strength of 1,200 kN. It can be seen that the strength is relatively increased due to the connection performance of the inner steel tube.

In the event of the design method considering the seismic performance based on the ductility such as the railway bridge, it can be judged that the higher the extreme strength after the yielding, the better performance. In the case of a design method considering over the constant allowable displacement as the failure, the two specimens have similar performance because they show almost the same stiffness up to the displacement of 10 mm. Moreover, in the case of the unconnected specimen of the inner tube, the lower part of joint opened temporarily, but it was restored after the test by the PC tension, and the residual deformation was about 15 mm. Even if a failure of the module joint occurs in SFT, it is expected that the waterproof function operates normally by the internal omega profile due to itself ductile behavior. In the case of the specimen with inner tube connection, the lower part of joint was also widened temporarily, but it was restored after the loading by the PC tension, and the residual deformation was about 40 mm which has relatively less resilience than unconnected cases. It is considered that after yielding, the connected inner steel tube resists external force such as buckling, which has relatively less resilient than that of the not connected case.



Experimental results show that the bending stiffness of the joints specimens is very similar according to presence and absence of the inner tube, but there was a difference in ultimate strength. Also, restoring force was decreased by connecting the inner tube. Therefore, when judging the performance of the module joint in SFT, it is reasonable to choose whether to calculate based on the maximum load in the load-displacement curve or the deformation limit of the joint with the purpose of the tunnel application.

3.2 *Comparison of Crack Patterns*

Figure 14 shows the cracking behavior of the specimens by acting load, and the cracks generated on the outer wall of the concrete with low tensile strength were observed by the bending moment. As the load increased, bending shear cracks began to occur at the end of the tapered section. Then, diagonal cracks was generated at the end of the beam. For PART A, the acting load portion, crushing characteristic occurred in the outer wall of the concrete while resisting the bending due to relatively large compression, and bending cracks occurred at the center of the tension portion in the opposite direction of the loading.

(a) Non-Connection (Front)

(b) Connection (Front)

Figure 14. Comparison of crack patterns.

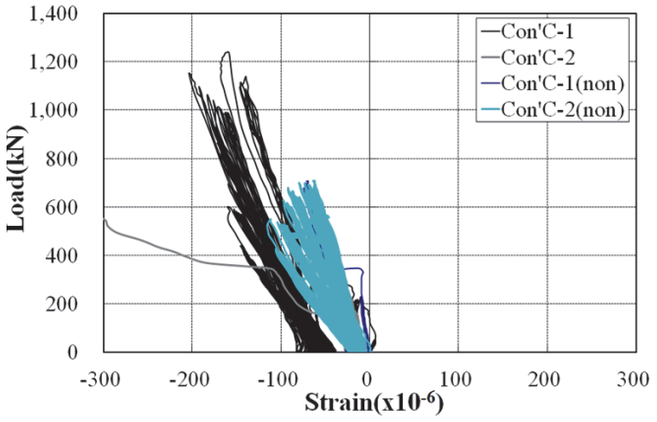


Figure 15. Concrete stains

In addition, it can be seen that cracks are more uniformly distributed over the entire cross section when the inner steel tube is connected. For the non-connection case having relatively smaller residual deformation observed the less cracks of 55% than in the connection case. It seems that the inner tube serves as a hinge in this structure. This can be exhibited on the concrete strain measured at the lower end of the tapered section (Figure 15). When the inner tube is connected, it shows a strain of 0.0002 at the maximum load, while it has a strain of about 0.0001 in case of without connection, which is measured up to about half. In this way, when the inner tube is connected, the bending moment is transmitted to the module portion (PART B) through the joint portion (PART A), and result in the wider cracks.

4 CONCLUSIONS

In this study, structural bending behavior of module joints with steel composite hollow RC in SFT applying prestressing method was studied experimentally. The performance of module joints in SFT was evaluated by experimenting with the connection of inner steel tube as the test variables which is responsible for safety when acting on the joints above the prestressing force. The main findings are summarized as follows,

(1) The bending stiffness of the module joints in SFT was very similar but there was a difference in strength. The maximum strength was increased from 700 kN to 1200 kN when the inner tube was connected, and the residual displacement was increased from 15 mm to 40 mm. However, this is superior to the maximum strength by connecting the inner tube, it is considered that the restoration force by PC tendon is reduced due to the deformation of the joint with bolting connection.

(2) Therefore, when designing the module joint, according to the application of SFT, it is possible to consider both the method which allowing the ductility behavior and tight controlling with bolting connection. In this case, it can be understood that a rational design is practicable by selecting criterion for judging the bending behavior performance of the module joint as either the maximum load or the deformation limit.

(3) Furthermore, considering the underwater environment, it is necessary to examine more various structural behaviors such as torsion which may affect the overall structure of the SFT. And the effects of deformation taking into account the foundation and the ground conditions should be fully examined.

ABSTRACT: In the past few decades, more attention has been paid to the longevity of infrastructure. The long-term environmental factors such as chloride invasion and carbonation penetration detrimental to concrete make reinforcement corrosion and shorten the service time of bridge structures, giving a gradually decrease of structural performance. Based on our previous study, the relationship between structural performance and service time can be displayed and the time point for maintenance or retrofit when structural performance proceeds below threshold values can be predicted. This paper presents a novel life-cycle based bridge management system (BMS) with extendable structure. In the developed system, a novel technology is known as "Metadata" was adopted to integrate all the bridge inspection records and the evaluation results in the photos on-site. In other words, a single photo capable of storing all the information related to bridge status was created with superimposing the data layers. Therefore, different photos were taken at different time point just become a resume of bridge status. The time history of bridge status considering material deterioration is accordingly able to be recorded and evaluated qualitatively and quantitatively. As a result, the purpose of life-cycle-based bridge management can be fulfilled. This technology benefits data mining of inspection and evaluation, the decision making on necessary maintenance efforts for long-term problem of the deteriorated bridge can be done with ease. Also, to identify the seismic behavior of the bridges shortly after the strike of an earthquake, this system has to possess the capability of rapidly estimating the risk of bridge damages caused by an earthquake. By incorporating the analysis of earthquake attenuation relationships and fragility curves, rapid estimation of seismic risk analysis system was established. A seismic risk assessment system, which can instantly estimate and visually demonstrate the level of damage to bridges due to a specific seismic event and the corresponding economic loss due to the damage of bridges, was developed and also served as a reference for seismic retrofitting program of existing bridges. The achievements attained in this study can be helpful for earthquake mitigation strategy in the future.

1 INTRODUCTION

As the rising number of natural disasters reported worldwide, the government and the public have put more and more attention on the structural safety of infrastructures. The bridges have become the most crucial transportation infrastructure as a result of the high development of the economy in Taiwan, and therefore the structural safety of bridge is one of the primary concern in public issues. Taiwan has a sub-tropical climate, warm and wet environment makes material deterioration with easy and give a significant influence on the service time of bridges. Also, Taiwan is situated in a collision zone between the Philippine Sea and the Eurasian tectonic plates and therefore suffers from earthquakes frequently. Frequent earthquakes have inevitably caused significant damages to the existing bridges. The damages of the bridges due to earthquake not only lead to the loss of many innocent lives but also interfere with the rescue efforts, generating the countless amount of cost to the society and economy.

To achieve disaster mitigation, having an efficient BMS is very important to increase the resilience of the bridges after a disaster. This paper introduces the new development of life-cycle-based BMS in Taiwan. The developed system can deal with the problems of material deterioration, earthquake, and flood and so on. Moreover, benefits bridge authority doing decision-making on bridge maintenance.

According to the previous studies (Sung et al. 2010, 2011), the relationship between structural performance and service time can be displayed and the time point for maintenance or retrofit when structural performance proceeds below threshold values can be predicted. As a result, the time history of bridge status considering material deterioration is accordingly able to be recorded and evaluated qualitatively and

quantitatively. Then the purpose of life-cycle-based bridge management can be fulfilled. It is definite that the correct record of bridge inspection work helps engineers update condition of the bridge structure and would be valuable for structural safety evaluation. In the developed system, "Metadata" was adopted to integrate all the bridge inspection records and the evaluation results in the photos on-site. All the information of bridge status during the different period of life-cycle can be preserved, in other words, the whole resume of bridge status is possible to be established and fulfills life-cycle maintenance. The developed system can improve the efficiency and the quality of bridge inspection work. Therefore the evaluation of bridge safety can be obtained more comfortable and more accurate.

2 DEVELOPED MODULES OF BMS

2.1 *Framework of the system*

In general, a bridge life-cycle can be divided into four stages of plan, design, construction, and maintenance, respectively. Among which, the maintenance stage preserves the longest time of the total structural service time of a bridge. That is to say, doing the maintenance work on infrastructures plays a significant role to make sure the qualified structural safety performance and the satisfied service quality. Focused on the maintenance stage, the framework of the developed BMS includes three main technical parts with cooperated functionalities (Thompson, P. D. & Kerr, B. 1998). The first part is the modularization function that involves network-level, project-level, and element-level according to the different way of management and applications.

The second functional part of the BMS is the information database which stores bridge inspection data. The principle of design of this section is the customization functions. Moreover, the system design frame of this part focuses on Model, View, and Controller, respectively, and thus abbreviated by MVC. The Microsoft ASP.NET MVC design frame is capable of reducing the component coupling between each part of components in the system and raises system capability on extension flexibility. The tools used for the data processing are MySQL Database and CouchDB, which can substantiate the table-column object in the database with flexibility.

The third functional part of BMS is the module that applies expert system algorithms to evaluate and rate the condition of structures. This part accomplishes the design and implementation of the visual interface interacting with specialist knowledge, integration engine of expert algorithms, the analysis core of the Neural-aided expert system, the graphic user interface of expert system operation, and the management of a database for bridge inspection data. The structural evaluation of bridge deteriorations needs a professional judgment. Therefore an expert-like algorithm has been developed in the system. In general, the algorithms embedded in the BMS have to be reviewed and modified according to the back-feed information from field observation and senior engineers' determination. Also, the BMS also focuses on integrating extendable and modifiable modules to be available to the practical use. Figure 1 shows the framework of the developed system, the input layer of which includes inspection record, bridge inventory and the descriptions of the related regulations.

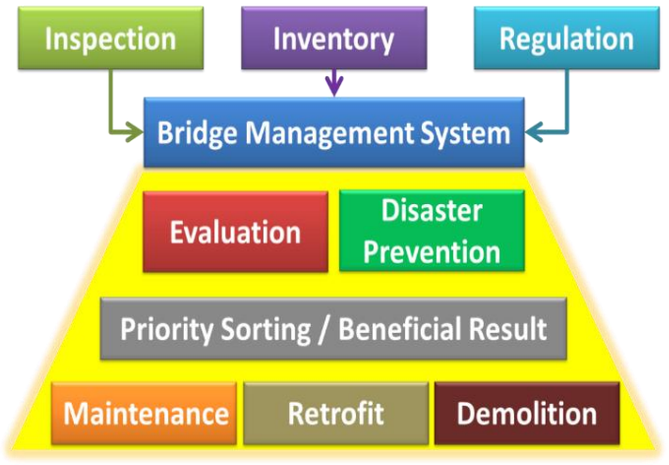

Figure 1. Framework of the developing BMS

In the proposed framework, the evaluation and disaster prevention modules are included as well in the system. The output layer provides bridge condition, priority sorting and the beneficial suggestions to authorities for making the optimal decisions. Figure 2 indicates the service bus which can be flexibly built to connect the other application functional modules.

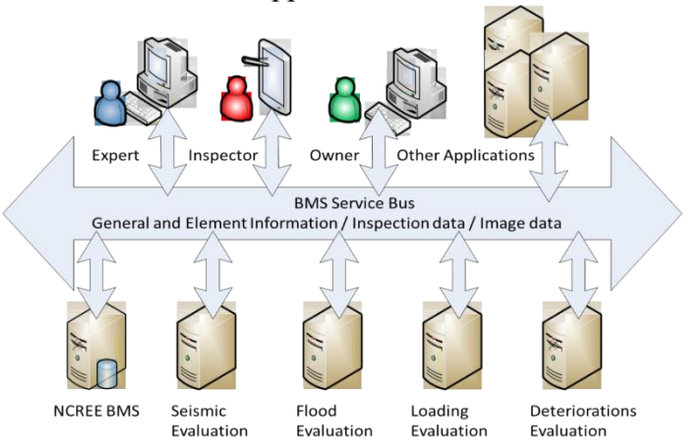

Figure 2. Service bus of the system

2.2 *Inspection module*

A flexible user-defined data frame of the database is proposed and constructed in the system, which allows the bridge engineers to keep the inspection easier and more efficient. An extended module was developed for having objective of simplifying field inspection

work by extracting representative items, building graphics operating interface and using intuitive and visual tools. To keep the raw data with less humanmade deviation, the core of this module aims at collecting the inspection data through the photos or illustrations but no evaluation by the inspectors.

The general information of a bridge includes bridge name, bridge location, date of inspection, design code used, load classification, date built, structural sections, structural length, number of spans, inspection records, and bridge structural descriptions available, as the essential data. They can be obtained either through review of design/construction drawings or the other technical documents and of course, can be investigated by site observation. The bridge components rating information is essential for following evaluation that includes traffic safety features, bridge deck condition, load bearing components, abutments, piers/bents or pile bents, superstructure, substructure, river channel protection, the approach slab and so on. It must be noticed that the purpose of BMS is to manage information about bridges and to assure their long-term serviceability for public use under owner's budgetary constraints. An inspection database is the core part of a BMS, which is built up of records obtained from maintenance activities.

Figure 3 shows the standard procedure of inspection work by using the developed system. First, the experienced inspectors must do the visual inspection and take the photos on site, second, the inspection photos will be upload to BMS database which with code-compatible evaluation module, and the evaluation can be performed by using the evaluation module. Final, the BMS can automatically export the inspection report for authority reviewing. Figure 4 shows the user-friendly visualization inspection system in developed system. The important information of the photos such as the location, the quantity message, crack length, crack width, and inspection date, etc. can be shown and the corresponding evaluation result can be determined automatically by the code-based evaluation module. All the inspectors have to do is to take the photos of damage but don't need to worry about what the bridge status should be evaluated. Just like the human health inspection process, this developed system separated functionality of inspection and evaluation. The advantage of this approach at least includes: (1) professional requirement of the inspector can be reasonably set up, too high-level qualification for senior engineers of design is unnecessarily applied to bridge inspection, (2) the humanmade deviation of evaluation result made by different inspectors is avoidable.

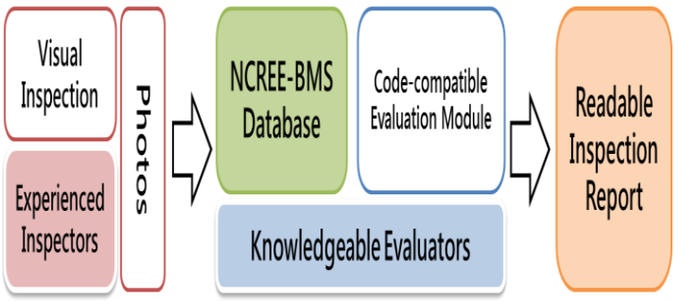

Figure 3. Procedure of inspection in developed BMS

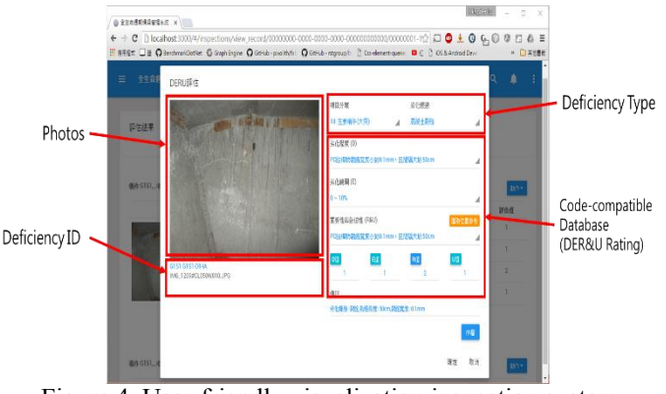

Figure 4. User-friendly visualization inspection system

2.3 *Disaster prevention modules*

In Taiwan, there are more than 25,000 existing bridges. A more significant part of them stride across the river and many bridges are reaching the old-age status. In addition to the material deterioration, earthquake and flood are two major types of disaster resulting in damage or failure to bridge structures. Based on the previous research work (Sung, Y.C. & Su, C.K. 2011), the neutralization (carbonation) and chloride-invasion into concrete usually result in material deterioration of reinforced concrete (RC) bridge and were adopted in the developed system. Figure 5 shows an estimation of possible time for reinforcement corrosion due to chloride-invasion of RC bridges along the coast. The seismic capacity of the deteriorated structure tends to degrade over time. By applying the method proposed, the plastic hinge properties of the neutralized or chlorided RC bridge column at different deterioration stages can be determined, and the decayed seismic capacity curves can be obtained through pushover analysis. As a result, the time-dependent fragility curves concerning some representative damage levels can be established, and the possible seismic loss can be expressed. Consequently, the seismic disaster prevention module can provide the failure probability of the bridge soon after an earthquake.

Furthermore, the BMS also connects the information with Taiwan Typhoon and Flood Research Institute (TTFRI) for scouring warning of the bridge. Figure 6 shows bridge scouring warning functionality in the flood disaster prevention module.

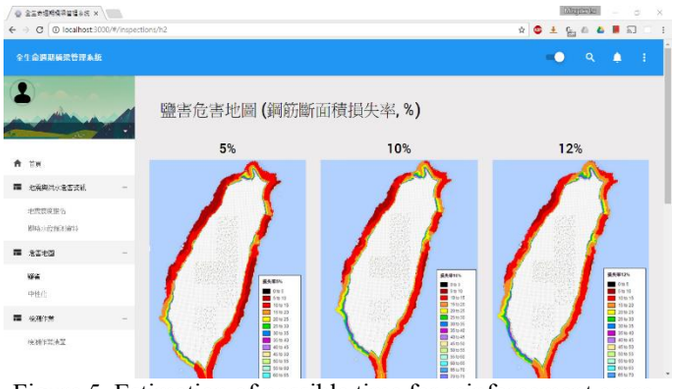

Figure 5. Estimation of possible time for reinforcement corrosion due to chloride-invasion of RC bridges along the coast

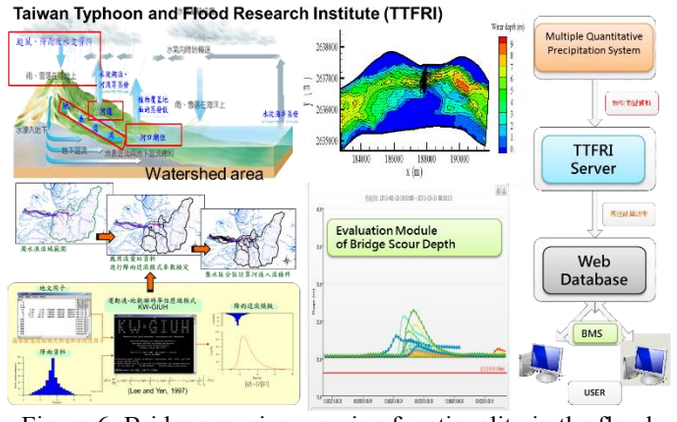

Figure 6. Bridge scouring warning functionality in the flood disaster prevention module

3 SIGNIFICANT FEATURES OF THE SYSTEM

3.1 *Seismic risk assessment module*

In the majority of cases when evaluating structures, fragility curves serve as the best indicator of the safety of a structure. A fragility curve represents the probability of a specific damage level for a particular type of structures under different levels of ground shaking. This information can be part of a disaster relief preparation plan for affected areas and a future reference when facing strong earthquakes to estimate the damages of the bridge as well as the lives and property loss.

As we know that an excellent seismic risk assessment system for the existing bridges should at least consist of four fundamental elements: (1) accurate simulation of earthquake, (2) sufficient database of seismic capacity of the bridges, (3) rapid evaluation of seismic loss and (4) visualized operation system. The first one deals with the nonlinear regressive analysis of attenuation law of peak ground acceleration (PGA). A relationship between PGA, seismic magnitude M and focus distance R is established to do the earthquake simulation. The second one relates to the seismic evaluation of many existing bridges through pushover analysis or time history analysis. From which, various structural damage statuses can be defined, and relevant statistical analysis can be done to obtain the fragility curves for seismic loss estimation. The third one concerns rapid calculation of probabilities with respect to various damage statuses under the situation of a specific earthquake. The cost, as well as time required for seismic repairing or retrofitting of the bridge, could be estimated instantly. The last one associates computer technology of software to exhibit visualization of the operation system. The objective-based technique is implemented to enhance the flexibility of system expanding.

Figure 7 presents the simulated earthquakes alongside the publicized earthquake records from the central weather bureau's (CWB). It shows that the simulated earthquake intensity maps obtained from this study and those released by CWB are quite similar. This result indicates that the nonlinear regression of attenuation law applied is satisfactory.

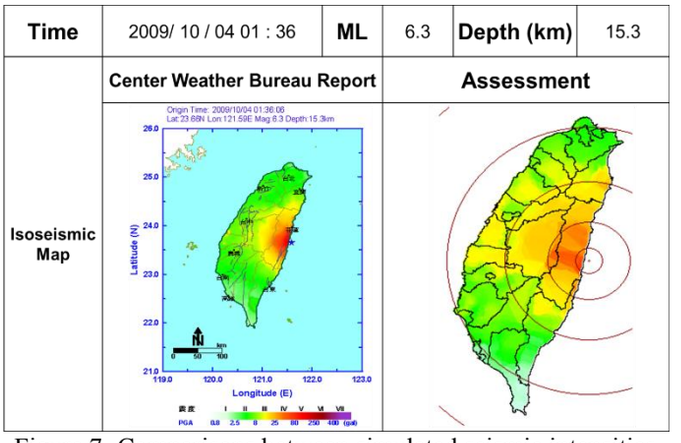

Figure 7. Comparisons between simulated seismic intensities and actual ones announced by CWB.

To establish a rapid seismic risk assessment system, the rapid estimation of expected damage of a structure under a specific earthquake event is crucial. The estimation can be accomplished by using the modified seismic evaluation method proposed (Sung, Y.C. et al. 2009.). However, due to the uncertainty in earthquake ground motion, and randomness of structure and soil properties, the estimation of expected damage is a probabilistic one. Figure 8 shows the estimated probabilities of different damage levels can be obtained immediately after an earthquake occurs as the PGA for each bridge site is known.

The fourth fundamental element of a good seismic risk assessment system for the existing bridges is a visualized operation system. It receives the input and command from the users while providing a window interface to present the results of the input values. The process management package is made up of some software components that includes an interface, window for the main program, data management components and file management components. Figure 9 shows the output the system displayed.

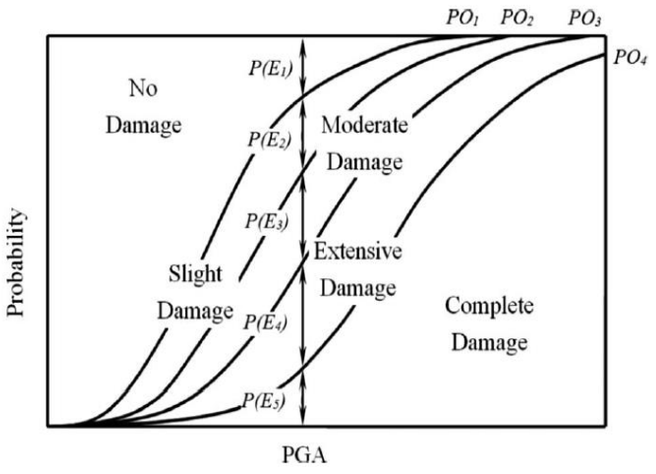

Figure 8. Fragility curves

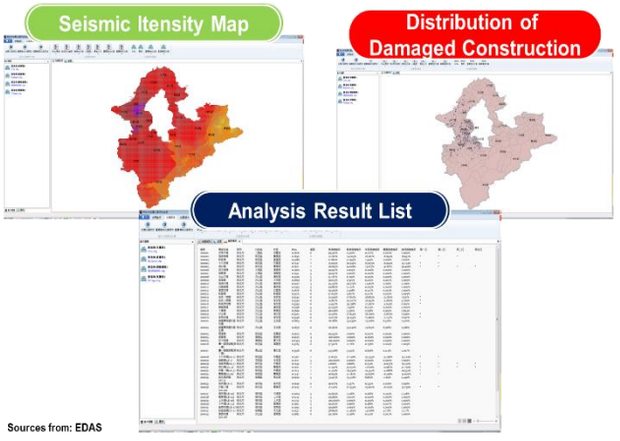

Figure 9. Output result of the seismic risk assessment

3.2 *Metadata technology application*

"Metadata" is a novel information technology which is applied and integrated with bridge inspection record photos on-site in the developing system of this study. The meaning of the terminology "Metadata" is data or information that provides information about other data, which puts the external field and inside office work of bridge inspection projects can be easily integrated with the high efficient division of labor by using such technologies.

Recently, the metadata has been extensively used to describe various data. For data of any type, metadata is the description of that data. To describe a digital photo with metadata often includes the brand of the camera creating this photo, exposure information (e.g., shutter speed), and descriptive keywords that could help one search this photo on a computer or the internet.

Metadata can be written outside or into a digital photo file. This study chose to write useful metadata into photos to facilitate the management of inspection photos whose number could be enormous. While a photo could contain all the required inspection results, all the inspection data we must manage is photos, no others. The management of inspection data becomes simple. Moreover, this choice of writing metadata into photos brings us the following advantages on bridge inspection.

First, users may classify, organize, or evaluate the metadata-embedded photos according to the preliminary inspection results contained in their metadata. In particular, the metadata embedded into a photo can be used to describe different deterioration patterns of a bridge part where the photo is taken. While capable of containing descriptive data, a photo could suffice to offer all inspection results without omission by itself. On the other hand, if metadata is enabled to describe cracks with geometric objects like points or polylines to record the crack distribution, such crack data may be depicted as a GIS (Geographic Information System) layer. Then this layer can be overlaid on or remove from the photo taken on the bridge part where those cracks are found (See Figure 10).

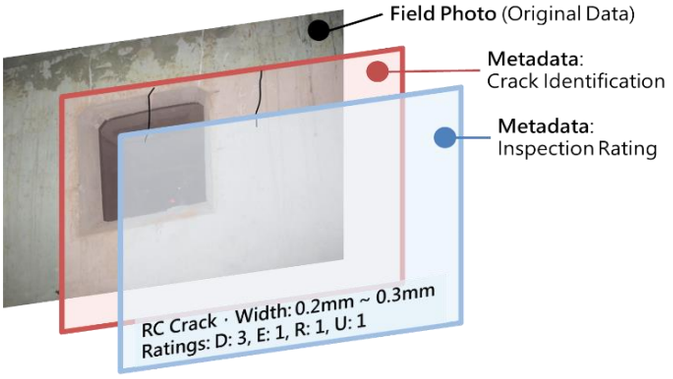

Figure 10. Depict metadata as GIS layers and overlay them on a photo

Operation Tool (OT), External Operation Tool (EOT), and Internal Operation Tool (IOT). The developed BMS offers Cloud Operation Tool (COT), a web application that helps the user upload inspection photos and then edit the metadata of those photos through its web interface. EOT is a mobile application (APP) that helps users write metadata into inspection photos on-site. Then they may upload these photos from their mobile devices to the developed BMS, or move these photos to their computers, then further process these photos using IOT shown in Figure 11.

IOT is a windows application that extends the functionalities of Windows Explorer. Working silently under Windows Explorer, this application identifies the inspection photos containing metadata, interprets and shows their metadata, and offers user interfaces for users to edit the metadata of a photo, upload photos, and even create reports that are supposed to use inspection photos.

Figure 12 shows that in addition to reading the metadata of photos, IOT can make the metadata as a grouping option for users to classify those photos in Windows Explorer. We can see three groups RP7, RP8, and RP12 there. Besides, Windows Explorer identifies each photo containing our metadata by sticking a graphical tag (an arrow-inside cloud) on the lower-left corner of that photo.

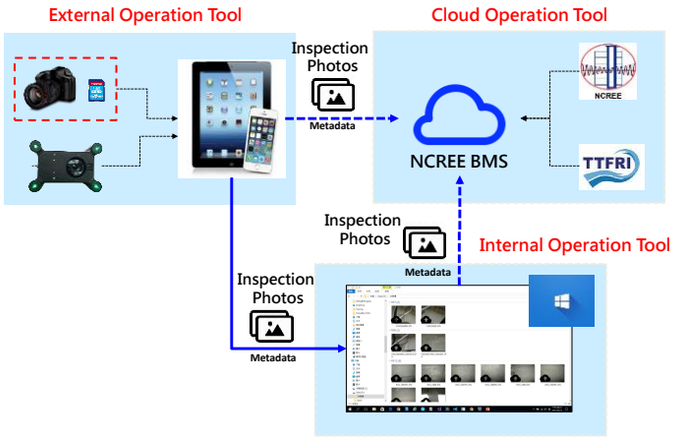

Figure 11. External, internal, and cloud operation tools to write metadata into inspection

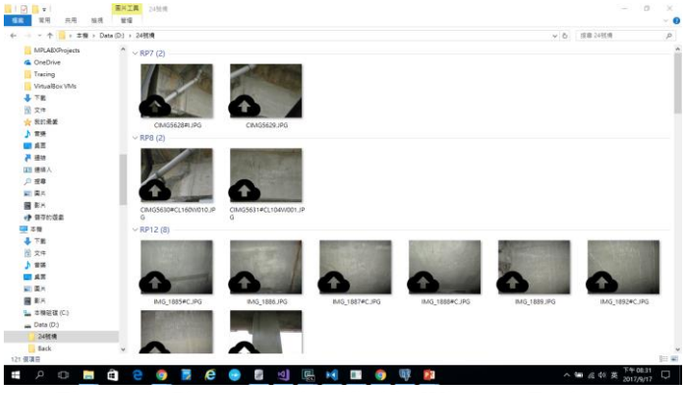

Figure 12. Photos are classified in Windows Explorer according to their metadata

In Figure 13, Windows Explorer shows the inspection results of photos including Ds, Es, Rs, and Us as well as those photos' the bridge names and element IDs. Figure 14 shows that IOT enables users to preview and edit a photo containing our metadata through a dialog that this tool offers in Windows Explorer. Figure 15 shows that we can select photos that containing our metadata of inspection and upload them at a time. It is worth to note that except for the uploading operation, all operations of IOT may be carried out off-line. While the user interface of a desktop application is often considered easier, smoother, and more efficient to operate than that of a web application, enabling users to conduct most of their work off-line makes IOT more effective than COT.

4 CONCLUSION AND REMARKS

In this paper, the developed framework of a life-cycle based bridge management system for bridge inspection and evaluation is introduced. One of the primary purposes of the developed BMS is to enhance the efficiency and the quality of bridge inspection work, to evaluate the capacity of bridge disaster resilience and to improve the exactitude of bridge information with code consistent result. The developed system provides the functionality of evaluating the time-variant structural capacity for bridge management and disaster prevention.

Two significant features of the system including seismic risk assessment and metadata benefit data mining of inspection and evaluation, the decision making on necessary maintenance efforts for seismic loss estimation and long-term problem of the deteriorated bridge. It is excepted that the achievements in this study could be helpful for disaster mitigation strategy in the future.

ABSTRACT: This work deals with the identification of modal frequencies for an existing footbridge through an *output only* technique. The structure has a continuous curved girder and belongs to a frequently used structural system all around the world in urbanized areas. Consequently, the development of a suitable and effective monitoring is of paramount importance for guaranteeing continuous serviceability and safety. Long-gauge fiber optic strain sensors are installed along entire structure, including locations where local damages, or deteriorations, are expected. Besides, a wireless network monitoring system is under development to be applied in parallel to fiber optic one for a comprehensive assessment of the stiffer component (the main-span) of the bridge where only minor strains are registered by the fiber optic sensors.

1 INTRODUCTION

Structural condition and safety can be attained through structural health monitoring (SHM) activities. Frequently, they consist in the analysis of the structural response that consists in recorded variables (e.g. time histories) processed by numerical methods. SHM is declined in four main phases, from the damage assessment to the prediction of the structural remaining life. The intermediate phases are the localization and the quantification of damage.

SHM can be also associated to resilience for bridge structures to prepare for and adapt to incremental changes or damages. In particular, the time required to recover after a damaging event the original performance is the critical aspect to be investigated. Therefore, the capacity to assess damage presence, localization and intensity has occurred is obviously essential for developing resilient structures and communities.

A recently proposed technique, termed as *output-only*, employs the use of structural response variables for the assessment of the structural conditions. It means that the knowledge of the input forces in terms of intensity, distribution and time histories is not required. This inherent simplification is particularly attracting owing to the wide range of applicability. E.g. when operating without interrupting transportation networks is needed (Domaneschi et al. 2013, 2015, 2016, 2017; Sigurdardottir & Glišić 2015).

Despite the number of SHM methodologies and implementations, as the extensive literature in the field demonstrates, engineers and contractors rarely employ SHM on the structures they are designing and building. Indeed, also the most effective SHM methodologies are usually restricted to specific conditions (type of structure, loading conditions, etc). Such limitations could be overcome integrating different SHM schemes in a single solution so as to cover wider conditions. Furthermore, education in SHM could be developed in a wider sense including it within the most common university courses.

This paper deals with the assessment of the modal characteristics of the Streicker Bridge at the Princeton University Campus through an output-only method. The response data in terms of longitudinal strains and curvature are used. The monitoring system consists in a fiber optic sensor network embedded in the footbridge concrete elements. It is strain-monitoring oriented, and its configuration cannot be changed. The results are compared to previous outcomes from literature and restrictions in the performance of fiber optic monitoring systems are confirmed on the mid-span of the footbridge. It is justified by the high stiffness that characterizes the central element of the structure, developing strains of minor intensity.

To overcome such limits a network monitoring system is proposed. It consists in a number of wireless sensors that can perform within a network, by bridging the signals from one sensor to the next one, or being connected to a single wireless router. The proposed network system is dynamic-monitoring oriented, and it has a flexible application on different scenarios and geometrical arrangements on the structure.

The dynamic wireless sensors network and the embedded fiber optic system are complementary in nature and combined they can provide a wide range of information.

2 THE STRUCTURE

The Streicker footbridge was completed in 2010 at the Princeton University Campus overpassing Washington Road (Figure 1). It is 104 m long and consists in a central main-span supported by a steel arch and four lateral approaching legs. The deck is a post-tensioned high-performance concrete girder. Steel columns with "Y" shape support the lateral legs. More details on the structure can be found in (Sigurdardottir & Glišić 2015).

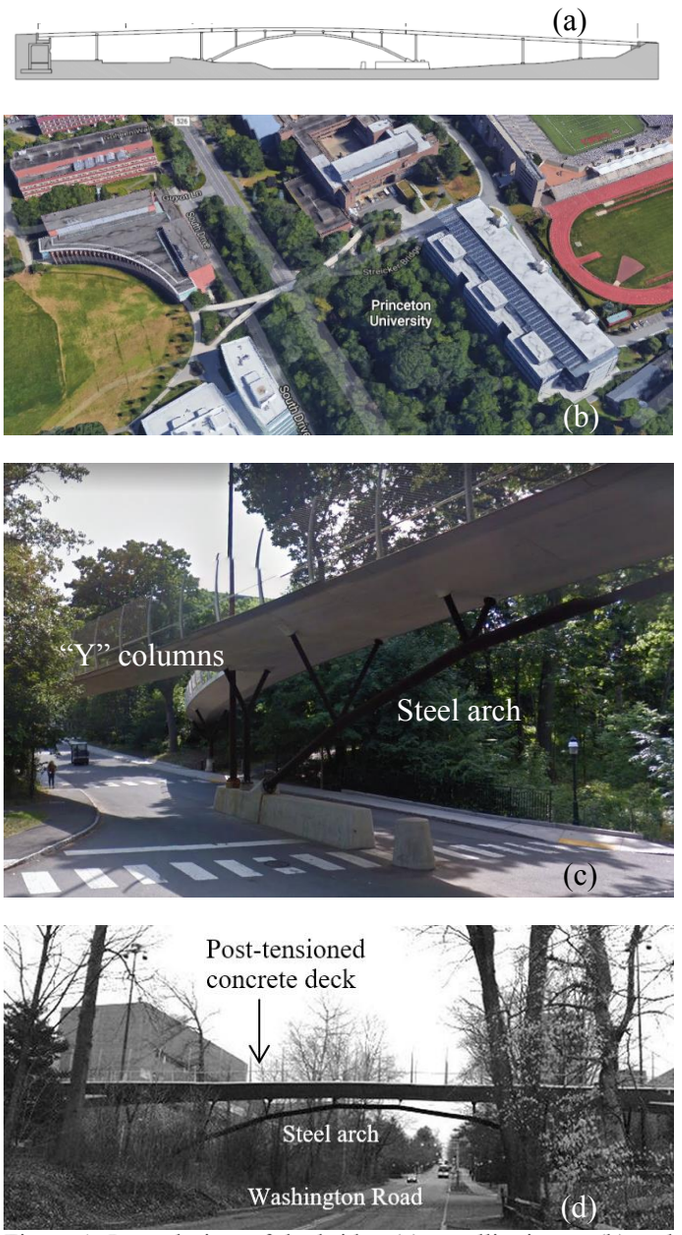

Figure 1. Lateral view of the bridge (a), satellite image (b) and detail of the supporting system (cd).

The four legs connect the bridge to the lateral bearings on the ground and the whole system results a slender varying cross section main girder. The original shape in the horizontal plane provides horizontal stability to the footbridge despite the intrinsic slenderness of the steel supporting columns. Vertical stability is provided also by the arch (Figure 1) in the central main-span and by the supporting columns under the legs. Cross section width increases from the midpoint of the main-span to the connections with the legs and then remains constant up to the ground bearings. The max deck depth is 0.6 m while the cross section diameter of the arch is 0.32 m.

3 THE STRAIN-MONITORING SYSTEM

Several SHM activities as detection of local damages and assessment of the dynamic characteristics of structures can be effectively performed by the use of long-gauge strain sensors. Among the others, fiber-optic sensors show a very high sensitivity and extend the monitored frequency range. Moreover, they have the advantage to allow implementations in aggressive environments where they have been proved unaffected by external perturbations (corrosion, electromagnetic interference, etc.).

The Streicker Bridge has been equipped with fiber optic sensors with the double aim of providing the structure of an effective monitoring system and also of profiting the University of an on-site laboratory for research and education on SHM. Both the purposes reflect the innovative visions of intelligent infrastructure and of dynamic educational facility.

Since the footbridge shows a fairly symmetric geometry, half of the main-span and the longest South-East leg only are equipped with the fiber optic sensors.

During the bridge construction, the sensors were embedded in the concrete deck using two different technologies. The first one is based on discrete fiber Bragg-grating (FBG) long-gauge strain and temperature sensors and the second one on distributed sensing employing Brillouin optical time domain analysis (BOTDA) for integrity monitoring. In the dynamic assessment of the present study only the first one is considered.

Discrete strain sensors can be classified as short- and long-gauge sensors with a length that spans e.g. from 0.01-0.1 m to 0.25–10 m respectively. The choice depends mainly by the material where they are embedded. For homogenous materials short ones can be suitable, instead for inhomogeneous materials long-gauge sensors give more benefits. Indeed, in the last case, long-gauge sensors allows to overcome local defects that introduce discontinuities in the mechanical material properties and consequently in the provided information concerning the local strain value.

The longitudinal strain in the bridge girder is the monitored parameter, while the derived one is the curvature (Domaneschi et al. 2017). This last is derived through parallel fiber optic sensors, one at the top and the other one at the bottom of the concrete deck cross section. Longitudinal strains are recorded

continuously with 250 Hz sampling frequency. The expected error in frequency is ± 0.06 Hz. In Sigurdardottir & Glišić (2015) additional details can be found.

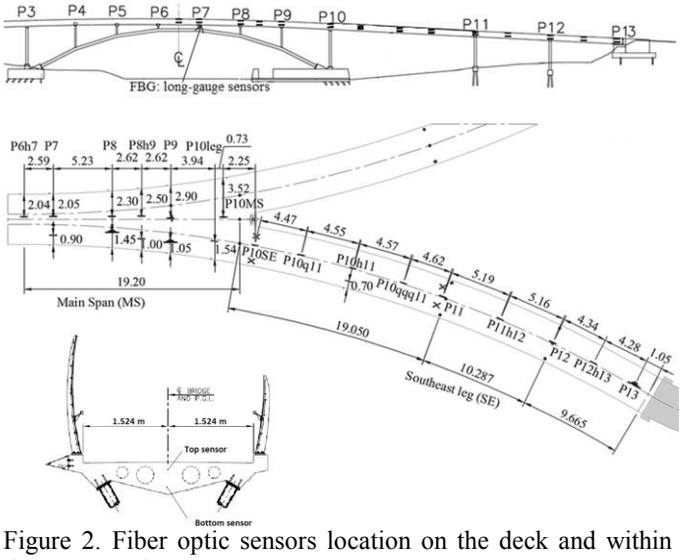

Figure 2. Fiber optic sensors location on the deck and within the cross section.

Figure 2 gives some details on the discrete sensors distribution on the bridge deck. Different topologies of the long-gauge FBG sensors are installed. The parallel one is only considered in this work and it consists of two FBG sensors parallel to the longitudinal axis of the deck aligned on the vertical symmetry axis. One sensor at the top and one at the bottom of the cross section. Parallel sensors capture axial strains in the cross section due to the internal normal force and bending moment. Bending moment in particular generates the girder curvature in the vertical plane. No significant shear or torsion forces are expected. Every long-gauge FBG sensor is temperature compensated (Sigurdardottir & Glišić 2015).

Bending moment M can be computed from curvature χ trough the strain data (ε_{top} , ε_{bottom}) and the structural characteristics (E, I respectively Young and inertia moduli).

$$\chi = (\varepsilon_{bottom} - \varepsilon_{top})/h \quad (1)$$

$$M = \chi EI \quad (2)$$

with h the vertical distance between the parallel sensors.

The monitoring system is distributed on the footbridge main-span on seven segments between columns P3–P10 (see Figure 2). Parallel sensors are at columns P7, P8, P9, and P10 and at two mid-spans between P6 and P7 (P6h7) and P8 and P9 4(P8h9). The South-East leg (three spans) is fixed to the main-span at one end and simply supported on the ground at the other end. The gauge length for the parallel sensors is fixed to 0.60 m.

4 LITERATURE REVIEW ON THE FOOTBRIDGE

The footbridge has been extensively tested in several experimental campaigns. Furthermore finite element (FE) simulations have been also performed with simple plane beam models. Therefore, literature data are available for comparison. In particular, the natural frequencies of the structure resulting from the experimental analyses are 3.11 Hz and 3.72 Hz. On the other hand, the natural frequencies evaluated using the FEM model were equal to 3.21 Hz and 3.77 Hz (Sigurdardottir & Glišić 2015). Vibration monitoring using a wireless MEMS accelerometer board is also reported in literature (Sabato 2015) and the modal frequencies are consistent with previous researches (3.08 Hz and 3.75 Hz). Records from 2010 tests – main-span.

The existing results from literature have been collected by employing specifically designed solicitation tests and quasi-static tests with heavy vehicles, group of pedestrians walking at specific frequencies or running peoples.

5 RESULTS

Two set of data are currently available for analysis, they were collected in 2010 and 2014. For both recorded sets of signals the input is unknown. The strains time histories from the parallel sensors are computed for obtaining the dynamic curvature in Equation (1) and the modal properties of the footbridge. It has been verified that curvature instead of strain vectors allows to halve the number of vectors to process without losing information (Domaneschi et al, 2017).

Collected curvature data have been processed in the frequency domain by computing power spectral density (PSD) through the *periodogram* function. The PSD of a stationary random process is, by definition, a real symmetric function mathematically related to the autocorrelation sequence by the discrete-time Fourier transform. The *periodogram* is an estimate of the PSD of a wide-sense stationary (weakly-stationary) random process, such as a finite-length segments of a signal.

5.1 *2010 tests – main-span*

All 2010 tests are performed on the main-span that resulted very stiff. So, a significantly low strain response from the embedded sensors results. Figure 3 reports a sample of records from sensors P6h7, P7 and P8. Perturbation or characteristic frequency contents cannot be identified.

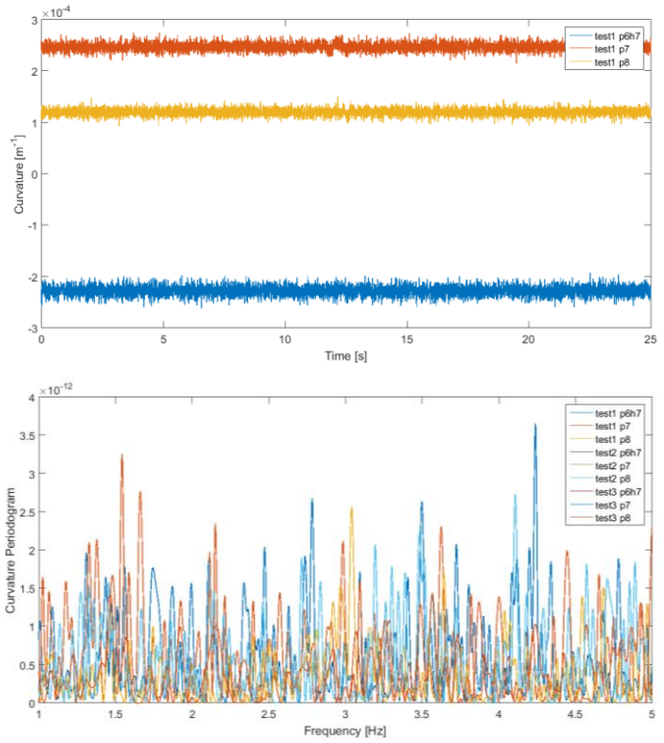

Figure 3. Sample of records (termed as set08 in the database, test 1-3) from sensors P6h7, P7 and P8.

5.2 *2014 tests – South-East leg*

Tests from 2014 are performed for extracting the legs characteristics. Thanks to the symmetry of the footbridge, the South-East leg of the bridge only is evaluated. The loading conditions are unknown but consist, as for 2010 tests, in pedestrians (groups of Campus students) that are walking and running randomly on the bridge at unknown frequencies.

Some additional explanations for explaining the acronyms for different sensors are the following ones: "P"=pier, Numbers=location of piers, "h"=halfway between sensors. So, P6h7 would stand for half way between pier 6 and pier 7, P10qqq11 for the 3rd quarter span (3/4th span) between pier 10 and pier 11, P10q11 for the 1st quarter span between pier 10 and pier 11. While, P7 means the sensors are located directly at pier 7.

Figure 4 depicts the processed results from the set termed as *DynamicPeaks1* in the database in both the time and the frequency domain. Some issues with the sensor system at P7 and P6h7 occur and data for those sensors are not available.

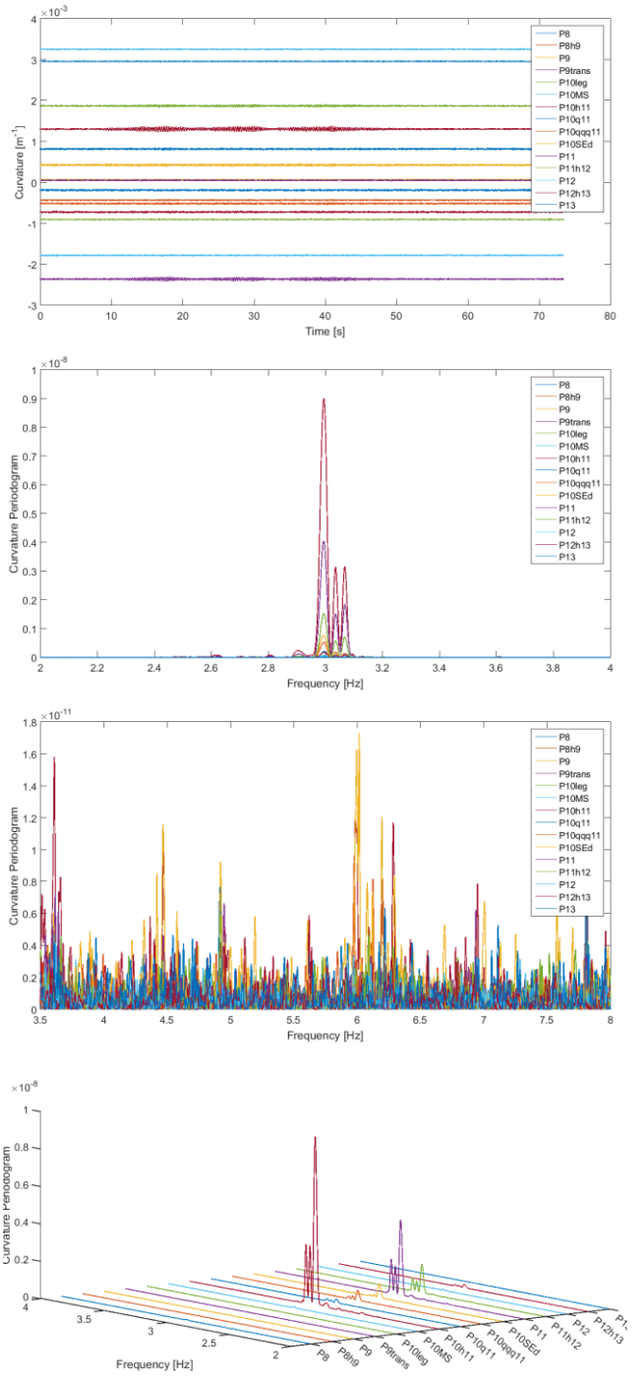

Figure 4. Processed results from the set termed as *DynamicPeaks1* in the database.

Figures from 5 to 10 reports the results in the frequency domain only for all the remaining data sets from 2014 tests. Figure 6 depicts also an overview of the time history records for *DynamicPeaks1* data set. The sensors between P10-P12 are characterized by the highest intensity responses.

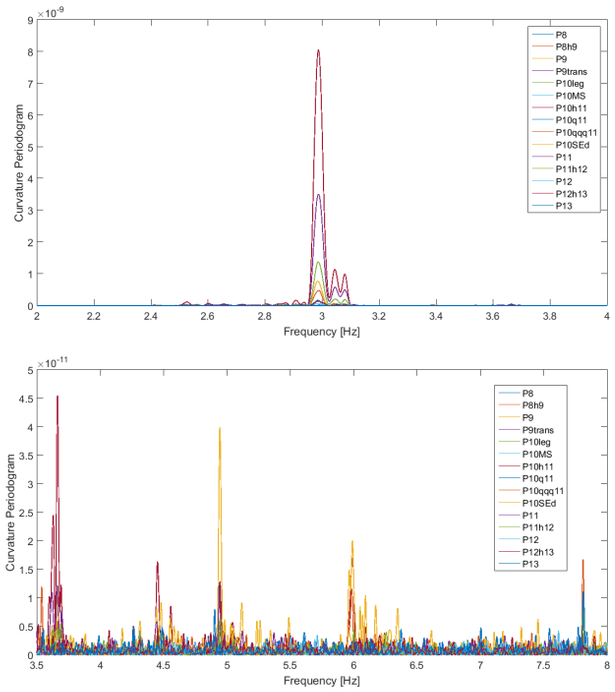

Figure 5. Processed results from the set termed as *DynamicPeaks2* in the database.

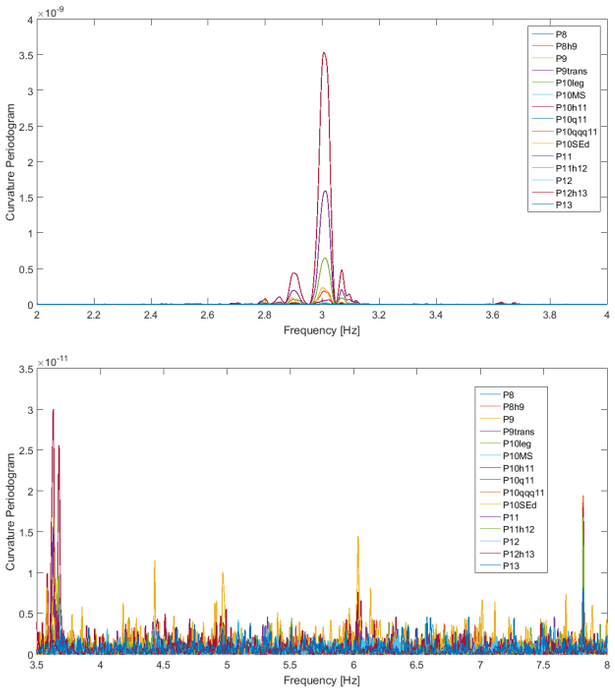

Figure 6. Processed results from the set termed as *DynamicPeaks3* in the database.

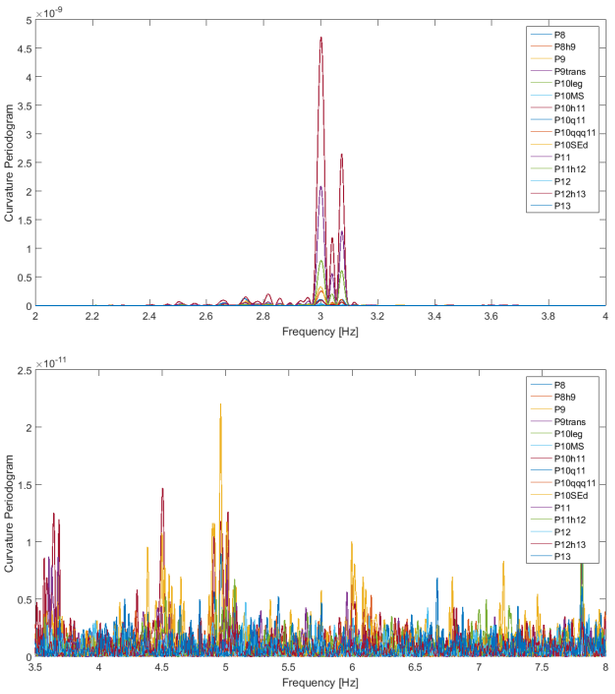

Figure 7. Processed results from the set termed as *DynamicPeaks4* in the database.

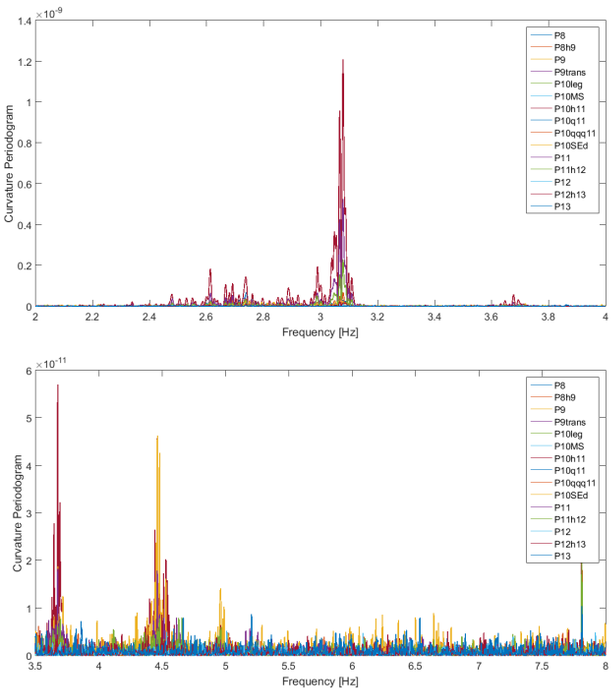

Figure 8. Processed results from the set termed as *RunningPeaks* in the database.

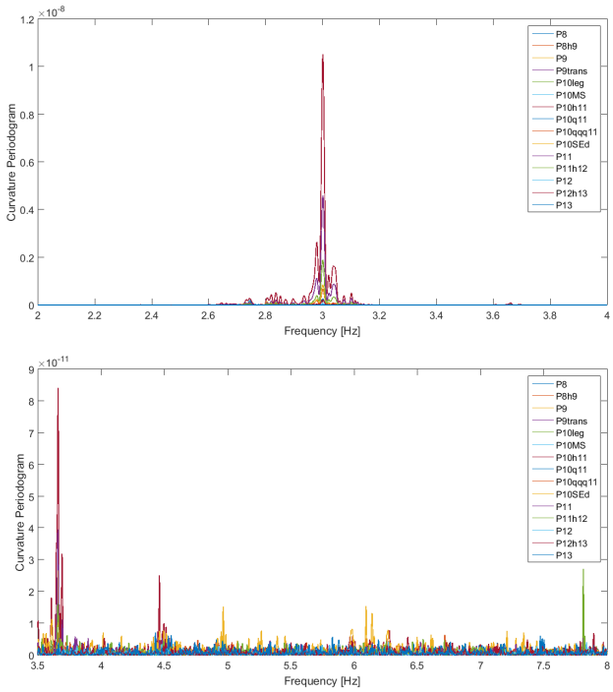

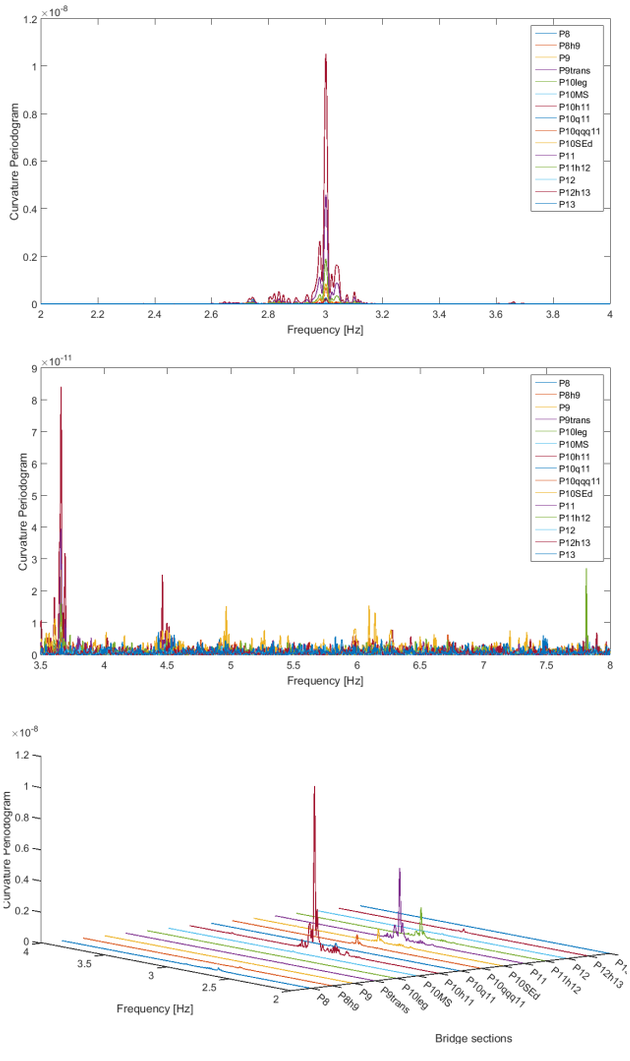

Figure 9. Processed results from the set termed as *DynamicPeaks41* in the database.

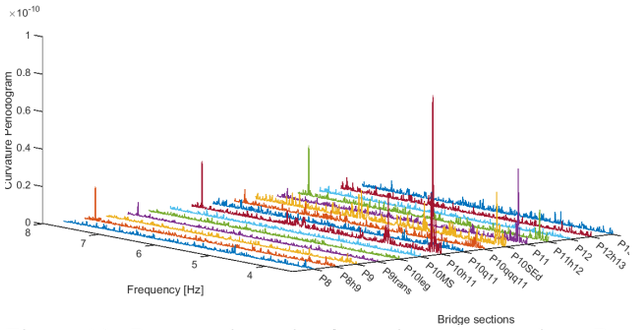

Figure 10. Processed results from the set termed as *DynamicPeaks42* in the database.

Table 1. Natural frequencies from 2014 tests (*DP=DynamicPeaks*, *RP=RunningPeaks*).

Signal	f_1[Hz]	f_2[Hz]	f_3[Hz]	f_4[Hz]	f_5[Hz]	f_6[Hz]
DP1	2.94	3.61	4.47	4.92	6.01	7.81
DP2	2.98	3.66	4.45	4.94	5.99	7.81
DP3	3.00	3.63	4.43	4.96	6.03	7.81
DP4	3.00	3.64	4.50	4.96	5.99	7.81
DP41	3.00	3.66	4.46	4.96	6.09	7.80
DP42	2.99	3.68	4.42	4.94	-	7.81
RP	3.08	3.67	4.46	4.96	-	7.81

From these results, the first amplification peak in the frequency domain is determined to be approximately 3 Hz for all of the experimental tests. This is a lower value with respect to those from literature in Table 1. Also, the second peak has lower values (approximately 3.6 Hz). The available results in the range [3.5 Hz, 8 Hz] highlight a third peak around 4.4 Hz, a fourth at 4.9, a fifth one at 6 Hz and last one at 7.8 Hz. Table 1 summarizes the results of the analyses from 2014 tests on the South-East leg of the footbridge for each recorded signal.

Owing to the location and topology of the embedded sensors, the recognized natural frequencies are reasonably associated to vertical flexural natural modes. Furthermore, comparable highlighted intensities in all data sets and the redundancy in the frequency values allow considering these outcomes accurate with satisfactory confidence.

The damping ratio of the first mode associated to 3 Hz natural frequency can be estimated by the applying the logarithmic decay formula at the sensor P10h11 and it is evaluated as 0.57%. This value, not reported by other research works in literature on the same footbridge, is compatible with others of similar slender structures (Shahabpoor et al., 2017; Van Nimmen et al, 2017).

6 THE PROPOSED DYNAMIC-MONITORING SYSTEM

A wireless monitoring system has been developed in parallel to the existing fiber optic elements to overcome the difficulties of the modal parameters identification on the main-span of the footbridge. Indeed,

the embedded strain sensors have registered only minor strains. The proposed solution comprises a wireless sensors network (WSN) for collecting inertial measurements. In detail, the network consists of 14 units, all synchronized together. Each unit is equipped with a three-axis accelerometer, a three-axis gyroscope, a magnetometer and a temperature sensor. The characteristics of each sensor in the sensing unit are detailed as follow:

- Ultralow noise density accelerometer ([20μg/√Hz]), range ±2/4/8g, resolution ≈4μg, 200 μA in measurement mode, drift 0.15 mg/°C.
- Low noise density gyroscope ([0.01deg/s/√Hz]), sensitivity scale factor 131 LSB/deg/s, full scale range 250 deg/s.
- The temperature sensor, resolution 0.25°, overall operating range [-40°,+125°], ultra-low power consumption 125nA@1Hz sample rate.
- Compass, sensitivity scale factor 0.6μT/LSB, full scale range ±4800μT.

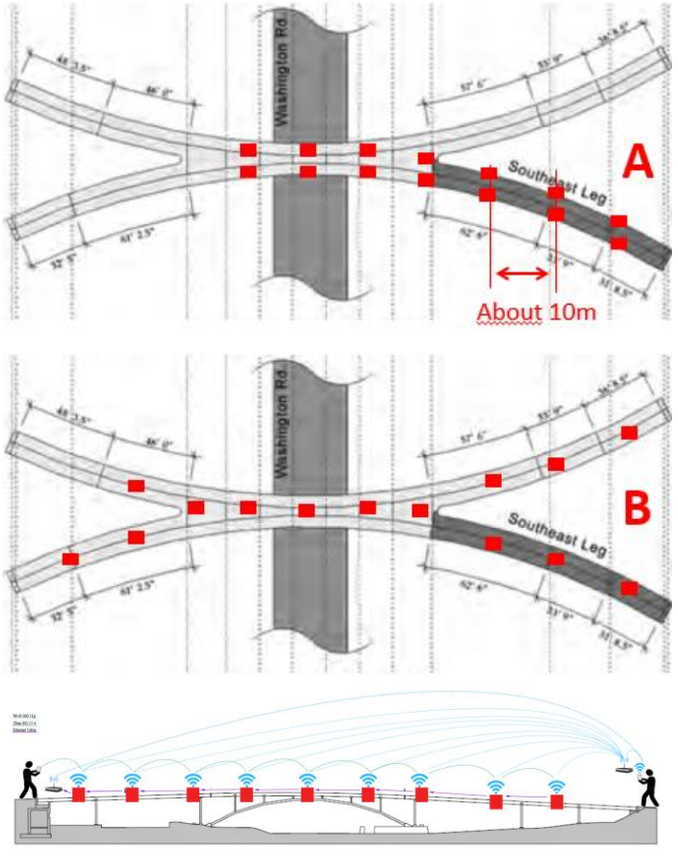

Figure 11. Proposed units distribution on the Streicker Bridge at the Princeton University Campus and the sensor network in different configurations.

The data are processed in real time through a custom architecture on an FPGA (Field Programmable Gate Array) and saved locally in a memory. Furthermore, they can be sent to the main control unit using the on-board Fiber Optics transceiver (up to 200km), over the air using Wi-Fi (IEEE802.11g) or ZigBee (IEEE802.15.4) standard.

The proposed WSN sets a new benchmark for inertial sensor performance with a power consumption for each unity of about 400μA, while the accelerometer noise performance is 11% better, gyro noise performance is 3% better and compass full scale range is over 4% better than competitive sensors.

The 14 units network can be arranged in different configurations on the bridge for confirming the outcomes from the fiber optic solution on the South-East leg and for collecting new information on the stiffer central span. In particular, Figure 11 reports two proposed units' distribution on the deck (A and B) and the WSN communication scheme. The first (A) evaluates the torsional modal components of the main-span and South-East leg through both the gyroscope records and two opposite vertical accelerations on the cross section. The evaluation of the complete structure is then performed through the second distribution (B), where the entire footbridge is covered by the WSN.

7 CONCLUSIONS

In this work, the modal characteristics of an existing footbridge on the Princeton University Campus in US are investigated. The investigation uses measurements collected by long-gauge fiber optic strain sensors embedded along the entire structure. Unknown pedestrian loading represents the external excitation. Therefore, the research can be ascribed within the *output-only* monitoring procedures.

The analysis firstly consider the time histories and the power spectral density of the distributed long-gauge dynamic curvature. For the South-East leg the dynamic characteristics are satisfactorily extracted and the damping ratio associated to the first identified mode is also computed. Comparison with literature results confirms the outcomes, even if slightly lower frequency values were noted. On the main-span, due to its high stiffness, the fiber optic sensors register only minor strains and characteristic modal properties cannot be identified.

In order to overcome such limitations, a wireless sensors network is proposed to integrate the embedded fiber optic system to provide a wide range of information.

The present investigation represents a first step toward the integration of the existing fiber optic system with a new wireless sensor network.

Effectiveness damage characterization for different sensor settings: full scale case

J. Grandón
Lind Engineering, Chile

F. Cerda
Universidad de Concepción, Chile

ABSTRACT: Structural health monitoring aims at reducing and control risks associated to different damages levels in diverse structures, through the implementation of sensors and a signal processing and analysis. This work develops a methodology based on the modal analysis for estimate the number of sensors necessary to characterize a determined structural damage level in a specific bridge.

1 INTRODUCTION

1.1 *Work description*

This work uses an acceleration register from a forced vibration test of the Z 24 bridge, located in Switzerland, where different damage scenario were inflicted by progressive settlement levels in one pier of the bridge. Then, modal parameters are extracted by means of the frequency domain decomposition algorithm (FDD) and is applied to different damage identification and localization methodologies. Specifically, two methods for damage identification (modal frequencies and modal assurance criteria) and three for damage localization (Yuen function, modal shape curvature and coordinate modal assurance criteria). Finally, through a statistic criteria (Fisher information matrix optimization) different optimized sensor settings are obtained for this bridge, then an evaluation of the damage characterization effectiveness level is done by a function through a regression from an error function and the number of sensors to use is determined.

2 STUDY CASE AND FIELD EXPERIMENT

2.1 *Z-24 Bridge Switzerland*

The Z24 is a prestressed concrete bridge, with three sections, two lanes and a distance between abutments of 63.4 m. It is located in Canton Bern, Switzerland, and connects the towns of Koppigen and Utzenstorf.

In the structure, 17 accelerometers were arranged simultaneously (15 in the slab and two in the intervened stock) plus three used as reference points or PR that are fixed at all times.

The 17 accelerometers were grouped on the axes HH-1, HH-2, HH-3, in nine zones along the bridge called setups. Each setup has five accelerometers per axis and two more located in the strain.

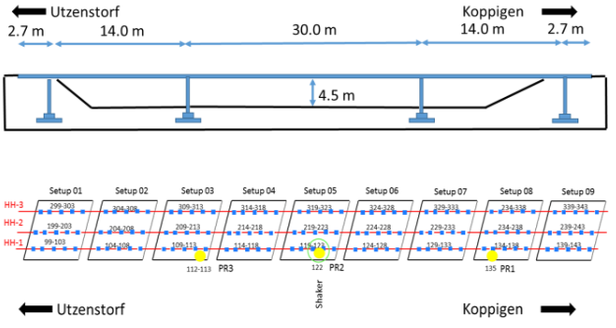

Figure 1. Z-24 Bridge

2.2 *Field test: forced vibration test*

The study case considered to generate different settlement conditions in the bridge on a real scale. Through an hydraulic system, damage scenarios were generated associated with different levels of progressive settlement (Kramer, Smet and de Roeck 2001).

The settlement was simulated by cutting the pier of the Koppigen area (axis 3). The dimensions of the three cuts are 0.4 m high, 1.1 m wide and 0.3 m thick.

The forced vibration test (FVT) used two sources of dynamic excitation capable of generating vibrations in different frequency bands. A large one located in the center, specifically at the reference point 2 (PR2) and a small one located at reference point 1 (PR1) to induce an excitation in the bridge in a cer-

tain frequency band, the excitation of both shakers ranged from 3 to 30 Hz.

The data collection at a rate of 100 Hz for 35 channels, was performed eight times (one for each damage condition) obtaining 8192 samples (Kramer, Smet and de Roeck 2001).

Table 1. Damage scenarios

Case	Date	Scenario
1	4/8/1998	First reference measurement
2	9/8/1998	Second reference measurement
3	10/8/1998	Settlement of 20 mm
4	12/8/1998	40 mm settlement
5	17/8/1998	80 mm settlement
6	18/8/1998	95 mm settlement
7	19/8/1998	Pier Inclination
8	20/8/1998	Third reference measure

3 THEORETICAL FRAMEWORK AND PROCEDURE

3.1 *Obtaining mode shapes: FDD*

The frequency domain decomposition (FDD) is a technique that allows modal parameters to be obtained without having knowledge of the input that affects the system. This technique is relatively similar to the classic approach where the modal parameters are estimated by simple peak picking. However, by decomposing the matrix of the spectral density function, the response spectrum can be separated into a set of systems of a degree of freedom, each corresponding to an individual mode.

With this decomposition technique, nearby modes can be identified with high accuracy even in the case of strong noise that contaminates the signal, and also the harmonic components of the response signal can be identified (Brinker et al., 2000).

3.2 *Damage identification: MAC*

The modal assurance criteria (MAC) is used as a measure to determine the level of correlation between the modes coming from the tests of a space without damage with a damaged space (Allemang y Brown, 1982).

3.3 *Damage localization: COMAC*

The coordinate modal assurance criteria (COMAC) is similar to the modal assurance criteria. The main difference is that this is a coordinate-by-coordinate comparison, so it delivers a vector of values that are associated to distances in the plane.

3.4 *Damage localization: Yuen Function*

The Yuen function provides another measure to quantify changes in a modal form. This function is defined on the length of a beam as a structure and is constructed from the mode vectors and the values of the modal frequencies of the system with and without damage.

3.5 *Damage localization: Modal Shape Curvature*

Another way to obtain spatial information of the damage in structures that work mainly to flexion is by calculating the derivatives of the modal forms. The derivative process has the effect of amplifying any discontinuity in the modal form caused by localized damage, which results in changes in the curvature of the element.

For a beam in which its modal forms can be approximated by measurements of discrete points equally spaced at a distance h over its length, the curvature of the modal form can be calculated using a central difference approach to the second derivative (Pandey y Biswas, 1991).

3.6 *Optimal positioning of sensors maximizing the Fisher information matrix.*

The maximization of the Fisher information matrix or covariance matrix is a criterion currently used in the SHM to position sensors along a given geometry (Meo and Zumpano, 2005) with the choice of strategic points that allow get as much information as possible from the dynamic response of the structure to achieve a modal recreation.

3.7 *COMEF*

The error matrix from the coordinate error function (COMEF), is used to determine the variation between an initial vector of reference ∅ ^ 1 vs the same eigenvector in an unknown time ∅ ^ 2.

The values of the normal vectors obtained from the modal reconstruction were used to verify the effectiveness in the configuration of sensors.

3.8 *Methodology*

To determine the degree of effectiveness or representativeness in the characterization of damage for different sensor configurations, the following procedure was carried out:

a) Modal shapes and frequencies were obtained.
b) Empirical normalization was applied.
c) Two criteria were applied for the identification of damage (modal frequencies and MAC) and three damage location criteria (the Yuen function, the modal curvature criterion and the COMAC).

d) Different configurations of sensors were estimated in order to characterize the damage by means of the Fisher information matrix maximization method, evaluating the level of effectiveness of this characterization through the COMEF error matrix.

This work used z axis data for obtain modal parameters. For that reason the modal forms obtained from that registers has vertical modes presents.

Using a basic finite element model, the basic vertical modes identified in this work are mode 1, 3 and 5. After that applying the FDD the vertical modes identified are same, 1, 3 and 5. So this work focus in these three modes.

In this work, we analyzed HH-1, HH2, and HH3-axes. The results from HH-3 axis were most accurate, most likely due to the influence of the excitation source for HH-1 and HH-2, all the results presented below correspond to those from this axis.

The data presented below in damage localization are for which the best results were obtained. In this case, all damage localization criterions show better results at mode 3.

4 RESULTS

4.1 *Modal shapes and frequencies*

The modal shapes obtained are presented below.

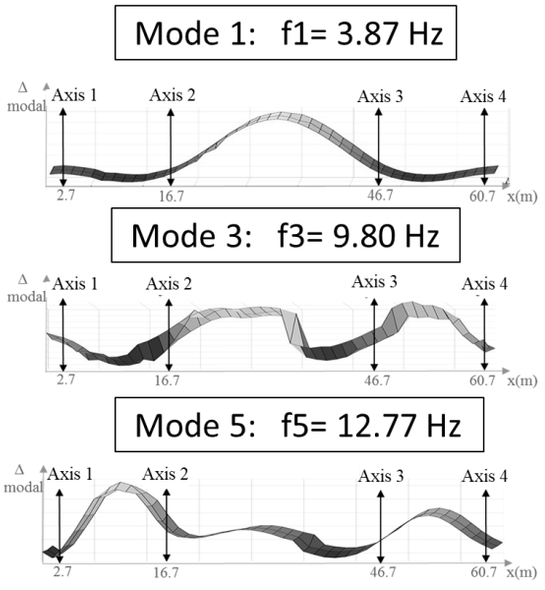

Figure 2. Modal forms

4.2 *Damage identification: frequencies*

From Figure 3, for the frequency of mode one, no considerable changes are observed throughout the different scenarios of measurement. This is a behavior is expected, since frequencies in low ranges are least affected by damage conditions.

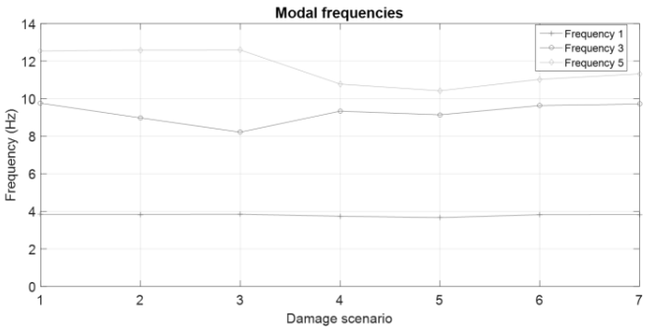

Figure 3. Modal frequencies

For the third natural frequency, there is a decrease from the scenario one (reference) to the scenario three (40 mm of settlement), which coincides with a progression of the damage on the bridge. In the scenario four, an increase in the frequency is observed, which is not expected as damage is increased, from a 40 mm settlement to 80 mm. For scenario five (90 mm of settlement), the frequency decreases again with respect to the previous scenario. For scenario six and seven (inclination of the pier and the third reference measurement) an increase in the value of the modal frequency was observed. The differences produced in scenario case number three and four are due to the fact that five days elapsed between one measurement and the other. So it could be possible the environmental conditions affected the system.

For the frequency of mode five, from the scenario one to three, it is not possible to see a clear reduction. For scenario four and five, a reduction in the value of the frequencies is observed. In scenarios six and seven a new increase of its value is observed. So it is not a consistent frequency decrease, as it would expect for the different damage increments.

4.3 *Damage identification: MAC*

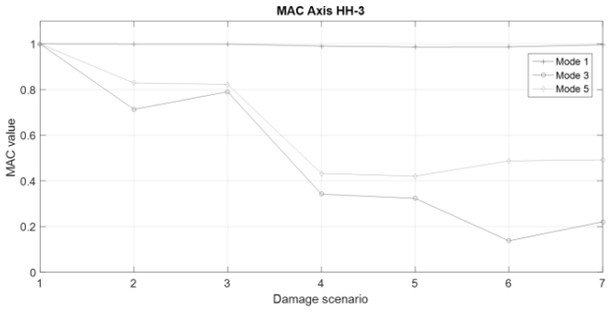

Figure 4. MAC values

From Figure 4, for mode one, it is observed that in all cases the MAC value is close to one. For mode three, there is a clear decrease trend in all cases where damage was simulated except for case number three. For mode five, a decreasing trend is observed except for case six, where there was a considerable approach to value one.

4.4 *Damage localization: COMAC*

The data presented below are for which the best results were obtained. In this case, all damage localization criterions show better results at mode 3.

The following Figure 5, 6 and 7 show the reference, undamaged mode shape on top, gray scale strips corresponding to the values obtained from the damage identification methodology, for each of the damage scenarios. At the bottom, there is a reference scheme of the bridge structure, to show the piers locations

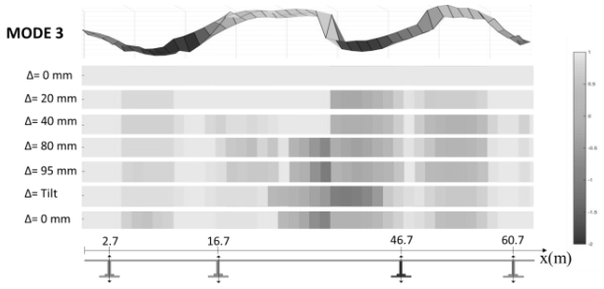

Figure 5. COMAC values

For scenario one (condition without damage, Δ = 0 mm) its length is light gray, since it is the base line for the modal comparison between the other states. For the condition of 20 mm of settlement small disturbances are evident around the second strain located in the area prior to 46.7 m and a small difference is observed for the area after 46.7 m. As the settlement conditions increase, the location of the damage and its magnitude also increase. For the inclination of the foundation, a considerable increase of the area after 46.7 m is observed. For the third reference measurement, it is observed that there is still damage, as the product of the different conditions previously imposed the bridge board suffered a cracking precisely in the areas where the COMAC indicated that there is damage.

4.5 *Damage localization: Yuen function*

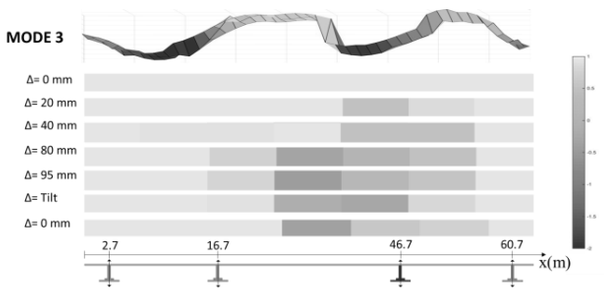

Figure 6. Yuen function values

There are two zones with damage, the largest in the area prior to 46.7 m and the other in the area after 46.7 m. However, in the area of 16.7 m and 2.7 m this criterion delivers damage, which does not agree with the documented.

4.6 *Damage localization: Modal Shape Curvature*

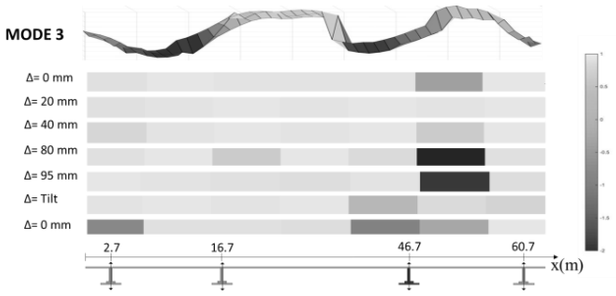

Figure 7. Modal Shape Curvature values

It is observed that it is not possible to detect a clear trend for all different cases.

4.7 *Sensor number and settings Fisher matrix*

Table 2 is presented with the different amounts of sensors used to obtain the different sensor configurations.

Table 2. Sensor number case

Case	Sensor Number
1	40
2	35
3	30
4	25
5	20
6	15
7	10
8	5

Figure 8 contains the different sensors settings for each case.

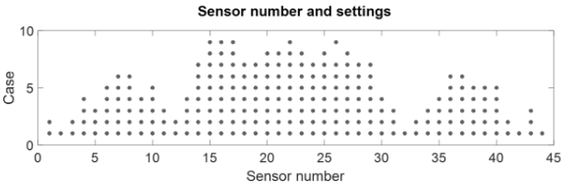

Figure 8. Sensor number and settings

It is observed that as the number of sensors decreases the trend indicates a high concentration in the center. That is interpreted as the need to have instrumented bridge areas that have greater span length.

4.8 *COMEF for different settings*

From Figure 9 and Figure 10 it is observed that as the number of sensors is greater, the error is smaller. Having an average error rate of 50% for the configu-

ration with 9 sensors, while an average error rate of 10% for the configuration with 30 sensors.

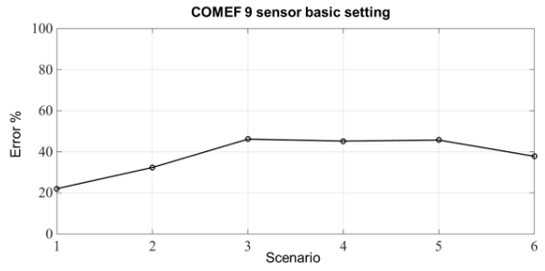

Figure 9. COMEF 9 sensor basic setting

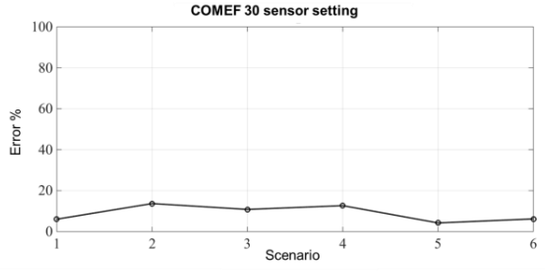

Figure 10. COMEF 30 sensor setting

4.9 *Damage characterization required level*

The previous results were stretched to obtain a relation between the desired damage characterization and the number of sensors to be used. For this purpose, the number of sensors used and the error percentage of the COMEF were compared, and an approximate function was obtained by means of a regression analysis.

The percentage of error of the COMEF is directly related to the level of representativeness or effectiveness in the characterization of the damage, which means, to a greater percentage of error, less number of sensors, therefore, a lower level of representativeness.

In the Figure 11it is presented the function that shows the level of effectiveness in the damage characterization. The function was calculated by means of an exponential adjustment with a confidence level of 95%, using three points to elaborate it.

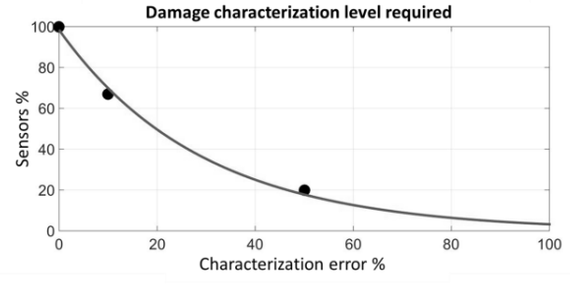

Figure 11. Damage characterization level required

It is observed that when passing the threshold of 10% of error (which is the one that was previously recommended) the percentage of error increases considerably, or in other words, the level of representativeness in the damage characterization decreases considerably.

It should be mentioned that product of the number of points that were used (three) the function resulting from the regression itself loses representativeness. However, the behavior of modal indicators is directly related to the number of sensors (as less quantity is available, less data volume is collected), corroborating the decreasing trend of the function that was obtained.

5 CONCLUSIONS

No positive results are obtained from damage detection techniques, since these criteria are too sensitive to environmental conditions and other variations that appear at the time of measurement.

The COMAC was the only damage location criterion that delivered the actual location of the damage along with its magnitude. The Yuen function and the modal curvature criterion did not give satisfactory results because, unlike COMAC, these two criteria come from mathematical approximations.

Product of the application of the location criteria it was observed that the damage suffered by a strain can be evidenced in the slab of the bridge, which is very useful considering that one of the main reasons of failure of the bridges in Chile has to do with scouring of the strains.

A valid function was determined, which allows entering as input the number of sensors to be used and delivering as output the level of representativeness in the damage characterization associated with that quantity, for this particular bridge.

The line of research in the future considers two points in particular:

1) The determination of a minimum number of sensors for this bridge, including economic, social aspects and also instrumentation.

2) Obtaining an instrumentation methodology to be applied in Chile, indicating the number of sensors needed for each specific bridge, minimum separation between them, position of the sensors with respect to the sources of excitation, choice of excitation source, etc.

Ambient vibration monitoring of a railway bridge for scour detection

C.W. Kim
Kyoto University, Kyoto, Japan
D. Kawabe, M. Kondo
West Japan Railway Company, Osaka, Japan

ABSTRACT: This study is intended to discuss a vibration-based scour monitoring of railway bridges under in-service condition. A long-term vibration monitoring was conducted on a railway bridge to investigate feasibility of the vibration-based scour monitoring in real-time. A high-precision three-axis wireless accelerometer was installed on the pier top to measure pier vibrations. Vibrations of bridge girders adjacent the observation pier were also monitored in order to clarify influences of bridge girder vibrations to pier vibrations. Both train-induced and ambient vibrations were investigated, and frequencies relevant to the pier were identified and adopted as a scour-sensitive feature. A Bayesian operational modal analysis in frequency domain was also applied to reduce the prediction error. Observations through this study showed that the pattern of the identified frequencies varied according to the water level as well as wind speed during the monitoring.

1 INTRODUCTION

The scour of railway bridges is one of the main causes of railway bridge failures during floods. How to provide a proper decision on the train operation control during heavy rain has been a keen technical issue for railway companies (Prendergast et al., 2013). West Japan Railway company operates more than 5000 km railways, for an example, and an improper decision to suspend operation due to floods leads to huge operating loss. The impact test on the bridge pier to identify changes in frequencies is a promising and conventional way of the scour detection (Abe *et al*. 2016). However, the impact test is a laborious and time-consuming method, and is inapplicable for the real time monitoring to make a proper decision on the train operation control during heavy rains. Therefore, the visual inspection during heavy rains has been adopted to make a decision for the operation control. An alternative way of the visual inspection as well as impact vibration test is utilizing ambient vibrations or microtremor although quality of the identified frequency information might be poorer than the impact test.

A real-time monitoring method focusing on bridge vibrations under operational conditions thus has been considered as an alternative method to the visual investigation for scour assessment during a flood. Since changes in structural integrity lead to changes in modal parameters such as natural frequencies, identification of modal parameters is the first step for the scour detection by means of vibration monitoring (Chang & Kim, 2016). Once sensors are installed and electric power is supplied in the observation bridge, the vibration monitoring guarantees highly frequent real-time scour inspection. The real-time vibration monitoring would help railway authorities to make a quick decision on resuming of train operation.

This study is intended to discuss a real-time scour detection focusing on changes in frequencies of a railway bridge pier that are identified from train-induced vibrations as well as microtremor. The accelerations of bridge girders connected to the target bridge pier are also examined to clarify influences of girder vibrations to the vibrations of the pier. For the real-time and long-term scour monitoring of the railway bridge, a wireless sensing device comprising a tri-axial accelerometer that can be remotely controlled was deployed on the top of the bridge pier.

Both stochastic subspace identification (SSI) (Overschee & Moor 1996) and Bayesian operational modal analysis (BAYOMA) (Au *et al*. 2013) are adopted to identify natural frequency of the bridge pier. The SSI is the adopted as a time-domain method

while the BAYOMA is adopted as a frequency-domain method. It is noteworthy that the Bayesian approach provides posterior probability distribution of the identified modal parameters and S/N ratio of modal responses, which is useful to assess reliability of observed data during flood. The influence of environmental factors such as water level, wind speed and passing train on identified pier frequencies is also investigated.

2 SYSTEM IDENTIFICATION

2.1 *Stochastic Subspace Identification*

In this study modal parameters of bridges in operational condition are identified utilizing the stochastic subspace identification (SSI) method that is a time domain method. The algorithm for the SSI is briefly described. Details about the SSI can be found in existing researches (*e.g.* Heylen *et al*. 1997, Overschee & Moor 1996).

The dynamic system of a structure is modeled by the state-space model as follows.

$$\mathbf{x}(k+1) = \mathbf{A}\mathbf{x}(k) + \mathbf{w}(k) \tag{1}$$

$$\mathbf{y}(k) = \mathbf{C}\mathbf{x}(k) + \mathbf{v}(k) \tag{2}$$

where $\mathbf{x}(k)$ and $\mathbf{y}(k)$ denote the state of structure and measurement at each time step k respectively. $\mathbf{w}(k)$ and $\mathbf{v}(k)$ denote the process noise and measurement noise vectors respectively, and are assumed to be stationary white noise.

System matrices **A** and **C** in Equations 1 and 2 which contain the modal information are estimated by means of the least squares method for the minimal prediction error of state $\mathbf{x}(k)$ given by the forward Kalman filter. The poles of the dynamical system provide modal properties of the dynamical system.

From the system matrices, we obtain the oblique projection matrix $\boldsymbol{O}_i$ that is estimated as following equation.

$$\boldsymbol{O}_i = \mathbf{Y}_\mathrm{f}\mathbf{Y}_\mathrm{p}^\mathrm{T}\left(\mathbf{Y}_\mathrm{p}\mathbf{Y}_\mathrm{p}^\mathrm{T}\right)^\dagger\mathbf{Y}_\mathrm{p} \tag{3}$$

where $(\cdot)^\dagger$ denotes the Moore-Penrose pseudo inverse matrix. $\mathbf{Y}_\mathrm{f}$ and $\mathbf{Y}_\mathrm{p}$ are block Hankel matrices of the future and past outputs respectively and defined as follows.

$$\mathbf{Y}_\mathrm{p} = \begin{bmatrix} \mathbf{y}(0) & \mathbf{y}(1) & \dots & \mathbf{y}(j-1) \\ \dots & \dots & \dots & \dots \\ \mathbf{y}(i-2) & \mathbf{y}(i-1) & \dots & \mathbf{y}(i+j-3) \\ \mathbf{y}(i-1) & \mathbf{y}(i) & \dots & \mathbf{y}(i+j-2) \end{bmatrix} \tag{4}$$

$$\mathbf{Y}_\mathrm{f} = \begin{bmatrix} \mathbf{y}(i) & \mathbf{y}(i+1) & \dots & \mathbf{y}(i+j-1) \\ \dots & \dots & \dots & \dots \\ \mathbf{y}(2i-2) & \mathbf{y}(2i-1) & \dots & \mathbf{y}(2i+j-3) \\ \mathbf{y}(2i-1) & \mathbf{y}(2i) & \dots & \mathbf{y}(2i+j-2) \end{bmatrix} \tag{5}$$

The singular value decomposition (SVD) is then applied to factorize $\boldsymbol{O}_i$ as

$$\boldsymbol{O}_i = \mathbf{U}\mathbf{S}\mathbf{V}^\mathbf{T} = (\mathbf{U_1}\mathbf{U_2})\begin{pmatrix}\mathbf{S_1} & \mathbf{0} \\ \mathbf{0} & \mathbf{S_2}\end{pmatrix}(\mathbf{V_1}\mathbf{V_2})^\mathbf{T} \simeq \mathbf{U_1}\mathbf{S_1}\mathbf{V_1^T} \tag{6}$$

where $\mathbf{U}$ and $\mathbf{V}$ are unitary matrices with the appropriate size and $\mathbf{S}$ is a diagonal matrix with non-negative elements. The diagonal elements of $\mathbf{S}$ are known as singular values of $\boldsymbol{O}_i$. Singular values in $\mathbf{S}$ are listed in descending order.

Therefore, the components in $\mathbf{U}_1\mathbf{S}_1\mathbf{V}_1{}^\mathrm{T}$ contain most of the information defining the elements in $\boldsymbol{O}_i$ and components in $\mathbf{U}_2\mathbf{S}_2\mathbf{V}_2{}^\mathrm{T}$ are regarded as trivial components. Theoretically, the optimal state sequence $\mathbf{X}_i = [\mathbf{x}(i)\ \mathbf{x}(i{+}1)\ \dots\ \mathbf{x}(i{+}j{-}1)]$ predicted by the Kalman filter in least square sense is obtained as follows.

$$\mathbf{X}_\mathrm{i} = \mathbf{S_1^{1/2}}\mathbf{V_1^T} \tag{7}$$

The significant components of orthogonal vectors in the state sequence can be extracted by applying SVD to $\boldsymbol{O}_i$, and the system matrices are obtainable from $\mathbf{X}_i$. The number of poles corresponds to the number of singular values determined in Equation 6. In other words, we can extract the significant modal components of the bridge from the measured acceleration data by the SVD.

2.2 *Bayesian Approach*

The identified frequencies and mode shapes of the bridge pier utilizing train-induced vibrations before flood can be collected, and the probability distribution of the collected frequencies are exploited as reference information. Therefore, it is possible to detect changes in stability of the bridge pier due to scour by comparing distributions of the identified frequencies before and after flood. However, a preliminary investigation on the target bridge, which is discussed in section 4, demonstrated that the identified frequencies by the SSI from a weak amplitude ambient vibration (microtremor) during the suspend operation due to the flood showed too large variations to be used in scour monitoring.

To cope with this technical problem, the Bayesian operational modal analysis (BAYOMA) (Au *et al*. 2013) as a Bayesian approach is adopted to identify natural frequencies of the bridge pier from microtremor during a flood. The Bayesian approach offers a powerful perspective for system identification that explicitly addresses uncertainty. It treats the modal identification as an inference problem where probability is used as a measure for the relative possibility of outcomes under a given model of the system and measured data. Another useful perspective of the BAYOMA is that it provides probability distribution of modal forces and power spectrum density (PSD) of prediction error.

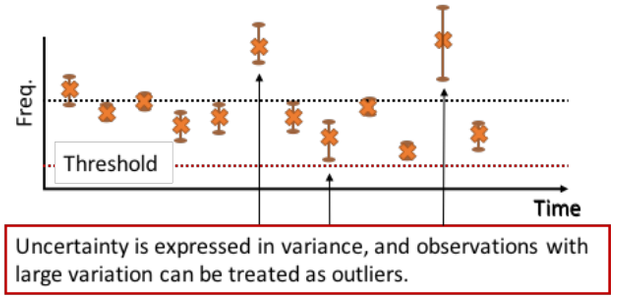

Figure 1. Identified frequencies by means of BAYOMA.

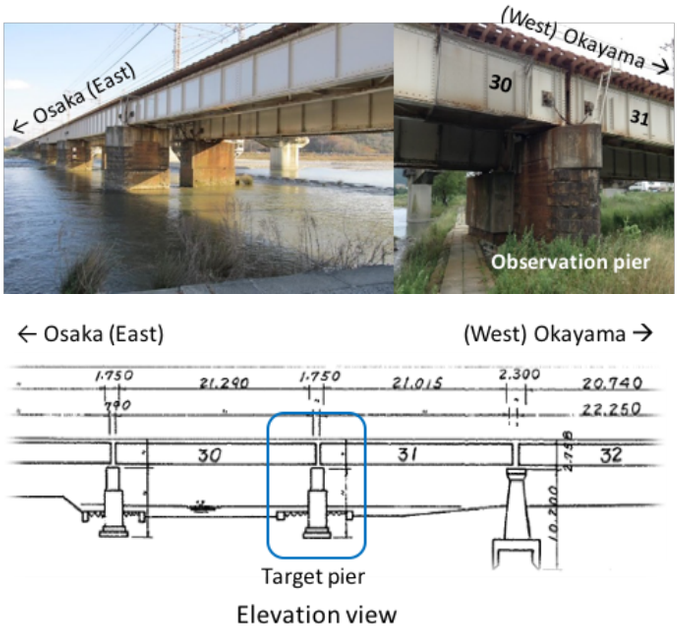

Figure 2. Photo and elevation view of the observation bridge and pier.

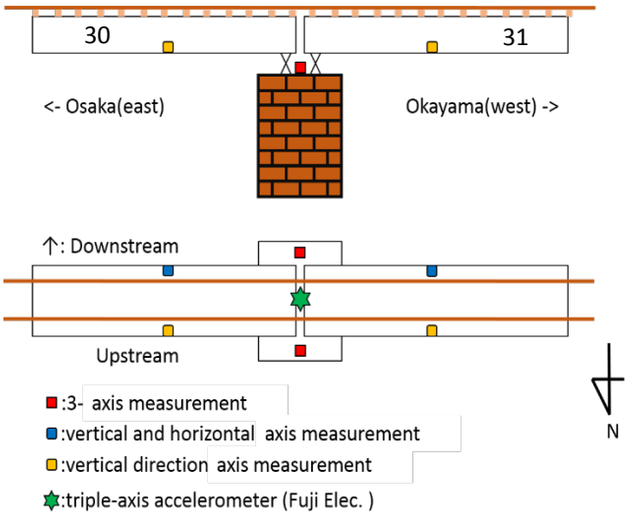

Figure 3. Sensor deployment map.

The coefficient of covariance (COV) and S/N ratio are adopted as indicator of uncertainty of identified values. Identified frequencies with low variance are selected utilizing the most probable value (MPV) which maximizes the posterior distribution in the Bayesian approach and the COV of the posterior distribution since the smaller the COV is, the smaller the uncertainty of the identified result is. Figure 1 shows the concept of mean and COV of identified frequencies by means of BAYOMA, and those with large variance can be treated as outliers.

The S/N ratio is the ratio of PSD of modal acceleration responses and PSD of prediction error, and a high S/N ratio can be interpreted as high-quality data comprising precise modal information of the bridge pier.

3 FIELD EXPERIMENT

The target bridge is commenced in 1890, and is located about 7 km far from the sea. It is a two-lane steel-girder railway bridge, and mass of the girder is around 30 t. Two lanes are connected at its superstructure, but two RC piers support each lane independently. The target bridge pier with a ship shape is located at the upstream, and train passes from the west to the east (see Figure 2).

Vibration modes of the bridge pier include rocking and sway modes of the pier and some modes are related to those of adjacent girders. Therefore, this study first estimates vibration modes of the bridge pier and adjacent girders by a network of cable accelerometers, and decides the target pier mode to be monitored for scour detection. It is noteworthy that the impact hammer test was conducted in 2011, and the rocking mode of the pier was identified as 15.93 Hz. Scour has not been occurred since then.

For practical applications, it is necessary to install sensors as few as possible to reduce monitoring cost. Therefore, one wireless sensor node, with an integrated tri-axial MEMS accelerometer (CPUKSNSS-00, Fuji Electric), was installed on the top of the bridge pier for the long-term and real-time scour monitoring. The wireless sensor enables us to control the sensor node remotely during floods. Sampling frequency was 200 Hz. The sensor deployment map is shown in Figure 3. An ultrasonic water level meter was also installed in the bridge.

On September 20 in 2016, typhoon no.16 was approached, and the water level was measured from 7:30 a.m. on September 20 to 16:00 a.m. on September 21. Figure 4a) shows the time history of the water level that denotes the distance between bottom flange of girder and the water surface, i.e. the higher the water level goes up, the smaller the measured value becomes. The water level starts to increase around 10:30 a.m. on September 20, and the peak water level of 1.8 m reached at 17:10 on September 20. The railway company has its own train operation criteria following water level, which are "Warning" at the water level of 2.5 m, "Reduce Speed" at the water level of 2.0 m and "Suspend Operation" at the water level of 1.5 m. The peak water level for the bridge was 1.8 m

that is between "Reduce Speed" and "Suspend Operation" levels. For information, time-history of wind speed (m/s) from 0:00 a.m. to 12:00 p.m. on September 20 is shown in Figure 4b) even though the observation point of wind was placed about 2 km distance from the target bridge.

4 SCOUR MONITORING

4.1 *Fundamental vibration modes*

This study first identified vibration characteristics from the train-induced vibrations measured for three days before flood utilizing the cabled sensors by means of the SSI. To extract stable structural modes from the stabilization diagram obtained in the SSI, this study determined a pre-selected frequency deviation tolerance as 0.25 Hz, 0.1 % as a pre-selected damping deviation tolerance, and 0.95 as a pre-selected lower bound of modal assurance criteria (MAC). It should be noted that the cable sensors were less sensitive to measure microtremor, and utilized only for measuring train-induced vibrations.

Figure 5 shows vibration modes relevant to the transverse mode of girders (4.8 Hz) and rocking motion of the pier (15.4 Hz) from the train-induced vibration. The identified dominant frequency of the bridge pier showed a smaller value than that of the impact test result, 15.9 Hz. However, considering additional mass by the passing train as well as bridge-train interaction (Chang *et.al.* 2014) it can be concluded that the frequency 15.4 Hz is relevant to the pier's rocking mode.

4.2 *Identified frequencies from microtremor*

The microtremor during the flood on September 20 was examined by means of the BAYOMA, and the identified frequencies from 14 Hz to 17 Hz were plotted in Figure 6 with PSD of the modal force, S/N ratio, wind speed and water level. The data length used in the identification was 1 minute. The horizontal axis shows a time scale in hour. The plots in Figure 6a) showed the mean and standard deviation of the identification frequencies. The coefficient of variation (COV) was estimated from the mean and standard deviation values to filter out outliers. In this study COV of 0.05 and S/N ratio of 2.5 were adopted as thresholds to remove outliers in the identified frequency. About 90 % of identified results were passed these filters. Those filtered results are plotted in Figure 7. During 0:00 to 9:00 a.m., when the wind speed and water level are low, identified frequencies and modal forces have scattered, and even the S/N ratio was low. On the other hand, during the period of strong wind from 9:00 a.m. to 15:00 p.m., modal forces and the S/N ratio are large, and identified frequencies showed less variation. In the period of the flood from 15:00 to 24:00, identified frequencies were clustered around 15.7 Hz.

Distributions of the frequency identified from microtremor during normal, strong wind, and flood conditions are summarized in Figure 8 in which mean values of the frequency under normal, strong wind and flood conditions were 15.9 Hz, 15.2 Hz and 15.7 Hz, respectively. There exists small difference between normal and flood condition. However, in comparing strong wind and flood conditions the mean frequency in the period of strong wind was 3.12% smaller than in flood period. Figure 9 shows the maximum PSD amplitude plot of the monitored accelerations, in which the PSD amplitude during the strong wind resulted in the most dominant.

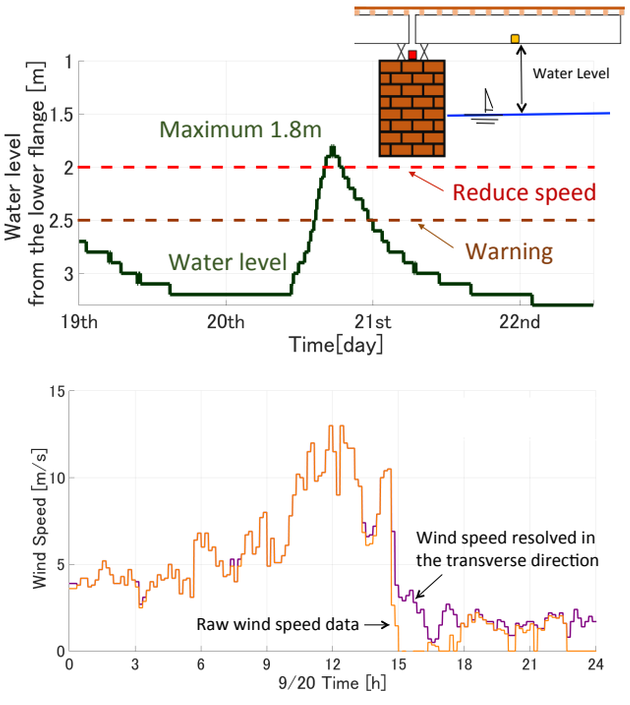

Figure 4. Water level and wind speed during typhoon no.16.

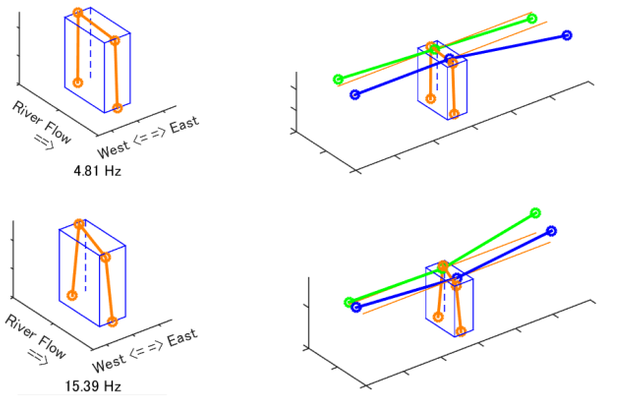

Figure 5. Identified mode shapes and dominant frequencies from the train-induced vibrations: a) near 5Hz for the transverse mode of girders, and b) near 15.9 Hz for rocking motion from the impact test.

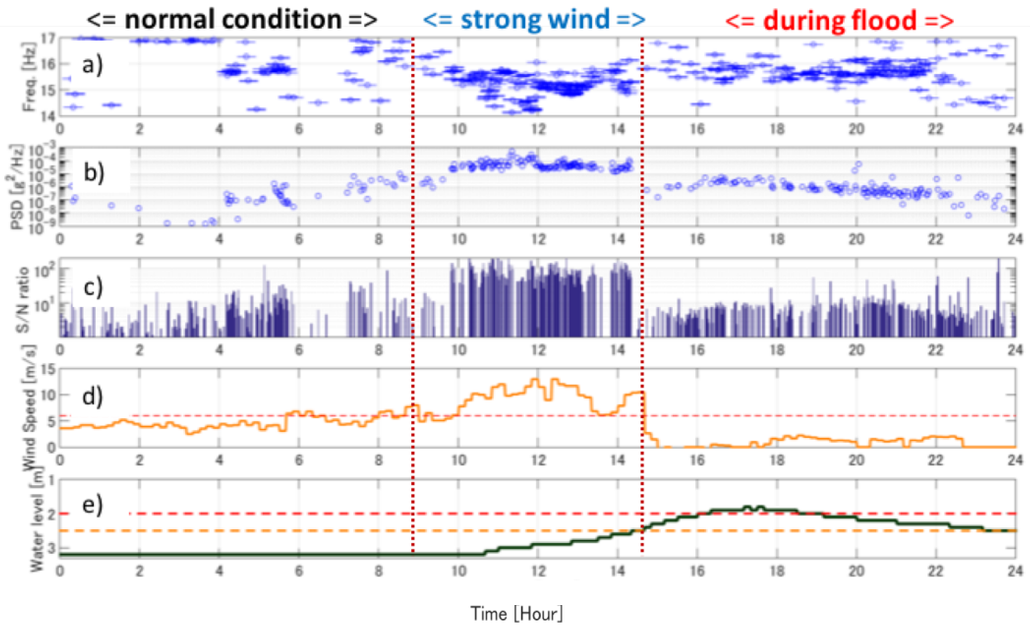

Figure 6. Bayesian approach: a) Identified frequencies; b) PSD of modal forces; c) S/N ratio; d) wind speed; and e) water level.

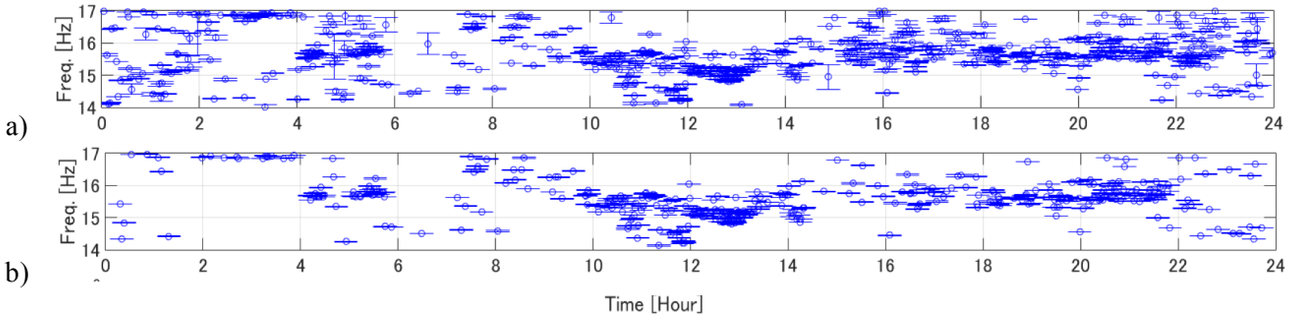

Figure 7. Bayesian approach (filtered identified frequencies): a) before being filtered; b) after being filtered.

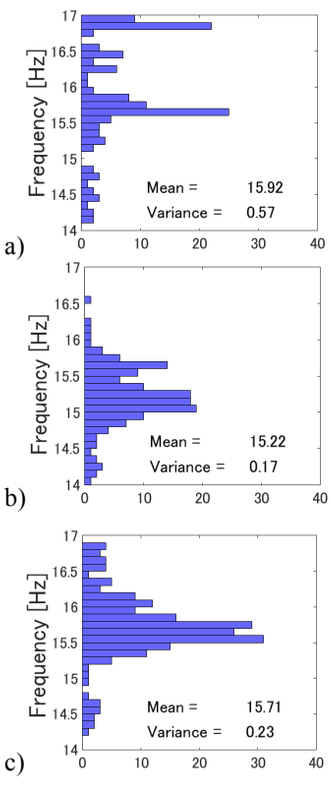

Figure 8. Identified frequency distribution: a) normal condition; b) strong wind condition; c) flood condition.

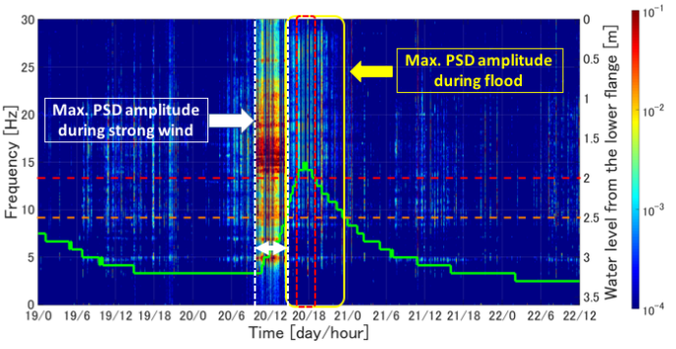

Figure 9. Maximum PSD amplitude.

Figure 10 shows the relationship between wind speed and amplitude of Fourier spectrum, which demonstrated the amplitude of Fourier spectrum drastically increased at wind speed of 6 m/s although the mechanism is not examined yet. It should be noted that there is no change in frequency during the flood, and can be concluded that low possibility of scour during high water level.

Distributions of identified frequencies before and after flood utilizing train-induced vibrations are shown in Figure 11, which demonstrates no notable changes in mean value and variance. It also demonstrates low possibility of scour due to the flood.

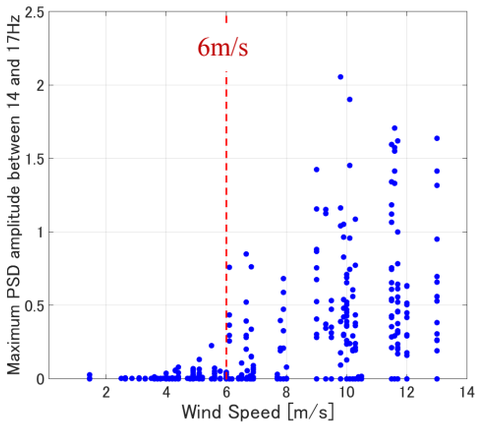

Figure 10. Relationship between wind speed and maximum amplitude of Fourier spectrum.

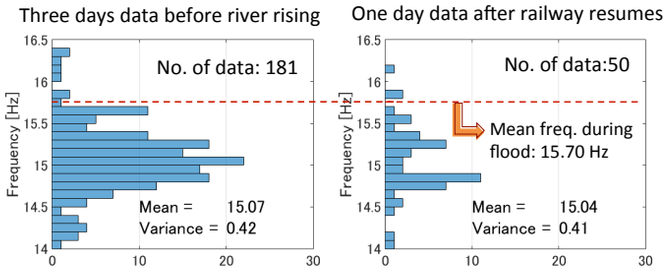

Figure 11. Distribution of natural frequency for one day after flood.

5 CONCLUSIONS

This study investigates a real-time scour assessment by means of vibration monitoring. The Bayesian approach and stochastic subspace identification are adopted for system identification. Influences of water level and wind speed were also examined. Observations from this study are summarized as follows:

The natural frequency of the bridge pier during a flood was identified in real-time, and there exists only a small difference between normal and flood conditions. However, comparing strong wind and flood conditions the mean frequency in the period of strong wind was smaller than that in flood period.

There was no notable change in frequency during the flood, and it can be concluded that low possibility of scour during high water level. Similar conclusion of low possibility of scour was derived from identified distribution before and after flood utilizing train induced vibrations.

System identification of a bridge by a sparse-like system matrix

T. Mimasu, Y. Goi & C.W. Kim
Department of Civil and Earth Resources Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: Wireless sensors in structural health monitoring are useful to simplify deployment and to realize a remote control of deployed sensors. However, wireless sensors operate in significant constraint on power consumption. Reduction techniques of radio communications in sensor networks are useful to extend the battery life. This study is intended to a method to utilize sensor grouping so as to reduce amount of data by radio communications between sensors. The sensor grouping is decided by considering correlations between sensors, and then the original system matrix is reconstructed into a sparse-like system matrix by replacing components for the weakly correlated sensor in the system matrix with zero. To verify the validity of the proposed approach, the sensor grouping is examined by means of simulations and field experiments. Observations demonstrated feasibility of system identification utilizing the sparse-like system matrix.

1 INTRODUCTION

Maintaining and upgrading civil infrastructures including bridge structures are important technical issues in many countries. Structural health monitoring (SHM) utilizing vibration responses of structures has been developed as one of the effective techniques to evaluate bridge conditions (Deraemaeker et al. 2007). Moreover, various ways to identify parameters of structures are proposed such as FDD (e.g. Brincker et al. 2001), SSI (e.g. Overschee et al. 1991) and MAR (e.g. Kim et al. 2012).

In recent years, introduction of wireless sensors to SHM is expected because of simple deployment and remote control of sensors (Chae et al. 2012, Nagayama et al. 2010). Wireless sensors have been improved as wide range of potential applications. However, cabling of sensors is labor and cost consuming. That is a driving force of using wireless sensors in SHM. However, there are technical issues remained to be solved, such as extension of battery life, time synchronization among sensors, reduction of data loss during radio communication and so on. Especially, reduction of power consumption of wireless sensor networks is needed for health monitoring of bridges that require long service period. One way to reduce the total power consumption is to reduce or to optimize the radio communication between sensor nodes since the radio communication accounts for a major portion of total power consumption (Agarwal et al. 2005).

There are techniques to reduce the amount of data such as compressive sensing (CS). This study focuses on a sparse-like system matrix that converted from original system matrix. In general, when the amount of radio communication related to vibration data decreases, the quantity of information relevant to bridge's physical properties also decreases. However, if the system matrix can be reconstructed with sparse components that link to weakly correlated sensors and communication only between sensors of strong correlation is considered, we can reduce communication between sensors of weakly related.

This study is intended to reconstruct the system matrix with sparse components in system identification by replacing components for the weakly correlated sensor in the system matrix with zero. As a feasibility study, the sensor grouping is investigated by means of simulation and field experiment on real bridges.

2 METHODOLOGY

2.1 *Multivariate auto-regressive model*

The equation of motion for a bridge is described as

$$\boldsymbol{m}_b\ddot{\boldsymbol{z}}(t) + \boldsymbol{c}_b\dot{\boldsymbol{z}}(t) + \boldsymbol{k}_b\boldsymbol{z}(t) = \boldsymbol{p}\boldsymbol{f}(t) \quad (1)$$

where $\boldsymbol{m}_b$, $\boldsymbol{c}_b$, $\boldsymbol{k}_b \in \mathbf{R}^{n\times n}$ denote the mass, damping, and stiffness matrices of the bridge, respectively. n denotes the degree of freedom of the bridge model. $\boldsymbol{z}(t) \in \mathbf{R}^n$ and $\boldsymbol{f}(t) \in \mathbf{R}^r$ denote the displacement and external force vectors, respectively. $\boldsymbol{p} \in \mathbf{R}^{n\times r}$

denotes a load matrix that provides the location of action. If we consider ambient vibration, this equation can be rewritten into a multivariate autoregressive model (MAR) as follows.

$$\boldsymbol{y}_n = \sum_{i=1}^{p} \boldsymbol{A}_i \, \boldsymbol{y}_{n-i} + \boldsymbol{v}_n \tag{2}$$

where $\boldsymbol{y}_n$, $\boldsymbol{A}_i$ and $\boldsymbol{v}_n$ denote the time-series of the output at each sensor, i-th autoregressive coefficient matrix and error term, respectively. AR coefficient matrix can be estimated by the least squares method. Vibration characteristics of bridges, such as frequency, damping and mode shape, can be identified from the AR coefficient matrix (Kim et al. 2012). In other words, AR coefficient matrix comprises essential information of vibration characteristics of bridges.

2.2 *Criteria of correlation between sensors*

Spatial correlation between sensors is considered as a parameter for the sensor grouping. In this study, correlation between sensors can be evaluated by signal noise ratio and identified mode shapes.

The signal noise ratio (SNR) is a measure of signal strength relative to background noise, and usually measured in decibels (dB) as shown in Equation 3.

$$SNR = 10 \log_{10} \frac{\sum_{n=1}^{L} \tilde{y}_n^2}{\sum_{n=1}^{L} |y_n - \tilde{y}_n|^2} \tag{3}$$

where $\tilde{y}_n$ denotes the time-series of each sensor estimated from the system matrix. The larger the SNR is, the smaller the effect of noise becomes. Therefore, the SNR is used to evaluate the correlations between sensors installed on bridges.

In the system identification utilizing the MAR model, the AR coefficient matrix is estimated from vibration responses of all sensors on the bridge. If wireless sensors are used to measure vibrations, it should be avoided to collect all measured data in one place like a parent node as the volume of vibration data is extremely big. One way to solve this issue is to convert vibration data to AR coefficient in the multi-hop communication. If AR coefficients can be structured step by step utilizing vibration data from a small group of sensors, system identification can be efficiently conducted without collecting all the data in one place.

The contribution of each AR coefficient to system identification is not uniform, and coefficients with low contribution to the system identification are negligible. It can be regarded as zero in other words. Therefore, this study uses SNR to evaluate AR coefficients of weak contribution in the system identification. It noteworthy that the SNR-0based grouping was not enough to include torsional modes, and the sensors relevant to the torsional mode are included in the sensor grouping even though contribution is not so strong.

2.3 *Sensor grouping method*

2.3.1 *Concept of sensor grouping*

If correlations of components in AR coefficient matrix are weak, we can neglect contributions of relevant sensors by replacing the relevant AR component with zero, and the AR matrix can be reconstructed like a sparse-like matrix.

In other words, if we reconstruct the AR coefficient matrix by replacing the AR coefficient relevant to a sensor with zero and the predicted time series with the reconstructed AR matrix are different from the time series by the original AR matrix, then it can be concluded that the sensor cannot be neglected to keep same information with the original matrix. Vice versa is also true, and we can only consider sensors with strong contribution. This is the concept of sensors grouping proposed in this study.

Time-series can be also estimated from the reconstructed AR coefficient matrix. The SNR is thus adopted as an index to show contribution of sensors, which is calculated by utilizing the measured time-series and estimated time-series as shown in Equation 3. If the SNR after replacing AR coefficient of a sensor with zero led to lower value than the initial SNR estimated from the original AR coefficient matrix that includes all components, then contribution of the sensor is high and should be considered in the sensor grouping. In other words, if SNR shows a lower value once the component of the AR coefficient matrix of a sensor is replaced with zero, then it means that the sensor includes important information so as to show high SNR if considered, and thus the sensor should be considered in the sensor grouping.

2.3.2 *Method of reconstructing system matrix*

First, i-th autoregressive coefficient matrix $\boldsymbol{A}_i$ and the time-series of the output $\boldsymbol{y}_n$ are expressed as Equations 4 and 5, respectively.

$$\boldsymbol{A}_i = \begin{bmatrix} a_{1,1}^{(i)} & a_{1,2}^{(i)} & \cdots & a_{1,m}^{(i)} \\ a_{2,1}^{(i)} & a_{2,2}^{(i)} & \cdots & a_{2,m}^{(i)} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m,1}^{(i)} & a_{m,2}^{(i)} & \cdots & a_{m,m}^{(i)} \end{bmatrix} \tag{4}$$

$$\boldsymbol{y}_n = [y_{1,1}^n \quad y_{2,1}^n \quad \cdots \quad y_{m,1}^n]^T \tag{5}$$

From the Equation 2, the output $y^n_{j,1}$ is reproduced by the sum of past output $\boldsymbol{y}^n_{j-i}$ multiplied by the AR coefficients. If the correlation between sensor j and sensor k is weaker than the other correlations, the contribution can be regarded as low. To estimate the AR coefficient assuming that there is no correlation between sensor j and k is essentially equivalent to replacing the AR coefficient $a_{j,k}$ with zero. An element

a)

b)

Figure 1. Bridge-A: a) photo; and b) elevation view.

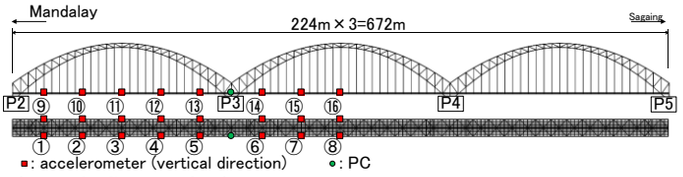

Figure 2. Sensor deployment.

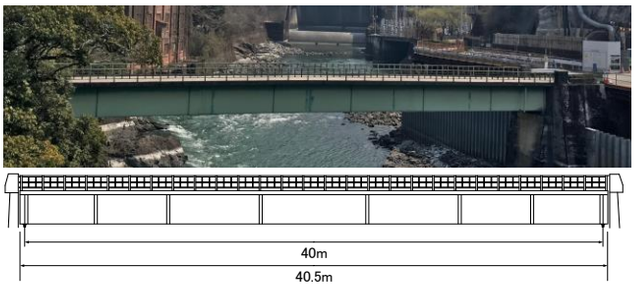
of AR coefficient matrix in Equation 4 assumed to be zero is determined based on the correlation between the sensors as described in section 2.2, and the AR coefficient matrix is reconstructed as a sparse-like matrix according to the assumption. The least square method is used for estimating the AR coefficient matrix. Thus, if AR coefficient matrix is reconstructed based on the correlation between sensors in system identification, a sparse-like AR coefficient matrix can be formulated as Equation 6.

$$\widehat{\boldsymbol{A}}_i = \begin{bmatrix} \hat{a}_{1,1}^{(i)} & \hat{a}_{1,2}^{(i)} & \cdots & 0 & 0 \\ \hat{a}_{2,1}^{(i)} & \hat{a}_{2,2}^{(i)} & \cdots & 0 & 0 \\ 0 & \hat{a}_{3,2}^{(i)} & \cdots & \hat{a}_{3,m-1}^{(i)} & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & \hat{a}_{m-2,2}^{(i)} & \cdots & \hat{a}_{m-2,m-1}^{(i)} & 0 \\ 0 & 0 & \cdots & \hat{a}_{m-1,m-1}^{(i)} & \hat{a}_{m-1,m}^{(i)} \\ 0 & 0 & \cdots & \hat{a}_{m,m-1}^{(i)} & \hat{a}_{m,m}^{(i)} \end{bmatrix} \quad (6)$$



By estimating AR coefficients each time in sequence from vibration data of sensors necessary for AR coefficient estimation, it is possible to compress the amount of radio communication in wireless communication.

3 STRUCTURAL ANALYSIS

3.1 *Target bridges*

This study investigates two different bridge types: one is a long span steel arch bridge and another one is a simply supported steel girder bridge.

a)

b)

Figure 3. Bridge-B: a) photo; and b) elevation view.

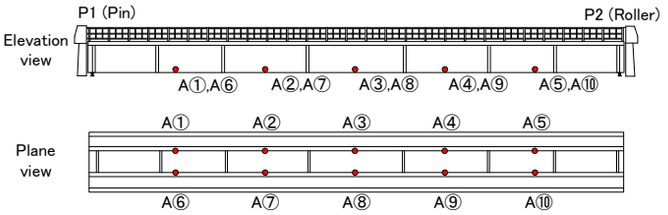


Figure 4. Sensor deployment.

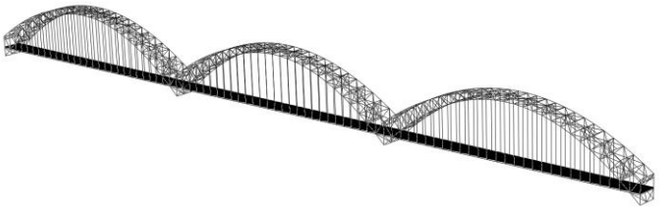

Figure 5. FE model of Bridge-A.

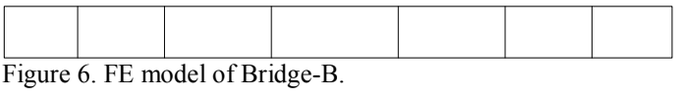

Figure 6. FE model of Bridge-B.

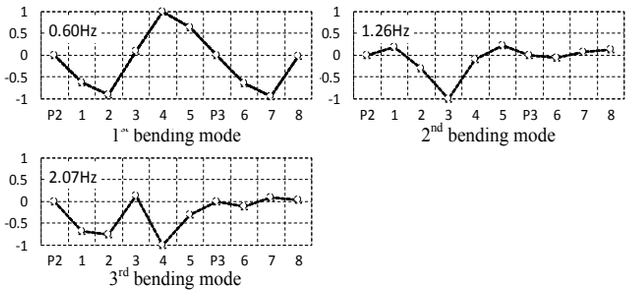
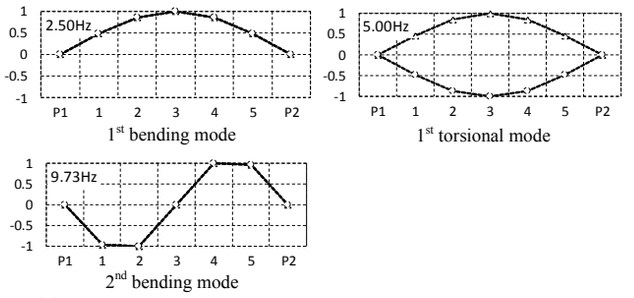


3.1.1 *Long span steel arch bridge*

The steel arch bridge comprises three spans of the through arch bridge and two spans of the through truss bridge (hereafter, Bridge-A) as shown in Figure 1. Total length and main span length is 1126m and 224m, respectively. Width is 16.6m. Observation position of the arch bridge is shown in Figure 2. 16 accelerometers were deployed on the bridge and also shown in Figure 2.



Ambient vibration responses of the bridge induced by passing vehicles were measured. Acceleration in vertical and horizontal directions were measured. However, this study discusses about the vertical responses.

3.1.2 *Steel plate girder bridge*

Another examined bridge is a simply supported steel girder bridge (hereafter, Bridge-B) that is shown in Figure 3. Total length and width are 40.5m and 4m, respectively. 10 accelerometers were installed on the bridge as shown in Figure 4. Forced vibration responses of the bridge induced by passing experimental vehicle were measured.

b) Bridge-B.

Figure 7. Results of the eigenvalue analysis.

a) Bridge-A.

b) Bridge-B.

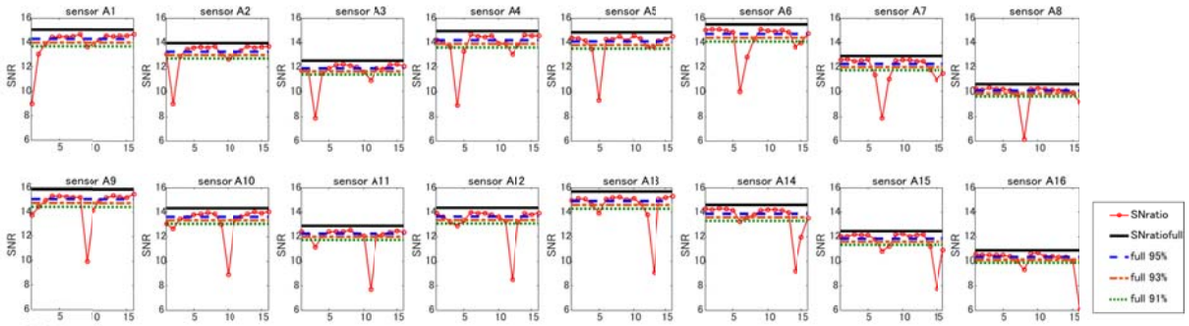
Figure 8. Frequencies and mode shapes identified from simulated vibration responses.

3.2 *FE models*

Dynamic response analysis under a white noise input were conducted as a preliminary investigation by means of the finite element (FE) method. The model of Bridge-A, shown in Figure 5, is created based on the design documents. There are sidewalks on both side of the bridge, which are ignored in the model as the design document was unavailable. The model consists of RC deck, main girder, suspension member, arch girder, cross girder and cross beam. Total number of nodes in the FE model was 12553, that of elements was 13089. As the boundary condition, pin support was assumed at the P1, P2 and P4, and roller support was assumed at the P3.

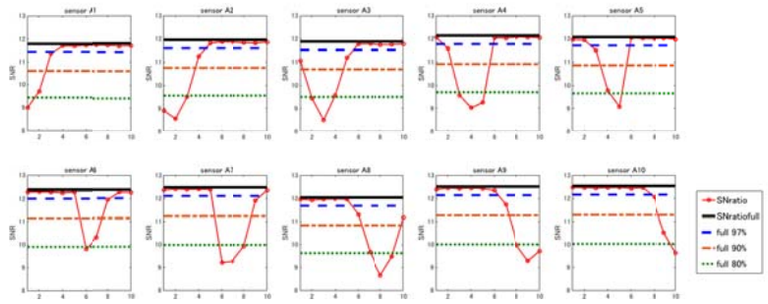
The FE model for the Bridge-B shown in Figure 6 was modeled to a grid structure. Structural details considered in modeling were referred from the documents of periodic inspection and information obtained from the field experiments since the design documents of this bridge was not available. All elements of the bridge were modeled as beams. The RC deck and main girder was considered as the composite girder. Young's modulus of steel and RC deck was assumed to 210GPa and 21GPa, respectively. Total number of nodes in the FE model was 26, that of elements was 32. Pin supported at the P1 and roller supported at the P2 were adopted as boundary conditions.

3.3 *Eigenvalue analysis*



Results of eigenvalue analysis of each bridge are summarized in Figure 7 where mode shapes are in elevation view. In this paper unless otherwise specified, horizontal axis and vertical axis indicate the location of sensors and normalized value of mode vectors, respectively. For the location of sensors in the horizontal axis, numbers 1 to 8 correspond to A1 to A8 beneath - ○ - and those numbers beneath - △ - correspond to A9 to A16 in Bridge-A. For the Bridge-B, numbers 1 to 5 correspond to A1 to A5 beneath -○- and those numbers beneath -△- correspond to A6 to A10. The target modes are 1st bending mode, 2nd bending mode and 3rd bending mode for Bridge-A. Those target modes For Bridge-B are 1st bending mode, 1st torsional mode and 2nd bending mode.

3.4 *System identification*

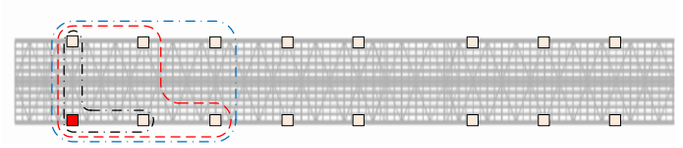


Dynamic response analysis of the bridges subjected to white noise inputs is conducted. Frequencies and mode shapes are identified by the MAR model from the simulated vibration responses, which are shown in Figure 8. For the Bridge-A, 1st bending and 2nd bending modes were comparable to those of eigenvalue analysis. Therefore, 1st bending and 2nd bending modes were considered to compare those results identified from the original system matrix and reconstructed system matrix. For the Bridge-B, three mode shapes were comparable to those of eigenvalue analysis.

3.5 *Applying the sensor group method*

Correlations between sensors are evaluated utilizing the simulation data. The SNR when the AR coefficient of each sensor is assumed to be zero is plotted in Figure 9. The description title on each graph indicates the target sensor. The horizontal axis shows the sensor number that is neglected in reconstructing the AR coefficient. The vertical axis indicates SNR when

a) Bridge-A.



b) Bridge-B.

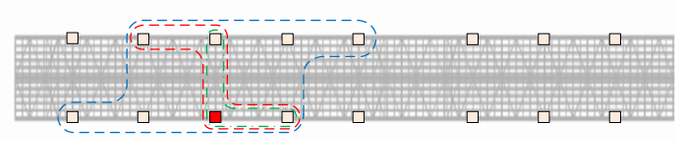


Figure 9. SN ratio of acceleration by reconstructing system matrix of multivariate AR model. (Horizontal axis: sensor to be neglected, Vertical axis: SNR)

the correlation between the target sensor and sensors to be neglected. For the Bridge-A, correlations between the target sensors and other sensors deployed along the same side were stronger than those between sensors deployed on the opposite side. In addition, the longer the length between sensors is, the weaker the correlation between the sensors becomes. For the Bridge-B, the same trends as Bridge-A were observed. The solid line indicate the SNR (SN ratio full) calculated utilizing the original AR coefficient matrix that considers correlation between all sensors. The broken line, dashed-dotted line and dotted line indicate the ratio to the SNR (SN ratio full), which are 95% (denoted to full 95%), 93% (denoted to full 93%) and 91% (denoted to full 91%) for the Bridge-A and 97% (denoted to full 97%), 90% (denoted to full 90%) and 80% denoted to full 80%) for the Bridge-B.

In this study, the threshold of SNR is artificially decided for each bridge, and sensor grouping is decided according to the threshold. In addition, the correlation that is necessary to correctly identify the mode shapes is also considered. For the Bridge-A, the correlation between sensors installed on the different span is unignorable since the SNR of sensors in the opposite girder resulted in lower SNR than the threshold. For the Bridge-B, the correlation between sensors installed on the different girders was negligible as SNR was not low even after replacing the component of the system with zero, but at least one sensor in the opposite girder should be considered so as to identify the torsional mode shape correctly. Examples of sensor grouping for each threshold are shown in Figure 10.

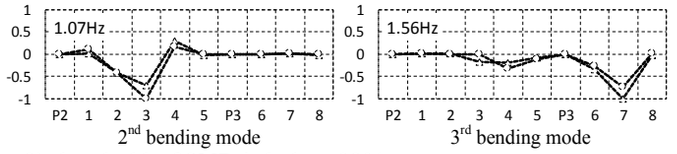
Figure 12. Frequencies and mode shapes identified from measured vibration responses.

Table 1. Differences in frequencies and MAC values.

	Mode	SNR	Error of freq.	MAC
Bridge-A	1st bending	95%	0.00Hz	0.95
		93%	0.03Hz	0.89
		91%	0.03Hz	0.65
	2nd bending	95%	0.03Hz	0.91
		93%	0.00Hz	0.81
		91%	0.03Hz	0.04
Bridge-B	1st bending	97%	0.00Hz	0.99
		90%	N/A	N/A
		80%	N/A	N/A
	1st torsional	97%	0.00Hz	0.99
		90%	N/A	N/A
		80%	N/A	N/A
	2nd bending	97%	0.01Hz	1.00
		90%	0.05Hz	0.99
		80%	0.01Hz	0.67

Figure 11 shows frequencies and mode shapes identified from the AR coefficient matrix that is reconstructed based on the sensor grouping. Differences in frequencies and modal assurance criterion (MAC) between modes before and after reconstruction are summarized in Table 1. The MAC in Equation 7 is used to evaluate the correlation between two different mode vectors.



$$MAC_{ij} = \frac{(\Phi_i^T \Phi_j)^2}{(\Phi_i^T \Phi_i)(\Phi_j^T \Phi_j)} \quad (7)$$

where Φ_i, Φ_j are two mode vectors. The MAC value is bounded between 0 and 1, in which 1 indicates fully consistent mode shapes and however, 0 indicates inconsistency.

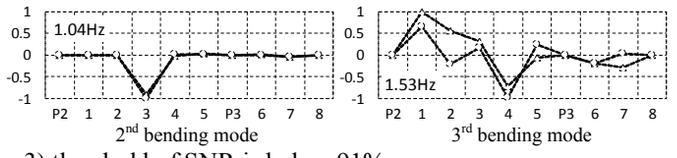


Table 1 shows that the difference in frequencies is up to 0.03Hz, and MAC for the 2nd bending mode is significantly small under the threshold of 91% for the Bridge-A. Under thresholds of 95% and 93%, the identified modes were comparable to the original modes. From the view point of reducing radio communications among sensors, it is better to select a sensor group with less sensors. Therefore, the sensor grouping under the threshold of 93% was selected. For the Bridge-B, 1st bending mode and 2nd bending mode were identified only under the threshold of 97%. Therefore, the sensor grouping under the threshold of 97% was considered. Although the frequency does not change so much, mode shapes were drastically changed.

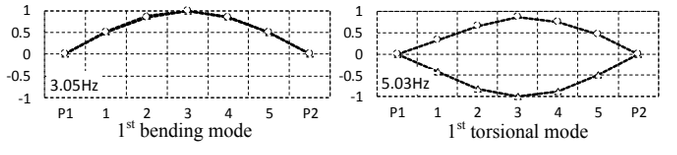
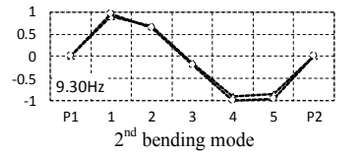
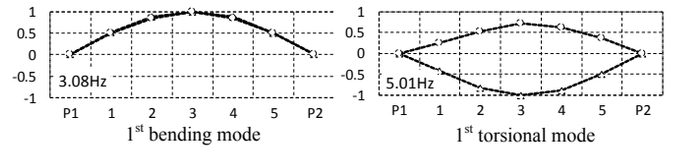
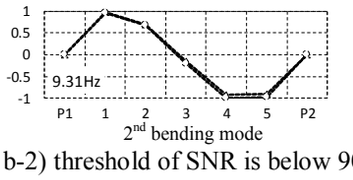


a-1) threshold of SNR is below 95%.

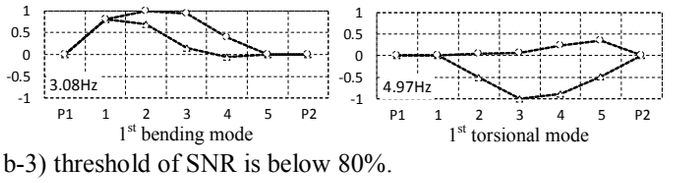


a-2) threshold of SNR is below 93%.





a-3) threshold of SNR is below 91%.



b-1) threshold of SNR is below 97%.

b-2) threshold of SNR is below 90%.

b-3) threshold of SNR is below 80%.

Figure 13. Identified natural frequencies and vibration modes by reconstructing system matrix; a) Bridge-A and b) Bridge-B.

4 SYSTEM IDENTIFICATION UTILIZING MEASURED DATA

4.1 *System identification*

Sampling rate of vibration measurement was 200Hz for both bridges. The lengths of vibration responses measured on Bridge-A and Bridge-B were 9000s and 10s, respectively. The frequencies and mode shapes identified from the measured vibration data by the MAR model are shown in Figure 12. Those mode shapes are comparable with those of eigenvalue analysis and identified from simulated responses. The comparison of frequencies identified from the simulated responses and the measured responses is summarized in Table 2, which shows that differences between simulation and experiment were from 7% to 27% for the Bridge-A, and from 2% to 7% for the Bridge-B. Insufficient information due to lack of design documents in FE modeling might be one reason for the difference.

Table 2. Comparison of frequencies identified from the simulated responses and measured responses.

	Mode	Frequency	
		Simulation	Experiment
Bridge-A	1st bending	0.62Hz	0.58Hz
	2nd bending	1.24Hz	1.02Hz
	3rd bending	2.07Hz	1.51Hz
Bridge-B	1st bending	2.80Hz	3.03Hz
	1st torsional	5.04Hz	4.95Hz
	2nd bending	9.71Hz	9.31Hz

Table 3. Differences in frequencies and MAC values.

	Mode	Threshold	Error of freq.	MAC
Bridge-A	2nd bending	95%	0.01Hz	0.95
		93%	0.05Hz	0.83
		91%	0.02Hz	0.72
	3rd bending	95%	0.01Hz	0.69
		93%	0.05Hz	0.04
		91%	0.02Hz	0.00
Bridge-B	1st bending	97%	0.01Hz	1.00
		90%	0.04Hz	1.00
		80%	0.05Hz	0.58
	1st torsional	97%	0.06Hz	0.99
		90%	0.03Hz	0.99
		80%	0.00Hz	0.70
	2nd bending	97%	0.01Hz	0.99
		90%	0.00Hz	1.00
		80%	N/A	N/A

4.2 *Correlation between installed sensors*

The SNR of vibration responses from the field experiment is estimated by using the same method discussed in Section 3 for simulation data. Correlations between sensors are almost same as those from simulated responses shown in Figure 9, and were omitted. Therefore, same sensor groupings as simulated responses are utilized to reconstruct the system matrix.

4.3 *System identification based on the reconstructed system matrix*

Frequencies and mode shapes identified from a sparse-like system matrix utilizing sensor groups are shown in Figure 13. The difference in frequencies and MAC values between before and after reconstruction are shown in Table 3. For the Bridge-A, the difference in frequencies is up to 0.05Hz. MAC value is large enough only when threshold is 95%. When thresholds are changed to 91% and 93%, the identified 3rd bending mode was not comparable with those from original AR coefficient matrix. Therefore, the sensor grouping was considered under threshold of 95% (see Figure 10 a) as examples of the sensor grouping). For the Bridge-B, 1st bending mode and 2nd bending mode are identified in all cases. Therefore, the sensor grouping under threshold of 90% was selected (see Figure 10 b) as examples of the sensor grouping).

5 CONCLUSION

This study investigates validity of system identification utilizing a sparse-like system matrix. Sensor grouping is examined by utilizing SNR which is an index indicating correlations between sensors. Dynamic response analysis is conducted by means of FE analysis as a preliminary investigation to decide the optimal sensor group. Field experiments are conducted to verify validity of the proposed method.

It is demonstrated that system identification utilizing a sparse-like system matrix based on the correlation between sensors is possible with a certain accuracy. The accuracy of system identification is significantly important for the sensor grouping. In addition, the accuracy of bridge model is also important to examine the optimal sensor group before sensors are installed on the bridges. Therefore, model updating of model parameter is needed. Future works will focus on feasibility study on actual wireless sensor networks, model updating and damage detection utilizing the sensor grouping.

Obtaining full-field response for optimal sensor placement

J. Kullaa
Metropolia University of Applied Sciences, Helsinki, Finland

ABSTRACT: Optimal sensor placement (OSP) algorithms may require vibration measurements from all candidate sensor positions. A combination of experimental and numerical campaigns is proposed to obtain the full-field data. First, the response under typical excitation is measured with a redundant sensor network. Then, Bayesian virtual sensing is applied to estimate the full-field response that can be further used for OSP. Numerical simulations were performed for a structure subject to unknown random excitation. Noisy response was measured with an initial redundant sensor network, and the full-field response was estimated. Noise was added to the virtual sensors to mimic physical measurements. An OSP algorithm was applied using the virtual sensor data. The resulting optimal sensor network with a given number of sensors was compared to the initial sensor network with the same number of sensors.

1 INTRODUCTION

Structural monitoring and control utilize vibration measurements acquired by a sensor network. For a limited number of sensors, it is important to place them at optimal locations. A very common algorithm for optimal sensor placement (OSP) is the effective independence method (EFI) (Kammer 1991, 1992). The main advantage of EFI is that the optimal sensor positions can be selected using the analytical mode shape vectors only.

Optimal sensor placement depends on the application. For example, the objective may be system identification (Cherng 2003, Papadimitriou 2004, Papadimitriou & Lombaert 2012), model correlation (Yap & Zimmerman 2000), model updating (Reynier & Abou-Kandil 1999), control (Han & Lee 1999), damage detection (Worden & Burrows 2001, Yi & Li 2012, Flynn & Todd 2010), impact identification (Malardo & Aliabadi 2013), communication cost minimization (Krause et al. 2006), or response estimation (Kullaa 2017).

For some algorithms, measurement data are needed at all candidate degrees of freedom (DOFs) to make the decision for OSP. Due to the high number of candidate DOFs, measurements from all those locations can be difficult or even impossible. An alternative solution is to perform simulations using the finite element method. However, the excitation is often unknown, which makes the predicted response unreliable. Both the spatial distribution and the time history of the load are usually uncertain.

Both of the aforementioned disadvantages can be avoided with a combination of experimental and numerical campaigns. First, the response under typical ambient excitation is measured using a limited number of sensors. Then, virtual sensing is applied to estimate the full-field response that can be further used for OSP.

Virtual sensing (VS) techniques can be used to estimate the quantities of interest using the available measurements. Virtual sensing can be either analytical (model-based) or empirical (data-driven) (Lin et al. 2007).

Analytical virtual sensing techniques use information available from a limited set of physical sensors together with a finite element model to calculate an estimate of the quantity of interest. Analytical virtual sensing in structural dynamics has been studied e.g. in the following papers. Avitabile (2005) applied virtual sensing to correlation of analytical and experimental models using model expansion. Sestieri et al. (2013) estimated rotational DOFs from a limited set of measured translational DOFs. Hjelm et al. (2005) estimated stress histories from acceleration measurements. Iliopoulos et al. (2014) applied virtual sensing to fatigue assessment of wind turbines. Full-field dynamic stress/strain field was estimated from limited sets of measurement data by Pingle & Avitabile (2011) and Harvey et al. (2013). Papadimitriou et al. (2011) introduced a technique that uses Kalman filter to estimate power spectral density of strain anywhere in the structure for fatigue assessment. Eftekhar Azam et al. (2015) de-

veloped a dual Kalman filter for estimating the unknown input and states of a linear system. Maes et al. (2014) compared three different response estimation algorithms: a joint input-state estimation algorithm, a Kalman filter algorithm, and a modal interpolation algorithm. Kullaa (2016a) applied dynamic substructuring to virtual sensing.

Empirical virtual sensing can be used to replace a temporarily installed or failed sensor (Liu et al. 2009). Empirical virtual sensing has also been used for damage or sensor fault identification (Kullaa 2010, 2011). The accuracy of estimation can be increased by increasing the number of sensors in the network.

A combination of empirical and analytical virtual sensing was proposed by Kullaa (2016b) for a more accurate full-field response. This technique is also used in this study to generate measurement data for an iterative OSP algorithm. In order to mimic real measurements, a proper amount of noise is added to each virtual sensor.

The OSP procedure uses the data from the candidate virtual sensors. Due to variable excitation, modelling errors, and an iterative OSP algorithm, the resulting sensor network may be sub-optimal. Nevertheless, the proposed method is believed to work in practice and result in desired accuracy for engineering purposes.

This paper is organised as follows. Bayesian virtual sensing is described in Section 2. Optimal sensor placement is introduced in Section 3 using the selected objective function. In Section 4, numerical simulations are performed for a structure subject to unknown random excitation. An optimal sensor network with a given number of sensors is searched for and compared with the initial sensor network with the same number of sensors. Finally, concluding remarks are given in Section 5.

2 BAYESIAN VIRTUAL SENSING

Virtual sensing techniques estimate quantities of interest using the available physical sensors. Empirical virtual sensing is based on available historical measurements of the same quantity that is being estimated. In analytical virtual sensing, the quantity of interest is estimated using the available measurements and the system model.

2.1 *Bayesian empirical virtual sensing*

Empirical virtual sensing is based on the correlation between the measured quantities. Empirical virtual sensing uses regression techniques that can be implemented using different statistical methods, for example linear regression or neural network regression.

2.1.1 *Measurement model*

Consider a sensor network measuring p simultaneously sampled variables $\mathbf{y} = \mathbf{y}(t)$ at time instant t. Each measurement $\mathbf{y}$ includes independent measurement error $\mathbf{w} = \mathbf{w}(t)$:

$$\mathbf{y} = \mathbf{x}_m + \mathbf{w} \tag{1}$$

where $\mathbf{x}_m = \mathbf{x}_m(t)$ are the true values of the measured degrees of freedom. The objective is to find a less noisy estimate for the true values $\mathbf{x}_m$ utilizing the noisy measurements $\mathbf{y}$ from the sensor network.

2.1.2 *Bayes' rule*

A subset of the physical sensors is estimated by partitioning each observation into observed variables $\mathbf{v}$ and estimated variables $\mathbf{u}$ (typically a single sensor u). The partitioned variables are

$$\mathbf{y} = \begin{Bmatrix} \mathbf{y}_u \\ \mathbf{y}_v \end{Bmatrix},\ \mathbf{x}_m = \begin{Bmatrix} \mathbf{x}_{m,u} \\ \mathbf{x}_{m,v} \end{Bmatrix},\ \mathbf{w} = \begin{Bmatrix} \mathbf{w}_u \\ \mathbf{w}_v \end{Bmatrix} \tag{2}$$

Measurement error $\mathbf{w}$ is assumed to be zero mean, independent of $\mathbf{x}_m$, with a known covariance matrix

$$\boldsymbol{\Sigma}_w = E(\mathbf{w}\mathbf{w}^T) = \begin{bmatrix} \boldsymbol{\Sigma}_{w,uu} & \boldsymbol{\Sigma}_{w,uv} \\ \boldsymbol{\Sigma}_{w,vu} & \boldsymbol{\Sigma}_{w,vv} \end{bmatrix} \tag{3}$$

where $E(\cdot)$ denotes the expectation operator. From Bayes' rule,

$$\begin{aligned} p(\mathbf{x}_{m,u} \mid \mathbf{y}) &= p(\mathbf{x}_{m,u} \mid \mathbf{y}_u, \mathbf{y}_v) \\ &= \frac{p(\mathbf{y}_u \mid \mathbf{x}_{m,u}, \mathbf{y}_v) p(\mathbf{x}_{m,u} \mid \mathbf{y}_v)}{p(\mathbf{y}_u \mid \mathbf{y}_v)} \end{aligned} \tag{4}$$

The distributions in (4) can be evaluated as shown in the following.

2.1.3 *Likelihood*

Assuming Gaussian noise $\mathbf{w}$, the likelihood is obtained using Equation 1:

$$\begin{aligned} &p(\mathbf{y}_u \mid \mathbf{x}_{m,u}, \mathbf{y}_v) = p(\mathbf{y}_u \mid \mathbf{x}_{m,u}) = N(\mathbf{y}_u \mid \mathbf{x}_{m,u}, \boldsymbol{\Sigma}_{w,uu}) \\ &\propto \exp\left[-\frac{1}{2} (\mathbf{y}_u - \mathbf{x}_{m,u})^T \boldsymbol{\Sigma}_{w,uu}^{-1} (\mathbf{y}_u - \mathbf{x}_{m,u}) \right] \end{aligned} \tag{5}$$

2.1.4 *Evidence*

For simplicity but without loss of generality, assume zero-mean variables $\mathbf{y}$. The partitioned data covariance matrix $\boldsymbol{\Sigma}_y$ is

$$\boldsymbol{\Sigma}_y = E(\mathbf{y}\mathbf{y}^T) = \begin{bmatrix} \boldsymbol{\Sigma}_{y,uu} & \boldsymbol{\Sigma}_{y,uv} \\ \boldsymbol{\Sigma}_{y,vu} & \boldsymbol{\Sigma}_{y,vv} \end{bmatrix} \tag{6}$$

The precision matrix $\boldsymbol{\Gamma}_y$ is defined as the inverse of the covariance matrix $\boldsymbol{\Sigma}_y$ and is also written in partitioned form:

$$\boldsymbol{\Gamma}_y = \boldsymbol{\Sigma}_y^{-1} = \begin{bmatrix} \boldsymbol{\Gamma}_{y,uu} & \boldsymbol{\Gamma}_{y,uv} \\ \boldsymbol{\Gamma}_{y,vu} & \boldsymbol{\Gamma}_{y,vv} \end{bmatrix} \tag{7}$$

A linear minimum mean square error (LMMSE) estimate for $\mathbf{y}_u \mid \mathbf{y}_v$ is obtained by minimizing the mean-square error (MSE) and can be computed either using the covariance or precision matrix (Kullaa 2010, Bishop 2006). If each sensor signal is estimated in turn, the formulas based on the precision matrix result in a more efficient algorithm (Kullaa 2010). The evidence $p(\mathbf{y}_u \mid \mathbf{y}_v)$ is also Gaussian:

$$\begin{aligned} p(\mathbf{y}_u \mid \mathbf{y}_v) &= N(\mathbf{y}_u \mid \mathbf{K}\mathbf{y}_v, \boldsymbol{\Gamma}_{y,uu}^{-1}) \\ &\propto \exp\left[-\frac{1}{2} (\mathbf{y}_u - \mathbf{K}\mathbf{y}_v)^T \boldsymbol{\Gamma}_{y,uu} (\mathbf{y}_u - \mathbf{K}\mathbf{y}_v) \right] \end{aligned} \tag{8}$$

where $\mathbf{K} = -\boldsymbol{\Gamma}_{y,uu}^{-1} \boldsymbol{\Gamma}_{y,uv}$. Notice that the evidence is merely a normalizing factor, independent of $\mathbf{x}_{m,u}$.

2.1.5 *Prior*

The prior distribution $p(\mathbf{x}_{m,u} \mid \mathbf{y}_v)$ is obtained from the measurement model (1) by partitioning and conditioning:

$$p(\mathbf{y}_u \mid \mathbf{y}_v) = p(\mathbf{x}_{m,u} \mid \mathbf{y}_v) + p(\mathbf{w}_u) \tag{9}$$

from which the prior mean is

$$\begin{aligned} E(\mathbf{x}_{m,u} \mid \mathbf{y}_v) &= E(\mathbf{y}_u \mid \mathbf{y}_v) - E(\mathbf{w}_u) \\ &= E(\mathbf{y}_u \mid \mathbf{y}_v) = \mathbf{K}\mathbf{y}_v \end{aligned} \tag{10}$$

and the prior covariance is

$$\boldsymbol{\Sigma}_{\text{prior},uu} = \text{cov}(\mathbf{x}_{m,u} \mid \mathbf{y}_v) = \boldsymbol{\Gamma}_{y,uu}^{-1} - \boldsymbol{\Sigma}_{w,uu} \tag{11}$$

The prior distribution is also Gaussian:

$$\begin{aligned} p(\mathbf{x}_{m,u} \mid \mathbf{y}_v) &= N(\mathbf{x}_{m,u} \mid \mathbf{K}\mathbf{y}_v, \boldsymbol{\Sigma}_{\text{prior},uu}) \\ &\propto \exp\left[-\frac{1}{2} (\mathbf{x}_{m,u} - \mathbf{K}\mathbf{y}_v)^T \boldsymbol{\Sigma}_{\text{prior},uu}^{-1} (\mathbf{x}_{m,u} - \mathbf{K}\mathbf{y}_v) \right] \end{aligned} \tag{12}$$

2.1.6 *Posterior*

The posterior distribution (4) is obtained by some manipulation, resulting in a Gaussian distribution:

$$\begin{aligned} p(\mathbf{x}_{m,u} \mid \mathbf{y}) &= c_1 p(\mathbf{y}_u \mid \mathbf{x}_m) p(\mathbf{x}_{m,u} \mid \mathbf{y}_v) \\ &= c_2 \exp\left[-\frac{1}{2} (\mathbf{x}_{m,u} - \hat{\mathbf{x}}_{m,u})^T \boldsymbol{\Sigma}_{\text{post},uu}^{-1} (\mathbf{x}_{m,u} - \hat{\mathbf{x}}_{m,u}) \right] \end{aligned} \tag{13}$$

where c_1 and c_2 are constants and the posterior covariance $\boldsymbol{\Sigma}_{\text{post},uu}$ is

$$\boldsymbol{\Sigma}_{\text{post},uu} = \text{cov}(\mathbf{x}_{m,u} \mid \mathbf{y}) = (\boldsymbol{\Sigma}_{w,uu}^{-1} + \boldsymbol{\Sigma}_{\text{prior},uu}^{-1})^{-1} \tag{14}$$

and the posterior mean is

$$\hat{\mathbf{x}}_{m,u} = \boldsymbol{\Sigma}_{\text{post},uu} (\boldsymbol{\Sigma}_{w,uu}^{-1} \mathbf{y}_u + \boldsymbol{\Sigma}_{\text{prior},uu}^{-1} \mathbf{K}\mathbf{y}_v) = \mathbf{a}_u^T \mathbf{y} \tag{15}$$

where $\mathbf{a}_u^T$ is

$$\mathbf{a}_u^T = \begin{bmatrix} \boldsymbol{\Sigma}_{\text{post},uu} \boldsymbol{\Sigma}_{w,uu}^{-1} & \boldsymbol{\Sigma}_{\text{post},uu} \boldsymbol{\Sigma}_{\text{prior},uu}^{-1} \mathbf{K} \end{bmatrix} \tag{16}$$

Equation 15 shows that the posterior mean is a weighted sum of the measurements of all sensors in the network.

Notice that the MSE of the posterior (14) is always less than that of the measurement error, $\boldsymbol{\Sigma}_{w,uu}$. Therefore, the posterior mean is more accurate than the actual measurement.

Generally, the predicted DOFs **u** may include several variables. In the sequel, **u** is one-dimensional including one sensor only. For each sensor *u*, a corresponding row vector $\mathbf{a}_u^T$ is computed. All these vectors can be assembled in a coefficient matrix **A** to estimate all virtual sensors simultaneously:

$$\hat{\mathbf{x}}_m = \mathbf{A}\mathbf{y} \tag{17}$$

where each row *u* of matrix **A** represents the corresponding sensor.

A diagonal covariance matrix is assumed with variances (14) in the corresponding row *u*.

2.2 *Combined empirical and analytical virtual sensing*

Analytical virtual sensing uses a mathematical model of the system together with available measurements to estimate the quantity of interest. In combined virtual sensing, both empirical and analytical VS are used to obtain a more accurate estimate of the quantity of interest. First, empirical virtual sensing is applied to estimate a less noisy measurement. The empirical estimates will then be used in subsequent analytical VS.

In linear structural dynamics, the structural response can be written as a sum of modal contributions:

$$\mathbf{x}(t) = \sum_{i=1}^{N} \phi_i q_i(t) \approx \sum_{i=1}^{n} \phi_i q_i(t) = \boldsymbol{\Phi}\mathbf{q}(t) \tag{18}$$

where $\mathbf{x}(t)$ is the displacement response, N is the number of DOFs in the finite element model, $n << N$ is the selected number of active modes, $\boldsymbol{\Phi}$ is the truncated modal matrix consisting of the selected mode shapes ϕ_i as columns, and $\mathbf{q}(t)$ are the modal, or generalized coordinates.

The System Equivalent Reduction Expansion Process (SEREP) algorithm (Avitabile 2005) is briefly outlined. If $\mathbf{x}(t)$ is divided into measured and unmeasured DOFs, $\mathbf{x}_m(t)$ and $\mathbf{x}_e(t)$, respectively, the mode shape vectors are divided correspondingly:

$$\mathbf{x}(t) = \begin{Bmatrix} \mathbf{x}_m(t) \\ \mathbf{x}_e(t) \end{Bmatrix} = \begin{bmatrix} \boldsymbol{\Phi}_m \\ \boldsymbol{\Phi}_e \end{bmatrix} \mathbf{q}(t) \tag{19}$$

The upper equation reads

$$\mathbf{x}_m(t) = \boldsymbol{\Phi}_m \mathbf{q}(t) \tag{20}$$

The exact values $\mathbf{x}_m(t)$ are not known, but the posterior distribution is used instead.

$$\hat{\mathbf{x}}_m(t) = \mathbf{x}_m(t) + \mathbf{e}(t) \tag{21}$$

where $\hat{\mathbf{x}}_m(t)$ is given by (17) and $\mathbf{e}(t)$ is the posterior error with zero mean and diagonal covariance matrix $E(\mathbf{e}\mathbf{e}^T) = \text{diag}(\boldsymbol{\Sigma}_{\text{post},uu})$. Using Equation 20, Equation 21 becomes

$$\hat{\mathbf{x}}_m(t) = \boldsymbol{\Phi}_m \mathbf{q}(t) + \mathbf{e}(t) \tag{22}$$

with the weighted least squares (WLS) solution (Bar-Shalom 2001):

$$\hat{\mathbf{q}}(t) = (\boldsymbol{\Phi}_m^T \mathbf{W} \boldsymbol{\Phi}_m)^{-1} \boldsymbol{\Phi}_m^T \mathbf{W} \hat{\mathbf{x}}_m(t) \tag{23}$$

where the weighting matrix $\mathbf{W}$ is the inverse of $E(\mathbf{e}\mathbf{e}^T)$.

Once the estimate of $\mathbf{q}(t)$ is solved, any DOF can be computed from Equation 19:

$$\hat{\mathbf{x}}(t) = \boldsymbol{\Phi} \hat{\mathbf{q}}(t) \tag{24}$$

The error covariance of the WLS estimate of $\mathbf{q}(t)$ (23) is (Bar-Shalom 2001):

$$\boldsymbol{\Sigma}_{\mathbf{q}} = (\boldsymbol{\Phi}_m^T \mathbf{W} \boldsymbol{\Phi}_m)^{-1} \tag{25}$$

Notice that the model error in $\boldsymbol{\Phi}$ is ignored.

Finally, any DOF can be estimated using Equations 24, 23, and 17:

$$\begin{aligned} \hat{\mathbf{x}}(t) &= \boldsymbol{\Phi} \hat{\mathbf{q}}(t) \\ &= \boldsymbol{\Phi} (\boldsymbol{\Phi}_m^T \mathbf{W} \boldsymbol{\Phi}_m)^{-1} \boldsymbol{\Phi}_m^T \mathbf{W} \hat{\mathbf{x}}_m(t) \\ &= \boldsymbol{\Phi} (\boldsymbol{\Phi}_m^T \mathbf{W} \boldsymbol{\Phi}_m)^{-1} \boldsymbol{\Phi}_m^T \mathbf{W} \mathbf{A} \mathbf{y}(t) \\ &= \mathbf{H} \mathbf{y}(t) \end{aligned} \tag{26}$$

where

$$\mathbf{H} = \boldsymbol{\Phi} (\boldsymbol{\Phi}_m^T \mathbf{W} \boldsymbol{\Phi}_m)^{-1} \boldsymbol{\Phi}_m^T \mathbf{W} \mathbf{A} \tag{27}$$

The error variances of the virtual sensors are

$$\text{var}\left[\hat{\mathbf{x}}(t)\right] = \text{diag}(\boldsymbol{\Phi} \boldsymbol{\Sigma}_{\mathbf{q}} \boldsymbol{\Phi}^T) \tag{28}$$

The covariance matrix of the virtual full-field data is obtained as follows (assuming zero means):

$$\boldsymbol{\Sigma}_{\hat{x}} = E\left[\hat{\mathbf{x}}(t)\hat{\mathbf{x}}(t)^T\right] = \mathbf{H} E(\mathbf{y}\mathbf{y}^T) \mathbf{H}^T = \mathbf{H} \boldsymbol{\Sigma}_y \mathbf{H}^T \tag{29}$$

In order to produce virtual measurements, the noise characteristics should be the same as in the actual measurement chain. Therefore, a (diagonal) noise covariance matrix must be added to the covariance matrix of the virtual sensors (29):

$$\boldsymbol{\Sigma}_{\hat{y}} = \boldsymbol{\Sigma}_{\hat{x}} + \boldsymbol{\Sigma}_w \tag{30}$$

3 OPTIMAL SENSOR PLACEMENT

The objective is to estimate the full-field response for OSP. The procedure is depicted in Figure 1. The procedure consists of both experimental and numerical methods. The experiments are performed for the structure using a network with a limited number of sensors and the numerical analysis uses a finite element model resulting in the truncated modal matrix including all candidate DOFs. Notice that the excitation remains unknown.

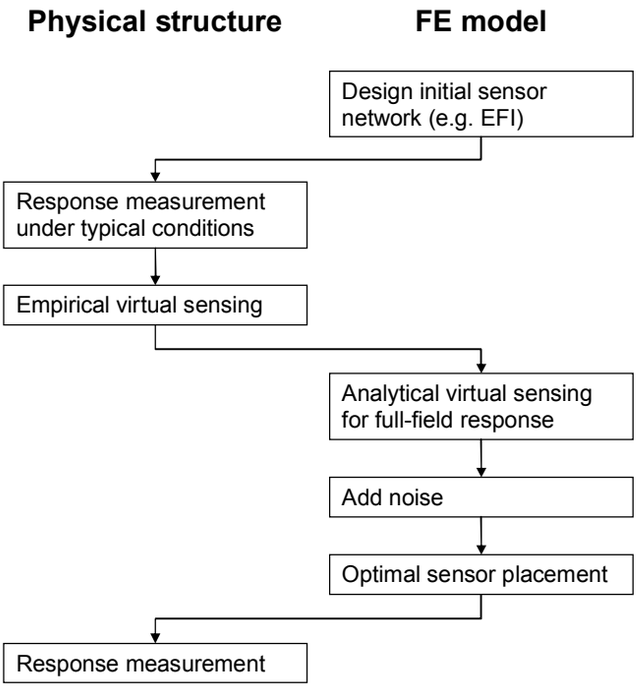

Figure 1. OSP procedure using both experimental and numerical methods.

First, an initial redundant sensor network is deployed. Response is measured under typical ambient excitation, because the excitation characteristics are expected to affect the optimal sensor placement.

Once the measurements are available, the full-field response is estimated as described in the previous section. An updated FE model is essential to produce accurate mode shapes in the desired frequency band. Independent Gaussian noise of full value is added to each virtual sensor to represent the measurement error in the actual measurement chain. The full-field response is used in the OSP algorithm like it was measured with physical sensors.

The proposed optimal sensor placement algorithm is an iterative procedure starting with an initial large sensor network including all candidate DOFs (backward sequential sensor placement, or BSSP). A single sensor is removed and the cost function is evaluated for the reduced sensor network. This is repeated for different sensor networks of the same number of sensors by removing each sensor in turn. Finally, the minimum cost is found, and the corresponding reduced sensor network is selected. The

process is repeated until the desired number of sensors or the required minimum accuracy is reached.

For the OSP algorithm in the following, the actual time histories are not needed, because the MSE and consequently the cost function can be evaluated from the covariance matrices and the modal matrix. The procedure is as follows.

1 Obtain the data covariance matrix of all candidate DOFs (30)
2 Do until stopping criterion (number of sensors or minimum accuracy)
3 For each sensor j, do
4 Remove sensor j
5 Update the covariance matrix (6) and compute the precision matrix (7). Store the diagonals of the precision matrix.
6 Compute the weighting matrix **W** in (23), which is the inverse of the diagonal posterior covariance matrix
7 Compute the error variance of all virtual sensors (Equation 28)
8 Evaluate the cost function (e.g. the maximum error variance)
9 Next j. Go to item 4
10 Find the removed sensor k corresponding to the minimum cost function
11 Remove sensor k permanently
12 Update data covariance matrix by removing the row and column corresponding to the removed sensor
13 Go to item 2

4 NUMERICAL STUDY

A structure for experimental data was not available for the present study. Therefore, experiments were replaced with numerical simulations. In order to make the study more realistic, two different FE models were used with intentional discrepancies between the two models. The first model represented the real structure (Fig. 2) while the second model was the actual FE model used for the full-field response estimation (Fig. 3).

The structure was a bridge deck with four longitudinal stiffeners. The length was 40 m and width 15 m. The deck was made of concrete with Young's modulus of E = 40 GPa, Poisson ratio of ν = 0.15, density of ρ = 2500 kg/m^3, and thickness of 250 mm. The steel stiffeners (E = 207 GPa, of ν = 0.30, ρ = 7850 kg/m^3) had a web with a thickness of t = 16 mm and a height of h = 1.4 m. The bottom flange had a thickness of t = 50 mm and a width of b = 700 mm.

In both models, the deck was modelled with shell elements. The stiffeners in the actual bridge were modelled with shell elements (Fig. 2). In the second model, they were modelled with beam elements and connected to the deck using rigid links (Fig. 3). The beam elements were assumed to be symmetrical I-profiles, which caused additional discrepancy compared to the real structure.

The ends of the beams were simply supported (the nodes of the bottom flanges in the first model and the beam nodes in the second model). Longitudinal displacements were fixed only at one end of the bridge. The corners of the deck were supported in lateral and vertical directions.

Two independent random loads were applied at nodes 774 and 872 in vertical direction (green squares in Fig. 2). Both excitation signals were low-pass filtered below 5.33 Hz. The standard deviation of either load was 100 N. The excitation was not measured.

Vertical accelerations were measured at 28 points shown in Figure 2. Same amount of noise was added to the signals, so that the mean signal-to-noise ratio was SNR = 21 dB.

Using the physically measured 28 accelerations, the empirical Bayesian virtual sensors were estimated. Then the full-field accelerations (all vertical DOFs of the bridge deck) were estimated using the truncated modal matrix from the finite element model of the bridge (Fig. 3). Full-value noise was added to all virtual sensors.

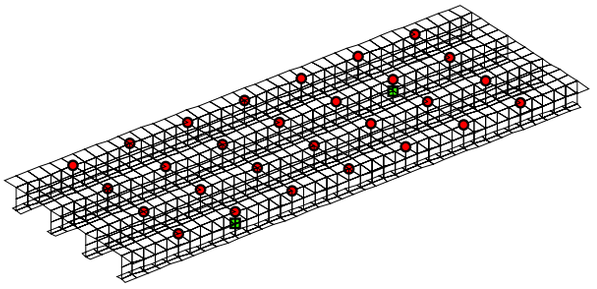

Figure 2. Finite element model representing the real structure. The initial 28 sensor positions are shown as red circles and the two excitation points as green squares.

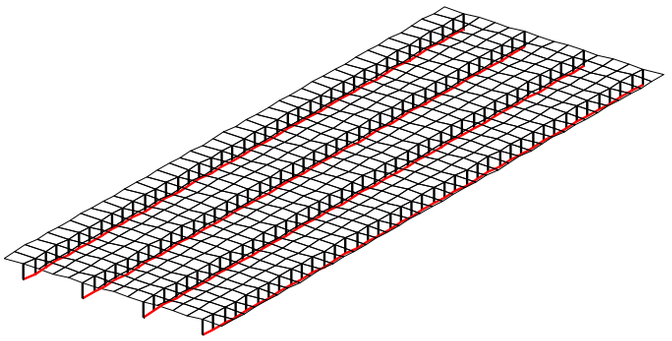

Figure 3. Finite element model of the bridge using shell and beam elements connected with rigid links.

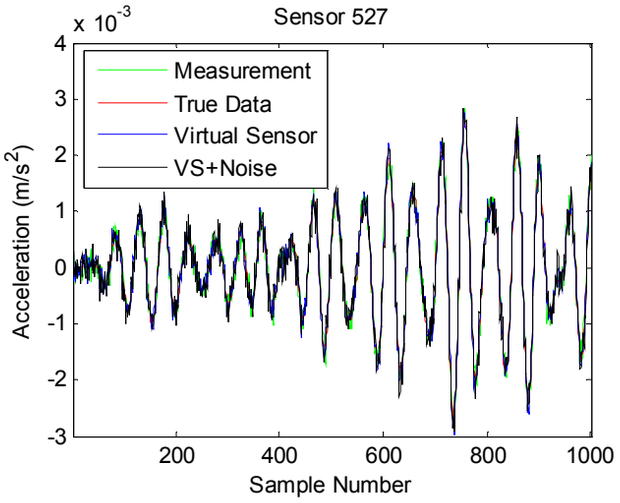

Figure 4. Time history of sensor 527. Red: true (noiseless) data. Blue: virtual sensor. Green: noisy measurement. Black: synthetic measurement (virtual sensor + noise).

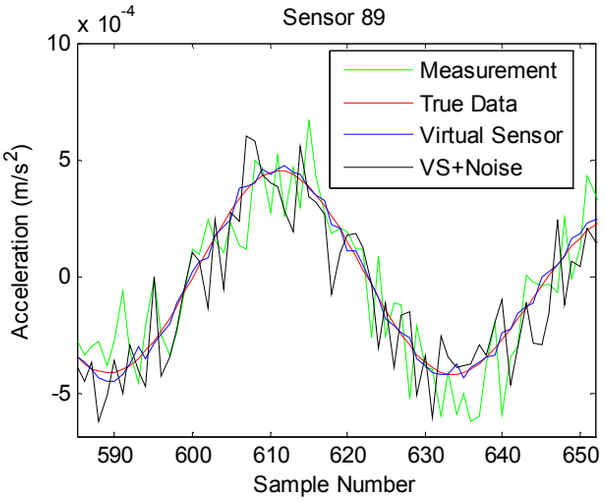

Figure 5. Detail of the time history of sensor 89. Red: true (noiseless) data. Blue: virtual sensor. Green: noisy measurement. Black: synthetic measurement (virtual sensor + noise).

A sample of virtual sensor 527 is plotted in Figure 4 and a detail of acceleration of virtual sensor 89 is shown Figure 5. The red curve is the noiseless true signal and green is the corresponding noisy measurement. The signals of the corresponding virtual sensors before and after noise addition are plotted in blue and black, respectively.

It can be seen that the virtual sensors closely corresponded to the actual signals and the noise levels in the actual and virtual sensors appear to be similar.

Once the full-field data were available, the next step was optimal sensor placement. In the present study, the objective was to minimize the error in the full-field response estimates using a minimum number of sensors. The cost function was the maximum standard deviation of the estimation error in the full-field virtual sensor data.

Starting with sensors at all 607 candidate positions (all vertical DOFs in the deck excluding the fixed DOFs) and removing one sensor in each round, the cost function was recorded and depicted in Figure 6. A comparison was made using the actual noisy measurements, and the corresponding cost function is shown in the same figure. The two data sets resulted in almost equal costs with a small number of sensors. In both cases, the cost function increased as the number of sensors was decreased, as expected.

Determining the number of sensors to be equal to 28, the optimal sensor positions are depicted in Figure 7 when using virtual sensors and in Figure 8 when using the actual measurements. The sensor positions were very similar in both cases. It can be seen that the sensors had a tendency to locate at six clusters. With this arrangement, the full-field data became most accurate.

A validation study was performed using a different realization of the random excitation. The excitation characteristics were the same. The standard deviations of the estimation errors of all virtual sensors were computed. Three sensor networks were analyzed: the two aforementioned optimal sensor networks and the initial equidistant network (Fig. 2). The errors are plotted in Figures 9–11 also showing the physical sensors. It can be seen that the optimal sensor placement was able to decrease the maximum error by almost 40% compared to the initial network with the same number of sensors. This demonstrates that designing the sensor positions can have an advantageous impact on the system performance.

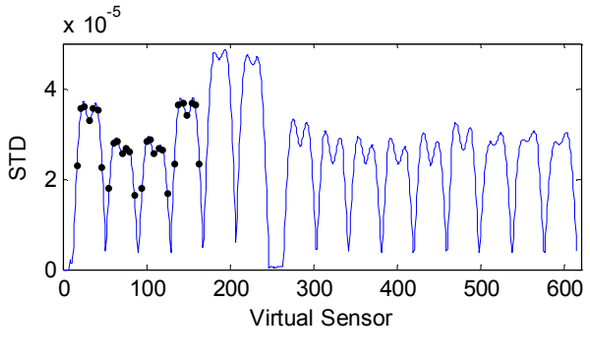

Figure 11. Standard deviations of the estimation errors in all virtual sensors using the initial sensor network in Figure 2 (shown with black dots) and a new realization of the excitation.

5 CONCLUSION

Optimal sensor placement was studied assuming algorithms that require sensor data from all candidate DOFs. Bayesian virtual sensing was applied to vibration measurements in order to obtain the full-field response data.

Because it is usually not possible to acquire measurements from all candidate positions, the response of the unmeasured DOFs has to be estimated. Simulating the response is another option, but since the excitation is unknown, the response may not be representative.

Full-field response data were estimated using Bayesian virtual sensing. The virtual sensors were less noisy than the corresponding hardware. Noise was added to all virtual sensors in order to simulate true measurements.

The finite element model must be accurate enough to represent the active mode shapes. Also, the number of sensors must be higher than the number of active modes to make the sensor network redundant.

Optimal sensor placement was studied for a bridge deck, in which the objective was to estimate the full-field response with desired accuracy. An iterative BSSP optimization algorithm was used, in which a single sensor was removed in each round from the initially fully occupied sensor network. The approach was to minimize the largest estimation error in the virtual sensors in each round.

In the proposed application, the actual time histories of the virtual sensors were not needed, because all necessary information was included in the statistical parameters. It should be noted, however, that the time histories could be computed whenever needed and the corresponding equations were derived.

In OSP, an engineering solution is often adequate. The sensor positions are sometimes guessed or located in an equidistant grid. The objective was to have a more sophisticated and cost-effective solution. Due to variable loading, there may not be an absolute optimum for the OSP problem. Nevertheless, data from a typical situation are preferred. In addition to loading, the finite element model includes modelling errors, the estimates of the sensor noise variances may be uncertain, and the BSSP algorithm may give a sub-optimal solution. Despite of these, it is believed that a good engineering solution can be found, which was also obtained in the numerical example. Experimental validation was left for a future study.

Potential of Drive-By Inspection for Railway Bridges

A. H. Eslami-Khouzani & C. Caprani
Department of Civil Engineering
Monash University, Melbourne, Australia

ABSTRACT: Drive-by bridge inspection (DBBI) is a promising indirect monitoring approach due to its potential advantages over direct bridge monitoring. These advantages include economy and accessibility: one moving vehicle can monitor many bridges, with just a few sensors; and it is easier to instrument a vehicle than a bridge. As a result of these attractive features, it is gaining increased attention from researchers. However, most of the research done on DBBI has been conducted on highway bridges only. The application of the approach to railway bridges is not yet known. This paper will identify the challenges that are unique to the drive-by inspection of railway bridges. Firstly, the physics of vehicle-bridge interaction (VBI) and train-track-bridge interaction (TTBI) is described, as these are fundamental to DBBI. Then, a review of the research already done for DBBI on highway bridges is presented. From this, the problems facing DBBI are identified. Some of these problems may not exist for railway bridges, while there may be some further complicating issues not present for highway bridges. Therefore, these issues are assessed using the different physics of VBI and TTBI. From this, the potential of DBBI for railway bridges is considered, and the relevant research challenges identified.

1 INTRODUCTION

Bridges are critical transportation assets which require frequent monitoring. Similar to many developed countries, more than 40 percent of bridges in Australia are over 40 years old. In this time their loading conditions have changed due to increases in freight and traffic volume, and so they require ongoing inspection and maintenance (RMS 2012).

Routine inspection methods of bridges are based on visual inspections and non-destructive periodic testing which are time-consuming and inefficient (Quirk et al. 2017). However, other inspection methods can be used to overcome the problem. Indirect approaches for structural health monitoring of bridges have gained more attention because of their time- and cost-saving potential. For example, the direct monitoring of a bridge's vibration requires the installation of many sensors and other supporting equipment. Contrast this with an indirect monitoring approach in which a sensor-equipped moving vehicle can monitor all bridges it crosses. The potential of determining the vibration response of bridges using this indirect monitoring approach was first confirmed by Yang et al. (2004). This approach has become known as drive-by bridge inspection (DBBI).

Most of the research so far on DBBI concentrates on highway bridges. This is curious because railway bridges typically have a much higher vehicle to bridge mass ratio, compared to highway bridges. As such, trains are well-suited to DBBI due to the strong vibrations that can be imparted. In principle, such vibrations of the bridge can then be used to monitor the health of the bridge. Further, due to the regularity of trains on many rail lines, knowledge of the bridge behaviour can be built up over time, allowing changes to be more easily detected. Nevertheless, in spite of these synergies, there are other factors that may reduce its suitability.

This paper examines the potential of DBBI for railway bridges. Parameters and physics related to indirect bridge monitoring are presented. A review of DBBI for highway bridges is then given, including a discussion of the problems facing it. Finally, challenges of DBBI for rail bridges are stated, and its potential for railway bridges is examined.

2 PHYSICAL PARAMETERS OF DBBI

The physical parameters important for DBBI of the combined vehicle-bridge system are considered next. The effects of these parameters on DBBI will be assessed in section 4.

2.1 *Vehicle parameters*

A railway vehicle generally consists of a car body, secondary suspension system, bogie, primary suspen-

sion system and wheelsets. Two rigid wheels coupled by an axle is called a wheelset, and is connected to the bogie frame by the primary suspension. The bogie frame and the car body are connected by the secondary suspension. In contrast to railway vehicles, there is no bogie or secondary suspension system in highway vehicles.

2.1.1 *Vehicle-to-bridge mass ratio*

During a vehicle traverse, the vehicle adds mass to the system altering its dynamic properties. Depending on the relative size of the vehicle-to-bridge mass, the effect can range from small to large. Yang et al. (2013) and Chang et al. (2014) both studied this effect finding that larger vehicle/bridge mass ratio leads to larger changes in the vehicle-bridge system frequency compared to the bridge alone. Compared to highway bridges, train mass is generally heavier than highway vehicles. This can cause noticeable deviations in the vehicle-bridge system frequencies. Therefore, it is clearly necessary to consider the effect of mass in TTBI to incorporate frequency variations during the traverse.

2.1.2 *Axle spacing*

For both road and rail, axle spacing is important to the response when coupled with vehicle speed and bridge natural frequency. If the time period between the successive axles of a train passing a bridge is an integer multiple of the period of one of the bridge natural frequencies, then a resonant response will occur. Then, subsequent axles enter the bridge in phase with the vibration, exacerbating the amplitudes.

The fundamental difference between rail and road bridges is the existence of repeated regular loads with identical axle spacing in trains which can lead to resonant behaviour in bridges at certain speeds. Even various combination of vehicles in highway bridges do not generate such resonance to the same range of railway bridges since the distance between vehicles is random (Cantero et al. 2016).

This phenomenon is readily found using simulations, where the model parameters can be precisely controlled. However in practice, it is far more difficult to observe, since the parameters tend to vary, e.g. vehicle speeds, bridge frequency, etc.

2.1.3 *Vehicle suspension*

Vehicle suspensions add damping to the dynamic system, increasing energy loss, and so reduce vibrations. Yu and Chan (2004) studied the effect of vehicle suspension system on the dynamic behaviour of bridges. They considered three types of suspension systems: a rigid connection to simulate vehicles without suspension; spring connections to simulate the leaf-spring system, and; pre-compressed springs to simulate an alternative form of the suspension system. They find that the suspension systems make an obvious impact on both the dynamic characteristics of vehicles and bridge response. In particular, the fundamental frequency of vehicles is significantly changed with different suspension systems.

2.1.4 *Vehicle/bridge energy transmission*

Although energy transmission from the vehicle body to bridge structure plays a key role in VBI systems, only a few studies have focused on the mechanism of energy transmission. In one of them the author examined three different kinds of wheels to investigate the resolution of bridge dynamic responses including (a) inflatable wheels with a diameter of 300 mm and a width of 85 mm, (b) Solid Rubber wheels with a diameter of 300 mm and a width of 50 mm, and (c) Polyurethane wheels with the same diameter, but a width of 70 mm. The last one is basically a metal wheel surrounded by a thin layer of 10 mm polyurethane. Considering these three different cases, Yang et al. (2013) recognised that the most favourable wheel to extract the bridge dynamic characteristics is the polyurethane one since it has very small and even distributions of frequency amplitudes with the least interfere with bridge frequencies. Consequently, it can be inferred that the train wheels are even more favourable types to measure the dynamic properties of bridges since they are effectively rigid wheels with direct contact to the rail surface.

2.2 *Driving Surface*

A road surface or pavement is usually made of materials such as asphalt or concrete laid on a compacted base course. The International Standards Organisation (ISO) classifies the roughness of road profiles into A (very good), B (good), C (average), D (poor) and E (very poor) (ISO 1995). Obviously, the rougher a road, the more a vehicle bounces (or vibrates) on it. Road roughness is measured using a power spectral density (PSD) function.

For railways, the driving surface consists of rails, fasteners, sleepers and ballast. Track irregularities are deviations in track profile from ideal geometry. There are two types of irregularities: periodic such as railhead corrugation, cross-beam and sleeper effects; and random irregularities which is also described using a PSD function. These irregularities increase the vibration of bridges and trains (Frỳba 1996). In contrast to roads, long periods of low-temperature influence the dynamic properties of the ballast and track due to ice formation in the ballast and frost in the ground (Gonzales et al. 2013).

In railways, transition zones from embankments to rigid structures such as bridges, also influence track properties. There is currently insufficient experimental data on the behaviour of such sections (Coelho et al. 2009). On the other hand, turnouts (including switches and crosses) provide flexibility to train movements. At these locations, train-track dynamic

interaction is more complicated than typical tracks since large disturbances occur as the wheels are transferred across lines in the switch panel or when the wheels pass the gap between wing rail and nose rail in the crossing panel (Kassa and Nielsen 2009).

2.3 *Measurement precision*

2.3.1 *Physical parameters*

Because of the dynamic interaction between the vehicle and the bridge, sensors mounted on the vehicle measure the combined vehicle and the bridge response as it passes the bridge. Accurate knowledge of the vehicle dynamic behaviour allows the bridge response component to be identified by somehow filtering out the vehicle response. Hence the dynamic characteristics of the bridge can be identified, at least in principle. Of course, in practice, there are many sources of noise and error that affect the problem.

The parameters that influence the measurement precision of bridge dynamic characteristics by DBBI have been investigated in the research already done. Consistently it is found that lower vehicle speeds and a bigger vehicle-to-bridge mass ratio both increase accuracy (Chen and Xia 2009). Other researchers considered the effect of road profile and found better accuracy for a smooth road profile (Chang et al. 2010, Yang et al. 2012). It seems that increased vehicle response through any means—low damping, low mass, rough pavement—may dominate the bridge responses.

In an experimental study by Yang et al. (2013), the influence of volumes of existing random traffic flow was considered. A four-span continuous bridge with a length of 113 m and a width of 17 m was studied. Continuous traffic flow with the speed of over 50 km/h was defined as a large volume and the reverse as a small volume. In the former, the first five bridge frequencies could be identified with high precision, while in latter only the first bridge natural frequency was identified with enough accuracy.

2.3.2 *Data acquisition*

One fundamental issue of DBBI relates to frequency spectrum estimation. The duration, T, of the recording is $T = L/v$ where L is the bridge length, and v the vehicle velocity (assumed constant). Regardless of the sampling rate, the smallest possible frequency, Δf, that can be distinguished for a full period of the recorded time series is

$$\Delta f = \frac{1}{T} = \frac{v}{L}. \tag{1}$$

Consequently, changes in frequency smaller than this amount cannot be found in the frequency spectrum. The relationship between the discernible frequency changes, bridge length, and vehicle velocity are apparent: slower speeds and longer bridges are better for detection of smaller frequency changes.

A few studies examine the influence of sampling frequency on indirect bridge monitoring. First, Lin and Yang (2005) derived the first natural frequency of a bridge using a passing vehicle with a sampling rate of 100 Hz and a record time of 200 s, while Cerda et al. (2014) mention an effective sampling rate is about 1650 Hz for a low speed of 10 to 30 km/hr. Chae et al. (2012) find that a sampling frequency more than 100 Hz is required to obtain clear peaks in the frequency domain for vibration measurements. In another study, Bu et al. (2006) examined a vehicle with a speed of 20 m/s and four sampling rates: 100, 200, 500 and 1000 Hz and observed that the sampling variation has a small effect on the accuracy of bridge frequency identification at this speed. As can be seen, so far the research findings on sample rate for DBBI are consistent with the simple analysis of equation 1.

3 REVIEW OF DBBI FOR HIGHWAY BRIDGES

In recent years, new methods have been presented based on indirect bridge monitoring. At first, the idea was mainly about identifying the fundamental frequency of the bridge. More recent research attempts to consider the bridge damping and mode shapes. These methods will be introduced and reviewed in this section.

3.1 *Frequency-based methods*

The feasibility of obtaining bridge frequencies using indirect monitoring has been confirmed both theoretically and experimentally. Frequency domain approaches are most prevalent for identification of the bridge frequency.

In an experimental study, Lin and Yang (2005) used a 1.4 t commercial truck as a tractor and exciter of the bridge, and a 0.65 t one as a trailer and receiver of the bridge's dynamic properties. The tractor-trailer system moves on a 6-span curved bridge with 30 m span lengths comprised of six prestressed I girders. The bridge fundamental frequency was found with high precision for speeds lower than 40 km/h from the response spectrum of the moving vehicle. They also find the existence of ongoing traffic to be advantageous since it increases the vehicle response. To have clear peak responses in the frequency spectrum, they recommend determining the vehicle dynamic properties and using lower speeds with increasing pavement roughness increases. In a follow-on investigation, Yang and Chang (2009b) used empirical mode decomposition (EMD) to find frequencies for higher modes of bridges. The theory was verified with experimental studies and again confirmed that ongoing traffic improves identification.

Other studies have examined the effects of other physical parameters—such as speed, mass, and vehicle suspension—on the identification of bridge frequency.

Using scaled laboratory moving vehicle experiments, Toshinami et al. (2010) and Kim et al. (2011), focused on short span bridges to identify the bridge frequency. For different speeds, they found that the spectral resolution of vehicle response for higher speeds is not as clear as for lower speeds (see equation (1)). However, the responses have higher magnitude spectral peaks at the bridge frequency. They also found that damping changes could be determined from a vehicle acceleration spectra.

Using both theoretical studies and full-scale experiments, Siringoringo and Fujino (2012) examine the impact of vehicle frequency and driving velocity on bridge response. Firstly, from a range of vehicle configurations, they found that the bridge frequency can be obtained using vehicles with different mass and suspension systems since the bridge frequency remains untouched (although its spectral amplitude varies). Secondly, they examined the bridge frequency for various speeds from 10 to 40 km/h.They found that the bridge frequency for speeds less than 30 km/h can be extracted clearly (see equation (1)). A full-scale experiment was performed on a 59 m span with steel-box simply-supported girders to verify the findings. They mounted an accelerometer on a light commercial vehicle and found that, as expected, increasing the speed beyond 30 km/h reduces the accuracy of bridge frequency estimation. This is found to be due to both higher wheel bouncing and shorter measurement durations.

In identifying the bridge frequency from a VBI event, regard must be paid to the frequency shift that occurs under the added vehicle mass. Yang et al. (2013) show that for a larger and smaller natural frequency of bridge (or vehicle) in relation to the other sub-system, the frequency changes in a convex and concave form respectively. The maximum change happens at mid-span. However, if the vehicle/mass ratio is lower than 1% (which is typical for highway vehicles and bridges), the frequency variation can be disregarded. In an interesting experimental investigation, Chang et al. (2014) used a truck with a weight of 250 kN moving on a simply-supported 62 m-span box girder bridge to study the effect of a parked vehicle on the bridge frequency. The parked truck had an 8.2% mass and 2.231 frequency ratio to the bridge. A 2.6% reduction in bridge frequency was found when the truck was parked in the middle of the span. A follow-up laboratory experiment found a 9% reduction in the system frequency, showing agreement between laboratory and field experiments.

Because the success of bridge frequency identification is strongly dependent on the clarity of its spectral peak, researchers have examined various filtering methods to improve accuracy. Yang et al. (2013) examine a band-pass filter (BPF) and singular spectrum analysis (SSA) finding that the best filtering technique is a combination of both. Malekjafarian and O'Brien (2014) used the Frequency Domain Decomposition (FDD) method. Compared to the Fast Fourier Transform (FFT), they found that when the bridge and vehicle frequencies are close, the FDD method is superior to plain FFT. In a different approach, Li et al. (2014) tried to obtain bridge parameters using an optimization method, the Generalized Pattern Search Algorithm (GPSA). The bridge first natural frequency and stiffness were found with an error of 3.3% in the presence of 10% signal-to-noise ratio. Finally, in a recent laboratory experimental study, Kim et al. (2017) used a tractor-trailer system with two trailers. The heavy tractor acted as an exciter to the bridge, and the spectral responses of the two trailers were subtracted from one another to remove the effect of road roughness, allowing clear identification of the bridge frequency.

It is clear from the review that there remain some practical issues to address to improve the accuracy of bridge frequency identification. These questions can be summarized as:

1. How to eliminate the effect of road roughness on the vehicle response?
2. How to overcome the bridge frequency changing during a passing vehicle in a VBI?
3. Which filtering technique gives the most clarity of bridge frequency in the response spectrum?

Overall though, it can be seen that the feasibility of bridge frequency extraction from a passing vehicle is confirmed theoretically and experimentally.

3.2 *Damping-based methods*

Even for simple problems, damping estimation is complex (Williams and Salawu 1997), and so for DBBI the difficulty of accurately determining the bridge damping is compounded by the complexity of the dynamic system. However, a few studies have attempted to use DBBI to identify bridge damping. In the main, the approach taken is to identify use the magnitude of the spectral peak at the bridge frequency to estimate its damping.

In a theoretical study, McGetrick et al. (2009) investigated the bridge natural frequency and damping behaviour using an instrumented moving vehicle. With increasing bridge damping, they find the PSD magnitude of bridge frequency peaks decreases. This result was confirmed in a laboratory experimental study (McGetrick et al. 2010) for three damping cases. It was found that by measuring the acceleration of the moving vehicle, damping alterations can be detected from the response spectrum. This was also confirmed in a separate experimental study (Kim et al. 2014). Keenahan et al. (2013) also tried to monitor bridge damping variations as an early warning for triggering an inspection. They studied both Rayleigh and hysteresis damping models using a tractor-trailer vehicle, finding that changes in damping can be detected by subtracting the accelerations of one axle

from the other. For bridge damping identification, González et al. (2012) propose a 6-step method using measured axle accelerations to estimate the road profile under each axle and finding the optimum bridge damping ratio that yields a single road profile. The method is found reasonably insensitive to many parameters, including a pothole. However, it has not been confirmed in a field experiment.

3.3 *Mode shape-based methods*

Bridge mode shape extraction is particularly useful for calibrating numerical models (Zhang et al. 2012). (Yang et al. 2014) point out that in contrast to the problem of frequency resolution (see equation (1)), DBBI offers an excellent spatial resolution, since the vehicle contacts the full length of the bridge. Indeed, they show that the amplitude history of the bridge frequency component of the response spectrum is proportional to the corresponding mode shape. This is also noted in (Feng and Feng 2016).

Some studies try to derive the bridge mode shapes using multiple vehicles and reduce the effect of road roughness by subtracting signals of similar axles. Oshima et al. (2014) considered two heavy trucks located before and after four monitoring vehicles moving at a constant velocity. The theory comprises:

1. Estimating road roughness and bridge displacement based on vehicle acceleration and the relative displacement between the mass and road surface.
2. Obtaining bridge displacement by subtracting one vehicle displacement from another one.
3. Converting the obtained displacement to a fixed coordinate by interpolating mode shapes using polynomial functions.
4. Estimating mode shapes based on fixed location deformations obtained in step 3.

They validated the theory by a VBI numerical simulation. Malekjafarian and OBrien (2014) also realised that the road roughness can be eliminated by subtracting signals of similar axles. They modelled two successive axles moving over a bridge, then applied the Short Time Frequency Domain Decomposition (STFDD) method to estimate bridge mode shapes based on the acceleration response of the passing vehicle. It was shown that bridge mode shapes can be extracted by a truck towing two trailers. In a complementary study, They enhanced the STFDD method to obtain mode shapes with higher accuracy (OBrien and Malekjafarian 2016). Malekjafarian and OBrien (2017) proposed the use of a mechanical exciter mounted on a trailer axle to produce excitation frequencies near the bridge first natural frequency. This was done to make the bridge frequency peaks clearer in the response spectrum. With a better peak, the Hilbert Huang Transform was used to estimate mode shapes with high resolution. The model was validated using a numerical simulation at a speed of just 2 m/s, although the authors admit that this low speed may not make it practical. Recently, (Kong et al. 2017) used a truck and two trailers in a field test on a three 16.7 m-span prestressed bridge. They simulated the truck-trailer system with two numerical models finding that multi degree-of-freedom models provide better results compared to the field results.

4 THE DBBI CHALLENGE FOR RAILWAY BRIDGES

Table 1 summarizes the key parameters affecting DBBI for train and highway bridges. As shown in the previous sections, some are common between both bridge types, and are already solved so are unlikely to pose a problem for railways. However, railway bridge DBBI has some particular issues. In this section, the key parameters of TTBI are surveyed to identify potential problems facing DDBI implementation for railway bridges.

4.1 *Resonant behaviour in railways*

For DBBI, the significance of resonance is that it will enhance bridge vibration, potentially leading to clearer spectral peaks. Resonance may occur in railway bridges due to regular axle spacing at certain speeds as it has been explained in section 2.1.2. It can also happen due to a matching between track irregularity wavelength and bridge frequency. In spite of the potential for resonance, there exist sources of noise that will reduce its effects, such as wheel defects and sleeper settlements as the train passes (Arvidsson and Karoumi 2014).

4.2 *Non-linear behaviour of the bridge*

Non-linear behaviour of both bridge frequency and damping occurs because of the track-ballast interaction. A few studies have examined this and found that the bridge natural frequency tends to decrease with vibration amplitude while bridge damping tends to increase with a non-linear behaviour (Ülker-Kaustell and Karoumi 2013, Battini and Ülker-Kaustell 2011). In addition, frequency changes of ballasted railway bridges occur, caused by seasonal effects on the stiffness. Gonzales et al. (2013) studied this issue and found that the main reason is ground frost and frozen ballast which can increase the bridge natural frequency by about 35% during winter.

Compared to DBBI for highway bridges, the extended sources of non-linear behaviour in railway brides compounds the difficulty of accurate identification of bridge dynamic properties.

Table 1: Parameters affecting DBBI for highway and railway bridges showing positive (+) and negative (-) influences

DBBI Parameter	Highway bridges	Railway bridges	Reference
Speed limit	✓(-)	✓(-)	Lin and Yang (2005)
Number of vehicle passages	✓(-)	✓(+)	Lin and Yang (2005)
Initial vehicle/bridge acceleration amplitude	✓(-)	✓(-)	Yang and Chang (2009a)
Noise	✓(-)	✓(-)	Li et al. (2014)
Vehicle-bridge mass ratio	✓(-)	✓(+)	Liu et al. (2009)
Vehicle-bridge frequency ratio	✓(-)	✓(-)	Museros and Alarcón (2002)
Ongoing traffic	✓(+)		Yang and Chang (2009b)
Road roughness	✓(-)		Oshima et al. (2014)
Resonant behaviour		✓(-)	Arvidsson and Karoumi (2014)
Freeze and frost		✓(-)	Gonzales et al. (2013)
Bridge-ballast interaction		✓(-)	Ülker-Kaustell and Karoumi (2013)
Wheel-rail contact		✓(-)	Zhai et al. (2013)
Transition zones		✓(-)	Namura and Suzuki (2007)
Turnouts		✓(-)	Kassa and Nielsen (2009)
Track irregularities		✓(-)	Zhang et al. (2010)

4.3 *Wheel-rail contact*

Ordinarily, TTBI modelling assumes that the wheel and rail are always in contact (Xia and Zhang 2005). However, in truth the displacement of bridge and wheel may not be the same, and a more detailed assumptions could be taken into consideration to reflect the real contact behaviour. Two common types of wheel-rail interaction modelling are Hertz and Kalker creep contact theories for normal and lateral contacts, respectively. However, there are some problems with these approaches, and the real behaviour of wheel and rail cannot be completely simulated (Zhang et al. 2008).

For DBBI application, the wheel-rail contact will add noise to the response of the system, when compared to a numerical model assuming perfect contact. However, compared with highway bridge wheel-road contact, it is considered that wheel-rail contact will be less noisy, and so better for railway DBBI.

4.4 *Vehicle-bridge mass*

Increasing non-linear behaviour of railway bridges has been found as the mass ratio changes from 0.1 to 3 (proportion of an eight-passenger car with two locomotives to a 34 m span length bridge) (Liu et al. 2009). Bogie-bridge mass ratio was also found to have a higher effect on dynamic responses of the bridge, than car body-bridge or wheel-bridge mass ratio.

For DBBI, the increased mass ratio means that railway bridges offer the potential for more accurate bridge characteristics identification, compared to highway bridges.

4.5 *Transition zones and turnouts*

Two other parameters to consider which do not exist in highway bridges are transitions zones and turnouts. Transition zones between the slab and ballasted track, or between bridge and embankment are sections with sudden changes in vertical stiffness. A few studies done on transition zones and recognised that wheel-rail load and accelerations increase abruptly, although its effect on bridge response is not studied yet (Namura and Suzuki 2007). Moreover, some researchers tried to model the train-turnout interaction to measure the wheel-rail contact force precisely. However, its impact on bridge response is not investigated as well (Kassa and Nielsen 2009). For railway DBBI, these aspects are likely to complicate the identification of bridge properties in practice by adding sources of noise to the system that are difficult to model numerically.

4.6 *Track irregularities*

Track irregularity has a strong influence on the train accelerations. Unlike, highways, there are four main types of irregularities to be considered in tracks including gauge, cant (superelevation), alignment, and vertical profile (elevation). Majka and Hartnett (2009) investigated the effect of random track irregularities on bridge dynamic response using a train-bridge interaction model. They observed that the influence of track irregularities on bridge vertical response is insignificant. However, train response is sensitive to them. Similarly, Du Kim et al. (2009) found that the wavelength of rail irregularity has a great influence on car-body acceleration and the relative displacement of wheelsets, but has a negligible impact on bridge vertical displacement. Using a combined Precise Integration Method (PIM)-Pseudo-Excitation Method (PEM) approach, Zhang et al. (2010) found random track irregularities have a great influence on the vertical random vibration of the whole system and rotational random vibrations of the double-track bridges. In a comparative study, Gu et al. (2010) examined the process of deterministic irregularities against stochastic ones for track irregularities in elevation. They showed that vertical displacement and dynamic impact load caused by deterministic irregu-

larities are more considerable than random irregularities, and proved it in a case study (Gu and Franklin 2010). In some of the most recent studies, researchers tried to construct precise stochastic models of track irregularities to investigate its effect on wheel/rail contact force (Panunzio et al. 2017, Xu and Zhai 2017). However, the influence of these models on the bridge response has not studied yet.

For DBBI of railway bridges, track irregularity excites the vehicle, improving the magnitude of acceleration responses, but adds to the spectral noise.

5 CONCLUSIONS

The key findings for DBBI are:

1. Low speeds (< 40 km/h) are needed for adequate spectral resolution.
2. Bridge excitation is improved with a heavy vehicle or by the presence of ongoing traffic, and gives better spectral visibility of the bridge. This is an advantage for railway bridges since trains are heavier than highway vehicles.
3. Spectral clarity of the bridge decreases with noise, and there are comparable sources of noise in both road and rail bridges.
4. Driving surface roughness is a significant source of noise.

Aspects of DBBI unique to railway bridges are:

1. Resonant response happens due to passing successive axle loads at certain speeds.
2. Freezing of ballast and frosting the ground causes variations in bridge responses.
3. Non-linear bridge behaviour due to the ballast.
4. Track irregularities, Wheel-rail contact, and wheel defects add significant noise to the system, and are not easily characterized.
5. Transition zones and turnouts increase wheel-rail loads influence dynamic responses.

The effect of these parameters on DBBI is not yet known. Nevertheless, as can be seen from the literature, the potential of drive-by inspection using instrumented vehicles is comparable between railway and highway bridges. Since DBBI is maturing for highway bridges, it seems that it is also well-suited to rail bridges. However, there remain unique challenges to overcome for successful DBBI on railway bridges.

Amirkabir University of Technology, 424 Hafez Ave, Tehran, Iran

ABSTRACT: Vibration-based methods for damage localizations often rely on a damage feature defined in terms of changes of modal or operational shapes. These methods allow detecting variations of the damage feature that can be ascribed to damage. Many of these methods are based on the detection of irregularities in the deformed shape of the structure. The accuracy of the methods proposed in literature is often verified on numerical models that, by their nature, cannot reproduce all the sources of uncertainties - environmental, operational, and experimental - that affect responses recorded of the structure. The availability of data recorded on real structures provides precious material for the verification of the real capabilities of the proposed damage identification algorithms. Due to several sources of uncertainty the values of the damage feature may undergo changes even in absence of any damage. This variability has to be properly accounted for in order to reduce the number of false or missing indications of damage. In this paper is investigated the influence of the uncertainties on the results provided by the Interpolation Method for damage localization. Specifically several different probabilistic models of the marginal probability of the damage feature are compared in order to verify select the one able to provide the highest accuracy in damage localization. The investigation is carried out with reference to the real case study of a prestressed concrete road bridge, the S101 Bridge in Austria. The bridge, built in the early 1960, is a typical example of a European highway bridge. Responses to ambient vibration have been recorded both in the undamaged and in several different damage scenarios artificially inflicted to the bridge. Damage was introduced by lowering one of the bridge piers and by cutting prestressing tendons of one beam of the bridge deck.

1 INTRODUCTION

The cost of maintaining bridge is a major part of the construction budget usually. Moreover if the inspection and monitoring system are not reliable, additional costs due to traffic delay will be added to the cost. Structural Health Monitoring (SHM) methods are one of the best tools for maintenance and inspection of structures that provide possibility of continuous inspection of the structure for damage detection in structural components. The general purpose of SHM is the rapid damage diagnosis of structure in order to ensure a proper safety level minimizing at the same time the maintenance costs. To achieve this goal the response of the structure has to be accurately recorded and robust algorithms for damage identification must be used to extract information from recorded data.

Non-destructive methods such as magnetic field methods, radiography, eddy-current methods, thermal field methods and acoustic or ultrasonic method are frequently used to inspect bridges. The main disadvantage of these techniques is that the location of damage must be known, why they are called a priori techniques. In the past few decades advances in sensors technology have significantly fostered the development of SHM methods and algorithms based on responses recorded by networks of sensors installed on the structure.

Vibration based methods are among the most effective tools for damage identification allowing to assess, at different levels of refinement, the structural health of structures equipped with a network of sensors. In reference Limongelli 2011 is presented the vibration-based Interpolation Method (IM) based on the detection of localized increases of curvature related to a reduction of stiffness.

This method has been extensively applied to the case of numerical models of bridges (Domaneschi et al, 2013 - Domaneschi et al, 2015) or using respons-

es recorded on a real bridge during a short monitoring carried out by impact tests (Limogelli et al 2014). An extended version of the IM has been proposed in reference (Limogelli et al 2017) based on a statistical modeling of the damage feature in the damaged configurations of the structure. The method was applied to the case of the prestressed bridge S101, artificially damaged with increasing levels of damage for research purposes (VCE, 2009; Sirigoringo et al., 2013). In reference (Limongelli et al, 2017) data recorded on the bridge in the several damaged configurations were used to check the capability of the proposed algorithm to localize damage.

Based on a previous applications of the IM on a multistory building (Limogelli et al 2014) a Lognormal probability distribution was assumed in (Limongelli et al, 2017) to model the damage feature in both the undamaged and the damaged configurations.

The validity of this assumption was not checked. Furthermore the statistical uncertainty connected with the limited amount of data available for a number of damaged configurations was not acknowledged. The damage localization algorithm was applied assuming as damage feature the Probability of Detection computed based on the conditional probability distribution. The latter, based on the available limited set of data data, was modelled as a lognormal distributions at all the instrumented locations.

In this paper, this statistical uncertainty will be accounted for by defining the damage feature as a function of the marginal probability distributions.

In the following of the paper the extended version of the Interpolation Method will be briefly outlined and the case study of the bridge S101 described. The second part of the paper reports the comparison of results related to different assumptions about the probability distribution of the damage feature.

The results provided by the IM depend on the choice of the threshold defined to select '*meaningful variations*' of the damage feature. This threshold is defined in terms of the accepted probability of the false alarm. An investigation on the sensitivity of results to this latter probability, for the different possible assumptions on the probability distributions of the damage feature is reported in the last part of the paper.

2 DAMAGE IDENTIFICATION

2.1. The Interpolation Error for damage localization

The Interpolation Method (IM) is based on the assumption of a beam-like behavior of the monitored structure and on the interpolation of the Operational Displacement Shapes (ODS) via a Cubic Spline function (Limongelli, 2011). Due to the so-called 'Gibbs phenomenon for splines' a localized discontinuity of curvature in the deformed shape of the structure causes strong oscillation of a cubic spline interpolating function at the location of the discontinuity. By defining the damage feature in terms of the interpolation error, an increase of this latter gives an indication of a variation of curvature therefore of a reduction of stiffness.

The method has been successfully applied for damage localization of bridges under seismic excitation or subjected to impact tests. In these cases the ODS can be computed form the Frequency Response Functions since the input is usually measured.

More details about these applications can be found in references (Limongelli, 2011; Domaneschi et al., 2014). When ambient vibrations or wind are used as a source of excitation, the input is unknown. In this case the Operational Deformed Shapes could still be estimated using on the Power Spectral Densities of the responses, assuming that the input is a white noise.

This assumption is widely applied in output only system identification (e.g. Brincker 2001, Peeters et al., 2001) and, even if it is not strictly verified over the entire frequency range, the PSDs give a good approximation of the deformed shape at different frequencies.

Under ambient vibrations the interpolation error can thus be defined as:

$$E(z,f_i)=\left[P_R(z,f_i)-P_S(z,f_i)\right] \quad (1)$$

being $P_R(z,f_i)$ and $P_S(z,f_i)$ the power spectral densities of the recorded (R) and interpolated (S) accelerations at location z and frequency f_i. 'Interpolated' means that are calculated from a cubic spline interpolation of the PDSs recorded at all the other instrumented locations.

In equation (1), the interpolation error depends on the considered ODS that is on the considered value of frequency. In order to characterize each location with a single error parameter, the norm of the error on the whole range of frequencies is considered:

$$E(z)=\sqrt{\sum_1^N E(z,f_i)^2} \quad (2)$$

The difference between the values of the interpolation error at a given location in two different configurations of the structure (reference and potentially damaged) or at two different moments of its life (beginning of monitoring and some-time afterward) should provide an indication about the existence of degradation at that location. Specifically an increase of the interpolation error should indicate the existence of an increase of curvature (decrease of stiffness) at the location where this variation occurs.

Due to several environmental (e.g. temperature or humidity) or operational (e.g. noise in recorded sensors, non-linear behavior of the structure, round off in signal processing) sources the values of the damage feature $E(z)$ may change even if there is no damage. In order to account for this, the statistical

variability of the interpolation error E has to be assessed. This issue will be addresses in the next section. Herein is reported the description of how the method is applied assuming known the statistical distributions of the damage feature in the undamaged and in the damaged configurations.

Herein we refer to damage as a stiffness loss at one section of the deck.

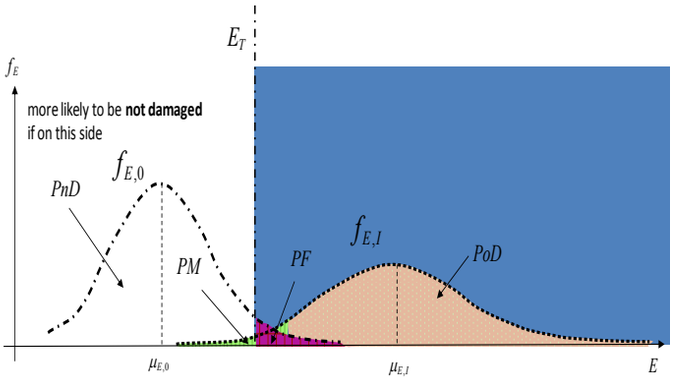

Figure 1. Distributions in the undamaged (J E,0) and in the inspection (*J E,I*) configurations

In Figure 1 the probability distribution of the interpolation error at one location z in the undamaged configuration $f_{E,0}$ is compared to the distribution in the inspection state $f_{E,I}$ assuming that the structure is damaged at z: damage induces a shift of the distribution toward a higher mean value of E.

In order to check the health of the structure, the distribution E_0 at each instrumented location z in the undamaged configuration has to be compared to the distribution E_I at the same location, calculated in the 'inspection phase'.

In order to compare the distributions pertaining to two different configurations, and also to select the locations where the highest variation of the damage feature occurs, will be utilized the Probability of Detection (PoD).

The PoD is the probability of damage being correctly denounced at location *z*, that is the probability that damage is denounced at *z* given the structure is damaged at z. The higher the PoD at location *z*, the higher the probability that location z is actually damaged.

In order to define this probability a threshold value has to be defined.

This PoD is given by the area under the probability distribution $f_{E,I}$ in the inspection (possibly damaged) phase, at the right of the threshold. For a given value of the threshold, the *PoD* at a given location increases with the severity of damage. Therefore the increase of the *PoD* at a given location will be assumed as an index of the increase of the severity of damage at that location.

Among all locations, the one corresponding to the highest value of the *PoD* will be assumed herein as the damaged one. The threshold E_T is defined herein in terms of the accepted probability of false alarm (PF) that is the probability that damage is denounced, given the structure is undamaged. This probability is given by the area under the probability distribution in the reference configuration $f_{E,0}$, at the right of the threshold.

The area under the distribution $f_{E,I}$, at the left of the threshold is the Probability of Missing alarm (PM) that is the probability that damage is not denounced, given damage exist at z.

The higher the threshold, the higher PM and the lower PF hence the choice of the threshold is always a tradeoff between the accepted probability of false and missing alarm.

In order avoid false alarms, a condition is imposed on the PoD based on the location of the mode of the damaged distribution with respect to the reference one. The mode of the distribution is the value corresponding to (one of) the maximum of the probability distribution

It is assumed that if the mode in the damaged configuration is higher with respect to the mode in the undamaged one, the location will be considered as 'damaged' and the corresponding PoD will be estimated as an index of the damage severity. If the mode is lower with respect to that in the undamaged configuration the location will be considered undamaged and the PoD will be assumed equal to zero.

2.2.Probabilistic model of the performance parameter

As described in the previous section, in order to account for the statistical variability of the damage feature its probability distribution has to be computed. This can be done using data recorded on the structure or using a numerical model. For the undamaged configuration the availability of recorded data is not an issue if a permanent monitoring system is installed on the structure.

For the damaged configurations of course this is not possible unless the structure is damaged and of course it would be never possible to dispose of responses corresponding to all the possible damage scenarios. The alternative could be a) the numerical modeling of the structure and of the possible damage scenarios or b) the probabilistic model of the damage feature.

The numerical modeling requires the model of the nonlinear behavior of the structure – for some type of structures this could be quite uncertain due to the many unknown involved in the problem – and of the environmental conditions – e.g. the temperature variation – that may alter the values of the damage feature irrespective of the damage state.

In some cases the numerical modeling could be not straightforward. The alternative probabilistic modeling presents other challenges but can possibly

exploit the knowledge of the structural behavior in the undamaged configuration.

The availability of data recorded on the S101 bridge provides an opportunity to check the modeling assumptions that could be made for a real case.

Specifically herein is reported an investigation relevant to the type of probability distribution that can be assumed for the damage feature in the damaged configurations. The aim is to verify the possibility to use the same distribution as in the undamaged configuration, just changing its parameters with the severity of damage.

In the next sections of the paper several different assumptions about the probability distribution of the Interpolation Error will be compared using data recorded on the S101 bridge to check the consistency of the assumption and the accuracy of results obtained.

3 THE CASE STUDY

3.1.The bridge S101

The S101 (see Figure 2) was a post-tensioned flyover of three spans for a total length of 56 m. In 2008 the bridge was demolished due to insufficient loading capacity and to allow the enlargement of underneath A1 Westautobahn. The bridge was supported on two couples of rectangular piers with a central span and the two side spans built in at the abutments. The structural cross section was a double webbed T-beams sustaining a slab with cross section of variable height with a minimum value of 20 centimeters at mid-span.

During the four days before its demolition, the Austrian bridge operator ASFINAG, owner of the bridge, allowed the execution of an experimental campaign of ambient vibration tests on artificially simulated damage scenarios. Ambient vibration tests were carried out between 10 and 13 December 2008. Progressive damage scenarios were artificially induced, simulating the settlement of a support by lowering one of the bridge piers and the loss of tension in the cables by progressively cutting a number of tendons.

A monitoring system, recording responses to ambient vibrations at several locations along the bridge deck in terms of accelerations, was installed by the Austrian company VCE, in order to provide a useful database for research purposes (VCE, 2009).

Responses of the bridge under the traffic in the underneath Westautobahn A1 were recorded by the network of three directional accelerometers throughout the three days of test.

Figure 2. The bridge S101: up) view; down) dimensions. From reference (VCE, 2009).

3.2.Simulated damage scenarios and network of sensors

The experimental campaign on the bridge can be divided into three phases corresponding to three different scenarios: 1) the initial (reference) configuration, 2) a support settlement, simulated through the cut of the north-western pier; 3) a loss of tension simulated by the cut of a number of tendons. In Table 1 is reported a summary of the sequence of tests on the several configurations of the bridge. More details of the tests sequence can be found in reference (VCE, 2009). In Phase 1 ambient vibrations were recorded in the undamaged configuration of the bridge.

In Phase 2, the pier was previously unloaded by applying a force on the bottom of the bridge slab with a hydraulic jack.

Table 1. Induced Damage scenarios

Scenario	Description of the scenario
U	Undamaged structure
A	Cut of the north-western column
B	First lowering the column (1cm)
C	Second lowering the column (2cm)
D	Third lowering the column (3cm)
E	Insertion of compensating plates
A_T	Column returned in original position
B_T	First tendon intersected
C_T	Second tendon intersected
D_T	Third tendon intersected
E_T	Fourth tendon partially intersected

Afterward the pier was cut at the base, near the foundation, and a slice of 10cm thickness was removed.

After the last reduction of pressure the pier underwent a total final settlement of 2.7cm. The lowering of the pier was carried out reducing the pressure in the jack in 3 steps. To simulate the repair of the pier, the initial configuration was restored by lifting the slab 6mm above the original level and inserting some compensating plates at the bottom of the pier. After the lifting, the closure of the cracks on the near pier was observed.

In Phase 3 the loss of tension in the cables was simulated by cutting an increasing number of tendons (see Table 1), in the same section of the deck corresponding to the pier previously cut (see Figure 2). During all the phases of test the bridge was instrumented with a dense network of sensors among which 15 tri-directional accelerometers along the bridge deck.

Due to the symmetry of the bridge, 14 sensors were deployed on the West side of the bridge to accurately capture its modal shapes and only one sensors (15) on the East side in order to differentiate torsional modes from flexural ones. The 15 sensors measured acceleration in the longitudinal, transversal and vertical directions, for a total of 45 signals for each test. In this paper only the results obtained by the analysis of the accelerations recorded in the vertical direction by the 14 sensors on the west side of the deck are reported. Accelerations were continuously sampled at 500 Hz during the three days of testing (10-13 December 2008). Data from each one of the damage scenarios (listed in Table1) were divided in several partial measurements corresponding to 5.5 minutes each.

4 DAMAGE IDENTIFICATION

The Interpolation Method outlined in section 2 has been applied to localize the several levels and types of induce damage based on the responses recorded by the network of 14 accelerometers installed on the west side of the bridge deck. For each response of 5.5 minutes duration (corresponding to 165.000 points at 500Hz sampling) the Power Spectral Density has been computed and used for the computation of the Interpolation Error according to equation (1). The entire set of data recorded throughout the three days of tests has been considered without any previous treatment or removal of portions of data.

4.1.Treatment of statistical uncertainties

Registration of responses of the bridge in the undamaged configuration was carried out for about 19 hours in the undamaged configuration (U) and for shorter times (between 1 and 5 hours) in the damaged configurations (A to E_T). Therefore, much more data are available for the reference configuration with respect to the damaged ones. Specifically, for the reference configuration, 152 samples of responses with duration 5.5 minutes are available while for the damaged configuration the total number of samples varies between 10 (for configuration E) to 85 (for configuration C_T). The distributions of the interpolation error obtained based on this sets of data are conditional to the particular considered sample that is to its mean and standard deviation: $f\left(E|\mu_E,\sigma_E\right)$. In reference (Limongelli et al., 2017) computations have been carried out with reference to the conditional probabilities $f\left(E|\mu_E,\sigma_E\right)$.

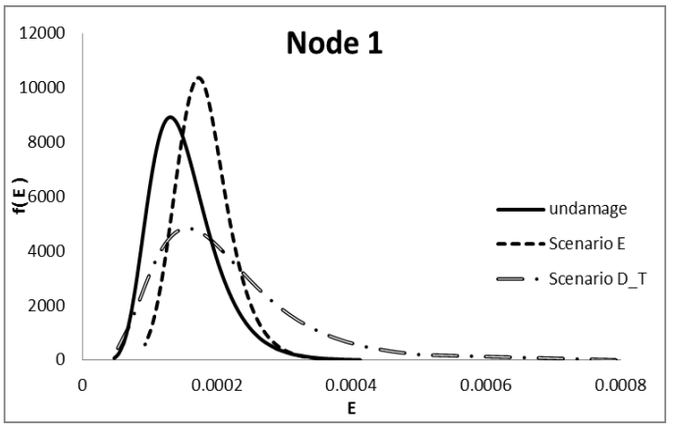
Herein the statistical uncertainty related to the limited number of samples will be taken into account by computing the marginal probability distribution $f\left(E\right)$ of the damage feature E through equation (3):

$$f\left(E\right)=\int_{-\infty}^{+\infty} f\left(E|\mu_E,\sigma_E\right)\cdot f\left(\mu_E\right)\cdot f\left(\sigma_E\right)d\mu_E d\sigma_E \qquad (3)$$

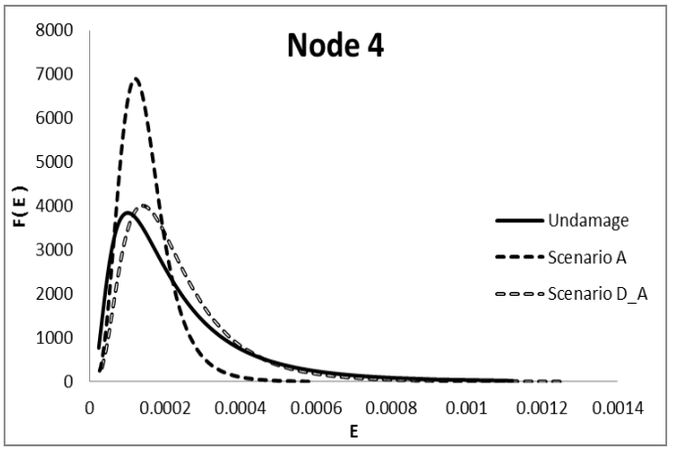
where μ_E and σ_E are the parameters of the probability distribution.

In order to retrieve the distributions $f\left(\mu_E\right)$ and $f\left(\sigma_E\right)$, a Monte Carlo simulation has been carried out assuming a normal shape of both distributions and generating a total number of 500 samples for each of the two distributions. Under these assumptions the integral in equation (3) has been numerically solved (Shampine, 2008) and a set of 150 samples of $f\left(E\right)$ has been generated.

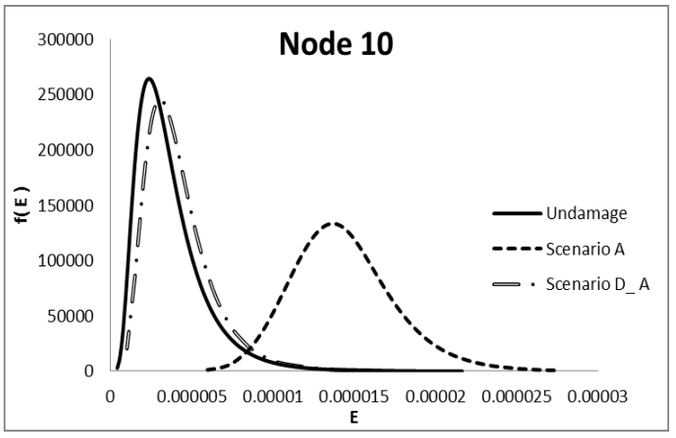
Figure 3 reports the marginal distributions (based on log-normal distribution) of the undamaged and damaged scenarios U, E and D_T. computed from equation (3) assuming a lognormal distribution for the conditional probability $f\left(E|\mu_E,\sigma_E\right)$.



In order to choose the appropriate probability density function for the marginal probability $f\left(E\right)$, several assumptions have been tested: gamma, lognormal and normal distributions.



The Kolmogorov-Smirnov has been carried out for the distributions relevant to all locations in order to check their accuracy. The test is based on a statistic (Stat) defined as the largest difference between the theoretical and the empirical cumulative distribution function. The critical value (Δ) depends on the size of the sample and on the level of significance of the test (Faber, 2012).



Based on these results the localization of damage has been performed assuming a lognormal model for the marginal probability $f\left(E\right)$. The Probability of Detection has been computed under this assumption and fixing the threshold in terms of a value of 1% for the accepted Probability of False alarm (PF).

Results (R) relevant to locations 11 and 12 are reported in Table 2 and show that for the modelling of $f\left(E\right)$ the log-normal and the gamma distributions have the highest accuracy with respect to all the oth-

ers. Similar results are obtained for the other sensors locations.

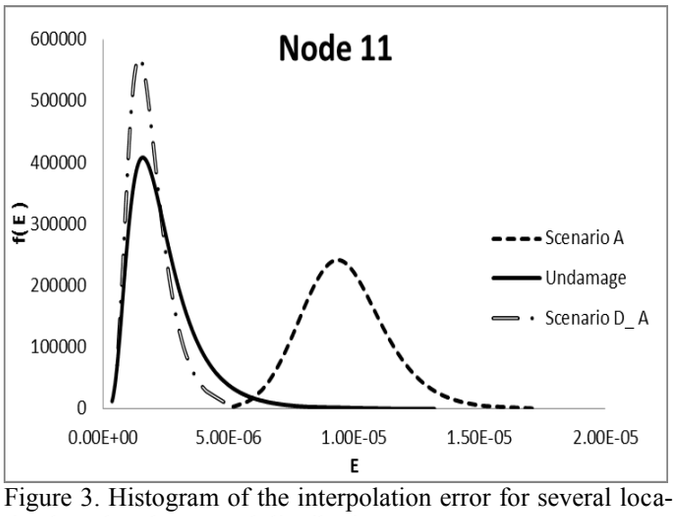


Figure 3. Histogram of the interpolation error for several location based on lognormal distribution

Table 2. Result of Kolmogorov-Smirnov test for nodes 11 and 12

		Log-normal		Gamma		Normal	
N	Δ	Stat	R	Stat	R	Stat	Res
11	0.072	0.025	**OK**	0.043	**OK**	0.092	**NO**
13	0.072	0.038	**OK**	0.058	**OK**	0.072	**NO**

4.2.Localization of damage

The location of the sensor number 11, is the closest to the lowered pier and to the beam section where the tendons were cut. This location is thus considered, for all scenarios, the damaged lone.

Figure 4 reports the values of the PoD at all the sensors locations (1 to 14) for scenarios A to E – corresponding to the lowering and following lifting of the pier.

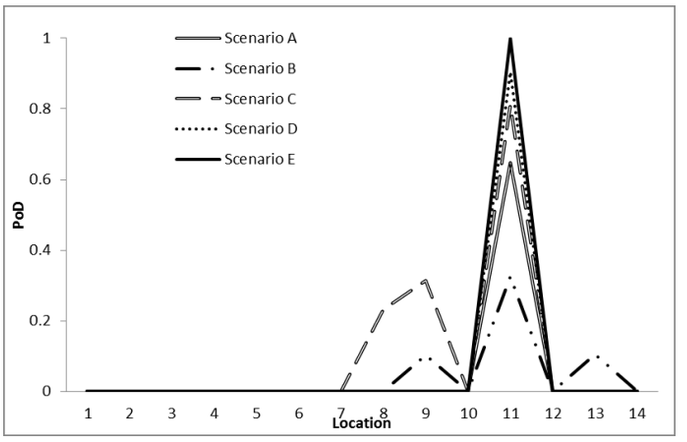

Figure 4. Probability of Detection based on the Log-normal distribution for $f(E)$ for damage scenarios A to E:

For all the scenarios related to the settlement of the pier (A to D) location 11 is correctly detected even if for the scenarios with the lowest amount of damage – A to C – some false alarms are present (see locations 8, 9, and 13). In scenario E the deck was lifted 6 cm over its original level. This certainly caused a variation of curvature even higher with respect to the one induced in scenario D by the lowering of the pier of 3cm. This is correctly detected by the method that finds the highest value of the PoD for scenario E.

The second damage scenario was induced by cutting a progressively increasing number of tendons at the top of one of the deck beams. This type of damage is not supposed to modify the stiffness of the structure thus no changes of the Operational Shapes were expected. This was actually confirmed by the results since no damage is detected for scenarios A_T to E_T.

5 INFLUENCE OF THE PROBABILISTIC MODEL

In this section will be investigated the influence

on the accuracy of damage localization, of the probabilistic model of the marginal probability $f(E)$.

Results similar to those reported in Figure 4 are obtained if the Gamma distribution is used to model the marginal probability $f(E)$.

In this second case the number of false alarms is slightly higher which is consistent with the lower quality of the fit indicated by the Kolmogorov-Smirnov test reported in section 4 (see Figure 5) .

The comparison of results obtained using different models for the marginal probability are reported Figure 6 for all the damage scenarios in terms of the PoD at location 11, the damaged one.

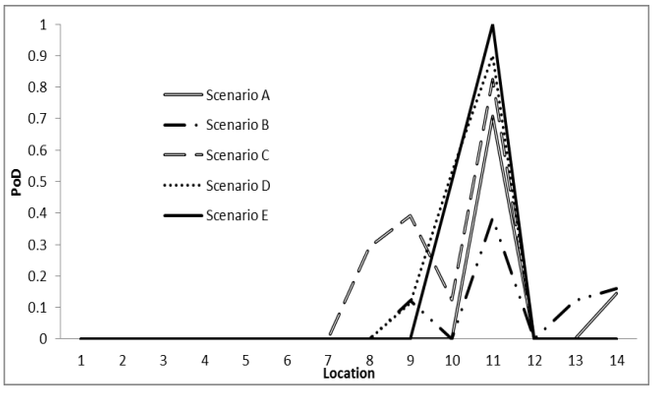

Figure 5. Probability of Detection based on the Gamma distribution for $f(E)$ for damage scenarios A to E:

At this location all the 3 models give reliable results indicating that the damage (represented by the PoD) increases starting from scenario B (1cm lowering of the pier) up to scenario E corresponding to the insertion of the compensating plates (lifting of 6cm over the original deck level).

As previously remarked the lifting of 6 cm over the original level certainly caused a variation of curvature even higher with respect to the one induced in scenario D by the lowering of the pier of 3cm. This is correctly detected by the method that finds the highest value of the PoD for scenario E. Starting from scenario A_T (the column is returned in its original position) and up to scenario E_T (the fourth tendon is partially cut) the PoD is always equal to zero, consistently with the expected behavior.

If other locations are considered the inaccuracy of the normal distribution with respect to the other two (lognormal and gamma) become more evident.

In Figure 7 are reported the values of the PoD at all the sensors locations for damage scenario E considering the three different probabilistic models. False alarms are found at locations 9 and 10 if the Normal distribution is used and a flase alarm is found at location 10 if the Gamma distribution is used. The most accurate results correspond the Lognormal model consistently with the results of the Kolmogorv-Smirnov test.

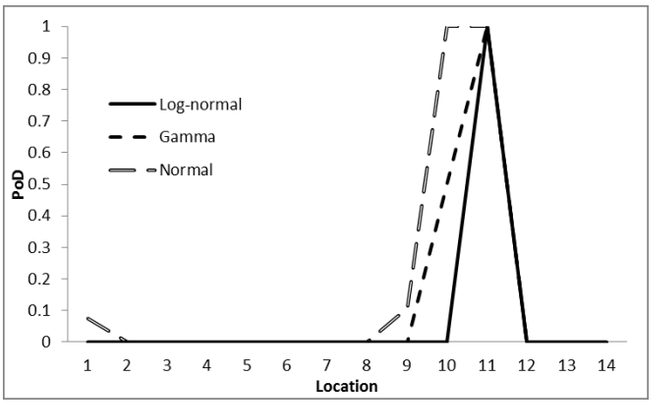

Figure 7. Comparison between the three probabilistic models for damage scenario E.

6 CONCLUSIONS

In this paper is investigated the influence of the probabilistic model of the marginal distribution of the Interpolation Error on the accuracy of damage localization.

Three distributions, Lognormal, Gamma and Normal have been considered and results compared in terms of the Probability of Detection. The latter is assumed as the damage feature.

The investigation has been carried out with reference to the case study of the S101m bridge for which data recorded in several damaged scenarios are available. The bridge was artificially damaged with several levels of severity and types of damage. The settlement of one pier and the loss of tension in the prestressing cables have been simulated by cutting respectively one of the piers and a number of tendons. Results show that the method is sensitive to the distribution chosen for the marginal probability. The Lognormal distribution - corresponding to the best-fit distribution according to Kolmogorov-Smirnov test – provides the most accurate results with the lowest number of false alarms with respect to the other tested distributions. The lognormal distribution corresponds to the best-fit both in the undamaged and in all the damaged distributions. This result is encouraging in the sense that, if confirmed

for other types of damage scenarios and structures, could enable to compute the distributions of the damage feature in the damaged configurations using the same probabilistic model of the undamaged configuration and changing the parameters based on the damage severity. As remarked, more investigations are needed to generalize this results and will be the object of further investigations together with the analyses of the sensitivity of results to the threshold value that is to the accepted probability of false alarm.

7 AKNOWLEDGEMENTS

The authors would like to thank the Vienna Consulting Engineers (VCE) company for providing the experimental data recorded during the tests on the S101 Bridge. The support of the Iranian ministry of science, research and technology (MSRT) to the stay of Amin Fathi at Politecnico di Milano is gratefully acknowledged.

Uncertainties reduction on modal parameters estimation in existing bridges using ambient and free-vibration tests

N. De Conto, F. Lorenzoni, F. da Porto, C. Modena
Department of Civil, Architectural and Environmental Engineering, University of Padova, Italy

ABSTRACT: The correct estimation of modal parameters has an important role in ensuring the structural reliability of existing bridges. Operational modal analysis provides rather accurate extraction of natural frequency and mode shape but the corresponding damping estimates are subjected to higher uncertainties. This paper reports the results of ambient and free-vibration tests performed on four different typologies of road and railway bridges: steel trusses, multi-girder reinforced concrete, masonry and reinforced concrete arch bridges. In one case data acquired by a continuous structural health monitoring (SHM) system over a period of one year are available. In another case the passage of trains is exploited to perform free decays. Several frequency and time domain identification techniques are used to process AVT, whereas measured free decays are analyzed by the logarithmic decrement method applied to the autocorrelation functions of the signals. Outcomes are compared, evaluating the quality of modal damping estimates and results accuracy.

1 INTRODUCTION

The correct estimate of modal parameters has an important role in ensuring the structural reliability of existing bridges. Experimental modal analysis is very helpful to estimate modal parameters especially for: (i) existing structures, for which it is difficult to find information about the structure characteristics; (ii) new structures, after construction, to evaluate whether the modal parameters projected at the design stage are correct and in case to implement solutions to reduce vibrations.

In recent years, ambient vibration tests are becoming increasingly important because of their practical and economical side, comparing to force vibration test (Andersen et.al. 1999, Omenzetter et.al 2013). Furthermore, data are collected during the normal use of the structure and consequently the identified modal parameters are associated with realistic vibration levels. This technique provides very accurate estimate of natural frequency and mode shape but corresponding damping estimates present a significant scatter. The variability on modal parameters extraction can be due to several issues such as: (i) the length of time histories acquired; (ii) ambient noises or errors in signal acquisition; (iii) the type of data processing; (iv) the environmental condition during tests. To this, we must add factors influenced by the structural typology such as: the friction mechanisms between different structural parts or molecular mechanisms between building materials. An important role in the damping estimation is carried out by signal processing method. In particular, it has been observed (Magalhães et al. 2010, Brownjohn et al. 2010) that similar natural frequencies and modal shapes are obtained using different identification techniques and processing approaches for the same time history. Otherwise, largest discrepancies are observed in the modal damping ratios. It has been seen how methods in the frequencies domain, and particularly the Enhanced Frequency Domain Decomposition EFDD (Brinker et al. 2010), which is very easy to use and requires a low computational cost, gives a good result for damping ratio if a high coupling is not present between the modes. On the other hand, time domain methods, especially the COV-SSI (Peeters & De Roeck 1999), give good results, with shorter time series, especially in the flexibles structures with closely spaced modes.

In this research, four different typologies of road and railway bridges (steel trusses, multi-girder reinforced concrete, masonry and reinforced concrete arch bridges) were tested using ambient excitations. In one case data acquired by a continuous structural health monitoring (SHM) system (Caldon et al. 2014) over a period of one year are available. In another case the passage of trains is exploited to perform free decays (Huang et al. 1999, Ülker-Kaustell et al. 2011).

The data processing is based on several state of the art identification algorithms, in time and frequency domain (Ewins, 1984). The application of

various algorithms is relevant to increase the confidence on the obtained results and to evaluate their advantages and drawbacks.

2 CASE STUDIES

2.1 *Case Study I - Multi-girder reinforced concrete bridge*

Ponte Nuovo del Popolo bridge (Fig. 1) is located in the city center of Verona, on the Adige river. It is a three-span arched reinforced concrete bridge with an outer coating made of stone.

Figure 1. View of the Ponte Nuovo Bridge in Verona

The bridge has a total length of 90.5 meters. The central arch has a span of 33.42 meters, while the two lateral ones are 25.23 meters long. The overall width of the deck is 14.32 meters. The structure supports a two-lane roadway, one for each direction, and two sidewalks. The top of the deck slab, made of RC, has a design thickness equal to 18 cm. The static scheme consists of seven main girders and eleven cross beams in the transverse direction with stiffening function. The seven girders and the slab, because of the bad maintenance over the years, reveal severe damage in the middle of the spans due to water percolation. Girders and cross beams concrete is highly deteriorated, moldy and carbonated (Fig. 2).

Figure 2. Damaged elements of the Ponte Nuovo Bridge

A monitoring system has been installed in order to evaluate the general behavior of the structure for the damage detection. The system is composed by six uniaxial acceleration sensors (acceleration transducers) (Fig. 3), sixteen linear potentiometers (displacement transducers) and seven strain gauges for reading the deformations. The dynamic monitoring system is configured to record acceleration time series at fixed time intervals, every 12 hours. Each time history acquired by the system has a length of 20 minute with a sampling frequency of 100 Hz.

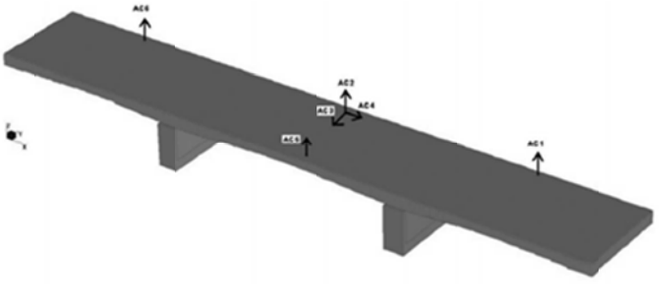

Figure 3. Sensor configuration of monitoring system of "Ponte Nuovo del Popolo" bridge

Thanks to the time histories acquired by the monitoring system, it was possible to evaluate how the type of data processing and the time length influence the estimation of the modal damping ratios. Two type of data processing have been considered: the EFDD and the SSI-UPC (Overschee & De Moor 1996). For each method, different parameters of the processing algorithms were considered as well as the length of time histories, varying between 3 and 20 minutes. In the case of the EFDD method, damping ratio estimates has a strong influence on time length and the number of points considered in the time segments used for the spectra calculation. This method was tested using 512, 1024 and 2048 points of the time segment. Figure 4, shows the results obtained with the EFDD method. It is possible to note that, if the number of point is not well chosen then the estimates can present high bias. For the analyzed case, there is a reduction in the damping estimation error if at least 1024 points and a minimum time length of 15 minutes are considered.

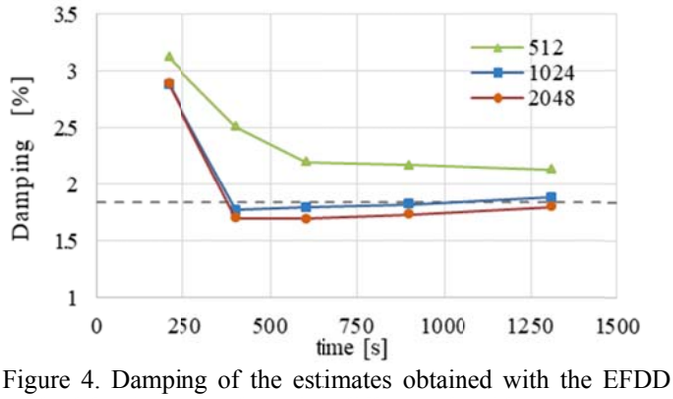

Figure 4. Damping of the estimates obtained with the EFDD method for the 1st modes using different algorithms parameters and different time lengths.

The parameter that has more relevant influence for the time domain method is the model order. The method was tested considering three different values of this parameter (80, 100, 150) and the same time length adopted in the previous method. Figure 5, presents results obtained by the SSI-UPC method. It

is clear that SSI method leads to good estimation using just 3 minutes of data and 150 point of the model order.

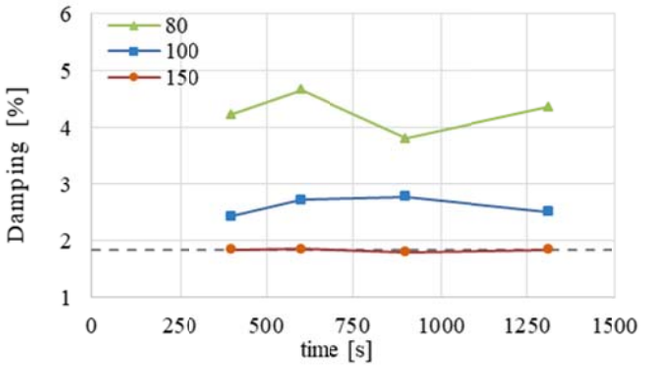

Figure 5. Damping of the estimates obtained with the SSI-UPC method for the 1st modes using different algorithms parameters and different time lengths.

The temporal evolution of the natural frequencies of the first seven vibration modes is presented in Figure 4. Each point of the graphs corresponds to a 12-hour average. The small blank spaces correspond to periods of system maintenance, for which no data is available. The high number of recordings acquired through the monitoring system allow to evaluate the presence of outliers and to evaluate dependencies of modal parameters with the environmental factors.

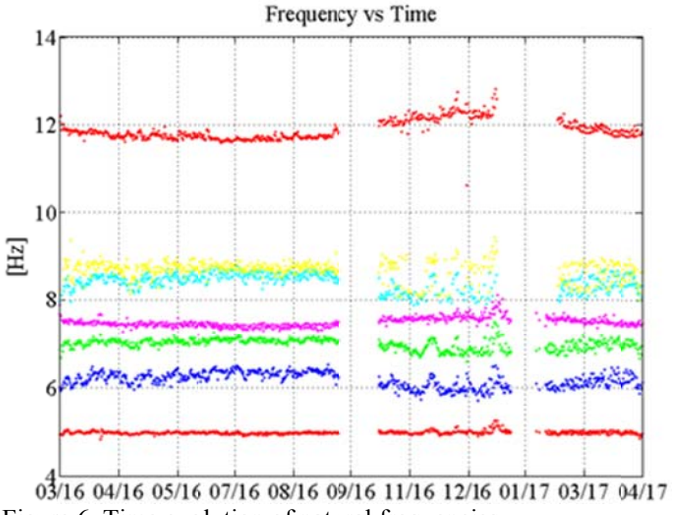

Figure 6. Time evolution of natural frequencies

Table 1. Modal Parameters

mode	$f_{[Min; Max]}$ [Hz]	f_{std} [Hz]	f_{CV} [%]	$\xi_{[Min; Max]}$ [%]	ξ_{std} [%]	ξ_{CV} [%]
1	[4.84 ; 5.24]	0.04	0.80	[0.60 ; 2.61]	0.30	22.72
2	[5.71 ; 6.53]	0.17	2.74	[0.81 ; 5.95]	0.68	15.81
3	[6.58 ; 7.50]	0.12	1.42	[1.08 ; 5.01]	0.65	19.36
4	[7.20 ; 8.12]	0.11	1.47	[0.43 ; 2.34]	0.36	25.17

The statistics of modal parameters extraction of the first four modes, are summarized in Table 1 where minimum, maximum, standard deviation and coefficient of variation (CV) of frequencies and damping values are presented. It is important to notice the significant difference between the standard deviation of frequency and damping ratio. Modal damping estimates present a higher scatter than the one observed in the natural frequencies, which is reflected in the CV.

2.2 *Case Study II – Steel bridges*

The Musile bridge (Fig. 7a) is located in Venice province along the railway line that connects Venice to Trieste. The steel trusses bridge was built in 1937 to cross Piave river.

It is composed by three spans of over 50m each. Every span is composed by double separate reticular structure equipped with diagonal roods and vertical supports that connect the two lower and upper beams. The structure is supported by masonry piers and abutments. Dynamic identification tests took place in September 2012.

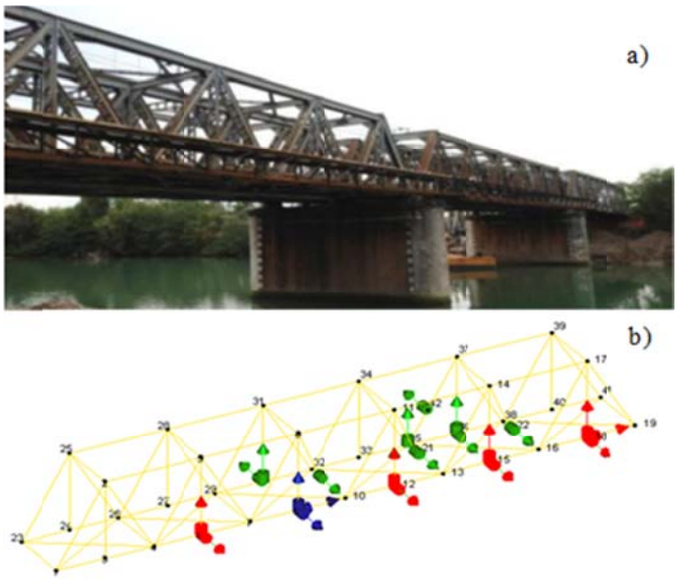

Figure 7. a) frontal view of the Musile bridge; b) sensor location and directions for all setups.

For the dynamic identification of the bridge 12 piezoelectric accelerometers were used, and placed in two different configurations (setups) for a total number of 11 measuring points in order to get the vibrations of the reticular trusses (Fig. 7b). The sensor records a signal of 1300 seconds long with a sampling frequency of 100 Hz. For both setup (Set1_MP and Set2_MP), during the acquisition time, a train passage was reordered. Modal parameters were extracted using time and frequency domain techniques. As a preliminary step the influence of the length of the time histories and the number of points considered in the time segments, used for the spectra calculation in the EFFD method, were evaluated. The time length of the output time series was modified from 350s to 660s. In the time series of 660s the passage of a train was recorded.

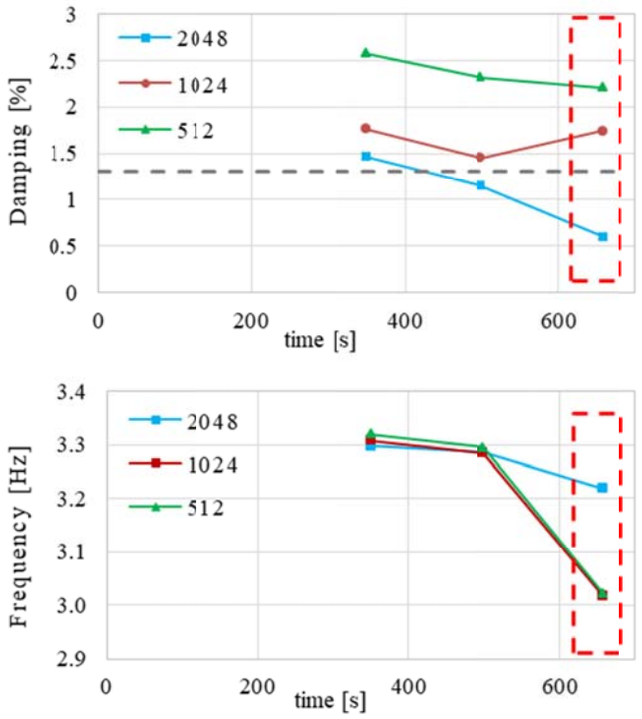

Figure 8. Damping and frequency obtained with the EFDD method for the 1 mode using different algorithms parameters and different time lengths.

Figure 8 shows the results. It is clear that, if in the recording of the time histories the hypothesis of white noise of the input are not satisfied (e.g. train transit, corresponding to the dashed rectangle in Figure 8) the estimates present several errors (both of frequency and damping). If trains are not considered (time length of 500s) the predicted outcomes with 1024 or 2048 points of the spectral density matrix converge to the same value.

For ambient vibration tests the modal parameters were estimated considering the time histories without the noise caused by train transits. Each time history was processed by the EFDD, SSI-COV and SSI-UPC methods. Thanks to the registration of the train passage, it was possible to perform a free vibration test (FVT). Natural frequencies and modal damping ratios of the bridge are identified by analyzing the free vibration response after the passage of a train. The methodology used to extract modal parameters consists of the following steps:

(i) isolate the part of the signal after the passage of the train (free decaying) and apply to the signal band-pass filters. Signal filtering is necessary to isolate contributions of the frequency of interest (Fig. 9a);

(ii) estimate the frequency applying the Fast Fourier Transform (FFT) algorithm;

(iii) calculate the autocorrelation function of the filtered signal of each accelerometer (Fig. 9b);

(iv) estimate the damping ratio applying the logarithmic decrement method to the autocorrelation function;

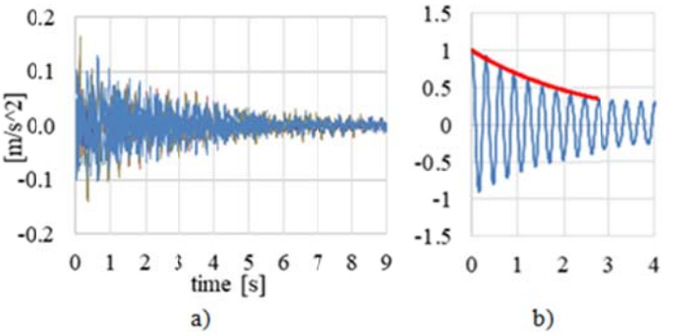

Figure 9. (a) Part of time history with free decays (b) Autocorrelation function for the time histories of one vertical accelerometers for the first setup.

Figure 10 summarizes the results of all used methodologies in term of frequency and modal damping ratio. The comparison between modal damping ratios, identified using FVT and ambient excitations, shows some differences. It is possible to note that the FVT allows to obtain excellent results, for frequencies and for damping, compared to ambient vibration test. This is due to the much higher level of vibrations. However, this type of methodology allows detecting just a few vibration modes. The estimated damping with AVT has higher standard deviation values with coefficients of variation of 70%.

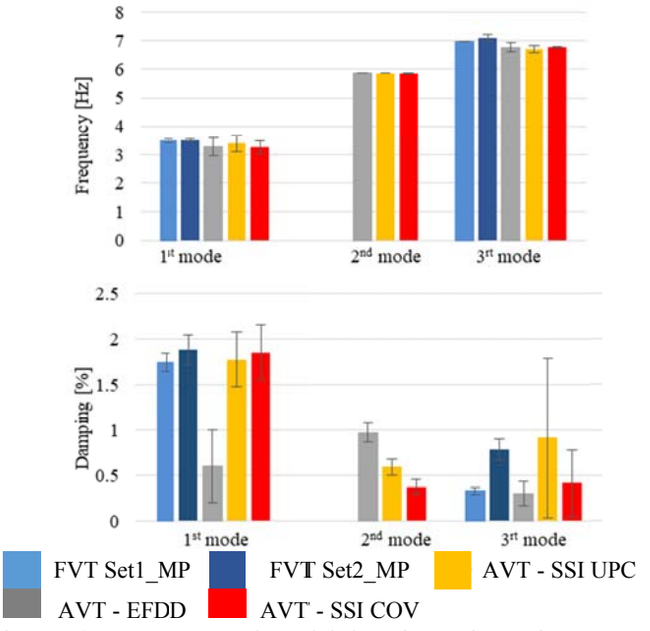

Figure 10. Frequency and modal damping ratios estimates provided the EFDD, SSI methods and free Vibration Technique.

2.3 *Case Study III – Masonry arch bridge*

The Gresal Bridge (Fig. 8) is located in the North-East of Italy, in Belluno province. It was built in the early XIX century and is currently used as a vehicular bridge. The structure is a three-span stone masonry arch bridge, with a total length of 67.40 m: the three spans are almost equal, the single arch clear length is about 15m; their shape is almost semi-circular with a radius of 7.39m, slightly increasing at the springers. The average thickness at the arch at

the key is 0.50m. The maximum height of the two piers is 12.75m and their section is rectangular.

Figure 11. View of the Gresal Bridge

During the month of March 2011, in collaboration with Veneto Strade S.p.A a dynamic identification test was carried out. To measure the response of the bridge eight piezoelectric accelerometers placed in three different configurations (setups) were used, one for every arch.

The structural response to ambient vibrations has been acquired for about eleven minutes with a sampling frequency of 100 Hz. During test execution, the bridge was not closed to traffic, which has been used as a natural load to excite the structure.

Time histories were processed with frequency (EFDD method) and time (SSI-UPC and SSI-COV method) domain methods. For the EFDD method it has been chosen to use a model with 2048 point and for the time domain method a model order n=170 for the SSI-UPC and n=100 for the SSI-COV. The bridge is rather massive and stiff and thus difficult to excite with ambient vibrations.

Figure 11 shows the results obtained in terms of natural frequencies and modal damping ratio. As expected, given the stiffness of the structure, high values of natural frequency are estimated. The results obtained with the three different methods are similar for the frequencies with low value of standard deviation (CV smaller than 3.5%). It was found a value of 4.96 Hz for the first mode, 8.29Hz for the second one and 10.41 Hz for the third one. Figure 13 shows the mode shapes for the first three vibration modes: the first one is a bending type in the transverse direction, the second one is a bending type in the longitudinal direction, while the third is torsional. Slight deviations are detected for damping but the predicted values have high level of standard deviations especially for the second and the third mode with CV greater than 100%.

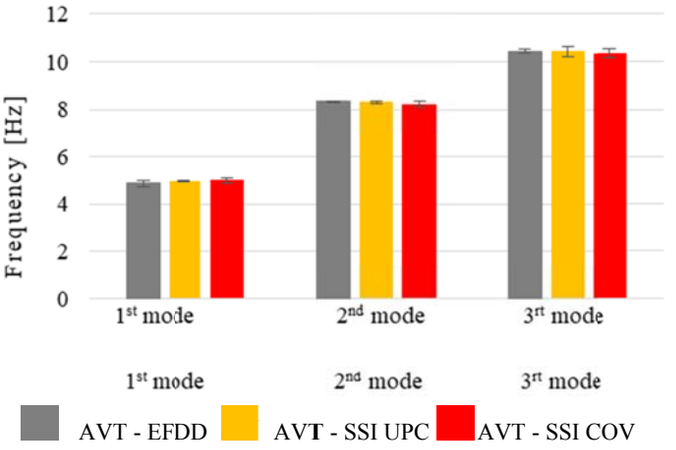

Figure 12. Frequency and modal damping ratios estimates provided the EFDD, SSI methods.

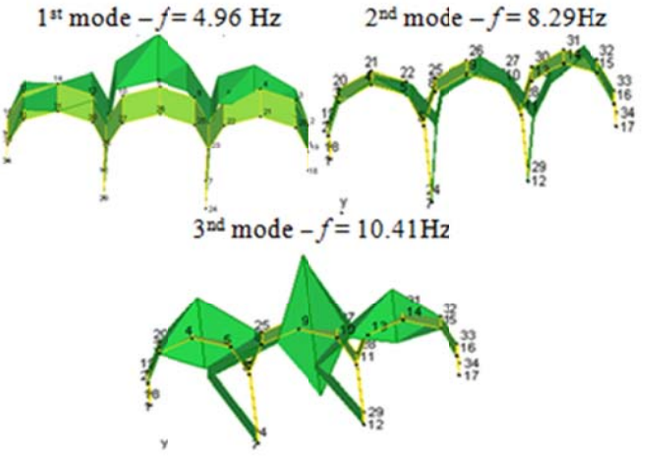

Figure 13. First three mode shapes for the Gresal Bridge.

2.4 *Case Study IV – Reinforced concrete arch bridges*

The bridge of St. Giustina is located in the Region of Trento (Italy) in front of the St. Giustina Dam. It is composed by a single arch span in reinforced concrete, with a total length of 68 m. The deck of the bridge is 9,00m wide for two traffic lanes and two sidewalks. The bridge is supported by two tapered arches (open spandrel arcs) linked together by several reinforced concrete beams. The height of the arch's section is 2,50m at the basis and 1,80m at the key. Along the length of the arch there are 16 vertical concrete columns that connect the arches with the slab, forming a rigid frame. All the columns are connected together with cross struts; the outer and higher columns are also transversally braced by X-shaped steel struts. The St. Giustina Bridge contains inside the concrete structure, the frame of the old steel bridge of St. Giustina erected in 1888. The old steel bridge was incorporated inside the new bridge in a reinforcement intervention in 1960.

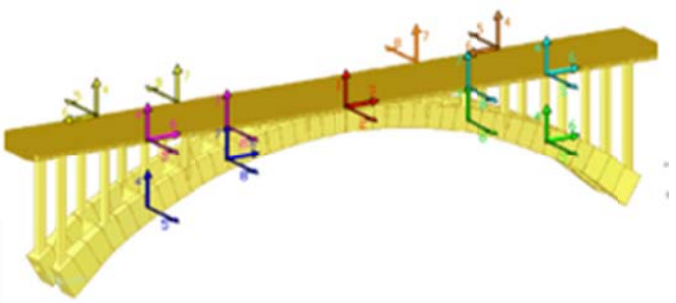

Figure 14. Sensor locations and directions of Santa Giustina Bridge.

In January 2010 ambient vibration tests were performed on the bridge to characterize its dynamic behavior. Tests lasted three day during which low temperatures were detected. Piezoelectric accelerometers with vertical axes were used to measure the bridge response. In order to obtain a good spatial resolution, eight different setups were used (Fig. 14). Three accelerometers were placed as reference sensors in the middle of the bridge and eight others were simultaneously moved to cover the entire area of the bridge. The structural response has been acquired for about eleven minutes with a sampling frequency of 100 Hz.

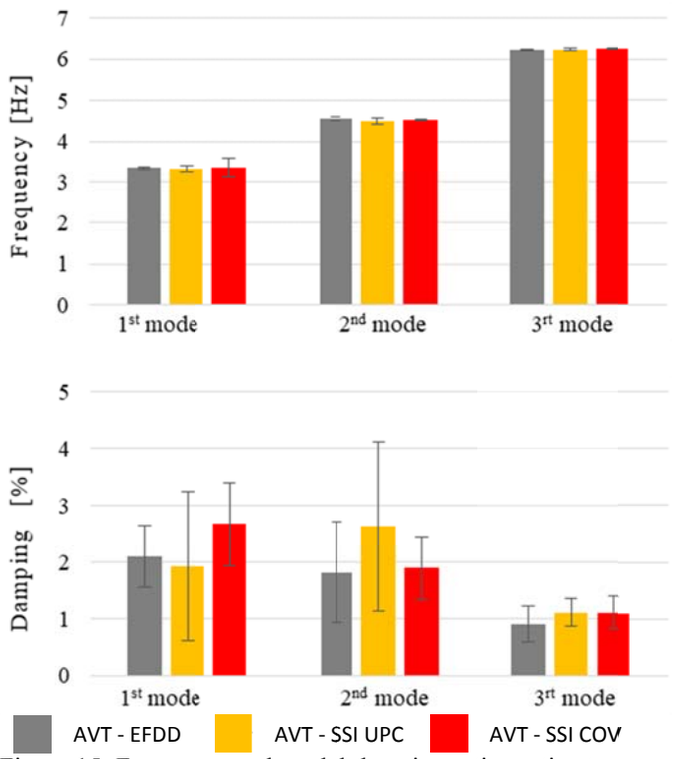

Figure 15. Frequency and modal damping ratios estimates provided the EFDD, SSI methods.

Time histories were processed with frequency (EFDD) and time (SSI-UPC and SSI-COV) domain methods. For the EFDD method it was chosen to use a model with 2048 point in the spectral analysis. A model order n=170 for the SSI-UPC and n=120 for the SSI-COV was considered sufficient for the correct definition of the signal. The results obtained with the three different methods are reported in Figure 15. The comparison between modal damping ratios identified using the three different identification algorithms shows some differences, especially for the first and second mode. However, all the values are within the interval of variation (defined by the standard deviation) presented for the AVT estimates.

3 COMPARISON OF THE RESULTS

In this paper, it has been analyzed the quality of estimates of the modal parameters. Table 2 shows the results for the four bridges analyzed. It is observed that every typology presents different behavior. For all structures, the algorithm used for the estimation of frequencies proved to be rather effective with low values of standard deviation (coefficient of variation CV from 0.3% to 8.5% for all modes). As expected, the modal damping estimate presents a much higher scatter with CV from 12% and 110% for the first two modes. In the end it is appropriate to compare the dynamic performance of the different structural typologies.

Steel bridges (ST) are very flexible and, as a consequence, easy to identify through ambient vibration tests. In the case of reticular steel bridges, due to symmetric geometry, just few sensors can get pretty accurate results. The principal modes (first transversal and second vertical) were identified using both time and frequency domain techniques that showed excellent results. AVT are not appropriate when the hypothesis of whiteness of the input are not satisfied (e.g. train transit). On the other hand, the passage of trains allows to perform FVT. In this case the results taken from the free decays are more accurate, because the noise influence is smaller (higher amplitudes).

Very susceptible to ambient vibration are also slender reinforced concrete arch (RCA) bridges. Indeed, like for the steel bridges, it was clearly simple to distinguish structural modes using basic techniques as PSD or FDD analysis because very clear and sharp peaks are identified. Despite these considerations, damping obtained has significant uncertainties with CV of standard deviation between 40% and 70%. This may be due to the use of relatively short time series (11 minute). Masonry arch (MA) bridge system identification encounters a challenging aspect. Damping estimates are characterized by the highest errors with a CV greater than 100%.

Multi-girder reinforced concrete (MGRC) bridges are rather easy to identify by ambient vibration tests. For the "Ponte Nuovo del Popolo" bridge a permanent SHM system was installed. Thanks to the available monitoring data over a period of one year it was possible to reduced drastically the uncertainties in the estimation of modal parameters (especially for damping ratios, resulting with a CV between 10% and 20%).

Table 2. Comparison of the frequency and damping ratio

	1st mode			2nd mode			3rd mode		
	f [Hz]	f_{std} [Hz]	f_{CV} [%]	f [Hz]	f_{std} [Hz]	f_{CV} [%]	f [Hz]	f_{std} [Hz]	f_{CV} [%]

4 CONCLUSIONS

This paper reports the results of ambient and free vibration tests performed on different bridge typologies to extract modal parameters and quantify the uncertainties in damping ratio estimation. It was observed that the extraction of this parameters is influenced by the structural typology, the length of the acquired time histories, type and parameters of the modal analysis algorithm. For railway bridges, it was noted that the train passage could bring to an unprecise estimation of frequency and damping due to the non-stationarity of the input signal.

It is possible to state that the extraction of natural frequencies and mode shapes are rather easy to identify using ambient vibration tests. Damping ratio presents higher uncertainties especially for stiff bridges and when the acquired time histories are too short. A permanent SHM proved to be very useful to reduce uncertainties of the estimates

ABSTRACT: Located at the shore of Geneva Lake, in Switzerland, the Chillon viaducts are two parallel structures consisted of post-tensioned concrete box girders, with a total length of 2 kilometers and 100m spans. Built in 1969, the bridges currently accommodate a traffic load of 50.000 vehicles per day, thereby holding a key role both in terms of historic value as well as socio-economic significance. Although several improvements have been carried out in the past two decades, recent inspections has demonstrated an alkali-aggregate reaction in the concrete deck slab reducing its strength. In order to strengthen the concrete deck and slow down further AAR, a layer of 40 mm of Ultra High Performance Fiber Reinforced cement-based Composite (UHPFRC) (incorporating rebars) was cast over the slabs, acting as a waterproof membrane and providing significant increase in resistance via the UHPFRC - RC composite action, in particular of the deck slab.
Two years after completing the works, a Structural Monitoring campaign was installed on the deck slab in one representative span, based on accelerometers, strain gauges, thermal and humidity sensors. This campaign seeks to reveal information on the behavior of UHPFRC-concrete composite systems, such as increase in stiffness, fatigue strength, durability and long-term performance. Consequently, the campaigns is expected to last for at least three years. A first insight of the analyzed results from the initial months of measurements is presented herein, along with future improvements or necessary changes on the deployment.

1 INTRODUCTION

The Chillon viaducts connect the Swiss region of Montreux and Villeneuve by means of two post tension concrete box girder structures, allocating a traffic load of 50.000 vehicles per day (Perret et al. 2014). With a length of 2 kilometers, divided in spans of 96, 98 and 104 m, these bridges along the shore of lake Leman stand not only as a critical item in the transport network, but also as a remarkable part of the cultural value of the region.

Since they were constructed in 1969, the bridges have been inspected and rehabilitated along the years, in order to maintain the safety levels in accordance with updated loads and codes. The last surveillance in 2014 revealed an Alkali-Silica Reaction (ASR) in an early stage, which motivated assessment of different solutions, both for strengthening the structure as well as diminishing the growing rate of the reaction. As established in Hobbs (1988), ARS is a combination of two phenomena: reactive aggregate and high humidity exposure. Currently, aggregates are selected carefully to avoid this type of issues, although for existing structures the only possible intervention involves minimizing the exposure of the section to water. Hence an ideal retrofitting method should serve as a waterproof membrane, while providing structural strength, as the ARS affects the concrete strength and its modulus of elasticity. In this context, an Ultra High Performance Fiber Reinforced cement-based Composite (UHPFRC) application on top of the existing deck was chosen as the most economical and convenient, based on numerous successful projects (Brühwiler & Denarié 2013, Martín-Sanz, Chatzi, & Brühwiler 2016). UHPFRC is characterized as an outstanding material for rehabilitation projects due to its exceptional mechanical and durability properties, low porosity and microcrak control. Furthermore, the works at each bridge were completed within a single month, rendering a short-term closure highly appreciated by the commuters (Bastien-Masse & Brühwiler 2015). Despite UHPFRC being used in past decades as a rehabilitation material, limited literature is available on the long term behavior for large scale projects.

Figure 1: View of Chillon viaducts at the shore of lake Geneva.

Taking into consideration the age of the bridges, the present structural damaged condition and the innovative solution used for their strengthening, a monitoring deployment was envisioned, aiming to render valuable information on the remaining lifespan of the viaducts. Structural Health Monitoring (SHM) techniques based on dynamic measurements are widely spread nowadays and can provide a non-invasive and convenient solution for bridge inspection and damage detection (Ko and Ni 2005, Brownjohn 2007). In this case, modal analysis will be combined with strain gauge measurements as well as temperature and humidity information, since it has been proven that the last two factors impose a variability in modal parameters, which can mask damage effects. Even though vibration-based methods have experienced a large improvement in recent years, with new sensors technologies and advances in automation, several drawbacks must still be overcome. Those shortcomings are related to a) lack of knowledge from the excitation source, as wind or traffic is usually not measured in Operation Modal Analysis (OMA), and b) the influence of environmental factors, as established by Peeters (2000). In order to assess the condition of the structures, these methods rely on changes on modal parameters, where a loss of stiffness indicates a possible damage scenario. Prediction of these events requires further analysis, since in reality, modal parameters are sensitive to several factors as well as deterioration. Starting by temperature effects, Kim, Park, & Lee (2007) observed that higher temperatures reduce modal frequencies, with more pronounced influence on flexural modes than on lateral ones. Watson & Rajapakse discovered that asphalt stiffness varies dramatically especially around the freezing point. Moreover, steel and concrete modules of elasticity are also considerably affected (Ubertini et al. 2017). However, further studies have shown that material properties are not the only factor that is altered. Taylor & Stanton (2010) echoed that friction coefficients for teflon bearings range between 3-5% at 25°C and 15% at -20 °C, and changes on support conditions shift the natural frequencies up to 50% (Alampalli 2000). Another modifying component pertains to the applied loads, including wind speed changes, which produce variations in structural dynamics (Cross et al. 2013), or heavy traffic in short span bridges, which varies structural mass and thus modal properties. In pursuance a method which differentiates ambient variability from damage, two main strategies have been followed: first, regression models, when the input is known and used to establish a relationship with the output (Wenzel 2009, Yuen and Kuok 2010) and second, pattern recognition methods, where imput is unknown and therefore Principle Component Analysis (PCA) is employed to obtain the representative components for the operational variations (Reynders & De Roeck 2014). Instead of PCA, AutoRegressive (AR) can be adopted, as demonstrated by Nandan and Singh (2011), or Polynomial Chaos Expansion (PCE) where the changes in environmental conditions can be described by stochastic propagation. In this paper, the latter will be applied following the works of Chatzi and Spiridonakos (Spiridonakos & Chatzi 2015; Spiridonakos, Chatzi, & Sudret 2016; Bogoevska, Spiridonakos, Chatzi, Dumova-Jovanoska, & Höffer 2017), where the method predicts the dynamic responses through meta-modelling. The structure of this paper is as follows: Firstly, the structural characteristics of the bridge are described, followed by a detailed explanation of monitoring implementation. Secondly, modal properties and strains are depicted, relating them with UHPFRC strengthening.The construction of a surrogate for the evolution of modal frequencies and strains, i.e., two quantities directly relating to the stiffness of the system, is described next, and finally concluding remarks are offered.

2 MONITORING DEPLOYMENT

2.1 *Structural description*

The viaducts of Chillon are two parallel structures with almost identical characteristics, constructed in the seventies by the same procedure. The box girder, comprising precast segments varying in height from

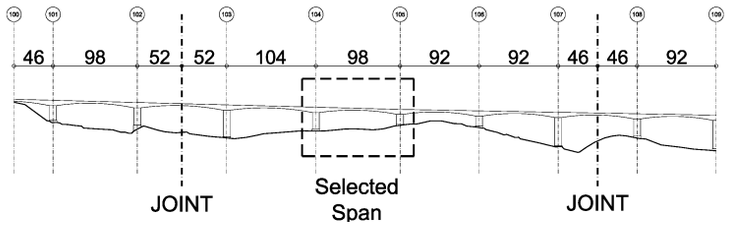

Figure 2: Selected monitored span.

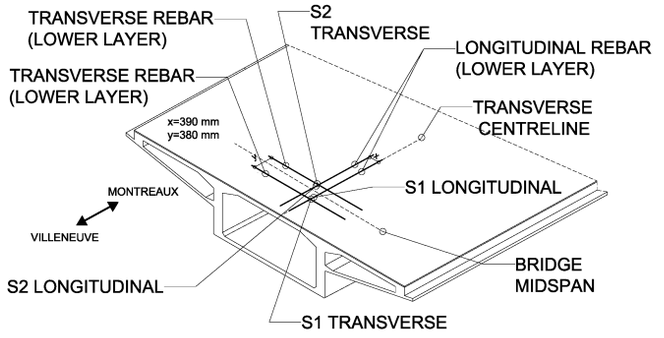

Figure 3: Bridge monitored sections and type of instrumentation.

5.2 to 2.2 m, was launched from the piers until midspan by means of a jacking frame and the interconnecting joints were concreted on site. Three different span lengths were included, in order to adjust the structure to the ground profile: 92, 98 or 104 m. The physical joints are located at the middle of the span, every five spans, creating a continuous deck over almost 500 m thanks to longitudinal prestress on the top section. In 2015, ARS was detected, leading to a strengthening campaign with UHPFRC. A layer of 40 mm with transverse reinforcement was applied, whereas on the supports, the thickness reached 50 mm to include additional longitudinal reinforcement up to 1/8 of the span. Eventually, the bottom zone of the supports was strengthened with conventional reinforced concrete.

2.2 *Monitoring deployment*

A primary objective of SHM lies in retrieving as much information as possible while using a limited number of sensors. In the case shown herein, it is not feasible to instrument both viaducts along the 2100 m they comprise. Therefore, a representative section is chosen, aiming to cover as many features as possible within the length of one span. The selected segment should gather the following characteristics: a) should be placed in the part of the viaduct closest to the lake (Viaduc du Lac), which is exposed to more wind and humidity, b) not be consecutive to the span with a cantilever joint, c) allow for a reasonable distance between power source and installation, d) maintain a straight profile to the extent possible. The span fulfilling the aforementioned requisites is number 5, with 98 m length and a non-symmetric shape (46m+52m) as depicted in Figure 2. The sensor placement is shown in Figures 4 and 5. In order to capture the mode shapes of the structure, eleven accelerometers built in ETH laboratory, are acquired by means of a GANTNER reading unit with 32 channels. Furthermore, three high precision accelerometers EPISENSOR type were used for a period of one month, in pursuance of a comparison between the custom and lower accuracy sensor and the higher precision (and higher cost) SED instrument. The latter were kindly offered by the Swiss Seismological Service institution for the purpose of this work. The environmental conditions were tracked by means of one humidity sensor and seven temperature sensors embedded in the concrete, located at the midspan of the bridge, on deck, walls and floor, to obtain a complete picture of temperature gradient inside the bridge. Finally, four strain gauges were installed as depicted in Figure 3, attached to the rebar. In order to limit the damage to the concrete structure to the absolute minimum, ground-penetrating radar techniques were deployed to display the reinforcement position and the cover concrete was locally removed. The cover is subsequently replaced again to ensure the protection of the steel. The latter sensors were connected to an HMB Data Acquisition System (DAQ), thus synchronization between both reading units (GANTNER and HBM) is required and relies on the PC clock to which they are connected. Datasets are stored every ten minutes, with a sampling frequency of 200Hz for the accelerometers, 100 Hz for the strains and 1Hz for environmental data.

3 MONITORING RESULTS

3.1 *Temperature and Humidity*

A common issue in SHM appears when part of the data is damaged or not completely recorded, due to power loss, program bugs or through the entry of dust particles inside the DAQs. In the case study shown herein, temperature, humidity and strains were missing over a period lasting 37 days (18th of March until 25th of May) and accelerations over 15 days (9th until 24th of May). In order to retrieve as much valid information as possible, humidity and temperature readings were collected from the nearest weather station, 8 kilometers from the viaducts at the same altitude. As the correlation between the bridge measurements and the station data results as adequate, the missing values were estimated by statistical methods. The procedure starts with first creating a Vector Autoregression (VAR) model, followed by the application of a Kalman filter, for the period where enough vibration data existed. The prediction provides accurate results, as observed in Figure 6, except at the point where vibration data is missing and therefore a jump on the expected trend is artificially created. Furthermore, despite the aforementioned correlation between variables, it is important to note the different behavior of each sensor depending on its location in the

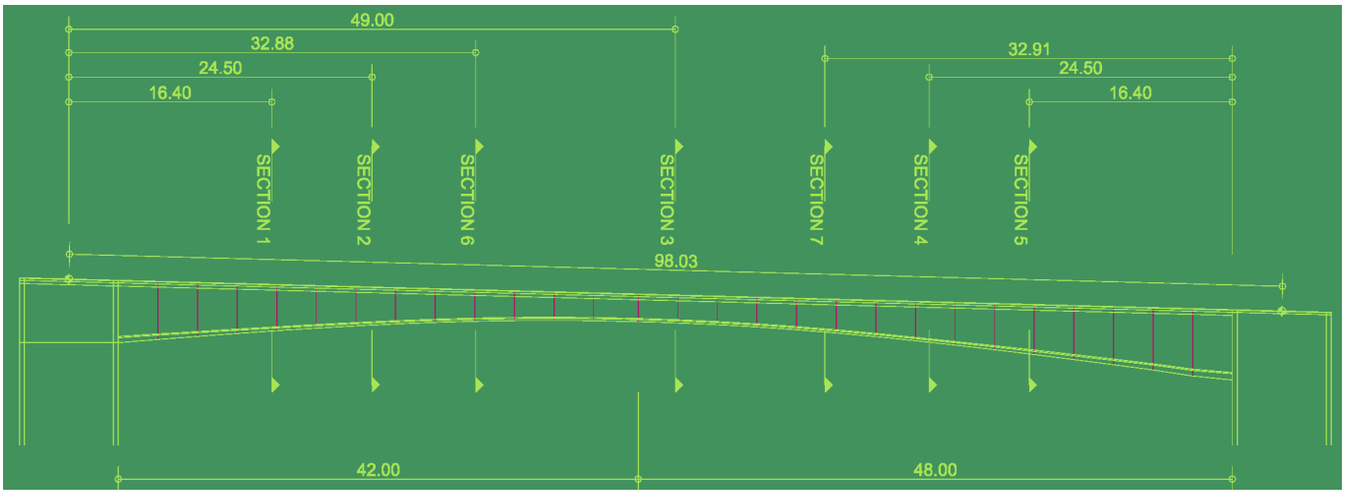

Figure 4: Viaduct instrumented segments

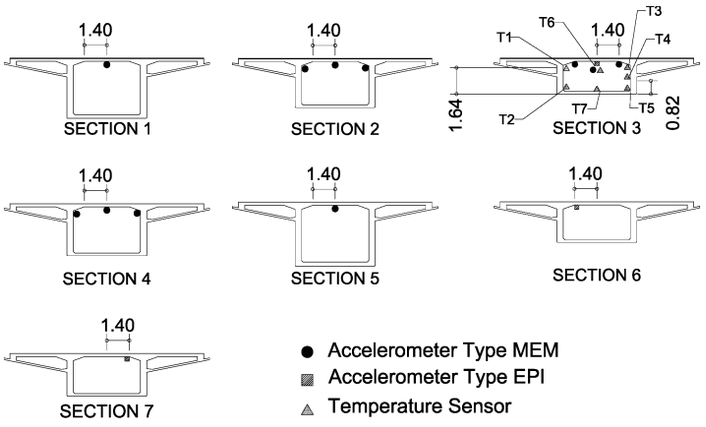

Figure 5: Sensor types and positions.

bridge. For example, sensors T6 and T7, positioned on the top and bottom deck respectively, present a trend very similar to the air temperature (with delay of four hours and a half, attributable to concrete thermal inertia), whereas sensors placed on the walls experience smoother temperature change with smaller amplitudes. Since the accelerometers are installed on the top deck, sensor T6 is taken as a reference for further analysis.

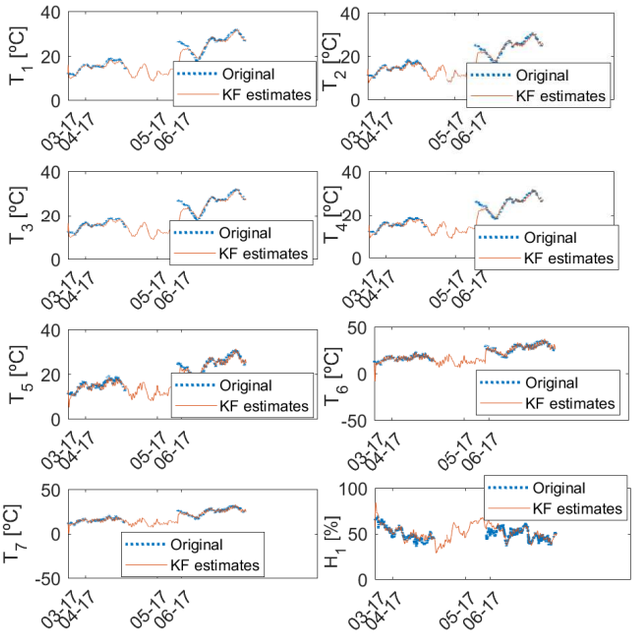

Figure 6: Estimated and original values from temperature and humidity sensors.

3.2 *Modal shapes and frequencies*

The reported period herein ranges from 24th of March to June 2017. In a previous campaign, a first evaluation of the acceleration data showed a low signal-to-noise ratio (SNR) due to grounding issues. This problem was remedied and, to confirm the validity of the data, three Episensors with high accuracy were installed and compared against the MEMs, revealing a good agreement between both systems (as observed in Figure 7). However, only the vertical channels are used for the analysis, ignoring at this stage the transverse ones, since the signal was not strong enough to obtain adequate results. The identification process to obtain the frequencies over time was achieved by contrasting several subspace methods, such as Stochastic Subspace Identification (SSI), Auto Regressive Ex-

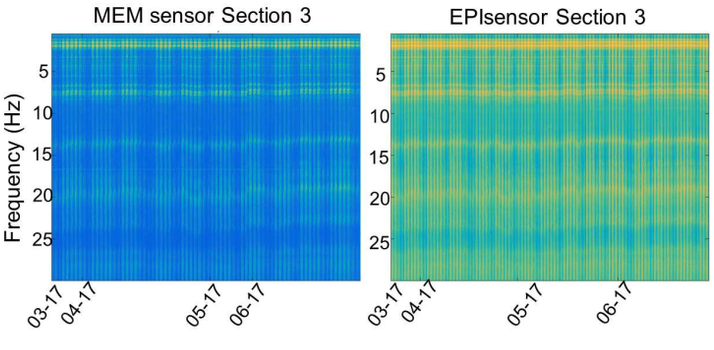

Figure 7: Frequencies over time from MEM sensor (left), Episensor (right).

ogenous model (ARX) and Eigensystem Realization Algorithm with Natural Excitation Technique (ERA NExT), using the built-in functions provided in MATLAB. Improved results were obtained with the latter, although a high order of the state space (120) was still required to capture more stable modes. Figure 8 depicts the need for model clustering, as a large number of modes appears in the range of 1 to 7 Hz and between 15 and 21 Hz. This process, based on Modal Assurance Criteria (MAC) and damping limited to 5% maximum, renders nine traceable modes along the three months of data. The identified modal shapes can be observed in Figure 9, along with frequency and damping in Table 1. Figures 10 and 11 present the evolution of the viaduct frequencies with respect to time and temperature during the analyzed period.

Table 1: Identified modes, damping and frequency.

	Frequency	Damping
Mode Number	Hz	%
Mode 1	1.175	0.012
Mode 3	1.547	0.015
Mode 5	1.904	0.011
Mode 13	3.700	0.006
Mode 21	5.628	0.021
Mode 23	6.732	0.009
Mode 28	7.824	0.003
Mode 31	13.954	0.014
Mode 32	16.694	0.001

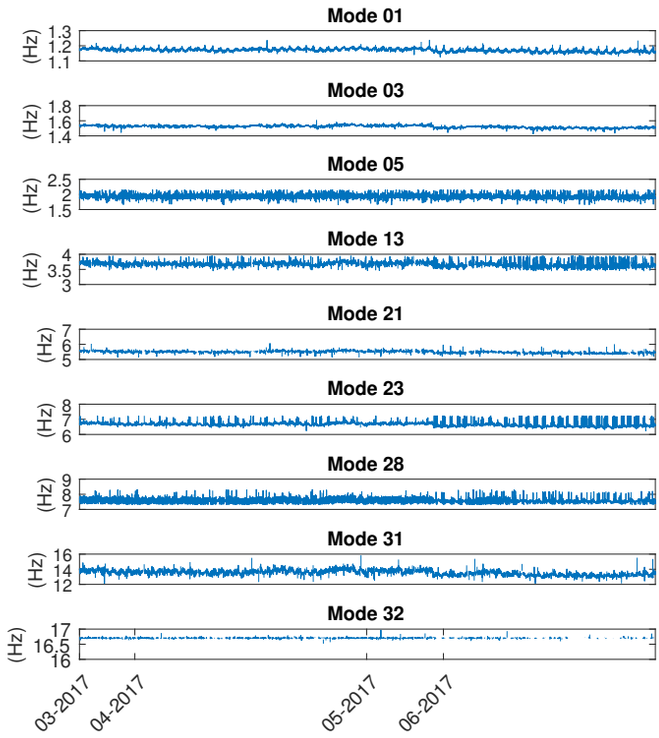

Figure 10: Frequencies evolution for the first nine modes over time.

4 MODAL UPDATE

As stated above, environmental changes can affect modal parameters and mask the effects of damage. In the case presented herein, a frequency shift can be observed due to temperature changes, more pronounced in modes 3, 21 and 31 than in the others, whereas variations in humidity bear a smaller impact. The field data indicates that the relationship between temperature and natural frequencies is inversely linear, decreasing the latter when the former rises. Although these results are in line with several examples found in the literature ((Cury, Cremona, & Dumoulin 2012), (Moser & Moaveni 2011)), a Finite Element Model has been developed, searching for validation of this results. To this end, the model tries first to match the conditions presented at the minimum temperature and then change the parameters most affected by the 30°C variation, to retrieve the final results. Following the work of Taylor & Stanton (2010), the bearing friction coefficient must be first reduced around 2,5% to account for an increase of temperature of 30°C. Secondly, the asphalt and concrete Elastic modulus were as well diminished, according to Lytton et al. (1993) and Fernando et al. (1993), respectively. Both references show a variance in the results depending on the type of aggregates, curing methods as well as applied loads, which render a range of values implemented on the FEM model through an iterative process. Finally, with regards to what UHPFRC is concerned, limited literature can be found on thermal dependent properties at environmental temperatures. In the BETON-FIB bulletin it was established that drying shrinkage is very low due mostly to the low poros-

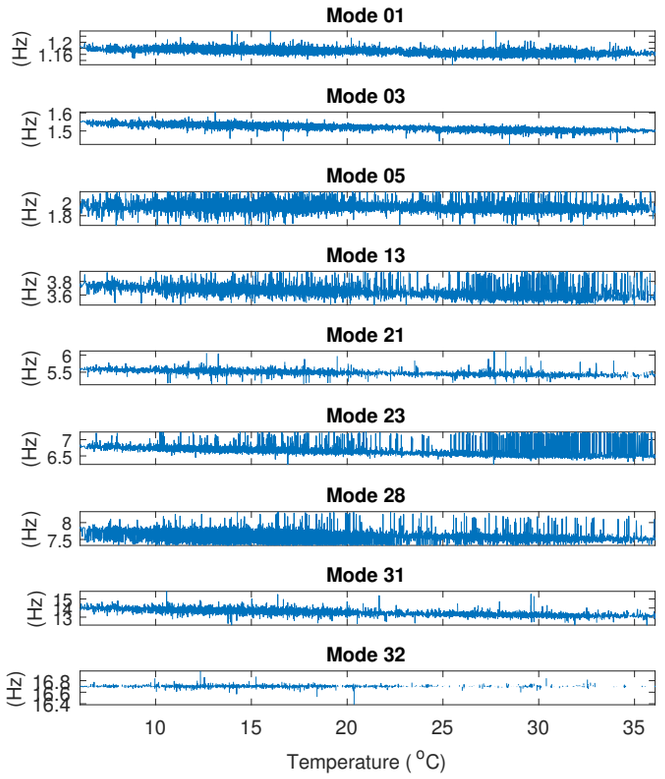

Figure 11: Frequencies evolution for the first nine modes over temperature.

ity of the material, whereas autogeneous shrinkage is large and may reach values higher than 1.2μm/mm. In terms of tensile creep, Garas, Kurtis, & Kahn (2012) demonstrated that microracking and porosity directly affect the behavior of this parameter, although heat treated UHPFRC shows a smaller compressive creep coefficient. Moreover, Dehn (2004) observed that hydrothermal reactions start to appear above 100 °C. With the aforementioned information in hand, and taking into consideration that the temperature variation reaches only 30°C, the E modulus of UHPFRC was left unchanged. At this point, it is important to note that the model exhibits a high sensitivity to friction coefficients at the bearings, noticed when the first matching process was performed. To this end, in the second round of model updating, the coefficient was changed only in a tight range in order to avoid fictitious results. Once a good agreement is achieved between the frequencies at maximum and minimum temperature for FE model and Chillon bridge, the bespoken parameters are modified following a linear law, obtaining Figure12 which can be compared to Figure11. The associated parameters for each temperature increment are displayed in Table 2. Although modes 5, 28 and 32 are not displayed, as the variation with temperature is almost imperceptible. Nevertheless, the remaining modes present a good agreement between FE model and reality, both at initial and final stage, proving the influence of environmental factors over the structure.

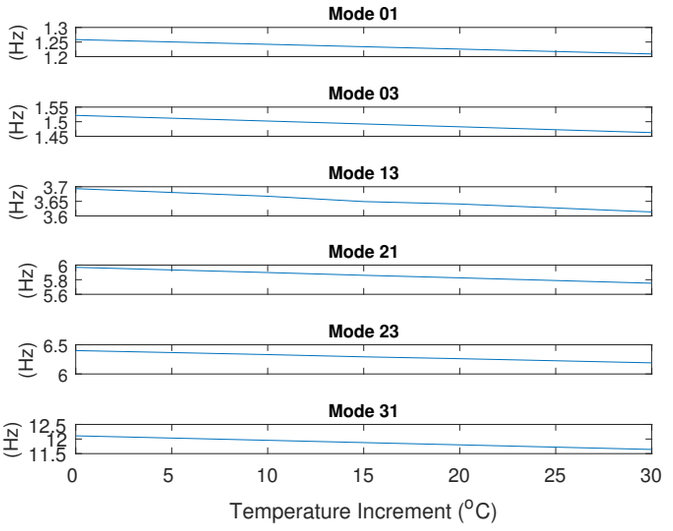

Figure 12: Frequencies evolution versus increment of temperature, obtained with FEM model.

5 STRUCTURAL IDENTIFICATION FRAMEWORK

The main goal of SHM is to predict damage or deterioration events at an early stage, by establishing certain operational characteristics that should remain constant if the structural safety is not in danger. As explained in the previous chapter, environmental conditions produce an effect on modal parameters which could conceal healthy states. Therefore, the framework presented herein, based on the works of Chatzi & Spiridonakos (2015), aims to describe dynamic characteristics varying with operational conditions by means of a statistical procedure based on PCE and Independent Component Analysis (ICA). The interested reader is referred to these sources for further details on the workings of these methods.

5.1 *Polynomial Chaos Expansion*

PCE permits to represent a random variable as a function of another random variable with a given distribution, as a polynomial expansion over multivariate products of polynomials that are orthonormal to that distribution. This method predicts the evolution of uncertainty in dynamical systems, which pertains to the case of SHM. Consider a system F conformed by several independent variables $\Xi_1 ... \Xi_N$, being N the number of variables. In the case explained herein those inputs will be the temperature and humidity, with a joint probability function (PDF) $p_\Xi(\zeta)$, while the output $Y = f(\Xi)$, with finite variance, will be also random and correspond to the structure frequencies. This output can be expressed as in Equation 1.

$$Y = f(\Xi) = \sum_{d(j)\in\mathbb{N}^N} \theta_j \phi_{d(j)}(\Xi) \tag{1}$$

being $\phi_{d(j)}$ the polynomial basis functions orthonormal to $p_\Xi(\zeta)$, d the multi-indices vector related to the multivariate polynomial basis and θ_j

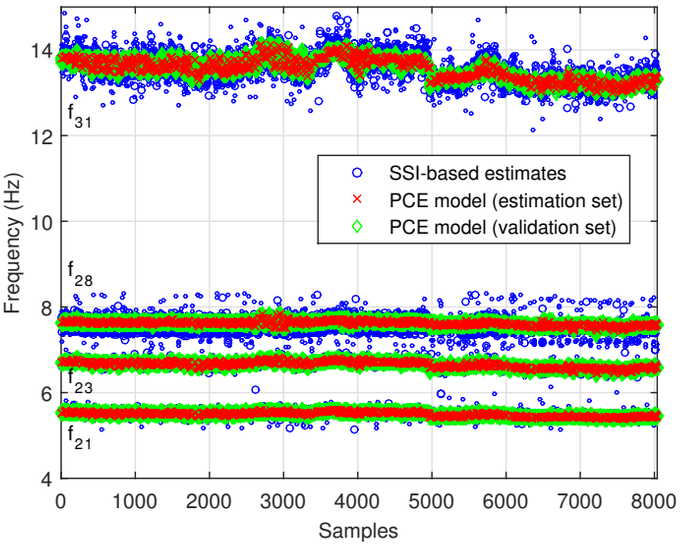

Figure 14: PCE natural frequencies estimates for modes 21, 23, 28 and 31, contrasting training and validation set with respect to SSI-based estimates.

the deterministic coefficients of projection, which are unknown. For a more detailed introduction to the method, the reader is referred to Blatman & Sudret. Nonetheless, a relevant characteristic of the approach should be noted: PCE relies on the independence of the inputs, which is not the case herein as temperature and humidity are directly correlated. To avoid this issue, Independent Component Analysis (ICA) is used, in particular the FastICA algorithm described in Hyvärinen & Oja (2000). Once these steps have been completed, the set of natural frequencies estimates is separated into training and validation sets. After discharging mode number 32 for not being stable enough, a total of 8543 samples is used out of 3000 constitute the training set.

5.2 *Results*

Figures 13 and 14 present the results for the training and validation sets, contrasted with the SSI- based frequency estimates. It may be observed that the method provides accurate predictions, even for mode 31 where the scatter is more pronounced. Nevertheless, damage prediction should be performed with a dataset comprising a longer time interval, where a full cycle of seasonal variations is present. This preliminary study shows that the method can be implemented for larger datasets, aiming to identify damage scenarios based on abnormal trends outside the estimated range. It should be mentioned that the process presented above was also performed for the strain values obtained from the four strain gauges installed on the bridge. However, the correlation between the environmental variables and the two longitudinal strain gauges, as well as for the two transverse, was discrepant and presented a value smaller than 0.75. In Figure15 the results from PCE analysis can be observed, showing that the method is not able to accurately capture the variations, in opposite to the previous example.

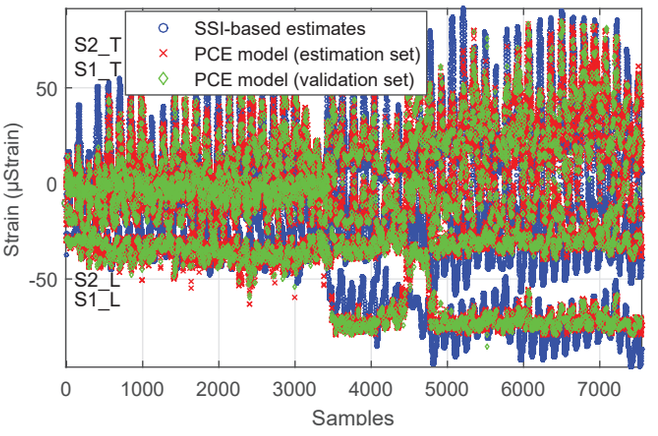

Figure 15: PCE strains estimates for the four strain gauges installed on the viaduct.

6 CONCLUSIONS

In this paper, the SHM deployement on Chillon viaduct is presented and the analysis of three months of data is explained. Natural freqquencies and damping is obtained through a SSI methodology , and contrasted with the environmental conditions, which are proven to constitute a relevant factor on modal analysis. Therefore, a physical model is implemented to validate the results obtained from the Subspace method, exhibiting a good agreement between them. Finally, a PCE methodology is applied in order to accurately describe the natural frequency fluctuations, achieving promising results for the current data. Further investigation should be conducted on the PCE outcome from strains and ambient data.

Development of Vibration-Based Parameters as Damage Sensitive Features for Bridge Structures

J.J. Moughty & J.R. Casas
Department of Civil and Environmental Engineering, Technical University of Catalonia (BarcelonaTech), Campus Nord, Calle Jordi Girona, 1-3, 08034, Catalonia, Spain

ABSTRACT: The process of damage identification in bridge structures traditionally involves the extraction of one or more of the numerous modal-based Damage Sensitive Features (DSFs) from vibration data obtained by direct sensor measurement. However the performance of these modal-based DSFs can suffer under changing environmental and operational conditions and are generally limited by their methodology, which assumes linear structural behaviour and signal stationarity. The present paper presents a detailed overview of the development of alternative DSFs derived from vibration characteristics, focusing on their conception, damage sensitivity evaluation and performance robustness assessment. Initially, selected vibration parameters are outlined to the reader before their damage sensitivity is determined on progressive damage test data obtained from a post-tensioned three-span bridge under ambient conditions using supervised machine learning techniques in conjunction with the Minimum Covariance Determinate (MCD) estimator to mitigate uncertainty surrounding sources of excitation. Secondly, the performance robustness of the vibration-based DSFs is assessed on highly non-stationary data obtained from a progressively damaged steel truss bridge subjected to vehicle excitation. Finally, a comparative evaluation of the vibration-based DSFs is made against modal-based DSFs performance from the literature.

1 INTRODUCTION

Although there are many damage detection methodologies available, there is still poor agreement on the optimal damage feature to use. A review of modal-based damage features in particular found that many may be over sensitive to external conditions, while others may be difficult to extract accurately in ambient conditions due to the low levels of input energy and presence of noise (Moughty & Casas, 2017a). Suitable damage features should be capable of being extracted consistently with ease, sensitive to damage and insensitive to external conditions. Furthermore, when planning the assessment of a bridge, the socio-economic value must also be factored, with more valuable structures deserving advanced assessment methods using multiple sensors and sensor types coupled with advanced analysis methodologies and bridge closures. However, the vast majority of bridge structures in the network are of lower socio-economic value and thus require a simple and effective methodology that is cost effective. The present study investigates the level of damage identification of four vibration parameters that can be extracted with ease and applied to both ambient and vehicle induced excitation responses without the need for bridge closures or additional input forces. The work presented herein advances previous work by Moughty & Casas (2017b) who assessed the damage sensitivity of a number of vibration parameters.

2 VIBRATION PARAMTERES

The selected vibration parameters used within the present study are explained in detail below:

Arias Intensity, defined by Arias (1970), is a vibration parameter used to describe an earthquake's energy over its total duration and is commonly used as an indicator of an earthquake's damage potential.

$$I_A = \frac{\pi}{2g} \cdot \int_0^\infty \ddot{x}(t)^2 \, dt \tag{1}$$

Destructive Potential Factor (DPF) is a variation of Arias Intensity, which was proposed by Araya & Saragoni (1984). It accounts for frequency characteristics in addition to vibration energy by including the variable υ_0, which is the number of zero crossings per unit of time.

$$P_D = \frac{\frac{\pi}{2g}.\int_0^{\infty} \ddot{x}(t)^2 \, dt}{{v_0}^2} \quad (2)$$

Distributed Vibration Intensity (DVI), first detailed herein, utilizes vibration intensity, which in simple harmonic motion context can be defined as $(I=a^2/f)$, where a is acceleration amplitude and f is frequency. The SI units of vibration intensity are mm^2/s^3, but its logarithmic power form of decibels (dB) is more commonly used. For the distributed variant employed in the present study, a Fourier transformation is applied to the acceleration response and the summation of the vibration intensity values is taken within a frequency range, denoted by (f_i) within the limits m-n in Equation 3. The frequency range should encompass the first few modes of vibration of the structure in question, in the present case the range is selected as $(m\text{-}n = 1Hz - 20Hz)$. In this way, Distributed Vibration Intensity may capture the damage sensitivity associated with energy and modal changes, while unwanted variation due to adjusting ambient conditions and frequency domain noise can be diminished over sufficient duration length, in addition to the application of Mahalanobis Squared Distance (MSD), as those variations are assumed to be Gaussian in nature.

$$DVI = \sum_{i=m}^{n} 10\log_{10}\left(\frac{{a_i}^2(f_i)}{f_i}/I_S\right) \quad \begin{matrix} for \;\; m \le f_i \le n \; (in\; Hz) \\ I_S = 10mm^2/s^3 \end{matrix} \quad (3)$$

Note that this parameter is assessed only in the ambient excitation case, as the vehicle-induced excitation test produces short, highly non-stationary responses that are deemed unsuitable for Fourier transformation.

Cumulative Absolute Displacement (CAD) is another novel vibration parameter that cumulatively sums a vibration signal, however in this case the acceleration signal is first transformed in displacements using integration and band-pass filtering to avoid drift.

$$CAD = \int_0^t |x(t)|dt \quad (4)$$

Note that this parameter is assessed only in the vehicle induced vibration case, as obtaining accurate displacements from long duration ambient induced accelerations is not feasible without additional known variables.

3 OUTLIER DETECTION METHODOLOGY

For the ambient condition test, the vibration parameters are assessed using Mahalanobis Squared-Distance (MSD), which is a common multivariate outlier detection algorithm that uses mean and covariance data to train and assess dataset continuity. MSD is determined as shown in Equation 5, where $\{X\}_\zeta$ is the potential outlier, $\{\bar{X}\}$ is the mean of the training data and $[\Sigma]$ is the covariance matrix of the training data.

$$D_\zeta = \left(\{\bar{X}\}_\zeta - \{X\}\right)^T [\Sigma]^{-1} \left(\{X\}_\zeta - \{\bar{X}\}\right) \quad (5)$$

In addition to the MSD, the Minimum Covariance Determinate (MCD) estimator is also employed to enhance robustness and reduce uncertainty regarding sources of ambient excitation by identifying and removing outliers from the training data prior to MSD. Although environmental conditions may remain relatively constant throughout the bridge test, the assumption of Gaussian distributed sources of ambient loading cannot be applied in some cases as one traffic lane under the bridge was still in operation throughout the test, in addition to feasible construction work nearby near-by. This leaves a case where the undamaged vibration data used to train the MSD may contain outliers itself due to passing traffic or construction vehicle activity, which is left included in the training data may negatively impact the subsequent test/damaged data results, particularly if the training data outliers are significantly dissimilar to the remaining data set. The MCD employed in the present study is the FAST MCD algorithm (Rousseeuw & Van Driessen, 1999), which removes erroneous data by first iteratively determining the subset of data whose covariance matrix has the lowest possible determinant to that of the total dataset. Once the MCD finds the data points that contribute most to abnormal variance compared to the remaining data, it returns newly updated mean and covariance values that can be used directly in the MSD.

4 TEST DATA

4.1 *Ambient Excitation - S101 Bridge*

The S101 Bridge was pre-stressed 3-span flyover near Vienna in Austria that had a main span of 32m and two 12m side spans. The deck cross-section was 7.2m wide double-webbed t-beam, whose webs had a width of 0.6 m. The height of the beam varied from 0.9 m in the mid-span to 1.7 m over the piers, as can be seen in Figure 1. In 2008, it was decided to replace the S101 Bridge due to insufficient carrying capacity and deteriorating structural condition being identified from visual inspection data.

A progressive damage test was conducted on the S101 Bridge across 3 days in 2008 though the completion of a number of sequential actions, which are presented in Table 1. Overall, the damage applied can be divided into two main stages; (1) simulated pier foundation settlement, (2) bridge deck stiffness loss through the severing of four pre-stressed tendons. During the test the bridge was closed to traffic, meaning that excitation was mainly ambient, although one traffic lane beneath the bridge was kept in use. As for environment sources of excitation, very

little temperature variation was observed throughout the test duration as sub-zero temperatures were kept within a 3 to 4 degree range due to persistent heavy cloud cover (VCE, 2009).

Vibration data was recorded by 13 accelerometers located on one side of the bridge deck, with a sample rate of 500Hz. Vibration recordings from the sensors did not cease throughout the progressive damage test. For the present study, the measured data was discretized into 66sec long segments of 33,000 samples.

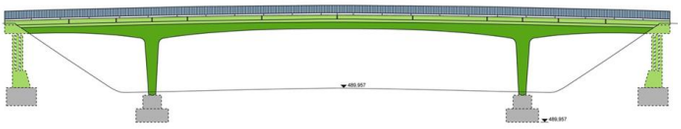

Figure 1. S101 Bridge longitudinal section

Table 1. Damage actions conducted on the S101 Bridge

Damage State	Description of Damage Actions
1	Undamaged
2	North-Western (NW) column cut through
3	First step of lowering bridge pier (1cm)
4	Second step of lowering bridge pier (2cm)
5	Third step of lowering bridge pier (3cm)
6	Compensating plates inserted & pier returned to original position
7	First pre-stressed tendon cut over NW pier
8	Second pre-stressed tendon cut over NW pier
9	Third pre-stressed tendon cut over NW pier
10	Forth pre-stressed tendon cut over NW pier

4.2 *Vehicle-Induced Excitation - Steel Truss Bridge*

The test data utilized within the present study has been obtained from a progressive damage test conducted on a Japanese bridge that was subjected to a moving vehicle excitation (Kim et al., 2013). The bridge in question was a simply-supported steel truss bridge that spanned 59.2m with a width of 3.6m and a max height of 8m. It was scheduled to be replaced in 2012, before which a progressive damage test was carried out while the bridge was closed to the public. Dynamic behavioral response was recorded from 8 uniaxial accelerometers, positioned as per Figure 2(b), with sample rates of 200Hz.

Table 2. Damage actions conducted on the Steel Truss Bridge

Damage State	Description of Damage Actions
1	Undamaged
2	Half cut in vertical member at mid-span
3	Full cut in vertical member at mid-span
4	Mid-span member reconnected
5	Full cut in vertical member at 5/8th span

The induced damage scenarios consist of severing vertical members of the truss structure in the locations presented in Figure 2(b). The progression of the damage states are described in Table 2 and presented in Figure 3. The damage actions began with the partial intersection of the mid-span vertical member (DMG1), before its full intersection was completed (DMG2). After which, the damaged member was reconnected (RCV) with a welded flange. Finally, the vertical member at 5/8th span was completed severed (DMG3).

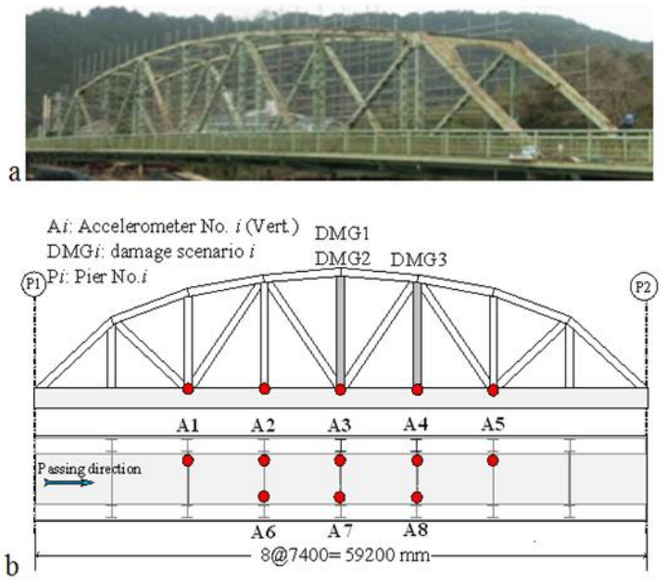

Figure 2. Steel truss bridge (a); Sensor & damage locations (b)

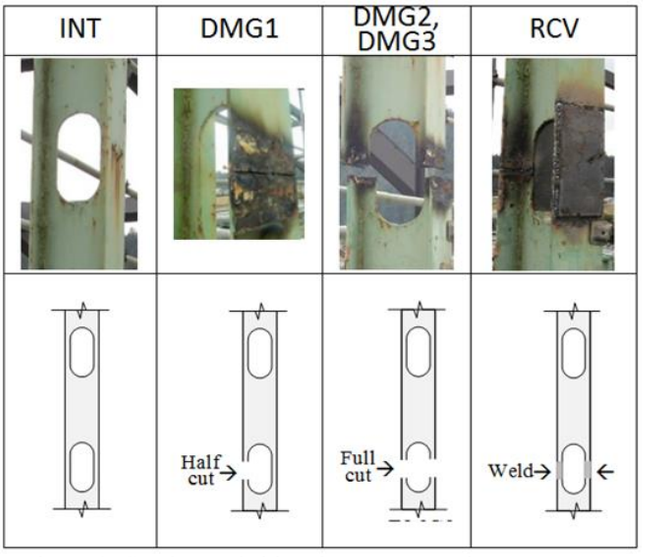

Figure 3. Steel truss bridge damage scenarios

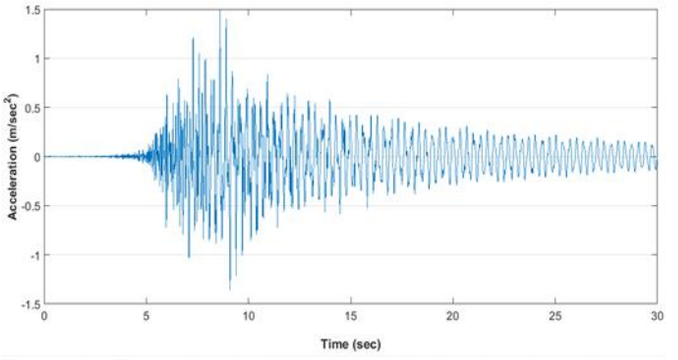

Figure 4. Example of vehicle induced vibration from the steel truss bridge (Sensor 3 – Undamaged Case)

For each damage scenario, a 21kN double-axle vehicle was driven across the bridge three times at approximately 40km/h to induce excitation. A sample time-history of acceleration response is presented in Figure 4. Note that no vehicle dynamics were obtained; however, the dynamic response of the bridge has been assessed in detail by Kim et al. (2014), who identified the first five vibration modes.

5 RESULTS

5.1 *Ambient Excitation - S101 Bridge*

The assessment of the chosen vibration parameters' damage identification ability under ambient conditions is conducted in two stages; (1) detection and (2) localization. There are three vibration parameters assessed herein; Arias Intensity (an energy-based parameter), Destructive Potential Factor (an energy-based parameter with empirical frequency denominator) and Vibration Intensity (an energy-based DSF with Fourier-based frequency denominator). The fourth vibration parameter, Cumulative Absolute Displacement, is not assessed under ambient conditions due to the difficulty of accurately obtaining displacements from ambient induced accelerations.
The MSD outlier detection algorithm is applied using 70% of the undamaged data to train, with 30% for validation and a threshold value of 95%. The MCD estimator is also applied to the training data to remove outliers that may be associated with unknown eternal sources of excitation.
For the first set of results for damage detection only, vibration parameters were extracted from thirteen sensor locations along one side of the bridge deck and were combined when input into the MSD outlier detection algorithm to increase damage sensitivity. For the second set of results for damage localization, the vibration parameters were not combined across sensors before MSD was applied, in this way the damage sensitivity is reduced, but possibility of damage localization is possible to assess.

Figure 5 to Figure 7 present the damage detection results of the vibration parameters; Arias Intensity, Destructive Potential Factor and Distributed Vibration Intensity, respectively. Both Arias Intensity and Destructive Potential Factor follow similar patterns, as is to be expected as both are measures of energy, however Destructive Potential Factor can deemed as more damage sensitive, particularly during the pier settlement test. In both cases the damage threshold is surpassed promptly as the pier is cut through, however the damage indicators return under the threshold sometime after the second pre-stressed tendon is severed. This may be explained by the fact that there was a duration of some hours between the second and third tendon cuts (night time) and temperature reduction and settling most likely occurred. Both parameters were able to sufficiently capture the sudden change in behavior exhibited by the bridge during the partial severing of the fourth pre-stressed tendon. It is worth noting that a visual inspection did not indicate any changes to have occurred between the third and fourth tendon cut.

In the case of the Distributed Vibration Intensity, the damage threshold is crossed promptly upon damage initiation and does not return throughout the remained of the test. Significant detail becomes visible via the Distributed Vibration Intensity, such as when the pier was fully cut through (~x=500); when the pier was returned to its original position (~x=1100); when a vibrating roller worked next to the bridge (~x=1300) and during the cutting of the final pre-stressed tendon.

In terms of damage localization capability of the three assessed features under ambient conditions, Figure 8 – Figure 10 present the results, where the vibration parameters of each sensor is assessed using MSD individually through time, revealing which sensor locations demonstrate the greatest damage sensitivity. The results are mixed, with Arias Intensity portraying false damage locations and failing to accurately locate the pier settlement, although it did signify damage at the correct location for during the third pre-stressed tendon cut, which coincided with cracking being observed at that time.

The Destructive Potential Factor and Distributed Vibration Intensity produced better results, although the Destructive Potential Factor highlighted damage in the center of the mid-span during pier settlement, while the Distributed Vibration Intensity correctly located the settlement and increasingly preferenced the same correct location for the pre-stressing loss.

5.2 *Vehicle-Induced Excitation - Steel Truss Bridge*

In this damage identification assessment there is the issue of controllability of each vehicle passage, as vehicle velocity and path can be difficult to consecutively replicate, therefore Sensor 1's Undamaged value is used as a fixed reference point for all of Sensor 1's subsequent damage states to account for some variation in vehicle passages. Additionally, the initial ambient bridge excitation level prior to vehicle passage was observed to fluctuate, which may impact the vibration parameters performance. To account for this, only passages with very low initial ambient bridge excitation are used.

Figure 11 to Figure 13 present the results of Arias Intensity, Destructive Potential Factor and Cumulative Absolute Displacement, respectively. Immediately, it can be seen that all vibration parameters can successfully detect and locate DMG 3 at Sensor 4, which is the most severe damage condition of the 3.

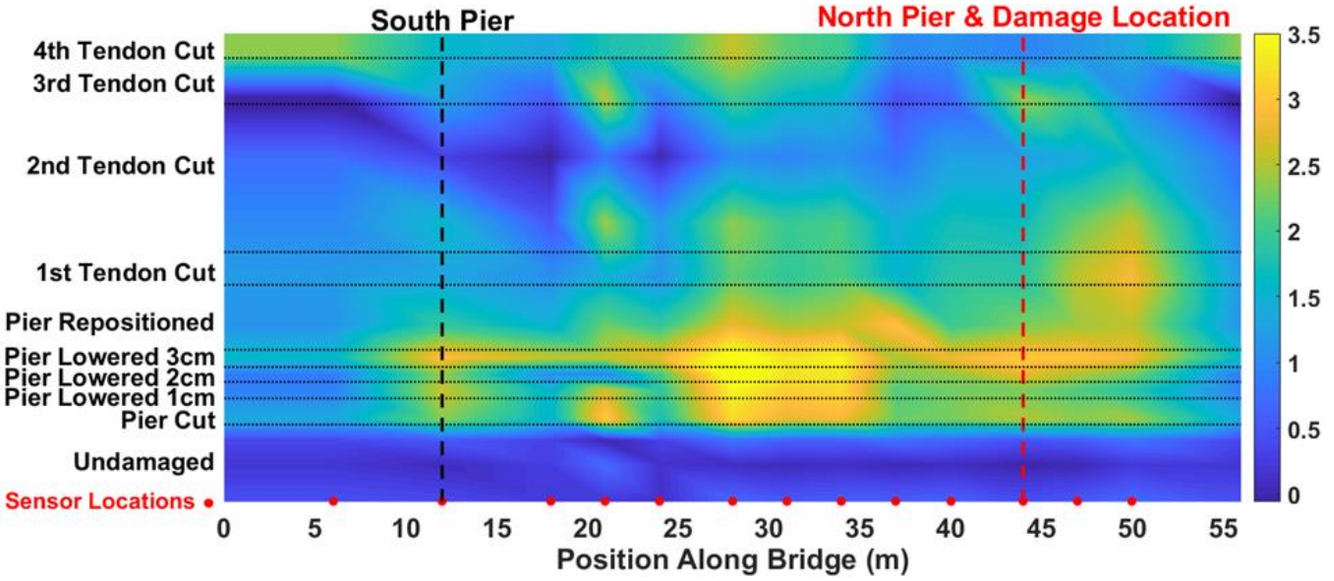

Figure 9. Mahalanobis Squared-Distance of Destructive Potential Factor as a damage sensitive feature for 13 sensors individually

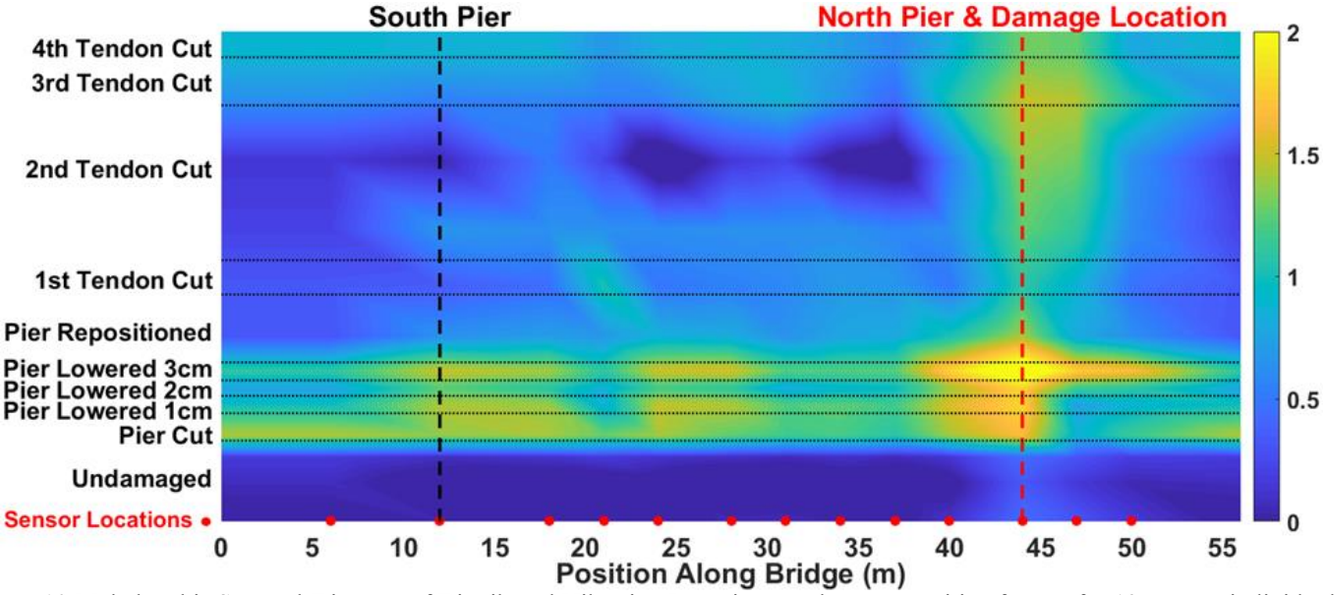

Figure 10 Mahalanobis Squared-Distance of Distributed Vibration Intensity as a damage sensitive feature for 13 sensors individually

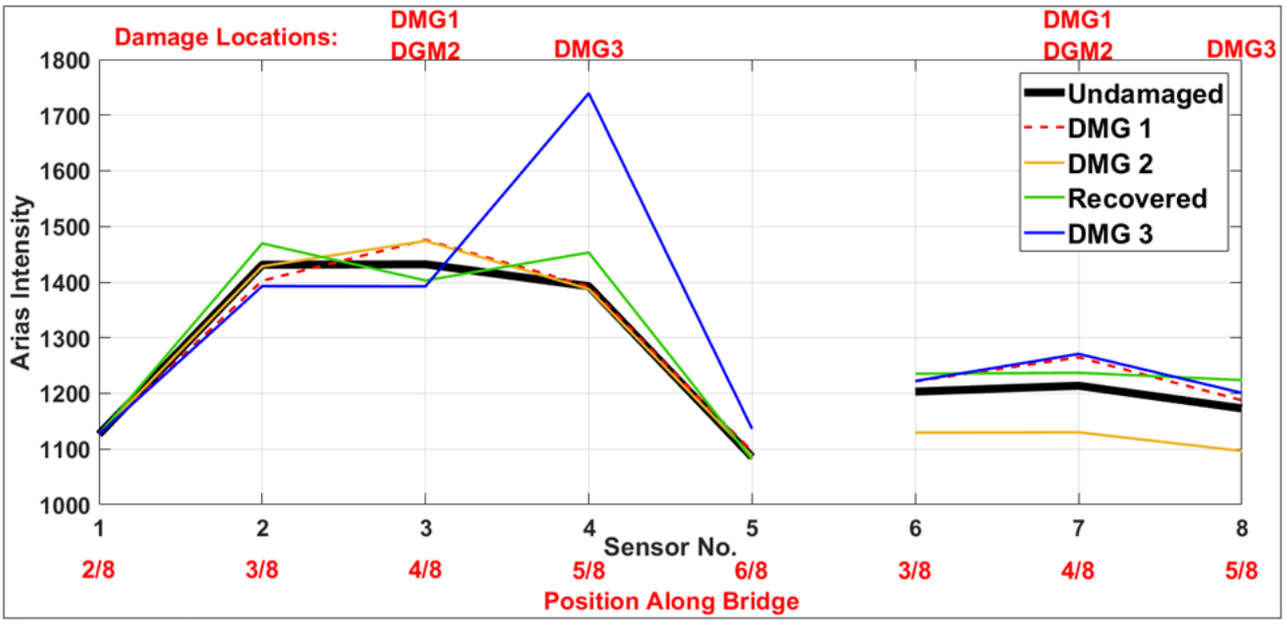

Figure 11. Arias Intensity across all sensors (Sensor 1 Undamaged used as a fixed reference point to account for variation in vehicle passages)

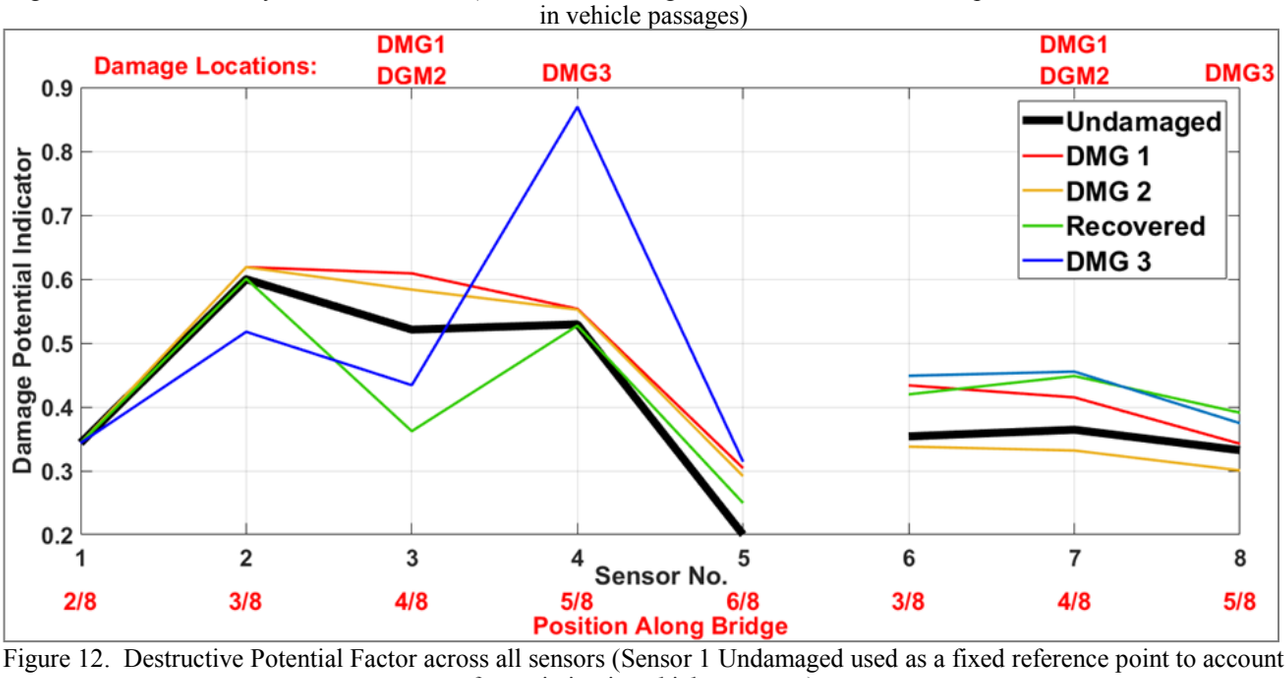

Figure 12. Destructive Potential Factor across all sensors (Sensor 1 Undamaged used as a fixed reference point to account for variation in vehicle passages)

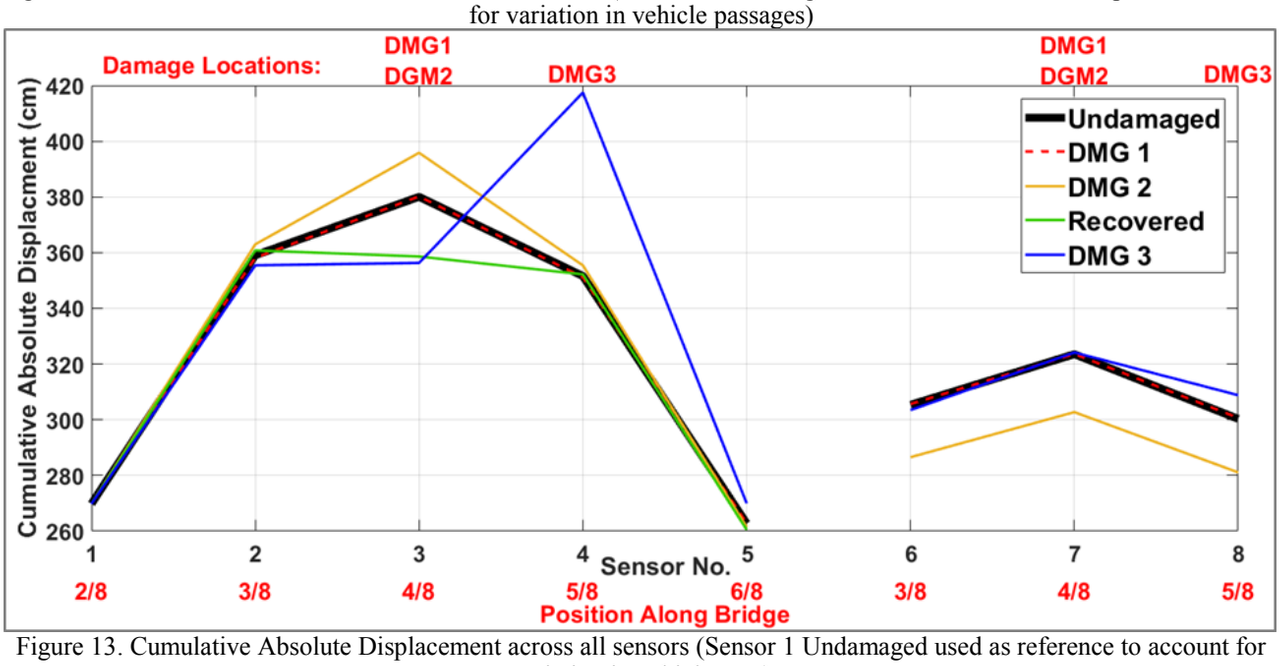

Figure 13. Cumulative Absolute Displacement across all sensors (Sensor 1 Undamaged used as reference to account for variation in vehicle runs)

The two damage conditions at the center span are also detected and located, although less pronounced. This is in line with Kim et al.´s (2014) findings using modal parameters. In the case of the recovered condition, all three vibration parameters show a reduction in damage, not only when compared to the previous two damage scenarios at that location, but also to the original undamaged case, signifying that the welded flange used to repair the center span actually enhanced its performance. This is again observed at Sensor 3 during DMG3.

For Sensors 6, 7 and 8, which are located on the opposite side of the bridge to the damage, results are less evident, save for the consistent trend of DMG2 portraying converse behavior to the opposite side of the bridge at Sensors 2, 3 and 4, which may indicate some compensating behavior or structural load redistribution through the truss elements.

6 DISCUSSION & CONCLUSIONS

To evaluate the damage identification capability of the assessed vibration parameters, results of from published works by VEC (2009) for the S101 Bridge and Kim et al. (2014) for the steel truss bridge are provided in Table 3 to Table 5 using modal frequencies, while Table 6 provides the percentage difference for the 3 vibration parameters assessed in the steel truss bridge assessment at the relevant damage locations.

Table 3. Modal frequency changes for the S101 Bridge pier settlement test under ambient excitation (VCE, 2009)

Mode	lowered 1cm	lowered 2cm	lowered 3cm
1st B. Mode	-2.2%	-3.2%	-10.6%
1st T. Mode	-4.6%	-6.7%	-14.4%
2nd B. Mode	-2.6%	-4.2%	-15.2%
2nd T. Mode	-12.3%	-18.8%	-24.3%
3rd B. Mode	+1.8%	+0.2%	-0.9%

Table 4. Modal frequency changes for the S101 Bridge for pre-stress failure test under ambient excitation (VCE, 2009)

Mode	1st Cut	2nd Cut	3rd Cut	4th Cut
1st B. Mode	-1.2%	-0.2%	-0.2%	-0.2%
1st T. Mode	-2.9%	-1.3%	-1.3%	-1.9%
2nd B. Mode	-1.2%	0.0%	0.0%	-0.2%
2nd T. Mode	-3.0%	-1.6%	-2.0%	-1.6%
3rd B. Mode	-3.4%	-1.3%	-0.6%	-1.3%

Table 5. Modal frequency changes for steel truss bridge damage test under vehicle induced excitation (Kim et al., 2014)

Mode	DMG1	DMG2	DMG3
1st B. Mode	+0.03%	-3.22%	-1.58%
2nd B. Mode	+0.16%	+0.09%	-5.51%
3rd B. Mode	X	-0.21%	-9.05%
4th B. Mode	+1.07%	+0.22%	-6.87%
5th B. Mode	+0.85%	+0.58%	-0.16%

Table 6. Vibration parameter changes from steel truss bridge damage test under vehicle induced excitation

Parameter	DMG1	DMG2	DMG3
Arias	+3.07%	+2.93%	+24.84%
DPF	+16.89%	+12.01%	+64.30%
CAD	+0.05%	+4.16%	+18.70%

Of the 3 vibration parameters assessed on the S101 Bridge under ambient excitation, the Distributed Vibration Intensity provided the greatest damage resolution per damage state and proved to be the best damage location indicator under ambient conditions. Due to the nature of the algorithm employed, an objective comparison with modal frequency changes from VCE (2009) is not possible, however from a subjective viewpoint, Distributed Vibration Intensity applied in this way seems to have performed more consistently.

Of the 3 vibration parameters assessed in the vehicle induced excitation test, the Cumulative Absolute Displacement produced results most in-line with reality by successfully detecting, locating each damage scenario with magnitudes equivalent to damage severity, indicating that it achieves up to Level 3 of the damage identification scale.

ACKNOWLEDGEMENTS

This project (http://trussitn.eu) has received funding from the EU's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No. 642453.
The authors would like to thank Prof. C.W. Kim of the Dept. of Civil and Earth Resources Engineering, Kyoto University, Kyoto, Japan for the generous sharing of the bridge data assessed within the present study.

ABSTRACT: The extraction of modal properties is a difficult task, especially when output-only data is measured. The accuracy of the estimation these modal properties is compromised by noisy signals, and signal filtering is required to suppress unwanted frequency content. Care is required to avoid over-filtering of the output data, which can eliminate valid structural frequency content. This paper describes the development of a bespoke signal processing algorithm to extract the modal properties of both simply supported post-tensioned (PT) steel and concrete sections. Dynamic impact testing was conducted on a series of different PT steel and concrete beams. Acceleration time-history data was recorded. This data was subsequently processed. The Fast Fourier Transform (FFT) was applied to the signal to convert into the frequency domain and a bespoke peak-picking algorithm was used to extract the natural frequencies of the beams. A comparison is made between the accuracy of the estimation of the modal properties for filtered and unfiltered data, and a sensitivity analysis of the filtering and peak picking parameters is conducted to determine the effect on the accuracy of the estimation of the modal parameters. The results show the effectiveness of the bespoke algorithm in increasing the accuracy of the estimation of the modal properties as opposed to the raw, unprocessed signals.

1 INTRODUCTION

Experimental modal analysis has been conducted on a series of steel and concrete beams in the lab (Noble *et al.*, 2015, 2016). The steel and concrete beams have been post-tensioned by treading a post-tensioning strand through their cross section and jacking the beam on a live end. A series of impact hammer strikes were applied to the tested structures, and the dynamic response of the structure was measured using an accelerometer. The output signal only was measured, no measurement signal was taken of the dynamic input signals therefore the experiments conducted are considered as output-only dynamic tests. These tests are becoming increasingly common, especially in the field of Operational Modal Analysis (OMA), in which the modal parameters of a structure are determined from the structures response to ambient vibration conditions. The modal properties are thus extracted from the Fourier Transform representations of the system output signals.

The testing was conducted in order to determine the existing relationship between post-tensioning force magnitude and modal properties of post-tensioned steel and concrete specimens, as there is significant disagreement between researchers in this field (Tse, Morse and Hinkle, 1978; Raju and Rao, 1986; Bartlett, 1987; Bažant and Cedolin, 1987; Bert, 1987; Saiidi, Douglas and Feng, 1994; Williams and Falati, 1999; Chan and Yung, 2000; Miyamoto *et al.*, 2000; Kim, 2004; Zhang and Li, 2007).

This paper outlines a bespoke signal processing algorithm, and subsequent bespoke peak-picking methodology applied to a series of impact response signals obtained from the dynamic testing described in full (Noble *et al.*, 2015, 2016). The paper is organized as follows; the fundamental theory behind digital signal processing is first introduced. The bespoke signal processing algorithm followed to filter the obtained signals is described in the following section. A detailed description of each of the steps of the signal processing algorithm and the effect of each signal filter on the raw data signal is subsequently described in the following sections. A curve smoothing function used to smooth both time and frequency domain representations is then described. The following section describes the peak-picking algorithm used to identify the natural frequencies of the structural system(s) tested. The cumulative effect of the filtering on the raw data is then outlined. The Inverse Fourier Transform is subsequently applied to the smoothed, normalized, filtered, frequency domain representation. Finally, conclusions based on the described filtering regime are drawn.

2 SIGNAL PROCESSING

The main assumption underlying all forms of modal analysis is that any dynamic response signal may be represented, in the time domain, as an infinite series of sinusoids, each with their own unique amplitude and frequency. The amplitudes are considered as the modal contribution of each mode of vibration to the overall dynamic signal, whereas the frequencies are defined as the natural vibration frequencies of the structural system, for the

corresponding mode shape of vibration. All other seemingly random portions of the vibration response are considered as a noise components of the system, and as such, asystematic.

2.1 *Noise*

Noise is any unwanted or seemingly random portions of the measured vibration response of the system. Quality assurance of the measured dynamic data is of utmost importance. The signals obtained should be of sufficient strength and clarity and free of excessive noise (Ewins, 2000). This unwanted frequency content is attenuated by appropriate use of signal processing and signal filtering that is outlined in detail in this paper.

2.2 *Aliasing*

Aliasing is an error associated with digital signal processing (DSP) in which the existence of very high frequency components in the signal are missed as the sampling rate is not large enough. It is not possible to determine any frequency greater than the Nyquist frequency, $\omega_{N_{yq}}$. The solution to this is to use an anti-aliasing filter. The anti-aliasing filter is a low pass, sharp cut-off filter. The type of filter implemented is usually a high order low pass Butterworth filter (Butterworth, 1930). Anti-aliasing filters are not automatically built-in to signal analysers and data collectors, and thus the signal must be post-processed.

2.3 *Leakage*

Leakage is a signal processing problem related to discrete signals and the definition of the Fourier Transform. The Fourier Transform is defined as an integral over the range of $(-\infty, +\infty)$. Leakage occurs due to the need to take only a finite length of time-history, coupled with the assumption of periodicity (Ewins, 2000). When the periodicity assumption is not valid and there is a discontinuity at the beginning or the end of the signal in the time domain, the resulting frequency spectrum does not indicate the original frequency. This frequency is actually not represented. Energy has `leaked' into a number of the spectral lines close to the true frequency and the spectrum is spread over several lines (Ewins, 2000). The effects of leakage were mitigated against throughout the course of this study by making use of *'zero padding'* (adding zeros before and after signal) which artificially removed the periodicity requirement. However, impact signals, experience minimal distortion due to leakage provided the signal is analysed over the appropriate region.

2.4 *Windowing*

Windowing involves the modification of the signal in the time domain in order to suppress the effects of unwanted frequency content and minimize the effects of leakage. Avitabile (Avitabile, 2001) warns that all windows distort data, as they distort the peak amplitude and appear to indicate more damping than actually exists. Avitabile (Avitabile, 2001) suggests in order to avoid the use of windows to continuously sample a periodic repetition of the data, or to completely observe the signal in one data sample. The latter is obtained by choosing impulse/impact excitation as the type of dynamic excitation, which was chosen as the form of input excitation for this study.

3 SIGNAL PROCESSING REGIME APPLIED TO OBTAINED SIGNALS

The following procedure was applied to the raw impact response signals obtained from the steel and concrete testing and presented in (Noble *et al.*, 2015, 2016);

1. The initial acceleration vs. time data obtained from the accelerometer attached to the steel or concrete beam following impact hammer strike was read in.
2. Initial *'zero padding'*, *'windowing'* and offset correction was applied to the obtained accelerometer data.
3. The initial data analysis was performed.
   - The Fast Fourier Transform (FFT) of the unfiltered initial acceleration-time data, as outlined above, was computed.
   - The peaks in the initial spectrum were computed using a bespoke peak picking algorithm – the peaks are the computed natural frequencies of the system.
4. The initial data was subsequently filtered. Following initial data analysis, the natural frequencies were unintelligible, thus the signal required to be filtered to remove excessive noise/frequency content corrupting the identification of the natural frequency. The *'zero padded'*, *'windowed'* and offset initial data was subsequently filtered as outlined below.
5. The following filtering was performed;
   - The *'zero-drift'* was removed by applying a low pass Butterworth filter to the data.
   - The signal was smoothed, first by removing electrical noise frequency content of 50Hz and all harmonics, and then by subsequently applying a smoothing function to remove excessive high-frequency noise in the signal.

- A high pass filter was applied to remove all low frequency noise components corrupting the signal.
- An anti-aliasing filter was applied to the data.

6. The data was then subsequently windowed again.
7. The FFT of the filtered acceleration-time data was then computed to convert the acceleration-time signal into the frequency domain.
8. The main peaks were then extracted from the frequency domain curve to determine the natural frequencies of the structural system.

Figure 1 outlines a flow chart describing the bespoke signal processing algorithm followed for the concrete beam specimens as outlined previously (Noble *et al.*, 2015, 2016).

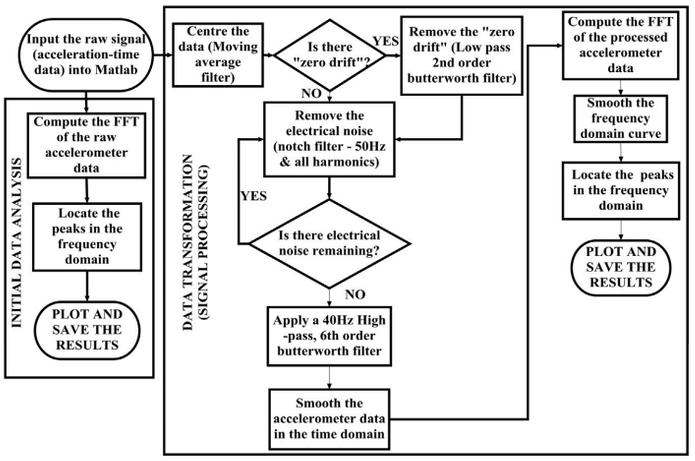

Figure 1. Signal processing flow chart as applied to the concrete beam tested (reproduced from (Noble *et al.*, 2016)*)*

In certain cases, the fundamental frequency may not be identifiable from the raw data signal, as evident for the signal represented in the time and frequency domains in Figure 2 and *Figure 3* respectively, and as outlined previously by (Noble *et al.*, 2016)

This paper identifies the need, in some instances for signal filtering and the removal of low and high frequency noise for the correct estimation of the fundamental frequencies of vibration.

3.1 *Initial 'zero-padding' and 'windowing'*

The initial data signal is characterized by the blue signal in Figure 2. The signal has an initial offset, as shown in Figure 2. The signal is initially processed by cutting an initial portion of the data in the time domain. The position of the maximum acceleration in the raw signal was identified, and the first 1/3 of the signal, from the initial acceleration to the maximum acceleration was removed, and thus the signal was 'windowed' in order to ignore/remove any frequency content in this portion of the signal. The remaining signal was then forced to begin at 0. The initial offset was removed by subtracting the initial offset from all parts of the signal. The red signal in Figure 2 is the result of preprocessing the blue signal by 'zero padding' and removing the initial offset.

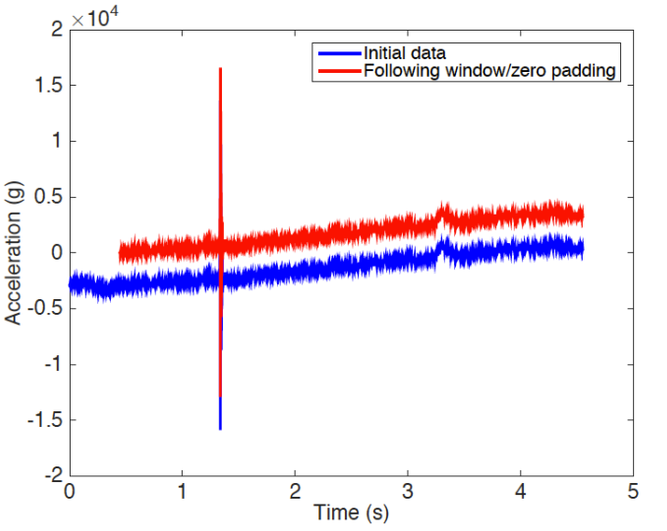

Figure 2. Raw output data collected (blue) and following windowing/zero padding (red) in the time domain

3.2 *Initial Data Analysis*

Figure 3 shows the initial frequency domain representation of the windowed data following initial processing (Figure 2). As shown in Figure 2, there is a very low frequency component in the signal, where the overall trend in the data is rising slightly from left to right. This is known as 'zero drift' and is an instrumentation error in the accelerometer. When the Fourier Transform is performed on the data, it assumes that all parts of the data/trends in the data are periodic, and that therefore the 'zero drift' is also a periodic component of the signal. As a result, the very low frequency content dominates the frequency domain representation of the signal, and thus the fundamental structural modes of vibration are not readily identifiable through peak-picking as they are drowned out by the dominance of the low frequency 'zero drift'.

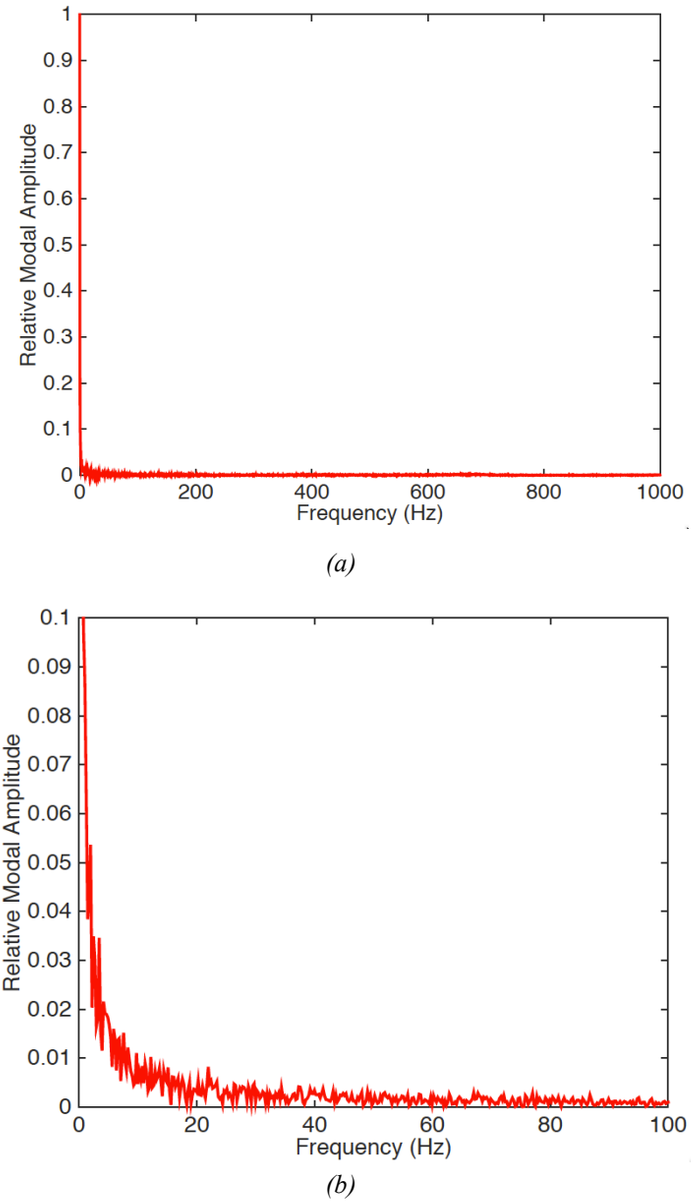

Figure 3. Frequency domain representation of the initial (raw) time domain data

3.3 *Moving Average Filter*

A moving average filter was applied to the initial data in order to remove the effects of some high frequency noise on the data signal. *Figure 4* shows both the time and frequency domain of the raw data signal following the implementation of a moving average filter. The blue data in both the time and frequency domain represents the unfiltered, raw initial data, while the red represents the data following the application of the moving average filter. The moving average filter is a standard technique in signal processing whereby the signal is smoothed by removing high-frequency, unwanted, line noise in order to uncover the fundamental structural frequencies. A moving average filter, of length N takes the average of every N consecutive samples in the signal, where N is the sample size. The filter itself has a delay of (N-1)/2, and this must be adjusted for in the filter. As outlined in *Figure 4*, the effect of the filter is to smooth the signal, removing unwanted high frequency noise.

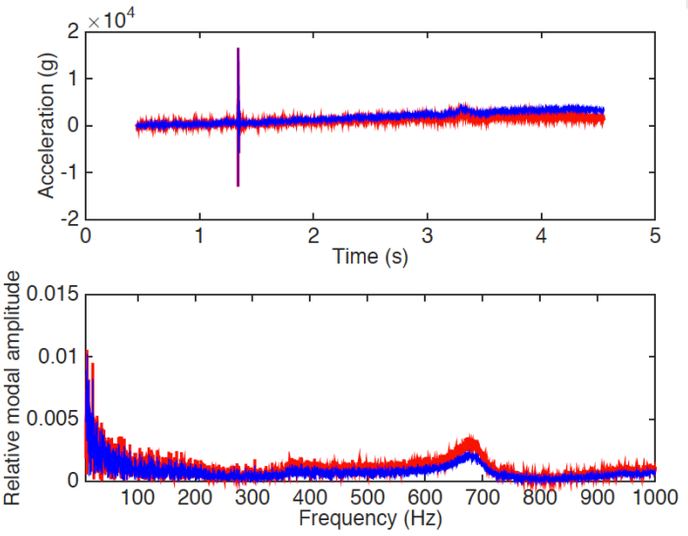

Figure 4. Time and frequency domain representation of raw data signal following application of moving average filter.

3.4 *Removing 'zero drift'*

As outlined in section 3.2, 'zero drift' is a low frequency noise component in the accelerometer signal due to an instrumentation error in the accelerometer, meaning that the signal oscillates about a non-zero or drifting datum. As outlined previously since the Fourier Transform assumes periodicity, this low frequency noise dominates the signal, thus making the structural vibration frequencies unintelligible. A low (2^{nd}) order, high-pass Butterworth filter, with a cutoff frequency of 0.1Hz was thus applied to the signal. This meant that low frequency components of the signal (<0.1Hz) were suppressed/attenuated, thus removing the very low frequency 'zero drift' from the data, and thus forcing the data to oscillate about the zero datum, as shown in *Figure 5*.

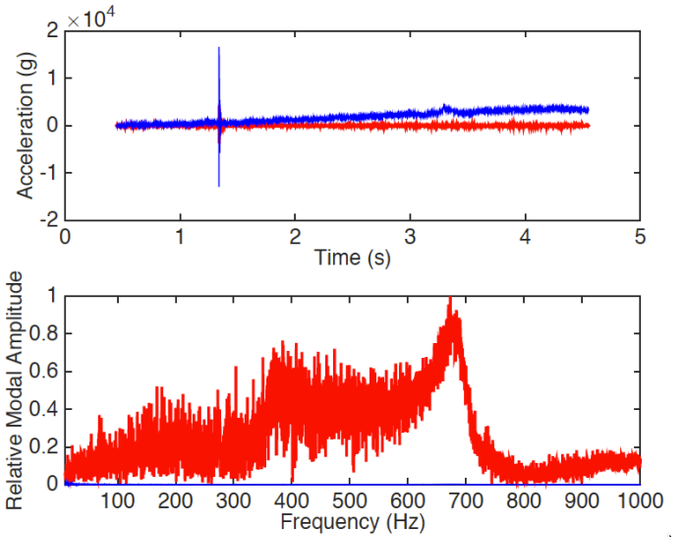

Figure 5. Time and frequency domain representations of raw data signal following removal of low frequency 'zero drift'.

3.5 *Smooth signal – remove electrical noise*

The main component of noise in the data is electrical noise. The sources of accelerometer noise can be broken down into the electrical noise from the circuitry that converts the mechanical vibration into a voltage signal that is thus correlated against a given acceleration, and the mechanical noise from the accelerometer itself. Ambient vibration of the system will also contaminate the pure structural signal. The A/C mains by which the accelerometer is powered has an alternating current with a frequency of 50Hz. This 50Hz signal, including all of its harmonics, is represented in the output data. This 50Hz electrical noise and its harmonics are filtered out by means of a 'notch' filter. A notch filter is a high order bandpass filter that removes specifically defined frequencies, while passing all other frequencies. *Figure 6* shows the result of applying a series of notch filters of 50Hz and its multiples to the data. The blue signal in *Figure 6* represents the raw signal, whereas the red signal represents the raw signal following removal of the electrical noise.

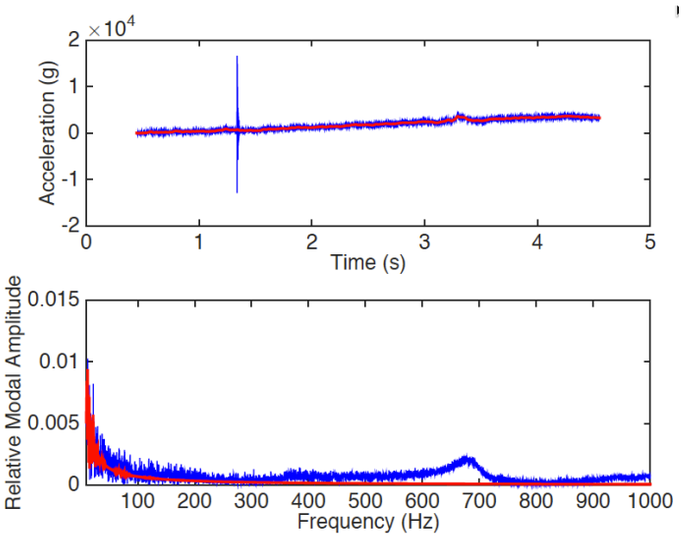

Figure 6. Time and frequency domain representation of raw signal before and after removal of electrical noise.

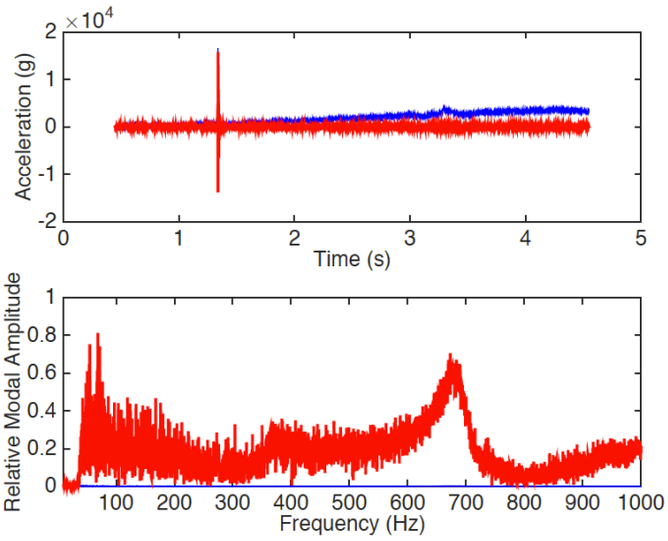
3.6 *High pass filter*

The fundamental bending frequency of the post-tensioned concrete beam sections tested was estimated to be 78Hz (Noble *et al.*, 2016). This estimation does not account for the effect of the mass of the jacks situated either end of the beam, tensioning the post-tensioning strand. The effect of the jacks should be to reduced the predicted frequency. The fundamental bending frequency, and subsequent harmonics were of interest in the testing conducted, thus a high pass filter was applied to the data in order to suppress the unwanted low frequency noise and to determine the fundamental bending frequencies via peak picking. *Figure 7* shows the time and frequency domain representation of the raw data signal following the application of the 40Hz high pass filter. The blue data represents the raw data signal, whereas the red signal represents the signal following application of the high order (8^{th} order) 40Hz high-pass filter. The frequency domain representation indicates the suppression of the frequency content of the signal <40Hz.



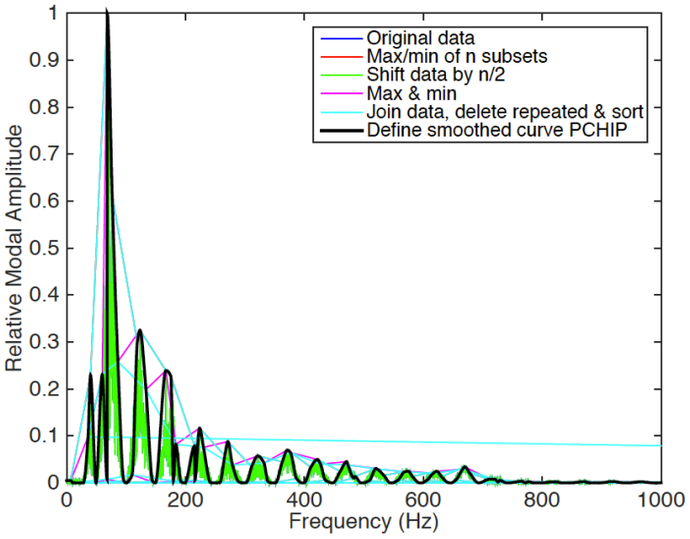


Figure 7. Time and frequency domain representation of raw data signal following application of 40Hz high pass filter.

3.7 *Curve smoothing function*

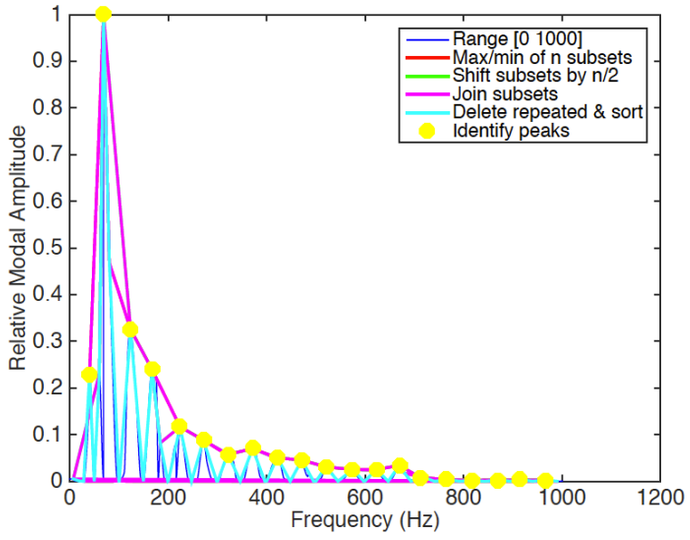

Figure 1 shows a flow chart outlining the series of different filters applied to the raw data. Following the application of each of the filters described previously, a frequency domain representation was obtained by which the fundamental structural vibration frequency could be obtained. In order to determine an estimation of the fundamental frequency, the frequency domain curve required smoothing. A smoothing algorithm was applied to the frequency domain data by identifying the most relevant points. With this aim, the data set is split into a series of n subsets. The smaller the value of n, the smother the final curve is. Then, the maximum and minimum values of the frequency domain representation of the data in each subset are calculated. In order to remove the effect of lag on the data, the data set is shifted by a value of $n/2$, and the new maximum and minimum values of the shifted subsets, calculated. In that way, the points identified during both rounds, which are up to $4n$ positions, represent the most relevant points of the frequency domain curve. Finally, a continuous curve is defined using a piecewise cubic Hermitic polynomial by interpolation within the identified points.

Figure 8(a) shows the performed steps of the curve smoothing function of the frequency domain

representation of a response signal. The blue curve shows the frequency domain representation of the filtered impact response signal in the range of interest of 0 to 1,000Hz. The red curve shows the definition of the maximum and minimum values in each of the defined subsets. The green curve shows the filtered impact signal shifted by n/2. The magenta curve shows the maximum and minimum values of the shifted subsets. The cyan curve shows the sorted data. Finally, the black curve shows the representation of the cubic interpolation function joining the maximum and minimum points in the subsets.

(a)

(b)

Figure 8. (a) Curve smoothing function of frequency domain representation of signal using piecewise cubic interpolation. (b) Peak-picking function of the smoothed frequency domain representation.

3.8 *Find the peaks in the frequency domain*

The peaks of the frequency domain representation of the signal, are, by definition, the natural frequencies of vibration of the structural system. The peaks are identified via a peak-picking algorithm. The peaks are identified using the *'findpeaks'* function in MATLAB (MATLAB, 2014). The function returns a vector with the local maxima and the corresponding index of the input signal vector. This index is then used to identify the corresponding frequency from the frequency vector. A local peak is a data point that is larger than its two neighboring points. The unsmoothed frequency domain representation produces too many local peaks to identify a fundamental frequency, therefore the frequency domain representation required smoothing. Figure 1 shows the steps involved in identifying the fundamental frequencies of the signal.

1. The smoothed frequency domain data was organized into column vectors and plotted (blue curve).
2. The data was filtered into the range of interest (0-1000Hz).
3. The filtered and smoothed frequency content was divided into a series of n subsets.
4. The maximum and minimum values of each subset was subsequently calculated (red curve).
5. The subset data was shifted by a value of n/2 (green curve).
6. The maxima and minima values of the shifted subsets were thus calculated and the values were joined (magenta curve).
7. The repeated values were deleted and the values were sorted (cyan curve).
8. The MATLAB (MATLAB, 2014) *'findpeaks'* function was thus used to identify the peaks in the smoothed frequency domain (yellow data points).

These peaks are identified as the fundamental frequencies of vibration. *Figure 8*(b) shows the steps of the function in graphical format. The fundamental frequency of vibration for the post-tensioned concrete beams tested was estimated to be 74Hz (Noble *et al.*, 2016). The fundamental frequency identified from peak-picking for the given signal was 69Hz. This represents a 7% error in estimation of the predicted fundamental frequency, however, the structural system tested included the mass of the jacks on either end of the beam (Noble *et al.*, 2016), and this is expected to reduce the expected frequency.

3.9 *Cumulative effect of filtering*

The subsequent sections describe the filters applied to the data in depth, and outline the effect of each individual filter on the raw data signal. *Figure 9* presents the time and frequency domain representations of the filtered signal following the

cumulative effects of the signal filtering as described in Figure 1 and subsequent sections.

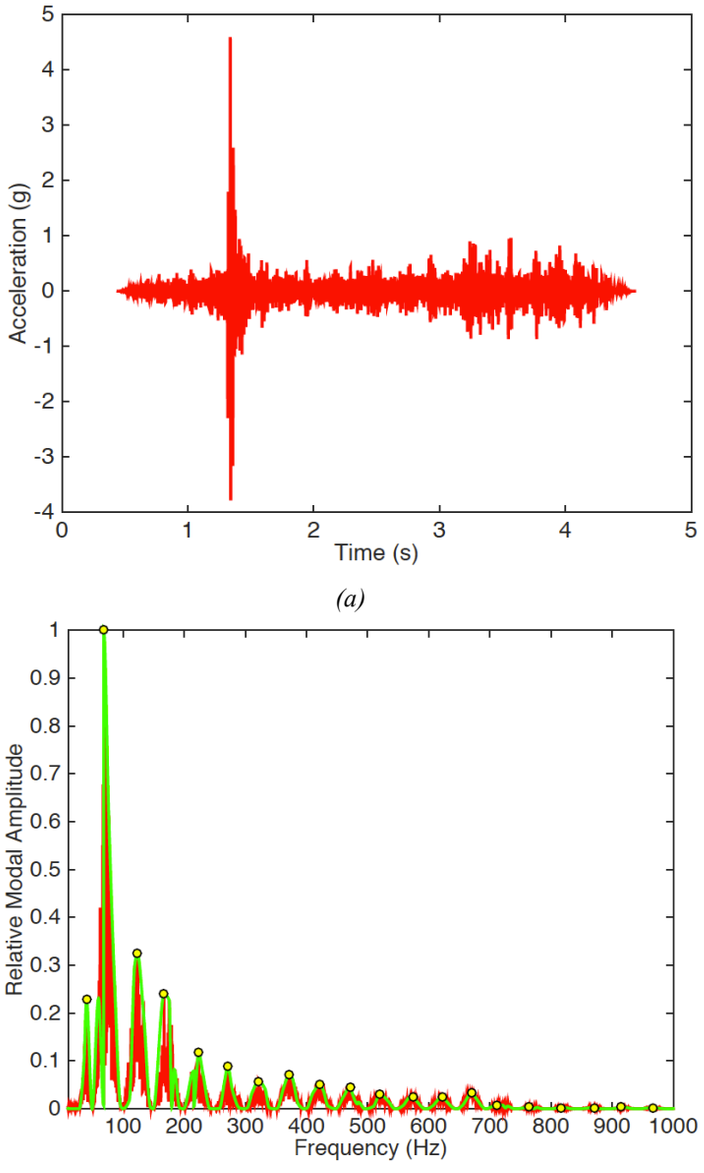

Figure 9. Time (a) and frequency (b) domain representation of filtered response signal

3.10 *Smoothed frequency domain curve*

Figure 10(a) shows the smoothed frequency domain representation of the output response signal. The Inverse Fourier Transform (IFT) was subsequently performed on the smoothed, normalized, frequency domain representation. The IFT transforms the signal from the frequency domain back into the time domain. Since the frequency domain representation has been normalized, the IFT does not represent the correct amplitude of vibration. This is not of interest however, as the frequency was the parameter of interest (Noble *et al.*, 2015, 2016).

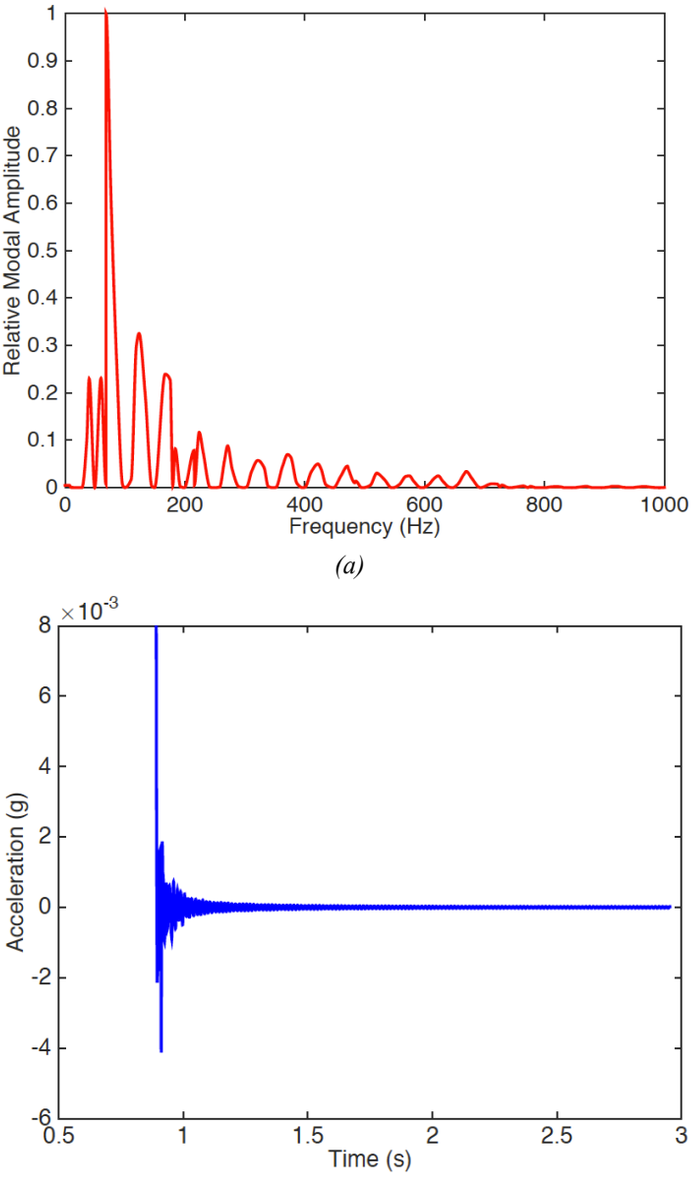

Figure 10. (a) Smoothed frequency domain representation of output response signal; (b) Inverse Fourier Transform (IFFT) of frequency domain representation of output response signal.

4 CONCLUSIONS

This paper outlined the importance and effect of signal filtering on raw acceleration response data for steel and concrete beams in order to identify the fundamental frequencies of vibration (Noble *et al.*, 2015, 2016). The paper outlines the difficulty in identifying the appropriate fundamental frequency using unfiltered accelerometer data. The effect of noise components is such as to distort the structural vibration signal, meaning that the main structural vibration frequencies may be unintelligible. The noise components may be removed through careful filtering. The filters applied to the accelerometer data, and described throughout the paper are; moving average filter, zero-drift filter, notch filter removing electrical noise, 40Hz high pass filter, and

an anti-aliasing filter. The most important filters in terms of identification of the natural frequencies are the zero drift and 40Hz high-pass filters, removing the dominant low-frequency noise components. The second most important filter in terms of structural frequency identification is the electrical notch filter, removing the electrical noise from the A/C circuitry in the accelerometer.

Care must be taken in signal filtering in order to avoid over-filtering. Over filtering of the signal leads to confirmation bias, furthermore, if care is not exercised, valid structural frequency content may be removed. The described signal processing regime allowed for the correct identification of the predicted fundamental frequencies of vibration for both steel and concrete sections as outlined previously (Noble *et al.*, 2015, 2016). Such an approach can be helpful for tracking frequency changes and real time monitoring and assessment of structural systems (Krishnan *et al.*, 2018).

5 ACKNOWLEDGEMENTS

The authors would like to gratefully acknowledge the financial support donated by the Irish Research Council (IRC) under its Embark initiative (Grant No. RS/2012/111). The authors would also like to sincerely thank Banagher Concrete, Heitons Steel, Roadstone Ireland, Fairyhouse Steel, and Freyssinet Ireland for their support in supplying testing materials throughout the duration of the project.

ABSTRACT

Several regions in Europe are prone to both seismic and scour hazards thus bridges can suffer from the joint actions of these two phenomena. The two types of hazards are actually independent as to the generation process but the loss of surrounding soil due to scour may significantly modify the dynamic parameters of the structure thus changing its response to a subsequent earthquake.

Permanent monitoring through vibration-based methods can be an effective support in bridge assessment procedures providing updated information about the structural state and performance. Information from the monitoring system allow both the prompt detection of a possible damage state after an extreme event and also support for long term assessment of the structural conditions.

For bridges under multiple hazard the possibility of using the same network of sensors for different hazards can increase the benefit/cost ratio related to the use of a monitoring system.

In this paper, some preliminary results of a numerical investigation carried out on the finite element model of a bridge under flood and seismic actions are reported. The numerical model of a multi-span bridge, developed using OpenSees, is subjected to a seismic base input considering several defined scour conditions. Scour has been modelled as the incremental increase in length of one of the piers and the effect of scour on the seismic response is investigated. The evolution of modal periods and of deck peak accelerations under seismic excitation have been studied in order to investigate the feasibility of these parameters as performance indicators able to detect the presence of scour in one piers for a bridge under seismic excitation. The first part of the paper reports a brief description of the main damage scenarios connected to scour and to seismic actions. The second part of the paper reports the results of a non-linear dynamic analyses of a scoured bridge under seismic input. Several scour depths have been considered in order to study the sensitivity of several vibration-based parameters to the intensity of the scouring.

1 INTRODUCTION

1.1 Bridge scour

Bridge scour is the term used to describe the removal of soil from around bridge foundations caused by adverse hydraulic action (Hamill 1999). There are three main forms of scour: general, contraction and local scour. General scour occurs naturally in river channels and is a fundamental behavior of evolving rivers. It involves the natural erosion and deposition behavior of a river channel that occurs due to changes in the hydraulic parameters governing channel form, for example flow rate or sediment supply (Forde et al. 1999; Federico et al. 2003). Contraction scour occurs due to the sudden increase in flow velocity at the location of a bridge caused by a narrowing of the river channel, as water is channeled between the sub-structural elements of a bridge (piers or abutments). The increased velocity has an associated increase in the shear stresses imposed on the streambed sediment. Once the threshold shear stress of a given bed material is surpassed, sediments are mobilized (Briaud et al. 1999). Finally, local scour occurs around individual piers or abutments due to their disruption of the local water-flow characteristics. The flow is channeled downward once it meets the obstruction, which can cause scour holes to develop on the upstream end of a pier due to the generation of horseshoe vortices. Furthermore, the flow separating at the sides of the pier causes wake vortices to form which can expand the scour hole around the pier (Heidarpour et al. 2010). Figure 1 shows a schematic of the scour process around a cylindrical pier-type object.

Scour is one of the leading causes of bridge failure worldwide (Briaud et al. 2001; Briaud et al. 2005; Melville & Coleman 2000; Wardhana & Hadipriono

2003). In the United States, bridge failure inventories claim that scour is either the leading factor or a major contributory factor to sudden bridge failure. For example, one study of 500 bridge failures that occurred between 1989 and 2000 in the United States claimed that 53% of the failures were attributed to flood-related mechanisms including scour (Wardhana & Hadipriono 2003). Another similar study from an earlier period specified scour as the primary cause of failure in 600 documented bridge failures (Shirole & Holt 1991). Scour represents a significant cost burden on infrastructure managers between preventative measures, inspections and associated repairs.

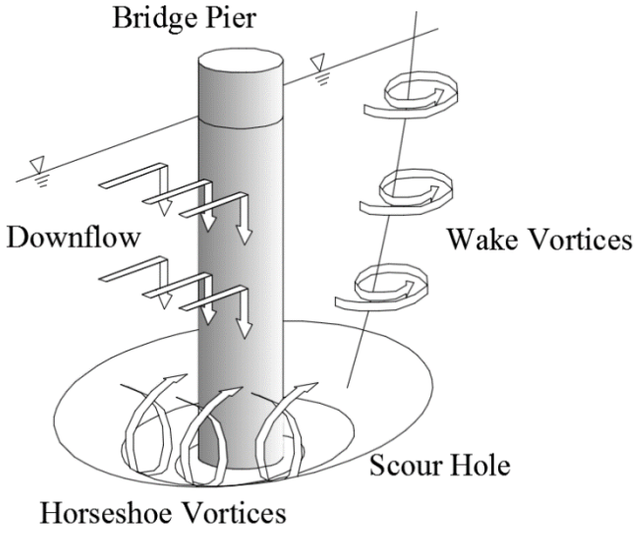

Figure 1: Schematic of local scour - modified from Prendergast & Gavin (2014)

Scour failures tend to occur quite suddenly and generally without much warning. For example, in North Dublin, Ireland in August 2009, a railway bridge on the main Dublin to Belfast rail line partially collapsed as a train passed overhead (Maddison 2012). Fortunately, there were no causalities in this particular incident, however the rail line was out of service for some time afterwards.

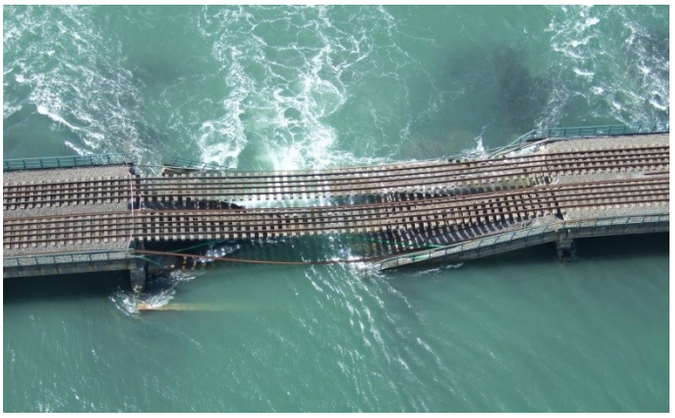

Figure 2: Collapsed Malahide Viaduct on Dublin-Belfast rail line (Maddison 2012)

Figure 2 shows a photo of the bridge after collapse. The bridge is located in a tidal estuary, and tidal scour was deemed to be the cause of collapse.

Monitoring of scour has become a topic of significant importance for asset managers. Scour monitoring was traditionally undertaken by visual means, whereby a diver would inspect the condition of a foundation at discrete periods. The main drawback of these methods is the subjectivity of the condition ratings, as well as the dangers of inspecting for scour during floods. For example, the primary focus of these inspections were to visually assess the magnitude of a scour hole, in terms of its depth, proximity to a foundation as well as any auxiliary impacts present (cracking or other evident damage). Moreover, scour holes tend to refill with sediment as flood waters subside making their detection by discrete visual means quite challenging. In response to the need for more reliable methods, several mechanical and electrical instruments have been developed to remotely monitor scour (Prendergast & Gavin 2014; Fisher et al. 2013). These instruments typically measure the depth of a scour hole near a foundation element with varying degrees of accuracy. A variety of methods exist that use physical sensors placed on or near the ground that move with changing bed level elevation (Hunt 2009; Briaud et al. 2011), or they rely on electromagnetic or sonic methods (Forde et al. 1999; Yu 2009; Nassif et al. 2002). One common drawback of the majority of these types of instruments is that they are typically incapable of assessing the *distress* experienced by the bridge due to the presence of scour at the foundations.

The need for more information on the condition of the structure due to scour has led to the evolution of the vibration-based scour monitoring field. Several authors have investigated how the dynamic response of bridges or specific bridge elements varies under scour, see (Briaud et al. 2011; Prendergast et al. 2016; Prendergast et al. 2017; Prendergast et al. 2013; Chen et al. 2014; Bao et al. 2017; Elsaid & Seracino 2014; Foti & Sabia 2011) among others. For example, Ju (2013) studied how the natural frequency of a bridge varied with scour incorporating fluid-structure interaction. Chen et al. (2014) present a case study of a vibration-based bridge scour detection scheme applied to a cable-stay bridge based on measuring ambient velocity changes. Prendergast et al. (2013) investigated how the natural frequency of a single pile varied as it was scoured, on a both a laboratory and field scale. Moreover, they put forward a numerical model capable of tracking the frequency change using site specific soil parameters. Prendergast et al. (2016; 2017) build on this method and investigate if scour can be detected and located using frequency measurements of an integral-type bridge structure.

The majority of these studies agree that the loss in stiffness due to scour can be traced using vibration

measurements, whereby the stiffness loss manifests itself as a change in modal properties (Doebling et al. 1996). This topic is receiving an increasing amount of interest in the literature in recent years.

1.2 Seismic actions on bridge performance

Collapse of bridges due to seismic actions may be the result of the application of old design codes that did not consider at all seismic design or did not apply capacity design principles. According to the capacity design principles, the design of the structures (or the upgrading for existing ones) has to be performed so as to enhance the energy dissipation capacity. This can be achieved avoiding brittle failures and allowing controlled energy dissipation.

The first goal is achieved designing the structure with a resistance with respect to brittle collapse mechanisms higher with respect to the resistance to ductile mechanisms. For example the resistance to shear failure has to be higher with respect to the resistance to bending failure and the resistance of the superstructure should be lower with respect to the resistance of the foundations. The second goal of controlled energy dissipation is pursued by allowing the formation of flexural plastic hinges in predefined (controlled) locations. This enables the development of stable collapse mechanisms and thus the dissipation a large amount of energy. For example in the case of a bridge this means that the structure is designed to allow the formation of flexural plastic hinges in as many piers as possible. On the other hand, such deformations are not allowed to occur in the deck and the foundations, which are designed assuming the maximum anticipated actions at the base of the piers.

The capacity design principles can be applied through proper detailing of critical regions (e.g. reduced spacing of the transversal steel bars in reinforced concrete structures, or reduced transversal sections in steel structures) and through design of the structural elements carried out based on the resistance with respect to brittle mechanisms and not based on the actions.

If capacity design is not applied, as is the case of most bridges built according to old design codes, brittle collapse mechanisms with very limited energy dissipation capacity are likely to occur.

Bridge piers usually represent one of the weak elements under seismic actions due to inadequate detailing (Anzlin et al. 2015) that limit their capacity to deform in the non-elastic range without sensible reductions of strength (ductility).

Another common bridge collapse mechanism is due to the collapse of the deck girders due to large relative displacements between pier columns. Collapse may occur at expansion joints due to compression or tension failures or – in case of simple supported girders - to the unseating of deck due to insufficient seat width (see Figure 5).

In simply supported span bridges the unseating of the bridge deck could be dually affected by scour due to the increased flexibility that increases the maximum potential displacement of the deck induced by seismic actions. In this paper, the effect of scour local to one of the piers on a multi-span bridge is investigated in terms of how it changes the seismic response of the bridge. This is investigated using numerical modelling, as discussed in the following section.

1.3. Seismic behavior of scoured bridges

The seismic response of a bridge depends on its dynamic characteristics that are strongly related to the stiffness of the piers. As remarked in section 1.1, scour causes a stiffness loss of the scoured pier due to the increase of clear length and this may sensibly affect the modal characteristics of the bridge. The increased flexibility in general, for bridges in stiff-medium soils – has a beneficial effect on the severity of the seismic action but at the same time leads to an increase of relative displacement that has a detrimental effect on other collapse mechanism linked for example to the unseating of the deck girders.

Furthermore the variation of the relative stiffness between piers induced by a single pier scouring induces a redistribution of the actions in the piers thus to a possible increase of the shear forces in non-scoured piers.

1.4. Monitoring of bridges under scour and seismic hazards

To date a number of bridges under seismic threat are monitored with permanent network of sensors. Despite the importance of the topic and the large number of bridges that may be under the combined hazard of scour and seismic actions, a limited number of studies have been devoted to this topic. The aim of this paper is to provide an insight to the behavior of a scoured bridge under seismic actions and to check the feasibility of simple vibration-based damage detection algorithms to detect damage induced by the joint hazard of scour and seismic action. Several data driven vibration-based algorithms of damage localization have been proposed in literature and can be used for the case of bridges under seismic excitation (Doebling et al. 1996, Limongelli 2010, 2011, 2014, Kim et al. 2002, Pandey et al. 1991, Ratcliffe 2000, Zhang et al 1998, among many others). In this preliminary study only the modal period and the peak acceleration have been used as indicators of a scouring condition in one of the bridge piers.In this paper, using numerical modelling the effect of scour local to one of the piers on a multi-span bridge is investigated in terms of how it changes the seismic re-

sponse of the bridge. The use of the variation of modal frequencies and of peak deck accelerations at the pier locations as indicators of scour in one pier is investigated with reference to several scenarios corresponding to increasing scour magnitudes.

2 FINITE-ELEMENT MODELLING

The effect of scour on the seismic response of a multi-span bridge is investigated numerically using OpenSees, an open source dynamic modeling software (MacKenna et al. 2016). Section 2.1 present the model used in this study, section 2.2 discusses how scour is modelled and section 2.3 presents how seismic motions are incorporated.

2.1 Multi-span bridge model in OpenSees

A six-span bridge supported by five I-shaped bridge columns (the cross-section is presented in Figure 3 and 4) was considered in this study. The deck of the structure was modelled as an elastic beam column with the geometrical characteristics representing a cross-section displayed in Figure 4. The abutments of the bridge were simplified into roller supports enabling the longitudinal movements of the bridge. The elastomeric bearings in the first and the last column were modelled with elastic springs whose stiffness was proportional to the shear modulus and the geometrical characteristic of the bearings.

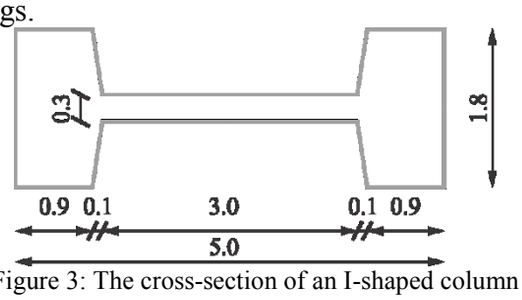

Figure 3: The cross-section of an I-shaped column

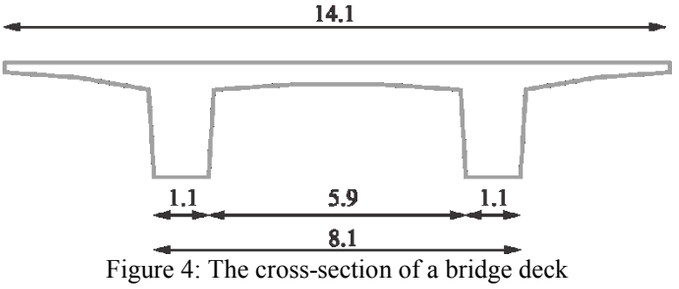

Figure 4: The cross-section of a bridge deck

2.2 Scour modeling

Local scour of one of the piers is modelled as an increase in the effective length. In total, 10m of scour is considered and only one pier is affected, pier 4 (see Figure 5). The scour depth is incremented in 2m increments and the seismic loading is applied for each scour condition in the perpendicular direction of the traffic (longitudinal direction).

2.3 Seismic modelling

OpenSees program platform (MacKenna et al. 2016) has been used for the modal and non-linear dynamic analysis of the bridge. The lumped plasticity model (Giberson 1969) was used for the modelling of a non-linear response of bridge columns. The characteristics of the non-linear spring located at the bottom of each column (see Figure 5) are based on the tri-linear idealization of the full moment-curvature analysis of a column cross-section. The material characteristic of discretized fibres of steel, unconfined and confined concrete are based on the recommendations of Eurocodes 8/2 (CEN 2005a) and 8/3 (CEN 2005b). The behavior of the non-linear spring was defined using Takeda hysteretic rules (Takeda et al. 1970) assuming the unloading stiffness factor to have a value of 0.5. The damping matrix was defined as a linear combination of the mass and initial stiffness matrices using a Rayleigh approach (Clough & Penzien 1993).

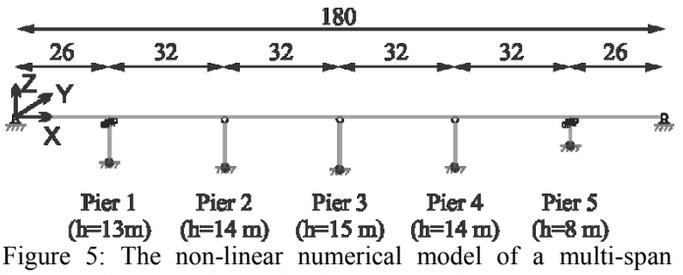

Figure 5: The non-linear numerical model of a multi-span bridge with springs located at the bottom of each pier.

3 ANALYSIS & RESULTS

In this section, the results of the analysis are presented. The model presented in the previous section is used to perform a modal study (section 3.1) and a seismic response analysis (section 3.2).

3.1 Modal analysis

The first two modal shapes obtained from the numerical model in OpenSees (by obtaining a solution of the Eigenproblem) (Clough & Penzien 1993) are shown in Figure 6 and 7 for both the no scour and full (10m) scour scenarios.
Mode 1 is a longitudinal mode (in the traffic direction) and mode 2 is a lateral bridge mode (perpendicular to the traffic direction). As expected, scour increases the global flexibility of the bridge, particularly in the transversal direction. The first two modal shape results due to a scour depth of 10m for the fourth pier (pier 4 in the numerical model) are shown in Figure 7. The comparison with the corresponding modal shapes relevant to the scenario without scouring points out the effect of the latter on these parameters. The asymmetry in the structure's stiffness before and after scour has shifted the modal displacement in the lateral direction towards the scoured pier. This is sensible as if we consider the

increased flexibility of the scoured pier, this should experience larger movements under a dynamic motion.

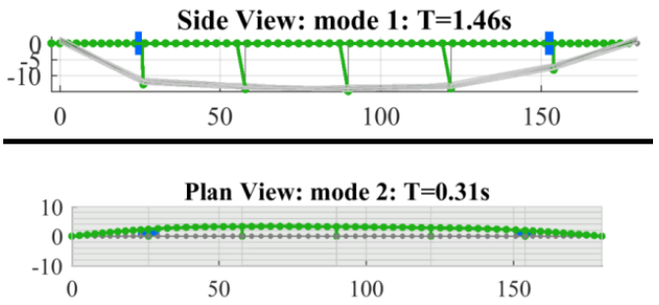

Figure 6: The 1st and 2nd mode shape of the bridge with no scouring

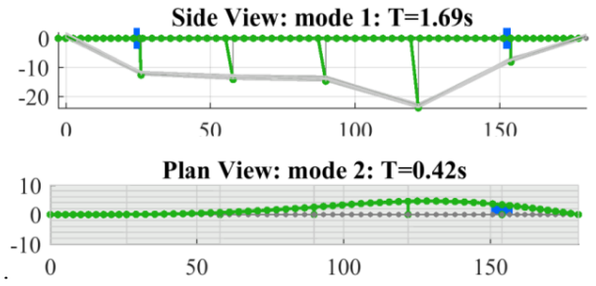

Figure 7: The 1st and 2nd mode shape of the bridge with 10 m scouring

The effect of different scouring depths (scour depth S between 0m and 10m) on the natural periods (first T_1 and second T_2) of the bridge is evident from the values reported in Table 1.

Table 1: 1st and 2nd modal periods (T_1 and T_2) of the bridge with different levels of scouring

Scour S [m]	**0**	**2**	**4**	**6**	**8**	**10**
T_1 [s]	1.46	1.54	1.6	1.64	1.67	1.69
T_2 [s]	0.31	0.34	0.37	0.39	0.41	0.42

Table 2: Variation of the 1st and 2nd modal periods of the bridge with different levels of scouring

Scour S [m]	**0**	**2**	**4**	**6**	**8**	**10**
$\Delta T_1/ T_1$ [%]	0.0	5.5	9.6	12.3	14.4	15.8
$\Delta T_2/ T_2$ [%]	0.0	9.7	19.4	25.8	32.3	35.5

As expected, both modal periods increase with the flexibility of the scoured pier. Scouring has a stronger effect on the second mode as shown in Table 2 by the percentage variations of the two modal periods with respect to the initial values: the percentage variation of the second mode is around twice or higher than the corresponding variation of the first one. This means that the effect of scouring on the dynamic response of this type of bridges is likely to be much higher in the transversal direction than in the direction of the traffic. For this reason in the following sections are reported the results of a dynamic analyses of the scoured bridge under a seismic input acting in the transversal direction - perpendicular to the traffic.

3.2 Seismic response under progressive scour of single pier

The response of the bridge under an applied seismic input is investigated for the range of scour depths presented in Table 1. A seismic motion with duration of approximately 40 seconds and scaled to peak ground acceleration (PGA) of approximately 1 m/s^2 is considered for the seismic analyses of the bridge. Figure 8 shows the time history of the scaled earthquake ground motion (Athens 1999 earthquake) used in this study and its response spectrum. The seismic excitation is applied in the lateral direction to the bridge (to excite mode 2), perpendicular to the traffic direction.

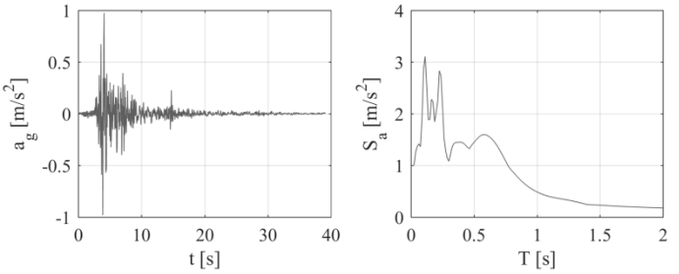

Figure 8: The earthquake ground motion record with peak ground acceleration of 1.0 m/s^2 considered for the lateral excitation of the bridge and the response spectra of the ground motion.

Responses to the applied ground motion in terms of absolute accelerations a, displacements u, and shear force F in the piers are shown in subsequent plots.

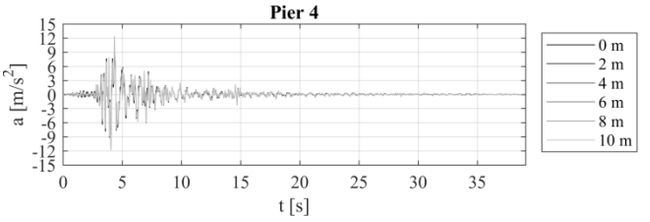

Figure 9: The time domain signal of the absolute acceleration a at the deck level of the Pier 4 for the bridge with no scour (S=0) and investigated levels of scouring (S=2, 4, 6, 8 and 10 m).

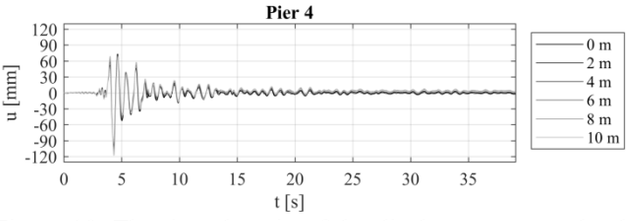

Figure 10: The time domain of the displacement u at the deck level of the pier 4 between the bridge with no sour (S=0) and investigated levels of scouring (S=2, 4, 6, 8 and 10 m).

Figure 9 shows the absolute acceleration measured at the deck level of the scoured column (Pier 4)

for scour depths ranging from 0m to 10m. The maximum (peak) acceleration increased under scour from 11.6 m/s^2 for 0m of scour to 12.4m/s^2 under 10m scour.

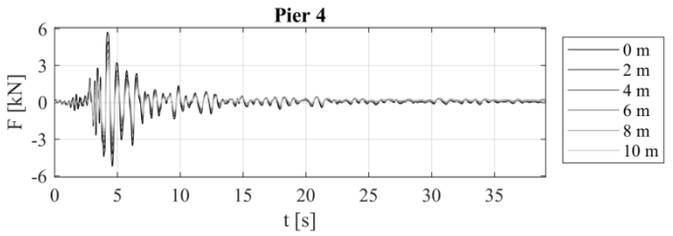

Figure 11: The time domain of the shear force F at the base level of the pier 4 between the bridge with no scour (s=0) and investigated levels of scouring (s=2, 4, 6, 8 and 10 m).

Figure 10 shows the displacement measured at the deck level above the scoured pier 4 for scour depths ranging from 0m to 10m under the applied seismic load (Figure 8). Figure 10 shows that some nonlinear plasticity is evident in the responses, particularly for larger scour depths.

The peak displacement observed at the deck level of the scoured pier 4 due to the applied seismic load increases from 0.1 m at the deck level for 0m of scour to 0.12 m for a scour depth of 10m affecting the pier. This is sensible as the increased flexibility of the scoured pier enables it to translate further under the applied excitation.

Finally, Figure 11 shows the absolute shear force calculated at the base of the scoured pier 4 due to the applied seismic load in Figure 8. The shear force is presented in kN. Scour depths are varied from 0m to 10m at pier 4 and the peak shear force calculated at the base of the pier decreases under scour from 5.72kN for the case where there is 0m scour to 2.92kN for the case where there is 10m scour at the pier.

Table 3: Maxima value of the shear in the piers Vp for different levels of scouring and maxima value of the total shear in the piers.

	Scour S [m]	**0**	**2**	**4**	**6**	**8**	**10**
F [kN]	Pier 1	1.56	1.56	1.52	1.52	1.52	1.52
	Pier 2	5.63	5.65	5.75	5.81	5.85	5.90
	Pier 3	5.76	5.77	5.89	5.90	5.91	5.90
	Pier 4	5.72	4.94	4.32	3.77	3.30	2.92
	Pier 5	1.01	1.03	1.02	1.03	1.04	1.04
F_T [kN]		19.7	18.9	18.5	18.0	17.6	17.3

Table 3 reports the absolute value of the maximum shear in each piers F and the total shear F_T in the piers. At the increase of the scour depth from S=2m to S=10m, the shear F decreases in Pier 4 (the scoured one) by almost 50% with respect to the initial value (un-scoured condition) and increases by values between 2% and 5% in the other piers. The scour is thus beneficial for the scoured pier but of course not for the other resisting elements where the effect of the increased flexibility of the bridge, leading to a reduction of the total shear in the piers F_T, is canceled by the redistribution of the internal actions induced by the change of stiffness ratios between piers.

As shown in Figure 12, with the increase of the scour depth, the normalized shear F/F_T (ratio between the shear force in the pier and sum of the forces in the piers) sensibly decreases in Pier 4 and increases (with a lower rate) in all the other piers. For example at the increase of the scour from S=2m to S=10m, the normalized shear F/F_T for pier 4 decreases from 29% to 17% and increases from about 29% to 34% for piers 2 and 3. The variation of shear forces in piers 1 and 2 due to scouring is much smaller due to the presence of the elastomeric bearings (the connection of the deck and the piers in the direction of seismic loading is not rigid) mon the tops of these piers.

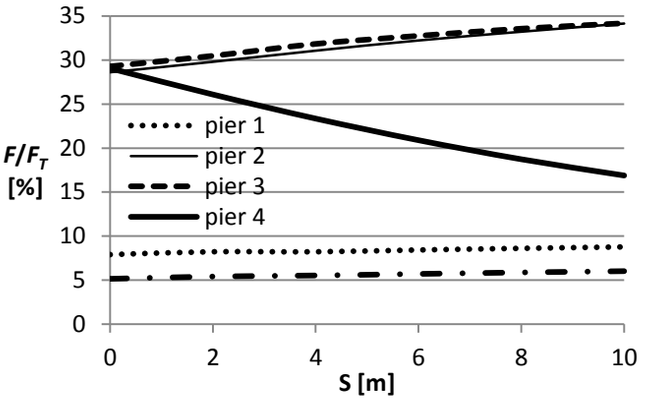

Figure 12: Maxima shear forces in the piers normalized to the total shear in the piers as a function or the scour depth

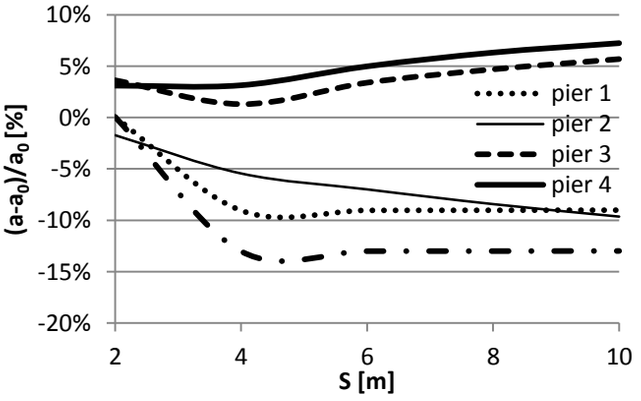

Figure 13: Variation of the maxima absolute acceleration normalized to the reference value a_0 as a function of scour depth

The percentage variation of the maximum absolute accelerations on the deck at the location of the piers are consistent with the variation of the second modal shape. At the increase of the scour depth, the acceleration increases in the scoured pier (pier 4) and in the pier nearby (pier 3) and decreases in the other piers as shown in Figure 13.

4 CONCLUSION

The effects of uncorrelated hazards, in the present case, scour occurrence and earthquakes is becoming a topic of increased interest. Though independent in their generation, the effect of an earthquake will vary depending on the scoured condition of the foundations. In this paper, the effect of local scour on the seismic response of a bridge was investigated briefly. A multi-span bridge was programmed using OpenSees and one of the piers was subjected to scour. Scour was modelled as the increase in the effective length of one of the piers with the remaining piers remaining unscoured. In total, 10m of scour was examined in increments of 2m. A seismic motion was applied to the bridge in the transverse direction (perpendicular to traffic) based on a modal study undertaken.

The effect of scour is to increase the peak displacement of the pier (at deck level), with a corresponding increase in the peak acceleration at the same level. The shear force at the base of the scoured column drastically decreases with scour, however this results in a redistributed higher shear being experienced by adjacent columns.

The increased flexibility of the bridge can be detected monitoring the increase of the modal period in the transversal direction, perpendicular to the traffic. The variations of the peak accelerations on the deck in the transversal direction show higher values at locations close to the scoured pier.

This paper presents preliminary results. Future research will investigate a more exhaustive set of parameters including multiple seismic records, various applied directions, variations in bridge properties and multiple scoured locations.

ABSTRACT: In this paper, the time-dependent reliability of PC girders in a marine environment is estimated considering the spatial variability of steel weight loss. Non-linear finite element (FE) analysis of aging PC girders is performed. Spatial variation of steel weight loss represented by uniform, Gaussian and non-Gaussian stochastic fields is included in the FE modelling. To obtain the relationship between input parameters and computational results from FE analysis, the response surface method is used for reducing the time required to repeat the structural analysis. The life-cycle reliability outcomes associated with three different models for the steel weight loss distribution are compared and discussed in an illustrative example.

1 INTRODUCTION

Steel corrosion in concrete structures due to chloride attack is one of the primary causes of deterioration. This results in cracking and spalling of concrete cover, loss of bonding strength between rebar and concrete, and shortening of service life. Life-cycle performance prediction of concrete structures plays an important role in the design of new concrete structures and in the decision making with respect to inspection, repair, strengthening, and demolition of existing concrete structures (Akiyama et al. 2010, 2012, 2014a, and 2017, Frangopol 2011, Frangopol et al. 2012, Yanweerasak et al. 2016).

Despite extensive research in this field, a number of issues still remain unclear. One of the main intricacies is the uncertainty associated with the physical parameters involved in the problem. Because of the presence of uncertainties, long-term structural performance must be predicted based on probabilistic methods and life-cycle reliability assessment methodologies should be established.

Spatial variability associated with material properties, geometry and environmental factors that affect the corrosion process of concrete structures has to be investigated further. Recently, a finite element (FE) analysis was used to evaluate the potential effects of corrosion damage on the structural performance of corroded RC beams (Shimomura et al. 2011), and its validation was verified by comparing the computed results to those of the test beams (Kallias & Rafiq 2010, Coronelli & Gambarova 2004). These studies focus on the damages as reductions in the effective material properties and geometry of the RC members, in which the effects of the corrosion were modeled by modifying the geometry of the steel and concrete elements and the constitutive laws of steel, concrete, and their bond interface. However, Coronelli and Gambarova (2004) reported that one of the primary challenges in the numerical simulation is the difficulty in quantifying the loss in the steel cross-section along the rebar length. In addition to the improved constitutive models, it is important to accurately estimate the location and level of the reinforcement corrosion in the FE analysis and adequately represent their damages as the input data into the FE models (Akiyama et al. 2014b). Therefore, the location and degree of the reinforcement corrosion must be adequately assessed if the performance of corroded RC structures is to be reliably predicted by the FE models.

The use of X-ray technology as a non-destructive method is a promising technique that avoids the aforementioned problems. Recently, Akiyama & Frangopol (2013) and Lim et al. (2016, 2017) have used the X-ray and digital image processing techniques to study and quantify the spatial variability in the steel weight losses along the corroded bars inside RC members. The advantages of this method are of considerable interest because (a) the evolution of the steel corrosion and its relationship with the corrosion cracking of the same corroded RC member can be studied at various points in time, and (b) a good accuracy of the estimated steel weight loss can be obtained. Moreover, these techniques can be used to derive the residual cross-sections of the corroded bar at various times and locations. Lim et al. (2016) reported the statistical information used for modeling

the spatial variability in the steel corrosion and incorporated with the probabilistic model to predict the long-term structural performance of corroded RC structures.

In this paper, based on the previous experimental results using X-ray (Lim et al. 2016, 2017), longitudinal steel weight loss over the PC girder is represented by one-dimensional Gaussian and non-Gaussian random fields, and uniform corrosion. Time-dependent failure probability of PC girder in a marine environment is estimated based on non-linear FE analysis with randomly distributed steel weight loss. The performance function to estimate the failure probability is defined by the comparison of the moment capacity at the yielding of steel and demand due to the self-weight and traffic load. To reduce the computational time of FE analysis, the response surface method (RSM) is included in the proposed life-cycle reliability formulation. In an illustrative example, fundamental insights on the spatial distribution associated with the steel weight loss are presented.

2 MODELING OF SPATIAL RANDOM FIELDS ASSOCIATED WITH THE STEEL WEIGHT LOSS IN CONCRETE STRUCTURES

2.1 *Spectral representation method*

The spectral representation method (SRM) is a versatile method in generating stochastic fields and processes (Shinozuka & Deodatis 1996). This method can be used within a Monte Carlo Simulation (MCS) to solve the stochastic problems in structural engineering. In this study, based on the formulations presented by Papakonstantiou & Shinozuka (2013), spatial variability associated with the steel weight loss in PC girders is represented by the one-dimensional Gaussian stochastic field:

$$f(t) = \sqrt{2}\sum_{j=1}^{N}\sqrt{2S_{f_0f_0}(\kappa_j)\Delta\kappa}\cos\left(\kappa_j t + \varphi_j\right)+\mu \quad (1)$$

where

$$\kappa_j = j\Delta\kappa \;;\; \Delta\kappa = \frac{\kappa_u}{N} \quad (2)$$

$$S_{f_0f_0}(\kappa_j) = \frac{\sigma^2 b}{2\sqrt{\pi}}\exp\left(-\frac{b^2\kappa_j^{\,2}}{4}\right) \quad (3)$$

φ_j= independent random phase angle distributed uniformly over the interval [0,2π], κ_u = upper cutoff wave number corresponding to the t axis in the space domain, μ = mean, and $S_{f_0f_0}$ = power spectral density function (PSDF). In this study, for all Gaussian random fields, the PSDF is given by Equation (3), where σ is the standard deviation and b is proportional to the correlation distance of the stochastic fields.

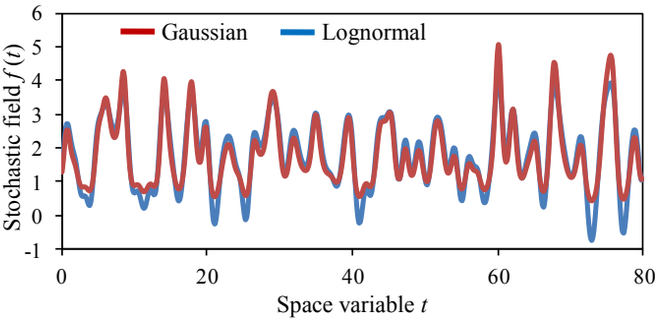

Figure 1 Comparison of Gaussian and lognormal stochastic fields assuming mean = 1.8, standard deviation = 1.0 and auto-correlation length parameter = 1.0

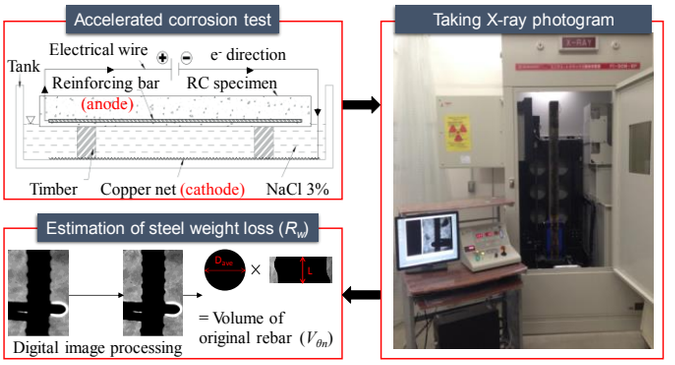

Figure 2 Procedure for estimating the steel weight loss in the corroded RC beam by X-ray and digital image processing

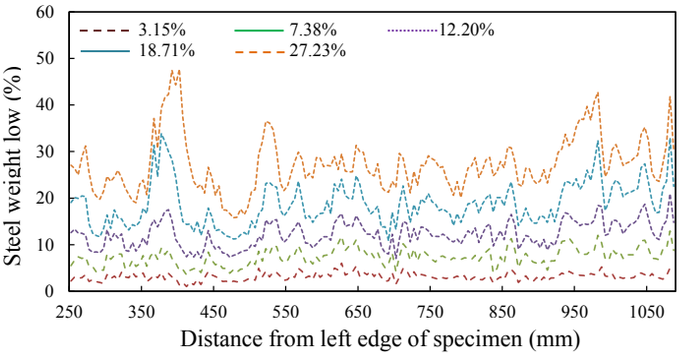

Figure 3 Example of relationship between steel weight losses along the length of the specimen

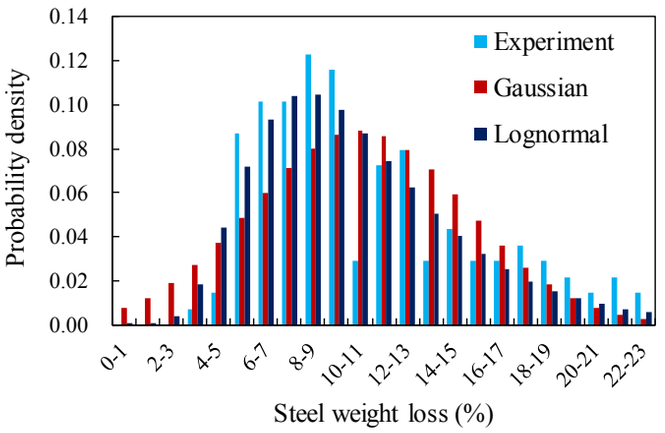
In addition, the Non-Gaussian stochastic field is simulated for the longitudinal steel weight loss according to the procedure presented by Shields et al. (2011).

Figure 1 shows an example of the one-dimensional Gaussian and lognormal stochastic fields.

2.2 *Spatial distribution associated with the steel weight loss in RC beam*

The parameters of the spatial distribution of the steel corrosion are calibrated based on the experimental results to visualize the steel corrosion distribution in RC specimens using X-ray techniques. These techniques have been applied to visualize the nonuniform steel corrosion distribution over the RC component.



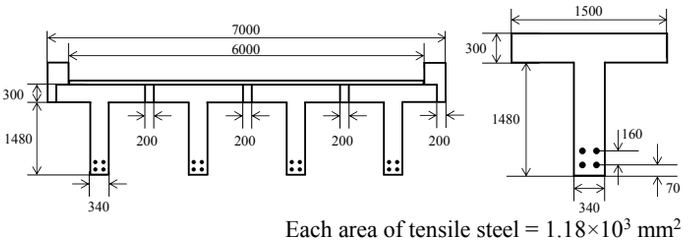


Figure 4 Probability density of steel weight loss

Figure 2 shows the procedure for estimating the steel weight loss of the corroded RC beam (Lim et al. 2016, 2017). The locations for taking X-ray image photograms of the RC beam corroded by electrical corrosion start from distances of 250 to 1090 mm with 14 times the 60 mm interval from the left side of the specimen. Figure 3 shows an example of the relationship between the distance from the left edge of a specimen and the local steel weight loss of the longitudinal rebar. The local steel weight loss was calculated by the volume of the sound rebar estimated by X-ray when $W_{xray,\,g}$ = 3.15%, 7.38%, 12.20%, 18.71%, and 27.23%, where $W_{xray,\,g}$ is the averaged steel weight loss of tensile rebar over the RC beam. Figure 4 shows the probability density of steel weight loss when the mean steel weight loss over the RC beam is 7.38%. It is confirmed that lognormal distribution has a better fit to the experimental data than Gaussian distribution. Therefore, a Non-Gaussian stochastic field is needed for the modeling of the spatial distribution associated with the steel weight loss.

In this paper, the spatial steel corrosion distribution based on experimental results shown in Figure 3 is used for estimating the parameters to reproduce the stochastic field independent of rebar diameter, water to cement ratio, concrete cover, and corrosion speed. Additional research is needed to investigate these effects on the statistics of the spatial variability of rebar corrosion. In addition, in this study, it is assumed that all longitudinal rebars have the same spatial variability of rebar corrosion. The corners in rectangular cross-sections can be more prone to corrosion. The spatial variability of steel corrosion in the transverse direction of RC components needs to be taken into consideration.

3 MODELING THE DETERIORATION OF PC GIRDERS DUE TO CHLORIDE ATTACK

Akiyama et al. (2010, 2012) proposed a probabilistic model for hazards associated with airborne chlorides by considering the spatiotemporal variation effects. The results of the hazard assessment associated with

Each area of tensile steel = 1.18×10^3 mm^2

Figure 5 Analyzed bridge girder (unit in mm)

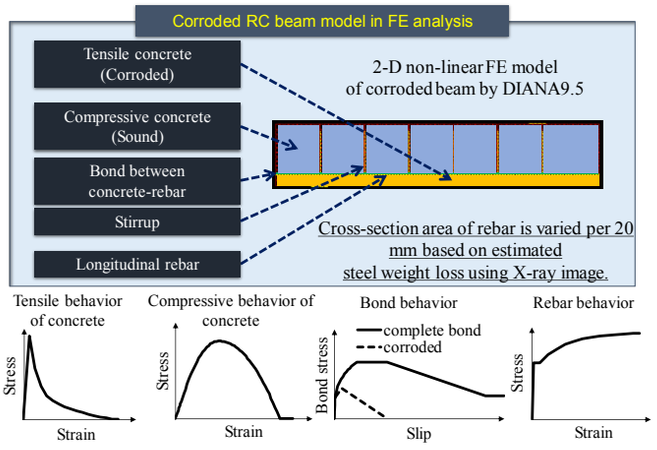

Figure 6 FE model and material constitutive model

airborne chlorides depend on the ratio of the sea wind, the wind speed at the analyzed location, and the distance from the coastline.

Using the hazards associated with airborne chloride, the steel weight loss MR_w (t) given the corrosion resulting from chlorides at time t is estimated using the following nine random variables.

x_1 : wind speed
x_2 : model uncertainty associated with attenuation of airborne chloride
x_3 : model uncertainty associated with relationship between airborne chloride and surface chloride concentration
x_4 : critical threshold chloride concentration at occurrence of steel corrosion
x_5 : model uncertainty associated with estimation by diffusion equation
x_6 : critical threshold of corrosion amount at crack initiation
x_7 : concrete cover
x_8 : steel corrosion rate before the occurrence of corrosion crack
x_9 : steel corrosion rate after the occurrence of corrosion crack

When representing the random fields, MR_w (t) is used as the mean in the Gaussian and non-Gaussian stochastic fields associated with the steel weight loss.

4 ILLUSTRATIVE EXAMPLE

4.1 *Description of PC girder and FE modeling*

Assuming that the PC bridge girder shown in Figure 5 has sufficient stirrups to prevent brittle failure, structural reliability associated with only flexural

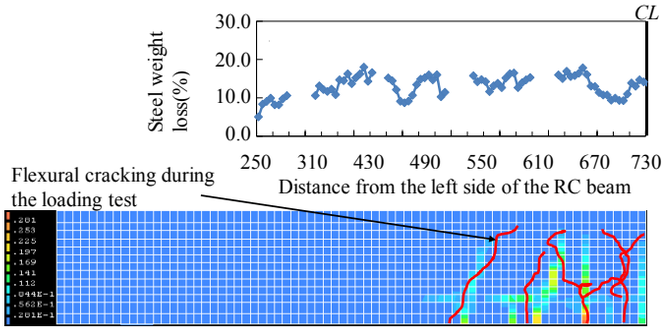

Figure 7 Comparison of contour of principal tensile strain, flexural cracking during the experiment and steel weight loss

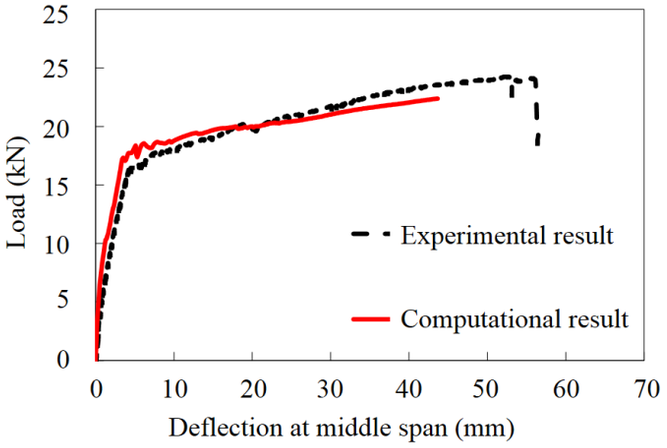

Figure 8 Comparison of computational and experimental results of the relationship between load and deflection

failure is estimated in this paper. Steel weight loss over the PC girder is represented by the discussed random field, simulated via SRM.

Based on the comparison of experimental and computational results, FE modeling of deteriorated concrete members has been investigated (Lim et al. 2016). Figure 6 shows the FE model and constitutive model of concrete in compression and tension, steel reinforcement, and bond stress-slip relationship. Based on the one-dimensional Gaussian and lognormal stochastic fields, the spatial variability associated with the reduced cross-sectional area of the rebar was modeled by varying the cross-sectional area in each steel truss element with a length of 20 mm (mid-point method). Since the expansion of the corrosion products caused the cracking and spalling of concrete, the concrete region that was damaged by corrosion exhibited a reduced performance compared to that of the undamaged concrete regions. The corrosion damage on the concrete cover was considered in the FE model by modifying the stress-strain relationship of the concrete, as suggested by Coronelli & Gambarova (2004). The residual bond stress-slip curve, as proposed by Kallias & Rafiq (2010), is used herein for the deteriorated steel concrete bond interface element, and the well-known bond stress-slip relation in CEB (1993) is used to model the perfect bond between steel and concrete.

It was confirmed that when the steel weight loss distribution in concrete members is obtained, the FE

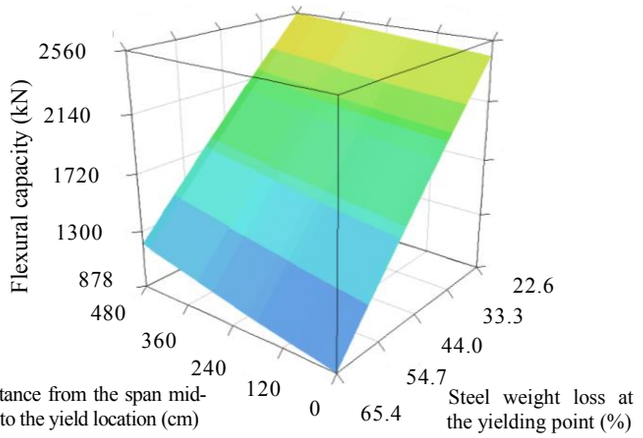

Figure 9 SRM used in the life-cycle reliability analysis

model could provide a better prediction of the flexural capacity of the corroded beams. Figure 7 shows the comparison of contour of the principal tensile strain obtained from the FE analysis, flexural cracking caused during the bending test, and steel weight loss. Figure 8 depicts the comparison of computational and experimental results of the relationship between load and deflection. Taking into consideration the actual steel weight loss of the corroded RC member, the FE model is in good agreement with the experimental results.

Using MCS with the FE analysis and SRM, life-cycle reliability of PC girders with randomly distributed steel weight loss can be estimated. However, the time required to repeat the FE analysis many times may be impractical. In this study, RSM is used to approximate the relation between the desired output of FE analysis and random variables (Okasha & Frangopol 2010, Liu et al. 2001, Frangopol et al. 2017). Figure 9 shows the RSM for obtaining the flexural capacity used in the life-cycle reliability analysis of PC girders.

4.2 *Estimation of moment due to the traffic load*

The critical flexural limit state for the PC girder is considered. Flexural resistance is compared with the bending moment due to dead and traffic loads. Following the computer simulation method of traffic load using the statistics of vehicles presented by Matsuzaki et al. (2010), the probabilistic density distribution of the bending moment is evaluated.

4.3 *Life-cycle reliability of PC girder*

The time-dependent failure probability of PC girder in a marine environment at the time $T = t$ after construction is estimated by

$$P_f(t) = \int_{0\%}^{100\%} \left\{ P\left(D_e > C_a \middle| MR_w = x\right) \cdot P\left(MR_w = x \middle| T = t\right) \right\} dx \quad (4)$$

where, $P\ (D_e > C_a \mid MR_w = x)$ is the conditional probability of exceedance of PC bridge girder capac-

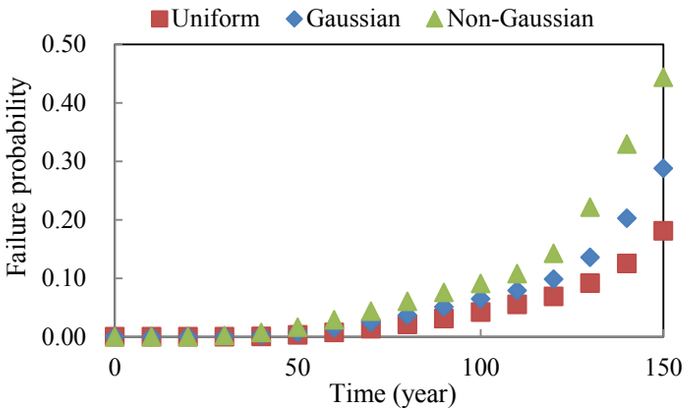

Figure 10 Time-dependent failure probability

ity C_a under traffic loading demand D_e, P ($MR_w = x|T = t$) is the conditional probability that MR_w is equal to x given $T=t$, and MR_w is the mean steel weight loss.

Figure 10 shows the effect of the different models of the steel weight loss distribution on the time-dependent failure probability of PC girder. Even if the global steel weight loss along the PC bridge girder is the same, the maximum local steel weight loss depends on the model of the spatial distribution. This result is in agreement with what found in other studies about non-uniform corrosion of steel beams (Christou & Bocchini 2014). The capacity C_a of a PC bridge girder assuming Gaussian and non-Gaussian stochastic fields simulated for the longitudinal steel weight loss could be smaller. Due to the tail difference between Gaussian and Non-Gaussian probability density functions, the failure probability assuming a non-Gaussian stochastic field is the largest as shown in Figure 10.
