$$\mathbf{L}_{21} = \begin{bmatrix}\mathbf{U}_1 & \mathbf{U}_2\end{bmatrix}\begin{bmatrix}\mathbf{\Sigma}_1 & 0 \\ 0 & \mathbf{\Sigma}_2\end{bmatrix}\begin{bmatrix}\mathbf{V}_1^{T} \\ \mathbf{V}_2^{T}\end{bmatrix} \in R^{2ns\times 2ns} \tag{38}$$

where $\mathbf{U}_1 \in R^{2ns\mathrm{x}2n}$, $\mathbf{U}_2 \in R^{2ns\mathrm{x}2n(s-1)}$, $\mathbf{V}_1 \in R^{2ns\mathrm{x}2n}$, $\mathbf{V}_2 \in R^{2ns\mathrm{x}2n(s-1)}$, and $\mathbf{\Sigma}_1 \in R^{2n\mathrm{x}2n}$ is a diagonal matrix containing $2n$ singular values related to the DOF of the bridge. Consequently, $\mathbf{L}_{21}$ is approximately

$$\mathbf{L}_{21} \approx \mathbf{U}_1\mathbf{\Sigma}_1\mathbf{V}_1^{T} \tag{39}$$

The diagonal matrix $\mathbf{\Sigma}_1$ is a proportional matrix separable into two square-root matrices (Katayama 2006). Based on this, one can obtain the observability matrix $\mathbf{\Gamma}_i$ and the state vector $\bar{\mathbf{X}}\mathbf{Q}_1$ as

$$\mathbf{\Gamma}_i = \mathbf{U}_1\mathbf{\Sigma}_1^{\frac{1}{2}} \tag{40}$$

$$\bar{\mathbf{X}}\mathbf{Q}_1 = \mathbf{\Sigma}_1^{\frac{1}{2}}\mathbf{V}_1^{T} \tag{41}$$

With the observability matrix available, the bridge system matrix $\mathbf{N}^{\mathrm{B}}$ can be obtained from the pseudoinverse calculation as

$$\mathbf{N}^{\mathrm{B}} = \underline{\mathbf{\Gamma}}_i^{\dagger}\overline{\mathbf{\Gamma}}_i \tag{42}$$

where $\underline{\mathbf{\Gamma}}_i \in R^{2n(s-1)\mathrm{x}2n}$ is the observability matrix $\mathbf{\Gamma}_i$ with the nethermost matrix $(\mathbf{N}^{\mathrm{B}})^{s-1} \in R^{2n\mathrm{x}2n}$ deleted; and $\overline{\mathbf{\Gamma}}_i \in R^{2n(s-1)\mathrm{x}2n}$ is the observability matrix $\mathbf{\Gamma}_i$ with the upmost unit matrix $\mathbf{I}_{2n} \in R^{2n\mathrm{x}2n}$ deleted.

The bridge system matrix $\mathbf{N}^{\mathrm{B}}$ is obtained from Eq.(42) in time-discrete form. It can be converted to the time-continuous form by taking the inverse operation of Eq.(17) as

$$\mathbf{N}_c^{\mathrm{B}} = \log\mathrm{m}\left(\mathbf{N}^{\mathrm{B}}\right)/\Delta t \tag{43}$$

where logm denotes the logarithmic matrix operation. The time-continuous bridge system matrix $\mathbf{N}_c^{\mathrm{B}}$ contains all the properties of the bridge. An eigenvalue decomposition of the system matrix $\mathbf{N}_c^{\mathrm{B}}$ returns the eigenvalues of the system

$$\mathbf{N}_c^{\mathrm{B}} = \mathbf{\Psi}\mathbf{\Lambda}\mathbf{\Psi}^{-1} \tag{44}$$

where $\mathbf{\Psi} \in R^{2n\mathrm{x}2n}$ contains the eigenvectors, $\mathbf{\Lambda} \in R^{2n\mathrm{x}2n}$ is a diagonal matrix containing the eigenvalues $\lambda_1, \lambda_1^{*}, \lambda_2, \lambda_2^{*}, \dots, \lambda_n^{*}$; where the symbol * denoting the complex conjugate.

3 RESULTS AND DISCUSSIONS

3.1 *Validation of proposed SSI method*

The frequencies of the examined bridge for the first five modes in the vertical direction are 1.99Hz, 5.52Hz, 7.73Hz, 7.71Hz and 7.91Hz, while the frequencies of the vehicle are 2.15Hz, 3.03Hz and 4.70Hz. These values are obtained from the modal analysis of the systems. The vehicle speed is assumed as constant of 5km/h and the bridge surface is smooth. Figure 2a shows the vertical acceleration of the truck tractor during the time that the vehicle is traveling on the bridge.

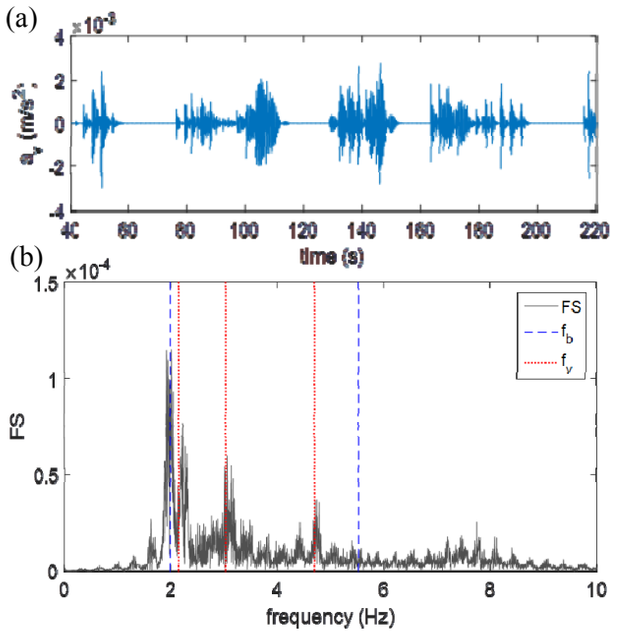

Figure 2. (a) Vertical acceleration of the tractor (b) Fourier spectrum for the vertical acceleration of the tractor.

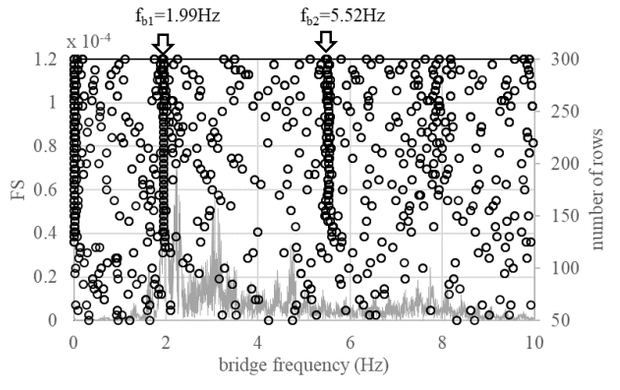

Figure 3. Identification of bridge frequencies by SSI method.

Figure 2b presents the corresponding Fourier spectrum. It is observed that both the frequencies of the vehicle, and the fundamental frequency of the bridge are visible in the Fourier spectrum. However, it is difficult to identify the second frequency of the bridge. In addition, a lot of disturbed peaks appear in the Fourier spectrum, which increases the difficulty of extracting the information of value.

In the following figures, the grey lines represent the Fourier spectra (FS) of the response of the truck tractor in the vertical direction, and the circles represent the bridge frequencies identified by the proposed SSI method, the bridge frequencies are considered to be successfully identified only if the circles create a line without much variation in value as the number of the rows (of the Hankel matrix) increases.

To estimate the bridge frequencies efficiently, the proposed SSI method is applied. The response of the vehicle is calculated by the VBI analysis and the dynamic properties of the vehicle are known.

Figure 3 shows the identification results obtained from the proposed SSI method, without considering the road roughness conditions. As the number of the rows in the Hankel matrix increases, the frequencies of the bridge stabilize gradually in lines. The two bridge frequencies can be efficiently identified from the figure. Meanwhile, the vehicle frequencies have been successfully suppressed.

3.2 *Effect of the road roughness condition*

It is known that the road roughness blurs the identification of the bridge frequencies from the vehicle response (Lin & Yang 2005). However, in reality, the irregularity on the bridge surface cannot be neglected. Thus, it is important to validate the efficiency of the proposed SSI method considering the road roughness condition. To this end, we define the road roughness profile of Figure 4 (Paraskeva et al 2017).

Figure 5 shows the results of the proposed SSI method, considering the road roughness conditions. Again, the first two bridge frequencies can be clearly identified. This example clearly demonstrates that the proposed SSI method has an advantage in practical applications.

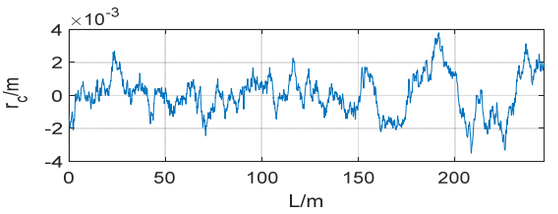

Figure 4. Road roughness profile on the bridge.

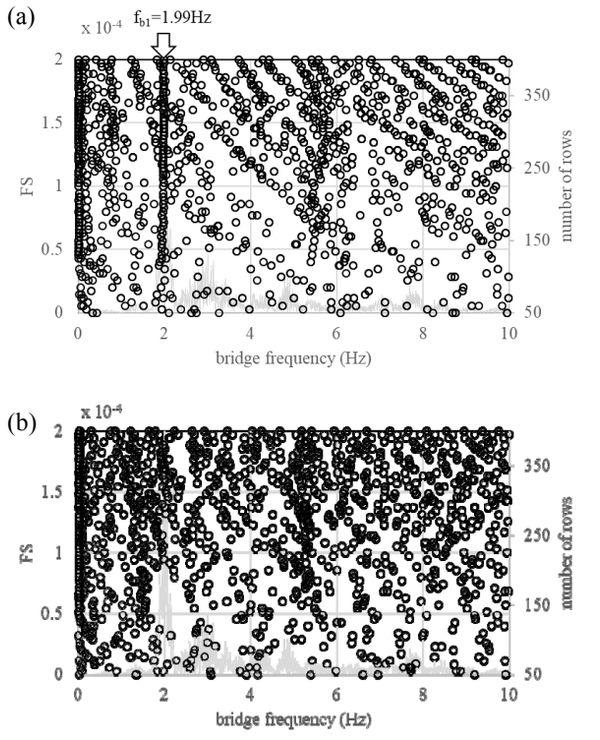

Figure 6. Identification of bridge frequencies by SSI method (a) V=10km/h (b) V=20km/h.

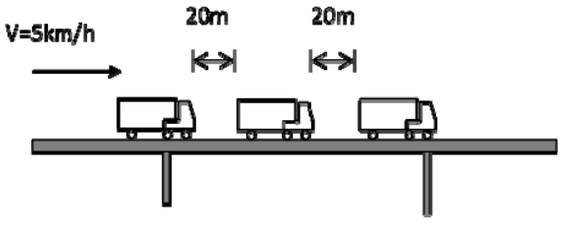

Figure 7. Configuration of the vehicle sequence on the bridge

3.3 *Effect of the driving speed*

This section examines the effect of the driving speed on the efficiency of the proposed SSI method. So far, a constant driving speed of 5km/h has been considered. In this section, we examine the effect of two more driving speeds (a) 10km/h and (b) 20km/h. The road surface is assumed to be smooth. Figure 6(a) shows the identification results by the proposed SSI method when the driving speed is 10km/h. Compared with the case that the driving speed is 5km/h, it is obvious that much more redundant circles appear in this figure, which increases the difficulty of distinguishing the bridge frequencies. As the driving speed increases to 20km/h (see Fig 6(b)), no concentrated lines can be identified, and the bridge frequencies cannot be extracted. Thus, a lower driving speed of the vehicle is beneficial to the accuracy of the proposed SSI method. These findings are in agreement with Yang & Chen (2015). The higher the speed of the vehicle is the shortest the duration of the vehicle on the bridge is which affects the identification procedure.

3.4 *Effect of on-going traffic*

This section examines the effect of the on-going traffic on the efficiency of the proposed SSI method. We use three vehicles running with a 20m relative distance, and speed 5km/h (Fig 7).

In Figure 8(a) all the vehicles have the same dynamic characteristics, and the 'monitored' vehicle is the second. Figure 8(b) repeats the analyses of Figure 8(a), considering the third vehicle as the 'monitored', i.e. it applies the proposed SSI method on the response of the last moving vehicle. The results show that in both cases, the concentrated line representing the fundamental frequency can be identified efficiently. However, the second frequency of the bridge is not that obvious.

In Figure 8(c), the first and the third vehicles have the same dynamic properties, while an additional mass of 26,113kg is added on the trailer of the middle vehicle. We use the response of the latest vehicle for the application of the proposed approach. Contrary to the previous results, we can now clearly identify the first three bridge frequencies. The comparison of Figures 8(a) to 8(c) indicates that the effect of the on-going traffic on the efficiency of the proposed approach is a very complicated phenomenon that merits further research.

4 CONCLUSIONS

The present study applies the SSI method combined with the vehicle-bridge interaction dynamic analysis, to extract the first eigenfrequencies of a straight re-

inforced concrete bridge, using the vibration response of a passing "monitored" vehicle. We examine the accuracy and the effectiveness of the proposed SSI method. The simulations show that the proposed stochastic subspace identification method can satisfactorily be applied for the identification of the bridge frequencies considering the road roughness conditions. This paper only offers a glimpse into the complex bridge system identification problem, and more research is needed to derive the decisive conclusions.

Study on compressive strength of steel plates with a partial loss of cross-sectional area

Kohei SAITO
Graduate School at Ritsumeikan University, Shiga, Japan
Katsuyoshi NOZAKA
Ritsumeikan University, Shiga, Japan

ABSTRACT: Many bridges in Japan had been built from 1950 to 1995, indicating that most of them have been in service more than 50 years. Corrosion has one of the most deleterious effects on steel structures, and this makes maintenance of steel bridges seriously problematic. It is necessary to establish rational criteria in order to accurately predict the residual strength and remaining life of existing steel structures. The objective of this research is to propose a simple expression that can identify the residual strength of steel plate members in compression.

1 INTRODUCTION

Many steel bridges now in-service face problems including corrosion, cracking, and deterioration over time. At the same time, local governments have to inspect the present state of bridges they manage and make future maintenance plans for these bridges. In order to prevent not only serious accidents, such as a bridge falling, but also to prevent inconvenience to users resulting from sudden bridge closure, it is important to clarify the state of every bridge at the present time and take suitable countermeasures.

Research on the residual strength of steel members with partial loss of cross-sectional area caused by corrosion or with cracks has been performed (Ex. Yamasawa et al. 2013 & Nogami et al. 2001), and residual strength evaluation equations have been proposed. However, results were presented under limited conditions such as girder dimensions. In addition, without information about application range, it is difficult to use these equations for practical work. As a result, they have still not come into wide use in practical work, and there is room for further improvements.

In this study, aiming for formulae applicable to practical work, parametric analyses were performed in order to investigate the compressive strength of steel members and propose simple equations.

The partial loss of cross-sectional area considered in this study represents the flanges of I-girders and box girders, and plate edges, a part prone to corrosion are mainly discussed. Partial loss caused by corrosion is often first discovered by a close visual inspection and presumably, in many cases, such corrosion is pitting. So, this study assumes cases in which corrosion causes pitting, resulting in partial loss of cross-sectional area. Therefore, by focusing on the most dangerous damage, it is thought to be possible to use results from this study for screening during maintenance of existing bridges.

2 OUTLINE OF THE ANALYSIS

FEM analysis (Finite Element Analysis) was performed using MSC Marc (MSC Software Corporation 2015), which is a general purpose non-linear structural analysis program, and four-node shell elements were used.

2.1 *ANALYSIS MODEL*

A flange of an I-girder and the flange of a box girder as shown in Figure 1 and in Figure 2 (indicated as I-model and B-model in followings) were modeled. SM490Y steel was used in both the I-model and B-model. I-model represents the bottom flange of girders near the intermediate support, the top flange of a steel railway bridge, and secondary members such as an end cross girder. As the box cross-section, girder and members under axial compressive force were considered.

The yield strength of SM490Y was set to be σ_y=355N/mm^2, and Young's modulus and Poisson's ratio are E=200,000N/mm^2 and ν=0.3, respectively. The elements were ddivided at 5 mm both in X- and Y-axis direction. As initial deformation, in the length direction, for both the I-model and the B-model, sinusoidal waves with half wave of 100 mm were given, and in the width direction, linear change

was given in the I-model, and a sinusoidal wave with half wave was given in the B-model.

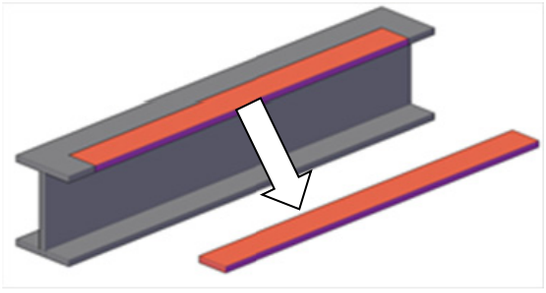

Figure 1. I-girder flange model (I-model)

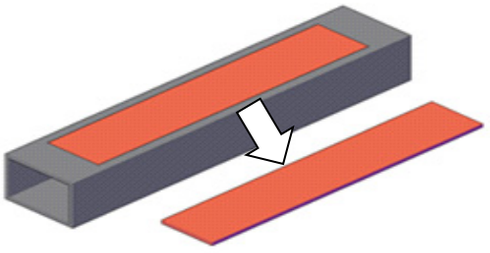

Figure 2. Box girder flange model (B-model)

Figure 3 shows the residual stress distribution used in the analysis. Regarding the I-girder cross-section model (I-model) shown in the top part of Figure 3, the residual stress distribution of only one side of the flange was used with reference to the residual stress distribution shown in Maeda et al. (2007). The bottom part of Figure 3 shows the one for box-girder cross section model (B-model), which assumed an idealized linear distribution shape with tensile residual stress of $1.0\sigma_y$ and compressive residual stress of $0.13\sigma_y$. This was defined by proportionally varying the residual stress distribution listed in Yamasawa et al. (2013).

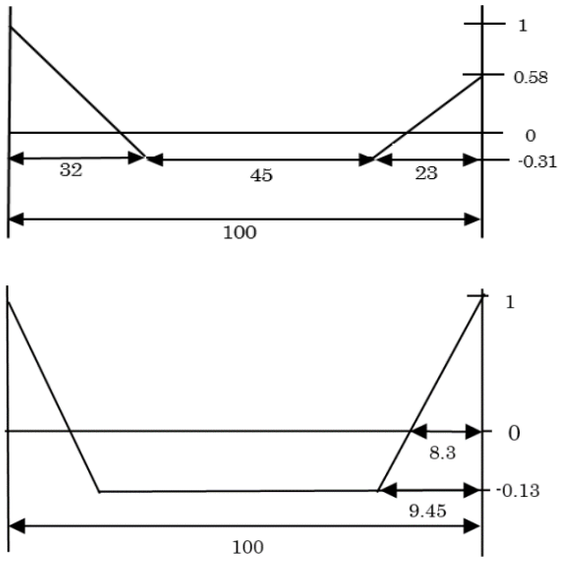

Figure 3. Residual stress distribution

2.2 *DETAILS OF I-MODEL*

The boundary conditions of the I-model were given as simple support on three sides and free on one side. Dimensions were set as 700 mm×100 mm, and the plate thicknesses (t) were the values shown in Table 1 to obtain the target width-thickness ratio parameter (R). The partial loss of cross-sectional area caused by corrosion was given as a partial loss of cross-sectional area of 10, 20, and 30% in the width and length direction respectively from the center of the edge (indicated as 10-10%, 20-20%, and 30-30% model in followings). In addition, in order to account for the effect of loss of cross-sectional area in the length direction so that the analysis was conducted expanding the partial loss in the sectional area to 20% and 30% (10-20%, 10-30%) only in the length direction while loss of cross-sectional area in width direction was fixed in 10%.

Table 1. Width-thickness ratio parameter and plate thickness (I-model)

R	1.2	1.0	0.9	0.8	0.7
t	5.5	6.6	7.4	8.3	9.5

2.3 *DETAILS OF B-MODEL*

The boundary conditions of the B-model were given as simple support on four sides. Its dimensions were set as three patterns: 500 mm×100 mm, 700 mm×100 mm, and 1,000 mm×100 mm. The plate thicknesses (t) and width-thickness ratio parameter (R) considered in this study were shown in Table 2. The partial loss of cross-sectional area caused by corrosion was given as 10, 20, and 30% in the width and length direction respectively from the center of the edge of the flange plate in Figure 2 (indicated as 10-10%, 20-20%, and 30-30% in followings). In addition, in order to account for the influence of partial loss of cross-sectional area caused by corrosion in the length direction, analysis was conducted expanding partial loss in the cross-sectional area to 20% and 30% (10-20%, 10-30%) only in the length direction, while loss of cross-sectional area was fixed as 10% in the width direction only for the 700 mm×100 mm model. The basic model without loss of cross-sectional area for B-model (0-0%) is shown in Figure 4, and the models with partial loss of sectional area of 10-10% and 10-30% are shown in Figure 5 and Figure 6 respectively.

3 RESULTS OF ANALYSIS

3.1 *I-MODEL*

Table 3 and Figure 7 shows the results of the I-model. In Figure 7, the vertical axis shows the value obtained by dividing the maximum stress of the analytical results by the yield strength (σ_u/σ_y), and the transverse axis shows the width-thickness ratio parameter. In addition, as reference, the dotted line represents $\sigma_u/\sigma_y = 0.5/R^2$, and the solid line represents $\sigma_u/\sigma_y = 1.0/R^2$. The maximum stress is the value obtained by dividing the maximum load obtained by the analysis by the cross-sectional area without loss.

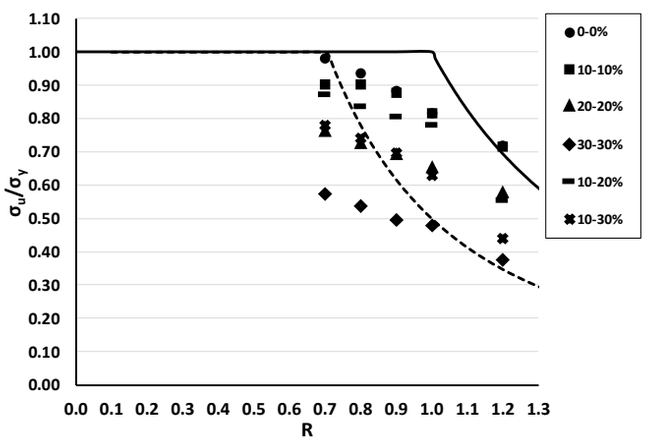

Figure 7. σ_u/σ_y -R relationship for the I-model

3.2 *B-MODEL*

The results of the B-model for 500mm×100mm, 700mm×100mm, and 1,000mm×100mm cases are shown in Table 4, Table 5, and Table 6 respectively. As in the case of the I-model, the results were organized based on the non-dimensional value (σ_u/σ_y) that was obtained by dividing the maximum stress of the analytical results by the yield strength. In following discussions, the lowest values among the cases for three aspect ratios is used, and these values are shown in Table 7 and Figure 8. In these figures, the transverse axis represents the width-thickness ratio parameter, and as reference, the dotted line represents $\sigma_u/\sigma_y = 0.5/R^2$ and the sold line represents $\sigma_u/\sigma_y = 1.0/R^2$. And the maximum stresses shown in Tables 4 to 7 and in Figure 8 were obtained by dividing the maximum load obtained by the analysis by the sectional area without loss.

4 DISCUSSION AND PROPOSAL OF THE RESIDUAL STRENGTH EQUATIONS

The results of the analyses performed in this study are used to propose residual strength equations.

4.1 *I-MODEL*

First, for the case without loss of cross-sectional area (0-0% model), Figure 7 is used to estimate the compressive strength as in Equation 1.

$$\sigma_u/\sigma_y = 0.8R^{-0.6} \quad (1)$$

Next, the width-thickness ratio parameter R', focused on the corroded part, is obtained in order to propose the residual strength equation for a case with loss of cross-sectional area. As shown in Figure 9, b' of the white part left by the partial loss of cross-sectional area is used to calculate the width-thickness ratio parameter assuming a plate with simple support on three sides and one side free. The R' obtained are shown in Table 8. Figure 10 shows the relationships between the newly obtained R' in the transverse axis and the maximum stress/yield strength (σ_u/σ_y) in the vertical axis. The vertical axis in Figure 10 obtained by dividing the maximum load obtained from the analytical results by the cross-sectional area considering loss of cross-sectional area. In addition, in Figure 10, for the purpose of comparison, the nominal strength curve (Japan Road Association 2002) for a column obtained by Equation 2 and Equation 3 is shown. Figure 10 reveals that in the cases of partial loss of cross-sectional area of 10-10%, 20-20%, and 30-30%, the residual strength could be estimated by the nominal compressive strength curve for a column.

$$\sigma_u/\sigma_y = \begin{cases} 1.109-0.545R & (0.2<R\leqq 1.0) \quad (2) \\ 1.0/(0.733+R^2) & (1.0<R) \quad (3) \end{cases}$$

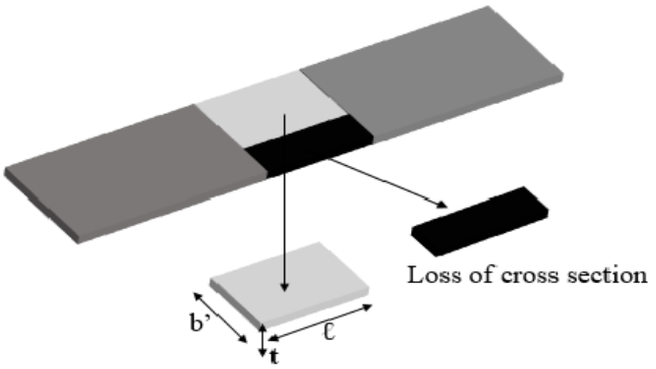

Figure 9. Derivation of width-thickness ratio parameter R'

		Width-thickness ratio parameter R'				
		1.2	1.0	0.9	0.8	0.7
Corroded (%)	10	0.59	0.48	0.44	0.39	0.34
	20	1.18	0.96	0.88	0.78	0.68
	30	1.77	1.48	1.32	1.18	1.03

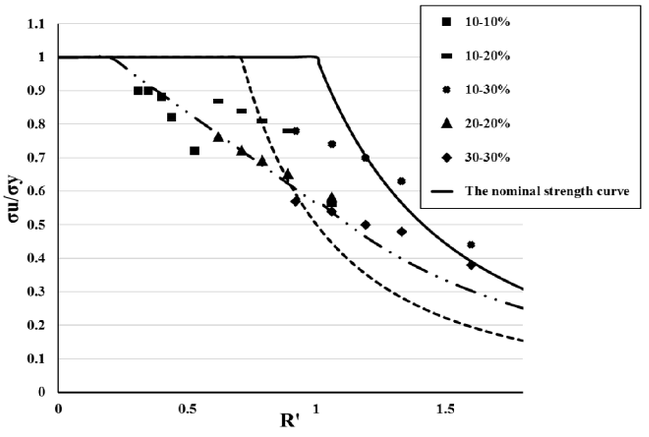

Figure 10. R'- σ_u/σ_y curve (I–model)

It can be stated that the buckling mode of the corroded part is similar to the buckling mode of a column and that the support condition—simple support on three sides and free on one side—is no longer effective. Figure 11 (10-10%, R=1.2) and Figure 12 (30-30%, R=1.2) show the buckling mode of the I-model. According to the buckling mode shown in Figure 12, it seems that the buckling coefficient can be calculated assuming that the effective buckling length (ℓ_k) is $\ell_k=0.9\ell$, considering the constraint conditions from the surroundings of corroded part. However, it is assumed that the value of σ_u/σ_y does not exceed that in the 0-0% case.

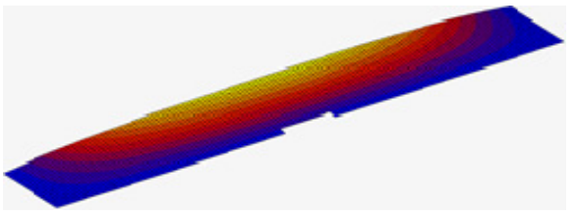

Figure 11. The buckling form of the I-model (10-10%, R=1.2)

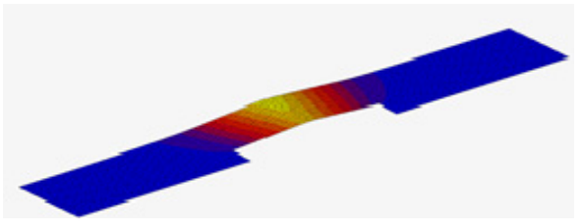

Figure 12. The buckling form of the I-model (30-30%, R=1.2)

Finally, in order to propose residual strength equations for cases, in which the partial loss of sectional area has expanded in the length direction (10-20%, 10-30%), a ratio of the partial loss of sectional area in the length direction is newly defined as β_l (%).

For the 10-20% and 10-30% cases in which the partial loss of cross-sectional area expanded in the length direction, the difference between σ_u/σ_y for 10-20% and 10-30% and σ_u/σ_y for 10-10%, in the case where the width-thickness ratio parameter R= 1.2 to 0.7, was calculated to obtain the respective average change (X). Table 9 shows these values, and Figure 13 shows the relationship between β_l and X. In the case where β_l=20 for example, the value of (σ_u/σ_y of 10-10%) - (σ_u/σ_y of 10-20%) for the five parameters of the width-thickness ratio parameter R=1.2 to 0.7 were calculated and the average values were obtained. Similarly, the value of β_l =30 are calculated, and the relationship of X=0.0054β_l was found by regression analysis as shown in Figure 13.

In brief, the residual strength equation for the cases where the partial loss of cross-sectional area expanded in the length direction (10-20%, 10-30%) is obtained using Equation 4 based on the value of 10-10% case.

$$\sigma_u/\sigma_y = (\sigma_u/\sigma_y \text{ of } 10\text{-}10\%) - (0.0054\beta_l) \qquad (4)$$

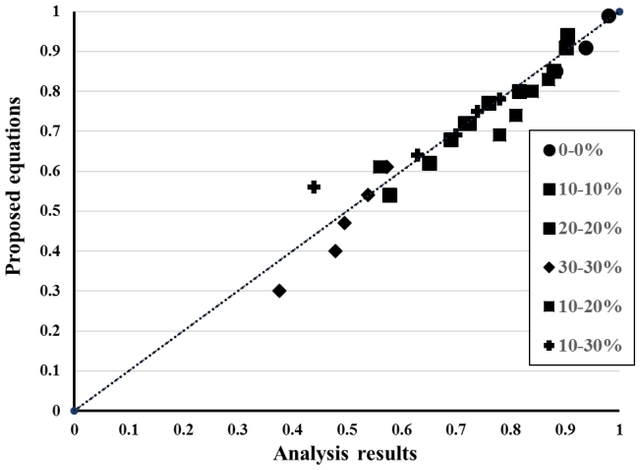

Figure 14. Comparison of estimated values and analytical results

The predicted values by the proposed equations, Equation 1 to Equation 4 are listed in Table 10. Figure 14 shows the comparison of estimated strength from the proposed equations on the vertical axis and the analytical results on the transverse axis.

Figure 14 reveals that there is a maximum error of 12% between the analysis values and values from the proposed equations, but it can be assumed that the analysis values can be roughly predicted. Therefore, it seems possible to use proposed equations to evaluate the compressive strength in a case with partial loss of cross-sectional area, assuming as a plate with simple supports on three sides and free on one side.

4.2 *B-MODEL*

First, in the case without loss of cross-sectional area (0-0%), the compressive strength is approximated by the Equation 5 based on Figure 8.

$$\sigma_u/\sigma_y = 0.75R^{-0.5} \qquad (5)$$

Next, as in I-model, the width-thickness ratio parameter R' focused on the corroded part is newly obtained in order to propose a residual strength equation. As shown in Figure 15, the width b' of the white part left by partial loss of cross-sectional area is used to calculate the width-thickness ratio parameter for a plate with simple supports on three sides and free on one side. Calculated value of R' are listed in Table 11. Figure 16 shows the relation-

ship R' that were newly obtained on the transverse axis and the maximum stress/yield strength value (σ_u/σ_y) on the vertical axis. Values in the vertical axis in Figure 16 were calculated by dividing the maximum load obtained from the analysis by the cross-sectional area considering loss of cross-sectional area. In addition, analytical results of a plate with simple supports on three sides and free on one side (700 mm×100 mm model) are plotted in Figure 16 for comparison purposes (legend in the figure is I-model 0-0%).

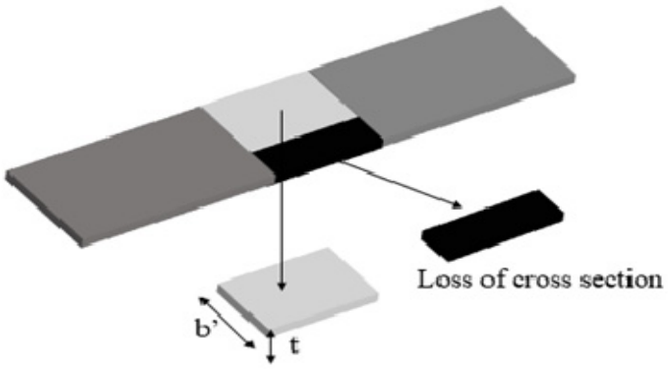

Figure 15. Derivation of width-thickness ratio parameter R'

Table 11. Width-thickness ratio parameter R'

		Width-thickness ratio parameter R'				
		1.2	1.0	0.9	0.8	0.7
Corroded (%)	10	3.40	2.78	2.45	2.18	1.91
	20	3.02	2.47	2.18	1.94	1.70
	30	2.64	2.16	1.90	1.70	1.49

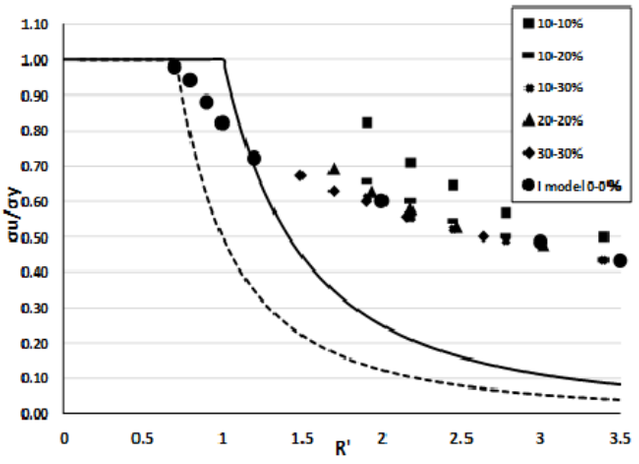

Figure 16. R'- σ_u/σ_y curve (B–model)

Figure 16 reveals that in the partial loss of cross-sectional area ratio of 20% or higher cases, the residual strength is superimposed on the results of I-model 0-0% case. It can be stated that the buckling mode of the remained part of the plate changes to one of a plate with the simple supports on three sides and free on one side, indicating that the support condition, simple supports on four sides, is no longer effective. However, in the case of partial loss of cross-sectional area ratio of 10-10%, a different trend is observed compared with that seen in I-model 0-0% case.

Therefore, for partial loss of cross-sectional area ratio of 10-10%, the residual strength is estimated by Equation 6 based on Figure 8, and for partial loss of cross-sectional area ratio of 20-20% or higher, residual strength is estimated by the strength curve for I-model 0-0% case, as shown in Equation 7.

$$\sigma_u/\sigma_y = 0.5R^{-1} \quad (6)$$

$$\sigma_u/\sigma_y = 0.8R'^{-0.5} \quad (7)$$

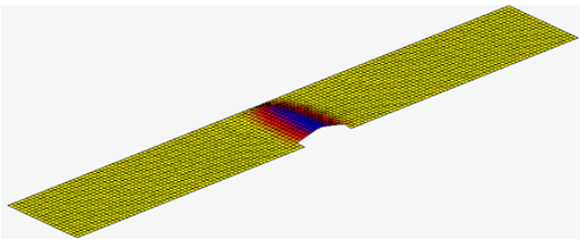

Figure 17. Buckling mode of the B-model (10-10%, R=1.2)

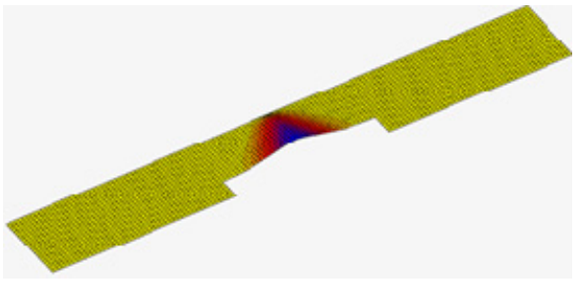

Figure 18. Buckling mode of the B-model (30-30%, R=1.2)

Figure 17 (10-10%, R=1.2) and Figure 18 (30-30%, R=1.2) show the buckling mode for B-model. Similar to I-model, in order to propose a residual strength equation for a case where the partial loss of sectional area expanded in the length direction (10-20%, 10-30%), the partial loss of sectional area ratio in the length direction is newly defined as β_B (%). In the 10-20% and 10-30% cases in which the partial loss of cross-sectional area expanded in the length direction, the difference between σ_u/σ_y for 10-20% and 10-30% and σ_u/σ_y for 10-10%, in all cases where the width-thickness ratio parameter R = 1.2 to 0.7, were calculated and the average change (X) was obtained. Table 12 shows these values, and Figure 19 shows the relationship between β_B and X.

Consequently, the residual strength equation for cases where the partial loss of cross-sectional area expanded in the length direction (10-20%, 10-30%) is proposed as Equation 8 with the value for 10-10% case as the standard.

$$\sigma_u/\sigma_y = (\sigma_u/\sigma_y \text{ of 10-10\%}) - (0.004\beta_B) \quad (8)$$

Table 12. β_B and average change

β_B	X
20	0.092
30	0.114

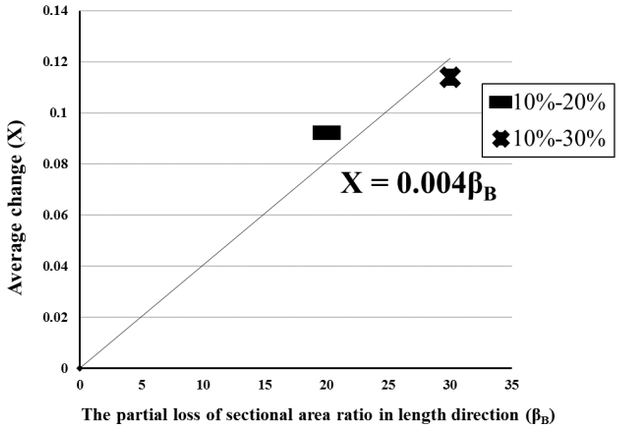

Figure 19. Estimation of relationship between X and β_B

Table 13. Predicted values by proposed equations

	σ_u / σ_y					
R	0-0%	10-10%	20-20%	30-30%	10-20%	10-30%
1.2	0.68	0.42	0.37	0.34	0.32	0.30
1.0	0.75	0.50	0.41	0.38	0.42	0.38
0.9	0.79	0.56	0.43	0.41	0.48	0.44
0.8	0.84	0.63	0.46	0.43	0.55	0.51
0.7	0.90	0.71	0.49	0.46	0.63	0.59

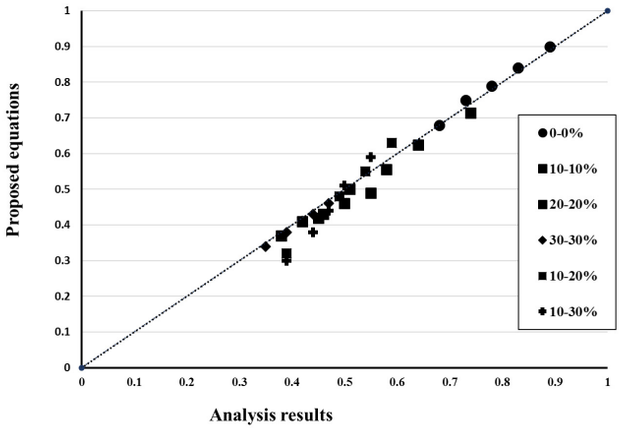

Figure 20. Comparison of estimated values and analytical results

Table 13 shows the predicted values by the proposed equations, and these are compared with the analytical results in Figure 20.

According to Figure 20, there is a maximum error of 9% for predicted values by the proposed equation; then, it is presumed to be possible to evaluate the compressive strength of a plate simply supported on four sides under partial loss of cross-sectional area considered in this study.

5 CONCLUSIONS

In this paper, compressive strength of plates with simple supports on three sides and one side free, and plates with simple supports on four sides having a partial loss of cross-sectional area caused by corrosion were investigated by performing FEM analysis combining a number of parameters. The results of analyses were used to propose compressive strength equations for a plate with a partial loss of cross-sectional area caused by corrosion.

The followings are major findings of this study:

[1] In a case where partial loss of cross-sectional area from the center of the edge of a plate with simple support on three sides and one side free was given, boundary conditions change, so that it is possible to evaluate the residual strength in partial loss of cross-sectional area of 10-10%, 20-20% and 30-30% as the standard strength curve of a column in a case where the residual part was considered to be a column.

[2] In the case where partial loss of cross-sectional area was given from the edge of a plate with support on four sides, if the loss is 20% or higher, the boundary conditions change, so it is possible to evaluate the residual strength as the standard strength curve in a case where the residual part is considered to be a plate with simple support on three sides and free on one side.

[3] From the above, equations that predict residual buckling strength, equations (1) to (4) for I-model and equations (5) to (8) for B-model, of a steel plate with partial loss of cross-sectional area caused by corrosion were proposed.

The analysis models in this study represented a part of a flange of a steel member subjected to compression. Therefore, it is necessary to carry out further study to find out if the proposed equation in this study can be used to evaluate the residual strength for members with partial loss of cross-sectional area (such as members subjected to flexure in particular).

Use of stochastic optimization in the analysis of weigh-in-motion data

F. El Hajj Chehade, R. Younes, H. Mroueh & F. Hage Chehade
Laboratory of Civil Engineering and geo-Environment (LGCgE) Lille 1 University, France
Modeling Center Doctoral School of Science and Technology, Lebanon
Lebanese University Faculty of Engineering, Lebanon

ABSTRACT: The calibration of traffic simulation models for bridge design or assessment is normally based on weigh-in-motion or WIM data, this implies the estimation of a large number of parameters related to load distribution and vehicle weights. In a similar stochastic problem, the use of genetic algorithm in the optimization process can greatly simplify the work by allowing the calculation of a very large number of parameters even with a small amount of data and conditions. This method is illustrated by an application example of genetic optimization to evaluate the correlation between the gross vehicle weight and its distribution on single vehicle axles.

1 INTRODUCTION

1.1 *Background*

The weigh-in-motion or WIM process is widely used all over the world, it consists in the estimation of total weight for a moving road vehicle and of the proportion carried per each axle by measuring the dynamic tire forces using specific sensors. Therefore the distribution of all axle weights can be provided directly from WIM data. Figure 1 present a redraw from Burnos & Rys (2017) for a pavement embedded WIM sensor.

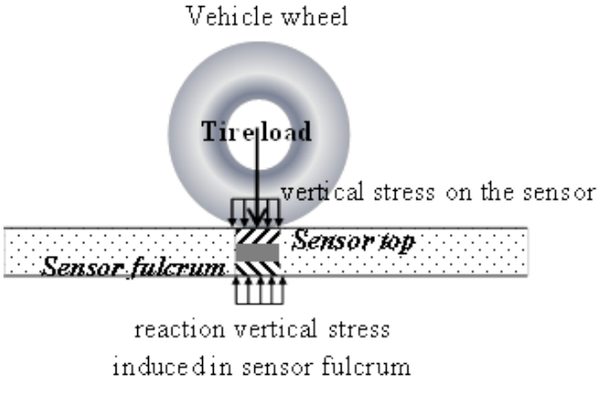

Figure 1. Schema of pavement embedded WIM sensor

The recorded WIM data on a multi-lane carriageway can then be used for the design or the assessment of highway bridges(O'Brien et al. 2006).

Bridge weigh-in-motion or BWIM systems constitute now an alternative way to the pavement-based weigh-in-motion systems and are considered more convenient and cost effective(Yu et al. 2016), these methods rely on measuring strains in some bridge components to estimate the vehicle weights; consequently, some algorithms have been developed to deduce axle loads especially Moses' algorithm.

1.2 *Approach*

The analysis of the recorded data from the real time traffic starts by fitting the histograms of measured data such as Gross Vehicle Weight (GVW), axle spacing, distribution of GVW, to a known probabilistic distribution which provides the basic parameters in the traffic simulation process.

The distribution of GVW between axles is used to illustrate the problem as it has a strong influence on the load effects especially on short to medium span bridges, from 10 to 35 m (Enright & O'Brien 2013)

Normally, the distribution of GVW should be performed for each axle in each vehicle class; it requires having the histograms of the distributions for each axle in all the vehicle classes, so a lot of data. In this paper we will try to do the same work based only on the global distribution of all axles.

The genetic algorithm is often used to interpret and analyze stochastic data from real world problem which cannot be assimilated to a well-defined mathematical function; weigh-in-motion data resulting from vehicle monitoring on highway have the same stochastic status. Genetic algorithm will be the basic

tool in this work.

2 GENETIC OPTIMIZATION

The most common type of stochastic optimization is represented by genetic algorithm (Holland, 1975) which constitutes a robust optimization tool mimicking the same process of natural selection (biological evolution). This algorithm is recommended when we have little analytical knowledge about the search domain and very large number of parameters, unlike the FMINS functions in Matlab which require the determination of an initial point that affects the optimization success, this random-search optimization algorithm is oriented by some genetic operators like selection, crossover and mutation which make its population more diverse and thus more immune to be trapped in a local optima and guarantee a global optima solution. The selection of an individual is based on how fit it is after a fitness evaluation process through a fitness function, also called objective function and the fittest ones have more chance to be inherited into the next generation, the strong tend to adapt and survive and the weak tend to die out, genetic algorithm uses the fitness function as Black Box and doesn't require any information about its structure or its mathematical model which isn't available in many real world problems, for example, axle weights data given from real time monitoring where it seems difficult to obtain explicit formula for the objective function with all constraints especially with variable and stochastic traffic loading , the general formulation of the fitness function to be minimized used in this optimization problem is mentioned in Equation 1:

$$\sum (y_1 - y_2)^2 \tag{1}$$

where y_1 is the data resulting from real time monitoring and y_2 the corresponding value resulting from genetic optimization, this function will be minimized by varying in each iteration the parameters described in Figure **5**, no matter if we have underweight or overweight, the goal is to reach a very small difference.

The main steps of genetic optimization can be summarized as follow:

1. Generate randomly initial population of individuals, each individual is assimilated to a chromosome and represents a set of the parameters which can be a feasible solution of the optimization problem;
2. Using the fitness function, calculate the fitness of each individual in the population;
3. Select the more fit individuals, those that give the minimum gap with the reference data, then cross over and mutate the remaining ones to form a new offspring while keeping the same initial population size or number of individuals;
4. Replace the current population with the transformed one;
5. Repeat steps 2, 3 and 4 until reaching the number of generations fixed at the beginning according to the problem circumstances.

This process is summarized in Figure 2.

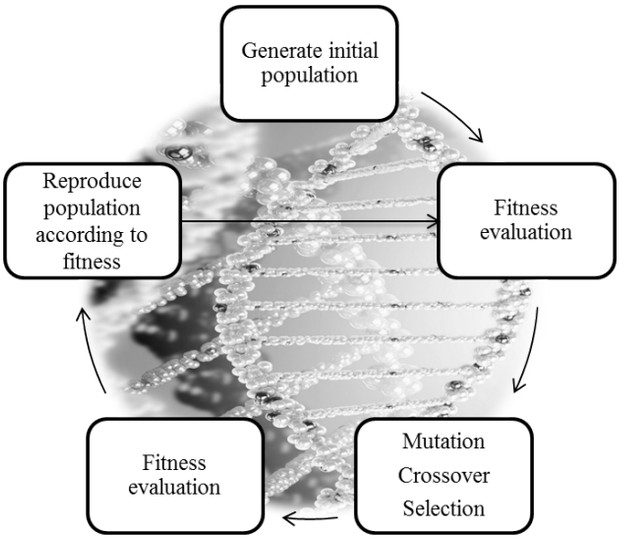

Figure 2. Schema of a simple genetic algorithm

3 MODELING DISTRIBUTION OF GVW BETWEEN AXLES

Normally vehicles can be simply classified according to their number of axles and axle layout, so the proportion of GVW carried per each individual axle is modeled for each vehicle class separately, this means that a very large number of parameters is to be estimated, for example Enright & O'Brien (2013) proposed a bimodal normal distribution for the proportion carried per each axle for each vehicle class, thus for the 6-axle vehicle class we should consider the histogram of the percentage of GVW for each axle separately in order to estimate the 6 parameters of the bimodal normal distribution, in total we need to estimate 36 parameters for the modeling of GVW distribution for only one vehicle class based on a complex analysis of the measured data in order to get the 6 histograms needed for the fitting process.Simon F. & Rolf(1999) proceeded in a similar way by considering bimodal beta distributions for modeling axle group loads for each vehicle class separately. In other cases, the proportion of GVW carried per axle is sometimes simply assumed as deterministic (GRAVE et al. 2000). Correlation be-

tween axle loads is also performed for each vehicle class in order to get the distribution of GVW among axles (Centre de recherche: ICOM EPF-Lausanne et al. 2006), for this purpose a complex work is established to deduce the correlation between axle loads for each axle on each vehicle class based on the correlation for every individual vehicle in this class. The latter case is chosen to prove the effectiveness of genetic optimization in the following paragraphs.

4 DESCRIPTION OF WIM DATABASE

The Swiss Federal Roads Office (FEDRO) has equipped the national road network in Switzerland with eight main weigh-in-motion monitoring stations(Treacy & Brühwiler 2011); the traffic data from the Mattstetten A1 motorway station are chosen to illustrate the proposed methodology in WIM analysis since they give a good representation of local or national traffic, these data are adopted as presented in the research work published by the FEDRO in 2006 (Centre de recherche: ICOM EPF-Lausanne et al. 2006) , all needed data are perfectly stripped in this report.

4.1 *Vehicle modeling*

According to the number of axles and axle layout, vehicles are classified in 12 classes with a known range of GVW for each vehicle class, the distributions of GVW for each vehicle class are also given and then fitted to bimodal beta distributions, since the proportion of each vehicle class from the total traffic is taken similar to that in the measured traffic, all GVW can be simulated using inverse-transform method as shown in Figure 3. Each class is designated by a series of characters which refer to the type and position of the axle, for example in case of *123a* class, all vehicles have one single axle, followed by a tandem then a tridem axle , the letter "a" means that vehicles in this class are articulated.The letter "r" refers to the vehicles with trailer. All vehicle class labels are summarized in Table 1.

Table 1. Labels of all vehicle classes

Vehicles alone	Vehicles with trailer	Articulated vehicles	Mixed vehicles
11	1111r	112a	111
12	112r	113a	122
22	1211r	122a	
	1112r		

After simulation of GVW, it should be distributed to the vehicle axles; as cited in the paragraph 3 , linear correlation between axle loads is performed for every axle in each vehicle class, for example to calculate the correlation between two loaded axles in a given class, we should plot for every measured vehicle, the load of the first axle as a function of the load of the GVW and so on, after that we can select the linear trend line that can describe the correlation function, an illustrative schema is used to explain the described procedure of calculating correlation coefficients (Figure 4), the general matrix of population used in the optimization process is presented in Figure 5.

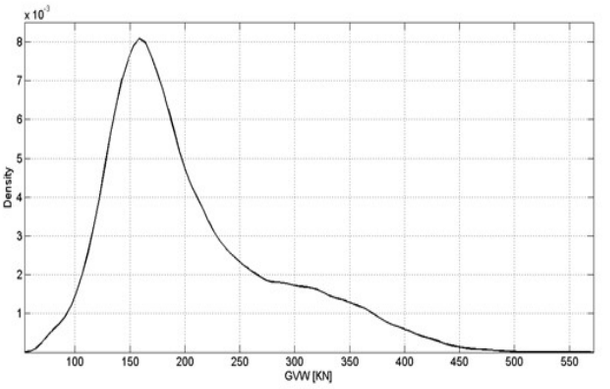

Figure 3. Distribution of GVW for all vehicles

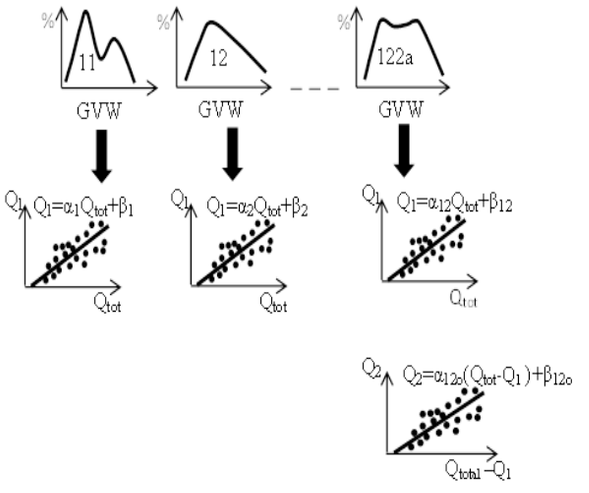

Figure 4. Calculation steps for correlation coefficients

4.2 *Filtering of WIM data*

The measured WIM data should be filtered to remove unreliable values, OBrien & Enright (2011) have well detailed the cleaning process, only vehicles more than 3.5 tones are retained , in our case, the following constraints will be considered to reject unreliable data:

1. Wheelbase > Vehicle length
2. Distance between two consecutive axles > 20 m
3. Distance between two consecutive axles <0.4 m
4. Sum of all axle loads > GVW
5. Axle load > 40 t
6. Axle load > 85% of GVW

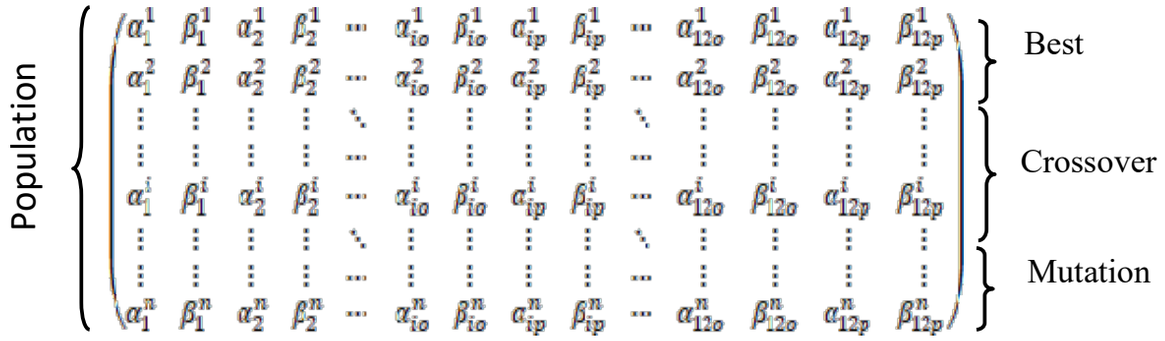

Figure 5. General matrix of population

Data cleaning constrains will be used to limit the search domain in the optimization process.

5 CALCULATION OF CORRELATION COEFFICIENTS

5.1 *General framework*

The proposed methodology will be summarized in the following flowchart:

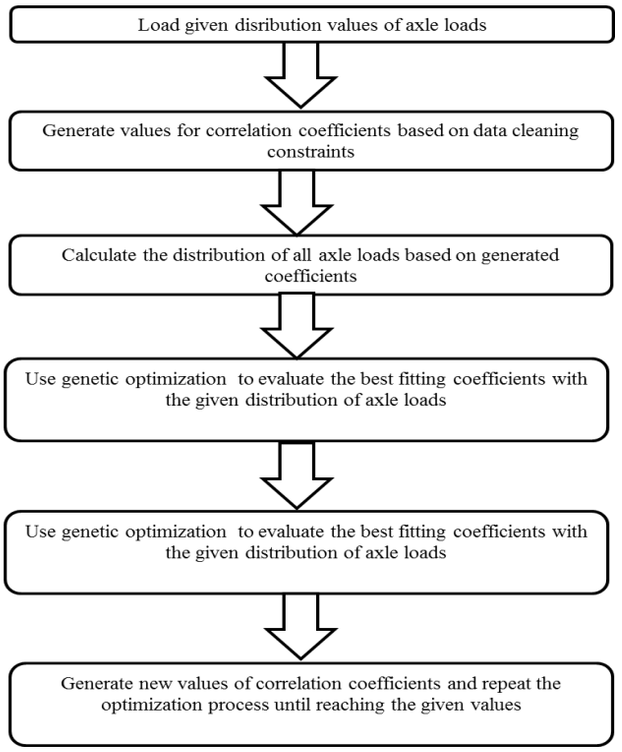

Figure 6. Flowchart of the proposed framework

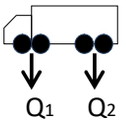
5.2 *Illustrative example*

To better present the proposed methodology, more details will be explained for the vehicle class 22 (trucks with two tandem axles). Q_{tot}, Q_1 and Q_2 are respectively the total vehicle weight, the weight supported by the first tandem and the weight supported by the second tandem.



The correlation equations can be written as follow:

$$Q_2 = \alpha_3 Q_{tot} + \beta_3 \tag{2}$$

$$Q_1 = Q_{tot} - Q_2 \tag{3}$$

The search domain for α and β can be limited according to the following constraints:

1. The slope of the correlation line should be less than 1 ($0 < \alpha_3 < 1$);
2. Axle weight should be positive ($Q_i > 0$) ;
3. Single axle load should be less than 40t;
4. Single axle load should be less than 85% of GVW.

Therefore, the intervals of α and β will be:

- $0 < \alpha_3 < 1$
- $$\begin{cases} 0 < Q_2 < 0.85 Q_{tot} \\ \Rightarrow 0 < \alpha_3 Q_{tot} + \beta_3 < 0.85 Q_{tot} \\ \Rightarrow -\alpha_3 Q_{tot} < \beta_3 < (0.85 - \alpha_3) Q_{tot} \end{cases}$$

This should be valid for all Q_{tot} in the vehicle class 22, so we can choose the minimum Q_{tot} in this class to reduce the search interval.

The same work is done for all the vehicle classes, so we will have to calculate 48 parameters between the identified maximum and minimum limits. (Figure 5)

5.3 *Results*

After 15 generations of 30 populations of the 48 correlation coefficients, the best fitting coefficient val-

ues are used to calculate the distribution of all vehicle axles for one million vehicles.

The distribution of all vehicle axles based on the optimization results relative to the given distribution is shown in Figure 7.

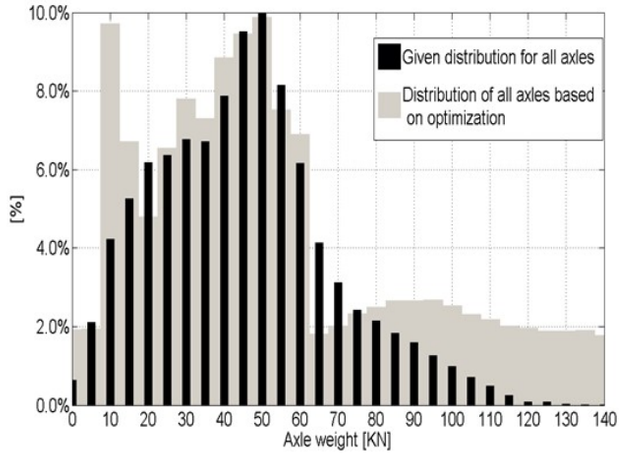


Figure 7. Given and simulated distributions of all vehicle axle loads

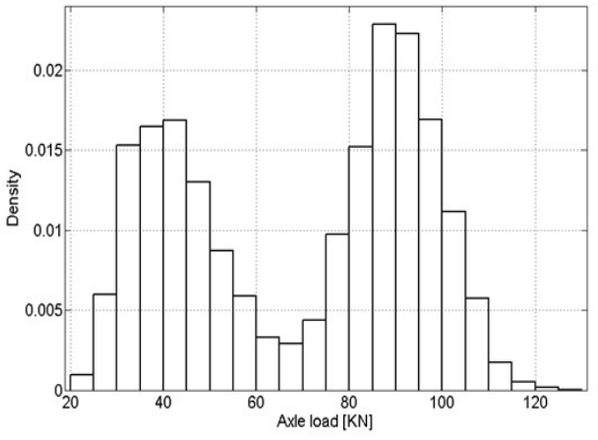

Figure 8. Distribution of Q_1 for vehicle class 22 based on calculated correlation coefficients

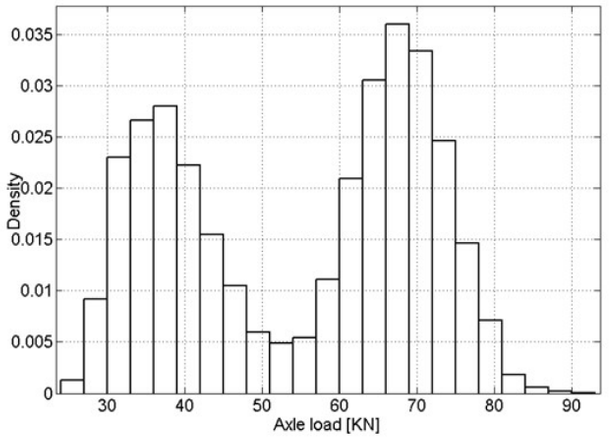

Figure 9. Distribution of Q_2 for vehicle class 22 based on calculated correlation coefficients; $Q_2=\alpha Q_{tot}+\beta$ /α=0.38, β=14.2

5.4 *Discussion*

The distribution of all vehicle axles based on the calculated correlation coefficients using genetic optimization is very consistent with the given distribution of all vehicle classes based on monitoring data (Figure 7). The distribution of every individual axle in each vehicle class can also be deduced, Figure 7-Figure **8** show the distributions of each axle for the vehicle class 22, in this case the values of correlation coefficients are also presented , α=0.38 and β=14.2, the distributions appear to be bimodal; it should be noted that, this is a sample from a set of 48 parameters calculated for 12 vehicle classes, this required a total of 15×30=450 iterations while improving the values of the searched coefficients in each new generation according to the minimum value of the objective function.

6 CONCLUSION

The proposed methodology allows calculating a large number of unknown parameters based only on a little amount of data and some constraints to limit the search domain.

In the same way, having the limitations for axle distances in each vehicle class and the general distribution of the axle distance, the probabilistic distribution for each distance in a given class can be detected directly from the general histogram and all the distribution parameters can be deduced using a global genetic optimization.

Genetic algorithm also constitutes a robust tool in the optimization process in BWIM techniques, it can be included in the Moses' algorithm in order to compute the GVW by minimizing the error between measured and theoretical response.

Parametric analysis of rib distortion in orthotropic steel decks

H. Fang & H. De Backer
Ghent University, Ghent, Belgium

ABSTRACT: In orthotropic steel decks, the trapezoidal section is one of the most widely adopted geometries for ribs. However, due to the existence of cut-outs in the crossbeams, the torsional rigidity of the ribs is fundamentally reduced by distortion, especially when the load was at mid-span and eccentric from the axis of the rib. The rib distortion causes high stress concentrations at the rib-to-crossbeam joint, which had become one of the most vulnerable details to fatigue. In this paper, the influence of 5 classical design parameters on the distortional behavior was analyzed based on finite element analysis. A refined finite element model of an orthotropic steel deck specimen (8.2 m × 4.1 m) was developed, adopting the sub-model analysis technique and the hot spot stress approach. Research results revealed that the distortional stress of rib-to-crossbeam joint was negatively correlated with the thickness of rib, positively correlated with the spacing of rib, the weld length of rib-to-crossbeam joint and the spacing of crossbeam. The height of crossbeam did not have obvious influence on distortional behavior. Approaches e.g. increasing the thickness of rib or decreasing the spacing of crossbeam would increase the stress of rib-to-deck joint while reducing the distortional stress.

1 INTRODUCTION

The orthotropic steel deck had been widely used in long-span bridges because of its light weight, high load carrying capacity, etc. Nevertheless, stress concentrations were easily caused because of the complex structure and the existence of numerous welds. Thus, fatigue damage had become the most severe problem when adopting orthotropic steel decks. Previous research revealed that typical fatigue cracks mainly appear at four locations, namely rib-to-deck joint, splice joint of the longitudinal rib, deck plate at the position of crossbeam and rib-to-crossbeam joint(De Jong, 2004). Relevant research about these fatigue-prone details had been reported(Kainuma, 2017, Nagy, in press) but the stress concentration at the rib-to-crossbeam joint caused by rib distortion was more or less ignored in previous research.

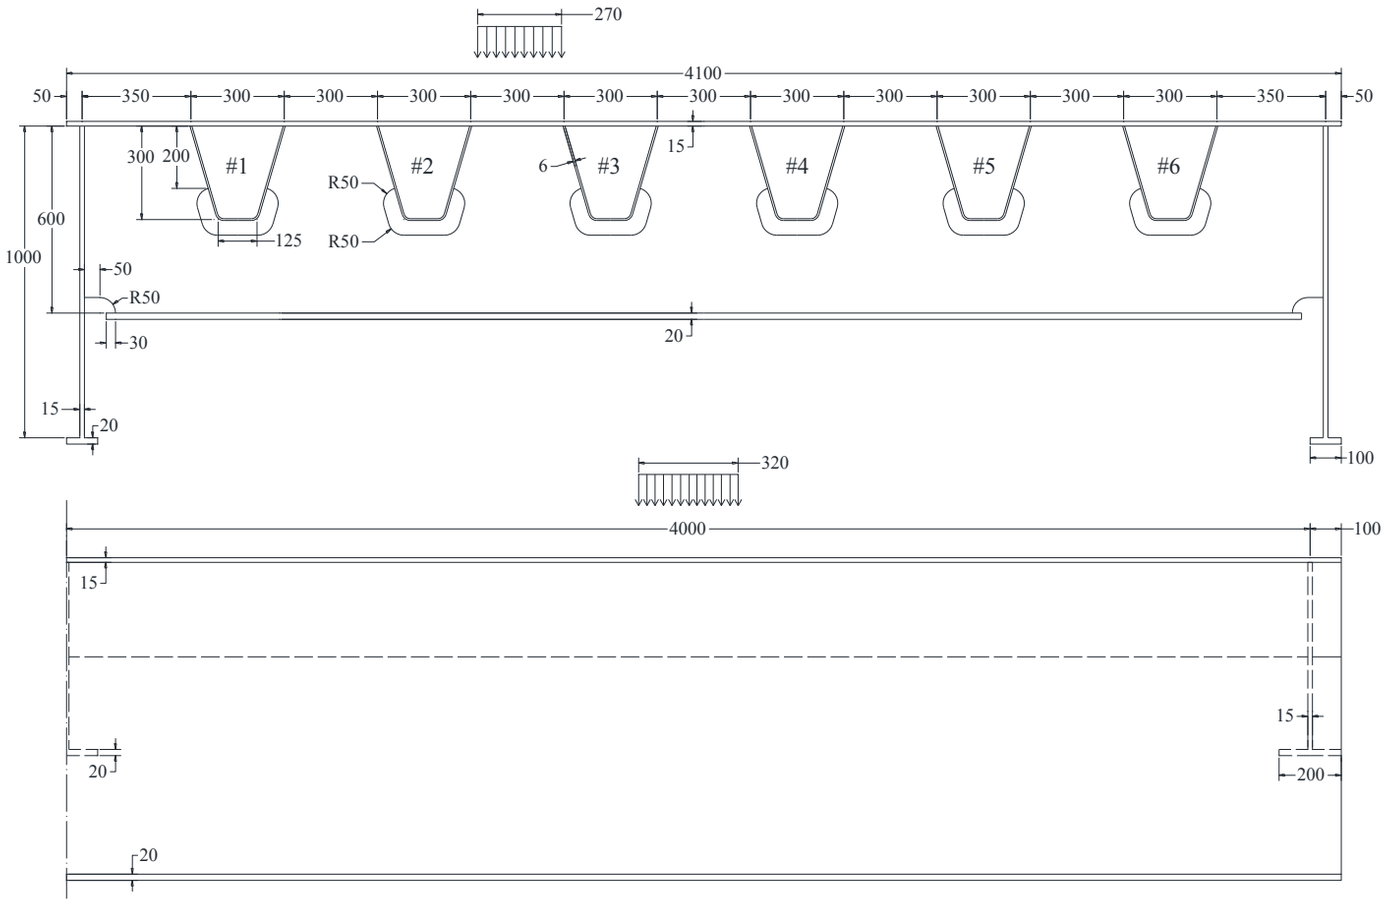
In orthotropic steel decks, the trapezoidal section was one of the most widely adopted geometries for ribs. However, due to the existence of cut-outs in the crossbeams, the torsional rigidity of the ribs was fundamentally reduced by distortion, especially when the load was at mid-span and eccentric from the axis of the rib(Connor, 2012). The rib distortion caused high stress concentrations at the rib-to-crossbeam joint. Moreover, when tension stress appeared on the outside of one stem of the rib, compression stress appeared on the outside of the other stem. Thus, the rib-to-crossbeam joint carried positive and negative stress alternately when vehicles passing by, which made the joint more vulnerable to fatigue damage. Nowadays, no explicit recommendations on relevant parameters with respect to the influence of rib distortion e.g. the weld length between rib and crossbeam, etc. were given in current major design codes.

This paper presented the influence of a number of classical design parameters on the distortional behavior, based on finite element analysis. Firstly, a refined finite element model of an orthotropic steel deck specimen was developed, adopting the sub-model analysis technique. The hot spot stress approach was also adopted to achieve a more accurate assessment of the stress ranges. Then, the influence of the considered parameters was calculated and analyzed, which will be the foundation for developing a simplified calculation method for the estimation of stress concentrations at the rib-to-crossbeam joint in further research.

2 PARAMETRIC STUDY OF RIB DISTORTION

2.1 *Finite element model*

In order to investigate the influence of classical design parameters on the distortional behavior, parametric analyses were performed using ANSYS. Initially, a standard orthotropic steel deck was designed, which was composed of 6 ribs, 3 crossbeams and 2 main girders. The longitudinal trapezoidal ribs were 300 mm high, 300 mm wide at the top and 125 mm wide at the lower soffit. Relevant geometries are shown in Figure 1.



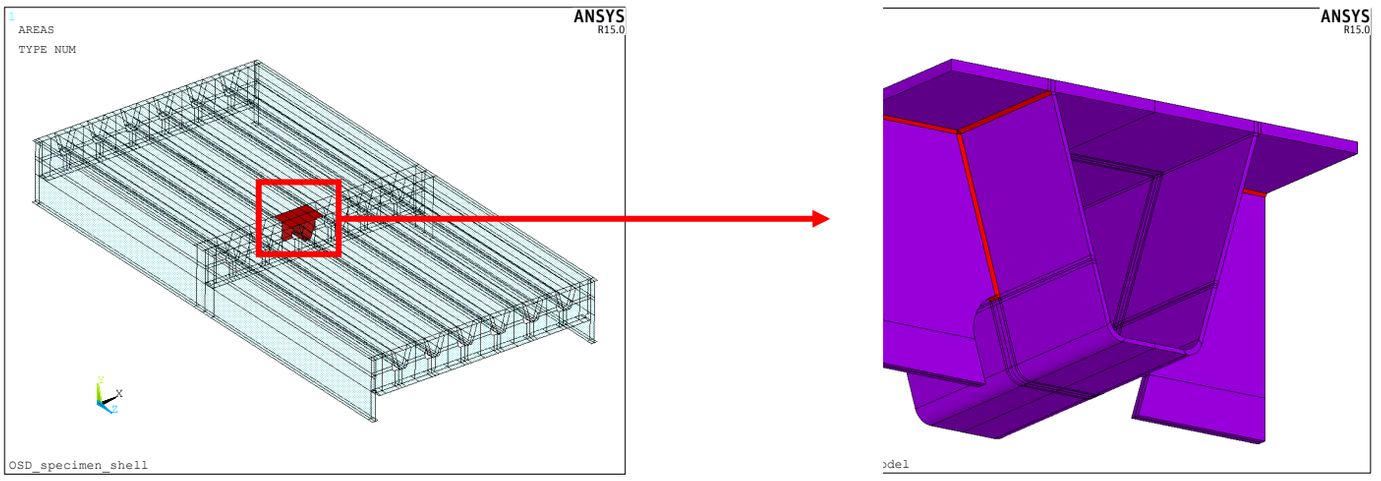


Fig. 1. Geometries of the standard orthotropic steel deck (unit: mm)

According to the design of the standard orthotropic steel deck, a global model was first built using shell element, as shown in Figure 2(a). In order to take the influence of welds into account and to get more accurate results of stress, a sub-model was built using solid element based on the global model. The sub-model was composed of segmental deck, rib, crossbeam and welds as shown in Figure 2(b). The location of the sub-model was at the middle crossbeam of the global model longitudinally and at the third rib (see Figure 1) transversally. Welds of the sub-model were modeled with a triangular profile. The weld throat thickness of 4 mm was used.

(a) global model (b) sub-model

Fig. 2. Finite element models of a standard orthotropic steel deck: (a) global model; (b) sub-model

Liner elastic properties of material were considered in both models. The modulus of elasticity 210 GPa and the Poisson's ratio in elastic stage 0.3 were adopted in analyses. According to previous research(Kolstein, 2007), the structural hot spot stress approach was more appropriate for this joint as well as the liner extrapolation method. Thus, based on the IIW recommendations (Hobbacher, 2015), two reference points were at a distance of 0.4 times and 1.0 times the thickness of the rib wall separately. The mesh size of elements close to the lower end of rib-to-crossbeam weld was controlled at 0.1 times the thickness of the rib wall to fulfill the IIW recommendations. The reference points and mesh nearby are shown in Figure 3.

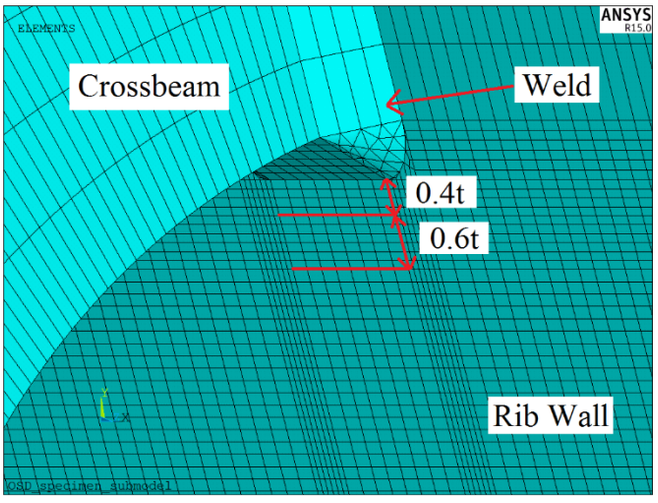

Fig. 3. Reference points and mesh

2.2 *Loadcase and boundary conditions*

According to Eurocode 1, the fatigue load model 2 was chosen since it was more appropriate to steel constructions. The axle load of 110 kN with wheel type C was adopted. The wheel contact area was 270 mm wide and 320 mm long. The dynamic amplification factor was 1.3. As mentioned before, the rib distortion was caused by eccentric load. Hence, one wheel load of 70 kN at mid-span and eccentric from the axis of the rib was adopted, as shown in Figure 1 and Figure 4. Because the real orthotropic steel deck specimen of this study was not covered by pavement, the dispersal of concentrated loads caused by the pavement was not considered in order to make contrast between the FEA results and the experimental results in the future.

The boundary condition of the global model was based on the support condition of the orthotropic steel deck specimen in reality. Six bearings were at the middle and two ends of two main girders separately, as shown in Figure 4. The contact area of a bearing was 80 mm × 80 mm. The boundary condition of the sub-model was extracted from the calculation results of the global model with corresponding geometries. The deformations of nodes along the cutting boundary between two models were placed on the sub-model as external loads. Since the cutting boundary was far away from the zone of stress concentration, final results were not affected.

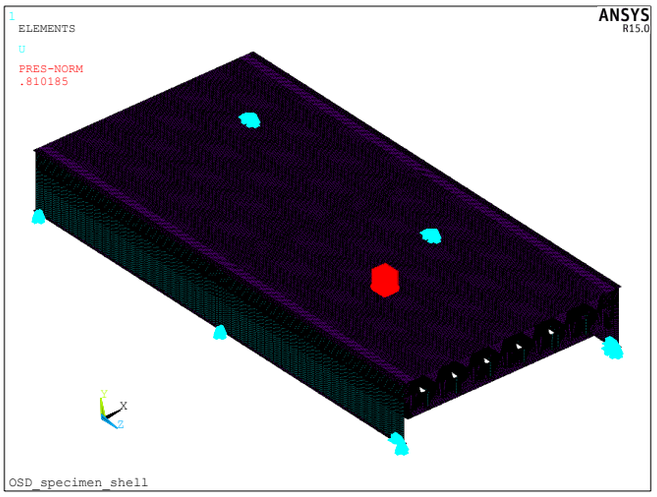

Fig. 4. Loadcase and boundary conditions

3 RESULTS AND DISCUSSION

In total 5 classical design parameters were considered, namely the thickness of rib, the transversal spacing of rib, the height of crossbeam, the longitudinal spacing of crossbeam and the weld length of rib-to-crossbeam joint. Among these parameters, the thickness of rib was determined by the stiffness of rib which was normally selected in accordance with the traffic category, etc. Thus, the second moment of area of ribs was treated as the constant reference when adjusting the thickness of rib. One rib and the deck plate of unit length, which was the upper width of rib plus the spacing of rib, were counted in the calculation. Relevant models with various parameters of this study are shown in Table 1.

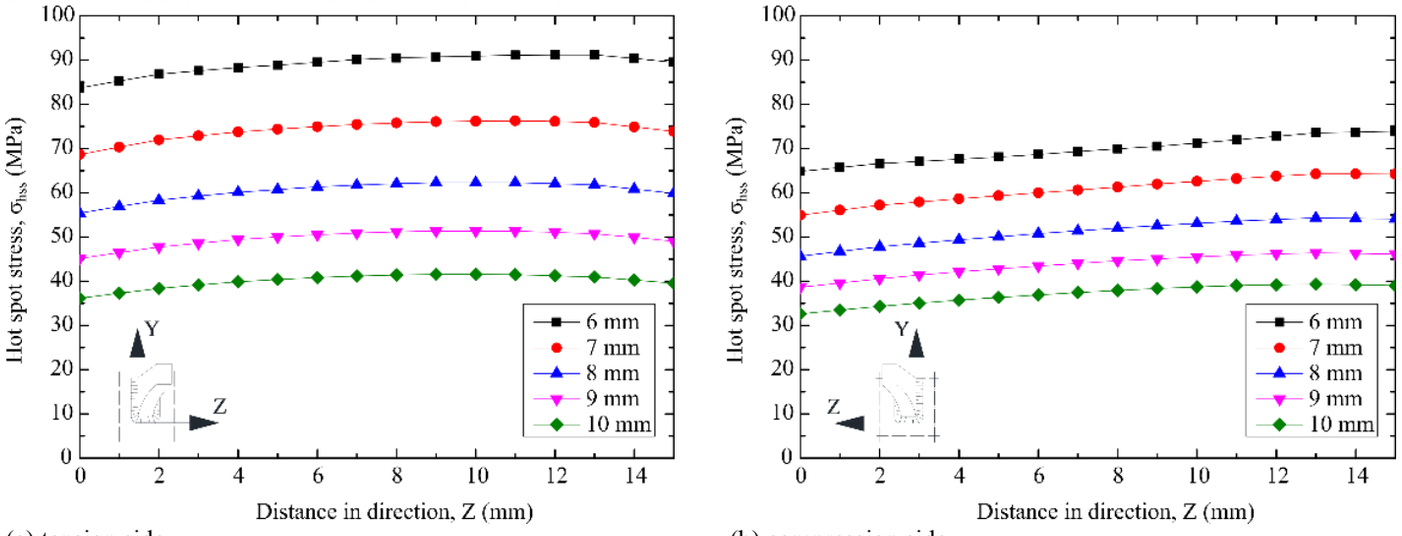

Table 1. Parameters of geometries

Model number	Height of rib	Upper width of rib	Bottom width of rib	Thickness of rib	Spacing of rib	Height of crossbeam	Spacing of crossbeam	Weld length of rib-to-crossbeam joint

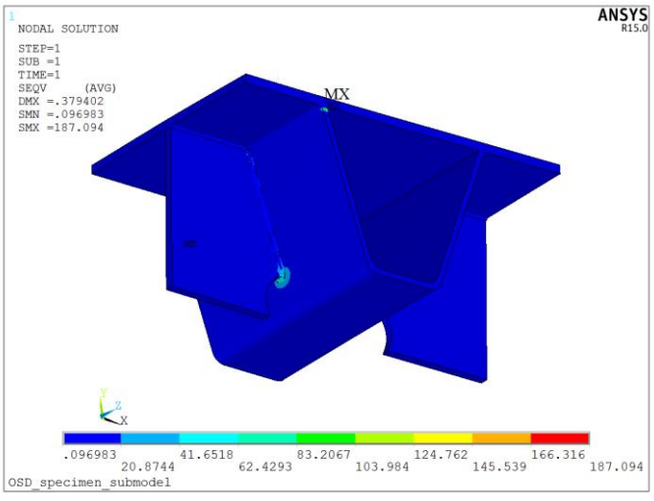
3.1 *Thickness of rib*

Figure 5 shows the influence of the thickness of rib on distortional stress. According to the figures, the distortional stress decreases as the thickness of rib increases. On the tension side, the average distortional stress decreases from 89.10 MPa to 40.09 MPa when the thickness of rib increases from 6 mm to 10 mm. On the compression side, the average distortional stress decreases from 69.72 MPa to 37.05 MPa as the thickness of rib increases. The decreasing amplitude is about fifty percent. The distributions of distortional stress on both sides are not influenced by this parameter.

(a) tension side (b) compression side

Fig. 5. Influence of the thickness of rib: (a) tension side; (b) compression side

The calculation result shows that when using a thicker rib, the stress of rib-to-deck joint increases at the same time. Figure 6 displays the calculation result of model 4 in Table 1, of which the thickness of rib is 10 mm. The stress peak appears at the rib-to-deck joint.



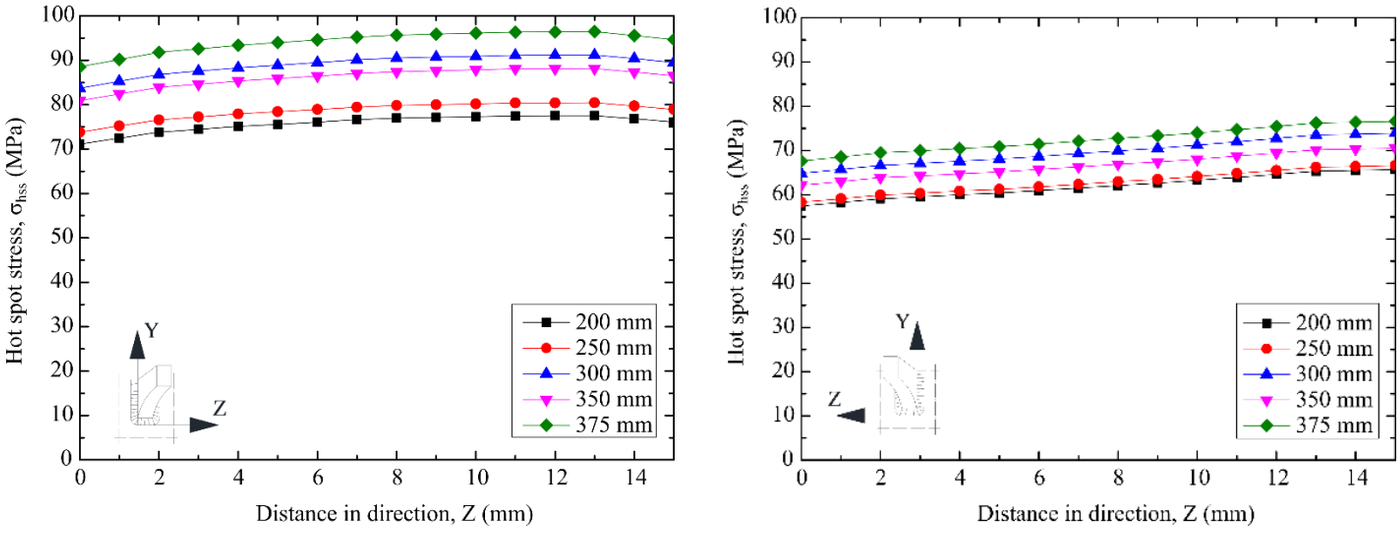


Fig. 6. Calculation result of model 4

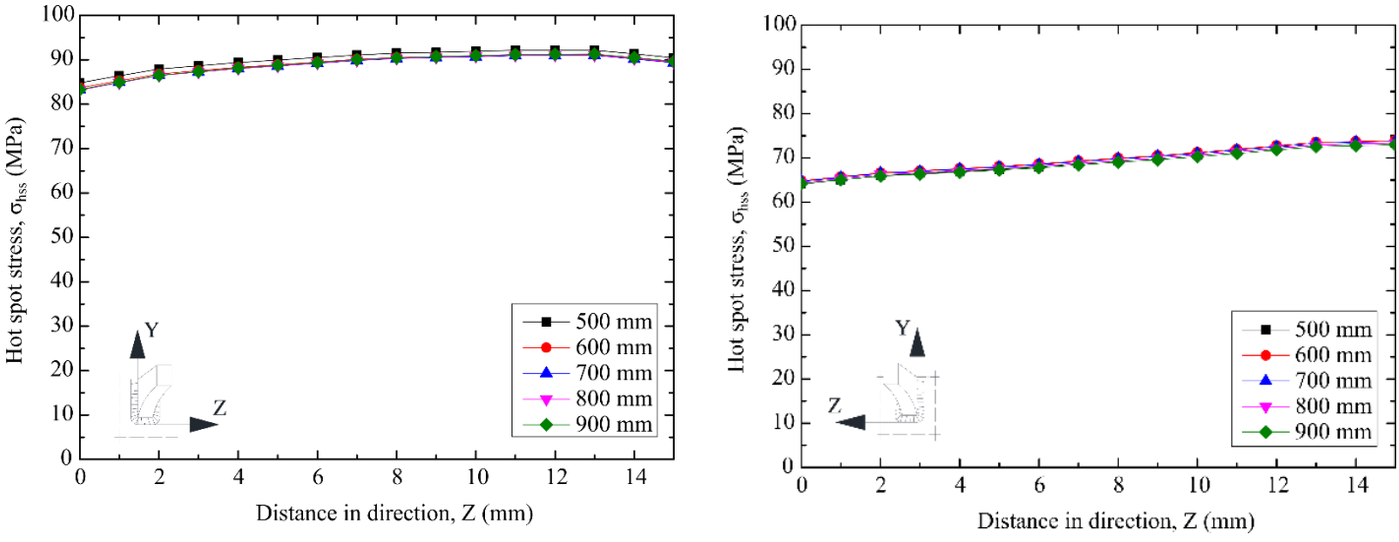
3.2 *Spacing of rib*

Figure 7 presents the influence of the spacing of rib on distortional stress. The distortional stress and the spacing of rib are positively correlated. On the tension side, the average distortional stress increases from 75.76 MPa to 94.22 MPa as the spacing of rib increased from 200 mm to 375 mm. Meanwhile, the average distortional stress increases from 61.89 MPa to 72.51 MPa on the compression side. Similar to the

thickness of rib, the spacing of rib does not change the distribution of stress.

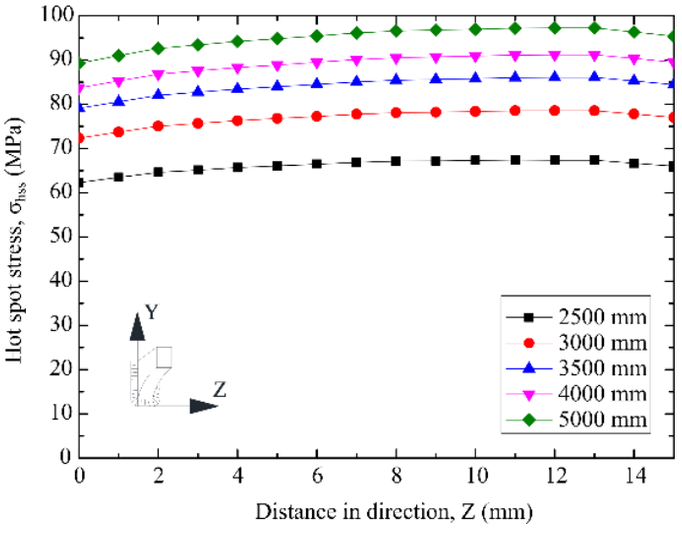


(a) tension side (b) compression side

Fig. 7. Influence of the spacing of rib: (a) tension side; (b) compression side

3.3 *Height of crossbeam*

Figure 8 displays the influence of the height of crossbeam on distortional stress. Compared to other parameters, the influence of the height of crossbeam is not obvious. On the tension side, the distortional stress decreases about 2.5 MPa as the height of crossbeam increases from 500 mm to 900 mm. On the compression side, the distortional stress remains the same as the height of crossbeam increases.



(a) tension side (b) compression side

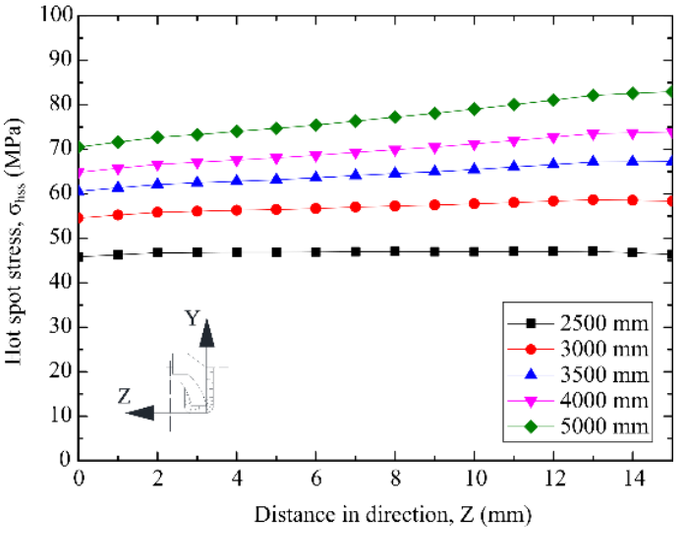


Fig. 8. Influence of the height of crossbeam: (a) tension side; (b) compression side

3.4 *Spacing of crossbeam*

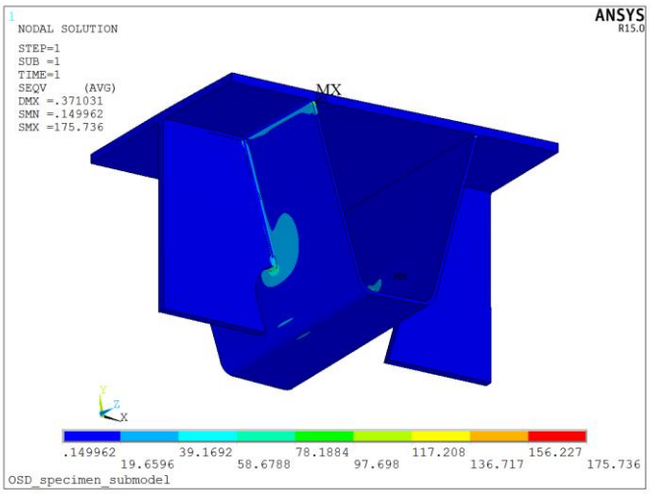
Figure 9 shows the influence of the spacing of crossbeam on distortional stress. The distortional stress and the spacing of crossbeam are positively correlated. When the spacing of crossbeam decreases from 5000 mm to 2500 mm, the average distortional stress of the tension side decreases from 95.04 MPa to 66.06 MPa and the average distortional stress of the compression side decreases from 76.99 MPa to 46.78 MP. On the compression side, the distribution of distortional stress trends to be more uniform as the spacing of crossbeam decreases.

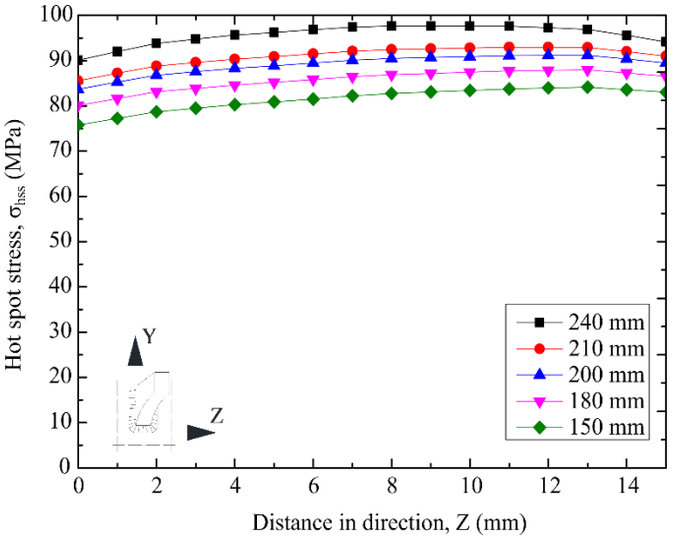
(a) tension side

(b) compression side

Fig. 9. Influence of the spacing of crossbeam: (a) tension side; (b) compression side

Similar to the influence of the thickness of rib, the stress of rib-to-deck joint increases when adopting a shorter span. Figure 10 displays the calculation result of the model 13 in Table 1, of which the spacing of crossbeam is 2500 mm. The maximum stress also appears at the rib-to-deck joint.





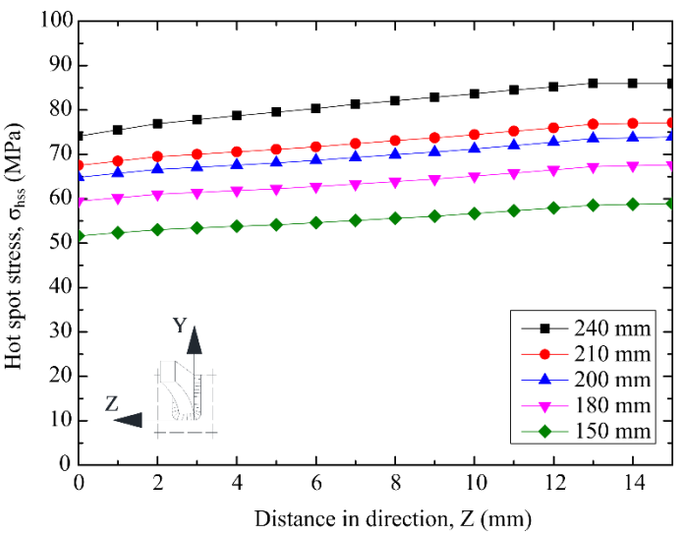


Fig. 10. Calculation result of model 13

3.5 *Weld length of rib-to-crossbeam joint*

Figure 11 presents the influence of the weld length of rib-to-crossbeam joint on distortional stress. The distortional stress and the weld length of rib-to-crossbeam joint are positively correlated. On the tension side, the average distortional stress increases from 81.50 MPa to 95.72 MPa as the weld length of rib-to-crossbeam joint increases from 150 mm to 240 mm. Meanwhile the position of the peak stress moves toward the middle position of crossbeam. On the compression side, this parameter appears relatively larger influence. The average distortional stress increases from 55.50 MPa to 81.28 MPa as the weld length increases but the distribution of stress does not change on this side.

(a) tension side

(b) compression side

Fig. 11. Influence of the weld length of rib-to-crossbeam joint: (a) tension side; (b) compression side

4 CONCLUSIONS

This paper investigated 5 classical design parameters on the distortional behavior of ribs in orthotropic steel deck. Based on the presented results, the following conclusions can be drawn:

- Among 5 classical design parameters, the distortional stress is negatively correlated with the thickness of rib, positively correlated with the spacing of rib, the weld length of rib-to-crossbeam joint and the spacing of crossbeam. The height of crossbeam dies not have obvious influence on distortional behavior.
- When designing an orthotropic steel deck, approaches e.g. increasing the thickness of rib and decreasing the spacing of crossbeam could reduce the distortional stress. However, on one hand, the stress of the rib-to-deck joint increases at the same time which made this joint easier prone to fatigue. On the other hand, thicker rib and shorter spacing of crossbeam would increase the overall weight of the orthotropic steel deck which would deteriorate merits of orthotropic steel deck. Thus, in order to reduce the distortion of rib and improve the fatigue performance, possible alternatives e.g. adding elements would be verified in further research.

ABSTRACT: The bridge over the Asón estuary at Treto, is located in kilometer point (KP) 173,800 of the N-634 road, formerly known also E-70, in the North of Spain, and has been continuously inspected and studied in recent years because of its bad general condition and its importance in the regional transportation network road. This bridge presented significant problems and the structural condition level was critical previously to its intervention in 2015. The rehabilitation project including the restoration of the structural and functional safety level of the structure was deled after material studies and tests were performed. The new updated of the structure fromthe old nineteenth centuries to the newstandard codes was also performed. This paper analyzes the recent experience in the rehabilitation and retrofitting of a singular rotating steel bridge.
A part from the "green" and safe-security aspects, the intervention took in to account all the social requirements of the population in the area who recovered the pride in this emblematic and centenarian infrastructure and it is, itself, a successful intervention from the resilient point of view.

1. INTRODUCTION

Bridge on the N-634 on its way through Colindres (Cantabria) was put into service in 1905 and, since then, it is an emblematic infrastructure of high traffic and pedestrian intensity. In 2016 his rehabilitation was faced. This rehabilitation required the development of very specific works in an environment of great natural and landscape singularity.
The structural non-uniformity of the bridge and the heterogeneity of the materials conditioned a rehabilitation clearly differentiated by the typology of the units and materials. This differentiated rehabilitation required the development of very specific works in an extremely worthy environment. Some innovative actions to mitigate the different sources of risks during the works on site are also explained. One of the most singular mitigation actions was the placement of a movable scaffold wearing an ad hoc encapsulation system in order to comply with the condition of no discharge to the Asón estuary of any sand blasting treatment for the cleaning of the rust on the entire surface of the elements.

2. STORY OF THE BRIDGE

2.1. Historical, administrative and technical background

Although the construction of Treto Bridge (Cantabria, Spain) is framed between 1893 and 1905, it was designed to satisfya previous long term demand. Indeed, it was framed in a territorial conflict by the preponderance of an old trade route that communicated the fishermen towns in the North of Spain and that is why it was call to be a nexus of union between the most important provinces (Cantabria, Basque Country and Castilla y León).
Thus, the project of the puddled iron bridge with two fixed spans and one swing span is approved in April 1890.
Most of the work for thefixed spans was carried out in Spanish workshops and those corresponding to the swing section by the Angler-Tilleur workshops from Liège (Belgium) "Figure 1".

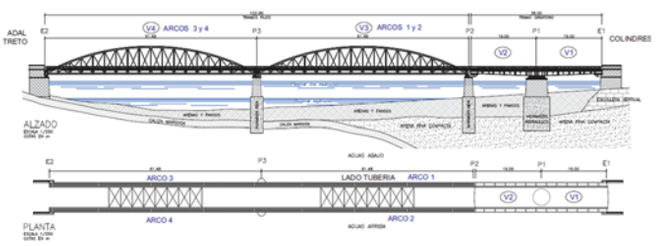

Figure 1. Elevation and plan view. Treto Bridge.

2.2. Bridge description

The total length of the bridge is of 161.74 m, each fixed (parabolic) section is 61.84 m and the swing section is 38.00 m long. The width lane "for carriages" was 9.90 m and had two pedestrian platforms 0.75 m wide in the fixed section and 1.42 m in the swing one. The width of the roadway was 5.50 m for both lanes.

It is a four-span puddled iron bridge composed of two fixed segments, isostatic, with a lower bow-string deck and a continuous swing segment, very different structurally from the previous ones. This superstructure is supported on piles and abutments made of masonry and hydraulic concrete cemented founded on the estuary.

The main structural elements of two fixed spans are the top chords that basically are arches with a variable height along the span according to a parabolic law of second degree that leads to the maximum use of the material. The arches are connected with transversal trusses limiting the vertical clearance. Thus, each fixed span defines a closed but permeable space through which the traffic circulates. The substructure is formed by abutments and masonry piers, two with an oval section and a third one with a circular one on which the swing unit connected with the deck thanks to a wheel mechanism made of an improved iron comparing with the fixed unit close to steel.

Originally and until the year 1940, the swing unit could rotate on the ring gear housed in the circular pile and be arranged perpendicular to the road, allowing the passage of boats, with a height of 3.37 m above the level of PMVE, measured from the underside of the board in fixed sections.

The swing was possible because the section was based on a circular pile of 6 m in diameter with a vertical axis of wrought puddled iron embedded in the center. To verify the movement, twelve conical casting wheels were arranged, on which the metal section was fixed by means of a circular wrought puddled iron disk of 2.40 m outside radius "Figure 2".

The pavement of the swing unit was designed and made of timber. In the other unit it was a bituminous pavement.

Figure 2: Mechanism for the swing span.

All structural elements are connected by rivets. According to the documentation related to the successive projects that gave rise to the Treto Bridge, the material used in it is wrought iron or puddled, 92.16%, which is one of the iron-derived materials that have been used successively in the construction of bridges, after the cast iron and before the steel.

The construction works of the bridge began in 1894, and it was inaugurated in 1905. In 1968, an intervention project was carried out as an emergency and in 1971. Since then, ordinary maintenance tasks have been carried out exclusively.

2.3. Inspections from the construction to 1960

There exist three reports that identified signs of oxidation, consequence of the insufficient protection of the metallic surfaces. They were solved with chopping and scraping of the rusted parts, and repainted with metallic paint based on silver glitter. In these reports is also described the blocking of the swing span, which had not been revolved since the first years of the post Spanish Civil war period.

2.4. Inspection in 1965

The inspection works carried out in 1965 analyzed for the first time the conditions of resistance and stability and looked for a solution to reactivate the turn of the swing section, although finally it was blocked.

In order to know the mechanical behavior of the bridge, a load test was carried out, and it was observed that in all the sections the vertical

displacements (3mm in the mobile and 12.5mm in the fixed ones) were recovered completely, from which it was deduced that the tensions were in the elastic range.

A chemical analysis of the steel of the bridge determined that the material was easily weldable by any procedure, and thus all the unions intervened, more than half, were repaired with this technique.

Finally, in 1966 a project was drafted in which a large number of actions were collected, among which were:

Table 1: List of relevant actions recommended

Relevant actions recommended in 1966
1. Union of the floor beams and bottom chords in the fixed units, which were in very bad conditions due to oxidation.
2. Stuffing of the bottom chords of a waterproofing material and lightweight to make them watertight, as they had insufficient drains and clogged. The proposed material was "termite concrete or similar" protected in its upper 5 cm with a lightweight concrete with aggregates.
3. The diagonals of the fixed units were not joined at the crossing points and they vibrated a lot when passing vehicles. To increase its stiffness, it was proposed to weld them to a sheet of 50x6 mm so that the cross section of each one was a T, and to join each pair of parallel diagonals together, in addition to welding them at the crossing point.
4. Repair of the metal formwork that constituted the resistant element of the forged of the parabolic sections. They were rusted due to seepage through the pavement and fill. Its repair was projected by sheet and welding and replacement of the filling by a rich concrete reinforced with a round mesh.
5. Replacement of timber sidewalks.

The consequences of this intervention has been observed and valued in the current intervention of 2016.

In 1986 the last rehabilitation project on the bridge was approved, which included only painting works. In summary, the bridge built in 1905 did not receive any type of intervention until 1965. Twenty years after these works, 1986, it was repainted and no works were carried out on the bridge until the approval of the rehabilitation project in 2016.

3. AIM OF THE REHABILITATION PROJECT IN 2016

The Ministry of Public Works in Cantabria (Spain) promoted an emergency project in 2015 to retrofit, protect and structurally rehabilitate a bridge that, from its origins, has been fundamental for the socioeconomic development of the area. The condition in which the bridge was 30 years after its last intervention was severe enough to drive a comprehensive rehabilitation project that would return the bridge to levels of structural security and service suited to the needs of the 21st century and, at the same time, conserving its essence.

4. INVENTORY OF MOST IMPORTANT DAMAGES

Corrosion, until the break, in many elements of the structure, highlighting the units between vertical and diagonal members, top and bottom chords, floor beams and bottom chords. It is a generalized damage caused by the deterioration and / or lack of protection, and it could beconsidered as a very risky damage because it endangers the safety of the pieces that are not easily accessible. Water accumulates easily, which intensifies corrosion, deteriorating the rivets and gussets and decreasing the strength of the union between structural elements.

Figure 3. Corrosion damage location. General condition.

The most relevant damages are included in the next Figure:

Table 2: General list of relevant damages.

Relevant damages
1. Instability of the diagonals to the compression efforts.
2. The bearing capacity of the lost puddled iron formwork elements has been exceeded.
3. Loss of section in bottom chords.
4. Unexpected displacement of the retaining walls in their encounter with the abutments.
5. Scour in abutments.
6. Damages caused in diagonals, vertical members and by the impact of vehicles
7. Deformations in diagonals and vertical members and struts caused by vehicle impacts.
8. Damages, unexpected deformations and displacements in masonry parapets of abutments.
9. Leakage

5. MILESTONES DURING REHABILITATION WORKS

It can be found below the solutions undertaken to restore the level of structural and functional saf ety of the structure, defined after the diagnosis study and after analyzing the pa thologies identified. The rehabilitation procedure is shown in Table 3.

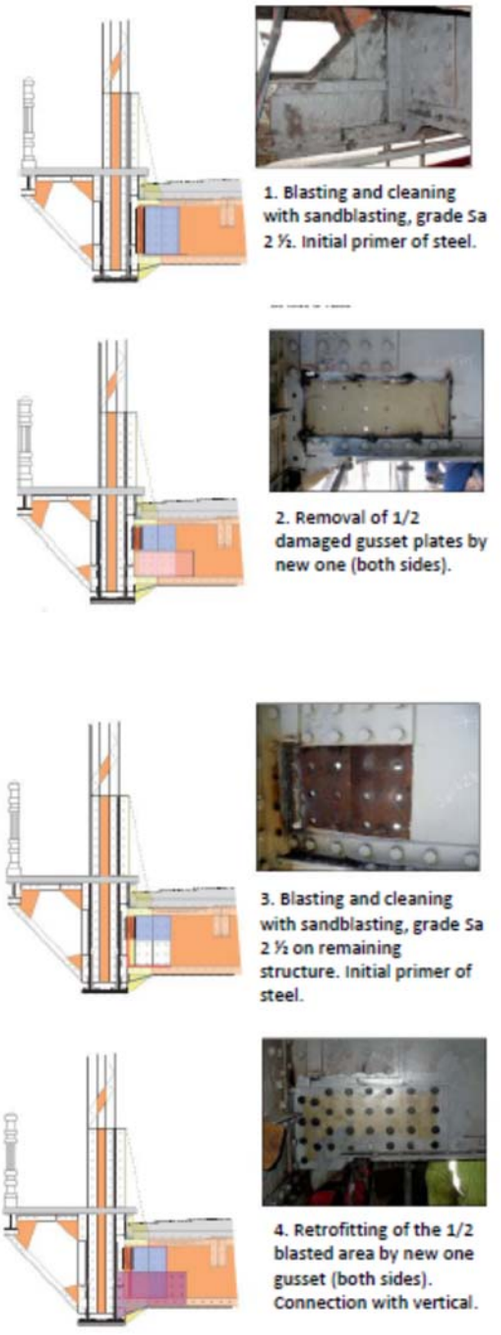
Table 3: General list of rehabilitation procedures

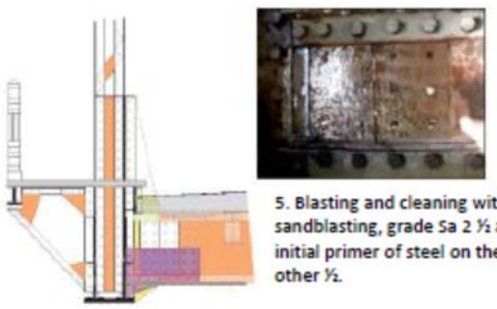
Rehabilitation procedures during works
1. Blasting and cleaning of all truss members with sandblasting, grade Sa 2 ½. Initial primer of steel. Protection and greasing of bearing devices.
2. Calculation and evaluation of the remaining life of the bridge and definition of the retrofitting details to restore the resistant sections of steel, by means of the provision of new steel elements. Replacement of all lost, broken or loose rivets.
3. Replacement of the existing riveted unions by high resistance screws.
4. Reinforcement of all floor beam-bottom chord-vertical connections in fixed spans. The main connections of t he bridge.
5. Reinforcement of all top chord-vertical connections in fixed units.
6. Rectification of diagonals in arches.
7. Dismantling of in ternal truss according to original version. 8. Replacement of 18 portal struts and sway bracings in fix ed units. Elimination of the existing subgrades (44 cm thick) on the original lost formwork supported by floor beams and stringers.
9. Complete removal of the pavement. Execution of reinforced concrete slabs connected to floor beams by bolts in fixed units. Execution of a waterproofing system on the new slabs. Cleaning and unblocking of the existing scuppers.
10. Construction of new scuppers to provide the deck greater drainage capacity.
11. Rectification and/or replacement of some verticals.
12. Replacement of damaged verticals in fixed spans.
13. Replacement of expansion joints.
14. Stuffing of the bottom chords of a waterproofing material and lightweight to make them watertight, as they had insufficient drains and clogged.
15. Retrofitting of stringers and floor beams in swing unit.
16. Anchoring new a traffic barrier system in the swing unit.
17. Widening of sidewalks, from 0.80 m to 1.90 m by means of metal brackets housing the water pipeline.
18. The original bridge railing was reproduced.
19. Replacing of the existing water pipeline with a diameter of 500 mm, by another with a diameter of 600 mm below the new sidewalks.
20. Protection of all the truss members of the bridge with a protective coating resistant to marine environment, (280 and 400 microns thick).

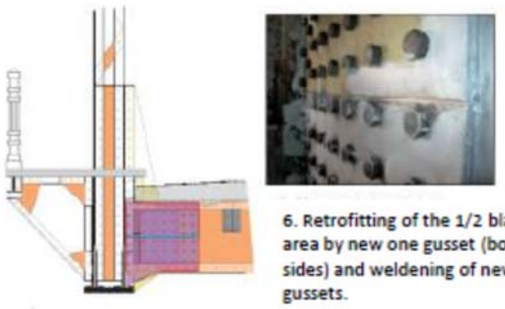
6. REHABILITATION OF MAIN CONNECTIONS

It has been considered as m ain connections those ones between bottom chord, vertical and floor-beam.

The rehabilitation of m ain connections consists in the replacement of old dam aged gusset plates by new ones following an eight steps procedure.







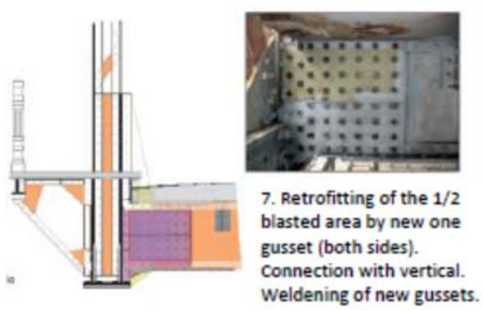


Figure 4: Rehabilitation of main connections.4 first steps.

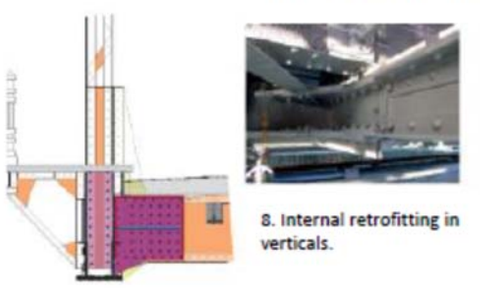

5. Blasting and cleaning with sandblasting, grade Sa 2 ½ and initial primer of steel on the other ½.

6. Retrofitting of the 1/2 blastedl area by new one gusset (both sides) and weldening of new gussets.

7. Retrofitting of the 1/2 blasted area by new one gusset (both sides). Connection with vertical. Weldening of new gussets.

8. Internal retrofitting in verticals.

Figure 5: Rehabilitation of main connections.4 last steps.

7. CONCLUSIONS

The complete analysis of Treto Bridge shows that it is a very advanced tec hnical and technological structure for its time. It is no t coincidental th at, despite the aggressive environm ent and the poor maintenance received since its construction, it has reached our days being a fundamental service for the users of the road and its neighbors and an iconic infrastructure for the region.

ABSTRACT: In the last 35 years, the South American region has been affected by events of diverse nature such as earthquakes, floods, volcanic eruptions, landslides, and others, generating infrastructure losses close to US$88,000 million (South American Council of Infrastructure and Planning [COSIPLAN], 2016). This context has led to the implementation of the methodology called Disaster Risk Management (GRD.) by COSIPLAN/IIRSA (Initiative for the Integration of Regional Infrastructure in South America), in conjunction with the countries members of this council, created with the aim of reducing the effects of natural and anthropogenic disasters in the country's infrastructure.

In addition to the work on infrastructure management developed in South America, Chile, through the Ministry of Public Works, the Pontifical Catholic University of Valparaíso and the Pontifical Catholic University of Chile, has proposed a methodology called Management of Risk Disaster at Regional Level (GRDR in Spanish), which is applied in one of the phases of the COSIPLAN methodology.

The aim of this methodology is to incorporatedecentralized information by enabling the participation of technical teams or sub-departments at city level, allowing for the generation of preventive early warnings, identifying and updating the structural damage indexes (in addition to maintenance plans) and executing reduced budgets at early stages.

The present work describes the most relevant aspects of this methodology, presents the results obtained in field applications, and describes an implementation proposal for Route 115 CH.

1 INTRODUCTION

Chile is the longest country in the world, with approximately 4,300 kilometers from north to south in its South American continental territory. It presents a variety of conditions regarding both weather and morphology along its territory. The physical characteristics of the Chilean territory are defined by Bordas (2006) as "one of the most seismically active areas of the planet, with a large number of volcanoes, an extensive coastline exposed to the Pacific Ocean, a mountainous territory stark altitudinal differences, and an intense pluviometric regime".

In this geomorphological context, there is a remarkable need to implement the methodology for Management of Risk Disaster at Regional Level (GRDR) with the objective that technical units that inspect state-owned structures take this geographical context into account at the time of inspection. These technical units, such as the Ministry of Public Works (MOP) and the Housing and Urban Development Service (SERVIU) are the onesresponsible for the development, implementation, and maintenance of public infrastructure in Chile. In addition, it is very important to take into consideration this methodology at the time of executing any intervention in the road infrastructure and when projecting future works within a road, in order to reduce the risk of disaster.

The application of the GRDR methodology provides a real and clearer perspective of the national road infrastructure, allowing forin-depth analysis of the most fragile areas of the network, supporting the decision-making process in the context of each structure studied, enabling finally a change in the current philosophy of the development of the national road network. COSIPLAN/IIRSA is fostering the application of this methodology in South America and in all its member countries, being Chile one of the pioneers in the application of this method.

The GRDR. method is based both on the road infrastructure as well as the climatological and morphological context where the structure is located, which means that the threats will take an important role at the time to inspect, repair and plan infrastructure belonging to the national road network. This method is focused on reducing the vulnerability of

infrastructure while reducing the risk of social and economic loss in the country in order to obtain a resilient road network.

2 CHILE'S PROPOSAL ON THE METHODOLOGY FOR DISASTER RISK MANAGEMENT IN REGIONAL INFRASTRUCTURE (GRDR)

With the purpose of complementing what has been done by COSIPLAN/IIRSA, on the progress made in probabilistic risk analysis, it has been proposed at the national level a methodology called Management of Risk Disaster at Regional Level (G.R.D.R), coordinated directly by the Ministry of Public Works. This method is applied at phase 2 of the COSIPLAN methodology, having an impact on actions to be implemented in phase 3, thus enabling a resilient response optimized to thecontext of the country (Valenzuela & Valenzuela, 2016).

The purpose of the methodology proposed by the Ministry of Public Works (MOP) is the integration of aspects of decentralization through regional management of the infrastructure, which implies that each region should be able to carryout surveys of their infrastructure, providing information through technical entities, allowing for the generation of early warnings, identification and updating of the damage indexes of the structures, which results in the management of risks in the Regional Infrastructure (Valenzuela & Valenzuela, 2016). Figure 1 shows this decentralized approach that collects information from regional technical units, which allows for infrastructure management at thelocal level and within the region's budgetary framework.

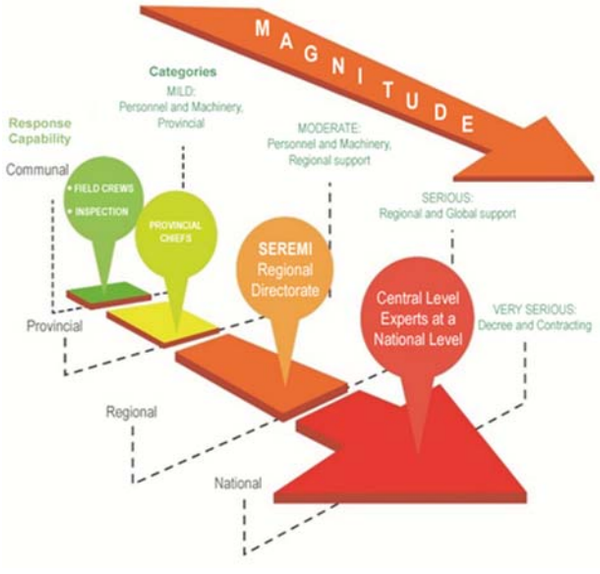

Figure 1. GRDR Methodology Alert Levels
Source: Author compilation.

Some of the benefits derived from the management of infrastructure at the regional level are the following: lower costs incurred at the stage of information collection, better knowledge of the "needs" of the region's communities, and better understanding of the structure's geographical context.

2.1 *Phases of the G.R.D.R methodology.*

The GRDR. methodology is comprised of four phases which help determine structures' pathologies and vulnerabilities to operating loads and external sources of stress. The methodology' s phases are the following:

Phase 1: During this phase, pathologies are identified in the elements constituting the selected structures in a road network, taking into consideration the operational burdens of the structure as well. Thismust be achieved in field inspections of the structure through the use of inspection sheets.

Phase 2: Once the structure has been assessed through the pathologies of its elements and the operational burdens, it is assessed overall, taking operational burdens into consideration; this survey, as in the previous phase, is achieved through the use of inspection sheets.

Phase 3: Once the structure's pathologies and operational burdens have been assessed, the exceptional loads (seismic activities, floods, volcanic eruptions, landslides, etc.) must be identified. When acting each on its own, a vulnerability index is generated for the structure.

In this phase, it is important that public institutions provide documentation and input from their own databases of local threats.

Phase 4: During this phase, the structure is assessed through a single external stress, as well as in the event of more than one external stress (e.g.: an earthquake and tsunami, or a volcanic eruption and landslides).

Phases 1 and 2 are activities commonly executed by the National Road Directorate for its road infrastructure. For bridges, the sheets contained within the Highways Manual, Vol. 7 are used most of the time.

The materialization of this methodology proposed by the MOP is carried out byprofessionals at the local units responsible for the maintenance and supervision of the national road network. These professionals must be trained by specialists in this methodology so

they can then survey the structures and provide an explanation for each pathology within each structure as well as guidance (Figure 2).

Figure 2. Training courses of GRDR Methodology.

3 PILOT PLAN ARICA Y PARINACOTA REGION

The first pilot plan to use this methodology consisted on the inspection oftraditional typology Poconchile and Chacabuco Bridges, located in the Arica and Parinacota Region, specifically along the 11 CH route, as well as a visit to the Sea Port Terminal of Arica. This is considered a bi-oceanic route, and so it is highly important to South America, as it connects countries such as Brazil to the Pacific Ocean.

The inspection program was developed with the aid of 20 professionals in charge of the inspections using the bridge sheet; they were divided into four groups of five inspectors each to get a correct assessment of the information obtained in the field, placing a great focus on the assessments of the sheets. This feedback from the professionals allows for the continuous improvement of these tools.

According to the assessment of the results gathered in the field (Valenzuela & Valenzuela, 2016), the groups perform as follows:

- **Group 1:** Through their comments on the sheet, this group failed to demonstrate their understanding of the inspection tool.

- **Group 2:** This group managed to correctly interpret the evaluation sheet, using the concepts provided to them. They generated comments regarding the position of the pathologies in the structure.

- **Group 3:** This group understood the location of the pathologies correctly, but failed to understand the application of the Risk Phase.

- **Group 4:** This group failed to correctly interpret the application of the sheet. They generated comments of a technical character, which are not considered within the scope of the sheets.

Some of the improvements considered for the implementation of these data sheets in future pilot plans focus on an improvement of the user guide, to fill the data sheets in a more orderly fashion in order to correctly guide the professionals and reduce the subjectivity of the data obtained. This is a relevant issue considering the subjectivity of the inspections carried out as part of this pilot plan.

4 PILOT PLAN LOS LAGOS REGION AND AYSEN REGION

The implementation of the tools developed within the framework of action of the GRDR methodology consists of a field test applied between kilometers 170 and 345 at Route 7 "Carretera Austral", corresponding to the second pilot plan for the above-mentioned methodology. This route is the main connection between these regions, becoming an important asset for Chile.

The main objective pursued in this process is to get validation and feedback from professionals with regard to the tools developed, particularly their applicability to the road network and its site context.

The pilot plan is based on the application of the visual inspection sheets developed by the GRDR team which is tested in different infrastructures and sectors vulnerable to threats, having their influence radius within the road network covered by the pilot plan. The procedure considers the participation of seven inspectors with different professional qualificationsin the structures, construction, and environment fields. These professionals are responsible for the field validation of the developed tools.

The inspection section of the selected pilot plan is considered as one of the sectors with the greatest fragility within Route 7 product of the morphological and climatical context of its environment, presenting multiple threats of varied nature. The latter, together with the presence of unique bridges (suspension and cable-stayed bridges), corresponds to the main motivations for the entity responsible for the administration of the GRDR methodology (Figure 3, 4 and 5).

Figure 3. Raya Bridge. Pier Damage.

Figure 4. Amarillo Bridge. Pier Damage.

Figure 5. Suspension bridge at Aysen region.

From the threats identified in the pilot plan, the entity in charge of coordination of the methodology and the multidisciplinary team that makes up the GRDR selected the following threats: volcanic activity, fire risk, landslide and flooding threats and river overflow (Figure 6).

These threats should be analyzed by the methodology, which corresponds in the first instance to an in-officecharacterization and ending with visual inspection in the field.

Figure 6. Landslide area on Route 7.

Generally, there is feedba ck from professionals, which is identified in all of the tools developed:

- The data sheets provide an easy-to-understand design for the user.
- Proposal of inspection protocols for the use of GRDR. data sheets
- The data sheets allow for having a historical and detailed record of the threat studied, in addition, to supplement it with ph otographic record. This registration is required in the inspection protocols, both for the m icro inspection of the structure as well as f or the m acro inspection of the threats.
- Incorporation of variables not provided for in the prior description: an example of this are the bonfires under the bridge structure.
- The possibility of using a tablet device to take photos and incorporate th em immediately into the report.

Figure 7. Inspection activities under GRDR Methodology.

The process for obtaining feedback indicated on each data sheet consists of the study of inspection instruments used in the field, complemented by the analysis of the videos corresponding to the technical meetings. These two sources of data provide important feedback for each one of the inspection data sheets. This process was carried out with each of the tools defined for the survey (Figure 7).

This allows for improving each of the data sheets, taking into account the observations obtained in thefield and by validating them with literature relevant to the topic.

5 RESULTS OBTAINED IN THE IMPLEMENTATION IN FIELD AND A PROPOSAL FOR IMPLEMENTATION IN ROUTE CH-115

The experience gained in the implementation of the pilot plans mentioned above, particularly in the one executed at Carretera Austral, as well as the identification and characterization of threats done in office demonstrate that some variables appear constantly in the events analyzed, being one of the most important the one corresponding to the morphological variables, in particular, the slope, which according to the studies carried out conditions all the events covered in the pilot plan of the Los Lagos Region and Aysen.

- **Volcanic threat "lahars":** The slopes directly affect the speed of the lahar, generating great drag of materials eroding works within the area of influence of this threat.

- **The threat of forest fires:** Because heat rises, the steepness of the slope is an important factor in the behavior of the fire and its spread. There is a danger associated with the slope percentage. Gradients below 15% are assumed as danger null, between 15 and 30% low danger, between 30 and 40% medium danger, 45 to 60% high risk and slopes of over 60% are considered extreme slopes (National Forest Corporation CONAF et al., 1999).

- **The threat of landslides:** Slope topography (its geomorphological features) condition the occurrence of landslides. These characteristics have a direct influence on the speed, energy, and volume of mass removals. Any alteration in the topographical features of the hillside can make it go from stable to unstable (Popescu, 2002).

  According to Hauser (1993), slopes with gradients greater than 25° in the headwaters of the drainage basins favor the formation of floods. In the case of slopes formed by rock, the slopes greater than 35° are those that generate a greater susceptibility to landslides.

It is of great importance that slopes are analyzed in all the tools developed in Phase 3 of the GRDR methodology, where the professionals responsible for the gathering of field information are able to analyze these variables and provide feedback in the best possible way through the inspection data sheets.

5.1 *Application of G.R.D.R. methodology to Route 115 CH*

With the objective of calibrating all procedures and products which are obtained by applying this methodology, it is necessary to have more pilot plans. All of the analyses developed in the pilot plans listed above can be interpolated to the context of Route 115 CH where there are threats that are reiterated with regard to the geomorphology present in the location of the route, such as forest fires, landslides and volcanic processes.
The existing threats in this route are:

Forest fire: fire outbreaks reported by CONAF along Route 115CH, where different fire outbreaks characterized mainly by low density can be appreciated. The density of forest fires exposed by CONAF depends on the number of forest fires per square kilometer that have occurred in the last five years: Low: from 1 to 5.; Medium: from 5 to 10, and High: more than 10.

Although there is a low density in the event analyzed, the present geomorphological context, the steep slopes, in particular, are determining factors for greater acceleration and ignition of forest fires, generating great risk in structures, especially to bridges built of a mixed structure of steel-concrete, which varies its supportive behavior.

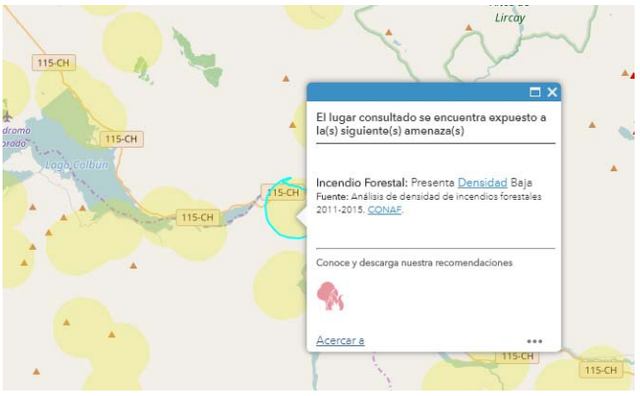

Figure 8. Threat of Forest Fires in Route 115 CH.

Landslides: in route 115 CH different landslides of rocks can be appreciated, such as the one that occurred in kilometer 128 of the road, Los Condores sector. This event is enhanced by the steep slopes in the high mountain road context.

Volcanic threat: on route 115 CH different levels of volcanic hazards are present according to the report carried out by the National Emergency Office ONEMI, where there are sectors on the route which are exposed to high volcanic hazards where its location includes the influence of the volcanic complex Laguna del Maule, Pedro-Pellado volcano, and Cerro Azul- Quizapu volcano.

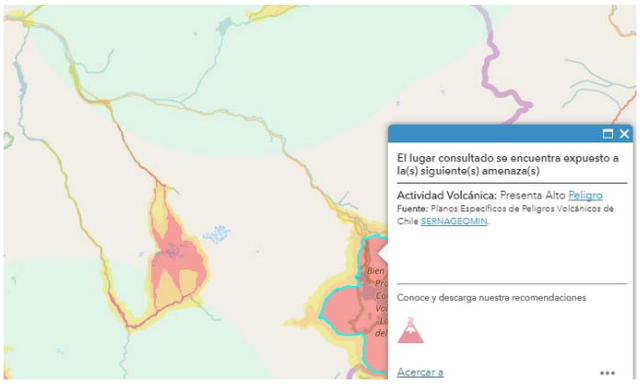

Figure 9. Volcanic Threat on Route 115 CH.

The geomorphological context present in Route 115 CH generates a significant risk to the structures present on this route, before which the implementation of the GRDR methodology is important, where the inspection of the structure considers a comprehensive analysis that takes into account the study of the structure, its location, and their interaction.

6 CONCLUSIONS

- The constant external threats to which the road infrastructure is constantly exposed make it the implementation of inspection methodologies necessary, both at the national and regional level, including all aspects described in this work.
- The current methodologies of inspection carried out by the Road Management Office (Dirección de Vialidad) and the data sheets contained in the Manual of Roads should be complemented to contain aspects relating to threats (external stress sources) that put at risk, in particular, the infrastructure of bridges.
- Continuous training of professionals involved in these tasks is required, with type data sheets and application manuals.
- The routes that have a high factor of importance, such as for example the bi-oceanic corridors, need to be constantly studied from the point of view of the threats that they are exposed to. The above should be complemented with routine and periodic inspections.
- With regard to the implementation of the pilot plan in the Carretera Austral, several zones which are influenced within the buffer of threats are shown, generating a great risk for infrastructure located in the route, generating the need to implement a methodology concerning risk management.
- The implementation of the G.R.D.R. methodology in the context of threats in Route 115CH can bring with it an improvement in the effectiveness of the road network in the area of analysis, providing tools to improve the management of the infrastructure at the regional level.

Fatigue behavior of full-penetration inclined cruciform welded-joints with artificial pit corrosion

X. Wei
Southwest Jiaotong University, Chengdu, China
Z.Y. Jie
Ningbo University, Ningbo, China

ABSTRACT: To investigate the effect of corrosion pit on fatigue damage evolution of welded joints, specimens of full-penetration inclined cruciform (FIC) welded joints with artificial corrosion pits were designed and fatigue tests of three kinds of welded joints in different corrosion depth were carried out. Based on fracture mechanics theory and maximum circumferential tensile stress criterion, crack propagation rate formula of FIC welded joints were derived with different corrosion pit. Research results showed that fatigue lives obtained from crack propagation rate formula have a good agreement with test results.

1 INTRODUCTION

Local damage of steel structure is always induced by corrosion and fatigue. Accumulated damage cause performance deterioration of steel structure and eventually will lead to structural failure and decrease the service life of steel structure. Due to the reduction of plate thickness and the increase of stress concentration, corrosion has effects not only on the ultimate static strength but also on the fatigue strength of welded joints. It was found that large stress concentration with corrosion pit was the major cause of the decrease of fatigue strength. Over the past few years, fatigue performance of corroded steel material has been studied extensively. But for steel welded joint, it is less than satisfactory with the existing information. Only a few literatures can be found on the aspects of this problem. Garbatov & Soares (2014) studied fatigue strength of corroded welded steel specimens with prior corrosion. Nguyen et al. (2012) applied the effective notch stress method to the analysis of time-dependent stress distribution and fatigue damage of a corroded oil tanker. Huang et al. (2014) evaluated the fatigue reliability of a complicated welded structure subjected to simultaneous random non-uniform corrosion and fatigue loading.

In this paper, test specimens of full-penetration inclined cruciform (FIC) welded joints with artificial corrosion pits were designed and fatigue tests of three kinds of welded joints in different corrosion depth were carried out. Nominal stress S-N curves and fracture mechanics theory were used to predict the fatigue life of FIC welded joints including artificial corrosion pits.

2 FATIGUE TEST

2.1 *Test specimens*

Full-penetration inclined cruciform welded joints were investigated, which include two long plate members and one short plate member, as shown in Figure 1. The inclined angle θ is 45°.

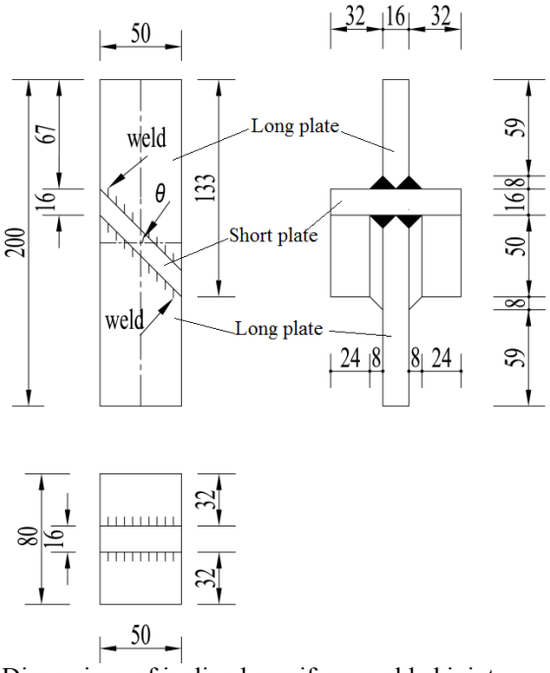

Fig.1 Dimensions of inclined cruciform welded joints

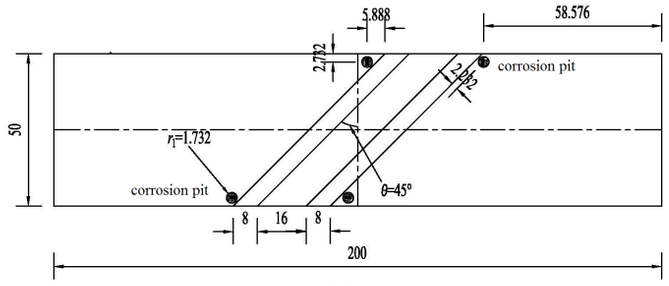

Three groups of test specimens were design for fatigue tests (list in Table 1). There are not corrosion

pits on specimens of group P0. Two kinds of artificial corrosion pits with spherical shape are considered in Group P1 and Group P2. The geometric parameters of the pits, including pit depth and pit radius, are listed in Table 1.

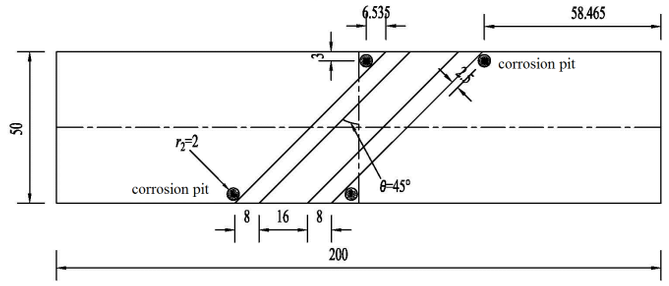

Table 1. Fatigue specimens

Group	No.	*depth* /mm	*radius* /mm	Δσ /MPa	P_{min} /kN	P_{max} /kN
P0	P0D1	0	0	140	12.4	124.4
	P0D2	0	0	160	14.2	142.0
	P0D3	0	0	180	16.0	160.0
P1	P1D1	1	2	140	12.4	124.4
	P1D2	1	2	160	14.2	142.0
	P1D3	1	2	180	16.0	160.0
P2	P2D1	2	2	140	12.4	124.4
	P2D2	2	2	160	14.2	142.0
	P2D3	2	2	180	16.0	160.0

Each specimen in group P1 and group P2 contains 8 artificial corrosion pits located on long members near the ends of welds (see Figure 2).

a) Pit 1

b) Pit 2

Figure2 location of corrosion pitting

The material of the FIC welded joints specimens is hot-rolled low alloy structural steel Q345qC, a typical structural steel for steel bridges in China.

Fatigue tests were performed under the axial tension loading condition. The test overview is shown in Fig.3. With force control and constant amplitude, sinusoid loading was employed for cyclic loading. The ratio between the minimum and maximum stresses was $R=\sigma_{min}/\sigma_{max}=0.1$. Based on the nominal stress method, 9 specimens were divided into three types with different stress range levels in every group. The peak value of fatigue loading was defined as P_{max}, whereas the minimum value was defined as P_{min}. The fatigue loading and stress range levels for each series of specimens are listed in Table 1.

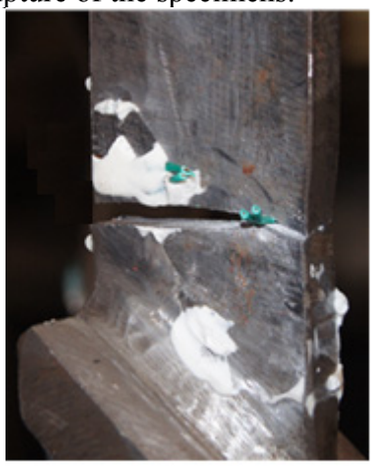

Figure3 Overview of Fatigue test

2.2 *Fatigue Test Results*

As shown in Figure4 (a), in all specimens without artificial corrosion pits the fatigue crack first occurred at the welded toe of the long plate member near short edge sides. Fatigue damage accumulated with increasing cycle number; cracks also penetrated the long plate thickness and propagated along the width of long plate. The fractured plate lost its carrying capacity with crack propagation, and the stress on the plate increased dramatically.

As shown in Figure4 (b), in most of specimens with artificial corrosion pits the fatigue crack first occurred at the corrosion pits of the long plate member near short edge sides. Fatigue crack propagated with increasing cycle number. Cracks decreased the effective area of the cross section of the specimens that carry the axial tension loading, thus leading to the final rupture of the specimens.

	P2D3	180	16.0	160.0	2.91E+05

3 NOMINAL STRESS S-N CURVE

Stress-based and fracture mechanics-based approaches are the two main approaches for fatigue life assessment of weld structure. By choosing different stress parameters, which are defined in Figure 5, the stress-based approaches can be divided into the nominal stress approach, the hot spot stress approach, and the notch stress approach.

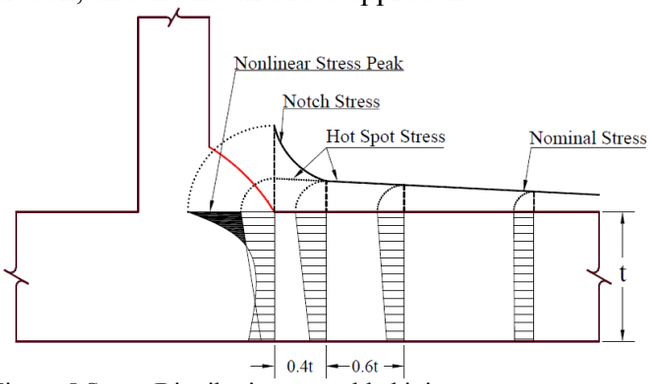

Figure 5 Stress Distribution on welded joint

Nominal stress does not include stress concentrations due to detail geometry, which is primarily determined based on the cross-section properties. Given the different S-N curves for common structural details, the effects of residual stresses, imperfections, welding procedures, and stress concentrations as a result of detail geometry are implicitly accounted for by the fatigue classification of typical details based on statistical evaluation of fatigue test data. The nominal stress range, number of loading cycles, crack location and the structural detail properties are the four main variables that control the fatigue performance of weld details. The nominal stress approach is easy to apply and is adopted in many fatigue design and fatigue life evaluation guidelines. However, its accuracy decreases for complex weld details.

To develop a general understanding of the fatigue performance of FIC welded joints with artificial corrosion pits, fatigue tests results of 9 groups were summarized in this study.

The fatigue test results of FIC welded joints are often plotted with the *S*-*N* curves. The relationship between *S* and *N* is:

$$\Delta\sigma^{m}N=C \tag{1}$$

or

$$\log N=\log C-m.\log\Delta\sigma \tag{2}$$

The fatigue design curves for welded joints have been proposed and adopted by many standards and recommendations, in which each curve is set at a constant slope of minus 3.0(m=3). Given that m=3, the least-squares method was utilized to obtain a linear fitted equation that generate a line of best fit from the data. The equation was based on the fatigue test data from Table 2.

For group P0, the relationship between *S* and *N* is:

$$\log N=12.58-3\log\Delta\sigma \tag{3}$$

Where, the standard deviation is 0.0175.

For group P1, the relationship between S and N is:

$$\log N=12.444-3\log\Delta\sigma \tag{4}$$

Where, the standard deviation is 0.0255.

For group P2, the relationship between S and N is:

$$\log N=12.257-3\log\Delta\sigma \tag{5}$$

Where, the standard deviation is 0.0266.

The aforementioned test results and three S–N curve equations are plotted in figure 6.

The design *S*-*N* curve is commonly selected at two standard deviations below the mean *S*-*N* curve, thus, the majority of the fatigue test data are above the lower-bound value. The fatigue life has a 97.7% possibility of survival with a 95.5% confidence level. The design *S*–*N* curve equation can be expressed as follows:

$$\lg N=\begin{cases}12.545-3\lg\Delta\sigma & Pit0\\ 12.394-3\lg\Delta\sigma & \text{Pit1}\\ 12.204-3\lg\Delta\sigma & Pit2\end{cases} \tag{6}$$

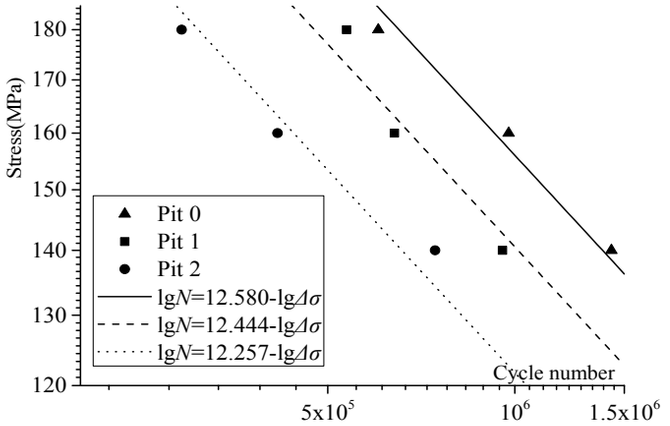

Figure 6 fatigue test results and fitted S-N curve

The test results and three S–N curves for design are plotted in figure 7.

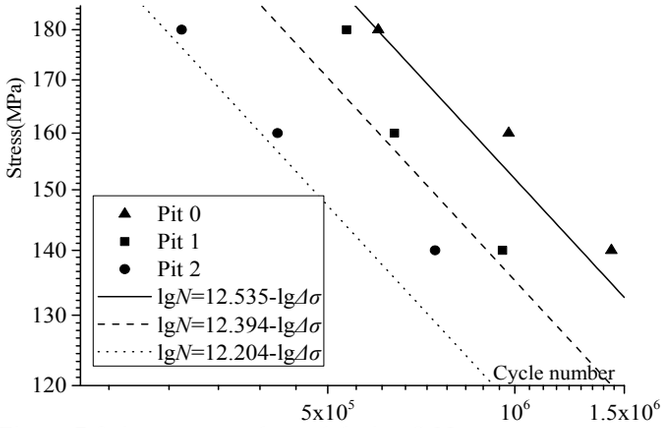

Figure 7 fatigue test results and design S-N curve

4 FRACTURE MECHANICS APPROACH

The fatigue fracture processes in FIC welded joints can be described from the point of view of fracture mechanics. The stress intensity factor (SIF) at the crack or slit tip is used as the basis of this approach. The process of fatigue failure of steel material is subdivided into the stages of crack initiation, stable crack propagation and unstable final fracture. the fatigue life of welded joints is exclusively propagation of very small cracks occurring in the mixed material zone of filler and parent materials at the toe and root of the weld seam, the propagation can be described on the basis of the crack intensity factor range, ΔK.
The fracture mechanics approach, independent of its degree of formalization, complements the nominal stress, structural stress, and notch stress assessments, which are the only basis for dimensioning and design of welded joints, by an assessment of failure safety and service life on the basis of detected actual defects or undetected assumed crack-like defects.
Under uniaxial stress field, there are three crack propagation modes, shown in Figure 8.
Crack mode I is opening mode (a tensile stress normal to the plane of the crack), crack mode II is sliding mode (a shear stress acting parallel to the plane of the crack and perpendicular to the crack front), and crack mode III is tearing mode (a shear stress acting parallel to the plane of the crack and parallel to the crack front)

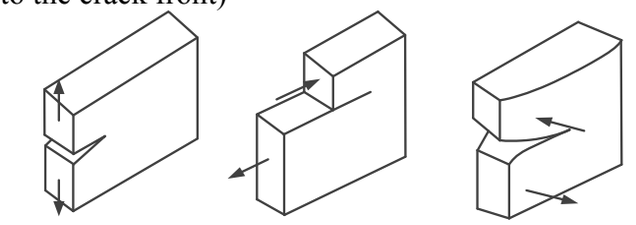

Figure 8 Crack mode in Fracture mechanics

For FIC welded joints, fatigue crack is propagating under tension-shear complex stress. Crack mode of FIC welded joints combines crack mode I and crack mode II. Mixed mode crack propagation criteria are needed to be investigate.
Generally, the mixed mode crack propagation and fatigue life are estimated via the following procedures: firstly, the direction and path of mixed mode crack propagation are determined by numerical methods (e.g. the finite element method (FEM) , boundary element method (BEM) and meshless methods); secondly, crack propagation rates are expressed by the effective stress intensity factor range; finally, fatigue life can be predicted by Paris law based on the effective stress intensity factor range.

4.1 *Mixed mode crack propagation criteria*

Spatial stress state of mixed mode crack front is shown in Fig. 1.

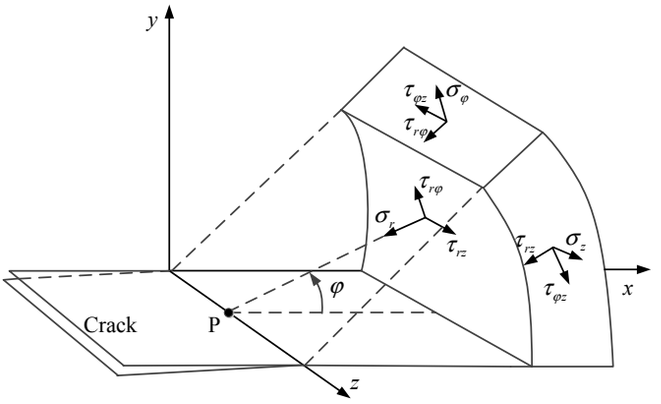

Figure 8. Spatial stress state of crack front

According to the superposition principle, stress components can be expressed in the cylinder coordinate system as:

$$\sigma_r = \frac{K_{\mathrm{I}}}{4\sqrt{2\pi r}}\left\{5\cos\left(\frac{\varphi}{2}\right)-\cos\left(\frac{3}{2}\varphi\right)\right\} - \frac{K_{\mathrm{II}}}{4\sqrt{2\pi r}}\left\{5\sin\left(\frac{\varphi}{2}\right)-3\sin\left(\frac{3}{2}\varphi\right)\right\} \quad (7)$$

$$\sigma_\varphi = \frac{K_\mathrm{I}}{4\sqrt{2\pi r}}\left\{3\cos\left(\frac{\varphi}{2}\right)+\cos\left(\frac{3}{2}\varphi\right)\right\} - \frac{K_\mathrm{II}}{4\sqrt{2\pi r}}\left\{3\sin\left(\frac{\varphi}{2}\right)+3\sin\left(\frac{3}{2}\varphi\right)\right\} \quad (8)$$

$$\tau_{r\varphi} = \frac{K_\mathrm{I}}{4\sqrt{2\pi r}}\left\{\sin\left(\frac{\varphi}{2}\right)+\sin\left(\frac{3\varphi}{2}\right)\right\} + \frac{K_\mathrm{II}}{4\sqrt{2\pi r}}\left\{\cos\left(\frac{\varphi}{2}\right)-3\cos\left(\frac{3\varphi}{2}\right)\right\} \quad (9)$$

$$\tau_{rz} = \frac{K_\mathrm{III}}{\sqrt{2\pi r}}\sin\left(\frac{\varphi}{2}\right) \quad (10)$$

$$\tau_{\varphi z} = \frac{K_\mathrm{III}}{\sqrt{2\pi r}}\cos\left(\frac{\varphi}{2}\right) \quad (11)$$

$$\sigma_z = \nu\left(\sigma_r+\sigma_\varphi\right) = \frac{8\nu}{4\sqrt{2\pi r}}\left\{K_\mathrm{I}\cos\left(\frac{\varphi}{2}\right)-K_\mathrm{II}\sin\left(\frac{\varphi}{2}\right)\right\} \quad \text{plane strain} \quad (12)$$

$\sigma_z = 0$ plane stress

where K_I, K_II,K_III are respectively the stress intensity factors of modes I, II and III, r, φ are polar coordinates at the crack tip, ν is Poisson's ratio, and σ_r, σ_φ, σ_z, $\tau_{r\varphi}$, τ_{rz} , $\tau_{\varphi z}$ are normal and shear stresses in the polar coordinate system.

Erdogan and Sih (1963) proposed the maximum circumferential stress criterion. The criterion adopts the following two basic assumptions: (1) crack will initiate in the direction of the maximum circumferential stress $\sigma_{\varphi,\max}$; (2) crack will grow when $\sigma_{\varphi,\max}$ reaches a critical value $\sigma_{\varphi,\mathrm{c}}$. According to assumption (1), the conditions that circumferential stress reaches the maximum are

$$\frac{\partial\sigma_\varphi}{\partial\varphi}=0 \quad \text{and} \quad \frac{\partial^2\sigma_\varphi}{\partial\varphi^2}<0 \quad (13)$$

Which yields

$$K_\mathrm{I}\sin\varphi+K_\mathrm{II}\left(3\cos\varphi-1\right)=0 \quad (14)$$

and

$$\varphi_0 = \pm\arccos\left\{\frac{3K_\mathrm{II}^2+K_\mathrm{I}\sqrt{K_\mathrm{I}^2+8K_\mathrm{II}^2}}{K_\mathrm{I}^2+9K_\mathrm{II}^2}\right\} \quad (15)$$

Where φ_0 is the crack initiation angle. The fracture criterion can be given as

$$\frac{1}{2}\cos\frac{\varphi_0}{2}\left[K_\mathrm{I}\left(1+\cos\varphi_0\right)-3K_\mathrm{II}\sin\varphi_0\right]=K_\mathrm{Ic} \quad (16)$$

Where K_Ic is the fracture toughness of the material under mode I loading condition.

According to the stress field of crack tip introduced in section 4.1, the effective stress intensity factor ranges, ΔK_{Ieff} ,$\Delta K_{\mathrm{II\,eff}}$ and $\Delta K_{\mathrm{IIIeff}}$, are expressed as:

$$\Delta K_{\mathrm{Ieff}} = \sigma_\varphi\sqrt{2\pi r} = \frac{1}{2}\cos\frac{\varphi}{2}\left[\Delta K_\mathrm{I}\left(1+\cos\varphi\right)-3\Delta K_\mathrm{II}\sin\varphi\right] \quad (17)$$

$$\Delta K_{\mathrm{IIeff}} = \tau_{r\varphi}\sqrt{2\pi r} = \frac{1}{2}\cos\frac{\varphi}{2}\left[\Delta K_\mathrm{I}\sin\varphi+\Delta K_\mathrm{II}\left(3\cos\varphi-1\right)\right] \quad (18)$$

$$\Delta K_{\mathrm{IIIeff}} = \tau_{z\varphi}\sqrt{2\pi r} = \Delta K_\mathrm{III}\cos\frac{\varphi}{2} \quad (19)$$

The effective stress intensity factor range ΔK_{eff} based on the maximum circumferential stress criterion is expressed as

$$\Delta K_{\mathrm{eff}}=\Delta K_{\mathrm{Ieff}} \quad (20)$$

Since the maximum circumferential stress criterion is relatively simple and easy to use in practical applications, and the criterion is validated by a large number of tests, the maximum circumferential stress criterion is recommended being used to predict the fatigue life of welded joints with mixed mode surface crack.

4.2 *Crack propagation equations*

The typical curve of the crack propagation rate da/dN (limes of the ratio of the increase of crack length, Δa, per number of cycles, ΔN) for metallic materials, measured in specimens with macrocrack, dependent on the (constant) stress intensity factor range, ΔK, at the crack tip subjected to pulsating tensile load.

Based on linear elastic fracture mechanics theory, according to the Paris laws, fatigue crack propagation rate of FIC welded joints is expressed as:

$$\frac{\mathrm{d}a}{\mathrm{d}N} = C\left(\Delta K_{eff}\right)^m \quad (7)$$

$$\Delta K_{eff} = Y\Delta\sigma_\varphi\sqrt{\pi a} \quad (8)$$

$$\int_{a_\mathrm{i}}^{a_\mathrm{c}}\frac{\mathrm{d}a}{C\left(Y\sqrt{\pi a}\right)^m} = \Delta\sigma_\varphi^m N \quad (9)$$

Where C, m are material constants, Y denotes the crack shape correction factor, $\Delta\sigma_\varphi$ denotes stress range, a denotes the crack size, N denotes the fatigue life, and a_i and a_c denotes the size of the initial crack and the critical crack, respectively. To simplify the calculation, crack shape correction factor Y is assumed to be a constant. Thus Eq. (9) can be rewritten as

$$\Delta\sigma_\varphi^m N = \frac{a_\mathrm{i}^{1-m/2}-a_\mathrm{c}^{1-m/2}}{CY^m\pi^{m/2}\left(m/2-1\right)} \quad (10)$$

The relation between stress range and fatigue life can be obtained from *S-N* curves defined by fatigue test, thus one can have

$$\Delta\sigma^m N = A \tag{11}$$

Where C is a material constant. The material constant C can be rewritten as

$$C = \frac{a_i^{1-m/2} - a_c^{1-m/2}}{AY^m \pi^{m/2}(m/2-1)} \tag{12}$$

Given Y =1, a_i =0.25 mm, a_c =16 mm, m=3, A=3.75×10^{12}, 2.74×10^{12} and 1.79×10^{12}, the fatigue crack propagation rate of the welded joint with no pit is expressed as

$$\frac{da}{dN} = 1.676\times10^{-13}(\Delta K)^3 \tag{13}$$

The fatigue crack propagation of welded joints with pit 1 is expressed as:

$$\frac{da}{dN} = 2.294\times10^{-13}(\Delta K)^3 \tag{14}$$

The fatigue crack propagation rate of welded joints with pit 2 is expressed as:

$$\frac{da}{dN} = 3.511\times10^{-13}(\Delta K)^3 \tag{15}$$

4.3 *Crack-shape factor*

Using FEM software Franc3D, numerical simulation of FIC welded joint were carried out. The numerical model of FIC welded joint is shown in Figure 9. Initial crack length is 0.25mm.

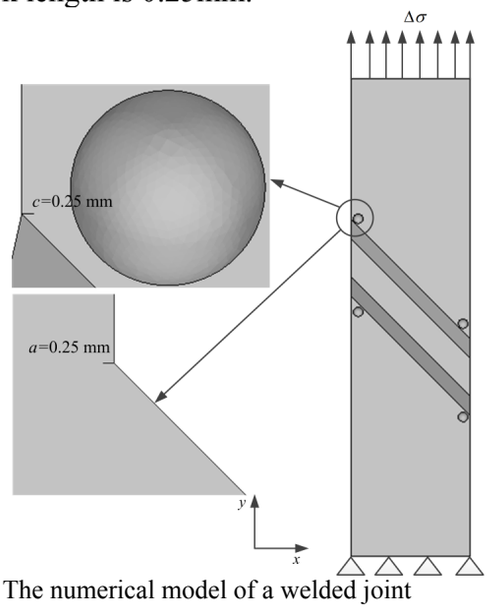

Figure 9. The numerical model of a welded joint

As shown in Figure 10, based on the maximum circumferential stress criterion, the relationship between crack-shape factor Y of the surface crack at the deepest point and crack depth ratio a/t of FIC welded joints with three different artificial corrosion pits were obtain

In Figure 10, it is observed that at the beginning crack-shape factor is in high value. With the increasing of a/t from 0.0 to 0.2, crack-shape factor is decreased from 1.9 to 0.8. With the increasing of a/t from 0.2 to 0.8, crack-shape factor have little fluctuation around 0.7. With the increasing of a/t from 0.8 to 1.0, crack-shape factor is increased from 0.8 to 1.3. When the crack depth ratio is about 0.5, crack-shape factor is in minimum value. The crack-shape factor rises with the increasing of pit depth. The effect of pit depth on the crack-shape factor becomes insignificant when a/t is greater than 0.3.

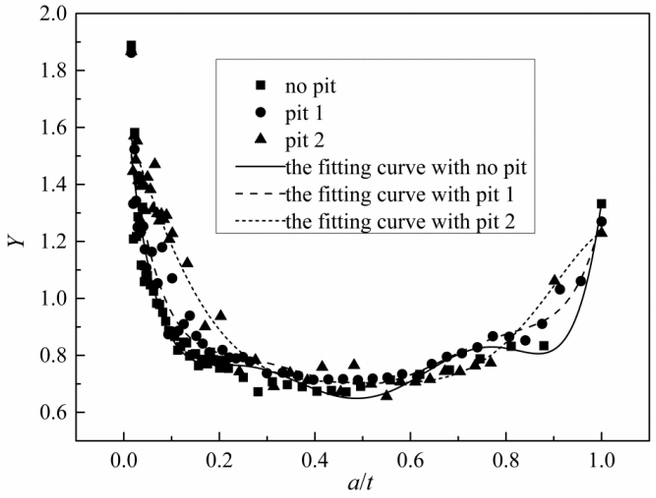

Figure 10 Curve of Y-a/t

Using a polynomial regression technique, crack-shape factor of FIC welded joints with no pit, pit 1 and pit 2 can be expressed as:

$$Y_1 = 1.619 - 16.039\frac{a}{t} + 111.606\left(\frac{a}{t}\right)^2 - 380.735\left(\frac{a}{t}\right)^3 + 666.512\left(\frac{a}{t}\right)^4 - 571.621\left(\frac{a}{t}\right)^5 + 190.199\left(\frac{a}{t}\right)^6 \tag{16}$$

$$Y_2 = 1.587 - 11.865\frac{a}{t} + 68.322\left(\frac{a}{t}\right)^2 - 200.171\left(\frac{a}{t}\right)^3 + 308.501\left(\frac{a}{t}\right)^4 - 237.090\left(\frac{a}{t}\right)^5 + 71.820\left(\frac{a}{t}\right)^6 \tag{17}$$

$$Y_3 = 1.609 - 5.978\frac{a}{t} + 14.663\left(\frac{a}{t}\right)^2 - 16.611\left(\frac{a}{t}\right)^3 + 9.143\left(\frac{a}{t}\right)^4 - 3.497\left(\frac{a}{t}\right)^5 + 1.944\left(\frac{a}{t}\right)^6 \tag{18}$$

4.4 *Fatigue life prediction*

Using equations (13)-(15), fatigue life of FIC welded joint with artificial corrosion pits can be predicted. In equations (13)-(15), the crack-shape factor is assumed to be 1, but it is a function of crack depth ratio in actual crack growth. In order to obtain more accurate fatigue life predictions, it makes sense to modify equations (13)-(15) based on formulas (16)-(18) and material constants of S-N curves. The modification of fatigue crack propagation rates based on the maximum circumferential stress criterion can be expressed as:

$$\frac{da}{dN} = 1.874\times10^{-13}\left(\Delta K_{\text{eff}}\right)^3, \text{ for no pit} \quad (19)$$

$$\frac{da}{dN} = 2.154\times10^{-13}\left(\Delta K_{\text{eff}}\right)^3, \text{ for pit 1} \quad (20)$$

$$\frac{da}{dN} = 2.632\times10^{-13}\left(\Delta K_{\text{eff}}\right)^3, \text{ for pit 2} \quad (21)$$

In terms of Equations (19)-(21), the fatigue crack propagation rates of welded joints with pit 1 and 2 are respectively 1.15 times and 1.40 times larger than that of the welded joint with no pit. The main reason is that the high stress field close to weld toe is affected by corrosion pits, and stress concentration factors of weld toes rise with the increase of pit depths.

Fatigue life prediction results are list in Table 3. Column (1) is the fatigue life prediction results calculated by equations (13)-(15); Column (2) is the fatigue life prediction results calculated by equations (19)-(21). Error between test result and column (1) are given in column (3) and maximum error is 30% ; Error between test result and column (2) are given in column (4), and maximum error is only 12.4%.

Obviously, fatigue prediction results from equations (19)-(21) are in good agreement with fatigue test results. Therefore, crack-shape factor obtained from the maximum circumferential stress criterion is recommended being used to predict fatigue life.

Table 3. Fatigue life prediction results

Group	Prediction×10^5		Test	Errors %	
	(1)	(2)	×10^5	(3)	(4)
P0S1	16.2	13.7	14.3	13.3	-4.2
P0S2	1.07	9.15	9.77	9.5	-6.3
P0S3	7.53	6.43	6.03	24.9	6.6
P1S1	9.82	9.98	9.55	2.8	4.5
P1S2	6.67	6.69	6.40	4.2	4.5
P1S3	4.85	4.70	5.36	-9.5	-12.3
P2S1	5.21	6.52	7.44	-30.0	-12.4
P2S2	3.38	4.37	4.15	-18.6	5.3
P2S3	2.40	3.07	2.91	-17.5	5.5

5 CONCLUSION

In this paper, combined fatigue test and fracture mechanics theory, fatigue behavior of full-penetration inclined cruciform welded-joints with artificial pit corrosion were investigated. the following conclusions can be drawn.

(1) Fatigue test results indicate that fatigue cracks initiate at the weld toes with the maximum stress.

(2)With the increasing of pit depth, constant parameter C is decreased in the relationship $\Delta\sigma^m N$=C in nominal stress approach. With the increasing of pit depth, fatigue crack propagation rate is increased in fracture mechanics approach.

(3) With the increase of crack depth ratio, the crack-shape factor falls at first and then rises.

(4)The maximum circumferential stress criterion is more suitable to predict fatigue growth behaviors of welded joints. Fatigue crack growth rates based on effective stress intensity factors are suitable for assessing fatigue life of welded joint with mixed mode cracks.

Stress-concentration effects due to weld root imperfections in orthotropic steel decks

H. De Backer, W. Nagy & A. Outtier
Ghent University, Ghent, Belgium

ABSTRACT: An orthotropic steel deck system consists of a steel plate supported by longitudinal stiffeners and transversal crossbeams. Orthotropic bridge decks are prone to fatigue cracking due to the complicated weld details and the direct action of traffic loads. Although the stiffener-to-deck plate detail is of high importance in these decks, this connection seems to be one of the most difficult welding details since it can only be welded from the outside. Therefore, the influence of the weld penetration ratio and the geometry of the weld root on the stresses in the stiffener-to-deck plate connection is investigated. In Siemens NX, detailed 3D models based on real stiffener-to-deck plate connections were modelled. These 3D models were then included in a reference model of an orthotropic bridge deck, which consists of 2D shell elements. A parametric study was executed varying the weld penetration ratio of each model and investigating the peak principal stresses. The results clearly indicated that the shape of the weld root imperfection has a high influence on the peak principal stresses. The smaller and sharper the shape of the weld root imperfection, the higher the stress concentrations. The parametric study also showed that the absolute value of the peak principal stress decreases for an increasing weld penetration ratio. This is in contradiction with most conclusions in literature. However, most studies calculated a general model, of which the translations and rotations occurring in the zone of interest were then transferred to a smaller 3D model. This is an important difference with the method used in this study, which allows redistribution of the stresses since the 3D model is included in the reference model.

1 INTRODUCTION

An orthotropic steel deck system consists of a steel plate supported by stiffeners in the longitudinal direction and by crossbeams in the transversal direction. One of the main advantages of an orthotropic steel deck bridge is its low dead weight. However, orthotropic steel deck bridges also have significant disadvantages. Fatigue cracking due to the complicated weld details and the direct action of traffic loads, which induces high stress variations, is an important problem.

In a weld, fatigue cracking can either start at the weld toe or at the weld root. While weld toe cracks are initially located in the weld toe line, weld root cracks will first penetrate through the weld material before appearing on the weld surface. Since weld root cracks can only be detected once they penetrated through the weld material and appear on the weld surface, they are often considered to be more dangerous than weld toe cracks.

In the orthotropic steel deck, the stiffener-to-deck plate detail is one of the most important welded joints. Unfortunately, this connection seems to be one of the most difficult welding details since it can only be welded from the outside. As a consequence, it is hard to control the weld quality with respect to weld penetration. Both a lack of penetration and an excessive weld penetration will cause additional stress concentrations, resulting in a reduced weld quality. Therefore, the influence of the weld penetration ratio and the geometry of the weld root on the stresses in the stiffener-to-deck plate connection is investigated.

2 EXPERIMENTAL EVALUATION OF REAL WELD GEOMETRIES

Several real welded stiffener-to-deck plate details were available (Figure 1), from these details test specimens were cut at well-chosen locations.

Three test specimens were cut from each welded stiffener-to-deck plate detail. Since these details were first tack welded before being completely welded using a fully automatic welding procedure, one of the three specimens of each detail was cut out in the area of the tack weld. In total 15 test specimens, from 5 different welded stiffener-to-deck plate details, are investigated. To study the weld irregular-

ities at the weld root, the test specimens were first grinded until a smooth surface was obtained, after which they were photographed using a microscopic camera. The pictures of each test specimen were then scaled to their real dimensions. The weld root imperfection of one of the test specimens is illustrated in Figure 2.

Figure 1. Real welded stiffener-to-deck plate detail

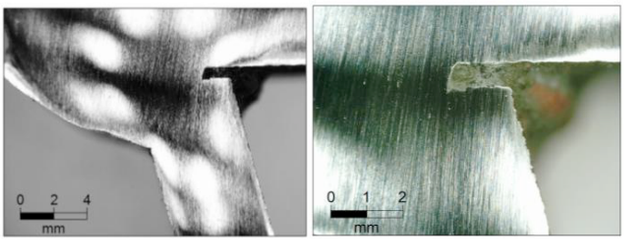

Figure 2. Scaled picture of the weld root of one of the models

The observations for the specimens containing a tack weld and those without a tack weld were compared. However, no clear relation seems to be present between the geometry of the weld root or the weld penetration ratio and the presence of a tack weld. An important observation that was made based on these pictures is the fact that only 7 out of the 15 test specimens has a weld penetration ratio that is higher than 66.7%, which is suggested by the Eurocode for a stiffener with a thickness of 6 mm. The requirements given by the Japan Road Association and the AASHTO LRFD Bridge Design Specifications, which are respectively a weld penetration ratio of 75% and 80%, are not even met by one of the test specimens.

3 FINITE ELEMENT MODELLING

The finite element software package Siemens NX 11 was used to model an orthotropic steel deck and a detailed model containing the real weld geometries.

3.1 *Reference model*

The reference model uses 2D shell elements to model part of an orthotropic bridge deck. It consists of two main beams, two transversal crossbeams, five longitudinal closed stiffeners and a deck plate. The deck plate and longitudinal stiffeners were assigned a shell thickness of 15 mm and 6 mm respectively. The structure was meshed using quadrilateral shell elements with an element size of 20 mm, which is sufficiently small for this global analysis model.

The entire deck has a steel grade S355 with a yield stress of 355 MPa and a mass density of 8750 kg/m³. With respect to the elastic material properties, a young's modulus of 210 GPa and a Poisson's ratio of 0.3 were assigned.

The boundary conditions were applied at the edges of the bottom flanges of the main beams. Four different bearings were used, which all allow rotation and prevent displacement in the vertical direction, but with respect to the displacements in the horizontal directions they are different. A schematic overview of the enabled horizontal displacements for each support, is given in Figure 3.

Figure 3. Boundary conditions of the bridge deck

Only one load case is used to determine the stresses in the weld root of the stiffener-to-deck plate detail. The detailed 3D model will be implemented at the connection of the second longitudinal stiffener from the right at mid-span, as depicted in Figure 4. Since the stresses will be determined in this detailed 3D model of the connection, a wheel load of 35 kN is applied in between the second and third stiffener from the right at mid span. In this way, tensile stresses will be generated in the stiffener near the weld root, which is devastating for fatigue. In addition, there will be no risk of any contact pressure due to the unwelded free surfaces of the deck plate and the stiffener. In such case, additional boundary conditions should be implemented on the finite element model to restrict faces from going through each other, which is physically not possible.

The surface area of this wheel load was determined according to wheel type A suggested in Eurocode EN 1991-2, being a rectangular area of 220 mm by 320 mm.

3.2 *3D model containing real weld geometries*

Based on the scaled microscopic pictures of the welded specimens, an AutoCAD model was drawn of the cross section of the 3D model. This AutoCAD drawing was then imported into the Siemens NX software, after which it was extruded over a length of 50 mm. It was then inserted into the 2D reference model of the orthotropic bridge deck on the left side of the second longitudinal stiffener from the right, at mid span. This is illustrated in Figure 4.

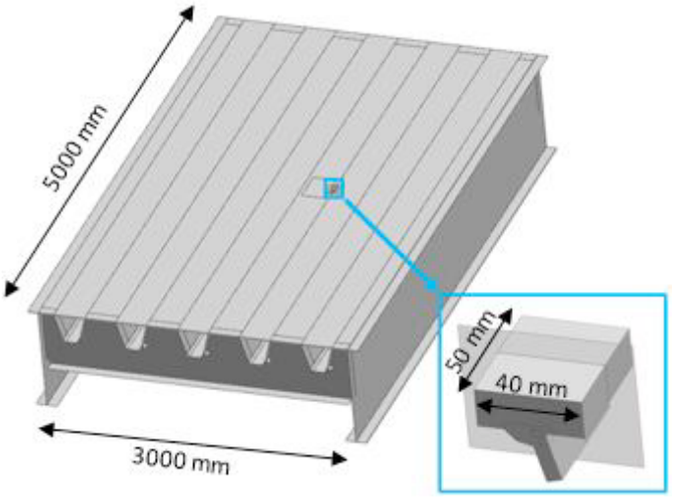

Figure 4. Boundary conditions of the bridge deck

The outside surfaces of the 3D model need to be connected to the matching edges of the 2D reference model, this was achieved by applying an edge-to-surface gluing constraint in Siemens NX.

The mesh of the 3D part was refined near the weld root imperfection. Stresses are eventually determined at the centre of the 3D part, in the plane that is indicated in Figure 4. The stresses at the outside edges of the 3D element are not considered since local stresses due to the transition from the 2D shell elements to the 3D elements arise at those locations. Therefore, the mesh size did not need to be very fine around those edges. It was only refined towards the weld root imperfection in the plane indicated in Figure 4.

Tetrahedral 3D elements were used to mesh the detailed model. Since namely the stresses around the weld root imperfection are of importance, the elements around this imperfection have 10 nodes (CTETRA 10). In the rest of the 3D model, tetrahedral elements with 4 nodes (CTETRA 4) are sufficient.

Eight of these models were modelled, four models based on the pictures of the test specimens (Model 1 to 4 in Table 1), one model with an 'ideal' rounded weld root, one model according to the effective notch stress method, one model with a 100% penetration ratio and one model with an excessive weld penetration. An overview of the weld root imperfections of these models is given in Table 1. The model according to the effective notch stress method is introduced because in literature, the influence of the weld penetration ratio is often determined based on this method. The effective notch stress method is discussed in the guidelines of the IIW, it includes replacing the actual weld root imperfection by an effective contour with a radius of 1 mm. The tip of that radius should coincide with the root of the real notch. The effective notch stress is then calculated based on the worst principal stress.

Table 1. Overview of the weld root imperfections of the 8 models that will be investigated.

	Cross-section of the model
Model 1	
Model 2	
Model 3	
Model 4	
Model with an 'ideal' rounded weld root	
Model according to the effective notch stress method	
Model with a 100% penetration ratio	
Model with an excessive weld penetration ratio	

Since some of the weld root imperfections of the models include relatively sharp angles, stress singularities can occur. At these stress singularity points the stress will not converge and it will in theory become infinite. In reality, the stress will have a finite value and therefore it is important to check if the

models contain such singularities or not. A convergence study was executed for all 3D models to ensure that no such stress singularity points occur. This is done by refining the mesh and making sure that the stresses around the weld root imperfection converge. The stresses in the models that are illustrated in Table 1, all converged and thus no singularities should be feared.

4 PARAMETRIC VARIATIONS

The influence of the weld root imperfection on the stress concentrations is investigated. A parametric study is done varying the weld penetration ratio of the models from Table 1. As already mentioned, the influence of the weld penetration ratio is often studied in literature based on the effective notch stress method. To make comparison with those studies possible, it was chosen to include a model in which the weld root is replaced by an effective notch.

The weld penetration ratio was varied from 52% to 90%. The reason for starting at 52% and not at 50%, is purely to avoid problems in the finite element model. If the weld root imperfection has a weld penetration ratio of 50%, the edge of the imperfection would coincide with the center line of the stiffener. This causes problems when connecting the tetrahedral elements to the 2D shell elements. Therefore, the lowest weld penetration ratio is 52%, after which it is increased to 60%, 70%, 80% and finally 90%. For each of the models, five different weld penetration ratios are thus studied. An example of the change in geometry for model 1 is illustrated by Figure 5.

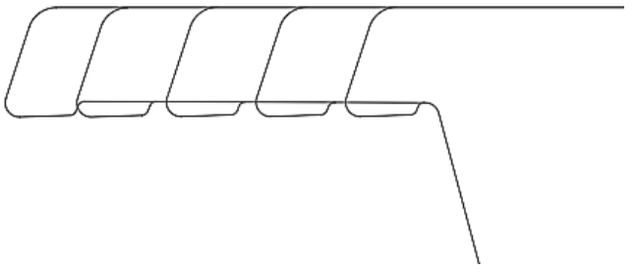

Figure 5. Varying weld penetration ratio for model 1

Once the finite element model has been calculated, it is important to select the most suitable stress output for evaluating the results. Although Von Mises stresses include the influence of shear stresses, it is chosen not to use these stresses since they do not distinguish compression and tensile stresses. Hence, principal stresses will be used

4.1 *Results*

The results provided by the Siemens NX software for a varying weld penetration ratio in case of model 1, are illustrated in Figure 6. A dark blue zone with high compression stresses is present at the upper left corner of the weld root imperfection. At the lower left edge of the imperfection a red zone with high tensile stresses is present. This is a consequence of the loading that was applied to the reference model, which causes tension near the weld root in the web of the longitudinal stiffener. The red tensile zone becomes smaller for an increasing weld penetration ratio, meaning that the principal stress is reduced for an increase of the weld penetration ratio. The location of this high compression and tension zone does not change relatively to the edge of the weld root imperfection.

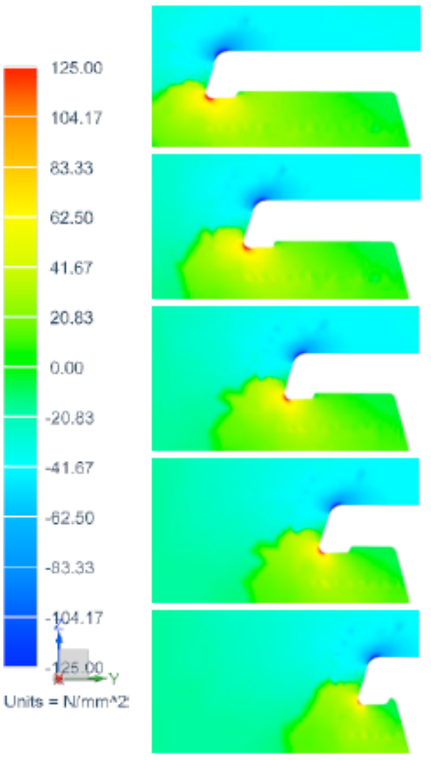

Figure 6. Evolution of the worst principal stresses in model 1 for a varying weld penetration ratio

Although Figure 6 clearly shows the location of the highest compressive and tensile stresses, it is difficult to compare the values of the peak stresses based on the color scale. Therefore, Figure 7 and Figure 8 show respectively the peak compressive and tensile principal stresses for each model in function of a varying weld penetration ratio.

The first observation that can be made is the fact that the shape of the weld root imperfection has a significant influence on the peak principal stresses. The smaller and sharper the shape of the weld root imperfection, the higher the stress concentrations. For both the compressive (Figure 7) and tensile (Figure 8) stresses, model 4 resulted in the highest values because of the small dimensions of its weld root imperfection. While for the compressive stresses model 3 showed the second highest values, the re-

sults for the tensile stresses indicated that model 2 has the second highest peak principal stress. This is due to the fact that model 3 has sharper edges at the upper side, at which the compressive stress peak is located, while model 2 shows a sharper geometry at the lower side, which is under tension.

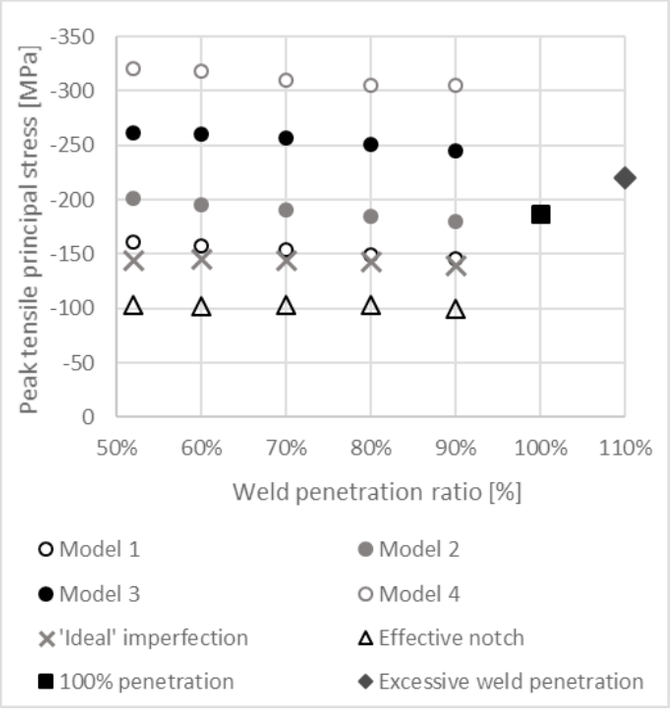

Figure 7. Overview of the peak compressive principal stresses in function of the weld penetration ratio

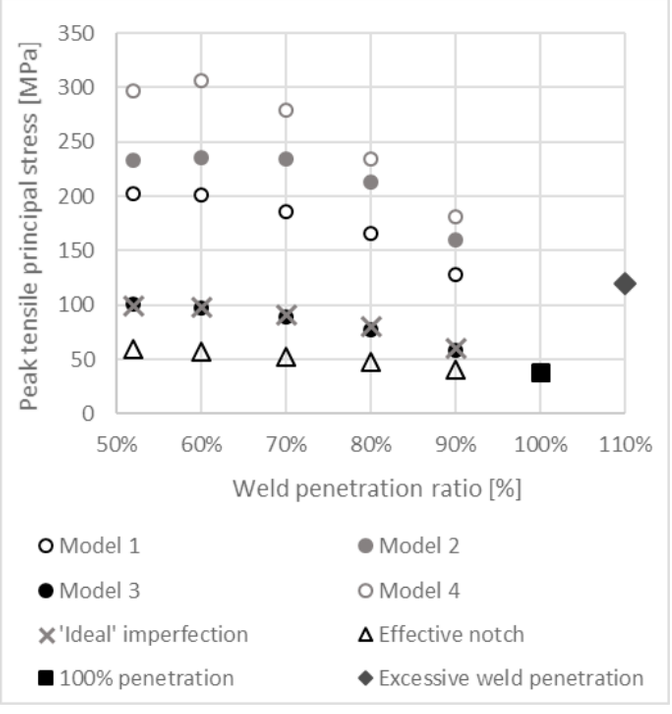

Figure 8. Overview of the peak tensile principal stresses in function of the weld penetration ratio

Based on the evolution of the values of the peak stresses, it can also be concluded that the absolute value of the principal stress decreases for an increasing value of the weld penetration ratio. The results of the models with a lack of penetration can also be compared to those of the models with a 100% penetration ratio and with an excessive weld penetration. In comparison with the other models, the model with a 100% weld penetration ratio does not show a high tensile stress peak. Since tensile stresses are the most devastating for fatigue, this would mean that for the load case that was tested in this study a 100% weld penetration ratio is beneficial for the fatigue resistance. However, obtaining a weld penetration ratio of 100% without having regular weld melt-through, is very difficult in practice, if not impossible. Therefore, the results of the model with an excessive weld penetration ratio are interesting. This model did show high stress peaks, but it is depending on the shape of the weld root imperfection if these stress peaks are higher or lower than those in the models with a lack of penetration.

For the load case that is tested in this case, the tensile stresses are more influenced by the weld penetration ratio than the compressive stresses. Since the tensile stresses are the most devastating for fatigue, the weld penetration ratio will thus significantly influence the fatigue resistance. This could be because the tensile stresses are located in the stiffener, of which the cross-section is smaller and more influenced by the weld penetration ratio compared to the deck plate, which is subjected to compressive stresses.

4.2 *Comparison with literature*

The results from the previous paragraph were first compared to the guidance rules with respect to the weld penetration ratio. The Eurocode suggests a maximum lack of penetration of 2 mm, which corresponds to a weld penetration ratio of 66.7% for a rib thickness of 6 mm. The Japan Road Association requires a weld penetration of 75% while the AASHTO LRFD Bridge Design Specifications suggests a weld penetration ratio of 80%. The 80% penetration limit seems to be a practical limit, since it is approximately the maximum penetration that could be achieved without regular weld melt-through.

The 70% to 80% weld penetration ratio that is suggested in several codes, does not result in the lowest principal stresses according to the results. An even higher weld penetration ratio of 90%, results for all models in a lower principal stress and thus a higher fatigue resistance. As already mentioned, the 80% limit is probably more a practical limit, since higher weld penetration ratios would result in regular weld melt-through.

Although the results in the previous paragraph clearly indicated that an increase in weld penetration ratio results in lower principal stresses, conclusions in literature do not confirm this. The studies of Sim, H.B. & Uang, C.M. 2012, Vu Dung, Sasaki, E., Tajima, K. & Suzuki, T. 2014 and De Backer, H. 2006

all conclude that an increasing in weld penetration ratio results in increasing stresses.

Sim, H.B. & Uang, C.M. 2012, Vu Dung, Sasaki, E., Tajima, K. & Suzuki, T. 2014 evaluated the influence of the weld penetration based on the Von Mises stresses in an effective notch model. The fact that the results in the previous paragraph were based on principal stresses does not justify the different conclusions, since the Von Mises stresses in these models also decrease for an increasing weld penetration ratio. The effective notch radius that is applied in the studies of Sim, H.B. & Uang, C.M. 2012 and Vu Dung, Sasaki, E., Tajima, K. & Suzuki, T. 2014 is 0.5 mm while the radius applied in the model of this study is 1 mm, according to the recommendations of the IIW. This will probably not justify the different conclusions either since all models in this study, independently of their size or shape, show the same relation: an increase in weld penetration ratio results in a lower principal stress.

A possible explanation for the contradiction could be the fact that none of these studies included the sub model in the global model. The nodal displacements of the global model were applied as boundary conditions on the sub model, not allowing a redistribution of the stresses. This is an important difference with the method used in this study, which includes a smaller 3D model into a large reference model and therefore does allow redistribution of the stresses. There is also the possibility that because of different loading cases, these studies included contact pressures between the unwelded free surfaces of the deck plate and the stiffener, which was not the case in this study.

5 FATIGUE BEHAVIOUR OF THE MEASURED WELD GEOMETRIES

5.1 *Stress concentration factors (SCF)*

The resistance to fatigue can be determined based on several methods that are suggested in literature. The nominal stress method evaluates the fatigue life based on the nominal stress range, local stress raising effects are thus not included. The hot-spot stress is determined by applying an extrapolation procedure using stresses in the vicinity of the weld. This method includes the stress-raising effects of the structural detail but excludes the stress concentration due to the local weld profile. Since these two methods eliminate the influence of the local weld profile, they are unsuitable for the purpose of this study. Finally, the effective notch stress method takes into account both the local stresses caused by the geometry of the structure and the stresses caused by the weld profile. This method consists of replacing the actual weld contour by an effective notch with a radius of 1 mm. Since most of the weld root imperfections that were modelled have dimensions smaller than 1 mm, this would again eliminate the influence of the shape of the weld root imperfection. Therefore, also the effective notch stress method is not suitable in this case.

Since these methods are unsuitable for comparing the fatigue behavior of the measured weld geometries, the comparison was done using a stress concentration factor. This factor is the ratio of the maximum stress in the weld root and the nominal stress. If the stress concentration factor of a structure is known, it should only be multiplied with the nominal stress in the detail to obtain the maximum stress occurring.

$$SCF = \frac{\sigma_{max}}{\sigma_{nom}} \tag{1}$$

For calculating the stress concentration factors of the models, the maximum stresses given in Figure 7 and Figure 8 are used. The nominal stress in the detail is determined based on the nominal stress in the reference model, which is equal to 30.6 MPa in the web of the stiffener near the weld root. Since the results are obtained by dividing all peak compressive or tensile stresses by the same factor, being the nominal stress, the conclusions regarding the influence of the weld root imperfection will be identical to those given in the previous sections.

Figure 9 compares the stress concentration factors of the different models to the stress concentration factor of the model with a 100% weld penetration ratio. This relative stress concentration factor ς is thus calculated according to equation (2), in which SCFx is the stress concentration factor for the model and weld penetration ratio under consideration and SCF100% is the stress concentration factor of the model with a 100% weld penetration ratio. The Eurocode suggests the fatigue life should be determined based on the bending moments and stresses in the stiffener. For this reason and since tensile stresses are the most devastating for fatigue, it is chosen to determine this relative stress concentration factor based on the tensile stresses in the models (Figure 8).

$$\varsigma = \frac{SCF_x}{SCF_{100\%}} = \frac{\sigma_{max,x}}{\sigma_{max,100\%}} \tag{1}$$

The assumption is made that the peak stress obtained from the model with a 100% weld penetration ratio is comparable to the nominal stress in the detail, meaning that this peak stress represents the stress in a stiffener-to-deck plate detail including the stress raising effects of the geometry and the weld. The latter is not included in the nominal stress. By determining the factors from Figure 9, the results of two 3D models are compared. This seems more accurate than comparing the results of the 3D models with the nominal stress of the reference model,

which consists out of shell elements. Since the stresses in the models can be up to 8 times higher than those in the model with a 100% weld penetration ratio, it would be safe to multiply the nominal stress in the reference model with this same factor. By increasing the nominal stress, which can then be used to determine the fatigue life of the detail, the weld root imperfections that can occur in the stiffener-to-deck plate connection could safely be taken into account.

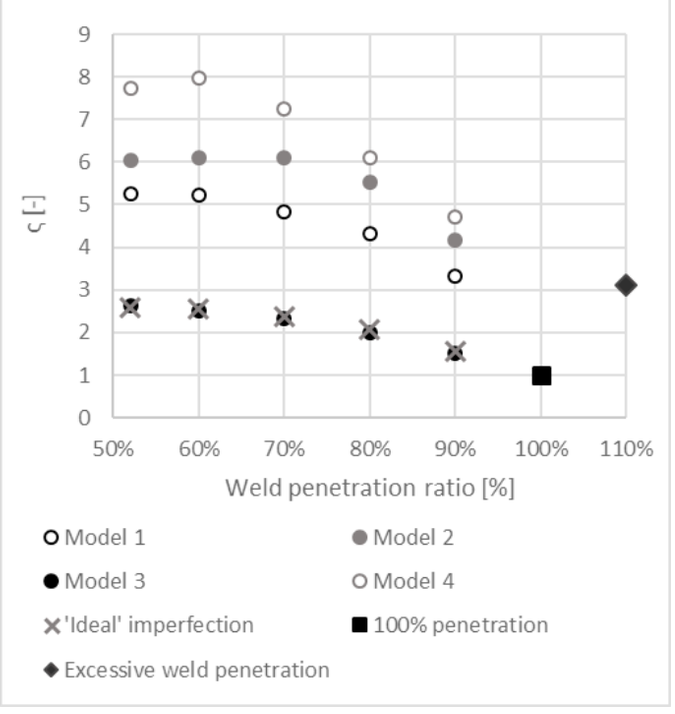

Figure 9. Relative stress concentration factor ς for a varying weld penetration ratio

5.2 *Estimated fatigue life*

As already explained, the guidance rules given by the Eurocode for calculating the fatigue resistance are not directly applicable in this case. In order to determine an estimation of the fatigue life, the guidance rules will thus need to be adapted. The nominal stress method suggests to determine the fatigue resistance based on the nominal stress in the stiffener and a fatigue curve, which has a fatigue class of 71 MPa for the stiffener-to-deck plate connection. It is proposed to multiply the nominal stress in the detail with the factors from Figure 9, which is the ratio of the stress concentration factor of the model under consideration and the stress concentration factor of the model with a 100% weld penetration ratio. Using this adapted nominal stress and the S-N curve with a fatigue class of 71 MPa, an estimation could then be made of the fatigue resistance of each model.

It is important to stress that determining the fatigue resistance in this way is not according to the recommendations of the Eurocode nor the IIW.

6 CONCLUSIONS

Each model showed a peak tensile stress at the lower side of the imperfection and a peak compressive stress at the upper side. The results clearly indicated that the shape of the weld root imperfection has a high influence on the peak principal stresses. The smaller and sharper the shape of the weld root imperfection, the higher the stress concentrations.

According to the results from the parametric study, the absolute value of the principal stress decreases for a decreasing lack of penetration. This is in contradiction with the conclusions in the studies of Sim, H.B. & Uang, C.M. 2012, Vu Dung, Sasaki, E., Tajima, K. & Suzuki, T. 2014 and De Backer, H. 2006. However, these studies all calculated a general model, of which the translations and rotations occurring in the zone of interest were then transferred to a smaller 3D model. This is an important difference with the method used in this study, which allows redistribution of the stresses since the 3D model is included in the reference model.

The results of the models with a lack of penetration were also compared to those of the models with a 100% penetration and with an excessive weld penetration. In comparison with the other models, the model with a 100% weld penetration did not show a high tensile stress peak. The model with an excessive weld penetration ratio did show high stress peaks, but it is depending on the shape of the weld root imperfection if these stress peaks are higher or lower than those in the models with a lack of penetration.

For the load case that was tested, the tensile stresses were more influenced by the weld penetration ratio than the compressive stresses. Since the tensile stresses are the most devastating for fatigue, the weld penetration ratio will thus significantly influence the fatigue resistance.

Finally, the guidance rules given by the Eurocode for calculating the fatigue resistance are not directly applicable. It is proposed to determine the fatigue resistance using the S-N curves with an adapted nominal stress, being the nominal stress multiplied with the ratio of the peak tensile stress in the model under consideration and the peak tensile stress in the model with a 100% weld penetration ratio.

AS5100.2: 2017 changes to traffic-barrier loadings – a Victorian perspective

B.E.Gibbens
Principal- Bridges
BG&E, Melbourne, Australia

ABSTRACT: The Australian Bridge Design Code AS5100 was revised in April 2017, resulting in substantial changes to the design requirements for bridge traffic barriers. This paper proposes improved analysis approaches to achieve greater barrier capacity and improved barrier constructability, and cautions where some design and detailing approaches may inadvertently lead to unsafe traffic barriers.
This paper postulates the likelihood that Australian road authorities have – since the turn of this century – over-spent many-tens-of-million dollars constructing unnecessarily-strong traffic barriers. The author argues the industry should move away from its reliance on engineering calculations for traffic barriers – and towards the physical load-testing of standardized bridge barrier systems. It is suggested that this alternative approach may reduce the demands on the structural configurations of traffic barriers and their supporting elements, and perhaps save road authorities significant monies over the long-term.

1 INTRODUCTION

1.1 *Code changes*

The Australian Bridge Design Code AS5100 was revised in April 2017, resulting in substantial changes to the design requirements for bridge traffic barriers. Both the magnitudes and 'effective-heights' of all Performance Levels were increased.

Table 1. Changes in traffic-barrier characteristics.

Performance Level	AS5100: 2004		AS5100: 2017	
	kN	He (mm)	kN	He (mm)
Low	125	500	150	600
Regular	250	800	300	900
Medium	500	1100	600	1200
High	1000	1400	1200	1500

* Effective-height (He) above top of trafficable surface

Vicroads is the road authority of the Australian state Victoria. In the period 1997 to the issue of AS5100:2004 – traffic barriers on Victorian projects including Melbourne's CityLink toll-road (circa 1998) – were designed to the requirements of Vicroads' Bridge Technical Note No. 971001 *Design Requirements for Bridge Traffic Barriers* which included the same requirements for barrier designs as the later AS5100:2004.
Notwithstanding twenty years' of unvarying design requirements – the author believes that designers continue to grapple with the identification of efficiently-proportioned traffic-barrier systems. The author anticipates the increased design requirements of AS5100:2017 will present a 'step-change' in the difficulty of designing and constructing bridge traffic barriers – both on- and off-structure. This paper critiques analysis and detailing approaches which benefit safe and efficient traffic barrier designs.

This paper also postulates the likelihood that Australian road authorities have – since the turn of this century – over-spent many-tens-of-million dollars constructing unnecessarily-strong traffic barriers. The author believes this is likely to be the case particularly for the buried-footings of off-structure barriers – when designers rely on engineering calculations rather than on physically-crash-tested barriers – for which none may exist for most of the Performance Levels outlined in either AS5100:2004 or AS5100:2017. With the recent and substantial changes to codified traffic-barrier loadings – this paradigm is likely to become worsened, increasing the probable over-spend on projects.

1.2 *Scope*

In the remainder of this paper – traffic barriers are discussed in the context of a 'steel post-and-rail' system which is mounted on the top of a concrete barrier in order to achieve the full containment 'effective-height'. The reader may extend these discussions to barrier systems which are either wholly concrete, or are wholly 'steel-post-and-rail'.

2 VICTORIAN INDUSTRY-APPROACHES

Within Victoria (traffic-barrier-upgrade projects notwithstanding) – it is broadly-possible to date a bridge structure by the nature of the traffic barrier which is mounted on it. For the bridges constructed in the late 1970s and 1980s by the MMBW and RCA (precursor authorities to Vicroads) – the traffic barriers are substantially similar to the barriers shown in Figure 1.

Figure 1. Bridge barriers similar to those of the 1970s and 1980s (barriers in this photograph were constructed in 2009 as facsimiles of those existing elsewhere on the same structure)

Due to increasingly-onerous traffic-barrier design-requirements; the advent of the design-and-construction (D&C) approach to procurement; numerous privately-funded toll-roads; and the increasing architectural contribution towards urban design – traffic-barriers are increasingly varied in their appearance and configuration. Common Victorian traffic barriers since 2000 are illustrated below in Figure 2.

Figure 2. Traffic barrier circa 2013 (left) and 2014 (right).

2.1 *On-structure barriers*

Since circa 2000 – Victorian traffic-barrier types have included longitudinally-continuous concrete barriers which utilized full-thickness in-situ stitches to join together precast units (e.g. the 1000 mm-long stitches on the Rob Sergi Bridge, Geelong). Also longitudinally-continuous is the concrete barrier at Burnley Viaduct (Monash Freeway) where precast panels provided backing formwork for a full-height carriageway-side facing of in-situ concrete.

Much more common has been the approach to utilise precast barrier units (nominally) 3000 mm or 6000 mm long, for all of Regular-, Medium-, and High-Performance levels. When the precast barrier-units support a steel post-and-rail system – with posts at 3000 mm centres – the structural advantage of the 3000 mm-long barrier system is improved, whereas the advantage of the 6000 mm-long barrier system is lost (i.e. is no better than that of 3000 mm-long units).

Some experimentation with post-spacing of 1500 mm or smaller centres has been undertaken for High-Performance barriers, however the author does not support this approach: the close spacing of posts increases the vertical strength of the barrier system at the cost of the system's horizontal strength – a load-path which is opposite to an efficient design.

There have been attempts at providing dowelling between the precast panels: for example steel dowels were used on the Eastlink toll-road, and grout-dowels on Craigieburn Bypass. In the author's opinion the latter approach is almost useless, and the construction effort for the former approach is disproportionate to the greater efficiencies that can be achieved by concentrating the design effort elsewhere.

In all cases – traffic barriers are set out vertical. This contrasts to the (sometimes) overseas approach whereby cast-in-place barriers are set out normal to the transverse grade of the deckslab.

Precast traffic barrier units are stitched to the deckslab via a continuous 'kerb stitch' as shown in Figure 3. This stitch is subject to reflected-cracking at the joints between the precast panels, and a vertical crack-initiator is formed into the green concrete.

Figure 3. Longitudinal kerb-stitch (steel levelling bracket for precast barrier unit also shown).

2.2 *Off-structure barriers*

Off-structure barriers include those in freeway medians, and on the approach and departure sides to the bridge. Off-structure barriers are increasingly being used to protect street furniture including gantry legs.

2.2.1 *Fill-embankments*

The barriers on bridge approaches are usually Regular-, and Medium-Performance level. When wholly

above the level of rock, the prevailing approach is to utilize 6000 mm-long precast units supported by piles. The lateral load-resisting capacity of a pile is significantly reduced when adjacent to a cut-slope. When the barrier is located close to a vertical edge, the piles are then either offset from the edge via buried tie-beams, or a large L-shaped cast-in-place footing is used. For the latter – a large shear key and granular sub-base is almost invariably required to resist sliding.

2.2.2 *Reinforced-soil walls*

L-shaped footings are commonly used atop reinforced-soil walls when the barrier is located close to the edge of the wall. For narrow-width embankments – the L-shaped footings may be tied together by reinforcing bars or by joining the concrete footings.

2.3 *Vicroads' requirements*

Vicroads' requirements for the design and detailing of traffic barriers are outlined in Bridge Technical Notes, and in the Standard Specification for Roadworks and Bridgeworks.

While not current at the time of writing this paper, the author supports the following detailing requirements which were stipulated by Section 671DC at the time of Victoria's Eastlink Project in 2005.

Contraction joints in the cast-in-place sections of concrete barriers (i.e. kerb stitch-pours) *shall coincide with the joints between precast sections of barriers. Reinforcement in the cast-in-place sections shall terminate and have the specified cover each side of contraction joints* (i.e. v-notch crack-initiators).

Where the deck slab is de-bonded from the top flange of beams to provide continuity at pier locations, the cast-in-place section of barrier shall also be de-bonded from the deck slab.

In other words – the flexibility of linking slabs should not be reduced by building traffic barriers into them.

2.3.1 *Welded railing*

Vicroads requires horizontal steel railings to be welded to their supporting posts. This approach results in a more robust and durable connection than for the archaic method whereby the railings were bolted to the posts via steel angle-sections.

3 ARCHITECTURAL CONFLICTS WITH TECHNICAL REQUIREMENTS

With the advent of D&C influenced by urban design, traffic barriers have been seen as a ready opportunity for architectural embellishment. Common urban-design outcomes include: the outside-face-patterning of precast panels, and the use of (sometimes) inefficiently-shaped steel railings and posts. This paper argues that urban design inputs towards what is a critical safety element should be moderated strongly by the engineer early in the design process. The reasons for this and the possible adverse implications versus best-practice engineering approaches are outlined in this chapter.

3.1 *Industry-norms regarding barrier setting-out*

3.1.1 *Panel lengths*

Although degraded in the current D&C era – the author contends that the following detailing approaches have been in evidence since at least the early 1970s.

A gap between the precast barrier units is located at pier centrelines when the spans are 'simple'.

Unless barriers are proven to be substantially isolated from the flexural behavior of the supporting beams due to shear-lag – longitudinally-continuous concrete barriers should not be continuous over piers – even if the spans are also continuous (e.g. the Rob Sergi Bridge, Geelong demonstrates full-thickness vertical flexural-cracks in the barriers over the piers). Hence a barrier joint should occur over piers.

An integer number of barrier units is provided in each bridge span. Each barrier unit is nominally 3000 mm long (or 6000 mm). The spacing of posts in both cases is also nominally 3000 mm. It is interesting to note this approach yields barrier lengths 3000 mm (+/- 5%) in the span-range 30 m to 200 m, with the variation increasing to (+/-10%) in the range 20 m to 30 m. The lengths of barriers in opposing spans may be different, however this difference should not be noticeable to the observer (compared to the disparate barriers in Figure 4), or consequential to the design.

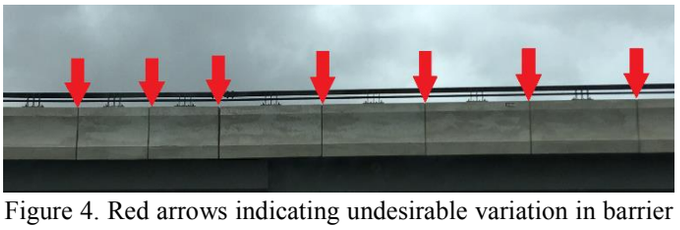

Figure 4. Red arrows indicating undesirable variation in barrier lengths.

3.1.2 *De-bonded deckslabs*

As argued earlier – traffic barriers should not be built into the linking slabs over the piers. Locating a barrier joint on the pier centerline divides the loss of deckslab connection between two barrier units. Interestingly – this approach is not evident in Figure 1.

3.1.3 *De-bonded structural footpaths*

For High-Performance barriers, especially – it is common for footpaths to be solid concrete, and for the traffic barriers to be built into both the footpath and the deckslab. In such cases – the imperative that linking slabs must flex without distress remains. This is achieved by de-bonding both the barrier and the footpath (or road median) from the linking slab, as shown in Figures 5 and 6, below.

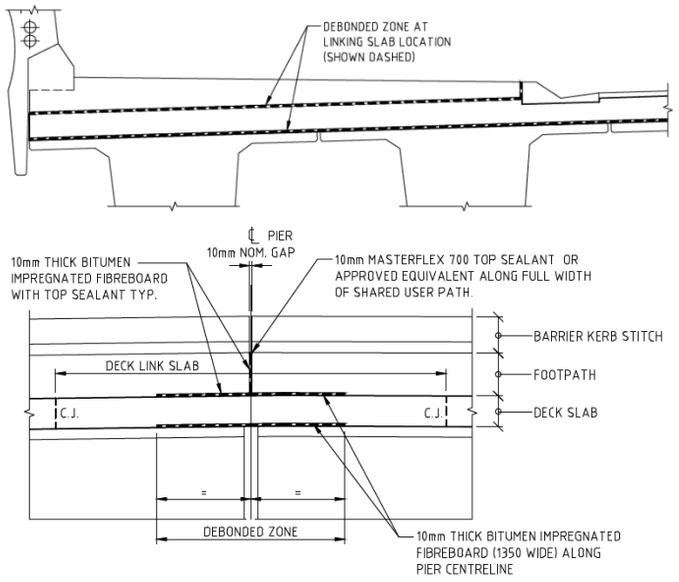

Figure 5. De-bonding of both footpath and linking slab.

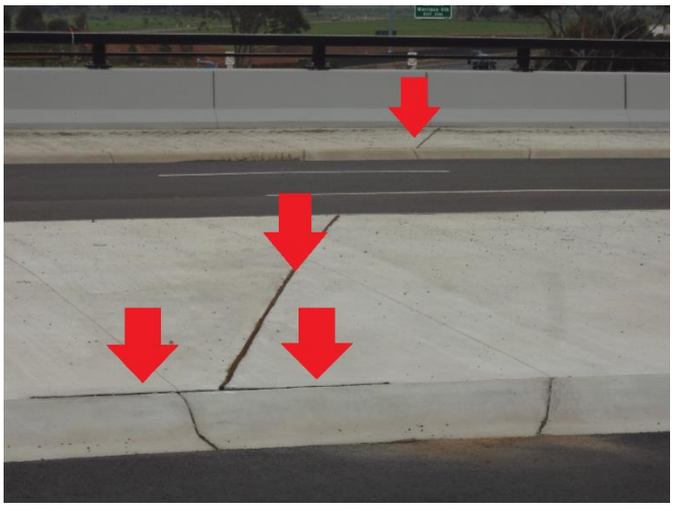

Figure 6. Locations of vertical jointing material at linking slab.

3.2 *Setting-out conflicts*

Industry norms towards the beneficial setting-out of traffic barriers were outlined in the forgoing text. The section below illustrates where urban-design inputs can run counter to these norms.

3.2.1 *Architectural patterning*

The selection and arrangement of barrier-unit lengths was outlined above. This arrangement is not affected by the decades-old Vicroads approach to utilize a pattern on the outside face of barriers which varies vertically, and not horizontally (Figure 7). When urban design mandates a patterned outside-face which varies horizontally – then many of the best-practice setting-out approaches illustrated above may be violated (Figures 8 and 9). In the case of Peninsula Link (Figure 9) – most bridges were two-span overpasses. The architectural pattern began on the centerline of the single pier – and extended outwards to opposite abutments on lengths of precast barrier units which matched the repeating pattern geometry. At expansion joints – the pattern merely 'ran out' of barrier. For bridges of greater number of spans than two – the barrier joints did not occur at pier centerlines – except in the unlikely cases where the span was exactly divisible by the length of the repeating pattern.

Figure 7. Pattern on barrier outside-face which varies vertically (Monash Freeway, Melbourne).

Figure 8. Pattern on barrier outside-face which varies horizontally (Charles Grimes Bridge, Melbourne)

Figure 9. Pattern on barrier outside-face with varies horizontally (Peninsula Link, Melbourne).

3.2.2 *Rail and post geometries*

Architectural input can also extend to the definition of the steel post-and-rail elements. For the reasons outlined later in this paper – the urban design input should be strongly moderated by the engineer, and ideally should be avoided.

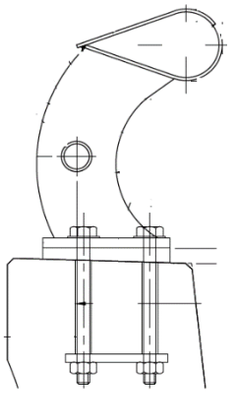

Figure 10. Architecturally-derived post and rail system (Geelong Bypass (2009), Princes Freeway interchange with Anglesea Road (2013), Baanip Boulevard (2015): all Victoria).

4 EFFICIENT TRAFFIC-BARRIER DESIGN

4.1 *Longitudinal and vertical strengths*

The most efficient way to design a traffic barrier is to mobilise the greatest length of foundations possible, while minimizing the nature of the foundations. This is achieved by maximizing the horizontal strength of the barrier system, and minimizing its vertical strength. As will be outlined later – it is possible for a barrier to be too strong in the vertical direction. To achieve a beneficial loadpath – a ductile system is usually required.

The vertical steel in the concrete component of the traffic barrier should be limited in recognition of the flow-on effect to the proportioning to the bridge deck-slab or off-structure-barrier footings. For full-height continuous-concrete barriers – the content of horizontal barrier reinforcement is usually great – in order to distribute the loading over as long a length of barrier as possible. When part-height concrete barriers support a steel post-and-rail – whether the concrete component is continuous is much less important – as most of the longitudinal distribution of load occurs at the level of the steel railing.

4.2 *Steel grades*

In order to maximize the longitudinal distribution of loading – high-yielding (e.g. 450 MPa) steel should be used for railing. Often it is preferable to use lower-yielding steel for the posts (e.g. 350 MPa). It is noted that locally-sourced circular rail-sections do not have a yield strength greater than 350 MPa.

4.3 *Barrier 'fusing'*

It is obvious that an efficiently-designed traffic barrier is not only a 'safety device' from the point-of-view of the road user – it must also act to protect the bridge from excessive damage. It may be unacceptable for particular elements in the load-path to be proportioned with greater strength than assumed for the distribution of load; greater strength is not always beneficial. For example – in order to maximise the longitudinal distribution of load – it is normally required that steel posts act (in the vertical sense) as load-limiting 'fuses'. If posts are stronger than necessary, or are spaced too closely together, then the vertical distribution of load may be amplified – possibly overloading a link in this unintended loadpath.

4.4 *Capacity-protection*

In exactly the same sense as is now required in AS5100.2:2017 for earthquake design – the capacity-protection of certain elements in the traffic-barrier load-path is mandated by AS5100. In particular the traffic-barrier-supporting element (e.g. deckslab) must be at least ten-percent stronger than the vertical strength of the barrier at the joint – in order than substantial in-elasticity or damage is restricted to occur within the (accessible) height of the barrier (Figure 11). This constitutes the capacity-protection of the supporting element by designing it to be stronger than the yield-capacity of the barrier (and accounting for the post-yield increase in reinforcement or steel stresses).

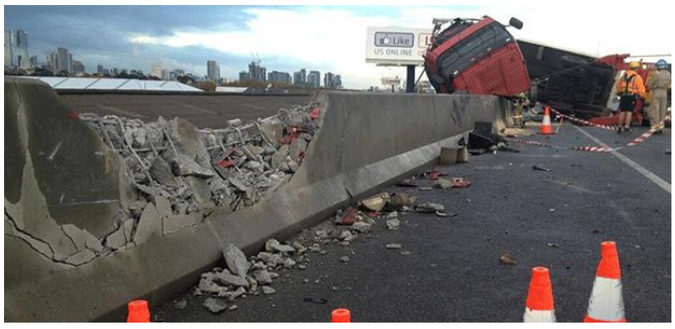

Figure 11. Incident on Bolte Bridge, Melbourne in 2013 (Grzebieta 2013).

5 ANALYSIS TECHNIQUES

5.1 *Yield-line*

The yield-line techniques of AASHTO (2007) and AS3845:2015 are implemented easily in the designs of both steel and concrete traffic-barriers. These codified approaches can be reproduced from first-principles by hand, and by non-linear computer analysis.

5.2 *Non-linear computer analysis*

Although the yield-line approach is an upper-bound solution – the lowest-energy solution may be improved upon if additional load-paths are introduced. For example – the addition of tension and torsion load-paths through the steel railing may be beneficial. Equally – and perhaps paradoxically – the omission of the torsional load-path under the yield-line approach may result in an unsafe design – for the reasons outlined in the next chapter.

6 POSSIBLE UNSAFE DESIGNS

6.1 *Buckling*

An efficient traffic-barrier design requires the barrier components to deform in a ductile manner. It follows that steel posts and railings must be 'compact', in order than buckling does not occur.

6.1.1 *Yield-line across barrier base*

The yield-line equations in AASHTO (2007), and AS3845:2015 assume the concrete barrier is continuous longitudinally. These codified methodologies do not acknowledge the possible vertical joints between precast barriers. The designer must always undertake the ancillary check of a horizontal yield-line across the base of the barrier. This simple yield-line is usually critical for 3000 mm- and 6000 mm-long precast traffic barriers. The vertical joints between precast barrier units essentially precludes the design from taking advantage of substantial horizontal load-distribution through the height of the concrete barrier – and relies most heavily on longitudinal distribution through the steel post-and-rail elements.

6.1.2 *Shear-moment interaction*

For a ductile (compact) steel post – the maximum shear force which develops in the post is a function of the plastic-section-capacity of the post, and the distribution of bending moment in the post. The interaction between shear and moment must be considered in the design, and when the applied moment is equal to the plastic-moment capacity – the shear strength is reduced significantly. It is for this reason, at least, that the author does not use column-section steelwork for posts, but prefers to utilize the twin webs of hollow sections.

6.1.3 *Double-curvature*

The standard yield-line approach assumes single-curvature in the steel traffic-barrier posts – whether single or double-railings are used. Whatever the number of railings used – when the torsional stiffness and torsional strength of railings is included in the analysis it is possible that double-curvature is induced in the posts – whether or not the moment in the post close to the railing is near the state of plastic-hinging. Double-curvature can increase the capacity of the traffic-barrier system. Under double-curvature the shear force in the post can be as great as twice the shear force in the post under the single-curvature condition i.e. under double-curvature, the post will be wont to 'fuse' at a higher level of loading, and will impart a greater load to the supporting elements. If not anticipated by the designer – the bolts may fracture, or the concrete barrier may become overloaded. In any case – if double-curvature is inadvertently overlooked, and the design assumes single-curvature, the element supporting the concrete barrier remains capacity-protected (i.e. the foundations / deckslab).

Post heights usually range from 250 to 550 mm tall. At the shorter end of this range – the presumption of double-curvature may even be invalid if the post acts as a rigid 'block' rather than as a flexible beam. In the former case it is questionable whether such a barrier can 'fuse' in a ductile manner. A three-dimensional 'shell-' or 'solid-element' finite-element analysis will confirm the true behavior of short posts.

6.1.4 *Too-strong posts and rails*

On Melbourne's Peninsula Link project – the traffic barriers were substantially configured by the urban designer, with only 'late' moderation by the engineer. The urban-design concept called for 273 mm-diameter circular-section railings (variously 9.2 mm and 12.7 mm thicknesses) supported by three-sided steel-box posts.

Figure 12. Traffic barriers on Peninsula Link, Melbourne.

The designer was faced with numerous challenges imposed on the project by the urban designer (PC 2017):

- Firstly the railing could only be procured in grade 350 MPa steel rather than grade 450 MPa.
- Secondly the (flexural) section modulus of the circular section was less than that of a smaller square hollow-section.

– Thirdly, advanced FEA analysis was required to demonstrate adequate shear-moment interaction of the railing – given that AS5100 did not assume that a circular hollow-section would ever be used as a 'beam'.
– And last, the three-sided box-post was found at first to be too strong. In other words the post was at first found to resist the impact load wholly at one location, without any beneficial longitudinal distribution through the railing – likely fracturing the supporting holding-down-bolt device and the traffic barrier, or both. The rear backing plate was necessary to eliminate local buckling of the thin-but-deep 'post side plates', however it was not until it was eliminated as a structural element by the inclusion of a thin horizontal slot immediately above the level of the baseplate – was the post (and its fixings) demonstrated to be a ductile element.

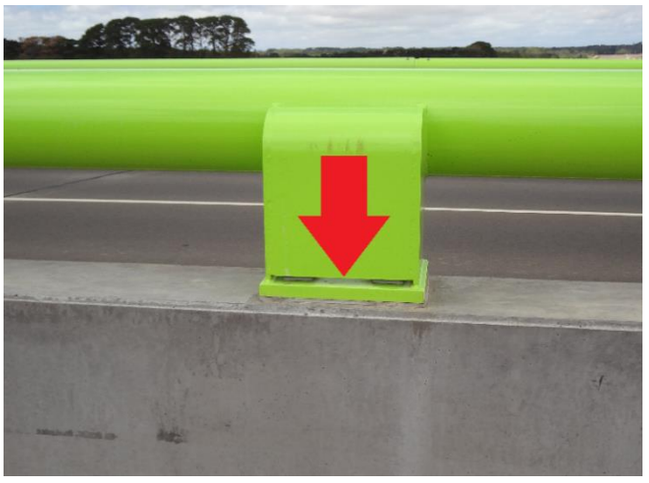

Figure 13. Slot at base of posts: Peninsula Link, Melbourne.

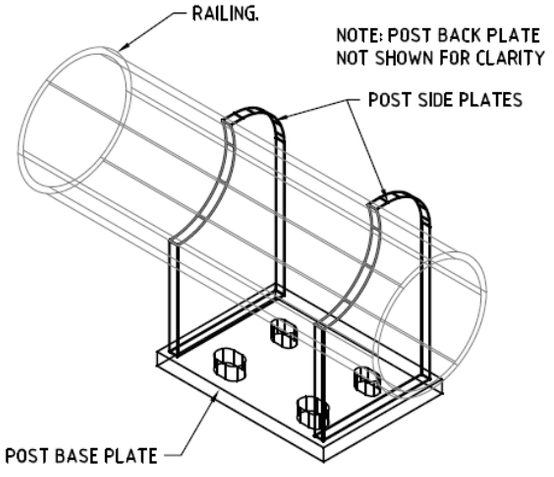

Figure 14. Isometric view of barriers: Peninsula Link, Vic.

In the preparation of this paper, the author reviewed a half-dozen Medium- and High-Performance traffic barriers constructed elsewhere in Melbourne over the last decade. Each of these barriers included a significantly-proportioned steel hollow-section railing. In the greatest case – the torsional strength of the railing was two-hundred percent the magnitude of the plastic-moment capacity of the post. This indicates the potential for a torsionally-continuous hollow-section railing to resist as much as four-times the plastic-moment capacity of the post, and supports the proposal that designers should be alert to the implications due to double-curvature – especially for bolt-group and concrete-barrier-unit designs.

7 POSSIBLE IMPROVEMENTS TO THE DESIGN APPROACH TO SUIT THE INCREASED AS5100:2017 LOADINGS

7.1 *Width of kerb-stitch*

Many designers continue to utilize a width of in-situ concrete kerb-stich of 280 – 300 mm, often resulting in poor constructability. The author has not (willingly) used a figure less than 350 mm for nearly twenty years. Increased barrier loading may require an even larger width of kerb – in order to relieve increased reinforcement contents.

7.2 *Kerb-stitch longitudinal reinforcement*

The author is unconvinced of the benefit of longitudinal reinforcement with the kerb stitch (Figure 3). Recent years have seen the use of un-tensioned 12.7 mm prestressing strand rather than 'black' reinforcement. The poor concrete-bond characteristic of un-tensioned strand is unlikely to benefit the crack-control of the kerb-stitch (due to differential shrinkage). The author is also unconvinced of the benefit of longitudinal kerb-stitch reinforcement towards the transfer of load between the overlapping reinforcement loops. As stated above – the critical barrier yield-line is normally a horizontal line across the barrier base – whereupon the kerb stitch is in a state of plane strain over the length of the yielding barrier-unit. Under these conditions – the compressive strength of the kerb concrete is increased greatly. It is interesting to note that for the case of the 'end-condition' where plane-strain does not exist (Araujo 2014) predicts that for closely-spaced overlapping loops – the concrete tensile strength is sufficient to tie the transfer of forces longitudinally, whereupon the crushing strength of the concrete compression struts becomes critical. The author is of the opinion that the deletion of longitudinal kerb stitch reinforcement, and its replacement with a steel-fibre concrete mix may benefit both the control of cracks due to differential shrinkage, and also benefit the transfer of load across the opposing loops. Steel fibres may be a useful method to restore constructability of this detail upon the likely increase in starter bar reinforcement content due to

increased loading. Steel fibres may also be an expeditious method to address vertical differential-shrinkage cracking of the detail.

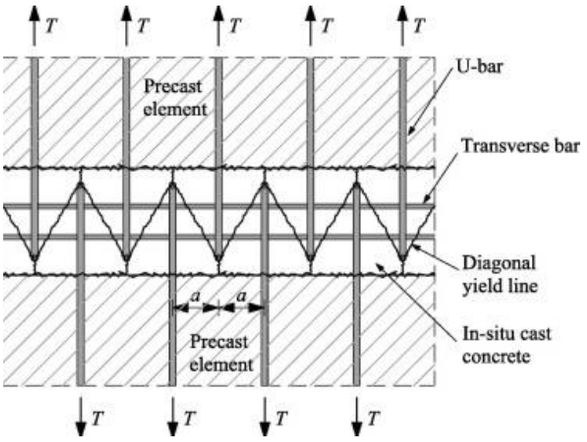

Figure 15. Schematic of load path for overlapping loops

7.3 *Continuous concrete barriers*

Increased barrier loading may see the increasing use of full-height concrete barriers which are also continuous longitudinally. Tall barriers may result in an experience akin to driving down a 'storm-water drain'.

7.4 *Thicker, longer, and heavier concrete barriers*

Increased barrier loadings may result in heavier barrier units. For many years the Victorian approach has been to use steel levelling-brackets as shown in Figure 3. For various reasons there have been bolt-punch-through failures of the C-shaped bracket. The engineer will need to reassess this detail for heavier barrier units. Additionally – the engineer should not utilize more than two levelling brackets, as has occurred in the state of Victoria. A greater number than two levelling brackets per barrier-unit results in an indeterminate support-system, for which the loading of the bolts/brackets cannot be controlled during erection – risking the overloading of one or more brackets. Indeed, a redundant levelling-support system can even jam and disallow adjustment.

7.5 *Analysis methods*

Increased barrier loading is likely to see the designer resort to finite element analysis as outlined above – in recognition of the advantage of post double-curvature towards increasing the load-capacity of the barrier system. Double-curvature in posts may reduce the sizes of the steel post and railing, however is likely to increase the sizes of holding-down bolts; the quantum of vertical barrier reinforcement; and also the deck-slab reinforcement content and thickness.

7.6 *Crash-tested barriers*

The author recommends that state road authorities undertake physical crash-testing of standardized traffic barrier systems – or at least undertake the physical load-testing to the codified static-design-loads. The author is of the opinion that such testing may be especially advantageous for off-structure barriers. The cost of load testing is likely to be orders of magnitude less than the likely deferred cost of conservative designs applied over the next decade's projects.

8 SUMMARY

Traffic barrier design to the former AS5100:2004 has proved complex to prepare and construct. For the last two decades at least – traffic barrier designs have proved problematic for new designs and traffic-barrier upgrade projects. The amendments of AS5100:2017 see the design requirements for traffic barriers increased substantially. Without clear precedent from local or international experience – the consequential effects on bridge design are anticipated to be onerous, and may be found on occasion to be prohibitive. The author postulates the industry should move away from its reliance on engineering calculations for traffic barriers – and towards the physical load-testing of standardized bridge barrier systems. It is hoped that this alternative approach may reduce the demands on the structural configurations of traffic barriers and their supporting elements, and perhaps save road authorities significant monies over the long-term.

Displacement-based seismic design to AS5100.2: 2017 – simplified

B.E. Gibbens
Principal- Bridges
BG&E, Melbourne, Australia

ABSTRACT: The Australian code of practice AS5100 *Bridge Design* was revised in April 2017. Significant changes see the analysis methods for seismic design and also earthquake return-periods brought closer to those of major world codes. While retaining the response-spectrum and time-history analysis approaches of the former code as 'normative' (both representing dynamic 'force-based' methods) – the 'informative' Appendix B of the new code allows the optional use of 'displacement-based' earthquake design.

This paper describes the empirical basis for displacement-based design, and seeks to clarify the differences and advantages of this method from the older force-based methods when applied to both new and existing bridges. Simplified approaches, and practitioner techniques are illustrated – with the view to encouraging the adoption of this modern and often beneficial approach to seismic design.

1 INTRODUCTION:

This paper encourages Australian engineers to adopt the new displacement-based approach to seismic design. This paper identifies the empirical basis of the method, and compares the advantages of the method with older force-based design approaches.

This paper contrasts the outcomes of the force- and displacement-based design approaches for both existing and new structures.

The displacement-based design (DBD) approach represents the state of art in the most seismic regions of the world. It is represented in the design codes of the United States, Canada, Japan, and Eurocode, and is prescribed by Californian Department of Transportation and New Zealand Transport Agency.

The revised AS5100.2: 2017 also removes the inconsistencies in earthquake return-period which existed beforehand with the supporting Australian design code AS1170.4:2007 *Structural Design Actions – Earthquake.*

2 AS5100.2: 2017 METHODS

The revised bridge code allows the following force-based design methods: static or dynamic (elastic) response-spectrum, and elastic or inelastic dynamic time-history analysis. The recently-developed displacement-based design approach is also now permitted.

2.1 *Response-spectrum analysis*

Response-spectrum analysis (RSA) is a force-based design approach which infers that the actions which develop in a structure are proportional to the inertial effects (accelerations) induced in the structure.

In order that the main elastic periods of the structure can be determined, the RSA-approach requires the structure's elastic stiffness to be estimated at the start of the design, however the true elastic stiffness is not known at this stage. The RSA approach also relies on the original stiffness assumptions in order to distribute the total-calculated inertial effect between components. This results in stiffer elements being reinforced more heavily than more flexible ones.

Under the RSA-approach, the designer must also assume the level of plasticity which may develop in the structure on an averaged basis, via the use of a 'structural-response' factor; plasticity is not calculated explicitly. Furthermore – the RSA approach does not facilitate the progressive development of inelastic behavior to be differentiated between the different components of the structure.

Response-spectrum analysis combines the results of multiple modes of vibration using the 'square root of the sum of the squares' (SSRS) or 'complete quadratic equation' (QDC) techniques. These methods of vector-addition obscure both the sign and true magnitude of structural displacements under earthquake, as will be illustrated later in this paper for the case of expansion-joint design.

2.2 *Displacement-based analysis*

In contrast to force-based design, displacement-based design recognizes that the actions which develop in the structure under earthquake are consequential to the displacement of the structure, rather than being the cause of the structure's displacement.

In contrast to force-based approaches – the understanding of initial element-stiffness and the possible rate-of-change of element-stiffness is achieved with the use of moment-curvature or equivalent relationships which are known at the start of analysis.

For displacement-based design, the strength of the structure is less important than its ability to displace. The DBD-approach may allow the strengths of components to be reduced and rationalized; different-stiffness elements may be proportioned similarly. The potential benefit of DBD towards existing structures is obvious. For the reasons outlined later in this paper, the application of the DBD design approach towards both new and existing structures compares favourably with forced-based design approaches. When a 'push-over' model supports DBD calculations – both the progression and levels of inelasticity are calculated explicitly, and are differentiated between components.

2.3 *Rules of thumb*

Before the empirical basis of the DBD approach is outlined, it is useful to consider the 'rules-of-thumb' which illustrate the interpretation of the dissimilar force-based technique.

Figure 1 shows a typical acceleration-period response-spectrum curve. On account of their high primary-response-period – flexible structures are part-isolated from the peak ground acceleration (T = 0 seconds), and are not susceptible to the large amplification of ground motions which can occur for stiffer structures (e.g. $0 < T < 0.75$ seconds). This is the 'period-shift' effect. Similarly, the effect of increased damping can reduce the amplification of ground motions.

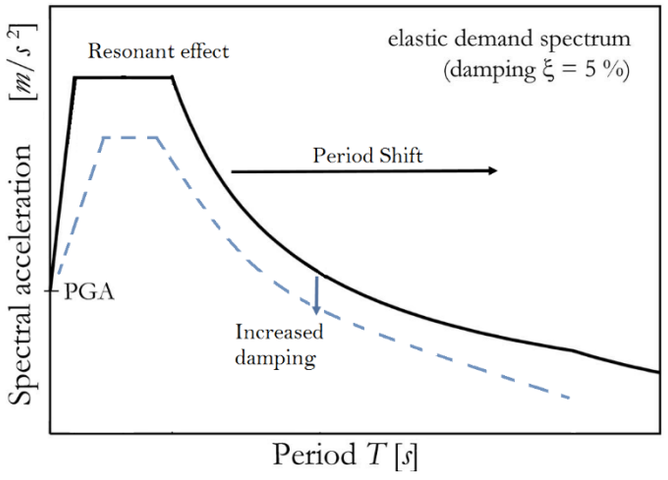

Figure 1. Graph of spectral acceleration versus structure period.

Under the DBA approach, these rules-of-thumb may be considered less-relevant, as outlined below.

2.4 *Equal-displacements rule*

The displacement-based design approach has been developed empirically. Physical experimental modelling predicts that a given structure which exhibits a predominantly single-degree-of-freedom response under earthquake loading – will displace a similar amount – whether this structure remains elastic, or develops an inelastic response (Fig. 2). Furthermore, this modelling predicts the earthquake-induced displacement would be: independent of the initial or final stiffness of the structure; independent of the level of plasticity which develops under the seismic action; and is independent of the strengths of components within the structure. This general result is indicated for structures with a fundamental period-of-vibration within the approximate range of ($0.7 < T < 3.0$ seconds), as indicated in Figure 2, below.

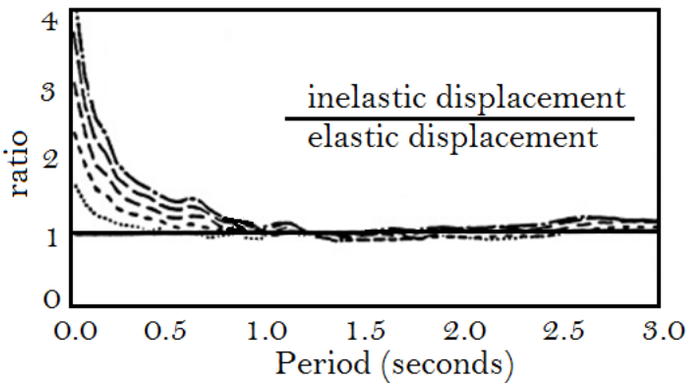

Figure 2. Variation of elastic and inelastic displacement-responses with fundamental period: single-degree-of-freedom oscillator (Pierino et al. 2003 & Miranda 2000 & ATC 1996).

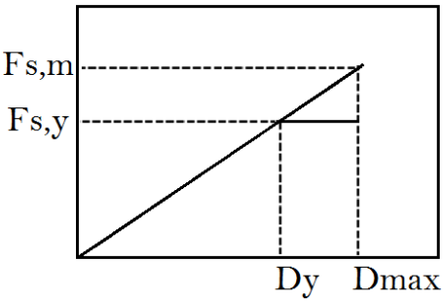

Figure 3. Equal-displacing elastic and inelastic responses (Priestley et al 2003).

For structures with a fundamental period in the range $0.7 < T < 3.0$ seconds: the elastic and inelastic responses (displacements) are not significantly different. In other words – whether the qualifying structure responds elastically, or in-elastically – the peak displacement is the same. Additionally, the maximum displacement is independent of the yield strength – ir-

respective of whether the response is elastic or inelastic. These outcomes constitute the 'equal-displacements' rule.

As inferred by Figure 3, the 'structural-response' factor is the ratio of the set of elastic actions divided by the set of inelastic actions – calculated for the same maximum displacement in the plastic range.

2.5 *Limits-of-validity*

In AS5100.2: 2017, the equal-displacements rule is held to remain true for structures with a primary mode of vibration in excess of the (second) 'elastic corner-period', which AS5100 takes as 1.5 seconds.
The Californian document ATC-32 provides design factors to extend the DBD approach to outside the limit-of-validity of the equal-displacements rule (ATC 1996).

3 SIMPLIFIED AS5100.2: 2017 APPROACH

Many of the Appendix B equations in the new Australian code may be daunting to the unfamiliar practitioner, who may undertake these calculations in the manner of following a 'cook-book', and without a clear appreciation of the technical basis of the design.

3.1 *Alternative DBD approaches*

Two alternative approaches to the DBD method are available under AS5100.2 Appendix B.

The first approach forms most of the AS5100.2 Appendix B, and requires hand calculations to be undertaken incrementally to define the displacement-capacity – which is then compared to the applicable 'displacement-spectrum' which defines the seismic displacement-demand.

The second approach uses a dynamic RSA analysis to define the seismic displacement-demand. An inelastic 'push-over' analysis is then used to demonstrate adequate displacement-capacity. It is this second approach which shall be the subject of the remainder of this paper.

3.1.1 *RSA versus 'push-over'*

In lieu of adopting of most of the Appendix B hand-calculations, the last paragraph of Clause B1 *General* permits a simplified DBD approach. For structures which qualify under the equal-displacements rule – the simplified approach allows an adequate seismic design to be demonstrated if the structure is proven capable to displace an amount at least as great as the displacement predicted by a linear response-spectrum analysis. In this case the response spectrum is of magnitude $1.5k_pZC_h(T)$. For safety – this design response-spectrum includes a 1.5 multiplier to the basic response-spectrum.

The simplified approach is undertaken in two stages. Firstly – the displacement-demand is predicted by a linear RSA analysis. Secondly – a non-linear 'push-over' analysis is undertaken to demonstrate the structure has sufficient ductility to displace at least as far as the displacement-demand.
The 'push-over' analysis will allow the states of stress and strain throughout the structure to be understood including the propensity for brittle-failure, and any susceptibility to P-Δ effects.

4 PUSH-OVER ANALYSIS

4.1 *Derivation of displacement-capacity spectrum*

Figure 4 outlines the generalized method to turn the force-displacement results from a non-linear push-over analysis into an acceleration-displacement 'displacement-capacity' diagram. The increasing base-shear versus structure-displacement is first plotted and then scaled versus the mass-coefficient and mode-participation factors (both of which are close-to-unity for 'single-degree-of-freedom' structures) in order to turn the base-shear in to pseudo-acceleration values.

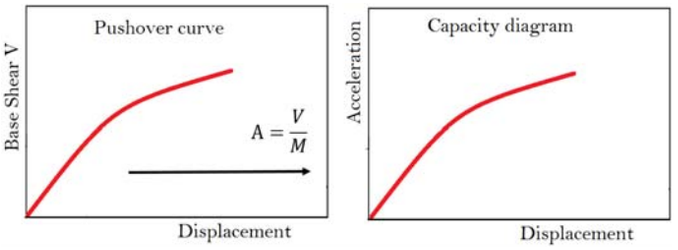

Figure 4. Derivation of displacement-capacity diagram.

4.2 *Derivation of displacement-demand spectrum*

Figure 5 outlines the generalized method to turn an acceleration-period (response-spectrum) curve into an acceleration-displacement 'seismic displacement-demand' diagram. In this case the following well-known single-degree-of-freedom dynamics equations are used, where ω_n = circular frequency; k = stiffness; M = mass; f_n = frequency; T = period; D = displacement, and where equations (1) and (2) are rearranged to equation (3).

$$f_n = \frac{\omega_n}{2\pi} \tag{1}$$

$$\omega_n = \sqrt{\frac{k}{M}} \tag{2}$$

$$D = \frac{AT^2}{4.\pi^2} \tag{3}$$

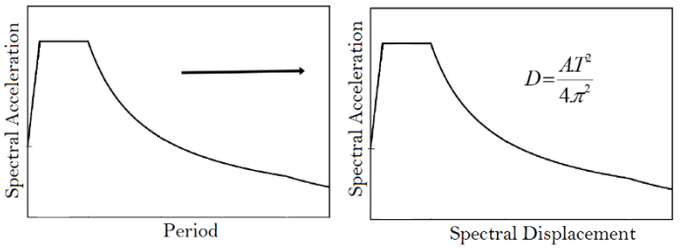

Figure 5. Derivation of displacement-demand diagram.

4.3 *Capacity-spectrum methodology*

Figure 6 overlays the 'displacement-capacity' and 'seismic displacement- demand' diagrams. Codified magnifiers notwithstanding, the earthquake design essentially reduces to confirming the bridge is capable to displace in excess of the displacement predictions of the elastic response-spectrum analysis. A structural member 'survives' the earthquake if the 'ductility-capacity' is greater than the 'ductility-demand'

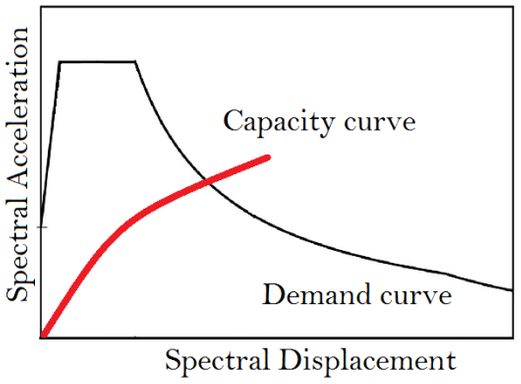

Figure 6. Super-position of displacement-capacity and displacement-demand diagrams. (Caltrans 2010 & Chopra 1999).

A pushover-analysis helps identify potential non-ductile or weak areas in the structure, and tracks the sequence of damages in each component in the structure. A pushover-analysis can show where the retrofitting is required, and the scope of retrofitting.

5 PREDICTING STRESS AND STRAIN

5.1 *Strength and stiffness interdependency*

Notwithstanding the necessary approximations of structure-materials and component-stiffnesses when using RSA modelling of displacement-demand, it must be recognized that the common design assumption that member stiffness is independent of strength is untrue. Instead – the curvature at first-yield is independent of strength – stiffness being directly proportional to flexural strength. In Figure 7: *M* is moment, φ is curvature, and φy and *My* are the states at first-yield of curvature and moment, respectively.

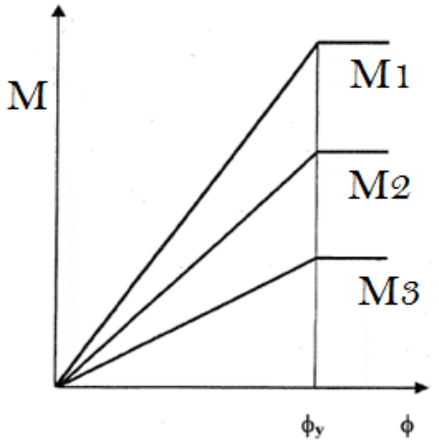

Figure 7. Yield-curvature is independent of moment capacity

5.2 *Ductility*

5.2.1 *Minor earthquake motion*

A 'ductile' design is one whereby the structure can deform in-elastically for several cycles without significant degradation of strength or stiffness. Not all bridges, or components of a bridge, will require a ductile earthquake design. Those bridge components which displace under the design displacement-demand an amount less than the yield-displacement-capacity of that component do not require detailing for a ductile earthquake design (i.e. the component responds in an elastic manner).

5.2.2 *Strong earthquake motion*

AS5100.2 Clause B17.1 contains the general and vague statement "*Potential plastic hinge locations in columns have to take into account the consequence of the possibility of the bridge being subject to excitation exceeding the design level".*

In order to ensure the dependable rotational-capacity at plastic hinges – Caltrans' Seismic Design Criteria (Caltrans 2010) requires each member to have a 'local' displacement-ductility capacity sufficient to achieve a total local-displacement in excess of three times the 'local' displacement at first-yield – irrespective of the magnitude of earthquake loading, and irrespective if global ductility is otherwise demonstrated.

5.3 *Capacity-protection and 'over-strength' design*

The objective of 'capacity design' is to confirm a structure may undertake controlled ductile-behaviour in order to avoid collapse in a design-level earthquake. This involves designing the structure to ensure ductile failure at key predictable locations within the structure and to prevent other failure types or damages occurring elsewhere in the structure.

The substantial in-elasticity which is allowed in columns can be used to 'protect' the superstructure

and the foundations from developing significant inelastic behavior. The plastic hinges in columns may be regarded as fuse-elements which limit the magnitudes of the actions developed in the structural components which are required to undertake essentially-elastic responses. It is essential, therefore, that this desirable fusing behavior can develop, and that brittle failure does not develop anywhere.

Additionally – most of the seismic displacement-capacity is achieved via the column plastic hinges. In order to assure the seismic displacement-capacity is achieved via the column hinges – the components of the structure which are to remain essentially-elastic in their responses – must be designed for the 'over-strength' properties of the column hinges.

For example – the shear force which develops in the columns at a high level of plasticity, and which must be resisted by the foundations and/or superstructure – is proportional to the post-yield stress in the column reinforcement, rather than the reinforcement stress at first yielding.

5.4 *Performance-based design*

Structural damage is strain-dependent, and can therefore be related to the displacement of the structure. The default performance criterion in AS5100.2: 2017 is for 'damage control' whereby the bridge shall maintain its structural integrity after the design earthquake. This contrasts to the requirements of other major codes which may also stipulate material-strain limits for earthquakes of lesser return-period – with the view to minimizing the repair effort, and the time a bridge may be out of service. The methodologies outlined in this paper are directly useful to assess material strains anywhere in the structure at any level of seismic loading.

5.5 *Buried elements*

The designer must understand the possible implications of strong columns on buried foundations. Whether column plastic-hinges 'capacity-protect' the pilecaps, or otherwise – substantial inelastic behavior in the columns may generate very large actions on foundations – especially shear force – as stress in the column reinforcement increases past nominal yield. The designer must consider the possibility of pile brittle-failure in any case, and also the level of pile 'damage' when a prescriptive 'performance-based' design is undertaken.

It is noted there that if the foundation is capacity-protected by hinging in the columns – then the foundation does not deflect beyond the level corresponding to plastic hinging of the columns.

6 DISPLACEMENT-BASED APPROACH

Figure 8 illustrates a bridge with columns of different height. Table 1 illustrates the merits of adopting the displacement-based seismic design approach in lieu of a force-based one.

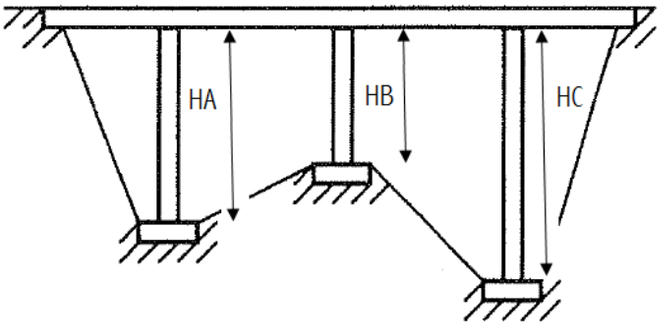

Figure 8. Multi-span bridge with different column heights

Table 1. Proportional-response to column height

	Force-based design	Displacement-based design
Stiffness	$1/H^3$	$1/H$
Shear force	$1/H^3$	$1/H$
Moment	$1/H^2$	similar
Reinforcement	$1/H^2$	similar
Ductility	similar	$1/H^2$

6.1 *Application of DBD to new structures*

The global ductility-demand is the ratio of total structure displacement to the structure displacement at the first point-of-yield, and varies depending on the type of structural system, and is analogous to the 'structural-response' factor used for force-based design. For new design, and when choosing framing, the designer should consider maximizing the inelastic response within the limits of the structural-response factors used for force-based design. This approach may maximize the use of a given tonnage of reinforcement, and lessen the demands of 'capacity-protection', if this is required. Performance-based limits to structural 'damage' should also be considered.

It has been the author's experience that an adequate seismic design of a new structure often follows (without revision) the prior proportioning and rationalization of reinforcement contents which is derived from non-seismic loadcases.

6.2 *Application of DBD to existing structures*

The explicit calculation of the states of stress and strain under the DBD-approach is useful for the review of existing structures which do not reflect modern reinforcement-detailing approaches, and which may not have been designed for seismic loading.

Archaic reinforcement detailing might be accepted if the DBD seismic design demonstrates that an existing structure can displace elastically in excess of the

seismic displacement-demand. Conversely – the DBD calculations may indicate that some structure-components exceed the yield-limit. If the original detailing is inadequate to assure ductility, then these components should be subject to a seismic retrofit.

6.3 *Example application to an existing structure*

DBD is particularly useful towards structures which were not originally designed for seismic loading. The author recently undertook a seismic assessment of the existing E.J. Whitten Bridge on the M80 Ring Road in Melbourne. This major bridge utilizes different-height concrete columns with almost-identical reinforcement contents. For this review – a force-based approach indicated the shorter and stiffer piers would become more-heavily loaded than the taller piers. An assessment using DBD indicated substantially improved results, especially for foundations.

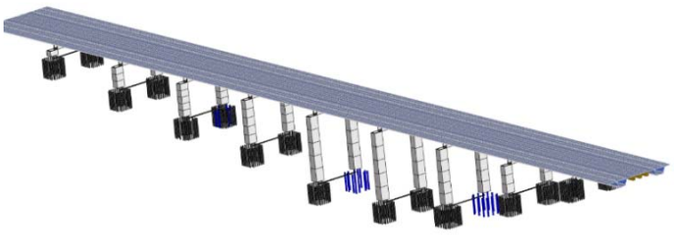

Figure 9. 3D bridge computer model (EJ Whitten Bridge)

7 PRACTITIONER TECHNIQUES

Useful modelling techniques which the author has used variously for new and existing structures are illustrated in this section.

7.1 *Response-spectrum model*

For concrete structures - linear-elastic RSA models usually assume 5% damping overall, although as much as 10% may be warranted for concrete structures with significant plastic-hinging (Caltrans 2010). The responses of foundations and superstructure are assumed to remain elastic, and a fifty-percent reduction of the column moment-of-inertia stiffness is normally adopted (AS5100.2: 2017 & Caltrans 2010). Foundation flexibility can contribute a significant proportion of the total structure displacement, and therefore should be modelled carefully. The axial stiffness of 'skin-friction-only' piles is often modelled as fifty-percent of that of end-bearing piles (AASHTO 2014).

7.2 *Finite-element 'push-over' models*

The author has developed and calibrated various push-over modelling techniques which can be used in conjunction with the finite-element package Strand7 or similar programs. These are outlined below.

7.2.1 *Non-linear column model*

In this model, beam elements which represent the column concrete are overlain by beam elements representing the column reinforcement (Fig. 10). The reinforcement is entered according to its true distribution in space using Strand7's user-defined 'BXS' section property. In order that Strand7's 'mesh-cleaning' function is not confused by overlapping elements which share the same end-nodes, the beam elements which represent the reinforcement connect to every-second node associated with the concrete-property beam elements.

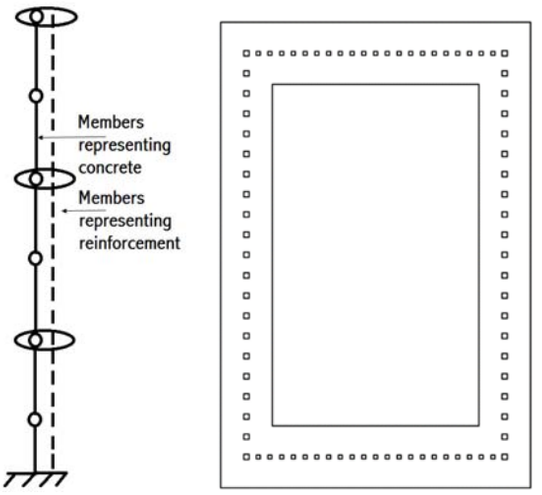

Figure 10. Beam-element model for non-linear column analysis

'Concrete elements' are programmed with the non-linear CEB-fip concrete-strength curve, including the characteristic of zero tension-capacity. Alternatively the Mander concrete-model (or similar) may be appropriate if earthquake detailing justifies the improved concrete strengths which result from substantial confinement. The 'reinforcement' beam-elements are programmed with a stress-strain curve which reflects the increase in reinforcement stress beyond the point of first yielding. The two connected elements constitute a 'composite' section from which a cracked-section analysis is derived (Fig. 11). A non-linear 'push-over' analysis will automatically calculate the true states of stress and strain – without the need to transform stresses. To avoid analytical non-convergence due to the abrupt loss of stiffness at zero-gradient locations on the material stress-strain curves – the author recommends that the 'push-over' is incremented as an imposed displacement, not an incremented (arbitrary) load.

The model described here is capable of describing the incremental change in cross-section stiffness and material strains at every stage through the imposed displacement. The locations throughout the structure which resist the seismic motions in-elastically (and which therefore must be ductile) are identified explicitly. In this approach, curvatures do not need to be calculated, however curvatures can be derived simply from the changes in deflected shape.

As a variation to this approach – if the designer prefers to utilize moment-curvature relationships in his non-linear push-over model, then these can be derived beforehand by the model in Figure 10.

Figure 11. Example Strand 7 output showing extent of cracking.

7.2.2 *Automated strut-and-tie models*

Figure 12 represents the model the author used to prove the capacity-protection of the superstructure of a major North-American balanced-cantilever bridge. In this example – the columns were built integrally into the pier table. In order to ensure the beneficial fusing of the plastic-hinge zones at both the top and bottom of the column – the pier table and foundations (including piles) were each designed for the 'over-strength' actions resulting from the plastic-hinging.

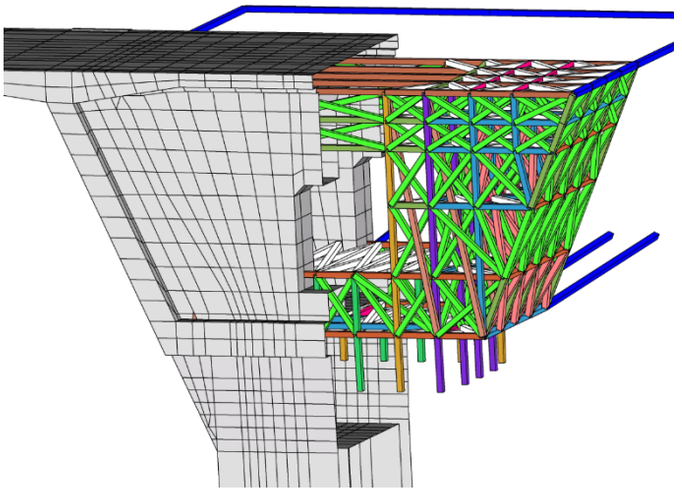

Figure 12. Isometric view of 3D strut-and-tie model: pier table.

Due to the difficulty in attributing a load-path within the diaphragm walls and webs of the pier table, while maintaining a sensible reinforcement pattern – the author undertook an automated non-linear strut-and-tie design – whereby the reinforcement was detailed before it was designed for earthquake. Next – the reinforcement crossing the location of the upper column hinge was assumed at the state of stress representing the steel's 'over-strength' properties. The load-path was derived automatically by the model, and vetted for its sensibility by the author.

For the E.J. Whitten Bridge review, the author applied a similar modelling approach towards automating the check of orthogonal reinforcement bands within the pilecaps (Fig. 13).

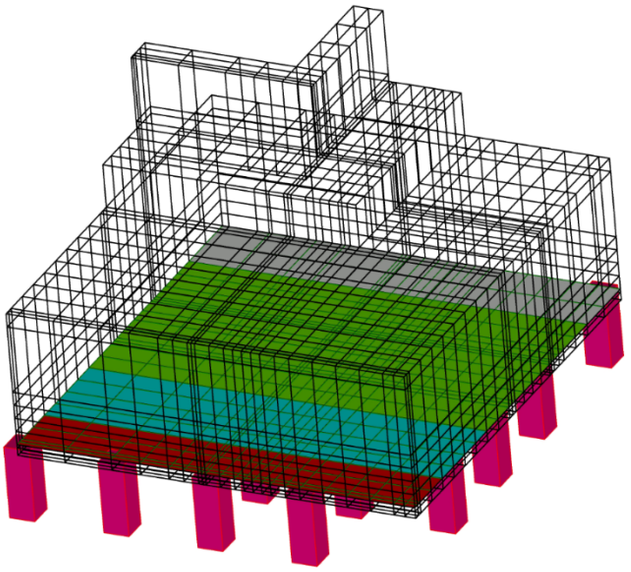

Figure 13. Automated non-linear strut-and-tie pilecap model.

In this model the reinforcement bands were represented in a 'smeared' sense by plate elements – for which non-linear steel properties were modelled. The concrete was modelled using 'brick elements', again with non-linear CEB-fib properties, and with the characteristic of zero tension-stress capacity. This model was combined with the non-linear push-over formulation outlined above, and also allowed the automated review of dozens of 'gravity-load' loadcases.

7.3 *Expansion joint design*

As illustrated beforehand, both of the RSA-method SRSS and CQC approaches to combining a multi-mode structural-response obscure the sign of bridge displacements. While unimportant for the design of abutment expansion-joints, the seismic movements which occur at expansion joints located within the length of bridge may be over-estimated by the RSA model – as the RSA results cannot differentiate between opening and closing movements, and whether the opposite sides of the expansion joint are moving in- or out-of-phase. The simple addition of a nominal beam-element across the expansion joint will allow the maximum expansion joint movement to be obtained from the beam-element's axial force. While this modelling trick solves the 'phase' question, the designer remains unclear whether this movement represents 'opening' or 'closing'. Only the resort to a n-linear time-history model may solve this remaining question. In any case – AS5100 does not require expansion joints to cater for seismic movements.

7.4 *Capacity-protection of knee joints*

When the plastic hinges which may develop in the columns are relied upon to achieve the seismic displacements – then the elements adjoining the hinges must be 'capacity-protected'. In such cases – pilecaps and pier crossheads must be capable to resist the actions which develop on account of the 'over-strength' properties at column hinges. For these elements – the complete loadpath must be demonstrated. Simply embedding the column reinforcement into a pilecap or into a column crosshead a 'development length', does not constitute an engineered outcome. Indeed – the act of merely adding bar cogs or 'bar heads' to the reinforcement, does not ensure a complete loadpath. As an alternative to first-principles calculations, the designer may engineer the capacity-protection of knee joints by referencing the empirical approaches of Caltrans (ATC 1996). As well as ensuring the capacity-protection of the knee joint, these empirical approaches often yield simpler reinforcement outcomes. For example the author's use of the empirical Caltrans method resulted in the deletion of all bar cogs on the triple-bar-bundle longitudinal reinforcement for the capacity-protected detail in Figure 14.

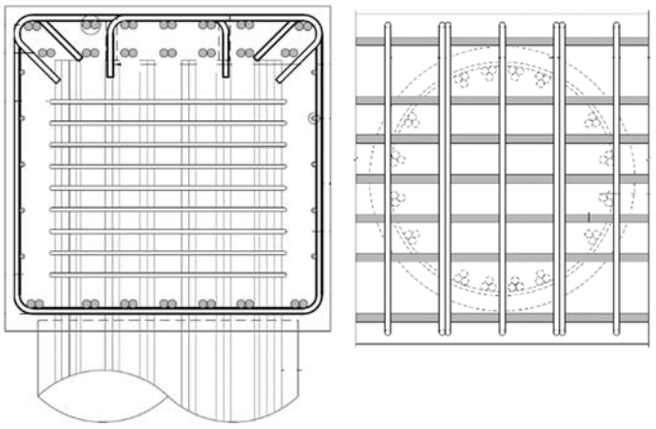

Figure 14. Capacity-protected knee-joint (empirical method).

7.5 *Distribution of reinforcement*

A detailing approach which can be used to alleviate reinforcement congestion recognises that the plastic capacity of a ductile reinforced-concrete section is essentially independent of the distribution of the reinforcement, as long as the layout is symmetrical about the plastic centroid (Fig. 15).

The capacity-protection of the Port Mann Bridge superstructure (Fig. 16) due to top and bottom column-hinges was achieved by distributing the reinforcement of the transverse tie-beams between the pier tables in the manner of Figure 15.

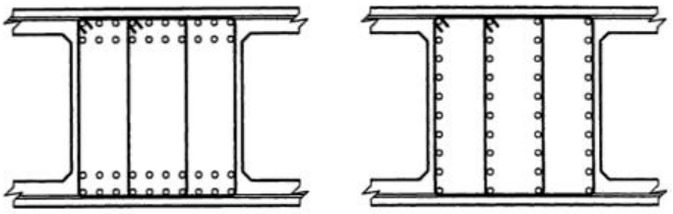

Figure 15. Similar-strength from different reinforcement layouts (both vertical and horizontal bending)

Figure 16. View of Port Mann Bridge pier table tie-beam.

8 CONCLUSIONS

This paper demonstrates the displacement-based approach to be a straightforward and beneficial method of assessing the seismic performance of new and existing bridges. In particular, the explicit calculation of material strains at any point in the structure allows the spatially-accurate identification of components which may require seismic-retrofit in order to achieve the appropriate level of component ductility.

How did the future work out? The tale of E.J. Whitten Bridge

R.A. Percy & P.J. Robinson
COWI, United Kingdom

ABSTRACT: The E.J. Whitten Bridge is composed of twin multi-span concrete viaducts that carry the M80 freeway over the Maribyrnong River in Melbourne, Australia. Overall length is around 518m long. The bridge was completed in 1995 and it now carries 160,000 vehicles per day. In 2017 widening of the structure commenced through the addition of a new deck structure between the existing viaducts. Unusually for a bridge, provision for widening had been made in the original foundation and pier design, although increased highway loads and seismic requirements required an innovative design approach. Through this case study, the paper comments on how well this bridge has stood up to the comparatively recent future. From this, and knowledge from similar works on other bridges, lessons are then drawn for today's designers and those procuring bridges to enable bridges to better withstand the test of time and to lower the cost of future works.

1 INTRODUCTION

Modern transport demands on bridges continue to increase. By their very nature, bridges are often highly utilized structures placed at key locations in the transport network. There is rarely excess capacity or convenient alternative routes, and hence they become critical pieces of infrastructure that are depended upon to operate 24/7 throughout the year. Resulting available maintenance periods are short and consequences of over-running works severe in terms of disruption and financial penalties imposed.

Figure 1. E.J. Whitten, Bridge

Historically the design of bridges has not fully anticipated or catered for this level of high service demand, and where designers have not anticipated the future well the shortcomings can be ruthlessly exposed. This paper looks at a comparatively recent bridge to review how the bridge has been adapted to meet current demands and the innovation necessary to enable this. Lessons are then drawn on how designers and owners can better future-proof their bridges.

The structure considered here is the E J Whitten (formally named Maribyrnong Bridge) located on the M80 around Melbourne, Australia. It is a major viaduct structure currently being modified to carry additional lanes of traffic. Unusually for a bridge structure, some provision had been made at the time of original design for future widening. Nevertheless, exceedance of anticipated future loads and constraints within the existing structure have demanded innovation and alternative approaches to successfully realise the widened design.

2 EJ WHITTEN BRIDGE

2.1 *Location and description*

The existing E.J. Whitten Bridge is a twin post-tensioned prestressed concrete box girder viaduct that forms part of the M80 Ring Road around Melbourne, Australia. The viaducts cross the

Maribyrnong River Valley and are composed of ten spans with total viaduct length of 520 m.

In addition to longitudinal posttensioning of the girders, the concrete box girder decks are also transversely prestressed, with the tendons running from cantilever tip to cantilever tip, typically at 3.6m intervals.

2.2 *History*

During the original design and construction of the bridge in the early 1990s, provision was made for future widening of the structure through infilling the central reserve gap between the two viaduct structures. The concept envisaged was a third concrete box girder that would be supported on a concrete crosshead beam between existing piers (see Figure 2). The construction technique assumed was to cast insitu the cross head beam and launch the concrete box girder (similar to the original construction technique. The original designer included key elements to facilitate the future widening including;

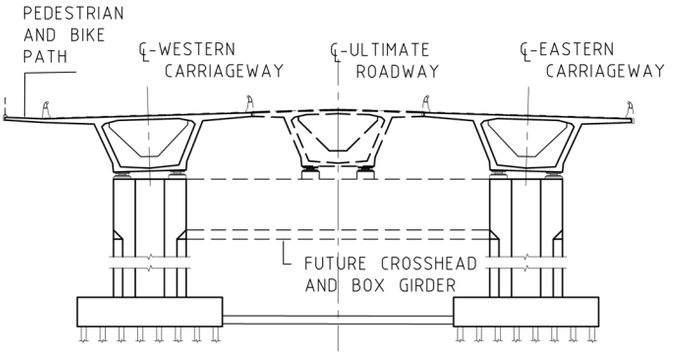

Figure 2. Image of the intended future widening concept (Noonan, 1994).

• Post Tensioning Ducts – 12 number (laid out in two rows of six) 105mm diameter ducts were provided across the top of the piers to allow for a post tensioned concrete crosshead beam to be installed.

• Foundations – the piers and foundations were designed for the loads from the future widened structure namely a third concrete box girder under T44 / L44 traffic loading. The original design also included a tie beam between pile caps to assist with any lateral forces from the portal frame action that would arise once the new crosshead beam is installed.

Aside from the provision of a new crosshead beam no new foundations or piers would be required for future widening except at the two bridge abutments.

• Deck Connection – the future concept anticipated an integral deck connection so top and bottom reinforcement was provided in the cantilever tip. When the widened structure is completed, under transverse load distribution, the inner cantilevers of the existing concrete box girders will be transformed from cantilever spans to continuous sections. This means the previous cantilever tip becomes an area of high sag moment. The original design accounted for this change in the behaviour of this element and provided sufficient reinforcement in both the top and bottom layers of bars to account for both the original and future behaviours of this section. The detail at the end of the cantilever ensured the transverse reinforcement extended beyond transverse tendon anchorages and cantilever tip u-bars so a connection between the new and existing reinforcement could be made.

• Articulation – bearings were provided with removable guide strips so the articulation could be changed in the widened condition. Main bridge abutments and expansion joints were aligned so that expansion joints in the widened structure could be made continuous over the full width.

2.3 *Widening*

In 2016, the widening of EJ Whitten Bridge was tendered by VicRoads as part of the Sunshine Avenue to Calder Freeway upgrade of the M80. With the Contract type being Design Contruct, the tenderers were free to propose alternatives to the reference scheme of a third concrete box. The winning tender design incorporated twin composite steel boxes with insitu concrete deck placed on precast concrete slabs. The superstructure was supported on new pierhead crossbeams, as the original design intended, and made integral with the existing deck. Advantage was taken of the presence of the existing structure to place the steel girders with a pair of gantry cranes running along the cantilevers of the original viaducts. The gantry cranes were also used to place the precast deck panels and the formwork for the pier crosshead beams.

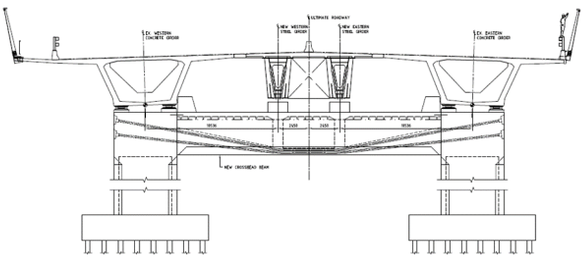

Figure 3. Typical section of actual widening scheme.

The final design solution is shown in Figures 3 and 4. A large major factor in adopting this design was the lighter weight of the superstructure elements

resulting in elimination of any strengthening requirements for the existing substructure. The form of the crosshead beams consists of insitu concrete sections built between existing pier columns to support the new bridge superstructure. Each end of the new crosshead beams was made integral to the existing pier columns. The post tensioning ducts provided within the existing piers were utilised for post tensioning as envisaged and were sufficient to provide the structural connection capacity between the existing pier and new crosshead.

The scope of works for the widening includes strengthening of the existing girders where necessary. As a design and construct contract it was necessary to determine the full extent of strengthening at tender stage through detailed analysis and assessment of the existing concrete girders. The design aimed to minimise strengthening and using steel girders helped this by achieving the necessary stiffness without weight. The steel girders were sized for stiffness, to limit bending of the slab from differential displacements between the new and existing girders. The girders also needed to satisfy height limits for transport and weight limits for the travelling gantry crane. This resulted in two 3.2m deep steel girders of 85 tonnes each (per 54m span).

The analysis was initially carried out using a 3D finite element grillage model, but was supplemented with a 3D shell model where greater accuracy was needed for the effects of distortion and slab bending. By using the shell model it was shown that strengthening was not required to the existing deck slab and the existing diaphragms.

Substantial benefit was taken from material testing of the existing concrete girders to avoid shear strengthening in the webs. The concrete was tested using 100mm diameter core samples and the results supported a cylinder strength of approximately 60MPa for assessment. This was a significant benefit compared to the design value of 45MPa, and showed the existing webs to be fully adequate without strengthening.

As part of the widening works some specific upgrades were specified by VicRoads. These included the addition of high anti-climb public safety barriers to the edges of each carriageway to provide enhanced safety, and the provision of high containment vehicle barriers.

The public safety barriers (PSB) were particularly problematic to fit as they were not considered in the original design, and hence there was a lack of viable attachment points. The provision of barriers over a long length requires a standardised post and panel system with repetitive components to achieve economy in not only production and installation, but also for future maintenance and repair where a standard panel can be swapped out. On the carriageway edge with the Shared User Path (SUP) for cyclists and pedestrians, there is a concrete fascia beam. However, this was not of sufficient size or well enough attached to the box girder cantilever to be able to form an anchorage for the significant post loads. Similarly, the cantilever tip was also lightly reinforced. This meant the post anchorage had to make use of the additional reinforcement provided locally to the original transverse deck prestressing anchorages to achieve satisfactory capacity. Although the additional reinforcement provides the capacity required, the post anchorages had to span the post tensioning anchors and be sufficient flexible in hold down bolt positions to avoid the congested reinforcement. On the other side of the carriageway there is no pedestrian path and the PSB posts were anchored on the rear face of the concrete vehicle parapets. This is also a fairly complex connection requiring the embedding of an anchorage plate under the inside face of the precast barriers.

Figure 4. Render of final widened configuration

The other user upgrade requirement that impacted the main bridge was the upgrade of the vehicle barriers to high containment level. With the capacity of the existing barrier limited by its connection to the deck, which in turn exceeds the cantilever's own capacity, the options for anchoring in a new higher containment barrier were limited. An alternative approach was used which replaced the barrier rails only and used a combination of rail continuity and tailored stiffness to achieve high containment performance. This was underwritten with finite element analysis including both vehicles and barrier modelling undertaken by a barrier impact simulation specialist.

A severe constraint on the design was the limitation on use of bonded dowelled in bars. Currently the use of bonded dowelled in bars is very restricted where a design is to be in compliance with VicRoads Technical Note BTN 2012/002. This means that the use of bonded dowelled in bars in tension was not used for any primary structural connections. This is a relatively severe constraint when strengthening and adapting an existing structure, particularly where many new elements are

to be made integral with the original structure. In the case of this structure, this affected the design of the stich between the new and existing decks; the connection of the pier connections to the crosshead beam and the integral connections between the new and existing abutment structures. In the case of the pier crosshead beam the problem was resolved by using the prestress to eliminate tension at the connection. For the deck stitch it constrained the solution to using existing reinforcement bars only, and making them work optimally. This resulted in having to achieve a high fatigue classification for the welded connection between the stitch reinforcement and the existing cantilever bars. For the abutments a shear only connection was sufficient however the problem of differential settlement between the existing and new abutments had to be catered for. Where differential settlement was predicted to be significant, dowelled bars in ducts were used, which were to be grouted when the full permanent load had been reached.

The integral nature of the final configuration meant that the original articulation would no longer suffice, as there would be two bearings with transverse restraint on the same pier axis. VicRoads also took the opportunity to specify the replacement of the existing bearings as part of the contact as these were over 20 years old. In addition, transverse seismic restraint blocks were required to be installed at each pier. The solution was to change the transverse restraint to occur at one of the new steel box girder bearings, whilst the longitudinal restraint remained at the three tall piers in the middle of the viaduct.

Future maintenance access and durability were important considerations in the design of the new structure and upgrades. Efforts were made to ensure that new steel elements such as the public safety barrier could largely be maintained either above deck or removed for off-site maintenance. With the new steel box girders being shielded by the concrete boxes either side they are in a relatively benign environment. Nevertheless, provision for future maintenance was made through four access hanging points per section being provided every 2m along the length of the structure. This will cater for a variety of access platforms formats and functions including local and whole bridge maintenance, and were therefore seen as a better option for the future, than designing a bespoke maintenance platform that itself requires maintenance and in time, refurbishment.

2.4 *Contract Form*

Contract forms such as Alliance, Early Constructor Involvement, or Design-Construct all permit the Designer to work with the Contractor from the early concept design stage to incorporate the constructors preferred construction methodology. This is highly advantageous particularly when working with existing structures. The design and construct contract created many challenges, such as the need to accurately determine strengthening requirements at tender stage. Several parts of the existing structure were found to be very near the limit where strengthening would be required. The difference between strengthening and not strengthening is a large cost and this required tender stage analysis to be very precise. This situation has the potential to impose substantial risk on the constructors and designers which could have been avoided through an alliance form of contract.

In this instance, the proposed use of gantry cranes to install the new steel box girders from the existing viaducts was a key decision which thereafter acted as a constraint on the remainder of the design. With the existing viaduct cantilevers having limited capacity, and to avoid needing to strengthen them, this constrained both the local wheel loads from the gantry and the weight of the new box girders. As the gantry cranes were also used to install the formwork for the pier crossbeams, much analysis effort was put into maximising construction flexibility whist respecting the weight limits the designers needed to operate within. Temporary cantilever props were required at each end of the bridge where the gantry crane wheel loads are not able to distribute loads into the cantilever in both directions

2.5 *Commentary on provision versus widening demands*

The new widening scheme has utilised all provisions made by the original designers, which makes the provisions a success. Access for construction and launching of the original envisaged scheme would have been difficult under the current constraints on traffic closures. Requirements to replace bearings under traffic load were not anticipated, and this required some local strengthening of the pier tops to be undertaken in advance. More generally, the higher traffic and seismic loading of current design standards was not anticipated.

Provision for future widening was less pronounced in the 130m concrete approach structure. In this case the concrete slab did not make direct provision for connection of the new deck and the expansion joints were not aligned, but a widening scheme was nonetheless achieved to match the existing structural form.

3 LESSONS FOR THE FUTURE

The case study provides an interesting example on how this structure has withstood the demands of time and upgrade work in order to cater for today's

transportation demands. Together with experience of maintenance and upgrade work from other bridge structures the authors have worked on there are some lessons we can propose for the future.

3.1 *Limitations of Code Compliant Design*

Whilst bridges are designed to the codes in force at the time, Code compliant design is not a guarantee that the bridge will see through its service life without problems. Unanticipated behaviour can still arise.

Codes and standards are through necessity a simplification to reduce a range of details and behaviours down to a level where they may be represented by rules and equations. Design innovation and constraint are increasingly necessary in modern design, but the research and testing behind the codes becomes more distant and inaccessible to the Engineer. This can permit the design of details, which were not adequately covered or were beyond the intent of the original research. Research and testing can also be dated and therefore may not adequately reflect the current transportation and environment conditions and current construction methodologies. Engineers should have greater access to this research to be able to make an informed decision on its adequacy.

Where the codes and research do not provide sufficient authority then Engineers need to acknowledge and promote the need to their Clients and Owners to undertake testing and research at design stage for novel and unusual features. Clients and Owners must recognise the value of this and allow sufficient time and funding. Prototypes, including full scale mock up modules can provide immense value to a project.

3.2 *Future provision versus retrofit*

In the case of EJ Whitten, the provision made for the future was largely successful - although only just given the increased demands of current loads. The lesson is to anticipate future demands and aim to build in sufficient reserve beyond that for the inevitable changes that will occur. Although it is not always possible to predict the future, trends are usually evident and provide a good basis. The most economical time to provide modest additional capacity is at the time of original construction.

Our experience of retrofitting is that it is often complex, and heavily constrained, and with a modest degree of additional foresight by the original owner and designer, would be made much easier and therefore more economic. Typically, access remains poor to many structures and often has to be upgraded in advance of the main works. Provision for replacement of bearings and movement joints also remains patchy even in comparatively recent structures. Restrictions on traffic closures required all bearing replacements on the existing girders to be done under full traffic load, but design requirements for many new structures (including the new parts of this structure) do not typically consider this. More focus needs to be placed on the adequacy and practicality of any provision made, as even if it is provided, it often insufficient and impacts unnecessarily on bridge operation. For example, movement joints, which inevitably require periodic replacement throughout the structure life, are typically concreted in, requiring major works to replace them; and bearings are rarely replaceable under full live load. Operation and maintenance need to be included as design input and design cases, and the operation and maintenance manual, at least at principles level, drafted prior to design.

Basic provisions for maintenance access are still often overlooked during design and yet basic provisions can improve the safety of the structure over its lifetime. As an example, the new steel girders for E J Whitten include multi-purpose drainage holes at regular intervals which can also function as hanging points for scaffold or future maintenance platforms. Such provisions are also likely to be used during construction for bolting platforms, or for ventilation of the girder confined space.

Additional provision for the future is also rarely economically feasible during strengthening as each further amount of reserve provided takes the structure further beyond its original design. Whilst more sophisticated analysis means new structures can be designed with greater optimisation (which itself will yield less future reserve) it can also be onerous for existing structures where the advent of computing power enables more exhaustive load conditions to be examined. This means that theoretical full utilisation of major components is comparatively common in existing structures even before upgrade works commence, and that the additional capacity yielded by upgrade is limited by extent of the structure requiring work.

3.3 *Analysis and investigation*

Analysis and investigative technology are able to investigate behaviour to a depth often not possible at the time of design, both through the power of modern analytical software and the use of instrumentation. The actual structure provides the best analytical model of behavior, and with ever increasing instrumentation options and decreasing cost it is possible to investigate behavior in some depth. This can often be used to mitigate the extent of intervention required and to manage problems which are predicted in service. The route itself can be instrumented for vehicle loading using weigh-in-

motion sensors, and used to inform a route or structure specific load model.

It is also apparent that the feedback loop from reality back to codes and standards is not strong. It is important that this is strengthened to ensure that mistakes or mis-judgements made in the past are not repeated. Design and construct contracts put increasing pressure on performance to the letter of the design codes, rather than permitting alternative approached based either on combinations of first principle approaches, supplementary evidence and research and reviewing the intent and application of the original code provisions

4 SUMMARY

Finally, whilst it is clear that future provision is best made at design stage, there is no standard guidance or approach, and asset owners or developers rarely see the incentive in doing so – despite the long-term cost to society. One key aspect of this is that even for today works Engineers are rarely able to close the highway for any significant length of time with the great economic cost to a wide range of stakeholders.

In the future full or even partial closures might be inconceivable.

5 ACKNOWLEDGEMENTS

The authors would like to acknowledge the other parties in the project who together with COWI jointly contributed to the successful outcome including co-designers ARUP and SMEC, the constructor Fulton Hogan, and the client VicRoads.

How strong is your bridge? Optimising New Zealand's longest road bridge.

J. Waldin, B. McHaffie & V. Wong
Opus International Consultants, Christchurch, New Zealand

ABSTRACT: Many nations around the world have a significant proportion of their road bridges approaching end of life. As an example, over 25% of New Zealand's existing State Highway bridges were constructed over a 15 year period between 1926 and 1941, many of which are expected to require significant repairs or replacement within the next 10-15 years. In addition to an aging asset, vehicle load requirements are also continuing to increase with a strong demand for heavier vehicles on roads. In New Zealand, the introduction of high productivity motor vehicles (HPMV's) has significantly increased the demands on existing road infrastructure, causing loads in excess of the capacity of most road bridges constructed prior to the early 1940's. Therefore, it is becoming essential for asset owners to utilise modern optimisation techniques to extend the life of these structures to avoid having to replace or strengthen a large number of bridges over a short period of time.

This paper outlines a case study of how modern optimisation techniques have allowed the longest bridge in New Zealand, the Rakaia River Bridge, to support increased loading without the need for costly strengthening or replacement. Optimisation has involved a wide range of conventional and state-of-the-art techniques, including materials testing, verification of boundary conditions, advanced modelling calibrated with field testing, and calculation of a statistically appropriate load factor and bridge specific impact factor. By refining both the capacity of the structure and the load demand, a significant increase in the bridges theoretical capacity was achieved, saving the asset owner over $10 M in strengthening costs.

1 BACKGROUND

1.1 *Aging assets*

One of the largest challenges to modern society is the ongoing maintenance of aging assets. In particular, a significant proportion of road bridges in Western society are approaching the end of their theoretical design life of around 90-100 years. During the Great Depression (circa 1929 – 1941) many nations undertook significant infrastructure spending to reduce the effect of the economic downturn and provide employment. This resulted in a significant number of new road bridges being constructed in many nations over this period. As an example, over 25% of New Zealand's existing State Highway bridges were constructed over a 15-year period from 1926 – 1941. Given the lower design and construction standards at the time, these structures are estimated to have operating lives of 90-100 years. As such, a significant proportion of bridges constructed during this period are nearing their theoretical end of life and may require significant repairs or replacement within the next 10-15 years.

1.2 *Increasing load requirements*

As technology improves, there is a constant demand for heavier and heavier vehicles to be accommodated on roads. Not only do heavier vehicles provide more efficient movement of freight, they also have the potential to reduce the number of truck movements, improving road safety and efficiency and reducing environmental impact.

In New Zealand, the current Gross Mass limit for legally configured Class 1 trucks is 46 T. However, changes to the Vehicle Dimension and Mass Rule in 2010 allowed High Productivity Motor Vehicles (HPMV's) complying with certain criteria to obtain route specific permits for up to 62 T. Whilst the majority of road bridges constructed since 1960 are able to support these loads using modern load factors; load effects from HPMV's are well in excess of more historic design loadings, particularly for bridges designed prior to 1942 to Traction Engine design loading.

In addition to current loads exceeding historic design loadings; modern ultimate limit state (ULS) load factors are typically higher than the effective load factors from historic working stress design. These effects compound, resulting in the ULS live load capacity of bridges designed prior to 1942 being as low as 65% of current HPMV load effects.

Given aging infrastructure and increasing load demands, it is important for asset managers to optimise the assessment of bridges to extend their life and avoid a wave of bridge replacements.

1.3 *Load factors for heavy vehicle permitting*

The NZ Transport Agency Bridge Manual specifies a design live load factor of 2.25 for Highway Normal (HN) vehicle loading. The current HN-HO-72 design loading was adopted in 1972 as an adaption of the H20-S16-T16 design loading, with the HN element based on the HA loading in BS 153 (Chapman et al 1974). The design load factor of 2.25 was originally

adopted from the AASHTO design codes in the 1980's when ULS design principles were first being adopted for road bridges in New Zealand. When assessing existing bridges, this load factor is reduced to 1.90 reflecting an increased acceptance of risk for structures with limited remaining life. Another reason for the reduction in load factor is that the statistical risk of overloading is reduced for bridges with limited remaining life given the shorter time period.

The NZ Transport Agency Bridge Manual allows this load factor to be further reduced to 1.75 where the following criteria are met:

i. The restrictive bridge must be one of a small number of bridges on an important route.
ii. The deterioration factors for the bridge shall be accurately assessed.
iii. The engineer shall be satisfied that the structure has a ductile failure mode.
iv. The accuracy of the bridge structural data shall be confirmed.
v. The bridge shall be inspected at no more than six-monthly intervals to observe any structural deterioration.
vi. The engineer shall be satisfied that early replacement or strengthening is feasible.

This criteria reflects an increased acceptance of risk where the consequence of damage is lower.

There is a formal vehicle permitting system in New Zealand to allow for the movement of vehicles heavier than legal Class 1 loading, while protecting road bridges from damage. Overweight vehicles with indivisible loads that cannot be readily reduced in weight are able to obtain Overweight Vehicle Permits over specific routes as well as area-wide permits for up to two years. Given the payload on these vehicles are known and indivisible, the risk of overloading is considerably lower than for normal freight vehicles. As such, Overweight vehicles are assessed using a live load factor of 1.49 compared with posting load factors of 1.90 for normal Class 1 vehicles in the NZ Transport Agency Bridge Manual.

Since 2010, High Productivity Motor Vehicles (HPMV's) with divisible loads have also been able to obtain HPMV permits on specific routes for up to two years. Given the increased risk of overloading of these general freight vehicles, they are assessed in the same way as legal Class 1 vehicles using a live load factor of 1.90.

2 RAKAIA RIVER BRIDGE

2.1 *Structural form*

The Rakaia River Bridge is located on State Highway 1S (SH1S) within the South Island of New Zealand just north of the Rakaia township. The bridge was constructed circa 1939, and comprises a two lane reinforced concrete T-beam superstructure, supported on reinforced concrete columns and pile caps, founded on driven reinforced concrete piles, as illustrated in Figure 1 below.

Figure 1. View of Rakaia River Bridge showing structural form

At 1.76 km long, the Rakaia River Bridge is the longest bridge in New Zealand, and consists of 144, 40 foot (12.2 m) spans. The bridge has expansion joints in the form of split piers generally every 5 spans. The bridge is currently managed by Opus International Consultants Ltd (Opus) as part of the Canterbury and West Coast Bridge Management Contract.

2.2 *Capacity*

Previous assessments of the Rakaia River Bridge indicated that it was under-capacity for supporting Full HPMV loading. Given the length of the Rakaia River Bridge, the cost of strengthening the bridge to support HPMV loading was estimated at over $10 M (NZD). Therefore, the NZ Transport Agency and Opus proposed allowing the bridge to operate at slightly higher stresses, as allowed for within Section 7.4.3 of NZ Transport Agency Bridge Manual (the Bridge Manual). Due to the size and value of this bridge, Opus developed a Structural Response Monitoring (SRM) system to give further confidence that the bridge could sustain the increased loads, and provide an early warning system to protect the bridge from progressive damage. This included a range of conventional bridge monitoring and testing techniques, such as visual inspections, material testing, crack monitoring and survey levelling; as well as more advanced monitoring systems using accelerometers, displacement transducers, vehicle weigh-in-motion testing, advanced bridge model calibration, and concrete condition assessment. Details of the development of this SRM system have been the subject of past papers (Waldin et al 2017, 2015) and hence will not be covered in detail within this paper.

3 OPTIMISATION TECHNIQUES

3.1 *General*

Given the ongoing increase in live loads on New Zealand roads and the desire to extend the life of structures to avoid major replacement costs; there is a strong desire to utilise modern techniques to optimise the assessed load capacity of bridges to avoid conservatively restricting vehicle movements or requiring replacement of structures. Many reinforced concrete T-beam structures built prior to 1942 are still in reasonable condition, as is the case for the Rakaia River Bridge. These structures have also been shown to have very low fatigue risk given their detailing and the relatively low traffic volumes on most New Zealand Highways. As such, serviceability limits are often not deemed to be critical for this form of structure, and ULS assessment becomes the limiting criteria. As such, this paper focusses solely on the ULS capacity of reinforced concrete T-beam bridges.

The NZ Transport Agency Bridge Manual requires the calculation of a GROSS live load assessment of critical members to determine whether a bridge can support normal highway loads, as outlined in equation 1.

$$GROSS = \frac{\phi Mn - \gamma_D \times M_{DL} - \Sigma\left(\gamma\left(OtherEffects\right)\right)}{\gamma_L \times M\left(PostingLoadEffect\right) \times I} \qquad (1)$$

To avoid conservatism and ensure the optimal capacity of a bridge is achieved, each factor of this formula can be reviewed and assessed in detail. This includes review of material strengths and member capacities (ϕMn); load factors for dead and live loads (γ_D and γ_L); dead load demand (M_{DL}); live load demands ($M_{Posting\ Load\ Effect}$); impact loading ($I$); and analysis techniques used to calculate the distribution of loads into critical members.

3.2 *Material Strength*

The strength of key materials such as reinforcing steel and concrete are typically taken as the lower 5th percentile based on material testing. Material strengths used for assessment are usually taken from figures specified on design drawings, or conservative values based on the era that a bridge was constructed. Testing of actual materials in a structure can result increases in strength, improving the assessed capacity of a structure. To further reduce the statistical variation of tested samples, the standard error of a group of bars or members can be considered where these act together in a structure (see Addendum 7A of the Bridge Manual for further details).

For the Rakaia River Bridge, Opus Research undertook non-destructive steel leeb hardness testing on 18 samples to derive the yield strength of the reinforcing steel. The average yield stress of the reinforcement was calculated as 288 MPa, compared with a previously assumed value of 250 MPa. Statistical assessment indicated that the lower 5th percentile yield strength for the whole sample set was 263 MPa for a single bar, and 280 MPa for a group of 12 reinforcing bars at the mid-span of the beams.

Concrete core samples were also taken and crushed to determine the material properties of the concrete. Concrete compressive strength results for the Rakaia River Bridge were highly variable, ranging from 17.0 – 62.0 MPa with an average of 35.7 MPa. This was likely due to the variability in the quality of materials and the quality of construction and compaction of the concrete. Samples with rounded greywacke aggregate were identified in three of the sample spans, and exhibited lower strengths. Samples with crushed greywacke aggregate were identified in the other two sample spans, and exhibited considerably higher strengths. Statistical assessment of the sample set in accordance with Section 7 of the NZ Transport Agency Bridge Manual was not considered appropriate as this yielded lower 5th percentile capacities below zero MPa. This is due to the concrete strength not being normally distributed. As such, the lowest tested capacity of 17MPa was considered an acceptable lower bound capacity for assessment purposes. In future, consideration should be given to altering the statistical figures in the NZ Transport Agency Bridge Manual to reflect that materials are typically more accurately represented by log-normal distributions rather than the current normal distribution figures shown.

3.3 *Member Capacities*

Modern analysis techniques generally provide very accurate assessment of the capacity of structural members. However, assumptions are often made to simplify assessments such as ignoring the effects of kerbs or upper reinforcing steel in the capacity assessment of reinforced concrete beams. By including these in the structural assessment, small gains in the assessed capacity can be achieved.

For the Rakaia River Bridge, the contribution of upper reinforcement was ignored, as recommended by the NZ Transport Agency Bridge Manual. However, a contribution from 50% of the kerbs was incorporated in the capacity assessment, as allowed for in the Bridge Manual. This increased the overall mid-span moment capacity of the superstructure by 10%.

3.4 *Boundary Conditions*

Boundary conditions at the end of members can play a significant part in the assessment of capacity. In particular, fixity at the end of spans will significantly reduce the mid-span bending moments. However, this can have a detrimental effect with additional hogging load occurring at beam ends.

For the Rakaia River Bridge, load testing indicated that the beams were exhibiting significant continuity over the spans, despite being designed to act simply supported with no steel continuity across the piers. This was due to monolithically placed concrete causing a propping force at the base of the beams. This has a significant effect on the bridges performance under service loads, with mid-span bending moments being only around half of those expected from simply supported beams. However, it is unknown whether these boundary conditions would continue under ULS loads, as excessive stresses at the base of the beams may result in failure of concrete sections, with the beams reverting to behaving simply supported. As such, the beams have been assessed to act simply supported under ULS loads, with an advanced monitoring system installed to provide a trigger for damage at the beam supports as an early warning system. The details of this system are provided in previous papers on this subject (Waldin et al 2017, 2015).

3.5 *Dead Load Demand and Load Factor*

Dead load demand is typically calculated using member and surfacing dimensions from as-built or construction drawings and typical material densities. In New Zealand, the density of reinforced concrete is commonly assumed to be 2400 kg/m3, however this can increase where the steel reinforcement ratio is high and reduce for lightweight concrete. Steel density is commonly assumed to be 7850 kg/m3 and surfacing is commonly assumed to weigh 2000 kg/m^3.

Site measurements, sampling and density testing can be undertaken to further refine the dead load demand. Section 7 of the NZ Transport Agency Bridge Manual also allows the ULS dead load factor to be reduced to as low as 1.10 where member dimensions are measured on site and density is verified. The Bridge Manual does limit the total load factor on all gravity effects to no lower than 1.25. However, if a statistical assessment of the variability of dead load is undertaken, this load factor could potentially be reduced below this value.

For the Rakaia River Bridge, no detailed measure up or density testing was undertaken as the cost of this was relatively high given the small gains in assessed capacity that may be achieved.

3.6 *Live Load Demand*

Load demand assumptions are typically based on a simplified load model which is used to represent a stream of legal vehicles. As these are based on averages used to represent a wide range of spans and structural forms; these will be inherently conservative and unconservative for some structures. As such, more accurate load demand models can be developed based on a stream of legal loads run across a particular bridge.

In New Zealand, the NZ Transport Agency Bridge Manual represents a stream of legally configured Class 1 vehicles as 85% of the Highway Normal (HN-72) design loading. HPMV's are represented by 90% of the HN-72 envelope for spans less than 25 m and 95% HN-72 for spans greater than 25 m. This is known to be unconservative for certain span ranges, particularly for shear effects in longer span bridges. However, statistical analysis has shown that when combined with the high design live load factors in the Bridge Manual, these load models provide an appropriate reliability index (Goodall & Hobman 2011). For span lengths less than 7 m, these load assumptions are generally conservative and over-estimate effects from legally configured vehicles.

For the 12.2 m spans of the Rakaia River Bridge, the critical mid-span moment effects from a stream of High Productivity Motor Vehicles is equivalent to 91% HN-72. Shear effects from HPMV's are equivalent to 89% HN-72. Therefore, the 90% HN-72 representation adopted in the Bridge Manual is very appropriate for this span range.

3.7 *Live Load Factor*

Live load factors used in modern design codes are typically generated through statistical reliability analysis. These utilize reliability factors, often termed beta factors (β), to calculate the probability of failure of an element over the design lifetime of a structure. β can be thought of as representing the number of standard deviations from the mean for a normally distributed data set, and takes into account variability in member capacity as well as load effects from streams of heavy vehicles. Member capacity is typically symbolized by R for resistance, with load effects symbolized by Q, as illustrated in Figure 2.

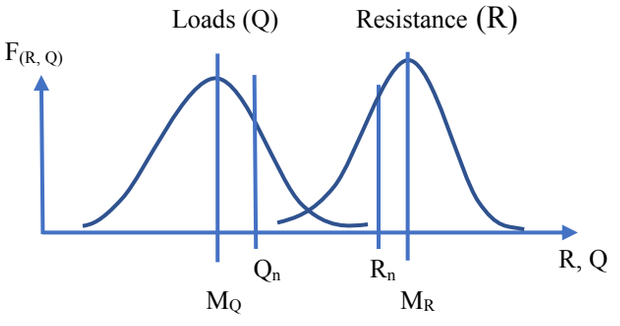

Figure 2. Distribution of load and resistance of a structure

M_Q and M_R represent the mean of the load effects and resistance, with Q_n and R_n showing the nominal load and resistance used for design. The failure point is located at the intersection between the load and resistance curves, with load factors set at an appropriate level to ensure the probability of failure is reliably low.

The statistical distribution of the difference between the resistance and capacity is shown in Figure

3. M_{R-Q} represents the mean of the difference between the resistance and load effects, with β representing the number of standard deviations from the mean to the point of failure where the load effects exceed the resistance of a critical member.

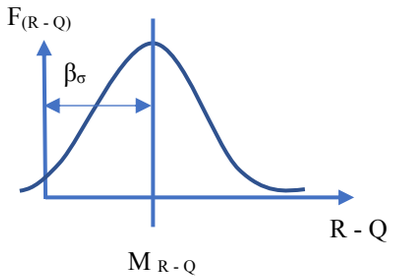

Figure 3. Distribution of difference between resistance and load on a structure.

Equation 2 indicates how beta factors are calculated with m_R and m_Q representing the mean of the resistance and maximum load effects, and σ_R and σ_Q representing the standard deviation of the resistance and the maximum load effects respectively.

$$\beta = \frac{m_R - m_Q}{\sqrt{{\sigma_R}^2 + {\sigma_Q}^2}} \quad (2)$$

Equation 3 shows the full beta factor calculation utilising the mean and standard deviation of various vehicle and material parameters. Further details on this formula can be found in the National Cooperative Highway Research Program report NCHRP 20-7/186 (Kulicki et al 2007), commissioned by the American Association of State Highway and Transportation Officials (AASHTO).

$$\beta = \frac{R_n \times \lambda_R \times (1 - k \times V_R) \times [1 - \ln(1 - k \times V_R)] - m_Q}{\sqrt{[R_n \times V_R \times \lambda_R \times (1 - k \times V_R)]^2 + {\sigma_Q}^2}} \quad (3)$$

Design load factors used in the NZ Transport Agency Bridge Manual have been checked against a desirable beta factor (β) greater than or equal to 3.5 (Goodall & Hobman 2011) assuming a design life of 100 years. A target β of 3.5 aligns with AASHTO's Load Resistance Factor Rating (LRFR) Bridge Design Specifications (Kulicki et al 2007)) and represents a probability of failure of 0.00023 over the design life, which is assumed to be 75 years in the AASHTO LRFD load factor calculations. This equates to a likelihood of failure of 1 in 4350 over the life of a structure.

Various international design codes also reference a minimum beta factor of β = 2.5 being acceptable for the assessment of structures in operation where risk is appropriately addressed through inspection and confirmation of a ductile failure mechanism or redundant load path. A beta factor of 2.5 represents a probability of failure of 0.0064 or a likelihood of 1 in 160 over the life of a structure. This is considered appropriate given existing bridges have more well defined live load effects than is the case at the outset of the design of a new bridge. Also, the incremental cost of a higher beta factor and higher load factors is relatively low for new bridges. However, the cost associated with conservatism in load factors for an older structure can be very high if it requires major strengthening works to take place. Beta factors of 2.5 also roughly align with the reliability factor for many existing bridges designed using the old Load Factor Rating (LFR) assessments prior to the adoption of Load Resistance Factor Rating (LRFR).

Table 1 outlines the live load factors specified in various bridge design codes for normal highway loading. As shown, the design and assessment live load factors used in the New Zealand Transport Agency Bridge Manual are relatively high compared with international bridge design and assessment codes.

Table 1. Distribution of difference between resistance and load on a structure.

Country and Code	Phase	Live Load Factor	Comments
New Zealand (NZTA Bridge Manual SP/M/022 3rd Ed. 2013 incl. 2016 amendments)	Design	1.84 – 2.25	Reduced from 2.25 for lightly trafficked rural roads.
	Assessment	1.75 – 1.90	Reduced from 1.90 for single restrictive bridges on key routes with ductile failure mechanisms.
Australia (AS 5100 2017)	Design	1.80	
	Assessment	1.60 – 2.00	Varies based on vehicle type.
Canada (CSA S6-2014 incl. 2017 amendments)	Design	1.70	
	Assessment	1.35 – 1.70	Varies with ductility, redundancy and inspection type.
United States of America (AASHTO LRFD; AASHTO annual for Bridge Evaluation)	Design	1.80 – 2.43	Varies with ductility, redundancy, importance and traffic volume.
	Assessment	1.40 – 1.80	Varies with traffic volume.
United Kingdom (BD 37/01; BD 21/01)	Design	1.65	Includes 1.10 factor for assessment inaccuracies.
	Assessment	1.65	Includes 1.10 factor for assessment inaccuracies.

Although the Bridge Manual does not specifically provide guidance around further reduction in load factors due to statistical assessment, reliability analysis and risk of failure; guidance from the Canadian and American design standards (CSA S6-2014 and AASHTO LRFD) could be considered where appropriate.

AASHTO's LRFD utilizes lower load factors for bridges with lower Annual Average Daily Traffic (AADT) given their statistical risk of overload is lower. This approach has not been adopted in New Zealand as lower volume roads are considered to have a higher risk of vehicle overloading given their more remote locations and reduced presence of enforcement and weigh stations. However, lower live load factors for assessment could be considered as a structure approaches end of life given the reduced likelihood of an extreme overload event. At present, this approach is not generally adopted within international bridge assessment codes, probably because reduced remaining life only has a relatively small probabilistic effect on load factors.

The Opus Report "Development of Bridge Design Loading for HPMV's" (Goodall and Hobman 2011) indicated that although moment and shear effects from HPMV's can exceed the theoretical 0.90 and 0.95 HN-72 design load envelopes; the design live load factor of 2.25 in the Bridge Manual was sufficiently large to ensure beta factors greater than 3.5 were still achieved for all typical bridge span ranges. For simply supported bridge spans less than 35 m, HPMV load effects were well modelled by the 0.90 and 0.95 HN-72 load envelopes and beta factors are generally well in excess of 3.5. This indicates that the current design live load factor of 2.25 used in the NZ Transport Agency Bridge Manual could potentially be reduced for simply supported bridge spans less than 35 m long.

3.8 *Bridge Specific Live Load Factor*

By using the Weigh-in-Motion data from the Rakaia River Bridge, a bridge specific live load factor was able to be developed. This was done using similar methods to the Opus Report "Development of Bridge Design Loading for HPMV's" (Goodall and Hobman 2011) and AASHTO's LRFD. Vehicles heavier than legal Class 1 loading were classified as either HPMV's or overweight vehicles based on their axle mass and configurations. The ratio of their load effects over the 12.2 m simply supported spans on the Rakaia River Bridge was then compared to the maximum load effects from legally configured Class 1 vehicles. These load effects were calculated from 12 months of Weigh-in-Motion data and plotted on a log-normal graph shown in Figure 4.

The data was then statistically extrapolated from 12 months to estimate the expected maximum load effects over a 20 year and 100 year period assuming 2.5% annual growth of heavy vehicles over this route. For more background on this extrapolation process, see NCHRP report 20-7/186 (Kulicki et al 2007). This statistical extrapolation is considered highly accurate compared with other international studies that have typically only used a few weeks of heavy truck data to extrapolate maximum predicted load effects over a 75 – 100 year design life.

Figure 4 indicates that the average (mean) maximum load effects over the 12.2m simply supported spans on the Rakaia River Bridge are expected to be 152% of the legal Class 1 load effects over a 100 year period. This is equivalent to 142% of HPMV load effects. The standard deviation of this 100 year maximum is estimated to be 0.167 based on the slope of the CDF curve. The mean maximum load effect over the estimated 20 year remaining life of the bridge are 140% of Class 1 effects and 131% of HPMV Effects.

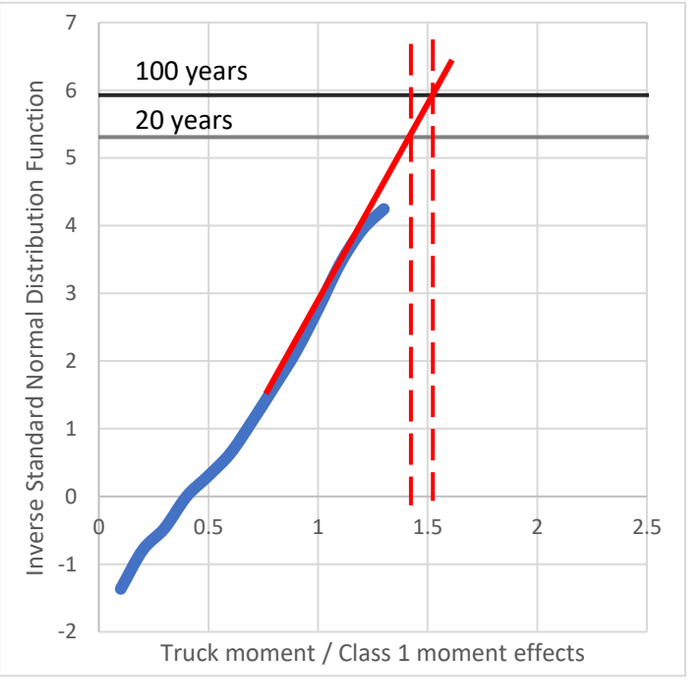

Figure 4. Extrapolated Cumulative Distribution Function of simply supported moment for trucks from Rakaia Weigh-in-Motion data from August 2016 – 2017.

Statistical analysis of permitted overweight vehicles provided a slightly higher mean maximum load effect of 175% of Class 1 load effects extrapolated over a 100 year period. However, overweight vehicles are well defined, indivisible loads with route specific permits. These are permitted using reduced load factors of 1.49 due to the significantly reduced risk of overloading. Over the Rakaia River Bridge, permitted overweight vehicles can reach load effects up to 120% of Class 1 load effects in their own lane, or over 200% Class 1 load effects for central travel at reduced speed. There is no definitive indication of any level of overloading of permitted overweight vehicles from the WiM data. As such, permitted overweight data has been removed from the WiM data to avoid skewing the data.

Parameters for the variability in material strengths in reinforced concrete bridges were calculated based on the material testing results from the Rakaia River Bridge. Table 2 indicates these parameters in comparison to the figures from NCHRP report 20-7/186 (Kulicki et al 2007). This indicates the material variability of the Rakaia River Bridge was similar, but slightly less than the average data sets used in NCHRP report 20-7/186. λ represents the bias between the nominal capacity and the mean and V represents the coefficient of variation.

Table 2. Bias and coefficient of variation for materials, fabrication and overall resistance of reinforced concrete bridges.

	Material and Fabrication Factors, F M		Professional Factor, P		Total Resistance, R	
Case Study	λ	V	λ	V	λ	V
NCHRP Report 20-7/186 Data for RC Bridges	1.12	0.12	1.02	0.06	1.14	0.13
SH1S Rakaia River Bridge	1.08	0.08	1.02	0.06	1.10	0.10

If a suitable beta factor is selected, the value of the resistance (Rn) and an appropriate live load factor can be calculated using Equation 3. Table 3 shows bridge specific live load factors for various design and assessment scenarios. The material capacity reduction factor (ϕ) could also be removed from the expected member resistance, further reducing the calculated live load factor. However, for the 144 span Rakaia River Bridge, this was still used given the number of spans increases the statistical risk of a weaker span reaching yield due to being overloaded.

Table 3. Bridge specific live load factors based on Weigh-in-Motion and material data from the Rakaia River Bridge.

Phase	**Remaining Life**	**Assumed Beta Factor**	**Calculated Live Load Factor**
Design	100 years	3.50	2.11
Assessment	100 years	2.50	1.84
Assessment	20 years	2.50	1.72

3.9 *Impact Factor*

The NZ Transport Agency Bridge Manual defines impact as outlined in Equation 4.

$$I = 1 + \frac{15}{L + 38} \tag{4}$$

Equation 4 applies to moment effects in simple or continuous spans and is capped at a maximum of 1.30. Moment in cantilevers, deck slabs, and shear effects are set at a constant value of 1.30. The Bridge Manual uses this same design impact factor for assessment. Given it is intended to represent an upper 5th percentile of impact loads, it may be considered conservative for certain structural forms.

For the Rakaia River Bridge, test loading of the bridge spans using a known load at various speeds indicated a maximum impact factor of 1.18. The fundamental frequency of the bridge beams was also measured and indicated that typical heavy vehicle speeds would need to be in excess of 130 km/hour to initiate resonance in the spans, and this is considered highly unlikely for heavy vehicles on this narrow bridge. This therefore reduces the likelihood of impact factors reaching the level of 1.3 specified in the Bridge Manual.

Considerably more vehicle runs are still required to give the test results more statistical accuracy. However, initial results indicate that the impact load factor in the Bridge Manual is likely to be conservative for this bridge form, and an impact factor of around 1.20 is likely to be more appropriate for this bridge.

3.10 *Structural Analysis*

Reinforced concrete T-beams were typically designed using simple load distribution models such as Courbon's method. The distribution of load within beams can now be more accurately assessed using the more sophisticated empirical methods in the latest AASHTO LRFD Design Code, or through a grillage or Finite Element model.

Assessment of the Rakaia River Bridge was undertaken using a grillage model in Microstran. This model was calibrated based on material testing and measurement of actual span behavior under loading, allowing it to be more accurately calibrated. This provided improvements in the assessed load spread through the superstructure resulting in an increase in the assessed load capacity of around 10%.

4 OPTIMISED CAPACITY

As outlined in Section 3, by refining both the capacity and the load demand on a structure, a significant increase in a bridge's assessed capacity can be achieved. Table 4 shows the effect that more detailed analysis of these parameters had on the assessed capacity of the Rakaia River Bridge, with the overall assessed capacity increasing from 65% Class 1 to 110% Class 1. Along with a sophisticated real-time monitoring system, this allowed the bridge to be opened to HPMV loading without the need for costly strengthening, saving the asset owner over $10 M in strengthening costs.

As well as the outcomes for the Rakaia River Bridge, a parametric study of 30 other reinforced concrete T-beams in New Zealand was undertaken. This study was used to provide information on the typical

range of improvements that can result from review of various capacity and loading inputs. The results of this study are also shown in Table 4.

Table 4. Typical variation in resistance and load parameters for reinforced concrete T-beam bridges following more detailed assessment and testing.

Parameter	Change after Rakaia Assessment	Effect on Rakaia GROSS Capacity	Typical Effect on GROSS Capacity of RC T-Beams
Steel Strength (fy)	+12%	+18%	0 – +20%
Concrete strength (f'c)	0% (no change)	0% (no change)	0 – +5%
Upper reinforcement	-	-	+2 – +4%
Integral kerbs	-	+10%	+5 – +15%
Boundary Conditions	*	*	*
Dead Load Demand (M_{DL})	0% (no change)	0% (no change)	0 – +5%
Dead Load Factor (γ_{DL})	0% (no change)	0% (no change)	0 – -15%
Live Load Demand (M_{LL})	-1%	-1%	-5% - +10%
Live Load Factor (γ_{LL})	+10%	+10%	-5% - +35%
Impact Loading (I)	-8%	+8%	0 – +20%
Structural Analysis	+10%	+10%	0 – +15%

* Although boundary conditions can play a significant part in assessed capacity, it is often difficult to prove that an assessed condition will remain when subject to ULS loads.

As outlined in Table 4, the most significant increases in assessed live load capacity of older reinforced concrete bridges can generally be achieved through testing of the steel reinforcement, incorporation of previously ignored structural components such as integral kerbs and upper reinforcing steel, refinement of the dead and live load factors, and more detailed structural analysis. Where the assessed ULS capacity of a bridge is still limiting the movement of heavy vehicles, review of other parameters can be undertaken to further refine the accuracy of an assessment. Although detailed truck data is often not available for a bridge, the beta and live load factor information in Section 14 of the Canadian Bridge Design Code (CSA-S16-2014) provides good guidance around reducing assessment load factors based on risk of failure. A similar approach could be considered for New Zealand road bridges. Alternatively, the Rakaia River Bridge assessment indicates that a live load factor of 1.75 could be considered for the assessment of all existing New Zealand bridges provided certain risk criteria are met.

5 CONCLUSIONS

In conclusion, the rate of significant bridge strengthening and replacements are predicted to increase significantly over the next 10-15 years. To ensure the rate of replacement and improvements is manageable, it is important for asset managers to optimise the assessment of bridges.

A detailed analysis of various capacity and load parameters was undertaken for the Rakaia River Bridge to optimise the bridges assessed live load capacity. The most significant gains in capacity were achieved through steel reinforcement testing, more detailed structural analysis calibrated with field testing, and the development of a bridge specific live load factor and impact factor. In particular, the design and assessment live load factors used in the NZ Transport Agency Bridge Manual have been shown to be relatively high compared to other international standards. This provides an opportunity for reduction in the load factor where it can be shown that the risks are effectively managed and at a level that is acceptable to the asset owner.

By refining both the capacity and the load demand of the Rakaia River Bridge, the bridges theoretical capacity was increased from 65% to 110% Class 1. Along with a sophisticated real-time monitoring system, this allowed the bridge to be opened to HPMV loading, saving the asset owner over $10 M in strengthening costs.

Performance of prestressed concrete girder in ultimate bending for AS5100:2004 and AS5100:2017

M.M. Melhem & C. Caprani
Department of Civil Engineering, Monash University, Victoria, Australia

M.G. Stewart
Centre for Infrastructure Performance and Reliability, University of Newcastle, New South Wales, Australia

ABSTRACT: In 2017, AS5100, the Australian standard for bridge design and assessment, underwent significant updates from the previous 2004 edition. While the assessment methods remain similar, the design methods for prestressed concrete bridge components, which are required for their assessment, have significantly changed. It is then of interest to determine the implications of the changes. To do this, the performance of an already-constructed Super-T girder is assessed for ultimate strength in bending. Using the deterministic method prescribed by the code, the performance requirement is not met using the current code, whereas it is met using the 2004 superseded code (the code used for its design). From this, it is apparent that reliability analysis could play a very useful role in assessing such bridges. Consequently, a reliability analysis is conducted and it is found that both codes give indices significantly higher than an accepted target reliability index. It is concluded that the level of conservatism of AS5100 should be further investigated.

1 INTRODUCTION

1.1 *Measuring Structural Performance*

Structural performance is commonly described as the ability for a structure to fulfil certain criteria (Cremona, 2013). Often, structural performance and structural safety are thought as the same measure. Indeed, this is the case if the criteria considered is the structural integrity. However, for bridge structures other requirements exist such as limits on deflection and prevention of concrete cracking. Hence, measurement of the performance of bridge structural components is more generally appropriate.

Traditionally, the performance assessment of bridge components is based on a combination of field test data and expert opinion (Akgul & Frangopol, 2003). Bridge ratings provide a quick, efficient and thus economical measure of bridge performance. However, ratings contain uncertainty as input parameters are subject to randomness and so may not reveal the true performance level. The use of a probabilistic approach can consider these uncertainties. Nowadays, bridge standards such as the American, Canadian, Danish, Swiss and British codes have moved away from traditional deterministic load rating processes and also allow the use of reliability analysis for bridge performance assessments (Wisniewski *et al.*, 2012). One international standard that is yet to adopt this change is the Australian bridge standards (AS5100).

1.2 *Australian Bridge Standards (AS5100)*

AS5100 is the Australian standard for the design of new bridges and assessment of existing bridges. In the 2004 edition, the code comprised of seven parts. Part 1 outlines the scope and design life of 100 years. Part 2 details the design load models and associated factors. Part 5 and Part 6 are used for the design of concrete and steel components, respectively. Part 7 details the procedures for the assessment of existing bridges.

In early 2017, the entire code underwent a significant revision. The latest revision included updated Parts 1 to 7, and the inclusion of new parts; Part 8 for rehabilitation and strengthening of existing structures, and Part 9 for new timber bridges (Pritchard, 2017a).

Although AS5100.7 (Bridge Assessment) has been considerably revised, the fundamental process remains the same as the superseded 2004 code (Pritchard, 2017b). Both codes infer the use of bridge ratings as the first-basis performance measure for capacity. Unlike the other international design codes, the use of reliability analysis for performance assessment of bridge components is not facilitated.

Both superseded and current codes indicate that the structural capacity of existing components is to be determined using the relevant design standards. For prestressed concrete (PSC) components, the applicable standard is AS5100.5 for concrete bridges.

Some significant changes between AS5100.5:2004 and AS5100.5:2017 exist (Hilton, 2017). Notably, in AS5100.5:2017 modified compression field theory is adopted for the shear and torsion design. Additionally, models for quantifying prestress losses are updated to better consider higher concrete grades. More minor updates include those of material properties for concrete, steel reinforcement, and strands, and the parameters for the simplified concrete stress block under ultimate strength in bending. Many updates are such that they match those found in the concrete code for building structures (AS3600:2009).

1.3 *Motivation*

There is no indication that the 2017 updates to AS5100 were made with any reliability basis or calibration. Consequently, the performance assessment of existing PSC bridge components designed to the superseded code may be different if assessed under the current code. If this is the case, then the performance levels of bridges designed and built under the 2004 code will differ from those to be designed and built from 2017. This could have implications for future management of these structures.

To investigate the code-implied performances, an already-constructed Super-T girder is assessed for flexural strength. Super-T girders are standard precast bridge girders used in Australian and New Zealand practice. The performance criteria (limit state) considered is ultimate strength in bending. The assessment is carried out two ways: applying the methods indicated by AS5100.7 (deterministic), and performing a reliability analysis (probabilistic). Both the 2004 and 2017 editions of the code are considered in this way. From these results, the AS5100 deterministic method of assessment is compared with probabilistic methods. Additionally, the implications of changing the AS5100.5 design rules, without changing the AS5100.7 assessment rules that rely on AS5100.5 can be inferred.

2 BRIDGE GIRDER DESIGN

The representative bridge girder in this study is one of five simply-supported PSC Super-T girders from a bridge deck spanning 33.5 m, previously studied in Caprani *et al.* (2017). The girder is 1500 mm deep (designation T4) and the outermost girder in the bridge deck, as this is the most heavily loaded. The design geometric properties and concrete properties of the girder are shown in Table 1.

The PSC girder is pretensioned with 56 No. 15.2 mm diameter 7-wire strands. The design requires each strand to be prestressed to 188 kN (P_j) and arranged within the girder as shown in Figure 1. The material properties for the strands in accordance to AS5100.5 (both editions) are shown in Table 2.

Table 1. Representative Girder Properties

Property	Symbol	
Compressive Strength (N/mm^2)	f'_c	65
Young's Modulus (kN/mm^2)	E_c	37.4
Gross Cross-Section Area ($\times 10^3$ mm^2)	A	934
Second Moment of Area ($\times 10^6$ mm^2)	I	348
Top fibre to section centroid (mm)	y_t	634

Table 2. Prestressing Strands Material Properties

Property	Symbol	
Strand cross-section area (mm^2)	A_p	143
Breaking strength (N/mm^2)	f_{pb}	1830
Young's Modulus (kN/mm^2)	E_p	195

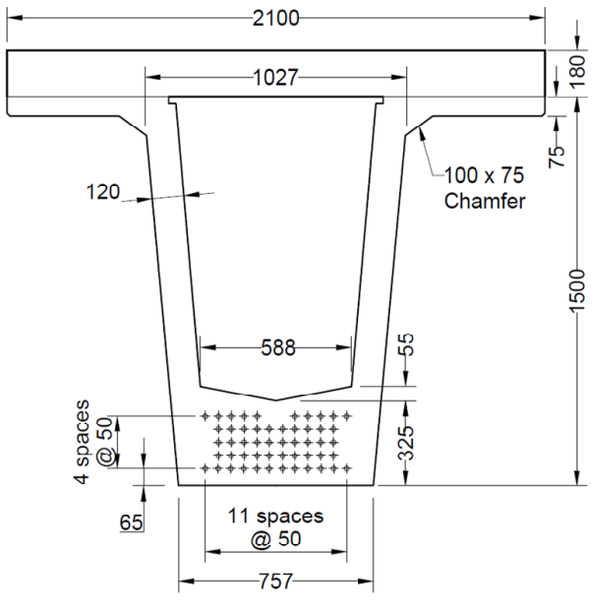

Figure 1. Strand arrangement of 56 No. 15.2 mm diameter 7-wire strands and dimension for representative girder including 180 mm *in-situ* overlay slab.

3 PERFORMANCE BY CODE

3.1 *Assessment Procedure*

In accordance to AS5100.7 (both years), the assessment of existing bridges involves determining the load rating factor (*RF*) for a given limit state, where the rating factor is expressed as:

$$RF = \frac{\text{Available capacity for traffic load effects}}{\text{Load effects of nominated rating vehicle}} \quad (1)$$

If the limit state considered is ultimate strength in bending, then the *RF* becomes:

$$RF = \frac{\phi M_R - M_D}{M^* - M_D} \quad (2)$$

where M_R is the nominal moment capacity; M^* the design moment (induced by non-traffic and the nominated rating vehicle, including all relevant factors); M_D is the design moment from all non-traffic loads (including relevant load factors); and ϕ is the capacity reduction factor. If $RF < 1$, then the bridge performance is deemed unsatisfactory.

3.2 *Loading Calculation*

Dead, superimposed dead, and traffic loads are considered for this work. The dead loads are the self-weight of the Super-T girder and a 180 mm *in-situ* concrete overlay slab. Asphalt surfacing and non-structural precast concrete edge barriers constitute the superimposed dead load (Caprani *et al.*, 2017). For traffic loads, the M1600 load model is critical and used in accordance with AS5100.2 (both years).

The bridge deck is modelled using a beam-and-slab grillage analysis, accounting for torsional stiffness of the elements. The design maximum ultimate bending moment (M^*) for the representative girder is obtained applying the relevant load factors, dynamic load allowance, and accompanying lane factors as specified in AS5100.2. As there are no differences in these factors between the 2004 and 2017 editions, M^* is the same for both codes. The design moment from all non-traffic loads (M_D) is also obtained for Equation 2. Maximum nominal values (load factors omitted) are obtained for later use in the reliability analysis. All these moment values are shown in Table 3 (Caprani *et al.*, 2017).

Table 3. Maximum bending moments for considered load components.

Load Component	Symbol	Moment (kNm)
Super-T Girder Self-Weight	M_i	2068
Girder + Overlay Slab	$M_i + M_{slab}$	3430
Superimposed Dead Load	M_{sdl}	869
Design Non-Traffic Load	M_D	5854
Traffic Load *	M_L	5154
Design ULS Load Combinations	M^*	14317

*includes dynamic load allowance and accompanying lane factors

3.3 *Capacity Calculation*

As indicated previously, the ultimate capacity of an existing concrete structure is to be estimated using AS5100.5. For ultimate strength in bending, both codes state to apply the following assumptions: (i) plane sections remain plane; (ii) concrete has no tensile strength; (iii) the distribution of compressive stress of the concrete is approximated by a rectangular stress block, and; (iv) the maximum compressive reinforcement strain does not exceed 0.003. These assumptions are depicted in Figure 2.

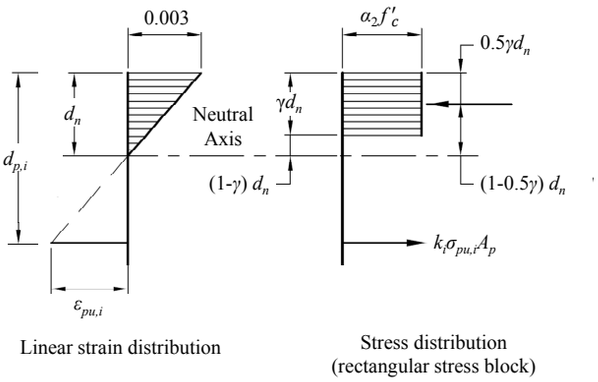

Figure 2. Strain and stress distribution assumption for ultimate bending for AS5100.5 (both editions). Concrete under compression and each row i of strands (out of n rows) are under tension. (Adapted from AS5100.5:2004).

Based on these assumption, the ultimate moment capacity (M_R) can be found from the sum of moments about the top fibre: the positive moment from the prestressed strands in tension (M_p) and a negative moment from the concrete in compression (M_c):

$$M_R = M_p - M_c \quad (3)$$

where:

$$M_p = \sum_{i=1}^{n} k_i \sigma_{pu,i} A_p d_{p,i} \quad (4)$$

in which k_i is the number of strands in row i of n rows and $d_{p,i}$ the depth from the top fibre to the centroid of the row of strands i. The ultimate stress of the strands in each row, $\sigma_{pu,i}$ is determined from strain compatibility. In general:

$$\sigma_{pu,i} = \min\left[f_{py}, \left(\varepsilon_{pe,i} + \varepsilon_{e,i} + \varepsilon_{u,i}\right) E_p \right] \quad (5)$$

where f_{py} is the yield stress of the strands, and the, prestress, decompression, and ultimate strains are:

$$\varepsilon_{pu,i} = \frac{P_j - \Delta P}{E_p A_p} \quad (6)$$

$$\varepsilon_{e,i} = \frac{k_i \left(P_j - \Delta P\right)}{E_c} \left(\frac{1}{A} + \frac{\left(d_{p,i} - y_t\right)^2}{I} \right) \quad (7)$$

$$\varepsilon_{u,i} = 0.003 \left(\frac{d_{p,i} - d_n}{d_n} \right) \quad (8)$$

Finally, the moment due to the compression block is:

$$M_c = \alpha_2 f'_c b \left(\frac{\gamma d_n^2}{2} \right) \quad (9)$$

where d_n is the depth from the top fibre to the neutral axis at ultimate, and b is the width of the top fibre.

In the parameters of the above equations there are three differences between AS5100:2004 and AS5100:2017 which are detailed next.

3.3.1 *Parameters for Rectangular Stress Block*

The parameters α_2 and γ for the rectangular stress block as shown in Figure 2 vary. For AS5100:2004, $\alpha_2 = 0.85$, and $\gamma = 0.85 - 0.007\ (f'_c - 28)$ with limits of 0.65 to 0.85. In AS5100:2017 these equations and limits were revised to better consider higher concrete grades; these are $\alpha_2 = 1 - 0.003 f'_c$ and $\gamma = 1.05 - 0.007\ f'_c$, where both parameters have limits of 0.67 to 0.85.

3.3.2 *Estimation of Yield Stress*

While the material properties for the strands may be provided by the manufacturer, AS5100.5 does provide some estimates for designers and assessors. For the yield stress of the strands (f_{py}), AS5100:2004 gives it as 85% of the breaking strength (f_{pb}), whereas for AS5100:2017, it is said to be 82% of f_{pb}.

3.3.3 *Estimation of Long-Term Prestress Losses*

A significant change from the 2004 edition of AS5100.5 are the methods for estimating long-term prestress losses (ΔP) in PSC members, particularly for time-dependent losses of concrete shrinkage and creep. AS5100.5:2004 estimates losses based on experimentally derived shrinkage and creep strains multiplied by k-coefficients to consider the environment, exposed dimensions, age of first loading, and commencement of drying of the member. Additional factors are included if any steel reinforcement in present (Gilbert *et al.*, 2015).

In AS5100:2017, the equations for the k-coefficients were revised and new coefficients were introduced to better consider higher concrete grades (Gilbert, 2002). Moreover, a new 0.8 factor for creep losses estimates was included to account for a reduction due to steel reinforcement present in the member. The shrinkage strain now includes the strain due to chemical reaction of hydration (autogeneous strain) as well as the drying strain that was previously only considered in AS5100:2004. In addition, different basic shrinkage strains are now present in AS5100:2017 to better reflect the difference in aggregates types around Australia.

The representative bridge is located in a temperate inland environment (such as near Melbourne). The long-term prestress losses (immediate and time-dependent losses 30 years after transfer) are calculated using the methods in AS5100:2004 and 2017 and are expressed as a percentage of the jacking force in Table 4. It is found that the 2004 code indicates substantially greater prestress losses, compared to the 2017 edition.

Table 4. Moment capacity calculation according to AS5100:2004 and 2017.

Description	Symbol	AS5100

Stress Block Parameters	α_2	0.85	0.805
	γ	0.65	0.67
Prestress Losses (% of P_j)	ΔP	26	20
Yield Stress (N/mm^2)	f_{py}	1500	1555
Moment Capacity (kNm)	M_R	18203	17548

3.4 *Rating Factor Performance*

The calculated girder moment capacities from the two codes are shown in Table 4. It can be seen that AS5100:2004 provides a greater design capacity than AS5100:2017. Notably, this is attributed to the higher estimation of the yield stress for the strands. For both codes, the Super-T is deep enough that all strands yield at the ultimate stage, thus a ductile failure mode results. Given these large ultimate strains, the prestress losses have no effect on moment capacity.

The *RF*s calculated for the two codes are shown in Table 5. For both codes, the capacity reduction factor for ultimate strength in bending is 0.8. It is expected that $RF > 1$ for the 2004 code because the girder was designed to this code. However, for the 2017 code, $RF < 1$, suggesting if the bridge is assessed today for the M1600 load model, the bridge performance is not satisfactory and additional investigations may be required.

Table 5. Rating factor (*RF*) performance of considered PSC girder for AS5100:2004 and 2017.

	AS5100

M_D (kNm)	5854	
M^* (kNm)	14317	
RF	1.03	0.97

4 PERFORMANCE BY RELIABILITY

4.1 *Assessment Procedure*

The rating factor measure of performance used above as stipulated by AS5100.7 is deterministic. In reality, the material, geometric and load effects are

random in nature and can be described through probability distributions. The performance measure can be then expressed as the probability of satisfactorily performing a certain criteria over the design life. A reliability analysis provides the probability of this happening through a reliability index (Nowak & Collins, 2013):

$$\beta \approx \Phi^{-1}\left(1-p_f\right) \tag{10}$$

where Φ^{-1} is the inverse standard normal distribution function and p_f is the probability of failure. If $\beta < \beta_T$, where β_T is the target reliability index, then the bridge performance is deemed unsatisfactory.

Target reliability indices are the acceptable level of performance of the structure. The selection of a suitable target reliability index varies widely in literature, and depend on a many factors such as the criteria considered, the associated costs should the performance not be satisfactory, and the costs for improving performance (Stewart *et al.*, 2016). AS5104 (2017), recommends an annual $\beta_T = 4.4$ for ultimate limit states with a relative low costs for performance measures and major bridge structures. However, the design life for AS5100 is 100 years, hence when converted, $\beta_T = 3.7$ and thus is used for this assessment

4.2 *Limit State Function*

Limit state functions, $g(\cdot)$, describe the boundary between acceptable and unacceptable performance of the structure (Nowak & Collins, 2013). For this assessment, the limit state function is:

$$g = R - Q \tag{11}$$

where,

$$R = \varpi M_R \quad , \quad Q = M_i + M_{slab} + M_{sdl} + M_L$$

in which M_R is the moment capacity; ϖ is the model error; M_i is the moment induced from self-weight; M_{slab}, the moment induced from in-situ slab; M_{sdl}, the moment induced from superimposed dead loads, and; M_L, the moment induced from traffic load. All variables are now considered random in nature and independent to each other.

4.3 *Random Variable Distributions*

Distributions of random variables can be described using bias factors and the coefficients of variation (Nowak & Collins, 2013). The bias factor (λ) for a variable is the ratio of the mean to the nominal value, and its coefficient of variation (V) is the ratio of its standard deviation to the mean. Some of these statistical parameters are widely published in the literature.

4.3.1 *Loading Distributions*

Table 6 lists the distribution type, λ, and V for the load effect random variables. As detailed in Caprani *et al.* (2017), the bias factor for traffic load effects depends on the probability of exceedance, p, for the design code load model and V:

$$\lambda_L = \frac{1+r\delta}{1+rs_p} \tag{12}$$

where, $\delta = 0.5772\ldots$ is the Euler-Mascheroni constant, $r = \left(\pi/V\sqrt{6} - \delta\right)^{-1}$, and $s_p = -\ln\left(-\ln\left(1-p\right)\right)$.

In accordance with AS5100.1, an ultimate design action has a 5% probability of exceedance during its design life of 100 years. This is the same for both editions of the code. Thus p = 0.05 and therefore $\lambda_L = 0.75$.

Table 6. Distributions for random variables in limit state function (Equation 11)

Variable	Type	λ	V	Reference
M_i	Normal	1.03	0.08	[1]
M_{slab}	Normal	1.05	0.10	[1]
M_{sdl}	Normal	1	0.25	[1]
M_L	Gumbel (Type 1)	0.75*	0.18	[2]
R	Log-Normal	1.11	0.06	[2]

* based on a design life (100 year) probability of exceedance
[1] (Rakoczy & Nowak, 2013)
[2] This study

4.3.2 *Resistance Distribution*

There exists a range of published values for the resistance in ultimate strength in bending of PSC members (Akgul & Frangopol, 2004; O'Connor & Enevoldsen, 2008; Rakoczy & Nowak, 2013; Foster *et al.*, 2016). However, none of these previous studies have investigated the resistance of Super-T girders. Hence, to determine the probability distribution of R for the 2004 and 2017 editions, simulation methods are used.

Based on a thorough search of literature, Table 7 list the variables in Equations 3 to 9 that are concluded to be random in nature, together with their respective published distribution type, λ, and V. Model error (ϖ) is ratio of experimental capacity to capacity calculated using the predictive model (Figure 2). Therefore, it must be included in the limit state function to better represent reality. The distribution of model error was obtained by Foster *et al.* (2016) from a database of experimentally tested concrete members detailed in Foster *et al.* (2015).

MCS is performed using Equations 3 to 9 to obtain the final distribution type and parameters for ϖM_R as a random variable of both editions of AS5100.5, where the number of simulations (N) was 10^7. Using the maximum likelihood estimator, a log-normal distribution is found to be a suitable fit for

the resistance distribution—its statistical parameters are shown in Table 6. Although the nominal value, mean, and standard deviation varies between the two codes, their bias factors and coefficients of variation are approximately equal.

Table 7. Distributions for random variables in moment capacity (Equations 3 to 9).

Variable	Type	λ	V	Reference
f'_c	Log-Normal	1.084	0.154	[1]
ΔP	Normal	1	0.3	[2]
A_p	Normal	1	0.015	[3]

[3] (Nowak & Collins, 2013)

4.4 *Methods for Reliability Analysis*

In this study, the reliability index (β) is computed in two ways; the first-order reliability method (FORM) and MCS using importance sampling (or IS-MCS). Further details about FORM and IS-MCS can be found elsewhere in literature (Lemaire, 2009; Melchers, 1999; Nowak and Collins, 2013). Importance sampling MCS is used, rather than naïve MCS, because the probabilities of failure to be calculated are small, requiring the number of MCS to be very large ($>10^9$) for a robust result.

4.5 *Reliability Performance*

Table 8 shows the reliability indices obtained using FORM and IS-MCS, and the corresponding probability of failures (p_f) for AS5100:2004 and 2017 for the design life of the structure. The results obtained by FORM and IS-MCS are similar, giving some confidence to the results. With both methods, the reliability index is greater for 2004 code than the 2017 code. That is, the rules in AS5100:2004 indicate the girder is performing better, compared to the rules in AS5100:2007. This is a similar result to the deterministic analysis findings. However, in both cases, the reliability indices far surpass the adopted target reliability index of 3.7. Therefore, although the performances are different, they are clearly satisfactory on this measure. This is a markedly different result to the deterministic rating factor approach.

5 CONCLUSIONS

The results of this study suggest that the deterministic assessment rating factor method in AS5100 may unreasonably conclude that a structural component is unsatisfactory, if the updated code is used for estimating capacity. This may lead to unnecessary allocation of funds for higher-tier bridge assessments, or strengthening measures to ensure the performance target ($RF \geq 1$) is met. The reason for the lower RF for the 2017 code is because of the lower estimate of the yield stress of strands. Thus, it can be argued that with more precise data about these material properties and other problem variables, a more precise RF can be obtained.

Table 8. Reliability performance (β, p_f) of the girder for AS5100:2004 and 2017 for the design life of 100 years.

Measure	Analysis	AS5100	
		2004	2017
β	FORM	5.95	5.75
	IS-MCS	5.93	5.74
p_f	FORM	1.4×10^{-9}	4.6×10^{-9}
	IS-MCS	1.5×10^{-9}	4.8×10^{-9}

But what if precise material data cannot be obtained? In this case a reliability analysis can be very useful as a direct calculation of level of safety or performance. Reliability analysis considers the uncertainty present in the relevant parameters to better determine the performance of the structure. When comparing β in Table 8 to a typical acceptable level of performance ($\beta_T = 3.7$) the results show the girder far surpasses this level. With probability of failure in the order of 10^{-9}, it suggests the performance for the girder is well beyond what are considered satisfactory limits internationally. Thus, when the uncertainty and randomness of the problem variables (including model error) are considered, otherwise unsatisfactory bridge girders can be shown to be satisfactory.

The amount by which the girder passes a reasonable performance level suggests that Australian bridge components may be performing too well. Unlike other international codes, there is no indication that the 2017 update to AS5100 was calibrated to a specific target reliability. A calibrated bridge design code is especially important when the capacity estimation for assessment is based on the bridge design rules. This Australian practice is different to other international design codes where different rules apply for the assessment of existing and the design of new bridge components, e.g. Canada.

As a relative comparison between the two code editions, the reliability index is found to be greater in the superseded code. This suggests that the 2017 revisions will lead to the design of new bridge components which perform marginally less well than those designed to the 2004 edition. This unusual result could perhaps have been avoided if a reliability basis had been adopted for the 2017 edition.

The use of probabilistic methods for bridge assessment in Australia is not facilitated in the 2017 version of AS5100.7. While the 2004 edition simply focused on the use of rating factors for performance

assessment, the 2017 edition encourages the use of higher-tier assessments. However, details on what constitutes higher-tier assessments is limited. The Austroads Project TP1952 is currently investigating appropriate methods that can be used (Ng *et al.,* 2017). The early stages of this project have suggested that probabilistic methods are one feasible approach. Indeed, this study has demonstrated the potential benefits of this approach. Moreover, a Danish study has compared the cost savings probability-based bridge assessment methods have over deterministic approaches (O'Connor & Enevolden, 2007).

Whether FORM, IS-MCS, or another method is applied, use of the reliability index for assessment of structural performance is shown in this study to be a valuable alternative to bridge ratings. Although such bridge ratings may be cheap to perform, the costs associated with decisions based on these outputs can be unnecessary. Hence, it is recommended that the next revision of AS5100 should facilitate probability-based bridge assessment, most easily by specifying a target reliability index to be achieved.

ACKNOWLEDGEMENT

The authors wish to thank Mr S. Mohanakumar and Mr G. Guo for development of coding for reliability analysis, and Mr T.M.T. Lui for his grillage analysis model. This research work was completed under a Noel Murray Scholarship at Monash University and supported by the Australian Government Research Training Program Scholarship.

Coupling finite elements to model steel to concrete bond

R.J. Gravina

Polytechnic School at the University of Sao Paulo, São Paulo, Brazil

ABSTRACT: There are several bond performance tests that are commonly used for steel reinforcement in concrete namely, bar pull-out test, beam bond test, beam end bond test. Experimental testing can be time consuming and material consumption is high, hence numerical models of the bond behavior of steel bar to concrete have been developed that can provide opportunity to simulate multiple parameters efficiently and cost effectively. The numerical analysis allows for the local bond stress and slip characteristics to be determined. Local bond stress versus slip relationships are needed to be able to simulate the behavior and deformations of concrete infrastructure, such as bridges under various loading conditions and environments using finite element analysis techniques. This paper presents a numerical model that adopts coupling finite elements to represent the contact behavior of steel to concrete. The ability of the numerical model to simulate the bond is compared to experimental results from a series of beam bending bond tests.

1 INTRODUCTION

The bond between concrete and its reinforcement is highly dependent on several major factors (*fib* bulletin 10, 2000; ACI 408R-03, 2003): i) chemical adhesion between the bars and the concrete – the chemical adhesion is provided by the cement and is created during the hydration process; ii) mechanical interlock involves the transfer of load between concrete and its reinforcement by means of a bearing interlock of the ribs against the concrete surface; iii) surface friction that is created from the roughness of the interface - is the force that resists motion, or more accurately, slip of the bar under loading conditions. Another aspect that highly influences the performance of reinforced concrete is the length of the bonded region of the reinforcing bar within the concrete element. Providing insufficient bond lengths will restrict the section in achieving its maximum debonding resistance.

Generally, bond failure of a steel reinforced concrete occurs over three stages. Firstly, the reinforced concrete element sustains a particular level of bond stress which is primarily attributed to the adhesive component of the bond. Once the peak bond stress has been obtained and cracking of the concrete has started, the adhesive component of bond has been overcome and mechanical interlock between the deformations of the bar and the surrounding concrete commences. This mechanical interlock continues until excessive local slip occurs such that the concrete between the bar deformations has sheared off. At this stage, only frictional component of bond remains until complete bond failure occurs (Haskett et al., 2008). In addition, with the primary cause of failure in structural applications related to splitting cracks, it follows that the concrete tensile strength would be one of governing factors related to the bond strength (Jones & Ramirez, 2016).

In addition to the major factors discussed above, the bond of steel reinforcement is also dependent on the compressive strength, the geometry of the concrete member and the bar placement in the member cross-section. However, fully anchored steel reinforcing bars are much more likely to yield before debonding.

The bond tests available in the literature can be divided according to the type of test: beam tests and pull-out tests. Pull-out tests are simple and have a good accuracy, since some care must be taken for the usual parameters (development length, concrete cover and bar diameter) for a correct evaluation of the real case (Almeida Filho et al., 2008). However, in the beam test, the concrete around the bar is also in tension, better simulating the real stress conditions of the flexure elements.

In this paper, a numerical model that adopts coupling finite elements developed by Bitencourt Jr. et al. (2015) to represent the contact behavior of steel to concrete is presented. The ability of the numerical model to simulate the bond is compared to experimental results from a series of beam bending bond tests.

2 NUMERICAL MODEL

In this section, the numerical model to describe the interaction between the steel bars and concrete based on the use of coupling finite elements (CFEs) is presented.

The procedure to describe the numerical model is depicted in Figure 1. Initially, concrete and steel bars are discretized in finite elements in a totally independent way (non-conforming meshes). Herein, three-node triangular finite elements and two-node truss finite elements were employed to represent concrete and steel bars. Then, CFEs are inserted in order to couple the initially independent meshes (see Figure 1(c)).

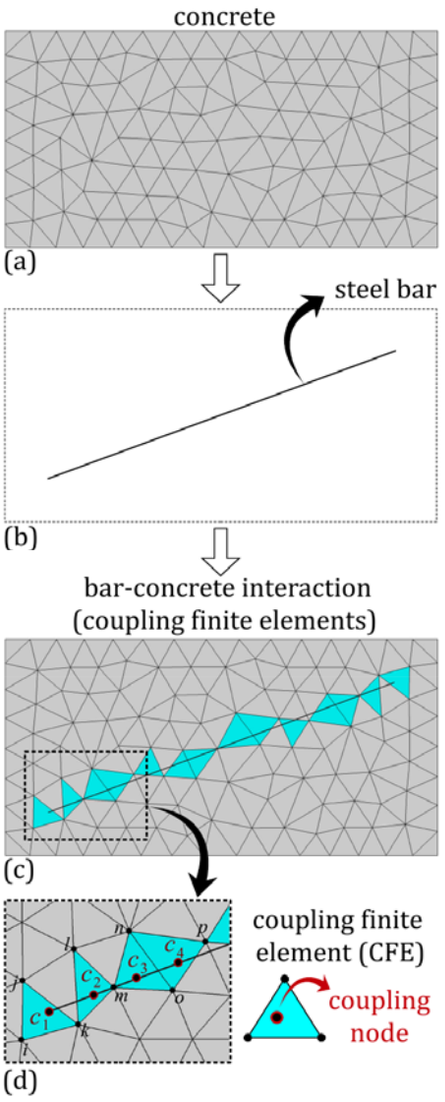

Figure 1. Coupling procedure for non-matching finite element meshes: (a) discretization of the concrete in FEs; (b) generation and discretization of the steel bar; (c) creation and insertion of the CFEs; (d) detail of the coupling in overlapping meshes.

As can be seen in Figure 1 (d), each CFE has the same nodes of a underlying finite element of the existing mesh and an extra node, coinciding with the loose node (this node is called the coupling node) that belongs to its domain. As a consequence, the CFEs overlap the finite elements of the original mesh around the coupling nodes "c_i". Note that for each loose node, one coupling finite element is required, as for example, $CFE_1=\{i,j,k,c_1\}$; where c_1 is the coupling node 1.

After the application of the coupling procedure (Figure 1 (c)), the global internal force vector and the stiffness matrix can be written as:

$$\mathbf{F}^{\text{int}} = \mathrm{A}_{e=1}^{\text{nel}\,\Omega_C}\left(\mathbf{F}_e^{\text{int}}\right)_{\Omega_C} + \mathrm{L} + \mathrm{A}_{e=1}^{\text{nel}\,\Omega_{SF}}\left(\mathbf{F}_e^{\text{int}}\right)_{\Omega_{SF}} + \mathrm{A}_{e=1}^{\text{nel}\,CFE}\left(\mathbf{F}_e^{\text{int}}\right)_{\Omega_{CFE}} \quad (1)$$

$$\mathbf{K} = A_{e=1}^{nel\,\Omega C}\left(\mathbf{B}_e^T\right)_{\Omega_C}\left(\mathbf{C}_{tg}\right)_{\Omega C}\left(\mathbf{B}_e\right)_{\Omega_C} + \mathrm{L} + A_{e=1}^{nel\,\Omega SF}\left(\mathbf{B}_e^T\right)_{\Omega_{SF}}\left(\mathbf{C}_{tg}\right)_{\Omega_{SF}}\left(\mathbf{B}_e\right)_{\Omega_{SF}} + A_{e=1}^{nel\,\Omega CFE}\left(\mathbf{B}_e^T\right)_{\Omega_{CFE}}\left(\mathbf{C}_{tg}\right)_{\Omega_{CFE}}\left(\mathbf{B}_e\right)_{\Omega_{CFE}} \quad (2)$$

2.1 *Steel bar/concrete interaction*

Consider the 4-node triangular coupling finite element (see Figure 2) constructed by the standard three-node triangular finite element and an additional bar node that belongs to its domain.

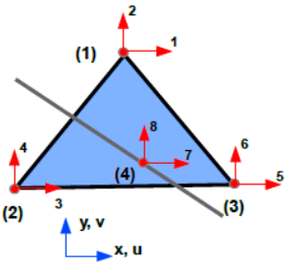

Figure 1. Steel bar/concrete interaction using 4-node coupling finite element.

The relative displacement $\left([[\mathbf{U}]]\right)$ can be defined as the difference between the displacement of the coupling node (C_{node}) and the displacement of the material point at the same position of the bar node $\left(\mathbf{X}_{C_4}\right)$:

$$\begin{aligned}\left[\left[\mathbf{U}\right]\right] &= \mathbf{D}_4 - \bar{\mathbf{U}}\left(\mathbf{X}_{C_4}\right) \\ &= \mathbf{D}_4 - \sum_i^3 \bar{N}_i\left(\mathbf{X}_{C_4}\right)\mathbf{D}_i = \mathbf{B}_e\mathbf{D}_e\end{aligned} \tag{3}$$

where, $\mathbf{D}_4$ stores the displacement components of the bar node, $\bar{N}_i\left(\mathbf{X}_{C_4}\right)$ $(i=1,3)$ are the shape functions of the underlying finite element (concrete), evaluated at point $\mathbf{X}_{C_4}$, and $\mathbf{D}_e$ stores the displacement components of the CFE.

Assuming a linear elastic model to describe steel bar/concrete interaction, the relation between the reaction force ($\mathbf{F}\left(\left[\left[\mathbf{U}\right]\right]\right)$) (owing to the relative displacement ($\left[\left[\mathbf{U}\right]\right]$) and the relative displacement is given by:

$$\mathbf{F}\left(\left[\left[\mathbf{U}\right]\right]\right) = \mathbf{C}\left[\left[\mathbf{U}\right]\right] = \mathbf{C}\mathbf{B}_e\mathbf{D}_e \tag{4}$$

where $\mathbf{C}$ is the matrix of elastic constants that assume very high values when perfect adherence is considered.

$$\mathbf{C} = \begin{bmatrix} C & 0 \\ 0 & C \end{bmatrix} \tag{5}$$

Since the relative movement of the reinforcement with respect to the concrete matrix is in essence a sliding in the direction of the reinforcement axis, it is necessary to use a local coordinate system (**n**,**s**), oriented such that the axis **n** coincides with the reinforcement axial orientation.
Thus, the relative displacement and its corresponding reaction force can be expressed as $\left[\left[\mathbf{u}\right]\right] = \mathbf{R}\left[\left[\mathbf{U}\right]\right]$ and, respectively $\mathbf{f} = \mathbf{R}\mathbf{F}$, where is the orthogonal rotation matrix between the local and global reference systems. The loss of adherence model can be easily represented by assuming an elastic constitutive model with distinct elastic constants, according to the local coordinate system:

$$\mathbf{C} = \begin{bmatrix} c_n & 0 \\ 0 & c_s \end{bmatrix} = \begin{bmatrix} c_n & 0 \\ 0 & C \end{bmatrix}, \quad c_n << C \tag{6}$$

The interaction force between the concrete matrix and the steel reinforcement, at coupling node, one may consider that this force results from the bond (shear) stress, τ, on the bond area (reinforcement-matrix interface) in the vicinity of the coupling node. Therefore, by assuming that the bond (shear) stress is constant in the vicinity of the node and that the size of the vicinity (influence length) that contributes to the resultant force in a specific node corresponds to the average of the half distances between the node "i" and its adjacent nodes of the reinforcement "j" and "k", the interaction force may be expressed as:

$$f_n = \tau(\left[\left[u_n\right]\right])PL \tag{7}$$

where $L = (L_{ij} + L_{jk})/2$ is the influence length and P is the perimeter of the reinforcement cross-section. Note that the slip, s, is given by the relative displacement in direction **n**, i.e., $s = \left[\left[u_n\right]\right]$. The remaining transverse component of the resultant force can be expressed as:

$$f_s = \beta(\left[\left[u_s\right]\right])PL \tag{8}$$

Finally, a constitutive model based on the continuum damage theory may be used to describe the constitutive relationship between the shear stress (adherence stress) and the relative sliding. Thus, the damage model can be described by the following equations:

$$\begin{aligned}
&\tau = (1-d)\bar{\tau} && \text{(constitutive relation)} \\
&\bar{\tau} = c_n\left[\left[\mathbf{u}\right]\right] && \text{(effective shear stress)} \\
&\phi = \|\tau\| - r \le 0 && \text{(damage criterion)} \\
&r = \max[\tau] && \text{(evolution law of the internal variable)} \\
&d = 1 - \frac{q(r)}{r} && \text{(evolution of the damage variable)}
\end{aligned} \tag{9}$$

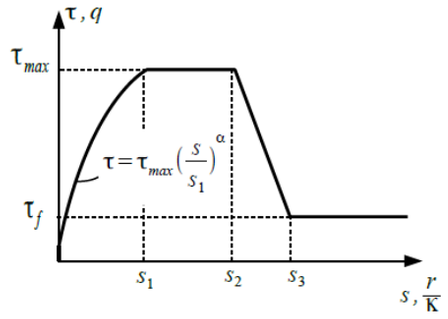
where c_n is the elastic stiffness constant (unit of stress per unit of length), $d \in [0,1]$ is the scalar damage variable, $\bar{\tau}$ is the effective shear stress, and r is the strain-like internal variable that assumes the maximum value reached by $\bar{\tau}$ during the load process. The function $q(r)$ represents the hardening/softening law of the constitutive model, and it may be adjusted to fit any bond slip model of type $\tau(s)$, considering the relationship $q(r) = \tau(r/c_n)$.
Taking as an example the bond-slip relationship proposed by the CEB *fib* Model Code, depicted in Figure 3 and described by the equations:

$$\tau(s)=\begin{cases}\tau_{\max}\left(\dfrac{s}{s_1}\right)^{\alpha} & \text{if} \quad s\le s_1\\ \tau_{\max} & \text{if} \quad s_1<s\le s_2\\ \tau_{\max}-\dfrac{(\tau_{\max}-\tau_f)(s-s_2)}{s_3-s_2} & \text{if} \quad s_2<s\le s_3\\ \tau_f & \text{if} \quad s>s_3\end{cases}, \tag{10}$$

the corresponding hardening/softening law is defined in terms of the stress- and strain-like internal variable as:

$$q(r)=\begin{cases}\tau_{\max}\left(\dfrac{r/c_n}{s_1}\right)^{\alpha} & \text{if} \quad r/c_n\le s_1\\ \tau_{\max} & \text{if} \quad s_1<r/c_n\le s_2\\ \tau_{\max}-\dfrac{(\tau_{\max}-\tau_f)(r/c_n-r_2)}{s_3-s_2} & \text{if} \quad s_2<r/c_n\le s_3\\ \tau_f & \text{if} \quad r/c_n>s_3\end{cases}, \tag{3}$$

where α, $\tau_{\max}$, τ_f and $s(i=1=1,2,3)$ are the parameters of the model, which depend on the concrete strength f_{ck}, the bar geometry (ribbed or smooth), the confining situation (confined or unconfined) and bond condition (good or poor), according to the CEB *fib* Model Code.



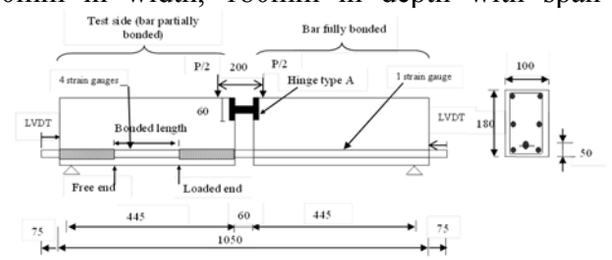


Figure 2. Interface stress bond-slip relationship (monotonic loading) proposed by CEB fib Model Code.

3 EXPERIMENTAL PROGRAM

3.1 *Test beam design and fabrication*

Beam bond tests specimens were reinforced concrete beams vertically loaded with a steel hinge at the top and the specimen separated at mid span to allow control of the internal force distribution (see Figure 4). Strain gauges were placed along the steel bar in the bonded region, which were used to determine strain and calculate slip at locations along the bar. Transducers were placed at the end of the bar to measure free-end slip. Two beam types were tested, for type B1 one side of the beam was be the test region and the other side was be fully bonded to ensure that bond failure occurs in the instrumented region. For beam type B1' there were two test sides where the bar was only partially bonded. The dimensions of both beams were 100mm in width, 180mm in depth with span of

1050mm. The target concrete compressive strength for the mix design was 35MPa. Deformed steel reinforcement as main tensile reinforcement of bar diameter 16mm and characteristic yield strength of 450MPa was used.

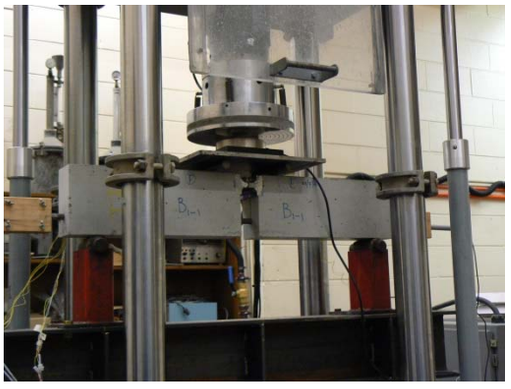

Figure 5. Beam B1 specimen

4 NUMERICAL ANALYSIS

In this section, the numerical model developed to simulate the behavior of the bending bond tests is presented. The results are also compared with those obtained in the experimental tests performed at the RMIT University.

4.1 *Description of the numerical model*

The tests involves two half-beams with a cross-section of 100x180mm², connected at the top by a steel hinge and at the bottom by the tested reinforcing bar with a diameter of 16mm embedded in concrete.

The concrete is assumed to be linearly elastic with Young's modulus of 34GPa and Poisson' ratio of 0.2. The steel bar is elastic perfectly plastic, with Young's modulus of 200GPa and yield stress of 450MPa. In the

region where bonded is considered a no n-rigid coupling procedure is applied to described the bond-slip behavior between the concrete and rebar with a continuum damage model adjusted to the CEB-FIP model code for good bond conditions (f_c=32MPa). Based on this strategy, the properties of the interface material adopted were: τ_{max}=9.0MPa; τ_f =0.4; s_1=0.6; s_2=0.6; s_3=6.0.

4.2 *Numerical Simulation of the bending bond tests*

Figures 6 and 7 display the discretized mesh and coupling finite elements adopted in the numerical analysis.

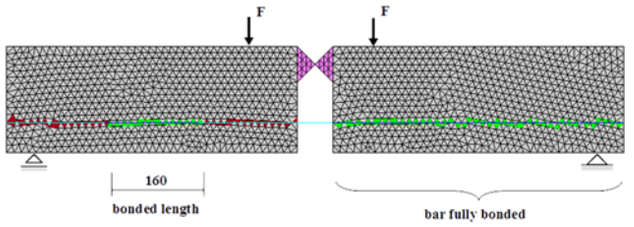

Figure 6. Beam B1

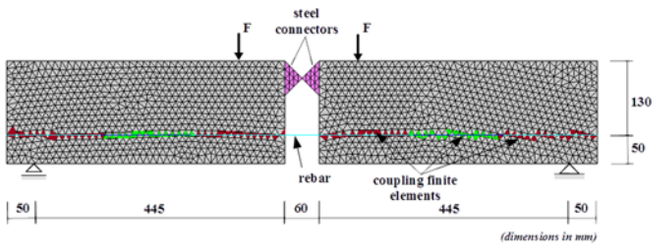

Figure 7. Beam B1'

The following graphs represent the ability of the numerical model to simulate the bond behaviour response by comparing the numerical results with results obtained in the experimental tests performed at the RMIT University. Figures 8 and 9 show the applied load vs mid span deflection, Figures 10 and 11 load vs bar end slip, and Figures 12 and 13 left slip vs tensile bar strain, and load vs tensile bar strain at strain gauge positions 1, 2 and 3, respectively in the bonded steel bar region comparisons. The numerical model has the capability to simulate the bond behaviour between steel bars and concrete with reasonable accuracy.

5 CONCLUSIONS

This paper presents a numerical model that adopts coupling finite elements to represent the contact behavior of steel to concrete. The ability of the numerical model to simulate the bond is compared to experimental results from a series of beam bending bond tests.

Shear and Torsion Design Review – Australian and International Standards

T. Hossain; S. Mikhael; A. Chaudry & S. Mohanakumar
ARCADIS, Melbourne, Australia

ABSTRACT: The shear and torsion design provision of the Australian Bridge Design Standard AS5100.5 has been revised significantly in 2017 and is now based on the Modified Compression Field Theory (MCFT). The MCFT approach is based on the equilibrium, compatibility and stress-strain characteristics of cracked concrete. The previous Australian Standard provisions, based on the parallel-chord truss model, considered the design effects of shear and torsion separately and are added later for reinforcement calculations. The cracked concrete capacity is also ignored under high shear and torsion. This is inconsistent to the true beam behavior and could lead to unsafe results for certain beams or underestimated capacity in other cases.
The Australian bridge stock includes bridges designed or strengthened to previous national design Standards including, apart from the recently replaced AS5100-2004, the Australian Bridge Design Code ABDC 1992 and the National Association of Australian State Road Authorities NAASRA 1976 Standard. The question that arises at this moment is where do these bridges stand as to their shear strength compared to a more consistent and accurate Standard provision and does the new Australian Standards' shear provision really indicate any strength issue that needs to be addressed? A review of the main areas of differences with the previous Standards provisions is presented in this paper with a comparison with those of other international Standards, mainly the AASHTO and the Canadian Standards. Comparison is also made with tested capacities of a limited number of published test results. Areas of major differences with the previous Standards that may affect the existing bridge stock are highlighted and a conclusion is drawn.

1 INTRODUCTION

Over the last few decades, great progress has been made in the analytical solution for shear and torsion design rules in concrete bridges. However, most of these highly sophisticated tools require considerable simplification to make them suitable for codes of practice. In addition, high-strength concrete has been increasingly used in the construction industry during the last few years, and any shear and torsion design procedure should be applicable across the wide range of concrete grades.

Many structural components in bridges are subjected to significant torsion in combination with shear that are critical in design. The previous Australian Code (AS5100-2004) was based on semi-empirical equations chosen to fit the available experimental data. On the other hand, the current Australian bridge standard (AS5100-2017), American bridge code (AASHTO LRFD 2012) and Canadian Standards (CSA 2014) offer two alternative design methods for shear and torsion. The first approach, referred to as the "simplified method", is based on the traditional semi-empirical models. The second approach, referred to as the "General Method", is a simplification of a more rational model named the Modified Compression Field Theory (MCFT). The MCFT is a powerful rational model capable of calculating the full response of sections subjected to shear, axial load, bending and torsional moments (Vecchio and Collins 1986, 1988, Collins and Mitchell 1991). It is noted that the above-mentioned specifications often give significantly different values of calculated ultimate shear strengths.

The objective of this study is to investigate the differences between the AS5100, AASHTO and CSA approaches for shear and torsion design provisions of concrete beams and to evaluate how well they represent the actual beam behavior through a series of statistical comparisons. The studies are made to compare the predicted strengths by using the national and international code approaches with nine (6) physical test results of reinforced concrete beams available from published experimental research.

2 REVIEW OF MCFT

The Modified Compression Field Theory, MCFT, is a shear model developed by Vecchio and Collins (1986), which is based on a variable angle truss model. The MCFT is a behavioral model that can be used to predict the shear stress and shear-strain response of an element subjected to in-plane shear and membrane forces. The formulation of MCFT includes equilibrium, strain compatibility, and a constitutive relationship for diagonally cracked concrete that enable determination of the state of stress (f_x, f_y, v_{xy}) in structural concrete corresponding to a specific state of strain (ε_x, ε_y, γ_{xy}). Using these principles, the MCFT accounts not only for Vs, but also the combined effect of the complex

shear resistance mechanisms that contribute to V_c without having to consider each mechanism individually. The theory considers cracked concrete as a material with its own stress-strain characteristics and accounts for tensile stresses in the concrete between cracks from the aggregate interlock mechanisms.

This method requires the calculation of the actual angle θ, and the crushing strength of the concrete struts. The crushing strength is a function of the tensile strain perpendicular to the strut. As with plasticity analyses, the MCFT predicts that a variable angle strut model will provide conservative estimates of shear strength over a relatively wide range of angles. For a particular design shear stress, a lower limit on θ is set to avoid crushing of the concrete in diagonal compression, while the upper limit on θ ensures yielding of the links. As the shear stress levels increase, the feasible range of angles becomes smaller.

All equations presented in this paper are in SI unit.

3 DISCUSSION OF CODE PROVISIONS

The authors reviewed several widely used shear-design methods, and the basis of these methods, for the purpose of identifying differences among these methods as well as positive attributes to be considered for incorporation into the AASHTO LRFD specifications' new simplified shear-design provisions. The reviewed methods were those in 2012 2012 AASHTO standard specifications, Canadian Standards Association's (CSA's) Design of Concrete Structures (CSA A23.3-94) and Australian Standard, both the previous 2004 and the latest 2017 revision.

3.1 *AASHTO LRFD 2012*

The general procedure of the AASHTO LRFD specifications is based on the Sectional Design Method (SDM) that provides a hand-based shear design procedure derived from MCFT in a simplified manner. In this procedure, the nominal longitudinal strain in the web ε_s and the shear stress are calculated. The shear strength is a function of 2 parameters θ the diagonal shear crack angle, and β that depend on longitudinal strain ε_s at the cross-section of interest and are illustrated in Equation 1 and 2 below:

θ = diagonal shear crack angle
$= 29 + 3500\ \varepsilon_s$
(1)

β = factor to measure the ability of cracked concrete to transmit shear stress across crack,

$$= \left(\frac{0.4}{1+750\varepsilon_s}\right)\left(\frac{1300}{1000+s_{xe}}\right) \quad (2)$$

where the first term models the strain effect and the second term models the size effect. This equation primarily derives from the aggregate interlock relationship. The effective crack spacing in the size effect term, s_{xe}, which accounts for the influence of aggregate size, a_g, is:

$$S_{xe} = S_x\left(\frac{35}{a_g+16}\right) \quad (3)$$

where s_x = crack-spacing parameter, the lesser of either d_v or the maximum distance between layers of longitudinal crack-control reinforcement.

AASHTO simplifies the MCFT by direct use of ε_s, the strain in the section at the level of the longitudinal tensile reinforcement, in the above equations instead of the strain at mid-depth ($\varepsilon_x = \varepsilon_s/2$) as is in the original MCFT. The strain in the ε_s for sections with prestressing tendons is computed by Equation 4:

$$\varepsilon_s = \frac{\frac{|M_u|}{d_v} + 0.5N_u + |V_u| - A_{ps}f_{po}}{E_sA_s + E_pA_{ps}} \quad (4)$$

Where M_u, V_u, and N_u are the factored moment and shear and the axial force (tension positive) at the section of interest. While V_p is the component of prestress force in the direction of shear and As, Es, Ap, Ep are the areas and Young's moduli of the regular and bonded prestressed reinforcement respectively. The term f_{po} is the stress in the prestressing reinforcement when loaded to an extent that the strain in the surrounding concrete is equal to zero. If the value of ε_s calculated is negative, account for the compressive stiffness of the concrete in the flexural tension flange is taken by adding the term E_cA_c to the reinforcement stiffness in the denominator.

The concrete contribution V_c to the shear capacity is controlled by the value of the coefficient β as illustrated by Equation 5 below:

$$V_c = 0.083\beta\sqrt{f'_c}\,b_v\,d_v \quad (5)$$

where f'_c = concrete compressive strength; b_v = effective web width; d_v = effective shear depth measured perpendicular to the neutral axis between the resultants of tensile and compressive forces due to flexure and ≥ greater of 0.9 x effective depth (d_e)or 0.72 x total depth (h).

3.2 *CSA 2014*

The CSA shear-design provisions are essentially the same as the AASHTO LRFD specifications except one significant difference of using longitudinal strain at mid-depth $\varepsilon_x = \varepsilon_s/2$ in the equations. The transverse shear reinforcement helps a member evenly distribute the shear stresses in cracked concrete; therefore, calculating strain at the level of the longitudinal reinforcement as in AASHTO is conservative. For members with transverse reinforcement, the CSA code suggests the factor controlling the contribution of the concrete β and θ as below:

$$\beta = \left(\frac{0.4}{1+1500\varepsilon_x}\right)\left(\frac{1300}{1000+s_{xe}}\right) \quad (6)$$

$$\theta = (29 + 7000\ \varepsilon_x)\ (0.88 + s_{xe}/2500) \quad (7)$$

The longitudinal strain ε_x at mid-depth is computed by Equation 8:

$$\varepsilon_x = \frac{\frac{|M_u|}{d_v} + 0.5N_u + |V_u| - A_{ps}f_{po}}{2(E_s A_s + E_p A_{ps})} \quad (8)$$

The concrete contribution V_c in CSA code is illustrated by Equation 9.

$$V_c = 2.5\beta f_{cr} b_v d_v \quad (9)$$

where $f_{cr} = 0.4\sqrt{f'_c}$ is the cracking strength of normal-strength concrete.

3.3 *AS5100.5-2004*

The empirical shear design provisions based on variable angle truss model in 2004 Australian Standard had their roots in the 45° parallel-chord truss model proposed by Ritter and Mörsch and was applicable for normal-strength concrete up to 65MPa compressive strength. The concrete contribution is a function of the type of shear cracking that controls (flexure-shear or web-shear) at a given cross-section. It also accounts for the axial compressive or tensile force in the section.

The 2004 standard considered the effects of shear and torsion separately with the effects additive which was somewhat incongruous to the beam behavior leading to unusual results particularly beam with high torsion loads. The concrete contribution to shear was based on empirical equation assuming shear stress remains constant over the depth of the web.

3.4 *AS5100.5-2017*

The basic expression used in the AS5100 at 2017 revision is similar to the CSA based on the MCFT where the distribution of shear stresses is assumed at mid depth of the effective shear section of interest. The only difference is with respect to the diagonal shear crack angle θ, which is a function of the longitudinal strain ε_x only unlike the CSA provision. Due to the smoother crack faces where cracks pass through, rather than around aggregate particles, and the resulting larger variability in the shear resistance of members with higher strength concrete, both AS5100 and CSA limits the concrete compressive strength f'_c to maximum of 65 MPa.

In the 2017 edition, for sections subject to combined actions of shear and torsion, torsion is accounted for by adjusting the value of shear stress and β and θ selected and ε_x calculated using the increased shear stress values. This approach is similar to what specified in the latest CSA and AASHTO standards. The reinforcement required for torsion is calculated separately, with θ selected using values of shear force and shear stress adjusted for torsion, and added to the reinforcement required for shear. It seems illogical that 2 different values of θ are used for sections subject to shear and torsion.

4 REVIEW OF PREVIOUS EXPERIMENTAL STUDY IN SHEAR & TORSION

In order to evaluate the accuracy of AS5100-2004, AS5100-2017, AASHTO and CSA it is imperative that the calculated results are compared against highly acclaimed experimental results. There were 2 particular test series that were adopted in this comparison: the first test series was performed by Arbesman which simulated two beam specimens (SA3 and SA4) (Gregori et al. 2007). These specimens were RC rectangular hollow sections and were tested under pure shear. The second test series was performed by Rahal and Collins, which simulated four beam specimens (RC2-2, RC2-4, RC2-1 and RC2-3) (Rahal & Collins 2003). These specimens were RC rectangular solid sections and were tested under combined shear and torsion. The RC2 specimens were part of a grid of beams. The central longitudinal beam was 6 m in length, with two transverse beams of 3 m length with the same section dimensions (as shown in Table 1). The test region was the region between the two transverse beams and was 2 m in length. The test beam was loaded with three actuators, supported on three spherical bearings with two actuators inducing torsional action and one inducing shear action.

The relevant material properties and section dimensions of the above-mentioned sections are listed in Table 1:

Table 1: Experimental Sections

	f'_c	f_y (ligs)	Total Width/Internal Width	Total Depth/Internal Depth
	MPa	MPa	mm	mm

[1]Hollow Section

The tested results, code comparisons and parametric comparisons are shown in Table 2 and 3 in Section 4 of this paper. The cross-section for test specimens (1), (2) and (3) are shown in Figures 1, 2 and 3 respectively.

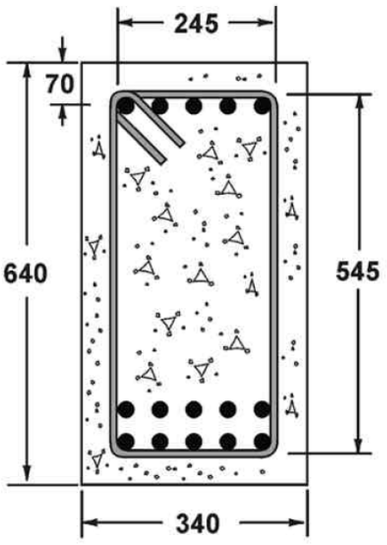

Figure 2: Rahal and Collins test specimen (2)

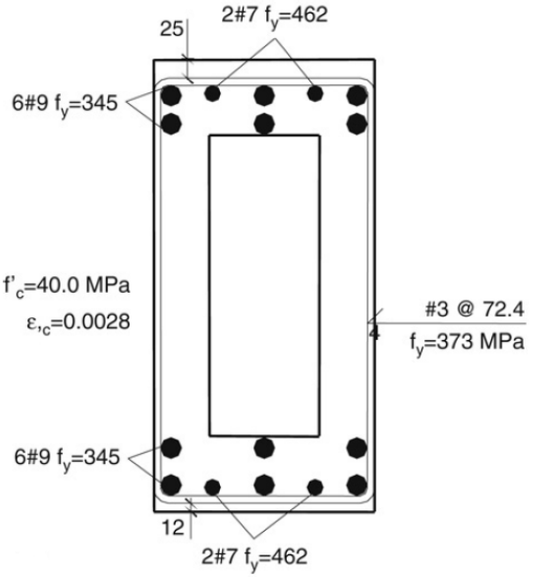

Figure 1: Arbesman test specimen (1)

5 CODE COMPARISON AND PARAMETRIC STUDY

Each sample was evaluated for its shear capacity using the various codes discussed in Section 3 of this paper. The resultant values were compared with the experimental values to ascertain which code provided the closest results to the experimental values and which code was most conservative. This comparison is shown in Table 2. In the scenario where shear and torsion were applied together, the requirement of transverse steel for torsion was calculated first and then subtracted from the amount of transverse steel provided in the section to assess the V_{us} component contribution to the section shear capacity. The angle of inclination of the concrete compression strut and the longitudinal axis of the member, θ, is varied between 30° and 45° as shown in Table 3. The purpose of which is to demonstrate the magnitude of change in shear capacity between codes. Table 4 presents the factored shear capacity for each respective code. Figure 4 and Figure 5 show column graphs depicting the direct comparison of unfactored shear capacity and factored shear capacity as shown in Table 2.

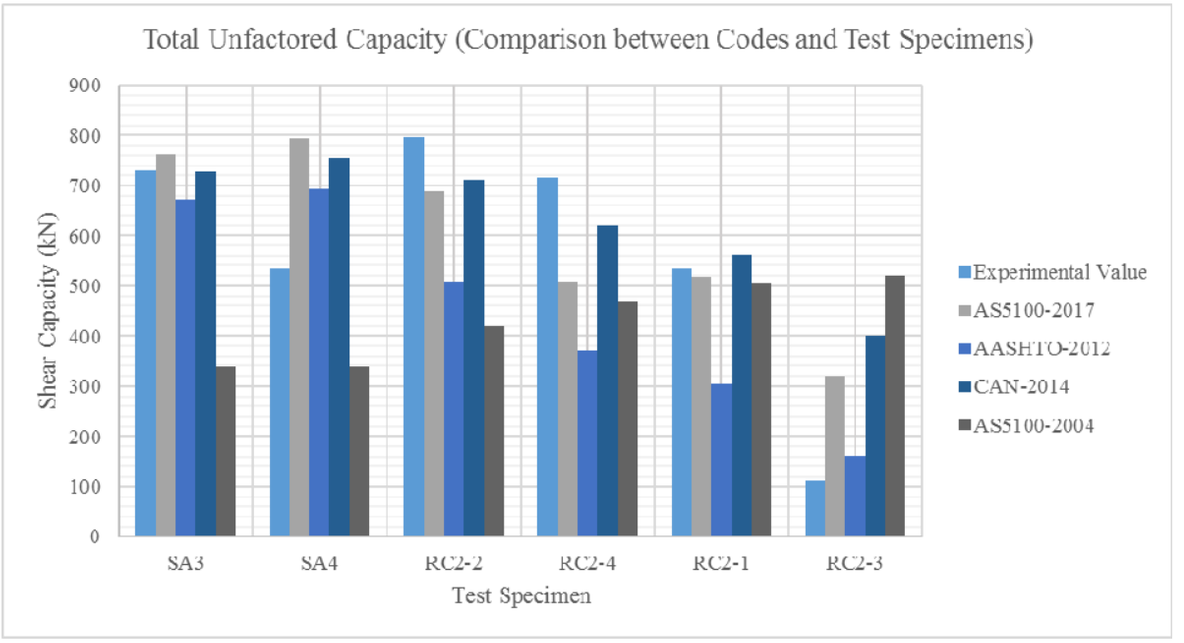

Figure 3: Total Unfactored shear capacity comparison between codes and test specimens

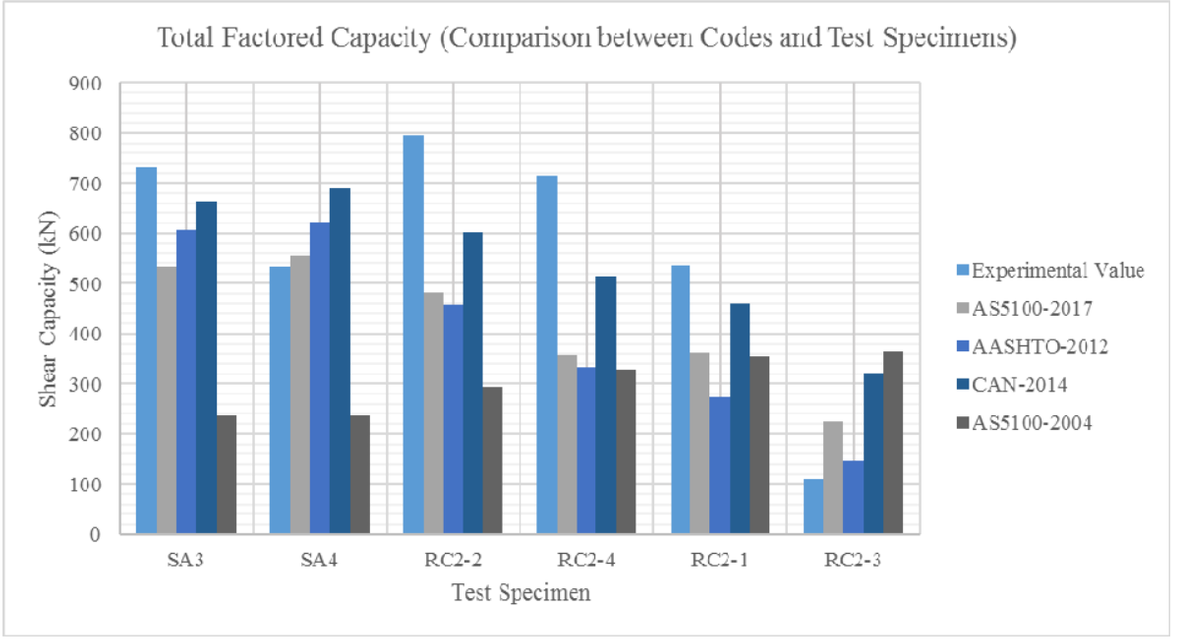

Figure 4: Total Factored shear capacity comparison between codes and test specimens

From the results presented in Figure 4, the following observations were made with respect to the unfactored shear capacity:

- AS5100-2017 provides the most efficient estimate of shear capacity of hollow section members in the database, followed by CSA-2014, AASHTO and AS5100-2004 respectively.
- For solid section members, CSA-2014 predominantly provides the most efficient estimate of the shear capacity, followed by AS5100-2017, AS5100-2004 and AASHTO respectively.

From the results presented in Figure 5, the following observations were made with respect to the factored shear capacity:

- For hollow section members considered in the database, CSA-2014 provides the most efficient estimate of shear capacity, followed by AASHTO, AS5100-2017 and AS5100-2004 respectively.
- For solid sections, CSA-2014 provides the most efficient estimate of the shear capacity, followed by AS5100-2017, AASHTO and AS5100-2004 respectively.
- The question that arises in this instance is that while AS5100-2017 has been modified to simulate a better estimate of shear resistance in concrete sections, why hasn't the capacity reduction factor been revised? The 0.7 reduction factor has been brought forward from the previous revision. The implication therefore is that there still remains a high level of uncertainty in the concrete code with respect to shear and torsion.

It is clear from the results that AS5100-2017 provides vastly different results to AS5100-2004 and one that is much closer to its international counterparts, particularly CSA-2014, although falling just short of the efficiency achieved by CSA in considering the total factored shear capacity.

6 CONCLUSION AND RECOMMENDATION

Understanding the behavior of reinforced concrete beams subjected to shear and torsion was always challenging. Despite many years of research, a unique design agreement on the best design model for shear and torsion design has not yet been reached. However, almost all the major code specifications around the world used to estimate shear and torsion capacity are now based on MCFT either in the originally developed model or in the further simplified method based on local national research. It is evident that the variation in the calculated shear and torsion capacity from different design codes can be high.

The CSA Standard shear provisions are most efficient for predicting the capacity of existing members because they are closest to the actual experimental loads achieved compared to those capacities estimated by AS5100-2017 and AASHTO-2012.

The recommendations of this paper are the following:

- Further testing on reinforced concrete and prestressed concrete beams should be undertaken in Australia to Australian construction standards and requirements to truly determine the accuracy of AS5100.5-2017 shear and torsion provisions.
- Further research to be undertaken to determine a suitable capacity reduction factor for shear and torsion in light of the new changes to the shear and torsion design provisions.

7 ACKNOWLEDGEMENTS

We would like to acknowledge Dr Amin Heidarpour, Head of Structures Group at Monash University for his assistance in providing relevant test papers from around the globe to make this analysis and discussion possible.

Intermodal research to increase the reliability of transport infrastructures

R. Holst
Federal Highway Research Institute (BASt), Germany

ABSTRACT: The transport infrastructures (rail, road, waterways) in Germany are ageing and a considerable proportion of them need to be repaired and upgraded. As the civil engineering structures for these modes of transport have much in common regarding their design and damage, and because it is necessary to find sustainable solutions for the future quickly, it makes sense to work together in this area. This takes place within the BMVI network of experts.

Due to the complexity and interdependencies between various aspects of the subject of "maintenance", it has also proved useful to conduct the joint activities in four key areas in parallel. There are "Condition Assessment/Monitoring", "Reliability", "Measures/Forecast/Vulnerability (Resilience)" and "Construction during road use".

All of this work is important to achieve technically expedient, environmentally friendly, long-lasting and economical construction projects on site. Here too, there is need for substantial optimisation to minimise interference with transport and the environment while nevertheless carrying out construction work of high quality.

Familiar processes and methods are explored, adapted and expanded, subjected to practical tests on an individual object and in pilot areas, and the findings obtained shared internally and with external actors.

Only in this way is it possible to take reasonable account of the challenges of ever faster changes to marginal conditions and amass a joint body of expert knowledge.

1 BACKGROUND/REQUIREMENTS

The rail, road and waterways transport infrastructures represent the backbone of economic prosperity, and form the foundation for future development in Germany. Many of these infrastructures, and especially civil engineering structures such as bridges, tunnels, sluices and weir systems, have now reached or even exceeded much of their planned service life. What is more, the impact has changed greatly compared to the planned impact, and in some cases even amounts to a change of use. A joint effort by all concerned is needed so that these infrastructures can continue to perform their set tasks, as the growing speed of economic change dictates that essential modifications are made quickly. The order of the day is therefore to systematically develop and pool the knowledge and experience from the various modes of transport, and to learn from each other.

2 BMVI NETWORK OF EXPERTS

2.1 *Network of experts*

For this reason, at the instigation of the Federal Ministry of Transport and Digital Infrastructure (BMVI), seven of the subordinated authorities that report to it have joined together to form a BMVI network of experts to manage the tasks ahead [1].

The BMVI network of experts is a new research format for departmental research. Its guiding theme of "Knowledge – Ability – Action" represents the most important levels of action and identifies the requirement to deliver results that are of practical relevance.

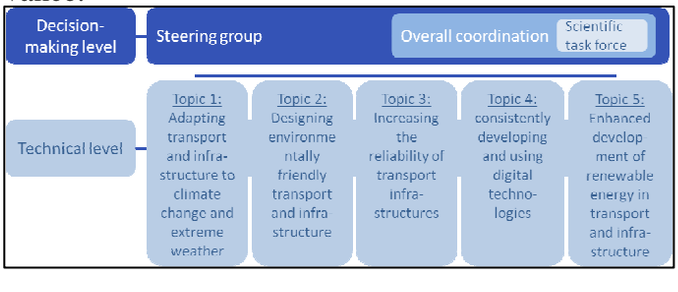

Figure 1: Structure of the network of experts [1]

Their objective is to address urgent transport questions of the future through innovations in the areas of adapting to climate change, environmental protection and risk management. In doing so, the network of experts builds directly on the principles of the Federal Government and its high-tech and sustainability strategy.

2.2 *Topics*

The Federal Highway Research Institute (BASt), Federal Institute of Hydrology (BfG), Federal Waterways Engineering and Research Institute (BAW), German Meteorological Service (DWD), Federal Office for Goods Transport (BAG), Federal Maritime and Hydrographic Agency (BSH) and Federal Railway Authority (EBA) all collaborate in the BMVI network of experts. Their competences and resources are initially being pooled in five topics:
1. Adapting transport and infrastructure to climate change and extreme weather events;
2. Designing environmentally friendly transport and infrastructure;
3. Increase the reliability of transport infrastructures.
4. Consistently developing and using digital technologies and
5. Stepping up the development of potential uses for renewables in transport and infrastructure.

3 TOPIC 3

3.1 *Tasks and objectives [2]*

The growing age of structures, the changing impacts and design weaknesses have an influence on the load-bearing capacity and stability of these structures and on their fitness for purpose. It is reasonable to assume that it will not be possible to safely accommodate the forecast volume of goods traffic unless there are targeted upgrading and replacement measures. In turn, this could lead to the inability to continue to guarantee unrestricted operational and transport related reliability in the form of the availability of transport routes. Suitable measures must be introduced to counter this issue.

Tasks were therefore divided into four key areas (SPT), because it will only be possible to maintain or improve reliability as a whole if all important aspects are dealt with together.

The strength of this new approach to research is that the institutions involved are able to directly bring their different approaches and thus strengths to the table, and that there is a continuous exchange between project team members. The BAW, for example, has large test facilities for directly simulating issues related to waterways. For decades, through its experience of contract research, BASt has very close ties to other research facilities and universities, ensuring that knowledge is not merely exchanged within the network of experts, but also with external actors, for example by means of workshops, milestone conferences and the website (www.bmvi-expertennetzwerk.de). Support groups staffed by members of the authorities involved are set up, particularly in connection with research projects that are being processed externally. Practical relevance and reference to potential users of the research results is guaranteed by the fact that employees of the waterways administration, of Deutsche Bahn AG and of road authorities in the Federal States are directly involved even during the processing phases.

This course of action replaces the classic approach of developing, presenting and practically implementing section by section with a combined approach. This demands transparent and flexible working practices on the part of all institutions and individuals involved.

The projects are processed in the following four key areas:

- SPT 301 (monitoring/assessment of condition);

- SPT 302 (reliability);

- SPT 303 (measures/forecast/vulnerability);

- SPT 304 (construction during road use).

Figure 2 shows the four key areas (SPTs), their content and interaction.

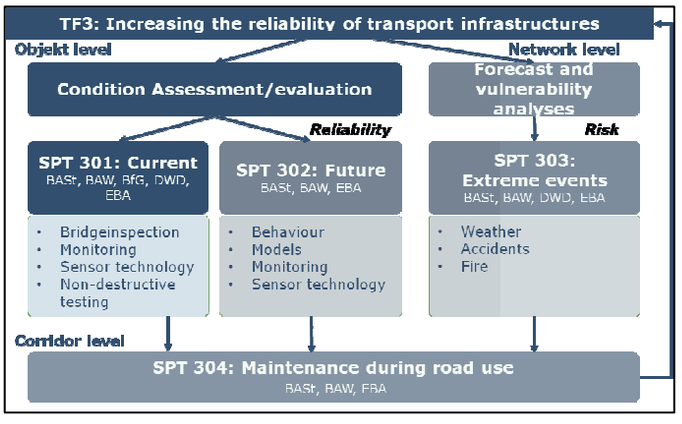

Figure 2: Interaction between the key areas

Figure 3 depicts the interaction between the institutions concerned and therefore the 3 modes of transport with their specialist topics.

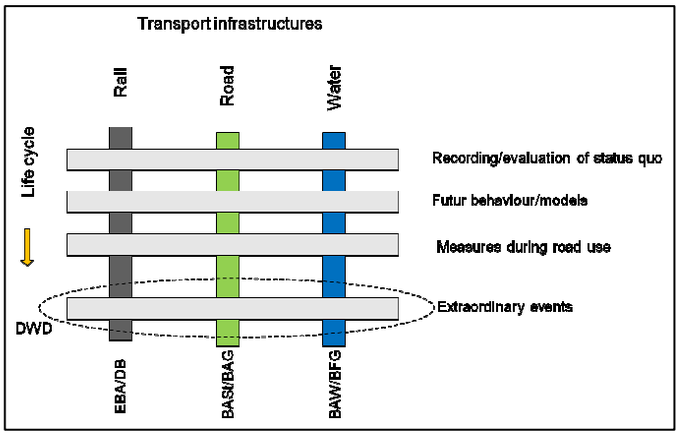

Figure 3: Links between key areas and authorities

3.2 *SPT 301 (condition)*

Recording the current and forecasting the future condition of civil engineering structures is the best foundation for technically practical, timely and economical construction work on these structures. The aim here is to purposefully supplement existing procedures with new technologies and succeed in providing additional information for following phases.

Imaging with the help of unmanned aerial vehicles (UAV) or unmanned aerial systems (UAS) has advanced in recent years to the extent that such equipment can be viewed to be completely practicable. For this reason, these devices are components in projects for all three modes of transport, and are designed to obtain additional and better information about structures and improve accessibility. The objective of the network of experts is to make the information and experience obtained available to all involved so that it can be consciously adapted to suit the needs of the respective mode of transport and introduced to practical use. This approach reduces the cost of research activities, both in financial and particularly also in temporal terms.

The purpose of a sub-project conducted by the Federal Institute of Hydrology (BfG) is to answer questions based on geodetic monitoring. One task here is to record measurement data from a combined sluice and weir system using a UAS. With the help of these results, the direct environment of the structure can be scanned, portrayed in a 3D format and the changes documented at defined intervals. This task should be performed both technically and economically with an eye to the future [3], enabling relevant changes to be detected at an early stage and requisite measures taken in good time.

As well as this aspect of documenting the position, the matter of partial or fully automated detection of damage to structures also plays an important role. The cost of recording and documenting the damage to structures in the course of the regular, usually nearby, structural tests is considerable and requires a high degree of preparation and follow-up work. Modern methods can provide very important support here. A UAS can reach all parts of the structures very quickly and take high quality digital images of them. It has been demonstrated, for example, that a surface image can be taken of pillars on a viaduct at a height of up to 100 m in less than 1 hour, including preparation time. The usually required deployment of an inspection device underneath the bridge with attached inspection platform takes several hours of operating time with at least 2 members of inspection staff.

Because data are fully digital, it is possible to very quickly create different images of diverse measuring campaigns. These clearly demonstrate the changes that have occurred since the last image was taken, and form an accurate basis - focussed on the essentials - for making a decision about possible courses of action.

During a test application on a retaining wall some years ago with cyclopean masonry (300 m long, 15 m high), artificial false edges in the range of a few centimetres could be repeatedly detected. The preparation of the necessary 3D model took several hours. These periods will be substantially reduced in future as Building Information Modelling (BIM) is developed. Experience based on sonar data from underwater components has recently shown that initial 3D presentations are possible directly on site in a few minutes.

Figure 4: Example of a UAV/UAS

Numerous images are created while flying over large structures, and until now these have had to be visually evaluated and assessed by trained staff. This task is very time-consuming and tiring for the staff involved.

It therefore makes sense to deploy existing techniques or develop new techniques to do this.

The Federal Railway Authority (EBA) [4] and the Federal Highway Research Institute (BASt) [5] are engaged in two projects dealing with this subject,

and both organisations are examining the problem from different perspectives.

The project [4] starts with a description of the damage which is necessary to permit simple classification on the basis of shape, progression and size. The evaluation logic is developed on the basis of this, defining which information the sensor system must be able to deliver for a meaningful analysis. The support system with which the sensor can be used should only be selected in the final step.

Parallel to this, a research project will investigate how partially or fully automated processes can be used to help detect damage, e.g. cracks. This is intended to reduce the work of those engaged in inspecting structures, who will then only need to take a close look at those areas of the structures that have been revealed by the algorithm to be suspect.

Finally, the results of both approaches will be evaluated and a decision taken in collaboration with end users about which approaches are beneficial for which areas and should be used in practice.

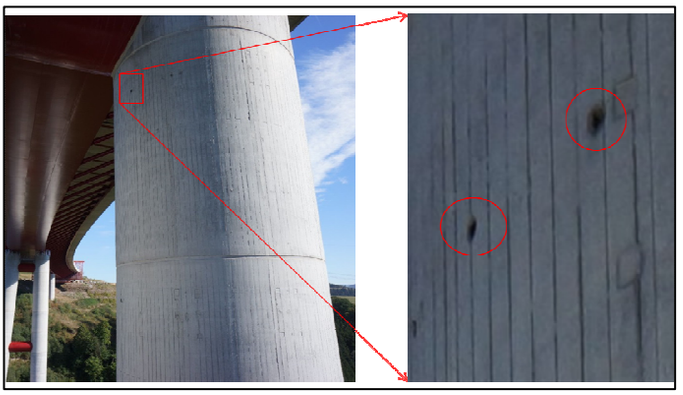

Figure 5: Close-up of damage detection

3.3 *SPT 302 (Reliability)*

Previous assessment procedures for evaluating the condition of civil engineering structures have been deterministic in nature. No consideration is taken of whether and with which likelihood damage is to be expected in as yet undamaged areas today and in the future, and how the damaged areas will behave in future. For this reason, different procedures will be examined or developed to incorporate reliability when assessing civil engineering structures for the specific issues of the different modes of transport. The results of the procedures are then to be evaluated and jointly appraised. In this way, the approach of working in parallel will allow qualified statements to be made about different reliability methods on comparable structures in a short amount of time.

Research facilities can then provide public authorities with an even more knowledgeable consultancy service, while simultaneously reducing the expense in their own organisation.

The following methods will be examined:

For structures on waterways such as sluices, weir systems and bridges, a risk classification will be performed for navigable waterway constructions. Classification of the risk of the structures will be based on meaningful operating data [6], whereby the load-bearing capacity is to be taken into consideration in addition to the condition-related rating system. This system is to be applied to all types of structure [7].

As well as this, the problem of surveying the revetments on the banks of rivers and canals will be considered. Based on interviews with experts, pilot trials will be conducted by the Federal Waterways Engineering and Research Institute and field measurements taken, and a calculation model developed. This will be based on reliability-based procedures such as the cohort survival model, Markov chains or Bayesian networks. A precise specification will emerge following the three basic evaluation steps [8].

Bayesian networks will specifically be used for road bridges. A suitable concept has been developed that estimates the reliability of road bridges on the basis of the structural data from the regularly performed structural inspections under DIN 1076 and the associated construction and damage data stored in the “SIB structures” program system.

The objective is to estimate a reliability index (= probability of failures, POF) by comparing the resistances or the limits of use with the effects of traffic loads [9].

The prerequisite for this is that the resistance in an undamaged state is produced from the measurement data of the resistance standards for the year of construction on a simplified static system. Damage detected by the structural inspection can be incorporated by reducing the resistance or the limits of use. This reduction is subject to many uncertainties, something that must also be taken into consideration. A simplified Bayesian network is used to enable a risk assessment to be performed with the scant information available at the beginning. With additional information, it is possible to improve these results with the help of the same Bayesian networks.

The impact for bridges is largely made up of traffic, and in particular heavy goods traffic. The necessary input variables can be found in current rules and standards and the corresponding national application documents.

3.4 *SPT 303 (Forecasts/vulnerability analyses)*

The structures in traffic infrastructure have been assessed with respect to planned impact such as traffic, wind and temperature. Developments over recent years, in particular in conjunction with climate change, have demonstrated, however, that extraordinary events increasingly exert a substantial influence on the safety and functionality, and thus the availability, of the structures. It is important, therefore, to

systematically record the events, e.g. as a result of heavy rainfall, flooding, phases of low water or hot spells, and to examine their impact on transport infrastructures.

It's a big advantage that the German Meteorological service (DWD) is likewise a partner in the network of experts and that an investigation into the impact of climate change on transport infrastructures is also covered under Topic 1.

With this approach, it's possible to take both short-term, localised events (local heavy rainfall) and more generalised and prolonged events or changes (heavy rain over a larger area and for a longer period, longer periods of hot weather and drought, climate changes) into account and to focus on obtaining the input variables required for the respective question.

One concrete requirement from experience is the development of an automated procedure which enables the barrage controls for the area of barrage-regulated, navigable waterways to be put in place quickly so that these waterways remain open to inland shipping on as many days as possible each year. This is also important in view of keeping the environmentally friendly waterways attractive for users, thereby making an important contribution to the sustainability of transport infrastructures.

The matter of "resilience" also plays a very important role in addition to sustainability, and simultaneously constitutes one of the two guiding themes of the network of experts.

Resilience is understood as shown in the cycle for Topic 3 in Fig. 6.

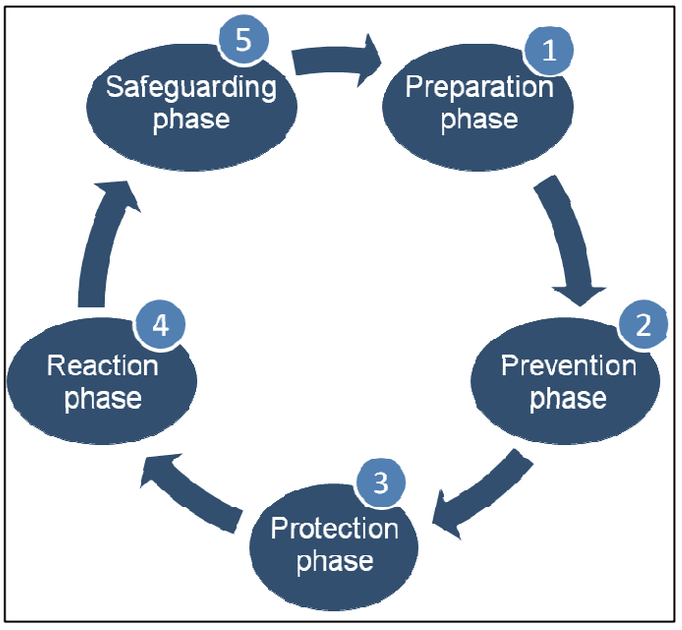

Figure 6: Resilience cycle

The objective is to guarantee the availability and safety of the road infrastructure in Germany even during extraordinary events. An approach to quantify availability and safety has been developed to this end.

3.5 *SPT 304 (Construction during road use)*

Due to the age and condition of structures, the availability of transport infrastructures can only be guaranteed in future if a considerable amount of work is conducted on maintenance and new building projects. The results of the preceding main topics provide important input variables, e.g. the current and forecast conditions and conduct under scheduled and extraordinary loads. The type, time and scope of necessary construction measures can then be calculated. The greatest challenge in connection with this is "construction during road use". Whereas new building projects are generally carried out on "greenfield sites", work on existing structures must focus on the safe and smooth flow of traffic and on environmental concerns.

The following aspects are dealt with in the network of experts:

- Maximisation of availability;
- Adaptation to changed conditions of use;
- Smart repair;
- Standardised flyovers.

Furthermore, Topic 2 examines the impact of material input from structures on the environment, in order to achieve the minimisation of damaging substances here in the future.

"Construction during road use" is characterised by the prime objective of keeping the influence on flowing traffic and the environment to a minimum while nevertheless ensuring that the quality of structures corresponds at least to that on green field sites.

This can be achieved as follows:

- By selecting construction methods that permit traffic to flow without reducing the number of lanes but with width restrictions;
- By selecting types of structures that need as little maintenance and repair work as possible;
- By optimising building processes to reduce work periods during road use;
- By the quality of structures at least equalling that of new builds and having the longest possible service lives.

Work on these different aspects will take place in parallel over the course of several projects. The first such project is concerned with designing draft structures which will only require minor structural adjustments during subsequent work to prepare the structure in accordance with new requirements. This method only makes economic sense for structures as from a certain size ($L > 100$ m), because the ratio between the original structure and the expense of subsequent changes (e.g. built-in components) would not otherwise be proportionate. This has produced

the following possibilities for reinforced and prestressed concrete structures:

- Anchor plates for the subsequent installation of struts on the cantilever;
- "Tube-In-Tube" or hollow box sections that are reinforced by an inserted box girder;
- Additional ducts for subsequently inserting further tendons;
- Unbonded tendons for the subsequent replacement of tendons;
- Adaptive systems, e.g. in the form of self-tensioning tendons.

This list is currently being supplemented by the possibilities for steel bridges.

In addition to these methods for new builds, others are also needed for work on existing structures.

The condition of structures in Germany has today already led to a growing tendency for the existence of restrictions, e.g. weight or speed restrictions on bridges, which can only be cancelled once the necessary construction work has been completed. This means it is necessary not only to optimise the construction work itself, but also to keep the lead times as short as possible. From the point of view of technicians, there is little leeway to influence legal requirements, e.g. to conduct a planning approval process in the case of construction work aimed at boosting capacity.

So that these periods don't go unused, it also makes sense to reduce construction times during road use by taking advantage of standardisation. Deutsche Bahn AG and the EBA have had calculations performed for standardised framework structures up to 16 metres long [10]. These affect around 80% of underpasses for Deutschen Bahn AG. Due to the high number of rail structures that will need replacing in coming years, this is a very big advantage. This is also the case in view of the fact that possible disruptions and closures on the railways are very limited, and that alternative routes or temporary structures are only available or usable to a limited extent.

Comparable investigations have been conducted for the road area. One possibility is the so-called "LEGO" bridge (bridge made completely from prefabricated parts). In 2016, it was decided following a competition that a bridge over the A46 near the city of Hagen should be erected using this method as a pilot project [11]. The expectation is that the planned construction time of 220 days can be reduced to 100 days. The construction work is scheduled for 2018. Following this, experience will be gathered and evaluated, regarding both the construction and the practicability in real use. Construction using prefabricated parts has advantages during prefabrication and erection, but produces very many more joints which, during operation, may prove to be areas that are penetrated by de-icing salts, thereby causing greater corrosion.

In addition to the examples set out here, there are also other ways of optimising "construction during road use" [12], e.g.:

- Integral construction;
- Use of shunting and lifting technologies;
- The structural addition of further lanes.

There are advantages and disadvantages as well as application limits regarding all of these variants, and it's always necessary to look at which variant offers the most expedient solution for the case in hand. Despite uniform rules and standards and potential solutions regarding implementation details – known as guideline drawings - bridge structures in Germany are always a unique specimen. This enables them to be adapted to the conditions on site. However, in view of the extent of upcoming construction work on bridges in future, all possibilities must be examined and incorporated so as to save time and money and to protect the environment. Only in this way will it be possible to reliably guarantee the availability of transport infrastructures in an environmentally friendly way in the future.

4 SUMMARY

The transport infrastructures in Germany are ageing and a considerable proportion of them need to be repaired and upgraded. This especially affects the rail, road and waterways modes of transport. As the civil engineering structures for these modes of transport have much in common regarding their design and damage, and because it is necessary to find sustainable solutions for the future quickly, it makes sense to work together in this area. This takes place within the BMVI network of experts.

Due to the complexity and interdependencies between various aspects of the subject of "maintenance", it has also proved useful to conduct the joint activities in four key areas in parallel. In this way, methods and processes to monitor and assess the condition of structures are being examined and further developed. As well as the improved documentation of the actual conditions, the future conduct of the structures with respect to reliability is also of great significance when moving in future from a reactive approach to a proactive approach that avoids undesirable states, i.e. to guarantee the availability of the transport routes. As a result of climate change and other factors, in future it will not be sufficient merely to consider the response of structures to planned impact, but also to unplanned impact. The topic of resilience plays a very crucial role, acting before, during and after events in a way that restores availability in the shortest possible time.

All of this work is important to achieve technically expedient, environmentally friendly, long-lasting and economical construction projects on site. Here too, there is need for substantial optimisation to minimise interference with transport and the environment while nevertheless carrying out construction work of high quality.

The authorities in the network of experts collaborate internally, but also with the contribution of external expertise. Familiar processes and methods are explored, adapted and expanded, subjected to practical tests on an individual object and in pilot areas, and the findings obtained shared internally and with external actors.

Only in this way is it possible to take reasonable account of the challenges of ever-faster changes to marginal conditions and amass a joint body of expert knowledge.

5 OUTLOOK

The first phase of the BMVI network of experts runs from 2016 to the end of 2019, and represents the identification phase. During this phase, the foundations will be laid for further action. The strategic plan envisages a further phase from 2020 – 2025, which will be the integration phase. During this phase, the findings obtained will be further developed for practical use.

An implementation phase up to 2030 is finally planned, during which results are to be realised in practice.

This plan should ensure that the transport system in Germany is resilient and environmentally friendly. Promoting and using new technologies and innovations for infrastructure and sustainable mobility are key points of the strategy.

This plan is not static, but is open to adjustments to planned aspects and the incorporation of new topics. The diversity of the experts involved offers the ideal basis for this.

Traffic safety and passenger comfort for steel railway bridges

E.-S. Hwang & D.-Y. Kim
Kyung Hee University, Yongin, Korea

ABSTRACT: Recently rapid-transit railway systems have been constructed in many developing countries due to its advantages in congestions and environmental problems. Railway bridges show many different aspects compared to road bridges and passenger comfort and traffic safety are one of them. In particular, deflection and acceleration due to repeated vibration characteristics have a structural weakness that can cause undesirable response. Especially steel railway bridges have been known to have weaknesses due to its relatively light weights compared to concrete bridges. The purpose of this study is to analyze the dynamic response of steel box girder bridges due to passing trains then propose the appropriate method to mitigate the level of vibration in terms of accelerations. Three steel railway bridges are tested and the theoretical model to analyze the dynamic response of the bridge by passing train are developed. For the verification of the model, the natural frequency extracted using the acceleration data measured in the bridge is compared with the natural frequency of the theoretical model. To mitigate the acceleration level of the bridge, parametric studies are performed to find the effectiveness of the method. Based on the analysis, the appropriate method is proposed for decreasing the acceleration of the bridge for passenger comfort and traffic safety.

1 INTRODUCTION

In Korea, transportation network has been developed mainly on the road, but recently, the perception of railway system is changing due to traffic congestion, environment, and safety issues. Due to the geographical feature of Korea, which has a lot of mountains and rivers, there are many bridges and tunnels. The total length of the railway line is 2,185,312 km, of which the bridge is 429,184 km, accounting for 20% of the total. In the case of railway bridges, the size and characteristics of loads are different from those of highway bridges, and traffic safety and the passenger comfort due to the vibration caused by the wheel load when the train passes through the bridge at high speed should be considered. In order to ensure the serviceability such as the traffic safety and passenger comfort of the train, the deflection and acceleration of the bridge should be examined. The purpose of this study is to investigate and evaluate the criteria for passenger comfort and traffic safety of railway bridges. The deflection and acceleration data are measured in the steel box girder bridges for about a month. Effects by axle weights, types of trains were analyzed. And traffic safety and passenger comfort has been checked by analyzing vertical acceleration and deflection of the bridges. The results are compared with international design criteria including UIC and Eurocode. Also numerical and measured values were compared through dynamic analysis.

2 DESIGN CRITERIA

In the design of railway bridges, most design codes specify the traffic safety and passenger comfort criteria as the serviceability check of the bridge. For the traffic safety, vertical acceleration and vertical deflection of the deck and deck twist are considered. For the passenger comfort, vertical deflection of the bridge is considered (BSI, 2005) (UIC, 2006).

2.1 *Traffic Safety*

According to Eurocode (CEN 2005), the maximum peak acceleration of the deck due to rail traffic should not exceed 3.5 m/s^2 for ballasted tracks and 5 m/s^2 for

slab tracks. This requires the dynamic analysis of the real train loaded on one track. Accelerations should be considered for frequencies up to the greater of 30 Hz, 1.5 times of the first mode natural frequency or the frequency of the third mode of vibration of the structure.

The vertical deformation of the deck is another criterion for the traffic safety. It includes vertical deflection along the track, rotation of ballasted bridge deck ends, angular rotations at the end of decks, and vertical displacement of bridge deck ends beyond bearings. The maximum total vertical deflection measured along any track due to rail traffic (LM71 Model) should not exceed L/600.

The twist of the deck is also important for the safety of the train. The criteria are for the twist of the deck to limit that four wheels of one bogie do not deviate one plane as shown in Figure 1. Limiting values of the deck twist are described in Table 1. UIC code has the similar criterion.

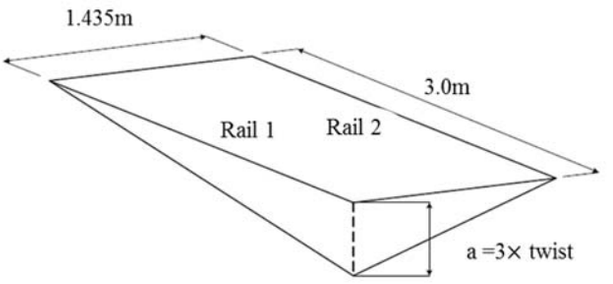

Figure 1. Definition of deck twist

Table 1. Limiting values of deck twist

Speed range V (km/h)	Maximum twist t (mm/3m)
$V \leq 120$	$t \leq 4.5$
$120 < V \leq 200$	$t \leq 3.0$
$V > 200$	$t \leq 1.5$

2.2 *Passenger Comfort*

Passenger comfort is determined by the vertical acceleration b_v inside the coach when train is passing the bridge. The limit values of the vertical acceleration b_v are depending on the level of comfort and shown in Table 2. However, design codes specify the vertical deflection along the center line of the track of the bridge instead of the acceleration of the cabin. Figure 2 shows maximum permissible vertical deflection δ for railway bridges with 3 or more decks corresponding to a permissible vertical acceleration of b_v = 1.0 m/s² which is taken by providing a "very good" level of comfort in a coach for speed V [km/h]. For a bridge composed of either a single span or two simply supported beams or two continuous spans, the values of L/ δ given in Figure 2 should be multiplied by 0.7. In case of continuous beams with three or more spans should be multiplied by 0.9. Table 3 shows the deflection limit for passenger comfort δ considering the very good level in case of speed V=350km/h, which represents the limiting values one of the test bridge in this study. In other levels of comfort, L/ δ is divided by b_v which is acceptable or good so that deflection can be easily calculated. In the case of bridges with double or more tracks, only one track is loaded for the calculation of the deflection.

Table 2. Recommended levels of comfort (Eurocode)

Level of comfort	Vertical acceleration b_v (m/s²)
Very good	1.0
Good	1.3
Acceptable	2.0

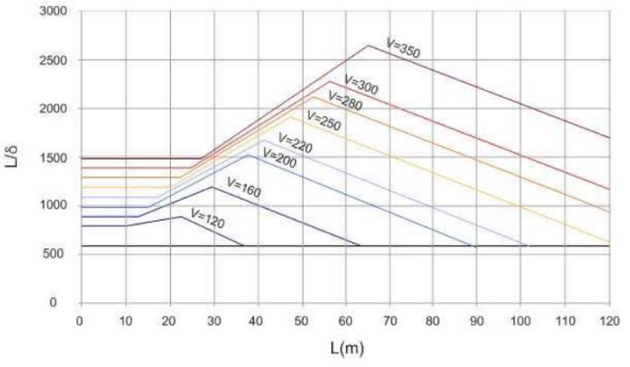

Figure 2. Maximum permissible vertical deflection for railway bridges (b_v =1m/s²)

Table 3. Limitation of maximum vertical deflection (b_v =1m/s²)

	Span length L(m)				
1 or 2 simple supported beams or 2 continuous spans	10	20	30	40	50
	L/1100		L/1200	L/1400	L/1600
	60	65	70	80	90
	L/1800	L/1900	L/1800	L/1700	L/1600
	100	110	120		
	L/1500	L/1400	L/1200		

3 FIELD TEST

3.1 *Test Bridges*

To collect the data for deflections and accelerations, sensors were installed at midspan of the bridge. Test bridges are steel box girder bridges as shown in Table 4. It was measured at the moment the train passed, and the period is over 40 days (Table 5).

3.2 *Measurement Results*

Figure 3 shows the typical cases of deflection and acceleration measurement results for A bridge. Addition to deflection and acceleration of the bridge, axle weights are mesured before the train enter the bridge by other weighing system. The measured axle weights are shown in Table 6. Results show the C.O.V. of about 15~19%.

Measured deflection and accelerations are summarized in Table 7. Maximum deflection and acceleration of A bridge are 5.384 mm and 0.453 g, respectively. B bridge are 3.056 mm and 0.24g and C bridge are 8.392 mm, 0.327 g, respectively. The deflection shows 20~27% C.O.V. On the other hand, the acceleration shows 35~89% C.O.V., larger than deflections.

Table 4. Test bridges

	Line	Type	Span length	Track
A	Jungang	Steel Box	35 m	Ballsted
B	Jungang	Steel Box	25 m	Ballsted
C	Kyungbu	Steel Box	40 m	Ballsted

Table 5. Measurement Overview

3.3 *Comparison with Design Criteria*

Table 8 shows the comparison of measured values with design criteria. Tthe limiting vlaues for traffic safety are L/600, and 58.33 mm, 41.67 mm, 21.05 mm for the A, B, and C bridges, respectively. And the passenger comfort are 20 mm (=L/1750) for A bridge, 16.67 mm (=L/1500) for B bridge and 21.05 mm (=L/1900) for C bridge. In case of deflection, three bridges are far less than design criteria. However, in case of acceleration, both of the bridges on the Jungang-line exceeded the design criteria by 127% and 173%, and the C bridge was also close to the reference value by 87.7%.

4 THEORETICAL ANALYSIS

4.1 *Verification of modeling*

In this study, each bridge is modeled using a commercial program (Midas 2005) to analyze dynamic behavior of steel box girder railway bridges (Figure 5). Plate and beam elements are used for steel box and slab and cross beam, respectively. In order to improve the accuracy of the dynamic analysis, a secondary static load of gravel track, railroad tie, and rails were added.

The load was used to generate the train load by using the actual measured wheel load and wheel spacing for comparison with the measurement results.

Unlike high-speed railway lines, test bridges are located on the general railway line, so various types of trains are passing. In this study, three types of trains with high frequency of passing were selected. In the case of A and B bridge on the Jungang-line, 28 axles, 32 axles, and 86 axles trains were selected. And the C bridge, which is the Kyungbu-line, selected 24 axles, 38 axles, and 54 axles trains.

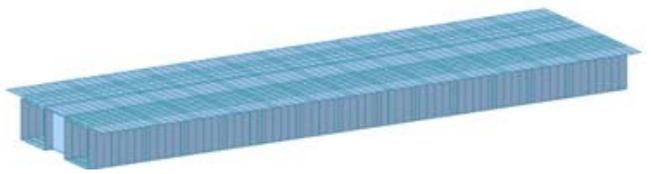
The time history analysis using the mode superposition method is based on the eigenvalue analysis, so the eigenvalue analysis must be performed. From the measured acceleration after the truck leaves the bridge, the natural frequency of the bridge is calculated using FFT process. Acceleration data are filtered at 30 Hz to minimize the noise. The results are shown in Figure 6 and summarized in Table 9. The natural frequencies of the bridges are also calculated from the numerical model. Both frequencies are in Table 9 and it shows similar values.

4.2 *Comparison with test results*

The measured values and the analytical values of each bridge are compared with respect to typical trains. Selected trains are shown in Table 10. Comparisons are shown in Table 11 and Figure 7 to 12.

For A bridge (Figure 7 and 8), in case of deflection, measured values and analytical value (using average axle weights) show similar values. However, acceleration values of the 28-axles and the 32-axles shows very large values than those of the analytical results. This may be due to the resonance of the train and the bridge. The resonance occurs when the effective beating interval of the train coincide with the natural frequency and the resonance speed can be calculated using following equation.

$$V_{cr} = \omega_1 \times S_{eff} \quad (1)$$



where, ω_1 is the natural frequency of the bridge and S_{eff} is effective beating interval.

For B bridge (Figure 9 and 10), the responses of 28 and 86 axle trains are compared. Deflections from experimental study are far less than the analytical study but accelerations show similar values and trends. As the velocity of the train increases, the acceleration tends to increase. However, the acceleration values are within the design code limits in the range of normal train speed.

In case of C bridge, the general results show the same trends and values as B bridge.

5 CONCLUSIONS

This paper investigates and evaluates the deflection and acceleration criteria for traffic safety and passenger comfort of the steel box girder railway bridge by experimental and analytical study. Tests have been performed over 40 days on three steel box girder bridges. Structural analysis of bridges by moving trains was performed to compare measured values with analytical values.

Following conclusions may be drawn from this study;

1. In case of measured deflection, results of this study fully satisfy design criteria in terms of passenger comfort and traffic safety.
2. In case of acceleration, some test values exceed the design limit in some bridges. Analytical values generally show the same trends as test values.
3. Displacements of the bridges at midspan are proportional with the number of train axes.

As a further study, both experimental and analytical studies should be carried out in order to reduce the vibration of steel bridges.

The Ultimate Limit State vs. Limit Analysis of masonry arch bridges

T. Kamiński
Wrocław University of Technology, Wrocław, Poland

ABSTRACT: The paper presents features of procedures dedicated to assessment of masonry arch bridges (MAB). Two essentially different approaches, i.e. based on the Ultimate Limit State and the Limit Analysis, commonly used in load carrying capacity evaluation of various structural systems are described and their potential and effectiveness in application to MAB are discussed. Various formulations of the methods are presented depicting fundamental differences between them. Basic features of the methods are explained in relation to characteristic structural behaviour of masonry arch barrel determined mainly by its non-tensile-resistant material. Limit criteria governing the methods are defined and commented. The margin of safety that is provided by means of safety factors (partial or global ones) within the corresponding methods is presented and used to show essential differences between the approaches. The theoretical considerations are supplemented with several case studies of advanced numerical analysis of bridges with different geometry realistically simulating behaviour of the structures at the ultimate loading. Carried out analyses are based on finite element models taking into account all crucial features of the bridges including nonlinear material properties as well as geometrical nonlinearities related e.g. to contact problem between structural components. Results of the simulations are referred to criteria of the theoretical assessment methods revealing their advantages and drawbacks in case of such structures. The work is summarised with conclusions giving basis for determination of general assessment procedures that could be included in still missing modern codes for evaluation of existing masonry arch bridges.

1 INTRODUCTION

Assessment of masonry arch bridges has been a research topic as well as a subject or engineering work for a long time. Therefore there is a large number of different approaches to the problem including both analytical and numerical methods. Application of each of the procedures needs deep understanding of its consequences in terms of the obtained results and possibilities of their further use.

Two essentially different approaches, i.e. based on the Ultimate Limit State (ULS) and the limit analysis (LA), commonly used in load carrying capacity evaluation of various structural systems are described and their potential and effectiveness in application to masonry arch bridges are discussed. Basic features of the methods are explained in relation to characteristic structural behaviour of masonry arch barrel determined mainly by its non-tensile-resistant material. Limit criteria governing the methods are defined and commented. Finally the margin of safety that can be reached by means of safety factors (partial or global ones) within the corresponding approaches are presented and further used to show essential differences between the approaches as well as to indicate the most appropriate way of analysis of masonry arch bridges.

2 THE ULTIMATE LIMIT STATE OF MAB

Analysis based on the Ultimate Limit State (ULS) is a common element of procedures dedicated to load carrying capacity evaluation of various structural systems. It is precisely determined by many standards (like Eurocodes) for designing of different structures including masonry walls, however in case of masonry arches the existing codes are not directly applicable.

Anyway, the idea of checking the ULS may be applied in analysis of MAB however it needs proper selection of the limit criteria and right understanding of

the results possible to get by means of such a verification.

The basic feature of the procedure in application to MAB is checking of a given limit criteria in a critical section of the arch barrel. The considered section is chosen as that one where the extreme values of a given criteria are exceeding the limit value first during increasing of the applied loads. Thus, the check is limited to a single section what is very conservative approach in case of masonry arch barrel regarded as a triple statically indeterminate element. It means that failure of a single section related to formation of a so-called plastic hinge do not threaten the global stability and safety of the whole arch. Only four hinges at least are needed to provoke the bridge collapse.

The limit criteria which one can formulate are corresponding to the level of:

1. tensile strength (f_t)
2. cracking depth (δ),
3. compressive strength (f_c)
4. shear strength (f_v)

The given order of the criteria is representing subsequent steps of real section gradual destruction with increasing load level. In the first step, the whole arch barrel is under compression what means that the thrust line is contained within the middle third of the arch profile i.e. the resultant force in each section of the arch lays within the section core.

Criterion 1. is related to control of cracking occurrence which takes place at the lowest level of loads (see e.g. Fig. 3). UIC Code 778-3R recommends value of $f_t = 0.5$ MPa. Practically the tensile strength should be assumed even lower: $f_t = 0.05 \div 0.10$ MPa what takes into account typical technical condition of MAB suffering from material degradation and overall cracked structure. It is a very conservative criterion as it corresponds to the first appearance of a crack at the edge fibres of the single section, what means that the most part of this section as well as all other sections are under compression.

Criterion 2. is more important than the previous one since it measures the resultant compressive force eccentricity acting in the section. It is expressed usually in a relationship to the arch thickness, i.e. $\delta = d_c/D$ where d_c is the cracking depth and D is the arch thickness. The limit value of δ is usually assumed equal to 0.7-0.8. UIC Code 778-3R recommends value of $\delta = 0.75$. Deeper cracking influences the arch durability because an intensive opening and closing of the crack may accelerate the material degradation.

Criterion 3. seems to be the most useful as it may indicate some real threat to the arch barrel stability. Exceeding the compressive strength leads to crushing of the material at the edge of the section and further to redistribution of internal forces. In extreme case it is related to significant deformation of the compressed part of the section, formation of a plastic hinge or even to punching-through of the arch in this area.

Criterion 4. is the least important condition since sufficiently large transverse forces to threaten the arch shear strength occurs very rarely. It may happen only in specific combinations of arch geometry (with low rise-to-span ratio) and loading conditions (distributed over wider area to eliminate hinge formation occurring before). This criterion will be therefore ignored further within this study.

The order of reaching the criteria 2. to 4. by corresponding static effects in a section may be changed in some unusual cases or some of them (mainly 2. and 3.) may be reached at the same time.

An important element of ULS analysis are partial safety factors. They are applied to loads (usually increasing their values) as well as to the material resistance (as reducing factors). This essential idea of the load and resistance factor separation is found to provide the largest level of the structure safety, however its usefulness to MAB will discussed further.

Linear or non-linear material models may be applied in ULS analysis but the linear models are appropriate at the level of criterion 1. only. The limit values to check the other criteria are possible to be calculated in linear models, however to perform reasonable verification the nonlinear models are indispensable.

There are many practical implementations for checking the presented limit criteria which are utilising both numerical, like FEM, and analytical solutions, based e.g. on the thrust lines (Heyman, 1982 or Harvey 1988) or interaction envelopes. Various formulations of the interaction envelopes were proposed by many authors including for instance *N-M* (Boothby, 2001) or *N-M-V* (Martín-Caro et al, 2001) envelopes.

3 THE LIMIT ANALYSIS OF MAB

Limit Analysis (LA) contrary to ULS concentrates on the real collapse load of a given structure only. Its application to MAB is very useful since it provides information on behaviour of the whole structure at extreme loads and on associated failure mode. It was elaborated by Heyman (1982). The main advantage of the LA is simultaneous consideration of all sections of the arch barrel. The limit criterion is the loss of the global stability of the structure which corresponds to the failure (ultimate) load value of a given loading scenario (usually a single axle load located over a quarter of the span). All input data to carry out the limit analysis defining both the loads as well as material properties should have characteristic (unfactored) values. By means of such analysis one can find out how far is any exploitation real load value from that one leading to collapse and in this way a realistic margin of safety may be determined. Following this concept, a global safety factor γ_{fL} may be applied to the collapse load value to determine the admissible load

for the given structure and loading scenario. According to British recommendations (Department of Transport, 2001) the safety factor should be $\gamma_{fL} = 3.4$.

As the result of limit analysis also the collapse mode corresponding to the ultimate load scenario is being found. It is mainly based on a four-hinge mechanism which is the critical (the most easily reachable) for definite majority of MAB topologies. Although other mechanisms are also possible theoretically, they usually correspond to load scenarios which are not the most unfavourable for the structure (e.g. a five-hinge mechanism in case of a concentrated force located in the mid-span).

In specific cases some difficulties with triggering of the structure failure (the mechanism of collapse) may occur, especially considering more complex load scenarios (like multi-axle vehicles). One can also encounter some problems analysing massive structures with thick arch and its low rise-to-span ratio or with large height of the backfill over the arch. Than so-called geometrical blocking of the arch may appear or failure of the soil itself may dominate limiting development of typical collapse mechanism of the arch. However, it does not show any general weakness of the LA but indicates limitation of its applied formulation simply not covering the actual mechanism governing the collapse in the given case. That kind of difficulties are related to general feature of MAB defined by large capacity and geometrical stability for which the only possible collapse mechanism requires sometimes consideration of extensive material crushing or structural system general reconfiguration including e.g. support movements.

Among the available solution methods applied in LA especially those based on upper bound theorems and discontinuous models, like Kinematic Method (Kamiński & Bień 2013), Rigid Block (RB) analysis (Gilbert & Melbourne 1994) or Discrete Element Method (DEM) (Costa & Kamiński 2016), are the most useful and efficient in determination of the ultimate load and failure mode of MAB. The continuous models of masonry, like those based on macro- modelling within Finite Element Method (FEM), are less effective in the expected failure simulation mainly due to strain localization problem. However, using e.g. a specific masonry discretization technique called meso-modelling (Kamiński 2008) may solve this problem and allow to search the ultimate load also within FEM as a lower bound approach.

4 SELECTION OF APPROACH

Selection of the most appropriate approach from among ULS and LA to solve a studied problem is dependent on the actual purpose of analysis i.e. whether it is an element of a designing process of a new structure or a check of an existing bridge. Thus, the ULS is the standard approach in the first case while the LA may be more convenient in the second one. Anyway, consideration of complex design load models is practically reachable in ULS only due to aforementioned problems.

Final choice of the procedure should consider also better control over the safety margin possible to get within the chosen approach. As it is shown in one of the next chapters with some representative case studies, this selection may be dependent on the analysed bridge geometry. Also fragility of results to inaccuracy of the problem formulation (related e.g. to wrong input data assumption or improper structure representation) should be also the matter of consideration.

To simplify the choice the basic feature of ULS analysis vs. Limit Analysis in application to masonry arch bridges is summarised in Table 1.

Table 1. Basic feature of ULS analysis vs. Limit Analysis of masonry arch bridges

Considered feature	Ultimate Limit State Analysis	Limit Analysis
Checked member/section	arch barrel single section	all sections of the arch barrel
Limit criteria	1. tensile strength (f_t) 2. crack depth (δ) 3. compressive strength (f_c) 4. shear strength (f_v)	global stability
Safety factors	partial safety factors (material & load factors)	global safety factor
Nature of parameter values	design	characteristic
Available solution methods	static method, FEM, thrust line method, interaction envelopes	Rigid Block Analysis, kinematic method, DEM, FEM, thrust line method
Model linearity	linear of non-linear models	non-linear models only
Load scenarios	any	single axle load mainly
Consideration of support settlement	available	not directly covered

Extent of load value increase (analysis duration time)	carried out until the first section failure	carried out until getting of the global collapse

5 THE APPLIED MODEL

5.1 *General description*

The aim of the computations is to determine the ultimate load bearing capacity considering the two approaches: based on ULS and LA. Plane two-dimensional Finite Element models of masonry bridges representing: the arch barrel, the soil above the arch barrel and in the access zones, pavement layer and a loading element are adopted in the analyses, see Figure 1. The model is defined as a plane-strain problem and it represents a unit width of the bridge structure what is a standard procedure validated by means of numerous laboratory and field tests (Kamiński 2010, Hojdys et al 2013 or Kamiński & Machelski 2016). The bridge is subjected to an external loading simulating a single axle pressure coming from a vehicle against which the load bearing capacity is being evaluated.

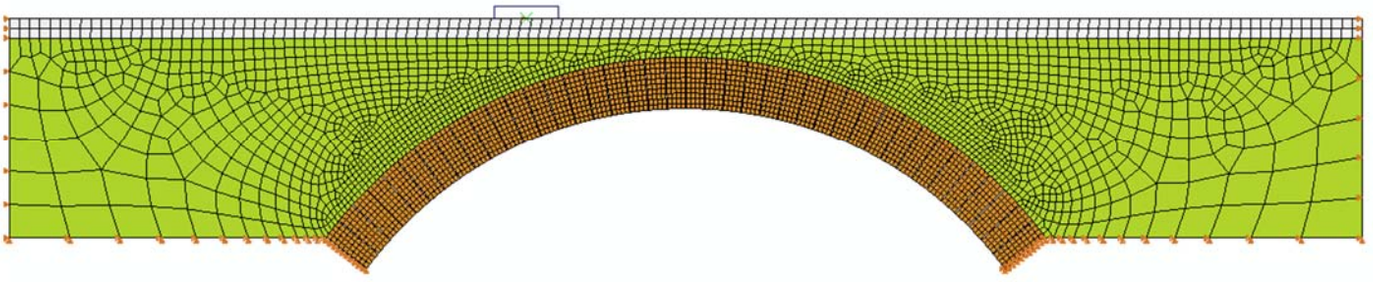

Figure 1. 2D FE model of a masonry arch bridge.

5.2 *Details of the numerical model*

The arch barrel is modelled as a continuous area, however an original modelling technique developed by author (Kamiński 2007, 2008), called meso-modelling, was used to discretise the masonry arch. The distinguishing feature of this modelling technique is division of the arch area into the so-called masonry segments, comprising groups of several masonry blocks together with the joints between them, and into layers of radial joints between the segments. The masonry segments are defined by an orthotropic material model with the mechanical characteristics defined using the a two-stage laminar material homogenization XY (according to Lourenço 1996). Since the selected radial joints (between the masonry segments) are the areas where the arch barrel cracking occurs forming the typical failure mode, they are modelled with special care. The material of joints defined as a plastic-damage model (proposed by Lubliner et al. 1989 and Lee & Fenves 1998) corresponds to the constitutive model of concrete. A simplified representation of σ-ε relationship for uniaxial behaviour of the mortar material is presented in Figure 2.

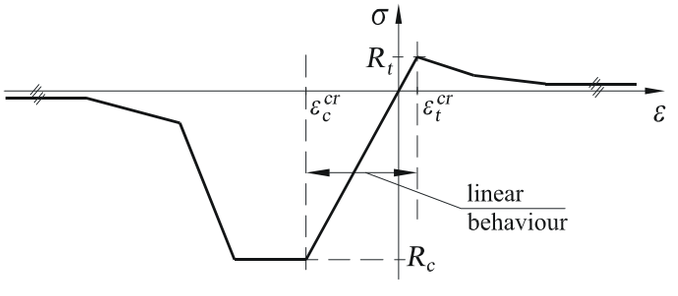

Figure 2. σ-ε relationship for uniaxial behaviour defining concrete-like material model of mortar.

The branches covering compression and tension outside the linear elastic range of σ-ε relationship are precise determined by means of strain hardening/softening curves. The initial yielding stresses at tension and compression are equal to: f_t = 0.10 MPa and f_c = 4 MPa correspondingly, while they are being reduced to one order lower values at extremities of the diagram in Figure 2.

Other main and common material properties of the bridges assumed in analyses are shown in Table 2 where: $\gamma_{M/pav}$,γ_f = unit weights of masonry/pavement and backfill; E_m, E_b, E_f, E_p = modulus of elasticity of mortar, bricks, backfill and pavement; c = cohesion of the backfill; ϕ = angle of internal friction of the backfill, μ = coefficient of friction between arch barrel and the soil.

Table 2. Material properties of the analysed bridges.

Parameter	$\gamma_{m/pav}$	γ_f	E_b	E_m	E_f	E_p	ϕ	c	μ
	kg/m^3	kg/m^3	GPa	GPa	MPa	MPa	deg	-	-
Value	2000	1850	10	1.0	50	100	45	10	0.4

The applied modelling technique significantly simplifies the mesh and reduces the number of required finite elements. At the same time it simplifies simulation of the arch failure and reaching the actual ultimate load of the structure which is usually impossible with application of typical continuous models like those based on macro-modelling technique. In many non-linear analyses presented in literature the

first problems related to numerical convergence are interpreted as the moment of getting the limit load level which in fact is much before the actual ultimate load of the analysed structure.

At the boundary between the backfill and the arch the contact elements are defined. They represent interaction between the contacting bodies by means of compressive and shear forces but without transfer of the tension.

The live load is applied by means of a rigid block acting through a contact line on the upper edge of the pavement covering the soil from the top (see Figure 1). Such a solution enables one to apply conveniently the load in any position without limiting the transverse displacements of the soil under the loading block. In the presented analyses the load is located at the quarter of the span. The boundary conditions limit the horizontal translation of the rigid body.

5.3 *Analysis procedure*

The solution is carried out incrementally in two consecutive steps: in the first one self-weight of all structural components is applied, in the second one the live load acting through the rigid block is added. The incremental application of the live load is controlled by means of the vertical displacement of the loading block. Such a solution gives a better control over the development of the global failure of the structure and enables one to reach and exceed the limit state which is the goal of the analysis. The ultimate (collapse) load P_{ult} is defined by the highest value of the load taken from the relationship between the vertical displacement u of the loading block and the applied concentrated force P equal to the reaction on the block. In the analysed cases a sufficient displacement u to reach the limit state is equal to a few centimetres. In most of the cases the number of increments was about 20 for the first step and at least 300 for the second step.

6 CASE STUDIES

6.1 *Considered bridge parameters*

The basic geometrical parameters of the analysed bridges are presented in Table 3, where L = arch clear span; r/L = rise-to-span ratio; D = arch thickness; h = backfill height over the crown; w = length of loading block. In total 8 various cases are considered varying in arch rise and thickness.

Table 3. Geometrical parameters of the case studies.

Parameter	L	r/L	D	h	w
	m	m	m	m	m
Values	5.0	1/2; 1/4; 1/6; 1/8	0.25;0,40	0.3	0.5

The material properties given in Table 2 are prescribed to the model components with their characteristic values. Although for ULS analysis the material self-weights should be factored, in fact diverse effect of different regions of the structure on the considered limit criteria influenced the decision to leave the masses of the materials unfactored.

6.2 *Results of analyses*

The main result of analyses are included in Table 4 corresponding to considered arch geometries in consecutive rows. In the central columns of the table various limit criteria defined on the basis of those presented in chapters 2 and 3 are indicated which are:

1. tensile strength of mortar (f_t)
2. cracking depth of a mortar joint (δ)
3. design value of the mortar compressive strength (f_{cd})
4. characteristic value of the mortar compressive strength (f_{ck})
5. the ultimate compressive stress value within the mortar (σ_{cu})
6. the ultimate load (P_{ult})

The design value of the mortar compressive strength (f_{cd}) is calculate on the basis of its characteristic value (f_{ck}) using a material safety factor $\gamma_m = 2.0$ (according to Eurocode 6, 2005).

For each case study the external load values P_c accompanying the moments of reaching the given failure criteria by the analysed static effects in the critical section are presented in the form of absolute value as well as a percentage of the ultimate load P_{ult}. As the critical section is taken that one where the static effects get the limit criteria first within the arch during the process of increasing the load. In all considered bridges the critical section of the arch has been localized directly under the live load. Also the limit criteria values governing each case are given in Table 4 differing in the values of δ and σ_{cu}. The other limit criteria values are assumed the same for all cases.

The criterion 3. (f_{cd}) is directly utilized in ULS analysis while the criterion 6. (P_{ult}) – in LA to calculate the admissible load values for the external loading according to the following equations 1 & 2 (for each approach correspondingly):

$$P_{adm.d} = \frac{P\left(f_{cd}\right)}{\gamma_f} \tag{1}$$

$$P_{adm.k} = \frac{P_{ult}}{\gamma_{fL}} \tag{2}$$

where $P_{adm,d}$ = admissible load calculated on the basis of ULS analysis; $P_{adm,k}$ = admissible load calculated on the basis of LA; γ_f = live load safety factor equal to 1.35 (according to Eurocode 1); γ_{fL} = global safety

factor equal to 3.4 (according to Department of Transport, 2001).

Table 4. Results of analyses

* stress equal to f_{ck} reached in another than the critical section
** ultimate compressive stress in the critical section lower than f_{ck}
*** cracking do not reach limit criteria δ

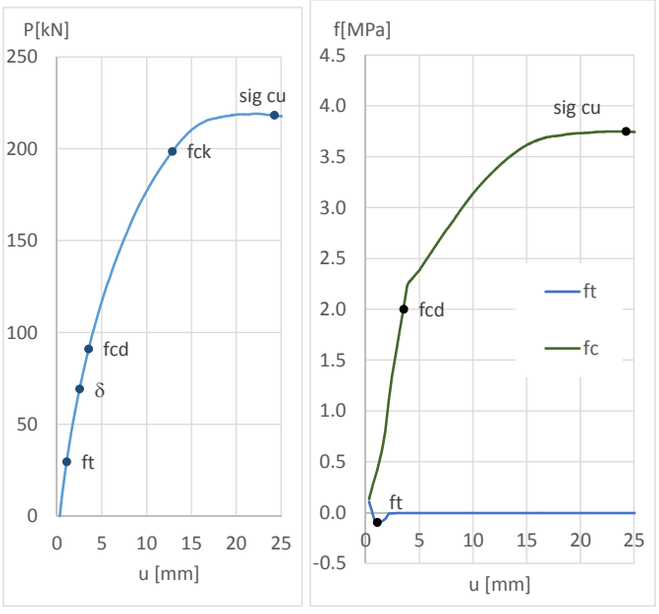

Figure 3. Obtained relationships for the bridge with r = 2.5 m and D = 0.40 m with marked points of reaching the limit criteria: a) load-displacement P-u, b) stress-displacement f-u

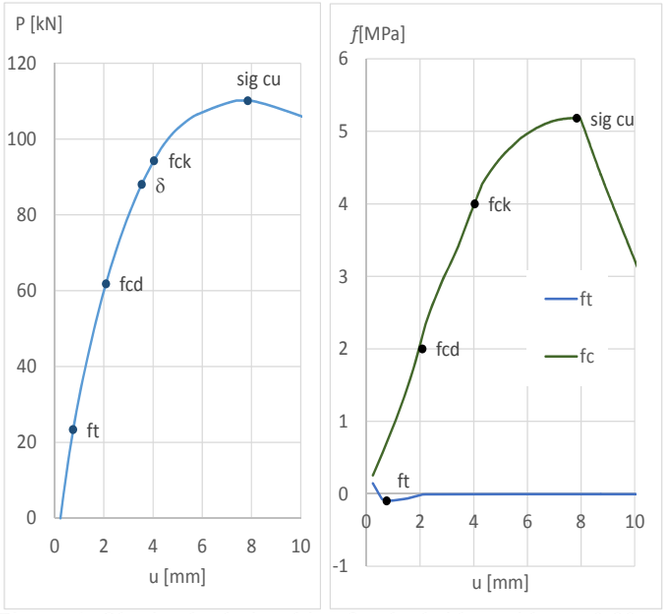

Figure 4. Obtained relationships for the bridge with r = 0.83 m and D = 0.25 m with marked points of reaching the limit criteria: a) load-displacement P-u, b) stress-displacement f-u

The calculated values of the admissible loads $P_{adm,d}$ and $P_{adm,k}$ are presented for each case study in the last two columns of the Table 4. Additionally the ratios of $P_{adm,d}$ to $P_{adm,k}$ are given at the bottom of each row on the percentage basis. At the bottom of the table average values of the ratios P_c/P_{ult} and $P_{adm,d}/P_{adm,k}$ expressed on the percentage basis are provided.

The relationships between applied force P and displacement u as well as between compressive/tensile stresses and displacement u for two representative cases of bridges: with r = 2.5 m, D = 0.40 m and r = 0.83 m, D = 0.25 m are shown in Figures 3 & 4, correspondingly. It the diagrams the characteristic points showing the moments of reaching the limit criteria by the controlled static effects are shown.

6.3 *Discussion of the results*

Obtained fundamental results including P_c/P_{ult} and $P_{adm,d}/P_{adm,k}$ ratios are generally quite similar for most of the considered cases. The order of criteria being reached by the controlled static effects along with the increase of the load P is similar for arches of a given r/L ratio. For deep arches they are ordered according to the list: f_t, δ, f_{cd}, f_{ck}, σ_{cu}, P_{ult}. However for shallow arches (with $r/L \leq 1/4$) the limit criterion δ is reached after f_{cd} (or even never). In some cases representing deep arches (with r/L = 1/2) f_{ck} is not reached in the critical section before P_{ult}. In such cases (which should be separately and more precisely studied) the ultimate compressive stress within the mortar of the critical section gets value $\sigma_{cu} < f_{ck}$ while f_{ck} is reached in another section.

Criterion f_t is satisfied at very low values of P not exceeding 22% (16% on average) of P_{ult} and thus it is not useful nor representative for the load bearing capacity evaluation of MAB.

Criterion δ equal to 0.7-0.8 is mostly reached by the critical section cracking but for specific structural system configurations it may be even more extensive in other sections after reaching σ_{cu} in the critical section. In one case of a flat thick arch it did not reach even 0.7. A separate careful study of δ development within the whole arch is planned as a subject of further works.

f_{cd} directly represents the fundamental limit criterion being checked within ULS procedures predicted e.g. by Eurocodes. It is reached for the considered typical structures at levels of P equal on average to 48% of P_{ult}.

f_{ck} is directly related to actual yielding of material in uniaxial compression, thus the level of P referring to this criterion should be of crucial importance. It is reached at P values close to 80% of P_{ult} on average.

σ_{cu} is presented as supplementary information to pay attention to the fact that material of the masonry arch is undergoing two- or three-axial compression what leads to the effect of reaching by the stresses values higher than f_{ck} (by even up to 30%). The ultimate stresses are reached on average at 99% of P_{ult} what is usually related to actual collapse of the structure.

The admissible load values P_{adm} calculated by means of both approaches are quite similar, however higher values are mostly obtained within ULS analysis. The opposite situation was encounter for only a single structures from the considered case studies representing a thick and shallow arch.

7 CONCLUSIONS

Comparison of two basic approaches to assessment of MAB in terms of their applicability, effectiveness and consequences of application has been presented. The essential results in the form of admissible load values P_{adm} calculated by means of the both methods are found to be generally similar with more conservative values obtained by means of Limit Analysis. Valuable information may be gathered following development of considered static effects (extreme stresses and cracking) within the critical section in the domain of load P revealing the gradual process of the structure destruction along with the increase of the applied loading.

Values of the applied load P_c corresponding to reaching by the static effects the successive limit criteria (f_t, δ, f_{cd}, f_{ck}, σ_{cu}) referred to the ultimate load value P_{ult} allow to answer the following general questions related to analysis MAB:

- what is the typical order of limit criteria which are consecutively satisfied along with the increase of the external load P, and

- how far from the ultimate load P_{ult} are the load levels P_c corresponding to reaching the limit criteria.

All these conclusions may be useful for defining the safe ranges of the MAB loading and establishing the safety factor for corresponding approaches. The presented work could be also a basis for selection of the crucial limit criteria to be included in modern procedures of ULS analysis of MAB. Such analysis should be a part of general procedures for condition evaluation of MAB (Helmerich et al. 2012, Kamiński & Bień 2015).

ABSTRACT: Linear and Nonlinear finite element (FE) models of the steel H-pile specimens used in the experimental test set up are developed using the computer program ANSYS to identify potential problems that may be encountered during testing and to improve the test apparatus. First, linear FE models of the steel H-pile specimens are built to determine maximum stress concentrations occurring in the HP sections and the steel base fixture used for fixing the pile to the testing frame. From these linear analyses results; the locations of stress concentrations in the HP sections are identified. Using these results, the test set up is modified to decrease the stress concentrations. Then, nonlinear FE analyses of the steel H-pile specimens are repeated on the modified specimen model to observe the distribution of stresses and strains in the steel HP sections and the steel base fixture. Then, low cycle fatigue tests are conducted to investigate the fatigue life of steel H-piles subjected to thermal induced cyclic strains/displacements. In the experimental part, HP220x57 pile specimens are tested to estimate the low cycle fatigue life of steel H-piles as a function of large flexural strain cycles with various amplitudes. Using the FEM, comparisons between FE model predictions and experimental test results are made in terms of fatigue life in the steel H-pile specimens. Consequently, it is shown that nonlinear FEMs of the steel H-pile used in the experimental part should be used to identify potential problems that may be encountered during testing and to improve the test apparatus if necessary.

1 GENERAL INSTRUCTIONS

Traditionally, engineers have used laboratory testing to investigate the structural behaviour of bridge, steel building products and systems subject to the expected wind loads, live loads, earthquake loads and the temperature-induced lateral displacements and to develop appropriate design rules. Laboratory testing is also used to develop new building products and systems. However, time-consuming and too expensive laboratory tests have delayed progress in this area. Thus, the product manufacturers and designers often decided on traditional designs to avoid expensive and time-consuming laboratory testing. However, advances in the field of computer aided engineering during the last two decades have changed this situation significantly in many engineering industries, especially in the field of structural and bridge engineering. In the bridge and steel building industry, the use of advanced FE tools has not only allowed the introduction of innovative and efficient building products, but also the development of accurate design methods.

Bridge structural and loading conditions can change over the life of the bridge. Especially, due to seasonal temperature changes, the abutments are pushed against the approach fill and then pulled away, causing lateral displacements at the top of the piles that support the abutments as shown in Fig.1. This may result in the reduction of their service life due to low-cycle fatigue effects. Although bridge engineers (Dicleli,2000, French et al., 2004, and Razmi 2013) have already predicted that low cycle fatigue may occur in the steel H piles of integral bridges due to thermal effects, only a few research studies and experimental test results have been found on this topic in the literature.

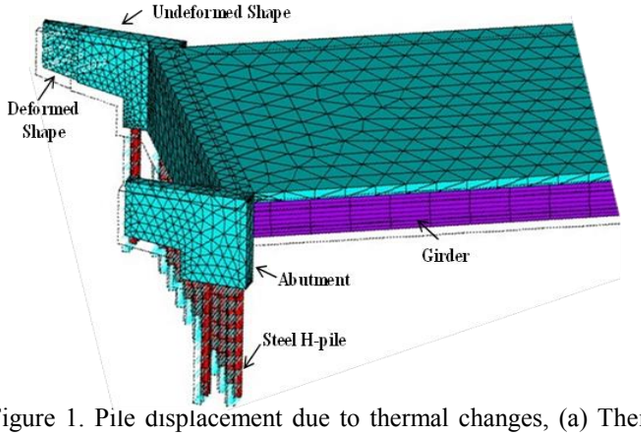

Figure 1. Pıle dısplacement due to thermal changes, (a) Thermal Expansion, (b) Thermal contraction

The main design resource for civil engineers, the American Association of State Highway and Transportation Officials (AASHTO), explains the importance of the fatigue issue in structures only (Wish, 2002), but does not provide any guidelines for fatigue design and its consideration in the steel pile of integral bridges. As the length of integral bridges increases, the temperature-induced lateral cyclic displacements in the steel H-piles at the abutments become larger as well. As a result, the piles may experience cyclic plastic deformations. This may result in the reduction of their service life due to low-cycle fatigue effects. Thus, it is necessary to exactly understand the behavior of piles under cyclic lateral loads. Thus, experimental measurement is needed. However, experimental measurements are often too expensive and time-consuming especially when integral bridge components (abutment, pile, etc.) are subjected to long arbitrary multi-axial cyclic loading histories in service life and also in some cases, experimental measurements can not be performed successfully as shown in Fig.2.

To avoid the huge cost and testing time required for conducting experimental tests, researchers often use some forms of FE analysis to carry out their research. FE analysis predictions have been widely used to evaluate the different models.

The main objective of this research study is to identify potential problems that may be encountered during testing as shown in Fig.2 and to improve the test apparatus for all bridge engineering structure as simulating the low cycle fatigue performance of steel H-piles via FE approach. Using FEMs of the steel H-pile specimens it will be possible to simulate cyclic behavior of steel H-piles under thermal effects in integral bridges, as in actual experimental test set up. Thus, FE models may be used to avoid the huge cost and testing time required for conducting experimental tests.

2. LINEAR FINITE ELEMENT ANALYSES

The main objective of the linear finite element analyses is to determine stress concentrations occurring in the HP sections and the steel base fixture. First, linear finite element models of the steel H-pile specimens are developed using the computer program ANSYS. Figure 3 shows the linear finite element model for the HP220x57 section. The HP220x57 section for bending about the strong axis is modeled. The steel base fixture is attached to the testing frame using 30 mm diameter bolts. The steel base fixture-pile interaction is modeled using the frictionless contact algorithm in ANSYS. In the FEM, the HP220x57 section is meshed using ANSYS's automatic mesh generation feature. However, the automatically generated mesh sizes are modified manually in ANSYS to obtain a more accurate simulation of the stress distribution (the mesh size is taken as 25 mm within contact regions and 50 mm within the rest of the model). The model consists of 63,897 tetrahedron elements and 20,657 nodes. Further details on the linear FEM of the test specimen are presented in the following subsections.

2.1 *Element Types*

In the FEM, a structure is divided into small and simple elements. The finite elements used in the model are composed of 10-node high-order tetrahedron elements. Every node has three degrees of freedom: translations in the nodal x, y and z directions. The element has a quadratic displacement behavior and is well suited to modeling irregular meshes (Yazdizadeh, 2010). Further, the contact algorithm of FEM requires definition of contacting surface. To define a contact pair completely, contact and target element have to be referred to same characteristic parameters (Kamil et al. 2011). For the contact elements, CONTA174 is used to represent contact and sliding between 3-D “target” surfaces and a deformable surface. For the target elements, TARGE170 is used to represent various 3-D “target” surfaces for the associated contact elements (Kadhim, 2012). The contact element 174 and target 170 are used as a contact surface-to-surface as shown in Fig.3.

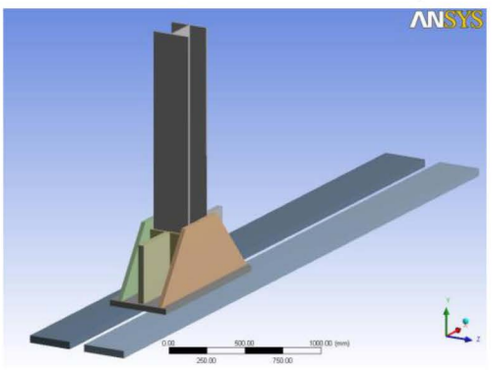

Figure 3. Finite element model for the HP 220x57 section.

2.2 *Contact modeling*

Contact mechanics is the study of the deformation caused by solid bodies that touch each other at one or more points (Popov, 2010). In this study, contact between the HP section and the connection plates is defined as surface-to-surface contact type. This contact type is established when a surface of one body comes in contact with the surface of another body. This contact type is commonly used for arbitrary bodies that have large contact areas (Thomas et al. 2006, Al-Mughairi et al. 2010). In this study, frictionless contact is chosen between the HP section and connection plates as gaps form in the model between contacting bodies. For the remainder of the model, bonded contact is chosen (for the contact with the side plates of the steel base fixture as shown in Fig.4).

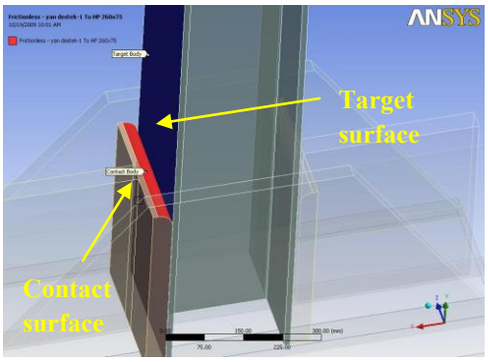

Figure 4. Details of contact surfaces

2.3 *Meshing*

To confirm mesh density used in the FEM, case studies with different mesh sizes on the HP section and connection plates are carried out. Mesh size and type are important for accurate stress values. Thus, four meshing options are tested and compared in the FEM: Automatic, Tetrahedrons, Hex Dominant and Sweep meshing options as shown in Fig.5. The first option, automatically-generated mesh, consists of 13,626 elements and 40,826 nodes. Tetrahedrons mesh consists of 62,303 elements and 20,207 nodes. The other mesh properties are shown in Table 1. In ANSYS, the number of the nodes leads to excessive computation time. Based on these mesh properties, Tetrahedrons meshing option is chosen because the obtained mesh has a better size distribution across the model and the number of the nodes. Then, the selected meshing type, the tetrahedron mesh, is tested using various sizing mesh starting with 250 mm and reducing the mesh size until the results become stable. When the stress values are stable, this mesh sizing can be applicable for FEM analysis. As shown in Fig.6, the maximum stress value in the HP section remains nearly constant for both 50 mm and 25 mm mesh sizes (526 MPa and 529MPa, respectively). Thus, the mesh sizes are input manually and taken as 25 mm within contact regions and 50 mm within the rest of the model.

2.4 *Material Model and Boundary Conditions*

In the nonlinear FEM, the main material model used in this structure is steel. Nonlinear material model is used for steel HP sections with Young's modulus of 200,000 MPa, Poisson's ratio 0.3, tensile yield stress 306 MPa and tensile ultimate stress 421 MPa for the HP220x57 steel section.

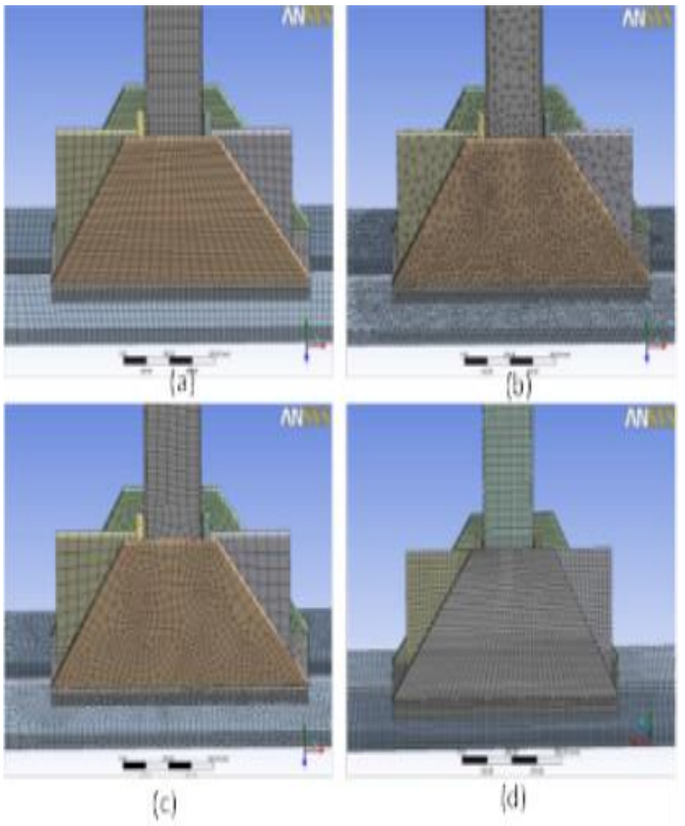

Figure 5. Mesh options, (a) Automatic Mesh generation, (b)Tetrahedrons Mesh, (c) Hex Dominant Mesh, (d) Sweep Mesh.

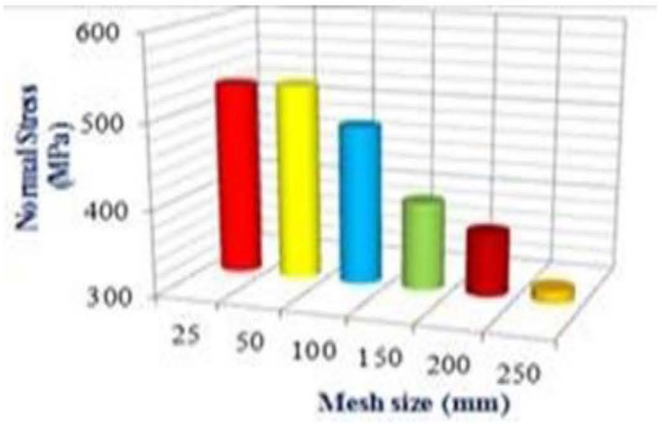
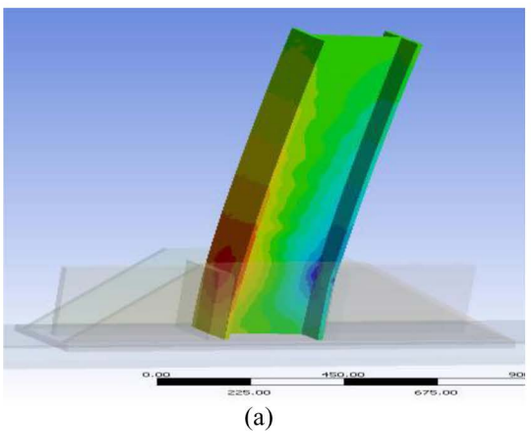
In addition to material model, correct definition of boundary conditions is of great importance in the FE analysis and, depending on the structure, can greatly affect the behavior. Thus, fixed support means that any movement of the body is restrained, is defined below surfaces of the structure as the boundary conditions. To compare between FE model predictions and experimental test results in terms of fatigue life in the steel H-pile specimens for various lateral and axial load values, fatigue damage model are defined in ANSYS as strain-based model.

Table 1.Numbers of Nodes and Elements for different mesh type.

Mesh Type	Number of Nodes	Number of Elements
Tetrahedrons	20207	62303
Automatic	40826	13626
Hex Dominant	47052	16026
Sweep	43922	14658





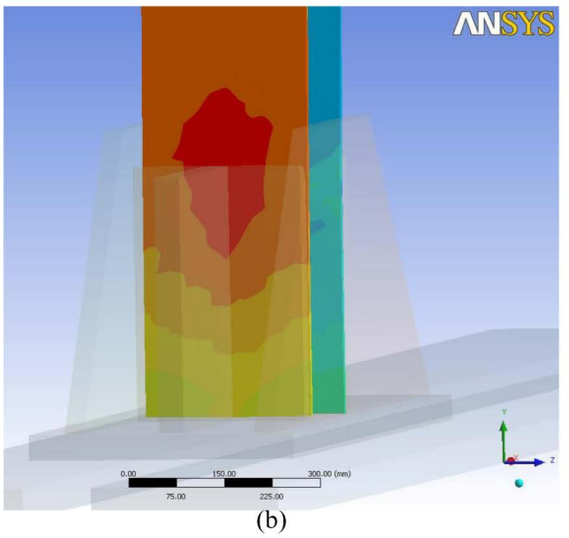


Figure 6. Stress value for different mesh size

3. FINITE ELEMENT MODEL RESULTS

The results obtained from the linear three dimensional FE analyses are evaluated for the HP220x57 sections. The distributions of the axial stresses are shown in Fig.7 for the HP220x75 section. The analyses results revealed that high axial stress concentrations exist around the connections of the HP 220x57 section and the 400 mm-high plate of the steel base fixture. The magnitude of these stresses is very high on HP section as noted from the 589 MPa stress value. This is indicative of local damage to HP section. Such local damage may be amplified under cyclic loading. To prevent these local damage (which do not occur in the case of steel H-piles embedded in concrete abutment), steel blocks are used between flanges of the HP section within the steel base fixture and the FEM is modified accordingly. In the case of the modified FEM, the presence of the steel blocks between the flanges of the HP section within the steel base fixture results in a more even distribution of stresses as shown in Fig.8. This results in a more uniform stress distribution over the flanges of the steel HP sections (e.g. the stress is reduced from from 676 to 338 MPa for the HP220x57 section as shown in Fig.8). Consequently, it is expected that the modified-test set up with steel blocks between flanges of the HP section will offer a better experimental set up for the HP220x57 sections. Stress distributions for these sections are shown in Fig.9 and 10.

4 FINITE ELEMENT MODEL RESULTS

4.1 *Specimen#1: A Maximum Strain of $\varepsilon_a=\pm 5\varepsilon_y$ in Bending about Strong Axis with No Axial Load*

FEM is constructed similarly according to actual HP220x57 steel in the test set up. For this reason, a lateral pressure is implemented over the entire top surface of the HP220x57 steel section in the ANSYS software to reach a flexural strain equal to five times the yield strain ($\varepsilon_a=5\varepsilon_y$) developed in the outermost fibers of the flanges. Then, FEM is solved based on above procedure explained in detail. Based on the FE analysis results, strain values for HP 220x57 steel sections are obtained as seen in Fig.11. Finite element analysis results show that maximum strain in the piles occurs in the flange of the HP 220x57 steel specimen right above the 465 mm-high steel base fixture.

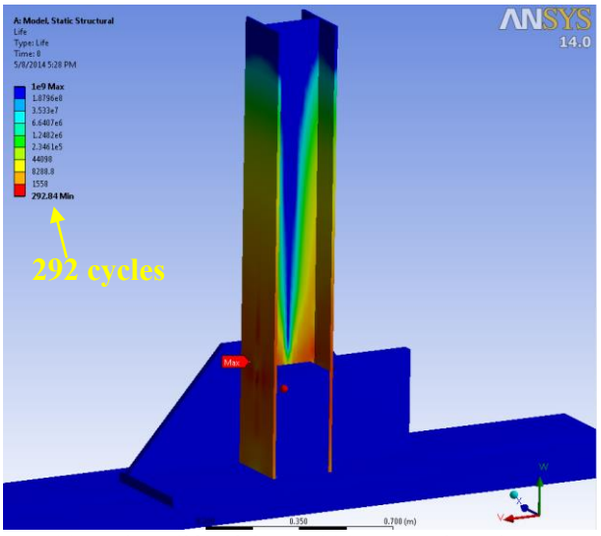

Figure 11. Fatigue life of the HP220x57 steel section on FEM

Using the FEM, fatigue life of HP220x57 steel specimen is investigated. In the FEM, the fatigue life of the HP220x57 steel specimen is obtained 292 cycles as seen in Fig.11.

4.2 *Specimen#2: A Maximum Strain of $\varepsilon_a=\pm 5\varepsilon_y$ in ending about Strong Axis with Axial Load*

A lateral pressure is implemented over the en-tire top surface of the HP220x57 steel section in the ANSYS software to obtain a flexural strain equal to five times the yield strain ($\varepsilon_a=5\varepsilon_y$) developed in the outermost fibers of the flanges as applied in test set up. To do so, ±64 mm lateral displacements are applied in the FEM as in the experiment test set up. Additionally, an axial load is also applied over the entire top surface of the HP220x57 steel section in the ANSYS software as seen in Fig.12. Average value of axial load is applied as 250 kN ($P=0.11P_y$) for the FEM. it is seems that local buckling takes place accurately above the 425 mm-high steel base fixture in FEM as seen in Fig.13. Finally, in the FEM, low cycle fatigue takes place when steel HP220x57 section is reached to the 585 cycles.

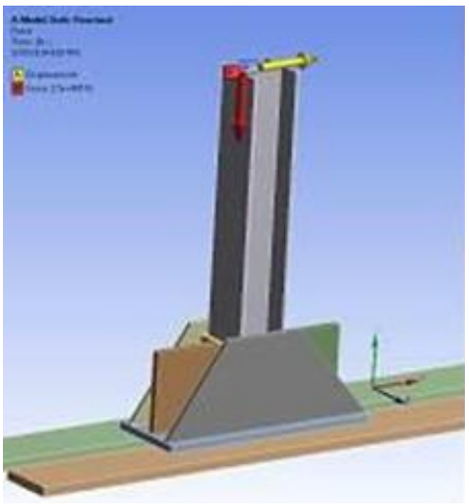

Figure 12. (a) Applied axial and lateral load in FEM,

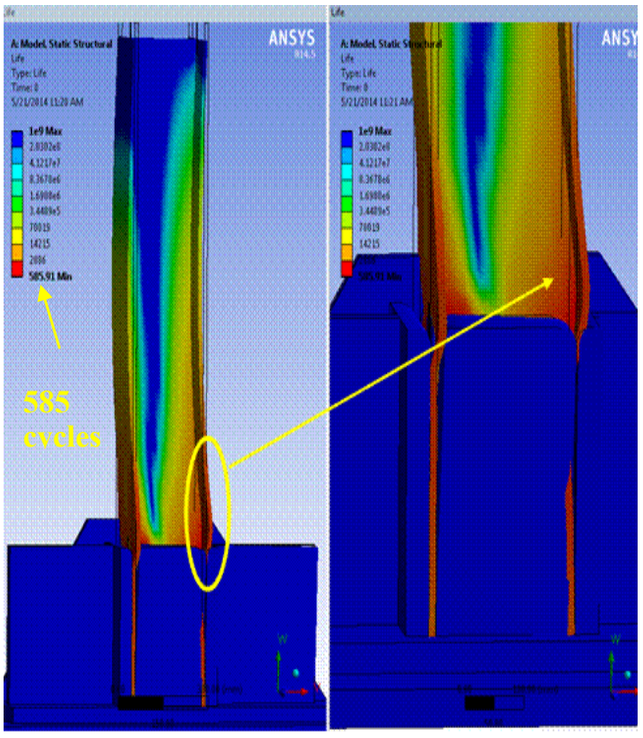

Figure 13. Local buckling due to low cycle fatigue in FEM

5 EXPERIMENTAL TEST SET UP

In this study, steel HP220x57 pile specimens are tested to investigate the effect of low cycle fatigue life of steel H piles at the abutments of integral bridges. For this purpose, constant amplitude reversed cyclic displacements are applied to the top of the cantilever HP220x57 piles using a servo-controlled hydraulic actuator operated in displacement control where a sinusoidal cyclic displacement waveform signal with a frequency of 0.5Hz is employed for displacement control at room temperature. Axial load is applied on the pile specimen due to the limitations of the test setup and lateral load is applied only in the strong axis direction. Detailed discussion of the experimental tests and test results are given in the following subsections.

5.1 *Test set up*

A cantilever steel HP220x57 section is tested to simulate the inelastic cyclic behavior of steel H-piles under thermal effects in integral bridges. The cantilever system has an upside down geometry of the pile-abutment system of an integral bridge as shown in Fig. 14. A steel fixture is designed to simulate the fixity condition of the pile to the integral abutment. A reinforced concrete fixture simulating the integral bridge abutment is not used in the tests due to possible damage and cracking of the reinforced concrete abutment upon cyclic loading that may result in loosening of the pile-abutment connection. This may then render the correct measurement of inelastic pile strains ineffective. Accordingly, as the focus of the research is to assess the low cycle fatigue life of steel H-piles, a steel fixture becomes more appropriate. The steel fixture is connected to the rigid test frame and the cyclic displacement is applied to the top of the cantilever HP steel section. The cantilever length is chosen to approximately correspond to the length of the pile effective in resisting the lateral movement due to temperature fluctuations (equivalent cantilever length). The equivalent cantilever length of the pile is calculated as the length from the top of the pile (where the maximum moment occurs) to the point of contra-flexure. For this purpose, a total of 128 static pushover analyses of typical integral bridges are conducted to determine the equivalent cantilever length of the steel H-piles that are used in the experimental part of this research study. Based on the pushover analyses results, the average equivalent length of a pile made of HP steel section is determined as 1.35 m. Accordingly, HP220x57 steel members are cut in 1.90 m length where the 0.4 m part is encased in the steel base fixture to provide fixity and the load is applied at approximately 0.15 m from the top of the pile (the centerline of the load is at 0.15 m from the pile top).

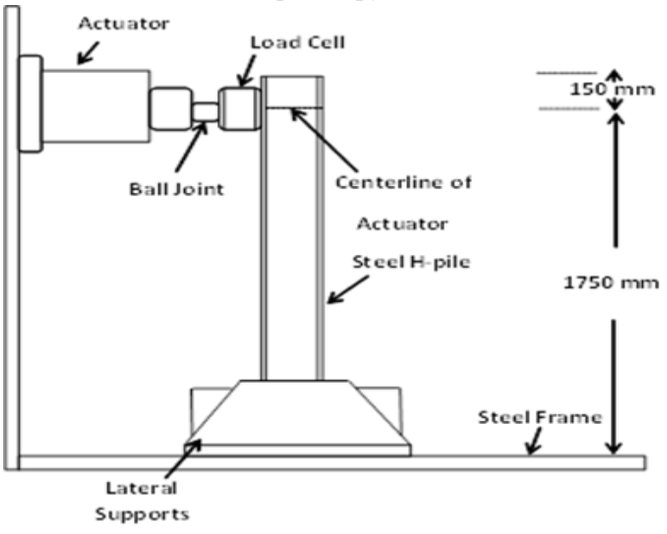

Figure 14. The equivalent pile system

5.2 *Instrumentation*

Three types of measuring devices are used to instrument the steel H-piles. These are, (i) electrical resistant strain gauges for measuring strains on the steel H–piles. (ii) Load cell for measuring the lateral load level, (iii) LVDT (displacement transducer) for measuring the lateral displacement. The test setup is shown in Fig.14. The HP steel section is vertically erected and fitted to the base fixture and the base fixture is bolted to the bottom of the test frame. The pile is instrumented with twelve strain gauges and three displacement transducers. The plan view of the configuration of the strain gauges on the pile cross-section is also shown in Fig.15. Strain measurements are required to correlate fatigue life of HP steel section with the cyclic strain amplitudes. Therefore, strain measurement is performed at the critical locations where fatigue failure occurs. Displacements, strains and lateral loads are measured and recorded using a data-logger (TDG-Ai8b). Furthermore, in the test set up, a displacement controlled hydraulic actuator capable of applying ±500 KN of load and a stroke of ± 125 mm is used to impose lateral cyclic displacements.

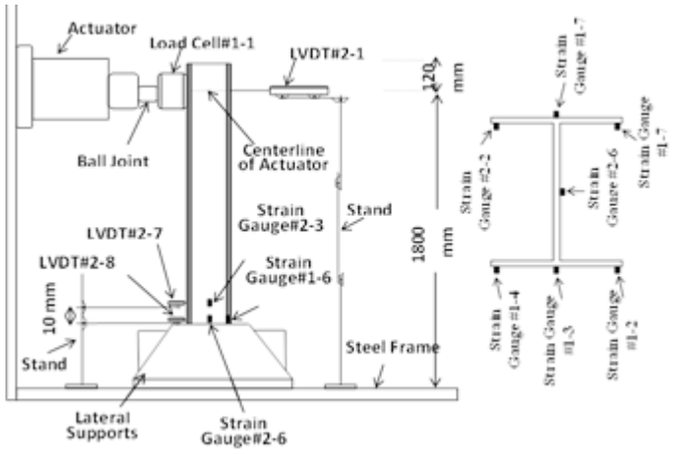

Figure 15. Experimental set-up: location of the strain gauges and LVDT.

6. EXPERIMENTAL TEST

6.1. Low Cycle Fatigue Test results of Specimen#1

The low cycle fatigue tests of Specimen #1 are conducted by applying only large amplitude strain cycles to the specimens. The amount of cyclic displacement at the top of the piles is controlled such that a flexural strain equal to five times the yield strain ($\varepsilon_a=5\varepsilon_y$) is developed in the outermost fibers of the flanges. This required the application of a cyclic lateral displacement of ±64 mm at the pile top. Fig.16 shows a typical HP220x57 pile specimen under cyclic lateral displacement. During the experimental testing of the piles under constant amplitude cyclic displacements/strains, the fatigue-induced cracks firstly developed in the intersection of the flanges and the web. The cracks then expanded towards the tips of the flanges under further cycling as shown in Fig.17. In the case of this test, the specimens fractured due to low cycle fatigue when the average number of cycles from the test reached 241.

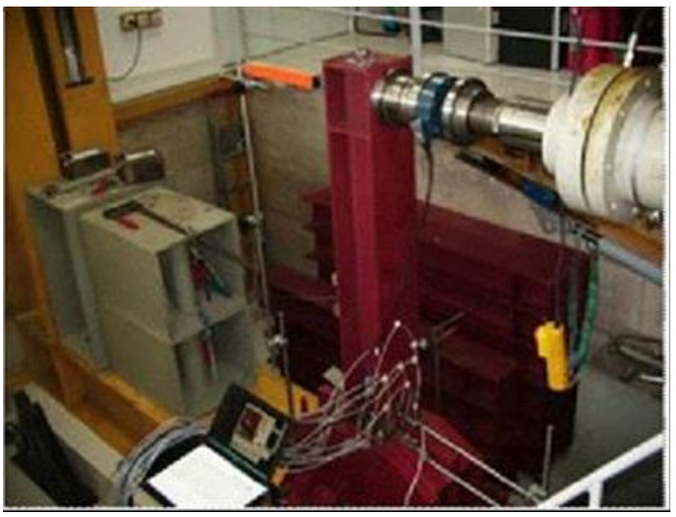

Figure 16. Specimen-1 under cyclic lateral load normal to its strong axis.

Figure 17. Front and side views of fatigue induced steel pile fracture right above the steel base fixture

6.2 Low Cycle Fatigue Test results of Specimen#2

In this phase of the research study, in addition to lateral load, axial load is also applied to the pile specimens made of a HP220x57 section (identical to that of Specimen #1) to explore the effect of axial load on the low cycle fatigue life of steel H piles at the abutments of integral bridges. The cyclic displacements applied to the top of the pile specimens are shown in Fig.18. To achieve the same large amplitude flexural strain level as in the case of Specimen #1 (five times the yield strain ($\varepsilon_a=5\varepsilon_y$)), the piles are subjected to a displacement of 64 mm at the top. In addition, axial loads are also applied as 360 kN, 156 kN and 280 kN during the push, normal and pull direction together with the lateral loads as shown in Fig.19. Average value of axial load is determined as 250 kN ($P=0.11P_y$).

Figure 18. Specimen-2 under cyclic lateral load and axial load.

Figure 19. (a) Push direction, (b) Mid-position, (c) Pull direction.

The results obtained from experimental test on HP220x57 section demonstrate that first fracture begins 341 cycles as shown in Fig.20-a. After 341 cycles, fracture starts to expand as shown in Fig.20-b. Finally, low cycle fatigue occurs when steel HP220x57 section is reached to the 508 cycles as shown in Fig.20-c. The result obtained from experimental test on HP220x57 section reveals that local buckling occurs exactly above the 400 mm-high steel base fixture as shown in Fig.20-d.

Figure 20. (a) First fracture occurs 341 cycles, (b) First fracture begins expansion after 341 cycles, (c) Front view of fracture occurs exactly above the 400 mm-high steel base fixture, (d) Local Buckling.

7 CONCLUSIONS

Followings are the conclusions deduced from this research study. In light of the data obtained from FE models of the steel H-pile specimens used in the experimental test set up, it is observed that high axial stress concentrations exist around the connections of the HP steel section and the 400 mm-high plate of the steel base fixture. It is observed that the magnitude of these stresses is very high on HP section. Due to the fact that this is indicative of local damage to HP section, FE model should be simulated to prevent these local damage before experimental tests are performed. At the large strain amplitude, due to local buckling of the flange, the reduction in fatigue life is observed. In light of the data obtained from FEM predictions, these local buckling can be predicted and prevented before experimental tests are performed. Further, it is observed that FE analysis predictions can be used to avoid the huge cost and testing time required for conducting experimental tests.

Comparing the FEM results and experimental test results of HP220x57 specimens, it is observed the observations from this numerical study are also verified experimentally. Thus, it may be possible to make a correlation and calibration between FEMs and experimental test results of the thermal induced cyclic displacements/strains on the low cycle fatigue performance of steel H-piles at the abutments of integral bridges. FEM predictions can be an excellent alternative of destructive laboratory test with an acceptable variation of results.

Experimental Investigation on the Low Cycle Fatigue Life of Piles

M. Karalar
Bulent Ecevıt Universıty, Department of Cıvıl Engineering, TURKEY
M. Dicleli
Middle East Technical University, Department of Engineering Sciences, TURKEY

ABSTRACT: In this study, the low cycle fatigue tests are conducted to investigate the fatigue life of steel H–piles subjected to thermal induced cyclic strains/displacements. Review of literature revealed that there are few experimental research data on the low cycle fatigue performance of integral bridge steel H-piles. For this purpose, experimental studies on full scale steel H-pile specimens are conducted to simulate cyclic behavior of steel H-piles under thermal effects in integral bridges by considering the effect of axial load combined with large amplitude strain cycles with various amplitude levels. Using experimental test results, the effect of axial load level is investigated on the low cycle fatigue performance of integral bridge steel H–piles. It is observed that the effect of axial load on the low cycle fatigue performance of integral bridge steel H-piles are so important to reduce the bending stresses in the steel H-piles and also increase the low-cycle fatigue performance of steel H-piles at the abutments of integral bridges at the moderate strain amplitudes. Moreover, it is observed that at large strain amplitudes the effect of local buckling should be considered more than the effect of axial load on the low cycle fatigue life of steel H piles at the abutments of integral bridges.

1 GENERAL INSTRUCTIONS

Integral bridges are jointless bridges where the superstructure is connected monolithically with relatively thin, stub abutments supported on a single row of piles that provide the required flexibility to allow for longitudinal movement of the bridge under thermal effects. A typical two-span, prestressed-concrete girder, integral bridge is shown in Fig.1. The most common type of piles used at the abutments of integral bridges is steel H-piles. The daily and seasonal temperature changes result in imposition of cyclic horizontal displacements on the continuous bridge deck of integral bridges and thus on the abutments, backfill soil, steel H-piles, and cycle control joints at the ends of the approach slabs. Consequently, the abutments are pushed against the approach fill and then pulled away, causing lateral deflections at the tops of the piles that support the abutments of the bridge.

As the length of integral bridges increases, the temperature-induced lateral cyclic displacements in the steel H-piles at the abutments become larger as well. As a result, the piles may experience cyclic plastic deformations. This may result in the reduction of their service life due to low-cycle fatigue effects. The number and amplitude of thermal-induced cyclic flexural strains in integral bridge steel H-piles are important parameters that effect their low cycle fatigue life. Close examination of the existing field measurement data for integral bridges revealed that the measured thermal-induced cyclic flexural strains in steel H-piles at the abutments consist of large amplitude, primary small amplitude and secondary small amplitude cycles (Dicleli & Albhaisi 2004). Although a few research studies on low cycle fatigue effects in the steel H-piles of integral bridges at the abutments are found in the literature (Arsoy et al.1999, Abendroth&Greimann 2005, Dicleli&A lbhaisi 2004, French et al. 2004, Razmi et al. 2013, Khodoir&Hassiatis 2013, Hallmark 2006], none of these research studies provide analytical and experimental results on the effect of the flexural strain cycles on the low cycle fatigue life of steel H-piles at the abutments of integral bridges until recently. However, in recent years, Karalar &Dicleli (2010) only studied the effect of the primary and secondary small amplitude flexural strain cycles on the low cycle fatigue life of steel H-piles at the abutments of integral bridges analytically using steel H pile cyclic strain data from the field measurements of several integral bridges in North America. Further, Karalar and Dicleli (2010) also conducted some experimental studies on full scale steel H-pile specimens to verify these analytical results. In this research study, the effect of strain cycles with various amplitude

levels on the low cycle fatigue life of steel H piles at the abutments of integral bridges is studied experimentally. The results from this research study are used to evaluate the thermal-induced low cycle fatigue life of steel H-piles. The observation regarding the experimental results of the low cycle fatigue life of steel H piles at the abutments become important as it provides evidence about the adequacy of the current design methods in relation to the low cycle fatigue life of steel H-piles at the abutments. The outcome of such a research study may also be used to develop design guidelines that may be used to design steel H-piles to endure low cycle fatigue effects throughout the service life of the bridge.

2 EXPERIMENTAL TEST SET UP

In this study, steel HP220x57 pile specimens are tested to investigate the effect of low cycle fatigue life of steel H piles at the abutments of integral bridges. For this purpose, constant amplitude reversed cyclic displacements are applied to the top of the cantilever HP220x57 piles using a servo-controlled hydraulic actuator operated in displacement control where a sinusoidal cyclic displacement waveform signal with a frequency of 0.5Hz is employed for displacement control at room temperature. Axial load is applied on the pile specimen due to the limitations of the test setup and lateral load is applied only in the strong axis direction. Detailed discussion of the experimental tests and test results are given in the following subsections.

2.1 *Test set up*

A cantilever steel HP220x57 section is tested to simulate the inelastic cyclic behavior of steel H-piles under thermal effects in integral bridges. The cantilever system has an upside down geometry of the pile-abutment system of an integral bridge as shown in Fig. 2. A steel fixture is designed to simulate the fixity condition of the pile to the integral abutment. A reinforced concrete fixture simulating the integral bridge abutment is not used in the tests due to possible damage and cracking of the reinforced concrete abutment upon cyclic loading that may result in loosening of the pile-abutment connection. This may then render the correct measurement of inelastic pile strains ineffective. Accordingly, as the focus of the research is to assess the low cycle fatigue life of steel H-piles, a steel fixture becomes more appropriate. The steel fixture is connected to the rigid test frame and the cyclic displacement is applied to the top of the cantilever HP steel section. The cantilever length is chosen to approximately correspond to the length of the pile effective in resisting the lateral movement due to temperature fluctuations (equivalent cantilever length). The equivalent cantilever length of the pile is calculated as the length from the top of the pile (where the maximum moment occurs) to the point of contra-flexure. For this purpose, a total of 128 static pushover analyses of typical integral bridges are conducted to determine the equivalent cantilever length of the steel H-piles that are used in the experimental part of this research study. Based on the pushover analyses results, the average equivalent length of a pile made of HP steel section is determined as 1.35 m. Accordingly, HP220x57 steel members are cut in 1.90 m length where the 0.4 m part is encased in the steel base fixture to provide fixity and the load is applied at approximately 0.15 m from the top of the pile (the centerline of the load is at 0.15 m from the pile top).

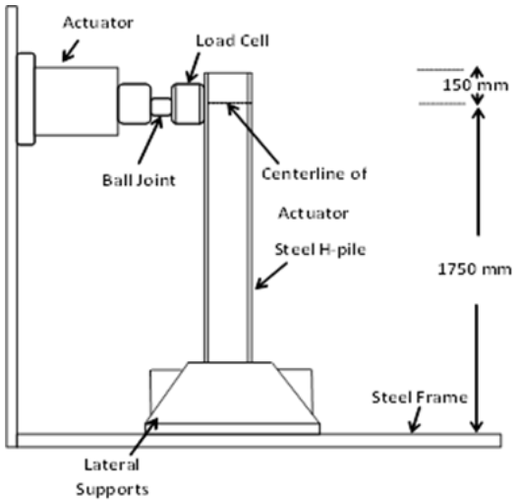

Figure 2. The equivalent pile system used in the experimental set-up

2.2 *Instrumentation*

Three types of measuring devices are used to instrument the steel H-piles. These are, (i) electrical resistant strain gauges for measuring strains on the steel H–piles. (ii) Load cell for measuring the lateral load level, (iii) LVDT (displacement transducer) for measuring the lateral displacement. The test setup is shown in Fig.3. The HP steel section is vertically erected and fitted to the base fixture and the base fix-

ture is bolted to the bottom of the test frame. The pile is instrumented with twelve strain gauges and three displacement transducers. The plan view of the configuration of the strain gauges on the pile cross-section is also shown in Fig.3. Strain measurements are required to correlate fatigue life of HP steel section with the cyclic strain amplitudes. Therefore, strain measurement is performed at the critical locations where fatigue failure occurs. Displacements, strains and lateral loads are measured and recorded using a data-logger (TDG-Ai8b). Furthermore, in the test set up, a displacement controlled hydraulic actuator capable of applying ±500 KN of load and a stroke of ± 125 mm is used to impose lateral cyclic displacements.

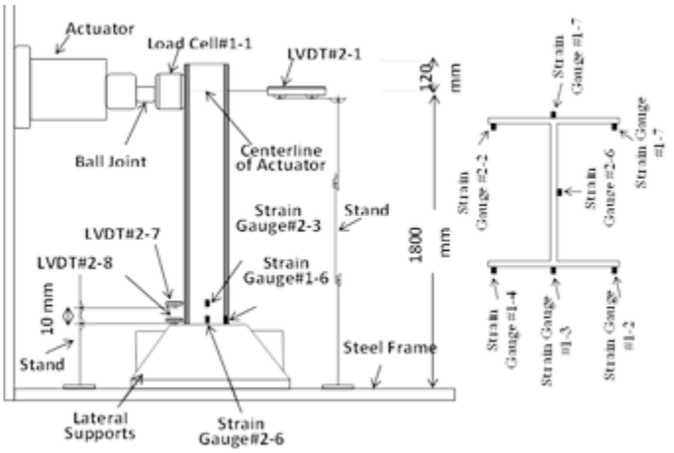

Figure 3. Experimental set-up: location of the strain gauges and LVDT.

3. EXPERIMENTAL TEST

3.1. Low Cycle Fatigue Test results of Specimen#1

The low cycle fatigue tests of Specimen #1 are conducted by applying only large amplitude strain cycles to the specimens. The amount of cyclic displacement at the top of the piles is controlled such that a flexural strain equal to two half five times the yield strain ($\varepsilon_a=2.5\varepsilon_y$) is developed in the outermost fibers of the flanges. This required the application of a cyclic lateral displacement of ±44 mm at the pile top. Fig.4 shows a typical HP220x57 pile specimen under cyclic lateral displacement. During the experimental testing of the piles under constant amplitude cyclic displacements/strains, the fatigue-induced cracks firstly developed in the intersection of the flanges and the web. The cracks then expanded towards the tips of the flanges under further cycling as shown in Fig.5. In the case of this test, the specimens fractured due to low cycle fatigue when the average number of cycles from the test reached 2134 cycles.

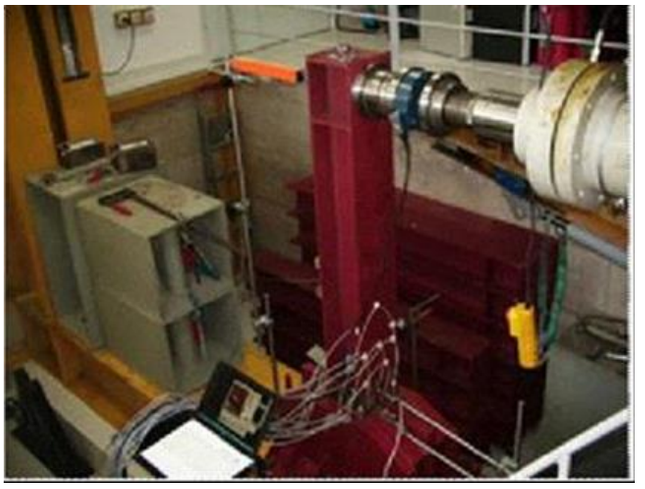

Figure 4. Specimen-1 under cyclic lateral load normal to its strong axis.

Figure 5. Front view of fatigue induced steel pile fracture right above the steel base fixture

3.2. Low Cycle Fatigue Test results of Specimen#2

The low cycle fatigue tests of Specimen #2 are conducted by applying only large amplitude strain cycles to the specimens. The amount of cyclic displacement at the top of the piles is controlled such that a flexural strain equal to five times the yield strain ($\varepsilon_a=5\varepsilon_y$) is developed in the outermost fibers of the flanges. This required the application of a cyclic lateral displacement of ±64 mm at the pile top. Fig.6 shows a typical HP220x57 pile specimen under cyclic lateral displacement. HP220x57 pile specimen Lateral Load-Micro strain Relationship for Specimen#2 is shown in Fig.7 (b). During the experimental testing of the piles under constant amplitude cyclic displacements/strains, the fatigue-induced cracks firstly developed in the intersection of the flanges and the web. The cracks then expanded towards the tips of the flanges under further cycling as shown in Fig.7. In the case of this test, the specimens fractured due to low cycle fatigue when the average number of cycles from the test reached 241.

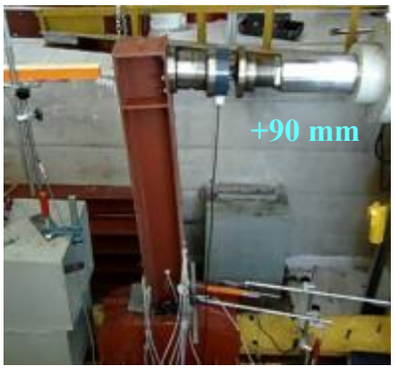
(b)

Figure 7. (a) Front and side views of fatigue induced steel pile fracture right above the steel base fixture, (b) HP220x57 pile specimen Lateral Load-Micro strain Relationship for Specimen#2.



3.3 Low Cycle Fatigue Test results of Specimen#3

The low cycle fatigue tests of Specimen #3 are conducted by applying only large amplitude strain cycles to the specimens. The amount of cyclic displacement at the top of the piles is controlled such that a flexural strain equal to ten times the yield strain ($\varepsilon_a=10\varepsilon_y$) is developed in the outermost fibers of the flanges. This required the application of a cyclic lateral displacement of ±90 mm at the pile top as shown in Fig.8. During the experimental testing of the piles under constant amplitude cyclic displacements/strains, the fatigue-induced cracks firstly developed in the intersection of the flanges and the web. The cracks then expanded towards the tips of the flanges under further cycling as shown in Fig.8. In the case of this test, the specimens fractured due to low cycle fatigue when the average number of cycles from the test reached 154.

Comparing the test results, it is observed as expected that the average number of large amplitude strain cycles to failure reduced when the yield strains level increased from the five times yield strain ($\varepsilon_a=5\varepsilon_y$) to ten times yield strain ($\varepsilon_a=10\varepsilon_y$) in the tests as shown in Fig.9.

3.4 Low Cycle Fatigue Test results of Specimen#4

In this phase of the research study, in addition to lateral load, axial load is also applied to the pile specimens made of a HP220x57 section (identical to that of Specimen #2) to explore the effect of axial load on the low cycle fatigue life of steel H piles at the abutments of integral bridges. The cyclic displacements applied to the top of the pile specimens are shown in Fig.10. To achieve the same large amplitude flexural strain level as in the case of Specimen #2 (five times the yield strain ($\varepsilon_a=5\varepsilon_y$)), the piles are subjected to a displacement of 64 mm at the top. In addition, axial loads are also applied as 360 kN, 156 kN and 280 kN during the push, normal and pull direction together with the lateral loads as shown in Fig.11. Average value of axial load is determined as 250 kN ($P=0.11P_y$).

Figure 10. Specimen-4 under cyclic lateral load and axial load.

Figure 11. (a) Push direction, (b) Mid-position, (c) Pull direction.

The results obtained from experimental test on HP220x57 section demonstrate that first fracture begins 341 cycles as shown in Fig.12-a. After 341 cycles, fracture starts to expand as shown in Fig.12-b. Finally, low cycle fatigue occurs when steel HP220x57 section is reached to the 508 cycles as shown in Fig.12-c. The result obtained from experimental test on HP220x57 section reveals that local buckling occurs exactly above the 400 mm-high steel base fixture as shown in Fig.12-d.

Figure 12. (a) First fracture occurs 341 cycles, (b) First fracture begins expansion after 341 cycles, (c) Front view of fracture occurs exactly above the 400 mm-high steel base fixture, (d) Local Buckling.

3.5 Low Cycle Fatigue Test results of Specimen#5

In this phase of the research study, in addition to large amplitude strain cycles, axial load is also applied to the pile specimens to investigate the effect of axial load level combined with large amplitude strain cycles with various amplitude levels on the low cycle fatigue life of steel H piles at the abutments of integral bridges. To achieve the same large amplitude flexural strain level as in the case of Specimen#3 (ten times the yield strain ($\varepsilon_a=10\varepsilon_y$)), the piles are subjected to a displacement of ±90 mm at the top. In the tests, average value of axial load is determined as 170 kN ($P=0.075P_y$). Fig.13 shows a typical HP220x57 pile specimen under cyclic lateral and axial load.

Figure 13. Step-by-step spread of local buckling and fracture throughout the pile flange.

4 CONCLUSIONS

The following discussion is aiming to qualitatively describe the effect of strain cycles with various amplitude levels due to daily and/or weekly temperature fluctuations. All the results are based on the assumption that the steel H piles of integral bridges response is primarily correlated to daily and/or weekly temperature fluctuations. Comparing the test results, it is observed that, as expected, number of cycles to failure is inversely proportional to the strain amplitude. The reduction in fatigue life is observed to range between 40% and 50% when the pile is subjected to larger strain amplitudes (10 times the yield strain). This is mainly due to local buckling of the flange under the effect of compressive stresses from the high compressive strains due to the effect of bending. Local buckling increases the local curvature and strains. This locally accelerates the cracking of the material. As a result of this large lateral buckling, fracture starts earlier and also low cycle fatigue in steel HP sections takes place at smaller cycles. Additionally, in the test, the effect of the axial load on small amplitude cycle is also investigated. It is observed that the effect of axial load on small amplitude cycle have a significant effect on the low cycle fatigue performance of steel H-piles in two ways: (i) when the pile is subjected to moderate strain amplitudes (five times the yield strain), the presence of axial load is observed to enhance the low cycle fatigue life of the pile. This mainly due to the fact that, the presence of axial load decreases the amplitude of the tensile strain that results in cracking of the material (it delays the initiation of the crack), (ii) when the pile is subjected to larger strain amplitudes (10 times the yield strain), the presence of axial load is observed to decrease the low cycle fatigue life of the pile. This is mainly due to local buckling of the flange under the effect of compressive stresses from the axial load and high compressive strains due to the effect of bending. Local buckling increases the local curvature and strains. Thus, it should be found an effective way to delay the local buckling to enhance the fatigue life of steel H-piles.

ABSTRACT: In this paper, we present the closed U-ribs deteriorated case with steel plate deck of bridge in service. In the investigation, we carried out a desk study of the deck to through details and to identify if there are any details that have a track record of causing problems on other bridges. Defect identification, detailed inspection, finding causes and evaluation were also conducted. This case will contribute to prevent similar case in the future and the ongoing development of operational and maintenance procedures for the life of the bridge.

1 GENERAL INSTRUCTIONS

1.1 *Research background*

Construction of facilities in Korea have leaned heavily toward quantitative aspects that emphasized "low construction costs" and "fast-track construction" during the period of rapid economic growth since 1970s. This resulted in weakness in qualitative aspects compared with leading countries, and the situation was aggravated by the lack of institutional initiatives for proper maintenance and investments in relevant fields.

The social perception of facilities are concentrated in expanding new facilities but paying no attention to the investment for maintenance, with arbitrary decision of the maintenance managements. The systematic maintenance managements had not been done due to the absence of the safety management relation laws in Korea until 1995s that had resulted in tragic disaster like the collapse of Songsu bridge in Seoul.

After that, The "Special Act for the safety Control of public facilities and multi-use facilities were finally initiated, which enhance the convenience of people who use public facilities and to ensure public safety and welfare.

The safety and maintenance management is sorted into two system, one is precautionary measures to prevent disaster of facilities which is called as "Construction Technology Management Act" and another is the restoration measures of facilities after accident which is called "Special Act for the safety Control of public facilities and multi-use facilities", "Framework Act on the Management of Disasters and Safety".

The facilities graded 1 and graded 2 among the important facilities classified by Korea government can be conceptualized according to Table 1. In-depth inspection in Korea, which should be done to facility graded 1 above mentioned within 1year every 5years after 10years has been completed, is carried out after a safety check for prevention of disasters and facility safety.

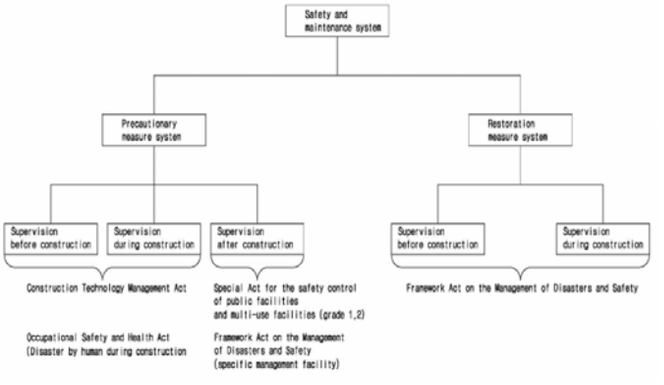

Figure 1 Act system on safety and maintenance of Korea facilities

In-depth inspection above is defined as the behavior to propose the possible solution including repair and reinforcement for facility having physical and functional defect investigated by field investigation and test for structural stability. Each representative bridge of different form , which is Suspension bridge, cable stayed bridge, arch bridge and truss bridge among facilities graded 1, are shown in Figure 2 and the completion year and condition grade of the facility graded 1 and 2 are shown in Figure 3 and 4.

Table 1 Facility graded

grade	Contents
Facility graded 1	・Bridge having form of superstructure such as suspension bridge, cable-stayed bridge, arch bridge, truss bridge ・Bridge having maximum span of 50m (except for one span bridge) ・Bridge over length 500m
Facility graded 2	・Bridge having maximum span of 50m ・Bridge over length 100m except for Facility graded 1

1.2 *INTRODUCTION OF LONG SPAN BRIDGE MANAGEMENT CENTER(LOBMAC)*

KISTEC(Korea Infrastructure Safety & Technology Co. is running Long Span Bridge Management Center(LOBMAC) to improve maintenance works based on unified remote monitoring system of long span bridges on national highway in Korea.

LOBMAC has 5 main missions as follows. LOBMAC consists of 3 divisions as shown on Figure 5. There are 26 Bridges under management of LOBMAC as of 2017 such as Table 2

1. Regular, and in-depth inspection(including of management facilities such as a trolley, elevator and dehumidifier)
2. Operation of the unified monitoring system
3. Real-time monitoring of the bridges in service life
4. Building and analyzing the database for monitoring data using FEA model
5. Consulting of monitoring system for long span bridges under construction

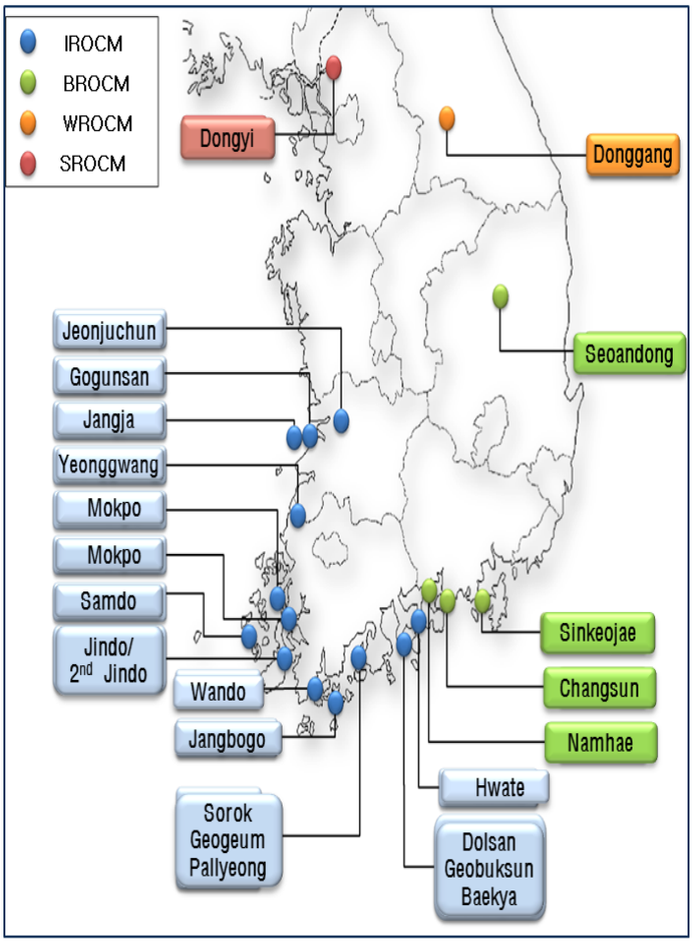

Figure 6 Bridges under management of LOBMAC

2 BRIDGE IN THIS PAPER

2.1 *Bridge Specification*

The bridge in this paper is one of the bridge under management of LOBMAC which is first constructed cable stayed bridge in the 1980s. The public service period has been aged for more than 30 years and design live load was improved from DB-18 to DB-24 through the performance improvement construction recently.

It has 484m total length involving 344m main span length, superstructure 3span of continuous stiffening girder. The deck plate is consist of 18 longitudinal U-ribs in the upper flange.[Figure 8]

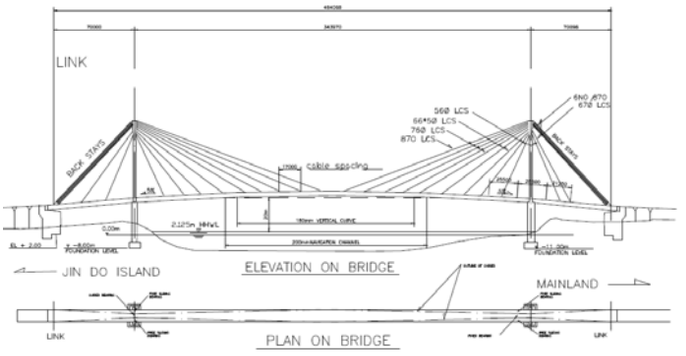

Figure 7 Longitudinal Drawing

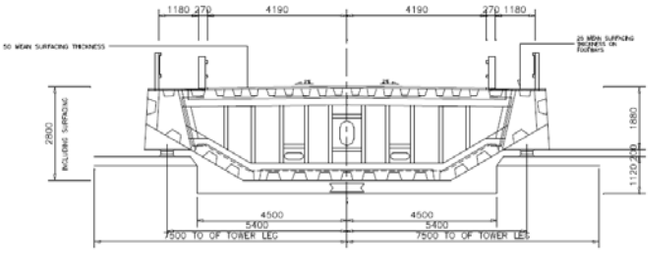

Figure 8 Cross-sectional drawing

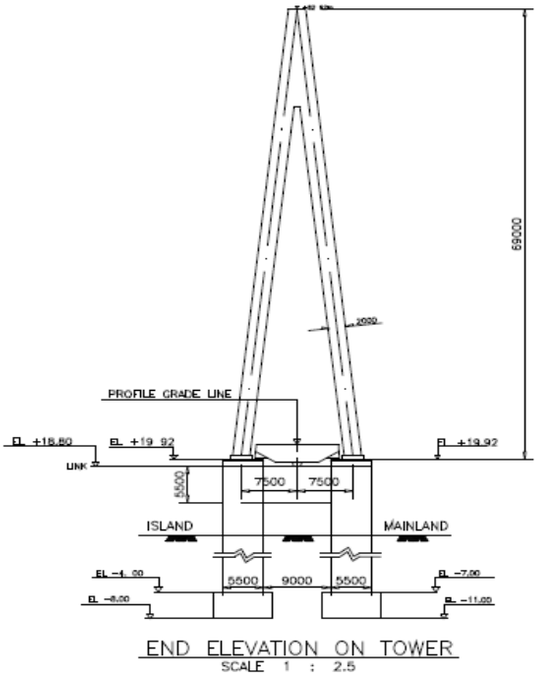

Figure 9 End elevation on pylon

2.2 *Maintenance and reinforcement history*

There were 7 tim es of Precision safety inspection(including urgent) & 2 tim es repavement were conducted during 30 years above. The dehum idification facility was installed in the stif fening girder in 1990's.

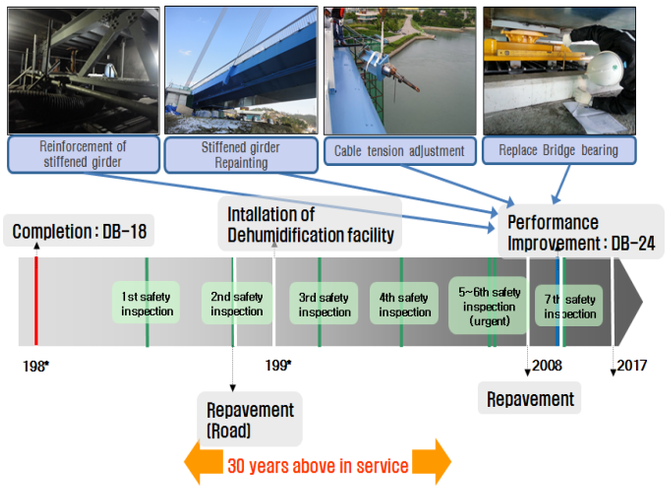

Figure 10 Maintenance history of the bridge

The maintenance history about painting and pavement what the particular factor to find causes of corrosion was summarized in Table 3 & 4.

3 DEFECT IDENTIFICATION

A cable stayed bridge deck is a vital part of the load carrying system of the bridge. Unlike a suspension bridge where the deck is simply a suspended stiffening element where local failures do not imperil the overall stability of the bridge, a cable stayed bridge deck is a primary load carrying element that carries the compression load generated by the horizontal component of the cable stayed forces. If the deck capacity is reduced then there is the outside risk that the deck could buckle locally which would be catastrophic for the bridge structure. Thus, deterioration of the bridge deck through corrosion could lead to a very serious problem if not rectified.

It has been noted by the inspectors that it is suspected that the water flow in the longitudinal U-ribs emanates from the top surface, implying that either surface could be cracked or have extraneous construction holes which are letting water through the surfacing.

There were two immediate issues to be resolved for this bridge and the problem of the influx of water into the U-ribs and the subsequent corrosion.

The first was to identify the source of ingress of the water and to stop it, thereby removing the potential for corrosion.

The second was to identify the extent of the corrosion and to assess its impact on the integrity of the bridge.

3.1 *Corrosion extent*

Corrosion was identified in 4 ribs in the upper flange of the total 18 ribs in the form of its painting heaving like an air pocket on external surface of the longitudinal U-ribs. It was corroded about 80m along the longitudinal direction after removal of heaved painting.[Figure 2]

Figure 11 Corrosion of Longitudinal U-ribs

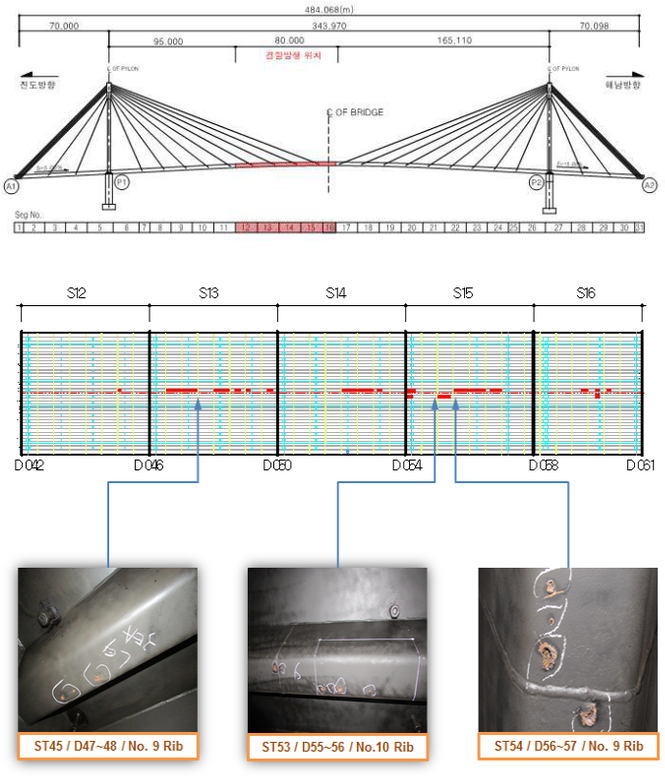

Figure 12 Location of corrosion by visual inspection

Table 5 Corrosion extent

Longitudinal rib No.	Location			Remark
	Segment	Diaphragm	Point(EA)	
9	S12~16	D45~61	71	
10	S15~16	D54~56 D59~60	10	

3.2 *Causes of corrosion*

The first step would be to investigate the extent of the ingress of water whic h will enable us to understand the extent of potential corrosion dam age and the likely sources of ingress into the deck.

It would be vitally im portant to identify the areas of ingress so that repairs may be made to the U-ribs.

The first stage would be to carry out a desk study of the deck to trough details and to identify if there are any details that have a track record of causing problems on other bridges. W e understood that at this stage the source of wa ter ingress has been identified as being at the location of the deck splices f or the make-up piece of the box section where bolted joints are present across the flange which were installed for the tem porary shear key. These joints are now redundant it would be expected that the holes were plugged by a suitable tapped thread so that the head did not project into the surfacing layer. It was not clear from video foot age taken of the troughs whether there are heads or nuts on these studs.

The four U-ribs that are affected were for the centermost. In each instant it would appear that the sealing protection of the bolts or threads has failed in every case and that a new detail would be required to reseal these holes.

A. As-built drawing & construction record

A total of 56 bolt holes were installed for shear key, a temporary fixture for transverse restraint on the upper part of the reinforced girder. And 16 of them were located within internal U-ribs.[Figure 13]

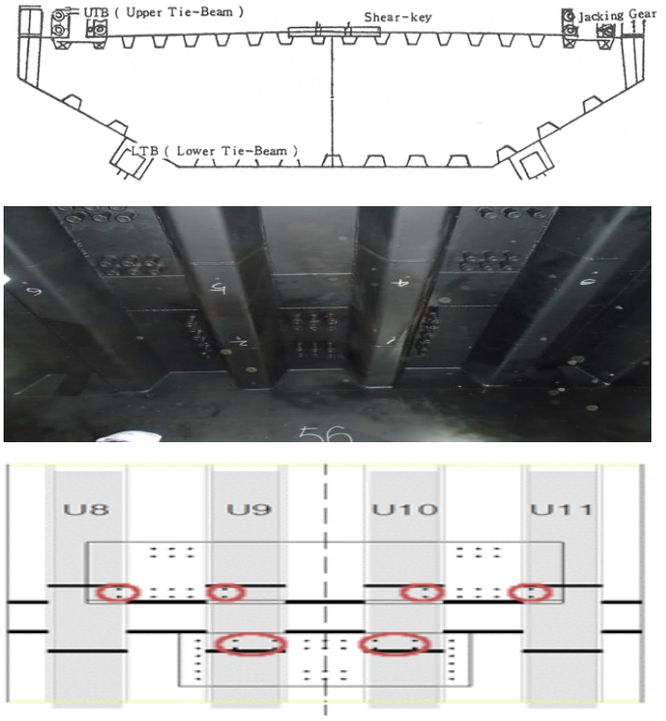

Figure 13 Deck details around the bolted tem porary works

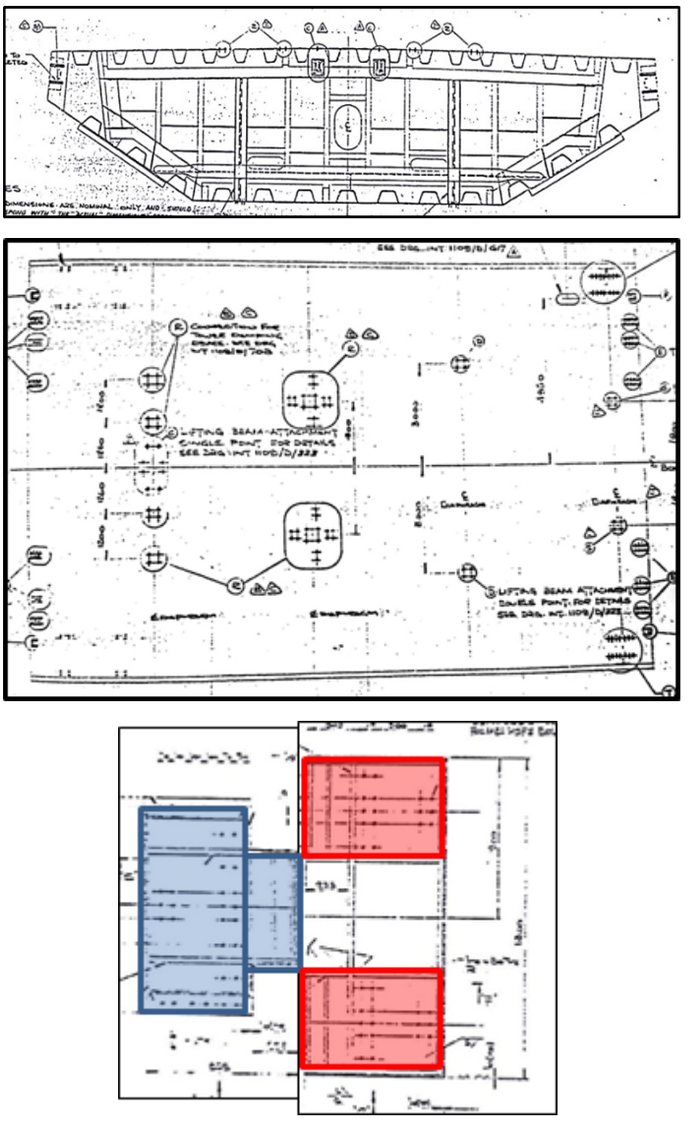

Figure 14 Location of Bolt holes & shear key details on as-built drawing

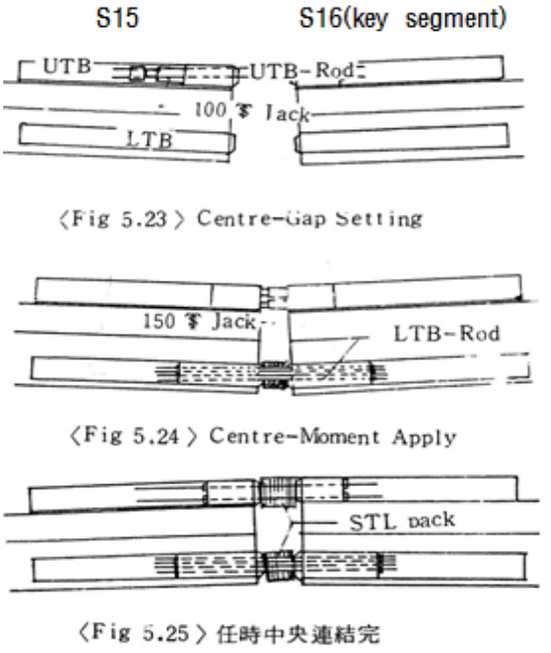

Figure 15 Closure Procedures of key segment

B. Maintenance and reinforcement history

As a result of analysis, it was found that the bolt holes drilled into the upper deck for tem porary works were not fully sealed. According to the record of whole repaving in 2008, bolt fracture & slip on the exposed part were checked.[Figure 7]

Figure 16 Bolts fracture & slip in perform ance improvement construction record

C. Previous inspection report

We checked out continuous water leak through a bolt holes from the top surface safety after reviewing inspection report.

(c) Corrosion & debris (d) Health condition not damaged

Figure 18 Corroded internal U-rib by borescope inspection

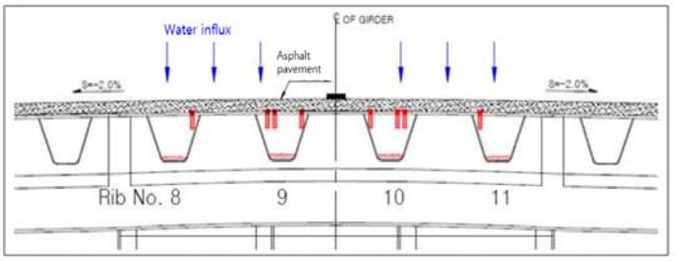

Figure 19 Estimated path of water inflow

4 FUTHER INVESTIGATIONS

Further investigations are scheduled as follows.

4.1 *Detail internal inspection using inspection robot*

Work has been carried out to date on som e limited borescope video studies. These show that there is a build-up of corrosion products on the bottom flange of the U-Ribs.

It would be required to ascertain how m uch damage had taken place from the corrosion of the steelwork. The extent of this build-up of deleterious m aterial was not clear from the borescope and the nature and extent of the m aterial should be investigated. Production of inspection robot is in progress to identify the exact extent of corrosion.

4.2 *Finite element analysis*

Finite element analysis is in progress to determ ine the penetrating location of inspection robot about

longitudinal & transverse directions, analytically. In the finite element analysis, MIDAS FEA, which is general purpose structural analysis software, was used. And the plate element was used in modeling of stiffening girder.

4.3 *Measurement of steel & coating thickness*

Ultrasonic testing to measure the thickness loss of the steel section of the U-ribs is scheduled.

4.4 *Repair & rehabilitation design*

The extent of the repair and rehabilitation design will depend upon the findings from the earlier investigations. It is anticipated that the design will need to provide a new means of sealing the bolt holes within the U-Ribs that can be demonstrated to be completely watertight, as well as establishing what if any repairs are required to replace material lost to corrosion within the troughs.

The development of a bold sealing design will be dependent on access to the top deck and the means by which resurfacing of the bridge deck is carried out. The design of the bolt sealing will need to be sufficiently robust so that it can withstand the rigours of removal of the deck surfacing by mechanical means. It is suspected that this may have played a part in the failure prior to this, but this is speculation at this point.

The rehabilitation design of the troughs will be developed based upon an assessment of the traffic loading requirements on the bridge deck to determine the minimum structural capacity of the U-Ribs. Clearly it would be needed to minimize the amount of strengthening and therefore if it can be shown that the loss of section is still sufficient for the current traffic loading on the bridge then strengthening may be avoided. However, this presupposes that we would carry out a specific live loading assessment.

The video footage taken from the borescope shows considerable debris within the troughs that would appear to be material that has parted company with the parent metal of the trough. If this is the case then there is likely to be significant loss of section, even though that is not appear to be any evidence of complete loss of section. It is expected to be proper that effective strengthening would be to cut out the existing trough and to re-weld a new segment in place.

Detailed inspections & record is required on the top surface of the exposed deck when the next whole repaving to prevent repetition case.

5 CONCLUSION

The bridge in this paper is one of the bridge under management of LOBMAC which is first constructed cable stayed bridge in the 1980s.

It has been noted by the inspectors that it is suspected that the water flow in the longitudinal U-ribs emanates from the top surface, implying that either surface could be cracked or have extraneous construction holes which are letting water through the surfacing.

Corrosion was identified in 4 ribs in the upper flange of the total 18 ribs by its painting heaving like an air pocket on external surface of the longitudinal U-ribs.

We carried out a desk study of the deck to through details and to identify if there are any details that have a track record of causing problems on other bridges. Defect identification, detailed inspection, finding causes and evaluation were conducted.

In this paper, we present only the part of research results obtained in the on-going research. Further investigations relating to be resolved of this bridge are scheduled.

This case will contribute to prevent similar case in the future and the ongoing development of operational and maintenance procedures for the life of the bridge.

ABSTRACT: Early-age cracking on concrete bridge decks is a major concern because it leads to premature deterioration of bridges. Most of the cracks formed during the curing stage of concrete are due to the drying shrinkage. This paper presents the experimental and analytical investigation of shrinkage-induced stresses and strains within large-scale bridge prototype. Three large-scale bridge decks of 7 x 10 ft were built using three different types of concrete mixtures: (1) a mixture containing 100% Portland cement, (2) a mixture incorporate Type-K cement and (3) a mixture containing partially saturated fine lightweight aggregate (LWA) to promote internal curing. The results show that the LWA concrete mixture induced the least amount of stresses within the deck while the Type-K developed the largest stresses at the end of six-month shrinkage period. The finite element simulation was used to predict the shrinkage of concrete decks with a reasonable accuracy.

1 INTRODUCTION

Cracks in concrete bridge decks are detrimental as it allows harmful substances to reach the reinforcing steel and initiate corrosion and compromise the integrity of the deck. Bridge decks are especially vulnerable to cracking due to their large surface-to-volume ratios, which exposes the concrete to a high-water evaporation rate.

Concrete shrinks due to moisture loss, temperature reduction or hydration reactions. When these volume changes are restrained, tensile stress develops in concrete which may cause cracking. Cracking often occurs in concrete bridge decks due to restrained shrinkage of concrete. Numerous research studies have been conducted to evaluate the causes of crack-ing in bridge decks through experimental and field investigations (Cheng and Johnston, 1985, Darwin et al., 2004, French et al., 1999, Horn et al., 1975, Neville, 1995). This includes altering the concrete mixture design (Streeter, 1996, Lawler et al., 2006, Brown et al., 2007), incorporating steel or polymer fibers or other additives (Altoubat and Lange, 2001, Naik et al., 2006, Subramaniam et al., 2005), and adjusting construction practices in terms of placing sequence, curing time and weather requirements (Issa, 1999, Krauss and Rogalla, 1996, Schmitt and Darwin, 1995).

In addition, studies have examined optimizing the structural design of bridge superstructures including changing the number of shear studs or the spacing between reinforcement (French et al., 1999, Frosch et al., 2002, Schmitt and Darwin, 1995). Some studies have also found that lowering the amount of restraint inside the concrete deck can help reduce crack formation as well. Another study modeled bridge deck shrinkage and found that the reinforcement within the deck leads to high tensile stresses in the concrete deck (Nagataki and Gomi, 1998).

Three types of concrete mixtures were studied in this research: (1) a deck containing 100% portland cement, (2) a deck incorporating Type-K cement (a shrinkage compensating cement), and (3) a deck containing partially saturated fine lightweight aggregate (LWA) to promote internal curing. Type-K cement is shrinkage compensating cement which, unlike portland cement, compensates for drying shrinkage by initially expanding during the early stages of hydration (Chaunsali et al., 2013, Gruner and Plain, 1993, Klein et al., 1961, Nagataki and Gomi, 1998, Pittman et al., 1999, Richardson et al., 2014). The mechanism of expansion in the Type-K cement concrete is a result of the early formation and stability of ettringite. The ettringite crystals need water to expand; therefore, moist curing must

be used or minimal expansion will occur. Numerous studies have concluded that the use of pre-wetted lightweight aggregate can minimize the development of autogenous and drying shrinkage through improved curing (Bentur et al., 2001, Bentz and Weiss, 2011, Wei and Hansen, 2008, Henkensiefken et al., 2009, Browning et al., 2011, Guthrie and Yaede, 2013). The pre-wetted fine aggregate extends the curing period by releasing absorbed water.

Cracking due to restrained shrinkage is a major concern for both serviceability and durability of concrete, but only limited research has sought to model the shrinkage of concrete by finite element (FE) analysis. Ngo and Scordelis (1967) presented the first finite element analysis of reinforced concrete that included the effect of cracking. In order to simulate the shrinkage phenomenon of concrete, some researcher converted the total shrinkage into thermal shrinkage by means of the method of Equivalent Temperature Difference (Attiyah et al., 2014, Kianoush et al., 2008, Ma and Gao, 2008). In this study shrinkage behavior was presented by converting the shrinkage induced strain into an equivalent temperature to simulate the cracking tendency of concrete.

This study strives to investigate shrinkage cracking through a combination of laboratory experimentation and finite element modeling. A specific objective of this research included the development of a finite element model that could correctly evaluate and predict the shrinkage induced stresses within a bridge deck. Three-dimensional FE models using ABAQUS were developed to determine the overall structural response due to shrinkage. The developed FE models were verified using experimental results from large scaled bridge decks. Three 7 x 10 ft concrete bridge bays were used for the verification of the FE models. The reinforcement and bay design details will be discussed in details in the finite element modeling section. Finite element model was used to monitor the stress and strain change within the concrete deck to predict the potential of cracking.

2 FINITE ELEMENT MODELING

The objective of the finite element (FE) analysis is the development of a model that predicts the stress-strain behavior of a bridge resulting from concrete shrinkage. The FE simulation conducted in the study was carried out using ABAQUS finite element software. To study the effects of shrinkage, as well as to better replicate full-scale bridges, large-scale bridge prototypes (also called bridge bays) measuring 7 × 10 ft with an 8 in thick slab were created using ABAQUS, as shown in Fig. 1. The size and shape of the bridge deck was scaled based on Illinois Department of Transportation standard design (Ardeshirilajimi et al., 2016, Chaunsali et al., 2013). The deck was surrounded by four C10×15.3 steel channels on the outside perimeter to simulate the continuity of an actual concrete deck. Two layers of epoxy coated reinforcement were placed within the deck with a top and bottom clear cover of 2 in and 1.75 in, respectively. The girders were spaced at m 5 ft. and were constrained by two C6×8.2 steel channels to prevent the girders from twisting.

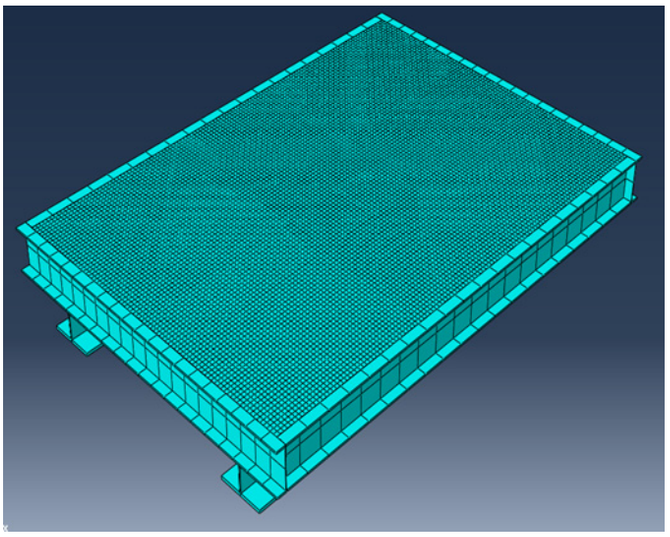

Figure 1. ABAQUS model of experimental deck.

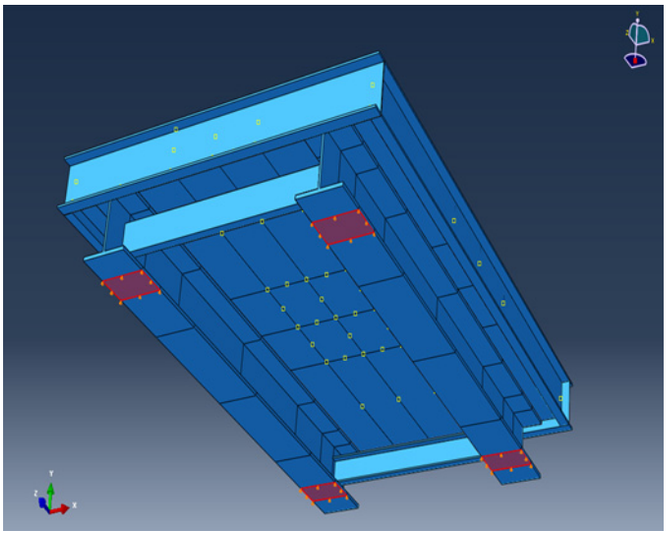

Figure 2. Boundary conditions; fixed in y direction (gravity direction) at the red marks.

The reinforcement was idealized using 2-node linear truss elements that consider only axial strain along the reinforcement length (T3D2 elements). The experimental deck, supporting girders and perimeter channels were modeled with 8-node linear brick elements (C3D8R continuum solid elements). Each node had three translational degrees of freedom in the x, y and z directions. The brick elements utilize reduce integration used to limit the number of integration points and reduce the running time with-out an unreasonable sacrifice of accuracy (ABAQUS, 2014).

The focus of the FE analysis is to model the shrinkage-induced strain before first cracking of the

deck with the entire analysis conducted in the linear elastic range. The concrete and steel material properties used for FE modeling are listed in Table 1. A different elastic modulus and weight-per-unit volume were used for the different types of concrete according to the measured mixture properties. An elastic modulus value consistent with a 28-day unconfined compressive strength and a Poisson's ratio of 0.2 was selected for all concrete materials. The thermal coefficient of concrete usually varies be-tween 3 to 8×10^{-6}/°F for normal-weight concrete (ABAQUS 2014). A thermal coefficient of 5.5×10^{-6}/°F was used for all types of concrete in this study.

Full bond is assumed between the steel and the concrete by sharing nodes at their intersection points. All the elements in the large-scale model are bound by applying tied constraints, except for the reinforcement that was embedded inside the concrete deck, which allowed the concrete and reinforcement to act together when the concrete is expanding or shrinking. The entire experimental deck was fixed in the gravity direction at the supports located at the bottom of the girders (Fig. 2).

Table 1. Mixture Properties

	Control	Type-K	LWA	Steel
Weight per unit volume (lb/ft^3)	142	141	136	490
Modulus of elasticity (ksi)	3770	3668	4380	29000
Poisson's ratio	0.2	0.2	0.2	0.3
Thermal coefficient of expansion (10^{-6}/°F)	5.5	5.5	5.5	6.5

3 EXPERIMENTAL BRIDGE BAY DESIGN

Experimental bridge "cut-outs" built with three different concrete mixtures was constructed using the dimensions described FE modeling section (Fig. 3). All the scaled concrete decks were constructed using the same steel sections, reinforcement size and type, and were placed at the same time of the year by the end of September to minimize variation in results due to environmental effects.

Multiple strain and temperature gages were installed within and on the surfaces of the concrete deck panels. To minimize interference from perimeter C-channels and supporting steel girders, all of the gages were installed towards the center of the deck, as shown in Fig. 4 and 5. Twenty strain gages were interspersed throughout the top and bottom reinforcement layers in both the longitudinal and transverse directions and was monitored for a period of six months. More gages were placed on the top layer of reinforcement, as this is generally where the greater amount of cracking is found and is of greater interest for this study.

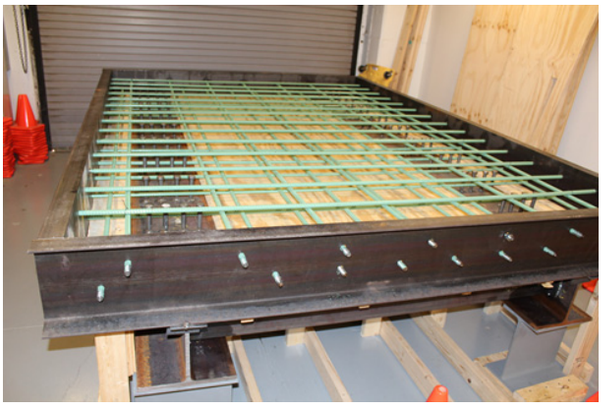

Figure 3. Experimental deck.

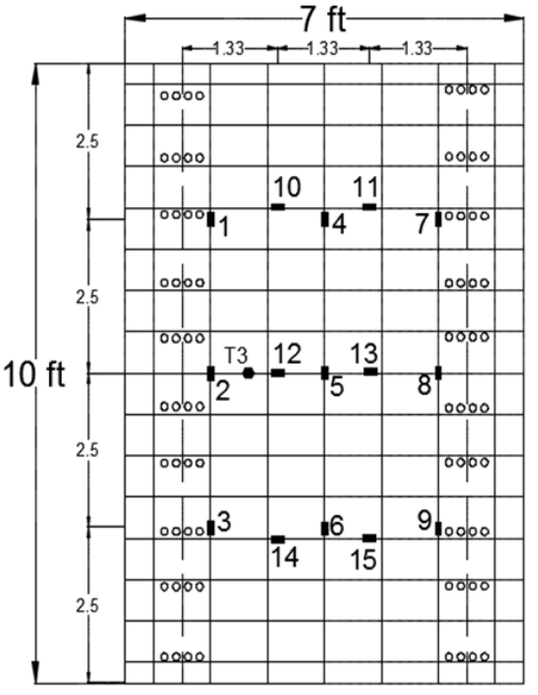

Figure 4. Strain gage location on top reinforcement.

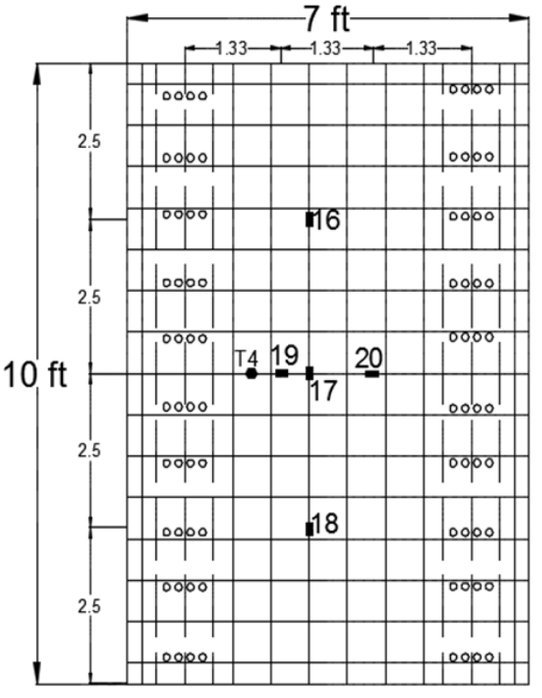

Figure 5. Strain gage location on bottom reinforcement.

A total of 15 strain gages were attached to the top layer of reinforcement, nine on the longitudinal reinforcement and six on the transverse reinforcement for each concrete deck (Fig. 4). Another five gages were installed on the bottom layer of the reinforcement including three on the longitudinal and two on the transverse reinforcement (Fig. 5). All foil gages were given a protective coating in accordance with manufacturer recommendations.

4 COMPARISON BETWEEN FE AND EXPERIMENTAL RESULTS

Strains measured in the longitudinal reinforcement are chosen to be the primary focus for this research because they represent the mechanism by which transverse cracking is initiated in actual bridge decks. Concrete initially expands during the 7-day curing period followed by shrinkage upon initiation of drying (in this case after 7 days). Strain data were recorded for a period of six months and the negative strain indicates shrinkage. Modeling of drying shrinkage strain directly using the FE method is not possible in ABAQUS, and as a result, an equivalent temperature load was used to model the shrinkage behavior of the concrete. After comparing all data collected from the experiments, it was obvious that the strain data collected from different locations within the experimental deck showed no obvious trend (Ardeshirilajimi et al., 2016); therefore, an average longitudinal total shrinkage strain (shown in Fig. 6) was used to determine the equivalent temperature load. The temperature load applied was uniform throughout the deck and was determined using the equation $\varepsilon = \alpha\Delta T$. The strain ($\varepsilon$, from the average longitudinal total shrinkage strain collected from the experimental data) divided by the concrete thermal coefficient of expansion ($\alpha = 0.5\times10^{-6}$/°F) yields the temperature load applied to the concrete deck in the FE model. Figure 7 shows the temperature load applied to each type of concrete. These temperature loads permit shrinkage strains to be mimicked using ABAQUS and the results from the comparison between the FE models and the experimental data are shown in Fig. 8 through Fig. 10.

As shown in Fig. 8 and Fig. 9, the strain results (ABAQUS compared with experiments) for the control and Type-K deck were very comparable until day 30, but by the end of 6 months, there was a deviation of about 50 με. However, the result for the LWA (Fig. 10) was almost identical. Overall, the temperature load that was applied to the three types of FE models, predicted results in good agreement with the data collected from the tested concrete decks.

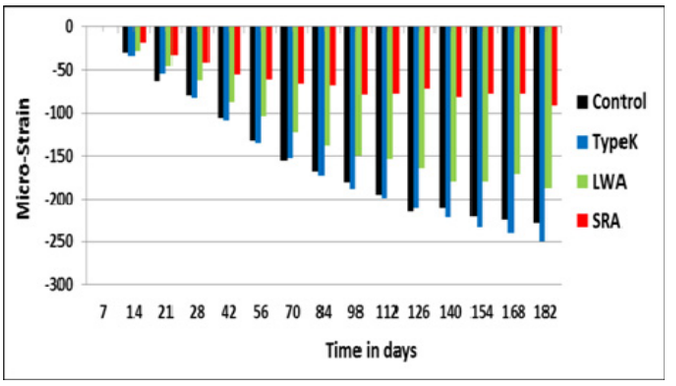

Figure 6. Average longitudinal total shrinkage of experimental deck.

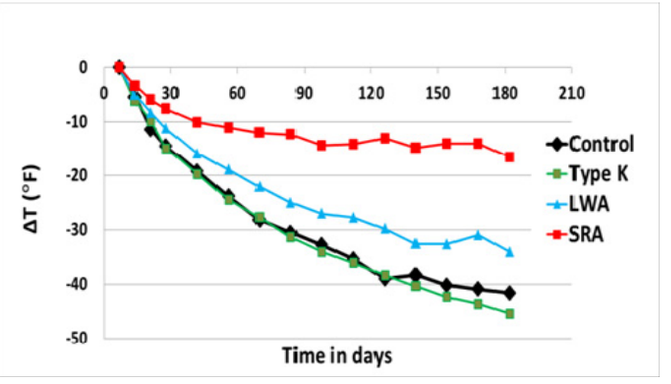

Figure 7. Temperature load applied to the FE model, in °F.

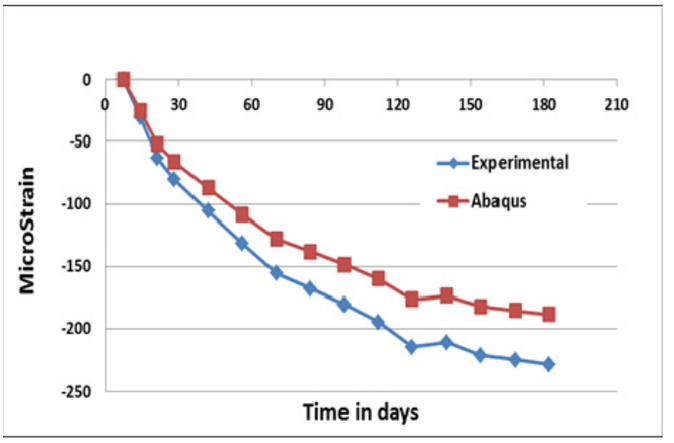

Figure 8. Control concrete deck.

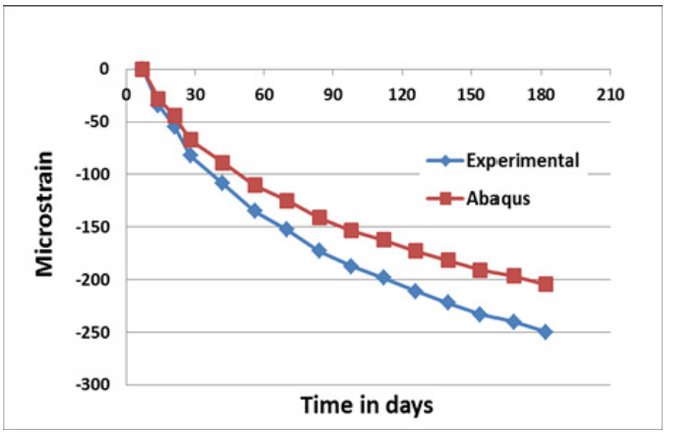

Figure 9. Type-K concrete deck.

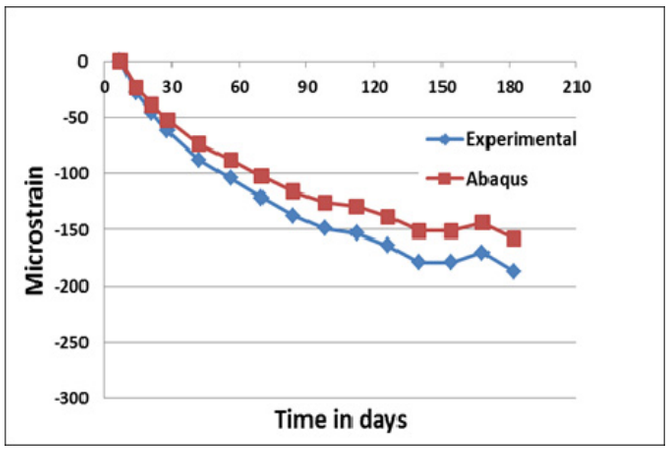

Figure 10. LWA concrete deck.

Longitudinal stress contours at the bottom layer of reinforcement inside the concrete deck for the three different types of concrete are shown in Fig. 11 to 13. Concrete containing internally cured lightweight aggregate (LWA) has a similar stress contour compared with the control mixture with a lower calculated stress at the center of the deck (279 psi and 236 psi for the control and LWA decks, respectively). On the other hand, the Type-K deck has a higher stress concentration around the supporting girders with a stress of 287 psi at the center of the deck.

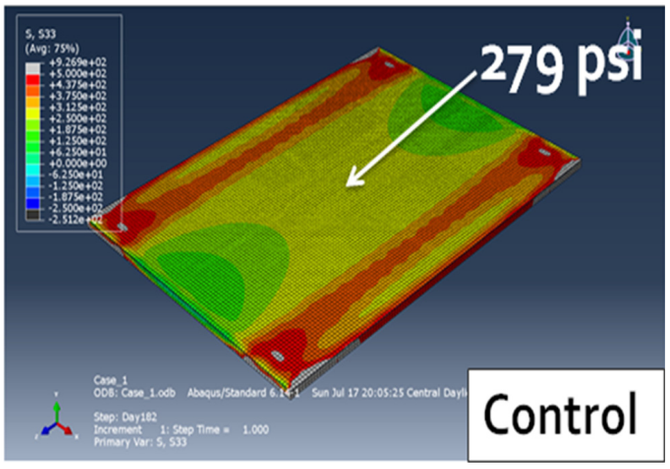

Figure 11. Control deck stress contours in longitudinal direction.

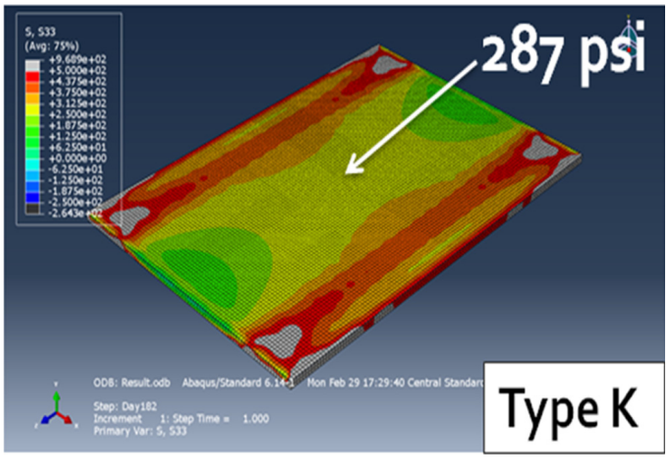

Figure 12. Type-K deck stress contours in longitudinal direction.

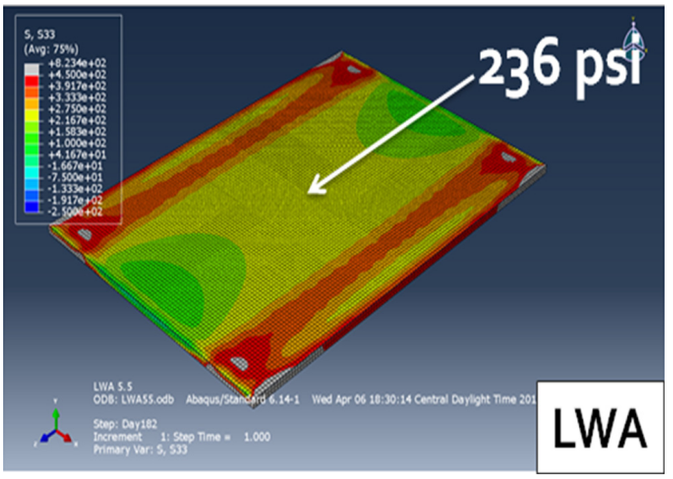

Figure 13. LWA deck stress contours in longitudinal direction.

The objective of this simulation is to evaluate the effect of drying shrinkage-induced strains on developing stress that cause cracking in concrete decks. It is possible that at early age tensile stress introduced by shrinkage strain exceed the tensile strength of concrete which may initiate cracking in bridge decks. Reduction in stress turns less chance of cracking inside the concrete deck which supports that LWA has the least amount of shrinkage among the three different types of concrete.

5 SUMMARY AND CONCLUSION

Cracks reduce the service life of concrete decks and it is a major safety concern for the bridge decks. Significant research has been conducted in the past on assessment of cracking in bridge decks through field investigation, but only limited research has sought to model the shrinkage of concrete by finite element (FE) analysis. In this study shrinkage of concrete in bridge decks is modeled using the finite element (FE) software ABAQUS. Through the application of a uniform equivalent temperature load, the shrinkage of concrete can be closely simulated in all experimental decks. The main focus of the FE modeling is to study the stress and strain induced by concrete shrinkage in generating early age cracking in bridge decks. The following conclusions are based on the experimental and analytical work presented in this paper:

- Shrinkage of the concrete deck can be predicted analytically with reasonable accuracy using finite element (FE) model.
- Finite element models can be used to predict the stress and strain within the concrete deck and as well as to predict the potential of cracking.
- LWA concrete mixture induced the least amount of stresses within the deck compared to control mixture.

- Type-K developed the largest stresses within the deck at the end of six-month shrinkage period.

Methods for fast and reliable determination of damping and tension force of stay cables

Thomas Mack

Roman Geier
Schimetta Consult, CEO, Vienna, Austria

ABSTRACT: After the construction of cable-stayed bridges it is always necessary in the framework of bridge inspections and special investigations to determine the static and dynamic parameters like cable force and the damping of the stay cable. Methods employed so far have often been too cost-intensive and time-consuming whereas the results have indicated in terms of the cable force deviations of up to ± 10%, which often proved to be insufficient for engineers and operators. In the framework of several research projects measurement and evaluation methods have been developed for both parameters and which can be applied faster and easier and at the same time improve the accuracy of the cable force determination to ± 1%. As concerns the damping parameter, an evaluation method has been developed which satisfies the constructive requirements and leads to reliable and reproducible damping values.

1 INTRODUCTION

Stay cables are decisive bearing elements of a cable-stayed bridge and are essential for the system stiffness and system damping. Today mainly prefabricated cables are used which are provided with a final or temporary corrosion protection. The laid ropes as well as parallel wire ropes usually consist of single wires with a diameter of 5-7 mm. These steel wires have a considerably higher carbon share than structural steel and correspondingly a higher stability. This, however, leads to a considerably lower ductility which manifests itself in a respective ultimate elongation.

Dynamic analysis is very important for cable-stayed bridges as well as suspension bridges in the project stage. In general vibrations of a structure can be stimulated by the effects of wind, traffic and earthquakes. The safety of a cable-stayed bridge is considerably determined by the aerodynamic behaviour. So far example dynamic instabilities were the reason for collapses of some early suspension bridges (Tacoma Narrows Bridge). Vibrations can clearly affect or reduce the load-bearing capacity, the durability (fatigue) as well as the serviceability limit strength (effects on the user).

Up to today the development of bridge construction has continued, constantly new materials and technologies have been used – the limits of technological feasibility have continuously shifted into the extreme range. Whereas increasingly wide spans have been successfully bridged, numerous structural problems have emerged which have to be considered during planning. The dynamic properties of the respective structure have assumed a special importance in this connection. As early as in the 19th century, after the disaster in the Tay Bay, dynamic load cases were considered important factors during the planning of structures.

In the course of history of bridge construction dynamic loads on bridges were to provide for big surprises frequently. In the 20th century in particular the spectacular collapse of the Tacoma Narrows suspension bridge in the US state of Washington on 7 November 1940 has to be emphasized in this connection, where fortunately no human-being was harmed. The catastrophic collapse of the Tay Bridge as well as the spectacular failure of the Tacoma Narrows Bridge in the USA in 1940 made the responsible engineers as well as the general public aware of the significance of dynamic effects in the building trade. World-wide the research activities in the field of dynamics were intensified.

Today the practical and easy availability of dynamic investigation methods has been reached by means of the possibilities of modern measuring and analysis techniques. Not only in the last few decades and centuries were engineers confronted with vibration problems at structures. Also during the last few years, despite sufficient knowledge of dynamic effects as well as the decisive structural parameters, vibration problems have continued to emerge in building, above all in bridge construction. Here above all the "Erasmus-Bridge" in Rotterdam opened to traffic in 1996 as well as the "Millennium

Bridge" in London opened on 10 June 2001 have to be mentioned.

From the shortly mentioned early as well as current vibration problems at bridges it is clearly recognizable that there is still extensive demand for research in the field of structural dynamics. Whereas for some problems respective solutions or assessment methods are already existing, there are still numerous fields where practical approaches and investigation methods are lacking. This publication shall provide the essential findings of the last few years with regard to the investigation and assessment of tension bars of stayed structures, especially the easy, secured and reproducible determination of the cable force and the damping of stay cables.

2 STATE OF THE ART

2.1 *Stay Cable Forces*

Bridges but also many other buildings have an individually developed vibration behaviour which may be addressed as vibration characteristic. This dynamic behaviour typical for a structure can be registered by appropriate measurements and be used for the assessment of the condition of the load-bearing structure and the determination of damages after respective evaluation. This structural response can be well described by the modal parameters eigenfrequencies, mode shapes as well as the respective damping values.

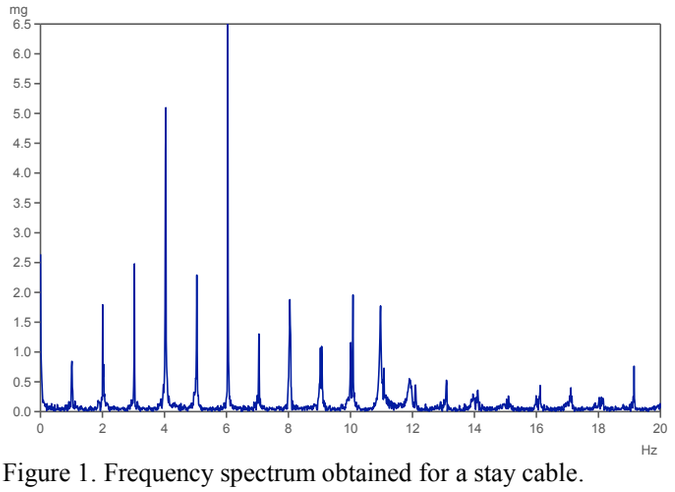

Figure 1. Frequency spectrum obtained for a stay cable.

The arrangement of the cables represents one of the decisive design criteria for cable-stayed bridges. The load-bearing behaviour, the construction procedure and the economic efficiency is substantially determined by the cable geometry. This is decisive above all for big spans. The spans of cable-stayed bridges have continuously grown since the development of this design type. The dynamic behaviour of the big bridges planned in the last few years therefore moved more and more into the centre of interest of the responsible engineers. Today no bridge is built anymore without performing wind tunnel and dynamic tests first where the behaviour of the total system as well as of the individual elements (cables) is investigated in detail (Geier 2004).

Dynamic analysis is very important for cable-stayed bridges as well as suspension bridges in the project stage. In general vibrations of a structure can be stimulated by the effects of wind, traffic and earthquakes. Vibrations can clearly affect or reduce the load-bearing capacity, the durability (fatigue) as well as the serviceability limit strength (effects on the user). The estimation of the fundamental modes is very important for planning and subsequent assessment. Whereas the natural vibrations can be very accurately determined by means of dynamic measurements, rules-of-thumb are an advantage for being able to roughly determine a frequency range on site or in the framework of planning. A connection between main span L as well as the first vertical bending eigenfrequency f of all bridges investigated by the authors (more than 100 structures) is shown in figure 2.

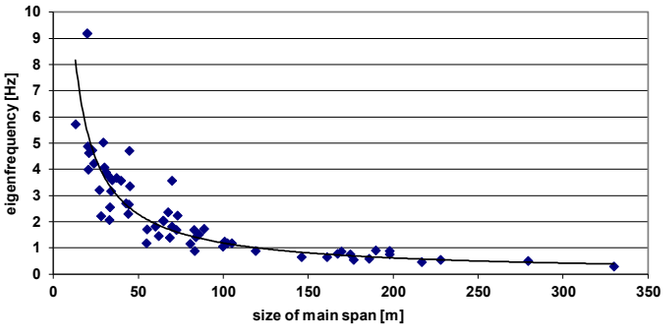

Figure 2. Relation between first vertical bending frequency and main span of the structure.

The function for the first vertical bending eigenfrequency derived from the measured frequency values exclusively for cable-stayed bridges is:

$$f = 84{,}309 \cdot L^{-0{,}9586} \approx \frac{100}{L} \qquad (1)$$

2.2 *Damping of stay cables*

An essential dynamic parameter which needs to be determined with cable-stayed bridges is the damping of the stay cables. Despite the most recent methods of calculation for modern bridge structures, as well as FE-modelling and wind tunnel tests damping continues to be a difficult parameter to determine and has to be determined on-site.

Given that the stay cables are a structural element very much prone to resonance due to wind and traffic, in the project phase vibration reducing external dampers are often designed which are configured for theoretical frequencies and damping values. For the reception of these structural elements nowadays it is

customarily necessary to determine the inherent damping of the cables and the damping with installed external dampers in order to check the design values and to prove the action mode of the external dampers.

For these measurements, according to the state of the art, acceleration sensors are installed and then ambient measurements or measurements with targeted excitation are performed. Based on the measured data the damping is determined through the reduction or distribution of energy. This can be achieved either in the time or frequency domain.

In the time domain the logarithmic decrement Λ can simply be determined. It describes the range of energy dissipation from amplitude to amplitude of a vibration. In nature the physical behaviour of a fading vibration is often times closest to a natural logarithm which accounts for its definition as the quotient of two successive vibration maximums and is described in the following formula:

$$\Lambda = \frac{1}{n} \ln \frac{y_0}{y_n} \tag{2}$$

Another evaluation method is the broad band method which is employed in the frequency domain. The determination is based on the idea that increasing damping causes faster energy reduction which leads to a compression of the frequency peaks in the spectrum and hence to an increase in broadness. The maximum energy peak in the frequency spectrum is divided through $\sqrt{2}$ and the energy level thus determined is cut with the frequency line. Both frequencies thus determined f_1 and f_2 are then used for the determination of damping according with the following formula:

$$\zeta = \frac{f_2 - f_1}{f_2 + f_1} \tag{3}$$

For both evaluation methods automated software packages have been already developed which implemented these formulas and which compare the measurement signal with the known functions of known damping (Mack 2017).

3 DEFINITION OF PROBLEM

3.1 *Stay Cable Forces*

In the framework of planning as well as the subsequently required maintenance of bridge structures engineers are increasingly confronted with stay cables and external tendons. On the one hand because cable-stayed bridges are increasingly designed and built due to their aesthetic appearance, on the other hand because in the framework of rehabilitations of old structures as well as in case of new designs external prestressing is more and more frequently used. In case of the complex cable-stayed bridges there is the additional problem that the condition as well as the current load-bearing capacity of the most sensitive load-bearing elements of such structures –cables and ropes – can only be checked with difficulty.

The main objective of the current research activities is the development of accurate, non-destructive methods for the determination of the tensile force effective in the cable on the basis of vibration measurements. Methods used up to now are either very time-consuming and expensive (for example by lift-off tests with a repeated application of the prestressing jack) or can cause damages in the cable itself, the anchoring structure or the input area of the cable forces. Principally up to now also vibration measurement methods were used for the determination of the effective cable force, the accuracy achieved in this process was, however, not satisfactory. Above all in case of high cable forces and short cables sometimes errors of up to ± 10% of the actual cable force could be determined.

A further ambitious goal of the research activities is the derivation of assessment parameters which enable the determination of the current condition of a tendon. Quantifiable and therefore comparable decision criteria have to be developed with which an objective assessment of the cable can be carried out. It is the aim to identify damaged and critical cables from the whole entity of stay cables by means of the evaluation of certain parameters on the basis of dynamic measurements. Consequently an efficient instrument for assessment is available on which rehabilitation measures or monitoring concepts can be based (Geier 2004).

3.2 *Damping of stay cables*

Stay cables have a theretically infinite number of natural vibration forms. Whereas with other structural elements the natural frequencies can be looked at and analyzed individually, with stay cables the vibration forms always overlap, given that they depend on each other. The harmonic content is always about several times the basic vibration.

In recent laboratory tests it was proven that despite excitation of a natural frequency with a shaker all the other natural frequencies are always present in the frequency spectrum. When the shaker excitation is stopped, the amount of energy created overlaps with the energies transferred to the neighbouring frequencies.

In detailed studies dedicated to the determination of damping in stay cables, superpositions of a large number of vibrations were ascertained in a large number of cases. The result of filtering for only one natural vibration form has also been indicative of significant overlapping and beat frequencies in the

measurement result. Figure 3 displays a typical image of a filtered result of a decay process. Several frequencies laying close together and which cannot be separated through filtering methods lead to these well-known time signals in stay cables based on which the determination of damping is extremely difficult.

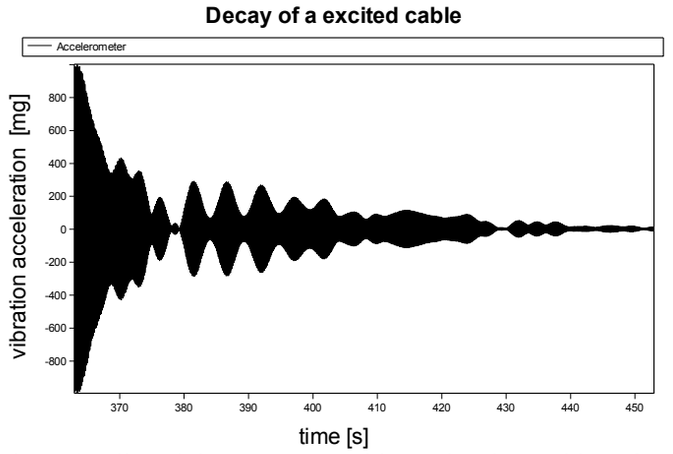

Figure 3. Filtered decay process with overlapping and beat frequencies.

The difficulty in terms of damping determination is the correct application of the evaluation methods known. With the broad band method the frequency peak is decisive which fails with beat frequencies given that we have several peaks laying next to each other. For the determination of the logarithmic decrement in time signal the peak-picking method is used, which has proven to be, given the beat frequency (apparent reduction of an energy which subsequently increases again) and the arbitrary use of peaks, difficult as well, considering that the results are often not reproducible through new evaluation staff. Given that automatisation in software programmes employs these methods, the results are also not secure and reproducible.

In order to be able to avoid these uncertainties and still to have a fast evaluation method, a combination of methods and a correspondingly new approach in terms of measurement, evaluation and representation of damping was elaborated in order to obtain secure and reproducible results (Mack 2017).

4 NEW DETERMINATION APPROACH

4.1 *System Identification and Stay Cable Forces*

In the scope of this work a practice oriented method was developed which enables the determination of the effective cable force under the consideration of the real bending stiffness of a cable. The accuracy of the force determination is clearly higher than for methods used up to now and therefore fulfils the requirements of engineering. As a real cable, however, deviates from the ideal concept very clearly, an accurate calculation of the cable force is much more complicated. In particular the bending stiffness of the stay cables is significant because it can exert a decisive influence on the eigenfrequency in a high band width as seen in Figure 4.

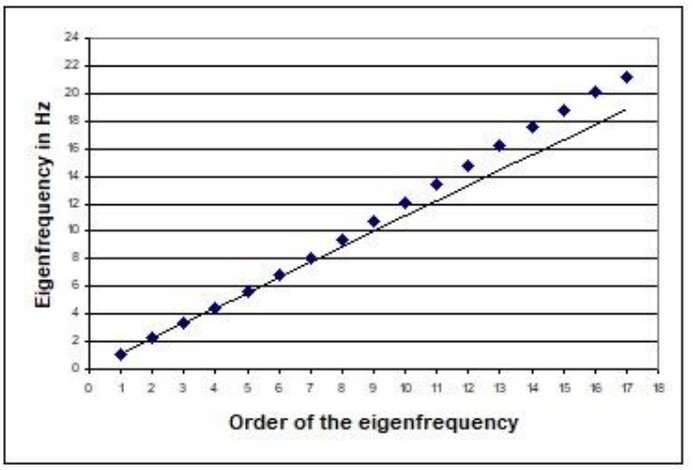

Figure 4. Shift of frequencies of a real cable.

If a complete flexibility of the stay cable (ideal concept of a tight wire) is assumed, the bending stiffness can be theoretically neglected. If the cable, however, deviates from this ideal concept (this is above all the case for thick and short cables), its bending stiffness is decisive for its behaviour. During the field measurements of stay cables it was realized that the harmonic succession of the eigenfrequencies (f_1, $f_2=2*f_1$, $f_3=3*f_1$,..., see Figure 5) valid for the tight wire is not valid for real bridge cables. A trend towards increasing frequency differences in the high bandwidth is recognizable. If the measured eigenfrequencies are compared with the linear progress, the influence of the bending stiffness is clearly visible. Whereas between the first 5-10 eigenfrequencies and their order k there is a linear coherence, the higher eigenfrequencies clearly deviate from this linear (ideal) progress.

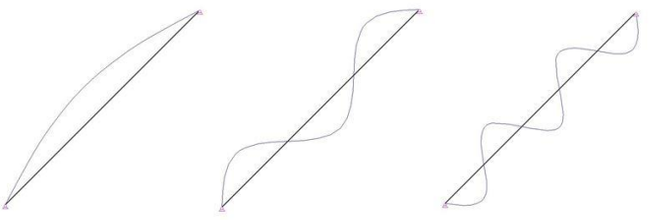

Figure 5. Basic mode as well as 3rd and 5th symmetric mode of a stay cable

The eigenfrequency of a cable is therefore dependent on the cable force and the bending stiffness, the fundamental modes ($\approx f_1$-f_5) of a cable being decisively determined by the cable force, the higher mode forms but also by the bending stiffness. The bending stiffness is of secondary importance to the dynamic behaviour due to the minor modal curvature of the fundamental mode during movement. The in-

fluence of the stiffness gains importance for a greater modal curvature of the cable in case of higher natural vibration modes. This effect is also plausible from the static point of view if a deformation of a bar equivalent to the vibration is produced by application of a static substitute load.

Of course technologies which are based on the analysis of the dynamic response of a cable under tension are very well known. Based upon ambient vibration testing quick and reliable evaluation of cable forces are possible. Numerous papers have been presented on this topic (Sa Caentano & Cunha 2003), (Peeters et al. 2002).

From stringed instruments the simple relationship between the measured natural frequency f_{ks} of order k and the cable force N is well known. In addition the free length of vibration L and the mass per unit length μ of the cable is required. This assumption is valid for frequency determination of the taut string:

$$f_{ks} = \frac{k}{2L} \cdot \sqrt{\frac{N}{\mu}} \tag{4}$$

In the beginning usually the first in-plane mode of the cable was used in practice, because the frequency was rather easy to obtain. But it turned out soon, that this approach did not fulfil the accuracy demands which have been defined for reliable testing. Consequently, during the last years the following two approaches usually have been employed:

(i) Consideration of the frequency of the first asymmetric vibration mode (which is the second frequency of the cable in the frequency response). The relationship according equation (4) is established consequently for the second mode described by k = 2.

(ii) Creating a mean value of the first 5 to 10 frequencies of the stay cable. When doing so, the first symmetric mode of vibration should be neglected before calculating the average.

Target of both methods is to determine a single, representative frequency which is used as input for equation (4). This procedure results in a more accurate estimation of the cable force. Although these two approaches seemed to fulfil the requirements of testing at the beginning, the demands with regard to non-destructive testing was continuously increasing.

Therefore the realistic dynamic behaviour of a stay cable is between the borderline cases of a hinged supported string represented by equation (4) and a massive beam with clamped boundary conditions and a certain bending stiffness EI. A solution with regard to the frequency was presented in (Morse & Ingard 1987):

$$f_k = \frac{k}{2L} \cdot \sqrt{\frac{N}{\mu}} \cdot \left(1 + 2 \cdot \sqrt{\frac{EI}{N \cdot L^2}} + \left(4 + \frac{k^2 \pi^2}{2}\right) \cdot \frac{EI}{N \cdot L^2}\right) \tag{5}$$

By considering these effects it is possible to determine an idealized frequency and a bending stiffness based on the measured basic and higher order modes. The application of this method was tested on several stay cables (Geier 2004) and the results have been compared to the design cable forces as well as to the basic identification method according equation (4). These tests have shown that the accuracy of determining the cable force is close to ± 1% of the real value.

4.2 *Combination of different Determination methods to evaluate the damping of stay cables*

The approach of damping in stay cables has been improved following the laboratory tests, verifications on existing bridges and control evaluations with existing measurement data which were conducted. For this purpose two evaluation methods were combined and demonstrated based on the possibility for reproduction of the measured vibration.

The damping depends as expected on the amplitude, but, given the beat frequencies, it cannot be directly opposed to the mere energy reduction. An envelope curve is generated instead, which corresponds to the logarithmic decrement, but considers the frequency of the main vibration, the starting energy value and the free oscillation time as decisive parameters. Based on the envelope curve and the peak-picking it is possible to determine the damping.

Through filtration the individual natural vibration forms are separated von each other and looked at individually. The beat frequencies and the super positions in each eigenfrequency cannot be separated any longer with the help of a filter, but through the determination of the individual responsible frequencies the decay process can be reversed through superposition of several harmonic vibrations and the damping can be thus determined iteratively whereas the reproduction is equated with the measurement signal.

In this way it is possible to determine the damping values of all natural vibration forms. Each eigenfrequency participates with the energy amount in the frequency spectrum pro quota to the total energy. Through transfer of these proportions to the individual damping values it is possible to determine the value of the vibration signal measured.

With other decay processes the determined values are slightly different as a result of the fact that through various excitation methods, but also various energy inputs and vibration directions different damping parameters are activated. In case of wind stimulation it is not clear which damping is activated and which remains inactive. This is why for the representation it is not an individual damping factor, but the indication of a „damping corridor“ like in figure 6 which is developed. Depending on the energy input the damping of the stay cable will be found in this corridor. For the evaluation of external dampers

the lower values are used, but one can also consider that with higher energy amount the inherent damping of the cable is also higher (Mack 2017).

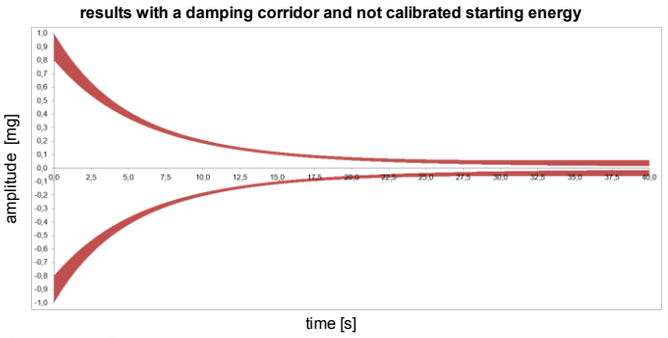

Figure 6. Result representation based on damping corridor and not calibrated start-up energy

5 APPLICATION EXAMPLES

5.1 *Force – Elbauenbridge, Schönebeck, Germany*

The determination of the stay cable has been recently conducted at the Elbauenbridge in Schönebeck. Die Elbauenbridge Schönebeck (Figure 7) is made up of two foreland bridges and the side sections of the river bridge, as well as the river area with the stay cables. The transverse section of the river bridge is made up of the trapezoidal hollow steel box with continuous cover plate and side steel consoles, as well as the overlying concrete pre-fabricated pieces and the carriage way concreted full width (Brand et al. 2013). In 18 m distance the transverse beams introducing the cables protrude and, together with the fan-shaped spreading of the 18 cable groups, create a new geometry on the superstructure, seen from the 75.30 m high pylon.

Stranded cables of the type DYNA Grip® manufactured by the company DYWIDAG-Systems International GmbH were used. The stranded stay cables are made up of seven galvanized, cold-drawn, plain individual wires with circular section. The stranded wires are surrounded by a corrosion protection wax and the entire fold is coated with a tight PE-jacket.

Ambient and stimulated measurements were conducted on this bridge. The acceleration sensor was fastened in the lower third of the pylon onto the stay cable. The stimulation was performed with the hand in order to introduce various amounts of energy and to activate various vibration and damping mechanisms, whereas the stimulation came either from the bridge deck or with the help of a riser.

Given the high-precision sensor technology and the evaluation method which took into consideration the bending stiffness, a short measurement period per cable was enough in order to be able to identify the eigenfrequencies of the first 10 natural vibration forms and to determine the cable forces reliably according with formula (5).

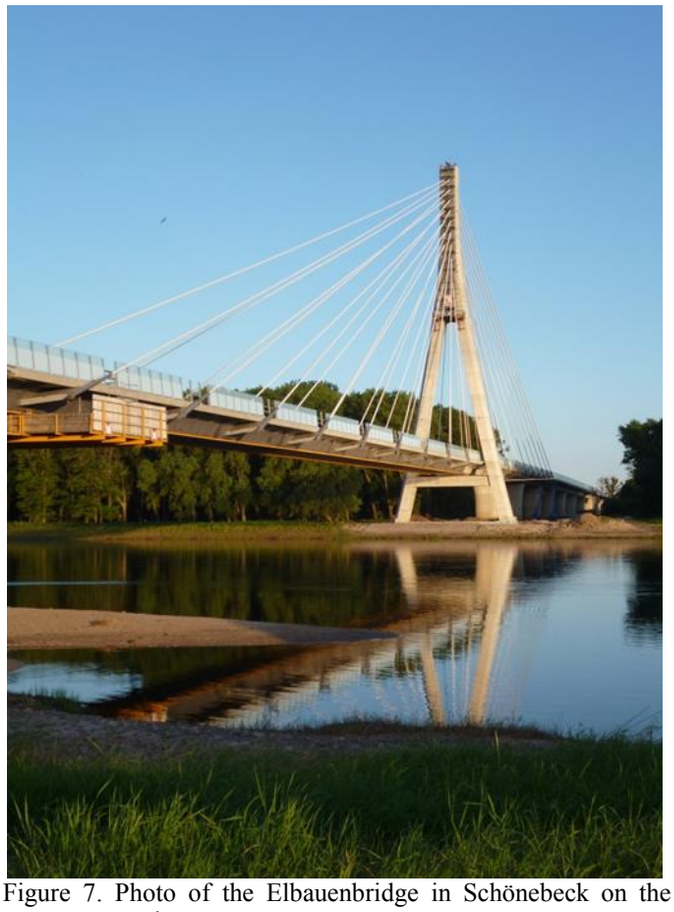

Figure 7. Photo of the Elbauenbridge in Schönebeck on the measurement day

5.2 *Damping – Abraham-Lincoln-Bridge, Louisville, Kentucky, USA*

The determination of damping and the development of methods were conducted when the vibration measurements were performed on the Abraham-Lincoln-Bridge in Louisville, Kentucky, USA. Here we have a cable-stayed bridge with 3 H-shaped pylons. The new structure has six traffic lanes for the traffic heading North.

The bridge is part of the Interstate 65 (I-65), has a total length of 761 m and the pylons are all located in Ohio River (Figure 8). The I-65 begins at the Interstate 10 in Mobile, Alabama, and leads to the Highways 12 and 20 in Gary, Indiana, a little South-East of Chicago, Illinois. The main pylon in the middle is somehow more massive and higher than the two neighbouring pylons. The structure is supported by a total of 88 stay cables. The stay cables were again provided and mounted by the company DYWIDAG-Systems International GmbH. Given that one could expect higher vibration paths for the cables as a result of the significant wind loads along the Ohio Valley, each cable was equipped with an external damper.

It was necessary to prove the function of the dampers and for this reason a vibration measurement was conducted for determination of the damping on a quarter of the cable (22 pieces). The measurements

were conducted one without the damper installed and once with the damper in operation.

Figure 8. Photo of Abraham-Lincoln-Bridge on the measurement day

Given the intensive vibrations caused by the construction works during the respective day, the measurements were conducted at night. Another time criterion was the asphalt paving. The weight of the asphalt influences the frequencies and thus the vibrations, so the measurements had to be conducted with or without asphalt.

An acceleration sensor and a position sensor were used for the performance of the measurements. The position sensor was mounted always on position L/8 where L represents the respective cable length in meters. The position sensor was mounted in the anchorage area where the vandalism protection tube ends in order to get the amplitudes near the damper, which was part of the protection tube. The steel tube itself is directly connected with the bridge deck and performs no swinging motion with the tube itself which made it possible to connect the damper with the tube. In order to get significant amplitudes as close to the damper as possible without entering the already closed envelope system the first point capable of vibration after the steel tube was used.

A static deflection and a dynamic stimulation in the middle of the cable were used as stimulation. For the static deflection a riser was used which moved the cable from its rest position with the help of a cord. The fork lift had the possibility to slowly perform the deflection by directing the fork upwards and finally releasing abruptly. In this way the cable was forced to die in its natural vibration form. For the dynamic stimulation a riser with arms was used by means of which a person located around the middle of the cable felt with his hand the strongest (usually the first) natural vibration form and then, using his hand, caused the cable to resonate.

The decay process was recorded by the sensors and a multitude of superpositions of vibrations resulted as indicated in Figure 9. Here it was possible to apply the new method which combines peak-picking and envelope curve in a fast and precise manner. With the determined parameters eigenfrequency, damping per eigenfrequency, energy level for each eigenfrequency and phase difference of the vibration, the superposition of all sine vibration was programmed, which reflects except a few deviations the actual recorded signal. The overlapping of these two signals is presented in Figure 9.

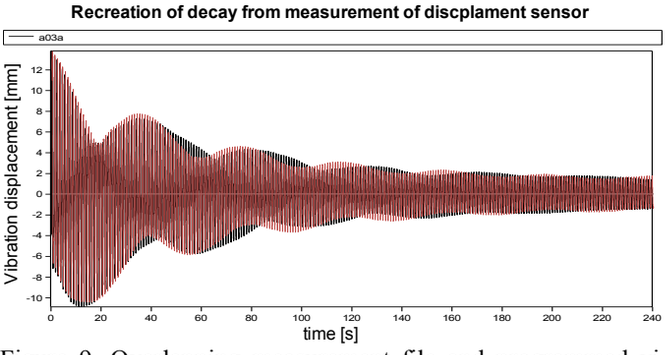

Figure 9. Overlapping measurement file and programmed vibration process with dynamic parameters determined

This application was repeated for all other cables and in this way it was possible to determine the damping which each cable reflects with each stimulation form. The values themselves were determined in a documented manner and based on the methods can be reproduced also by other evaluation staff.

By reproduction of the vibration in the software for the control of overlapping it was possible to document the damping with absolute certainty.

6 CONCLUSION

All known methods for cable force determination and damping determination in stay cables have been used for decades and are permanently in development with a view to determine the dynamic critical behaviour of structures and cable components. Often times difficulties were encountered given that stay cable determinations displayed deviations of ± 10% as compared to other measurement methods or the target force and the damping values obtained through other measurements and evaluation methods were not reproducible.

These newly developed methods have on the one hand the advantage of a higher exactness of ± 1% for the stay cable determination, but also for the damping in a large number of cases and, on the other hand, a fast and cost-efficient application. The measurements for the stay cable determination can be conducted in the lower anchorage area by using acceleration sensors and, taking into consideration the bending stiffness, it is possible, based on the determination of the first 10 eigenfrequencies, to reliably determine the cable force.

The mounting and stimulation at a higher place is more convenient for damping, given that otherwise the determination of secure values is not possible. Instead, the use of the combined methods and the reproduction of the vibration can be performed fast

and in a documented manner which is beneficial to the structure operator and designer. With the help of this application it is possible to obtain a damping corridor in which, in terms of the energy level, during resonance, the cable damping is located in this corridor, depending on the activated damping mechanisms In this way one can take into consideration all behavior patterns for simulations and verifications.

These applications render cost-intensive verifications conducted with the help of vibration generators and a large number of sensors unnecessary any longer whereas the values can be determined and verified any time in a reliable manner.

Noise radiation from steel bridge structure - Old Årsta bridge Stockholm

A. Olsen
Vibratec Akustikprodukter ApS, Kvistgaard, Denmark

R.S. Lützen, S. Holmes
Lloyds Register, Copenhagen, Denmark

ABSTRACT: The 1929 Old Årsta bridge in central Stockholm (Sweden), owned and operated by the Swedish Transport Administration(Trafikverket), is a monumental structure of architectural value and infrastructural importance to the city. Following recent renovation work, an increase of train noise was observed. Hence, the Swedish Transport Administration decided to mitigate the noise. A multi-step project was defined to this end. The present paper presents the findings of the pre-study, the purpose of which was to investigate the noise radiation from the bridge. This involved vibro-acoustic modelling by Statistical Energy Analysis (SEA), laboratory testing of various Constrained Layer Damping (CLD) configurations at different temperatures, as well as similar CLD tests on a mock-up, noise and vibration measurements on the actual bridge, and acoustical beamforming measurements.

1 INTRODUCTION

Constructed in 1920 to 1929, the Old Årsta bridge is a monumental double track steel arch bridge with a steel deck and a main span of 151 m. It is located on one of the main railway lines of Stockholm (Sweden) and recently underwent refurbishment to upgrade bridge bearing capacity. This included a new bridge deck in terms of a full steel deck with welded longitudinal and transversal girders. The deck is connected to the supporting arch using hangers and columns. The track of the retrofitted deck is now based on a Pandrol VIPA rail fastening system. Following construction of the new bridge deck, increased noise from train passages was reported. The Swedish Transport Administration initiated a project with focus on noise reduction from the bridge, including the present pre-study. Given an around the clock average interval of only 6 minutes between trains, a non-intrusive execution was required. Hence, for the investigation no access was allowed to the top of the bridge deck. Similarly, any recommended mitigation means would have to be installed from below.

To the west of Old Årsta bridge, in parallel at approximately 45 m distance, runs a newer bridge, which proved to be a useful platform for measuring train passage noise. Furthermore, to the North a concrete bridge, having the original fasteners on ballasted track as the new bridge before retrofitting, is located on the same line as Old Årsta.

2 METHOD

Past noise control actions for Old Årsta bridge involved modifying the track from wooden sleepers to resilient rails fasteners (Cox 2007, Thompson 2009). Given the current restrictions on access, track modification was no longer a relevant option. Instead, focus was placed on the potential of targeting the bridge steel structure itself. Thompson (2009) lists several such examples, with varying results in terms of noise reduction. In the discussion, it is mentioned that the achieved reduction was limited in general by the amount of damping already present in the untreated structure. Furthermore, the balance between rolling noise and noise radiated by the bridge structure plays a limiting role.

In certain cases, structural damping may be added using vibration absorbers (Schrey & Veit 2017). This solution is, however, quoted as being suitable only for frequencies below 150 Hz.

In this study, which was undertaken on behalf of the main contractor Skanska by Vibratec and the consulting branch of Lloyd's Register (LR), the potential of Constrained Layer Damping (CLD) for noise reduction was investigated. A general challenge of CLD solutions is the inherent temperature dependence of the viscoelastic material. However, previous successful experience was found for an outdoor industrial application in mid-continent climate (Olsen et al. 2016). This was achieved using CLD patches with two viscoelastic materials, having different properties.

For Old Årsta Bridge an engineering approach was decided. An empirical investigation of noise and vibration of the existing, untreated bridge was combined with numerical simulations using SEA as well as laboratory measurements. The study outline was:

- Empirical investigation of noise, and corresponding vibration
- Identification of noise contributors, particularly train (rolling noise) vs. bridge contribution
- Establishment of prediction model
- Use of prediction model with CLD damping input from lab tests and SEA model
- Identification of the optimum CLD configuration and expected noise reduction

In the following, comments are given to the various measurements and modelling actions. The measurements were taken 5-7 April 2017 during wind speed 2-4 m/s mostly western wind and about 10°C.

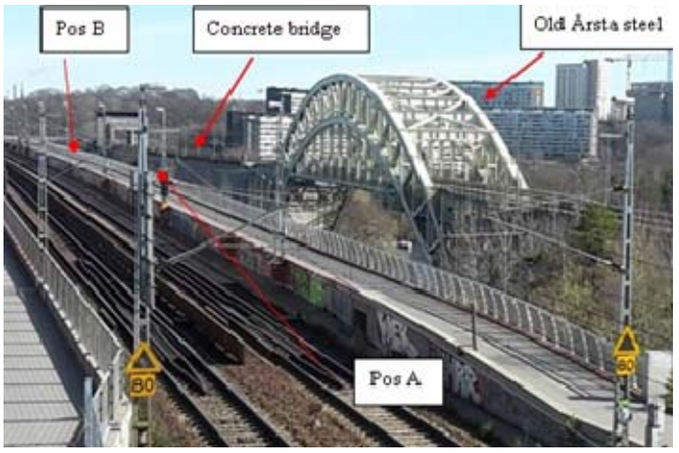

Figure 1. Measurement positions

2.1 *Noise and vibration measurements*

As the study focuses on Old Årsta steel bridge, it was necessary to find a means of identifying start and stop times for trains crossing the bridge. To that end, a "train detector" system was installed. This consisted of a 1 mV/(m/s^2) accelerometer on the underside of the deck, at each end of the bridge. The individual passage of every bogie, sometimes even every wheelset, was clearly distinguishable from the recorded time series. The train detector system furthermore enabled determination of the train speed. Of the considered passages, an average of 88 km/h was found, typically ranging from 80 to 95 km/h.

Using a multi-channel, 24 bit data acquisition system, the train detector accelerometers were recorded to a laptop in parallel with 5 accelerometers of sensitivity 1 mV/(m/s^2). Train passages were measured for accelerometer positions representing the main components of the bridge, collecting several passages per measurement position. Sample frequency was 6400 Hz.

Simultaneously, a separate measurement system for recording noise was placed opposite the steel bridge, at Pos A. This autonomous system was a sound level meter BK2270 with its microphone fitted in an outdoor microphone kit. The system continuously recorded time series with maximum useable frequency 3300 Hz, in 24 bit quality.

2.2 *Microphone array measurements*

At Pos B, a limited number of measurements were taken with LR's in-house developed 2D array consisting of 56 microphones, see Figure 2. A sample rate of 5000 Hz was used. These were taken at the end of the measurement campaign, when the train detector system had been disabled, hence, train speeds were unknown.

Figure 2. Array measurement setup

The spatial resolution from the applied position was insufficient for directly separating noise contributions from train, rails, and bridge using basic Delay and Sum algorithm. However, a few useful observations were indeed made. The array included a centred and calibrated camera, providing one still image per train passage.

2.3 *Structural dynamic measurements*

2.4 *Point mobility of bridge components*

Point mobility was measured of several components of the Old Årsta bridge, using an instrumented impact hammer of 0.26 mV/N and a magnet mounted accelerometer of sensitivity 100 mV/(m/s^2). An LR in-house tool was used for processing complex FRF spectra as an average of 5-10 hits per position, with no data window applied. These were input to industry standard modal analysis software BK PULSE Reflex Modal. The Rational Fraction Polynomial-Z algorithm was applied to extract natural frequencies and damping ratio for each measurement position, for the frequency range 50-1000 Hz.

2.4.1 *Test of temperature dependent CLD damping*
At LR's lab a climatic chamber was established to test the structural damping of an 18 mm x 70 mm x 1400 mm steel beam sample with several different CLD add-on treatments, designed and provided by Vibratec. The beam thickness corresponds to the deck and main girders of the Old Årsta bridge components. The width and length were selected to ensure bending modes starting at 50 Hz, to represent the bridge plating as well as possible. At temperatures, +20, +5, and -10 °C the resiliently suspended beam was excited by continuous white noise from a shaker with introduced force transducer. The vibration response was captured with 7 accelerometers. Post-processed FRF spectra were, as in Section 2.3, introduced to modal analysis software and analysed up to 1000 Hz. Analysis was performed with combinations of Rational Fraction Polynomial-Z, Alias-Free Polyreference, and Polyreference Time, depending on the properties of the test specimen. Mode shapes were used qualitatively to separate bending modes from torsion and lateral modes, as only bending modes were considered relevant for the noise control of Old Årsta bridge. This approach provided temperature and frequency damping ratio estimates, which should be regarded as engineering linear approximations of the non-linear viscoelastic behaviour.

2.5 *Large-plate mock-up test with different CLD configurations*

At Vibratec's workshop in Estonia, an indoor test at approximately 15°C was performed on an 18 mm x 1400 mm x 2000 mm steel plate elastically suspended from a crane. For 6 different CLD configurations, random impacting was performed with a hammer, and the vibration was recorded with two accelerometers. The resulting vibration time series were input to industry standard Operational Modal Analysis software ARTeMIS Modal and analysed using Stochastic Subspace Identification (SI) algorithms as well as Enhanced Frequency Domain Decomposition (EFDD).

2.6 *Numerical Statistical Energy Analysis model for insertion loss*

Commercial software VAOne for Statistical Energy Analysis (SEA) was used for establishing a numerical, vibro-acoustic model of the bridge without hangers and arches,

A line of distributed, vertical uncorrelated point forces placed in the centre line of one track. They were assigned white noise with 1 N amplitude each. With this excitation, the SEA model was used to calculate the un-calibrated resulting noise in a horizontal distance of 45 m, corresponding to the physical Pos A. This was first done with low-level structural damping assigned to all bridge elements, corresponding to the present stage of the untreated bridge. Subsequently, CLD configurations were investigated by assigning the lab test damping of Section 2.4.1 to individual bridge components and calculating the un-calibrated resulting noise. Subtraction from the noise of the untreated bridge thus provided an insertion loss corresponding to that particular CLD configuration. The SEA model output was presented in 1/3-octave bands from 160 to 2500 Hz.

2.7 *Combined prediction model*

A simple prediction model was established, describing the noise contribution at Pos A for each major bridge component (deck, longitudinal girders, flanges of longitudinal girders, etc.). The model combined statistically averaged vibration spectra with radiation index spectra. The resulting sound power spectra were propagated to the distance of Pos A using a simple spherical spreading law.

For prediction of the various CLD configurations, the measured input vibration spectra of the untreated bridge were first corrected for insertion losses. The latter were either calculated using the SEA model of Section 2.6, or using simple algebraic expressions proportional to the relative increase of damping ratio.

2.8 *Considered CLD configurations*

10 different CLD configurations were tested in the climatic chamber at LR. The CLD's varied from either simple single layer to multi-layer solutions. Previous experience (Olsen et al 2016) with CLD configurations in temperature dependent applications indicated that single layers only provide high performance in either high or low temperature environment, depending on the properties of the damping material. Therefore, the relevance of combining damping materials is essential and reported in the literature, for example (Jones 2001).
In this project, two different damping materials were used. Each material consisted of a 1.4 mm bitumen layer, with viscoelastic glue on each side with release liner. Only difference between the two types is the viscoelastic glue.

The damping materials are usually manufactured in sheets of 1000 mm x 1000 mm with release paper on each side, for easy mounting. The two basic damping material solutions used in this project are shown in Figure 3.

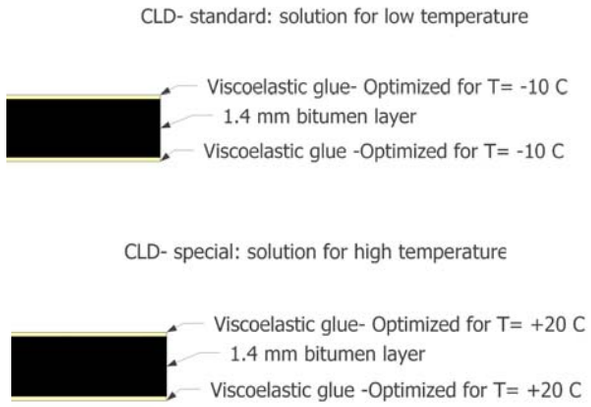

Figure 3. Basic viscoelastic materials and glue

Each type of material is normally considered as a single layer, however note that this is a 3-layer system, since glue as well as bitumen layer has viscoelastic behavior.

The two materials were used in the 10 CLD configurations that are shown in Table 1.

The following terms are used for simplicity:
A: Steel beam sample (18 mm thick)
B: CLD-Standard (app. 2 mm including glue)
C: CLD-Special (app. 2 mm including glue)
D: Sandwich steel bar (2 mm)
E: Sandwich steel bar (1 mm)
F: Constraining steel bar (3 mm)
G: Constraining steel bar (5 mm)

Table 1. CLD configurations

Sample ID	Layers	CLD patch thickness mm
1	A/B/G	7.0
2	A/C/G	7.0
3(shaker ref. A)	A/(B/C)/G	9.0
4	A/(2xB/C)/G	9.0
5	A/C/D/B/F	9.0
6	A/B/D/C/F	9.0
7	A/(2XB/C)/G	9.0
8	A/B/C/G	9.0
9(shaker ref. I)	A/C/B/G	9.0
10	A/(B/C)/E/(B/C)/G	9.0

In order to have the most realistic setup in relation to real world application, each of the CLD configurations were mounted on the 18 mm steel beam, using weld studs. This ensured that local de-bonding was minimized. A torque of 30-50 Nm was used for tightening of the lock bolts, depending on the manufacturing tolerance of the steel bars. For structural and practical reasons, the weight of the CLD systems are restricted to approx. 40-45 kg/m^2, which mean that the max. thickness of the constraining steel plate is app 5.0 mm. Generally, for CLD systems, increased thickness of the constraining plate leads to increased damping ratio.

Local de-bonding of damping layers will have an influence on the measurements and lower the damping ratio, due to non-contact zones. However, in real applications it is very difficult to completely avoid this. Weld studs are also used in real installation, as CLD patches are mounted vertical and below steel decks, which mean that gravity forces will influence the contact pressure.

No numerical or analytical estimates were performed for the composite damping ratio of the various configurations, as the general Ross, Kerwin and Ungar (RKU) equations (Jones 2001, Nashif 1984) are only valid for simple configurations such as sample IDs 1 and 2. Multi layers may be predicted with RKU equations but given the limited information of the viscoelastic glue damping properties, the theoretical and analytical approach is difficult. Understanding the viscoelastic glue better will require several measurements and extraction of the damping ratio as well as complex E-modulus of the glue.

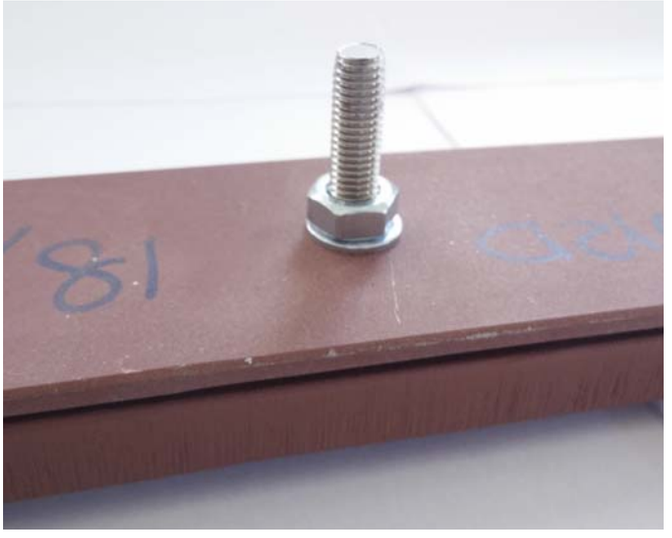

Figure 4. Steel beam with weld studs

3 RESULTS

3.1 *Findings noise & vibration at steel bridge*

Figure 5 shows passage noise spectra at Pos A, synchronised from the train detector system to precisely the passage of the steel bridge. Due to the intense traffic on both parallel bridges care had to be exercised to identify undisturbed passages with only one train at a time. A total of 8 undisturbed passages were identified. Based on time synchronization with the train detectors, 1/3-octave band spectra corresponding to the passage of the steel bridge were extracted, see Figure 5.

.

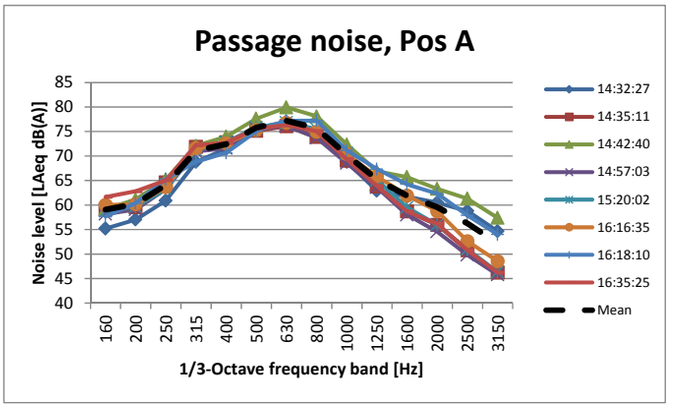

Figure 5. A-weighted 1/3-octave band spectra at Pos A (in front of steel bridge).

The passage time was typically about 6 s, and the average overall noise level was 83 dB(A), with a standard deviation of 1 dB. In Figure 5 it is seen that the noise is dominated by the 500-800 Hz range. It is seen that the range 250-800 Hz has relatively little spread, while the passages vary much more for higher frequencies. Realizing that train wheels typically become effective acoustic radiators above about 1 kHz, this might indicate that the noise contribution below 1 kHz is dominated by the bridge properties, while noise about 1 kHz is more strongly influenced by the individual vehicle.

At one point when the train detectors were not in operation, a handheld sound level meter BK2250 was used to measure at Pos B in front of the concrete bridge. For the same train passing the steel bridge, the corresponding spectrum was extracted from Pos A. One such example is shown in Figure 6.

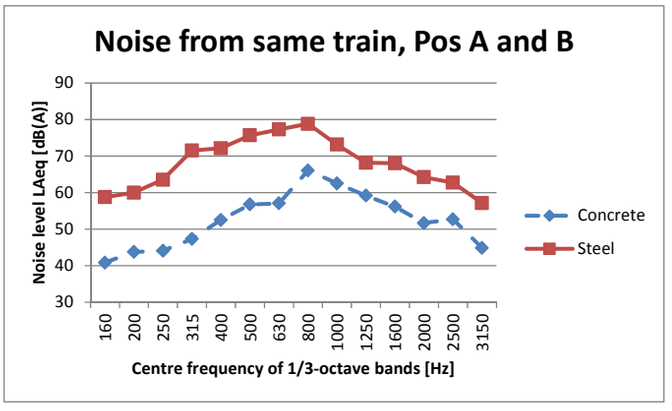

Figure 6. A-weighted 1/3-octave band spectra for same train, in front of concrete and steel bridges.

In Figure 6, the spectrum from the front of the steel bridge is clearly louder than in front of the concrete bridge. Overall levels here increased by 15 dB. Following the approach by Cox (2007) it is reasonable to assume that noise at Pos B is dominated by the train (actually, rolling noise) contribution, as the concrete bridge is unlikely to radiate significantly. Assuming that the 1-2 kHz range is dominated by the train contribution at both bridges, an increase of 10 dB in this range was determined as an average of 6 train passages. It is assumed that this is the increase in rolling noise caused by the different track and fastener types. This is in line with typical findings of 5-10 dB rolling noise increase (Thompson 2009). From this finding, the rolling noise on the steel bridge was predicted as the average spectrum at the concrete bridge (Pos B) plus 10 dB. The corresponding overall level was 78 dB(A).

By using the train detector system, vibration spectra of train passages were extracted for several bridge components. By means of example, the vibration spectra at deck underside positions are shown in Figure 7. For the deck, an average overall level L_v of 133 dB re. 10^{-9} m/s was found, with a standard deviation of approximately 1.5 dB.

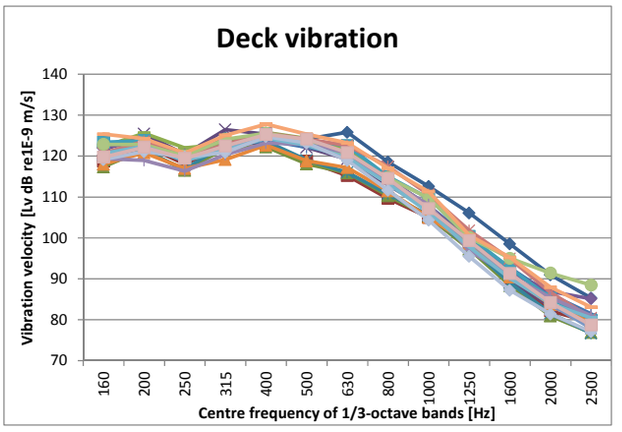

Figure 7. Measured vibration velocity spectra of deck underside, average of 22 passages.

3.2 *Findings from microphone array measurements*

An array example of 1.6 s of a train passage is shown in Figure 8, for frequency range 1 to 2 kHz. The spatial resolution obtained with the array was insufficient to separate the radiating components, mainly due to the large distance between measurement position and the bridge. The colours indicate the upper 6 dB of the measured noise level range. When inspecting a sequence of analyses corresponding to the train passages (not shown here) the various "hot spots" appear fairly concentrated (as in Figure 8) and travel with the train along the bridge. It seems likely that these spots relate to the rolling noise of the bogies. It is furthermore observed that the bridge arches do not appear to radiate significantly, as they do not "light up" in these plots.

For lower frequencies, e.g. 600-800 Hz (array plot not shown), the "hot spots" became unrealistically large due to the wavelength proportional spatial resolution. Though less clear than for the kilohertz range, the "hot spots" still mostly appear round/elongated and centred in the train/deck region.

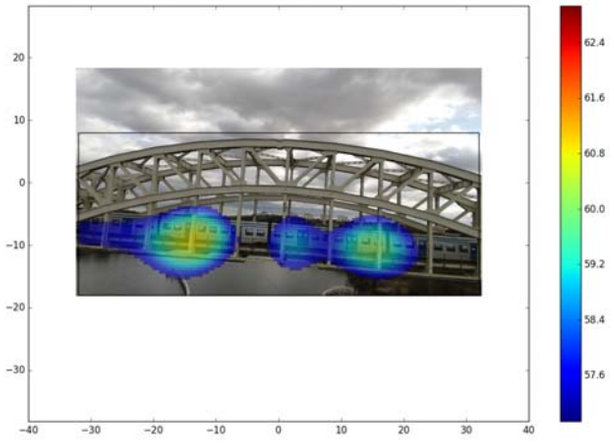

Figure 8. Microphone array analysis for frequency range 1-2 kHz, using Delay and Sum.

3.3 *Findings from structural dynamic measurements*

By means of example, Figure 9 shows a stability diagram (0-500 Hz range) of the modal analysis performed on point mobility input from a position on the longitudinal girder. Corresponding natural frequencies (0-1 kHz) and damping ratios are included. Generally, it was found for the bridge components that in the frequency range of interest the damping ratio was typically 0.5-1%. Furthermore, as in the case of the girder, lowest natural frequencies were found in the 50-100 Hz range. Both observations are positive as to the noise reduction potential of adding structural damping, as this requires many and at best low-damping, resonant modes.

From the lab climatic chamber damping tests, it was found that various CLD configurations demonstrated damping ratios up to about 14% at certain frequencies, see e.g. configuration I of Figure 10. However, as in the case of configuration I, the same CLD performed rather poorly at other temperatures. Other configuration provided more consistent damping across frequency and temperature, e.g. configuration 3 (Shaker ref. A) of Figure 11.

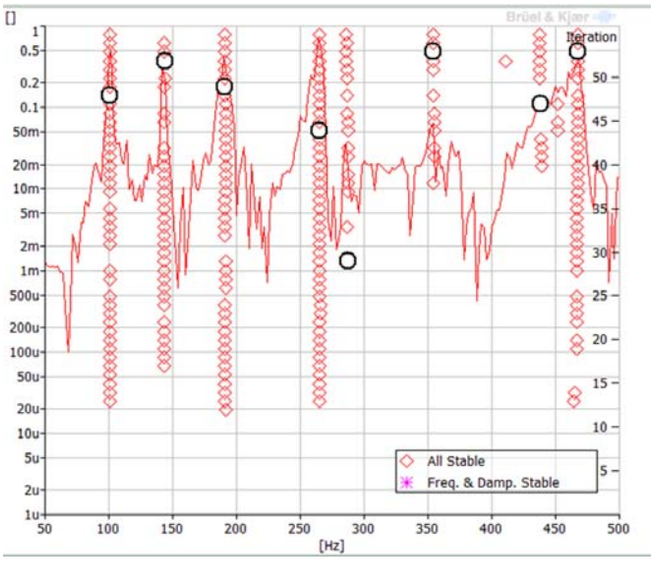

Figure 9. Example of mobility analysis results from longitudinal girder.

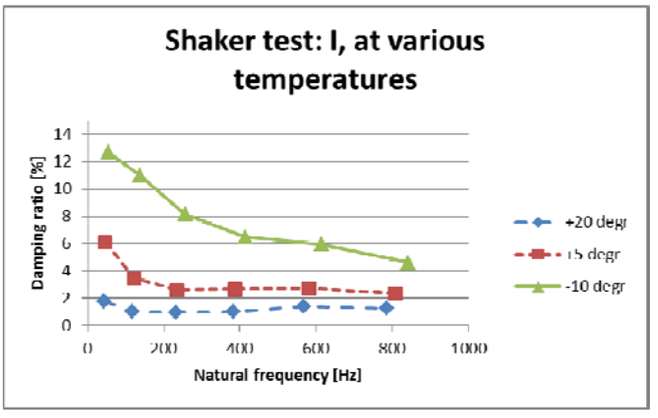

Figure 10. Lab damping test of CLD configuration I

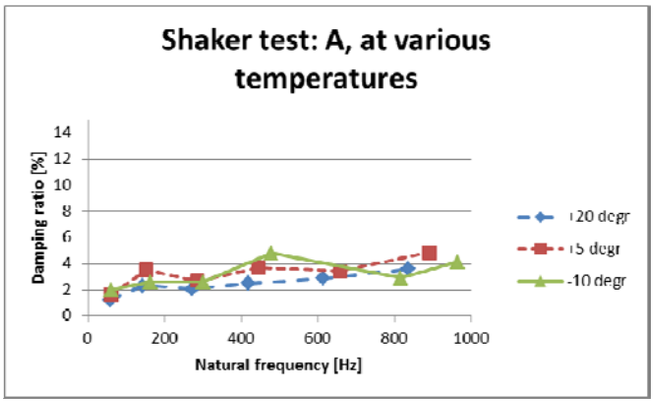

Figure 11. Lab damping test of CLD configuration 3 (shaker ref. A)

3.4 *Findings from SEA model*

Following a conservative approach, it was decided to assign a damping ratio of 1% to all bridge components in the untreated stage.

Figure 12 illustrates that noise insertion loss IL_p of the various bridge components are generally not the same, even in the shown configuration where all

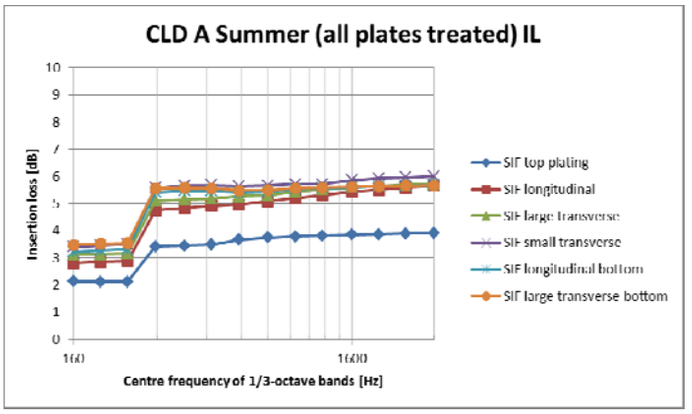

Figure 12. Example of SEA calculated insertion loss from CLD configuration 3, summer temperature

plates are assigned the same damping ratio. This is a consequence of the energy- wise closely coupled set of sub-systems, with forcing taking place on one system (the deck/top plating).

3.5 *Findings from prediction model*

In terms of overall values, the model predicted 84 dB(A), which is slightly higher than the measured 83 dB(A). Given the involved uncertainties, this seems an acceptable agreement. From Figure 13 it follows that the frequency range up to 800 Hz according to the prediction model is dominated by radiated "bridge noise", i.e. the noise produced by vibration of the bridge plating and girders. Above 800 Hz the "train", or rolling, noise takes over and dominates. This is in line with expectations from literature.

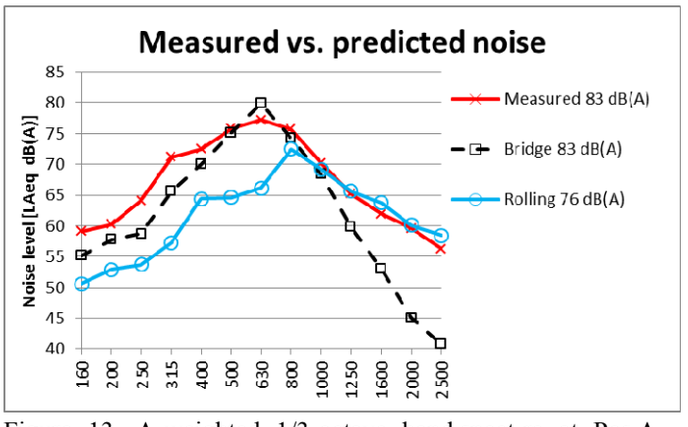

Figure 13. A-weighted 1/3-octave band spectra at Pos A, measured and predicted spectra

One step further, the prediction model shows the distribution and ranking of noise contributions from the different bridge components for the untreated bridge, see Figure 14. It follows that the most significant components are the deck, and longitudinal girders. From Figure 14 it can be assessed that the potential for noise reduction based entirely on reducing the bridge contribution is approximately 7 dB, in

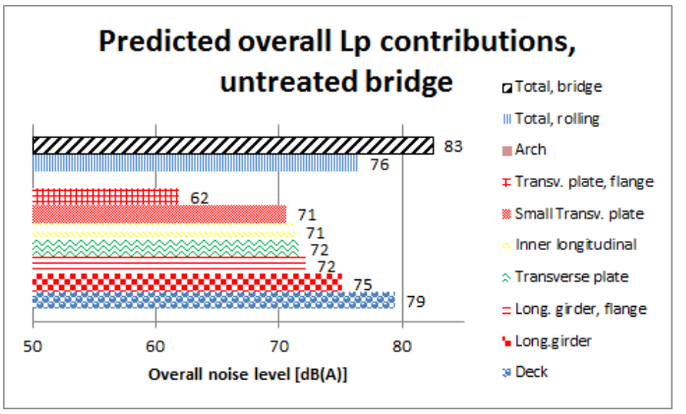

Figure 14 – Distribution of component related noise contributions for untreated bridge

the hypothetical case that the bridge radiated noise is reduced by about 20 dB or more.

With reference to the prediction results of the untreated bridge, the noise at Pos A for each of the CLD configurations was calculated using the prediction model. It was found that the bridge noise contribution could be reduced by up to 8 dB. The overall noise, when including train/rolling noise, could be reduced by up to 4 dB by several of the CLD configurations. As illustration, the predicted, detailed reduction corresponding to the use of Sample ID 3 (Shaker ref. A) is shown in Figure 15.

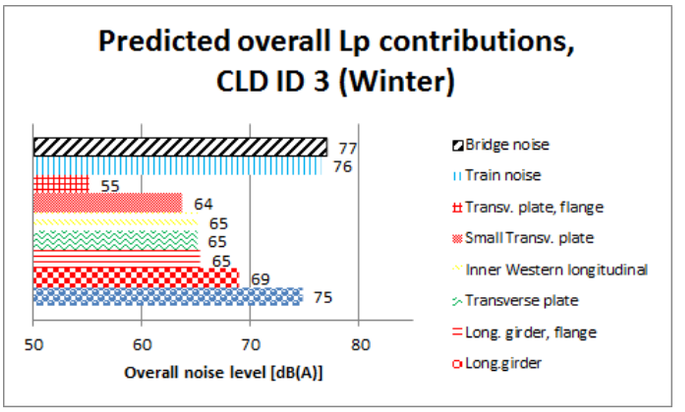

Figure 15. Example of predicted noise reduction for winter temperature using CLD ID 3 (shaker ref. A). Predicted overall level is 80 dB(A), corresponding to a reduction of 4 dB. Reduction of the bridge noise is 6 dB

4 CONCLUSION

Using a combination of different measurement techniques and numerical modelling, a simple prediction model was established for the train passage noise. Introduction of laboratory based damping data for various Constrained Layer Damping (CLD) solutions, allowed assessment of the potential for noise reduction by means of only treating the bridge components. A significant potential was found. Furthermore, it was found that CLDs based on specific combinations of two viscoelastic materials could provide relatively consistent noise reduction across frequency and temperature.

Based on the presented findings, the Swedish Transport Administration has started to implement the use of CLD treatment for the Old Årsta bridge.

ACKNOWLEDGEMENTS

This study was financed by the Swedish Transport Administration and SKANSKA, and the authors wish to express their gratitude to these organisations for constructive collaboration. In addition, thanks to the many colleagues at Vibratec and LR who helped with the project.

Damping performance identification for large-scale dampers of a cable-stayed bridge

X.H. Hu & C.X. Ge
Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: Hydraulic dampers were broadly used in the seismic design of structures, especially in those long span cable-stayed bridges. However, the practical performance of those dampers is quite difficult to acquire and predict. Aiming to understand the damping performance of dampers of Sutong bridge, an experimental method based on vibration testing was proposed in this paper. Firstly, dynamic response numerical simulation of a SDOF model under random excitation with lower frequency about 0.065Hz and higher damping property were carried out. A damping ratio identification method was proposed and verified based on simulated random acceleration output. Then, field testing was performed, and several acceleration gauges were mounted on the bridge. The longitudinal vibrations were gathered, and the damping ratio had been identified four times during the past two years. The results show that the overall damping ratio of those large-scale hydraulic dampers kept in the relatively constant level, which reveals that the performance of those dampers was in a relatively good condition.

1 GENERAL INSTRUCTIONS

With the construction material and technology continuing to improve, the main span of cable-stayed bridge rush to the 1km level in the reasonable structure system. The cable-stayed bridge system gradually developed as: floating system, semi-floating system and tower-beam consolidation system. In order to avoid several problems such as too large displacement of the tower due to the excessive displacement of the girder in the floating system, the unreleasable temperature load stress of girder and the excessive bending moment of tower by seismic load in the consolidation system, the semi-floating system with a certain constraint is the preferred proposal of long-span cable-stayed bridge. Domestic and foreign scholars have also developed an elastic connection device and viscous damper as the tower-beam connection. Kyu-Sik Park compared the damping effect on a standard cable-stayed bridge with different connections, namely, semi-active stiffness dampers, semi-active friction damper, passive dampers mixed connection in his article. Agrawal A.K. and Yang J.N. adopted the lead rubber bearing as the passive control element working together with the ideal hydraulic actuator as the active control element, and also obtained the ideal damping effect. Sutong Bridge, as a cable-stayed bridge with a main span of 1088 meters, also took three structure systems into consideration in the design process. By comparing the shear force and the bending moment at the bottom of tower, and the longitudinal displacement of the girder in the floating system and semi-floating system with viscous dampers or hydraulic buffers under the earthquake load, the large-scale viscous dampers is the final connection between tower and girder as a longitudinal constraint of girder. Four 67DP-17621-01 dampers produced by Taylor Company were installed in the vicinity of each tower respectively (Figure 1).

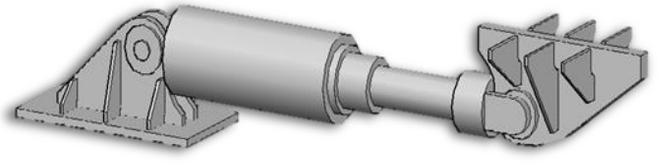

Figure 1 67DP-17621-01 dampers of Taylor company

Large damper is a long-term service component in the normal maintenance of the bridge during the operation. Because viscous dampers always bear very large pressure in each second, the requirements of materials and the manufacturing process are very strict. It is also common abroad that viscous dampers have to replace before the service life due to premature failure. Dampers of South Korea high-speed railway were all replaced soon after the installation because of oil spill. Greek peace and friendship

gymnasium large-scale dampers that only worked several years were also replaced in the 2004 Olympic renovation, which wasted a lot of manpower and material resources.

At present, most of the scholars focus on the study of the performance of the damper itself, and simulate the seismic performance under earthquake in the finite element model. The positive conclusions are got in the computer or lab. However, the damper conditions and effects in the real bridge lack of data support. In this paper, the assessment process of the damper performance, are mainly based on the field-measured data for further analysis and research.

The manual of Taylor dampers installed on the Sutong Bridge mentions that only a visual inspection is required for the 35-year life cycle without the need for maintenance or replacement. Since Sutong Bridge open to traffic, the maintenance and management of the tower-beam damper is also limited to the appearance inspection of whether the damper cylinder is leaking or not. Based on the field measurement data to analyze and study, we can further understand the Sutong Bridge tower-beam damper long-term performance without interrupting normal operation of the Sutong Bridge, to assess the bridge components and guide maintenance scientifically.

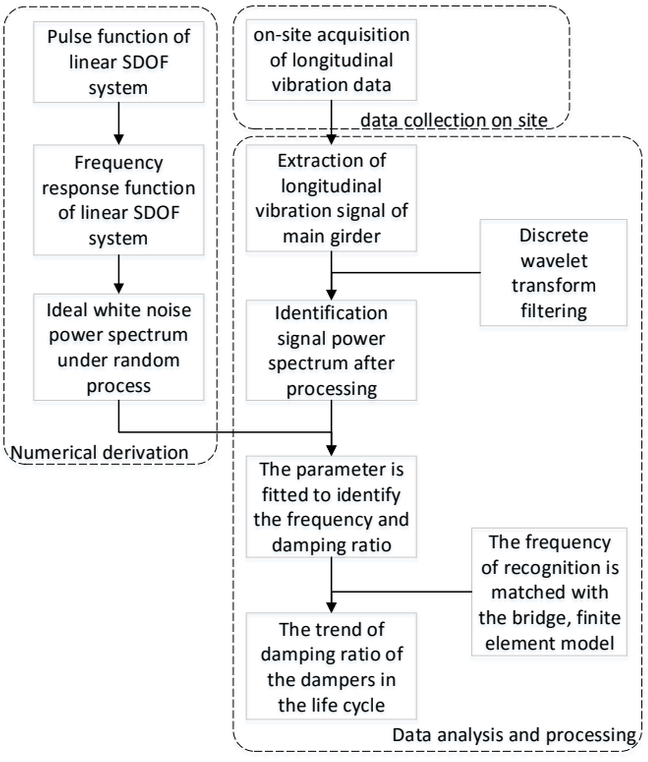

Figure 2 Technical route of this paper

In this paper, the cable-stayed bridge is simplified as a single-degree-of-freedom linear system, and the vibration power spectrum is deduced under random process with the ideal white noise excitation. Then, based on the field-measured data of damper, the longitudinal vibration data of the main beam are extracted by the wavelet transform filtering method, and then the recognition of vibration power spectrum is carried out. Finally, the power spectrum of the field recognition is fitted with the derived formula to obtain the approximate frequency and damping ratio of the longitudinal vibration. After repeated tests in a long period, the performance of the tower beam dampers is forecasted.

2 RANDOM RESPONSE OF SDOF LINEAR SYSTEM UNDER WHITE NOISE

The installation of viscous dampers at the tower-beam joints is a typical local damping nonlinear increasing problem to the long span cable - stayed bridge. In the study, the single-degree-of-freedom evaluation model of Soneji B.B. and Terenzi G. can be used to replace the nonlinear system with viscoelastic dampers by using the concept of additional damping ratio. The two systems have the same energy consumption in simulation.

Already simplifying the system to a linear system, according to the simplification method proposed by Li Guohao about first-order longitudinal mode shape of a single-degree-of-freedom model, the whole bridge is simplified to a system whose longitudinal stiffness is same as the pylon's thrust stiffness and the mass is equal to the girder mass plus with participated mass at the top of the tower. The random excitation of the environment to the main beam is similar to white noise excitation. We use the knowledge of structural dynamics to solve the frequency response function and power spectrum of the system, and gradually deduce the power spectrum of the SDOF system under white noise environment.

2.1 *Frequency response function of SDOF system*

Considering the SDOF linear vibration system, the motion equation is

$$m\ddot{Y}(t)+c\dot{Y}(t)+kY(t)=X(t), Y(0)=\dot{Y}(0)=0 \tag{1}$$

m is the equivalent mass, c is damping parameters, k is stiff of the system. Expression (1) can transform to no-dimensional form：

$$\ddot{h}(t)+2\xi\omega_0\dot{h}(t)+\omega_0^2 h(t)=\frac{1}{m}\delta(t) \tag{2}$$

where $\omega_0=\sqrt{\frac{k}{m}}$ is the system natural frequency; $\xi=c/2m\omega_0$ is damping ratio of system.

Suppose $Y(t)=H(\omega)e^{i\omega t}$, the motion equation can rewrite as follow:

$$[(i\omega)^2+2\xi\omega_0(i\omega)+\omega_0^2]H(\omega)e^{i\omega t}=e^{i\omega t}\cdot\frac{1}{m} \tag{3}$$

where $i=\sqrt{-1}$, the solution of equation (3) is:

$$H(\omega)=\frac{1}{m}\frac{1}{(\omega_0{}^2-\omega^2)+2i\xi\omega_0\omega} \tag{4}$$

$H(\omega)$ is a complex function whose amplitude (5) and phase (6) are as follow:

$$\left|H(\omega)\right|=\frac{1}{m}\frac{1}{\sqrt{(\omega_0{}^2-\omega^2)+(2\xi\omega_0\omega)^2}} \tag{5}$$

$$\psi=\tan^{-1}\left\{\frac{2\xi\omega/\omega_0}{1-(\omega/\omega_0)^2}\right\} \tag{6}$$

2.2 *Response power spectrum under ideal white noise*

The autocorrelation function $R_Y(\tau)$ of stationary random process $Y(t)$ under white noise is:

$$R_Y(\tau)=E[Y(t)Y(t+\tau)]$$

$$=\int_{-\infty}^{+\infty}h(u)\int_{-\infty}^{+\infty}h(v)R_X(\tau+u-v)\mathrm{d}u\mathrm{d}v \tag{7}$$

$$S_Y(\omega)=\frac{1}{2\pi}\int_{-\infty}^{+\infty}R_Y(\tau)e^{-i\omega\tau}\mathrm{d}\tau=H(-\omega)H(\omega)S_X(\omega) \tag{8}$$

Consider that $H(-\omega)$ and $H(\omega)$ are conjugate functions, so power spectrum can deduce further as below:

$$S_Y(\omega)=\left|H(\omega)\right|^2S_X(\omega)=\frac{S_0}{m^2[(\omega_0{}^2-\omega^2+4\xi^2\omega_0{}^2\omega^2]} \tag{9}$$

$$R_Y(\tau)=\frac{\pi S_0}{2m^2\xi\omega_0{}^3}e^{-\xi\omega_0|\tau|}(\cos p\tau+\frac{\xi\omega_0}{p}\sin p|\tau|) \tag{10}$$

$$\sigma_Y{}^2=\frac{\pi S_0}{2m^2\xi\omega_0{}^3}=\frac{\pi S_0}{ck} \tag{11}$$

The expression (9) can be written as a fitting function with a_1, b_1, c_1:

$$S_Y(\omega)=\frac{a_1}{(b_1{}^2-\omega^2)^2+4c_1{}^2b_1{}^2\omega^2} \tag{12}$$

$$S_{\ddot{Y}}(\omega)=\omega^2S_{\dot{Y}}(\omega)=\omega^4S_Y(\omega) \tag{13}$$

where $a_1=\frac{S_0}{m^2}$, $b_1=\omega_0=2\pi f_0$, $c_1=\xi$ are three fitting parameters needed. The damping ratios is obtained as well.

3 DISCRETE WAVELET TRANSFORM

The idea of wavelet transform is different from the Fourier transform which decomposes the signal into an infinite length of the sine, cosine function. It is defined as a finite length wavelet that transforms the signal over the entire time domain. Its essence is actually the convolution of different scales wavelet function with the signal:

$$\langle u,K\rangle=\int_{-\infty}^{\infty}u(t)K(t,a,b)\mathrm{d}t \tag{14}$$

$u(t)$ is a signal with finite energy which is expressed as follow:

$$E_u=\int_{-\infty}^{\infty}\left|u(t)\right|^2\mathrm{d}t<\infty \tag{15}$$

$K(t,a,b)$ is a scaled and shifted version of the complex conjugate of the wavelet $\psi(t)$. This wavelet $\psi(t)$ has a zero average：

$$\int_{-\infty}^{\infty}\psi(t)\mathrm{d}t=0 \tag{16}$$

and fulfills the following condition of admissibility.

$$\int_{-\infty}^{\infty}\frac{\left|\hat{\psi}(\omega)\right|^2}{|\omega|}\mathrm{d}\omega<\infty \tag{17}$$

Throughout this text, $\hat{(\bullet)}$ will be used to denote the Fourier transform. In addition, the wavelets is normalized $\|\psi\|=1$ and centered around $t=0$.

With the wavelet chosen, a set of functions is obtained by scaling the wavelet by a and shifting it by b . the resemblance between the signal and the scaled and shifted wavelet is given by means of inner product. To preserve the normalization of the wavelet at each scale, the wavelet is divided by $\sqrt{a}$.

$$T_\psi[u](a,b)=\frac{1}{\sqrt{a}}\int_{-\infty}^{\infty}u(t)\overline{\psi\left(\frac{b-t}{a}\right)}\mathrm{d}t \tag{18}$$

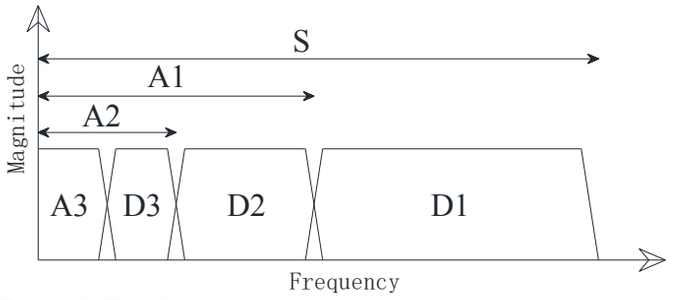
where $\bar{\bullet}$ denotes complex conjugation.

Compared with the continuous wavelet transform, the principle of discrete wavelet transform is almost the same. The scale parameters a and the shift parameters b in the continuous wavelet transform are continuous real numbers. Therefore, the computational complexity is huge and the redundancy of the data is greatly increased.

Discrete wavelet transform discretizes the scale a and the shift b, that is, only the partial scales and the shifts are picked out and calculated which makes that the analysis is very effective. What's more, after

the discrete wavelet transform, the effective information of the signal will not be lost, just because the wavelet basis function has orthogonality. The total length of the signal after the decomposition did not change by down sampling. The correlation redundancy between the two points in the wavelet space was eliminated.

The discrete wavelet with orthogonality has four filters, which can decompose the large and small scale information from the signal and reconstruct it in the next step. In the discrete wavelet analysis process, setting the threshold to the decomposition of the signal, the reconstruction of the signal can filter out part of the data. Decomposition filter can also continue break down into next layer followed the first layer to achieve frequency domain refinement by multi-layer decomposition. Taking the three-layer decomposition for instance, the interval of the frequency can be refined to the one eighth of total frequency range (see Figure 3).



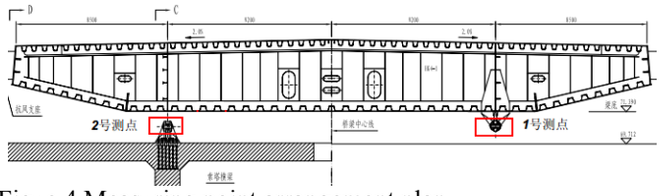


Figure 3 The frequency distribution of three - layer wavelet decomposition

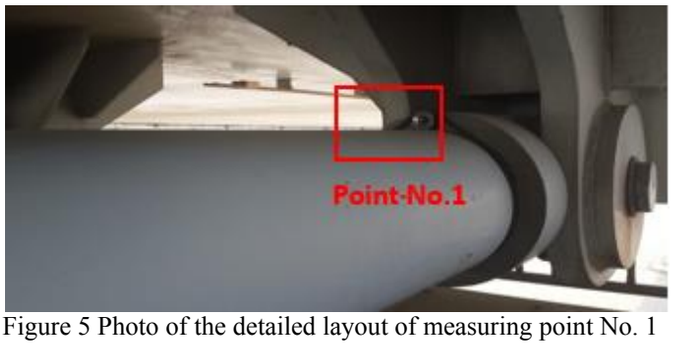
4 FIELD DATA COLLECTED

The experiment was carried out under the condition of temperature of 15 ~ 20 Celsius degrees and wind speed of 3 ~ 4 m/s. The measuring points were located at the tower-beam damper on the north side of the north tower of Sutong Bridge. There were two measuring points in the experiment. No.1 point located downstream, while No. 2 point located upstream (Figure 4, Figure 5). The data of the longitudinal vibration of the main girder were collected by acceleration sensor installed on the tower-beam damper. This experiment employed the 3082T2 data acquisition instrument of china orient institute of noise and vibration and KD12000 acceleration sensor.

Figue 4 Measuring point arrangement plan



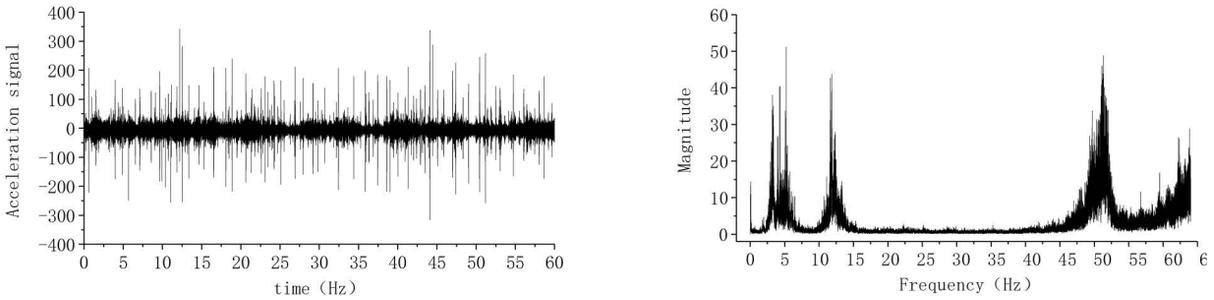


Figure 5 Photo of the detailed layout of measuring point No. 1

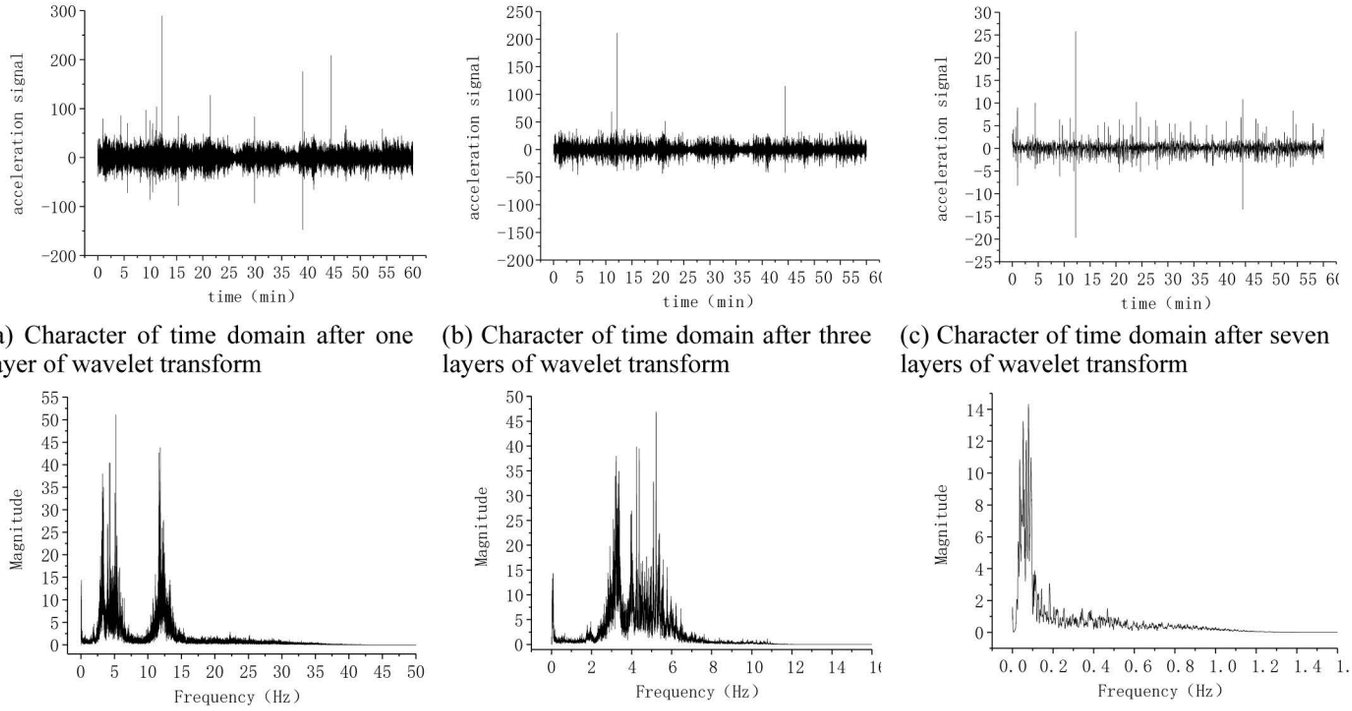
Having finished the installation of the sensor and the collector, we set the sampling frequency as 128Hz. And in order to ensure the results similar to the smooth process, the sampling time needed to extend to some degree and finally set as 3600 seconds. According to the experimental requirements, the experiment was repeated on April 17th, 2014, April 27th, 2015 and November 9th, 2016 respectively, to observe the system damping ratio trend over time.

5 DATA ANALYSIS

Firstly, the fluctuation of the original data in time domain and the power spectrum in the frequency domain are analyzed (Figure 6). From the perspective of the time domain, it can be seen that the vibration data are random. Meanwhile, the frequency domain reflects that there are several frequency peaks. The first frequency peak is near 0Hz, which is also the closest to the girder longitudinal vibration frequency and need to extract and further analysis. The peaks around 5Hz ~ 10Hz is mainly affected by the vibration of the vehicle passing by, different speed may lead to the main beam vibration frequency is different; and 45Hz frequency is not the structure of the vibration, and therefore not in the range of the study. In order to better perform the first-order longitudinal vibration of the main beam, it is necessary to use the reasonable method to carry on the preliminary processing to the data, and the signal close to the longitudinal frequency of the main beam is kept as complete as possible.



(a) Time characteristics of the original data for one hour (b) Frequency characteristics of the original data for one hour

Figure 4 Measured original data in the time domain (a) and frequency domain (b)

5.1 *Filtered by discrete wavelet transform*

The discrete wavelet is used to decompose the data into two components, namely high-frequency components and low-frequency components. The high-frequency components remove through threshold, and then reconstruct with the low-frequency components without any further processing. The low-frequency components are preserved after decomposing and reconstructing, thus achieving the purpose of low-pass filtering. In the process of analysis, Coiflet biorthogonal wavelet is selected. In addition to good ability of reconstruction, Coiflet wavelet has better symmetry, longer support length and higher disappearance moment. In the matlab software, the data were preliminarily decomposed by different layers (see Figure 7), and the changes in the time domain and frequency domain were observed by the increase of the number of wavelet layers.

It can be seen from Figure 7, with the gradual increase in the number of wavelet decomposition layer, some peaks of vibration signal removed in time domain. In view of frequency domain, the range of suppression high frequency gradually increase. After decomposing the first layer, the range of low-pass is 0 ~ 40Hz, and deeply decomposed into the third layer, the range is 0 ~ 12Hz, and finally to the seventh layer, the range of the low-pass is only 0 ~ 1.4Hz. During the process of decreasing the frequency range of the low pass filter, the power spectrum of the low frequency range does not change which means that the wavelet filtering method has better filtering effect on the signal. The desired frequency ranges only including longitudinal vibration has extracted successfully with the seven layers' decomposition and reconstruction of wavelets transform.

5.2 *Identification of system damping ratio*

The power spectrum filtered by the seven-layer wavelet transform is fitted according to the formula (12) deduced in chapter 2.2. Least square method based on the given function are used to fit the three parameters a_1, b_1, c_1. The equivalent mass of the main beam is unchanged and the relationship of $a_1 = \frac{S_0}{m^2}$, so a_1 is mainly to reflect the power spectrum density of the white noise. The fitting value b_1 can converted to the first-order longitudinal frequency of the main beam with $f_0 = \frac{b_1}{2\pi}$. c_1 is the damping ratio of the longitudinal vibration.

Taking the measured data of point No. 1 (see Figure 8) in 2014 and the measured data of the point No. 1 in 2016 (see Figure 9) for examples, it can be seen that the fitted curve matched the power spectrum well.

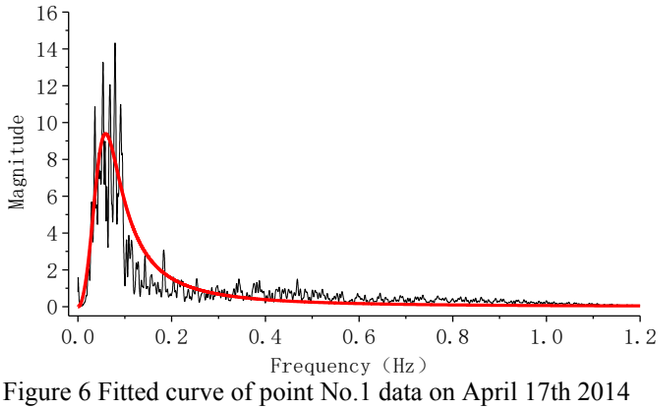

Figure 6 Fitted curve of point No.1 data on April 17th 2014

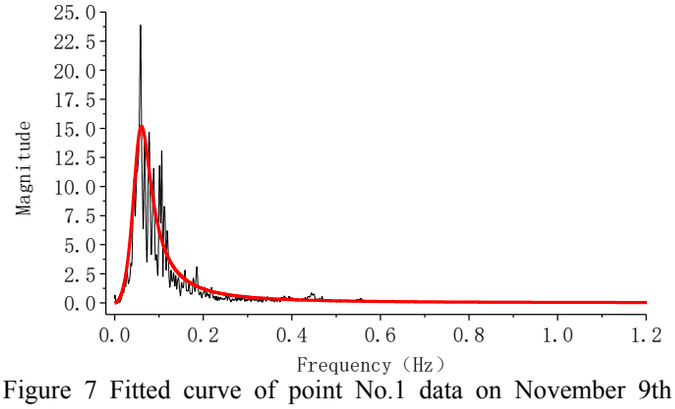

Figure 7 Fitted curve of point No.1 data on November 9th 2016

Table 1 Fitted recognition results of first-order longitudinal frequency and damping ratio

date	2014/04/17			2015/04/27			2016/11/09		
point	No.1	No.2	average	No.1	No.2	average	No.1	No.2	average
a_1	2.568	2.666	2.117	2.072	2.166	2.319	1.692	1.562	1.527
f_0	0.0595	0.0564	0.0580	0.0608	0.0614	0.0611	0.0596	0.0599	0.0601
c_1	0.5988	0.6112	0.605	0.5147	0.5614	0.5381	0.4403	0.4839	0.4621

To avoid the deviation of an experiment, we calculate the results of the two measured points and calculate the average in Table 1. Through the data in the Table 1, the white noise power of two points is relatively close in the same hour and slightly different for different periods. The identified first-order longitudinal vibration frequencies of the main beam in three experiments are very close. In addition, the first-order longitudinal vibration frequency of finished bridge(0.060 Hz) and the finite element model with the pile cap and pile foundation into consideration(0.0637 Hz) are also close to the identified result, which verifies the correctness of the measured data.

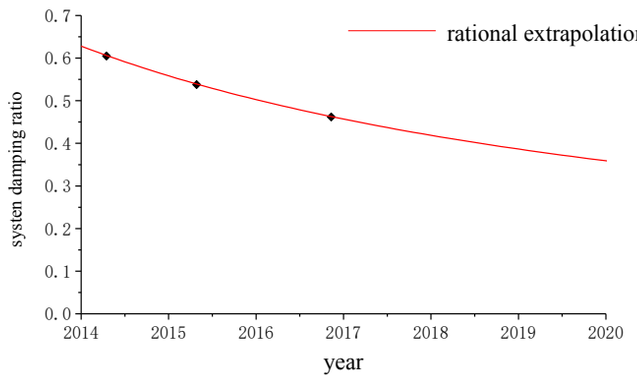

Figure 8 The extrapolation of system damping ratio trend

Time of the three experiments in accordance with horizontal axis, the system damping ratio as the vertical axis, we fit the damping ratio trend of the system. It is found that the damping decay rate gradually decreases with the passage of time (Figure 10), which also reflects the slow degradation of the performance of the damper.

Based on current data, the damping ratio of tower-beam damper will continue to decay in the future life cycle. This paper only selected three data in three years to compare and predict due to the time constraints. Whether the trend of the damping ratio is still like this need to collect more data to support in certain intervals for more accurate evaluation. This identification method can help the bridge maintenance team combine with the vibration data to assess the performance of large-scale damper based on a simple visual inspection. Even beyond the service life of the dampers, it is also a good basis to determine whether dampers need to be replaced, and result in more scientific management of the important components of the bridge.

6 CONCLUSIONS

In this paper, the formula of power spectrum of single degree of freedom system under random process is deduced, and the longitudinal vibration data of Sutong Bridge are collected and analyzed three times in three years. Filtered the measured signal by wavelet transform method, the damping ratio of large tower beam damper can be identified in the field experiment. The identification and prediction of damping ratio and performance can lead more and more scientific maintenance and management of the bridge damper.

Based on the analysis and elaboration of the experimental data in this paper, the following conclusions are obtained:

1. The longitudinal vibration of the Sutong Bridge is equivalent to a linear single-degree-of-freedom system, while the excitation of the environment is similar to the white noise excitation, which can effectively simplify the problem. The formula of power spectrum in random process can deduce in this condition and with the field measured data fitted with the formula, the system damping ratio can be identified without affecting the traffic.

2. With the number of layers of discrete wavelet transform increasing, the recognition resolution of the signal in frequency domain increases. Remove the specified decomposed signal through threshold, and then reconstruction signal can be the wanted signal to achieve low-pass, or band-pass, or high-pass filter. Meanwhile, the decomposition process did not affect the total length of the signal by down sampling, even neither the reconstructed data due to the orthogonal wavelet.

3. With the measured power spectrum fitting with the formula deduced, the system damping ratio can be obtained. The three-year system damping ratios in accordance with the chronological order, we can find that the damping performance of the tower beam damper is still in a good condition but also in a process of slow degradation. The extrapolation of the current data analysis results can predict the attenuation curve of the tower beam damper over time. In order to predict the curve of the damper performance better, it is necessary to repeat the experiment for more data and further analysis.

4. The only maintenance for the tower-beam dampers of Sutong Bridge is the visual inspection to determine whether they work normally. The method in this paper can better monitor the performance of the damper, which leads to repair and replace the damper in time when the tower-beam damper failed to consume energy. In addition, it can also provide a basis of whether we need to replace the tower-beam damper beyond its service life for ensuring the normal operation of the bridge.

Use of Comparative Vacuum Monitoring Sensors for Automated, Wireless Health Monitoring of Bridges and Infrastructure

Dennis Roach
Sandia National Laboratories, New Mexico, United States of America

ABSTRACT: Economic barriers to the replacement of bridges and other civil structures have created an aging infrastructure and placed greater demands on the deployment of effective and rapid health monitoring methods. To gain access for inspections, structure and sealant must be removed, disassembly processes must be completed and personnel must be transported to remote locations. Reliable Structural Health Monitoring (SHM) systems can automatically process data, assess structural condition, and signal the need for specific maintenance actions. They can reduce the costs associated with the increasing maintenance and surveillance needs of aging structures. The use of in-situ sensors, coupled with remote interrogation, can be employed to overcome a myriad of inspection impediments stemming from accessibility limitations, complex geometries, the location of hidden damage, and the isolated location of the structure. Furthermore, prevention of unexpected flaw growth and structural failure could be improved if on-board SHM systems were used to regularly, or even continuously, assess structural integrity. A research program was completed to develop and validate Comparative Vacuum Monitoring (CVM) sensors for crack detection. Sandia National Labs, in conjunction with private industry and the U.S. Department of Transportation, completed a series of CVM validation and certification programs aimed at establishing the overall viability of these sensors for monitoring bridge structures. Factors that affect SHM sensitivity include flaw size, shape, orientation and location relative to the sensors, along with operational environments. Statistical methods using one-sided tolerance intervals were employed to derive Probability of Flaw Detection (POD) levels for typical application scenarios. Complimentary, multi-year field tests were also conducted to study the deployment and long-term operation of CVM sensors on aircraft and bridges. This paper presents the quantitative crack detection capabilities of the CVM sensor, its performance in actual operating environments, and the prospects for structural health monitoring applications on a wide array of civil structures.

1 INTRODUCTION

Multi-site fatigue damage and hidden cracks in hard-to-reach locations are among the major flaws encountered in today's extensive array of aging structures and mechanical assemblies. The costs associated with the increasing maintenance and surveillance needs of aging structures are rising. The application of Structural Health Monitoring (SHM) systems using distributed sensor networks can reduce these costs by facilitating rapid and global assessments of structural integrity. These systems also allow for condition-based maintenance practices to be substituted for the current time- or cycle-based maintenance approaches thus optimizing maintenance labor [1]. Other advantages of on-board, distributed sensor systems are that they can eliminate costly, and potentially damaging, disassembly, improve sensitivity by producing optimum placement of sensors with minimized human factors concerns in deployment and decrease maintenance costs by eliminating more time-consuming manual inspections. Current structural maintenance operations require personnel entry into normally-inaccessible or hazardous areas to perform mandated, nondestructive inspections. These processes are not only time consuming but they provide the opportunity to induce damage to the structure. The use of in-situ sensors for monitoring the condition of structures and mechanisms, coupled with remote interrogation, can be employed to overcome inspection difficulties including the remote location and expansive distribution of critical structures such as railway bridges and rail cars. Prevention of unexpected flaw growth and structural failure could be improved if on-board health monitoring systems are used to more regularly assess structural integrity [2, 3]. The ease of monitoring an entire network of distributed sensors means that structural health assessments can occur more often, allowing operators to be even more vigilant with respect to flaw onset.

1.1 *Comparative Vacuum Monitoring*

Comparative Vacuum Monitoring (CVM) is a simple pneumatic sensor technology developed to detect the onset of cracks. CVM sensors are permanently installed to monitor critical regions of a structure. The CVM sensor is based on the principle that

a steady state vacuum, maintained within a small volume, is sensitive to any leakage [4]. A crack in the material beneath the sensor will allow leakage resulting in detection via a rise in the monitored pressure. Figure 1 shows top-view and side-view schematics of the self-adhesive, elastomeric sensors with fine channels etched on the adhesive face along with a sensor being tested in a lap joint panel. When the sensors are adhered to the structure under test, the fine channels and the structure itself form a manifold of galleries alternately at low vacuum and atmospheric pressure. Vacuum monitoring is applied to small galleries that are placed adjacent to the set of galleries maintained at atmospheric pressure. If a flaw is not present, the low vacuum remains stable at the base value. If a flaw develops, air will flow from the atmospheric galleries through the flaw to the vacuum galleries. When a crack develops, it forms a leakage path between the atmospheric and vacuum galleries, producing a measurable change in the vacuum level. This change is detected by the CVM monitoring system shown in Figure 2. It is important to note that the sensor detects surface breaking cracks once they interact with the vacuum galleries. Since the sensor physics is based on pressure measurements, there is no electrical excitation involved. These sensors can be attached to a structure in areas where crack growth is known to occur. On a pre-established engineering interval, a reading will be taken from an easily accessible point on the structure.

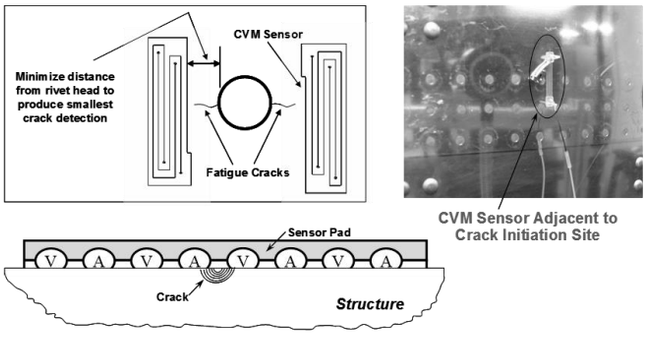

Figure 1. Schematics depicting operation of CVM sensor and polymer sensor mounted on the outer surface of a riveted lap joint.

2 APPLICATIONS FOR CRACK DETECTION USING CVM SENSORS

Recent events have demonstrated the need to address critical infrastructure surety needs [5]. The applications for CVM sensors can include such diverse structures as: buildings, bridges, trains and subway vehicles, mining structures, railroad cars, trucks and other heavy machinery, pressure vessels, oil recovery equipment, pipelines, steel transmission towers, ships, tanks and a wide array of military structures. Damage can arise from service loads as well as from external impact, off-design conditions or malevolent attacks.

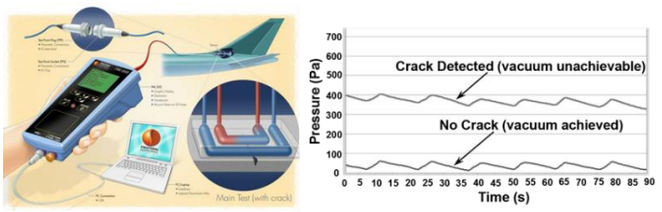

Figure 2. Crack detection monitoring with CVM system and pressure response used to indicate the presence of a crack.

In the matter of bridge refurbishment alone, the National Bridge Inventory Database (Fed. Highway Admin. 2003) indicates that 30% of the 600,000 bridges in the United States are "structurally deficient." In addition, a majority of the rail bridges in U.S. are operating beyond their initial design life. A bridge that is "structurally deficient" is still strong enough and stable enough for use; however, closer scrutiny of the bridge is required to ensure its continued, safe operation. In 2006, the American Society of Civil Engineers (ASCE) issued a report on the status of the U.S. infrastructure. It assessed everything from roads to hazardous waste systems and gave the country's infrastructure an overall grade of "D". Steel superstructure bridges built during the interstate construction boom of the 1950s and 1960s are reaching or surpassing their initial design lifetime. Depending on their level of maintenance, some bridges are showing visible signs of deterioration.

On September 30, 2006, part of an overpass collapsed in Montreal. On August 1, 2007, an Interstate 35 bridge crossing the Mississippi River in Minneapolis failed. The collapse of the Interstate 35 bridge prompted many questions regarding the health of similar structures around the world and their associated maintenance programs. Figure 3 shows three bridge failures – in Minneapolis, Montreal and Connecticut – and one bridge in Delaware with a large fatigue crack that was discovered and repaired prior to any catastrophic failure.

3 CVM PERFORMANCE ASSESSMENT USING ONE-SIDED TOLERANCE INTERVALS

The Federal Aviation Administration's Airworthiness Assurance Center at Sandia Labs, in conjunction with industry and airline partners, completed validation testing on the CVM system in an effort to adopt Comparative Vacuum Monitoring as a standard NDI practice [5-6]. Fatigue tests were completed on aircraft components to grow cracks in representative structure while the vacuum pressures within the various sensor galleries were simultaneously recorded. A fatigue crack was propagated until it engaged one of

the vacuum galleries such that crack detection was achieved and the sensor indicated the presence of a crack by its inability to maintain a vacuum. Probability of flaw detection assessments were coupled with on-aircraft flight tests to study the performance, deployment, and long-term operation of CVM sensors on aircraft. The result was a series of flaw detection curves that can be used to propose CVM sensors for aircraft crack detection. One set of test specimens were wing box fittings from the Boeing 737 which was the chosen CVM application from Delta Air Line's fleet. Figure 4 shows the details of one test series addressing a wing box fitting application along with installation of CVM sensors for the flight test program.

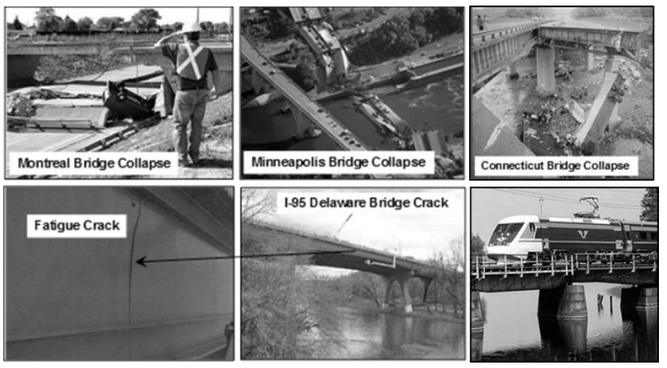

Figure 3. Applications for in-situ crack detection using CVM sensors.

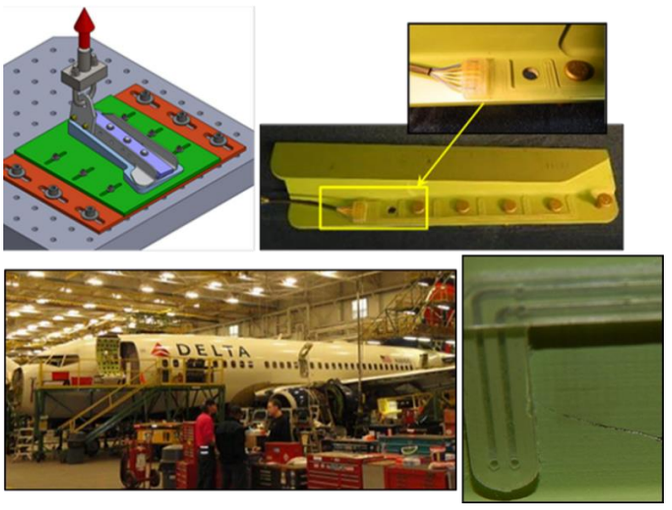

Figure 4. CVM testing on wing box fitting with close-up showing fatigue crack crossing into CVM sensor and installation of CVM sensors on Delta Air Lines aircraft for flight tests.

SHM reliability calculations will depend greatly on the complexity of the structure and geometry of the flaw profile. Since it is based on a sample of the entire population (n data points), the confidence is less than 100%. Thus, the One-Sided Tolerance Interval (OSTI) is greatly affected by two proportions: 1) the percent coverage which is the percent of the population that falls within the specified range (normally chosen as 90%), and 2) the degree of confidence desired (normally chosen as 95%). The data analyzed here consisted of fatigue cracks that were propagated in various metal specimens with the direction of growth aligned with the CVM mounted sensors. The data captured is that of the flaw length at the time for which the CVM provided sustainable detection. With these assumptions, there exists a distribution on the flaw lengths at which detection is first made. In this context, the probability of detection for a given flaw length is just the proportion of the flaws that have a detectable length less than that given length. That is, the reliability analysis becomes one of characterizing the distribution of flaw lengths and the cumulative distribution function is analogous to a Probability of Detection (POD) curve. Assuming that the distribution of flaws is such that the logarithm of the lengths has a Gaussian distribution, it is possible to calculate a one-sided tolerance bound for various percentile flaw sizes. To do this, it is necessary to find factors $K_{n,\gamma,\alpha}$ to determine the probability γ such that at least a proportion $(1-\alpha)$ of the distribution will be less than $X - K_{n,\gamma,\alpha}$ where X and S are estimators of the mean and the standard deviation computed from a random sample of size n. The data captured is the crack length at CVM detection. From the reliability analysis, a cumulative distribution function is produced to provide the maximum likelihood estimation (POD). This stems from the one-sided tolerance bound for the flaw of interest using the equation:

$$T_{POD(90,\,95)} = X + (K_{n,\gamma,\alpha})(S) \qquad (1)$$

where T = tolerance interval for crack length corresponding to 90% POD with a 95% confidence; X = mean of detection lengths; K = probability factor (~ sample size and confidence level desired); S = standard deviation of detection lengths; n = sample size; $1-\alpha$ = detection level; and γ = confidence level.

Because of physical, time or cost constraints, it is often impractical to inspect an entire population. Due to the limited number of data points, the reliability calculations induce a penalty by increasing the magnitude of the K (probability) factor. As the number of data points increases, the K value will decrease and the POD numbers could also decrease. The formula in equation (1) is set-up to produce the upper bound for the tolerance interval which represents the actual POD value. With the same parameters described above, the maximum likelihood estimate describing the optimal performance on the Probability of Detection for the OSTI approach can be calculated as:

$$\mathbf{POD} = \frac{1}{xS\sqrt{2\pi}} EXP\left(\frac{-(\ln(x)-X)^2}{2S^2}\right) \qquad (2)$$

As an example, the data acquired from CVM fatigue tests on 2.54" (0.1") thick 2024-T3 aluminum structure were used to calculate the 90% POD level for CVM crack detection. This POD curve, representing

the 95% confidence level, is plotted in Figure 5. The maximum likelihood estimated POD function, representing the optimum performance for CVM crack detection, was calculated from equation (2) and is plotted alongside the 95% confidence bound. The overall POD value (95% confidence level) for CVM crack detection in 2.54 mm thick aluminum skin was determined to be 0.58 mm (0.023”). In this particular instance, it was desired to achieve crack detection before the crack reached 0.1” in length so this goal was achieved. In over 200 fatigue tests conducted using CVM sensors there were no false calls produced by the sensors.

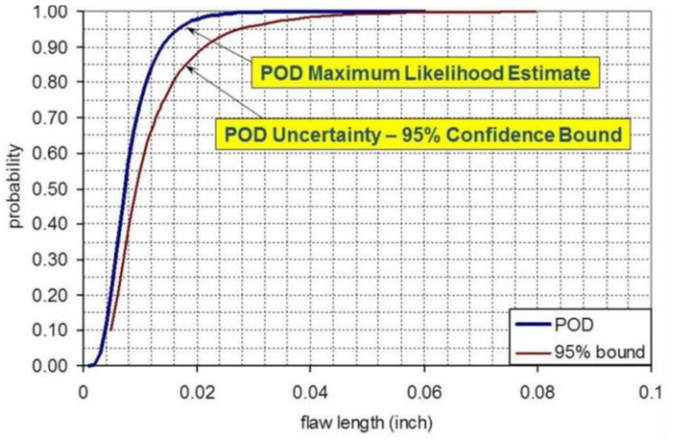

Figure 5. Probability of crack detection curves showing detectable flaw lengths for CVM sensors.

The results sited above are valuable for thin-walled structures such as those used in aircraft, automotive, and some pipeline construction. However, many civil structures use thick steel members. Earlier studies revealed that the thickness of the plate can affect CVM performance so additional performance tests studied CVM crack detection in thick-walled structures. Aircraft use thinner materials and have crack detection requirements of 1.27 mm to 2.54 mm in length. Civil structures contain thicker materials, have higher safety factors and can tolerate longer cracks such that their crack detection requirements are in the range of 12.7 mm to 25.4 mm in length. Additional tests studied CVM sensors monitoring cracks in 9.5mm thick steel. For the loaded structure, CVM crack detection occurred when the fatigue cracks ranged from 1.02 mm to 1.78 mm in length. For the unloaded condition, CVM crack detection occurred when the fatigue cracks ranged from 1.52 mm to 9.65 mm in length. However, regardless of whether the sensor monitoring is completed during a loaded or unloaded condition, the results indicate that CVM sensors could reliably detect fatigue cracks well before they reach 12.7 mm (0.5”) in length.

4 MULTI-CVM SWITCH-BASED SYSTEM FOR REMOTE BRIDGE MONITORING

A real-time monitoring system was developed for remotely interrogating a distributed array of CVM sensors on a transportation bridge structure. It uses a series of pressure switches that can continuously monitor structures remotely via a wireless transmitting device. Sensors were placed in known fatigue critical locations on the bridge structure. When a crack breaches a sensor, the pressure switch is opened and, in turn, triggers a message that is sent to a central maintenance center. Up to 50 switches can be powered by one vacuum pump. The CVM monitoring system, shown in Figure 6, was mounted at a centralized point on the structure of interest. Sensors can be made in almost any shape and out of a material to suit the required environment. Multiple sensors can be arranged to monitor the growth of a crack. It may be that there is a known crack and a sensor placed ahead of the crack will be triggered if the crack grows. Often there are known critical locations at joints or welds that require monitoring. The CVM monitoring system can continuously update web sites or send automated text messages or e-mails so that operators can quickly and remotely ascertain the condition of a structure and determine if maintenance action is required. Solar cells were used to recharge the onboard batteries so that the system can provide continuous, real-time monitoring for 3-4 years without maintenance. Multiple years of field operation has revealed excellent bridge health monitoring capabilities of such an SHM system.

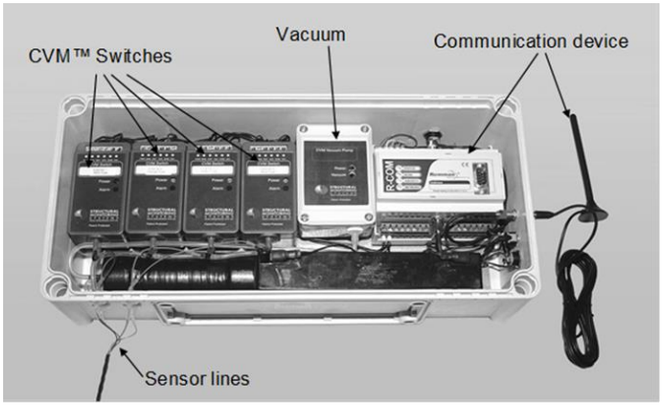

Figure 6. Real-time, remote monitoring system for a network of CVM sensors.

5 CONCLUSIONS

The effect of structural aging and the dangerous combination of fatigue and corrosion has produced a greater emphasis on the application of sophisticated health monitoring systems. Corrective repairs initiated by early detection of structural damage are more

cost effective since they reduce the need for subsequent major repairs and may avert a structural failure. Through the use of in-situ CVM sensors, it is possible to quickly, routinely, and remotely monitor the integrity of a structure in service and detect incipient damage before catastrophic failures occur. These sensors can be attached to a structure in areas where crack growth is known to occur. On a pre-established monitoring interval, a reading can be taken remotely or from an easily accessible point on the structure. Each time a reading is taken, the system performs a self-test. This inherent fail-safe property ensures the sensor is attached to the structure and working properly prior to any data acquisition. In several structural categories studied, the CVM sensors provided crack detection well before the crack propagated to the critical length determined by damage tolerance analyses. In addition, there were no false calls experienced in over 200 fatigue crack detection tests. The sensitivity, reliability, and cost effectiveness of the CVM sensor system was demonstrated in both laboratory and field test environments.

Global SHM, achieved through the use of sensor networks, can be used to assess overall performance (or deviations from optimum performance) of large structures such as bridges, pipelines, transport vehicles, and buildings. The ease of monitoring an entire network of distributed sensors means that structural health assessments can occur more often, allowing operators to be even more vigilant with respect to damage onset.

Considerations for identification of moisture in building materials using Bluetooth®

R. Helmerich, L. Moldenhauer, G. Voigt, F. Adao
Bundesanstalt für Materialforschung und -prüfung

E. Köppe
SmartSensorik GmbH Michendorf, Germanys

ABSTRACT: The vulnerability of low-quality concrete of some bridges to ageing and deterioration while they are exposed to environmental conditions during their service life, influence of growing population and climate changes, is a well-known effect and requires survey. For survey, the development of a low cost, cost-efficient sensor network to be embedded for continuous or attached to the surface for periodic monitoring is essential. Changing ground water conditions, flood or even leakage in fresh or disposal of waste water can lead to increased moisture content in building materials and structural elements as walls or floors. Moisture allows the transport of other adverse chemicals that might reduce the durability of structures. The paper presents a feasibility study about the capability of microwave modules as Bluetooth® or ZigBee with frequency range at 2,4 GHz to create advanced Wireless Sensor Networks (WSN) for estimation and visualization of moisture distribution in infrastructure assets. It was found that the value of the received signal strength indication (RSSI) depends on the moisture content and can be the basis for the moisture distribution inside a massive structure. The microwave modules may be used to compose networks outside and inside of building materials or structural elements. The higher the number of connections between BLE modules, the more precise and the more distant information can be obtained from the network. Mesh networking was applied to increase the quantitative information.

1 INTRODUCTION

1.1 *Task to solve*

Bridge structures are ageing while they are exposed to changing environmental conditions as temperature or moisture, influence of growing population and climate changes during their service life. Changing ground water conditions, flood or even leakage in fresh or disposal of wastewater pipes can cause increased moisture content in building materials and structural elements as walls or floors. Moisture allows the transport of other adverse chemicals that are reducing the durability of structures. This is the reason, why early indication of moisture is required to immediately undertake preventive measures. Moisture allows adverse chemicals to penetrate the structure, Without moisture chemical processes as Alcali Silica Reaction (ASR) or Delayed Etringit Formation (DEF) that are reducing the service life of structural concrete, would not be possible.

1.2 *Idea to apply*

The propagation of electromagnetic waves in a medium depends on the character of the medium, e.g. air sand or concrete. This character changes, if the medium gets moist. Water is damping the signal strength of microwave signals. Aim of the project is to survey the changes of the signal strength due to changes in the medium in periodic or continuous measurements. The basic research was related to the feasibility and capability of a network of microwave modules to estimate the moisture distribution in massive structures of infrastructure assets (Helmerich, Voigt, Adao, Moldenhauer, & Köppe, 2018).
It is well known from heating food, that water absorbs energy at a frequency of 2,45 GHz, wavelength 122 mm, commonly used to heat food in a microwave. The same frequency range is used for data transfer by Bluetooth®, ZigBee and other protocols.
To reduce the number of influence parameters during the basic investigations, the influence of changing moisture in a medium on changes of microwave signal strength was considered, only. Other influence factors as salt, thickness, temperatures or cracks were not considered.

1.3 *Setup to use*

A network with optimum microwave modules will be proposed. The modules can be attached to both sides of a structure (existing structures, see Figure 1) or shall be embedded into specimen during the construction process of any new cast concrete structure (see Figure 2. Externally attached microwave-module networks have the advantage, that they can be reused in future.

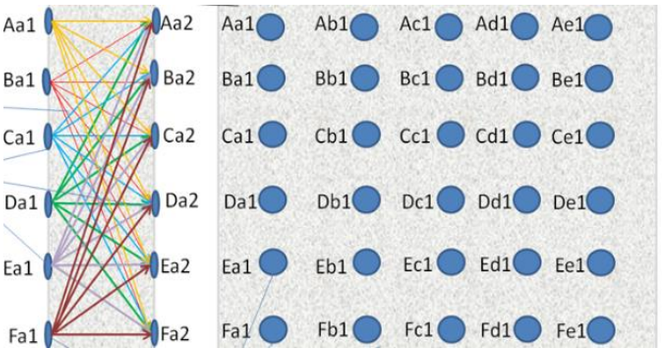

Figure 1. Symbolic measurement traces for monitoring set-up with modules (Blue) attached to the surface of an existing structure, side view and front view.

The network to develop includes making use of advanced Wireless Sensor Networks (WSN)
Inside of sand or other structural material, distributed microwave sensors will provide information about their signal strength and send the message about their signal strength to the adjoined microwave modules.

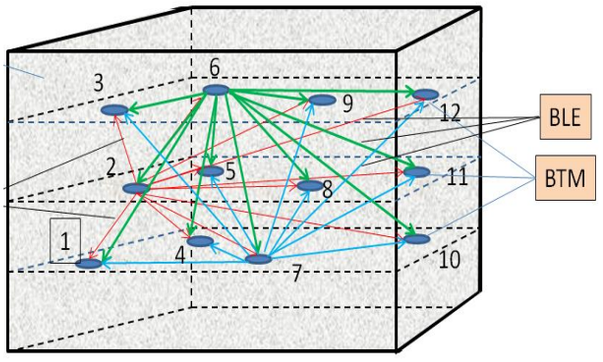

Figure 2. Symbolic measurement traces for monitoring set-up with modules (Blue) embedded in a cast concrete structure.

A fully meshed network of microwave sensors might be able to transfer data deep inside a structure. The reach of ZigBee, Bluetooth®, Bluetooth®Low energy and other specifications is up to 100 m (in air), in fully meshed networks even more.
The higher the number of connections between microwave modules, the more precise information can be obtained from the network. Finally, mesh networking can be applied to increase the quantitative information.

Further part of the project is a feasibility study about localization of distributed modules inside the concrete and signal strength and send the message about their signal strength to the neighboring microwave module.

2 TASKS AND TOOLS

2.1 *Project idea*

All mentioned methods cannot penetrate massive structures. The project idea was to create a meshed network consisting of microwave modules that are communicating in 2,45 GHz. The modules may be embedded in a new structure or externally bonded to an existing bridge structure. Measure for the moisture content is the different damping of the signals due to changing moisture content.
Increasing moisture content influences the damping and finally the RSSI. Consequently, the change of the microwave signals allows the application to estimation of the moisture content either from outside and/ or from an embedded set of modules (Köppe, Moldenhauer, Helmerich, Haamkens, & Wittmann, 2016). Finally, if the method is further developed, it will be applicable in bridge embankments, substructures, road ways or bridge main structures.

2.2 *State of the art of humidity measurements*

Drilling holes and estimating the moisture of the drilled powder is the most popular minor destructive technique to estimate moisture in practice. Another minor destructive technique is the microwave borehole method. Further quantitative non-destructive techniques use sensors attached to the surface. These methods are the time domain reflectometry or complex resistivity method. The complex resistivity method looks at resistivity magnitudes relative to a reference resistor. The frequency range is typically between 1 kHz to 1 MHz. Other methods use the electrical conductivity which is simply the reciprocal value of the electrical resistivity These methods provide information for the near surface area.
Commercial modules, e.g. produced by Texas Instruments, contain a microchip, e.g. Sensirion chip to measure local moisture. The data is transferred by Bluetooth®. If they were protected against water, it would be possible to embed them. Data transfer is only in one direction, from the local position to the reading unit in a smart phone or tablet (Moldenhauer & al, 2016).
Other researchers measure the local moisture with a microchip and transfer the data by Radio Frequency Identification (RFID) RFID can be active or passive. As the lifetime of the sensors depend on the energy supply, the passive solution is given the priority, as it

is more energy saving. In this case sensor is activated from a reading device passing over the surface. Disadvantage is the fact, that the RFID reader must be relatively close to the surface and the sensor should not be deep inside the structure (Stoppel & Fakhouri, 2014).

2.3 *Networks for moisture measurements and IoT*

The idea about a wireless network for the estimation of moisture distribution in a massive medium by means of microwave signal change analysis is not known to the developers.
In difference to past projects, the microwave signals as e.g. Bluetooth® or ZigBee were not used to transfer a signal measured by a digital microchip, but the signal change itself was the measure of the investigated parameters in the presented project.
As basic tasks for the feasibility of the idea, the following questions need answers:

- How does the damping due to moisture content generally influence the distance of the signal transfer in air and moist sand?
- What is the influence of polarization?
- What are the optimum module?
- What is the optimum set-up of the network?
- Is a connection to the IoT useful?

2.3.1 *Damping*

How does the damping due to moisture content generally influence the distance of the signal transfer in air and moist sand? In a vacuum, the electromagnetic signal would not change, in air only slightly. In concrete, the distribution of moisture is usually not homogeneous, as the curing starts from outside. The inner part cures as latest. In difference to concrete, in sand it is possible to distribute the moisture homogenously and estimate the content precisely. Therefore, the preliminary tests were carried out with sand to get an idea about the influence of the damping due to moisture on the transfer distance and the change of the Received Signal Strength Indicator (RSSI).

2.3.2 *Polarization*

What is the influence of the polarization? Electromagnetic waves radiate into a three-dimensional space. The microwave antenna has usually an antenna polarization. The antenna polarization must be known and has to be considered during the analysis of the measured damping.

2.3.3 *Selection of the optimum module*

A second series of tests was carried out with an LinTech-Module including a BLE chip BTM-800 (by Rayson) BLE sensor ((Adao, Helmerich, Voigt, Moldenhauer, & Neumann, 2017). The BLE-module was provided together with a sniffer.
The optimum module for a mesh network fulfilling the requirements of the project to receive and forward data packages was developed, composed and provided by our project partner LinTech GmbH.

2.4 *Optimum set up for a network*

2.4.1 *Choice of Network*

The high requirement for communication of each sensor with the twelve neighboring modules to obtain the maximum information about the damping between all modules, were the basis for the choice of a full mesh communication network. The concept was realized and the function was tested with 27 NC2400-modules embedded in fresh and curing concrete.
The number of measurements at a time is limited by the memory of the modules and the maximum size of one data package supported by the protocol of the meshed network. The important information in this case is the receiving node id number, the sending node id numbers and the corresponding RSSI value. This information will then be wrapped up into a data package (Voigt, Helmerich, & Rückschloss, 2017).
If data is transferred to a node close enough to the SmartHub (gateway) then the data is transmitted to the NC2400 in the SmartHub. Advantage of the full mesh network is, that in case one module would not survive any more, the package transfer would go automatically through other nodes.

2.4.2 *Connection to IoT*

The SmartHub (gateway) is equipped with a mobile cellular module in remote areas. This makes it possible to get access to the data via a server from the office or elsewhere, on site or when visiting the contractor.

2.4.3 *What is the optimum communication protocol*

The optimum microwave device passes data over a long distance with minimum need for energy. Usually the data is transferred via a mesh network. The maximum number of data transfers offers a full mesh network. Mesh networks- in difference to tree networks- allow the data transfer in two directions if needed.

2.5 *How can microwave modules serve as a sensor?*

Any electromagnetic source transmits the electromagnetic waves into a 3D space. Usually the electromagnetic wave is used for transmission of data. The transmitter therefor needs energy supply in the range of Milliwatts. Some of this transmitting energy gets lost on the way between transmitter and receiver through the medium as air, dry or moist building material (Voigt, Helmerich, & Rückschloss, 2017).
Due to the swinging of waterdipoles at a frequency of 2,4 GHz we expect a more significant change of signals on their way through the medium between transmitter and receiver. Water dipoles influence the

absorption of energy. A second advantage is the usage of modules in the frequency range of 2.4 GHz are introduced protocolls, e.g. for Bluetooth®, Bluetooth®Low energy or ZigBee, that the mayority of notebooks tablets or mobile phone could receive directly and wireless.

2.6 *What is the role of water dipoles?*

Damping of the electromagnetic signal in moist environment is much higher than in dry medium or even in air. The polar nature of water with the characteristic dipole moment is responsible for the electric properties of the moist material. At a frequency of 2,45 GHz water dipoles start to swing. Given the assumption that the distance and material between transmitter and receiver of two sensor nodes are known it is now possible to find a correlation between the RSSI value and the moisture content between these two sensors (Voigt, Helmerich, & Rückschloss, 2017).
As a first step, the influence of moisture on the Received Signal Strength Indicator (RSSI) between two modules was analyzed. The first module transmits a signal in the range of 2,45 GHz and the second module receives this signal. It is well known that the value of the received signal strength indication (RSSI) depends on the moisture content.
The higher the number of connections between any two modules, the more precise information can be obtained from the network. Finally, mesh networking can be applied to increase the quantitative information.

2.7 *Modelling the moisture damping coefficient*

The damping of the signal strength depends on the damping of an electromagnetic material in air (L_{FS}) and due to the material (L_M). Further influence parameters are the antenna gain of the transmitting ($G_{t\ dBm}$) and receiving antenna ($G_{r\ dBm}$). The losses on the transmitting ($L_{r\ dBm}$) and receiving ($L_{r\ dBm}$) sides as well as the losses during transfer ($-L_{FS}-L_M$) are considered The following equation expresses the resulting link budget (Moldenhauer, 2016):

$$P_{r\,dBm} = P_{t\,dBm} + G_{t\,dBm} - L_{t\,dBm} - L_{FS} - L_M + G_{r\,dBm} - L_{r\,dBm}$$

2.8 *What are the alternative modules*

Common modules, that are based on the highly available Bluetooth®Low Energy standard, emit electromagnetic waves, whose signal strength gets dampened by water molecules.
For first feasibility tests we applied the TI module in order to get the additional information about local moisture from the Sensirion microchip in sand, see

Figure 3. Commercial TI Module with included microchip to determine local moisture.

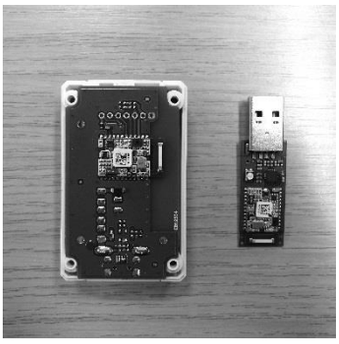

Figure 4. BLE-sensor provided for preliminary tests (provided by Lintech GmbH).

This effect serves as the basis on determining the moisture level in material. We will show how to apply this method in a meshed sensor network for online monitoring.
The BLE-standard does not allow that BLE Modules act as transmitter and receiver in a full-mesh network. Therefore, it was necessary to switch to a final module, produced by NeoCortec that is emitting microwaves in the 2.45 GHz range as well. The NC 2400 was used in the final LinTech-modules for communication and is also placed on the SmartHub.

2.9 *Modelling*

For the visualization of the preliminary RSSI measurements, the maximum likelihood expectation maximization (MLEM) algorithm (Adao, Helmerich, Voigt, Moldenhauer, & Neumann, 2017) was applied. MLEM, a grid was defined that was representative for the investigated area. The assumption was made that the loss of signal strength is linear along the distance between the transmitter and receiver.

3 NETWORK COMMUNICATION

3.1 *Components of the communication network*

For the design of the communication network we established the following requirements:
- Computing unit
- BLE-Interface and WLAN
- Mobil cellular module
- local memory
- NC2400 interface
- power supply
- water proof casing

The main point of the network is the wireless transfer of data. Along with the transmitted and received signal strength, the names of the transmitting and receiving module must be transmitted.

3.2 *SmartHub- the gateway*

To receive the data output of the modules, a gateway was designed. The computing module is an intel Edison, including Bluetooth Low energy and WiFi. The gateway, in our study, has wired connections to power supply and an USB- interface. For external gateways, a solar panel may provide energy together with a battery. A mobile cellular module and an SD-card enable the data transfer to the internet (Voigt, Helmerich, & Rückschloss, 2017).

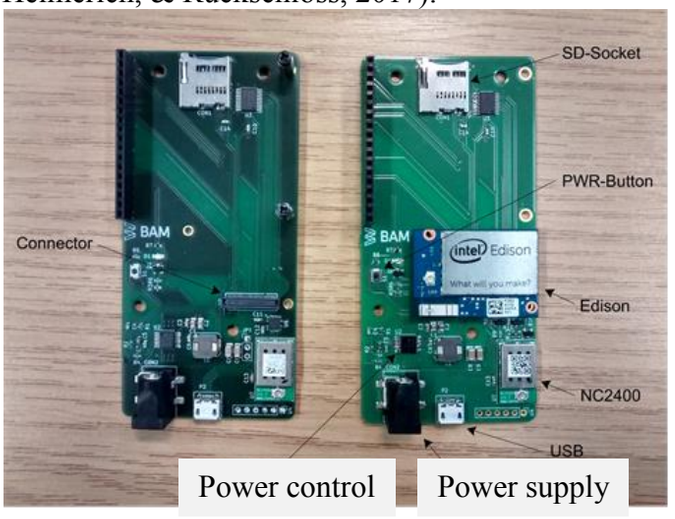

Figure 5. SmartHub (Gateway) carrying the data processing unit, power supply, NC 2400 module. A FONA 3G was added later.

From the SmartHub, the data could be stored in a cloud and accessed from elsewhere.

3.3 *Computing unit*

With the computing unit or platform, you want something fast, relatively easy to use and preferably bringing along as many interfaces as possible on the list. Given the tasks an operating system is necessary in any case. Thus, a popular choice would be a Raspberry Pi, Beagle Bone Black, C.H.I.P. Pro or the Intel Edison as a prototype platform. Basically, any will work fine, but when the choice was made only the Intel Edison already had WiFi and Bluetooth on board. It was also small scale and could be easily integrated into a custom circuit board, which would be necessary anyways since some modules like the mobile cellular module need to be connected externally on another board anyways. (Voigt, Helmerich, & Rückschloss, 2017).

3.4 *How to choose an optimum network setup*

The software architecture of the network is visible from Figure 6 (Helmerich, Voigt, Adao, Moldenhauer, & Köppe, 2018).

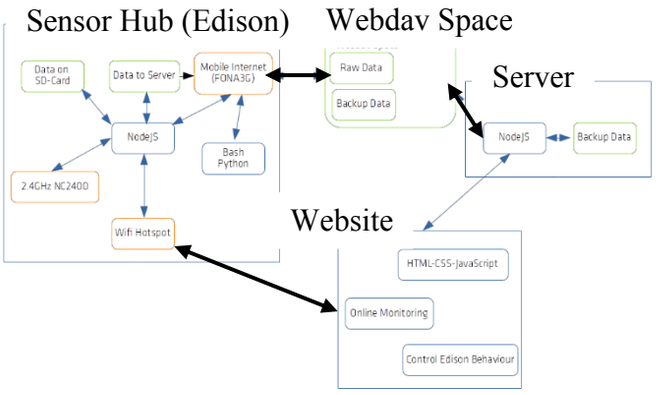

Figure 6. Flow chart of the network architecture.

4 EXPERIMENTAL STUDIES

4.1 *Modules embedded in sand*

Three experimental studies were carried out:

- Embedded modules to estimate the different signal transfer distance in moist sand with different moisture content
- Influence of antenna polarization regarding the wave path
- Influence of the location of the antenna
- Embedding sensors in a massive specimen
- Test of the function of the module network

4.1.1 *Influencing the signal transfer distance*

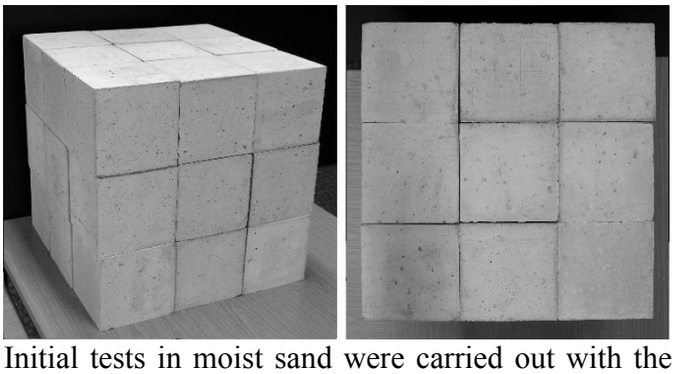

Figure 7. Set-up for preliminary tests with concrete cubes

Initial tests in moist sand were carried out with the module by TI. The advantage was the fact, that a microchip for local moisture measurement was included and the weight difference allowed the precise calibration of the moisture content. The module allowed basic investigation of the maximum reading distance from the embedded sensor depending on the distance between receiver. A mobile phone with the app provided by TI served as the receiver (Köppe, Moldenhauer, Helmerich, Haamkens, & Wittmann, 2016).

The first test series was carried out with a TI-module in sand, the TI-App on a mobile phone with enabled Bluetooth function served as receiver. The RSSI was

analyzed in moist sand. External B®LE-Nets may be reused.

4.1.2 *Visualization of a moist core*

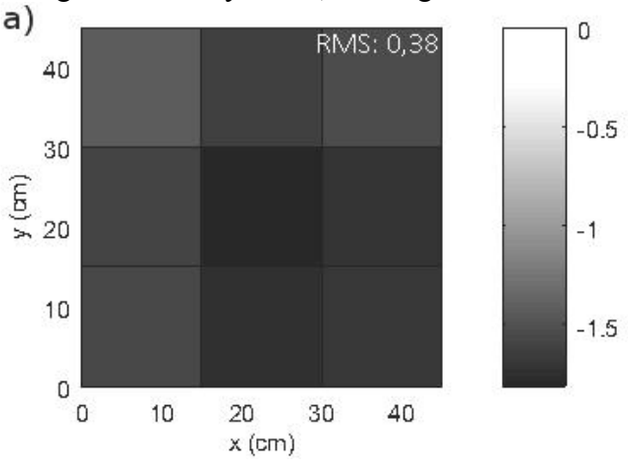
A series of experiments with modules attached to the surface of a bigger cube 45 x 45 x 45 cm, composed of 27 concrete cubes 15 x 15 x 15 cm. Nine cubes were laid in each of the three layers. The middle cube was saturated with water, as seen in the visualization using the MLEM algorithm

4.2 *Experimental studies with externally attached sensors*

To be flexible, experiments were carried out with a series of concrete cubes. Thus, it was possible to compose walls or larger cube by means of the smaller cubes. Dry cubes were than replaced by water saturated cubes to check the ability to visualize the wet cube using processed RSSI data by MLEM, computed tomography.

4.2.1 *Influence of moisture content on the RSSI*

The influence of the moisture was simulated in measurements with one water-saturated cube inside a wall of eight further dry cubes, see Figure 7.



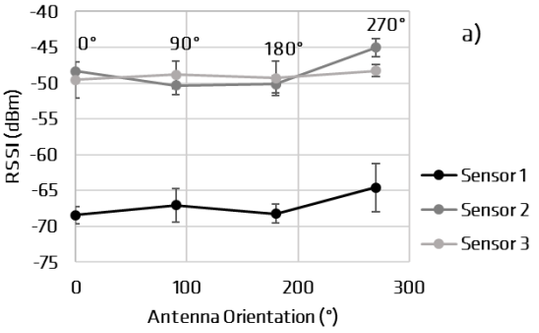


Figure 8. RSSI distribution map calculated with the MLEM algorithm, scale in dBm/m according to measurements on the cube in Figure 5.

The observed change of the moisture content was not directly proportional to the change in RSSI. The change in the RSSI was higher when moisture content was changing above 50% of its initial total weight. Below this level, the change in the RSSI was lower. This means that humidity monitoring with BLE sensors becomes increasingly challenging as water content lowers in concrete (Helmerich, Voigt, Adao, Moldenhauer, & Köppe, 2018).

4.2.2 *Influence of the polarization on the RSSI*

The polarization has an influence on the measured

RSSI, see . The RSSI differs up to 10 % (± 2.5 dBm) depending on the angle of the position of the receiving module. This means, that for all traces of microwaves the antenna orientation must be known and considered in the final analysis of the network. The results show, that the antenna polarization must be well known and needs deeper investigation. The knowledge about the characteristic of any microwave antenna and the correlation with the real moisture content is an important part of the calibration before data analysis.

Figure 9. Influence of the antenna orientation on the RSSI of a 15 cm thick specimen (diagram a).

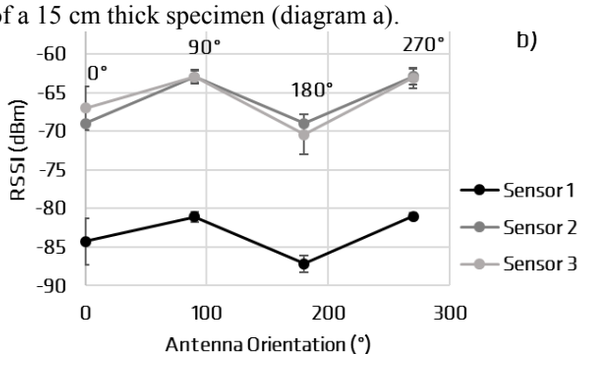

Figure 10. Influence of the antenna orientation on the RSSI of a 45 cm-thick specimen (diagram b).

4.3 *Experimental studies with embedded modules in concrete*

A watertight casing was constructed to safe the sensitive modules from moisture during the casting of concrete and curing. Different variations for embedding the modules into concrete were tested as shown in Figure 11.

For the first tests, the modules were attached to a grid made of a kind of stable fishing line as seen in Figure 12. The modules were fixed to fishing line in three levels with nine modules in each layer.

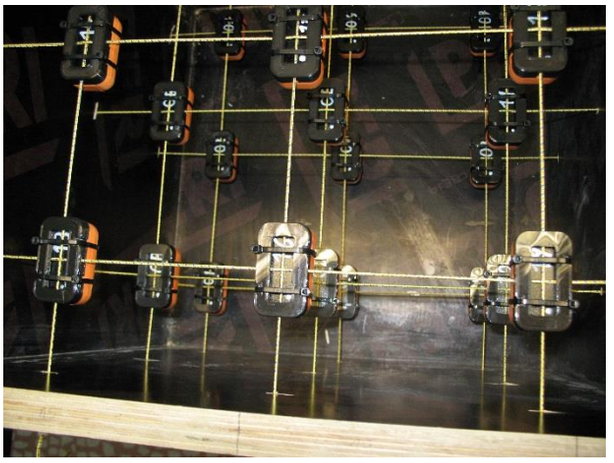

Figure 12. Encased sensors attached to a fishing line before casting the concrete.

4.4 *Localization of modules*

During the tests, as shown above, all modules had the same orientation related to the specimen´s external edges. If modules would be used in practice, it would be probably not economic to attach them to the reinforcement or fix the modules in a grid. The plan is to ad robust modules to the final concrete mixture to reduce the additional workload on construction sites. This procedure would require a localization of the modules after casting and getting additional information about their orientation after hardening of the concrete. In the current stage of research, the localization of microwave sensors is not possible. For preparation for this next step, a study was prepared about concepts for localization.
The localization and obtaining information about the final antenna orientation need adding inertial sensors to the microwave module, consisting of an 3D-accelerometers and 3D-magnetic field sensors.
None the less, ultrawideband (UWB) modules were attached for distance measurements and compared to distance measurements in air without concrete as feasibility measurements for the continuation of the current study.

4.5 *Specimen with embedded microwave modules*

In this basic research, all modules embedded in a specimen will have the same orientation and a regular distribution in three layers. Given, there are 27 microwave modules embedded in a massive structure. It was appointed in our concept that any sensor is transmitting the following information to their closest twelve neighbors: Name of the transmitting module, transmitted signal strength, the addressed module and then the received signal strength is added. In case the

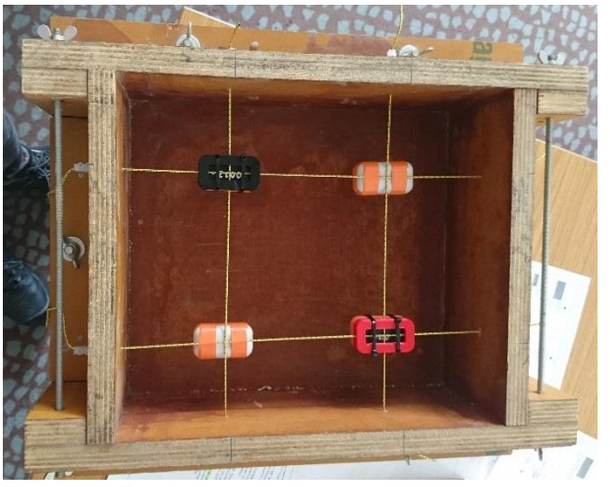

Figure 11. Feasibility of different encasing for modules.

module has received this information from other sensors, the next package will include the information from module x including the transmitted signal strength and the received signal strength from the receiving module y including its name.
As seen in Figure 13, the measurements were started before casting the concrete. The data acquisition worked reliable as described in chapter 3.

Figure 13. Continuous measurement starting before casting.

After casting, the monitoring continued during the curing period of the specimen. The data was made available via a server and could be accessed

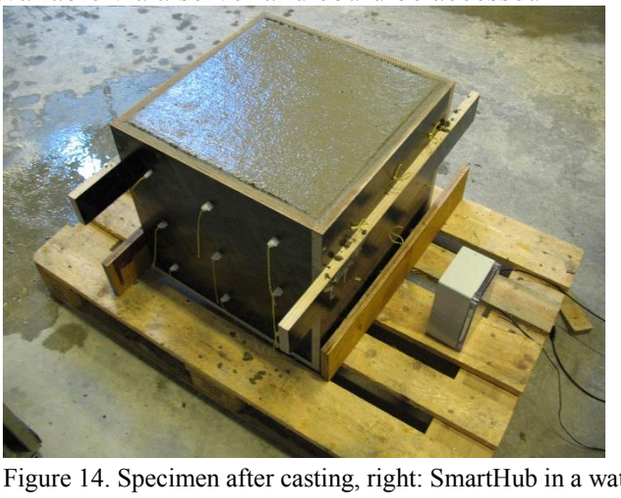

Figure 14. Specimen after casting, right: SmartHub in a water proof casing for data collection from modules inside the concrete specimen.

All measurements were accessible any time via internet. Depending on the potential hazard, the frequency of data acquisition may be adapted to the need. Less data acquisition means longer lifetime of the embedded sensors as the batterie lives longer.

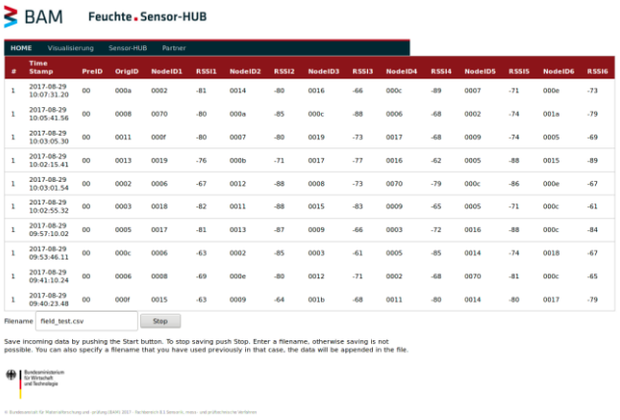

Figure 15. Web-based data access of the SmartHub.

5 FURTHER RESEARCH NEEDS AND OUTLOOK

The results of one year intensive testing and development are promising. So far, we have shown the basic principles on how Bluetooth Low Energy modules can be used to qualitatively show the distribution of moisture in a building material. An Explanation on the meshed sensor network used has been given and a straight forward selection of modules to set up such a network has been presented.

Besides microwave modules in the 2.45 GHz range, UWB modules will be added. The modules will be further equipped with 3D-accelerometers and 3D-magnetic field sensors to characterize the location and orientation of randomly distributed modules.

Next steps should focus on localization of the sensors and visualization of an embedded data set. Final goal is a set of randomly distributed microwave modules, which will communicate with their closest neighbors to provide information about their location and indication about the received signal strength.

As further step the number of modules and measured distances should be increased along with the number of cells in the MLEM-analysis to increase the resolution of the damping of signals distribution.

Ultimately, our goal will be to do a time -lapse of already calibrated distribution images, which can help us continuously monitor and visualize humidity changes. To do this we will need data time series that are long enough to observe humidity variation in concrete.

6 ACKNOWLEDGEMENT

The basic research was carried out together with the SME Lintech GmbH under the ZIM-KOOP program of the German Minister of Economic affairs and Energy (BMWI) supported by the German Society of Engineers (VDI) under contract number 16KN050827. We acknowledge the fruitful cooperation with the LinTech GmbH and the national funding provided by BMWI.

Quantifying increases in maintenance costs of prestressed reinforced concrete (PRC) bridges due to increasing fatigue from heavier traffic loads

M. Frizzarin, L. Mancassola, P. Franchetti
Franchetti Group, Rome, Italy

ABSTRACT: Over the life cycle of a road bridge, traffic flow over time can exceed initial predictions, sometimes due to new code allowances. This extra traffic can compromise bridge integrity over time and decrease its service life. The aim of this work is to quantify the extra funds necessary for maintenance interventions over a given time interval to preserve the original lifespan of prestressed reinforced concrete (PRC) bridges. The method begins with the evaluation of the reduction in bridge service life due to increasing fatigue loads. Subsequently, the total sufficiency rating (TSR) parameter is used to estimate the decay of bridge health over its lifespan. Those variables are then translated into an estimate of the funds required for further maintenance interventions over the time period considered. This method will be a useful tool for bridge maintenance managers for estimating maintenance costs.

1 INTRODUCTION

1.1 *Load increases over road bridge life cycles*

Road bridges are designed to resist fatigue induced by traffic passing over them. Design parameters are generally specified by construction rules and/or codes in force in the region where and at the time when a given bridge is built.

Over the last few decades, however, some countries have approved new legislation that increased the allowable weight limits for some types of multi-axle vehicles. Moreover, the number of vehicles circulating in recent years has increased beyond expected thresholds, and this holds also for the number of heavy vehicles in circulation. In many cases, design codes for new bridges have been updated to account for the transit of heavier vehicles.

As a consequence of these changes, however, older bridges are now loaded with heavier and more frequent loads than were anticipated when they were built, and are therefore more vulnerable to fatigue problems. They will therefore require more maintenance interventions than originally anticipated in order to stay in service over their planned lifespans.

1.2 *A method for maintenance cost estimation*

This paper introduces a method to estimate the extra maintenance costs necessary over a given time interval to preserve bridge integrity and counteract fatigue problems despite traffic load increases.

The procedure, valid for highway prestressed concrete bridges, can be summarized as follows:

1. Evaluate the variations in service life due to changes in traffic fatigue loads;

2. Estimate the evolution of bridge health degradation over time for two traffic load conditions, that is, the original theoretical load conditions and the actual load conditions;

3. Evaluate the increase in maintenance costs over the designated time period using the results of the previous assessments steps in order to ensure that the health conditions of the bridge over time remain the same as those expected at the beginning of the life cycle of the structure.

2 PRESTRESSED CONCRETE BRIDGE SERVICE LIFE ESTIMATION

The first step of the method is to assess the theoretical service life of the bridge when it is subject to variations in load conditions. The service life is calculated following Jin-song Zhu et al. (2015), taking cable corrosion and fatigue from traffic loads into account and assuming unchanging environmental conditions.

Cable stress inside the PRC beam due to traffic cyclic loads, $\Delta\sigma$, is first calculated for two load conditions, called scenario 1 (S1) and scenario 2 (S2). These scenarios represent the service load conditions before and after a change in the fatigue loads to which the bridge is subjected, respectively.

Service life estimations also require a measure of the frequency of the heavy loads traveling over the bridge, defined as the ADTT (Average Daily Truck Traffic volume) parameter.

The cumulative number of truck passages, N_f, for the bridge age t (years) is estimated as show in in Eq. (1):

$$N_f(t) = 365 \times ADTT \times \frac{(1+\alpha)^t - 1}{\ln(1+\alpha)} \quad (1)$$

where α is the annual rate of traffic increase.

The number of stress cycles, N, over the entire life cycle of the bridge can be calculated according to the S-N curve in Eq. (2):

$$\lg N = 8.08 - 3.5 \lg S \quad (2)$$

where S is the stress amplitude of the prestressing strand induced by one truck passage, taking into account corrosion and dynamic impact. It is given by Eq. (3):

$$S = \mu \times \lambda \times \Delta\sigma \quad (3)$$

where μ = impact factor and λ = stress concentration factors of prestressing strands induced by corrosion pits, as defined in Eq. (4):

$$\lambda \begin{cases} 1{,}045 + 0{,}00335(t_1 - t_0) & round\ \ pit \\ 1{,}039 + 0{,}00313(t_1 - t_0) & oval\ \ pit \\ 1{,}095 + 0{,}00234(t_1 - t_0) & triangular\ \ pit \end{cases} \quad (4)$$

where t_0 is the reinforcement corrosion period in years and t_1 is the life of the bridge in years.

When $N_f(t) = N$, the bridge life limit has been reached, and, therefore, the theoretical service life of the bridge, t_T, can be predicted by combining Eq. (1) and Eq. (2), as written in Eq. (5):

$$t_T = \frac{\ln\left\{\frac{10^{8.08} \times \ln(1+\alpha)}{365 \times ADTT \times [\mu \times \lambda \times \Delta\sigma]^{3.5}} + 1\right\}}{\ln(1+\alpha)} \quad (5)$$

Therefore, the residual life of the bridge is equal to t_T-t. This procedure is repeated for S1 and S2.

3 TSR AND BRIDGE LIFE EVOULTION

Restoration costs over the life of a bridge life strictly depend on the condition of the structure. An objective quantification of the condition of a bridge is not trivial, especially with respect to future needs. The total sufficiency rating (TSR) parameter method (Pellegrino et al. 2011, Zanini et al. 2016a, c) is therefore applied. This numerical parameter has been developed to give an objective indication of bridge health and the urgency of intervention. It takes into account several key characteristics of the bridge: bridge age, the importance of the structure in the traffic network, traffic intensity, road type, defects in structural and non-structural elements (obtained from bridge inspections), and the importance of those elements in the global functionality of the bridge. As discussed specifically below, knowing the trends in the TSR over time allows for the prediction of the costs of rehabilitating the bridge to a safe state over the various life phases of the structure. TSR values can range from 1 to 100, with the maximum value at the beginning of the life of a bridge. The TSR decreases over time with the decay of the health of the structure. Zanini et al. (2016c) stated that it is appropriate to consider a parabolic decrease trend for the TSR over time, as shown in Eq. (6):

$$TSR(t) = at^2 + bt + c \quad (6)$$

Using the method described in this paper, the goal is to obtain two TSR decay curves for the two different load cases so that they can be compared, i.e. parameters a_1, b_1, and c_1 for S1 and a_2, b_2, and c_2 for S2. They are evaluated with the following boundary conditions:

1. The TSR values for both curves must both start with the same value (the maximum) at the time the bridge came into use, i.e. $TSR_1(0) = TSR_2(0)$ and $c_1 = c_2$;

2. The TSR must go down to 1 at the end of the theoretical service life of the bridge (calculated as shown in the previous section);
3. The actual value of the TSR for S2 can be calculated by collecting data via visual inspection of the bridge elements. This is the third point in the calibration of the S2 life curve;
4. Changes in load conditions usually do not start at the beginning of the life of the bridge, but instead emerge over time. To model these changes, the same decay rate for the two curves is assumed for the first years of bridge life, and so the same first derivative is used for the two curves for $t = 0$ (i.e. $b1=b2$). This boundary condition is expressed in Eqs. (7), (8), and (9).

$$TSR_1'(0) = 2a_1 * 0 + b_1 \quad (7)$$

$$TSR_2'(0) = 2a_2 * 0 + b_2 \quad (8)$$

$$(TSR_1' = b_1) = (TSR_2' = b_2) \quad (9)$$

This last boundary condition allows the S1 life curve to be plotted as well. Figure 1 represents the generic application of the method. The significant points useful in the construction of the curves are indicated in the figure.

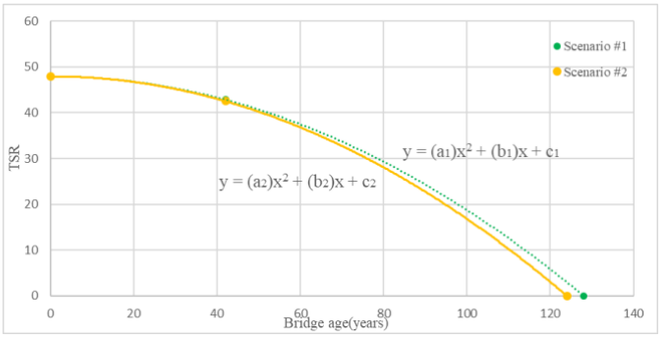

Figure 1. TSR life curves for scenarios 1 and 2.

A comparison of the two life curves of the two different load cases shows that, over any given time interval, the vertical difference (i.e. TSR variation) over time increases because, in the scenario with increased loads, the bridge deteriorates faster (Fig. 2). This incremental difference represents the deterioration of bridge health over the period analyzed due to the increased load increment.

For any given period (t_A-t_B) the loss is quantifiable as:

$$\Delta TSR = \Delta TSR_B - \Delta TSR_A = \left[TSR_2(t_B) - TSR_1(t_B)\right] - \left[TSR_2(t_A) - TSR_1(t_A)\right] \quad (10)$$

4 MAINTENANCE COSTS

The last target of the methodology is to translate the effects of the load increment on bridge health, as calculated with the procedure presented above using the TSR, into a monetary value representing additional retrofit costs.

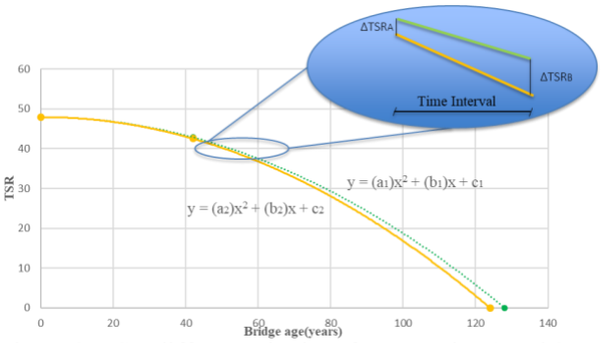

Figure 2. TSR difference in time for scenarios 1 and 2.

Zanini et al. (2016a, b) have examined a set of 150 existing bridges and calibrated a series of curves that correlate unitary maintenance costs (UMC) (€/m²) and the TSR.

For every bridge in the dataset, they evaluated the TSR, and derived unit costs from a comprehensive analysis of maintenance operations performed by the company responsible for the bridge over the last few years. This procedure allowed them to incorporate the maintenance protocols commonly adopted by the owners of the types of structure analyzed and their relative real costs into the BMSs (bridge management systems).

Cost estimates are inherently dependent on the local maintenance costs in effect at a given place and time. In Zanini et al. (2016a and b), the authors use Italian prices, estimations of which were validated by a review of Italian national (A.N.A.S. S.p.A, 2014) and local (Veneto Strade S.p.A, 2014) official unit price lists by assessing each element and CV (*Condition Values*) of each analyzed structure, as well as the unitary costs per square meter related to the sequence of possible maintenance sub-phase operations, and comparing them with information coming from the bridge owners.

Figure 3 represents the dataset used for UMC-TSR curve calibration.

The UMC-fitting equation for reinforced concrete and prestressed reinforced concrete bridges is shown in Eq. (11) below:

$$UMC = 3316.4 - 777.8 \times \ln(TSR) \quad (11)$$

With this equation, it is possible to convert the TSR differences between the two scenarios into monetary units, and quantify the extra maintenance costs due to the change in load scenarios.

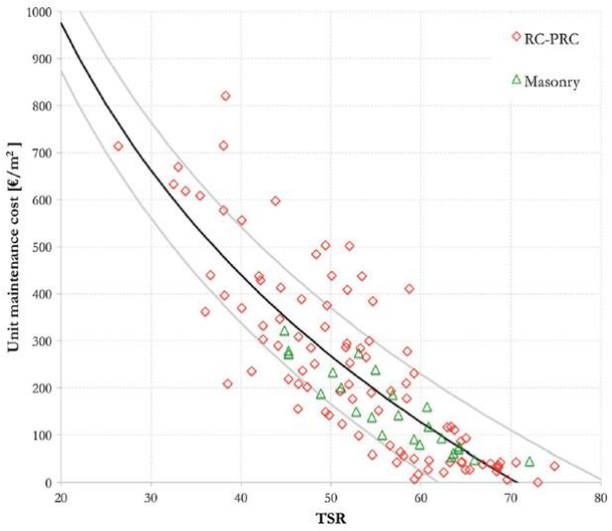

Figure 3. Unit maintenance cost vs. TSR value.

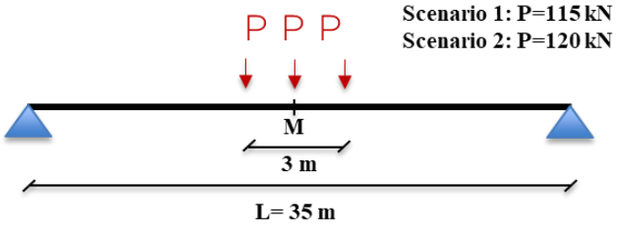
5 CASE STUDY

In the following case study, a prestressed concrete bridge with a simple supported span of 35 m is considered (Fig. 4). The span is composed of 8 prestressed concrete I beams shaped with a paraboloid variation of the height along the length (maximum in the middle, minimum at the bearings). The deck is completed with a cast-in-place concrete slab.

Figure 4. Bridge structure used in the case study.

Two different load conditions are examined. S1 considers a triaxial load with a distance between axes of 1.5 m and a load per axis equal to P = 115 kN. The total load is 345 kN. S2 uses the same configuration but with P = 120 kN (Fig. 5).



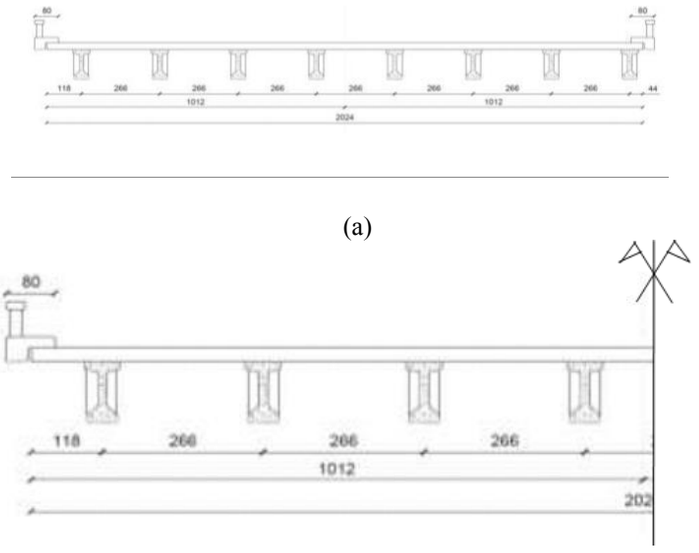


Figure 5. Scheme of bridge structure and load cases.

It is assumed that the two loads represent the service load condition before (S1) and after (S2) a variation in the construction code requirements.
The method considers an impact factor coefficient to amplify the static response to take into account the dynamic effects of traffic loads. In this specific example, and in the absence of specific dynamic tests, the dynamic effects are taken into account by multiplying the static load by a dynamic Factor (DF) defined by the national construction code in effect where the bridge is located:

$$DF = 1 + 1.06\left(\frac{20}{L+50}\right) = 1.2494 \qquad (12)$$

where L is the length of the span (m).

(a)

(b)

Figure 6. (a) bridge middle span section; (b) detail of half of the section.

By multiplying P by DF, the updated values of P become P = 143.7 kN for S1 and P = 149.9 kN for S2. The maximum bending moment in section M is then calculated, and the maximum stresses in the steel cables are derived according to section characteristics (Fig. 6).

For the described example, the maximum cable stress amplitudes in the middle span section are $\Delta\sigma$ = 3.14 MPa for S1 and $\Delta\sigma$= 3.56 MPa for S2.

In order to estimate service life, the frequency of the loads is also needed. This parameter can be estimated with, e.g., the use of weight-in-motion measurements. The frequency of the triaxial load is computed this way using the ADTT parameter mentioned above. In the case study, a 46-day experiment was run. The value of ADTT is calculated as follows:

$$ADTT = \frac{Total\#trucks}{\#days} = \frac{16.000}{46} = 348 \quad (13)$$

N_f for the bridge age t (years) is estimated as shown in Eq. (14):

$$N_f(t) = 365 \times ADTT \times \frac{(1+\alpha)^t - 1}{\ln(1+\alpha)} \quad (14)$$

where α is the annual rate of traffic increase, evaluated as 0.04 for the study case.

The number of stress cycles, N, over the entire life cycle of the bridge can be calculated using the S-N curve, as in Eq. (15):

$$\lg N = 8.08 - 3.5 \lg S \quad (15)$$

where S is given by Eq. (16):

$$S = \mu \times \lambda \times \Delta\sigma \quad (16)$$

with μ = the impact factor previously cited and accounted for through DF, and λ = stress concentration factors of prestressing strands induced by corrosion pits, as defined in Eq. (17):

$$\lambda \begin{cases} 1{,}045 + 0{,}00335(t_1 - t_0) & round \quad pit \\ 1{,}039 + 0{,}00313(t_1 - t_0) & oval \quad pit \\ 1{,}095 + 0{,}00234(t_1 - t_0) & triangular \quad pit \end{cases} \quad (17)$$

where t_0 is the reinforcement corrosion period in years and t_1 is the life of the bridge in years.

When $N_f(t)=N$, the bridge life limit has been reached, and therefore the theoretical service life of the bridge can be predicted by Eq. (18):

$$t_T = \frac{\ln\left\{\frac{10^{8.08} \times \ln(1+\alpha)}{365 \times ADTT \times [\mu \times \lambda \times \Delta\sigma]^{3.5}} + 1\right\}}{\ln(1+\alpha)} \quad (18)$$

In the case study, the same environmental conditions are considered for S1 and S2: round pits and $t_1=t_0$. The service life of the bridge in the two different load cases is estimated as t_T = 151 years for S1 and t_T = 147 years for S2. The incremental change in traffic is responsible for a theoretical bridge service life reduction of 4 years.

5.1 *TSR calculation*

The procedure starts with the calculation of the TSR of the structure at the present time, based on inspection reports available for the structure.

Visible elements of the bridge examined are beams, slabs, piers, pier top beams, bearings and joints. Non-visible/not-inspected elements are the pavement, safety barriers and the drainage system. Barely visible elements, e.g. pier foundations or waterproofing of the deck, are not considered in this method (i.e. their weight W is zero). The bridge is situated along a highway (RT = 0.80), with long deviations or unsuitable alternative roads (NBI = 0.96). It is a very busy roadway (TI = 0.90). The bridge is 43 years old (AF = 1). All other parameters necessary for the TSR calculation are listed in Tables 1 and 2 (*Condition Factor CF, Condition Value CV, Weight of the Element W*). Table 1 illustrates the main parameters for the TSR calculation for the bridge when it opened, and Table 2 refers to 2016, the year inspections were made.

Table 1. TSR method parameters for new bridge

Visible Elements	CF	CV	W
Beams	1	100	12
Piers	1	100	12
Pier top beams	1	100	10
Slabs	1	100	10
Bearings	1	100	10
Joints	1	100	6
Non-Visible Elements			
	CF	CV	W
Pavement	1	100	4
Drainage system	1	100	6
Safety barriers	1	100	4
Pier foundations	1	100	0

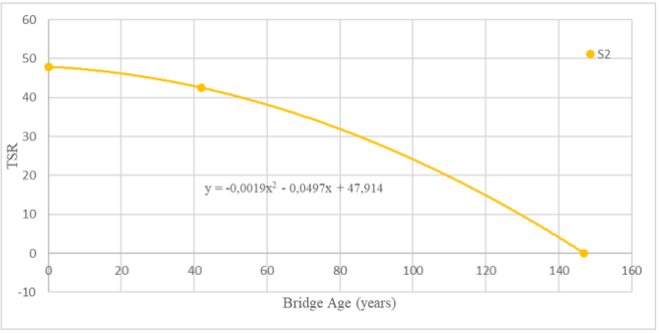

Table 2. TSR method parameters for bridge in 2016

Visible Elements			
	CF	CV	W
Beams	1	100	12
Piers	2	75	12
Pier top beams	1	100	10
Slabs	1	100	10
Bearings	2	75	10
Joints	1	100	6
Non-Visible Elements			
	CF	CV	W
Pavement	3	50	4
Drainage system	3	50	6
Safety barriers	3	50	4
Pier foundations	3	50	0

CV and CF for the various bridge elements are attributed based on the evidence from that inspection.

The TSR_0 value obtained is 47.914, while TSR_2 (2016) is 42.512. With those values, the parabolic

decay curve for S2 can be calibrated. It is shown in Figure 7.
b_1, c_1 and the service life of 151 years, as well as the

S1 curve can be calibrated, as shown in Fig. 8.

Figure 7. Life decay curve for scenario 2.

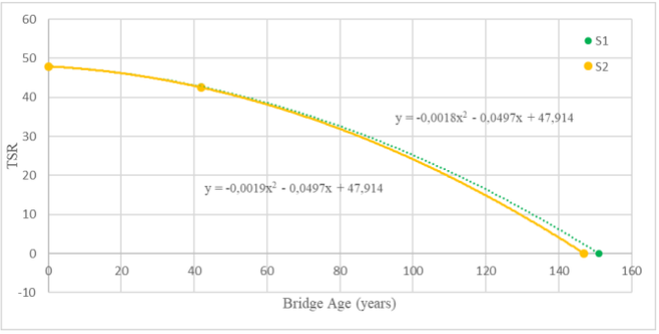

Figure 8. Life decay curve for scenarios 1 and 2.

The authors have taken into account the fact that service life calculations have been made for different loads over the whole life of the structure. However, decay is a non-linear phenomenon that hastens in the last few years of the life of a bridge (Zanini et al. 2016c). Because of this, if a change in load conditions happens in the first few decades of the life of a bridge and it is not a significant fraction of the load intensity/frequency itself, the procedure is basically insensitive to the effective starting time of the change in bridge loads. What matters is the variation in time of the TSR parameter, not its absolute value.

5.2 *TSR variations*

A period of 30 years, from t_A= 41 years (2015) to t_B = 70 years (2044), is considered and shown in Figure 9. The period corresponds to the concession period of the bridge.

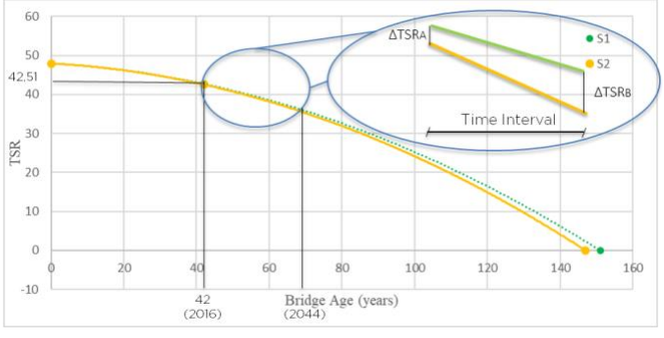

Figure 9. Bridge decay comparison between S1 and S2 over a 30-year period.

The equations of the two curves have been already calculated as previously explained, so their TSR values can be extrapolated for the desired time interval. Results are summarized in Table 3.
Over the 30 years of the grant, the load increment will cause a loss of 0.335 in the TSR parameter.

Table 3. TSR values and variations over the time interval considered.

	TSR	
	t_A	t_B
Scenario 1	42.701	35.751
Scenario 2	42.512	35.227
Difference ΔTSR_{1i-2i}	0.189	0.524
Global Diff. ΔTSR		0.335

5.3 *Cost estimates*

Using Equation (11), all TSR values are converted into monetary units. Results are shown in Table 4.

Table 4. UMC values corresponding to TSR values according to Eq. 12.

	UMC (€/m²)	
	t_A	t_B
Scenario 1	396.3	534.53
Scenario 2	399.81	546.32
Difference $(€/m^2)_{2i-1i}$	3.44	11.49
Additional maintenance cost (€/m²)		8.05

The additional maintenance budget required to cope with the extra traffic load increment is then quantified as 8.05 €/m². Since the bridge surface is 708.4 m² (20.24 m wide and 35 m long), the total amount is 5,702 €.

6 CONCLUSIONS

The method presented in this paper incorporates the results of recent research on the subject of bridge life-cycle analysis and the economic evaluation of bridge maintenance in order to yield an objective method of quantifying restoration costs so as to save bridges from additional damage and deterioration caused by increasing load conditions over their lifespans. The method is applicable to prestressed reinforced concrete bridges, and its precision is strictly correlated with the number and level of detail of the inspections performed during bridges' life cycles.

The proposed method could be a useful tool for bridge managers to use to estimate possible variations in the maintenance costs of bridges for which they are responsible during a given concession period.
This work could be expanded with the creation of databases of parametric costs to be applied in different countries all over the world. This additional data could enhance the calibration of the correlation curves used in this paper, which would allow the proposed method to become more standardized. The authors are also extending the method to steel structures, which suffer from well-known vulnerabilities to traffic cyclic loads.

ABSTRACT: This paper introduces structural assessment and strengthening of a rein forced concrete pylon which experienced torsional deformation. The pylon with a hexagonal hollow section is the lower part of the cable-stayed bridge under construction. As a floating crane hit the cantilever end of the super-structure of the bridge constructed through cantilever erection method, torsional deformation of 1.2 degree occurred along the pylon. After the collision, torsional cracks were observed on the outer and inner surfaces of the hollow pylon. The structural assessment of the pylon was conducted with nonlinear finite element analysis to simulate structural behavior. The result showed that yields of transverse and longitudinal reinforcements were not significant when the floating crane collided. After the super-structure of the bridge was restored to the original position, there were residual strains in the reinforcements, but stresses almost returned to near the origin. Therefore, it could be concluded that there were no significant damage to the pylon. In spite of little deterioration on the structural capacity, the client decided to strengthen the pylon by wrapping it with GFRP sheets after repairing cracks.

1 INSTRUCTION

The steel-composite cable-stayed bridge with 1,305 m span experienced floating crane collision. Super-structure of the bridge consists of Edge-type and I-type of 2 steel-composite for the main girder, and H-type precast concrete structure for the deck. The cable was Multi Strand Cable with 2 side arrangement. For the foundation, cast-in-place concrete pile was applied.

The accident occurred when the super-structure of the bridge was collided with the floating crane which was working at the port in the construction site. As a result, the super-structure was deformed due to the lateral load. Meanwhile, the pylon was cracked due to torsional deformation. After the collision, the super-structure and pylon were restored to the original position. And then, it was observed that inner and outer surfaces of the lower part of the pylon were diagonally cracked due to the torsion. Because of the damage on the pylon, it was required to investigate safety of the bridge not only during the construction but also under the service. Therefore, this study focuses on the evaluation of the structural safety of the pylon damaged by the collision, at the present time as well as after the construction.

2 PYLON OF CABLE-STAYED BRIDGE

The pylon where the accident occurred was H-type reinforced concrete structure. Due to the torsion caused by the collision, cracks occurred from the bottom to 16 m height among the total height of 90.5m. The foundation of the pylon was 16, 24, and 4.5 m in the longitudinal, transverse, and height directions, respectively. Fig. 1 shows the dimension of the cross-section at the bottom of the pylon. As presented in the figure, the pylon had a hexagonal hollow section with a dimension of 5 and 10 m in the longitudinal and transverse directions, respectively, consisting of walls with a thickness of 1 m.

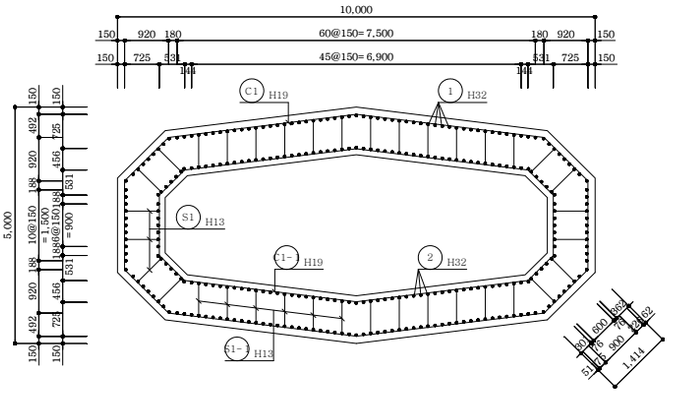

Figure 1. Dimension of the cross-section at the bottom of the pylon

3 DAMAGE STATUS

During the construction of the cable-stayed bridge, the floating crane collided with the super-structure as shown in Fig. 2. The collision occurred at the distance of 62 m from the pylon. Because of the accident, the lateral displacement of 1.75m occurred at the other end of the super-structures (① in Fig. 3) while deviation of 90 cm at the key-segment as presented in Fig 2(b), (c), and (d). In addition, lots of torsional cracks occurred at the lower part of the pylon (② in Fig. 3). After restoring the bridge to the original position, the maximum crack width was measured to 1.4 mm. Fortunately, no damage was found at the connection between the pylon and the super-structure.

4 FIELD INVESTIGATION OF THE STRUCTURE

4.1 *The pylon*

The pylon subjected to the collision was investigated in detail after setting temporary facilities on the inside and outside of the pylon.

(1) Lower part of the pylon

On the inner and outer surface of the pylon, many cracks with an inclination of about 45 degrees were observed because of torsion due to the collision of the floating crane. The crack width ranged from 0.1 mm to 1.4 mm.

(2) Leg part of the pylon

In the leg part of the pylon, the cable anchorage was generally in good condition with little damage; only several cracks less than 0.2 mm width were observed inside. It was inferred that the cracks were caused by concrete shrinkage. It has been decided to have appropriate maintenance.

4.2 *Bridge deck*

The top surface of the bridge deck was generally in good condition, but some cracks with 0.1 mm width were observed in some sections. In addition, breakage and peeling occurred on the top surface of right side deck of the pylon. It is considered that the cracks on the deck were caused by concrete shrinkage, not by the collision with the floating crane.

4.3 *Support*

At the time of the collision with the floating crane, the vertical support was deviated about 150 mm, which exceeded the allowable limit of 50 mm.

5 SAFETY EVALUATION OF THE PYLON

5.1 *Summary of the analysis*

3D nonlinear finite element analysis was conducted to simulate the structural behavior of the pylon. The analysis employed VecTor 3[(1)] which was a nonlinear analysis program using 8-nodes or 6 nodes solid elements. Since VecTor 3 is based on the Modified Compression Field Theory (MCFT), it is well known that nonlinear behavior of reinforced concrete structures is predicted in good accuracy. From the analysis results, the structural behavior such as loading capacity, deformation, and crack patterns can be investigated in detail.

In order to consider the effect of the collision on the structural behavior of the pylon, 3D nonlinear finite element analysis was conducted through three phases; 1) analysis for the torsion dueto the collision, 2) analysis for the restoration, and 3) analysis for the structural behavior under lateral load. In order to evaluate original structural capacity, analysis without any damage was conducted with lateral load as well.

5.2 *FE Model of the structure*

To model the pylon more, the cross-section was divided into rectangles and triangles as shown in Fig. 4. As presented in Fig. 5, the pylon was modelled with total 8 layers; each layer had a height of 2 m. Longitudinal and transverse reinforcements embedded in the pylon were modelled as smeared through the designated concrete elements. Since the foundation was considerably stiff, the bottom of the pylon was fixed in the model.

In addition to the pylon, the super-structure above the pylon was also modelled. Consequently, the actual

collision with the floating crane could be described through the displacement load applied at the location where the floating crane collided, as presented in Fig. 6 which was so similar to the actual situation as presented in Fig. 7.

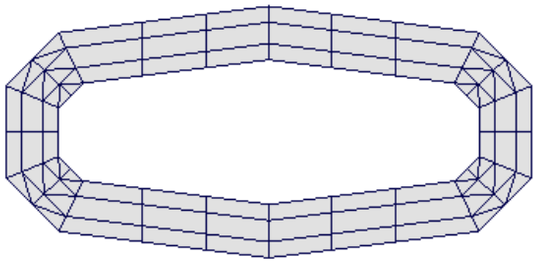

Figure 4. FE Model of the cross-section of the pylon

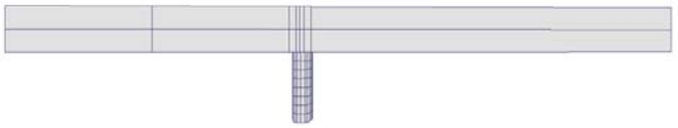

Figure 5. Front view of the FE model for the structure

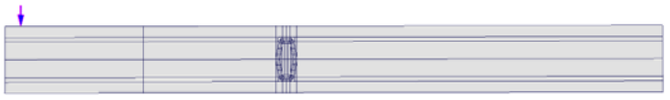

Figure 6. Plan view of the FE model for the structure

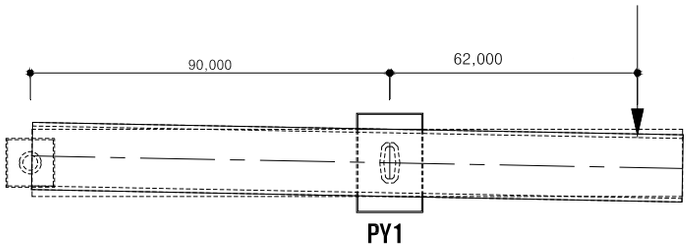

Figure 7. Location of the floating crane collision

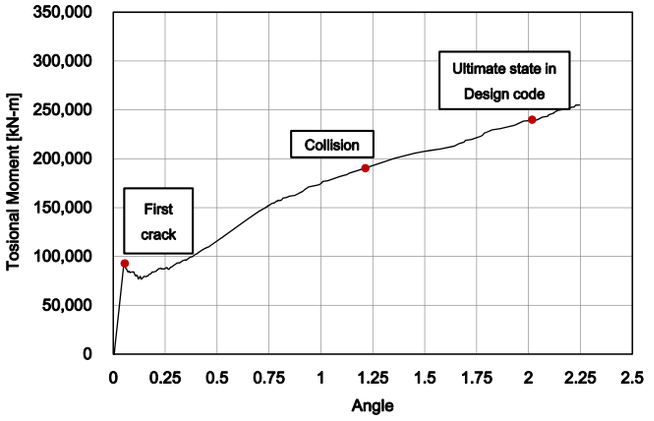
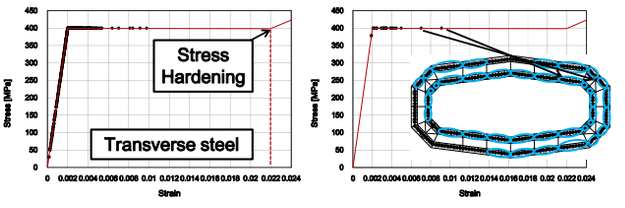
5.3 *Analysis results*

(1) Torsional behavior of the pylon

Torsional behavior of the pylon predicted by the analysis has been presented in Fig. 8. As can be seen in the figure, the pylon had sufficient torsional stiffness before the initial cracking. Once the pylon was cracked due to the torsion, the torsional stiffness decreased and the torsional moment increased as the torsional angle increased. This is a kind of the typical torsional behavior of reinforced concrete members. It is noted that the torsional moment corresponding to the ultimate state in the design code was 239,493 kN-m. As can be seen in the figure, the torsional moment caused by the collision was evaluated to about 190,000 kN-m. Therefore, since the torsional moment caused by the collision was smaller than the torsional moment corresponding to the design criteria, it can be concluded that torsional failure was not reached by the collision.





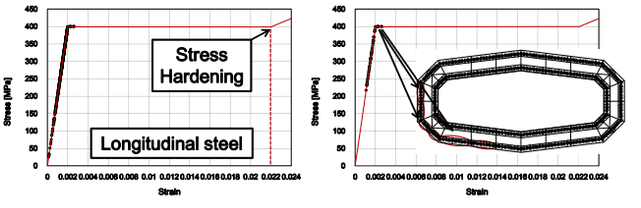


Figure 8. Torsional behavior of the pylon

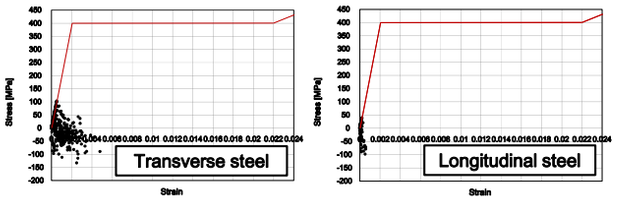
(2) State of the reinforcing bars in the pylon

Figure 9 shows the stress and strains of the transverse and axial reinforcements immediately after the collision. Immediately after the collision, it was predicted that the maximum deformation of the reinforcing bars occurred at a height of 8 ~ 10 m from the bottom of the pylon. In this section, the strains reached up to 0.00977 and 0.00255 for transverse and axial reinforcements, respectively. Since the maximum strains were only 44% and 12% of the strains to initiate the strain hardening for SD400 reinforcing bars, it could be seen that damage on the reinforcements was not significant.

(a) Stress-strain(transverse) (b) Yielding point(transverse)



(c) Stress-strain(longitudinal) (d) Yielding point(longitudinal)

Figure 9. Stress-strain states of reinforcements upon the collision

Fig. 10 shows the stresses and strains in each reinforcing bar after the restoration of the pylon from the deformation due to the collision. As shown in the figure, the reinforcing bars which experienced yielding upon the collapse were restored to small residual stress and

strain after the restoration. However, some reinforcing bars showed relatively considerable residual stress and strain.

(a) Transverse steel (b) Longitudinal steel

Figure 10. Stress-strain states of reinforcements after the restoration

(3) Structural capacity against flexural moment

After the construction is completed, the torsional behavior of the pylon is not considerable any more. Instead, flexural and shear behaviors are main consideration. Therefore, it is important to investigate the structural behavior of the pylon under flexure and shear considering the damage caused by the collision. Fig. 11 shows the analysis results for the flexural moment-displacement responses of the pylon with or without the damage. As presented in the figure, the typical flexural behavior was predicted; a high stiffness before the initial cracking, followed by decrease in the stiffness due to flexural cracks, and increase in the flexural strength as the lateral displacement increases. The analysis also showed that the flexural strength of the pylon damaged by the collision was 470,625 kN-m, which was only 5% lower than that of the pylon with no damage. Therefore, it can be seen that the effect of the damage was not significant on the flexural strength of the pylon.

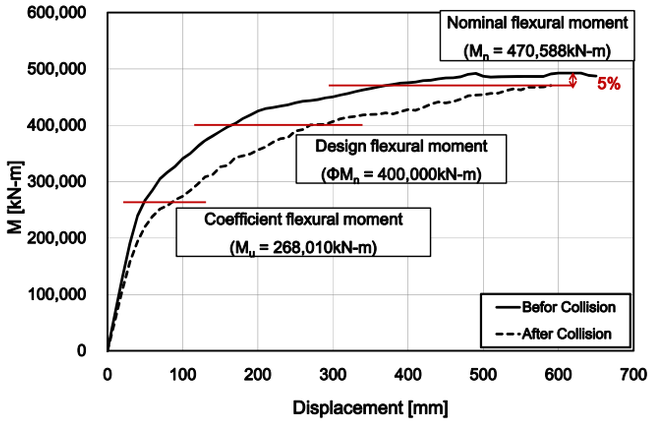


Figure 11. Flexural performance of pylon

In addition, the nominal bending strength calculated by simple theory according to the design code[2] is almost the same as 470,588kN-m, and the design nominal bending strength is about 1.18 times larger than 400,000kN-m and is about 1.76 times larger than the coefficient bending strength 268,010kN-m appear.

Therefore, although the pylon was damaged due to the torsional moment caused by the collision with the floating crane, it was evaluated that the flexural strength of the damaged pylon considering safety factor ($\emptyset M_n$) exceeds the design flexural moment with factored loads (M_u). Consequently, it can be concluded that there is no serious problem on the structural safety of the pylon in spite of the damage.

6 CONCLUSION

(1) Due to the torsion caused by the collision with the floating crane, it was analyzed that the transverse and axial reinforcements in the pylon experienced the yielding. However, since the maximum strain was much less than the strain to initiate the strain hardening, it can be concluded that structural safety of the pylon was not significantly deteriorated by the collision.

(2) The flexural strength of the pylon damaged by the collision was interpreted to be about 5% less than that of undamaged pylon. The flexural strength of the damaged pylon was evaluated to 1.8 times the design flexural moment due to factored loads.

(3) The maximum bending moment generated during the hypothesis is within the elastic range of the member and it is considered that there is no additional cracking of the member due to the progress of the process.

(4) As the pylon was cracked by the collision, it was decided to apply glass fiber-reinforced polymer sheets on the inner and outer surfaces of the pylon so that the durability and structural capacity of the pylon could be enhanced.

Parametric analysis of dissipative rocking superstructures

Z. Chegini
WSP Opus Intl. Consultants, Christchurch, New Zealand
A. Palermo
University of Canterbury, Christchurch, New Zealand

ABSTRACT: A hybrid connection has been developed for prefabricated concrete bridge superstructures by combining unbonded longitudinal post-tensioning and axial mild steel dissipaters. The connection aims to increase energy dissipation, introduce self-centering and improve overall structural performance during seismic loading. It can be used as an alternative to seismic isolation, resulting in reduced maintenance costs. The connection was tested in a large-scale precast concrete bridge specimen at the University of Canterbury. The specimen exhibited a desirable flag-shape hysteretic response when subjected to transverse quasi-static cyclic loading. The experimental results were extrapolated to various bridge geometries and design target values through parametric analysis. The effects of superstructure beam type, length of bridge, number of spans and target ductility on the transverse force-displacement relationship of the superstructure configurations was investigated. The structures were designed using a direct displacement-based (DDBD) method and analyzed with a modified version of the revised monolithic beam analogy (rMBA). The results show that higher target ductility values decrease the superstructures' secant stiffness, increase their fundamental period and significantly reduce the base shear and necessary reinforcement ratio (for both mild steel dissipaters and post-tensioning). For low ductility levels (μ=1) greater superstructures lengths generally result in higher ratios of base shear demand to seismic weight due to their larger seismic mass. However, as target ductility levels increase, the secant stiffness of the structures decrease, and greater superstructure lengths result in a decrease in the ratio of base shear demand to seismic weight. Finally, an expression to find the equivalent viscous damping in dissipative rocking superstructures was found by calibrating results from the parametric analysis to theoretical values.

1 INTRODUCTION

Prefabrication of bridge superstructures is a popular method which offers several advantages such as reduced construction time, higher construction quality and improved work-zone safety. Traditionally, a concrete bridge superstructure is either designed to be monolithic with the cap beam and abutments through moment resisting connections or is simply supported on bearings. Numerous instances of failure of simply supported bridge superstructures subjected to seismic loading have been observed, including unseating of the superstructure (Kawashima & Unjoh 1997, Zhiqiang & Lee 2009, Buckle et al. 2012, Schanack et al. 2012, Palermo et al. 2012) and damage to the cap beam or abutment shear keys (Silva et al. 2009). Such forms of failure can be mitigated to a certain extent by increasing the seating length and connecting adjacent sections of the superstructure with steel linkages (Wood & Chapman 2013). However, these solutions do not eliminate the fundamental issue of residual displacements in simply supported superstructures under transverse seismic loading.

In this paper, a connection is proposed between simply supported superstructure spans which combines unbonded longitudinal post-tensioning and mild steel dissipaters to improve the behavior of simply supported superstructures under transverse seismic loading. The post-tensioning provides a self-centering capability by reducing the residual deformation of the superstructure, which in combination with the properties of the axial mild steel dissipaters, creates a hysteretic behavior characterized by flag-shaped loops in the connection (Figure 1). Such 'hybrid' connections were originally developed for use in precast concrete frames (Priestley et al. 1999) and later used in shear walls and bridge piers (Mander & Cheng 1997, Palermo et al. 2007, Marriott et al. 2009,

White et al. 2016). Unlike traditional monolithic moment-resisting connections, which are designed to provide ductility and dissipation through plastic hinging, hybrid connections allow for the inelastic demand to be accommodated outside the precast elements (in the mild steel or dissipative devices) while other parts of the seismic-resisting structure remain elastic and relatively intact. When used between spans of a simply supported bridge superstructure, hybrid connections can be used to reduce residual displacements, introduce dissipation, and in general improve the performance of the bridge under transverse seismic loading.

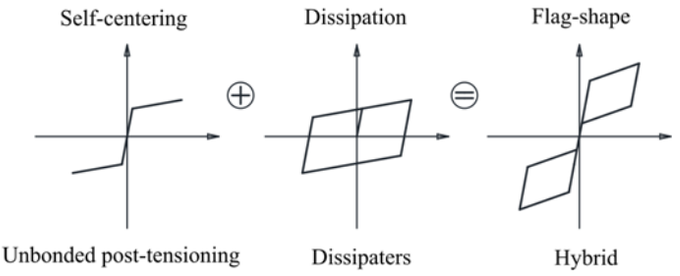

Figure 1. Flag-shape hysteresis loop of a hybrid connection

This paper presents results from quasi-static cyclic testing on a 1:3 scale, 2-span precast concrete bridge specimen featuring hybrid connections in the superstructure, followed by finding from a parametric analysis on several superstructure configurations which were performed to extrapolate the experimental results to various geometries.

2 EXPERIMENTAL TESTING

2.1 *Prototype bridge*

The prototype structure which the test specimen was based on was representative of a typical short-span concrete highway bridge in New Zealand (Figure 2). A span length of 13m and a width of 10.35m (one lane in each direction) was considered for this bridge. The superstructure beams comprised standard double hollow-core sections as described in the NZTA Research Report 364 (NZTA 2008), which are typically manufactured separately and assembled on-site using a combination of transverse post-tensioning and grout. The substructure consisted of two seat-type abutments and a central pier and cap combination. The center of mass of the super structure was located 7m above the base of the pier. The footings shown are for indicative purposes only.

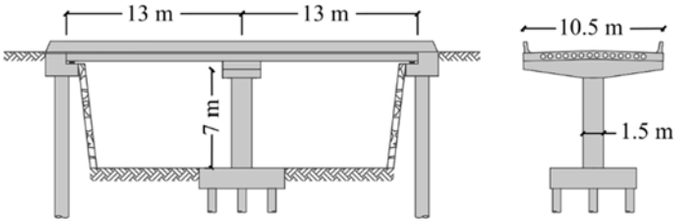

Figure 2. Prototype bridge on which the test specimen was based on

The prototype bridge was designed according to the New Zealand Standard (NZS 2004), and was assumed to be of a 'normal' importance level and located in Christchurch with a seismic zone factor of 0.3, soil type C and no near field effects. A target ductility of 3 and target drift of %2.7 was adopted for its design.

2.2 *Specimen details*

The test specimen was a 1:3 scaled model of the prototype bridge. It consisted of abutments supported on two square columns which represented the abutment piles, a foundation for the central pier, a central circular pier, a rectangular cap beam and two hollow core superstructure spans, all which were prefabricated off-site and assembled in the laboratory. In order to facilitate assembly of the superstructure the hollow-core slabs were cast as one piece rather than in smaller segments. PVC pipes were used to provide the hollow ducts (cores) in the slabs.

The abutment piles were supported by steel foundations, and connected to the abutments with grouted dowels. To decrease the tensile stresses in the concrete and increase the bending moment capacity of the piles, a 32mm MacAlloy bar was used to post-tension each pile to 150kN. The piles were braced using 25mm diameter Reidbraces in order to further increase the lateral stiffness of the abutment-pile combination.

The central pier, concrete foundation and cap beam were post-tensioned together to 700kN using a 40mm MacAlloy bar. Two 25mm grouted dowel bars connected the pier and cap beam to prevent their relative rotation. At the bottom of the pier four 25mm threaded bars mounted on brackets on the pier and grouted in the foundation provided a similar restraint.

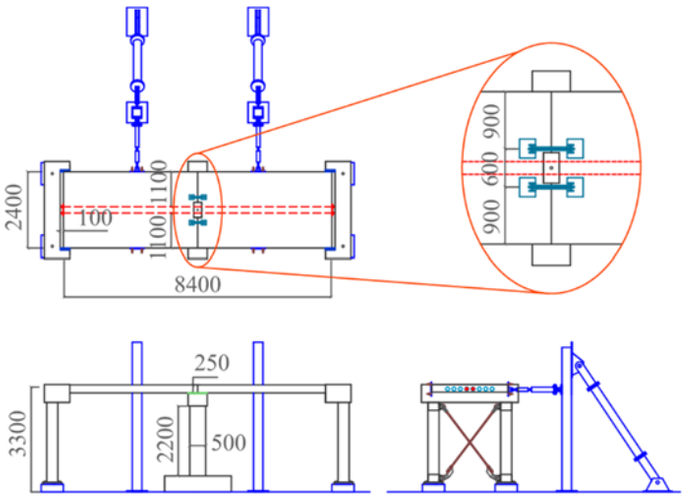

Figure 3. Details of test specimen

The superstructure was simply supported on the abutments and cap beam. The external shear keys on the abutments provided lateral restraint for the superstructure in the transverse direction. Elastomeric bearings of type IRHD60 with a thickness of 25mm were placed vertically between each superstructure segment and the abutment shear keys to prevent stress concentration and concrete damage. The corners of the superstructure spans were protected from similar effects with 6mm armoring plates installed before pouring and connected to the concrete using steel studs. Since the aim of testing was to study the response of the superstructure to transverse loading, the superstructure was isolated from the cap beam using 20mm ultra-high molecular weight polyethylene (UHWMPE) bearing plates which were in contact with the protective armoring steel of the superstructure.

The superstructure was post-tensioned longitudinally using two 15.2mm VSL post-tensioning tendons which passed through the two central ducts in the concrete section. A 100mm gap separated the end of each span from its adjacent abutment to allow rotation of the superstructure without engaging the abutments. In practice, this gap can be bridged using methods similar to those used in deck joints, such as engineered cementitious composite link slabs (Kim et al. 2004, Lepech & Li 2009), which can undergo considerable deformations with minimal damage.

The axial dissipaters were manufactured from G300 mild steel rods, and were reduced to a cruciform with a cross sectional area of 215mm^2. The dissipaters were confined in a steel tube strengthened with stiffeners to prevent buckling. Two dissipaters were used for testing, which were connected to the top surface of the superstructure using a combination of steel brackets and bolts.

Several tests were performed each using different values of post-tensioning force in the superstructure and specifications of axial dissipaters.

This paper presents the results of two tests, the first featuring axial dissipaters between the superstructure spans and second test lacking mild steel dissipative devices.

Figure 4. View of test specimen in the laboratory

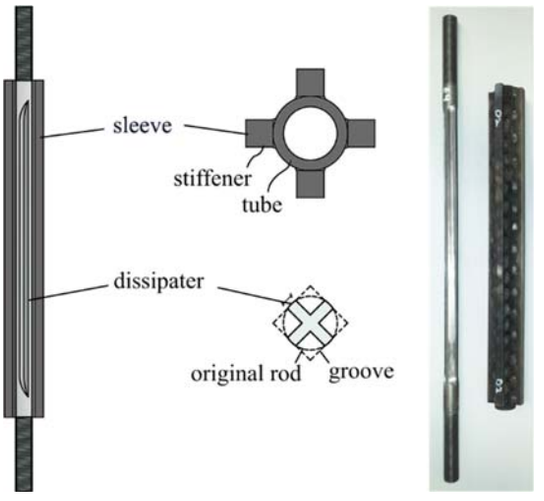

Figure 5. Axial dissipaters used in testing

The initial post-tensioning force in the superstructure in both tests was close to 150kN, however this value is slightly lower in the second test due to loss of post-tensioning

2.3 *Loading protocol*

A displacement-controlled cyclic loading protocol in accordance with ACI 2008 was used for testing, and is shown in Figure 6. Transverse loading was applied at the superstructure level using two actuators with a maximum capacity of 500kN which were mounted onto reaction frames. The force was applied to the center of the spans, imposing rotations in opposite directions.

Due to friction between the superstructure and UHWMPE bearing pads, supplementary gravity loading would have affected the results of the testing and increased the amount of transverse loading for a given displacement. However, the amount of increase in lateral force is dependent on the bearing properties and

superstructure weight and can be easily calculated and considered in the analytical modeling by addition of a Coulomb friction to the force-displacement diagrams. Therefore, no supplementary gravitational forces were applied to the test specimen.

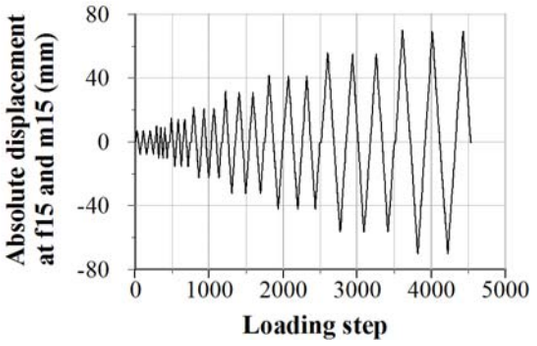

Figure 6. Loading protocol

2.4 *Analytical modeling*

The superstructure's response to transverse loading was modeled using the revised Monolithic Beam Analogy (rMBA), developed by Palermo (2004). The moment-rotation relationship of hybrid connections cannot be established using conventional section analysis methods. The rMBA finds a relationship between the concrete strain and depth of the neutral axis in a hybrid connection by comparing it to a monolithic plastic hinge. This method recognizes three stages of deformation in the connection; before decompression, after decompression and prior to yielding, and after yielding. The relationship between the concrete strain in the extreme compression fiber and the neutral axis depth during each of these stages can be found using Equation 1. The moment-rotation relationship of the connection is then found using an iterative approach which involves applying an incremental imposed displacement to the connection, assuming a neutral axis depth, finding the concrete strain in the extreme compression fiber, calculating the forces in the section and checking for equilibrium. If equilibrium is not met the procedure is iterated using a revised neutral axis depth. Finally, the bending moment at the imposed rotation is calculated and the rotation is increased and the process is repeated.

$$
\begin{aligned}
&\textit{if} \quad 0 < \theta_{imp} \le \phi_{dec} \frac{L_{tot}}{3}; \\
&\qquad \Delta_{imp} = \Delta_{eq} = \phi \frac{L_{tot}^2}{3} \\
&\textit{if} \quad \theta_{dec} < \theta_{imp} \le \left(\phi_y - \phi_{dec}\right) \frac{L_{tot}}{3}; \\
&\qquad \varepsilon_c = \left(\frac{3\theta_{imp}}{L_{cant}} + \phi_{dec} \right) \cdot c \\
&\textit{if} \quad \left(\phi_y - \phi_{dec}\right) \frac{L_{tot}}{3} < \theta_{imp} \\
&\qquad \varepsilon_c = \left(\frac{\dfrac{3\theta_{imp}}{L_{cant}} - \left(\phi_y - \phi_{dec}\right)}{\dfrac{3L_p}{L}\left(1 - \dfrac{L_p}{2L_{cant}}\right)} + \phi_y \right) \cdot c
\end{aligned}
\tag{1}
$$

Further details regarding the rMBA method can be found in Palermo (2004).

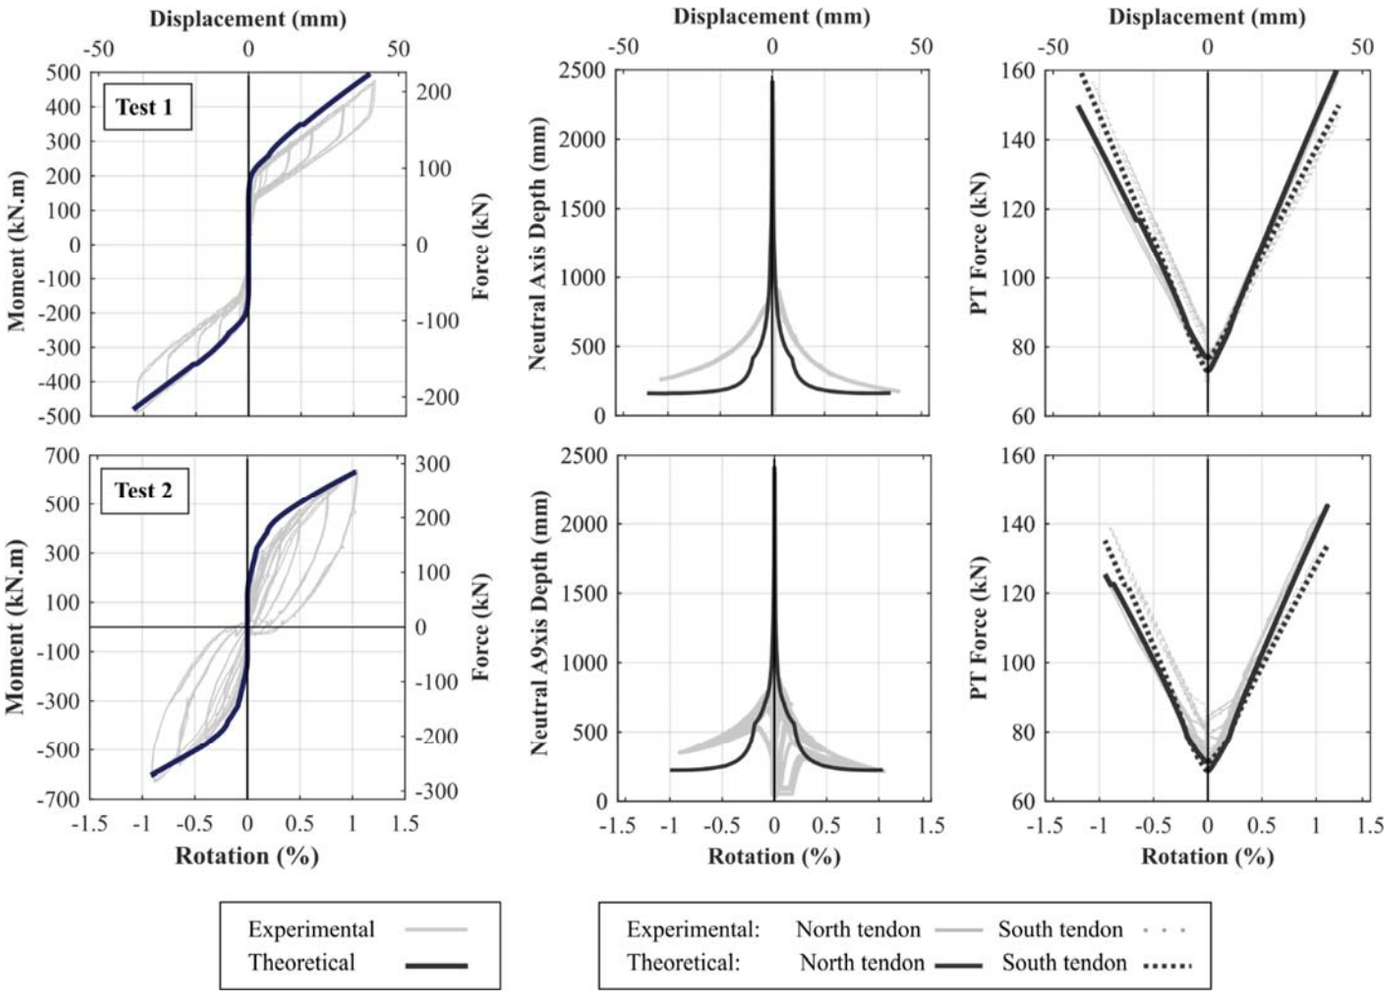

Figure 7. Comparison of experimental and analytical results for test setups with and without axial mild steel dissipaters

2.5 *Comparison of experimental and analytical results*

The experimental and analytical results of both tests are shown in Figure 7. The area encompassed by the moment-rotation plot in the first test is a result of Coulomb friction between the cap beam and superstructure. The moment-rotation plots of the second test show a promising flag shaped hysteresis loop which confirm the self-centering and energy dissipation properties of the hybrid superstructure. It is possible to achieve a higher self-centering to dissipation ratio by increasing the amount of post-tensioning in the tendons and also reducing the friction between the superstructure and cap beam.

The comparison shows that the rMBA method can be used to model the moment-rotation behavior of two-span precast concrete superstructures featuring a hybrid connection between the spans with remarkable accuracy.

3 PARAMETRIC ANALYSIS

3.1 *Superstructure configurations*

Various superstructure configurations were considered for the parametric analysis. First, three standard precast concrete superstructure beam types (NZTA 2008) with different cross sections (shown in Figure 8) and span lengths were selected. The number of spans in the superstructures ranged from 2 to 5, and the designs were performed with target ductility values ranging from 1 to 15. The span lengths were dependent on the beam type, being equal to 16, 20 and 30m for 650mm deep double hollow-core, 900mm deep double hollow-core and 1225m deep Super-T beams respectively. The superstructures were assumed to be supported on low-friction bearings and therefore unrestrained and independent from the piers in the transverse direction.

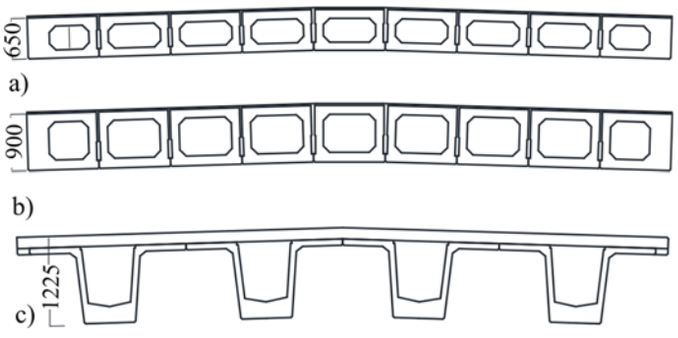

Figure 8. Superstructure beam types considered in the parametric analysis; a) 650mm deep double hollow-core, b) 900mm deep double hollow-core, 1225mm deep Super-T beams.

The post-tensioning tendons used in design of the superstructure configurations were 15mm VSL strands, which were assumed to be located at the center of the superstructure beam (bridge spine) to minimize excessive strains. The initial post-tensioning value of the tendons was taken as equal to 50% of yield strength (0.1% proof loading), to provide a sufficient safety margin from brittle failure of the tendons.

The dissipaters were assumed to be tension-compression steel devices manufacture from G300 mild steel, similar to those used in the experimental testing. The dissipaters were assumed to be installed at the edges of the superstructure beams to maximize their contribution to the resisting moment. This placement results in an increase in dissipater strain and a decrease in the yield displacement of the system.

3.2 *Design*

A direct displacement based procedure was used for designing the post-tensioning and dissipative devices in the superstructure connections. A parabolic displacement profile similar to that of a simply supported beam under uniform distributed loading was used for the superstructure, which is a profile traditionally used in the direct displacement based design of bridges with transverse load-resisting abutments (Priestley et al. 1996).

The seismic design parameters were chosen in accordance with NZS 2004, and were similar to those used in the experimental testing.

3.3 *Revised monolithic beam analogy for dissipative rocking superstructures*

The rMBA discussed in section 2.4 was modified for use in dissipative rocking superstructures, by comparing them to a simply supported beam with "weak joints', or regions of potential plastic hinging, and subjected to uniform distributed loading. The additional displacement of the dissipative rocking superstructure at its center, after decompression, was equated to that of the simply supported superstructure. Three stages of deformation were considered; prior to decompression (or gap opening) of the hybrid connections, after decompression and before nonlinearity, and after nonlinearity. The nonlinearity can be geometric or a result of yielding of the dissipaters, depending on the configuration.

$$\begin{aligned} &n_{spans}=2; && \kappa=1\\ &n_{spans}=3; && \kappa=2\\ &n_{spans}=4; && \kappa=4\\ &n_{spans}=5; && \kappa=6 \end{aligned} \tag{2}$$

The relationship between the concrete strain in the extreme compression fiber and the neutral axis depth during each of these stages can be found using Equation 3. The coefficient κ is dependent on the number of spans, and is given in Equation 2.

$$\begin{aligned} &if \quad 0<\theta_{imp}\le\phi_{dec}\frac{L_{tot}}{8};\\ &\qquad \Delta_{imp}=\Delta_{eq}=\phi\frac{L_{tot}^2}{8}\\ &if \quad \theta_{dec}<\theta_{imp}\le\left(\phi_y-\phi_{dec}\right)\frac{L_{tot}}{8};\\ &\qquad \varepsilon_c=\left[\kappa\theta_{imp}L\left(\frac{8}{L_{tot}^2}\right)+\phi_{dec}\right]\cdot c\\ &if \quad \left(\phi_y-\phi_{dec}\right)\frac{L_{tot}}{8}<\theta_{imp}\\ &\qquad \varepsilon_c=\left(\frac{\dfrac{8\theta_{imp}}{L}-\dfrac{n_{spans}^2\left(\phi_y-\phi_{dec}\right)}{\kappa}}{\dfrac{8L_p}{L}\left(1-\dfrac{L_p}{2L}\right)}+\phi_y\right)\cdot c \end{aligned} \tag{3}$$

The superstructure configurations considered for the parametric analysis were modelled using the developed rMBA method.

3.4 *Analysis results*

Results of the parametric analysis show the effects of superstructure length on base shear demand, and ratio of base shear demand to the seismic weight of the superstructure. Figure 9-a shows the overall relationship between these values and the superstructure length, based on ductility levels. It can be seen that in general, the value of base shear increases with increase in superstructure length (and mass), however as a general trend it decreases at higher ductility levels. Figure 9-b shows the base shear to superstructure weight ratio (V/W) as a function of superstructure length and target ductility. For low ductility levels (μ=1) a longer superstructure generally results in a higher V/W. However, as ductility levels increase, a greater superstructure length results in a lower V/W ratio. This can be attributed to the decreased stiffness and increased natural period of the structure at higher ductility levels. At the lower range of ductility, the period of the equivalent structure coincides with the equal acceleration or equal velocity section of the design spectra, leading to an increase in the ratio of base shear demand to superstructure weight.

The parametric analysis was also used to establish a relationship between equivalent viscous damping of the structure, ξ_{eq}, and ductility, μ. The equivalent viscous damping is composed of two components; the

initial elastic damping, ξ_0, and the hysteretic damping, ξ_{hyst}, as shown in Equation 4.

$$\xi_{eq} = \xi_0 + \xi_{hyst} \tag{4}$$

The equivalent hysteretic damping ratio can be calculated by comparing the energy dissipated by a viscous damper with the energy dissipated from nonlinear behavior in a stabilized steady-state response (Jacobsen 1960), as shown in Equation 5.

$$\xi_{hyst} = \frac{1}{4\pi} \cdot \frac{E_{Diss}}{E_{sto}} = \frac{1}{2\pi} \cdot \frac{A_{hyst}}{F_0 u_0} \tag{5}$$

Where A_{hyst} is the area encompassed by the flag-shape hysteresis loop, and F_0 and u_0 are the maximum force and displacement in the force-displacement plot respectively.

For structures with hybrid connections, the equivalent hysteretic damping should be modified by a function of the re-centering ratio of the hybrid connections (Equation 6). The re-centering ratio is equal to the bending moment contribution from the post-tensioning tendons divided by the bending moment provided by the dissipative devices (Equation 7).

$$\xi_{eq} = 5 + \frac{1}{1+\lambda} \cdot \xi_{hyst} \tag{6}$$

$$\lambda = \frac{M_{pt}}{M_{dis}} \tag{7}$$

Where M_{pt} and M_{dis} are the contributions of post-tensioning steel and dissipative devices to the resisting bending moment in the connections respectively.

The area encompassed by hysteresis loops in the force-deformation plots found from analysis of the superstructure configurations was calculated and used to find the corresponding hysteretic damping for each configuration, ξ_{hyst}. The resulting values were modified by the re-centering ratio, λ, also found from the analysis and added to the 5% assumed elastic damping to find the equivalent viscous damping, ξ_{eq} (Equation 7).

The results of these calculations are shown in Figure 10. The equivalent damping ratio for structures with hybrid connections was calculated using a method proposed by Priestley (2007) and has also been plotted in the same graph (Equation 8).

$$\xi_{eq} = 0.05 + R_\xi \left(\frac{\mu - 1}{\mu\pi} \right) \tag{8}$$

Where R_ξ depends on the properties of the hybrid connections and type of dissipative rocking system.

$$R_\xi = 0.435 \tag{9}$$

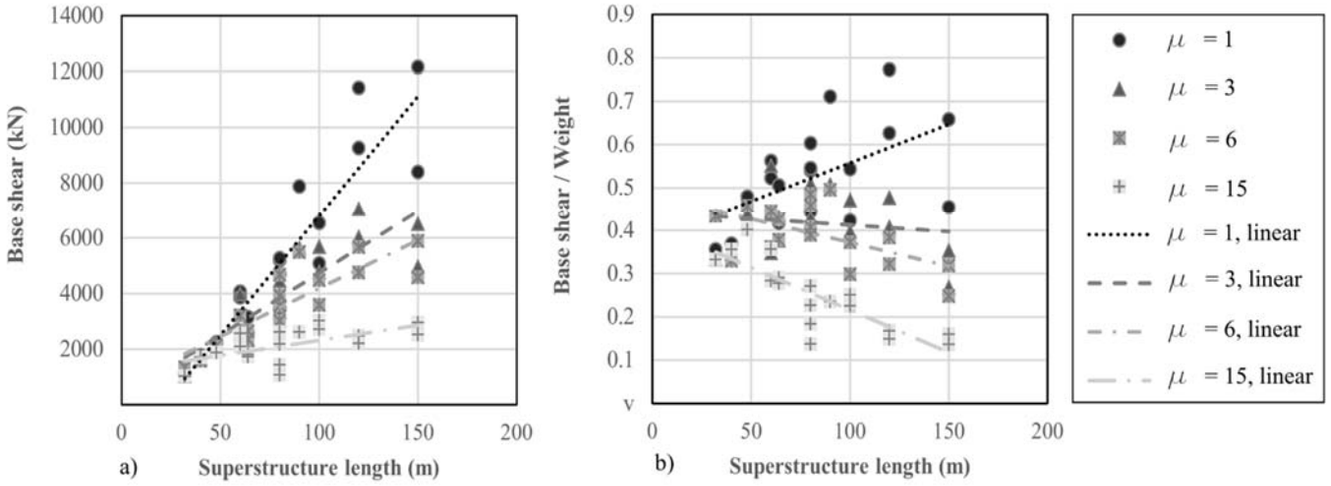

Figure 9. Relationship between base shear demand and superstructure length based on results from parametric analysis

The value of R_ξ for dissipative rocking superstructures was calculated to minimize the square root of the sum of squares between Priestley's method (Equation 8) and the mean value of the damping values found from the parametric analysis (Equation 5), and is given in Equation 9.

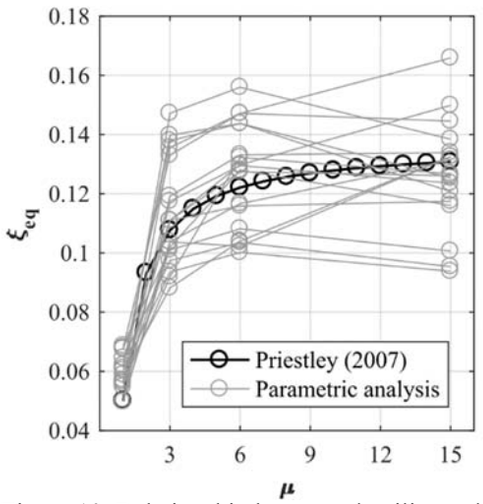

Figure 10. Relationship between ductility and equivalent damping

4 CONCLUSIONS

A hybrid connection was developed for prefabricated concrete bridge superstructures by combining unbonded longitudinal post-tensioning and axial mild steel dissipaters. The study comprised of experimental testing on a large-scale two-span precast concrete bridge and a parametric analysis to extrapolate the results of testing to various superstructure configurations.

The experimental testing was performed on a 1:3 scaled specimen typical of typical short-span bridges in New Zealand. The specimen was subjected to quasi-static transverse cyclic loading, and exhibited a desirable flag-shape hysteretic response when dissipative devices were installed between the two spans. The experimental results were extrapolated to various bridge geometries and design target values through parametric analysis. The structures were designed using a direct displacement-based (DDBD) method and analyzed with a modified version of the revised monolithic beam analogy (rMBA). The effects of superstructure beam type, length of bridge, number of spans and target ductility on the transverse force-displacement relationship of the superstructure configurations was investigated.

The results show that higher target ductility values decrease the superstructures' secant stiffness, increase their fundamental period and significantly reduce the base shear and necessary reinforcement ratios (for both mild steel dissipaters and post-tensioning). For low ductility levels, greater superstructure lengths generally result in higher ratios of base shear demand to seismic weight due to their larger seismic mass. However, as target ductility levels increase, the secant stiffness of the structures decrease, and greater superstructure lengths result in a decrease in the ratio of base shear demand to seismic weight. Finally, an expression to find the equivalent viscous damping in dissipative rocking superstructures was found by calibrating results from the parametric analysis to theoretical values.

ABSTRACT: In this paper, the mechanical properties of alkali activated concrete (AAC) produced from three different fly ash sources were studied. Class C fly ashes (Sk, TH, and KC) were located in the State of Missouri, USA where used in this study. The three fly ashes had different chemical composition. The workability of the mixtures was assessed based on the slump value of each mixture. The mechanical properties including the compressive, splitting tensile, and flexure strengths were tested. The compressive strength was tested at different ages including 1, 7, 28 days. Elevated heat curing regime was applied on the three fly ashes in an electric oven. The temperature of the oven was constant at 70 ºC for 24 hours. The results revealed that the workability and the mechanical properties depended mainly on the calcium content of the fly ashes. The Sk fly ash that had lowest calcium content showed high slump value. With decreasing the calcium content in the fly ash, the mechanical properties were improved. The strength of all mechanical properties has a slightly or constant development with time. The compressive strength reached to 41.28, 39.85, and 36.43 Mpa for Sk, TH, KC that were ordered from the lowest to highest calcium content, respectively. The splitting tensile strength results showed a good match with AS 3600 code. However, the flexure strength results showed a good match with ACI 318. Proposed equations were suggested to predict the splitting tensile and flexure strengths of the AAC with R^2 higher than 0.90.

1 INTRODUCTION

Recently, the environmental concern has been developed and become a worldwide objective to reduce using the materials that cause environmental issues. The concrete has been widely used in the construction industries due to the low cost, high strength, low maintenance, and good durability [1]. Therefore, the demand of the concrete has been kept increasing significantly. However, the main binder of the conventional concrete is the ordinary Portland cement (OPC). Manufacturing the OPC has been associated with a serious environmental issue. Where, producing one ton of the OPC released approximately one ton of carbon dioxide (CO_2) emission into the atmosphere [2]. In addition, the industry of OPC is responsible for 5% of manmade CO_2 emissions [2]. Therefore, finding a replacement for the OPC became urgent.

It has been reported that the materials that rich in silica SiO_2 and alumina Al_2O_3 had the ability to react with alkali activators to form a new binder [3]. This process named as geopolymerization. This process starts with dissolving the silica and alumina species from the source material in presence of the alkali activators to form free SiO_4 and AlO_4 tetrahedral units [3]. With time, the tetrahedral units are connected to yield polymeric precursor and shared all oxygen atoms to form an amorphous polymer material (called: geopolymer) [4].

Fly ash (FA) was widely used as a source of the aluminosilicate due to its low cost and availability [5]. The ASTM requirements of the class C FA to have (SiO_2+Al_2O_3+F_2O_3) in between 70 % and 50 %, however that this classification is not based on the calcium content but usually class C FA is associated with high calcium content compared with class F FA. Due to the high calcium presence of calcium in class C FA, it interferes with the microstructure geopolymerizaition process and alter the microstructure [6]. In addition, it associated with a short setting time and low workability [7, 8].

One of the advantages of the alkali-activated system based class F FA that it can be cured for a short period at high temperature and gain a high strength at the early stages. On the other hand, using class C FA preferred in case of ambient temperature curing regime due to the formation of calcium silicate hydrate (CSH) and/or calcium aluminate silicate hydrate (CASH) [9, 10] which known as the hydration process. Studying the applicability of using the elevated heat curing regime in the precast plants was investigated in this study. Three different FAs con-

tain high calcium content which higher than 20 % were used to produce AAC. The mechanical properties included the compressive strength splitting tensile strength, and flexural strength was studied.

2 EXPERIMENTAL PROCEDURE

2.1 *Materials*

Commercially available dolomite used in this study as the coarse aggregate with a maximum size of 19 mm (3/4 in) and specific gravity of 2.76. Missouri river sand used as the fine aggregate in this study with the maximum specific gravity of 2.60. The coarse and fine aggregates were used in a saturated surface dry condition (SSD), where the water content and the total absorption were determined for both aggregate and the total absorption. So, the difference between them was taken into considerations during calculating the added water to the mixture to make the aggregate in SSD condition. Both coarse and fine aggregates passed the ASTM C33 [11] particles sizes limits.

Locally available fly ashes (FAs) were used in this study. Three different FAs were collected from Sikeston (Sk), Kansas City (KC), Thomas Hill (TH), Missouri State, USA. The mineral compositions of the FAs were given in Table 1. The mineral compositions were analyzed by X-ray fluorescence as described in ASTM D4326 [12]. As shown in Table 1, the three FAs have different mineral compositions and all of them have high calcium content higher than 20 %. According to ASTM C618 [13] requirements, the three FAs were classified as class C where the summation of SiO_2, Al_2O_3, and Fe_2O_3 was in between 70 % and 50% for all of them. The particles size distribution test was conducted on the four FAs using Microtrac S3500 series size analyzer. The diameters that at it 50% of the particles passed (D_{50}) were 12.81, 16.25, and 16.13 μm for Sk, KC, and TH, respectively.

The alkali activator solution was prepared by mixing sodium silicate (Na_2SiO_3) and sodium hydroxide (NaOH) solutions. The selected mixing ratio between the two solutions was 1.0 by weight based on a previous study [7]. The sodium silicate solution was brought in solution from PQ Corporation with a modulus ratio M_s (SiO_2/Na_2O) of 2.0, where SiO_2 = 29.4%, Na_2O = 14.7%, and H_2O = 55.9%. However, the sodium hydroxide was in pellets form with purity of 100%. The sodium hydroxide pellets were dissolved in distilled water to prepare alkaline solution 24 hours to let it cool down to the room temperature prior to use. The molarity of the sodium hydroxide was fixed at 10M.

Table 1. Chemical composition of the FAs by XRF.

Chemical composition	Sk (%)	KC (%)	TH (%)
SiO_2	43.91	42.25	40.43
Al_2O_3	20.12	17.91	17.53
Fe_2O3	4.96	4.73	4.72
CaO	21.24	25.86	24.07
MgO	4.29	4.74	9.39
Na_2O	2.87	1.58	1.17
K_2O	0.70	0.56	0.48
TiO_2	1.36	1.44	1.40
P_2O_5	0.51	0.89	0.79
MnO	0.05	0.04	0.02
LOI*	0.40	0.12	0.62
Sum(SiO_2 + Al_2O_3 + Fe_2O_3)	68.99	64.89	62.68

* Loss on ignition.

2.2 *Sample preparation*

Three mixtures were designed to represent the properties of high calcium FAs (Class C) AAC. The concrete details were summarized in Table 2. The volume of the limestone and sand in the mixture represented almost 65 % of the total volume. The water (W) content included the water that already existed in the alkali activators solutions and the extra added water to make the limestone and water under SSD condition. The alkali activator solution-to-fly ash (Alk/FA) ratio was 0.30. The water-to-fly ash ratio (W/FA) was 0.35 for KC FA and 0.34 for Sk and TH. The Alk/Fa ratio was selected according to a previous study and the W/FA ratio was design to reach a slump value in between 150 and 200 mm [7].

Table 2. Concrete mixture design.

Material	Sk (Kg/m^3)	KC (Kg/m^3)	TH (Kg/m^3)
Limestone	959	959	959
Sand	799	799	799
FA	450	450	450
SH	67.5	67.5	67.5
SS	67.5	67.5	67.5
W	78.3	82.8	78.3

The mixer that was used to mix the materials was a normal mixer. The mixing procedure started with mixing the limestone and sand in a dry condition in the mixer for 1 minute. Then the FA was added and mixed for more 1 minute. The W was added gradually to all dry materials for 2 minutes. The two alkali activators solution were mixed together prior to adding them to in the mixer gradually for 5 minutes. Then the mixture was left to be mixed for another 5 minutes.

The mixed AAC was cast into cylinders in two layers according to ASTM C192 [14]. Also, concrete beams 150 (height) x 150 (width) x 600 (length) mm was casted into steel molds. The mixing was done at the ambient temperature 23 ± 2 ºC in the laboratory room. Directly after casting, the molds were covered with a plastic oven bag to prevent moisture loss. The cylinders were placed in an electric oven and cured for 24 hours at 70 ºC. then the cylinders was demolded after getting them out of the oven and let-

ting them cool down at the room temperature until the test age.

2.3 *Sample testing*

The workability of the AAC was assessed by conducting the slump test. The slump test was done according to ASTM C143 [15].The compressive strength of the concrete cylinders was tested following the ASTM C39 [16]. Three samples were tested for each mixture and the reported data were the mean of the three results. The cylinders were tested at 1, 7, and 28 days. The splitting tensile strength of the concrete cylinders was tested following the ASTM C496 [17] and the flexure strength of concrete beams was tested according to ASTM C78 [18] at 7 and 28 days.

3 EXPERIMENTAL RESULTS AND DISCUSSION

3.1 *Slump of fresh concrete*

The slump of the three FAs fresh mixtures was shown in Figure 1. It can be seen that with increasing the calcium content of the TH FA, the slump value was reduced compared with Sk FA. Although the calcium content of KC FA was the highest one among the three FAs, it showed the higher slump value due to the higher water content in the KC FA mixture.

The decrease in the slump in SK FA comparing with TH FA was directly related to the particles size distribution of the FAs, where the SK FA has the lower particles size distribution (D_{50}) among the three FAs, which means more surface area, higher dissolution rate and lower workability.

3.2 *Mechanical properties*

The compressive strength development of AAC at 1, 7, 28 days was shown in Figure 2. It is clear that the curing regime had a significant influence on the compressive strength development with time. Unlike the conventional OPC concrete, there was not a significant development in the compressive strength with time, where the improvement in the compressive strength from 1 day to 28 days was less than 15% as summarized in Table 3. This was related to the type of curing regime. The curing at elevated temperature was substantial for inducing the geopolymerization process, thereafter forming the N-A-S-H gels. This concept was agreed with previous researchers [19-21]. The curing regime was in the oven at an elevated temperature for 24 hours, so the water that was existed in the sample was consumed during the curing period. Therefore, there was enough water to form calcium silicate hydrate (C-S-H) and/or calcium aluminate silicate hydrate (C-A-S-H) that can form under the ambient temperature without any need for elevated temperature due to existing high calcium content in the raw FAs.

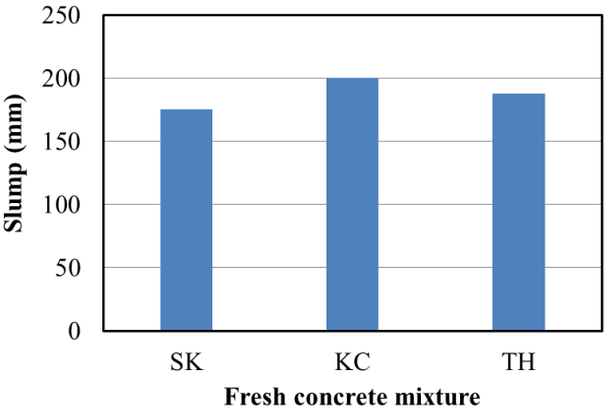

Figure 1. Slump of fresh AAC.

Comparing the compressive strength of the AAC based the three FAs, the FA that had lowest calcium content (Sk) showed the higher compressive strength among the three FAs. However, the FA that had highest calcium content showed the lowest compressive strength among the three FAs. This is mainly related to the geopolymerization process that relied on the silica and alumina content, in addition the alkali activators (SS and SH). So, the presence of the calcium in the geopolymerization process was considered as a contaminant and alter the microstructure of the aluminosilicate chains [6], which caused a decrease in the compressive strength of the AAC that cured under elevated temperature condition.

Table 3. Percentage of compressive strength development of AAC.

FA	Compressive strength (SD*) at 1 day (MPa)	Compressive strength (SD*) at 28 days (MPa)	Percentage of strength development (%)
Sk	37.83 (0.31)	41.28 (1.42)	9.12
KC	31.92 (0.80)	36.43 (1.00)	14.12
TH	37.08 (1.63)	39.85 (1.77)	4.74

* Standard deviation.

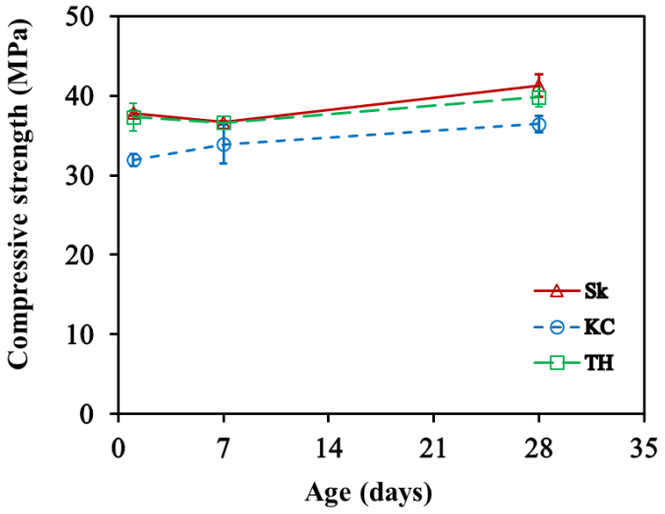

Figure 2. Compressive strength development of AAC.

The splitting tensile strength of the three AACs based the three FAs were shown in Figure 3. The results were presented the same trend as the compressive strength, whereas the FA that had the lowest calcium content (Sk), showed the higher splitting tensile strength among the other FAs. However, the splitting tensile strength was decreased with increasing the calcium content in the FAs. Moreover, the strength showed a slight increase from 1 day to 28 days.

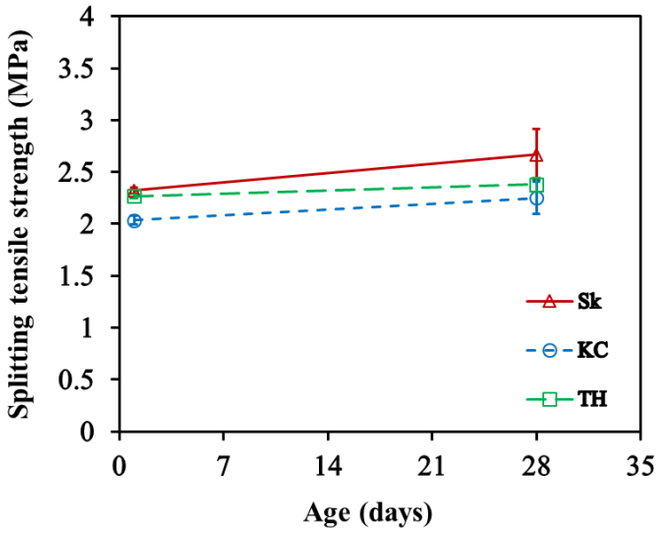

Figure 3. Splitting tensile strength development of AAC.

For design calculations, the ACI 318 [22] and AS 3600 [23] suggested equations that related the tensile strength with the compressive strength expressed in Equations 1 and 2, respectively. In addition, several researchers proposed different equations that adapted their results given in Equations 3 [24].

$$f_t = 0.56(f_c)^{0.5}, \text{ ACI 318 (2014)} \quad (1)$$

$$f_t = 0.40(f_c)^{0.5}, \text{ AS 3600 (2001)} \quad (2)$$

$$f_t = 0.17(f_c)^{0.75}, \text{ Ryu et al. (2013)} \quad (3)$$

Where f_t = splitting tensile strength; and f_c = compressive strength.

In Figure 4, the experimental results of this study were plotted along with the previous equations. As shown in Figure 4, the splitting tensile strength results in this study were generally lower than the strengths calculated using the ACI 318 equation, however, they were close to the AS 3600 and [24] equations. Accordingly, Equation 4 was proposed to model the relationship between the splitting tensile strength and compressive strength with a coefficient of determination of 0.986 of AAC based high calcium FA.

$$f_t = 0.38(f_c)^{0.5} \quad (4)$$

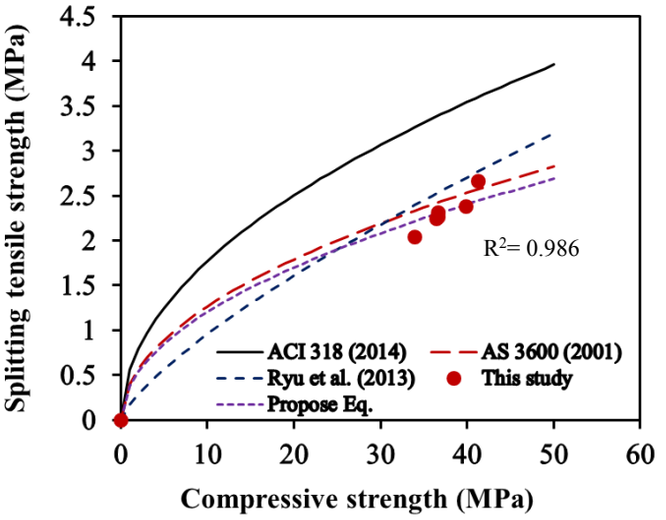

Figure 4. Relationship between splitting tensile strength and compressive strength of AAC.

The flexural strength of the three AACs based the three FAs were presented in Figure 5. The results were exhibited the same trend as the compressive strength, whereas the FA that had the lowest calcium content (Sk), showed the higher flexural strength among the other FAs. However, the flexural strength was decreased with increasing the calcium content in the FAs. The strength showed a slight increase from 1 day to 28 days for KC FA, however, the flexural were almost the same at 1 day and 28 days for Sk and TH.

Figure 6 shows the relationship between the flexural strength and the compressive strength of the AAC. In addition, the design codes equations, e.g. ACI 318 and AS 3600 along with a previously proposed equation [25], were plotted in Figure 6 and presented in Equations 5, 6, and 7, respectively. The results of this study showed a slightly higher flexural strength than the design codes equation, however, they were less than the proposed equation by Diaz. Therefore, a newly proposed equation has suggested the relationship between the flexural strength and

compressive strength with a coefficient of determination of 0.919 of AAC based high calcium FA and given in Equation 8.

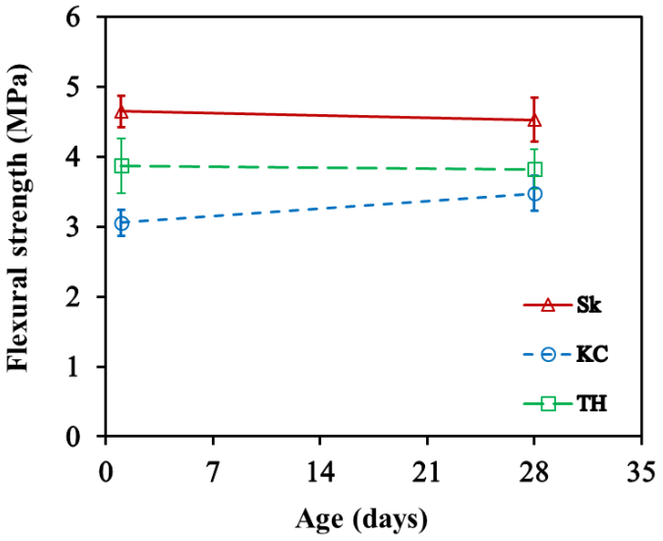

Figure 5. Flexural strength of AAC.

$$f_r = 0.62(f_c)^{0.5}$$, ACI 318 (2014) (5)

$$f_r = 0.60(f_c)^{0.5}$$, AS 3600 (2001) (6)

$$f_r = 0.69(f_c)^{0.5}$$, Diaz-Loya et al. (2011) (7)

$$f_r = 0.64(f_c)^{0.5}$$ (8)

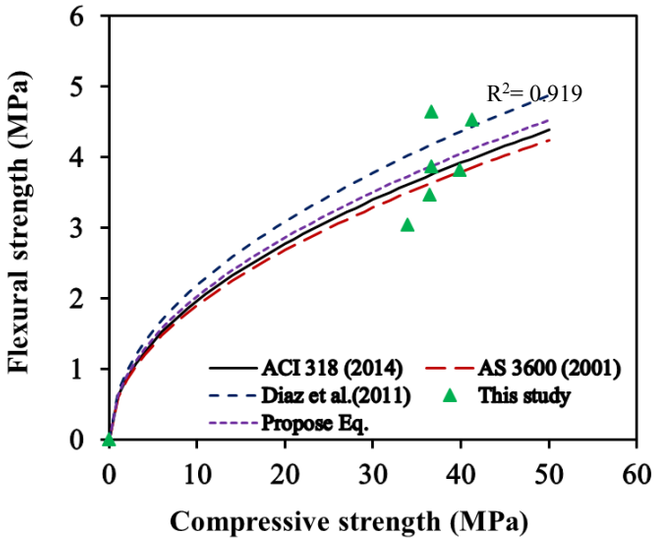

Figure 6. Relationship between splitting tensile strength and compressive strength of AAC.

4 CONCLUSION

The fresh and mechanical properties of the alkali-activated concrete (AAC) were investigated in this study. Class C FA was used to synthesize the AAC. The results revealed the following: with increasing the calcium content in the FA, the slump value was reduced and the mechanical properties including the compressive, splitting tensile, and flexure strengths were reduced in case of curing the concrete at an elevated temperature of 70 ^{o}C for 24 hours. The splitting tensile and flexure strengths of the AAC had a good correlation with the design codes (ACI 318 and AS 3600) that were developed mainly for the Ordinary Portland cement concrete.

5 ACKNOWLEDGMENT

This research was supported by the Missouri Department of Transportation (MoDOT) and Ameren Corporation. In kind contribution of the fly ash from Headwaters Resources is appreciated. However, any opinions, findings, conclusions, and recommendations presented in this paper are those of the authors and do not necessarily reflect the views of the sponsors.

Bayesian integration of NDT with corrosion model for service-life predictions

S. A. Faroz & S. Ghosh
Structural Safety, Risk and Reliability Lab, Department of Civil Engineering
Indian Institute of Technology Bombay, Mumbai, India

ABSTRACT: Corrosion damages reinforced concrete (RC) bridges primarily through the loss of steel rebar volume. Theoretical corrosion growth models are usually employed to predict this loss of steel over the life of a RC structure. Typically, these models fail to provide realistic estimates of the actual corrosion observed in the field. Alternatively, non-destructive testing/evaluation (NDT/E) or monitoring is used to evaluate the current state of a structure. However, either of these two approaches, alone, fails to provide a comprehensive understanding of how a bridge is expected to deteriorate over its lifetime. In order to be able to manage a degrading bridge over its service-life, it will be beneficial to scientifically combine the predictive capability of the theoretical degradation model and the data obtained from NDT/E for assessing the residual life of a structure. In this paper, this is achieved through a sequential Bayesian updating to address the issue of uncertainty present in the (i) physical process of corrosion and in the (ii) corrosion growth model used for prediction. The parameters of the updated corrosion growth model are stochastic in nature. A robust estimation of the time-varying steel loss due to corrosion is obtained incorporating these parameter uncertainties. The updated model is further used for the reliability assessment of a corroding RC bridge slab. Based on the target reliability, service-life of a bridge is obtained considering flexural failure.

1 INTRODUCTION

Reinforced concrete (RC) highway and railway bridges, which form an integral part of the transportation infrastructure, degrade gradually over time, primarily due to environmental effects and possible overloading. Condition surveys in saline environment have indicated that reinforcement corrosion is the most critical cause of degradation (Almusallam et al. 1996).

As loss of steel due to corrosion can be linked to various damage states (Faroz et al. 2016), the primary interest of a maintenance/structural engineer is to track the steel loss due to corrosion (Faroz et al. 2014). As the rebars are embedded in concrete, they are unavailable for a visual inspection, unless the cover concrete is destroyed. A precise estimation of the residual steel area of rebars is possible through the destruction of cover concrete, however destruction of concrete may only lead to further acceleration of the deterioration process (besides, the destructive tests are costly). Therefore, it is not always practical to go for a destructive testing. To circumvent this situation, the linear polarisation resistance (LPR) technique is the most common non-destructive technique (NDT) (Andrade & Martínez 2005) used for the on-site evaluation of corrosion rate, which can be used to predict the loss of rebar diameter/cross-section area (IRC 2002).

However, such NDT inspections give only the instantaneous condition of the structure and cannot be used independently for predicting its future degradation. In order to be able to manage a degrading structure over its service-life, it will be beneficial to combine the predictive capability of the theoretical degradation model and the data obtained from inspections (Ghosh & Faroz 2016, Faroz 2017, Faroz & Ghosh 2017).

Engineers usually take the aid of mathematical models to predict the degradation. A common issue in this is the use of deterministic prediction models. For example, one finds considerable scatter in actual steel loss data as compared to predictions by a deterministic steel loss model (Malumbela et al. 2012), signifying that such models are incomplete. The use of deterministic models giving point estimates, thus, becomes inappropriate. Due to the (unavoidable) presence of uncertainties in a natural phenomenon like corrosion, it is necessary that structural performance be treated within a probabilistic framework (Ellingwood 2005). The basic idea here is that, in a probabilistic setting, such deterministic models can be "completed"

by introducing "correcting" random variables (RVs) (Ditlevsen 1982) into the model.

This motivates the present work in modifying the existing corrosion loss estimation models with limited monitored data using Bayesian updating (Faroz et al. 2017). The Bayesian approach facilitates the integration of prediction model and inspection data, towards an overall uncertainty quantification for the engineering system/phenomenon under consideration. This paper presents a methodology for a probabilistic evaluation of the time-dependent corrosion loss of rebars in a RC slab bridge. A generalised procedure for the Bayesian updating of a steel loss model, using measured "limited" instantaneous data, is presented. A numerical study is also carried out to illustrate the proposed procedure, using data adopted from existing literature. The service-life of the bridge is determined considering the probability of its flexural failure. The primary objective is to show how integrating the NDT/E information with some prior knowledge (i.e., mathematical degradation model) of the bridge leads to significantly better estimations and consequently better decision-making in the life-cycle bridge management.

1.1 *Illustrative RC slab bridge*

For the purpose of demonstration, we consider a simply-supported RC two-lane slab bridge of span 6.4 m and width of 10.5 m (including a kerb width of 0.55 m at each side). The overall depth is 550 mm and effective depth $d = 500$ mm. The slab is reinforced with Fe415 20 mm rebars at a centre-to-centre spacing of 180 mm (on the tension side only), and M25 grade of concrete is used. This bridge is designed for the limit state of collapse due to flexure considering self weight (25 kN/m^3), 60 mm thick wearing course (22 kN/m^3), and live load due to class AA tracked vehicle as per IRC (2014). The bridge is designed as per IRC (2011) specifications, for the load combination $1.35\text{DL}_s + 1.75\text{DL}_w + 1.5\text{LL}$, DL_s being the dead load due to self weight, DL_w being the dead load due to wearing course and LL the live load of class AA tracked vehicle. LL comprises of the vehicle static load and impact effect. The effective width method is adopted for the dispersion of live loads. For the purpose of analysis, a $b = 1000$ mm strip of the bridge slab is considered.

NDT inspections of corrosion rate are done biennially (IRC 2002) from the initiation of corrosion ($t = 0$) upto 20 years. It is assumed that all the subsequent inspections are performed using the same NDT instrument. These inspection are done at the mid-span of the simply supported slab under consideration.

2 PROBABILISTIC CORROSION MODEL

The rate of 'uniform' reduction of rebar diameter (δ) due to corrosion can be obtained using Faraday's law (Mangat & Elgarf 1999):

$$\frac{\mathrm{d}\delta}{\mathrm{d}t} = \frac{2A}{\rho z F} i_{corr}(t) \tag{1}$$

where, $F = 96494$ As (Faraday's constant), $A = 55.85$ g (atomic weight of Fe), $z = 2$ (valency of corrosion reaction), and $\rho = 7.85$ g/cm^3 (density of Fe). The corrosion rate, $i_{corr}(t)$, is measured in μA/cm^2 and time (t) in year. As F, A, z and ρ are universal constants, we assume the overall modeling discrepancy to be present in the model of $i_{corr}(t)$ only. By introducing the correcting random variable E into the estimation, the true model of i_{corr} is given as

$$I_T(t) = i_{corr}(t) e^E \tag{2}$$

where E is assumed to follow a zero mean Gaussian distribution: $E \sim \mathcal{N}(0, \sigma_E)$, and $I_T(t)$ describes the true value of the corrosion rate.

Usually the corrosion rate of a corroding structure is a function of time, typically due to seasonal variations. However, an annual average time-invariant rate of corrosion have been adopted in many studies focusing on the probabilistic assessment of corroding structures (Enright and Frangopol 1999, Val and Stewart 2003, Stewart 2004, Firodiya et al. 2015). Thus,

$$i_{corr}(t) = C \tag{3}$$

where C is the random variable representing the time-invariant corrosion rate. Combining Eq. (2) and Eq. (3) the corrosion model becomes

$$I_T = C e^E \tag{4}$$

and the reduction in the rebar diameter is

$$\delta(t) = \frac{2A}{\rho z F} \int_0^t I_T \mathrm{d}t = 0.02325 I_T t \quad \text{(mm)} \tag{5}$$

3 BAYESIAN MODEL UPDATING FOR CORROSION

It is sufficient to update the corrosion rate model with in-situ measurements of corrosion rate, whose parameters are $\boldsymbol{\xi} = [C \quad \sigma_E]^\top$. The NDT measurement of corrosion is taken as the actual corrosion rate and used for updating.

3.1 *Likelihood function*

The parameter $\boldsymbol{\xi}$ conditioned predictive distribution of corrosion rate based on Eq. (4) is

$$f(I_T|\boldsymbol{\xi}) = \frac{1}{I_T \sigma_E \sqrt{2\pi}} e^{\left[-\frac{(\ln I_T - \ln C)^2}{2\sigma_E^2}\right]} \tag{6}$$

Eq. (6) is used to form the likelihood function for a reading of I_T as $f(\hat{I}_{T_j}|\boldsymbol{\xi})$, where $\hat{I}_T$ is the measured

value of the corrosion rate. For m number of measurements of the corrosion rate, assuming each to be statistically independent of the other the overall likelihood function can be formed as

$$\mathcal{L}(\boldsymbol{\xi}) = \prod_{j=1}^{m} f(\hat{I}_{T_j}|\boldsymbol{\xi}) \tag{7}$$

3.2 *Prior distribution*

The parameters $\boldsymbol{\xi} = [C \quad \sigma_E]^\top$ can take only positive values. Therefore their prior distributions are modelled as a lognormal distributions. A prior estimate of corrosion rate may be obtained from $\frac{37.8(1-\text{w/c})^{-1.64}}{x}$ (Val & Stewart 2003). For water-cement ratio w/c $= 0.45$ and effective concrete cover $x = 50$ mm, a corrosion rate of 2.015 μA/cm^2 is obtained, which is taken as the mean of C. Its coefficient of variation (COV) is taken as 0.3 (Enright & Frangopol 1999) leading to the following prior:

$$\ln C \sim \mathcal{N}(0.6575, 0.2936) \tag{8}$$

Stewart (2009) reported that the COV of corrosion rate can vary from 0.25 to 0.6 for typical covers and concrete strengths. The corresponding lower standard deviation is adopted as the 0.5 percentile value and the upper standard deviation as the 99.5 percentile value to form the prior distribution of σ_E:

$$\ln \sigma_E \sim \mathcal{N}(-0.2479, 0.17) \tag{9}$$

The joint prior distribution is taken as the product of the densities of individual parameters, by assuming the parameters to be independent of each other:

$$f'(\boldsymbol{\xi}) = f(C)f(\sigma_E) \tag{10}$$

3.3 *Corrosion rate inspection data for model updating*

As suggested by IRC (2002) a prescriptive inspection may be done every two years. In this work, during such a biennial inspection the corrosion rate is measured using the LPR technique. Recently, Guo et al. (2014) have proposed a comprehensive model to predict the time-varying corrosion rate:

$$\begin{aligned} i_{corr}(t) = &\left[e^{-6000(M_c-0.75)^6}\right] \times \left[\frac{(1-\text{w/c})^{-1.64}}{x}\right] \\ &\times \left(\frac{C_{so}+C_{th}}{2C_{th}}\right) \times \left[e^{2283\left(\frac{1}{284.15}-\frac{1}{T_m}\right)}\right] \\ &\times \left\{\frac{(T_h-T_l)\sin[2\pi(t-a_s)]}{8.6(t-a_s)} + 7.6\right\} \end{aligned} \tag{11}$$

This model is complicated in the sense that it considers many environmental factor. In the present work, it is assumed that this model is exact and values are generated for corrosion rate and used for updating the assumed model. This model is used only to supplement the lack of actual corrosion rate measurements. In this relation, M_c is the moisture content, w/c is the water cement ratio, C_{so} and C_{th} are the water soluble and threshold chloride concentration (kg/m^3) at the steel level, respectively. T_m is the annual mean temperature (K) at the depth of steel, T_h is the average high temperature (K) and T_l is the average low temperature (K). a_s is corrosion initiation season factor.

Values of the parameters used in the above equation are adopted from Guo et al. (2014). The temperature values however are taken from Allampallewar & Srividya (2008) for Santacruz in Mumbai, India, with w/c $= 0.45$ and $x = 50$ mm. It is assumed that corrosion rate is measured biennially upto 20 years from corrosion initiation, after which no measurement is made. Fig. 1 shows biennial values of the measured corrosion rate, $\hat{I}_T$ obtained by introducing some randomness in Eq. (11). Since in real life, corrosion rate values may not follow a deterministic relation, the randomness is induced to simulate such uncertainty. This randomness is in the form of a multiplicative lognormal random variable with mean 1 and standard deviation 0.1. Using a lognormal RV ensures positivity of the quantity. The value obtained from Eq. (11) is multiplied by a sample value of this lognormal RV. These values are considered to be the readings taken by the LPR based NDT at the mid-span of the bridge at any inspection time. As a simplification, it is assumed that the "uniform" corrosion rate at any other location in the bridge remains the same.

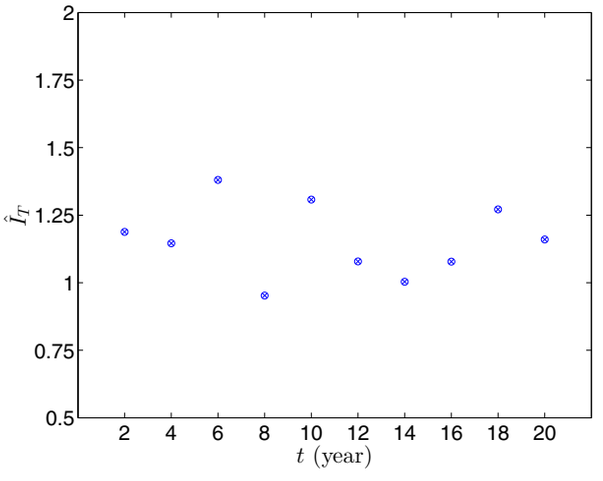

Figure 1: Biennial values of measured corrosion rate for updating

3.4 *Updating*

The model parameters are updated to the posterior $f''(\boldsymbol{\xi})$ using Bayesian inference

$$f''(\boldsymbol{\xi}) \propto \mathcal{L}(\boldsymbol{\xi})f'(\boldsymbol{\xi}) \tag{12}$$

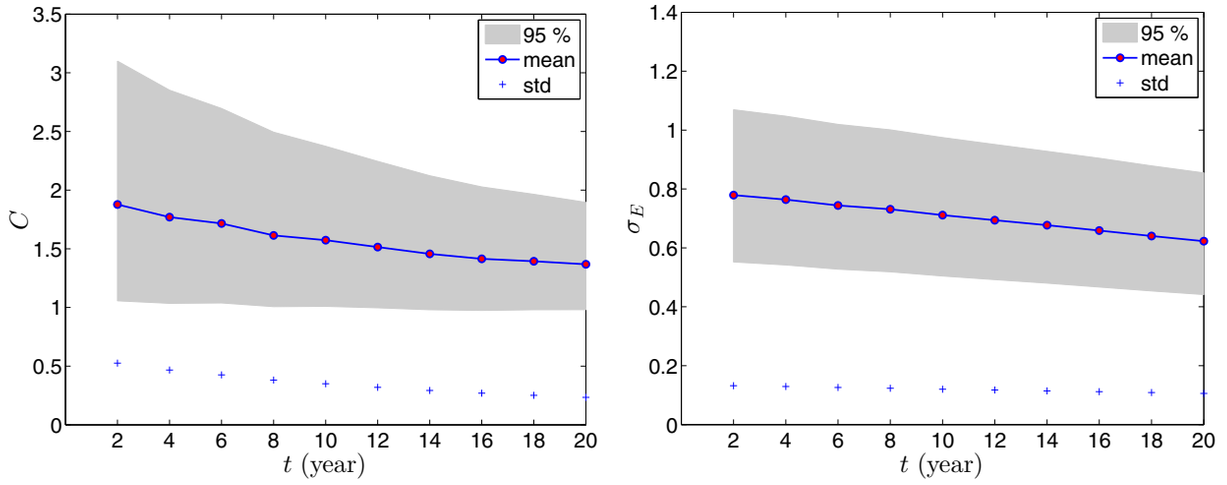

Figure 2: Mean and 95% bounds for the updated parameters, C and σ_E

through the Metropolis algorithm. In the Metropolis simulation, $N = 5,00,000$ samples are generated and used for inference after "thinning" at 10 samples and applying a suitable "burn-in". Fig. 2 shows the mean and 95% confidence interval of the parameters, updated at each new measurement in every two years. It is observed that the spread indicated by the 95% interval reduces as more inspection information are included for updating the corrosion rate model.

3.5 *Robust model prediction*

The (corrosion model parameters) $\boldsymbol{\xi}$-conditioned predictive distribution of the true corrosion rate (I_T) for any time t is as per Eq. (6). Once the corrosion rate model is updated, the parameters $\boldsymbol{\xi}$ are available in the form of sample values. In most of Bayesian inferences applied to model updating in engineering problems, either the sample mean or the sample median value is used for prediction (Faroz 2017). This ignores the parameter uncertainty. In the present work, a single parameter-unconditioned distribution of I_T, which includes the variability due to the random samples of $\boldsymbol{\xi}$, can be obtained using the total probability theorem for a robust predictive distribution for any time t:

$$f(I_T) = \int_{\boldsymbol{\Xi}} f(I_T|\boldsymbol{\xi}) f''(\boldsymbol{\xi}) \mathrm{d}\boldsymbol{\xi} \tag{13}$$

The above PDF can be approximated by using the N samples $\boldsymbol{\xi}^{(k)}$ from $f''(\boldsymbol{\xi})$:

$$f(I_T) \approx \frac{1}{N} \sum_{k=1}^{N} f(I_T|\boldsymbol{\xi}^{(k)}) \tag{14}$$

Samples of I_T from the above PDF can be obtained as (Sankararaman & Mahadevan 2013):

1. Generate $u \sim \mathcal{U}(0,1)$ and select one set of parameters $\boldsymbol{\xi}^{(k)}$ (obtained from updating)
2. Obtain I_{Tk} from $u = \int_0^{I_{Tk}} f(I_T|\boldsymbol{\xi}^{(k)}) \mathrm{d}I_T$
3. Repeat Steps 1-2 to obtain samples of $I_{Tk}, k = 1, \ldots, N$

4 DEGRADATION OF FLEXURAL CAPACITY

In the present work only the reduction in rebar cross-section is considered in determining the remaining flexural capacity of the bridge slab. Other effects of corrosion, such as reduction in rebar yield stress, loss of rebar ductility, loss of bond, etc., are ignored.

4.1 *Pitting corrosion*

Due to uniform reduction, the residual diameter at any instant t is

$$D(t) = D_0 - \delta(t) \tag{15}$$

where, D_0 is the diameter of the uncorroded bar. The assumption of uniform corrosion is an idealistic assumption, a realistic estimation of the failure of a structure due to corrosion needs to account for pitting effects (non-uniform corrosion). The pitting effect can be accounted through the application of an area spatial heterogeneity factor R (Zhang et al. 2014). R is characterised by a Gumbel distribution whose parameters, the scale (ν) and the location (κ), are expressed as functions of the mass loss ratio (η_t) at time t:

$$\eta_t = \frac{D_0^2 - D(t)^2}{D_0^2} \tag{16}$$

As suggested by Zhang et al. (2014), the statistics of R is defined for a rebar element length of 150 mm, the parameters of the Gumbel distribution for a 20 mm diameter rebar being

$$\nu = 0.454\eta_t + 1; \qquad \kappa = 0.329\eta_t \tag{17}$$

Assuming full correlation of steel loss between rebars at a given location at any time, the minimum residual steel area comprising of n_b rebars is calculated as

$$A_{\min}(t) = \frac{n_b \frac{\pi}{4} D(t)^2}{R(t)} \tag{18}$$

4.2 *Probabilistic flexural capacity estimation*

Following the specifications of the Indian Standard for RC design, the time-varying moment capacity of the singly-reinforced RC slab is calculated as (Faroz et al. 2016)

$$M_r(t) = f_y A_{\min}(t) \left[d - 0.77 \frac{f_y A_{\min}(t)}{b f_c} \right] \tag{19}$$

Here, b is the (effective) width of the slab, f_y is the yield strength of steel and f_c is the crushing strength of concrete. Variations in the geometric parameters such as d, b are neglected (Ranganathan & Deshpande 1987) and their nominal values are adopted as best estimates. The statistical properties for material parameters are given in Table 1 (Faroz et al. 2016).

Table 1: Statistics of material parameters

	Distribution	Mean	Standard deviation	Unit
f_y	Lognormal	461.9	41.57	N/mm^2
f_c	Normal	31.6	4	N/mm^2

To infer the probabilistic information of the time-varying moment capacity considering non-uniform corrosion, we propose the following sampling steps:

1. Draw samples of corrosion rate I_T at time t from $f(I_T)$ of Eq. (14).
2. Compute the reduction in diameter $\delta(t)$ from Eq. (5) and obtain the reduced diameter $D(t)$ using Eq. (15)
3. Evaluate η_t from Eq. (16) and the Gumbel parameters of R as in Eq. (17)
4. Sample R for the parameters obtained in Step 3. and obtain $A_{\min}$ using Eq. (18)
5. Sample f_y and f_c from their respective distributions
6. Compute the moment capacity M_r using Eq. (19)
7. Repeat above steps to obtain N samples of M_r

Note that all samples with $\delta > D_0$, $D_0 < 0$, $R < 1$, $f_c < 0$ or $M_r < 0$ are discarded.

5 ESTIMATION OF SERVICE LIFE BASED ON FLEXURE CAPACITY

Figure 3 shows load arrangement causing the maximum moment at the mid-span of the bridge for the Class AA tracked vehicle. The length (4.82 m) of the uniformly distributed load (UDL) is obtained based on the effective width method of load dispersion for

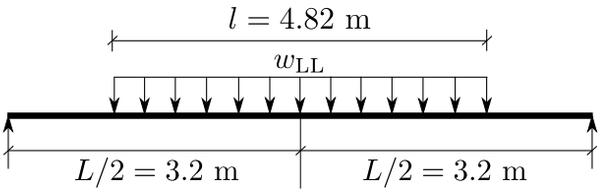

Figure 3: Sketch of bridge

the Class AA tracked vehicle. The value of this UDL with impact is $w_{\mathrm{LL}} = 25$ kN/m (unfactored). For a lack of information on the distributional nature of live load defined in the relevant Indian codes, the live load intensity on this bridge is considered known. The dead load intensity w_{DL} is also assumed to be deterministic. The external moment at the midspan is therefore

$$M_q = \frac{w_{\mathrm{DL}} L^2}{8} + \frac{w_{\mathrm{LL}} l(2L - l)}{8} \tag{20}$$

The limit state function for collapse against flexure at the mid-span can now be expressed as

$$G(t) = M_r(t) - M_q \tag{21}$$

In the limit state M_r is the only random variable. At any given time t, with the knowledge of the distribution of M_r the instantaneous probability of failure can be computed as

$$P_f(t) = F_{M_r}(M_q) \tag{22}$$

where $F_{M_r}(\cdot)$ is the cumulative distribution function (CDF) of $M_r(t)$. However in the present case, we have N sample values of M_r at time t, with which the probability of failure can be computed as

$$P_f(t) = \frac{1}{N} \sum_N \mathbb{I}(G(t) < 0) \tag{23}$$

where $\mathbb{I}(G(t) < 0) = 1$ for $G(t) \leq 0$ and 0 otherwise. The results are expressed in terms of the instantaneous reliability index ($\beta(t)$) which is related to the instantaneous failure probability estimate as

$$\beta(t) \approx -\Phi^{-1}[P_f(t)] \tag{24}$$

Here, $\Phi(\cdot)$ is the standard normal CDF operator.

To assess the service-life of the bridge, an acceptance criterion is required. In this work, this criterion is set at the minimum acceptable reliability or target reliability (β_T) for the structure. The service-life is considered terminated if the actual reliability, $\beta(t)$, falls below this value. The target reliability index for Consequence Class 2, considering repair is 3.3, and for closing down a structure is 2.5 (structure becoming unfit) (Steenbergen & Vrouwenvelder 2010).

Fig. 4 shows the reliability degradation over time, based on the sequential updating of the corrosion model. The thick continuous (blue) line shows the reliability plot based on sequential updating and predicted degradation for every biennial measurement

conducted. This line shows a sudden change on the predicted reliability value at every two years. This is because a new measurement is done biennially and the updating of the model causes this sudden shift. Considering this, a smoothed time-varying "reliability profile" is created for this structure. This profile can be compared with the two β_T lines, one for repair and one for closing down the structure. Based on this, the bridge reaches a repair requirement in 2.78 years from the initiation of corrosion. One should note that this decision is reached after updating the degradation process through only the first LPR measurement (at $t = 2$ years). From the reliability profile, closing down the structure is recommended at the tenth year of corrosion. However, if we take a look at the thick continuous line, this closing is predicted at 9.29 years based on the update available on the eighth year, that is when we take the previous measurement. Of course this estimate would be wrong and one should take a note of the trend visible in the "profile" plot and estimate accordingly. However, such trends will not be visible if the measurements are not repeated multiple times. The thin continuous (blue) lines show the predictions based on the updates stopping after the fourth and the sixth year. These two lines show a considerable difference in the service-life prediction based on closing down the bridge, with 8.25 years and 8.68 years of service-life predicted by the four-year and six-year updates, respectively.

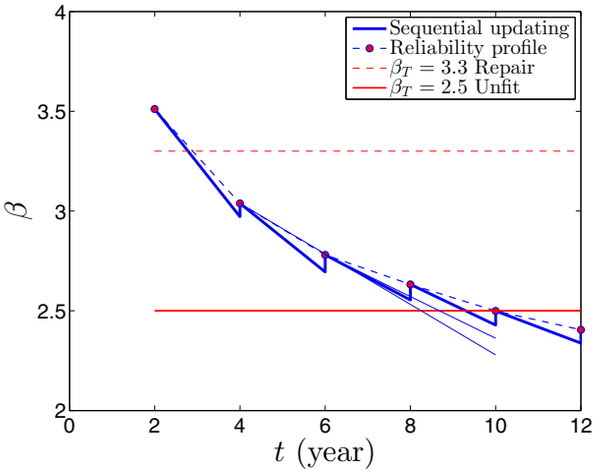

Figure 4: Degradation of reliability over time

6 CONCLUSIONS

Corrosion of rebars is the primary durability concern in RC structures. From a structural engineering point of view, loss of rebar area is the most significant aspect of corrosion because it may eventually lead to the possible collapse of a structure. The present study proposes a novel approach of Bayesian updating of an existing steel loss model based on monitored data. This paper presents the estimation of the service-life of a bridge in a probabilistic framework using sequential updating based on biennial LPR measurements of the corrosion rate. It also demonstrates the computation of this service-life for a RC slab bridge. The probabilistic framework has the advantage of including the uncertainty of the corrosion phenomenon, which can be easily incorporated into the time-varying reliability estimation for a degrading structure, and its service-life estimation. The results show the importance of obtaining a trend in the "true" degradation based on measurements taken at multiple time instants.

The proposed framework of corrosion reliability analysis can be further extended to include complexities, for example, (a) the corrosion initiation time, (b) the uncertainty in NDT measurements, (c) a probabilistic load model, (d) the spatial variability of corrosion, and at a larger scale, to come up with an ageing management system for corroding RC structures.

Brunei Temburong Link – Temburong Viaduct

Naeem Hussain
Arup Fellow, Director, Global Bridge Leader

Sammy Yip
Associate, Arup Hong Kong

John Cain
Senior Engineer, Arup Melbourne

ABSTRACT: Brunei Temburong Link is one of the largest infrastructure projects currently being constructed in South-East Asia. It is a 30km dual 2-lane road link which will connect the main Brunei districts of Muara, Tutong and Belait with the isolated district of Temburong which is separated by the Malaysian state of Sarawak. The link comprises of approximately 3km of tunnels, viaducts and at-grade road on land, 14km of marine viaduct across Brunei Bay, two navigation channel cable stay bridges and 12 km of swamp crossing viaduct. The paper will describe the feasibility study and detail design of the Link focussing on the unique construction of the swamp forest viaduct.

1 INTRODUCTION

1.1 *Location*

Brunei is located on the north coast of the island of Borneo in Southeast Asia.

Apart from its coastline with the South China Sea, it is completely surrounded by the state of Sarawak, Malaysia; and is separated into two parts by the Sarawak district of Limbang (Figure 1).

This physical separation of Temburong district from the majority of Brunei has significantly affected the economic development of the district and Brunei as a whole. Despite comprising 23% of the total land area of Brunei, Temburong only contains 2% of the population.

Figure 1 Map of Brunei

To travel to Temburong by land requires passing into and out of Sarawak through a long circuitous route typically involving significant waiting times at the borders which can result in a journey time of up to four hours between the central business district of Bandar Seri Bagwan and the main district town of Bangar (Figure 2). Alternatively it is possible to travel by speedboat across Brunei Bay and then up-river to Bangar. Neither of these alternatives offer 24 hours a day accessibility.

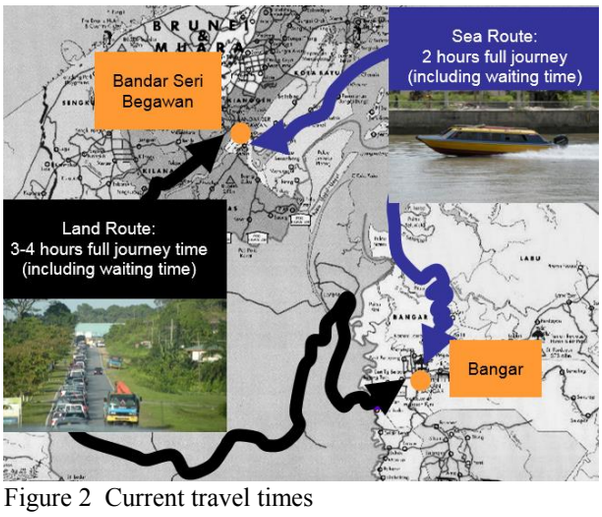

Figure 2 Current travel times

2 ROUTE SELECTION

2.1 *Optional Alignments*

A route selection exercise was carried out to determine the most favourable alignment across Brunei Bay as well as the optimum connection points in both Brunei-Muara and Temburong districts. In order to assess the route options, the goal achievement matrix technique was adopted considering the following criteria:

- Planning and Land Matters
- Environmental Issues

- Transport Planning
- Impact on Local Community
- Engineering
- Implementation Programme
- Cost

Within each of the criteria listed above, sub-criteria were investigated and scored. Sensitivity studies were carried out varying the weight assigned to each of the criteria in order to confirm the robustness of the route selection.

The above assessment considered information from various sources, including available master plans. Spatial data was overlaid and correlated using a Geographic Information Systems (GIS) model. This enables multiple layering of geographic data to ensure that all captured information is correlated and taken into account in the development of the alignment.

An example screenshot from the GIS model is shown in Figure 3. In this case the four different routes that were considered are overlaid on the growth areas in Temburong which were extracted from the masterplans. The existing road network, designated navigation channels, mangrove forests of high ecological value and national boundaries are also shown. These are just examples of the many layers of information which were included.

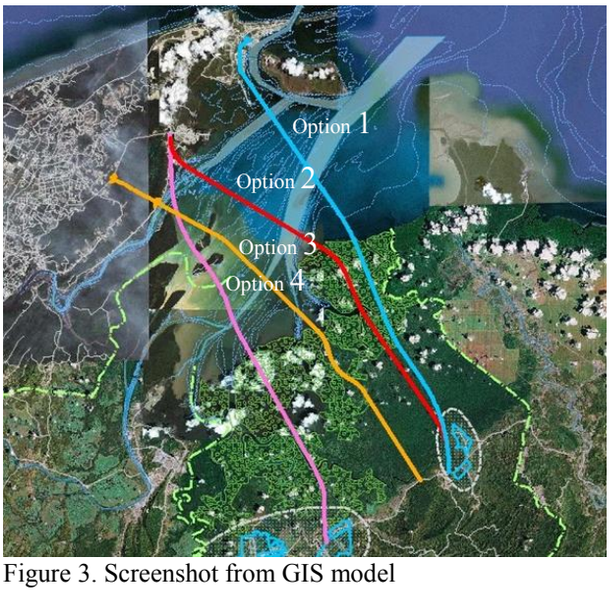

Figure 3. Screenshot from GIS model

2.2 *Chosen Alignment*

Option 3 (refer Figure 3) was selected as the preferred route with the highest score under a range of sensitivity tests. The advantages are summarised as:
Transport Planning: It provides the shortest travel distance and travel time between Brunei-Muara and Temburong.
Planning and Land Matters: It requires minimal private land acquisition and hence has the least land issues and anticipated to be more acceptable to the general public.
Environmental: It will avoid encroachment in conservation mangrove areas and minimise encroachment through production mangrove areas.
Stakeholder Opinion: It was the preferred alignment of the majority of stakeholders.

3 TEMBURONG SWAMP VIADUCT

3.1 *Location and Alignment*

Following completion of the Feasibility Study for the 30 km long Brunei Temburong Link, the project was divided into several construction packages. The location and alignment of the 12 km low height piled slab viaduct crossing the peat swamp forest in the Temburong District is shown in Figures 4 & 5

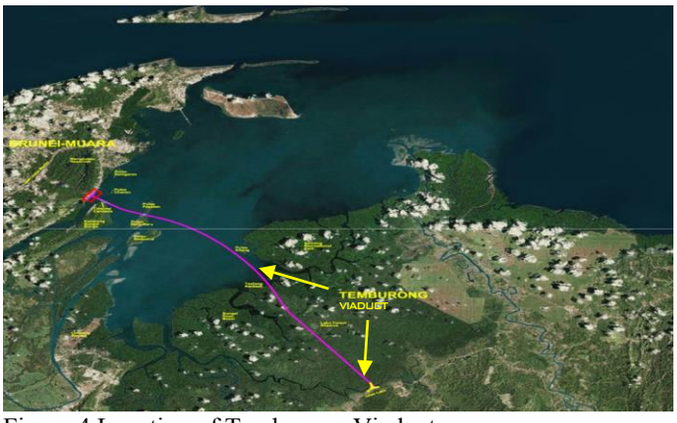

Figure 4 Location of Temburong Viaduct

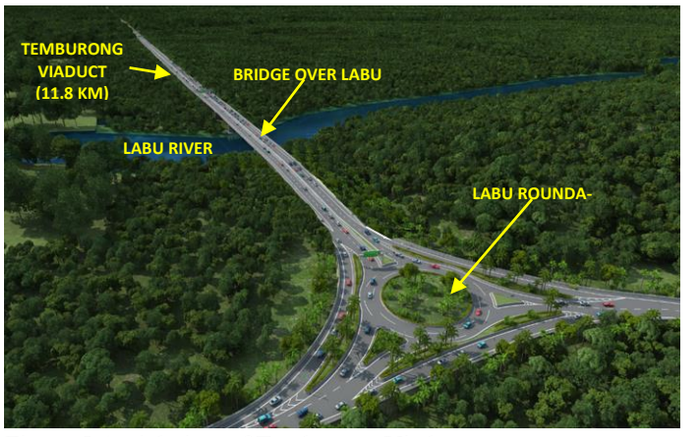

Figure 5 Aerial view of Temburong Viaduct

The peat swamp forest has unique and endangered flora and fauna. The soil conditions consist of soft peat overlying soft marine clay with depths exceeding 70m. Due to these challenging ground conditions and in order to safeguard the flora and fauna of the swamp forest, a top-down construction method has been developed, with all construction undertaken from deck level.

3.2 *Design Development*

The concept of using a series of short spans to cross a swamp is not new. Given the poor ground conditions, loadings from shorter spans are usually all the

soil can accommodate. This did pose quite a problem however as typically, for such a long viaduct, a larger span concept would be more desirable, to reduce the number of spans and foundations required.

3.3 *Key Considerations*

For this viaduct, the key considerations that have defined the design are:

- Programme and cost
- Ground conditions
- Environmental and site constraints
- Construction method

3.3.1 *Ground Conditions*

The ground profile comprises of a very soft peat layer of depths up to 4m and overlying soft marine clays at depths up to 70m. Water level is up to the ground level at high tides. The peat material has very little strength and is unable to support any large construction machinery or plant.

Figure 6 Typical site conditions

The soil has very little capacity in supporting load both axially and laterally. The minimal lateral resistance from the peat layer means that piles would be essentially unrestrained throughout the overlying peat layer. For the proposed design of 12m span length, the piles are being driven up to 80m for a large proportion of the alignment. Increasing the pile length will increase the risk of pile damage during the pile driving process.

3.3.2 *Environmental and site constarints*

The viaduct crosses the peat swamp forest which is in turn surrounded by mangrove forest, both of which are essentially untouched. To minimise the potential impact on the environment, the project Environmental Impact Assessment restricts the use of embankments. As shown in Figure 7, there are only three points of access to the alignment. Since temporary access roads by embankment are prohibited, there can only be a maximum of four working fronts. This further called for a design that could be constructed easily and quickly.

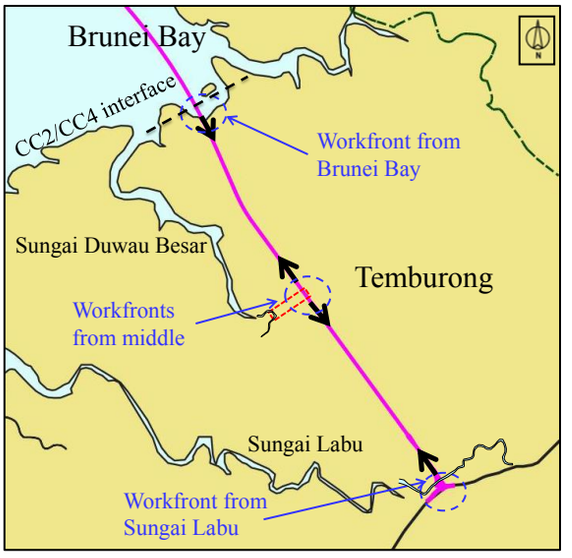

Figure 7 Work fronts

3.3.3 *Top-down construction*

The constraints required a design that could be constructed in a top-down manner, meaning material delivery, and installation of structural components (including piles, pile caps and superstructure) can be carried out from the viaduct deck already erected. Bridge scheme.With the key considerations in mind, evaluation of options was carried out and the following describes the key features of the scheme.

3.4 *Span length*

Determining the span length was an iterative process. The primary factor was the limited foundation capacity due to the poor ground conditions.

The span was chosen such that only a single row of piles are required at each pier, to minimise the size and weight of the precast pile cap.

With construction needing to take place at deck level and the carriageways only 10m wide, a shorter span length that would permit smaller structural components and equipment was preferred.

Consideration to the crane size and lever arm for installing the piles and pile caps was also given.

Considering the above, a 12m span was chosen.

3.5 *Viaduct Deck Structure*

The viaduct consists of almost 200 no. 120m long piled slab modules. Each module consists of 10 no. 12m spans. The design maximises the use of precast concrete elements and repetition, enabling construction to be undertaken in a fast track manner, a necessity to meet the completion date.

Each pier foundation consists of 4 no. 0.9m diameter concrete spun piles, with a precast pile cap. The piles and precast cap are connected via a cast in-situ pile plug at each pile.

The superstructure comprises of five precast double T beams per span, which are landed onto the precast pile caps.

Four deck slab stitch pours connect the double T beams together to form the deck slab, whilst an in-situ diaphragm pour connects the double T beams to the precast pile cap, completing the structure. Figures 8 and 9.

It was decided that the deck would be of monolithic design for two main reasons; to reduce the number of bearings required and to maximize the foundation efficiency.

Reducing the number of bearings reduces the amount of maintenance required over the structure's life. This is critical due to the remote location of the bridge and difficulty in accessing the deck soffit and to support machinery from ground level. An added advantage is that during construction, the number of bearing installation is minimised

A deck cast monolithically with the substructure also meant that the piles would experience double curvature in bending, reducing their effective buckling length. This was critical given the pile length and poor lateral capacity of the soil.

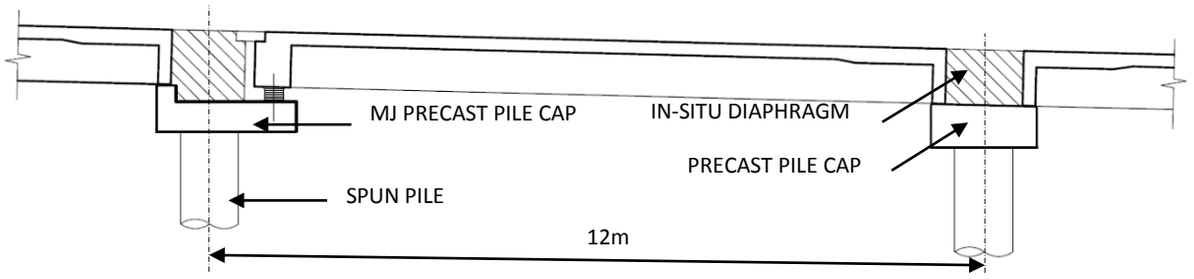

Figure 8. Typical elevation of the Piled Slab Viaduct (M.J included)

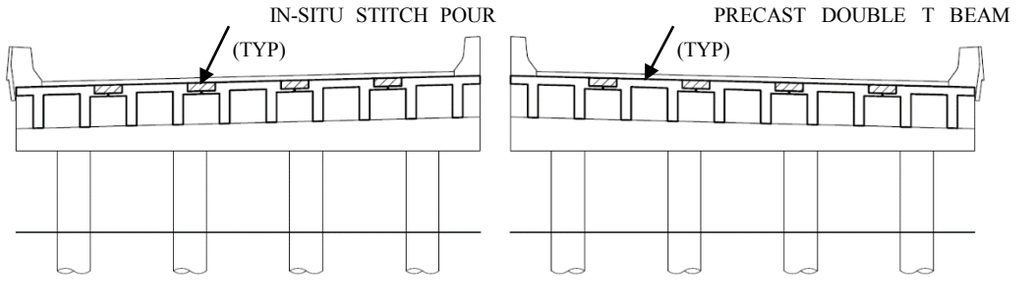

*Figure 9. Typical section of the Piled Slab Viaduct*Monolitic joints

3.6 *Foundations*

3.6.1 *Piling*

Prestressed precast spun piles were chosen primarily due to their cost relative to steel piles. Another reason was the concern of durability and corrosion of steel piles in the aggressive soil condition. The spun piles are being manufactured in lengths up to 30m and are welded together via steel plates located at each end. The prestressed strands within the piles, are welded to these plates to ensure continuity across the total pile, when lengths are connected.

3.6.2 *Precast pile cap*

The precast pile cap is a solid concrete element with voids to permit encasement of the piles.

The precast pile cap is of varying depth, such that when the double T beams are landed, the deck will be at the correct slope and grade.

Four steel I sections will be cast into each precast pile cap, each spanning across a pile void.

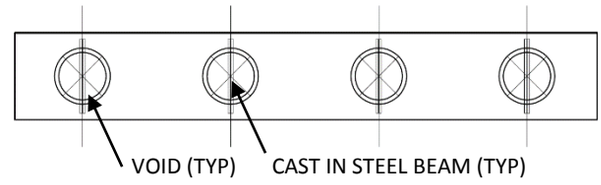

Figure 10 Plan of precast pilecap

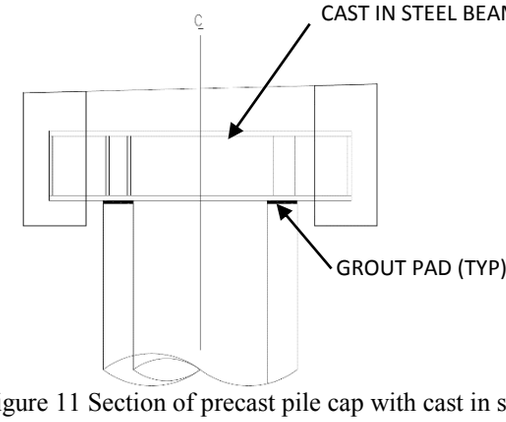

Figure 11 Section of precast pile cap with cast in steel beam

The steel beams are pivotal in both the construction and permanent cases. Firstly the beams are used as a means of temporary support when landing the precast pile cap on top of the piles. This arrangement (as opposed to having the cap soffit land

onto the pile) enables a void in the precast that is large enough to account for the pile tolerance. Furthermore the accuracy at which the pile must be cut at is reduced, as only two points per pile are in contact with the cut face.

The additional pile plug reinforcement is then installed and the in-situ pile plugs are cast. The pile cap self-weight now becomes "locked" into the steel beam. At this stage the steel beam detail has the advantage of providing a positive connection between the pile plug and the precast pile cap, without the need for excessive reinforcement being needed to be fixed on site. In addition the top of the spun pile becomes embedded within the pile plug pour. This protects the pile pre-stressed strand exposed during cutting from getting corroded.

Once the plug has been partially cured, the T-beams can be landed. At this stage the plug and steel beam act compositely and the self- weight of the precast double T beams is "locked" into the precast pile cap and composite pile plug connection.

3.6.3 *In-situ pile plug*

The in-situ pile plugs provide fixity between the spun piles and the precast pile cap. The critical consideration in designing the pile plug was ensuring there was sufficient space for the reinforcement for cases where the pile has been installed slightly away from the specified position

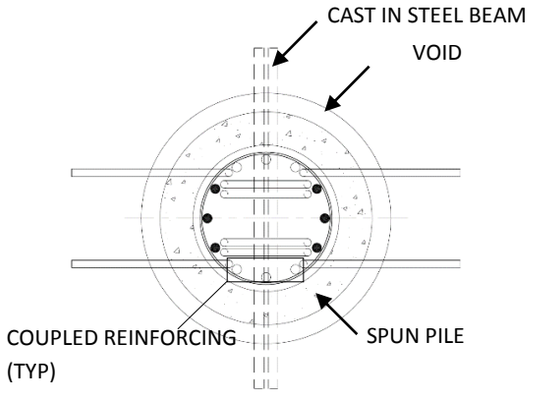

Figure 12 Plan of pile plug connection

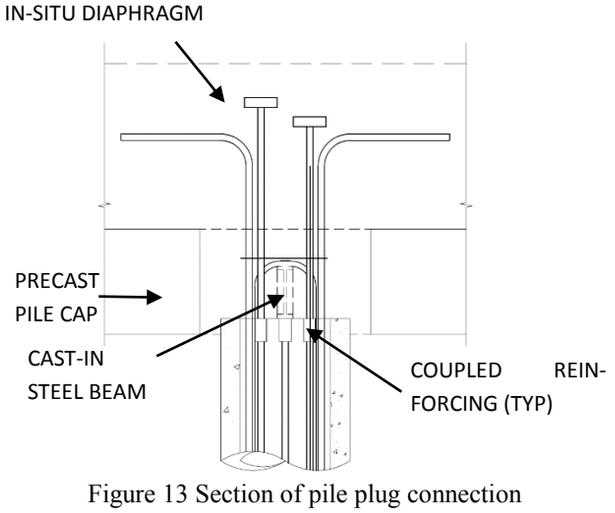

Figure 13 Section of pile plug connection

3.6.4 *In-situ diaphragm*

The in-situ diaphragm ties the precast double T beams to the precast pile cap substructure, ensuring a monolithic connection between the piles and the double T beams.

The in-situ diaphragm reinforcement comprises starter bars from the precast pile caps (to form the composite torsion element), pile plug and the precast deck beams on either side

When cured, the in-situ diaphragm works compositely with the precast pile cap. The combination of torsional and shear forces govern the design

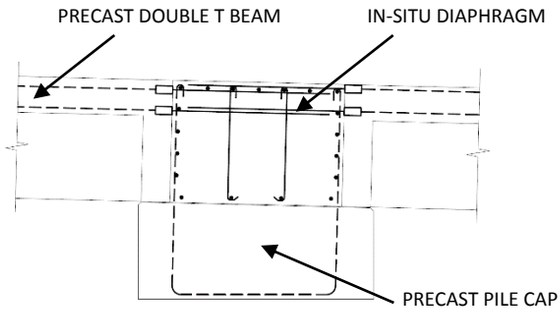

Figure 14 Section of cast in-situ diaphragm

4 CONSTRUCTION METHODOLOGY

Throughout the design process, the construction methodology and expected duration was critically scrutinised. As a result of design progression, two construction methods were devised; the standard method and fast track method. The fast-track method is being used

4.1 *Fast track construction method*

The construction is based on the use of tracked cranes and platforms working as a train. The platforms span between the row of piles.

The front part of the train comprises of three platforms for each carriageway with piling cranes sitting on the platforms. The guide for the piles is cantilevered from the platform.

Following the piling cranes there are other cranes that install temporary platforms, erection of precast pile caps and the T-beams. The combination of temporary platforms and completed deck structures allows delivery of insitu concrete, precast piles, pile caps and t-beams.

The sequence of construction is shown diagramatically in Figure 15 below, with the actual construction shown in Figure 16.

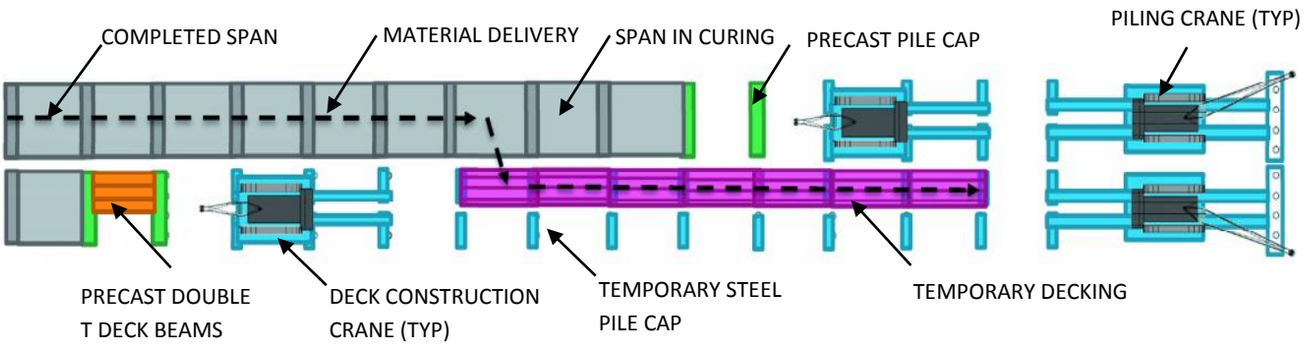

Figure 15 Fast track sequence of construction

Figure 16 Aerial views of construction

5 CONCLUSION

The Temburong swamp crossing design focused on simplifying the construction process and is enabling the construction to be carried out rapidly and entirely from deck level. The design reduces the amount of reinforcement fixing and in-situ concrete work required on site, ultimately to minimise the impacts to the surrounding forest and to maximise speed of construction.

Effect of cracks on air-tightness of vacuum tube bridge structures

P. Devkota & J. Park
Department of Civil and Environmental Engineering, Wonkwang University, Iksan, Republic of Korea.
E. Choi
Department of Civil Engineering, Hongik University, Seoul, Republic of Korea.

ABSTRACT: Air resistance is a very important consideration for any kinds of vehicles that travel at high speed. The vacuum tube transportation system is therefore considered as one of the most effective transportation system, which can maintain the high speed of the train by minimizing the air resistance. The air resistance can be minimized by reducing and maintaining air pressure inside the tube. For bridges with vacuum tube structures, the impact of externally applied loads on the air-tightness performance level should be taken into consideration. Therefore, the aim of this work is to study the effect of load-induced cracks on the air-tightness of concrete vacuum tube structures. To achieve this aim, a predictive model that describes the crack width is adopted and the cracking pattern on the vacuum tube structure is analyzed. The leakage rate of air through the cracks is then assessed and finally, the relationship between the crack behaviour and its effect on the air-tightness of vacuum tube structure is established.

1 INTRODUCTION

The development of fast, reliable and efficient transportation system is the prerequisite for the rapid development of the country. On the way of developing the transportation system as the fast, reliable and efficient system, the vacuum tube transportation system came into consideration. The vacuum tube transportation system is also known as the super speed tube train (SSTT) system, where the trains are expected to operate with the practical speed of 700km/h (Cassat et al. 2003, Lee et al. 2008). Therefore, this system is considered as the most effective transportation system that will be able to substitute the existing system in the sense of its operating speed.

The main idea for the development of vacuum tube transportation system (Figure 1) is to create the vacuum inside the concrete tube structure by maintaining the internal air pressure as low as possible so that the train operating inside the tube will undergo less air resistance, which ultimately increases its speed. The train, theoretically, can operate with the speed of 8000 km/h on the maglev lines through vacuum tubes but due to the great cost expected for its construction, operation, and maintenance, the system has never come into realization. Recent studies on the super speed tube train conducted by Cassat et al. (2003) and Lee et al. (2008) have aimed the operating speed of train up to 700km/h provided that the internal pressure of the tube is maintained as low as 0.1atm. Maintaining the air pressure of the tube at low level is a very challenging task. Several factors such as the material of the structure, discontinuities present in the structure such as construction joints, bolted regions, and load-induced cracks will have an effect on the air-tightness performance of the tube structure. Park et. al (2013) had studied the effect of material and discontinuities on the tube airtightness and concluded that the concrete material with high strength and the tube with less number of discontinuities is most appropriate for maintaining the airtightness of the tube. But that study lacks on consideration of the effect of cracks induced by external loads applied on the structure. Concrete structures are subject to cracks under service loads, which will cause great effect on the air-tightness due to potential air leakage.

This study describes the effect of load-induced cracks on airtightness of concrete vacuum tube structures. Under the application of external loadings, the cracks will be induced on the structure and air will inflow through the cracked portion, which is shown schematically in the figures 2 and 3. The induced cracks will show the effect on the airtightness performance of the structure. The cracks developed due to the application of external loads will increase the air inflow rate decreasing the air resisting capacity of the vacuum tube structure, which ultimately decreases the speed of the train inside the tube. The study on the effects of cracks is therefore essential to the description of the airtightness of concrete tube struc-

tures. For a study about the effect of crack on airtightness, the calculation of crack properties and the leakage rate are the important requirements.

The analytical crack model is developed from the mathematical expression proposed by Rizkalla for estimating and describing the effect of the air inflow through cracks developed due to the external loads. The crack length, width, and depth are defined as the damage indicators for the prediction of internal pressure change due to air flow. This study develops an analytical model that describes the air pressure behaviour in the vacuum tube structure and develops the relationship between load induced cracks and tube airtightness. The external load applied on the structure is assumed to be sufficient enough to form the crack in the tube structure, where the internal pressure is initially dropped down to ten percent of the atmospheric pressure. The formula for describing the internal pressure change or air inflow with time inside the tube structure is derived first based on Rizkalla formula. The pressure change inside the tube structure directly depends upon the air flow through the cracks. The results obtained from the analytical study of Rizkalla formula are calibrated with the results obtained from the experimental study.

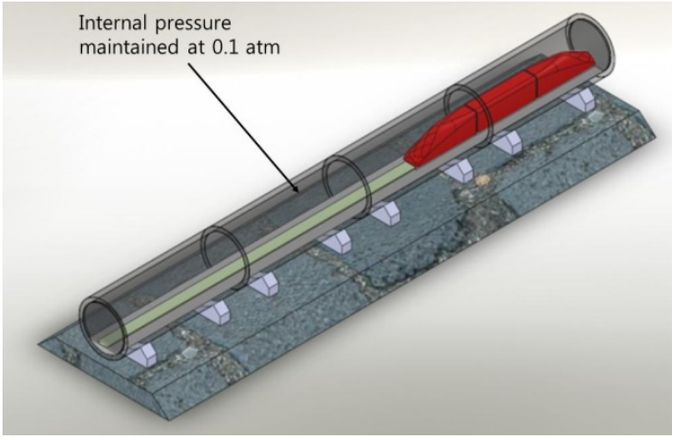

Figure 1. Vacuum tube transportation system (Park et al. 2013)

2 MODEL FOR AIR PRESSURE CHANGE DUE TO CRACKS:

Air tightness in any structure is the resistance to inward or outward air leakage through the possible leakage points. The pressure difference between inside and outside of the structure will propel for the air leakage through the cracks that are formed due to the application of external loads. The flexural cracks due to loadings would be developed on the structure as shown in figure 2. The rate of flow increases with the increase in number, width, and length of the cracks. From the design point of view, it is necessary to anticipate the amount of pressure change due to air inflow into the vacuum tube structure with time. Nam. (2010) & Park et al. (2013) had explained about the design variables like capacity and spacing of the vacuum pump along with their operating time and the operating speed of train with the consideration of airtightness of the structure. The change in pressure due to the flow of air can be determined by using various leakage rate formulas. The Bernoulli's equation was used by Choi et al. (2016) to determine the change in internal pressure along with time. Bernoulli's equation is expressed in equation (1), which relates the pressure change with some variables such as velocity, density and elevation difference between two points.

$$p_o + \frac{1}{2}\rho \cdot {v_o}^2 = p(t) + \frac{1}{2}\rho \cdot (v(t))^2 \qquad (1)$$

where p_o is the atmospheric pressure, v_o is the velocity of the air outside the structure, ρ is the density of the air, $p(t)$ is the internal pressure at time t, and $v(t)$ is the velocity of the air inflow measured inside the crack.

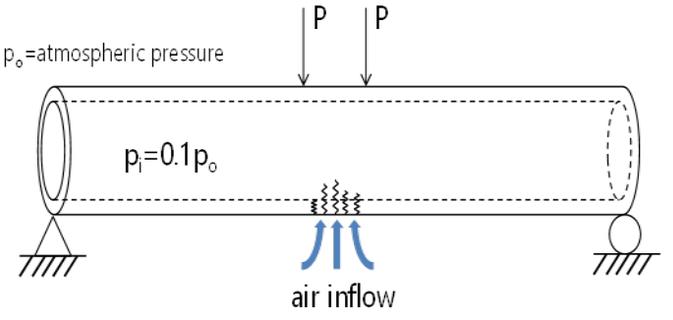

Figure 2. Loading on the tube structure (Choi et.al 2016)

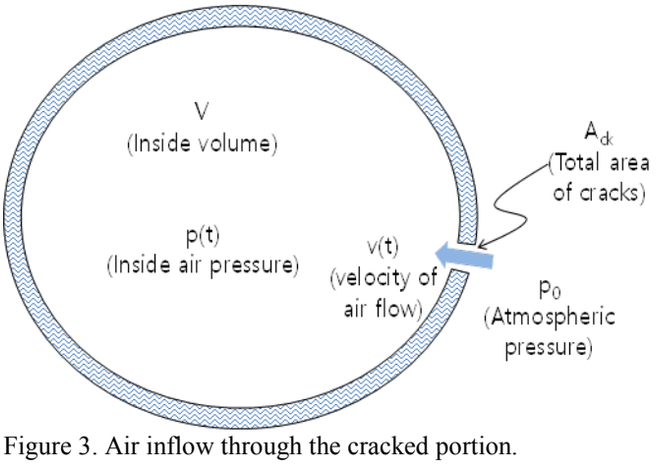

Figure 3. Air inflow through the cracked portion.

In fact, the change in pressure along with time in the concrete tube structure is affected by many other variables such as friction, viscosity, and temperature, which Bernoulli's formula does not account for.

According to Scoppe et al. (2012), the method by Rizkalla et al. (1984) provides the most reasonable and consistent result for the calculation of air leakage through cracks developed on a concrete structure. The effect of friction and viscosity of the air is explicitly

considered in the model. In this study, the Rizkalla formula is adopted for development of mathematical model for describing the internal pressure change due to cracks.

3 DERIVATION OF ANALYTICAL MODEL FOR PRESSURE CHANGE:

Rizkalla et al. (1984) developed the leakage rate formula through cracks by performing the experiment on eight reinforced wall specimens. This formula was formulated by modeling the idealized isothermal flow of air between two plates as shown in Figure 4, which is known as Poiseuille flow. The formula was developed by assuming a uniform crack width through the thickness of the wall and the flow is assumed as isothermal, steady and uniform.

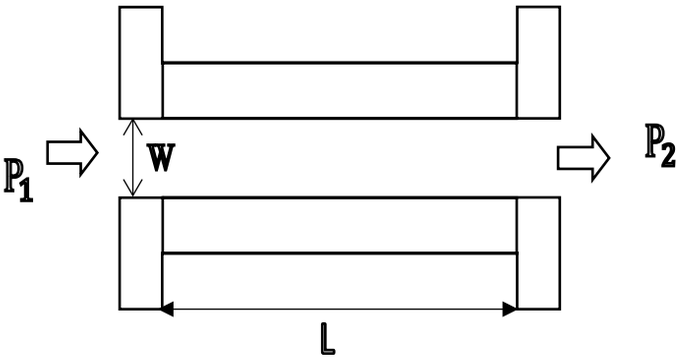

Figure 4. Flow between the plates

The flow formula developed by Rizkalla is:

$$\frac{P_1{}^2-P_2{}^2}{L}=\left(\frac{k^n}{2}\right)\left(\frac{\mu}{2}\right)^n (RT)^{n-1}\left|\frac{P_2Q}{B}\right|^{2-n}\frac{1}{1.42N*W_{avg}{}^3} \quad (2)$$

where, p_1 = Inflow pressure; p2 = outflow pressure; L = thickness of the wall; k = wall roughness coefficient; μ = Viscosity of the gas; *R* = Gas constant; *T* = Absolute temperature; *n* = Flow coefficient; *B* = Average measured crack length; *Q* = Total flow rate; *N* = Number of cracks; W_{avg} = Average crack width (input in feet).

Rizkalla had developed the formula for leakage rate by assuming the flow between the plates but our study deals with the flow of atmospheric air towards the concrete tube through the cracks formed. Initially, the internal pressure was maintained at ten percent of the atmospheric pressure but the change in pressure occurs due to the flow of air through cracks and internal pressure started to change. For determining the change in internal pressure with time, the differential equation is developed by using the Rizkalla formula.

$$\frac{P_1{}^2-P_2{}^2}{L}=C_1*\left|\frac{P_2Q}{B}\right|^{2-n} \quad (3)$$

where,

$$C_1=\left(\frac{k^n}{2}\right)\left(\frac{\mu}{2}\right)^n (RT)^{n-1}*\frac{1}{1.42N*W_{avg}{}^3}$$

$$n=\frac{0.195}{(N*W_{avg}{}^3)^{0.063}}$$

$$k=8.702\times10^6\left(N\cdot W_{avg}{}^3\right)^{0.367}$$

From the above equation (3),

$$Q=\frac{B}{P_2}\left(\frac{P_1{}^2-P_2{}^2}{C_1L}\right)^{\frac{1}{2-n}} \quad (4)$$

If, $C_2=\frac{B}{(C_1L)^{\frac{1}{2-n}}}$ then,

$$Q=\frac{C_2}{P_2}\left(P_1{}^2-P_2{}^2\right)^{\frac{1}{2-n}} \quad (5)$$

If the case of the vacuum tube, the atmospheric pressure corresponding to the outside/atmospheric pressure (P_1) can be considered as constant regardless of the flow time if the temperature and attitude are constant. If the air enters through the cracks in the tube, the outlet pressure that is the pressure inside the tube will rise with time. Thus, the pressure (P_2) will be the function of time and can be expressed as below:

$$Q(t)=\frac{C_2}{P_2(t)}\left(P_1{}^2-P_{2(t)}{}^2\right)^{\frac{1}{2-n}} \quad (6)$$

If the temperature inside and outside the tube are equal, the pressure rise inside the structure will be proportional to the air inflow; in other words,

$$P_1Q=\frac{dp_{2(t)}}{dt}V \quad (7)$$

Then, comparing above two equations (6) and (7),

$$\frac{P_1C_2}{V\cdot P_2(t)}\left(P_1{}^2-P_{2(t)}{}^2\right)^{\frac{1}{2-n}}=\frac{dp_{2(t)}}{dt} \quad (8)$$

If $C_3=\frac{P_1C_2}{V}$, $r=\frac{1}{2-n}$ then,

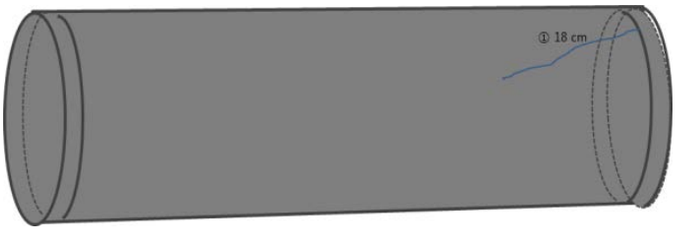
$$\frac{dp_{2(t)}}{dt} = \frac{C_3\left(P_1{}^2 - P_{2(t)}{}^2\right)^r}{P_2(t)} \quad (9)$$

Integrating both sides, we get the pressure inside the tube as:

$$P_2(t) = \sqrt{P_1{}^2 - [(2r-2)(C_3 t + C)]^{\frac{1}{1-r}}} \quad (10)$$

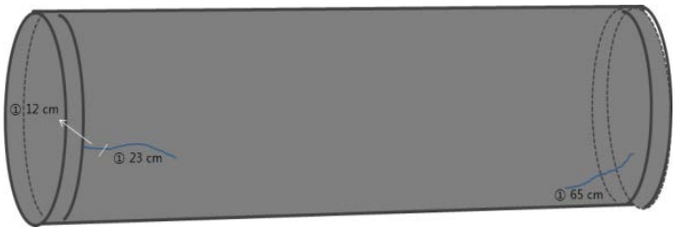
At the initial condition that the pressure inside the tube is 0.1 times the outside pressure, that is, $P_2(t)$ at $t = 0$, is $0.1P_1 = P_0$, then C will be as below:

$$C = \frac{\left(P_1{}^2 - P_0{}^2\right)^{1-r}}{2r-2} \quad (11)$$



Therefore, if the number of cracks (N) and average crack width (W_{avg}) are known, the change in internal pressure in a vacuum tube structure with time could be anticipated mathematically by using the formula expressed above in equation (10).

4 EXPERIMENTAL STUDY:



The experimental test was conducted to evaluate the cracking and air leakage behaviour of concrete vacuum tube structure. The concrete tube structure with radius 0.195m, length 2m and thickness 0.035m was modeled and constructed in the laboratory. A vertical point load of 35 kN is applied on the mid-span of the structure and the cracks are expected to develop in the structure with this loading condition. Under this loading condition the crack length, average width, and numbers are measured manually and found to be 1.18m, 0.1mm and 3, respectively as shown in figure 5. The figure displays the front and rear view of the tube structure with cracks developed on it.

5 COMPARISON OF EXPERIMENTAL AND ANALYTICAL RESULTS:

Based on the calculations made analytically by using Rizkalla formula for the change in internal pressure with time due to cracks, the analytical results are compared with that of the experiment. Detecting and measuring the cracks present on concrete is really a tough task and the measured data are subject to a great deal of errors. During the experiment, the measurement of crack length and numbers is quite easy as compared to crack width so we expect that we had extracted more accurate data for number and length of the cracks. For minimizing the error associated with crack width, it is necessary to refine it. The crack width data are refined by calibrating the experimental data with the analytical data, as shown in figure 6. The nonlinear regression analysis is done to find out the best-fit curve for both experimental and analytical results, which gives the refined data for the crack width. From the experiment, the crack width value was found to be 0.1mm whereas after refining value of crack width is found to be 0.04mm, which is 2.5 times lesser than that given by experiment. The numerical modeling can be done by using the nonlinear finite element program, Midas FEA (Midas I.T. 2016) which considers the total strain crack model (Ngekpe B.E. 2016) for the analysis. The data obtained from numerical modeling can be used for calibration in order to obtain the more refined model which could be part of the future study.

6 NUMERICAL SIMULATION AND PARAMETRIC STUDY:

The actual dimension for the concrete tube structure has not been determined yet, so only a conceptual study is being conducted at present. The dimension of the tube structure can only be determined after finalizing the detailed design. Therefore, in this study, the tube structure with an inner diameter of 0.39m, length of 2m and thickness of 0.035m is assumed as the baseline dimension for an illustrative purpose. Crack is used as the damage indicator for studying the airtightness of the tube structure. The parameters of the crack, such as crack length, width and numbers are varied in order to identify the sensitivity of the crack with the airtightness of the system.

The change in internal pressure with time for different values of crack width, number and length are shown in figures 7, 8 and 9 respectively. For studying the change in internal pressure with time, crack width is varied from 0.01mm to 0.04mm keeping the crack length and number constant at 1m and 3 respectively, crack length is varied from 1m to 15m keeping the crack width and number constant at 0.002m and 3 respectively and crack number is varied from 1 to 15 keeping the crack width and length constant at 0.002m and 1m respectively. Initially, it was assumed that the internal pressure is dropped down to 10 percent of the atmospheric pressure. The pressure increases more rapidly when either crack width or crack length or both of them increases. Figures 10, 11 and 12 show that the time required for the internal pressure to reach the specified value decreases as width, numbers, and length of the crack increases. These trend analyses could be effectively used for determination of the limit states of cracks associated with the system airtightness.

It is necessary to assume that the vacuum pumps present in the tube structure reactivate when the internal pressure reaches a certain value, which is not more than initially maintained internal pressure. For this study, 50 percent of the atmospheric pressure is assumed to be the limit value of pressure. The analysis result shows that if the width of the crack is maintained below 0.02mm with the fixed crack length and number of 1m and 3, and length of the crack is maintained below 1m with a fixed width and number of 0.02mm and 3, then time for reactivating the pump will be longer than eight minutes. Eight minutes is a short period for reactivation of the pump, which shows that the airtightness performance of the tube is not satisfactory. Therefore, the crack widths lengths and numbers are needed to be maintained as low as possible for ensuring the better airtightness performance of the tube structure.

7 CONCLUSION:

The experimental, as well as the analytical study is carried out to investigate the behavior of the load induced crack and its effect on airtightness of the concrete tube transportation system. The experiment is conducted to determine the crack properties and change in internal pressure due to crack. The analytical model describing the pressure change inside the tube structure due to cracks is developed by using Rizkalla formula. The nonlinear regression analysis between the analytical and experimental curves of change in internal pressure with time is done to obtain the best-fit curve describing the refined data of crack width. The numerical simulation of the data can effectively show the trend of the system airtightness due to the changes in selected control variables such as crack width, number and length. Time for the internal pressure to reach a pre-defined, pump-reactivating pressure was also monitored for changes in the control variables. These trend analyses could be effectively used for determination of the limit states of cracks associated with the system airtightness.

ABSTRACT: A follow-on case study revisits the site of a small highway bridge crossing an ephemeral stream in an arid area of Texas with little hydrologic information. The bridge has presented chronic problems and maintenance issues for years because of stream instability. The bridge is at US Highway 62—180 where it crosses Guadalupe Arroyo in Culberson County. Texas.

Bed load sediment transport through the reach adjacent to the bridge appears inhibited. The authors originally concluded that the inhibition of bed load sediment movement through the bridge reach must be addressed for any solution to be effective; sediment accumulated since construction in 1959 must be allowed to disperse downstream, and sediment arriving at the site in the future must pass the reach without further accumulation upstream of the bridge. The authors conjectured engineered solutions that failed to address the inhibition of sediment movement through the reach by restoring stream geometry to a condition favorable to bed sediment movement would doom conventional approaches such as bank armoring to continued failure. Despite these recommendations, a construction project intended to stabilize the situation using only conventional bank armoring took place in 2009. This continued case study involves revisiting the site as it exists in 2017, and documenting the performance of those measures under conditions of extreme bed load sediment movement. The original case study was presented at the 7th TRB International Bridge Engineering Conference in San Antonio, Texas.

The authors find that this provides a unique opportunity to examine both the performance of bank armoring in areas of extreme bed sediment load, and document the stability state of the stream at another point in time, eight years after the original data was collected. A more complete understanding the interaction of roadway bridges with the geomorphic environment in which they exist is essential for their long-term performance and survival.

1 INTRODUCTION

Culberson County, Texas, is located in the far western part of the state (Figure 1). The region has rugged terrain, low mean annual rainfall (approximately 250 mm), sparse desert scrub vegetation, and is traversed by several mountain ranges including the Guadalupe Mountains, that extend North into New Mexico. The sparsely populated area has few improved roadways. United States Highways 62 and 180 (US 62-180) are co-aligned, crossing the bridge area from northeast to southwest, entering Texas from New Mexico and traversing the lower levels of the Guadalupe Mountains and Guadalupe Mountain National Park.

The subject bridge was constructed in 1959, and crosses an ephemeral stream known as Guadalupe Creek, or Guadalupe Arroyo. The stream adjacent to the bridge has exhibited stream instability, first coming to the attention of the Texas Department of Transportation (TxDOT) as lateral migration threatening the southwest abutment and embankment, and accompanied by aggradation of the stream bed adjacent to and within the bridge opening.

TxDOT planners were unaware of the connection

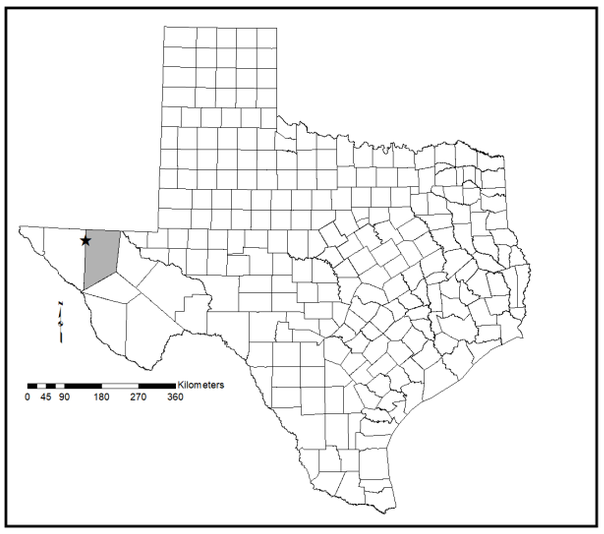

Figure 1: Culberson County, Texas (shaded) Star denotes the bridge location.

between lateral migration and aggradation in 2008 following the submission of a consulting engineering report that focused on erosion as the culprit. Upon reviewing the report, visiting the site, and reviewing historical overhead imagery the authors found was evidence that stream-bed aggradation on stream bed lateral migration played an important role that had been overlooked in the consultant report. A subsequent report on the issues, and recommended guidance for addressing them, was prepared for TxDOT in 2009 (Herrmann 2009). That report concluded that the natural hydraulic geometry of the stream had been obliterated, resulting in inhibited sediment transport through the bridge reach, and chronic aggradation. The recommendations in that report included restoration of the geometry necessary for transport, and allowing accumulated sediment to disperse downstream. The report specifically stated that addressing bank erosion solely by bank stabilization was unlikely to succeed, and noted that addressing the dominant problem would require work off of TxDOT right-of-way, necessitating easements onto private land.

At the 2010 TRB International Bridge Engineering Conference in San Antonio, Texas a case study of the bridge was presented (Herrmann & Cleveland 2010) (Herrmann 2013); in which the authors described the situation in detail. The case was thought to be of considerable interest to bridge engineers and managers in areas of similar climate and geology.

TxDOT funded a $561,375 USD project under the American Recovery and Reinvestment Act of 2009 (ARRA) constructed in 2009-2010, with a time frame too short to allow acquisition of the necessary easements; the project deployed revetment-type bank stabilization. This paper re-studies the site as it appears in 2017, approximately 7 years after the completion of the original project, to assesses the viability of bank stabilization revetments in similar cases, and the consequences of overlooking the role of hydraulic geometry and bed load sediment transport in stream stability.

2 WATERSHED DESCRIPTION

The watershed contributing to the bridge site is just over 100 sq. km. in area. The area is divided among two major and four minor subwatersheds, ranging in area from 0.31 to 48.2 sq. km. The longest flow path from the most remote point on the watershed to the bridge is approximately 22 km. In that distance, the elevation falls from 2667 m. on Guadalupe Peak to 1170 m. above MSL (NAD 1983); a fall of 1497 m. in 22 km. However, in the last 2.025 km. leading to the bridge, fall is 25 m., still quite steep, but gentler than on the mountain slopes.

The Guadalupe Mountains generate orographic rainfall on the mountain slopes themselves, but little of that rain falls in the surrounding desert. Much of the discharge that passes the bridge results from rainfall in the mountains, when rainfall at the site may be completely absent. There are no long-term stream gauges in the area, and rain data is anecdotal. Lack of rainfall statistics by which to model rainfall-runoff, and dissimilarity to other stream gauge sites, makes hydrologic estimation of discharge very difficult or impossible. Interestingly, Guadalupe Arroyo begins high and at extremely steep slopes, but empties into a dry ”salt flat” to the west. Gradient vanishes as it approaches the lake.

Figure 2 is a map of the watershed, with subwatershed boundaries, areas, and longest flow paths denoted. There exist two suitable sites along tributaries where access is readily available to measure hydraulic geometry.

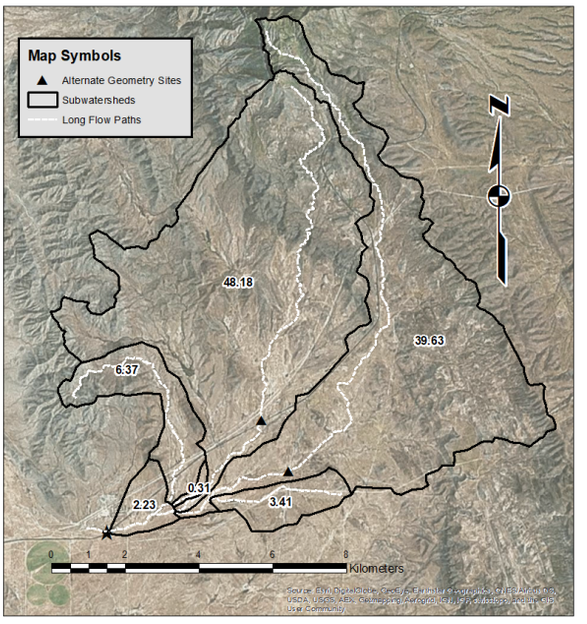

Figure 2: Guadalupe Arroyo Watershed and Subwatersheds. Star denotes the bridge location. Subwatershed areas are in square kilometers.

Watershed vegetation is predominantly upper Chihuahaun desert-type; sparse, drought-tolerant plants, cacti and succulents, pinon, juniper, and woody shrubs. There is substantial bare rock outcrop. Soils are thin and spotty on the slopes, composed of the products of mass wasting, and of thick alluvium adjacent to streams. Streams are all ephemeral- smaller streams may exhibit flow only a few times a year, or none in drought years.

3 STREAM AND SEDIMENT

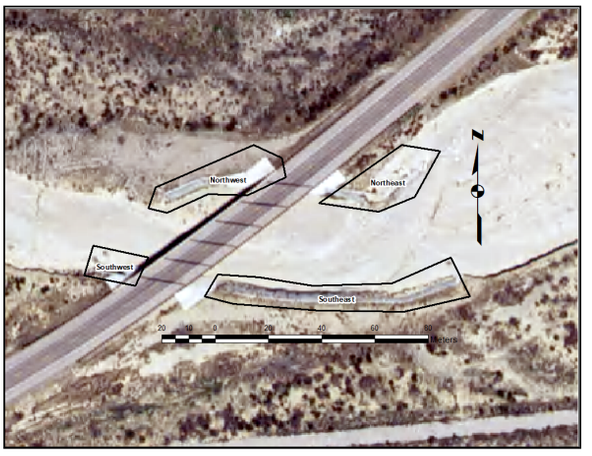
Guadalupe Arroyo is atypical for the extreme elevation change and gradient change over its course, otherwise it resembles many desert streams. Sediment supply is substantial and exhibits a wide size distribution, ranging from silt to large boulders. Because it is ephemeral, 70-80 percent of the sediment transport is likely bed load, rather than suspended load. For the large particles to be transported regularly, hydraulic geometry must be favorable; bank full shape and dimensions are critical to that transport (Rosgen 1996). Figure 3 gives a visual assessment of the sediment in the immediate area of the bridge.

The previous case study concluded that the construction of the bridge had changed hydraulic geometry from natural to one that only considered water, and that sediment transport through the bridge reach had been inhibited. The authors estimated approximately 230 cu. m. of sediment per year had accumulated in the reach approximately 500 m. upstream of the bridge, in the 50 years between construction in 1959 and the study in 2009. The larger particles were preferentially retained, and the stream bed elevated as much as 2-3 meters, forcing lateral movement of the stream by erosion of the banks. Ground artifacts and overhead imagery indicated at least 5 previous attempts to address lateral movement by bank stabilizing revetments.

Figure 3: View of the bridge showing sediment size and distribution. Large particles are readily evident, and are preferentially retained in the bridge reach. (May, 2017 photograph)

4 2009-2010 PROJECT

In 2009, TxDOT funded a construction project intended to address the threat to the Southwest abutment of the bridge using flexible revetment treatments. The common TxDOT practice for addressing this type of issue is rigid concrete slope paving, which is ingrained in the institutional mindset despite a poor performance record. The Herrmann 2009 report recommended that slopes would be best treated with flexible treatments, but cautioned that restoring hydraulic geometry was also needed, and that without restoration of the hydraulic geometry slope treatment would be unlikely to succeed. Despite this specific recommendation, slopes received their armor but the channel restoration was not applied. Figure 4 shows the locations of the various revetments constructed in 2009-2010 and referred to subsequently in this paper.



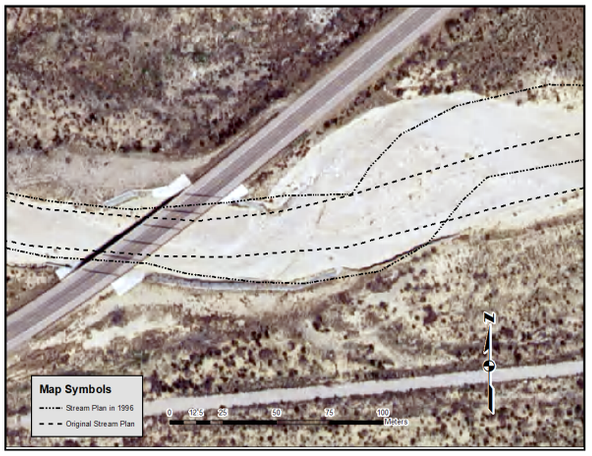


Figure 4: Location of revetments constructed in 2009—2010 with respect to the bridge. (2015 imagery)

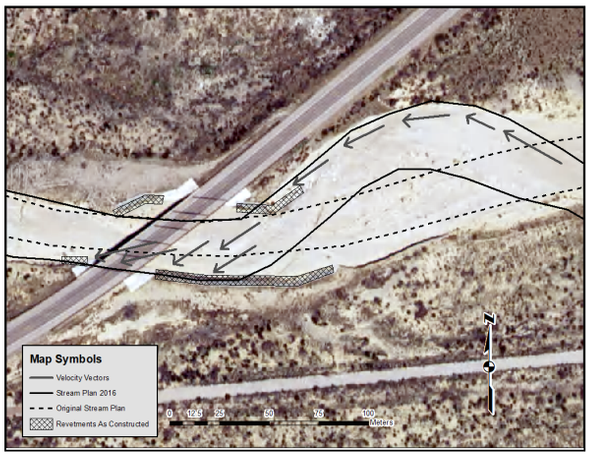

The top of Figure 5 shows the author's estimate of the natural condition stream bank plan view (dashed lines), as well as stream bank plan view circa 2009, both overlaid on 1996 imagery. The figure demonstrates that stream migration was already substantial by 1996 (37 years after construction of the bridge). A series of short-wavelength meanders was developing, indicating flattening of the streambed grade. No artifacts of the original stream geometry are visible in imagery from that time in the vicinity of the bridge, but upstream and downstream it appears natural.

The bottom of Figure 5 shows the natural condition along with the plan as existed in 2016. The meanders are continuing to develop, despite the construction in 2009-2010 of revetments. Velocity vectors of incoming flow are approximated. In two places, at the upper right and lower center, the meanders have resulted in velocity vectors directly impinging on highway embankments and abutments. This redirection of velocity is, in fact, the ultimate cause of problems at the site. Erosion of embankment and abutment material is the visible and immediate threat to the bridge; meander movement is the direct cause of the velocity redirection; aggradation of the stream bed is the cause

of the meander movement, and inhibition of sediment transport through the bridge reach by destruction of hydraulic geometry favorable for bed sediment movement is the cause of aggradation.

(a) Approximate original stream plan overlaid with plan as in 1996 imagery.

(b) Location of revetments constructed in 2009, and with flow velocity direction vectors.

Figure 5: Stream changes between 1996 and 2009, (2015 imagery)

Figure 6 shows two views of the revetments as constructed, shortly after the completion of the project. The top of the figure is taken from near the east end of the southeast revetment, and is looking west, through the bridge. The northwest and southwest revetments can be seen through the bridge opening. The near-bridge end of the northeast revetment can be seen in the same photograph. The bottom photograph looks west northwest from the same point, and shows the remainder of the northeast revetment. No resemblance to a natural stream geometry has been reestablished – the entire bridge opening is presented as area of flow. The practice of creating a geometry that appears to present greater conveyance of water is the activity that triggers instability in such ephemeral streams by creating a ”dead zone” with respect to stream power/sediment transport – essentially a sediment trap.

(a) Revetments viewed west through the bridge from the east.

(b) The northeast revetment viewed from the same point as above.

Figure 6: Post-project photographs from March, 2010.

5 SITE CONDITIONS IN 2017

In May, 2017, the authors revisited the site to assess the effectiveness of the previous project, after 7 years of service. At that time personnel and equipment were at the site to begin data collection for a future replacement project of $1 million USD. The necessity of a repair/replacement project was obvious; the revetments placed in 2009-2010 had failed completely in critical areas, re-exposing the embankments and abutments to severe erosion. Figure 7 show the northeast revetment, and Rigure 8 the southwest revetment. The impinging flow has undermined the revetments, which have collapsed. The stream bed elevation is still approximately what it was prior to construction, indicating bed movement under high flow conditions to considerable depth of sediment.

(b) Southwest revetments viewed in May, 2017.

Figure 8: Southwest revetments after project and in 2017.

(a) Sagging southeast revetment in 2017.

(b) Relatively undamaged northwest revetment, 2017.

Figure 9: Project revetments as seen in May, 2017.

Figure 7 shows before and after views of the debris remaining from the northeast (top) and southwest (bottom) revetments. The remains of concrete footings are readily visible, as they have been uprooted completely. Impinging flow as indicated by flow vectors in Figure 5 ”flanked” the revetments and continued to erode the embankment behind, completely destroying the revetments.

The southeast and southwest revetments were intended to provide protection for the west abutment, undermining of which was the first problem recognized at this bridge. Figure 9 (top) shows the damaged southeast revetment. The undermining of the southeast revetment progressed beneath the bridge and caused a catastrophic failure of the southwest revetment. Direct impinging flow accompanied by extreme bed movement, presented forces that revetments could not withstand.

Of the four ”corners” of the bridge, only the northwest revetment remained unharmed, as shown in Figure 9 (bottom). Because of the geometry of flow, it stood in an area of relatively slack water with no impinging flow.

6 DISCUSSION

The study is an opportunity to observe the effects of human activities on a very fragile system, and how those activities can echo for decades. The preponderance of damage appears to have occurred in calendar year 2015. Rainfall depth in the area in 2015 was approximately 80th percentile of recorded rainfall, or roughly corresponding to a 5-year annual recurrence interval. Damage to the extent observed in seven years, with the largest rainfall in a single year of that frequent depth, and no single month showing an exceptionally large rainfall depth is unexpected, and may be said to be unacceptable.

The transportation branch of the civil engineering community has historically designed stream-crossing structures with consideration only for the passage of water. Streams convey at least two media – water and sediment.

In arid environments, the vast preponderance of streams only flow under conditions of recent rainfall. The inevitable movement of the products of mass wasting from geologic features can only occur during those flows. Bed load sediment transport is the principle mechanism of that movement. The consideration of large bed load movement, and the stream power to accomplish it, should be a part of the design and maintenance processes for transportation structures, in arid areas if not everywhere. Some knowledge of geologic processes, especially fluvial geomorphology, should be accessible to design engineers.

Stream instability such as meander migration, streambank lateral migration, avulsion, embankment erosion, and aggradation/degradation may be symptoms, rather than causes. As in health, treatment of the symptoms may do nothing to cure the underlying cause. In this case, the symptoms are lateral instability, meander development, and meander migration, resulting in threats to the bridge abutments and embankments. The cause is attributed to the destruction of the natural hydraulic geometry (as bankfull stream configuration) necessary for continued sediment throughput decades ago, when the bridge was constructed. Natural sediment movement was inhibited. The resulting accumulation of sediment has locally altered the stream bed gradient, which has resulted in a change in the planform in the reach occupied by the bridge. Several references on fluvial geomorphology exist, and can be of considerable use to the engineer performing designs in fragile streams. Examples are Leopold, Wolman, & Miller 1992, Leopold 1994, Leopold 1997, and Bull & Kirkby 2002.

Figure 10 shows a longitudinal profile (from a digital elevation model) of the stream, beginning approximately 400 m. downstream and progressing approximately 1000 m. upstream. The aggraded reach is clearly shown in this profile as a level section. Many cubic meters of material have accumulated in the upstream reach since 1959. Maintenance forces have

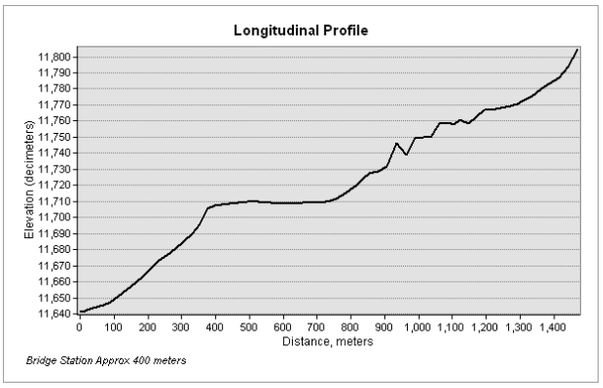

Figure 10: Guadalupe Arroyo Longitudinal Profile. The ”flat” reach beginning at 400 meters is the location of the existing bridge. Flat reaches are indicative of aggradation.

Figure 11: View of box culvert at the crossing of US 62/180 by one of the Guadalupe Arroyo tributaries. Note the accumulation of sediment.

found it necessary to remove large amounts from the bridge opening every year; imagery over time shows material being replaced in the eroding areas, to later be transported away by the erosive forces of water.

As mentioned earlier, four sites present themselves within the same watershed for examination (Figure 2). The measurement of geometry, specifically bankfull width and depth of the stream channel, allow the development of a ”watershed curve” relating those features to contributing area. This analysis would facilitate the calculation of appropriate dimensions for reestablishment in the bridge reach.

Two of the sites thought to be suitable from imagery proved unsuitable in field reconnaissance, the westernmost site proved to have no defined stream channel at all, while the next-westernmost proved to have been heavily impacted by aggradation itself; hydraulic geometry was divided among several braided channels. The box culvert at that location contained approximately 1 meter of sediment accumulation (Figure 11). The presence of this depth of sediment is indicative of impact to the tributary similar to that at the main bridge location.

The remaining two sites provided points for graphing three hydraulic variables- bankfull depth, width, and flow area versus base 10 log of contributing area (Rosgen 2008). Projecting upwards to the entire area contributing at the bridge results in an estimate of these dimensions needed at that location. Figure 12 is a plot of bankfull depth (left) and bankfull width (right) in meters, versus contributing area in hectares. Flow area is estimated as $2/3$ of the bankfull depth times width. Bankfull depth rounded to 1.5 meters, width of 18 meters, and flow area of 17.5 square meters, approximate the hydraulic dimensions needed at the bridge site.

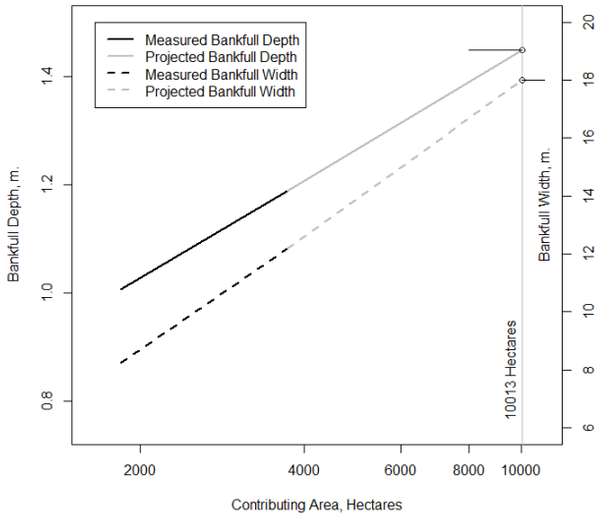

Figure 12: Guadalupe Arroyo bankfull dimensions. Black lines connect two measured site dimensions, while grey lines project from the contributing areas associated with those dimensions to the full watershed contributing area of 10013 hectares.

7 CONCLUSIONS

The examination of the Guadalupe Arroyo site over the period 2008-2017, and the critical examination of attempted treatment, provides several learning opportunities:

1. The visible symptoms of a problem may be misleading. Engineers should use the best science available to ascertain the true nature of a problem.

2. Failure to address the actual problem may result in early failure of expensive projects.

3. Ephemeral streams in arid areas may be extraordinarily fragile. Great care should be taken to avoid disturbing their natural geometry.

4. Moving bed sediment may well include particles much larger than are expected to move easily.

5. Large bed particles may be segregated at locations where stream power is reduced, creating large deposits.

6. Bed sediment may move to depths that exceed ordinary expectation, in areas with steep slopes and large bed material gradation range.

7. Commercially available revetments perform poorly under conditions of impinging flow and large bed sediment movement.

It is clear that the funds spent in 2009-2010 to address long-running stability problems at Guadalupe Arroyo were not well-spent. It appears to have been at least the sixth attempt since 1959 to address the situation with bank stabilizing revetments. The authors contend that further attempts at bank protection will continue to be unsuccessful; recognition that aggradation is the underlying driver, and restoration of favorable hydraulic geometry would be more likely to succeed.

The case under study here emphasizes the fragile nature of ephemeral streams in arid areas, and the ambiguity that may be present at problem sites. Engineers attempting to address problem sites have need of some knowledge of fluvial processes and sediment transport; brute force approaches may be futile. Unless favorable hydraulic geometry is restored to the stream for approximately 500 meters upstream of the bridge, the development of meanders in that reach will continue. In the absence of restoration of the hydraulic geometry, attempts to protect the bridge ends from damage by bank revetment have repeatedly proven futile in the past. There is no reason to believe that further attempts along those lines will meet with success.

In general, the emphasis placed on the design of drainage structures is to conduct only water. As stated earlier, streams invariably transport at least two media- water and sediment. Few engineers are trained or knowledgeable in stream stability and the role of bed load sediment transport. Bed load sediment transport is, even today, poorly understood from a theoretical standpoint. Neglecting the role of sediment in the function of bridges can lead to chronic, expensive bridge damage, as well as adverse impacts to the environmental state of streams.

Chair of Steel, Lightweight and Composite Construction, Ruhr-Universität, Bochum, Germany

ABSTRACT: Cold-drawn high-strength steel for prestressing applications and stay cable bundles is suspected to have reduced fatigue resistance at low temperature between -20° and -50°C (Nürnberger 1981a, Kobrin 1974). For strands as tensile elements of a stay cable, high stress range results from combined low dead loads and high traffic loads and fatigue loading is decisive for the cable design (Svensson 2011). An experimental research project at Ruhr-Universität Bochum investigated the fatigue behavior of 7-wire strands (R_m = 1860 N/mm²) at low temperatures. In total 108 fatigue tests were carried out. The tests were equally distributed at room temperature and at low temperature [-30°C to -50°C]. The specimens were anchored particular in a laboratory anchorage which takes failure on the free length. Similar tests with equal fatigue parameters were carried out with a standard wedge anchorage to investigate the behavior in the anchorage region. In addition to 88 single-stage fatigue tests 20 multi-stage fatigue tests were carried out at room temperature and at low temperature. The multi-stage fatigue tests can be separate in structural durability program tests and in tests with a progressively increasing load range. Latter can be used for an alternative calculation of the endurance strength of strands (Prot 1948).
The single-stage fatigue tests at room temperature showed the expected differences between laboratory and wedge anchored strand specimens. Moreover the results showed a tendency to a reduced fatigue strength for laboratory anchored strands at low temperatures. The fatigue resistance decreased to the level of the anchorage zone at room temperature. A superimposed effect for the fatigue resistance of wedge anchored strands at low temperature was not found. The multi-stage fatigue tests confirmed the reduced fatigue resistance of laboratory anchored strands at low temperature. Moreover an underestimation of the material for the cumulative damage calculation with the linear miner rule can be observed.

1 INTRODUCTION

Stay cable bridges are often used for medium to long spans in different parts of the world and climatic regions. For these bridges, parallel strand bundles with 7-wire strands made of cold-drawn high-strength steel are used worldwide. The fatigue strength usually increases with decreasing temperatures (Suresh 2004). However, former investigations on the strand material show a serious reduction of the endurance strength. Modern strand material possesses higher fatigue resistance (Heeke 2016) in general, but it is unclear if a comparable reduction of the endurance strength at low temperature exists. A follow-up question concerns the usage of the standard wedge anchorage, which provokes micro-notches in the strand surface (Nürnberger 1981b). Normally a fatigue crack starts in the anchorage region at the strand surface by means of notching effects or fretting corrosion with the inner wedge profile. For notched steel specimens in general a higher reduction of the fatigue strength can be found with decreasing temperature (Stephens et al 2001). This leads to the suggestion of a superimposed effect of low temperatures on the endurance strength of prestressing strands.

A bridge bears different stress situations which can be counted to a load spectrum (i.e. rainflow method, reservoir-counting, etc.). By means of the cumulative damage calculation a load spectrum can be calculated to a single-stage fatigue loading. For this calculation different models are available. These models are based on different assumptions (i.e. sequence effects, linear or non-linear damage accumulation, micro damages below the endurance strength). The effect of low temperature on the endurance strength of multi-stage fatigue loading on strands, material and anchored specimens, is accordingly a practical issue and is experimentally analyzed in this paper.

2 TEST PROGRAM & RESULTS

2.1 *Single-stage fatigue tests*

Single stage fatigue tests at room temperature (RT) T_{RT} = 23°C ±5°C and at low temperature (sub-zero temperature = SZT) T_{SZT} = -40°C ±10°C constitute the basis of the test program. First, two test series were carried out on laboratory anchored (Lab) strands at both temperature regions. Second, two test series with specimens anchored by means of a standard wedge anchorage (System) were performed. All

test series were carried out in accordance with the Interactive Method which requires fatigue tests with a varying stress range from the endurance strength up to very high stress ranges with upper loads close to the yield limit. The tests are separated into blocks with four tests in the first block and further with five tests per block. In the first block the both first tests are carried out with high stress ranges, the last two tests are carried out above and below the currently calculated endurance limit. In the following blocks a similar procedure but with each three tests in the low cycle fatigue regime was conducted. Fig. 1 shows a typical schema of the Interactive Method. For all fatigue tests a constant lower load of 29% of the nominal tensile strength was chosen.

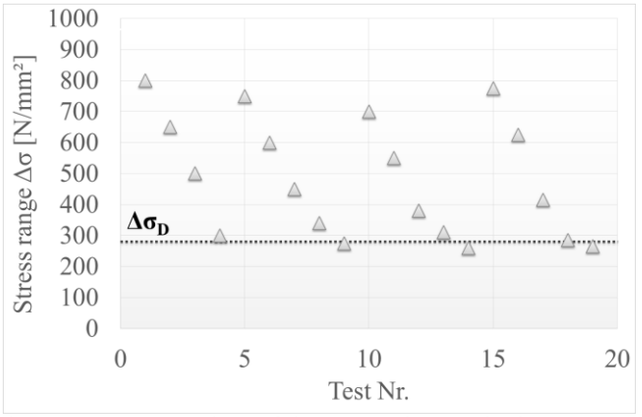

Figure 1. Test procedure of the Interactive Method

The fatigue test was stopped if either wire breakage occurred or 1.1×10^7 load cycles were completed without failure. In the isolated test setups for testing at SZT an increase in the stroke range was used for breakage detection. After test stop for a non-broken specimen a second fatigue loading far more intensive as the first loading was subjected to the specimen. All run-outs were broken in the second stage loading. Afterward the result was checked in comparison with the other test results. If no significant reduction of the fatigue strength was found, the first test was counted as run-out and the second loading was counted as a fully independent fatigue test.

Table 1. Single stage fatigue testing program

Anchorage	Temperature	n
Lab	RT	19+5
Lab	SZT	19+1
System	RT	19+3
System	SZT	19+3

In total 88 single-stage fatigue tests was carried out and are summarized in Table 1. Additionally the parameters of the wöhler functions are shown. Fig. 2 shows all test results and the four different wöhler curves for each test series in a double-log Δσ-N diagram. Three results from series System SZT were found as outliers and were ceased for the further analysis. For the calculation of the wöhler curve parameter all run-outs were recounted to 10^7 load cycles to ensure a conservative data analysis. The stress range can be calculated as a function of three parameters according to the following equation:

$$\Delta\sigma = \Delta\sigma_D + (R_m - \sigma_u - \Delta\sigma_D) \bullet a^{(\lg N)} \quad (1)$$

where R_m = nominal tensile strength; σ_u = lower load; $\Delta\sigma_D$ = endurance strength; N = load cycles; and a & b = positive dimensionless parameter.

System SZT	253	0.9982	4.395

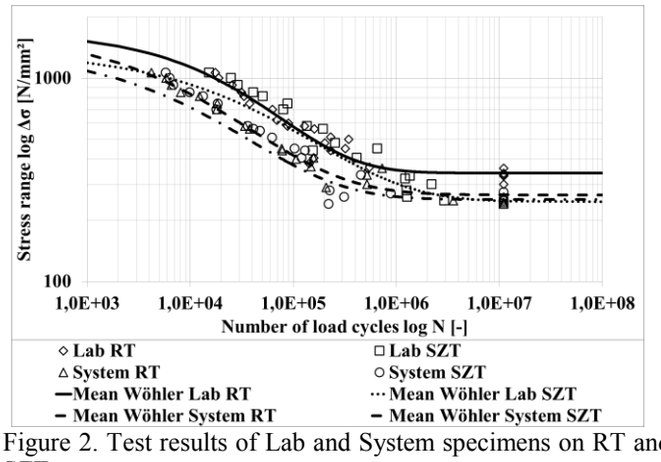

Figure 2. Test results of Lab and System specimens on RT and SZT

2.2 *Multi-stage fatigue tests*

Multi-stage fatigue tests were carried out to analyse the effect of low temperatures on the fatigue behavior of stay cables with common load scenarios. Fatigue tests with specimens with laboratory (Lab) and wedge anchorage (System) were again performed, both at room (RT) and low temperatures (SZT).
The multi-stage fatigue tests based on the purpose by Gasner et al. (1964) which determine operational stability program tests to investigate the fatigue strength of construction elements under a random load. The program tests were based on amplitude collectives who can be described as following:

$$\ln H_i = \left(1 - \frac{\Delta\sigma_{a,i}}{\Delta\sigma_{a,\max}}\right)^{\nu} \ln H_0 \quad (2)$$

where H_i is the cumulative load cycle number for a given stress amplitude $\sigma_{a,i}$; H_0 = block size; $\sigma_{a,max}$ = maximum value of the amplitude collective;

and ν = shape parameter of the collective. The steady function is transferred to a stair step curve with 8 steps which means 8 different stress amplitudes.
The tests were performed with a block size of H_0 = 400,000 load cycles to ensure a significant repetition of the load spectrum and ν = 2.0 which is a lower value for typical bridge traffic loading (Heuler et al. 2005). All tests were carried out with a fixed lower load level mentioned in Chapter 2.1. A test was stopped after 28 block repetitions (11,200,000 load cycles) or if a wire breakage occurred. For the case of a run-out an additional fatigue loading $\Delta\sigma_{add} = \Delta\sigma_{max}$ was performed on the concerning specimen.
All Lab RT specimens withstood the multi-stage fatigue loading and withstood an additional fatigue loading in the amount of an undamaged specimen, as shown in Table 3. Only in the first multi-stage fatigue test at low temperature (SZT) a run-out was found.

	700	3,724.6	

*Start of $\Delta\sigma_{add}$ after unplanned test stop

All tests with System at SZT failed during the multi-stage fatigue loading. In comparison for all specimen at RT with System run-outs occurred, but for $\Delta\sigma_{max}$ = 700 N/mm² two repetitions were made due to unplanned and unexpected breakages. While in the first test an unplanned stop occurred and $\Delta\sigma_{add}$ was applied to the specimen, in the second test the early breakage incited to a second test repetition. Nevertheless the high scatter of this results show the difficulties in fatigue especially with multi-stage loading.

2.3 *Progressive load increase fatigue tests*

In addition to the multi-stage fatigue tests, a fatigue test procedure for a faster determination of the endurance strength of specimens was used for all categories mentioned above. The procedure was developed by Prot (1948) and modified by Dengler & Harig (1980). A minimum of two specimens is needed and both started with a stress range below the assumed endurance strength. For both tests the stress range increased with every load cycle by means of a specific load increasing rate ω. For practical reasons the load increasing was carried out in blocks of a size of 10,000 load cycles. The increasing rates were $\omega_1 = 10^{-4}$ N/mm²/load cycle and $\omega_2 = 10^{-3}$ N/mm²/load cycle which resulted in 0.15 kN/block and 1.5 kN/block. For the calculation of the endurance strength the breakage stress range was noted and placed in a $\Delta\sigma$-ω^n diagram. The linear extrapolation of the connection line between the test results to the ordinate with ω = 0 shows the endurance strength of the specimen.
The results of the load increasing tests on strands with laboratory anchorage and system anchorage are presented in Table 4. All tests were carried out with a constant lower load as mentioned for the single-stage fatigue tests. Tests with a low load increasing rate reached higher load cycles due to a longer duration in the non-destructive fatigue regime below the endurance strength. Remarkable is the result of the first load increasing rate on room temperature compared to the same test on low temperature.

3 ANALYSIS AND INTERPRETATION OF THE RESULTS

3.1 *Single-stage fatigue tests*

A statistical analysis for each series was carried out. In a first step, a non-constant standard deviation with n_{cum} = n/2 from low to high number of load cycles for the calculation of the standard variation was used. Afterwards the 5% quantil values were calculated:

$$\Delta\sigma_{p\%} = \Delta\sigma_m \pm k_n \bullet \Delta\sigma_s \quad (3)$$

where $\Delta\sigma_m$ = mean value of the fatigue strength for a given N, k_n = fractil factor for normal distribution, and $\Delta\sigma_s$ = standard deviation. A second regression

analysis using Eq. 1 was made for the determination of the 5% quantil curve. Next step was the transformation of the wöhler curve into a bilinear fatigue resistance curve which can be describes by the inclinations k1 and k2. For the transformation a limitation of the fatigue resistance curve by means of the yield limit and the lower load was made:

$$\Delta\sigma_{Lim,m} = R_{p,0.1,m} - \sigma_u \tag{4}$$

where $R_{p,0.1,m}$ = mean value of the actual yield limit with a permanent elongation of 0.1% (determined by five static tensile tests).
And in case of the 5% quantil:

$$\Delta\sigma_{Lim,5\%} = R_{p,0.1,5\%} - \sigma_u \tag{5}$$

where $R_{p,0.1,5\%}$ = 5% quantil value of the actual yield limit with a permanent elongation of 0.1%. The bilinear fatigue resistance curve starts at the limitation point and needs the knee point of the wöhler curve k1/k2. The knee point is made with the tangent on the wöhler curve with the fix point at the limitation point and the horizontal expression of the endurance limit. The intersection point marks the knee-point k1/k2, the inclination k1 can be calculated:

$$k1_m = \left(\log \frac{\Delta\sigma_{D,m}}{\Delta\sigma_{Lim,m}} \frac{N_{\lim}}{N_{k1/k2}} \right)^{-1} \tag{6}$$

And in case of the 5% quantil:

$$k1_{5\%} = \left(\log \frac{\Delta\sigma_{D,5\%}}{\Delta\sigma_{Lim,5\%}} \frac{N_{\lim}}{N_{k1/k2}} \right)^{-1} \tag{7}$$

With the inclination k1 the dependent inclination k2 can be calculated:

$$k2 = 2 \bullet k1 - 1 \tag{8}$$

The results of the analysis are summarized in Tables 5 and 6.

Sys. SZT	3.00	5.00	600

In the end the analysis of the single stage fatigue test leads to the results summarized in Fig. 3 and Fig. 4, which shows the technical endurance strength for each series at different levels from $2x10^6$ load cycles to 10^8 load cycles. The values are given for the mean value curves and the associated 5% curves of the wöhler curve and the bilinear fatigue resistance curve.

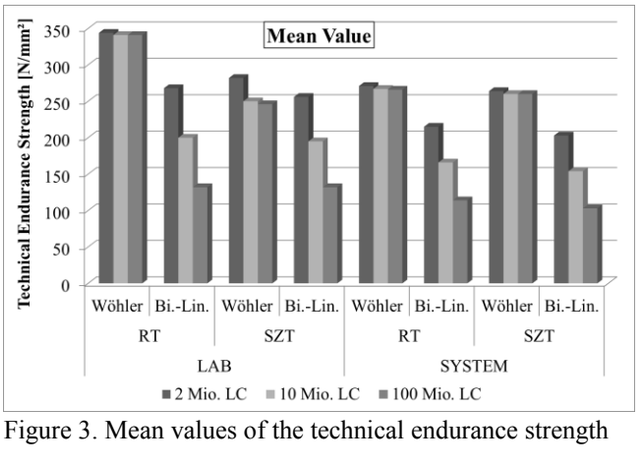

Figure 3. Mean values of the technical endurance strength

A clear trend can be seen with a high difference between room temperature and low temperature for laboratory anchored specimens. No significant difference can be found for wedge anchored specimens between room and low temperature. The decrease of the fatigue resistance from laboratory anchorage to wedge anchorage is in the same order as the reduct ion of the fatigue resistance by means of temperature decreasing for laboratory anchorage. This can be ob

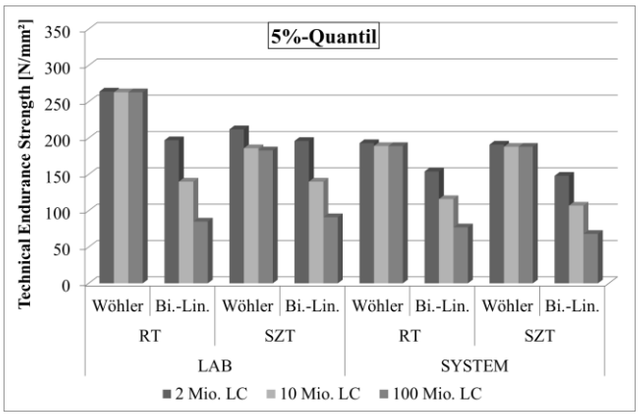

Figure 4. 5% quantil of the technical endurance strength

served in Fig. 5 which shows all mean value functions in a double log Δσ-N diagram. Additional a historical fatigue range shows the results of former fatigue tests, the reference curves of the international recommendations for stay cables from PTI and fib are additionally shown.

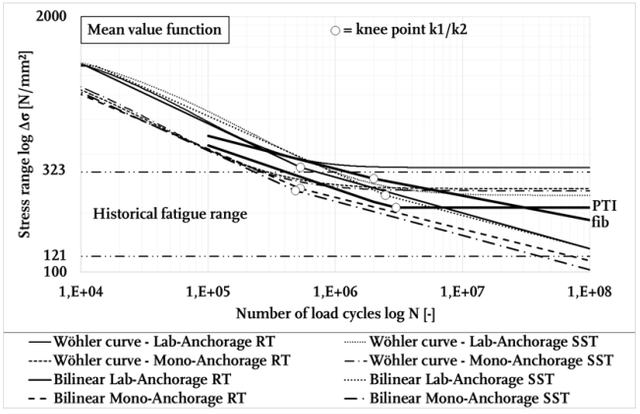

Figure 5. Summarized analysis results of the single-stage fatigue tests

3.2 *Multi-stage fatigue tests*

Linear and non-linear damage accumulation analysis was made. The following linear methods were applied: [1] the original wöhler curve (Palmgren 1924), [2] the elemental rule of Miner (1945) (k2 = k1), [3] the bilinear fatigue resistance curve by Haibach (2006) and [4] the modification of the bilinear resistance curve by Zenner & Liu (1992). The results of the established wöhler curves obtained from the single-stage fatigue tests were used to calculate the parameters of the different models.

The findings of the first two linear methods are shown in Table 7, besides the additional damage $d_{i,add}$ is shown here for Run-Outs.

Table 7. Damage D and $d_{i,add}$ found by linear damage analyis

The linear damage accumulation leads to an overestimation of the calculated damage. Especially for Run-outs an additional damage $0.68 \leq d_{i,add} \leq 2.25$ can be found. Moreover the system anchored specimens shows the higher tendency to an overestimation of the calculated damage.

Table 8 presents the linear damage accumulation in accordance to the Miner Origin and the bilinear modification by Zenner & Liu (1992).

Both methods do not use an endurance limit and hence the calculated damage increases in all tests.

Therefore the overestimation here is aggravated compared to [1] and [3].
The non-linear damage accumulation analysis was carried out in accordance to the methods of [5] Subramanyan (1976), [6] Hashin & Rotem (1978) and [7] Manson et al. (1967). All models were configured by means of the single-stage fatigue data. The results of the analysis are summarized in Table 9.

The analysis model by Subramanyan (1976) fail in the calculation of the System RT with the highest $\Delta\sigma_{max}$ if additional fatigue loading after the Run-out was carried out. In other cases especially for Lab SZT a good agreement can be seen. The calculation made by Hashin & Rotem (1978) shows in general the best agreement in all multi-stage fatigue tests while the calculation method in accordance to Manson et al. (1968) delivers some extraordinary overestimations due to the non-linear nature of the analysis. In general it is obviously that reduced fatigue strength in multi-stage fatigue tests can be observed at SZT directly and after the linear and non-linear damage accumulation analysis. These findings can be seen for Lab and System specimens.

3.3 *Progressive load increasing fatigue tests*

The findings of the progressive load increasing tests analysis depends on the load increasing rate ω and the exponent n. While ω is chosen before the test, n can be determined in different ways. In the origin form by Prot (1948) of the load increase tests n = 0.5, a modification was made by Dengel & Harig (1980) gives n = 1/(k1+1) which consider the inclination of the wöhler curve in the regime of the fatigue strength. Table 10 shows the results of the analysis and the comparison with the endurance strength $\Delta\sigma_{D,W}$ established by the single-stage fatigue tests. In three of four cases the accelerated method is in the vicinity of the Wöhler results for $\Delta\sigma_{D,P}$ (n=0,5). Only for Lab specimens at room temperature a high overestimation was observed. This overestimation remain nearly unchanged for $\Delta\sigma_{D,P}$ (n=1/(k1+1)), but here the other results shows a high underestimation.

Table 10. Endurance limits from progressive load increasing fatigue tests in comparison to the wöhler endurance limit

	$\Delta\sigma_{D,W}$	**$\Delta\sigma_{D,P}$ (n=0,5)**	**$\Delta\sigma_{D,P}$ (n=1/(k1+1))**
	[N/mm²]	**[N/mm²]**	**[N/mm²]**
Lab RT	341	509	483
Lab SZT	247	280	106
Sys. RT	266	230	153
Sys. SZT	253	249	167

Regarding the effect of SZT in comparison of RT a clearly tendency can be seen in the fatigue tests under progressive loading. The Lab specimens show a clear reduction in the fatigue strength while no significant difference for System specimens can be seen.

4 CONCLUSIONS

The effect of low temperature on the fatigue strength of cold-drawn high strength steel strands has been experimentally investigated. Four wöhler curves and bilinear fatigue resistance curves have been determined based on the results of 88 single-stage fatigue tests. A statistical analysis of the test data showed the different scatter of the wöhler and bilinear curves. In the low cycle fatigue regime the fatigue strength of Lab specimens increases if the temperature is decreased from RT to SZT.For these low temperatures, a significant reduction of the endurance limit was additionally verified. The reduction of the endurance limit by means of SZT has a comparable amount as the reduction by means of the harmful effects initiated by the wedge anchorage.
The results of multi-stage fatigue tests with a typical bridge load collective confirmed the decreasing effect of SZT on the fatigue strength of 7-wire strands. These results also indicated the tendency of slightly lower fatigue strength for wedge anchored strands. Common linear and non-linear analysis overestimates the accumulated damage compared to the multi-stage fatigue tests. The results of the progressively increasing load tests provide experimental evidence on the suitability of this test method for the determination of the endurance limit of system anchored strand specimens. For laboratory anchored strands, the test results a harmful effect under SZT compared to RT to the endurance limit.

Multi-scale finite element model updating of highway bridge based on long-gauge strain response

Shizhi Chen & Gang Wu & Huile Li.
Key Laboratory of Concrete and Prestressed Concrete Structures of the Ministry of Education, Southeast Univ., Nanjing 210096, China.

ABSTRACT: The damages in the bridges severely endangered their lives. In order to ensure the safety and facilitate daily maintenance, the methods for detecting damages were needed. Conventional damage identification methods based on finite model updating achieved in precisely damage detection. However, their processes of finite element updating would cost a lot of computing time. Also, the finite element updating methods require multi-order modes of the bridges, which are difficult to obtain in actual scenes with regular traffic condition. Under such circumstances, this paper presented a bridge finite element updating method based on long-gauge strain response. This method utilizing long-gauge FBG sensors has two steps. The first step is to detect the location of the damage initially using a damage localizing method. Then in the second step, on the basis on step 1, the damage would be further determined through finite element updating through a multi scale element model to measure the location and extent of the damage more accurately. With the combination of step 1 and 2, the computation complex would be reduced greatly without harming the identification accuracy. In order to verify this method, an experiment was conducted in laboratory. In the experiment, the long-gauge strain response of the bridge models with a damage condition was extracted by the long-gauge FBG sensors mounted beneath them. Utilizing this method, the damage conditions can be successfully detected in the bridge model, which verified the potential of this method.

1 INTRODUCTION

Bridges, as one of the lifeline civil engineering structures, play an important role in the economic sphere and people's safety. The designed life expectancy of these bridges usually ranges from 50 to 100 years. During the service life of bridges, the performance will deteriorate when they are subjected to normal traffic load, occasional excessive load, and earthquake load. Moreover, because of the steady development of the global economy and national transportation industries, traffic loading has significantly increased in recent decades. This would further accelerate the deteriorating process of the bridges (Richardson & Jones 2014). Under this circumstance, it is essential to operate routine monitoring of bridges to prevent potential damages.

Nowadays, structural health monitoring is becoming more and more popular. Compared with conventional manual inspect, it is less time consuming and more efficient which could fulfill long-term damage monitoring of the bridge (Brownjohn 2007). In this field, there are many damage identification techniques, among which finite element (FE) model updating technique is an efficient way for damage location and extent identification (Teughels & De Roeck 2004, Brownjohn et al. 2001).

FE model updating techniques have been a viable approach to correcting an initial mathematical model based on monitored data. The objective of structural model updating is to reduce inherent modeling errors in FE models due to simplifications, idealized connections, and uncertainties of material properties. Updated FE models, which have less discrepancy with real structures, give more precise predictions of structural property for future analyses (Jaishi & Ren 2005). It can be an effective way for structural damage identification.

As mentioned above, the procedure of model updating aims to adjust the uncertain properties of the FE model by minimizing iteratively the differences between the measured reference index and the corresponding analytical predictions.

Currently, there are two kinds of model updating methods, direct model updating method and indirect model updating methods. Direct model updating techniques involve updating models using a single updating formula or series of formulas based upon modal parameters (Eskew & Jang 2017). Indirect model updating technique involves optimization of parameters in the model, such as stiffness, young's modulus based on discrepancies between model and monitored structural information. Compared with indirect model updating method, direct method does not ensure the connectivity and physical meaning of the model. Hence, most studies about model updating nowadays belong to indirect updating method.

For reference index to updating model, most methods usually choose natural frequencies and modal shapes of the structure. A lot of studies succeeded in utilizing these indexes for FE model updating. However, in actual engineering natural frequencies do not contain spatial information which is not sensitive to structural local damage and modal shapes are not easy to obtain, especially for high level modes which are usually more sensitive to local damage of the structure (Salawu 1997, Hong *et al.* 2014). All these difficulties made it very inconvenient for application in SHM systems. Some new indexes were proposed, such as mode shape curvatures, modal strain energy, and other modal based dynamic characteristics for model updating with better performances.

As for the process to adjust FE model parameter, it is a parameter optimization process, whose object function is to minimize the difference of reference index between FE model and actual engineering by optimizing the uncertain properties in FE model, such as element stiffness. Optimizing algorithm such as genetic algorithm, particle swarm algorithm need run FE model independently in every iteration, as a result of which the process would be time consuming and inefficient. To solve this problem, time needed for running FE model need to be reduced. Therefore, FE model need to be simplified as far as possible without harming the accuracy. Besides, response surface method was also an effective way for this problem.

Under such circumstance, in this article, based on monitored long-gauge strain signal, a two-step FE model updating method is initially proposed. A new reference index in time domain and a new corresponding object function is established. The feasibility of the method has been verified through a vehicle-bridge interaction simulation on the basis of an indoor model experiment.

2 THEORETICAL BACKGROUND

2.1 *Long-gauge FBG sensor*

The long-gauge FBG sensor was proposed by Li & Wu (2007). The basic structure of this sensor is presented in Figure 1. The long-gauge FBG sensor consists of two end anchor points with an FBG between them. The shield sleeve plays the role of protection and keeps the inner FBG free from structural deformation. With this structure, the sensor could measure the average strain between two anchor points unlike conventional sensors based on single-point measurement. In practical engineering, conventional point sensors are easily affected by discontinuous characteristics of structures, such as cracks and inclusions. In contrast, long-gauge FBG sensors are more robust to these characteristics owing to their structure (Kim *et al.*, 2016). One other advantage of this sensor is its multiplexing capacity. This capacity means that, to cover a certain region of a structure, many sensors can be installed with minimal wiring. For large structural engineering projects, such as bridges, its installation would be more convenient than that of conventional strain gages because each normal strain gage requires at least two lead wires, which would lead to a large number in total (Kang *et al.*, 2007; Moyo *et al.*, 2005). In addition, it still has the advantages of traditional FBG sensors, such as immunity to electromagnetic interference, light weight, and small size like Figure 2 shows.

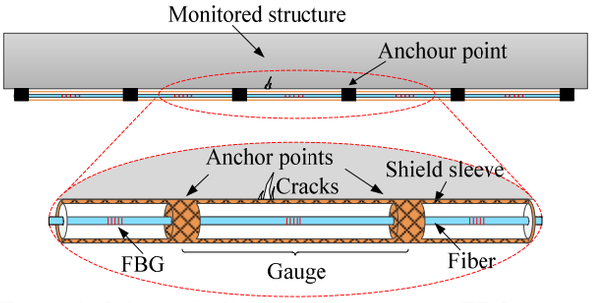

Figure 1. Schematic diagram of long-gauge FBG sensor.

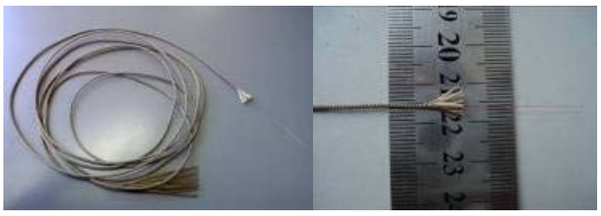

Figure 2. actual scene of long-gauge FBG sensor.

2.2 *Damage identification method*

The damage identification method is proposed by Chen *et al.* (2017) which utilized long-gauge strain influence line (SIL). For brevity, the method is simply introduced here and all the details of this method are thoroughly provided in Chen *et al.* (2017).

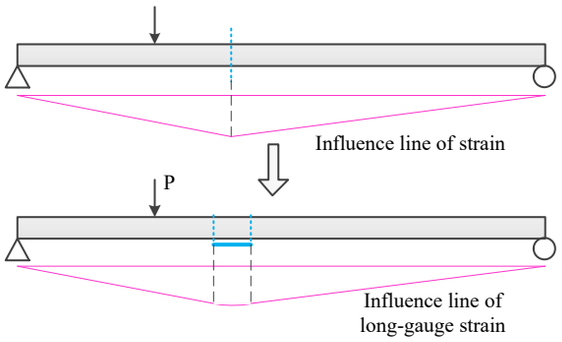

Figure 3. Comparison between traditional SIL with long-gauge SIL.

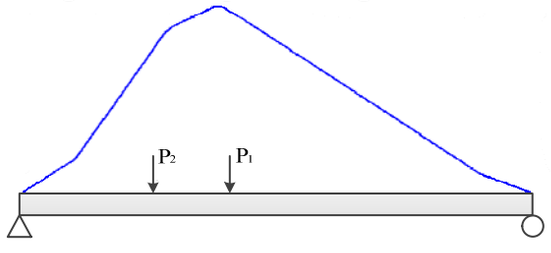
According to classic structural mechanics, the static long-gauge strain history of a single moving force is:

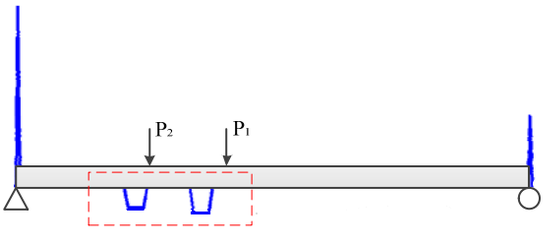
$$\varepsilon(x)=\begin{cases}\dfrac{(L-x_i)y}{(EI)_i L}x & x\in[0,x_i)\\ \dfrac{x_i y}{(EI)_i}\left(1-\dfrac{x}{L}\right) & x\in[x_i,L]\end{cases} \quad (1)$$

In the meantime, based on the definition of long-gauge strain, the relationship between conventional 'pointy' strain and long-gauge strain can be expressed in Equation 2.



$$\bar{\varepsilon}_m(x)=\frac{1}{l_e}\int_{ml_e}^{(m+1)l_e}\varepsilon(x)\,dx \quad (2)$$

After substituting Equation 1 into Equation 2, the formulas of long-gauge SIL can be obtained. The specific expressions of long-gauge SIL are omitted here because of their complexity. The core of this damage identification is focused on one special property of long-gauge SIL. Long-gauge SIL is a two order function only when the load is within the range of the sensor, like Figure 3 shows.



Beyond the range of the sensor, it is a linear function of t. Taking two order derivative of long-gauge SIL, Equation (3) can be deduced.

$$\frac{d^2\bar{\varepsilon}_m(t)}{dt^2}=\begin{cases}0 & t\in[0,ml_e/v)\\ -P\cdot v^2\cdot\dfrac{n\bar{y}_m}{(\overline{EI})_m} & t\in[ml_e/v,(m+1)l_e/v)\\ 0 & t\in[(m+1)l_e/v,L/v]\end{cases} \quad (3)$$

in which n is the total number of the gauge distributed along the entire span of the girder.

a. long-gauge strain influence line under a two-axle vehicle

b. two order derivative of long-gauge strain influence line

Figure 4. long-gauge strain influence line and its two order derivative.

Figure 6 displays the two order derivative of long-gauge SIL under two moving loads. According to Equation (3), it can be seen that the height of each rectangular part in Figure 4 is related to structural bending stiffness within each sensor. According to this relationship, the damage location can be initially located.

An index vector would be obtained by combining two order derivative (TOD) of SIL in each gauge which contains structural spatial information.

$$Index=\{TOD_1,TOD_2,\cdots,TOD_n\} \quad (4)$$

2.3 *Two-step FE model updating method*

The flow chart of this two-step model updating method is proposed in Figure 5. The first step is to locate the damage using the damage identification method introduced in the last section. Then in the second step, the FE model would be established in a multi-scale manner to reduce calculating time. The gauge where damage is located would be established using solid elements. For the other parts of the bridge, only beam element would be used. The disposal of the connection between different elements is displayed in Figure 6. The freedoms of solid elements are coupled with the node of beam element by several constraint equations.

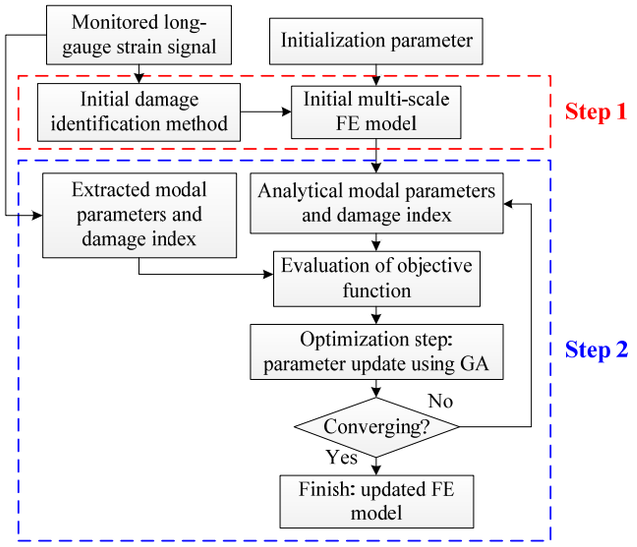


Figure 5. Flow chart of two-step model updating.

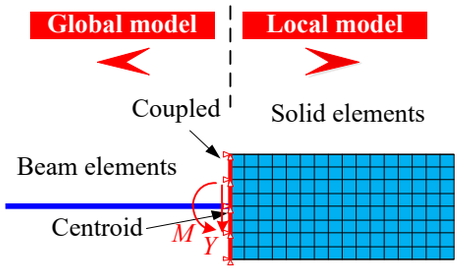

Figure 6. Connection between beam elements and solid elements.

As for the object function of this updating method, it is a combination of frequency and time domain index, which is shown in Equation (5).

$$\min f(x)=\alpha\cdot\frac{\left\|Index_s-Index_m\right\|}{\left\|Index_m\right\|}+\beta\cdot abs\left(\frac{f_s-f_m}{f_m}\right)+\gamma\cdot\left(E_s-E_0\right)^2 \tag{5}$$

where α, β, γ are optimization parameters and the last item of the function is for regulation in order to avoid solutions with no physical meanings. Subscript s, m represent the model simulated information and monitored information, respectively. In addition, index vector need to be normalized in advance in order to quantify the difference. E_0 is original elastic modulus.

The frequency of the monitored structural is obtained through Frequency domain decomposition (FDD) method.

The optimization genetic algorithm is utilized to solve this problem. Genetic algorithm (GA) is an excellent global optimization method inspired by the process of natural selection that belongs to the larger class of evolutionary algorithms. It has been verified to be an efficient method in application in structural engineering (Ye & Wu 2017).

3 VEHICLE BRIDGE COUPLING SIMULATION

In this section, a vehicle bridge coupling (VBC) system is developed to verify this model updating method. In-service bridges normally work within the linear-elastic range under routine traffic load; therefore, the following derivation was carried out under the assumption of elasticity.

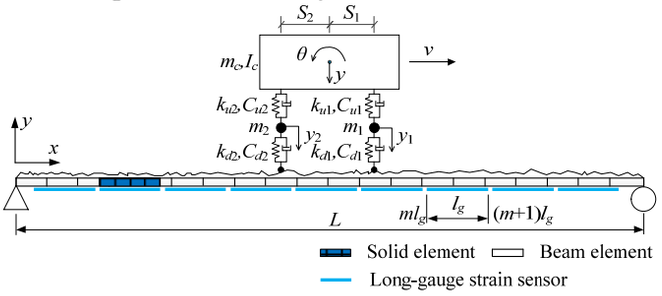

Figure 7. Model of the vehicle-bridge interaction system.

Figure 7 shows a four-degrees-of-freedom (DOFs) vehicle model moving at a uniform speed v over a simply supported bridge whose bottom surface is covered by long-gauge FBG sensors with l_g gauge length. Using the Lagrange formulation, the equation of motion of the vehicle model is derived as follows (Law & Zhu 2004, Wu & Law 2011):

$$\begin{bmatrix}\boldsymbol{M}_{c1}&0\\0&\boldsymbol{M}_{c2}\end{bmatrix}\ddot{\boldsymbol{Y}}+\begin{bmatrix}\boldsymbol{C}_{c11}&\boldsymbol{C}_{c12}\\\boldsymbol{C}_{c21}&\boldsymbol{C}_{c22}\end{bmatrix}\dot{\boldsymbol{Y}}+\begin{bmatrix}\boldsymbol{K}_{c11}&\boldsymbol{K}_{c12}\\\boldsymbol{K}_{c21}&\boldsymbol{K}_{c22}\end{bmatrix}\boldsymbol{Y}=-\begin{Bmatrix}0\\\boldsymbol{P}(t)\end{Bmatrix}+\begin{Bmatrix}0\\\boldsymbol{P}_0\end{Bmatrix} \tag{6}$$

in which $\boldsymbol{Y}$ is the response vector of the vehicle, which corresponds to four DOFs; $P(t)$ is the interaction force vector between the vehicle and bridge; and P_0 is the static axial weight of the vehicle. $\boldsymbol{M}_c$, $\boldsymbol{C}_c$, $\boldsymbol{K}_c$ are submatrices of the vehicle's mass, damping and stiffness matrices, respectively.

The intact bridge is assumed to be an Euler-Bernoulli beam. And damaged gauge is modeled using solid element for finer solution. The equation of motion of the bridge can be expressed as:

$$\boldsymbol{M}_b\ddot{\boldsymbol{R}}+\boldsymbol{C}_b\dot{\boldsymbol{R}}+\boldsymbol{K}_b\boldsymbol{R}=\boldsymbol{H}_l\boldsymbol{P} \tag{7}$$

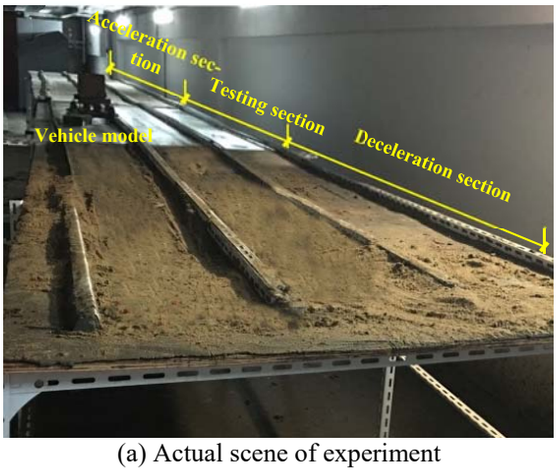
where $\boldsymbol{M}_b$, $\boldsymbol{C}_b$ and $\boldsymbol{K}_b$ are the mass, damping and stiffness matrices of the bridge structures, respectively, $\boldsymbol{C}_b$ is obtained with the assumption of Rayleigh damping, $\boldsymbol{R}$ is the nodal displacement vector of the entire bridge, the point (.) above $\boldsymbol{R}$ represents derivation with respect to time, and $\boldsymbol{H}_l\boldsymbol{P}$ is the equivalent nodal load vector. $\boldsymbol{H}_l$ is the location matrix of each axial interaction force.

According to the equilibrium of the interaction force between the bridge and vehicle, the coupled equation of motion of the vehicle-bridge interaction system can be obtained by combining Equation (6) with Equation (7):

$$\boldsymbol{M}(t)\ddot{\boldsymbol{Z}}+\boldsymbol{C}(t)\dot{\boldsymbol{Z}}+\boldsymbol{K}(t)\boldsymbol{Z}=\boldsymbol{F}(t) \tag{8}$$

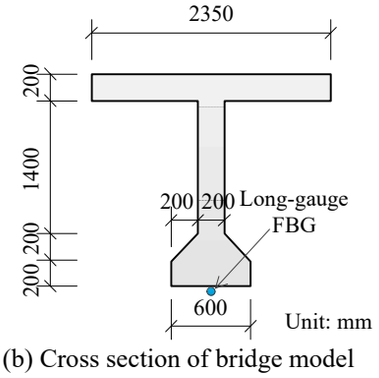
where $\boldsymbol{Z}=\{\boldsymbol{Y}^T\ \boldsymbol{R}^T\}^T$ is the total displacement vector of the vehicle-bridge interaction system; $\boldsymbol{M}(t)$, $\boldsymbol{C}(t)$ and $\boldsymbol{K}(t)$ are the mass, damping and stiffness matrices of the entire vehicle-bridge interaction system; and $\boldsymbol{F}(t)$ is the external force vector.

Equation (8) can be solved by the Newmark-β method. Then, the dynamic nodal response of the bridge under a moving vehicle can be obtained. Then coordinating with the arrangement of long-gauge FBG sensors, the dynamic long-gauge strain response can be extracted.



4 NUMERICAL VERIFICATION BASED ON EXPERIMENT

Based on the theory of last section, a VBC simulation was developed based on the results of Wu *et al.* (2017)'s indoor experiment. The actual scene of the model experiment is presented in Figure 8. The bridge model consists of five T-beams which are made of



plexiglass. The detail of the model bridge cross-section is shown in Figure 8 (b). Whole model can be divided into three sections longitudinally, acceleration section, testing section and deceleration section, just as Figure 8 displays. The testing section is 3 m long. The model vehicle is a biaxial vehicle as shown in Figure 9. In order to monitor the long-gauge strain response caused by moving model vehicle, 9 long-gauge FBG sensors whose gauge length is 30mm were attached on the bottom surface of testing section.

Based on the arrangement of the experiment, a VBI system was established in ANSYS and Matlab software. The bridge model consists of 18 beam elements and 95 solid elements. 9 long-gauge strains under the bridge are extracted corresponding to 9 long-gauge FBG sensors in experiment. The FE model is presented in Figure 11. In order to mimic the experimental situation, white Gaussian noise is added to the original signal using the command 'awgn' in Matlab. The signal-to-noise ratio is set as 20 dB, because with this value, the simulation results are more close to the results obtained in Wu *et al.* (2017)'s experiment. The optimization process is achieved by MATLAB optimization tool box. In each iterative generation, population size is set as 50.

In experiment, the beam section within gauge 4 is cut in order to reduce 10% bending stiffness in gauge 4. The initial FE model is established using original designed parameters.

(a) Actual scene of experiment

(b) Cross section of bridge model

Figure 8. (Wu *et al.*, 2017)'s experimental arrangement.

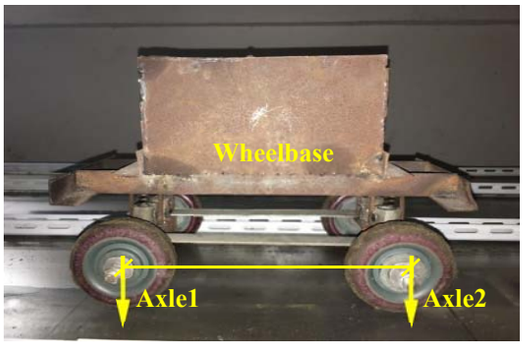


Figure 9. Vehicle model adopted in (Wu *et al.*, 2017)'s experiment.

Firstly, using method introduced in section 2.2, the damage location can be directly decided, as shows.

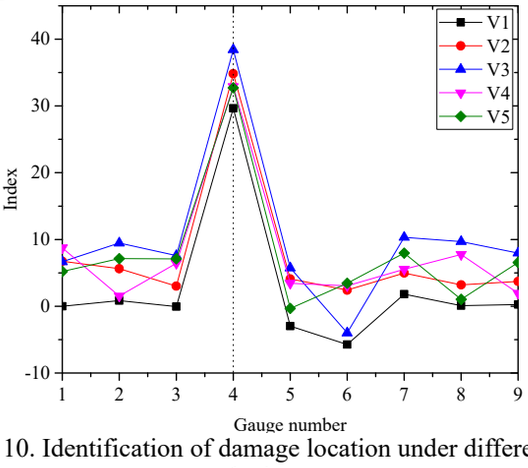

Figure 10. Identification of damage location under different velocity

Then the FE model's 4th gauge is modeled using solid elements. Choosing elastic modulus as optimizing parameter, after 50 generations' iteration in GA, the value of object function converged, just as Figure 12 shows. The blue circle represents the mean performance in each generation and the red point is the best individual in each generation. The whole optimization process seems to be successful. Meanwhile, the distribution of the beam before and after optimization is displayed in Figure 13, where object, initial and after optimization represent the actual one in experiment, initial value in FE model and the one updated using GA, respectively. It can be observed that after optimization, the bending stiffness error between actual structure and updated FE model is reduced dramatically.

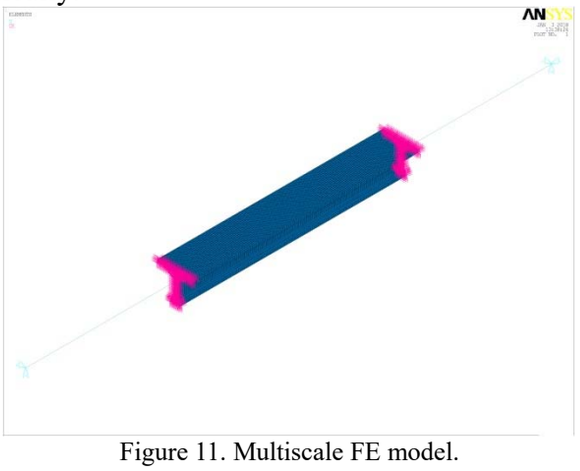

Figure 11. Multiscale FE model.

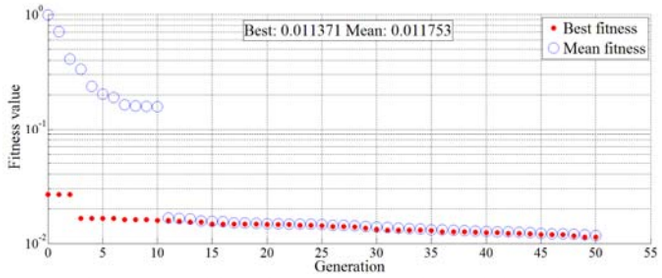

Figure 12. Object function value in each iteration.

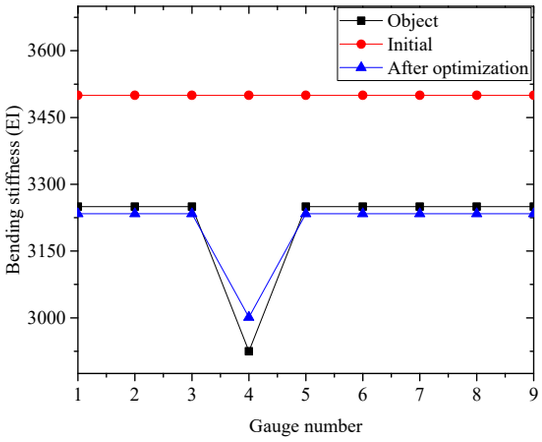

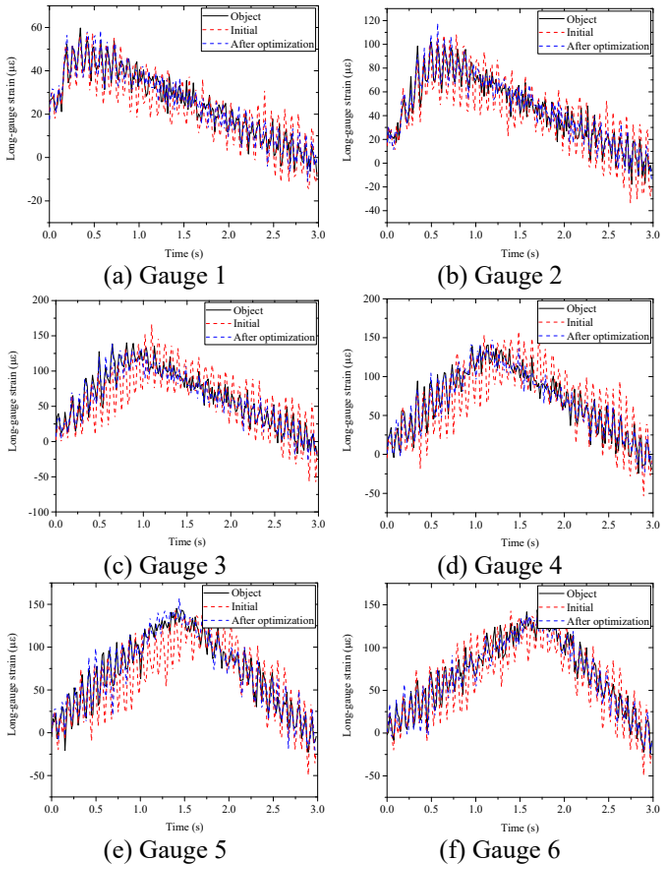

Figure 13. Identified bending stiffness distribution.

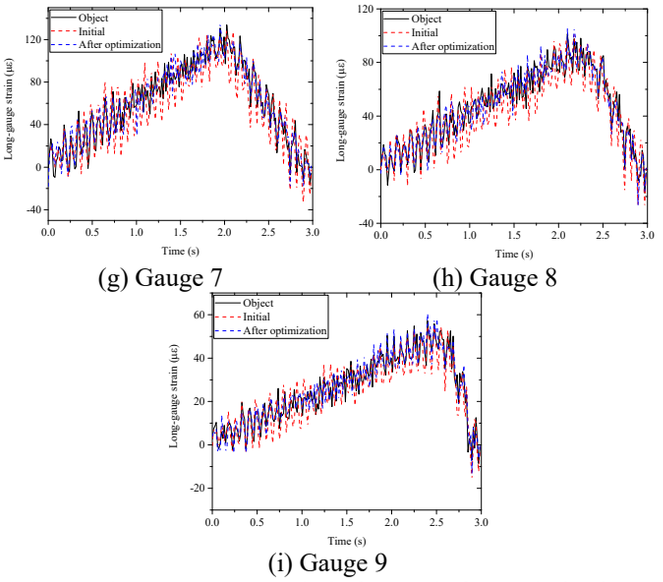

In order to further examine the updated model's performance, the long-gauge strain time history in each gauge is compared with actual monitored signal, displayed in Figure 14. The difference between initial model and updated model is obvious. The performance of updated model is much more similar to the actual monitored signal. The error of FE model has been successfully controlled at a low level.

5 CONCLUSIONS

In this article, a two-step multi-scale model updating method was initially proposed based on monitored long-gauge strain signal. Its feasibility is initially verified through numerical simulation combined with an indoor model experiment. It can be found that it has the potential to be utilized in actual application. Even though, the in-situ testing is needed in the future.

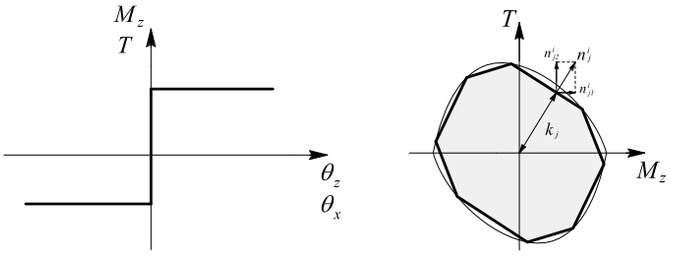
ABSTRACT: The paper concerns the analyses carried out on an old, severely damaged 34.70 m long and 9.20 m wide R.C. grillage deck, composed of four longitudinal beams and five cross-beams. The deck is part of a 28-spans viaduct, built in 1968, which exhibits a severe corrosion state, due mainly to salted water coming from the roadway platform. The study is aimed at assessing how the bearing capacity of the structure varies over time, depending on the progression of corrosion phenomena, and to searching for the corresponding collapse mechanisms. The work starts by presenting the hypotheses and algorithms at the base of the Limit Analysis procedure developed for the specific purpose of this study, followed by a brief recall of the damage model assumed to represent the deterioration in time of the mechanical properties. The most important conclusions highlight how the damage, represented according to different scenarios, determines not only a reduction of the local bearing capacity, but also an internal force redistribution towards the undamaged structural elements. The conclusions of the study were taken into account in the actual design of the deck repairing interventions. In fact, the design focussed not only on substituting/repairing the elements which had undergone the most damage, but also assessed the robustness of the deck in its entirety, verifying that the undamaged elements had sufficient bearing capacity to carry the increase of internal forces derived from the redistribution mechanism.



1 INTRODUCTION

As known, R.C. and P.C. bridges and viaducts with some decades of service life may exhibit severe damage states due to aggressive agents from environmental and service conditions. For this reason, many Road and Highway Administrations are faced with two typical problems: *(a)* in designing new bridges, estimate their bearing capacity after a certain amount of years from construction time under given environmental and service condition; *(b)* for existing bridges, assess their residual bearing capacity in the damaged state after a certain amount of years from construction time. Both these problems may be solved through a unique approach consisting in an analysis of the diffusion of the deterioration processes induced by aggressive agents, followed by the analysis of the damaged structure. This research is specialized to grillage decks made of beams and cross-beams. The deterioration process is supposed to be induced by chlorides diffusion and is investigated by means of the Cellular Automata technique. The structural assessment is carried out through Limit Analysis by considering the reinforcement reduction due to corrosion. With reference to the case of a grillage deck built in the 60s and severely damaged, the results of the analyses allow to evaluate how the damage reduces the bearing capacity of the most exposed elements at present and how the internal forces redistribute towards the undamaged structural element. For new bridges, the results of this methodology allow to assess the structural response at different times of their life.

2 LIMIT ANALYSIS FORMULATION

The Limit Analysis and its applicability to R.C. structures have been widely studied and discussed in the works by (Martinez y Cabrera, Biondini, Malerba, & Bontempi 1997), (Biondini & Frangopol 2008), (Conti, Malerba, & Quagliaroli 2017) and others. For

the purpose of this work, a force-based finite element for the Limit Analysis of three-dimensional R.C. framed structures is proposed. The hypotheses of small displacements and stable structure are assumed. Interacting internal generalized plastic forces are the bending moment M_z and the torque moment T. Shear effects are neglected. Stresses and correlative generalized plastic strains are related by a rigid perfectly-plastic constitutive law Fig. 1(a). In this way, the behavior of the discrete cross-sections where the plastic strains tend to develop, can be represented by a plastic hinge which makes this kinematic behaviour possible and, at the same time, fully transfers the corresponding plastic values of the bending moment and torsion. The ultimate values of M_z and T are correlated through a curve in the (M_z-T) plane, which bounds a convex domain containing the origin of the axis Fig. 1(b). Such a frontier can be idealized by a stepwise approximation, which, for safety's sake, is assumed inscribed within the effective curve. We assume that the formation of plastic hinges occurs at the ends of the elements. The resulting approximations can be overcome by increasing the number of the elements. The plastic collapse is reached when the set of generalized plastic hinges allows the activation of a kinematic mechanism, for which the equilibrium can no longer be satisfied. In the discretization, distributed loads are replaced by equivalent concentrated loads applied in an appropriate number of cross-sections.

(a) Rigid plastic behaviour. (b) T-M_z domain.

Figure 1: Limit Analysis hypotheses.

2.1 *Equilibrium and compatibility conditions*

For the generic *j-th* element of the structure, the equilibrium conditions are set in accordance to the force method. In the local coordinate system, by removing the rigid body motions, the internal forces $\mathbf{r}_i = [M_z, T]$ at the sections ($x = 0, l$) are expressed in function of the basic forces $\bar{\mathbf{Q}}_j$ at the end nodes n_1, n_2 (Fig. 2) from simple equilibrium equations $\mathbf{r}_i = \mathbf{h}_b \bar{\mathbf{Q}}_j$. In the same way, the end global forces $\mathbf{Q}_j$ are derived from $\bar{\mathbf{Q}}_j$ as $\mathbf{Q}_j = \mathbf{h}_l \bar{\mathbf{Q}}_j$. Through a coordinate transformation, the end global forces $\mathbf{Q}_j$ are rewritten in the global coordinate system as $\mathbf{Q}_{g,j} = \mathbf{T}_\alpha \mathbf{Q}_j = (\mathbf{T}_\alpha \mathbf{h}_l)\, \bar{\mathbf{Q}}_j = \mathbf{H}_{g,j} \bar{\mathbf{Q}}_j$, with $\mathbf{T}_\alpha$ the orthogonal transformation matrix and $\mathbf{H}_{g,j}$ the transformed equilibrium matrix for *j-th* the element.

By assembling over all the *ne* elements, we obtain the global equilibrium equations which correlate the vector $\mathbf{Q}_t$, containing all the element basic forces, to the external nodal forces vector $\mathbf{F}_e$, by means of the equilibrium matrix $\mathbf{H}$ of the whole structure.

$$\mathbf{F}_e = \sum_{j=1}^{ne} \mathscr{A}\left(\mathbf{Q}_{g,j}\right) = \sum_{j=1}^{ne} \mathscr{A}\left(\mathbf{H}_{g,j} \bar{\mathbf{Q}}_j\right) = \mathbf{H}\mathbf{Q}_t \qquad (1)$$

Compatibility conditions are derived through the Virtual Force Principle, by equating the virtual internal work $\delta W_i = \delta \mathbf{Q}_t^T \mathbf{q}_t$ to the external one $\delta W_e = \delta \mathbf{F}_e^T \mathbf{s}$.

From Eq. 1, we have $\delta \mathbf{F}_e = \mathbf{H} \delta \mathbf{Q}_t$ and stating $\delta W_e = \delta W_i$, we obtain $\delta \mathbf{Q}_t^T \mathbf{H}^T \mathbf{s} = \delta \mathbf{Q}_t^T \mathbf{q}_t$. Since such an equation is valid for any choice of $\delta \mathbf{Q}_t^T$, the compatibility equations are finally derived as:

$$\mathbf{q}_t = \mathbf{H}^T \mathbf{s} \qquad (2)$$

The compatibility matrix $\mathbf{H}^T$ is the transposed of the equilibrium matrix $\mathbf{H}$. In these correspondences, the vector of the forces $\mathbf{F}_e$ works for that of the displacements $\mathbf{s}$ in the global reference system, as the vector of the basic forces $\mathbf{Q}_t$ works for that of the basic displacements $\mathbf{q}_t$.

2.2 *Yield condition and flow rule*

The constitutive law for a *perfectly-plastic* material must include: *(i)* a *yielding criterion*, which defines the stress state corresponding to the starting of the plastic flow (the yield function curve is convex) and *(ii)* an *associated flow rule*, through which the increments of the plastic strains are correlated to the actual stress state. In the present case, where the only active generalized plastic stresses for the *i-th* critical

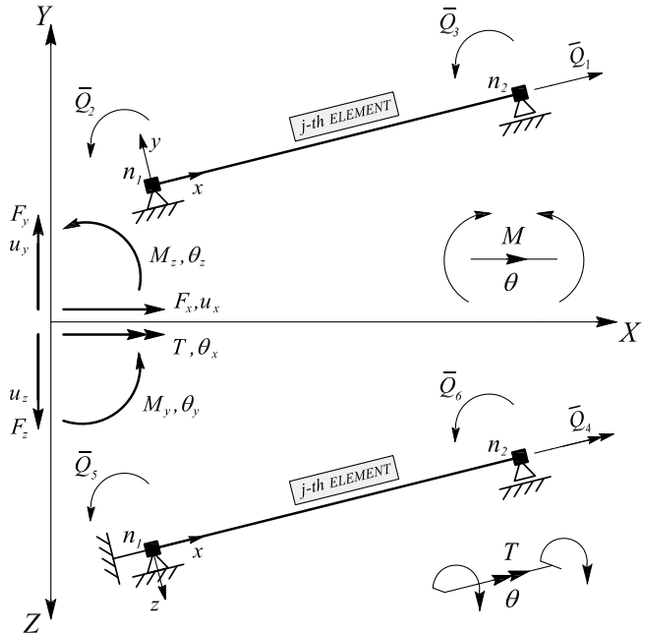


Figure 2: Static Field: reference system and *j-th* element without rigid body modes both in *x-y* and *x-z* plane.

cross-section are the bending moment M_z and torsion T, the yielding criterion has the shape shown in Fig. 1(b), which can be defined by the equation $f_i(M_{z,i}, T_i) = 0$. The stress state must verify the condition $f_i(M_{z,i}, T_i) \leq 0$. Having modelled the yielding criterion by a stepwise linearization with q sides for each *i-th* plastic domain, the yielding criterion for the *i-th* critical cross-section may be written in matrix form as $\mathbf{\Phi}_i = \mathbf{N}_i\mathbf{r}_i - \mathbf{k}_i \leq 0$ where $\mathbf{\Phi}_i = [\phi_1^i \quad \phi_2^i \quad \dots \quad \phi_{q_i}^i]^T$, $\mathbf{N}_i = [\mathbf{n}_1^i \quad \mathbf{n}_2^i \quad \dots \quad \mathbf{n}_{q_i}^i]$, $\mathbf{n}_j^i = [n_{j1}^i \; n_{j2}^i]$ and $\mathbf{k}_i = [k_1^i \; k_2^i \; \dots \; k_{q_i}^i]^T \geq \mathbf{0}$. For each element the yield criterion becomes $\mathbf{\Phi}_i = \mathbf{N}_i\bar{\mathbf{Q}}_i - \mathbf{k}_i \leq 0$ and assembling these conditions for the whole structure one has:

$$\mathbf{\Phi}_t = \sum_{j=1}^{ne} \mathscr{A}\left(\mathbf{\Phi}_j\right) = \mathbf{N}\mathbf{Q}_t - \mathbf{k} \leq 0 \tag{3}$$

The associated flow rule for the *i-th* critical cross-section is given by equations $\theta_{z,i} = \mu_i \partial f_i / \partial M_{z,i}$ and $\theta_{x,i} = \mu_i \partial f_i / \partial T_i$ where $\mu_i > 0$ is the multiplier that allows plastic flows only for the points lying on the yielding curve, for which the normal is oriented outside the domain, that is $\mu_i f_i(M_{z,i}, T_i) = 0$. For the linearized case with q sides, by introducing the vector $\boldsymbol{\mu}_i = [\mu_1^i \quad \mu_2^i \quad \dots \quad \mu_{q_i}^i]^T \geq \mathbf{0}$ and collecting the terms μ_i^j relative to each side of the linearized frontier, we finally have $\mathbf{d}_i = \mathbf{N}_i^T \cdot \boldsymbol{\mu}_i$ with $\mu_j^i \cdot \phi_j^i = 0$ $(j = 1, \cdots, q)$ and $\boldsymbol{\mu}_i \geq 0$. The flow rule can be written for the generic element by connecting the vector of plastic strain $\mathbf{d}_i$ with the vector of basic displacement $\bar{\mathbf{q}}_j$ by means of the compatibility equations $\bar{\mathbf{q}}_j = \mathbf{N}_i^T \; \boldsymbol{\mu}_i$. By assembling all the element contributions for the entire structure, the corresponding compatibility equations become:

$$\mathbf{q}_t = \sum_{j=1}^{ne} \mathscr{A}\left(\bar{\mathbf{q}}_j\right) = \mathbf{N}^T \cdot \boldsymbol{\mu} \tag{4}$$

with

$$\begin{cases} \mu_j^i \cdot \phi_j^i = 0 \qquad j = 1, \cdots, q \\ \boldsymbol{\mu} > 0 \end{cases}$$

2.3 *The static and the kinematic approach*

With reference to a generic structure, let $\mathbf{P}_0$ be a vector of constant loads and $\mathbf{P}$ a vector of loads whose intensity varies proportionally to a unique multiplier $\lambda \geq 0$. We assume that for $\lambda = 0$ equilibrium and compatibility are satisfied. We search for the multiplier λ_c associated to the collapse load. In mathematical terms, the *upper* (Eq. 5) and *lower* (Eq. 6) bound theorems of Limit Analysis are traduced in the following dual linear constrained optimization problems, solved here by means of the Simplex Method.

$$\lambda_c = max(\lambda) \begin{cases} \lambda\mathbf{P} - \mathbf{H}\mathbf{Q}_t = -\mathbf{P}_0 \\ \mathbf{N}\mathbf{Q}_t \leq \mathbf{k} \\ \lambda \geq 0 \end{cases} \tag{5}$$

$$\lambda_c = min(\mathbf{k}^T\boldsymbol{\mu} - \mathbf{P}_0^T\mathbf{s}) \begin{cases} \mathbf{N}^T\boldsymbol{\mu} - \mathbf{H}^T\mathbf{s} = \mathbf{0} \\ \mathbf{P}^T\mathbf{s} = 1 \\ \boldsymbol{\mu} \geq 0 \end{cases} \tag{6}$$

In this way, Eq.(5) requires finding a maximum multiplier, while Eq.(6) a minimum one. It must be underlined that in the second case, the minimum condition is related to the work done by the proportional loads $\mathbf{P}$ for the displacements $\mathbf{s}$ associated with the collapse mechanism. Since this mechanism is correlated to an arbitrary multiplier, it results univocally identified by the condition $\mathbf{P}^T\mathbf{s} = 1$. As known, the uniqueness of λ_c does not necessarily mean the uniqueness of the collapse mechanism, or that of the stress field at collapse.

2.4 *Time-variant Limit Analysis*

In the previous Limit Analysis, the cross-sectional performance is quantified by using fixed values of the quantities $\mathbf{N}$ and $\mathbf{k}$, which define the yielding criterion and the flow rule. However, due to the reinforcement deterioration corresponding to the damage state at certain time, such quantities, as well as the corresponding collapse multiplier λ_c, vary over time. In order to account for such a variability, a specific analysis of the deteriorating cross-sections is firstly required to build the modified frontiers $f(M_z, T) = 0$ and the functions $\mathbf{N} = \mathbf{N}(t)$ and $\mathbf{k} = \mathbf{k}(t)$. In this way, a time-variant Limit Analysis leading to the time evolution of the *complete solution* (collapse multiplier, collapse mechanism and internal stress distribution at the incipient collapse) is performed by solving the previous linear programs at different time instants.

3 DAMAGE MODELLING IN R.C. STRUCTURES

Concrete structures exposed to environmental aggressive agents, like sulphates and chlorides, are subjected to lifetime degradation which may lead to the deterioration of concrete and the corrosion of steel reinforcement (C.E.B. 1992). In this context, the attention is focussed only on chlorides induced corrosion of steel bars. In fact, when chlorides, which are critical in a marine environment or come from the application of de-icing salts on bridge platforms exceed a threshold value in carbonated concrete, they can cause a progressive deterioration of the mechanical properties of the materials. In addition, damage induced by mechanical loading interacts with the environmental factors and accelerates the deterioration process. For these reasons, the safety of reinforced concrete structures exposed to corrosion needs to be checked over time by means of a durability analysis able to account for both the diffusion process and the corresponding mechanical damage, as well as for the coupling effects between diffusion, damage and structural behaviour.

3.1 *Modelling of diffusion process*

The diffusion process is described by the Fick's law (Glicksman 2000):

$$D\nabla^2 C = \frac{\partial C}{\partial t} \tag{7}$$

where D is the diffusion coefficient, $C = C(\mathbf{x}, t)$ is the mass concentration of the aggressive agent at point $\mathbf{x} = (x, y, z)$ at t time, and $\nabla C = \mathbf{grad}C$. Based on the work of (Biondini, Bontempi, Frangopol, & Malerba 2004) and (Titi 2012), the analytical solution of the linear partial differential equation (7) is carried out by using a special class of evolutionary algorithms called *Cellular Automata*. This computational technique consists of a regular uniform grid of sites or *cells*, theoretically having an infinite extension, with a discrete variable in each cell, that can take on a finite number of states. During time, Cellular Automata evolve in discrete time steps according to a set of local evolutionary rules. For the diffusion problem in two-dimensions, the Fick's law can be accurately reproduced by the following evolutionary rule (Biondini, Bontempi, Frangopol, & Malerba 2004):

$$C_i^{k+1} = \phi_0 C_i^k + \frac{1-\phi_0}{4} \sum_{j=1}^{2} \left(C_{i-1,j}^k + C_{i+1,j}^k \right) \tag{8}$$

where the discrete variable $C_i^k = s_i^k = C(\mathbf{x}_i, t_k)$ represents the concentration of the aggressive agent at time t_k in the *i-th* cell of the automaton located at point $\mathbf{x}_i = (y_i, z_i)$ of the cross-section, $C_{i\pm1,j}^k$ is the concentration in the adjacent cells $i \pm 1$ in the direction $j = 1, 2$ and ϕ_0 is a suitable evolutionary coefficient related to the rate of mass diffusion. Additionally, the diffusion process can be regulated according to a given value of the diffusion coefficient D by relating the grid dimension Δx and the time step Δt through the relationship:

$$D = \frac{1-\phi_0}{4} \frac{\Delta x^2}{\Delta t} \tag{9}$$

Finally, in case of constant diffusivity, the value of the central evolutionary coefficient $\phi_0 = 1/2$ usually ensures a good accuracy of the automaton.

3.2 *Modelling of mechanical damage*

The structural damage can be introduced as a degradation of the law of the effective resistant areas for steel bars. This degradation is effectively evaluated by means of a dimensionless damage index $\delta_s = \delta_s(t)$ which gives a direct measure of the damage within the range [0;1].

$$A_s(t) = [1 - \delta_s(t)]\, A_{s0} \tag{10}$$

where $A_{s0} = \pi\, D_0^2/4$ is the area of the undamaged bar at the initial time $t = t_0$. The damage rate of the material depends on the mass concentration $C = C(\mathbf{x}, t)$ of the aggressive agent at a point $\mathbf{x} = (y_i, z_i)$ of the cross-section. Based on available data for corrosion rate under chloride attack, a linear relationship between the damage rate and the mass concentration is assumed:

$$\frac{\partial \delta_s(\mathbf{x}, t)}{\partial t} = \frac{C(\mathbf{x}, t)}{C_s \Delta t_s} = \rho C(\mathbf{x}, t) \tag{11}$$

where C_s represents the value of constant concentration $C(\mathbf{x}, t)$ in a certain position and at a specified time instant, which leads to a complete damage of the steel bar after the time period Δt_s. In addition, the initial conditions $\delta_s(\mathbf{x}, t_{cr}) = 0$ with $t_{cr} = max\{t \,|\, C(\mathbf{x}, t) \leq C_{cr}\}$ is assumed, where C_{cr} is a critical threshold of concentration. Finally, the damage rate coefficient $\rho = (C_s \Delta t_s)^{-1}$ is related to the materials and it must be set according to the actual rate of the damaging process (Bertolini, Elsener, Pedeferri, Redaelli, & Polder 2013).

4 APPLICATION TO A GRILLAGE DECK

4.1 *Structure, materials and loads*

An old 34.70 m long and 9.20 m wide R.C. grillage deck, composed of four longitudinal beams and five cross-beams, is studied. This deck is part of 28-spans viaduct built in Italy in 1968, which exhibits a severe corrosion state, due mainly to salted water coming from the roadway platform. The main dimensions of the grillage, as well as the geometry, dimensions and reinforcement layout of the structural members are shown in Fig. 3. In particular, the cross-beams present a constant section whereas the longitudinal beams exhibit a variable section all along the deck span. Fig. 4 shows further details of the reinforcement layout of the longitudinal beams. Tab. 1 lists the type of stirrups in all the members.

Table 1: Distribution of stirrups in the beams.

	A	*B*	*C*	*D*	*E*	*F*	*Cross-Beam*
ϕ [mm]	14	14	14	12	12	12	10
s [cm]	15	16	20	20	22	20	20

As concerns the material characteristics, in the Limit Analysis, only the concrete compression strength $f_c = -30\, MPa$ and the steel yielding stress $f_{sy} = 375\, MPa$ are involved.

From the structural point of view, the grillage deck is modelled by four simply supported longitudinal beams and five cross-beams with spacing 2.63*x*8.66 m (Fig. 5). The deck is considered to be subjected to a fixed load, corresponding to the self-weight ($g = 30\, kN/m$) and a variable part, due to traffic loads to be increased until collapse. According to Load Model 1 defined by (EN 1991), the traffic load acting on the deck consists of concentrated loads $Q = 300\, kN$, represented by a tandem system with two axles, and of

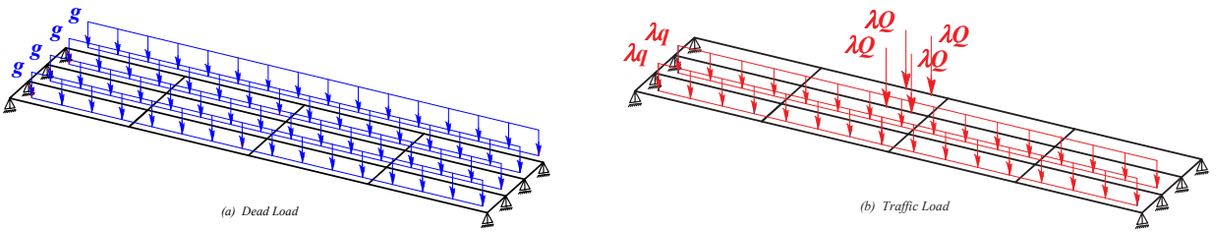

Figure 5: Structural model and loading conditions.

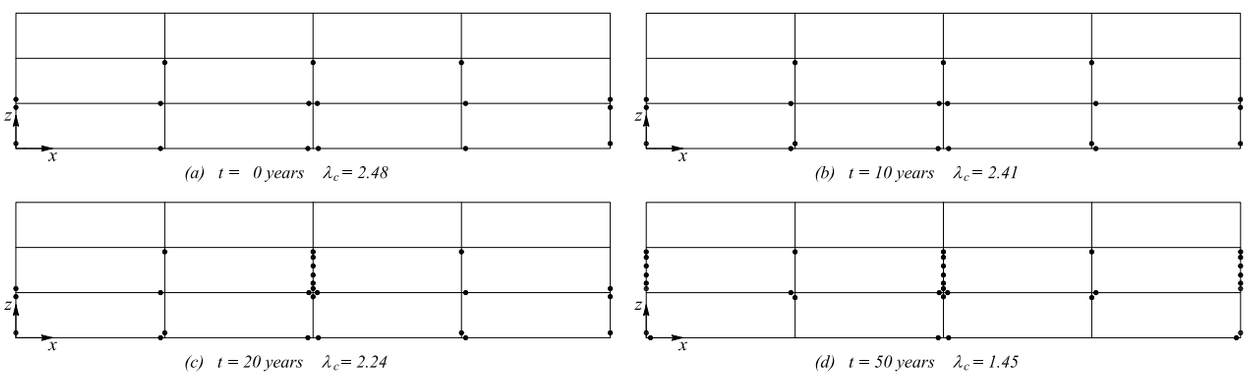

Figure 6: Limit Analysis. Time evolution of the collapse multiplier and relative distribution of the plastic hinges on the deck.

uniformly distributed loads $q = 13.5kN/m$, as shown in Fig. 5. For the analyses, the distributed loads are replaced by statically equivalent concentrated loads.

4.2 *Damage scenario*

The damage of the longitudinal beams caused by the application of salts based de-icing substances (containing chloride ions) coming from the above roadway is one of the main causes of deck deterioration. As a consequence, this chloride-induced corrosion leads to a reduction of the steel area, which may cause a premature failure of the structure.

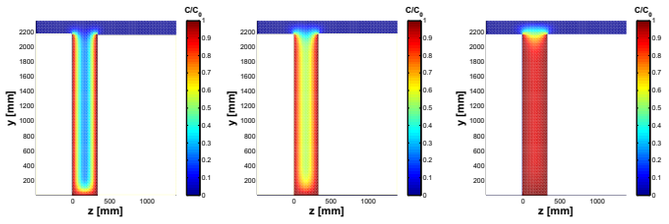

Figure 7: Concentration maps $C(x,t)/C_0$ of the aggressive agent over time ($t = 10$, $t = 20$ and $t = 50$ years).

In this case, the chlorides corrosion attacks is defined as follow: (i) the longitudinal position of the corroded zone is localized over a length of 3 m in the central zone of one of the edge longitudinal beams; (ii) the sectional distribution of corrosion is assumed to be located along the two laterals and the bottom sides of the corresponding cross-sections, with a constant concentration $C(t) = C_0 = 3\%$, as Fig. 8 shows. Once the corrosion scenario has been defined, the diffusion problem must be solved both in the sectional domain and in time. The Cellular Automata technique is applied, assuming a nominal diffusivity coefficient $D = 10^{-11}\, m^2/s$, a grid dimension $\Delta x = 10\, mm$ and a time step $t = 0.16$ years. According to the provisions given by (Fib 2006), the damage rates are defined by the values $C_{cr} = 0.6\%$, $C_c = C_0$ and $\Delta T_s = 20$ years. Since in this case the deterioration process reproduces a severe damage of materials, as it may occur for heavily chloride-contaminated concrete and high relative humidity, the steel damage rate coefficient ρ is assumed as $0.02/C_0$. The results of the diffusion process are highlighted in Fig. 7, where the concentration maps $C(x,t)/C_0$ of the aggressive agent at time instants $t = 10$, $t = 20$ and $t = 50$ years are shown for the cross-section. The mechanical damage induced by chloride diffusion can be appreciated from diagram of Fig. 8. It is interesting to note that the corrosion propagation starts after only 2 years. Finally, after 20 years, the reduction of the bars cross-section becomes significant.

4.3 *Main results and comments of the analyses*

A series of limit analyses over time accounting for chloride-induced corrosion were conducted to investigate the corresponding grillage deck performance.

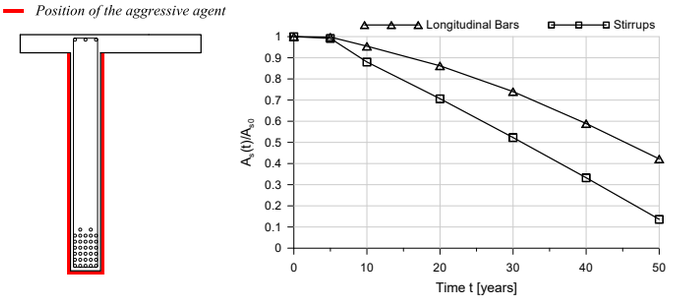

Figure 8: Sectional distribution of the aggressive agent and time reduction of bar areas in the damaged cross-section.

As expected, Fig. 6 highlights a significant variation of the collapse load multiplier, which decreases from $\lambda_c = 2.48$ to $\lambda_c = 1.45$ as the damage increases over time. Interesting results are obtained also in terms of redistribution of the internal stress resultants and a consequent modification of the collapse mechanism. In fact, the effects of the localized corrosion scenarios involve not only the damaged longitudinal beam but also the undamaged cross-beams. Such a redistribution may be highlighted with reference to Figs. 6, 9, 10, 11. Fig. 9 shows the bending moment diagram for the edge damaged longitudinal beam. The moment progressively reduces in time, gradually exhibiting a pronounced kink at the section in correspondence of the cross-beam at the quarter. The location of the generalized plastic hinges corresponding to the damaged state at $t = 0$, $t = 10$, $t = 20$ and $t = 50$ years is shown in Fig. 6. As the reduction of the mechanical properties for the damaged longitudinal beam becomes evident (*t=20 years*), the Limit Analysis predicts the formation of new plastic hinges in the central cross-beam and its relative collapse may occur. These results are confirmed by the bending moment and torsion diagram at incipient collapse for the central cross-beam, as shown in Fig. 10. As time increases (*t=40 years*), additional hinges will form in the end cross-beams which collapse under the combined action of bending moment and torsion (Fig. 11). In the redistribution process, the collapse mechanism moves from the central to the end undamaged cross-beams, searching for, in the grillage deck, new load paths through the contribution of new collaborating

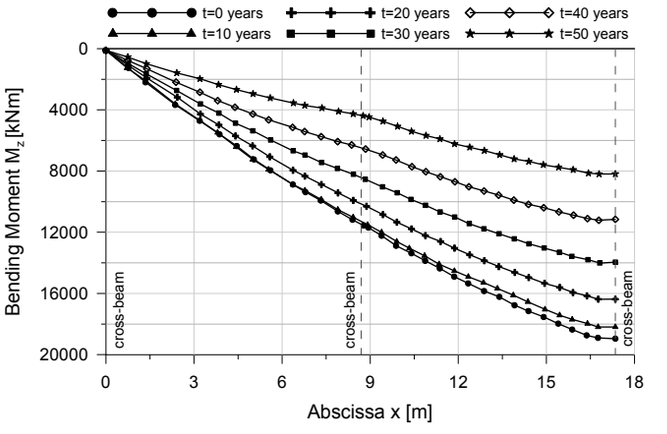

Figure 9: Edge longitudinal beam. Time evolution of bending moment at the collapse after 0 to 50 years.

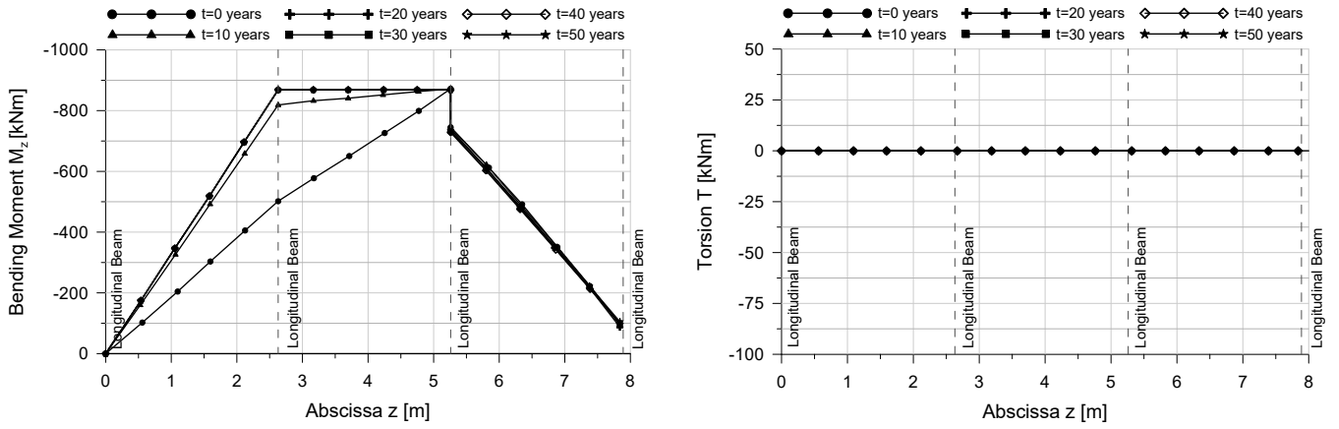

Figure 10: Time evolution of bending moment and torsion at collapse for the central cross-beam.

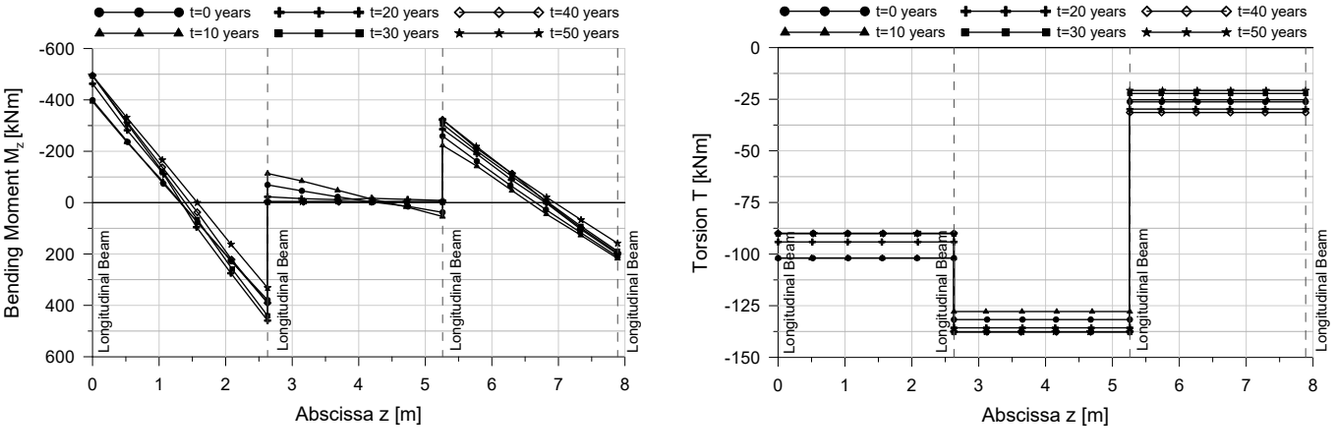

Figure 11: Time evolution of bending moment and torsion at collapse for the end cross-beam.

parts. Typical, from this point of view, is the torsional contribution of the end cross-beams, accentuated by the increasing of the relative rotations of the longitudinal beams at the supports.

5 CONCLUSIONS

A Limit Analysis of a damaged R.C. grillage deck, has been carried out. After a short recall of the two fundamental theorems of plasticity, a damage model is assumed to represent the deterioration of mechanical properties over time. The deterioration process induced by chlorides diffusion is investigated by means of the Cellular Automata technique. The structural performance is assessed at different times by taking into account the reinforcement deterioration corresponding to the damaged state at that time. The results demonstrate the usefulness of this approach in identifying the structural components that more significantly affect the system performance when damage develops. As shown through the application, the damage reduces the local bearing capacity over time and cause a progressive redistribution of internal forces towards undamaged structural elements, called to collaborate with the damaged ones in new load paths configurations. For this reason, it is important, when designing repairing interventions, to verify and possibly increase the bearing capacity of the undamaged components in light of the additional role that may be called to play. This brings to an increase of the overall robustness of the deck.

ABSTRACT: In this paper, an approach consisting in the analysis of the diffusion of the deterioration processes induced by aggressive agents, followed by the analysis of the damaged structure is presented. The damage process, induced by chloride diffusion, is modelled through a Cellular Automata algorithm. The structural analysis is based on R.C. spatial beam element, dealing with both mechanical and geometrical nonlinearities. The proposed method is applied to studying the structural response, both at the serviceability and ultimate limit states, of a damaged, 50-years-old R.C. grillage deck exhibiting a severe corrosion state. The analyses show how damage effects at a given time reduce the overall bearing capacity of the deck and how the internal forces redistribute from damaged to undamaged structural parts. Such a methodology may be useful both in designing new bridges, in estimating their performance over time under given environmental and service condition, and for existing bridges, in assessing their residual bearing capacity in the damaged state after a certain period from construction.

1 INTRODUCTION

All around the world, the majority of R.C. and P.C. bridges and viaducts with more than 40-60 years of service life exhibits damage states which reduce their structural reliability and require increasing inspection and maintenance costs (Biondini & Frangopol 2017). For this reason, many Road and Highway Administrations are faced with two typical problems: *(a)* in designing new bridges, estimate their bearing capacity after a certain amount of years from construction time and under given environmental and service condition; *(b)* for existing bridges, assess their residual bearing capacity in the damaged state, reached after a certain amount of years from construction time. In this paper, an approach which may contribute to dealing with this type of assessments is presented. It consists in the analysis of the diffusion of the deterioration processes induced by aggressive agents, followed by the analysis of the damaged structure. The analysis of the diffusion process is developed by using a special class of evolutionary algorithms, called Cellular Automata. Based on such a model, the mechanical damage coupled to diffusion is then evaluated by introducing a damage index in the degradation law of the effective resistant area of rebars. For a given time from the end of construction and for given environmental conditions, this allows to evaluate the amount of corrosion in the rebars and their actual resistant area. Then, a Nonlinear Finite Element Analysis, based on R.C. spatial beam element dealing with both mechanical and geometrical nonlinearities, allows to assess the structural response both at the serviceability and ultimate limit states. The proposed method was applied in the study of a damaged, 50-years-old R.C. grillage deck exhibiting a severe corrosion state. For different and progressive sampling times and for increasing applied loads, analyses show how the internal forces redistribute and how the load multiplier reduces as corrosion progresses.

2 DAMAGE MODELLING IN R.C. STRUCTURES

Concrete structures exposed to aggressive environments are subjected to lifetime degradation induced

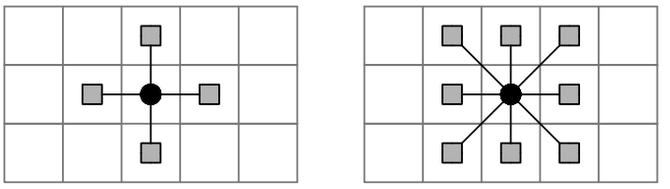
by the kinetic process of diffusion of chemical components, such as sulphates and chlorides, driven by concentration gradients inside the material volume (Glicksman 2000). In this context, the attention is focused only on chlorides induced corrosion of steel bars. In fact, when chlorides, which are critical in a marine environment or come from the application of deicing salts on bridge decks, increase beyond a threshold value in carbonated concrete, they may lead to the deterioration of the concrete and the corrosion of the reinforcement. Moreover, damage induced by mechanical loading interacts with the environmental factors and accelerates the deterioration process (C.E.B. 1992). The diffusion process, the amount of corrosion in the steel bars and their actual resistant area at a given time from the end of construction and for given environmental conditions, are firstly modelled. Then, a Nonlinear Finite Element Analysis of the damaged structure is carried out.

2.1 *Modelling of the diffusion process*

The simplest model to describe the kinetic process of chemical components diffusion in solids is represented by Fick's first law, which assumes a linear relationship between the mass flow and the concentration gradient by introducing an effective diffusion coefficient D_e. The combination of the Fick's model with the mass concentration principle leads to Fick's second law. Assuming an isotropic media, the problem is described by the following second-order partial differential equation:

$$-\nabla \cdot (-D_e \nabla C) = \frac{\partial C}{\partial t} \tag{1}$$

where $C = C(\mathbf{x}, t)$ is the mass concentration of the aggressive agent at point $\mathbf{x} = (x, y, z)$ at the t time, and $\nabla C = \mathbf{grad} C$. Even though D_e in reinforced concrete structures depends on relative humidity, on temperature and on the internal stress field, for the sake of simplicity a diffusion coefficient $D_e = D$, constant in time, is here assumed.



From the numerical point of view, the analytical solution of the linear partial differential equation (1) exists only for a limited number of problems. In general, numerical procedures are necessary to deal with arbitrary domains, different position of steel bars and complex boundary conditions. In order to model the diffusion process, the evolutionary algorithm called *Cellular Automata* is adopted. This computational technique, presented in the works of (Biondini, Bontempi, Frangopol, & Malerba 2004) and (Titi 2012), consists of a regular uniform grid of sites or *cells*, theoretically having an infinite extension, with a discrete variable in each cell that can take on a finite number of states. In particular, Fick's laws in two dimensions can be accurately reproduced by the following evolutionary rule:

$$C_i^{k+1} = \phi_0 C_i^k + \frac{1-\phi_0}{4} \sum_{j=1}^{2} \left(C_{i-1,j}^k + C_{i+1,j}^k \right) \tag{2}$$

where the discrete variable $C_i^k = s_i^k = C(\mathbf{x}_i, t_k)$ represents the concentration of the aggressive agent at time t_k in the cell i of the automaton located at point $\mathbf{x}_i = (y_i, z_i)$ of the cross-section, $C_{i\pm1,j}^k$ is the concentration in the adjacent cells $i \pm 1$ in the direction $j = 1, 2$ and ϕ_0 is a suitable evolutionary coefficient related to the rate of mass diffusion. Fig. 1 presents the typical pattern of cells involved in the evolutionary rule for 2D cellular automata with $r = 1$, but patterns of higher complexity can also be proposed. Additionally, the diffusion process can be regulated according to a given value of the diffusion coefficient D by relating the grid dimension Δx and the time step Δt through the relationship:

$$D = \frac{1-\phi_0}{4} \frac{\Delta x^2}{\Delta t} \tag{3}$$

To ensure a good accuracy of the automaton, a suitable value of the central evolutionary coefficient in case of constant diffusivity is $\phi_0 = 1/2$.

Figure 1: Neighbourhoods for 2D cellular automata with radius $r = 1$.

2.2 *Modelling of the mechanical damage*

The structural damage can be viewed as a degradation of the mechanical properties which make the structural system less able to withstand the applied loads. The main effect of corrosion in concrete structures is the reduction in the bar mass. Once the diffusion process is solved, such a damage can be evaluated by introducing a suitable degradation law for the steel area:

$$A_s(t) = [1 - \delta_s(t)]\, A_{s0} \tag{4}$$

where $A_{s0} = \pi\, D_0^2/4$ is the area of the undamaged bar at the initial time $t = t_0$ and $\delta_s = \delta_s(t)$ is the dimensionless damage index which gives a direct measure of the deterioration within the range [0;1].

Despite the complexity of damage processes in concrete structures exposed to corrosion, the damage index $\delta_s = \delta_s(\mathbf{x}, t)$ at a point $\mathbf{x} = (y_i, z_i)$ of the generic cross-section is correlated to the diffusion process by

assuming a linear relationship between the rate of damage and the concentration $C = C(\mathbf{x}, t)$ of the aggressive agent:

$$\frac{\partial \delta_s(\mathbf{x}, t)}{\partial t} = \frac{C(\mathbf{x}, t)}{C_s \Delta t_s} = \rho C(\mathbf{x}, t) \tag{5}$$

In this equation C_s represents the value of constant concentration $C(\mathbf{x}, t)$ in a certain position and at a specified time instant, which lead to a complete corrosion of the steel bar after the time period Δt_s. In addition, the initial conditions $\delta_s(\mathbf{x}, t_{cr}) = 0$ with $t_{cr} = max\{t \,|\, C(\mathbf{x}, t) \leq C_{cr}\}$ is assumed, where C_{cr} is a critical threshold of concentration. Finally, the damage rate coefficient $\rho = (C_s \Delta t_s)^{-1}$ is related to the materials properties and it must be set according to the actual rate of the damaging process.

3 FORMULATION OF A DETERIORATING R.C. SPATIAL BEAM ELEMENT

A R.C. spatial beam element, able to account for both the mechanical and geometrical nonlinearities, is presented. Its formulation refers mainly to the works of (Bontempi, Malerba, & Romano 1995) and (Malerba 1998). The adopted model assumes that the cross-sections rotate and translate remaining plane. Shear deformability and torsional warping are neglected and perfect bond between steel and concrete is assumed. In the present extension, the F.E. takes into account the effects due to the structural damage. At the section of abscissa ($0 \leq x \leq l$), the displacement field of the beam element $\mathbf{u} = [u_0(x)\ v_0(x)\ w_0(x)\ \varphi_x(x)]^T$ is discretized and interpolated in terms of nodal displacement $\mathbf{q}$ so that $\mathbf{u}(x) = \mathbf{N}(x)\mathbf{q}$. The matrix of displacement functions $\mathbf{N}(x)$ is defined by adopting the Hermitian shape functions of a linear elastic beam having uniform cross-sectional stiffness and loaded only at its ends. The generalized strains $\mathbf{e}_s(x) = [\varepsilon(x)\ \chi_z(x)\ \chi_y(x)\ \theta(x)]^T$ are given by $\mathbf{e}_s(x) = \mathbf{B}(x)\mathbf{q}$, where $\mathbf{B}(x)$ contains the derivatives of the shape functions. At the same section, the strain field $\boldsymbol{\varepsilon} = [\varepsilon_x\ \gamma_{xy}\ \gamma_{xz}]^T$ at a fiber at the distance (y, z) from the beam axis is given by:

$$\boldsymbol{\varepsilon} = \mathbf{a}_s(y, z)\mathbf{e}_s(x) = \mathbf{a}_s(y, z)\mathbf{B}(x)\mathbf{q} \tag{6}$$

with:

$$\mathbf{a}_s(y, z) = \begin{bmatrix} 1 & -y & z & 0 \\ 0 & 0 & 0 & -z \\ 0 & 0 & 0 & y \end{bmatrix}$$

Through the Principle of Virtual Displacements, we state that the virtual internal work δW_i is equal to the external one δW_e due to (a) distributed applied loads acting along the axis of the beam $\mathbf{f}_p$, (b) the forces directly applied at the nodes $\mathbf{f}_n$ and (c) the end forces through which the beam interacts with the rest of the structure $\mathbf{f}_q$ (Fig. 2). Finally, by imposing $\delta W_i = \delta W_e$, we obtain the vector of the equivalent nodal forces $\mathbf{f}_{ne}$ and element restoring forces $\mathbf{f}_q$.

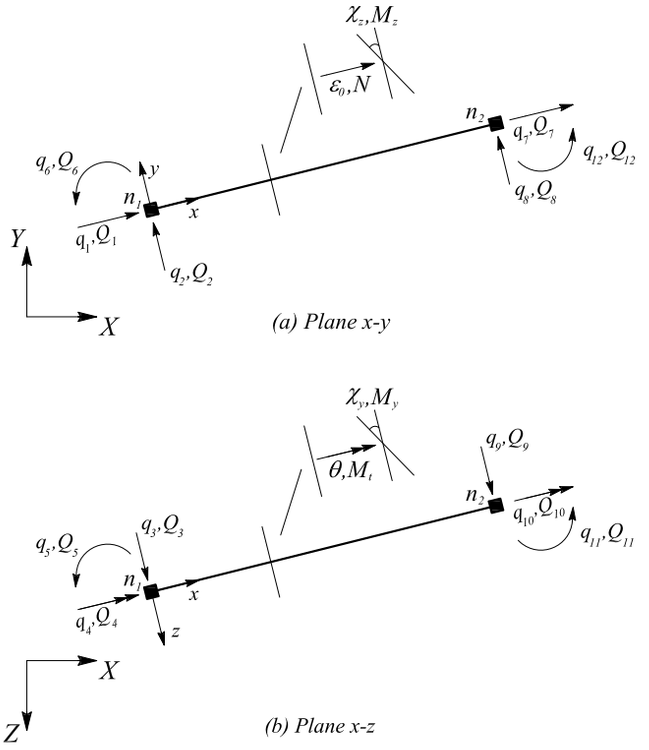

Figure 2: Spatial beam element notations. Static and kinematic fields.

$$\mathbf{f}_{ne} = \int_0^l \mathbf{N}^T(x)\mathbf{f}_p(x)dx + \mathbf{f}_n + \mathbf{f}_q \tag{7}$$

$$\mathbf{f}_q = \int_0^l \mathbf{B}^T(x)\mathbf{f}_s(x)dx \tag{8}$$

The section restoring forces $\mathbf{f}_s = [N\ M_z\ M_y\ M_t]^T$ are evaluated as:

$$\mathbf{f}_s = \int_A \mathbf{a}_s^T(y, z)\boldsymbol{\sigma}(x, y, z)dA \tag{9}$$

By substituting Eq. (9) in Eq. (8), the element restoring forces can be expressed as $\mathbf{f}_q = \mathbf{K}\mathbf{q}$. The element stiffness matrix $\mathbf{K} = \int_0^l \mathbf{B}^T(x)\mathbf{k}_s(x)\mathbf{B}(x)dx$ is function of the stiffness matrix $\mathbf{k}_s(x)$ of the section of abscissa x. The numerical integration of $\mathbf{k}_s(x)$ requires a suitable stress-strain constitutive law. As known, in the case of R.C. sections, axial and flexural forces can be derived from a uniaxial stress-strain relationship $\sigma_x = \sigma_x(\varepsilon_x)$, whereas shear and torsion depend on more complex membrane or volumetric mechanisms, usually modelled through plane or spatial trusses. In this formulation, we assume that bending and torsional behaviors are uncoupled. As a consequence, the derivation of the stiffness matrix $\mathbf{k}_s$ and the section restoring forces $\mathbf{f}_s$ is given by the sum of two components. The matrix $\mathbf{k}_s$ is expressed as $\mathbf{k}_s = \mathbf{k}_{s,\varepsilon} + \mathbf{k}_{s,\gamma}$ where $\mathbf{k}_{s,\varepsilon}$ is associated to the axial-bending response and $\mathbf{k}_{s,\gamma}$ is related to the torsional behavior. For each section, matrix $\mathbf{k}_{s,\varepsilon}$ is integrated over the area of the

composite element and by assembling the contributes of concrete and steel. In order to deal with sections of arbitrary shape, the generic cross-section is divided into subdomains. Through a parametric transformation of each subdomain into a unit square parent domain, Gaussian integration rules can be carried out with several integration strategies (Quagliaroli, Malerba, & Sgambi 2015). The matrix $\mathbf{k}_{s,\gamma}$ is derived by describing at the sectional level the torsional response in the form of $M_t = k_\theta \theta$. To this purpose, we assume a bilinear constitutive law able to account the response of the section both prior and after concrete cracking (Fig. 3).

$$M_t = \begin{cases} (GK)\theta & |\theta| \leq \theta_{cr} \\ \mu(GK)\theta & \theta_{cr} < |\theta| \leq \theta_u \end{cases} \tag{10}$$

where G is the shear modulus and $\mu = K_{cr}/K$ is the ratio between the torsional stiffness after and before cracking.
Similarly, the vector $\mathbf{f}_s$ can be expressed as the sum of two terms related to normal and tangential stress respectively, as $\mathbf{f}_s = \mathbf{f}_{s,\varepsilon} + \mathbf{f}_{s,\gamma}$.

$$\mathbf{f}_{s,\varepsilon} = \int_A^l \mathbf{a}_s^T(y,z) \cdot \sigma_x(\varepsilon_x(x,y,z))dA \tag{11}$$

$$\mathbf{f}_{s,\gamma} = M_t(x) \tag{12}$$

The generalized stresses N, M_y and M_z are computed from Eq. (11) by integrating over the sectional domain the nonlinear uniaxial constitutive models. On the contrary, the term $\mathbf{f}_{s,\gamma}$ is derived at the sectional level according to M_t-θ relationship. Then, the vectors of equivalent nodal forces $\mathbf{f}_{ne}$ and restoring forces $\mathbf{f}_q$ are evaluated by numerical integration over the length l of the beam. The damage effects associated to prescribed values of the corrosion penetration index δ_s are included in this formulation by assuming $A_{sm} = A_{sm}(\delta_s)$ for the *m-th* steel bar located at $\mathbf{x}_m = (y_m, z_m)$ whereas no damage for concrete is assumed. As a consequence, at each time instant t the corresponding deteriorating stiffness matrices $\mathbf{k}_s = \mathbf{k}_s(x,t)$ and $\mathbf{K} = \mathbf{K}(x,t)$ are computed (Biondini & Vergani 2012). It is worth noting that corrosion can selectively be applied to damaged structural elements

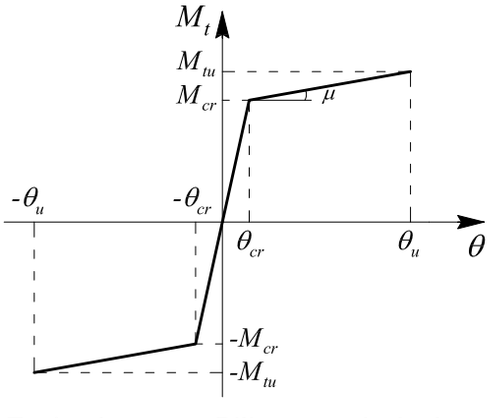

Figure 3: Torsional response. Bilinear constitutive law.

with a different level of penetration in each reinforcing bar. Finally, relating these quantities to the global reference system and by assembling the equilibrium equation of the whole structure, we obtain:

$$\mathbf{f}_r(\mathbf{s}) = \mathbf{f}(\mathbf{s}) \Rightarrow \mathbf{K}\mathbf{s} = \mathbf{f}(\mathbf{s}) \tag{13}$$

where $\mathbf{K} = \mathbf{K}(\mathbf{s}, t)$ is the overall stiffness matrix and $\mathbf{s} = \mathbf{s}(t)$ is the vector of nodal displacements. Being the problem nonlinear, both the assembled restoring forces $\mathbf{f}_r$ and the applied loads $\mathbf{f}$ are depending on the unknown displacements $\mathbf{s}$ of the whole structure. The solution of this nonlinear problem is obtained through a tangent approach for prescribed values of corrosion penetration index δ_s.

4 APPLICATION TO A GRILLAGE DECK

4.1 *Structure, materials and loads*

A R.C. grillage deck, belonging 28-spans viaduct built in Italy in 1968, is studied. The viaduct is approximately half a century old and exhibits a severe corrosion state, due mainly to salted water coming from the roadway platform. The deck, with a span of 34.70 m and a width of 9.20 m, is composed of four longitudinal beams and five cross-beams. Fig. 4 shows the main dimensions of the deck, as well as the geometry, dimension and reinforcement layout of the main structural members. In particular, the longitudinal beams present a variable section, with height and width respectively increasing and decreasing from the abutments to the mid-span of the viaduct. On the contrary, the cross-beams have constant main dimensions and are reinforced with six bars with a nominal diameter equal to 28 mm. Further details about reinforcement layout of the longitudinal beams are shown in Fig. 5. Tab. 1 lists type and dimensions of the stirrups in all the members.

Table 1: Distribution of stirrups in the beams.

	A	*B*	*C*	*D*	*E*	*F*	*Cross-Beam*
ϕ [mm]	14	14	14	12	12	12	10
s [cm]	15	16	20	20	22	20	20

As concerns the material characteristics, concrete is modelled by a no-tension, uniaxial stress-strain law, according to the parabola-rectangle law. The design compression strength is $f_c = -30\,MPa$, with a transition strain $\varepsilon_{c0} = -0.002$ and an ultimate strain $\varepsilon_{cu} = -0.0035$. The steel is modelled by an elastic-perfectly plastic stress-strain diagram, symmetric both in tension and compression, with a yielding stress $f_{sy} = 375\,Mpa$, elastic modulus $E_s = 206000\,MPa$ and ultimate limit strain $\varepsilon_{su} = 0.06$.

With reference to the beam model shown in Fig. 6, the grillage deck is modelled by four simply supported longitudinal beams and five cross-beams with

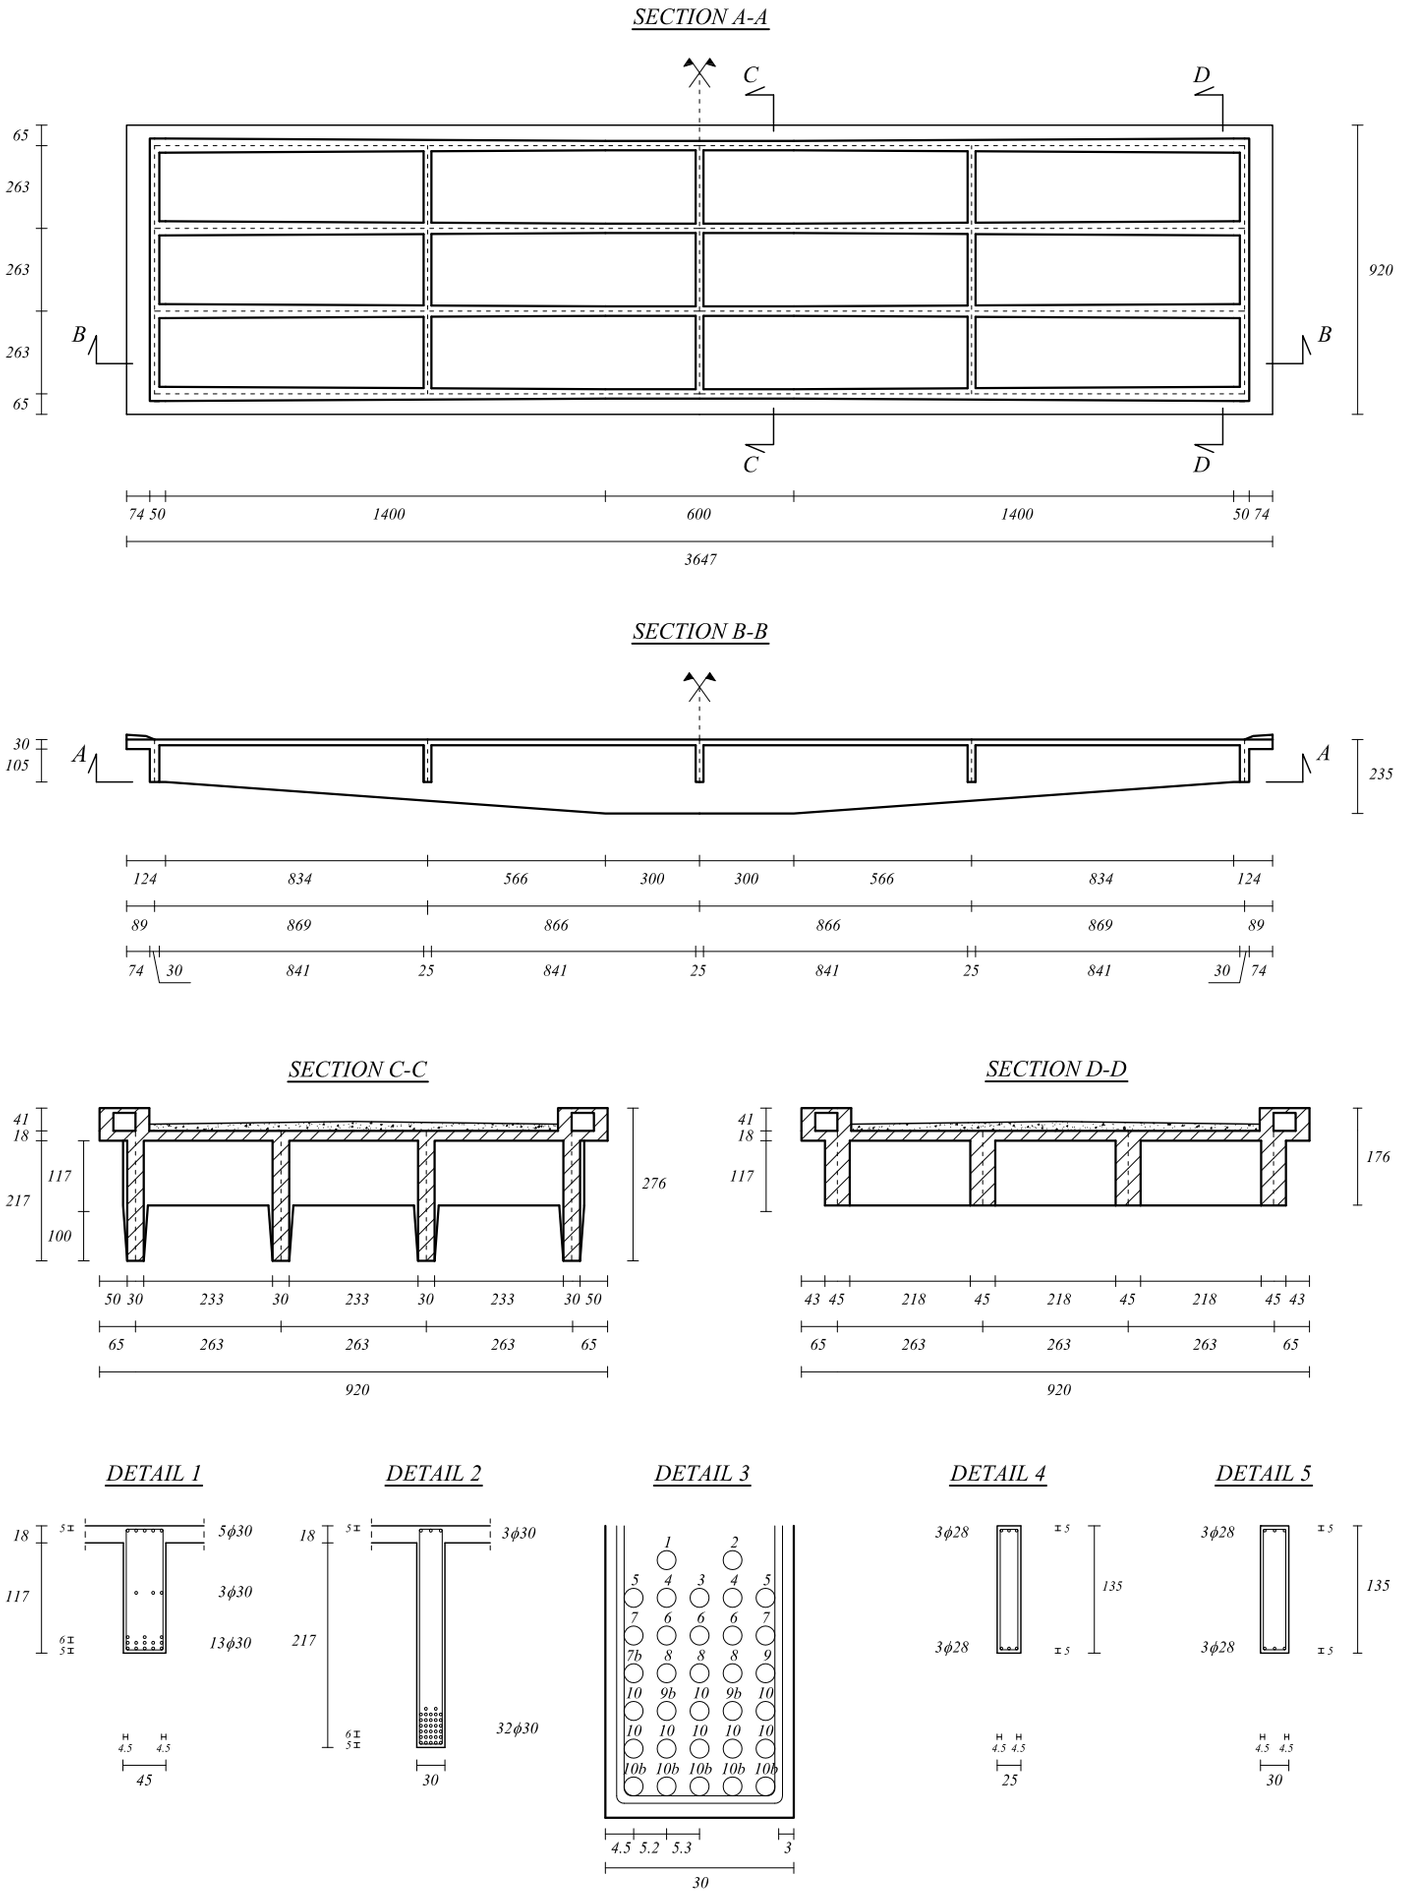

Figure 4: R.C. grillage deck. Geometry and reinforcement of the characteristic sections. Details 1, 2 and 3 refer to the longitudinal beams section. Details 4 and 5 identify the cross-beams section.

spacing 2.63x8.66 m. The total applied load is composed of a fixed contribution, corresponding to the dead load of the deck ($g = 30\,kN/m$) and of a variable part, corresponding to the traffic load to be increased until to the collapse. For the traffic load, Load Model 1, according to (EN 1991), is adopted: it consists of concentrated loads represented by a tandem system with two axles as well as of uniformly distributed loads. In this way, the traffic loads are distributed as shown in Fig. 6, where q is equal to $13.5\,kN/m$ and Q is $300\,kN$. In order to model the layout and the areas of steel reinforcements, each longitudinal beam is subdivided into 66 finite beam-elements, while each cross-beam is subdivided into 15 elements.

4.2 *Damage scenario*

Under the action of permanent loads, the intersection between the edge longitudinal beam and the cross-beam is usually affected by a negative bending moment which can lead to the cracking of the slab and cause some seepages on the edge beam. Since the water coming from the roadway platform is characterized by a high concentration of de-icing salts (chloride ions), a critical corrosion scenario may ensue causing premature losses of bearing. Concerning such a corrosion scenario, the chlorides corrosion attacks is defined as follow: (i) the longitudinal position of the corroded zone is located in a 3 m long tract, astride the central zone of one of the edge longitudinal beams; (ii) the sectional distribution of corrosion is assumed to be located along the two laterals and at the bottom sides of the corresponding cross-sections, with a constant concentration $C(t) = C_0 = 3\%$, as Fig. 8 shows. Once the corrosion scenario has been defined, the diffusion problem must be solved both in the sectional domain and in time. The cellular automata technique is applied, considering a nominal diffusivity coefficient $D = 10^{-11}\,m^2/s$, a grid dimension $\Delta x = 10\,mm$ and a time step $t = 0.16$ years. According to the (Fib 2006) provisions, the damage rates are defined by the values $C_{cr} = 0.6\%$, $C_c = C_0$ and $\Delta T_s = 20$ years. Since in this case the deterioration process reproduces a severe damage of materials, as it may occur for heavily chloride-contaminated concrete and high relative humidity (Bertolini, Elsener, Pedeferri, Redaelli, & Polder 2013), the steel damage rate coefficient ρ is assumed as $0.02/C_0$. The results of the diffusion process are highlighted in Fig. 7, where the concentration maps $C(x,t)/C_0$ of the aggressive agent at time $t = 10$, $t = 20$, $t = 40$ and $t = 50$ years are shown for the midspan cross-section. The amount of mechanical damage induced by chloride diffusion and its evolution over time is plotted in Fig. 8. Now, for the given environmental and loading conditions, at each sampling time the Nonlinear Finite Element Analysis of the deck allows to assess its structural response in the damaged state both at the serviceability and ultimate limit states.

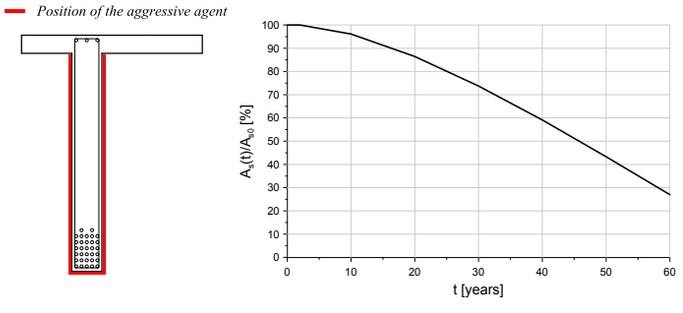

Figure 8: Midspan section. Surfaces exposed to the aggressive agent and reduction of the total steel area over time.

4.3 *Main results and comments of the analyses*

At the beginning, the damage effects are investigated on the service performance of the grillage under only its self-weight g (Serviceability Limit State, *SLS*).

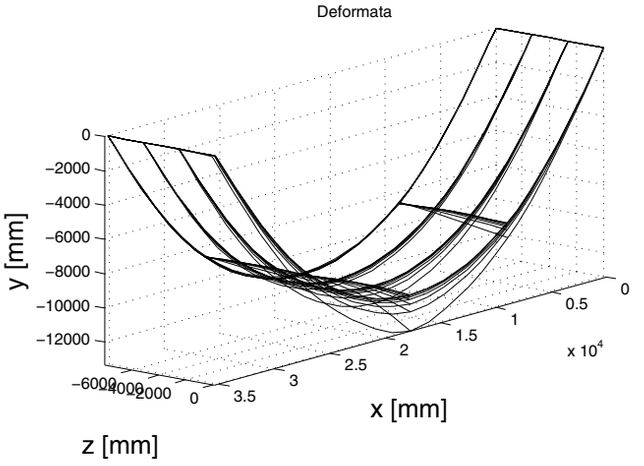

Figure 9: Deformed shapes over time of the deck at Serviceability Limit States under self-weight (scale factor equal to 200).

The localized damage involves both an increase of the deformability of the longitudinal and transversal beams and a redistribution of the internal forces. As time increases, the results of these analyses show that: *(a)* the overall deformed shape loses its symmetry (Fig. 9); *(b)* the weakening of the longitudinal beam under constant loading due to the deterioration process calls for a supporting contribution from the central cross-beam increasing over time. The kinks at midspan in the bending moment diagrams of the longitudinal beams, shown in Fig. 10, highlight the progression of this redistribution mechanism for $t = 0 \div 50$ years; *(c)* the corresponding contribution of the central cross-beam, shown in Fig. 11, through the plot of its bending moments diagram, becomes clear just after 10 years and rapidly increases from $t = 10$ to $t = 50$ years, and this may lead to the failure of the cross-beams, even if undamaged.

Another series of assessments concerns the performance of the deck at the Ultimate Limit States (*ULS*) under the combined action of permanent and traffic loads. The severe reduction of the cross-section of the steel bars, starting from 20 years from the end of construction (Fig. 8), leads to a remarkable decrease of

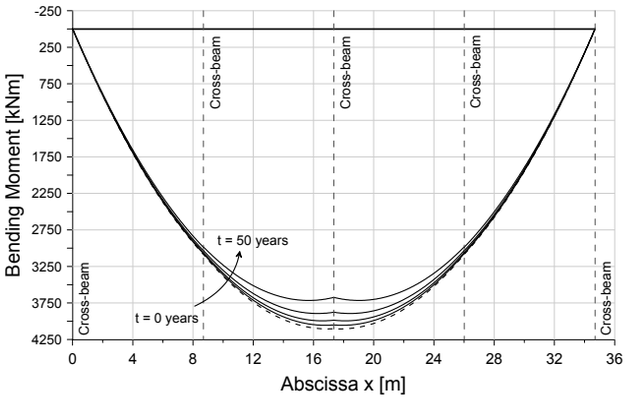

Figure 10: Bending moment along the longitudinal edge beam at *SLS* for different sampling times ($t = 0 \div 50$ years).

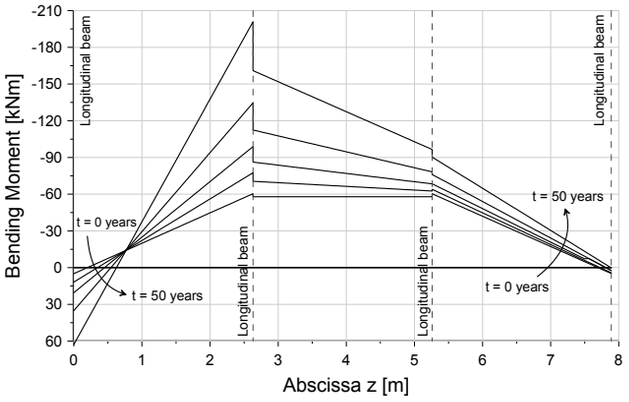

Figure 11: Bending moment along the midspan cross-beam at *SLS* for different sampling times ($t = 0 \div 50$ years).

the ultimate load bearing capacity over time. Fig. 12 shows the progressive reduction of the load multiplier over time, whereas the red and the blue lines represent respectively its safety and collapse limits: safety limit is crossed at 48 years and collapse limit at 55 years. While the *SLS* analyses highlight the redistribution of the bearing functions in the deck due to the damage progression even without service loads, the *ULS* results give fundamental information as concerns the loss of bearing capacity for the worst combination of the traffic loads. Both these types of results contribute in answering to the basic questions posed by public Authorities as concern the safety level of a bridge structure and the decisions in terms of proper maintenance actions and/or rehabilitation interventions.

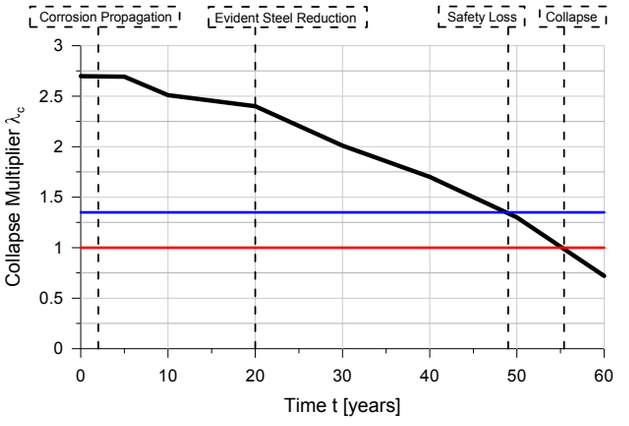

Figure 12: Collapse multiplier over time at *ULS*.

5 CONCLUSION

In this paper, an approach consisting in the analysis of the diffusion of the deterioration processes induced by aggressive agents, accompanied by the structural analysis of the damaged system is presented. The deterioration processes, induced by chloride diffusion, is modelled through a Cellular Automata algorithm. The structural analysis is based on R.C. spatial beam element, dealing with both mechanical and geometrical nonlinearities. The proposed method was applied in studying the structural response, both at the serviceability and ultimate limit state, of a damaged, 50-years-old R.C. grillage deck exhibiting a severe corrosion state. This deck typology is representative of a large number of bridges built in the 60s and the damaged pattern, concerning mainly the edge longitudinal beams, is very common. Each analysis studies the effects of increasing applied loads for a specific damaged state at a given time. By setting different and progressive sampling times, it is possible to highlight how the spread of the damage reduces the overall bearing capacity of the deck and how the internal forces redistribute from damaged to undamaged structural parts. This information could provide a reliable reference to establish a hierarchy of protection techniques, as well as to plan proper maintenance actions and repair interventions.

Wangchen Yan
College of Civil Engineering, Hunan Univ., Changsha, Hunan 410082, China

ABSTRACT: Overloaded trucks could induce considerable fatigue damage on bridges over the time, especially on steel bridges. Recent years has seen a fast-increasing number of overload permit requests which bring a large amount of workload for bridge administration. Therefore, developing rational vehicle weight limits and overload permit checking procedures is highly desired. In this study, a method for determining proper vehicle weight limits is proposed based on the consideration of the cumulative fatigue damage of bridges. A typical steel-concrete composite girder bridge is adopted as an example for illustrating the proposed method. The results from this study can not only be used to develop vehicle weight limits and assist overload permit checking but also to assess the fatigue damage and predict the future development of fatigue damage of existing bridges.

1 INTRODUCTION

The phenomenon of truck overloading is very common around the world and is becoming more and more serious despite the enforcement of various truck weight and size regulations. Overloaded trucks pose a great threat to the safety and durability of existing bridges. Recent years has seen a fast-growing number of overload permit requests for road authorities to deal with. Under such circumstances, rational vehicle weight regulations and effective overload permit checking systems are highly desired.

The basic idea in evaluating the permit request of an overweight vehicle is to check the ratio of the stress imposed by the overweight vehicle to the design load effect and make sure that the overstress ratio is controlled under an acceptable level (TRB 1990; Correia & Branco 2006). Various methods have been developed for predicting the longitudinal stresses on the bridge girders which are checked against the acceptable limits. A way for doing this is to perform detailed structural analysis. However, it may be very time consuming and requires detailed information of the bridge structure which may be difficult to collect (Vigh & Kollár 2006, 2007). Simplified structural analysis methods, such as the beam line analysis method, influence line method, two-dimensional finite element analysis, etc., have also be adopted to calculate the stresses (Vigh & Kollár 2006, 2007; Correia & Branco 2006; Correia et al. 2014). However, these simplified analysis methods are often conservative to some degree (Wood et al. 2007).

Another simple way is to check the axle loads of the vehicle against the allowable limits. The Federal Bridge Gross Weight Formula adopted in the USA is a typical example. However, some researchers criticized the overstress criterion adopted in developing existing bridge formulas for not considering the damage of bridges due to the repeated loads or overloads (Ghosn 2000). In addition, no consistent allowable overstress ratios are adopted by different organizations (*Bridge Formula Weights* 1994; Vigh & Kollár 2006; Correia & Branco 2006). In this study, a method for determining vehicle weight limit was proposed by considering the cumulative fatigue damage of bridges due to repeated vehicular loads. A typical steel-concrete composite girder bridge was used as an example for illustrating the proposed method. The results indicate that this method can also be adopted to assess the fatigue damage and predict the future development of fatigue damage of existing bridges.

2 VEHICLE LOADS

The axle configuration of vehicles has a significant influence on the stresses of bridges. It is therefore a very important fact that should be considered when conducting overload permit checking and setting vehicle weight limits. Two typical truck models were

used in the present study, including the HS-20 design truck specified in the AASHTO LRFD code (AASHTO 2012), which was used in this study for calculating the design load effect, and the design fatigue truck specified in the AASHTO fatigue guide specifications (AASHTO 1990). The fatigue truck was utilized in calculating the cumulative fatigue damage caused by the traffic loads on the bridge and was also adopted as the reference model for overweight trucks.

The simplified configuration of the two trucks is shown in Figure 1. It is noted that these two trucks have very similar configurations except the axle distance between the middle and rear axles (denoted as L in Fig. 1), which is 4.27 m and 9.14 m, respectively, for the HS-20 truck and the design fatigue truck. A gross vehicle weight (GVW) of 320 kN was set for the two truck models. This weight was found by researchers to be a good representative of the effective gross weight of heavy trucks on the highway (Chotickai & Bowman 2006).

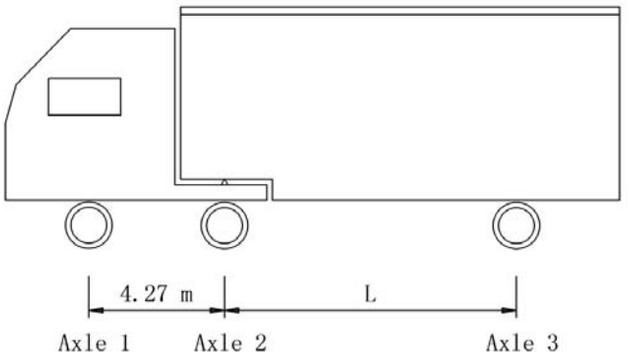

Figure 1. The truck models adopted in the present study

To investigate the effect of GVW of the overweight trucks on the fatigue damage of bridges, five more GVW values were considered for the overweight trucks, namely, 363 kN, 400 kN, 445 kN, 489 kN and 534 kN. To make the analysis simple, the overweight trucks were assumed to have the same axle spacing of the design fatigue truck. In addition, the extra weight of the overweight truck is proportionally distributed to each truck axle. An ADTT of 2000, which is used in the AASHTO (2012) code in the design, was adopted in this study.

3 BRIDGE MODEL

3.1 *Finite element model of bridge*

In the present study, a typical simply-supported steel-concrete composite girder bridge designed according to the AASHTO LRFD code (AASHTO 2012) was adopted for the purpose of illustration. This bridge is 30.48 m in length and 9.75 m in width. Figure 2 shows the cross section of the bridge. As shown in the figure, this bridge consists of five identical steel I-girders with spacing of 2.13 m and height of 1.61 m, the details of which are listed in Table 1. A 3-dimensional (3D) finite element (FE) model of the bridge was built using the ANSYS program, as shown in Figure 3. In this FE bridge model, the concrete bridge components including the deck, steel girders and guardrail were modeled by solid elements while the steel diaphragms were modeled by shell elements. In addition to the end diaphragms, three intermediate diaphragms were arranged with the purpose of distributing the live load more evenly.

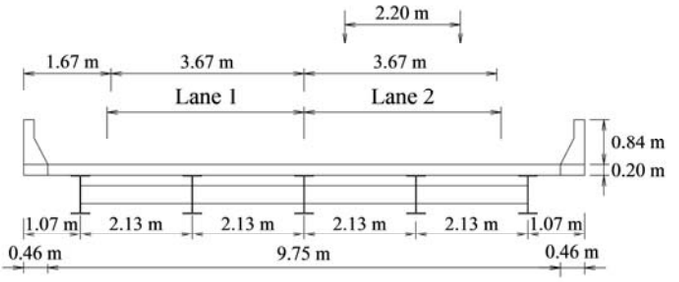

Figure 2. Cross section of the bridge considered

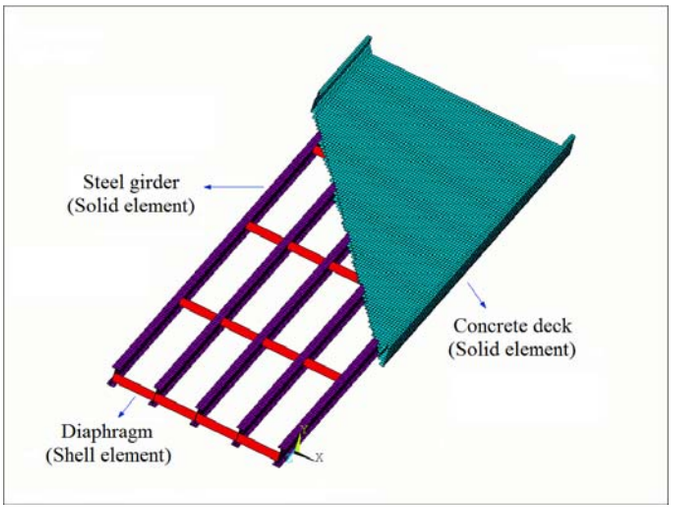

Figure 3. FE bridge model

Table 1. Details of the steel I-girders of the bridge considered

Cross -sectional area	Moment of inertia	Initial Young's modulus	Poisson's ratio
m^2	m^4	GPa	
0.02	0.0011	210	0.25

Studies have shown that the dominant internal force for small-to-medium-span bridges is usually the bending moment which governs the design of bridge cross sections (Brühwiler & Herwig 2008; González et al. 2011). Therefore, in the present study only the bending stress on the bridge girders was considered. Besides, only one loading case with the truck loading in the slow lane was considered, as shown in Figure 2, for the following reasons. Firstly, the chance of two overweight trucks present on the bridge at the same time is very small (Fu & You 2009; Zhang & Cai 2012). Secondly, the case with one truck loading in the slow lane is also suggested by the AASHTO LRFD code (AASHTO 2012) for fatigue consideration. Assuming that the bridge is free from any fatigue damage, the maximum static bending stresses on the bridge girders under the action of different trucks are shown in Table 2. It should be noted that these results were obtained when the truck was loaded at the most unfavorable longitudinal position. In addition, a detailed finite element analysis was used to obtain the girder stress.

Table 2. Maximum static bending stress on the bridge girders caused by different trucks

Truck Type	GVW	Bending stress
	kN	MPa
HS-20 design truck	320	31.88
Design fatigue truck	320	26.86
	363	30.28
	400	33.38
Overweight tr;uck	445	37.13
	489	40.80
	534	44.56

3.2 *Accumulated fatigue damage on bridges*

The Miner's cumulative damage model (Miner 1945), which is usually referred to as Miner's Rule, was adopted in the present study in calculating the cumulative fatigue damage of bridges. Miner's Rule was suggested for the calculation of effective stress range by the AASHTO LRFD code (AASHTO 2012) and has been widely used in bridge design (Fatemi & Yang 1998). With the obtained stress time history, Equation 1 was then adopted to calculate the vehicle-induced cumulative fatigue damage on the bridge girders:

$$\mathrm{CFD}(t)=\sum_i \frac{n_i}{N_i} \tag{1}$$

where n_i and N_i are the actual number of stress cycles and the fatigue life corresponding to the ith stress-range S_i, respectively. In addition, only stresses larger than 3.45 MPa caused by the passage of a truck was considered. The rainflow counting algorithm was adopted in the present study to count the number of stress ranges (Downing & Socie 1982).

4 VEHICLE WEIGHT LIMIT ANALYSIS METHOD

The goal of overweight vehicle management is to control the overstress due to the overweight vehicles under an acceptable level to ensure the safety of the bridge structure. Based on the experience from previous studies (Vigh & Kollár 2007; Correia & Branco 2006), in the present study the stress ratio (SR), which is defined as the stress due to the overload to the stress caused by the design load vehicle (as shown in Eq. 3), was used as the basis for permit checking.

$$SR = \frac{S^{OV}}{S^{DLV}} \tag{2}$$

where S^{OV} and S^{DLV} are the bending stresses caused by the overweight truck and the design load vehicle, respectively.

To consider the dynamic effect of vehicle load when calculating the CFD, a dynamic load allowance of 0.15 as specified in the AASHTO LRFD code (AASHTO 2012) was added to the static bending stress range. Based on the dynamic bending stress range, Equation 1 was used to calculate the CFD, while Equation 2 was used to calculate the SR, which was used as the basis for permit checking. The detailed procedure is illustrated by the flowchart in Figure 4.

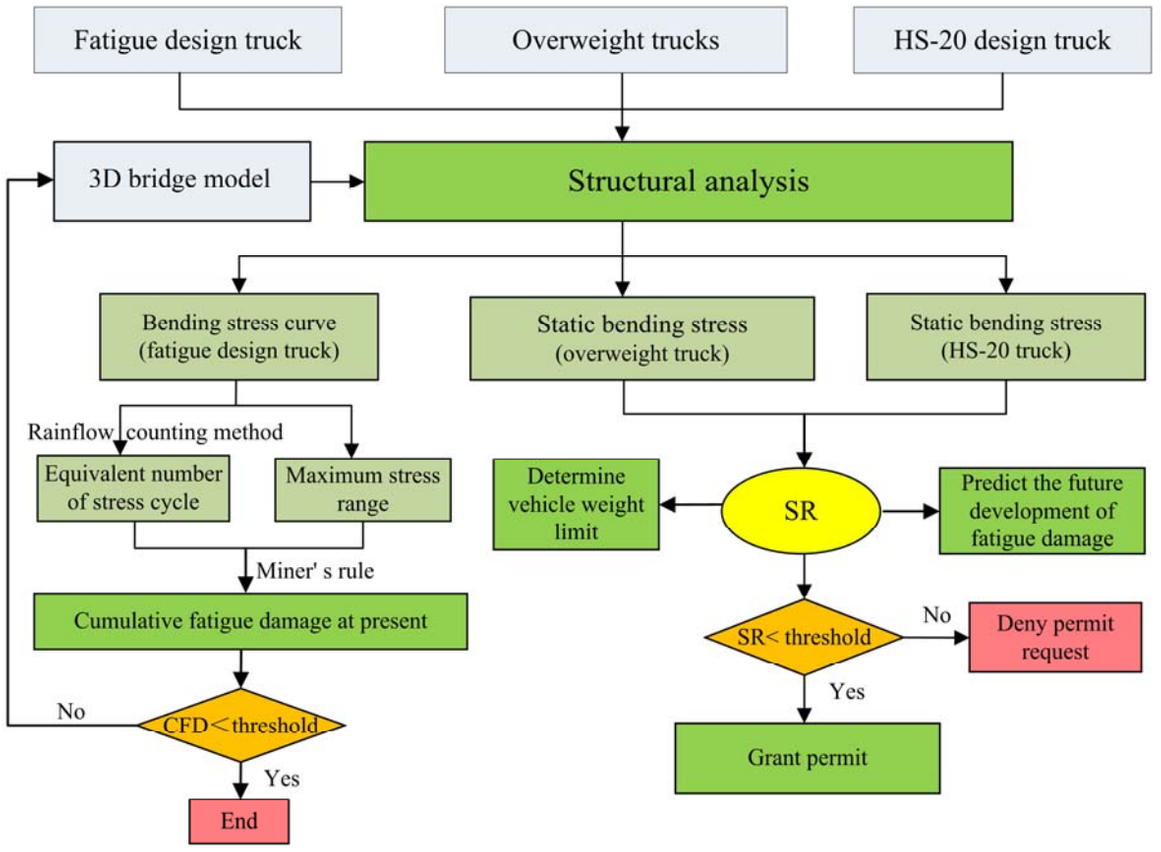

Figure 4. Flowchart for determining vehicle weight limit and making permit decision

5 VEHICLE WEIGHT LIMIT ANALYSIS CONSIDERING THE CFD OF BRIDGES

Selecting a proper threshold value for SR is critical to determine whether an overweight vehicle should be granted a permit. Once determined, the threshold SR value generally sets the limits on the GVW for different trucks. In general, if the SR value due to an overloaded vehicle is less than the threshold value adopted, the vehicle could be granted an automatic permit. For a new bridge, adopting different threshold values of SR means allowing vehicles with different GVWs to cross the bridge and will cause different levels of fatigue damage after a certain period of time.

For the purpose of illustration, it was assumed that bridge girders are replaced when the CFD index of the bridge girders reaches 0.5, which usually corresponds to a poor condition rating (Cha et al. 2014). It should be noted that in reality the decision of bridge girder replacement is made based on many factors, such as the condition rating of the bridge components, the priorities of the DOT, and the availability of funds, etc. (INDOT 2010).

Figure 5 shows the development of bridge fatigue damage with time under different threshold values of SR adopted, assuming that the trucks strictly obey the weight limits. From Figure 5 it can be seen that the selection of threshold value of SR has a significant effect on the cumulative fatigue damage of the bridge structure. For example, for the bridge under consideration, it takes more than 75 years for the CFD on the bridge girders to reach 0.5 if a SR of 0.7 is adopted while it only takes about 10 years if a SR of 1.4 is adopted. Therefore, selecting different SR values can make a big difference in the resulting fatigue life of bridges.

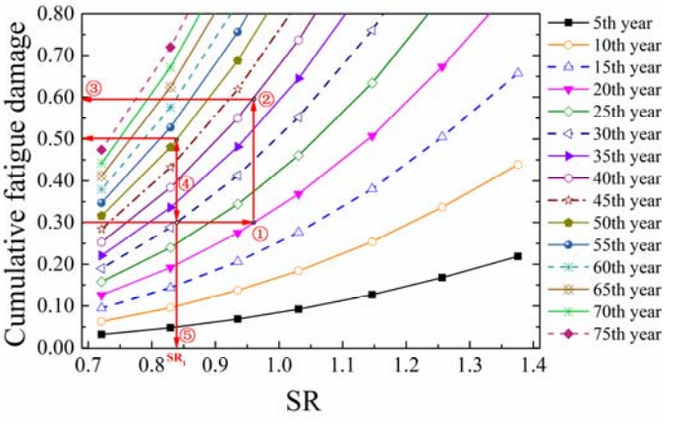

Figure 5. Development of fatigue damage under different threshold values of SR

Based on the relationships between the CFD and the influencing factors, such as the servicing time, and SR, a method for determining vehicle weight

limit was proposed considering the CFD of bridges. This method works for both new bridges as well as existing bridges.

For a new bridge, based on the relationships between the CFD and the two parameters, namely, the SR and the service time, as shown in Figure 5, the threshold value of the SR can be obtained in order to achieve the desired service life of some key bridge components, for example, the girders. Once the threshold value of SR is determined, the truck weight limit can then be obtained by back calculation using Equation 2. In the present study, an example was adopted to illustrate the proposed procedure and it was assumed that the replacement of bridge girders is undertaken at the point when the CFD of the bridge component reaches 0.5. Assuming the bridge under consideration has the relationships between different parameters as shown in Figure 5 and the expected service life of the bridge girders is 25 years, it can be found from Figure 5 that it takes 25 years for the CFD of the bridge girders to reach 0.5 if a SR value of 1.05 is taken. Therefore, in order to achieve the desired service life, a SR value of 1.05 should be taken as the threshold value. Since the design stress of the bridge girders is calculated to be 31.88 MPa, as listed in Table 2, the allowable stress due to an overweight truck is therefore calculated as 1.05 times 31.88 MPa, which gives 33.47 MPa. According to the results in Table 2, this stress corresponds to a GVW of about 400 kN. It should be noted that the overweight truck is assumed to have the same geometric sizes as the fatigue design truck in this analysis. Therefore, during the implementation of the weight regulations in practice, vehicles with weights under 400 kN can be granted an automatic pass. For a truck that is heavier than 400 kN, structural analysis may be performed to determine whether the overweight truck should be granted a pass or not. If the truck leads to a stress of larger than 33.47 MPa on the bridge girders, then the permit request of the truck can be rejected. Otherwise, the truck may be issued a permit.

In addition to determining the weight limit for new bridges, Figure 5 can also be used to guide the determination of vehicle weight limits for bridges in service. To illustrate the process, the steel-concrete composite girder bridge was used again as an example. In this example, the following assumptions were made: (1) this bridge has been in service for T_0 (=20) years and the cumulative fatigue damage on the bridge girder is estimated as CFD_0 (=0.3); and (2) the expected service life of the bridge girders is T_{exp} (=40) years at the point when the CFD reaches the threshold value of 0.5. The detailed procedure is illustrated in the following with the step numbers also marked in Figure 5 for the purpose of convenience.

Step 1: Find the intersection (numbered as Point ①) between the SR-CFD curve for the T_0th (20st) year and the horizontal line with CFD=0.3.

Step 2: From Point ① obtained in the previous step, draw a vertical line down and find the intersection point of this vertical line and the CFD curve for the T_{exp}th (=40th) year, as denoted as Point ②.

Step 3: Find out the CFD value at Point ② (denoted as CFD_{exp}) and compare it with the threshold value of 0.5 as denoted by Point ③. If the CFD_{exp} exceeds the threshold value of 0.5, more restrictive vehicle weight limit needs to be enforced in order to achieve the desired service life. Otherwise, less restrictive vehicle weight limit may be used. For this example, the CFD_{exp} is equal to 0.59, which is greater than the threshold value and more restrictive vehicle weight limit should therefore be enforced.

Step 4: Draw a vertical line that intersects with the CFD curves for the T_{exp}th (=40) year and the T_0th (=20) year; calculate the vertical distance between the two intersection points and compare this distance with the margin value between the threshold CFD (0.50) and the current CFD (0.30), which gives 0.2. Move the vertical line to the left or right until the vertical distance between the two intersection points is equal to the margin (0.20), which is shown by the number ④ in Figure 5.

Step 5: Find out the intersection of the final vertical line as determined from the previous step with the horizontal axis, which is denoted as Point ⑤. The SR value at Point ⑤ is the threshold SR value that should be adopted in determining the vehicle weight limit. In this example, a value of 0.84 should be adopted as the threshold for weight limit purposes.

6 CONCLUDING REMARKS

A method for determining vehicle weight limit and overload permit checking was proposed which can consider the cumulative fatigue damage of bridges due to repeated vehicle loading. The proposed method can also be used to predict the future development of fatigue damage with assumed traffic information in the future. A typical steel-concrete composite girder bridge was used as an example for illustrating the proposed method. One important finding from this study is that the threshold value of stress ratio adopted in determining weight limits has a significant effect on the resulting cumulative fatigue damage of bridge components and therefore their fatigue life. Since the allowable stress ratios adopted by different codes are different, in order to determine a reasonable allowable stress ratio, further

analysis may be required.

ABSTRACT: The wind monitoring data collected from July to August 2015 of a large span suspension bridge in East China Sea and 32 vortex-induced vibration events during this period are studied in this paper. Firstly, the wind speed, wind direction, gust factor and turbulence intensity during the vortex-induced vibration are calculated. The results show that the wind speed and direction can be used to predict the occurrence of the vortex-induced vibration. And then, by the statistics of wind speed and direction of vortex-induced vibration events and the normal conditions, the occurrence probability of vortex-induced vibration can be determined by taking advantage of the data recorded by a single anemometer. Finally, data fusion theory is carried out to determine the occurrence probability of vortex-induced vibration by combining the results of multiple anemometers. The analysis result is available to develop the management measures to manage the vortex-induced vibration.

1 INTRODUCTION

1.1 *Research backgrounds*

When the near-ground airflow of the atmospheric boundary layer passes through the bridge section, flow separation and periodic vortex shedding will occur which results in alternating changes in positive and negative pressures on the upper and lower surfaces of the main beam. Alternate changes of the pressure may cause the bridge to occur vortex-induced vibration in the transverse or twisting direction (Haber, 1982). Vortex-induced vibration is a kind of common wind-induced vibration of bridge. Although the vortex-induced vibration does not have a strong destructive nature, it will cause structural damage or fatigue damage because of its low wind speed, long lasting vibration, and seriously affecting the driving comfort and safety. Since the 1990s, the rapid development of new technologies, materials and construction technologies make the bridge structure more flexible. With the span of bridges becoming larger and larger, the occurrence probability of vortex-induced vibration is increasing. Therefore, the way to estimate the amplitude of vortex-induced vibration correctly and put forward reasonable and effective vibration suppression measures need to be developed urgently during the design of large span bridges. The effect of wind on structures has been studied since long ago. The study of vortices by human began around 1500 years ago. The earliest fluid vortex study is carried out by Da Vinci who is known for his artistic achievements. Through the observation of stream in-depth, Da Vinci obtained the basic understanding of the movement of the vortex and proposed the concept of 'eddy' for the first time (Maurin, 1998). As is shown in Figure 1, he painted a lot of paintings about 'eddy' in his life. He took a lot of time to observe the overall shape of the flow. He found that vortex was very evident in the flow of fluid around the blunt body. Nowadays, the movement characteristics of vortex is still one of the hot spots.

Figure 1. Da Vinci's painting of the vortex.

Vortex-induced vibration is a very complex fluid-solid coupling phenomenon (Shimada, 1991). However, vortex-induced vibration is not paid sufficient attention in the initial stage due to insufficient un-

derstanding of wind pressure. It is difficult to obtain the analytic solution of vortex-vibration problem and solve the problem of vibration-induced vibration by purely theoretical method (Uetani, 2000). Therefore, the semi-empirical model should be established based on the actual vibration. By selecting the undetermined parameters in the empirical model, the actual situation of the model can be obtained and the complicated flow solid coupling problem can be solved. Bishop and Hassan first used the 'vanderpol oscillator' to describe the turbo-kinetic equation of the cylinder in 1963, which was later adopted by many scholars. Hartlen-Currie experience model is constructed by Hartlen in 1970 based on 'vanderpol oscillator'. Through the selection of appropriate parameters, the model can correspond to the characteristics of vortex-induced vibration observed from the test results quantitatively. Skop et al solved the problem that the parameters of the Hartlen-Currie model were not related to the physical parameters of the system and proposed the 'modified vanderpol oscillator model' (Kassem, 1992). By the literature review above, it is obvious that the current research on the vortex-induced vibration of the bridge mainly aimed at avoiding the occurrence of the vortex-induced vibration. The vortex-induced vibration analysis theory is carried out to guide the design of the bridge. However, due to the shortcomings of the existing theoretical research and insufficient consideration of bridge environment in the design process, it is impossible to ensure that all bridges will not occur vortex-induced vibration. So, how to predict the occurrence of vortex-induced vibration and take targeted management measures for those bridges that frequently occur vortex-induced vibration make a lot of sense.

1.2 *Study content*

In the 21st century, more and more countries have paid attention to the maintenance and management of bridges especially those large span bridges. Europe, America and Japan, South Korea, and Hong Kong SAR have proposed a new method 'Active and preventive maintenance and management'. According to the new idea, various types of structural health monitoring sensors were installed on some important bridges. More and more civil engineers began to study on the bridge structural health monitoring data analysis to improve the maintenance technology and methods. Bridge maintenance and management with monitoring data quickly became the focus of world. At present, most of the large span bridges have installed monitoring system which provides effective method of predicting and early warning of vortex-induced vibration based on monitoring data. In the field of bridge engineering, data mining technology has been widely used in bridge health monitoring data analysis, data mining analysis of bridge monitoring data has been carried out according to the characteristics of the bridge monitoring data and set up clustering model, relational model and time series model. These three mathematical models can be used to judge and identify the current health condition of the bridge. Under this background, the wind monitoring data collected from July to August 2015 of a large span suspension bridge in East China Sea and 32 vortex-induced vibration events during this period are studied in this paper. There are four indexes may be selected to represent the characterization of wind field, which are wind speed, wind direction, turbulence intensity and gust factor.Firstly, the wind speed, wind direction, gust factor and turbulence intensity during the vortex-induced vibration are calculated. It is determined that the wind speed and direction should be used as the index to predict the occurrence of the vortex-induced vibration. However, the turbulence intensity and gust factor are not associated with the occurrence of vortex-induced vibrations. And then, by the statistics of wind speed and wind direction of vortex-induced vibration events and normal conditions, the occurrence probability of vortex-induced vibration can be determined by taking advantage of a single anemometer. Finally, data fusion theory is carried out to determine the occurrence probability of vortex-induced vibration by combining the results of multiple anemometers. The analysis result is available to develop the management measures of the bridge before the occurrence of vortex-induced vibration.

2 BACKGROUND ENGINEERING INTRODUCTION

The suspension bridge in East China Sea is one of the largest sea-crossing bridge between Zhoushan mainland and islands link project. The trend of the bridge is from north to south. What's more, the hydrogeological conditions of the bridge area are complex, the wind environment is complicate and the technical requirements are high. The bridge is a two-span suspension bridge with 1650m main span and 578m side span which is the second largest span suspension Bridges. The stiffening beam adopts the separated steel box girder with the lifting arm. The steel box girder is 3.51m high and the total width is 36m. The tower of the bridge is 211m and the rise span ratio of the main cable is equal to 1/10. The elevation of the bridge is shown in Figure 2. The wind field of the bridge site are complex because the summer typhoon and the winter monsoon may affect the bridge. To provide reliable data to assess the safety of the bridge under wind effect, two propeller anemometers and six three-directional ultrasonic anemometers were installed to collect the wind field data of the bridge site. As is shown in Figure 2, propeller anemometers and three-directional ultrasonic

anemometers are installed on the top of the pylon and the deck, respectively. Two propeller anemometers (AN1, AN2) are installed in the north and south pylon of the bridge. The three-directional ultrasonic anemometers (UA1-UA6) are installed on the upper and lower sides of the stiffened beam at the 1/4, 1/2 and 3/4 of the main span, respectively.

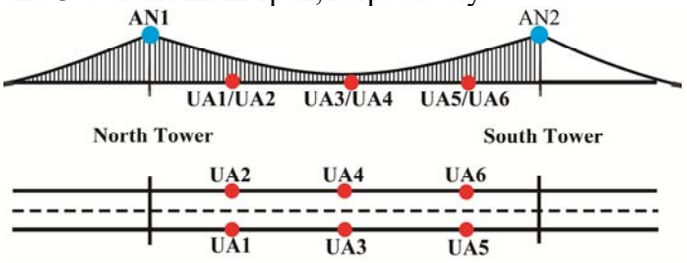

Figure 2. The layout of wind speed sensor.

Through the records of the bridge manager, the bridge has occurred 97 times vortex-induced vibration from 2013 to 2015, including 26 times in 2013, 35 times in 2014, 36 times in 2015. The main information of those vortex-induced vibration events, such as the bridge vibration frequency, wind speed, wind direction and duration et al are recorded. As presented in Table 1, it is the main information of some vortex-induced vibration events.

Table 1. The main information of some vortex-induced vibration events of a bridge in East China Sea.

Events number	Vibration frequency	Wind speed	Wind direction	Duration time
	hz	m/s	degree	minute
1	0.3284	10.45	311	30
2	0.3287	9.85	310	160
3	0.3269	8.97	134	40
4	0.3271	8.68	155	70
5	0.3257	7.59	132	30
6	0.4357	9.47	313	100

3 PREDICTION PARAMETERS ANALYSIS OF VORTEX-INDUCED VIBRATION

3.1 *Parameters of wind speed and wind direction*

By the preliminary data integrity and accuracy check of the data collected by the propeller anemometers (AN1, AN2) and three-directional ultrasonic anemometers (UA1-UA6) during the vortex-induced vibration, the wind field data of three-directional ultrasonic anemometers are recorded completely. What's more, the wind speed and wind direction of these anemometers are related with the occurrence of vortex-induced vibration. To improve the efficiency of data analysis, three of all the six three-directional ultrasonic anemometers are selected. That is, only one anemometer in the same longitudinal section is selected to carry out the occurrence probability analysis of vortex-induced vibration. Therefore, the monitoring data collected by UA1, UA3 and UA5 are set as the study object. In addition, by the statistics of the occurrence time of vortex-induced vibration, there are 86 vortex-induced vibration events occurred in July and August of all the 97 vortex-induced vibration events. Therefore, the wind monitoring data collected from July to August 2015 and 32 vortex-induced vibration events during this period are studied in this paper to carry out the occurrence probability analysis of vortex-induced vibration.

The wind speed collected by the three-directional ultrasonic anemometers installed on the large span suspension bridge is defined as $u(t), v(t)$ and $w(t)$, in each direction, respectively. The definition of wind speed $u(t), v(t)$ and wind direction Φ in the plane relative to the bridge axis are shown in Figure 3 and the vertical wind speed $w(t)$ is from bottom to the top. The angle of the bridge axis is about 45 degrees.

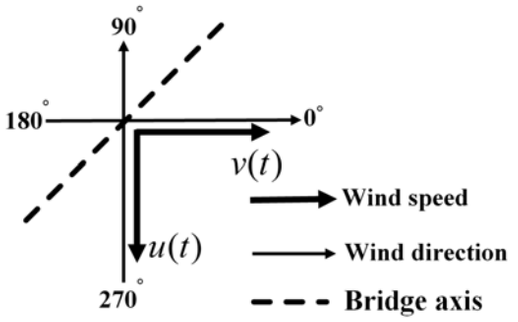

Figure 3. The schematic of wind speed and direction.

The base interval is set as 10-minute. What's more, the mean wind speed in the plane and the corresponding direction angle are defined as U and Φ, respectively. The average vertical wind speed is defined as W. The monitoring wind data are calculated and analyzed as follows:

$$U = \sqrt{\overline{u(t)}^2 + \overline{v(t)}^2} \tag{1}$$

$$\cos\Phi = \overline{u(t)}/U \tag{2}$$

$$W = \overline{w(t)} \tag{3}$$

Where $\overline{u(t)}, \overline{v(t)}$ and $\overline{w(t)}$ = the average wind speed of 10-minute. According to formula (1)-(3), the mean wind speed in the plane U and corresponding direction angle Φ of the 32 vortex-induced vibration events can be obtained by analyzing the wind data collected by three-directional ultrasonic anemometers. The mean wind speed in the plane U during the vortex-induced vibration and normal conditions calculated by the UA1 anemometers is shown in Figure 4. Figure 5 shows the corresponding direction angle Φ.

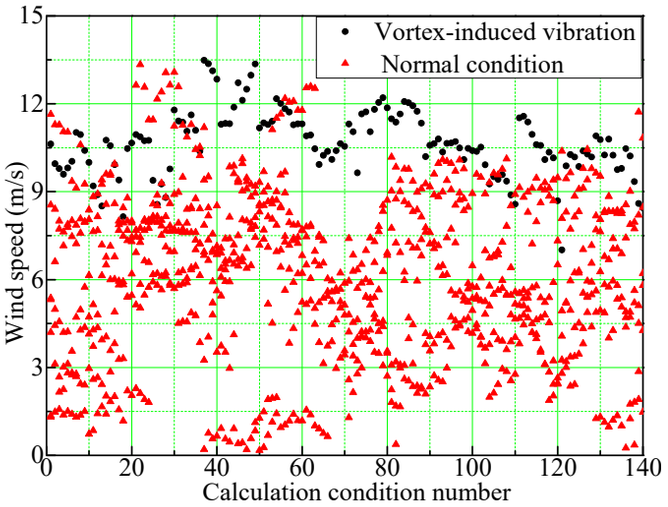

Figure 4. The mean wind speed in the plane *U*.

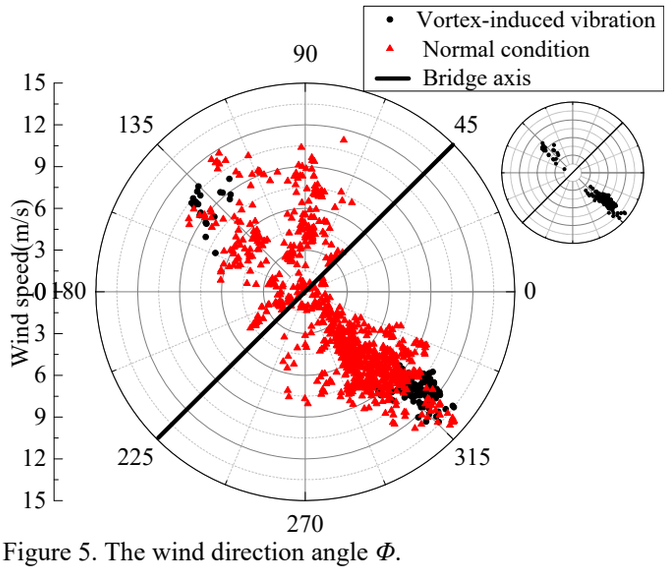

Figure 5. The wind direction angle *Φ*.

It is obvious in Figure 4 that the wind speed ranges from 8.5 m/s to 10.5 m/s when the vortex-induced vibration occurs. There is no vortex-induced vibration when the wind speed is out of this range which indicates that the wind speed is an important characterization parameter of vortex-induced vibration. Therefore, the wind speed is selected as one of the parameters in the process of predicting the occurrence of vortex-induced vibration. Similarly, it can be found from Figure 5 that the distribution of wind direction during the vortex-induced vibration is from 125 degrees to 150 degrees or 305 to 330 degrees whose difference is about 180 degrees. However, there is no vortex-induced vibration if the wind direction is out of this range. In addition, the statistics results of wind direction also indicate that vortex-induced vibrations can occur only when the direction between the wind and the bridge are about 90 degrees. Through the above analysis, wind speed and direction have obvious characteristics in the case of happening vortex-induced vibration. Therefore, the wind speed and wind direction must be taken as parameters to carry out the occurrence probability analysis of the vortex-induced vibration.

3.2 *The parameter of turbulence intensity*

The fluctuating wind speed in the horizontal direction and transverse direction in the plane are defined as u_t, v_t respectively. Moreover, the fluctuating wind speed in the vertical direction is defined as w_t. u_t, v_t and w_t can be calculated according to the following formula:

$$u_t(t) = u(t)\cos\Phi + v(t)\sin\Phi - U \tag{4}$$

$$v_t(t) = -u(t)\sin\Phi + v(t)\cos\Phi \tag{5}$$

$$w_t(t) = w(t) - W \tag{6}$$

The turbulence intensity reflects the pulsating intensity of the wind which is defined according to formula (7)-(9). The turbulence intensity is the key parameter to determine the pulsating wind load of the structure. So, the turbulence intensity should be calculated to analyze whether it is related to the occurrence of vortex-induced vibrations.

$$I_u = \frac{\sigma_u}{U} \tag{7}$$

$$I_v = \frac{\sigma_v}{U} \tag{8}$$

$$I_w = \frac{\sigma_w}{U} \tag{9}$$

Where, σ_u, σ_v and σ_w = the standard deviations of the pulsating wind speed for u_t, v_t, and w_t in 10-minute, respectively. As is shown in Figure 6, it is the turbulence intensity for every 10-minute during the 32 vortex-induced vibration events and the normal conditions according to the data collected from UA1 anemometers.

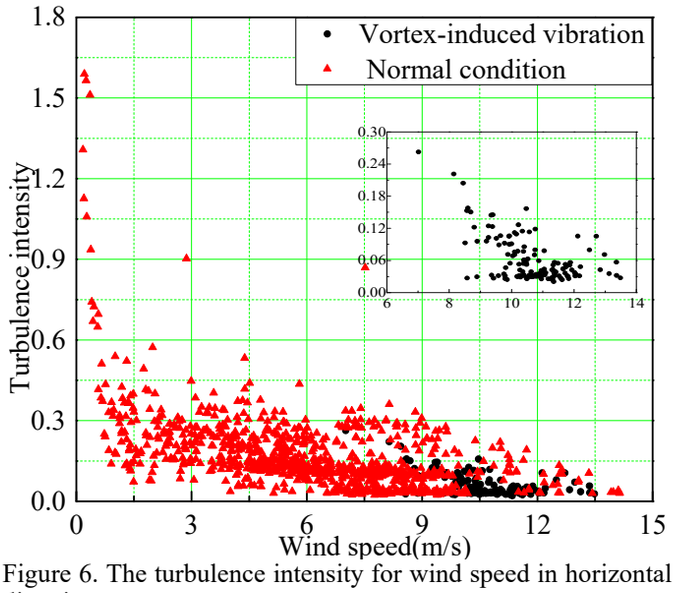

Figure 6. The turbulence intensity for wind speed in horizontal direction.

It is shown in Figure 6 that the turbulence intensity of the wind field of the large span suspension bridge

varies from 0 to 0.3 during the vortex-induced vibration. However, the turbulence intensity of most of normal conditions also range from 0 to 0.3. It indicates that the vortex-induced vibration is not related to the turbulence intensity. Therefore, the turbulence intensity cannot be used as a parameter to predict whether the vortex-induced vibration occurs.

3.3 *The parameter of gust factor*

The fluctuating intensity of the wind is often expressed by gust factor that is the ratio of the maximum wind speed over the duration of the gust duration to the average wind speed U in 10-minute. The gust duration t_g usually is set as 2-3 seconds in structural wind works and t_g is taken as 3 seconds in this paper. The basic formula to calculate the gust factor is as follows:

$$G_u(t_g) = \frac{\max\left(\overline{u(t_g)}\right)}{U} \tag{10}$$

$$G_v(t_g) = \frac{\max\left(\overline{v(t_g)}\right)}{U} \tag{11}$$

$$G_w(t_g) = \frac{\max\left(\overline{w(t_g)}\right)}{U} \tag{12}$$

Where, G_u, G_v and G_w = the gust factor of the pulsating wind speed for u_t, v_t, and w_t in 10-minute, respectively. In general, the greater the t_g, the corresponding gust factor will be smaller, when t_g =10-minute, $G_u = 1, G_v = G_w = 0$. As is shown in Figure 7, it is the gust factor for every 10-minute which is determined by the equations (10)-(12).

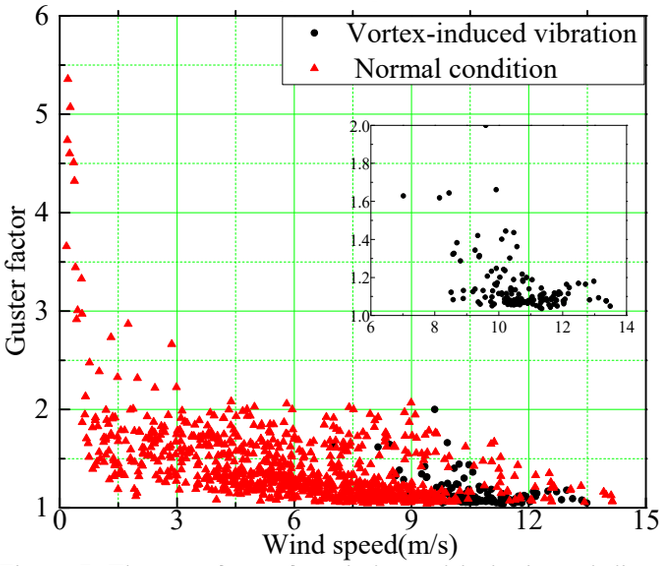

Figure 7. The gust factor for wind speed in horizontal direction.

It is shown in Figure 7 that the gust factor of the wind field of the large span suspension bridge varies from 1.0 to 2.0 during the vortex-induced vibration. However, the gust factor of most of normal conditions also ranges from 1.0 to 2.0. It indicates that the vortex-induced vibration is not related to the gust factor. Therefore, the gust factor cannot be used as a parameter to predict whether the vortex-induced vibration occurs.

Originally, there are four indexes that can be selected to represent the characterization of wind field, which are wind speed, wind direction, turbulence intensity and gust factor. Through the analysis above, wind speed and wind direction have obvious specificity when the vortex-induced vibration occurred. However, neither the turbulence intensity nor the gust factor are associated with the occurrence of vortex-induced vibrations. Therefore, wind speed and wind direction are selected as the parameters to predict the occurrence probability of vortex-induced vibration in this paper.

4 THE OCCURRENCE PROBABILITY ANALYSIS OF VORTEX-INDUCED VIBRATION BASED ON MULTI-PARAMETERS

4.1 *The occurrence probability analysis of vortex-induced vibration based on wind speed*

In last section, the wind speed and wind direction are determined as the parameters to calculate the occurrence probability of vortex-induced vibration. According to the records of the vortex-induced vibration events of the long-span suspension bridge, the vortex-induced vibration mainly occurs in July and August. What's more, the occurrence probability of vortex-induced vibration at other times is scarcely possible and can be negligible. Therefore, the selected 32 vortex-induced vibration events studied in this paper occurred between July and August 2015. So, the wind speed and wind direction data that are collected by the three-directional ultrasonic anemometers (UA1, UA3, UA5) during the period are used to analyze the occurrence probability of vortex-induced vibration in this paper. As shown in Figure 8, it is the 10-minute average wind speed U calculated from July to August in 2015 ranges from 8.5m/s to 13.5m/s.

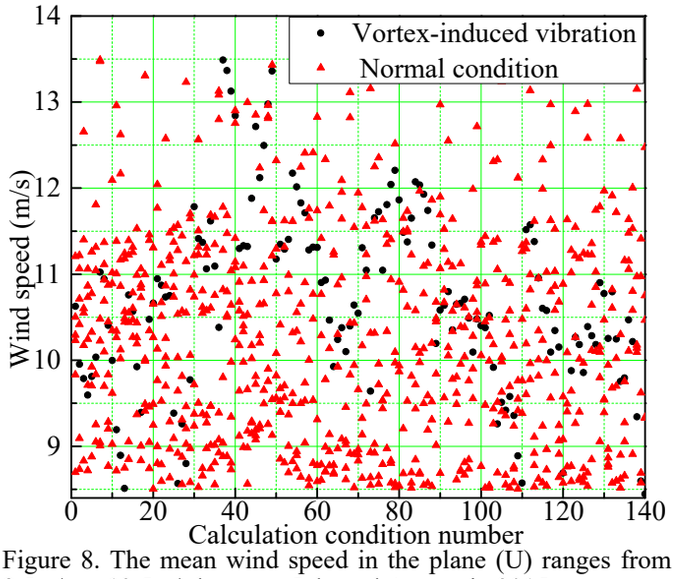

Figure 8. The mean wind speed in the plane (U) ranges from 8.5m/s to 13.5m/s between July and August in 2015.

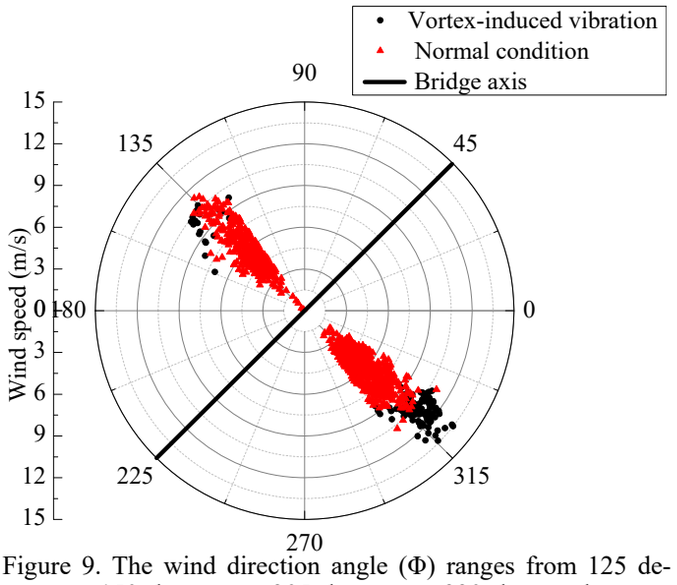

Figure 9. The wind direction angle (Φ) ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees between July and August in 2015.

Through the analysis of the average wind speed during the vortex-induced vibration of the bridge, it is evident that the vortex-induced vibration occurs only when the wind speed is in the range of 8.5m/s to13.5 m/s. What's more, 10-minute is set as a calculation condition in this paper. There are 891 conditions whose average wind speed U range from 8.5m/s to 13.5m/s and 141 of them occurred vortex-induced vibration. Based on the statistical results, it can be calculated that the occurrence probability of vortex-induced vibration of the bridge is 15.7% when the wind speed ranges from 8.5 m/s to 13.5 m/s recorded by the sensor UA1. When the wind speed ranges from 8.5 m/s to 13.5 m/s, the occurrence probability of vortex-induced vibration of the bridge is 14.6% and 14.3% recorded by the sensor UA2 and UA3, respectively.

4.2 *The probability analysis of vortex-induced vibration based on wind direction*

Similarly, the wind direction is also determined as the parameter to calculate the occurrence probability of vortex-induced vibration. As shown in Figure 9, it is the 10-minute average wind direction Φ calculated from July to August in 2015 ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees.

Through the analysis of the average wind direction during the vortex-induced vibration of the bridge, it is evident that the vortex-induced vibration occurs only when the wind direction is in the range of 125 degrees to 150 degrees or 305 degrees to 330 degrees. Based on the monitoring data collected by the three-directional ultrasonic anemometer (UA1), the wind direction ranges 125 degrees to 150 degrees or 305 degrees to 330 degrees have a total of 1145 conditions. However, there are 141 of the 1145 conditions happening the vortex-induced vibration. Based on the statistical results, it can be calculated that the occurrence probability of vortex-induced vibration of the bridge is 12.3% when the wind direction ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees recorded by the sensor UA1. When the wind direction ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees, the occurrence probability of vortex-induced vibration of the bridge is 11.8% and 12.1% recorded by the sensor UA2 and UA3, respectively. Because of the space limit, the detailed calculation process of UA2 and UA3 is not given here.

4.3 *The probability analysis of vortex-induced vibration by combining wind speed with wind direction*

According to the analysis results, the occurrence probability of vortex-induced vibration is 15.7% when the wind speed ranges from 8.5m/s to 13.5 m/s. The occurrence probability of vortex-induced vibration is 12.3% when the wind direction ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees recorded by the sensor UA1. The occurrence probability of vortex-induced vibration is determined by the wind speed parameter and the wind direction parameter indivindividual. In this section, the wind speed and wind direction are combined to

determine the occurrence probability of vortex-induced vibration. As shown in Figure 8, it is the 10-minute average wind speed U ranges from 8.5m/s to 13.5m/s and the average wind direction ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees calculated from July to August in 2015.

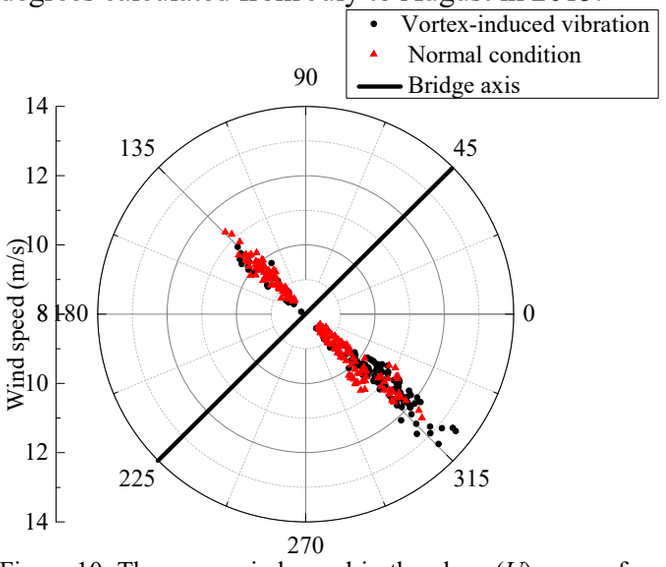

Figure 10. The mean wind speed in the plane (U) ranges from 8.5m/s to 13.5m/s with wind direction angle (Φ) ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees between July and August in 2015.

Through the analysis of the average wind speed and wind direction during the vortex-induced vibration of the bridge, it is evident that the vortex-induced vibration occurs only when the wind speed is in the range of 8.5m/s to13.5m/s as well as the wind direction ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees. Based on the monitoring data collected by the three-directional ultrasonic anemometer (UA1), a total of 208 conditions are available for both the wind speed and wind direction. However, 141 of the 208 conditions occurs the vortex-induced vibration. Based on the statistical results, it can be calculated that the occurrence probability of vortex-induced vibration of the bridge is 67.7%. That is, if the wind speed ranges from 8.5m/s to 13.5m/s and wind direction ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees recorded by the sensor UA1, the large span suspension bridge has a 67.7% probability of occurring vortex-induced vibration. Similarly, if the wind speed is in the range of 8.5m/s to 13.5m/s and the wind direction ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees, the occurrence probability of vortex-induced vibration of the bridge is 59.4% and 64.3% recorded by the sensor UA2 and UA3, respectively.

5 THE PROBABILITY ANALYSIS OF VORTEX-BASED VIBRATION BASED ON DATA FUSION THEORY

5.1 *Dempster-Shafer Evidence combination theory*

Due to the huge scale and complex characteristics of the bridge structures, it is necessary to use a variety of sensors to monitor the bridge structure to get better results. Therefore, many types of sensors will inevitably produce a lot of similar or different types of signals. It is a much worth studying subject how to deal with these signals effectively and analyze the collected data of these sensors to get better and more accurate conclusion. The common data fusion algorithms are Bayesian theory, Dempster-Shafer Evidence theory and Neural Network theory et al. Bayesian theory is a data fusion algorithm based on Bayesian statistical inference. Because the target information and the priori information of the monitor play an important role in the whole fusion system, the effectiveness of the Bayesian data fusion system theory will depend on all kinds of prior information (Matsumoto, 1992). However, the bridge monitoring system is a very complex and the structural parameters of different bridges differ greatly. So, it is very difficult for us to effectively extract a variety of a priori information. Dempster and Shafer put forward that the theory of evidence is the extension of probability theory in the 1970s. They establish the one-to-one correspondence between the proposition and the set and transform the uncertainty of the proposition into the uncertainty of the set. In addition, the theory of the evidence is the uncertainty of the set. Dempster-Shafer Evidence theory satisfies the axioms that is weaker than the probability theory and can distinguish between uncertain and unaware differences. When the probability value is known, the theory of evidence becomes probability theory. Thus, probability theory is a special case of evidence theory. When the priori probability is difficult to be obtained, the Dempster-Shafer Evidence theory is more appropriate than the probability theory.

5.2 *The occurrence probability analysis of vortex excitation vibration by combining multi-sensor*

In the evidence theory, a sample space is called a recognition framework, which is often represented by θ. θ consists of a series of objects which are mutually exclusive and contain all the objects should be identified. The definition of θ as follows:

$$\Theta=\{\Theta_1,\Theta_2,\cdots\Theta_n\} \tag{13}$$

Where the object Θ_i is called a 'monad' of Θ. If a recognition framework only contains one 'monad', it is called a collection of 'monad'. Then, $m(A)$ is defined to represent the degree of confidence to hypothesis A that is given the evidence. That is, the degree of trust in the proposition 'x is in A'. One of

the basic strategies of Dempster-Shafer Evidence theory is to divide the set of evidence into two or more irrelevant parts and use them to judge the identification framework independently. Then, different parts are combined by the Dempster-Shafer Evidence combination rule. Let Bel_1, Bel_2 be two trust functions based on different evidence, Bel is the trust function obtained after combining the evidence. If m_1, m_2, and m represent the basic probability distribution functions for Bel_1, Bel_2, and Bel, respectively, the Dempster-Shafer Evidence theory combination rule can be expressed as:

$$m(A)=\frac{\sum_{A_1\cap A_2=A} m_1(A_1)m_2(A_2)}{\sum_{A_1\cap A_2\neq\varnothing} m_1(A_1)m_2(A_2)} \tag{14}$$

It can be proved that the orthogonal sum meets the commutative and the associative law. The final evidence obtained from the combined evidence is independent of the order in which the composition is made. So, if there are multiple combinations of evidence, m can be obtained by recursive computation of m_1, m_2,…m_n. Then, the Dempster-Shafer Evidence theory combination rule can be expressed as:

$$m(A)=\frac{\sum_{A_1,\cdots A_k\subset\Omega,\ \bigcap_{i=1}^{k}A_i=A} m_1(A_1)\cdots m_k(A_k)}{\sum_{A_1,\cdots A_k\subset\Omega,\ \bigcap_{i=1}^{k}A_i\neq\varnothing} m_1(A_1)\cdots m_k(A_k)} \tag{15}$$

The monitoring data recorded by UA1, UA2 and UA3 three-direction anemometers are selected to calculate the occurrence probability of vortex-induced vibration of the bridge. As the above calculation analysis, if the wind speed ranges from 8.5m/s to 13.5 m/s and wind direction ranges from 125 degrees to 150 degrees or 305 degrees to 330 degrees recorded by the sensor UA1, the large span suspension bridge has a 67.7% probability of occurring vortex-induced vibration. Similarly, the occurrence probability of vortex-induced vibration of the bridge is 59.4% and 64.3% recorded by the sensor UA2 and UA3, respectively. According to equation (15), the occurrence probability of vortex-induced vibration is 84.6% through orthogonal combination analysis based on the Dempster-Shafer Evidence theory.

6 CONCLUSIONS AND PROSPECT

Through the preliminary analysis of the monitoring data collected by the three-direction anemometers installed on a large span suspension bridge in East China Sea, the wind speed and wind direction are selected as the parameters to predict the occurrence probability of vortex-induced vibration in this paper. Then, it is determined that the occurrence probability of vortex-induced vibration of the bridge is 67.7%, 59.4% and 64.3% respectively by analyzing the data of each anemometer. Finally, the data fusion theory is used to combine the results of the three anemometers and the occurrence probability of vortex-induced vibration of the bridge is 84.6%. However, only the wind speed data during the vortex vibration is analyzed and the vibration data of the bridge is not analyzed. There is no doubt that the accuracy of prediction of the occurrence probability of vortex-induced vibration of the bridge will be greatly improved if the wind speed data and the vibration data are combined.

Development of phased array ultrasonic test system for detection of fatigue crack of rib-to-deck weld of orthotropic steel deck system

H. Shirahata
Department of Urban and Civil Engineering, Tokyo City University, Tokyo, Japan

ABSTRACT: Fatigue cracking of the orthotropic steel deck system has been one of the serious problems. This study focuses on rib-to-deck weld of a trough rib. Nondestructive testing is necessary, because a fatigue crack is initiated at the weld root of a closed section, and visual inspection is practically impossible. Recently, the phased array ultrasonic test systems have been developed and applied in some fields This study aims at the development of a phased array system and investigates the applicability to the rib-to-deck weld of two types of fatigue cracks; one is deck crack and the other is bead crack. The system consists of two phased array transducers, fl w detector, personal computer, and a scanner. Two transducers were set on a deck plate and a rib plate to detect deck and bead cracks, respectively. The number of elements that can be excited and received at a time was 128. Two types of specimens considering deck and bead cracking were prepared. Fatigue tests were carried out. At every 100 kilocycles, the specimen was taken out of the test site, and ultrasonic tests were applied. In the next step, the amplitude of loading was changed in order to make beach marks. Those procedures were repeated until fatigue failure. After failure, a comparison between the actual propagation of a fatigue crack and the result of ultrasonic test was made. Relatively good agreement could be observed, and the result showed that the fatigue cracks of approximately 2 to 3 mm could be detected by the phased array ultrasonic test system.

1 INTRODUCTION

1.1 *Orthotropic steel deck system and fatigue crack*

Fatigue cracking of orthotropic steel deck system is a serious problem in Japan and many countries (Wolchuk 1999, Wolchuk 1990, Connor & Fisher 2006, Ya, Yamada, & Ishikawa 2011). Fatigue cracking has been reported in almost all the types of welded joints (Federal Highway Administration (FHWA) 2012). This study focuses on rib-to-deck weld, because it is the longest and the most important to support the traffic Figure 1 (a) shows an under view of the orthotropic steel deck system. Regarding the longitudinal rib, a closed section was employed, because of the increase of torsional rigidity and decrease of weld lines. In Japan, U-shaped trough ribs have been applied.

As shown in figur 1 (b) the conventional trough rib in Japan measures 240 mm in height and 300 mm in length. Deck and rib plates are 12 and 6 mm thick, respectively. Figure 1 (c) shows details about rib-to-deck weld in Japan. In 2002, specification on rib-to-deck weld penetration were established. The penetration should be 75 % of the rib plate thickness, while before 2002, there was not description of the penetration (Miki 2006).

In the rib-to-deck weld, two types of fatigue cracks have been reported. One is deck crack and the other is bead crack. In both cases, a crack is initiated at the weld root. Since it is a closed section, visual inspection cannot be applied.

1.2 *Ultrasonic test*

Among nondestructive techniques, ultrasonic test has played a very important role to detect internal defects. The conventional ultrasonic technique is pulse echo method. In the pulse echo method, one or two transducer(s) are used. A defect can be detected by locations where indications can be obtained in scanning and incident angle of a transducer. However, detection of the cracks in figur 1 (d) is difficult There are three reasons. One is the limited accessibility. It is difficul to move transducers back and forth nearby the rib-to-deck weld. The second is incident angle is fi ed around 70 degrees. Defect echo cannot be received until a deck crack becomes 6 mm or longer. Larger incident angle is preferable, but, it also gets more sensitive about the surface condition. The third is existence of reflectors In case of bead crack, especially, weld root corner, weld root tip, and crack tip can be scatterer of the incident wave. That makes it more difficul to distinguish each of those echoes.

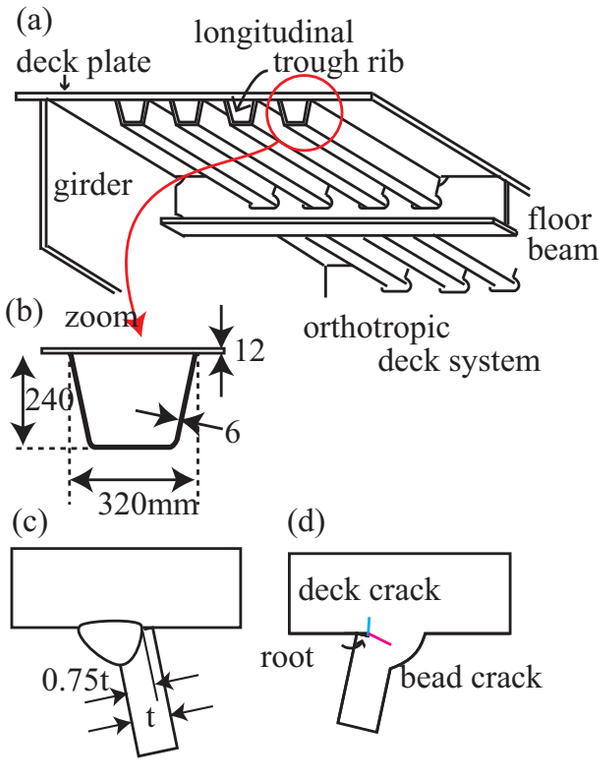

Figure 1: Orthotropic steel deck system and fatigue cracks in rib-to-deck weld

In recent year, phased array ultrasonic test systems have been investigated and applied (Drinkwater & Wilcox 2006, Azar & Wooh , Holmes & Wilcox 2005, Weston M. 2012). As shown in figur 2 (a), many small elements are aligned in a phased array transducer housing. The size of those elements is usually about half of the wave length in steel. By the phased array system, condition of incident wave can be changed. As shown in figur 2 (b), when an element of left side is excited first and the next element is excited after a certain time interval one after another, incident wave moves toward right side. The direction of incident wave can be changed by changing the time interval. In the same manner, incident wave can be focused shown in figur 2 (c).

The objective of this study is to apply phased array ultrasonic system to rib-to-deck weld to detect fatigue cracks. The system also includes software based testing conditions such as focal law and incident angle settings, because the cracks are located very close to the testing surface. In order to evaluate the performance of the system, fatigue and ultrasonic tests were carried out for both deck and bead cracks. The minimum crack size of detection was investigated.

2 PHASED ARRAY ULTRASONIC TESTING SYSTEM

Figure 3 shows the phased array ultrasonic testing system developed in this study. The system consists of computer, fl w detector, transducers, scanner and encoder. The fl w detector is 24 by 16 by 18 cm. It can excite 128 elements and receive from 128 elements at a time. Two linear phased array transducers of 10

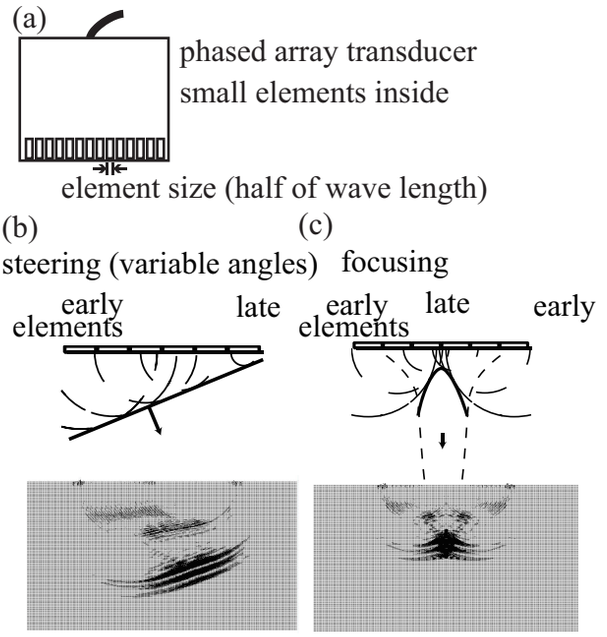

Figure 2: Concept of phased array ultrasonic testing, steering and focusing

MHz and 32 elements were used. Inside of the case, 32 elements are aligned with the pitch of 0.31 mm, as shown in figur 3 (b).

Figures 3 (c) and (d) show more details about transducer and scanner, respectively. A polystyrene wedge was attached to a transducer for large angle of refraction. Crack propagation direction depends on many factors such as the position of wheel, leg size, and throat thickness. It is difficul to predict the crack type, precisely. The system was developed, intended to detect both types of crack at the same time. Therefore, the scanner can hold two transducers, namely, rib transducer and deck transducer. In addition, actual inspection is carried out by overhead position. There are some magnets inside of the frame of the scanner. The scanner is connected fl xibly by hinge, because the angle between deck and rib plates are not always kept the same due to the weld deformation.

3 IMAGE RECONSTRUCTION

Figure 4 shows image reconstruction method called synthetic aperture focusing technique (SAFT) (Schmerr 2015). As step 1, shown in figur 4 (a), the reconstruction area is divided into small mesh. In this case, the mesh size was determined to be 0.2 mm. The area was 20 mm by 20 mm, covering weld bead, rib plate, and deck plate. As step 2, in figur 4 (b), pick up one of the grid points k. In the next step 3 in figur 4 (c), with the combination of grid point k, transmitter channel i, and receiver channel j, wave propagation path and time t_0 were calculated, based on Snell's law. Suppose that wave form obtained by that combination was define as $w_{ij}(t)$. In step 4, the amplitude of $w_{ij}(t_0)$ was added to image intensity $h(k)$ at the grid point k.

$$h(k) \leftarrow h(k) + w_{ij}(t_0) \quad (1)$$

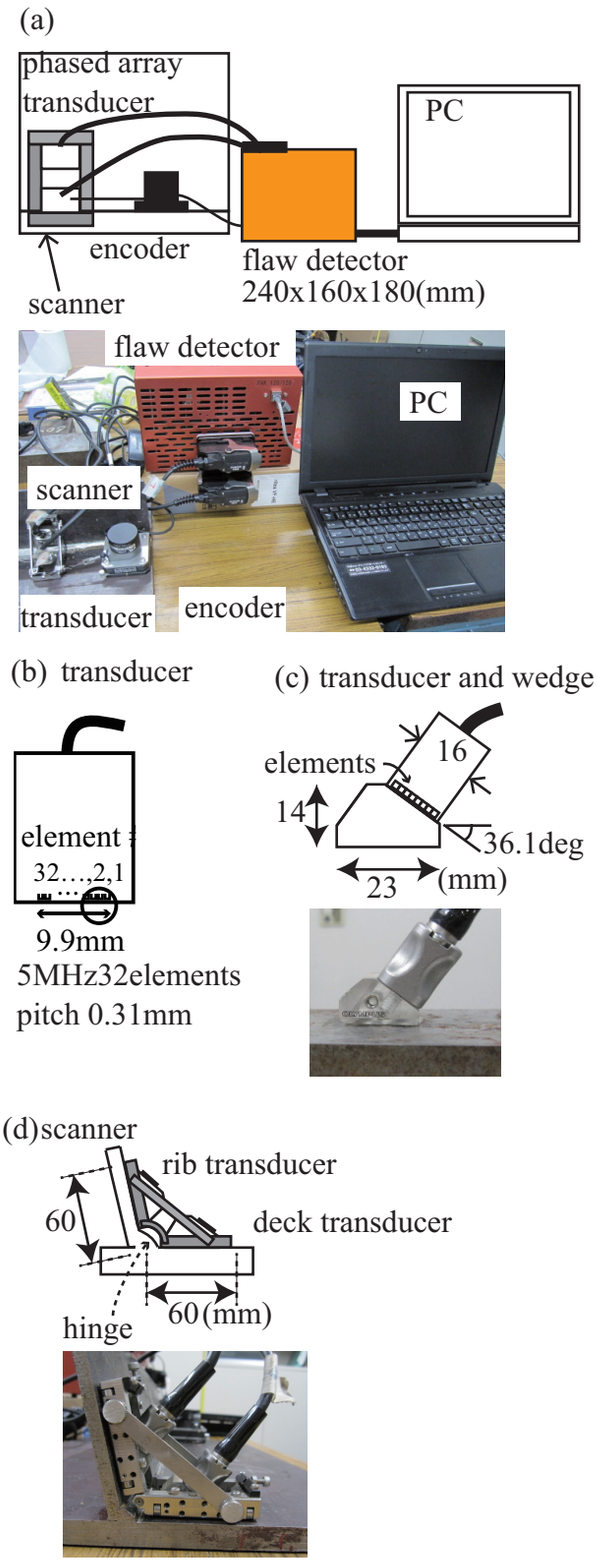

Figure 3: Phased array ultrasonic testing system developed in the study

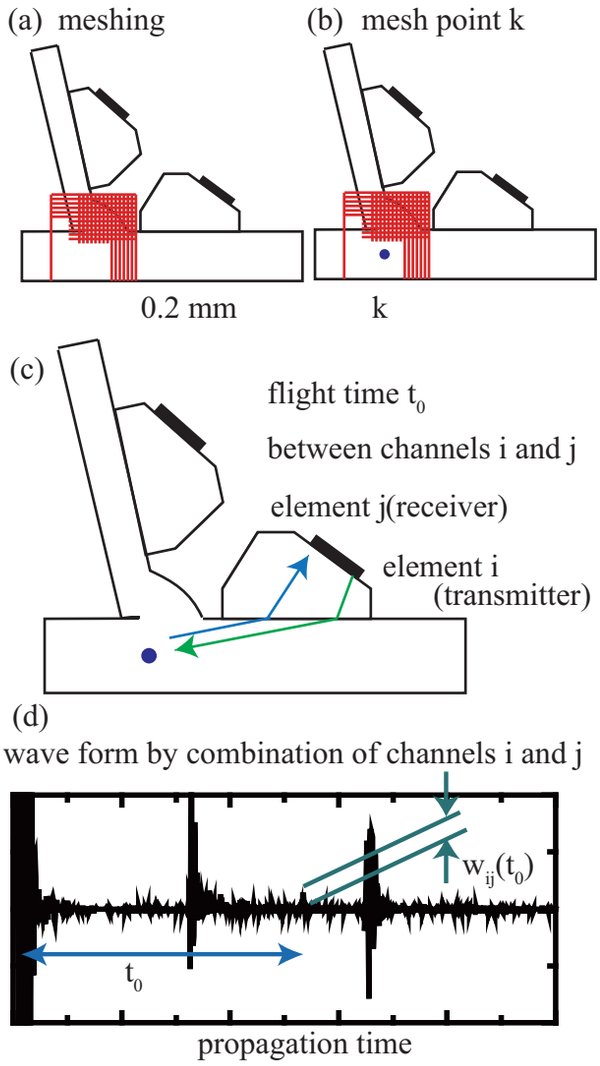

Figure 4: Image reconstruction method by synthetic aperture focusing technique (SAFT)

By taking those summation with respect to grid point k, transmitter channel i, and receiver channel j, image intensity can be obtained.

$$h(k) = \sum_{k} \sum_{i} \sum_{j} w_{ij}(t_k) \tag{2}$$

In case of calculation of wave propagation path, complicated paths such as geometrical reflectio could be considered. This is called multi-SAFT. Since SAFT is superposition of wave forms in the time domain, image of weak reflecto such as point source could be enhanced. Comparing with the conventional B scope display, SAFT has those advantages.

4 FATIGUE AND ULTRASONIC TESTS AND SPECIMENS

4.1 *Deck crack*

Fatigue and ultrasonic tests were carried out. Figure 5 shows the test specimen for deck crack. A T-shaped specimen was prepared. The geometry of the specimen was the same as the rib-to-deck weld; thickness

of deck and rib plate was 12 mm and 6 mm, respectively. The inclination of rib plate to deck plate was about 12 degrees.

As shown in figur 5 (b), 4 point bending was applied, straddling the rib plate in order to simulate the stress condition when a deck crack is propagated.

At every 100 thousand cycles, loading was interrupted, and ultrasonic test was conducted. Those combination of fatigue and ultrasonic tests was repeated until failure. The loading amplitude was 50 kN. Beach mark test was also conducted by changing the loading amplitude of 25 kN. The specimen failed at about 1.1 million cycles. The picture shown in figur 5 (d) shows the failure surface. Figure 5 (c) shows the sketch of beach marks. The numbers are locations of crack edges and depth at 0.8 and 1.0 million cycles.

In ultrasonic tests, two transducers on deck and rib plates were used. Figure 6 explains the focal law settings. Regarding the deck transducer, shown in fig ure 6 (b), the incident angles varied from 35 through 85 degrees. The focal point was determined to be 6 mm below the test surface that is half of the deck plate thickness. In case of deck crack, indication could be obtained by direct and one bounce path in the deck plate. Regarding the rib transducer, as shown in fig ure 6 (c), the incident angles varied from 45 through 85 degrees. The focal point was 12 mm below the test surface that is twice of rib plate thickness. In case of bead crack, direct path could not be expected.

Wave form data were acquired along the weld line with the pitch of 1 mm. After data acquisition, image reconstruction by the SAFT was applied. Figure 7 shows the wave propagation paths in consideration. One was direct propagation path without bounce at the bottom surface of the plate in figur 7 (a). The other was one bounce path at the bottom in figur 7 (b).

4.2 *Bead crack*

Figure 8 shows the test specimen of bead crack. The specimen was a little skewed cruciform welded joint. The angle is 12 degrees that is the same angle as actual details. Tensile force was applied along the rib plate. The amplitude of cyclic load was 50 kN. Same as the deck crack test, beach mark was introduced by changing the loading amplitude.

Figure 9(a) shows the fatigue test site. Cyclic load was applied along the 6 mm plate. This condition was a load carrying cruciform joint and bead crack could be expected (Frank & Fisher 1979). Same as the deck crack specimen, every 100 thousand cycles, ultrasonic test was carried out. The specimen was failed at about 1.4 million cycles. Figure 9(b) shows the failure surface, along the rib plate. The bottom of the picture was weld root. Figure 9(c) is a sketch of beach mark that shows the propagation of fatigue crack.

Figure 10 shows the ultrasonic test for bead crack specimen. Wave form data were acquired along the

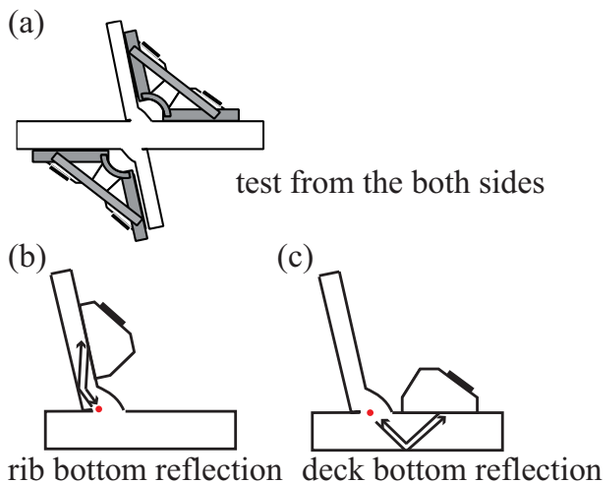

Figure 10: Ultrasonic test of bead crack specimen and paths considered in SAFT

200 mm weld line with the pitch of 1 mm. As shown in figur 10(a), the test was conducted from both sides. When applying SAFT, after data acquisition, two paths were considered. One was reflecte path of the rib transducer shown in figur 10 (b). The second was reflecte path of the deck transducer.

5 TEST RESULTS AND IMAGE RECONSTRUCTION

5.1 *Deck crack*

Figures 11 shows wave forms. As shown in fig ure 11(b), an echo could be observed at a distance of around 34 mm, while no echo could be seen in fig ure 11 (a). The incident angle of the transmitted wave was 50 degrees. Considering the geometry, the location of the reflecto should be about 3.0 mm below the test surface. Such indication was obtained after 800 or 900 thousand cycles. From the beach mark shown in figure 5 (c) and (d), around 3 mm could be the critical size to detect by the system.

Figure 12 (a) shows the three dimensional reconstructed SAFT image before loading. The image was reconstructed by deck relfected path. Images could be seen around the weld root. In contrast, no echo could be found by direct path. Figure 12 (b) shows images at 1.0 million cycles by considering direct path. From the side view, the maximum crack depth was estimated 6.7 mm and actual crack was about 6 mm deep. The front view of figur 12 (b) also shows relatively good agreement with the sketch of beach mark shown below. Figure 12 (c) shows images at 1.0 million cycles by reflecte path. The locations of indication and the actual crack showed agreement, however, the crack depth could not be estimated correctly.

Ultrasonic test estimated the crack length shorter than actual. The minimum size of detection was investigated by checking cross sections one by one. Around 3 mm was the critical size for detection by the phased array ultrasonic system.

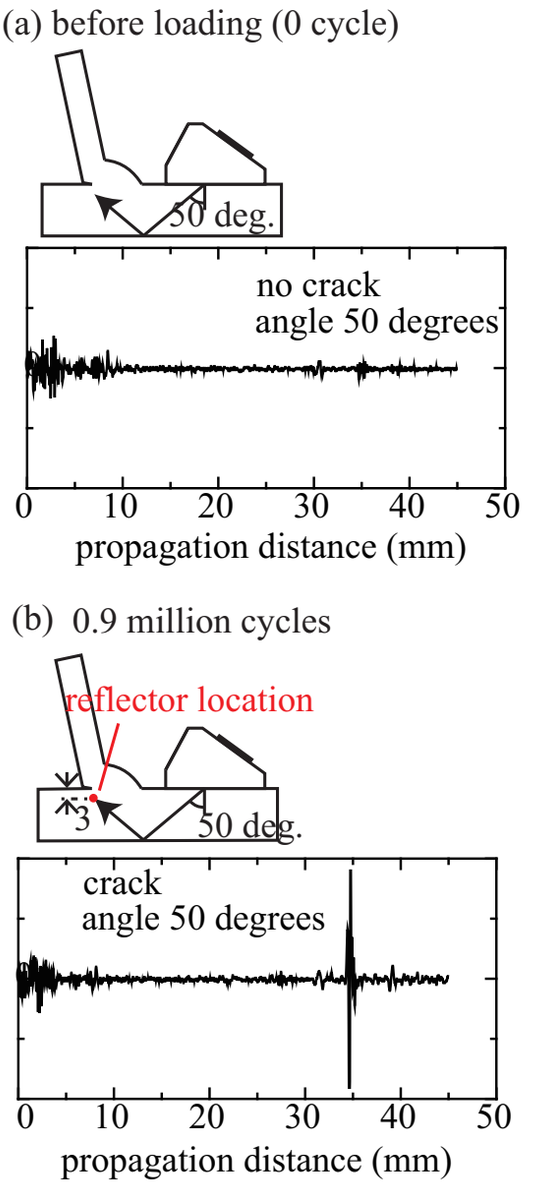

Figure 11: Wave forms of ultrasonic test of deck crack

5.2 *Bead crack*

Some examples of wave forms are shown in figur 13. Figure 13 (a) was acquired before loading. In this case, indication could be obtained at 21 mm with the incident angle of 67 degrees. Figure also contains the geometrical consideration. The location of the reflec tor and the corner of the weld root agreed. In fig ure 13 (b) at 0.9 million cycles, another echo could be found at 25 mm with the incident angle of 55 degrees. Considering the geometry, the location of the reflecto should be inside of the weld deposit. That suggests propagation of fatigue crack.

Figure 14 (a) shows images before loading. Two images can be found. Main reflector in the geometry were weld root corner and tip of the root.

Images at 1.3 million cycles are shown in figur 14 (b). The image was reconstructed by reflecte path of rib transducer. Comparing with figur 14 (a), images around root tip became longer. However, it is difficul

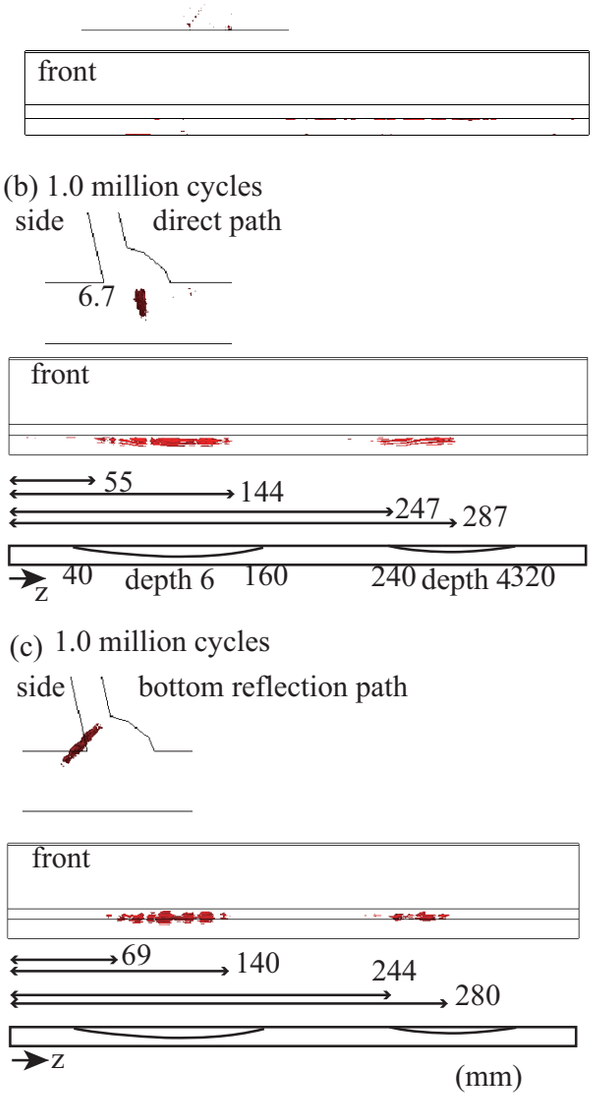

Figure 12: Three dimensional images by SAFT of deck cracks

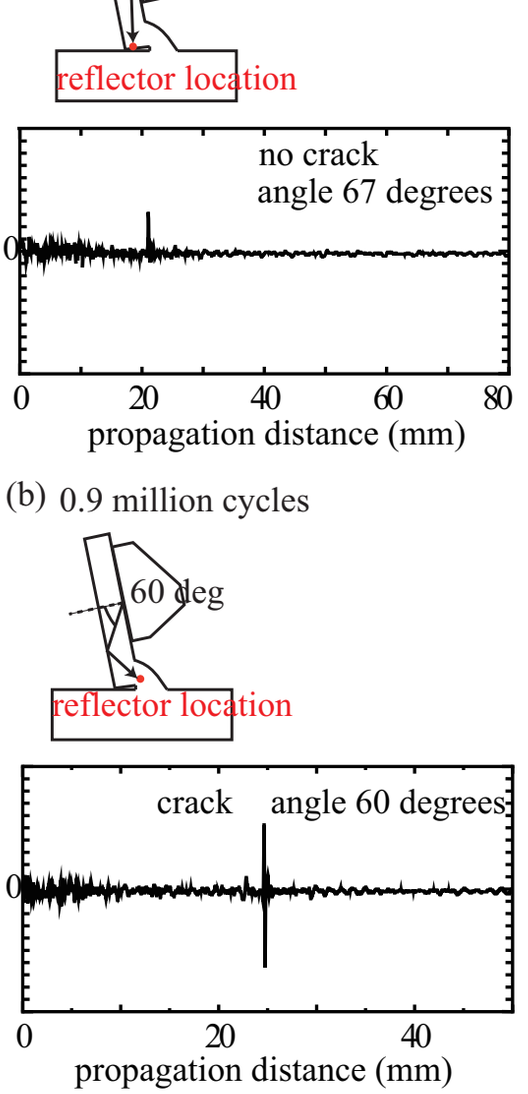

Figure 13: Wave forms of ultrasonic test of bead crack

to estimate the crack length in the weld line direction by front view, because images by weld root could be seen, too.

In order to pick up only the crack echo, temptation to reconstruct images by the deck transducer was made. The crack echoes obviously could be received by the reflecte path at the deck bottom by the deck transducer. The result is shown in figur 14 (c). Inside of the weld metal, an image could be seen. Figure 14 (c) also contains the sketch of beach mark below. The length of crack by the image reconstruction was 100 mm, while the actual crack length by beach mark was 151 mm. The length of indication was shorter than the actual crack length. The minimum size of crack of detection was also 2 or 3 mm, in case of bead crack.

6 CONCLUSIONS

Conclusions obtained in this study are as follows:

(1) Phased array ultrasonic test system for orthotropic steel deck was developed. The system employs two transducers in order to detect both deck crack and bead crack.

(2) Image reconstruction system by the use of synthetic aperture focusing technique was developed. The system takes account of multiple reflectio paths in the plate.

(3) Deck crack could be detected by bottom reflec tion path and direct path. At first crack echo could be obtained by the incident angle of 50 degrees. As the crack propagated, echo could be obtained by larger incident angle of 80 degrees.

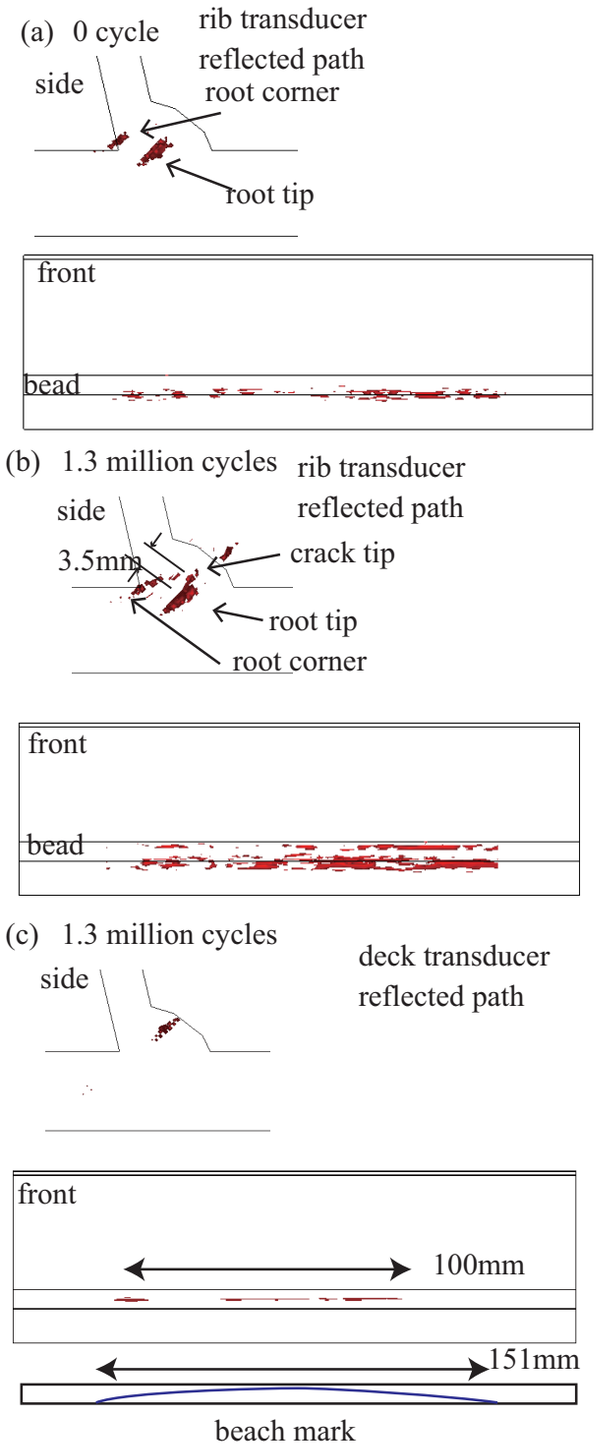

Figure 14: Three dimensional images by SAFT for bead cracks

(4) Crack indication could be obtained by the rib bottom reflectio path. Image of root tip propagated according as the crack propagation. Bead crack could be detected by the combination of the rib and deck transducers.

(5) The crack images were shorter than actual crack length in the weld line direction. That was due to the lack of resolution. The minimum size of crack of detection was about 3 mm for both deck and bead cracks.

Improvement of crack length estimation in the weld line is the next step.

Inspection of steel bridges by modal hammer from bridge deck only

B.T. Svendsen, G.T. Frøseth & A. Rønnquist
The Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: Many steel railway bridges have an open deck construction where the secondary load carrying system of the bridge consist of stringers and cross girders including the connections between these. The relevant structural components are located below the bridge deck, making this system difficult to access. Hence, inspecting such bridges in the field requires extensive equipment such as scaffolding, resulting in major costs and traffic downtime to cover all inspections due to the number of bridges in the infrastructure. This paper investigates the use of modal characteristics as a method of bridge inspection. The objective is to establish an efficient approach to identify severe structural faults. In this study, the riveted steel bridge at Hell Bridge Test Arena is used. Based on the results obtained from using accelerometers and a modal hammer, the modal characteristics of key components in the load carrying system is determined and compared to each other.

1 INTRODUCTION

The Norwegian railway network was mainly constructed in the period between 1854 and 1962. Riveted steel bridges was the preferred construction and material type until the first reinforced concrete bridges used for shorter spans were introduced around 1941. Most of the original infrastructure have been replaced except for many bridges that are still in service today. These bridges are still used despite aging and the associated damage accumulation. Being able to detect damage early is important to prevent further damage and ensure safe and reliable use.

The Hell Bridge Test Arena is a full-scale laboratory where an old railway bridge is moved to new foundations on land. The bridge is an open deck steel riveted truss bridge with a span of 35 m. The bridge serves as a test arena for research and development including structural health monitoring (SHM), damage detection, inspection and service life estimation. The purpose of the test arena is to assess new sensor technology, monitoring algorithms and SHM techniques on a real structure in a controlled environment to establish reliable, cost effective and time efficient inspection methodologies.

SHM refers to the process of implementing a strategy for damage detection of structures. The SHM process involves the observation of a system, i.e. the structure, over time to determine the current state of the health of the structure. This is obtained by using periodically sampled dynamic response measurements, extract features sensitive to damage from these measurements and perform statistical analysis of these features (Farrar & Worden, 2007).

Depending on the application, SHM is performed in a short-term or long-term perspective. Short-term SHM is damage detection based on information obtained from the structure through a defined and short period of time, e.g. through inspection. Long-term SHM obtains information from the structure over a long period of time, typically months or years.

SHM is a research topic that has received a lot of attention the past 30 years and focuses on solving the many challenges with the aging infrastructure of the world. Bridge monitoring programmes, which in the last decade have evolved into SHM systems, have historically been implemented for the purpose of understanding and calibrating models with respect to structural load and response (Brownjohn, 2007). Reducing maintenance and inspection costs is considered one of the main motivations for performing SHM today.

Due to low accessibility, inspection of structural components in the secondary load carrying system of old steel railway bridges is difficult to perform from the bridge deck. That is, inspecting bridges in the field requires major resources. This is due to the need for extensive equipment to access critical components and due to the number of bridges in the infrastructure. This has led to the motivation of investigating alternative inspection methods for damage indication and ultimately detection. The first step in a general approach is to find indication of damage as

a basis for determining further inspection. The Hell Bridge Test Arena has a known fault in its secondary load carrying system, i.e. in a longitudinal stringer which is currently subject to investigation.

This paper investigates the use of variation in estimated modal characteristics as a method for bridge inspection. Analysis techniques in both time and frequency domain are explored. Modal data is extracted based on imposed vibration obtained from a modal hammer and a set of accelerometers. By establishing modal characteristics of beam elements connected to damaged and undamaged joints, results are compared and differences are established in order to detect damage. The overall objective is to establish if the method considered is feasible to identify severe structural faults in the connections between stringers and cross girders.

2 DAMAGE DETECTION

2.1 *Background*

The basic principle of damage detection algorithms is that the structural characteristics parameters are functions of the physical properties of a structural system, consisting of mass, damping and stiffness. Hence, damage in those physical properties will cause changes in the structural characteristics parameters (Seo, Hu & Lee, 2015). In other words, damage will somehow change the stiffness, mass and energy dissipation of the structure, which in turn will change the global dynamic properties. Damage detection algorithms applied to bridge structures are mainly vibration-based and strain-based.

In the secondary load carrying system, the connections between the longitudinal stringers and cross girders consists of angle bars. For the stringers subject to investigation, one of the joint connections is severely damaged and significant vertical movement is experienced when the stringer is subjected to load. The stringer including its joint connection is referred to as the damaged structural component, whereas the other stringers including their joint connections are referred to as undamaged structural components.

The damage results in a change of structural stiffness in the local structural system considered. For this study, it is believed that this change of stiffness can be reflected by analysing time series obtained from imposed vibrations. Response is measured from accelerometers located on the damaged and undamaged structural components. By performing analysis in both time and frequency domain, results are compared and it is established if 1) it is possible to find indication of the damage and 2) which of the analysis methods used will best render results for indication of the damage investigated. Several analysis techniques are considered; moving standard deviation and cross correlation are analysed in time domain, whereas coherence and frequency response functions (FRF) are analysed in the frequency domain using MATLAB (The MathWorks Inc, 2017).

A brief theoretical overview of the different techniques are presented in the following section. A general reference for the theory presented is made to (Wirsching, Paez & Ortiz, 2006).

2.2 *Time domain*

2.2.1 *Moving standard deviation*

Moving standard deviation provides a measure of dispersion, i.e. a quantification of the variation in the data points along a predefined window length in the time series. For the time series of acceleration response considered, a, made up of N scalar observations, the standard deviation is defined as

$$\sigma = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}\left|a_i - \mu\right|^2} \tag{1}$$

where μ is defined as the mean of a:

$$\mu = \frac{1}{N}\sum_{i=1}^{N} a_i \tag{2}$$

In the analysis performed, the unbiased normalization factor $N-1$ is used instead of N for the sample standard deviation. Furthermore, the window length is set to 9 data points, i.e. the standard deviation value for each point calculated includes 9 elements.

2.2.2 *Cross correlation*

The cross correlation is a function that measures the correlation between two different random processes. The cross correlation function is defined as

$$R_{A1A2}(t_1, t_2) = E[A_1(t_1)A_2(t_2)] \tag{3}$$

where $E[A_1(t)A_2(t)]$ is the expected value of the function defined by the random processes $A_1(t)$ and $A_2(t)$. If both random processes are stationary, the cross correlation function depends only on the time lag $\tau = t_2 - t_1$:

$$R_{A1A2}(\tau) = E[A_1(t)A_2(t+\tau)] \tag{4}$$

Equation 3 and 4 provides the basic definition of the cross correlation without further derivations. In this study, the cross correlation is used to measure the similarity of two acceleration response time series, $A_1(t)$ and $A_2(t)$, i.e. the similarity between $A_1(t)$ and shifted copies of $A_2(t)$ as a function of the lag (The MathWorks Inc, 2017).

2.3 *Frequency domain*

2.3.1 *Coherence*

The coherence provides a measure of the linear dependence between two signals for a specified range of frequencies.

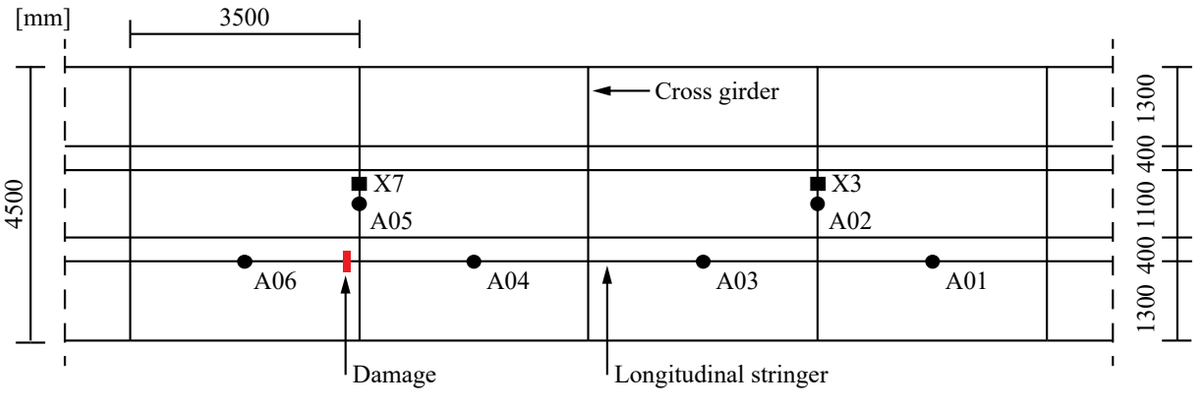

Figure 1. Illustration of the instrumentation setup. Plan view of part of the Hell bridge test arena.

The coherence is a non-dimensional measure and has values between 0 and 1. Values near 1 imply a linear relationship between the signals at a certain frequency. The coherence is defined as:

$$\gamma^2_{A1A2}(\omega) = \frac{|S_{A1A2}(\omega)|^2}{S_{A1}(\omega)S_{A2}(\omega)} \quad (5)$$

Here, $S_{A1A2}(\omega)$ denotes the cross spectral density of $A_1(t)$ and $A_2(t)$, and $S_{A1}(\omega)$ and $S_{A2}(\omega)$ denotes the auto spectral density function of $A_1(t)$ and $A_2(t)$ respectively.

2.3.2 *Frequency response function*

The frequency response functions (FRF) are established as the fundamental measure of the dynamic behaviour of the linear system considered. Equation 6 defines the FRF for a single-input, single-output (SISO) case where X, or $X(\omega)$, represents the response of the system and F, or $F(\omega)$, represents the external load:

$$H_{XF} = \frac{G_{XF}(\omega)}{G_F(\omega)} \quad (6)$$

Here, $G_{XF}(\omega)$ is the cross spectral density of the response and the force, $G_F(\omega)$ is the auto spectral density of the force and H_{XF} is the FRF of the response caused by the force.

It should be noted that the theory as presented here is given in terms of angular frequency ω (rad/sec), whereas the results presented in Section 4 is given in terms of frequency f (Hz).

3 INSTRUMENTATION

The instrumentation consisted of six tri-axial accelerometers mounted on four longitudinal stringers and two cross girders. All beam members were accessible from the bridge deck. Figure 1 shows the instrumentation setup. The accelerometers were positioned at the mid span of the structural elements.

The testing was performed by using a modal hammer in a roving configuration. The accelerometers were placed at fixed locations and impacts were induced at predetermined locations. Several impacts were induced, however only one impact per location was selected for analysis purposes. This was done due to the desired quality and similarity between the time series obtained.

For many bridges, the deck is the most easily accessible area for general inspection. The aim of the presented research is to establish an inspection methodology to be applied from the bridge deck. Therefore, impacts at location X3 and X7 on the cross girders, from the bridge deck, were performed. Each recording resulted in a time series of 30 sec, where 5 sec was recorded prior to the impact and 25 sec was recorded after the impact. The sampling rate was set to 2048 Hz.

As seen in Figure 1, accelerometer A06 is located on the damaged longitudinal stringer while accelerometers A01, A03 and A04 are located on undamaged stringers. Accelerometer A02 and A05 are located on the cross girders. The instrumentation setup is symmetrical about the cross girder depicted in the middle of Figure 1, and is chosen for the purpose of comparing results from a damaged and undamaged structural area. In the following, results obtained from the accelerometers are compared in both time and frequency domain. Indication of damage is established based on any differences in the results obtained from analysis. Based on the instrumentation setup, differences in the results analysed from accelerometer A06 is in particular expected.

4 RESULTS

4.1 *Time domain*

4.1.1 *Moving standard deviation*

Figure 2 shows the moving standard deviation of the acceleration response of sensors A01, A03, A04 and A06 for impact location X3 and X7. As stated in Section 2.2.1, the window length is set to 9 data points.

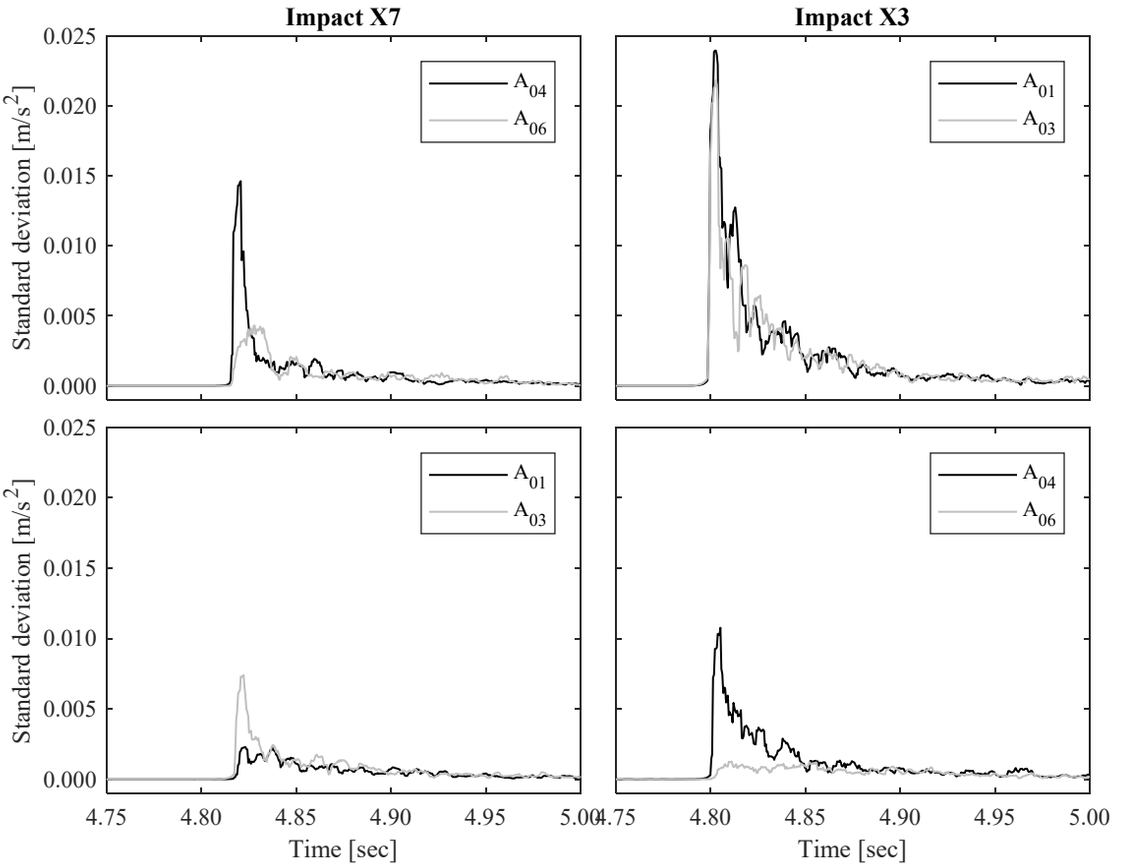

Figure 2. Moving standard deviation of sensors A01, A03, A04 and A06 for impact location X7 and X3.

This provides plots of the acceleration response where the highest peaks in the signal are smoothed leaving a more clear representation of the time series.

If no damage is present in the structural system, it is expected that the results for sensors A01 and A03 for impact location X3 is similar to the results for sensors A04 and A06 for impact location X7. This means that the response curves should follow each other closely for sensor pair A01 and A03 at X3 and pair A04 and A06 at X7. The top left plot in Figure 2 shows a clear difference in the response of sensor A06, located on the damaged structural component, compared to A04, located on the undamaged structural component. It should be noted that the top plots shows results for impacts induced close to the sensor pairs. Considering the top right plot of Figure 2, it is seen that the response from sensors A01 and A03 on undamaged structural components are similar to each other. The top half of the figure therefore indicates that the moving standard deviation can be used to detect damage in the joints between stringers and cross girders.

The bottom plots in the figure shows results from the sensors located further away from their respective impact locations. Here it is seen that the magnitude and energy of the signal decays with distance from the impact location. The peak value obtained from these sensors are lower than from the sensors closer to the impact locations shown in the top plots of the figure. This partly explains the difference in the results for sensor A06 at impact location X7; the vibration is not transmitted through the damage location and the signal has to travel a longer distance. This is then reflected in the acceleration response.

When comparing sensor A06 for impact location X3 with A01 for impact location X7, both acceleration response curves have a similar trend. This means that the response of an undamaged structural component is similar to that of the damaged component when the impact location is further away from the studied components. This implies that the impact location needs to be in the vicinity of the damaged structural components to reliably detect indication of damage. In conclusion, multiple impact locations must be evaluated to fully determine indications of damage in the structural system using moving standard deviation. Furthermore, one of the impact locations must be in the vicinity of the damaged structural components to detect damage.

4.1.2 *Cross correlation*

Observations made from evaluating the moving standard deviation of the acceleration response are also made by analysing the cross correlation. Figure 3 shows the normalized cross correlation of sensors A03, A04 and A06 to sensor A02 for impact location X3, and the cross correlation of sensor A04, A03 and A01 to sensor A05 for impact location X7.

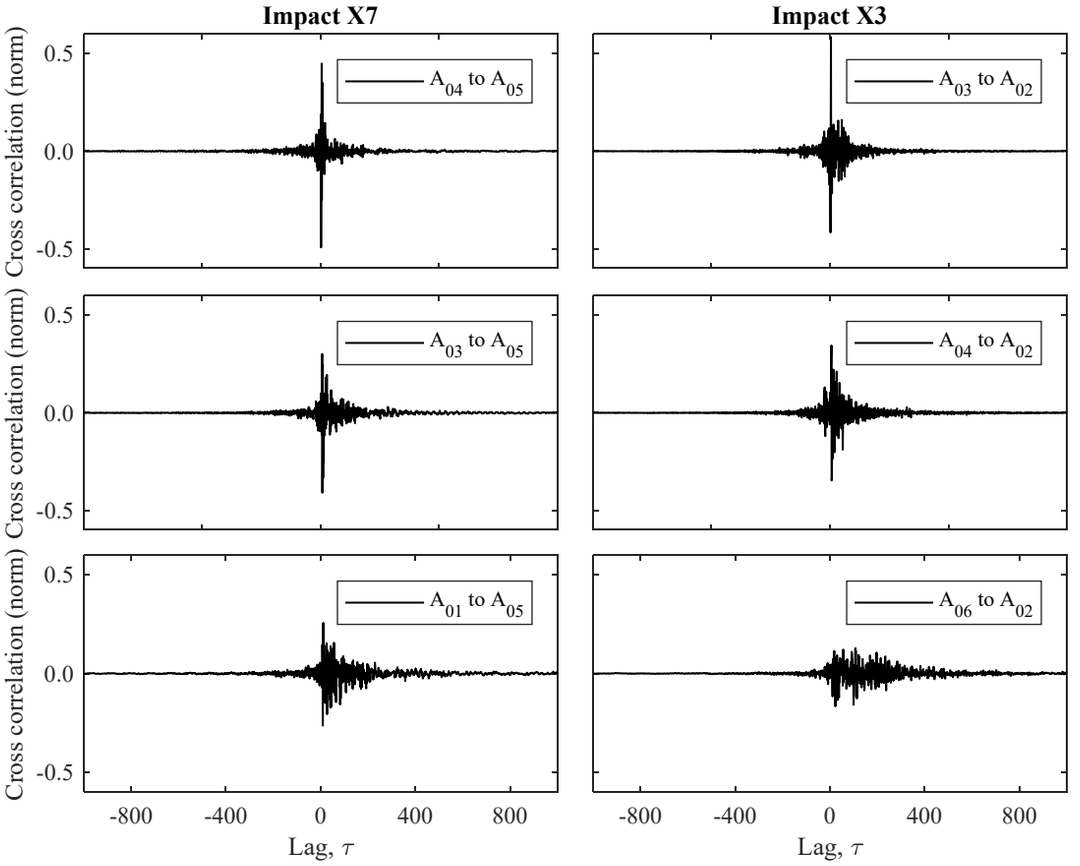

Figure 3. Normalized cross correlation for relevant sensors, impact location X7 and X3.

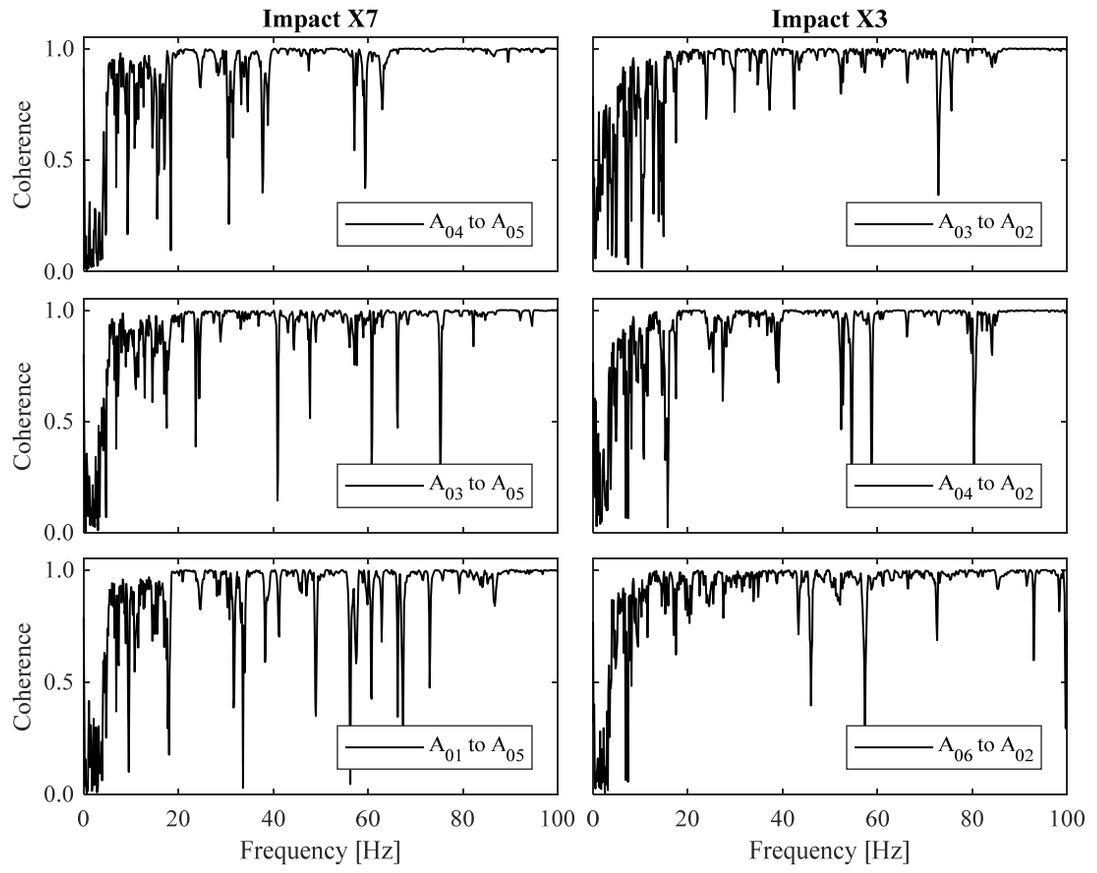

Figure 4. Coherence for relevant sensors, impact location X7 and X3.

Sensor A02 and A05 are given as reference accelerometers to impact locations X3 and X7, respectively. It is noted that the cross correlation is established for the specific sensors with a symmetry in the instrumentation setup in mind. Hence, similar trends in the plots for impact location X7 is also expected for X3 if no damage is present in the system.

For impact location X7, stronger cross correlation is observed closer to the reference accelerometer A05. Generally, this is as expected when considering the location of the sensors with respect to their reference accelerometers; a shorter distance for the signal to travel results in a stronger correlation assuming no damage is present in the structure to cause differences in the results. A similar trend is seen for impact location X3, except for sensor A06 to its reference accelerometer. It is clearly seen that the cross correlation of sensor A06 to A02 is weaker and has a different shape compared to sensor A01 to A05. The time difference between maximum correlation for sensor A06 to A02 was found to be 0.0122 sec compared to 0.0044 sec for sensor A01 to A05. In comparison; the same time difference observed for sensor A04 to A02 and sensor A03 to A05 was both 0.0034 sec, and the time difference for sensor A03 to A02 and sensor A04 to A05 was 0.0020 sec and 0.0010 sec respectively. There are uncertainties related to these results due to only one induced impact is analysed per impact location. Nevertheless, these results shows a trend indicating a significant difference in the cross correlation of the acceleration response for sensor A06.

Based on the results shown in Figure 3, differences in the results indicating damage is observed despite the impact location being further away from the damaged structural component. Hence, the results obtained for sensor A06 to A02 for impact location X3 may in this case indicate that the impact location not necessarily must be in the vicinity of the damaged structural component. However, further work are needed before a reliable conclusion of this can be made.

Similarly as with the moving standard deviation, it is concluded that the cross correlation plots indicates a difference for the damaged structural component compared to the undamaged structural components.

4.2 *Frequency domain*

Based on the sampling frequency used in the measurements, a high range of frequencies are available for analysis. Screening analysis has been performed and the results obtained from these analyses did not render additional information than found in the frequency range of 0 to 100 Hz. Hence, this range of frequency is used in the analysis presented in the following.

4.2.1 *Coherence*

The coherence in frequency domain provides similar information as the correlation in time domain. In Figure 4, the coherence is plotted for the same sensors and impact locations as for the cross correlation. Based on the results obtained for the coherence it is difficult to draw any clear conclusions. For sensors A04 to A05, and A03 to A02 for impact locations X7 and X3 respectively, fewer distinctive peaks are observed compared to the bottom plots. For sensor A06 to A02 at impact location X3, a few peaks are observed in the higher frequency range of 80 to 100 Hz which is not indicated in other plots. However, it is difficult to distinguish differences in these plots indicating any presence of damage. In general, the coherence is strong in similar frequency ranges for the response measured from all sensors subject to investigation.

4.2.2 *Frequency response function*

The FRFs are established for sensors A01, A03, A04 and A06 for impact locations X3 and X7 in Figure 5, with a similar setup as shown in Figure 2.

The low-frequency range representing global dynamic behaviour of the bridge is represented in all measured locations. There is a noticeable difference in the results obtained for sensor A03 seen for impact location X7. Here, the peak obtained approximately at 25 Hz is not indicated contrary to what is seen from the other sensors on both impact locations X3 and X7. Based on the analysis performed, there is no obvious explanation of this. However, this observation is considered of minor relevance for the results investigated.

For the results obtained in the high-frequency range, i.e. from 60 to 100 Hz, no clear trends or behaviour is seen that indicates the presence of damage. The same yields when considering the distance of the sensors with respect to the impact locations; the top plots shows results from the sensors located close to the impact, and the bottom plots further away from the sensors.

For sensor A01 and A03 at impact location X3, it is expected that the response is fairly similar since both sensors were located on an undamaged structural component. Furthermore, similar behaviour in response is not expected for sensor A04 and A06 at impact location X7 since sensor A06 is located on the damaged component. In this case, comparing the top plots in the figure gives no indications of damage present in the structural system, contrary to what is seen for the similar plots of moving standard deviation in time domain as shown in Figure 2.

Similar to the results obtained for the coherence, it is difficult to draw conclusions based on the results obtained from analysing the FRFs.

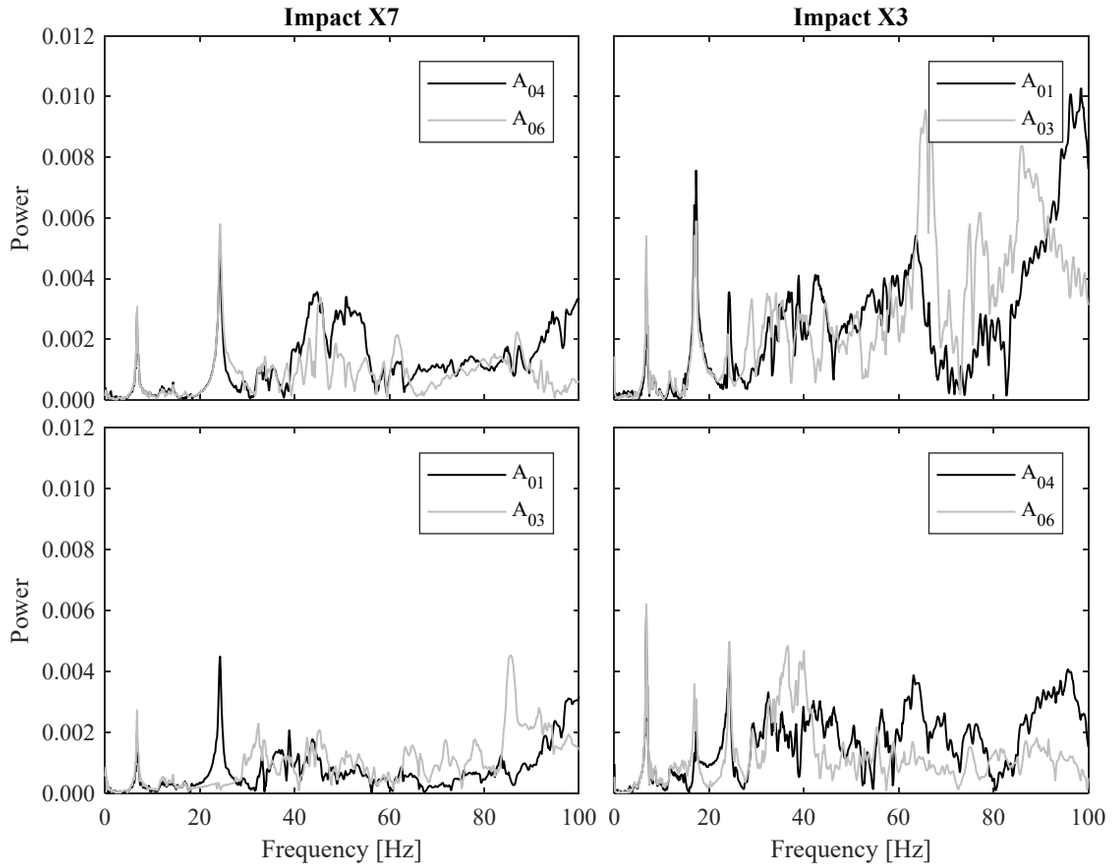

Figure 5. FRF of sensors A01, A03, A04 and A06 for impact locations X7 and X3.

4.3 *Comparison between time and frequency domain*

When comparing the results obtained, the trends established from the results in time domain is not seen in frequency domain. Two conclusions are made based on this. First, the damaged structural component causes a change in the transmission of the signal that is seen primarily in time domain and second, the change in transmission of the signal is most likely represented in a high-frequency range. This range of frequency is not subject to thorough investigation in this study.

Global dynamic structural response of the bridge is established from the FRFs of all measured locations. If the damage is represented at much higher frequencies, it is questionable if 1) it is possible to detect this type of damage and 2) how reliable such results then may be. It may well be that this is highly dependent on the damping in the structure making it difficult to detect this type of damage. Using more advanced analysis methods for indicating this type of damage in frequency domain is subject to further work.

In general, the FRFs describes local and global structural response. The transmission as seen in time domain only describes local phenomena, i.e. local structural response or as in this case, deviations. Changes in the global frequencies and modes could probably be detected if the change in the structural system caused by the damage is large enough. This is because the damage is also a part of the global modal parameters and not only a local deviation.

5 CONCLUSIONS

This paper presented a method for performing bridge inspection from the bridge deck by investigating modal characteristics obtained from imposed vibration. The method utilizes analysis techniques applied both in time and frequency domain. Based on the results obtained, the following conclusions are drawn:

- An indication of structural damage is found when analysed in time domain and not in frequency domain. The indication of damage is seen based on differences in the results obtained from the damaged compared to the undamaged structural components.
- Analysis techniques such as moving standard deviation and cross correlation provides better indication of this type of damage than analysis techniques such as coherence and FRF.
- The type of damage investigated is difficult to observe in frequency domain. This is believed to be due to 1) the many global and local natural frequencies indicated by all sensors which makes distinctions difficult to find and 2) the damage investigated is likely to be represented at higher

frequencies than subject to investigation and included in this study.
- The time domain analysis techniques presented are considered feasible for detecting damaged components from the bridge deck. The method may be used to indicate damage and strengthen the decision criterion for selecting areas in the structure subject to further inspection.

ABSTRACT: Internal defects are normally developed in concrete bridge structural components during long-term operations under heavy loads of the vehicles. Conventional methods for the structural health monitoring, such as visual inspection, chain dragging, and hammer sounding, provide only surface cracks and partial subsurface defects, hence, it might be less accurate to predict the subsurface delamination. Infrared thermography has proven to be an effective way to detect delamination. However, sizing of the delamination is a difficult task, especially for special shapes. This study aims to investigate the effect of lateral thermal diffusion on predicting delamination size by using Finite Volume Method (FVM), then points out the drawbacks of Full Width at Half Maximum (FWHM) method in measuring non-planar subsurface delaminations. In addition, results of the numerical method and the experimental study of impulse thermography (IT) are compared. It indicates that FVM is a reliable tool for modelling infrared thermography (IRT) technique.

1 INTRODUCTIONS

Internal deteriorations occur in components of a concrete bridge after long time operations, especially for the bridge's deck which directly subjected to heavy loads of the vehicles. In most countries, inspection and maintenance actions include visual inspection in combination with several conventional methods such as hammer sounding and chain dragging. These kinds of methods are mainly used to detect moderate to severe delaminations in concrete structures. However, their major drawbacks are labor-intensive, technician's skills, and traffic control requirements (Transportation Research Board 2013). Many advanced tools for non-destructive testing including Impact Echo, Ultrasonic Pulse Echo, Ultrasonic Surface Waves (IAEA 2002), Ground-Penetrating Radar (Pollock et al. 2008), and active/passive IRT (Transportation Research Board 2013) have been introduced via many research works, guidelines, and national standards that contribute significantly in the maintenance field. Every method has its own advantages and shortcomings that should be applied in a certain circumstance. For example, the active IRT method is proven to be an effective and fast to detect the defects in high-conductivity materials (a few milliseconds) (Maldague 2001), but it takes a long time in detecting for low-conductivity materials such as concrete, plastic, or wood (take several minutes to hour depending mainly on the external heat source energy, distance of heating, and depth of defects) (Maldague 2001, Huh et al. 2016, Vaghefi 2011, Pollock et al. 2008). Therefore, the method is better to use in cooperation with passive IRT and visual inspection. For the upper surface of a bridge deck, passive IRT can be used without any supporting of external heat source. Other parts of a concrete bridge structure, especially where not exposed directly to the sun, a visual inspection should be carried out in advance to locate questionable defective locations. Then, active IRT can be applied to measure the area and depth of the defects in detail.

Delamination is defined as the separating of concrete into layers due mainly to corrosion of embedded reinforcing bars over time (Transportation Research Board 2013), and when the delamination grows gradually; it splits out of the concrete structure. This phenomenon is called "spalling". Delamination normally develops in horizontal layers with planar and non-planar shapes that might depend on external loading (i.e. vehicle's wheels) and non-loading issues (i.e. reinforcing bars, temperature, shrinkage, differential settlement, freeze-thaw cycle) (Portland Cement Association 2002). In fact, however, less or no document mentions about the shape of delamination because it develops inside the concrete that is impossible to observe by human eyes. The detection of location of the delaminated area is not a difficult task when the structure is inspected by IRT technique. However, a quantitative evaluation of the defective area to some extent is hard to be

accurate because of the effect of delamination's shape. In this paper, therefore, the IT method, a kind of active IRT, is used to detect subsurface defects in the concrete structural components which are not exposed directly to the sunlight. A simple three-dimensional FVM model was simulated and its results were verified with those from the experimental study. A more complex FVM model has been built to investigate the effect of lateral thermal diffusion in measuring the size of non-planar detects. Different shapes and depth of defects are investigated including planar, V-shape, and A-shape delaminations.

2 EXPERIMENTAL STUDY

2.1 *Principle of impulse thermography*

The IT technique uses halogen lamps as an external heat source to transfer heat to the concrete in a transient mode. In three mechanisms of heat transfer, i.e. conduction, convection, and radiation, the heat flux is transferred dominantly into the concrete core by conduction mechanism. Mathematically, when the specimen's surface is subjected to a Dirac impulse of magnitude I_0, the impulse heating response of a semi-infinite half-space can be obtained by Equation 1 (Almond & Pickering 2012) whereas the resulting temperature, T_s, changes at a depth z beneath the surface at a time t. Obviously, a real impulse is different from an ideal Dirac pulse because it has finite values of amplitude and duration (Maldague 2001).

$$T_s(z,t) = \frac{I_0}{e_1\sqrt{k \cdot t}} \exp\left(\frac{-z^2}{4 \cdot \alpha \cdot t}\right) \quad (1)$$

where $\alpha = k/(\rho \times C_P)$ is the thermal diffusivity of material, e_1, ρ and C_P are the thermal effusivity, mass density and specific heat capacity of the concrete, respectively. Hence, the response at the surface ($z = 0$) that an IR thermal camera can measure will be

$$T_s(0,t) = \frac{I_0}{e_1\sqrt{k \cdot t}} \quad (2)$$

However, when a planar delamination exists at $z = d$ from the surface, the heating response at the surface above the delaminated zone under a Dirac delta function impulse of magnitude I_0, has a different value that can be expressed by Equation 3.

$$T_d(0,t) = \frac{I_0}{e_1\sqrt{k \cdot t}}\left[1 + 2\sum_{n=1}^{\infty} R^n \cdot \exp\left(-\frac{(n \cdot d)^2}{\alpha \cdot t}\right)\right] \quad (3)$$

In which the $R = (b - 1)/(b + 1)$ is the reflection coefficient of the concrete-air interface, which is close to 1.0; and b is defined as the ratio of thermal effusivities between two media, $b = e_2/e_1$, where the e_1, e_2 are the thermal effusivity of concrete and air (delamination), respectively.

A delamination blocks the conduction of heat from the surface, causing the temperature above the defective area, $T_d(0,t)$ has a slower cooling rate than those at the non-defective area, $T_s(0,t)$ (Almond & Pickering 2012). Therefore, the thermal contrast (or so-called absolute contrast), $\Delta T(0,t)$, can be expressed by Equation 4. The absolute contrast can help to recognize the defect inside the concrete, especially when the absolute contrast reaches its peak value.

$$\Delta T(0,t) = T_d(0,t) - T_s(0,t) \quad (4)$$

Based on the previous research works (Huh et al. 2016, Vaghefi 2013, Maierhofer et al. 2003, Maierhofer et al. 2006, Maierhofer et al. 2007, Tran et al. 2017), with the same delamination size and shape but different depth, the shallow one is expected to show a higher absolute contrast than the deeper one. In addition, the deep delamination will indicate a longer observation time than the shallower delamination. For concrete inspection, it takes a long time to test an object, hence, the heating and cooling curve usually has the shape as described in Figure 1. It is noted that the observation time is the time that the absolute contrast reaches its peak value after turning off the heat source. This is an important parameter to be used throughout this research.

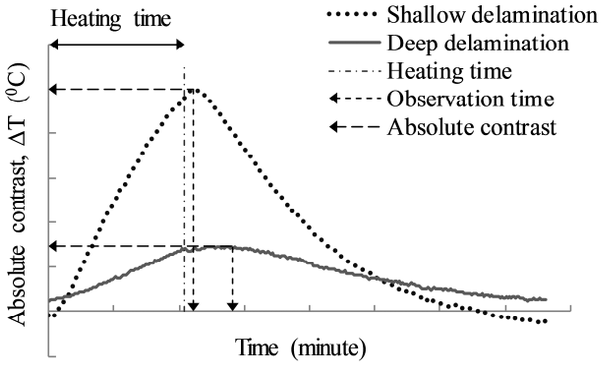

Figure 1. Absolute contrast vs time.

2.2 *Testing preparation*

A concrete specimen was built in the laboratory with embedded two artificial delaminations, which were folded by an angle of 11°, so-called "A-shape" and "V-shape" as shown in Figure 2. The IT technique was conducted with a heat energy of 3000W using six halogen lamps which were placed at 1.2m from the concrete specimen's surface, expecting a good

uniform heating. A high-quality IR thermal camera, FLIR SC660, was used to record the surface temperature in both heating and cooling time of the process, as illustrated in Figure 3. This high-resolution camera can detect infrared emission at a wavelength band from 7.5 μm to 13 μm. Its thermal sensitivity (or NETD) is smaller than 0.003 K and its spatial resolution (IFOV) is 0.65 mrad (FLIR SC660 Catalog, 2014). The average ambient temperature and relative humidity were around 18.6°C and 68%, respectively, measuring by a thermohygrometer in the laboratory where the influence of wind can be minimized.

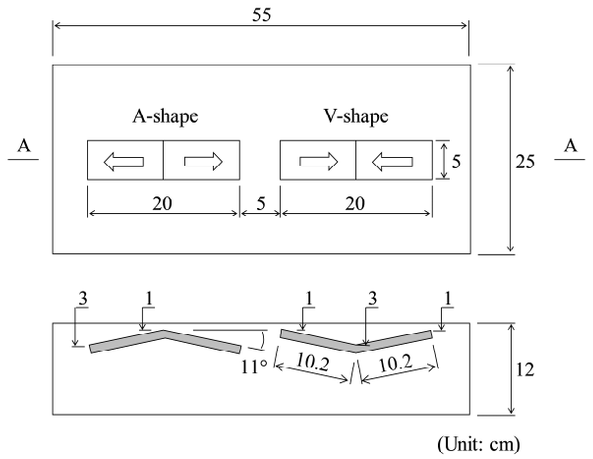

Figure 2. Details of artificial delaminations embedded in the concrete specimen.

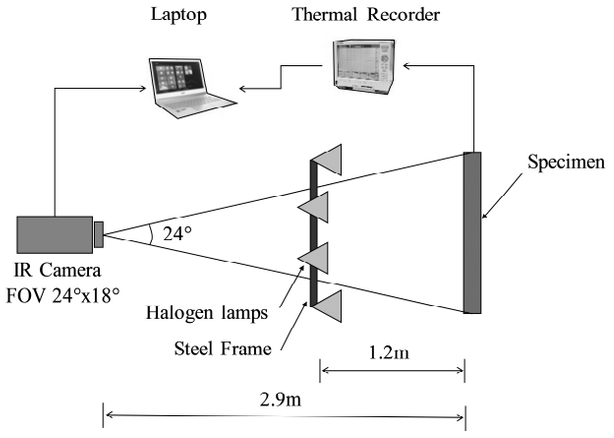

Figure 3. Experimental Set-up.

To estimate the incident heat flux coming to the concrete slab, three thermocouple points were embedded in the concrete slab at 3.3 cm depth to measure the temperature of the inner sound core. Then, the heat flux can be estimated corresponding to the energy stored in the slab volume, using Equation 5 (Holman 2010, Maldague 2001) based on the different temperature between the surface (measured by IR camera) and the inner core (measured by Thermal recorder Yokogawa MV2000).

$$I_0 = \frac{Q}{A \cdot t} = \frac{C_P \cdot m \cdot dT}{A \cdot t} \tag{5}$$

where Q is the heat required for heating an object (J), C_P is the specific heat capacity (J/kg°C), assumed as 800 J/kg°C (Maldague 2001), $m = \rho \times V$ is the mass of the object (kg), dT is the temperature difference (°C), A is the surface area received heat (m^2) and t is the time of heating (second). Thickness of the object used for calculating the mass is 0.033m, which is the distance from specimen's surface to the thermocouples. The estimated heat fluxes per area, I_0 (W/m^2) are calculated and summarized in Table 1.

Table 1. Calculated heat flux after 15-min. heating.

Thermocouple point	Temp. at the surface	Temp. at 3.3 cm	Temp. difference	Heat flux
	°C	°C	°C	W/m^2
1	21.0	19.5	1.5	105.6
2	20.6	19.2	1.4	98.6
3	20.9	18.8	2.1	147.8
Average	**20.8**	**19.2**	**1.7**	**117.3**
Measurement device	IR camera	Thermo-couple		

3 THREE-DIMENSIONAL MODELS

All the numerical simulation analyses in this research were conducted by ANSYS Fluent using Finite Volume Method (ANSYS 2010, ANSYS 2013). To verify the numerical model with the experimental study, all models were stimulated by a receiving heat flux as calculated in Table 1. Then, a more complex model was developed to assess the effect of lateral thermal diffusion in sizing of the delaminations.

3.1 *Simulation of simple model*

A simple numerical model was simulated with two different types of boundary conditions for the side walls. The model is shown in Figure 4. A semi-infinite boundary condition which is infinite in X-Y plane parallel to the concrete front surface, is applied to all side walls of the model, so-called FVM-1, and a limited boundary condition allows the surface of the side walls to exchange heat with surrounding ambient temperature, namely FVM-2. The Tetrahedron type of element was applied with the

maximum and minimum sizes of 8×10^{-3} m and 6.16×10^{-5} m, respectively. A total number of elements is 278,788. The physical properties of the models are listed in Table 2. As mentioned above, two models were applied by a uniform heat flux of 117.3 W/m^2 in 15 minutes as calculated in Table 1.

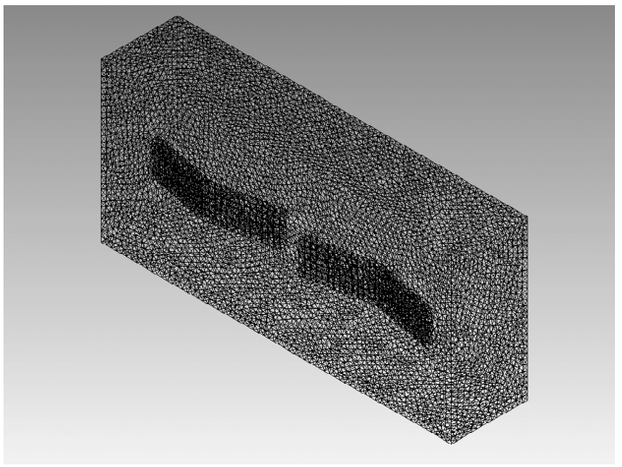

Figure 4. FVM simple model.

Table 2. Physical properties of materials (Maldague 2001).

Thermal characteristics	Concrete	Delamination
Mass density, ρ (Kg/m^3)	2400	20
Specific heat capacity, C_P (J/Kg.°C)	800	1500
Thermal conductivity, k (W/m.°C)	1.0	0.03
Emissivity, ε	0.95	-

3.2 *Comparison between simple FVM model and experimental results*

Results of the surface temperature from both the two FVM models and experimental study are shown in Figure 5, and their temperature profiles A-A are illustrated in Figure 6. It shows that the surface temperature profiles of both methods are relatively similar values, except for an abnormal peak temperature on the left side of V-shape delamination. The reason might come from the quality of the concrete slab which contains several tiny air voids at near surface that raising the temperature. This can be seen more clearly in the thermal image (a lighter color dot inside the darker circular area in Figure 5).

For the boundary conditions of FVM-1 and FVM-2, the results showed different values of temperature nearby the side walls of both models, while values are similar for other parts. Particularly, they were 20.4°C and 19.0°C for FVM-1 and FVM-2, respectively. The reason of sharply collapsing temperature at the side walls of the FVM-2 is because the model accepted the inner heat leaking out at the side walls in order to balance the inner temperature with surrounding ambient temperature around the concrete slab (in this case, it was around 18.6°C as mentioned above). The temperature was slowly falling down in the case of FVM-1 model due to the infinite boundary condition. On the other hand, the side wall of the real concrete slab behaves differently from the finite volume model. Particularly, the heat diffusion of the experimental study is faster than those in the FVM models.

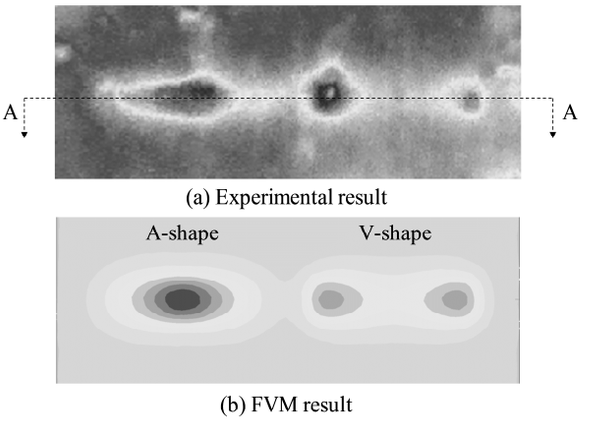

Figure 5. Experimental and FVM-1 surface temperature.

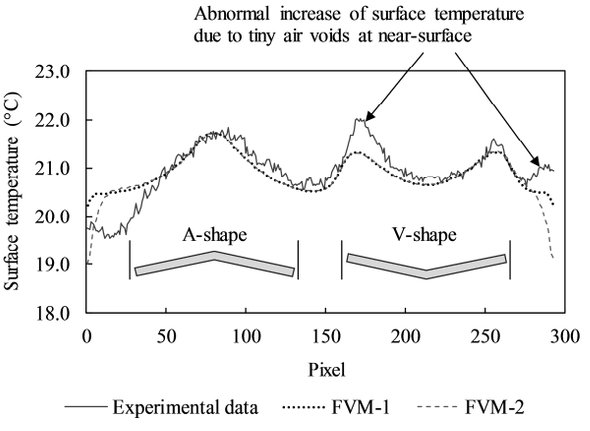

Figure 6. Surface temperature profile A-A above V-shape and A-shape delamination on both experimental study and FVM models.

Discussing on the characteristics of the shape of delamination, here is the capacity of containing heat (or degree of heat loss) in front of delamination. As displayed in Figure 7 about the cooling time of surface temperature in the experimental study, the V-shape delamination reduces its thermal contrast with a slower rate than the A-shape. As a result, we will

have more time to observe delaminations via IR camera screen. In other words, after a certain cooling time, the V-shape delamination might keep better contrast on the thermal image than the A-shape delamination.

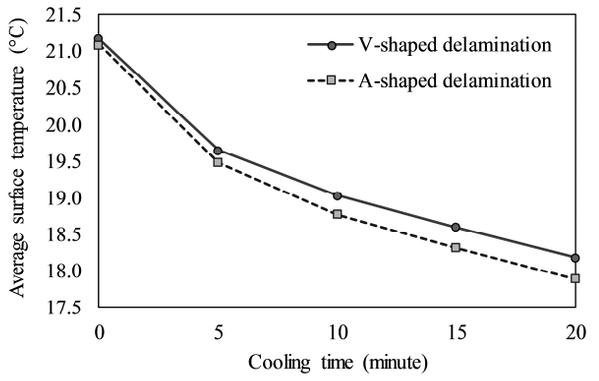

Figure 7. Characteristics of temperature reduction in the cooling period (experimental data), after 3000W heating in 15 minutes.

Figure 8 shows that the relative errors between experimental study and FVM-1 model are smaller than 2%, except for the influence of low-quality and the side wall boundary areas where the errors occur up to 3.5%. It indicates that the FVM results are reliable to be applied for IRT technique. This verification brings us to develop a more complex model to investigate the effect of lateral thermal diffusion on both planar and non-planar delaminations. Then, the conventional method of sizing defects, i.e. FWHM, usually used for sizing planar defects, is then applied to measure non-planar delaminations.

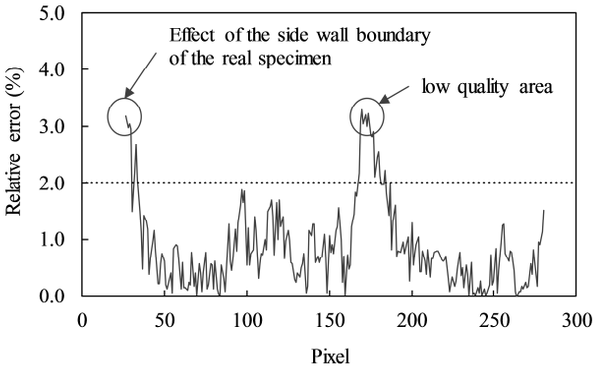

Figure 8. Relative error of experimental and FVM-1 result.

3.3 *Development of a complex model*

A three-dimensional complex numerical model was developed by ANSYS Fluent using FVM, denoted as FVM-3. The mesh was generated to divide the model into small Tetrahedral elements and its geometry is shown in Figure 9. The maximum and minimum size are 8.0×10^{-3} m and 8.16×10^{-4} m, respectively. The objective of this numerical model is to investigate the lateral thermal diffusion of a given heat flux with various depths and shapes of defects. To achieve this goal, the front face of the model was applied by a heat flux as mentioned in Table 1, with an assumption that the heat exchange between the model and the surrounding atmosphere occurs only through the front and back face of the model. The initial inner temperature of the concrete slab was averaged from thermocouple data as 17.6°C and the ambient temperature and the relative humidity were kept same as the previous models. The ambient temperature was applied to the back side of the slab as an initial condition. The physical and thermal properties of materials used in the model are listed in Table 2. In the model, twelve delaminations were simulated. The left column in Figure 9 is the A-shape delaminations with an average depth distributed from 2 cm to 5 cm. Similarly, the middle and right columns are V-shape and planar delamination, respectively.

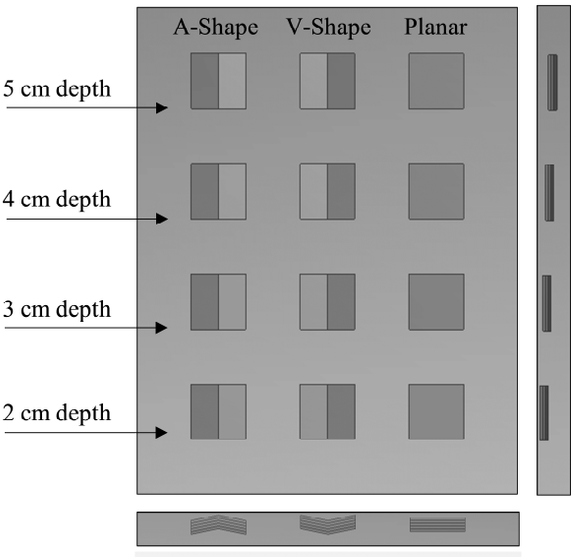

Figure 9. Three-dimensional complex numerical model.

4 ANALYSES AND DISCUSSIONS

4.1 *Effect of lateral thermal diffusion*

As mentioned above, Equations 1 to 3 are analytical expressions with assumptions of uniform heating and one-dimensional. However, the lateral thermal diffusion behaves abnormally when the heat flux incidents a finite delamination. In particular, heat flow spreads laterally over the front face of the delamination. The characteristics of lateral thermal diffusion are controlled by the depth and properties of the defects (i.e. size, thickness, and shape) (Kretzmann

2016a, Almond & Pickering 2012). A shallow and large size of defect contains a small volume of trapped heat above the defect causing a rapid reflection of heat flux toward the surface, which produces a high surface contrast (Kretzmann 2016b), while a larger volume of trapped heat above a deeper defect makes a diffusion developing significantly in all directions.

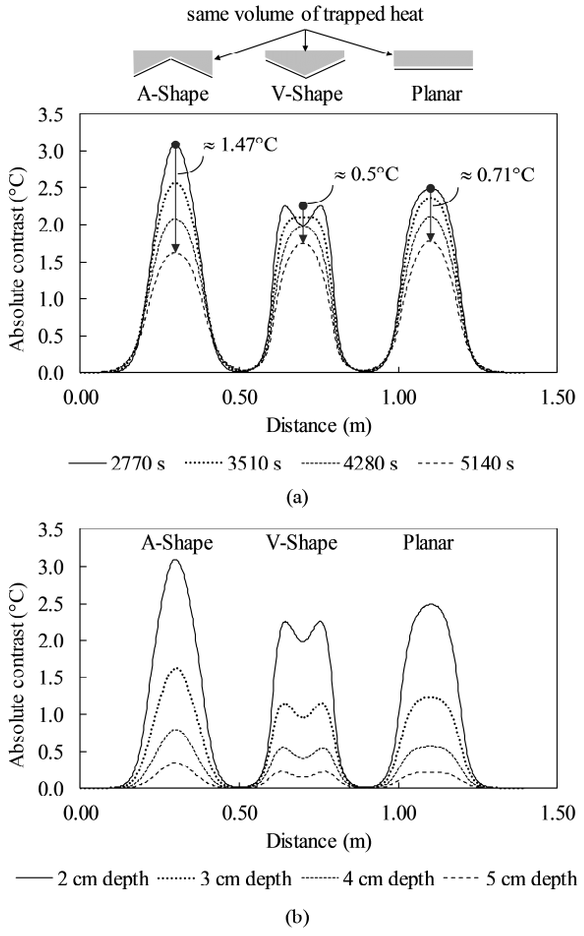

Figure 10. (a) Delaminations at 2 cm depth with different cooling times; (b) Delaminations at different depths with the same cooling time of 2770 s.

For the three special delaminations at 2 cm depth that contain the same volume of trapped heat as shown in Figure 10a, the A-shape delamination shows the fastest degradation of heat, whereas the V-shape delamination indicates the slowest decrease of heat loss. Particularly, the temperature of A-shape, planar, and V-shape decreases approximately 1.47°C, 0.71°C, and 0.5°C, respectively within the time from 2770 s to 5140 s. The slow temperature decrease for the V-shape delamination is same as in the previous discussions on experimental results. In addition, the shape of the surface temperature profile indicates the influence of lateral thermal diffusion. The V-Shape and Planar delamination show a larger width value at half maximum than that of the A-shape, indicating that the lateral diffusion of the A-shape is significant.

On the other hand, the surface temperature profile reflects the shape of the delamination at early time. It clearly shows the delamination's shape at 2770 s (around 16 minutes of cooling), while the temperature responses of the three delaminations are relatively similar at 4280 s as illustrated in Figure 10a.

Figure 10b shows the surface temperature responses at 2770 s above delaminations located at different depths. Shapes of shallow delaminations show clearer than those of deeper ones because of a significant lateral thermal diffusion in all directions. Therefore, it is more difficult to recognize the shape of deep delaminations compared with the shallow ones.

4.2 *Defect sizing*

The FWHM method is used to measure the defect's size in this study. The method works with the assumption that the temperature response above the defective area is Gaussian where the peak corresponding to the center of the defect (Almond & Lau 1994, Saintey & Almond 1995). The results of predicted size at observation time for different depths are summarized in Table 3. To consider the predicted and real size, the relative error is used with a negative value means that the predicted size is smaller than the real size.

Table 3. Predicted sizes obtained by FWHM.

Predicted size (cm)				Relative error (%)		
Depth	A	V	Planar	A	V	Planar
2	15.6	19.5	18.4	-22.1	-2.5	-8.1
3	16.6	19.7	18.4	-17.2	-1.4	-7.8
4	17.2	19.9	18.7	-14.1	-0.5	-6.5
5	17.7	20.1	19.0	-11.5	0.3	-5.1

Table 3 shows that the predicted sizes of V-shape and planar delaminations are more accurate than A-shape delaminations. One should emphasize that the best result comes from V-shape, whereas the worst result is the A-shape, especially for the delamination at 2 cm depth with an error of 22.1%. As a result, the predicted size is just round 15.6 cm comparing to the real size of 20 cm. It can be concluded that the FWHM is not a suitable method to estimate A-shape delamination. Using a different method for sizing the special shape delamination such like A-shape should be further studied. In addition, a consideration of different gap angles of both A-shape and V-shape is also interesting. However, these studies are beyond the scope of this paper.

Figure 11 shows the time dependences of predicted sizes with different delamination's shapes using FWHM method. It is noted that the predicted sizes

for V-shape and planar delaminations show the same manner with previous works. In particular, the predicted size shrinks with elapsed time (Almond & Lau 1994, Saintey & Almond 1995). However, the A-shape delamination shows an inverted trend. The size swells against time.

On the other hand, Figure 11b also indicates that it is possible to measure the size of V-shape and planar delamination at the beginning of cooling time at 1800 s (after turning off the heat source) without sacrificing much accuracy.

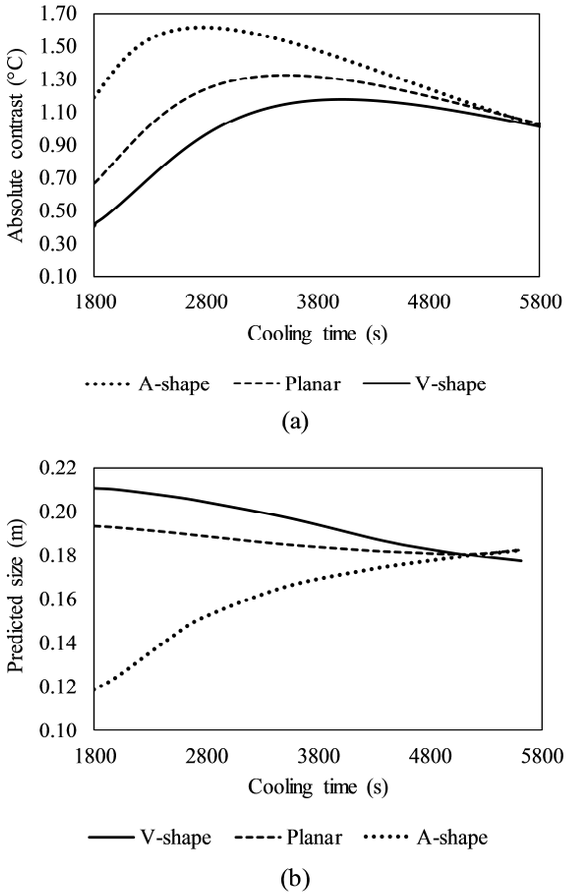

Figure 11. (a) Cooling curve of delamination at 3 cm depth; (b) FHWM obtained by FVM in the time domain.

5 CONCLUSIONS

The data of impulse thermography test obtained from the experimental study were analyzed for special shape delaminations. Then, the experimental results were verified to those from the simple FVM model. A more complex three-dimensional FVM model was simulated to analyze the effect of lateral thermal diffusion for delaminations with different depths (from 2 cm to 5 cm depth) and shapes (A-shape, V-shape, and planar). The FWHM method was used to predict the size of the defects. Results show that the relative errors between experimental study and FVM model are lower than 2%, indicating that the finite volume method is a reliable tool for modeling infrared thermography technique.

Based on both experimental data and FVM analyses, considering the heat loss above the defective area, the A-shape delamination shows a faster degradation of heat than the V-shape and planar delamination. In other words, as the same testing conditions, the V-shape and planar delaminations show better and longer contrast on the thermal image than the A-shape delaminations. In practice, this can help technicians having more chances to detect defects on site. In addition, the shape of delamination can be observed at early of cooling time with a shallow delamination. With a longer cooling time and deep delamination, it is difficult to recognize the real shape of the defect.

Finally, the conventional method FWHM is proven to be a good method in sizing planar subsurface delamination. However, based on FVM analysis in this study, it is not a suitable method for predicting the size of A-shape delaminations.

Corrosion Segmentation and Quantitative Analysis Based on Deep Neural Networks

Dalei Wang, Bo Peng & Yue Pan
Department of Bridge Engineering
Tongji University, China

ABSTRACT: Corrosion is one of the most common and severe problems in the daily maintenance of steel bridges. So far manual visual inspection remains a popular method in the corrosion detection, which means a large amount of labor power as well as material and financial resources are wasted in routine maintenance and quantitative criteria of evaluating corrosion could be hardly obtained due to the subjective judgments of inspectors. With the development of computer vision techniques in recent years, corrosion inspection could be achieved through image segmentation based on deep neural networks besides quantitative indexes such as area, distribution and corrosion rate could be obtained at the same time, which quantifies and standardize the evaluation criteria of corrosion in steel bridges. Furthermore, image segmentation and analysis based on deep neural net-work shows high robustness in the real complex scenarios and could be applied in actual bridge inspection rather than laboratory scenarios.

1 INTRODUCTION

Corrosion is a natural process during which time materials interact with the environment and leads to deterioration of the material properties. Corrosion has caused huge economic losses for a long time. It is reported that in America steel corrosion led to a cost of $170 billion in 2012 and this cost raised to $2.5 trillion in 2016. Roughly speaking, economical losses caused by steel corrosion could account for 3% ~ 4% of GDP of each country.

In civil engineering, steel corrosion is the most common form, which leads to deteriorations of strength, plasticity, stiffness and other mechanical properties in varying degrees. People spend a lot of money and labor forces for manual inspection and repair works every year. Thus, to improve the economic performance and promote the informational inspection, the research of advanced auto-inspection system has already been very critical.

Currently, during the processing of manual inspection, disease image data acquisition is one of the major works. Image data are useful for bridge inspectors to record the diseases information and evaluated the health status of the bridge structure. To preferable use these data and develop inspection system toward intelligence, a novel corrosion detection method based on computer vision and deep neural networks is proposed, which is an important part of another big project but not discussed in this paper. This method can detect and rank the corrosion directly on disease images with high precision, and it makes quantitative analysis of disease become true.

The general practice in corrosion detection is to create standard corrosion images of different degrees in advance, so that the inspectors could com-pare the actual corrosion regions with these standard images to obtain evaluation results. This manual inspection approach highly relies on the experience and subjective consciousness of inspectors, and as a result of which the inspection results are not always credible.

Steel corrosion detection could be achieved through computer vision techniques. The process of detecting corrosion regions from steel surface is equivalent to segment the images into foreground (corrosion regions) and background (non-corrosion regions). Hence corrosion detection could be converted to semantic segmentation in computer vision, which means representation of corrosion regions can be realized by establishing appropriate segmentation criteria.

Segmentation criteria could be founded considering the color and texture differences between corrosion regions and non-corrosion regions. Early studies try to find proper color configuration in different color spaces such as RGB, HSV and other 14 spaces to achieve corrosion segmentation (Chen PH et al. 2009); related studies combine color information with region texture and improve the applicability of seg-

mentation algorithm (Shen HK et al. 2013); in addition some studies train a SVM classifier to enhance the segmentation performance in rust satin regions (Liao KW & Lee YT 2016). Segmentation algorithms based on digital image processing show certain applicability in laboratory scenarios, but the real problem lies in the complex actual scenarios. The varying illuminations, shadows, and object occlusions lead to high randomness in corrosion images so that segmentation could hardly be achieved through manual designed criteria. A feasible way to solve this problem lies in the semantic segmentation methods using deep neural networks.

Semantic segmentation based on deep neural networks date from attempts for fully convolutional networks (Shelhamer E et al. 2014), where segmentation masks can be obtained by upsampling the low resolution heatmap calculated from the convolutional networks. Recently an overview on semantic segmentation (Garciagarcia A et al. 2017) investigate and analysis the prevalent segmentation networks including SegNet (Badrinarayanan V et al. 2017), DeepLab (Chen L C et al. 2017), CRFasRNN (Zheng S et al. 2015) etc., then divide the architectures into two categories called "decoder variants" and "integrating context knowledge".

In this paper, a simplified semantic segmentation network with decoder variants is developed which aims at corrosion detection. At the beginning of all, the network architecture is introduced in Section 3. Then, the training process and data set information are represented in Section 4. The testing results and quantitative analysis of corrosion images are shown in Section 5. At last, summaries and conclusions are drawn in Section 6.

2 NETWORK ARCHITECTURE

2.1 *Overall Architecture*

The decoder variants architecture is chosen in designing segmentation network, which could be divided to encoder (downsampling) and decoder (upsampling) parts. U-Net architecture (Ronneberger O et al. 2015) is also referred in our network, meaning that feature fusion is achieved by combining feature maps of different levels in downsampling and upsampling steps. In addition, batch normalization shows significance in accelerating training process and preventing overfitting. The overall architecture of our segmentation network is shown in Figure 1.

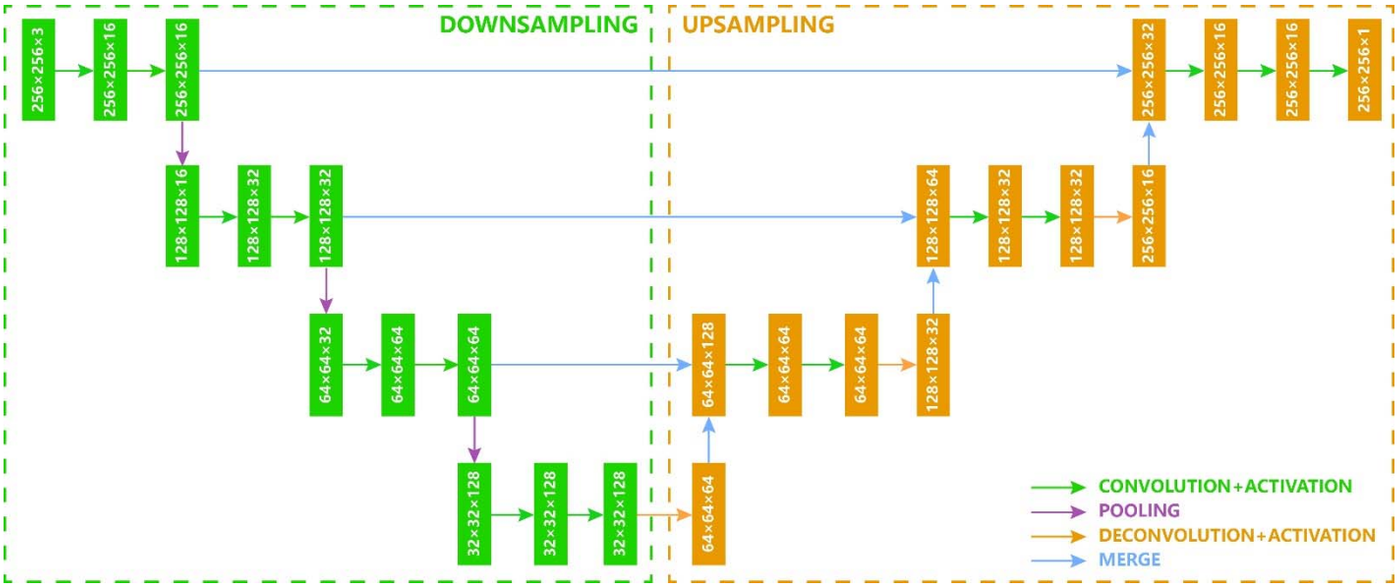

Figure 1 Overall architecture.

2.2 *Convolution Layers*

Convolution is a common operation in digital image processing. The calculation process is shown as follows: Firstly, a subarray is extracted from the original image. Then, an element-wise multiplication is applied to this subarray with a given kernel (or filter). Finally, the multiplication results are added up with a bias and we get the final output value for the input subarray. These steps are repeated until every pixel of the input image is performed. The mathematical expression of convolution is shown below:

$$S(i,j) = (I * K)(i,j) = \sum_m \sum_n I(i+m, j+n) K(m,n) + bias \quad (1)$$

where $S(i,j)$ = output value in (i,j); $I(i+m,j+n)$ = input value in $(i+m,j+n)$; $K(m,n)$ = kernel value in (m,n).

Convolution could also be realized as a local information extractor by which local features, e.g. edges, gradients and textures. The extracted features are converted to more abstract features after stacking convolution layers, and then the recognition task is achieved through these high-level features.

During the down-sampling process, there are two convolution layers with padding in each block. The kernel size is fixed as 3×3, and the stride is fixed as 1

so that the channels will increase with resolution unchanged in each block.

2.3 *Pooling Layers*

Pooling layers are another important component in convolutional neural networks, where feature maps are reduced to decrease computation. In addition, invariants can be obtained after pooling layers, which means small translations of the input will not affect the final output.

There are two kinds of pooling layers widely used today, called "average pooling" and "max pooling". In average pooling, the average of a rectangular neighborhood from the central pixel (pooling window) is calculated as the output, while in max pooling the maximum of the pooling window is extracted. Expressions of the two pooling methods are shown below:

$$avg_pool(x,y) = avg\{I(x+i,y+j) \mid -p \le i \le p, -q \le j \le q\} \tag{2}$$

$$max_pool(x,y) = max\{I(x+i,y+j) \mid -p \le i \le p, -q \le j \le q\} \tag{3}$$

Max pooling is proved an efficient operation in compressing features and accelerating training process. Therefore, max pooling is selected in our network and the pooling window size is fixed as 2×2.

2.4 *Activation Functions*

Nonlinear capacity is obtained through activation functions in neural networks. Sigmoid function is the most common activation function in standard artificial neural networks, and its expression is shown below:

$$\text{sigmoid}(x) = \frac{1}{1+e^{-x}} \tag{4}$$

Sigmoid function maps an arbitrary real number into the interval (0, 1), which could be understood as the probability that the sample is classified as positive. Gradient vanishment in back propagation is the main problem for deep neural networks with sigmoid functions, therefore the sigmoid functions are always replaced with other activation functions. The commonly used activation function in deep neural networks is ReLU function, which truncates the input value retaining the positive part and suppressing the negative part. The expression of ReLU function is shown below:

$$\text{ReLU}(x) = \max(0, x) \tag{5}$$

ReLU function is used in all the layers in our network except the final output layer, where sigmoid function is used instead. Since the final output layer is equivalent to handling a binary classification problem (corrosion or non-corrosion), the output of sigmoid function in the final layer is deemed as the probability that a pixel is classified as corrosion.

2.5 *Upsampling Layers*

The input image is transformed to an n-dimension vector which represents the probability of different categories in image classification tasks, while a segmentation mask with the same resolution as the input image is obtained in semantic segmentation. Therefore, upsampling becomes a necessity in handling the reduced resolution feature maps.

Deconvolution is the main method of upsampling at present. Strictly speaking, deconvolution is not the reverse operation of convolution and the proper name of "deconvolution" should be "transposed convolution" or "fractional convolution". The process of deconvolution is to upsample the input image by zero padding and then operate convolution on the upsampled image. There are trainable kernels in deconvolution compared to bilinear interpolation and unpooling so that deconvolution could also be recognized as a feature extractor. Deconvolution is used in upsampling layers in our network with the height and width of feature maps doubled while the number of channels reduced to half.

2.6 *Batch Normalization*

Batch normalization (Ioffe S & Szegedy C 2015) is a well-known trick aiming at accelerating training process and preventing overfitting. The original distribution of a given input can be adjusted to a proper form after batch normalization. Firstly, the original distribution is normalized to zero mean and unit variance:

$$\hat{x}^{(k)} = \frac{x^{(k)} - \mu_B}{\sqrt{\sigma_B^2 + \varepsilon}} \tag{6}$$

where $x^{(k)}$ = the k th sample of the batch; μ_B=the mean (expectation) of the batch; σ_B^2= the variance of the batch; ε=a minimum preventing 0 denominator; $\hat{x}^{(k)}$ =the kth normalized sample.

Then, two trainable parameters are introduced in the linear transformation of $\hat{x}^{(k)}$:

$$y^{(k)} = \gamma \hat{x}^{(k)} + \beta \tag{7}$$

where γ , β = trainable parameters in batch normalization; $y^{(k)}$= output of the kth sample after batch normalization.

The original distribution is adjusted to a proper form with β mean and γ^2 variance after batch normalization. There is no difference between parameters in batch normalization and other layers since the batch normalization is just a linear transform.

Batch normalization is applied after every block in downsampling and upsampling steps for severe overfitting will occur without batch normalization.

2.7 *Loss Function*

Sigmoid function is used in the final layer in our network, which maps the output into the interval (0,

1), and the result is deemed as the probability of each pixel classified as corrosion. The result of sigmoid function is denoted as p, then:

$$p = P(y^{(i)} = 1 \mid x^{(i)}; \theta) \tag{8}$$

where $y^{(i)}$ = the label of ith pixel of the image with 1 representing corrosion and 0 representing non-corrosion; $x^{(i)}$ = the ith pixel of the image; θ = parameters in our network.

The loss function used in our network is called "negative log-loss" (or "binary cross-entropy"), as is shown below. The loss function is the measurement between the predicted distribution and the actual distribution, and it takes the minimum if and only if the two distributions are equal.

$$J(\theta) = \sum_{i=1}^{m} -y^{(i)} \ln p - (1 - y^{(i)}) \ln(1 - p) \tag{9}$$

A regularization term is also added to the loss function as a penalty to prevent overfitting. L2 regularization is selected in our network, which can be expressed as:

$$\Omega(\theta) = \frac{1}{2} \|\theta\|_2^{\,2} = \frac{1}{2} \theta^T \theta \tag{10}$$

Then, the total loss function $\tilde{J}(\theta)$ is:

$$\begin{aligned} \tilde{J}(\theta) &= J(\theta) + \lambda \Omega(\theta) \\ &= \sum_{i=1}^{m} -y^{(i)} \ln p - (1 - y^{(i)}) \ln(1 - p) + \frac{\lambda}{2} \theta^T \theta \end{aligned} \tag{11}$$

where λ = regularization term factor representing the significance of regularization term in the total loss function, and is set to 1 by default.

2.8 *Adam Optimizer*

The training process of deep neural network is equivalent to minimizing the loss function from optimization perspective. First order optimization algorithms are widely applied in training deep neural networks, the most common one of which is called "stochastic gradient descent" (SGD). A random sample $x^{(i)}$ with corresponding label $y^{(i)}$ are used each time in updating parameters until all the samples in training set are traversed. The updating rule for SGD is shown below:

$$\theta_t \leftarrow \theta_{t-1} - \eta \cdot \nabla_\theta \tilde{J}(\theta; x^{(i)}; y^{(i)}) \tag{12}$$

where η =the learning rate; $\nabla_\theta \tilde{J}(\theta; x^{(i)}; y^{(i)})$ = gradient of the loss function with regard to parameters θ.

SGD gains high calculation efficiency by performing one update a time and avoids convergence to local minima from fluctuation. However, the main difficulties of SGD stem from learning rate schedule, which means high learning rate may lead to non-convergence while low learning rate may lead to slow convergence. On the other hand, SGD may stuck in saddle points (e.g. the loss function takes minimum in x direction but maximum in y direction) since the gradients of these points are zero in all directions.

Adam algorithm (Kingma DP & Ba J 2014) is used instead of vanilla SGD in training our network. The estimates of gradients are calculated in updating parameters, as is shown below:

$$g_t \leftarrow \nabla_\theta \tilde{J}_t(\theta_{t-1}; x^{(i)}; y^{(i)}) \tag{13}$$

$$m_t \leftarrow \beta_1 \cdot m_{t-1} + (1 - \beta_1) \cdot g_t \tag{14}$$

$$v_t \leftarrow \beta_2 \cdot v_{t-1} + (1 - \beta_2) \cdot g_t^{\,2} \tag{15}$$

$$\hat{m}_t \leftarrow \frac{m_t}{1 - \beta_1^{\,t}} \tag{16}$$

$$\hat{v}_t \leftarrow \frac{v_t}{1 - \beta_2^{\,t}} \tag{17}$$

$$\theta_t \leftarrow \theta_{t-1} - \eta \cdot \frac{\hat{m}_t}{\sqrt{\hat{v}_t} + \varepsilon} \tag{18}$$

where g_t = gradients with regard to parameters θ at timestep t; m_t = biased first moment estimate of gradients; β_1 = exponential decay rate of m_t; v_t = biased second moment estimate of gradients; β_2 = exponential decay rate of v_t; $\hat{m}_t$ = bias-corrected first moment estimate of gradient; $\hat{v}_t$ = bias-corrected second moment estimate of gradient.

Adam is one of the best first order optimization algorithms at present. The actual learning rate can be modified adaptively in training process which leads to high computation efficiency, and it has been proved that deep neural networks always converge faster with Adam compared to vanilla SGD through practice and experience. The hyperparameters in Adam algorithm are set as η=10^{-4}, β_1=0.9, β_2=0.999, ε=10^{-8} in training process.

3 TRAINING NETWORK

3.1 *Dataset*

A corrosion dataset, which contains 440 corrosion images, captured on Sutong bridge, is used in training and testing our network. The raw images in the dataset are 709×1067 resolution color images with 3 channels, and the corrosion regions are marked with LabelMe annotation tool (Torralba A et al. 2010). Some of the raw images and segmentation masks are shown in Figure 2.

Considering the characteristic of bridge corrosion image data with low positive and high negative ratio, patches split from raw images are used in training to prevent OOM (out of memory) error and overfitting issues.

In detail, 1026 patches with 256×256 resolution are split from the 440 raw images, and the histogram of the patches with corrosion rate are shown in Figure 3.

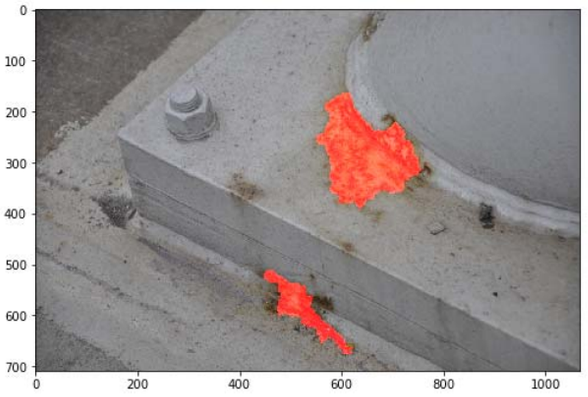

Figure 2 Image with segmentation mask.

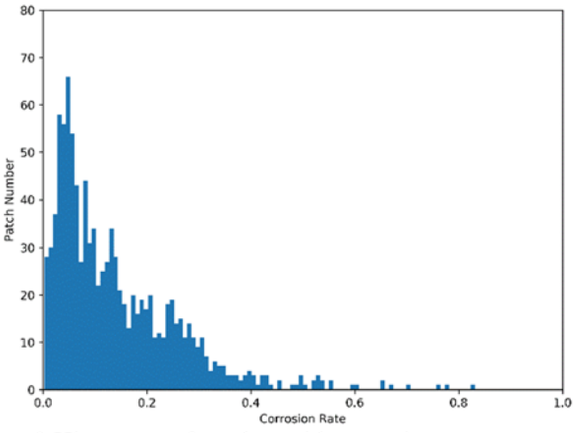

Figure 3 Histogram of patches with corrosion rate.

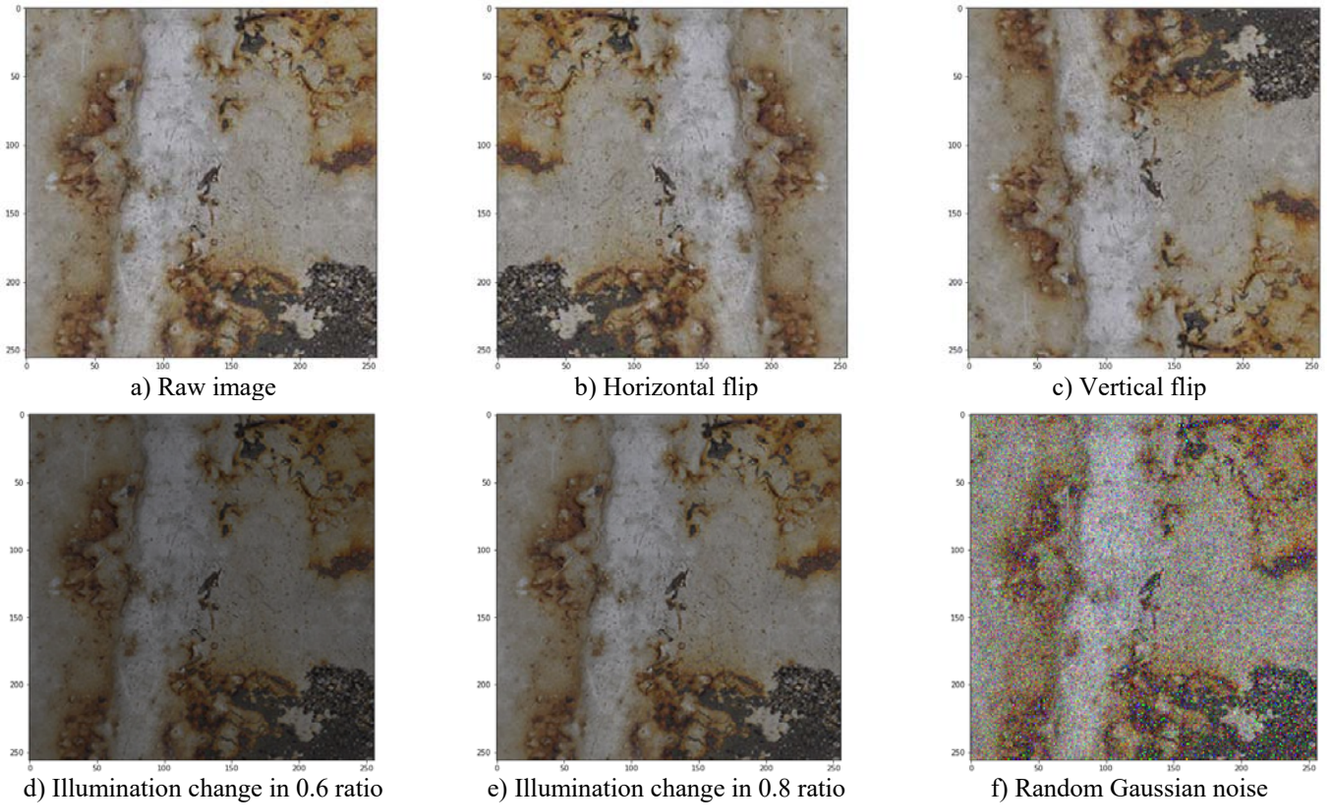

3.2 *Data Augment*

Considering that more corrosion images lead to better training effect, data augment is applied to extend dataset. Horizontal flip and vertical flip combined with illumination change and random Gaussian noise are applied to make more data. Finally, 6156 images including original patches are generated to train and test our network and some of the enhanced patches are shown in Figure 4.

3.3 *Training Process*

The dataset is divided to training set and testing set with the ratio of 9: 1, which means 5540 images including 556 images in validation set are used in training while the others are used in testing. The images are shuffled in the training process and only one image is used in a training step. An epoch means all the training images are traversed and we propose 50 epochs in the training process.

The segmentation network is implemented with TensorFlow framework and the initial learning rate is set to halve when the accuracy in validation set no longer rises, and the minimum learning rate is set to 1×10^{-10}. It takes 500~520 s in a training epoch and the total time cost is about 7 h on a workstation with 16 GB RAM, Intel Xeon E3-1505M v5 @2.80GHz CPU and Nvidia Quadro M2000M GPU. The loss, accuracy and learning rate decay curves are shown from Figure 5 to Figure 7. The binary accuracy with 92.55% in training set and 90.56% in validation set is achieved after 50 epochs.

4 TEST RESULTS

4.1 *Network validation and testing*

Corrosion segmentation is equivalent to the binary classification of every pixel in the image. There are 4 conditions in classification considering the actual and predicted results, as is shown in Table 1.

Table 1 Truth table for binary classification.

		Predicted Conditions	
		Predicted Condition Positive	Predicted Condition Negative
Actual Conditions	Condition Positive	True Positive (TP)	False Negative (FN)
	Condition Negative	False Positive (FP)	True Negative (TN)

Precision and recall for classification can be defined as:

$$Precision = \frac{TP}{TP + FP} = \frac{p_{11}}{p_{11} + p_{01}} \tag{19}$$

$$Recall = \frac{TP}{TP + FN} = \frac{p_{11}}{p_{11} + p_{10}} \tag{20}$$

where p_{11}= pixels predicted as corrosion and labeled as corrosion, which is *TP*; p_{01}= pixels predicted as corrosion but labeled as non-corrosion, which is *FP*; p_{10}= pixels predicted as non-corrosion but labeled as corrosion, which is *FN*.

Precision and recall are two common metrics used in classification, where precision describes how the model could find the targets as accurately as possible while recall describes how the model could the targets as many as possible. They are a pair of negatively related metrics in most cases, therefore a threshold is required in classifying predicted conditions. PR curve is used to verify classification threshold, as is shown in Figure 8, and intersection of precision and recall is 0.5, which is selected as classification threshold in our network.

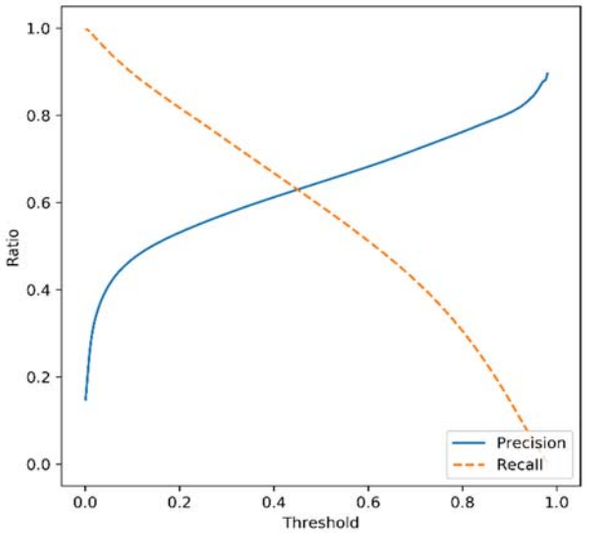

Figure 8 PR curve with classification threshold.

In addition to testing patches, our network is also applied to the raw images, which are resized to 704×1024 considering the input requirement. Some of the testing results are shown in Figure 9, where *TP* regions are painted green, *FP* regions are painted blue and *FN* regions are painted red.

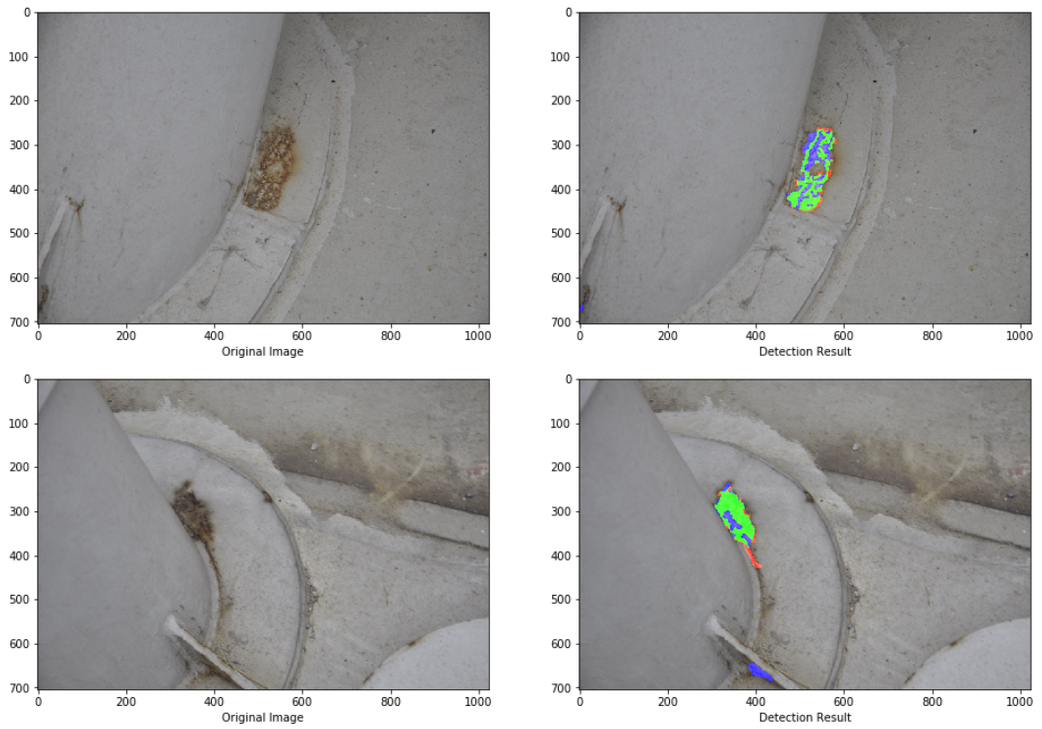

Figure 9 Some of the detection results on raw images.

The testing results on raw images show good adaptability of our network for main corrosion regions can be detected from the raw images. *FP* regions are mainly distributed around the edges of the corrosion or the regions hard to mark in raw images, while *FN* regions are mainly distributed in the shadow part or indistinguishable part.

4.2 *Quantitative Analysis*

Quantitative analysis can be achieved since corrosion segmentation mask is obtained through our network. Firstly, corrosion regions are split considering their connectivity and isolated points are removed with morphology open operation. Then, corrosion regions painted with random colors are shown in Figure 10.

Area of a corrosion region is defined as the pixels in it, as is shown below:

$$A_i = \sum p_i,\ p_i \in Region_i \tag{21}$$

Hence, corrosion rate is defined as the ratio of its area and the total pixels in the image:

$$corrosion\ rate_i = \frac{A_i}{Area} \tag{22}$$

And the total corrosion rate is defined as the total area of corrosion divided by the total pixels in the image:

$$total\ corrosion\ rate = \frac{\sum_i A_i}{Area} \tag{23}$$

Then, the quantitative analysis of the detected image is shown in Table 2.

Table 2 Quantitative analysis of the detected image.

Region Number	Corrosion Area	Corrosion Rate
1	227	0.031%
2	25	0.003%
3	1439	0.200%
4	1051	0.146%
5	48055	6.666%
6	25	0.003%
7	1043	0.145%
8	1359	0.189%
9	260	0.036%
10	333	0.046%
Total	53817	7.465%

The corrosion area can be converted to actual area of corrosion regions with standard imaging, and the actual corrosion rate can be obtained. In addition, the histogram which indicates the distribution of corrosion regions is available if scanning the surface of steel structures. The quantitative analysis could therefore provide data support for evaluating structural performance and formulating maintenance strategy.

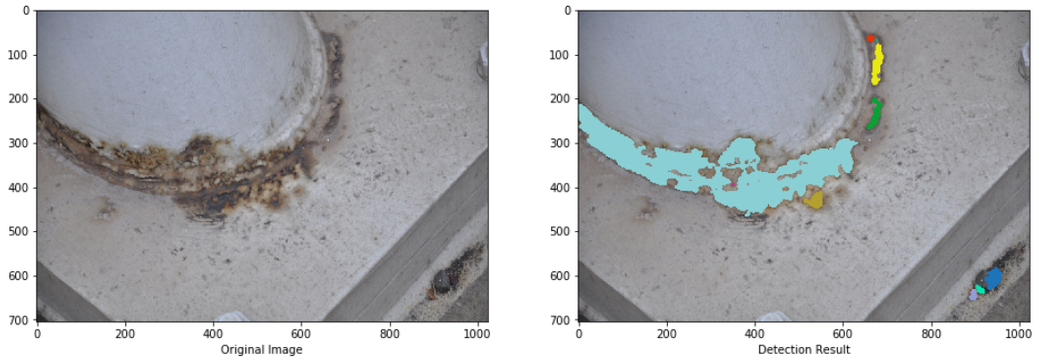

Figure 10 Detection results for quantitative analysis.

5 CONCLUSION

A novel corrosion detection method based on deep neural networks is proposed in this study. The network is trained through patches with 256×256 resolution and the dataset is extended through data augment. The binary accuracy with 92.55% in training set and 90.56% in validation set is achieved in the training process. Our network is also tested on the raw images and the testing result shows adaptivity for major part of corrosion could be detected from background.

Only qualitative analysis is provided through traditional methods, while quantitative analysis can be achieved through our segmentation network. Corrosion area, corrosion rate and total corrosion rate are proposed to qualitatively analyze the corrosion degree of steel surface, Besides, the actual corrosion indicators could also be obtained with the help of standard imaging. Our method can be extended to arbitrary structural surface defection theoretically, and the detection results can also be improved with more abundant data.

ABSTRACT: It is necessary to gain the information on the mechanical, chemical, and fracture properties of their materials in order to find out cause of damage and examine retrofitting methods for repairing damaged steel bridges. One of the properties used to investigate retrofitting methods is fracture toughness. Charpy impact tests are conducted in order to examine fracture toughness. The size of test specimens of Charpy impact tests is specified in Japanese Industrial Standards. Test specimens must be shaped according to the specific size, but it is desirable to take smaller material from sound material. Therefore, this study aims to make test specimens with small steel pieces in order to estimate fracture toughness. The size of small steel pieces was set as they can be taken from stop holes or bolt holes. Test specimens were made with these small steel pieces by electron beam weld. Then the effect of steel piece size on Charpy absorbed energy was examined.

1 INTRODUCTION

Fatigue damage in steel bridges has been reported (Japan Road Association, 2007 and 2009). In order to identify the cause of fatigue damage or examine the retrofitting methods of damaged steel bridges, it is necessary to gain the information on the mechanical, chemical and fracture properties of their materials. For example, test specimens of Charpy impact tests are made with the material taken from the base material of damaged bridges and Charpy impact tests are conducted in order to examine the fracture toughness. When test specimens are taken from damaged bridges, it is desirable to take smaller material from sound material.
When stop holes are bored for preventing the crack propagation or the holes for high tension bolts are bored for retrofitting damaged bridges by the bolted splice steel plates, cores can be gained after holes are bored. And it is effective and useful to use stop hole cores or bolt hole cores as the test specimens.
The previous study examined to make the test specimens with small steel pieces and conducted Charpy impact tests by using the test specimens in order to estimate fracture toughness (Ono et al., 2012). A small steel piece gained from cores was connected to another steel plates by electron beam weld (EBW) from one side of test specimen as shown in Figure 1, and it was cut and shaved into the test specimen so that V-notch is placed in center of the small steel piece.

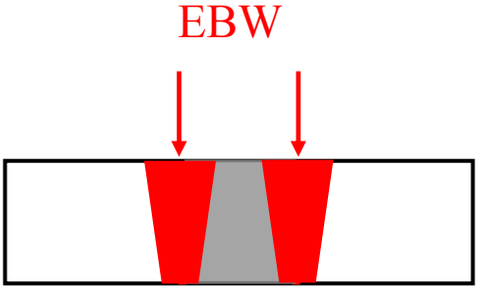
In this study, the size of small steel pieces was changed and its effect on Charpy absorbed energy was examined. SBHS400, which was introduced in Japanese Industrial Standards in 2011, was used in the experiment.

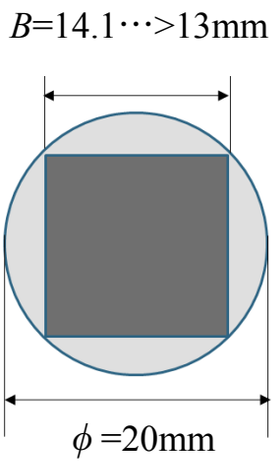
2 TEST SPECIMENS

The procedures how to make test specimens are explained and heat-affected zones of test specimens are examined in this chapter.

2.1 STEEL PLATE USED TO MAKE TEST SPECIMENS

In this study, test specimens were made of SBHS400 plate and its thickness was 27mm.





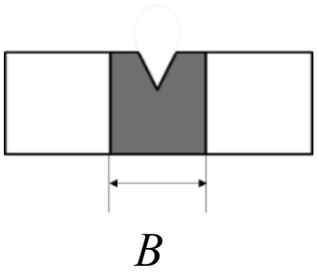


Figure 1 The method of conducting EBW to make test specimens

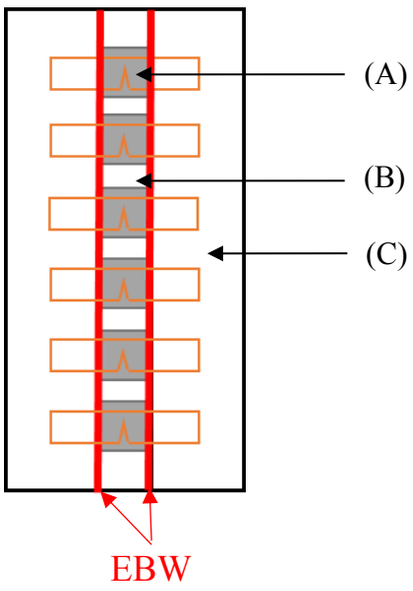
(a) A core and a steel piece

(b) Location of a steel piece including V-notch area

Figure 2 Relationship between assumed core and gained steel piece



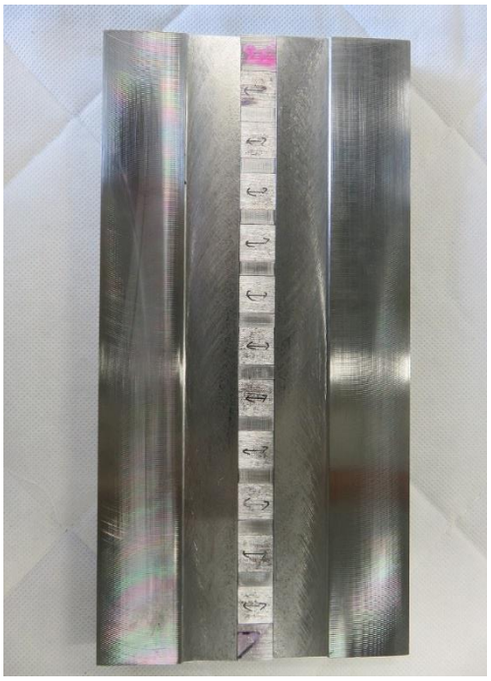


Figure 3 Procedure of making test specimens by EBW

Picture 1 Steel pieces and plates actually listed

2.2 ASSUMED SIZE OF CORES

A small steel piece corresponding to a core is connected to another steel plates by EBW. It is thought that size of cores which is assumed to be gained is 20mm in diameter. Figure 2 shows relationship between an assumed core which can be obtained from a stop hole or a bolt hole and a small steel piece in which V-notch is made.

Table 1 Welding condition of EBW

Voltage(kV)	Current(mA)	Welding speed(mm/min)
60	73	270

As shown in Figure 2, the square steel piece whose size is 13mm can be gained from the stop-hole-size core whose diameter is 20mm. In consideration of Figure 2, 13mm is decided as the maxim size '*B*' of square steel pieces gained from the stop-hole-size cores.

2.3 TYPES OF TEST SPECIMENS

In case of making test specimens by welding, the effect on the change in the material properties should be considered. Some previous studies (Seo et al., 1982; Seo et al., 1983) shows that such change in the materials affect Charpy absorbed energy and adequate test results cannot be gained if each EBW line is too close. Therefore, the width of small steel pieces ('*B*' in figure 2) was changed and its effect on Charpy absorbed energy was examined. '*B*' was set in 9mm (test specimen 'B09'), 11mm (test specimen 'B11') and 13mm (test specimen 'B13') in the experiment.

2.4 PROCEDURE OF MAKING TEST SPECIMENS BY ELECTRON BEAM WELD

The welding condition of EBW used to make test specimens is shown in Table 1 and Picture 1.
The outline of the procedure of making test specimens is as follows.

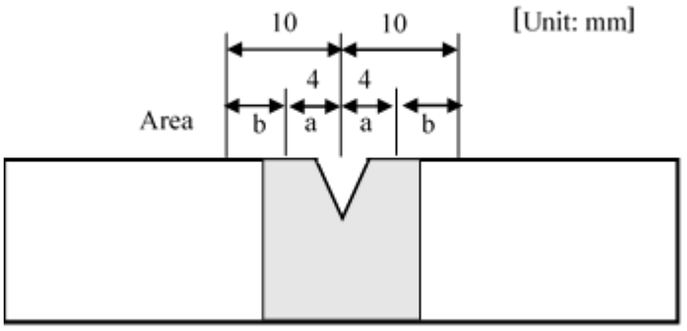

Figure 4 The areas in which Vickers hardness was examined (‘B13’)

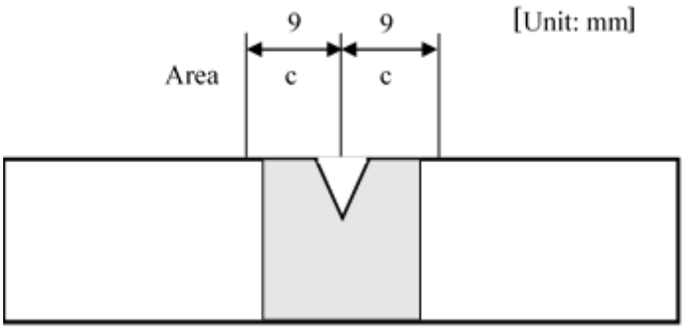

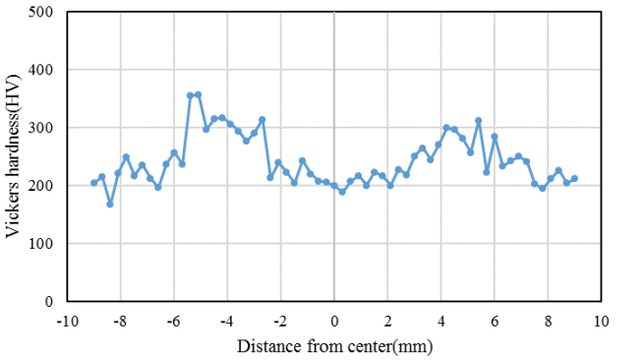

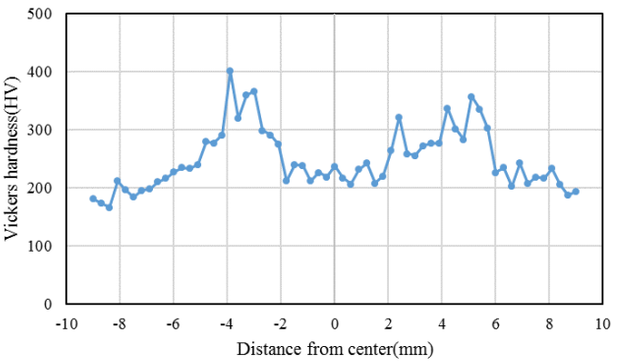

Figure 5 The areas in which Vickers hardness was examined (‘B09’, ‘B11’)

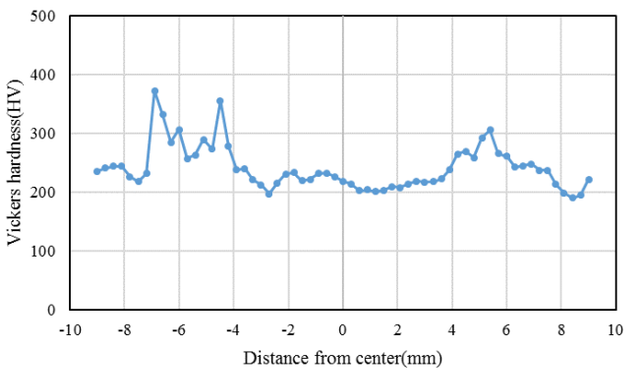
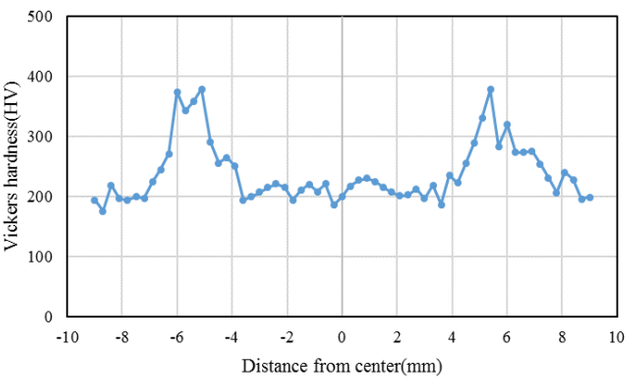
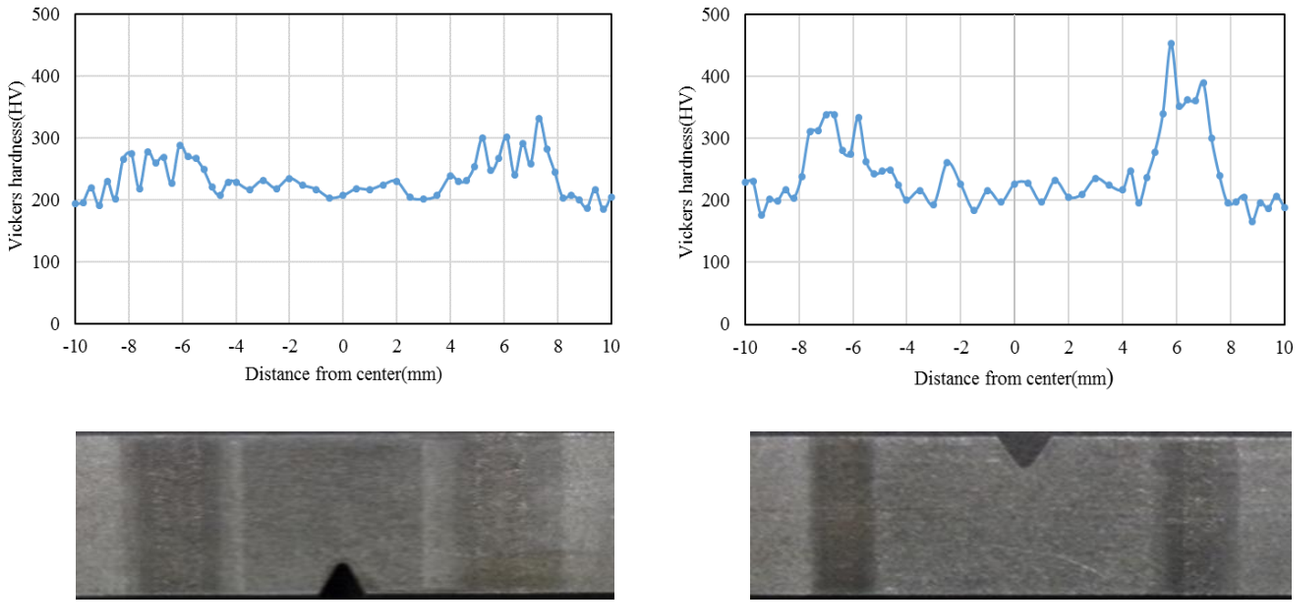


(a) Front surface



(b) Back surface

Figure 6 Results of Vickers hardness tests and macrostructure tests (‘B09’)



(a) Front surface

(b) Back surface

Figure 7 Results of Vickers hardness tests and macrostructure tests (‘B11’)

(a) Front surface (b) Back surface

Figure 8 Results of Vickers hardness tests and macrostructure tests (‘B13’)

・Small steel pieces corresponding to the main part of test specimens (‘A’ in Figure 3) , steel spacers (‘B’ in Figure 3), edge parts of the test specimens (‘C’ in Figure 3) and backing metal are set as shown in Figure 3.
・EBW is conducted from one side of steel plates.
・Making test specimens are completed by cutting them and shaving them off until the predetermined size and thickness of full size Charpy V-notch impact test specimens specified in Japanese Industrial Standards.

2.5 VICKERS HARDNESS TEST AND MACROSTRUCTURE TEST

In order to investigate heat-affected zone of test specimens by EBW, Vickers hardness tests and macrostructure tests were conducted. The weight of Vickers hardness test in this investigation was 4.9N. The location of the measuring points is the center of the height of test specimens. In test specimens ‘B13’, interval of measuring points is 0.5mm in the area ‘a’ of Figure 4 and 0.3mm in the area ‘b’ of Figure 4. In test specimens ‘B09’ or ‘B11’, interval of measuring point is 0.3mm in the area ‘c’ of Figure 5.
Figures 6, 7, and 8 show results of Vickers hardness tests and macrostructure tests of test specimens B09, B11 and B13 respectively.
According to the results of Vickers hardness tests and the macrostructure tests, it is found that heat-affected zone by EBW on the front surface is wider than that on the back surface. And the fact that heat-affected zone of test specimen becomes closer to the V-notch is indicated as the width of small steel piece gets smaller.

3. CHARPY IMPACT TESTS

Charpy impact tests were conducted with test specimens by EBW and standard test specimens without EBW. The size of test specimens was set to that specified in Japanese Industrial Standards. The test temperatures for the Charpy impact tests were 0°C, -30°C and -60°C. Figure 9 shows the results of Charpy impact tests. The averages of results of 3 test specimens are calculated in order to compare Charpy absorbed energy of each type of test specimens as shown in Figure 10.
According to Figure 9, the differences between maximum value and minimum value of the Charpy absorbed energy of standard test specimens are 41.9J at 0°C, 26.8J at -30°C and 55.5J at -60°C. The scatter of the Charpy absorbed energy is relatively large like this.
Figure 9 and Figure 10 shows that the Charpy absorbed energy of test specimens ‘B09’ is lower than that of other types of test specimens. Although the Charpy absorbed energy of test specimens ‘B11’ and ‘B13’ is almost the same as that of the standard test specimens as for the results at 0°C and -30°C, the Charpy absorbed energy of two of the three test specimens ‘B11’ is lower compared with that of test specimens ‘B13’ and standard test specimens about the results at -60°C. However, the difference in Charpy absorbed energy of test specimens ‘B11’ at -60°C may not be significant in consideration of the

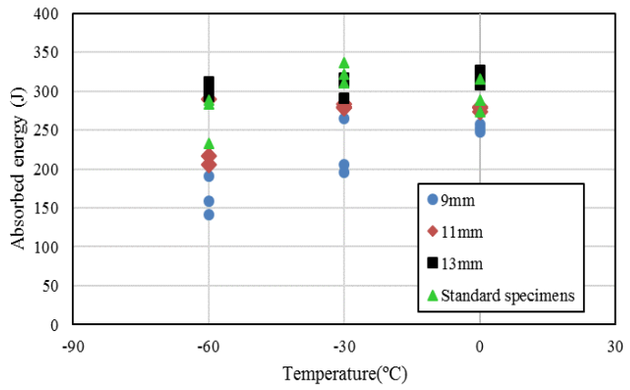


Figure 9 Results of Charpy V-notch impact tests

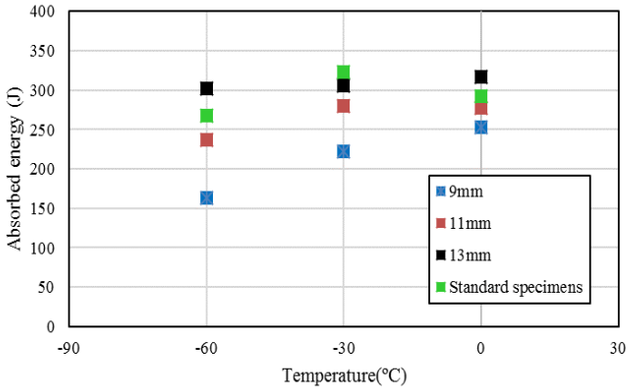

Figure 10 Results of Charpy V-notch impact tests (Average)

scatter of the Charpy absorbed energy of standard test specimens as shown in Figure 9. The test results of test specimens 'B11' will be investigated in detail in the future works. These results indicate the possibility that Charpy absorbed energy can be adequately evaluated with test specimens made with small steel pieces.

4. CONCLUSIONS

Test specimens for Charpy impact test are made with small steel pieces by electron beam weld (EBW) and the effect of width of small steel piece on Charpy absorbed energy are examined in this study.

The results indicate that Charpy absorbed energy depends on the width of steel pieces. And Charpy absorbed energy of test specimens by EBW is almost the same as that of test specimens without EBW when the width of small steel pieces is 13mm. This fact indicates the possibility that the Charpy absorbed energy can be adequately evaluated with the test specimens made with small steel pieces by EBW.

Charpy absorbed energy of test specimens by EBW will be investigated in detail when the width of small steel pieces is 11mm.

A two-stage static structural system identification by observability method

ABSTRACT: Structural system identification (SSI) is a powerful tool for the assessment of the current condition of structures in operation. The basic assumption is that the deterioration of structures is reflected in the change of structural parameters. In SSI, the observability of these parameters depends on the location and the number of sensors. If the available sensors are less than the required ones, some parameters might not be observed. Furthermore, the incapability of identifying all parameters might occur when the sensors are sufficient but placed improperly. An investigation was carried out using SSI by observability method when then number of measurements is the same as the number of sensors. It is seen that a large proportion of the studied measurement sets cannot ensure the observability of all parameters. To improve the observability of structural parameters, a two-stage static SSI method is presented to fully exploit the information in the measurements. In the first stage, the SSI problem is treated in a linear manner and thereby the computation is greatly reduced. In the following stage, the nonlinear relations among the variables in the formulated system are recovered and thus the capability of the method to observe those structural parameters is enhanced.

1 INTRODUCTION

To avoid the potential safety and economical problem due to the deterioration of existing structures, condition assessment of existing structures has become a critical issue. A very common means of implementing condition assessment is Structural System Identification (SSI). SSI is related to the process of estimating structural parameters based on the measured structural response (e.g. deflections, rotations, strains, acceleration). A basic assumption behind SSI is that the change of structural condition can be reflected in the variation of structural parameters.

Due to the difference of the loading, SSI can be categorized as static (Lozano-Galant et al. 2013; Sanayei & Saletnik 1996) or dynamic ones(Li et al. 2017; Jiang & Adeli 2007). Many researches have been focused on the dynamic part. However, much less attention was paid to the static case. Regarding the treatment on uncertainties, these method can also be classified as probabilistic and deterministic methods. The former methods yield a point estimate or an interval estimate of estimations based on the posterior distributions while the latter methods pinpoint a best set of parameters minimizing the square sum of deviation between the measured and the predicted response.

However, these methods do not address the issue of whether the observability of the structural parameters. A vital issue for any SSI method is whether the parameters are observable or not given a particular measurement set. This can be addressed by Observability Method (OM). OM provides the information whether all the unknowns or a subset of the unknowns can be uniquely determined or not. Its application in parameter estimation includes water transport network(Díaz et al. 2016), traffic network(Castillo et al. 2013) or power systems(Abur & Exposito 2004). SSI by OM is a deterministic static SSI method first introduced by Lozano-Galant(Lozano-Galant et al. 2013), which has the advantage of less computation cost than probabilistic methods. In this method, the finite element model for the structure to be assessed has to be defined first. Then the equilibrium equations of the model

are formulated. A series of algebraic operation are applied to this system of equations in such a way that all the unknowns and knowns are separated in different parts of the equations. Step by step example is provided in (Lozano-Galant et al. 2013) and (Lei, Lozano-Galant, et al. 2017).

The identifiability of the structure by any method relies on a good selection of measurements. More measurements are generally desirable for the identifiability of parameters. On the converse, less sensors means less instrumental, operational costs and data processing. It is interesting to find the optimal number of measurements and the location of the sensors for successful identifications. A similar issue was addressed in power system using OM (Abur & Exposito 2004). In the context of power system that is fully specified by n parameters, the question is posed as how the select measurements from m ($m>n$) available measurements to identify the system. If a measurement set of n measurements is able to identify all the n parameters and the drop of any measurement fails to do so, then this set is defined as essential set. In the context of SSI, if the number of measurements was less than the number of unknown parameters, the system would become indeterminate (Bakhtiari-Nejad et al. 2005; Sanayei & Saletnik 1996), i.e. only a subset of the parameters might be identified. Moreover, even if the number of measurements equals to the number of unknowns, if those are not properly chosen, the system might still be indeterminate. An increase in measurements or a better placement of sensors can lead to an increase in the number of identified parameters. Eventually, this process will lead to the identification of all parameters, which is referred as full observability.

Sensor placement has been addressed by many authors (see (Sanayei et al. 1992; Chang & Pakzad 2014; Malings & Pozzi 2016)). However, most of them focus on the dynamic case. In the static SSI by OM, observability tree method was proposed to analyze the sequence of identified parameters during the recursive steps of SSI by OM (Lozano-Galant et al. 2015). It was found that improper selection of the measurement set may stop the identification prematurely and thus fail to identify all the unknowns even with more measurements than unknowns. However, underlying mechanism is not clear and the solution was not found at that time. In this paper, the reason of the failure is revealed as the lacking of some nonlinear constraints during the last recursive step. Also, the original method is updated as a two-stage method. In the first stage, the SSI by OM is carried out until no more parameter is obtained. In the second stage, the lacking nonlinear relations among variables are appended by adding nonlinear constraints via optimization techniques.

2 STATEMENT OF THE PROBLEM

From direct stiffness method, the nodal equilibrium equations for 2D beam models can be expressed as:

$$K \cdot \delta = f \tag{1}$$

where the global stiffness matrix K contains the information of flexural stiffness, EI_j, axial stiffness, EA_j, length L_j and the element connectivity. The displacements vector δ contains the horizontal, vertical and rotational displacements of node i, i.e. u_i, v_i and w_i. The external force vector f contains the horizontal forces, vertical forces and moments applied on node i, i.e. H_i, V_i and M_i.

Once the geometry, the boundary conditions and the load case are specified, then the nodal displacements δ will be uniquely determined by any parameter set. In the case of N_A unknown axial stiffnesses and N_F unknown flexural stiffnesses, this is saying that these N_A+N_F mechanical parameters uniquely specify a set of displacements of the structure. In the inverse analysis, due to the linearity of this system, N_A+N_F measurements are expected to be sufficient to identify all parameters. For simplicity, the ability to identify all parameters of the structure is referred as full observability in this paper. If merely a subset of these parameters are identifiable, then it is referred as partial observability. Hence, in the essential sets (the sets containing the necessary and sufficient number of measurements to achieve full observability), the number of required measurements is N_A+N_F. However, this statement has been verified elsewhere(Lozano-Galant et al. 2015) and it was found that full observability might not be achieved with N_A+N_F measurements due to improper selection of the measurements, which is related with the placement and type of measuring devices. Previous explanation was that the recursive steps stopped too early without identifying all parameters. However, the underlying cause for this premature end of the recursive steps was not uncovered at that time. This is one of the major interests of this paper, which can also be employed for the sensor placement strategy.

For practical reason, Eq. (1) can be transformed as:

$$B \cdot z = D \tag{2}$$

Eq. (2) is the result of applying static condensation technique together with the separation of each column, with regard to different unknowns, into several columns and the merger (addition) of those resultant columns related with the same unknowns in the equilibrium equations (Eq. (1)). After these algebraic operations, all the known quantities are collected in the coefficient matrix B and the vector D. Hence, B and D are known. The unknown vector z is

always of two types: (1) monomials of degree one, e.g. $\{EA_j, EI_j, u_i, v_i, V_i$ and $M_i\}$, or (2) monomials of degree two, e.g. $\{EI_j u_i$ and $EA_j v_i\}$. Note that both, EA_j and EI_j are regarded as monomials of degree one. (For more technical details, readers are strongly recommended to review (Lozano-Galant et al. 2013; Nogal et al. 2015)). If the vertical deflection, v_i, or the rotation, w_i, appearing in these products, $EI_j v_i$ or $EI_j w_i$, are measured, then the flexural stiffness, EI_j, will be uncoupled and separated from those and the vertical deflection v_i or the rotation w_i will be absorbed in B. Otherwise, these products will appear in z in the form of monomials with degree of two and, as per requirements of OM, be regarded as linear in z. However, from a mathematical point, if the unknowns of a system are coupled, then they should satisfy certain constraints. Nevertheless, this requirement is not satisfied in SSI by OM and therefore sometimes leads to the failure to identify all parameters.

In order to clarify this deficiency from the lack of constraints in SSI by OM, a 4-node simply supported beam (Figure 1.a) is studied here. For brevity, it is assumed that the flexural stiffnesses of elements 1 and 3, EI_1 and EI_3, the length of element, L, and the external vertical load at node 2, V_2, are known. Since the axial stiffness is not activated by this load case, hence N_A=0 and the terms associated with axial behavior are removed from the observability equations. Thus, the target parameter is the flexural stiffness of the element 2 (in red), EI_2, i.e. N_F=1. Then one measurement suffices to achieve full observability since N_A+N_F=1. Assume the vertical deflection of node 2, v_2, is measured.

In the first step, the system of equations given by OM is as follows:

$$B_1 \cdot z_1 = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & \frac{4EI_1}{L} & \frac{2EI_1}{L} & 0 & 0 \\ \frac{12v_2}{L^3} & -\frac{12}{L^3} & \frac{6}{L^2} & \frac{6}{L^2} & 0 & 0 & 0 & -\frac{6EI_1}{L^2} & -\frac{6EI_1}{L^2} & 0 & 0 \\ \frac{6v_2}{L^2} & -\frac{6}{L^2} & \frac{4}{L} & \frac{2}{L} & 0 & 0 & 0 & \frac{2EI_1}{L} & \frac{4EI_1}{L} & 0 & 0 \\ -\frac{12v_2}{L^3} & \frac{12}{L^3} & -\frac{6}{L^2} & -\frac{6}{L^2} & 0 & 0 & \frac{12EI_2}{L^3} & 0 & 0 & \frac{6EI_2}{L^2} & \frac{6EI_2}{L^2} \\ \frac{6v_2}{L^2} & -\frac{6}{L^2} & \frac{2}{L} & \frac{4}{L} & 0 & 0 & \frac{6EI_2}{L^2} & 0 & 0 & \frac{4EI_2}{L} & \frac{2EI_2}{L} \\ 0 & 0 & 0 & 0 & 0 & 0 & \frac{6EI_2}{L^2} & 0 & 0 & \frac{2EI_2}{L} & \frac{4EI_2}{L} \\ 0 & 0 & 0 & 0 & -1 & 0 & 0 & \frac{6EI_1}{L^2} & \frac{6EI_1}{L^2} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & -\frac{12EI_2}{L^3} & 0 & 0 & -\frac{6EI_2}{L^2} & -\frac{6EI_2}{L^2} \end{pmatrix}$$

$$\begin{pmatrix} EI_2 \\ EI_2 v_3 \\ EI_2 w_2 \\ EI_2 w_3 \\ V_1 \\ V_4 \\ v_3 \\ w_1 \\ w_2 \\ w_3 \\ w_4 \end{pmatrix} = \begin{pmatrix} M_1 + \frac{6EI_1 v_2}{L^2} \\ V_2 - \frac{12EI_1 v_2}{L^3} \\ M_2 + \frac{6EI_1 v_2}{L^2} \\ V_3 \\ M_3 \\ M_4 \\ 0 \\ \frac{12EI_1 v_2}{L^3} \\ 0 \end{pmatrix} = D_1 \tag{3}$$

$$z_1 = z_{p1} + V_{n1} \cdot \boldsymbol{\rho_1} = \begin{pmatrix} EI_2 \\ EI_2 v_3 \\ EI_2 w_2 \\ EI_2 w_3 \\ \boldsymbol{V_1} \\ \boldsymbol{V_4} \\ v_3 \\ \boldsymbol{w_1} \\ \boldsymbol{w_2} \\ w_3 \\ w_4 \end{pmatrix}_{particular} + \begin{pmatrix} \frac{1}{v_2} & -\frac{L}{v_2} & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} \\ 0 & 0 & -L \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{0} \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} \rho_{1,1} \\ \rho_{1,2} \\ \rho_{1,3} \end{pmatrix} \tag{4}$$

It is seen that the unknown V_1, V_4, w_1 and w_2 are observed. As mentioned above, these observed variables are deemed as known and used as input for the next recursive step. Note that this new input will update Eq. (2) and thus new parameters might be observed. The updated system of equations obtained in the next recursive step is as follows:

$$B_2 \cdot z_2 = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ \frac{12v_2}{L^3} + \frac{6w_2}{L^2} & -\frac{12}{L^3} & \frac{6}{L^2} & 0 & 0 & 0 \\ \frac{6v_2}{L^2} + \frac{4w_2}{L} & -\frac{6}{L^2} & \frac{2}{L} & 0 & 0 & 0 \\ -\frac{12v_2}{L^3} - \frac{6w_2}{L^2} & \frac{12}{L^3} & -\frac{6}{L^2} & \frac{12EI_2}{L^3} & \frac{6EI_2}{L^2} & \frac{6EI_2}{L^2} \\ \frac{6v_2}{L^2} + \frac{2w_2}{L} & -\frac{6}{L^2} & \frac{4}{L} & \frac{6EI_2}{L^2} & \frac{4EI_2}{L} & \frac{2EI_2}{L} \\ 0 & 0 & 0 & \frac{6EI_2}{L^2} & \frac{2EI_2}{L} & \frac{6EI_2}{L} \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -\frac{12EI_2}{L^3} & -\frac{6EI_2}{L^2} & -\frac{6EI_2}{L^2} \end{pmatrix} \cdot \begin{pmatrix} EI_2 \\ EI_2 v_3 \\ EI_2 w_3 \\ v_3 \\ w_3 \\ w_4 \end{pmatrix} =$$

$$\begin{pmatrix} M_1 + \frac{6EI_1 v_2}{L^2} - \frac{4EI_1 w_1}{L} - \frac{2EI_1 w_2}{L} \\ V_2 - \frac{12EI_1 v_2}{L^3} + \frac{6EI_1 w_1}{L^2} + \frac{6EI_1 w_2}{L^2} \\ M_2 + \frac{6EI_1 v_2}{L^2} - \frac{2EI_1 w_1}{L} - \frac{4EI_1 w_2}{L} \\ V_3 \\ M_3 \\ M_4 \\ V_1 + \frac{12EI_1 v_2}{L^3} - \frac{6EI_1 w_1}{L^2} - \frac{6EI_1 w_2}{L^2} \\ V_4 \end{pmatrix} = D_2 \tag{5}$$

The general solution for system (5) is given as:

$$z_2 = z_{p2} + V_{n2} \cdot \boldsymbol{\rho_2} = \begin{pmatrix} EI_2 \\ EI_2 v_3 \\ EI_2 w_3 \\ v_3 \\ w_3 \\ w_4 \end{pmatrix}_{particular} + \begin{pmatrix} \frac{1}{w_2} & 0 \\ \frac{v_2 + w_2 L}{w_2} & 0 \\ 1 & 0 \\ 0 & -L \\ 0 & 1 \\ 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} \rho_{2,1} \\ \rho_{2,2} \end{pmatrix} \tag{6}$$

As no null row exists in the null space matrix, the identification process is stopped. However, the main reason of the premature end of the recursive steps is that the nonlinear constraints, e.g. $EI_2 v_3 = EI_2 \cdot v_3$, are not incorporated into the process.

From the simply supported beam example, an explanation for the observability method being incapable of ensuring identifiability is provided algebraically. This analysis reveals the lacking of nonlinear constraints among the variables.

To further understand the phenomenon, exhaustive estimations are carried out on an academic

simply supported beam example (see Figure 1). In this example, the 15-m beam is discretized into five elements each with the length of L. A downward vertical load with the magnitude of 100 kN is applied at the node 3.

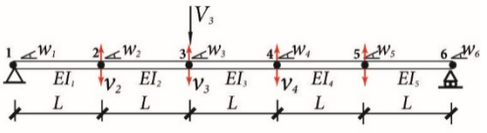

Figure 1 A simply supported beam with five flexural stiffness

Since the axial behavior of the beam is not excited in this loading case, the target parameters for this model are the flexural stiffnesses of the five elements, EI_1~EI_5. Their values are deliberately chosen as 1.5E6 kN·m^2, 1.2E6 kN·m^2, 1.1E6 kN·m^2, 1.4E6 kN·m^2 and 1.0E6 kN·m^2. In this structure, the displacements include w_1~w_6 and v_2~v_5, i.e. 10 in total. All the exact displacements are calculated in SAP2000 and used as the input in SSI by OM. The target parameters are EI_1~EI_5, i.e. N_F=5, whereas the axial stiffnesses are disregarded due to the load case, i.e. N_A=0. Therefore, five measurements are sufficient to identify the whole structure. In order to check the number of essential sets, an exhaustive investigation is carried out on all sets having 5 measurements. Hence SSI by OM is carried out on C_{10}^5 =252 combinations of 5 measurements from {w_1~w_6 and v_2~v_5}. The occurrence of different number of identified flexural stiffness by the observability method, $N_{F,OM}$, and the associated proportion are summarized in Figure 2.

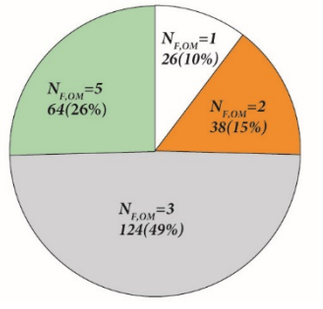

Figure 2. Occurrence of different number of identified flexural stiffness by the observability method, $N_{F,OM}$.

For those measurement sets that are related with $N_{F,OM}$=5, the physical location of the measurements are well distributed along the beam. If the measurements are taken intensively at local areas, redundancy of measurements will emerge. For instance, in the case of measuring {v_3, w_3, v_4, w_4 and w_6}, all displacements of element 3 are measured and hence EI_3 is identified. However, due to lack of any information on v2 or w2, EI_2 cannot be identified. Similarly, EI_4 cannot be identified due to the lacking of any information about v_5 or w_5. The identification of EI_5, which should follow the identification of EI_4, is not executed neither. This renders the measurements v_6 and w_6 ineffective. From this analysis, it can be deduced that one reason for partial observability is that the number of effective measurements is less than the number of unknowns.

Another reason for the partial observability is the termination of the observability flow. Take the measurement set {v_1, w_1, v_2, v_3, v_5, v_6 and w_6} for instance. The identifications of {EI_1,w_2} and {EI_5,w_5} are, respectively, enabled by the measurements {v_1,v_2,w_1} and {v_5,v_6,w_6}. Likewise, the identification {EI_2, w_3} is enabled by the measurements {v_2, v_3, w_2}. Hence, all known displacements, either measured or estimated, are {v_1, w_1, v_2, w_2, v_3, w_3, v_5, w_5, v_6 and w_6}. However, the lack of any information about v_4 or w_4 terminates the observability flow, and thereby fails the identification of EI_3 and EI_4, despite {v_3, w_3, v_5 and w_5} are known.

3 APPENDING NONLINEAR CONSTRAINTS TO SSI BY OM

From the last section, two reasons for the partial observability are presented: (1) the premature end of the recursive steps and (2) the ineffective measurements due to redundancy in the measurement sets.

Adding the nonlinear constraints might be a good solution to alleviate the partial observability induced by the two causes. Hence, we add the nonlinear constraints to the original algorithm.

3.1 *The condition of using the nonlinear constraints*

Whenever possible, optimization procedure should be avoided since it will increase the computation burden. This depends on a distributed placement of sensors.

SSI by OM will be always carried out in the first stage until no more parameters can be observed. If not all parameters are observed, the observability equations from the last recursive step of the first stage will be used in the optimization. It should be highlighted that the SSI by OM is a linear procedure, which is very fast and efficient. In the second stage, the nonlinear relations among variables will be recovered so that more parameters might be observed.

3.2 *Adding the nonlinear constraints*

In the optimization during the second stage, variables will be categorized as one of the three types:

(1) Coupled variables V_c;

(2) Single variables V_{s1}, which already exist in the unknowns z;

(3) Single variables V_{s2}, which do not exist in the unknowns z.

For instance, consider the unknown z { EI_2w_2, EI_2w_3, EI_2v_3 and EI_2}, then coupled unknowns V_c include {EI_2w_2, EI_2w_3 and EI_2v_3}. The single variables from V_c are {EI_2, w_2, w_3 and v_3}. Since EI_2 exists in z, it is categorized as V_{s1} whereas {w_2, w_3 and v_3} are categorized as V_{s2}. The new unknown z^* is {EI_2w_2, EI_2w_3, EI_2v_3, EI_2, w_2, w_3 and v_3}. The nonlinear relations are imposed by forcing the equality between the coupled variables and the product of associated single variables.

3.3 *Optimization procedure*

The optimization procedure is formulated as finding the minimum of the square sum of the residuals of the observability equations while subjected to the nonlinear constraints. The active-set algorithm in the optimization toolbox of Matlab is used here. In order to improve the convergence rate as well as the computation efficiency, numerical scaling technique is applied. After this scaling, the initial values for all variables are set as ones. The lower bound and upper bound for each element are 0.1 and 10, respectively.

A flowchart summarizing all the necessary procedure is available in (Lei, Nogal, et al. 2017).

4 APPLICATION OF THE PROPOSED METHOD

4.1 *Comparison with SSI by OM for the simply supported beam example*

To demonstrate the strength of the proposed method, the structure in Figure 1 is analyzed again with the 252 enumerated measurement sets.

The flexural stiffnesses of the five elements are 1.5E6 kN·m^2, 1.2E6 kN·m^2, 1.1E6 kN·m^2, 1.4E6 kN·m^2 and 1E6 kN·m^2. The scaling factor for the parameters are chosen as 1E6. Hence, the scaled estimate should be [1.5, 1.2, 1.1, 1.4 and 1]. The initial values for these parameters randomly sampled from the uniform distribution on [0.8, 1.2].

The occurrence of different number of identified flexural stiffness by the constrained observability method, $N_{F,COM}$, and the associated proportion are summarized in Figure 3. After adding the nonlinear constraints, that the majority of the sets yielding $N_{F,OM}$ = 3 by OM, alter to yield $N_{F,COM}$ = 5 by COM. The discontinuity of the observability flow can be overcome by applying the nonlinear constraints. For instance, in the final step of the observability analysis on the measurement set {v_1,w_1,v_2,v_3,v_5,v_6,w_6}, the up-to-date information, apart from the original measurements, contains the estimated displacement {w_2,w_3,w_5} and flexural stiffnesses { EI_1,EI_2,EI_5}. Despite the information of {v_3,w_3,v_5,w_5}, EI_3 and EI_4 cannot be identified due to the lack of any of {w_4,v_4}. However, these parameters can be identified with the imposition of associated nonlinear constraints. An explanation is that the compatibility requirement of the displacements at the mutual node of elements 3 and 4, i.e. the displacements of the node 4, and the nonlinear constraints force the solution. This deduction can be justified by another case. For measurement set {v_1,w_1,v_3,w_3,v_5,w_6,v_6}, only the identification of { w_5, EI_5} is attainable using OM. Note that the condition of the previous deduction is satisfied here for both pairs of elements 1,2 and elements 3,4 since all the displacements of nodes 1,3,5 are known. As expected, this set yields the full observability by COM, which further verifies the deduction.

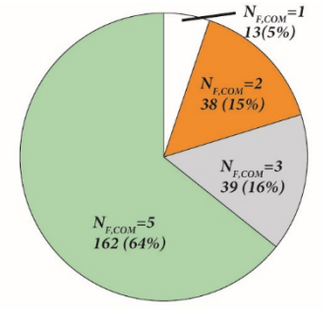

Figure 3. Occurrence of different number of identified flexural stiffness by the constrained observability method, $N_{F,COM}$.

For this example, it is seen that if some of the sensors are placed too intensively at a local area, then other sensors will be placed sparsely in the remaining areas in the case of essential sets. This leads to the loss of information in these remaining areas, or leads to the partial observability. A reexamination has been performed on those sets where no improvement is obtained with COM. For instance, if the information obtained by measurement is considered as a geometric constraint on the deflection shape of the structure, the estimation of the parameters {EI_1, EI_2, EI_3} is not fixed. That is, a relation can be established among them but it is impossible to get a unique estimate of these parameters.

From the comparison of the results obtained by OM and by COM, it can be seen that COM, as an extended version of OM, enhances the performance of the original method. The number of essential sets soars from 64 to 162. Nevertheless, if the sensors are placed too intensively, there still exists possibility of partial observability. Hence, distributed placement of sensors is strongly recommended.

4.2 *Application in a large frame*

To test the performance of the proposed method in the case of more complex and realistic structures, the SSI by observability techniques of a large frame is described here.

This 13-story structure is adapted from (Lozano-Galant et al. 2013). It is 39 m in height and 32 m in width. It is assumed that the structure can be described by eight flexural stiffnesses and eight axial stiffnesses. The parameterization of the structure and the baseline values of the sixteen parameters are demonstrated in Figure 4. In order to demonstrate the robustness of the proposed method, 4 parameter sets of the 16 parameters are generated by the product of the baseline values and some perturbation factors that are sampled from the uniform distribution on [0.8,1.2].

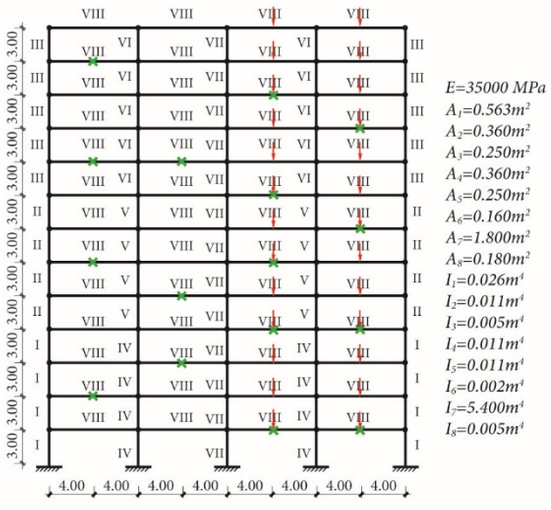

Figure 4. Parameterization of the FEM for the 13-story building

In previous study, 156 vertical deflections were measured. In this study, the number of measurements is the same as the number of unknowns. According to the estimations of these parameters for these four sets obtained via SSI by COM, the maximum percentage deviation between the estimations and the true values are within 2 percentage.

5 CONCLUSION

In SSI, the observability of structural parameters is related to both the number and the location of measurements. In this paper, we focus on the case of having the same number of measurement as that of structural parameters. The lacking of some nonlinear constraints is demonstrated first. Subsequently, an exhaustive examination of observability for all possible measurement sets reveals the insufficiency of the existing method. Then a two-stage SSI by COM is proposed as a solution to this problem. The efficiency of the proposed method is validated by the great improvement regarding the number of observable parameters for the 252 measurement sets. It is seen that the inclusion of the nonlinear constraints enhance the ability of the original method to identify structural parameters given the same measurement set.

ACKNOWLEDGEMENT

This work was partially funded by the Spanish Ministry of Economy and Competitiveness and the FEDER fund through the grant project (BIA2013-47290-R) directed by Jose Turmo. It is also to be noted that part of this work was done through a collaborative agreement between Tongji University (China) and Technical University of Catalonia, UPC, BarcelonaTech. This included an exchange of faculty financed by the Chinese government. The financial support from the High End Foreign Experts program (GDW20143100115) from the Chinese government is greatly appreciated. Funding for this research has been provided to Mr. LEI Jun by the Chinese Scholarship Council through its program (No.201506260116) and by the Spanish Ministry of Economy and Competitiveness through its program (BES-2014-07022).
