T.Y. LIN LECTURE

Bridge maintenance, renovation and management – Research and development of governmental program in Japan 2
Y. Fujino

KEYNOTE LECTURES

Life-cycle reliability of bridges under independent and interacting hazards 16
M. Akiyama & D.M. Frangopol

Assessment of the dynamic behaviour of railway bridges for high-speed traffic 36
R. Calçada

A vision for vision-based technologies for bridge health monitoring 54
N. Catbas, C.Z. Dong, O. Celik & T. Khuc

The engineering and management of major steel box girder bridges; lessons from West Gate Bridge 63
I. Firth

Managing existing bridges – On the brink of an exciting future 70
R. Hajdin

Timber bridges in Australia, where to from here? 88
J.A. Hilton

Innovative and sustainable operation and maintenance of bridges 100
J.S. Jensen

Long term bridge performance program status and preliminary results 112
B.V. Johnson, J.E. Purdy & D.H. Liu

Value of monitoring data for long-span bridge operation – Aerodynamic point of view 130
H.K. Kim, S.J. Kim, S. Kim & W.H. Jung

Design concept of the Twin River Bridges in Chongqing 141
M.C. Tang

MINI-SYMPOSIA

MS01: Innovations and world leading research and practice in bridge management systems

Organizers: N. Powers & S. Joshi

Experience of management of bridges prior to and post evaluation of BMS on NH network of India 149
S. Joshi, N. Naga & U. Rajesh

BIM related workflow for an image-based deformation monitoring of bridges 157
N. Hallermann, J. Taraben & G. Morgenthal

Utilizing BMS to develop programs and reports for PEI transportation 165
D.J. Evans & R.M. Ellis

Creating the basis for implementing BIMS in existing infrastructure components 172
J.S. Jensen & F.R. Gottfredsen

Creation of "live data" for existing infrastructure 179
F.R. Gottfredsen & H. Pedersen

A simulated maintenance costing using a Markov deterioration model for bridge components 187
H.D. Tran, S. Setunge, Y.C. Koay & H. Luczak

Maintenance cost evaluation based on bridge performance degradation model 194
S.H. Kim, W.H. Heo, J.G. Choi & M. Gombosuren

An integrated model-based bridge management system 198
S.T. Hou, G. Wu & H.L. Li

Indian Bridge Management System – Overview and way forward 205
S. Joshi & S.S. Raju

Bridge management implemented by the South African National Roads Agency 206
E.J. Kruger & A.A. Nyokana

The optimal maintenance strategy of bridge using Bayesian approach 214
J.H. Lee, K.Y. Lee, S.M. Ahn & J.S. Kong

Development and implementation of digital bridge management systems in the Gulf region 219
D.E. Moore & S. Naelini

Research on bridge management system based on BIM technology 226
Y.D. Qin & R.C. Xiao

Bridge maintenance strategies – A brief comparison among different countries around the world 231
M.C. Scutaru, C.C. Comisu, G. Boacă & N. Ţăranu

The development of a modern bridge asset management system 239
A. Sonnenberg

Risk assessment for bridge management systems 246
P.D. Thompson

What are the attributes of a superior bridge management system? 254
H.D. Tran, S. Setunge, Y.C. Koay & H. Luczak

Using Petri-Net modelling for a data-driven approach to bridge management and safety 262
P.C. Yianni, L.C. Neves, D. Rama, J.D. Andrews & R. Dean

Network importance of Melbourne's metropolitan bridges – Development of a strategic bridge prioritisation framework 270
S. Di Cicco

MS02: Innovative methods in strengthening of concrete bridges

Organizers: R. Kalfat, R. Al-Mahaidi & B. Pham

Experimental investigation into the fatigue life of patch anchors used to anchor FRP laminates bonded to concrete 279
A. Al-Saoudi, R. Al-Mahaidi & R. Kalfat

Mathematical analysis of an innovative method for strengthening concrete beams using pre-stressed FRP laminates 285
S.R. Atashipour, J. Yang, R. Haghani & M. Al-Emrani

Bond performance of FRP-strengthened reinforced concrete in aggressive environmental conditions 294
R.J. Gravina, J. Li, H. Aydin, S. Setunge, P. Visintin, S.T. Smith & R. Al-Mahaidi

Developments in external post tensioning strengthening – An update of latest innovations and applications 302
D. Cecan & P.Y. Souesme

S-N curves for RC beams strengthened with FRP 310
L.C. Meneghetti, M.R. Garcez & R.M. Teixeira

UHPFRC technology to enhance the performance of existing concrete bridges 318
E. Brühwiler

Strengthening of concrete bridges girders using FRP and patch anchors 325
R. Jumaah, R. Kalfat & R. Al-Mahaidi

FRP strengthening of concrete structures using AS5100-2017 332
H.B. Pham

Flexural FRP strengthening of concrete bridges using an innovative concept 339
J. Yang, R. Haghani & M. Al-Emrani

CFRP strengthening of ASR affected concrete piers of railway bridges 346
M. Lima, R. Salamy & D. Miller

Feasibility of reinforcement in Brazilian concrete highway bridges using carbon fiber-reinforced polymer 354
A. Medeiros, W. Mazer, C.E. Rossigali & T.N. Bittencourt

Influence of arch bridge skewness 358
A. Outtier, E. Van Puymbroeck & H. De Backer

Ensuring safety and assessment of life-cycle costs using SHM for concrete bridges 365
J. Creighton, S.N. Kazi & K. Islami

MS03: Developments and trends in composite steel-concrete structures

Organizers: S.H. Kim, K.F. Chung & G. Ranzi

Push-out test on shear behavior of joint structure between corrugated steel web and concrete lower slab 374
S. Wang, Y. Liu, J. He & C. Li

Effect of rebar strength in Y-type perfobond rib shear connectors 381
S.H. Kim, O. Han, K.S. Kim, S.J. Kim & J.Y. Shin

Energy dissipating characteristics of Y-type perfobond rib shear connectors 386
S.H. Kim, K.S. Kim, O. Han & J.G. Choi

Strengthening of steel girder flanges with concrete-filled ribs 390
S.H. Kim, J. Shin, O. Han, K. Hwang & K.B. Rho

Redundancy evaluation of composite twin I-girder bridges in fractured condition 393
H. Lam, W. Lin, T. Yoda & K. Ono

Group effect of Y-type perfobond rib shear connectors 401
O. Altanzagas, E. Ganzorig, S.H. Kim, O. Han & T.S. Kim

Evaluation of the ultimate response of post-tensioned composite slabs 408
G. Ranzi

Service behaviour of composite steel-concrete slabs with a simplified approach and a hygro-thermo-chemical-mechanical model for the non-uniform shrinkage evaluation 412
M. Bocciarelli & G. Ranzi

Behavior of an innovative demountable steel-concrete connector under static loading 416
F. Yang & Y. Liu

A new era of steel bridge service life 424
F. Piccoli, R. Pavan & E. Siviero

Designing long integral bridges for environmental loading in South Africa 430
S.A. Skorpen, E.P. Kearsley & E.J. Kruger

Seismic performance and retrofit evaluation of hollow-core composite bridge columns 437
M.M. Abdulazeez, A. Gheni, N. Colbert & M.A. ElGawady

MS04: Strengthening, monitoring and life-cycle assessment of steel bridges

Organizers: E. Ghafoori, R. Al-Mahaidi, X.L. Zhao, M. Motavalli & M. Dawood

Fatigue improvement of welded bridge details in stainless steel using high-frequency mechanical impact treatment 446
M. Al-Emrani, P. Shams-Hakimi, C. Schneider, Z. Barsoum & H. Groth

The effect of the CFRP properties on the fatigue strengthening of steel plates in multiaxial loading 452
N.J. Aljabar, X.L. Zhao, R. Al-Mahaidi, E. Ghafoori, M. Motavalli & Y.C. Koay

Improving the fatigue design of orthotropic steel decks 458
H. De Backer, W. Nagy & A. Outtier

Flat Prestressed Unbonded Reinforcement (FPUR) system for strengthening of steel I-beams 465
A. Hosseini, E. Ghafoori, M. Motavalli, A. Nussbaumer, X.L. Zhao & R. Al-Mahaidi

Prestressed FRP-strengthening and wireless monitoring of a metallic bridge in Australia 472
E. Ghafoori, A. Hosseini, R. Al-Mahaidi, X.L. Zhao, M. Motavalli & Y.C. Koay

The peak stress method for fatigue analysis of welded details 481
G. Meneghetti, A. Campagnolo & B. Atzori

Prolonging the service life of steel truss bridges 489
A. Pipinato, R. Pavan, P. Collin, R. Hallmark, S. Ivanov, R. Geier & M. van der Burg

Steel bridge retrofit solution for movable cases 497
R. Pavan & A. Ruzzante

Steel box-girder bridge diseases identification based on computer vision system 504
D. Wang, Y. Pan & B. Peng

Bond behaviour of CFRP-steel double-lap shear joints exposed to marine atmosphere 512
Q.Q. Yu, R.X. Gao, X.L. Gu & X.L. Zhao

Drilling-hole shape for retarding the fatigue crack propagation 517
Z.Y. YuanZhou, B.H. Ji & Z.Q. Fu

Study on crack stop holes in weld of orthotropic steel bridge decks 521
Z.Q. Fu, G.Y. Sun, Y. Yao & B.H. Ji

Fatigue performance of hammer-peened diaphragm-to-rib welds in orthotropic steel decks 528
Q.D. Wang, B.H. Ji & Z.Q. Fu

Fatigue stress analysis of diaphragm-U-rib welding joints and local optimization 534
Y. Zhi, Y.X. Wang, H.B. Sun & B.H. Ji

Grouting compactness monitoring of concrete-filled steel tube arch bridge using electro-mechanical impedance technique 541
Q. Feng, Y.B. Liang & T.H. Yi

Study on soil-steel bridge response during backfilling 547
T. Maleska & D. Beben

Experimental investigation of retrofitted web-gap regions in steel bridge girders 555
M. Motaleb, M. Rahman, R. Hindi, W. Lindquist & A. Ibrahim

Investigation of live load deflection limit for steel cable stayed and suspension bridges 559
E.S. Hwang, D.Y. Kim & K.J. Park

MS05: Advancements in performance assessment, monitoring, and management of bridges under fatigue deterioration

Organizers: M. Soliman & D.M. Frangopol

Large-scale strain sensing approach for detecting fatigue cracks in steel bridges 567
X. Kong, J. Li, C. Bennett, W. Collins, S. Laflamme & H. Jo

Fatigue assessment of concrete girder bridges based on traffic information 576
P.J. Zhang, C.S. Wang, Q. Wang & L. Duan

Historical load effects on fatigue of metallic railway bridges 584
B. Imam & P.A. Salter

Multi-objective optimum service life bridge management based on fatigue damage detection 592
S. Kim & D.M. Frangopol

Probabilistic fatigue life prediction employing an advanced crack propagation model 598
Y.-J. Lee, J.H. Lee & S. Lee

Development of calibration factor for fatigue assessment 605
J.Y. Park, H.K. Kim & Y.C. Park

Fatigue assessment of deteriorated steel bridge members considering corrosion 609
Y.C. Park, L.S. An & H.K. Kim

Reliability analysis of steel bridges under propagating fatigue cracks 614
H. Ali & M. Soliman

A non-concurrent multiscale simulation of fatigue crack on orthotropic steel decks 620
B. Wang, H. De Backer & A. Chen

Numerical fracture mechanics analysis of distortion-induced fatigue in steel bridges 626
C.S. Wang, B. Cui, N.X. Ma, L. Duan & Y.Z. Wang

Fatigue life assessment of reinforced concrete bridges from monitoring data 634
P. Junges, R.C.A. Pinto & L.F. Fadel Miguel

Measurement of time-dependent corrosion of steel bridge from corrosion monitoring 642
S.-H. Jeon, J.M. You, J.-H. Ahn, K.-I. Cho & Y.S. Jeong

Structural monitoring of Eltham Rail Trestle Bridge using advanced non-destructive testing techniques 650
M. Maizuar, L. Zhang, S. Miramini & P. Mendis

Fatigue life assessment of damaged steel strands 654
Y.C. Park, S.M. Yoo, C.Y. Kim & M.S. Park

MS06: Footbridges: Advances in vibration serviceability assessment

Organizers: C. Caprani, F. Tubino, K. Van Nimmen & F. Venuti

Dynamic analysis of scissors-type of deployable pedestrian bridge under earthquake 659
Y. Chikahiro, S. Zenzai, S. Shigeru & I. Ario

A dynamic system identification of the Ha'penny footbridge 660
R. Donnelly, M. Nogal, P. Gorman & A.J. O'Connor

Parameter identification of a biodynamic walking model for human-structure interaction 668
A. Firus, J. Schneider, H. Berthold, M. Albinger & A. Seyfarth

Robust vibration serviceability assessment of footbridges for crowd walking excitation 675
K. Lievens, P. Van den Broeck, G. De Roeck & G. Lombaert

Model updating of a GFRP footbridge using Tchebichef moment descriptors 683
J.W. Ngan, C. Caprani & Y. Bai

Vibration serviceability assessment of a multi-span footbridge 691
J.W. Ngan, C. Caprani & A. de Lacy

A study of pedestrian evacuation on bridge sidewalk by simulation method 699
Z.R. Jin, X. Ruan & Y. Li

Uncertainty propagation in serviceability assessment of footbridges 706
F. Tubino, L. Pagnini & G. Piccardo

Vision-based methodology for characterizing the flow of a high-density crowd 713
J. Van Hauwermeiren, P. Van den Broeck, K. Van Nimmen & M. Vergauwen

Using full-scale observations to estimate the parameters governing human-structure interaction 721
K. Van Nimmen, P. Van den Broeck & G. Lombaert

Comparison between structure- and crowd-based mitigation strategies on vibrating footbridges 728
F. Venuti & A. Reggio

Dynamic study of Yangtze River Bridge at Chongqing-Lichuan railway 736
K.J. Chen, Y.P. Zeng & S.X. Chen

FIR and IIR filtering and data driven stochastic subspace identification for the continuous dynamic modal parameter identification of cable stayed bridge 741
I. Khan, K. Malik, S. Ali & D. Shan

MS07: Recent advances in bridge design and construction

Organizers: U. Attanayake & H. Aktan

Deployable mobile bridge created from *Origami* 751
I. Ario, S. Ono, I. Tanikura, Y. Chikahiro, M. Nakazawa, P. Pawlowski, C. Graczykowski & J. Holnicki-Szulc

Rational decision-support system for selecting bridge construction alternatives 759
U.B. Attanayake & H.M. Aktan

Standardizing lateral bridge slide design 767
U.B. Attanayake & H.M. Aktan

Accelerated construction of robust bridges through material and detailing innovations 775
B. Graybeal, Z. Haber, I. De la Varga & R. Spragg

Bearing friction values for slide-in bridge construction 783
K.R. Johnson, S. Dorafshan, M.W. Halling, M. Maguire, P.J. Barr & M.P. Culmo

Dynamic effects caused by SPMT bridge transport 791
S. Dorafshan, M. Maguire, M.W. Halling, P. Barr & M.P. Culmo

Development of precast slab using ultra high strength fiber reinforced concrete for replacement on highway bridge 797
T. Kitamura, W. Zhao, I. Iwasaki, M. Kishida, Y. Ishihara & I. Iwaki

An advanced technique for the analysis of box girder bridge superstructures 805
K. Kashefi & A.H. Sheikh

Construction simulation of cable-stayed bridges 813
J.A. Lozano-Galant, D. Xu & J. Turmo

Design of pergola structures for high speed rail bridges 820
A.P. Ranasinghe & E.G. Honarvar

How new performance based contracts add value in maintenance contracts 825
J.D. van der Walt & E. Scheepbouwer

Design method for scissors-type bridges 832
Y. Hama, I. Ario & K. Adachi

MS08: Submerged floating tunnels and underwater tunnel: Design, safety and maintenance issues

Organizers: L. Martinelli, Y. Xiang & B. Faggiano

Dynamic interaction with travelling vehicles in a submerged floating tunnel 838
M.G. Mulas, L. Martinelli & G. Palamà

Maximum stresses in mooring lines during parametric excitation 845
D. Cantero & A. Rønnquist

Overview on the structural features of Submerged Floating Tunnels 851
B. Jiang, B. Liang, B. Faggiano, G. Iovane & F.M. Mazzolani

Research on the finite element analysis method of the bucket foundation of submerged floating tunnel 859
J. Xiang, X. Feng, S. Feng & J. Mao

Feasibility study on a submerged floating tunnel for the Qiongzhou Strait in China 865
B. Jiang, B. Liang, B. Faggiano, G. Iovane & F.M. Mazzolani

Research on simulation of traffic loads in submerged floating tunnel 872
B. Jiang, S. Wu, B. Liang & L. Chen

Submerged floating tunnels under seismic and seaquake loadings 877
L. Martinelli

SFTs under dynamic loads: New design issues and numerical simulation 885
F. Perotti, F. Foti, L. Martinelli & M. Tomasin

An experimental study on bending behavior of composite hollow RC in Submerged Floating Tunnel (SFT) 893
J.H. Seo, D.H. Won & W.S. Park

A novel life-cycle based management system for disaster mitigation of bridges 901
Y.C. Sung, K.C. Chang, C.C. Chen, C.C. Hsu, K.W. Chou & H.H. Hung

MS09: Vibration-based structural health monitoring of bridges: Research and applications

Organizers: M.P. Limongelli, J.R. Casas & A. Cunha

Monitoring footbridges using wireless mesh networks 909
M. Domaneschi, C. Apostoliti, G.P. Cimellaro, B. Glisic & K. Kliewer

Effectiveness damage characterization for different sensor settings: Full scale case 917
J. Grandón & F. Cerda

Ambient vibration monitoring of a railway bridge for scour detection 923
C.W. Kim, D. Kawabe & M. Kondo

System identification of a bridge by a sparse-like system matrix 929
T. Mimasu, Y. Goi & C.W. Kim

Obtaining full-field response for optimal sensor placement 937
J. Kullaa

Potential of drive-by inspection for railway bridges 945
A.H. Eslami-Khouzani & C. Caprani

The interpolation method for vibration based damage localization: Influence of feature uncertainties 953
M.P. Limongelli & A. Fathi

Uncertainties reduction on modal parameters estimation in existing bridges using ambient and free-vibration test 961
N. De Conto, F. Lorenzoni, F. da Porto & C. Modena

Monitoring of the Chillon viaduct after strengthening with UHPFRC 968
H. Martín-Sanz, V. Dertimanis, L.D. Avendaño-Valencia, E. Chatzi & E. Brühwiler

Development of vibration-based parameters as damage sensitive features for bridge structures 976
J.J. Moughty & J.R. Casas

A bespoke signal processing algorithm for operational modal testing of post-tensioned steel and concrete beams 984
D. Noble, M. Nogal, A.J. O'Connor & V. Pakrashi

The effect of local scour of a single pier on the vibration parameters of a multi-span bridge under seismic excitation 992
A. Anžlin, L.J. Prendergast, K. Gavin & M.P. Limongelli

MS10: Corrosion and safety of existing concrete bridges

Organizers: M. Akiyama, D.M. Frangopol & H. Matsuzaki

Effect of different steel weight loss distributions on the life-cycle reliability of PC girders 1001
N. Nishiya, H. Fukushima, A. Sakurai, M. Akiyama, P. Bocchini & D.M. Frangopol

Optimum strengthening strategy for deteriorating reinforced concrete bridges 1007
H. Baji & C.Q. Li

Strengthening of reinforced concrete bridges by external prestressing 1015
L.H.B. Pinheiro, L.M. Trautwein & L.C. Almeida

Inhibiting corrosion of prestressed cables using an ultrasonic impregnation process 1020
X. Hallopeau, P.M. Dubois & D. Michaux

Effects of current density on the spatial variability associated with steel corrosion and flexural behavior of corroded RC beams 1024
S. Lim, H. Song, M. Akiyama & D.M. Frangopol

Seismic failure mode evaluation of bridges with deteriorated isolators 1029
H. Matsuzaki, Y. Kubo, T. Tsumura & S. Unjoh

Durability of reinforced concrete bridges in marine environments 1036
R.E. Melchers & I.A. Chaves

Damage accumulation in aging highway bridges considering multiple earthquake events 1044
B. Panchireddi, U. Yadav & J. Ghosh

Optimum lifetime inspection and maintenance planning for bridges considering utility 1052
S. Sabatino & D.M. Frangopol

FEM approach to appraise bridges affected by Alkali-Silica Reaction (ASR) 1058
R.V. Gorga, L.F.M. Sanchez, B. Martín-Pérez & M. Noël

Techniques to rehabilitate bridge columns affected by Alkali-Silica Reaction (ASR) 1066
L.F.M. Sanchez, M. Noël & V.A.A. Santos

Influence of tendon breaks on structural behavior of concrete beams 1074
H. Kaneko, K. Suzuki, K. Amaya, K. Hamaoka, M. Hara, M. Fukuda, E. Sasaki, P. Tuttipongsawat, T. Kuroda, K. Takase & Y. Ikawa

MS11: Special elements in bridge construction and practice

Organizer: M. Nasser Darwish

Bridges approach slabs with fibre reinforced polymers 1083
M. Nasser Darwish

Guidance on defects in hidden bridge components 1091
T.M. Pape, P. Burnton, J. Collins, D. Ashurst, P. Sparkes, J. Webb & C. Christodoulou

Captain Cook Bridge bearing replacement 1099
W. Mengel, P. Adams, W. Hansford & J. Spathonis

Reliability assessment of reinforced concrete pylons subjected to biaxial bending 1107
J. Hyeon Kim & H. Sung Lee

Experimental research on shear behavior of rubber-ring perfobond connector 1115
Y.Q. Liu, Y. Liu & F. Wang

Effect of hinge-type connections on the lateral cyclic behavior of a prestressed high-strength concrete pile 1123
B. Lim, J.W. Kang, Y.J. Kim & H. Yoon

Seismic vulnerability analysis of typical bearings for simply supported railway bridges 1131
G. Yang, J. Dong & D.S. Shan

Hanger replacement effect: Experimental and numerical investigation on the Bosphorus Bridge 1139
S. Bas, N.M. Apaydin, A. Ilki & N. Catbas

Investigation of limit temperature span of continuous bridges considering track-bridge interaction 1145
Y.H. Yan, D.J. Wu & Q. Li

MS12: Bridge safety evaluation and risk assessment: Code requirements vs. practical considerations

Organizers: M. Liu & H. Nassif

Code development for existing structures: Influence of concrete strength statistics 1153
B.L. Badimuena & S.M.C. Diniz

Risk-based performance evaluation for concrete bridge deck repair 1161
H. Huang & M. Liu

The bridge assessment maze 1169
C. Jager, T.M. Pape, P. Shaw & R. Heywood

Bridge risk management: Credibility gaps 1177
P.S. McCarten

Codes and standard issues in assessing existing bridges 1185
R. Pavan & E. Siviero

Horizontal interface shear requirements for precast prestressed concrete bridge beams with slender webs in beam and slab bridge constructions 1192
M. Slevin & A.J. O'Connor

Bridge safety assessment for strength II limit state in AASHTO LRFD specifications 1200
H. Nassif, P. Lou & P. Truban

Large skewed bridge for high speed trains. Northwest of Spain 1204
C. Jurado

Repair and retrofitting of bridges – present and future 1208
H. Singh

Displacement coefficient method for bridge subjected to pulse-like ground motions 1216
K.Y. Liu, S.T. Wang, C.C. Hwang & C.H. Kuo

The condition of Padang's bridges after 2009 earthquake disaster 1224
Masrilayanti, R. Kurniawan, Nidiasari & Nurhamidah

MS13: Advanced computational and experimental techniques for extreme load performance of bridges

Organizers: J. Hashemi, R. Al-Mahaidi & D.M. Frangopol

Advanced nonlinear finite element modelling of reinforced concrete bridge piers 1231
E.P.G. Bruun, A. Kuan, G.T. Proestos, E.C. Bentz & M.P. Collins

Seismic analysis of a stone masonry arch railway bridge 1239
C. Costa, A. Arêde & R. Silva

Numerical assessment of composite bridges subjected to Wildland Urban Interface (WUI) fires 1247
A.P. Dissanayake, S. Setunge, S. Venkatesan, K.A.M. Moinuddin & D. Sutherland

Joint irregularity in the seismic behavior of highway bridges 1256
M.C. Gómez-Soberón, A.E. Gómez-Benítez & R.J. Aguirre-Eligio

Linking seismic resilience into sustainability assessment of limited-ductility RC bridges 1264
A.Y. Al-Attraqchi, M.J. Hashemi, R. Al-Mahaidi & P. Rajeev

Study on impact behavior of piers subjected to vehicle collisions 1272
R.W. Li & D.Y. Zhou

Fragility analysis of non-ductile RC bridges subjected to extreme hydrodynamic forces 1279
I.M.I. Qeshta, M.J. Hashemi, R.J. Gravina & S. Setunge

Dynamic response of an isolated bridge under basic pulse-type ground motions 1286
M.H. Tsai & Z.Y. Jiang

Research on seismic performance of self-compacting concrete bridge columns 1294
Z. Wang, H. Duan, H. Wei, J. Yang & X. Sun

Seismic fragility of high-speed railway bridge with high pier 1299
J. Dong, D.S. Shan, G.J. Yang & Y.P. Zeng

Research on the influence law of central buckle on long-span suspension bridge's dynamic and seismic performance 1306
L.P. Liu, Y. Liu & Y. Li

MS14: Steel bridge rehabilitation

Organizer: M. Sakano

Ayala bridge, retrofitting of an historic steel bridge in Manilla (Philippines) 1314
V. Buchin-Roulie, N. Kaczkowski, A. Gros & F. Tesson

Orthotropic steel bridge deck study with UHPFRC cold composite overlay 1319
L. Duan, T.O.N. Houankpo, C.S. Wang & E. Brühwiler

Effect of diaphragms on the exterior girders during bridge construction 1327
F. Hraib, L. Hui & R. Hindi

Inspection of Bingo Bridge by using high-sensitivity magnetic nondestructive testing 1333
T. Ishikawa, Y. Kuramitsu, H. Furuta & K. Tsukada

Theoretical analysis of CFRP bonding repair method using low-elasticity adhesive at the plate end 1337
K. Komon, T. Ishikawa, H. Suzuki, Y. Fujii & H. Namaki

Fatigue strength and improvement effect of the center stay rod 1343
S. Kawano, S. Ogo, A. Okumura, Y. Mizokami & M. Sakano

Repair of corroded steel plate girders with ultra-high performance concrete 1350
K.F. McMullen, A.E. Zaghi & M.P. Culmo

Retrofitting method against fatigue cracking of web gap plates 1359
C. Sakamoto, M. Sakano, H. Konishi & M. Koyama

Adhesive and bolting reinforcement for distortion-induced fatigue of steel bridges 1367
Y.Z. Wang, B. Cui, Q. Wang, L. Duan & C.S. Wang

Vibration study of train passing bridge with small radius and reverse curve 1375
Y.M. Song, D.J. Wu & J. Zhang

Repairing a sinking bridge over Guadalquivir river 1384
C. Jurado

MS15: Bridge loading – measurement and modelling

Organizers: C. Caprani, A. Nowak, E.J. O'Brien & X. Ruan

Traffic load patterning on long span bridges 1389
D. Guo & C. Caprani

Traffic and wind simulation for extreme loads on long-span bridges 1397
A.A. Hayrapetova, A.J. O'Connor, J.D. Sørensen & H.S. Toft

Developing a new bridge live load model for South Africa 1405
P.F. van der Spuy & R. Lenner

Using images to estimate traffic loading on long-span bridges 1411
F. Daize, E.A. Micu, E.J. O'Brien & A. Malekjafarian

Long span bridges – current age & design life – a global survey 1417
J. De Maria, C. Caprani & D. Guo

A new method to understanding loading and traffic characteristics of traffic flow 1427
X.J. Wang & X. Ruan

Bridge live load models in U.S. and Europe 1434
A. Ramesh Babu, A.S. Nowak & E.J. O'Brien

Bridge network planning for heavy vehicles in Queensland 1442
T.M. Pape, P.A. Shaw, C. Doherty, G. Danicic, A. Robertson & D. Wilson

Strength evaluation of prestressed concrete bridges by dynamic load testing 1450
E.S. Hernandez & J.J. Myers

Limiting exterior girder rotation during construction for non-skewed bridges 1456
L. Hui, F. Hraib & R. Hindi

Impacts of specialized hauling vehicles on the Texas bridge network 1462
J. Weissmann & A.J. Weissmann

Impact of quantity of weigh-in-motion data on load effects on bridges 1467
A. Žnidarič, M. Kreslin, J. Kalin & G. Turk

MS16: Bridge monitoring: Techniques and results regarding bridge condition and loading

Organizers: E.O.L. Lantsoght & D.A. Hordijk

Structural health monitoring and serviceability assessment of bridges in Romania 1476
C.C. Comisu, M.C. Scutaru, N. Ţăranu & G. Boacă

Deformation monitoring of a simply supported railway bridge under varying dynamic loads 1484
K. Faulkner, F. Huseynov, J. Brownjohn & Y. Xu

DIC-monitoring of full-scale concrete bridge using high-resolution wide-angle lens camera 1492
P.S. Halding, J.W. Schmidt & C.O. Christensen

Monitoring crack width and strain during proof load testing 1500
E.O.L. Lantsoght, C. van der Veen & D.A. Hordijk

Twenty years monitoring of a high strength concrete cantilever bridge 1507
E.O.L. Lantsoght, C. van der Veen, H. van der Ham & A. de Boer

Estimating climate effects on bridge decks deterioration 1515
S. Liu, H. Zhu, L. Yang & M. Habib

Railway bridge monitoring system using inertial sensors 1522
P. Olaszek, D. Sala, M. Kokot & M. Piątek

Non-destructive testing of bridges – Health assessment & monitoring 1530
C.R. Raikar

Rating of masonry arch bridges in USA 1536
A.P. Ranasinghe, N.Y. Khadbai & A.K. Ranasinghe

Monitoring design for long-span bridges 1540
K. Suzuki, C. Miki, E. Sasaki & A. Tanabe

Testing of bridge structures using laser scanning method 1548
W. Anigacz, D. Beben & J. Kwiatkowski

SPECIAL SESSIONS

SS01: Perturbations on SHM results due to environmental changes

Organizers: M. Baessler, F. Hille, W.H. Hu & G. Morgenthal

A study on diverse strategies for discriminating environmental from damage based variations in monitoring data 1557
M. Baeßler & F. Hille

Automated operational modal analysis of a lively footbridge for tracking long term dynamic behaviour 1565
D.H. Tang, W.H. Hu, J. Teng, E.S. Caetano & Á. Cunha

Damage detection under environmental variability using Bayesian virtual sensing 1569
J. Kullaa

Assessment of MEMS-based sensors for inclination measurements 1577
S. Rau & G. Morgenthal

Fine temperature effect analysis based time-varying dynamic properties evaluation of long-span suspension bridges in natural environments 1585
J.S. Zhu & Q.L. Meng

Inverse analysis using compatible displacements 1590
J. Lei, D. Xu & J. Turmo

SS02: Continuous bridge monitoring and damage detection

Organizers: A. Miyamoto, E. Brühwiler, R. Kiviluoma & P. Hradil

Combined structural and traffic monitoring of steel suspension bridge 1597
P. Hradil & K. Koski

"Pocket-monitoring" for the fatigue safety verification of bridge members in steel and reinforced concrete 1605
E. Brühwiler

Structural risk assessment and management through the capture of dynamic movement 1613
M. Kudrenko

Continuous structural health monitoring for short and medium span bridges 1618
A. Miyamoto

A strain sensor based monitoring and damage detection system for a two-span beam bridge 1627
P. Waibel, O. Schneider, H.B. Keller, J. Müller, O. Schneider & S. Keller

Automatic data collection system for structural health monitoring 1635
A. Yabe, T. Iye & A. Miyamoto

SS03: Bridge safety, maintenance and management under hazards and changing climate

Organizers: Y. Dong, M. Soliman & D.M. Frangopol

Vulnerability of bridges exposed to coastal hazards and climate change 1643
G.P. Balomenos, S. Kameshwar, B. Bass, J.E. Padgett & P. Bedient

Probabilistic multi-hazard assessment of seismic and scour effects on bridge structures 1650
Z. Chen & X. Guo

Reliability based corrosion damage assessment for concrete bridge decks under a changing climate 1658
L.I. Peng & M.G. Stewart

Risk-informed assessment of climate change by considering deterioration and hazards 1666
Y.H. Li & Y. Dong

Climate change and potential impact on the seismic vulnerability of highway bridge structures 1672
M. Mortagi & J. Ghosh

SS04: Structural health monitoring for infrastructure asset management

Organizers: J. Li, X.-W. Ye, T.-H. Yi & H.P. Chen

Traffic load modelling for urban highway bridges using weigh-in-motion data 1681
T.L. Huang, J.J. Liao, J. Zhong, J.W. Zhong & H.P. Chen

Acceleration response analysis of a long-span steel arch bridge subjected to high-speed trains integrating SHM data 1689
H.L. Li, Y.L. Ding, H.W. Zhao & S.T. Hou

Optimal weight problem for response sensitivity-based damage identification 1696
J. Zhou, L. Wang & Z.-R. Lu

A mesoscopic analysis of chloride diffusion with adaptive mesh refinement 1703
Z. Pan, D. Wang, R. Ma & A. Chen

Bridge displacement monitoring using acceleration measurement for efficient bridge management 1710
Y. Umekawa & H. Suganuma

Guide for a successful monitoring project from Finland 1718
J. Wuorenjuuri

Bending-shear fatigue behavior of concrete girder bridges 1725
M. Yuan, D. Yan & Y. Liu

SS05: Self-sensing and connected infrastructures for a smart transport future

Organizer: F. Giustozzi

Global instrumentation, vehicle, track and bridge on operation railway of MRS logistic railway 1731
R. Montoya & L. Fernando Martha

Pervasive fibre-optic sensor networks in bridges: A UK case study 1738
L.J. Butler, M.Z.E.B. Elshafie & C.R. Middleton

Shear force-based method for detecting vehicle speed and axle spacing 1746
L. Deng, W. He, Y. Yu & C.S. Cai

Virtual design of adaptive road-bridge-types in a comprehensive 5D-BIM assessment 1754
M. Nöldgen, J.B.P. Lim & S. Giebat

TRUSS-ITN methods for detecting bridge damage from response to traffic 1761
A. González, D. Martínez, E.J. O'Brien, M. Casero, J.J. Moughty, J.R. Casas, M. Vagnoli, R. Remenyte-Prescott, J.D. Andrews, F. Huseynov & J. Brownjohn

SS06: Advances in corrosion modelling of steel bridges

Organizer: M. Mahmoodian

Structural reliability analysis of corroding steel bridges using random-field representation 1770
V. Aryai, M. Mahmoodian, N.V. Ferdowsi & F. Ariai

Corrosion risks: Assessment of enclosed spaces, monitoring real bridges 1776
M.W.K. Bowers

Effect of corrosion on mechanical properties of steel bridge elements 1783
L. Li, M. Mahmoodian & C.Q. Li

3D cellular automata based numerical simulation of atmospheric corrosion process on weathering steel 1791
J.S. Zhu, X.Y. Guo & J.F. Kang

Structural performance of bridges under deterioration processes: Bicentenario bridge 1798
J.D. González & F.A. Cerda

Predictive modelling of the deterioration of Australian state bridge network 1806
H.D. Tran, S. Setunge, Y.C. Koay & H. Luczak

SS07: European standardization of quality specifications for roadway bridges

Organizers: J.R. Casas & J.C. Matos

Quality specifications for roadway bridges in Europe 1814
J.R. Casas & J.C. Matos

Quality specifications and performance indicators for road bridges in Europe 1822
A. Strauss, S. Fernandes, J.R. Casas, L. Mold & J.C. Matos

Quality control plan for RC bridges exposed to flooding events 1832
N. Tanasic & R. Hajdin

Monitoring in management of roadway bridges 1839
J. Bień, T. Kamiński & M. Kużawa

Bridge management in Australia and New Zealand: Current approaches and future needs 1845
M.M. Melhem, C. Caprani & A. Ng

Repair and retrofitting of bridges under IBMS protocol 1852
S.S. Raju & T. Kiran Kumar

SS08: Construction management issues in bridge engineering and construction

Organizer: M. Nasser Darwish

The construction of the new Tappan Zee Bridge 1860
R.D. Csogi

A case study of early cracks of a concrete pylon 1867
J. Song & X.F. Shi

A case study of using a support vector machine on bridge inspection data 1873
Arong, S. Murakami & Yiliguoqi

Evaluation of slab lifting strategies for maintenance of middle slabs in double-deck tunnels 1881
S.M. Kim, Y.K. Cho & B.K. Park

Research and application of maintenance for a combined highway-railway bridge 1887
J. Fu, T. Zhang, Z. Li, Q. Ding & J. Huang

SS09: CIM: Community Information Modeling – The new frontier of civil engineering

Organizers: G.P. Cimellaro, M. Domaneschi & S. Mahin

Fuzzy based tool to measure the resilience of communities 1895
O. Kammouh, A. Zamani Noori, M. Domaneschi & G.P. Cimellaro

Resilience assessment of city-scale transportation networks using Monte Carlo simulation 1902
O. Kammouh, A. Cardoni, S. Marasco, G.P. Cimellaro & S. Mahin

Seismic resilience of electric power networks in urban areas 1911
S. Sordo, M. Domaneschi, G.P. Cimellaro & S. Mahin

Seismic resilience of bridges in transportation networks 1920
M. Domaneschi, G. Scutiero, G.P. Cimellaro, A.A. Khalil, C. Pellecchia & E.M. Ricciardi

Resilience framework for seaport infrastructure: Theory and application 1928
A. Balbi, M.P. Repetto, O. Kammouh & G.P. Cimellaro

Seismic damage assessment of a virtual large-scale city model 1936
M. Domaneschi, S. Marasco, G. Scutiero, A. Zamani Noori, O. Kammouh, V. Taurino & G.P. Cimellaro

SS10: Assessment and evaluation of deteriorated bridges

Organizers: H.K. Kim & J.R. Casas

Seismic retrofit of truss bridge for highway and railway 1944
T. Hanai, T. Tamura & Y. Hirayama

Safety assessment of bridges for transportation of power plant generator 1951
I.Y. Paik, K.H. Jeong, M.K. Jun, J.H. Jeong, S.-H. Hong, H. Koo & R.C. Lee

Evaluation of adhered sea-salt particle amount to bridge, anti-adhesion countermeasures 1958
A. Toktorbai uulu, H. Katsuchi & H. Yamada

Influence of collision on structural performance of steel girder 1966
E. Yamaguchi, Y. Tanaka & H. Tsuji

Sectional analysis of corroded wires in chloride-contaminated tendon 1972
C.H. Yoo, S.H. Bong, H.K. Kim & Y.C. Park

GA-based model updating for existing bridges 1976
J.C. Kim, J. Yoon & S. Shin

SS11: Life-cycle structural redundancy, robustness and resilience of bridges under multiple hazards

Organizers: F. Biondini & D.M. Frangopol

Survey on life-cycle structural performance indicators for bridges 1983
F. Biondini & D.M. Frangopol

Seismic resilience of road bridges: Lessons learned from the 14 November 2016 Kaikōura earthquake 1988
A.I. Sarkis, A. Palermo, O. Kammouh & G.P. Cimellaro

Renewal-theory-based life-cycle risk assessment of bridge deck unseating under hurricanes 1996
D.Y. Yang & D.M. Frangopol

Life-cycle seismic resilience of aging bridges and road networks considering bridge capacity correlation 2004
L. Capacci & F. Biondini

Time-dependent probability of exceeding restoration levels in resilience analysis 2012
F. Nocera, P. Gardoni & G.P. Cimellaro

Computational investigation on the piers of a U-slab bridge under raising flood intensity 2020
M. Nasim, S. Setunge, H. Mohseni & S.W. Zhou

SS12: Centenary bridges – An insight into construction and technology history

Organizers: P. Cruz & P.G. Malerba

The dream of building bridges over the Tagus River mouth in Lisbon 2029
P.J.S. Cruz

Articulated and continuous cantilever bridges after a century of experience 2037
P.G. Malerba

Whipple's 1841 Bowstring Truss – World's first scientifically designed Truss bridge 2045
I.A. Nitschke & F.E. Griggs Jr.

The use of machine learning techniques to assess damage in critical infrastructure 2053
M.A. Terra, R.A. Pereira Junior, L.F.M. Sanchez, M. Noël & W.R. Junior

Shear capacity of an existing RC bridge deck slab: FE analysis using continuum elements 2061
J. Shu

Rehabilitation of timber bridge piles using a wrapping system 2069
R. Borzou & W. Lokuge

Investigating snipe depth in girders and corbels in timber bridges 2075
J. Cohen, W. Lokuge & N. Herath

SS13: Value of information of SHM for life-cycle management of bridges

Organizers: S. Thöns, M. Stewart, D.G. Lu & A.J. O'Connor

Sensitivity analysis of value of information framework 2081
M.S. Khan, S. Ghosh, J. Ghosh & C. Caprani

Health monitoring data modeling and reliability prediction of an actual bridge based on ARMA model 2089
D.G. Lu, W.H. Zhang & Z. Zhao

Assessment of terrorism risk mitigation measures for iconic bridges 2097
S. Thöns & M.G. Stewart

Evaluation of fatigue crack propagation considering the modal superposition technique 2105
C.S. Horas, G. Alencar, R. Calçada & A. Jesus

Inspection and assessment of one of Australia's earliest masonry bridges 2113
D. McDonnell, D. Ashurst & I. Berger

SS14: Resilience of bridges to climate change, natural & man-made hazards

Organizers: A.J. O'Connor & M. Nogal

Seismic performance of bridges with rocking piers in Hanshin Expressway 2122
K. Azumi, K. Sugioka & N. Mitsukawa

Resilience assessment of highway bridges using SMA-based isolation bearings 2128
Y. Dong, Y. Zheng & Y.H. Li

Resilience evaluation of a cable-stayed bridge 2133
H. Gil, K. Han, S. Seo & J. Park

Seismic fragility of highway bridges considering improved bearing deterioration modeling 2138
S. Shekhar & J. Ghosh

Structural behavior of a steel-concrete composite beam under fire condition 2146
M.S. Kang, H. Pak, J.W. Kang, S.H. Kee & B.J. Choi

The performance estimation of pile-protective structures using simplified collision model 2154
G.H. Lee

Effect of slenderness-ratio parameter on seismic performance of steel piers 2160
H. Takezawa, K. Ono, S. Okada & K. Azumi

SS15: Latest developments on jointless bridges

Organizers: B. Briseghella, W.P. Yen & B.C. Chen

Trial design study on integral abutment bridge supported on UHPC-RC segmental pile 2166
G.D. Chen, B.C. Chen, F.Y. Huang, Y.Z. Zhuang & H. Tabatabai

Parametric studies on seismic behavior of integral abutment steel bridges considering SSI 2173
Q. Zhao, S. Dong, Z. Qi & B.C. Chen

Research on SSI simulation method of integral abutment bridge under earthquake 2181
Q. Zhao, J. Qiu, Z. An & Z. Qi

Seismic behavior and cyclic tests on integral abutment–pile joints 2189
Q. Zhao, Y. Li, Z. Qi & B.C. Chen

Design and construction challenges of jointless bridges in seismic regions 2197
B. Khaleghi & W.P. Yen

Fatigue strength improvement of welded joints using SBHS700 by applying ICR treatment 2205
Y. Ono & K. Kinoshita

Three bridges with the same name "Kömürhan Bridge" 2213
N. Apaydin & O. Yaldiz

SS16: Revised fatigue detail categories for bridges (in European standards)
Organizer: U. Kuhlmann

Assessment of fatigue tests to review detail categories of EC3 2220
H. Bartsch & M. Feldmann

Recommended fatigue strengths of thick-walled circular K-joints and influence of weld root irregularities 2228
S. Bove, M. Euler & U. Kuhlmann

Considering high frequency mechanical impact treatments in design 2236
S. Breunig & U. Kuhlmann

Statistical analysis of fatigue test data according to Eurocode 3 2244
K. Drebenstedt & M. Euler

Quantifying uncertainty in visual inspection data 2252
J. Bennetts, G. Webb, S. Denton, P.J. Vardanega & N. Loudon

BrIM bridge inspections in the context of industry 4.0 trends 2260
M. Salamak & M. Januszka

SS17: Smart bridge components: Monitoring and optimization of EJs, bearings and dampers
Organizer: K. Islami

"Smart" bridge expansion joints enabling optimized decision-making at different life-cycle stages 2269
P. Savioz, K. Islami & V.V. Ghodke

Advances in materials and further improvements in bridge pot bearings 2277
S.N. Kazi, V.V. Ghodke & C. Sarmiento

Breaking the Asphalt code – Polyurethane flexible plug expansion joint 2285
C. Sarmiento, G. Pope & S.N. Kazi

Critical factors in minimizing total life cycle costs of bridge expansion joints 2294
G. Pope, J. Creighton & V.V. Ghodke

Smart bridge components (expansion joints, bearings, seismic devices) for intelligent infrastructure 2302
K. Islami, N. Meng & C. O'Suilleabhain

SS18: Challenges for bridge technology implementation and management in developing countries
Organizers: T.N. Bittencourt, M.A. Valenzuela, F.C. Carrizo & M. Márquez

Maintenance plan proposal on cable-stayed bridge: Application to Yelcho Bridge 2311
M. Márquez, J. Campusano, F. Hernández, J. Errazuriz & M.A. Valenzuela

Management systems for inspection and maintenance of Chilean road bridges 2319
M. Márquez, M.A. Valenzuela, G. Arias, M. Pertierra & C. Sepulveda

Dynamic analysis of a steel-concrete composite railway bridge considering vehicle-bridge interaction 2327
L.R. Ticona Melo, T.N. Bittencourt, D. Ribeiro & R. Calçada

Management system for natural risk disaster on infrastructure: A regional approach 2335
M.A. Valenzuela, N. Valenzuela, A. Peña-Fritz & R. Romo

Strengthened Chilean bridges using carbon fiber: State of knowledge 2343
M. Márquez, M.A. Valenzuela & H. Pinto

UAV: First Chilean proposal of use on road bridge inspections 2350
M.A. Valenzuela, N. Valenzuela, A. Peña-Fritz, D. Torres & M. Márquez

SS19: Bridge deterioration modeling and probabilistic bridge maintenance needs forecasting
Organizers: R. Goyal, M. Whelan & T.L. Cavalline

Predictive fidelity of bridge deterioration models: Probabilistic vs deterministic 2359
R. Goyal, M. Whelan & T.L. Cavalline

Life cycle assessment for civil engineering structures of railway bridges 2367
G. Lener, J. Schmid & A. Strauss

National-scale bridge element deterioration model for the USA 2373
P.D. Thompson

Damage location in experimental/numerical models by acceleration amplitude change 2380
R.L. Silva, L.M. Trautwein, L.C. Almeida, G.H. Siqueira & C.S. Barbosa

Early detection of reinforcing-bar corrosion with linearized inverse scattering method 2385
T. Tsunoda & K. Suzuki

Fragility curves for concrete girder bridges under flood hazard 2393
F. Kalendher, S. Setunge, D. Robert & H. Mohseni

SS20: Monitoring and assessment of bridges using novel techniques
Organizers: A. Strauss, K. Bergmeister & D.M. Frangopol

Performance analysis of distributed optical fiber bonding adhesives to concrete 2401
A. Barrias, J.R. Casas & S. Villalba

Structural performance assessment using digital image correlation systems 2409
A. Strauss, R. Wendner, M. Marcon, B. Krug, P. Castillo & D.M. Frangopol

Development of response-based load and resistance factor rating (RB-LRFR) methodology 2416
M. Ghosn, B. Sivakumar & E. Senturk

Monitoring-based quantification of input parameters for chloride ion ingress models 2424
M. Šomodíková, B. Teplý, A. Strauss & I. Zambon

In-service stress and strain behavior of Missouri bridge A7957 2432
H.H. Alghazali & J.J. Myers

GENERAL SESSIONS

Numerical assessment of the load-carrying capacity of a masonry bridge 2439
R. Silva, C. Costa & A. Arêde

Fatigue performance of diaphragm cutouts in steel box girder 2446
C.X. Li, L. Ke, Z.Y. Chen, Y.M. Xiong & Z. Hu

Assessment of shear lag in pultruded GFRP bridge decks 2453
S. Zhang & C. Caprani

Dynamic response analysis of widening bridge due to moving vehicles 2461
Y. Li, T. Yang, Z. Li & L. Liu

A preventive strengthening strategy for aged steel columns 2470
W. Lin, N. Taniguchi, T. Yoda & S. Satake

Generalized Pareto distribution for reliability of bridges exposed to fatigue 2477
M. Nesterova, F. Schmidt, E. Brühwiler & C. Soize

Numerical model updating of cable-stayed bridge based on experimental data 2485
I.C. Santos, J.L.V. Brito & E.S. Caetano

Rotational stiffness between vertical and horizontal members of system supports 2493
J.H. Won, H.D. Lee, A.R. Oh & N.K. Jang

Research on transverse mechanical property of widened box girder bridge 2499
W.Q. Wu, H. Zhang & Z.X. Tang

Sensitivity and reliability analysis of long span cable stayed bridge 2507
X. Wang, W. Wu, J. Zhang & Y. Cai

The development of the reinforcement method for U-shaped rib on orthotropic steel decks to improve the fatigue durability from the lower side 2515
H. Yatsumoto, A. Tabata, H. Kobayashi, S. Inokuchi & H. Matsushita

Effect of the shear deformation in the structural system identification methods 2522
J.A. Lozano-Galant, D. Tomás, G. Ramos & J. Turmo

Optimizing rehabilitation strategies for bridge decks under performance-based contracting setting 2529
M. Alsharqawi, T. Zayed & S. Abu Dabous

Impacts of dynamic loads on the soil-steel bridges 2537
D. Beben

Automated steel bridge coating inspection using neural network trained image processing 2545
A. Elbeheri & T. Zayed

Inspection, structural health monitoring and maintenance of a cable-stayed bridge in Vienna, Austria 2552
P. Furtner

Determination of stay cable forces using highly mobile vibration measurement devices 2558
G. Morgenthal, S. Rau, J. Taraben, T. Abbas & N. Hallermann

Estimation of bridge frequencies from a passing vehicle 2566
N. Jin, T.S. Paraskeva & E.G. Dimitrakopoulos

Study on compressive strength of steel plates with a partial loss of cross-sectional area 2573
K. Saito & K. Nozaka

Use of stochastic optimization in the analysis of weigh-in-motion data 2581
F. El Hajj Chehade, R. Younes, H. Mroueh & F. Hage Chehade

Parametric analysis of rib distortion in orthotropic steel decks 2587
H. Fang & H. De Backer

Rehabilitation of the swing bridge from 1905, North of Spain 2594
F. Collazos-Arias, D. Garcia-Sánchez, M.L. Ruiz-Bedia, O.-R. Ramos-Gutiérrez & M.-A. Delgado-Nuñez

Management of risk disasters: Application in Aysen and Valparaiso, Chile 2599
M.A. Valenzuela, N. Valenzuela, P. Moraga, F. Pineda, M. Márquez & R. Romo

Fatigue behavior of full-penetration inclined cruciform welded-joints with artificial pit corrosion 2606
X. Wei & Z.Y. Jie

Stress-concentration effects due to weld root imperfections in orthotropic steel decks 2613
H. De Backer, W. Nagy & A. Outtier

AS5100.2: 2017 changes to traffic-barrier loadings – a Victorian perspective 2621
B.E. Gibbens

Displacement-based seismic design to AS5100.2: 2017 – simplified 2629
B.E. Gibbens

How did the future work out? The tale of E.J. Whitten Bridge 2637
R.A. Percy & P.J. Robinson

How strong is your bridge? Optimising New Zealand's longest road bridge 2643
J. Waldin, B. McHaffie & V. Wong

Performance of prestressed concrete girder in ultimate bending for AS5100:2004 and AS5100:2017 2651
M.M. Melhem, C. Caprani & M.G. Stewart

Coupling finite elements to model steel to concrete bond 2658
R.J. Gravina, L.A.G. Bitencourt Jr. & L.C. Meneghetti

Shear and torsion design review – Australian and international standards 2664
T. Hossain, S. Mikhael, A. Chaudry & S. Mohanakumar

Intermodal research to increase the reliability of transport infrastructures 2672
R. Holst

Traffic safety and passenger comfort for steel railway bridges 2679
E.S. Hwang & D.-Y. Kim

The ultimate limit state vs. limit analysis of masonry arch bridges 2687
T. Kamiński

Importance of simulation in the design of experimental tests 2695
M. Karalar & M. Dicleli

Experimental investigation on the low cycle fatigue life of piles 2703
M. Karalar & M. Dicleli

Investigation on the closed longitudinal U-ribs corrosion of cable stayed bridge with steel plate deck 2709
K.Y. Lee, S.H. Jin, D.S. Oh, H.S. Joo & D.K. Kim

Experimental and analytical investigation of bridge deck under restrained shrinkage 2717
M. Rahman, Y. Chen, R. Hindi, A. Ibrahim & W. Lindquist

Methods for fast and reliable determination of damping and tension force of stay cables 2724
T. Mack & R. Geier

Noise radiation from steel bridge structure – Old Årsta bridge Stockholm 2732
A. Olsen, R.S. Lützen & S. Holmes

Damping performance identification for large-scale dampers of a cable-stayed bridge 2740
X.H. Hu & C.X. Ge

Use of comparative vacuum monitoring sensors for automated, wireless health monitoring of bridges and infrastructure 2747
D. Roach

Considerations for identification of moisture in building materials using Bluetooth® 2752
R. Helmerich, L. Moldenhaue, G. Voigt, F. Adao & E. Köppe

Quantifying increases in maintenance costs of Prestressed Reinforced Concrete (PRC) bridges due to increasing fatigue from heavier traffic loads 2760
M. Frizzarin, L. Mancassola & P. Franchetti

Assessment of concrete pylon of cable stayed bridge with floating crane collision 2767
J.H. Lee, S.-C. Lee, H.-Y. Kim & S.K. Park

Parametric analysis of dissipative rocking superstructures 2771
Z. Chegini & A. Palermo

Mechanical properties of alkali activated concrete based class C fly ash 2780
E. Gomaa, S. Sargon, A. Gheni & M.A. ElGawady

Bayesian integration of NDT with corrosion model for service-life predictions 2786
S.A. Faroz & S. Ghosh

Brunei Temburong Link – Temburong Viaduct 2793
N. Hussain, S. Yip & J. Cain

Effect of cracks on air-tightness of vacuum tube bridge structures 2799
P. Devkota, J. Park & E. Choi

Preface

One of the biggest challenges facing bridge asset managers globally is to effectively, efficiently and safely manage aging and deteriorating bridges while also accommodating ever increasing loading. The budgets available are often constrained which adds to the challenge considering the cost of maintenance, operation and construction steadily increasing. In this context, academics and practitioners are rising to the challenge with research and practice focusing on innovative approaches to understand the problem and develop and implement solutions. IABMAS conferences bring together academic and technological developments in the fields of bridge maintenance, safety, risk, management, life-cycle performance, resilience, sustainability, among others. The most recent developments in the field are expected to be discussed at the 9th International Conference on Bridge Maintenance, Safety and Management (IABMAS'18), held in Melbourne, Victoria, Australia, July 9–13, 2018 (www.iabmas2018.org).

The First (IABMAS'02), Second (IABMAS'04), Third (IABMAS'06), Fourth (IABMAS'08), Fifth (IABMAS'10), Sixth (IABMAS'12), Seventh (IABMAS'14) and Eighth (IABMAS'16) International Conferences on Bridge Maintenance, Safety and Management were held in Barcelona, Spain, July 14–17, 2002, Kyoto, Japan, October 18–22, 2004, Porto, Portugal, July 16–19, 2006, Seoul, Korea, July 13–17, 2008, Philadelphia, USA, July 11–15, 2010, Stresa, Lake Maggiore, Italy, July 8–12, 2012, Shanghai, China, July 7–11, 2014, and Foz do Iguaçu, Brazil, June 26–30, 2016, respectively.

IABMAS 2018 is organized on behalf of the International Association for Bridge Maintenance and Safety (IABMAS) under the auspices of VicRoads, Australia with the organizational support of Monash University, Swinburne University of Technology, RMIT University and the Australian IABMAS Group. IABMAS encompasses all aspects of bridge maintenance, safety and management. Specifically, it deals with: bridge repair and rehabilitation issues; bridge management systems; needs of bridge owners, financial planning, whole life costing and investment of the future; bridge-related safety and risk issues and economic and other implications. The objective of the Association is to promote international cooperation in the fields of bridge maintenance, safety and management for the purpose of enhancing the welfare of society (www.iabmas.org). The interest of the international bridge community in the fields covered by IABMAS has been confirmed by the large response to IABMAS 2018 call for papers. The Conference Secretariat received over 660 abstracts, 385 of which were selected for final publication as full papers and presentation at the Conference within mini-symposia, special sessions, and general sessions.

Contributions presented at IABMAS 2018 deal with the state of the art as well as emerging concepts and innovative applications related to the main aspects of bridge maintenance, safety, risk, management and life-cycle performance. Major topics include: new design methods, bridge codes, heavy vehicle and load models, bridge management systems, prediction of the future traffic models, service life prediction, residual service life, sustainability and life-cycle assessments, maintenance strategies, bridge diagnostics, health monitoring, non-destructive testing, field testing, safety and serviceability, assessment and evaluation, damage identification, deterioration modelling, repair and retrofitting strategies, bridge reliability, fatigue and corrosion, extreme loads, advanced experimental simulations, and advanced computer simulations, among others.

Maintenance, Safety, Risk, Management and Life-Cycle Performance of Bridges contains 393 contributions, comprising the T.Y. Lin Lecture and 10 Keynote Lectures, and 382 technical papers from all around the world. This volume provides both an up-to-date overview of the field of bridge engineering and significant contributions to the process of making more rational decisions on bridge maintenance, safety, risk, management and life-cycle performance of bridges for the purpose of enhancing the welfare of society. The Editors hope that these Proceedings will serve as a valuable reference to all concerned with bridge structure and infrastructure systems, including students, researchers and engineers from all areas of bridge engineering.

Acknowledgements

The Editors are extremely grateful to all the people who contributed to the scientific program and organization of the IABMAS 2018 Conference. The Editors would like to express their sincere thanks to all authors for their contributions, to the members of the International Scientific Committee for their role in ensuring the highest scientific level of the Conference, and to the members of the Local Organizing Committee for their time and efforts dedicated to making IABMAS 2018 a successful event.

Moreover, the Editors wish to thank all organizations, institutions, and authorities that offered their sponsorship. A special acknowledgement has to be given to VicRoads for being the lead host and organizer of the conference and to Monash University, RMIT University and Swinburne University of Technology for being co-hosts and organizers. Also, a special thank you to the International Association for Bridge Maintenance and Safety (IABMAS) and IABMAS Australia for endorsing and supporting the conference organization.

IABMAS 2018 was conceived in 2011 with the support of the Melbourne Convention Bureau which was invaluable to support the conference in the early stages and obtaining hosting rights. The conference has been planned and developed in close consultation and cooperation with several individuals, in particular Frieder Seible, Honorary Chair of the Conference. Thank you for your invaluable support for the conference and its organization.

The Editors are also extremely thankful to Tulio N. Bittencourt, Joan Ramon Casas, Airong Chen, Hitoshi Futura, Michel Ghosn, Pier Giorgio Malerba and Richard Sause, co-chairs of the International Scientific Committee and Geoff Taplin, co-chair of the Local Organizing Committee.

Finally, the Editors wish to express their sincerest appreciation to Diana Cavasinni, Kate Stevens and all the team at ICMS Australasia, who professionally managed the Organizing Secretariat with outstanding expertise, patience, energy and commitment which have been very important for the successful organization of this Conference.

Bridge maintenance, renovation and management - Research and Development of governmental program in Japan

Y. Fujino
Institute of Advanced Sciences (IAS), Yokohama National University, Yokohama, Kanagawa, Japan

ABSTRACT: The collapse of over-130m suspended roof with casualties of nine people in Sasago Tunnel of one of the major highways near Tokyo in 2012 has led to strong doubts about the current quality and safety of infrastructure, and immediately brought public attention to the issue of infrastructure degradation in Japan. Japanese government decided to invest on research and development for efficient management of infrastructure through implementation of science and advanced technology. The emphasis is placed on bridges. The new research and development (R&D) program named "Infrastructure maintenance, renovation and management" was started in 2014 under the Council of Science, Technology and Innovation (CSTI)'s Strategic Innovation Program (SIP). The 5-years program covers various subjects of infrastructure maintenance with key technologies in condition assessment using non-destructive testing, monitoring and robotics; long-term performance prediction of infrastructure, development of durable high-quality of material for repair and replacement, and management of large amount of bridges and other infrastructure data using advanced information and communication technologies (ICT). The program consists of about 60 research projects involving universities, government research institutes and industries. This initiative is expected to prevent further accidents and setting an example for efficient bridge and infrastructure maintenance by reducing the burden of maintenance works and cost. In the lecture, outline and major output of this SIP program are explained.

1 INTRODUCTION

The economic sustainability, security and well-being of a nation depend heavily on the reliable functioning of infrastructure typically such as roads, highway and bridges. After five decades of development, the stocks of infrastructure in Japan have reached enormous amount of over US$7000 billion as shown in Figure 1.

A comparison of construction age of highway bridges in USA and Japan is given in Figure 2. In USA, large volume of construction started in 1930s. Bridge accidents like the complete collapse of Silver Bridge in 1967 due to poor maintenance took place around 1970s and bridge inspection became mandatory in early 1970s. Bridge management based on inspection data has been developed (Yanev, B, 2007). On the other hand, in Japan large volume of bridge construction started in 1960s as shown in Figure 2.

Built between the 1960s and 1980s, majority of infrastructure have stood for three to four decades (Fujino & Siringoringo 2011). Most works on highways started in late 1960s, bridges in early 1970s, dams and harbors in early 1980s. Some of the infrastructures are not in good condition now. Demand for rapid availability of infrastructure in the past sometimes might have led to poor design; poor construction quality or structures built using undeveloped technology. Some of bridges are deteriorating due to increasing traffic volumes, the use of anti-freezing salts and humid environment. Figure 3 shows a RC bridge deck with cracks due to salt and a bridge deck with holes. Figure 4 shows a RC wall with many cracks due to Alkali-Silica Reaction (ASR).

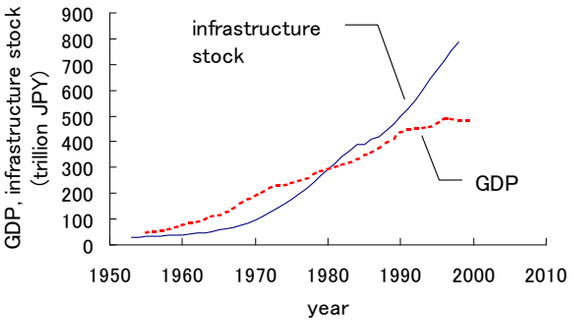

Figure 1. Accumulating infrastructure stock and GDP in Japan.

Suspended roof for air ventilation in Sasago Tunnel (Figure 5) on the Chuo Expressway near Tokyo collapsed over 130m in length in Dec. 2, 2012 and

fortunately involved only 9 deaths because of very low traffic volume at that time. This is the first maintenance-related accident with involvement of human loss. The accident has brought serious public attention to the issue of infrastructure degradation and led to strong doubts about their current quality and safety.

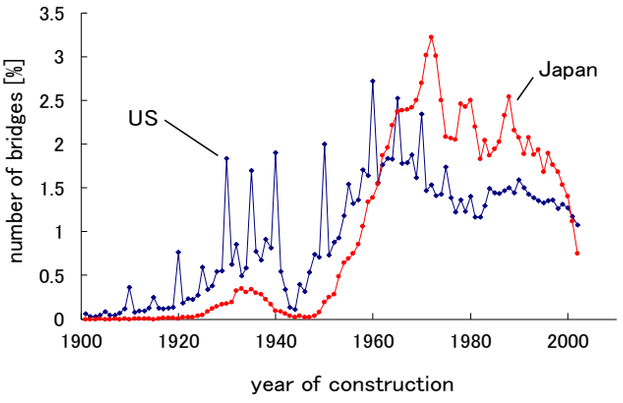

Figure 2. Comparison of yearly changes of construction of highway bridges in USA and Japan

Realizing this condition, Japanese government decided to invest on research and development for efficient infrastructure management. A new R&D program named "Infrastructure maintenance, renovation and management" was launched in 2013 under the Japanese Council of Science, Technology and Innovation (CSTI)'s Cross-ministerial Strategic Innovation Promotion Program (SIP). The 5-years program covers various subjects with key technologies in condition assessment, non-destructive testing, monitoring and robotics; long-term performance prediction, development of high-quality durable material for repair and replacement, and infrastructure management using advanced information and communication technologies (ICT). The program consists of over 60 research projects involving universities, research institutes and industries. This initiative is expected to prevent further accidents and setting an example for efficient infrastructure maintenance by reducing the burden of maintenance works and cost (SIP 2014 a).

Figure 3. Deteriorated RC bridge decks

2 INFRASTRUCTURE CONDITION IN JAPAN

After the Sasago Tunnel accident, Ministry of Land, Infrastructure, Transport and Tourism (MLIT) declared that 2013 was the first year of the maintenance era, and is trying to put more emphasis on the maintenance rather than the construction. However, no one knows how much is needed for the infrastructure maintenance entirely, because there has not been such an experience in the past.

Figure 4. Cracked RC retaining wall due to Alkali-Silica Reaction(ASR)

Figure 5. Accident in Sasago highway tunnel in Japan Dec. 2nd, 2012

In the past couple of years, expressway companies in Japan released their large-scale repair and renovation plans, and the costs for the repair and renovation were estimated. The Metropolitan Expressway's estimate was about US$ 5 billion and three NEXCO companies' (East Nippon Expressway Co. Ltd., Central Nippon Expressway Co. Ltd. and West Nippon Expressway Co. Ltd.) estimate was about US$ 25 billion. It was the first time that the concrete cost estimates were shown and it was considered to be very significant. Followings are the breakdown of the NEXCO's estimate: US$ 4 billion for earthworks, US$ 3 billion for tunnels and US$ 17 billion for bridges. Ninety percent of the bridge costs go to concrete bridge deck slabs. The reason behind this high percentage is that bridge deck slabs all over the country are heavily damaged. This condition is mainly caused by overloaded trucks and the actual loads that are significantly heavier than the design live loads. Deterioration of concrete bridge deck slabs did not attract many attentions from research-

ers in the past, because they were not considered as major structural members.

Generally, locations of the large-scale repair work and renovation were determined roughly considering factors such as inspection results, periods after completion and deterioration rates. However, after detailed investigations the repair and renovation plans might change considerably. Therefore, it is of great interests of civil engineering communities to find a roadmap in reducing the cost, for example US$ 25 billion for the NEXCO Expressway companies,

while at the same time reducing the burden of infrastructure deterioration to the next generations.

Figure 6. Ten SIP projects and their Program Directors

3 CROSS-MINISTERIAL STRATEGIC INNOVATION PROMOTION PROGRAM (SIP)

Based on Japan revival strategy and the science, technology and innovation comprehensive strategy, the Council for Science, Technology and Innovation(CSTI), Cabinet Office, Government of Japan, has founded “Cross-ministerial Strategic Innovation Promotion Program (SIP)”, and included “Science, Technology and Innovation Promotion Expense” in the budget of Cabinet Office for fiscal year 2014 (SIP 2014).

There are five most important task for the Science Technology Innovation Policies, namely: (1). Realization of clean and economical energy system (Energy), (2). Realization of healthy long life society (Healthy Long Life),(3). Development of next generation infrastructure (Next Generation Infrastructure), (4). Community revival by utilization of community resources (Community Resources), and(5). Quick reconstruction and recovery from Great East Japan Earthquake disaster (Reconstruction and Recovery). Among the five most important tasks the SIP selected Energy, Next Generation Infrastructure, Community Resources to promote one of the most urgent issues that is the economic revival and set up 10 subjects. Afterwards, they nominated a talent representing the industry/academy as a Program Director (PD) for each subject (see Figure 6).

Each PD, who has been assigned at the cabinet office, prepared and promoted research and development plans. They include several important issues from basic research to exit strategies (practical applications and commercialization) and this was conducted in close cooperation with relevant ministries and agencies.

4 IMPLICATION OF SELECTION OF INFRASTRUCTURE THEMES FOR SIP – FUSION OF CIVIL ENGINEERING AND ADVANCED TECHNOLOGIES CONDITION IN JAPAN

The Ministry of Land, Infrastructure, Transport and Tourism (MLIT) has recognized the importance of the stock management of infrastructure for some years now, but many local governments do not carry out infrastructure inventories and inspections satisfactorily. However, after the abovementioned Sasago Tunnel collapse incident, “inspection” as a basis for management became compulsory for road infrastructure starting from July 2014. This can be seen as a great momentum for recognition of the importance of infrastructure maintenance in all over the country.

Under such circumstances, the CSTI that usually deals with advanced technologies such as biotechnology and nanotechnology, has selected “Infrastructure maintenance, renovation and management” as one of ten subjects of the SIP.

It is specially mentioned that infrastructure is selected for the SIP subjects, besides the Energy and Community Resources. In the SIP research and development, innovation by the application of research outputs to the society is expected, and the infrastructure is considered to be one of the important fields for that.

Selection of maintenance related topics, which was widely considered inconspicuous before, for the SIP among many topics of Next Generation Infrastructure remarks a new era in the science and technology policy in our country. And this may yet indicate that the time is now changing.

Furthermore, the program promotion system is clearly different from the one that we had before. One of the keywords for the SIP is “innovation by the cooperation,” and the infrastructure related research and development is conducted based on close cooperation among miniseries, such as Ministry of Land, Infrastructure, Transport and Tourism (MLIT), Ministry of Education, Culture, Sports, Science and Technology (MEXT), Ministry of Economy, Trade and Industry(METI), Ministry of Internal Affairs and

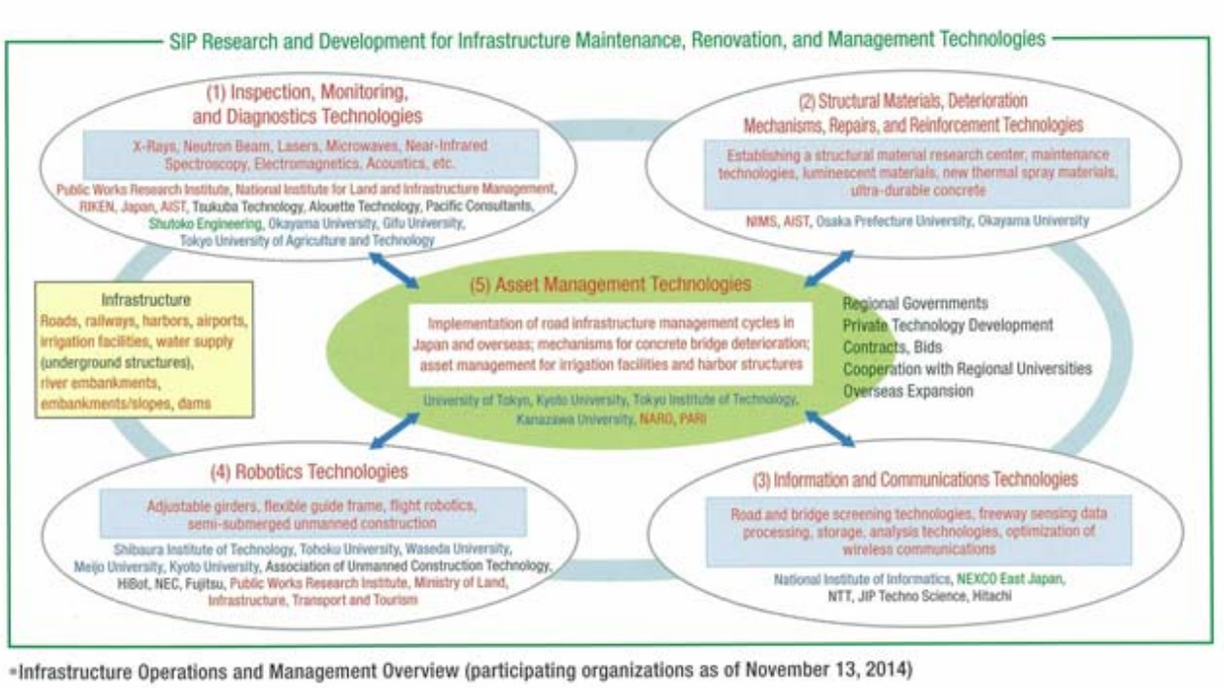

Figure 7. Five fields of R&D in SIP-Infrastructure

Communications (MIC), and Ministry of Agriculture, Forestry, and Fisheries(MAFF), national laboratories, universities, and private enterprises, for the total of five years, of which 3.5 years are remaining.

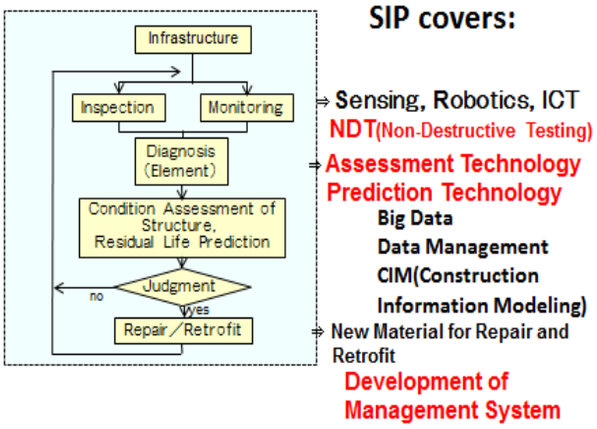

Figure 8. Flow of infrastructure maintenance and management

So far, miniseries, such as MEXT, METI, MIC, are generally interested in advanced technologies since they believed that advanced technologies will create new industries. It is commonly said that "civil engineering is far from the frontier of advanced technologies or that it is on the opposite side of advanced technologies." However, now there is a genuine perception that the time is changing. In order to know the conditions of existing infrastructures, latest technologies in robot and sensing are needed. Communication and data treatment technologies dealing with enormous amount of information of infrastructures obtained by sensors are important, and to discuss deteriorations of structural materials, most advanced material technologies are necessary. For repair, strengthening and replacement, new materials should be used. Therefore, advanced technologies are becoming increasingly important to civil engineering, and the mixture between advanced technologies and civil engineering has created new establishment (Fujino et al 2009).

5 RESEARCH THEMES FOR INFRASTRUCTURE MAINTENANCE, RENOVATION AND MANAGEMENT

In SIP "Infrastructure Maintenance, Renovation and Management Technology R&D", the following five R&D fields are set up as shown in Figure 7, and R&D proposals were invited;

1. R&D for inspection, diagnosis and monitoring technologies. To develop efficient and effective inspection or monitoring technologies that can gather data showing infrastructures deterioration levels.
2. R&D for structural materials, deterioration mechanisms, repair and strengthening technologies. To develop and establish simulation technologies for deterioration mechanisms of structural materials or the deterioration process prediction systems for structures.
3. R&D for information and communication technologies. To develop data management technologies that can utilize enormous information on infrastructure maintenance, renovation and repair.
4. R&D for robot technologies. To develop maintenance or repair robots that can implement efficient and effective inspection/diagnosis. To

develop the robots that allow investigation and/or work needed at dangerous disaster sites.

5. R&D for asset management technologies.

In parallel with R&D 1-4, outcomes of each R&D are applied to the real infrastructure management. Furthermore, asset management technologies that allow efficient maintenance with limited budgets and human resources are developed.

6 INNOVATION OF INFRASTRUCTURE MANAGEMENT CYCLE BY SIP

The R&D for asset management technologies includes development of systematic management technologies aiming at minimization of lifecycle costs, development of asset management technologies applicable to local governments and nationwide, and establishment of basis for overseas expansion by organizing technical exchange platform with overseas infrastructure owners and individuals with relevant knowledge and experience.

The flowchart of the asset management is shown in Figure 8. Technical developments and managing circulation of technology outcomes for local governments and other infrastructure owners would be the important role of an SIP Program Director. If the use of sensors and robots are necessary at the locations, then implementation of these technologies would greatly change the style of development.

Following the SIP policy that highly regards the exit strategies we are trying to lead the basic research to the better direction, to expand various R&D from the basic to the outcomes and to innovate the infrastructure management cycle.

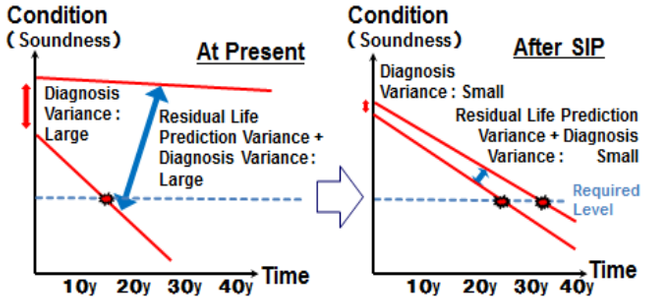

Figure 9. Residual life prediction of deteriorated infrastructure at present(left) and after SIP (right)

Furthermore, we aim at realizing resilient infrastructure systems that utilize the most advanced ICT (Information and Communication Technology) and IRT (Information and Robot Technology) developed in Japan. This is expected to help in reducing the required costs. As shown in Figure 9, the present residual life prediction is not accurate because diagnosis and prediction variance are large. However, after completion of SIP projects the residual life prediction is expected to be more accurate because diagnosis and prediction variance will be smaller, which mean reduction in the required cost. And this may lead to further expansion of the products to South-east Asian countries having similar problems, which means great opportunities for overseas business expansion.

Selected themes were determined last year from many proposals received in the categories of 5 R&D fields mentioned above. The budget of about 30 million US$ per was allocated to all of these themes every year since 2014.

We appreciate understanding and cooperation from all participants and other relevant experts involved.

7 SOME OF ONGOING SIP-INFRASTRUCTURE PROJECTS

7.1 *UAV for bridge inspection –Drones and others-*

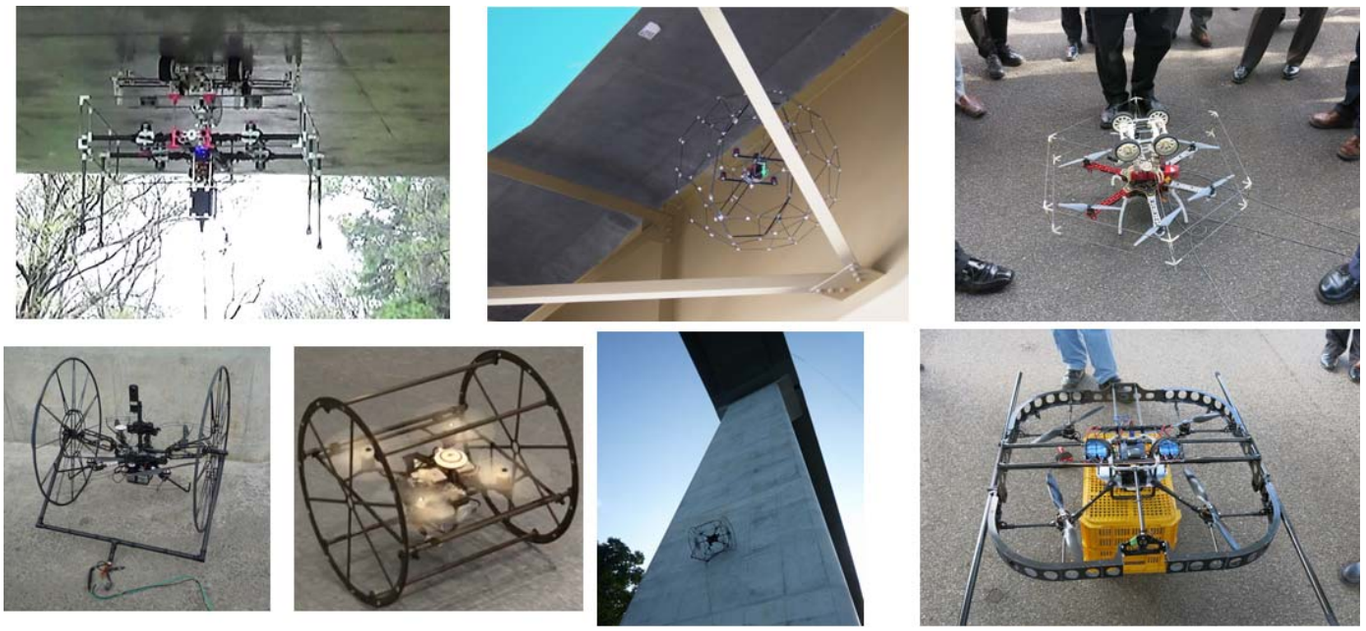
After the Sasago tunnel accident, visual and hands-on inspection of bridges, tunnels and other facilities in highways and roads became mandatory. The interval is 5 years and hammering is to be done if necessary.

Hands-on bridge inspection of bridge from the back side and high piers needs special equipment and hence can be very expensive. It is also labor consuming. To overcome these problems, applying UAV to bridge inspection, at least to its screening is a natural choice. In SIP-infrastructure, various types of UAV including drones are being developed for inspection of bridges and tunnels (Figure 10).

One of the advantages of use of UAV is to capture the surface conditions of bridge components such as RC bridge decks by video and/or camera and can be stored in digital data. Automatized process to identify cracks in concrete surface from the photos is also being developed.

7.2 *Ultrasensitive magnetic nondestructive testing for evaluation of steel infrastructure*

Professor Tsukada's team is developing a non-destructive testing (NDT) method using highly-sensitive magnetic measurements for evaluation of steel infrastructure such as bridges. To ensure the safety of infrastructure, simple and accurate inspection methods are essential. Conventional magnetic testing techniques are simple and inexpensive; however, they can only detect surface defects. In this study, we developed a magnetoresistance (MR) sensor based on two types of NDT instruments that can detect not only surface defects but also inner defects.



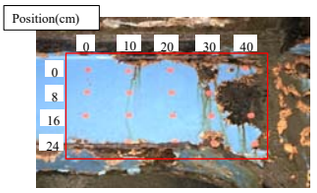


Figure 10. Drones being developed in SIP for inspection of bridge girders and piers

To detect the thinning depth caused by corrosion of thick steel plate, extremely low-frequency eddy current testing (ELECT) with an applied magnetic field ranging from 1 Hz to 1 kHz was developed. The steel thickness was estimated by analysis of the magnetic spectroscopy, which was traced using the obtained multi-frequency magnetic vector signals as shown in Figure 11.

As a result, steel plate thinner than 20 mm could be measured within 0.1 mm resolution. Moreover, the shape of the back-side corrosion was determined by scanning with a magnetic probe. Compared with ultrasonic testing, ELECT has the advantage of non-contact, which enables detection even on rough, corroded or coated surfaces.

Position (cm)	Estimated thickness (%)				
	y = 0	10	20	30	40
x = 0	86	73	59	53	53
8	53	73	59	57	40
16	53	59	56	56	39
24	43	50	54	45	46

Figure 11. Bridge corrosion investigation using ELECT

To detect an inner crack in steel, we developed unsaturated AC magnetic flux leakage (USAC-MFL) testing using an MR gradiometer. Conventional MFL methods need a strong applied magnetic field to ensure that the magnetization characteristic of the steel becomes saturated so that the magnetic field leakage is measurable. They need a strong power source, and therefore they are not suitable for field testing. To solve this problem, a gradiometer with two highly sensitive MR sensors to detect weak magnetic field intensity and the change in the phase-shifted signal caused by the crack were applied. A sharp signal change was detected just above not only the surface but also the inner crack without being influenced by the variations in steel remnant magnetization. As the frequency of the applied magnetic field was decreased, a deeper inner crack was observed, and then an inner crack at a depth of 10 mm could be detected. USAC-MFL is helpful for covering undetectable regions of the surface and subsurface (the dead zone) of ultrasonic testing.

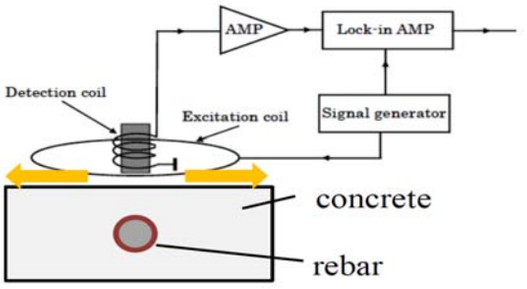

Figure 12. Schematic illustration of EM-NDE method

7.3 *Advanced Nondestructive Evaluation Technology for RC structures*

Novel nondestructive evaluation (NDE) technology using electromagnetic (EM) methods has being developed to assess the degradation of RC structures. Target of the EM NDE technology is to detect the covering depth, diameter of rebars as well as degree of their corrosion in RC structures. Figure 12 is the schematic illustration of the method being developed. The probe composed of an excitation coil and a detection coil. AC magnetic field is produced by an excitation coil and applied to the con-

crete. In response to the excitation field, magnetic field is produced by the rebar due to magnetization and eddy current, which lead to the output signals with 90-degree phase difference. The output signals contain the information on magnetic permeability and electric conductivity of the rebar and corrosion products on the surface. By scanning the surface of the RC structure by the prove, degree of corrosion of rebar can be evaluated.

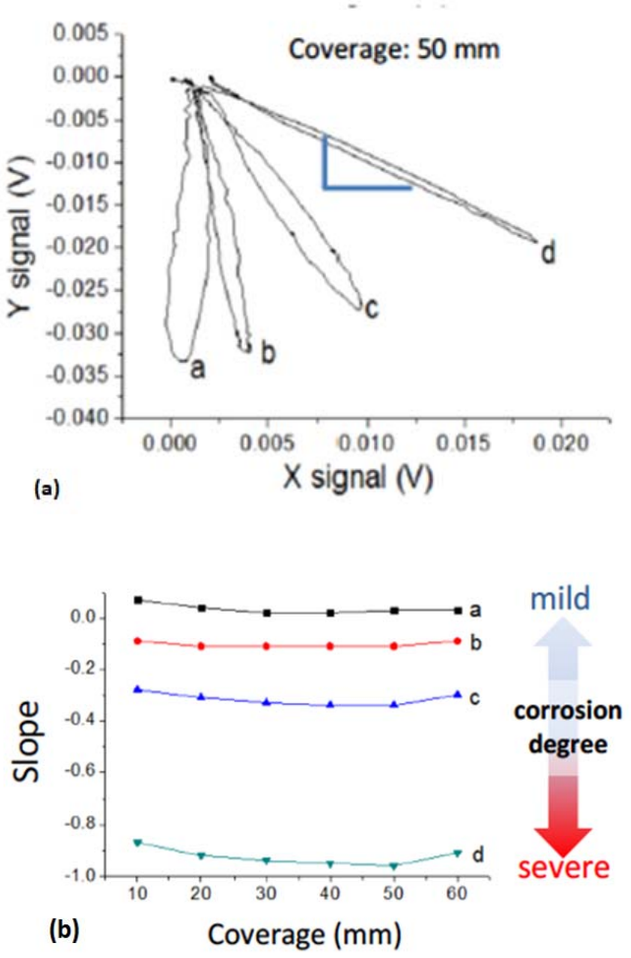

Figure 13. Example of measurement data by EM-NDE method.

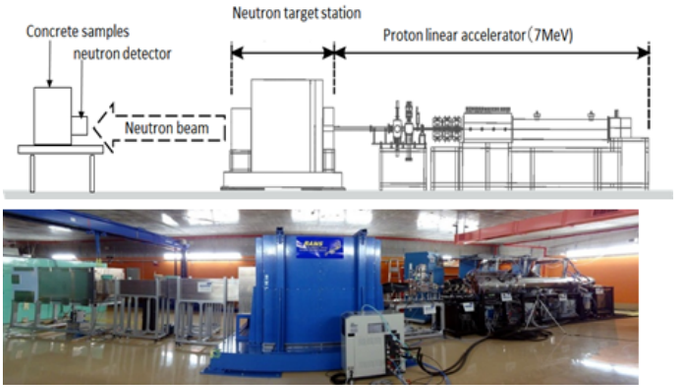
Figure 13(a) is an example of the data obtained from the developed EM-NDE for four rebars with different degree of corrosion. (a) is data for the rebar without corrosion and (d) for the most severely corroded one. With increasing the degree of corrosion, the slope of the loops changes. According to the slopes the degree of corrosion can be classified as shown in Figure 13. By changing the frequency of an excitation field, it is also possible to detect the position of the rebar and to measure the coverage. This technique may be useful for the efficient planning of the repairing and/or replacement of the RC structures and will lead to reduction of maintenance cost.

7.4 *Nondestructive Measurement Method to Detect Water/Void inside Slabs using Compact Neutron Source*

Neutrons have the power to penetrate metals or heavy elements such as calcium, silicon, and iron, while they have high sensitivity to detect such light elements as hydrogen, boron. An accelerator-driven compact neutron system has been developed in RIKEN for practical use on job sites. Nondestructive inspection methods which is in type using transmission imaging and backscattered neutrons to detect void and water in concrete are developed with using RANS (RIKEN Accelerator-driven Compact Neutron Source). The backscattered neutron imaging of the water and the void in different position under 6cm thick concrete are shown as in Figure 15, and experimental set up is shown as in Figure 14. The water distribution under the concrete can be seen four times brighter than common concrete. This method is quite sensitive to detect water under such thick concrete as from 1cm until 30cm (Ikeda et al.2017)



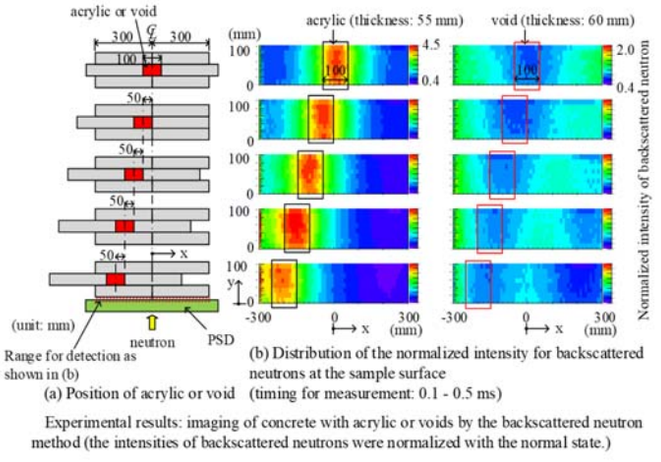


Figure 14. Backscattering experimental set up of compact neutron system

Experimental results: imaging of concrete with acrylic or voids by the backscattered neutron method (the intensities of backscattered neutrons were normalized with the normal state.)

7.5 *Damage Detection by Advanced Digital Signal Processing of UHF-Band Ground Penetrating Radar Data*

Maintenance costs of bridge slab have been increasing especially in developed countries. As an essential part of the structure, current condition evaluation of bridge slab using dense hammering test requires extensive manpower and is time-consuming. To overcome this difficulty, a non-contact radar-based inspection technique is proposed using (Mizutani et al. 2017). In contrast to visually-based reflected-wave image inspection technique commonly used in the fields of mining, oil and geology that is strongly depends on the inspectors' ability and expertise; in this research bridge slab condition is evaluated by automatic reflected wave signals analysis in a fast and objective manner. This is important because the technique should be applicable to many inspected bridges.

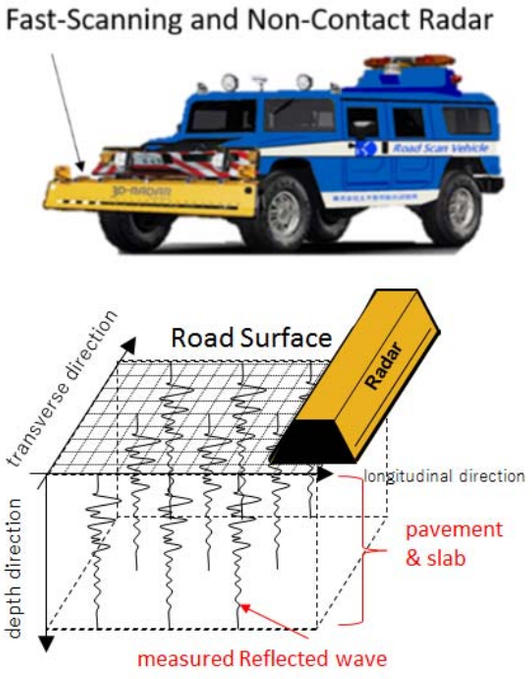

Figure 16. Ground penetrating radar (GPR) mounted on inspection car and its measuring principle.

To detect the damage of slab, an advanced signal processing technique for the reflected wave signal measured by UHF-band Ground Penetrating Radar (GPR) was proposed (Mizutani et al. 2017). A university of Tokyo research group by Dr. T. Mizutani utilizes a vehicle-mounted GPR that can obtain three-dimensional data (transverse direction, depth direction and longitudinal direction) at max. 80 km/h (Figure16). The proposed damage detection algorithm proposed can process the 100 m-length data in just a few seconds, and the damage area can be automatically detected (Figure 17(a)). To validate the algorithm in detail, a real scale bridge slab in which ideal damage was embedded was constructed. Employing the algorithm to the measured data, damage area was clearly detected especially after fulfilling the damage with water because water that has entered the concrete reflects electromagnetic waves more strongly (Figure 17 (b)) (Mizutani, T. et al., 2017)). Measurement on a number of actual bridges are currently being conducted to verify accuracy of the method. In addition, a new radar system suitable for detecting the damage of the deck is also being developed (Yamaguchi, T. et al., 2017).

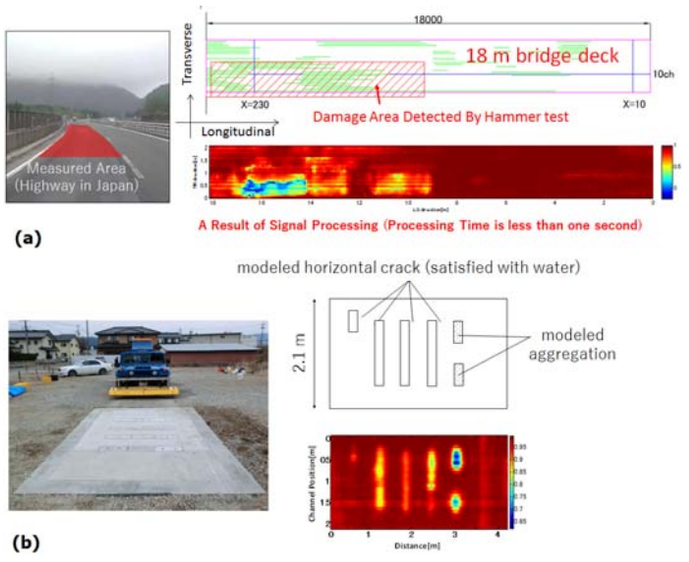

Figure 17.(a) Detection of damaged area by advanced signal processing technique, (b) validation by damage-embedded bridge slab model.

7.6 *Survival analysis of risk factors affecting deterioration of RC deck slabs in Northeast Japan*

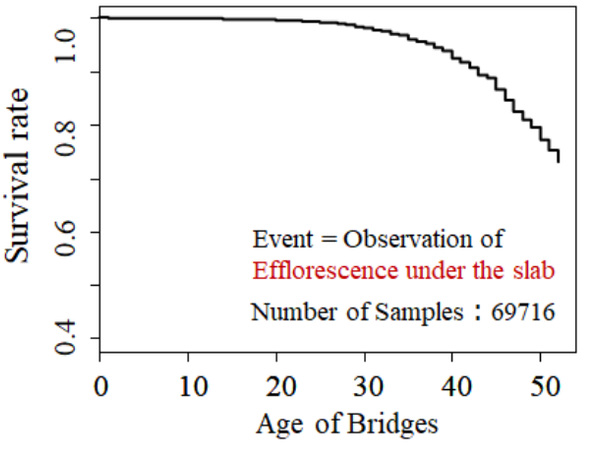

Figure 18. An example of Estimated Kaplan-Meier survival curves

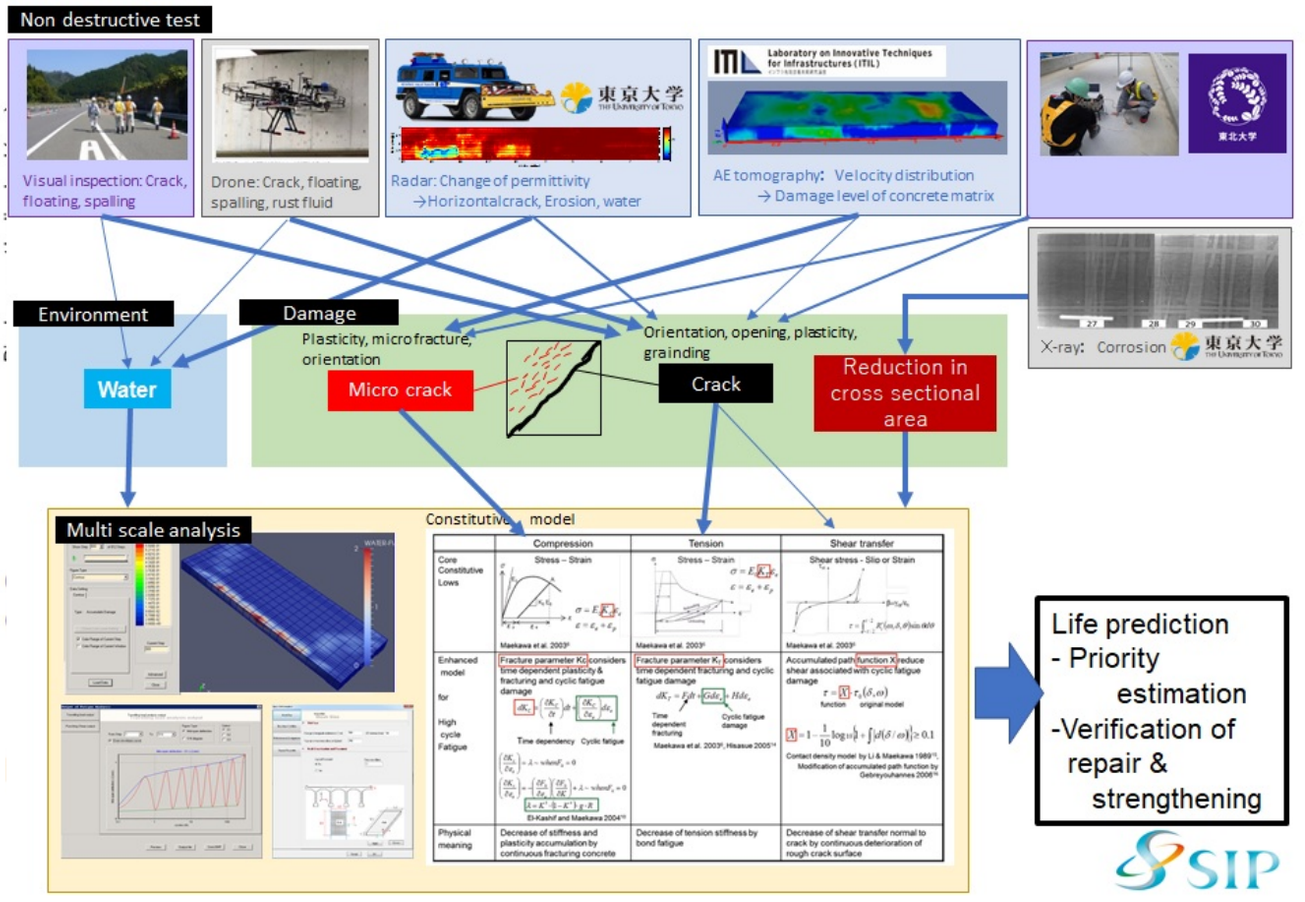

Figure 19. Schematic process of data assimilation to estimate remaining life of existing road bridge decks.

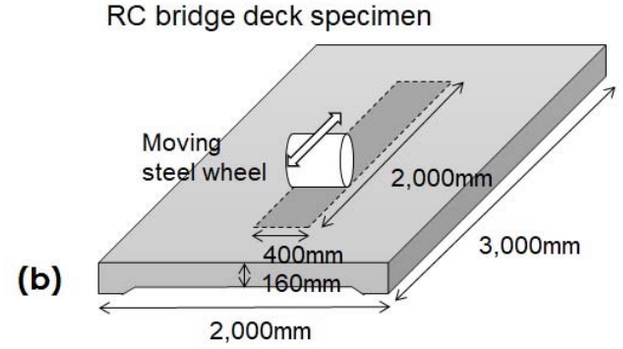

Figure 20. (a) wheel running test machine, (b) dimensions of RC deck specimen and position of wheel load.

Implementation of data-driven efficient maintenance that supports decision making by engineers is absolutely expected for rational infrastructure management. A university of Tokyo group led by Professor T. Ishida applied survival analysis to identify dominant deterioration risk factors of RC deck slab in Northeast Japan by analyzing 80,000 inspection records of national roads. Firstly, Kaplan-Meier estimator analysis for estimating the survival curve of time-to-event data is applied (Figure 18).

By estimating the survival curve, salt damage is indicated as a major cause of deterioration. Secondly, the group applied Cox regression analysis to quantify structural and environmental deterioration factors (Table 1). As a result, the predominant risk factors are explained as the rainfall in specific seasons and the movement of water on the surface of slabs. Additionally, a comparative study using 60,000 records of highway inspection data is done to check the congruence of the analytical results for two datasets distributed in the same area. A methodology for estimating future risk is also proposed (Yamazaki and Ishida 2015).

7.7 *Remaining Fatigue Life Assessment of Damaged RC Decks -Data Assimilation of Multiscale Model and Site Inspection-*

For predicting remaining fatigue life of RC bridge decks subjected to traveling wheel-type loads, Pro

Figure 21. Data assimilation with crack patterns in wheel running test.

fessor K. Maekawa at the University of Tokyo group is developing a data assimilation procedure coupled life-span simulation with inspection data at site as shown in Figure 19 (Tanaka, Y. et al., 2017a). Multi-scale analysis with hygro-mechanistic models, developed by the group is used for the platform of data assimilation on which the visual inspection of cracking on the members' surfaces and/or non-destructive test such as the acoustic emission (AE) tomography are numerically integrated.

For verification, the wheel running load experiments of slabs (Figure 20) were conducted with continuous data acquisition of both crack patterns and the acoustic emission data over the life till failure (Tanaka, Y. et al., 2017b). Visually inspected cracks are converted to space-averaged strains with Bernoulli-Euler theory. Imbalance in deformation and forces are compensated by numerical predictor-corrector cycles and non-inspected internal cracks are re-produced. Consequently, data assimilation succeeded to predict remaining fatigue life as shown in Figure 21. The 3D field of elastic wave identified by AE tomography is also converted to the fracture parameter of concrete. Although no information on cracking is available, the proposed assimilation method successfully reproduces most probable internal cracks over the volume of analysis domains, and the remaining life of the deck slabs inspected was successfully predicted.

8 INNOVATION

Since the industrial revolution in the late 18th century, technological developments have been continuously advancing. For the past few decades, information technologies based on computers have added in the technological development and we are now in the stage of the second industrial revolution. Integration of various technologies including information technologies can generate new values in the society. This is the Innovation and innovation is becoming a very important keyword.

In SIP infrastructure, to solve problems related to infrastructure maintenance, renovation and management, not only civil engineering but also other disciplines such as material sciences, mechanical engineering(robotics), electrical engineering and electronics(sensors), informatics are essentially important and proper integration of various disciplines is absolutely needed to produce new and valuable outcomes. As the program director, I always encourage the SIP players to interact with group of other disciplines and emphasize interaction as the key to produce innovative products.

Civil engineering is often considered to be rather traditional and conservative for are number of reasons. Civil engineering structures are exposed to harsh environment for a long time like 50 years or even more than 100 years, involving very large uncertainties and their replacement are very difficult. Civil engineering structures are mostly owned by public sectors such as central and local governments and they are very sensitive to the safety and accidents of civil structures such as bridges and tunnels. All these circumstances, requirements and challenges naturally make civil engineers conservative.

However, conservative and traditional view do not always hinder innovation. In history, we have seen many prominent civil engineers who are proved to be very innovative Isambard Kingdom Brunel, Gustave Eiffel and John A. Roebling (Figure 22) are the notable examples. Isambard Kingdom Brunel for example is known as one of the most ingenious figures in engineering history. He is widely respected in UK, because his projects contained many innovative solutions to long-standing engineering problems. Brunel achieved many engineering firsts, including new technique for construction of bridges, viaducts and tunnels. Brunel is perhaps best remembered for designs for the Clifton suspension bridge in Bristol, but his works spanned beyond civil engineering as he was also involved in development of SS Great Britain, the first propeller-driven iron ship.

Figure 22. Great engineers known for their innovations that have shaped the engineering world (left to right: Isambard Kingdom Brunel-UK (1806–1859), Gustave Eiffel – France (1832-1923), John Augustus Roebling – Germany -US (1806-1869)

History also witnesses the raise of Gustave Eiffel from France. His innovative metal-structure design still supports buildings, bridges and even statues that last until now. He started to work on a system of standardized prefabricated bridge which was very innovative at the time. He was also a pioneer in combining analytical approach with an insistence on a high standard of accuracy in drawing and manufacture. John A. Roebling, an American engineer who invented an innovative wire rope that aided in revolutionizing modern long-span cable-suspended bridge in the world. He is known for daring to try an untried problem, without a precedent and undertaken with his innovation and great engineering solution. These are several world's renowned engineers who have made engineering breakthrough and accomplishments through their innovative solutions.

Figure 23. Great engineers from Japan known for their innovation and leadership, left Dr. Isamu Hiroi (1862- 1928) and right Dr. Kouichi Furuichi (1854-1938)

I would like to introduce Dr. Isamu Hiroi (1862-1928) whom I believe that is one of the great and innovative civil engineers in Japan (Figure 23). Even though he was born in a small town of southern island, he chose Sapporo Agricultural College in Sapporo, Hokkaido which the northern part of Japan. The reason is that he wanted to contribute the development of new area, Hokkaido. Teachers in the college were all American and the college was full of American-style. After the graduation, he went to the United States and joined a bridge company to learn advanced steel bridge engineering. After coming back to Japan, he was appointed a professor of Sapporo Agricultural College.

Figure 24. North breakwater in Otaru Port, Hokkaido completed in 1909

In 1894, he was assigned to be adjunct engineer at Hokkaido Development Bureau and he was asked to supervise construction of 500m breakwater in Otaru Port in Hokaiddo in 1894 (Figure 24). To accelerate the construction efficiently, he concluded that the project need to utilize a mechanized construction system and the breakwater was constructed by machine he ordered from the UK (Figure 25). Note that machine had never been used in construction before in Japan. Cement was very expensive at that time, and to reduce the cost, he developed concrete with volcanic ash. He was confident with strength of this new concrete, but not fully confident about its 100-year long-term durability (Figure 25(c)). So, he made 50,000 test pieces of this concrete and ordered them to be tested for strength a piece a year to make sure that that the strength of concrete used in the breakwater is adequate. This method resembles a monitoring without using sensors. I think that Dr. I. Hiroi was really innovative.

Figure 25. North breakwater in Otaru Port. (a) Large machine used for construction of breakwater, (b) completed breakwater, (c) concrete pieces for long-term performance evaluation

Dr. Kouichi Furuichi (1854-1938) (Figure 23), the first professor in Dept. of Civil Engineering and the first president of Imperial College of Tokyo, thought Dr. Hiroi was so excellent in engineering and research, and recruited him to a professor of bridge engineering chair at Imperial College of Tokyo in 1899. This is a very prestigious position. He continued to pursue new technologies and produced many eminent researchers and engineers. He published a steel bridge book which had a very high reputation internationally and he proposed a formula on the wave pressure, namely Hiroi Formula which has been used widely in the world until recently. He also started research on wave power generation 100 years ago.

Prof. K. Furuichi became the first president of the Japan Society of Civil Engineering (JSCE) when it was founded in 1914. In his inaugural speech, he said that civil engineers had to be leaders of leaders. This means that civil engineers are expected to be coordinators of projects. In his speech, he said to researchers should "widen/extend your research as far as possible according to your interest and the societal need, but make civil engineering be in the center of your research". I feel strongly that Prof K. Furuichi is appealing to all civil engineers to be innovative. I feel strongly that Prof K. Furuichi is appealing to all civil engineers to be innovative and this idea was followed closely by Dr. Hiroi.

Civil Engineering is basically problem-oriented, need-driven and needs to seek for methods, tools and knowledge of other disciplines, hence interdisciplinary is genuinely the nature of civil engineers. The spirit of innovation and interdisciplinary was instilled and manifested in the SIP projects mentioned here. We expect that this spirit will bring out the maximum outcome that can be implemented in infrastructure maintenance, renovation and management.

It should be mentioned that in addition to maintenance, renovation and management using non-destruction evaluation techniques mentioned above, in the past few decades we have seen monitoring evolved to a continuous and permanent installations throughout a structure's lifetime (Abe et al 2014, Fujino et. al. 2009). Continuous monitoring provides data on a structure's behavior under various loading and environment conditions, including unexpected extreme events. Monitoring has been shown to be particularly useful for understanding real structural behaviors in depth, revealing unknown factors that were not considered in design and providing structural information for necessary retrofits after extreme events (Fujino et al 2016, 2018). Therefore, best practices in monitoring, maintenance, renovation and management will hopefully allow us to maintain our infrastructure in their best qualities in an effective and efficient manner.

9 CONCLUDING REMARKS

This paper describes the new research and development (R&D) program named "Infrastructure maintenance, renovation and management" was started in 2014 under the Japan Council of Science, Technology and Innovation (CSTI)'s Strategic Innovation Program (SIP). covers various subjects of infrastructure maintenance with key technologies in condition assessment using non-destructive testing, monitoring and robotics; long-term performance prediction of infrastructure, development of durable high-quality of material for repair and replacement, and management of large amount of bridges and other infrastructure data using advanced information and communication technologies (ICT). The program consists of about 60 research projects involving universities, government research institutes and industries. Stared in 2014, the SIP-Infrastructure project is now coming into its 5th year and will conclude at 2019 spring.

As explained in this paper, all sub-projects deal with emerging problems in evaluation of civil infrastructure conditions in an interdisciplinary and innovative manner. They are now in the final stage the projects and working hard to maximize the final output. The common goal is to have all the outcomes finally implemented in infrastructure maintenance, renovation and management. It is also expected that the outcomes of SIP-Infrastructure would be implemented outside Japan.

ACKNOWLEDGEMENT

The author would like to acknowledge the following individuals for their tremendous support. Dr. Dionysius Siringoringo (Yokohama National University) for the help in preparing the manuscript. Prof. K. Maekawa, Prof. T. Ishida, Dr. H. Tanaka, Dr. T. Mizutani (University of Tokyo), Prof. K. Tsukada (Okayama University), Dr. D.He, Dr. M. Shiwa, Dr. K. Tsuchiya (NIMS), Satoshi Takaya (Kyoto Univ.) and Dr. T. Otake (RIKEN) for providing very valuable data and information.

Life-cycle reliability of bridges under independent and interacting hazards

Mitsuyoshi Akiyama
Waseda University, Tokyo, Japan

Dan M. Frangopol
Lehigh University, Bethlehem, PA, USA

ABSTRACT: After recent large earthquakes, field investigations confirmed that several bridges were severely damaged and collapsed not only due to the earthquake, as an independent hazard, but also to the subsequent tsunami, landslide or fault displacement. In addition, material deterioration might cause further seismic damage to bridges. Therefore, it is important to study both independent and interacting hazards and their effects on the reliability of bridge and bridge networks. Although earthquake is still a dominant hazard to bridges in many earthquake-prone countries, a life-cycle reliability approach has to consider both independent and interrelated hazards causing bridge failure. Such an approach is presented in this keynote paper. In addition, issues related to life-cycle analysis, design, risk, resilience and management of bridges under earthquake and other hazards are discussed. Finally, the concepts and methods presented are illustrated on both single bridges and bridge networks.

1 INTRODUCTION

Bridges may be susceptible to damage during an earthquake event, particularly if they were designed without adequate seismic detailing. Bridge columns built using earlier design codes (i.e., without proper seismic detailing) often lack adequate flexural strength and ductility capacity, and/or shear strength. When subjected to strong ground motions, they have the potential to exhibit brittle failure. Several destructive earthquakes in Japan shown in Figure 1 inflicted various levels of damage on the structures and infrastructures. The investigation of these negative consequences gave rise to serious discussions about seismic design philosophy and to extensive research activity on the retrofit of as-built bridges (Akiyama et al. 2014).

There are several performance indicators that can be related to the possible occurrence of local and global failures, including system ductility, redundancy, failure times, redundancy, robustness, and resilience (Biondini & Frangopol 2016). These performance indicators need to be included into the practical design for bridges (Biondini & Frangopol 2018). A review of performance indicators and metrics is available in Ghosn et al. (2016). These performance indicators are expected to change over time due to structural deterioration and time-variant resistance (Zhu & Frangopol 2012, Barone & Frangopol 2014, Frangopol & Saydam 2014).

System ductility is the ratio of ultimate displacement at collapse to the corresponding displacement at first failure. This performance indicator is related to the energy dissipation capacity of the structural system and is generally a key factor in seismic design concept based on capacity design criteria (Akiyama et al. 2012a). Structural redundancy denotes the ability of the system to redistribute among its members the loadings that can no longer be sustained by damaged members after the occurrence of a local failure (Frangopol & Curley 1987, Frangopol & Nakib 1991). The load distribution capacity is a desirable structural feature to ensure suitable system performance under the strong excitations (Bertero & Bertero, 1999). Structural robustness can be viewed as the ability of the system to suffer an amount of damage not disappropriate with respect to the causes of the damage itself (Saydam & Frangopol, 2011).

Reliability-based performance indicators, which account for the uncertainty in both resistance and load, have been the basis for establishing the safety levels of structural design codes. Although reliability-based performance indicators can provide adequate information on the safety of bridge components and individual bridges, they lack the ability to reflect the

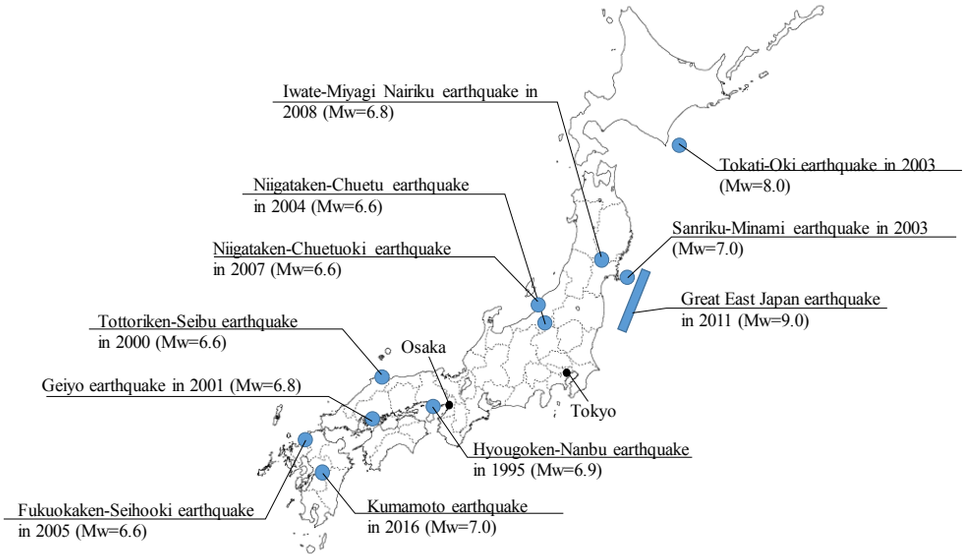

Figure 1. Recent large earthquakes in Japan after the 1995 Hogoken-Nanbu (Kobe) earthquake

outcome of a failure event in terms of economic losses. On the other hand, risk and risk-based performance indicators offer additional information on the performance of structural systems under various hazards. Risk allows combining the probability of component or system failure with the consequence of the event.

As observed in recent catastrophic disasters (e.g. 2011 Great East Japan earthquake and 2016 Kumamoto earthquake), because the transportation network, including bridges, plays a crucial role in the evacuation of affected people and the transportation of emergency goods and materials, the functionality of the network after a disaster must be investigated (Unjoh 2012). A significant amount of research efforts has shifted the focus from the analytical of individual components of the infrastructure to the investigation of entire distributed civil infrastructure systems and networks (Stergiou & Kiremidjian 2010, Bocchini et al. 2011, Saydam et al. 2013, Torbol & Shinozuka 2014, Dong & Frangopol 2017).

Transportation systems are needed to perform economic and strategic activities, and, immediately, after a catastrophic event, they allow rescue operations to be initiated. However, the flow capacity of a transportation network would be reduced significantly if its constituent bridges are damaged. Bridges are considered as weakest links in road transportation system because of their vulnerability to hazards (Lee et al. 2011, Frangopol & Bocchini 2012). Robustness and recovery of the transportation network as a whole highly depends on the performance of its individual bridges. Large-scale hazards can damage many bridges in a transportation system simultaneously, and the loss resulting from this damage can be classified into two categories: initial direct loss caused by structural damage and indirect loss caused by downtime of the network before its full recovery. The initial loss is determined by the vulnerability of the components in the system to the hazard event. The indirect loss due to downtime largely depends on the overall recovery time and trajectory of the network (Zhang et al. 2017). Indirect losses as a consequence of cascading failures (i.e. negative economic, social and environmental consequences) are key factors that affect the restoration time of a community from the event. In order to account for these cascading failures in the community, network dependency and cross-dependency should be included in the risk assessment of the community (Masoomi & van de Lindt 2018), although they are outside of the scope of this paper.

The prompt restoration of critical infrastructure facilities after an extreme event is always a goal of paramount importance (Bocchini & Frangopol 2012a, b). To quantify the promptness of the restoration, it has become customary to use the concept of resilience. Even though there are several definitions of resilience in the literature, the most widely accepted definition is provided by Bruneau et al. (2003): "resilience is defined as the ability of social units (e.g., organizations, communities) to mitigate hazards, contain the effects of disasters when they occur, and carry out recovery activities in ways that minimize social disruption and mitigate the effects of future earthquake." For example, the definition of seismic resilience combines information from technical and organizational fields, from seismology and earthquake engineering to social science and economics (Cimellaro et al. 2010).

Hutt et al. (2016) and Tirca et al. (2016) considered downtime and recovery of existing steel buildings and proposed the seismic strategies in order to achieve increased resilience. Previous efforts to investigate the functionality of networks have proven that damage to components directly cause a major degradation in the functionality of the entire network. Bocchini & Frangopol (2012a) considered resilience as a measure of the ability to recover the functionality of bridges along a highway segment, subjected to an extreme event of any kind, in a fast and economically efficient way.

The environmental, social, and economic impacts of structural activities have become an increasingly significant issue in modern sustainability conscious design, assessment and management methodology

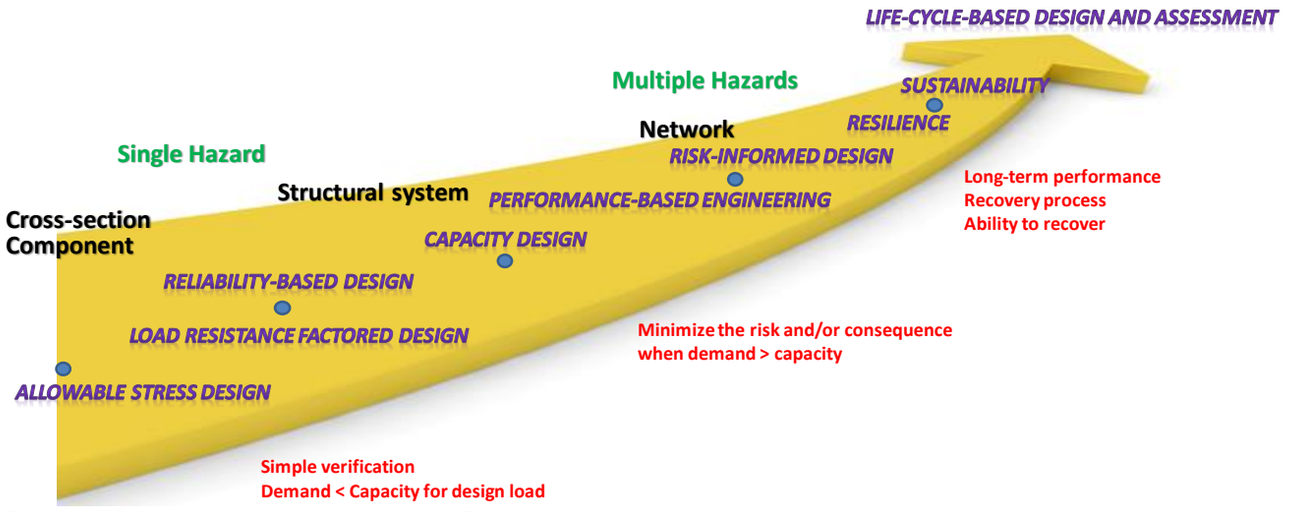

Figure 2. Progress of structural design methodology: From the classical allowable stress design method toward the life-cycle-based design and assessment of network involving bridges under multiple hazards

aiming to ensure structural sustainability in a life-cycle context (Du and Karoumi 2013, 2014, Wang et al. 2018). Sustainability includes social, economic, and environmental metrics to evaluate structural performance and can serve as a useful tool in decision making associated with civil infrastructure systems (Dong et al. 2014). Wang et al. (2018) proposed a novel life-cycle design methodology consisting of six steps: Level 1 -safety and reliability design, Level 2 -durability design, Level 3 -economic evaluation, Level 4 -local environmental evaluation, Level 5 -social evaluation, and Level 6 -global environmental environment. Gencturk et al. (2016) developed a life-cycle sustainability assessment framework which can be used for sustainability quantification of reinforced concrete (RC) buildings subjected to earthquakes. The sustainability through various stages of the lifetime of an RC building was obtained in terms of cost and downtime (related to the economy component), environmental emissions and waste generation (related to the environmental impact component), and deaths (related to society component).

Resilience emphasizes the impact of infrastructure damage, failure, and societal recovery when subject to hazards with a low probability of occurrence and potentially high consequences. On the other hand, sustainability concentrates on current and future resource management, and addresses the impacts of planning and development on the economy, society, and the environment. A sustainable infrastructure system needs to include resilient and adaptive capabilities to ensure its long-term sustainability. Some of the most promising solutions for resilience are actually also sustainable in nature (Mackie et al. 2016). Meanwhile, Bocchini et al. (2014) proposed a unified approach by combining resilience and sustainability and concluded that a systematic unification of resilience and sustainability is mandatory.

Design and assessment of structures have been geared towards addressing the most dominant hazard at the location of interest. However, the possibility of structures experiencing multiple hazards of different types during their service life needs to be considered. The design methodology of bridges must shift towards a more comprehensive approach of addressing multiple hazards to ensure adequate performance under different loading scenarios (Chulahwat & Mahmoud 2017, Gidaris et al. 2017). Quantification of the reliability and risk associated with damage to each bridge considering multi-hazard exposure helps in prioritizing retrofit activities for bridges in a network. There are different types of hazard such as: independent hazards, correlated hazards, concurrent hazards, and cascading hazards (Asprone et al. 2010, Akiyama & Frangopol 2012b, 2013a, Kameshwar & Padgett 2014).

Life-cycle performance approaches of RC structures exposed continuously to the attack of chloride ions in seismic prone regions were proposed by several investigators (Akiyama et al. 2011, Alipour et al. 2011, Biondini et al. 2014, Rao et al. 2016a, b, among others). Several researchers estimated the seismic risk or resilience of road network taking into consideration the effect of corrosion on the bridge performance deterioration (Rokneddin et al. 2013, Biondini et al. 2015, Kurtz et al. 2016, Alipour & Shafei 2016, Zanini et al. 2017).

Zhang et al. (2013) presented a holistic framework for fatigue reliability analysis of long-span bridges under combined dynamic loads from vehicles and wind. Even though the stresses from either the vehicle loads or wind loads may not be able to induce serious fatigue problems alone, the superposed dynamic stress ranges cannot be ignored for fatigue reliability assessment of long-span bridges.

Scour plays an important role in the seismic response of bridges since it weakens the foundation of the structure. A multihazard reliability-based or risk-based framework for evaluating the structural response of bridge under the combined effects of scour and earthquake events has been investigated (Banerjee & Prasad 2012, Dong et al. 2013, Alipour et al. 2013, Yilmaz et al. 2016, Chandrasekaran & Banerjee 2016).

Figure 4. Typical failure mode of RC columns designed before the 1990s: Damage to RC columns with the cut-off of the rebars (photos (a) and (b) taken by the first author; and photo (c) courtesy of East Japan Railway Company)

A multi-hazard optimization framework for wind and seismic loading for two suspended floor slab isolation system was developed by Chulahwat & Mahmoud (2017). Their results highlighted the effectiveness of tuning the suspended slab system to meet the wind and seismic performance objectives.

Structural damage accumulation resulting from the action of sequences of seismic excitations has been investigated in the assessment of life-cycle system reliability and performance (e.g. Esteva et al. 2011, Esteva et al. 2016). Meanwhile, since it may take a time to repair the bridges after a mainshock, the aftershocks have the potential to cause more severe damage to bridges. Seismic hazards associated with aftershocks are not explicitly accounted for in modern bridge design codes, nor in emerging methodologies such as performance-based seismic design. Nazari et al. (2015) developed a methodology that can quantify the changes that would be needed in the structural design of a building to account for aftershock hazards and illustrate it by using a basic nonlinear model of a building. Probabilistic risk and resilience of highway bridges under mainshock and aftershock sequences were estimated for implementing risk mitigation strategies and equipping decision makers with a better understanding of structural performance under seismic hazards (Dong & Frangopol 2015).

Significant advances have been accomplished in the field of earthquake engineering. However, there is a need to promote further research for developing concepts and methods in order to design and assess resilient and sustainable bridges and bridge networks in a life-cycle context. This paper provides an

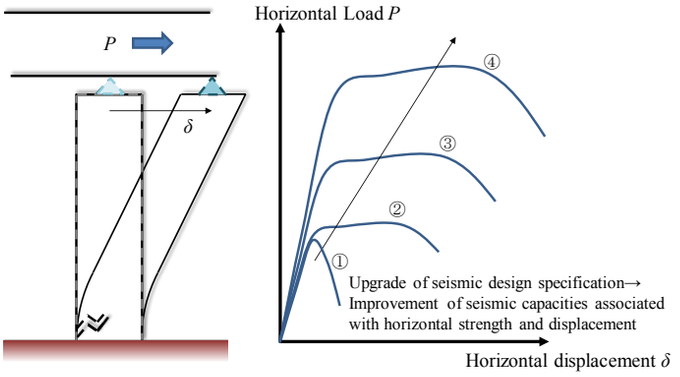

Figure 5. Improvement of seismic capacities associated with horizontal strength and displacement

overview of bridge design methodology progress together with the lessons from recent large earthquakes in Japan. Several performance indicators necessary to be implemented into the practical design and importance of taking into consideration the effect of multiple hazards on the life-cycle performance deterioration of bridges are introduced. Finally, the concepts and methods presented are illustrated on both single bridges and bridge networks under single and multiple hazards.

2 TOWARD LIFE-CYCLE BASED DESIGN AND ASSESSMENT OF BRIDGES UNDER MULTIPLE HAZARDS

Figure 6. No. 5 Inohana viaduct taken after the 2003 Sanriku-Minami earthquake and after the 2011 Great East Japan earthquake (Note: the viaduct was retrofitted before the 2011 Great East Japan earthquake) (both photos taken by the first author)

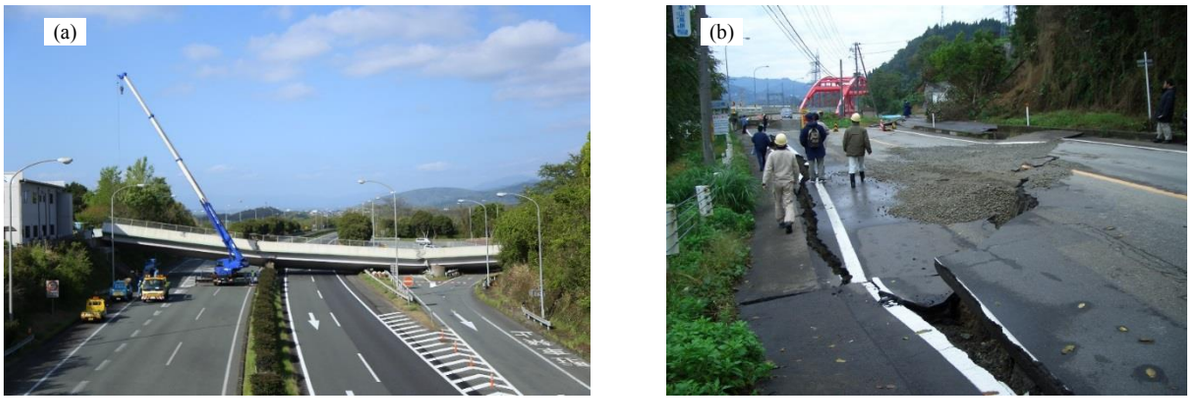

Figure 7. Example of post-disaster functionality deterioration of road network (photo (a) courtesy of Mr. Matsunaga at Kyodo Engineering Consultant Co. LTD.; and (b) taken by the first author)

method toward the life-cycle-based design and assessment of transportation networks involving bridges under multiple hazards. The structural safety in design is traditionary quantified by comparing the structural capacity, *R*, with the load effect, *L*. The uncertainties in *R* and *L* are implicitly considered when assigning the minimum allowable safety factor. Static and linear elastic analysis were performed to estimate *R* at the component-level. The designers did not predict the whole behavior of bridges under excitation and did not identify the possible failure mode when subject to the unexpected seismic action. Also, there is a lack of proper knowledge on structural details. Figures 3 and 4 show typical failure modes of RC columns designed according to the old design code. RC bridge piers had insufficient shear reinforcement and/or have cut-offs of longitudinal rebars without adequate anchorage length at the midpoint of bridge pier.

Based on the experience of seismic damage to bridges and research progress on earthquake resistance, shear and ductility designs of RC components were modified. Figure 5 shows the relationship between horizontal load and displacement of a bridge pier. According to the revisions of seismic design codes, lateral strength and displacement ductility have been improved (Kawashima 2000). Also, several seismic retrofitting methods have been developed. Figure 6 shows the damaged states of the Shinkansen viaducts taken after the 2003 Sanriku-Minami earthquake and the 2011 Great East Japan earthquake. The retrofitted columns of the viaducts performed well, with almost no damage during the 2011 Great East Japan earthquake (Akiyama & Frangopol, 2012b). There have been no reports on the damage of retrofitted RC columns or on the undesirable consequences elsewhere in the retrofitted bridge.

In current semi-probabilistic load resistance factored design, the concept of the reliability index is introduced in code calibration. The uncertainties in *R* and *L* are considered separately by assigning different load factors and resistance factors through rational calibration procedures, where target reliability index for each type of structural element is assigned to maintain an acceptable probability of failure (Liu et al. 2009). The structural components are designed based on either ultimate limit states or serviceability limit states or both (Estes & Frangopol 2001).

Evolution of structural design methodologies from allowable design method to load resistance factored design method has revealed the importance of uncertainty consideration in balancing economical and safety aspects of structural designs (Liu et al. 2009). With the development of computer technology, *R* and *L* at the structure-level could be evaluated by the nonlinear and dynamic analysis considering uncertainties and correlations. A reliability-based capacity design procedure was proposed to obtain the hierarchy of resistance of the various structural components and failure modes necessary to ensure a suitable plastic mechanism and avoid brittle modes (Akiyama et al. 2012a). Although the capacity design method has been developed to maximize post-event operability and minimize the cost of repairing bridges after a

Figure 8. Matsurube Bridge collapsed due to the land slide during the 2008 Iwate-Miyagi earthquake (both photos taken by the first author)

Figure 9. Koizumi Bridge collapsed due to the tsunami during the 2011 Great East Japan earthquake (both photos taken by the first author)

severe earthquake, consequences associated with functionality and recovery cannot be explicitly incorporated in the reliability-based capacity design method.

Figure 7 (a) shows the collapse of as-build bridges over the Kyushu Expressway preventing traffic passage after the 2016 Kumamoto earthquake. Figure 7 (b) shows the damage to embankment. Although the nearby bridge did not have any damage, the functionality of the post-disaster road network deteriorated severely. In addition, field investigations after recent large earthquakes in Japan confirmed that several bridges were severely damaged and collapsed not only due to the earthquake, as an independent hazard, but also to the subsequent tsunami, landslide or fault displacement. Figure 8 shows the collapse of Matsurube bridge during the 2008 Iwate-Miyagi Nairiku earthquake. The abutment was displaced by the landslide due to the strong ground motion. Figures 9 and 10 show the photos of Koizumi Bridge and Utatsu Bridge taken after the 2011 Great East Japan earthquake. Koizumi Bridge had the superstructure supported by five RC bridge piers. The superstructure was displaced more than 400 m from the original position. The concrete superstructure of Utatsu Bridge was washed away. Koizumi Bridge had been retrofitted by a seismic damper to prevent the excessive superstructure response under strong excitations. Also, RC bridge piers of the Utatsu Bridge were retrofitted by jacketing to improve their capacity against the strong ground motions (Akiyama et al. 2013b). Retrofitted bridges could prevent the failures from the strong ground motion; however, they could not prevent the washout of superstructure due to a giant tsunami. For these bridges, tsunami was the dominant hazard.

Figure 11 shows Aso Bridge taken before and after the 2016 Kumamoto earthquake. Aso Bridge was constructed in 1970. The center of Aso Bridge was an arch with a simple span and continuous three-span girders on both sides. The Aso Bridge would be completely destroyed due to a huge landslide or fault displacement caused by the 2016 Kumamoto earthquake. The Aso Bridge was retrofitted before the 2016 Kumamoto earthquake; however, for this bridge, the ground motion was not the dominant hazard. Figure 12 shows Okirihata Bridge taken after the 2016 Kumamo earthquake. This bridge was designed based on the design code revised after the 1995 Hyogoken-Nanbu earthquake. Rubber bearings, including elastomeric bearings and seismic isolators, had been installed to improve the seismic performance. All rubber bearings at the abutments and three piers were ruptured. Since the landslide occurred in the mountains directly beside the bridge, this damage might have been caused by not only the ground motion but also landslide effects. Please note that the cause of the Aso Bridge and Okirihata Bridge collapses is still under investigation.

Reliability-based approach for bridges under multiple hazards considers uncertainties associated with loads, resistance and modelling. However, this approach is not able to account for the consequences incurred from bridge failure. A framework for quantifying the functionality loss of road networks involving bridges and other road structures (e.g. tunnels and embankments) is needed based on the occurrence of a main shock and subsequent cascading

Figure 10. Utatsu Bridge collapsed due to the tsunami during the 2011 Great East Japan earthquake (all photos taken by the first author)

Figure 12. Okirihata Bridge damaged due the ground motion and/or land slide (all photos taken by the first author)

hazard events (i.e., aftershocks, landslides, fault displacements or tsunamis). Constructing all structures with high-performance requirements that prevent any damage or failure due to severe earthquakes, giant tsunamis and/or huge landslides would be too expensive and impractical. A risk-based decision-making approach at the network-level needs to be developed for identifying the dominant hazard, most vulnerable structures and determining the priority of upgrade and/or repair actions.

Performance-based engineering has gained significant attention and is being used in many areas of structural engineering. Performance-based earthquake engineering has been at the frontier among natural hazards (Attary et al. 2017). This framework is based on the total probability theorem and can be disaggregated into different analysis phases that include hazard analysis, structural analysis, fragility analysis, and loss analysis. When the limit states of the structure are mutually exclusive, the probability of losses due to failure can be determined by multiplying the probability of failure by the probability of losses which is provided by (Ellingwood 2006a, b)

$$P[Loss > L] = \sum_{LS}\sum_{H} P[Loss > L|LS]\,P[LS|H]\,P[H] \quad (1)$$

$$P[Loss > L] = \sum_{LS} P[Loss > L|LS]\,P[LS|H_s] \quad (2)$$

where $P[H]$ is the probability of occurrence of hazard H, $P[LS \mid H]$ is the conditional probability of the limit state LS given the occurrence of H, $P[Loss > L \mid LS]$ is the probability of loss exceeding L given the limit state LS, and $P[LS \mid H_s]$ is the conditional probability of the limit state LS given the postulated hazard scenario.

Lounis & McAllister (2016) reported that the consequences associated with sustainability can be grouped as follows:

- Social consequences: fatalities, injuries, illnesses, psychological trauma, reputation damage, reduction/loss of service, public fear, loss of political support;
- Economic consequences: deterioration of structural system, damage to contents, loss of income, loss of productivity, delays in service delivery, user's costs; and
- Environmental consequences: irreversible environmental damage (depletion of resources, extinction) and reversible environmental damage (pollution, oxygen depletion in bays).

With regards to resilience, there may be similar social and economic consequences of failure. Additional consequences associated with resilience may include (Lounis & McAllister 2016):

- Functionality consequences: loss of community service, loss of facility use for its intended function, loss of other systems or services due to dependence on damages system; and
- Recovery consequences: time to restore system functionality results in delays and losses in restoration of

Figure 13 Debris generated by the tsunami due to the 2011 Great East Japan earthquake (photo (a) taken by the first author; and photo (b) courtesy of Dr Takahashi at Kyoto University)

Figure 14. Material deterioration observed in the field investigation after the 2011 Great East Japan earthquake (all photos taken by the first author)

other systems, costs to restore system reduce or delay funding for other services and systems.

In addition to the above consequence, the impacts of disaster waste management systems, in particular economic and social impacts, need to be investigated in terms of sustainability (Brown & Milke 2016). The environmental impacts of the disaster were substantial. For example, following the tsunami due to the 2011 Great East Japan earthquake, large areas of farmland were flooded with salty water and contaminated by sea sediments, which led to long-term soil contamination of high fertile agricultural land by metal and metalloid compounds (Portugal-Peperia & Lee 2016). As a result of the earthquake and subsequent tsunami, approximately 23 million tons of disaster debris was generated (see Figure 13), with more than 12 million m^3 of tsunami deposits left in the flooded area. The structural and geotechnical utilization of the concrete and soil fraction in the disaster debris and tsunami deposits has presented a huge challenge to engineers since (1) the clearance of debris and tsunami deposits is an urgent task which must be completed within a few years, and (2) although a large amount of waste-mixed concrete and soil can be recycled and used in the reconstruction, their properties have temporal and spatial variations (Inui et al. 2012). If poorly managed, the waste can have significant environmental and public health impacts and can affect the overall recovery process (Brown et al. 2011).

Field investigation conducted after the 2011 Great East Japan earthquake confirmed that some of RC structures and bridge steel bearings were severely deteriorated due to chloride-induced corrosion as shown in Figure 14. A life-cycle approach is needed in the risk assessment, mitigation procedure, and quantification of resilience and sustainability, because the effect of aging and environmental aggressiveness can reduce the structural performance and functionality, and it depends on the time of occurrence of the event (Biondini et al. 2015). The classical time-invariant structural design and assessment methods need to be revised to account for a proper modeling of the structural system over its entire life-cycle by taking into account the effects of deterioration process, time-variant loadings, and maintenance and repair interventions, among others (Biondini & Frangopol 2016). It is crucial to implement rational management strategies that maintain performance of bridges within acceptable levels through their life-cycle. As shown in Figure 2, life-cycle design and assessment methodology can encompass all the key concepts such as risk, resilience, sustainability, and multiple hazards learning from the past disasters. However, there is still a need to fill the gap between theory and practice by incorporating life-cycle concepts in structural design and assessment codes (Frangopol & Kim 2014, Biondini & Frangopol 2018).

As mentioned earlier, there have been many studies investigating the risk and resilience through quantitative approaches and application to case studies, among others, to bridge structures in transportation networks. They highlighted the importance of resilience for reducing the consequences of failures and

Figure 15. Rigid frame in the tsunami affected region taken after the 2011 Great East Japan earthquake (all photos taken by the first author)

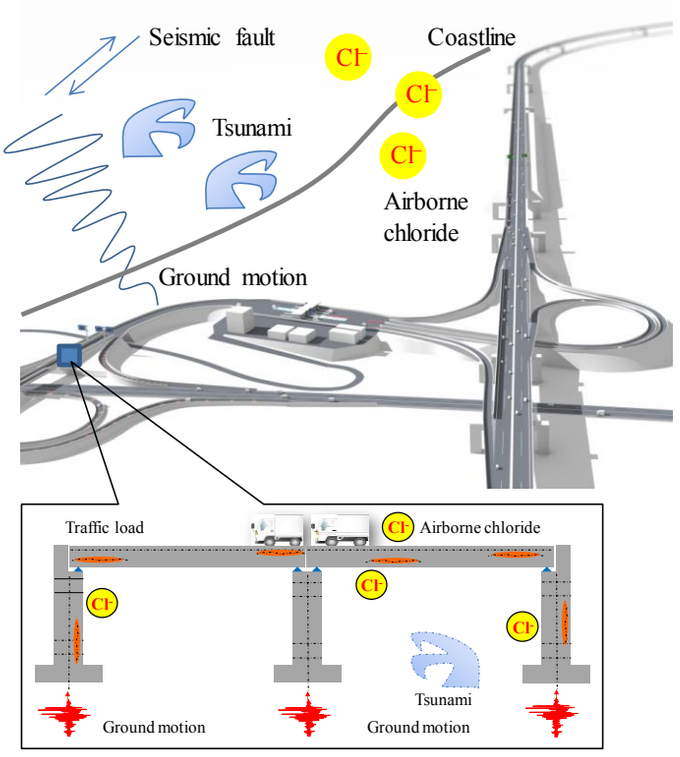

Figure 17. Bridges belonging to a network under independent and interacting hazards

enhancing serviceability subsequent to the occurrence of damage. However, the current literature is lacking studies and researches on the contribution to resilience coming from structural control. It is important to recognize that the capacity design approach is to carefully manage plastic deformations for ensuring life safety for the design event and collapse prevention for the maximum considered earthquake. Postearthquake restoration of damaged piers is challenging, time-consuming and cause traffic disruptions. Simple ductile structures are neither robust, nor do they exhibit rapidity as they are not easily repaired. Enhancing the robustness of bridge can improve the resiliency of the bridge itself and the surrounding community by reducing repair costs and downtime after an extreme event. Several interesting robust and resilient structures have been developed experimentally and computationally (Akiyama et. al. 2012c, Lehman et al. 2015, Echevarria et al. 2016, Domaneschi & Martinelli 2016, Rodgers et al. 2016, Iqbal et al. 2017, Mitoulis & Rodriguez 2017).

Compared with the conventional girder bridges, a rigid frame structure had less damage due to the effect of tsunami or landslide as shown in Figures 15 and 16. The rigid frame structure could be appropriate for the bridge under the hazards associated with tsunami and landslide. Figure 16 shows that the abutment of Aso-Choyo Bridge could not support the PC box girder after it was transversely displaced by the landslide. However, since both the superstructure and substructure were rigidly connected and behaved as a continuous unit, the severe damage to the Aso-Choyo Bridge due to this landslide was not observed. Further research is needed to investigate the robust and resilient bridges under multiple hazards.

Figure 17 shows an individual bridge and road network near a coastal line. Seismic and tsunami hazards have to be considered in the design and assessment of bridges and road structures belonging to the network. Also, bridges in the coastal area were deteriorated due to chloride-induced corrosion. When estimating the life-cycle reliability of bridges, it is important to consider the spatial distribution associated with the

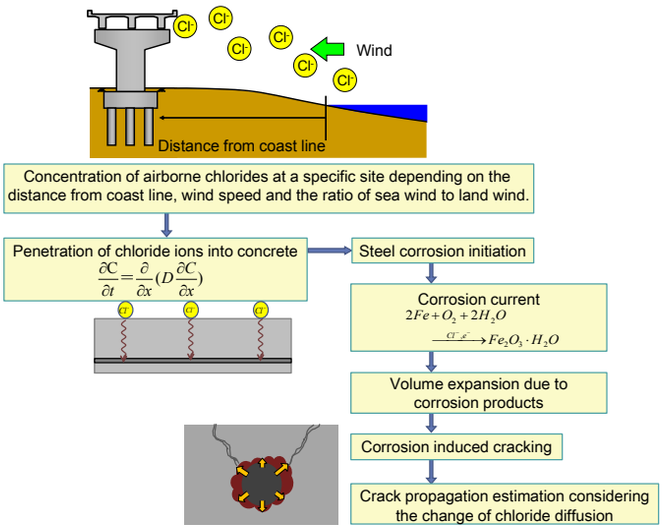

Figure 18. Flowchart for evaluating the deterioration process of RC structures in a marine environment (adapted from Akiyama et al. 2015)

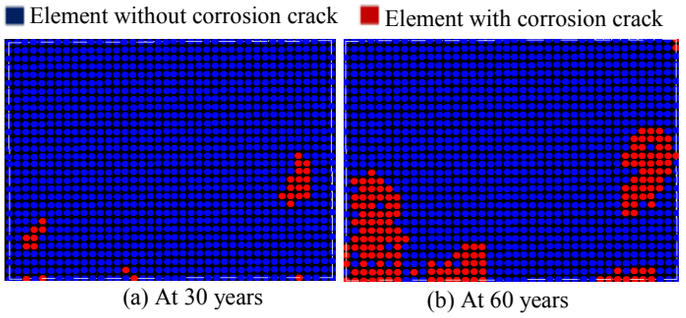
seismic intensity of ground motion, hydrodynamic features, and the amount of airborne chloride. Comparing life-cycle reliabilities among structures belonging to a network under seismic and tsunami hazards and hazards associated with continuous deterioration (such as those associated with corrosion and fatigue) is useful for identifying significant threat scenarios and for assessing and mitigating the risk associated with structural damage and collapse.

In the following sections, several challenges for enhancing the life-cycle reliability and for mitigating the risk of both single bridges and bridge networks under multiple hazards are introduced.

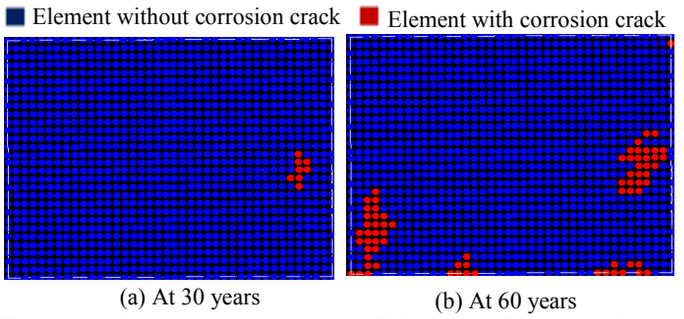
3 LIFE-CYCLE RELIABILITY OF BRIDGES UNDER INDEPENDENT HAZARDS: MECHANICAL AND ENVIRONMENTAL HAZARDS



A time-dependent model has been developed that can simulate all stages of corrosion including corrosion initiation, crack initiation and propagation (Akiyama et al. 2010, 2012d, 2017, Papakonstantinou & Shinozuka 2013). Regarding the life-cycle reliability estimation of RC structures in an aggressive environment, the exact influence of environmental factors affecting degradation mechanisms is difficult to predict as they vary in time and space. Probabilistic hazard assessment associated with environmental stressors has to be included in the life-cycle reliability analysis of RC structures. Figure 18 shows the flowchart for evaluating the degradation process of RC slab in a marine environment.

It is well recognized that the material properties of a RC structure and structural dimensions are random due to the spatial variability associated with workmanship and other factors. This randomness cause spatially corrosion damages such as corrosion cracks and cover spalling. It is of great importance to simulate deterioration processes in a stochastic field context. Modeling the spatial variability of model parameters gives one the ability not only to quantify the probability of degradation but the extent of damage as well. As an example, based on the formulations presented by Papakonstantinou & Shinozuka (2013), spatial variability associated with the random variables used in the degradation process of a RC slab is represented by a 2D Gaussian stochastic field. The power spectral density is

$$S_{f_0 f_0}(\kappa_1,\kappa_2)=\sigma^2\frac{b_1 b_2}{4\pi}\exp\left[-\left(\frac{b_1\kappa_1}{2}\right)^2-\left(\frac{b_2\kappa_2}{2}\right)^2\right] \quad (3)$$



where b_1 and b_2 are proportional to the correlation distance of the stochastic fields along the x_1 and x_2 axes, respectively. In this illustrative example, it is assumed that b_1 and b_2 are both equal to 1.0. Further research is needed to investigate how power spectral density and its parameters can be determined to represent the spatial distributions of variables used in the degradation model.

Figures 19 and 20 show examples of RC slab plan views in Niigata City and Uwajima City, respectively, and illustrates the elements with corrosion cracks from a random realization at 30 years and 60 years after the construction (Miyamoto et al. 2015). Due to the difference of airborne chloride hazard, RC slab in Niigata City has more elements with corrosion cracks. For this case study, it was simply assumed that the concrete element cracks when the tensile stresses due to the volume expansion of corrosion products reach the tensile strength of concrete. If a bridge is located in earthquake-prone region or heavy traffic route, or both, it is necessary to consider the effect of material corrosion on life-cycle structural performance considering the spatial distribution associated

(a) At 30 years (b) At 60 years

Figure 19. Cracked area patterns of RC slabs in Niigata City

(a) At 30 years (b) At 60 years

Figure 20. Cracked area patterns of RC slabs in Uwajima City

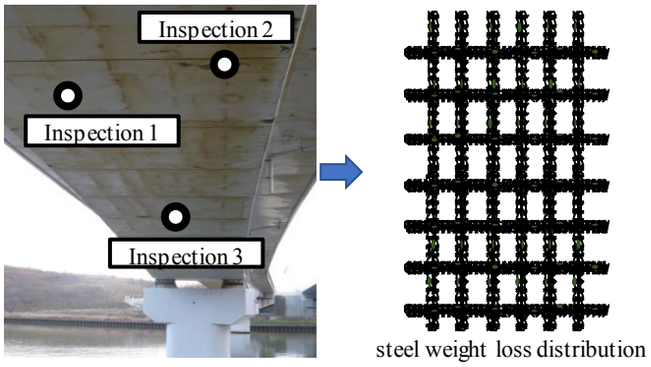


Figure 21. Estimation of steel weight loss distribution based on limited inspection results

with the material properties and mechanical stressors. Flexural and shear strength, and ductility capacity cannot be correctly estimated by using a very simple structural model (e.g. cross-section analysis using the reduced area of rebars).

Also, for existing bridges, what is actually important and difficult in their life-cycle reliability estimation is how to accurately predict the degree and location of the current material deterioration and how to adequately quantify this deterioration in terms of input data in the fragility analysis (Akiyama & Frangopol 2014, Yanweerasak, et al. 2016). As shown in Figure 21, identifying the possible spatial distribution of material corrosion over a large structure based on the limited number of inspection results and updating the life-cycle reliability are demanding and challenging problems. Owing to the uncertainties, the predicted life-cycle performance, despite how accurate or advanced the tools used to obtain this performance were, may deviate from the actual performance exhibited by the structure over time. A frequent updating of the life-cycle performance is required as new information become available (Okasha & Frangopol 2011).

In the seismic probabilistic risk assessment, the annual probability of exceedance of seismic capacity is

$$p_{fa} = \int_0^\infty -\frac{dp_0(\gamma)}{d\gamma} \cdot P\left[D_e \geq C_a \middle| \Gamma = \gamma\right] d\gamma \qquad (4)$$

where $p_0(\gamma)$ is the annual probability that the seismic intensity, Γ, at a specific site would exceed a value γ; and $P\left[D_e \geq C_a \middle| \Gamma = \gamma\right]$ is the fragility, which is the conditional probability of the seismic demand D_e exceeding the seismic capacity C_a conditioned upon the seismic intensity γ.

In the calculation of the conditional probability $P\left[D_e \geq C_a \middle| \Gamma = \gamma\right]$ of bridge piers in a marine environment, the effect of corrosion has to be taken into consideration. The demand depends on the results of seismic hazard assessment; however, the seismic capacity depends on the results of hazard associated with airborne chlorides. As the steel weight loss of rebars increases, the seismic capacity decreases. Using the total probability theorem, the annual probability of exceedance of seismic capacity C_a under earthquake excitation at t years after construction can be expressed as

$$p_{fa}(t) = \int_0^{100} \int_0^\infty -\frac{dp_0(\gamma)}{d\gamma} \cdot P\left[D_e \geq C_a \middle| \Gamma = \gamma, C_w = c_w(t)\right] \cdot f\left(c_w(t)\right) d\gamma \, dc_w \qquad (5)$$

where $P\left[D_e \geq C_a \middle| \Gamma = \gamma, C_w = c_w(t)\right]$ is the probability of the seismic demand D_e exceeding the seismic capacity C_a conditioned upon the seismic intensity γ and steel weight loss $c_w(t)$; and $f(c_w(t))$ is the probability density function (PDF) of $c_w(t)$.

Based on the comparison of the experimental and computational results of corroded RC columns subjected to cyclic loading, Akiyama et al. (2011) confirmed that the accuracy of the results of corroded columns is approximately the same as that of noncorroded columns. To ensure the computational accuracy of δ_u as shown in Figure 22, the average steel weight loss in the plastic hinge of a RC bridge pier must be estimated correctly.

For an existing RC bridge pier, this could be estimated based on the discrete inspection results associated with the steel weight loss. Yanweerasak et al. (2016) presented a procedure for estimating the mean and variance of steel weight loss in the plastic hinge of corroded RC structures based on inspection results. Variance of steel weight loss depends on the number and space interval of inspection locations based on the statistical estimation error process (Honjo & Otake 2013). The variance is used as the observation noise during the updating process. $P\left[D_e \geq C_a \middle| \Gamma = \gamma, C_w = c_w(t)\right]$

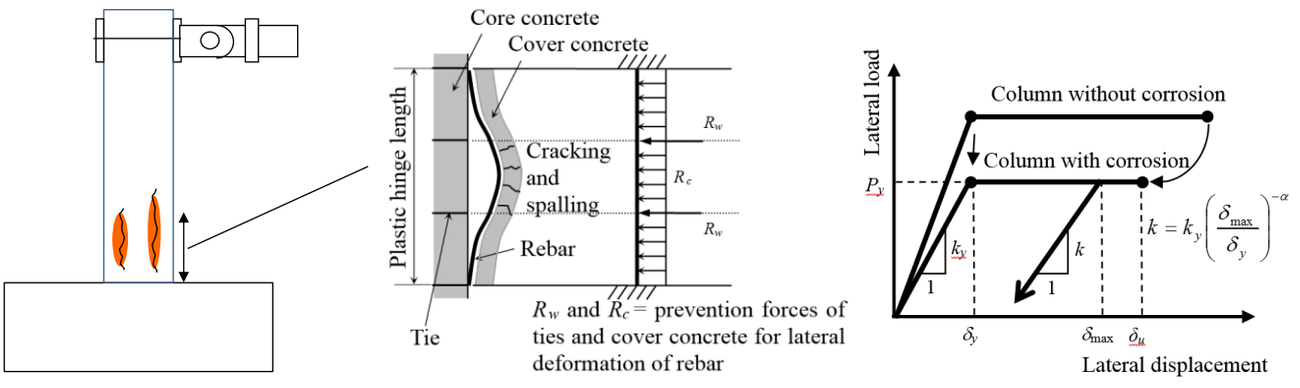

Figure 22. Buckling model of a longitudinal rebar in the plastic hinge of corroded RC column subjected to cyclic loading

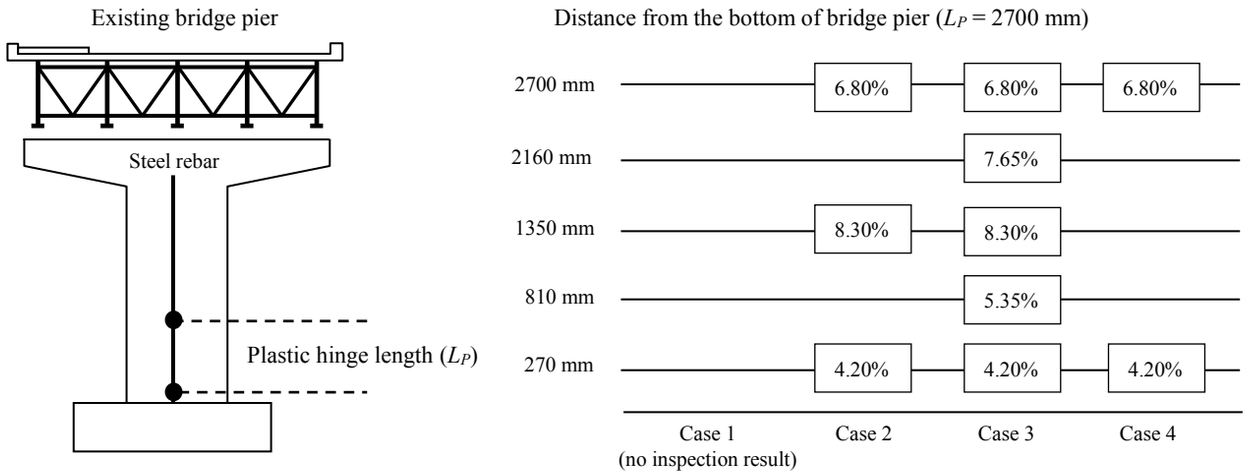

Figure 23. Assumed location of the steel weight loss measurements in the plastic hinge

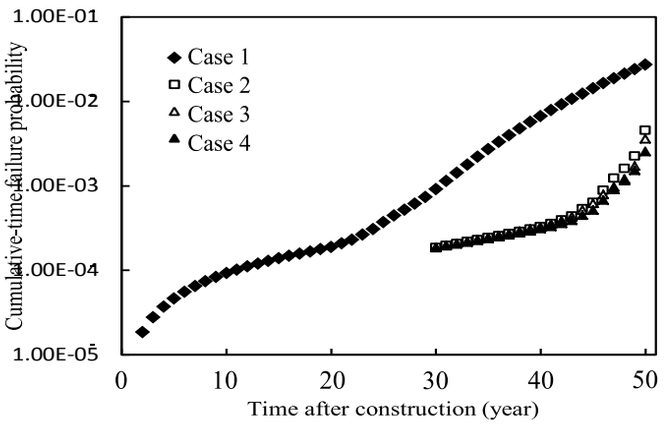

Figure 24. Relationship between the cumulative-time failure probability and the time after construction (years)

in Equation 5 is estimated using the updated random variables.

As an illustrative example, the locations of the steel weight loss measurements are assumed as shown in Figure 23. The simple average is almost the same among Cases 2, 3 and 4, but, the number of inspection points are different. Figure 24 shows the updated cumulative-time failure probability based on the inspection data using Sequential Monte Carlo Simulation (SMCS) (Akiyama et al. 2010). The cumulative-time failure probabilities of Cases 2, 3 and 4 at year 30 are smaller compared with that of Case 1. From Figure 24, although the cumulative-time failure probabilities are nearly identical for Cases 2, 3 and 4 because the magnitudes of steel weight loss from the inspection results are almost identical, a significant difference in the correlation among random variables can be confirmed. Figure 25 shows the correlations between x_3 and x_5 using 100,000 samples of SMCS, where x_3 and x_5 are random variables associated with airborne chloride and surface chloride concentration relation, and associated with estimation by diffusion equation, respectively. Before updating, the random variables are assumed statistically independent. After updating, all random variables related with the prediction of the steel weight loss were updated simultaneously by SMCS. These results illustrate that, as expected, having more inspection locations can provide a more accurate reliability assessment.

For a RC bridge pier subjected to the cyclic loading, the plastic hinge is formed at the bottom of the pier. The ductility capacity depends strongly on the corrosion level of plastic hinge. Meanwhile, it's difficult to identify the possible failure region of corroded concrete girder subjected to traffic load. The severity of damage due to corrosion of RC structures primarily

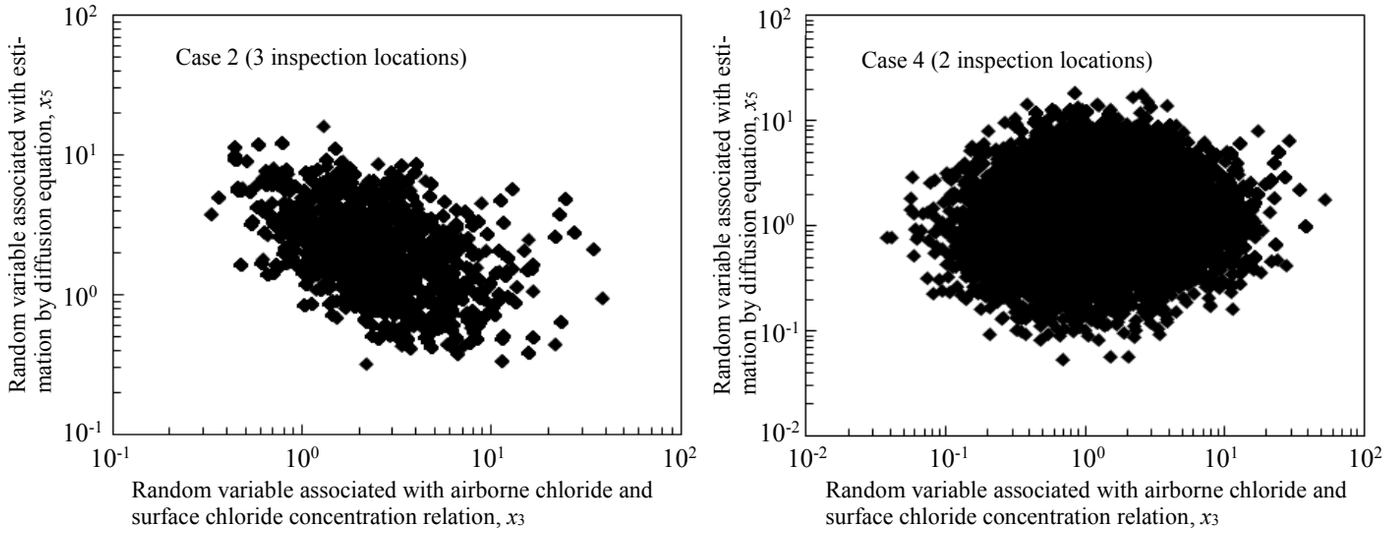

Figure 25. Effect of the number of inspection locations on the variability associated with random variables used in the prediction of steel weight loss (adapted from Yanweerasak et al. 2016)

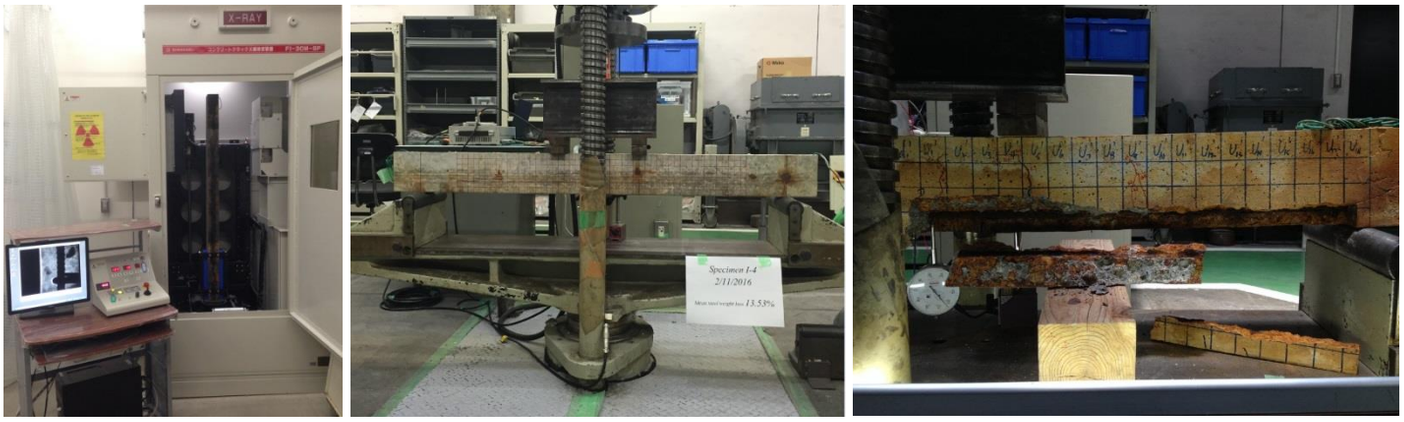

Figure 26. X-ray machine at Waseda University to visualize the corroded rebars embedded in the concrete beam

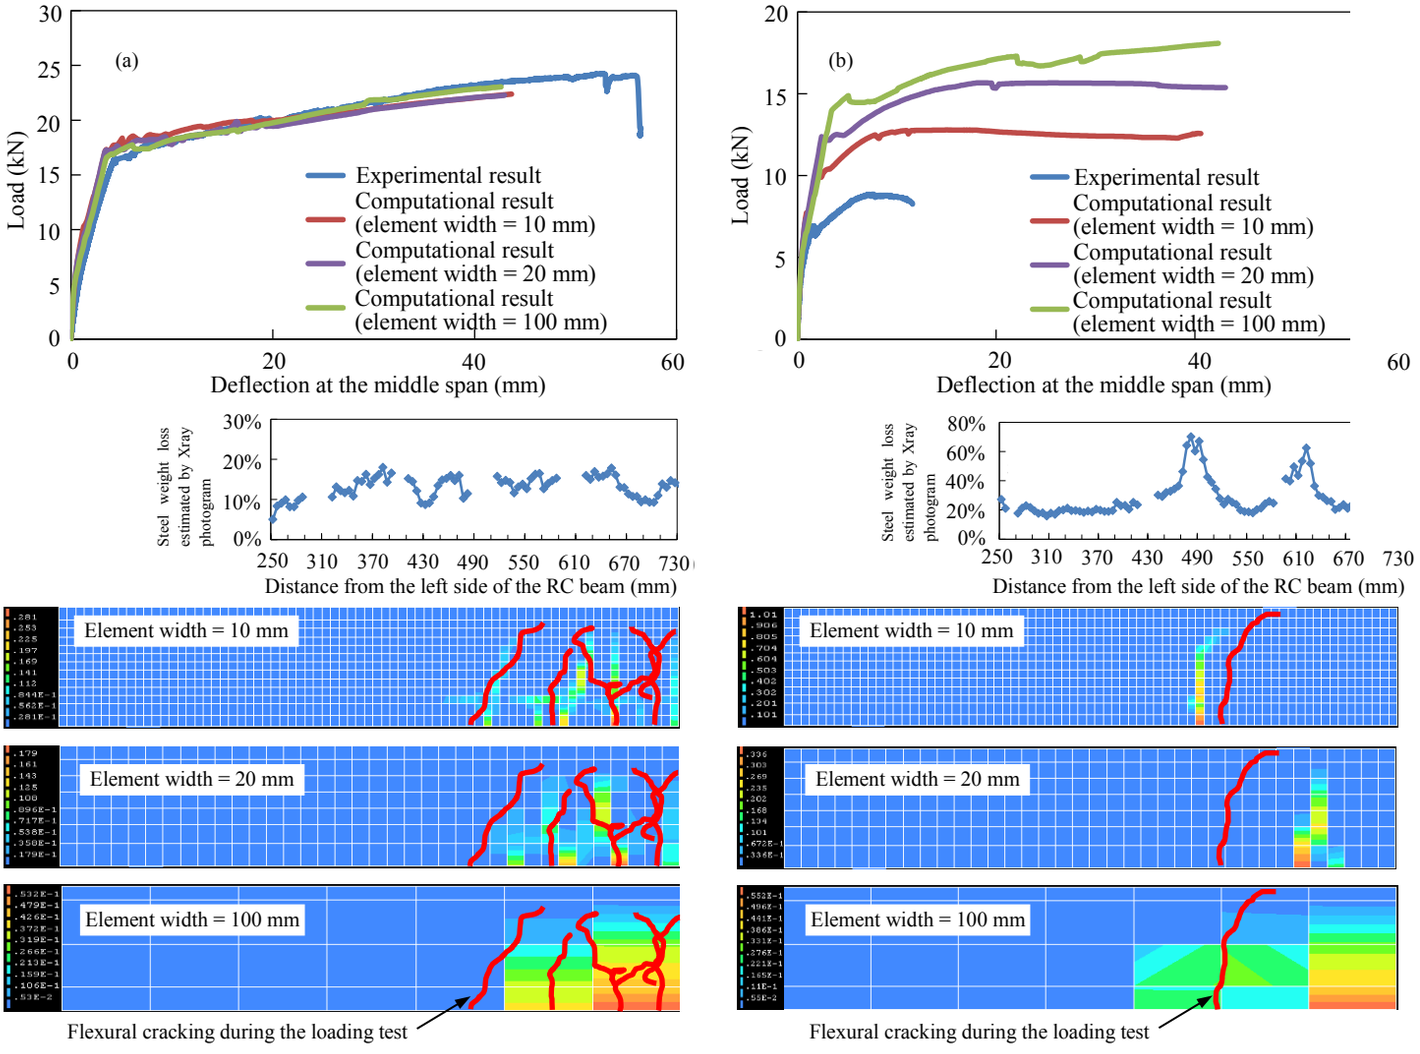

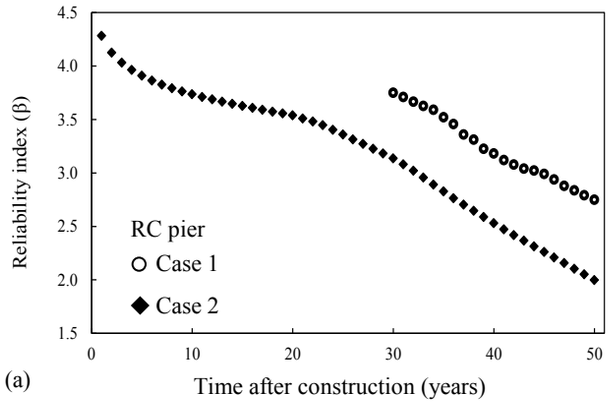

Figure 27. Effect of element size in FE model on the computational results of corroded RC beam: (a) average steel weight loss over RC beam = 12.1%; and (b) average steel weight loss over RC beam = 25.5%

depends on the magnitude and location of the steel corrosion. Spatial distribution associated with the material corrosion in concrete girder has to be investigated.

To understand the steel corrosion growth process and the change in the spatial variability of steel corrosion with time, continuous monitoring is necessary. X-ray photography has been applied to observe steel corrosion in RC beams (Akiyama & Frangopol 2014, Lim et al. 2016, 2017). They estimated the steel weight loss by the digital image processing of the X-ray photograms. The nonuniform distribution of steel weight loss along rebars inside RC beams determined using X-ray radiography and its correlation with longitudinal crack widths and loading capacity were experimentally investigated (see Figure 26). A finite element (FE) analysis method has been used to simulate the structural responses of the corroded beams when considering two different inputs (i.e., uniform and non-uniform cross-sectional area of rebars over the beam). Comparing the numerical results of the flexural responses of the simulated beams to those of the test beams in the experimental study, the effect of mesh size on the accuracy of the FE model was investigated.

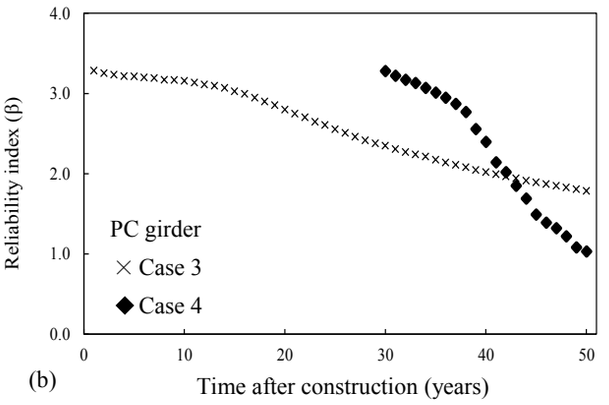

Figure 28. Life-cycle reliabilities: (a) RC pier; and (b) PC girder

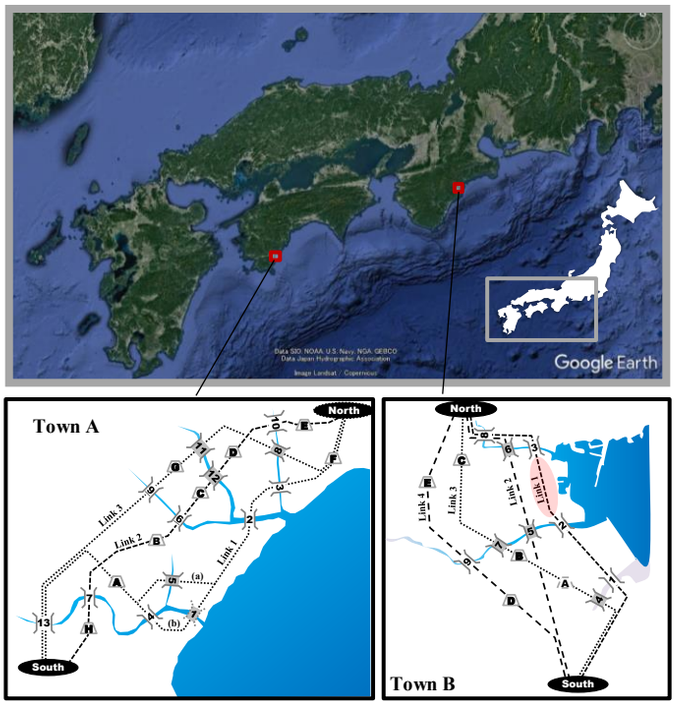

Figure 29. Example of road network affected by the anticipated Nankai Trough earthquake

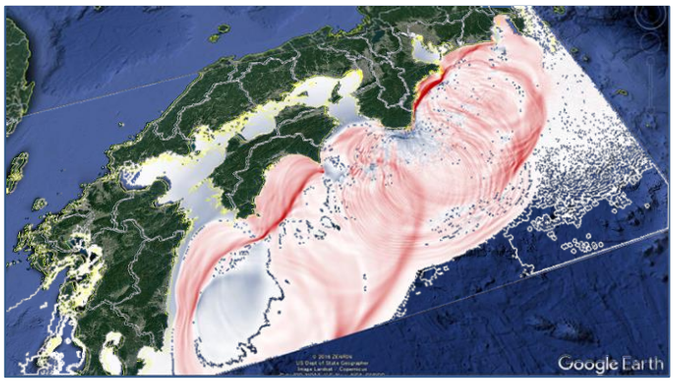

Figure 30. Propagation analysis of tsunami caused by the anticipated Nankai Trough earthquake

Figure 27 shows the comparison of computational and experimental results of the relationship between load and deflection, and the comparison of contour of the principal tensile strain obtained from the FE analysis, flexural cracking caused during the bending test, and steel weight loss. Average steel weight losses over RC beam shown in Figures 27 (a) and (b) are 12.1 % and 25.5%, respectively. As shown in Figure 27, when the spatial distribution of steel weight loss seems to be more uniform, the effect of mesh size on the computational results can be ignored. However, when the spatial variability becomes larger, the computational results depend on the mesh size. Spatial distributions associated with the bond properties and internal and external cracks due the volume expansion of corrosion products are not considered in the computational results shown in Figure 27. More studies on this topic are needed for further improvements in FE modeling.

Figure 28 shows the comparison of life-cycle reliability of bridge pier under seismic and airborne chloride hazards with that of bridge girder under traffic load and airborne chloride hazards. Comparing life-cycle reliabilities among the bridge components under multiple hazards can make the determination of the priority of intervention actions possible.

4 LIFE-CYCLE RELIABILITY OF BRIDGES UNDER INTERACTING HAZARDS: SEISMIC AND TSUNAMI HAZARDS

Frameworks for multihazard risk assessment have been reported in the literature as described earlier. Tsunami intensity is correlated with the magnitude of the oceanic earthquake, and a bridge may have severe damage due to the strong ground motion before the tsunami arrives. Difficulties in estimating the reliability of bridges under tsunami hazards are similar to those associated with bridges under aftershocks. Strong aftershocks have the potential to cause extensive structural damage. Damaged structures due to mainshock are even more susceptible to incremental damage due to aftershocks because their reduced structural capacity decreases the threshold of the ground motion intensity needed to cause further damage.

Yeo and Cornell (2005) divided the seismic performance assessment and design process into simpler components in terms of the description, definition and quantification of earthquake intensity measures (*IM*s), engineering demand parameters (*EDP*s), damage measures (*DM*s) and decision variables (*DV*s). Commonly used examples of the above parameters are peak ground acceleration (PGA) and first-mode

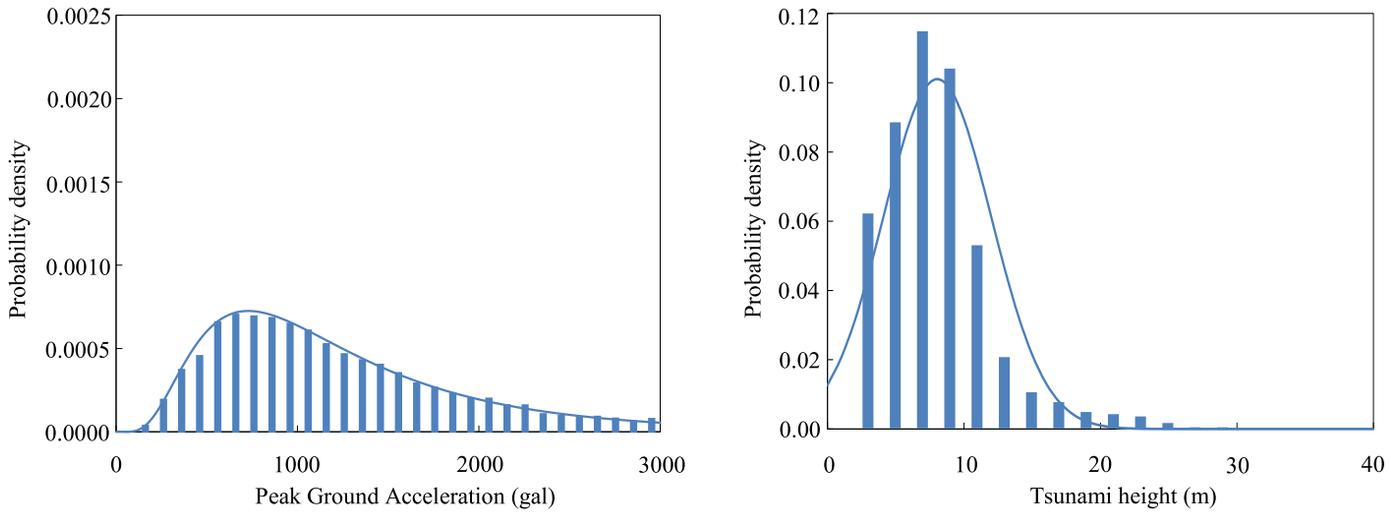

Figure 31. Example of probability densities of peak ground acceleration and tsunami height at the Town A in Figure 29

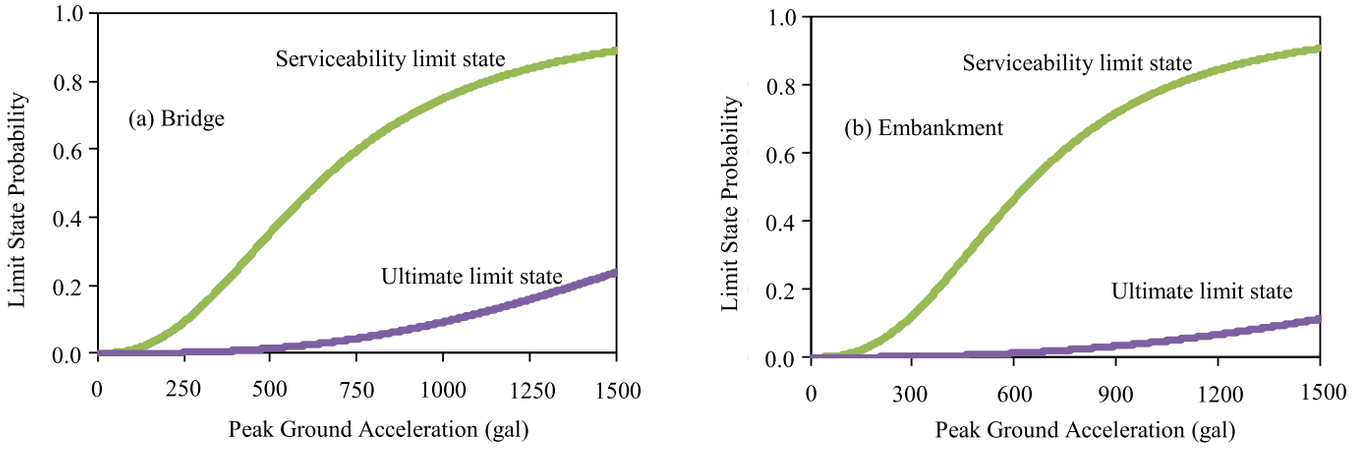

Figure 32. Example of seismic fragility curves of bridge and embankment associated with the serviceability and ultimate limit states

spectral acceleration (*IM*s), interstory drift ratios, inelastic component deformations and floor acceleration spectra (*EDP*s), damage states of structural and nonstructural elements (*DM*s) and fatalities, financial losses and downtimes (*DV*s). Based on the total probability theorem, the mean annual rate $v(DV)$ of exceeding a given level of $DV = x$, is (Yeo and Cornell 2005)

$$\upsilon(DV) = \iiint G\left(DV|DM\right) dG\left(DM|EDP\right) dG\left(EDP|IM\right)\left| d\lambda\left(IM\right)\right| \qquad (6)$$

where λ (IM) is the mean annual rate of exceeding a given IM and is obtained from a conventional probabilistic hazard analysis. $G(EDP|IM)$ is the complement of the cumulative distribution function of EDP conditioned by a given level of IM (i.e., $G(EDP|IM) = P[EDP \geq y|IM = x]$ while in the continuous case $G(EDP|IM) = f_{EDP|IM}(y|x)dy$ is the conditional probability density function times dy).

Based on Equation 6, Yeo and Cornell (2005) discussed the reliability of structures under aftershock hazard. If a structure had the mainshock with the intensity MI and damage state SI due to the mainshock, the mean rate exceeding a given DV in post-mainshock time interval $[0, t_{max}]$ is (Yeo and Cornell 2005)

$$\upsilon_a^{t_{\max}}\left(DV \mid MI, SI\right) = \int_{DM}\int_{EDP}\int_{IM}\sum_{i} G_a(DV \mid DM, i)\, dG_a(DM \mid EDP, i)\, dG_a(EDP \mid IM, i)\, d\lambda_a^{t_{nax}}\left(IM, i \mid MI\right) dG_a(i \mid MI, SI) \qquad (7)$$

where the subscript a refers to the aftershock environment, $\lambda^{tmax}{}_a$ is the mean number of aftershocks exceeding a given IM in post-mainshock time interval, and $G_a(i|MI, SI)$ is the probability that the structure is in damage state i after the mainshock given MI and SI. The inclusion of $G_a(i|MI, SI)$ means an additional integral over all possible post-mainshock damage states i.

Equation 7 can be used for estimating the reliability of bridges under tsunami hazards. IM could be the hydrodynamic features such as tsunami wave velocity and height, and EDP and DM could be the tsunami demands and structural damage states due to the tsunami in the estimation of dG_a in Equation 7. In addition, if reliability will be estimated given the occurrence of the earthquake, Equations 6 and 7 can be simplified because it is not necessary to consider the earthquake occurrence rate.

It is expected that the damage and the economic loss resulting from the anticipated Nankai Trough earthquake and its associated tsunami would be larger

Table 1 Failure probability of the bridge and embankment at the Town B in Figure 29

Extreme Event	Bridge			Embankment		
	2	5	9	A	B	E
Ground motion	0.106	0.106	0.106	0.157	0.157	0.157
Tsunami	0.648	0.629	0.573	0.857	0.742	0.157

than those resulting from the 2011 Great East Japan earthquake. As an illustrative example, reliabilities, life-cycle cost and recovery time of road networks including bridges and embankments in Town A in Kochi-Prefecture and Town B in Mie-Prefecture under both seismic and tsunami hazards due to the anticipated Nankai trough earthquake are computed. Figure 29 shows the schematic layouts of the investigated network. The parameters associated with the fault movement caused by the anticipated Nankai trough earthquake are determined based on Central Disaster Management Council (2003).

It is difficult to evaluate the exact fault movement during the seismic event since uncertainties associated with fault movement vary in time and space. The average stress drop at the seismic fault is assumed to be random. Seismic intensity at the bridge site given seismic event is estimated by the attenuation relation. In this case study, the PDF of the PGA given the occurrence of the anticipated Nankai Trough earthquake is calculated. Figure 30 shows an example of tsunami propagation computation to obtain the PDF of the tsunami wave height and velocity at the locations of bridges and embankments analyzed. Horizontal 2D tsunami analysis based on non-linear long-wave theory (Goto et al. 1997) is performed in this simulation. The PDF is calculated by Monte Carlo Simulation (MCS) using the random variables associated with the seismic fault and considering the difference of roughness coefficient among the locations of interest.

Figure 31 shows an example of probability densities of PGA and tsunami height at the Town A in Figure 29. Also, Figure 32 shows the seismic fragility curves of bridge and embankment for the serviceability and ultimate limit states.

The PDF of the hydrodynamic forces given the tsunami height can be identified based on MCS. Then, the hydrodynamic horizontal and uplift forces are applied to bridges. When estimating the tsunami fragility of bridges, a push-over analysis using hydrodynamic forces given tsunami height is performed to compare the tsunami capacity with the tsunami demand. Tsunami fragility of embankments can be estimated by comparing the heights of embankment and tsunami.

Table 1 lists the failure probabilities of Bridge 2, Bridge 3, Bridge 9, Embankment A, Embankment B, and Embankment C at the Town B shown in Figure 29. It can be confirmed that the failure probabilities of bridges due to tsunami decrease with the distance from the coastline. As listed in Table 1, the seismic and tsunami reliabilities depend on the locations of bridge and embankment in the road network. When the structure is located near the coast line, the failure probabilities need to be estimated considering the effect of both seismic and tsunami hazards on the structural performance.

The ground motion induced- and/or tsunami induced damage to bridges cause the deterioration of the post-disaster road network functionality. The

Table 2 Damage state and residual percentage relation (after Guo et al. 2017)

Damage State	*LDI*	Residual Percentage (%)	
		Traffic-carrying capacity	Free-flow speed
None	$0 \le LDI < 0.5$	100	100
Slight	$0.5 \le LDI < 1.0$	100	75
Moderate	$1.0 \le LDI < 1.5$	75	50
Excessive	$1.5 \le LDI < \infty$	50	50
Complete	∞	0	0

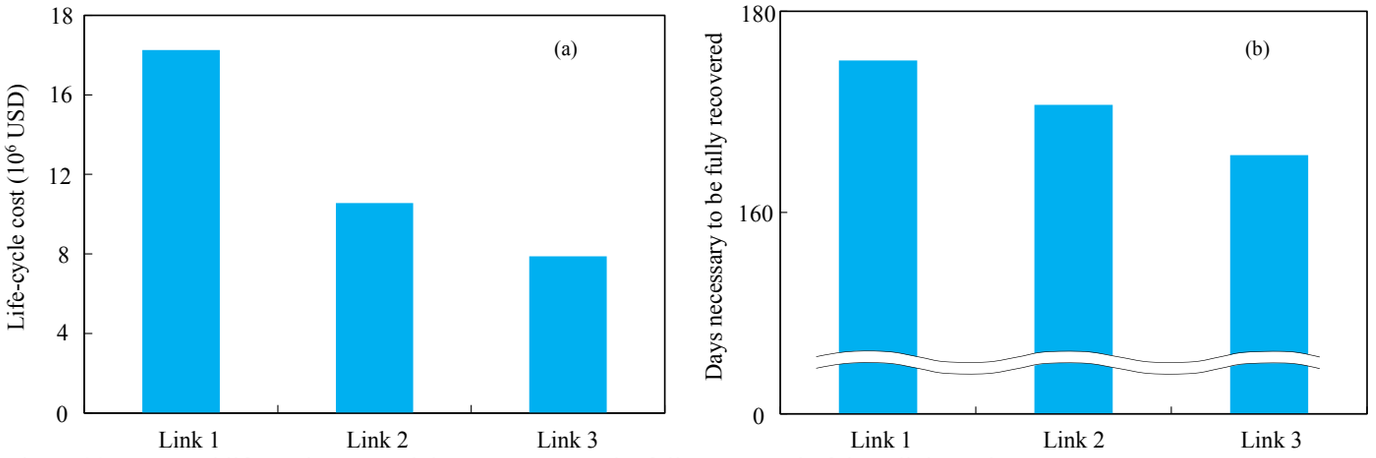

Figure 33. Expected life-cycle cost and days necessary to be fully recovered of three links at the Town B

damaged bridges can be open, closed or partially open within a bridge network. Consequently, traffic flow in the links can be different and speed limits might be reduced for various damage conditions of the link (Frangopol et al. 2017). As there may be several bridges located on the link, the damage state of each bridge can affect the functionality of the investigated link. The performance of a link after an earthquake can be expressed in terms of link damage index (*LDI*) provided by (Chang et al. 2002)

$$LDI(t) = \sqrt{\sum_{j=1}^{n} BDI_j((t))^2} \tag{8}$$

where n is the number of the bridges located in the link, and BDI_j is the expected damage index of bridge j.

After earthquakes, the damage states of individual bridges are generally divided into five levels: none, slight, moderate, extensive and complete damage states. The damage states with these linguistic descriptions are quantified by the bridge damage index (*BDI*) with discrete values of 0, 0.10, 0.25, 0.75 and 1, respectively. A value of 0 corresponds to no damage, while 1 corresponds to the complete collapse of the bridge. The none, slight, moderate and major damage states are associated with $LDI \leq 0.5$, $0.5 < LDI \leq 1.0$, $1.0 < LDI \leq 1.5$, and $LDI > 1.5$, respectively (Chang et al., 2000). The increase in the damage state of the link will reduce the link traffic capacity and speed limit. In this case study, the relationship between damage state and residual percentage of traffic-carrying capacity and free-flow speed listed in Table 2 (Guo et al. 2017) was used.

Figures 33(a) and 33(b) show, respectively, the expected life-cycle cost and days necessary to be fully recovered from the event of three links, Link 1, Link 2 and Link 3 at the Town B. As shown in Figure 29, the bridges and embankments belonging to Link 1 have higher failure probabilities, implying higher life-cycle cost and days necessary to be fully recovered, because both ground motion and tsunami can cause the damage to structures. Reliability and risk approaches are useful to identify the dominant hazard and most vulnerable structure, and to make the decision on the priority for upgrade and/or repair actions.

5 CONCLUSIONS

This keynote paper overviewed the progress of structural design methodology from the deterministic allowable stress design method toward the life-cycle-based design and assessment of bridges and bridge networks under multiple hazards. Field investigations after recent large earthquakes in Japan confirmed that several bridges were severely damaged and collapsed not only due to the earthquake, as an independent hazard, but also to the subsequent tsunami, landslide or fault displacement. In addition, the collapse of as-build bridges over highways prevented the traffic passage. Even if the bridge has no damage during the seismic event, damage to embankment can deteriorate the functionality of the post-disaster road network. A probabilistic life-cycle framework for quantifying the functionality loss of road networks involving bridges and other road structures is needed for the occurrence of a main shock and subsequent cascading hazard events. A risk-based decision-making approach at the network-level is necessary for identifying the dominant hazard and vulnerable structures requiring the strengthening and retrofit.

Because the transportation networks play important roles for the evacuation of affected people and the transportation of emergency goods and materials, it is necessary to recover the functionality of these networks as soon as possible after a severe natural disaster. To quantify the promptness of the restoration, it has become customary to use the concept of resilience. In addition, the economic, environmental and social impacts of disaster waste management systems need to be investigated in terms of sustainability. If the disaster waste is poorly managed, this can have significant environmental and public health impacts and can affect the overall recovery process. Consequences associated with the resilience and sustainability must be studied and implemented into the risk estimation of bridge network under multiple hazards. Life-cycle design and assessment methodology can encompass all the key concepts such as risk, resilience, sustainability, and multiple hazards learning from the past disaster lessons.

Finally, the concepts and methods presented are illustrated on both single bridges and bridge networks with an emphasis on earthquake, tsunami and continuous deterioration. Further research is needed to enhance the framework for estimating the reliability and risk of bridges under interacting hazards. Specifically, the integration of bridge performance under multiple independent or interacting hazards in a comprehensive life-cycle infrastructure network in terms of performance, management and optimization under uncertainty (Frangopol 2011, Frangopol & Soliman 2016) must be investigated.

ACKNOWLEDGEMENTS

The authors express sincere appreciation to Dr. Masayuki Yoshimi, National Institute of Advanced Industrial Science and Technology of Japan, for his suggestions related to seismic fault parameters. The authors also thank Prof. Shunichi Koshimura at Tohoku University for many suggestions on the topic of tsunami propagation analysis. Special appreciation is extended to Dr. Sopokhem Lim and Mr. Kengo Nanami at Waseda University. This work was supported by JSPS KAKENHI Grant Number JP 16H02357 and 16KK0152 and the Institute for

Research on Safety and Security of Greater Tokyo. The support by grants from U.S. National Science Foundation Award CMMI-1537926 and the U.S. Federal Highway Administration Cooperative Agreement Award DTFH61-07-H-00040 is also gratefully acknowledged.

The opinions and conclusions presented in this paper are only those of the authors.

Assessment of the dynamic behaviour of railway bridges for high-speed traffic

R. Calçada
University of Porto – Faculty of Engineering, Porto, Portugal

ABSTRACT: To make a rigorous analysis of the dynamic behaviour of railway bridges a method for 3D analysis of the train-structure dynamic interaction, developed by the centre of competence in railways of the Faculty of Engineering of the University of Porto (CSF-FEUP), is described. Subsequently, several case studies developed by CSF-FEUP are presented, showing the efficiency and the usefulness of the developed method and enabling the achievement of different objectives, such as: i) the running safety assessment of trains moving over long bridges subjected to earthquake actions; ii) the track stability and wheel-rail contact stability safety assessment on short span railway bridges; iii) the running safety assessment of trains for settlement of the backfill at transition zones to railway bridges.

1 INTRODUCTION

In railway bridges the dynamic effects induced by high speed traffic can be very significant due to the rapid rate of loading, the passage of successive loads with uniform spacing which can create resonance and the variations in wheel loads resulting from track irregularities. The assessment of these dynamic effects is of the utmost importance because excessive vibrations and deformations can endanger traffic by creating unacceptable changes in track geometry, can lead to ballast instability, unacceptable reductions in wheel-rail contact forces and create conditions which cause passenger discomfort. The dynamic effects induced by the simultaneous action of traffic and earthquakes loads should also be considered in some scenarios. Transitions to railway bridges are zones where significant dynamic effects also occur due to the rapid degradation of the track, mostly due to the development of settlements in the backfill.

In this lecture an accurate, efficient and robust algorithm to analyse the vehicle structure dynamic interaction, is described. The formulation takes into account the vertical and lateral dynamic interaction between railway vehicles and structures. Most of the existing methods treat the contact forces in the normal and tangential directions as external forces, whereas the proposed formulation uses a finite element to model the behaviour in the contact interface. The formulation is divided into three main parts: the geometric problem, consisting of the detection of the contact points; the normal contact problem, in which the forces are determined based on the Hertz nonlinear theory; the tangential contact problem, in which the creep forces, that appear due to the rolling friction contact, are calculated. The proposed method is based on the finite element method, which allows the analysis of structures and vehicles with any degree of complexity and the consideration of the deformations undergone by the two systems.

The method is applied to study the running safety of a railway vehicle moving over a viaduct subjected to earthquakes. The viaduct is based on an existing flyover type structure of the Portuguese railway network composed by simply supported box girders. The influence of the seismic intensity, track irregularities and train speed in the train running safety is evaluated. Unlike the majority of the studies in this field, in which the earthquake is assumed to start at the instant the train enters the bridge, the randomness of the earthquake has been accounted for by considering different time offsets between the beginning of the excitation and the entry of the vehicle in the viaduct. Furthermore, four levels of seismic intensity and two levels of track quality have been considered in the study. Regarding the seismic loads, artificial accelerograms have been generated from the elastic spectra described in Eurocode 8 Part 1 (CEN, 1998) with peak ground accelerations corresponding to moderate events with return periods less than 475 years, which is the reference return period of the design seismic action associated with the no collapse requirement. Since no significant nonlinearity is likely to be exhibited in the columns for these levels of seismicity, all the analysis have been per-

formed in the elastic domain with a reduction in the stiffness of the columns to account for the concrete cracking. The track irregularities have been also generated based on analytical power spectral density functions. The running safety of the train is evaluated based on the safety criteria existent in the literature, such as Nadal, Prud'homme and wheel unloading criteria.

The method is also applied in a probabilistic study to understand how the variability of the train, track and bridge parameters affects the dynamic behaviour of a short span bridge. Since the limit state functions are extremely complex when a large number of variables are considered, simulation techniques were applied. Simulations techniques allow a large number of experiments to be performed, taking into account the real variability of the train-track-bridge system parameters. A bridge with six simply supported spans of 12 m each was selected as case study. The accelerations at several points of the span and the wheel-rail contact forces were analysed for several hypothetical scenarios. The Monte Carlo method will allow the evaluation of how the dynamic response of the train-bridge system is affected by changes in its properties and which variables play the most important role in the dynamic behaviour. Besides determining which variables are the most important for the dynamic response, a safety assessment of the bridge, based on the simulation results, was also performed in order to establish train speed limits on the bridge.

The method is also applied to develop a more efficient and robust numerical approach to study the effect of differential settlements on the dynamic train-track interaction. In addition, the numerical approach is innovative in that in takes into account: i) all the relevant components of the track, bridge and backfill; ii) the train model with primary and secondary suspensions; iii) the train-track interaction at the wheel-rail interface and between the sleepers and the ballast layer – a fundamental aspects to account for the development of hanging sleepers and the negative effects in the dynamic train-track interaction; iv) a previous calibration and validation procedure that used extensive field measurements obtained in the track, presented in earlier studies (Alves Ribeiro et al. 2014; Paixão et al. 2014; Paixão et al. 2015a); v) realistic longitudinal level profiles of the track that resulted from settlement profiles (based on earlier studies (Schooleman 1996; England et al. 2000; Kempfert & Stadel, 2000; Luomala & Nurmikolu, 2012; Abu-Farsakh & Chen, 2014) imposed on the track.

Within the scope of a research project on transition zones, the authors have used an earlier version of this model, which proved to be very accurate for simulating the dynamic behaviour of the train-track system at a transition zone to a bridge in a Portuguese railway line (Paixão et al., 2014). That study comprised an extensive validation of the model using field measurements, but it did not address the topic of differential settlements. As a result of that work, the model was adapted to assess the influence of the shape and amplitude of the settlement profiles of the backfill, thus contributing to a better understanding of the dynamic behaviour of the train-track system at transition zones.

2 TRAIN-STRUCTURE DYNAMIC INTERACTION

2.1 *Introduction*

The wheel-rail contact model and the vehicle-structure coupling method used for the 3D analysis of the train-structure dynamic interaction are described. The wheel rail contact model is divided into three main parts: 1) the geometric problem, consisting of the detection of the contact points; 2) the normal contact problem, in which the forces are determined based on the Hertz nonlinear theory; 3) the tangential contact problem, in which the creep forces, that appear due to the rolling friction contact, are calculated. The vehicle-structure coupling formulation is based on the finite element method, which allows the analysis of structures and vehicles with any degree of complexity and the consideration of the deformations undergone by the two systems.

2.2 *Wheel-rail contact model*

The wheel-rail contact model is the key point of the train-structure interaction method, since the position of the contact point between wheel and rail significantly influence the contact forces and, consequently, the behaviour of the vehicle moving over the structure. The model is based on a contact finite element developed specifically for this purpose that takes into account the behaviour in the contact interface and guarantees the coupling between the vehicle and structure when contact occurs (see Neves et al. 2012; Neves et al. 2014; Montenegro et al. 2015 and Montenegro et al. 2016 for details). The contact formulation of the element consists of the geometric problem, the normal contact problem and the tangential contact problem, which are described in Sections 2.2.1 to 2.2.3, respectively.

2.2.1 *Geometric contact problem*

The geometric contact problem consists of determining the location of the contact points between wheel and rail. In order to do this, the wheel and rail profile surfaces are first parameterized as a function of two surface parameters that define its geometry. Then, the location of the potential contact points is determined online during each step of the dynamic analy-

sis using the following set of nonlinear equations (see Fig. 1).

$$\begin{cases} \mathbf{t}^t_{r,y} \cdot \mathbf{d}^t_{wr} = 0 \\ \mathbf{t}^t_{w,y} \cdot \mathbf{n}^t_r = 0 \end{cases} \tag{1}$$

where $\mathbf{t}^t_{r,y}$ and $\mathbf{t}^t_{w,y}$ are the tangent vectors to the rail and wheel surfaces, respectively, at the potential contact point along the lateral direction, $\mathbf{n}^t_r$ is the normal vector to the rail surface at the same point and $\mathbf{d}^t_{wr}$ is the vector that defines the relative position of the potential contact point of the wheel with respect to the potential contact point of the rail, given by

$$\mathbf{d}^t_{wr} = \mathbf{u}^t_W - \mathbf{u}^t_R \tag{2}$$

where $\mathbf{u}^t_W$ and $\mathbf{u}^t_R$ are the positions of the potential contact points of the wheel and rail, respectively. The superscripts *t* indicate that the vectors are defined with respect to the target element coordinate system presented in Montenegro et al. (2015). The first condition described by Eq. (1) ensures that the tangent vector to the rail is perpendicular to the vector defining the relative position of the point of the wheel with respect to the point of the rail. The second condition ensures that the normal vector to the rail is perpendicular to the tangent vector to the wheel, as shown in Fig. 1.

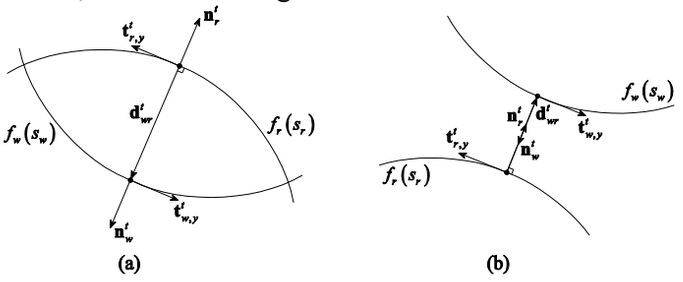

Figure 1. Potential contact points between the two surfaces: (a) actual contact and (b) no contact.

It is important to notice that the system of equations (1) may have multiple solutions if one of the contact surfaces is not convex. Therefore, the concave region in the transition zone between the tread and flange is neglected, and an approximation to the surface is adopted.

The potential contact points determined with the procedure described above have to fulfil a last condition, that is, the parametric surfaces have to intersect each other. As shown in Fig. 1b, the conditions described in Eq. (1) are satisfied but there is no contact. This condition can be expressed mathematically as

$$\mathbf{d}^t_{wr} \cdot \mathbf{n}^t_r \leq 0 \tag{3}$$

which means that the intersection between two bodies is guaranteed only if the vectors $\mathbf{d}^t_{wr}$ and $\mathbf{n}^t_r$ point in opposite directions, as depicted in Fig. 1a. The penetration *d* is given by

$$d = \left\| \mathbf{d}^t_{wr} \right\| \tag{4}$$

This procedure is performed for both the tread and flange region, thus allowing the detection of one contact point in each region of the wheel

2.2.2 *Normal contact problem*

When two non-conforming bodies are compressed against each other, they will deform around the first point of contact and form a contact area. In the present investigation, the nonlinear Hertz contact theory (Hertz, 1882) is used to analyse the normal contact problem. Although this theory can only deal with non-conformal contact, where the contact area is small when compared with the dimensions of the two bodies and the relative radii of curvature of the surfaces, this assumption is acceptable in railway applications, since the wheel and rail have considerably different shapes. However, more complex contact shapes, namely, multi-Hertzian and non-Hertzian, may be necessary for analysing local problems such as wear, in which a detailed analysis of the local stresses in the contact area is essential. Thus, the normal contact force F_n between the wheel and rail is given by

$$F_n = K_h \, d^{\frac{3}{2}} \tag{5}$$

where d is the penetration defined in Eq. (4) and K_h is a generalized stiffness coefficient that depends on the material properties of the bodies in contact, such as the Young modulus and the Poisson ratio, and on the curvatures of the surfaces at the contact point.

2.2.3 *Tangential contact problem*

Due to the elasticity of the bodies and the external applied normal load, some points on the contact area may slip while others may adhere when the bodies are allowed to roll over each other. The difference between the tangential strains of the bodies in the adhesion area leads to a small apparent slip, called creep, which is crucial for the determination of the tangential forces that develop in the contact area.

These forces, called creep forces, can be calculated through the creepages, which consist in the relative velocities between wheel and rail at the contact point, normalized to the vehicle forward speed. In the present work, the longitudinal and the lateral creep forces are precalculated and stored in a lookup table, based on USETAB (Kalker, 1996), to be later interpolated during the dynamic analysis as a function of the creepages and the semi-axes ratio of the contact ellipse. This table has been calculated with the software CONTACT (2011) which is based on Kalker's exact three-dimensional rolling contact theory (Kalker, 1990).

2.3 *Vehicle-structure coupling*

The train-structure dynamic interaction problem is solved using the direct method developed by Neves et al. (2014). In this method, the governing equilibrium equations of the vehicle and structure are complemented with additional constraint equations that relate the displacements of the contact nodes of the vehicle with the corresponding nodal displacements of the structure. Montenegro et al. (2015) extended the formulation to take into account the geometry of the wheel and rail and the behavior of the contact interface by using the finite contact element referred in Section 2.2. Hence, the vehicle-structure coupling is mathematically expressed as

$$\begin{bmatrix} \overline{\mathbf{K}} & \overline{\mathbf{D}} \\ \overline{\mathbf{H}} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \Delta \mathbf{a}^{i+1} \\ \Delta \mathbf{X}^{i+1} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\psi}\left(\mathbf{a}^{t+\Delta t,i}, \mathbf{X}^{t+\Delta t,i}\right) \\ \bar{\mathbf{r}} \end{bmatrix} \tag{6}$$

where $\overline{\mathbf{K}}$ is the current effective stiffness matrix of the vehicle-structure system, $\overline{\mathbf{D}}$ is a matrix that relates the contact forces, defined with respect to the target element coordinate system, with the nodal forces defined in the global coordinate system, $\overline{\mathbf{H}}$ is the transformation matrix that relates the nodal displacements of the target elements, defined in the global coordinate system, with the displacements of the auxiliary points defined with respect to the target element coordinate system, $\boldsymbol{\psi}$ is the residual force vector that depends on the nodal displacements $\mathbf{a}$ and on the contact forces $\mathbf{X}$ and $\bar{\mathbf{r}}$ the vector with the irregularities in the contact interface. The superscript $t+\Delta t$ indicates the current time step, while i and $i+1$ denotes the previous and current Newton iteration, respectively. Equation (6) consists of a mixed system of equations composed by equilibrium equations of motion and constraint equations to couple the vehicle to the structure. These equations, whose unknowns are incremental nodal displacements and contact forces, are solved using a Newton-type iterative scheme. The detailed formulation of the direct method, and in particular of the system of equations (6), may be found in Neves et al. (2014) and Montenegro et al. (2015).

3 ASSESSMENT OF TRAIN RUNNING SAFETY ON BRIDGES SUBJECTED TO EARTHQUAKES

3.1 *Introduction*

In the present section, a study regarding the running safety of a railway vehicle based on a Shinkansen train moving over a viaduct subjected to earthquakes (Montenegro et al. 2016). The viaduct is based on an existing flyover type structure of the Portuguese railway network composed by simply supported box girders (Malveiro et al. 2013). The main objective of the present study consists of evaluating the influence of the seismic intensity, track irregularities and train speed in the train running safety.

3.2 *Train-structure dynamic model*

The structure used in the present study is based on the Alverca viaduct, a flyover structure that belongs to the Northern Line of the Portuguese railway network (see Fig. 2a). The actual structure consists of several simply supported spans with lengths of 16.5 m, 17.5 m and 21 m supported by columns with heights ranging from, approximately, 5 m to 15 m (Malveiro et al. 2013). In the present study, the actual mechanical and geometrical properties of the cross sections of the deck and columns have been adopted. However, for simplicity of the model, the span lengths and column heights have been kept constant in the whole structure. Therefore, the viaduct considered in the present work has a total length of 630 m divided into 30 simply supported spans with 21 m length each, supported by columns with 10 m height.

The deck consists of a prefabricated and prestressed U-shaped beam on which pre-slabs serving as formwork to the concrete upper slab cast in situ were placed, forming a single-cell box girder deck (see Fig. 2b). The deck is directly supported in the columns and abutments by elastomeric-reinforced bearings. Each span is fixed in one extremity and longitudinally guided in the other, being the transverse direction fixed on both edges. The track in the existent viaduct consists on UIC60 rails with an Iberian gauge of 1.688 m, elastomeric rubber pads, prestressed concrete monoblock sleepers and a 25 cm ballast layer under them. However, since the study is carried out with a Japanese high-speed train, the standard gauge of 1.435 m has been considered in the numerical model, as well as the JIS60 rail profiles. The columns have a rectangular solid cross-section with dimensions 2×1 m^2.

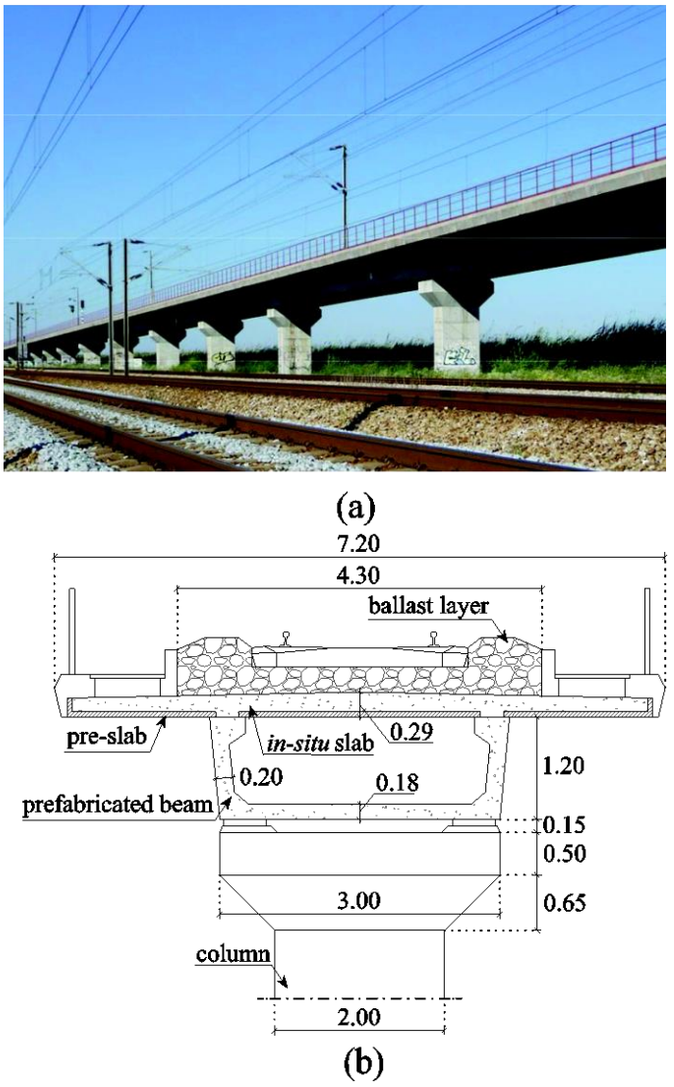

Figure 2. Alverca viaduct: (a) perspective view and (b) deck cross-section.

The numerical model of the viaduct has been developed in ANSYS. The deck, columns, sleepers and rails are modelled using beam finite elements, while the bearing supports, ballast and pads are modelled using linear spring dampers. Mass point elements are also used to model the ballast mass and the non structural elements such as safeguards and edge beams of the deck. The connection between the top of the columns and deck, as well as the connection between the deck and the track, is accomplished by rigid frame elements. In order to guarantee a correct representation of the transition zones between the structure and the embankment, an extension of the track has been modelled in both extremities of the viaduct. A schematic representation of the numerical model together with a detail of the cross section and the deck joint above the columns is illustrated in Fig. 3 (the track is not included in Fig. 3a for simplicity). Although the spans are disconnected from each other, the track confers a certain amount of transversal stiffness to the deck, as can be seen in the detail depicted in Fig. 3c.

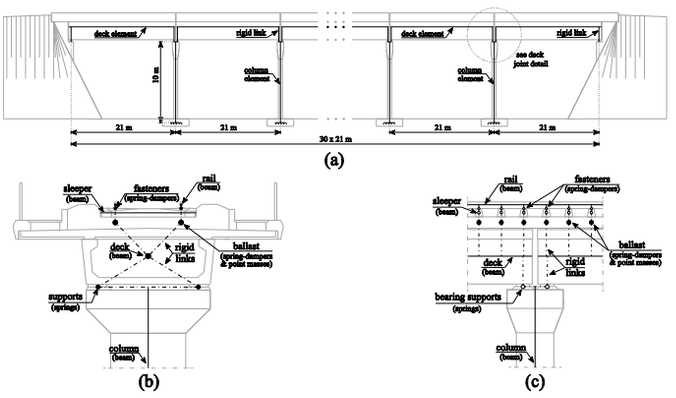

Figure 3. Numerical model of the viaduct: (a) elevation view, (a) cross-section and (b) deck joint.

The vehicle used in the present work for the dynamic analysis is based on a Japanese conventional type high-speed Shinkansen train with all the cars independent from each other. A schematic representation of the dynamic model of the railway vehicle is illustrated in Fig. 4. The springs and dampers of the suspensions are denoted by k and c and the masses and rotary inertias are indicated by m and I. The longitudinal, lateral and vertical distances are denoted by a, b and h, respectively, s refers to the lateral distance between the initial contact points and R_0 is the nominal rolling radius. The subscripts cb, b and w indicate carbody, bogie and wheelset.

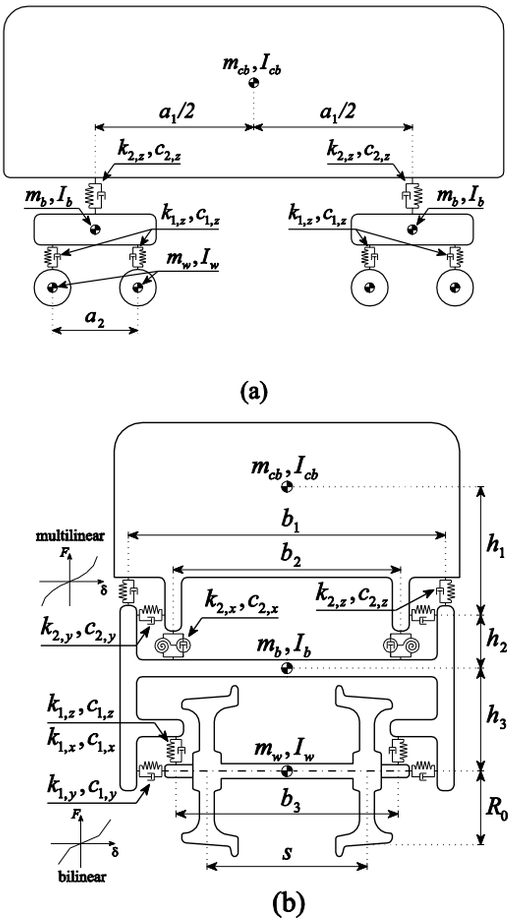

Figure 4. Dynamic model of the railway vehicle: (a) lateral view and (b) front view.

The carbody, bogies and wheelsets are modelled using beam finite elements, and the suspensions are modelled using spring dampers in the three directions. The springs used to model the suspensions are characterized by bilinear laws, except the one used to model the secondary transversal suspension. This suspension follows a multilinear law to simulate the presence of rubber stoppers whose stiffness increases gradually. These stoppers are used to avoid large lateral displacements of the carbody not only during normal operation, but especially during earthquake. The masses and rotary inertias are modelled using mass point elements, located at the center of mass of each component.

3.3 *Seismic excitation*

The seismic excitations adopted in the present study consist of artificial accelerograms generated from the elastic spectra described in EN 1998-1 (2004), with PGA corresponding to moderate events with relatively high probability of occurrence and return periods less than 475 years, which is the reference return period of seismic action for the no collapse requirement.

This type of seismic actions is of the utmost importance, since the running safety of trains might be jeopardized not only by intense earthquakes, but also by moderate seismic events, which may not cause significant damage to the structure. Therefore, four levels of seismic intensity with return periods of 95 (proposed return period for the damage limitation requirement of Eurocode 8), 150, 225 and 310 years have been considered in the present study.

The seismic excitation is imposed along the lateral direction and, since the data regarding the soil properties is scarce, the spatial variability of the seismic action is not considered in this work.

The artificial accelerograms have been generated with the software SeismoArtif, which uses a random process of adjustment by correction in the frequency domain. The target elastic spectra have been defined for the seismic zone 2.3 of the Portuguese territory and for a soil type A (NP EN 1998-1, 2009), with an importance factor of 1.0, as proposed by EN 1998-2 (2005) for railway bridges.

3.4 *Analysis scenario*

For each level of irregularity and seismic intensity, the safety of the vehicle is evaluated for running speeds ranging from 200 to 350 km/h with 10 km/h steps. Furthermore, for each speed, five scenarios with different time offsets between the beginning of the earthquake and the entry of the vehicle in the viaduct are considered in order to cover a wider range of combinations. The coordinate of the first wheelset xi at the instant the earthquake starts is schematized in Fig. 5. The coordinate xi is defined with respect to the coordinate system (x,y) positioned at the beginning of the viaduct and the subscripts i = 1, 2, ..., n indicate the scenario number

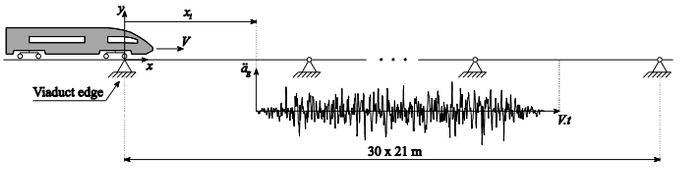

Figure 5. Coordinate of the first wheelset at the instant the earthquake starts.

Track irregularities have also been accounted for, since they may be an important source of excitation for both the structure and the vehicle. In the present work the track irregularities have been generated based on the stochastic Gaussian ergodic process described in Claus & Schiehlen (1998).

Two levels of track quality have been considered: 1) regular operation limit.; 2) alert limit defined in the EN 13848-5 (2008). In all the scenarios, the effect of the irregularities has been accounted from the beginning of the analysis. The profiles have been generated with 2000 discrete frequencies with wavelengths ranging between 3 and 25 m.

3.5 *Running safety analysis*

Fig. 6 shows the vertical and lateral contact forces in the left wheel of the second wheelset calculated for the aforementioned scenario.

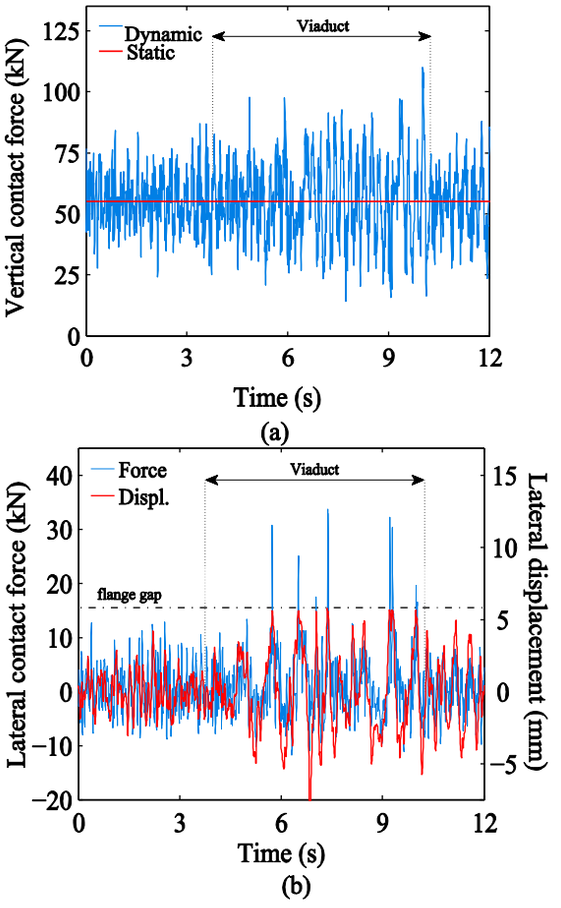

Figure 6. Contact forces in the left wheel of the second wheelset: (a) vertical and (b) lateral.

The lateral contact forces in Fig. 6b are superimposed on the relative lateral displacements between wheel and rail. It is clear that the peaks observed in the lateral force are due to the wheel flange impacts, since they occur at the same moment as the gap between the flange and rail closes (approximately 6 mm).

Fig.7 shows the Nadal and wheel unloading criteria obtained for the left wheel of the first wheelset when the vehicle is running at 200 km/h and 350 km/h. It is clear that both the lateral and the vertical dynamics are affected by the running speed of the vehicle.

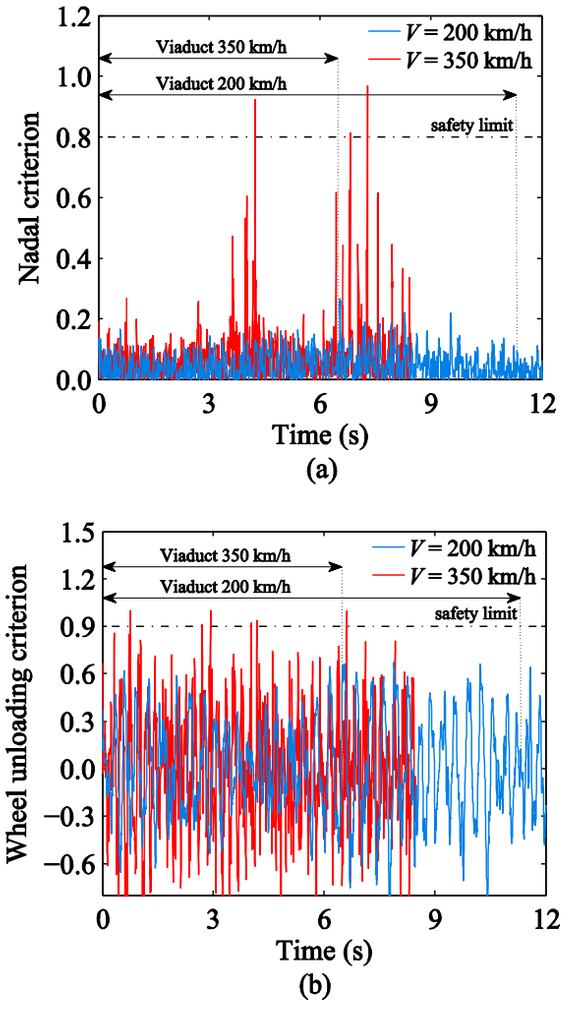

Figure 7. Safety criteria for the left wheel of the first wheelset in a scenario with an earthquake with $T = 150$ years and track quality corresponding to the alert limit: (a) Nadal and (b) wheel unloading

The Nadal and wheel unloading criteria obtained for the left wheel of the first wheelset when the vehicle crosses the viaduct at 350 km/h with the two levels of track quality and without any earthquake load, are depicted as an example in Fig. 8. Several peaks can be observed in the Nadal criterion time-history when the vehicle runs on the track with worse quality. These peaks are mostly related with lateral impacts between the wheel flange and rail, which can lead to wheel flange climbing or track panel shift and subsequent derailment.

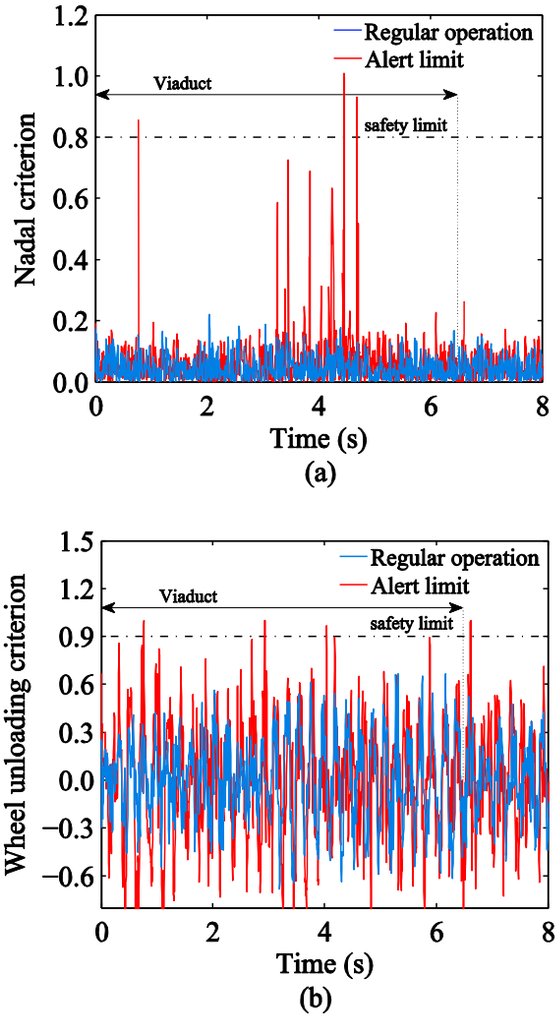

Figure 8. Safety criteria for the left wheel of the first wheelset in a scenario with $V = 350$ km/h and without seismic excitation: (a) Nadal and (b) wheel unloading

The global envelope of each of the analysed safety criterion, as function of the running speed of the vehicle and of the seismic intensity, calculated for the two track quality levels considered in the present work, is plotted in Fig. 9. Each point corresponds to the maximum seismic intensity that guarantees the safety of the vehicle for each running speed, considering the envelope of the five scenarios to account for the time offset between the beginning of the earthquake and the entry of the vehicle in the viaduct.

As expected, the tendency observed in all the criteria is similar, indicating that the risk of derailment increases with the increasing of the running speed and seismic intensity. It may be observed that the risk of derailment due to the wheel unloading is null when the train runs over a track whose quality corresponds to the regular operation limit. For this level of irregularities, the Prud'homme criterion proved to be the most conservative, since it controls the derailment risk for all the speeds. However, this tendency changes for poorer quality tracks, in which the

Nadal and wheel unloading criteria define the safety zone, as may be seen in Fig. 9b. Hence, for the track with better quality, the vehicle remains safe at every speed if no earthquake occurs, while for the track with poorer quality, the derailment risk predicted with the wheel unloading criterion and with the Nadal and Prud'homme criteria significantly increases for speeds above 270 km/h and 300 km/h, respectively.

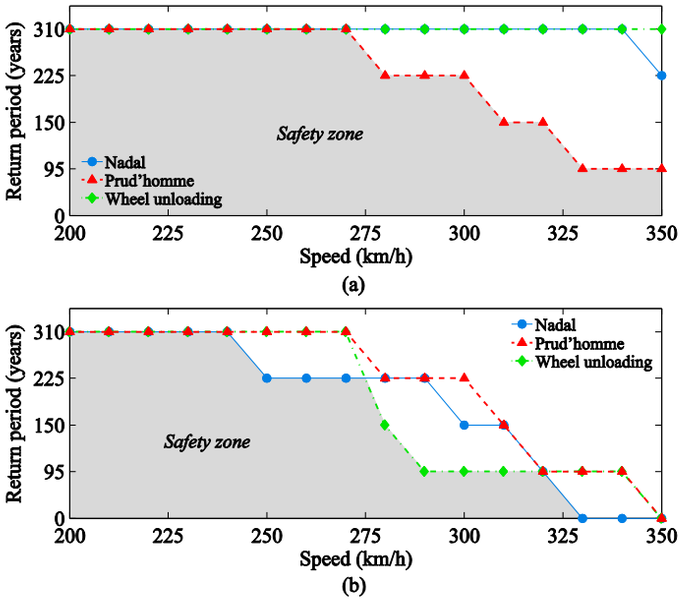

Figure 9. Running safety charts obtained for levels of irregularities corresponding to the (a) regular operation limit and to the (b) alert limit.

4 PROBABILISTIC ASSESSMENT OF THE DYNAMIC BEHAVIOUR OF A SHORT SPAN RAILWAY BRIDGE

4.1 *Introduction*

The safety assessment of a short span composite high-speed railway bridge is presented. Two different failure modes are assessed: the running safety of trains due to loss of contact between the wheel and the rail and track instability due to excessive deck vibrations. This provides examples of limit state functions with different degree of complexity and enables the understanding of how this complexity affects the efficiency of the assessment.

4.2 *Train-structure dynamic model*

Canelas Bridge (Fig. 10) is located in the Northern line of the Portuguese railway and is composed of six simply supported spans of 12 m each, with a total length of 72 m. The bridge deck is a filler beam consisting of two half concrete slab decks, each supporting a single ballasted track, with nine embedded rolled steel profiles HEB 500, which is a typical deck solution for short span high-speed railway bridges.

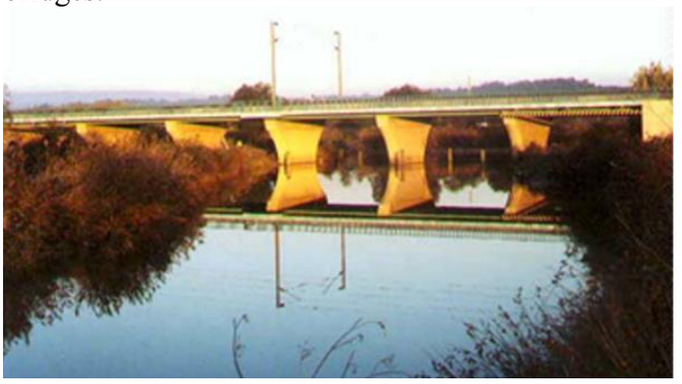

Figure 10. Canelas railway Bridge.

A 2D model was developed and was discretized using beam elements. A single span was modelled and only one track was analysed, as the two half slab decks are independent. The deck was modelled as a beam positioned at the corresponding centre of gravity. The bearings were also included in the numerical model as springs positioned at the corresponding centre of rotation. Regarding the ballasted track, the rails were modelled as beams with the properties of a UIC 60 rail. The beam representing the rail is connected in parallel to a set of springs and dampers, with stiffness k_{pa} and damping c_{pa}, respectively, simulating the rail pads. Below the spring-dashpot set a series of lumped masses, with mass M_s, simulate the sleepers. These lumped masses are also connected in parallel to another set of springs and dampers, with stiffness k_b and damping c_b, respectively, simulating the ballast layer. The shear behaviour of the ballast layer due to composite effects was also accounted for through horizontal springs with stiffness s_r.

A schematic representation of the track-bridge numerical model is shown in Fig. 11.

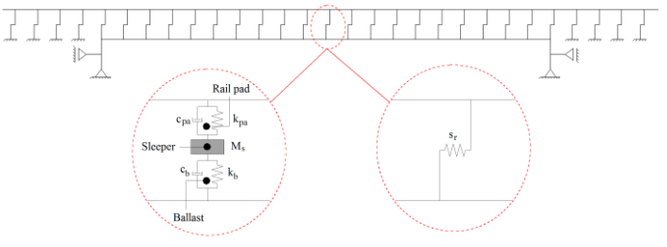

Figure. 11. Track-bridge numerical model.

Track irregularities were randomly generated using power spectral density functions using the SNCF proposal. the wavelength range D1 defined by EN13848-5 (2005) was considered, limiting the analysis to wavelengths between 3 m and 25 m. In order to comply with the quality demands of CEN the maximum standard deviation of the generated track irregularities profiles was limited to 1.5 mm over a track extension of 200 m.

The dynamic behaviour of the bridge was assessed for the crossing of a TGV double high-speed train, which is an articulated train. It is composed by a total of 20 coaches: four power cars, four power passenger cars and twelve passenger cars. The articulated structure only comprises the power passen ger cars and the passenger cars. In the articulate part of the train the bogies are located between ca bodies and are connected by car body–bogie joints In Rocha et al. (2014) the influence of the train mod el was analysed and it could be concluded that a simplified model allows obtaining accurate results A schematic representation of the train and the cor responding numerical model is illustrated in Figur 12.

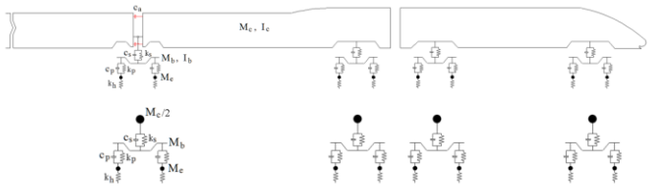

Figure 12. Schematic representation of the TGV double train numerical model.

4.3 *Train-structure dynamic response*

To provide a better understanding of the dynamic behaviour of the train-bridge system the response is analysed for speed ranging from 200 km/h to 450 km/h.

For the particular case study of this lecture two of the main critical safety aspects of dynamic response are the bridge deck accelerations and the wheel unloading coefficients.

Regarding the bridge deck accelerations, the ¾ span was identified as the critical one. The maximum acceleration obtained at this section for increasing train speeds is presented in Figure 13. The black line represents the results for the case where all the variables take their mean value whereas the circles correspond to results obtained from MC simulation, illustrating the variability of the dynamic response for different train speeds.

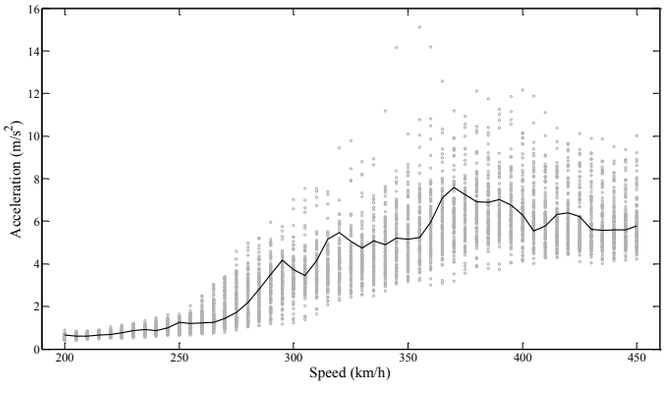

Figure 13. Maximum bridge deck acceleration at the ¾ span section.

With respect to the wheel unloading, the maximum unloading coefficient for increasing train speeds is presented in Fig. 14. Similarly, the black line corresponds to the average scenario whereas the circles correspond to results obtained from MC sim-

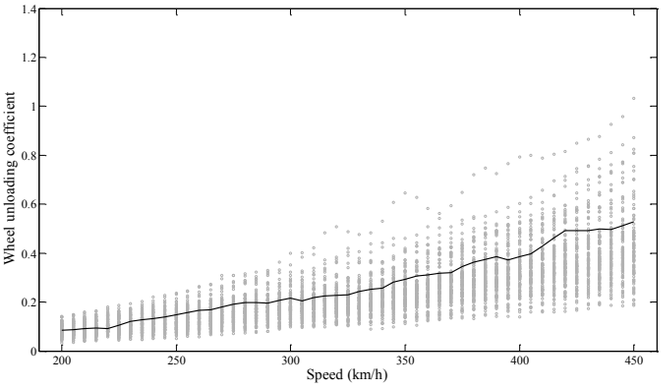

Figure 14. Maximum wheel unloading.

Both the maximum value and the dispersion of the unloading rate show a tendency to increase with speed. However, this is a rather complex phenomenon that depends on a large number of parameters. It is influenced not only by the dynamic response of the bridge (which is affected by both the bridge and track properties) but also by the track irregularities profile.

4.4 *Train running safety*

The running safety of the train is assessed through the analysis of the wheel unloading coefficients.

In its most usual form the wheel unloading, η_U, is calculated by:

$$\eta_U = 1 - \frac{Q_{dyn}}{Q_{sta}} \tag{7}$$

where Q_{sta} is the static load of each wheel and Q_{dyn} is the dynamic wheel load. CEN limits the unloading to 90% of the static wheel load, corresponding to a 10% safety margin. Since a stochastic analysis is performed and the variability of the train, the track and the bridge is accounted for, no safety margin was used to assess the train running safety. Thus, in this paper the limit for the wheel unloading coefficient is 1. The train is considered to run safely on the bridge if the estimated probability of failure due to wheel unloading is lower than 10^{-4}, which corresponds to a reference value in the Joint Committee on Structural Safety Probabilistic Model Code (JCSS, 2001).

In Fig. 15 the distribution of the wheel unloading coefficient is represented for several wheels of the train crossing the bridge at 425 km/h for a sample of 20,000 Monte Carlo simulations.

The results for the several train wheels regarding the distribution are very similar, as can be confirmed by the shape of the curves for each wheel and also by the obtained mean and standard deviation.

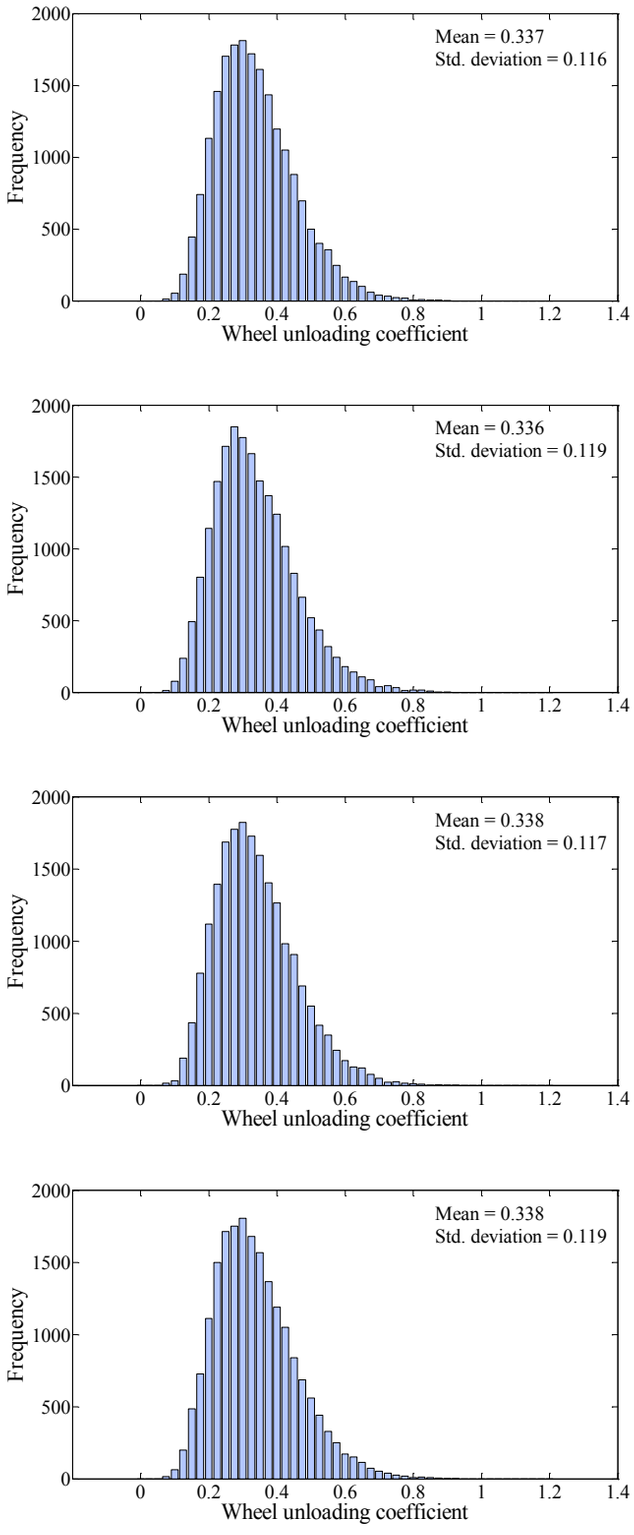

Figure 15. Wheel unloading coefficient distribution for individual wheels.

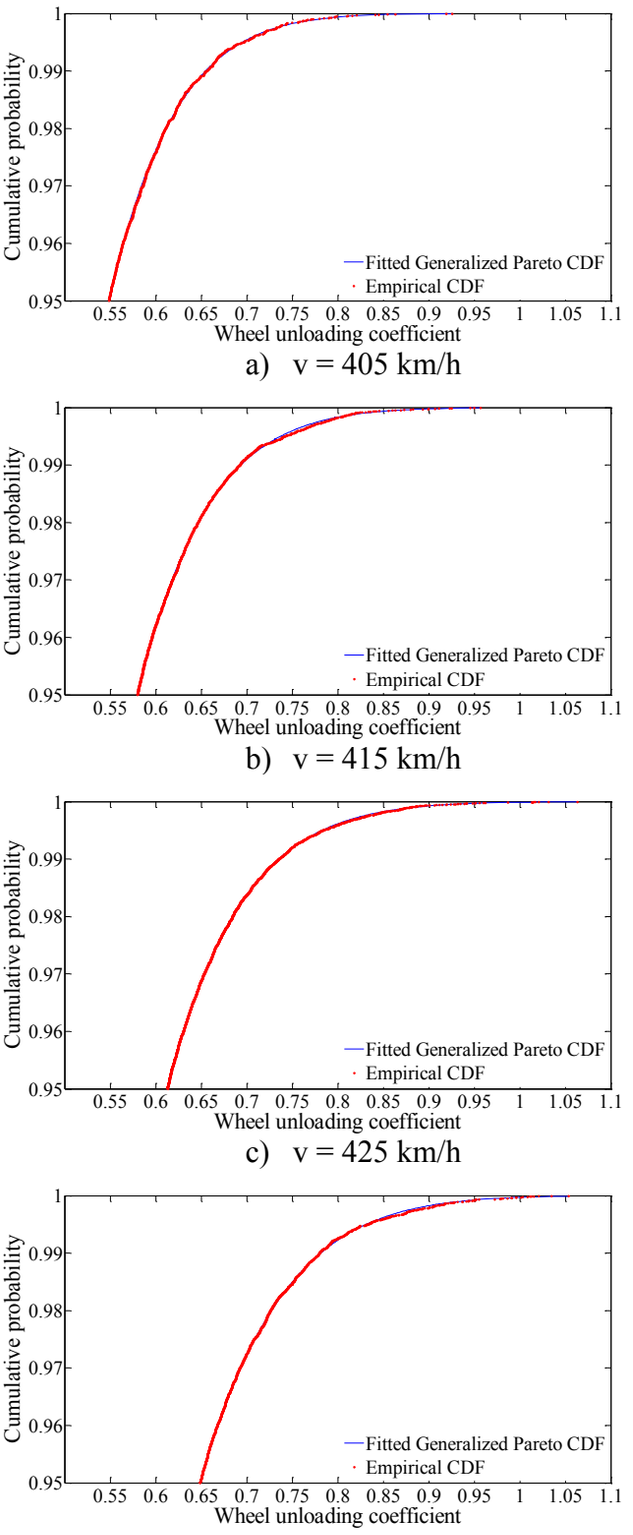

Figure 16. GPD fit to the upper tail of the wheel unloading coefficient distribution.

An example of the fit of the GPD to the data obtained from the simulations is shown in Fig. 16 for different train speeds.

The fit to the data is very good and this is confirmed by the obtained R^2 index values for the several fits performed, which are always above 0.99, regardless of the train speed that is analysed. Therefore, the accuracy of the estimates is assured.

The probability of failure was estimated for increasing train speeds and these results are shown in Fig. 17.

The depicted results correspond to the global analysis. It can be observed that the safety threshold (dashed line) is not exceeded for speeds up to 420 km/h, which make this the train speed limit to ensure the running safety.

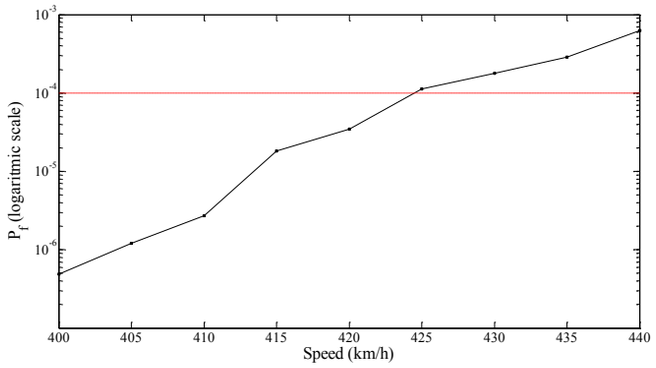

Figure 17. Evolution of the estimated probability of failure with the train speed.

For most train speeds in the vicinity of the failure region less than 20,000 simulations were sufficient to accurately estimate the probability of failure. However, for the critical train speed of 425 km/h, 50,000 simulations were performed. This is explained by the fact that the estimated probability for this train speed is extremely close to the safety threshold. As the sample size increased the value kept varying between the safe and the unsafe side. Even though this was not strictly necessary, as the estimated probability of failure had stabilized fairly well and the confidence intervals were always above the safety limit, for accuracy purposes the number of simulations was increased until the estimated probability stabilized on one of the sides for a sufficient number of sample size increments.

In the critical range of speed the dynamic response of the train-bridge system is governed by the impulsive loading due to the passage of the train at high-speed rather than resonant effects, as had been shown in Rocha et al. (2014). Therefore, the wheel unloading, and consequently the probability of failure, shows a tendency to increase with speed. However, the unloading rate is also dependent of the track properties and of the track irregularities. For this reason, it can be said that the estimated probability of failure depends on a rather complex combination of both the bridge and track dynamic properties and the irregularities profile.

4.5 *Track instability*

The safety due to track instability is assessed by the bridge deck acceleration. For each simulation the maximum acceleration along the bridge deck is identified and selected as representative to assess the safety. The track instability is characterized by the loss of interlock between ballast grains, leading to the loss of the lateral resistance of the sleepers. Laboratory tests confirmed that the ballast instability only tends to occur for deck accelerations higher than 7 m/s^2 (Zacher & Baeβler, 2009). Below this limit the sleeper hardly moves and no loss of lateral resistance is observed. However, EN1991-2 (2003) limits deck acceleration to a maximum of 3.5 m/s^2 for ballasted tracks, which indicates that a safety factor of 2 is applied. Since the safety of the train-bridge system is only at risk when deck accelerations are over 7 m/s^2, the probability of failure of the train-bridge system is established as the probability of the bridge deck reach this acceleration level.

Similarly to what was done in the assessment of the train running safety, to begin the discussion of this failure mode the maximum acceleration is presented for a sample of 50,000 Monte Carlo simulations for a train speed of 285 km/h in Fig. 18.

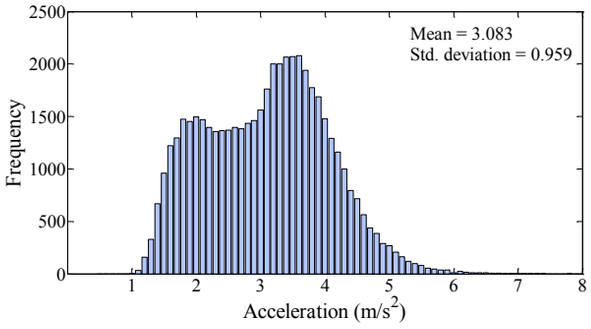

Figure 18. Maximum bridge deck acceleration distribution.

In this case, however, the obtained distribution is not unimodal, due to the existence of two distinct types of response: resonant and non-resonant behaviour. Fig. 19 illustrates the evolution of the estimated probability of failure for increasing train speeds.

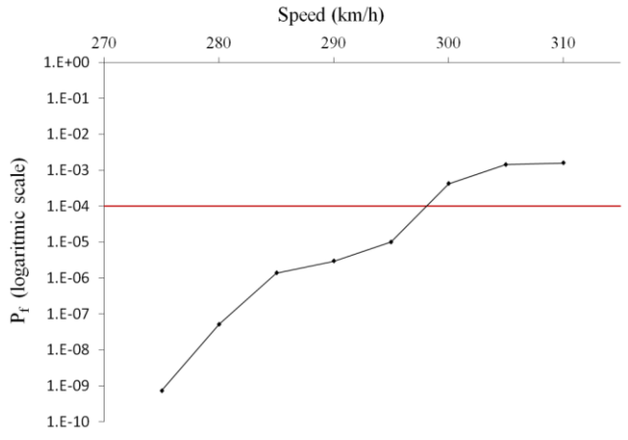

Figure 19. Estimated probability of failure for increasing speeds.

As mentioned before, probability values up to 10^{-4} are considered to be acceptable to measure failure due to the instability of the ballast layer. Analysing Fig. 19 it can be seen that this value is not exceeded for speeds lower than 295 km/h which, therefore, can be seen as an estimate of the train speed limit to be imposed on the bridge.

From the analysis of Fig. 19 it can also be observed that if a more conservative approach was performed, lowering the limit for the probability of failure to values up to 10^{-5}, the speed limit would not be very different, decreasing only 5 km/h to 290 km/h.

5 ASSESSMENT OF THE DYNAMIC BEHAVIOUR OF THE TRAIN-TRACK SYSTEM AT RAILWAY TRANSITION ZONES

5.1 *Introduction*

Within the scope of a research project on transition zones, an earlier version of this model, which proved to be very accurate for simulating the dynamic behaviour of the train-track system at a transition zone to a bridge in a Portuguese railway line (Paixão et al., 2014), was used. That study comprised an extensive validation of the model using field measurements, but it did not address the topic of differential settlements. As a result of that work, the model to assess the influence of the shape and amplitude of the settlement profiles of the backfill, thus contributing to a better understanding of the dynamic behaviour of the train-track system at transition zones, was adopted.

5.2 *Train-track dynamic model*

The numerical model was developed in ANSYS. It comprises a track stretch of about 57 m on the embankment (on the backfill of the bridge's abutment) and a stretch of approximately 115.5 m on the bridge (on the abutment and on the deck), as illustrated in Fig. 20a.

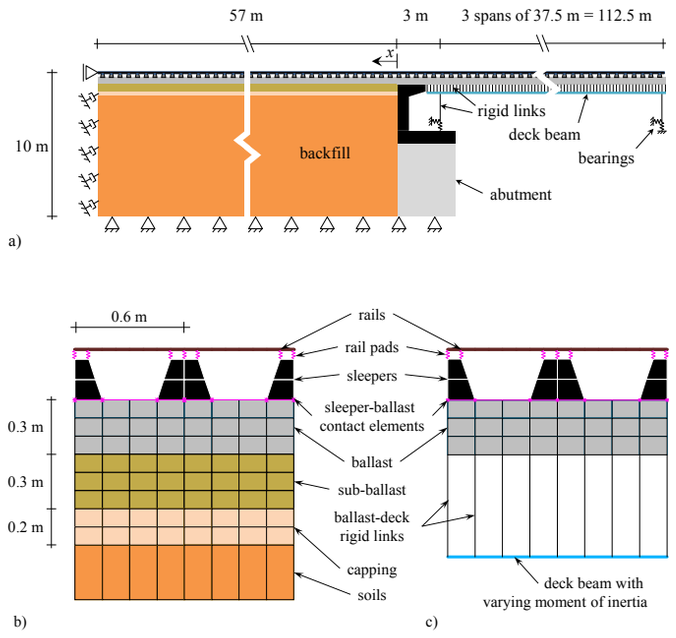

Figure 20. Schematic representation of the numerical model (a), and detailed aspects of the track on the backfill (b) and on the bridge (c).

Although it is a 2D model, the numerical method was developed to represent the behaviour of a full track cross-section and it has successfully been applied to the study of transition zones, following extensive calibration and validation works with field measurements (Alves Ribeiro et al., 2014; Paixão et al., 2014).

The model developed for this study, in particular, considers various aspects of the track superstructure, its substructure and the bridge, using 24,537 nodes and 28,096 elements. The two rails (type UIC60) were modelled as one continuous beam with 0.075 m long elements, with a cross-section area of $2\times7.7\times10^{-3}$ m^2 and a moment of inertia of $2\times30.55\times10^{-6}$ m4. The pairs of rail pads on each sleeper were modelled as three independent vertical spring-damper elements, as depicted in Figure 20b-c. Following previous experimental and numerical studies (Alves Ribeiro et al., 2014; Paixão, 2014; Paixão et al., 2014; Paixão et al., 2015a), the rail pads were considered to have a vertical stiffness of k_{rp}=160 kN/mm and a vertical damping value of c_{rp}=17 kN.s/m.

Plane-stress elements with 4 nodes were used to represent the sleepers, the bridge abutment and the layers of ballast, sub-ballast, capping and embankment soils (Figure 20b). In ANSYS it was possible to define the width values of each plane-stress element, which were initially calibrated using reduced 3D static models. This process basically uses an optimization algorithm to minimize the differences in the vertical displacements between the 3D and the 2D models.

Contact elements on the bottom node of the sleepers and on the surface of the ballast layer were included at the sleeper-ballast interface to account for the eventual separation of these two track components and to study the development of the hanging sleepers (Figure 20b-c).

Viscous boundary conditions were included in the left vertical boundary of the model (Figure 1a), to minimize the effect of wave reflections. The displacements of the bottom nodes of the model were vertically restrained.

The deck of the bridge was modelled as one continuous beam with 0.15 m-long elements located at the centre of gravity of the deck's cross section. Initial tests showed that it was necessary to model at least three spans of the bridge to account for the influence of the bending of the deck on the behaviour of the train-track system.

Bearing in mind that this study addressed transition zones in the Portuguese railway network, the dynamic analysis was performed taking into consideration the fastest passenger train in service in Portugal - the tilting "Alfa Pendular" train, travelling at 220 km/h (Figure 21a). Figure 21b shows the train model considered in the study (Ribeiro et al. 2013). The bogies and car bodies were considered as rigid bodies.

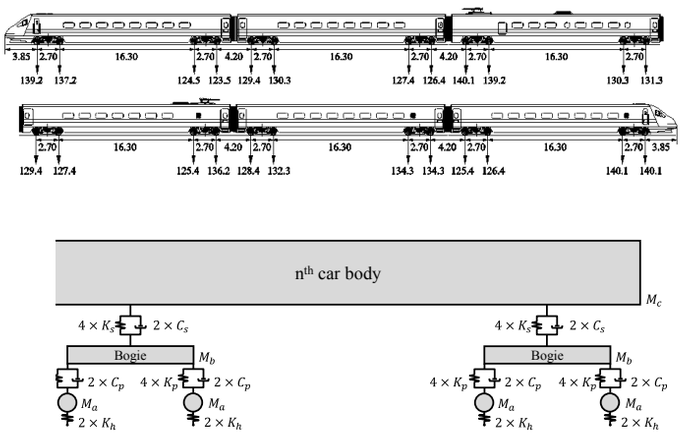

Figure 21. The "Alfa Pendular" train: a) distances between axles (in m) and approximate loads (in kN); b) model of one of the 6 coach cars.

5.3 *Backfill settlement scenario*

In an attempt to simulate scenarios in which settlements occurred in the backfill, at the substructure level, the authors altered the mesh of the model to reproduce those conditions. Four hypothetical scenarios of uniform settlement of the backfill were studied, considering a maximum settlement value of δ_max= 1, 5, 10 and 15 mm in each case (Fig. 22).

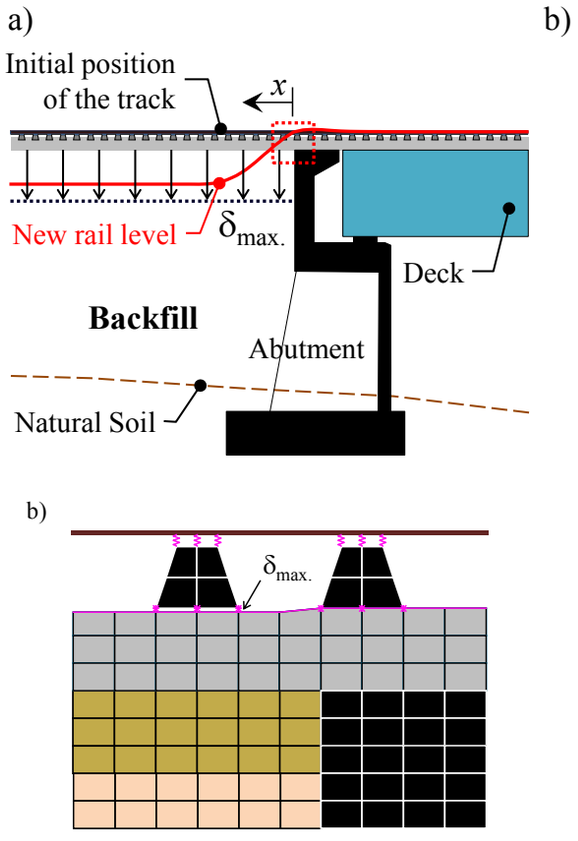

Figure 22. Backfill settlements: a) schematic representation; b) detail of the top nodes of the ballast layer moved downwards by δ_{max}.

Aiming at assessing the influence of different settlement profiles on the levelling of the track and on the dynamic response of the train-track system, four shapes of hypothetical settlement profiles were studied, as depicted in Fig. 23:

U – uniform settlement of the track substructure along the approach;

W – settlement profile resulting from a wedge-shaped backfill using materials with improved mechanical properties (Paixão et al., 2015b): unbound granular material (UGM) and cement-bound mixture (CBM);

S – sharp settlement variation at the bridge approach;

G – gradual settlement variation at the bridge approach.

For each shape (U, W, S and G), four settlement profiles were analysed corresponding to different maximum amplitudes of settlement, δ_{max}: 1, 5, 10 and 15 mm. The first profile shape, U, regards the scenarios presented earlier in section 3.1. The settlement profiles were also applied to the top nodes of the ballast layer in the model (Fig. 22).

The four profile shapes under study were determined in resemblance with profiles reported by railways infrastructures managers (ERRI, 1999; Nicks, 2009) and based on previous studies (Schooleman, 1996; England et al., 2000; Kempfert & Stadel, 2000; Luomala & Nurmikolu, 2012; Abu-Farsakh & Chen, 2014).

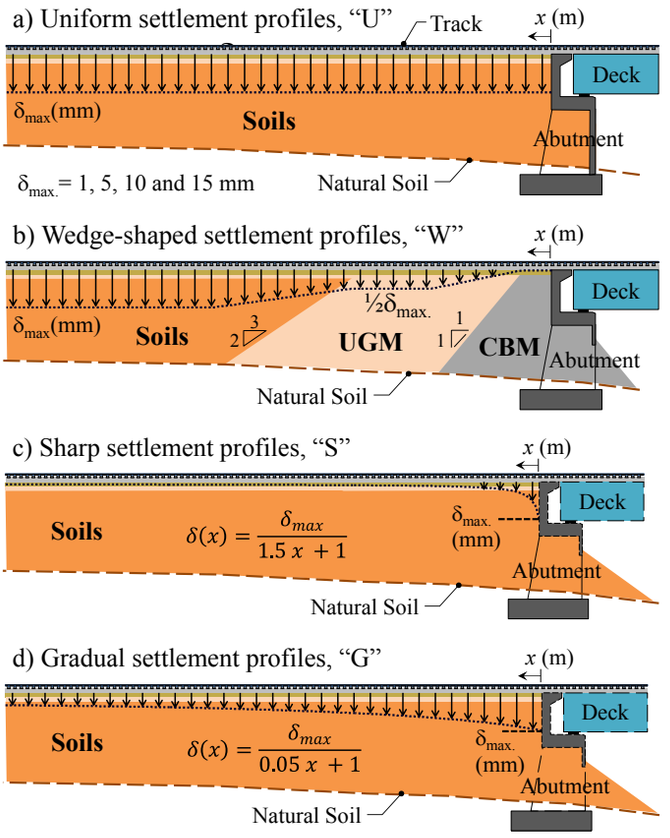

Figure 23. Schematic representation of the settlement profile shapes U, W, S and G.

As mentioned earlier, due to the bending stiffness of the rails, some sleepers were hanging from the rails with gaps under them. For each profile shape,

the number of hanging sleepers increased with the value of δ_{max}. The position of the hanging sleepers is identified in Fig. 24 with the respective size of the gap.

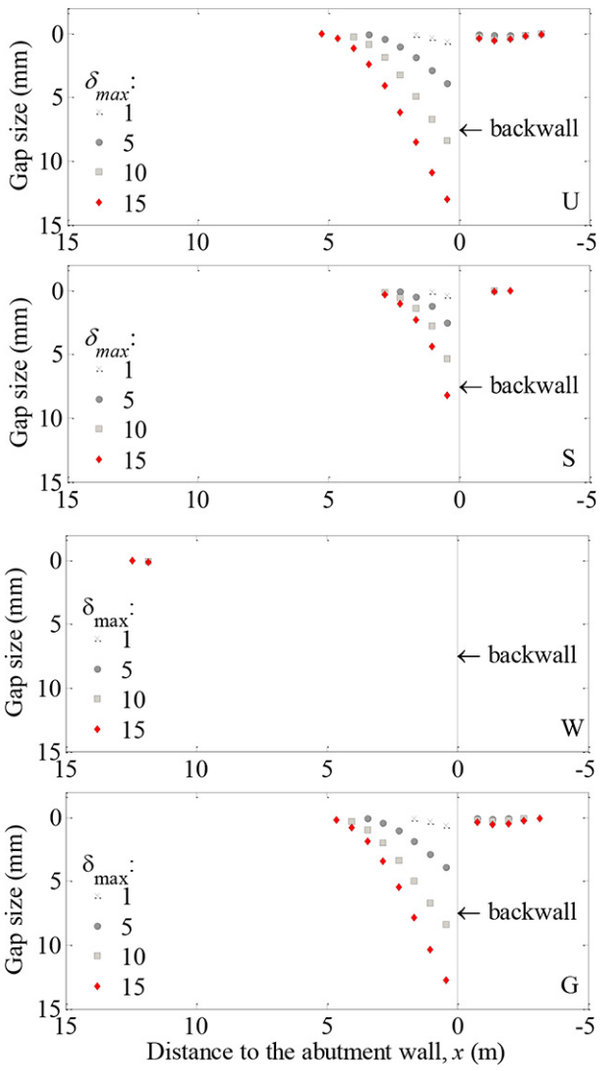

Figure 24. Location of hanging sleepers and respective gap sizes in unloaded conditions.

As expected, profile shapes U and G yielded the highest number of hanging sleepers and the largest gaps for each value of δ_{max}, for example: in shapes U and G, with δ_{max}=15 mm, the results revealed 9 and 8 consecutive hanging sleepers, respectively, and maximum gap sizes of about 13 mm.

Fig. 25 shows peak variations of the normal train-track interaction force (in percentage) for the first eight axles of the train, calculated as $\Delta P_p=(P_p-P_s)/P_s$, where P_s is the static axle load of 132 kN and P_p is the peak axle load. The results confirm that very low variations of the train-track interaction can be expected for profiles with shape W, suggesting reduced track degradation. On the other hand, the amplitude of the interaction force in the remaining profile shapes seems to increase significantly with the settlement, due to the sharp variations of the rail's position at the approach to the abutment. Some variability is observed, depending on the profile's shape and value of δ_{max}, and there are a few cases where the load increased by 100 to 150% in profiles with shapes U and G.

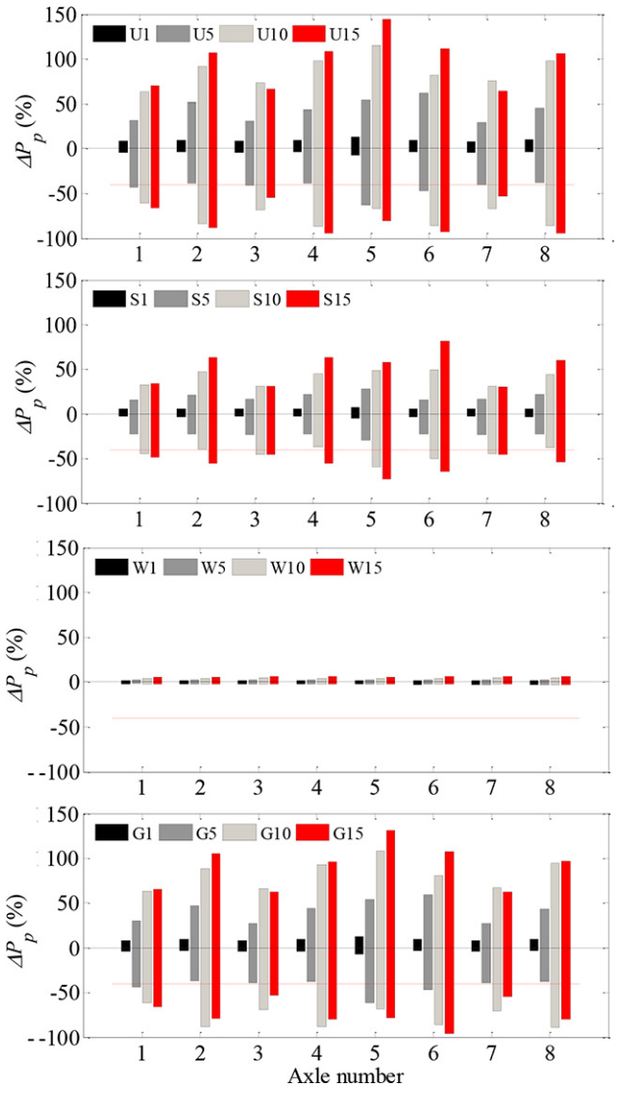

Figure 25. Peak variations of the dynamic train-track interaction force.

To illustrate the severity caused by the hanging sleepers, Fig. 26 shows peak values of the total contact force obtained between the underside of each sleeper and the ballast layer, depending on the value of δ_{max} and the distance from the sleeper to the abutment wall, x. Profile shapes U and G produced comparable results and seem to yield very severe situations, amplifying the load on the ballast by about 1.7, 3.6, 5.0 and 5.8 times, under the sleeper aligned with the abutment wall, when δ_{max}= 1, 5, 10 and 15 mm, respectively. This aspect suggests a significant increase in the degradation of the ballast layer with increasing δ_{max}. On the other hand, profiles with shape W did not evidence significant amplifications of the contact forces – the peak values were kept between 55-65 kN for all the sleepers in the different cases. Numerical studies by Lundqvist and Dahlberg (2005) using 3D models reported that the case of one unsupported sleeper with a gap of 1 mm can increase loads onto the ballast from approximately 50 kN to

70 kN - about 1.4 times - considering a static axle load of 107.5 kN travelling at 216 km/h. A similar result was obtained in a profile with shape S with δ_{max}= 1 mm, which had two hanging sleepers with smaller gap sizes of 0.4 and 0.1 mm, but considered a higher axle load of 132 kN, travelling at about 220 km/h, and resulted in a force increment from 55 kN to 79 kN - also by about 1.4.

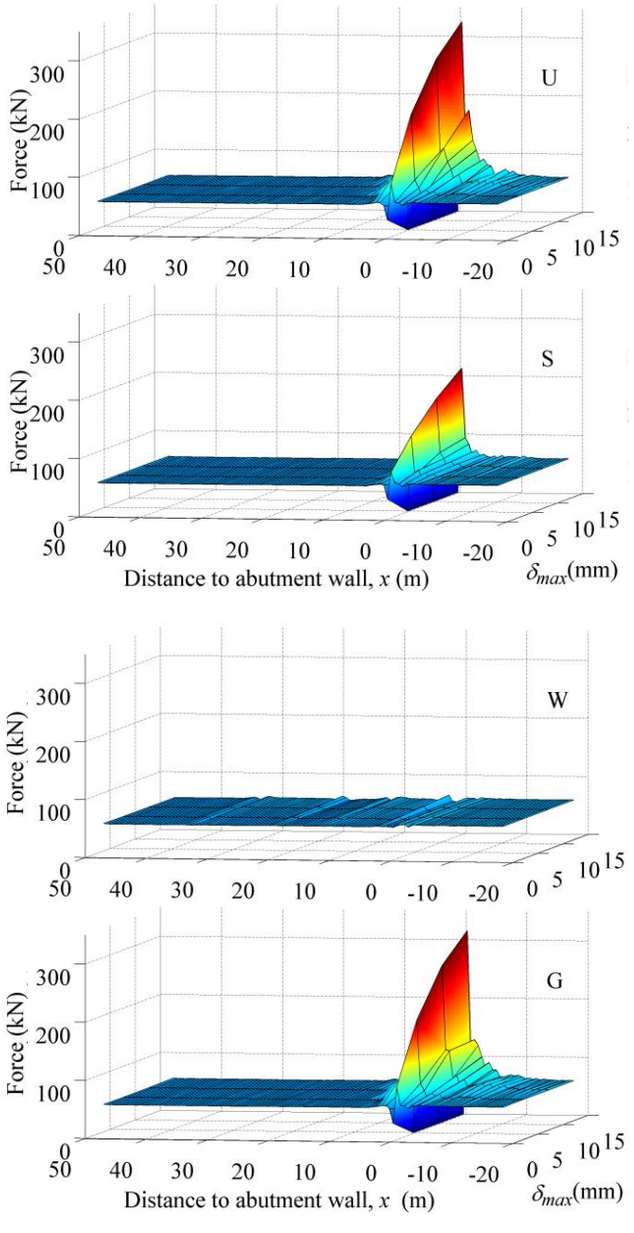

Figure 26. Peak contact forces between sleepers and ballast layer.

The authors also noticed that, in each tested case, the highest peak loads occurred at the sleepers that were not hanging, but were adjacent to the hanging sleepers that had the largest gaps (in these cases, the first sleeper behind the abutment wall, at about x=-0.15m). This can be explained by the fact that the static weight of the rail and of the hanging sleepers, plus part of the axle load, was directly transferred to those sleepers that were not hanging. Similar observations were reported in other numerical studies (Lundqvist & Dahlberg, 2005; Varandas et al., 2014).

Fig. 27 shows peak vertical accelerations of the sleepers along the transition. Again, profile shapes U and G seem to produce similar results with increasing acceleration values of δ_{max}, not only near abutment wall, but also in a zone stretching by about 10 m on the backfill and on the bridge

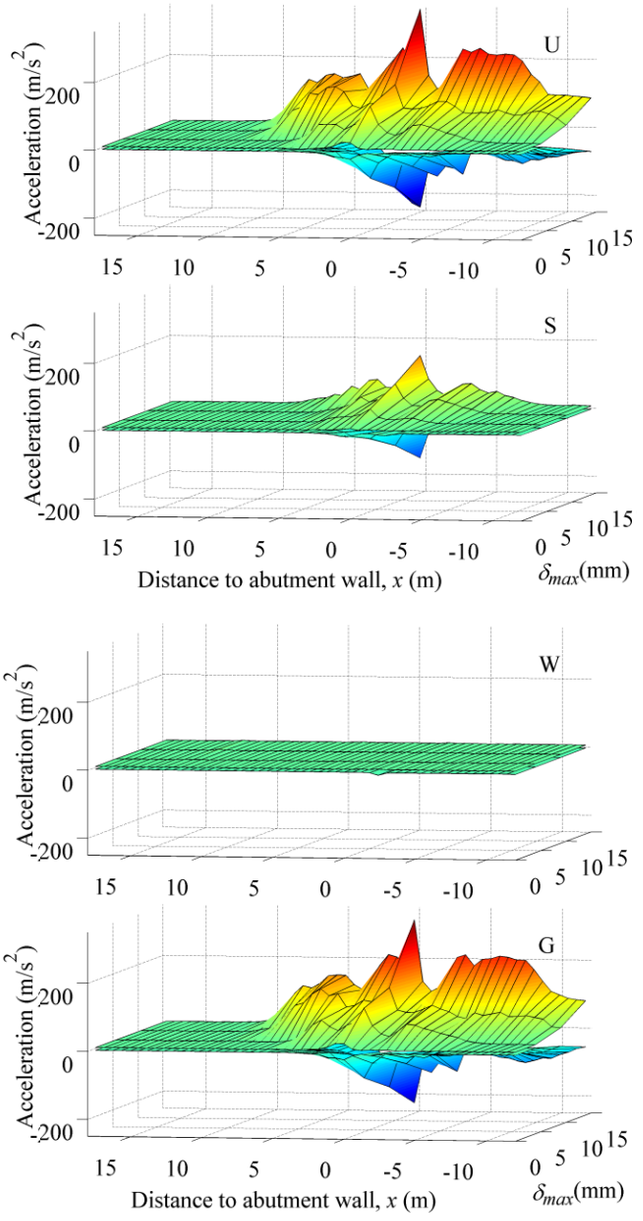

Figure 27. Peak vertical accelerations of the sleepers, along the transition zone.

6 CONCLUSIONS

A wheel rail contact formulation for analysing the nonlinear dynamic interaction between vehicles and structures is presented. This method takes into account the geometry of the wheel and rail surfaces in order to accurately evaluate the vertical and lateral interaction. An enhanced node to segment contact element is used for modelling the behaviour in the

contact interface in the normal and tangential directions. This approach is generally more efficient than treating the normal and tangential contact forces as external forces. The constraint equations that relate the displacements of the vehicle and structure are imposed using a direct method. In contrast with other contact formulations such as the penalty method, the proposed formulation does not require additional penalty parameters and is less likely to lead to ill conditioned systems.

A study regarding the running safety assessment of trains moving over bridges subjected to earthquakes is presented. Since the running safety of trains might be jeopardized not only by intense shakings, but also by moderate earthquakes, which may not cause significant damage to the structure, only seismic events with relatively low return periods and high probability of occurrence have been considered. Nevertheless, although the columns do not experience significant damage for these levels of seismic intensity, a methodology to account for the reduction in their stiffness due to concrete cracking is proposed. The influence of the seismic intensity level, running speed and track quality in the running safety of a high speed railway vehicle moving over a viaduct is discussed. Unlike the majority of studies, in which the earthquake is assumed to start at the instant the train enters the bridge, the randomness of the earthquake is accounted for by considering different time offsets between the beginning of the earthquake and the entry of the vehicle in the viaduct. The results have shown that, even for the moderate seismic intensities considered in the present study, the train safety is put at risk in a considerable number of scenarios, especially due to the risks of derailment caused by wheel flange climbing. These results prove the importance of taking low intensity earthquakes into account in the design of railway bridges, even if they do not represent a major threat to the structure integrity. The track quality has also a strong influence on the running safety, since, even without considering the effect of the earthquake, the values of the Nadal and Prud'homme criteria increased approximately 5 times for the track with poorer quality.

The assessment of the running safety of high-speed trains over a short span railway bridge using a probabilistic approach was also presented. A filler beam bridge with spans with a length of 12 m was selected as case study. The existence of track irregularities was accounted for along with the variability of parameters related to the bridge, the track and the train. The obtained distribution for the wheel unloading coefficient was unimodal. For this reason, attempts were made to fit known distributions to the data obtained from the simulations. The lognormal distribution was the most likely to fit the data, however, adequate tests led to the rejection of this hypothesis. Consequently, the modified Monte Carlo method, which combines Monte Carlo simulations with the classical GPD, was used to assess the running safety of the trains over the bridge. The analysis allowed concluding that the train speed must be limited to 420 km/h in order to ensure the running safety of the trains over the bridge. The speed limit to guarantee the running safety is significantly higher than that obtained when analysing the track stability, 295 km/h. Therefore, it can be concluded that when no lateral actions are taken into account the safety of the train-bridge system is governed by the deck acceleration, which is related to the track stability. In future developments lateral actions will be included in order to provide a better understanding of the influence of such actions on the running safety of high-speed trains.

A numerical study on the influence of the settlement profiles of the backfill in the dynamic train-track interaction at the approach to railway bridges - the transition zone – was presented. To that aim, a numerical model was used to simulate the effect caused by different shapes of settlement profiles and different settlement amplitudes (up to 15 mm). It was possible to conclude that the number of hanging sleepers and the gap between the sleepers' underside and the ballast layer depend not only on the maximum settlement amplitude, but also on the shape of the profile. In addition, the development of differential settlements on the backfill can lead to critical situations in terms of track degradation (due to excessive load on the track) and safety requirements (offload limits and loss of axle-rail contact). In some scenarios, the vertical accelerations of the axles may exceed maintenance-related limits, established by some railway infrastructure managers. In general, peak axle loads and accelerations increased with the amplitude of the settlement, but it may also depend on the shape of the settlement profile. Normally, the greater the number of hanging sleepers and gap sizes, the higher the vertical accelerations of the sleepers and the larger the vertical contact forces between the sleepers and the ballast layer. Despite these downside aspects, a very good level of passenger comfort was observed in all tested scenarios. The cases of settlement profiles associated with wedge-shaped backfills indicate an adequate behaviour of the train-track system because none of the limits related to track degradation or safety were exceeded. This finding supports the conclusion that wedge-shaped backfills seem adequate to address the problems related to abrupt variations of the track's stiffness and differential settlements normally found at transition zones. Although this study comprises a theoretic approach, the obtained results may be regarded as recommendations for the design of bridge approaches, particularly, with the suggestion to include wedge-shaped backfills at these locations of the railway tracks. To account for the variability of the development of settlement profiles at transition

zones, further research is necessary and improvements in the model need to be introduced. For example, future developments could include the incorporation of the plastic deformation behaviour of the geomaterials, aiming at predicting the development of more realistic settlement profiles, and testing and comparison of other structural solutions for transition zones, such as approach slabs, under sleeper pads or different backfill designs.

A Vision for Vision-based Technologies for Bridge Health Monitoring

N. Catbas, C.Z. Dong, O. Celik & T. Khuc
University of Central Florida, Orlando, Florida, USA

ABSTRACT: Condition assessment of bridges evolved over the years with the advances in non-destructive evaluation technologies, field tests and structural health monitoring. As a result, technological advances changed the resources that bridge engineers can tap into; however, the requirement for practical, low-cost and effective approaches has remained the same. The writer and his research team have explored vision-based technologies to fulfill such requirements. In this paper, first the vision-based technologies will be presented along with capabilities and limitations. A review of basic concepts, available camera, lens and other peripherals are reviewed along with some of the algorithms for analyzing computer vision data. A framework of image-based structural identification is proposed to obtain structural parameters by using a full con-contact method on vision related techniques. By using a camera system, traffic over the bridge will be identified and classified into classes and sub-classes for vehicle weight estimation. Finally, some solutions and example applications from a laboratory bridge, a footbridge and a railroad bridge are presented.

1 INSTRUCTIONS

Structural health monitoring (SHM) has been employed as an effective approach for structural assessment and decision making for bridges. Due to the advances in technology, SHM has received attention from researchers and civil infrastructure owners over the last several decades. Decision making by means of SHM data in real-life structures has some challenges and discussed extensively by Catbas & Kijewski-Correa (2013). Especially for bridge engineering applications, certain challenges have been presented and discussed such as challenges in field-work for sensor instrumentation, cable wiring, data acquisition, power and transmission arrangement for wired and wireless sensing. These challenges can make certain SHM applications inconvenient, time consuming, and expensive. Additional considerations that need to be resolved are as follows: the inspection and monitoring of existing structures may require service interruptions due to traffic closure; it may be difficult to obtain access for instrumentation work for some large or sensitive bridges; some bridges or network of ordinary highway bridges may warrant just intermittent monitoring with portable systems instead of permanent and continuous monitoring systems. As a result, the development of effective, convenient and inexpensive monitoring tools for situations outlined above and also for large populations of bridges has become more important.

To address the limitations of conventional sensor-based SHM, imaging and computer vision methods have been considered as potential alternatives due to advances in related technologies (Webb et al. 2014). Unquestionably, the main advantage of vision-based approaches is contactless implementation that accelerates monitoring and reduces maintenance cost of structural assessments. As examples for bridge applications, a hybrid sensor-camera St-Id system for bridge monitoring has been developed and demonstrated in the laboratory (Zaurin & Catbas 2010) and also for real bridges (Catbas et al 2012). Although some of these challenges related to structural assessments have been addressed by utilizing image processing and computer vision methods such as detection and quantification of cracks and surface damages of structures (Abdel-Qader et al. 2003, Gul et al. 2013, Yamaguchi & Hashimoto 2010), and displacement measurement of structures (Khuc & Catbas 2014, Kim et al. 2013, Lee et al. 2007), a very few of complete studies in the context of structural identification (St-Id) have been presented (Khuc & Catbas 2017). Structural identification (St-Id) is a transformation of system identification that focuses on creating a numerical or nonphysics-based model of a dynamic system based on its measured response.

2 BASICS FOR VISION-BASED MONITORING

The main idea of vision-based monitoring is to convert the target motion in an image to the actual motion in a physical quantity such as millimeter. In recent literature, many researchers proposed their procedures of vision-based displacement measurement methods. In this study, the authors first summarize the state-of-the-art and then give a general procedure as illustrated in Figure 1. There're four steps in this procedure, including: 1) camera calibration; 2) initial image capture and feature extraction; 3) visual tracking and 4) displacement calculation.

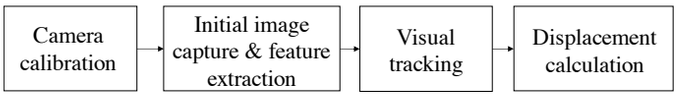

Figure 1. General procedure of the vision-based displacement measurement.

In the first step, there're two prevailing methods: the planar homography matrix method and the scale factor method. Using the planar homography matrix between the image and physical world, it is possible to convert the image entities to the physical world objects (Zhang 2002). In this study, instead of planar homography matrix, for convenience, the authors use the scale factor to convert the target motion in pixels to physical metric such as millimeter. More details about the scale factor calculation can be found from the literatures (Dong et al. 2015, 2017a, b, Khuc & Catbas 2016, 2017, Ye et al. 2016a, b, c). In the second step, one needs to select the tracking region, which includes the measurement targets in the field of view of the initial image. According to the visual tracking methods used in the third step, image preprocessing is utilized to extract useful features from the tracking region. Researches, who use digital image correlation (DIC) in frequency domain or space domain, just select the target regions as the patterns, and the image intensities of the patterns play the role of visual tracking features. Other researchers extract key points and descriptors such as Shi-Tomasi corners, SURF, SIFT, FREAK, etc. as the tracking features and the corresponding visual tracking method includes Lucas-Kanade optical flow estimation (Dong et al. 2017a) and key point matching based on nearest neighborhood approximation (Khuc & Catbas 2017). The third step is to track the selected targets in the subsequent images captured by the camera continuously and locate the targets' new positions. Here except the tracking algorithms mentioned above, dense optical flow algorithms and phase-based optical flow algorithms are also good choices. Finally, with the scale factor, s, applied to the displacements in pixels, the actual displacements at time t with a physical unit are obtained: $(x_t - x_0)$s, horizontally, and $(y_t - y_0)$s, vertically.

3 SYTEM CONFIGURATIONS

It is important to pick and choose the right cameras, lens and software as well as other associated peripherals for a particular bridge engineering application. The vision-based displacement measurement system consists of a suite of image acquisition device and image processing software. In general, the image acquisition device includes a camera and a lens. As shown in Table 1, some typical components including cameras, zoom lenses and synchronization modules. The selection of image acquisition device depends on the application scenarios and requirements for real-time monitoring or post processing. If one just wants to acquire the images during the experiments and do post processing, portable cameras are good options, because they are easy to setup and don't need external power supply. Also, portable cameras have on board storage mechanism, which means that the videos or images can be directly stored in the built-in storage or SD card. And the exposure time can easily be controlled and fixed to a specific value, which makes the cameras have the uniform sample rates. However, the portable cameras are not programmable so that connecting with computers and working with other sensors synchronously can be very hard to achieve. The 4K action camera (Z camera E1) listed in Table 1 can be synchronized with several cameras via a master-slave series connection. The industrial cameras are programmable and have input-output interface, which can be connected with computers and controlled by software. These cameras can work with other sensors synchronously. The synchronization can be achieved by the external controlling system. Here NI 6343 Multifunction I/O Device and MindVision trigger module are listed as the external controlling system. There are two video/image output interface for industrial cameras: USB 3.0/2.0 and GigE. USB2.0 is becoming out of date and most of the USB camera are using USB 3.0. USB3.0 has a higher transmission speed and higher volume bandwidth (5 Gbit/s) than GigE cameras (1000 Mbit/s). And in general, the frame rate of USB3.0 cameras are higher than GigE camera. But there is a tradeoff: the transmission distance of the USB3.0 cameras is much shorter (less than 5m) than the GigE cameras (100m). Camera arrangement and synchronization in a wide range is very hard for USB3.0 camera. Even though this problem can be solved by adding fiber optic cable or using the zoom lens with longer focal length, the cost would be increased greatly. For long span bridge monitoring with the requirement of multi-point and wide range distributed camera arrangement where the sample rate is not very high, GigE

may be more suitable. Since most of the industrial cameras and lenses are separated, the selection of zoom lenses is determined according to different measurement distance and requirement of accuracy. Remarks are noted in Table 1.

Table 1. Components of vision-based displacement system.

Item		Model	Technical Specifications	Remarks
Camera	Portable camera	 Sony HDR-SR10	Resolution: 1920 × 1080; Frame rate: 30 fps; On board image storage; Carl Zeiss Vario-Sonnar T Lens; 15x Optical Zoom, 3.1-46.5 mm;	High resolution, with own zoom lens, suitable for close range measurement
		 Canon VIXIA HF R42	Resolution: 1920 × 1080; Frame rate: 60 fps; On board image storage; Zoom Ratio: 53x Advanced*/32x Optical/1060x Digital; Focal Length: 2.8-89.6mm.	High resolution, with own zoom lens, suitable for close range measurement
	4K action camera	 Z camera E1	Multiple video resolutions: 4096x2160 @24fps; 3840x2160 @24fps/25fps/30fps; 2880x2160 @24fps/25fps/30fps; 1920x1920 @24fps/25fps/30fps; 1920x1440 @24fps/25fps/30fps; 1920x1080 @24fps/25fps/30fps; 1920x1080 @50fps/60fps; 1280x720 @50fps/60fps/**240fps**; 840x480 @25fps/30fps; Mount: Micro Four-Third; On board image storage.	High resolution and can be switched to different video resolution and frame rate according to the application scenarios, portable, easy to set up
	Industrial camera	 Basler ace-acA2040-120um	Resolution: 2048 × 1536; Frame rate: 120 fps; Pixel Size (H × V): 3.45 μm × 3.45 μm; Mono/ Color: Mono; Sensor Type: CMOS; Shutter: Global Shutter; Interface: USB 3.0; Mount: C mount; Synchronization: software trigger/hardware trigger/free-run.	High sample rate and high resolution, can be controlled by computer, real-time displacement monitoring and image acquisition for post processing, programmable
		 MindVision- MV-GE131gc-t	Resolution: 1280 × 960; Frame rate: 72 fps; Pixel Size (H × V): 3.75 μm × 3.75 μm; Mono/ Color: Color; Sensor Type: CMOS; Shutter: Global Shutter; Interface: GigE; Mount: CS mount; Synchronization: software trigger/hardware trigger/free-run.	High sample rate, can be controlled by computer, real-time displacement monitoring and image acquisition for post processing, programmable, cost-effective
Lens		 Olympus M.Zuiko ED 75-300 II	Zoom: 75-300mm; Manual zoom; Aperture: F4.8-607; Mount: Micro Four-Third.	Long distance, high resolution
		 Navitar 12x zoom lens	24X Zoom with 2X extender; High magnification; Mount: C mount;	Super long-distance zoom, long span bridge displacement measurement
		 6-60mm lens	Zoom: 6-60mm; Manual zoom; Aperture: F1-1.6; Sensor size: 1/3"; Mount: C/CS mount	Light and easy to control; with luminosity control
		 5-100mm lens	Zoom: 5-100mm; Aperture: F1-1.8; Sensor size: 1/3"; Manual zoom; Mount: C/CS mount	Light and easy to control; with luminosity control
Synchronization			32 AI (16-Bit, 500 kS/s);	It need to connect with

module	NI 6343 Multifunction I/O Device	4 AO (900 kS/s); 48 DIO USB Multifunction I/O Device.	computer and can synchronize conventional sensors and cameras via LabVIEW
	 MindVision Tigger module	Four channel output trigger; Flash control.	On board control, programmable, digital output, can trigger industrial camera.
	 Z camera master-slave Synch module	Master-slave control; input-output series connection.	For portable camera with I/O function, wire control gives high synchronization accuracy

4 COMPUTER VISION-BASED STRUCTURAL IDENTIFICATION

In this paper, a new St-Id framework for bridge monitoring using computer vision technologies is presented, and subsequent computer vision-based bridge monitoring examples are developed within the context of St-Id. In brief, traffic loading induced from multiple vehicles is estimated including axle loads and load locations by utilizing a combined detection and localization computer vision algorithm on image data from a traffic-camera. Simultaneously, other cameras (response-cameras) are deployed under the bridge to measure bridge displacements at multiple locations to those vehicles by means of a non-target vision-based displacement monitoring. Then, the input data (traffic loading) and output data (displacement responses) are processed with an image-based structural identification (iSt-Id) system to obtain a new indicator for bridge damage detection, named the displacement Unit Influence Surfaces, UIS (Khuc & Catbas 2017). Similar to natural frequencies and mode shapes of structures, the UIS is one of a few structural parameters that can be derived as a function of only structural characteristics. It means that the UIS can be employed as a powerful structural indicator for the assessment of bridges. The UIS of a laboratory bridge have been successfully obtained and illustrated on subsequent sections. Those UIS that were obtained have shown consistence and reliability, and enabled a new fully contactless iSt-Id implementation.

In this research, traffic vehicles are categorized into classes for example sedan, SUV, minivan, bus, truck, semi-trailer, etc., and the weight distribution of each class can be studied based on the manufacture's vehicle specification and/or using Weigh-In-Motion (WIM) database. In order to detect each type of vehicle in a scene, for instance the semi-trailer class, the Haar (Viola & Jones 2001) and/or HOG (Dalal & Triggs 2005) features corresponding to semi-trailer trucks are extracted to represent for this class. Thus, those object features are used to develop a classification algorithm based on booting technique (Viola & Jones 2001), which can rapidly find regions where a particular class may occur. The initial and successful implementation for detecting and classifying small-scale vehicles has been demonstrated in the UCF Structural Lab, which is illustrated in Figure 2.

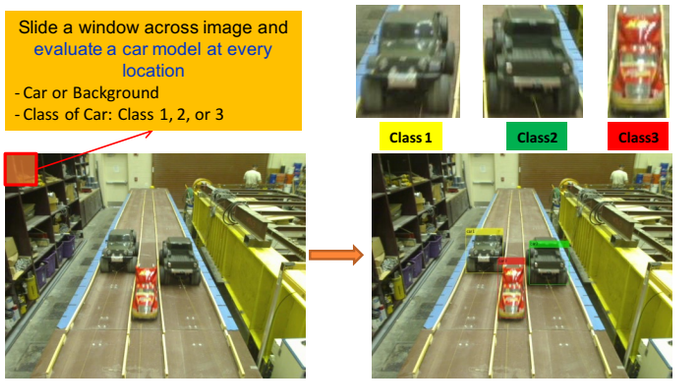

Figure 2. Three types of vehicles detection and classification.

5 NON-TARGET DISPLACEMENT MEASUREMENT BASED ON VISION APPROACH

While using some certain of sensors such as linear variable differential transformers (LVDTs) and slide wire potentiomers are the most common sensors to collect displacement data, those conventional sensors are not convenient in the field as they require a fixed reference frame. In addition to conventional sensors, use of cameras as special sensors that can collect motion of targets attached at structures in distance, has gained attention recently. As a novel sensing approach, a new vision based method is proposed and will be exploded to measure bridge displacement without using any attached target on the structures. To implement this idea, the authors will extract key-points from the images of the measurement location, to match those key-points between the consecutive frames to determine the pixel based displacement, and to convert the pixel displacement

to the engineering unit (e.g. inch, mm). Although there are several robust methods related to extracting key-points, some well-established algorithms such as Scale Invariant Feature Transform (SIFT) (Lowe 2004), Speed-up Robust Feature (SURF) (Bay et al. 2008), Binary Robust Invariant Scalable Keypoints (BRISK) (Leutenegger et al. 2011), and Fast Retina Keypoint (FREAK) (Alahi et al. 2012) have been explored in a comparative fashion to obtain the measurement location key-points and match them across images. The proposed non-target displacement measurement method has been implemented in the UCF Structures Lab as shown in Figure 3.

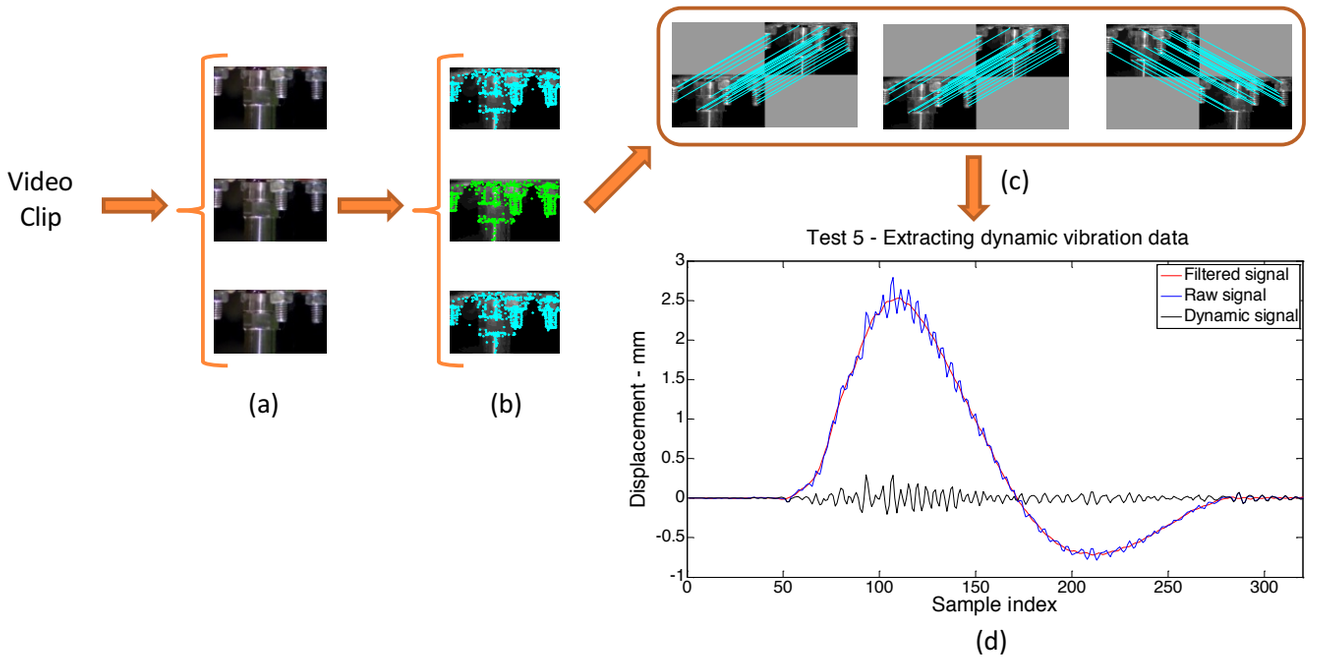

Figure 3. Overview of non-target displacement measurement method; (a) Measurement locations, (b) Extracted key-points as virtual makers, (c) Matching key-points, (d) Get dynamic displacements

6 RESULTS FROM LABORATORY TESTS

The proposed iSt-Id framework has been conducted in a bridge model at the University of Central Florida (UCF) Structures Lab. The experimental bridge called UCF 4-Span Bridge Model consists of two 304.8cm main continuous spans and two 120cm approach spans. The bridge deck includes a 3.18mm steel sheet at 120cm wide which is composited with two HSS 25x25x3mm girders separated 60.96cm from each other. As a bridge test set-up for SHM studies at the UCF, there are a number of sensors attached in the model such as strain gages, accelerometers, LVDTs, tilt-meters, and Fiber Bragg Grating (FBG) sensors. Moreover, some common damage scenarios can be simulated in the model by changing stiffness of the structural system and/or of the supports. The result from one test is shown in Figure 4. It is seen that each blue dot location (*x*-bridge length, *y*-bridge width) presents for a combined position of multi-vehicles on the bridge deck. The z-unit displacement value of a particular blue dot is a normalized response (displacement herein) to effects of multi-vehicles loadings. In time domain, each blue dot corresponds to the frame of the video clip recorded by the traffic-camera, and the response of z value must be obtained synchronously.

The UIS is determined by fitting a number of discrete data points (e.g., blue dots in Figure 4). Therefore, combination of several tests is a need for the regression analysis. Figure 5 shows a displacement UIS obtained from several random data sets for one-fifths-span locations of the bridge girder for the undamaged condition (Baseline). To confirm consistency of the proposed method results, a total of fifteen (15) UIS are obtained for each measured position by randomly selecting five (5) tests out of forty (40) tests database. Consequently, some characteristics of those 15 UIS including volume, maximum and minimum values are calculated to compare with the ones of the mean-UIS. It is seen that the characteristics from those UIS are very close (± 6% error interval for maximum values, and only ± 3% error interval for minimum and volume values), which confirms the outcomes of are consistency and reliability of the proposed method (the unit influence surfaces, UIS). Consequently, the UIS can be utilized for damage detection purpose.

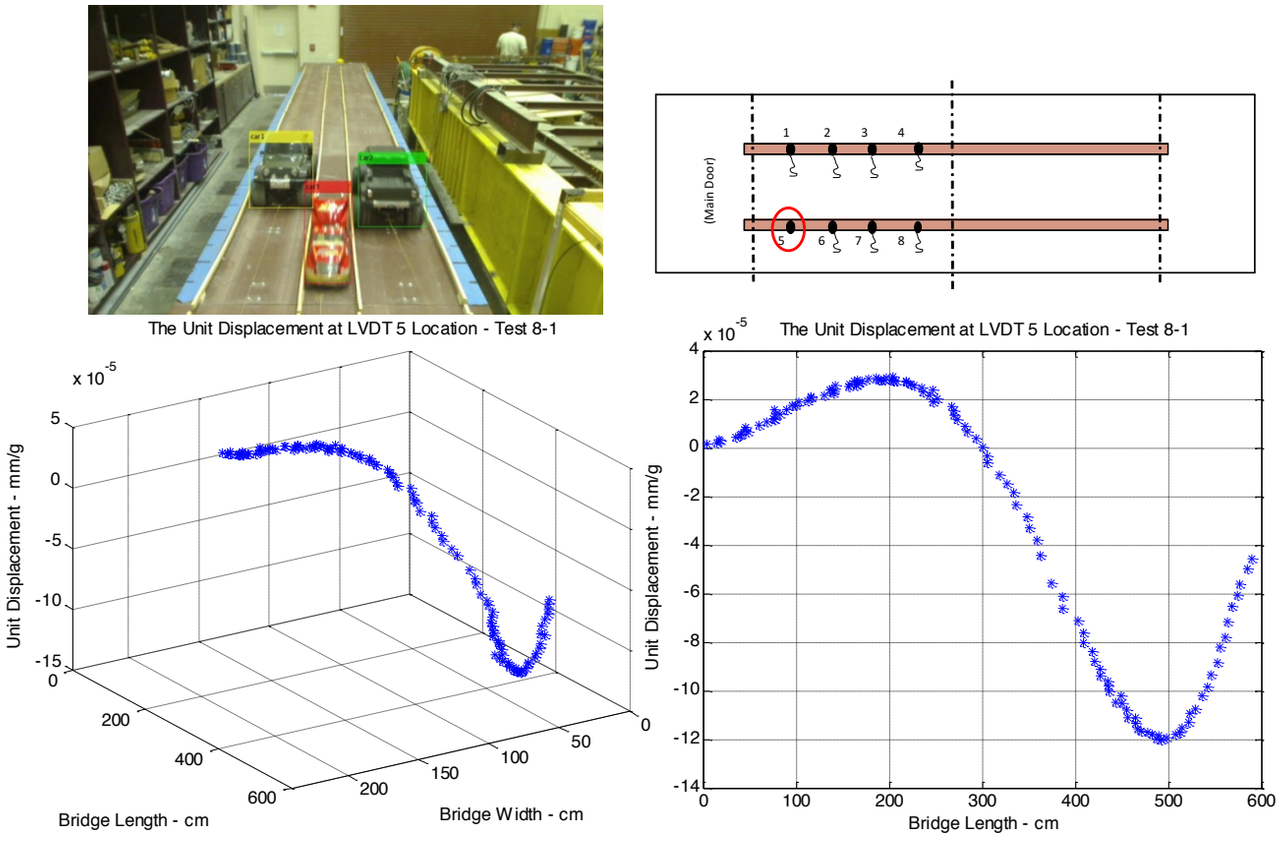

Figure 4. The unit displacement data at a certain measured location

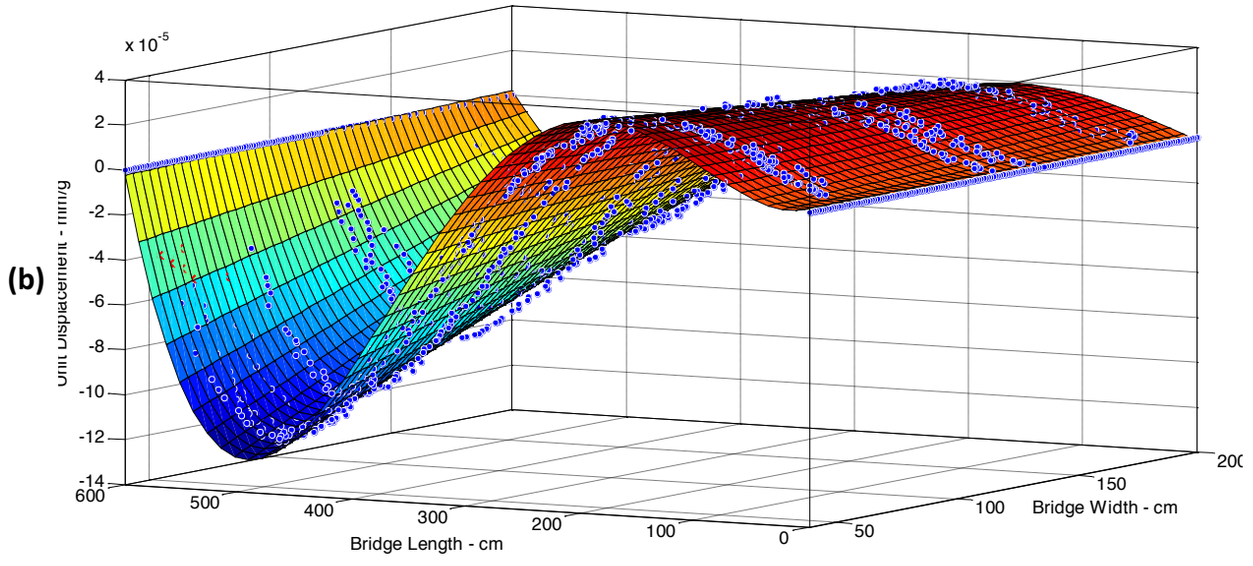

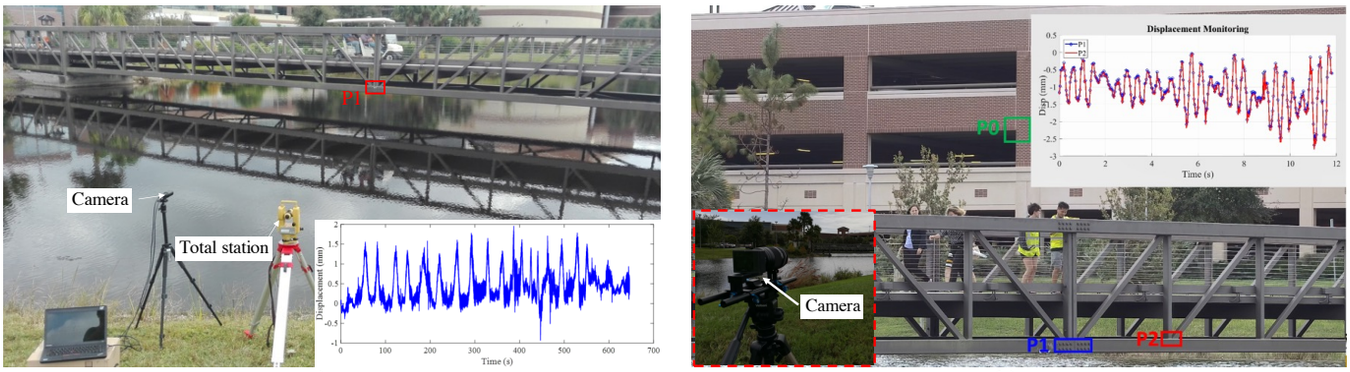

Figure 5. The displacement unit influence surface obtained by fitting from several test data sets

7 REAL LIFE IMPLEMENTATION EXAMPLES

In this section, two examples of real life examples, one from a footbridge and one from a railroad bridge are presented. Figure 6 illustrates the displacement measurement of a footbridge on UCF campus. For this footbridge, golf cart and human loading (walking and jumping) are the two main loads. In the first scenario as shown in Figure 6a, an industrial camera and a total station were set up to measure the bridge displacement at P1 induced by the golf cart when it travelled back and forth on the bridge. The distance

from the location of the camera and the total station and P1 is 18.3 m. The displacement time history was obtained by processing the image sequence acquired by the camera and the maximum displacement was about 1.5 mm. The total station gave 1.75 mm as the maximum displacement and it was almost the minimum resolution. Here, the total station can only measure the static displacement not dynamic one. Comparing the results from vision-based method and total station, it can be seen that the vision-based method shows good performance for dynamic structural displacement measurement. Figure 6b shows the bridge displacements of two points (P1 and P2) under human loads. The camera used here was an 4k action camera which was placed 60 m away from the P1. Since this camera was placed further away at a location with ground vibration, it could easily be disturbed by the wind and ground vibration. As a result, a stationary point P0 was selected to eliminate the camera motion. The revised displacements, which were obtained by subtracting the displacement of P0 from P1 and P2 respectively, were assumed the corrected ones. The measurement results not only show the whole process of human loading but also give a high accuracy. The precision here was smaller than 0.01 mm.

a) b)

Figure 6. Displacement measurement of a footbridge under: a) golf cart loading; b) human walking and jumping

Figure 7 shows a railway bridge in the city of Winter Park near Orlando, Florida. A 4K action camera was placed about 40 m away from the measurement point, P1. To eliminate the camera motion, a stationary point P0 was selected as the reference point. The camera recorded the whole process when the trained crossed the bridge. As shown in Figure 7, the displacement time history of P1 clearly indicates the bridge deformation at midspan. The red dash line box shows the moments starting from the train getting on the bridge and departure from the bridge. The maximum displacement is around 11.5 mm.

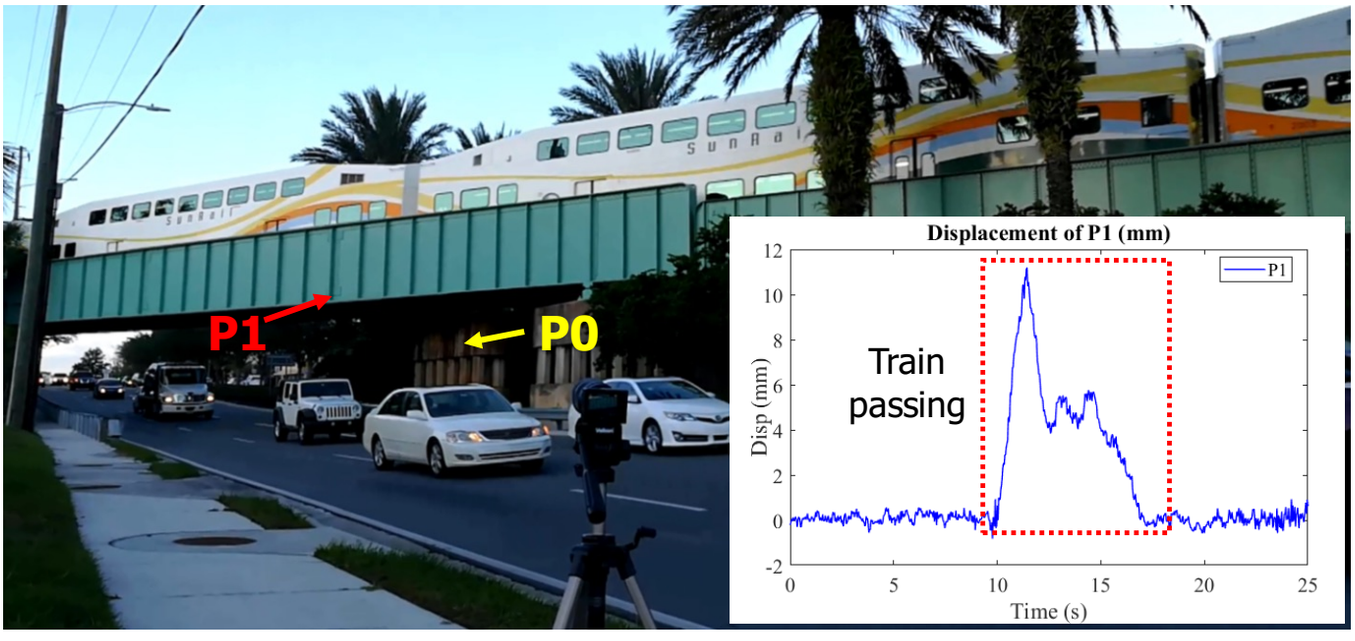

Figure 7. Displacement measurement of a railway bridge when a train passing through

8 CONCLUSIONS

This paper introduces an overview of vision-based monitoring of structures. Prevailing algorithms are briefly reviewed, and image acquisition devices are discussed according to various application scenarios. First, a laboratory study is presented where structure is monitored using cameras and sensors within the context of structural identification. A new indicator for bridge damage detection, entitled Unit Influence Surfaces, UIS, is presented and demonstrated. UIS is a powerful index that can be obtained using cameras that monitor vehicle traffic on bridges and also responses of the critical locations of the structure. The dynamic displacements of bridge girders to those vehicle loads at several measured locations can be obtained. The input effects including vehicle loadings, vehicle locations, and output displacements of the bridge structures can be obtained to determine a series of displacement unit influence surfaces (UIS). Quantitative analysis of the UIS have confirmed its consistency and reliability that enables applications of using the UIS in damage detection and damage localization. Next, a footbridge and a railroad bridge monitoring study as real life examples are presented. These studies were conducted without interrupting the traffic and without the need to have access for sensor or target installation.

Computer vision based monitoring of bridges has major positive impacts for structural safety and assessment of especially large population of bridges. The sensor based structural health monitoring (SHM) technologies have somewhat matured and are available; yet, permanent and continuous of such SHM may be economically feasible for only a small fraction of bridges such as structurally critical or landmark bridges. In the meantime, a large population of routine highway bridges will still rely on visual inspection by the inspectors/engineers. Cost-effective and easy to use camera based technologies can support field inspections of such structures while also eliminating time-taking field installation of sensors. Besides, the data obtained using computer vision-based monitoring can be further employed for structural damage detection, condition assessment, etc., which are also currently carried out using conventional sensors. As a result, cost and time could be saved for the SHM of ordinary bridges. It is anticipated that such SHM would support decision-making and planning for structure management and maintenance.

The engineering and management of major steel box girder bridges; lessons from West Gate Bridge.

I. Firth
COWI, London

ABSTRACT: Steel box girder bridges are in use for long spans all over the world. They represent an economic solution for such structures, but must be properly conceived and carefully detailed if they are not to be a long-term maintenance burden for their owners. Ten years ago, the West Gate bridge in Melbourne (Figure 1) was substantially strengthened and upgraded to accommodate an extra traffic lane in each direction and to deal with a variety of problems that had arisen since its construction in the 1970's. This paper describes the background to the development of the steel box girder genre, and outlines some of the strengthening, refurbishment and ongoing maintenance work on the bridge. It also touches on some lessons learnt from other similar major steel box girder bridge structures.

1 INTRODUCTIONS

Steel box girders provide an efficient and economic solution for long span bridges, and are frequently used for more modest spans as well. After a rather shaky start, their behaviour and design are now well understood, and when properly detailed and constructed, with well-conceived operation and maintenance plans in place from the outset, modern steel box girder bridges provide an economic long term solution for most long span situations.

Early examples from the 1960's have suffered due to insufficient understanding of design or maintenance issues at the time and frequently because of poor attention to detail. In addition, the enormous increase in traffic since then has placed extra demands which were not envisaged at the time of their design. As a result, several have subsequently undergone substantial refurbishment and repair. The lessons that have been learnt have informed and thereby improved the practices and procedures now generally adopted in design, construction and maintenance for more modern steel box girder bridges, such that they are not expected to exhibit maintenance problems to the same degree in future.

However, memories are frighteningly short, and those charged with teaching engineering students or training young professionals are in some cases ignorant of the tragic events of the past, with the dangerous consequence that old mistakes are in danger of being repeated. Whether it is to avoid tragic collapse or more likely costly repair and maintenance, it is vital that those involved in the design and construction of steel box girder bridges, and those responsible for teaching and training younger engineers, are aware of what has gone before so that the mistakes of the past are not merely repeated.

2 THE STEEL BOX GIRDER STORY

Some of the earliest examples of modern steel box girder bridges were constructed across the River Rhine in the 1950's to replace bridges destroyed during World War Two, although the origins of the form go back much further to the wrought iron and eventually steel tubular bridges of the mid to late 19th century, mainly in the UK. [1] The development of welding technology in the 1920's and 1930's and the desire to reduce weight, particularly on longer spans, led to the emergence of lightweight girders with an orthotropic deck comprising a thin

steel plate with longitudinal stiffeners welded underneath.

This form of stiffened deck plate, with closed, torsionally stiff trough stiffeners for improved transverse dispersion of local wheel loads, has evolved over the years partly through theoretical analysis and partly through empirical development from first-hand experience. Huge leaps in the understanding of the fatigue performance of the welded details in orthotropic decks have been made since those early days, but it is surprising how much variation still exists, even now, given that by and large they all do the same job.

A major step-change for the long span story occurred with the Severn suspension bridge, designed by Freeman Fox and Partners and completed in 1966. (Figure 2) This aerodynamically streamlined closed box girder was the first of its kind and substantially lighter than the foregoing steel truss designs. It has been copied in a variety of forms ever since for long span structures, and even for some shorter spans

Fig. 2 - The Severn Bridge, England

The Severn bridge started a flurry of activity which saw many new steel box girder structures emerging in the mid to late 1960's. But then tragedy struck in 1970 with the collapse during construction of the Milford Haven bridge on 2nd June and the West Gate bridge on 15th October. The investigations that followed in the UK [2] and Australia [3] pointed to a combination of errors in design and construction, and led to feverish activity to develop new design and workmanship rules as well as improved procedures for design and construction control. There is much more to be said about this particular episode in the box girder story, but mostly in connection with design and construction, rather than operation and maintenance, which is the principal theme of this conference. Nevertheless, the lessons learnt from that time still reverberate today, and influence all modern steel box girder bridge projects.

After a significant appraisal and re-design process (particularly extensive for West Gate which was originally designed with a concrete deck but rebuilt with an orthotropic steel deck [4]), both failed bridges were rebuilt, as was the Koblenz bridge over the Rhine which had also collapsed during construction in November 1971. Other steel box girder bridges already built or under construction at the time were strengthened, usually by the addition of extra stiffening and plating to webs, diaphragms and bottom flanges, in what became known as the Merrison Strengthening programme.

In the ensuing years, experience with the bridges in operation began to reveal weaknesses of a different kind. Fatigue cracks were observed after only a few years in details subject to high local stress fluctuations due to passing traffic. In particular, the welds attaching the longitudinal trough stiffeners to the deck plate and transverse diaphragms were susceptible, as were other locations where live load stress concentrations occurred. The situation was exacerbated by the rapid growth in vehicle weights and numbers during the 1970's and 1980's.

In the UK, the structures of the Severn Crossing were assessed and substantially strengthened [5], in which a significant aspect was the improvement of the orthotropic deck weld details. The research carried out and the lessons learnt as part of that programme have informed steel box girder design ever since, and have resulted in much improved long life performance of orthotropic deck designs.

Steel box girders are also used increasingly with a composite concrete deck instead of an orthotropic deck in cases where the disadvantage of added weight in the concrete deck is outweighed by the long-term advantage of reduced maintenance demand in the steelwork. That is not to say that composite concrete decks are maintenance-free, but the absence of the fatigue-prone weld details in a steel orthotropic deck is a distinct benefit.

But for the longest spans, all-steel box girders still hold sway, and will continue to do so at least until we gain greater confidence in the use of lighter weight carbon and glass fibre composites, whose long term performance and maintenance issues are as yet not fully appreciated.

3 DESIGN AND ASSESSMENT STANDARDS

The collapses in 1970 triggered an extraordinary amount of research and development into the behaviour of thin steel plated structures. The previous relevant design standard in the UK, BS153 [6], was already known to be inadequate in such cases. Requests for urgent research funding had been made to the UK Government in the 1960's but sadly funds had not been forthcoming. Now, in the light of the tragic circumstances, the money was suddenly miraculously available and it is said that about 30 years

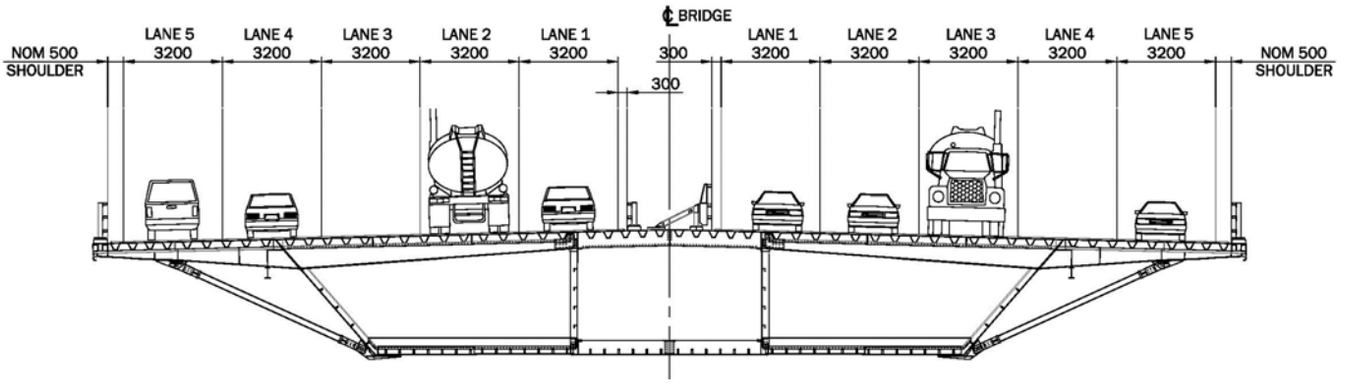

Fig. 3 – Typical Cross Section showing lane layout

of research was carried out in three years, such was the urgency and importance of the work.

Under the auspices of the Merrison Committee of Inquiry, new design and workmanship rules were rapidly developed, and the urgency was such that designers were being issued with amendments to design clauses for them to incorporate as their designs evolved. The new rules, known as the Interim Design and Workmanship Rules (IDWR) [7] were comprehensive, treating aspects such as residual stresses due to welding, imperfections, orthotropic behaviour and other issues explicitly in a rigorous way not found elsewhere. However, the rules were also complicated and demanded a certain degree of expertise and specialist knowledge in their interpretation, so eventually a simpler design standard was called for. In his Gold Medal Address to this Institution of Structural Engineers in 1989 [8], Dr. A.R. Flint, a key member of the Merrison Committee, reflected that in the race to find solutions there was no time to be brief in the code drafting. This required more time, and it wasn't until 1982 that the new steel bridge code BS5400 parts 3 and 6 [9] finally emerged to replace the now obsolete BS153. This was a simpler document, easier to apply and more suited to design, but with the simplification came some conservatism.

In Europe, the Eurocodes have since largely taken over for the design of new bridges. The inevitable and inherent conservatism built into the codes has little impact on the economic outcomes for the project when used in the design of new bridges. But for the assessment of existing bridges, and in particular those designed before the mid 1980's, the use of such conservative design standards would result in an under-estimate of residual structural capacity in some instances and thus potentially lead to unnecessarily costly strengthening. Consequently, for the assessment of steel bridges in the UK, the applicable standard is BD56 [10] which applies the relevant clauses of BS5400 part 3 [9] but with modifications to suit assessment. At the time of writing, the author is involved with updating BD56 in line with the wide-ranging review of the whole of the UK's Design Manual for Roads and Bridges. [11]

Thus, for the assessment of major steel box girder structures older than about 30 years, it is recommended that a Bridge Specific Assessment approach should generally be adopted. Benefits of this approach arise from the improvements in structural capacity obtainable by using appropriate assessment standards, and the IDWR is still considered by many to be the most appropriate for treating the actual behaviour in most cases. And also in certain cases, the adoption of a Bridge Specific Assessment Live Load model (BSALL) can have a marked benefit where this is less onerous than the standard codified loading model. This was the approach taken in the West Gate Bridge assessment referred to below.

4 OPERATION AND MAINTENANCE

Designers today are thankfully much more conscious of the need to design for ease of operation and maintenance than they were 50 years ago. Early steel box girders were typically provided with very poor access provisions by designers who naively thought that their creations would not need regular, routine inspection and maintenance. Operators found that they needed to close busy traffic lanes to gain access to the interior because the designers had simply not considered such things.

Today, this is thankfully one of the most important items on the list of essential considerations in the design of a major steel bridge, but it was not always so. It is not until you have experienced first-hand the awful shortcomings of a bridge where this has not been a priority that you can really appreciate how important this is. As a bridge designer, the author is grateful that his early experience concerned the assessment, strengthening and upgrading of bridges which were all deficient in the matter of easy access and maintenance. A good bridge designer needs to understand the needs of those responsible for the long term management and maintenance of the bridge, and must ensure that easy access to all parts requiring inspection is provided.

In recent years there has been a trend towards using vehicle-mounted telescopic working platforms to

gain access to the underside of the bridge instead of a travelling gantry running on rails permanently fixed to the bridge. Such travelling gantries themselves need maintenance, and their relatively infrequent use means that considerable costs can be incurred just ensuring that the gantry is safe to use each time. A vehicle dedicated to this activity has to be constantly checked and certified as safe to use, so is often preferred by bridge owners, particularly as the vehicle can generally be used on many bridges in their network. Such a vehicle was made specifically to suit the geometry of West Gate Bridge by Moog in Germany and can also be used on other bridges in Victoria. (Figure 4)

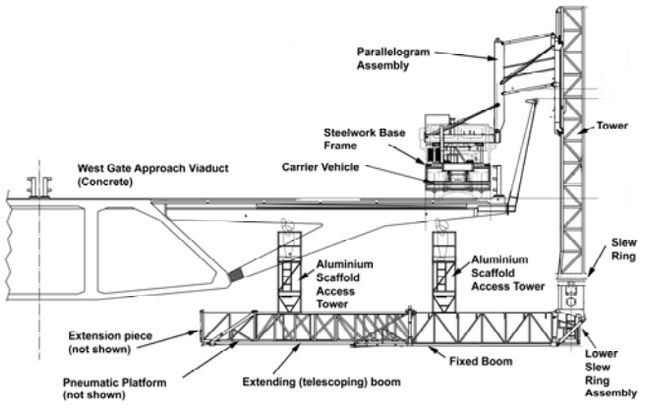

Fig. 4 – Vehicle-mounted telescopic platform (MBIP)

The use of drones for close-up inspection of inaccessible part of bridge is also now commonplace, and coupled with intelligent systems using GPS with the camera, it is possible to generate inspection reports quickly and semi-automatically, pinpointing the location of defective or suspect details requiring further close-up investigation. The pace of change is very rapid in this area.

Access for inspection is fundamental, but even more so is the need for very careful detailing in the first place. Stress concentrations, sharp changes in direction in load paths experiencing fluctuating stresses, and corners where it is not possible to see critical welds and details up close are all examples of the kind of issues which should be avoided. Sadly, too often such details are overlooked by inexperienced designers or subsequently changed by contractors, without proper oversight by someone familiar with the challenges of steel bridge maintenance. There is no doubt that the little extra cost and effort required to get such things right at the outset will save a fortune in long term maintenance costs and avoid all sorts of difficulties for the owner later.

On West Gate bridge, as on other steel box girder structures in the author's experience, there are many problematic details which tend to be repeated throughout the bridge. We have identified a family of repetitive details in need of regular inspection and occasional intervention on the transverse cross-frames, which occur generally every 3.2m. (Figure 5). Every detail is categorised according to its vulnerability – how susceptible it is to high fluctuating stresses, for example – and its criticality – the potential significance for the integrity of the bridge if the detail is found to contain a defect. This is arrived at by detailed finite element analysis and evaluation, and in some cases actual instrumentation and monitoring over an extended period.

Such a system has the benefit of allowing the bridge management team to deploy limited resources most effectively by focusing on the most vulnerable and most critical details. So for example, a detail which is vulnerable but not critical may be allowed to develop a defect without too much concern, and one that is critical but not vulnerable probably does not require very regular inspection. But those that are both vulnerable and critical receive the greatest scrutiny, and procedures have been pre-determined so that the maintenance team knows what to do in the event that a defect needing repair is found in such a location.

Having worked hard to establish this system, it is now only necessary for the bridge managers to seek

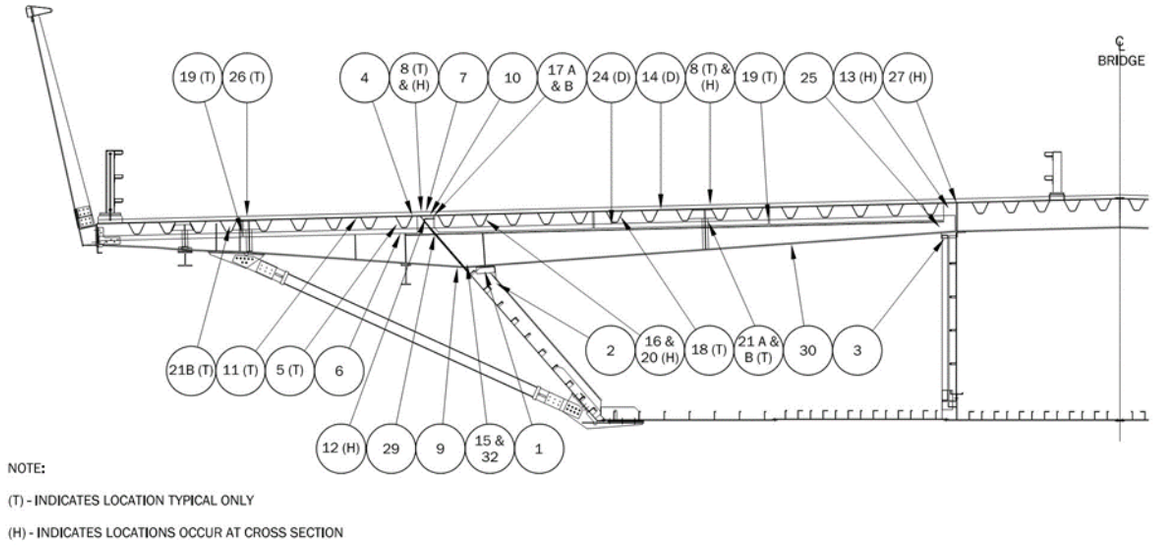

Fig. 5 – Critical details on a typical cross-frame in West Gate bridge outer cell.

advice from the assessment team if a new type of defect is encountered of if something unexpected occurs that needs to be evaluated. The majority of the inspection and repair work is thus relatively routine.

Modern instrumentation and monitoring techniques are developing all the time, and it is now commonplace to specify the inclusion of relatively sophisticated structural health monitoring systems on major new bridges. These are intended to assist the bridge maintenance team by enabling them to focus attention on those parts of the bridge most needing it and reducing the need for regular intervention elsewhere.

In some situations, intelligent systems are being introduced to automatically trigger an alert in the event that certain strain or displacement thresholds are exceeded in critical details. This would be a very extensive and costly exercise for a major bridge, and is unlikely to be economic when there the structure has the luxury of full time maintenance staff as at West Gate. Such systems are more likely to be justifiable for smaller structures which do not have a resident or frequently visiting inspection team. In such circumstances, an intelligent early warning system can alert a network management team that an inspection is needed, and such systems are set to become much more commonplace in the years ahead.

5 LESSONS FROM WEST GATE BRIDGE

The West Gate bridge carries the busy M1 motorway across the Yarra River just south west of Melbourne city centre. It is nearly 50 years since the tragic collapse during construction that killed 35 people, and the reverberations of that event are still felt today. Originally designed with four lanes in each direction and a hard shoulder, the increase on traffic demand through the 1980's and 1990's was such that widening to 2x5 lanes became essential. At the same time, assessments of the bridge had shown that it was in need of strengthening and upgrading to meet future demands.

The structure is a five span cable stayed bridge, 848m long, with a main span of 336m. It has a 3-cell steel box girder which is supported by the cable stays along the centreline. The whole structure, including the long curving post-tensioned concrete box girder approach viaducts, was upgraded and strengthened to carry the extra traffic lanes between 2007 and 2011. The work was carried out by an Alliance comprising VicRoads, main contractor John Holland, and designers Flint & Neill (now COWI) for the steel bridge and SKM (now Jacobs) for the concrete approaches.

The work was extremely challenging, not least because of the logistics of keeping the motorway open and the traffic flowing at all times, getting men and materials inside the bridge to carry out the work safely and efficiently, and dealing with hazards such as removing red lead paint before certain works could progress. Details of the works on the steel bridge are covered more fully elsewhere [12], but in a nutshell, they mainly entailed:

- additional stiffening of webs and flanges,
- reinforcement of existing plates and stiffeners,
- adding steel props to support the cantilevers,
- replacing waisted shank "Gilbert Roberts" bolts with conventional parallel shank HSFG bolts, and reinforcing bolted splice joints by the addition of extra bolts, typically using Tension Control Bolts,
- strengthening the internal diaphragms in places,
- reinforcing the steel box section towers, and
- substantial improvements in internal access provisions to enable all of the above and facilitate future ongoing maintenance.

The works also included the addition of a high fence to deter would-be suicides, as well as upgrading the vehicle containment barriers along the edges of the deck.

Following the main strengthening works, attention turned to dealing with the ongoing maintenance issues, and the classification of potentially defective details referred to above was carried out. Specific repair procedures were developed, with operatives trained in the particular and sometimes complex welding procedures necessary in certain cases.

Fatigue cracking is commonplace with bridges of this type and age, and a specific fatigue management strategy always needs to be developed in order to ensure the ongoing long term integrity of the structure. Most critical are any fatigue cracks that if left to grow could propagate into the parent plate and cause more extensive damage and/or become much more difficult to repair.

In some cases, the detail is such that the only solution is to provide an alternative load path so that high stress concentrations, typically at corners of the ends of welded connections, are removed. In others, it is simply a matter of grinding out and re-welding if a crack extends beyond a pre-determined critical length. In still others it may be possible simply arrest the crack growth by drilling a hole to encompass the crack tip, or even just to leave it alone and not worry about it (as in cases of low vulnerability and low criticality). Every detail has its own peculiar characteristics, which is why each type has been assessed on its merits considering the fluctuating stress state, any alternative load paths, the steel material quality and so on, and the generic monitoring and repair procedures agreed.

Sometimes, in carrying out the repair, the welders encounter poor quality steel plate, which can significantly hamper their ability to carry out a sound repair. These days we tend to be much more aware of the dangers of accepting poor plate material into

steel bridges and we have quality control procedures in place to prevent it (or should have) in new steel bridge construction. But back in the 1970's the procedures and the understanding were not quite so advanced as they are today, and as a result some poor plate can be encountered from time to time. This then requires special treatment, and sometimes the pre-agreed repair procedure will no longer suffice. Either the damaging stress state needs to be improved by creating an alternative load path or in some other way, or some of the poor parent plate may need to be removed and the detail reconstructed in a more invasive intervention.

In all of this work, it is necessary to use a considerable amount of experience and engineering judgement to arrive at the appropriate solution. This is because the analysis of crack growth rates and residual life can be very uncertain due to the uncertainties in:

- the true state of stress (including locked-in fabrication stresses)
- the actual cyclic live load stresses
- the idealisation of a complex and changing stress field close to the weld tip
- the material properties in general and the fracture toughness properties in particular

By working closely together between the inspectors, welders and the design and analysis team the best solution for each observed defect can be developed.

The details of the fatigue cracking and the management of crack repairs has been covered in a previous IABMAS paper [13] so it is not proposed to go into them again here. The West Gate team has completed the repair of the majority of the important observed defects, and the ongoing monitoring and management processes in place will ensure the long term integrity of the bridge.

6 OTHER LESSONS

Generally speaking, and with the exception of the well-known orthotropic steel deck issues, the majority of fatigue-prone details occur in transverse elements of the bridge. Cross-beams, cross-frames, diaphragms and cantilevers which support the deck are loaded mainly by transient live loads (there is relatively little permanent load stress in such elements) and are therefore much more likely to suffer fatigue damage than those elements which are also designed to carry significant permanent loads. So such elements need particular careful treatment in the design and should receive extra scrutiny in maintenance inspections. However, it is not only such locations that generate problems.

One unexpected problem which we have encountered elsewhere, not on West Gate, concerned the behaviour of unstiffened bottom flange panels in the middle of the span where the flange is in tension. When designing a tension flange which is never expected to experience compression, it would be tempting to leave out any longitudinal stiffeners. Why add the extra stiffening material and workmanship when the plate can carry the tension quite satisfactorily without? However, when the flat bottom flange plate is welded, such as to transverse cross-frames or stiffeners, the weld distortion can result in the panel becoming bowed upwards in an inverted classic "hungry horse" profile. Then when additional tension appears in the flange due to transient loads, the flange tries to straighten out. In the case we were asked to investigate, this straightening out was sufficient to cause relatively high local bending stresses at the cusp of the profile where the welds were, leading eventually to fatigue damage.

This case was further complicated because the upwards bowed profile acted rather as if it was pushed upwards under compressive forces. When loaded out of plane and then released the plate "popped" back up rather like if you push down on the roof of your car and then release your hand. There was no external compression applied to the flange, but the boundary restraints and residual stresses in the system created a stress state similar to that as if there were.

So the lesson from this example was firstly that going for flat, thin, unstiffened tension flange plates in a box girder in an attempt to save weight may be a false economy, and secondly that nothing is quite what it seems. We frequently come up against reminders, like this, that the apparently obvious behaviour is not necessarily what is actually going on when it comes to steel box girders. The actual stress state in this flange was much more complex than a simple analysis would predict. Again, experience counts for a lot in this field.

7 CONCLUSION

This paper has shown the importance of diligent and effective inspection and maintenance in the management of major steel box girder structures such as West Gate Bridge. Modern materials and design and workmanship practices are such that when properly applied by experienced designers, with particular care being taken over small details, steel bridges will not experience the same maintenance challenges faced by their predecessors.

Close liaison between inspection and maintenance teams on the bridge and the design and assessment teams in the office is essential to derive an effective and efficient system for long term economic management of such bridges.

Managing Existing Bridges – On the Brink of an Exciting Future

R. Hajdin
Infrastructure Management Consultants GmbH, Zurich, Switzerland
and
Faculty of Civil Engineering, University of Belgrade, Serbia

ABSTRACT:
It is widely accepted that safety and serviceability are primary concerns in bridge design. However, for the most of bridges' service life, these concerns are addressed indirectly by a qualitative measure, defined herein as condition state, which is based upon observable damages recorded during inspections. Condition state is at best, only loosely correlated to safety and serviceability. It would be more reasonable to address safety and serviceability in inspection process directly, using the information on bridge performance obtained during the design and construction. The future Bridge Management Systems (fBMS) should therefore include this information allowing assessment of safety and serviceability based on inspection results. By including Bridge Information Models that are currently being developed and Structural Health Monitoring, the fBMS will become an invaluable decision-support tool not only for maintenance planning but also for issuing special permits, specification of heavy vehicle corridors, risk assessment due to natural hazards, etc.

1 INTRODUCTION

There is a broad consensus that the benefits of road infrastructure for the society cannot be overestimated. The investments in road infrastructure raise the growth potential of a national economy, which can be fully exploited by efficient utilization of the road infrastructure. It is difficult to quantify the economic benefit of road infrastructure but its lower bound is estimated to be between 4% (U.S. DOT, 2015) and 10% (Kurte & Esser, 2008, ARE, ASTRA, 2006) of Gross Domestic Product (GDP). Apart from purely economic benefit, the road infrastructure enables road users to be involved in various activities that yield private, public, and social benefits (Frischmann, 2012). Maintaining these benefits on the long run in economically efficient, environmentally responsible, and socially reconcilable manner is the fundamental task of road authorities. They are bound to provide fast, safe, comfortable, and affordable travel.

Bridges are critical components of the road infrastructure as they ensure fast and safe passages over otherwise hardly surmountable obstacles. From the users' perspective, it is irrelevant whether a road is carried by a bridge or being in a tunnel or merely resting on soil, so long it provides safe and fast travel from origin to destination. In this context, it is necessary to define what is meant by fast and safe.

There are codes of practice that apply to the design of a road infrastructure and they are related to clearance, speed, and weight allowance. The design travel speed defines the minimum legal travel time on an arbitrary road link. In reality, this minimum travel time can be achieved only in the case of unrestricted traffic flow i.e. if road capacity is sufficiently higher than traffic volume. Based on the current or future traffic, one can specify some travel time – exceeding the minimum travel time - as the "**fast travel**". Clearly, the actual travel times will scatter significantly and the measure of this scatter needs to be consider when defining "fast travel". In this context, one often refers to travel time reliability.

The **safe travel** however is somewhat difficult to define since it doesn't imply absolute protection from undesired events. When travelling, there is always a probability of undesired events, which can harm life and limb, induce economic losses and damage environment. The sufficiently low probability of such undesired events defines "safe travel".

The bridges can play significant role regarding the travel time since their posting can lead to detours and therefore to increased travel time. Furthermore, bridges or parts of them can fail harming life and limb and inducing adverse consequences for economy and environment. A failed bridge can also cause detours and therefore impact travel times. In some cases, a failed bridge can render a region completely inaccessible with disastrous economic effects. It is therefore not surprising that the **structural safety** is the primary concern of bridge owners since it affects both safe and fast travel. Besides structural safety the bridge owners care about **serviceability**, which relates to user comfort that can be affected by deflections and vibrations of a bridge. If safety or serviceability requirements are not met, the bridge will be posted or even closed affecting adversely road users and the whole economy.

Following the definition of the "safe travel", a bridge is regarded as structurally safe if the probability of failure during its service life doesn't exceed some nominal value. Similar approach applies to serviceability in which the exceedance probability of some service limits (deflection, frequency, etc.) must be sufficiently low. Most modern codes of practice for bridge design have adopted this concept (e.g. CEN EN 1990, 2002). In addition, the bridge riding surface must also fulfill the requirements applicable to pavements.

The owners need to ensure that their bridge inventory fulfills the safety and serviceability requirements during their service life and therefore maintain the benefits of road infrastructure. Considering the extent of the road infrastructure in developed countries, this is increasingly challenging task. The tools currently available to owners to fulfill this task seem not to be adequate and, in this paper, recommendations are made that may facilitate the management of existing bridges in future.

2 CHALLANGES

Safety and serviceability were always the primary concerns in bridge design. However, in course of time the requirements have changed significantly and the existing bridges are characterized by the several generations of design codes. In course of time, the codes of practices have changed both regarding actions and resistance models. It is therefore not surprising that the old, otherwise undamaged bridge may not fulfill safety and/or serviceability requirements for the current traffic loading.

Furthermore, safety and serviceability can be jeopardized by deterioration processes or sudden events. The resistance of deteriorated bridges can in time reach a level, at which there is an immediate danger of structural failure. In addition to it, the new insights (e.g. statistical analysis) in frequencies and magnitude of sudden events can render some bridges as unsafe and require posting or even their closure.

The increasing traffic volume and traffic loads are probably the most significant challenge regarding the existing bridges. The traffic mix is shifting toward the larger share of heavy weight vehicles, effectively increasing the occurrence probability of load situations that exceed current design loads. Furthermore, there is an increasing number of special transports, i.e. the ones that exceed legal limits and require special permits. In Switzerland, some of these transports cannot be regarded as accidental actions but rather frequent actions as passages occur on weekly or even daily basis. Similar situation is also in the USA as reported in (Lou, et al., 2018). This trend will increase in the future as the transportation industry is interested in using larger trucks with higher axle loads in order to improve economies of scale. The stiff competition will also lead to platooning i.e. to the trains of wirelessly coupled trucks. The wireless coupling allows to significantly reduce the safety distance between the trucks. This seems to result in a particularly aggressive load situation as these trucks also break simultaneously. The break forces that are mostly neglected in road bridges must be considered in the future and existing bridges need to be assessed for this load situation.

Finally, climate change may lead to more frequent and intensive gravitational hazards, such as flooding, avalanches, landslides, rockfalls, etc.

In summary, the prudent bridge owner needs to plan and execute timely intervention in order to cope with following challenges:

- Potentially unsafe bridges that are designed using bygone codes of practice.
- Bridges with reduced resistance due to deterioration or mechanical damage.
- Bridges exposed to natural hazards that are not or not adequately considered in design.
- Increasing traffic volume and loads that can render some bridges unsafe.
- Increased exposure of bridges to natural hazards due to climate change.

The current approach and tools available to bridge managers in practice seem to be hardly adequate to cope with these challenges. In the following chapters the gradual evolution of these tools towards more efficient bridge management is outlined.

3 CURRENT ASSESSMENT AND DECISION-MAKING

Bridge Management practice differs quite significantly from country to country, but the common denominator is that it relies on visual inspections. The visual inspections are – if performed by a qualified structural engineer – cost efficient and very valuable

source of information. During the inspection, the observation is recorded and evaluated. The result of inspections is qualitative indicator, which is named differently from country to country as condition rating, condition state, condition class, etc. Herein, the term condition state is used. Whereas in the design phase the safety and serviceability concerns are addressed directly in quantitative manner, in the service phase, based on inspection results the condition state is determined. The condition state is a vague measure for the deviation of inspected bridge from the "as new" condition. The direct assessment of safety and serviceability is regarded as not cost efficient since it is commonly assumed that it always requires an in-depth material investigations and structural analysis.

Based on condition state, owners trigger often costly in-depth investigations or even maintenance actions. In practice, once an in-depth investigation based on condition state is triggered, the maintenance intervention is very likely to follow, even if a bridge can still be used without restrictions. The reasons are different from country to country, but one is surely the visual appearance and related perception of safety that entice owners to remove all visible damages with appropriate maintenance interventions. In some (rare) cases, a maintenance action is triggered if a bridge fails structural safety and serviceability checks, with the load and resistance models for the design of new bridges. This is clearly inadequate and uneconomical, given the remaining service life and possibilities to reduce uncertainties on existing bridges. Thus, some countries have introduced safety and serviceability checking formats for existing bridges in their code of practice (e.g. SIA, 2011).

The above-mentioned approach seems not to be very logical. In the design phase, the wealth of information about safety and serviceability for different load situations is created. This information is unstructured and mostly in paper form. After the commissioning of newly constructed bridge, the documents containing this information is handed over to the bridges' owners or operators that act further on as trustees of the bridges assigned to them. The documents are mostly in archives and in general not easily accessible. During the service life, inspections are performed with no consideration of safety and serviceability information produced during the design phase. It only within the in-depth investigation that the safety and serviceability are assessed again. There is a substantial gap during the service life of a bridge, in which decision are made based on qualitative indicators, that are sometimes unrelated to the key concerns of bridge owners: safety and serviceability.

In most countries, bridge management is supported by databases, in which the results of inspections are stored, sometimes in great detail. The information from design phase i.e. critical load combinations, safety factors, assumed traffic loads is usually not stored in these databases. In some road agencies, there are load rating software that facilitate evaluation of special transports, but it is rarely used in conjunction with inspection results.

Even more surprising is that the relevant information on safety and serviceability is often not stored in the database after maintenance interventions. It can be assumed that the provisions of the current code of practice are fulfilled due to maintenance interventions, but it is not recorded if these are exceeded and by what margin.

It should be noted that within the in-depth investigations a substantial work effort is necessary to find information from the design phase or previous maintenance activities. In some cases, the information on existing bridges is lost due to negligence or some accident (e.g. fire, flooding).

In some ways, the current bridge management undergoes amnesia because

- relevant information from the design phase and/or in-depth investigation is not stored and/or
- information is stored only in paper form and is lost due to negligence or accidents.

It is not that bridge owners and operators are not aware of this deficiency, but to remedy it, they need to be provided tools and resources to efficiently store and access the elaborated information on their bridge inventory. In the time of growing awareness of data importance and big data, it is high time to establish an organizational setting for business processes to ensure the benefit of collected data on the long term.

4 ASSESSMENT

The challenges listed in chapter 2 can be only efficiently coped with, if the bridge owners have all necessary information at their fingertips. This means that the current databases need to be significantly improved to accommodate all relevant information either from design phase, inspections, or maintenance interventions. This transition can be quite costly and therefore needs to be performed gradually in several phases as outlined in the following chapters.

4.1 *Safety and serviceability of undamaged bridges*

The information on safety and serviceability margin of an undamaged (virgin) bridge is essential in the service phase. This information should be structured and include all relevant load cases, which would also allow owners to have a clear picture of possible failure modes and related vulnerable zones that need to be observed in more detail.

The current databases are not structured to accommodate the graphical representation of structural systems and load situations. The material properties and load effects need also to be included in the database

as searchable data and coupled with graphical representations. The same apply to load models and provisions of current and previous codes of practice.

A large effort is required to obtain and store information for all existing bridges and this cannot be done within a short time period. Ideally, it could be done together with inspections or in-depth investigations and in this way, one can gradually fill the database.

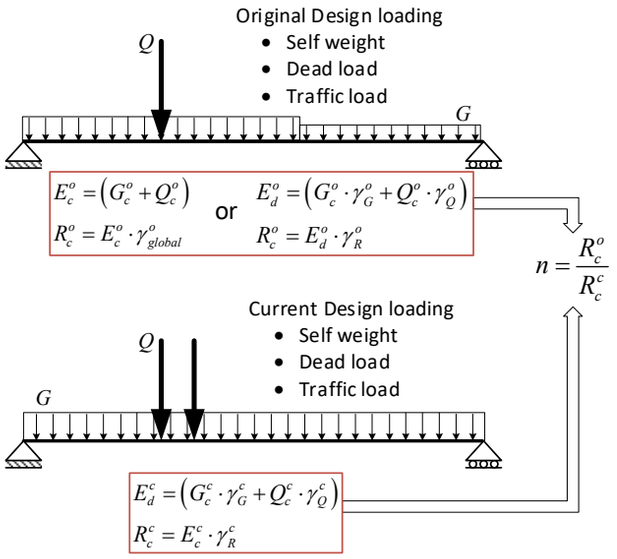

Figure 1: Assessment of safety and serviceability margins

Fortunately, there is a simplified method to assess safety and serviceability margins due to traffic loads. If the load model used originally for the design of a bridge is known, one can assume that the bridge is designed according to it. This means that the bridge resistance is in minimum as high as to sustain the internal forces due to the load model multiplied with the safety factor. In some sense, the originally used design load model is a proxy for the resistance (or service limit) of the bridge. However, to obtain internal forces, one still need a structural system.

Based on the experience from the load rating software (Hajdin & Despot, 1999) and (BMVI, 2016) most non-landmark bridges can be simplified with a series of simply supported beams. Somewhat more sophisticated alternative is to model a bridge with a continuous girder as used in traffic simulations (Freundt & Bönning, 2011, Meystre & Hirt, 2006, Enright & O'Brien, 2013). The simplified model considers only the load transfer in longitudinal direction. The load transfer in traverse direction i.e. across the deck is indirectly considered by defining appropriate effective widths. If the bygone codes of practice didn't require dimensioning in traverse direction, the presented simplification can be problematic. Furthermore, modelling of skew decks or girders with skewed support with simply supported beams is challenging and requires good understanding of the load carrying paths in these structures.

The current load model, i.e. the one that represent current traffic is to be applied on the same simplified structural system and maximum moment and shear forces are compared with the ones of the original design code. This concept is explained in Figure 1 following the notation of the (CEN EN 1990, 2002). For the loading situation used in design, the load effect E_c^o is computed. For the bygone codes of design this value is multiplied with the global safety factor to obtain the characteristic value of required resistance R_c^o against the computed load effect. If the design is performed correctly one can assume that the real resistance value (i.e. allowable stress) will not be lower than R_c^o. For the newer code with partial safety factors, the load effect E_d^o need to be evaluated and this value is multiplied with the partial factor γ_R^o covering the uncertainty in the resistance model to obtain R_c^o. The current design loading is assumed to mirror the current traffic loading sufficiently well and therefore one can expect that the load effects from the real loading will not exceed the load effect of design loading E_d^c. The required resistance due to the current design R_d^c can be computed by multiplying E_d^c with γ_R^c. The degree of compliance is the ratio of required resistances R_c^o and R_d^c. The values below 1 indicate that the bridge may have a safety deficit.

Clearly, using this simplified method, safety and serviceability reserves that stem from bridge specific detailing and dimensioning decisions cannot be assessed. To this end one needs to perform a thorough structural analysis on more sophisticated structural system. Nevertheless, the simplified method can be efficiently used for screening purposes.

Owners can decide, based on their needs to store

– the actual structural system as used in analysis or
– a continuous girder model as used often used in simulation to obtain maximum load effect or
– a series of simply supported beams as in some load rating software.

Independent of this choice, the results of a thorough structural analysis on an adequate structural system can be used to update the resistance (or service limits) of the model stored in the database. The safety or serviceability margins against the current design loads can be expressed therein either as

– the degree of compliance n, that can be evaluated for each load situation as a ratio between the available resistance/service limit and resistance/service requirements based on the total factored load effect, or as
– the traffic load capacity factor with which the traffic load can be multiplied and still fulfill the safety and serviceability requirements.

The latter seems to be more useful for owners to assess special transports or future traffic load.

4.2 *Reliability*

The modern codes define the safety and serviceability in terms of reliability i.e. the probability that a bridge will be fit for purpose during its service life. The partial safety factors in modern codes are calibrated to satisfy these reliability requirements. In (CEN EN 1990, 2002) the target annual reliability index β for safety is 4.7 (corresponds to occurrence probability of $1.3 \cdot 10^{-6}$) and for serviceability 2.9 (corresponds to occurrence probability of $1.9 \cdot 10^{-3}$). The bridge is considered as safe and serviceable if specified reliability indexes are not below these target values. If for an existing bridge the degree of compliance is above 1,

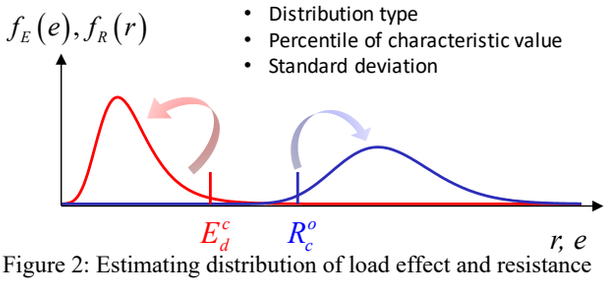

Figure 2: Estimating distribution of load effect and resistance

one can assume that the reliability index for safety exceeds the target value. However, the degree of compliance below 1 doesn't necessarily mean that the bridge doesn't meet reliability requirements. In (Das, 1999) traffic load capacity factor is evaluated based on reliability assessment for 15 similar concrete bridges in UK that are constructed in 1960's and 1970's to the same design requirements. Nevertheless, the traffic load capacity factors – derived from reliability assessment - vary between 1.9 and 5.2. Given that at that time the design was based on global safety factor, the results are not surprising. For the bridges that are designed or examined using modern codes of practice the scatter is significantly smaller as demonstrated in (Mertz, 2005). However, even for these bridges the evaluation of reliability may be economically beneficial if existing bridges can still be used without restrictions.

Assessing the reliability of existing bridges can be tedious task as one needs to model all actions and material properties as stochastic variables. However, based on experience and available data, a simplified reliability assessment can be performed using the similar approach to the one in chapter 4.1 (see also Braml & Wurzer, 2012). The original design load situation can be used to assess the characteristic value of resistance against the chosen failure mode. For the example in Figure 1, the characteristic value of resistance is R_c^o. If the percentile of the characteristic value R_c^o and the type of its distribution is known, one can obtain the resistance distribution for a chosen failure mode. The recommendations for percentiles of characteristic values, standard deviations and distribution types based on construction materials can be found in literature (e.g. JCSS, 2013). To compute load effects current design loading needs to be used. In general, several actions contribute to load effect and their characteristic values represent different percentiles of their distributions. In addition, the actions are modeled with different distribution types. For instance, the load effect due to the traffic load is normally modeled by extreme distributions. This is supported by measurements and simulation that are performed within research projects all over the world (e.g. Freundt & Bönning, 2011, Meystre & Hirt, 2006, Mertz, 2005, Caprani, 2013). After all, traffic load models are derived from probabilistic analysis based on traffic simulations and weigh-in-motion measurements (e.g. Calgaro & Sedlacek, 1992). The distributions for the self-weight and dead load as well as for other actions can be derived based on percentile assumption of their characteristic values following the recommendations from literature (e.g. JCSS, 2013). The derivation of distribution for load affect *e* and resistance *r*, for the chosen failure mode is illustrated in Figure 2.

The load effect can be determined on the simplified structural system and the reliability index can be computed. The reliability obtained in this manner can be regarded as a rough estimate as the material and action uncertainties are modeled based on literature and experience data. These results can be improved if reliability analyses would be performed on the relevant sample of the bridges of same type. The systematic detailed reliability analyses can be also used to update assumptions regarding distribution of stochastic variables.

The traffic load capacity factor can be also obtained based on reliability assessment as in (Das, 1999). It is a deterministic coefficient with which the stochastic effect of traffic load can be multiplied and still fulfill the reliability criterion.

4.3 *Inspections and impact of damages*

The inspection procedures need not to change significantly. However, there is some additional information that is indispensable if the effect of deterioration and damages is to be appropriately considered in assessment of bridges:

– Based on the design documentation, relevant failure modes need to be defined. These failure modes correspond to the critical load situations used in design and
– for each failure mode, vulnerable zones (Linneberg, et al., 2017 and NYSDOT, 1997) are to be defined, in which damages have the largest impact on safety and serviceability.

Experienced inspectors know intuitively where are these zones, but they can confirm themselves with the readily available information (Hajdin, 2017a). The damages outside vulnerable zones can also trigger failures, but for them to occur the extent of damage needs to be significantly larger than in the vulnerable

zones. If this seems likely, one needs to define an additional failure mode that can be triggered by the observed damages.

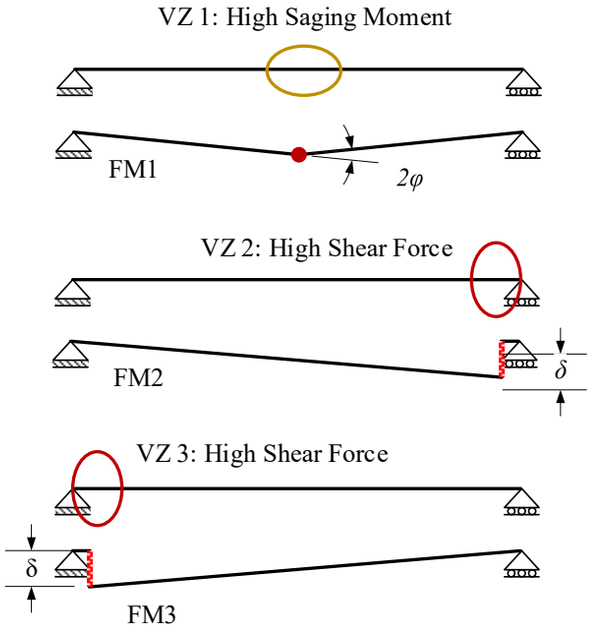

Figure 3: Vulnerable zone and failure modes

For a simply supported beam the vulnerable zones and corresponding failure modes are illustrated in Figure 3. In this example failure modes (FM1, FM2 and FM3) are chosen to be collapse mechanisms. However, other failure modes can be selected based on owner's preferences. For instance, the extent of spalling or crack width can be chosen to be failure criteria.

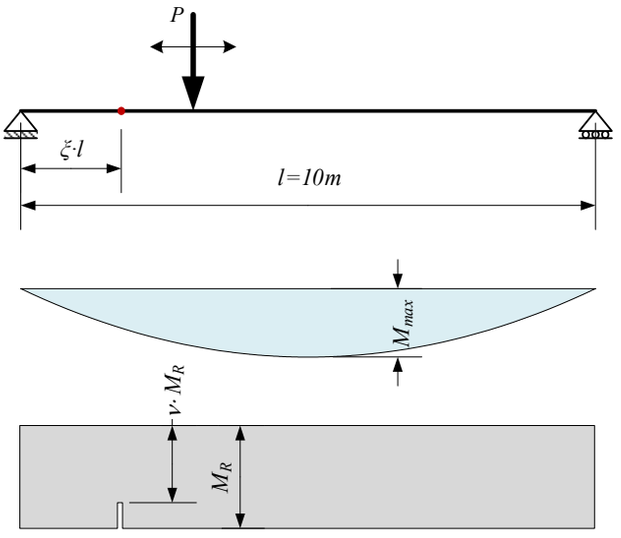

Figure 4. Load and resistance of damaged beam

For each failure mode, the corresponding degree of compliance, if semi-probabilistic format is used, or reliability, if probabilistic assessment is required, is to be evaluated for an undamaged bridge. This can be done beforehand either using the simplified approach described in chapter 4.1 and 4.2 or by in-depth examination as described in chapter 4.4. For illustration purposes of this procedure, a simply supported beam with the span of *10m* as in Figure 4 is assumed to be loaded only by live load *P,* whose maximum annual value is normally distributed with the mean value of *100kN* and the standard deviation of *12kN*. Permanent loads are neglected in this example. The resistance to bending moment is assumed constant along the beam and normally distributed with the mean value of *500kNm* and the standard deviation of *40kNm*. Only failure mode FM1 is considered. Since both load effect and resistance are normally distributed, the reliability index and corresponding probability of failure can be computed as follows:

$$\beta = \frac{\mu_{M_R} - \frac{\mu_P \cdot l}{4}}{\sqrt{\sigma_{M_R}^2 + \left(\frac{\sigma_P \cdot l}{4}\right)^2}} = \frac{500 - 250}{\sqrt{40^2 + \left(\frac{120}{4}\right)^2}} = \frac{250}{40 \cdot \sqrt{\frac{25}{16}}} = \frac{1000}{200} = 5.0 \quad \Rightarrow P_f = 2.87 \cdot 10^{-7} \tag{1}$$

The à priori reliability i.e. the reliability of undamaged bridge meets the criteria according to (CEN EN 1990, 2002).

Once an observation has been collected, the impact of this observation on safety and serviceability is to be evaluated. Based on the observation the rough estimate of resistance reduction can be made, even if the uncertainty is large. The same damage and related resistance reduction can have different impact on reliability of different bridges. If the safety margin of undamaged bridge is large, it can clearly withstand much larger damage than the one with slim margin. It is therefore that the same damage i.e. the same condition state can lead to different decisions, based on the safety margin of the undamaged bridge.

In the illustrative example it is assumed that the observed damage lead to reduction of resistance, but there is uncertainty regarding the magnitude of this reduction. This uncertainty can be expressed by a discrete distribution as in Table 1.

Table 1. Likelihood of resistance reduction – an example

Resistance reduction (1-ν)	5%	10%	15%	20%
Likelihood	60%	20%	10%	10%

In most databases the location of damages is not recorded. This means that the location of damage is not known and therefore a uniform distribution along the whole length must be assumed. The reliability index can be expressed as a function of damage location as follows:

$$\beta(\xi) = Min\left(\frac{\nu \cdot \mu_{M_R} - \mu_P \cdot \xi \cdot (1-\xi) \cdot l}{\sqrt{\sigma_{M_R}^2 + (\sigma_P \cdot \xi \cdot (1-\xi) \cdot l)^2}}, 5\right) \quad (2)$$

With available information one can evaluate the probability of failure as follows,

$$P_f = \sum_{i=1}^{4} \vartheta_i \int_0^1 \Phi(-\beta(\xi)) \cdot d\xi \quad (3)$$

where ϑ_i represents the likelihood values of discrete distribution from Table 1. The resulting reliability index is

$$P_f = 3.15 \cdot 10^{-5} \Rightarrow \beta = 4.00 \quad (4)$$

which means that à posteriori (after inspection) reliability index doesn't meet the requirements of (CEN EN 1990, 2002). However, this assessment can be improved with some additional information: The reliability index can be plotted as a function of damage location ξ as in Figure 5. In this plot, the zone with an effect on reliability index is clearly visible. If the damage location is known, the reliability index can be updated. For instance, if the damage is in the far left quarter of the span, the reliability index is not affected i.e. the bridge meets the reliability criterion. On the other hand, if the damage is in the middle of the span the reliability index would be

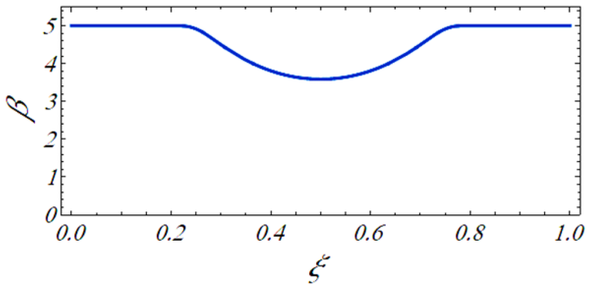

Figure 5. Safety index in function of damage location

$$P_f = 1.66 \cdot 10^{-4} \Rightarrow \beta = 3.59 \quad (5)$$

which means that the bridge doesn't meet the reliability requirements. With this approach the inspection data can be rationally used in reliability assessment taking into account the uncertainty associated with it. The likelihoods as in Table 1 can be refined as more data are collected.

In the example above, an isostatic system is chosen, which means that a local failure in one of the vulnerable zones is sufficient to trigger collapse of a bridge. For hyperstatic systems several local failures are required to trigger the collapse. It is therefore necessary to associate vulnerable zones to collapse mechanism. For a frame bridge a possible collapse mechanism and associated vulnerable zones are indicated in Figure 6 with orange ovals. It is assumed that the hogging plastic moments over the columns are 40% higher than the sagging plastic moment in mid-span. The inspection revealed that the damages in the mid-span lead to a plastic moment reduction of 15% and the ones over the columns are responsible for the plastic moment reduction of 5%. However, to assess reliability, one needs to estimate the reduction of resistance for the whole bridge and not only of vulnerable zones. In this case the resistance is equal to the internal dissipation work and the resistance reduction can be obtained by comparing the dissipation work of undamaged frame with the dissipation work of damaged frame:

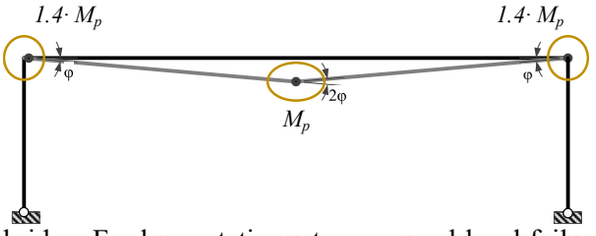

Figure 6: Vulnerable zones and a collapse mechanism of a frame bridge

$$r = \frac{0.95 \cdot 2 \cdot 1.4 \cdot M_p + 0.85 \cdot 2 \cdot M_p}{2 \cdot 1.4 \cdot M_p + 2 \cdot M_p} = \\ = \frac{4.36}{4.8} = 0.91 \quad (6)$$

The resistance reduction amounts to 9%, which is significantly smaller that 15% plastic moment reduction in the mid-span. The relationship between the vulnerable zones and failure modes is conceptionally described in section 5.3.

Finally, it should be noted that the presented approach can be implemented as Bayesian net as in (Hajdin, et al., 2018). Bayesian nets are particularly useful in combination with Structural Health Monitoring (SHM) (Cawley, 2018). The monitoring data can be used on-the-fly to assess reliability of bridges.

4.4 *In-depth investigations*

If the results of an inspection raise doubts regarding acceptable safety and serviceability, the in-depth investigation should be triggered. The in-depth investigation should include all measures that may reduce uncertainties such as testing of material properties, checking of dimensions, stiffness measurements, etc. Furthermore, archive documents must be duly examined since they may reveal assumption made regarding load situations and material properties. For hidden

structural elements such as foundations and reinforcements, old plans are the only source of information. Finally, the exposure of bridge to natural hazard needs to be investigated based on the newest findings (e.g. update of magnitudes, re-assessment of site condition).

The structural analysis needs to be performed with nonlinear methods that address failure modes appropriately and yield realistic failure probabilities. This doesn't necessarily mean that sophisticated analysis is necessary, in most cases the skillful application of the limit theorems of the theory of plasticity, as in previous section, is sufficient.

The bridge should be examined for all relevant load situations and the results need to be stored in the database in a structured form. Gradually, by means of in-depth investigations, high quality information on all bridges will be stored in the databases allowing bridge owner to manage their inventory efficiently.

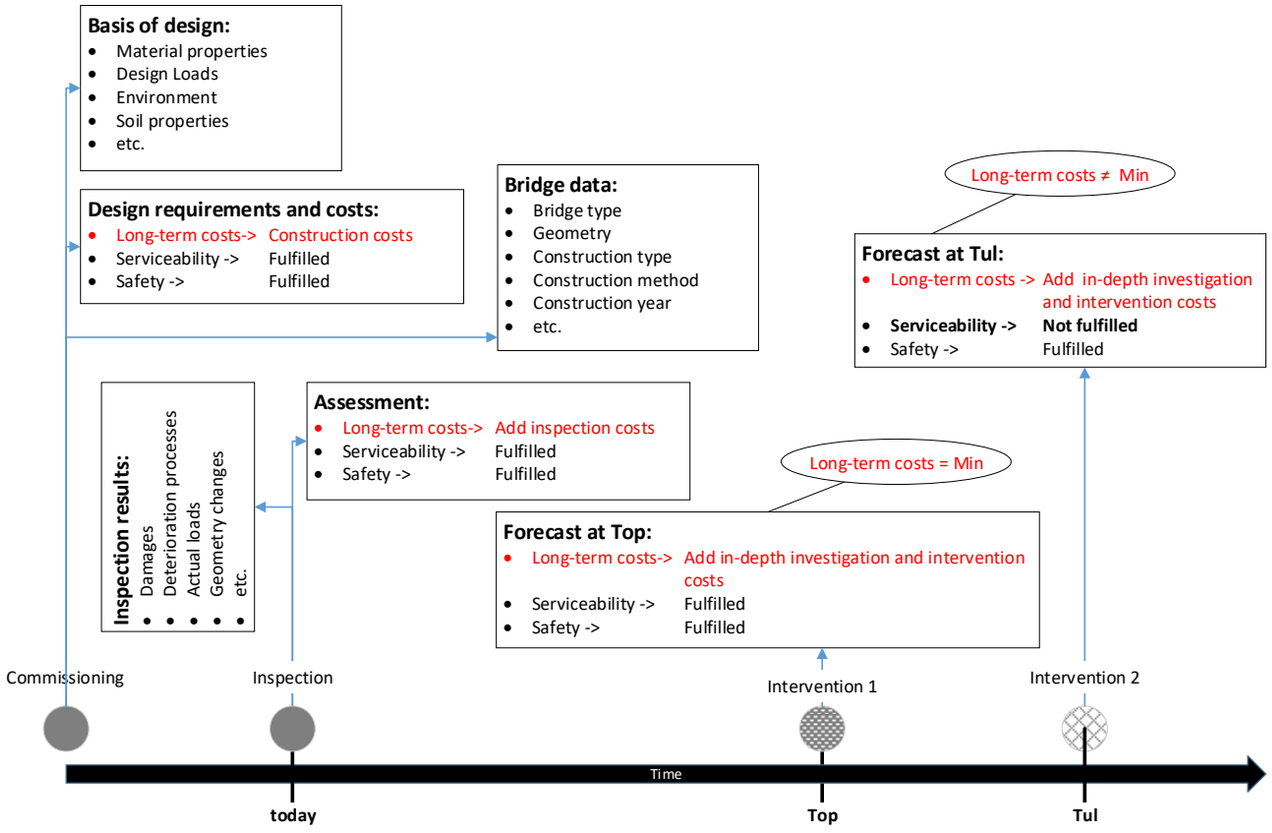

Figure 7: General approach to mid- to long-term maintenance planning

The growing experience will also allow for more accurate assessment of reliability based on inspections as Bayesian nets can be updated introducing new high-quality data.

4.5 *Special transports and corridors*

The outlined approach, which allows the assessment of safety margins and reliability level for each bridge can be a basis for issuing of permits for special transports or to define dedicated corridors for typical special transports. In the future one can think of defining several road classes based on the traffic load model for which they fulfill safety and serviceability requirements. It is very likely that in the future that vehicles or trains of wirelessly coupled vehicles will be registered for certain road classes. This also means that several traffic load models in codes of practice need to be defined. It is intuitively clear that current "one size fits all" approach is not economical. The requirement for roads need to be tailored according to the traffic that they need to accommodate.

5 MAINTENANCE PLANNING

Bridge Management is not confined to bridge assessment following inspections but also includes maintenance planning. The short-term maintenance planning is based on in-depth investigations and structural analysis and include detailed specification of interventions that are to be taken shortly thereafter. The mid- to long-term maintenance planning is a process, in which different intervention scenarios are developed. The interventions are not specified in detail and their costs are rough estimates backed by experience. The goal is to estimate financial and other needs well

in advance and avoid unpleasant surprises. Furthermore, early planning allows to choose the optimum time for interventions and reduce long-term costs.

The general approach is presented in Figure 7, where it is assumed that an inspection is performed "today". The results from the inspection revealed some damages that in conjunction with the actual loads lead to worsening of the safety and serviceability levels that, however, still meet the requirements for existing structures. This procedure is explained in previous chapters. For mid- to long-term maintenance, planning forecasts for serviceability and safety are performed predicting that serviceability criterion will be not fulfilled at the time instance marked "Tul". This means that the intervention needs to be executed no later than at that point in time, if serviceability requirements are not to be violated. However, it may well be that a scenario that includes an intervention at the time instance "Top", has lower long-term costs than the one with the intervention at the time instance "Tul". The Figure 7 doesn't show any interventions after "Tul", but normally the ensuing interventions are considered in long-term costs.

The forecasts of safety and serviceability over time defines the time instance at which, at the latest, an intervention is necessary. However, these forecasts cannot be used to define the type and the costs of the interventions. To this end afore-mentioned qualitative indicators (e.g. condition rating, condition state, condition class, etc.) are used. The application of qualitative indicators to generate interventions is well-established in current approaches to maintenance planning as explained in the following chapter. The problem lies with the usage of these qualitative indicators as proxies for safety and serviceability. The worst condition state represents herein the safety and serviceability threshold. To remedy this problem of mid- to long-term maintenance planning adaptations are suggested that are explained in the following chapters.

5.1 *Current approach to maintenance planning*

Currently, maintenance planning is based on qualitative indicators. The procedure can vary quite significantly from country to country, but the main distinction lies in the choice of **assessment unit**. The assessment unit is the physical entity of the lowest granularity that is assessed during inspections. The assessment units can be whole bridges, bridge components (super-, substructure and equipment), bridge elements, group of damages or even single damages. All these different assessment units can be found in current BMS, based on the owner or operator's needs.

The scale of condition state is chosen in such a manner that only if an assessment unit is assigned into the worst condition state – being a proxy for safety and serviceability thresholds - immediate interventions are required. The maintenance planning considers therefore only interventions that are to be initiated before the worst condition state is reached. The optimum maintenance intervention(s) is/are the ones that minimize the long-term agency costs and in some cases user costs during these interventions, as in (Schiffmann & Hajdin, 2017).

The interventions are performed on **planning units** that in some BMS coincide with assessment units and in the others, they differ from them. If assessment units are damages, then it is often more reasonable to plan interventions on affected bridge element or the whole bridges than on a single damage. Based on the condition state of assessment units, the intervention on planning units are determined based mostly on heuristic rules. To this end, technically feasible maintenance intervention on planning units are catalogued together with their unit costs and effectiveness. For instance, for the same condition states of assessment units, both rehabilitations on elements as well as replacement of the whole bridge are technically feasible. The choice of the optimum intervention is subject to minimization of the long-term costs as in (Adey & Hajdin, 2011).

This approach has significant drawbacks since it focuses solely on restoring damage-free bridges, without considering directly the safety and serviceability or consequences of possible failures. It is therefore that mid- to long-term maintenance planning can significantly deviate from the short-term planning and executed interventions, which are often triggered by safety and serviceability criteria.

5.2 *Deterioration models*

The key ingredient of mid- to long term maintenance planning is a deterioration model. The deterioration model allows condition state forecasts of assessment units and determine possible maintenance interventions in the future. The deterioration models can be derived from physico-chemical deterioration processes, and there is significant research in this area (e.g. Roelfstra, et al., 2004, Alnaggar, et al., 2017). Notwithstanding the undeniable progress in this research, most deterioration models in current BMS are based on statistical analysis of past condition data (e.g. Lethanh, et al., 2017, Hajdin & Peeters, 2008). Many BMS use Markov chains to model deterioration as it supports the discrete scale for condition states and transition probabilities can be easily derived from condition data. Finally, with Markov decision process, which is based on Markov chains and catalogued interventions, the optimum set of intervention can be estimated with modest computational effort. However, Markov chains are mostly employed for elements or components, whereas their applicability for individual damages waits to be proven.

5.3 *Improvements to current approach*

The current approach to mid- to long-term maintenance planning based on condition states of assessment units is used quite successfully to define maintenance scenarios and estimate long-term costs. However, it doesn't consider safety and serviceability directly and therefore the estimation of the optimum time instance to perform intervention can be quite wrong. A bridge with high safety and serviceability margin may be used significantly longer than suggested by an assessment unit in the worst condition state. The opposite is also true: A bridge barely meeting serviceability requirements may need to undergo an intervention even before a single assessment unit reaches the worst condition state.

age or a damage group. Consequently, the deterioration models need to be developed for these assessment units and based on the evolution of these assessment units, the safety and serviceability can be evaluated. The current deterioration processes used for elements and components can be quite useful as baseline for calibration of deterioration models for damages and damage groups.

The improved approach is presented in Figure 8 with damage group as assessment unit as in Swiss Bridge Management System KUBA. An individual damage can also be a damage group, so there is no loss of generality if a damage group is used as an assessment unit. The basic bridge data include apart from element data also the most probable failure

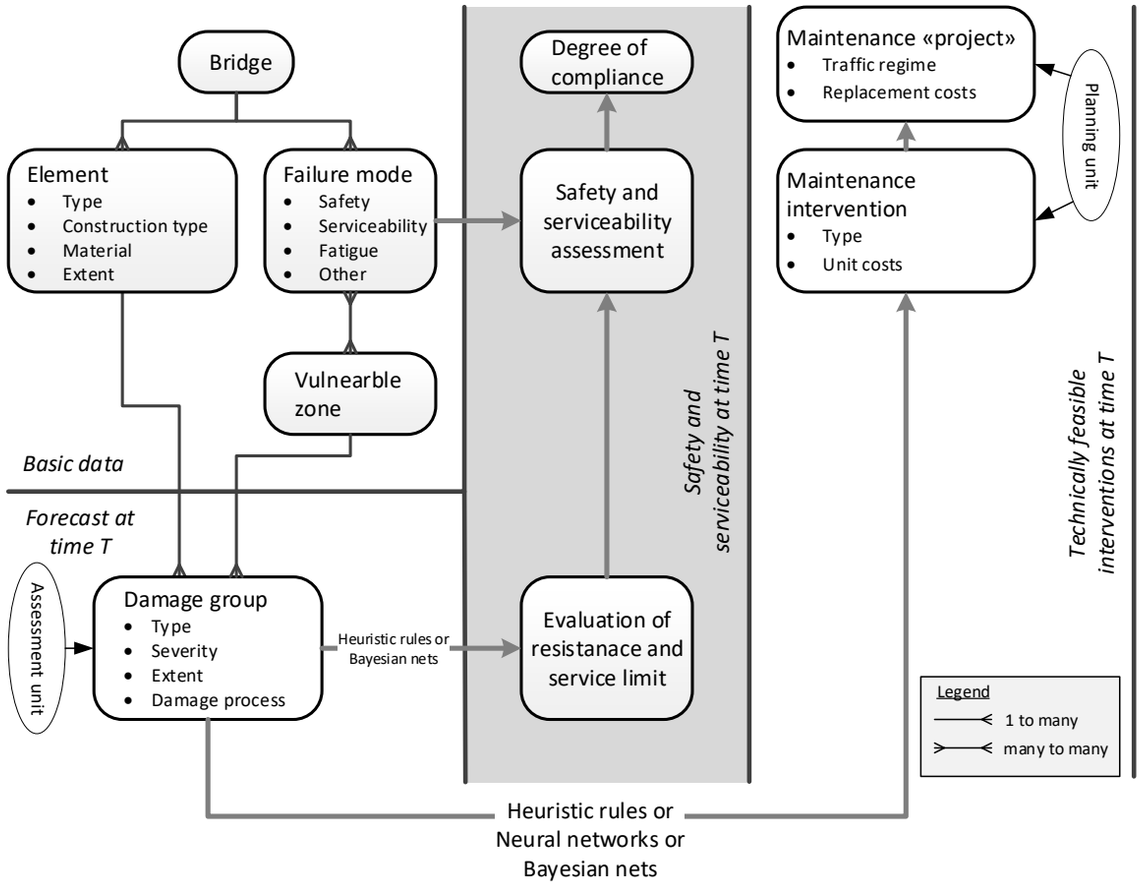

Figure 8: Assessment of degree of compliance related to safety and serviceability and determination of maintenance intervention at time T

On one side, it is necessary to estimate both condition states of assessment units and based on them define intervention scenarios on planning units and related costs. On the other side, the reliable forecast of safety and serviceability are needed to estimate the remaining service life without interventions. It is shown in the previous sections that meaningful safety and serviceability assessment is possible only if individual damages or damage groups underlying the same damage process are assessed. This means that the assessment unit must be either an individual damage or a damage group.

modes. These failure modes can be determined from bridge design documents as explained in 4.3. A bridge can have several elements and several failure modes. A failure mode can include several vulnerable zones as shown in 4.3. For instance, a collapse mechanism of an hyperstatic structure has always several places where rupture or yielding occurs and these are vulnerable zones. These vulnerable zones can also participate in several failure modes. Hence, there is many-to-many relationship between the "Failure mode" and "Vulnerable zone".

Using the deterioration model for an assessment unit, the severity and extent of the damage group can be predicted at some time point T. The impact of the damage group on resistance and/or service limits in vulnerable zones can be estimated using heuristic rules or Bayesian nets (Hajdin, et al., 2018). Following the same procedure as in 4.1, the degree of compliance for safety and serviceability at the time T can be assessed. These steps are represented in the gray column in Figure 1 to highlight the addition to current maintenance planning procedure.

The path from damage group forecast at time T to maintenance interventions is already implemented in KUBA and many other BMS. Herein, the catalog of technically feasible maintenance interventions for each damage type and severity of a given element type is of pivotal importance. The cataloged interventions are characterized by their unit costs and effectiveness. The cost predictions are generated by the heuristic rules and optimization depend on these data. The catalog is the result of a statistical analysis of executed preservation projects and is subject to changes reflecting developments in construction industry. The unit costs refer to a specific measurement unit. The unit for maintenance work on steel elements, for example, is the square meter [m^2], i.e. the surface area. This unit must be the same unit used to measure the extent of damage groups.

The technically feasible maintenance interventions are then aggregated using heuristic rules and threshold values in maintenance "projects" on bridge level. The quotation marks indicate that these are no engineering "project", but rather a very general outline of the maintenance work that is feasible at the time T. In addition to "projects" aggregated from elements, a replacement "project" is added as an option, as it can be assumed that it is the costliest maintenance option. For the high-volume bridges, a traffic regime and eventual closures during the execution of the maintenance works needs to be defined. This information is needed to evaluate societal costs. The interested reader can find further details on estimation of user costs in (Adey, et al., 2012).

A maintenance intervention results in improvement in degree of compliance regarding safety and serviceability. Currently, the estimation of this improvement is not possible, since there are only data on improvement in condition states. Also, similar refers to the effectiveness of the intervention. Still, the effectiveness of intervention related to condition states can be useful: If the condition state is restored to the best condition state after the intervention, one can assume that also the degree of compliance of the undamaged bridge is restored.

In summary, the proposed improvements allow decision maker to

- estimate remaining intervention-free service life of a bridge in rational manner, using safety and serviceability assessment,
- consider the improvement in safety and serviceability and compare with the costs to obtain this improvement, and
- plan reliable financial needs and needs for other resources on mid to long-term, considering the forecasts of traffic loads.

The data collection effort to implement these improvement is quite modest. However, the data needs to be collected conscientiously and the procedure to evaluate degree of compliance related to safety and serviceability needs to be updated to match performed in-depth investigations.

One step further would be to replace the degree of compliance with reliability assessment at some time T as explained in 4.2. The estimation of reliability over time (e.g. Mandić Ivanković, et al., 2017) is just a stepping stone to estimation of risk over time. This topic will be discussed in 6.2.

6 OUTLOOK

6.1 *Application of BIM in assessment*

It is foreseeable that in not so distant future, Building Information Models (BIM) of both newly built and existing bridges will be available (see e.g. Chipman, et al., 2016 and BMVI, 2015). These models will be included into the Bridge Management System (BMS) and will significantly enhance the quantity of useful information in fBMS. A BIM can embed realistic structural system of a bridge as well as the relevant load situations (buildingSMART, 2018). The evaluation of the reliability or safety/serviceability would be therefore possible quasi, on-the-fly within the fBMS, provided that the observations and results from SHM can be adequately integrated in BIM.

In principle, the inspection results can be directly captured in the BIM using photogrammetry or some other procedure. Cracks, spalling, deformation, and other defects will be a part of a BIM, which in most cases alter the BIM geometry. An information model and a candidate binding to Industry Foundation Classes (IFC) has been developed by (Hüthwohl, et al., 2018). This study demonstrated that that IFC provides sufficient functionality to serve as a basis for integrating relevant defect information and imagery.

In Figure 9, this future approach to bridge management is illustrated. A column as a part of a BIM is shown on the far left. On this column, a spalling area is observed (second from left). This spalling area is captured photogrammetrically as a 3D model and merged with the BIM of an intact column. The result is shown in BIM (third from left). The embedded structural system is also updated: The resistance of the column can be reduced due to spalling and the internal forces i.e. bending moment (M) and axial force (N) can be compared with the reduced resistance (e.g. using interaction diagram). In this manner, the degree

of compliance can be updated. Clearly, also the uncertainty of the material properties and spalling effect on resistance can be taken into account, so that the probability of failure can be determined.

The results of past inspections, e.g. damages are stored in a temporal BIM, which is an enhancement of the existing temporal databases. This would enhance possibility to statistically estimate deterioration models. Furthermore, the temporal BIM is a valuable data source that will allow researchers to better understand physical deterioration processes. The data stored in fBMS include also other changes that a bridge experience during its life span. This includes strengthening, widening, seismic retrofit and other structural changes. In short fBMS is similar to the 6D BIM or Asset Information Model (Wikipedia, 2017), which continues to be updated during the whole service life of a bridge.

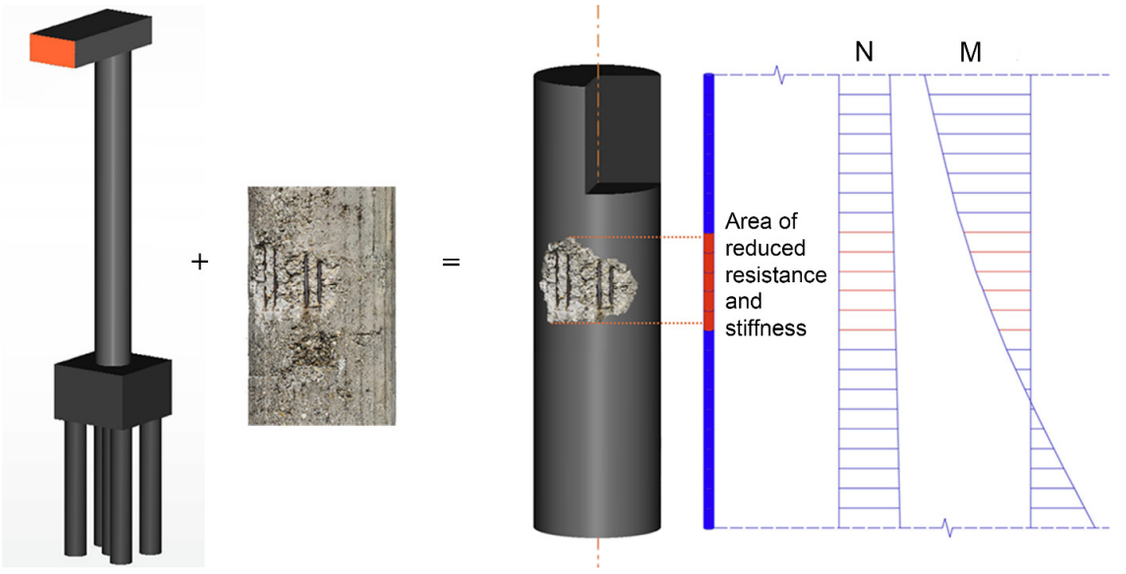

Figure 9: Integration of damage into BIM

For purposes of maintenance planning, the BIM with damages can be used as the basis for the deterioration simulation, which can provide significantly more accurate forecast that the current methods. The reasons for this are twofold:

- The resistance and loads i.e. probability of failure of an intact structure is duly taken into account.
- The exact location of a defect is known so that its effect on the safety and serviceability can be assessed in a more accurate manner.

The same applies to maintenance scenarios, which can be determined more accurately, both regarding their types as well as regarding their costs rdtimates.

There are still large obstacles that need to be overcome to develop fully functional fBMS. In particular, the modeling of cracks, spallings, chemical degradation and internal damages is still in infancy. It is also feasible to include fBMS into a GIS Systems, which would open further analytical possibilities regarding the natural hazards or advanced deterioration (Heitzler, et al., 2017).

6.2 *Risk-based maintenance planning*

The reliability thresholds related to safety and serviceability as defined in (CEN EN 1990, 2002) are values that apply to all bridges disregarding the traffic volume they carry or their environment. This can be questioned for two reasons. In sections 2 and 4.5, the one reason regarding traffic was discussed: The traffic load used in assessment procedure needs to correspond to real traffic situation at the bridge site. This can be done using nowadays abundantly available weigh-in-motion data or by instrumenting bridges with simple structural systems (e.g. Treacy & Brühwiler, 2014). This customized traffic load that is developed for each road section can allow significant number of low volume bridges to meet requirements in the codes of practice.

The second reason not discussed so far, relates to consequences of potential failures. It is questionable that the same safety index (reliability) is required for the failure with small consequences as for the ones with high consequences. It seems that this one-size-fits-all is not economical. Indeed, in (SIA, 2011) the required safety indices are graded according to the consequences of failure. Given that the risk is defined as expected consequences of a failure, the provisions in (SIA, 2011) are actually replacing reliability thresholds with risk thresholds. Risk thresholds are not new in engineering: They are used to evaluate road accidents, exposure to natural hazards and in many other areas. In most cases, the risk thresholds are not given as a single value, but rather as an acceptable area in a risk matrix that spans occurrence rate and consequences of failure. This acceptable area is often called ALARP-area, which stands for risk that

is "**a**s **l**ow **a**s **r**easonably **p**racticable". The term "practicable" raises a suspicion whether the risk thresholds are really needed. It implies that there should be a balance between the effort (e.g. money, resources) to reduce risks and the outcome of this effort i.e. risk reduction. If both the effort and the achieved risk reduction are expressed in monetary terms, then they can be compared and if risk reduction is higher than the effort to achieved it, then this effort is beneficial. In context of this paper, the effort can be understood as maintenance intervention costs to reduce risks. Theoretically, all maintenance interventions, whose costs are lower than the achieved risk reduction are beneficial and should be undertaken. This means that the acceptable risk is dependent on the available, technically feasible maintenance interventions to reduce it. This is nothing else but **proportionality** principle that often governs human behavior. In (SIA, 2011), the proportionality principle finds it application as it requires to evaluate the ratio between discounted, monetized risk reduction and the discounted costs of maintenance interventions for the remaining service life. This long-term perspective can directly be applied to risk-based maintenance planning.

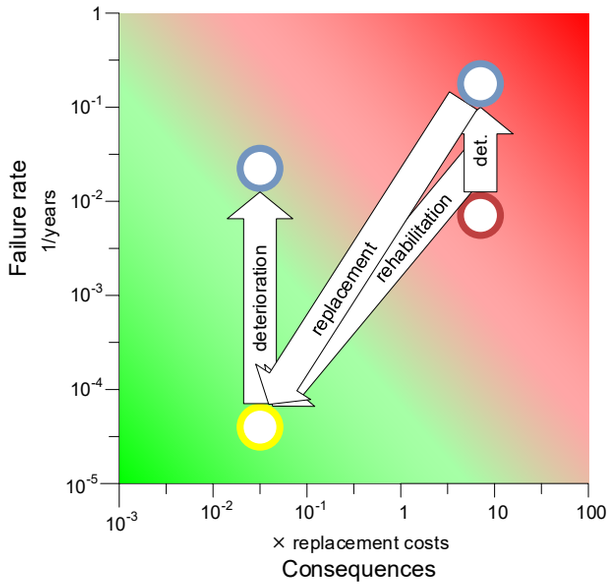

Figure 11: Maintenance scenario and basis scenario

For each maintenance scenario, a corresponding monetized risk (or rather its rate) as function of time can be developed and its discounted value at some arbitrary time instance can be evaluated. This absolute value cannot be used directly as it needs to be compared with the one of basis scenarios, which can be also a "do nothing" scenario. It is the difference in discounted value of risk between these two scenarios that is of interest. The costs of sequence of intervention that are included in maintenance scenario can be also discounted to the same time instance, and the difference to the basis scenario is evaluated. Assuming that the basis scenario has higher discounted value of risk but lower maintenance costs, the maintenance scenario is more beneficial than the basis scenario if risk reduction exceeds the higher costs of maintenance scenario. It should be therefore favored over the basis scenario.

The above reasoning is illustrated in Figure 11. The risk of a bridge is evaluated based on the failure rate and the related consequences with the red circle in a risk matrix. Within 10 years, the structure would reach blue circle, in which the failure rate is so high that the structure has to be replaced due to the immediate danger of failure. In this case this is assumed to be the basis scenario. In order to prevent the immediate danger of failure, a rehabilitation intervention in 5 years is considered. This rehabilitation represents the maintenance scenario. Both interventions reduce the risk to the same level and the risk after the interventions is represented with the yellow circle. This means that replacement and rehabilitation reduce both the failure rate and the consequences. In course of time the deterioration proceeds further 65 years. In year 70 the cut-off is set and afterwards neither maintenance costs nor risk are being considered.

The same colour coding applies to Figure 10. The benefit (=risk reduction) of the rehabilitation intervention compared to replacement is represented with the shaded area above horizontal axis. Both interventions costs and risk are normalized by replacements

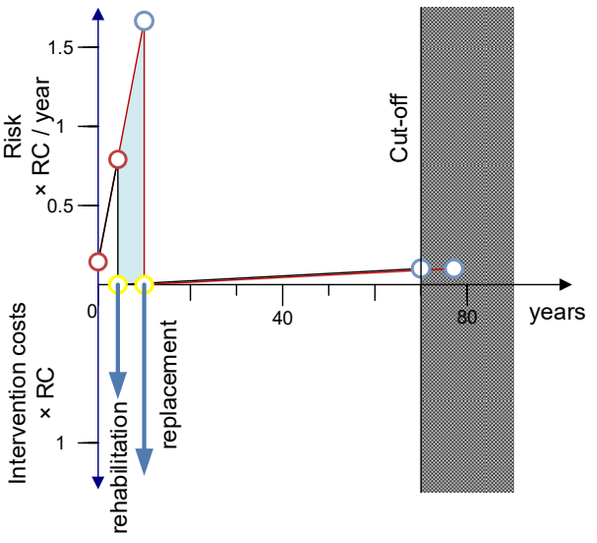

Figure 10: Risk and cost comparison

costs (RC) in Figure 10. The risk reduction can be computed as follows

$$\Delta R = \int_0^{70} \Delta r(t) \cdot e^{-\gamma t} dt \qquad (7)$$

where r is risk, γ is the compound discount rate and t is time. The difference in the costs of two scenarios can be evaluated with following expression:

$$\Delta C = C_{Rehab} \cdot e^{\gamma \cdot 5} - C_{Repla} \cdot e^{\gamma \cdot 10} \quad (8)$$

Finally, the net benefit of the maintenance (rehabilitation) strategy versus basis (replacement) strategy is as follows:

$$NB = \Delta R + \Delta C \quad (9)$$

It is obvious in this example that the rehabilitation strategy should be chosen since it both incurs higher risk reduction and lower intervention costs.

The outcome of maintenance intervention i.e. the risk reduction at some time instance T, needs to be assessed. To this end, both the effect of maintenance intervention on reliability as well as on consequences needs to be evaluated. In this manner, one can evaluate, for the chosen maintenance scenario, the risk development over time, and compare it with the basis scenario.

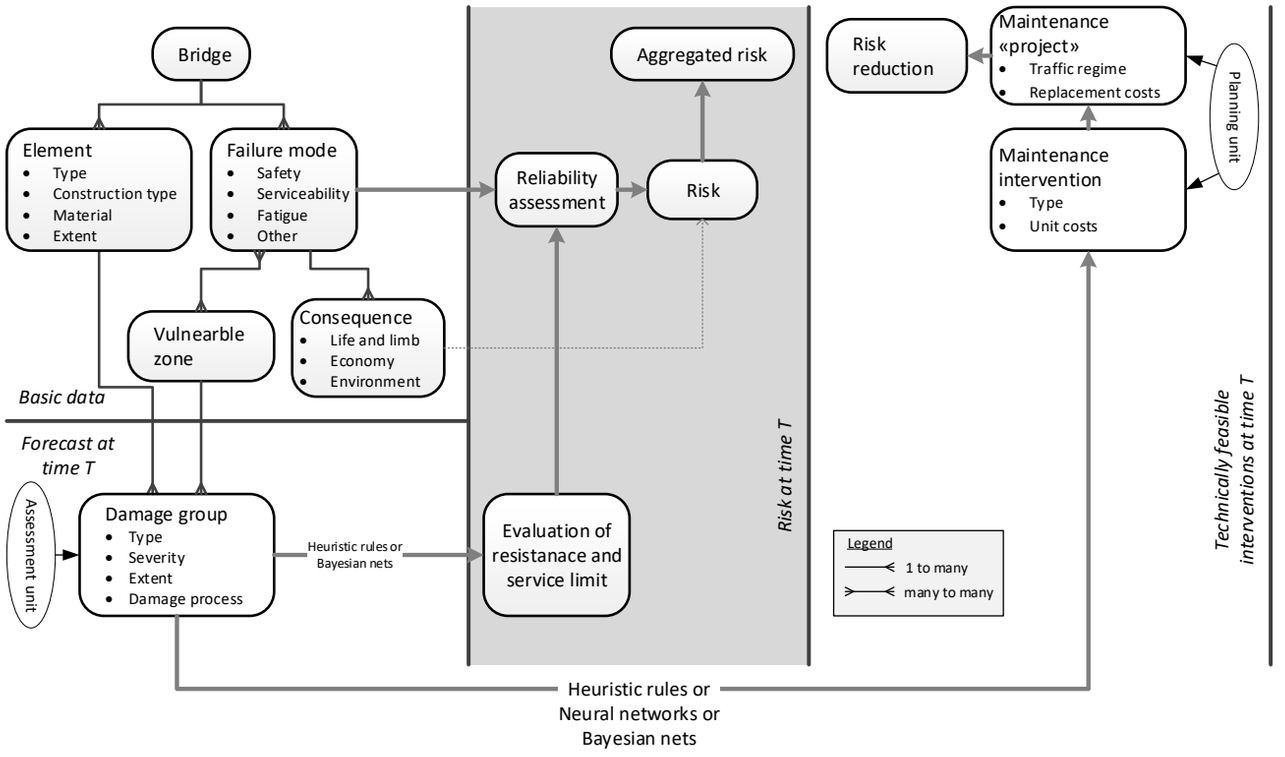

Figure 12: Assessment of risk and risk reduction due to maintenance intervention at the time T

The decision whether the maintenance scenario should be followed even if the achieved risk reduction is higher than the additional costs of maintenance scenario depends also on the available financial means and other resources. The set of interventions within the maintenance scenarios needs to fit into available resources and the scenario that have the maximum net benefit (risk reduction – costs) will be executed. This also means that the acceptable risk is directly dependent on the amount of available resources.

Based on the explanations above, one can adapt the current mid- to long-term maintenance planning that is to be supported by fBMS as shown in Figure 12. Each failure mode can have different consequences, which can be divided in three main categories and several subcategories (Faber, et al., 2009). These consequences are used for the risk evaluation related to each failure mode. The risks due to different failure modes need to be aggregated taking into account the correlation between these failure modes. Strictly taken, only risks of failure modes that are mutually exclusive can be summed together.

6.3 *Natural hazards*

The one of the challenges listed in section 2 are the natural hazards. On one hand, older bridges are often not or not adequately designed for natural hazards and on the other hand it is likely that the climate change has an adverse impact on frequency and intensity of gravitational hazards.

The risk-based maintenance planning explained in previous section is actually developed for natural hazards and is being used by agencies world-wide (e.g. ASTRA, 2014). It allows therefore to treat natural hazards in the same way as, for instance, traffic loads. The failure modes and corresponding probabilities of failure must be defined in the same manner as it is described for traffic loads. This task can be more difficult than the one for traffic loads, since some bridges are not design for extreme loadings. These bridges must be examined for different frequency and intensity of hazard events. Based on this analysis the

failure probability can be assessed as a function of hazard intensity.

This approach for local scour induced by flooding events as the predominant cause of bridge collapses is discussed in (Tanasic & Hajdin, 2017). Herein, the failure modes are based on water-soil-structure interaction. This means that the resistance of a bridge and its ability to prevent collapse of river bed under the foundation is duly considered. The failure modes and the associated vulnerable zones are determined both for the structure and soil below foundations.

Following the need to improve the behavior of bridges in an earthquake event, a risk-based approach, similar to the one explained in this chapter was developed by (Padgett, et al., 2010) for girder bridges.

6.4 *Risk and social equity*

The risk-based maintenance planning explained in previous chapter has a significant drawback. The consequences for life and limb needs to be monetized, which is highly controversial ethical issue. The virulence of this issue can be lingered if the mortality and/or injury rate is evaluated for each maintenance scenario. Based on this data one can require that the incremental investment i.e. the difference in investment between an arbitrary maintenance scenario and the next more expensive scenario needs to exceed some value for additionally saved human life or for additionally avoided injury (Adey, et al., 2009). This value, also called marginal costs of saving lives, can be coupled to GDP and therefore can be different from country to country. By setting a threshold to marginal costs of saving lives, the social equity can be reinforced as the scarce resources to save human lives can be justly distributed if the same marginal costs of saving lives are used not only across different regions, but also across different live saving activities (health, crime prevention, etc.).

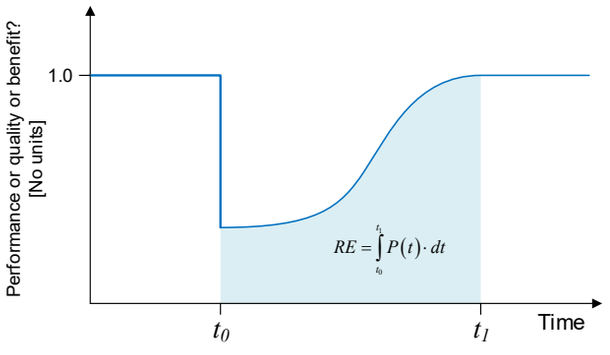

Figure 13: Recovery curve and resilience

The concept of marginal costs can also apply to other types of consequences such as user costs, travel time, environmental impact etc. This can foster sensitivity analysis and improve the accepted value system within communities.

6.5 *Resilience and risk-based maintenance planning*

Given the current interest of research community in resilience coupled with public call for more "resilient" road infrastructure, there is an open question if and how the resilience should influence decision-making in bridge management.

The term itself comes from Latin "resilens", which is the present participle of the verb "resilire" or in English "to spring (bounce) back" or "to rebound". In realm of civil engineering it was firstly adopted in seismic engineering to describe the "ability of social units to mitigate hazards, contain the effects of disasters when they occur, and carry out recovery activities in ways that minimize social disruption and mitigate the effects of future earthquakes" (Bruneau, et al., 2003). The effect of a natural disaster such as earthquake is described in Figure 13. At the time instance t_0 the earthquake occurs with an adverse effect on the performance, quality or benefit of infrastructure. The recovery starts immediately after the earthquake and at the time instance t_1 the infrastructure is fully restored. The dynamics of this recovery is represented with a recovery function $P(t)$ and the resilience is computed as a definite integral of the recovery function between t_0 to t_1. If the recovery function is expressed as a performance function, then the resilience is average performance between t_0 to t_1 (Bocchini, et al., 2014).

To analyze the resilience of a bridge (or any other entity) the criterion on the ordinate in Figure 13 and recovery function for different hazards needs to be defined. Given that the benefit of a bridge is in ensuring fast and safe passages for road traffic over otherwise hardly surmountable obstacles, the impact of a damaging event would be a good criterion to analyze resilience. Following the reasoning in section 1, the impact of a damaging event can be quantified by user costs. They emerge from the change in traffic pattern that result in additional travel time and change in accident rates. Conversely, the benefit of a bridge can be quantified by user costs of its complete closure as in (VSS, 2003). It should be noted that strictly taken this benefit applies only for a single bridge on otherwise fully operational road network. This means that the benefit of the bridge under consideration can significantly change in already damaged network (Adey, et al., 2003). For instance, the benefit of a bridge on the only remaining road connection between two regions after the failure of all other connections can hugely increase. Given that, for the resilience analysis only the recovery function is of interest and the above problem can be efficiently solved by normalizing benefit to values between 0 and 1. The recovery function is therefore independent from the network condition before the onset of a damaging event. Consequently, it can be regarded as technically feasible recovery function. Actually, the recovery function is

subject to availability of resources (Faber, et al., 2017) and in case of major damaging event they might not be available, leading to waiting time for recovery to begin. This effect is out of the scope of this paper. In summary, the resilience is defined an average normalized benefit of a bridge from the onset of damaging event to the full recovery.

The damaging events can occur at some rate governed for instance by a Poisson process. A possible realization of this Poisson process with different event intensity is shown in Figure 14. The resilience

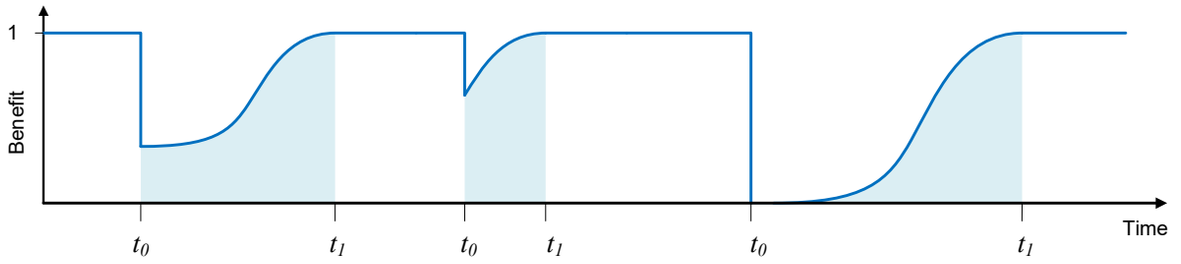

Figure 14: Possible realization of the sequence of damaging events

can be evaluated for each event, or an average can be computed for any given time horizon including infinity. In most cases, the time interval between the damaging events is large enough to accommodate time needed for recovery, as illustrated in Figure 14. If this can be assumed, as it is implicitly done for risk-based maintenance planning in which the user costs are explicitly considered in decision-making process, the resilience is additional information that can hardly influence decision making. It can however be used for communication purposes, stating that a bridge exhibits its resilience of, for instance, 90% meaning that the damaging events has reduced its benefit to the users by 10%.

If the probability that a damaging event occurs before a bridge is recovered from previous one cannot be neglected, then it must be considered in estimation of the consequences. This will also have an impact on the decisions regarding maintenance scenarios, preferring the ones that are more expensive i.e. the ones with shorter recovery times. The resilience can be very useful information to justify the need for more resources since it is easy to communicate. With the resilience the owner can also illustrate the point-of-no-return i.e. the resource threshold at which no full recovery is possible. Furthermore, resilience hat an undoubted positive connotation, which is not the case with the term “risk”, and therefore more acceptable to general public.

The resilience analysis of a bridge can be enhanced with deterioration that can gradually decrease benefit of a bridge or lead to a larger drop in benefit when damaging event occur. The interdependency between the sudden damaging events and gradual deterioration and its impact on resilience is studied in (Hajdin, 2017b).

In summary, the resilience is a very useful information, more easily understood than risk. However, the change in resilience need to be accompanied with associated costs and other resources. Furthermore, owners can set threshold values for resilience that enter decision-making process. This is equivalent to setting constraints on user costs and eliminating maintenance scenarios that don’t meet these constraints, similar to limiting the marginal costs of saving lives discussed in section 6.4.

7 CONCLUSIONS

The need for more economic utilization of transportation infrastructure is also a challenge for bridge owners. They need to have readily available, high quality information on their bridge inventory in order to cope with gradual deterioration, growing traffic demands and increased frequency and magnitude of natural hazards. To obtain and store this information is a task that cannot be accomplished in a short time. In this paper, the methods are proposed that use data that is already available and allow their gradual refinement. They allow better exploitation of inspection results to assess safety and serviceability and improved decision making regarding in-depth investigations and maintenance interventions. The assessment of safety and serviceability during the whole service life allows also more responsive processing of special permits and established corridors for heavy weight vehicles.

The presented methods are only stepping stones toward a new generation of BMS that will integrate BIM and allow more accurate and prompt information on bridge behavior. Current databases need to be enhanced with BIM. The data generated during the design and construction process must be handed to the owner or operator that act henceforth as their trustees. It is essential that this data can be transparently and intuitively used in the exploitation phase. To this end, the owners need to set requirements that are independent of software packages used in design and construction phase.

Finally, the owners and/or operators must provide both financial and personal resources to maintain a

fBMS and its data. Owners need in-house competence both in structural and decision engineering as well as in information technology similar to the banking sector, where competence in information technology, financial and decision engineering is required. It is not a coincidence that in both sectors the term "Asset Management" is widely used.

8 ACKNOWLEDGEMENTS

This paper is partially based upon work supported by the German Federal Highway Research Institute under grant FE 15.0628/2016/LRB. Parts of paper address the work from COST Action TU-1406, Quality specifications for roadway bridges, standardization at a European level (BridgeSpec), supported by COST (European Cooperation in Science and Technology). The author is the leader of the Working Group 3 of the COST Action TU1406.

Timber bridges in Australia, where to from here?

J.A. Hilton
Global Service Leader Bridges and Civil Structures, Aurecon, Sydney, Australia

ABSTRACT: There is estimated to be over 11,000 timber road bridges owned by Local Government in Australia today. The majority were constructed in the second half of the 19th century and the first half of the 20th century as simple girder bridges with spans up to around 10-12m. Bridge lengths varied from single spans up to viaducts several kilometres in length. The bridges utilised Australia's then plentiful supply of exceptional quality hardwood which could generally be sought close to the bridge site. Today, a substantial number have fallen into disrepair. This is particularly so for the timber bridges owned by Local Government due principally to lack of sufficient funds and increasing shortage of good quality hardwood. The fact that until recently there has been no Australian Standard for the design of timber bridges has also been an issue. Recent studies have indicated that approximately 30% of Local Government timber bridges are in a "poor" to "very poor" condition. To make the required step change a collaborative public-private solution is recommended. These defective bridges represent a "Whole of Government" long-term community safety risk. The reality is that timely replacement of Local Government bridges is simply not provided for in Local, State or Federal Government capital programmes. The author is chairman of Australian Standards Committee BD090-08, responsible for the technical input to the new bridge design standard, AS 5100.8 "Bridge Rehabilitation and Strengthening". This is the first Australian Design Standard to address the rehabilitation of timber bridges. This paper draws on the learnings from the development of this Standard.

1 DEVELOPMENT IN AUSTRALIA

1.1 *Historical context*

The first timber bridges in Australia were constructed by the aborigines. There is ample documented evidence of felled trees used as creek crossings, as dams for collecting fish and as vantage points for catching fish.

Figure 1 Typical bridge constructed by aborigines

The first bridge built by European settlers was also a timber structure, across the Tank Stream near the corner of what is now Bridge and Pitt Streets, in Sydney in October 1788. John Meehan's "Plan of the Town of Sydney, 1807" also shows two others, one near Hunter Street, and another in King Street (O'Connor 1985).

Each of these bridges comprises longitudinal timber girders, supporting timber planking and supported on timber trestles and abutments.

Although none of these early bridges survives today, they form the rudimentary forerunners of tens of thousands of similar timber structures constructed in Australia in the 19th century.

Coming in to the first half of 20th century, when both structural steel and reinforced concrete bridges were being developed throughout the western world, timber bridges could in many cases still be constructed cheaper and quicker in Australia than the steel and concrete alternatives, particularly in country areas.

Essentially structural timber members did not have to be transported from factories very distant from the bridge site and particularly for long or multiple bridges, concurrent activities of timber felling, dressing and erection implied speedy construction.

Refer Figure 2 for a typical timber trestle bridge example.

Figure 2 Typical timber trestle bridge

Bridge designers in the 19th century drew on British bridge-carpentry traditions which we can now trace back to Roman times. Refer Figure 3 for an artistic image of Caesar's bridge across the Rhine constructed during the Gallic War in 55 BC. The Roman technique comprised machine driven raking timber pile supporting a timber headstock to form piers, in turn supporting a timber superstructure comprising longitudinal girders and cross decking, all very similar to the timber bridges in Australia today.

Figure 3 Roman bridge over the Rhine (artists impression)

Using this form of construction with discrete spans of around 6-8m the Romans constructed small creek crossings and viaducts several hundred metres long. A key component of the construction is the use of driven timber piles. The Romans developed a special drop hammer for this process, as reconstructed in the image in Figure 4.

There are more than 40,000 bridges in Australia. It is estimated that approximately 27,000 of these are timber bridges. Most of these are simple timber trestle bridges similar to the original Roman concept, the majority constructed at least 80-120 years ago.

1.2 *Structural form*

Typical superstructure details for the Australian bridges are noted in Figure 5, and typical substructure details are noted in Figure 6. Sizes shown are typical only.

Superstructures generally comprise longitudinal (usually round) girders spanning between trestle piers. The girders are spaced at around 1.4m centres, and support transverse timber decking. In more recent designs it was found more cost effective to install longitudinal timber sheeting across the decking to both act as a wearing surface and provide a degree of water tightness to the timber below. Timber barrier railing was originally constructed, although in many cases it has been replaced with steel guardrail.

Figure 4 Roman drop hammer for piles (reconstructed)

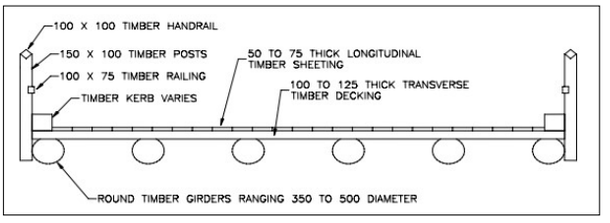

Figure 5 Typical Australian bridge cross section

Piers and abutments comprise timber piles usually driven to refusal on competent material. These are braced diagonally in plane. Longitudinally stability is obtained by a combination of the piles together flexing, plus abutment soil pressure. The piles are notched to allow installation of twin capwale (headstock) beams, configured to support the longitudinal girders. Abutments are similar in form to piers with timber sheeting behind for fill retention.

A common feature is the use of corbels between girders and pier headstocks. Though there are potential structural benefits to girder capacity by introducing partial structural continuity at piers (provided the

bolt system is tight) the main reason provided by early sources was that the time for girder replacement due to end deterioration could be extended.

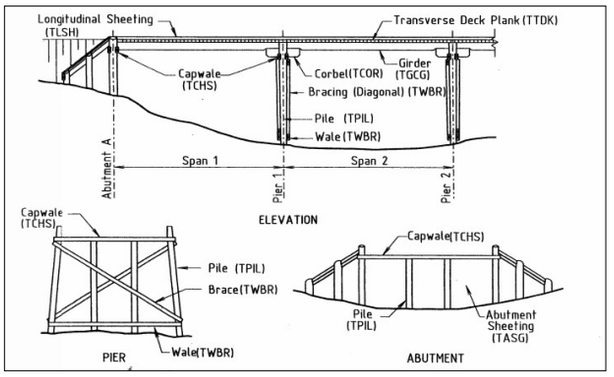

Figure 6 Typical Australian bridge elevation and plan

Except for the subsequent installation of SLT (stress laminated timber) or plywood decking in specific instances all timber used for these bridges is hardwood. In particular the heartwood of the hardwood, the inner region of the trunk, and comprised of dead cells as the sapwood growth front has moved out. Because sapwood is rich in nutrients such as starch, it is very susceptible to fungal attack when it remains on structural timber, and is generally removed when the timber is dressed.

There are a number of reasons for the success of timber bridges in Australia. Eucalypt timbers available were far superior to northern hemisphere softwoods in their ability to survive long term exposure to the elements. The strongest and most enduring Australian bridge timber, ironbark, was known in Britain as a superior ship-building timber by at least the mid-nineteenth century.

For valley crossings timber viaducts were cheaper than embankments with real advantages in low afflux under flood conditions. Two of the longest timber viaduct bridges in Australia were the rail structures at Yarra Glen (2296m) and Wagga Wagga (3106m).

1.3 *Typical defects*

Typical defects of these bridges are noted.

1.4 *Case study: Tharwa bridge*

Tharwa Bridge is a four-span timber Allan truss bridge originally constructed around 1895. It is the only four span structure of its type in the world and is considered to be of exceptional national heritage significance. It is now being fully restored. This work has been undertaken with careful consultation to a very detailed conservation management plan, and in full conformance with the AS5100 to T44 loading.

Figure 15 Tharwa bridge

The work included the following;

- Provision of a steel underslung girders to temporarily support the existing bridge deck and provide continued traffic access during the refurbishment operation
- Complete reconstruction of the four Allan truss spans, enhanced for T44 loading
- Erection of a new stress laminated timber (SLT) deck. The deck was over 100m in length and was constructed off the bridge and then launched into position over temporary rollers. This is understood to be over double the longest SLT deck span previously erected by launching.
- Strengthened main span piers using jet grouting and micropiles
- Development and installation of heritage style traffic barriers designed to AS5100 crash loading
- Strengthened approach span piers using new generation carbon fibre technology

Figure 16 Tharwa bridge during construction

Construction of the timber superstructure was undertaken by RMS's own construction personnel us-

ing specialist techniques to replicate the original methods of construction.

The work was undertaken by Roads ACT who engaged ACT Procurement Solutions as project managers, Aurecon for the bridge design, RMS for the timber superstructure construction, Guideline Constructions for the substructure strengthening and Arenco for the supply and installation of the temporary bridging. Specialist advice on the timber engineering was provided by Prof Keith Crewes of UTS and Ray Taylor provided construction advice on the SLT.

2 LOCAL GOVERNMENT CONTEXT

2.1 *Extent of bridges*

The National Local Roads Data System (NLRDS) reports in 2011 that there are 27,939 bridges under Local Government management. This is distributed between the States as noted in Figure 17.

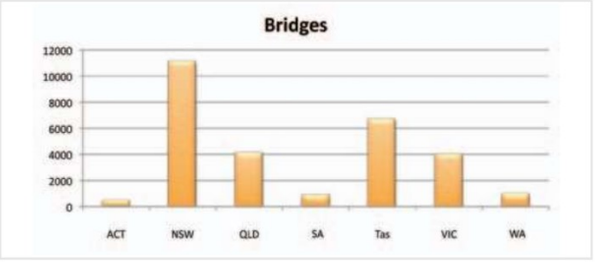

Figure 17 Distribution between states

There appears to be no consolidated national survey of the exact number or condition of timber bridges owned by Local Government. However, it is estimated that approximately 11,000 Local Government owned bridges are of timber construction. Adequate maintenance of these bridges has been problematic. A recent national survey (Roorda 2013) was undertaken to review the condition of Local Council roads and bridges. The survey was responded to by Councils covering $87B of an estimated $144B of total Local Government owned road assets. The survey showed 30% of timber bridges were reported as being in poor to very poor condition.

2.2 *Shortfall in maintenance*

Problems Local Government asset owners are confronted with;

- Increasing shortage of quality large section hardwood. In the early days of timber bridge construction there appeared to be an inexhaustible supply of good quality, high strength hardwood timbers. Today, some 100-150 years later, much of the high-quality timbers have disappeared and other regions of forest reserves have restrictions to logging for environmental and ecological reasons.
- Insufficient funds to construct replacement structures. It is understood that funding to Local Government for timber bridge replacement has been nominally linked to CPI increases at best, at a time when deterioration of these structures is accelerating
- Ongoing need for the assets to remain in safe and usable conditions under increasing design axle loads associated with the higher mass limits. For example, the same TMR bridges with a design load for 16 tonnes trucks in 1925 are load rated for 42.5 tonnes semi-trailers today.
- Until recently no available Australian standard for the design of timber bridges

In 2015 the Institute of Public Works Engineering Australia (IPWEA) identified 474 timber bridges in regional NSW as being in "poor condition" and "representing a high-risk profile for likelihood of failure and high consequences". Refer Table 1.

Table 1

Region	Good	Fair	Poor	Total
North Coast	238	581	309	*1128*
New England	63	108	42	*213*
Hunter	62	76	27	*165*
South East	49	65	21	*135*
South West	22	27	24	*73*
Illawarra	9	38	13	*60*
Orana	1	14	28	*43*
Sydney	2	2	10	*14*
Total	*446*	*911*	*474*	*1831*

It is noted that this report is simply based on a survey of 1831 timber bridges, and does not reflect the total number of Council owned timber bridges in NSW, estimated to be over 3500.

A further study initiated by the Australian Local Government Association (ALGA 2013) noted as follows;

"Bridges link people and jobs, children and schools, patients and hospitals and businesses and markets. Bridges literally bring communities together, yet so many of our regional communities are struggling because of the challenge of maintaining tens of thousands of older bridges. Local Government's own studies have revealed the parlous state of some of our bridges and have highlighted the need for a partnership with other levels of government in dealing with what is a national issue. It's an issue which touches on questions of equality, national productivity and safety."

A specific example is Kyogle Council in northern NSW. Kyogle Council have approximately 200

timber bridges, around 30% of which are rated in "poor" condition. The 2013 Kyogle Council published *Fact Sheet 4 – Bridges* states;

"Council's current funding levels for bridges are $880,000 per year for replacements and $556,000 per year for maintenance. At this level of expenditure, it will take another 58 years to replace the remaining timber bridges. In this time period, many of these will need to have weight limits imposed, or be closed altogether. This could have significant impacts on the local economy and the health and well-being of the affected communities."

2.3 *Need for a new approach*

There is a clear need for a new approach to deal with the large and increasing number of timber trestle bridges in "poor" or "very poor" condition owned by local government. This new approach should include the following;

- Use of the new Bridge Standard, AS 5100.8 which for the first time covers the design and rehabilitation of timber bridges. It is considered that the lack of an Australian Standard for timber bridges has inhibited timber bridge upgrades.
- A better understanding of both the reasons that Australian timber bridges deteriorate and reliable long-term types of repair
- A better understanding of replacement bridge forms available for timber bridges sufficiently deteriorated that repair solutions are not an option. Care is required here. Typical highway bridge structural forms used for bridges on local roads can be very costly, and unwarranted. Conversely there are very low-cost bridge forms in the market which do not comply with the requirements of AS 5100 and are anticipated to require a high level of maintenance in the medium to long term.

To make the required step change a collaborative public-private solution is recommended. These defective bridges represent a "Whole of Government" long-term community safety risk. The reality is timely replacement is simply not provided for in Council, State or Federal Government capital programmes. It is noted that there are examples overseas where this approach has been adopted.

2.4 *Case study: Pennsylvania RBR Project*

The Pennsylvania Rapid Bridge Replacement (RBR) Project is the first multi-asset public-private partnership (PPP) project to be undertaken in the US, using a "bundled" contract approach to replace 558 structurally deficient (SD) bridges across Pennsylvania.

The project is being delivered as a Design-Build-Finance-Operate-Maintain (DBFOM), availability payment, PPP concession, between the Pennsylvania Department of Transportation (PennDOT) and the Plenary Walsh Keystone Partners (PWKP) consortium. The consortium was awarded the contract in October 2014.

Figure 18 Typical replacement bridge in Pennsylvania

The RBR Project will make a substantial contribution to reducing the large backlog of SD bridges in the state. PWKP is managing the financing, design and construction of the replacement bridges and will then be responsible for their maintenance for 25 years after construction. Construction is expected to take approximately four years from commercial close. The project will involve the full demolition and replacement of all 558 replacement bridges, which are primarily single and multi-span bridges on smaller state highways, many located in rural areas. The bridges in the project are of a similar size and design, allowing for prefabrication, mass production, equipment reutilisation and standardisation.

3 DESIGN STANDARDS

3.1 *General*

In April 2017 the new Australian Design Standard for bridges, AS 5100 was released. For the first time, it included a Part for rehabilitation of bridges, and in addition, for the first time included a Part for the design of timber elements on bridges.

AS 5100 was originally developed for the design of new bridges. Although Part 7 of the Standard relates to the strength rating of existing bridges, the previous AS 5100 generally did not refer to the specific applications of design and construction for the repair, rehabilitation, strengthening or widening of existing bridges. Following numerous requests from industry, this has been addressed with the introduction of Part 8, "Rehabilitation and strengthening of existing bridges", which forms part of the new revised AS 5100.

Specifically, Part 8 sets out minimum requirements and procedures to:

- Repair or rehabilitate to restore a structure to its original or intended level of service

– Extend the remaining service life of the structure
– Strengthen to restore capacity due to structural deterioration
– Strengthen to increase capacity for live load (such as in response to a proposed increase in vehicle loads), barrier loading, collision loading, earthquake loading and other loading
– Change the function of a structure (such as a road bridge to a pedestrian/cyclist bridge)
– Widen an existing structure

3.2 *Design specifics*

Figure 19 typical timber bridge

Firstly, the dynamic behavior of timber bridges is very different to steel or concrete structures. This is recognised with a reduction in the dynamic load allowance to be not less than 0.2 (0.25 for timber bridges with SLT decks), compared to a DLA of 0.3 to 0.4 noted in Part 2 of the Standard.

Timber elements in a bridge can vary considerably from design drawings, certainly more than for either steel or concrete structures. This is recognised in the nominated load factors. Refer Table 2, which also provides requirements from Part 2 of the Standard for comparison.

Table 2

Material	Ultimate Limit State	
	Load reduces safety	Load increases safety
Timber	1.4	0.8
Concrete	1.2	0.85
Steel	1.1	0.9

Capacity reduction factors are generally lower than equivalent values for steel or concrete, to reflect the inherent relative variably of timber. In addition, a distinction is made between primary structural elements (whose failure could result in collapse of a significant portion of the structure, such as girders) and secondary structural elements (whose failure would result in a localized collapse, such as stringers and decking). Details are noted in Table 3.

Table 3

	Secondary structural element	Primary structural element
Sawn timber F17 grade or higher	0.85	0.75
Round timber	0.70	0.60

The design capacity of a timber member in bending is also a function of duration of load, size and extent of timber shaving. Timber is a resilient material, can withstand significantly higher loads when applied of a short duration.

Typical reduction factors for member capacity for different loadings are as follows;

– Permanent actions, 0.57
– Serviceability live load, 0.80
– Ultimate design live load (T44), 0.97
– Other ultimate actions (eg braking, log impact), 1.00

Characteristic strength and stiffness properties for common replacement timber elements are designated in Table 4.

Table 4

Stress	Bending	Tension	Shear	Comp'n	E
F27	67	42	5.1	51	18
F22	55	34	4.2	42	16
F17	42	25	3.6	34	14

4 DETERIORATION

4.1 *General*

The main reasons that Australian timber bridges deteriorate are noted below. We have incorporated this into the Design Standard.

4.2 *Splitting due to shrinkage*

Moisture can exist in wood as water or water vapour in the cell cavities and as chemically bound water within the cell walls. As green timber loses moisture to the surrounding atmosphere, a point is reached when the cell cavities no longer contain moisture, but the cell walls are still completely saturated with chemically bound water. This point is called the 'fibre saturation point'. Wood is dimensionally stable while its moisture content remains above the fibre

saturation point, which is typically around 30% for most timbers. Refer Figure 20.

Bridges are normally constructed from green timber which gradually dries below its fibre saturation point until it reaches equilibrium with the surrounding atmosphere. As it does so, the wood shrinks but because it is anisotropic, the maximum shrinkage occurs parallel to the annular rings, about half as much occurs perpendicular to the annular rings.

Figure 20 Splitting due to shrinkage

The relatively large cross section timbers used in bridges lose their moisture through their exterior surfaces so that the interior of the member remains above the fibre saturation point while the outer layers fall below and attempt to shrink. This sets up tensile stresses perpendicular to the grain and when these exceed the tensile strength of the wood, a check or split develops, which deepens as the moisture content continues to drop. As timber dries more rapidly through the ends of the member than through the sides, more serious splitting occurs at the ends. Deep checks provide a convenient site for the start of fungal decay.

Shrinkage also causes splitting where the timber is restrained by a bolted steel plate or other type of fastening. This splitting can be avoided by allowing the timber to shrink freely by using slotted holes. As timber shrinks, it tends to lose contact with steel washers or plates, so the connection is no longer tight. Checking the tightness of nuts in bolted connections is therefore a standard item of routine maintenance for timber bridges.

4.3 *Insect attack (termites and marine borers)*

Australia has a large number of different species of termites which are widely distributed. Most termite damage to timber bridges occurs through subterranean termites which require contact with the soil or some other constant so urce of moisture. Termites live in colonies or nests which may be located below ground in the soil, or above ground in a tree stump, hollowed out bridge member or an earth mound. Attack by subterranean termites originates from the nest, but may spread well above ground level, either inside the wood or via mud walled tubes called galleries which are constructed on the outside of bridge members. These galleries are essential for termites as they require an absence of light, a humid atmosphere and a source of moisture to survive.

Figure 21 Insect attack

An example is shown in Figure 21. Termite attack, once established, usually degrades timber much more quickly than fungi, but termite attack in durable hardwoods normally used in bridge construction is usually associated with some pre-existing fungal decay. This decay accelerates as the termites extend their galleries through the structure, moving fungal spores and moisture about with their bodies. Termites can be controlled either by eradication of the nest (by direct chemical treatment or by separation of the colony from its sustaining moisture) or by installation of chemical and physical barriers to prevent termites from entering a bridge or attacking timber in contact with the ground.

Damage to underwater timber in the sea or tidal inlets is usually caused by marine borers, and is more severe in tropical and sub-tropical waters than in colder waters. They are controlled by reducing the oxygen content. The two main groups of animals involved are:

molluscs (teredinindae) these borers destroy timber at all levels from the mudline to high water level, but the greatest intensity of the attack is just below water level. While only a few small holes may be visible on the surface of the pile, it is possible that the interior of the pile may be completely eaten away.

crustaceans these attack the wood on its surface, making many narrower and shorter tunnels than those made by the teredines. The timber is steadily

eroded from the outside. Attack is generally limited to the tidal zone in water containing at least 1% salinity, but they can survive at lower temperatures than the teredines.

4.4 *Fungal attack (rot)*

Both internal and external decay (commonly known as rot) of timbers used for bridges is often caused by fungi.

Figure 22 Fungal attack

Fungal growths will not develop unless there is a source of infection from which the plants can grow. Fungi procreate by producing vast numbers of microscopic spores which may float through the air for long periods and can be blown for considerable distances. These spores will not germinate and develop unless there is—

- an adequate supply of food (wood cells);
- an adequate supply of air or oxygen (immersion in water inhibits fungal growth);
- a suitable range of temperatures (highest risk between 20°C and 25°C); and
- a continuing supply of moisture (highest risk in unseasoned timber).

Once established, the decay fungi continue to grow at an accelerating rate as long as favourable conditions prevail. Depriving the fungi of any one of these required conditions will effectively curtail the spread of decay. Moisture change can affect decay indirectly because drying often leads to surface checks, which may expose untreated parts of timber or create water traps. The most common rotting areas in timber bridges are internally in log girders, corbels and piles (piping), and in sawn timbers with exposed ends and at interfaces.

4.5 *Weathering*

Weathering is the gradual deterioration of sawn or log timber due to its exposure to sun, wind and rain. Refer Figure 23.

Figure 23 Weathering

Weathering can be a serious problem especially to the exposed end grain of untreated or unprotected wood, where severe rotting can occur around the connections. The exposed ends of transverse deck planks are susceptible to this defect.

4.6 *Fire*

Wood itself does not burn. The effect of heat is firstly to decompose the wood (a process known as 'pyrolysis') and it is some of the products of this decomposition that burn if conditions are suitable. In theory, wood decomposes even at temperatures as low as 20°C (at the rate of 1% per century). At 93°C the wood will become charred in about 5 years.

Large section round timbers, as used in bridge construction, have good resistance to fire, and, except during a severe bush fire, usually survive quite successfully.

5 TYPES OF REPAIR

5.1 *General*

The following presents a number of reliable long-term types of repair. We have incorporated these into the Design Standard. These should be considered before deciding that a bridge replacement is required.

5.2 *Splicing of piles*

While splices can provide a solution to local deterioration of timber piles, splices should not be applied to too many piles in the same structure, especially near ground level. Splicing should be limited to no more than 1 in 4 piles in a group unless a detailed

engineering assessment of the overall substructure is carried out.

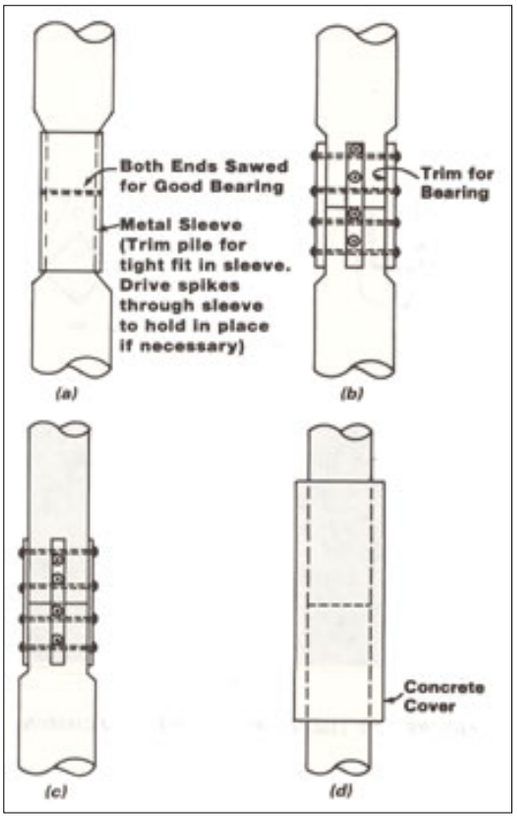

Figure 24 Pile splices

Typically, deterioration of piles occurs at or near ground lev el where both moisture and oxygen are abundant. Without oxygen, the potential for deterioration is low. Splices in piles should be located a minimum of 1.2 m below ground level and ideally below a permanent water table. Splicing will generally be more durable in a low permeability soil than a granular soil.

The interface should be liberally coated with a gel or grease type remedial preservative and wrapped with a geotextile fabric to help contain the treatment, and secured with galvanised steel plates and bolts.

5.3 *Additional girders*

Two additional girders can be installed directly adjacent to a damaged or under-strength member (one on each side). It is important to provide additional girders on both sides so that the correct load distribution between the girders in the span is maintained.

5.4 *Concrete overlay*

Due to uncertainties in long-term composite action between overlays and timber decks, concrete overlays are not considered to contribute to strength or stiffness in the longitudinal direction, and should ignore in strength calculations for the timber girders. However, they improve the transverse distribution of load, and therefore should be modelled in the transverse direction in the grillage model. Concrete overlays are considered structural when assessing the local effects of the transverse timber decking. Refer Figure 25.

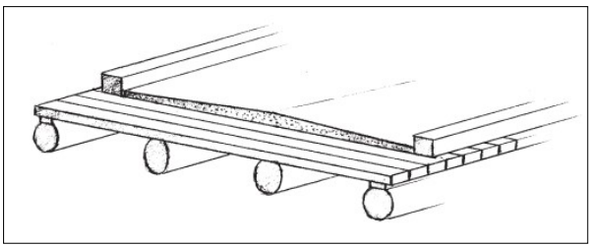

Figure 25 Concrete overlay

Early concrete overlays were designed as thin, flexible running surfaces providing a weatherproof cover to the timber deck. Consequently, many of the overlays carried out in the early 1970s are now failing, having badly cracked due to timber flexibility under traffic loading, and are leaking water. Concrete overlays designed today are thicker and contain more steel reinforcement than the earlier overlays. With increasing guardrail requirements, another important consideration for the concrete overlay is to provide adequate connection for a guardrail appropriate to the current standards

5.5 *Timber concrete composite bridge decks*

Figure 26 Timber concrete composite construction

The timber concrete composite (TCC) system can be used to replace deteriorated timber girder superstructures of spans up to 12 m. refer Figure 15.

These are built in panels with each panel having two round timber girders which are made semi-composite with a concrete deck by steel shear connectors. Generally, the TCC decks do not have a wearing surface applied and the vehicles travel directly on the concrete. These modules should, in effect, be treated as disposable units, as there is little that can be done to repair them once they lose

strength through damage or deterioration. The timber girders cannot be replaced, nor can the shear connection between the components be properly reinstated.

5.6 *Replacement of timber piers*

Typically, deterioration of timber piles occurs at or near ground level where both moisture and oxygen are abundant. It is possible to substantially increase the durability of a timber pier by providing a concrete pile cap below ground level which extends at least 300 mm above ground level, with a timber trestle pier founded on top of the concrete pile cap.

However, the connection between the concrete and the timber at the base of the pier is not able to take substantial bending moments, and so this solution should be limited to those bridges with four or less spans, which are not subjected to high flood or debris loading, and where both abutments have sufficient capacity to take all forces due to braking loads.

5.7 *Stress laminated timber bridge decks*

The stress laminated timber (SLT) system uses 35 to 45 mm thick timber laminates of widths from 140 to 290 mm (and wider where manufactured wood products are utilised). These laminates are oriented on edge (upright) and stressed together using high strength bars or prestressing strands to form a solid structural slab. The SLT decks re quire both a waterproofing system as well as a wearing surface. Since the SLT system provides a strong structural slab, these decks can support any bitumen based wearing surface without cracking.

Figure 27 Installation of an SLT

For spans up to 8 m, the SLT deck system generally represents a reduction in overall dead load as the deck replaces the stringers, decking and sheeting.

5.8 *Replacement of members*

There are two practical methods of strengthening and upgrading existing timber girder bridges and deck systems using the same general design style. The size of the girders can be increased or additional girders added. In most cases, obtaining larger girders is becoming more difficult. Therefore, in a bridge where the existing girders are sound, additional girders should be added between the existing members to strengthen the superstructure. If there is variability in the sizes of the timber girders then a proper engineering evaluation must be performed as the load carried by the girders is related to their stiffness.

All timber components should be ordered by specifying the size, strength grade, seasoning requirements (green, 12 months air dried or kiln dried) and durability class. If unseasoned or air-dried timber is ordered then a larger size must be specified (add 5%) to cover shrinkage of the timber as it seasons with time.

6 CONCLUSIONS

Timber bridges are the most common form of bridge construction in Australia. There is ample evidence that the first timber bridges were constructed by the aborigines. With European settlement, this number increased. It is estimated that there are now over 11,000 timber bridges owned by Local Government. Recent studies have indicated that approximately 30% of these bridges are in a “poor” to “very poor” condition. To make the required step change a collaborative public-private solution is recommended. These defective bridges represent a “Whole of Government” long-term community safety risk. The reality is timely replacement is simply not provided for in Council, State or Federal Government capital programmes.

Innovative and sustainable operation and maintenance of bridges

Jens Sandager Jensen
COWI A/S, Kongens Lyngby, Denmark

ABSTRACT: How can learnings from innovative and sustainable operation and maintenance (O&M) of bridges contribute to improved planning for and design of bridges? The present paper will highlight how important it is to consider O&M issues already in the planning and design phase. Durable solutions as well as easy access for inspection, repair and renewal projects together with considerations regarding necessary traffic regulating measures are vital to cost optimal operation. Likewise, asset management systems that are able to provide precise and current performance information are vital to cost optimal operation.

Today's society demands solutions that maximise reliability and availability as well as minimise costs, environmental impacts and the probability of loss of life and limb. To accommodate this it is important both to take into account experience from O&M and the possibilities that comes with application of new technologies.

1 INTRODUCTION

Transportation infrastructure support economic growth and a satisfactory quality of life for the citizens. Optimal technical and economic planning, design, execution and operation of transportation infrastructure, such as bridges, is crucial in order to support these goals.

It is important to consider operation and maintenance (O&M) aspects already in the design phase. Durable solutions as well as easy access for inspection, repair and renewal projects together with considerations regarding necessary traffic regulating measures are vital to cost optimal operation. Today's society demands cost optimal, safe and sustainable solutions. To accommodate this it is important both to take into account experience from O&M of existing bridges and the possibilities that comes with new technologies (Jensen, 2010, Jensen, 2016 and Paulsson et al, 2016).

It is well known that decisions made early in a project has the greatest impact on performance and Life Cycle Costs, see Figure 1.

Planning is important. Such planning may comprise Corrosion Protection Plans (CPP), Building Information Modelling (BIM), O&M-manuals, Structural Health Monitoring Systems (SHMS), Life Cycle Cost (LCC) studies, Operational Risk Analyses (ORA) and Asset Management System. These tasks shall be tailored to the individual bridge or a portfolio of bridges. Naturally, the scope of work varies from small size culverts to major suspension bridges.

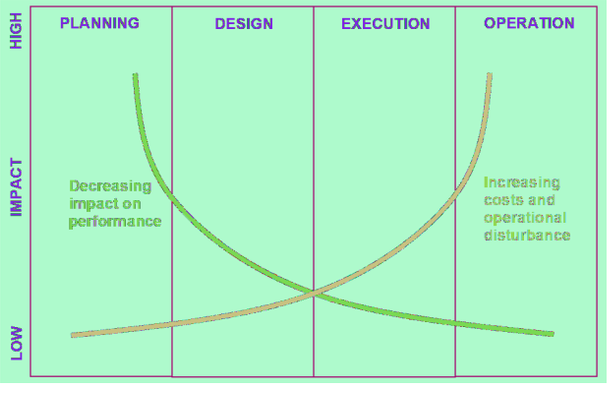

Figure 1. Impact on performance and costs during different project stages (Linneberg et al, 2016).

CPP's comprise corrosion protection strategies that takes into account durability (service life models), access and O&M instructions for the bridge management. Durability shall be ensured through a design with the right material specifications, proper drainage details etc. as well as high quality execution. Furthermore, service life models shall be robust and transparent so that they may be verified during operation and updated in order to reflect current per-

formance. This argument is valid for a great number of components, where hands-on knowledge on long-term performance is a key to successful planning. Asset management systems should be able to provide these long-term performance data in a structured and transparent way. This may also allow for extrapolation of data within a portfolio of bridges.

The principle of Building Information Modelling (BIM) is used in modern asset management systems to manage all stages of new infrastructure projects, i.e. design, construction and operation. Many bridge owners would like to use this technology for existing bridges also. The first step would be to establish a 3-D model of the geometry. Often a combination of scanning and imagery has proved successful. In this way owners move from "dead" data in paper records to "live" and fully digital data based on the principle of BIM, which can be used in asset management.

Major bridges call for bridge specific O&M manuals. They will provide the necessary basis for safe and cost optimal O&M for such a large investment by the society. A lean Structural Health Monitoring System (SHMS) is also a vital component for a major bridge as a mean for obtaining data describing the exposure conditions and performance of the structure.

A systematic identification of Life Cycle Costs facilitates a holistic approach to cost optimal design. Similar to current O&M planning this could include user costs (delays etc.) and possible sustainability indicators.

Finally, application of risk analyses in design as well as during O&M has proven beneficial (Linneberg et al, 2013). In this way, the likelihood or occurrence rate is considered alongside the consequence. One example is bridge-specific Operational Risk Analyses (ORA) that have been performed for many existing major bridges. Often they recommend risk mitigating measures such as fire protection of main cables, improved drainage and strengthening of barriers and railings. ORA's are reviewed and updated on a regular basis, say every 10th year, or when significant accidents occur. Also, risk review, risk assessment and risk management is used when hidden defects in existing bridges are investigated (CIRIA, 2017).

2 CORROSION PROTECTION PLANS

2.1 *Introduction*

CPP's comprise corrosion protection strategies that takes into account durability (service life models), access and O&M instructions for the bridge management. Durability shall be ensured through a design with the right material specifications, proper drainage details etc. as well as high quality execution. Furthermore, service life models shall be robust and transparent so that they may be verified during operation and updated in order to reflect current performance. This argument is valid for a great number of components, where hands-on knowledge on long-term performance is a key to successful planning. Asset management systems should be able to provide these long-term performance data in a structured and transparent way. This may also allow for extrapolation of data within a portfolio of bridges.

2.2 *Outline of a CPP*

The benefit of a bridge design based on a CPP is two-fold. Firstly, for each type of component, the plan provides the required corrosion protection and durability measures to achieve a satisfactory service life with due attention towards varying exposure conditions. The implementation is carried out through adequate design, quality control and assurance incl. control of suppliers and manufacturers and the entire construction work process. For major bridges, a project specific O&M Manual implements the required caretaker principles of operation, inspection and maintenance.

Secondly, through the overall concept of the bridge design, attention is given to limit future operational restrictions and to keep the amount of inspection and maintenance at an appropriate level through a number of durability enhancing features.

The CPP shall demonstrate that the design will achieve the required service life. This includes optimisation of e.g.:

- Drainage
- Concrete cover (and possible use of membranes)
- Concrete mix
- Use of admixtures to reduce cracking (permeability)
- Reinforcement type
- Fibre reinforcement of concrete
- Steel grade (fatigue)
- Steel coating system
- Preparation for cathodic protection

For non-replaceable components the service life is typically in the range of 100-150 years.

For replaceable components easy access for inspection, repair and renewal projects together with considerations regarding necessary traffic regulating measures shall be considered. Cost-benefit analyses / Life Cycle Costs studies may assist economic optimal design of replaceable components. In Denmark typical service lives for bridge components under normal operation has been developed as a joint task between Danish Owners, Consultants and Contractors, see Table 1.

For concrete structures, the CPP shall detail deterioration mechanisms and the strategies that will be used to mitigate the deterioration to ensure that service life requirements are met.

Table 1. Typical service lives for bridge components under normal operation (Håndbog, 2014).

Bridge Component	**Service Life (years)**
1. Asset in general	50-100
2. Wing walls	50-100 10-15 (coating)
3. Slopes	25-50 20-30 (gabion and sheet piling)
4. Abutments	50-100 25-50 (parement) 10-15 (coating)
5. Piers incl. foundations	50-100 25-50 (parement) 10-15 (coating)
6. Bearings	25-50
7. Load carrying superstructure	50-100 10-15 (coating of concrete) 25-40 (hot-dip galvanizing) 15-25 (coating of steel)
8. Waterproofing	30-50
9. Edge beams	30-50 (in-situ cast) 20-40 (prefabricated) 10-15 (joints and coating of concrete)
10. Parapet / railing	30-50 20-40 (hot-dip galvanizing) 10-20 (coating of steel)
11. Bridge surfacing	30-50 (asphalt base layer) 15-25 (asphalt top layer) 15-20 (polymer surfacing) 20-30 (tiles) 10-15 (bitumen joints) approx. 30 (track and sleeper) 15-25 (ballast)
12. Expansion joints	30-50 (general) 50-100 (cast-in parts) 15-25 (sealers) 10-15 (joints)
13. Drainage	20-30 (grating) 10-15 (suspension) 25-50 (pump pit)
Other elements	20-30 (signals, lighting) 25-50 (e.g. stairs, sluice elements)

For reinforced concrete structures, the following deterioration mechanisms are often considered:

- Alkali Aggregate Reaction (AAR)
- Sulphate attack
- Delayed Ettringite Formation (DEF)
- Freeze-thaw
- Carbonation induced corrosion
- Chloride induced corrosion

As seen from the above list, one of the design objectives is to slow the transport of chlorides from the environment through the concrete cover to the reinforcement location. Durability modelling according to Fib Bulletin 34 (Fib, 2006) provides the technical background for analysing depassivation over the target service life in a probabilistic framework. One of the major advantages of probabilistic models is that they are excellent for sensitivity studies as well as for updating based on on-site data, ref. (Engelund et al, 2008).

For steel structures, the objective is to minimise number of joints, avoid fatigue prone details, use dehumidification where beneficial (e.g. suspension cables, box girders), apply state of the art materials (e.g. wear parts in bearings) and specify excellent coating with a long service life. Thus, it is essential to consider operation during design. The design should be able to answer questions such as: how to replace sliding material in bearings (ref. Figure 2), partial or full replacement of expansion joints and does outer steel tower or deck area promote inspection and recoating using robots? It is evident that Inspection and Maintenance (I&M) supported by robots is the future. They may provide accurate data, reduce labour costs, reduce risk exposure of staffing (primarily work environment related) and accelerate execution. Even though this technology develops rapidly, current state-of-the-art has to be considered during design, e.g. unobstructed travelling paths.

The same principles also apply for design of electrical and mechanical (E&M) systems, especially that they shall be easy to inspect, maintain and replace as they have shorter service lives than the bridge structure.

A key part of any major bridge design is also to provide ready access for inspection and maintenance. Providing ready access will significantly reduce long-term costs associated with I&M. Furthermore, access equipment is much cheaper for the Owner if provided during construction than during operation. Often such facilities may be of benefit for both the construction and the operation phase. Access facilities will be used in combination with drones, robots etc., i.e. access facility design has to consider current state-of-the-art in these related areas.

Figure 2. Replacement of sliding material at the Sjaelland-Faroe bridge.

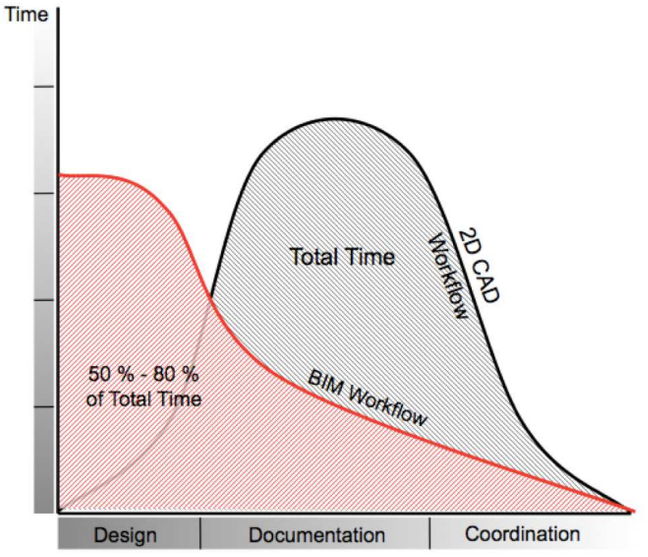

Figure 3. Potential for savings with a BIM workflow.

3 BUILDING INFORMATION MODELLING

3.1 *Introduction*

Building Information Modelling (BIM) is a data-enriched collaborative process that utilises intelligent, object orientated, three-dimensional (3D) parametric models to realise efficiencies throughout the lifecycle of a facility or asset, ref. (McKenna et al, 2016). These years BIM awareness in architecture, engineering and construction sector increases significantly.

The BIM model is used in a workflow where different model characteristics are used for different purposes. The workflow for a standard concrete bridge design may comprise a 3D general model, an analytic model, a Finite Element model, formwork/arrangement drawings, reinforcement drawings and a steel bending schedule.

There is a huge potential for savings when utilizing a BIM workflow, see Figure 3. When owners, architects, engineers and contractors have access to the same model many clashes between the different stakeholders can be handled early in the program/planning and design phase. Also the level of automation releases more time for design, when compared to tradition CAD use, where 2D drawings documented the design in a way, so that the contractor was able to construct the project.

Furthermore, 3D models may be used for generating 3D PDF files that can be used for dynamic verification of constructability etc.

The 3D models may be extended with information related to time (scheduling), costs, as-built documentation and operation. This is sometimes referred to as 4D, 5D, 6D (etc.) BIM models; however, 3D+ models may be the most suitable term.

In COWI, we have developed the 'COWI BIM Wheel', which we use when discussing information exchange with Clients and other project stakeholders, ref. Figure 4. Based on the 'COWI BIM Wheel' we align expectations and tailor the BIM setup to the Client needs and outlook for the future.

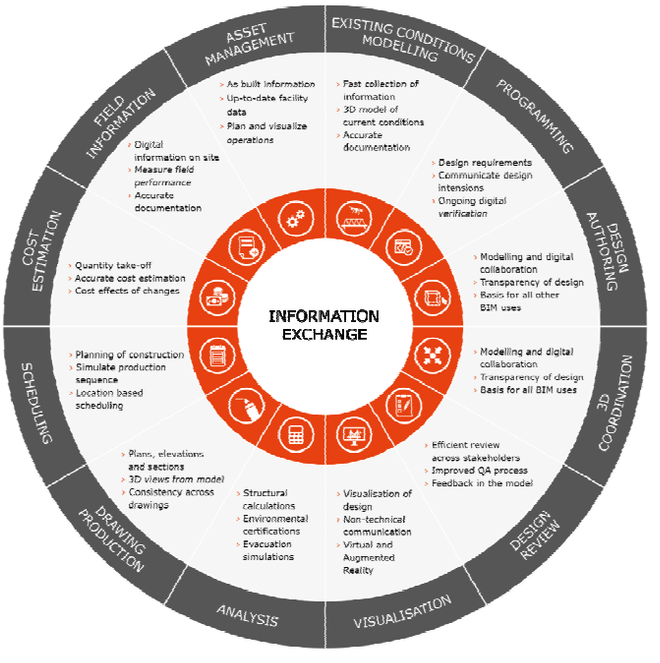

Figure 4. COWI BIM Wheel © COWI A/S.

It isexpected that the next generation of bridge inspector's work using augmented reality glasses in the same way as e.g. Caterpillar is using augmented reality during repairworks. In this way, the bridge inspector may have material descriptions, execution records, previous inspection results, operation and maintenance requirements etc. all relevant for the element right in from of him and displayed on top of the physical reality.

3.2 *Existing bridges*

The principle of Building Information Modelling (BIM) is used in modern asset management systems to manage all stages of new infrastructure projects, i.e. design, construction and operation. Many bridge owners would like to use this technology for existing bridges also. The first step would be to establish a 3-D model of the geometry. Often a combination of scanning and imagery has proved successful. In this way owners move from "dead" data in paper records to "live" and fully digital data based on the principle of BIM, which can be used in asset management.

UAV technology (unmanned aerial vehicle) is one of the possible technical developments that can be used to generate a 3D model of the geometry. Increased stability and control combined with lower prices has resulted in a booming industry within this area. In addition, the mobile industry has pushed the development for sensor and camera technology (thermography etc.); therefore, a more advanced tool package can be carried by UAVs.

COWI has performed a number of UAV inspections on Danish bridges. The first trials where performed to establish a common understanding between bridge inspectors and drone pilots. The bridge inspectors quickly realized the challenge of locating each observation by video, due to the comprehensive size of the structure and the many identical surfaces. Therefore, COWI developed a new easy-to-use, web-based tool "COWI Virtual Inspection" (CVI) where a 3D model can be created based on the images from the UAV inspection. On top of this surface model, images are applied. All data collected are automatically tagged with geographical, axial and time information.

Damage intensity, extend and location should be described during an inspection. The CVI tool has made it easy to locate each visual damage. In Figure 5, a snapshot of the CVI screen is shown for an anchor block. In the CVI model it is possible to mark/highlight defects, write defect specific text, assign condition rating and click anywhere on the structure and get close-up pictures of defect or other information of interest. In Figure 6, a close-up of a drainage pipe is shown. Furthermore, comparison of close-ups of defects taken at different point in time is possible. This provide a powerful tool for performance prediction.

This approach will for large structures reduce the hours spend significantly and reduce the amount of traffic interruption. In the future, it is foreseen that structures can automatically be screened by UAVs, where image recognition software will be able to point out relevant areas, where a hand-near inspection is needed.

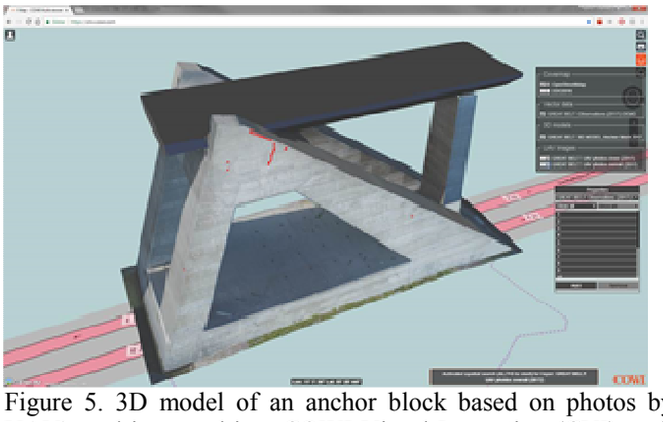

Figure 5. 3D model of an anchor block based on photos by UAV's and imported into COWI Visual Inspection (CVI) tool. Minor defects are highlighted in red color.

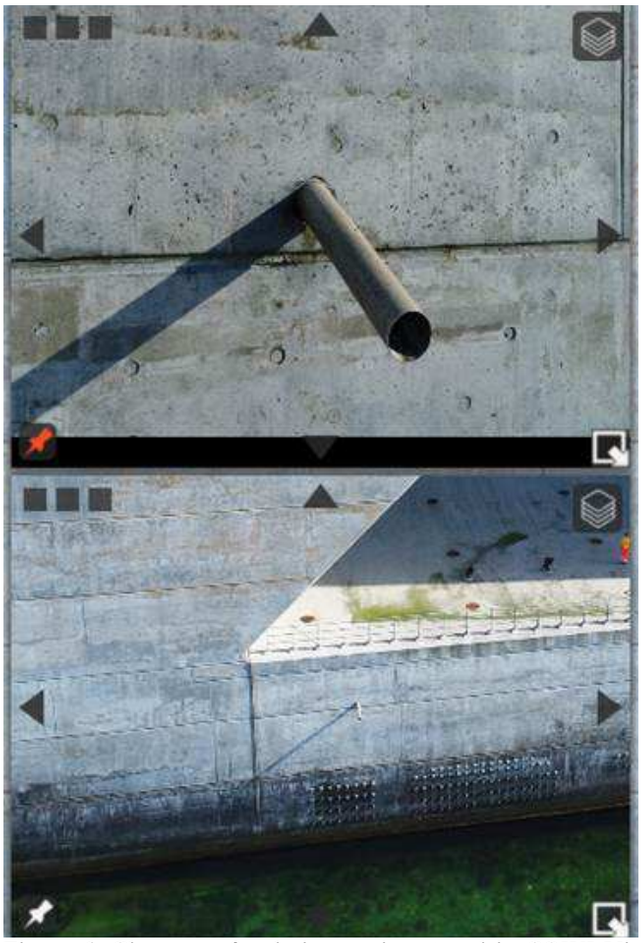

Figure 6. Close-up of a drainage pipe stored in COWI Visual Inspection (CVI) tool.

4 O&M 'MANUALS' FOR MAJOR BRIDGES

4.1 *Introduction*

Major bridges call for bridge specific O&M 'manuals'. The term manuals has been stated within punctuation marks (' '). The reason is that the term manuals should be understood in a very broad way. As reasoned in the previous chapter, O&M of bridges are moving away from paper records into real-time data-driven O&M and possibly into augmented reality, i.e. the term manuals is to be understood as data and structures that allow for supplementing new data.

'Manuals' shall provide the necessary basis for safe and cost optimal O&M for such a large investment by the society. A lean Structural Health Monitoring System (SHMS) is also a vital component for a major bridge as a mean for obtaining data describing the exposure conditions and performance of the structure.

4.2 *Outline of a O&M 'Manual'*

A O&M 'manual' for a major bridge shall be applicable for use in the following ways:

- As a basis for scheduling and planning of O&M
- As a basis for training of inspection and maintenance (I&M) personnel
- As a source for forms, instructions, check-lists and other information
- As a basis for audits according to the quality management system implemented for bridge
- Linking and ensuring consistency with existing rules, instructions and procedures at the local authority

The O&M 'manual' is recommended to comprise the following minimum information:

- Table of content
- Scope
- Description of the bridge
- Operational instructions
- Instructions for principal inspections
- Replacement procedures
- Spare part inventory
- Appendices

The O&M 'Manual' shall be based on as-built information incl. possible birth certificates. Furthermore, the O&M 'Manual' shall be in a format that is easy to update.

5 STRUCTURAL HEALTH MONITORING SYSTEM

A Structural Health Monitoring System (SHMS) is essential for optimising O&M of major bridges. It shall provide input for a safe and cost-efficient bridge management with minimal traffic restrictions or disturbance.

Initial analyses of hazards and deterioration mechanisms map the requirements for the SHMS. From this, on-structure installations and functions of data management and control can be specified in a reliable, easy-to-operate and cost-efficient way. As our industry becomes more and more technical and economic comfortable with large quantities of data (big data), transparency and easy operation become essential characteristics.

By monitoring the actual exposure conditions and performance of the bridge through the SHMS, the bridge manager can compare the data collected against the fundamental design assumptions and make an assessment of the remaining service life and plan inspections if required. The data can also be used to identify areas where mitigation may be necessary before significant deterioration occurs, minimising future maintenance costs and enhancing the bridge's service life.

Bridge SHMS consists in general of 4 important technical elements:

- Sensors placed on the structure. These modules house various sensors, depending on the nature of the structure.
- A data communication system for the transfer of the collected data to a remote computer.
- A database application, which collects, stores and processes the sensor data in real time, providing an evaluation of the condition of the structure based on application areas such as user safety, trouble shooting, natural disaster follow-up and maintenance optimisation.
- Processed data can be used to derive service life models, enabling the bridge owner to decide if structural components shall be replaced or whether the service life of the component can be prolonged. As usual, it shall be highlighted that results are no better than the underlying model and the quality of input.

In Figure 7 shows an example of a simple measurement campaign that is used for re-estimating the remaining fatigue life of an orthotropic steel deck. The campaign was only running for a limited period of time.

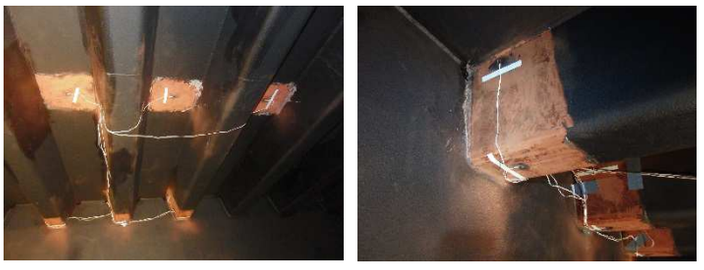

Figure 7. Simple measurement campaign in order to re-estimate remaining fatigue life in an orthotropic steel deck.

6 LIFE CYCLE COSTS

6.1 *Introduction*

A systematic identification of Life Cycle Costs facilitates a holistic approach to cost optimal design. Similar to current O&M planning in some countries this could include user costs (delays etc.) and possible sustainability indicators.

Life Cycle Cost (LCC) studies are performed for nearly all major bridges at some stage of their service life. Such studies are typically based on net present values. LCC studies are considered as part of an overall assessment in parallel with other important issues such as risk assessment, environmental assessment (incl. LCA), traffic impact assessment etc.

LCC may be carried out as part of feasibility studies to find the most cost-efficient solution, as part of detailed design to determine and possible minimize an in-service budget for the owner, as part of the tender to evaluate the most attractive bid proposal, or as part of the operation to evaluate the optimum operation and maintenance strategy. For the latter case, monetization of user costs (e.g. delays) may become the decisive factor.

The society's increasing awareness of whole life environmental impact related to infrastructure is reflected by the fact that some Infrastructural Managers now also request Life Cycle Assessments to assist their decision-making. Two recent research projects reflect this awareness: MAINLINE (MAINtenance, renewaL and Improvement of rail transport iNfrastructure to reduce Economic and environmental impact, EU 7th framework programme) and ETSI (Nordic research project on Life Cycle Cost, Environment and Aesthetics for road bridges). Reference is made to (Linneberg et al, 2014 and Linneberg et al, 2016) on key parameters needed in order to provide reliable and possibly integrated LCC and LCA results. In that reference, it is highlighted that some of these parameters need detailed as well as governmental considerations. Intervention strategies driven by performance profiles, where:

- degradation
- monitoring and examination techniques
- availability of real data
- life extension by refined structural models and/or strengthening
- new construction methods and logistics

may add complexity into the decision making.

A widely used approach for comparing environmental, financial and social impacts is the so-called triple bottom line accounting approach. However, some countries has developed cost equivalents associated with environmental impacts. For instance, Rijkswaterstaat (part of the Dutch Ministry of Infrastructure and Enviroment) has published a list of corresponding shadow prices. With these it is possible to integrate financial and environmental impacts. However, such shadow priced should be country specific and their implementation should be supported by the government. Another approach would be the application of multi-objective optimization models, which is a systematic approach to evaluate multiple conflicting criteria in decision making. Analytical Hierarchy Processes and Multi-Attribute Utility Functions is two approaches that tackled this goal. Both methods has been adopted within infrastructure decision making on network level by e.g. the COST TU1406 action (COST TU1406).

6.2 *Good news for concrete structures*

In order to aid owners, operators and their consultants, a task group under fib (Fédération Internationale Du Béton) has been established to prepare a

state-of-the-art report regarding LCC analyses of concrete assets. The state-of-the-art report will contain a description of existing LCC standards and guidelines, their applicability, the definition of different cost elements, the treatment of uncertain information in a reliability or risk based framework, etc. providing the reader with background information and methodology for preparation of such analysis. Moreover, the report will contain case studies, presenting the applicability of the methodology presented in the report. The state-of-the-art report is due by the end of 2018, ref. (Matos et al, 2017).

6.3 *O&M drivers*

O&M drivers are actions related to elements that consume a major part of the maintenance budget during the bridge service life. Typically, these elements have a high unit price, short service life when compared to the bridge service life and are difficult to maintain or replace.

LCC studies typically confirm that it is cost optimal to specify premium quality for these O&M drivers. For some components, such as surfacing, it is even more evident if LCC estimates consider indirect or society costs such as costs related to traffic interruption (delay due to congestion, speed limitation and/or possible detour).

Components belonging to this category of elements are edge beams, coating, bearings (major bridges), expansion joints (and joints in general) and surfacing (incl. waterproofing). As seen, poor performance of some of these elements are not critical in relations to structural safety.

Identification of O&M drivers is furthermore dependant on the O&M strategy. LCC of a well maintained coating is not the same as LCC of coating that has been allowed to degrade to technical failure. In general, preventive maintenance is superior to corrective maintenance.

Through search criterions, O&M drivers may be obtained from the data gathered in a Bridge Management System (BMS).

6.4 *Tendering*

Low LCC require early planning. One of the important decisions during this planning is the contractual setup. Contracts shall support low LCC, stable budgets, right timing and innovation where appropriate (Simonsson et al, 2016).

When offering design and build contracts functional requirements shall ensure low LCC. Implementation of other constraints in a design and build tender material is not easy or at least it requires a robust evaluation model that favours minimal future O&M costs.

Design, Build, Operate and Maintenance (over a certain period) contracts favours low O&M costs during the period of operation. The contract shall describe robust and transparent requirements (performance thresholds) as well as performance indicators and models that shall document satisfactory performance. Chloride ingress in concrete structures is one example, where extensive description of performance models and thresholds is needed.

When entering a Public-Private-Partnership contract the risk over a certain period is split between the partners. Because of this mutual involvement over a certain period, Public-Private-Partnership often promote low LCC during the contract period as well as during the total life of the bridge.

Functional requirements in a tender document addresses requirements to the performance of components. Most often functional requirements only deal with the initial quality of the component. One of the reason is that supplier warranty has a time limitation that typically covers immediate construction faults that materialize within the first 5 years. A 10% reduction of a stated service life is typically outside such warranties. It is the author's experience that requirements to the initial quality of components may not be sufficient in order to obtain optimal LCC.

Initial performance shall be supplemented with requirements to component performance during the entire service life where possible.

However, functional requirement shall not be a technical barrier in EU-terms, i.e. the Owner cannot specify a certain manufacturer where he has good experience. Functional requirements shall allow more than one supplier to be qualified. As an example, bearings for major bridges are high cost elements, the wear parts (sliding material) have short service lives (especially if dirt enters and result in extensive friction) and their replacement may require closing of the bridge towards traffic. Because of this, one of the functional requirements is improved and documented resistance of the sliding material.

A LCC model as part of the tender evaluation model could supplement functional requirements. Such a model could, on a component level, favour low initial cost, low maintenance costs, low replacement costs, low quantity and/or high service life. The model should match the degree of freedom to the component in question. When considering bearings, maybe the only degree of freedom should be the quantity (supplementing functional requirements), i.e. this will favour bridge types with minimum amount of bearings. As seen, such a degree of freedom has nothing to do with quality.

Only allowing the Contractor to freely estimate LCC associated with his bid does not provide objective information that can be used in a tender evaluation. If it is purely up to the Owner to perform a LCC study of each bid, and rank them according to a simple evaluation model, the evaluation model shall be robust, transparent and part of the tender material. The Swedish Transport Administration has initiated such work (Safi et al, 2015). However, further work

is needed to robustly integrate it with their established procedures.

6.5 *Key parameters*

As defined in ISO 15686-5, the discount rate is used to convert cash flows occurring at different time to a common time to reflect the time value of money (Net Present Value, NPV). ISO 15686-5 suggests using the real discount rate in order to exclude the impact of future inflation in the LCC evaluation.

It is stressed that the discount rate probably has the most significant impact to the final results in a LCC evaluation and hence the selection of a suitable discount rate is crucial for the decision-making. A high discount rate will tend to favour options with low capital cost, short life and high recurring cost; whilst a low discount rate will have the opposite effect.

In many countries, the government regulates discount rates. However, research and development projects also provide guidance, such an example is INNOTRACK that provided guidance in adopting discount rate for European rail projects.

A general constraint is the fact that the public tend to value immediate returns; the concept of optimal design selection based on LCC is, therefore, fundamentally at odds with political systems. This conflict is further detailed in (Corotis, 2009).

The time period studied (also known as analysis period, time horizon or mission time) is the period of time over which LCC is to be evaluated. The length of the analysis period is dependent on the nature of the project. The following are the factors, suggested by INNOTRACK, for consideration when determining the duration of the study period for LCC analysis:

- The time period studied should be at least equivalent to the life-span of a great part of the components, at least one entire life-span of the majority of the replaceable components.
- When comparing alternatives where the majority of the components have different life cycles, the time horizon should be long enough to avoid distortions, at least one cycle of the most long-lasting components.
- Too long a time period will increase the uncertainties and risks on the project appraisal (difficulties to forecast technological scenarios, economy trends and social welfare issues over very long periods).
- The range of values to be adopted for the time period in rail should be in clear consensus with most recent guidelines and practices on the project appraisal standards.
- The definition of any time period studied for comparison of alternatives with very different life span should address homogeneous and consensus criteria to estimate the residual values.

Although INNOTRACK focus on tracks the same arguments are valid for other infrastructure assets.

7 OPERATIONAL RISK ANALYSES

Application of risk analyses in design as well as during O&M has proven beneficial. Application of risk analysis ensure that the likelihood or occurrence rate is considered alongside the consequence. One example is bridge-specific Operational Risk Analyses (ORA) that have been performed for many existing major bridges. Often they recommend risk mitigating measures such as fire protection of main cables, improved drainage and strengthening of barriers and railings. ORA's are reviewed and updated on a regular basis, say every 10th year, or when significant accidents occur.

Another initiative is to develop and maintain a risk log to mitigate risks during the lifetime of a bridge or a portfolio of bridges. It is in the interest of the society to have an overall picture of which hazards influences e.g. traffic safety and maybe even passability.

The purpose of an operational risk analysis is:

- to assess risks related to operation of the bridge
- to compare these to the risk acceptance criteria, and, if these criteria cannot be fulfilled, to propose risk reducing measures

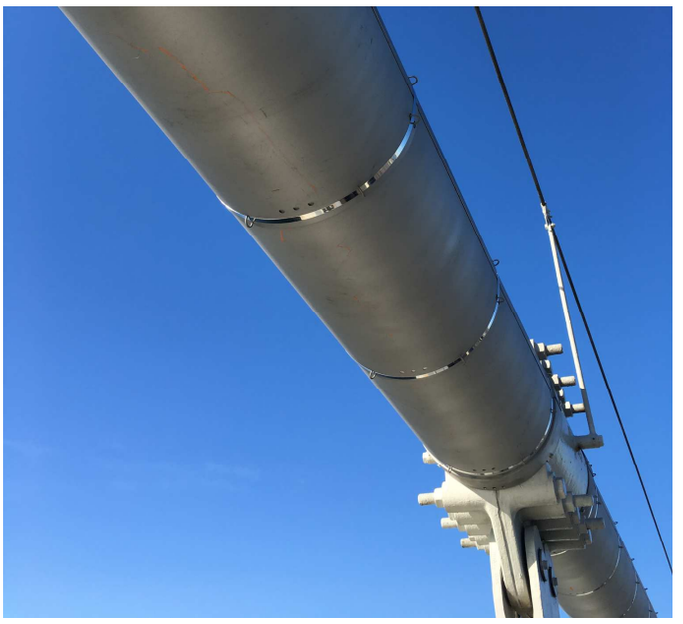
A systematic approach will lead to identification of risks as well as requirements and recommendations on operational measures. A follow up on the risk distribution as well as requirements and recommendations may then be performed at certain intervals.

An example of recommendations for an existing suspension bridge in Sweden was:

- Improved drainage. Open channels should be closed, so that flammable liquid cannot burn in the channel with due consequence for the bridge deck. In addition, drainage capacity should be increased, so that flammable liquids are drained way from the bridge, which decreases the risk associated with a fire from a tank transporter.
- Strengthening of crash barriers. Renewal of crash barriers so that they fulfill current standards,

The above recommendations was implemented in 2016-2017.

Another example of application of an ORA is related to ship impact analysis. If the probability of a critical failure is larger than 10^{-6} per year, an ALARP (As Low As Reasonable Practicable) procedure has to be performed. The procedure consist of identification of risk mitigating measures (reduction of frequency or reduction of loss of lives), review of measure effectiveness, and estimation of mitigation costs. On that basis an acceptable solution may be identified, ref. (Dansk Standard, 2016).



When accidents on major bridges occur, it is relevant to revisit the ORA. When a truck caught fire at the New Little Belt Bridge in Denmark, ref. Figure 8, a protective or risk mitigation measure was suggested.

Figure 8. Fire on the New Little Belt suspension bridge.

In 2017 main cable protection was installed consisting of insulation material and a protective cover, ref Figure 9.

Also, risk review, risk assessment and risk management is used when hidden defects in existing bridges are investigated. Sudden weight restrictions and emergency closures on roadway bridges are often because of hidden defects. Hidden defects are defects that are hidden from sight (inspection within touching distance) or not obvious on first observation. CIRIA has provided a guidance for detection and management of hidden defects in bridges, ref. CIRIA, 2017. The recommended practice consist of a three-step procedure comprising risk review, risk assessment and risk management. As part of the risk-review two key questions has to be asked during review of existing information: What do the records say? and What is not recorded? Also two questions has to be asked on site during inspections: What can I see? and What can I not see?

Figure 9. Protective cover (against fire) installed on the New Little Belt suspension bridge.

The CIRIA guideline provides extensive guidance on identifying key hazards, their consequences, associated deterioration mechanism and their control measures. An example of a somewhat hidden defect is the AAR affected bridge slab (supported by columns), where a cut-though is shown in Figure 10. Clearly, this is a undesirable situation since the bridge has no shear reinforcement.

Figure 10. AAR affected bridge slab (supported by columns) with no shear reinforcement.

8 ASSET MANAGEMENT SYSTEM

Asset management systems should among other things be able to provide long-term performance data in a structured and transparent way. Asset management systems should also allow for extrapolation of data within a portfolio of bridges.

8.1 *Major Bridges*

Major Bridges are often born with a Bridge Management System (BMS) tailored for the bridge in question. This system is the anchor point for data handling. Data may come from:

- SCADA (Supervisory Control And Data Acquisition) system
- Structural Health Monitoring System (sensors, images etc.)
- Building Information Modelling (BIM) system
- Documents
- GIS data
- etc.

Among other things, such a system should be able to provide easy storage and data-retrieval for operation and maintenance of the bridge.

8.2 *Regular bridges and portfolio of bridges*

Quality Control Plans (QPCs) should define at which interval the quality controls are necessary and for which conditions more detailed investigations or interventions are necessary.

In case of regular bridges, performance indicators are established for their components. These indicators can be qualitative or quantitative and they can be obtained during principal inspections, through a visual examination, a non-destructive test or a temporary or permanent monitoring system. Then, obtained indicators are compared with performance goals, in order to evaluate whether the quality control plan is accomplished.

It is verified that there is a large disparity in Europe regarding the way these indicators are quantified and how such goals are specified. Therefore, COST Action TU1406 has brought together, both research and practicing community in order to accelerate the establishment of a European guideline in this subject, ref. (COST TU1406).

The desired quality of the whole bridge can be affected by a single dysfunctional component or by the combination of several dysfunctional components. The decrease in bridge quality clearly depends on the degree of components' dysfunctionality.

However, in order to assure a desired quality with minimum traffic interruptions, bridge owners launch preventative actions when the risk of service impairment, interruption or increase in life cycle costs reaches some predefined level. Implicitly the owners define herewith the accepted risk. This accepted risk depends upon the established performance goals for each component or combination of bridge components.

COST TU1406 has established a procedure, which would allow the bridge owner to define a QCP for each individual bridge. The QCP operates on component and system level (one bridge at a time). The QCP methodology may be implemented in a BMS.

Managing a portfolio of bridges is somewhat different from managing one bridge at a time. For a portfolio of bridges, downstream or network level consequences may become essential. Such consequences may include the importance of the bridge within the network, i.e. maximising network functionality.

8.3 *Some notes on next generation of asset management systems*

In recent years, cognitive analytics and Internet of Things (IoT) has emerged also in bridge management. Cognitive computing is a tool that brings structure in unstructured data (often of huge amounts) in order to find new patterns, relations and interpretations. Cognitive computing has also found its way into the health sector and financial services to name but a few.

9 CONCLUSION

When we design new bridges, it is important that we learn from decades of operation and maintenance of bridges. Likewise, it is important to realise that consideration of operation and maintenance in the planning and design phase has the greatest impact on bridge performance and life cycle costs.

Understanding and prediction of bridge performance during its service life is essential. Agreeing on performance predictive models and how they are verified in a robust and transparent way is important for all stakeholders dealing with operation and maintenance of bridges.

Today's society demands solutions that maximise reliability and availability as well as minimise costs, environmental impacts and the probability of loss of life and limb. To accommodate this it is important both to take into account experience from O&M and the possibilities that comes with new technologies.

New technologies may comprise e.g. probabilistic performance models, operational risk assessment and Building Information Modelling in design of new bridges or established for existing bridges using e.g. photos taken by UAV's (Unmanned Aerial Vehicles). Such photos may be used for establishment of a 3D-model (a digital twin) and mark-up of damage location. These mark-ups are then basis for detailed inspection (within arms-reach), possibly using the benefit of Augmented Reality. The use of UAV's has proven beneficial also for bridge inspection but legislation on the use of UAV's and other robots (over/near the traffic) needs some adjustment with due attention towards the risks associated.

Life Cycle Costs studies are widely adopted within design of major new bridges as well as analysing

different maintenance strategies for existing bridges. Once environmental impacts are capitalized by the government, e.g. in a similar way as detour and waiting time for cars and trucks in done in Denmark, they will become need to know information also for the bridge society. For now we may use the triple bottom line accounting approach, i.e. prepare three different and separate bottom lines: profit (costs), people (social) and planet (environment), ref. (Elkington, 1997). These three bottom lines may be combined using multi-objective optimisation models in order to make a comparison of impacts.

In recent years, cognitive analytics and Internet of Things (IoT) has emerged in the health and financial sectors. We now also see that it has emerged into bridge management. Operated by people with a solid experience within operation and maintenance these new technologies has very interesting perspectives.

ABSTRACT: The United States Department of Transportation, Federal Highway Administration's Long-Term Bridge Performance (LTBP) Program is a 20-year minimum research program that will produce a comprehensive database on bridge condition and performance based on data collected from over 1,000 bridges assembled in 14 data collection clusters and 10 national highway corridors. The systematic research approach of the Program includes a development phase which provided guidance and tools for the operational or data collection phase. Key to the program is the LTBP Bridge Portal which is a web-enabled interface to the database being developed. To provide cost-effective and efficient data collection, the LTBP Program developed innovative data collection and analysis technologies; specifically the RABIT™ was an early product of the Program enabling bridge evaluation and research quality data collection while reducing time on the bridge. Data collected using RABIT™ and other nondestructive (NDE) test results are used to enhance bridge performance knowledge and to develop more accurate bridge element deterioration models. The LTBP Program will include a variety of research projects to address the influence of a multitude of factors on bridge performance such as vehicular live loads and other environmental factors. The products from this program will be data-driven tools, including predictive and forecasting models, which will enhance the abilities of bridge owners to optimize their management of bridges. Concrete bridge deck performance was identified as one of the key bridge performance issues in the LTBP Program. The overall objective of the LTBP Program is to inspect, evaluate, and periodically monitor representative samples of bridges nationwide to collect, document, maintain, and manage high-quality quantitative performance data over an extended period of time by taking advantage of sensing and nondestructive evaluation (NDE) tools and technologies such as impact echo (IE), ground penetrating radar (GPR), half-cell potential (HCP), ultrasonic surface waves (USW), and electrical resistivity (ER). This paper presents the condition change of a bridge deck in Virginia over a 6 year period. The assessment covered corrosive environment and corrosion processes, concrete degradation, and deck delamination. Deterioration progression from periodic NDE surveys is illustrated qualitatively by condition maps and quantitatively by condition assessment numbers. The results demonstrate the ability of NDE technologies to capture and quantify progression of deterioration. Strong agreement between different NDE technology results improves the confidence level of the condition assessment of the deck. The LTBP has the capability for establishing a direct relationship between data-driven condition measures in the form of NDE test results and bridge performance. The Program is striving to do this first for bridge decks and then will address steel and concrete superstructures, substructures and foundations. Along with detailed inspections and NDE tests, the program is assessing the influence of truck weights and overall bridge stiffness on bridge performance. While definitive conclusions will not be available for several years, preliminary benefits of the program include a web-based data storage application, hundreds of protocols for systematic data collection and testing, and systematic collection and cataloging of reference bridge plans, preservation actions, costs, and historical design standards. This program presents a unique opportunity to collaborate with other similar efforts to leverage other research that is focused on understanding how various factors influence bridge performance.

1 INRODUCTION

1.1 *Program Background*

The Long-Term Bridge Performance (LTBP) Program is a 20-year (minimum) research effort to collect scientific performance field data from a representative sample of bridges nationwide that will help the bridge community better understand bridge deterioration and performance. The products from this program will be a collection of data-driven tools, including predictive and forecasting models, which will enhance the abilities of bridge owners to optimize their management of bridges.

The program was created by legislation as the Safe, Accountable, Flexible, and Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) for surface transportation, and was enacted by the United States Congress in 2005.

Aging and deterioration of bridges in the United States (USA) mandates developing efficient strategies for bridge maintenance, rehabilitation, and repair. Bridge decks deteriorate faster than all other bridge components because of the routine application of deicing salts, repeated freeze-thaw cycles, direct application of traffic loading, and other damaging effects. Concrete bridge deck performance was identified as one of the key bridge performance issues in the FHWA's Long Term Bridge Performance (LTBP) Program (Brown, 2014). To improve the understanding of the mechanisms and timing of bridge deck deterioration because of the effects of age, material types, traffic loading, and climatic conditions, high quality performance data should be collected over an extended period of time, and condition assessment should be conducted periodically.

Given the large, diverse population of bridges throughout the USA, one of the most significant challenges to the LTBP Program was selecting representative bridges. The sampling challenge was mitigated by selecting “reference bridges” and representative clusters of bridges in the same vicinity of the “reference bridges” that have similar characteristics (age, type, climate, and maintenance practices). This selection helps compare the performance of concrete bridge decks of a similar type geographical area but, for instance, carry different traffic loads to ascertain the influence of traffic load on deck performance.

The common practices of State transportation departments for condition assessment and monitoring of concrete bridge decks have been visual inspection, sounding methods, and destructive methods. While visual inspection and sounding methods have their merits, they are limited when used for the early detection and characterization of defects. Similarly, while destructive testing usually provides reliable assessment of the structure, the time and effort needed make this type of test impractical. As a result, the need emerged for nondestructive evaluation (NDE) technologies that can qualitatively and quantitatively assess the condition of concrete decks. The qualitative nature of NDE data helps capture deterioration progression, and its quantitative nature assists in developing more reliable deterioration, predictive, and life cycle cost models. Since concrete decks are affected by various deterioration processes, multiple NDE technologies should be used for condition assessment. The commonly used NDE technologies to assess and monitor the condition of bridge decks include impact echo (IE), ground penetrating radar (GPR), half-cell potential (HCP), ultrasonic surface waves (USW), and electrical resistivity (ER). In addition to providing comprehensive information about the deck condition, combining the results of different NDE technologies increases the confidence level of detection.

1.2 *Vision*

The LTBP Program will serve as the national platform for strategic long-term investigation of in-service bridge performance.

1.3 *Mission*

Foster improved bridge performance, health, stewardship, and management through the analysis of research-quality data collected over a minimum of 20-year period on a large representative sample of U.S. highway bridges. To achieve this, the Program is designed to:

- Improve knowledge of bridge performance.
- Advance research in deterioration and predictive models.
- Apply life-cycle cost analysis effectively.
- Improve inspection/condition information through nondestructive evaluation (NDE) and structural health monitoring (SHM).
- Further the advancement of technology used for the assessment of critical but hidden bridge elements and components.
- Support development of improved bridge design methods and maintenance/preservation practices.
- Quantify the effectiveness of various maintenance, repair, and rehabilitation strategies.
- Improve the operational performance of bridges with the potential to reduce congestion, delay, and accidents.
- Promote the next generation of bridge management systems.

1.4 *The Meaning of Bridge Performance*

One simple definition of performance is that performance equates to accomplishment of a specified purpose or set of purposes. For the purposes of the LTBP Program, the following definition is used: Bridge performance encompasses how bridges function and behave under the complex and interrelated factors they are subjected to day in and day out—traffic volumes, loads, deicing chemicals, freeze-thaw cycles, rains, or high winds. Bridge design, construction, materials, age, and maintenance history also play roles in performance. Performance is usually associated with some set of standards, whether absolute or relative, and performance can be measured against those standards. In baseball, for example, one purpose of a batter is to hit safely, and a measure of the batter's performance is the batting average—the number of hits divided by the number of at-bats. A batter hitting over 0.300 is considered to be performing very well.

The purpose of a bridge is inherent in the NBIS definition: to carry vehicular traffic or other moving loads over a depression or obstruction such as water, highway, or railroad.

Transportation users expect a given bridge to accomplish its purpose in a satisfactory manner as measured against several objectives. Bridges should do the following:

- Present a minimal safety hazard to users during normal service.
- Present minimal obstruction to the free flow of traffic at all times.
- Have a minimal negative impact on the local and global environments.
- Present an acceptable level of risk against catastrophic failure.
- Present an aesthetically pleasing appearance.
- Accomplish all of the preceding elements with minimal life-cycle costs.

As a performance indicator for a baseball batter, batting average is a simple index with a range of 0.000–1.000. The batting average is a useful measure, but it does not reflect the value of the batter to the baseball team in a complete manner. Other related factors are also important, including hits with runners in scoring position; number of bases reached via singles, doubles, triples, and home runs; percentage of times reaching base safely; or even the outcome of at-bats in which the batter does not hit safely. In the same manner, the overall performance of a bridge cannot be described by any one rating, index value, or other individual parameter.

The differences in batters' levels of performance are analogous to the differences in bridges' levels of performance. Imagine bridge A is located in an arid (dry, no-freeze) climate and bridge B is located in a northern (wet, freeze) climate. The bridges are steel multi-girder simple span bridges that were built in the same year. The girders on bridge A are rated 8 on the NBI scale, nearly new condition. The girders on bridge B are rated 4, for poor condition with advanced section loss and deterioration. In comparing the relative performance of each bridge, factors such as annual snowfall, amount of deicing salts applied, and condition of the joints must be considered. Also of importance are the type and frequency of preservation treatments applied to the bridge (e.g., sealing joints, washing the superstructure, etc.). Continuing the analogy, baseball factors such as hits with runners in scoring position could be the equivalent of traffic and heavy trucks carried on the bridges.

There are many different ways to measure bridge performance. Some of these measures are in the form of an index value calculated from a defined formula using input data such as NBI condition ratings and traffic volumes. Numerical indices such as the Federal Sufficiency Rating (SR), California Bridge Health Index and Finnish National Road Administration (Finnra) Repair Index have been used for quite some time to define bridge performance. (FHWA, 2005, Sheppard & Johnson, 1999) For example, SR is an index calculated from an established formula and has a range of 100 (representing an entirely sufficient bridge) to 0 (representing an entirely insufficient or deficient bridge). An SR value of less than 50 indicates a low level of performance but does not reveal the specific characteristics of the bridge that render it deficient.

Other measures are based on whether or not a bridge meets some defined criteria. These include classification as Structurally Deficient (SD) or Functionally Obsolete (FO) and whether a bridge meets or exceeds defined deflection limits. Still other measures reflect a level of operational capacity or service, including posted load, load rating, rideability of the bridge wearing surface, traffic congestion near or on the bridge, number of accidents on the bridge, and percentage of rain events and floods that overtop the bridge. Most of these measures can be applied to an individual bridge or to a population of bridges, such as bridges on the NHS or bridges of a certain type and material.

Each measure has value depending on the person using the measures and the purpose for using it. For example, commercial interests, shippers, and drivers can use simple measures of posted weight limits or geometrical dimension limitations to weigh performance in terms of durability, operational capacity, and roadway safety, all important factors in supporting a free flow of goods and services. These measures do

not readily support a better understanding of bridge performance because it is difficult to correlate changes in these measures with underlying causes of changes in performance. Additional work is needed to better understand and develop solutions to improve bridge performance.

Experience has shown that the performance of any specific bridge is dependent on complex interactions of multiple factors, many of which are closely linked, including the following:

- The original design parameters and specifications such as bridge type, materials of construction, geometry, and load capacity.
- The initial quality of materials and of the as-built construction.
- The varying environmental conditions of climate, air quality, and surrounding soil.
- The extent and severity of corrosion or other deterioration processes that affect component strength or structural behavior (e.g., bearings locked up due to corrosion products).
- The traffic volumes and frequency and the weight of truck traffic carried by the structure.
- The type, timing, and effectiveness of preventive maintenance, minor and major rehabilitation actions, and ultimately, replacement actions.

All of these factors combine to affect the condition and operational capacities of the bridge and its structural elements at any given point in the life of the bridge. While simple measures such as those described in this chapter are currently used to evaluate overall performance, a better performance measure would be an indicator of the qualitative or quantitative impact of a parameter or set of parameters on some specific aspect of bridge performance.

Because bridge performance is a complex issue, it is useful to organize the primary issues relating to bridge performance into general categories. As shown in Figure 1, the primary issues in bridge performance can be divided into four general categories: structural condition (for durability and serviceability), functionality (safety and traffic capacity), structural integrity and risk (for safety and stability), and costs to the user and to the agency.

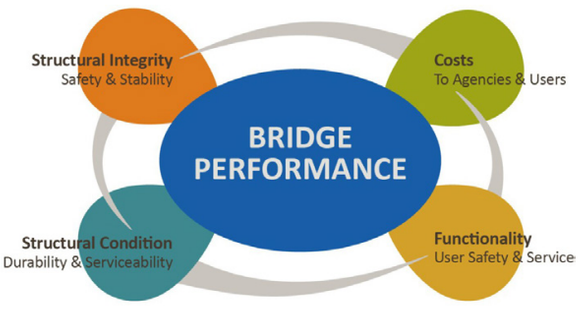

Figure 1. Main Categories of Bridge Performance Issues

Many relevant factors combine to affect performance under each of these four main categories. The LTBP Program will focus on the relevant factors related to structural condition listed in Table 1. Within this category are many specific performance issues that could be studied over the long term to achieve better understanding. For each of these specific performance issues, there are multiple data items that may be gathered to evaluate performance.

Table 1. Performance Issues for Structural Condition

Category	Important Data or Factor
Structural condition—durability and serviceability	Structure type
	Structural materials and specifications
	Structure age
	As-built material qualities/conditions
	As-built const. qualities/conditions
	Truck loads and other live loads
	Environment—climate, air quality, and marine atmosphere
	Snow and ice removal operations
	Type, timing, and effectiveness of preventive maintenance
	Type, timing, and effectiveness of maintenance and rehabilitation
	Flooding, hydraulic design, and scour
	Subsurface soils and settlement

2 SYSTEMATIC APPROACH

2.1 *Designing the Experiment*

The work included in this step provides the detailed framework for each experimental study that will address one of the high-priority bridge performance issues. The thought process behind each study also provides input into the final stage of step 2 (adopting and developing specific data protocols for each of the chosen data collection methodologies). Once each specific study is designed, the final approach to data collection on the critical parameters can be revised as necessary. The revision might mean eliminating or adding parameters to fine-tune the data collection protocols and/or modify the testing frequencies.

A well-designed experimental program is the key to collecting data that will support a better understanding of bridge performance. The design begins with postulating the critical questions about what governs the performance issue being studied. For example, when considering bridge decks that are untreated (that

is, have not been overlaid with a wearing course or treated with a sealing compound), critical questions might include the following:

1. What is the current condition of the deck concrete?
2. What is its permeability?
3. What is the rate of deicer application on the deck?
4. What is the existing chloride profile in the deck?
5. What is the rate of corrosion, if any, on the reinforcing steel?
6. What are the annual climate fluctuations in the vicinity of the bridge?
7. What is the truck load history that this deck has been exposed to?

In addition to current values, how will the value of these parameters or measurements change over time? A proper experimental study can be developed only after such questions are addressed.

Each experimental study will be developed to assess the relationships of one or more of these critical issues to some aspect of the performance of the deck. For example, studying annual climate fluctuations might elicit data that suggest a significant relationship between freeze-thaw cycles and a measured level of scaling of the surface of a concrete deck.

Each study's parameters will include types of testing to be done and the instrumentation and sensors to be deployed. For example, answering the question about the condition of concrete decks might require a field survey of a deck using the conventional chain drag method (chain dragged across deteriorated concrete makes a hollow sound) or mapping cracks visible on the surface or taking advantage of technology such as ground penetrating radar (high-frequency electromagnetic waves detect cracks, voids, and delamination).

The LTBP researchers also will develop data collection protocols, such as standard test methods, frequency of testing, and duration of the study. Finally, the researchers will select a representative sample of bridges for the study.

2.2 *Pilot Study*

The LTBP Program adopted a systematic approach including a developmental phase and an operational phase. A pilot study in the developmental phase was a key part of implementing Federal Highway Administration's (FHWA) Long-Term Bridge Performance (LTBP) Program. This study involved the detailed inspection and testing of bridges representative of the most common superstructure types, physical bridge layouts, and environmental conditions likely to be considered within the program. The seven bridges selected for the pilot phase are located in California, Florida, Minnesota, New Jersey, New York, Utah, and Virginia (Fig. 2). These different bridges provided a platform for the LTBP Program research team to test data collection protocols in a variety of settings that may pose technical or logistical challenges, such as the presence of an overlay on the deck, high traffic volumes on and/or under the bridge, or a waterway under the bridge.

Figure 2. Seven Bridge Pilot Program

2.3 *Development Phase*

The backbone of the LTBP Program is a data management system. The LTBP Bridge Portal, currently available via FHWA's website and continually undergoing enhancement serves as the data management system for the Program (Fig. 3). The portal currently includes readily available data sources such as historical National Bridge Inventory (NBI) data, augmented with National Bridge Element (NBE) level data as it becomes available, as well as data collected from field efforts, legacy data mining, weather data, as well as cost and maintenance data as these become available. The LTBP Bridge Portal provides visualization of data through a Geographic Information System (GIS) interface with robust searching and filtering capabilities as well as tools for data analytics. Eventually the portal will incorporate data-driven tools for the analysis of both raw data and processed data developed throughout the program's duration.

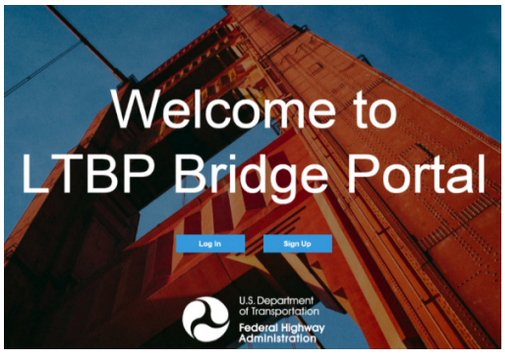

Figure 3. Bridge Portal

Following the pilot study, a legacy data mining data collection approach was developed. Legacy data mining is the collection of bridge documentation (design plans, specifications, standards, and more) and extraction of data and information that is relevant to the determination of bridge performance and condition. The bridges in this sample were selected to provide context, assess variability, and ensure that the bridges selected for field data collection are representative.

Legacy data mining is nationwide, covers 965 bridges, with 445 bridges complete with statistical analysis. For each bridge between 684 to 707 data elements are collected depending on the type of bridge. These data elements are statistically analyzed leading to the selection of bridges for field data collection in the operational phase of the program.

The developmental phase is complete and produced the following:

- LTBP Bridge Performance Primer Report (FHWA-HRT-13-051, LTBP Bridge Performance Primer).
- High Priority issues were identified with input from State transportation departments include untreated and treated decks, bearings, joints, prestressing steel strands, and steel beam coatings.
- Legacy data mining initiated using existing data sources.
- Bridge portal developed and FHWA LTBP Program External SharePoint site established.
- 51 data collection protocols published and distributed to LTBP Program contractors and State Coordinators for use and dissemination. (FHWA-HRT-16-007, Long-Term Bridge Performance (LTBP) Program Protocols, Version 1).
- 170 additional data collection protocols in development and under peer review.
- Strategic and Operational Research Matrices were developed.

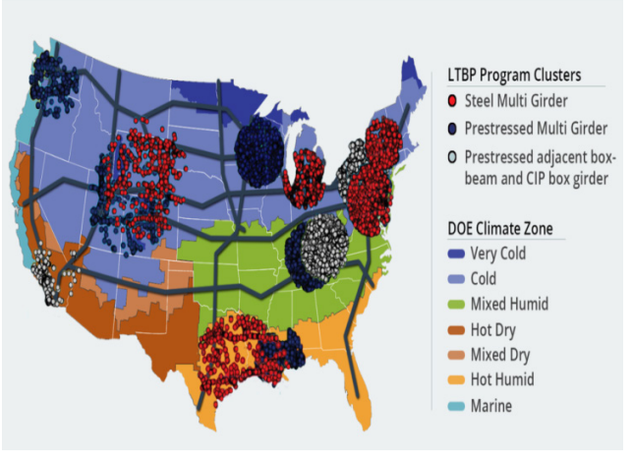

Figure 4. LTBP Program

2.3 *Operational Phase*

The operational phase of the program is on-going and will be ramping up in the near future. A structured approach has been established that groups bridges of similar characteristics (design and environmental exposure) into 14 clusters and nine corridors (Fig. 4). Cluster bridges are selected to allow the investigation of various inputs and attribute influences on pe rformance.

Bridge performance is measured (data collection) and tracked through targeted use of technology and enhanced visual inspection procedures.

Three rounds of data have been collected on 24 Mid-Atlantic cluster bridges with data collected in 2013, 2015 and 2017. Data collection, guided by the data collection protocols, has been achieved through visual inspection, material testing, nondestructive evaluation technology, and modal testing.

It is evident from the data collection effort that development and implementation of new technologies is warranted to achieve the required data quality on a cost-effective basis. Maintaining data quality over time requires that the data collection effort is reliable and repeatable, while minimizing disruption to travelers caused by traffic control while providing safety to the public and to the data collection teams.

To achieve the quality of data needed and to reduce cost and disruption to traffic, the LTBP program is developing new technologies. To date, a Robotic Assisted Bridge Assessment Tool or RABIT™ has been developed. This technology, first developed as a prototype (Fig. 5) has demonstrated its effectiveness in providing multiple NDE technologies mounted on a single platform to assess the condition of bridge decks.

Figure 5. RABIT™ Prototype

Based on the performance of the prototype version of RABIT™, the program has invested in the development of four additional RABIT™s that improve on the prototype design with more reliable performance and improved software. This technology assesses bridge condition while the bridge remains open to traffic using lane closures only. Prior NDE data collection efforts would require complete bridge closure.

Currently, the Program is evaluating a modal testing technology (Fig. 6) that produces calibrated finite element models and analysis of modal performance of bridges. This technology allows for the identification and quantification of load distribution on a bridge through finite element analysis. The testing of a bridge span is performed in approximately 30 minutes and like RABIT™ required only lane closures. Traditional modal testing procedures require closures and over 8 hours of data collection setup, collection and tear down.

Figure 6. Automated Modal Testing

2.4 *Deterioration Modeling*

Initial deterioration model development has employed three sets of deck condition data collected on the Virginia Pilot Bridge using manual NDE technique and RABIT™. 2-D contour maps of deck condition determined using Impact Echo, Electro-Resistivity, and other NDE technologies have been instrumental in the development of an initial bridge deck deterioration model.

The modeling effort is now expanding to utilize bridge element condition data provided by the Oregon Department of Transportation from 2009 to today, complementing the research conducted on the Virginia Pilot Bridge. California, New Jersey, New Hampshire, and Massachusetts Departments of Transportation are also providing bridge element condition data for deterioration model development. Exponential- and Weibull-based deterioration curves are being tested with variables for average daily truck traffic (ADTT), structure age, skew, deck structure type, deck protection and others to determine deck condition today, matching field data collection and projecting into the future.

2.5 *The Influence of Vehicular Live Loads on Bridge Performance*

A pooled fund study of the influence of vehicular live loads on bridge performance is underway and combines resources from seven states with LTBP program funds with the goals to:

- Develop a National Bridge Traffic Database
- Determine and quantify influence of trucks on bridge component performance

There are two fundamental questions that the research program is addressing:

- What are the current truck loads on our nation's bridges?
- What are the impacts of increased truck loads on the durability of the nation's bridges?

There have been changes in truck geometry, axle configurations, suspension, and tire characteristics. Common loaded truck weights are stipulated to have increased in some cases from 32,660 kg (72 kips) (design truck) to more than 49,900 kg (110 kips). (FHWA, 2016)

The research study is beginning by instrumenting a bridge in Oregon to evaluate both bridge response to environment (primarily temperature) and to truck live load. The instrumentation system is collecting data on bridge response for every foot of travel by a truck over the bridge requiring data to be collected at 150 Hz. A weigh-in-motion system is being placed 200 ft. upstream of the bridge with a video camera to capture single and multi-presence of trucks and individual truck gross vehicle weight, axle weight and axle spacing.

By knowing both environmental response and live load response, researchers will be able to identify which bridge elements are especially affected by truck loads.

By answering these two questions, bridge deterioration models attributed to truck loads are being developed to assist bridge owners in developing bridge maintenance, preservation, and rehabilitation strategies.

2.6 *Collaboration and Outreach*

Critical to the success of the Program is the partnerships and collaboration that occurs between State Departments of Transportation, researchers and academia (universities and the Transportation Research Board) and industry. Collaboration occurs through a variety of methods inclusive of in-person and virtual meetings of the State Coordinators and Special Activities Committee of the Transportation Research Board (TRB) to provide technical guidance to the Program, the TRB Long-Term Infrastructure Performance Committee to provide programmatic guidance to the Program and through Technical Advisory Committees and Expert Panels that address specific technical program content at a grass roots level. Attendance and presentation of progress by FHWA representatives at technical committee meetings of the American Association of State Highway and Transportation Officials (AASHTO) provide a forum for industry collaboration and guidance.

Each of these collaborative initiatives keeps the Program focused on its vision, goals, and objectives and assures that the products of the research program are relevant to the needs of bridge owners.

3 DATA DRIVEN, REPEATABLE CONDITION ASSESSMENT USING NON-DESTRUCTIVE EVALUATIOM (NDE)

3.1 *Example Data Collection Effort for Bridge Decks*

This section of the paper demonstrates the ability of NDE technologies to monitor deck performance and capture deterioration progression with time.

3.2 *Description of the Bridge*

This study was performed on a bridge carrying southbound U.S. Route 15 over Interstate 66 (I-66) in Haymarket, Virginia. The bridge (structure number 14178) is 84.1 m (276 ft.) long and 12.8 m (42 ft.) wide and was built in 1979. The bridge is a two-span, six-girder steel built-up superstructure (Figure 6) with a bare, cast-in-place 200 mm (8 in.) thick reinforced concrete deck constructed with removable forms. The southbound carries two lanes of traffic.

The deck condition (including corrosion, deterioration, delamination, and concrete degradation condition maps) of the deck has been monitored four times since 2009, most recently in May 2015 (in years 2009, 2011, 2014 and 2015). The NDE results from the periodic surveys will be used to better understand deck performance and monitor deck deterioration progression with time.

Figure 7. (top) Side view of the bridge and (bottom) the deck surface of the southbound U.S. Route 15 bridge, Haymarket, VA.

All the NDE measurements were collected on a 0.6 m by 0.6 m (2 ft. by 2 ft.) grid, except for the GPR surveys which were conducted in the longitudinal direction of the bridge with survey lines 0.6 m (2 ft.) apart. It took two 5-hour (total 10 hours) lane closures to survey the deck. In other words, considering that the surveyed deck area was about1020 m^2 (11000 ft^2), the surveys were conducted at production rates of about 102 m^2 (1100 ft^2) per hour. A section of the deck surface with clearly visible patches and spalling is shown in Figure 7.

3.3 *NDE Technologies Description and Results*

3.3.1 *Electrical Resistivity (ER)*

The electrical resistivity of concrete decreases as the moisture and chloride concentration increases (Whiting & Nagi, 2003). It has been observed that a resistivity of less than 5 kOhm-cm supports very rapid rebar corrosion (Brown, 1980). A four-point Wenner probe is used for resistivity measurements (Fig. 8).

The assessment of the corrosion progression is illustrated in Figure 9. The ER maps in Figure 9 describe concrete resistivity in kOhm-cm. The threshold for corrosive environment was identified to be 30 kOhm-cm based on correlations with other NDE methods. It can be clearly observed qualitatively that ER captured corrosion progression during the 6 year period. Expansion of corrosion affected areas and increase of severity of corrosive environment in 2015 occurs in the same areas identified as corrosive in 2009.

Figure 8. Electrical resistivity survey

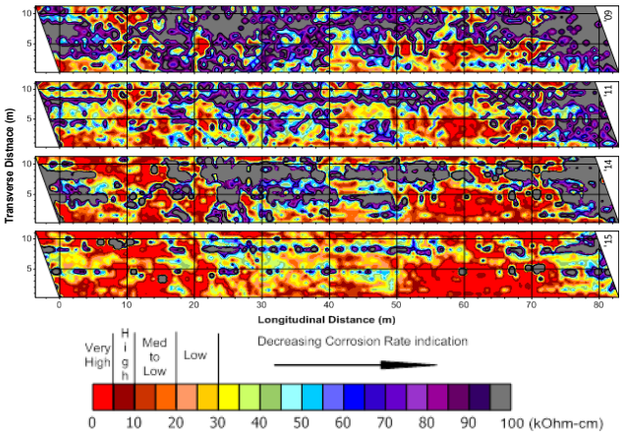

Figure 9. Corrosion assessment maps from ER surveys conducted on the bridge deck from 2009 (top) to 2015 (bottom).

Since the data obtained from NDE technologies are quantitative, they can be used to assess the condition of decks quantitatively and compute a condition assessment number. The condition assessment number combines the effect of the extent and severity of deterioration obtained from the NDE surveys. The NDE measurements and the calculated condition assessment numbers, which vary from 100 for the best condition to 0 for the worst, could be entered to the bridge management systems to assist bridge owners in data-driven decision making regarding maintenance, rehabilitation, or replacement of the deck. The condition assessment number of each type of defect is calculated as a weighted average of percentages of the deck area, with different severity levels of that specific defect. The area described as sound is assigned a weight factor of 100, fair to poor grade is 50, and severe is a factor of 0.

The ER-based corrosion condition assessment numbers and the percentages of the decks areas are compared in Table 2 for the 2009 and 2015 ER surveys. The four corrosion states are defined by four electrical resistivity ranges: less than 10 kOhm-cm as high, 10 to 20 kOhm-cm as moderate, 20 to 30 kOhm-cm as low, and above 30 kOhm-cm as very low. The corrosion condition assessment number for the deck dropped from 86 to 41 in 6 years. The overall decrease in condition assessment numbers is well-reflected in the increase of deck area in different severity levels of corrosion. The majority of the deck area had very low corrosion rates in 2009, while the majority of the same had high to moderate corrosion rates in 2015.

Table 2. Corrosion Assessment from ER: Condition Assessment Number and Percentages of Deck Area.

		Distribution			
Bridge -Year	**Condition Assessment Number**	**Very Low (%)**	**Low (%)**	**Moderate (%)**	**High (%)**
2009	86.3	72	15	10	3
2015	40.9	22	17	17	44

3.1.2 *Ground Penetrating Radar (GPR)*

A qualitative assessment of the deck condition can be made using a GPR survey through measuring the attenuation of electromagnetic waves on the top rebar level (Barnes & Trottier, 2000). The amplitude of the reflection will be highest when the deck is in a good condition. Moisture, chloride ions, iron oxide, cracks, and air-filled delaminations alter dielectric properties and increase the attenuation of electromagnetic waves. Thus, zones of highly-attenuated signal in GPR attenuation maps indicate locations of likely concrete dete-

rioration, delamination, and/or corrosive environment. A GPR survey conducted using a 1.5 GHz ground coupled antenna is shown in Figure 10.

Figure 10. GPR survey using a 1.5 GHz ground coupled antenna.

GPR condition maps obtained from GPR surveys of the deck in 2009 to 2015 are shown and compared qualitatively in Figure 11. The GPR threshold levels of deterioration are specific to the bridge conditions and equipment used and were obtained from correlations with other NDE technologies. The correlations between the attenuation levels and condition grades are indicated in the figure. A serious condition is described for both bridges with attenuation level of below -20 dB. Similar to ER, GPR qualitatively captured deterioration progression in the deck during the 6 year period. The progression and level of deterioration correlate well with the corrosion progression captured during the ER surveys. The similarity can be attributed to the fact that both measurements are primarily affected by the same elements affecting the electrical conductivity and dielectric value of concrete: moisture, chlorides, salts, etc.

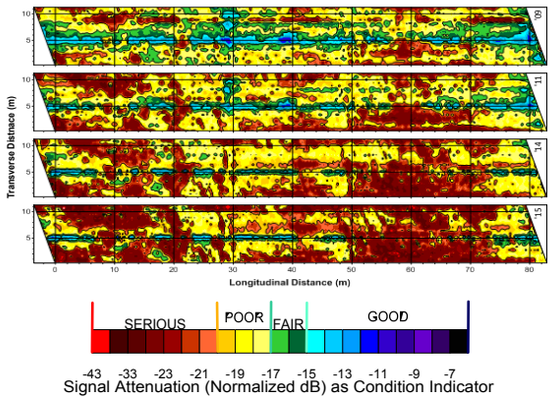

Figure 11 Deterioration condition maps from GPR survey on the bridge deck in 2009 (top) and 2015 (bottom).

To quantify deterioration progression, the condition assessment numbers along with the percentages of the decks areas at various severity levels of deterioration are compared in Table 3 for the 2009 and 2015 GPR surveys. The GPR condition assessment number for the deck dropped from 48 in 2009 to 22 in 2015. A large percentage of the deck area was in a poor condition in 2009, while most of the deck area is currently in a serious condition.

Table 3. GPR Assessment: Condition Assessment Number and Percentages of Deck Area

		Distribution			
Bridge-Year	Condition Assessment Number	Good (%)	Fair (%)	Poor (%)	Serious (%)
2009	48.1	14	24	41	21
2015	22.4	5	5	35	55

3.1.3 *Impact Echo (IE)*

IE has been successfully implemented in detecting and characterizing delamination in bridge decks (Sansalone, 1993).

IE measurements can be made by using a single IE probe, consisting of an impactor and a receiver (Fig. 12 (top)) or by using multiple IE probes (Fig. 12 (bottom)), each consisting of an impactor and a sensor.

The primary objective of IE testing is to locate reflectors (bottom of the deck or a delamination) in the deck. The extent and position of reflectors can be estimated by analyzing the frequency response of the waves reflected from the reflector.

Figure 12. Two types of IE testing systems: (top) an IE cane and (bottom) a stepper.

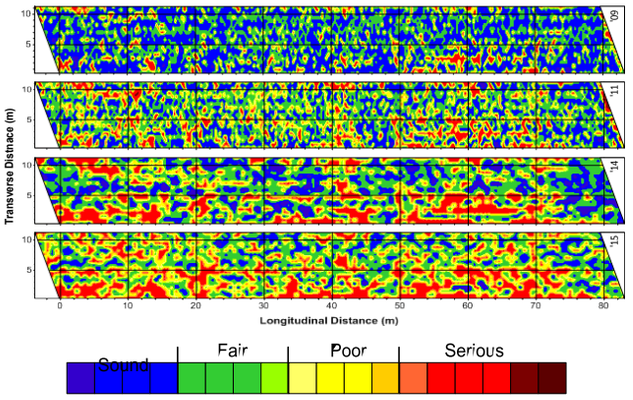

Figure 13. Delamination maps from IE surveys conducted on the bridge deck from 2009 (top) to 2015 (bottom).

The results from IE surveys on the deck are shown in Figure 13. The condition is described as good or sound when the depth of the reflector based on the measured response frequency matches the thickness of the deck. In the case of a delaminated deck, reflections of the compression wave occur at shallower depths, causing a shift in the response spectrum towards higher frequencies. Depending on the extent and continuity of the delamination, the partitioning of energy of waves being reflected from the bottom of the deck and delamination may vary. Initial delamination (fair condition) is described as occasional separations between the two deck zones. Thus it will have two distinct peaks corresponding to reflections from the bottom of the deck and the delamination. Progressed delamination (poor condition) is characterized by a single peak at a frequency corresponding to the depth of the delamination. Finally, in cases of wide or shallow delaminations, the dominant response of the deck to an impact is characterized by a low frequency response of flexural mode oscillations of the upper delaminated portion of the deck. This condition is graded as a serious condition and is always in the audible frequency range.

Figure 13 depicts the condition of the deck obtained from the IE surveys conducted from 2009 to 2015. The maps illustrate progression of delamination during the 6 year period.

Similar to the ER and GPR results, the condition assessment numbers from the 2009 and 2015 IE surveys, along with the percentages of the decks areas at various severity levels of delamination, are compared quantitatively in Table 4. The delamination condition assessment number for the deck dropped from 69 in 2009 to 40 in 2015. While a large percentage of the deck area was sound in 2009, the majority of the deck was extensively delaminated in 2015.

Table 4. Delamination Assessment from IE: Condition Assessment Number and Percent of Deck Area.

		Distribution			
Bridge-Year	Condition Assessment Number	Sound (%)	Fair (%)	Poor (%)	Serious (%)
2009	69.5	54	26	4	15
2015	39.9	21	31	7	41

3.1.4 *Ultrasonic Surface Waves (USW)*

Other deterioration processes may lead to expansive stresses (cracks) within the concrete and either reduce mechanical properties or alter dielectric properties. The USW method is effective for detecting and measuring changes in mechanical properties. Surface waves are stress waves traveling along the surface of the deck, with their body extending to the depth of approximately one wavelength (Nazarian, 1993). Therefore, as long as the USW testing is limited to the wavelengths comparable to the deck thickness, the surface wave velocity will be controlled by concrete properties (elastic modulus). Devices like the portable seismic property analyzer (PSPA), shown in Figure 14, can be used in the evaluation of concrete modulus by the USW method.

Figure 15 depicts the condition of the deck obtained from the USW surveys conducted in 2009 and 2015. The maps illustrate progression of delamination during the 6 year period. Table 5 compares the condition assessment numbers and percentages of USW results from 2009 and 2015.

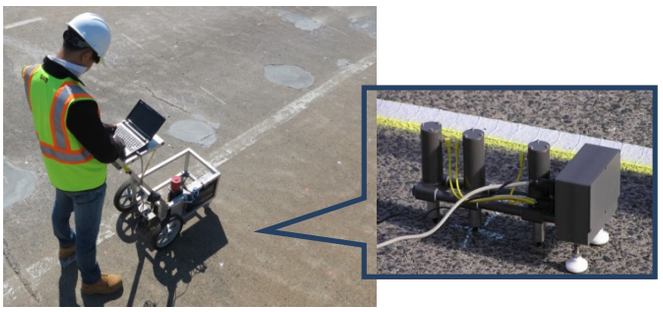

Figure 14 Surface wave testing using a PSPA.

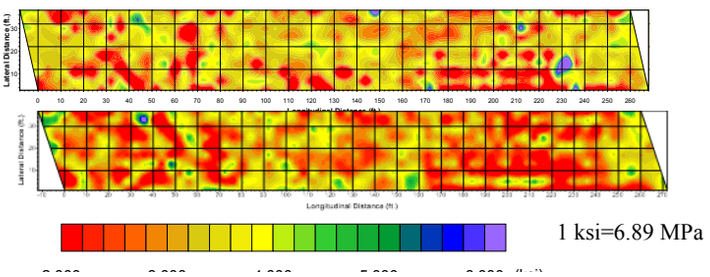

Figure 15 Concrete modulus maps from USW surveys conducted on the bridge deck in 2009 (top) and 2015 (bottom).

Table 5. Concrete Quality Assessment from USW: Average Modulus and Standard Deviation.

	Distribution				
Bridge-Year	**< 3,500 ksi (%)**	**3,500 – 4,500 ksi (%)**	**> 4,500 ksi (%)**	**Mean *E* (ksi)**	**STDEV (ksi)**
2009	66	29	5	3,286	705
2015	68	27	5	3,008	988

3.4 *NDE Summary*

The condition of the deck of the southbound U.S. Route 15 Bridge in Haymarket, Virginia was monitored over a period of 6 years to improve knowledge about the bridge deck performance and to better understand progression rates of different deterioration and defect types over an extended period of time.

Results of the surveys over a 6 year period show that NDE technologies have the ability to monitor deterioration progression with time, whether qualitatively through increase of deteriorated areas or quantitatively through changes in condition assessment numbers. Expanding deterioration and increasing severity of deterioration in 2015 occurs in the same areas as identified as deteriorated in 2009 in all NDE condition maps. The condition assessment numbers facilitate development of more objective and realistic deterioration and prediction models for the bridge deck.

The complementary use of multiple NDE technologies identifies corrosion as the primary cause of damage in the deck. The NDE results provide strong correlation between the ER and GPR condition maps, explained by similar electrical properties affecting the two. Additional correlations are established regarding delamination detection between GPR and IE, and USW and IE, and concrete degradation between USW and GPR. These correlations also point to corrosion as the primary cause of deterioration for these decks.

4 DETERIORATION MODELING

Since its initialization in 2008, the Federal Highway Administration (FHWA) Long-Term Bridge Performance (LTBP) Program has been collecting valuable quantitative data for bridges, such as visual inspection data, non-destructive evaluation (NDE) data and legacy data, etc. As the data continually grow in dimension, size and depth, the development of a scientific data analysis module to complement this unprecedented bridge research effort is critical. In this section a novel statistical approach, *LTBP Data-Driven Deterioration Modeling Method* (D^3M^2), is described for scientific analyses of LTBP data. It is comprehensible, flexible and accurate.

This section covers the following topics: A description of the challenges with the traditional approach for deterioration modeling; an introduction of the LTBP D^3M^2 and its strengths; questions and answers about the LTBP approach; a working example with electrical resistivity (ER) data is provided to demonstrate the application of the learning methodology; and a prototype is provided.

4.1 *Challenges Faced By Traditional Deterioration Modeling*

The traditional approach of deterioration modeling in the literature consists of two steps:

1) Select a model *functional form* (MFF). Select a model functional class (MFC), e.g. linear, hazard-based, Markovian, etc. Select a set of deterioration variables (e.g. traffic, age), and determine how they would be incorporated into the selected MFC (e.g. perhaps decide that traffic and age form an interactive factor, traffic age, aside from their individual impacts on deterioration). The variables are most commonly incorporated into the selected MFC through assigning variable coefficients, and the result is an MFF. Take the following formula for example:

$$P(7|7) = \frac{1}{1+\exp(\beta_0+\beta_{ADTT}\cdot ADTT+\beta_{AGE}\cdot AGE+\beta_{ADTT\&AGE}\cdot ADTT\cdot AGE)},$$

where P(7|7) is the probability of a bridge (element) having a condition rating of 7 in the next year given that in the current year it is 7; exp is the natural exponent; ADTT is average daily truck traffic; and the βs are coefficients to be estimated. The MFF in the Equation is of Markovian-logit class; and

2) Model estimation. Perform statistical estimation[1] on data and determine the means and variances of the coefficients. This might include MFF refinement, which investigates if some variables should be removed based on certain statistical criteria.

This approach, while prevalently used in the literature and practice, is rather restrictive in the following senses:

- By selecting an MFF, one inherently assumes that it describes data the best, or better than other candidates. It is only when a very poor fit is produced that the engineer would consider choosing a different MFF;
- This approach can potentially lead to compromised estimation accuracy. New selections of MFF are only initiated when the fits are very poor, while relatively poor fits may be considered acceptable.

[1] Parameter updating is considered to be a form of model estimation.

○ The approach has limited flexibility. A new selection means a new iteration of the entire process, with no memory of previous results. Furthermore, the integration of different opinions (e.g. different MFFs or coefficient values) is challenging since only one MFF can be selected each time, especially when the opinions are drastically different.

4.2 *The LTBP D3M2: How Does It Work?*

The LTBP data analysis module takes a different approach. Instead of selecting an MFF prior to data mining, it incorporates the learning of MFF into the analytical process. This improves deterioration modeling efficacy and allows incorporation and competition of different opinions.

Before further discussion, it is worthwhile pointing out the difference between two terms that will be used repeatedly throughout the rest of the whitepaper: MFF and *model*. An MFF consists only of structural denotations and its coefficients have no numerical values. (For example, Equation 1 is an MFF and the βs have no numerical values.) Once model estimation assigns its coefficients numerical values, an MFF becomes a model. Therefore, the distinction lies in whether the coefficients have numerical values (Fig. 16).

Figure 16. Distinction between "MFF" and "model"

The LTBP data analysis module consists of two steps (demonstrated from a hypothetical agency's point of view): (1) proposing candidate models and (2) Statistical Learning. A discussion of each step follows.

4.2.1 *Step 1: Proposing Candidate Models*

As an example, in developing potential models, first a particular agency decides that two MFFs, A and B, are desirable for its inventory, and proposes multiple candidate models (*not* MFFs). Experienced bridge practitioners within the agency propose models I, II and III, which are of MFF A, B and A, respectively. In the meantime, the agency also has close collaboration with academia and its research partners propose models IV, V and VI, of MFF B, A, B, respectively. Furthermore, it can also develop a model VII of MFF A solely based on data. The pool of candidates is summarized in Table 6.

Table 6. Summary of Candidate Models for the Hypothetical Agency

Source	Practitioner Experience			Research Community			Statistical Estimation
Model #	I	II	III	IV	V	VI	VII
MFF Category	A	B	A	B	A	B	A
Initial Weights	10 %	20 %	10 %	20 %	10 %	20 %	10%

By including both MFFs in the candidate pool, the LTBP data analysis module explicitly allows MFF to become a learning component; therefore, the restriction of a fixed MFF has been lifted and different opinions can be flexibly integrated. In fact, the module allows as many MFFs to be included as the agency desires.

It is worth noting that learning the impact of a certain deterioration variable also can be considered during the formation of the candidate pool. For example, if II and III differ in nothing but the coefficient of ADTT, the comparison between the two models essentially provides information on the impact of ADTT on deterioration.

The agency then proceeds to assign model-specific weights, as shown in Table 6. The weights are interpreted as prior probabilities of the models being the underlying truth. For example, model III has an initial weight of 10%, which means:

$$\Pr(\textit{model III is the true model}) = 10\%.$$

The weights offer the agency further flexibility in deterioration modeling, as it can choose how much it favors each model initially (and even adjust the weights in the process of learning). The relative magnitudes of the model weights provide information on the relative significances of the models, e.g. the agency considers model II to be twice as important as model III.

4.2.2 *Step 2: Statistical Learning*

Once the candidate pool is formed, the agency proceeds to learning, which uses to another novel feature of the LTBP D^3M^2: learning is not achieved through model estimation, but rather selection of one or more models from the candidate pool based on their fits to

data. The selection is done through updating the weights of the models. And intuitively, models that agree with data gain weights, while those that do not lose weights. The updating for probabilistic models is derived from conditional probability theories, as explained below.

- After each data collection, the agency evaluates the likelihood of observing the collected data under model i ($i \in \{I, II, III, \dots, VII\}$), which can be interpreted as how much data is agreeing with model i:

  $$likelihood(data|model\ i) = \Pr(observed\ data\ if\ model\ i\ was\ true);$$

- Then the joint probability that the collected data are observed and that model i is the true model is given by:

  $$\Pr(model\ i\ was\ the\ true\ model\ observed\ data) = \Pr^{old}(model\ i\ was\ the\ true\ model) * likelihood(data|model\ i)$$

- The probability of observing the collected data simply becomes:
  $\Pr(observed\ data) = \sum_{i=I}^{VII} \Pr(model\ i\ was\ the\ true\ model)$; and

- Finally, the new weight of model i given the collected data can be calculated as:

  $$\Pr^{new}(model\ i\ is\ the\ true\ model|data) = \frac{\Pr(model\ i\ was\ the\ true\ model\ \&\ observed\ data)}{\Pr(observed\ data)}.$$

It follows that the entire updating process is data-driven.

4.3 *The Strengths Of The LTBP D^3M^2 Method*

The strengths of the LTBP D^3M^2 are:

- Built-in MFF learning. Agencies can choose to include as many MFFs as they desire, even when they are drastically different, as long as they can be assessed in a common metric. Likelihood immediately emerges as a fit choice, since deterioration is most often described by probabilistic models due to its stochasticity arising from unaccounted variables, measurement errors, etc. The traditional approach does not allow learning of MFFs;
- Agencies ability to fully utilize their resources. Agencies have rich in-house practitioner experience and/or academic support. By including multiple models, they can maximize the utility of available resources. They also assign the initial model weights as they see fit and adjust them in future learning, offering them more flexibility;
- Flexibility in Accommodate Changes: Error-tolerant. With the LTBP D^3M^2, agencies can add or remove candidate models at any given time, to accommodate changes in bridge design, new/outdated materials, etc. and preserve learning results at the same time;
- Learning/fine-tuning the impacts of certain deterioration variables. By proposing proper candidate models, agencies can fine-tune the impact of a deterioration variable; and
- Guaranteed improvement in deterioration model accuracy. Liu and Madanat (2015) showed that the LTBP D^3M^2 is guaranteed to improve deterioration model accuracy through successive updating.

4.4 *Questions About The LTBP D^3M^2 Method*

Question: Can the LTBP D^3M^2 erroneously delete a model due to the randomness in data in its early phase?

Answer: No. If a model was deleted in the early phase of learning, the likelihood of it might have diminished significantly compared to those of the other models. Therefore deletion is statistically significant. Nonetheless, an agency can add back the model anytime if it has concerns about erroneous deletion, simply by giving the model a new weight α, and timing the other model weights by $1 - \alpha$.

Question: Can the LTBP D^3M^2 give predictions of bridge (element) condition ratings when it has numerous models?

Answer: Yes. The LTBP D^3M^2 can generate bridge element condition ratings by weighing the individual predictions of each model. This is because the model weights are essentially probabilities. Therefore agencies can use the LTBP D^3M^2 to predict deterioration.

Question: If none of the candidate models is the true model, how does the LTBP D^3M^2 arrive at the true model?

Answer: The LTBP D^3M^2 can provide the right direction to test new models. For example, if three models differ in nothing but the coefficient of ADTT, which are 0.1, 0.2, and 0.3 respectively. Suppose that learning assigns the most weight on the model with ADTT coefficient = 0.3, second on 0.2 and least on 0.1. It is an indication that the coefficient is bigger

than 0.3 and agencies can accordingly sample new models and keep improving model accuracy.

Question: How does the LTBP D^3M^2 take into consideration the maintenance history of a bridge when modeling its deterioration?

Answer: First, it is necessary to distinguish two concepts: *deterioration curve* and *deterioration history*. Deterioration curve depicts a mathematical relationship that describes how the condition of a bridge (e.g. NBI deck condition rating) naturally degrades with time by accounting for a set of explanatory variables. Hence, it is monotonically non-increasing and can be considered a (relatively) objective "fact" that does not alter with respect to the maintenance actions performed on the bridge. Deterioration history, on the other hand, is the trajectory of the condition of a bridge, considering *both* condition degradations due to natural deterioration and condition improvements due to maintenance actions. Graphically, one would observe jumps associated with maintenance actions and pieces of deterioration curves in between.

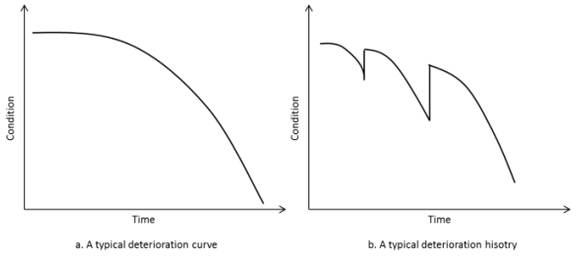

Figure 17: Comparison between a typical deterioration curve and a typical deterioration history

Therefore, the LTBP D^3M^2 is intended for the learning of deterioration curves. Deterioration histories are critical concepts in the discussions of life-cycle costs.

4.5 *A Working Example: Learning Deterioration Models With ER Data*

In this section, the LTBP D^3M^2 is demonstrated with ER data collected on the Virginia (VA) LTBP pilot bridge. (ER data represents a simple example of basis for modeling deterioration.)

4.5.1 *Proposing Candidate Models*

It is first assumed that the true deterioration model (representing nature) is:

$$ER^{t+1} = \frac{ER^t}{1+\exp(\alpha+\beta\cdot ADT+\varepsilon)}, \text{ with } \alpha = -5.5,$$

$$\beta = 0.0001 \text{ and } \varepsilon \sim N(0, \sigma = 0.5^2)$$

Therefore, deterioration modeling should: 1) identify the MFF; and 2) learn the values of α, β *and* σ. Our hypothetical agency, however, is not aware of either, and is choosing between two MFFS:

A) $ER^{t+1} = \frac{ER^t}{1+\exp(\alpha+\beta\cdot ADT+\varepsilon)}, \varepsilon \sim N(0, \sigma^2)$; and

B) $ER^{t+1} = 0.9 \cdot ER^t - 2 + \vartheta,\ \vartheta \sim N(0, \mu^2)$.

The candidate models that it accordingly proposes are:

	MFF A					MFF B
Source	Practitioner Experience		Research Community		Statistical Estimation	
α	-5.25	-5.25	-6.25	-6.25	-6.25	ϑ = 0.25
β	0.0001	0.0000	0.0001	0.0000	0.0001	
σ	0.5	0.5	0.4	0.4	0.5	
Weight	18%	18%	18%	18%	18%	10%
No.	1	2	3	4	5	6

Figure 18: Hypothetical agency's candidate models

It follows that the agency proposed five models of MFF A, and one model of MFF B. The *Weight* row sums up to 100%, with the heights of the boxes representing the magnitudes of the weights.

4.5.2 *Statistical Learning*

2009 ER data from the VA pilot bridge is used as the "seed" data for the initialization of the learning process, and all subsequent ER data is simulated according to the above Equation on a biannual basis. It is important to point out that *simulated data is strictly for demonstration purposes*; once field data are collected, they will be used for practical deterioration learning. The updated results for 2011 ER data (simulated from 2009 ER data) are in Figure 19.

It follows that model 6 is ruled out after one update, due to its inconsistency with the underlying truth. Its weight (10%) is accordingly distributed to all the other five candidate models, whose weights also changed according to how well they describe the simulated data. After 17 updates, the results are given in Figure 20.

No.	1	2	3	4	5	6
α	-5.25	-5.25	-6.25	-6.25	-6.25	ϑ=0.25
β	0.0001	0.0000	0.0001	0.0000	0.0001	
σ	0.5	0.5	0.4	0.4	0.5	
Weight +Δ	18%+8.35%	18%+0.94%	18%+2.44%	18% -2.53%	18%+0.77%	10%-10%

Figure 19: Updating results with 2011 simulated ER data

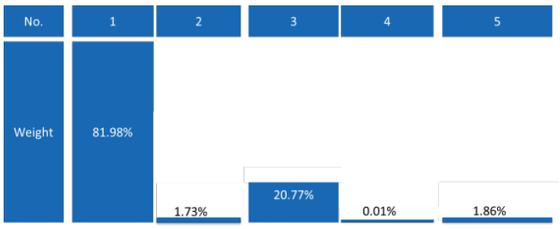

Figure 20: Learning results after 17 updates

After 17 updates, model weights are drastically different from their initial values. We can accordingly draw the following conclusions:

1) Model 6 is quickly ruled out in the updating process; therefore it is not a good candidate; and
2) Models 1 and 2 (or models 3 and 4) differ only in the coefficient for ADT. With model 1 taking significantly heavier weight than model 2, one can conclude that a coefficient of 0.0001 is more suitable to describe ADT's impact on deterioration than a coefficient of 0.0000 (which means traffic has no impact). Likewise for σ, 0.4 is possibly a more appropriate value than 0.5 by comparing the weights of models 3 and 5.

How does the LTBP D^3M^2 fit into the big picture? With the learning and prediction capabilities of the LTBP D^3M^2, an agency can generate parallel predictions for multiple indices, e.g. ER, half-cell potential (HCP), impact echo (IE), ground penetrating radar (GPR), etc. Therefore the agency can use predicted information to calculate a fused[2] condition index anytime without having to worry about loss of information, as illustrated in Figure 21.

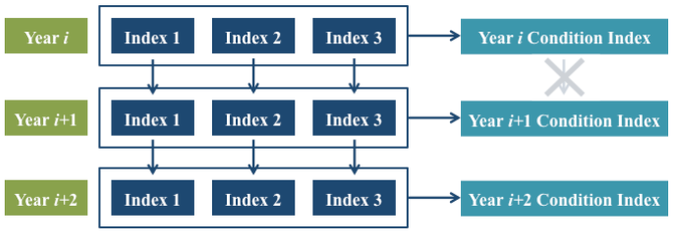

Figure 21: Closing the loop: using the LTBP D^3M^2 to do data prediction and fusion

When the agency feeds multiple indices in year i into a designed formula to generate year i's condition index, a fraction of information contained in {Index 1, Index 2, Index 3} will be inevitably lost. (An alternative interpretation is loss of definition). If it only uses year i's condition index to do prediction, the loss of information will propagate, and eventually predictions will be unacceptably inaccurate. In contrast, with the LTBP D^3M^2, the agency can generate predictions for individual indices, and just apply the fusing formula anytime that it needs a condition index.

4.6 *The Prototype Of The LTBP D^3M^2*

In Figure 22, a prototype web-based interface for the LTBP D^3M^2 is illustrated. The most noteworthy strength of the prototype is its simplicity. Instead of eliciting MFFS and numerical coefficients from practitioners, it allows them to visually examine if a deterioration model is matching their experience by simply looking at the graph on the right-hand side. It also offers the flexibility of inputting the user's own deterioration model(s) if preferred. Therefore, the LTBP D^3M^2 is not only a statistically sound and comprehensible data analysis module, but also has the potential to be developed into a useful, practical tool.

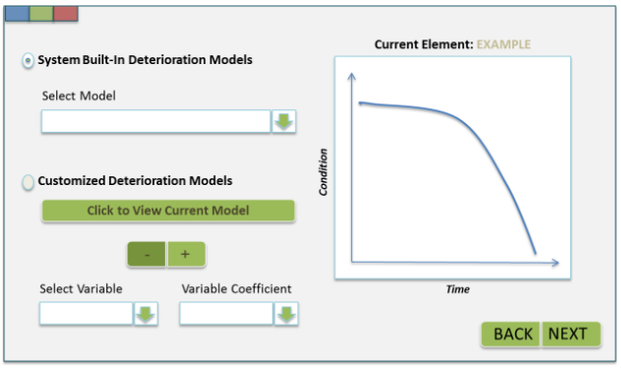

Figure 22: Prototype of the LTBP D^3M^2

5 PRELIMINARY RESULTS

5.1 *Data Collection Consistency*

The use of NDE as the primary measure of deterioration and performance has been shown to provide a consistent basis for modeling.

5.2 *Deterioration Modeling*

The results of three rounds of NDE data for bridge decks have been demonstrated to provide a useful basis for estimating deterioration rates. Additional testing is planned to assess the margin of increased reliability if more than three rounds are used. A LTBP Deterioration Modeling Learning tool has been developed to assure the most accurate model is fitted to the NDE data collected in the Program.

[2]Index fusing herein refers to process of integrating information contained in an array of indices to generate one index, or an index array of reduced dimensions.

5.3 *Sample Size and Reliability*

The use of reference bridges correlated to cluster bridges over a range of bridge types, climatic conditions, and truck traffic will provide a reliable basis for modeling condition and performance of bridge elements.

6 CONCLUSIONS

6.1 *Data-driven Bridge Performance Program*

One simple definition of *performance* is that performance equates to accomplishment of a specified purpose or set of purposes. For the purposes of the LTBP Program, the following definition is used: Bridge performance encompasses how bridges function and behave under the complex and interrelated factors they are subjected to day in and day out—traffic volumes, loads, deicing chemicals, freeze-thaw cycles, rains, or high winds. Bridge design, construction, materials, age, and maintenance history also play roles in performance. Virtually everyone in the United States, from bridge maintenance engineers to the everyday road user, has a stake in ensuring that the performance of bridges is good or excellent in terms of durability, operational capacity, roadway safety, resistance against failure, environmental neutrality, and life-cycle costs. Each group needs to have confidence in their understanding of the indicators by which they measure bridge performance. For the everyday commuter or casual user, an indicator such as Federal SR may suffice. For commercial interests, shippers, and drivers, a simple measure of bridges with posted weight limits or geometrical dimensions may suffice. These groups also need assurance that satisfactory bridge performance is being provided at reasonable costs, as reflected in gasoline taxes, tolls, other roadway fees, and other revenue sources devoted to maintaining performance.

Members of the bridge community such as designers, construction engineers, inspectors, maintenance engineers, and bridge management personnel who are responsible for maintaining performance must be able to properly and effectively evaluate bridge performance in more precise and targeted manners. They must break down bridge performance into very specific issues that can be adequately evaluated in terms of cause and effect. This will allow them to identify actions or programs that will ensure a high level of performance at a reasonable cost. This report describes a breakdown of bridge performance issues into four categories of performance: structural condition (for durability and serviceability), functionality (safety and traffic capacity), structural integrity (for safety and stability), and risk and costs to the user and to the agency. This breakdown helps isolate the most critical aspects of bridge performance and provides the basis for long-term research studies that will improve understanding of these issues.

Making a proper evaluation of bridge performance can be a formidable task given the many factors that can govern performance under different circumstances. The LTBP Program is being implemented to identify the most critical aspects of bridge performance and conduct studies that will result in the high-quality data necessary to better understand how multiple, variable factors govern those aspects of performance. This effort should ultimately lead to the ability to implement policies and actions for bridge programs that will improve performance and extend the life of bridges at minimum cost.

The LTBP has the capability for establishing a direct relationship between data-driven condition measures in the form of NDE test results and bridge performance. The Program is striving to do this first for bridge decks and then will address steel and concrete superstructures, substructures and foundations. Along with detailed inspections and NDE tests, the program is measuring truck weights and overall bridge stiffness to determine how those factors influence bridge performance. While definitive conclusions will not be available for several years, preliminary benefits of the program include a web-based data storage and retrieval application, hundreds of protocols for systematic data collection and testing, and systematic collection and cataloging of reference bridge plans, preservation actions, costs, and historical design standards.

This program is a unique opportunity to collaborate with other similar efforts to leverage other research that is focused on determination of factors that influence bridge performance.

Value of monitoring data for long-span bridge operation – Aerodynamic point of view

Ho-Kyung Kim, Sunjoong Kim, Sejin Kim & WoongHee Jung
Seoul National University, Seoul, Korea, Rep.

ABSTRACT: Wind-induced unexpected events for cable-supported bridges are introduced for the purpose of sharing authors' experiences regarding to data utilization for cause investigation, securing countermeasures, and design feedbacks. The events include two cases of vortex-induced vibration and one case of rollover accident of running vehicle over the bridge deck. The utilized data include the basic acceleration and wind speed data, but wind tunnel tests, data processing techniques, system identification with operational modal analysis (OMA), Measure-Correlate-Predict analysis, and Long Short-term Memory were applied to increase the value of data obtained. The results demonstrate that the damping identification from OMA is an essential issue as a serviceability performance index for flexible long-span bridge. Also, the vulnerability assessment procedure of running vehicle to strong side wind can be utilized for the effective traffic control by utilizing long-term and short-term wind speed data. By these way, examples of increasing the value of data for long-span bridge operation are demonstrated in an aerodynamic point of view.

1 INTRODUCTION

Structural health monitoring (SHM) systems are commonly used in most long-span bridges. Although a lot of data are being accumulated from various sensors, there are relatively few examples the monitored data are used directly in bridge operation judgement and decision-making process. In this study, the authors share their experiences of using the monitoring data in the process of identifying incidents, finding causes and countermeasures for long-span bridges in operation over the past years. The reviewed cases are the vortex induced vibration (VIV) observed in two cable-supported bridges, the estimation of the damping ratio through operational modal analysis in the cause identification procedure, and the rollover accidents during strong winds experienced in another bridge. Since all the cases were caused by wind, the wind speed data as well as the wind tunnel test results were used together. The data used were simple and basic ones such as the measured acceleration and wind speed data, but the data analysis techniques such as system identification, wind tunnel tests, and a deep learning algorithm were utilized to increase the value of data. By demonstrating the procedure, the authors would like to share their experiences and knowledges on the value of data by which one can assess and operate the flexible sea-crossing bridges with more confidence in aerodynamic point of view.

2 CONCEPTUAL APPROACH

In many cases, the expansion of knowledge begins with the observation of unexpected events. Events related to winds on bridges can include vibration of bridges or damage to facilities. Since the data acquired through the SHM system during specific events on the bridge is limited, it is common to carry out wind tunnel tests or computational fluid dynamics analysis for better understanding the phenomenon. At the same time, data processing techniques are utilized to mine useful information from data.

The approach to the VIV event begins with a review of the oscillating wind speed region, vibration mode and amplitude. This can be easily determined from the wind speed and acceleration response data of the SHM system. VIV is caused by vortex trails falling from the trailing or leading edges of the deck. Since VIV is prevented from the design stage through wind tunnel tests combined with deck shape adjustment, if the VIV is observed in the field, the wind tunnel test should be performed again to determine the cause. Note that VIV is a resonant phenomenon that occurs due to the tuning between the frequencies of deck motion and harmonic load from vortex trails, hence the amplitude varies depending on the modal damping ratio. Since the wind tunnel tests are per-

formed at the design stage following the assumed design damping ratio, the VIV amplitude can be larger than expected when the damping ratio of the actual bridge is below the design damping ratio. Therefore, it is necessary to evaluate the damping ratio after completion of the bridge for the modes for which VIV is potentially triggered.

Damping can be estimated from the operational modal analysis (OMA) by utilizing ambient vibration data, but it requires knowledges in setting the parameters for data processing and system identification. Because the basic assumptions of OMA are based on white noise excitation and stationary response, appropriate modulating is required when the measurement data shows nonstationarity. Through this process, it is possible to evaluate the damping ratio even to the higher-order modes with higher accuracy. This is a procedure to increase the value of the data provided.

Running vehicles can be exposed to strong horizontal winds for sea-crossing cable-supported bridges with decks installed at high altitudes to ensure sufficient space under the bridge. It is necessary to control vehicle passage over a specific wind speed according to the result of risk assessment to side wind, or to install windshields to secure vehicle safety. Even in this case, long-term wind speed data can be importantly utilized. The frequency data of wind speed according to wind direction is preferably obtained from the SHM system on the bridges. If these data are not sufficient in terms of duration, it may be necessary to convert long-term data obtained from nearby weather stations onto bridges. Since the wind velocity distribution for each lane cannot be obtained directly from the SHM system, it is necessary to secure more sophisticate data through the wind tunnel tests using the deck model. Using these data, it is possible to evaluate the vulnerability of the running vehicle by considering the specific wind condition of the bridge, and to take effective measures to control the traffic.

At least a few hours are necessary to implement an operational decision such as a bridge closure. Also, the time to re-open the bridge operation is also an issue to bridge operators as well as passengers. Therefore, the bridge operator needs a technique to predict the wind speed over the deck a few hours earlier. The prediction of wind speed by the Meteorological Agency is generally available for the typhoon events, but the prediction of wind speed over the deck, which is located in the boundary layer, is physically more complicated. In this case, if short-term wind speed prediction based on a deep learning algorithm becomes possible, it will increase the value of existing wind data for a more reliable decision-making.

The authors would like to introduce the case of increasing the value of the measurement data for each subsequent event and expanding the engineering knowledge therefrom.

3 EVENT 1: VORTEX-INDUCED VIBRATION OF A PARALLEL CABLE-STAYED BRIDGE

3.1 *Observed VIV*

The Jindo Bridge consists of two parallel-disposed cable-stayed bridges. Two similar decks are located with a net distance of 9.9m. While the unexpected VIV was observed at Bridge 2 which was located upstream, the wind velocity was maintained as 9.8-11.5 m/s for two hours (Seo et al. 2013). Since the VIV amplitude exceeded the allowable level, as shown in Figure 1, a series of wind tunnel tests and operational modal analysis were performed to identify the main causes of VIV.

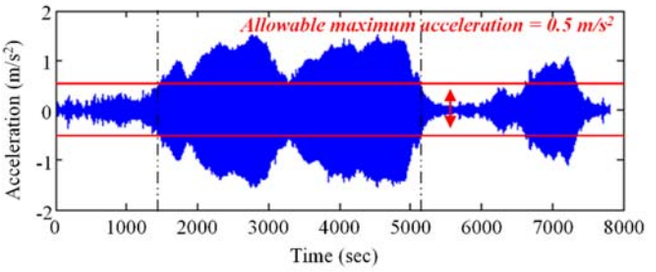

Figure 1. Vertical acceleration of the deck in Bridge 2 at the center of main span

3.2 *Cause investigation via wind tunnel test*

The main purpose of wind tunnel tests was to identify 1) the reason why VIV amplitude was amplified in tandem arrangement by applying a particle image velocimetry, and 2) the relationship between amplitude of VIV and damping ratio.

Figure 2 showed the VIV amplitude of single and parallel disposition together. The VIV in the upstream deck is clearly amplified due to the effect of downstream deck.

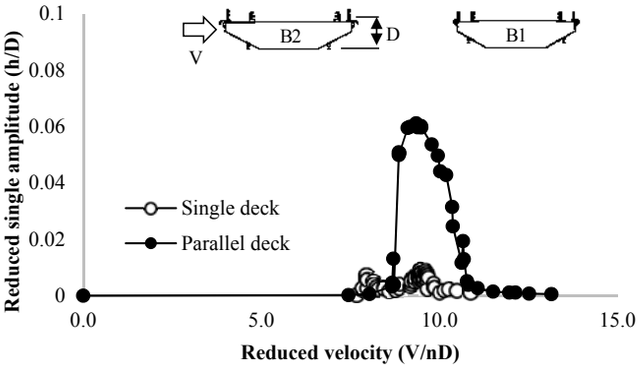

Figure 2. Amplitude of VIVs in both a single deck and parallel decks

Figure 3 shows the reason of amplitude amplification. In this phase-averaged flow streams between two decks at the lock-in wind velocity, the Karman-type vortex trails behind the upstream deck was magnified to motion-induced vortices, which induced interference VIV in upstream deck (Seo et al. 2013).

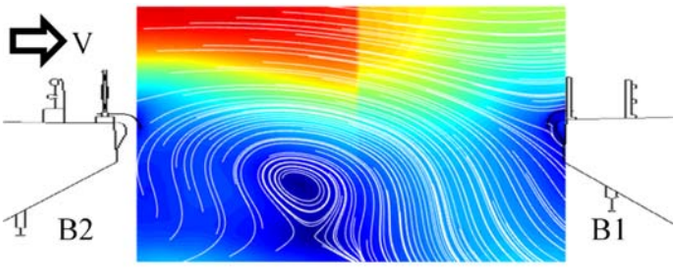

Figure 3. Phase-averaged flow streams at the phase of π/2

Since this phenomenon was not well reported to bridge engineers before, continuing investigations followed by variating the gap distance between two decks (Park et al. 2017). The effect of relative differences in the natural frequencies of two bridges was also investigated (Park & Kim 2017).

Figure 4 shows the relationship between the amplitude of VIV in upstream deck to the damping ratio in wind tunnel setup (Seo et al. 2013). It clearly shows the high sensitivity of VIV amplitude to damping ratio. Based on this graph and observed amplitude of 0.19m, a potential damping ratio of Bridge 2 can be approximated as 0.21%, which is much less than the design damping ratio of 0.40% recommended in design guidelines (KSCE, 2006).

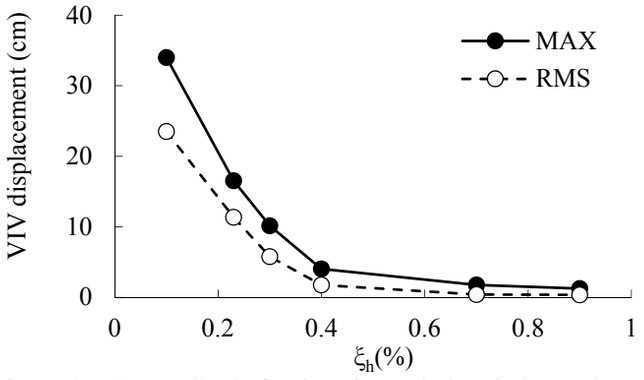

Figure 4. VIV amplitude for damping ratio in wind tunnel

3.3 *Damping identification via operational modal analysis*

Based on thorough wind tunnel tests, two main causes were indicated. The first cause was the amplification of VIV in upstream deck owing to the close parallel disposition between two decks, and the second one was unexpected low damping ratio of Bridge 2. The Natural Excitation Technique combined with Eigen Realization Algorithm (NExT-ERA) technique (Caicedo, 2004) was applied as an OMA to three-day acceleration data measured at the center of mid-span in both bridges (Kim et al. 2013). Figure 5(a) shows the identified damping ratios for each segmented 20-min data. A large scattering was observable, but the mean value of the damping ratio was 0.28%, which showed a somehow agreement with the predicted one in wind tunnel tests. However, the damping ratios for Bridge 1 was identified much higher than those for Bridge 2 by showing around 0.69%, as shown in Figure 5(b). In fact, the damping ratio is an inherent property of bridge and, even two similar bridges in terms of materials and overall shapes show a quite different level of damping ratio.

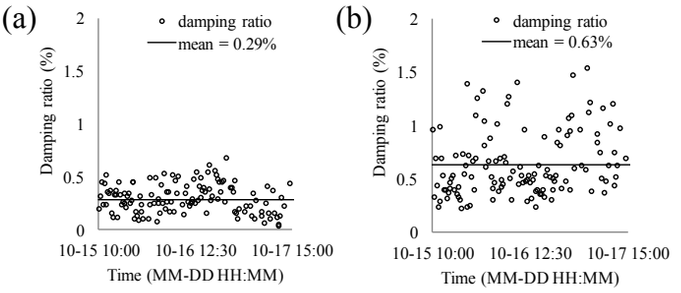

Figure 5. Estimated damping ratio of (a) Bridge 2 and (b) Bridge 1

3.4 *Automated parameter selection and signal stationarization process for NExT-ERA*

The automated proper parameter selection process for NExT-ERA was suggested to reduce the large error bound due to poor parameter selection and achieve similar level of correctness of heuristic parameter selection. To make suitable criteria for each algorithm parameter, a series of parametric studies using numerical simulation and operational monitoring data was performed, respectively. It was found that the number of FFT (NFFT) of 2^{15} with 60 min data provided the accurate estimation in terms of mean and coefficient of variance (COV). A size of Hankel matrix was determined corresponding to the shape of calculated impulse response function (IRF). To overcome the limitation of non-structural model-based algorithm, the sensitivity analysis was performed using each estimated value according to a system order. The median value of estimated damping ratios provided a converged value successfully. This automated parameter selection process accomplished more accurate damping estimation compared to the result of heuristic parameter selection (Kim et al., 2016).

When the number of traffic lane over the bridge is only one or two for one direction and the traffic volume is not high, the ambient vibration signal at the sensor position show an envelope as a vehicle is approaching and fading away. Since OMA assumes that the signal to be analyzed is a stationary white-noise process, the envelop-like signal obtained from running vehicles can also contribute the scattering in structural identification. Kim & Kim (2017) confirmed that the over/underestimated damping ratio due to nonstationarity in traffic-induced vibration can recovered and the uncertainty of the estimated damping ratios was reduced by applying the signal stationarization process based on amplitude-modulating (AM) function.

Figure 6 illustrates the estimate damping ratio according to parameter selection according to three

comparative approaches. Blue circles (denoted as 'Basic') indicated the primitively estimated damping ratios, and red circles (denoted as 'Proper parameter selection') meant the result after a proposed parameter selection procedure. An identified damping ratio with signal stationarization is referred to as 'P.P.S + Stationarization' or 'w/ stationarization'.

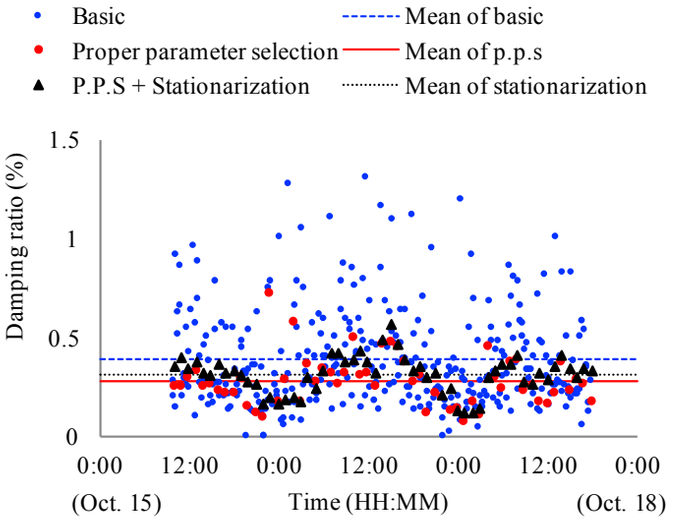

Figure 6. Estimated damping ratio of the Jindo Bridge corresponding to proper parameter selection

As can be seen, a large scattering in damping estimates due to the over/underestimated damping ratio was significantly reduced. By applying a proper parameter selection, a mean value of estimated damping ratios slightly decreases from 0.37% to 0.28%, while COV dramatically reduced from 69.44% to 43.29%, which was acceptable value compared to the COV of heuristic parameter selection. It is clear that the proposed proper parameter selection of NFFT, data length, size of Hankel matrix and system order was automated as well as effective to enhance the accuracy of damping estimation based on operational modal analysis (Kim et al. 2016). Furthermore, by applying the signal stationarization process, COV also reduced as a level of 31.84% from P.P.S of 43.29% while mean value was almost same with the case of P.P.S. This COV of combined case was slightly larger than the COV of stationarization case. In the consideration of the result of free vibration test of 0.33%, the case of stationarization gave more accurate identification in terms of bias and variance error.

3.5 *Environmental effect on the identified damping ratio*

The previous section shows the reduced uncertainty in OMA-based damping estimation by proper parameter selection with signal stationarization process. Nevertheless, the variation of damping ratio was still found with a large range of 0.1% to 0.6%. The reason for these variations should be further identified.

Interestingly, the change in estimated damping ratio shows a repeating pattern with a duration of 24 hours. The damping ratio started to increase in the morning and maintained a constant value until the evening. After that, it decreased and showed a relatively low value until dawn. This tendency was repeated for 3 days.

In order to assess the effect of environmental factors on the variation of damping ratio, correlation analysis was performed for root-mean-square (RMS) amplitude, the number of vehicle and temperature. While a RMS amplitude of acceleration was calculated from a monitoring data, the number of vehicle and temperature were not obtained from the SHM system. Therefore, instead of the number of traffic, the number of peaks in the measured acceleration was counted inevitably. Figure 7 showed that the number of local maxima was successfully counted from the measurement acceleration of the bridge. For the temperature of the bridge, the atmosphere temperature measured at an automatic weather station (AWS) at 10 km from the bridge was used for correlation analysis.

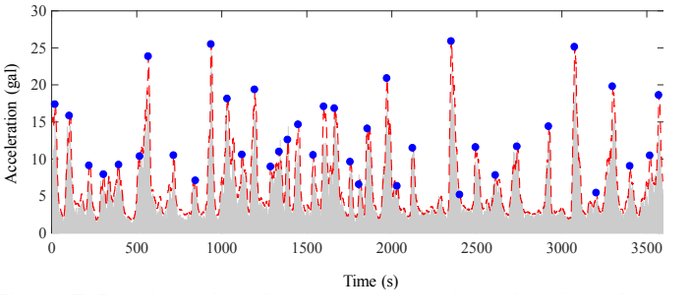

Figure 7. Local maxima from the measured acceleration of the Jindo Bridge

Since each unit is different, the normalized (average of 0 and standard deviation of 1) distribution of four parameters over 3 days was shown in Figure 8. It is clear that the trends of the four variables were much similar. The correlation analysis results for the damping ratio were shown in Table 1. As can be seen from Table 1, it can be confirmed that the variable with the highest correlation was the number of the vehicle while the tendency toward temperature was the lowest. Interestingly, unlike vehicle numbers, the RMS amplitude is not high. This is presumably due to the amplified response to the lock-in range.

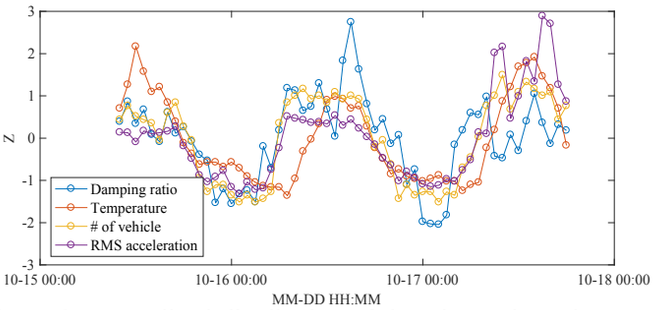

Figure 8. Normalized distribution of damping ratio and representative environmental factors according to time evolution (3 days)

Table 1. Correlation coefficient between identified damping ratios and environmental factor

	Damping ratio	RMS Acceleration	Number of vehicle	Temperature
Damping ratio	1.000	0.475	0.735	0.438
RMS acceleration		1.000	0.850	0.682
Number of vehicle			1.000	0.708
Temperature				1.000

In the lock-in range, the bridge was subjected to a vortex-shedding force, which amplified the vibration amplitude of the bridge deck. Figure 9(a) shows that the number of vehicle is identical for 3 days, but the RMS amplitude rapidly increased on October 17 when the corresponding mean wind speed was within the lock-in wind velocity. However, these VIVs seem not to contribute to damping identification in NExT-ERA. As shown in Figure 9(b), regardless of larger amplitude due to VIVs, identified damping ratios did not increase as much.

A correlation analysis between estimated damping ratio and environmental factors was re-performed without lock-in range data set. Table 2 also summarizes the correlation coefficients between identified damping ratios and environmental factor without lock-in range data set. Also, in this case, the factor that has the highest correlation with the damping ratio was the number of vehicles. Note that the correlation coefficient between damping ratio and RMS amplitude increased rapidly from 0.475 to 0.761. As a result, the coefficient between RMS acceleration and the number of vehicle was also enhanced from 0.850 to 0.968 which is almost 1.0.

3.6 *Discussions*

VIV observed in the upstream deck was induced by the magnified motion-induced vortex trails generated behind the deck due to the blockage effect by the downstream deck. Accordingly, the interactive VIV was identified to be sensitive to the open gap width between two decks.

Another issue of low damping ratio also attracted keen interest of engineers. The damping ratios for both bridges were identified from OMA for the field-monitored data. Even though both bridges were designed as a concept of twin bridges, the estimated damping ratios showed a wide difference. The damping ratio for the upstream bridge, subjected to interactive VIV, was estimated to be 0.28%, while that of the downstream bridge was more than 0.6%.

Since the design damping ratio of the steel cable-supported bridge was set to 0.4% in a design guideline, the estimated damping ratio was much lower than expected. Therefore, if necessary, the level of design damping ratio can be lowered to accommodate a potential possibility of low damping ratios of flexible structures, which adopt higher-strength materials and simpler connections.

Accordingly, it is recommended for bridge owners to secure initial damping ratios for dominant modes and to confirm the validity of wind-resistance design in terms of design damping ratios. The proposed parameter selection process allows to automate damping estimation process from operational monitoring data, so that it can lead to obtain a reliable damping estimation in real time without the controlled experiment or engineering judgements.

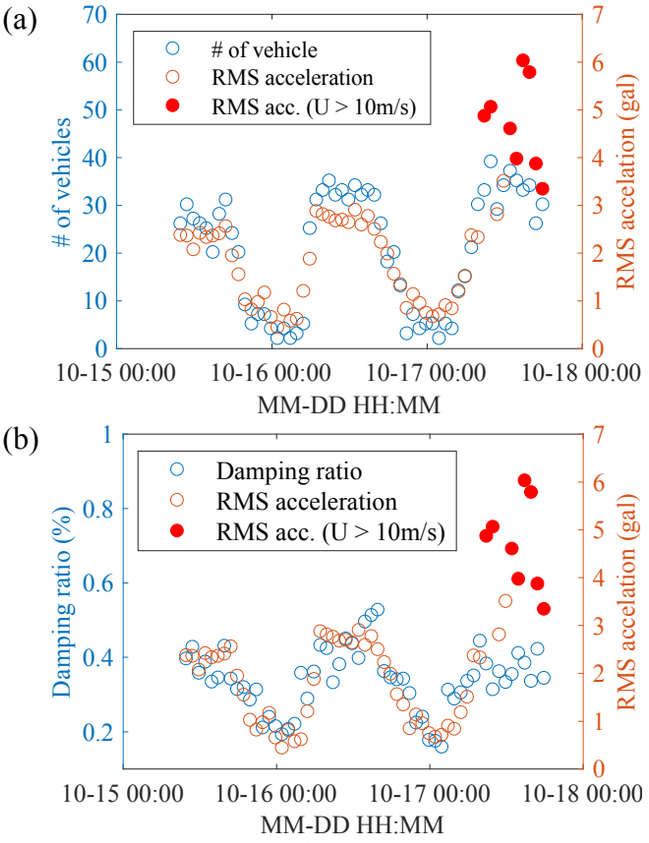

Figure 9. The distribution of RMS acceleration with (a) corresponding the number of vehicle and (b) identified damping ratios

Table 2. Correlation coefficient between identified damping ratios and environmental factor without lock-in range data set

	Damping ratio	RMS Acceleration	Number of vehicle	Temperature
Damping ratio	1.000	0.761	0.805	0.447
RMS acceleration		1.000	0.968	0.674
Number of vehicle			1.000	0.663
Temperature				1.000

4 EVENT 2: VORTEX-INDUCED VIBRATION OF THE YI-SUNSHIN BRIDGE

4.1 *Observed VIV*

The investigation bridge, the Yi Sun-shin Bridge (YSS Bridge) is a suspension bridge with a main span length of 1,545m with a streamlined twin-deck section. A large VIV was observed for two hours on Oct. 26, 2014. At that time, the temporal screens were applied on the bridge railings for maintaining curing temperature of the replaced wearing surface as shown in Figure 10.

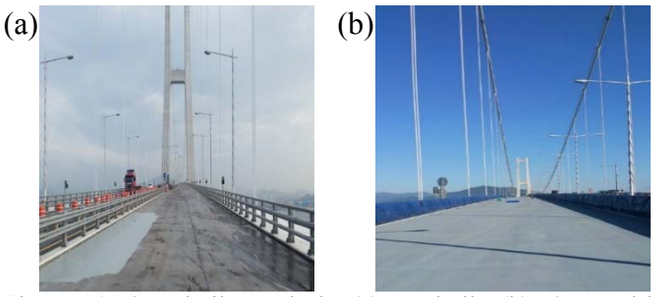

Figure 10. Guardrails on decks (a): As-built, (b): Covered by temporal screens

Unfortunately, the built-in SHM system was not work properly at that time, and only a global navigation satellite system (GNSS) sensor at the center of the main span worked. As a result, the time history of displacement could be obtained from the GNSS sensor, as shown in Figure 11. The maximum vibration amplitude reached 0.52m in double amplitude and the motional frequency was identified to be 0.3176Hz, which was the 4th symmetric vertical mode, as shown in Figure 12.

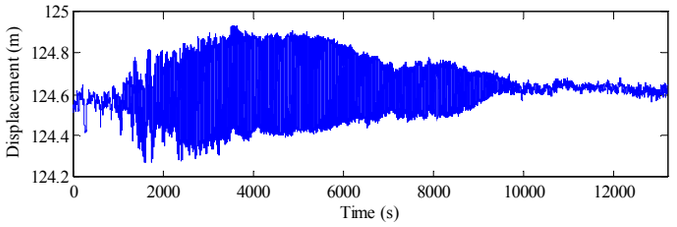

Figure 11. Measured displacement of VIV

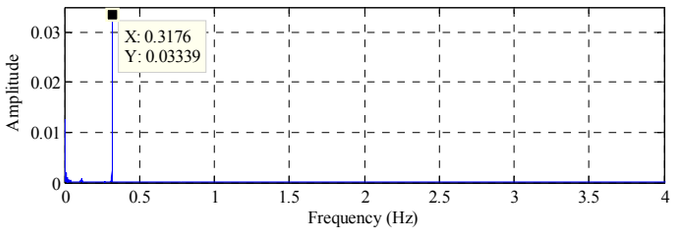

Figure 12. PSD of measured VIV

4.2 *Cause investigation via wind tunnel test*

A series of wind tunnel test was performed using a 1:70 scale model to reproduce the observed VIV. The detail dimensions of set-up model are described in Figure 13.

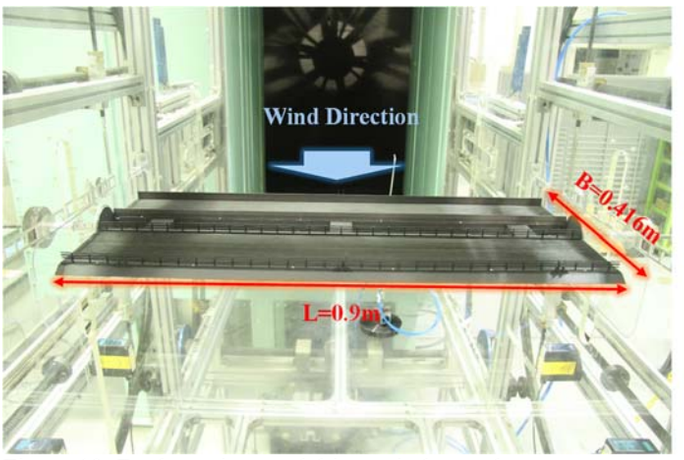

Figure 13. Deck section model in a wind tunnel

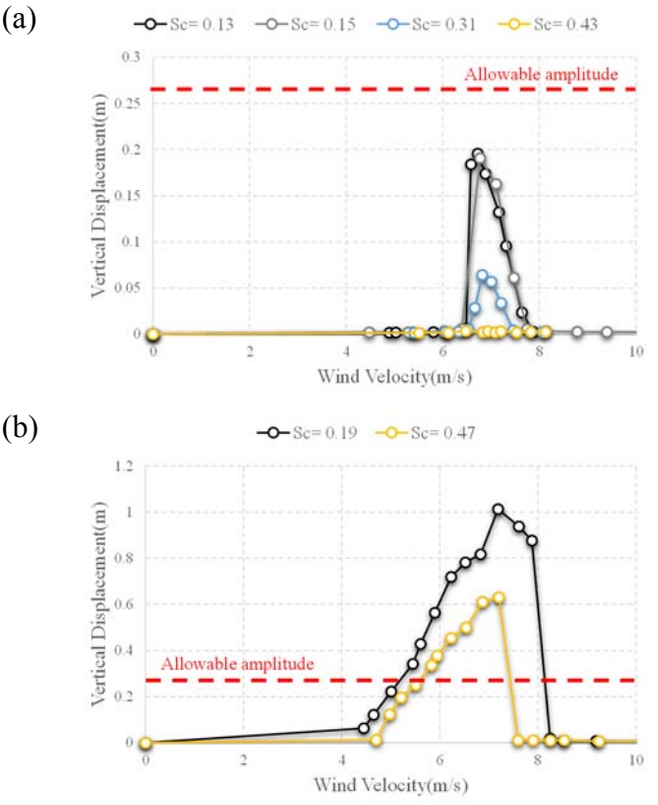

Figure 14. V-A curve: (a) original section, (b) original section with temporal screens

A two of comparative railing configurations was considered for a cause investigation. The first case was an as-built section, while the second one was a section with a temporal screen on the railings. Figures 14(a) and 14(b) illustrate V-A curve for the vertical displacement of two cases, in which S_c denotes the Scruton number. All responses are calculated in double-amplitude. As can be seen, the amplitude of VIV exceeded an allowable limitation only for a case with temporal screens. The amplitude of VIV was strongly influenced by Scruton number. Even in the case of original section, a relatively high level of vibration was observed with low S_c. For the case of a temporal screen on railings, a VIV amplitude still exceeded the limitation even with the design damping level.

4.3 *Cause investigation via operational modal analysis*

The interesting aspect is that the bridge deck was oscillated in the 4th vertical mode, in which the damping ratio (or Scruton number) of 4th vertical mode seems to be substantially less than other modes. Thus, the modal damping ratio was identified from the ambient vibration data measured from built-in accelerometers.

The ambient vibration data obtained for a duration of 1 hour was utilized. PSD of measured acceleration shown in Figure 15 indicates that the 4th vertical mode (0.32Hz) was well developed in ambient vibration data. Two output-only system identification methods, the frequency domain decomposition (Brinker, 2000) and NExT-ERA, were implemented to estimate the modal damping ratio.

At first, the frequency domain decomposition was applied. Frequency response function for each mode were obtained by the peak picking method from the singular values of the spectral matrix. Then, the auto correlation function of each mode could be obtained via inverse FFT of selected frequency response function (FRF). The natural frequency was calculated by counting of zero crossing and the modal damping ratio was estimated from logarithmic decrements.

For the NExT-ERA, a correlation function was calculated with the number of FFT of 2^{16} points with the overlapping of 2^{15}. A size of 3,500 by 3,500 was used to build a Hankel matrix. A calculated auto correlation function and implemented one are illustrated in Fig 16.

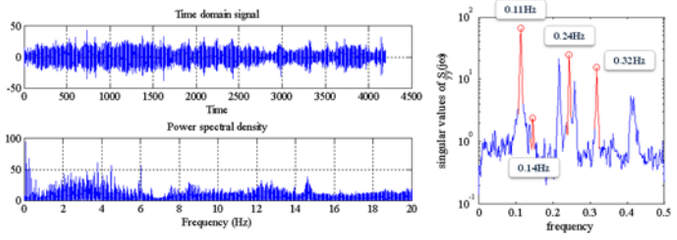

Figure 15. Measured ambient vibration data: (a) acceleration, (b) PSD and (c) components of symmetric vertical modes.

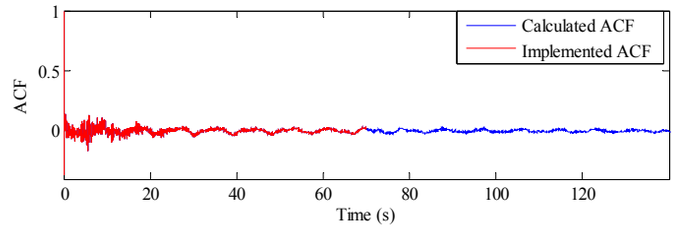

Figure 16. Auto-correlation functions

Table 3 summarizes the results of OMA, in which VS1 denotes the "1st Vertical Symmetric mode". The modal damping ratio of the 4th vertical mode is 0.42% that is the level of design guideline, while 1st, 2nd and 3rd modal damping ratios are 1.26%, 2.42% and 0.44%, respectively. This result clearly shows that the occurrence of the 4th vertical mode VIV would be related to a relatively low modal damping ratio.

Table 3. OMA result (frequency and damping ratio)

Methodology	VS1	VS2	VS3	VS4
FDD	0.11Hz 1.26%	0.15Hz 2.42%	0.24Hz 0.44%	0.32Hz 0.42%
NExT-ERA	0.11Hz 1.17%	-	0.24Hz 0.45%	0.32Hz 0.38%

4.4 *Discussions*

The source of the unexpected vibration observed in 2014 on a suspension bridge was the temporal screens used for curing the epoxy-coated pavement. The bridge was subjected to the vortex-induced vibration tuned to the 4th vertical mode, for which the modal damping ratio was identified to be relatively small than other modes. The bridge at the current normal operational condition, without the temporal screens, is identified to be aerodynamically stable as it was thoroughly verified via the wind tunnel tests at the design stage.

5 EVENT 3: OVERTURNING ACCIDENT ON GWANGAN BRIDGE

5.1 *Two trailer accidents on bridge*

Figure 17. The 2nd trailer overturning accident on a suspension bridge (Retrieved from http://news20.busan.com/controller/newsController.jsp?newsId=20120404000160)

On April 3rd, 2012, two consecutive trailer overturning accidents were observed on the approaching span of a suspension bridge with double deck, as shown in Figure 17. The recorded 10-minute averaged wind speed when these accidents happened were 14.3m/s and 11m/s at the height of accident site, which were much lower than the limit wind speed of 25m/s for bridge closure. Since the trailer is relatively vulnerable to wind as well as the accidents occurred in a curved section, the limit wind speed of 25m/s seems not to be enough for this condition. In order to figure out cause of these accidents and to assess vulnerability of vehicle safety, vehicle analysis and probabilistic risk assessment are proceeded based on collected data.

5.2 *Estimation of critical wind speed via vehicle analysis*

In order to calculate critical wind speed of trailer, vehicle analysis is performed based on a quasi-static theory (Batista & Perkovic 2014; Kim et al. 2016). Static model of trailer is constructed with one axle and one hitch point considering reaction forces of tire and hitch point, as shown in Figure 18. Also effect of cant and curvature are reflected during analysis by including gravity and centrifugal forces into equilibrium equations.

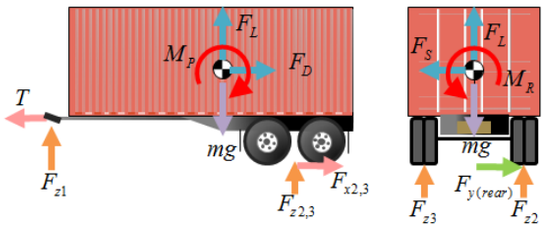

Figure 18. Established static model of trailer

Based on pictures of accident and collected information, basic information of the overturned trailer such as weight and dimension are assumed as shown in Table 4.

Table 4. Information of investigated trailer

Distance between hitch point and C.O.G*	3.6m
Distance between axle and C.O.G*	3.0m
Height of hitch point	1.4m
Height of C.O.G*	1.7m
Track width	1.86m
Weight of trailer	6.7t

* Center of gravity

Through vehicle analysis, vertical reaction forces of tires can be estimated for any wind condition, and critical wind speed is determined when one of vertical reaction forces becomes zero. Critical wind speed is determined for 16 wind directions with 22.5-degree interval.

Two straight road sections are located at both side of the curved section, and critical wind speed curves (CWCs) which show variation of critical wind speed for wind direction are determined for each section. Vehicle speed is assumed to be 50km/h, and curvature and cant of curved road are 450m and 2%, respectively. Since vehicle experiences various wind direction on curved section, minimum critical wind speed is selected for each wind direction. Estimated CWCs are shown in Figure 19.

A shift of CWC about 70 degree between two straight roads can be found due to change of travel direction, as shown in Figure 19. This difference indicates that accident possibility can be largely influenced by the vehicle location even under the same wind condition. In case of curved road, a flat portion could be observed in CWC due to the change of travel direction on the road. In other words, possibility that vehicle meets most critical wind direction on curved road is much larger than that on straight road. Also, even centrifugal force can make vehicle unstable if wind load acts in the same direction. These characteristics of curved road might be the reason of the overturning accidents, and particular traffic control strategy is required considering these points.

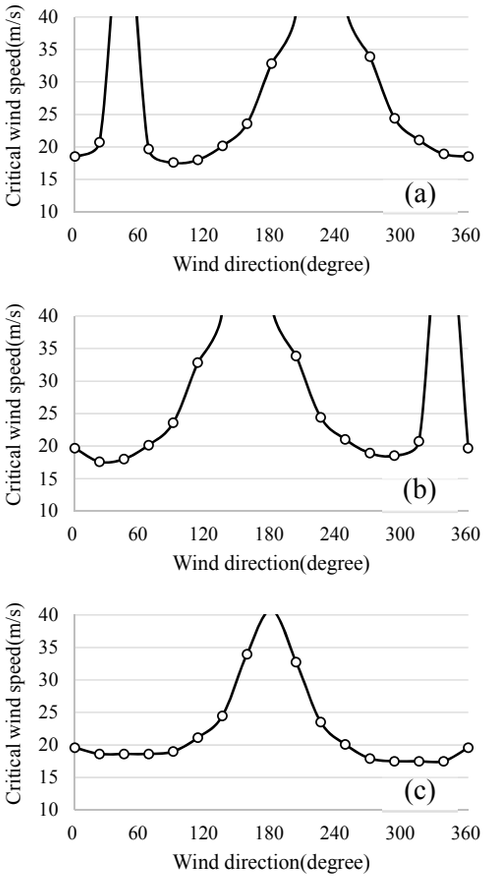

Figure 19. Critical wind speed curves for three sections: (a) straight road 1, (b) straight road 2 and (c) curved road

5.3 *Risk assessment using long-term measured data*

Probabilistic analysis is also performed to assess the frequency of daily maximum wind speed that exceeds CWC. Long-term wind data measured at nearby weather station are obtained to estimate probabilistic model of wind speed for each wind direction. Period of obtained data is 20 years and data type is 10-minute averaged daily maximum wind speed.

In order to reflect wind properties, Measure-Correlate-Predict (MCP) method (Carta et al. 2013) is applied which modifies long-term data based on field-monitored data. Field-monitored data of one year could be obtained which was measured from 2012.01.01 to 2012.12.31 at top of the tower of the bridge (see Figure 20).

Both of wind data have almost linear relation that correlation coefficient is estimated about 0.78 (see Figure 21). First-order regression model in equation (1) is utilized to convert long-term data which considers mean and standard deviation of wind speed.

$$U_T = \frac{\sigma_T}{\sigma_W} U_W + m_T - \frac{\sigma_T}{\sigma_W} m_W = 2.89 U_W - 3.34 \quad (1)$$

where U, σ, m are wind speed, standard deviation and mean of wind speed, respectively. Subscript W refers to the weather station and subscript T refers to the top of the tower.

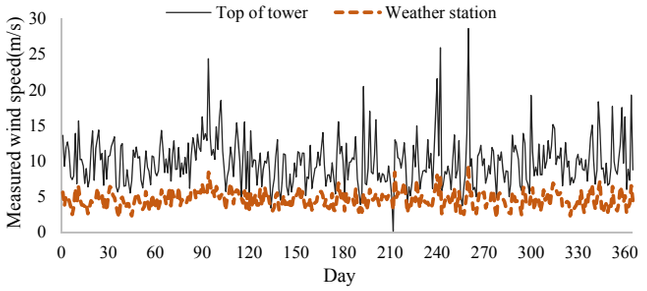

Figure 20. Wind data measured at bridge site and weather station

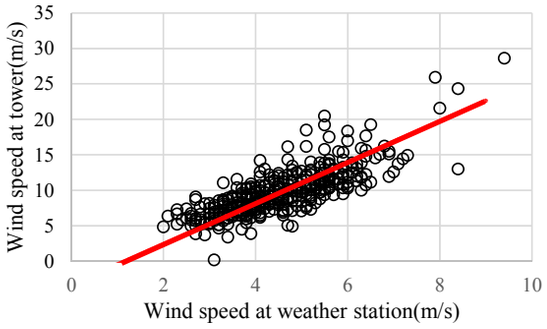

Figure 21. Correlation between two wind data sets (R=0.78)

The wind speed data measured at the top of the tower was transformed to those at the deck level by the exponential law for the wind profile in boundary layer.

Probabilistic distribution function is estimated using Generalized Extreme Value (GEV) distribution model. All wind data is classified into 16 directions with 22.5-degree interval, and three coefficients, location, scale and shape parameters, are estimated for each direction by the maximum likelihood method (Coles 2001). Figure 22 demonstrates an example of estimated cumulative distribution function.

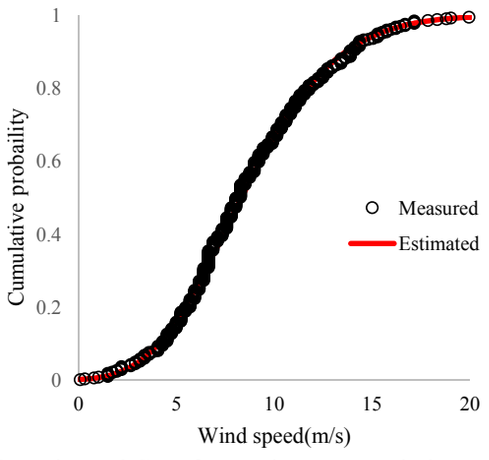

Figure 22. Estimated CDF for south-western wind

After estimation, a probability that wind speed exceeds CWC, P_E, is evaluated by considering 16 wind directions as equation (2) (Kim et al. 2016).

$$P_E = \sum_{all\ direction} P_i \times P_{E|dir=i} \quad (2)$$

where P_i is the probability that the direction of the wind is i, and $P_{E|dir=i}$ is the conditional probability that wind speed exceeds the critical wind speed for i.

Finally, by multiplying 365 days to P_E, number of days for traffic control, N_C, which is the risk index can be estimated. N_C is estimated for three road sections - two straight roads and one curved road. Additionally, in order to compare with other vehicle types, large van and passenger car are also investigated (Kim et al. 2016), and assumed vehicle speed is 60km/h. The results are shown in Figure 23.

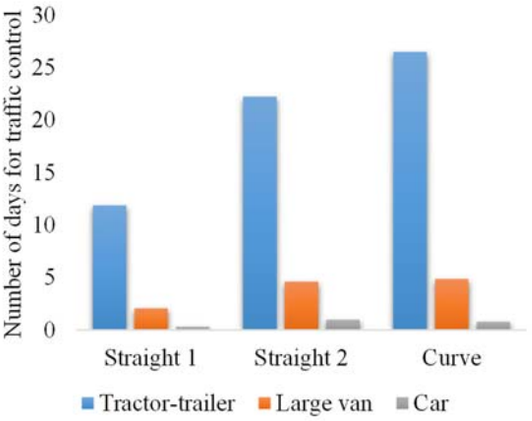

Figure 23. Estimated N_C for 3 sections and 3 vehicle types

According to Figure 23, straight 1 is safer than other sections, and the main reason for this difference is wind direction. Based on the wind rose of the bridge site, main wind direction is south-western which is almost parallel to direction of straight 1 section.

Another interesting point is that tractor-trailer is much vulnerable than other types of vehicle. It exceeds 5 days, a criterion for side-wind vulnerability, in all section. This result indicates the necessity of appropriate measure to secure trailer safety such as traffic control strategy.

Two parameters, vehicle speed and loading ratio, are investigated for traffic control strategy. According to Figures 24 and 25, both parameters can affect on risk index dramatically. The operator of the bridge has applied a limit vehicle speed as 40km/h when mean wind speed exceeds 10m/s. By decreasing the vehicle speed to 40km/h, the risk index for Straight 1 also decreases less than 5 days. Another efficient option to secure safety is increasing vehicle weight. If loading ratio, a ratio between loading weight and vehicle weight, increases to 50%, the risk indices for all directions reduce to 5 days.

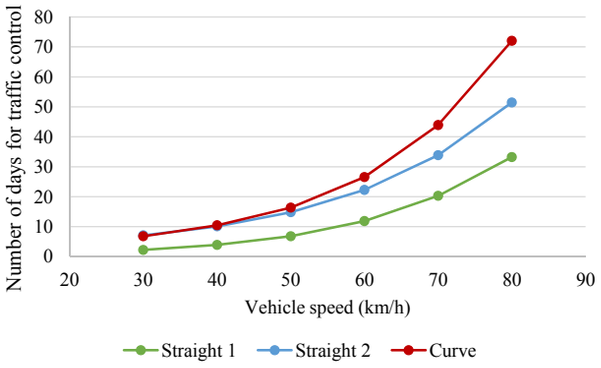

Figure 24. Variation of N_C according to vehicle speed

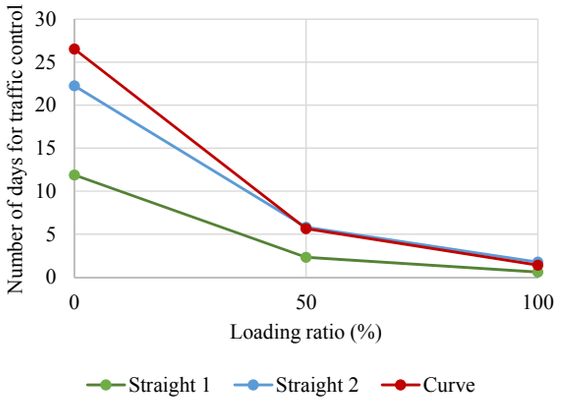

Figure 25. Variation of N_C according to loading ratio

5.4 *Short-term prediction of wind speed*

Operational actions such as closing the bridge require times to prepare it. Also, it should be important to predict when a normal operation can be restored. Accordingly, the short-term prediction of wind speed over the bridge deck is another issue in bridge operation during strong side wind.

Since wind speed data has nonstationarity, prediction model, which can handle nonstationary data, is required to increase prediction accuracy. Long Short-term Memory (LSTM), which is known to be suitable for dealing with time series, is applied to predict wind speed. LSTM is a deep learning algorithm, which is proposed by Hochreiter & Schmidhuber (1997). The basic structure of the LSTM is called LSTM Block, as shown in Figure 26. LSTM block consists of a cell state(c_t) and three gates, which are input(i_t), forget(f_t), and output gate(o_t).

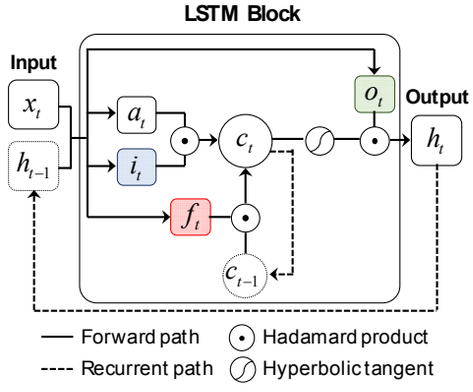

Figure 26. Structure of LSTM Block

Wind speed data measured at top of the tower of the bridge from 2003 to 2013 were obtained. The wind speed data is processed to 1-hour maximum wind speed from 10-minute wind speed. Wind speed during the typhoon Sanba is targeted to predict. In order to increase prediction accuracy, three typhoons, which are similar to the typhoon Sanba, are selected and wind speed data during those typhoons are utilized as training data. Wind speed is predicted from 1 hour to 6 hours in advance and prediction results are presented in Figure 27.

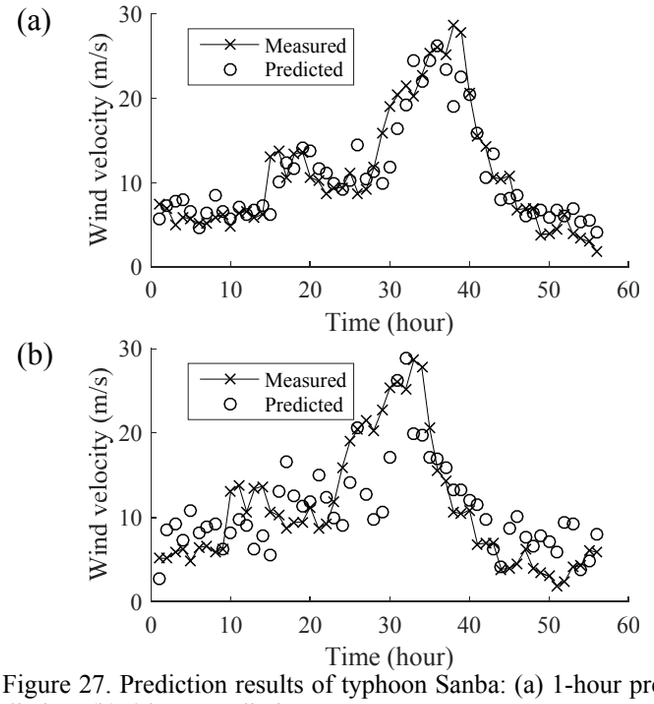

Figure 27. Prediction results of typhoon Sanba: (a) 1-hour prediction, (b) 6-hour prediction

As shown in Figure 25, the prediction accuracy is satisfactory, although the accuracy tends to become lower from 1-hour to 6-hour prediction in advance. Furthermore, the prediction model can capture the time of increasing and decreasing of wind speeds.

5.5 *Discussions*

Since vulnerability of vehicle from strong wind highly depends on not only wind speed but also other factors such as wind direction, vehicle speed and weight, traffic control strategy should be previously specified by considering these factors and road conditions in order to secure vehicle safety. Also, wind prediction based on deep learning algorithm can be a useful measure for prompt action during strong wind. All these procedures are parts of the best practices of increasing value of data available.

6 CONCLUSIONS

The data obtained from the field include much more information as demonstrated in case studies. However, soft technologies such as data processing, system identification with operational modal analysis (OMA), Measure-Correlate-Predict analysis, and Long Short-term Memory are also required to mine more accurate information from available data. Also, wind tunnel test is indispensable to compensate unmeasured areas of certain physics from field monitoring data, particularly for the aerodynamic events as demonstrated.

The findings from operational monitoring and corresponding analysis can feedback to enhance the current design practice, as demonstrated for the importance of design modal damping ratios of completed bridges. The damping identification from OMA is an essential issue as a serviceability performance index for flexible long-span bridge. Also, the vulnerability assessment procedure of running vehicle to strong side wind can be utilized for the effective traffic control by utilizing long-term and short-term wind speed data. By these way, examples of increasing the value of data for long-span bridge operation are demonstrated in an aerodynamic point of view.

Design Concept of the Twin River Bridges in Chongqing

M.C. Tang
T.Y. Lin International, San Francisco, California, USA

ABSTRACT: Chongqing is bisected by the Yangtze and Jialing Rivers, into three parts: Nanan in the south, Yuzhong in the middle and Jiangbei in the north. The Twin River Bridges are two cable-supported girder bridges: the Dongshuimen Bridge crosses the Yangtze River from Nanan to Yuzhong, while the Qianximen Bridge crosses the Jialing River from Yuzhong to Jiangbei. A tunnel under the entire Yuzhong District connects the two bridges. The bridge site offers the best vantage point of the City, so aesthetics were critically important for the design. The bridges carry four lanes of city traffic and two rapid transit tracks with very stringent design requirements. The girders are steel truss structures with orthotropic plates and the towers are made of concrete. The bridges were designed based on the concept of partially cable-supported girder bridge. This paper describes the development of two alternative design concepts and the final construction of these bridges.

1 INTRODUCTION

Chongqing is located in the middle of China. It is one of four municipalities in the country. The other three are Beijing, Shanghai and Tianjin. In China, a municipality is a city that directly reports to the central government, equivalent to a province. With a population of 32 million, Chongqing is the largest among the four municipalities. It is probably the largest city in the world with respect to population.

Chongqing is very hilly. It also has many rivers. The Yangtze River passes through the entire city diagonally. Besides the Yangtze, there are other rivers such as the Jialing, Wujiang, and Fujiang, etc. They all flow into the Yangtze River. With so many hills and rivers, Chongqing needs many bridges. It has also built many bridges. As of the end of 2017, the Municipality has over 15,000 bridges.

Metropolitan Chongqing is bisected by two major rivers, the Yangtze River in the south and the Jialing River in the north. These two rivers divide the metropolitan into three parts: the southern district, the northern district and the Yuzhong Peninsula in the middle, where the central business district is located. The southern district is called Nanping, the northern district is called Jiangbeijui. The Jialing River flows into the Yangtze at the tip of the peninsula.

The Twin River Bridges consist of two bridges: the Dongshuimen Bridge crosses the Yangtze connecting the southern district to the Yuzhong Peninsula and the Qianximen Bridge crosses the Jialing River connecting the Yuzhong District to the northern district. A tunnel under the Yuzhong Peninsula connects the two bridges so through traffic can flow from the Southern District directly to the Northern District without going through the streets of the Yuzhong Peninsula. (See Figure 1.) However, there are ramps at the peninsula to allow traffic to enter the Yuzhong District as well.

Both bridges have two decks. The upper deck carries four lanes of city traffic and the lower deck carries two tracks of transit trains. Chongqing will ultimately have 13 transit routes totaling over 500 km in length. The Twin Bridges are on Route #6.

Because of the bridges' high visibility, aesthetics were an important consideration during the bridge type selection process.

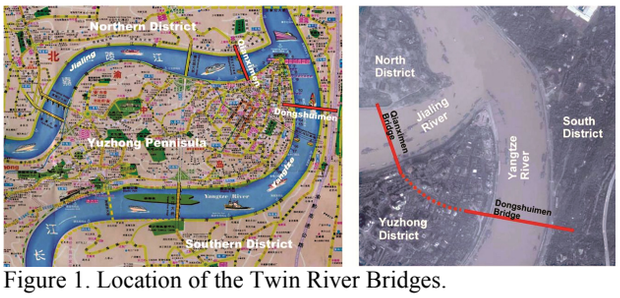

Figure 1. Location of the Twin River Bridges.

In 2008, the owner held an international design competition to select the final design concept. More than 20 bridge schemes were submitted by consulting firms encompassing all types of bridges includ-

ing girder, suspension, cable-stayed, arch, and extradosed bridges, and combinations thereof. The owner finally selected the partially cable-stayed girder bridge scheme proposed by the joint venture of Chongqing Communication & Research Institute and T.Y. Lin International. The joint venture had also submitted a suspension bridge scheme, which, incidentally, was the runner-up to the partially cable-stayed girder bridge scheme. As the technical director for the joint venture, the writer was responsible for the conceptualization of both bridge schemes.

2 BRIDGE TYPE SELECTION

The configuration of the Dongshuimen and Qianshimen Bridges had to satisfy aesthetic, geographic, and technical criteria. Because they were to be located between three city districts, they had to be harmonious with three disparate surroundings. They had to complement one another and they had to stand on their own. Finally, the bridges could not obstruct views of the city from various vantage points.

Navigational requirements and local geology demanded minimum main span lengths of 445m and 340m for the Dongshuimen and Qianximen Bridges respectively. The lack of a side span at the Yuzhong side of the Qianximen Bridge limited the number of towers to a single tower. Both span requirements influenced the type selection process.

In addition, the girder bridge had to be at least 12m deep to accommodate transit tracks on its lower deck. Such a deep girder has to be a truss for two reasons: to offer transit passengers a more open view of the area and to increase the transparency of the bridges themselves. A solid girder would look much too heavy in this area.

Another key factor during type selection was that the city had just constructed two major arch bridges not far away: the Caiyuanba Bridge and the Chaotianmen Bridge. Therefore, an arch bridge was not a favorable choice.

The choice of a conventional cable-stayed bridge was discarded because it would obstruct one's view of the city. A 340m span single tower cable-stayed bridge must have a tower protruding approximately 170m above the deck level. The bridge would be roughly 60m above normal water level so the total height of such a tower would be approximately 230m tall—taller than almost every building in the city. A conventional cable-stayed bridge would also have too many cables, further hindering the view of the city.

A regular girder bridge was also discarded because of the bridges' relatively long spans.

Consequently, it was decided that the bridges should be either a pair of partially cable-stayed girder bridges or a pair of suspension bridges for their relatively shorter towers and fewer cables. Both minimalist designs that would least disturb the surrounding space.

Keeping in mind the locations of the bridges in relation to the Yuzhong Penninsula, it was natural that the two bridges should be similar. Therefore, the writer conceptualized two schemes—a pair of suspension bridges and a pair of partially cable-stayed girder bridges.

3 SUSPENSION BRIDGE SCHEME

The suspension bridge scheme is comprised of two single tower suspension bridges with 496m main spans each, as shown in Figure 2. The side spans of both bridges are 250m long. They both have two planes of cables. The towers are 100m above the deck.

Figure 2. Renderings of a pair of suspension bridges.

On the Yuzhong Penninsula, where the rock formation is very fractured, it would be difficult to anchor the main cables in the soil, unless an extremely large anchor block and a major tie back system to transfer the cable force deep into the ground was used. Because there are numerous buildings in the area, the tie-back anchors would compromise the foundations of these buildings. Therefore, conventional suspension bridges were deemed unsuitable for these two bridges.

Self-anchored suspension bridge scheme was also studied. A 496m span self-anchored suspension bridge is technically possible, despite its record-setting length. However, it would be very expensive. To build a self-anchored suspension bridge, the girder must be erected before the cables can be suspended. This would require placing costly temporary piers in the river. The busy river traffic and swift current during the high water season would pose a danger to any temporary intermediate supports due to possible ship collisions. Besides, it would be much more expensive. Consequently, the idea of self-anchored suspension bridges was discarded.

To resolve this problem of anchorage, a special concept was introduced.

As mentioned above, the fractured rock is not good for tension. But it is capable of resisting compression. Thus it would be perfect if we could change the anchoring force from a tension force into a compression force.

The transit tunnel that connects the two bridges runs under a street on the Yuzhong Peninsula. The tunnel is about 600m long with a subway station in the middle, as shown in Figure 3.

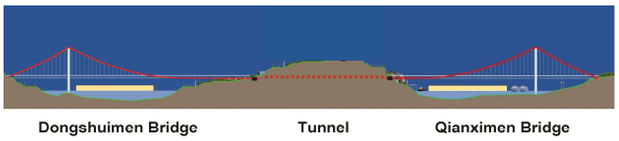

Figure 3. Connecting the main suspension cables through the Yuzhong Pennisula.

Making use of this arrangement, we had studied three anchoring schemes:

1 Instead of having to anchor the cables to an anchor block at the end of the bridge, it is possible to extend the main cables of each suspension bridge over the length of the tunnel and anchor them on the other face of the peninsula so the cables would exert a compression force on the rock, Figure 4a. In this scheme, the anchoring force is always equal to the cable force. Each bridge is an independent structure that does not affect the behavior of the other.
2 Because the two suspension bridges have the same span length and girder configuration, the cable force of the two bridges should be approximately equal all the time. If we use a pair of cables to connect the main cables of the two suspension bridges together, the combined structure will be similar to a suspension bridge with two towers, Figure 4b. In such an arrangement, loading on one bridge will affect the behavior of the other bridge. This will make the analysis much more complicated, especially because the tunnel is on a horizontal curve so there will be friction force along the curve the magnitude of which is difficult to predict.
3 To solve this problem we proposed to use a pair of connection cables, which are slightly larger than the main cables to connect to two anchor blocks which are located at the outer faces of the tunnel, Figure 4c. The connection cables are stressed to a force slightly higher than the maximum force in the main cables. If C_p is the cable force under permanent load, C_L is the cable force due to live load and other loads, and C_R is the minimum residue compression force we want to keep at the anchor blocks, the force in the connection cables, C_C, should be $C_C = C_p + C_{L,\,max} + C_R$ where C_p , and $C_{L,\,max}$ are known values while C_R is a value selected by the engineer. To assure that there is always a compression force acting on the rock, we proposed $C_R \approx 0.2\ (C_p + C_{L,\,max})$. Thus, under service conditions, the minimum compression force at the interface between the anchor block and the rock surface would be C_R, while the maximum compression force at the interface would be $C_R + C_{L,\,max} - C_{L,\,min}$ where $C_{L,\,min}$ is negative. Because the main component of cable force in a suspension bridge is due to its permanent load, the actual anchor force required is much smaller than the force in the main cables.

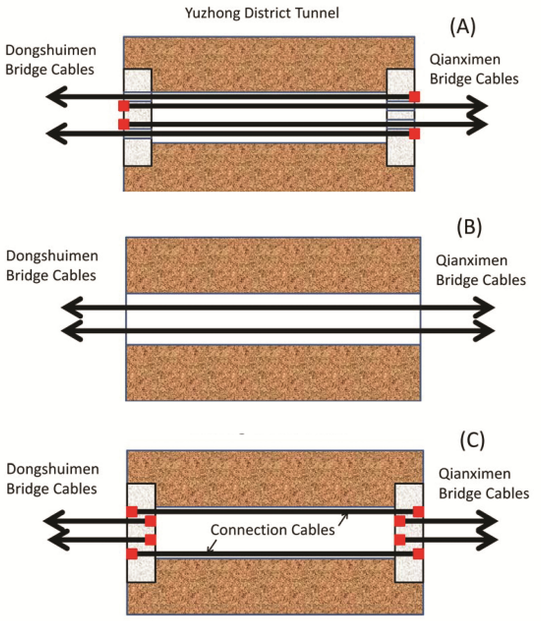

Figure 4. Anchorage schemes of the main cables.

Thus, the anchor blocks will always exert a compression force on the rock formation of the Yuzhong Peninsula. This is preferable for the fractured rock in the area. The connecting cables can run through a separate chamber underneath the transit tunnel. The chamber can be excavated and constructed simultaneously with the transit tunnel. Because this cable chamber is directly underneath the transit tunnel, there will be no right-of-way issues and the cost will be minimal. This anchorage arrangement basically separate the structure into two individual suspension bridges so the structural behavior of one bridge will not affect the behavior of the other bridge.

Figure 5 Rendering of the Suspension Bridge Scheme

The shape of a suspension bridge is usually very graceful. Therefore, a simple portal configuration for the towers of both bridges will fit well with the suspension cables, as shown in Figure 5. From afar, it looks like the two bridges are holding up the Yuzhong Peninsula. It would have been a very spectacular view!

Aesthetically, the pair of suspension bridges were attractive and compatible with one another. As well, they complemented the landscape and were transparent in elevation.

4 PARTIALLY CABLE-STAYED GIRDER BRIDGE SCHEME

Compared to the tower of a suspension bridge, the tower of a conventional cable-stayed bridge is typically twice as tall. In this scenario, while the span of the bridge may be reduced to 340m, its tower would remain 170m above the deck. Such a tall tower would not complement the surrounding landscape. Furthermore, a conventional cable-stayed bridge has many cables. They obstruct views of the city. Therefore, conventional cable-stayed bridges are not suitable for this bridge site. In order to satisfy all design requirements and aesthetic expectations, a pair of partially cable-stayed girder bridges was selected, as shown in Figure 6.

Figure 6. Renderings of the partially cable-stayed girder bridge scheme.

At the time of this proposal, the concept of a partially cable-stayed girder bridge, (Tang 2007), has been applied successfully to the design of several medium-span bridges in China, most notably the Taijiang Bridge in Sanming and the Sanhao Bridge in Shenyang. While the spans of the Twin River Bridges are much longer, the girder depths of these two bridges, at 12m, are also much deeper. Thus, the span to girder depth ratio is comparable to that of the previously designed medium-span partially cable-supported girder bridges.

The minimum main span length of the Dongshuimen Bridge is 445m. Thus, the span to girder depth ratio is 445/12 = 37. The minimum main span length of the Qianximen Bridge is 340m. Its span to girder depth ratio is 340/12 = 28.3. These ratios are within the workable range of partially cable-stayed girder bridges.

The Dongshuimen Bridge has two towers while the Qianximen Bridge has one tower. All three towers are 100m high above the upper deck. Each tower of the Dongshuimen Bridge carries nine pairs of cables. The tower of the Qianximen Bridge has ten pairs of cables. All of the cables are located on a single plane on the center line of the bridge. The upper deck is an orthotropic steel deck with a minimum deck plate thickness of 16mm. The main floor beams are 2.00m deep. The lower deck consists of four longitudinal beams located directly under the rails. Transverse girders are 1.20m deep. The lower floor system is also an orthotropic deck with open ribs. The orthotropic deck serves as a platform next to the tracks. It acts monolithically with the lower chord of the main truss.

It is the desire of the owner that these two bridges are to be signature structures of the City. With a single plane of cables in the middle of the box girder, the towers can be either a diamond shape or an inverted Y shape. However, those tower shapes would not have been sufficiently distinctive to satisfy the aesthetic requirement. After extensive studies, the very special tower shape as shown was adopted. It simulates the shuttle of a Chinese weaving machine. The writer had studied this tower shape for a long time but has not been able to find a suitable bridge for it. Most bridges in China have six lanes or more, a six-lane bridge girder would be too wide for this tower shape. It would loss its elegant slenderness. The Twin River Bridges are four lane bridges, which are perfect for this slender tower configuration!

Figure 7. Renderings of the partially cable-stayed girder bridges.

As shown in Figure 7 above, the bridges are located at the tip of the peninsula. Both bridges can be seen from various view points of the city. Therefore, it is more harmonious if all three towers have the same shape. Figure 8 shows the basic dimensions of the tower. Because the ground elevation of each tower is different, the very bottom portion of the towers can be slightly different from each other. For the tower with lower ground elevation the tower shape is extended longer. However, at normal water level, all three towers look the same.

The lower portion of the tower has an oval cross section, as shown in Figure 8. The two ends are circular and the middle part consists of two flat surfaces. The upper portion of the tower has the same basic shape except the middle part is cut out to receive the girder. The radius of the circular surface is constant over the entire height of the tower. Thus, we can reuse most of the formwork, which is a major cost in concrete construction.

Both the Yangtze and the Jialing are busy waterways. Therefore, ship and barge collision must be carefully considered. The lower portion of each tower has relatively thick walls to resist any possible impact by barges or ships. The smooth oval shape of the tower cross section is also beneficial in redirecting the ship impact forces away from the tower.

Even though the tower looks curvy, the center of gravity of the members in the towers are close to straight lines.

The top of the tower is separated into two symmetrical arms by a vertical slit. All cables are anchored to inclined steel anchor plates inside the slit. The anchor plates are welded to two large vertical steel plates, each of which is attached to the face of the slit in the concrete tower head by means of shear studs. There are two concrete blocks that connect the two tower arms together, one at the top and one at the bottom. These two concrete blocks are to resist the bending of the tower arms due to the eccentricity of the cable anchorage to the arms. Light can shed through the slit to give the tower head a much lighter appearance. The concrete blocks can also serve as anchorage blocks for temporary cables during possible rehabilitation. It is envision that the temporary cable strands can just wrap around the concrete block, which has a round surface. They can be reinforced using a curved steel plate on top of the concrete surface, if required.

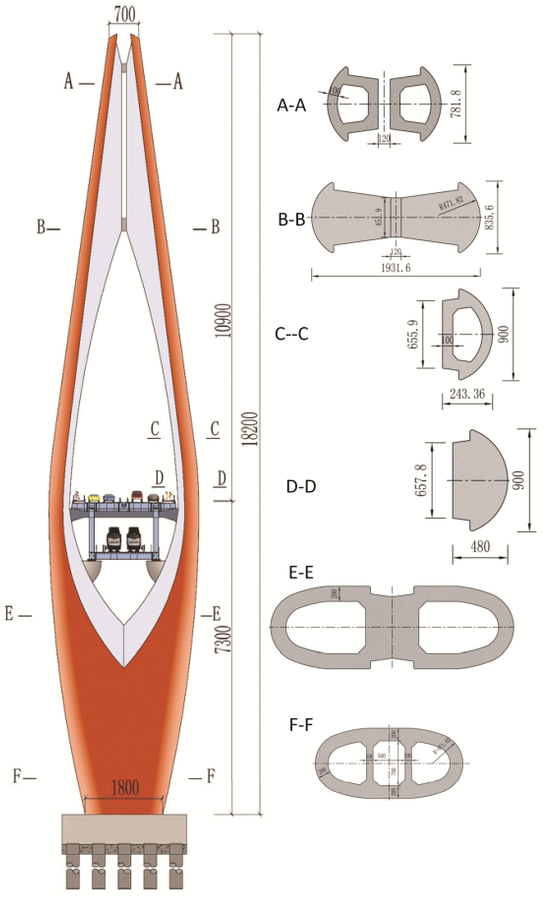

Figure 8. Tower and tower cross sections.

5 THE GIRDER

The main girder of the two bridges is a steel truss. The girder is about 12m deep except at the end of the Qianximen Bridge where the girder is deepened to accommodate additional cross beam for the transition. This girder depth was required for the transit tracks. Such a deep girder would be a disturbance to the river view if it were solid. Therefore, a steel truss was selected to make the girder look more transparent.

The cross section of the truss is as shown in Figure 9. It carries four lanes of city traffic and two pedestrian paths on the upper level and two tracks of transit on the lower level. The upper level has an orthotropic steel bridge deck with flat ribs.

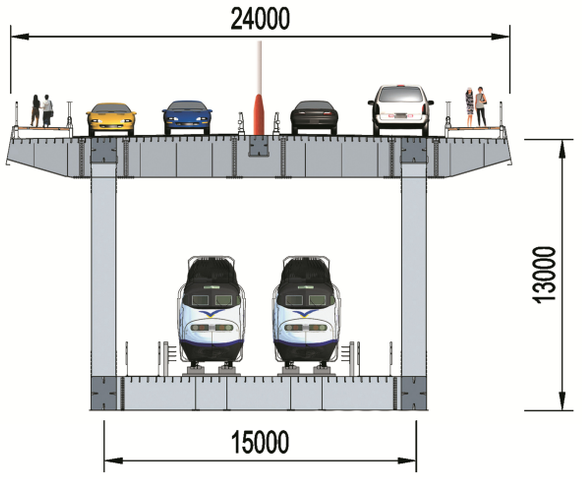

Figure 9. Truss girder cross section

There are several possible ways to support the rails of the transit tracks in a bridge. For these two bridges, the owner decided on a concrete supporting plate version, which is very heavy. In a cable-stayed bridge, the axial force in the girder is directly proportional to the weight of the girder. Therefore, the axial force in the girder of these two bridges is very high.

The reason to use flat ribs instead of the more popular trapezoidal ribs is a better guarantee of welding quality of the ribs to the deck plate. The Twin River Bridges are cable-stayed girder bridges, which have very high longitudinal axial forces in addition to the high bending moment in the girder. They cause high stresses in the orthotropic deck. In addition, the lower level of the Twin River Bridges was designed to carry trains, which are very heavy. To resist the high axial force and bending moment it is necessary to have more steel area in the deck. Therefore, a heavier orthotropic steel deck is actually beneficial for the structure. The beefier open rib orthotropic deck is not a disadvantage to the bridge. The other reason for using open ribs is that the Twin River Bridges have a single plane of cables located in the center line of the bridge girder. The transverse bending moment of the girder causes tension in the top deck in the transverse direction. This transverse tensile stress in the deck plate must be designed for fatigue stresses. Therefore, it is more desirable to make sure that higher quality welds between the ribs and the deck plate can be readily achieved. Thus, open ribs are a better choice.

Another important consideration in the selection of open rib is due to the quality control of the fabrication. Welding in an orthotropic deck with trapezoidal ribs requires very high quality control. If this cannot be assured, open ribs are a better choice.

The partially cable-stayed girder bridge scheme was selected by the owner for the final design.

6 DESIGN CONCEPT – THE PARTIALLY CABLE-STAYED GIRDER BRIDGE

Partially cable-supported girder bridge is a subset of partially cable-supported girder bridge. Because a 12m deep girder is required to accommodate the transit tracks on the lower level, the main truss girder itself provides a relatively high capacity for carrying the loads. The concept of partially cable-stayed girder bridge, as described in “Rethinking Bridge Design: A New Configuration,” (Tang 2007), can be applied here with great advantage. The idea is to design a girder bridge, the load capacity of which is to be supplemented by cable forces. The cable forces are selected so as to provide what is needed to bring the total capacity of the bridge to the required level. Therefore, the cable forces can be assigned with relative freedom.

Figure 10 portrays the design procedure of a partially cable-stayed girder bridge. For simplicity, we use a uniform steel girder under uniform load as example. Figure 10a illustrates a three-span uniform steel girder under a uniform load. Figure 10b shows the positive and negative bending moment in the girder under the given uniform load and the moment capacities of the girder. Portions of the girder do not have a sufficient capacity to resist the bending moment caused by the load on the girder. Figure 10c shows the shortage in capacity. To address this issue, a cable-stay system, as shown in Figure 10d can be used to produce an additional bending moment capacity, as shown in Figure 10e, to make up the difference can be added as indicated by Figure 10f.

There are many combinations of cable forces that can produce bending moments that will satisfy or exceed the demand requirements not assumed by the girder’s moment capacity as shown in Figure 10e. It will be advisable to assign cable forces in such a way as to gain certain advantages in fabrication and/or in construction. For example, to simplify construction of the girder, we can select a set of cable forces that will have the same vertical component. This will allow us to have one design for all cable anchorage points in the girder. Alternatively, we can assign the same force to all cables to simplify cable manufacturing.

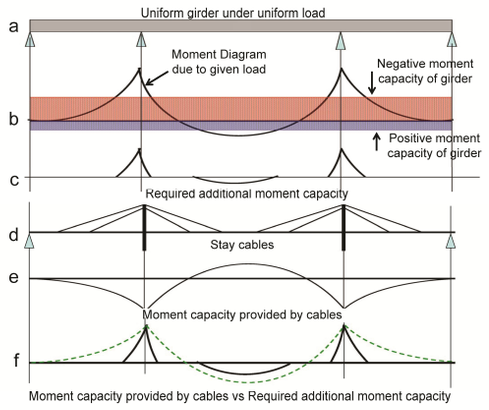

Figure 10 The Concept of Partially Cable-Stayed Girder Bridge

A partially cable-stayed girder bridge is an economical solution in that it fully utilizes the capacities of both the deep girder and the stay cable system. In addition, a single plane of cables has a transparent appearance and satisfies the aesthetic criteria for this location.

7 CONSTRUCTION

China has built many long span cable-stayed bridges in the last 30 years. Today, construction of cable-stayed bridges is relatively routine. The towers of both bridges are located at shallow water or rock outcrop so foundations can be constructed rather easily. However, foundation construction of bridges in Chongqing must be carefully scheduled to avoid the high water season, which runs from about May to October each year. The water level can rise over 30 meters above the normal water level. Therefore, the foundation of the towers was constructed within one low water season to eliminate the need of high cofferdams.

The towers were constructed using jump forms with 2m lifts. Wood forms were used to better suit the curvature of the surface. Wood forms are also sturdier so the resulting surface is smoother.

The girders were built as cantilevers. The method is rather routine.

8 COLOR SCHEMES

We have done an extensive study on the color of the bridge. Figure 11 shows a few color combinations we originally proposed. During the design stage, the latest color scheme was chosen. However, after the bridge was complete, the owner decided to have the color combination as shown in Figure 12. Red is a rather popular color in China.

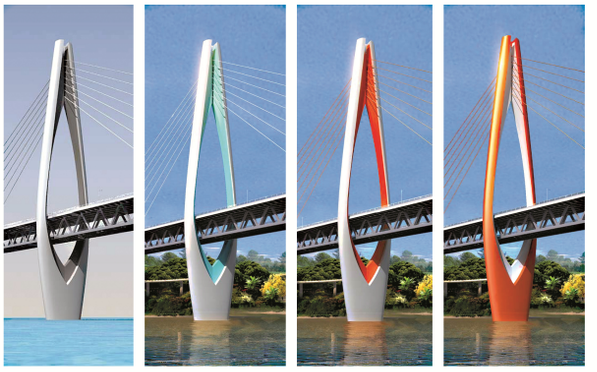

Figure 11. Various color schemes of the towers.

Figure 12 The completed bridges.

9 A BEAUTIFUL ADDITION TO THE BRIDGE CAPITAL OF CHINA

Since the opening up of China 30 years ago, bridge construction has been a focus of infrastructure developments there. In 1996, the City of Chongqing was separated from Sichuan province and became a special municipality, reporting directly to the central government. Chongqing has since become one of China's most vibrant cities. The city's rapid development has led to the construction of many new bridges. Indeed, Chongqing is often called the "Bridge Capital of China" because of its plethora and variety of bridges. The Dongshuimen Bridge and the Qianximen Bridge are two more beautiful additions to this "Bridge Capital of China."

1 ABSTRACT

India has second largest road network in the world having a Road Network of over 5,472,144 kilometres (3,400,233 mi) which comprises 1,00,087.02 km National Highways which includes over 35,733 Bridges. If we want to repair and rehabilitate these Bridges, current information looks inadequate, also Indian scenario needs trained and responsive manpower to be proactive to repair and rehabilitate the Bridges. Fund allocation required is huge. There is lack of training and manpower to handle the work of this magnitude. Even in recent past before Indian Bridge Management System (IBMS), Digital Inventory of Structures (Bridges & Culverts) including year of construction of various structures and criteria for defining condition of structures did not look feasible. The historical data of inspections and maintenance works was recorded which was piecemeal and thus it founds to be the main hurdle in developing a scientific management system. If the same scenario continues further which may not provide a better trait for Improving the life span of structures existing on National Highways of country, which in turn will have a direct impact in the development of Country.

Importance of maintenance of any infrastructure to keep it in serviceable condition during its entire service life needs no emphasis. In fact the huge cost invested in creating the infrastructure loses its significance and becomes irrelevant if due attention is not given towards its regular maintenance. A timely and appropriate intervention can only be planned if relevant data and tool for logical & scientific analysis is available.

Indian Bridge Management System (IBMS) is developed to create an inventory of all bridge assets in India and apply a technical logic to manage the Bridge asset during its life cycle. It generates detailed inventory data and condition ratings of assets to ensure that dynamics of deterioration process are captured and this dynamism in the deterioration process guides the inspection and rehabilitation of bridges. The system allows the user to assign priority to maintenance activity based on the present condition of the Bridge.

Indian Bridge Management System (IBMS) is the largest platform in the world with a database of more than 1,61,739 bridge structures owned by single owner.

2 MANAGEMENT OF BRIDGES PRIOR TO AND POST IBMS

2.1 *Pre-IBMS:*

In the earlier days management and maintenance of bridges were done by collecting the data by using the bridge register which were manually written with the technical details and identify the distress visually by standing on the structure by the respective authorities which are kept in the form of hard copies and they can't be able to access and identify the distress that occur in the bottom side of the structure via., girders, bearings, pedestal, substructure etc. Likewise they were collected the data of the bridges which are falling in their respective boundaries, which makes very difficult to access for further references and for further comparison of data to the ministry in order to take the decision. If the same phenomena continues then the management and maintenance of thousands of bridge data had become a real challenge for bridge engineers without having a systematic approach for a decision making. Repairs, Rehabilitation and Retrofitting need authentic, reliable and factual data in real time to enable efficient solutions. In order to overcome these problems a digital platform came into picture which is called IBMS.

The following mishaps which happened in the past one and half year in the country had highlighted for the need of IBMS.

Case:-1 – British Era Bridge Collapse on Mumbai-Goa Highway, Maharashtra

British Era Bridge which is over 100 years old bridge connecting from Mumbai to Goa and is crossing over Savitri River in Raigad district in the state of Maharashtra had collapsed on the mid night of 02.08.2016. Because of this tragic accident around 22 people from two buses had swept away.

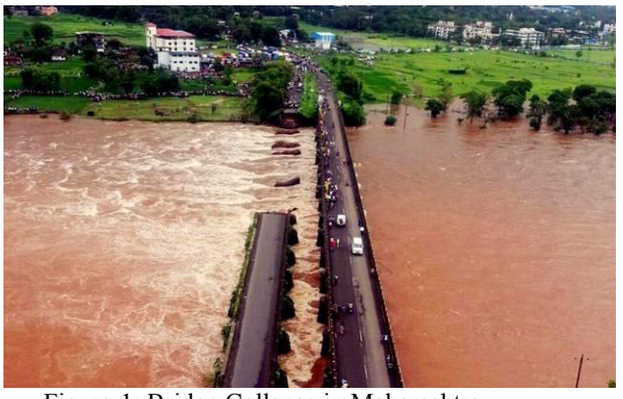

Figure-1: Bridge Collapse in Maharashtra

Case:-2 – Collapse of Bridge in Araria District, Bihar

Collapse of a Bridge which is connecting a village in Araria district of Bihar state on 18.08.2017 had feared drowned 3 people (1-Woman, 1-Girl & 1-Man).

Figure-2: Bridge Collapse in Bihar

2.2 *IBMS System:*

Development of the system posed its own challenge as the system to manage asset had to be developed in a manner where the field studies could be conducted with minimum effort and in which maximum details could be collected. The volume of the database was also posing a challenge; it is anticipated that the overall data base will consist of over 1,61,739 culverts and bridge data. This is a huge volume to handle for a management platform. The bridges have to be given a unique identity number which was the first step of inventory creation. Then their precise location details in form of Latitude and Longitude had to be collected in an Auto mode using the Ground Positioning system. Once these details are collected, the engineering properties of the bridge design, material and other technical details of the bridge are being collected. These are essential components of inventory collection process. On completion of inventory data, the structural component rating is done using a 0 to 9 scale to define the status of various bridge components like Foundation, Piers, Super structure, Deck, Scour rating, waterway adequacy, structural status and also Socio- Economic parameter which decide the importance of the bridge in relation to its contribution to daily social and economic activity of the area in its immediate vicinity. A scale of 0 to 9 was used to ensure that the in-experience of Field engineers (Over 2000) in using rating system does not critically affect our analysis once the inventory is complete.

3 POST IBMS

Data collection is in real time and should have on site stamping for location (Latitude and Longitude) to embed for all bridge data collected. Collection system is capable of uploading photos and data collected by User in Auto mode. On completion of all entries, the bridge data shifts from bridge for Update to Bridge for Submit. The software needs the user to remain online or logged in till the time the data is uploaded or transferred to the server. Classification of bridge is done by a series of alpha numeric strings which is based on specific details of the bridge. There are 5 such strings used to classify the bridge. They being

Table:-1 Classification of Strings

S.No.	Strings used to classify the Bridge	Parameters considered
1	National Identity number	State Code, RTO Zone, Type of road, Road/Highway Number, Chainage and Bridge Cumulative Number
2	Bridge Location number	Latitude & Longitude
3	Bridge Classification number	Structural Form, Material of Construction, Type of Bridge, Loading as per IRC, Age of Bridge, Traffic Lanes on Bridge, Bridge Structure Crossing Feature, Length of the Bridge & Width of the Bridge
4	Bridge Structural and Functional Rating number (SR and FR)	Rating for Deck, Rating for Superstructure, Rating for Substructure, Rating for Bank & Channel, Rating for Structural Evolution, Rating for Vertical Clearance, Rating for Waterway Adequacy & Rating for Scour Efficiency
5	Bridge Socio- Economic rating number (SER)	Rating for Connectivity between two Cities, Rating for Average Daily Traffic, Rating for Social Importance, Rating for Economic Growth, Rating for Alternate Route & Rating for Environmental Importance

Inventory compiles Structural rating (SR), Functional rating (FR) & Socio- Economical rating (SER).Below chart depicts the logical flow of event and decision making within IBMS Inspection and testing module.

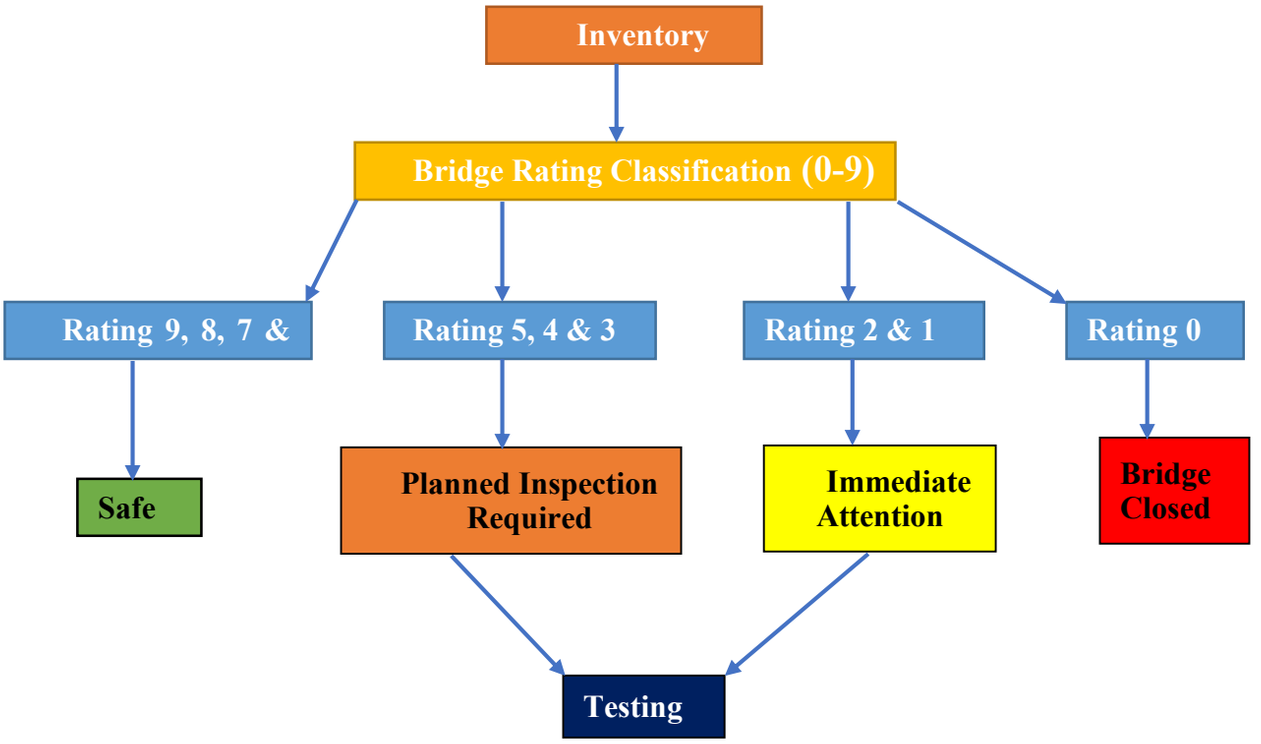

Figure-3: Flow of event and decision making within IBMS (Source: Author)

In the first task, inventory data and rating is completed, the same is required to be validated during the inspection stage.

The second task during Bridge Inspection, the Bridge Inspection Engineer has to ascertain the ratings provided during inventory. This provides for in built validation of data collected during inventory. Based on the observations of the bridge parameters and the environment and traffic condition existing at bridge location, it is essential for the bridge Inspection engineer to reassess the rating provided by the Inventory engineer. This procedure fulfils the need for self-validation of all data that ensures that data used by IBMS in processing is correct and validated.

The third task during the inspection process is to complete the prognosis of distress in bridge if any distress is observed. To be able to do this, it is critical that the Bridge Inspection Engineer to understand the various deterioration processes and what type of distress causes this deterioration process to happen.

3.1 *Identification of Distress Bridges:*

In order to distinguish the distress bridges (Structurally inadequate) in this category we had considered the following components into account,

- Rating for Integral & Non-Integral Deck.
- Rating for Superstructure.
- Rating for Substructure.
- Rating for Scour Efficiency.

By considering the above components into account we had found 6551 number of bridges that are structurally inadequate and their details are given below,

As per the Type of Bridge

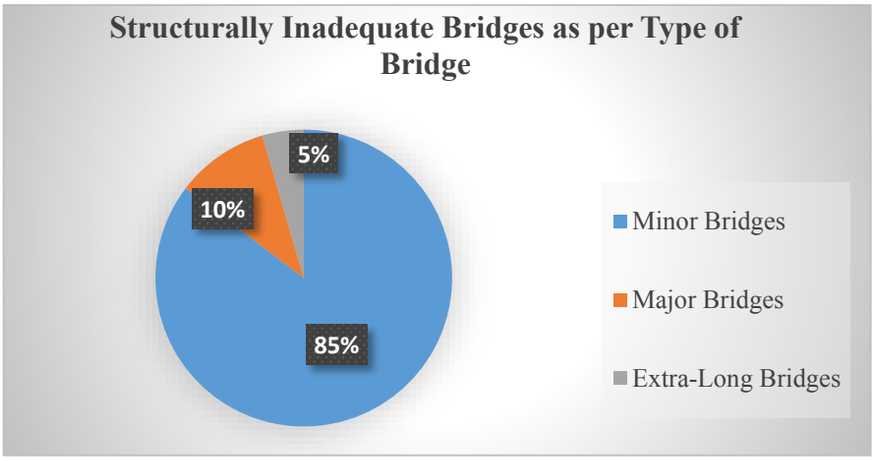

Figure:-4 Structurally Inadequate Bridges as per Type of Bridge (Source: Author)

As per the Age of Bridge

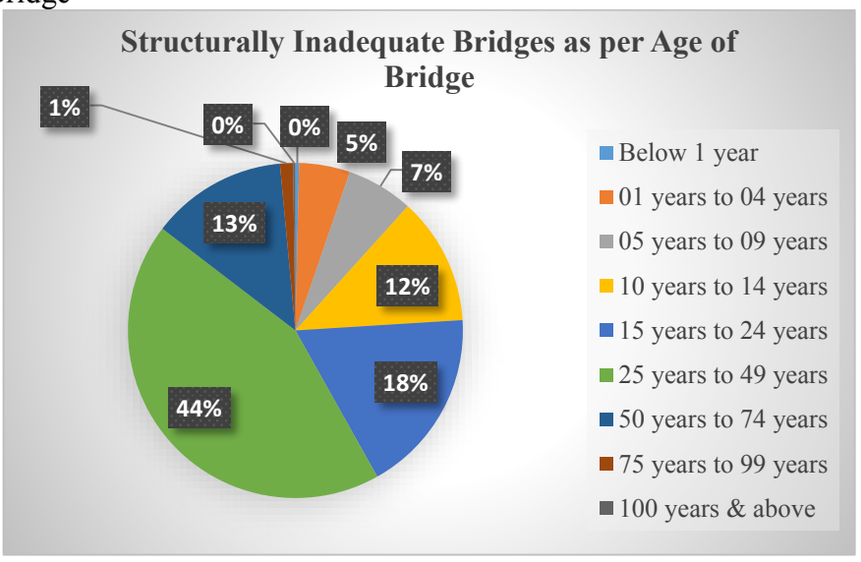

Figure:-5 Structurally Inadequate Bridges as per Age of Bridge (Source: Author)

In order to distinguish the distress bridges (Functionally inadequate) in this category we had considered the following components into account,

- Rating for Bank & Channel.
- Rating for Waterway Adequacy.
- Rating for Vertical Clearance.

By considering the above components into account we had found 4807 number of bridges that are functionally inadequate and their details are given below,

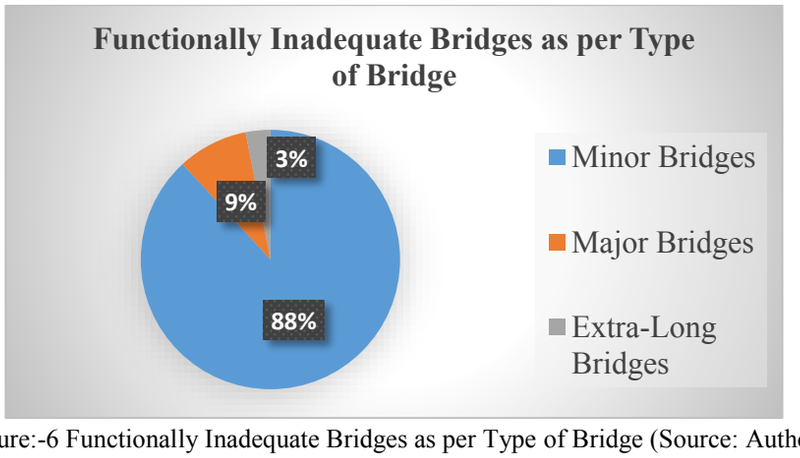

Figure:-6 Functionally Inadequate Bridges as per Type of Bridge (Source: Author)

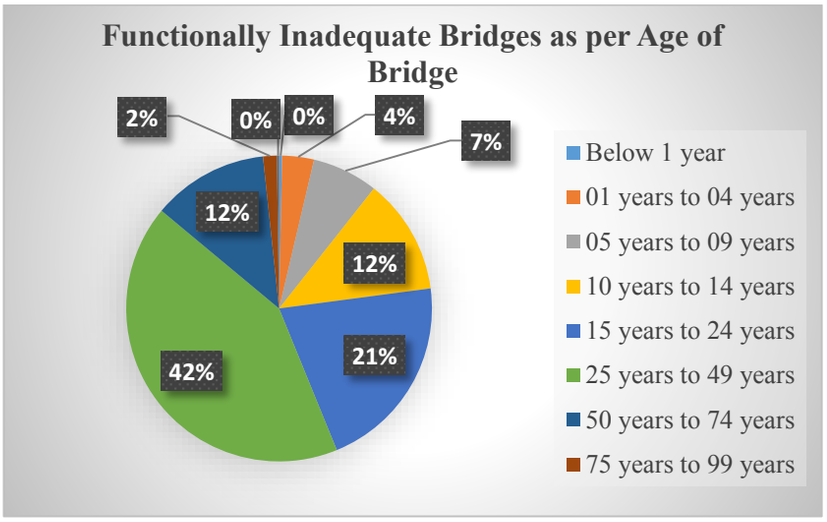

Figure:-7 Functionally Inadequate Bridges as per Age of Bridge (Source: Author)

The Distress in bridge is any situation that is not designed and has occurred. Deterioration is the manifestation or propagation of this distress in a continuous manner to cause alarm. Bridge Inspection Engineer based on his expertise and knowledge will judge the reason for the distress to have occurred and this form the prognosis of distress. The main cause of distress which sometimes results in manifestation of other type of distress or is severe is called the primary cause of distress. The subsequent distress that gets manifested or resultant due to primary distress is called secondary distress. Distress can occur in specific and localized manner as much as it can occur in the overall structure. The final distress map of the bridge may be a result of multiple causes (primary cause and secondary cause) and combined effect of both primary and secondary causes. This could at times make it difficult to determine the correct primary cause. Primary cause can be defined as the cause that is seen to the maximum and has resulted in most extensive distress from among the all the other causes.

Ideally it is better to eliminate the causes rather than identify the cause. This could result in a matrix of causes. From among these identified causes, the primary cause can be confirmed if not properly identified initially.

Based on the cause the following parameters need to be assigned a rating. This assignment is based on the various symptoms observed and for which a rating scale of 0 to 9 is used. 0 rating is assigned for very severe condition and 9 is assigned to no distress condition.

The parameters identified for compilation of deterioration matrix are as defined in below table. These three causes are further classified based on the cause as under and ratings are assigned to each of the parameters from 0 to 9.

Table:-2 Causes of Deterioration

S.No.	Causes	Parameters	Ratings
1	Aggression by Mechanical	Impact	
		Abrasion	
		Erosion, Cavitation & Wear	
		Over load	
		Fatigue	
2	Aggression by Physical	Temperature	
		Shrinkage induced Distress	
3	Aggression by Chemical	Aggression by Carbon dioxide & Chlorides	
		Aggression by Sulphates	
		Aggression by Carbonation	
		Alkali-aggregate reaction	

Once the assignment of rating is done for distress, this is used to identify the method of testing to be adopted. The application of test on the component of bridge is decided by the Structural ratings matrix.

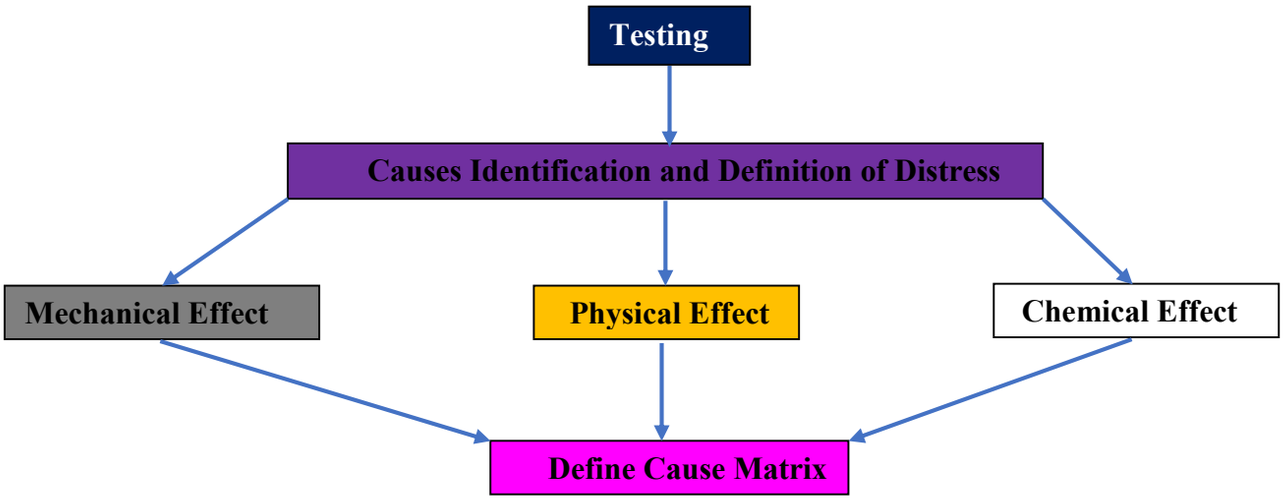

Figure-8: Decision making post testing within IBMS (Source: Author)

3.2 *Define Cause Matrix:*

By defining cause matrix to be able to capture the combined effect of each of the process, we assign rating number to each of the process and then combine these rating in the form of a Deterioration Matrix P.

$$P = \begin{pmatrix} \text{Mechanical} & \text{Physical} & \text{Chemical} \end{pmatrix}$$

This creates the deterioration matrix which identifies the main cause of deterioration and also the secondary cause of deterioration

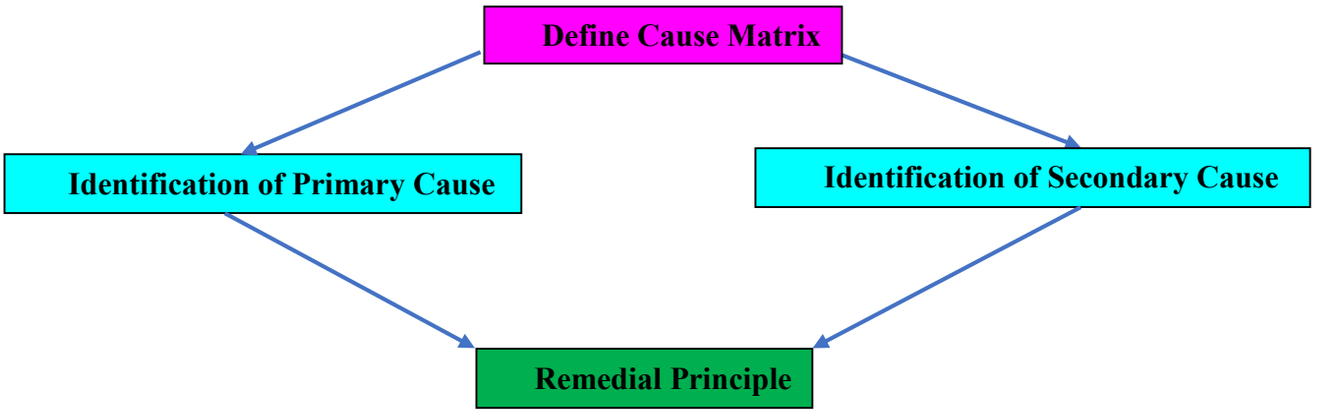

Figure:-9 Decision making post Cause identification within IBMS (Source: Author)

3.3 *Principle Adoption:*

During identification of the cause of distress, laminar behavior of the bridge is to be accounted for most the distress affects the lamina of the bridge component. Such effect causes the surface lamina of the component to deteriorate faster than the section. Such effects are to be recorded and accordingly the repair strategy is to be selected.

Once the principle cause is identified, certain principles only can be adopted to address that cause. However as the bridge structure is massive, contributory factors and principle factor could be affecting the bridge in certain specific areas/ locations. In such cases the locations cause will dictate the repair principle. Certain principle of repair need to applied to the whole bridge structure and such principles have to be applied post all other repair principles are applied.

4 CONCLUSION

IBMS had completed two years of implementation and one major cycle of inventory and inspection had been completed. The first year's work required 20 months to complete due to large volumes of structures to be managed.
The findings of first cycle has resulted in completion of inventory of over 169758 Structures on the National Highway network in India. Of these there are 36,673 bridges. From these bridges IBMS has identified over 6551 bridges to have structural inadequacy and over 4807 bridge to be functionally inadequate.

IBMS aims to render all bridges safe by application of Maintenance Repair/Rehabilitation Strengthening & Replacement (MRSR) modules to the bridges few at a time (presently using the First Repair Worst Damage (FRWD) protocol to bridges whose rating is below 3) and once all bridges are rendered safe (rating above 5), the efforts would be directed to improve on the efficiency of the management of bridges by ensuring all bridges have repeat rating above 6 and would only require timely maintenance.

The above method provides for a logical sequence to decision making and eases the process of decision making till the point where the principles for remedial measures are defined for application. The only thing that is left for the field engineer to do is to be able to properly estimate the correct extend of distress and then define the application area for the suggested remedial measure.

The quantification can also be automated once the as built drawings of the bridges are available and then on this drawing we superimpose the distress. The future of IBMS shall involve application of BIM (Bridge Information Modelling) to IBMS. Technology exploitation is the motto of our IBMS and hence we are looking for future trends that can be applied to this process.

BIM related workflow for an image-based deformation monitoring of bridges

N. Hallermann, J. Taraben & G. Morgenthal
Bauhaus-Universität Weimar, Weimar, Germany

ABSTRACT: Conventional inspections are based on intensive visual investigations. Though, the process of data capturing and post processing for extracting significant structural information, i.e. geometrical changes, is a complex task. Unmanned Aircraft Systems (UAS) offer a significant improvement of inspection and guarantee high quality images which are essential for reliable inspection results. The gathered data can be geo-referenced which offers the possibility of a highly accurate 3D modelling of structures in relation to a direct referenced visualization of detected changes or damages. The paper shows a case study of UAS-based monitoring of bridge pier deformations. An approach for a simplified extraction of basic geometries from 3D point clouds for a quantification of deformations generated from aerial images by the use of Computer Vision methods is introduced. A reproducible workflow for the recording, processing and evaluation of a change detection and condition documentation is provided with regard to Building Information Modelling (BIM).

1 INTRODUCTION

The conventional inspection of critical structures as bridges is based on intensive visual periodical investigations performed by specially trained inspectors. Though, the process of data capturing and post processing for extracting significant structural information, i.e. geometrical changes, is a very complex task. Due to the immense size of large structures, the inspection and thereby the data acquisition is time consuming, technically complex and cost intensive. In particular the inspection of critical structural components and hot spots that are hard to reach is mostly done by specially skilled workers trained as industrial climbers or by the use of specialized equipment.

Unmanned Aircraft Systems (UAS) or often called as drones equipped with high-resolution cameras can simplify and accelerate inspection tasks (Morgenthal et al. 2015). The extreme wind stability of the flight system and the fully compensated camera guarantee high quality images which are essential for reliable inspection results. The gathered data can be geo referenced relating inspection results to locations on the structure. This offers the possibility of a highly accurate 3D modelling of structures in relation to a direct referenced visualization of the detected changes or damages, like deformations or distortions (Hallermann et al. 2014).

The paper shows a possible application and case study of UAS-based inspection and monitoring of bridges or bridge elements. In regard to the post processing, an approach is introduced for simplified extraction of basic geometries from 3D point clouds generated from high resolution images by the use of modern Computer Vision methods. The extraction results are further used for a quantification of displacements, deformations or distortions of the surveyed structure. A reproducible workflow for the recording, processing and evaluation of high quality image-based damage detection and structure condition documentation is provided with regard to an implementation in Building Information Modelling (BIM).

2 DRONE BASED SURVEY OF INFRASTRUCTURE

2.1 *Drone technology*

The rapid technological development of UAS to professional high-end systems in the last years offer the potential for various applications in the infrastructure sector especially for the inspection and monitoring of large and complex structures such as bridges. Based on interdisciplinary research of the authors and project partner Intel, small but powerful drones were developed and designed with the scope on aerial image-based survey and monitoring of structures for supporting the bridge inspectors directly in simplifying and accelerating their data capturing pro-

cess. Aim and result of these projects were the definition of technical requirements for an UAS which are suitable for applications in civil engineering sector. The Intel Falcon 8+, shown in Figure 1, is such a highly professional rotary-wing UAS designed for survey, inspection and monitoring applications.

Figure 1. Unmanned Aircraft System Intel Falcon 8+.

This extremely wind stable up to wind speeds of 15m/s, but very light weight (2.8 kg takeoff weight) and electrical operating system is based on a multi-rotor platform with eight rotors in V-shape configuration. The special configuration with the centered high-performance flight control unit allows for a unique field of view in all flight situations. Equipped with triple redundant Autopilot (AscTec Trinity) a highly accurate stabilization, positioning and orientation of the flight system is guaranteed, also during complex wind conditions and in short distances to the structure. Position accuracy and stability, in addition to the redundancy of each motor-rotor combination guarantee a maximum of safety and allow for complex outdoor and also indoor flight missions. The payload of 800g allows for the use of high resolution system cameras like the Sony Alpha7R (full-frame sensor, 36MP). The camera is mounted on an actively stabilized and compensated camera mount with an adjustable camera tilt of 90° up and down. Flight operation for an automatic data acquisition can be performed by the support of an advanced GPS-based navigation software tool. High-performance battery packs enable flights up to 15 minutes. Current research of the authors and technological developments focus on structure orientated flight missions based on optimized flight paths in relation to a minimized number of images and active collision avoidance systems based on Intel RealSense technology.

2.2 *Pilot studies and former research*

Former investigations of the authors have shown that high quality and high resolution aerial images taken by professional UAS can be used for 3D-reconstructions and also detailed visual damage detection of structures based on modern photogrammetric and computer vision methods. These studies focused on large retaining walls or heritage structures with a well textured surfaces (natural stone) shown in Figure 2.

Figure 2. Investigated structures in former research projects, top: large retaining wall along Highway 4, Germany, bottom: Anna-Ebert-Bridge, Magdeburg, Germany.

The potential and applicability of UAS in the field of civil engineering are shown in different case studies (Morgenthal & Hallermann 2014a, Morgenthal & Hallermann 2014b, Hallermann et al. 2015a, Hallermann et al. 2015b,).

Furthermore, UAS can also help to enhance the different steps in regard to the BIM lifecycle of planning, construction, operation and maintenance and rehabilitation of structures. Other than the above mentioned inspection and maintenance during operation especially the planning process could be supported by current geo-referenced 3D data of construction sites based on aerial images for an interactive and transparent planning process (Fruchter et al 2016).

3 CASE STUDY DEFORMATION MONITORING OF BRIDGE PIERS

The applicability of high accurate UAS and aerial image based survey and deformation monitoring of bridges or bridge element was investigated on a modern semi-integral railway bridge. Due to the special type of construction, the pier heads show large displacements in the longitudinal direction essentially caused by changes in temperature. Therefore, special attention has to be paid for the monitor-

ing of these pier displacements and deformations during the periodical inspection over the whole lifetime.

The case study focused on the UAS-based data acquisition and the determination of the longitudinal pier head displacements and entire deformations of the extreme slender piers at different times respectively different temperatures. Based on high resolution aerial images taken by the UAS close to the structure one pier was reconstructed twice in 3D for the extraction and comparison of displacements and deformations. For this, a simplified approach from high detailed geo-referenced point clouds to single displacement information of the pier was developed.

3.1 *Case study object Scherkonde Viaduct*

The Scherkonde Viaduct is a 576.5 m long and 4 m high semi-integral railway bridge of the new ICE high speed railway track from Berlin to Munich, shown in Figure 3. The bridge was built in 2011 and is situated in Thuringia in the center of Germany.

Figure 3. Scherkonde Viaduct (railway bridge), Germany.

The 14-span girder bridge manufactured in prestressed concrete has a construction height of 2 m at the spans and 3.5 m at the supports. The superstructure is monolithically linked to the western abutment and the piers. The piers are wall slabs with a constant thickness of 1.50 m and have a width of 5.50 m at the top and a constant taper ratio of 1:40. These very slender and flexible piers allow for the compensation of large deformations in the longitudinal direction due to temperature, creep and shrinkage. Due to the construction type and the constraint forces in the system, the piers cannot be connected to the superstructure monolithically in the axes 11, 12 and at the eastern abutment in axis 13. Consequently, bearings that move longitudinally are used there. The western abutment in axis 0 is a fixed point to carry the longitudinal forces. At the eastern end of the bridge there is an expansion joint that compensates the large deformations. The foundations of the piers were constructed with large-bore piles of up to 19 m in length, so that can be assumed a fixed support of the piers.

3.2 *Data acquisition and 3D-reconstruction of a bridge pier for deformation monitoring*

For the investigation of the pier head displacements due to temperature changes on the longest piers with a length of approx. 32 m was recorded twice, first in August 2016 (mean temperature of 19°C) and second in April 2017 (mean temperature of 6°C), in team operation from all sides by using an Intel Falcon 8. The investigated pier is shown in Figure 4 left and the data recording in team operation (one UAS-pilot and one camera operator) in Figure 4 right.

Figure 4. Investigated pier of the Scherkonde viaduct. Data recording in team operation (right).

Due to the safety features of the flight system and the very experienced pilot team, the recording could perform under complex weather conditions and under running traffic without any disturbances. The aerial images should be used for a highly accurate 3D-reconstruction. Furthermore, they should also be used for automatic surface analysis, e.g. for an automatic detection of anomalies like cracks or stainings. This requires a very high resolution of the pier surface in the aerial images. That leads to a maximum recording distance of 4.5 m to the structure. The recorded images with a mean object resolution of 0.6 mm/pixel were used for a geo-referenced, true scale and color fidelity 3D-reconstruction using modern Computer Vision methods like Structure-from-Motion (SfM) explained in (Hallermann et al. 2015a). SfM requires a minimum image overlap of 70% in the horizontal direction and 30% in vertical direction which leads to a very high number of aerial images. The 1250 images were recorded on 10 vertical lines around the pier only from bottom to the top of the pier shown in a schematic view Figure 5. It shows that the manual data recording leads to a various distance and angles of view to the object which influences the accuracy and quality of the 3D reconstruction of the pier directly. To avoid such position variations in data recording structure orientated flight path and reliable collision avoidance systems has to develop and implemented directly on the UAS.

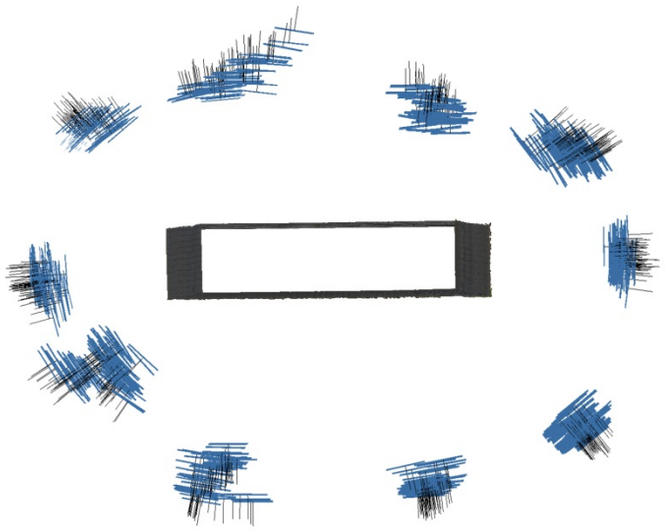

Figure 5. Reconstructed image positions around the pier, view from above.

The whole process of data capturing of one pier was completed in only 25 minutes.

The geo-referencing of the images respectively the point cloud was carried out by only 4 ground control points attached next to the food of the pier and determined by conventional tachometry. These ground control points or often called markers have to be well recognizable in the aerial images and measured as accurately as possible. Based on the high image quality and resolution (RAW-data processing) a dense RGB-coded point cloud could be generated for 3D-modelling of the pier in detail. Figure 6 shows the color-coded 3D-point cloud of the pier.

Figure 6. RGB color coded roughly cut 3D point cloud of the investigated pier (110,000,000 points, height approx. 29 m).

For the 3D-reconstruction of the pier, only a quarter of the maximum image resolution was used. The generated point cloud contains approx. 110,000,000 3D color-coded measurement points. Table 1 summarizes the recording parameters and the results of the 3D-recontrution of the pier of the measurement campaigns.

Table 1. Record parameters and reconstruction results.

No. of images	1250
mean Object distance	4.50 m
mean image resolution	0.6 mm/pixel
3D point cloud	approx.110,000,000
accuracy	± 1.7 mm
3D-object resolution	2.4 mm/pixel
point density	17 points/ cm²

Further tests and analysis with the generated data sets show that much more dense 3D reconstructions were possible by using the half (approx. half a billion points) or the full resolution (approx. 2 billion points) of the images. That leads to billions of measurement points which help to detect small geometrical defects on the pier surface (concrete spellings) but leads also to a rapidly increasing amount of data. So cloud to cloud or cloud to mesh comparisons are extremely computationally extensive and time consuming.

3.3 *Information extraction – pier displacements and deformations*

The extraction of significant information regarding displacements and deformations based on 3D point clouds leads to a possible structural evaluation of the structural condition. Depending on the accuracy and density of the given point cloud, the complexity of the geometry and the parameters for a certain analysis the extracted information can differ in terms of significance. The case study on the previously explained bridge proposes a method for the analysis of point clouds from bridge piers and highlights some of the main adjustments that can influence the analysis results. The aim of the method is the extraction of the displacement at the pier head and the deformations along its height. To show the analysis steps two piers were recorded in different seasons and therefore different temperature conditions are used.

3.3.1 *Point cloud analysis*

The developed method requires a rectangular cross section of the test object that can change the dimensions along the height of the pier as in the example. To enable a comparison of more than one analysis the point clouds should be geo-referenced or at least

have an equal start and end point. Before starting the automatically process of displacement extraction the generated roughly cut point cloud has to be preprocessed in that way that the pier is cropped exactly at the joined between pier and superstructure. Due to the soil covered pier foot of approx. 2 m, it has to be considered that the starting point of the pier could not be recorded by images and also is not reconstructed.

Step 1 divides the point cloud in a defined number of sections S along the longitudinal axis. The result is an array of cross sections where the four edges and the center point have be extracted. Depending on the ratio of S to the absolute number of points in the cloud n results the number of points contained in a section that should be enough for the following edge reconstruction. Figure 7 shows exemplarily selected sections from the original point cloud which has a total height of 28.750 m. Divided into 200 sections each section covers a height of 14.375 cm containing average 500000 points. The values x and y are indicating the position in the local coordinate system of the entire bridge itself. That means y describes the longitudinal and x the transverse direction of the bridge.

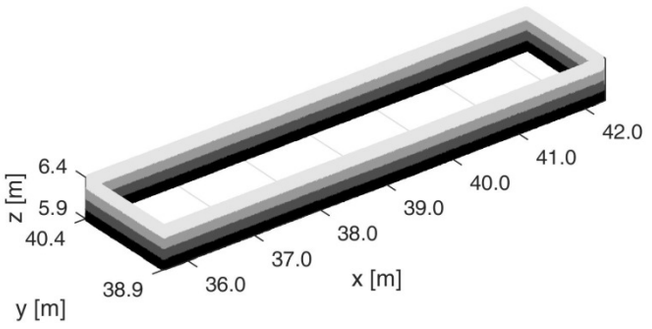

Figure 7. Exemplary view on a subset of 4 sections separated from the original point cloud of 100,000,000 points with a height of 14.375 cm each

Step 2 takes each section and fits a linear function on a defined percentage of points p contained in the single sides of the cross section. The resulting intersections form all edges of the cross section and accordingly the intersection of the diagonals is generating its center point. It is not recommended to take the edge points directly from the raw point cloud, i.e. by a bounding box. In this case the missing accuracy while reconstructing sharp edges using image based reconstruction methods leads to significant reduction of analysis precision and increases the number of outliers in the longitudinal axis. Furthermore, typical edges on concrete structures are beveled that a direct picking of the edge in the point cloud is not possible. Important for the selection of relevant points is to balance a preferably high percentage of possible points excluding the influence of the noised edge areas as shown in Figure 8. For each face, 80% of the possible points were selected which is expressed by the points colored in black.

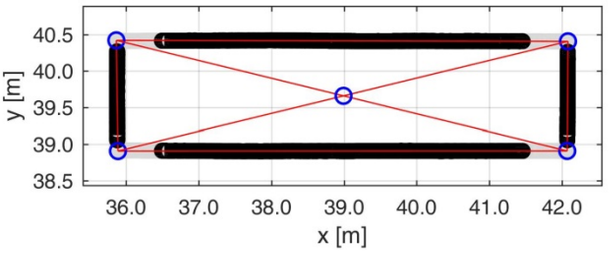

Figure 8. Raw points of a cross section (grey) reduced from 475,417 to 389,112 relevant points used for the linear fit (black) and the constructed edges and center points (circles) of the 100th of 200 sections at a height of 14.55 m at the bridge pier.

Step 3 merges the constructed center points of each cross section. A figure of the real position of these points along the longitudinal axis with a discretization directly related to S is assembled. After this step, outliers could be identified and eliminated before a comparison of two different states respectively point clouds. Figure 9 shows a mapping of the constructed edges by the described method. On height 27.2 m reconstruction outliers due to anomalies in edge detection can be identified and eliminated before further comparisons.

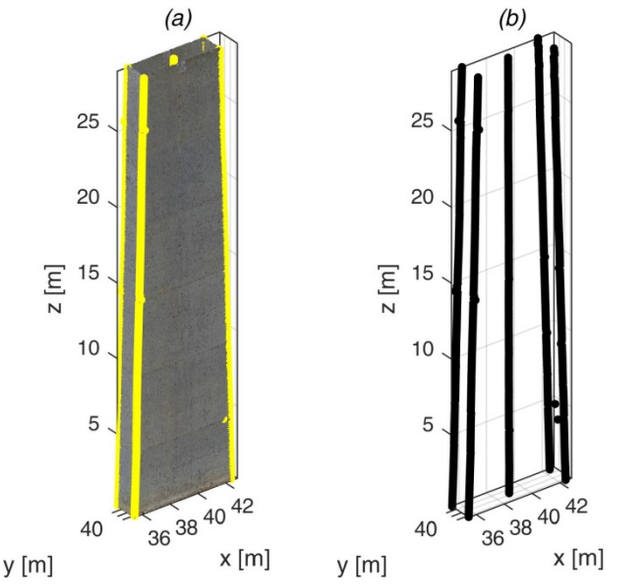

Figure 9. (a) Original point cloud with constructed edges composing 200 sections (grey) and (b) view on single edges including the longitudinal center axis which is used for further comparison

Step 4 includes the comparison of results regarding the differences of center points of different states to get the deformations along the longitudinal axis of the bridge pier and the total displacement at the pier head. The average amount of relevant points n_r that

were used for the reconstruction process are estimated by

$$n_r = \frac{p \cdot n}{S}$$

This value can be used to evaluate the significance of possible results regarding the complexity of the analyzed geometry. Figure 10a shows the comparison of the longitudinal center axes positions of two states with a ΔT = 13 K and Figure 10b the related differences of the positions configuring the deformation figure (grey) of the bridge pier in longitudinal direction combined with a smoothed function.

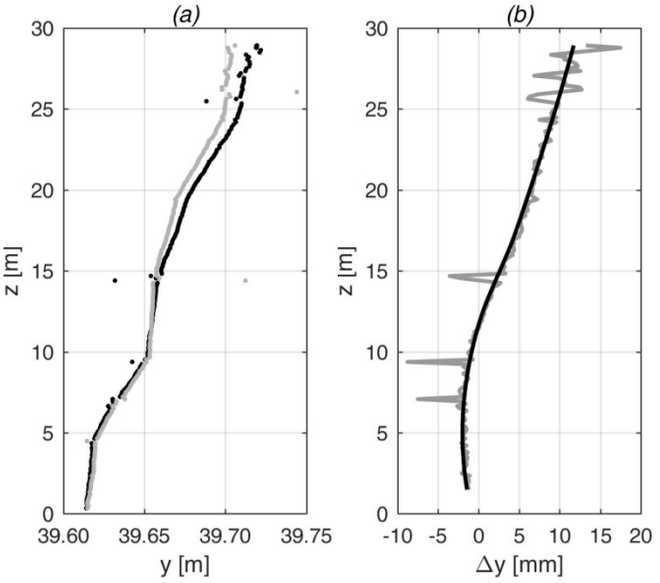

Figure 10. (a) Comparison of the longitudinal center axes positions of two states with a ΔT = 13 K and (b) the related differences of the positions configuring the deformation figure (grey) of the bridge pier in longitudinal direction combined with a smoothed function (black).

3.3.2 *Parameter study*

For the point cloud analysis the main parameter n, S and p were investigated regarding their influence on the single analysis steps and the results. Therefore the original point clouds of 100,000,000 points were subsampled with random distribution to four considerably smaller point clouds. The incremental reduction should represent a minimum number of points or minimum point density to get reliable results.

Figure 11 shows the compared cross sections of randomly subsampled point clouds considering (a) a section of a 200,000 points cloud reduced from 963 to 780 relevant points, (b) a section of a 100,000 points cloud reduced from 476 to 390 relevant points, (c) a section of a 50,000 points cloud reduced from 239 to 196 relevant points and (d) a section of a 25,000 points cloud reduced from 118 to 92 relevant points

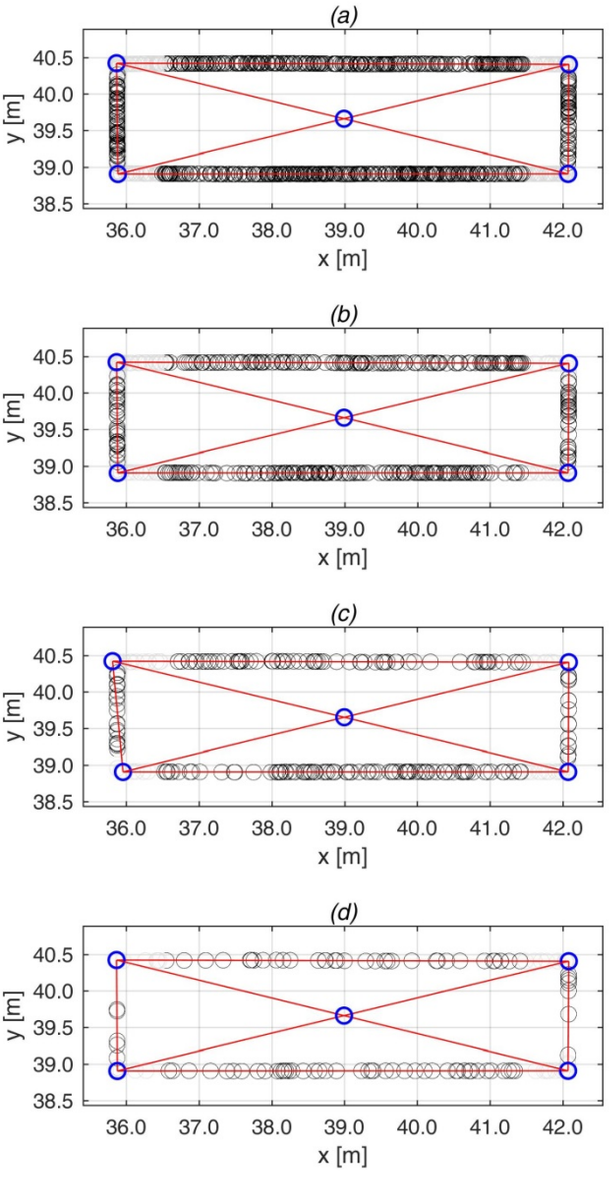

Figure 11. Compared cross sections of randomly subsampled point clouds considering (a) a section of a 200,000 points cloud reduced from 963 to 780 relevant points, (b) a section of a 100,000 points cloud reduced from 476 to 390 relevant points, (c) a section of a 50,000 points cloud reduced from 239 to 196 relevant points and (d) a section of a 25,000 points cloud reduced from 118 to 92 relevant points.

The comparison was done by the previously described states from August 2016 with an average temperature of 19°C and from April 2017 with an average temperature of 6°C. As Table 2 shows it is possible to achieve comparable results even if the size of the original point cloud was reduced to 0.025%. Of course the simple rectangular geometry of the cross section is supporting this effect, but it shows that the detection of deformations is already possible at a small amount of data which effects also a small amount of needed storage.

Table 2. Characteristic values and the displacements at the top of the pier from analyses of the given point clouds with the parameters p = 80 % and S = 200 on the bridge pier of h = 28.75 m height, a surface area of A = 445.34 m² and a temperature difference of ΔT = 13 K.

Total points (point cloud)	Point density [pts/m²]	average n_r/section	Δx [mm]	Δy [mm]
100,000,000	224,549	400,000	-6	10
200,000	449	800	-6	13
100,000	225	400	-7	13
50,000	112	200	-8	11
25,000	56	100	-9	10

For point clouds smaller than 25,000 points the reconstruction of most sections was incomplete and thus the edges not extractable using the developed algorithm. In the shown case the growing uncertainty of reconstruction is the consequence of a less detailed described surface. The points itself keep their precision as previously described. Additionally reducing the number of points gives more weight to outliers or defective reconstructed points.

4 CONTEXTUAL DATA MODELING

During the entire workflow for image based deformation analysis, a high amount of heterogeneous data compared to a single recording of reference points is accumulated that should be somehow connected to a related building model for further monitoring and evaluation. Namely the flight path for the UAS data recording, recorded high resolution images, point clouds and the analysis outcome including the inputs for each processing step should be context related and time-referenced stored to have a well-documented inspection report. To link this extremely high amount of data to building models it requires a certain level of compression and filtering for effective access in the future. Open data bases which keep the main part of non-interpreted data in a common readable structure linked to an inspection object in a building model could be one approach. The outcome of point cloud analyses that covers only the pure deformation data could be written directly in a building information model to keep the relevant information for inspections exchangeable with the building element information. This method enables the separate use of the entire monitored data and other building information while having a logical link among them which enables a comparison and evaluation of consecutive inspections.

5 ACKNOWLEDGEMENTS

This work was supported by the Free State of Thuringia and the European Social Fund (ESF) under the project number 2016 FGR 0026. Furthermore, the authors would like to thank the Deutsche Bahn Netz AG for their support of the flight campaigns and Intel for the technical support.

6 CONCLUSIONS

This paper presented a promising approach and the capability of using Unmanned Aircraft Systems (UAS) for the aerial image-based deformation monitoring of bridges or bridge elements including geo-referenced highly accurate survey. The high-end flight systems provide a fast and safe data acquisition without causing disturbances in usability of the structure. Here the bridge inspectors will be noticeably relieved. The high-quality image data can be used for geo-referenced analysis of the structure based on modern photogrammetric computer vision methods. This could drastically increase the efficiency of monitoring. The modern computer vision methods described allow the fully automatic generation of a dense 3D reconstructions from digital imagery. After performing successful test on real structures future research should be focused on methods for automatic damage detection and quantification of damage. Automated evaluation process could lead to an objective and improved damage detection.

Utilizing BMS to Develop Programs and Reports for PEI Transportation

D.J. Evans
Department of Transportation, Infrastructure and Energy, Charlottetown, Prince Edward Island, Canada
R.M. Ellis
Stantec Consulting Ltd, Edmonton, Alberta, Canada

ABSTRACT: The Prince Edward Island Department of Transportation, Infrastructure and Energy (TIE) is responsible for the densest network of roadway and bridges per capita. Over the last 11 years, TIE has taken steps to implement bridge management processes including implementing an advanced bridge management system (BMS) which has enabled the department to make significant improvements in the management of inventory and inspection data, the inspection process, tracking and reporting condition thru a standard condition index, performing asset valuation, and in handling of inspection photos, videos, plans and other documents.

TIE are optimizing treatment costs for maintenance and replacement costing models as well as utilize the BMS's powerful analytical tools in determining their Capital Program for five years and ten years, including placing limits on available budgets. Risk principles are being applied using Bridge Criticality and Urgency (BCU) and Risk Analysis to determine structures which pose significant risk. TIE have also adopted a bridge asset valuation methodology and are in the process calibrating Sufficiency Index (SI), which includes appraisals of load carrying capacity, scour, flood, seismic, safety as well as condition and risk, all of which are handled by BMS.

The department utilizes the BMS to analyze the inspection data and develop a five year capital program based on lifecycle cost analysis, and correlating the results of the network bridge condition index and risk profiles produced by the BMS.

The department also utilizes the data produced by the BMS to report on the current and forecasted overall condition of the network to the Minister and Deputy Minister of TIE, as well as other key performance indicators.

This paper will look at the methods the department uses in order to determine their capital program as well as review information that is reported to the Minister and Deputy Minister on an annual basis.

1 INTRODUCTION

The Province of Prince Edward Island (PEI) is situated on the east coast of Canada and is the smallest of all the Canadian Provinces.

The Province has 5660 km of natural waterways throughout its land mass and is crossed at various locations by 5600 km of roadway network with over 1500 structures.

The Province has three main sources of income, which include tourism, agriculture and aquaculture.

The Province has spent the last 9 years developing and maintaining a Bridge Management System (BMS) for the provincial network of structures. Of the 1575 structures, only 266 are inspected on a biennial basis (IE. Once every two years). As of the end of 2015, the department will have completed a fifth full round of biennial inspections.

This paper discuss how the Province is tracking the overall Bridge Condition Index (BCI) and Risk Profile (BCU) over time based on the current budget constraints by utilizing some of the analytical tools which are incorporated into the BMS for their forecasting and budgetary considerations.

2 BRIDGE INSPECTION ON PEI

2.1 *Inventory*

The department has roughly 1575 structures province wide that we are responsible for. Of these, we have only inspecting 266 larger, bridge type structures with a few larger buried structures.

Like most jurisdictions across Canada, our inventory is a product of the construction boom from the late 50's to the early 90's. A good portion of the Province's inventory is at or very near its intended design life and many structures are nearing the end of service life.

Like most all jurisdictions, the department continues to struggle with condition of the inventory

and the available capital dollars which are available to address these issues.

More information regarding the evolution of bridge inspections and bridge management in Prince Edward Island can be found in Evans et.al, 2014 and Evans, et.al, 2012.

3 BRIDGE MANAGEMENT SYSTEM

3.1 *Evolution of BMS on PEI*

Like most other jurisdictions, PEITIE have historically relied on hard paper copies of our safety inspections with a rudimentary spreadsheet for asset management data. This housed such information as structure ID, structure type, material, span length, age (if known), location, route number, and other basic information.

After a literature review, the department decided on the best fit BMS for our inspection program, which was Ontario Bridge Management System (OBMS) (Thompson et.al, 2003).

The department's consultant had been working on significant improvements to the OBMS and in 2010 the department licensed and implemented the new Stantec BMS 2010 platform as the new PEI BMS (Evans et.al, 2010).

3.2 *BMS 2010*

The PEI BMS accepts inspection data in the OSIM format, calculates the Bridge Condition Index (BCI), produces all of the reports the previous system produces, and provides several other significant enhancements. The BMS meets or exceeds all the requirements of documents such as the AASHTO Guide to Bridge Management (AASHTO, 1994) and Bridge Management in Europe (BRIME 2002).

BMS2010 offers the following capabilities that were of interest to the Department:

1. Improved photo, video, document management including search capabilities,
2. Automated project scoping and treatment selection using engineering models and benefit-cost analysis ,
3. Element, project and network level risk analysis,
4. Network-level priority programming and budgeting,
5. Network and individual bridge target performance analysis,
6. Risk-based decision making (See Figure 1),
7. Risk-based setting of inspection frequencies.
8. Bridge asset valuation
9. Tracking Critical Findings
10. Automated reporting of key performance indicators (KPI)

For further information regarding the capabilities of BMS2010 and other features, please refer to Evans et.al, 2014, Evans et.al, 2012, Ellis et.al, 2012 and Dalziel et.al, 2012.

4 TRACKING AND FORECASTING BRIDGE CONDITION AND RISK VERSUS BUDGETS OVER TIME USING ANALYTICAL TOOLS

The Province uses the analytical tools available in the BMS in order to greatly assist with the capital programming, for an annual and 5 year basis, to determine what projects should be completed first and what can be deferred until after the 5 year period.

The Province is also tracking the condition and risk profile across the entire network of inspected structures and reports on the overall trend as to whether or not we are seeing improvement in the overall network condition and risk, or if more resources are required.

Additional information regarding BMS2010's analytical tools can be found in Evans et.al, 2014.

4.1 *Tracking Condition and Risk versus Budgets over time*

4.1.1 *2016 Bridge Condition Index (BCI) Results*

The results of the condition inspections conducted in 2017 yield an overall Bridge Condition Index (BCI) for each structure. BCI is grouped into three categories corresponding to GOOD (BCI>70), FAIR (60<BCI<70), and POOR (BCI<60). Structures that are in POOR condition generally are found to have maintenance or rehabilitation needs with near term timing (now or within 5 years). Structures with FAIR condition can be expected to not have needs for more than 5 years, while structures in GOOD condition have no needs in the next 10 years.

PEI TIE are also able to review the BCI distribution over the entire inspected network and see where our threats are moving forward in the very near future.

4.1.2 *Risk Profile*

The department has been inspecting structures using a BCU rating since 2011 and we have been tracking the risk profile of the inspected network since this time. In general, the higher the BCU rating, then the higher risk category the structure is in.

We currently have a matrix of risk from low, medium, medium–high and high risk category. The matrix is indicated in Figure 7 for all inspected structures. As can be seen, the tables and graphs indicate

that the department is currently at risk, as over 25% of the network is in High risk, and over 27% is in Medium-High risk. PEI TIE is currently reviewing our five year capital bridge construction plan to include these structures in the program. The department is also looking at conducting more periodic reviews of our higher risk structures in order to maintain an acceptable level of safety across the network. The Risk Profile is specifically designed to address risks associated with structure element condition and considers element type, structural behavior and failure mode, condition, defects and criticality of defects, together with structure importance, traffic volume. More details are available in Ellis et al, 2012.

4.1.3 *Structure Sufficiency Index*

PEI TIE has been experimenting with a prototype Sufficiency Index. The structure Sufficiency Index (SI) is a compilation of the BCI, BCU as well as other important operational factors; such as, load rating; scour potential; flood potential; fatigue critical elements; approach road geometry; structure lane width; barrier index; etc..

Additional information can be found in Evans et.al, 2016

4.2 *Condition and Risk Tracking vs. Budgets*

We have been tracking the BCI breakdown of the network of structures since 2012. We have also tracked the risk profile of the structures since 2011. The following table outlines the BCI Breakdown from 2012 through to 2016. So, the natural question becomes, “How are we doing?”

More information can be found in Evans et.al 2016.

5 REPORTING CONDITION, RISK AND PROGRAMMES TO DEPARTMENT HEADS

The Bridge Management Software is an excellent tool in providing high level information to the department heads and directors.

The department reports annually to the senior management both in written form and through presentation.

5.1 *Reporting to Senior Management*

Once TIE staff are satisfied that the inspections are complete and closed, the analysis is completed and verified and the prioritization is complete, we are then comfortable with reporting this to senior management.

Reports typically begin with the evolution of our bridge inspection and bridge management program. Since senior management changes from time to time, this is always included.

Reporting will then dive into our network, our inspections for the previous season and the results of our Bridge Management Software as well as out proposed 5 year program (discussed in Sec. 5.2).

In general we report on the inspection results, including: BCI (see Tab. 1 and Fig. 1); BCI Distribution (see Fig. 2); Risk distribution (see Fig. 3); BCI and Risk trending (See Figs 4, 5); and Sufficiency index (See figure 6).

The BCI has been found to be useful not only as an excellent condition reporting tool; but, also as a performance measure. For example, the condition of an inventory can be entirely represented with the following figures:

- average BCI = 70.3
- distribution of G/F/P equal to 47% / 27% / 26%.

Table 1 – BCI Breakdown of All Inspected Structures

Condition State	Percentage of Inspected Structures
Good (BCI > 70)	47 %
Fair (60 < BCI < 70)	27 %
Poor (BCI < 60)	26 %
Average BCI	70.3

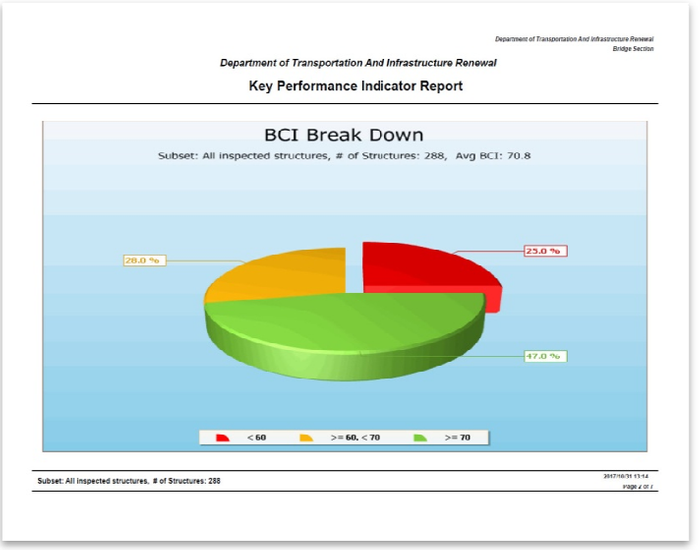

Figure 1- BCI Breakdown All Inspected Structures

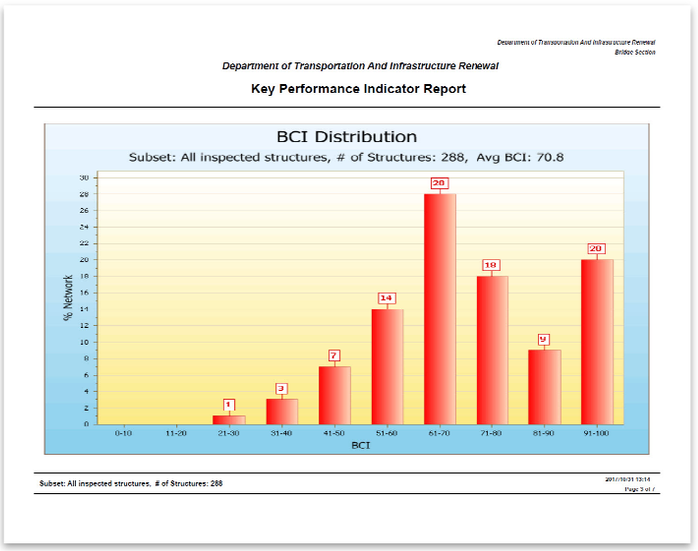

Figure 2 – BCI Distribution All Inspected Structures

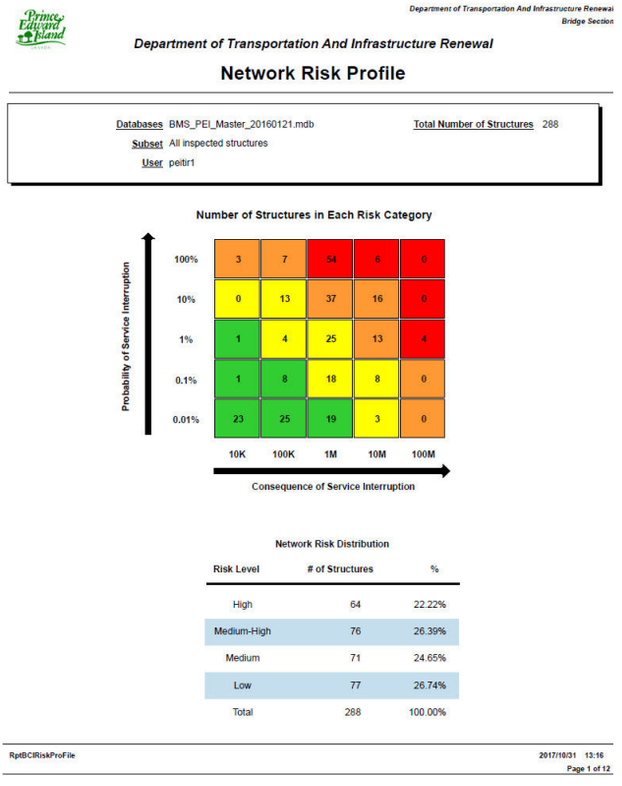

Figure 3 – Network Risk Profile

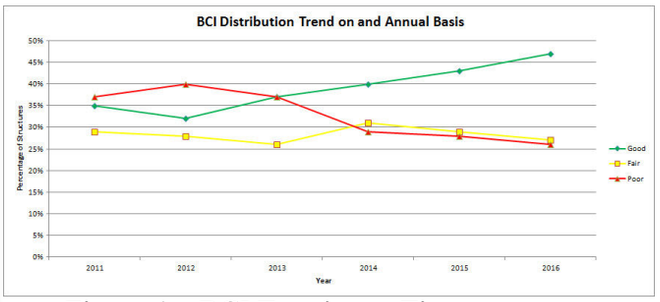

Figure 4 – BCI Trend over Time

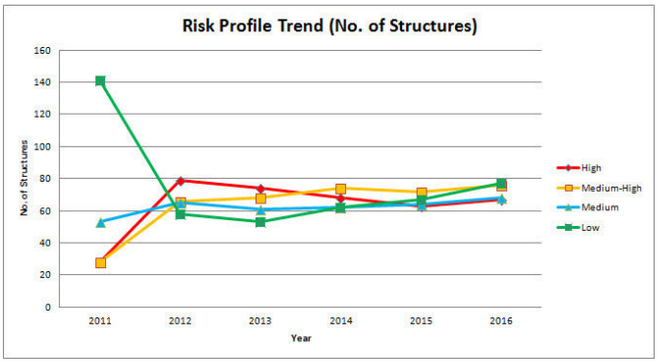

Figure 5 – Risk Profile Trend over Time

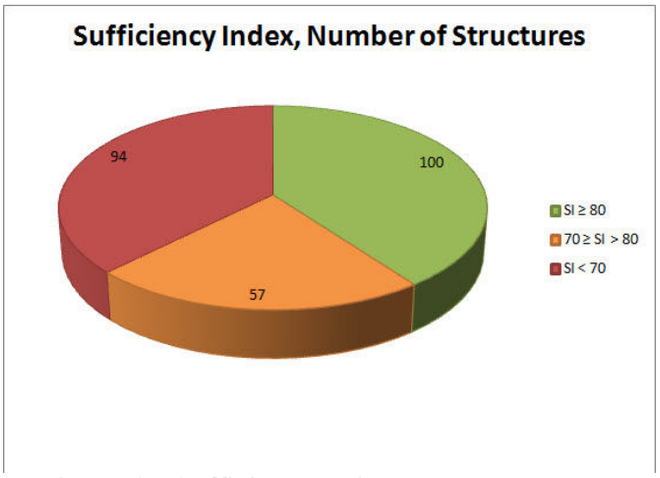

Figure 6 – Sufficiency Index

In conjunction with this, we also report on suspected performance deficiencies and associated maintenance needs or recommended works. See Tables 2, 3 and 4 for a summary of the inspection findings.

Table 2 – Performance Deficiencies

Performance Deficiency	No. of Occurrences
1-Load Carrying Capacity	1033
2-Excessive Deformations	86
3-Continuing Settlement	45
4-Continuing Movements	124
5-Seized Bearings	8
6-Brng. not Unif.Load/Unstbl.	20
7-Jammed Expansion Joint	9
8-Pedestrian/Vehicular Hazard	280
9-Rough Riding Surface	101
10-Surface Ponding	21
11-Deck Drainage	20
12-Slippery Surfaces	0
13-Flooding/channel Blockage	15
14-Undermining of Foundation	40
15-Unstable Embankments	77
16-Other	233
TOTAL	2112

Table 3 – Maintenance Needs

Maintenance Need	Timing			No. of Occurances
	Now	1 Year	2 Years	
1-Lift/Swing Bridge Maintenance	0	0	0	0
2-Bridge Cleaning	13	44	25	83
3-Bridge Handrail Maintenance	43	157	156	357
4-Painting Steel Bridge Struc	0	20	42	62

11-Animal/Pest Control	2	2	1	5
12-Bridge Surface Repair	5	32	61	98
13-Erosion Control at Bridges	22	42	58	123
14-Concrete Sealing	0	0	2	2
15-Rout and Seal	1	16	64	81
16-Bridge Deck Drainage	2	12	9	23
17-Other	92	116	165	377
TOTALS	204	599	1247	2061

Table 4 – Recommended Works

Timing	No. of Occ.	Cost
Urgent	28	$904,440
< 1 year	116	$2,639,857
1 - 5 year	463	$9,521,860
6 - 10 year	98	$1,810,235
None	4	$20,200
Total	709	$14,896,592

Based on the information above, we utilize the BMS' forecasting tools to report on future condition of the network, in Periods 1 and 2, based on three scenarios. These are: 1) Do nothing (shown in figure 7); 2) Unconstrained budgets (shown in Fig. 8); and 3) Constrained Budget (shown in Fig. 9).

Figure 7 – BCI Forecast Summary – Do Nothing

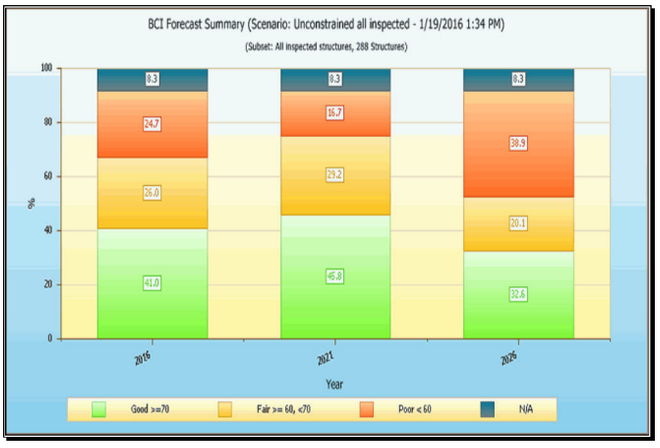

Figure 8 - BCI Forecast Summary – Unconstrained Budgets

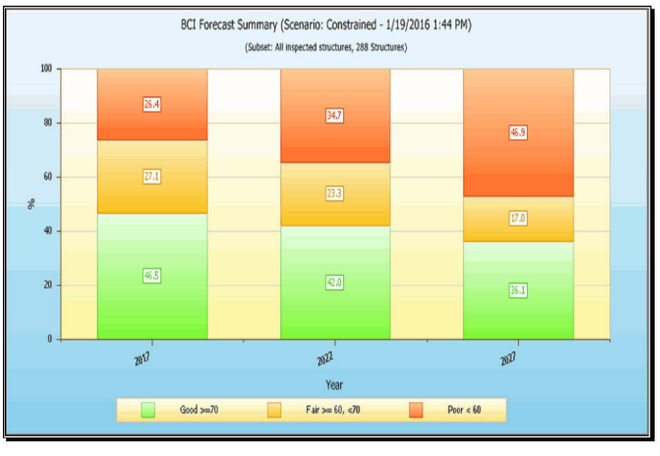

Figure 9 - BCI Forecast Summary – Constrained Budgets

5.2 *Program Development*

Once the annual inspections are complete and the consultants have reviewed them critically, the department reviews the inspection information for completeness, accuracy and consistency. Early inspection reports required 3 to 4 iterations of this; however, due to time and experience, the department

has only very minor comments on each inspection cycle.

Once the inspections are finalized and closed, only then do department staff begin to develop the bridge program, looking at Period 1 (Years 1 through 5) and Period 2 (Years 6 through 10); however, we only report on Period 1.

The bridge program is formulated by the following routine:

- *Review of the BCI values and determine the risk factors associated which each structure that are in fair to poor condition state.*
- *Conduct a Project Analysis for the structures with unconstrained budgets to determine the actual need in any given period P1 or P2. Conduct an analysis with constrained budgets, setting the Risk analysis factors to 100 (IE do not include risk).*
- *Conduct an analysis to include constrained budgets and risk parameters.*

Once all of the program analyses are complete, we can then correlate the results and determine the best course of action based on the inspection data only.

We then look at factors such as geometric and functional obsolescence, importance of highway network (local road, collector, arterial, etc.) as well as Average Annual Daily Traffic (AADT) and Average Daily Truck Traffic (ADTT) on each of the structures on the program in P1. Since the system is not capable of allocating budgets to account for the socio-economic impacts of the proposed structure replacement(s), the department needs to do this manually.

After this is done, we can then start prioritizing the program based on the project analysis conducted by the system, the highway classification, the AADT and ADTT and the condition and risk parameters set forth through the inspection program. This will become our 5 year program and this is what gets reported to senior management (see Fig. 10).

Figure 10 – 5 Year Program List

6 CONCLUSIONS AND CLOSING REMARKS

Since 2007, the department has come a long way in how we manage our highway bridge assets, from virtually nothing to implementing and using a state-of-the-art bridge management software system. The system is capable not only of collecting basic information of each structure; but, integrating the inspection data and developing a bridge condition index (BCI) for each structure.

Using the network-level priority tool and automatic project scoping tool, the BMS will conduct life cycle cost analyses and benefit/cost rations for each structure, based on the element condition data entered into the BMS. The system will then calculate a capital program for a variety of user defined scenarios; such as, ‘do nothing, unlimited budget, constrained budgets, or key performance targets.

In concert with this, we have trained our inspectors to identify the criticality and urgency of any given element on the structure and the system will

conduct a risk analysis on the entire network to determine those in the high risk categories versus those in the lower to medium risk categories.

The department now relies very heavily on the inspections and BMS analysis in determining its capital program for the next 5 years and forecasting to 10 years. It must be stated; however, that while this tool is extremely useful in determining our capital program, it is not a replacement for engineering judgment, which we exercise on a routine basis.

The BMS output and subsequent reports to Senior Management outlines the need for additional funding in order to maintain a serviceability of the highway structure network. There are areas of significant risk that the department is assuming on a number of structures that are currently being inspected. We have no real indicator on how this translates into the remaining portion of the highway network that is not currently being inspected; however we are beginning to include these structures in our inspection program It will take several years for this data to be input into the system and calibrated.

With the reports and graphical representations that are reported to Senior Management, we have been successful in obtaining additional funds for capital investments across our network of bridge structure. Senior management can quickly visualize the importance of the bridge structure network, the condition and risk parameters associated with the network and what the consequences are if budgets remain stagnant or decrease over time.

We are reducing the number of structures on our network by closing or severing non-essential or seasonal roads as required.

In closing, we will continue to conduct routine inspections on our network of structures and are beginning to include all our smaller structures. We realize that budgets are constrained and we will continue to work within these confines as required; however, the reports show that there will be consequences as a result.

7 ACKNOWLEDGMENTS

The Department would like to acknowledge Stantec Consulting Ltd., the consultant for the bridge management program, the BMS implementation project, inspection training courses, and support of the bridge management system.

Creating the basis for implementing BIMS in existing infrastructure components

J. S. Jensen & F. R. Gottfredsen
COWI A/S, Denmark

ABSTRACT: In recent years the concept and use of a Building Information Modelling System (BIMS) has acquired increasing attention in asset management. The core of BIMS is a 3D-model of the assets under consideration. For new structures this is not a problem as they will usually be designed by means of 3D models. For existing structures on the other hand, this poses a challenge, as 3D models of the structures will usually not exist. In recent years COWI has been involved in a number of projects where different approaches have been used to establish 3D-models of existing infrastructure assets. Two such projects will be described in this paper. Further prerequisites for using BIMS on existing structures are also presented. This includes existence of an object hierarchy as well as availability of relevant as-built documentation. Further, this paper discusses the similarities and differences between a BIM system and an Asset Management System (AMS).

1 INTRODUCTION

The principles of Building Information Modelling System (BIMS) is widely used to manage all stages of new building projects, i.e. design, construction and maintenance. Hence, BIMS have many of the same features as a traditional Asset Management System (AMS).

Usually the basis for an asset management system were mainly documents: specifications and drawings from the construction stage, reports from inspections and rehabilitation proposals from the operation stage. Today, the basis for a modern asset management system is usually an information system developed and updated during the design and construction stages. Many general asset management systems supports automated, optimal maintenance management using the data as stored in an infrastructure database.

Recently, COWI has been involved in projects for two major clients where it has been the objective to create the basis for applying the principles of BIMS for existing infrastructure facilities as a basis for an asset management system:

- The Storebelt Link in Denmark
  This link comprises a major suspension bridge, a low bridge and a twin tube railway tunnel.
- The Montenegrin Railway authorities.
  The project comprised the 106 tunnels on the main railway through Montenegro from the Adriatis Sea in the south to the border to Serbia in the north.

In both cases the first step in the process – to create a BIMS in the operations stage - has been to establish a 3D-model of the infrastructure. This goal has been obtained by using a combination of laser scanning and video imagery. Further, provisions have been made to register all data concerning the present condition of the infrastructure in a structured manner, and in formats, that allows data to be fed into a BIMS based asset management system.

2 SHORT INTRODUCTION TO BIM(S)

Building Information Modelling (BIM) and Building Information Modelling System (BIMS) as subjects have received much attention in recent years. There is, however, some confusion with respect to what it actually means.

The National Building Information Model Standard Project Committee defines BIM as:

> *Building Information Modeling (BIM) is a digital representation of physical and functional characteristics of a facility. A BIM is a shared knowledge resource for information about a facility forming a reliable basis for decisions during its life-cycle; defined as existing from earliest conception to demolition.* (NBIMS-US 2017)

BIMS is presently used mainly on new construction projects as part of Computer Aided Engineering (CAE). In BIMS each object is assigned a unique code describing type and location. The type code will also show the object's hierarchal position within

the structure, the object assemblage. A number of attributes containing information about the object are then assigned to all the objects. Attributes could be material properties, supplier information, date of purchase/delivery, specification on spare parts, etc.

Retrieving a list of objects from the CAE model can be used by the procurement office to estimate quantities. It can also be used as basis for an Operation and Maintenance Manual, but with one major reservation: Items (i.e. objects) that are normally not maintainable as separate objects, like reinforcement inside a concrete structure, are consequently not covered by the manual.

Similarly the implementation of BIMS on an existing structure should handle maintainable objects only.

It is also important to note, that object breakdown should only be performed to the level of the smallest object that is being maintained "on its own" by the maintenance organization.

3 RELATIONSHIP BETWEEN BIMS AND AMS

An Asset Management System (AMS) is a system – usually based on a software package – that is used to carry out asset management, which in turn can be defined as:

> *Asset Management is the combination of management, financial, economic, engineering and other practices applied to physical assets with the objective of providing the required level of service in the most cost effective manner. It includes the management of the whole life cycle (design, construction, commissioning, operating, maintaining, repairing, modifying, replacing and decommissioning/disposal) of physical and infrastructure assets.* (LGAM 2017)

BIMS and AMS clearly share a number of common features but also there are some clear differences.

The main similarities are found to be that the same information is stored and handled:

- information on the design and construction of the structural assets (materials data, suppliers data, etc.)
- information on the geometry of objects (dimensions, quantities, etc.)
- etc……

In the present context the major differences in the way BIMS and AMS are traditionally used is:

- BIMS is used from the first conceptual design of a structure and the core of BIMS is a 3D model of the structure which may be extended to 4D (fourth dimension is time) and 5D (fifth dimension is cost/economy). Also, a major aspect in BIMS is that it shall support and promote the exchange of information between the different parties (owners/architects/designers/contractors) involved during design and construction of structures.
- AMS is usually launched after the design and construction stages, or – in recent cases - during the last stages of construction, one of the main purposes being to manage economy and operational services.

4 USING BIMS ON EXISTING INFRASTRUCTURE COMPONENTS

For existing structures, not having a BIM associated to it, a 3D model need to be established in order to effectively implement BIM as this model shall act as the link between the object hierarchy and the information related to each object.

For an existing structure, a basic BIM system would contain the following information:

- Object Identification Number (OIN) (Being part of an Object Identification System (OIS))
- Basic structural information (material data, production information (supplier, date of manufacture, etc.)),
- O&M-related documents (manuals inspection plans, inspection reports, etc.)
- As build documentation (especially drawings).

All the above information may be linked to the relevant objects (as attributes) in a 3D representation of the structure. Hence, it is essential to have a detailed 3D representation of the structure.

5 TWO CASE STUDIES

In the two case studies presented below the objective has been, as a first step to establish a BIMS, to establish a 3D model of the existing structures.

Further, an object hierarchy needs to be established and existing information that shall be fed into the BIMS shall be identified.

5.1 *Description of structural assets*

5.1.1 *The Storebelt Link*

The Storebelt Link is situated in the center of Denmark, as shown on Figure 1, and connects the two main islands Zealand and Funen. The link comprises five main parts:

- the East Bridge: a 6,8 km long suspension bridge (road only)
- the West Bridge: two parallel 6,6 km long box girder bridges (railway and road)
- the East Tunnel: a 8 km long twin tube bored railway tunnel
- The Sprogoe Island: an island forming the transition between the East and West Bridge (road) and the East Tunnel and the West Bridge (rail).

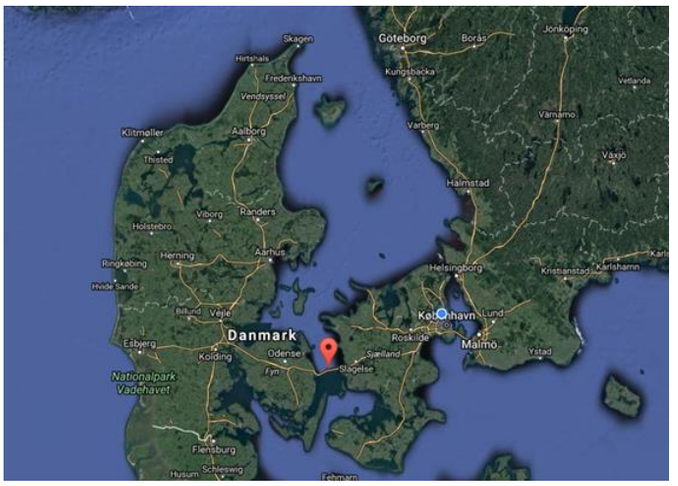

Figure 1 The Storebelt Link (at red marker) is placed in the center of Denmark. It connects the two major islands Zealand and Funen by road and rail. © Google Maps.

– area for toll station and administration at Halsskov (On Zealand at eastern approach to the link)

The link was constructed in the years from 1988 to 1998. The railway link opened in June 1997 and the road link opened in June 1998.

5.1.2 *The Vrbnica – Bar railway line in Montenegro*

This railway line runs through the central part of Montenegro from the Adriatic Sea at Bar to the border to Serbia at Vrbnica in the north as shown in Figure 2.

The railway line is app. 100 km in length and includes 106 tunnels with a total length of app. 53 km.

The shortest tunnel is 40 m long and the longest is 6.171 m.

The railway line is a single-track line except at a few stretches around stations where it comprises up to 3 tracks. Three tunnels are so close to a station that they also comprise three tracks – two in full and one in part.

5.2 *Data collection*

The way of collecting data for the two referenced projects have been somewhat different in nature. However, the starting point for both projects, BIMS wise, has been from scratch.

5.2.1 *The Storebelt Link*

For the Storebelt Link the collection of data needed to establish a 3D model of the main structures is a process that is foreseen to take years due to the mere size of the assets.

To date (autumn 2017) data for 3D-models has been collected for the following parts of the Storebelt link:

– the two anchor blocks,
– the Sprogoe Island,

Figure 2 The main railway line in Montenegro going between Bar at the Adratic Sea (south) and Vrbnica at the Serbian border (north).

– Tollstation area and administrative center at Halsskov.

Data has been collected by means of UAV's that fly around the anchor blocks in a predefined pattern taking a large number of high resolution photographs – app. 5.000 for each anchor block.

At present COWI is using two different types of unmanned aerial vehicles (UAV's) for data collection. The newest of the two types is shown in Figure 3.

As the recorded photographs are overlapping they can be processed digitally to produce a 3D model of the anchor blocks. The model is georeferenced and measurements can be made directly on the model.

5.2.2 *Montenegro Railways*

For the project in Montenegro a somewhat different approach has been adopted. Data was sampled by two means:

– 360° camera (a la street view images),
– laser scanning

The camera inspections were used to perform an initial visual inspection in the office of all the tunnels. This initial inspection was used to get the first impression of the current state of the tunnels and data from the initial inspection was used to plan the detailed on-site inspection that was carried out later in the project.

Figure 3. UAV type Matrice 210 RTK from DJI. The UAV can be equipped with two cameras.

Figure 4. Mobile mapping system placed on a flatbed wagon and pulled by a dresine.

The detailed outcome of this part of the project is presented in another paper at this conference.

The Mobile Mapping System used for the laser scanning of the tunnels consisted of the following components:

- 2 laser scanners,
- GNSS System (Global Navigation Satellite System),
- INS (Inertial Navigation System).

The equipment was installed on a flatbed wagon and driven through the tunnels by means of a dresine at a moderate speed of app. 20 km/h. The setup is shown in Figure 4.

The laser scanning resulted in a point cloud for each tunnel. The point clouds are so detailed that they almost resemble a black/white 3D image of the tunnels. A small example is shown in Figure 5. Due to the use of GNSS and INS the point clouds can be positioned globally in absolute terms, i.e. by means of global xyz-coordinates.

5.3 *1.1 Object hierarchy*

An object hierarchy was developed for the Storebelt Link when it was designed. This original hierarchy is still being used.

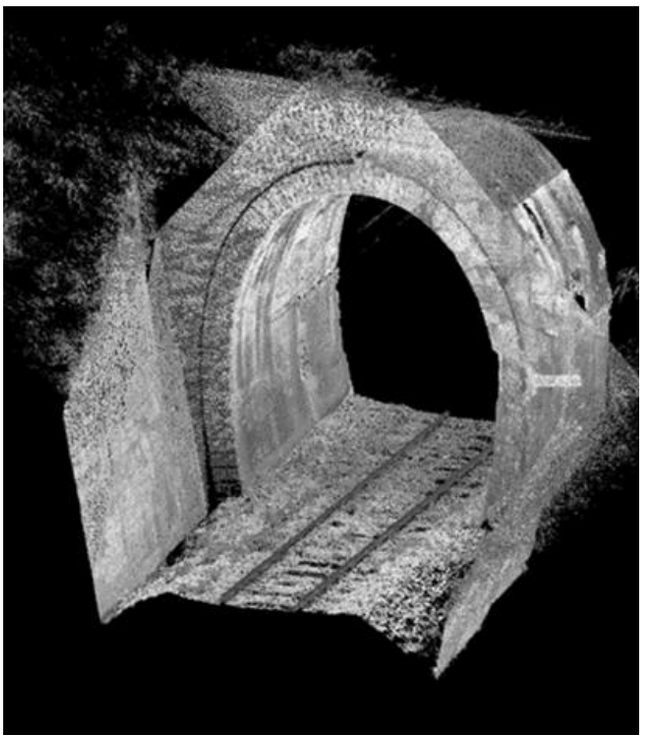

Figure 5. Example of outcome of point cloud from laser scanning. Only the tunnel portal is shown.

Figure 6. Example showing how the eastern anchor block of the Storebelt East Bridge is subdivided into objects at level 4: foundation, front leg(s), spreading chamber(s) and saddle house.

The East Bridge is at level 1 and the anchor blocks at level 3. The division of an anchor block into next level objects is illustrated in Figure 6.

For the tunnels on the railway in Montenegro no object hierarchy has been developed previously.

A simple hierarchy was developed:

- level 1: Tunnel no./name
- level 2: relative stationing within tunnel (each tunnel was divided into a number of virtual "rings" – each 1 m wide.)

Figure 7. Image from COWI Multiviewer showing the 3D-model of an anchor block from the Storebelt East Bridge (right), an overview picture (bottom left) and a close-up of observed crack (top left). The red and blue annotations are used to identify different types of observations.

6 DATA HANDLING

6.1 *Digital images*

As a versatile tool for handling different kinds of georeferenced data COWI has developed a special tool. The tool, entitled COWI Multiviewer, is fully web based and can be used to store and present data in a number of different formats. An image of one of the anchor blocks – taken from COWI Multiviewer - is presented in Figure 7.

A special application of the COWI Multiviewer – known as COWI Virtual Inspection Tool (CVI) – can be used to carry out desk inspections of structures based on digital images fed into the viewer.

The COWI Multiviewer is just shown here as an example of an application able to handle digital images. It is assumed that standard BIMS applications can handle this kind of information in a similar manner.

6.2 *Inspection data*

For 20 years COWI has developed and used dedicated databases to register observations from inspections carried out on large infrastructure.

The use of databases has a number of advantages over a paper-based system:

- Predefined defects
  A core component of the databases is a hierarchy of predefined defects. Usually the predefined defects will cover more than 95% of the observations. The use of predefined defects assure a uniform registration of defects even when 5 or more inspectors are involved in an inspection.
- Easy registration in the field
  The database is installed on a tablet pc so that registration can be done directly in the database. Hence, a full and final registration is made on the spot.
- Optimal data handling
  As 95% of the defects (or more) are described by means of a rather limited number of predefined defects it is easy to handle the data and do reports directly from the database.
- Easy exchange of data between systems
  Data from the inspection databases may be easily interchanges with higher level Asset Management Systems or BIMS by means of standardized data formats such as Excel, csv-format, txt-format or the like.

Further in BIMS a direct link can be established between a main structural component and the inspection database containing

Currently COWI is involved in the development of tools that may combine data in such inspection databases with the COWI Virtual Inspection Tool in COWI MultiViewer.

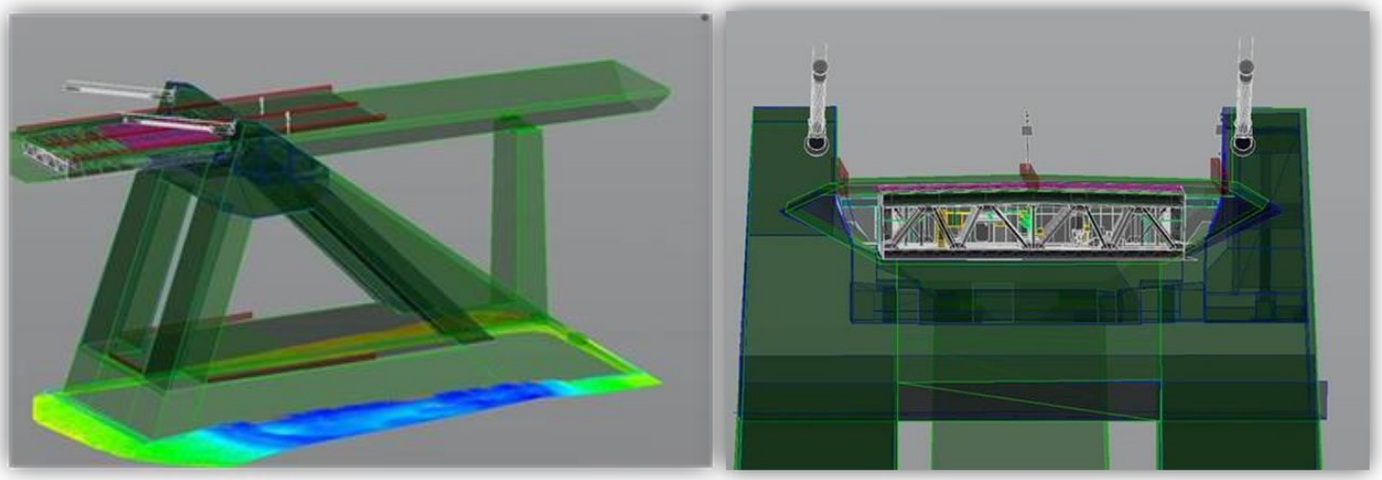

Figure 8. 3D-model of anchor block based on images taken by a UAV combined with the 3D-model of an interior part of the bridge deck based on a point cloud from laser scanning.

6.3 *Monitoring data*

Most modern infrastructure is equipped with a number monitoring equipment that can carry out automated monitoring and also

As the level of monitoring increases also the need for effective handling and processing of data increases.

Over the last 10 years COWI has been involved in the development of systems and tools that can handle and process data from monitoring systems such as

- Cathotic protection systems
- dewatering system for tunnel ramps at Storebelt East Tunnel,
- inspection of bridge bearings,
- hanger fluctuation.

It is foreseen that the handling of monitoring data will soon be an integral part of BIMS.

7 SHORT TERM PERSPECTIVES

Video recordings and high resolution digital images can be used to prepare inspection, structural assessment and reporting in the office.

Repeating full video inspection at regular intervals is an effective way to monitor changes in the condition of infrastructure that are often large in size and a challenge to access in all details.

Information from different sources may be combined, which is shown in the example in Figure 8. This example combines a 3D-model of one of the anchor blocks on the Storebelt East Bridge with the result of a laser scanning of the interior of the bridge deck at the same location.

8 LONG TERM PERSPECTIVES

Automatic image processing can be used to monitor changes in the condition of structures based on changes in visual appearance.

Also it will be possible soon to detect some defects by means of automated image processing. This may include:

- development and changes in crack patterns,
- spalling concrete,
- ingress of water in concrete structures,
- corrosion on steel surfaces,
- degradation of surface treatment on steel structures.

Further, the data may be gathered by UAVs that are remotely controlled from an office to inspect (visually) specific and remote parts that may be difficult to access in person or UAVs that are programmed to fly a prescribed route in order to inspect a structure at certain intervals.

All of the above information will (probably) be handled, documented and communicated by means of BIMS. That is why BIMS is such an interesting issue also for existing structures.

9 CONCLUSION

The main advantage of implementing an asset management system incorporating the special features of BIMS on existing infrastructure components, compared to traditional AMS, is the fact that a direct and intuitive link between the components and the related information can be obtained by means of a 3D model.

Another, and in fact very important advantage is that most AMS available on the market in the future will be incorporating features from BIMS. Systems

that are based on an alphanumerical object identification system are foreseen to die out. Hence, the need for 3D models of existing infrastructure components will increase in the coming years.

This paper has given some examples on rational ways to establish a functional 3D-model for existing assets.

The future will show how AMS and BIM can co-exist and be combined to promote a more effective and rational way to handle the huge amount of information related to infrastructure components from the first conceptual studies, over commissioning, operation and final decommissioning.

Some of the basic features of BIMS – the fact that it is visually based and intuitively and easy to interpret - makes it a strong and versatile tool when it comes to communicating information such as inspection data or graphics based on monitoring.

Creation of "live data" for existing infrastructure

F. R. Gottfredsen & H. Pedersen
COWI A/S, Denmark

ABSTRACT: A recent project concerning the central railway line in Montenegro comprised visual, detailed and special inspection, condition evaluation and action plan for rehabilitation works on all tunnels and galleries. This generated a huge amount of information and data to be structured and processed for various objectives. It was requested that data should be delivered in a format suitable for future incorporation in a BIM system. Therefore, it was decided to adopt a "fully digital" approach. An initial visual inspection was performed based on a full video recording of all tunnel surfaces. Geodetic survey was performed by laser scanning and continuous 3D point clouds of the inside of the tunnels were obtained. Defect registration was performed by pre-defining of a number of typical defects. A purpose made inspection database was used for registration of observations on the spot. Afterwards, an Action Plans for Rehabilitation Works weas generated directly from data in the Inspection Database.

1 INTRODUCTION

The objective of this paper is to provide an example on how a vital part of an Asset Management System for an infrastructure component can be effectively established, being far into the operational phase.

COWI has been involved in a recent project in Montenegro "Special inspection of 106 tunnels and development of the Main Designs for their rehabilitation (urgent measures on the tunnels according to the priority established based on the special inspection findings) on the railway line "Vrbnica-Bar" (SEETO Rail Route 4), Component 1 – Inspection of Tunnels", that provides a good basis for such an example. The main characteristics of the basis of this project are the following:

- there exists no information system for the component: railway tunnels and galleries, civil works
- data as captured in the inspection phase of the project is requested to be "provided in accordance with a format suitable for easy transfer to a future Building Information Modelling System (BIMS)"
- the results obtained from the inspection activities should also be used by:
  1) a Consultant to prepare Main Design,
  2) the Montenegrin Railway to select tunnel rehabilitation works to be executed urgently,
  3) the Montenegrin Railway to develop detailed rehabilitation strategies ,
- information gathered during the inspection, survey, evaluation and further recommendation of rehabilitation strategies comprises a huge amount of data, that can only be handled in an effective way by use of computer applications.

This paper describes the selected main approach and methodology, the activities for capturing, structuring, evaluating, processing and delivering data that are prepared for entering into an Asset Management System (AMS) (or a BIM system).

Further, the paper describes in brief how the data can be used directly in the coming phases for operation and maintenance of the railway infrastructure, with or without implementation of an AMS. Finally, some thoughts are given onhow benefit of the data could be improved by implementation of a few, simple data processing tools.

2 STRUCTURAL ASSETS

The railway line between Bar and Vrbnica runs through the central part of Montenegro from the Adriatic Sea at Bar to the border to Serbia at Vrbnica in the north as shown in Figure 1. The railway line is app. 100 km in length and includes 106 tunnels and 14 galleries with a total length of app. 53 km.

The shortest tunnel is 40 m long and the longest is 6.171 m. The galleries are between 10 and 100 m in length.

Figure 2 The main railway line in Montenegro going between Bar at the Adratic Sea (south) and Vrbnica at the Serbian border (north).

The railway line is a single-track line except at a few stretches around stations where it comprises up to 3 tracks. Three tunnels are so close to a station that they also comprise three tracks – two in full and one in part.

3 METHODOLOGY

3.1 *Main project tasks*

The main project parts, that was dealing with inventory data, comprised:

1 Inspection of 106 tunnels and 14 galleries
- an initial visual inspection of all components,
- a detailed inspection of all components, for in depth inspection of observed defects and damages,
- special inspection of selected structural parts.

2 Geodetic Survey
Laser scanning of all tunnel and gallery surfaces

3 Defect Registration
Performed during detailed inspection. Observation of all defects (innate as well as inflicted damages). Registration according to type of damages and location of each defect.

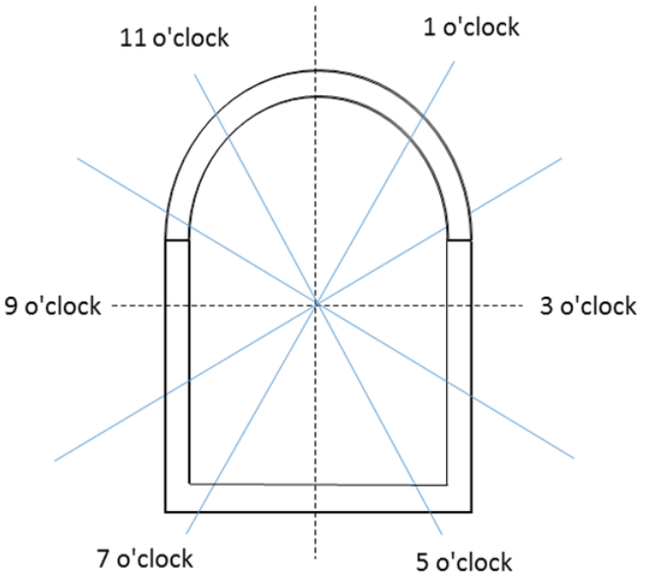

Figure 2. Definition of "clock wise" system to define placement of defects within the tunnel cross section.

4 Action Plan for Rehabilitation Works
Recommendation of types of rehabilitation works related to observed defects and estimated degradation rates.
Composition of rehabilitation works into Rehabilitation Projects related to individual tunnels or set of tunnels.
Estimates of costs and time for each tunnels rehabilitation works
Development of Rehabilitation Strategies

3.2 *Selected approach*

In order to assure that the data achieved from inspections could be available for various usages and be readily entered into a future BIMS, the following was decided:

– all data should be in digital form and should be live data (in native format, not pdf-files),
– most general system formats should be used:
  - Microsoft Office (Excel, Access, etc)
  - AutoCad and Microstation

Based on these decisions the following performance of project activities were selected:

– Visual inspections based on video recordings,
– Geodetic survey based on mobile laser scanning to obtain 3D point clouds,
– Digital Defect Registration using an Access database developed for this project
– Monitoring of temperatures in selected tunnels: (as frost resistance was a major issue)
– Preparation of an Action Plan for Rehabilitation Works for all tunnels and galleries. Data is structured from defect registration according to tunnel numbers and processed in ordinary Excel sheets.

As no BIMS for the infrastructure exists the following, very simple structure of the element hierarchy was selected:

– Level 1: Tunnel number
  The tunnels are numbered from Vrbnica (at Serbian border) to Bar (at Adriatic Sea), starting with number 147.
– Level 2: Ring number in tunnel (construction section number), or portal number (A or B)
– Level 3: Definition of local system for data registration.
  - A "clock-wise" system for local registration of data within a tunnel was used (See Figure 2).
  - The tunnel is seen in the direction of increasing chainage (i.e. in the direction Vrbnica – Bar).

4 DESCRIPTION OF ACTIVITIES

4.1 *Visual inspection*

The requested visual inspection was performed as a CPV recording of all tunnels and galleries.
(CPV is an acronym for COWI Panoramic View which is a 360° recording based on the same technology as Google Street View©)

The CPV recording device was installed on top of a car that was positioned on a flatbed rail wagon driven through all tunnels and galleries by a dresine. The installation is shown in Figure 3.

CPV images were recorded in a cooperation between the project team and the Montenegrin Railways (ŽICG).

Panoramic images were recorded with 5 frames/sec, which gives an image for each app. 28 cm while driving 5 km/h and app. 39 cm while driving 7 km/h.

For each tunnel and gallery, a file containing the CPV-recording was created.

The outcome of the CPV was a full 360° image of the tunnel surface (lining) of all tunnels and galleries.

In a dedicated viewer, it was possible to look through all the recordings. The viewer made it possible to pan and zoom so that all parts of a tunnel section could be viewed in detail. Single images (screen dumps) of certain details can be generated and saved.

From the CPV all defects above a certain size could be observed. This meant that signs of water ingress could be seen – typically as dark patches. However, it was not possible solely from the recordings to evaluate the amount of water entering the tunnel.

Furthermore, spalled concrete and areas with deteriorated concrete could be identified from the CPV. Larger cracks (w > 0,5 mm) could also be observed, especially if they were accompanied with water ingress. At the same time, medium size cracks (width between 0,2 mm and 0,5 mm) could under certain conditions be identifiable, whereas smaller cracks (w < 0,2) could not be observed from the CPV.

From the CPV the size of identified damages were initially assessed simply by assessing the size directly from the images.

Although the GPS installed on the recording device is not working in tunnels, it is anticipated that the chainage can be determined within a tolerance of app. 0,5 m, which was found to be adequate to reliable re-find in the tunnels damages identified from the recordings.

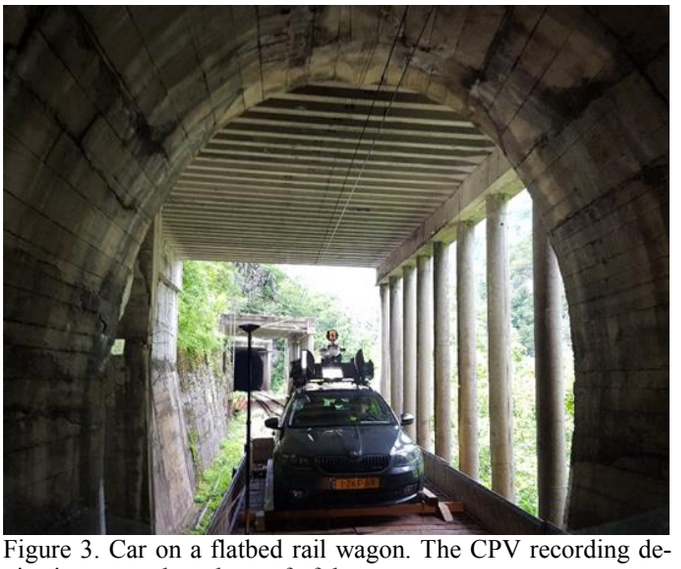

Figure 3. Car on a flatbed rail wagon. The CPV recording device is mounted on the roof of the car.

4.2 *Geodetic survey*

The geodetic survey of the interior of the tunnels was performed with a mobile laser scanning, running on a flatbed wagon. From the mobile mapping high density continuous 3D point clouds of the inside of the tunnels were obtained. The 3D point clouds have a very high relative accuracy. Furthermore, the point clouds can be used for any measurements inside the tunnels for any future work and in that way they are considered an asset for the railway company and all maintenance / rehabilitation works to be undertaken in the future. Cross sections and longitudinal profiles are generated from the point clouds. Clearance profiles are imposed on cross sections for evaluation of tunnel geometry.

The laser scanning recording system was installed on a flatbed wagon driven by a diesel dresine. The installation is shown in Figure 4.

Main components of the mobile mapping system are:
– Two laser scanners, positioned tilted along driving direction to collect as many objects as possible. Each laser scanner can collect up to 1.016 Mio. points per sec.

Figure 4. Flatbed rail wagon with laser scanning equipment mounted on it. The wagon is moved with help from a dresine.

– One GNSS (Global Navigation Satellite System)/GPS (Global Positioning System), receiving satellite observations for United State satellite system and European satellite system. Satellite observations are stored each second.
– One INS (Inertial Navigation System), tracking changes in speed movement together with rotation of the vessel. Data motion is stored twice every second.
– Odometer/wheel sensor, tracks the amount of distance travelled by the wheels.
– Computer for tracking and storing information.

Original output from the laser scanning is a 3D point cloud. For each single point in the point cloud, an intensity value is collected depending on the surface. The point cloud can be imported and viewed in different standard CAD and GIS (Geographical Information System) software.

Derived presentation from the point cloud can be a 2D cross sections with specified intervals along the alignment or wherever there are interesting features, which have to be investigated.

The left part of the figure shows the original point cloud. The right part shows a generated cross section. Within this cross section is shown four clearance profiles defined by the project. The objective was to identify possible clashes between the required clearance profiles and the tunnel lining. In this project clash test was done every 20 m where the length profile was straight and every 5 m where the length profile was curved.

The point cloud were also used as basis for the development of longitudinal profiles with indication of the stationing. Figure 6 shows an example of this.

The 3D image that is also the outcome of the point cloud from the laser scanning is illustrated in Figure 7.

4.3 *Defect registration*

Defect registration is composed of three parts:
– Overall registration (Inspector, weather …),
– Location of the defect (tunnel number, section number, local "watch" coordinate,
  Characterization of the defect.

The core of the registration methodology is the definition of a number of predefined defects.

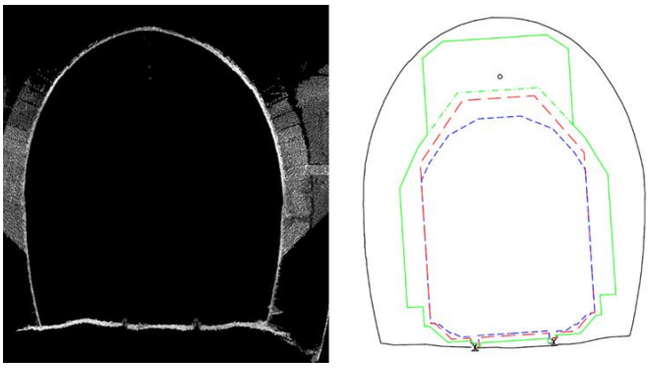

Figure 5. Point cloud of tunnel on the left. A cross section with different clearance profiles included are shown on the right.

Each predefined defect is characterized by means of the following parameters:
– defect type,
– cause,
– level of water ingress,
– size,
– extent.

Each defect was given a defect mark by the inspector. The defect mark reflects the inspectors engineering judgment concerning the severity of the defect. The definition of the defect marks that were used are given in Table 1.

Table 1. Definition of defect marks (DM).

DM	Description
1	Severe defect (heavily deteriorated concrete and/or extensive water ingress) that may endanger structural safety (failure/overload) or safety of passing trains (e.g. due to falling concrete).
2-	Significantly deteriorated concrete (up to 0,5 m in depth) and extensive water ingress, but no immediate risk of structural failure or safety of passing trains. Damages will probably cause disturbance to train traffic e.g. due to ice forming.
2	Significantly deteriorated concrete and/or significant water ingress, but no risk of structural failure or safety of passing trains. Damages may cause some disturbance to train traffic e.g. due to ice forming.
2+	Deteriorated concrete (up to 0,2 m in depth) and significant water ingress, but no risk of structural safety or safety of passing trains. Water ingress is unlikely to cause disturbance to train traffic.
3	Smaller, less significant defect.

Defect recording was done on the spot by use of a tablet loaded with an Access database prepared for the project. The database is entitled Inspection Database.

The registration was done by choosing relevant values for type, water ingress, size and extent as well as the defect mark in a number of drop down menus in the input page of the database.

Further, the input page allows the inspector to register any pictures related to the defect and finally it is possible to add relevant remark in a free text box.

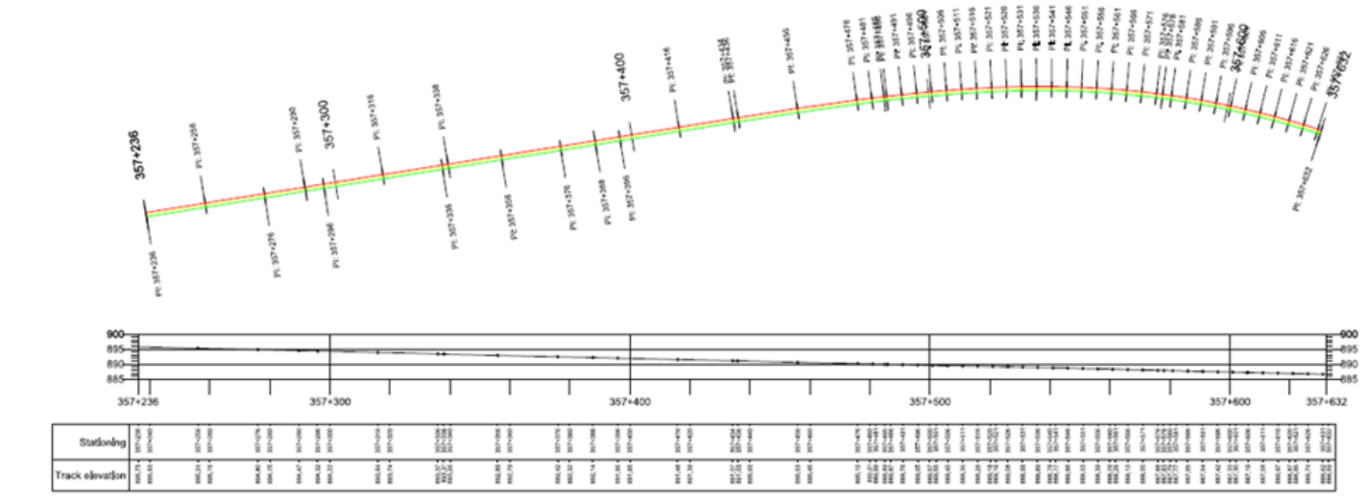

Figure 6. Horizontal and vertical profile of a single tunnel obtained from the laser scanning (example). On the vertical profile the chainage where cross sections have been defined (as shown to the right in Figure 5) is indicated.

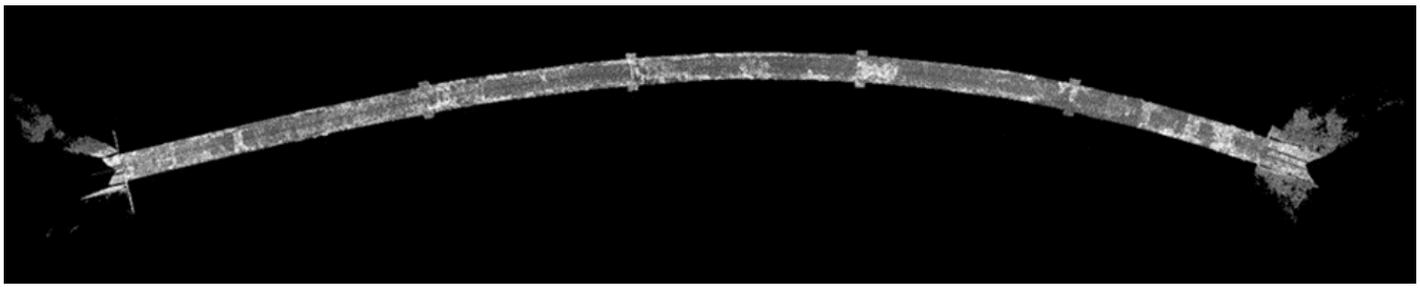

Figure 7. Point cloud of a single tunnel (example) – seen from above.

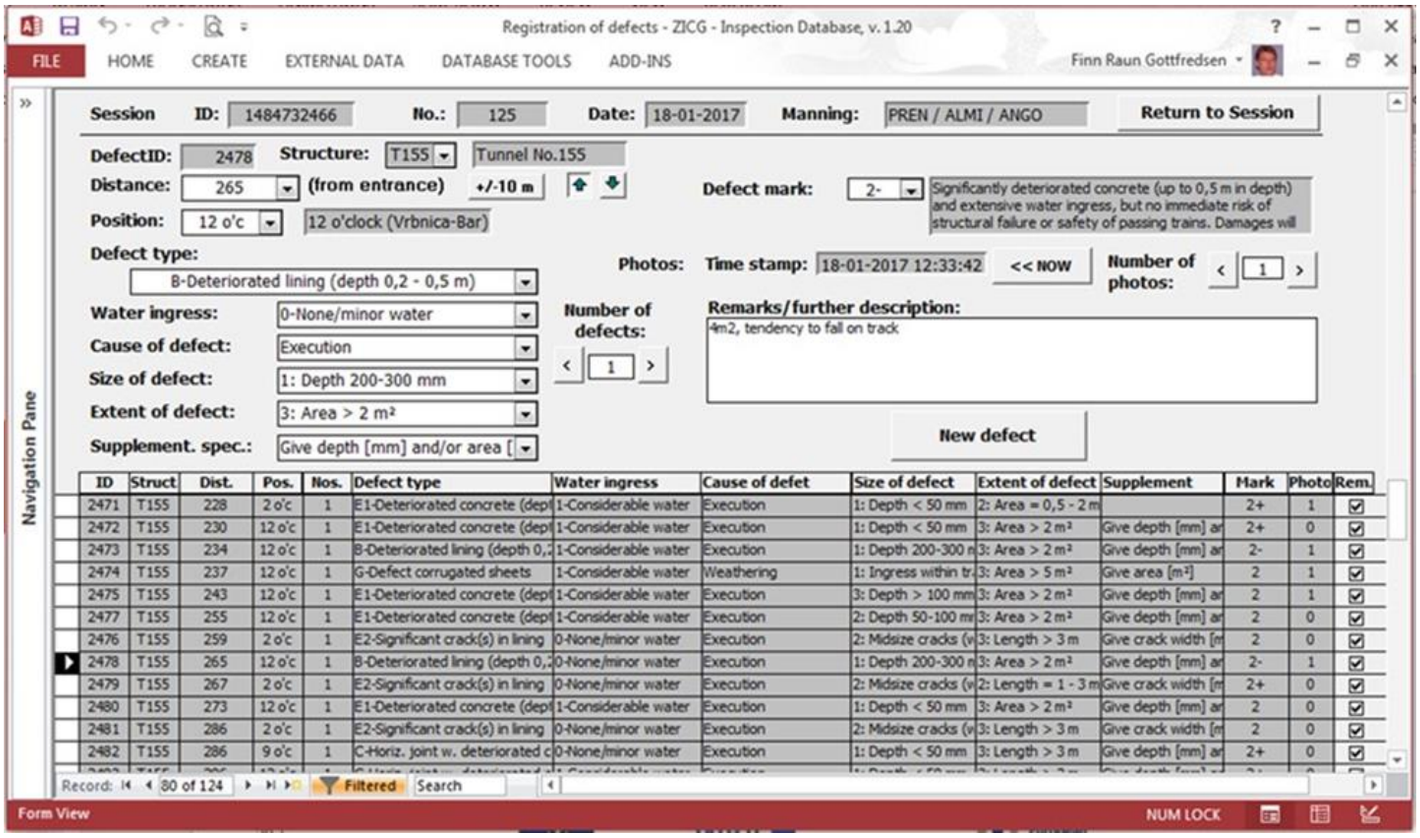

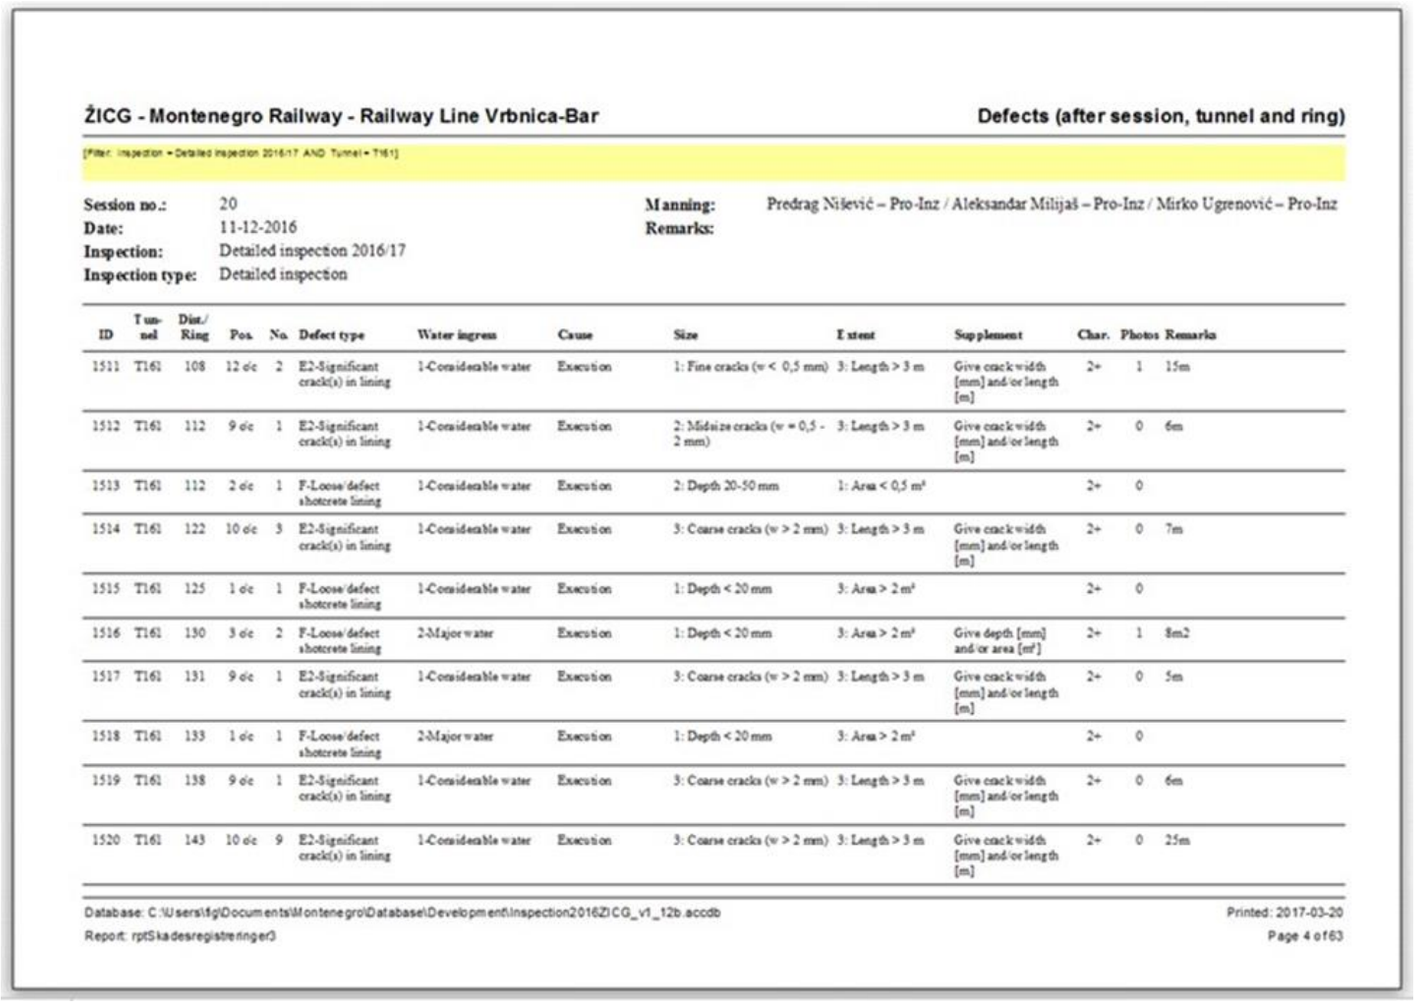

Figure 8. Input page in the Inspection Database. Input is done in the upper part of the page – mainly using drop-down menus. In the lower part of the page, observations already registered in the database can be seen.

Figure 9. Sample page of a standard report from the Inspection Database.

The input page is shown in Figure 8 The input part of the page is at the top. The lower part shows observations already registered in the database. It is observed that most data are chosen from drop down menus. That makes registration very quick and intuitive. The registration database also contains a versatile report facility, by which a number of specialized reports can be easily defined and retrieved.

All basic parameters of the defects are shown in one of the standard reports defined in the Inspection Database. An example of this report type is shown in Figure 9. As can be seen the defects are sorted according to tunnel and "ring"-number.

4.4 *Temperature registration*

As part of the special inspections carried out during the project a number of temperature loggers where installed in four tunnels during the winter period. Five loggers where installed in each of the tunnels: one close to each end, one logger app. ¼ of the tunnel length from each portal and one in the middle. It was considered of interest to monitor and map the temperature within the tunnels, due to the fact that:

- The number of freeze-thaw cycles may have a considerable impact on the degrading of the concrete lining.
- The risk of ice building, due to ingress of water in the tunnels, is dependent on the temperature inside the different tunnels.

Four tunnels were chosen for temperature monitoring in order to be representative for both the geography as well as the length of tunnels.

Very simple (and cheap) data loggers type EL-CC-1-FG from Lascar Electronics were used to log the temperature. These loggers can only be used once.

An example of logged temperature data is shown in Figure 10. It is clearly recognized how temperatures fluctuate during the day –especially close to the portals. Also, it can be seen that the temperature only changes moderately over the length of the tunnel.

For tunnel T232 – which is situated just south of the center of Montenegro – only a few freeze/thaw cycled could be observed during the winter of 2016/17.

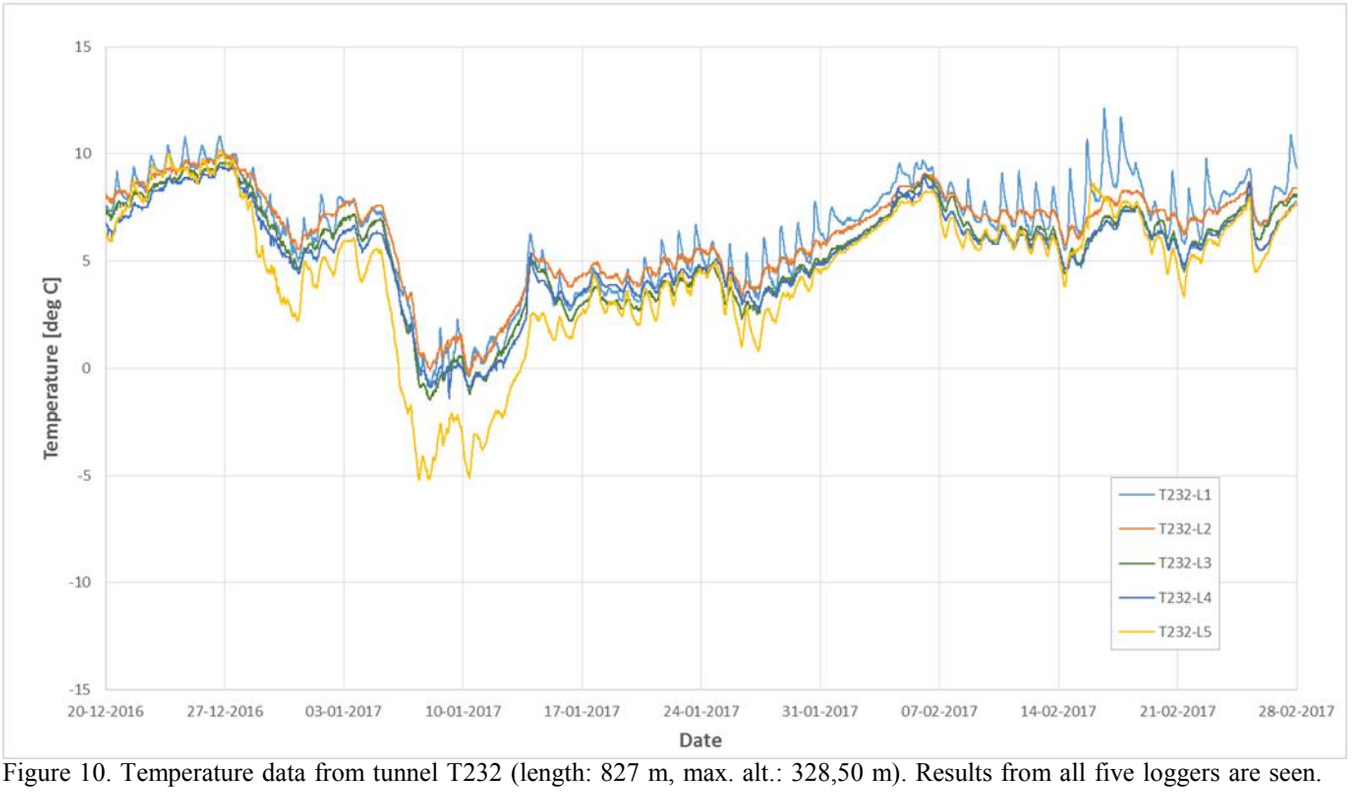

Figure 10. Temperature data from tunnel T232 (length: 827 m, max. alt.: 328,50 m). Results from all five loggers are seen. Loggers L1 and L5 were placed close to each of the portals, L2 and L4 were placed ¼ of the tunnel length inside the tunnel, L3 was placed in the middle of the tunnel.

4.5 *Action Plan for Rehabilitation Works*

Based on the findings from the detailed inspection carried out in all 106 tunnels 12 standard repair types where defined.

Based on the detailed registrations in the Inspection Database, which were exported to Excel, a repair was assigned to all defects having a Defect Mark of 2, 2- or 1, i.e. the three most severe categories, cf. table 1. From the individual registrations the type and extent of repair was defined for each defect.

Defects and the associated repairs where summarized for each tunnel, resulting in an Action Plan for Rehabilitation Works for each tunnel.

The spreadsheet system was expanded to include cost estimates and construction time estimates related to each repair type. Again, the estimates were summarized for each tunnel. Influence of railway operation was included in the estimate of construction time.

In this way an Action Plan for the whole railway line was developed containing a rehabilitation plan for each tunnel or for a set of tunnels positioned on a certain railway section. For each Rehabilitation Project was estimated a total cost, a total construction period and manning from Contractors.

Based on these Rehabilitation Projects was developed a set of rehabilitation strategies.

As an example Figure 11 shows the estimated duration of rehabilitation works and the estimated "number of men" necessary for various scenarios.

Scenario number	Works included	Length of railway closure	No. of ineff. hours	Duration of rehab. works [years]	Estimated number of men
A1	All structural repairs. No TSI-SRT related works.	12 hours	2	10,0	11
A2		8 hours		16,7	
A3		5 hours		33,3	
B1	All structural repairs. All TSI-SRT related works.	12 hours	2	10,0	30
B2		8 hours		16,7	
B3		5 hours		33,3	
C1	Structural repairs type RA1 + RA2. No TSI-SRT related works	12 hours	2	6,0	12
C2		8 hours		10,0	
C3		5 hours		20,0	
D1	Structural repairs type RA1 + RA2. TSI works TSI06-TSI08	12 hours	2	6,0	38
D2		8 hours		10,0	
D3		5 hours		20,0	

Figure 11. Estimated duration of railway closure and estimated number men for different rehabilitation scenarios. It is interesting to note that the available length of tunnel closure has a significant impact on the estimated duration.

It is interesting to note how the length of available railway closures has a significant impact on the estimated duration of rehabilitation works.

5 DELIVERABLES

5.1 *Workshops*

In order to promote the Beneficiary's (Montenegrin Railways) use and benefit of the data a number of workshops with participation of potential users from Montenegrin Railways were performed.

On these workshops possibilities of enhanced use of the data acquired during the project was discussed. Further, possibilities and plans for future implementation of an AMS was discussed. The Montenegrin Railways are still considering what available standard system to invest in.

5.2 *Data*

A hard disk with all the collected data was delivered to the Montenegrin Railways at the end of the project. The following data were included on the hard disk:

- CPV recordings (including a freeware viewer),
- Laser scanning recordings,
- Cross sections with clearance profiles, incl. facility for easy access to selected tunnels,
- Defect Registration Access Database, which can be accessed and used (but not altered) on any Windows-based pc,
- Spreadsheets containing plans for Rehabilitation Works and Strategies.

The total amount of data collected during the project amounted to app. 3,5 TB equal to 3.500.000 MB.

6 LESSONS LEARNED

The project presented in this paper had an effective duration of 15 months. As described previously the project comprised 106 tunnels and 14 galleries situated on a single-track railway line going across Montenegro. The total length of tunnels/galleries is about 53 km.

During the fairly short period of time available for the project the following tasks were carried out:

- 360° recordings of all tunnels and galleries (called CPV),
- laser scanning of all tunnels and galleries,
- cross sections where determined and compared to clearance profiles for all tunnels at short intervals (max. 20 m distance),
- initial visual inspection based on CPV,
- detailed inspection of all tunnels and galleries (almost 20.000 observations where registered in the Inspection Database),
- a rehabilitation plan was established for each tunnel. The plan included cost estimate and time needed for rehabilitation.

The task described above could only be carried out in a rational and effective way by extensive use of digital data registration and data handling.

The project has shown that video recordings can be used as an effective tool when performing a visual inspection of infrastructure components such as tunnels and galleries.

Video recordings should not stand alone, as some defects cannot be effectively observed without being close to the structures. However, it is possible to use the video recordings effectively as a screening tool to optimize the planning of detailed inspections.

Effective handling of data from the detailed inspection, by means of a purpose made Inspection Database, has made it possible to develop individual rehabilitation plans for all the 106 tunnels.

7 ACKNOWLEDGEMENTS

The technical assistance described in this paper was financed under the Western Balkans Investment Framework (WBIF) which is a joint initiative of the EU, International Financial institutions, bilateral donors and the governments of the Western Balkans which supports socio-economic development and EU accession across the Western Balkans through the provision of finance and technical assistance for strategic investments, particularly in infrastructure, energy efficiency and private sector development.

COWI wants to acknowledge the funding that made this project possible.

Further, COWI wants to express its appreciation of the positive collaboration shown by the Montenegrin Railways during the project, which made it possible to get the access to the tunnels needed to carry out the project in an efficient manner.

Y-C. Koay & H. Luczak
VicRoads, Melbourne, Australia

ABSTRACT: Road bridges are life line structures essential to ensure community mobility. Bridge management agencies currently adopt streamlined and cost-effective approaches to facilitate maintenance of their aging and deteriorating bridge assets. One typical approach is based on different levels of inspection before making a decision on repair or replacement. In such approach, the deterioration level of bridge component is expressed through time-varying discrete condition states (e.g. use of 4 condition states with 1 being good and 4 being poor) which are defined by type and severity of structural deterioration and damages at the time of inspection. In utilizing the inspected condition data, past studies successfully applied the Markov deterioration model to understand and predict the rate of deterioration of bridge components. Based on that, optimal rehabilitation and replacement policies for bridge components have been developed in several past studies. However, one important management problem, which has not been addressed in previous studies of bridge maintenance, is to identify the next inspection time for a bridge component with known current condition that will result in lowest operational cost over a planning horizon. Furthermore, the effect of early intervention on inspection and maintenance cost has not been well investigated. From cost-saving and risk perspective, finding the optimal inspection time and repair intervals, while keeping bridges at a reasonable level of service, is of interest to the bridge management agencies. The model proposed here integrates the Markov deterioration model and a cost rate function through a computational procedure for deriving the lowest-cost inspection time of bridge components with various known condition states. A case study with bridge condition data is presented to demonstrate the benefit of this study.

1 INTRODUCTION

1.1 *Background*

Road Bridges are part of essential infrastructure assets to the human living. They are long life structures expectedly exceeding 100 years of service life as required by the latest version 2017 of bridge design standard AS 5100 in Australia. During their service life, road bridges are subjected to various deterioration processes and random damage events that adversely affect their serviceability and structural safety. For the example of commonly used reinforced concrete (RC) bridge components, the structural deterioration processes have been known due to a number of phenomena including corrosion of concrete, corrosion of reinforcement, concrete creep and fatigue resulting in excessive cracking, loss of strength and material (Jamali et al., 2013, Stewart, 2010). The random damage events include traffic and collision accidents, and natural hazards such as bushfire, flooding, earthquake (Gidaris et al., 2017, Agbelie et al., 2017, Frangopol et al., 2017). As a result, road bridges can be subjected to various maintenance, rehabilitation and replacement (MRR) actions during their lifetime.

Industries such as bridge management agencies are expected to adopt more streamlined and cost-effective MRR management approaches to facilitate structural safety, and service performance under constraints of limited funding, and reduced environmental footprint. The common management practice is based on different levels of inspection before making a decision on MRR actions (Sonnenberg, 2014). In such approach, the visual inspection with inspection interval of 2-3 years is commonly adopted (Rashidi et al., 2016). The deterioration level of bridge component is considered to be captured through time-varying discrete condition states (e.g. 4 condition states with 1 being good and 4 being poor). The condition state is rated by type and severity of structural defects such as cracking, corroded steel and spalling, which are found during inspection (Principal Bridge Engineers, 2014).

In the past and even in some current bridge management systems, the MRR decisions are often based the knowledge and experience of bridge engi-

neers after evaluating observed defects (Safia et al., 2013, Parr et al., 2010). With the advance of deterioration modelling and simulation technology, it is desirable to use prediction from deterioration models and simulated costing to further streamline inspection frequency and annual budget and understand cost-benefit of various MRR options.

As far as deterioration is concerned, the data-driven deterioration models using Markov chain theory (Moomen, 2016, Bu, 2013) is often adopted as compared to the mechanism-based deterioration models (Vatteri et al., 2016, Jamali et al., 2013) because the former modelling approach can utilize the available inspection data while the later modeling approach, despite more accurate, requires data that are not available and costly and difficult to obtain.

Based on deterioration models, several inspection and maintenance approaches have been developed. Robelin and Madanat (2007) developed a Markov decision process to determine optimal maintenance and replacement policies for bridge decks in their worked examples. Saydam and Frangopol (2015) proposed an innovative risk-based maintenance optimisation methodology for existing deteriorating bridges to find the optimum maintenance options and timing.

However, one important management problem, which has not been addressed in previous studies of bridge maintenance, is to identify the next inspection time for a bridge component with known current condition that will result in lowest operational cost over a short planning horizon. Furthermore, the comparative cost saving of various early intervention strategies have not been well studied.

1.2 *Aims and objectives*

This study develops a computational procedure to find the inspection interval with lowest cost for asset management of bridge components. The Markov chain theory is used to model the change of discrete condition states and Monte Carlo simulation is used to find optimal inspection interval with the lowest cost. A case study with actual inspection data is presented to demonstrate the benefit of this study.

With the trend of embracing sustainable development for increased population, the challenge to bridge management agency is to prove the efficiency in asset management during the expected service life. The proposed procedure demonstrated through one example with specific assumptions would contribute to improve MRR strategy for bridge program, and reliability analysis for prioritization and long-term management.

2 METHODOLOGY

2.1 *Overview*

The methodology is developed to obtain the simulated inspection and maintenance strategies over the planning horizon. It is based on the widely adopted routine inspection with 4 rated conditions. The methodology contains the four following steps:

1. Calibrate the Markov model
2. Generate N simulated pathways of condition change over the selected planning horizon by using the calibrated Markov model
3. Define cost rate function
4. Apply cost rate function to the simulated pathways of condition changes to obtain the average cost rates for various scenarios.

2.2 *Markov model*

The Markov model is based on the stochastic theory of Markov chain (Madanat et al., 1995), which describes a system that can be in one of several condition states at any time, and it can stay still or move to another state at each time step with some transition probabilities. This theory is well suited for observation of level 2 condition data of bridge elements because the snapshot inspection reveals the condition state at the time of inspection and the unchanged and changed condition states over time can be captured with the transition probabilities.

The most important property of the Markov chain is that the probability of movement depends only on the current condition regardless of the history of movement, called memoryless property. This means that a) the currently known condition can represent for the accumulated deterioration up to the current time and b) the future condition does not depend on how long it stays in previous conditions. This property is well suited for long life assets such as concrete. In the opposite is usage-based assets such as light bulbs and machineries in which their future condition depends on how long they have been used in the past.

The Markov model is mathematically expressed as a matrix M of transition probabilities:

$$M = \begin{bmatrix} P_{11} & P_{12} & P_{13} & P_{14} \\ P_{21} & P_{22} & P_{23} & P_{24} \\ P_{31} & P_{32} & P_{33} & P_{34} \\ P_{41} & P_{42} & P_{43} & P_{44} \end{bmatrix} \quad (2)$$

where P_{ij} is the probability of moving from a condition state i to a condition state j over a unit time step. In this study, P_{ij} is assumed zero if i>j meaning improved condition is not modeled due to lack of maintenance data.

The memoryless property can be used to predict the probability vector [P_1 P_2 P_3 P_4] at any future time

T, given the known current condition with certainty or probabilities [C_1 C_2 C_3 C_4] as shown in the Kolmogorov Equation:

$$[P_1\ P_2\ P_3\ P_4]_T = [C_1\ C_2\ C_3\ C_4] * M^T \quad (3)$$

Several calibration techniques have been used to calibrate the Markov model, this study uses the proven Bayesian Monte Carlo simulation technique (Micevski et al., 2002) to estimate the transition matrix M of the Markov model.

The predictive performance of the Markov model is commonly validated using the Chi-square test on a separate dataset that is not used in the calibration of the Markov model (Micevski et al., 2002). The validation dataset is often randomly selected from 15-20% of the entire dataset.

2.3 *Simulated condition changes*

The evidence of inspection data and the theory of Markov chain show that for the same group of bridge component (e.g. group of concrete girders). Each member of group can experience any of many possible sequences of condition changes during their expected lifetime, saying 100 years. For example, staring from condition 1 as a newly constructed concrete girder in 1980, a possible sequence of condition change could be demonstrated as follows:

Start from year 0,
Condition 1 continues from year 0 to year 20,
Condition 2 continues from year 21 to year 34,
Condition 3 continues from year 35 to year 69,
Condition 4 starts at year 70.
End at failure at year 75.

From the demonstrated sequence, several observational points are: a) the conditions 1-4 are rated condition from the routine inspection, b) the exact timing of condition change is not known with the snapshot inspection approach (as compared to continuous monitoring approach) but can be detected by the closest inspection, c) the condition 4 often is not meant an immediate and actual failure but can be seen as the most likely leading to an actual failure, d) the time to enter condition 4 is uncertain and can be before or beyond the expected life of 100 years.

The 2000 sequences of random condition changes as demonstrated above can be simulated by using the calibrated Markov model as follows:

1. Start as condition 1 at current year 0 with current probability distribution [1 0 0 0]
2. Use Equation 3 to compute the probability distribution as next year (i.e. current year+1)
3. Randomly select the condition at the current year+1 from the probability distribution
4. The selected condition becomes the current condition and repeat the process until planning horizon T is reached.

2.4 *Cost rate function*

For an inspection-based asset management strategy, the cost rate function for such sequence of condition changes can be defined as shown in Equation 4 (Hong et al., 2014, Yanaka et al., 2016, Frangopol et al., 2017).

$$CR(TI) = \frac{1}{T}\left\{\begin{array}{l} \sum_{i=1}^{ni} a_i b_i * CI * e^{-\varepsilon * i * TI} + \\ + \sum_{j=1}^{nj} CM * e^{-\varepsilon * tMj} + \\ + \sum_{k=1}^{nk} CF * e^{-\varepsilon * tFk} \end{array}\right\} \quad (4)$$

where CR (dollar/year) is the average cost per year over a planning horizon of T years;

CI is unit inspection cost (dollar/structure), CM is repair cost (dollar/structure), CF is replacement cost (dollar/structure),

ni is number of inspection, nj is number of repair/rehabilitation, nk is number of replacement;

TI is inspection interval, tMj is time at the jth repair, tFk is time at the kth replacement,

T is planning horizon, ϵ is annual interest rate with typical value of 5%;

a_i, b_i are ≥ 1 and are the penalty costs acting on inspection cost due to the inspection interval is too large to detect the occurrence of poor conditions for repair or replacement.

Equation 4 shows the MRR cost over the service life of any existing bridge component. The MRR cost includes the inspection cost, repair cost and replacement cost. The capital cost can be added to Equation 4 for life cycle cost design of new component.

The exponent function in Equation 4 is to transform cost value at various future time into cost value at present time as per the concept of interest rate for proper comparison.

The key decision variable of Equation 4 is the inspection interval that should be optimised to have the lowest cost rate. A too short interval results in numerous inspection, which have higher chance of detecting poor conditions but come with higher inspection cost. A too long interval results in lower inspection cost but often fail to detect when repairable defects or failures occur.

A penalty is therefore applied for too long inspection interval that misses the repairable defects or worst condition. For example, it can be chosen that repair action will be taken if component condition is

3 or 4. A penalty of an inspection cost can be applied if that condition is not detected for a given inspection interval. Obviously, without penalty, the inspection interval will tend to be longer so that cost rate decreases. The penalty can also be viewed as a cost difference between planned and emergency repair/replacement in which user cost is also included. The user cost can contain time cost, vehicle cost, accident cost and so on.

2.5 *Applications*

From the simulated sequences of condition changes in Section 2.3, the average time from condition 1 to poor conditions can be calculated. This information can be seen as the average service life of the structures for financial accounting. It is noted that some structures might have longer service life and others have shorter life.

When the above simulated sequences are applied with cost rate function, two management strategies can be formed.

The first strategy is to search for lowest inspection cost over the short-term planning. This strategy can be applied for non-critical structures such as kerb and railing whose consequences of failure and repair are minor. In this case, the Equation 4 is applied with CM and CF assigned to zero. The search for lowest cost is conducted by using Monte Carlo simulation as follows. The inspection intervals from 1 to 20 years are fed into the 2000 simulated sequences of condition change. For each inspection interval, the average of inspection cost is calculated from the 2000 simulated sequence and is recorded. The inspection interval with lowest inspection cost can be found among different inspection intervals.

The second strategy is whether early intervention should be applied to reduce the total life cost because when inspection and MRR actions are included, the random sequence of condition changes can be revised as follows:

Start from year 0,
  Condition 1 continues from year 0 to year 20,
  Condition 2 continues from year 21 to year 34,
  Condition 3 continues from year 35 to year 69,
  Condition 4 starts at year 70,
  Detected by inspection at year 72,
  MRR action,
  Becoming Condition 1 at year 73 or new year 1,
  Condition 1 continues from year 73 to year 100 or new year 1 to new year 27,
End at design year 100.

The search to find the lowest MRR costs can be found in the similar manner with that of inspection cost.

3 CASE STUDY

The concrete open girder coded VR2C from level 2 inspection database of VicRoads is used to demonstrate the benefit of this study. This component is associated with 200 bridge structures.

One issue is called the first inspection because the average built year is 1972 with standard deviation of 21 years. However, the first recorded inspection year was 1995. It is not sure whether any maintenance action had been conducted from built year until first inspection record. Taking example of the 2C open girder, it has been found that there are 239 first inspections out of 757 inspections and 144 out of 239 cases shows 100% in condition 1. This means the use of first inspection data would likely to reduce the rate of deterioration as compared to second and third and later inspections (hereafter called second-up inspection data)

Another study (Ackah 2016) has found the similar issue. To ensure reliable data, the effect of first inspection records on the outcome of MRR costing is investigated in this study by comparing all-inspection containing first-inspection with second-up inspection.

The average cost of level 2 inspection is $150 AUD per bridge structure. This inspection cost is taken as unit cost and other cost is represented as relative to this cost. The costs of repair and replacement are not available in the database and thus are assumed to be 20 and 60 times of inspection cost, respectively.

4 RESULTS

4.1 *Comparison of deterioration rates*

The Markov models are calibrated and pass validation test with the level 2 inspection data. The calibrated transition matrix for old bridge is shown as a demonstration in equation 5 and 6 for all-inspection and second-up inspection.

$$M(all)=\begin{bmatrix} 0.9934 & 0.0052 & 0.0008 & 0.0006 \\ 0 & 0.9984 & 0.0009 & 0.0007 \\ 0 & 0 & 0.9972 & 0.0028 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (5)$$

$$M(\text{second})=\begin{bmatrix} 0.9894 & 0.0082 & 0.0018 & 0.0006 \\ 0 & 0.9889 & 0.0104 & 0.0007 \\ 0 & 0 & 0.9991 & 0.0009 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (6)$$

Table 1 shows the average time from condition 1 to condition 4 for various cases. The effect of first inspection is on the recently built bridge structures, which is more significant than on the low traffic.

Table 1. Average time from condition 1 to condition 4 for built year and traffic volume.

Factor	All Inspection	Second Up inspection
Old age	187	187
Young Age	174	125
Low Traffic	180	168
High Traffic	168	167

4.2 *Whole life maintenance strategy*

The whole life maintenance strategy can be whether to repair at condition 2 or 3 that would produce lowest annual cost. Table 2 shows the results for different factors with input parameters as follows. The expected service life is 100 years, the interest rate is 5%, the repair cost is 20 times inspection cost, the replacement cost is 60 times inspection cost and the penalty cost is the same with inspection cost.

The results of Table 2 indicate that the repair at condition 3 with shorter inspection interval can still have better cost-saving than at condition 2 with longer inspection interval. This finding can help focusing inspection strategy on detecting condition 3, which is addressed in the subsequent section.

Table 2. Effect of repair at condition 2 and 3 on the lowest annual cost and inspection interval for second up inspection data.

Factors	Repair at condition 2		Repair at condition 3	
	Lowest annual cost*	Inspection Interval	Lowest annual cost*	Inspection Interval
Old age	0.021	50	0.0156	48.6
Young Age	0.055	35.8	0.047	22.8
Low Traffic	0.032	49	0.026	32.6
High Traffic	0.032	49.2	0.029	37.5

* Based on unit cost of $1 for inspection cost.

4.3 *Inspection strategy*

Given the preferred condition 3 for early intervention as identified in the previous section of whole life maintenance, the inspection strategy can be focused on detecting condition 3. Figure 1 shows the annual cost rates for different inspection intervals for the case of detecting condition 3 from condition 1 under low traffic volume over the short planning of 20 years with penalty of twice inspection cost and zero interest rate.

From this figure, the lowest inspection cost rate as 11 years can be found for both cases of All inspection and Second-Up inspection. The highest inspection cost obviously occurs at 1-year interval. As the inspection interval time increases, the annual cost rate decreases until the lowest because after that point, the annual inspection cost starts increasing due to the effect of penalty. The lowest cost rate of second-up inspection is slightly higher than the all-inspection.

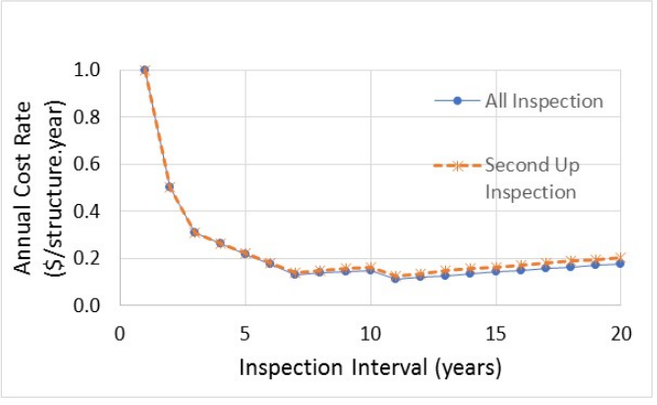

Figure 1. Annual cost rate for different inspection intervals.

Figure 2 shows the number of undetected poor conditions (i.e. the selected condition 3 in this study) for the same case of low traffic volume with second-up inspection. As expected, the lowest number of zero undetected occurs at the inspection interval of 1 years. As the inspection interval increases, the annual number of undetected cases also increases. This is the risk associated with longer inspection interval and lower inspection cost.

As a result of Figures 1 and 2, asset engineers should be aware of the cost and benefit of various inspection intervals and the effect of first inspection.

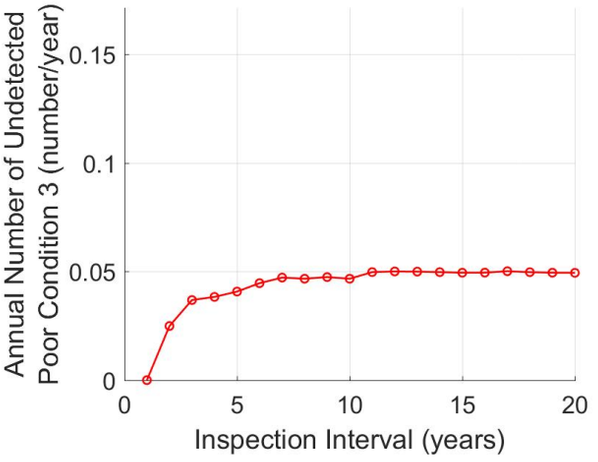

Figure 2. Annual number of undetected poor conditions for various inspection intervals

Table 3 shows the lowest cost, inspection intervals and annual numbers of un-detected poor condition 3 for different factors on Second-up inspection data.
All four factors have the same inspection interval but the lowest inspection cost and number of undetected poor condition are found with old structures. The other extreme is surprisingly found with young structures. This could be due to the implication of old design and construction methods as compared with the newer ones.

Table 3. Lowest cost inspection interval for different factors on Second up inspection data.

Factors	Lowest annual cost*	Inspection interval	Number of undetected poor condition 3
Old age	0.060	11	0.011
Young Age	0.071	11	0.036
Low Traffic	0.067	11	0.020
High Traffic	0.068	11	0.021

* Based on unit cost of $1 for inspection cost.

5 DISCUSSION

This study is limited to the case of concrete material with a demonstration on open girder 2C. However, the methodology can be extended to all bridge elements with different material.

The effect of traffic volume and age are investigated in this study. Further studies can look at the impact of interest rate and other contributing factors such as exposure class and percentage of truck.

The detailed costing for user cost, which constitutes the penalty used in this study, and maintenance cost together with discount rate will be established in future works.

The comparison between Markov model and other stochastic models such as Gamma process model (Edirisinghe et al., 2013) will be further investigated.

6 CONCLUSION

Deterioration models can significantly improve the efficiency of asset management of bridge networks. This study demonstrated an application of Markov deterioration model for determining risk-based inspection and maintenance strategies through development of a computational methodology. The methodology incorporates Markov deterioration model with cost rate function and Monte Carlo simulation to search for the inspection interval with lowest inspection cost, and whole life maintenance cost.

The major innovation of this methodology is the ability to simulate the condition changes of bridge elements due to deterioration over a planning horizon. Furthermore, the methodology also allows to capture the condition improved due to rehabilitation actions and the restart of deterioration process after rehabilitation for inspection and maintenance strategies.

The findings are that the inspection interval with lowest inspection cost can be used with informed risk. Early intervention can be done on condition 3 instead of condition 2 for lower maintenance cost. The outcomes of this study can provide understanding of risk and cost-saving when making decision on inspection and whole life maintenance strategies.

Maintenance Cost Evaluation based on Bridge Performance Degradation Model

S. H. Kim, W. H. Heo, J. G. Choi & M. Gombosuren

School of Civil and Environmental Engineering, Yonsei University, Seoul 03722, Korea

ABSTRACT: This study proposes the future life cycle cost evaluation method, in which the future performance degradation models are adopted to estimate the future maintenance cost and the expected loss due to the bridge safety. A procedure to adjust the future performance degradation model is proposed based on the bridge inspection records and considering the site environments. The basic degradation model is adopted from the previous research results, which are developed through the regression works with many local bridge inspection records. When the previous inspection records are not available, the current performance level is the only information to adjust the degradation model. The effect of previous inspection records is examined in the study. The expected loss in LCC is estimated through the reliability evaluation based on the local traffic load effect evaluation and the future performance degradation model. The case study has been performed with a PSC girder highway bridge.

1 INTRODUCTION

As the number of aged and deteriorated bridges that require proper maintenance and rehabilitation is increasing globally, the reasonable maintenance planning and budget allocation for such bridges is necessary. The performance degradation of a highway bridge may be depending diversely on both the construction quality and its local site environments, such as traffic condition, corrosion environment, maintenance level, etc. The most reasonable maintenance plan should be set based on the current performance level and future degradation pattern. The future deterioration model may be adjusted properly utilizing the performance degradation history based on the bridge inspection records, which may represent the site environments as well as the initial construction quality.

This study assesses the maintenance cost arising from the performance degradation of a PSC girder bridge. Bridge performance evaluation based on its reliability is used to estimate the maintenance cost. The performance degradation of bridge can be assumed to be attributable to diverse conditions in the site environment. This study proposes a method of developing a performance degradation model that considers traffic characteristics and corrosion environments as the site environment and that is based on the result of previous evaluations of an in-service bridge. It also explains the result of the maintenance cost analysis for the purpose of setting a reasonable repair schedule based on the performance degradation model.

2 TRAFFIC LOAD MODEL

The probabilistic traffic load characteristics such as daily traffic volume, heavy vehicle proportion, heavy vehicle weight model, and heavy vehicle consecutive traveling mode may play an important role in the highway bridge performance reliability during the service life of the bridge. The consecutive travelling characteristics of heavy vehicles are widely understood to cause the unintentional high load effects, especially on medium span bridges. The Markov transition probability matrix models are developed based on the site traffic load survey data to include the consecutive travelling effects in the estimation of maximum traffic load effects in the intended service period. Table 1 lists the consecutive traveling coefficients and proportions of single vehicles to heavy vehicles, which is the very important parameter in the models (Kim et al., 2017). Table 2 explains how the consecutive travelling models affect the extreme traffic load effects on a simple model bridge (30m span). The values in Table 2 are the annual 95% extreme live load effects normalized with the design live load effect.

Table 1. Transition probability matrix models.

(a) Heavy vehicle proportion : 25%

Type	Consecutive traveling coefficient (Consecutive traveling probability: %)					Simple vehicle proportion (%)	
	P	B	T	TT	ST

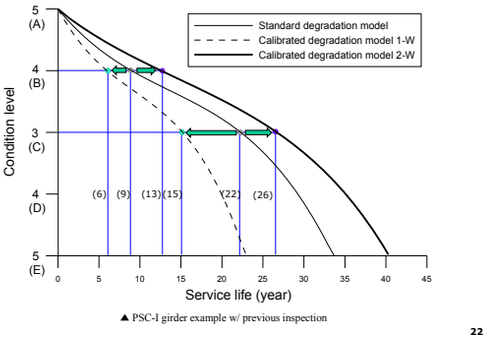
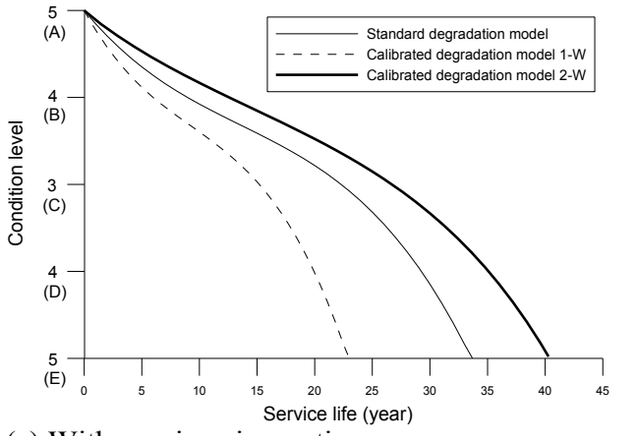
3 PERFORMANCE DEGRADATION MODEL BASED ON INSPECTION HISTORY

3.1 *Calibration of performance degradation model considering inspection results*

The performance degradation of a PSC girder bridge is believed to be influenced by various site environments. Future performance degradation is estimated by calibrating a representative degradation model using past inspection results of the bridge. Figure 1 shows an example of the degradation model corrected by inspection history. Table 3 shows an example of the inspection history. In Table 3, 1-W and 2-W show the cases of regular inspections. 1-W/O and 2-W/O present cases with no past inspection reports. Figure 2 shows the calibrated degradation function. A degradation model may provide inaccurate estimation of future performance degradation depending on the availability of past inspection results. However, a degradation model that has been corrected by past inspection results is not so sensitive to the availability of previous inspection data as long as the current performance status is included. This implies that the proposed calibration method can provide a stable degradation model that does not rely too much on past inspection data.





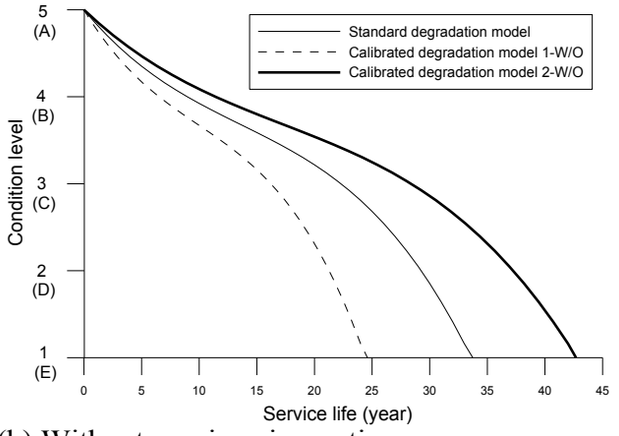


Figure 1. Calibration of performance degradation model

Table 3. Example inspection histories of PSC-I girder.

History	Year of inspection															
	2	4	6	8	10	11	13	15	16	18	20	21	23	25	26	28
1-W	A	A	B	B	B	B	B	C	C	-	-	-	-	-	-	-
1-W/O	-	-	-	-	-	-	-	-	C	-	-		-	-	-	-
2-W	A	A	A	A	A	A	B	B	B	B	B	B	B	B	C	C
2-W/O	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	C

(b) Without previous inspections

Figure 2. Calibrated performance degradation models

3.2 *Performance-based resistance deterioration model based on corrosion environments*

The existing concrete cracks should be considered when evaluating the deterioration of resistance capacity due to a corrosion environment. The corrosion environments of bridges are classified as mild, normal, and severe. Figure 3 presents the cross-sectional profiles of the example bridge (Kim et al., 2016). The performance-based resistance deterioration model is developed by combining a resistance deterioration model and performance degradation model (Figure 4). Figure 5 shows the resistance capacity of PSC girder bridges in various site environments. The estimated decrease in resistance capacity varies according to the crack width measured at the bridge.

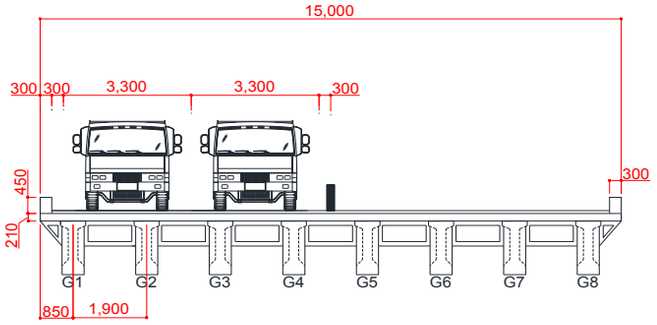

Figure 3. PSC-I bridge (span=30m)

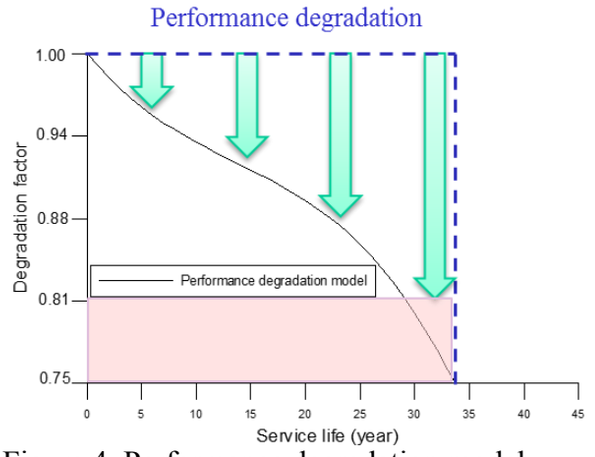

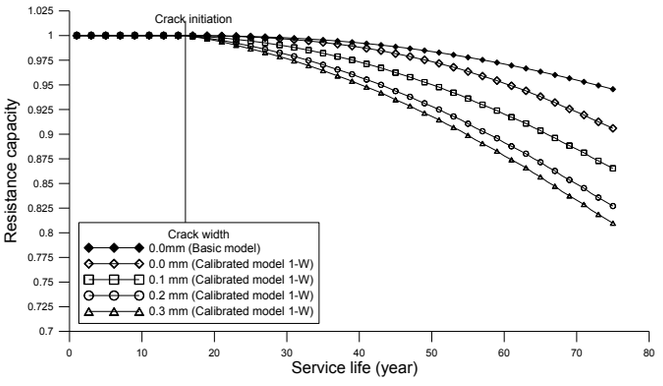

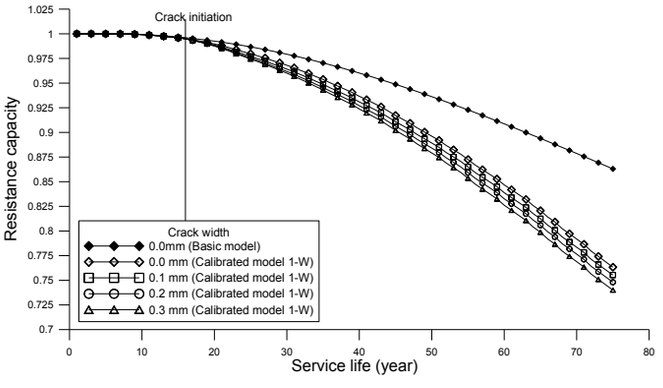

Figure 4. Performance degradation model

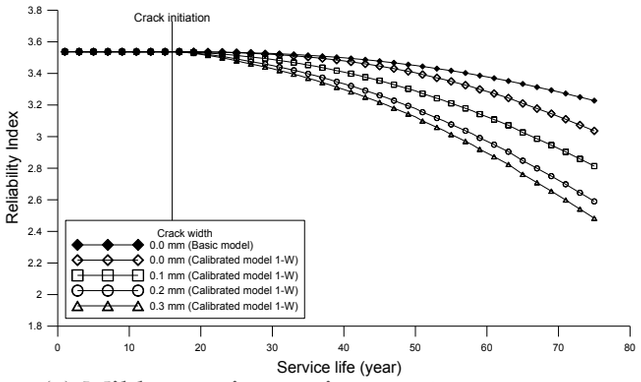
(a) Mild corrosion environment



(b) Severe corrosion environment

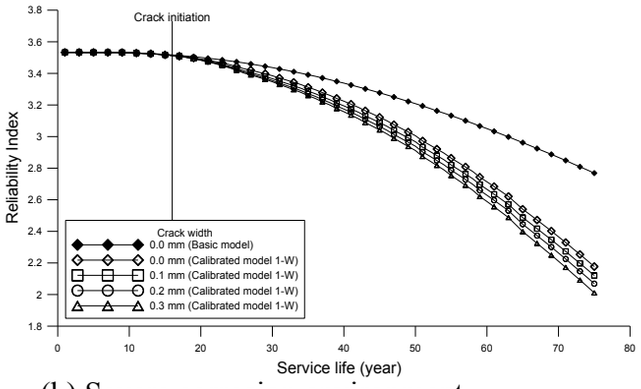


Figure 5. Performance-based resistance deterioration model

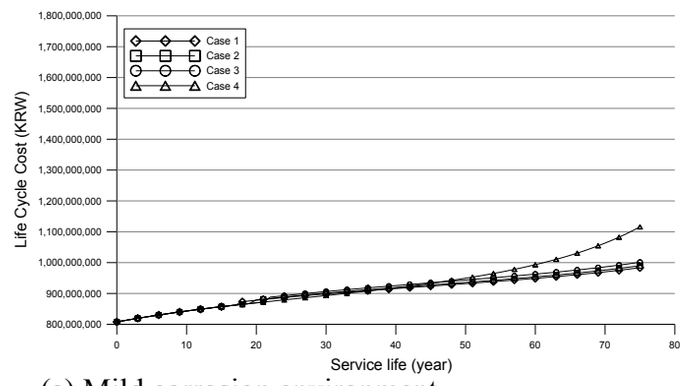
3.3 *Reliability evaluation considering resistance deterioration model*

The expected performance degradation is evaluated in terms of the reliability level as shown in Figure 6, in which the probabilistic models of the bridge resistances and loadings are included. The traffic load effect model has been developed through the Monte Carlo simulations based on the traffic models mentioned above for the inventory bridge.

(a) Mild corrosion environment



(b) Severe corrosion environment

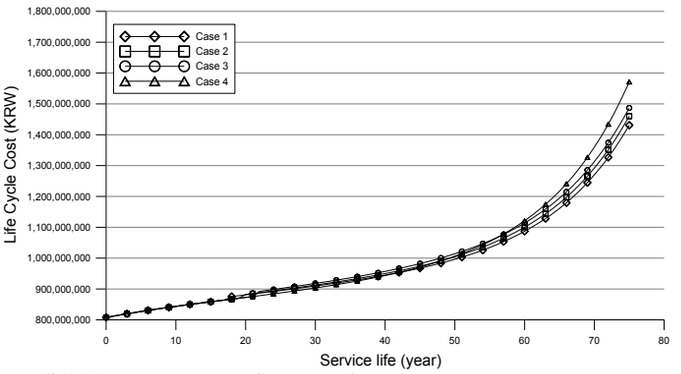


Figure 6. Reliability evaluation considering performance-based resistance deterioration model

4 MAINTENANCE COST EVALUATION BASED ON PERFORMANCE DEGRADATION OF BRIDGE

Figure 7 shows the maintenance costs of bridges that were evaluated based on the performance-based resistance deterioration model by considering traffic characteristics and corrosion environment. When the corrosion environment is mild and the traffic characteristics is normal, performance degradation slows down and maintenance costs decrease. By contrast, when the corrosion environment is severe and the traffic characteristics is normal, performance declines rapidly and maintenance costs increase accordingly. These results indicate that site environments influence the performance degradation characteristics and maintenance costs of bridges.

(a) Mild corrosion environment

(b) Severe corrosion environment

Figure 7. Maintenance cost evaluation

5 CONCLUSION

In this study, the maintenance cost based on performance degradation was evaluated for PSC girder bridges. A method of developing a performance-based resistance deterioration model by considering traffic characteristics, corrosion environment, and inspection history was proposed to analyze the performance degradation of bridges. The proposed method was found to be very efficient in considering systematically the performance degradation characteristics based on bridge inspection results as well as site environmental characteristics, such as traffic conditions and others factors that contribute to structural deterioration. If the proposed method is applied to the development of maintenance plans, it is expected to be helpful in establishing a rational plan.

An Integrated Model-Based Bridge Management System

S.T. Hou, G. Wu & H.L. Li
College of Civil Engineering in Southeast University, Nanjing, Jiangsu, China

ABSTRACT: How to manage and maintain aging bridges becomes a critical issue in both engineering research and practice. This paper presents an integrated bridge management system for tracking and assessing the structural condition of bridges. First, the system supported by JAVA software platform collected model-based data of bridges. Second, the authority management and task dispatch were established for transport agencies. Next, the interactive 4D models of the bridges with structural information and history record of multiple data can be visualized. 3D panorama created by special cameras provided the surrounding environment of each bridge in website browser. Furthermore, inspectors can use mobile apps to capture and update bridge damages. It is found that the interactive 4D models can facilitate data sharing and avoid the barriers from other Building Information Modeling software. The developed system can lead to a more automated and powerful practice for bridge management and similar applications in bridge management.

1 INTRODUCTION

Recently, the rehabilitation and management of bridges has become a big concern in China. According to the Report from ASCE, as of 2016, America's Infrastructure Scores is D+, and C+ for bridges, the U.S. has 614387 bridges, almost four in ten of which are 50 years or older, and 9.1% of the nation' s bridges were structurally deficient in 2016 (ASCE, 2017). In Japan, many highway bridge were built in 1950s, many of which have seriously deteriorated over the years. China has experienced the golden age of infrastructure construction, the total number of bridges is 805300. However, due to the factors such as the increase in traffic volume and weight, almost 90000 bridges were structural deficient.

While the number of bridges that are in such poor condition as to be considered structurally deficient is decreasing, bridge maintenance method are approached to keep bridges safe. Since the collecting data generated from the inspection and monitoring, and the demand to predict the bridge condition and decision making is urgent using these numerous data. The necessity of developing a practical bridge management system points out.

The development of a comprehensive bridge management system is essential (Akgul, 2017). Such a system should enable not only store the data, and evaluate the condition of bridges, but also the capacity to make the decision which takes into account the limits funds that are available for bridge maintenance.

The Pontis bridge management system of a AASHTO product, includes the inspection data, recommends the preservation policy and predicts the needs and performance for the agency. It also supports the agency-specific needs (Robert & Marshall, 2003). Pontis provide the assessment function mainly based on the inspection data, and 3D model has not widespread used until now. J-BMS is applied to existing reinforced concrete bridges, it provides the performance evaluation of bridges and the maintenance strategies considering the cost minimization and quality (Miyamoto et al. 2001). Ongoing efforts to develop to the road management system based on Pontis have resulted in KUBA-MS in Swiss, several distinguished features have exploited including condition assessment and forecast, elaboration of working program (Hajdin, 2000). For current bridge management system especially in China, the documents are stored in print version or textual comment in database. Chan & Guan (2016) defined a integrated framework for modeling and imaging, and ultimately highlighted the need for alternative approaches to bridge inspection to more accurately monitor the current condition of key structural elements in a model-based method. McGuire (2016) presents a method and prototype implementation for bridge inspection and evaluation in Bridge information modeling, using BIM software can analyze and present that information to help make decisions on the basis of the damage location and provide maintenance recommendations.

This paper presents an integrated bridge management system for tracking and assessing the structural condition of bridges, the system links the information about several stages of a bridge (e.g., design, inspection, and maintenance) to an interactive 4D model incorporating different record events, 3D panorama created by the special cameras was supported in this system, and the surrounding environment of each bridge can be seen in the website browser. In addition , a rule-based expert system to support the decision-making is provided in this system. The methodology in this system will be describes from user perspective.

2 PROPOSED FRAMEWORK

Current BMS provide different modules to perform their functions (Marzouk & Hisham, 2012). Figure 1 shows the proposed framework of the integrated BMS and Figure 2 shows the connectivity between different functions in this system. The full description of the proposed framework is provided in the below section.

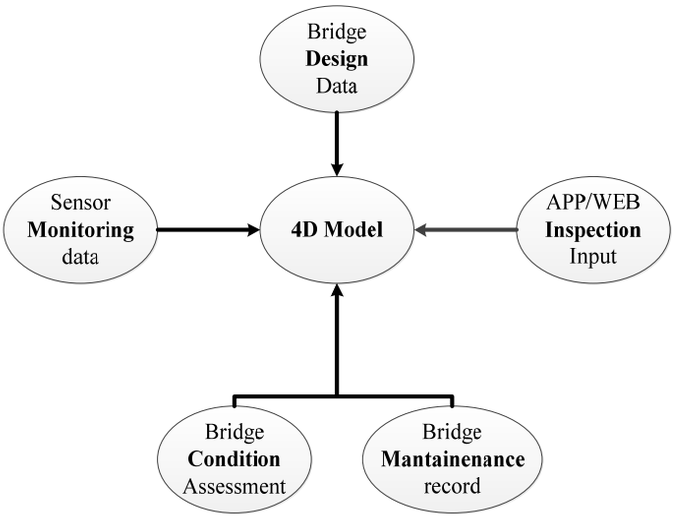

Figure 1. Proposed framework of the integrated BMS

The system supported by the Java software platform mainly contains five modules, and web-based property guarantees no proprietary software needed. The MVC design pattern is selected for the present framework. This pattern enforces the separation between the input, processing and output of an application. Each of these components handles a discrete set of tasks, enabling loose coupling and the ability to change one component without affecting the others (Potel, 1996).

Java database connectivity (JDBC) is a programming framework for Java developers writing programs that access information stored in databases. The system connects with MySQL to present bridge information of the name, type, location, properties, components and other data in specific functions. MangoDB system is designed to store the sensor data in corresponding tables (Hammad et al. 2006). Android application is developed in Java software platform for the inspection, the data captured on mobile phones could be stored in the MySQL database mentioned above.

4D model in this system means the 3D model of bridges with multiple information in element level, interactivity makes the element labeled with the corresponding data, it is supported by the WebGL which is a JavaScript API for rendering interactive 3D graphics within any compatible web browser without the use of plug-ins. WebGL based on the OpenGL can be used in HTML5 elements.

2.1 *System right management*

This system designed for the bridge owner and agencies to manage bridges in China efficiently, and inspection departments are granted permission to login their account for recording and browsing bridge deterioration in appointed modules. Research institutes could consult the inspection and monitoring data by means of the permission given by managers. The construction staff could upload the reinforcement or maintain plan in their account in this system. Super administrators are set up to manage the whole users as shown below.

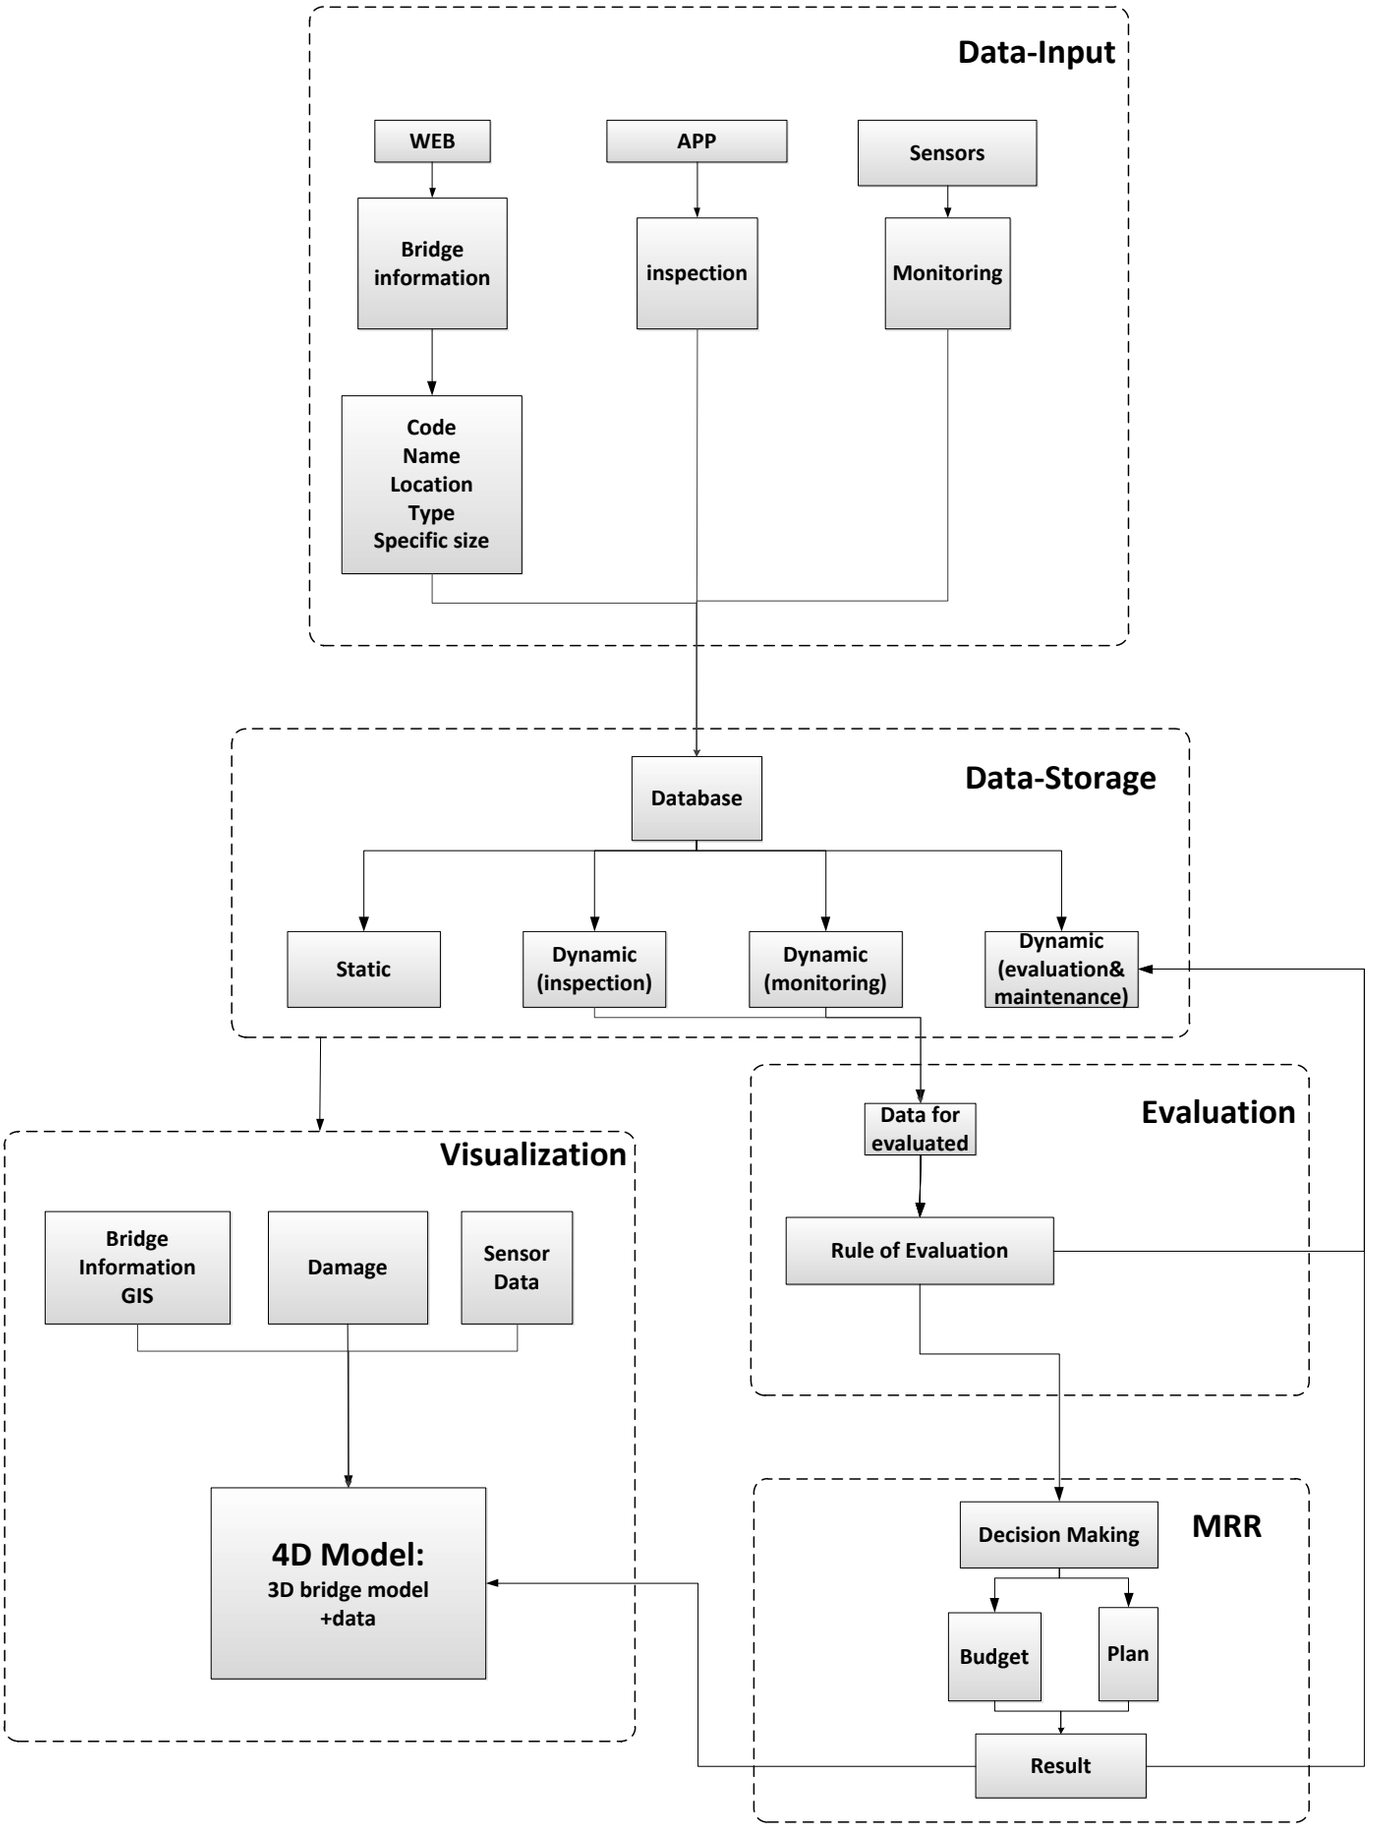

Figure 2. Connectivity between different functions

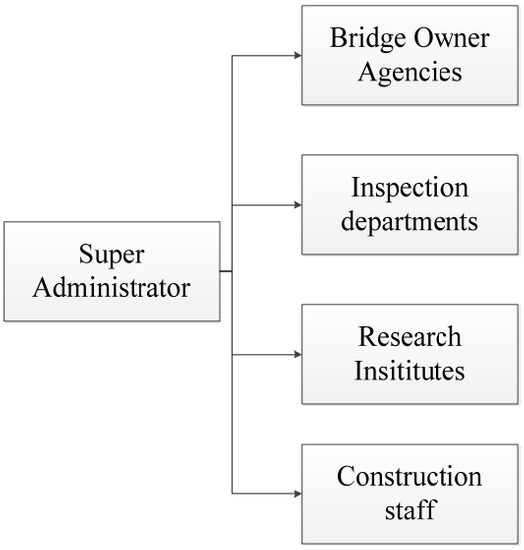

Figure 3. User roles in system

2.2 *Location-based bridge selection*

Due to the superior spatial data handling capabilities, geographic information system (GIS) technology is increasingly being considered for implementation in many BMS (She et al. 1999), Bridge location information from the MySQL database is selected for the GIS visualization in this system, Baidu map used in China provides an open API wrapper for drawing objects onto maps, bridges represented by their center points could be seen in the map based on the location information, bridge distribution is perfectly shown in the BMS.

2.3 *Mobile-based inspection*

In the proposed method below, an inspector uses a mobile install the app to capture the damage information about type, amount, severity, location and photo during the inspection period, and the data could be used and visualized on the website based on the shared database (Lee & Yi, 2004).

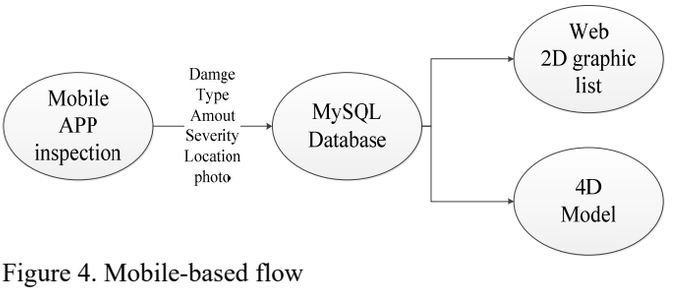

Figure 4. Mobile-based flow

2.4 *Monitoring*

The system provides several sensor interfaces based on the material and transmission type. For the wireless connection, UDP or TCP/IP ports and programs are developed to receive data in high or low frequency depend on the sensor sample rate. The data received from wire sensors mainly sent by the base station in Internet, related path folders are created to store in the BMS. Piezoelectric, optical fiber and electromagnetic type are considered, and corresponding algorithms are applied to manage different kinds of sensor.

2.5 *Evaluation and maintainnence*

According to the Evaluation Criteria of Highway Bridge Technical Status in China, bridge scores and ratings are calculated by the relevant algorithm based on the inspection data in the system. After that, deficient bridges with low scores are listed and maintenance information is sent to the bridge owners, the budget and plan for these bridge could be recorded in this system (Hai, 2008).

2.6 *Integrated model*

A 4D *model* of every bridges in this system is developed for visualizing different types of data, for example, displaying the damage changes in a bridge3D model at a specific time or during a specific period of its lifecycle. Visualization has powerful functions for interacting with the system in a virtual reality modes, inspection and condition data can be integrated in the 4D model. At the same time, 3D panorama show the real environment around the bridge which facilitates the inspection or construction work if necessary. The integration of 4D model with the 3D panorama builds a powerful function for virtual reality.

3 CAPACITY OF MODEL-BASED BMS

The structure of the prototype system follows the framework architecture explained above, the system integrates an interactive 3D model of a bridge with an object-relational database, GIS and tracking components, and multimedia equipment to develop a 4D model for BMS that can be used, on-site mobile application is developed for capturing and updating damage information, 3D panorama function provide the real environment around the bridge. the specific function of every module is explained below.

3.1 *Basic information*

The first menu in system is basic information. The login interface contains a GIS-based map which show the distribution and condition of bridges in system, the label which represent the center point of bridge location has six colors, express the class 1, 2, 3, 4, 5 and unclassified condition. The condition of bridges depends on the evaluation scores in the

Evaluation Criteria of Highway Bridge Technical Status (ECHBTS). The total number of bridges and the historical curve included in this system can be queried, and the summarizing of bridge condition and bridges to be repaired could also be queried in this page. Modal window is created to show the code, location, and scores of bridges when the color label clicked in GIS map.

Another submenu is the list with condition or fuzzy search of bridge information contains name, type, time, location and department, user could add, delete or modify the bridge basic information in this page. It should be pointed out that the specific information about the structure and element is shown in several lists with a modal window which contains the link to 4D model and 3D panorama.

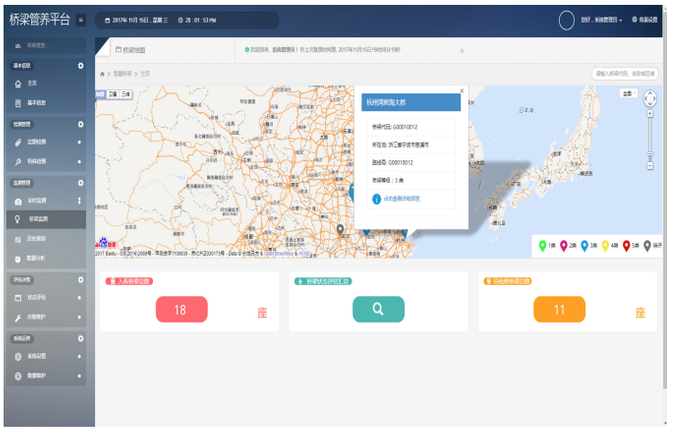

Figure 5. GIS-based map

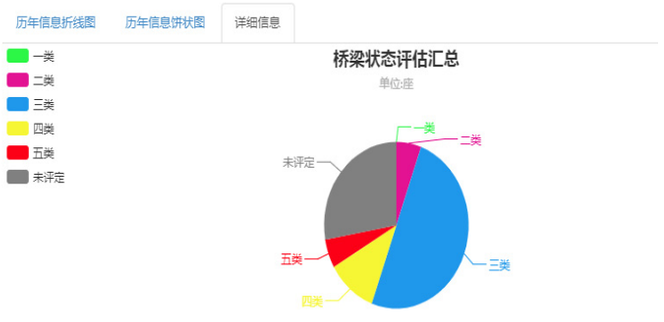

Figure 6. Summarizing of bridge condition in pie chart

3.2 *Inspection management*

In this menu, task dispatch and damage input are the main function. User of bridge owner could designate staff with regular inspection task of which the condition and collection could be referred in this page. Each task for capturing and updating damage of bridges could be utilized both in Web or mobile phone. The web provides the list the bridge code, task code, bridge name and the staff, user could record the damage by element level of bridges as shown below. Inspection record of damage could be seen in the submenu ordering by time, and the connection of 4D model with damage information also contained, the colored element shows the severity of damage in this region as shown in Figure 8.

Figure 7. Mobile application for damage inputting

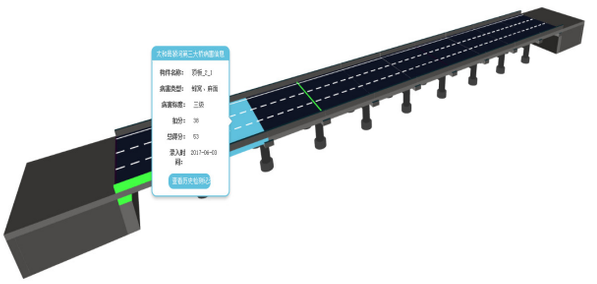

Figure 8. 4D interactive model with damage information

3.3 *Monitoring management*

This menu mainly focuses on the three monitoring type of bridges, including long-term real-time monitoring, construction monitoring, and special monitoring. The bridge list of monitoring in each type could be searched which contains bridge code, name, location and department. Sensors in each monitoring bridge could be set, and the real-time data in curve could be seen in each sensor page as shown in Figure 9.As with inspection management, the historical data could be queried with condition search option.

Figure 9. Real-time monitoring data of displacement sensor

3.4 *Evaluation and decision-making*

With the inspection data recorded in database, the condition scores could be displayed in this menu, details of damage and evaluation also recorded within list and 4D model as is shown later. After evaluation finished, corresponding maintenance work including replacement of abutment, main grider reinforcement, expansion joint replacement, etc. will be recorded in this menu.

Figure 10. Evaluation information in pie chart

3.5 *System operator*

This menu is opened only for the super administrator, the authority of using functions mentioned above and user management could be facilitated, and new type of department for special work could be created as well.

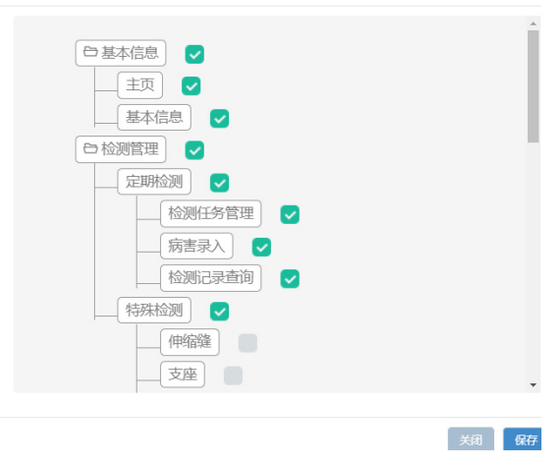

Figure 11. Authority and user management

3.6 *4D model and 3D panorama*

The 4D model mentioned above built after the basic information completed, virtual universes in WebGL can be created from scene graphs. Scene graphs are assembled from objects to define geometry, location, orientation, and the appearance of objects. The model contains the necessary element of bridges including main grider, pier, abutment, bearing, expansion joint, foundation and the merchandising. All element information obtained from MySQL database, and cloud picture is applied to identify the detail about damage severity, sensor location and the maintenance record. As Figure 11 shown, 5 options represent basic, damage, evaluation, maintenance and sensor model respectively. The basic model shows the type of bridges and the detail of every element, details in damage, evaluation and maintenance are shown in element level which could be referred by the interactive function. Last model displays the sensor layout on the bridge, and the real-time data curve could be seen by click the link on the modal window.

Figure 12. 4D interactive model

3D panorama theory in this system is shown below, six photos mapping six cube face taken with special lens created a 360-degree cylindrical panorama. Environment around bridges can be known in this function which facilitates the on-site inspection and construction.

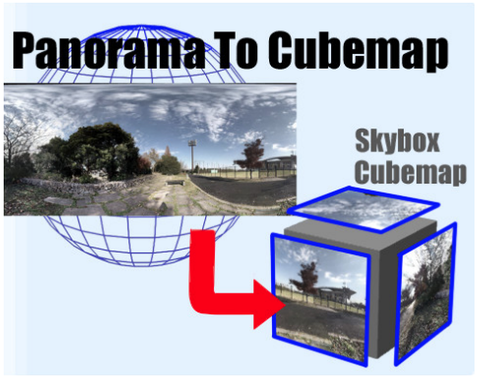

Figure 13. 3D panorama Theory

4 CONCLUSION

This paper proposed a new type bridge management system applied in China, and discussed the features of this system. The first attempt is to establish the database to support the integrate 4D bridge models, on-site mobile application for damage capturing and updating also mentioned. the following conclusions can be stated:

(1) the authority management and task dispatch including inspection, monitoring and maintenance were established for transport agencies. The related officials can be informed of dangerous bridges via e-mail.

(2) 4D models of the bridges were created using model-based data. The structural information and history record of inspection data, monitoring data, sensor location, evaluation data and maintenance data can be visualized by the interactive interface. 3D panorama created by the special cameras was supported in this system, and the surrounding environment of each bridge can be seen in the website browser. The integration of 4D model with the 3D panorama builds a powerful function for virtual reality.

(3) port expansion was exploited with hardware interface. Inspectors can use mobile apps to capture the bridge damages, and inspection data and reports are automatically recorded according to the prescribed form.

It is found that this system can effectively improve the work efficiency of bridge management, and the interactive 4D models can facilitate data sharing and avoid the barriers from other Building Information Modeling software. Further testing of the developed components of the system in practical situations is necessary to improve the functionalities and usability of the system. It should be noted that this research is still in progress and many aspects are still to be implemented and tested.

Indian Bridge Management System - Overview and Way forward

Sachidanand Joshi
Team Leader- Research on IBMS project
Director- IDDC Engineers Pvt. Ltd.

Sitarama Sagi Raju
Co- Researcher IBMS project
Managing Director- IDDC Engineers Pvt. Ltd.

ABSTRACT
Indian Bridge Management System (IBMS) was initiated by Ministry of Road Transport and Highways, Government of India in September 2015. In a country where no formal bridge management system exists, the task to get IBMS going in a short time was a herculean task. Initial development was based of the practicality of the implementation. Some basic parameters essential to define the bridge and ensure sufficient data is collected to digitize the management system was put in place.

Inventory and Inspection module of the system was commissioned in October 2015 and first cycle of various bridges inventorized and inspected,.

Table 1. Inventory of structures – IBMS October 2017

Sr. No.	Type of Bridge	Total Number
1	Culvert < 6 (CV)	133085
2	Extra-long Bridge length above 150m (EL)	1744
3	Major Bridge length above 60m (MA)	3395
4	Minor Bridge length 6m to 60m (MI)	31534
	Total	169758

We had found 6551 number of bridges that are structurally inadequate and their details are given below

Table-2 Distress bridges - IBMS June 2017

Sr. No.	Type of Bridge	Number
1	Minor Bridges	5591
2	Major Bridges	664
3	Extra-Long Bridges	296
Total		6551

Bridges and a structure was completed within 14 months. The paper outlines the challenges and solutions provided during the initial period. It outlines the various modules that are under implementation post this inventory and inspection module. Testing and definition of remedial measures is the next module which aims to make safe all bridges on Indian National Highways (NH).

Once safety issues of the bridges are addressed, the efficient management policies will be implemented. Such an approach has enabled us to identify bridges which need rehabilitation intervention to make them safe in a short span of 18 months. Work on bridge repairs will begin post monsoon season.

IBMS will ensure the birth of Indian Bridge Rehabilitation Industry as none exists today. IBMS seeks expertise in this area. Volume of work is estimated to be USD 750 Million.

IBMS at present covers only 3% of road network and soon will cover about 45% road network when it is implemented in all 29 regional states of the country.

Bridge management implemented by the South African National Roads Agency

E.J. Kruger
The South African National Roads Agency SOC Limited, Pretoria, South Africa

A.A. Nyokana
The South African National Roads Agency SOC Limited, Pretoria, South Africa

ABSTRACT: Bridge management methods are becoming more and more sophisticated and costly. However, the goal of bridge management is sometimes lost in the desire to collect more and more data. The basic aim should always be to identify critical defective bridges to implement timely interventions. The cost of inspections must be balanced against budgets actually allocated towards repair. Prioritization lists of defective bridges must make sense or else the credibility of the management system will be brought into disrepute. The South African national Roads Agency SOC Ltd in common with other state institutions, uses a defects based system, referred to as the DER System, for inspections and not a condition based system. Outlined in the paper is inspection requirements and how structures are categorized from good to critical using the "deduct method" of prioritization. The simple calculation of how the asset values of bridges are determined is also outlined.

1 INTRODUCTION

The The South African National Roads Agency SOC Limited (SANRAL) is a state-owned company that was formed in 1998 with a mandate to finance, improve, manage and maintain the national road network in South Africa. The national road network consists of approximately 22000 km of paved roads with a total of about 3750 bridges. Unlike road pavements structures, bridges generally have a longer design life and so the pressure to delay bridge repairs in budgets is evident. Institutions need to be aware that the repair and rehabilitation of structures cannot be delayed indefinitely as this sometimes leads to disastrous failures with all the associated negative consequences.

Bridges are important elements of the national road network making effective management and proper maintenance of these structures essential. An appropriate systems approach to the management of bridges should assist the managing authority in identifying the best time for maintenance intervention and the most appropriate allocation of funds.

2 THE STRUCTRES MANAGEMENT SYSTEM DEVELOPED FOR SANRAL

Prior to 1998 an overall condition based system was used for the management of bridges for the national roads. It was found to be ineffective in that bridges in need of repair were not high on priority lists whilst bridge not in need of repair were higher up the priority lists. This lead to resistance against relying on results from the then bridge management system. Under this old condition based system the inspector had to rate each and every element of a structure regardless if there are defects or not. The ratings were then combined for similar members to get an overall condition rating for the members and then for the overall structure.

The inability to identify critical structures needing urgent repair resulted in SANRAL's management to decide to scrap the old condition based management system and to develop a totally new system. In 1998 SANRAL contributed to research into a new defects based system by the Council for Scientific and Industrial Research (CSIR) and a consulting engineer a defects based system. The CSIR system became known as STRUMAN (Structures Management) and was

further developed and refined in collaboration with SANRAL. This system, also referred to as DER System, is now used for the management of bridges on the national road and provincial road, and some metropolitan road networks.

The priority lists for repair that are obtained using this system have been refined and now give good believable priority lists. As a result, regional management now accepts that the right bridges have been identified for repair.

The decision to move from an old system with years of accumulated data was brave one in that the old data had to be scrapped.

3 THE DANGER OF UNEXPECTED FAILURES

When failures occur inevitably there is an accusation by the public and politicians that the authority did not inspect the structures or do repairs.

SANRAL recently on the 9th August 2017 at 01h15 had such a case where a pedestrian bridge structure collapsed onto the busy N3. Fortunately, the collapse occurred on a public holiday and nobody was killed. The bridge did not collapse onto any vehicle. However, three trucks and a car did drive into the bridge as can be seen in Figure 1. The initial reaction of the public was that SANRAL did not maintain the bridge and that was the reason for the collapse. It was fortuitous that a full inspection of the bridge had been done in Late July 2016, the previous year, with no defects of any significance being noted, by the accredited and appropriately qualified bridge inspector. Refer to Section 6 of this paper for the requirements for inspectors.

Figure 1. Collapsed Pedestrian Bridge into highway

SANRAL appointed independent consultants who were on site within 3 hrs of the collapse to investigate and report on the cause of the collapse. The report indicated that the collapse was caused by an 8.1 ton roll of steel that was not secured to a truck coming off and impacting the pier at about 90km/hr. Statistically the accident was an extremely rare event. The point of including this incident in this paper is that the bridge had been inspected. This helped in answering media questions and parliamentary questions. Regular bridge inspections are important.

4 THE DEFECTS BASED SYSTEM KNOWN AS THE DER SYSTEM

As mentioned previously the system used by SANRAL is a defects based system or DER system.

DER refers to the degree; extent and relevancy of a defect as described below:

D = Degree of defect: How bad or severe the defect is
E = Extent of defect: How widespread is the defect on the inspection item being inspected
R = Relevancy of defect: The consequence of the defect with regards to the structural/functional integrity of the inspection item or the safety of the user of the structure.
U= Urgency of repair item

The worst defect per element is rated for the Degree (D), Extent (E) and Relevancy (R) (to the bridge element in question). The ratings are done for each sub-item and only the worst defect on the inspection sub-item is rated. Only defects are rated as to their effect on the element under consideration. The importance of the element with the defect in relation to the structural integrity is taken into account by applying weighting factors which range from 0 to 5, for example guardrails have a weighting of 0 and abutments have a weighting of 5.

The DER rating system is essentially a four-point rating system on a scale of 0 to 4 as shown in Table 1 below:

Table 1. Valid DER values.

Rating	D (Degree)	E (Extent)	R (Relevancy)	
X	Not applicable			
U	Unable to inspect			
0	No visible defects			
1	Minor	Local	Minimum	No structural integrity or safety issues
2	Moderate	More than local	Moderate	Some possible structural integrity or safety issues
3	Warning	Less than general	Major	Structural integrity or safety compromised
4	Severe	General	Critical	Potentially a serious impact on structural integrity and/or user safety

The Relevancy (R) rating is critical and it is important that the inspector understands the effect of a defect on the member in question. Inspectors also indicate the Urgency (U) of the repair needed. The Urgency ratings are shown in Table 2 below.

Table 2. Urgency values

U - URGENCY					
Record	Monitor	Routine	< 10 yrs	< 5 yrs	ASAP
R	0	1	2	3	4

There are defects that will never be repaired and are thus marked as R (record purposes only). If defects need monitoring then U=0. U=1 (Routine) means that the repairs are routine such as replacement of damaged guardrails.

Figure 2 below shows a sample photo from an inspection defects report of a bridge with a vertical crack in the abutment. The rating for this defect is a follows:

D = 4; E = 2; R = 4 and U=4 (ASAP)

Figure 2. Vertical crack in abutment wall

This bridge was on the priority list but because there were two authorities involved agreement as to who will pay for the repair is ongoing. The procurement process to appoint a contractor is underway at the time of writing this paper.

In a one year period the crack has widened further as can be seen in Figure 3 below but the rating remains as D=4 E=2 and R=4. The urgency remains U=4. Fortunately the wall is far enough from the railway line not to endanger trains if it totally collapses. The road above will be affected but not catastrophically. The bridge is being continuously monitored by the SANRAL routine maintenance contractor whilst a contractor is being procured to repair the wall. The bridge will be widened at the same time.

Figure 3. Vertical crack widened further after one year.

5 THE INSPECTION PROCEDURE

The DER rating system is characterized by a simple inspection procedure which consists of:

a) A practical visual inspection of the following twenty-one (21) standard bridge items as shown in Tables 3. For major culverts fourteen (14) items are inspected and are as shown in Table 4.

Table 3. Standard bridge inspection items and their weight

Inspection Item	Weight
01. Approach Embankment	2
02. Guardrail	0
03. Waterway	2
04. Approach Embankment Protection Works	2
05. Abutment Foundations	5
06. Abutments	5
07. Wing/ Retaining Walls	4
08. Surfacing	1
09. Super-structure Drainage	1
10. Kerbs / Sidewalks	1
11. Parapet	3
12. Pier Protection Works	1
13. Pier Foundations	5
14. Piers & Columns	5
15. Bearings	3
16. Support Drainage	1
17. Expansion Joints	2
18. Longitudinal Members	5
19. Transverse Members	3
20. Decks & Slabs	5
21. Miscellaneous Items	0

Table 4 Standard major culvert inspection items and their weight

Inspection Item	Weight
01. Apron slab & cut off walls	3
02. Wing/retaining/head walls	4
03. Scour protection works	3
04. Embankment/s	2
05. Waterway	5
06. Road slabs	3
07. Roadway joints	1
08. Guardrails	1
09. Parapets/handrails	3
10. Walls	5
11. Top slab	5
12. Invert slab/foundations	5
13. Cell deformation	5
14. Miscellaneous items	0

b) A single bridge inspection sheet is used and one defects photo's sheet. All photos are geotagged.
c) Estimated quantities of the repair work for each defect are estimated during the inspection. Each of the repair activities has a unit rate that is used in the budget module to determine an estimated budget for the repair of the structure.
d) The urgency of each repair item is also recorded including the time limits. The BSMS can separate out what is termed routine road maintenance (RRM) repair items (U=1) that do not require specialists' knowledge, such as grass cutting or guardrail repair. If U=1 for a repair item it is allocated to RRM section for repair.
e) If an item is marked as Routine (R), it is reported as for record purposes only and will not be repaired.
f) If any defect poses an immediate danger to the public the inspector is required to rate the defect as "Make Safe" and to notify SANRAL to address the defect immediately.

For the larger bridges, the inspection of decks and bearings is done using an Under Bridge Inspection Unit (UBIU) to enable inspectors to get close to items. Figure 4 shows the use of the UBIU during inspections.

The use of drones has been investigated but their use has some disadvantages. If for instance videos are taken of all bearings and other elements these videos still need to be viewed by inspectors who are qualified engineers. This will take an inordinate amount of time. In addition, the drone operators must be licenced by the civil aviation authorities. Awkward locations are also not able to be inspected using drones.

Thus presently SANRAL presently does not make use of drones for inspection but acknowledges that their use has certain advantages. The big disadvantage in South Africa is that drones are presently not allowed to be operated over roads.

Figure 4. Under bridge inspection unit used for inspection

6 THE CLASSIFICATION OF BRIDGES AND MAJOR CULVERTS

A bridge is classified as a structure with a span equal to or greater than 6 m, or a total length of 20 m or more or an opening of 36 m^2 or greater. A major culvert is classified as a structure with dimensions less than those defining a bridge but with clear span (as measured horizontally at the soffit perpendicular to the faces of its supports) length equal to or larger than 2.1 m, or diameter equal to or larger than 2.1 m, or total cross-sectional opening area equal to or larger than 5 m^2. Another structure type called a cellular bridge has also been introduced. This is a structure that classifies as a bridge based on its dimensions but looks like a culvert in that is it has the typical features of a major culvert and is inspected as such. All service culverts (including all agricultural lined irrigation canals) are classified as major culverts regardless of size except if they fall within the bridge classification. The maintenance of lesser culverts falls under road maintenance contract and does not presently form part of the BSMS priority list. This may change in the future.

7 TRAINING AND QUALIFICATION OF INSPECTORS

Principal inspections play a vital role in the BSMS and are carried out by inspectors that are suitably qualified and experienced in bridge design and rehabilitation. Bridge inspectors must have a minimum of 5 years relevant bridge design experience for engineers or minimum of 10 years relevant bridge design experience for technologists. They must be registered as professional engineers or technologists in South Africa.

For culvert inspectors, the only requirement is that they shall have a diploma or degree with a minimum

of 5 years relative experience. Verification inspections and strategic bridges inspections are conducted by senior bridge inspector who must be Professional Engineers with a minimum of 15 years full time bridge design experience and have made bridges as their full-time career. For large strategic bridges a under bridge inspection unit is used obtain better access as shown in Figure 4.

In addition to the above experience and qualification an inspector must have attended a two day Technical Methods for Highways (TMH) 19 DER Methodology course in bridge and culvert inspections accredited by the Committee of Transport Officials (COTO) Structures Subcommittee. Case studies are presented by experienced engineers to give examples of the rating of defects and the lessons learnt from previous inspections as to when inspectors got ratings wrong or correct. Emphasis is placed on the actual design experience of inspectors so they can correctly interpret defects and their relevancy in the field. Thus it is impossible to use lower qualified persons to do inspections unless a more rigorous course lasting months is done. This approach although used in other countries has not be adopted in South Africa.

In order to be accredited as COTO certified inspectors, applicants must pass the exam written at the end of the training workshop. Slide presentations and lectures are presented on the first day and a practical bridge inspection field trip is undertaken on the second day as shown in Figure 5.

Figure 5: Course attendants at the practical bridge inspection field trip.

8 BRIDGE MANAGEMENT SYSTEM AS PART OF THE INTEGRATED TRANSPORT INFORMATION SYSTEM (ITIS)

The bridge and structures management system (BSMS) is one component of SANRAL's Integrated Transport Information System (ITIS) for the management of its assets and information. The BSMS contains of inventory and location information on the approximately 10000 different structures types that form part of the national road network, these include major culverts, lesser culverts, service culverts, bridges, tunnels, retaining walls and sign gantries.

The BSMS is used for the analysis of structures data to identify out of a large number of structures, a single serious degree (D=4) of defect that has high relevancy (R=4) on one element that can cause failure of a structure. For example, if a single beam of a bridge deck is severely damaged but all the other beams are undamaged, then it must be this beam that is used in the prioritization model.

Network level principal inspections are conducted every five years on the bridges and major culverts. This provides network-based results which allows for undertaking of repairs of individual bridges based on the results of the whole bridge network. At a network level, the bridges with the highest risk will be identified and appear at the top of the priority list. SANRAL uses the priority list generated, bridges and other structures are grouped into projects which could be done by a single contractor. Single outlier bridges or structures in need of repair are put out as single projects if they are large enough otherwise they are combined into road rehabilitation or upgrade projects in the area.

9 IMPLEMENTATION OF THE BRIDGE INSPECTION PROGRAMME

The bridges on the network are split into inspection packages based on their location and route description. Packages are created in BSMS which is on the Integrated Transport Information System (ITIS) web portal. On the BSMS, inspectors have access to the previous inventory and photo reports but not the previous inspection reports. Blank inspection reports are available for download for use during the field inspection. The work carried out by the inspector during the inspection programme comprises of following:

a) Compilation of previous inventory sheets and blank inspection report;
b) Field inspections;

c) Input of the inventory and inspection data (including geotagged photographs) into the computer using specially programmed ITIS software.

Inspectors are issued with the TMH 19 Manual for the visual assessment of road structures and are assigned rights to access the bridges and submit inspection and inventory data to SANRAL using the ITIS software. The inspection information is first approved by SANRAL before it is published to the BSMS.

10 CALCULATION OF OCI SCORE USING DER RATING SYSTEM

Once inspections have been properly captured and approved the overall condition index (OCI) for each structure is calculated using the values of DER rating system. This is a multi-level method applied to first to inspection sub-items (1) and then inspections items (2) to calculate the total structure deduct points.

The deduct points for the inspection sub-items is calculated using Equation 1 below:

$$dp_{ij} = DP_{max} \times \frac{(D+0.25E)\times R^{1.5}}{40} \quad (1)$$

where D, E and R are the degree, extent and relevancy ratings for inspections sub-item j of item i respectively and DP_{max} is the maximum deduct points for inspection sub-item. The agreed value for DP_{max} is 65, resulting in the worst OCI score of 9. Previously the agreed DP_{max} value was 75 but this resulted in structures with negative or zero OCI scores. As such when the OCI score was applied to the structure asset value, structures with negative or zero OCI scores had a negative or zero asset value which cannot be the case.

The inspection sub-item with the highest deduct point is used to calculate the deduct points for the inspection item as shown in Equation 2 below:

$$DP_i = \frac{w_i}{w_{max}} \times dp_{imax} \quad (2)$$

where DP_i is the calculated deduct points for inspection item i; w_i is the weight for inspection item i; w_{max} is the highest weight for the inspection items making up the structure up and dp_{imax} is the highest deduct points calculated for any inspection sub-item j making up inspection item i. For example the inspection Item 13 – 'pier foundations' for a three span bridge will have two inspection sub-items for the two pier foundations.

The five inspection items with the highest deduct point are used to calculate the deduct points (DPs) for the structure as shown in Equation 3 below:

$$DP_S = DP_{i1} + 0.3DP_{i2} + 0.1DP_{i3} + 0.05DP_{i4} + 0.05DP_{i5} \quad (3)$$

where DP_{ij} is the deduct points for the inspection item such that DP_{i1} is the primary inspection item with the highest deduct point and DP_{i5} is the inspection item with the fifth highest deduct point. The contribution to the total deduct point of a structure from the five highest inspection items is based on the similar deduct method applied in pavement management where the primary, secondary, tertiary and additional inspection items contribute 100%, 30%, 10% and 5% respectively.

The overall condition index for the structure is calculated using Equation 4 below:

$$OCI = 100 - DP_S \quad (4)$$

OCI ratings can range from 9 (worst condition) to 100 (best condition) with a structure falling into one of the five condition categories described Table 4 below.

Table 5. Condition and functional categories

Condition Category	Index Range	Condition Category Description	Functional Category Description	Colour Code
Very Good	85 - 100	Asset is still like new and no problems are expected.	Good service levels at all times	Blue
Good	70 – 85	Asset is still in a condition that only requires routine maintenance to retain its condition.	Mostly good service levels with isolated problems occurring at certain times.	Green
Fair	50 – 70	Some clearly evident deterioration and would benefit from preventative maintenance or requires renewal of isolated areas.	Reasonable service but with intermittent poor service.	Orange
Poor	30 – 50	Asset needs significant renewal or rehabilitation to improve its structural integrity	Generally poor service levels with occasional very poor service being provided.	Red
Critical	9 - 30	Asset is in imminent danger of structural failure and requires substantial renewal or upgrading with less than 10% of EUL remaining.	Very poor service levels at most times.	Purple

The previous system used to calculate the OCI score resulted in structures in a poor condition falling in the 50 -75% condition category. However, when it came to allocating funds for projects, the accountants did not understand why structures with an OCI score greater than 50% were considered to be in poor condition and in need of repair.

The condition and functional categories shown in Table 5 are based on the DER system and are in line with the ones applied to the pavement management systems. These categories allow for structures in a poor and critical condition (less than 50%) to be easily identifiable by all and included in the priority list of bridge repair projects. Based on the inspection and

inventory information, the system generates live reports and dashboards containing:

a) Detailed Inventory and Inspection reports
b) Inventory and defects photo reports
c) Priority Index for all structures
d) Routine maintenance activities for each structure

The figures below show some of the dashboards output generated by the BSMS:

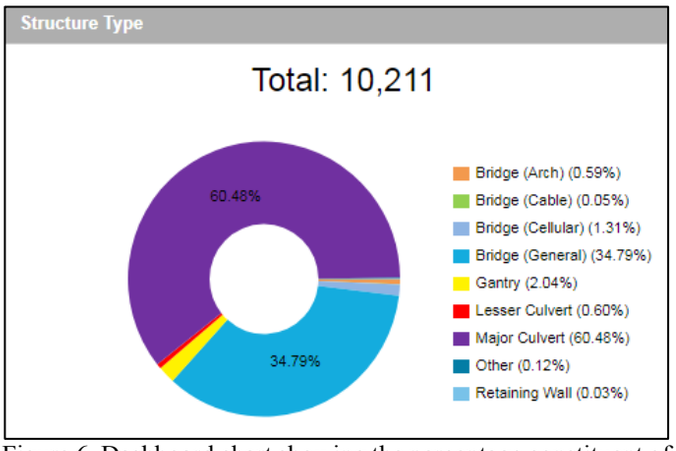

Figure 6. Dashboard chart showing the percentage constituent of the different structure types

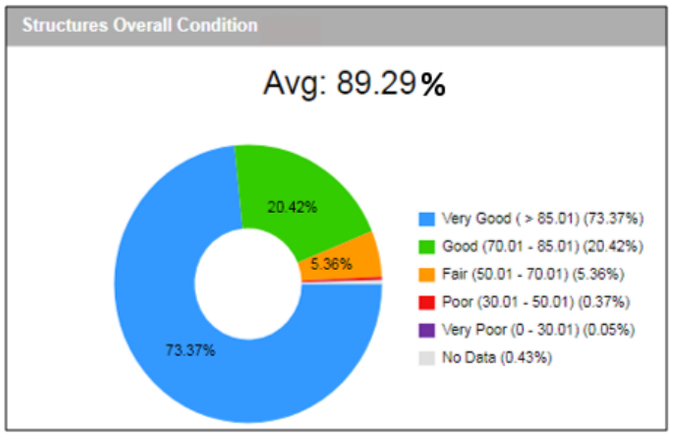

Figure 7. Dashboard chart showing the percentage of bridges in the different condition categories

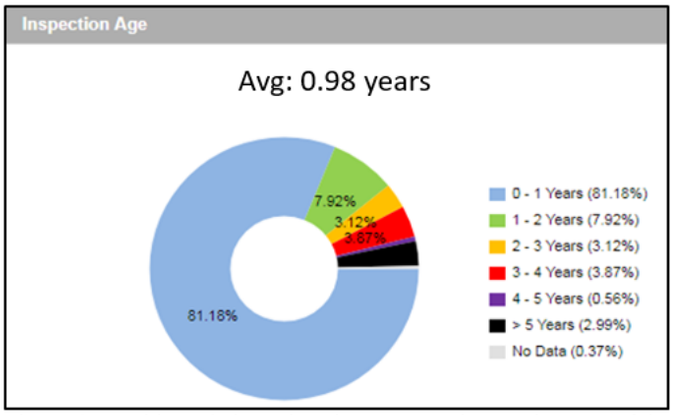

Figure 8. Dashboard chart showing average inspection age of the bridges of less than a year.

11 THE BRIDGE ASSET VALUE CALCULATION

The asset value of bridges is determined by calculating the depreciated replacement cost of the structure that is based on the Overall Condition Index of a bridge.

Firstly, the Gross Replacement Cost (GRC) for each bridge (this is the cost of the bridge if built new) is calculated using Equation 5 below:

$$\text{GRC} = \text{Deck Area} * \text{Mat. Unit Rate} * \text{Adj. factor} \quad (5)$$

The Material Unit Rate (this is the rate per m^2 of deck area) is recalculated each year using the average of 3 standard sample bridges that are given to an experienced contractor quantity surveyor to price. The same 3 bridges are used each year. This is also compared to recent construction projects and the rate per m^2 of deck area.

For structures with a pier or abutment height of less than 8m the unit rate per m^2 value is kept constant. This accounts for approximately 90% of all bridges. For bridge with abutments or piers greater than 8m high the unit rate adjustment shown in Equation 6 below:

$$\text{Material Unit Rate} = A + B * \max[0, (C - 8)^{0.6}] \quad (6)$$

where A is the base unit rate (for bridges with piers or abutments up to 8m high), B is the pier height adjustment rate and C is the maximum pier height on the bridge.

A perpetual life is assumed for bridges and the depreciation is related to bridges OCI score with the Depreciated Replacement Cost (DRC) for bridge calculated using Equation 7 below:

$$\text{DRC} = \text{GRC Bridge} * (\text{OCI}/100) \quad (7)$$

If a bridge is repaired and rehabilitated then the Depreciated Replacement Cost (DRC) will increase. Any change in the bridge deck area due to bridge widening or lengthening will obviously increase the replacement cost of the structure. The formula avoids the detailed depreciation of individual elements of a bridge such as joints, bearings, piles etc. It is the view of the authors that more complex valuations should be avoided so as not to overly complicate the calculation of asset values. The method used by SANRAL is realistic and has yielded good results.

After repairs or work is done on bridges fresh inspections are required by the consulting engineers so as to keep the data current. This updating of data although important has in the past been neglected and

penalties on consultant fees have had to be introduced to force compliance.

12 CONCLUSION

The BSMS is an invaluable tool in assisting SANRAL to carry its mandate which is to manage and control the national road network infrastructure. The inspection procedure is simple and effective as it only focuses on defects, thus elements in good condition are not rated reducing the data capture time required. The defects based deduct point system has led to a better allocation of bridge repair projects and a more appropriate allocation of funds for bridge repair projects. The system is able to streamline the function of the RRM as defects that do not require specialists' attention are allocated RRM.

The Optimal Maintenance Strategy of Bridge using Bayesian Approach

Jin Hyuk Lee, Kyung Yong Lee, Sang Mi Ahn & Jung Sik Kong
School of Civil, Environmental and Architectural Engineering, Korea University, Seoul, Korea

ABSTRACT: For the efficient life-cycle maintenance of bridge, prediction of future bridge performance based on the current performance must be required and it is possible more rational decision-making through the higher accuracy of the prediction model of bridge deterioration.

In other words, predicting a performance of bridges is important to reduce the costs of maintenance, repair, rehabilitation and replacement of bridges. To establish the optimal maintenance strategy and planning, there are needs to consider bridge performance history and prediction of maintenance time. In this study, performance models of bridges are developed on the basis of condition index of the bridges by a statistical and probabilistic method. The condition index(or grade) resulted from visual inspection and are associated with bridge damage. (corrosion, fatigue, crack, water leak, scaling, etc.) Factors causing these defects are considered in bridge element performance model. Also, the predicted performance includes a lot of uncertain factors because the condition index of bridge elements were observed by person. So, when inspector determine the bridge condition index(or grade), it is essential to perform In-depth inspection and monitoring using device.

While performing a detailed inspection of all parts of a bridge and/or assigning an experienced inspector have reduced a significant part of errors contained in the prediction model, such personnel-based existing maintenance may result in enormous maintenance costs since it is difficult for a bridge administrator to estimate the bridge performance exactly at a targeting management level, thereby disrupting a rational decision making for bridge maintenance.

In this study, to solve this problem, a Bayesian updating method which is related to updating prior information of bridge deterioration is used to the optimal maintenance strategy in Bridge Management System(BMS) considering the uncertainty of inspection data. Also, examples of application are presented, showing the effects of inspection and updating on domestic(Korea) bridge maintenance strategies.

That is, we propose a bridge maintenance scenario model based on Bayesian updating and discuss the uncertainty of inspection data obtained from a bridge. The main purpose of this research is to verify advantages of the Bayesian-updating-driven preventive maintenance in terms of the cost efficiency in contrast to the conventional periodic maintenance.

1 INSTRUCTIONS

Predicting a performance of bridges is important to reduce the costs of maintenance, repair, rehabilitation and replacement of bridges. To establish the optimal maintenance strategy and planning, there are needs to consider bridge performance history and prediction of maintenance time.

In bridge maintenance, the method having been used broadly is inspection, but it is not free from uncertainty and error. Also, most people just know intuitively that doing accurate prediction of performance by inspecting status of structure.

This study is done in order to certify that predicting performance by updating data gained from inspection of bridge using Bayesian method.

The main purpose of this study is to verify, that updating performance model related to optimal repair and rehabilitation cost have sufficient advantages in an aspect of bridge maintenance.

2 UPDATING EXISTING PERFOMANCE MODEL USING BAYESIAN APPROACH

2.1 *Development of element life cycle performance model*

To develop element performance models of the bridges, a multiple regression analysis is carried out

on the basis of a database of condition indices and influence factors making the structures deteriorated. A detail procedure is shown in Figure 1. The multiple regression analysis is a statistical process for estimating relationships between a dependent variable and one or more independent variables.
Prior to the multiple regression analysis, deteriorating rates for each element of the bridges according to changing time were calculated by univariate regression analysis. The deteriorating rates are considered by a dependent variable in the multiple regression analysis. A length of the bridge, traffic volume, amount of surface chloride and humidity are regarded as independent variables.

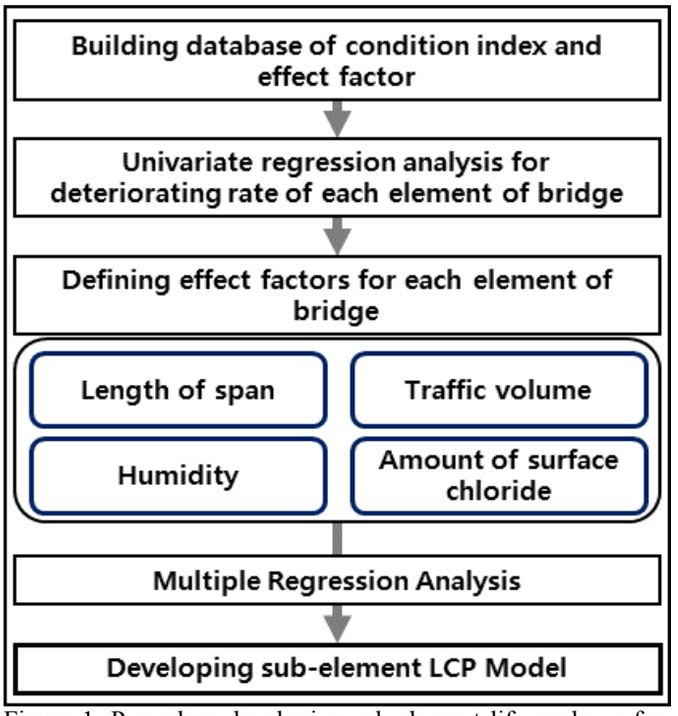

Figure 1. Procedure developing sub-element life cycle performance model

Additionally, these independent variables have correlation between them.
In consideration of the correlation terms, the deteriorating model equation is defined as Equation 1 below:

$$y = a_0 + a_1x_1 + a_2x_2 + a_3x_3 + a_4x_4 + a_5x_1x_2 + a_6x_1x_3 + a_7x_1x_4 + a_8x_2x_3 + a_9x_2x_4 + a_{10}x_3x_4 \quad (1)$$

Where y is life-cycle performance model and it means deteriorating rate proposed by the multiple regression analysis, a_0 is constant, a_1~a_{10} are coefficients about the independent variables, x_1 is the length of the bridge, x_2 is the traffic volume, x_3 is the amount of surface chloride and x_4 is the humidity.

2.2 *Updating models using Bayesian probability theory*

Predicting performance through LCP models that are suggested based on statistical method needs to be updated by applying monitoring data in order to improve prediction accuracy. New monitoring information obtained by inspection can often include errors and uncertainty as to the quality of the inspection, experience of the inspectors, and environmental conditions during inspection. To reduce uncertainty in the information, an update method was utilized based on the Bayes' theorem as proposed by Frangopol et al. (2008). Bayes' theorem is to estimate the posterior when given the prior and likelihood function. In this study, the new information measured by the inspector is regarded as likelihood function that can be approximated by a normal distribution with mean and standard deviation. At the time of the inspection, the developed performance model of the structures is considered prior information. As a result, the posterior becomes information updating the models. The procedure of updating deterioration model based on Bayes' theorem is shown in Figure 2.

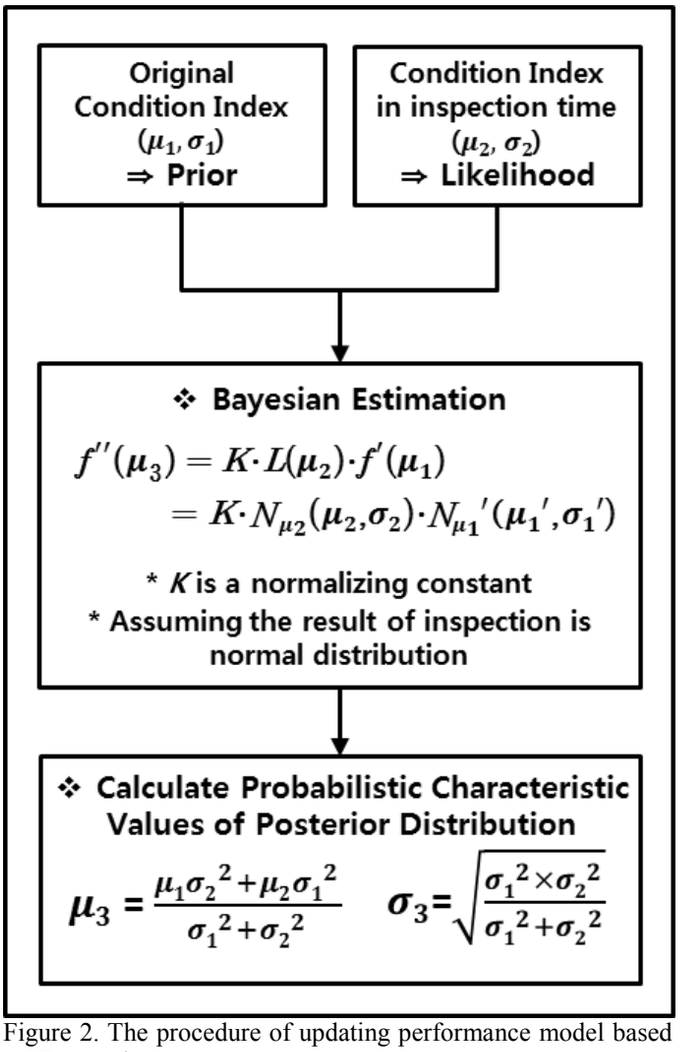

Figure 2. The procedure of updating performance model based on Bayes' theorem

Through Figure 2., μ_1, σ_1 can be defined in probabilistic characteristic values of prior, which means original condition information. And μ_2, σ_2 can be defined in likelihood information when inspection is

applied in particular time. After updating in monitoring time, the existing performance model is updated by Bayes' theorem.

It is important to observe that the posterior variance of μ, as given by σ_2 in Figure 2., is always less than σ_1^2 or σ_2^2; that is, the variance of the posterior distribution is always less than that of the prior distribution or of the likelihood function (Ang, A., W. Tang., 2007). And procedure of verification can be seen in Figure 3.

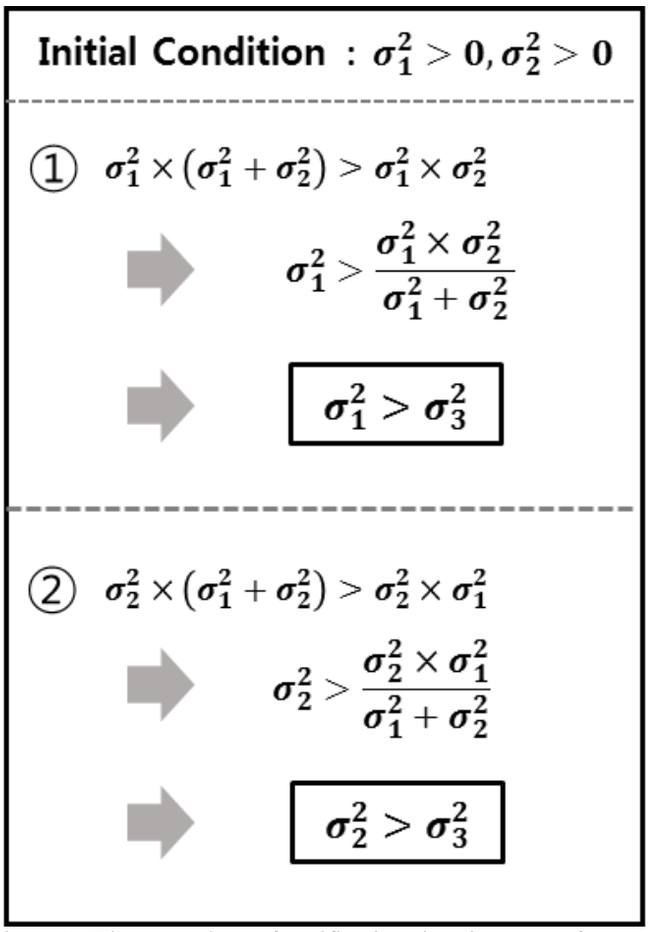

Figure 3. The procedure of verification that decrease of uncertainty of updating performance model based on Bayes' theorem

3 VALIDATION OF BAYESIAN UPDATING SCENARIO

3.1 *Application to domestic bridge element*

Consider the fatigue crack monitoring technology of the youngjong grand bridge steel girder. And target bridge element information is indicated in Table 1.

Table 1. Analysis condition of target bridge element.

Division	Quantity
Span length	300m(6@50)
Width	2m(Two Lane)
Area	600㎡
Discount rate(q)	3%

In Figure 4, performance model of a steel girder are shown. the y-axis means condition index and x axis means service life (years). Also, full line is mean(μ_1) slope of steel girder, dotted line is standard deviation(σ_1) slope.

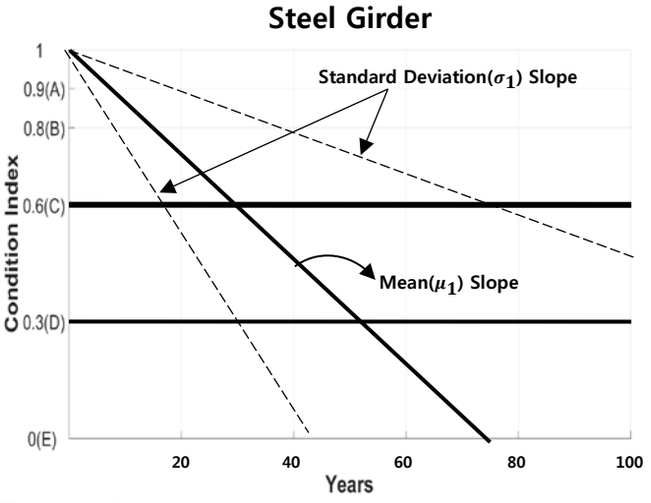

Figure 4. Condition index model for steel girder.

In Figure 5, d ecreased standard deviation slope of steel girder after inspection time is shown.

According to quality of the new information obtained by the inspection, quality of the updated models is different. For instance, in Table 2. case1~4 are set depending on variability of inspection accuracy. In the case of performance model of steel girder, the prior's mean is 0.709 and standard deviation is 0.188. Based on Baye's theorem, the updated model is calculated in the Table 2. After updating the models, the posterior's standard deviations are smaller than the prior. It means that updating models through reflecting the result of the inspection can reduce the uncertainty that is included in the performance model.

Table 2. Case study according to the quality of the inspection's result.

Case	Prior		Likelihood		Posterior	
	Mean	Std. Dev.	Mean	Std. Dev.	Mean	Std. Dev.
Case1	0.871	0.188	0.871	0.05	0.871	0.048
Case2	0.871	0.188	0.871	0.1	0.871	0.088
Case3	0.871	0.188	0.871	0.15	0.871	0.117
Case4	0.871	0.188	0.871	0.2	0.871	0.137
Case5	0.871	0.188	0.915(5%↑)	0.05	0.912	0.048
Case6	0.871	0.188	0.827(5%↓)	0.05	0.830	0.048
Case7	0.871	0.188	0.915(5%↑)	0.2	0.892	0.137
Case8	0.871	0.188	0.827(5%↓)	0.2	0.850	0.137

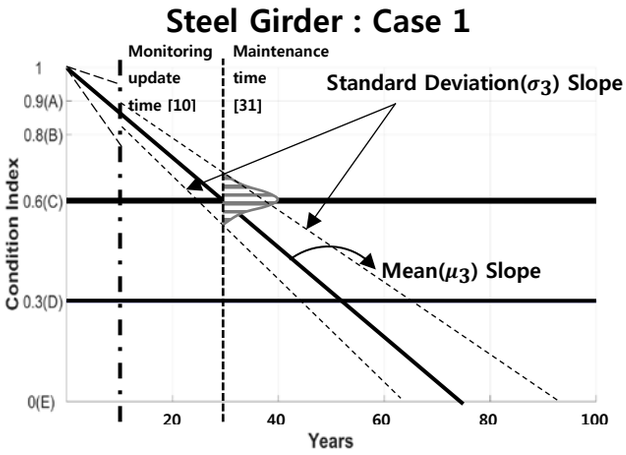

Figure 5. Condition index model for steel girder based on Bayesian(monitoring) updating at 10years

Also, for comparing the posterior by Case, a total maintenance cost is calculated. The total maintenance cost equation in this study is defined as equation 2 below:

$$C_{MAI}^{Total}(t) = \sum_{t=1}^{T} \frac{1}{(1+q)^t}\{C_{INS}^{rins}(t) + C_{INS}^{pins}(t) + C_{INS}^{psdia}(t)\} + \frac{1}{(1+q)^t} \times C_{MAI}^{C-grade}(t) \times P_{MAI}^{C-grade}(t) \quad (2)$$

Where $C_{MAI}^{Total}(t)$ is the total maintenance cost at time t, q is discount rate, $C_{INS}^{rins}(t)$ is regular inspection cost at time t, $C_{INS}^{pins}(t)$ is precise inspection cost at time t, $C_{INS}^{psdia}(t)$ is precise safety diagnosis cost at time t, $C_{MAI}^{C-grade}(t)$ is maintenance cost distribution when mean(μ_1) slope reaches C grade, and $P_{MAI}^{C-grade}(t)$ is probability distribution of maintenance when mean(μ_1) slope reaches C grade. The steel girder cost of maintenance function (In this case only) is shown in Figure 6.

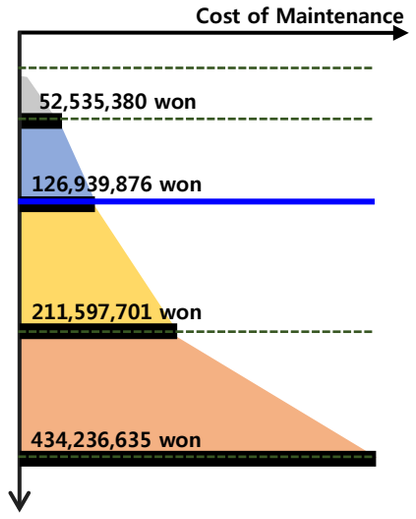

Figure 6. The steel girder cost of maintenance function.

Such as above information, it is possible to calculate each maintenance cost at time t (31years) by case.

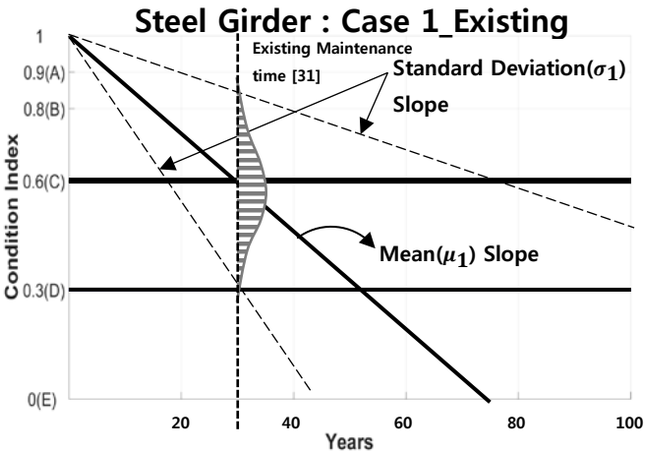

Figure 7. Existing condition index model for steel girder

And compare to existing case $C_{MAI,existing}^{Total}(31)$ (Figure 7.), it is possible to predict about 15% cost savings in case 1.

Through cost analysis by case, it shows that the more quality of the inspection is good, the more cost efficiency of the total maintenance is higher.

That is, by reducing the uncertainty of probability distribution at specific time(t) through Bayesian updating, matching cost of maintenance areas are decreased.

4 CONCLUSION

This study propose the methods of updating existing LCP models of the bridge elements by using the result of the inspection. In reliability analysis and cost efficiency of inspection, if condition is poor compared with the initial predicted condition, the probability of failure is increased as a result cost of failure is increased. Even though the result about condition from bridge inspection is presented worse than prediction, the execution of bridge inspection should be done because the supervisor can estimate the bridge condition and sets maintenance scenario for safety of bridge until the target bridge life. If researchers can use the real damage detection data and errors of inspection method, these result would be more reasonable and powerful.

In further study, considering the optimal maintenance algorithm would be updated for helping decision-making.

Development and implementation of digital bridge management systems in the Gulf region

D.E. Moore
Qatar Country Manager, Aurecon
S. Naelini
Managing Director, AMX Solutions

ABSTRACT: The dramatic expansion of road and rail infrastructure in the Gulf region serves as a barometer for the rapid economic growth that has taken place in the region since 2006. Until 1999, there were approximately 40 operational bridges in the Emirate of Dubai and since then more than 400 new bridges have been constructed and brought into service. Similar stories can be told for Abu Dhabi and Qatar. Although few in number, aging road infrastructure also needs to be maintained, such as the Shindagha Tunnel (ca. 1975) and Maktoum Bridge (ca. 1963) in Dubai, which serve as critical transportation links in the community. This paper describes the modules of the bridge management systems developed for these Gulf states, including the inspection rating system and calculations for estimating asset condition and prioritizing repairs. We touch upon the lessons learnt in developing systems, future developments and the need for bridge management systems to be adaptable in order to remain relevant to business operations and asset managers.

1 INTRODUCTION

1.1 *The need for a digital BMS*

Over the last two decades, cities in the Gulf region have experienced a construction boom in buildings, aviation and transportation infrastructure. Up until 1999 there were approximately 40 operational bridges in the Emirate of Dubai and since then more than 400 road bridges have been built and opened. Similarly in Qatar, there are currently 200 operational bridges, with future expansion set to provide more than 1000 bridges over the next 5 years.

Due to the rapid expansion in physical infrastructure and improvements in technology, government authorities in the Gulf are increasingly looking for ways to create efficiencies in managing maintenance activities, integrate bridge maintenance with other enterprise systems, and maximize the value of maintenance spending.

Traditional, paper-based methods of maintaining infrastructure are no longer viable. Governments now expect digital tools which leverage information and communication technology (ICT) and which are aligned with the country's digital strategy for economic improvement (Qatar General Secretariat of Development Planning. 2011). An integrated digital asset management system is an asset management tool which will help to meet these objectives.

1.2 *Diversity of Structures*

Road structures and assets in the Gulf region are extremely varied and therefore any asset management solution needs to be highly flexible and adaptable.

A single asset management solution is needed to manage a variety of structure types for different government departments. Typical road assets in the Gulf region include concrete and steel bridges, bascule bridges, cable stay bridges, floating concrete pontoon bridges, a variety of footbridge types, long tunnels and underpasses, and camel crossings. Other structure types include wharf structures, pump stations, fountains, as well as street furniture and lighting.

The maintenance of electromechanical systems for transportation assets also needs to be addressed in a single asset management system.

Since electromechanical systems are inspected and maintained differently to structural systems, this can be challenging to implement in one BMS.

1.3 *Regional considerations*

Another point to note in the development of asset management systems in the Gulf is that structures in the region typically have to contend with severe exposure conditions. Summer in the Gulf is extremely hot and humid, with temperatures reaching 45 degrees C and a humidity of 90%. Ground investigations have also found that the soil is comprised almost

entirely of crushed shells and sea coral, making the groundwater highly saline and the concentrations of chlorides and sulfates extremely high (Sherif, 2011).
The extreme environmental conditions in which road assets are constructed means that design standards and details are often different to those used in Europe and other parts of the world. Concrete structures are designed to have very small crack widths to help prevent carbonation and ingress of chloride ions. This often means that steel reinforcement quantities in concrete structures are higher, with an increased concrete cover to reinforcement. Exposed concrete surfaces are also often coated with multi-part coating systems which are designed to help prevent ingress of carbons and chlorides through the concrete surface.
For the inspector, a coating on the exposed concrete surface makes it difficult to interpret the true condition of the concrete underneath. In addition, the inspector needs to be familiar with the Gulf design standards and the impact this may have on interpreting the defects which have been identified. The BMS also needs to be customized in consideration of the design and construction methodologies in the Gulf, to take account of the repair methods and procedures used by local authorities and contractors.

2 SYSTEM MODULES

2.1 *Internal integration*

For a BMS to function efficiently, system modules need to be integrated internally to minimize duplication and user inputs, and to achieve optimal performance in line with effective operational asset management.
The inventory module is considered to be the foundation off which the rest of the BMS operates. Inventory contains data on the elements of the asset, which is effectively a digital version of the physical asset. The inventory drives the rest of the BMS modules.
The inspection module is derived from the inventory module. The digital elements of the asset are pushed into the inspection module to form the basis of the inspection sheet. Inspection ratings are allocated to asset elements and sub-elements. The inspection rating procedure and methodology need to be robust and relevant to scoring of defects assigned to the asset sub-elements, in order to calculate structural condition and prioritize the repair of defects.
System calculations need to be tailored to be relevant to the business enterprise, which will calculate condition and prioritize repairs in accordance with business requirements.
Cost of works need to be estimated based on enterprise rates, or bill of quantities, so that estimated costs are relevant to the government authority implementing the BMS.
Finally, the rating and condition of sub-elements, defects and cost of repairs, all need to be linked back to the inventory module for a complete integration.
The following sections describe the system modules in detail.

2.2 *System dashboard*

It is important that the BMS has a customizable dashboard displaying summary information for the user, and to provide quick links to relevant modules. The dashboard should display information such as the last structure accessed by the user, including Structural Condition Index (SCI), lists of structure types, GIS map information and quick-access links to reports, charts and filters.
From the dashboard the user should be able to quickly find relevant information for his daily work and access other modules.
The dashboard display and content should be user role based to streamline operational requirements and system navigation.

2.3 *Inventory Module*

Establishment of the inventory database is crucial for integration with all other BMS modules, and forms the foundation off which the other modules operate. The inventory framework drives the inspection elements, the condition calculations, the prioritization of structures and ultimately the works management.
The inventory module is structured to contain the asset types applicable to the government authority, such as bridges, tunnels, underpasses, footbridges, etc. At this point, the user needs to map elements and sub-elements for each of the asset types, similar to the way an asset would be categorized in a BIM (Building Information Model).
The inventory module also captures details such as general photographs, location information, contact information, ancillary elements and electromechanical equipment related to the asset.
The elements and sub-elements contained in the inventory module brought into the inspection module, which effectively creates a unique inspection form for each individual structure, and stays with that structure until alterations warrant a new or modified element or sub-element mapping. A typical breakdown of elements and sub-elements is shown in Table 1.
The BMS contains a standard list of sub-elements per element, according to the unique structure type, which automates the input of the structure sub-elements. If a sub-element is not relevant to a particular structure, then a quantity of zero is allocated or not included.

Table 1. Examples elements and sub-elements for a typical bridge structure.

Location	Element	Sub-element
Approach	North approach	Embankment
		Retaining walls
		Road surface
Superstructure	Span 1	Deck
		Girders / Beams
		Traffic barriers
Substructure	North abutment	Front wall
		Bearing seat
		Bearings
		Expansion joint

Sub-elements are measured to correlate with the inspections methodology, which is generally in m^2 for exposed surface areas, linear meters for expansion joints and a unit count for items such as bearings.

2.4 *Inspection Module*

Past or future inspections are scheduled in the inspection module, as a General Inspection, Principle Inspection or an Electromechanical inspection. The inspection is created in the system by the user and a unique reference number is generated by the system.
Structure elements and sub-elements are imported from the inventory module. Sub-elements are rated by the inspector according to the DERU (Degree, Extent, Relevancy and Urgency) scoring methodology, which is described in detail in the next section.
Defect ratings are input primarily through the inspection summary screen, which is a tabulated representation of the asset sub-elements. The values of degree, extent and relevancy are entered into the table for each sub-element. A color-coding aligned with the value of relevancy (green, amber and red) gives the user a visual sense of the overall condition of the structure.
At this stage the inspector also inputs the description of the defect, along with photographs and an estimation of the urgency (maximum timeframe) to repair the defect. The work required to repair the defect back to "as-new" condition is also estimated at this stage by the inspector, via a Bill of Quantities in the system library.

2.5 *Works management*

In the BMS, 'works' refers to identified work that needs to be carried out on assets. This work is necessary in order to ensure the structures operate in a safe manner and provide the required level of service to the road network users.
Generally, works are identified during the condition inspection of structures and are primarily repair works that eliminate identified defects and restore structure elements to the original, or as-new working condition.
Works may also arise from the need to upgrade the structure, such as widening or strengthening, to provide the required level of service.
Further, works may arise from taking preventative measures to ensure longer service life of structures is achieved at low cost to the users.
In all of the above-mentioned cases, and regardless of the source, all identified works are added to the BMS 'Work Bank' either as part of the inspection data or as an individual work item added to each structure.
A comprehensive, objective and time-based prioritization process is applied to all works in the BMS, which ensures the works management team schedules maintenance works objectively and in line with corporate policies of the maintaining authority.

2.6 *Budget module*

The BMS budget module is designed to ensure budget allocation and expenditure are monitored as works are planned and performed on the assets.
In the region, it is quite common to have multiple maintenance contracts in place to carry out routine and preventative work on groups or even individual structures. Each maintenance contract needs to be budgeted and monitored and, most importantly, accommodate variations during contract period.
The budget module presents the expenditure profile of each maintenance contract across all types of works such as accidents, preventative, special requests and any other. It also manages multiple budget sources such as additional budget allocation for special events or unforeseen events such as major bridge strikes.
The budget module, while allowing each contract to be monitored and managed separately, also presents a comprehensive budgetary performance across all contracts to illustrate authority's overall performance.
Generally due to budget constraints, not all planned works are carried out as intended and while maintenance works are carried out new, and sometimes very urgent, works are identified either from inspections or even during maintenance works.
The BMS budget module accommodates unforeseen and new works and reallocates works across multiple years dynamically.

2.7 *Deterioration module and Life Cycle Costing*

Life cycle costing (LCC) utilizes deterioration models that are assigned at sub-element level. There is a library of deterioration models for materials types such as concrete or steel, and for components such bearings and expansion joints. Users can modify existing or add new deterioration models to the library as required. Each model has a number of performance strategies that are linked to service levels and trigger maintenance works.

Based on the BMS inventory and system customization, each structure type sub-element inherits a deterioration model and is analyzed for the duration of the life cycle analysis. Sub-element projected conditions are presented together with works identified during the analysis. Overall asset condition is then calculated and compared for various maintenance strategies with actual asset conditions from inspection history also superimposed.
A monitoring regime is in place to compare actual maintenance works with that predicted for each maintenance strategy from the LCC analysis. This will allow users to compare and improve the LCC analysis at asset level.

3 INSPECTION RATING PROCEDURE

3.1 *DERU Inspection Rating Procedure*

A simple yet robust inspection rating procedure, and the accurate capture of inspection information, is the foundation of a good Bridge Management System. For the Dubai BMMS the DERU (degree-extent-relevancy-urgency) procedure has been adopted. Inspection forms are created from the inventory module, which minimizes the risk of not capturing important inspection data in the field.
The DERU rating procedure is based the DER rating system (degree-extent-relevancy), as documented by de Fleuriot et al. (1995), with the later addition of urgency by Nordengen et al. (2000).
The DERU procedure forces the inspector to focus on each characteristic of the defect at a time, eliminating the need to combine defect characteristics (for example degree and relevancy) and applying one score for both characteristics. De Fleuriot (1995) considers that the DER procedure results in more precise inspection information being captured, and thereby a more accurate determination of overall condition.
The DERU is defined as:

- D refers to the Degree of severity (how bad is the defect?)
- E refers to the Extent of the defect (how common is the defect or what percentage of the sub-element is affected?)
- R refers to the Relevancy of the defect (what is the effect on structural integrity and safety of the user?)
- U refers to the Urgency to carry out the remedial work to repair the defect, measured as a time limit (when does it need to be repaired?).

The relevancy rating is considered the most important rating (Moore et al. 2011). The relevancy rating coerces the inspector to review the defect while considering the consequences of the defect concerning the safety and serviceability of the system as a whole. For example, identical defects may be present at two locations on an asset; for example, severe concrete cracking on the bridge approach retaining wall as well as to the bridge deck soffit at mid-span. While the defect may be the same the relevancy of these defects differs, while the degree and extent of the defects may be identical. A higher relevancy score forces the defect to be prioritized over defects of the same severity level.
The degree and relevancy ratings are based on a five-point system, from 0 (no defect) to 4 (most severe). Limits are defined for degree based on the relevancy rating; degree can be greater than, but never be less than the relevancy rating. It is possible to have a very severe defect which has a low relevancy to the overall integrity of the structure, however a defect with a high relevancy, which may impact structural integrity or safety to users, should not be rated as having a low degree of severity.
The extent rating takes consideration of how common the defect is on the given sub-element, and is generally expressed as a percentage of the sub-element area or unit.
The urgency rating is also a five-point rating, from 0 (routine maintenance) to 4 (should be repaired as soon as possible, within the next 12 months). The urgency rating is based on the inspector's view on the maximum timeframe of when the defect should be repaired, considering probable future events.

3.2 *System calculations*

Based on the DERU ratings provided in the inspection module, the BMS calculates the following indices:

- Structural Condition Index (SCI)
- Priority Index (PI)
- Relevancy Index (RI)

These indices are used to rank structures in different ways and we find that using a combination of indices provides the best results when prioritizing repairs to assets.

3.2.1 *Structural Condition Index (SCI)*

The structural condition index (SCI) is provides an estimation on the overall condition of the asset and is measured as a percentage. SCI is the weighted summation of the condition of all the sub-elements on a particular asset and provides an average condition for the structure.
The sub-element condition index *Icii* and is calculated for all sub-elements of the structure as follows:

$$Icii = 100 - \frac{100\left(D+\frac{E}{25}\right)R}{32} \quad (1)$$

where D = degree; R = relevancy; and E = extent.

The value of 25 is used to normalize the extent rating back to a value of 4 when $E = 100\%$, and the value of 32 is used to normalize the equation overall; i.e. $(D_{max}+E_{max})R_{max} = (4+4)4 = 32$.
The result of *Icii* is given as an integer between 0 and 100. The division condition index *Ici* is calculated as the weighted average of all sub-elements:

$$Ici = \sum_{i=0}^{n} IciiWi \,/\, \sum Wi \qquad (2)$$

where W = the weighting given to sub-elements based on perceived importance, as a five-point scale.

The structural condition index SCI is calculated as:

$$SCI = \sum_{i=0}^{n} Ici/n \qquad (3)$$

where n = total number of divisions assigned to the structure. The result of the SCI calculation is an integer number between 0 and 100.
One disadvantage of the structural condition index is that for larger and more complex assets which contain many sub-elements, the averaging of the conditions across all elements may cause critical defects to be lost in in the overall SCI.

3.2.2 *Priority Index (PI)*

The priority index (PI) is used to rank assets in order of defect criticality and is based on a modified *Icii* for each asset sub-element condition. Each sub-element is placed into a range according to the *Icii* condition rating of that sub-element. Four ranges are available and are defined as *Icii* of less than 50 (poor), between 51 and 74 (warning), between 75 and 99 (acceptable) and 100 (excellent).
A series of calculations are performed whereby the priority index is anchored by the lowest *Icii* sub-element condition rating of the asset and the higher *Icii* ratings are weighted downwards to make them less relevant in the overall calculation.
The aim of the priority index is to amplify the asset sub-elements which are considered to be in a critical condition, reducing the effects of averaging the condition of the asset, which occurs in the SCI calculation. The outcome of the priority index calculation is that structures with a higher number of *poor* or *warning* sub-element conditions will obtain a higher priority index than those with relatively few poor condition ratings and a higher number of less severe sub-element conditions.
The result of the priority index calculation is an integer number between 0 and 100.

3.2.3 *Relevancy Index (RI)*

The relevancy index is another method of ranking structures with a focus on the relevancy ratings for each sub-element of the asset. One disadvantage in using this method is that the relevancy index score is not capped to any range and it is not possible to give the asset an effective score out of one hundred, making it difficult to monitor the asset's deterioration over time. The index is used to rank assets in a network in relation to one another.
The relevancy index is calculated by counting the number of R = 4, R = 3, R = 2 and R = 1, then ranking the structures in that order. The structures with higher numbers of high relevancy ratings will have a higher relevancy index. This is a simple but effective approach to prioritizing structures.

3.3 *Combining Indices*

The system user can employ a single index or a combination of indices to determine an overall prioritization of works. The user should first examine the results derived from each index and determine which index provides the result which best suit the desired outcomes and preference. The prioritization of defects then feeds into the annual maintenance budgets. From our experience across government authorities in the Gulf region we generally recommend the following combination and order of indices:

1. Structure Priority Index rating (PI) rating
2. Sub-element Relevancy Index rating (RI)
3. Sub-element urgency rating (U)

We have found that the overall Structure Condition Index (SCI) is generally not a good indicator of priority for the repair of defects, since the averaging of sub-element conditions over the structure tends to reduce the impact of high criticality defects.

4 SYSTEM SOFTWARE

The bridge management systems implemented in the Gulf region began as desktop versions. Through user interaction and feedback, as well as a measure to make the system future ready, the desktop versions were developed into web-based asset management systems to accommodate all the operational business processes including integration with other corporate systems.
Detailed quality control and assurance approvals were implemented both for inspection and for work ordering business processes. Corporate GIS map services are also consumed on both PCs and Android mobile devices.

4.1 *System architecture*

High level system architecture is presented in Figure 1 below.

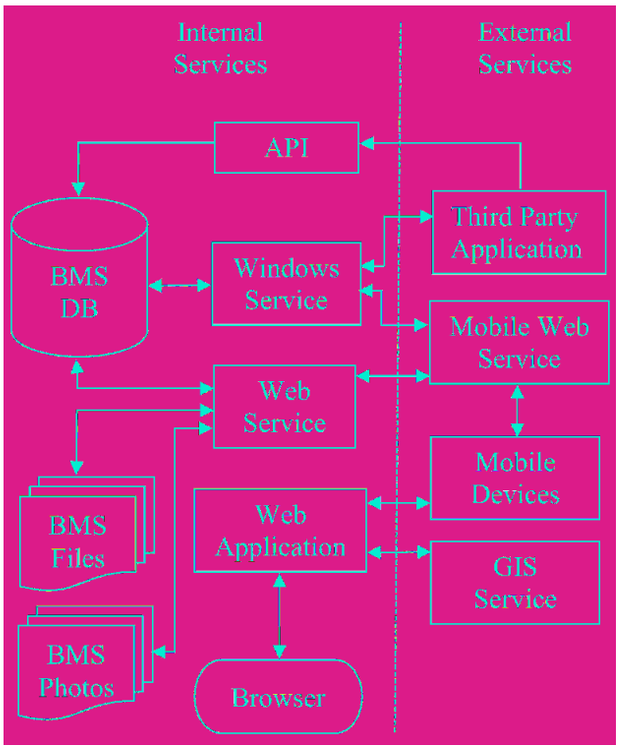

Figure 1. BMS system architecture.

A number of servers are in place delivering system operations in line with client's IT governance policies.

4.2 *Web-based system*

Using a web-based solution allows the user to access the BMS from any computer with internet access. Previously, desktop systems were based on Microsoft Windows platforms but this can be cumbersome to manage for information technology departments. A web-based system allows tailoring of a multitude of security and system maintenance requirements and maintenance of all asset management needs. The look and feel of a web-based system can be adapted to particular design requirements and remains responsive under all operational scenarios.

4.3 *Separation of structural and electromechanical systems*

As new construction methods, materials and equipment are incorporated into new assets, maintaining authorities are faced with unique challenges in the maintenance management of both structural and electromechanical systems. The management of structures and electromechanical systems should be handled separately, ideally by splitting them into two distinct modules. Independent inventory, inspection and maintenance processes should be developed for both, then recombined at the reporting level to deliver a unified approach to management operations.

4.4 *Integration with other enterprise systems*

Using multiple software systems is commonplace in large government departments and seamless integration between them is essential to delivering correct contextual information and avoiding data duplication. Government authorities in the Gulf region are typically implementing advanced enterprise architecture solutions in order to provide a single enterprise integration platform. The enterprise service bus (ESB) provides a means of communication between interacting software applications. It is essential that a modern asset management system be able to integrate rapidly and safely across multiple data resources.
Through the ESB the BMS is able to integrate with other enterprise systems such as IBM Maximo for works execution and management, enterprise GIS services, electronic document management systems and other specialized systems such as abnormal loads management systems.

4.5 *Mobile Inspection devices*

An effective BMS allows field staff to use mobile devices for inventory and inspection data collection. Allowing field data to be downloaded and uploaded via mobile devices minimizes inspectors' time in the office, reduces error, as well as allowing for the faster identification of any potential safety concern.
Dedicated BMS web services are in place to facilitate all data exchanges between BMS database and the field devices. Mobile devices must continue to function without internet connection and seamlessly update as soon as connection is reestablished. Multi factor authentication confirm user identities and complies with client's security policies.

5 LESSONS LEARNED

While highway asset management processes are the core requirements of a BMS, efficient delivery of these processes is of paramount importance in ensuring optimum use of available resources.
Through our experience in developing and implementing bridge management systems in the region, we have come to learn the importance of implementing a BMS that is client-operations focused, aligned with best asset management practices. The system must be adaptable to future business process, which may be envisaged by the client, but not yet implemented. Government departments are looking to continuously improve performance across all levels of operation and they are looking for a BMS that will

assist in delivering the key performance indicators established by the organization.
We have also learned that early stakeholder engagement and change management advisory services are critical success factors when developing and implementing a new asset management system into an existing organization. The implementation of a BMS will impact on a broad range of stakeholders inside and outside the maintaining authority, including other departments, senior management, inspectors and contractors. Any one of these stakeholder could derail the implementation process if they have not been included in the engagement process.
Similarly the authority will certainly undergo some form of internal change with respect to workflows, roles and organizational structure. The early recognition of these changes is important for a successful implementation of a BMS.

6 FUTURE DEVELOPMENTS

6.1 *Building Information Modelling (BIM)*

Future developments for the BMS include the adoption of Building Information Modelling (BIM) as an enhancement to the graphical user interface. A BIM is a 3D graphical model, or intelligent digital version of a physical thing, which can be assigned metadata, or attributes and information, regarding particular model sub-elements.
We envisage that the BIM of an asset will be created or imported into the BMS and the inventory sub-elements will be linked to the corresponding sub-elements of the BIM. In order to make the BMS future ready, the sub-elements in the inventory module need to be designated and assigned attributes while keeping in mind that BIM will one day be incorporated. Eventually the inventory module will be populated simply by importing the BIM into the BMS, which contains all of the correct divisions and attributes needed for the BMS to function.
The benefits of making the step to integrate BIM into the BMS are many. The user experience will be enhanced by seeing the virtual asset in 3D and having the ability to examine elements of the structure or system in a visual way. Defects can be displayed on the digital structure, providing the user with an overview not possible in a data table. Commentators such as McGuire et al (2016) also note that BIM is an effective tool in facilitating the inspection and evaluation of bridges.
The adoption of BIM into BMS is to ultimately provide a reality context to the user in using the right maintenance decisions (Moore et al. 2017).

7 CONCLUSIONS

In a world that is continuously changing, and changing at an ever-increasing rate, improvement to business operations is a perpetual process as is improvement to the asset management systems that facilities short and long term operational planning.
It is imperative that BMS applications remain adoptable and relevant well into the future, which serve to maintain operational continuity and promote operation improvements.
Digital asset management systems must be built on system architecture that can adapt to change and remain relevant into the future. In addition, the inspection rating systems and calculations performed in the BMS for condition and prioritization must be robust and reliable.
The asset management systems implemented in the Gulf region have been designed and customized with these attributes in mind in order to meet client expectations. Future developments in the BIM interface are the next step in the digital evolution of BMS applications in the region.

Research on Bridge Management System Based on BIM Technology

Y.D. Qin & R.C. Xiao
Department of bridge engineering, Tongji University, Shanghai, China

ABSTRACT: To promote the efficiency of bridge management work, the advanced BIM technology is applied in bridge management system (BMS), and thus the life cycle performance of bridge structure could improve. In the process of establishing the BMS based on BIM, the first step is to parameterize the bridge structure information during its whole life cycle, including geometric and physical information, load information, detection information, evaluation information and maintenance information of bridge. Then the logical relationships between the parameters are analyzed, and the BIM model used for bridge management is built. The BIM model in design stage contains structural static information and load information, with extensible information schema. The information in the design model is inherited and developed by the one in the construction stage. This model is more accurate because the component model is modified according to the manufacturing process, and the structure model is modified according to construction monitoring data. Finally, the as-built BIM model is close to the practical structure and is used as the BIM model in the maintenance and management stage. The durability of the bridge is precisely evaluated in BIM model combined with data of the structural health monitoring system and the bridge structural technical condition inspection results. Moreover, the maintenance plan could be simulated and tested in the BIM model. This new BMS could guide the bridge structural rehabilitation work more effectively and economically. The bridge management system based on BIM technology enables collaborative management of life-cycle information of bridge, and thus allocate manpower, material and financial resources with high efficiency.

1 INRODUCTION

Bridges suffer deterioration problems caused by the initial defects, the deterioration of natural conditions, the vehicle overload, etc., during the operation stage. So reasonable management and maintenance are needed to improve the life cycle performance (Frangopol and Liu, 2007). It is commonly believed that the bridge management system (BMS) is one of the best measures to improve the life-cycle performance of bridge due to the success of several BMS, such as the AASHTOWare Bridge Management (formerly named PONTIS) in the USA (Golabi and Shepard, 1997). Another BMS in the USA, the BRIDGIT, was developed under the AASHTO-sponsored National Cooperative Highway Research Program (Hawk, 1999). Japan developed the J-BMS for damaged concrete bridges (Miyamoto and Motoshita, 2015). In addition, Switzerland, Arabia, the United Arab Emirates, Sweden, Italy, Turkey and other countries have also developed their BMS according to local bridge management situation (Hajdin, 2004, Yehia et al., 2012, Safi et al., 2013, Fruguglietti et al., 2014, Akgul, 2016).

The rapid development of information technology provides the bridge management system with technical support for upgrading. The combination of civil engineering and information technology is Building Information Modeling (BIM), which manages the whole process of design, construction, and operation of building project efficiently through the digital description of physical and functional characteristics of structural components. To share all kinds of information across architecture, engineering, construction, and owner-operator industries, the interoperability of exchanging information is the base for BIM technology (Steel et al., 2010). IFC (Industry Foundation Classes) is the most widely adopted BIM data format standard at this moment (Solihin et al., 2016).

In analogy to BIM, bridge information modeling (BrIM) is introduced for design, construction, maintenance and operation of bridges (Chen and Shirole, 2006). The first step of establishing BrIM model is the 3D spatial model. Ji proposed a data format based on IFC to describe complex geometric

information of bridge, but this method can only be used in the bridge design stage (Ji et al., 2013). Karaman *et al.* suggest a 3D geometric representation of highway bridge for design and construction stages (Karaman et al., 2013). Ali studied the application of BIM technology in concrete and bridge parametric design model of the beam, bridge deck, and bearing (Ali et al., 2014). Nagarajan investigated and developed the XML format for steel bridge design and construction work (Nagarajan, 2010). Furthermore, Hu deepened Nagarajan's work by establish an efficient and extensible data exchange protocol to exchange bridge data, which is called OpenBrIM (Hu, 2014).

However, the application of BIM/BrIM in operation and maintenance stage is less than that in design or construction stage. Yalcinkaya applied latent semantic analysis to the abstract of 975 academic articles, and the results revealed that researches related to maintaining and managing are less than 10% (Yalcinkaya and Singh, 2015).

If BrIM technology is introduced into bridge operation work, the sharing and integration of monitoring and inspection information would improve the efficiency of bridge management and maintenance work. Jeong proposed a BrIM framework for supporting bridge monitoring and management applications (Jeong et al., 2017b). This framework is based on attempts of introducing emerging information technology into bridge monitoring, such as NoSQL database (Jeong et al., 2016b) to handle time-series data and unstructured bridge information, and cloud-based platform (Jeong et al., 2017c) to store and process enormous volume of data such as sensor information and traffic video images. The formation of BMS based on BIM technology is of great significance for the improvement of life cycle performance of bridges. The main content of this paper is the function modules of BMS based on BIM and brief research framework of combining BIM and BMS.

2 BRIDGE MANAGEMENT SYSTEM

2.1 *The development of BMS*

Bridge management work includes structural inspection and monitoring, performance evaluation, and maintenance and repair in operation phase. BMS is a comprehensive system related to bridge engineering, disease mechanism, detection technology, data acquisition technology, geographic information system (GIS) technology.

In 1988, the Federal Highway Administration of US developed the first BMS in the world, the National Bridge Inventory (NBI) database (Small et al., 1999). NBIS collected and maintained inspection information and gave appraisal ratings for allocating federal funds. After the success of NBI, the Federal Highway Administration developed the PONTIS bridge management system. In PONTIS BMS, bridges are described as sets of elements, such as decks, beams, bearings, columns, etc. The data format of these elements are developed by several State highway agencies and the Federal Highway Administration so that the information could be shared across agencies and bridge management systems (Fruguglietti et al., 2012). The PONTIS bridge management system supports network-level and project-level decision making on the condition and functional obsolescence of bridges (Inkoom et al., 2017). Another BMS in the USA is the BRIDGIT, which has many similarities with PONTIS (Hawk, 1999).

The development of bridge management system in China began in the mid-1980s. The CBMS developed by the Ministry of Transportation Highway of China contained 4 databases and 7 subsystems. The 4 databases are bridge static information database, dynamic information database, document database and evaluation decision database, and the 7 subsystems provide different functions such as analytic hierarchy process evaluation, cost analysis, statistical analysis, maintenance plan, etc.

The Tongji University has developed the urban bridge management system of Shanghai, which includes six function modules, which are the geographic information module, the file management module, bridge monitoring module, technical condition evaluation module, maintenance countermeasure module and heavy vehicle route plan module.

2.2 *The function modules of BMS*

The function of BMS depends on the requirement of the agencies of highway management. Take the urban bridge management system of Shanghai as an example to introduce the typical function modules of BMS.

2.2.1 *Database Module*

The bridge database is used for the storage, query, modification, and analysis of static and dynamic information of the bridge, such as the structural dimensions, material properties, inspection information, evaluation data, maintenance history, etc.

It is the cornerstone of BMS that it determines the reliability and availability of bridge management system.

2.2.2 *Evaluation Module*

The core function of BMS is the evaluation of bridge technical condition. Using the analytic hierarchy process (AHP) and the variable weight assessment method, the bridge condition is evaluated with appropriate indexes according to collected inspection and monitoring data. Moreover, the structural health monitoring system is integrated to realize forecast-

ing function. According to the results of evaluation, the bridge technical performance trend could be further predicted.

2.2.3 *Prediction Module*

This module aims to predict the deterioration trend of bridge technical condition. The theory of time series analysis is brought in to establish seasonal prediction model based on monitoring data. The prediction result simulates structural degradation trends and forecast critical moment, and then clarifies the demand for bridge maintenance and repair plan.

2.2.4 *Maintenance Plan Module*

The BMS can provide maintenance plan decision support. At the project level, the bridge maintenance plan decision is based on the damage inspection, monitoring data and the prediction model. The maintenance plan module selects appropriate management measures, including maintenance, repair, reinforcement, and even reconstruction. At the network level, that is to determine the maintenance priority of the bridges and the funds allocating based on the severity of bridge technical condition, the urgency of repair and the amount of disposable funds.

2.2.5 *Auxiliary functions*

The BMS provides the administrative departments with some specific functions required to improve the applicability. For example, the file management module stores drawings, photographs and other related documents of bridge projects. The GIS module displays geographic data visually. The mobile technology assists the field man in the query and input of information.

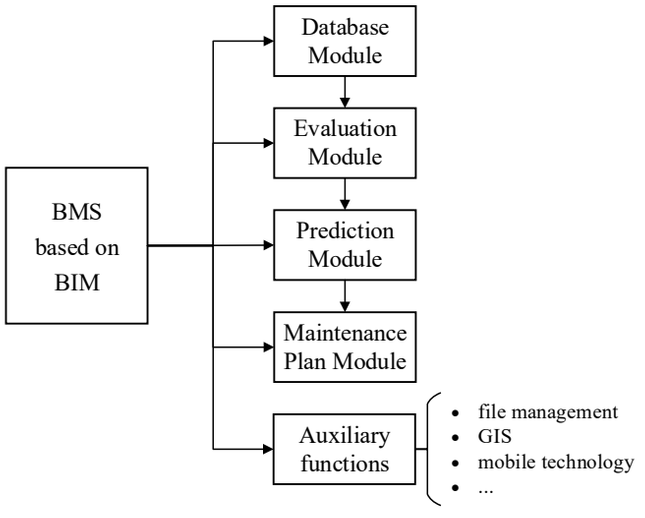

Figure 1. Function modules of BMS.

2.3 *Technology to be improved*

However, due to various reasons, the BMS does not play its proper role in the process of bridge management at the present stage. Firstly, the bridge condition is not simulated accurately because the tedious bridge data input work is manual in many cases and different types of information are processed by isolated systems of design, construction, and operation. This results in a lack of consistency of data exchange because the data source is not traceable. Secondly, the current evaluation method is experience-based, and thus it is subjective to a large extent. At last, the authorities lack preventive maintenance measures for bridges. Before the repair or reinforcement work is carried out, the bridge damage has happened.

To sum up, the core problem of current BMS is the unavailability of necessary data during the lifecycle of the bridge. The prerequisite of the success of bridge management work is a comprehensive description of the bridge structure, including construction conditions, structural geometric and physical data, design standards, etc.

To obtain and integrate all the information needed for bridge management, it is necessary for BMS to collect and update information from all date source automatically, instead of inefficient and imprecise manually input. After that, BMS establishes static and dynamic information database of the bridge. The static information refers to the information that is unchangeable after the bridge is built, such as the geometry dimension and material properties, etc. The dynamic information refers to that related to time, including the load data, the structural damage type and location, and health monitoring data, etc. Only if the static and dynamic information database of the bridge is built, the goals of other functions in BMS could be achieved.

3 BRIDGE MANAGEMENT SYSTEM BASED ON BIM TECHNOLOGY

As for the evaluation, prediction and decision support function, the basis is a comprehensive database of the bridge. There are some limitations in the current information management of BMS. The solution to this problem is the application of BIM technology to establish a life cycle integrated information database.

To create such a BIM-based database, the first step is to parameterize the bridge structural and non-structural information and develop the logical relationship among the parameters, including structural geometry and physical information, load information, detection information, monitoring information, evaluation information, and maintenance information in design, construction and operation stages.

3.1 *In design stage*

The BIM model in design stage mainly contains structural geometry information, physical information, and load information. The typical data model in design is the finite element model used for the calculation and analysis, and the CAD drawings of the project.

Firstly, the proper encoding method of components of the bridge structure is designed. So, both the bridge structural and non-structural components are identified into reasonable hierarchy levels. After the component is numbered, the geometric model is created by the bridge designers. The bridge structure is different from the traditional architecture as the locating axis of a bridge is usually spatial curved and the section type is more complex and variable. Because the bridge structure is suitable for parametric design, at present, we are working on a parametric design method in which the bridge structure is divided into the three layers of axis, form, and component.

3.2 *In construction stage*

The BIM model in construction stage inherits from and deepens that in design.

On the one hand, the BIM model LOD (level of details) is increased according to the component manufacturing process as the prefabrication technology has been widely used in civil engineering. The bridge BIM model get information from the component model used by the factory and integrates the manufacturing data. On the other hand, as for the whole structure of the bridge, the position information of each component and election history in the BIM model are updated according to the construction monitoring system. Finally, the as-built BIM model conforms to the actual situation of the bridge. That means the static information of design and construction stage is preserved completely in the BIM model, which is used as the initial BIM model in the subsequent operation stage.

3.3 *In operation stage*

In the operation stage, dynamic data is generated by structural health monitoring system and bridge technical status inspection results, and is used to update the BIM model.

Several methods of using BIM technology to store and analyze the detected damage or monitoring information of bridge structure has been proposed (McGuire et al., 2016, Jeong et al., 2017a). However, because the amount of data during the operation of the bridge is enormous (Jeong et al., 2016a), so the pre-processing technology and storage method requires further study, such as the cluster analysis of the similarity of sensor data. The BIM model is capable of evaluating the durability of the bridge structure and then simulating the implementation effect of maintenance and repair more accurately than before.

3.4 *Life-cycle BIM*

BIM technology can unite all the involved industries during the life-cycle of a bridge project and share all the information among them. The consistency of all the static and dynamic information of the bridge is the solution to the isolation problem of design, construction, and operation. It is obvious that this aim of a building information model with a continuous flow of information needs data transfer method among tens of kinds of modeling and analysis software. Only after that, the BMS could create the bridge database with all the information offered by the BIM model to evaluate and predict the performance of the bridge structure and then give a reasonable maintenance plan decision support.

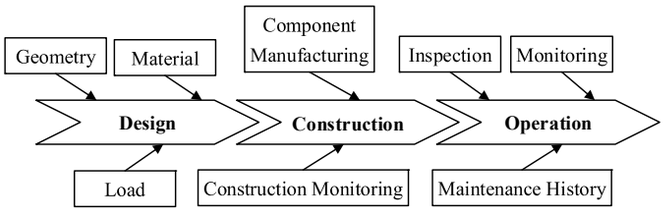

Figure 2. Information Source of BIM model during life cycle of bridge.

To achieve the goal of sharing BIM data, it is necessary to establish the BIM data format standard which meets the needs of each industry in the whole of the bridge. Models at different stages can inherit component and structure data from the earlier stages, and participants of bridge engineering, such as suppliers and contractors, also share data with the others.

At this moment, one of the main limitation that restricts the application of BIM technology in bridge management is that there is no applicable as-built BIM model. With the help of BIM, the static information of design and construction stages will be well recorded. Then in operation stage, the dynamic data is used to update the BIM model so that the integrated database of BMS is established. After that, the other functions could be more efficient and accurate.

4 CONCLUSION

The establishment of BMS based on BIM technology can comprehensively manage information in the whole life cycle of the bridge and achieve the goal

of allocating manpower, material, and funds economically and coordinately.

Firstly, the information of the whole life cycle of the bridge is parameterized, including structural geometry and physical information, load information, inspection information, evaluation information and maintenance history information.

Secondly, establish the proper BIM data format standard suitable for bridge management. The point is that the static and dynamic data in BIM models of the design, construction and operation stages can be reused by following stages.

Finally, the BMS evaluate the structural durability and simulate of the maintenance effect taken the structural health monitoring data and inspection results into account and guide the bridge management work.

ABSTRACT: Both national and international agencies have attempted over time to implement inspection and maintenance systems to ensure an accurate assessment of bridge structures in administration. Due to the development of the road network around the world, but also due to the historical contexts, bridge inspections, assessment and maintenance strategies differ from country to country, with managed structures being maintained under different technical conditions. With the development of the transport network, budgets allocations have become unsatisfactorily, with the number of structures growing. This has increased the importance of carrying out regular inspections and maintenance work from the very first stages of the emergence and development of degradation. Thus, researchers and managers have come with the conclusion of the need to create and implement an integrated, trustworthy system responsible for providing the data needed to make the best decisions regarding the inspection, assessment and maintenance of patrimony structures. The implementation of this system leads to ensuring user safety, optimal traffic, budget allocation and efficient use of available funds. Another reason for applying an efficient bridge assessment and maintenance system is the need to estimate the strength of patrimony structures needed to calculate the current and future safety levels of the transport network. This system aims at avoiding the execution of maintenance and rehabilitation works that are not a priority for those structures, leading to high costs, delays in the delivery of goods and services, and increased waiting times in traffic.

The present paper aims to carry out a comparative critical analysis of the inspection and intervention strategies implemented in several countries in Australia and Europe, including Romania. This comparison would like to highlight the strengths of several bridge maintenance strategies and methods to provide an overview of them.

1 INTRODUCTION

In operation, roads and bridges are permanently undergoing a degradation process from the time of their construction and commissioning. This is mainly due to traffic, exceeding the permissible axle weight and the action of environmental agents (Comisu et.al., 2017). In order to prevent trafficking from being affected by inappropriate conditions of the road network, different ways of permanent surveillance and overhaul of roads and bridges have been implemented throughout the world. The main purpose is to identify, from the very first stages, the emergence and development of degradation and to repair it in the shortest possible time (AND 504, 2007).

Regular technical inspections are the most useful and effective tools implemented by engineers in charge with road network management; they are used to assess any structural damage or loss of resistance caused by various factors, both internal and external. The complexity of the analyses carried out during the technical inspections varies depending on the structural type, the static scheme and the material from which the bridge is built. This is because it is necessary to provide the most accurate answers, which are then used to make decisions on budget planning and the execution of the maintenance work required for the structure (Pavelescu, 2013).

Since any administrator of a road network is forced to deal with budgetary constraints, maintaining bridge structures in optimal conditions becomes a priority. Researchers from all over the world have come to their aid by creating different progressive testing methods. They start from visual inspections, evaluating to the most detailed computer added analysis or laboratory analysis.

The most important advantages of implementing a regular bridge evaluation system through regular inspections are the possibility of detecting any defects from the early stages of their development, the investigation of the causes of their occurrence and optimal decision making on how to remediate them and prevent expensive repair work.

Inspection of an in-service structure is required in order to:

- Check its technical state and whether traffic can be carried out in optimal conditions both in the present and in the near future
- Identify the presence of any degradation or defect that may affect the user's safety
- Draw up a plan of the measures that need to be taken in order to maintain the safety and the execution of maintenance work

The main purpose of inspections is to observe and record the technical state of the entire structure or just some of its components in order to provide engineers responsible for its administration with the necessary data to make the best decisions in time. These decisions concern both the timely implementation of the intervention work and the extension of these works.

The main objectives of the bridge structure inspection are:

- Determining the occurrence of degradation from the earliest signs and monitoring their development;
- Determining the appearance, extent and causes of degradation of the materials used in the structure execution;
- Determining the appearance of any changes that will affect the safety and durability of the structure over its life span;
- Assessing the efficiency of various maintenance and repair works;
- Data recording for uploading capacity evaluation;
- Determining the technical state of the entire structure or of certain components.

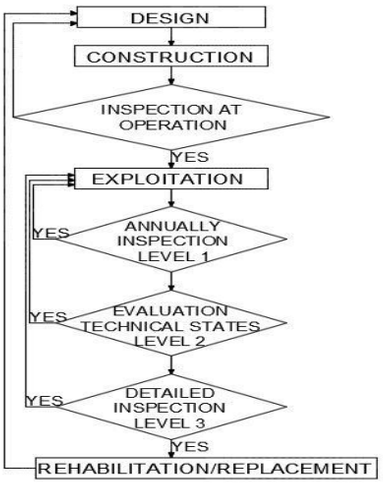
2 INSPECTION TYPES USED IN SEVERAL COUNTRIES

Currently, the most commonly used methodology for monitoring the technical condition of bridges is visual inspection. Depending on the extent of degradation and how it affects the traffic safety, the structure manager will decide to use non-destructive tests during the inspections. The types of inspections used in various countries in the European Union and around the world are described below.

2.1 *Australia*

There are several road administrations operating in this country; some of them have overall state responsibilities, others only territorial. These administrations are:

- -Main Roads Western Australia – Western Australia (WA);
- -Department of Infrastructure, Planning and Logistics – Northern Territory (NT);
- -Department for Planning, Transport and Infrastructure – South Australia (SA);
- -Department of Transport and Main Roads (TMR) – Queensland (Qld),
- -Roads and Maritime Services at Ministry of Roads, Maritime and Freight – New South Wales (NSW);
- -VicRoads or the Roads Corporation of Victoria – Victoria (Vic);
- -Department of State Growth – Tasmania (Tas);
- -At the Australian Government level, road administration is the responsibility of Department of Infrastructure, Regional Development and Cities – Infrastructure and Regional Development.



Each road administration has set up its own inspection system for the administration of structures with spans of more than 3 m. However, these systems are quite similar. All manuals are based on the Pontis bridge maintenance system, which is used by the US road administration.

The manuals describing how and how often inspections should be done are *Bridge Inspection Manual* (2004) in Part IV – *Procedures* and *Manual Part one – Bridge Inspection Policy* (2014). Thus, the verification of the bridge degradation degree is divided into 3 levels as follows (Fig. 1):

- Level 1 is represented by the inspection carried out during the periodic maintenance works execution. It is primarily aimed at checking the degradation state of the structure, in particular the safety of the road users, and identifying any degradation that would create resistance and safety issues in the future. This type of inspection is carried out annually on any bridge, regardless of the material, the static scheme and/or the degradation state. Level 1 consists of a visual inspection of all the visible and easily accessible elements of the structure, being integrated into the execution of the current maintenance work. It is necessary for the inspection to be carried out by a person with a rather extensive experience in the field of road and bridge maintenance. Any work performed at this stage is recorded in the Structure Maintenance Program, where the type, nature and cost of these works are identified
- Level 2 of inspection is primarily intended to estimate the current technical state of the structure under consideration. The data collected at this stage is used to: identify structural defects and quantify their extent, estimate the cost of repair, rehabilitate or replace the structure according to the degradation extent, determine the remaining

life of the structure, assess the load capacity, assess the entire structure or just some of its elements after the periodic maintenance or rehabilitation works. Level 2 inspections are carried out by qualified personnel (accredited by road administrations dealing with that structure) with extensive experience in the design, construction, inspection, maintenance or rehabilitation of bridges. The verification of the technical condition at this stage takes place only visually, covering all components of the structure located above the water. Foundation elements below the water level require trained divers specialized in structure analysis.

– Level 3, the most detailed inspection, is coordinated by a structural engineer. These inspections include, besides the visual examination of the structure, non-destructive tests and the structural analysis of the bridge. The main objectives of these inspections are to analyse structural behaviour, degradation status and load bearing capability, evaluate the remaining lifetime of the structure and determine the appropriate intervention strategy. The Australian authorities have imposed that the personnel responsible for carrying out inspections at level 3 should be engineers, members of the Australian Institute of Engineers or any other equivalent institution accredited by the State. At the same time, at least 5 years of experience in the field of bridge design and construction are required. From the frequency point of view, level 3 inspections take place only on the recommendation of the level 2 inspection reports, on the discovery of the load bearing capacity decrease or on a technical audit program. The inspection included in level 3 is composed of a close visual examination of all structural elements. When the inspector in charge deems necessary, different non-destructive tests are performed to highlight the presence and quantify the extent of degradation on the analysed structure.

– Figure no. 1. Inspection chart in Australia

The data resulting from the above inspections are collected, processed and stored through 2 specially designed programs. Thus, WA used the system called MRWA (Main Roads Western Australia) Bridge Management System, and ACT used the NSW Bridge Management System (Mirzaei et al., 2014). However, in 2014, not all road authorities in Australia had implemented information management systems. These systems would be developed and implemented in the future.

2.2 *Austria*

In Austria, the inspections are carried out by the Road Administration for all bridges whose spans reach or exceed the length of 2 m. The data from these inspections are used to assess both the structure state and how the entire in-service road network is affected. There are three types of inspections:

– Superficial inspections carried out by the personnel responsible for the structure maintenance. They report any occurrence of a defect or degradation of easily observable structural parts.
– General inspections are carried out by qualified staff, under the direction of a bridge engineer. These inspections take place every two years and after an extreme event in the life of the structure (e.g. earthquake, flood, etc.). Only the accessible elements of the structure are inspected.
– Major inspections are performed every six years for all structures. Their main objective is to provide detailed information on the state of the bridge. Based on these data, it is recommended to carry out various maintenance or rehabilitation works, depending on the needs of the structure.

2.3 *Denmark*

Bridges are managed by the Danish Road Directorate. Those with spans greater than 5 m are subject to 3 types of inspections:

– Superficial or routine inspections are carried out during on-site maintenance by the personnel responsible for their execution, with the aim of detecting major degradation and changes in the operating conditions of the structure.
– Main inspections are carried out by qualified personnel, every three years. However, depending on the technical state of the structure, this period may vary between 1 and 6 years. Within them, there is a visual check of all the accessible elements of the structure.
– Special inspections are carried out according to the recommendations made by the qualified personnel during the main inspections. Those inspections are made to evaluate the technical condition of all structural elements. In-situ or laboratory tests are also included, if necessary. Special inspections must always be carried out before regular maintenance works or capital repairs.

In Denmark, the road administration developed a computerized data collection and management program for bridge structure inspections called the DANBRO Bridge Management System. The first version of this program was carried out around 1975; since 2010 an improved version has been utilized. The only drawback of this program is that it is used only by the structure administration on the national and regional roads, consultants and builders (Mirzaei et al., 2014, Hearn et al., 2005).

2.4 *France*

The French Road Administration (Ministry of Ecology, Energy, Sustainable Development and the Sea, Transport Infrastructure Directorate) carries out the following inspections of all bridges with an opening of more than 2 m:

- Superficial inspections take place annually. They are done during the annual maintenance work and finalize with a report. This report contains the necessary data to identify the bridge, the date of the inspection, along with any observed defect or change in the structure.
- Assessment inspections consist of the rapid visual inspection of all bridge elements. These inspections are carried out by qualified personnel every three years.
- Detailed periodic inspections are carried out on bridges with medium and large spans every six years. However, the inspection period may vary between 1 and 9 years, depending on the technical condition and age of the structure. On this type of inspection, all structural elements are checked by qualified personnel in order to determine the different bridge-specific pathologies.
- There are two types of detailed inspections: preliminary inspections, before the execution of the main repair works and inspections carried out at the end of the warranty period.
- Exceptional inspections are made after the occurrence of various major events in the life of the bridge (e.g. earthquakes, floods, execution of various construction in the vicinity of the construction)

The program that manages data from field inspections is called LAGORA. Bridges, culverts, tunnels and retaining walls are recorded under this program (Hearn et al., 2005).

2.5 *Germany*

The German Highway Research Institute implemented the DIN 1076 program to monitor the technical condition of all bridges through 4 types of inspection:

- Surface inspections take place annually, with the main purpose of discovering the occurrence and development of major flaws that affect the safe operation of the structure. These inspections are carried out by the personnel responsible for managing the structure.
- General inspections take place every three years and consist of visual inspections of all accessible elements of the structure. In exceptional cases, various in situ non-destructive tests are permitted to monitor and capture different data about the degradation evolution or extent.
- Major inspections are visual assessments of all bridge elements. Various tests are carried out to determine the physical and chemical properties of the materials from which the structure is built. These inspections take place every six years from the bridge opening.
- Special inspection is carried out when the data from the structure indicates the necessity of carrying out various maintenance works.

The same research institute also recommended the use of the GBMS (Bauwerk Management System) program to manage data on the approximately 10.000 bridge structures under the German Federal Ministry of Transport. This program was implemented from the beginning of 2015 (Mirzaei et al., 2014, Hearn et al., 2005).

2.6 *Norway*

In this country, the first inspections done by the road manager (the Norwegian Public Road Administration) over a bridge are admission inspections (at the end of the structure execution or at the end of the main repair works) and end-of-warranty inspections. The main purpose of this inspection is to check the good behaviour of the newly built structure or of the repairs. It should be noted that in Norway, bridges are considered to be the structures whose span is equal to or greater than 2.5 m.

In exploitation, bridges are subjected to the following 3 types of inspections:

- The overall inspection is a visual inspection of all bridge components in order to detect any degradation that will affect the load capacity, traffic safety and the environment. This type of inspection takes place annually and it is carried out by the staff responsible for maintaining the structure.
- Major inspections are aimed at verifying the functionality of the analysed structure and determining the type of periodic maintenance work required to repair or maintain the bridge in optimal operating condition. These inspections take place every five years and are executed by qualified personnel.
- Special inspections specifically target any degradation or displacement of the structure that affects its technical condition. These works are performed when the previous inspections identified different defects that need to be monitored at shorter intervals of time than with the general inspection. The qualified personnel responsible for

conducting these inspections shall visually examine the affected area, while performing different in-situ tests, particularly with regard to the physical and chemical properties of the materials used to build the structure.

To ease decision-making on the maintenance and rehabilitation need and for easier management of data, the Norwegian Public Roads Administration developed the BRUTUS program in 1995. It contains data on bridges and various other types of structures of particular importance, managed by the Norwegian Public Roads Administration and local municipalities (Mirzaei et al., 2014, Hearn et al., 2005). At this point, the version implemented in 2013 of the BRUTUS program can be considered to be one of the best performing programs of its kind.

2.7 *Poland*

There are four types of inspection of all bridges, regardless of span, in public administration (Polish Railways and Local Roads Administrations) in Poland. These types of inspections are:

- Routine inspection takes place 4 times a year, being carried out by the personnel responsible for maintaining the structure. The purpose of these inspections is to confirm the safety and functionality of the analysed structure and to discover those defects that require the immediate execution of the remediation work.
- General inspection takes place annually, after an extreme event in the structure life, or on the recommendation of the routine inspection, with the aim of identifying any changes of the structure. These inspections are carried out by qualified personnel, namely an engineer responsible for managing bridges, with special training.
- Main inspection is carried out every five years or following a general inspection. It is performed by a specially prepared team, under the guidance of an experienced engineer.
- Special inspection is carried out only when necessary, at the suggestion of the inspections presented above.

In Poland, two transport infrastructure management programs have been developed. Thus, in the case of bridges tracking and other construction within the railway network, PKP Polish Railway Lines SA, their administrator, implemented the SMOK program responsible for managing the data from the inspections presented above. The first version of this program was implemented in 1997, the current version dating back to 2001 (Mirzaei et al., 2014).

Equivalent to the presented program, regional and local road administrations have developed and implemented for the first time in 2001 the SZOK program. The version currently in use dates back to 2010. Under the current version data on both bridges, tunnels, supporting walls and other work related to the road area are managed.

2.8 *Romania*

In Romania, roads are divided into 3 categories, each with an administrator (National Company for Road Infrastructure Administration, Country Councils and Local Councils). The Romanian norms in force at the time of publication of this article stipulate the submission of the entire road network to 5 types of inspections or revisions, each with different complexities (AND 504, 2007). The minimum regulated span of the bridge structures that is included in the national inspection system is 5 m (STAS 5629, 1992).

According to the standards, road and bridge revisions are (Fig 2):

- Supervision revision is the verification of the integrity and safety of the road through the entire management sector, including bridges and visual observations of road infrastructure. In the case of bridges, only visible track elements are inspected. This type of revision is carried out by the personnel responsible for the maintenance work currently employed in the road administration. Theoretically, surveillance revisions take place daily on the European roads, every 2 days on the national roads and twice a week on other public roads.
- Current revision is carried out by the head of the unit directly responsible for managing the bridge under review, once a month. The recommendations resulting from the visual inspections at this stage are recorded in the Administrator's Register and it is required that they be remediated in the shortest possible time.
- Periodical review takes place twice a year (usually in the spring and autumn), being carried out by a committee consisting of 3 members of the administrator. The checks in this revision are similar to those performed in the current revisions, and consist of visual examinations of the structure. In addition, cross-sections of the bedrock are also provided to assess bed obstruction.
- Special revisions are done after the occurrence of calamities (floods, earthquakes, landslides, etc.) or extreme events (accidents, changes in structural behaviour) by committees appointed by the structure manager.

All revisions presented above are performed by visually examining the analysed structure. According to AND 522 – 2006, every 5 years administration specialists or bridge experts perform the calculation of the technical status index of the analysed structures in order to classify the structure and plan the funds needed for the structural repair or rehabilitation. At this stage, non-destructive tests on the bridge, which are not mandatory, may also be carried out.

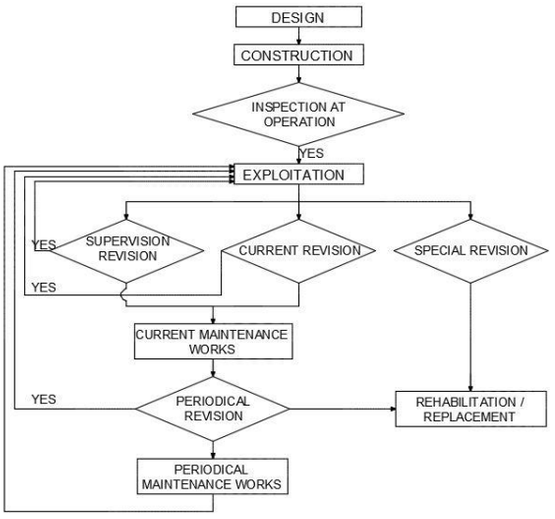


Figure no. 2. Inspection chart in Romania

2.9 *Slovenia*

In Slovenia, the Ministry of Infrastructure performs 4 types of inspections on all bridges with span of at least 5 m, as follows:

- Surface inspection is carried out annually by the personnel responsible for the structure management, along with the maintenance work. This inspection is a visual examination of all structural elements
- General inspection consists of a visual inspection of all accessible elements of the structure and takes place every 2 years. It is done by qualified personnel, under the strict guidance of an engineer responsible for verifying the framing structure.
- Major inspection takes place every six years, being a visual inspection of all structural elements. Specially trained staff prepares reports for all observed degradations and a list of recommendations for performing the required repairs.
- Special inspection is carried out on the recommendation of the staff responsible for the previous inspections. The purpose of this type of inspection is to produce a map of all recorded defects. If necessary, in-situ non-destructive tests are recommended to easily classify defects discovered and determine the best ways to correct them.

2.10 *Spain*

The road administrators of this country (Spanish Ministry of Public Works) have implemented 3 types of inspections, namely:

- Surface inspection is carried out at the initiative of the personnel responsible for the maintenance work. This type of inspection is used to verify the functionality of the structure and to discover the possible degradation that will affect traffic safety and load capacity over time. Due to the fact that, in the superficial inspections, the personnel does not have access to the use of the various tools for inspecting all the elements of the structure, the verification will be limited to the accessible components.
- Main and general inspections are carried out by qualified personnel, and consist of visual checks of the bridge components. These inspections take place every 2 to 5 years, depending on the structure maintenance policy, degree of degradation and age.

In this country, the Spanish Management System (SGP) was implemented to assist road network administrators in planning and carrying out the maintenance work required for bridge structures. The main users of this program are Ministerio de Fomento (Ministry of Development), Road Demarcations and Road Maintenance Areas. The current version of this program was implemented in 2013, but the program dates back to 2005 (Mirzaei et al., 2014).

2.11 *Sweden*

The bridge inspection in this country is carried out by the Swedish Road Administration as follows:

- Regular inspection is designed to detect and report the occurrence of any degradation that may affect the load-bearing structure's capacity and the safety of traffic participants. This inspection is visually carried out by the specially qualified personnel of the contractor performing the maintenance on the part of the road on which the structure is located.
- Surface inspection is carried out by the same staff as regular inspection at specific time intervals (once every 6 months for highways and national roads and once a year for the rest of public roads). The main purpose of these inspections is to identify in the early stages those degradations which, with their development, will affect structural safety.
- General inspection is carried out every three years for all structures having a span larger than 5 m. It consists of a visual inspection of all the structural elements of the bridge. The main objectives of these inspections are to evaluate the performance of previous work, to discover degradations which, if not remedied in a timely manner, will lead to a decrease in load capacity and safety of road users and increased remediation costs.
- Major inspection is the verification of the technical condition of all the elements of the bridge under consideration, including through non-destructive tests. These inspections are carried out every six years, with the objective of detecting and assessing degradations which will affect traffic safety and structure functionality in the following 10 years if no intervention is carried out, and also those degradations whose development will lead to remediation costs.

– Special inspection is carried out only when the situation requires it and when it is assumed that there is certain rapid degradation that would seriously affect traffic safety until the following inspection.

The Swedish Road Administration has implemented the BaTMan (Bridge and Tunnel Management System) program responsible for data management from the above-mentioned inspections. This program is used in the entire country by the Swedish Transport Administration, the Swedish Association of Local Authorities (about 70 out of a total of 290 authorities), the Stockholm administration, the Stockholm-based transport, the State-subsidized private Roads, the Gothenburg harbour, consultants and private firms that carry out maintenance work. The first version of BaTMan dates back to 1987. Nowadays the Swedish administration is using the 4.2 version, implemented in 2011 (Mirzaei et al., 2014).

2.12 *Switzerland*

In Switzerland, the Federal Roads Office (FEDRO) has implemented 3 types of inspections to determine bridge degradation and remedy it in the shortest possible time:

– Main inspection takes place every 5 years, consisting of a visual inspection of the entire structure.
– Intermediate inspection is carried out between two consecutive main inspections aiming at verifying the technical condition of a structure component or the evolution of a degradation process.
– Special inspection is carried out whenever the institutions responsible for the administration of the structure consider it necessary, especially after the occurrence of extreme events in the structure life.

In addition to these inspections, observations are done on bridges as part of the road network monitoring system. These observations consist of the visual check of the degradation state and the serviceability of the structure, and they are carried out by qualified personnel.

KUBA is the computerized data collection software from field inspections developed and implemented by the Swiss Federal Roads Authority. In 2014, version 5.1.2 was implemented, the first version dating back to 1989. In Switzerland, the KUBA program is used by both the Swiss Federal Roads Office and other road administrations in the country (Mirzaei et al., 2014).

2.13 *United Kingdom*

Road administrations in the UK (e.g. local authorities, Scottish, Northern Ireland and Wales authority, but especially Highways England) have implemented 4 types of inspections applicable to all bridges whose span exceeds 3 m. These inspections are (Fig 3):

– Surface inspection carried out by the road maintenance personnel takes place at regular intervals. The main purpose is to check the structure and discover those defects that affect or will affect structural safety in the near future or those that lead to significant increase of the remediation costs.

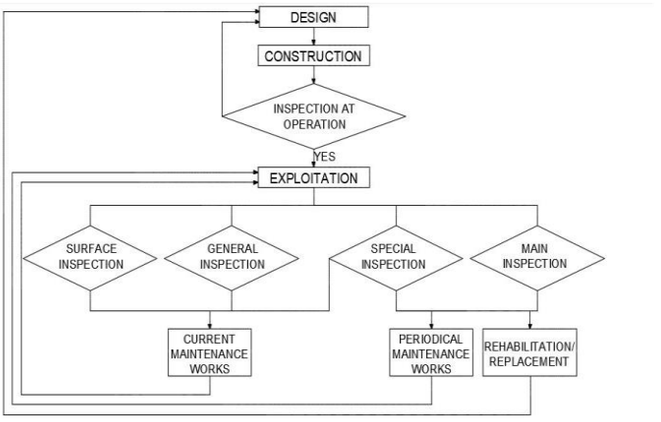

Figure no. 3. Inspection chart in United Kingdom

– General inspection consists of a visual examination of both the structure itself and the easily accessible parts of the supporting members and the river bed. This type of inspection does not use special equipment or non-destructive tests. The periodicity established by the administrators is approximately 2 years after the main inspection or since the last general inspection.
– Main inspection consists of a very precise check of structural elements in accessible areas. The examination is carried out by qualified personnel at specific time intervals, which were established in the bridge construction phase. Most often, these inspections take place every six years; but the range can be extended up to 10 years for new structures. The first main inspection takes place one month before the bridge is put into operation
– Special inspection is carried out only when:
  * it is necessary to examine the various types of degradation discovered during the previous inspection and which could endanger the traffic safety;
  * a structure is built with innovative materials or designed with special solutions;
  * it is necessary to investigate specific elements of the structure;
  * the structure has been subjected to exceptional loads.

In the United Kingdom, the reports of all previous inspections are entered into an electronic database called SMIS where they can be accessed by the personnel concerned with the structure (Hearn et al., 2005).

3. CONCLUSIONS

The methods for assessing the bridge degradation degree differ from country to country, although they all seek to provide similar information. The main differences are mainly represented by the format in which the information of the structure manager and the framing of the bridges in different technical classes are presented.

As it can be seen from the information presented above, the inspection and verification methods of the bridge technical condition used in different countries around the world present a number of advantages, but also various disadvantages. With this in mind, the following can be concluded:

- The most complete system for assessing management structures is the system applied in Germany. The main advantage is the use of non-destructive tests at all levels of inspection, except for superficial inspections.
- Due to the obvious advantages, it is recommended to develop and implement data collection, processing and storage programs in as many countries as possible. These programs make it easier for people to assess all of the available data on the management structures, leading to more efficient design and execution of maintenance and repair work. In the literature (Mirzaei et al., 2014, Bevc et al., 2009, Everett et al., 2008), the BRUTUS program developed and used in Norway is considered to be one of the most advanced data processing programs from the structures inspection.
- In order to better assess the bridge technical condition and to discover and remedy the degradations still in their early stages of development, it is advisable to use non-destructive tests. This leads to an efficient management of the limited budget funds available, due to the fact that remediation of degradation in the early stages of development requires less expense than when degradation affects structural safety. Also, for the same reason, it is recommended that various systems be implemented to continuously monitor the technical condition for the most important bridges in administration.

This paper presents a comparative analysis of strategies for carrying out inspections in different countries around the world, such as Australia or countries in the European Union. This comparison aims to highlight the existing differences, providing support to road managers in studying and developing the most effective way to carry out bridge inspections. Also, the main BMS systems are responsible for preventive measured information from the inspection and verification of structures.

This paper is part of a complex research program developed within the Technical University ”Gheorghe Asachi”, The Faculty of Civil Engineering and Building Services of Iasi, Romania. This research concerns the study and development of Structural Health Monitoring (SHM) systems for bridges.

The development of a modern bridge asset management system

A. Sonnenberg
Pitt&Sherry, Melbourne, Australia

ABSTRACT: An asset management system has been developed to manage bridge infrastructure. The system includes risk assessment, predictive modelling, load assessment, capital renewal prioritisation and optimisation algorithms. The system is a valuable tool for Universities and other interested parties to apply their deterioration models as well as extract data required to develop deterioration curves. For asset owners it holds the intellect required for them to efficiently manage the life cycle of their infrastructure from commissioning, inspection, maintenance, rehabilitation and renewal.

1 INTROCUTION

The demand for good asset management tools is increasing as the number assets under management increases and the staffing of organisations decreases. There is also increased expectations from the community to achieve greater levels of service without increasing expenditures.

To tackle these increased demands Pitt&Sherry engineers and programmers have been working on the development of an asset management system over the last 15 years. Although the system allows the management of all types of assets the system includes a number of specific modules, such as the bridge module.

1.1 *Key features*

Key features provided by the asset management system include:

1. Inventory data
2. Condition Assessment
3. Risk assessment
4. Financial management
5. Predictive modelling
6. Optimisation
7. Level of service tracking
8. Heavy Vehicle route assessment
9. Capital renewal
10. Reporting

A benefit of capturing data for a range of asset classes in the one system is that the system seamlessly interrelates the data between various asset classes, such as the bridge assets utilising information from the road assets when determining bridge barrier risks.

2 INVENTORY DATA

2.1 *Location*

The system provides multiple methods to cross reference location information. The primary method is via the longitude and latitude of the asset. Using this information the location of assets and defects are displayed on a map within the software.

Location referencing in the form of chainage along the road or path on which the bridge is located is also provided. The software automatically determines the road segment on which the structure is located.

As assets are modified the location of widenings, lengthening and strengthening's can also be recorded.

A proof of concept was developed to automatically generate 3D models of bridges by using the component data collected from inspections to show where each component is located with respect to the other. Although it was found possible to generate a 3D model automatically there was little benefit for most bridges as they aren't complex.

2.2 *Structure data*

The asset owner records the size and date of construction of the original structure, any widenings and lengthening. The software then determines the plan dimensions of the structure.

Other data about the assets is recorded such as the owner, span material, span type, what it crosses, the

clearance above, clearance below and the traffic width.

Information about the age of structures is feed through by the software to the components of the structures. Users are able to modify the age of each and every component if required. For example a component may be replaced on part of the original structure and its date of replacement can be recorded.

3 INSPECTIONS

A requirement of bridge asset management system is the ability to schedule and record inspections. The system needs flexibility to cater for various inspection practices across jurisdiction's. The software can accommodate the inspection manuals of various road authorities in Australia including VicRoads, Roads and Maritime Services and Queensland Department of Transport and Main Roads. The authority manuals use similar inspection methodologies and are based on practices developed in America. The main deference's between each manual is how components are described and measured. For example the State of Queensland (2016) manual describes the condition of components based on the quantity of each component in each condition, of each span, while Vicroads Technical Services (2014) utlises the percentage of each component, in each condition, in the structure as a whole.

The ability be mobile with the asset management system is important for cost efficient and accurate inspections. The software supports inspections using android, IOS and win10 mobile devices. The inspector can choose to have inspection information available as well as information regarding the asset. In this way inspectors can audit asset generic information, such as the name of the river which an asset crosses will in the field.

For larger structures it is important to be able to inspect only part of the structure at a time. Moreover large bridges have structural, electrical and mechanical systems that require regular inspections to be undertaken by separate specialists. The software is coded so that each specialist can do their work acting independently of others while the data is synchronised into one location.

4 RISK ASSESSMENT

The system allows the estimation of risk based on a variety of parameters, including risks related to:

1. Poor condition leading to bridge failure
2. Inadequate load capacity
3. Barriers substandard
4. Flood immunity

4.1 *Bridge Condition*

In 2011 the inconvenience of bridge closure was highlighted when over 200 campers along with their vehicles were stranded in Wilsons Promontory National park. The only route in and out of the park was cut by a wash away of a bridge approach requiring the campers to be Heli-evacuated a great expense. Such sites should be treated as having a high consequence should failure occur.

The risk of a structure of poor condition failing is managed by the system using a risk assessment procedure that creates a risk score which is used to rank the risk of bridge site to another. The risk is derived by the system using the consequence of failure and the probability of failure. A structure with components with unfavorable consequence of failure are provided with a high weighting. The system also assumes higher probabilities of failure to components that are in poor condition. This is an area in which further research could be undertaken to determine appropriate values to be used in the assessment. At this stage the parameters are based on engineering judgement. It is hoped that with larger and more complete data sets the data may be mined in order to determine more accurate estimates for the probability of failure.

Components within areas of the network that are critical to the functioning of the network are given a greater consequence weighting reflecting the cost and inconvenience when these areas of the network are out of service.

4.2 *Inadequate load capacity*

In 2016 a bridge failed in Italy under the passage of a 108 tonne permit vehicle killing one person. Although the bridge was found defective prior to the collapse the bridge was not closed and the operator of the permit vehicle not informed of the hazard. Having a good asset management system which stores load capacity and permit information can assist in the response time in these circumstances thereby reducing the probability of failure leading to loss of life.

The Risk of overload in the asset magnement system Pitt&Sherry has developed is managed by way of a load assessment tool. The configuration of permit vehicles is entered into the system, along with capacities so that a range of vehicles and bridges can be checked. The checks are used to determine if the bridges have sufficient capacity to cater for the vehicles.

The tool is used to identify bridges that require posted load limits to mitigate the risk of failure. Another use of the tool is that if damage occurs to a bridge it is possible to assess the seriousness of the damaged and review what permits are currently outstanding on a bridge. This mitigates the risk that a

permit vehicle may inadvertently travel of a bridge that has been recently damaged.

4.3 *Barrier Risk*

The asset management system greats risk scores for each bridge component and ranks them. The user then selects the highest ranking scores to contribute to an overall risk score. Typically, the highest risk component is assumed to be reflective of the overall risk of an asset but there is the option to use a collection of high ranking components to be reflective of the overall risk of the asset.

Barriers are assessed using both the chart based and site specific requirements of the bridge design code, Austroads (2017). Every barrier on each bridge performance level is stored and compared with the ideal performance level suggested by the bridge design code. The process is automated as the data such as annual average daily traffic and percentage heavy vehicles is shared from the road asset information within the asset management system. By sharing this information from the road asset to the bridge asset avoids duplication of data and allows for the automatic update of barrier risk information once road usage data is updated.

4.4 *Flood immunity*

At this stage flood immunity is simply stored as a recurrence interval to prevent inundation. With advances in technology it should be possible to associate a bridge with a river / catchment and make prediction using meteorology data in real time.

5 FINANCIAL MANAGEMENT

Asset owners need to report annually on their financial status to ensure compliance with regulatory requirements. Fainical data also assists in making prudent decisions with the management of assets. Beside keeping track of work order expenses the software enables users to record the construction cost, replacement cost, current cost and written down value of assets. The software assists the users in this process by allowing unit rates for both the structures current cost and replacement cost to be stored. These unit rates are multiplied by the structures plan area to determine the total costs or the user can enter the costs directly.

The deprecation of assets can be undertaken utilising one of three options. The first option is a traditional straight line depreciation methodology where deprecation is made a linear rate assuming a useful life of the asset which was estimated when it was first put into service. The second methodology is to adjust the useful life based on calculations through the software's predictive modelling capability. The last method is to use the predictive modelling capability of the software to undertake an asset revaluation of the asset.

6 PREDICTIVE MODELLING

The predictive modelling module of the software helps asset owners determine the useful life of their assets. The modelling utilises information from various aspects of the software including, generic data, financial data and condition data as diagrammatically displayed in Figure 1.

The condition data obtained from bridge inspections is used in conjunction with a deterioration curves to predict the useful life of components. The software allows for the export of condition data from the database. The condition data enables the development of deterioration curves. Sample data from bridge abutments inspected in Victoria, Australia is provided in figure 2. The data indicates considerable scatter in the results. The general trend is for bridge abutments to deteriorate with age, consistent with expectations. The data suggests that abutments could be expected to last on average more than 120 years provided they are considered serviceable at 70% or more of new condition.

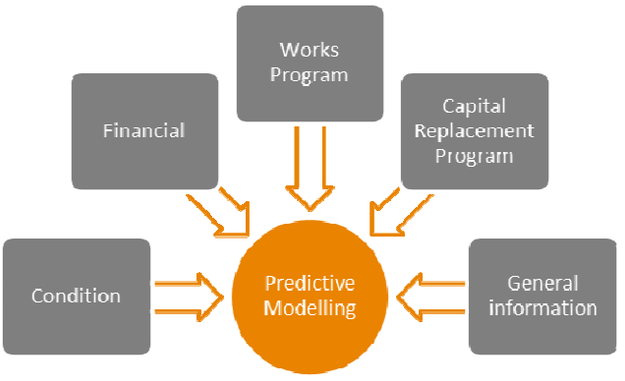

Figure 1. Inputs into predictive modelling

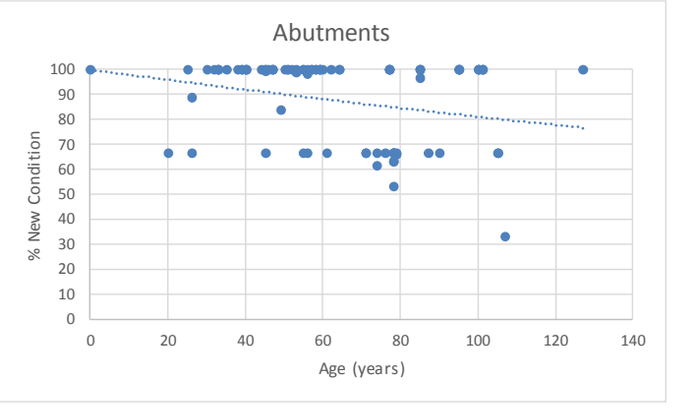

Figure 2. Deterioration curve for bridge abutments

A sample of condition data for compression joint seals is provided in Figure 3. The data indicates considerable scatter in results. The trend is for seals to deteriorate with age. After approximately 40 years the seal are expected to be in 70% of new condition in contrast to abutments reach this condition after approximately 120 years of age. The data is consistent with expectations that expansion joints are

less durable than main structural components of a bridge.

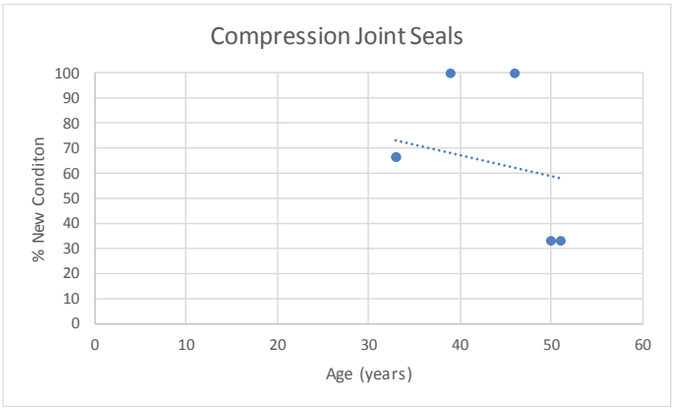

Figure 3. Deterioration curve for compression joint seals

The quality of the deterioration curve is affected by the base data used to generate it. Some asset owners don't accurately record the age of their bridges or the time at which works are done on their components. By making it easy to collect data and by utilising data from a range of clients should provide valuable data for researchers to create accurate deterioration curves. Plans are in place to allow the asset management system to use the data collected to self learn deterioration curves.

Due to a lack of reliable data the software allows the user to enter theoretical deterioration curves such as on the one displayed in Figure 4.

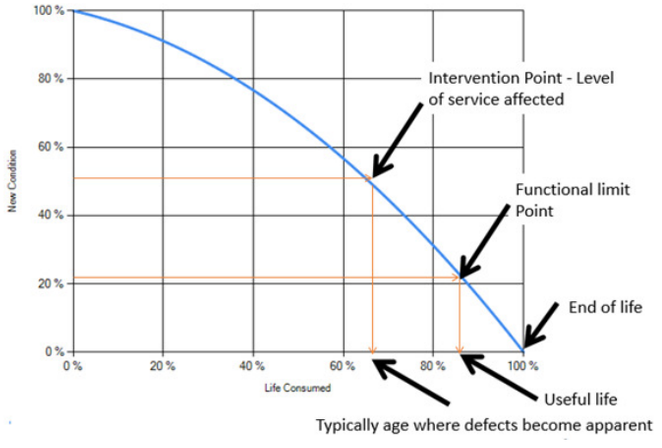

Figure 4. Theoretical deterioration curve

The software stores intervention levels for each component and functional limits. The intervention level is defined as the condition at which an asset owner considers undertaking works while the functional limit is the point at which the component reaches it useful life.

The software utilises the stored condition after repair of a component to forecast the life extension achieved by the proposed repair. The software also summaries the condition based valuation of the structure before and after the repair. The cost of a repair can be compared with the benefit obtained from the repair.

7 OPTIMISATION

7.1 *Works Management*

The works management system has two types of works order, Basic and Advanced. Basic work orders allow for the collection of defects onto a work order. These defects are found by the end user using search tools and then appended by them to a work order.

An advanced work order allows for the automatic allocation of defects to a work order provided the User selects the structures and the defect types they would like the software to monitor. With this type of work order as soon as the inspector identifies a defect that matches the criteria then the defect is allocated to the work order by the software.

Another function of advanced work orders it that preventative works can be scheduled. In the case of preventative works the user determines that part or parts of structures that require works. The user can also confirm the condition after repair work is done and the nature of the work eg. Maintenance or Capital expenditure.

The predictive modelling tool estimates the value of the assets components before and after works. In this way the asset owner can observe the cost benefit of the proposed works and undertake works on assets that provide the best cost benefit. At this stage the risk reduction benefit of undertaking works isn't factored into the software but works are underway to do this. The risk reduction may take the form of safety, economic and political risks.

8 LEVEL OF SERVICE

Level of service provided by structures varies depending on a range of factors. Factors to consider include

- Load capacity
- Barrier performance level
- Flood immunity
- Clearance for over height vehicles
- Volume of traffic catered for
- Number of lanes

At this stage the software doesn't link these service levels together however an algorithm has been developed to do so. The algorithm is based on the premise that there is benefit in providing a service which is largely dependent on the number of people utilizing the asset.

8.1 *Load Capacity*

Load capacity is important not only for safety but also important so that the structure can meet the community's needs. For some bridges only pedestrian

traffic is required to be catered for while for others heavy load platforms need to be catered for.

To determine the benefit a structure provides or could provide three classes of travel are consider. Light vehicles, Heavy vehicle (travelling without permit) and Oversize and Over mass vehicles traveling under permit. By understanding the quantity of each type of vehicle currently using a structure and the number of these vehicles that could potentially use a replacement structure enables an estimation of the benefit a replacement structure may provide.

8.2 *Barrier performance level*

Barriers provide protection to road users. The level of protection to be afforded is specified by the bridge design codes. The Austroads Bridge Design Code is based on providing a level of protection based on a cost benefit analysis. For low risks sites the code specifies lower, less cost costly barriers.

Levels of protection less than that specified by the design code are view as undesirable with respect to level of service. The benefit between one type and another barrier type can be determined by estimating the cost differential between the installation of those types of barriers.

8.3 *Flood immunity*

Flood immunity protection afforded to road users is important for the safety of road users as well as for productivity.

Every year lives are lost due to vehicles being swept off structures and towns are isolated from supplies due to the inundation of roads. The cost the isolation of roads is estimated by storing the detour length for bridges closed by flooding and by estimating the flood return interval for structures.

For structures know to inundate regularly procedures can be put in place through the software to search for these during times of expected flooding and to ensure appropriate safety measures are but is place to protect road users.

8.4 *Clearance for over height vehicles*

The software records the clearance above and below assets. It is anticipated in the future this information will be utilised to automatically check oversize vehicle request across the network.

8.5 *Volume of traffic*

Bridges are designed to cater for a certain volume of traffic. When this volume is exceeded the bridge is not meeting the level of service expectations and there will be increased benefit in either widening, duplicating or replacing the bridge to provide the desired level of service.

9 HEAVY VEHICLE ROUTE ASSESSMENT

9.1 *Permit requirements*

Under relevant legislation General Mass Limit (GML) vehicles such as buses, semi trailers and B-Doubles don't need specific permits to cross most bridges.

Higher Mass Limit (HML) vehicles need to observe relevant designated networks during their travel. Most State Government roads provide access to HML vehicles, while there is limited access to local roads.

All vehicles need to observe posted load limit signs for bridges.

Permit assessments are required for oversize and over mass vehicles, along with Special Purpose Vehicles. Over mass vehicles may have an axle tonnage greater than that allowed for under general operation or a mass density (close axle spacing) exceeding the provisions of a GML vehicle. In these instances, the Heavy Vehicle Operator needs to apply for a permit through the National Heavy Vehicle Regulator (NHVR). The permit requests are made online with the Heavy Vehicle Operator keying in the types of vehicle and their relevant registration details, axle masses, axle spacing and wheel configuration. The Operator is also required to state the route for which they desire the permit.

The NHVR distributes permit request through to the relevant authorities so that they can undertake the permit assessment. The authorities determine whether it is safe to grant access and if such access would cause a detrimental effect to other road users. A request may be denied if it would lead to an unsafe situation or adversely affect the functionality of a bridge or culvert asset.

9.2 *Benefits of permits*

The permit system provides operators with reassurance regarding the safety of their proposed vehicle to travel on the network, the safety of other road users and the wider community.

In 1996, the National Road Transport Commission (NRTC) Australia determined that even allowing minor increases of axle masses to GML vehicles could lead to significant saving to the community. The benefits included the ability to carry heavier loads, lower export costs, fewer vehicles, improved safety and improved environmental performance.

Like the benefits obtained from GML to HML vehicles, similar benefits extend to granting of permit vehicles access, provided the bridges have sufficient capacity to support the loading. Permit vehicles often carry indivisible loads that can't simply be split and are common place in heavy construction such as mining and civil infrastructure.

9.3 *What needs to be assessed*

When a heavy vehicle operator requests a permit there is an associated list of bridges and culverts that need to be assessed. These structures can be expected to take a range of forms since bridge construction technology has evolved.

Pre 1940 structures were designed for loads typical of a steam roller of 15 tonnes hauling a number of wagons. Due to the comparatively light loading structures where typically designed from short spans of timber girders.

It was not until 1946 that the design load increased to design vehicle representing approximately 32 tonnes. At that stage cast in place and precast concrete bridges become popular.

In 1967 there was a 30% increase in the design loads to approximately 44 tonnes. New precast concrete forms of structures were developed to accommodate the increased loading along with the ability to span further.

In 2004 the design load increased to approximately 160 tonnes with the intent of catering for increases in loading requirements of another 100 years.

9.4 *Inputs into the assessment*

To undertake an analysis in the asset management sytem the following inputs are required.

- Customer details.
- Vehicle configuration
- Structure capacity information
- Vehicles and structures to be analysed

The software has been configured to take the information provided by the NHVR or to be manually entered by the end user.

The structure capacity information is entered into the asset management system by a bridge engineer. Information is required relating to the shear capacity, positive and negative bending moment capacities. The capacities are provided at points of interest along each span. Support capacities and arrangement are also entered.

To streamline the process a generic capacity input can be used whereby the capacity information is modelled off the assumption that the original design load capacity is achieved.

Once structure information is entered by the Bridge Engineer the asset owners permitting officer may enter the vehicle details for assessment and choose the structures to be analysed on the route.

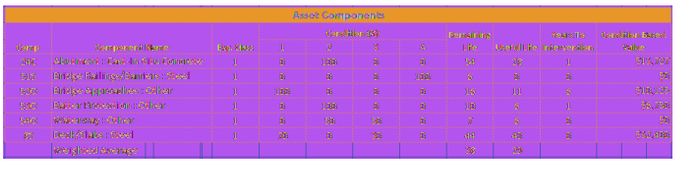
9.5 *Results*

Assuming a vehicle passes all checks then it would be permitted to travel. The assessment may indicate a travel restriction is required, such as marked lane or centreline travel. If the checks aren't passed then the outcome is either not to permit the vehicle to travel or to undertake further engineering assessment.

9.6 *What are the benefits of automation*

Automation provides a range of benefits to the network wide assessment of permits. These benefits include

- Information from previous assessments can be used for future assessments
- Using an automated process provides for consistency of results
- Undertaking assessment in an asset management system allows for integration with other systems and allows for the history of permits to be stored against each customer and asset
- Less experience staff may participate in the heavy vehicle checks



Perhaps the greatest benefit of implementing a rigorous automated process is to minimise the potential of death or injury caused by inadvertently permitting a vehicle to cross a bridge with inadequate capacity.

10 CAPITAL RENEWEAL

Asset renewals occur for a variety of reasons. First and foremost consideration should be given to the service level expected from the assets by the community. Service levels vary by asset class. But common to all classes is the need to maintain assets in a serviceable condition.

In order to assist in the asset renewal programming process the software stores the proposed replacement date the asset owner chooses. Where the replacement date is not provided by the user, the software's predictive modelling will estimate the replacement date based on the remaining useful life for the asset. This value is obtained from the weighted average useful life of the asset components. Table 1 provides an example report from the software to demonstrate the process. The table shows how a bridge has a range of components with varying useful lives. Short lived items often are of low value and may be maintained compared to components with longer lives that tend to be more expensive and difficult to maintain. When the long life items begin to fail the useful life is typically reached. The exception is when the useful life is limited by other service level factors. In this instance the asset owner may desire to replace the asset sooner, in which case they would not utilise the software automatically calculated useful life.

Table 1. Useful life.

The software is capable of predicting 100 years forward, well exceeding most asset owner's re-

quirements, as asset management planning's are normally for a 10 to 20 year period. The software is clever in that it utilises both work order and condition information.

11 REPORTING

The software includes a range of tailored reports to address specific asset management needs. Should users find that software's tailored reports don't meet their needs user defined reporting is also provided. User defined reporting gives access to all database fields and the option to modify how data is presented. Queries/reports can be saved and shared with other users/or run later allowing for changes in asset data to be tracked.

The user defined reporting makes visible the SQL queries run so that those accustomed to SQL can automate the sharing of software's data with other databases and software. Tailored reports typically include the option for the insertion of attachments into Microsoft word documents and/or spreadsheets. In the case of spreadsheets attachments are conveniently extracted and labelled by the software utilising descriptors such as asset number, date etc. and then hyperlinked back to the spreadsheet.

Tailored reports include:

- Asset reports
- Inspection program reports
- Inspection detail reports
- Defect summary reports
- Works reports
- Financial summary reports
- Depreciation reports
- Risk reports
- Predictive modelling reports (both at the asset level and network level).

12 CONCLUSION

Modern bridge asset management systems are required to enable asset owners to manage large asset basis with limited funds and staff. A system has been developed over the last 15 years which allows asset owners to apply engineering and scientific judgement to predict future outcomes and manage the associate risks with bridge assets.

Risk assessment for bridge management systems

P.D. Thompson
Consultant

ABSTRACT: A National Cooperative Highway Research Program (NCHRP) project was commissioned to develop a Guideline for Risk Assessment for Bridge Management Systems (BMS), to be used within a BMS to estimate the beneficial effects of bridge risk mitigation and replacement on transportation performance, as a part of BMS methods for project utility and benefit/cost analysis. The Guideline describes methods for developing service disruption scenarios, and then estimating the likelihood and consequences of these scenarios. Likelihood probability models are provided for 16 hazards including earthquake, landslide, storm surge, high wind, flood, scour, wildfire, temperature extremes, permafrost instability, overload, over-height collision, truck collision, vessel collision, sabotage, advanced deterioration, and fatigue. These models are based on published research gathered from a wide variety of sources, and consistent with the AASHTO Guide for User and Non-User Benefit Analysis for Highways (the "Red Book").

1 INRODUCTION

Transportation Asset Management uses data and analysis to improve decision making, with the goal of providing the desired level of service in the most cost-effective manner. A Bridge Management System (BMS) contains features to apply bridge inventory and condition data to assess the costs and benefits of preservation, risk mitigation, and replacement activities, to support management decision making processes such as project definition, priority setting, resource allocation, and programming.

BMS have long had functionality to estimate the effects of agency actions on the long-term cost of maintaining the desired level of service. Recent BMS innovations have opened the door to multi-objective assessment of additional stakeholder concerns including safety, mobility, and environmental sustainability (Patidar et al 2007). Bridges affect these concerns by means of their functional characteristics, and by means of the risk that natural or man-made hazards might disrupt transportation service.

National Cooperative Highway Research Program (NCHRP) Project 20-07, Task 378 was commissioned by the American Association of State Highway and Transportation Officials (AASHTO) Subcommittee on Bridges and Structures to develop a Guideline for Risk Assessment for Bridge Management Systems, to be used within a BMS to estimate the beneficial effects of bridge risk mitigation and replacement on transportation performance, as a part of BMS methods for project utility and benefit/cost analysis. AASHTOWare Bridge Management was explicitly targeted, but the methodology is intended to be usable with any BMS using the data typically collected by, or available to, US highway agencies.

The final Guideline describes methods for developing service disruption scenarios, and then estimating the likelihood and consequences of these scenarios. Likelihood probability models are provided for 16 hazards including earthquake, landslide, storm surge, high wind, flood, scour, wildfire, temperature extremes, permafrost instability, overload, over-height collision, truck collision, vessel collision, sabotage, advanced deterioration, and fatigue. Consequences of service disruption are estimated in dollars for recovery cost, safety, mobility, and environmental sustainability. All of these models are based on published research gathered from a wide variety of sources, and consistent with the AASHTO Guide for User and Non-User Benefit Analysis for Highways (the "Red Book"). The economic basis for risk assessment is designed to be compatible with existing use of life cycle cost analysis in BMS, as well as with the

utility framework provided in AASHTOWare Bridge Management.

1.1 *Risk in bridge management systems*

Bridge management systems (BMS) typically provide functions to capture inventory and inspection data for each bridge, and then provide a set of mathematical models to analyze each bridge to forecast future conditions, performance, and costs (Figure 1). As a part of this functionality, BMS apply a set of decision rules to generate one or more alternative projects intended to relieve performance deficiencies and/or to reduce future costs. The software forecasts future performance and costs conditional on a project alternative and implementation year. A do-nothing scenario is also analyzed using similar models. By comparing each project alternative with the do-nothing alternative, a project benefit is estimated.

Typically a BMS will generate far more project candidates with positive benefits than can be funded under anticipated resource constraints. It then becomes necessary to prioritize. Practically all modern BMS use a benefit/cost ratio as the priority-setting criterion. Given a list of selected projects in a fiscally-constrained program, the BMS estimates future network condition and performance outcomes. Such estimates can be used for evaluating and comparing program alternatives, and for establishing performance targets and resource allocations.

Most fully-developed bridge management systems compute project benefits using a life cycle cost analysis, as depicted in Figure 1. In some cases, this life cycle cost analysis can include the user costs associated with functional deficiencies. Risk assessment that is fully integrated with this BMS analysis framework adds a second model to accompany the life cycle cost analysis in computing project benefits. The risk assessment uses information about the project and the effects of the project on future bridge characteristics, to compute a portion of the project benefit.

1.2 *Performance concerns and measures*

Transportation agencies typically list their major goals and objectives in their enabling legislation, mission statements, strategic plans, or other broad policy documents that communicate with stakeholders and the public. For transportation asset management in general, a set of national goals have been defined by the US Congress in 23 USC 150(b):

- Safety
- Infrastructure condition
- Congestion reduction
- System reliability
- Freight movement and economic vitality
- Environmental sustainability
- Reduced project delivery delays

Congestion reduction, system reliability, and freight movement are often considered together as "mobility." Elsewhere in the legislation, agencies are also called upon to minimize long-term costs and manage risks. Each state DOT typically has a similar list of goals. In bridge management decision making, the most relevant concerns are cost, safety, mobility, and environmental sustainability, with condition and risk potentially influencing all of the other goals.

When conditions of individual bridges are compared with each other, or when one bridge is tracked over time, it is common practice to use a bridge health index (Shepard and Johnson 2001). To characterize risk on a comparable basis, it is possible to use a concept of resilience or vulnerability (NYSDOT 2013). Network conditions or resilience can be characterized as the percent good or percent poor, perhaps weighted by deck area.

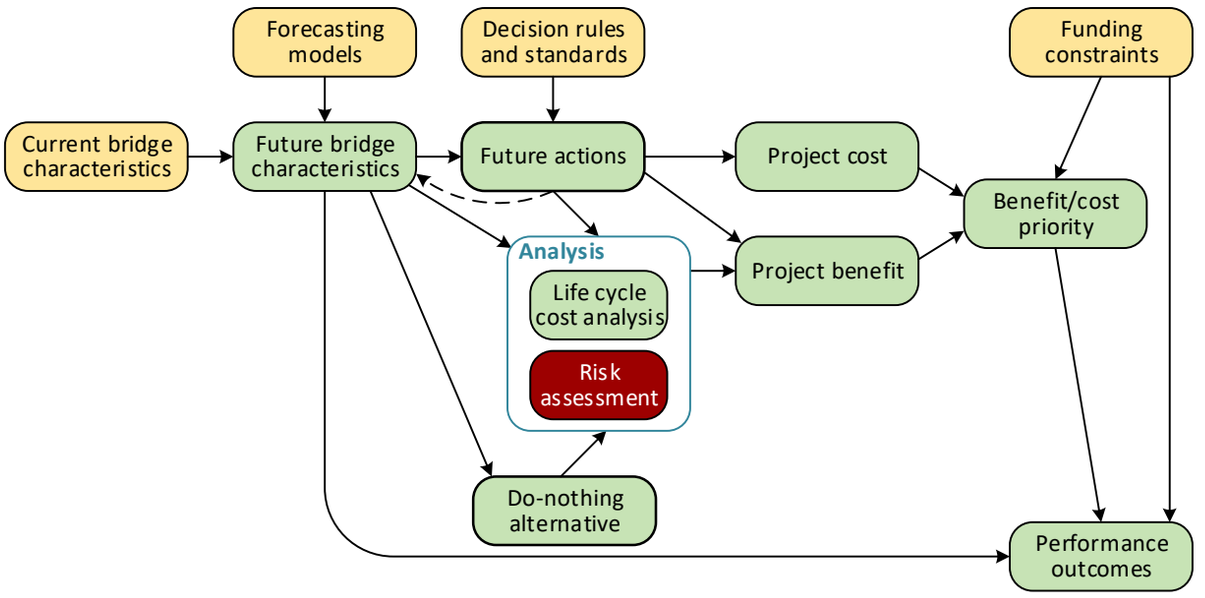

Figure 1. Role of risk in a bridge management system framework.

For benefit/cost priority-setting, it is necessary to describe performance of the network as affected by a given bridge. Cost varies from one bridge to another based on size and potentially other factors. Risk mitigation benefits also vary from bridge to bridge because of traffic volume, detour length, and potentially other factors. NCHRP Report 590 explores ways of combining safety, mobility, and other project benefits, taking traffic and detour length into account, to estimate project benefits as a type of utility function (1). As an alternative, it is possible to estimate project benefits in the form of user costs, as is done in Florida DOT's analytical process (Sobanjo and Thompson 2013). This latter approach simplifies the means of combining risk benefits with life cycle cost reduction. The Guideline described in this paper supports both methods.

2 OVERALL FRAMEWORK

The Guideline presents the risk assessment procedure as a series of worksheets. While the worksheets could in principle be filled out by hand, most agencies will want to implement them either by entering corresponding data in a bridge management system, or by creating a spreadsheet or other software to run the calculations. The worksheet format is intended to make the structure and data requirements as transparent as possible.

Each agency will want to choose which hazards and performance criteria to address, and customize the procedures to fit their own needs and resources. The modular worksheet structure is designed to allow agencies to "mix and match," to plug in the modules which best fit their needs (Figure 2).

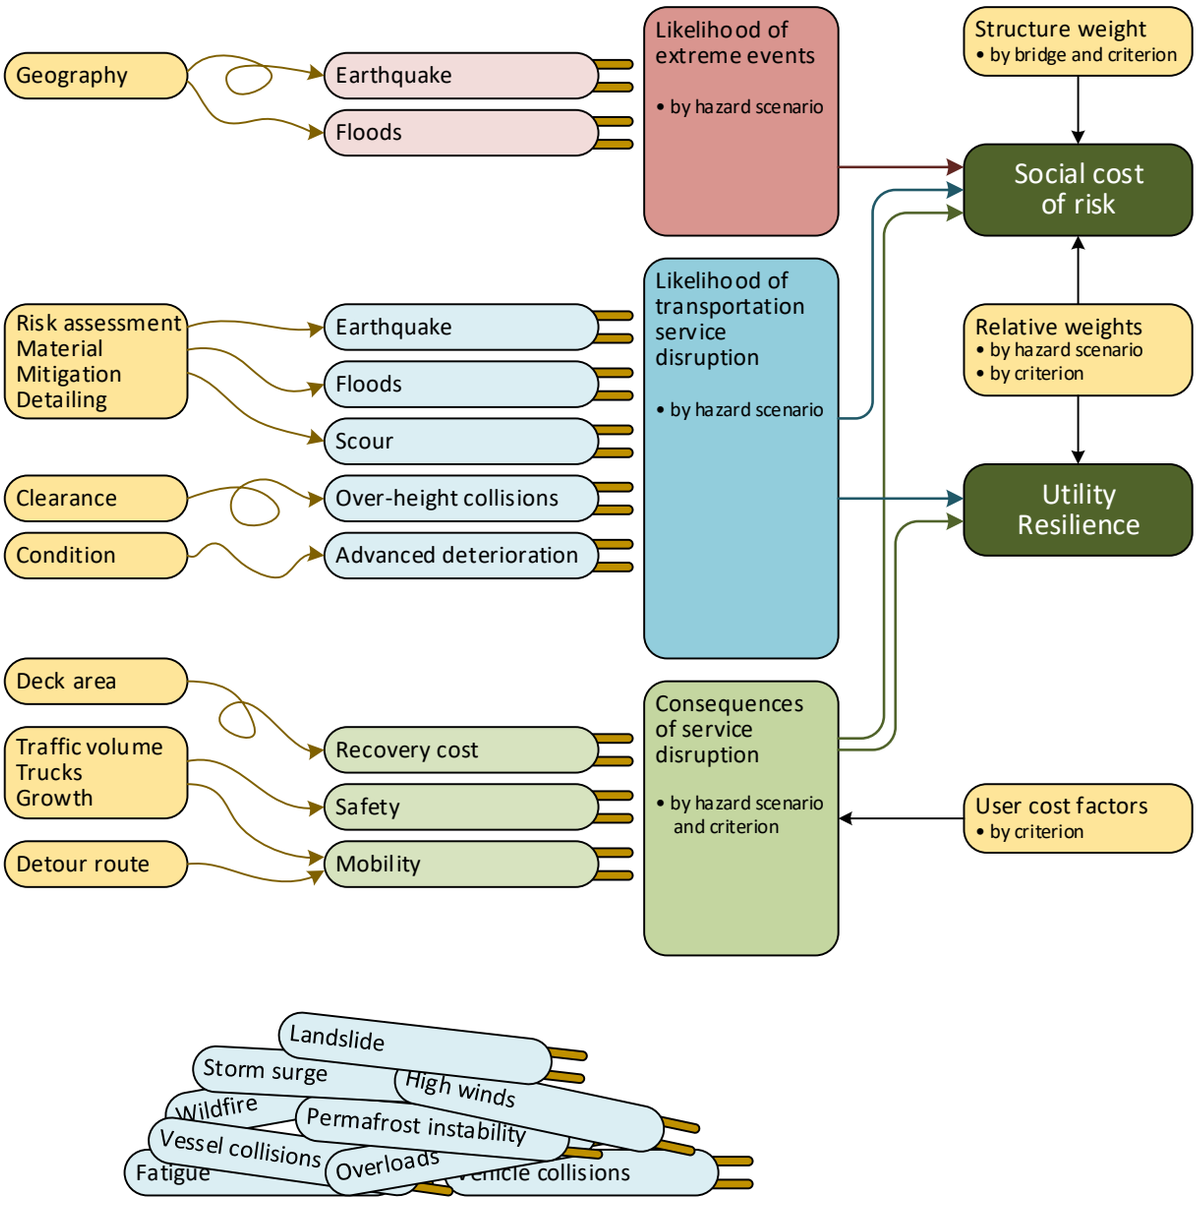

Figure 2. Plug-in architecture of the risk analysis.

Depending on the hazards to be addressed, the agency will choose among plug-in modules for the likelihood of extreme events, the likelihood of service disruption, and the consequences of service disruption. The agency defines a set of hazard scenarios and applies the modular analysis to compute social cost and/or utility for use in the priority-setting and resource allocation functions of the BMS.

2.1 *Hazard scenarios and performance criteria*

The disutility of an adverse event depends on the nature and magnitude of the hazard, and on the effect on each performance concern. In order to reflect these influences in a reasonable way, the following concepts are defined:

- Hazard scenarios, denoted in the equations using the subscript *h*, entail extreme events of a specific magnitude (if applicable), or the cumulative effect of an ongoing adverse process, causing a defined impact on transportation service. For example, a hurricane of at least magnitude 4 that destroys a bridge.
- Performance criteria, denoted using the subscript *c*, represent agency objectives that may be compromised by a hazard scenario. Examples are cost, safety, mobility, and environmental sustainability.

Each agency will select the hazard scenarios and performance criteria to be analyzed consistently across all bridges. An important decision is the level of disruption that should be incorporated into the threshold for recognition of a hazard scenario. Some of the options are:

- The structure is damaged to at least a defined damage level, typically corresponding to the agency's distinction between routine work orders for repair, and programmed capital projects for mitigation, rehabilitation or replacement.
- Near-term or long-term costs are increased.
- Transportation service is disrupted, causing a loss of performance in terms of safety or mobility.
- Environmental resources or the property of others are damaged.

Any or all of the above could have a role in defining the criteria for a hazard scenario. For an understandable and consistent analysis, however, it is important to be consistent in definitions across all hazard types. The Guideline is flexible in allowing agencies to adopt any reasonable set of criteria. However, the service disruption criterion is recommended for primary emphasis, for the following reasons:

- Most of the states having existing risk management capabilities as part of bridge management use this as their criterion.
- For most hazard classes, events that cause service disruption also cause structure damage.
- Service disruption events are typically regarded as more severe than damage-only events, and are more likely to be captured in historical records.
- Damage that is significant enough to disrupt service is typically more expensive to repair and more urgent than damage that does not disrupt service.
- Events belonging to some of the hazard types are not typically recognized as risk consequences unless they disrupt service. Examples are extreme temperature, settlement, advanced deterioration, and fatigue.

In considering which hazards to include in the BMS risk analysis, the following questions should be considered:

- Within the agency's jurisdiction, does the hazard occasionally cause service disruptions or otherwise meet the criteria for a hazard scenario? "Occasionally" should be interpreted in a consistent way, such as at least once every 100 years for a given bridge.
- Do the likelihood or consequences of the hazard scenario differ from one structure to another or one part of the jurisdiction to another? This likelihood could apply to extreme events, to structure damage, or to service disruption. Consequences could apply to any agency objective such as cost, safety, mobility, or environmental sustainability.
- Does the hazard apply to a significant number of bridges? If only a handful of bridges can experience the hazard, then it might be more appropriate to perform site-specific analyses rather than including a model within the BMS.
- Does the agency have treatments available to mitigate the hazard that would be programmed using the BMS? Bridge replacement is a relevant treatment, but in that case the question is, does the magnitude of the hazard make a difference in the choice of replacement or in the priority of replacement?
- Is the hazard significant enough in decision making to justify the additional data collection, particularly field assessment that may be required in order to consider the hazard within the BMS?

The level of detail represented in hazard scenarios can vary based on agency preference. It is likely that most agencies will want to keep the model simple by defining only a small number of scenarios to represent the broader range of possible adverse events. Increasing the number of scenarios increases the development and computational effort, but gives a more precise estimate of outcomes and risk.

If a hazard scenario includes the occurrence of an extreme event, it is desirable to use the event magnitude for which agency's structures are typically designed. For example, if bridges are typically designed to withstand a 100-year flood, then the 100-year flood is the extreme event magnitude to use, and the extreme event probability is one percent.

2.2 *Project Summary Worksheet*

Figure 3 shows the Project Summary Worksheet, presenting intermediate and final results of the risk calculations for a single bridge and project as developed in the Guideline. Input data requirements are provided in the upper two blocks of cells.

The lower two blocks of cells are calculation results. Green cells are results, in thousands of dollars, gathered from worksheets provided for each type of consequences. Red cells are extreme event probabilities gathered from worksheets for each type of hazard scenario. Blue cells are service disruption probabilities gathered from worksheets for each type of hazard scenario. Gray cells are configuration parameters set on a separate worksheet. White cells in the lower two blocks are calculated on the worksheet itself.

2.2.1 *Likelihood of service disruption*

The likelihood of service disruption in this framework varies by bridge, based on bridge characteristics, and also varies by hazard scenario. It has two parts:

LE_{bh} = likelihood of occurrence of the extreme event of given magnitude that is specified by hazard scenario h, estimated for bridge b.

LD_{bh} = likelihood of a specific magnitude of service disruption, conditional on the occurrence of the extreme event specified in hazard scenario h, estimated for bridge b.

The total likelihood of hazard scenario h on bridge b is $LE_{bh} \times LD_{bh}$. The two likelihood estimates are separated because different data sources and methods are used to calculate them, as described below. These likelihoods are the probability of the indicated event occurring in any one year. Agencies using AASHTOWare Bridge Management may want to use the Assessments feature of that system as a basis for estimating one or both of the likelihoods. Other bridge management systems may also have features to allow inspectors to record risk assessments made in the field.

NCHRP 20-07 (378) Risk Analysis

Sheet B - Project summary

Bridge ID	**010001**			
Alternative	**Do nothing**	Deck area (sq.ft)	20,000	
Program year	**2017**	Program cost ($000)	12,345	

Roadways	On structure				Under structure			
Func class	11 - Urban interstate				14 - Urban other principal arterial			
Utilization	ADT	54,000	Trucks	5.50%	ADT	21,000	Trucks	3.00%
Roadway	Length (ft)	200	MPH	55	Length (ft)	100	MPH	45
Detour	Miles	2.1	MPH	45	Miles	1.0	MPH	45

From BMS data. If multiple roadways, use the total ADT and most significant roadway, projected to program year.
Length on-structure is bridge length. Length under-structure is bridge width..

Hazard scenarios		Consequences ($000)				Likelihood			Risk
ID	Scenario	Cost	Safety	Mobility	Environment	Extreme	Disruption	Weight	Cost ($k)
1	Earthquake-100	12,345	50	6,000	600	1.00%	5.00%	1.00	9.50
2	Flood 100a	12,345	50	6,000	600	1.00%	10.00%	1.00	19.00
3	Flood 100b	100	0	2,000	200	1.00%	20.00%	1.00	4.60
4	Flood 500	12,345	50	6,000	600	0.20%	50.00%	1.00	19.00
5	Overheight	100	70	200	40	--	5.00%	1.00	20.50
6	Deterioration	50	0	200	40	--	10.00%	1.00	29.00
7	Fracture	12,345	0	6,000	600	--	0.50%	1.00	94.73
8								1.00	0.00
9								1.00	0.00
10								1.00	0.00

Risk cost and vulnerability	Cost	Safety	Mobility	Environment
Struc weight	20,000	75,000	134,400	134,400
Criteria weight	1.00	1.00	1.00	1.00
Risk cost ($k)	102.79	3.63	79.00	10.90
Vulnerability	5.1394	0.0483	0.5878	0.0811

Risk analysis results	
Maximum unit risk cost:	100.00
Vulnerability index:	0.0586
Utility:	**94.14**
Social cost of risk ($000):	**196.31**

Figure 3. Project Summary Worksheet.

2.2.2 *Consequences of service disruption*
Consequences are defined as an economic quantity, that varies by bridge, based on bridge and network characteristics. It also varies by hazard scenario and performance criterion.

CQ_{bhc} = consequence, estimated in dollars per disruption event, to performance criterion c on bridge b, conditional on the occurrence of the service disruption specified in hazard scenario h.

Consequences include the agency costs of disaster recovery as well as an economic value assigned to safety, mobility, and environmental impacts. The dollar value of recovery cost is typically estimated using economic models and normal agency cost estimation practices, or by classifying potential losses in ranges using judgment. Methods for other types of consequences are described below.

2.3 *Performance measures*

The basic ingredients described in the preceding section are used to compute performance measures for decision support purposes. The following performance measures are needed:

RC_b = Social cost of risk for bridge b. This variable should be structured and scaled so a savings in cost can be used in the benefit of a benefit/cost ratio for priority-setting, and so the BMS resource allocation and optimization models can minimize it network-wide. It may increase over time due to deterioration, traffic growth, or increased hazard likelihood; and it may decrease if an agency action improves bridge characteristics such that life cycle costs, risks, or road user inconvenience are reduced. Its values can range from 0 to positive infinity.

U_b = Utility for bridge b. This variable should be structured and scaled so it can be understood as the degree of resilience of an individual bridge. It provides a uniform unitless scale for comparing the status of one bridge with other bridges, or for tracking performance of a bridge over time. Its values can range from 0 to 100, where 0 is the worst possible performance and 100 is the best possible performance.

2.3.1 *Social cost*
In the recommended methodology, social cost of risk is the weighted sum of the social costs of all hazard scenarios and all performance criteria:

$$RC_b = \sum_h \sum_c RC_{bhc} \quad (1)$$

RC_{bhc} = statistical expected value of weighted social cost, in dollars per year, of hazard scenario h on bridge b for criterion c.

$$RC_{bhc} = W_c \times W_h \times LE_{bh} \times LD_{bh} \times CQ_{bhc} \quad (2)$$

The variable W_c is a weight given to each performance criterion in the cost equation. It should be 1.0 by default, but can be more or less than 1.0 to increase or decrease the contribution of a criterion in the calculation. For example, if W_c=1.2 for c=safety, then safety is given 20% additional cost in the risk calculation. Similarly, W_h is a weight given to each hazard scenario. For example, if W_h=1.1 for h=earthquakes, then earthquakes are given 10% additional cost, perhaps to reflect the difficulty of incident response and the importance of supporting evacuation plans. The other variables in this equation are computed from bridge and network characteristics as introduced above.

2.3.2 *Utility*
Utility is a concept related to social cost, but is designed to be used when making a direct comparison between bridges (disregarding their relative size), or when tracking performance over time. It is equivalent to resilience. The scale is intentionally designed so each bridge can potentially score a perfect 100 or a worst-case 0 depending on its ability to resist hazards. By definition, agency actions should be able to improve this resilience to nearly 100 on any bridge, given sufficient resources.

Depending on the structure of the bridge management system, there may or may not be a mathematical relationship between utility and social cost. AASHTOWare Bridge Management, for example, is designed to compute utility first, at the work candidate level, and then convert this to social cost at the program level for computation of the benefit/cost ratio. Other systems may compute utility from social cost, or treat the two concepts as equivalent, or compute the two measures independently. Utility is meant primarily as a communication tool, while social cost is more rigorously defined for priority-setting and resource allocation.

To compute utility, it is common to first compute vulnerability as the product of likelihood and consequence of each separate adverse scenario for each separate performance criterion. Then the results are additive, and utility is:

$$U_b = (1 - V_b) \times 100 \quad (3)$$

The quantity V_b can be called the vulnerability index, on a scale where 1.0 is maximum vulnerability and 0 is no vulnerability. One way to compute vulnerability is:

$$V_b = \frac{URC_b}{MaxURC} \tag{4}$$

where

$$URC_b = \sum_h \sum_c \frac{RC_{bhc}}{SW_{bc}} \tag{5}$$

The value URC_b can be called the unit risk cost. It is the same risk cost as in equation 2 except that it is normalized to remove the effects of consequence scale. *MaxURC* is determined by computing URC_b for every bridge (or a representative set of bridges) in the database and finding the maximum value, which then defines the worst end of the vulnerability scale for the agency. SW_{bc} is called the structure weight, and is computed in different ways for different performance criteria, as follows:

Cost	Deck area (sq.ft.)	
Safety	Average daily traffic (ADT)	(6)
Mobility	ADT × Detour length (miles)	
Environmental sustainability	ADT × Detour length (miles)	

After an agency first computes or estimates its *MaxURC*, this quantity is not likely to change very quickly over time. Therefore it might not be necessary for the agency to re-compute this constant unless it makes significant changes in its risk assessment process, such as by adding more hazards.

The advantage of having a linear relationship between vulnerability and social cost is the fact that social cost can be computed from vulnerability, which is a necessity for AASHTOWare Bridge Management and is desirable for keeping any BMS framework relatively simple.

3 SUBMODELS

The Guidelines provide recommended methods and alternatives for likelihood of extreme events, likelihood of service disruption, and consequences of service disruption. The study collected methods from existing literature and did not have resources to develop new methods. There are significant opportunities for future research to develop new and better methods for many of the hazards and criteria that can be assessed within this framework.

3.1 *Likelihood of extreme events*

Certain hazards, specifically earthquake, landslide, storm surge, high wind, flood, wildfire, extreme temperature, and truck collisions, are triggered by short-duration events which are unusual and unexpected at any given site, but which occur with regularity across the inventory. Some of these hazards, such as earthquakes, are so abrupt that they have unavoidable safety consequences. Others, such as floods, occur with some advance warning, allowing operational practices which may improve safety in exchange for a compromise in cost and/or mobility.

What all the extreme events have in common is that a portion of the likelihood of service disruption is unaffected by normal agency actions, but is related more to bridge location. This can be significant for decision making because, for example, an agency is powerless to prevent earthquakes, but can, with appropriate resource allocation, make programmatic decisions that increase the ability of bridges to resist earthquakes.

3.1.1 *Natural extreme events*

For a given agency, geographically-referenced data on extreme event likelihood is available from several sources. Ideally, such a data set has polygons representing zones where the event return period is estimated to be 100 years. This return period is most appropriate for bridge risk analysis since it is most likely to approximate or exceed the remaining service lifespans of most bridges. It is equivalent to a probability of one percent. Such data sets often have polygons for alternative return periods such as 20 years or 500 years, which can form the basis for defining additional hazard scenarios if this is applicable for decision making. Alternative return periods also can be used for interpolating extreme event probabilities for locations between polygon boundaries.

As an example, the U.S. Geological Survey (USGS) National Seismic Hazard Maps display earthquake ground motions for various probability levels across the United States. They represent a uniform probability (either 2% or 10%) that the ground acceleration will exceed the given value over 50 years. These can translate directly to an event likelihood for a corresponding hazard scenario. FEMA, NOAA, USFS, and various state agencies are potential sources of geographic hazard data.

3.1.2 *Man-made extreme events*

The Guideline also provides suggested methods for gathering incident data that might be used for human-caused extreme events such as overloads, over-height truck or tanker truck collisions, vessel collisions, and sabotage. In some cases existing data sources can be used to gain insight into the overall statewide probability of some of these hazards, which can form the basis for individual site estimates.

3.2 *Likelihood of service disruption*

For hazard classes that involve extreme events, the likelihood of service disruption is the probability that service is impacted, conditional on the occurrence of

the related extreme event scenario. While the extreme event probability depends mainly on location or other exogenous factors, the service disruption probability typically depends on structure characteristics. Certain hazards, such as advanced deterioration, are not associated with extreme events but have service disruption probabilities (e.g. restricted load ratings requiring posting) that depend only on structure characteristics. Models are provided for the following hazards:

Earthquake	Permafrost instability
Landslide	Overload
Storm surge	Over-height collision
High wind or tornado	Tanker truck collision
Flood	Vessel collision
Scour	Sabotage
Wildfire	Advanced deterioration
Temperature extremes	Fatigue

The Guideline presents worksheets and examples for several generic methods to approximate the disruption probability, that can be applied to most hazard classes even with minimal data availability. These include a judgment-based risk assessment; scoring tables; analogies to other known risks; polling of maintenance personnel; and allocation of statewide long-term incident experience.

These methods can be used separately or in combination, exploiting whatever data the agency can locate, to bracket reasonable risk estimates for each hazard class.

The Guideline also documents methods developed from past research studies that are specific to certain hazard classes, most notably for scour, overloads, over-height collisions, tanker truck collisions, terrorism, advanced deterioration, and fatigue. In some cases, such as scour, multiple alternative models can be found in the literature.

3.3 *Consequences of service disruption*

The likelihood models described above provide the typical probability or frequency, each year, that a service disruption event can be expected to take place. Consequence models then assign a dollar value to each disruption event. The monetization methods are already standardized in the AASHTO Red Book, which is widely used in life cycle cost, value engineering, and regulatory analyses (AASHTO 2010). The Red Book provides unit costs for accidents, travel time, and vehicle operations. The Guidelines provide worksheets and examples of research-based procedures to estimate the safety and mobility impacts, in terms of excess accidents, hours of delay, and miles of detour. These can then be converted to dollars using AASHTO Red Book parameters.

In addition to recovery cost, safety, and mobility, the Guideline also presents an environmental sustainability model based on estimates of vehicular emissions. It uses the approach from FHWA's Highway Economic Requirements System (FHWA 2005). This methodology, updated from earlier research in California, relies on a study that simulates vehicular air pollution emissions under various scenarios of congestion, speed, and volume. Six pollutants are included in the analysis: carbon monoxide, volatile organic compounds, oxides of nitrogen, sulfur oxides, small particulate matter, and road dust. To establish a dollar value and relative weights of the pollutants, the study uses earlier research on the economic impact on health and property damage caused by these pollutants.

4 CONCLUSIONS

The Guidelines document produced by NCHRP 20-07(378) will be of considerable help to agencies wishing to incorporate realistic risk assessment models into the decision support functions of bridge management systems. Based on a wide range of existing research studies, the models have been simplified as needed so they are compatible with the data and software commonly available to transportation agencies. When bridge management systems such as AASHTOWare Bridge Management are configured to use these models, no significant additional effort is required in order to consider risk routinely in combination with life cycle cost in decision making.

ABSTRACT: Many projects are in progress to enhance the current capabilities of Bridge Management Systems (BMSs). This paper investigates the BMS from its expectations relating to transparent policy, decision support and improved organizational work to its core components including inventory database, inspection and condition rating, deterioration models, cost and optimization models, and risk assessment. Major features and capabilities of different bridge management systems in the world are presented and the gaps in the current systems have been identified.

1 INTRODUCTION

1.1 *Background*

Bridge network is a complex system because it often contains thousands of bridge structures with different materials (e.g. concrete and steel), designs (e.g. girder and cable stayed) and sizes. Each bridge structure has a hierarchy of component types, component groups and components (e.g. component group can be substructure and components will be pile and abutment) and is subjected to various management activities (e.g. funding, inspection and load rating) that constantly require storage, analysis and communication of mass data.

To manage such complex bridge network, the bridge management systems (BMS) have evolved significantly from paper-based to computerized systems. It is common to define the BMS as a rational and systematic approach to organize and carry out all activities related to managing a network of bridges (Woodward et al., 2001, Akgul, 2013). The aim of BMS is to assist bridge asset managers and engineers to provide cost effective decisions for planning of maintenance and rehabilitation and replacement (MRR) and for identifying the future funding requirements. In this sense, the BMS is a complex and interactive system between objects (data and information), actions (decision making) and outcomes (performance measures).

The importance of the BMS was further recognized in 1993 when a US legislation outlined the compulsory requirements for a BMS model, which consists of 5 decision support components. The sixth component, risk model, is later added by the industry. The six components of the current BMS are:

i. Database (inventory, inspection data, maintenance data etc.)
ii. Condition rating model (field evaluation of bridge condition)
iii. Deterioration model (prediction of condition of bridge components)
iv. Cost model (identification of cost and benefit)
v. Optimization model (search of optimal MRR strategies)
vi. Risk model (risk ranking and risk assessment)

The US-initiated BMS models can be viewed as a basis for further developments leading to current BMS models used by bridge management agencies around the world.

1.2 *Aims and contributions*

The aims of this study are two folds. First, it reviews the goals and objectives that are expected from the BMS by all stakeholders of bridge networks. Second, it compares decision support components of the current BMS supplied by commercial-vendors, self-developed by bridge agencies or advanced by research projects.

The major contribution of this study is to identify the current gaps in BMS and to support bridge industry in improving asset management of bridge networks.

2 EXPECTATIONS FROM BMS

2.1 *Creating transparent management policy*

Thompson et al. (2012) described all stakeholders of bridge networks, which are grouped into outside stakeholders (e.g. public, specific user groups and regulators) and internal management team (e.g. asset managers, bridge engineers and maintenance technicians). The expectations from all stakeholders can be summarized as follows (Sobanjo and Thompson, 2011, Thompson et al., 2012):

1. Knowledge of current condition of bridge networks
2. Accounting and financial reports
3. Cost-benefit based funding options
4. Importance or risk ranking of individual bridges
5. Long-term cost-effective management plans

2.2 *Assisting improved decision making*

Condition state data provides quantitative data about the physical condition and performance of bridge elements. Element level data is an essential part of the BMS functions. Element level inspections can track the effectiveness of action over time by showing the various condition states and how they may change over time after the bridge element is either repaired, replaced, or left alone. Potential applications for short and long term asset management of bridge networks agencies includes (Thompson et al., 2012, Woodward et al., 2001):

6. Justifying the timing and scope of rehabilitation and replacement.
7. Justifying funding for preventive or early maintenance.
8. Planning adequate resources, parts and equipment to meet maintenance needs.
9. Reducing the overall frequency of rehabilitation and maintenance work zones.
10. Estimating life expectancy and the life-extension effects of preventive maintenance activities on constructed facilities such as pavements and bridges.
11. Comparing two or more alternative maintenance, repair, and rehabilitation alternatives on a facility, under differing assumptions and discount rates.
12. Determining the optimal preventive maintenance interval for constructed facilities.
13. Determining the optimal annual expenditure level on periodic maintenance activities.
14. Comparing design alternatives based on their relative lifecycle costs; for example, comparing a conventional material with a more expensive low-maintenance material.
15. Determining the price point where a low-maintenance material becomes cost-effective.
16. Proactively grouping future preservation work on multiple assets into projects based on the anticipated convergence of their end-of-life conditions.
17. Selecting design alternatives for the various assets on a corridor, such that preservation and replacement interventions likely can be synchronized and long-term traffic disruptions can be minimized.
18. Multi-objective prioritization of programmed projects, using life extension as one of the criteria.
19. Allocating funding.
20. Determining the effect on asset life and long-term costs for variations in near-term funding levels.
21. Establishing research priorities for improved life spans of bridge assets.

2.3 *Enhancing efficiency of agency/organization*

The BMS can be part of a journey towards improved performance in the bridge agency/organization by supporting and enhancing the operational flow and work efficiency as follows (Thompson et al., 2012):

22. Improving the consistency of accounting reports.
23. Improving management guidance and accountability.
24. Building credibility with oversight bodies and elected officials.
25. Increasing the level of cooperation vertically and horizontally among the units of the organization,
26. Increasing the shared understanding of agency objectives and constraints across the agency and with its customers and stakeholders,
27. Increasing the use of quantitative measures of performance,
28. Being more proactive in using agency decisions and actions to improve future performance,
29. Using performance measurement for accountability,
30. Gaining more effective support from decision support tools, and
31. Increasing the drive among all employees to improve the agency's performance.

3 COMPARISION OF CURRENT BMS

3.1 *Inventory Database*

The inventory database is aimed to store and allow exchange of data and information generated during service life of bridges (Akgul, 2013). The traditional 2-D relational tables with structured query language are currently popular among BMSs including self-developed RAS of VicRoads of Australia, research-translated PONTIS of US and commercial dTIMS of Canada. Recently, for building assets 3D visualization is enabled using building information model (BIM), which hasn't yet been used for bridges. BIM is a database model with virtual 3D objects of the structures and multiple-stakeholder collaboration platform (Pärn et al., 2017, Guillen et al., 2016). BIM not only significantly improves the visualization of hierarchy structures such as bridges but also allow seeing through the whole service life with additional time –based (4D) changes and cost-based (5D) activities by related stakeholders.

BIM is first applied to construction of buildings and infrastructures and some commercial providers include ZUUSE in Australia and ACONEX worldwide.

One obvious benefit of BIM is that the location of inspection defects can be quickly entered into the 3D images of bridges without going through the complex numbering code of the 2D Tables. However, the major challenge for BIM application to BMS is the cost-effective conversion of many existing structures and 2-D drawings into 3D BIM. Several solutions such as 3D laser scanning and image-based technique have been reported by researchers (Gimenez et al., 2015, Lu and Lee, 2017).

3.2 *Inspection practice*

The key task of the bridge management process is inspection and condition rating because it provides the basis for subsequent assessment and evaluation of a bridge. The inspection is the first line of safety, and can report when dangerously deficient conditions of structures are found (Hurt and Schrock, 2016).

Only US is found to have legislation requiring regular inspection of 2-year interval to be conducted for each bridge. In other countries, it is considered as the responsibility of the asset managers to conduct regular bridge inspection. The Road Management Act in 2004 in Victoria State of Australia dramatically changed the legal liability of public agencies for road design, operation and maintenance, and having in place a process for reducing reasonable risks. This removed the immunity previously, government officials had under the concept of nonfeasance (Geiger et al., 2005).

A brief summary of inspection practices among Australia, US and Europe is presented as follows.

3.2.1 *US*

There are 5 types of inspections such as routine inspection, damage inspection and so on. The AASHTO recommends using 4 condition states with percentage distribution approach for condition rating of bridge elements such as piles, bearing as compared to brand-new condition. The FHWA specifies 9 condition states with single-condition approach for condition rating of 3 bridge components, namely, deck, superstructure and substructures from inspection reports of their elements. In addition, 9 condition states are also used to appraise the 3 bridge components with regards to serviceability, i.e. under current traffic demand and requirements.

3.2.2 *Australia*

The inspection practice is to conduct 3 levels of inspection as compared to brand-new condition, in which level 1 is screening, level 2 is routine visual and level 3 is detail. Based on inspection reports, four condition states from 1-4 are used to rate condition of bridge elements such as piles, girders by using condition state percentage distribution approach. A detailed comparison of inspection practices between major road agencies in Australia can be found in the work by Sonnenberg (Sonnenberg, 2014).

3.2.3 *Europe*

A detailed investigation into inspection practices of bridges in Europe has been conducted under an international scanning program of best practice by the US FHWA (Hearn, 2005, Hurt and Schrock, 2016). The results show that 3 levels of inspections are often adopted by European countries. They are cursory or safety inspection (annually or quaterly), general or routine inspection (2-3 years) and principal or detail inspection (5-6 years).

The condition rating of bridge component often uses 4 rating scales; however, it is different with US and Australia in a way that the rating scale is associated with recommendation of repair urgency and assessment of damage effect of element on the whole bridge.

3.3 *Element condition rating*

As reviewed in the previous section on inspection practice, bridge elements are commonly rated using percentage distribution from defects found during inspection. For example, a reasonable rating for concrete deck would be [0% 15% 75% 10%] for 1 (good) to 4 (worst) condition states. An unexpected case would be [75% 15% 0% 10%] because there is a significant difference in conditions for the deck which are operated in exactly the same environment. However, bridge engineers could argue that the difference can be due to the location of defects which are subjected to direct and more loadings than other

locations. Another reason could be due to a construction defect that allows occurring of corrosion.

The element condition rating with percentage distribution makes it difficult to report, prioritized comparing and be utilized for deterioration models. Several methods have been used to convert percentage distribution into a single condition rating as far as defects are concerned and their impacts to the whole bridge are treated separately. The common method is called weighted average (Rashidi et al., 2016):

$$Single_Cond = \frac{\sum_{i=1}^{4} i * perc_i}{100} \quad (1)$$

where i is condition state from 1 to 4 (for example) and $perc_i$ is percentage in condition i.

Table 1 shows the outcome of conversion from 4-state percentage distribution into single condition rating from 1-4 as an example for several methods including the one proposed in this study. The conservative or worst first method produces single condition rating according to the worst condition found regardless the value of its percentage. The semi-conservative or worst percentage takes into account the percentage value of the worst condition. It does not rate at condition 4 because condition 4 is not fully developed. This method however, does not recognize the difference between two cases. This can be acceptable given that the analysis of inspection data of VicRoads reveal that such unexpected case occurs less than 5% of inspection data.

The remaining 2 methods produce single condition rating that can be misleading because both cases of example are rated below condition 3 while part of condition 4 is already present. The method developed by Sobanjo et al. (2011) actually produces condition index from 0 (failure) to 1 (good), which is then converted into 1-4 for ease of comparison in this study.

Table 1. List of methods converting condition state percentage distribution into single condition rating (1 to 4 as an example)

Methods	Reasonable case [0% 15% 75% 10%]	Unexpected case [75% 15% 0% 10%]
Weighted average	2.95	1.45
Sobanjo at al. (2011)	2.95	1.45
Conservative	4	4
Semi-conservative (proposed)	3.1	3.1

3.4 *Deterioration models*

"We had bags of data, but not much information." —Maintenance Concessionaire (Geiger et al., 2005) explains the typical situation of a bridge asset manager. A bridge deterioration model is a mathematical model that is calibrated with inspection data to provide current and future prediction of asset condition as well as their deterioration rate, which is crucial information for planning of maintenance and rehabilitation and renewal programs. One advantage of a good deterioration model is that when the rate of deterioration is predicted as slow, the interval of routine inspection and the service life can be extended resulting in significant savings.

The predictive accuracy of deterioration models is a challenging issue. Sweden BMS is one of a few that does not actually adopt deterioration models. Instead, the knowledge and experience are used to decide future inspection and maintenance (Safia et al., 2013, Fu and Devaraj, 2008). Many more BMSs use deterioration model as a core module for planning and optimization. The stochastic deterioration models have been recommended to replace the deterministic models to improve accuracy and to account for uncertainty of deterioration process (Cavalline et al., 2015, Sobanjo and Thompson, 2011, Fu and Devaraj, 2008). Figure 1 shows the poor fitness of deterministic models for modelling the decreasing percentage in condition 1 (good) over time when condition data have large variation or uncertainty.

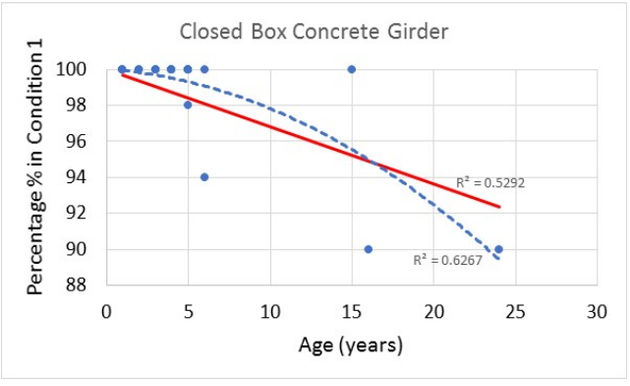

Figure 1. Fitting of deterministic models with condition data

Among stochastic models, the Markov chain model is commonly used for modelling deterioration of bridge. The major attractive feature of Markov is the memoryless property, meaning the future condition is dependent on the current condition, regardless of how it arrived at the current condition. This is suitable for long-life structures such as bridges. In the opposite, is usage-based structures such as pavements and machinery, where future condition depends on past conditions, i.e. how long they have been used.

The Markov model is the built-in deterioration model of PONTIS BMS, while others still use the deterministic models. In the latest version of PONTIS, the Weibull survival model is used to capture the time spent in condition 1 before moving into condition 2 because it is found that Markov model has higher rate of deterioration in condition 1. Figure 1 shows such a pattern of staying in condition 1 for 5 years before the deterioration process starts. From condition 2, the deterioration process is captured by the Markov model in PONTIS. To allow more user choices, the commercial dTIMS BMS allows to input user-defined deterioration models as deterministic or stochastic models.

3.5 *Cost models*

Cost models are an important component in the BMS because they affect short and long-term management decision through cost-benefit analysis. Various cost models have been developed in the literature such as MRR cost, life-cycle cost, user cost and MRR cost. The MRR cost can be easily calculated from the inventory database, which often includes the operating cost of bridge, monitoring cost, repair cost and rehabilitation cost.

The lifecycle cost (LCC) model is commonly available in the commercial BMS. The LCC model includes not only the MRR cost but also the failure cost (Vacheyrouxa and Corotis, 2013), which relates to user cost. The repair and rehabilitation cost in the LCC model can take into account the costs incurred from deterioration, accidents and hazards (Vacheyrouxa and Corotis, 2013).

The user cost model describes the user cost as a cost incurred by the users as a result of bridge deficiencies related to load postings, inadequate, deck width, poor alignment, and limited vertical clearance and accidents. The user cost models are adopted in the PONTIS BMS, which is the well-known model developed by Chen and Johnston and is currently adopted in the BMS of North Carolina State (US) (Cavalline et al., 2015). The user cost can be broken down into 3 main components: travel time cost, vehicle operating cost and accident risk cost. The user cost can also be calculated for the case of detour and no detours (Sobanjo and Thompson, 2011).

3.6 *Optimization models*

The current optimization models in BMS of bridges agency focus on single objective optimization to search for the optimal MRR actions and management strategies over a planning horizon. The common optimization tasks include:

- Minimization of the expected cost of MRR actions over planning time by using probabilistic prediction (Hong et al., 2013)
- Search for repair or replace option to a specific bridge structural component given different life-spans of repair and replacement by minimizing lifecycle cost (Safia et al., 2013).
- Minimize the rehabilitation cost in order to optimize the allocation of the available budget (Darbani and Hammad, 2007)

The approaches to maintenance optimisation implemented in the current bridge management systems are based on single objective optimisation, and more specifically on the minimisation of life cycle maintenance costs, which represents the present value of all the costs incurred throughout the life cycle of a bridge structure, including the costs of design, construction, maintenance, repair, rehabilitation, replacement, demolition and, in some instances, the user costs.

In considering sustainable management of highway bridges, the single-objective approach becomes inadequate and other objective functions should be considered, such as structural reliability and user cost (Shim et al., 2017). Several researches are undertaken in these areas aiming to add other optimization criteria. This can be replaced by a multi-objective optimisation problem as the bridge owner or manager seeks to satisfy implicitly and simultaneously several objectives, such as the minimisation of life cycle costs to owners and users, improvement of public safety, security and serviceability, improvement of bridge functionality, minimisation of environmental impacts and maximisation of economic benefits (Lounis and Daigle, 2013).

3.7 *Risk models*

The general perception of risk is assessing both probability and severity of a loss to a system. Risk is often quantified as a product of likelihood of failure and consequence of failure. Risk is often estimated for bridge element and risk of the whole bridge is often obtained through system reliability analysis in which the serial system (failure of any element becomes system failure) is commonly adopted for simplicity.

Likelihood of failure can be based on condition-based deterioration models, physical-based structural reliability models and fragility curves of bridge elements. The deterioration models are described in the previous section.

The physical-based structural reliability models are often based on deterioration mechanisms such as corrosion and cracking for reliability estimation (Vu and Stewart, 2000, Yogalakshmi et al., 2017, Stewart and Val, 2003, Stewart, 2010).

The fragility curves are defined as cumulative probability function of exceeding limit state condi-

tional on the human-induced (e.g. accident collision and fire) and/or nature-induced (e.g. earthquake, flooding, scour) hazards and attributes of bridges (e.g. length, width) (Gidaris et al., 2017).
The consequence of failure can be based on cost models described above.

Risk assessment is aimed to identify all possible hazards and threats to the system and is then used in risk management, which is to reduce the likelihood of failure and to mitigate the consequence of failure.

In several commercial BMS, risk ranking based on prediction of deterioration models is often used for prioritized planning of maintenance. In the PONTIS BMS, risk ranking model is implemented by the Bridge Health Index (BHI) developed by California State, which is a single number bridge index that measures the health condition of a bridge. This scale index is based on percentages that range from 0 to 100 percent. The basic principle of BHI is driven by the condition and the weight of each component of the bridge. Furthermore, in PONTIS, risk assessment model is also available for various hazards such as fire, flooding, scouting and earthquake.

Risk management can be implemented through inspection and maintenance. For example, Reising (2014) developed a risk-based inspection procedure for determining the inspection interval as follows:

i. Selecting a bridge for analysis,
ii. Determining the damage modes for the bridge components based upon engineering experience, design characteristics, material characteristics, and environment using the information obtained from the Risk Assessment Panel. The result is known as the occurrence factor.
iii. Evaluating the consequence factor concurrently, but independently
iv. Combining the occurrence factor and consequence factor in a risk matrix, the inspection interval can be determined. The longest inspection intervals occur when both the occurrence factor and consequence factor are low. Bridges with high occurrence and high consequence factors are inspected the most often.

This rational approach focuses inspection efforts on bridges where safety or serviceability are likely to be disrupted by targeting the scope of the inspection on the most likely and high consequence damage modes. Following the inspection, bridges that exhibit deteriorating conditions are reassessed to determine a new occurrence factor and a new inspection interval. Once established, consequence factor typically remains constant throughout the life of the bridge because the worst-case scenario remains constant. The developed procedure was applied to the Indiana bridge network in US.

Al-Wazeer (2007) developed a risk-based bridge maintenance methodology to find optimal maintenance strategies for individual bridge elements and for individual bridges in the network that can best utilize limited resources allocated for maintenance. The methodology can be summarized in the following steps:

a. Defining the system for risk analysis and management,
b. Modeling the element-level data needed for developing the methodology,
c. Evaluating the probabilities of failure in the condition states of the elements,
d. Estimating the failure consequences for the elements,
e. Estimating the risk associated with the condition states of the elements based on the probabilities and consequences of failure,
f. Determining the optimal maintenance actions in the condition states based on the maintenance cost and risk associated with the elements,
g. Identifying the element maintenance scenarios of implementing and/or delaying the optimal maintenance actions within the planning horizon,
h. Evaluating the cost and risk associated with the element maintenance scenarios,
i. Filtering the maintenance scenarios based on budget constraints and target risk,
j. Ranking the element maintenance scenarios based on their effectiveness of risk reduction,
k. Selecting the optimal maintenance scenario for each bridge element,
l. Selecting the best maintenance strategy for a bridge based on the available resources allocated for bridge maintenance, and
m. Prioritizing the bridges for maintenance.

4 DISCUSSION

This study investigated the BMSs and their components that are currently available or being developed. One important aspect of BMS that has not been mentioned in the previous sections, is the user-interface with mobile technology. It is observed that most commercial BMS allows web-based access, mobile-apps data input with touchscreen ability. This means end-users can communicate with BMS anywhere and anytime. The report from BMS is now supported by advanced data analytics tool such as Qlik sense that can link with GIS map and can produce real-time visual reports. The increasing trend of adopting BIM in BMS and the advancement of smart sensors poses a new challenge. Real-time integration of smart sensors for structural health monitoring will be future features in BMS

A gap observed in existing systems is the ability to link the structural capacity or load rating to the BMS. In the risk based methodology proposed by

Al-Wazeer (2014) opportunity exists for the capacity to be integrated in to decision making when calculating the probability of failure.

Another missing aspect is the ability to use material durability models to predict deterioration of components of bridges where a known mechanism (eg: chloride ingress in concrete) may initiate degradation.

A superior BMS could use the condition data driven deterioration models for bridge components as the base system with durability driven models superseding the data driven models where applicable. A risk based methodology can incorporate the structural capacity in to the decision making.

5 CONCLUSIONS

A number of comprehensive BMSs are being used by major road authorities in the developed world. Major features of these systems include inventory, deterioration prediction models, cost benefit or life cycle cost and optimised decision making. Superior systems may integrate risk and resilience under hazards in to decision making as well. Following gaps have been identified in current BMSs:

a. The use of 3D visualization BIM models
b. The multi-objective optimization
c. The integration of smart sensors
d. The relation between load rating with inspection data, structural health monitoring and current demands.
e. Use of mechanistic deterioration models for components vulnerable to known mechanisms of degradation to improve accuracy.

ABSTRACT: Bridge portfolio managers have a difficult task managing a large, varied portfolio of aging assets in a squeezed financial climate and on networks with increasing usage. Therefore, decision support tools are becoming more and more integral in managing portfolios of this scale. The model presented in this paper is designed to show a modern, data-driven approach to modelling which would sit as the base for the predictive module of a Bridge Management System (BMS). Extensive research has been carried out in this area however, it has usually resulted in bridge deterioration models; the approach taken in this research is to create a unified system model to encapsulate deterioration, inspection and maintenance to make a Whole Life-Cycle Costing (WLCC) model to offer new insight for bridge portfolio managers. The model in this research uses a Petri-Net (PN) approach which was decided upon as it is flexible enough to incorporate a complex deterioration module, calibrated with over a decade of historic inspection records, corporate policies regarding inspection and maintenance and even certain maintenance practices that are often overlooked. Using the model as a robust foundation, an investigation in the stressors which affect bridge deterioration is carried out. A low-cost, rapid approach to identifying which stressors are driving bridge deterioration is presented. The results indicate which stressors are a safety concern by accelerating the deterioration of bridge assets. Additionally, the results can be used in the PN model to create enhanced deterioration profiles. The resulting model is able to provide more accurate forward prediction capabilities of the assets condition over time, enhancing asset safety predicitons.

1 INTRODUCTION

Railway networks are often critical to the economy as they facilitate the movement of a both freight and commuters. This reliance creates an enormous amount of pressure on the railway and those who manage it. In the UK, a step change is due to occur with the roll-out of the European Train Control System (ETCS) which will introduce moving block signalling, allowing trains to run closer together for greater network throughput (Technical Strategy Leadership Group (TSLG) 2012). Although this development will improve passenger experience, it increases the pressure on the backbone infrastructure. This research focuses on bridge management using the example of the UK railway network, which is owned and managed by Network Rail (NR), however the techniques and results presented would be of interest to any organisation managing similar assets. With increasing asset usage, there is reduced opportunity for asset possession which means analytics and decision support tools are becoming increasingly more important. An investigation into the key stressors which cause deterioration is presented, along with their financial and operational effects, which allows bridge managers to more efficiently allocate resources to avoid assets falling below the safety critical threshold.

2 STOCHASTIC BRIDGE MODELS

A number of studies have been carried out to understand the deterioration behaviour of bridges. Stochastic models seem to be the preferred choice for modelling structural deterioration as they mimic the "micro-response" observed with structural deterioration (Morcous, Lounis, & Cho 2010, Ditlevsen 1984), as well as the deterioration behaviour being naturally stochastic (Frangopol, Kallen, & van Noortwijk 2004).

The most popular technique for stochastic modelling of structural deterioration is the Markov model (Frangopol, Kallen, & van Noortwijk 2004). Jiang & Sinha 1989 was one of the first studies to use this approach for bridge deterioration. The authors carried out a study in Indiana, USA, on a population of 5,700 bridges where 50 where chosen as random samples to calibrate the model with. The authors convert the condition of the assets to a scoring system used by the Federal Highway Administration (FHWA) which ranges from 0-9 with 0 being an element in poor condition and 9 being an element in a new condition. The authors discuss the methodology which they use to calibrate the Markov Transition Probability Matrices (TPMs) using the historic condition data of the bridges. The authors found that the deterioration rate varied over the lifetime of the asset. The approach used in this study was utilised by the AASHTO in the creation of PONTIS, which is one of the most successful BMSs (Sobanjo & Thompson 2011).

Scherer & Glagola 1994 studied a population of 13,000 bridges in Virginia, USA. The authors develop a 7-state Markov model to predict the condition of bridge assets. To increase the computational efficiency, the authors group similar assets based on the structure type, age, number of spans, climate and loading. This reduced the number of Markov model states from $7^{13,000}$ to 7^{216}. The paper is pioneering in grouping assets by operational and structural attributes. Although there is little justification as to why those attributes were chosen, it demonstrates that creating groups of assets with similar deterioration profiles is a successful approach.

Agrawal, Kawaguchi, & Chen 2010 also utilised a 7-state Markov model to study a population of 17,000 bridges in New York, USA. The authors use historic data of bridge elements to calculate the effect of stressors using probabilistic lifetime distributions. One of their main comparisons was between bridges built with standard structural steel and those built with weathering steel. The results of the comparison was that the rates of deterioration were similar for the first 20 years of the assets life, but beyond that the weathering steel demonstrated lower levels of deterioration than the standard steel. Investigating the stressors that affect bridge deterioration were key to this study, however the focus was mostly on the construction materials rather than external environmental stressors.

Huang, Mao, & Lee 2010 focused on the external stressors that affect bridge deterioration on a population of 2,128 reinforced concrete structures in Taiwan. Analysis was carried out on the structures deterioration behaviours to identify major and minor stressors by the types of defects that they cause. The authors identify traffic loading as a major stressor in the deterioration of the reinforcement bars and distance from the coast as a factor in causing spalling and fragmentation. Cracking seems to be one of the most prevalent types of defects as the results show that it is affected by 8 of the 10 stressors. The authors also identify that the peak monthly rainfall seems to be a major cause of concrete honeycombing. Finally, the distance from the coast is identified as a factor that affects structural deterioration, but was categorised as a minor stressor. However, the authors recognise that there were very few bridges in the population which would be classified as coastal.

Le & Andrews 2014 created a PN-based WLCC bridge model using a modularised sub-net approach. A sub-net was created to model the deterioration of each major bridge component, each sub-net was then calibrated with historic bridge data. The authors focused on metallic bridges with specialised sub-nets relating to the condition of the element coating and the condition of the underlying steel. The authors develop the model further to introduce Coloured Petri-Nets (CPNs) which enables a variety of features including the ability to perform state resets and enable tokens to hold tuple information about their respective bridge element. Monte Carlo (MC) simulation is performed using the model from which WLCC outputs are calculated. The paper demonstrated the flexibility of the PN approach and the suitability of CPNs to the application.

A number of studies have been evaluated which can be categorised into two main groups: 1) the studies which use historic bridge data to develop a bridge deterioration or WLCC model and 2) the studies which analyse historic bridge data to try to deduce the factors affecting bridge deterioration rates. The approach in this paper is to investigate the main external environmental factors affecting bridge deterioration and combine them into a WLCC model to understand the financial, operational and safety implications of the stressors over the lifetime of the asset.

3 CONDITION ASSESSMENT AND INDUSTRY POLICIES

3.1 *Condition Scores*

The industry guidelines on the examination of bridges (Network Rail 2012b) explain that bridge elements are inspected according to a matrix condition scoring system relating to the severity and extent of the defect, known as Severity Extent Rating (SevEx). The scores are alpha-numeric (e.g. B3) and range from

A-G where A is no visible defect to G which is permanent structural deterioration and from 1-6 where 1 is no extent to 6 where the defect extent is greater than 50% of the element surface area.

3.2 *Condition Assessment*

Condition assessments are used to schedule inspections as well as decide upon maintenance actions. SevEx is used to score each element during an inspection, but these are then converted to a numerical Structure Condition Marking Index (SCMI) afterwards. A good SevEx score would result in a high SCMI score e.g. an element in a new condition would be allocated an A1 SevEx score which would then be converted to an SCMI score of 100. The industry policies on future inspections and maintenance actions (Network Rail 2012a) describe SCMI thresholds which have been back-converted to SevEx scores for the purpose of this research to keep the method of condition assessment consistent.

3.3 *Maintenance and Inspection Policies*

The inspection frequency is dependant upon condition, an element in a good condition (A1 to D2) would only need to be inspected every 12 years, an element in moderate condition (B6 to F3) would need to be inspected every 6 years and an element in poor condition (D6 to G6) would need to be inspected every 3 years (Network Rail 2012a).

Maintenance follows a similar pattern, with an element in good condition (B2 to D2) only being eligible for a Minor Repair, an element in moderate condition (B5 to F3) being eligible for a Major Repair. Elements in a worse state are deemed to be below the Basic Safety Limit (BSL) and would need to be replaced, relating to SevEx condition states D6 to G6. It should be noted that the A1 condition state is the only condition state which is not eligible for any maintenance (Network Rail 2010).

4 DATA SOURCES

A number of different data sources were used for this work, all of which were provided by NR. These include the asset register, known as CARRS, the historic inspection data and the historic maintenance data, which is split between the Cost Analysis Framework (CAF) and MONITOR depending on the party that carried out the maintenance. In total the datasets cover 1998 to 2014 with inspection data for 25,949 bridges which breaks down into 273,427 major elements inspected and 1,397,748 inspections of minor elements.

Railway bridges are often comprised of either concrete, masonry or metallic elements. Concrete bridges are becoming increasingly common which means the management of them is becoming more important too. For this reason, concrete was chosen as the material type focused on in this research with the main girder elements chosen as the exemplar element. The dataset includes 4,434 concrete bridges, with 407,708 inspection of concrete main girders. Elements with a single inspection were discounted as at least two inspection are required to calculate a condition delta.

Figure 1: Basic PN components presented from left to right: 1) transition, 2) place, 3) marked place, 4) arc.

5 PETRI-NETS

Although Markov models have traditionally been the preferred technique for modelling bridge deterioration (Morcous 2006), they suffer from limitations including: difficulties in calibrating the TPMs (Frangopol, Kallen, & van Noortwijk 2004), difficulty considering maintenance actions in the model (Morcous, Rivard, & Hanna 2002b, Robelin & Madanat 2007) and state based explosion issues (Agrawal, Kawaguchi, & Chen 2010, British Standards Institution 2012). Although it is still understood that structural deterioration is a stochastic process and therefore, a stochastic model will best capture that behaviour, (Frangopol, Kallen, & van Noortwijk 2004), the model enhancements presented in this research benefit from the flexibility of the PNs approach.

PNs are directed bipartite graphs created from places and transitions. Tokens occupy places and indicate the system state e.g. a token in the place "Requires Maintenance" would indicate that the system is in a state requiring maintenance. Transitions move tokens between places and are calibrated with a firing criterion known as a guard. For example, a transition configured with a firing delay equal to the Mean Time to Repair (MTTR), could move a token from a "failed" place to a "working" place to model a system being repaired after a failure. Arcs are used to illustrate the dependencies between places and transitions. No two places or two transitions can be directly connected.

5.1 *Coloured Petri-Nets*

CPNs offer numerous features over simple PNs which are useful for modelling more complex systems (British Standards Institution 2004) including: 1) enabling tokens to contain tuple information e.g. asset age 2) allowing the use of reset arcs which help simplify the model and 3) allowing more complex transition guards including stochastic and programmatic guards (Jensen 1997).

Figure 2 shows a CPN where transition Ω is inhibited by the marked place β. If the transition were able

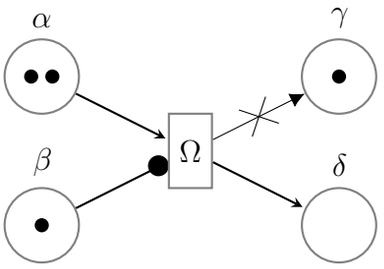

Figure 2: CPN example with both inhibitor arc and reset arc.

to fire, it would remove all tokens in place γ, this is represented by the arc with cross.

6 CPN WLCC MODEL

The CPN model which has been developed is at a Tier 3 level i.e. it focuses on asset and sub-asset level. The model follows the modular sub-net approach which is common with this type of modelling technique. The modules connect in a cyclic way, broadly describing the life-cycle of an asset: starting with the component condition module which contains the deterioration characteristics, through to the inspection module that triggers the maintenance module which, in turn, improves the condition of the bridge components in the deterioration module.

6.1 *Component Condition Module*

The component condition module, which can be seen in Figure 3, mimics the SevEx matrix described in Section 3. The decision to retain the 2-D condition matrix rather than convert to a linear scale, as is the de-facto standard (Cesare, Santamarina, Turkstra, & Vanmarcke 1992, Morcous 2006, Le & Andrews 2014, Network Rail 2010), was that: 1) structural defects have individualistic characteristics and converting defects to a linear scale would involve weightings which introduces subjectivity and 2) the source inspection data uses the SevEx framework so using this data directly avoids any transformations which enables a more accurate calibration of the deterioration profile.

In the module, transitions move tokens, representing bridge components, between the condition states. Lifetime distributions could not be reliably calculated as the inspection data was of insufficient frequency. Therefore, the transitions are calibrated with a constant failure rate where failure is defined as moving to a worse condition state. For example, in Figure 3, there are two tokens representing two different bridge components at different levels of deterioration. These components are considered individually and move through the condition states independently i.e. triggered at different times, along different routes.

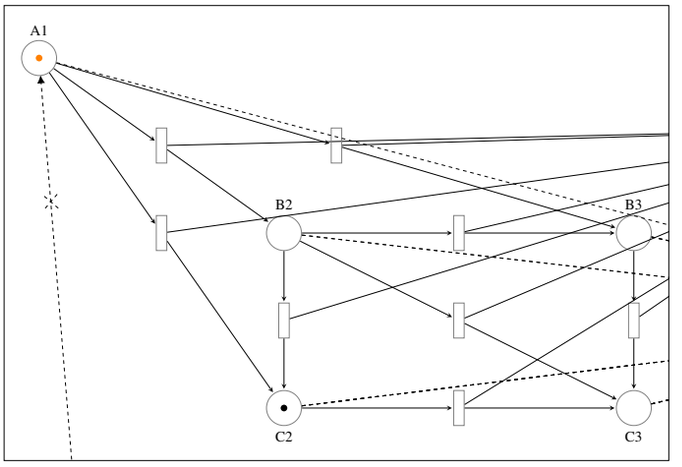

Figure 3: CPN component condition module. A reduced number of condition states are shown for illustrative purposes. The total number of states is 31 which cover SevEx conditions A1 to G6.

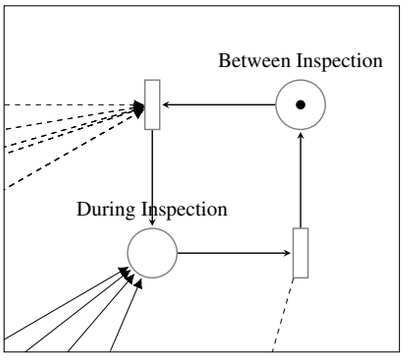

Figure 4: The condition assessment module.

6.2 *Condition Assessment Module*

The condition assessment module schedules inspections on the bridge components. The transition which initiates inspections is calibrated to fire in accordance with the industry guidelines for inspection (Network Rail 2012b). The industry policies describe how the condition relates to the frequency of inspection; the way this is represented in the model is with dashed arcs to the transition, which uses the marking of places to deduce the condition and then calculate the appropriate firing delay. The transition which fires to indicate the completion of an inspection is calibrated with the average length of time required for inspections according to industry experts. Tokens in this module do not contain tuple information and simply indicate the system state by their presence/absence e.g. “between inspection”.

6.3 *Rehabilitation Module*

Once an inspection occurs, a decision about element rehabilitation is made. The industry guidelines detail the type of rehabilitation to rectify different defects (Network Rail 2012a). The rehabilitation options, Minor rehabilitation, Major rehabilitation and Replacement, have each been calibrated with historic data from CAF and MONITOR for both cost and durations which were then verified by industry experts. These attributes were used to calibrate the transitions in Fig-

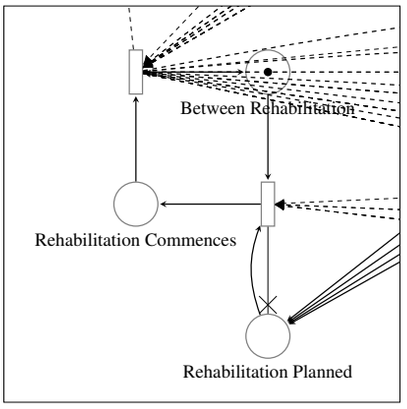

Figure 5: The rehabilitation module makes extensive use of CPN features to closely mimic the complex processes involved.

ure 5.

One major feature which was incorporated into the model required detailed expert judgement of the rehabilitation process. This situation occurs when the element has deteriorated into a worse state during the time between inspection and rehabilitation where the planned rehabilitation is no longer sufficient. This normally would only occur when then condition is near the boundary of rehabilitation actions or the element deteriorates particularly quickly. In Figure 5 this is represented by dashed arcs which are used to deduce whether the rehabilitation action is still appropriate based on the condition of the element. If the rehabilitation action is no longer appropriate the maintenance teams would have to return to that element at a later date to carry out the appropriate rehabilitation action; this delays the repair, increases WLCC and increases pressure on maintenance teams.

6.4 *Model Simulation and Outputs*

With the use of stochastic transitions and complex guards in the CPN model, simple PN analytics are unavailable which means the model must be simulated to understand its behaviour. A MC approach was used for this. The model outputs shown in this section result from a simulation starting with a concrete beam element in an A1 condition over a 100 year period. To simulate an entire bridge asset, a token would be added for each bridge element. A single element was chosen for this example for illustrative purposes to avoid conflicting deterioration profiles and enable a visually clear behavioural trend. A total of 10,000 iterations were carried out to ensure consistent results.

Figure 6 shows the condition of the element over time. The model, in this configuration, uses the standard industry maintenance policies, described in Section 3. The condition starts the simulation with a deterministic A1 condition, hence the high probability of residing in an A1 condition at the end of the first year. The downward slope of the condition continues until the 12th year when an inspection and subsequent maintenance action take place, resulting in an uplift in condition. This process starts the saw-tooth

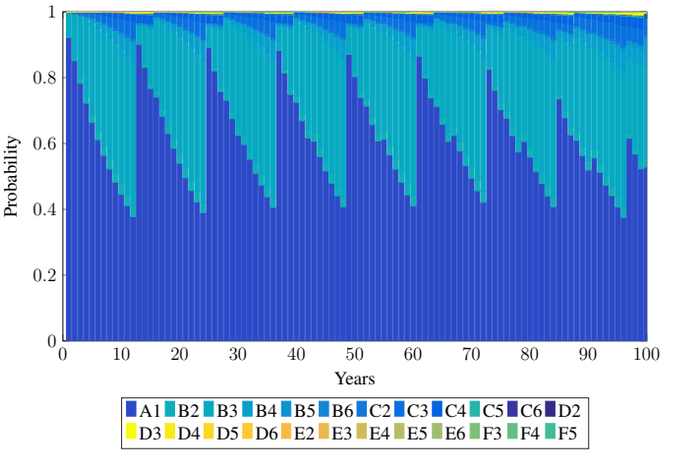

Figure 6: Model simulation outputs showing the condition over time of a concrete girder element.

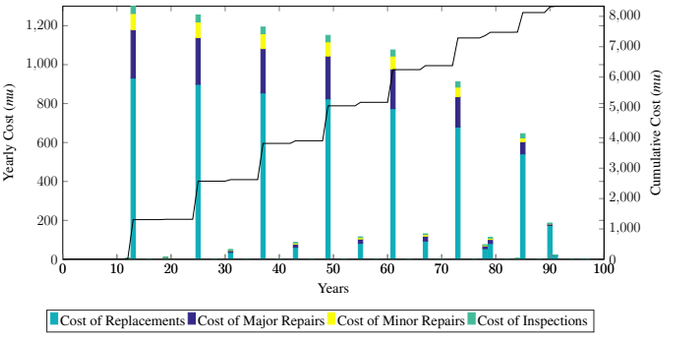

Figure 7: Model simulation outputs showing the cost per year and cumulative cost over time of a concrete girder element.

cycle which continues over the life of the simulation describing the cycle of deterioration, inspection and maintenance.

Figure 7 shows a similar cycle, but from a financial perspective. It can be seen that costs are only realised in years when inspections and maintenance occurs, which coincide with the condition uplifts seen in Figure 6. It should also be noted that when the maintenance teams are required to return to an element, as described in Section 6.3, a second set of expenditure is realised, which can be seen in the figure as the smaller bars between the normal cycles.

7 INVESTIGATION INTO STRESSORS

The model presented so far considers generic bridge elements. From the literature reviewed, there seem to be a number of external environmental factors which can cause varying rates of deterioration in bridge elements. A number of studies have highlighted that there are “other” factors which can contribute to bridge deterioration (Morcous, Rivard, & Hanna 2002a, Sobanjo 1997, Arditi & Tokdemir 1999), but to be able to investigate these a sufficiently large portfolio of bridges and wide enough dataset is required.

As mentioned in Section 3, during inspections the element conditions are recorded using the SevEx system. Rather than convert these alpha-numeric scores to a linear system to carry out stressor analysis, it was

decided that retaining their format would avoid the need for weightings which can introduce subjectivity. Therefore, an approach was developed which considers each of the 31 condition states as nodes with the "length" of the paths connecting the nodes to be equivalent to the Mean Time to Failure (MTTF), following the approach of the deterioration module seen in Section 6.1. The most likely route from node to node through the network is the route which has he lowest MTTF. This allows the use of a classic routing algorithm (Dijkstra 1959) to calculate the time it would take for an element to reach a condition requiring Major Rehabilitation or Replacement from its current condition.

The methodology would be to select an attribute which could be a contributor to structural deterioration (e.g. amount of rainfall), and divide up the population into equal groups e.g. structures exposed to $<$700mm of rainfall per year or $\geq$700mm of rainfall per year. Then calibrate a network diagram for each of the groups, calculating the shortest path for each condition state to the thresholds for Major Rehabilitation or Replacement. The results can be compared as a quick visual indicator to identify if that particular attribute may be a significant factor in structural deterioration.

7.1 *Structure Configuration*

Structural configuration was analysed to ascertain if it is a key factor in deterioration. Railway bridges are usually configured as either underline bridges or overline bridges. Underline bridges carry the railway over obstacles, for example a roadway or river.

The population of underline and overline bridges were taken as two groups and analysed using the methodology described in the previous section. The results can be seen in Figure 8. The results give a visual indication that underline bridges deteriorate faster than overline bridges in general, which can be seen by the lower amount of time required to reach the threshold requiring rehabilitation. The difference highlighted by these results is most likely caused by the different stress profiles caused by the different types of vehicular traffic. The results indicate that these two bridge configurations should be treated as separate groups.

7.2 *Distance to Sea*

The distance of each bridge asset to the sea could be calculated using the assets location, provided in the CARRS dataset, with a shorelines database (National Oceanic and Atmospheric Administration (NOAA) 2015). The approach used in this paper was to divide the population of bridges from the coast inland i.e. a split at 10Km would create two groups of assets, bridges within 10Km to the sea and bridges 10Km or further from the sea. The population was split every

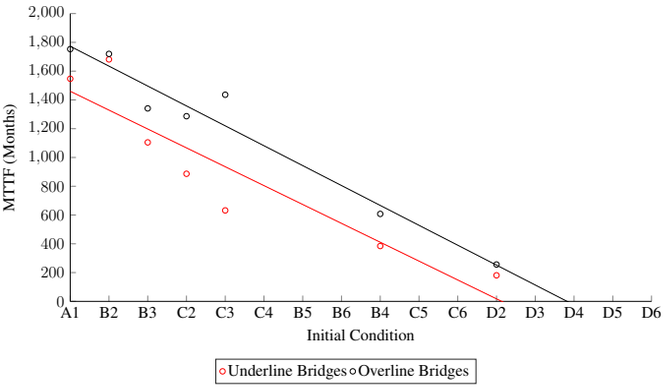

Figure 8: Analysis results of different bridge configurations to deteriorate to the Major rehabilitation threshold.

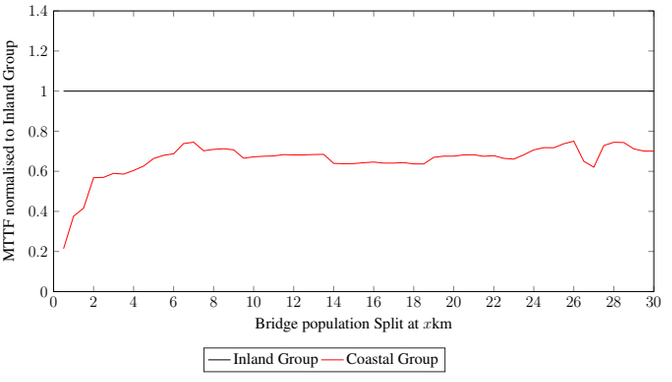

Figure 9: Bridge behaviour at different points from the sea, tested to a condition state requiring Major rehabilitation.

0.5Km up to 30Km inland. The groups would then be analysed with the methodology described in the previous section.

The results can be seen in Figures 9 and 10. They show the inflection point between inland and coastal bridge behaviour. This was tested with a concrete girder element starting in an A1 condition and deteriorating to a state requiring Major rehabilitation in Figure 9 and a state below the BSL, requiring element replacement in Figure 10. The results show that there is, in general, a significant difference in the deterioration rate between the coastal and inland bridge groups with the MTTF being around 30% lower for the coastal group than the inland group. From these results, it can be seen that the distance to the sea is a factor affecting deterioration and the data suggests that the groups should be split with: 1) assets severely affected by the sea at 0-5Km, 2) assets in moderate exposure to the sea at 5-25Km and 3) assets with minimal/no exposure to the sea beyond 25Km.

8 WLCC MODEL CONSIDERING STRESSORS

Although the identification of stressors is useful for portfolio grouping, a greater advantage is gained by bridge managers by understanding the financial and safety implications of bridges exposed to those stressors is. Therefore, it is possible to enhance the component condition module, seen in Section 6.1, which controls the rate of element deterioration, with the results from previous section. The way this works in

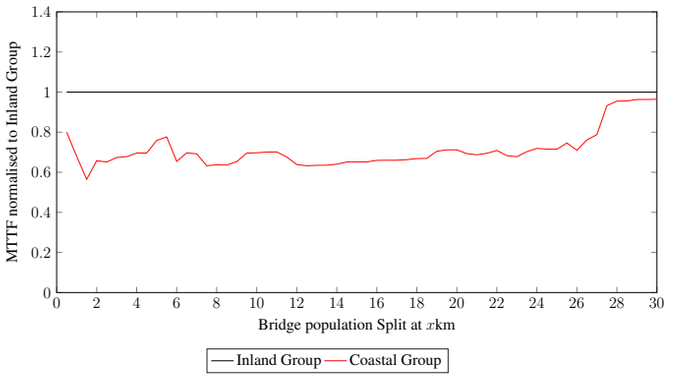

Figure 10: Bridge behaviour at different points from the sea, tested to a condition state below the BSL, requiring element replacement.

practice is to embed the stressor information in the tuple of the bridge element token in the CPN model. The transitions are calibrated with each of the deterioration profiles based on the different stressors. The transitions use a stressor identifier in the token tuple to determine the appropriate firing delay to replicate the appropriate deterioration profile for an element exposed to that particular environmental factor.

A simulation has been carried out with a concrete girder element, starting in an A1 condition, inspected and maintained to the industry standard "managed" maintenance regime over a 100 year period. The results have been summarised in Table 1. It can be seen that the generic deterioration profile (ID1), in which stressor information is not considered, costs 7,900*mu* over a 100 year period, which correlates to the model output seen in Figure 7. When running the simulation of the concrete girder element with different structure configurations, IDs 2 and 3 are the model WLCC outputs, corresponding to overline and underline bridges. It can be seen that overline bridges cost considerably less than underline bridges. It should be noted that there are other structure configurations, but overline and underline bridges make up 94% of the portfolio. When simulating the concrete girder element on structures at different coastal proximities, the results are more divergent (IDs 4, 5 and 6). It can be seen that the WLCC of an inland bridge (ID6) is comparatively low whereas a structure which is closer to the sea (ID5) costs significantly more at 1.7 times that if ID1. Furthermore, structures that are very close to the sea, at maximum exposure to the saline atmosphere, cost almost twice the baseline WLCC seen in ID1. The variation in capital expenditure between these groups varies significantly and reveals a great deal to bridge portfolio managers.

As well as increased financial burden, factors which cause rapid deterioration can also cause issues with maintainability. This is evident when comparing Figures 8 and 8. In Figure 8, the deterioration rate is slower and so the delay time between inspection and maintenance is acceptable. However in Figure 8 the sawtooth curve begins to deviate suggesting that intermediate rehabilitations are beginning to occur. The

Table 1: Stressor simulation WLCC results.

ID	Structure Configuration	Distance to Sea (km)	WLCC (nearest 100*mu*)	Relative Cost to ID 1
1	All	0 - Inf	7,900	1.000
2	Overline Bridges	0 - Inf	3,600	0.460
3	Underline Bridges	0 - Inf	7,100	0.906
4	All	<5	15,100	1.918
5	All	5-25	13,700	1.736
6	All	>25	2,800	0.355

situation under which this occurs is when the element has deteriorated further than expected on an initial rehabilitation attempt and so the maintenance teams must return. This causes an increase in WLCC, increases possession time of the asset and reduces maintenance efficiency. The safety implications are that assets exposed to stressors which cause rapid deterioration are more difficult to manage and therefore there is a higher likelihood of the element straying below the BSL.

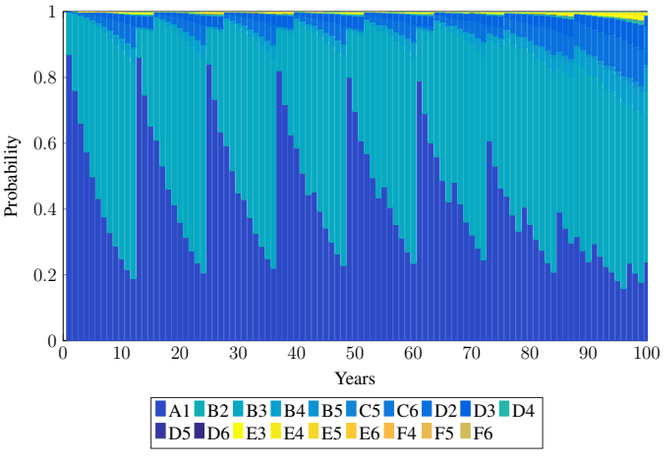

Figure 11: Simulation of a concrete girder element <5Km from the sea.

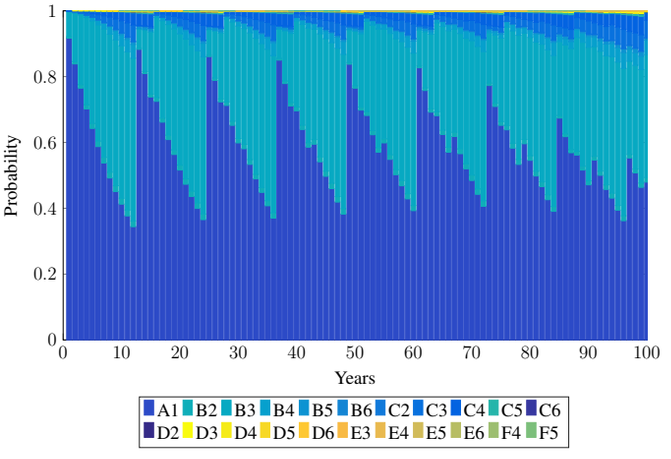

Figure 12: Simulation of a concrete girder element >25Km from the sea.

9 CONCLUSION

The international standards for Asset Management (AM) discuss safety as a key aspect of good AM (International Organization for Standardization 2014). With an aligned AM strategy and objectives, understanding the main risks that can cause an asset to breach the safety threshold can be avoided. In the work presented, a robust WLCC model was presented which develops new insight into how the policies which govern the management bridge assets affect them using historic condition data. Then an analysis into the main factors affecting deterioration allow bridge managers to understand the environmental factors which are the highest risk of causing rapid deterioration. Finally, by combining the stressor analysis and the WLCC model, a financial, safety and maintainability insight can be gained about the stressors, all of which can improve the AM understanding and help mitigate risks of assets falling below the BSL.

Network Importance of Melbourne's Metropolitan Bridges – Development of a Strategic Bridge Prioritisation Framework

S. Di Cicco
Manager Structures, VicRoads Metropolitan North West Region

ABSTRACT: VicRoads manages a network of some 1,700 bridges across metropolitan Melbourne. Many of these bridges are critical for the safe operation of the transport network which provides for the movement of passenger and freight vehicles and public transport users. The development of bridgeworks programs, to address maintenance, repair and bridge capacity deficiencies therefore requires careful prioritisation.

VicRoads has typically prioritised its bridgeworks programs based on the age and condition of a bridge as well as any changes in performance requirements that inevitably occur over time, such as the introduction of heavier freight vehicles and/or trams.

While the above approach has also taken into account factors such as the importance of the bridge to the transport network, there has not been to date an explicit framework upon which bridgework priorities could be based on. As a result, VicRoads has had mixed success in procuring funding for its bridgeworks program.

In response, VicRoads is developing a prioritization methodology, referred to as a 'Strategic Bridge Prioritisation Framework' (or "Framework" for short) to ensure that the broader needs of the transport network are seen to be strategically and effectively accounted for.

This paper presents the key features and benefits of the 'Framework' which include:

• Adoption of a rational methodology for the prioritisation of bridge projects based on maximising benefits to the overall transport network and the community.
• Priorities to be seen to clearly and transparently addressing the criticality and strategic value of the bridge project to the overall transport network and reflecting both short and long term bridge asset management strategy.
• Implications for the community clearly identified, should the works not be funded. These implications could include service reductions, load limits, increased travel times, environmental effects and associated economic costs.
• Development of consolidated business cases for the management of VicRoads bridges which maximise benefits to the overall transport network and the community.

Keywords: bridge assessment, bridge maintenance, asset management strategy, prioritisation methodology.

1 INTRODUCTION

VicRoads manages a network of some 1,700 bridges across metropolitan Melbourne. Many of these bridges are critical for the safe operation of the transport network which provides for the movement of passenger and freight vehicles and public transport users.

The development of bridgeworks programs, which specify works based on the assessment of maintenance and repair needs as well as bridge load capacity deficiencies therefore requires careful prioritisation.

This paper reports on the development of a prioritisation methodology, to ensure that bridgework programs are prioritised to ensure that the broader needs of the transport network and the associated benefits to the community are strategically and effectively accounted for.

2 BACKGROUND

VicRoads has typically prioritised its bridgeworks program (which includes assessment, maintenance,

repair and/or bridge strengthening activities) based on the age of the bridge, its load capacity and its condition.

While this approach has also taken into account factors such as the importance of the bridge to the passenger and freight networks, (as well as economic costs to the community should any identified works not be carried out) there has not been to date an explicit framework against which bridge assessment and maintenance could be prioritised.

Additionally, internal reviews within VicRoads business areas responsible for managing bridge assets have identified this basic reliance on bridge condition data as a potential weakness of funding submissions.

This paper reports on a prioritisation methodology currently being developed. The methodology is referred to as a 'Strategic Bridge Prioritisation Framework' or "Framework" for short.

Details of the methodology are provided including its aims, what criteria it is based on, its limitations and finally, following stakeholder review, additional enhancements have been identified..

3 STRATEGIC BRIDGE PRIORITISATION FRAMEWORK

3.1 *General*

In recent years, VicRoads has had mixed success in obtaining funding for bridge repair, maintenance and bridge strengthening projects. Key reasons for this mixed success include:

- A lack of clarity about why certain bridges were put forward for funding over others. In particular, the way in which bridge projects were being prioritised as part of a long term asset management strategy, was not clear.
- Uncertainty regarding the criticality of the bridges to the overall transport network, particularly the implications for the community if the proposed works were not carried out.

The development of the Framework which addresses these issues encapsulates several components:

- Identification and weighting of criteria which were considered for bridge prioritisation purposes. These included factors such as access to local facilities, volume of traffic, congestion, and importance of the bridge to the public transport network.
- Identification of data sources for each of the criteria.
- Development of a Geographical Information System (GIS) to provide geographical data for all bridges (eg. how close a bridge is to a school or hospital)

The Framework provides a mechanism for VicRoads to prioritise all of the bridges in the metropolitan area for the purposes of determining which bridges are most significant to the transport network. "Significance" is a difficult concept to define for the purposes of the Framework. What it means in essence is that a "significant bridge" is one that plays an important role in a local or whole of metropolitan capacity for a mix of user groups, including freight, commuter, private vehicles, public transport and others. In particular, the Framework identifies the network importance of the bridge should an incident occur which causes the bridge to be shut for a period of time to undertake repairs.

The Framework encapsulates a range of weighted factors or inputs which together are used to create a priority list for all bridges in the metropolitan network. This is a strategic approach which seeks to tell us which bridges, on balance, are most important for the network.

There is no 'scientific' approach to the weighting and scoring process, instead it relies on experienced judgment combined with an iterative approach which takes into account Government priorities, experience and expertise within VicRoads and other agencies about how the transport network operates, and an understanding of bridge users and their needs.

The Framework and GIS is intended to support existing VicRoads management tools and interface with the existing VicRoads' bridge condition information.

The Framework, addresses the significant challenges faced by VicRoads with regard to identification and prioritisation of the required maintenance, repair and/or strengthening works and will take into account economic impact factors in the prioritisation process. Specifically, the Framework will:

- Provide a transparent, coherent and cohesive process to assist VicRoads to prioritise the assessment and maintenance of its metropolitan bridge network.
- Be used as a decision making tool by VicRoads to identify and demonstrate remedial or strengthening priorities.
- Provide a basis by which to plan and prioritise future data collection including periodic inspection of bridges.

The Framework can usefully address the potential weaknesses of previous funding bids by identifying the bridges' relative network importance, supple-

menting condition data and the economic case by providing a justification of why one bridge requiring works may be prioritised for funding over another.

3.2 *Framework*

3.2.1 *Framework Methodology - Categories*

In this Framework, five categories have been identified. These categories cover key issues that should be considered when deciding the importance of a bridge to the network. They also provide a strategic fit with VicRoads priority networks such as the Principal Freight Network (PFN). These five categories are weighted, and drive the overall bridge rankings. The five categories are:

- Freight movement – this refers to the importance of a bridge for the movement of freight within the metropolitan area and beyond.
- Vehicle movement – this refers to the significance of the bridge for all road vehicles and the congestion on the route.
- Features below bridge – the feature below the bridge may be important in the event of a disruption to the bridge or major maintenance. An event of this nature has the potential to disrupt whatever activities take place below the bridge in question, be that a road, rail or a major asset such as the Port of Melbourne.
- Community access – this refers to the significance of a bridge for the local community to gain access to local services such as a hospital, school or emergency provider.
- Commuter movement – this refers to the importance of the bridge for the public transport network. This focuses on the impact for road based services such as trams and buses.

3.2.2 *Framework Methodology – Criteria*

These include factors such as proximity to services such as hospitals, volume of traffic, and whether the bridge is on a freight route or public transport route. These have all been weighted, and data sets have been identified and assigned to each of these measures.

An overall 'score' for each bridge can then be calculated which reflects the data and weightings for each criterion and for each category. The proposed Framework is illustrated in Figure 1 (next page).

Refer to Figure 1-The Framework, criteria and weightings

3.3 *Framework Outputs*

The table below shows the Top 30 bridges based on their network importance rank considering all VicRoads bridges in the Metropolitan area database.

Refer to Figure 2 for table

The bridges at the top of the list with high scores are generally those which:

- Cater for a number of transport modes combined with high traffic volumes
- Are included on the strategic freight network
- Are on a preferred traffic route

Bridges with a low traffic volume which do not have a public transport mode do not appear at the top of the list.

Note that the Westgate Bridge was not scored as the most important bridge on the network (refer Cl 3.4.3 - Stakeholder Views, below).

3.4 *Framework Enhancements*

3.4.1 *Economic Impacts*

Another factor which needs to be taken into account when prioritising bridge projects is the economic cost to the community if maintenance or rehabilitation work is not carried out. Service reductions such as the imposition of a load limit or emergency lane closures (to carry out unplanned repair) carry a measurable cost to the community and the environment in the form of additional travel time and vehicle km travelled.

It is intended to incorporate a theoretical economic cost for each bridge into the Framework. All prospective bridge repair, maintenance or strengthening projects will incorporate an economic impact element demonstrating the costs to the community should the project not proceed. These costs can be considered an economic benefit of the project if implemented. It is therefore beneficial that the economic value in completing the required work is known.

This can be achieved by assuming traffic restrictions would be applied on the bridge until maintenance could be completed. The economic cost of the scenarios considered can then be calculated from the direct cost of the reductions in level of service as well as the impact of this on other road users.

The scenarios generally considered fall into two categories as follows, on the basis that avoidance of maintenance could result in either a planned, long-term load restrictions or an unplanned, short-term closure to allow emergency remedial maintenance to occur.

• A load restriction, forcing articulated vehicles to divert around each bridge and where applicable, restricting trams from crossing the bridge. This scenario provides the likely impact on the community in the event that bridge capacity was found to be deficient and heavy vehicles were diverted. It can be assumed that lighter commercial and private vehicles, pedestrians and cyclists are not affected by the load restriction.
• A total bridge closure, forcing all vehicles to divert around the bridge. This scenario provides the likely impact on the community in the event that bridge condition required the bridge to be closed for a short period to undertake emergency repairs in the event of a structural failure.

The table below shows an example of the annual avoided costs of imposing a 12 month load limit and restricting trams on Victoria Street Bridge over the Yarra River. Articulated vehicles will primarily divert around this bridge, under the load limit scenario using Studley Park Drive and Bridge Road, resulting in articulated vehicles spending more time on the road and travelling further distance. This frees up capacity on Victoria Street such that light vehicles travel a shorter net distance but spend more time on the road.

Restricting trams results in public transport users spending more time travelling to their destination. The effect is a net cost to the economy if a load limit and tram restrictions are imposed on Victoria Street Bridge over the Yarra River.

Victoria Street - SN6248			
	Light	Articulated	Tram
Daily Δ Hours	0	20	2,000
Daily Δ KMs	-240	-210	N/A
Annual Cost - 12 month load limit + tram restrictions			
Travel time	$ 36,000	$ 519,000	$ 7,110,000
Vehicle operating costs	$ 21,000	-$ 157,000	N/A
Externalities	-$ 5,000	-$ 73,000	N/A
Total per vehicle Class	$ 52,000	$ 289,000	$ 7,110,000
Capital costs	N/A	N/A	$ 2,000,000
Total Annual Cost			$ 9,451,000

The costs were calculated using the Austroads Guide to Project Evaluation (AGPE04-12) including:
- Road user costs (travel time costs and vehicle operating costs)
- Non-user costs (environmental externality costs)
- Capital costs.

It is proposed to include an element of the economic impact as a criterion within the bridge prioritisation Framework. The GIS can facilitate this by calculating the best diversion route for each bridge and multiplying this by traffic volume. This factor when viewed independently of the Framework will give an accurate ranking of the expected economic costs of imposing a load limit or diversion for each bridge. However this factor will also be weighted and added to the Framework and overall ranking of each bridge.

3.4.2 *Bridge conditions*

Bridge condition is not included in the Framework. The current intent of the Framework is to assess the bridges importance within the overall road network from a traffic and community point of view.

Using condition data to determine which projects should receive funding has traditionally been based on the technical need or urgency of the condition. Carrying out repairs and maintenance as a result of condition based assessment only will not necessarily serve the community efficiently, although it may be required to maintain the current level of service of a particular bridge. However if that bridge is not critically important to the network or the community, then accepting a lower level of service (load restriction) may be a better use of resources.

Effective asset management requires tools such as this Framework to more accurately target scarce resources.

Adding bridge data such as condition data to the GIS is a process which is proposed to be part of a wider Bridge Management System. This is a system where all data related to a bridge including drawings, reports, previous inspections, photographs etc. is housed in a database along with its geographical and condition information. The database and geographical information can then be filtered and queried according to user priorities. Advanced and well maintained Bridge Management Systems can alarm when inspections or maintenance is due. With the addition of maintenance cost rates it is possible for such systems to forecast future expenditure.

3.4.3 *Stakeholder Views*

A series of workshops in August and September 2014 were held to showcase the methodology of the Framework and seek feedback regarding its applicability and accuracy. The current Framework was also presented to key internal VicRoads stakeholders and their views have been taken into consideration in the

development of the Framework, however further work remains.

One of the main outstanding issues concerned the lack of consideration for future growth, which is not currently scored under any of the weighted factors. The importance of the Principal Freight Network was also raised and how the development of freight corridors can be captured in the Framework.

The applicability of the Framework to regional areas was also an issue for concern. Current factors considered, and their weightings, could skew the scoring of bridge assets in favor of the metropolitan regions. This could possibly lead to unequal funding allocations. How to fairly apply the principle of connectivity to the scoring of assets was discussed at many of the workshops. It was noted that connectivity in regional areas may be more important than in metropolitan areas where a readily available alternative route exists. The nature of connectivity is different in rural areas given that community facilities need not be close to a bridge to impact on its importance. Quite often no readily available alternative route is available to a school / hospital etc. The Framework needs to be amended somehow to reflect this.

The fact that the Westgate Bridge was not scored as the most important bridge on the network was noted. The Westgate is generally considered the most important bridge on the network from a strategic point of view. It's scoring falls down on community and public transport factors. The importance of the connectivity of the bridge, given that an alternative route is not readily available, appears to be the key factor in the framework requiring attention.

3.4.4 *Future Steps*

A number of the following modifications are planned in the future based on feedback from users and funding agencies:

- Investigate the addition of a GIS route calculation to determine the distance required to take an alternate route around the bridge in the event of a closure or load restriction. This factor, when multiplied by traffic or freight volume, can be considered as an economic impact criterion and weighted accordingly.
- The development and rollout of a web based GIS interface to allow VicRoads staff to use and develop the tool. For example this will allow users to query the database which bridges are on a Principal Freight Network and rank this subset according to priority for targeted inspections or maintenance.
- Adopting the GIS to calculate Framework criteria more suited to rural locations. For example, bridges within 1-2km of a school or hospital to be given the same score as a bridge within 50m of a hospital in urban areas. These kinds of modifications will reduce disadvantage to rural areas for project funding.
- The investigation and development of additional categories and criteria based on bridge replacement value and complexity. This can be achieved by weighting criteria associated with bridge dimensions (length, height etc.)
- Increase ratings for traffic flow to 5 categories to incorporate roads which have the very highest traffic volume on the network and ensure they have a sufficiently high ranking (e.g. Westgate Bridge).
- The investigation and development of additional categories and criteria based on bridge heritage value. This can be achieved by using data from the Heritage Victoria database.
- Future Growth in traffic volumes to be determined from Victorian Integrated Transport Model (VITM) and incorporated into the Framework under the vehicle movement category – a future VITM model will incorporate expected changes to the network in the future.
- Future growth in Commercial vehicles (%CV) to be determined and added to the freight movement category.
- Bus passenger numbers per route to be added in the Commuter Movement category.
- Development of route priority classes within the GIS such as the Principal Bike Network and future Freight Network classes.

4 CONCLUSIONS

1. VicRoads has had mixed success in obtaining funding for bridge repair, maintenance and bridge strengthening projects. Key reasons for this mixed success include:

   - A lack of clarity about why certain bridges were put forward for funding over others. In particular, the way in which bridge projects were being prioritised as part of a long term asset management strategy, was not clear.

   - Uncertainty regarding the criticality of the bridges to the overall transport network, particularly the implications for the community if the proposed works were not carried out.

2. As a response, VicRoads commissioned AECOM (1) to develop a 'Strategic Bridge Prioritisation Framework' methodology.

3. The key features and benefits of the 'Framework' include:

   - Adoption of a rational methodology for the prioritisation of bridge projects based on maximizing benefits to the overall transport network and the community.

   - Priorities to be seen to clearly and transparently addressing the criticality and strategic value of the bridge project to the overall transport network and reflecting both short and long term bridge asset management strategy.

   - Implications for the community clearly identified, should the works not be funded. These implications could include service reductions, load limits, increased travel times, environmental effects and associated economic costs.

   - Development of consolidated business cases for the management of VicRoads bridges which maximise benefits to the overall transport network and the community.

4. Future improvements to the 'Framework' being considered include:

- Integration of the Framework with existing VicRoads management tools and bridge condition information.

- Possible addition of a GIS route calculation to determine the distance required to take an alternate route around the bridge in the event of a closure or load restriction. This factor, when multiplied by traffic or freight volume, can be considered as an economic impact criterion and weighted accordingly.

- The development and rollout of a web based GIS interface to allow VicRoads staff to use and develop the tool. For example this will allow users to query the database which bridges are on a Principal Freight Network and rank this subset according to priority for targeted inspections or maintenance.

- Adopting the GIS to calculate Framework criteria more suited to rural locations. For example, bridges within 1-2km of a school or hospital to be given the same score as a bridge within 50m of a hospital in urban areas. These kinds of modifications will reduce disadvantage to rural areas for project funding.

- The investigation and development of additional categories and criteria based on bridge replacement value and complexity. This can be achieved by weighting criteria associated with bridge dimensions (length, height etc.)
- The investigation and development of additional categories and criteria based on bridge heritage value. This can be achieved by using data from the Heritage Victoria database.
- Increase ratings for traffic flow to 5 categories to incorporate roads which have the very highest traffic volume on the network and ensure they have a sufficiently high ranking (e.g. Westgate Bridge).

- Future Growth in traffic volumes to be determined from Victorian Integrated Transport Model (VITM) and incorporated into the Framework under the vehicle movement category – a future VITM model will incorporate expected changes to the network in the future.

- Future growth in Commercial vehicles (%CV) to be determined and added to the freight movement category.

- Bus passenger numbers per route to be added in the Commuter Movement category.

- Development of route priority classes within the GIS such as the Principal Bike Network and future Freight Network classes.

Experimental investigation into the fatigue life of patch anchors used to anchor FRP laminates bonded to concrete

A. Al-Saoudi, R. Al-Mahaidi & R. Kalfat
Swinburne University of Technology, Melbourne, Australia

ABSTRACT: During the recent decades, the number of vehicles passing the bridges has dramatically increased in many many countries around the world compared with initial design consideration. Excessive cycling loading lead to fatigue degradation in the structural element and if untreated, severe damage may occur. Externally bonded Fiber Reinforced Polymers (FRPs) has become one of the successfully methods of upgrading and retrofitting reinforced concrete RC structures such as bridges and highways. Although extensive research has been carried out to investigate the performance of this exterior strengthening systems, the majority of report studies addressed the effectiveness of this technique under monotonic loading. However, to date, no unique design guidelines specified the fatigue life behaviour of this externally FRP anchorage devices when subjected to cyclic loading. This paper presents the experimental results of externally FRP bidirectional sheets bonded to RC beams and subjected to different cyclic load application. The results demonstrated on the basis of maximum stress ratio and relative fatigue number of cycles. The outcomes of this study showed that there is no fatigue degradation when the maximum stress ratio is 60% of the ultimate static capacity, and the fatigue test remained running until 5.6 million cycles without observing any crack initiation along the bond line. Further details of the test results with recommendation for future research study are also outlined.

1 INTRODUCTION

All bridges and highways experience numerous levels of cyclic loading throughout their lifetime. This is due to loading and unloading cycles caused by the passage of heavy trucks and vehicles. Excessive cyclic loading has been found to result in fatigue degradation in structural members. Externally-bonded FRP composites adhered to the concrete had become a popular method for strengthening RC structures, typically highway and railway bridges. Many existing concrete bridges are being strengthened with FRP composites due to increased loading or deterioration.

External application of FRP material provides a practical solution for improving the overall performance of reinforced concrete structures. This application can also be used in a repair capacity for structures that have undergone moderate earthquake damage or to reinforce structures that are considered vulnerable or sub-standard. The effectiveness of using externally-bonded FRP in the retrofitting process depends primarily on the interface bond behaviour between the FRP sheets and the concrete substrates. The major role of the interface between FRP externally bonded to concrete is the mechanism of shear stress transfer between the two materials. Research has shown that the bond interface between FRP and concrete in concrete beams strengthened with externally-bonded FRP plays a crucial role (Chen and Teng 2001). FRP debonding failure is very frequently observed in these structures under both static and fatigue loadings. Previous studies have shown that stresses in CFRP laminates are transferred to concrete beams via the adhesive interfaces, and the effectiveness of the strengthening technique is largely determined by the bond behaviour between the CFRP material and the concrete (Kalfat and Al-Mahaidi 2011).

Although extensive research has been conducted on the behaviour of the externally FRP-concrete bond interface, the vast majority of the work has been concerned with monotonic static loading, and few studies have been concerned with the bond behaviour under cyclic loading that can be caused by seismic tremors or traffic loads (Martinelli and Caggiano 2014). Different test methods were conducted by Belarbi (2011) to assess the average interfacial bond strength, including single-lap, double-lap, bending, and inserted tests. These strengthening methods were used in many research studies. For instance, Chen and Teng (2001), Chen et al. (2012) and Xie et al. (2016) performed fatigue tests on beams strengthened in flexure using one

and two strips of CFRP on the soffit surface. The authors found that the beams strengthened with two strips had greater fatigue life than beams with a single strip of strengthening due to the effectiveness of the dual strips in restraining crack opening

The aim of this research study is to investigate the fatigue life performance of externally bonded FRP-to-concrete joints anchored with bidirectional fabric patch anchors. Anchorage devices are typically used to mitigate the longitudinal shear stresses and peeling stresses that often initiate at fibre termination points inducing premature debonding failure of FRP-to-concrete joints. Generally, anchors have several types, however, the patch anchor is the main type considered in this research study which utilizes bidirectional fabric sheets. In particular, anchors are used in this research to achieve higher strain in the FRP prior to debonding and allow a higher degree of strengthening to be achieved using less material. The main problem with bonding and debonding is the mechanism and mode of failure that can occur between the FRP and the concrete surface, while debonding issues play an important role in member performance and safety. This paper presents the experimental results of investigating the fatigue life performance of externally FRP bidirectional sheets bonded to concrete surface and subjected to different static and cyclic load application. The results demonstrated on the basis of maximum stress and relative fatigue number of cycles. The results showed that no fatigue degradation was observed when the maximum stress is 60% of the ultimate static capacity, and the fatigue test remained running up to 5.6 million cycles without failure occurred. Further details of the test results and summary of conclusion are outlined in the following sections.

2 EXPERIMENTAL WORK

2.1 *Specimen design*

Six specimens of RC blocks with dimensions of 400 × 400 × 250mm were prepared for this experimental study. Each specimen was reinforced with steel cages of N4 Φ12mm closed ties through each direction. A spacing of 120mm was allowed between the bars with a reinforced cover of 30mm.

2.2 *Specimen preparation*

After casting the concrete, all specimens were painted with water-based wax emulsion (cure compound), as this liquid material provides efficient curing in minimum time. Following the curing stage, sand-blasting was implemented on the larger faces of the concrete blocks (400 x 400mm). This is to ensure that both surfaces had an adequate level of roughness so that ideal bond application could be achieved between the FRP material and the concrete surface.

2.3 *Use of FRP application*

The specimen had two layers of bidirectional fabric sheets applied to the concrete, with CFRP laminate strip placed between each fabric layer. The fabric sheet with dimensions of 400 x 300mm was applied to the concrete surface. The first fabric layer and its saturant component were applied using the wet-lay-up method and left for a sufficient time to reach a tacky state. The specimens were then cured for 72 hours using a set of 250W heat lamps to maintain a curing temperature of 35C. When the specimens were cured, strain gauges were attached at selected locations evenly along the CFRP laminate surfaces and across the bidirectional sheet, as shown schematically in Figure 1. A typical photograph of the anchored model inside the test machine is depicted in Figure 2.

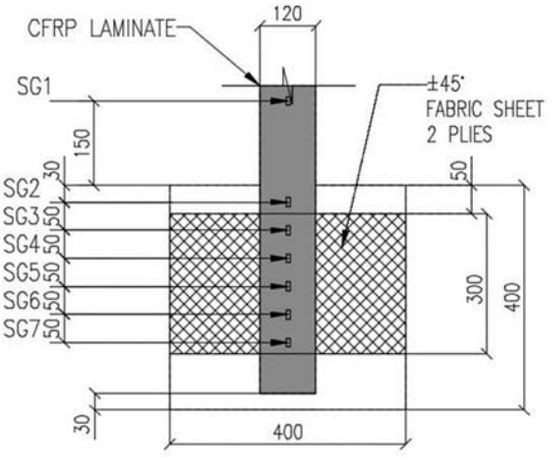

Figure 1. Sketch of the anchored model

Figure 2. Anchored model inside the MTS machine

2.4 *Material properties*

Most of the material properties supplied by the manufacturers were tested experimentally to verify the properties prior to their use in the FRP application. However, some parameters were used as per manufacture' specification, noted with (*). A summary of the materials properties used in the experimental tests is presented in Table 1.

Table 1. Summary of material properties.

Properties	Concrete	Saturant	CFRP laminate	CFRP sheets
Compressive strength, (MPa)	32	-	-	-
Tensile strength (MPa)	2.7	>50*	21	3790*
Young's modulus, (GPa)	42	>3.0*	181	230*

3 EXPERIMENTAL WORK

3.1 *Instrumentation of the test frame*

The experimental work was conducted on a steel frame first designed by Kalfat et al. (2011). However, the frame was developed further to comply with fatigue test considerations. The rig configuration was arranged so that it could perform the near end-supported single-pull test. The test frame has two steel plates top and bottom where the specimen can be placed and secured by bolts. As the fatigue test includes applying loads at high frequency, some modifications to the test frame were adopted in order to increase its stiffness. These included replacing the top and bottom plates with thicker plates of 50mm thickness each, and the addition of extra vertical thread bars to ensure high levels of resistance to the cyclic loads with minimal movement and vibration. Figure 3 shows a sketch of test frame.

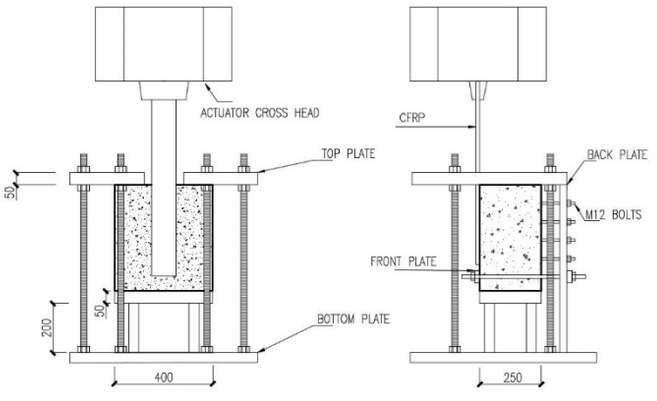

Figure 3. Sketch of the test frame

3.2 *Results*

In total, two static tests and four fatigue tests were performed on the anchored model. The average static failure load was used to assess the maximum and minimum stress of fatigue loading. Two points were used to study the fatigue life behaviour on the basis of maximum stress ratios and corresponding fatigue number of cycles, S-N relationship. These points were 70 and 60% of the ultimate static capacity. Each point represents a fatigue test which was repeated on an identical specimen for comparison and validation purposes. The details of the experimental results with conclusion outcome are presented below.

The two static tests showed good agreement in the failure load, and the first anchored specimen failed at 157kN and the second failed at 163kN. The average ultimate static failure load was therefore considered to be 160kN. It is important to note that the two static tests presented good correlation results in the strain distribution during the applied load as shown in Figure 4 and 5.

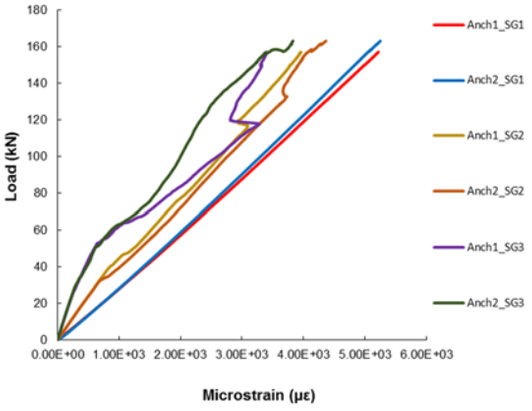

Figure 4. Static test: Load vs. micro-strain (SG1; SG2; SG3)

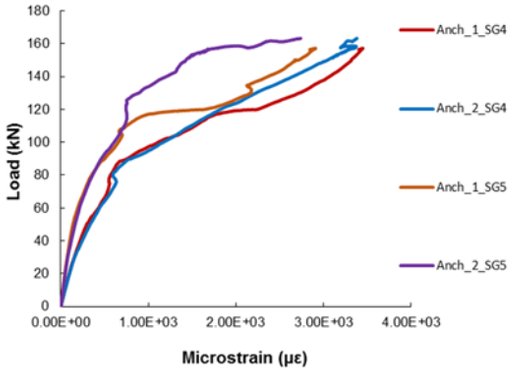

Figure 5. Static test: Load vs. micro-strain (SG4; SG5)

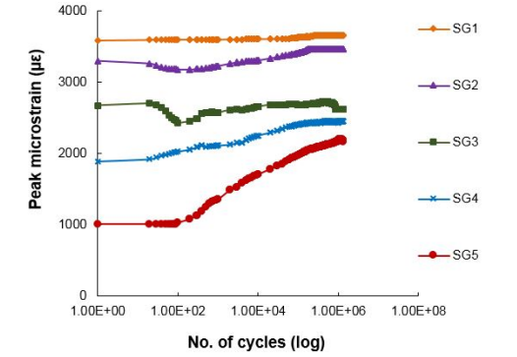
Based on the two static test results, the fatigue test matrix was set to test four specimens under cyclic loading. Two maximum stress ratios were used to reveal the fatigue life behaviour on the basis of the S-N relationship. These maximum stress ratios were 70 and 60% of ultimate monotonic strength. Each test was repeated on an identical specimen so that the results could be compared. Table 2 presents the fatigue test matrix with the results obtained.

Table 2. Experimental test results

Fatigue test ID	Stress ratio %	Load range (kN)	Fatigue no. of Cycles	Stopped without failure (No. of Cycles)
AF1	(20-70%)	(32-112)	1,355,000	
AF1-R	(20-70%)	(32-112)	607,100	
AF2	(20-60%)	(32-96)		5.6M*
AF2-R	(20-60%)	(32-96)		4.0M*

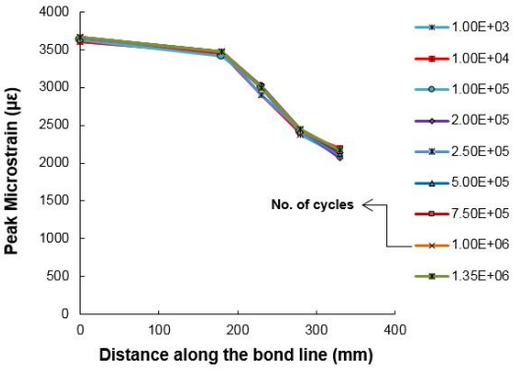
* M: Million

The first fatigue test (AF1) was run with minimum and maximum stresses of 20-70% and 32-112 kN respectively. Five strain gauges were attached to the laminate and fabric sheet to measure the strain distribution along the bonding line. The results showed a steady increase in strains (SG1-SG3) as the number of cycles increased. However, strain gauges SG4 and SG5 had gradual increment during the fatigue loading, as shown in Figure 6(a). The test was run until failure occurred at 1,355,000 cycles, when the full patch anchor delaminated from the concrete surface. No global signs of debonding were observed under the cyclic loading. Figure 6(b) demonstrates the measurement of peak micro-strain versus the distance along the bond line under cyclic loading. The results showed that the strains exhibited a linear decrease between strain gauge SG1 and SG2, and once the distance exceeded 180mm, the reductions in the micro-strains commenced to be a non-linear trend over the bonding area. This indicates that delamination was initiated at the edge of the block. At 280mm from SG1, the strains started to reduce dramatically until full patch anchor separation occurred at failure



The repeated tested (AF1-R) showed very good correlations with the peak micro-strain over the fatigue number of cycles and distance along the bond line compared to the first fatigue test (AF1). However, the test failed at 607,100 cycles, which is approximately half the fatigue number of cycles recorded in fatigue test one (AF1). Despite this difference in the fatigue number of cycles, both tests failed in the same failure range (below 2 million cycles). The maximum strain measured in the first fatigue test and the repeated test was very close, with 3900με and 3660με respectively. Figure 7(a) demonstrates the peak micro-strain versus the number of cycles. The strain distribution along the bond line measured from SG1 exhibited the same behaviour as that observed in the first fatigue test, as presented in Figure 7(b)

The second fatigue test (AF2) was run with minimum and maximum stresses of 20- 60% and 32-96kN respectively. Six strain gauges were used along the bonding area to reveal the strain distribution under fatigue loading. The first strain gauge (SG1) located at the free end of the laminate exhibited a steady trend during the entire test. However, the peak micro-strains of the other five gauges (SG2-SG6) showed an almost regular increase with increased number of cycles. The maximum strain reached was approximately 3250με, which is slightly below the maximum strain recorded in the first fatigue test when subjected to a maximum stress of 70% of the ultimate static strength. The test continued cycling until 5.6 million cycles without any global signs of crack propagation observed. The test was then stopped and the specimen failed by static tensile loading. Figure 8(a) presents the peak micro-strains of six gauges with the logarithm number of cycles. All the six strain gauges showed a steady trend along the bond line, as depicted in Figure 8(b). Gradual reduction was captured until about 180mm from SG1 where the gauges commenced to diverge. This indicates that cracks started to generate along the bonding area after more than 5 million cycles.



The repeated test of the second fatigue test (AF2-R) was run for 4 million cycles without any debonding initiation or degradation in the bonding zone observed. The test was then stopped and failed by static test. The strain gauge readings present a steady trend in most gauges; however, after a million cycle loadings, some gauges exhibited a slight increase in the strain measurement as the number of cycles increased, as shown in Figure 9(a). When the behaviour of strain gauges was examined along the bond line, it was found that during the first million cycles, the peak micro-strain of most gauges had a divergent trend until 180mm. The divergence behaviour remained constant and levelled off when approaching the farthest distance of strain gauge, SG6. This is because the applied tensile fatigue load generates shear stresses between the bonding layers, which decrease when moving from strain gauges SG2 and SG6. These shear stresses resist the tendency of debonding and as a result cause a reduction in the micro-strain readings. Figure 9(b) shows the peak micro-strain measurements in relation to the distances along the bond line.

3.3 *Mode of failure*

The experimental tests showed that the mode of failure of all static and fatigue tests occurred in the concrete cover with full separation of the patch anchors from the concrete surface. No slippage of the laminate was observed between the two fabric sheets, which confirmed that good bonding was achieved. Figure 10 depicts the mode of failure of the anchorage model.

4 CONCLUSION

In summary, the experimental investigation of anchored model indicate that the use of anchorage devices of CFRP laminate with two fabric sheets provides additional strength to RC structures. When these anchorage strengthening systems were examined under fatigue loading, the results showed that a maximum stress ratio of 70% of the ultimate static failure had a low fatigue life and failure occurred before 2 million cycles. However, when the anchored specimen was subjected to a maximum stress of 60% of the static strength capacity, no fatigue degradation occurred up to 5.6 million cycles. The results indicated that there is no fatigue issues with externally-bonded FRP anchorage systems when the maximum stress ratio is 60% and below. In addition, further research needs to be conducted to validate the results and to enable design guidelines to be proposed for practical engineers

Mathematical analysis of an innovative method for strengthening concrete beams using pre-stressed FRP laminates

S.R. Atashipour, J. Yang, R. Haghani & M. Al-Emrani
Chalmers University of Technology, Gothenburg, Sweden

ABSTRACT: This paper presents mathematical modeling and analytical solution of an innovative method for strengthening of flexural concrete members using pre-stressed carbon fiber reinforced polymer (CFRP) laminates without the need for mechanical anchorage. Bonding CFRP laminate in a pre-stressed state to the tensile part of flexural members is an effective method to improve their bending performance. The elimination of end anchors is found to be possible by using an innovative pre-stressing device capable of creating a step-wise decreasing profile of pre-stressing force towards each end of the CFRP laminate. The proposed innovative pre-stressing device consists of a multiple of aluminum tabs interconnected by steel bars having different diameters. The pre-stressing force is applied to the end tab and evenly distributed among all tabs. Each tab is mechanically fastened to the CFRP laminate. Two 10-mm-thick GFRP plates are used as force-transfer medium to connect the pre-stressing device to the CFRP laminate. An efficient mathematical modeling of the innovative system is developed and corresponding governing equations are solved analytically. A comparative study is conducted between the stress and displacement results of the step-wise pre-stressing method and that of conventional methods where pre-stressing is performed in one step.

1 INTRODUCTION

Fiber reinforced polymer (FRP) composite materials have been increasing used in the retrofitting of civil infrastructure since the research efforts started in the mid-1970s. The range of applications, at the present, has expanded from concrete members to masonry, timber, and iron structures (Bakis et al., 2002). When it comes to flexural strengthening of reinforced concrete (RC) structures, using bonded carbon fiber reinforced polymer (CFRP) laminates as the externally bonded reinforcement (EBR) has become a common technique (Meier, 1995). Compared to previously used steel plates, CFRP composites offer advantages such as light-weight, superior tensile strength and corrosion resistance.

A major drawback of bonded FRP laminates is debonding, i.e. separation of the strengthening laminate from the structure due to high interfacial stresses at stress raisers such as intermediate cracks or ends of the laminate. To utilize the CFRP laminates more efficiently, it is suggested to pre-stress them before bonding to concrete members (Meier, 1995; El-Hacha et al., 2001). In case of flexural strengthening of RC members, using pre-stressing in EBR instead of passive EBR offers the following benefits:

– Significant increase of ultimate load bearing capacity;
– provide active strengthening in terms of carrying a portion of the self-weigh in addition to the live load;
– Further improve the serviceability performance by enhancing the bending stiffness and delaying the onset of cracks;
– Enhance the durability of cracked RC members by reducing the width of existing cracks and delaying the formation of new cracks;
– Increasing the utilization ratio of the CFRP material, since introducing the pre-stress either changes the failure mode from premature debonding of CFRP due to intermediate cracks to the tensile rupture of the laminate or delays the debonding.

The major challenge of using pre-stressed CFRP is the need for anchorage at the ends of CFRP laminates. High shear stress, due to so called shear lag effect, would develop—at the moment of pretension release—in the bond line between the CFRP laminate and the concrete substrate at the end zones (Al-Emrani and Kliger 2006, Haghani et al., 2009). Without end anchorage, immediate shear failure of concrete substrate would occur and consequently the debonding of the CFRP laminate. Previous study by (Meier, 1995) indicated that without end anchorage the CFRP laminate may be debonded from the con-

crete substrate at a pre-stressing levels as low as 5% of the ultimate strength of CFRP. A case study of interfacial shear stress analysis based on the closed solution developed by Al-Emrani and Kliger (2006) showed that the typical anchorage length of bonded CFRP laminates can be as short as 50 mm. The same equations showed that upon removing an 80-kN-prestressing force, interfacial shear stress of about 94 MPa would be built up at the end of the laminate. Therefore, in the conventional pre-stressing technique the mechanical end anchorage is necessary to avoid premature debonding by transferring the peak shear stress from bond line into the concrete beam. The most commonly used mechanical anchor system is composed of two steel plates installed on the concrete with help of bolt fasteners, clamping the CFRP laminate before the pre-stressing force is released.

There are, however, some shortcomings associated with using mechanical anchors. Doubts about the long-term performance of such anchors, the need for further modification of the concrete element to fit the steel plates and inspect-ability of anchors are among the most important challenges. To resolve the problem, developing non-metallic anchors was studied by Kim et al. (2008). However, non-metallic anchors have not yet been commercialized and are not available on market.

Researchers in EMPA (Stöcklin and Meier, 2001; Meier and Stöcklin, 2006) first put forward a pre-stressing method—the gradient anchorage method—without the need for mechanical anchorage system. This method introduces a gradually decreasing pre-stressing force toward the ends of CFRP reinforcement, which is realized by releasing the pretension force using a computer controlled system in a number of segments. In each segment, the adhesive in the bond line is fast cured by means of elevating the temperature in the adhesive layer. The reduscton continues until the pre-stressing force is reduced to zero at the end of the laminate. The major benefit of gradient anchorage is the aesthetic and durability which is comparable with regular passive CFRP strengthening. Even though this method eliminates the need for mechanical anchors, it is too complicated to be realized in practice as it involves use of a sophisticated electro mechanical system to make the curing and gradual force release possible.

2 DEVELOPMENT OF AN INNOVATIVE SOLUTION

Setting the same goal of eliminating the end anchorage, an innovative stepwise pre-stressing method and a device were proposed and developed by Haghani et al. (2015). This pre-stressing method is the focus of this paper. Different from EMPA's approach, the stepwise pre-stressing method is able to—within one jacking action—achieve a stepwise decreasing profile of pre-stressing force in the CFRP laminate towards the ends (Haghani and Al-Emrani 2016). Previous experimental verification (Yang et al., 2017) showed that the application of this new pre-stressing method can realize the 'self-anchorage' of CFRP laminate at pre-stressing levels equivalent to 27% of ultimate tensile strength without using end anchors, and the ultimate CFRP laminate utilization ratio of ca. 80% before the separation failure of CFRP reinforcement.

The pre-stressing device, shown in Figure 1, consists of eight aluminum tabs that are inter-connected with a series of springs—steel bars with different designed diameters. The tabs are connected to the CFRP laminates via a medium (GFRP plate with dimensions of 1250 mm x 80 mm x 10 mm). The GFRP plates were bonded to CFRP laminate using a specially designed epoxy adhesive. The GFRP plate has embedded nuts that enables a bolted connection to the device.

The function of the pre-stressing device is to evenly distribute the total amount of pre-stressing force through these tabs to the CFRP laminate. The pretension force transferred from the pre-stressing device to the CFRP plate in each segment is dependent on the ratio of cross-sectional stiffness between the CFRP and springs (steel bars). Considering the increasing diameter of steel bars towards the CFRP ends, the pre-stressing force transferred to the CFRP is decreasing gradually segment by segment toward the end. Aided by this mechanism, it is possible —with merely one jacking action—distribute the pre-stressing force into CFRP laminate in a step-wise manner decreasing the force profile towards the CFRP ends.

The pre-stressing device would be maintained for 24 hours to assure that the epoxy develops sufficient strength to transfer the interfacial stresses to concrete beam. The pre-stressing force would then be released and the device removed. Upon the release of the pre-stressing device (aluminum tabs and steel bars), the pre-stressing force in CFRP would be transferred to concrete through cured adhesive layer. The magnitude of shear stress developed along the bond line, in this manner, is directly related to the gradient of axial pretension force in the CFRP laminate. Considering the gradient of the decreasing pre-stressing force within 1250 mm anchorage length, the developed shear and peeling stress were controlled to such a level that the adhesive bond line and adjacent concrete had sufficient strength to withstand the interfacial stress. Previous numerical and experimental studies proved that it was possible to reduce the shear and peeling stresses in the bond line below 1.0 and 0.2 MPa, respectively, given a pre-stressing force of 80 kN distributed by ten steps (tabs) (Haghani et al., 2015).

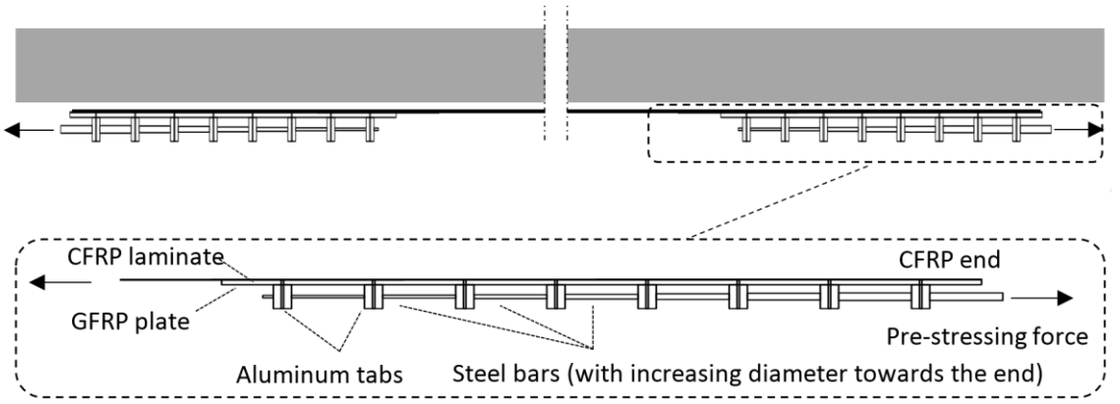

Figure 1. Configuration of pre-stressing device connected to CFRP laminate via GFRP plate.

3 MATHEMATICAL MODELING OF THE INNOVATIVE METHOD

Mathematical simulation of the strengthened concrete beam with composite pre-stressing method is here divided into two distinguished steps: the first, static displacement and stress distribution within the CFRP and GFRP layers as well as the shear stress in the adhesive layer in between them; and the second, the static response of the equilibrium state of the adhesive layer bonding the strengthening laminate to the beam.

3.1 *Step 1: Tension in the strengthening CFRP-GFRP layer*

Consider a thin layer of CFRP of length L, having two GFRP layers of length L_0 bonded to its ends. Due to symmetry of the system with respect to its middle point, the origin of the coordinates system is assumed in the middle and only half of it is considered. N number of local loads will be applied into the GFRP through N discretized points (i.e. where the pre-stressing device is connected to the GFRP). Therefore, N+2 distinguished parts (i = 1,2,…, N+1) will be assumed for each half-length as follows

Only CFRP part ($i=1$):

$$0 \le x \le L/2 - L_0$$

CFRP bonded to GFRP ($i = 2,3,...,N+2$):

Distance between n-th anchorage point to the next ($0 \le n \le N$); $n+2 \equiv i$: (1)

$$L/2 - L_0 + \frac{n}{N+1} L_0 \le x \le L/2 - L_0 + \frac{n+1}{N+1} L_0$$

It should be clarified that n = 0, N indicate the start point of GFRP bonded to CFRP, and the end point near the beam end location, respectively. Clearly, for i = 1, the displacement function:

$$\delta_{c,1} = \frac{P_0}{EA_c} x, \quad 0 \le x \le L/2 - L_0 \tag{2}$$

where P_0 is the total axial load applied to the pre-stressing layer before bonding to the beam, and EA_c is the axial stiffness of the CFRP laminate.

To analyze the portions corresponding to the CFRP-bounded-to-GFRP parts (i.e. i = 2,3,…,N+2), an infinitesimal differential element is considered, as shown in Figure 2. From equilibrium equations of each differential part we have

$$\frac{\mathrm{d}P_{g,i}}{\mathrm{d}x} = B_a \tau_i \tag{3.1}$$

$$\frac{\mathrm{d}P_{c,i}}{\mathrm{d}x} = -B_a \tau_i \tag{3.2}$$

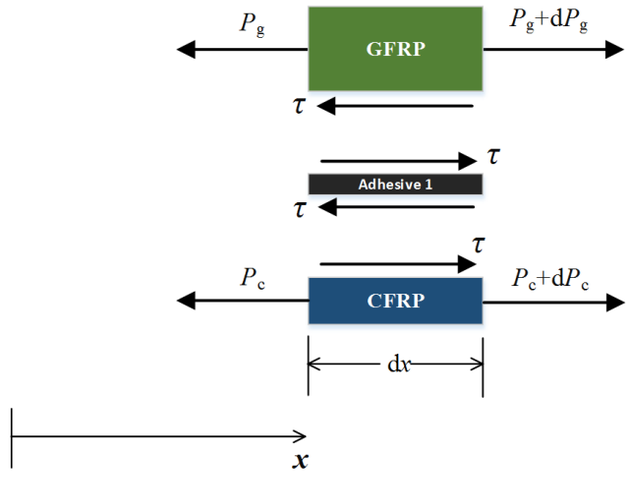

Figure 2. Differential element of GFRP-bonded-to-CFRP parts.

Using the definition of the shear strain in the i-th part of the thin adhesive layer, one can write

$$\tau_i = \frac{G_a}{t_a}(\delta_{g,i} - \delta_{c,i}) \tag{4}$$

where G_a and t_a are the shear modulus and thickness of the adhesive layer between the GFRP and CFRP (we nominate it here adhesive type-1), respectively. Also, $\delta_{g,i}$ indicates the axial displacement of the GFRP part in the i-th part at the x level, whereas $\delta_{c,i}$ is that of the CFRP part. Indeed, the differentiation of the aforementioned displacement functions are expressed as

$$\frac{\mathrm{d}\delta_{g,i}}{\mathrm{d}x} = \frac{P_{g,i}}{EA_g} \tag{5.1}$$

$$\frac{\mathrm{d}\delta_{c,i}}{\mathrm{d}x} = \frac{P_{c,i}}{EA_c} \tag{5.2}$$

in which $P_{g,i}$ and $P_{c,i}$ are respectively the axial load in the i-th part of the GFRP and CFRP. Apparently, EA_g and EA_c are the axial stiffness of the GFRP and CFRP parts, respectively. Differentiating Eq. (5) with respect to x and substituting Eqs. (5.1,2) into it yields

$$\frac{\mathrm{d}\tau_i}{\mathrm{d}x} = \frac{G_a}{t_a}\left(\frac{P_{g,i}}{EA_g} - \frac{P_{c,i}}{EA_c}\right) \tag{6}$$

Differentiating Eq. (6) with respect to x and replacing Eqs. (3.1,2) into it, leads to a differential equation in terms of the shear stress as follows

$$\frac{\mathrm{d}^2\tau_i}{\mathrm{d}x^2} - \omega^2\tau_i = 0 \tag{7}$$

where

$$\omega = \sqrt{\frac{B_a G_a}{t_a}\left(\frac{1}{EA_g} + \frac{1}{EA_c}\right)} \tag{8}$$

The solution of Eq. (7) can be represented as

$$\tau_i = c_{1,i}\cosh(\omega x) + c_{2,i}\sinh(\omega x) \tag{9}$$

By substitution of the obtained solution from Eq. (9) into Eqs. (3.1,2) and integrating the results, the axial loads in the GFRP and CFRP parts are determined as follows

$$P_{g,i} = \frac{B_a}{\omega}\left[c_{1,i}\sinh(\omega x) + c_{2,i}\cosh(\omega x)\right] + c_{3,i} \tag{10.1}$$

$$P_{c,i} = -\frac{B_a}{\omega}\left[c_{1,i}\sinh(\omega x) + c_{2,i}\cosh(\omega x)\right] + c_{4,i} \tag{10.2}$$

The constants $c_{3,i}$ and $c_{4,i}$ are not independent of each other, and their relationship can be obtained, after substituting Eqs. (9) and (10.1,2) into Eq. (6) in the form

$$c_{4,i} = \frac{EA_c}{EA_g}c_{3,i} \tag{11}$$

Now, we determine the mathematical functions for the displacements in CFRP and GFRP parts by substituting Eqs. (10.1,2) into Eqs. (5.1,2) and integrating the results, as follows

$$\delta_{g,i} = \frac{B_a}{EA_g\omega^2}\left[c_{1,i}\cosh(\omega x) + c_{2,i}\sinh(\omega x)\right] + \frac{c_{3,i}}{EA_g}x + c_{5,i} \tag{12.1}$$

$$\delta_{c,i} = -\frac{B_a}{EA_c\omega^2}\left[c_{1,i}\cosh(\omega x) + c_{2,i}\sinh(\omega x)\right] + \frac{c_{4,i}}{EA_c}x + c_{6,i} \tag{12.2}$$

Substitution of Eqs. (9) and (12.1,2) into Eq. (4) yields

$$c_{6,i} = c_{5,i} \tag{13}$$

It is evident that for each portion of the GFRP-bonded-to-CFRP, as described in Eq. (1), four boundary conditions are required to be satisfied to determine the four independent constants: $c_{1,i}$, $c_{2,i}$, $c_{3,i}$ and $c_{5,i}$. Assuming symmetry of the beam with respect to its middle point, it is expected that the axial displacement at $x = 0$ to be zero. Thus, using Eq. (2) and considering the free edge of the GFRP, at the location of bonding to CFRP, the two boundary conditions at this location are represented as

$$\text{at } x = L/2 - L_0 : \begin{cases} \delta_{c,2} = \dfrac{P_0(L/2 - L_0)}{EA_c} \\ P_{g,2} = 0 \end{cases} \tag{14}$$

The first part of Eq. (14) relies on the continuity condition in the displacement in the CFRP laminate before and after the edge of GFRP layer.

At the end point of the pre-stressed laminate, the axial load would be zero in both GFRP and CFRP; i.e.,

$$\text{at } x = L/2 : \begin{cases} P_{c,N+2} = 0 \\ P_{g,N+2} = 0 \end{cases} \tag{15}$$

Also, the following four continuity conditions must be satisfied at any location of the N tab anchorages:

$$\text{at } x = X_i : \begin{cases} P_{g,i-1} - P_{g,i} = P_0/N \\ \delta_{g,i-1} - \delta_{g,i} = 0 \\ P_{c,i-1} - P_{c,i} = 0 \\ \delta_{c,i-1} - \delta_{c,i} = 0 \end{cases} \tag{16}$$

$(i = 2, 3, ..., N+1)$

Obviously, X_i indicates the horizontal coordinate of the i-th tab location, and is expressed as

$$X_i = L/2 - L_0 + \frac{i-1}{N+1}L_0 \tag{17}$$

Eqs. (15), (16) and (17) gives a set of 4×(N+1) algebraic equations in terms of the same number of constant coefficients.

The outcome of the described analytical solution will be implemented into the second step to determine the stress distribution as well as displacements in the beam, adhesive layer and the pre-stressing composite layer in an equilibrium state.

3.2 *Step 2: Bonding the prestressing composite layer to the concrete beam*

Assume that the pre-tensioned composite laminate is bonded to the concrete beam. In an equilibrium state, the beam will be under compression and a negative

bending moment (i.e. the bottom surface of the beam under compression). The pre-stressing layer will lose some of its tensile stress. To analyze this step, a differential element of the beam together with the composite layer and the adhesive in between is considered, as illustrated in Figure 3.

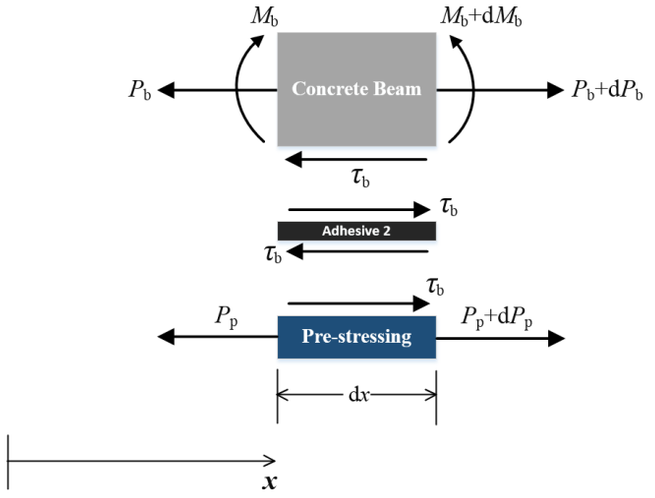

Figure 3. A differential element of the concrete beam, strengthened with the composite pre-stressing layer.

From the static equilibrium state of each part of the differential element shown in Fig. 3, the following equations are obtained

$$\frac{\mathrm{d}P_{b,i}}{\mathrm{d}x} = B_A \tau_{b,i} \tag{18.1}$$

$$\frac{\mathrm{d}P_{p,i}}{\mathrm{d}x} = -B_A \tau_{b,i} \tag{18.2}$$

$$\frac{\mathrm{d}M_{b,i}}{\mathrm{d}x} = Y_c B_A \tau_{b,i} \tag{18.3}$$

where $\tau_{b,i}$ is the shear stress in the i-th portion of the beam after installing the pre-stressing layer; $M_{b,i}$ and $P_{b,i}$ are the bending moment and axial load appears in the i-th part of the beam, in an equilibrium situation after installation of the pre-stressing layer; $P_{p,i}$ is the final equilibrium value of the axial load in the i-th part of the pre-stressing layer after losing some of its initial tensile load. Also, B_A is the width of the adhesive type-2 which is used for bonding the pre-stressing layer to the concrete beam, and Y_c is the transverse distance between the beam neutral-axis to the bottom surface, where the pre-stressing layer is glued. Using the definition of the shear strain in the adhesive layer, the following expression is obtained for the shear stress function in that layer:

$$\tau_{b,i} = \frac{G_A}{t_A}(\delta_{p,i} - \delta_{b,i}) \tag{19}$$

in which G_A and t_A are the shear modulus and thickness of the adhesive type-2.

It is evident that the pre-stressing layer will lose a part of its initial axial stretching load after it is bonded to the beam. The loss in the pre-stressing axial load, in the i-th part, is represented as

$$\Delta P_p = P_{0,i} - P_{p,i} \tag{20}$$

where $P_{0,i}$ in the function of the initial pre-stressing load before bonding to the beam, at the i-th part; and $P_{p,i}$ is the final axial load after installing the pre-stressing layer to the beam. Therefore, the axial strain of the pre-stressing layer in the second stage can be expressed as

$$\frac{\mathrm{d}\delta_{p,i}}{\mathrm{d}x} = \frac{P_{0,i} - P_{p,i}}{EA_{p,i}} \tag{21}$$

in which $EA_{p,i}$ is the axial stiffness of the pre-stressing layer at the i-th part. The strain at the bottom surface of the concrete beam, corresponding to the second stage, due to the bending action and the compression, can be represented as

$$\frac{\mathrm{d}\delta_{b,i}}{\mathrm{d}x} = \frac{-P_{b,i}}{EA_b} + \frac{-M_{b,i}Y_c}{EI_b} \tag{22}$$

where EA_b and EI_b are the axial and bending stiffness of the beam, respectively. Now, we differentiate Eq. (19) and substitute Eqs. (21) and (22) into it and obtain:

$$\frac{\mathrm{d}\tau_{b,i}}{\mathrm{d}x} = \frac{G_A}{t_A}\left(\frac{P_{0,i}}{EA_{p,i}} - \frac{P_{p,i}}{EA_{p,i}} + \frac{P_{b,i}}{EA_b} + \frac{M_{b,i}Y_c}{EI_b}\right) \tag{23}$$

Differentiating Eq. (23) one more time and inserting Eqs. (18.1,2,3) into it will result in an uncoupled differential equation in terms of the adhesive shear stress (adhesive type-2) in the form

$$\frac{\mathrm{d}^2\tau_{b,i}}{\mathrm{d}x^2} - \Omega_i^2 \tau_{b,i} = \lambda_i \frac{\mathrm{d}}{\mathrm{d}x} P_{0,i} \tag{24}$$

where

$$\Omega_i = \sqrt{\frac{B_A G_A}{t_A}\left(\frac{1}{EA_{p,i}} + \frac{1}{EA_b} + \frac{Y_c^2}{EI_b}\right)}$$
$$\lambda_i = \frac{G_A}{t_A EA_{p,i}} \tag{25}$$

Similar to the first step, here we consider N+2 separate regions for each half of the strengthened beam. The first region (i = 1) is related to the part of the beam which is strengthened with the CFRP; and other regions (i = 2,3,…,N+2) indicate N+1 distinguished regions in the strengthened beam with CFRP-bonded-to-GFRP layer, from the inner edge of the GFRP till the end of that, in between the N tab connection points. For the case i = 1, we have:

$$P_{0,i} = P_0 = \text{const.} \tag{26}$$

Therefore, Eq. (24) may be rewritten, for this case, as follows

$$\frac{\mathrm{d}^2\tau_{b,1}}{\mathrm{d}x^2}-\Omega_1^2\tau_{b,1}=0 \tag{27}$$

where

$$\Omega_1=\sqrt{\frac{B_A G_A}{t_A}\left(\frac{1}{EA_c}+\frac{1}{EA_b}+\frac{Y_c^2}{EI_b}\right)} \tag{28}$$

The solution of Eq. (27) is represented in the form

$$\tau_{b,1}=d_{1,1}\cosh(\Omega_1 x)+d_{2,1}\sinh(\Omega_1 x) \tag{29}$$

Substituting Eq. (29) into Eqs. (18.1-3) and integrating the results yield

$$P_{b,1}=\frac{B_A}{\Omega_1}\left[d_{1,1}\sinh(\Omega_1 x)+d_{2,1}\cosh(\Omega_1 x)\right]+d_{3,1} \tag{30.1}$$

$$P_{p,1}=-\frac{B_A}{\Omega_1}\left[d_{1,1}\sinh(\Omega_1 x)+d_{2,1}\cosh(\Omega_1 x)\right]+d_{4,1} \tag{30.2}$$

$$M_{b,1}=\frac{Y_c B_A}{\Omega_1}\left[d_{1,1}\sinh(\Omega_1 x)+d_{2,1}\cosh(\Omega_1 x)\right]+d_{5,1} \tag{30.3}$$

Only two of the constant coefficients $d_{3,1}$, $d_{4,1}$ and $d_{5,1}$ are independent. Therefore, by substituting Eqs. (26), (29) and (30.1-3) into Eq. (23), the following relationship is obtained between the aforementioned constants:

$$d_{5,1}=\frac{EI_b}{Y_c}\left(-\frac{1}{EA_b}d_{3,1}+\frac{1}{EA_c}d_{4,1}-\frac{P_0}{EA_c}\right) \tag{31}$$

Now, we substitute Eqs. (30.1-3) into Eqs. (21) and (22), and integrating the results and obtain:

$$\begin{aligned}\delta_{p,1}=&\frac{B_A}{EA_c\Omega_1^2}\left[d_{1,1}\cosh(\Omega_1 x)+d_{2,1}\sinh(\Omega_1 x)\right]\\&-\frac{1}{EA_c}d_{4,1}x+d_{6,1}+\frac{P_0}{EA_c}x\end{aligned} \tag{32.1}$$

$$\begin{aligned}\delta_{b,1}=&-\frac{B_A}{\Omega_1^2}\left(\frac{1}{EA_b}+\frac{Y_c^2}{EI_b}\right)\left[d_{1,1}\cosh(\Omega_1 x)+d_{2,1}\sinh(\Omega_1 x)\right]\\&-\frac{1}{EA_b}d_{3,1}x-\frac{Y_c}{EI_b}d_{5,1}+d_{7,1}\end{aligned} \tag{32.1}$$

It should be pointed out that Eqs. (32.1,2) rely on the fact that $EA_{p,1} = EA_c$. Easily, it could be shown, by substituting Eqs. (29) and (32.1,2) into Eq. (19), that:

$$d_{7,1}=d_{6,1} \tag{33}$$

Now, we develop the analytical solution for the cases i = 2,3,…,N+2. To this end, we obtain the complete solution of the inhomogeneous Eq. (24) by inserting the function of the axial load in the stretched composite layer from Eq. (10.2) in the first stage. Consequently, for the cases i = 2,3,…,N+2 we obtain:

$$\begin{aligned}\tau_{b,i}=&\frac{\lambda_i B_a}{\Omega_i^2-\omega^2}\left[c_{1,i}\cosh(\omega x)+c_{2,i}\sinh(\omega x)\right]\\&+d_{1,i}\cosh(\Omega_i x)+d_{2,i}\sinh(\Omega_i x)\end{aligned} \tag{34}$$

where

$$\Omega_i=\sqrt{\frac{B_A G_A}{t_A}\left(\frac{1}{EA_g+EA_c}+\frac{1}{EA_b}+\frac{Y_c^2}{EI_b}\right)},\qquad \lambda_i=\frac{G_A}{t_A(EA_g+EA_c)},\qquad (i=2,3,...,N+2) \tag{35}$$

and ω is given by Eq. (8). Substituting Eq. (34) into Eqs. (18.1-3) and integrating the results lead to

$$\begin{aligned}P_{b,i}=&\frac{\lambda_i B_a B_A}{(\Omega_i^2-\omega^2)\omega}\left[c_{1,i}\sinh(\omega x)+c_{2,i}\cosh(\omega x)\right]\\&+\frac{B_A}{\Omega_i}\left[d_{1,i}\sinh(\Omega_i x)+d_{2,i}\cosh(\Omega_i x)\right]+d_{3,i}\end{aligned} \tag{36.1}$$

$$\begin{aligned}P_{p,i}=&-\frac{\lambda_i B_a B_A}{(\Omega_i^2-\omega^2)\omega}\left[c_{1,i}\sinh(\omega x)+c_{2,i}\cosh(\omega x)\right]\\&-\frac{B_A}{\Omega_i}\left[d_{1,i}\sinh(\Omega_i x)+d_{2,i}\cosh(\Omega_i x)\right]+d_{4,i}\end{aligned} \tag{36.2}$$

$$\begin{aligned}M_{b,i}=&\frac{\lambda_i B_a B_A Y_c}{(\Omega_i^2-\omega^2)\omega}\left[c_{1,i}\sinh(\omega x)+c_{2,i}\cosh(\omega x)\right]\\&+\frac{B_A Y_c}{\Omega_i}\left[d_{1,i}\sinh(\Omega_i x)+d_{2,i}\cosh(\Omega_i x)\right]+d_{5,i}\end{aligned} \tag{36.3}$$

In a similar manner, we identify relationship between the three coefficients d3,i, d4,i and d5,i though substituting Eqs. (36.1-3) into Eq. (23) and obtain

$$d_{5,i}=\frac{EI_b}{Y_c}\left(-\frac{1}{EA_b}d_{3,1}+\frac{1}{EA_g+EA_c}d_{4,i}-\frac{EA_c c_{3,i}}{EA_g(EA_g+EA_c)}\right) \tag{37}$$

The displacement functions are determined by substituting Eqs. (36.1-3) into Eqs. (21) and (22) and integrating the results, as follows

$$\begin{aligned}\delta_{p,i}=&\\&\frac{1}{EA_c+EA_g}\left\{\frac{B_a}{\omega^2}\left(\frac{\lambda_i B_A}{\Omega_i^2-\omega^2}-1\right)\left[c_{1,i}\cosh(\omega x)+c_{2,i}\sinh(\omega x)\right]\right.\\&\left.+\frac{EA_c}{EA_g}c_{3,i}+\frac{B_A}{\Omega_i^2}\left[d_{1,i}\cosh(\Omega_i x)+d_{2,i}\sinh(\Omega_i x)\right]-d_{4,i}x\right\}+d_{6,i}\end{aligned} \tag{38.1}$$

$$\delta_{b,i} =$$
$$-\frac{\lambda_i B_a B_A}{(\Omega_i^2-\omega^2)\omega^2}\left(\frac{1}{EA_b}+\frac{Y_c^2}{EI_b}\right)\left[c_{1,i}\cosh(\omega x)+c_{2,i}\sinh(\omega x)\right]$$
$$-\frac{B_A}{\Omega_i^2}\left(\frac{1}{EA_b}+\frac{Y_c^2}{EI_b}\right)\left[d_{1,i}\cosh(\Omega_i x)+d_{2,i}\sinh(\Omega_i x)\right]$$
$$-\frac{1}{EA_b}d_{3,i}x-\frac{Y_c}{EI_b}d_{5,i}x+d_{7,i} \qquad (38.2)$$

Substituting Eqs. (38.1,2) into Eq. (19) indicates that

$$d_{7,i}=d_{6,i} \qquad (39)$$

In the above equations, five independent constant coefficients $d_{1,i}$, $d_{2,i}$, $d_{3,i}$, $d_{4,i}$ and $d_{5,i}$ are to be determined from five boundary conditions for each region. As it was mentioned earlier, assuming N number of tab anchorage points, N+2 number of distinguished regions are considered for the second stage. Therefore, the total number of 5(N+2) boundary and continuity conditions should be established. Considering the symmetry of the strengthened beam, the boundary conditions at the center is set as follows

$$\text{at } x=0: \begin{cases}\delta_{b,1}=0\\ \delta_{p,1}=0\end{cases} \qquad (40)$$

Also, three boundary conditions are to be satisfied at the free end of the strengthened layer and the beam as follows,

$$\text{at } x=L/2: \begin{cases}P_{p,N+2}=0\\ P_{b,N+2}=0\\ M_{b,N+2}=0\end{cases} \qquad (41)$$

At each level of the anchored tabs as well as the level of the interior GFRP start point, the following continuity conditions must be satisfied:

$$\begin{aligned}&P_{b,i-1}-P_{b,i}=0,\\ &\delta_{b,i-1}-\delta_{b,i}=0,\\ &P_{p,i-1}-P_{p,i}=0,\\ &\delta_{p,i-1}-\delta_{p,i}=0, \qquad (i=2,3,...,N+2)\end{aligned} \qquad (42)$$

4 NUMERICAL RESULTS & DISCUSSION

In this section, numerical results of the developed mathematical modelling are presented using a simple programming code in MAPLE. Geometrical dimensions and material properties of the concrete beam, the two types of adhesives, CFRP and GFRP layers are presented in Table 1.

The concrete beam has a rectangular cross section of height 300 mm and width 200 mm. The CFRP composite laminate is stretched through eight tabs, using the innovative device, and totally, it will be subjected to 80 kN initial tensile load before bonding to the concrete beam.

Table 1. Geometric dimensions and material properties of the beam and the strengthening layer's constituents.

Material properties		Geometric properties	
E_g (GPa)	6.2	A_g (mm^2)	80×10
E_c (GPa)	214	A_c (mm^2)	82×1.45
E_b (GPa)	36	A_b (mm^2)	200×300
G_a (GPa)	0.23	t_a (mm)	1.0
		B_a (mm)	80
G_A (GPa)	2.7	t_A (mm)	1.0
		B_A (mm)	82
		Y_c (mm)	150
		L (mm)	3800
		L_0 (mm)	1250

In Figure 4, comparison of axial load distribution in the strengthening layer, in the equilibrium state, is shown between the innovative method and the conventional method with uniform stretching. It should be noted that, in the conventional way of strengthening concrete beams, the composite layer is simply stretched at the ends which results in a uniformly distributed pattern for the axial stress before its installation. It can be seen from Figure 4 that there exists an edge effect; or so-called boundary layer phenomenon at the axial stress. This will cause a high shear stress value at the adhesive layer between the beam and the strengthening layer at the end (i.e. at x = L/2), as shown in Figure 5. Therefore, this would be the origin of failure in the structure under a low value of external load, compared to its real load capacity.

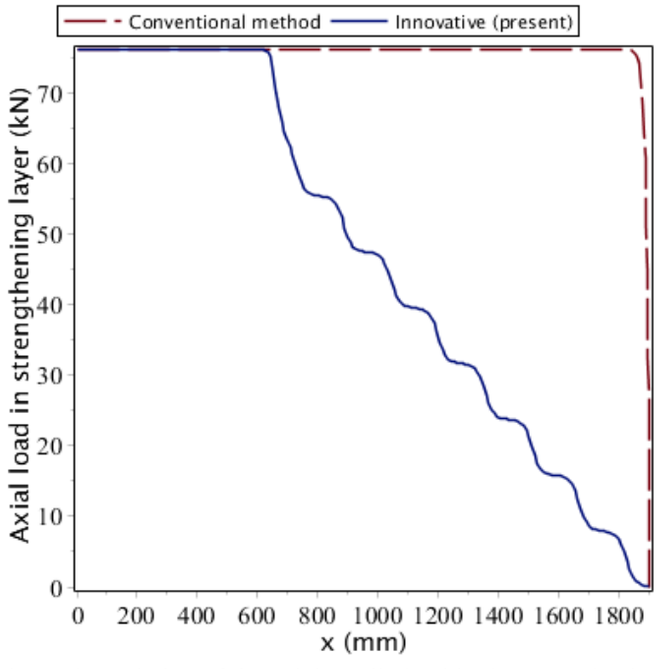

Figure 4. Variation of the axial tensile load in the strengthening layer in an equilibrium state, based on the present innovative and conventional methods.

It can be observed from Figure 4 that, unlike the conventional method of strengthening the concrete beam, the innovative method of strengthening the beam will result in a step-wise increase in the axial load to the maximum value at a location far from the ends. It enables the possibility of self-anchoring of the CFRP laminate to the beam; so, unlike the conventional method, there would be no need for using mechanical end anchors.

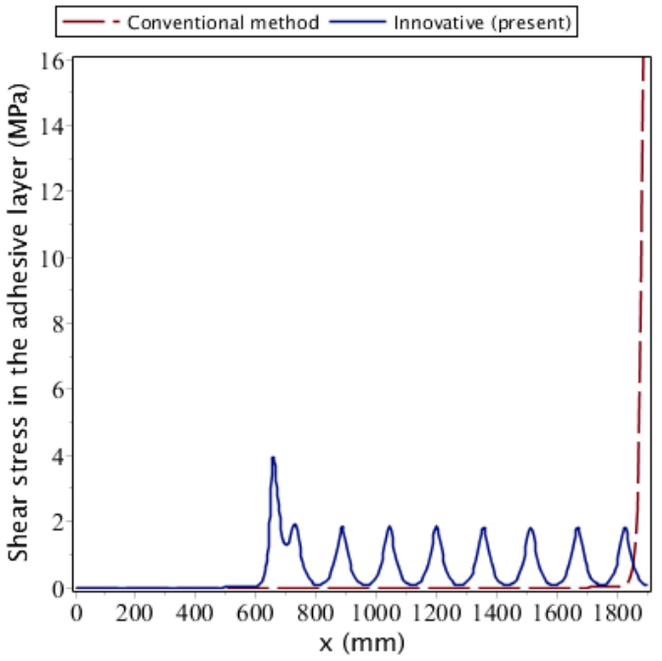

Figure 5. Shear stress distribution in the adhesive layer between the concrete beam and the strengthening layer in an equilibrium state, based on the innovative and conventional methods.

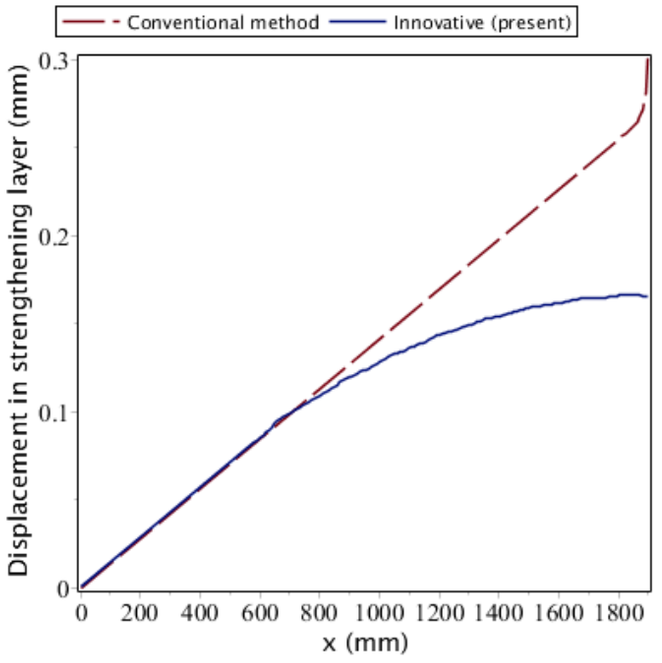

Figure 6. Variation of the axial displacement in the strengthening layer in an equilibrium state, based on the present innovative and conventional methods.

It can be observed from Figure 5 that the maximum shear stress in the adhesive layer, based on the innovative method, is less than ¼ of the corresponding value in the conventional method.

Another remarkable observation that might be drawn from Figure 5 is a peak value of the shear stress at the inner end point of the GFRP. In order to diminish this peak stress value, a tapered end is suggested for the inner end region of the GFRP bonded to the CFRP, instead of a sudden change in the geometry and axial stiffness of the strengthening layer.

Comparison of the axial displacement of the composite strengthening layer, based on the conventional method and the innovative method, are illustrated in Figure 6.

5 CONCLUSIONS

In this paper, a mathematical model and corresponding analytical solution were established for an innovative method to use pre-stressed CFRP laminates for strengthening of concrete beams without the need for mechanical anchorage. The elimination of the end anchors was found to be possible by using the proposed innovative pre-stressing device. Using the new innovative pre-stressing device, a step-wise decreasing profile of pre-stressing force towards each end of the CFRP laminate was obtained. It was observed that the maximum shear stress at the adhesive layer between the concrete beam and the composite strengthening laminate would be decreased significantly to a level which could be taken by the strength of the adhesive layer and the concrete substrate.

ACKNOWLEDGEMENT

The work in the paper is a part of SUREBridge project which has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration. SUREBridge project is co-funded by Funding Partners of the ERA-NET Plus Infravation program.

ABSTRACT: Bonding fibre-reinforced polymers (FRP) to reinforced concrete (RC) members has become a popular means for enhancing load carrying capacity and extending service life of bridge structures. However, there is uncertainty surrounding the long-term durability of flexurally strengthened members. This paper presents work on an experimental program to determine the debonding resistance of FRP-to-concrete interface considering environmental conditions and material durability. Further a mechanics based model that considers the intermediate-crack (IC) debonding behavior at the FRP-concrete interface as both a local and global mechanism along the length of a beam is also presented. The model is shown to be able to accurately predict the load-deflection response of FRP-strengthened beams considering the bond properties at the FRP-to-concrete interface.

1 INTRODUCTION

Externally bonded (EB) FRP as a simple and cost-effective means, has been widely used to strengthen/rehabilitate RC structures deteriorated over time due to exposure to harsh environments and/or increased load demands. To strengthen underperforming RC structures, adhesively bonded steel platewere firstly utilised (Hamoush & Ahmad 1990), however, the corrosion of the steel plating material exposed directly under variety of environmental conditions including wet/dry cycles, thermal cycles, alkaline attack, acid attack and chloride attack has resulted in long-term durability issues (Bertolini et al. 2013). Therefore, fibre-reinforced polymers (FRPs) were introduced to combat the steel corrosion issue. FRP is material that has several advantages compared to steel including its superior corrosion resistance, high tensile strength-to-weight ratio and non-magnetic nature (Teng et al. 2002, Teng et al. 2007). Despite the excellent mechanical and chemical properties, the long-term bond durability is still susceptible to environmental exposure.

Recently, large amount of research has been conducted on short-term and long-term bond durability of external bonded FRP plate to concrete substrate, including wet/dry cycling (Li et al. 2010, Shrestha et al. 2014, Hassan et al. 2015), water consistent immersion (Barger 2000, Pack 2003, Au & Büyüköztürk 2006, Lai et al. 2009, Nishizaki & Kato 2011, Huang & Ye 2013, Shi et al. 2012, Aydin et al. 2014, Shrestha et al. 2014), chemical attack (Mukhopadhyaya et al. 1998, Barger 2000, Homam et al. 2001, Pack 2003, Alfar et al. 2006, Fava et al. 2007, Abbas 2010, Pan et al. 2010, Al-Rousan et al. 2013, Aydin et al. 2014, Hassan et al. 2015, Zhou et al. 2015), thermal cycling (Mukhopadhyaya et al. 1998, Barger 2000, Green et al. 2000, Homam et al. 2001, DohnAlek 2006, Hu et al. 2007, Subramaniam et al. 2007, Colombi et al. 2010, Li et al. 2010, Yun & Wu 2011, Kabir et al. 2016, Shi et al. 2012, Hong et al. 2014) and elevated temperatures (Blontrock 2003, Pack 2003, Wu et al. 2005, Dai et al. 2012, Leone et al. 2009, Klamer et al. 2005, Li et al. 2010, Adelzadeh 2013).

Reviewing the experimental studies has revealed that the environmental conidtion of thermal cycling based on freeze/thaw, moderate temperature and sustained temperature has been studied comprehensively, however, a knowledge gap exsits in the area of cycling under moderate temperature.

A wide range of simulated environmental conditions was also recently summarized by Aydin et al. (2016). Geometric, material and conditioning regime differences in test procedures have been widely explored with the general outcome being that the degradation of joint strength is dependent on the change in shear strength of the adhesive relative to the concrete shear strength with prolonged exposure. Further the maturity of the concrete specimens was also found to effect the performance of the long-term durability test. Specimens exposed to harsh environments when compared to 0 day control

samples experience a significant increase of concrete strength, observed even after as little as 28 days and as long as 20 years (Wood 1992).

The environmental conditions that effect durability of FRP strengthened concrete structures are natural and artificial degrading conditions such as temperature variation, moisture effect, sulphate, and/or acid environments. An extensive experimental program to investigate the durability and debonding resistance of composite based strengthening techniques for deteriorated structures is currently underway. The experimental program considers the following environmental conditions, temperature cycle, wet-dry cycle, salt water/ chloride content, sulphate attack and acid attack.

In this paper the influence of thermal cycling on CFRP strengthened concrete elements is only presented. A total of 27 CFRP plates and sheets strengthened concrete specimens were casted and tested. Three different types of adhesives were applied. The thermal cycling was selected ranged between 10 °C and 40 °C, which is most common average lower-bound and upper-bound daily service temperature can be found on concrete structures.

2 EXPERIMENTAL PROGRAM

2.1 *Materials*

An FRP plate externally strengthened concrete system consists of three important components including FRP plate, adhesive layer and concrete substrate. An FRP plate is bonded to concrete substrate depending on adhesive.

Two FRP systems were used in this study, pultruded plate and wet-layup systems with a dimension of 50 mm (width)* 400 mm (length). The thickness of the pultruded plate is 1.4 mm and for the wet layup sheet, 3 layers were used, each layer has thickness of 0.139 mm. The mechanical properties of CFRP plate and sheet were provided by the supplier which is shown in Table 1.

Table 1:Summary of Mechanical Properties of the CFRP

FRP Type	f_{ut} *(MPa)*	E_{frp} *(GPa)*	ε_{ut} *(%)*
FRP Laminate	2800	160	1.7
FRP Sheets	4300	234	1.8

A total of three types of adhesives were used in this study, including two adhesives for FRP laminate system (high and low viscosity ones) and one adhesive for FRP wet layup systems, the details of the adhesive are found in Table 2.

Table 2: Summary of Adhesives' Properties

Property	*High Viscosity*	*Low Viscosity A*	*Low Viscosity B*
Tensile Modulus	4500 MPa	4500 MPa	1495 MPa
Tensile Strength	33 MPa	30 MPa	32 MPa
Shear Strength	>15 MPa (Concrete Failure)	-	35 MPa
Elongation at Break	1.00 %	0.90 %	4.60 %
Glass Transition Point	62 °C	58 °C	56 °C
CTE	$9*10^{-5}$ per °C	$4.5*10^{-5}$ per °C	-

Note: "-" means information is not available.

The concrete blocks that used for strengthening base were pre-mixed and delivery to the site on the date of pouring. The concrete was pouring into 45 customized plywood moulds which have inner dimensions of 150×150×300 mm. And another 18 concrete cylinders with a diameter of 100mm and height of 200 mm were also casted by the same batch of concrete at the same time. The detail properties of the concrete are given in Table 3 and Table 4.

Table 3: Concrete Mix Design

Component	*Volume*
Cement	300 kg/m3
Water	200 L/m3
Sand	890 kg/m3
14mm Aggregate	865 kg/m3

CT-0	0	0	26.05
CT-3	0	3	26.53
T-3	3	0	25.35

3 TEST PREPARATION

3.1 *Sample Preparations*

The concrete blocks were demould after 24 hours after casting and wrapped with an insulation blanket for 28 days. To ensure proper curing environment, water was sprayed every second day. After 28 days, the concrete blocks were then sent for sandblasting to remove a thin top mortar layer and expose the underlying aggregates to assure a good quality bond. The CFRP plate and sheet were cut into 50 mm (width)*400 mm (length) strips. The surface of the

CFRP plates was gently wiped with sandpaper to remove a thin layer of fibre dust, and it was then cleaned with liquid ethanol, whereas, the CFRP sheets need merely cleaned by liquid ethanol. Before the attachment, an air gun was used to clean the dust and losing parts from the concrete surface, and a layer of release film was glued on the boundary of the bond region to avoid misplacement of adhesive in an unwanted area. The bond area was 50 mm (width)* 220 mm (length) located at the center of the concrete surface, a 40 mm unbonded section was left on the front to prevent the wedge failure. The detail bond scheme is found on Figure 1.

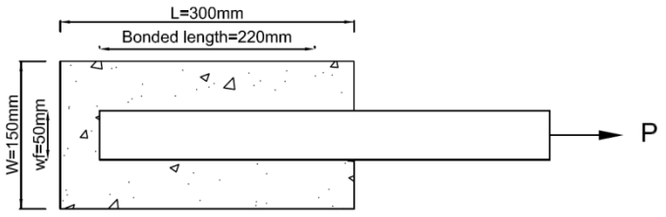

Figure 1: Specimens Details

3.2 *Environmental Conditioning*

A total of 45 samples were scheduled for this experimental investigation, including 9 control samples, 18 aged control samples and 18 conditioning samples. The normal and aged control samples were left out from environmental exposure and kept in an ambient laboratory environment with average 22 °C. The conditioning samples were exposed to temperature cycling between 10 °C to 40 °C inside a temperature controlled chamber with 50 % humidity setting (Figure 2). Each cycle takes 24 hours (12 hours at 10 °C and 12 hours at 40 °C). The conditioned samples were tested after 84 cycles (3 months) and 336 cycles (12 months). At the end of each conditioning duration, the samples which were planned to be tested were removed from the temperature chamber and leave in ambient laboratory condition for 7 days before conducting the pull-out test.
The details for each specimen was listed in Table 5. The the sample ID can be interpreted; the first group letters C stands for control, T stands for temperature cycling, the second group of letter A for low viscosity B, S for high viscosity, W for FPR sheet bonded with low viscosity A sample, the following number are the testing sequence, the third group is stands for the conditioning duration, 0 for control, 3 for 3 months and 12 for 12 months.

Figure 2: Temperature Chamber

3.3 *Test Setup*

The single lap shear test (SLS) was set up horizontally. The Concrete specimen was placed on a metal base. In front of the metal base, a positioning frame was established to ensure the alignment of the specimens with hydraulic actuator and also avoid horizontal movement of the concrete prism. Additionally, an overhead restrain was placed on the rear top of the specimen to prevent the concrete specimens from vertical movement due to pull-out force. Two aluminium plates (50 mm×100 mm) which were applied to prevent CFRP from splitting were attached on both sides of the CFRP on the loaded end. Two LVDTs were set up, one was placed on the rear end of the concrete blocks to monitor the displacement of the concrete, another LVDT was placed on the top of the concrete specimens against an L-shaped metal which is close to the loaded end which was glued on the CFRP plate to measure the CFRP and concrete relative slip. The SLS test performed using a hydraulic actuator which can provide a maximum of 200kN pull-out force. A displacement control program was used for this experiment, a speed rate of 0.2 mm/min was selected. The SLS tests were stopped only the completely interfacial debonding was observed.

4 RESULT AND DISCUSSION

The 0 and 3 months' test results can be found in Table 5, and the specimens designed for 12 months' conditioning are still ongoing.

4.1 *Failure Mode*

Most of the specimens have its failure plane remained at the concrete substrate. A few specimens were found to have failure plane between adhesive

and FRP plate, which is resulting from poor workmanship, so these were excluded from this analysis. The typical failure mode can be observed on Figure 3.

4.2 *Change of Load vs Slip Curve*

When comparing the peak load of the control samples to that of 3 months' aged samples, the obvious increase was found in the aged ones. The increase in peak load for high viscosity, low viscosity A and low viscosity B samples were 13 %, 6 % and 3 % respectively. The increase can be explained by the concrete maturity; the compressive strength of concrete was observed increased over 3 months from 26.05 Mpa to 26.53 Mpa. On the contrary, the debonding load of the speicmens under 84 temperature cycling decreased, the peak loads of all the conditioned specimens were found lower than the 3 m onths' aged samples, however, the low viscosity B and low viscosity A bonded specimens have their peak loads even lower than the 0 months controlled samples. This may indicate that the high Viscosity was potentially working as a p rotective coating that prevents the influence of the thermal cycling from the concrete substrate, whereas, low viscosity B adhesive was found severely deteriorated which may contribute to its lower T_g value (Table 1). The changes of the peak loads are found on Figure 4.

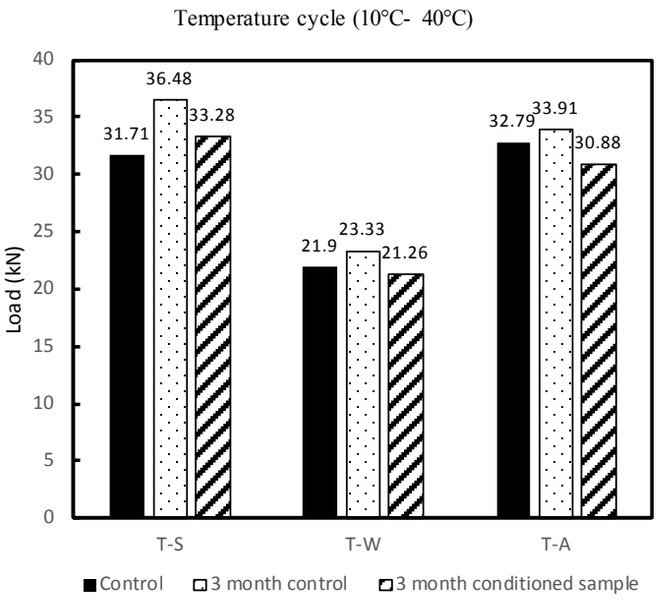

Figure 4:Comparison of Control, Aged and Conditioned Samples

Additionally, the ultimate slip of all the specimens were compared (Figure 5). It can be observed that the ultimate slip for most of the controls experienced no noticeable changes compared to 3 month aged prisms, nevertheless, reduction on the ultimate slip was found on high viscosity and low viscosity B bonded specimens after 3 months' temperature cycling. On contrast, the low viscosity A adhesive bonded wet layup samples had larger slip after temperature cycling.

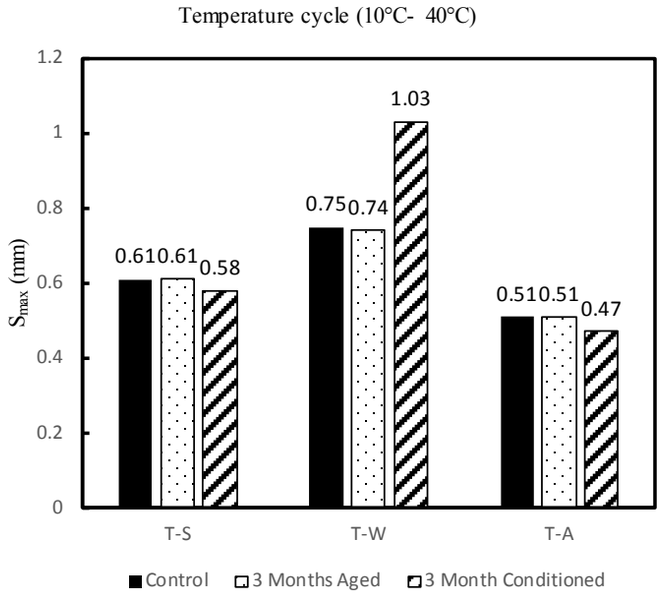

Figure 5:Summary of Ultimate Slip

EXTRACTION OF BOND PROPERTY

A numerical model based on the partial-interaction theory can be applied to extract the bond property of the tested samples. Its accuracy and efficiency has been proved by many previous literatures (Zhang et al. 2016, Haskett et al. 2008, Visintin et al. 2013). In this study, a bilinear bond-slip relationship (Figure 6) was chosen, which is considered as a simple and accuracy model to simulate the shear stress and slip relationship between concrete and FRP (Wu & Yin 2003). The bilinear model can be divided into three sections including ascending, softening and friction components, the governing equation for mentioned components can be presented as the follows:

Ascending $$\tau = \frac{\delta}{\delta_{\max}} \tau_{\max} \quad (1)$$

Softening $$\tau = \left(\frac{\tau_{\max} - \tau_f}{\delta_1 - \delta_{\max}} \right) (\delta_1 - \delta) \quad (2)$$

Friction $$\tau = \tau_f \quad (3)$$

It needs to be noted that this presented mechanics based partial interaction behaviour model can cope with any bond-slip relationship, material property and shape. The fundamental concept of this model has been explained on (Haskett et al. 2008). The correct force and strain value at each stage can be determined by its boundary conditions. In the case, the bonded length is greater than the effective bond length, the boundary condition is $\frac{ds}{dx} = 0$ (Slip strain) and s (Slip) =0 at the free end. If the bonded length is shorter than the effective bond length, the boundary condition becomes $\varepsilon_{frp} = 0$ at the free end.

The input parameters are including mechanical properties of FRP and concrete, and selected bond-slip relationship, in this case, the bilinear relationship (δ_1, δ_2, τ_{max} and τ_f). The main output includes slip, strain, stress and force at a different position along the bonded length, a global force-slip curve simulated by this model shown in Figure 7.

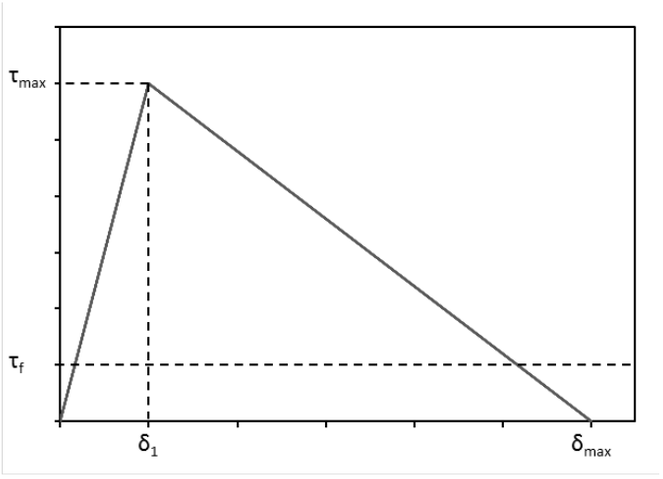

Figure 6:Bilinear Bond slip relationship

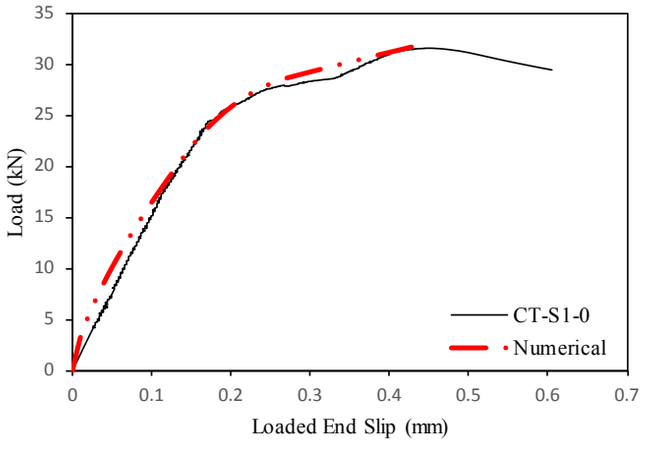

Figure 7:Global Force vs Slip Curve

When comparing the interfacial fractural energy (G_f) of the control samples which is the area under

the stress-slip curve with the aged ones and the aged specimens with conditioned ones, G_f in most of the cases increased, except for the low viscosity B bonded samples which remained almost no changes. However it is obvious that the interfacial energy significantly dropped when comparing aged samples with conditioned ones, 30.1 %, 14.6 % and 15 % for high viscosity, and low viscosity B bonded specimens. The bond-slip properties extracted from experiment results from this study can be found in Table 6.

Table 6: Summary of Bond Slip Property

5 CONCLUSION

To investigate the influence of thermal cycling on externally bonded CFRP plate or sheet to concrete bond, a total of 27 specimens were tested. Based on the results, some conclusion may draw:

1. No obvious change in failure plane thickness was observed.
2. The maximum joint strengths decrease after 3 months' thermal cycling comparing to 3 months' aged samples. The strength of conditioned low viscosity A and low viscosity B adhesives bonded specimens are even lower than the non-aged control samples.
3. Change of ultimate slip was found after the conditioning, for the high viscosity and low viscosity B strengthened specimens, the ultimate slips were reduced. The low viscosity A bonded specimens have their ultimate slip increased significantly.
4. The mechanics based partial interaction model has shown its effectiveness in extracting the bond property of the sample with and without environmental conditioning.
5. The interfacial fractural energy was reduced after 3 months' 10 °C to 40 °C temperature cycling when compared to 3 months' aged specimens.

Developments in External Post Tensioning Strengthening – An update of latest innovations and applications

D. Cecan & P.Y. Souesme
Freyssinet, Sydney, Australia

ABSTRACT: In recent years external post-tensioning technology has been revolutionized to a point where it is commonly considered as the most cost effective, durable, and efficient strengthening solution for civil and industrial structures. This paper describes the latest developments in strengthening by external post-tensioning and reviews main applications on various recent projects with a particular focus on challenging technical aspects.

1 INTRODUCTION

1.1 *Context*

Any civil engineering structure is intended to perform one or more functions which are not necessarily constant over time. The initial functions, i.e. those for which the structure has been built, could potentially be modified either voluntarily because of a desired change of the functions or an extension of the lifetime, or involuntarily because of external actions. Three main causes can lead to the loss of the structure's initial intended purposes:

a) *Aging of the structure* – sudden or gradual loss of resistance (degradation of materials, section losses);
b) *External factors* - overloading, earthquakes, pollution, aggressive environmental factors, vehicle or vessel impact, flood events, soil movements…;
c) *Human related factors* - design errors, poor construction quality, lack of maintenance, act of terrorism …

Considering the current global context of cost control and sustainable development policies there is a constant requirement to increase the service period of these structures. Therefore, the need for modern and effective measures to optimize their service life, while respecting their value, represent a challenging objective for the project. There is currently a diverse range of strengthening and repair techniques available for different scenarios that have proven their reliability. However, the strengthening measures must fulfill a very restrictive set of constraints for each specific case.

1.2 *Strengthening considerations*

The success of the operation essentially relies on the quality of the diagnosis, the clear identification of the purpose of strengthening and its solution. If one or another is not completed appropriately, the operation might lead to a poor cost performance or even new type of structural disorders after few years of works completion.

When a structure has been identified to be understrength, it is important to design an engineering solution that fulfils the following requirements:

a) Structural requirements

- Restore or improve structural integrity;
- Increase the load carrying capacity without excess stress or strain in the structure;
- Avoid a major change in the behavior of the structure as a result of over-strengthening or over-stiffening;
- Improve the in-service performance;
- Avoid increasing the self-weight of the structure;
- Accommodate a variety of existing defects such as cracks, extensive loss of corrosion, etc.;
- Improve the robustness and ductility;
- Provide sufficiently rapid gains in strength;
- Avoid creating maintenance liabilities;
- Improve the resistance to fire events;
- Improve or preserve the architectural value and aesthetics;

– Provide a durable and sustainable solution.

b) Construction requirements

– Create a safe working environment for the workforce on site;
– Minimize disruption to the traffic, canal, road or railway system;
– Perform the works in a minimum time;
– Minimize the impact on the environment (noise, pollution, …)

c) Be cost-effective within the constraints identified above.

1.3 *Main Structural Disorders and Deficiencies Scenarios*

The disorders that affect a structure or one of its elements may be due either to a deterioration of its materials, or to a structural problem.
One of the most common material disorders is corrosion. Unlike reinforced concrete structures, where the corrosion can be detected by simple visual inspection (cracking, peeling, spalling, corroded steels, etc.), in prestressed concrete, once the corrosion reached the tendon, it is often generalized and the disorders are often serious without being visible.

There are several types of structural disorders and its associated capacity deficiencies. The most common ones are listed below:

– Flexural deficiency capacity;
– Shear deficiency capacity;
– Torsional deficiency capacity;
– Disorders due to the concentrated loads;
– Disorders due to lateral thrusts.

Structural failures are usually caused by excessive tension leading to cracking. Therefore, the most appropriate repair and strengthening method is to improve the tensile strength of the structure and its resistance to cracking without causing a significant change in the fundamental structural behavior. Although many of the existing structures have been damaged in the form of extensive cracking, experience shows that these structures could regain substantial capacity with limited degree of strengthening.

In this context, the research in materials and development of strengthening systems opened up many opportunities for structural strengthening by external prestressing. The paper presents below different scenarios and innovative strengthening by external post-tensioning techniques which addressed the requirements and challenges of the structure.

2 EXTERNAL POST-TENSIONING STRENGTHENING SYSTEM

2.1 *General Principles*

Post-tensioning is based around the principal of applying compressive loads into a structure once it has reached an appreciable strength (i.e. concrete has hardened), in order to increase the compression to a level that compensates the tension stresses generated by any service or construction load scenario.

These external loads that induce the structure into compression are developed by means of post-tensioned tendons consisting of one or more 7 wire strands.

Tendon profiling is typically evaluated with respect to bending moments in the structure. The tendons can be straight or profiled depending on the extent, location, and orientation of the loads. It is therefore possible to generate radial to the tendon reactions on the existing structure by changing its profile through a careful arrangement of deviators and anchor blocks, see Figure 1.

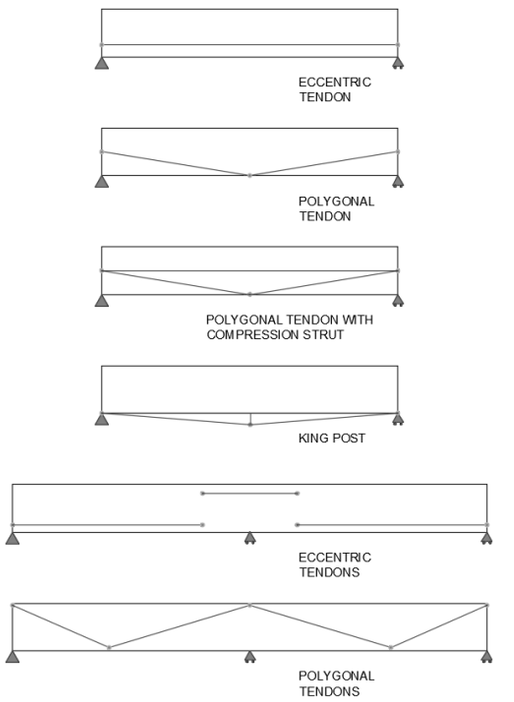

Figure 1: Example of feasible tendon lay-outs with external post tensioning

2.2 *Scope of application*

External post tensioning strengthening is applicable to a wide range of existing constructions provided that the structure has enough capacity to withstand the additional external forces applied by the prestressing for all the load scenarios. The local resistance due to the presence of the anchorages is rarely an issue because it can be overcome by providing an appropriate anchorage design or local strengthening which will enhance the load diffusion. External post-tensioning can be used to improve the performance of any kind of construction or structural

component, be it timber, reinforced or prestressed concrete, steel or composite.

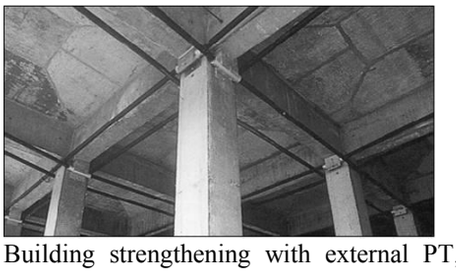

Figure 6: Building strengthening with external PT, Source: Freyssinet

2.3 *Tendons*

Generally, the most relevant type of tendons for strengthening applications with external post-tensioning, consists of greased and sheathed strands (15.7", 1860 MPa, 279 kN breaking load) placed in a HDPE duct injected with cement grout before tensioning of the tendon. This has the advantage of increasing the durability of the prestressing by increasing the number of barriers against corrosion. Also, by making each strand independent from each other, the breakage of one strand doesn't affect the force in the remaining strands allowing for each strand to be replaced if needed.

2.4 *Anchoring to the structure*

Depending on the structural configuration, construction constraints and quantity of strands in each tendon there are several options available for the anchorage detailing.

The most innate solution, whenever possible, would consist of directly anchoring the additional external tendons to elements of the existing structure. For instance, housing the additional tendons anchorage units in new cast-in-situ concrete blocks at deck-ends as shown in the Figure 7, or diaphragms, would ensure a direct compressive force load transfer into the existing structure. However, in practice, this solution is not always the most appropriate due to the amount of works and constraints associated with the preparation of cast-in-situ works, access works behind the girder ends or abutments, and associated traffic disruptions in case of bridge applications.

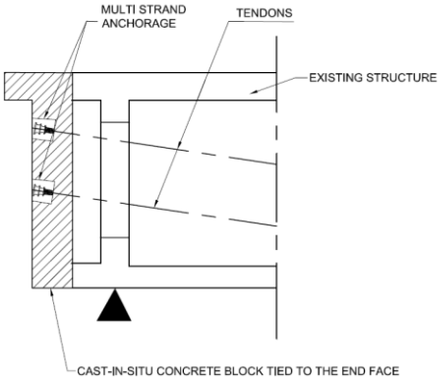

Figure 7: Anchoring the tendons on the face end

In practice, most of the time, the project requirements do not allow the addition of supplementary concrete members, walls to the existing structure. For such cases, the anchorages are housed inside a reinforced concrete or steel "blister" which is connected and secured to the main structure using either standard reinforcing bars working in shear or prestressed bars utilizing friction between the blister and the substrate, see Figure 8.

In the latter case, the prestressing solution offers the most benefit because it provides a confining

force to the anchorage trumplate preventing the spalling and bursting effects, reduced time for concrete surface preparation (light scabbling completed by 3-pin scabblers for concrete grooves instead of deep scabbling), and minimizing the number of core holes in the vertical web wall (lower risk to cut existing reinforcing steel or post-tensioning), particularly when using large diameter stress bars.

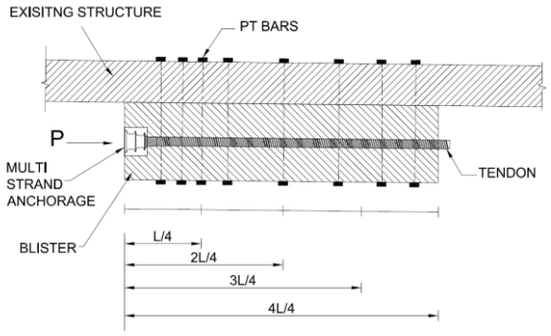

Figure 8: Anchoring the tendons sideways by means of PT bars

2.4.1 *Design - General Requirements*

There are different standards covering the design of shear transfer at the interface between dissimilar materials or two concrete cast at different times.

For instance, AASHTO 2012 Section 5.8.4 "Interface Shear Transfer – Shear Friction" provides a set of rules based on a model which accounts for interface reinforcement, cohesion, and shear-friction resistance contributions for different scenarios:

$$V_{ni} = c.A_{cv} + \mu(A_{vf}.f_y + P_c)$$

V_{ni}	Nominal interface shear resistance
c	Cohesion factor (for corbels, brackets applications: c = 0)
A_{cv}	Area of concrete considered in interface shear transfer
μ	Friction coefficient, depending on the blister / concrete interface
A_{vf}	Area of interface shear reinforcement crossing the shear plan within the area A_{cv}
f_y	Yield stress of reinforcement, design value limited to 413 MPa
P_c	Permanent net compressive force normal to the shear plan

It should also be noted, this design is based on extreme limit state events and it does not specifically cover the service limit states requirements (SLS). For structural elements such as blisters, deviators, etc. anchored to the concrete through a prestressed friction interface, it is prudent to satisfy the absence of tension zone developments (crack opening) at service limit states.

For instance, the French norm NF P 95-104, specifically intended for the design of strengthening by additional prestressing, requires the following conditions to be justified for applications without shear reinforcement:

1) Ultimate Limit State (ULS):

$$\gamma_p.N_p.\frac{\mu}{\gamma_\mu} \geq 1.35.P_m$$

2) Service Limit State (SLS):

$$\gamma_p.N_p.\mu \geq P_m$$

$\gamma_p \leq 1$	Safety coefficient to account for uncertainty related to the transverse prestressing load, commonly used 0.85
γ_μ	Safety coefficient to account for uncertainty related to the friction coefficient, commonly used 1.2
μ	Friction coefficient, depending on the blister / concrete interface
N_p	Total PT Bars residual stressing force
P_m	Tendon prestressing force

Table 1. Commonly used friction coefficient values following NF P 95-104

Designation	Friction coefficient μ
Cast-in-situ concrete blister against old concrete, scabbling up to rebars	1.00
Cast-in-situ concrete blister against old concrete, simply cleaned	0.75
Precast concrete blister with an interposed resin	0.50
Steel blister with a striated face against fresh concrete	0.45
Steel blister with a striated face with an interposed resin or mortar on the old concrete	0.37

For example, in application of the NF P95-104 norm, anchoring a precast blister housing an anchorage of 13 strands (15.7", 1860 MPa) (~2720 kN) would require approximatively 6 x Ø40mm PT bars (1030 MPa).

For cast-in-situ blisters anchored to the existing structure by means of shear reinforcement and prestressed bars the following conditions, as amended by the article No. 501 of ITBTP 1992, should be satisfied:

1) Ultimate Limit State (ULS):

$$(\gamma_p N_p + A_{cv} \times \frac{f_y}{\gamma_s}) \times \frac{\mu}{\gamma_\mu} \geq 1.35.P_m$$

γ_s	Reinforcement strength reduction factor

2) Service Limit State (SLS):

$$\gamma_p.N_p.\mu \geq P_m$$

Different friction coefficient values can be adopted by the project, providing that, a series of tests are carried out in accordance with the design assumptions, construction methodology and material used.

2.4.2 *Cast-in-situ concrete blister*

The blocks can be cast either internally or externally to the structure. This method offers the advantage of blister construction in a confined space or for applications where the access and handling is limited. In practice, connecting the new blister by means of passive reinforcement to the existing structure is not always possible as the required length for anchoring the shear reinforcement is greater than the member depth. Also, if anchoring a blister by means of reinforcing bars only, increases the overall size of the blister. The option of anchoring the blister to the existing structure by means of PT bars or combining it with reinforcing bars offers a more compact solution.

Figure 9: Cast-in-situ concrete blister anchored with PT bars, Westgate Bridge Strengthening, Source: Freyssinet

2.4.3 *Precast concrete blister*

Precast concrete blocks present an interesting solution where the minimum time for intervention is required. Also, this option guarantees a better quality as the precast block is manufactured in a controlled casting environment.

For instance, several advanced initiatives in precast concrete blister design and more generally in strengthening by external post-tensioning have been achieved as part of the Hammersmith Flyover project in London, where the existing post tensioning system of a 630 meter long concrete precast segmental bridge built in the 1960's has been fully replaced. The project requirements, mainly related to the congested urban environment, tight programme and maintaining the traffic on the deck at all times, challenged the engineers to develop new solutions to meet the client's key objectives. As a result, the new post-tensioned tendons were anchored to the existing structure through precast Ultra-High Performance Fibre Reinforced Concrete (UHPFR) blisters fixed to existing structure with Freyssibars+HTSR (High Tensile Strength Resistance bars, f_{pk} = 1200 Mpa). The choice of UHPFRC combined with Freyssibars+HTSR allowed the design to be compact enough to preserve the headroom under the deck (reduction of 50% of concrete quantities and 30% of number of bars compared to traditional anchors blocks fixed with traditional PT bars fpk = 1030 MPa) and to optimize the tendons' eccentricity. The friction coefficient between UHPFRC blister and existing concrete, as well as the design of the blisters were validated by tests.

Figure 11: Hammersmith Flyover project, London – External post-tensioning strengthening system, Source: Freyssinet

Figure 12: Hammersmith Flyover project, London – Installation of precast blisters, Source: Freyssinet

2.4.4 *Steel blister*

Steel blocks can be an interesting option for configurations where there is a lack of space to place a concrete block. This solution offers rapid installation however constructability (heavy to install) and durability can be a trade off to the concrete blister solution. Also, anchoring a steel blister requires a greater clamping force (more PT bars) when comparing with a concrete blister as a result of reduced friction factor.

Figure 13: Example of steel blister, Source: Freyssinet

2.4.5 *Bond-friction Anchorage Freyssinet 1R15*

For monostrand applications an efficient and innovative system developed by Freyssinet is the 1R15 bond-friction anchorage, see Figure 15. This system eliminates the provision for the supply, design and fabrication of the blisters detailed above which might result in a substantial savings for the project.

The 1R15 anchorage is a bond-friction type anchorage made of cast iron. The bottom surface at the back end of the anchorage, is provided with steel indentations to create shear interlock with concrete through epoxy resin.

Initially, the system has been developed for building works but further applications revealed that it can offer a cost-effective alternative solution for multistrand applications by combining the anchors in an appropriate arrangement.

For example, the 1R15 system was an alternative solution adopted for Cobbadah Creek Bridge strengthening in NSW, Australia (see Figure 14), which enabled the elimination of major road works involving significant traffic disruption. For this project, all the external post tensioning components were installed by use of hand tools below the roadway without impeding the traffic flow.

Figure 14: Cobbadah Creek Bridge, Strengthening with 1R15 external post-tensioned system, Source: Freyssinet

Figure 15: Cobbadah Creek Bridge, 1R15 anchorages arrangement, Source: Freyssinet

2.5 *Deviators*

The tendon deviation is provided by additional elements 'deviators', the function of which is to transfer the resulting component from tendon deviation into the existing structure. The deviator brackets are detailed in function of the project constraints and are dependent on the type of strand system being used (multistrand vs monostrand), curvature of the deviation, site constraints, and so forth. For multistrand deviators similar detailing to the anchor blocks can be used with either concrete blisters or steel brackets.

The deviators need to be designed to ensure that the radius of tendon in deviators, generally comprising bent steel tubing, shall comply with the minimum required values.

Figure 16: Westgate Bridge, Melbourne - Combined deviator / blister concrete block, Source: Freyssinet

For monostrand applications, it is important to ensure that the correct bend radius and separation of strands is achieved by designing the blister specifically to meet these requirements. Otherwise, within the bundle of strands, the transverse pressure arising from stressing the tendon on a curve leads to ripping of the individual HDPE sheath which is too thin to withstand the corresponding strains. In practice, a multitube saddle with flared ends to allow for strand angular misalignment is generally provided.

HDPE deviators as shown in the Figure 17, are also feasible providing they are designed to withstand the transverse pressure arising from tension in the tendons.

Figure 17: HDPE Deviator for monostrand application, Source: Freyssinet

2.6 *Advantages of External Post-Tensioning Strengthening*

External post-tensioning is generally more effective than passive strengthening methods including steel bands, concrete thickening, additional reinforcement, and carbon fiber for structural strengthening. It provides an active force that does not require further deflection to activate the strengthening system, and provides negligible additional structural mass to the structure.

The advantages of strengthening by external post tensioning systems are summarized below:

- High structural efficiency;
- Capability of applying the desired load conditions and its amount to the structure in a controlled manner;
- Insignificant increase in deadweight;

- Reduces the live load stresses and deflections;
- Cost-effective, low cost of strengthening works;
- Ease of installation and overall speed of construction;
- Limited or no disruption to the traffic;
- Adaptable, replaceable and controlled strengthening system (ability to adjust or to replace the strengthening in the future);
- Durable (active system).

3 REVIEW OF STRENGTHENING APPLICATIONS – CASE STUDY

3.1 *Flexural deficiency capacity*

External post-tensioning strengthening is in the most cases associated with flexural deficiency capacity either in the longitudinal or transversal direction of the main structural components.

Figure 18: SLU, Burnley Viaduct, 1R15 strengthening system, Source: Freyssinet

However, it can also be used for members such as decks, diaphragms, headstocks (see Figure 19), or more generally any structural elements requiring an increase in flexural capacity.

The strengthening by post-tensioning is normally designed as in the case of a new structure, assuming an ordinary prestressed member due to the fact that it's an active strengthening system (the loads are applied to the structure with the stressing of the tendons). It should be noted that the effect of creep and shrinkage may generally be less significant due to the age of the existing concrete.

Figure 19: M2U, Terry's Creek Bridge – Pier headstock strengthening, Australia, Source: Freyssinet

3.2 *Shear deficiency capacity*

Disorders due to a lack of shear and potentially combined with torsion resistance are usually sever but rather rare. Generally, if the structure is deficient in flexure then strengthening by external post-tensioning with a polygonal tendon layout makes the strengthened structure compliant with respect to the shear capacity. In some situations, the longitudinal post-tensioning strengthening is not enough to provide the required additional shear capacity. For such cases, the existing structure is reinforced with additional vertical stirrups usually made of post tensioned bars.

The design of shear reinforcement needs to be undertaken after a careful structural diagnosis and appreciation of the crack widths. If the structure presents a significant cracking then it is very likely that the existing stirrups have been plasticized. It is therefore prudent to size the additional prestressing to equilibrate the total required shear load.

Figure 20: Pont du Royaume, - Shear strengthening of the webs by stress bars combined with transverse prestressing of the bottom slab, Avignon, France

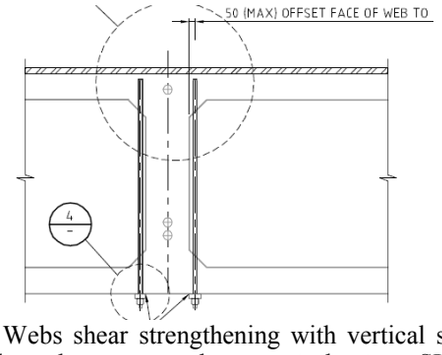

Figure 21: Webs shear strengthening with vertical stress bars anchored through epoxy anchorage at the top, SLU, Yarra Bridge, Australia, Source: Freyssinet

3.3 *Modification of initial scheme*

3.3.1 *M2 Motorway, Sydney, Australia*

The following example, based on the M2 Motorway widening operation in Sydney, illustrates a successful and cost efficient modification of the initial static scheme of existing bridges with external post-tensioning. For this project, the motorway widening was associated with relocation of the substructures of overpasses. Profiled external post tensioning tendons were designed to provide the required increased capacity as well as to achieve the load transfer from the old to the new supports during the stressing.

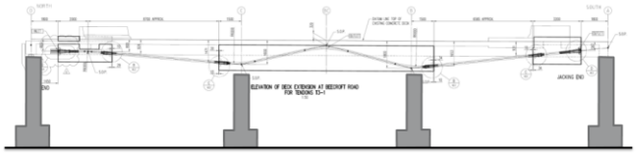

Figure 22- M2 Motorway, Sydney, Initial Static Scheme, before stressing of external post tensioned tendons

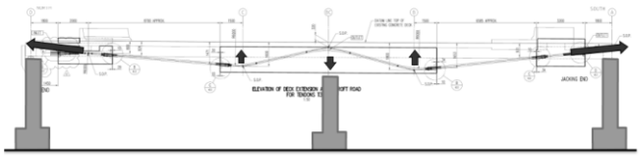

Figure 23- M2 Motorway, Sydney - Final arrangement

3.3.2 *Binh Trieu Bridge, Ho Chi Minh, Vietnam*

The 560 meter long crossing composed of a main steel bridge (3 spans measuring 160 meters) and two simply supported prestressed beam girders approach spans (10 spans measuring 250 meters on one side and 6 spans measuring 150 meters on the other was built in the 1960s.

Figure 24: Binh Trieu Bridge – Concrete approach spans & Steel Bridge, Source: Freyssinet

The aim of the strengthening was to widen the bridge in order to create a specific lane for cycles on one side only and to make the bridge complying with new construction codes (vehicles and seismic loads).

As a consequence of the increased loads, the solution was to make both access viaducts continuous by grouping the 5 or 6 spans together, using external prestressing. To ease execution, the cables were chosen to be 2 to 3 spans in length and were crossed on piers. Transverse blocks were built to ensure correct deviation and proper anchorage of new longitudinal cables.

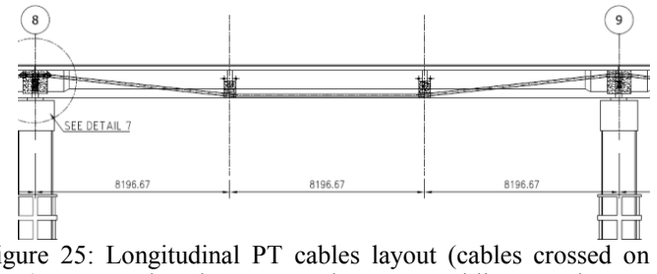

Figure 25: Longitudinal PT cables layout (cables crossed on piers) connected to the structure by concrete blisters and transversal PT cables

The chosen and implemented engineering solution for this projected which consisted in a complete change of the static behavior of the bridge, allowed the reduction of the material quantities when compared to alternative solutions, as well as completion of the strengthening works with a minimum disruption to the traffic.

4 CONCLUSIONS

With the recent development in structural analysis, design and post-tensioning systems, external post-tensioning has become one of the most cost effective, constructible and relatively simple methods for strengthening concrete bridges available today. It is relatively quick to install, has low aesthetic impact and can be designed to be retrofitted to accommodate almost all concrete bridge structure types. In addition, the following provides the key conclusions that can be drawn from the recent experiences:

- External post tensioning provides a wide range of solutions to address different types of disorders and deficiencies on concrete, steel or timber structures. Several options and systems are available depending on the final intent, types of corrosion protection, construction requirements, etc.;
- A careful assessment is essential prior the design phase in order to ensure that all the strengthening in conjunction with the project and environmental requirements have been considered;
- The strengthening projects leads to strong mutual dependence between all the parties involved (Client, Main Contractor, Designer, specialist Subcontractor). As such, it is recommended to have a careful balance between the design and the constructability. Furthermore, the project management structure in place should ensure strong links between the key players.

S-N curves for RC beams strengthened with FRP

L.C. Meneghetti

R. M. Teixeira
Federal University of Pará, Belém, Brazil

ABSTRACT: Externally bonded FRP may increase the fatigue life of RC beams due to the reduction of the steel stress level if compared to unstrengthened beams. In general, fatigue failure is marked by the gradual deterioration of the steel rebars, which leads a stress transfer to the Fiber Reinforced Polymer (FRP), until failure. Steel stresses higher than 80% of yield stress are associated with FRP debonding, while steel stresses below the fatigue limit will never lead to fatigue failure. The lack of data regarding fatigue life of FRP strengthened beams, mainly when related to low stress levels, leads to general fatigue analysis with S-N curves developed for different FRP systems and stress ranges. Aiming to improve the fatigue life analysis of RC beams strengthened with FRP this paper aims to develop specific S-N curves for different FRP systems, through the Maximum Likelihood Estimation Method (MLE). Experimental data with runouts of fatigue tests found in literature and generated through an experimental program were used to adjust the fatigue model aiming to characterize the large scatter between the results of fatigue tests from the different sources. The proposed fatigue models for the different FRP systems represent accurately the declivity of the fatigue curves for FRP strengthened RC beams.

1 INTRODUCTION

Cyclic loading are one of the main causes of RC deterioration in bridges because repeated loading and unloading cycles may lead to fatigue (Demers 1998, Ye et al. 2014, Song & Yu 2015). A typical RC highway bridge deck with a design life of 40 years may experience a range of 10^7 to 10^8 cycles (Barnes and Mays 1999), or, according to the Canadian Standard Association, a minimum of 58 x 10^8 loading cycles of varying intensities (CSA, 2014). In this perspective, fatigue may significantly reduce the expected lifetime of a RC structure, resulting in catastrophic failure even with applied loads below the structural capacity of the elements (Demers 1998).

Fatigue life becomes a crucial question since the lack of data regarding FRP post-strengthened elements leads to superficial analysis that consider the same S-N curves for different FRP systems and stress ranges. Thus, although FRP strengthening design methods are now established and many guidelines exist, fatigue design procedure is still an ongoing research topic.

Fatigue analytical models can link theory with observed data to provide a good prediction of future observations (Ye et al. 2014) or even can be useful for deciding aspects to be explorated in real scale fatigue tests. Fatigue tests are, in general, expensive, and curve fitting of fatigue data is time-consuming, as well as fatigue tests. On the other hand, engineering designers need to make safe use of these complex fatigue life data, especially for unconventional materials like composites (Meneghetti et al. 2017).

Aiming to improve the fatigue life assessment of RC beams strengthened with FRP, the goal of this paper is to adjust specific S-N curves for different FRP systems. An extensive database, with experimental data gathered from the literature, have been used to adjust fatigue models through Maximun Likelihod Estimation (MLE) aiming to characterize the large scatter between the results of fatigue tests from the different sources.

The MLE allows the use of runout data that are not used in classical regression analysis due to the fact that the number of load cycles at failure is unknown or even because the number of load cycles at which the test was interrupted is completely arbitrary (Taras & Greiner 2009). Runout data, in fact, are not as complete as test data resulting from a fatigue test up to failure, but also show that the tested member

could achieve more than the number of load cycles at the test interruption.

Distinct fatigue models have been developed considering four post-strengthening categories of FRP Externally Bonded Reinforcement (EBR) with FRP strips and sheets with and without additional anchorage.

2 MAXIMUM LIKELIHOOD ESTIMATION

The relation between the nominal steel stress range ($\Delta\sigma$) and the number of cycles at failure (N) is given by the well-known form expressed in Equation 1, where m>0 and k>0 are real numbers that can be estimated by linear regression of under the constant-amplitude fatigue regime.

$$N = \Delta\sigma^{-m}\, k \tag{1}$$

Equation 1 can be written in log-log scale with $x = logN$, $y = log\Delta\sigma$, $B = -m$, and $A = log(k)$, resulting Equation 2.

$$x = By + A \tag{2}$$

In the log-log system B represents the slope of the S-N curve and A denotes the intersection with the horizontal axis, as it can be seen in Figure 1.

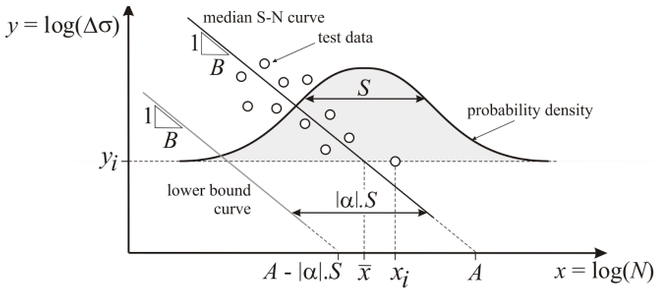

Figure 1. Variables used in the S-N model.

Considering the statistical nature of N, Equation 2 can be rewritten, according to ASTM E739-10 (2015), as Equation 3, which means that for a given $\Delta\sigma$, $x = logN$ obeys a normal distribution with median $\bar{x}$ with a non-exceedance probability of 50%.

$$\bar{x} = E\,[x][y] = By + A \tag{3}$$

For other probabilities, the standard deviation (S) for log(N) must be multiplied by α and computed as shown in Equation 4. The factor α defines different non-exceedance probabilities of the normal distribution and can be defined as $\alpha = \Phi^{-1}(p)$, where $\Phi^{-1}(p)$ is the standard normal inverse cumulative distribution function for a specific probability of failure.

$$x = By + (A + \alpha S) \tag{4}$$

International codes, such as CEP-FIP (2010), recommend the 5% fractile S-N curves for fatigue assessment and design of RC members if failure happens in steel rebars.

Linear regression analysis is frequently used to fit experimental datasets collected from the literature, through the Least-Square Method. In such case, only failure points are considered and runouts are excluded from the analysis. Apart from that, the Constant Amplitude Fatigue Limit (CAFL) position is, in general, arbitrarily chosen and prediction bounds of linear regression curves are based on fatigue data scatter in the finite-life region, which results less accuracy in the high cycle fatigue region (D'Angelo et al., 2014).

The application of the Maximum Likelihood Estimation (MLE) in the fatigue field, through a five-parameter random fatigue model, was first proposed by Pascual and Meeker (1999). A generalised methodology based on MLE for the inclusion of runouts, as well as different probability distributions of fatigue life, was proposed by Sarkani et al. (2007), based on a Weibull distribution. When applied to fatigue, MLE determines the S-N curve that describes the most likely location of each fatigue test result, including runouts.

For a given set of x_i independent observations obtained in different y_i levels, and considering the transformation $z_i = [x_i - \bar{x}(y_i)]/S$, the likelihood function is given by Equation 5 , in which $\delta_i = 1$ for failure, $\delta_i = 0$ for runout, $f(z_i;\theta)$ is the probability density of z_i, $F(z_i;\theta)$ is the cumulative probability distribution of z_i, and $\theta = [\,A\ B\ S]$ is the vector of parameters of the fatigue model.

$$\Gamma(\theta) = \prod_{i=1}^{n} [f(z_i;\theta)]^{\delta 1} [1 - F(z_i;\theta)]^{1-\delta i} \tag{5}$$

Assuming that data may be adjusted through a normal distribution in log-log scale, the likelihood function $L_i(\theta)$ for a single test result is given by Equation 6, where $\varphi(z_i;\theta)$ is the standard normal probability density of z_i and $\Phi(z_i;\theta)$ is the standard normal cumulative probability function of z_i.

$$L_i(z_i;\theta) = \delta_i \{log[\varphi(z_i;\theta)] - log[SN_i]\} + (1 - \delta_i) log[1 - \Phi(z_i;\theta)] \tag{6}$$

The log-likelihood function of the entire dataset is given by the contribution of each dataset, according to Equation 7.

$$\Lambda(z_i;\theta) = \sum_{i=1}^{n} L_i(z_i;\theta)] \tag{7}$$

The set of parameters θ that maximizes the function $\Lambda(z_i;\theta)$ can be determined using popular optimization algorithms, such as the native *fmincon* function of the Matlab Optimization Toolbox (Mathworks 2010), for instance. In this case,

algorithms are used to minimise $-\Lambda(z_i;\theta)$ which is the same as maximizing $\Lambda(z_i;\theta)$, when initial constraints are given to θ to limit the search space within a feasible region.

3 FATIGUE DATABASE

Experimental data of fatigue tests with runouts, reported by Barnes and Mays 1999, Meier 2000, Al Rousan & Issa 2001, Masoud et al. 2001, Papakonstantinou et al. 2001, Wight & Erki 2003, Aidoo et al. 2004, Heffernan & Erki 2004, Gussenhoven & Breña 2005, Masoud et al. 2005, Quattlebaum et al. 2005, Silva Filho 2005, Ekenel et al. 2006, Rosemboon & Riskalla 2006, Toutanji et al. 2006, Al Saraj 2007, Gheorghiu et al. 2007, Meneghetti 2007, Wang et al. 2007, Ferrier et al. 2011, Charalambidi et al. 2016, Mahal et al. 2016, Peng et al. 2016, and Huang et al. 2017 have been used to generate the proposed fatigue models.

Fatigue test data were generated through cyclic loading tests carried in reinforced concrete beams post-strengthened with different FRP systems and techniques. The following assumptions were considered to generate the proposed fatigue models: i) database collected constitutes a random sample from a population of all possible test results; ii) individual results, in terms of fatigue life, are random samples from a log-normal population. A random sample is required for a meaningful evaluation of population parameters, confidence limits, and tolerance intervals (Meneghetti et al., 2011).

Data have been classified in four post-strengthening categories, according to the FRP system and application technique, as shown in Table 1.

Table 1. Data categories.

Category	FRP System	Technique
1	FRP strips	EBR, anchorage
2	FRP strips	EBR, no anchorage
3	FRP sheets	EBR, anchorage
4	FRP sheets	EBR, no anchorage

Tables 2 to 6 show the reported fatigue tests used to generate the proposed fatigue models with data that reasonably represent the actual vehicular loading and frequency experienced in practice.

Table 2. Reported fatigue test results for category 1, FRP strips, EBR, additional anchorage.

4 S-N CURVES

Specific S-N curves were obtained through the native *fmincon* function of the Matlab Optimization Toolbox (Mathworks 2010). The MLE solution was found considering a start point $\theta_0 = [16\ 3.7\ 0.5]$ and data were first classified in four categories, as shown in Figures 2 to 5.
Table 6 presents the MLE detected parameters of the four fatigue models and estimates of $\Delta\sigma$ at 2 million cycles.

Table 6. MLE parameters of the four fatigue models for different probabilities at 2,000,000 cycles.

Cat.	Intercept A	Slope B	St. Dev. S	Δσ at 2mi cycles	
				$p = 25\ \%$	$p = 5\ \%$
1	8.59	-1	0.45	34.85	25.08
2	8.71	-1	0.65	21.62	13.41
3	20.66	-6.08	0.89	131.55	118.96
4	17.51	-4.85	0.35	155.25	147.31

Black dots on Figures 2 to 5 represent data associated to tests that were interrupted when before fatigue failure, and, therefore, indicate that the specimen could support a higher number of cycles, with the possibility to achieve infinite fatigue lifetime.

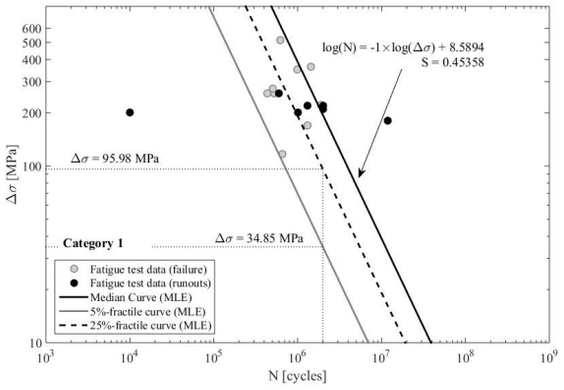

Figure 2. Maximum Likelihood Estimation for Category 1, FRP strips, EBR, additional anchorage.

The MLE model estimates quite different S-N curves for strips (Figures 2 and 3) and sheets (Figures 3 e 4) at 2 million cycles, which is confirmed by the huge change in the slope of the curves.

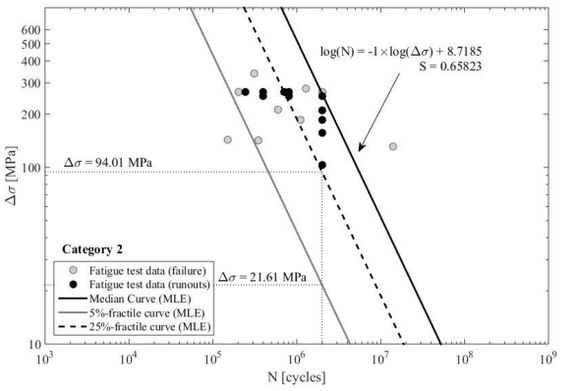

Figure 3. Maximum likelihood estimation for Category 2, FRP strips, EBR, no additional anchorage.

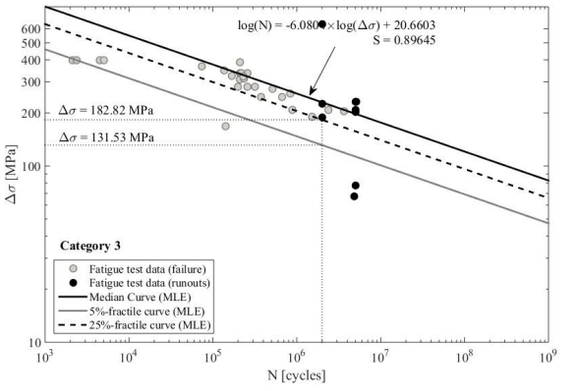

Figure 4. Maximum Likelihood Estimation for Category 3, FRP sheets, EBR, additional anchorage.

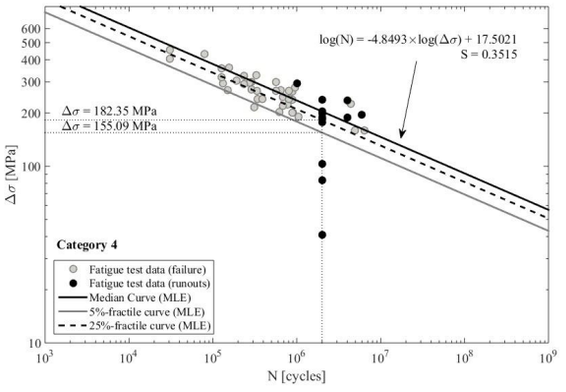

Figure 5. Maximum Likelihood Estimation for Category 4 , FRP sheets, EBR, no additional anchorage.

In the case of FRP strips, results of 5% fractile curves at 2 million cycles seems to confirm the positive effect of the additional anchorage, which is not endorsed by the results of FRP sheets. In fact, one of the most common anchorage system for FRP EBR, especially sheets, is the use of uni or multidirectional FRP U-wraps. If not perfectly executed, the radius of the FRP U-wraps may experience stresses concentration that induce premature failures at the anchorage system (Figure 6). Experimental results of Skuturna & Valivonis 2016 revealed that steel clamps are the most

effective anchorage system for FRP EBR, when compared to steel pins, U-wraps, and over support.

Figure 6. Premature failure at the FRP U-Wrap anchorage.

Aiming to ratify this findings, specific S-N curves were obtained considering 2 categories, strips (Figure 7), sheets (Figure 8), and curves that consider all data (Figures 9), whose MLE parameters and estimates of at 2 million cycles are presented in Table 7.

Table 7. MLE parameters of the four fatigue models for different probabilities at 2,000,000 cycles.

Cat	Intercept A	Slope B	St. Dev. S	Δσ at mi cycles	
				p = 25 %	p = 5 %
strips	8.644	-1	0.56	91.65	25.99
sheets	18.97	-5.43	0.63	180.09	138.89
all	15.85	-4.10	0.69	162.63	111.67

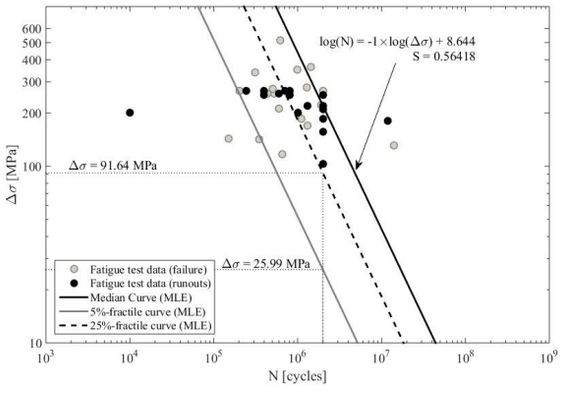

Figure 7. Maximum Likelihood Estimation for FRP strips, categories 1 and 2.

Figures 7 and 8 that aggregate data of anchored and unanchored FRP strengthening, confirm the findings of S-N curves for each category, presented in Figures 2 to 5, especially for the case of FRP sheets. S-N curves of FRP strips may be underestimated the fatigue life due to the lack of fatigue data for beams post-strengthened with FRP strips in the high cycles region.

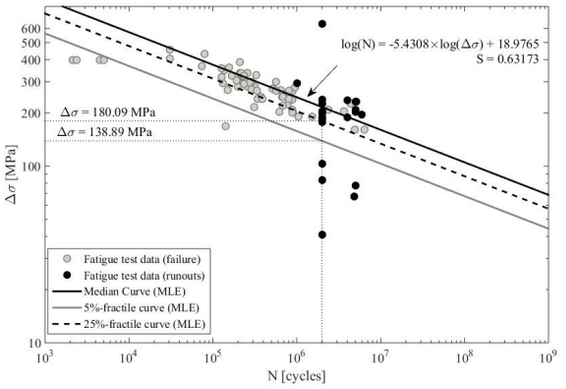

Figure 8. Maximum Likelihood Estimation for FRP sheets, categories 3 and 4.

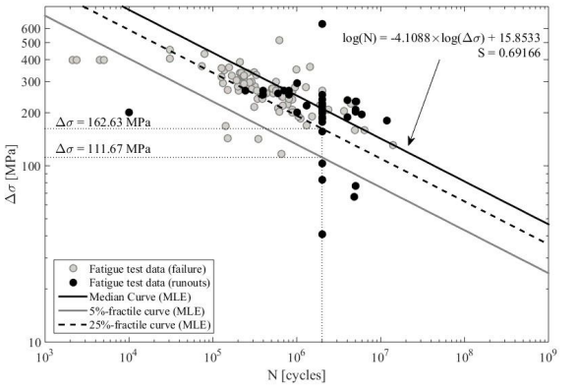

Figure 9. Maximum Likelihood Estimation for FRP strips and sheets, all categories.

S-N curves of Figure 9 with data of all categories show that the use of the same model for all types of FRP and techniques may underestimate the fatigue limit for FRP sheets and overestimate the results for FRP strips.

It is important to highlight that the fatigue design in the current bridge design specifications is based in the CAFL, the stress range below which the constant amplitude fatigue tests do not exhibit cracks after millions of cycles. The CAFL is, in general, arbitrarily chosen: 5% fractile curves are frequently used to determine the stress range that corresponds to a specified number of cycles, i.e. AASHTO allowable fatigue stress range for highway bridge design specifications, that depends on the structural element and redundancy of loading paths (AASHTO 2002).

On the other hand, in real life, structural elements are subjected to varying fatigue loads, and not to constant amplitude fatigue loadings. Fatigue models based in linear log-log S-N curves, frequently used if fatigue assessment, however, are not able to predict the fatigue limit. For this, fatigue models originated from non linear log-log SN curves are needed.

The fatigue limit, endurance limit, or fatigue strength for unstrengthened beams (ACI 215R 1997), may be estimated using the equation 8 where σ_{min} is the minimum steel stress level, pointing out that stress amplitudes lower than 138MPa could be ignored.

$$\Delta\sigma = 161 - 0.33\sigma_{min} \quad (8)$$

Apart from the results of Category 4 (sheets, no additional anchorage), the fatigue models do not show any positive effect on the endurance limit of the original steel rebars at 5% fractile curve. However, given the large scatter of fatigue data and the reduced size of the database available, especially regarding the use of FRP strips and data related to low steel stress ranges, further tests and confirmation of this tendency are necessary before any consideration on the endurance limit for FRP strengthened beams is made.

5 CONCLUSIONS

Based on data gathered from the literature, it was possible to adjust models based MLE method. Different declivities have been found for the adjusted fatigue life models, which highlight specific aspects of each category.

The declivity of the fatigue curves accurately represent the fatigue behavior of FRP strengthened RC beams, especially for FRP sheets, and can be used to support proper post-strengthening design, to avoid future unnecessary interventions.

The anchorage system may influence the fatigue behaviour of FRP strengthened beams especially in U-wraps anchorages, since if minimum radius is not respected, eventual stress concentrations on the anchorage system may induce premature failures.

More fatigue tests data with post-strengthened RC beams submitted to different higher and lower steel stress ranges may be useful, in the future, to ratify these findings.

UHPFRC Technology to enhance the performance of existing concrete bridges

E. Brühwiler
Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland

ABSTRACT: "UHPFRC" stands for Ultra-High Performance Fibre Reinforced Cementitious Composite materials. UHPFRC – complemented with steel reinforcing bars – serves as an external reinforcement increasing the ultimate flexural and shear resistances as well as the fatigue resistance and stiffness of the RC members, thus strengthening for higher live loads. UHPFRC is waterproof and crack-free under service conditions and thus improves the durability. The concept of the UHPFRC Technology consists in adding a thin layer of UHPFRC to an existing member in reinforced concrete (RC) in order to enhance its structural resistance and durability. The UHPFRC Technology is applied in Switzerland for more than 10 years. Basic principles are presented and the characteristics of the UHPFRC Technology are highlighted by two applications to enhance the performance of two large existing highway bridges.

1 THE UHPFRC TECHNOLOGY

"UHPFRC" stands for Ultra-High Performance Fibre Reinforced Cementitious Composite material produced from cement and other reactive powders, additions, fine hard particles, water, admixtures and high amount of short and slender steel fibres. UHPFRC does not comply with the definition of "concrete", and therefore, UHPFRC should not be called "concrete" as is evidenced in Figure 1a. It is fundamental to understand UHPFRC as an individual material with specific properties leading to a technology with own features. This is the first basic principle when designing with UHPFRC to enhance existing structures.

The second principle is that UHPFRC is complemented in a targeted manner with reinforcing steel in order to enhance structural performance and economy of applications. Subsequently, the terms reinforced UHPFRC (or short: R-UHPFRC) are used.

Reinforced concrete (RC) structures like bridges, retaining walls or buildings often show insufficient performance in terms of structural resistance and durability when exposed to severe environmental influences and high mechanical loading. Interventions to improve deteriorated concrete structures are a heavy burden from the socio-economic viewpoint since they lead to significant intervention costs and user costs. (RC structures are cheap at construction but turn out to be costly during their use because of premature repair and rehabilitation.) Many conventional "retrofitting" using concrete and repair mortar are not durable, and therefore, novel concepts for the improvement of RC structures must be developed.

This leads to the 3rd principle of the UHPFRC Technology. The targeted addition of a thin layer of strain-hardening UHPFRC to an existing member in reinforced concrete (RC) enhances the structural resistance and the durability of existing RC structures. The two basic concepts are shown in Figure 1b; they lead to the structural system of composite R-UHPFRC – RC elements.

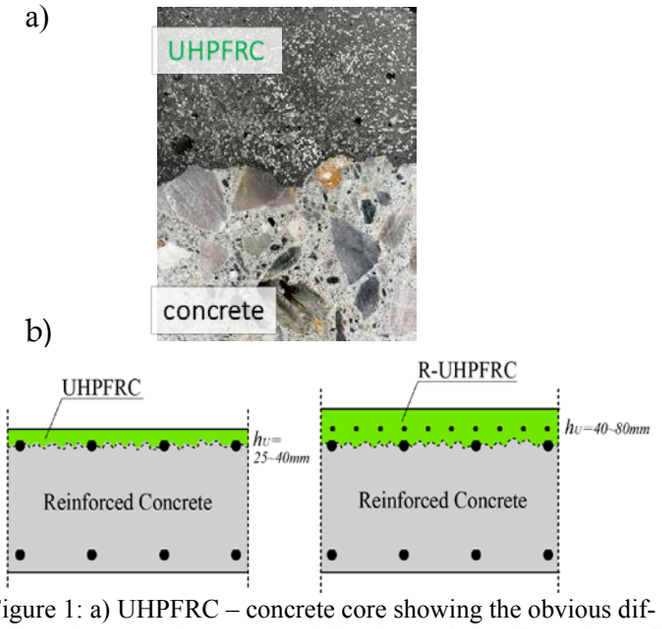

Figure 1: a) UHPFRC – concrete core showing the obvious difference between the two materials; b) Basic configurations of structural elements combining UHPFRC and RC: left: UHPFRC layer (25 to 40mm) has a protective function only; right: R-UHPFRC layer (40 to 80mm or more) has structural resistance and protective functions.

This paper presents the design of the strengthening of (1) the box girder and (2) multiple beam girder of existing concrete bridges. Simple analytical formulas are provided for the preliminary design of the strengthening, i.e. determination of the increase in structural resistance. The UHPFRC Technology to enhance structural performance of these two frequent types of bridge girders are highlighted by application cases.

2 PERFORMANCE OF UHPFRC

The required performance of currently used strain-hardening UHPFRC is summarized in [1-3]. Other fibre reinforced cementitious materials with lower performance – also designated as "UHPC" or high-strength concrete – do not qualify for the designs and applications described in this paper.

The tensile behaviour of strain-hardening UHPFRC is of first importance for strengthening purposes presented in this paper. The uniaxial tensile behaviour of plain UHPFRC has to comply with the indications and values given in Figure 2a. The significant strain-hardening deformation ε_U of more than 2‰, while the (uniaxial) tensile strength f_{Ut} reaches values ranging from 8 to 14 MPa, can only be obtained with fibre contents of more than 3 volume-% of straight steel fibres with an aspect ratio of at least 65.

The main reasons to complement UHPFRC with steel reinforcing bars to obtain R-UHPFRC are a significantly improved tensile behaviour and reduced scatter of UHPFRC properties [4, 5]. Small diameter steel reinforcing bars (arranged with relatively small spacing) provide in-plane continuity to the UHPFRC layer and ensure its monolithic action with the RC element in flexural members. The rebars not only significantly increase the resistance but also improve the deformation capacity and strain-hardening behaviour of UHPFRC. The mechanical behaviour in tension of R-UHPFRC is described by linear superposition of the reinforcing steel and the UHPFRC tensile behaviours (Fig. 2b).

Relatively modest UHPFRC compressive strength of 130 MPa is generally sufficient in the context of the present strengthening concept. The modulus of elasticity of UHPFRC in tension and compression is 45 to 50 G Pa which is not significantly higher than the one of concrete. For composite R-UHPFRC – RC members, this is advantageous with respect to deformation-induced stresses due to temperature and shrinkage effects.

UHPFRC has extremely low permeability and water conductivity due to the extremely dense matrix making strain-hardening UHPFRC impermeable for liquids, crack-free under service conditions and thus durable.

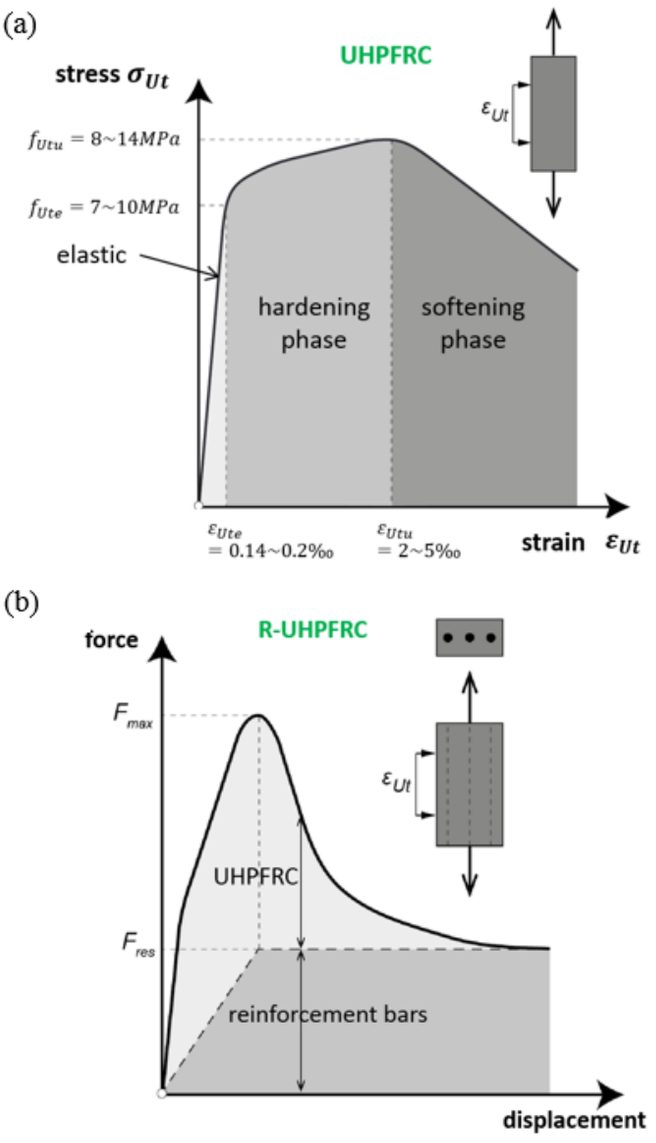

Figure 2: Characteristic tensile behaviour of a) plain UHPFRC and b) R-UHPFRC

3 STRUCTURAL RESPONSE OF R-UHPFRC – RC COMPOSITE BEAMS

The author and his team have investigated the structural concept of composite R-UHPFRC – RC elements (Fig. 1b) over more than 18 years (see [1] and references in [2, 3]).

3.1 *Behavior in bending*

When in tension, the R-UHPFRC layer principally acts as an added flexural reinforcement chord for the RC element. Both the steel rebars and the UHPFRC contribute to the resistance. RC beams strengthened with an R-UHPFRC layer are characterized by a significant increase in elastic stiffness and ultimate resistance when compared to the initial concrete element.

The bond between UHPFRC and concrete is obtained by preparing the concrete substrate surface by high pressure water jetting or sand blasting. The concrete substrate has to be wetted and needs to be wet when the layer of UHPFRC is cast. This surface

preparation provides full bond be tween UHPFRC and concrete substrate. In fact, pull-out fracture tests (force applied perpendicular to the surface) show the expected fracture in the concrete (and not at the interface or in the UHPFRC). Thus, the composite R-UHPFRC – RC section behaves monolithically.

The plastic post-peak rotation capacity of strengthened RC beams is maintained with an appropriate design of the rebars in the UHPFRC layer. Also, smooth high yield strength reinforcing bars in the UHPFRC layer offer high increase in resistance while the post-peak rotation capacity remains ductile. The structural behaviour in terms of moment – curvature relation and the ultimate bending moment are calculated using the conventional sectional model with the extension to account for the R-UHPFRC layer in the monolithic section (Fig. 3).

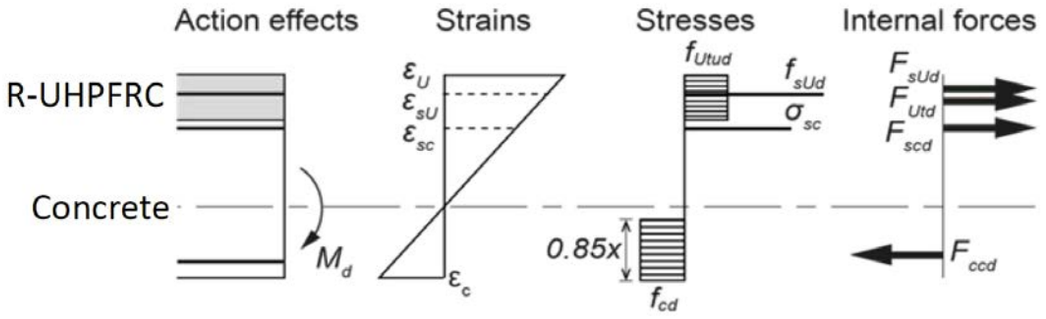

Figure 3: Plane section analysis for bending resistance at Ultimate Limit State ULS.

When subjected to compressive stresses, the R-UHPFRC layer acts as a compression flange but the high UHPFRC compressive strength cannot be fully exploited. This is because the compressive strength of the adjacent concrete below the UHPFRC layer often is 3 to 6 times lower, and thus concrete would crush prior to the UHFPRC reaching its compressive strength.

3.2 Behaviour in combined bending and shear

As was shown by tests on composite beams, the addition of a layer of UHPFRC delays the formation of the inclined shear crack in the concrete section. For many geometric configurations, the layer of UHPFRC modifies the failure mode from shear failure with little deformation to a ductile flexural failure mode.

A shear failure is observed in a composite section only for specific geometric and material configurations. Due to the experimentally observed failure mechanism (Fig. 4), the ultimate shear strength is composed of the contributions due to (1) concrete web crushing V_{Rc}, (2) vertical steel reinforcement yielding V_{Rs} and (3) the two hinge-bending mechanism of the R-UHPFRC layer V_{RU}. Accordingly, analytical expressions have been deduced to calculate the ultimate shear strength [6, 7].

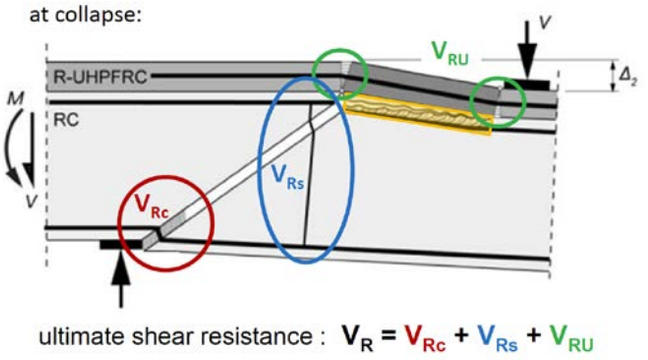

Figure 4: Shear failure mechanism at ULS

3.3 Fatigue behaviour

The results of bending fatigue tests on R-UHPFRC – RC beams revealed the existence of a fatigue limit at 10 million cycles at a fatigue stress level of about 50 % of the ultimate static resistance of the R-UHPFRC – RC beams [8]. Consequently, fatigue design rules for R-UHPFRC – RC members under bending fatigue need to account for steel rebar and UHPFRC fatigue resistances. Fatigue stresses are calculated using an elastic sectional model similar to the one shown in Figure 3.

4 TWO APPLICATIONS

4.1 Introductory remark

In Switzerland, the technology of enhancing the structural performance of existing RC structures by a layer of R-UHPFRC was applied for the first time in October 2004. Since then, more than 50 structures have been strengthened using the UHPFRC Technology. Subsequently, the conceptual design for the enhancement of two large highway viaducts is presented.

4.2 Improvement of the Chillon Viaducts [9]

4.2.1 Motivation and objectives

Located in Switzerland, the Chillon viaducts are two parallel posttensioned concrete highway bridges built in the late 1960s (Fig. 5). To insure structural safety for future traffic demands, it was decided to strengthen the slab by adding a layer of R-UHPFRC acting as an external tensile reinforcement for the slab and main girder.

Figure 5: Chillon Viaducts along Lake Geneva.

4.2.2 Motivation and objective

The concept implemented in 2014/15 consisted in casting one layer of R-UHPFRC on the deck slab (Fig. 6) to achieve the following beneficial effects:

- increase the slab's ultimate (bending and shear) resistance in the transverse direction
- increase the slab's stiffness to reduce fatigue stresses in steel rebars in the concrete
- increase the hogging bending moment resistance and the stiffness of the box girder
- provide waterproofing to protect the existing concrete of the slab from water and chloride ingress, thus improving durability
- limit duration of the intervention.

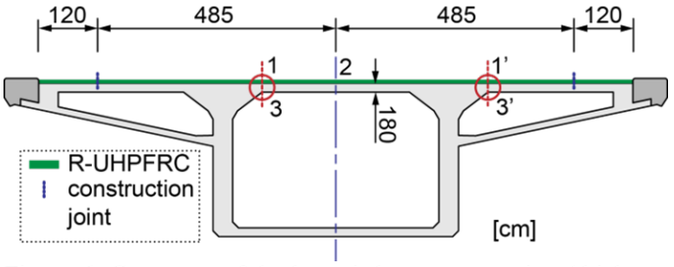

Figure 6: Geometry of the box girders cross-section (thickness of R-UHPFRC layer: 50mm over piers and 40mm in the spans).

4.2.3 Pre-dimensioning

As illustrated in Figure 6, the concrete bridge deck slab has a total thickness h_c of 180 mm. The transversal 16-mm diameter top steel rebars are positioned at a height d_{sc} of 152 mm from the intrados and spaced at 125 mm. There is no transversal prestressing in the bridge deck slab. The layer of UHPFRC has a thickness of h_U of 40 mm and is reinforced transversally with 12-mm diameter rebars also spaced at 125 mm. The centre of these rebars is at 16 mm from the top of the concrete. Over the piers, the thickness of the UHPFRC layer was increased to 50mm, and 12 mm rebars spaced at 125mm were placed in the longitudinal direction (in addition to the transverse rebars) to increase the negative (hogging) moment resistance of the box girder in the longitudinal direction.

The *transversal bending resistance of the deck slab* was calculated using the resistance model according to 3.1. For negative bending moment, the ultimate bending resistance m_{Rd} for sections 1 and 1' (Fig. 6) is equal to 165.5 kN m/m. The ultimate bending resistance of the strengthened slab is 73% higher than the resistance of the RC section alone. For positive bending moments, the layer of UHPFRC is in compression and mainly contributes to the resistance by reducing the height of the compression zone and thus increasing the static height. The ultimate positive bending resistance at section 2 is increased by 33%.

The deck slab does not have any shear reinforcement. *Ultimate shear resistance* v_{Rd} of the composite element was thus calculated as the sum of the concrete contribution v_{Rc} and the UHPRRC contribution v_{RU} according to Chapter 3.2. With an angle of the inclined crack estimated at 35°, the shear resistance of the composite slab section is 265 kN /m. The UHPFRC layer contributes to 33% of the total shear resistance. Due to the R-UHPFRC reinforcement, the increase in shear resistance is 40% according to the resistance model presented in [7].

The increased shear resistance is significantly higher than for the flexural failure mode, and the flexural failure mode is predominant even in shear prone loading situations.

4.2.4 Execution

All listed requirements and structural functions were realized by the casting of just one layer of R-UHPFRC using a machine (Fig. 7) on the concrete surface prepared by removal of 10mm by hydrojetting. The large volume of 2'350m^3 of fresh UHPFRC was produced on-site in a ready-mix plant. During the summers 2014 and 2015, the UHPFRC layer was cast over the two 2'120 m long viaducts, each in less than 30 working days.

Testing according to quality assurance given in [1] revealed that the UHPFRC complied with the requirements for strain-hardening UHPFRC. The fresh UHPFRC had to show thixotropic behaviour as it was cast on slopes of up to 7%. An asphalt layer and bituminous pavement, overall 6-cm thick, were finally placed on the UHPFRC surface to obtain the drivable road surface. The overall self-weight of the structure was not increased significantly.

Figure 7: UHPFRC casting machine (up) and fresh UHPFRC layer after casting (down)

4.3 Improvement of three highway viaducts consisting of multiple PC precast girders

4.3.1 Motivation and objective

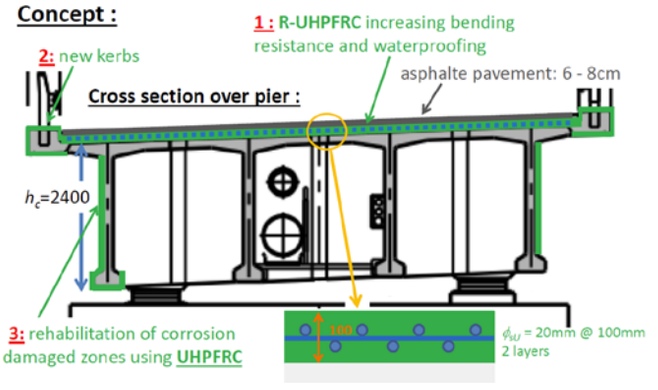
Three 45 years old highway twin viaducts of identical construction follow each other in a hilly area in Central Switzerland to form a total length of 1'050m (Fig. 8a). The superstructure of the viaducts is composed of four slender precast prestressed girders with lengths of 40m. These girders have been designed as simple span beams, but during construction, they were monolithically joined over the piers (to avoid joints) to form a continuous girder. The realized hogging moment capacity (over the piers) is relatively low. In view of future traffic demands, the viaducts need to be strengthened to increase the load bearing capacity. They also need to be rehabilitated because of rebar corrosion damage.

4.3.2 Conceptual design

The basic idea of the strengthening of the superstructure is the following: since the original hogging moment capacity is low, it can be increased significantly by adding a strong R-UHPFRC layer on top of the slab (Fig. 8b).

Allowing for plastic moment redistribution from mid-span (sagging moment range) to the piers (hogging moment range) at ULS, the required load bearing capacity of the superstructure is obtained (Fig. 8c). This moment distribution is however only possible if the relevant cross sections allow for plastic hinges of sufficient ductility. This condition has been verified in the present case.

The 100 mm thick R-UHPFRC flange extends by 6 m on each side of the pier such that the strong R-UHPFRC layer also increases the shear resistance of the girder near the piers according to the mechanism shown in Fig. 6.



The rest of the deck slab (sagging moment region) is strengthened by a 45 mm thick UHPFRC layer with rebars in the transverse direction such as to increase the torsional stiffness of the open cross section allowing for more effective distribution of high concentrated forces in the transverse direction of the cross section while reducing moment peaks.

In addition, the UHPFRC layer on the deck slab provides the waterproofing, and UHPFRC is also used to rehabilitate local rebar corrosion damage on the outer girders and bottom flanges because of superior performance compared to repair mortars.

a)

b)

c)

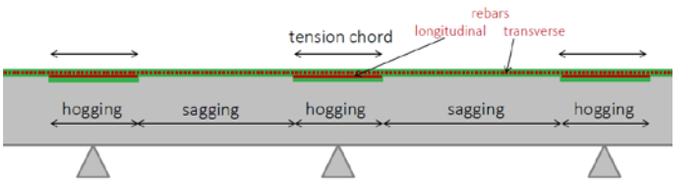


Fig. 8 a) View of one of the three twin viaducts; b) Intervention concept (cross section at pier); c) concept of strengthening: increasing the hogging moment capacity.

4.3.3 Pre-dimensioning

Bending moment capacity: With design values for the tensile strength of UHPFRC and steel rebars of respectively 8 MPa and 435 MPa, and the UHPFRC cross section and rebar area as given in Figure 8b, the tensile force developed at ULS by the R-UHPFRC flange is F_{RUd} = 3'480 kN per meter width. (78% of this tensile force is due to the steel rebars; 22% is due to the UHPFRC.) The internal lever arm y_U of the cross section (i.e. distance between the resultant tensile force and compression force), plastified at ULS, is estimated to be about 1.8 m, and thus, the additional hogging (negative) moment capacity in the longitudinal direction is: $\Delta M_{RUd} = y_U \cdot F_{RUd} = 1.8m \cdot 3.48MN = 6.3MNm/m$.

This additional moment capacity is sufficient to obtain the required moment bearing capacity of the superstructure. Obviously, increasing the tensile reinforcement leads to higher compressive stresses in the lower part of the cross section over the pier. In the present case, the compression zone was not fully exploited before strengthening and the compressive strength increased over time to reach after 45 years a compressive strength about 30% higher than the 28-day-compressive strength assumed in the initial design. These are the reasons why the dimensions of the compression zone are sufficient also after strengthening.

Shear resistance: The resistance model (Fig. 4) was applied to the 2.5m high girder. The following contributions to the ultimate shear resistance of one strengthened girder were obtained: (1) concrete web crushing V_{Rc} = 426 kN; (2) two hinge mechanism of the R-UHPFRC layer V_{RU} = 305 kN; (3) steel reinforcement: vertical rebars (stirrups) and vertical component of two inclined post-tensioning cables in the concrete girder web: V_{Rs} = 813 kN. Thus, the ultimate shear resistance of the strengthened girder is the sum of (1) to (3): V_{Rd} = 1'544 kN. This ultimate shear resistance is 90% higher than the shear resistance before strengthening and 34% higher than the acting shear force. Actually, the shear resistance is enhanced to such an extent that bending failure will prevail. In addition, non-linear FE analysis was performed confirming the formation of the expected failure mechanism and the analytically determined ultimate shear resistance.

Slab strengthening in the transverse direction: The R-UHPFRC layer leads to a thicker slab of higher stiffness allowing for more effective transverse distribution of concentrated loads. This favourable effect was considered and precisely determined in the detailed dimensioning.

The pre-dimensioning was used to validate the feasibility of the intervention concept. Detailed design by means of non-linear FE analyses gave deeper insight into the performance of the R-UHPFRC strengthening concept.

4.3.4 Execution

The works to improve the three viaducts are currently conducted. In 2017, chloride induced rebar corrosion damage at outer girder webs and bottom flanges were rehabilitated using UHPFRC. In addition, suitability tests have been performed to validate the UHPFRC material and the machine-made UHPFRC casting. In 2018 and 2019, UHPFRC layer is cast on the deck slab of the viaducts using a casting machine.

5 VALIDATION

The presented UHPFRC Technology for the enhancement of existing concrete bridges is validated by qualitative comparison with the traditional method using concrete, instead of strain-hardening UHPFRC, leading to the following arguments:

UHPFRC has an optimised compact matrix consisting of particles and a water/binder ratio typically lower than 0.20, which results in a material that has no free water, and no (communicating) capillary pores; consequently UHPFRC is waterproof and thus durable. On the contrary, concretes show significant amounts of communicating capillary pores because of the relatively high w/c-ratio larger than 0.40; consequently, concrete cannot be considered as durable, i.e., durability problems like rebar corrosion, frost damage or alkali-aggregate reaction are likely to occur even for improved concrete.

UHPFRC shows much higher tensile strength with significant deformation capacity (ductility) compared to concretes; consequently, the tensile strength of UHPFRC is considered in the design of strengthening interventions (like the ones presented in this paper). This significantly enhances the ultimate resistance and also the stiffness of strengthened R-UHPFRC – RC structural members. On the contrary, the tensile strength of concrete must not be taken into account in the determination of structural resistance, also because of brittleness.

The compressive strength of UHPFRC is about 3 - 5 times higher the one of high strength concretes. This is a further reason why relatively thin additional layers in UHPFRC are sufficient.

Because of the aforementioned differences in mechanical performance of the two materials, a strengthening layer in concrete (following similarly the concept presented in this paper) would result in a thicker concrete cover and overall layer thickness, more rebars and additional measures (like waterproofing membranes) to guarantee durability. Overall, the additional relatively thick layer in high strength concrete would lead to an important increase in dead weight of the bridge structure which is likely to trigger additional (costly and time consuming) strengthening interventions.

In addition, additional measures, f.ex. to guarantee durability, and more complex works in the case of traditional methods are time-consuming and offer more sources of errors. This leads to more important restrictions for the user of the structure and thus significantly higher (indirect) user costs.

Overall, despite the fact that concrete is a cheap material compared to UHPFRC, the overall cost of a UHPFRC strengthening intervention on existing structures is significantly lower … which is actually

the main reason why in Switzerland numerous applications have already been realised. Obviously, it is erroneous to compare the material cost only of concrete and UHPFRC, since in many countries labour and machine costs are significantly higher than material costs. The cost for the overall intervention finally counts, and the material cost is only a (minor) part of it.

6 CONCLUSIONS

The strengthening method using a layer of strain-hardening UHPFRC is an effective method in terms of technical performance. Significant tensile strain-hardening and high tensile strength of the UHPFRC is required for the improvement of concrete bridges.

The design of the strengthening intervention is based on a clear concept with a targeted consideration of the structural behaviour and performance of the given structure to be improved as well as the UHPFRC material properties.

The UHPFRC strengthening concept has been demonstrated in this paper by means of two large viaducts of common design, i.e. box girder and multiple beam cross sections. Simple analytical formulas are sufficient to validate this intervention concept.

The presented R-UHPFRC technology to improve the resistance and durability of existing concrete structures is cost-effective at execution and economic. Actually, lower intervention costs (when compared to traditional methods) are the main reason for the increasing number of applications of the R-UHPFRC technology in Switzerland.

ABSTRACT: Factors such as population growth, higher volumes of commuter and freight traffic and heavier vehicles have increased the demands placed on existing bridges throughout Australia. Alongside the necessity for structural rehabilitation and strengthening in order to prolong the service life and increase the safety of existing bridges, many innovative materials such as advanced fibre reinforced polymer composites (FRPs) have become popular as a means to strengthen existing reinforced concrete (RC) members in flexure, shear and torsion, via bonding of the FRP to the external surface of the member. Despite the many advantages of FRP materials, a commonly documented failure mode is premature debonding of the FRP from the concrete substrate. It is well understood that the bond strength between the FRP and concrete members can be improved when sufficient anchorage is provided thereby preventing the critical mode of FRP failure. Anchorage systems have the potential to significantly improve the bond performance of FRP systems thus permitting higher levels of strengthening at a fraction of the cost. To date the authors have researched the patch anchors concept which consists of bi-directionally oriented fibre sheets bonded to the surface of the FRP strengthening and the adjacent primarily through a series of FRP-to-concrete joint direct shear tests. More recently, the patch anchors were implemented in the shear strengthening of a large scale prestressed beams for the first time which takes into account omitted factors in joint assemblies such as: size effect, combined flexural/shear stresses, diagonal shear cracking (potentially intersecting the FRP within the anchorage zone) and other failure modes such as web shear crushing or concrete crushing. An evaluation of patch anchor performances in large-scale beam applications will be presented in this paper long side a comparison of results between joint assemblies and full-scale implementations.

1 INTRODUCTION

A major problem that has been emerging in recent years is the need for strengthening of existing infrastructures due to factors such as: increased loading, corrosion of reinforcing steel, design defect or deterioration. Many technologies have been presented to solve this problem which included the use of composite materials, such as Fibre Reinforced Polymers (FRP) as externally bonded reinforcement. The materials lend them selves as excellent for strengthening applications due to their high tensile strength, light weight, high durability and ease of installation (Koutas & Triantafillou 2013). As a result, FRP's have been used successfully to strengthen members in flexure, shear and torsion (Panigrahi, Biswal & Barik 2014).

Despite the many advantages of FRP's for strengthening applications, the occurrence of prema-ture debonding currently limits the level of material utilizations to 15-30% for most shear strengthening applications. Debonding for shear strengthened members typically occurs at the intersection of the FRP with a propagated diagonal shear crack which initiates a debonding failure at the crack which propagates towards the nearest FRP free end. One of the most effective techniques to suppress or delay the occurrence of FRP debonding is the use of FRP anchorage systems (Grelle & Sneed 2013). The types of anchorage systems available for shear strengthened members were summarized by Kalfat et al. (2013) as: FRP (spike) anchors, NSM anchors, me-chanical substrate strengthening, patch anchors, hybrid anchors, mechanically fastened steel plates or FRP embedment into concrete flanges.

Patch anchors were developed by Kalfat and Al-Mahaidi (2014) and showed promising results in increasing the utilization of the CFRP laminate when tested on the level of FRP-to-concrete joints. In this method, the ends of the laminate are sandwiched between two CFRP bidirectional fabric sheets, the anchors are applied externally and no drilling is re-

quired. Therefore, in this study patch anchors performance is tested on large scale beams strengthened with externally bonded CFRP laminates in shear.

2 EXPERIMENTAL PROGRAM

2.1 *Specimen Details*

Three full scale post-tensioned T-beams were constructed with span length of 5000 mm and a depth of 1050 mm. The properties of the beam are depicted in Figure 1. The beam was reinforced with eight Ø32 mm diameter longitudinal reinforcement and one Ø32 mm post-tensioned threaded bar in the bottom and 2N20 bars in the top. Shear reinforcement consisted of 2 legs of N10 ligatures at 475mm spacing throughout the span. Both the longitudinal and shear reinforcement were chosen in order to ensure that the beam failed in shear.

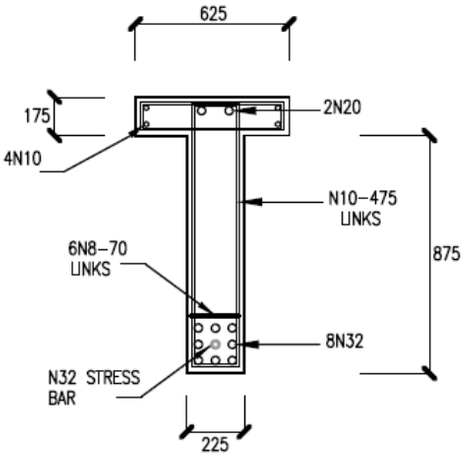

Figure 1. The beams cross-section details.

Three T-Beams were tested using three point bending configuration. The first specimen was strengthened and functioned as a control beam as depicted in Figure (2.a). The second specimen (ST series) was strengthened using CFRP side bonded laminates. Twelve strips were installed at each end of the beam with spacing of 300 mm c/c as shown in Figure (2.b). The third beam (STA series) used the same strengthening configuration as the ST series beams with the addition of patch anchors at each end of the laminates. Hence, the laminate was anchored at both ends using two plies of CFRP bi-directional sheets with ± 45° fabric as shown in Figure (2.c).

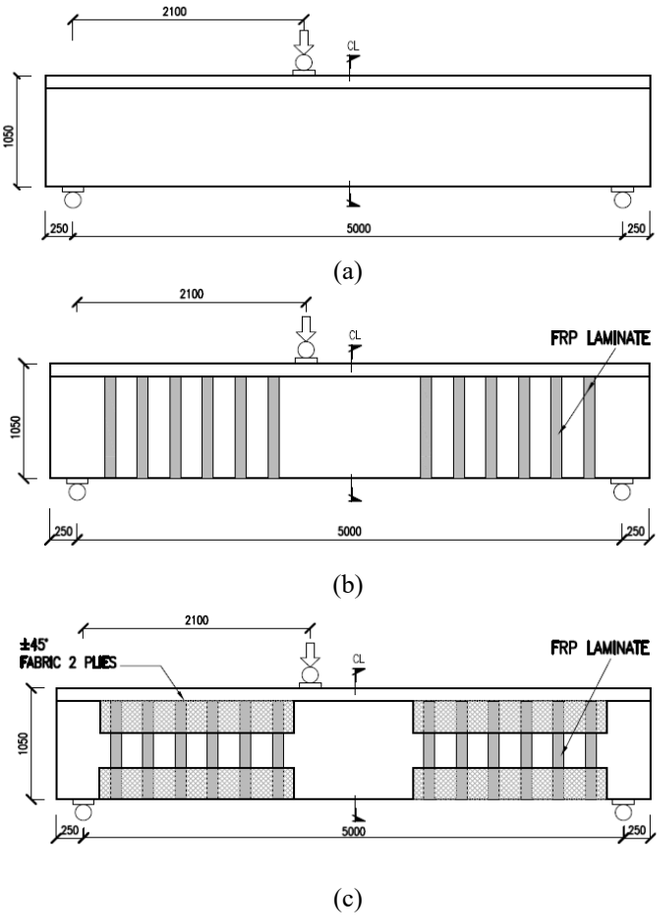

Figure 2. (a) Control Specimen, (b) Strengthened Specimen, and (c) Strengthened Specimen with CFRP Sheets Anchors.

2.2 *Patch Anchor Application Process*

The patch anchoring method consisted of using CFRP bi-directional sheets with $\pm 45^{\circ}$ fabric as anchors at the ends of the laminate. This involved sandwiching each laminate in between two layers sheet. The application process included surface preparation where webs of each beam were sandblasted to achieve a surface roughness corresponding to 60 grit sandpaper. The first layer of sheet was saturated with epoxy resin and applied to the concrete surface over the 1800 mm bond length. This was followed by applying the pultruded CFRP laminate strips in the required locations. lastly, the second layer of the CFRP bidirectional sheet was applied to complete the installation of the patch anchors. Figure 3 shows the patch anchors with the laminates after finishing the application. The curing process took 7 days, and heat lamps were used to provide a 40 °C curing environment to accelerate the curing process as shown in Figure 4.

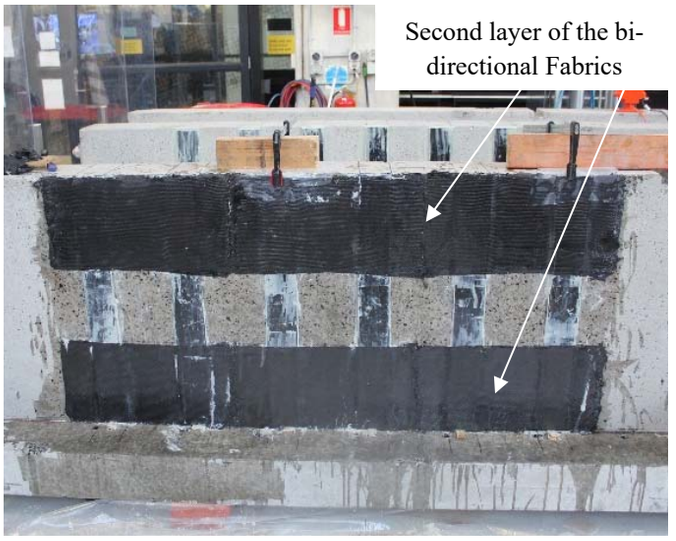

Figure 3. Patch anchors application.

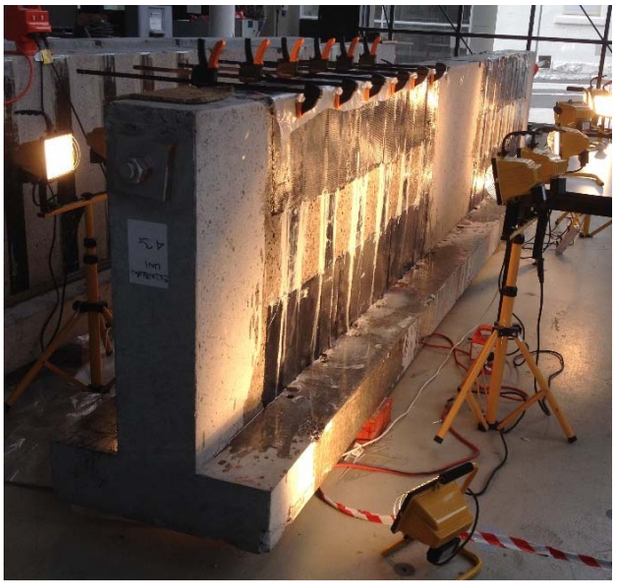

Figure 4. Curing using projectors.

3 TEST DETAILS

The beams were tested in the Smart Structures Laboratory at Swinburne University of Technology using a 5 MN universal testing machine as shown in Figure 5. Each beam was tested twice in order to extract more results from the beams. This was achieved by forcing the failure on one half of the beam only. Extra external clamping was provided in the second half of the beam, in order to increase the shear capacity and keep it unharmed during the test. Prior to testing the beams, 18 holes with a diameter of 22mm were drilled on each side of the flange, this was followed by installing 20 mm diameter high tensile all thread through these holes. Steel bearing plates were used at the top and bottom of the beam with a thickness of 30 mm as shown in Figure 6. Each bar was stressed to a force of 100 kN using a hydraulic jacks as shown in Figure 7.

Figure 5. The beam inside the 5MN machine.

Figure 6. The beam with the all thread bars and the steel plates.

Figure 7. Stressing the bars using the hydraulic jack.

Image correlation photogrammetry was used to monitor the strain in the laminates during the tests as shown in Figure 8. Additionally, strain gauges were also installed on the laminates for additional verification. Six laminates were instrumented with strain gauges, thirteen strain gauges were used for each test.

Nine strain gauges were installed at the middle of the fourth laminate along its length, with gauge spacing of 100 mm. The rest of the laminates were instrumented with one strain gauge at the middle. The results, which have been obtained from the strain gauges, were later compared with the strains obtained from the Correlated Solutions device.

Table 1 presents the martial properties of the FRP laminates and sheets used in the tests, and table 2 shows the adhesive and staurant properties; in addition, table 3 plots the compressive strength of the three beams.

Beams	*Compressive Strength Value (MPa)*
Control Beam	59.8
Strengthened Beam	62.4
Strengthened Beam with Anchors	64.7

4 TEST RESULTS

4.1 *Load-Displacement*

The use of Patch anchors has increased the load carrying capacity of the beam by 63.9% when comparing the maximum load reached of the beam with anchors and the peak load of the control beam as shown Table 4. Figure 9 presents the load-displacement curves of the tested beams. Moreover, using the unanchored CFRP laminate in the ST series beams resulted in a maximum load increase of 32.7% when comparing to the control beam.

Table 4. Maximum load for the tested beams.

Beam	*Symbol*	*Maximum Load Value kN*	*Percentage increase over control beam*
Control Beam	C	1216	
Strengthened Beam Test 1	ST1	1454	(19.6%)
Strengthened Beam Test 2	ST2	1614	(32.7%)
Strengthened Beam with Anchors Test 1	STA1	1967	(63.9%), (35.3%)
Strengthened Beam with Anchors Test 2	STA2	1948	(60.2%), (20.7%)

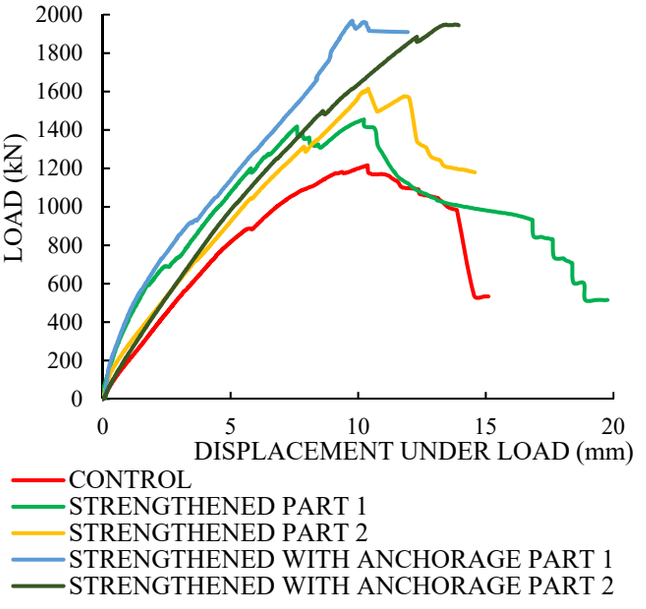

Figure 9. Load-Displacement diagram for the all beams.

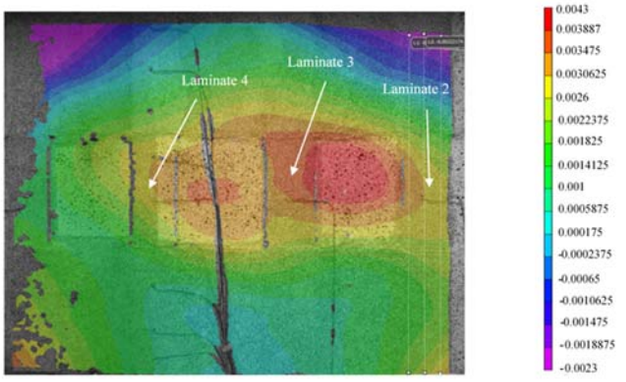
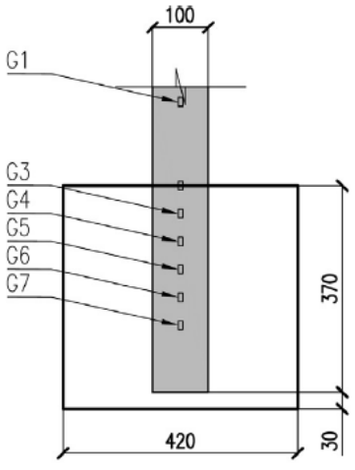
4.2 *CFRP Strains*

The CFRP Strains in the strengthened beams were observed and measured, in order to study the effect of the patch anchors on the CFRP Laminates strains and their role in improving the ultimate shear capacity of the beams. Figure 10 displays the strains in the critical three laminates of the strengthened beam with anchors. The maximum strains in the laminates (in the tested beams) which have been obtained from using the image correlation photogrammetry system have been compared with the strains of the laminates in the joints that have been tested by Kalfat and Al-Mahaidi (2014), these joints are shown in Figure 11; in addition, table 2 presents a comparison between these strains. The average of the strain along the observed laminates has been examined and plotted in Figures 12 for the strengthened Beam. In this figure the strain is plotted with different loadings, in order to distinguish the load at which the maximum strain is recorded and the load at which the laminate debonded. From the obtained results it can be concluded that the use of the patch anchors has increased the strain in the laminates and they enhanced the utilization of the laminates strength.





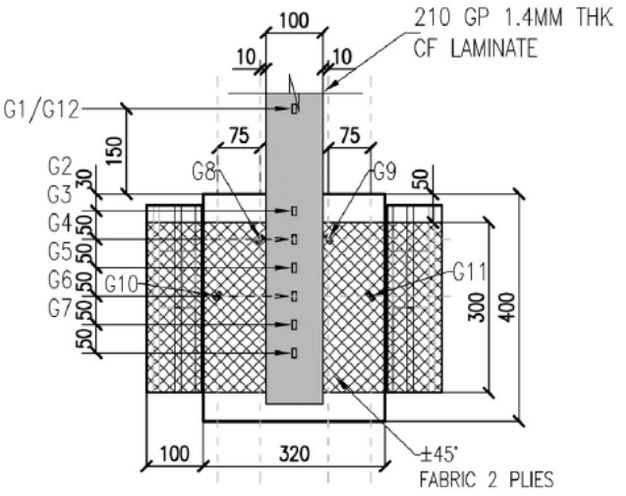


Figure 10. Plot of the CFRP laminates' strains in the strengthened beam with Anchors part 1 (Photogrammetry).

Table 2. Maximum strains obtained from the experimental results of (Kalfat and Al-Mahaidi 2014), and Maximum strains obtained from the experimental tests of the beams.

Tested beams	*Max Laminate 2 Strain*	*Max Laminate 3 Strain*	*Max Laminate 4 Strain*	*(Kalfat and Al-Mahaidi) Joints Strain*
	(με)	*(με)*	*(με)*	*(με)*
ST1	2953	3614	2443	3012
ST2	3578.87	3435.45	4445.40	3012
STA1	4114	3744	3111	5218
STA2		4960.085	4586.49	5218

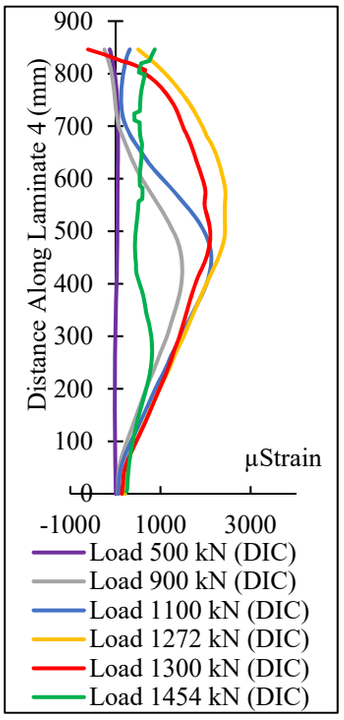

Figure 12. Strain along laminates 2, 3, and 4 in the strengthened beam test 1, at different loadings.

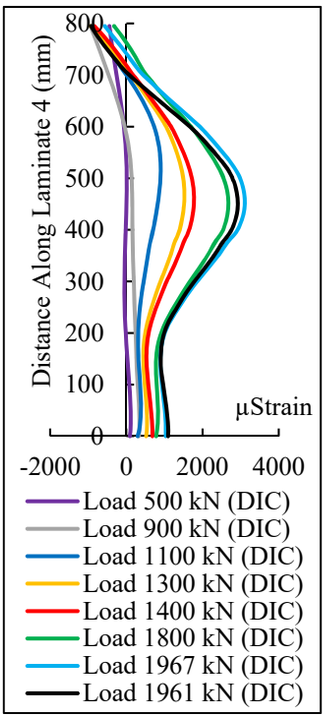

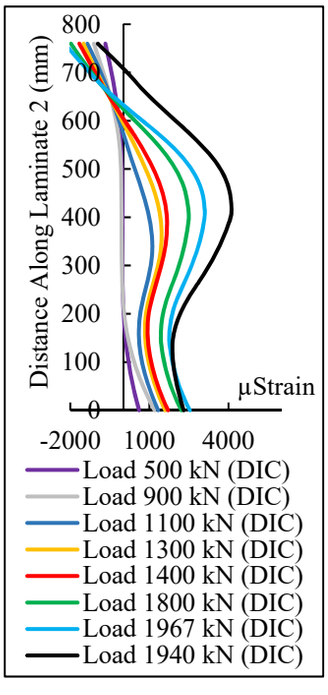

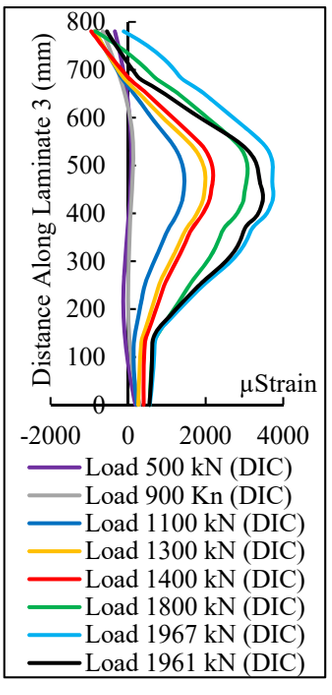

Figure 13. Strain along laminates 2, 3, and 4 in the strengthened beam with anchors test 1, at different loadings.

It should be noted that the use of the patch anchors increased the strain in the CFRP Laminates, from 2953 micro-strain (obtained from the CFRP in the strengthened beam without anchorage first test) to 4114 micro-strain (obtained from the anchored beam first test), these readings represent the strain in laminate 2 in the beams. Laminate 3 strain was 3614 micro strain in the strengthened beam and was 3744 micro strain in the anchored beam. Moreover, the strain in laminate 4 increased from 2443 micro strain to 3111 micro strain as noted before in the previous table and charts; moreover, from Figure 13 which shows the strain along the laminates for the strengthened beam with anchors first test.

CONCLUSION

In the current paper, the effectiveness of the patch anchors as an anchorage system for the CFRP laminates in the shear strengthened large scaled post-tensioned T-beams was investigated experimentally. In this anchoring method, the CFRP laminates strip, at the web part of the T-beam, was sandwiched with two layers of bi-directional CFRP sheets with ±45° fabrics. Theses anchors were used at both ends of the laminate strip. It can be concluded from the achieved results that:

- Using the patch anchors has delayed the premature debonding of the laminate, and that has resulted in enhancing the utilization of the laminates, which has been proven by the increase in the laminate strain in the anchored specimens.

- The shear capacity in the tested beams has been considerably enhanced with the use of the CFRP laminate strips as an external strengthening method for the shear deficient beams; in addition, the anchors also improved it further beyond the unanchored specimens. This can be noted with the increase of the load carrying capacity of the tested beams.

ACKNOWLEDGEMENT

The support of FYFE Asia Ltd is gratefully acknowledged for sponsoring this project and supplying all the CFRP material used.

FRP strengthening of concrete structures using AS5100-2017

H. B. Pham
SMEC Australia

ABSTRACT: The new Australian Bridge Design Standard AS5100-2017 provides guidance on the design of reinforced and prestressed concrete structures using fibre reinforced polymer composites (FRP). This is the first design standard for FRP strengthening in Australia which cover many relevant topics including material specification, installation, inspection and maintenance, flexural strengthening, shear and torsional strengthening, and axial strengthening. The paper provides some background information for some of those topics. Relevant Australian and international researches are reviewed and summarized. As noted in the paper, understanding of the mechanic and theories behind FRP strengthening is important before a safe and efficient design can be achieved.

1 INTRODUCTION

1.1 *General*

Strengthening of concrete structures using fibre reinforced polymer (FRP) is gaining popularity in Australia. This is due to not only many advantages that this technique can offer but also the increasing awareness among asset owners, engineers and contractors. The new AS5100-2017 was released early 2017 marked another significant step in FRP strengthening in Australia where a state-of-the-art guidance is provided in AS5100.8 Clause 3.6.2 and Appendix A.

This paper describes a background for some of the information provided in this standard. What presented here is the author's own interpretation and the reader should contact Standards Australia if he/she wishes to send queries on the standards.

1.2 *References*

The guidance on FRP strengthening in AS5100 is the result of the works by many people. It is based on VicRoads Standard Specification 688, international design guides, and international and Australian researches. Inputs from local suppliers were also incorporated.

2 GENERAL REQUIREMENTS FOR FRP STRENGTHENING

Clause 3.6.2 provides a very brief summary of the general requirements for FRP strengthening.

The strength of the existing concrete surface affects the bond and the performance of the FRP system. The minimum tensile and compressive strengths required by AS5100 are1.5 MPa and 17 MPa, respectively. This is consistent with the recommendation from AS 440.2R. These requirements should apply for the concrete adjacent to the bond only and for bond-critical applications only.

FRP bond performance is sensitive to other factors including adhesive properties, environmental conditions and workmanship. As a result, a comprehensive and strict inspection scheme is a must.

While a 30 year design life is mentioned in the standard, a longer design life can be achieved and ensured by routine inspections and maintenance. FRP system can be repaired relatively easily using techniques as outlined in Pham (2009) and TR 57 Report.

Validation of FRP composite system by testing is typically not required provided it is designed and proof engineered by qualified personnel who have proven track records of working with FRP materials and bridge strengthening.

3 MATERIALS

AS5100.8 Clause A2 defines general requirements for constituent materials. It is important that sufficient details are provided for all materials. They must be of a satisfactory standard with evidence of acceptable quality control procedures, test methods and results.

An attempt was made in the standard to categorise carbon laminates, carbon fabrics, glass fabrics, aramid fabrics as well as adhesive and resin materials. In the author's opinion, the properties stated should be for guidance only and materials with different engineering properties might be allowed provided that they satisfy the general requirements mentioned above and the system has been appropriately engineered.

Table 1. Typical reinforcing fibre material property ranges

Property	CFRP Laminates	CFRP Fabrics	GFRP Fabrics	AFRP Fabrics
E (GPa)	140-245	215-600	60	100
f_t (MPa)	2000-2800	2600-4300	2800	2800
Fibre fraction	~65%			
Fibre density (g/cm3)		1.6	2.2	1.3

Resin materials need to be compatible with reinforcing materials and substrates and are able to transfer the shear force between the two materials. One important property is the bond strength which must not be less than 1.5 MPa for bond-critical applications.

It is worth noting that the typical resin material glass transition temperature is between 60 to 80 degree C. This means the FRP system will become ineffective when the temperature reaches that level. Insulation can be provided to ensure service appropriate temperatures.

4 INSTALLATION, INSPECTION AND MAINTENANCE

AS5100.8 Clause A3 provide requirements for surface preparation, application and trials. These requirements appear to be based on existing specifications and FRP system provider's application guides. As the effectiveness and durability of FRP a system are dependent on many factors, a trial is highly recommended. Trials can be inexpensive and very effective method to ensure a successful application of FRP.

Clause A4 sets out the requirements for inspection, performance testing and maintenance. These requirements are self-explanatory. They are again based on existing specifications, FRP system provider's application guides and the writers' experiences.

Pull-off tests are relatively easy to be carried out and shall be conducted in addition to component testing. A successful test would have the failure surface in the concrete as shown in Figure 1.

Figure 1. A pull-off test dolly

5 DESIGN

General design requirements are covered in Clause A5 of the standard.

The minimum strength requirement is consistent with ACI 440.2R. This limit is to ensure the non-strengthened structural member have sufficient strength to sustain permanent loads and 75% of service transient loads. Coupled with ductility requirement specified in Clause 6.3.3, this ensure that if debonding occurs for any reasons (vandalism, overloading…), the structure is still ductile and allows sufficient warning before total collapse. It is worth noting that for bridge structures, the live loads that are typically on the bridge are less than 75% of the design live loads.

The environmental reduction factors are based on the recommendations by ACI 440.2R. These are considered appropriate at this moment. Recently, there has been much research on this topic and it is expected that these factors would be revised.

6 FLEXURAL STRENGTHENING

The basic principles and design assumptions of flexural strengthening are similar to those for normal-reinforced or prestressed sections. The FRP strengthened section is assumed to follow beam theory. However, there are fundamental differences in the behavior of normal reinforced or prestressed girders to FRP strengthened girders. These are explained below.

6.1 *Importance of construction staging and long-term effects*

For a typical ductile bridge girder section, the section strength at ultimate is reached when the steel reinforcements have yielded and the top concrete fibre strain reaches the crushing strain (3000 microstrain). A typical strain distribution at ultimate is shown below (Figure 2).

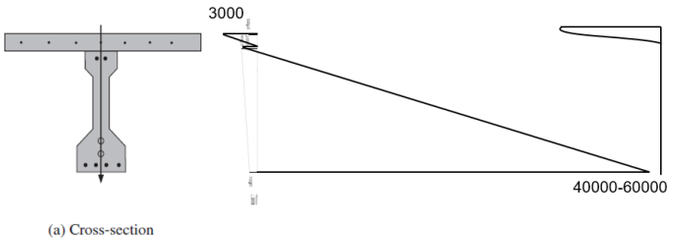

Figure 2. Strains in a typical bridge girder at ultimate (microstrains)

The strains at ultimate are therefore well defined and much higher that the strains developed using service limit state. As a result, the effects of construction staging, and creep and shrinkage are often ignored in the calculation of the girder ultimate capacity. This also means that the calculation is relatively straight forward.

For FPR strengthened girders, the concrete and reinforcement (steel and FRP) strains at ultimate can be much lower than those in normal reinforced or prestressed girders (Figure 3). This is due to the fact that the controlling strain is often the FRP debonding strain which is often less than 6000 microstrain.

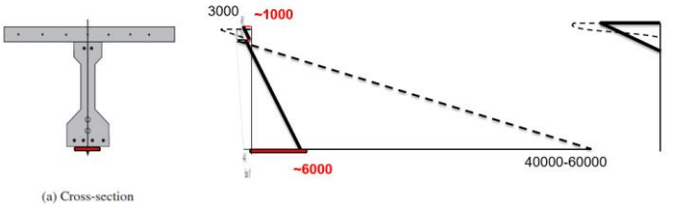

Figure 3. Strains in a typical FRP strengthened bridge girder at ultimate (microstrains) (shown as solid lines) as compared to those in normal underreinforced girder (shown as dotted lines)

As a result, effects of construction staging are significant and cannot be ignored in the calculation of the girder ultimate capacity. It is worth noting that permanent effects are already locked in prior to FRP is bonded introducing another stage. While the effects due to creep, shrinkage and relaxation might be ignored at ultimate, they would alter the strain levels and affect the calculation of the capacity reduction factor.

Accounting for construction staging and long-term effects is not straight forward. However, if it is ignored, the strain in the FRP might be underestimated by up to 50% and therefore the moment ultimate capacity might be overestimated significantly. Calculation of strains would involve an iterative progress.

6.2 *Material stress-strain curves*

When the compression strain in the concrete top fibre is much less than 3000 microstrain, the use of Whitney rectangular stress block may not be accurate. The recommended concrete stress strain relationship as decribed in AS5100.8 Clause A6.2.3 is taken from Desayi and Krishnan (1964) and by Todeschini et al. (1964).

A full stress strain relationship for prestressing steel is also required to determine the strengthened capacity. Due to potential low strains at ultimate, the ultimate tensile strength of prestressing steel might not be achieved and the strength gain might be sensitive to the assumed stress-strain curve. Stress-strain models are available in ACI440-2R or Skogman et al. (1988).

6.3 *Failure modes*

Unlike normal reinforced or prestressed concrete girders, FRP strengthened girders have much more failure modes. These modes are summarized in Clause A6.3.1 which is adapted from Pham and Al-Mahaidi (2002) and Pham (2005).

6.4 *Capacity reduction factors*

Equation A6.3.2 is based on ACI 440.2R Equation 10.2.7 which is in turn based on ACI 318. In this equation, it is taken that the section is ductile when the steel yields at ultimate. This was developed for normal reinforced concrete beams. This approach is generally different to AS5100 approach which defines ductility based on the depth of the neutral axis. Due to the reasons noted in Section 6.2, if Equation A6.3.2 is used, it is possible that the strengthened section has lower strength than the non-strengthened section due to lower reduction factor. In the author's opinion, a capacity reduction factor of 0.8 should be adopted for the following reasons:

- Ductility is the capacity to see warning signs (large deflection, cracking…) before collapse. Pham (2005) has shown that after debonding of FRP, the tested beams retain its original strength and ductility.
- AS5100.8 Clauses A5.3, A6.1 and A6.3.3 have ensured that in the scenarios when FRP debonding occurs (with or without low strains in steel reinforcement at ultimate), the structure does not collapse. Total failure would only occur if the non-strengthened girder reaches its ductility limit.

Other benefits of using the 0.8 factor are:

- This is consistent with AS5100 approach regarding capacity reduction factors. The ACI approach is not consistent with Australian standards (for example, we do not have capacity reduction factor of 0.9 when a section is highly ductile).
- This would avoid many difficulties/confusions among designers.
- This approach is safe because we have only allowed ductile sections to be strengthened and we have ensured that unstrengthened

sections have adequate capacity to avoid total collapse without early warmings.

Equation A6.3.2 does not apply for prestressed sections. The reader needs to refer to Clause 10.3.1.3 in ACI 440.2R for the equation for prestressed sections. This would be added to AS5100 in the next revision.

6.5 *FRP debonding strains*

The common failure modes are FRP IC debonding which is initiated from a flexural crack, and FRP end interfacial debonding and concrete cover separation that both occur from the FRP end due to high shear stresses there. The failure mechanisms are illustrated below.

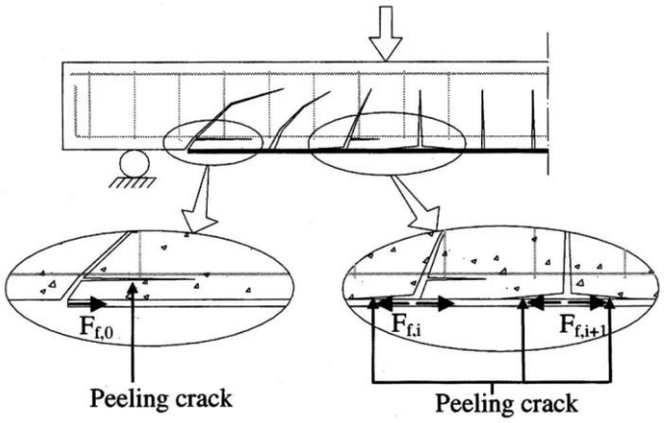

Figure 4. FRP debonding mechanisms

Equation A6.3.5.2 is based on the work by Teng et al. (2003). This equation has been verified by Pham and Al-Mahaidi (2004) and proven to be accurate. It is worth noting that the debonding strain is inversely proportional to the square root of FRP stiffness. As shown below, FRP becomes less effective as its thickness is greater than 2mm. It is recommended that the number of FRP layers is limited to 2 or 3.

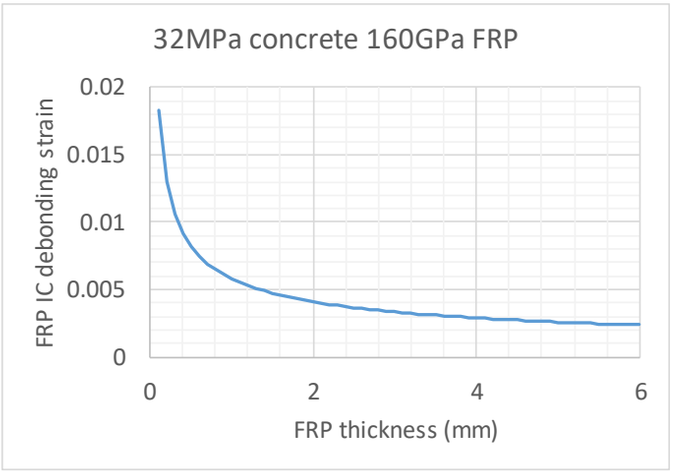

Figure 5. FRP IC debond strains versus thickness

Equation A6.3.5.3(1) is based on the work by Pham and Al-Mahaidi (2006). The longitudinal shear stresses in the adhesive layer or in the concrete level of the nearest reinforced should be limited to a shear strength limit of 0.17 sqrt(f'_c). This is consistent with the recommendation in AASHTO Guide Specification (2012).

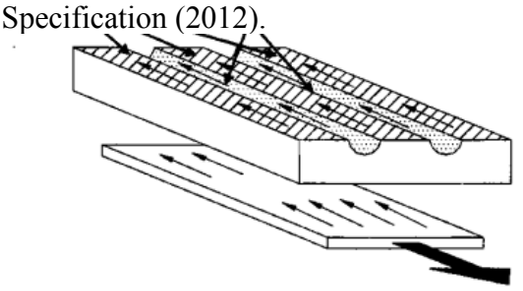

Figure 6. Surfaces where longitudinal shear stresses act

For near surface mounted FRP strengthened beams, the IC debonding strain is higher. The limit is based on ACI 440.2R. Interfacial debonding should not be critical and cover separation can be checked in the same way as surface bonded FRP.

Near surface mounted FRP is often used on the top of a deck to strengthen the hogging region. Recommendations for detailing is not available in AS5100 but can be found in ACI440.2R. In addition, a layer of cementitious grout is recommended to provide insulation from hot asphalts. A layer of coloured asphalt could also be used as an indicator for future pavement work. It is worth noting that a wide FRP laminate bonded in a shallow recess does not behave similarly to a near surface mounted FRP rod or narrow strip.

6.6 *Serviceability Limit State*

The creep rupture and fatigue stress limits are based on ACI 440.2R. The serviceability stress limits are modifications form the requirements in ACI 440.2R.

6.7 *Notes*

- Simplified code equations do not apply for complex bridge girder strengthening.
- Calculation of the capacity of a retrofitted composite prestressed section requires an iterative process considering of construction staging. This is often done by specialised spreadsheets or softwares.
- Increasing FRP thicknesses does necessarily increase the capacity as thicker FRP would debond at a lower strain.
- Using thinner FRP and increasing bond areas would improve the strength enhancement.

The level of strengthening will depend greatly on the element existing level of reinforcing, geometry and section buildup. However, as a guide, the typical in-

creases in flexural strength due to bonding FRP are as below.

Table 2. Typical increases in moment capacity

Section	Potential increase in moment capacity
Non-composite reinforced sections	50%
Composite reinforced sections	40%
Non-composite prestressed slabs	30%
Non-composite prestressed box girders	15%
Composite pretensioned I girders	10%
Composite Teeroff girders	5%

7 SHEAR AND TORSIONAL STRENGTHENING

Shear strengthening is often carried out by bonding laminates on both the soffit and the sides of the beam. The laminates on the sides act like steel stirrups to cross diagonal cracks. They can be narrow strips placed at certain spacing or wide plates covering the entire shear span. The main direction of the fibres can be vertical or inclined to intersect shear cracks. The shear laminates can also be anchored by being wrapped around the beam or by mechanical anchorage (Figure 7).

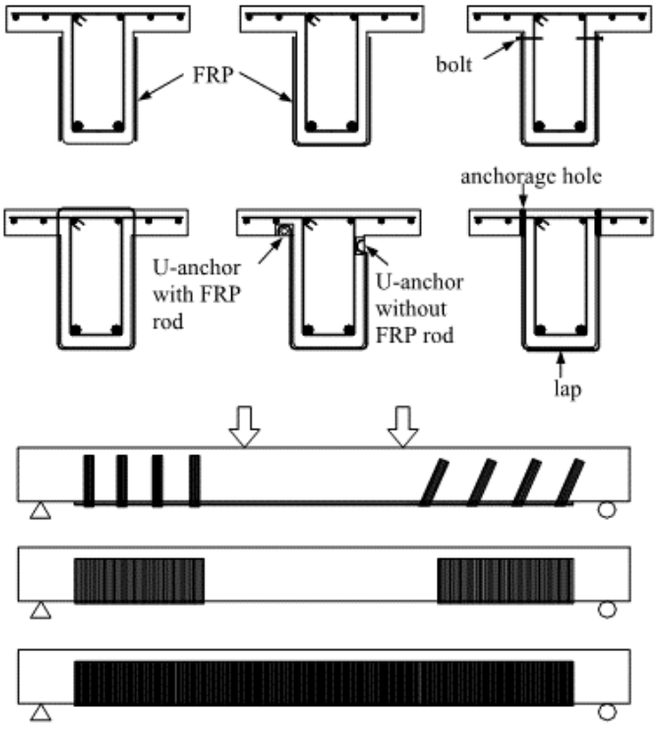

Figure 7. Shear strengthening using FRP

Several shear related failure mechanisms of FRP shear laminates have been identified including tensile rupture, debonding through the concrete near the bond interface or localised failures. The ultimate shear strength can be calculated as the sum of the portions contributed by concrete, steel stirrups and FRP shear laminates. Expressions used to calculate the portion of the shear force contributed by FRP laminates were based on the truss analogy or more rigorous compression field theory. To predict the maximum force that FRP shear laminates can undertake, a reduction in the FRP capacity due to stress concentration or debonding needs to be considered.

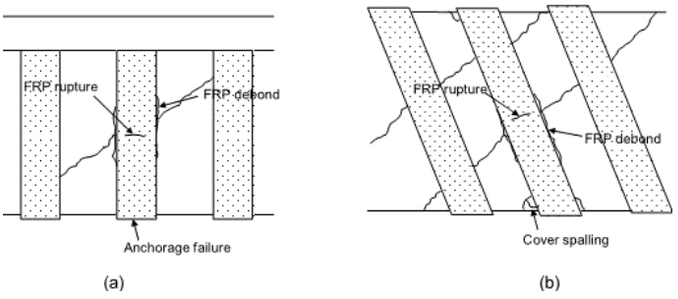

Figure 8. Failure modes in RC beams strengthened in shear and torsion

Equation A7.2.2 is based on the truss analogy. The effective strain equations in Clause 7.2.3 are based on ACI 440.2R and researches by Priestley et al. (1996) and Khalifa et al. (1998). These strains can be as low as 0.0015 which is much lower than the FRP ultimate limit strain (the standard specifies an upper limit of 4000 microstrain for shear strengthening). This highlights the fact that the higher strength FRP does not necessarily results in higher shear strength. Providing more layers of FRP would increase the FRP shear contribution slightly. However, it is recommended that the number of plies/laminates is kept below 3.

Torsional strength of concrete beams with bonded FRP can be determined using the principles set out in AS5100.5 Clause 8.2.5. with T_{us} replaced by (T_{us} + T_{uf}). The angle θ_t is as calculated in AS5100 Clause 8.2.4, and the area A_t can be taken as the area of a polygon with vertices at the centre of the longitudinal bars.

Equation A7.3.3 is based on a torsional truss analogy. This approach is consistent with fib Bulletin 14 with some modification as described in Adrian and Al-Mahaidi (2007). This formula has been verified and proven to be conservative.

8 AXIAL STRENGTHENING WITH CONFINEMENT

Equations for axial strengthening are based on ACI 440-2R. Wrapping concrete columns with FRP provides confining stresses that result in higher concrete strength as well higher strain at ultimate. N-M moment interaction diagrams will need to be constructed taking into account the concrete confined stress-strain curve.

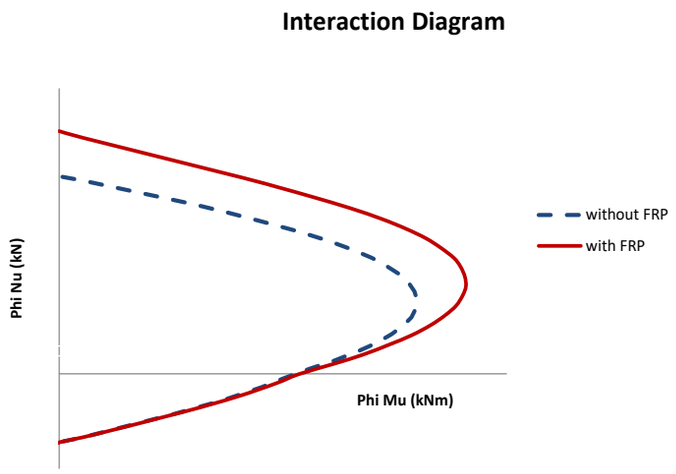

Figure 8. N-M curves for a concrete column with and without FRP

9 ANCHORAGE OF FRP

Detailed knowledge of the bond behaviour between FRP and concrete is fundamental in designing structures retrofitted by bonding FRP strips or sheets. The bond failure interface occurs in a thin concrete layer just under the adhesive layer. There have been great difficulties in developing a simple and accurate method to predict the bond strength. An inherent challenge is the fact that the shear strength of the failure interface can vary significantly due to variation in concrete properties (cement paste properties, aggregate properties and distribution near the bond surfaces). These properties can be sensitive to concrete mix, concrete casting, type of cement and aggregate and surface preparation. As a result, the more reliable prediction formulas tend to be empirical or semi-empirical.

Another challenge in deriving a strength model is due to variations in the test set-ups and a variety of failure modes. Past studies have indicated that tension is transferred to the concrete mainly via shear stress in a short length nearest to the loaded end called the effective bond length. The bond load does not increase once the bond length exceeds the effective bond length.

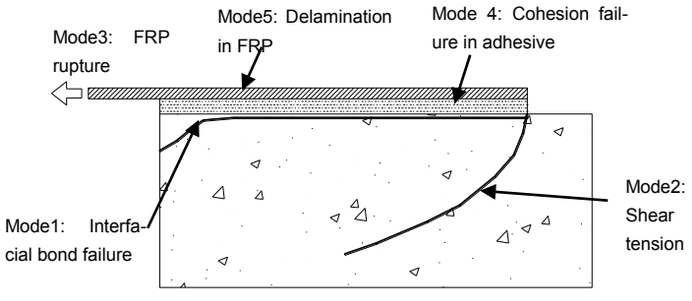

Figure 9. Possible failure locations in a shear-lap test

There have been a number of models developed to predict the bond strength. These models were summarized and verified by Pham and Al-Mahaidi (2014). AS5100.8 Formula A9.1 is based on TR55 report which appears to be modification of the formulas developed by Neubauer and Rostary (1999). These formulas were verified and found to be reasonably accurate (Figure 10).

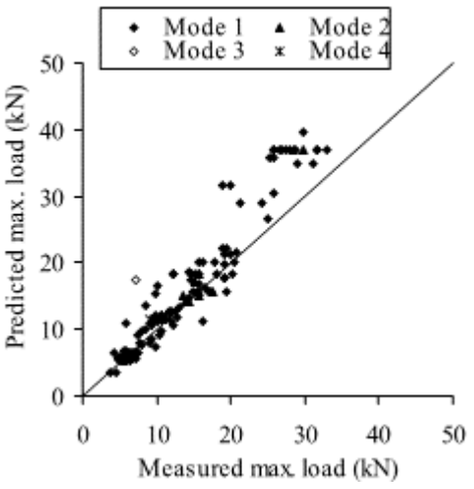

Figure 10. Verification results for Neubauer and Rostary's model by Pham and Al-Mahaidi (2014)

Anchorage devices for FRP are often designed from first principles. These can be made of FRP or steel.

There appears to be a lack of guidance in AS5100-2017 on detailing for FRP flexural strengthening. It is recommended that designers refer to ACI-440 for guidance in detailing.

10 SUMMARY

AS5100.8-2017 provides a detailed guidance into FRP strengthening. A good understanding of FRP strengthening is essential during the design and selection of the system. Much of complexity is due to the fact that FRP tends to debond from concrete prematurely. As a result, stringent installation and inspection requirements are a must. The design often involves complex calculations and a thorough assessment of the system. It is recommended that both the design and construction of FRP strengthening are reviewed by experienced personnel.

11 ACKNOWLEDGEMENT

The author would like to acknowledge other members of the Standards Australia Working Group BD-090-08 FRP Strengthening Sub-Group who, together with the author, developed Appendix A of AS5100.8-2017. The author would also like to acknowledge Professor Riadh Al-Mahaidi who led the research in FRP strengthening in concrete structures at Monash University.

Flexural FRP Strengthening of Concrete Bridges Using an Innovative Concept

Jincheng Yang[1], Reza Haghani[1], Mohammad Al-Emrani[1]
[1]*Chalmers University of Technology, Gothenburg, Sweden*

ABSTRACT: This paper presents an innovative method for flexural strengthening of reinforced concrete (RC) bridges using pre-stressed carbon fiber reinforced polymer (CFRP) laminates as externally bonded reinforcement (EBR) and glass-fiber reinforced polymer (GFRP) deck panels. The work was a part of an EU-funded project called sustainable refurbishment of existing bridges (SUREBridge). The innovative features of this concept include the tensile reinforcement of the section using self-anchored pre-stressed CFRP laminates and compressive reinforcement of the section using tailor-made GFRP deck panels at the same time. The flexural behavior of RC T-section beams, strengthened using this concept, has been studied experimentally. Four 6-meter-long beams—three strengthened with bonded pre-stressed CFRP laminates in bottom with a pre-stressing force of 100 kN and GFRP deck panels on the top side and one as control beam—were tested in four-point bending configuration. The results indicated a substantial increase of ca. 160% in ultimate load carrying capacity of the strengthened beams as well as considerable improvements in flexural stiffness and cracking loads. The strengthened beams also displayed a ductile behavior after debonding of externally bonded CFRP laminates while maintaining the maximum load level before debonding due to the strong bond between the GFRP decks panels and the concrete beam. It was concluded that the proposed method has the potential to be introduced as a reliable method for strengthening of old concrete bridges.

1 INTRODUCTION

1.1 *Existing challenges and demands*

There exist about one million bridges in Europe. Over 90% of these bridges have concrete decks. 65% of concrete and steel/concrete composite bridges are older than 50 years. Bridge owners and traffic authorities in European countries, therefore, are dealing with a substantial number of old bridges which are turning structurally deficient and geometrically insufficient. Results of surveys from SUREBridge project reveal that 70% of the reported damage in concrete bridges are related to decks and edge beams. A study conducted within the European project "Sustainable Bridges" (PANTURA Project, 2012) revealed that a top priority from the bridge management point of view is to develop non-disruptive strengthening and repair techniques for bridges. It also indicated that two major problems involved with existing bridges are (i) the aging and lack of load bearing capacity of the superstructure, and (ii) the need for wider decks to accommodate the increased traffic volume. Therefore, the refurbishment of existing bridge structures, in this context, includes not only strengthening, repair and upgrading, but also geometric changes such as widening the bridge deck to provide more traffic volume capacity.

1.2 *SUREBRIDGE concept*

SUREBridge stands for sustainable refurbishment of existing bridges and was an EU funded project within the framework of Infravation program. To meet the demands put forward by road authorities and bridge owners, the SUREBridge refurbishment concept chose to take a holistic approach to further upgrade the structural capacity and geometry of bridge superstructures beyond what traditional refurbishment methods offer. In brief, it consists of using bonded carbon fiber reinforced polymer (CFRP) laminates (in pre-stressed or passive state) as externally bonded reinforcement (EBR) on the bottom side of the bridge deck or girders in sagging moment areas and simultaneously installing prefabricated light-weight glass-fiber reinforced polymer (GFRP) deck panels installed on the top of the original concrete deck. The idea is to create a "sandwich" strengthening scheme in which the amount of tensile and compressive strengthening is balanced. Taking advantage of the superior tensile strength of CFRP and possibility for geometric widening using tailor-

made GFRP deck panels, the SUREBridge solution aims to upgrade the existing old concrete bridges to the desired load and service capacity levels.

The major innovations of the SUREBridge solution to be addressed in this paper include (i) a new pre-stressing method developed for EBR technique without mechanical anchorage system at CFRP ends, and (ii) developing a tailor-made GFRP composite decking system providing a desired amount of stiffness and strength to the existing cross-section.

1.2.1 *Innovative CFRP pre-stressing method*

Bonded CFRP laminates using EBR technique in passive (i.e. un-prestressed) has become widely accepted as a structurally effective and cost-efficient method for strengthening of concrete structures. Thousands of structures have been strengthened and repaired using this technique in the past three decades. However, one problem associated with using passive CFRP strengthening laminates is the debonding of the laminate at fairly low strains from the concrete substrate. The separation of the laminate is attributed to so-called "intermediate cracks" which are points of stress concentration along the bond line. Debonding phenomenon significantly reduces the cost efficiency of the strengthening as it usually takes place at strains well below the ultimate strength of the laminate. It is believed that the utilization ratio of bonded CFRPs for flexural strengthening is limited to 40%. To increase the efficiency, researchers have suggested to use pre-stressing in the laminate before bonding. It has been shown that using pre-stressing not only increases the utilization of the material but also offers advantages such as postponing the yielding of the internal reinforcement, reducing the crack width and thus improved durability, and improved fatigue behavior. However, a problem associated with pre-stressed bonded FRP laminates is the emerge of very high interfacial stresses close to the ends of the laminate which necessitate the use of mechanical anchors. Using mechanical anchors, so far, has been considered as the biggest hindrance towards widespread use of pre-stressed CFRP laminates despite the advantages they offer.

A new concept developed at Chalmers University of Technology allows for using pre-stressed laminates without the need for mechanical anchorage (Haghani and Al-Emrani 2015).

This innovative method is based on gradient introduction of the pre-stressing force in the CFRP laminate by means of a device (see Figure 2) and thus controlling the magnitude of the interfacial shear stress. A recent experimental study (Yang et. al 2017) showed that the application of the new pre-stressing method can realize the 'self-anchorage' of CFRP laminate at a pre-stressing level equivalent to 25% of ultimate tensile strength of the strengthening laminate without end anchors, and achievable ultimate utilization ratio of approximately 80% before debonding of the CFRP reinforcement.

1.2.2 *Tailor-made GFRP deck panels*

Another innovative feature of SUREBridge solution is to install prefabricated GFRP sandwich panels as a reinforcement on top of the existing concrete deck, creating a new FRP-concrete composite decking system. The major benefits of installing the GFRP deck panels on the existing concrete deck include:

- providing the possibility to widen the original concrete deck to meet the demand from clients regarding the geometric insufficiency;
- The GFRP deck helps to relax the compressive stress in the concrete deck;
- Enhancing the sectional resistance by contributing to the overall bending stiffness of the section.

2 EXPERIMENTAL PROGRAM

2.1 *Test specimens*

Four 6-meter long RC beams with T-shape cross-section were cast. The reference specimen, B1, was left without strengthening while specimens B2 to B4 were strengthened suing SUREBridge concept—by applying pre-stressed CFRP on the bottom side of the beams and GFRP deck panels on the top. The cross-sectional configuration of specimens is shown in Figure 1.

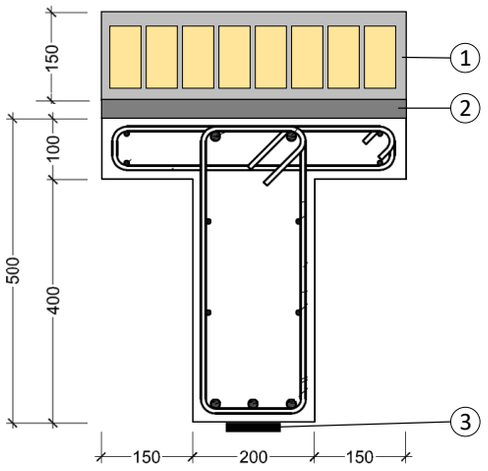

Figure 1. Cross-section of the beam specimens. Notes: 1—GFRP panel in B2-B4; 2—10-mm-thick bond layer using epoxy adhesive in B2 and 30-mm-thick bond layer using low-shrinkage mortar in B3 and B4; 3—pre-stressed CFRP plate

The concrete of grade C35/45 was used to cast the T-beams, as later was verified by compressive cube tests. The CFRP laminates were 5.3-meter long with a nominal cross-section of 81.98 mm × 1.45 mm. The designed pre-stressing force was 100 kN. Tensile tests on CFRP coupons were conducted according to ASTMD3039 to characterize the mechan-

ical properties of laminates. The material properties are listed in Table 1.

Table 1. Summary of material properties

* values provided by suppliers

The difference between B2, B3, and B4 specimens was mainly due to (i) the connection method between the GFRP deck and the T-beam, and (ii) the orientation of GFRP decks installed on top of the beams (Table 2). In specimen B2 and B3, the GFRP deck panels were oriented with webs in the longitudinal direction (i.e. strong direction) along the beam while the panels in specimen B4 had webs in the transverse direction of the beam. The GFRP deck panels were manufactured with vacuum assisted resin transfer molding (VARTM) method. The prefabricated sandwich decks were 6-meter long and 0.5-meter wide. The nominal thickness of top and bottom skins was 19.1 mm, while the webs were 8.5 mm thick and 112 mm high with a spacing of 110 mm.

Table 2. GFRP GFRP panel and connection method in specimen B2, B3 and B4

Specimen	Type of GFRP deck/panel	Connection method	Bond material
B2	GFRP panel with longitudinal webs	Epoxy-based adhesive bonding	Sto SK 41
B3	GFRP panel with longitudinal webs	Low-shrinkage mortar bonding	Weber 702
B4	GFRP panel with transverse webs	Low-shrinkage mortar bonding	Weber 702

2.2 *Pre-stressing method and implementation*

The innovative pre-stressing device (Figure 2) consists of eight aluminum tabs, which are interconnected with a series of springs (i.e. steel bars with different diameters). The tabs are then connected to the CFRP laminate via a medium (a 10-mm-thick GFRP plate in Figure 2). The GFRP plates (length of 1200 mm) with built-in steel nuts were bonded to the CFRP plate in advance. The pre-stressing device was then bolted to the GFRP plate using high strength M6 bolts. The function of the pre-stressing device is to evenly distribute the total amount of pre-stressing force via these tabs over the length of the CFRP laminate.

Aided by this innovative mechanism, it was possible to—with merely one jacking action—distribute the total pre-stressing force in the CFRP laminate in a step-wise manner and control the gradient of the pre-stressing force in the laminate as intended in the design. A detailed description of the pre-stressing process can be found in Haghani and Al-Emrani (2016) and Yang et al. (2017).

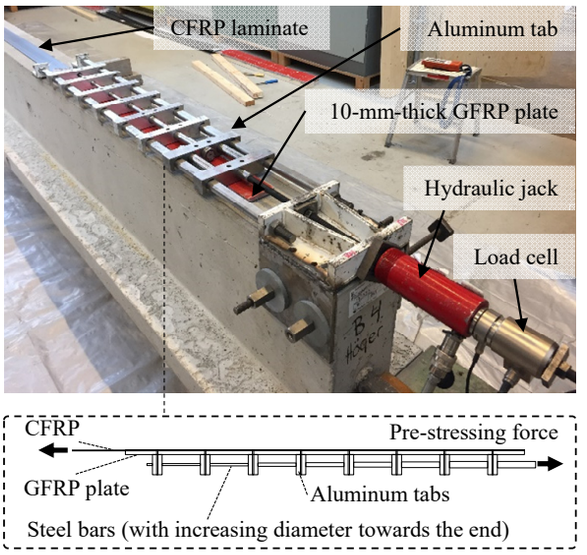

Figure 2. Pre-stressing device mounted on the bottom side of web during tensioning the CFRP laminate

The pre-stressing device was mounted on the concrete beam using temporary anchors. After pre-stressing and curing of the epoxy for 24 hours, the device was removed (Figure 2). Upon the release of the pre-stressing device (aluminum tabs and steel bars), the pre-stressing force in CFRP was transferred to the concrete through the adhesive layer. Previous experimental studies by Yang et al. (2017) proved that it was possible to control the shear and peeling stresses in the bond line below 0.5 and 0.1 MPa, respectively, given a pre-stressing force of 80 kN distributed by eight steps (i.e. tabs).

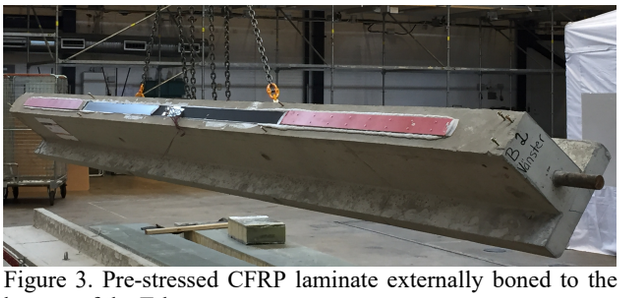

Figure 3. Pre-stressed CFRP laminate externally boned to the bottom of the T-beam

2.3 *Installation of GFRP deck*

Before installation, the top surface of flanges in each T-beam was coarsened with sandblasting in the workshop. In specimen B2 the GFRP deck was

bonded to concrete beam with 10-mm-thick epoxy adhesive, see Figure 4. In specimen B3 and B4, the surfaces of the GFRP deck panels were pre-coated with coarse aggregates with help of an epoxy adhesive. The aggregates were emery stones with a diameter size of 1 mm to 3 mm. The distribution density was 12 kg per square meter. The GFRP panels were first connected to concrete beam with M24 dowels. The dowels served as an extra safety measure in case the cement-based mortar between the GFRP and concrete fails. They also provided a 30-mm gap (i.e. thickness of the mortar layer) through using adjustment washers and nuts before laying down the deck panels on concrete beams. After building the formwork around the beam flange, a low-shrink mortar was used to cast the 30-mm-thick bond layer. The well-mixed mortar was poured into the gap from one side along the beam (Figure 5). Meanwhile, the mortar was vibrated to assure a good flow of the mortar and uniform distribution. The cement-based mortar was left for curing of 28 days before the flexural test.

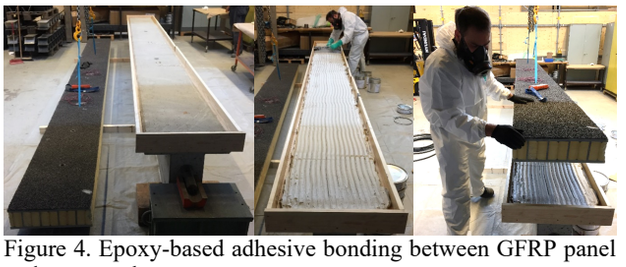

Figure 4. Epoxy-based adhesive bonding between GFRP panel and concrete beam

Figure 5. Low-shrinkage mortar bonding between GFRP panel

2.4 *Test setup and monitoring devices*

The beam specimens were simply supported with a clear span of 5.7 meters (Figure 6). The monotonic loads from two hydraulic jacks were applied in the displacement-control manner to form a four-point bending configuration. The loading speed was 1 mm/min before the yielding of tensile reinforcement bars (B1) or the failure of the CFRP laminates (B2-B4), and then increased to 6 mm/min after that. The distance (center-to-center) between two hydraulic cylinders was 1.3 meter. The size of load prints under the hydraulic cylinders was 400 mm × 400 mm × 30 mm. A rubber pad was used between the load print and the top of the GFRP panels to transfer the load. In each specimen six linear variable differential transformers (LVDT) were used to obtain the mid-span deflection during the tests. Two strain gauges were installed on the bottom surface of each CFRP laminate at the mid-span to monitor the tensile strain from the pre-stressing process till the end of the flexural test.

3 TEST RESULT AND ANALYSIS

3.1 *Load-deflection curves*

The load vs. mid-span deflection curves were plotted for all four beams and are illustrated in Figure 7. They indicate the critical states of specimens from the onset of cracks, through the yielding of tensile steel reinforcement bars, to the failure of externally bonded CFRP laminates, till the end of the tests. The control specimen B1 exhibited a typical behavior expected from an RC beam.

The yielding of the internal reinforcement was obtained at a load of ca. 134 kN. Accounting for the strain hardening of the steel reinforcement, the ultimate load carrying capacity of the beam was determined to be ca. 155 kN. It was decided to terminate the test at deflection of 120 mm. The test result for this specimen matched well with the theoretical prediction of yielding load at 130 kN and ultimate load at 159 kN. In specimens B2-B4, there is a significant

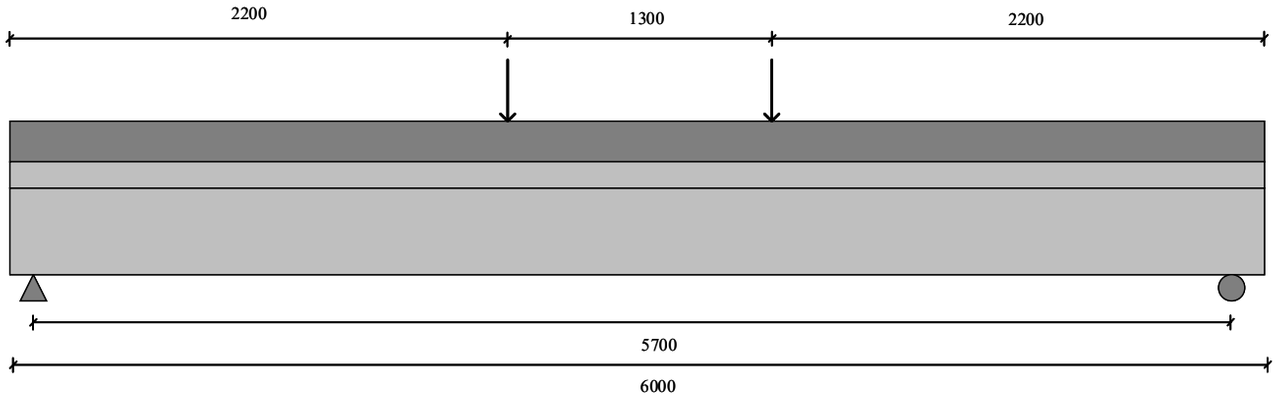

Figure 6. Configuration of specimens with location of loads. The GFRP panel on top of T-beam is only for specimen B2, B3 and B4 (Dimensions are in mm).

*5 Load at maximum crack width reaching 0.3 mm in B1 and 0.2 mm in B2, B3 and B4
*6 Ultimate load

drop of the load due to debonding of the CFRP laminate at a deflection of ca. 50 mm. What is to be highlighted is the contribution of the GFRP deck panel in the load carrying capacity of the beam after CFRP debonding resulting in substantial load bearing capacity. In specimens B2 and B3, the load increased and even exceeded the maximum load achieved in the presence of CFRP laminates. It was decided to terminate the tests due to safety reasons (the tests were continued to deflections up to 210 mm).

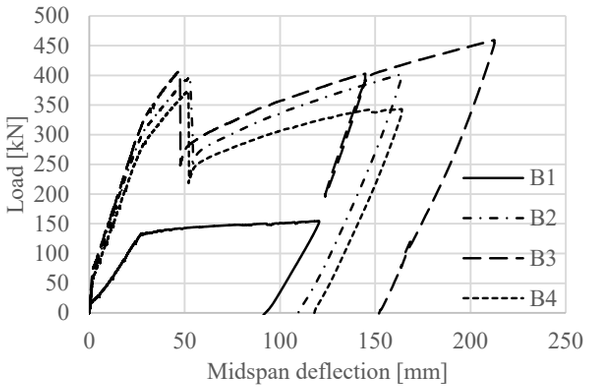

Figure 7. Load-deflection curves of specimens B1-B4

3.2 *Improvements in SLS and ULS*

The behavior of the beams in serviceability and ultimate limit states were studied. The criteria for comparison include the cracking load, stiffness and the ultimate load bearing capacity as reported in Table 3.

3.2.1 *Delayed onset of cracks*

Contribution from the increased stiffness by adding the GFRP deck panels and the pre-stressing force in the CFRP laminate, it significantly increased the cracking loads in strengthened sections. According to Table 3, the cracking load of specimen B1 increased from 18.7 kN to ca. (61~77) kN in specimens B2-B4.

3.2.2 *Improvement of bending stiffness*

The bending stiffness was estimated based on a certain section of load-deflection curves with deflection values between 10 mm (after cracking initiated) and 20 mm (before yielding of rebars). It showed that the estimated bending stiffness of the strengthened specimens increased by 82~99% compared with the reference specimen without strengthening.

In Eurocode 2 the maximum allowed deflection of RC beams is L/250 of the net span, which equals to ca. 23 mm for the tested beams. The load bearing capacity at this deflection increased from 114 kN in Specimen B1 to 261 kN, 275 kN and 242 kN in specimens B2-B4, equivalent to 114~143%, respectively.

3.2.3 *Control of maximum crack width*

In Eurocode 2 the maximum allowed crack width is limited to 0.3 mm for normal RC beams in XC2. The crack widths were measured along the full-span at different load levels starting from 30 kN to 120 kN (for B1) and to 180 kN (for B2-B4) to evaluate the effect of strengthening on crack width. The maximum crack width at each monitored load step is plotted in Figure 8.

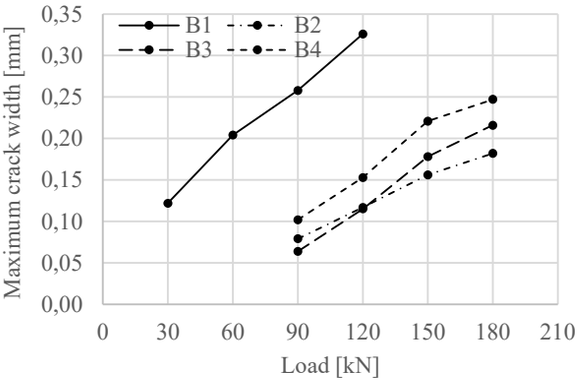

Figure 8. Maximum crack width monitored at different load levels

The load at a maximum crack width of 0.3 mm in specimen B1 was estimated to be ca. 108 kN using linear interpolation. In the strengthened specimens, the cracks did not exceed a width of 0.25 mm. It is worth to mention that the strengthened beams can

satisfy the limit of 0.2 mm for XC3 and 4 at significantly higher loads. The load at a crack width of 0.2 mm in specimen B1 was ca. 60 kN while it was increased to ca. 135, 165 and 180 kN in specimens B2-B4 respectively.

3.2.4 *Ultimate load bearing capacity*

The comparison of ultimate load bearing capacity among the specimens is shown in Table 3. Specimen B1 reached the maximum load of ca. 155 kN. The ultimate loads of specimen B2-B4 were determined at loads when debonding of the CFRP laminate took place. The comparison showed a significant improvement (141~162%) of the ultimate load capacity after the strengthening.

It is worth mentioning that the strengthened beams continued to increase the load levels beyond this limit after CFRP debonding. Even though the design for strengthening shall be based on debonding of the CFRP laminate, the ultimate load carrying capacity resulting from the composite action of the concrete beam and the GFRP deck panels would provide a suitable safety margin in a semi-ductile behavior.

3.3 *Ultimate utilization ratio of CFRP laminate*

In EBR technique using passive CFRP laminate, the maximum strain in the laminate is often limited to ca. 5‰) due to the risk of intermediate crack debonding. In specimens B2-B4, a pre-stress level equivalent to ca. 25% of the ultimate strain (3.23‰) was used. When the failure of CFRP took place (Figure 9), the tensile strain in the CFRP laminates reached 10.94‰, 10.37‰ and 10.87 ‰ in B2-B4, respectively. The ultimate utilization ratio of CFRP in terms of tensile strength therefore reached 80~84% indicating a 100% increase in the utilization ratio.

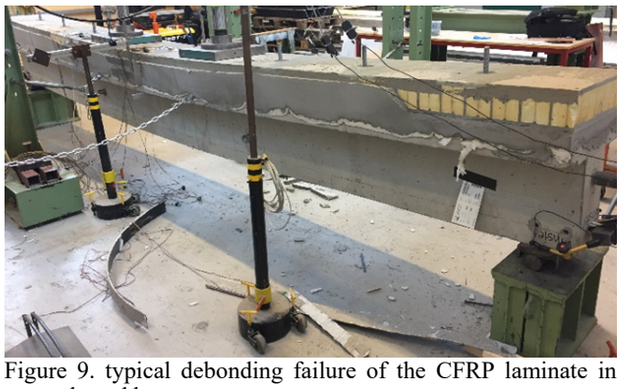

Figure 9. typical debonding failure of the CFRP laminate in strengthened beams

4 CONCLUSIONS

The four-point bending tests were carried out on concrete beams strengthened with bonded pre-stressed CFRP laminates and GFRP deck panels. Tests results indicate significant improvements in the behavior of the beams in SLS and ULS.

The innovative method for pre-stressing CFRP laminate as EBR could successfully eliminate the need for mechanical anchorage system at the ends of CFRP for a pre-stressing force of 100 kN. It could realize the 'self-anchorage' of CFRP laminate with a pre-stressing level equivalent to 25% of the tensile strength, and obtain an ultimate utilization ratio up to 80~84% when debonding of CFRP occurs.

The flexural behavior of strengthened specimens (B3&B4) using mortar bonding method exhibited satisfying performance compared to that of (B2) using traditional epoxy adhesive bonding. The used low-shrinkage mortar is a promising alternative to cast the bond layer between the RC section (with the sandblasted surface) and GFRP component (coated with coarse aggregates).

The specimens implemented with SUREBRIDGE solution demonstrated significant improvement in SLS and ULS:

- The onset of cracks was delayed from 19 kN of B1 to 61~77 kN in B2-B4.
- The estimated bending stiffness of cracked section increased by 82~99% after strengthening compared to the reference specimen.
- The crack width in strengthened beams at the same load level (120 kN) was ca. 35~47% of that in B1.
- In ultimate limit state, the capacity of strengthened specimens at CFRP failure was 141~162% greater than that of the reference beam

5 NOTATION

The following symbols are used in this paper:

E_{11} = mean value of young's modulus of GFRP skin of the sandwich panel along the direction of webs

E_{22} = mean value of young's modulus of GFRP skin of the sandwich panel perpendicular to the direction of webs

$E_{cfrp.m}$ = mean value of young's modulus of CFRP laminate

$E_{s.m}$ = mean value of young's modulus of steel reinforcement bars with diameter of 16 mm

$f_{c.11.u}$ = mean value of compressive strength of GFRP skin of the sandwich panel along the direction of webs

$f_{c.22.u}$ = mean value of compressive strength of GFRP skin of the sandwich panel perpendicular to the direction of webs

$f_{c.m}$ = compressive strength of concrete cubes (side length of 150 mm) cured for 140 days in the same condition with the RC beams

$f_{s.t.m}$ = mean value of tensile strength at rupture of steel reinforcement bars

$f_{s.y.m}$	=	mean value of yielding stress of steel reinforcement bars
$f_{t.11.u}$	=	mean value of tensile strength of GFRP skin of the sandwich panel along the direction of webs
$f_{t.22.u}$	=	mean value of tensile strength of GFRP skin of the sandwich panel perpendicular to the direction of webs
K	=	bending stiffness
P_{cr}	=	cracking load
$P_{max.cr}$	=	load at maximum crack width reaching 0.3 mm in B1 and 0.2 mm in B2, B3 and B4
$P_{max.def}$	=	load at deflection of 22.8 mm (equals to 1/250 of net span)
P_u	=	ultimate load
Δ_{imp}	=	improvement compared with reference specimen B1
$\varepsilon_{cfrp.u}$	=	mean value of ultimate tensile strain of CFRP laminate

CFRP Strengthening of ASR affected concrete piers of railway bridges

M. Lima, R.Salamy, D.Miller
Sterling Group Consultants

ABSTRACT: Alkali-Silica Reactions (ASR) occur in concrete due to chemical reactions between the alkali (sodium and potassium) hydroxides in the concrete pore solution. Under certain circumstances, these reactions cause internal expansion (commonly known as "concrete cancer"). The swelling within the concrete can potentially result in cracking of the concrete impairing its function and shortening its service life. This paper presents the outcomes of engineering inspections, material properties investigation and strengthening design of concrete piers and abutments of four railway bridges located on the Mildura Line in Victoria. The inspection findings are discussed in detail and engineering interpretation is presented including the potential remediation options for the observed defect including steel/concrete jacketing and CFRP wrapping. The cons and pros of these methods are discussed and CFRP wrap is selected as a suitable method. The assumptions for CFRP strengthening design and challenges during application of concrete epoxy injection and CFRP are highlighted.

1 INTRODUCTION

The Alkali Silica Reaction (ASR) refers to the formation of an expansive gel through the reaction of alkalies and silicates in concrete (Monette, Gardner et al. 2002, Fournier, Bérubé et al. 2004). In the presence of sufficient moisture, the gel expands and puts pressure on the surrounding cement paste and aggregates, which can lead to cracking (Fournier, Bérubé et al. 2004). Three factors are required for the reaction: a) sufficient moisture; b) the presence of reactive aggregate and c) a high level of alkalinity. The reaction cannot occur without any of these elements (Talley 2009).

The mechanism of ASR is as follows: a high level of alkaline ions in the pore solution will essentially attack the silica bonds in the aggregate and cause the silica to dissolve. Then, the silica goes into the concrete pore solution and it reacts with the alkaline ions present in the solution. The chemical reaction between the silica and the alkali ions form an alkali-silica gel around the edge of the aggregate. In presence of sufficient moisture, the gel expands and pushes against the surrounding concrete causing high localised pressure. This pressure can result in micro-cracking of the concrete, and over time with exposure to moisture, the cracks expand and can be visible with the naked eye (Farny and Kosmatka 1997, Talley 2009). This schematic of this process is showed in Figure 1.

The type of aggregate, exposure environment and alkali content of concrete affects the severity of reaction. Having cracks in structure adversely affects the durability of concrete by exposing the interior portions of concrete to environmental agents. Several cases of ASR have been reported in Australia in dams and bridges (Shayan and Lancucki 1986, Shayan 1988, Shayan and Quick 1992, Ross and Shayan 1996, Shayan 1999, Shayan, Wark et al. 2000, Shayan, Al-Mahaidi et al. 2008, Shayan, Xu et al. 2015). Several cases of ASR affected structures are presented in HB79 'Guidelines on minimizing the risk of damage to concrete structures in Australia' (StandardsAustralia 2015).

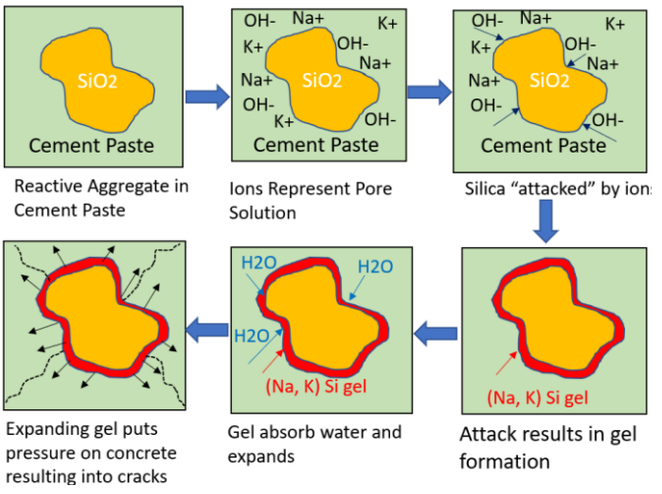

Figure 1 . Schematic of ASR mechanism

Previous investigation indicates that the cracking of the concrete affects the strength properties of concrete (Mohammed, Hamada et al. 2004, Shayan, Al-Mahaidi et al. 2008, Shayan, Xu et al. 2015); however, the load carrying capacity of the of the structure might not be proportionally reduced (Monette, Gardner et al. 2000, Shayan, Al-Mahaidi et al. 2008, Shayan, Xu et al. 2015). In addition, the deterioration effects are more significant for small elements in comparing to large elements due to the larger ratio of crack depth to dimension of the element (Shayan 2016). The impact of different factors in ASR affected structures has also been investigated (Shayan, Xu et al. 2015, Shayan 2016). Considering the history of ASR issues in Australia, this paper presents the engineering inspection outcome and strengthening design of four railway bridges with brief overview of the crack injection and repair.

2 STRUCTURAL DESCRIPTION

Four bridges with 56 total piers and abutments were inspected and evaluated. All bridges were simply supported girders on plain concrete piers comprised of four main girders with timber transoms on top. A brief description of each structure is provided herein.

Bridge A: the bridge has 17 spans in total consisting of two different span lengths - 9m (15 spans) and 12m (2 spans). One span of this bridge was over a creek. The average height and width of the piers were approximately 2.6m and 3.4 m respectively. The year of construction was 1957.

Bridge B: the bridge has 15 identical spans of 9m in length. Three spans of this bridge were located over a pooled water area/pond. The average height and width of the piers were approximately 2.5m and 3.3 m respectively. The year of construction is 1957. A general photo of this bridge is shown in Figure 2.

Bridge C: the bridge has 7 identical spans, each 9m in length. The height of the piers varies from 0.5m to 4.4m, while the width of the piers is constant (approximately 3.6m). The year of construction was 1958.

Bridge D: the bridge has 13 spans in total with span lengths of 12.2m (4 spans), 9.1m (7 spans) and 9.7 m (2 spans). Two spans of this bridge are located over a river. The width of the piers was 3.3m and 5.4m and average height of the piers was 2.5m. The year of construction was 1957.

Figure 2 . General view of piers – Bridge B

3 ENGINEERING INSPECTION AND MATERIAL TESTING

The inspection revealed that the piers of all bridges included in this investigation were mass concrete without reinforcement. To investigate the concrete properties and provide appropriate solution for the potential ASR, five concrete samples were taken from the middle piers of each bridge to conduct laboratory investigation. The length of the samples was about 170mm and the diameter was 75mm (Figure 3).

Four out of five concrete samples from each bridge were tested for compressive strength AS 1012.14 (Standards Australia 2014) and Alkali Silica Reactivity ASTM C856 (ASTM C856 2017) and one sample was kept as reference. These samples were taken from a minimum of three different piers to capture the overall behaviour/condition of the concrete piers. The concrete strength of the samples in both dry and wet condition were obtained to provide a better insight of the concrete properties considering various environmental conditions. Dry and wet conditions best represent the actual environment of the piers as only a few of them were located at the middle of creeks (within water) while some of them were in dry land. The result of the concrete compressive strength tests for these samples are presented in Table 1.

Petrography analysis was based on the treatment of thin cross-sections of the core samples with a laboratory prepared Uranyl Acetate solution and examination both pre-treatment and post-treatment under Ultra-Violet light. The grey coloured concrete cross sections of the cores are shown in Figure 4. The lab results revealed that the concrete was generally well compacted and has a high proportion of large aggregate. Some orange coloured staining and minor voids were observed within the concrete cores.

Figure 3 . Concrete coring of Bridge A

The petrography analysis revealed that the coarse aggregate is predominantly Carbonatite. The maximum sizes of the aggregates and voids are presented in Table 1. Severe microcracking was observed in and around the aggregate, however, no visible macrocracking was evident in the analysis. The cores show the presence of crystal formation within the voids of the concrete. There was evidence of Ettringite Formation, Alkali Silica Reactivity (ASR) and delayed Ettringite Formation. Crystalline needles were evident in the voids. The Ettringite Formation appeared to be in early stages and may continue to increase, although the extent and timeframe for this is unknown. There was also ASR gel visible in some cracks surrounding the aggregate. Severe microcracking is present both within the aggregate and throughout the surrounding concrete.

Table 1. Concrete material properties for bridges

BRIDGE	COMPRESSIVE STRESS (MPA)			SIZE (MM)	
	S1 (dry)	S2 (wet)	S3 (wet)	Aggregate	Voids
A	34.5	19.0	26.0	≥50	≤3
B	45.5	33.0	26.0	≥50	≤3
C	43.5	18.5	30.5	≥25	≤5
D	31.5	12.5	24.5	≥ 25	≤7

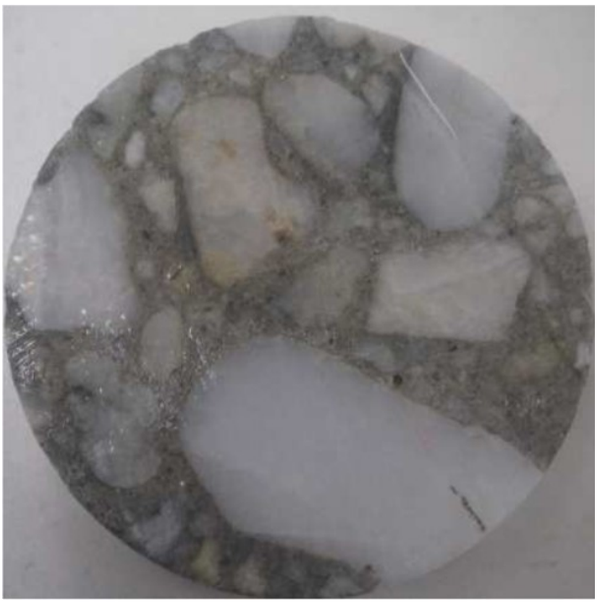

Figure 4 . Cross section of concrete core for petrography analysis of Bridge A

Extensive cracking was observed within most of the concrete piers of the bridges. The width and length of the cracks varied between 0.1mm to 10mm. A sample of pier crack mapping is presented in Figure 5.

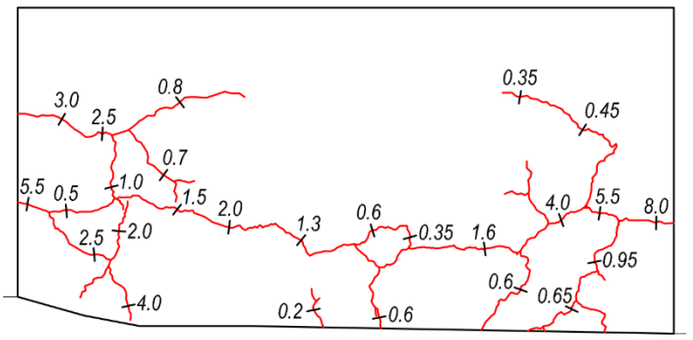

Figure 5 . Crack mapping of Pier 2 – Bridge C

4 CFRP STRENGTHENING DESIGN AND APPLICATION

Considering the condition of the piers and the existence of ASR, injection of the cracks and waterproofing was recommended for all affected piers. Also, for piers with severe cracking, a strengthening design was provided. A few alternatives were considered for strengthening of these piers including CFRP wrapping; concrete jacketing, and steel jacketing. The pros and cons of these methods are as follows:

- Steel/ concrete jacketing usually requires heavy machinery.
- The total labour cost for concrete/steel jacketing are likely to be equal or even higher than CFRP wrapping method. However, the required

time and line interruption for concrete jacketing is more than CFRP application.
- The curing time for concrete jacketing is more than CFRP wrapping.
- The access constraints are also challenging for jacketing option as the bridges; located off the road.
- For those cracks that are propagated below the ground level, more soil excavation is required for jacketing for scaffolding purposes.
- CFRP has unique properties, including high strength-to-weight ratio, high fatigue endurance, environmental degradation and corrosion resistance (Lima, Doh et al. 2016).

Therefore, the CFRP wrapping was favoured due to the budget and construction time constraints during occupation of the rail corridor.

Several investigations have been completed on CFRP strengthening of ASR affected structures and various levels of success are reported for different types of structures and environmental conditions (Haddad, Shannag et al. 2008, Talley 2009). The geometry of an element has a key role in the ultimate performance of the CFRP application in concrete columns/piers and maximum efficiency achieved in wrapping of circular columns/piers (Shayan, Xu et al. 2009). AS5100.8 (2017) provides some guidance for design of CFRP strengthening of elements with various shapes and materials. The formula provided for CFRP strengthening of concrete columns/piers is based on the stress-strain curve of an FRP confined section. The maximum confinement pressure (f_l) is as follows:

$$f_l = \frac{2E_f t_f \epsilon_{fe}}{D} \geq 0.08 f'_c$$

Where D is either the diameter of a circular cross section or the dimension as shown of Figure 6; E_f is the average FRP modulus of elasticity; t_f is the total FRP thickness of all layers; ϵ_{fe} is the effective strain level in the FRP at failure.

For different cross sections, AS 5100.8 provides efficiency factors (κ_a and κ_b) and for circular cross section, the shape factors may be taken as 1. For rectangular cross section, the shape factors are as follows:

$$\kappa_a = \frac{A_e}{A_c}\left(\frac{b}{h}\right)^2; \qquad \kappa_b = \frac{A_e}{A_c}\left(\frac{h}{b}\right)^2$$

Where b and h are the section dimensions as shown in Figure 6. Based on AS5100.8, the aspect ratio (h/b) shall be less than or equal to 2. The dimensions h and b shall be less than 900 mm.

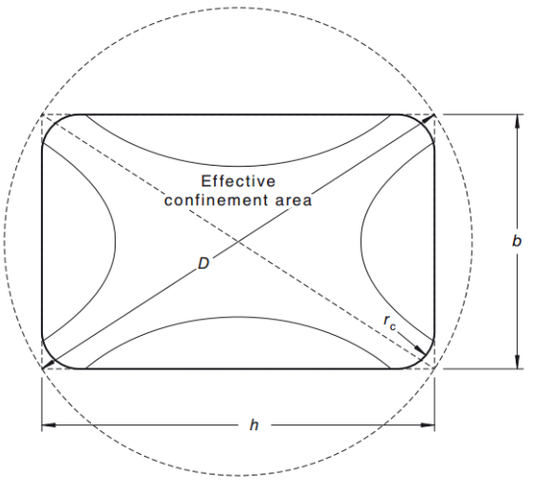

Figure 6 . Equivalent circular cross section (AS 5100.8)

A_e/A_c is the ratio of the effective confinement area and the concrete cross sectional area as follows:

$$\frac{Ae}{Ac} = \frac{1 - \frac{\left[\left(\frac{b}{h}\right)(h-2r_c)^2 + \left(\frac{h}{b}\right)(b-2r_c)^2\right]}{3A_g}}{1-\rho_g}$$

Where r_c is the radius if rounded corners and ρ_g is the longitudinal steel reinforcement ratio.

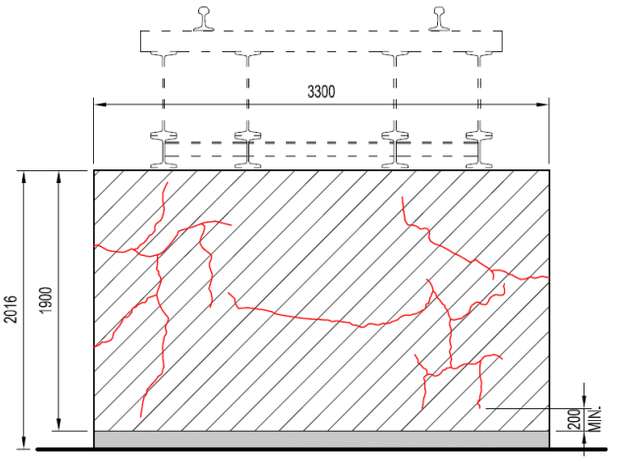

Figure 7 . CFRP strengthening scheme for Pier 2 – Bridge C (dimensions are in mm)

The aspect ratio for the piers in this project was b= 1200mm and h=3300mm which is beyond the specification of AS5100.8. However, the crack injection and CFRP strengthening in this project was mainly to improve the durability, integrity of the structure by minimising the water ingress into concrete and control the crack expansion. The enhancement of axial load carrying capacity of the piers was not the main purpose of this project. For design purposes, it was assumed that the cracks are epoxy injected, strengthened by CFRP, are coated and water ingress in insignificant or minimal. However, the design of the CFRP wrapping was completed based on the conservative assumption that the lifetime expansion of concrete

piers will not exceed 0.5%. This assumption was made in absence of monitoring data for the concrete piers. Based on this assumption, the design consists of one layer of vertical and one layer of horizontal CFRP sheets (Figure 7). The thickness of each layer of CFRP was t_f = 0.129mm and the modulus of elasticity was E_f = 230GPa. The combination of vertical and horizontal layers was proposed in order to constrain the scattered cracks and those that propagated diagonally. Strengthening of the piers was completed in four stages as follows:

Concrete patch repair: delamination ("drummy") survey using a hammer was completed for detection of incipient spalls and delamination. The defective concrete was then removed and repaired with approved mortar (Figure 8).

Figure 8 . concrete patch repair of abutment – Bridge A

Crack injection: a summary of the crack injection procedure is as follows: a) all impurities including dirt, dust, loose particles, oils, grease, coatings, and efflorescence was cleaned from the surface of the concrete for 50mm either side of the crack; b) injection entry ports were installed along the cracks at intervals no greater than 200mm (Figure 9-10); c) injection ports were located on all pier faces and exposed abutments faces; d) bonded-on injection fittings or injection fittings placed into drilled holes were also acceptable; e) the surface of the cracks were sealed between the injection ports.

Injection of the epoxy initiated at the lowest entry port and continued until it appeared at the closest horizontally adjacent port; f) once all horizontally adjacent ports were injected, then injections continued until epoxy appeared at the closest vertically adjacent port; g) two to four cores (maximum one core from each side of the pier) were extracted from the piers with the largest size of crack (greater than 1mm). Each core had a diameter of at least 50mm and depth of at least 400mm and was positioned centrally between injection ports with a crack located centrally at the surface of the core; h) the bond strength of the injection epoxy to the inside surfaces of the crack and the depth of the penetration (Figure 11) was verified by using the extracted core samples trough the repaired cracks; i) the injection pressure was between 150Psi to 200Psi. Low viscosity material was used for cracks under 5mm width while a medium to high viscosity material was used for wider cracks. For crack that were extended to the ground level, minimum soil excavation of 500mm was completed in order to ascertain that the cracks are epoxy injected properly (Figure 12).

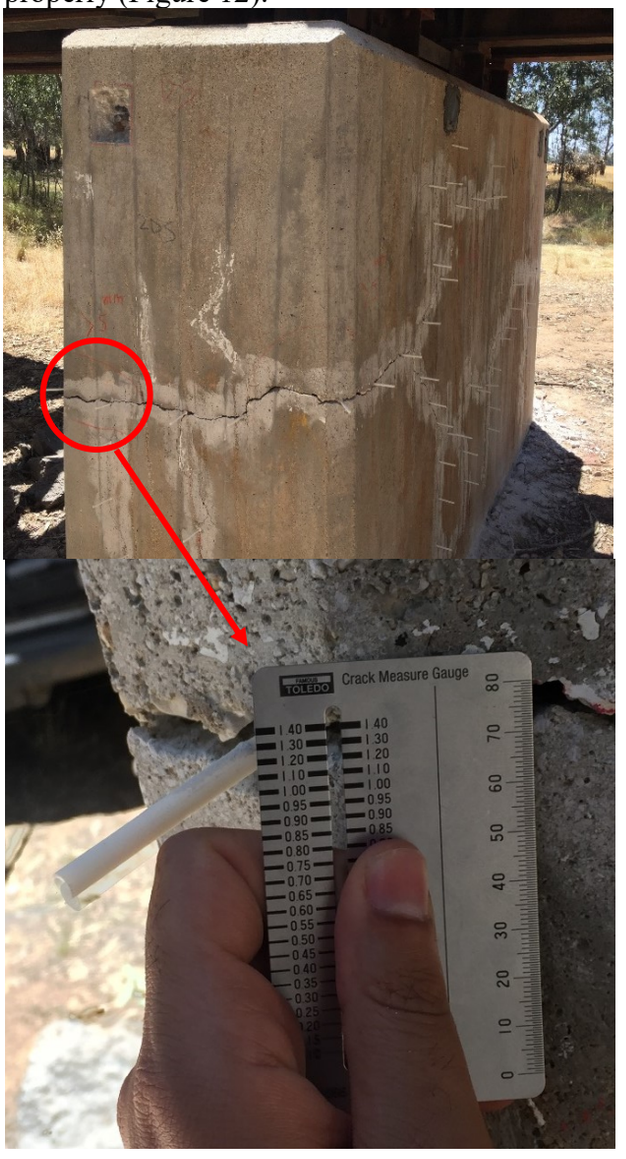

Figure 9. Installation of injection entry points - Bridge B

Figure 10. crack sealing prior to injection - Bridge A

Figure 11 . Depth of epoxy penetration – Bridge A

Figure 12. Soil excavation for extended cracks below ground level

Due to the nature of ASR cracks and inadequate sealing in limited cases (Figure 13), there were air traps (Figure 14) revealed after coring. In these cases, a layer of wax was applied over the leakage point and the injection was continued as normal.

CFRP wrapping: a summary of CFRP wrapping procedure is as follows: a) abrasive blast cleaning equipment was used to mechanically prepare the surface of the concrete within the CFRP wrap application areas; b) corners which the CFRP wrap was to be applied around were rounded or chamfered to a minimum radius of 25mm by grinding; c) the application of vertical layers of CFRP were completed, then another layer of horizontal CFRP was wrapped around the piers continuously; d) the CFRP wrap was extended at least 200mm beyond the crack location; e) the manufacturer's instructions were used for mixing and applying the Carbon Fibre Wrap Primer to the prepared substrate; f) the resin was applied to all areas of the fabric without any dry spots, trapped air, bubbles or blisters; g) once application was completed, a protective sheet was applied to ensure safety against rain, sand, dust and other contaminants.

Figure 13 . Inadequate sealing over the crack and epoxy leakage - Bridge A

Figure 14 . Air trap in crack injection- Bridge A

Coating and sealing: a summary of coating and sealing procedure is as follows: a) the surface was cleaned prior to coating to maximise bonding; b) previously painted surfaces were cleaned and sound and all traces of peeling or loose paint were removed; c) primer was applied as a single coat over the entire surface, and then a top coat was applied in accordance with the manufacturer's instructions over the base

coat; d) application of the final coating system was implemented on continuous and pin-hole free surfaces. A minimum dry film thickness (DFT) of 160 microns was required after achieving full cure. The quality control testing of all stages was in accordance with AS 5100.8 or relative standards/guidelines.

A monitoring period of 2 to 3 years was recommended to validate the assumed value for expansion rate and modify the CFRP wrapping design where required. If monitoring reveals that the recorded expansion rate of the concrete exceeds the assumed value of 0.5% within the structure's remaining service-life, then a new evaluation based on the observed condition will be required to identify any requirement to the modification of the proposed CFRP wrapping design.

5 CONCLUSION:

This paper presents the CFRP strengthening of the piers of four railway bridge with a summary of inspection findings and material testing as well as the design approach and assumptions. Also, a summary of CFRP application steps is provided for engineers' references. The crack injection and some of the challenges during application is also highlighted. the following points are the significance of this project:

- The CFRP wrap was selected as a suitable material for strengthening of ASR affected piers due to its superb properties, time and budget of the project as well as handling and transportation of the material to site.
- The design of CFRP assumed that the lifetime expansion of concrete piers will not exceed 0.5%. This assumption was made in absence of monitoring data for the concrete piers. Further monitoring and measurement is required in order to validate this assumption. If monitoring reveals that the recorded expansion rate of the concrete exceeds the assumed value of 0.5% within structure's remaining service-life, then a new evaluation based on the observed condition will be required to identify any requirement to the modification of the proposed CFRP wrapping design in necessary.

- It is critical for this application that crack injection to be conducted properly by a qualified contractor and active supervision. During the construction phase, there were some challenges for crack injection and CFRP application. The crack sealing should be properly completed prior to injection. Even though, due to the nature of ASR cracks that are interconnected inside the concrete piers, there are always a chance of leakage from some areas that seems no cracks exists. In these cases, the contractor should apply wax or other appropriate material to prevent any leakage and continue the injection.

ABSTRACT: *Due to increase of traffic weight, there is a need to check if the bridges designed and built in the 1960s support current traffic load effects. In this context, some bridges in a ring road around Curitiba city in southern Brazil were revised. They were designed for 36-ton class and the requirement of the Brazilian design code raised to 45-ton. The research reported in this paper focus on the feasibility of carbon fiber reinforced polymers on the reinforcement of three highway bridges. The reinforcement design proved to be feasible in two bridges, with flexural and shear reinforcement in up to three layers of carbon fiber composites. However, in one of the bridges the reinforcement was technically infeasible, as it would require up to seven layers of carbon fiber composites. According to the manufacturers of the FRP it is not possible to apply more than four layers.*

1 INTRODUCTION

Design of Brazilian highway bridges meet the design code ABNT NBR 7188 (2013), in which the live load model is composed of a 3-axle vehicle and a distributed crowd load (Fig. 1). The configuration of this design loading follows the pattern of the ancient Brazilian design code ABNT NB-6 (1960), which was based on the German design code DIN 1072 (1952). The weight of the main load model have been increased over time, from 36-ton in the 1960s to the current heavier vehicle load equal to 45-ton. This change occurred in 1982, the magnitude updates occurred to follow the increasing allowable gross vehicle to transit in Brazilian highways, mainly from the 1970s. The current version of the ABNT NBR 7188 (2013) kept the 450 kN total weight of the load model (Rossigali et al. 2015).

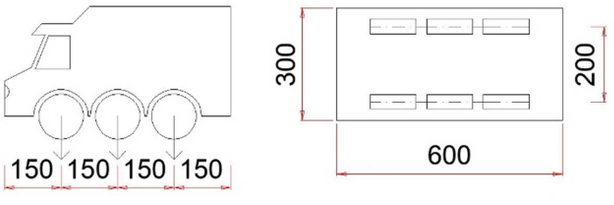

Figure 1. Side view if the current Brazilian load model vehicle (ABNT NBR 7188, 2013). Units: cm.

According to Mendes (2009), most highway Brazilian bridges were design in the 1960s and the 1970s and have the following features: 83% are reinforced concrete deck girder bridges; 93% have maximum length lower or equal to 40 meters; 64% were designed according to NB-6 36-ton vehicle. It means that a large amount of the Brazilian highway bridges are low-span reinforced concrete RC structures.

Usual problems identified in existing reinforced concrete bridges are the diagonal cracks that identify shear deficiency (Higgins et al. 2012). In reinforced concrete, cracks are caused either by the applied loads or by shrinkage and thermic stresses (Mostafa et al. 2010). After flexure cracks initiate in a reinforced concrete structure and turn diagonal, besides the reduction of the flexural stiffness there is a considerable reduction of the capability in transfer the shear forces: the shear stiffness is not elastic (Ramezansefat et al. 2017). These lead to the conclusion that the Brazilian bridges designed according to the 1960 Brazilian code NB-6 do not bear current traffic effects and necessarily must be reinforced (El Debs & Malite 2002).

Besides these facts, some ancient highway bridges are reaching their design lives. The overestimation of the concrete contribution to shear resistance during design (Higgins et al. 2012), the continuous growth in traffic volume of commercial vehicles, shrinkage, fatigue of the reinforcement bars, temperature effects and the lack of a maintenance policy of these structures also play a role on their deterioration. The cracking arising and growth cause the prolonged exposition of the steel, which means in some bridges a considerable level of corrosion of steel re-

inforcement. Corrosion might increase the volume of steel by until six times, damaging the concrete at the vicinity (Grace et al. 2012).

In this scenario, many strategies are available to reinforce the RC bridges. One of the most usual is the epoxy injection to vanish the cracks followed by an increase of the transverse section and of the reinforcement. The main disadvantage of this measure is that it is time-consuming. Other alternatives are steel plate reinforcement, that is worldwide available, but increases weight, but the gain in stiffness is low; post-tension that requires careful work and its very useful contain or reverse displacements. In this sense, new strategies are needed. For instance, the surface-bonded strips of carbon fiber reinforcement polymers (CFRP) are becoming a widely useful alternative to strengthen concrete members like columns, slabs, beams and piers (Liu et al. 2011, Vosooghi & Saiid 2013).

The main goal of this paper is to describe the CFRP reinforcement design of three highway bridges locates at Paraná State, Brazil. They are located at the Curitiba's city ring road. The CFRP reinforcement was a request of the Transportation Ministry in 2012, looking for a fast and light solution.

2 FEATURES OF CFRP

2.1 *The main advantages of using CFRP*

According to Vosooghi & Saiid (2013) the CFRP increases the concrete confinement and then prevents splice failure even at large deformations. It increases the ductility and ultimate strength capacity of the structural member. The stiffness is also increased, although not to the initial values of the undamaged reinforced concrete element.

At high service loads after rehabilitation with CFRP, a brittle fracture may occur after delamination (Mostafa et al. 2010). Partial delamination led to an initial drop in the strength capacity of a CFRP-reinforced beam, but subsequently it acquires a high deformation capacity. Besides, the corrosion resistant, the great pullout strength, the installation relatively simple and the fabric very thin and thus light, increasing little dead load to the RC members are many reasons the motivate the use of CFRP to RC bridge reinforcement.

2.2 *Limitations on the use of CFRP*

On the other hand, Liu & Sun (2010) and Ramezansefat et al. (2017) point some characteristics of the CFRP can be disadvantages. The carbon fibers cannot bear compression, only tension; small curvature radius or edges are difficult places to apply the CFRP; the application of CFRP requires a very careful and meticulous work.

There is a limit, depending on the manufacturer, of CFRP layers that can be superimposed. Generally, more than four layers are very difficult to execute. In this case, the carbon fiber and the epoxy resin would fall by its self-weight during application. Because of its high price, the application of CFRP is not worth in large strengthening areas.

2.3 *Other features of the CFRP*

The shear strength of the CFRP strips depends on the flexural details, besides concrete and the reinforcement. In general, the smaller the CFRP wrap thickness, the grater the pullout strength. The application of longitudinal CFRP in beams does not increase shear capacity, thus is not effective to diagonal crack locations (Higgins et al. 2012). The application in columns in the hoop direction is quite effective (Grace et al. 2012). The debonding of the CFRP generally occurs at the vicinity of the cracks.

In terms of a life-cycle analysis, the initial construction costs of a CFRP reinforced bridge is quite higher than the traditional steel bars reinforcement, but the substantial reduction in maintenance costs makes this alternative more cost-effective in a long-term comparison (Grace et al. 2012). The CFRP strips can be placed to furnish flexural or shear strengthen. Its Young's modulus is comparable to steel and its rupture strength is huge in comparison to concrete and steel: a typical value is 3 GPa.

Application of CFRP in general follows the steps (Vosooghi & Saiid 2013): remove the loosing concrete (with an impact hammer); clean the area (with compressed air); repair the concrete with grout, mortar etc. (recommended only high-early-strength, low-shrinkage grout); perform the epoxy injection; smooth the element surface; apply a prime layer; apply the CFRP fabric carefully; apply a cover resin layer; repeat CFRP if necessary; curing of the system.

3 REINFORCEMENT DESIGN USING CFRP

In terms of design using CFRP as reinforcement in RC structures, it is reasonable to assume that a certain fraction (e.g. 50%) of the original shear strength of the transverse steel to avoid conservative results in terms of number of layers of CFRP (Vosooghi & Saiid 2013).

Due to the lack of a Brazilian code for the use of CFRP, one can adopt the traditional RC calculus of the Brazilian code for design of reinforced concrete structures, ABNT NBR 6118 (2014). Other strategies are use the American code ACI 318 (2008) or the CEB-FIP Model Code (2010) manual. In this paper, it was used the ACI 318 procedure to design the CFRP reinforcement of the RC bridges.

4 BRIDGES INFORMATION AND REINFORCED DESIGNS

Three bridge designs are presented, all of them being part of the Curitiba City´s ring road in southern Brazil, according to Table 1.

Table 1. Bridges' information.

Bridge over	num. of spans	Span
	units	m
Eduardo Sprada St.	1	37.5
José Luis St.	3	27.0
		22.0
		27.0
Cyro Correia St.	1	35.0

All bridges have the same one-cell box type cross section as Figure 2.

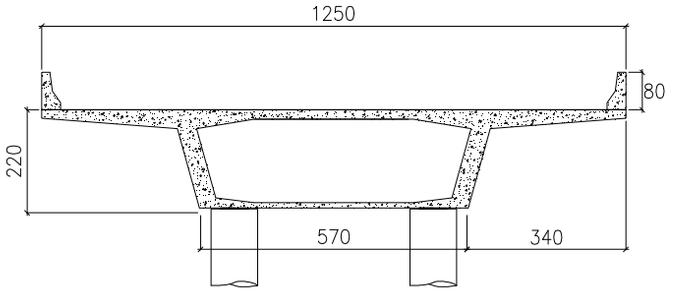

Figure 2. Transverse section of the bridges. Units: cm.

4.1 *Bridge reinforcement design*

To calculate the amount of CFRP necessary to reinforce each bridge, the soliciting bending moment M_{sd} and shear force Q_{sd} was obtained for the vehicle load equal to 45-ton envelope of stresses. The resistant bending moment M_{rd} and shear force Q_{rd} were calculated considering the real concrete cross section (25MPa) and the steel reinforcement. According to the ACI 318 procedures, the area of fibers A_f is calculated considering a fiber thickness of 0.165 mm, that leads to the number of layers of CFRP for the bending reinforcement. The relation width/spacing w_f/s_f was calculated to obtain the number of layers of CFRP for the shear reinforcement. This data is present in Table 2 for bending and Table 3 for shear reinforcement.

Table 2. Bridge CFRP bending reinforcement

Bridge over	M_{rd}	M_{sd}	A_f	n. CFRP layers
	kN.m	kN.m	cm^2	units
Eduardo Sprada St.	21091	13065	61.3	7
José Luis St.	22134	18540	26.5	3
Cyro Correia St.	11224	12839	-	-

For the bridge over Eduardo Sprada Street, the number of seven layers of carbon fiber reinforced polymers was technically infeasible. According to the manufacturers of the CFRP, it is not possible to apply more than four layers. In this case, the carbon fiber and the epoxy resin would fall by its self-weight during application. For the bridge over José Luis Street the CFRP for bending reinforcement is feasible. For the bridge over Cyro Correia Street the bending reinforcement was not necessary due to the soliciting bending moment is lower than the resisting bending moment.

Table 3. Bridge CFRP Shear reinforcement

Bridge over	Q_{rd}	Q_{sd}	w_f/s_f	n. CFRP layers
	kN	kN		units
Eduardo Sprada St.	8489	4340	6.0	3
José Luis St.	6748	4999	1.4	3
Cyro Correia St.	7762	4260	5,1	3

Shear reinforcement was necessary for all the bridges. According to ACI 318 (2008) procedure for shear reinforcement using CFRP, when the relation w_f/s_f is greater than 1, one single layer of carbon fiber is not enough. To calculate the number of layers necessary Equation 1 is used.

$$\frac{w_f}{s_f} = \frac{V_f}{2.n.t_f.f_f.d_f} \quad (1)$$

Where V_f = the extra shear force that the CFRP will support; n = the number of layers; t_f = the thickness of the carbon fiber blade; f_f = the ultimate tensile stress of the carbon fiber; and d_f = depth of the carbon fiber blade for shear reinforcement.

5 CONCLUSIONS

A maintenance policy is imperative to guarantee the safety level of the Brazilian bridges.

In some cases the number of necessary CFRP layers is high enough to turn this reinforcement alternative unfeasible; in these cases there is a need to investigate other solutions like traditional reinforcement, post-tensioning and others. Nevertheless the CFRP is a remarkable reinforcement alternative.

It was a request of the Transportation Ministry in 2012 to verify the economic and technical feasibility of the CFRP reinforcement in those three bridges. Surprisingly, after five years, the bridges are still active and no reinforcement was made in none of them. Considering this, two assumptions can be made: (i) the weight of the main load model of 45-ton is maybe overestimated and the safety factors used for bridges' design (for both loads and resistances), according to Brazilian design codes, contribute for an additional safety margin; and (ii) the service life of these bridges is reaching their end.

Influence of arch bridge skewness

A. Outtier, E. Van Puymbroeck & H. De Backer
Ghent University, Ghent, Belgium

ABSTRACT: Designers try to find new ways to make landmark bridges slenderer and distinctive. A new trend for arch bridges is placing the arch not co-linear with the bridge axis, but slightly skew. While visually attractive, this concept introduces a number of design problems which are not normal for arch bridges: the arch becomes subjected to significant out of plane bending moments, a permanent torsional effect develops, hangers are not possible in certain areas because of conflict with traffic and the tied arch concept becomes quite difficult to realize. The aim of this research is to study the skew arch concept using finite element modelling. A parametric study is undertaken to investigate the main design problems and to find an allowable application area in terms of bridge span, bridge deck width and skewness of the arch. Hereby, two different skew arch hanger configurations are considered including also a minimization of the number of hangers.

1 INTRODUCTION

For centuries, bridges have played an important role in the traffic system to allow passage across a body of water, a valley or a road.

The construction material for bridges evolved from timber in the early ages, to stone masonry during the Roman period and the Middle Ages. In those periods, compressive strength of the materials could be relied upon whilst tensile strength could not. Hence, an arch bridge structure was often the logical choice as it transfers the loads towards a horizontal thrust at the abutment by means of compression forces in the arch shape. With the invention of iron during the industrial revolution, larger span bridges became possible containing elements with a significant tension strength.

Nowadays several designs of bridges exist. They vary depending on the nature of the terrain where the bridge is located, the function of the bridge, the required span length, the materials used to build it and the available funds for the bridge construction. As a consequence, a distinction can be made between beam bridges, truss bridges, arch bridges, suspension bridges, cable stayed bridges and movable bridges. Concrete and steel are the most frequently used materials for bridges. Steel is preferred for longer span bridges due to a larger strength to weight ratio compared to concrete.

Over the years, several configurations for arch bridges have been developed. Old arch bridges are associated with fairly massive brickwork structures. In this way, the possibility of tension forces could be minimized. The last century, the use of steel and reinforced concrete allowed more slender and elegant arches. Depending on the position of the deck with respect to the arch and the load transfer from the deck to the arch, different arch type bridges can be distinguished. The deck can run below, through or above the arch. A tied arch can be used to minimize the horizontal thrust forces on the abutment. In arch bridges where the deck runs below a single arch, lateral loading of the arch can be critical for the bridge design. Therefore, the single arch is often split in two arches which are interconnected to get a better resistance against lateral loading.

Designers try to find new ways to make landmark bridges slenderer and distinctive. A new trend for arch bridges is placing the arch not co-linear with the bridge axis, but slightly skew. Besides aesthetical benefits, the skew position makes the single arch more resistant against lateral loading and the arch abutments do not form an obstruction for the road traffic. Nevertheless, while visually attractive, this bridge concept introduces a number of design problems which are not normal for arch bridges: hangers are not possible in certain areas because of conflict with traffic, the tied arch concept becomes quite difficult to realize, the arch is besides axial compression also loaded by significant bending moments and the arch becomes subjected to a permanent torsional effect.

2 STATE-OF-THE-ART

Currently, only a few skew arch road bridges have been constructed. This implies the absence of a large number of studies concerning the skew placement of the arch in single span road bridges.

Most of the bridges are located in the United Kingdom. The two most known projects are the Hulme Arch Bridge in Manchester and the Clyde Arc in Glasgow. According to Warren 2009 and Apostolidis 2011, both bridges form a gateway into the city and thereby symbolize a plan to increase the quality in the neighboring urban environment. The skew placement of the arch results in an asymmetric cable arrangement. These cables generate significant out of plane bending moments in the arch rib. These bending moments are the most determinant factor for the arch design. Therefore, the arch no longer behaves like a conventional parabolic arch which is in pure compression under a uniformly distributed load. Due to the out of plane bending moments, the arch behaves more like a laterally loaded bending member.

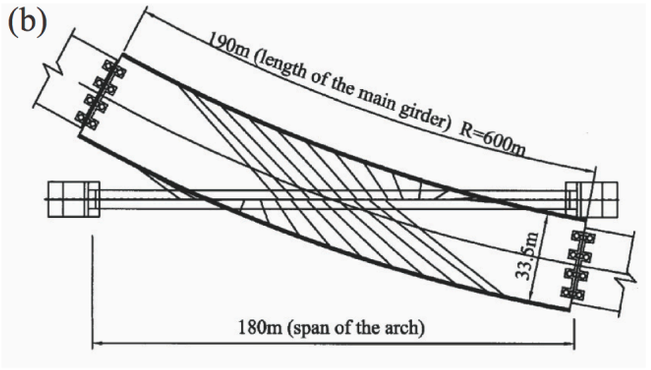

Figure 1. Arch bridge

Qiu et al. 2010 performed a stability analysis of a specific shaped arch bridge (Figure 1), namely a straight arch suspending a curved deck. Therefore, it will exhibit similar properties as a skew placed arch carrying a straight deck. Due to the skew position of the arch compared to the deck, the hangers are placed in a diagonal position contrary to the standard vertical direction in straight arch bridges. They cause large bending moments, compression forces, shear forces and torsion in the arch rib. Nevertheless, the new slanting direction of the hangers tends to resist any deformation of the arch out of its plane and hence increases the structure stability. Similar to straight placed arches, the restraining boundary conditions at the arch spring and the rise-to-span ratio significantly influence the overall structural stability. The stability coefficients for fixed arch springs are more than twice the coefficients for pin-ended arch springs. The stability is found to decrease drastically for very small or large rise-to-span ratios. An optimal rise-to-span ratio for the considered bridge is found to be about 0.37. They noted that this value is larger than the optimal ratio for normal, non-skewed arches analyzed in other studies. The more the design of the bridge deviates from a rise-to-span ratio of 0.37, the less reliable the bridge design, Qiu et al. 2010.

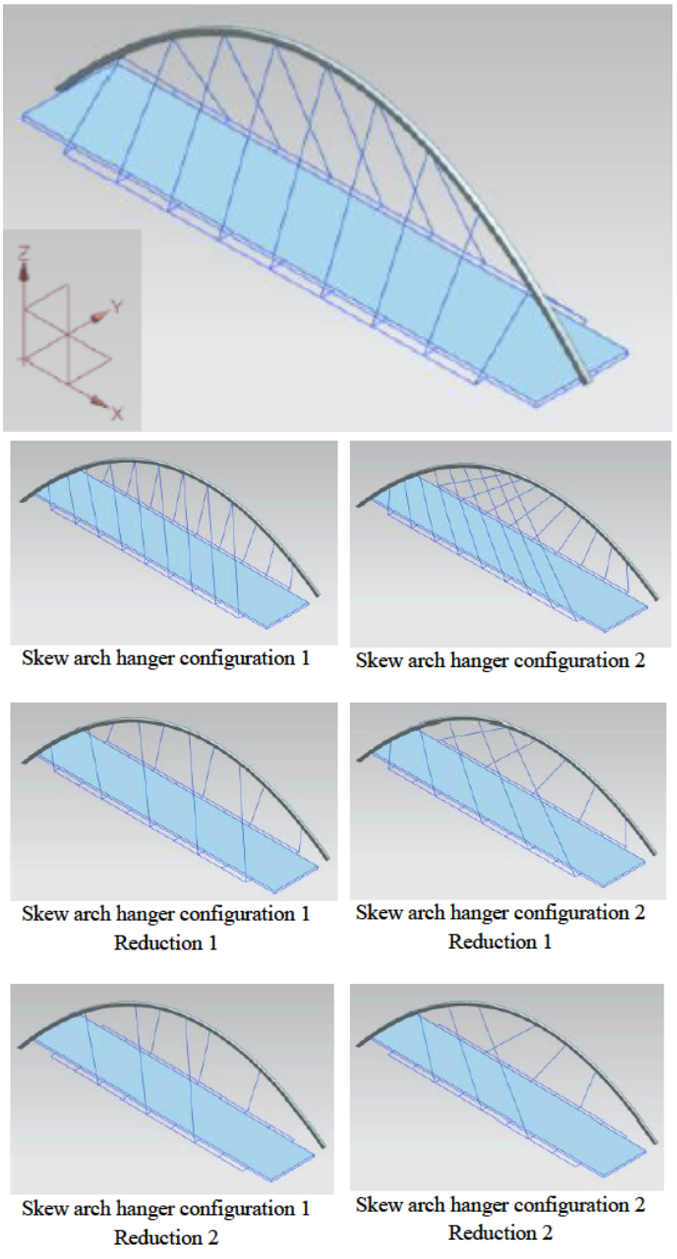

Figure 2. Straight arch bridge model and the different variations

3 REFRENCE BRIDGE MODELS

3.1 *Design*

The aim of this research is to study the skew placement of arches for single span road bridges using finite element modelling. Therefore, a parametric study is undertaken to determine the main design problems and to find an allowable application area

in terms of bridge span, bridge deck width and skewness of the arch. The investigated ranges for each parameter are based on existing skew placed arch bridges. All the results are compared to a straight arch bridge configuration (Figure 2) with the same bridge length, deck width and number of hangers as the skew arch bridges.

When the arch in the straight arch model is placed in a skew position the hangers would come in conflict with traffic. Hence, the hanger configuration for straight arch bridges is not practically applicable for skew arch models. Therefore, for the skew arch bridge concept, appropriate cable configurations need to be developed. Hereby, the cables inclining across the bridge deck have to provide enough headroom above the carriageway in order to allow the largest design vehicles to pass safely below the hangers. Therefore, a minimum free height of 5 m is assumed, based on guidelines in EN 1991-1-7. Even with special developed hanger arrangements, outriggers for hanger connection and pedestrian provisions are a necessity to avoid vehicle-cable impact. It can be concluded that the required clearance has a significant influence on the overall design of skew arch bridges. It imposes criteria to both the bridge dimensions as to the hanger configuration. Therefore, it indirectly has an effect on the internal force distribution and hence on the structural behavior. A hanger configuration which limits the out of plane bending, the determining design factor for skew arch bridges, has a disadvantageous effect on the provided clearance and vice versa. This resulted in two configurations: skew arch hanger configuration 1 inducing minimal bending moments in the arch and skew arch hanger configuration 2 providing the largest possible vehicle clearance (Figure 2). Based on aesthetical preferences the number of hangers is often chosen as small as possible. Therefore, the effect of reducing the number of hangers in configuration 1 and 2 is investigated (Figure 2). A second reduction in the number of hangers is also considered, as for the removed outer hangers often problems arise with vehicle-cable conflict.

The skew arch reference bridges have a span length of 100 m, an 18 m wide deck and an arch skewed over 16° with respect to the bridge axis. The arch has a parabolic shape and its crown is located 30 m above the deck. The arch has a square box section with a side of 1 m and a thickness of 50 mm. The arch is modelled using 2D elements and is considered fixed at its ends. The deck is made up out of a 20 cm thick concrete layer supported by longitudinal and transverse steel girders. The four longitudinal girders are spaced 6 m while a transverse girder is foreseen each 10 m. The girders are modelled as I profiles with a height of 1500 mm, width of 750 mm and web and flange thicknesses of 50 mm. The transverse girders extend 2 m outwards of the longitudinal girders to provide a connection with the hangers. To avoid locally high deformations at the connection, the outriggers are interconnected by 500 mm diameter tubes with a thickness of 50 mm. The bearings at the bridge deck ends restrain vertical motions. Moreover, at one side also longitudinal motions are resisted. The deck is fixed in the transverse displacement direction at one of the outer points for each of the two edge transverse girders. The hangers are implemented as rod elements without compressive strength. They have a diameter of 100 mm and a tensile strength of 1500 N/mm². Each time a cable is connected to the arch, a diaphragm is provided in the arch cross section. The steel for the deck and arch is S355 and the concrete used in the deck has a quality of C40/50.

3.2 *Analysis of the reference models*

In comparison to straight arch bridges, uniform loads in combination with a skew arch position and skew arch hanger configuration lead to out of plane bending moments in the arch rather than the development of axial compression forces. Hence, the arch is used more as a beam then as an arch. Hereby, the self weight of the bridge components and the uniform traffic loads dominate the bridge design. The presence of significant bending moments illustrates that the arch is not used efficiently in skew arch bridges. Based on the occurring stresses and deformations, skew arch configuration 1 and 2 use the arch material less efficient than a straight arch model, respectively with a factor 1.35 and 3.

The most loaded arch section is located at the crown for the reference model with configuration 1. On the other hand, it is positioned horizontally a distance 0.33 times the span length from the arch ends when configuration 2 is considered. An opposite behavior is observed for the critical deck section. The middle of the deck deflects the most for configuration 2, while for configuration 1 the critical deck section is situated 10% of the span length more towards the abutment.

The arch behavior is determined by the X, Y and Z force components that each cable transfers to the arch. The magnitude of each component is determined by the geometric arrangement of the cables and by the load distribution on the deck. Hence, the bridge design is rather limitedly affected by the skew arch position but by a larger extent determined by the hanger configuration which accompanies the skew arch. The Y and Z force component create respectively out and in plane bending moments. As the cables insert their forces into the bottom plate of the box section, the resulting force component works with some eccentricity with respect to the center of gravity of the arch cross section. This develops some torsion in the arch. The arch in the reference model with skew arch hanger configuration 2 is subjected to at least three times larger in plane, out of plane and torsional moments than the arch in configuration

1. Hereby, the out of plane bending moments dominate the design of the arch. The importance of the out of plane bending moments is much more pronounced for the arch in the model with configuration 2. While the arch for the skew arch configuration 1 remains nearly completely in compression, the arch for the skew arch configuration 2 is subjected to significant tensile forces. As the out of plane bending moments are the critical internal forces, the lateral deformations are the dominant deflection component. Skew arch bridges with configuration 1 are much more resistant against asymmetric mobile loads than straight arch bridges. The arch deflections under asymmetric loads in the reference model with skew arch hanger configuration 1 and 2 are respectively 0.5 and 0.85 times the deformations in straight arches. As a consequence, skew arch bridges work, based on the arch deformations, more efficient than straight arch bridges if the proportion of the live to dead load is rather large. This is because the live load can induce significant load differences on the two deck halves.

It can be concluded that configuration 1 is a more structurally efficient skew arch bridge concept than configuration 2. Nonetheless, configuration 2 is less prone to vehicle-cable conflicts than configuration 1 and therefore corresponds to less stringent requirements to provide enough clearance.

4 PARAMETRIC STUDY

When a bridge parameter is investigated, all the other parameters are considered to be fixed to the corresponding value in the reference bridge design. In this way, all the resulting changes in bending moments, stresses and deformations are completely dedicated to that single parameter adaptation.

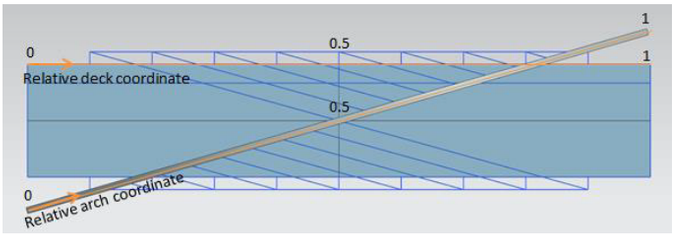

Figure 3. Definition of relative arch and deck coordinate

4.1 *Influence of the span length*

As the bridge span increases, the distance between two successive hangers enlarges, the cable inclination changes, the rise-to-span ratio diminishes, the ratio of the lateral distance between the arch abutments and the bridge length decreases, the relative stiffness of the deck and arch reduces, the application area of the mobile loads enlarges, the effect of the dead load increases and the clearance below the hangers reduces. As a consequence, the bending moments increase quadratic when the bridge becomes longer. As the span length increases, the relative importance of the out of plane bending moments compared to in plane bending reduces. This indicates a more efficient use of the arch structure.

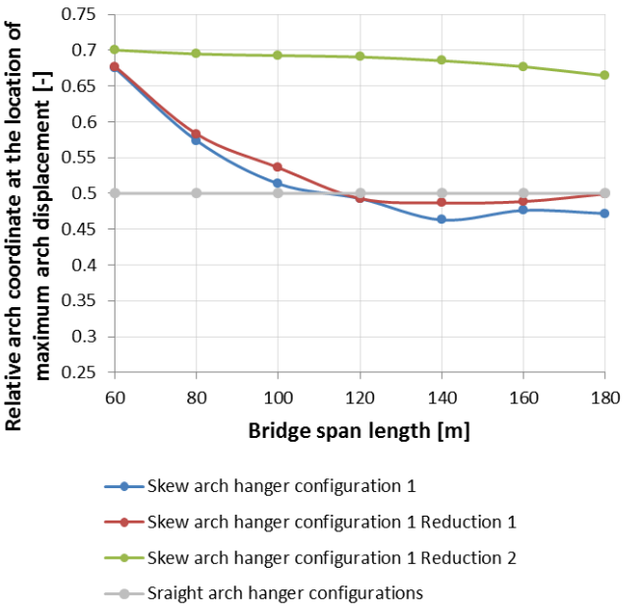

Figure 4. Relative arch coordinate of maximum arch displacement in configuration 1 for varying span length

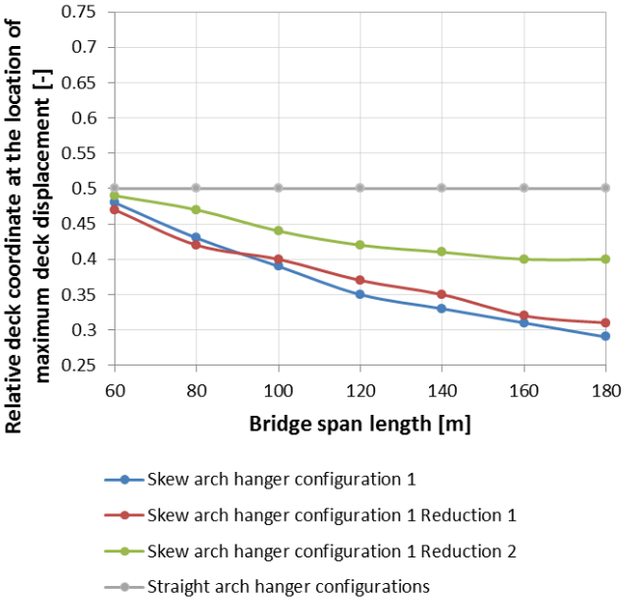

Figure 5. Relative deck coordinate of maximum deck displacement in configuration 1 for varying span length

For longer bridges with configuration 1, the critical arch section shifts horizontally from a location 0.3 times the span length separated from the abutment towards the arch crown. The critical deck section shifts from the middle of the deck towards a distance 0.3 times the deck length from the deck ends. The shifts are illustrated in Figure 4 and Fig-

ure 5, respectively for the arch and the deck. The graphs display a relative coordinate which is defined in Figure 3.

In the reference design with configuration 2, the critical arch and deck section shift from the same original sections to respectively 0.33 and 0.45 times the bridge length from the abutment.

For the reference model with varying span length, the out of plane bending moments show a maximum value for the model with the skew arch hanger configuration 1 with a deck length of 160 m (Figure 6). To avoid failure of the reference bridge, design the span length has to be limited to 120 m for the model with skew arch hanger configuration 1. Nevertheless, the length should be below 100 m to reduce the risk of vehicle-cable conflict in the reference model. For the reference bridge design with skew arch hanger configuration 2, the span length has to be limited to 70 m in order to avoid yielding of the arch. The difference in behavior between configuration 1 and 2 reduces as more hangers are left out of the model.

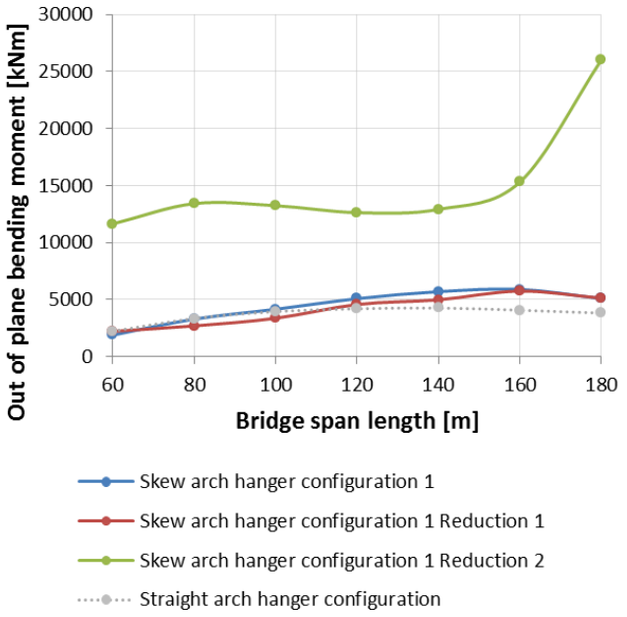

Figure 6. Out of plane bending moments in arch with hanger configuration 1 for varying span length

For all the investigated span lengths for the model with skew arch hanger configuration 1, the first reduction in number of hangers has only a limited influence on the bending moments (Figure 6), stresses, deformations and hence on the global arch behavior. The second reduction for the number of cables on the other hand has a much more pronounced influence (Figure 6), leading to unacceptable arch stresses and deck deformations. The outer cables, which are removed for the second reduction in number of hangers, tend to restrain lateral arch deflection and only limitedly affect the vertical arch motion. It should be noted that although the most outer cables play an important role to minimize the deformations and stresses, they cause problems with respect to clearance for driving vehicles on the other hand.

Contrary to the results for configuration 1, a first reduction of the number of hangers in configuration 2 causes already a significant increase in critical bending moments in both the arch (Figure 7) and the deck.

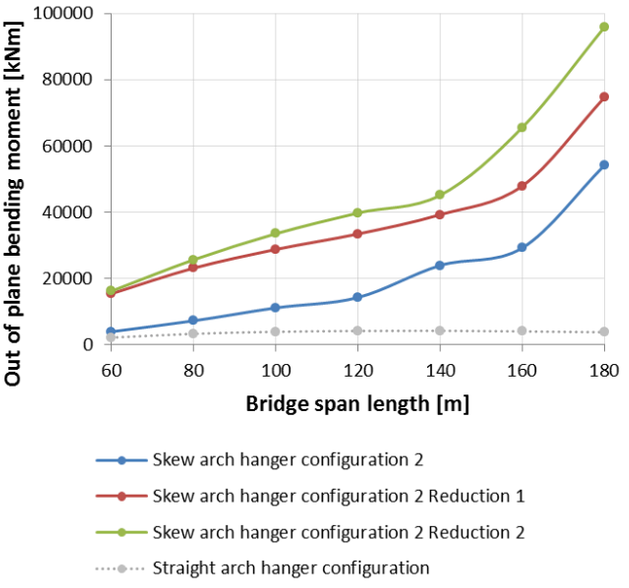

Figure 7. Out of plane bending moments in arch with hanger configuration 2 for varying span length

Similar observations about minimizing the number of hangers in configuration 1 and 2 are valid for changing the deck width or the angle of skewness.

4.2 *Influence of the deck width*

Compared to the modification of the span length, a more linear increase in bending moment is observed when the deck width is enlarged. As the rise-to-span ratio does not change for varying deck widths, the relative importance of the out of plane bending compared to the in plane bending moment remains large for each deck width. Hence, out of plane bending remains determining for the bridge design.

For increasing deck widths, the position of the critical arch and deck sections respectively shifts from 0.25 and 0.3 times the span length distanced from the deck extremity towards the center of the bridge. On the other hand, for each investigated deck width, the most loaded arch and deck sections in the reference models with skew arch hanger configuration 2 remain respectively 0.3 and 0.5 times the bridge length horizontally separated from the abutment.

When varying the deck width, or span length, the bending moments in both the arch and the deck are much more critical when hanger configuration 2 is

considered compared to the use of hanger configuration 1. To avoid yielding of the steel in the arch, the bridge deck width has to be limited. For the geometry and arch thickness considered in the reference model, the deck width has to be below 21 m for the models with skew arch hanger configuration 1 or configuration 1 reduction 1 and below 10 m for the models with skew arch hanger configuration 2 or configuration 2 reduction 1. Nevertheless, to prevent vehicle-cable conflict, the deck width should be limited to 18 m in the model with configuration 1. An upper boundary of 14 m and 6 m applies for the model with skew arch hanger configuration 1 reduction 2 and skew arch hanger configuration 2 reduction 2 respectively.

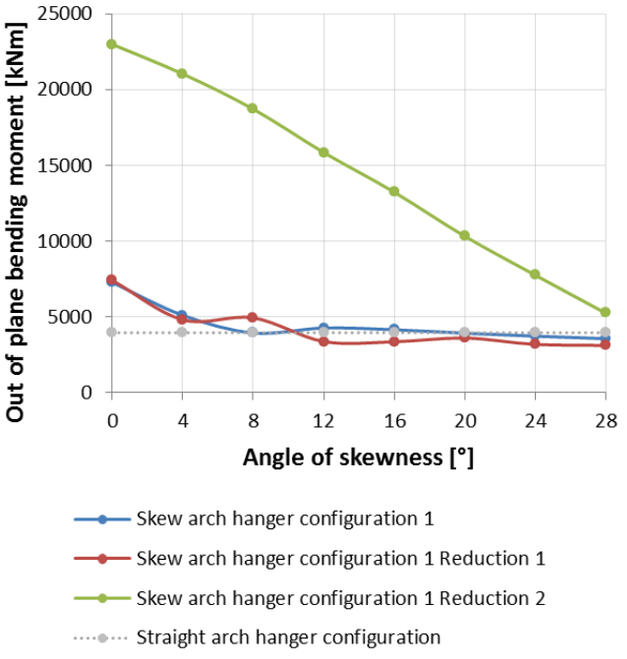

Figure 78. Out of plane bending moments in arch with hanger configuration 1 for varying angle of skewness

4.3 *Influence of the angle*

When changing the angle of skewness, nearly all the changes in the arch and deck behavior can be assigned to the modification of the cable inclinations and hence to the force transfer by the hanger arrangement. In the reference models with skew arch hanger configuration 1 and reduction 1, the arch is used most efficiently for angles of skewness larger than 12°. Hereby, an upper boundary of 25-30° applies for practical and realistic applications. Nevertheless, for angles larger than 16°, the minimum required vehicle clearance is no longer present in the reference model. In reality, this translates to arch abutments which will be located next to the bridge deck, indicating that the angle of skewness is often related to the deck width. For angles larger than 12°, the out of plane bending moments are minimal (Figure 8) as are the resulting maximum arch and deck deformations. Nevertheless, the out of plane bending moments remain determining in the bridge design and the contribution of the axial compression in the force transfer through the arch remains limited. For angles in between 12° and 16°, the design out of plane bending moment is similar to the design moment for straight arch bridges with the same dimensions as the reference models (Figure 8).

For the range 12-16° of skewness angles, the location of the critical arch section is situated near the arch crown. This is because the critical section shifts in between an angle of 8° and 12° horizontal from 0.25 to 0.5 times the bridge length separated from the arch end. This is observed in Figure 9.

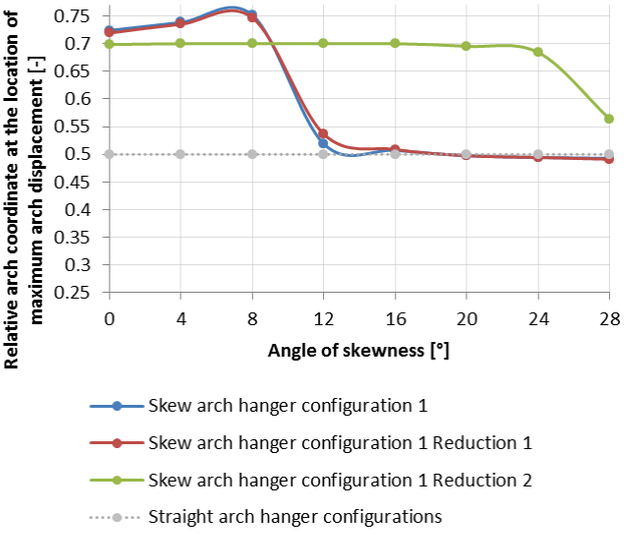

Figure 9. Relative arch coordinate of maximum arch displacement in configuration 1 for varying angle of skewness

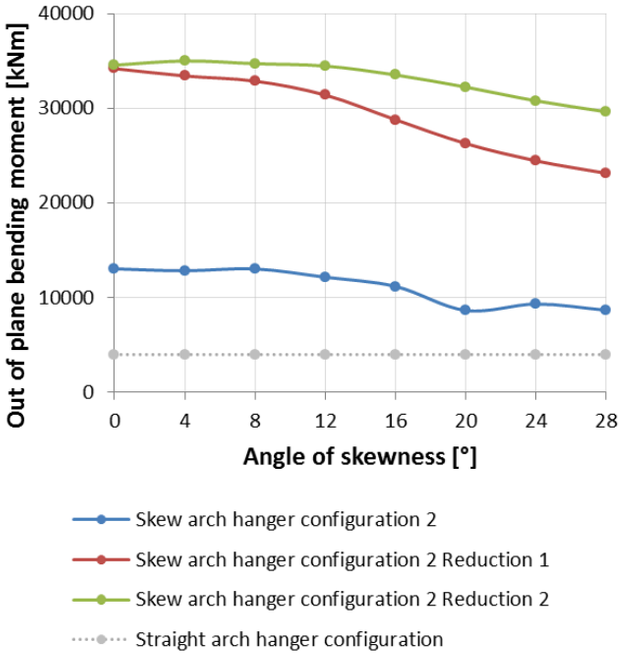

Figure 10. Out of plane bending moments in arch with hanger configuration 2 for varying angle of skewness

For angles in between 6° and 28°, the critical deck location shifts from the bridge center towards a distance 0.3 times the span length from the abutment.

For the bridge structure where the number of hangers is reduced a second time, the optimum angle of skewness lies beyond practical and realistic angles of skewness (>30° in Figure 8).

In comparison to configuration 1, no optimum angle of skewness exists for bridges with skew arch hanger configuration 2. For increasing angles of skewness, the inclination of the cables becomes more and more advantageous. Hence, the largest practically applicable angle of skewness that is still realistic should be chosen in order to minimize the bending moments (Figure 10).

Nonetheless, the bending moments in configuration 2 remain always a factor 2-3 larger than the design moments in arrangement 1. Consequently, configuration 2 is at least a factor 2-3 less efficient compared to straight arch bridges. As the arch abutments are in reality often located immediately next to the bridge deck, configuration 2 can be used for relatively wide bridges compared to the span length. The reason is that for those bridges the angle of skewness of the arch is large. For large but realistic angles of skewness, the critical arch and deck section are located at a horizontal distance of 0.33 and 0.45 times the span length from the abutment.

5 BUCKLING ANALYSIS

In comparison to straight arch bridge models which buckle in an out of plane sine wave due to large axial arch compression, no global arch buckling is observed for skew arch bridges. The reason is that no relevant load combinations exist which load the arch mainly in axial compression. Under the effect of the deadweight and uniform mobile loads, the arch is subjected to significant in and out of plane bending moments. At the locations where bending moments are maximal, the arch has the largest deformations and is subjected to the most severe curvature. Due to this maximal arch curvature, critical compression forces develop within the webs of the arch box section. Eventually this compression can induce local plate buckling of a web of the arch box. The most efficient way to prevent the local plate failure is increasing the shell thickness of the arch or adding stiffeners. The difference in buckling behavior between the models with skew arch hanger configuration 1 and 2 and the effect of changing the bridge span length, bridge deck width and angle of skewness is determined by the difference in magnitude and location of maximal arch deformations. For the reference skew arch models 1 and 2 from Figure 2, the loads in the critical load combination can increase respectively with a factor 12.81 and 11.25 before inducing local plate buckling. Hence, buckling will only be observed when the stress levels in the arch steel have already largely exceeded the yield strength. This indicates that buckling is not a stringent requirement for the design of skew arch bridges. Consequently, no sudden failure due to buckling is expected. (Figure 11)

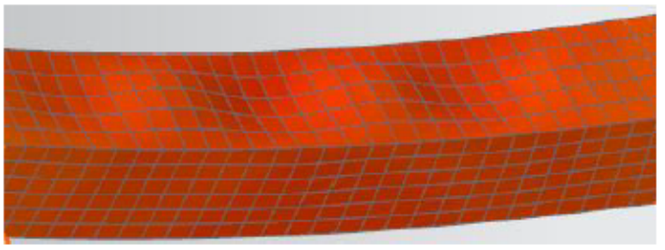

Figure 11. Local plate buckling in a web of the arch box

6 CONCLUSIONS

Skew arch bridges deform less than straight arch bridges under asymmetric live loads and can therefore be useful when the live to dead load ratio is large.

Furthermore, it can be concluded that a skew arch bridge with hanger configuration 1 is structurally more efficient than a skew arch concept with cable configuration 2. Nevertheless, the useful deck width in configuration 1 is lower than for configuration 2 due to vehicle-cable clearance requirements.

In bridges with skew arch hanger configuration 1, the number of hangers can be quite low without inducing more stringent design conditions than for a bridge with a lot of cables.

In order to use the bridge material most efficiently, the angle of skewness should be at least 12° when opting for hanger configuration 1 or should be designed as large as possible for a bridge with hanger configuration 2. For both bridge concepts an upper boundary in the range of 16°-30° is assumed for practical and realistic applications. Nevertheless, for configuration 1 the upper limit is often induced by vehicle clearance regulations. Practically, arch abutments next to the bridge deck form a good design.

K. Islami
Mageba SA, Bulach, Switzerland

ABSTRACT: The application of Structural Health Monitoring (SHM) systems to structures has proven to provide key performance statistics of bridges post-construction, which was not previously possible. Analysis of statistics logged by SHM is very useful in understanding the behaviour of these structures under various sets of circumstances.

This paper discusses a variety of recently implemented SHM systems on concrete bridges. Implementation of SHM systems greatly reduces ambiguity in relation to material properties and structural capacity, and optimises inspection and maintenance programmes. The versatile range of applications presented was developed with the input of structure owners and design engineers, and an in-depth case study on concrete box girder bridges in a subsidence area is included.

Both static and dynamic approaches were adopted, and they successfully demonstrated the necessity and ease of use of such systems. The immense gains in efficiency that SHM systems offer over alternative manual monitoring methods are also discussed.

1 INTRODUCTION

The ability to observe, monitor and understand the behaviour of built structures is paramount in order to avoid critical or perhaps even catastrophic occurrences. As such, there is a definite need for the implementation of technologies that enable key stakeholders, whether they be asset owners or engineers, to examine structures in real-time and hence be able to respond efficiently and effectively in the event that undesirable situations transpire.

Structural Health Monitoring (SHM) systems enable physical parameters of interest to be measured and analysed, with the intention of assessing the actual condition of a structure. These systems utilise advanced electronic devices in the form of measuring instruments (sensors and cables), data collection units and data evaluation software to continuously record both local and global structural properties, and ultimately provide the end user with the information that they require to make the assessment.

The finite element method (FEM) approach has been employed successfully in recently designed structures, and enables the properties of the materials used for construction to be fully exploited. Hence, by undertaking comparison between the design expectations and actual performance of a structure, one can be assured that it is functioning satisfactorily. However, it is evident that many existing structures presently in service were designed before the implementation of current design standards and specifications, and hence there is an obligation to carry out the necessary work to ensure that their performance fulfils the requirements of today. This becomes even more important when considering the general trend of ever-increasing vehicle loads and traffic volumes over time.

This paper will examine the safety advantages and life cycle optimisation opportunities that are made possible by SHM systems. Two key case studies will be presented to demonstrate the benefits for both existing and recently-constructed concrete bridges.

2 ENSURING SAFETY OF CRITICAL INFRASTRUCTURE - COMPARISON OF SHM WITH MANUAL INSPECTION & MONITORING METHODS

Bridges are undoubtedly crucial pieces of infrastructure responsible for the safe passage of immeasurable numbers of people around the world every day. Due to this, there is an inherent obligation to monitor the integrity of these structures, as unavoidable deterioration due to external influences combined with the potential effects of insufficient

design can certainly compromise their safety, stability and usability.

Asset management teams have the responsibility of performing routine inspections of bridges to observe and report their condition, and consequently identifying necessary maintenance or repair actions. In Australia, this is typically managed by the state road authorities. The frequency and degree of inspections would generally be dictated by the following factors at minimum:

- Previously observed and reported structural condition
- Complexity of the structure
- Environmental surrounds, which may result in accelerated deterioration; for example, the potential for subsidence described in Section 3 of this paper for the Hunter Expressway Bridges

Some questions that could be asked of manual inspection and monitoring regimes are:

- Is the correct amount and type of data being gathered?
- Is the data being processed and output in a way that is conducive to effective maintenance and remediation strategies?

Whilst contemplating the above questions, it is also important to note that the cost and time investment required to carry out manual inspections increases significantly when a structure is located in a remote or difficult-to-access place. The Ponte Nanin bridges are situated near the town of Mesocco in the Swiss Alps, a region of relatively undeveloped rugged terrain, as shown in Figure 1. Modification work was undertaken on these bridges in 2004 to increase their load capacity, which was achieved by adapting the bearings and pier-to-deck connections. There was an inherent requirement to deliver continuing validation that the revamped design of the structure and its resulting performance was acceptable. Due to the isolated location of the bridges, a permanent automated monitoring system was selected to accomplish this (Moor et. al., 2013).

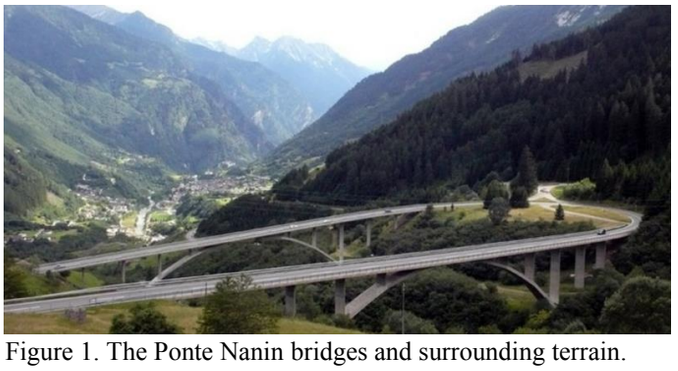

Figure 1. The Ponte Nanin bridges and surrounding terrain.

In Figure 2, a diagram illustrating the simplified process of data acquisition, analogue to digital conversion, transmission to the monitoring station and finally receipt by the end user is provided.

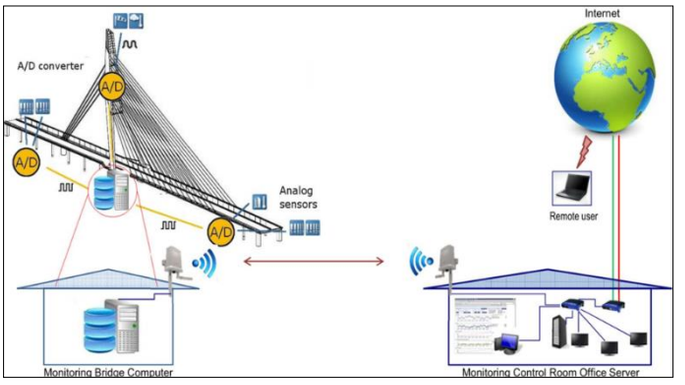

Figure 2. Data acquisition scheme used for SHM systems

Data is collected by a range of sensors and conveyed by the SHM system's computer to a monitoring server, from which a user can view information via their personal computer or mobile devices. From a flexibility perspective, SHM systems have much to offer. The reduced requirement for physical inspection has a positive effect on safety and costs over the life of the structure.

The SHM system for Ponte Nanin was designed to function under the constraints imposed by the bridges' site, namely the non-existence of electricity and telecommunications systems. A solar panel was employed to deliver power to the monitoring system, as shown in Figure 3.

Figure 3. Solar panel of the Ponte Nanin monitoring system.

A low-frequency solution was adopted in order to provide adequate information whilst working under the aforementioned limitations. Gathered data is transmitted to the user via the mobile telephone network. If necessary, the user can adjust the sampling rate from the standard 15 minute frequency to provide more information as required. The parameters measured for these bridges consist of:

- Expansion joint movements
- Bearing loads
- Temperature (ambient and structural)
- Humidity

Expansion joints and bearings are some of the most often overlooked yet critical components of a bridge. Bridges are dependent on the performance of expansion joints to create a safe trafficable riding surface, and on bearings for transferring loads, movements and rotations from the superstructure to the substructure. If the functionality of a bearing is impeded for any reason, its inability to transfer loads, movements and rotations would result in accumulation of forces at some point in the surrounding structure, which could result in the onset of major damage and hence compromise the safety of the structure and its users (Islami et. al., 2016).

The Ponte Nanin bearings feature pressure sensors, which enable the SHM system to calculate the loads sustained due to the forces imposed by the bridge deck. The motivation for utilising these monitoring devices was the need to understand the change in load paths caused by the structural modifications made to the bridges, and hence to certify that the actual behaviour post-modification met design expectations. An image of the bearing monitoring setup is given in Figure 4. If load measurements were to be taken manually instead of via automated monitoring, data would only be available for specific points in time, the accuracy of the measured data would be hard to verify, and therefore it would be much more difficult to gain confidence in the performance of the structure and the bearings. Additionally, the need to make multiple journeys to manually inspect the structure would definitely contribute to increasing its life-cycle costs.

Figure 4. Bridge bearing capable of load measurement.

The data records for the Ponte Nanin Bridges over a period of approximately 9 years are presented in Figure 5.

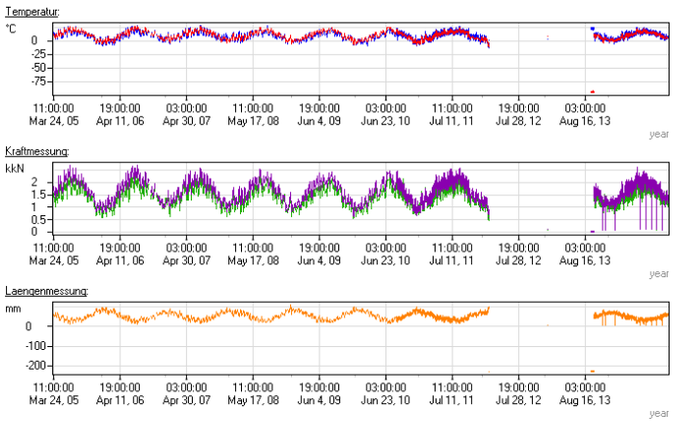

Figure 5. Temperature, bearing loads and expansion joint movements from a period of approximately 9 years.

The forces recorded by the bearings are seen to correlate reasonably well with the temperature profile. That is, the highest loads are experienced at the highest temperatures, and vice versa. The SHM software allows graphs to be generated to illustrate the relationship between two variables of interest, allowing conclusions to be drawn about the behaviour of the structure. In the case of force and temperature, force is a measured variable and temperature is an influencing variable. This is shown in more detail in Figure 6. A linear relationship between these two variables is apparent.

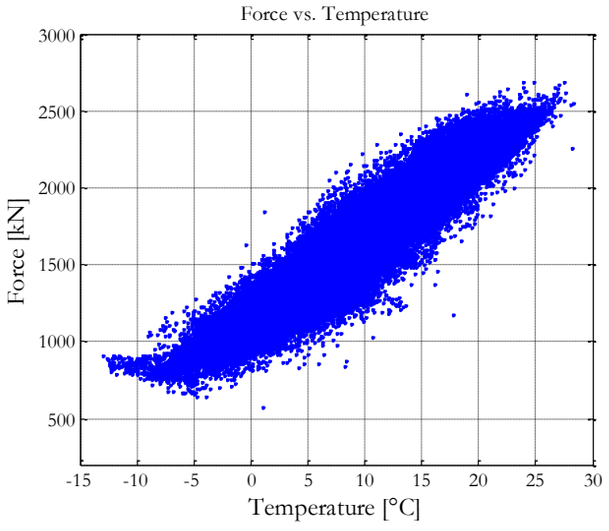

Figure 6. Plot of force measured in bearings vs. temperature.

In Figure 7, the relationship between displacement of the structure at the expansion joints and temperature is shown. It can be seen that the bridge experiences maximum longitudinal displacement (deck contraction) at the lowest temperatures, which fits well with anticipated behaviour.

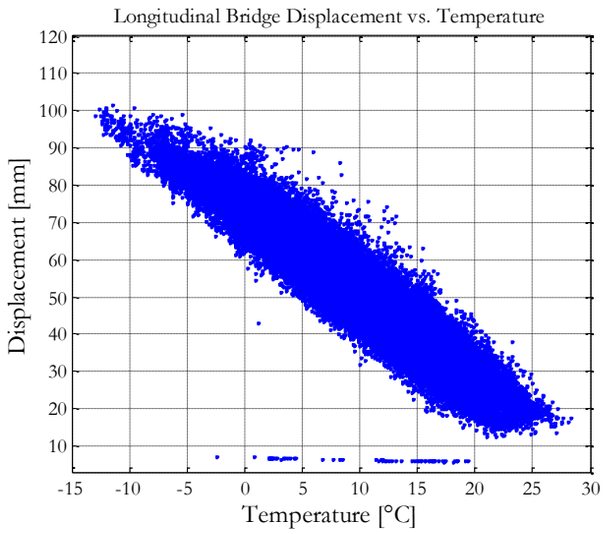

Figure 7. Plot of longitudinal displacement vs. temperature.

From an analysis of the output data from the SHM system presented in Figures 5-7, the user can make judgements regarding structural performance and determine whether any corrective actions are required. If the data shown here was to be collected via manual monitoring and measurement methods, the following points would be apparent:

- Manual setup of the measuring equipment would be time-consuming and cumbersome
- Access to the relevant parts of the structure, for example under the bridge deck to measure bearing loads, would be difficult and potentially dangerous to the inspection team
- Accuracy of data collected via manual means is dependent on the inspector's experience and proficiency, and as such may be questionable. This can result in subjective assessments, which are not useful for proposing efficient maintenance measures
- Manual inspection and monitoring provides data at a discrete point in time, whereas automated monitoring provides continuous data, making it easier to identify and track abnormalities in the performance of the structure over time

The intention of this case study is not to discount the need for physical inspection and monitoring of structures, but rather to demonstrate that a correctly designed SHM system can offer many benefits to the user, by providing objective and accurate information in an efficient manner.

An optimum duration of frequency for determining the condition of bridges can be reached through the combined use of monitoring and conventional inspections (Wenzel, 2008). This brings together the precise quantitative data delivered by automated monitoring and the qualitative data obtained by visual and physical inspection of bridge elements. Thus, with the ability to increase the safety of a structure and its users, automated monitoring systems shall complement and augment the standard inspection practices followed by asset owners.

3 ASSESSMENT OF LIFE-CYCLE COSTS

Bridges are long-term investments that will inevitably require ongoing expenditures in order for them to remain in service. A key challenge for asset managers is to determine the most cost-effective way in which to achieve this (Hawk et. al., 2003). In Figure 8, the relative distribution of costs for a bridge is shown, categorised into the five key areas of design, construction, maintenance, rehabilitation, and user costs (due to diversions, traffic congestion etc. while maintenance or renovation work is carried out).

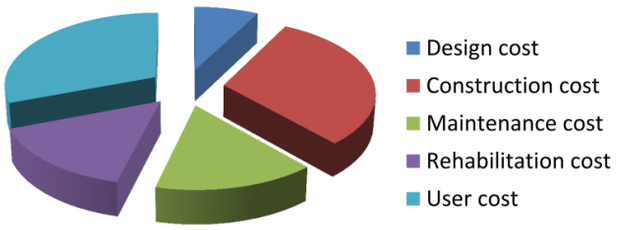

Figure 8. Cost distribution graph for a typical bridge.

From Figure 8, it is evident that the combined maintenance and rehabilitation costs for a bridge comprise approximately 40% of its overall cost. This figure is vast, especially when considering the known magnitude of bridge construction costs (typically in the tens to hundreds of millions of dollars). Therefore, any opportunity to reduce maintenance and rehabilitation costs would be highly advantageous.

The use of SHM systems can result in substantial reduction of life-cycle costs associated with maintenance and rehabilitation, and hence optimisation of service life for a given structure. By providing precise up-to-date information related to present condition, the user is able to more efficiently deal with issues before they become problematic and require exhaustive remediation.

Additionally, the data collected by automated monitoring systems can be input back into statistical deterioration models to provide a more accurate prognosis of the structure's future requirements (Cho et. al., 2007). This allows for more effective planning and scheduling of upcoming maintenance activities.

In Figure 9, a general depiction of the comparison of life-cycle costs over a 50-year period for structures with and without monitoring and maintenance is presented.

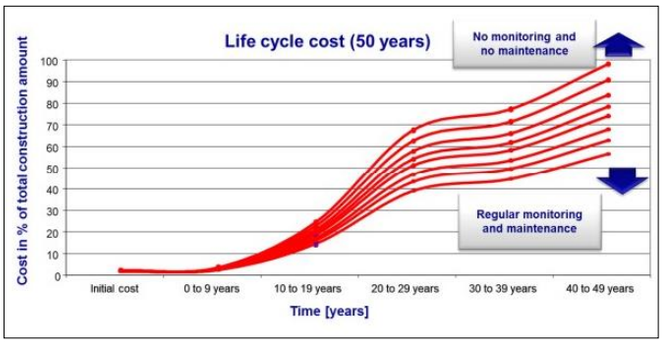

Figure 9. Comparison of life-cycle costs over a 50-year period.

It can be seen that over time, the difference in life cycle cost (expressed in Figure 9 as percentage of total construction amount) between unmonitored and monitored structures increases steadily. After 50 years, the life-cycle costs for structures with no monitoring or maintenance are approximately 80 percent higher than their counterparts. Based on this relationship and considering that bridges are often designed for a service life of 100 years or more, the importance of SHM systems becomes apparent.

Seven concrete box girder bridges of varying lengths (ranging from 155m to 337m) were constructed as part of the Hunter Expressway project in New South Wales and opened to traffic in 2014. Views of the bridges are shown in Figures 10 & 11.

Figure 10. Underside views of some of the seven bridges with SHM systems installed.

Located approx. 170 km north of Sydney in a mining region, the risk of settlement due to ground subsidence prompted the use of SHM systems on these bridges (Islami et. al., 2014). An aerial view of the terrain surrounding the structures is presented in Figure 11.

Figure 11. Topography surrounding the Hunter Expressway, a region with potential for subsidence due to mining activities.

Bridges form critical links as part of the transport infrastructure network. If any structural elements are damaged, there will likely be severe consequences which will always result in amplification of costs, to the detriment of the asset owner and users. The potential settlement and resulting undesirable movement of structural elements on the Hunter Expressway Bridges could require costly rectification measures post-construction, with the likelihood that the bridge would have to be closed to traffic to undertake these works. This would pose additional direct financial costs for the labour, equipment and machinery required, as well as economic and social costs to the local community.

The use of automated structural monitoring was deemed to mitigate these risks significantly, with the ability to inform the relevant personnel of any unexpected movements at the exact time of their occurrence. This provides greater control over the risk management of the structure without the need for regular engagement of inspection teams, which would allow maintenance and/or remediation to be carried out as and when required, thus minimising life-cycle costs.

The monitoring systems utilised on the Hunter Expressway Bridges are depicted in Figure 12, and were designed to capture the following parameters of interest:

- Settlement of piers with respect to the abutments
- Settlement of abutments
- Movement of the abutments with respect to the longitudinal and transverse axes of the structure
- Temperature at piers and abutments

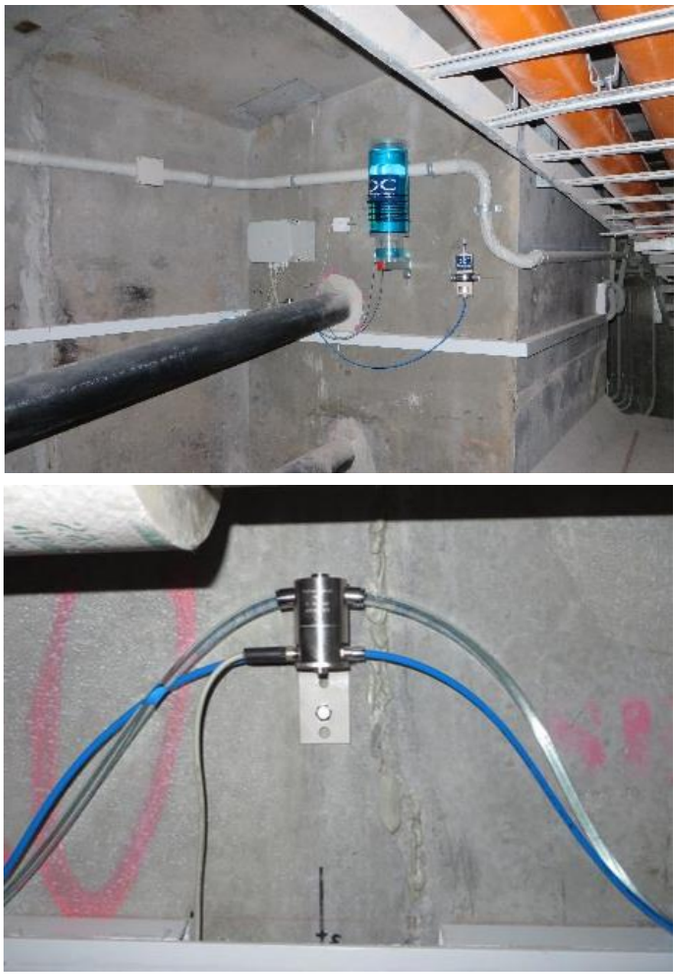

Figure 12. Close-up view of SHM system components.

The data collected by the SHM system is transmitted in real-time to the "monitoring cockpit" which is accessible remotely via the Internet. This means that data can be viewed at any time and from almost any location. From this platform, the user is able to analyse the actual values measured by each sensor on the given structure, which are able to be compared with minimum and maximum permissible values to give an indication of current performance. There are also "alarm values" programmed to alert the user of atypical behaviour. This functionality enables the user to make an informed decision about the necessity to implement further inspection, maintenance or repairs. A sample of the monitoring cockpit for the Hunter Expressway Bridges is shown in Figure 13.

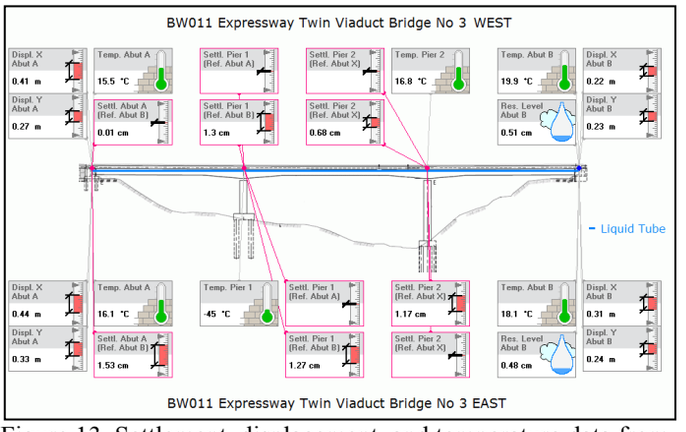

Figure 13. Settlement, displacement, and temperature data from the east and west sections of one bridge – Cockpit view.

From Figure 13, the user is able to gain an insight into the parameters of interest for this structure. The measured values are shown alongside the location of the respective sensors for data collection on the bridge, making it easy for the user to isolate the particular values that they are interested in observing. A quick glance would be sufficient to indicate that settlements, displacements and temperatures are within acceptable limits. The cost and inconvenience of measuring these values at the multiple relevant locations using alternative manual methods of monitoring would be significant for a single inspection, let alone for regular inspections. This emphasises the efficiency gains that SHM systems can offer to users.

All data and tables generated by the SHM system can be downloaded for further analysis. Data can be exported as a CSV file to enable processing, manipulation and presentation to achieve required outcomes, as shown in Figure 14.

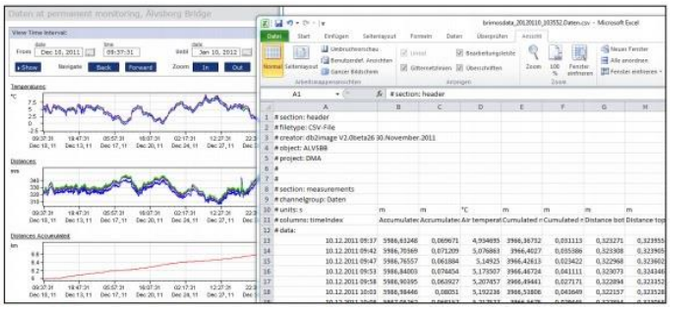

Figure 14. Data presented in CSV form.

Figure 15 shows that there is a relationship between environmental factors (in this case temperature) and the settlements experienced by the piers. The largest settlements measured by the SHM system occurred at the higher end of the temperature spectrum. In Figure 16, the relationship between longitudinal displacement and temperature is shown.

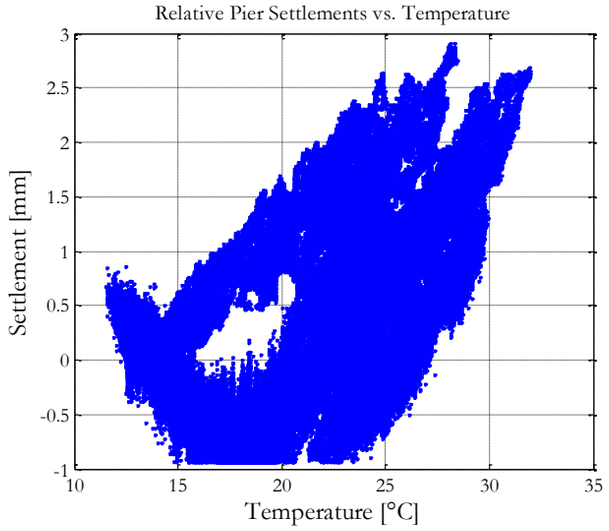

Figure 15. Relative pier settlements vs. abutment temperature.

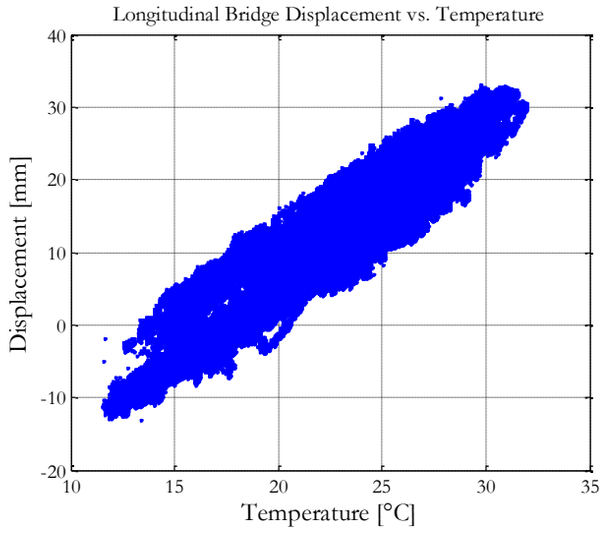

Figure 16. Longitudinal displacement vs. temperature.

Figure 16 shows that there is a distinct linear relationship between longitudinal displacement and temperature. Intuitively, the bridge experiences the largest displacements at higher temperatures, and minimal displacements within a temperature range of approximately 15-20°C. From both Figures 15 and 16, it can be seen how strongly temperature variations influence the various movements occurring in the structure.

There are situations where it may be desirable to eliminate specific influencing factors, such as temperature, in order to gain a better understanding of the relationships between less dominant variables. This can be achieved through the use of regression modelling, which is beyond the scope of this paper, but is described in detail by Islami & Modena (2013).

Further data from one of the Hunter Expressway Bridges is presented in Figure 17. This represents behaviour of the structure over a 19-month period.

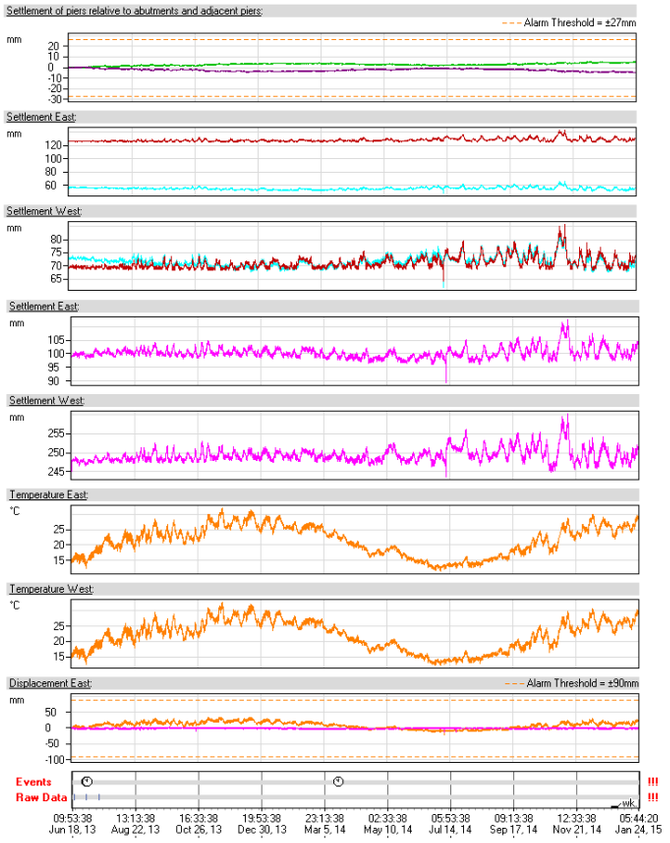

Figure 17. Settlement, temperature and displacement recorded over a period of 19 months.

It can be seen that relative settlement of the piers is quite stable and reaches a maximum value of approximately 7 mm, well below the indicated alarm threshold value of 27 mm. The temperature profile matches the expected seasonal fluctuation (peak in November-January and trough in June-August), and the settlements and displacements follow this profile as commented previously for Figures 15 & 16.

The implementation of SHM systems on the Hunter Expressway Bridges from the beginning of their service lives will allow any required corrective measures to be taken proactively rather than reactively, effectively decreasing life-cycle costs. These bridges form a key part of the road network in New South Wales, and it is therefore necessary to ensure that they remain in a safe and serviceable condition. It can be confirmed that since the SHM systems were installed on the bridges, there has been no evidence of substantial settlements. The ability to monitor the structures constantly over time safely allows this judgement to be made, and it would be difficult, if not impossible, to arrive at the same conclusion if monitoring was undertaken solely via manual methods.

4 CONCLUSIONS

It is evident that Structural Health Monitoring systems can effectively increase safety and optimise life-cycle costs for concrete bridges. This is achieved by making it possible to identify and deal with issues before they can result in structural damage and require costly repair works.

Whether employed on existing or newly-built structures, automated monitoring enables collection of useful data in a manner that is extremely accurate, safe, efficient and cost-effective. The potential to reduce the need for expenditure on maintenance and repair, and therefore allow structures to remain safely in service for years to come, reinforces the need to implement this essential technology on a wider scale.

ABSTRACT: Pre-stressed concrete girder with corrugated steel web is one of the promising steel and concrete hybrid structures which are widely applied to highway bridges. The joint structure between concrete and steel is an important part of such structure. Firstly, the application of various shear connectors for joint structure was introduced and compared for the mechanical performance, such as headed stud and perfobond strips shear connectors weld on the flange or the corrugated steel web embedded in the concrete slab directly. In order to improve the construction quality of concrete and durability of joint structure, a new joint structure that placing lower slab on the inner side of corrugated steel webs with perforated plate connector is proposed in this study. Then, push-out tests with different parameters including plate height, plate thickness, and plate shape were carried out to study shear strength, shear stiffness, failure modes and relative slip characteristics of proposed joint structure. Finally, on the basis of test results, the calculation formula of shear capacity for proposed joint structure is proposed, which can accurately predict the shear strength. All the findings of proposed joint structure in present study can provide reference for its application in practical bridge.

1 INTRODUCTION

A pre-stressed concrete girder with corrugated steel web is one of the promising concrete and steel hybrid structures applied to highway and railway bridges. The way to substitute corrugated steel webs for concrete webs of a box-girder bridge will result in no restraint among the slabs and webs, which will alleviate influences on the box girder due to concrete creep, drying shrinkage and temperature differences. Pre-stressing can be efficiently introduced into the top and bottom concrete slabs due to the so-called "accordion effect" of the corrugated webs (He *et al.* 2012a). Based on the promising new type hybrid structure, their flexural, shear and torsional behavior, fatigue performance and engineering applications have been experimentally and analytically studied (Sause and Braxtan 2011; Mo and Fan 2006; Ibrahim *et al.* 2006; He *et al.* 2012b,c; He *et al.* 2014 a, b).

The connection between concrete and steel is an important part of composite structure. The shear studs, perfobond strips (PBLs) and angle shear connectors welded on the flange or the corrugated steel webs embedded in the concrete slab directly are generally used for the joint part. He (2011) investigated composite bridges with corrugated web domestic and abroad to analyze the number and proportion of different kinds connectors, and found that headed studs were adopted most for corrugated web bridge in early time, such as Shinkai Bridge (Kondo *et al.* 1994) in Japan and Altwipfergrund Bridge (Novák *et al.* 2007) in Germany. And angel connector was the most popular one used in such kind bridges in France and Japan, U-shape reinforcements welded on the angel help the connector deform ductile, and the longitudinal reinforcements bear out-of-plane moment. The PBL connector was developed in the eighties by the German company for the design of the third bridge over the Caroni River in Venezuela (Leonhardt *et al.* 1987). Push out test results show that PBL shear connectors are advantageous from the viewpoint of fatigue strength (Hosaka *et al.* 2002). However the out-of-plane moment performance for single perforated plate is relatively weak, so studs welded on both sides of the perforated plate or Twin PBL connectors were used to improve this condition. Ebina *et al.* (2004) conducted an extensive research to obtain the mechanical characteristics (shear and out-of-plane bending behavior) of twin perforated ribs connector, also the force transmission mechanism and fatigue characteristics under out-of-plane bending moments caused by transverse deflection of concrete slab were discussed. Corrugated steel webs have very low axial rigidity, which requires relatively flexible shear connectors. Corru-

gated steel web embedded in the concrete as shear connector without using a top steel flange was initiated in Hondani Bridge. Nakasu *et al.* (2000) carried out the experiments and finite element (FE) analysis for several types of specimens changing plate thicknesses and embedded depths of corrugated steel webs to investigate a long-term behavior of embedded connector. Kosa *et al.* (2006) carried out experimental and analytical investigations on flexural and shear behavior of composite girders with corrugated steel webs to make clear ultimate behavior and failure mechanism of embedded connection. Novák & Röhm (2009, 2010), investigated the load bearing behavior of an embedded corrugated steel web in combination with concrete dowels under longitude shear and transverse bending respectively. On the basis of these studies, simple design rules for shear connection in the ultimate limit state were developed. Kim *et.al.* (2011) carried out push-out test of corrugated perfobond rib shear connections. Test results showed that the failure was determined by concrete bearing with small deformations of inclined panel, and shear strength increased much than standard perfobond rib connector due to the shear resistance of the inclined rib panel.

When stud or embedded connections used for the joints between corrugated steel webs and concrete lower slab, construction quality of concrete and water proofing of the joints requires special attention. With a view to these problems, Ono *et al.* (2006) prepared some specimens modeled the embedded connection and carried out accelerated corrosion tests of the specimens. The results showed that durability of the embedded connection is increased by sealing the border between steel and concrete and by embedding paint in concrete. Shiji *et al.* (2008), He (2011) adopted the joint structures as shown in Fig.1, and the validity of placing lower slab on the inner side of corrugated steel webs was confirmed. It was proved that the bottom flange was beneficial to the concrete construction quality, as well as the durability of the interface between concrete slab and corrugate web.

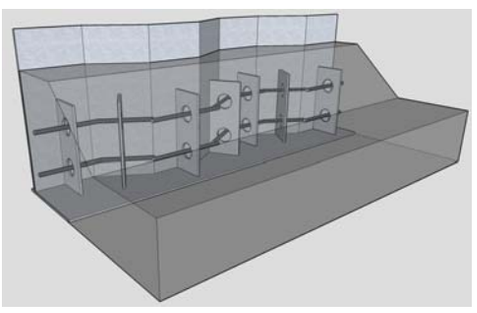

Figure 1. Joint structure between lower slab and corrugated web

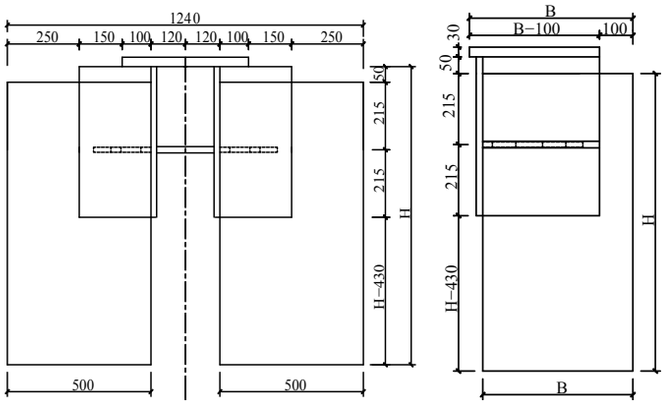
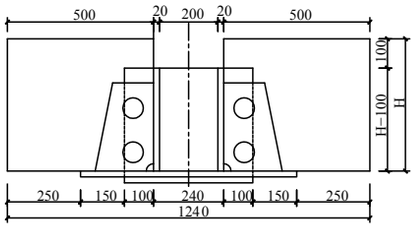
Since shear loading capacity, failure modes and relative slip characteristics of proposed joint structures are different from those of conventional ones. Therefore, standard push-out tests are carried out to investigate the influence of different parameters (thickness, height and shape of perforate plate) on the shear behavior. Based on the results of model tests, a formula for calculating shear strength is proposed. All the findings of experimental works at present study may provide reference for the application of such joint structure in bridge construction.

2 EXPERIMENTAL PROGRAM



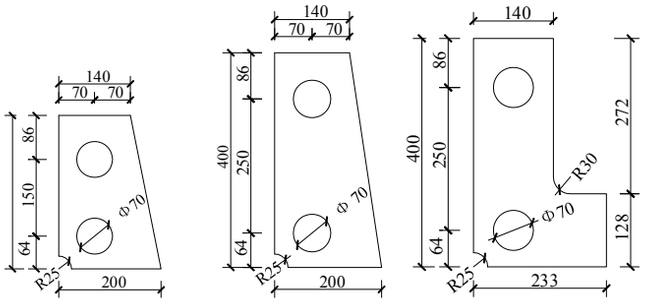
2.1 *Test specimen*

Referring to standard push-out test of headed stud connector, punching shear tests of perforated plate connectors in out-of-plane direction were carried out to verify the shear strength and relative slip. There are four test specimens prepared to investigate the influence of the geometrical parameters of perforated plate including the height, thickness and shape (L-shape or Trapezoidal shape) on shear behavior of joint structure. The push-out test specimens are shown in Fig.2, and the test parameters are list in Tab.1. The thickness of concrete block for all the specimens is 500mm, the width of concrete block is 450mm for DPS1 and DPS 3, while 500 for DPS2 and DPS 4. The distance from perforated plate to bottom of concrete block should be large enough to prevent local damage of concrete block, which was adopted as 685 and 785mm for DPS1,3 and DPS2,4, respectively. These push-out tests focus on shear strength of perforated plate in perpendicular direction, so the diameter of penetrating reinforcement through 70mm- diameter holes is chosen as 20mm to meet the minimum reinforcement requirements.



In order to prevent tension failure of concrete block, 16mm-diameter reinforcements with spacing of 100mm and 8mm-diameter stirrups with spacing of 150mm were arranged in concrete block.

Table 1. Parameters of test specimens (unit: mm)



No.	PBLs					Concrete block	
	h	b_1	b_2	t	shape	B	H
DPS1	300	140	200	16	Trapezoidal	450	900
DPS2	400	140	200	16	Trapezoidal	500	1000
DPS3	300	140	200	10	Trapezoidal	450	900
DPS4	400	140	233	16	L	500	1000

2.2 *Material properties*

The material properties including compressive strengths, tensile strengths and Young's modulus of three cubes at 28 days after the casting of the concrete with nominal strength of 55MPa are given in Tab.2. The mean tensile properties of samples cut from the steel component (Q345) such as perforated plate, the flange, loading plate and the reinforcements (HRB400) of the specimens are summarized in Tab.3.

Table 2. Material properties of concrete (unit: MPa)

Sample	Compressive strength	Tensile strength	Young's modulus ($\times 10^4$)
1	54.46	3.87	4.28
2	52.71	4.32	4.41
3	54.58	4.55	4.09
Mean	53.92	4.25	4.26

Table 3. Material properties of steel (unit: MPa)

Component		Yield strength	Tensile strength	Young's modulus
Plate	10mm	430	558	1.99×10^5
	16mm	400	531	2.02×10^5
	20mm	410	526	1.96×10^5
	30mm	423	551	2.01×10^5
Rebars	16mm	527	644	1.97×10^5
	20mm	499	664	2.00×10^5

2.3 *Loading and measurements*

Push-out specimens are tested in a hydraulic testing machine. A loading plate was installed at the top of the steel beam, in order to achieve a uniformly distributed load among all the connectors of each specimen. At the bottom of the concrete slabs, a layer of fine sand was paved to reduce concentrated reaction forces between specimens and the test bench. For the loading process, force control was applied with a rate of 5kN/min till 40% of the expected failure load, in this stage loading and unloading for 5 times to check the stiffness degradation of specimen. Subsequently, displacement control is used until the load dropped to 80% of the maximum load or obvious failure of the specimen was observed. The loading rate for the latter stage is 0.01 mm/s.

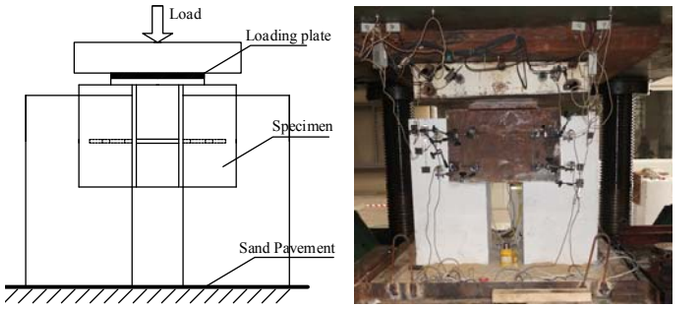

Figure 3. Test set-up

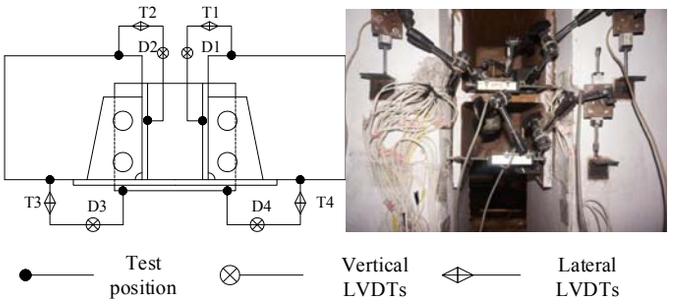
Four linear variable differential transformers (LVDTs) were symmetrically mounted at both the front and back sides of the specimen, and fixed at the same height to the perforated plate, as shown in Fig. 4. The transversal and vertical relative slip between the steel beam and the concrete block was measured by four gauges T1~T4 and D1~D4 respectively. The applied load and relative slips were recorded continuously and automatically. Besides the measurement of displacement for specimens during loading process, cracking initiation and propagation on the surface of concrete block were observed.



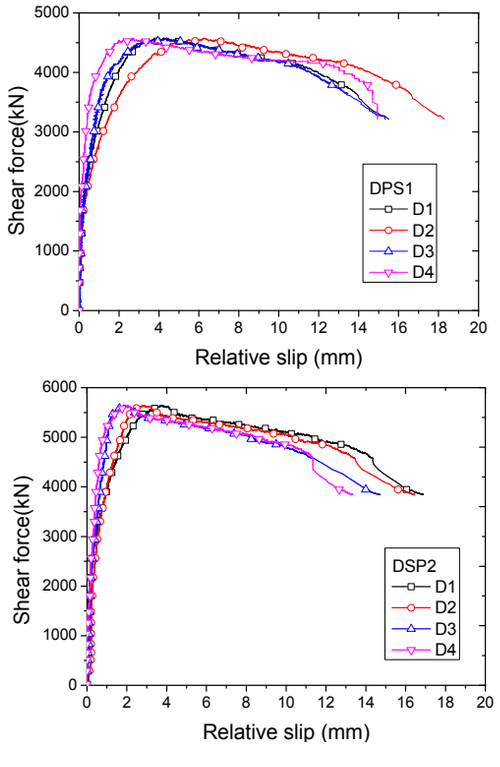


Figure 4. Relative slip measurement

3 EXPERIMENTAL RESULTS AND DISCUSSION

3.1 *Load-slip relationship*

The slip between steel plate and concrete slab occurred as the applied load increased. The slip from four LVDTs versus the shear load is plotted in Fig.5. It can be found that the load-slip relationship of plate dowel is nearly linear up to 1/3 of the maximum load (the relative slip is about 0.2mm). Besides, the shear force of perforated plate connector under serviceability limit states is usually not greater than 1/3 of the maximum load (V_u). Hence the shear stiffness, k_s, is defined as the secant modulus at the point where the applied load (V_y) related to the relative slip of 0.2mm in this study. Then, with the increase of shear load, the concrete under perforate plate damaged, load-slip curve became nonlinear, shear stiffness of perforated plate reduced gradually. When the applied load reached the limit state, relative slip increased rapidly until failure, and the slip at specimen failure is 2 times more than the slip corresponding to ultimate load, showing good ductility.

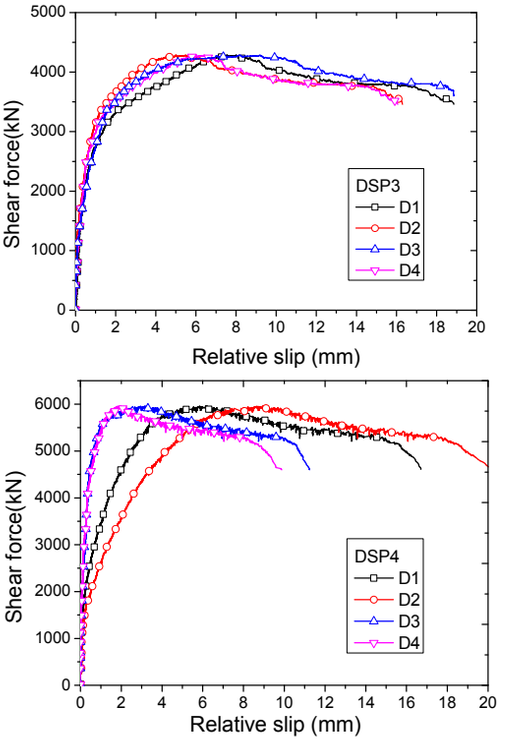

Figure 5. Load-slip curve

3.2 *Failure mode*

The failure modes of test specimens involved failure of concrete slab and deformation of perforate steel plate. The concrete punching shear failure was occurred on the corner of shear connector for all specimens, specimen DPS3 was selected as an example, as shown in Fig.6. The initial crack appeared on the concrete slab near the position of perforated plate connector. As the load increased, cracks gradually spread out toward the top and bottom of the concrete slab, mostly in the neighborhood of the steel beam.

Figure 6. Typical failure mode (Specimen DPS3)

After loading of push-out tests, the specimens were dismantled and concrete block was cut off directly under perforated plate to investigate the inner failure modes. The concrete under perforated plate damaged in the zone of approximate triangle shape near steel flange, which was similar to rectangular perforated plate connector in previous study (He 2011). Concrete in the disassembly specimen was

removed to investigate the deformation of perforated plate. The perforated plates for all the specimens were almost intact after loading of the test. In addition, no cracks or fracture were found in the perforated plates and weld seam for all the specimens.

3.3 *Shear strength and stiffness*

The push-out test results are summarized in Table 4, including the shear strength, shear stiffness and slip deformation. The shear strength (V_u) is defined as the maximum load during the tests; the relative slip at maximum load is defined as peak slip (s_p). The shear stiffness (k_s) represents the secant slope at applied load V_y corresponding to relative slip of 0.2mm, as mentioned before.

Table 4. Shear strength and shear stiffness

Specimen	Shear strength		Shear stiffness		
	V_u/kN		s_p/mm	k_s/kN·mm^{-1}	V_y/kN
	Test	*Cal.*			
DPS1	2273	2148	4.8	4190	838
DPS2	2821	2864	2.8	6100	1220
DPS3	2143	2148	5.5	3420	684
DPS4	2977	2860	2.3	6970	1394

Note: the value of shear strength and stiffness represent the related value for one perforated plate connector

The shear stiffness which reflects deformation capacity of perforated plate connector changed from 3000 to 7000kN/mm. The shear stiffness of specimen DPS3 with thinner thickness is smaller than that of specimen DPS1. And shear stiffness of specimen DPS4 with L-shape is slightly larger than that of specimen DPS2 with trapezoidal shape.

From Table 4, it can be found that: the shear strength of specimen DPS2 with the perforated plate height of 400mm increased about 24% in comparison to that of specimen DPS1 with the perforated plate height of 300mm, also the shear stiffness enhanced about 1.45 times. With the increasing of perforated plate height, the compression area of concrete under perforated plate also increased, therefore the shear strength and stiffness were improved. When the thickness of perforated plate increased form 10mm (DPS3) to 16mm (DPS1), the shear strength and stiffness increased about 6% and 18% respectively, indicating increase of plate thickness can also improve the shear strength and stiffness to a certain degree. When the plate shape change from trapezoidal shape (DPS2) to L-shape (DPS4), the ratio of shear strength for DPS4 to that for DPS2 is 1.05, while the ratio of shear stiffness for DPS4 to that for DPS2 is 1.14, which indicate that the plate shape with the same area has slight effect on shear strength, but certain effect on shear stiffness.

4 SIMPLIFIED ANALYTICAL METHOD

4.1 *Calculation of shear strength*

The calculation of punching shear strength was deduced referring to the calculation method of angel shear connector (PCTS 2005) with the similar resistant mechanism, which includes the compressive strength of concrete and the shearing strength of welding part. The perforated plate connector and steel web were welded in double side, and the compressive area of concrete is effective in triangle part around the welding line, which was verified by experimental failure mode, the shear capacity of plate dowel is calculated as follows:

$$V_u = \min(R_1,\ R_2,\ R_3) \tag{1}$$

$$R_1 = A f_{ck}^{'} / k \tag{2}$$

$$R_2 = \sum a L_1 f_y / \sqrt{3} \tag{3}$$

$$R_3 = t\left(b + h\right) f_y / \sqrt{3} \tag{4}$$

Where R_1 is compressive resistance of concrete; R_2 is shear resistance of welding part; R_3 is shear resistance of plate material; A is area of perforated plate; f_{ck}' is compression strength of concrete; b, h, t is the width, height and thickness of perforated plate respectively; k is the reduction coefficient, k=1.28 refer to He *et al.* (2011); a is theoretical thickness of welding; L_1 is effective length of welding; f_y is yielding strength of steel.

4.2 *Comparison and discussion*

Table 4 also shows the calculated shear strength of push-out test specimens. All the specimens are failure due to concrete crush at the position of perorated plate connector. So the compressive resistance R1 represents shear strength for all the test specimens. And the ratio of calculate shear strength to test one for specimens DPS1~4 is 0.95, 1.02, 1.00, 0.96 respectively, the mean value of these ratios is 0.98, with the corresponding coefficients of variations of 0.03. Therefore, the proposed calculation equations (1~4) can reasonably predict shear strength of perorated plate connector with high accuracy.

The shear strength ratio of calculation value to test one for specimen DSP1 has the same degree comparing with specimen DSP3, indicating that the increase of plate thickness slightly affected shear strength, if perforate plate is thick enough.

The shear strength ratio of calculation value to test one for specimen DSP4 is slightly lower than that for specimen DSP2. The concrete compressive resistance is inclined to decrease with slender shape, since only specimen DSP4 is applied for studying the influence of plate shape, more specimens with different width and height should be tested in the future.

The shear strength from previous test (He 2011) and present test results are compared with calculation ones, as shown in Fig. 7. The average value of the ratio of the test shear strength to theoretical calculation one is 0.98, with the corresponding coefficients of variations of 0.1, indicating that the shear strength of perforate plate connector can be predicted according to theoretical calculation formula (1~4). Also, the value of parameter k=1.28 is verified by the comparison between tested and calculated results.

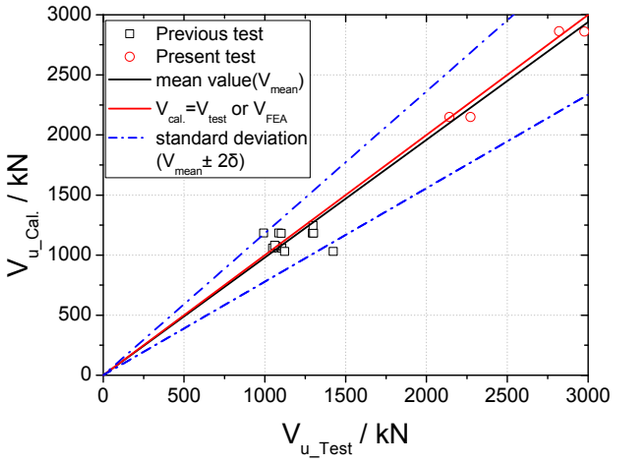

Figure 7. Comparison of shear strength from test and calculation

5 CONCLUDING REMARK

Push out tests of perforate plate connector were conducted, typical failure mode under punching shear load was observed, and the effects of key parameters including material properties, the shape and thickness of the perforated plate on shear capacity and stiffness were clarified: the increase of the plate thickness and area can improve the shear strength. Concrete damage took place adjacent welding edge under failure loading. Shear strength calculation based on effective compressive area of concrete is deduced. The theoretical analysis results are in good agreement with the experimental results. And reduction coefficient k is verified as 1.28 from test results for safe side.

All the experimental and theoretical calculation results can provide a reference for the design of joint between corrugated steel web and lower concrete slab. Since this paper ignores the contribution of the corrugated web itself to shear bearing capacity, the magnitude of its influence needs to be further studied.

ABSTRACT: Rebars improve composite structure constructability and efficiency. Transverse rebars in the Y-type perfobond rib shear connector influence both shear strength and ductility. Performance characteristics of Y-type perfobond rib shear connectors with various transverse rebar strengths and diameters need to be identified. Push-out tests were done with Y-type perfobond rib shear connectors with various transverse rebars. Strain gauges monitored the strain histories with both push force and relative slip between the perfobond rib and composite concrete block. The concrete block surface was photographed to confirm the surface crack formation time and pattern. Strain histories indicate that surface cracks initiated after the nominal yield strains of the rebars were exceeded. Shear resistance can be increased and the surface crack formation delayed by using high-strength transverse rebars. However, a balanced design is needed to achieve shear resistance and ductility. Excessive strength transverse rebars may cause early damage on, and failure of, the Y-ribs.

1 INTRODUCTION

Composite structures, which use varied materials in one structure, are being researched extensively because of their structural efficiency. Steel-concrete composite structure is a representative composite structure that is widely used in diverse infrastructures and buildings around the world. The steel-concrete composite structure has effectively combined the characteristics of steel, which is robust against tension, and the characteristics of concrete, which is robust against compression. The composite behavior of shear connectors is essential to manifest the structural rigidity and strength of the composite structure effectively. A shear connector is a mechanical device that prevents vertical and horizontal separation and connects the steel and concrete to transmit stress effectively. To improve the efficiency of composite structures, various shear connectors have been researched and developed, such as stud shear connectors (Viset et al., 1956), perfobond rib shear connectors (Leonhardt et al., 1987), and Y-type perfobond rib shear connectors (Kim et al., 2013).

The stud shear connector, which is the most widely used shear connector in the world, was developed by Viset et al. (1956), and its usability was verified through experiments. However, stud shear connectors are vulnerable to fatigue and strength degradation due to weld quality. To address this problem, a German design company developed the perfobond rib shear connector in 1987 (Leonhardt et al., 1987). The perfobond rib shear connector has advantages over the stud shear connector, such as excellent shear performance and the possibility of mass production. However, it also has disadvantages such as the troublesome arrangement of transverse rebars in the dowel holes, lower ductility than that of studs, and susceptibility to brittle fracture. To overcome these shortcomings of the perfobond rib shear connector, Kim et al. (2013) developed the Y-type perfobond rib shear connector, which is a new type of shear connector. This Y-type perfobond rib shear connector has greater shear resistance performance and ductility compared to the conventional perfobond rib shear connector, and has improved the constructability problem of the transverse rebars of the perfobond rib shear connector (Kim et al., 2014; 2015).

Owing to the recent increase in demand for large structures, the performance requirements of structures are increasing; from the perspectives of economy and safety, there is a gradual increase in the strength of materials used in composite structures. Past experiments on the Y-type perfobond rib shear

connector evaluated the shear resistance performance and ductile behavior to examine its applicability to highway bridges and composite frame structures with general structural steel and concrete. Although the need for high-strength materials is under the spotlight owing to the increasing demand for large structures, research on the Y-type perfobond rib shear connector is insufficient. Therefore, additional behavior analysis of the Y-type perfobond rib shear connector should be conducted according to the characteristics of the high-strength materials. This study aims to identify the effect of transverse rebar strength on shear resistance of Y-type perfobond rib shear connector. For this purpose, the behavior of shear connectors is verified through experimental studies with various transverse rebars: SD400-D16, D500-D16, SD500-D19, and SD500-D22.

2 SPECIMENS AND MATERIAL PROPERTIES

2.1 *Push-out test specimen*

The twelve specimens were made in accordance with Eurocode-4 to evaluate the shear resistance and ductility of the Y-type perfobond rib shear connector. The Y-type perfobond rib used SS400 as the steel plate with a height of 100 mm, width of 80 mm, thickness of 10 mm, and dowel hole diameter of 40 mm. The arrangement interval of the transverse rebars was 120 mm, and three types of specimens were made with the diameters of 16 mm, 19 mm, and 22 mm. The concrete block used concrete with a compressive strength of 50 MPa, and was designed with the following dimensions: thickness of 280 mm, width of 600 mm, and length of 750 mm. Fig. 1 shows the dimension of the push-out test specimens according to the diameter of the transverse rebars.

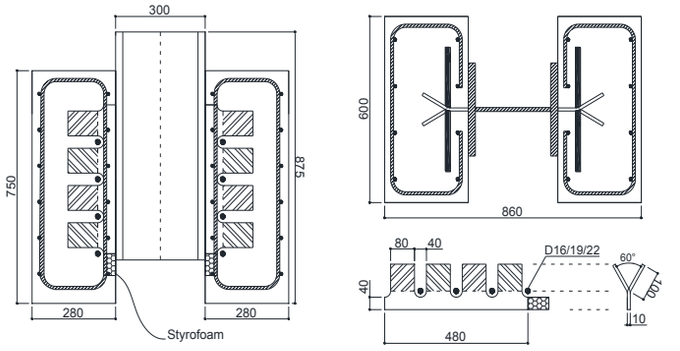

Figure 1. Dimension of push-out test specimen with Y-type perfobond rib shear connectors (unit: mm).

In order to examine the effect of transverse rebar strength, strain gauges were attached to the transverse rebars before being embedded in concrete parts. As shown in Fig. 2 the strain gauges (SG-1 and SG-2) were attached at the critical point of the transverse rebars.

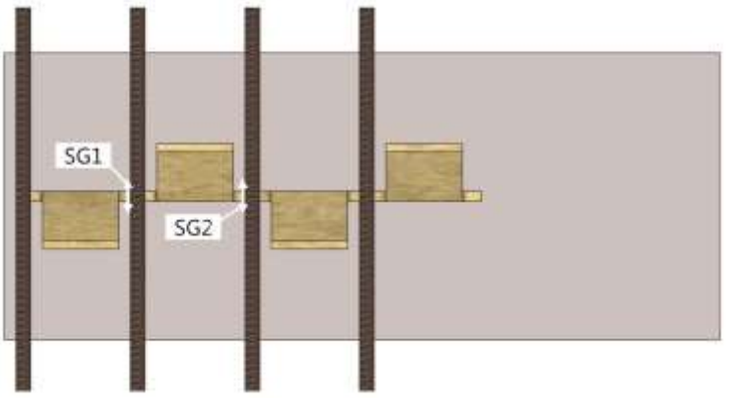

Figure 2. Attached position of strain gauges.

2.2 *Material properties*

Concrete with designed compressive strength of 50 MPa was employed for the push-out test specimens. The 12 concrete cylindrical specimens were manufactured, cured under the same conditions, and compressive strength tests were conducted to check the quality of the materials. There are four groups of test specimens which had different curing periods and each group contains three test specimens. Three groups of test specimens had standard curing period of 14 days, 21 days, and 28 days respectively and the other group had test-day standard curing. Table 1 lists the results of compressive tests of concrete. Steel material properties of SS400 steel for structural steel, SD400/SD500 steel for transverse rebar steel, and SD400 steel for reinforcement steel were obtained from the test reports. Steel material properties of the push-out test specimens are shown in Table 2.

Table 1. Concrete compressive strength.

Curing time	Test results	Average
14-days	41.5 MPa	42.9 MPa
	42.8 MPa	
	44.5 MPa	
21-days	48.2 MPa	49.2 MPa
	49.3 MPa	
	50.2 MPa	
28-days	49.7 MPa	50.1 MPa
	50.2 MPa	
	50.5 MPa	
Before test	50.3 MPa	50.7 MPa
	50.8 MPa	
	51.1 MPa	

Table 2. Properties of structural steel and rebar.

	Yield strength	Tensile strength	Elongation
SS400	288 MPa	470 MPa	29.0%
SD500	560 MPa	700 MPa	14.7%
SD400	510 MPa	610 MPa	21.0%

3 PUSH-OUT TEST

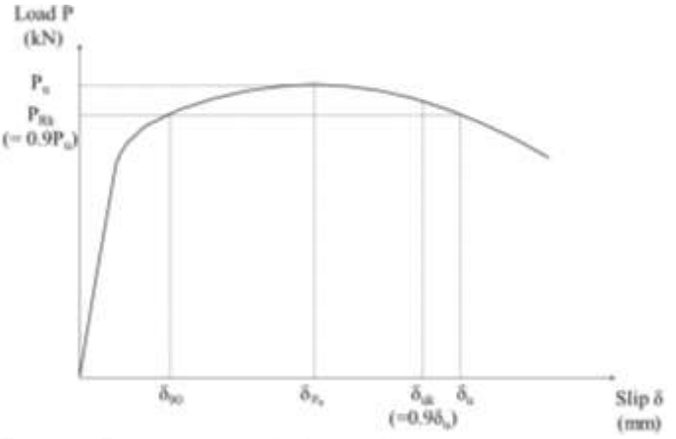
The push-out test proposed by Eurocode-4 was conducted using the 5,000 kN universal testing machine (UTM) to evaluate the shear resistance and ductility of Y-type perfobond rib shear connector and analyze the structural behaviors with strength of transverse rebar as variables. To measure the relative slip between the concrete and structural steel, L-shaped aluminum angles were attached 350 mm below the top of the concrete block and four linear variable differential transformers (LVDTs) were installed. The load was applied by controlling the displacement and the load rate was set to 0.02 mm/s to prevent the failure of specimen within 15 minutes according to the method proposed by Eurocode-4. White paint and grid lines were applied on the surface of concrete block to observe initial crack occurrence. Fig. 3 shows the test set-up of push-out tests.

(a) Front view (b) Side view

Figure 3. Push-out Test set-up.

4 PUSH-OUT TEST RESULTS

Test results of SD400-D16, SD500-D16, SD500-D19 and SD500-D22 specimens are evaluated based on the load-relative slip characteristics obtained by push-out tests. Fig. 4 shows the determination of relative slips for ductility assessment. The characteristic resistance P_{RK} refers to a value that corresponds to 0.9 times the peak shear resistance P_u with regard to relative slip capacity δ_u. The characteristic slip, δ_{uk}, refers to a relative slip that corresponds to 0.9 times δ_u. In Eurocode-4, δ_{uk} is recommended as 6 mm or higher. In this study, P_u and δ_{uk} according to Eurocode-4 were used to evaluate the peak shear resistance and ductility of Y-type perfobond rib shear connectors. To consider initial stiffness, the ductility ratio (δ_u/δ_{90}) proposed by Kim et al. (2013) was used when evaluating the ductility of the Y-type perfobond rib shear connectors. δ_u/δ_{90} refers to the ratio of relative slip capacity to the initial relative slip. Furthermore, δ_{pu} and δ_{cr} were used to compare the shear behavior of each specimens. δ_{Pu} refers to relative slip with regard to the peak shear resistance P_u and δ_{cr} refers to relative slip with regard to initial surface crack formation.



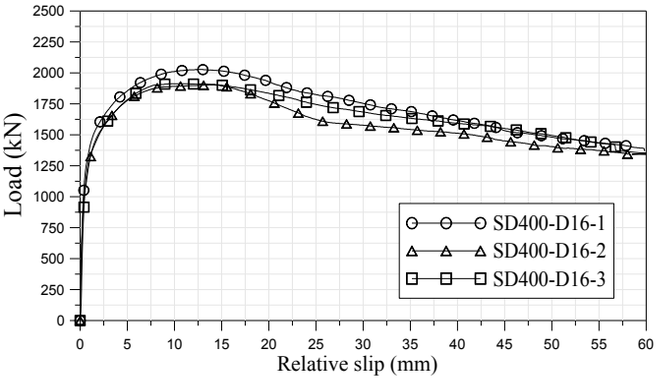


Figure 4. Determination of relative slips

4.1 *Shear resistance and ductility*

In the case of specimens with SD400-D16, the average P_u and δ_{Pu} measured were 1,948 kN and 12.5 mm. In terms of ductility, the average values of δ_{uk} and the δ_u/δ_{90} were calculated as 22.0 mm and 5.8, respectively. In the case of specimens with SD500-D16, the average P_u and δ_{Pu} measured were 1,970 kN and 12.4 mm. In terms of ductility, the average values of δ_{uk} and the δ_u/δ_{90} were calculated as 20.5 mm and 5.4, respectively. In the case of specimens with SD500-D19, the average P_u and δ_{Pu} measured were 2,076 kN and 12.7 mm. In terms of ductility, the average values of δ_{uk} and δ_u/δ_{90} were calculated as 24.3 mm and 5.3, respectively. In the case of specimens with SD500-D22, the average P_u and δ_{Pu} measured were 2,175 kN and 19.5 mm. In terms of ductility, the average values of δ_{uk} and the δ_u/δ_{90} were calculated as 34.6 mm and 5.8, respectively. Fig. 5 shows the load-relative slip curves of each specimen.

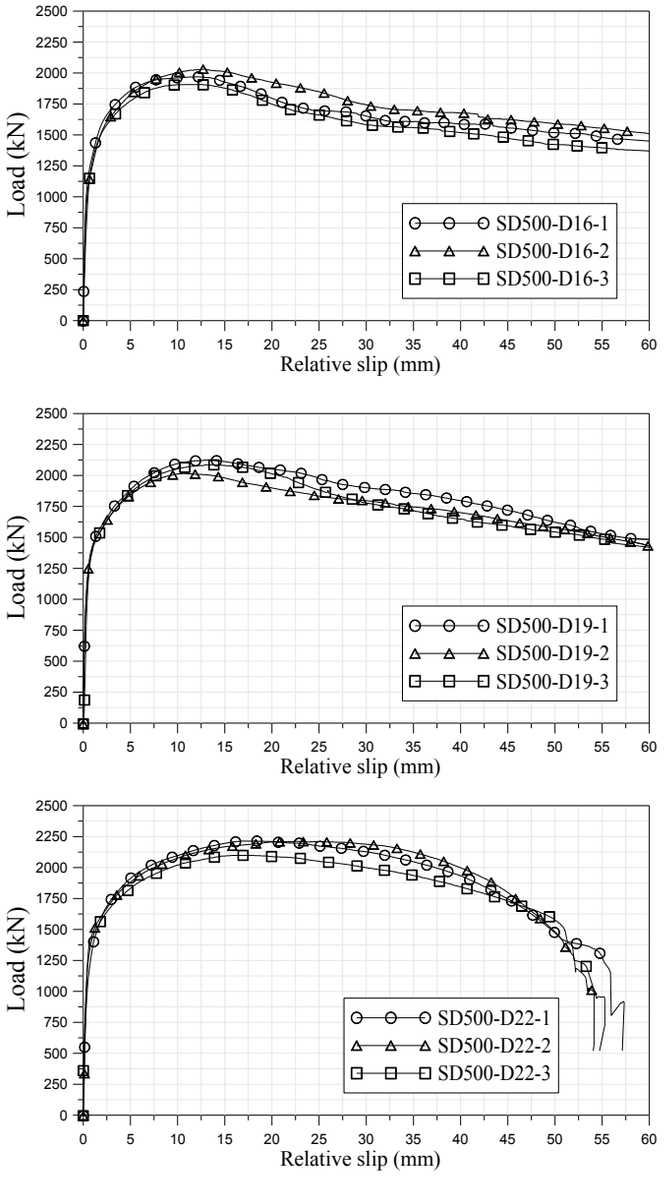

Figure 5. Load-relative slip curves

The results of the specimens of SD500-D16 do not exhibit significant changes from SD400-D16 in terms of P_u, δ_{pu}, δ_{uk}, and δ_u/δ_{90}. On the other hand, the P_u increased with the rebar diameter in SD500: the rate of increase from SD500-D16 to SD500-D22 was approximately 10.5 % and that from SD500-D16 to SD500-D19 was 5.4 %. The shear connectors with D16 and D19 of SD500 developed peak shear resistance at similar δ_{pu} whereas the SD500-D22 developed P_u at the δ_{pu} of 19.5 mm. In terms of ductility, δ_{uk} also increased significantly by 18.5 % from SD500-D16 to SD500-D19 and by 68.8 % from SD500-D16 to SD500-D22. The ductility ratio decreased by 1.9 % from SD500-D16 to SD500-D19, and increased by 7.4 % from SD500-D16 to SD500-D22. It can be observed that the Y-type perfobond rib shear connectors with D22 rebars of SD500 shows different shear behavior as compared to D16 and D19.

4.2 *Initial crack occurrence and failure modes*

Through the occurrence time of crack on the concrete surface and strain of transverse rebars, the effect of strength and diameter of transverse rebar on the concrete crack was confirmed. As shown in Fig. 2, the strain gauges (SG1 and SG2) attached to the critical strain point of transverse rebars. The Fig. 6 shows the strain histories monitored at the SG1 and SG2 and relative slip of initial surface crack occurrence time.

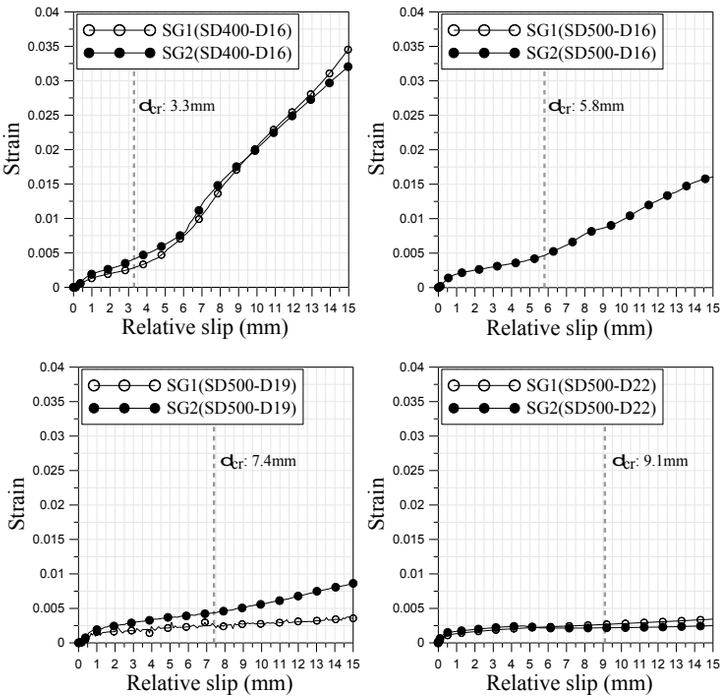

Figure 6. Strain history and δcr of transverse rebars

The initial surface crack occurred at the relative slips of 3.3 mm in the SD400-D16, and 5.8 mm in the SD500-D16 rebars of SD500. Also, the initial surface crack occurred at the relative slips of 7.4 mm in the SD500-D19, and 9.4 mm in the SD500-D22. Therefore, the initial surface crack is significantly influenced by the tensile strength and the increase in diameter of the rebars.

After the push-out tests were completed, concrete blocks were removed to confirm the deformation of the Y-ribs. As shown in Fig. 7, the deformation of the dowel hole of the Y-rib adjacent to the transverse rebar increases with increasing diameter of transverse rebar. In the case of SD500-D16 and SD500-D19, some damage occurred to the Y-ribs, and as shown in Fig. 6, significant deformation occurs in the transverse rebars as well. However, the Y-ribs were cut in SD500-D22, and the transverse rebars were much less deformed. In the curve after the δ_u in Fig. 5, the behavior characteristics for each failure mode can be confirmed. The mixed failure modes for SD500-D16 and SD500-D19 show a gradual decrease in shear force after δ_u, while the Y-rib failure for SD-D22 shows a decrease in shear force after δ_u and a decrease in the occurrence of Y- ribs failures.

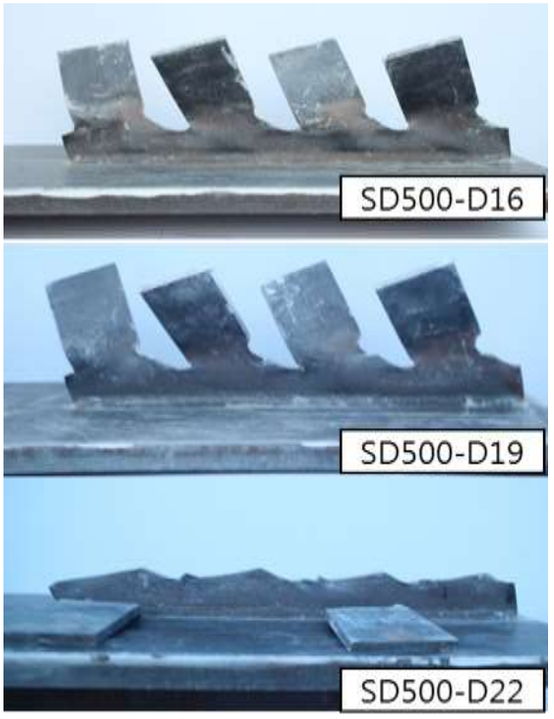

Figure 7. Deformed shape of Y-ribs.

5 CONCLUSION

The performance characteristics of Y-type perfobond rib shear connectors have been evaluated to identify the effect of transverse rebar on shear resistance, ductility, failure mode, and initial surface crack occurrence. Push-out test specimens with Y-type perfobond rib shear connectors were manufactured with various rebar strengths and diameters. The strength and diameter of the transverse rebar are found to be very important to control the behavior of shear connector. It was confirmed that the increase of the diameter of transverse rebar improves the shear strength (P_u) and ductility (δ_{uk}) of the shear connection part. The P_u increased about 5.4 % from SD500-D16 to SD500-D19 and about 10.5 % from SD500-D19 to SD500-D22. The δ_{uk} also increase significantly, 18.5 % from SD500-D16 to SD500-D19, and 68.8 % from SD500-D16 to SD500-D22. Also, it was confirmed that when the transverse rebar diameter increased as compared with Y-rib section, it changed from a mixed failure mode to a Y-rib failure mode.

The increase in strength of transverse rebar did not affect P_u and δ_{uk}, but had an effect of delaying initial crack occurrence. This effect also occurred when the transverse rebar diameter increased. Therefore, the balanced design between the transverse rebar and Y-rib is found to be very significant in controlling the shear behavior of Y-type perfobond rib shear connector.

Energy dissipating characteristics of Y-type perfobond rib shear connectors

S. H. Kim, K. S. Kim, O. Han & J. G. Choi
School of Civil and Environmental Engineering, Yonsei University, Seoul 03722, Korea

ABSTRACT: This study involves investigating the Y-type perfobond rib shear connector to reveal its superior ductile capacity when compared with those of the traditional stud-type shear connectors. It is expected that the excellent ductile behavior of the Y-type perfobond rib shear connectors can be utilized for energy dissipating devices in seismic structural excitations. In this study, the energy dissipating characteristics of the Y-type perfobond rib shear connectors are evaluated. Monotonic loading tests and cyclic loading tests of the Y-type perfobond rib shear connector are conducted. The specimens with various rebar diameters are fabricated, and the accumulated energy dissipations in each cyclic loading are evaluated. The decreasing characteristics of both energy dissipating capacity and shear resistance stiffness of Y-type shear connections during the cyclic loadings are examined.

1 INTRODUCTION

Steel-concrete composite structures have been used in various infrastructures and buildings for decades. In order to achieve composite action in a steel–concrete structure, it is necessary to install shear connectors between the steel and concrete. The shear connections of structures under seismic loading play an important role in load distribution, collapse prevention, and energy dissipation (Bursi et al., 1999). Therefore, the structural performance of the shear connection under a high displacement cyclic loading significantly influences the seismic performance of a composite structure.

An investigation of the Y-type perfobond rib shear connector revealed its superior ductile capacity when compared to those of traditional stud-type shear connectors as well as traditional flat-type perfobond rib shear connectors (Kim et al., 2013). Additionally, the hysteretic behavior of Y-type perfobond rib shear connectors exhibits superior energy dissipating capacity and residual strength (Kim et al., 2017(b)). This study involved evaluating the hysteretic behaviors of the Y-type perfobond rib shear connectors. Monotonic loading tests and fully reversed cyclic loading tests with high deformation of the Y-type perfobond rib shear connector were conducted. Specimens with various diameters (D10, D13, and D16) of transverse rebars were fabricated.

2 SPECIMENS AND MATERIAL PROPERTIES

2.1 *Push-out test specimen*

The six specimens were fabricated based on a previous study (Kim et al., 2017(b)) to evaluate the hysteretic behavior of the Y-type perfobond rib shear connectors with various transverse rebar diameters. The Y-type perfobond rib consisted of a steel plate with a height of 50 mm, width of 70 mm, thickness of 8 mm, and dowel hole diameter of 30 mm (Kim et al., 2017(a)). The arrangement interval of the transverse rebars was 100 mm, and three types of specimens were fabricated with diameters of 10 mm, 13 mm, and 16 mm. A concrete slab with a compressive strength of 30 MPa was used and was designed with dimensions including a thickness of 150 mm. Given the loading cases and diameter of the transverse rebar, the names of the specimens were defined as M-D10 (monotonic loading and 10 mm diameter rebar), C-D10 (cyclic loading and 10 mm diameter rebar), M-D13 (monotonic loading and 13 mm diameter rebar), C-D13 (cyclic loading and 13 mm diameter rebar), M-D16 (monotonic loading and 16 mm diame-

ter rebar), and C-D10 (cyclic loading and 16 mm diameter rebar). Figure 1 shows the dimension of the specimens based on the diameter of the transverse rebars. In order to apply load in the pull-out direction, a [ㅂ]-shaped steel plate with sufficient stiffness was installed and attached to the specimen as shown in Fig. 2.

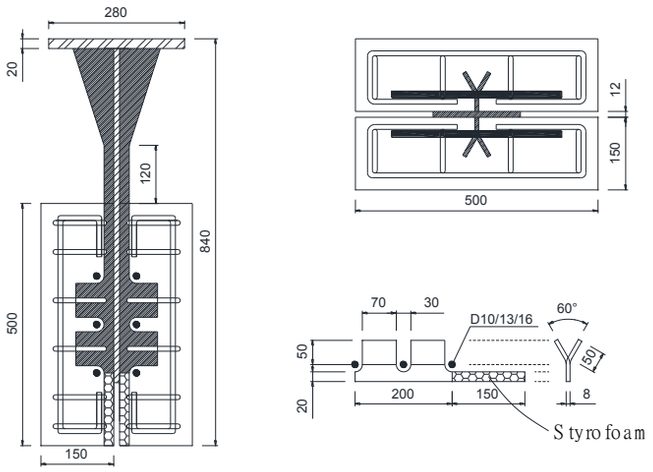

Figure 1. Dimension of the specimen with Y-type perfobond rib shear connectors (unit: mm).

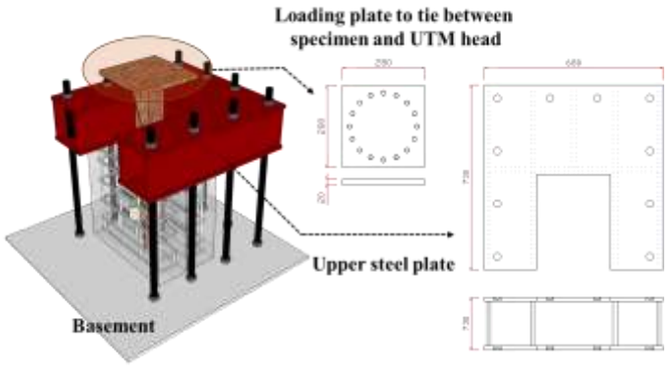

Figure 2. Illustration of the test set-up.

2.2 *Material properties*

Concrete with a designed compressive strength of 30 MPa was employed for the specimens. Twelve concrete cylindrical specimens were manufactured and cured under the same conditions, and compressive strength tests were conducted to check the quality of the materials. Table 1 summarizes the results of the compressive tests of concrete. The test results revealed the material properties of SS400 steel for the structural steel and SD400 rebar for the transverse rebar. The material properties of the push-out test specimens are listed in Table 2

Table 1. Concrete compressive strength.

Curing time	Test results	Average
28 days	29.7 MPa	30.6 MPa
(Test day)	30.5 MPa	
	31.5 MPa	

Table 2. Properties of the structural steel and rebar.

	Yield strength	Tensile strength	Elongation
SS400	389 MPa	451 MPa	25%
SD400-D10	515 MPa	613 MPa	20%
SD400-D13	516 MPa	611 MPa	19%
SD400-D16	446 MPa	639 MPa	17%

3 CYCLIC LOADING TEST

The push-out tests and cyclic loading tests were conducted by using a 1,000 kN universal testing machine (UTM) to evaluate the shear behavior under monotonic loading and cyclic loading of the Y-type perfobond rib shear connector with respect to various diameters of the transverse rebar. The load was applied by controlling the displacement. The displacement and load data of the tests were measured via UTM, and were recorded. Figure 3 shows the fully reversed cyclic loading conditions to evaluate the hysteretic behavior of the shear connection. The pull–push loadings corresponding to ±0.2, ±0.4, ±0.6, ±0.8, ±1.0, ±1.5, ±2.0, ±3.0, ±4.0, ±5.0, ±7.5, ±10, ±15, ±20, ±30, and ±40 mm were applied for three cycles at a time.

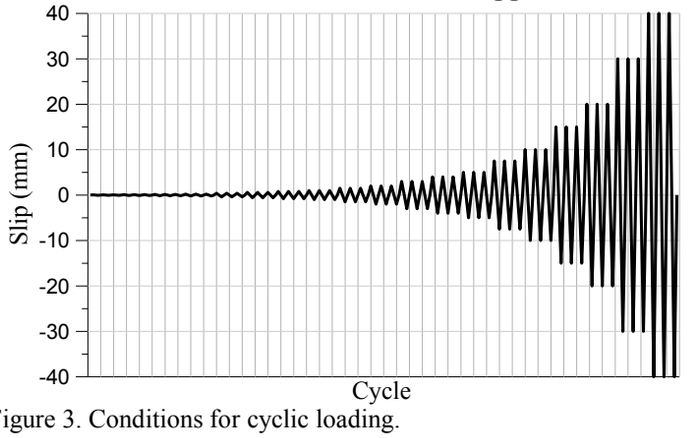

Figure 3. Conditions for cyclic loading.

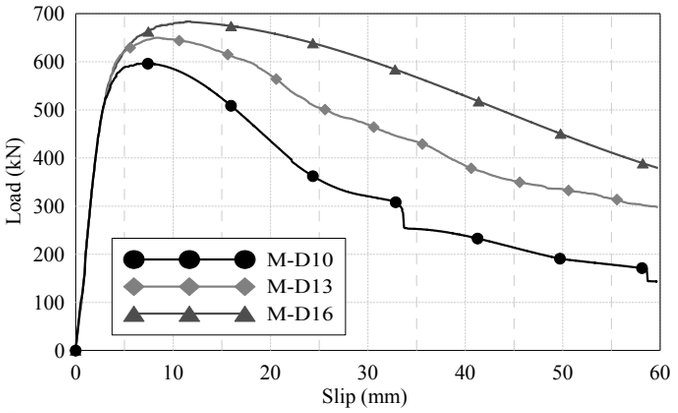
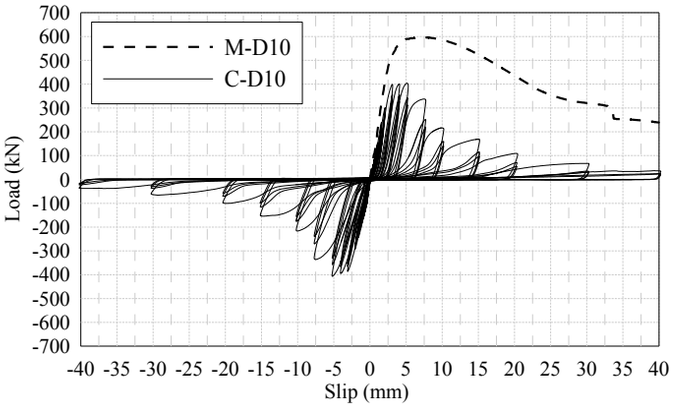
4 TEST RESULTS

The monotonic loading test results of M-D10, M-D13, and M-D16 are shown in Fig. 4. The shear strengths of M-D10, M-D13, and M-D16 were measured as 596 kN, 650 kN, and 684 kN, respectively.





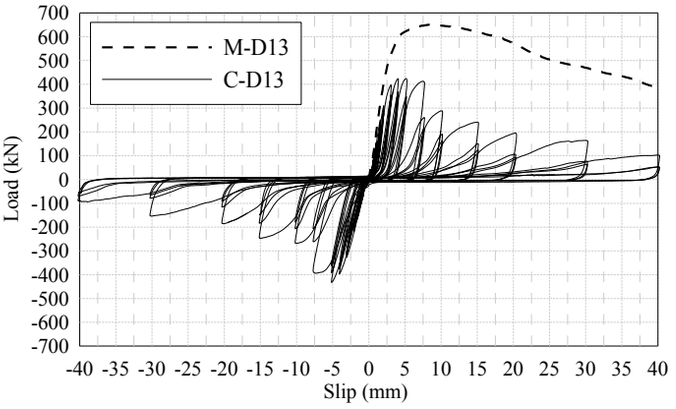


Figure 4. Load–slip curves of the monotonic loading tests

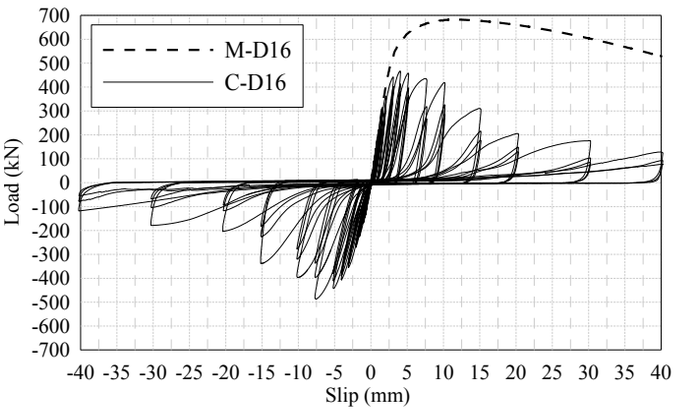

The load–slip curves of the monotonic loading test and cyclic loading test of specimens with the same transverse rebar diameter are shown in Fig. 5. As shown in Fig. 5, the shear strength determined by the backbone curve of the Y-type perfobond rib shear connectors with D10, D13, and D16 decreased by 32.2%, 34.7%, and 31.7%, respectively. Figure 6 shows the dissipated energy of C-D10, C-D13, and C-D16 with respect to cyclic loading in each cycle. The cumulated dissipated energies for C-D10, C-D16 was 22,497kN·mm, 35,558kN·mm and 43,982kN·mm respectively.

(c) M-D16 and C-D16

Figure 5. Load–slip curves of the monotonic loading test and cyclic loading test.

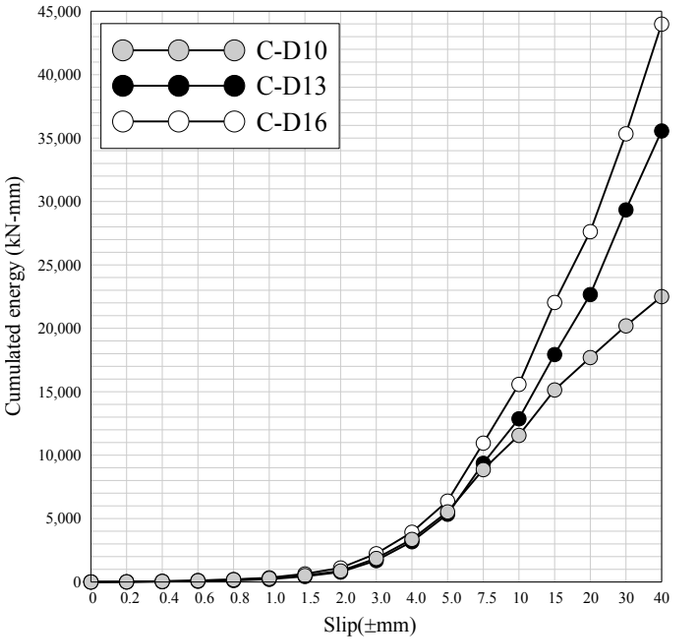

Figure 6. Dissipated energy after each loading cycle.

5 CONCLUSION

In this study, the hysteretic behavior of Y-type perfobond rib shear connectors with various diameters of transverse rebars was experimentally evaluated. The energy dissipation and shear strength degradation were evaluated by using the load–slip curves obtained from monotonic and cyclic tests. The test results of the specimen with a high diameter transverse rebar revealed superior residual shear strength and energy dissipating capacity. Additionally, sudden failure of the shear connection was not observed in any specimen. It is expected that the superior hysteretic behavior of the Y-type perfobond rib shear connectors can be utilized for energy dissipating devices in seismic structural excitations.

ABSTRACT: The flanges of steel girders in the compressive region are strengthened with the longitudinal steel stiffeners in general practices. The new details of concrete-filled longitudinal ribs have been proposed to strengthen the compressive flanges in steel girders in this study and its behaviors have been evaluated through both experimental and numerical studies. The concrete-filled longitudinal ribs may contain the special type perfobond rib shear connectors to increase the composite action between the steel flange and concrete part in the rib. The transverse rebars are installed through the U-type dowel spaces in the perfobond ribs to improve the composite action between the concrete part and longitudinal steel rib also. The both ends of transverse rebar are welded to the insides of steel rib. The transverse rebars are found to play important roles for the composite strengths of the proposed details in the section under the bending moment. When the longitudinal ribs are welded to the compressive steel flanges, the thermal-prestressed tensile stresses may be introduced to the flanges that will experience the compressive stress due to the service actions. The longitudinal ribs may be designed with high-strength steel than the flange steel, because the longitudinal ribs will be subjected to the thermal-prestressed compressive stresses.

1 INTRODUCTION

The continuous steel box girder bridges have negative moment regions. To strengthen bottom flanges, the longitudinal stiffeners are used or the bottom flange may get thicker.

In this study, the concrete filled steel tube (CFT) is proposed to strengthen the bottom flanges in the negative moment region. This method guarantees the structural performance with low amount of steel. The design concept is that the steel tube confines the concrete, and the concrete resists the compression. And by combining the Y-type perfobond rib shear connector, the compressive stress can be distributed effectively in the concrete.

2 PROPOSED DESIGN SECTION

The section of AASHTO steel box girder is shown in Figure 1. The dimension of the T-section stiffener is in Figure 1. The concrete filled steel tube has been designed in 4 cases.

The proposed steel box girders are shown in Figure 2 and 3, and the section of the concrete filled steel tube and the Y-type perfobond rib shear connectors are shown in Figure 4.

Figure 4. Dimensions of the concrete filled steel tube and the Y-type perfobond rib shear connector (Unit: mm)

3 PERFORMANCE EVALUATION

The trial models are 4 cases which are summarized in Table 1. The model, TS, represents the section in Figure 1 with usage of T-section stiffener, and CFT-1, 2, and 3 are the sections with the concrete filled steel tubes as shown in Figure 2 and 3. The proposed girder model shown in Figure 5 is evaluated under varying load using the FEM analysis.

Table 1. Model cases

Model	Bottom flange thickness (t) [mm]	Steel Area [mm^2]	Number of stiffener/CFT
TS (AASHTO)	41.3	103,266	1
CFT-1 (1 CFT)	41.3	103,266	1
CFT-2 (3 CFT)	34.7	103,266	3
CFT-3 (3 CFT)	25.0	78,247(0.76)	3

The compressive stresses at the bottom flange at the interior support are compared in Table 2 and plotted on Figure 5. Table 2 contains the stress levels under the loading which generates either 150MPa or 200MPa in the model, TS.

Table 2. Compressive stresses in Bottom Flange

Model	Stage 1 [MPa]	Stage 2 [MPa]
TS	150	200
CFT-1	136	182
CFT-2	117	162
CFT-3	137	195

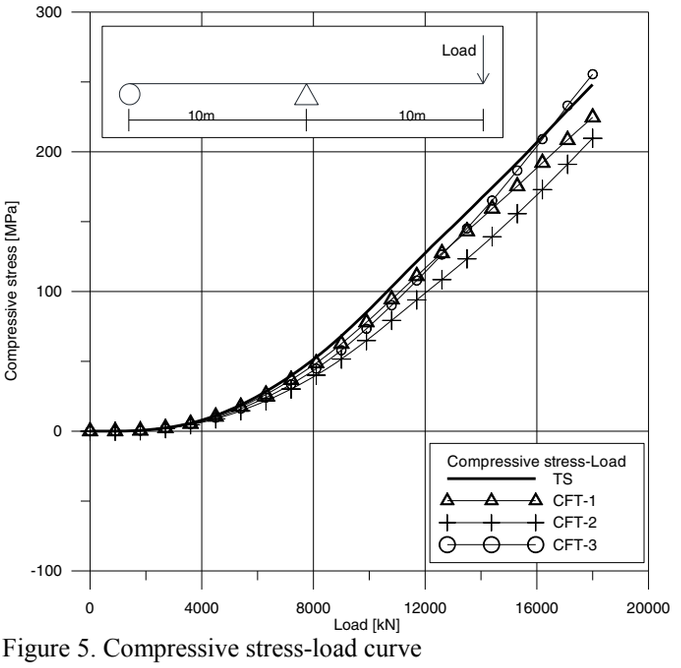

Figure 5. Compressive stress-load curve

4 NEW COMPRESSION TEST FOR CFT

It is hard to build the whole model such as steel box girders to evaluate a structural behavior of CFT. The new type of model is proposed to minimize the analysis for a structural behavior of CFT. It describes bottom flange and CFT in compression and negative moment region. Figure 6 shows the model specification.

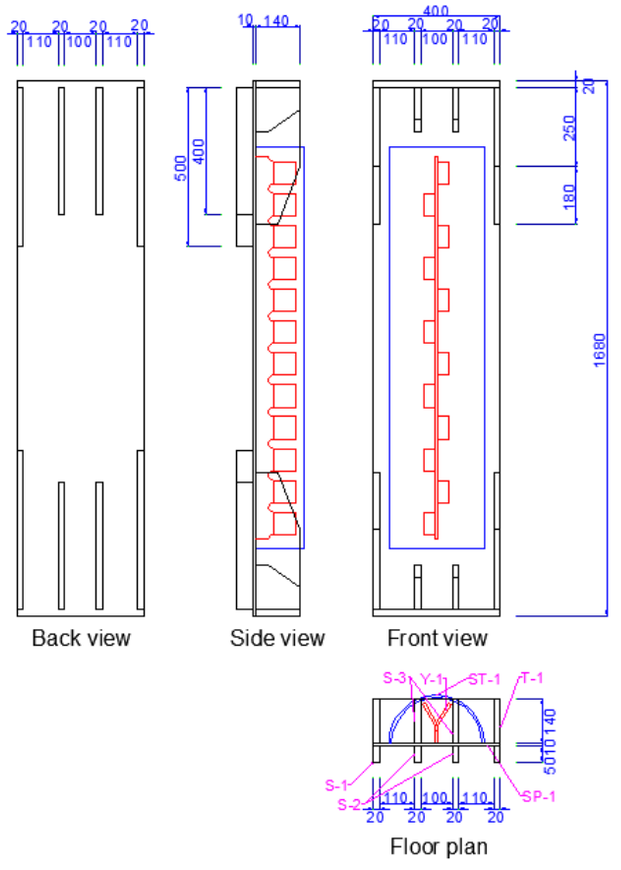

Figure 6. New type analysis model

This model has the concept that the compressive force is applied vertically to the model, and assumes

that the whole area is on compressive zone. There are four types of models that are composed of H20L100-30, H40L80-30, AASHTO-Stiffener, and No shear connector (Y-type rib dimension; H: Height, L: Length, Y-shape angle; Unit: mm).

The model is performed with linear analysis to compare the performance of CFT and stiffener in the same conditions. The analysis method is that the stress caused by the external compressive force sets equal for each model. And the value is extracted when the stresses are in same statement for each model. Table 3 and Figure 6 show the results. The results using Y-type perfobond rib shear connectors are almost same, and thus there is not the effect of the size of the shear connector. And the compressive force on the bottom flange is 55.7% of the force on the no shear connector specimen. But in case of AASHTO-Stiffener, it shows that 60% of the compressive force for Y-type perfobond rib shear connector, is needed to occur in the same stress. Thus, the CFT type has more advantage to secure the structural stiffness than AASHTO-Stiffener.

Table 3. Compressive force in same stress

Model	Compressive force [kN]
H20L100-30	292.81
H20L100-30	295.13
AASHTO-STIFFENER	173.40
No shear connector	163.62

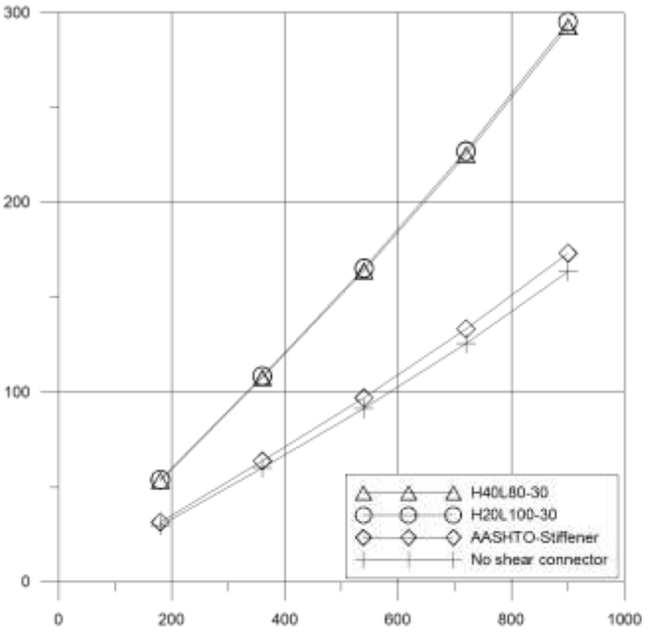

Figure 6. Analysis results on the new type model

5 CONCLUSION

The concrete filled steel tube are found to be applied effectively to the bottom flanges of the steel box girder in the negative moment region near the interior supports, and reduce the amount of the steel used.

The new type of CFT model minimizes the procedure of the analysis. And through the analysis of the model, Y-type perfonbond rib shear connector is the more efficient stiffener than the existing AASHTO-Stiffener in compressive area.

Redundancy Evaluation of Composite Twin I-Girder Bridges in Fractured Condition

H. Lam, W. Lin, T. Yoda & K. Ono
Waseda University, Tokyo, Japan

ABSTRACT: Despite commonly used in highway bridge design in Japan, composite twin I-girder bridge system is currently classified as non-redundant mainly due to the oversimplified assumption in the current bridge design. In this study, two composite twin I-girder bridge models are tested to investigate the mechanical behavior and redundancy analyses of the composite twin I-girder bridge system in fractured condition. Numerical models were first validated based on the experimental results. Hereafter, numerical study was carried out to investigate the effect of fracture location and the effect of concrete slab on the redundancy level of the composite twin I-girder bridge system. Results show that the fracture at the mid-span section is the most critical damage condition comparing to other fracture locations. In addition, the concrete slab is found as the main structural component that ensures the survivability of the composite twin I-girder bridge system in fracture condition.

1 INTRODUCTION

Comparing to non-composite steel girder bridges, the composite twin I-girder bridge structure is highly beneficial from its composite action due to the use of connections between top flange of the steel and concrete slab which allow the bridge to have higher span to depth ratio and much lighter bridge structure (load carrying capacity per unit weight). For this reason, steel-concrete composite twin I-girder bridge system is commonly used in highway bridge system. Particularly in Japan, the number of the twin I-girder bridges has been increasing significantly in comparison with other bridge types in recent twenty years mainly due to the low construction cost required for this type of bridge, as shown in Figure 1 (Nagai 2006). On the other hand, such a bridge is rarely used in the United States because all two girder bridges are classified as non-redundant and fracture critical (AASHTO 2012). However, several past experiences have shown that composite twin I-girder bridge systems do not collapse in the severe fracture condition and thus should not be classified as non-redundant bridge system. This is due to the effect of the concrete slab in three-dimensional space which is served as an alternative load path in redistributing the load from one girder to the other girder in the twin I-girder bridge system under fracture condition (Lam et al. 2014). In current research trends, redundancy is considered as a very important measure to prevent the bridge structure from collapse. Researchers sometimes considered redundancy as a criterion for bridge rating. Moreover, by introducing the term redundancy in the structural design, fully collapse of the bridge structures can be highly avoidable. For this reason, a study was carried out to evaluate the redundancy level and mechanical behavior of the Composite Twin I-girder Bridge Systems in critical fractured condition.

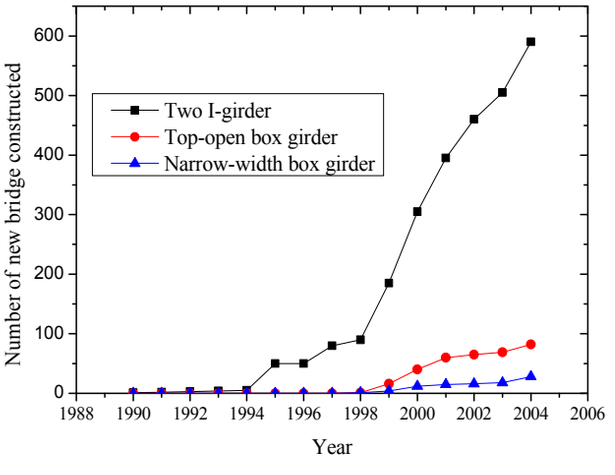

Figure 1. Number of bridges constructed in Japan

2 DETAILS OF TEST SPECIMENS

This study focuses on the redundancy analysis of the composite twin I-girder bridge in damage condition. Two test specimens of composite twin I-girder bridges were fabricated including an intact specimen and a damaged specimen. The intact specimen, hereafter called Specimen-1, is used for investigating the behavior and response of the bridge without any damage. The damage specimen, hereafter called Specimen-2, is used for investigating the behavior and response of the bridge in critical fracture condition. In both specimens, girder-1 refers to the main girder side subjected to loading, and girder-2 refers to the other main girder. The dimensions of the two specimens are identical. For Specimen-2, artificial fracture of full web and bottom flange had been imposed on mid-span section of girder-1 as can be seen in Figure 2. The cross-section of the bridge model is shown in Figure 3(a). The details of the main girder and transverse beams are shown in Figure 3(b). Two rows of shear stud connectors with the diameter of 19 mm and the height of 80 mm were employed on top of the flanges of the main girders to ensure the composite action between the concrete slab and the steel girders. The side view and top view are shown in Figure 4 and Figure 5, respectively. To comply with JRA specification (2002), two layers of reinforcement are installed in the slab. As shown in Figure 6, reinforcing bar type SD345 with 10 mm in diameter is used with the 100 mm spacing in both longitudinal and transversal direction. Further details of the test specimens can be found at Lam et al. (2017).

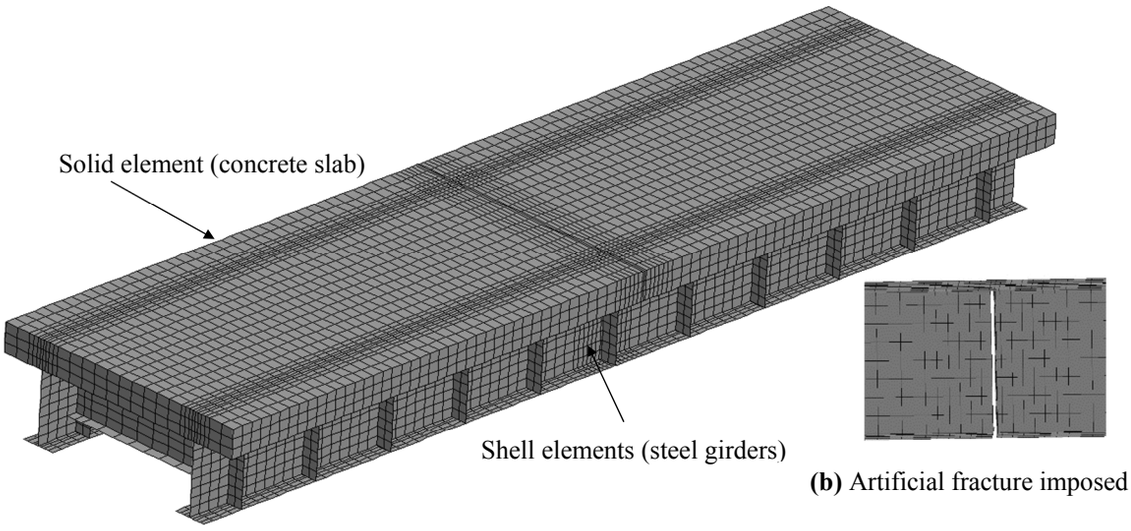
3 NUMERICAL MODELS

3.1 *Numerical simulation*

In the numerical model, Finite Element Method with the aid of TNO Diana 9.4.4 software was employed for modeling and analyzing the bridge model. Both material nonlinearity and geometrical nonlinearity were included in the nonlinear analyses. The concrete slab is modeled by using the 8-node solid elements with 24 degrees of freedom. The reinforcement bar is modeled by using embedded bar elements. The steel girders, transverse beams, and vertical stiffeners are modeled by 4-node curve shell elements. Spring elements were used for modeling the shear studs and interface elements were used for simulating the interface friction between the concrete slab and main girders top flanges. Phase analyses and load increment method were employed to analyze the bridge model. Perfect bond between reinforcement bars and concrete was assumed to simplify the numerical model. The dead load (self-weight) is analyzed in the first phase following by the applied live load in the second phase. The overview of the numerical model is shown in Figure 7. The fracture is modeled by reducing the young modulus of the element at the fracture section to near zero value.

3.2 *Materials properties*

3.2.1 *Concrete*



Smeared cracking model was employed for the cracking of concrete slab. The concrete compressive strength is taken as 33 MPa. The tensile strength of the concrete was calculated according to Equation 1 suggested by JSCE (2002), in which the f_t and f_c' denote tensile and compressive strengths of concrete, respectively. The stress-strain curve due to JSCE (2002) was employed to simulate the compression behavior of concrete, as shown in Figure 8. The factor of k_1 and ultimate compression strain ε_{cu} was determined according to Equation 2 and Equation 3. Experimental tension-stiffness curve proposed by Nakasu et al. was used in the numerical analyses to reflect the softening of concrete.

$$f_t = 0.28 f_{ck}^{'\,2/3} \tag{1}$$

$$k_1 = 1 - 0.003 f_{ck}^{'} \le 0.85 \tag{2}$$

$$\varepsilon_{cu}^{'} = \frac{155 - f_{ck}^{'}}{3000}; 0.0025 \le \varepsilon_{cu}^{'} \le 0.0035 \tag{3}$$

In which $\sigma_c^{'}$, $\varepsilon_c^{'}$ and $f_{cd}^{'}$ denote the compressive stress, strain, and design compressive stress of concrete, respectively.

(a) Overview of numerical model

(b) Artificial fracture imposed on girder

Figure 7. Numerical models

3.2.2 *Structural steel and reinforcing bars*

The stress-strain relationship for structural steel and reinforcing bars shown in Figure 9 and Figure 10 were adopted in numerical models (JSCE 2006). The ultimate strain for steel and rebar is taken as 20 %. Table 1 provides details of material properties of reinforcing bar and steel plate including yield strength and ultimate strength.

3.2.3 *Shear stud*

To model the shear stud inside the concrete slab, 3D nonlinear spring elements are employed. For each stud, one spring is used to model the behavior in the normal direction and two other springs are used to model the behavior in tangential directions. The constitutive relationship of the spring is given by Equation 4 suggested by Ollgaard et al. (1971) and illustrated in Figure 11, in which the ultimate shear force loading capacity of studs was specified by JSCE (2002), as shown in Equation 5.

$$Q=Q_u(1-e^{-0.7S})^{0.4} \tag{4}$$

$$Q_u = \min.\begin{pmatrix} (31A_{ss}\sqrt{(h_{ss}/d_{ss})f_{cd}^{'}}+10000)/\gamma_b \\ A_{ss}f_{ss}/\gamma_b \end{pmatrix} \tag{5}$$

where S: slip of the shear stud (mm), A_{ss}: area of the shank of the stud (mm^2), d_{ss}: diameter of the shank of the stud (mm), h_{ss}: height of the stud (mm), f_{cd}: design compressive strength of concrete (N/mm^2) (=f_{ck}/γ_c), f_{ck}: the characteristic compressive strength of concrete (N/mm^2), f_{ss}: design tensile strength of the stud (N/mm^2) (=f_{sk}/γ_s), f_{sk}: characteristic tensile strength of the stud (N/mm^2), γ_c: material factor of concrete (=1.3), γ_s: material factor of stud (=1.0), γ_b: member factor (=1.3).

Material	Yield Strength (MPa)	Ultimate Strength (MPa)
Steel Plate (6mm)	450	577
Steel Plate (8mm)	389	548
Steel Plate (12mm)	389	548
Reinforcing Bar(D10)	406	544

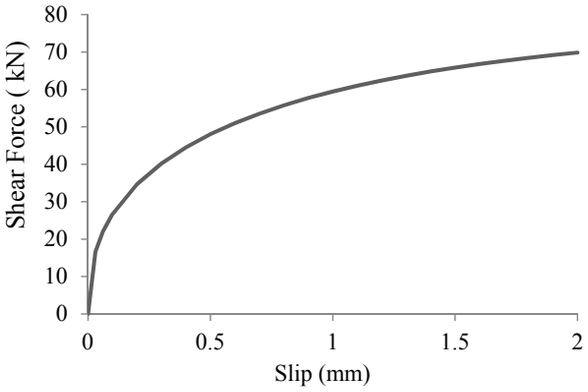

Figure 11. Shear force-slip relationship of shear stud

3.2.4 *Interface between steel and concrete*

In this study, the experimentally based bond-friction interface model suggested by Okada et al. (2006) was employed to simulate the composite action between the steel girder and the concrete slab, as shown in Equation 6 and Equation 7. The maximum bond stress f_{bo} and the corresponding slip was taken as 0.5 N/mm^2 and 0.06 mm, respectively.

$0 \le \Delta u_t \le \Delta u_t^0$:

$$f_{\tan} = \frac{f_{bo}}{1.9}\left(5\left(\frac{\Delta u_t}{\Delta u_t^0}\right) - 4.5\left(\frac{\Delta u_t}{\Delta u_t^0}\right)^2 + 1.4\left(\frac{\Delta u_t}{\Delta u_t^0}\right)^3\right) \quad (6)$$

$\Delta u_t > \Delta u_t^0$:

$$f_{\tan} = f_{bo} \quad (7)$$

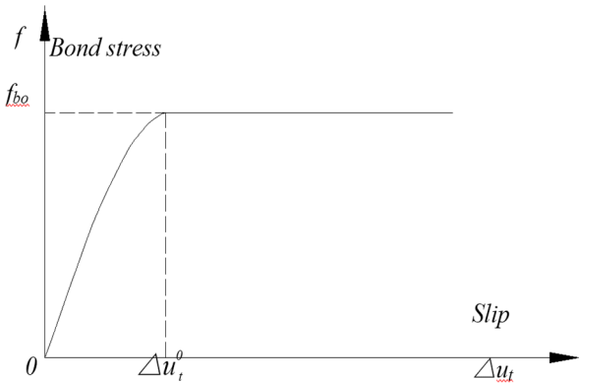

Figure 12. Bond stress slip relationship of interface between the steel and the concrete

3.3 *Numerical model validation*

The load-deflection curves from numerical analyses and experimental results were shown in Figure 13 for Specimen-1and Figure 14 for Specimen-2. Consistent results between experimental models and numerical models can be observed. The numerical models used in this study are proved to be accurate to predict the performance of both intact specimen and damaged specimen under vertical loading condition. The system stiffness of the experimental specimen and numerical model is well agreed for the elastic stage.

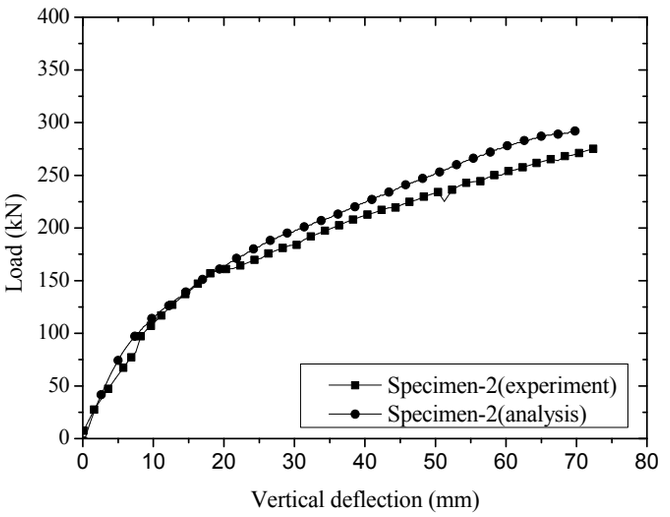

Figure 14. Load-deflection curves of Specimen-2

4 PARAMETRIC STUDY

4.1 *Redundancy evaluation of bridge models*

To ensure the safety of the bridge in critical damage condition, using redundant bridge system is the most effective way because a redundant bridge system generally resists the collapse caused by the failure of one of its structural members. In this study, redundancy is defined as the property of the bridge structure itself that guarantees its survival after an incident initiated by partial or full damage on the critical member of the bridge system. The redundancy level in this study is determined by comparing the remaining load carrying capacity of the bridge in damage condition (Specimen-2) with the design load of the bridge in intact condition. The equation 8 below is used to determine the redundancy level in this study:

$$R_d = \frac{P_{damage}}{P_{design}} \tag{8}$$

where:
R_d: Redundancy level of the bridge system
P_{damage}: Load carrying capacity of the damaged bridge
P_{design}: Design load of the bridge system

In this study, the load carrying capacity of the damaged bridge is determined by FEM with the nonlinear analyses (P_d *=292 kN*). Meanwhile, as the test specimens were designed according to Japanese specification (JRA, 2002), the design load for the intact bridge system is taken as the applied load level corresponding to the allowable stress level of the steel provided by JRA (2002), which means:

$$P_{design} = P(\sigma_{allowable}) \tag{9}$$

According to the Japanese specifications (JRA, 2002), $\sigma_{allowable}$ for the steel SM490 used for the test specimen in this study is 185 MPa corresponding to the $\varepsilon_{allowable}$ of 925 μ. According to the analyses results of the intact specimen, the design load is taken as follow:

$$P_{design} = P(\varepsilon_{allowable} = 925\mu) = 210kN \tag{10}$$

$$\mathrm{R}_d = \frac{P_{damage}}{P_{design}} = \frac{292\ kN}{210\ kN} = 1.39 \tag{11}$$

The R_d*>1* indicates that the remaining load carrying capacity of the bridge in the critical damaged condition in this study is large enough to sustain the design load and thus can be considered as redundant bridge system.

4.2 *Effect of fracture on the redundancy level of the bridge*

In this section, the redundancy level of the bridge system in relation to the fracture location is determined. Fracture at the mid-span section, near the support, and at the 1/4 span section were compared to determine the most critical damaged location. A total of five different scenarios (including one associated with experiment program) are included in determining the most severe fracture condition, as shown in Table 2. The redundancy level for each damaged case is determined according to Equation 8 and summarized in Table 3. The results indicated that, compared with the fracture near the support (Case-2 and Case-3) and fracture at one-fourth span section (Case-4 and Case-5), the fracture at the mid-span section is the most critical fracture location for the test specimen in this study as assumed in the experimental program.

Table 2: Details of each damaged case

	Fracture section	Loading section
Case-1	Mid-span	Mid-span
Case-2	Near support	Damaged section
Case-3	Near support	Mid-span
Case-4	1/4 span	Damaged section
Case-5	1/4 span	Mid-span

4.3 *Alternate load path and the effect of concrete slab*

Previous study shows that the transverse beam alone in the twin I-girder bridge model has no effect on the behavior of the bridge in fracture condition (Lam et al. 2014). By comparing the twin girder model with one girder model with the same design, the effect of concrete slab on the redundancy level of the twin girder bridge model when the bridge in fracture critical damage condition can be determined. The fracture section is assumed at the mid-span section, which is determined as the most critical fracture location. The cross section of one girder model is shown in Figure 15. The overview of the numerical model is shown in Figure 16.

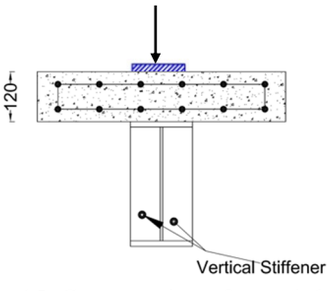

Figure 15. Cross section of one girder model

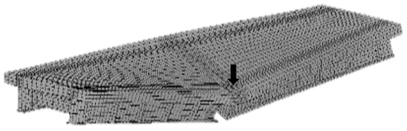
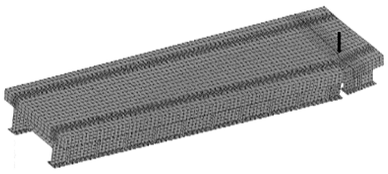
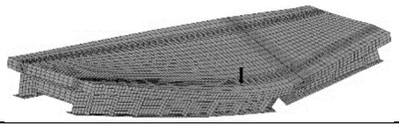
Table 3: Redundancy level for each damaged case







Damage Cases	Loading and damaged conditions	P_{damage} (kN)	P_{design} (kN)	R_d
Case-1		292		1.39
Case-2		532		2.53
Case-3		464	210	2.21
Case-4		417		1.98
Case-5		537		2.55

Figure 17 shown the load-deflection curves of the one girder and twin girder model in both intact and damaged conditions. The redundancy level of both models is determined according to Equation 8 and presented in Table 4. Results show that the load carrying capacity of the one girder model is much smaller than the design load, which deems the one girder as non-redundant. Meanwhile, by comparing one girder and twin girder model, based on the assumption that transverse beam is not effective as reported in the previous study, it can be clearly seen that the composite twin I-girder bridge can be classified as redundant bridge system totally depend on the alternative load path produced by the concrete slab that transfers the load from damaged girder to the intact girder.

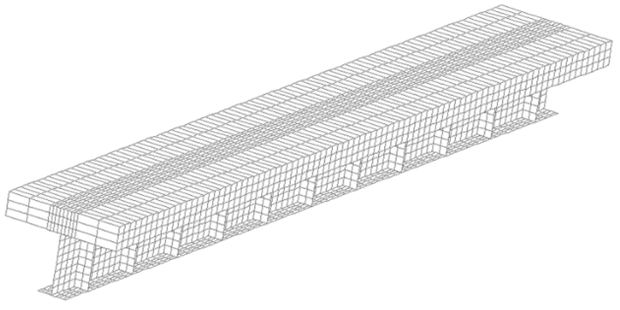


Figure 16. Overview of one girder model

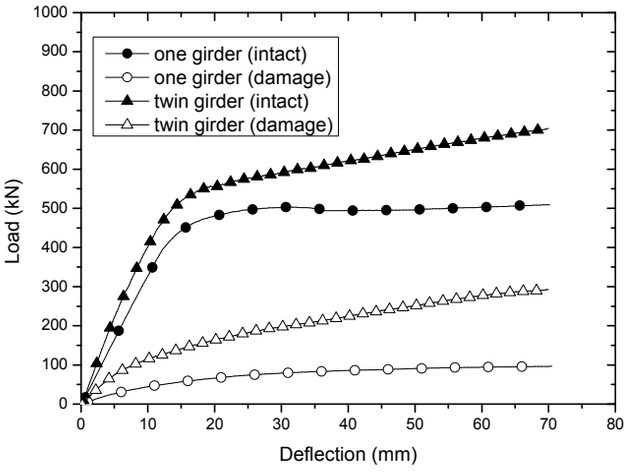

Figure 17. Load-deflection curves of the one girder and twin girder models

Table 4: Redundancy level of one girder and twin girders models

Models	P_{damage} (kN)	P_{design} (kN)	R_d
One girder	97	187	0.52
Twin girders	292	210	1.39

5 CONCLUSIONS

This study was carried out to investigate the effect of the fracture on the redundancy level of the composite twin I-girder bridge system. Finite element method with nonlinear analyses is used to determine the behavior of the bridge models in different damage cases. The validity of the numerical models is achieved by comparing with the experimental results. The finding of this study can be summarized as follow:

- The composite twin I-girder bridge models used in this study can be classified as redundant bridge system in critical fracture condition.
- It was confirmed that the fracture at the midspan section is the most critical fracture location comparing to the fracture near the support and at one-fourth span section.
- The concrete slab is determined as the alternative load path in composite twin I-girder bridge system which guarantees the redundancy level of the bridge in fracture critical condition.

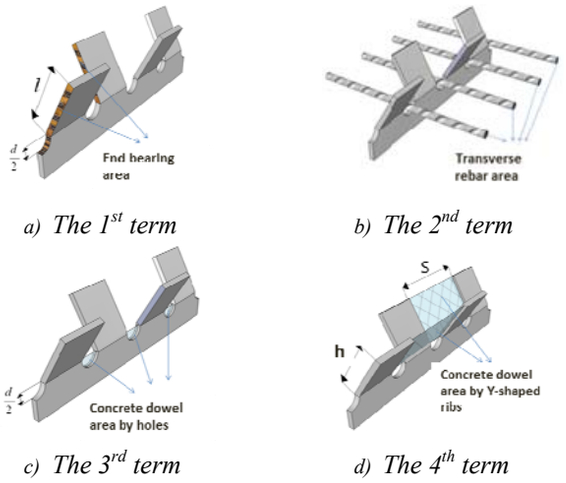
ABSTRACT: Many shear connectors may need to be arranged together in group to achieve the required shear strength in the design stage of the composite connection. In most practical situations the space to install the shear connectors may be limited. The shear strength of the individual Y-type perfobond rib shear connector may not be obtained if the Y-type perfobond rib shear connector layers are placed too much close to other adjacent layers. It has been investigated in the previous study that the total shear resistance of the flat-type perfobond rib shear connector group may either increase or decrease depending on the spacing between the adjacent layers.

This study is designed to verify the effect of the spacing between the adjacent layers of Y-type perfobond rib shear connectors and propose the proper design rule to estimate the shear strength in the multi-layer shear connectors. The double layer specimens with various spacings have been push tested. The minimum adjacent spacing for the specimens has been selected considering the limited distance due to the inclined Y-ribs to each other. The Y-ribs in the standard Y-type perfobond rib shear connector are inclined with 30-degree, and may bother the Y-ribs from the adjacent shear connector. Two different spacings of 120 mm and 300 mm are selected as the minimum and maximum distances. The maximum 300 mm spacing is selected considering the height of the shear connector. The parametric study for the spacings between 120 and 300 mm have been performed using the numerical FEM models. The numerical FEM model has been verified and improved based on the experimental test results. The effect of transverse rebar diameters is also examined. The shear resistance formula is proposed for the double layer shear connectors.

Keywords—Y-type perfobond rib shear connector, push-out test, group shear connector, rib arrangement and spacing

1. INTRODUCTION



Steel-concrete composite structures are one of the advanced solutions, by combining steel and concrete advantages: steel provides the resistance to tension stresses, while concrete is associated to compressive stresses and enhances the stability and fire capacities of the steel section. To achieve this structural behavior in a steel-concrete composite structure, shear connector's needed to be designed accurately and economically. There are many types of shear connectors that have been studied by previous researchers. One of the latest advanced shear connector type is Y-type shear connector developed by Kim at al., 2013 [1], in which combines advantages of both stud types and the conventional flat type perfobond rib shear connectors [2].

Kim et al. (2013), first obtained shear resistance formula for single Y-type perfobond rib shear connector by consider four variables, which those are concrete strength, rebar, rib thickness, and Y-shaped angle. The proposed shear resistance formula is described in Eq. (1.1).

$$Q = 3.428 \cdot \left(\frac{d}{2} + 2h\right) \cdot t \cdot f_{ck} + 1.213 \cdot r \cdot A_{tr} \cdot f_y + \\ + 1.9 \cdot n \cdot \pi \cdot \left(\frac{d}{2}\right)^2 \sqrt{f_{ck}} + +0.428 \cdot m \cdot h \cdot s \cdot \sqrt{f_{ck}} \quad (1.1)$$

In equation (1.1), the first term indicates the end bearing resistance of the concrete by the Y-type

perfobond rib. The second term represents transverse rebars placed between the Y-shape ribs affects the shear resistance (see Fig. 1 (b)). The third term explains concrete dowel resistance caused by the holes and affects the shear resistance (see Fig. 1 (c)). The fourth term represents the concrete dowel resistance by Y-shaped ribs and affects the shear resistance (see Fig. 1 (d)).

Fig.1. *Mechanical characteristics of Y-type perfobond rib shear connector* [1]

Kim et al. (2014) and Kim et al. (2015), improved the shear resistance formula by considering additional push-out tests involving the rib width and height, concrete strength, number of transverse rebar, rib thickness, height, which can be significant when influence of shear resistance of Y-type perfobond rib shear connectors.

Lastly, Kim et al. (2017), modified shear resistance-equation for Y-type perfobond rib shear connector by performing push-out tests with additional design variables considered in previous study. An important modification was introduced by excluding the 3rd term, because the hole in Y-type perfobond rib connectors is semi-circular and has lesser effect on the total shear capacity of connector's, only 0.85% [3]. In addition, the yield strength of the transverse rebar was replaced the compressive strength of concrete due to considering predominant failure of concrete.

Furthermore, the authors found that, when the number of ribs increases the shear resistance increases, but the increasing rates are decreased and converged to 44% from two-four, four-six, six-eight rib systems. To reflect this effect the authors introduced a reduction factor R_n, and the shear resistance equations focusing on multiple ribs expressed as Eq.(1.2) and Eq.(1.3).

$$Q_u = 11500\, f_{ck}{}^{0.3} \cdot S_{rib} + R_n \cdot f_{ck}{}^{0.3} \left[700 \cdot n \cdot A_{tr}{}^{0.75} + 2600\,(n-2) \cdot S_{rib}\right] \quad (1.2)$$

In previous expressions:

$$S_{rib} = (w/80)^{0.95} \cdot (h'/120)^{0.3} \cdot (d/40)^{0.3} \quad (1.3)$$

$h' = h + 0.5 \cdot d$

R_n is the reduction factor, $R_n = 1/(n-1)^{0.12}$

Several attempts have been made to consider multiple arrangements of perfobond rib shear connector in shear resistance equations.

Studnika et al. (2004), studied the twin parallel arrangement perfobond connectors. Author found that some interaction between them leads to an overall resistance that is less than the sum of the resistance of the individual connectors. In their study they proposed Eq. (1.4) and (1.5) to predict this overall resistance P_{twin} from the resistance of each individual connector P_{RK} that placed side by side with an axial placing b (mm):

$$P_{twin} = k_d \cdot P_{RK} \quad (1.4)$$

$$k_d = 1.66 + \frac{b-100}{14000} \le 1.85 \quad (1.5)$$

Jun Okada, Teruhiko Yoda and Jean-Paul Lebet (2004) [5], investigated shear strength reduction equations (η) of the grouped arrangement of stud connectors. Based on the analytical results, the shear strength reduction equations of the grouped arrangement are proposed in Eq. (1.6) - (1.8).

$$P_{group} = \eta \cdot P_{sin\,gle} \quad (1.6)$$

$3 \le C_1 < 13$ уед

C25/30: $\eta = 0.023\ C_1 + 0.70$ (1.7)

$C_1 \ge 13$ уед

C25/30 – C50/60: $\eta = 1.0$ (1.8)

Liu Yang-qing, Liu Yu-qing, Zheng Shuang-jie (2016) [6], investigated effects of plate spacing on shear stiffness of perfobond rib shear connector. The main influence factor for the shear stiffness of perfobond connector is the spacing-diameter ratio, which is suggested to be no less than 3.3 when multi perfobonds are arranged in parallel. Authors developed new formula Eq (1.9) and Eq. (1.10) for perfobond shear stiffness (k_s), which accounts for the influence of plate spacing (α_e).

$$k_s = \alpha_e \left(0.27 + 0614\, n_E n_d^2\right) E_c d \quad (1.9)$$

$$\alpha_e = \begin{cases} 0.5 + 0.15\dfrac{e}{d}, & \dfrac{e}{d} < 3.3 \\ 1.0, & \dfrac{e}{d} \geq 3.3 \end{cases} \qquad (1.10)$$

2. PUSH-OUT TEST

Push-out tests were undertaken to examine group effects of the Y-type shear connector, considering distance between adjacent shear connectors. The distances were selected as 120 mm and 300 mm. For the shape of the bent rib configuration of group-Y-type shear connectors, the minimum acceptable spacing is 120 mm. Series of test specimens are denoted as S1, G2-120, G2-300 respectively. Table 1 describes conditions of variables for each series of specimen. For each series, three specimens with the same specifications are manufactured to make sure that the tests results are reliable.

Table 1. Push-out test series

Division/ Name	*S (mm)*	*Shape dimensions $W \times H \times t$ (mm)*	*Transverse rebar diameter d_{tr} (mm)*	*Hole diameter d_h (mm)*
S1	-	80 x 100 x 10	16	40
G2 - 200	120	80 x 100 x 10	16	40
G2 - 300	300	80 x 100 x 10	16	40

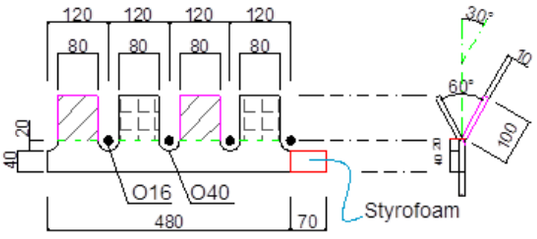

Fig. 1. *Dimensions of Y-shape rib*

The concrete compressive strength of 53.7 MPa, steel beam and Y-shape ribs SPHC (JIC G 3131 standard) steel grade with nominal yield stress of 307.2 MPa, all rebars of SD400 steel grade with a nominal yield stress of 400 MPa was used for the test.

2.1. Test set up

Push-out tests are performed at the KCL (Korea Conformity Laboratory) laboratory which is the top testing and inspection laboratory. After the specimens had been cured for about 28 days, they were placed in the "seismic isolation devices test & evaluation system" machine (see Fig. 2) with loading capacity of 30000. A monotonic load was applied in the displacement control method, and the load rate was set to 0.03 mm/s to prevent failure for less than 15 min, according to Eurocode 4 [7].

The push-out test stopped when the load decreased by 20% of the ultimate load. The load was applied until the displacement reached 50 mm. Each push-out specimen was equipped with eight LVDTs. Grid lines were drawn on the concrete surface of all specimens (Fig. 2), and a high-resolution camera was used to record the crack paths during the test. Push-out test set-ups are shown in Fig. 2.

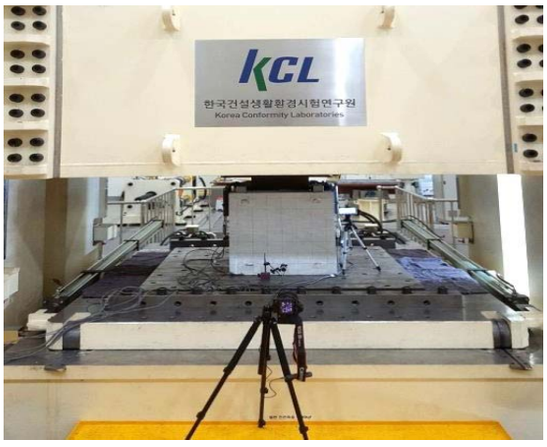

Fig.2. *Push-out test set up*

a) Front side of the specimen *b) Left side of the specimen*

Fig. 3. *Push-out test set up*

2.2. Test results

Results of push-out test series of a single Y-type perfobond rib shear connector S1, for group connector series G2 - 120 and G2- S300 are presented in Table II. The load-slip curve for all the series of specimens is shown in Fig. 3. The average ultimate load for single S1 was 1682.66 kN, and G2-120 had an ultimate load of 3320.33 kN that was approximately 1.97 times higher, compared with the single S1 specimen. For G2-300, the average ultimate load was 3830.18 kN, which is approximately 2.28 times, higher than that of a single S1 specimen. In case of an average characteristic slip is 19.5 mm, 35.2 mm and 34.5 mm respectively, the test results are much higher than that is required by "Eurocode 4" [7]. As

shown in Fig. 3, the series of specimens exhibit a similar load-slip behavior. These results indicated that the Y-type shear connector has a high ductile behavior both in single and grouped test series.

Table 2. Push-out test results

Types	*S (mm)*	*Average Ultimate Load* P_u *(kN)*	*Average Relative slip* δ_u *(mm)*	*Average Characteristic slip* δ_{uk} *(mm)*
S1	-	1682.66 (1.0)	21.4 (1.0)	19.3
G2-120	120	3320.33 (1.97)	28.8 (1.34)	25.9
G2-300	300	3830.2 (2.28)	38.3 (1.79)	34.4

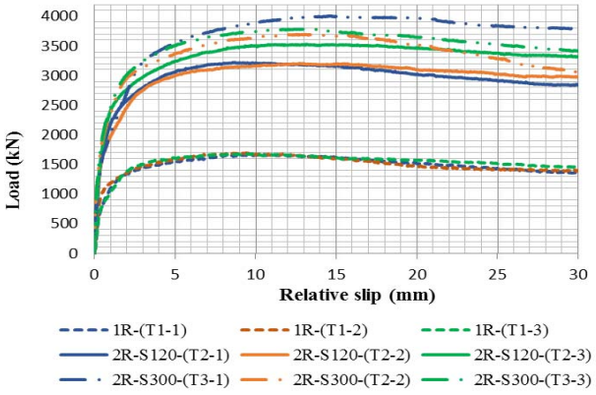

Fig .3. *Load-slip curves of experimental tests*

3. NUMERICAL ANALYSES

A 3D finite element model of the push-out test was developed using ABAQUS/Explicit software. Firstly, FE models were built with the use of exact geometry, analysis method, suitable contact interactions, constraints, boundary conditions, load application, material models, and a mesh to accurately model the actual push-out test specimens. Both geometric and material nonlinearity are also included in the analytical model.

3.1. Numerical modeling

A FE model consists of six parts as used in push-out tests: concrete slab, Y-type perfobond rib shear connector, steel beam, reinforcement rebars, transverse rebar, and rigid basement. Taking advantage of symmetry to reduce the size of the problem, only one-half of the specimens are modeled. A concrete damage-plastic model (CDPM) was used to simulate the non-linear behavior of the concrete, and a non-linear elastic-plastic model was used in the steel beam, Y-shape ribs and rebars. The concrete slab was meshed with a three-dimensional solid element C3D10M. Then the steel beam and Y-type perfobond rib shear connector were modeled into a three-dimensional reduced solid element C3D8R, while rebar elements were modeled into three-dimensional tress element T3D2.

Material properties of the steel and concrete are presented in Table 3 and Table 4 [8], [9].

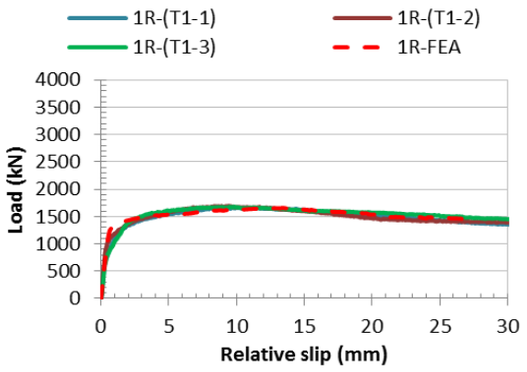
Table 3. Steel material input in ABAQUS

Material	*Parameter*	*Value (MPa)*
Structural steel	E_s – Elastic modulus	210,000
	σ_{ys} – Yield stress	307.2
	σ_u – Ultimate stress	379.3
	ν – Poisson's ratio	0.3
Reinforcement rebar	E_s – Elastic modulus	200,000
	σ_{ys} – Yield stress	500
	σ_u – Ultimate stress	600

Table 4. Concrete material input in ABAQUS

Material	*Parameter*	*Value*
Concrete	E_{cm} – Elastic modulus	36426.3 (MPa)
	f_{ck} – Concrete compressive strength	53.7 (MPa)
	f_{ct} – Concrete tensile strength	5.37 (MPa)
CDPM	ρ – Density	2350 (kg/m^3)
	ψ – Dilation angle	40°
	$\in$ – flow of potential eccentricity	0.1
	σ_{b0}/σ_{c0} – ratio of the strength in the biaxial state to the strength in the uniaxial state	1.16
	K_c – shape of deviatory trace	0.667
	μ – Cohesion	0
	ν – Poisson's ratio	0.3

All parts are positioned together to form an assembly, and appropriate constraints and contact interactions are defined between them. Therefore, to ensure similar conditions for the tests conducted, FE models were used in a displacement-controlled method for loading steps. The applied displacement is linearly increased by the amplitude function. The relative slip in accordance with the loading steps was measured as the displacement of the end of the steel beam node. Nodes of elements on the bottom face of the rigid-base part which was fully constrained to the reference point at the bottom are named as "RP".



3.2. Validation numerical model

The finite element model developed in this study is validated against experimental test results. The load-slip behaviors obtained from the finite element

analyses are compared with experimental studies are shown in Fig. 9. Table 5 summarizes load-relative slip characteristics of obtained from the FEA and experimental tests. It can be observed that both FE analyses and experimental results match excellently in terms of curve shapes, ultimate shear strength and ductility. According to the Table 5, the average ratio of ductility obtained in the test to the numerical simulation, indicate a range from 0.96 to 1.09. Mismatches of numerical results compared to experimental results for slip capacity, are approximately 8% and considered to be correct. Mismatching ratios of shear resistance were 1.4%, 2.2 % and 7.2% for 1R, 2R – S120 and 2R – S300 specimens respectively. Therefore, taken together, the numerical model simulated in this study can be used to evaluate and predict not only the ultimate shear capacity but also the ductility of the Y-type perfobond rib shear connector having various specifications.

Fig. 9. *Load-slip curves of experimental tests*

3.3. Parametric study

A spacing between parallel arrangement of adjacent shear connectors were varied within the range from S = 80 mm to S = 350 mm. The results of analytical study were presented in Table 6 and Fig. 4, as load-relative slip curves of the specimen with different spacing. Shear reduction factors represented in Table 6, are 1.86 - 2.0 times higher than in a single shear connector. Therefore, it is indicated that the influence of the grouped arrangement is negligible, when spacing is greater than 300 mm.

Table 6. Results of parametric study

Spacing	Results of parametric study (FEA)					
	P_u	P_{RK}	δ_u	δ_{uk}	k	Inc (%)
S1	1808.4	1627.56	21.2	19.1	1.0	-

4. DEVELOPMENT OF SHEAR RESISTANCE FORMULA FOR GROUP Y-TYPE PERFOBOND RIB SHEAR CONNECTOR

4.1. Shear strength reduction factor

Shear strength reduction factor k is determined by ratio of spacing between the adjacent shear connector (S) and transverse rebar diameter (d_s).

Numerical results indicate that the influence of adjacent shear connector can be estimated from acceptable minimum spacing of 120 mm to the maximum possible spacing of 300 mm. The shear resistance linearly increases as the spacing increases, gradually approaching the behavior of a single shear connector resistance. The beta values are acquired by regression analysis. Based on evaluation of $\beta_0 = 1.811,\ \beta_1 = 0.009$, the new formula for the group Y-type shear connector is given by Eq. (4.1) and Eq. (4.2).

$$k\left(\frac{S}{d_s}\right) = \begin{cases} 1.87, & \frac{S}{d_s} \le 7.5 \\ 1.81 + 0.009\left(\frac{S}{d_s}\right); & 7.5 < \frac{S}{d_s} < 22 \\ 2.0 & \frac{S}{d_s} \ge 22 \end{cases} \quad (4.2)$$

$$Q_u^G = k\left(\frac{S}{d_s}\right) \cdot Q_u^S \quad (4.3)$$

In previous expression:

Q_u^G - Shear resistance of a group Y-type perfobond rib shear connector (кН)

Q_u^S - Shear resistance of a single Y-type perfobond rib shear connector (кН)

k - Shear reduction factor, considering the spacing and transverse rebar diameter ratio

Based on Eq. 4.1 shear strength reduction factor can be calculated as shown in Fig. 5. The main influence factor for the shear resistance of a group Y-type perfobond rib shear connector is the spacing-transverse rebar diameter ratio (S/d_s), which is suggested to be no less than 7.5. When the spacing factor (S/d_s) increases shear strength increases and peaks at 22.

The shear resistances obtained from the numerical analysis are compared to verify the proposed shear resistance evaluation formula, Equation (4.2). Fig. 6. compares the shear resistances of the numerical analysis and given formulas.

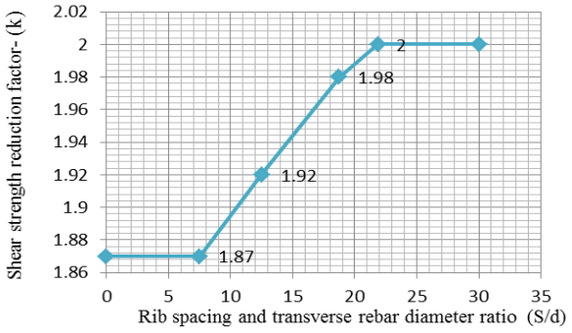

Fig. 5. *Shear strength reduction factor*

In Fig. 6, dots are placed closer to the diagonal dash line, meaning that the formula is fairly accurate in estimating the shear resistance of the group Y-type perfobond rib shears connectors. Table 7 summarizes the comparisons between the numerical simulation and estimated shear resistance of a group Y-type perfobond rib shear connector.

Table 7. Comparison shear resistance of numerical analysis and proposed formula

S MM	Eq 1.4 Q_u^S	$k\left(\frac{S}{d_s}\right)$	$\frac{S}{d_s}$	Eq 4.3 Q_u^G (EQ)	Q_u^G (NUM)	$\frac{NUM}{EQ}$

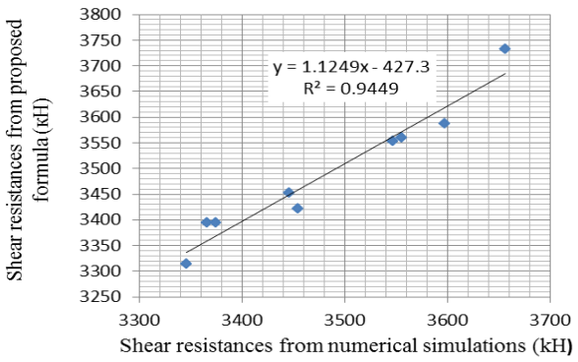

Fig. 6. *Evaluation of proposed formula*

5. CONCLUSION

Effects of spacing between adjacent shear connector on the shear resistance of group Y-type shear connectors is analyzed through the push-out test and numerical analysis. Following conclusions were drawn:

1) Push-out test results indicated that shear strength evaluation factor is 1.97 in double row specimens with 120 mm spacing, due to some overlapped stresses around a shear connector area. In double row specimens with spacing of 300 mm, shear strength evaluation factor is determined by 2.28 points.
2) Concrete damage-plastic model (CDPM) was used to simulate the non-linear behavior of the concrete, non-linear elastic-plastic model was used in steel beam, Y-shape ribs and rebars. The numerical analyses showed good agreement with experimental results.
3) The main influence factor for the shear resistance of group Y-type perfobond rib shear connector is the rib spacing-transverse rebar diameter ratio (S/d_s), which is suggested to be no less than 7.5. When spacing factor (S/d_s) increases shear strength increases and peaks at 22.
4) Based on numerical and experimental results shear strength evaluation formula for group Y-type shear connector is developed.

ACKNOWLEDGEMENTS

This research project was conducted in Structure & Bridge Engineering Lab. at Yonsei University. The authors would also like to acknowledge cooperation from members of Structure & Bridge Engineering Lab. at Yonsei University.

Evaluation of the ultimate response of post-tensioned composite slabs

G. Ranzi
School of Civil Engineering, The University of Sydney, Australia

ABSTRACT: Post-tensioned composite slab systems consist of concrete slabs poured on thin-walled profiled sheeting and prestressed soon after casting. This paper presents a theoretical model aimed at evaluating the ultimate moment resistance of this form of construction. In the first part of the paper the key equations describing the model are introduced and these are then followed by the model validation carried out against experimental results available in the literature. The comparisons carried out between the experimental measurements and the calculated capacities show good agreement.

1 INTRODUCTION

Post-tensioned composite steel-concrete slabs are widely used in Australia for floor systems in building applications. These represent an economical form of construction which consist of thin-walled profiled steel sheeting, post-tensioning strands and concrete (Figure 1). While the use of post-tensioned concrete floor solutions has been widely adopted over the last decades, the use of steel sheeting as permanent formwork for this type of application has been proposed in the last few years as a replacement for conventional plywood formwork. From a structural viewpoint, once the concrete has hardened, the contribution of the profiled sheeting as external reinforcement depends on the interaction between the steel sheeting and the concrete and, as such, this form of construction is classified as a composite system. With the use of post-tensioning, concrete cracking is significantly reduced, therefore enhancing the flexural stiffness and strength when compared with conventional composite slabs.

In 1990, Schravendeel et al. (1990) pointed out the potential advantages in adopting post-tensioned composite slab solutions based on strength considerations. A few years later, Koukkari (1999, 2001) investigated the behaviour of unbonded post-tensioned slabs. A composite prestressed slab system was proposed using the Tekdek steel deck which was prestressed prior to delivery to site. (Bailey et al., 2006) Three ultimate tests were carried out by Patrick and Lloyde (2008) to compare the structural response of a composite slab, a post-tensioned solid slab and a post-tensioned composite slab prepared with Fielders KF57 steel deck. The samples were simply-supported with a total length of 5 m and a distance between roller supports of 4 m.

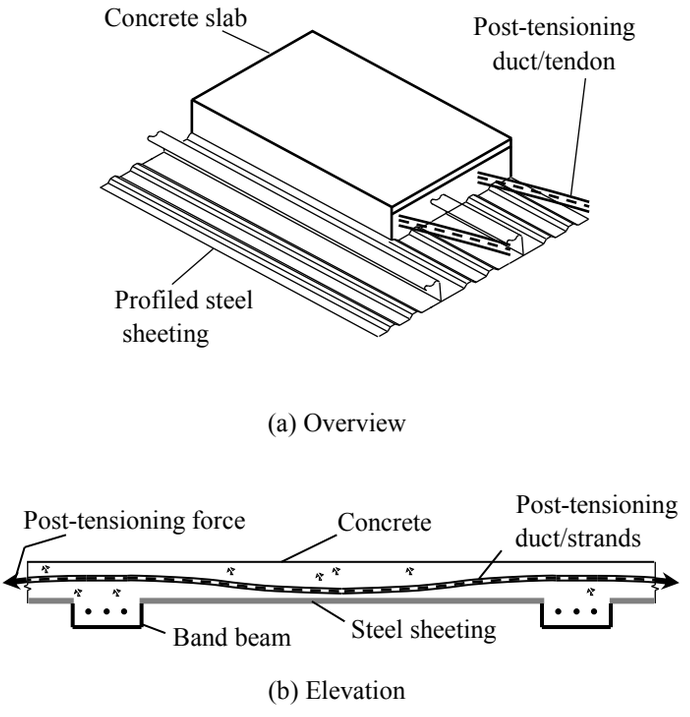

Figure 1. Typical post-tensioned composite slab.

They reported a significant increase in strength of the post-tensioned composite slab when compared to the capacities exhibited by the composite and post-tensioned solid samples, with the latter exhibiting premature bond failure between the strands and surrounding grout. For the post-tensioned composite

sample they highlighted that the test was terminated due to the fracture of the steel deck at the nearly estimated full shear connection capacity, calculated making use of a nonlinear cross-sectional analysis while ignoring slip effects. (Patrick and Lloyde, 2008) Experimental work on post-tensioned composite slabs was also proposed by considering their ultimate response, e.g. (Ranzi et al., 2013a; Ranzi and Ostinelli, 2017) and their time-dependent behavior produced by creep and shrinkage effects, e.g. (Ranzi et al., 2013b, 2013c).

In this context, this paper presents a theoretical model for the evaluation of the ultimate resistance of post-tensioned composite slabs that is validated against test results available in the literature, e.g. (Ranzi et al., 2013a; Ranzi and Ostinelli, 2017). The comparisons carried out between the predictions obtained with the proposed theoretical model and those measured during the experiments show good agreement.

2 THEORETICAL MODEL

A theoretical approach is briefly presented in the following to determine the ultimate resistance of post-tensioned composite slabs. The model builds on current design practice for composite slab design, e.g. (EN 1994-1-1, 2004), and on the design procedure adopted for prestressed floors, e.g. (Gilbert et al., 2016). The assumptions of the proposed model can be summarized as follows (Ranzi et al., 2017): (i) no tensile stresses are resisted by the concrete; (ii) plane sections remain plane and perpendicular to the member axis before and after loading; (iii) a rectangular stress block is used to depict the concrete stresses (here introduced, without any loss of generality, based on Australian guidelines (AS3600, 2009); (iv) full and partial shear connection is used to describe the interface behaviour between the sheeting and the slab (where the partial shear connection depicts the condition in which the shear connection represents the critical component at a particular cross-section); (v) the response of the prestressing is described using a simplified procedure; and (vi) the components forming the structural member are assumed to be ductile and possible failure due to limited ductility needs to be verified separately, e.g. rupture of the steel sheeting as observed in the composite post-tensioned test reported in reference (Patrick and Lloyde, 2008).

With the proposed approach, the ultimate moment of the post-tensioned composite section is determined as follows:

$$M_u = N_c z_c - N_{pre} z_{pre} + M_{pr} \tag{1}$$

where N_c and N_{pre} describe the axial forces resisted by the concrete component and by the prestressing strands, respectively, the lever arms z_c and z_{pre} depict the distances of the concrete and prestressing forces, respectively, from the line of action of the force resisted by the profiled steel sheeting N_p, and M_{pr} is the plastic resistance of the profiled steel sheeting. (Ranzi and Ostinelli, 2017) The calculations of the terms contributing to the ultimate moment capacity M_u is outlined in the following and the associated stress and strain diagrams are illustrated in Figure 1.

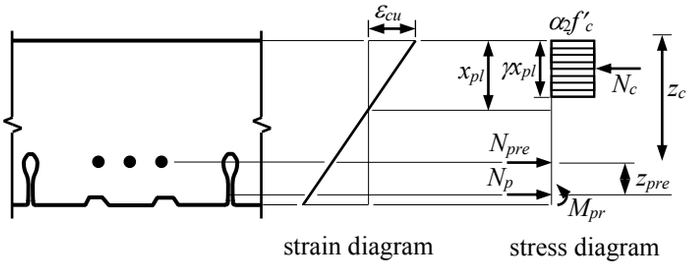

Figure 1. Stress and strain distribution considered in the design model.

The concrete response at ultimate conditions has been described, without any loss of generality, based on Australian design recommendations (AS3600, 2009), while material representations of other design standards could be specified as well. In this manner, the concrete strain ε_{cu} in the extreme fibre of the slab at the ultimate moment condition is assumed to equal 0.003. The compressive resistance of the concrete can then be calculated as: (AS3600, 2009)

$$N_c = \alpha_2 f'_c \gamma x_{pl} b \tag{2}$$

which assumes a stress equal to $\alpha_2 f'_c$ (with f'_c being the characteristic strength of the concrete and α_2 being defined in Equation 3a) to be resisted by the concrete over a height of γx_{pl}, x_{pl} defines the distance between the neutral axis and the slab top fibre (reduced by γ provided in Equation 3b), and b depicts the width of the slab. The parameters γ and α_2 are used to define the concrete stress block to be used in design and is determined in the following based on Australian guidelines (AS3600, 2009):

$$\alpha_2 = 1.0 - 0.003 f'_c \qquad 0.67 \le \alpha_2 \le 0.85 \tag{3a}$$

$$\gamma = 1.05 - 0.007 f'_c \qquad 0.67 \le \gamma \le 0.85 \tag{3b}$$

The axial contribution of the prestressing strands N_{pre} is here accounted for as follows:

$$N_{pre} = \sigma_{pu} A_{pre} \tag{4}$$

where A_{pre} depicts the area of the strands located at a distance d_{pre} from the top fibre of the cross-section to the centroid of the prestressing steel, and σ_{pu} can be determined using a simplified expression (applicable when the minimum effective stress in the strands is not less than $0.5 f_{bc}$) available in reference (AS3600, 2009). For the 7-wire ordinary strands commonly specified for composite post-tensioned

floors the following properties apply: A_{pre} = 98.6 mm^2, f_{preb} = 1870 MPa, f_{prey} = 1533 MPa and f_{preb} / f_{prey} = 0.81978609. σ_{pu} is determined based on Australian guidelines as (AS3600, 2009):

$$\sigma_{pu} = f_{pb}\left(1 - \frac{k_1 k_2}{\gamma}\right) \tag{5}$$

with f_{pb} being the characteristic minimum breaking load of the prestressing strand, and parameters k_1 and k_2 being calculated from:

$$k_1 = 0.28 \qquad \text{for } f_{ypre}/f_{pb} \geq 0.9 \tag{6a}$$

$$k_1 = 0.4 \qquad \text{for } f_{ypre}/f_{pb} < 0.9 \tag{6b}$$

$$k_2 = \frac{1}{b_{ef} d_{pre} f_c'}\left[A_{pre} f_{pb} + A_{pe} f_{yp} + \left(A_{st} - A_{sc}\right) f_{ys}\right] \tag{7}$$

where A_{st} and A_{sc} define the tensile and compressive reinforcement (i.e. steel reinforcing bars) with f_{ys} being its yield strength, b_{ef} represents the effective concrete width, and f_{ypre} and f_{yp} describe the yield strength of the prestressing strands and of the steel sheeting, respectively.

Partial shear connection theory is used to consider the influence of the profiled steel sheeting in the analysis. With this approach, the force resisted by the sheeting N_p is determined as follows:

$$N_p = \min\left(N_\tau, N_{FSC}\right) \tag{8}$$

in which N_τ depicts the shear connection force relying on mechanical interlock, and N_{FSC} defines the axial force that the profiled steel sheeting could resist in the case of full shear connection (i.e. when the interface between the concrete and the sheeting is not the weak component of the member). The value for N_τ is calculated with respect to the interface shear strength τ_u that depicts an experimental representation of the shear-bond response exhibited between the sheeting and the concrete that needs to be identified experimentally for each profiled sheeting to be used for post-tensioned floor applications. The terms N_τ and N_{FSC} can be expressed as:

$$N_\tau = \tau_u b L_x \tag{9}$$

$$N_{FSC} = \min\left(N_{yp}, N_{c(\max)} - N_{pre(\max)}\right) \tag{10}$$

where τ_u is the interface shear strength between the sheeting and the concrete obtained from experimental tests, L_x represents the distance of the cross-section under consideration to the nearest support, $N_{c(max)}$ and $N_{pre(max)}$ describe compressive and tensile capacities of the concrete and prestressing components, respectively, and N_{yp} depicts the axial force resisted by the profiled sheeting at yield. These terms can be calculated as:

$$N_{c(\max)} = \alpha_2 f_c' \gamma D_c b \tag{11a}$$

$$N_{pre(\max)} = f_{pb} A_{pre} \tag{11b}$$

$$N_{yp} = f_{yp} A_{pe} \tag{11c}$$

in which A_{pe} is the area of the profiled steel sheeting. Obviously, the maximum compressive force available in the post-tensioned solid slab (i.e. $N_{c(max)}$ - $N_{pre(max)}$ in Equation 10) depend on the prestressing force level and a check might need to be carried out at the end of the calculations to ensure that the adopted N_{FSC} is within the available prestressed solid slab capacity.

For the profiled steel sheeting considered in the validation presented in this study, τ_u equals 210 kPa. The flexural contribution of the profiled steel sheeting is then determined using:

$$M_{pr} = 1.25 M_{pa}\left(1 - \frac{N_p}{N_{yp}}\right) \leq M_{pa} \tag{12}$$

where M_{pa} represents the plastic moment of the profiled sheeting.

3 VALIDATION

The proposed model is applied in in this section to predict the ultimate moment resistance of the specimens outlined in references (Ranzi et al., 2013a; Ranzi and Ostinelli, 2017). The material and geometric properties adopted in the numerical calculations are those obtained from material testing and from measurements of the samples, therefore reflecting the condition of the tested specimens. Details regarding the samples and the testing can be found in references (Ranzi et al., 2013a; Ranzi and Ostinelli, 2017).

The ultimate moments evaluated using the proposed approach are summarized in Table 1.

Table 1. Summary of comparisons between experimental and calculated ultimate moment resistances.

Sample ID	Experimental ultimate moment (M_{exp})	Calculated ultimate moment (M_u)	M_u / M_{exp}
	kNm	kNm	
S1*	152.1	140.2	0.92
S2*	124.2	105.1	0.85
S3*	170.0	159.8	0.94
S4*	174.9	155.3	0.89
S5*	250.9	239.2	0.95
S6*	265.9	250.8	0.94
CK1**	132.8	127.2	0.96
CK2**	144.6	137.7	0.95

* from reference (Ranzi and Ostinelli, 2017)
** from reference (Ranzi et al., 2013a)

The comparisons between the experimental and the predicted values show good agreement. This can be observed considering the ratios of the estimated ultimate moments (i.e. M_u) over the measured capacities (i.e. M_{exp}) reported in Table 1, where M_u / M_{exp} and remained in the range of 0.89-0.96 for all test samples except specimen S2. In the case of sample S2, the specimen exhibited a flexural shear failure and its ultimate moment prediction was $M_u/M_{exp} = 0.85$.

4 CONCLUSIONS

This paper has presented a theoretical model for the evaluation of the ultimate resistance of post-tensioned composite slabs. The main equations describing the model have been presented and have been validated against experimental measurements available in the literature. The comparisons between predicted and experimental moment resistances showed good agreement.

Service behaviour of composite steel-concrete slabs with a simplified approach and a hygro-thermo-chemical-mechanical model for the non-uniform shrinkage evaluation

M. Bocciarelli
Architecture, Built Environment and Construction Engineering Department, Politecnico di Milano, Italy

G. Ranzi
School of Civil Engineering, The University of Sydney, Australia

ABSTRACT: Composite steel-concrete floors are widely used throughout the world for building applications. These floors usually consist of composite slabs supported by steel beams in steel framed construction and of post-tensioned composite slabs carried by band beams in concrete buildings. The design of composite floors is commonly governed by serviceability limit state associated with deflection limits. Recent research has pointed out that a non-uniform shrinkage profile occurs in slabs cast on profiled steel sheeting. In this context, this paper provides a brief overview of the main factors influencing the service behavior of composite slabs and of a model capable of predicting their long-term deflections considering two approaches for the evaluation of the non-uniform shrinkage profiles, i.e. a simplified approach and a hygro-thermo-chemical-mechanical model. The adequacy of the proposed prediction models is then outlined by comparing the long-term deflections calculated with the proposed approach and those measured experimentally from long-term tests carried out on selected composite and post-tensioned composite slab samples that have been reported in the literature.

1 INTRODUCTION

Composite steel-concrete floors are widely used throughout the world for building applications. Their design is commonly governed by serviceability limit state associated with deflection limits. Recent research has pointed out that a non-uniform shrinkage profile occurs in slabs cast on profiles steel sheeting, i.e. composite slabs, due to the inability of the concrete to dry from its underside because of the presence of the sheeting, e.g. (Al-deen et al., 2011, 2015; Al-deen and Ranzi, 2015; Gholamhoseini et al., 2014; Gilbert et al., 2012; Ranzi et al., 2013a, 2013b). In this context, this paper provides a brief overview of the main factors influencing the service behavior of composite slabs and of a model capable of predicting their long-term deflections considering two approaches for the evaluation of the non-uniform shrinkage profiles, i.e. a simplified approach and a hygro-thermo-chemical-mechanical model. Their main differences relies on the fact that the simplified procedure uses a linearly-varying shrinkage profile as input in the design steps (Ranzi 2017), while the refined multi-physics model needs the evaluation of the temperature and relative humidity distributions for the determination of the non-uniform shrinkage effects (Bocciarelli et al., 2017). The use of the hygro-thermo-chemical-mechanical model requires an inverse analysis procedure to be carried out for the characterisation of the numerous parameters that it needs in input. The adequacy of the deflection prediction model is then briefly outlined by comparing the long-term deflections calculated and those measured experimentally from long-term tests carried out on selected composite and post-tensioned composite slab samples that have been reported in the literature.

2 CONCRETE BEHAVIOUR: NON-UNIFORM SHRINKAGE PROFILES

The service behavior of concrete structures is influenced by concrete time effects, such as creep and shrinkage. This section intends to outline the key features describing the development of non-uniform shrinkage profiles in composite floors. For this purpose, two unreinforced and unloaded concrete slabs are considered and differ for their exposure conditions, i.e. one slab being exposed to dry on both sides (Figure 1a) and one being exposed on one side and sealed on the other (Figure 2a). In the former case (Figure 1a), the slab is able to dry from both its top and bottom faces and it exhibits constant total deformations over time (Figure 1b). For design purposes, it is well accepted to simplify the problem and to assume that these total deformations can represent the shrinkage distributions. In reality, the real shrinkage distribution is nonlinear, e.g. (Gilbert and Ranzi 2011). When considering the unreinforced slab with exposure conditions similar to those of a composite slab (Figure 2a), the asymmetric drying

conditions produce a linearly varying total deformation profile over time (Figure 2b). Under the assumption of using linear shrinkage profiles for design purposes, it is possible to relate the total deformations to a simplified shrinkage distribution. Also in this case, the real shrinkage profile would be nonlinear.

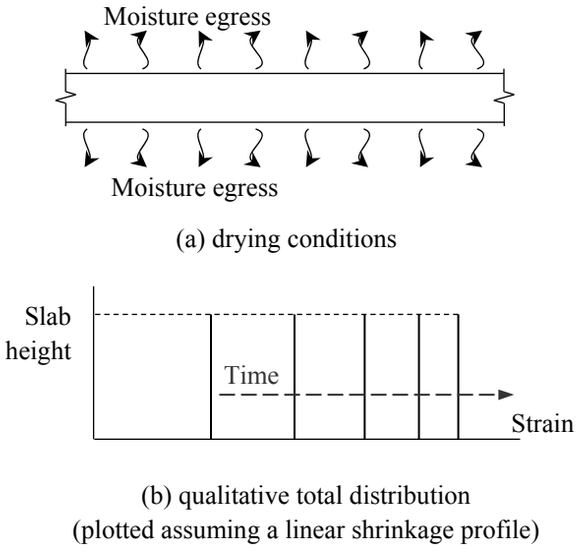

Figure 1. Drying conditions and qualitative total deformations for slab exposed on both sides.

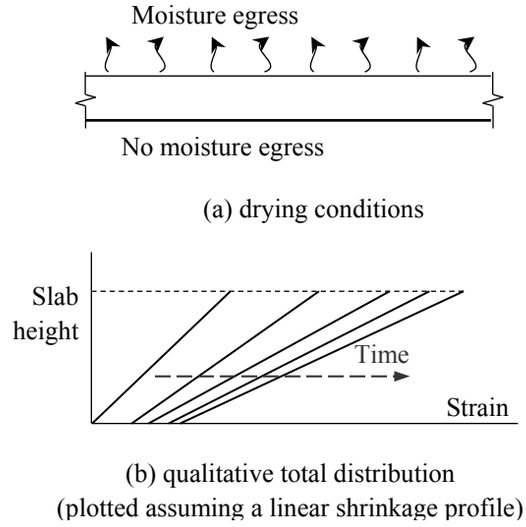

Figure 2. Drying conditions and qualitative total deformations for slab exposed on one side only.

3 MODELLING

3.1 *Model description*

The deflection predictions at service conditions account for the contribution of a number of components. These usually consist of the instantaneous deflection δ_0 produced by the short-term service loads, of the deflection δ_{cc} produced by creep effects and of the component δ_{cs} induced by shrinkage. Details of the design model can be found in (Ranzi 2017). In particular, the instantaneous deflection is determined performing an analysis of the composite slab adopting an effective flexural rigidity. The latter can be evaluated following common design specifications recommended for reinforced concrete slabs, as performed in the Australian guidelines (AS3600 2009). The creep deflection is calculated relying on the effective modulus method, e.g. (Gilbert and Ranzi 2011), and considering only the sustained part of the short-term service load. The remaining shrinkage deflection is obtained by evaluating the effects produced by a shrinkage-induced curvature κ_{cs} at different locations and calculated as a weighted value between the curvature exhibited under uncracked condition $\kappa_{cs.uncr}$ and the one developed for cracked conditions $\kappa_{cs.\,cr}$. The weighting term in this case is the distribution coefficient γ_{cs} that considers the degree of cracking exhibited in the slab for the applied service load. Based on this, the shrinkage-induced curvature at a particular cross-section is determined as follows:

$$\kappa_{cs} = (1 - \gamma_{cs}) \kappa_{cs.cr} + \gamma_{cs} \kappa_{cs.uncr} \quad (1)$$

The evaluation of the shrinkage profile is carried out in this paper considering two procedures, i.e. one based on a simplified approach and one relying on the use of a hygro-thermo-chemical-mechanical model.

3.1.1 *Simplified approach for the evaluation of the non-uniform shrinkage*

The shrinkage profile to be used in the design (assumed to be linearly varying) is determined based on a reference shrinkage value ε_{sh} obtained from reinforced concrete guidelines, e.g. (AS3600 2009), by adopting a hypothetical thickness equal to the thickness of the composite slab and assuming both sides of the slab to be exposed. The non-uniform shrinkage distribution is then defined considering a linearly varying profile possessing values of 1.2 ε_{sh} and 0.2 ε_{sh} at the top (exposed) and bottom (sealed) sides of the slab, respectively. The definition of the shrinkage reference strain is a consequence of the fact that the top and bottom values of the non-uniform shrinkage profile have been calibrated experimentally against those exhibited by companion concrete slab samples exposed on both sides with same thickness as the composite specimens.

3.1.2 *Use of a hygro-thermo-chemical-mechanical model for the evaluation of the non-uniform shrinkage*

The determination of the non-uniform shrinkage distribution to be used for the evaluation of the shrinkage deformations and deflections can be carried out using a hygro-thermo-chemical-mechanical model, such as the one presented in (Bocciarelli et al., 2017). Such a multi-physics approach requires an extensive set of parameters to be used in input

that can be identified by means of inverse analysis techniques. Examples of how this model is suitable for the representation of shrinkage effects has been described in (Bocciarelli et al., 2017).

3.2 *Model validation*

The proposed deflection model has been validated against long-term tests available in the literature on composite slabs and post-tensioned composite slabs. For the purpose of this paper only selected experimental tests have been selected and presented in Figures 3-6.

In particular, Figure 3 reports a comparison between the values calculated with the design model (using the simplified approach for the definition of the non-uniform shrinkage effects) and the experimental measurements recorded in a long-term test of a composite slab whose details can be found in (Gholamhoseini et al 2014, Gholamhoseini 2014). In this case, the results relate to a sample cast on a Fielders' KF70 profiled steel sheeting. A second long-term test carried out on a composite slab is depicted in Figure 4. (Al-deen et al 2015) Also in this case the non-uniform shrinkage profile has been obtained with the simplified approach. In this case, a Stramit Condeck HP profiled sheeting was used in the preparation of the specimen. The third comparison presented in this paper relates to a post-tensioned composite slab also cast on a Stramit Condeck HP profile and its comparisons are illustrated in Figure 5 by using the simplified approach for the non-uniform shrinkage representation (Ranzi et al 2013b). The same profiled steel sheeting is used for the post-tensioned sample whose measurements and comparisons with predicted values are shown in Figure 6 (Ranzi et al., 2012) . In this case both simplified and hygro-thermo-chemical-mechanical model have been used for the evaluation of the non-uniform shrinkage distributions. Both approaches are shown to provide good predictions.

In summary, the deflection predictions based on the use of a non-uniform shrinkage profile well match the experimental deflections recorded over time, while the use of a constant shrinkage distribution underestimates the deformation.

4 CONCLUSIONS

This paper has provided a brief overview of recent advances related to the serviceability limit state design of composite floor systems. In particular, it has presented a design model for the evaluation of deflections at service conditions. The particularity of this work relies on the ability of the proposed formulation to account for the development of a non-uniform shrinkage profile, observed in recent long-term experimental tests carried out on composite slabs and post-tensioned composite slabs, to occur due to the inability of the concrete to dry from its underside. The evaluation of the shrinkage profile has been carried out considering two procedures, i.e. one based on a simplified approach and one relying on the use of a hygro-thermo-chemical-mechanical model. The validity of the proposed approach has been validated by comparing the numerical calculated values to the measured deflections of selected composite and post-tensioned composite samples. In all cases, the adopted model implemented with a non-uniform shrinkage profile has shown to well match the experimental data while the use of a uniform shrinkage has underestimated the deformations.

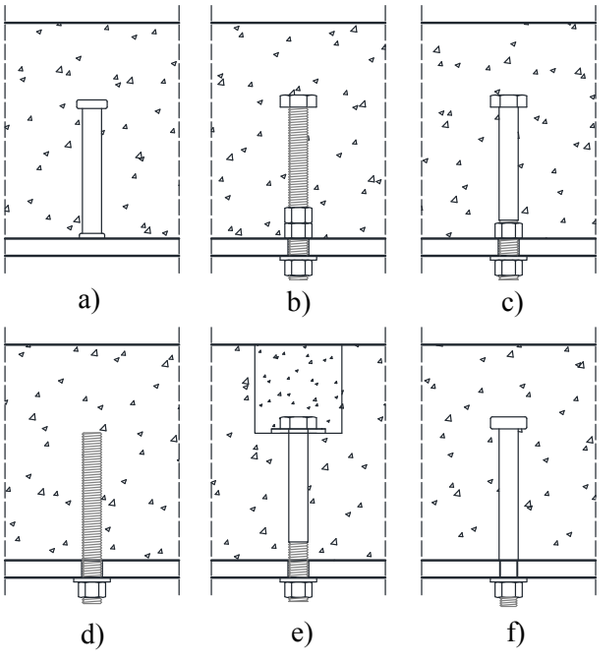
Behavior of an innovative demountable steel-concrete connector under static loading

Fei Yang, Yuqing Liu
Department of Bridge Engineering, Tongji University, Shanghai, People's Republic of China

ABSTRACT: Using suitable bolted connectors in lieu of conventional welded stud connectors may have great advantages in terms of the accelerated construction of composite bridges and the concrete slab replacement considering the life-cycle design of composite bridges. An innovative demountable steel-concrete connector, which mainly consists of a short bolt, a long bolt and a coupler, is proposed in this paper. Compared with other existing demountable bolted connectors, the proposed innovative demountable connector could render the dismantling of concrete slabs more convenient. Static push-out tests are carried out on three groups of demountable bolted connector specimens for investigating their failure mode and the fundamental mechanical behavior. The test results demonstrate that the failure mode of proposed demountable connectors is that the shank of short bolts is sheared off directly without local concrete crushing under couplers. The shear bearing capacity can be approximately estimated as 0.8 times of the tensile strength of short bolts. The peak slip of the steel-concrete interface grows with the increase of the bolt shank diameter. The clearance between bolt shank and bolt hole has an effect on the shear stiffness of innovative demountable connectors. The fundamental mechanical behavior of the innovative demountable connector can be a reference for the connector arrangement in the steel-concrete interface of composite bridges employing the proposed innovative bolted connector.
Keywords: composite bridge; demountable connector; shear behavior; push-out test; accelerated construction

1 INTRODUCTION

Steel-concrete composite superstructures have a great advantage in terms of the structural performance and the accelerated bridge construction especially exhibited in short to medium span continuous girder bridges (Brozzetti 2000; Nakamura et al. 2002; Hanswille 2011). In the construction of steel-concrete composite bridges, the welded headed stud connector has become the most prevailing connector for achieving the composite action between steel girders and concrete slabs owing to its outstanding mechanical performance and rapid welding technique. There also has been a comprehensive research production focusing on the mechanical behavior of the welded stud connector (Xue et al. 2012; Lin et al. 2014; Lin et al. 2016). On the other hand, if the concrete slabs of composite bridges deteriorate seriously under overloaded traffic scenarios and environmental actions, dismantling or strengthening of deteriorated concrete slabs are supposed to be implemented for extending the service life of composite bridges. However, it would be rather costly and time-consuming to dismantle the damaged concrete slabs which are fully attached to the upper flange of steel girders by welded stud connectors (Lachemi et al. 2007; Umphrey et al. 2007). In the design stage of the composite bridges, therefore, the issue of replacing the concrete slabs should be taken into account to improve the structural sustainability of composite bridges and to reduce the structural life-cycle cost.



Bolted connectors can be an option for the connection between steel girders and concrete slabs in composite bridges. A concrete slab attached to steel girders using bolted connectors could be dismantled more conveniently than using the most prevailing welded stud connector. Therefore, a reasonable configuration for the steel-concrete bolted connector is necessary and significant to realize the dismantling work of concrete slabs effectively. Currently, bolted connectors are rarely employed in the construction of steel-concrete composite bridges due to lack of detailed research and design specifications.

In this paper, an innovative demountable steel-concrete bolted connector is proposed after examining the existing researching on the demountable bolted connectors and comparing their configurational characteristics. The innovative demountable connector mainly consists of a long bolt, a short bolt and a coupler, which could render the dismantling of concrete slabs more convenient. Static push-out tests are carried out on three groups of demountable bolted connector specimens for investigating their failure mode and the fundamental mechanical behavior including shear bearing capacity, slip performance and shear stiffness. The experimental results for the innovative demountable connector can be a reference for the connector arrangement in the steel-concrete interface of composite bridges employing the proposed innovative bolted connector.

2 CONFIGURATION OF BOLTED CONNECTORS

2.1 *Existing bolted connectors*

Recently, there has been some research work in terms of using demountable bolted connectors to achieve the composite action between steel girders and concrete slabs. Figure 1 shows the configuration of the conventional welded stud connector and five types of existing demountable bolted connectors, and the configurational characteristics of those bolted connectors will be given a detailed explanation as follows.

a) Welded headed stud connector
b) Type I Double-nut bolt
c) Type II High-strength bolt
d) Type III Adhesive anchor
e) Type IV High-tension friction-grip bolt
f) Type V Headed stud bolt

Figure 1. Configuration of bolted connectors.

Kwon et al. (2010) proposed three types of post-installed bolted shear connectors for achieving the composite action in existing non-composite bridges built in America before the 1970s. Those three types of post-installed bolted connectors were called Double-Nut Bolt (Type I, Figure 1b), Adhesive Anchor (Type III, Figure 1d) and High-Tension Friction-Grip Bolt (Type IV, Figure 1e). The pretension in Type I bolted connector was only induced on the bolt shank between the upper and the bottom nuts, and the initial shear stiffness of this bolted connector could be improved by the pretension. The bolt in Type III bolted connector could not be pretensioned because of its special geometry configuration, and eventually this bolted connector was selected for application in strengthening the non-composite bridge owing to its simple configuration and low-cost installation. The through high strength bolt was exploited in Type IV bolted connector, which could attach the concrete slab to the top flange of steel girders. But the concrete adjacent to the bolt shank has to bear local compressive stress induced by the pretension of the high strength bolt.

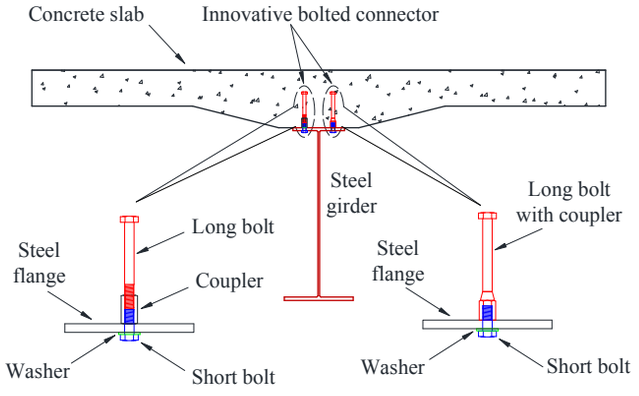
Pavlović et al. (2013) investigated the shear behavior of Type II demountable bolted connector through push-out experimental tests, and Figure 1c exhibits the configuration of this bolted connector. He believed the competitiveness of the prefabricated concrete slab could be improved through embedding Type II bolted shear connectors into the prefabricated concrete slab, and the prefabricated concrete slab could benefit the accelerated construction and of composite bridges. Moynihan & Allwood (2014) thought that a demountable connection between steel girders and concrete slabs could not only develop the composite action in the constructional stage but also permit the reuse of steel girders and concrete slabs after the dismantling the composite bridges at the end of their service life. Type II demountable bolted connector was utilized in the construction of the experimental composite beams, which were implemented in static loading tests for investigating the performance of the demountable bolted connector and the composite beam.

Chen et al. (2014) believed that a suitable bolted connector was needed to achieve composite action between steel girders and precast concrete slabs from the perspective of the accelerated construction of composite bridges. High-strength through-bolt connectors, whose configurations just like the High-Tension Friction-Grip Bolt (Type IV, Figure 1e) proposed by Kwon, were examined under static push-out tests. Liu et al. (2015) thought that an innovative demountable high-strength friction-grip bolt shear connectors (Type IV, Figure 1e) in composite beams could greatly enhance the sustainability of building infrastructures. Some practical design recommendations were proposed for predicting the shear bearing capacity and the load-slip curve of the bolted connector. The configuration of the last type bolted connector was proposed by Dai et al. (2015) They reformed the conventional welded headed studs into demountable bolted connectors which are depicted in Figure 1f. The configurational characteristic of Type V demountable bolted connector was that its shank diameter in the bolt hole was 1 to 3 mm less than the diameter of the shank embedded in concrete slabs. The mechanical performance of this type bolted connector is closer to that of the conventional welded stud connector.

2.2 *Proposed demountable connector*

An innovative demountable steel-concrete bolted connector as shown in Figure 2 is proposed for facilitating the dismantling work of concrete slabs in

composite girder bridges. There are two configurations for the demountable bolted connector which are exhibited in Figure 3. As is shown in Figure 3a, the proposed demountable bolted connector with Type I configuration consists of a short bolt, a long bolt, a washer and a coupler. The long bolt and coupler for Type I demountable connector could be manufactured as one component which could be seen in Figure 3b. The configuration of the proposed demountable bolted connector could be much simplified in Type II configuration, but the long bolt embedded in concrete slabs need to be specially produced by the manufacturer. In this research, the demountable bolted connector with Type I configuration will be examined since all components of Type I demountable connector could be obtained.



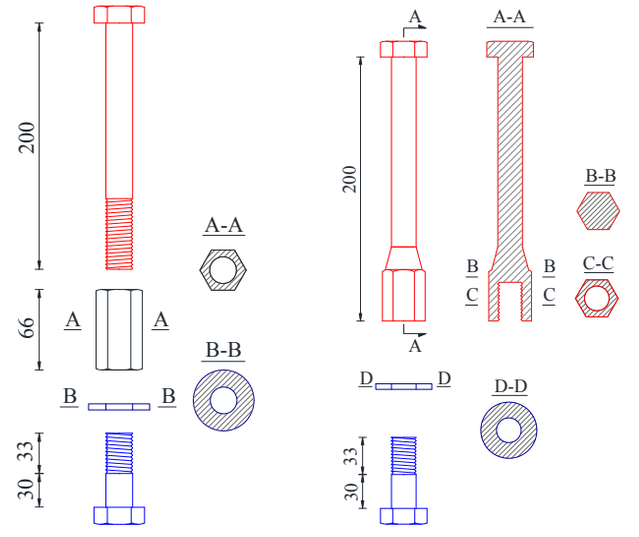


Figure 2. An innovative demountable bolted connector.

a) Type I configuration b) Type II configuration

Figure 3. Configurations of the innovative connector.

If the proposed demountable bolted connector is used in composite bridges with cast-in-place concrete slabs, the short bolt, washer and coupler should be installed firstly on the top flange of steel girders, and then the long bolt could be screwed into the coupler. Lastly, concrete slabs could be cast after the installation of the demountable bolted connectors. Whether imposing pretension on the short bolt or not depends on the mechanical requirement of the steel-concrete interface of composite bridges.

If the proposed demountable bolted connector is used in composite bridges with prefabricated concrete slabs, all components of the proposed demountable bolted connector should be installed on concrete slab formworks before pouring the concrete of slabs firstly. When the concrete strength of prefabricated slabs gets to the design target, formworks of concrete slabs should be dismantled along with short bolts and washers, and long bolts and couplers of demountable connectors are embedded in prefabricated slabs. When assembling the prefabricated slab on steel girders, shorts bolts and washers should again be screwed into couplers from the underside of the top flange of steel girders. Therefore, the position of short bolt holes in the top flange of steel girders should be drilled much accurately for the use of the demountable bolted connector in the prefabricated concrete slabs.

As is shown in Figure 2, when dismantling concrete slabs of composite bridges using demountable bolted connectors, screwing out the short bolts from the underside of the steel flange could separate steel girders and concrete slabs completely. However, if concrete slabs are attached to steel girders with the existing bolted connectors as shown in Figure 1, the nut below the steel flange should be removed first, and then concrete slabs need to be lifted up with the bolted connector embedded in concrete slabs to implement the dismantling work, which may be feasible but rather complicated. Consequently, the innovative demountable bolted connector could render the dismantling of concrete slabs more convenient.

In the following, static push-out tests will be introduced for investigating the failure mode and fundamental mechanical performance of the innovative bolted connector. The shear bearing capacity, load-slip curve and the shear stiffness of the innovative bolted connector will be discussed in detail.

3 DESIGN OF PUSH-OUT TESTS

3.1 *Program of push-out tests*

Table 1 exhibits the main variables for each group of push-out tests. There are three bolt diameters in total including M18, M22 and M27, and all their strength are grade 8.8 which means that the characteristic tensile strength of the bolt is 800 MPa and the yield-strength ratio of the bolt is 0.8. Type I configuration in Figure 3a shows the dimension of the long bolt, coupler and short bolt of the M22 demountable bolted connector. All the shank length of M18, M22 and M27 long bolts are 200 mm. The height of M18, M22 and M27 couplers are 3 times of their internal diameters, which are 54 mm, 66 mm and 81 mm, respectively. The shank length of M18, M22 and M27 short bolts are 57 mm, 63 mm and 70.5 mm, respec-

tively. To ensure the reliability of shear performance and tensile performance of the demountable bolted connector simultaneously, both the long bolt and the short bolt should be screwed into the coupler 1.5 times length of their internal diameters.

Table 1. Program of push-out tests.

Specimen	Strength	Diameter (mm)	Clearance (mm)	Concrete Age (days)
B1	Grade 8.8	18	0.15	57
B2			0.26	58
B3		22	0.31	60
B4			0.30	70
B5		27	0.51	68
B6			0.47	72

There exists clearance between the bolt shank and the bolt hole in the steel plate. The installation of short bolts may be difficult if the clearance is too small, while the shear stiffness of demountable bolted connectors may decrease if the clearance becomes much larger. So the clearance between the bolt shank and the bolt hole is set to be 0.2 mm up to 0.5 mm when drilling the bolt hole in steel plates. In the fabrication process of each bolted connector push-out specimen, the diameter of each bolt shank and the interior diameter of the corresponding bolt hole were measured for obtaining the clearance between the bolt shank and the bolt hole of each demountable bolted specimen. Table 1 lists the average clearance of four bolted connectors for each bolted push-out specimen. The actual average clearance for B1 to B6 specimens is between 0.1 mm and 0.5 mm. The average clearance for B5 and B6 specimens with M27 bolted connectors is much larger which is closer to 0.5 mm.

During casting the concrete of push-out specimens, standard prisms (150 mm × 150 mm × 300 mm) and cubes (150 mm × 150 mm × 150 mm) were cast at the same time. The concrete compressive strength was obtained from both the prism and the cube compressive tests, the concrete tensile strength was obtained from the cube splitting tests, and the modulus of elasticity of the concrete was determined using the prism compressive tests. The test material properties of the concrete are listed in Table 2. During the static push-out loadings, as shown in Table 1, specimen B1 was loaded with the shortest concrete age which was 57 days and specimen B6 with the longest concrete age which was 72 days. Therefore, it could be inferred that the concrete actual compressive strength of each specimen might exceed 50 MPa.

Table 2. Material properties of concrete.

Testing Age	Cube Strength (MPa)	Prim Strength (MPa)	Tensile Strength (MPa)	Young's Modulus (GPa)
7 days	34.8	32.9	—	38.75
28 days	48.9	43.4	4.62	40.63

3.2 *Strength of short bolts*

The axial tensile tests were carried out on M18, M22 and M27 short bolts of the innovative demountable bolted connector. Figure 4 shows the final appearance of M22 short bolts, and it can be seen that the necking deformation in the threaded part of each shot bolt is significantly obvious after the load-displacement enters into the descending branch.

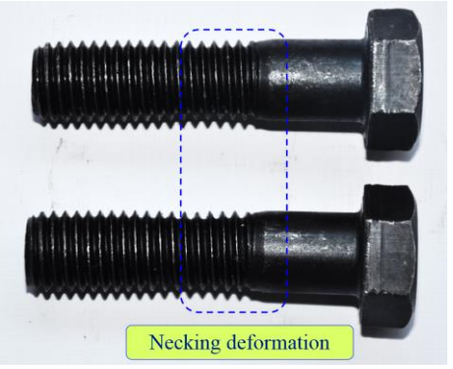

Figure 4. Failure model of tensile test for short bolts.

3.3 *Strength of connecting sleeves*

For investigating the connecting performance of the coupler in the proposed demountable bolted connector, axial tensile specimens were fabricated through using M18, M22 and M27 couplers to connect two long bolts whose diameter were consistent with corresponding couplers. In each axial tensile specimen, the long bolt threaded shank which was screwed into the coupler was 1.5 times of the bolt diameter. Figure 5 shows the failure mode of axial tensile tests for M22 axial tensile connecting specimens, and it can be seen that the fractured section locates in the threaded part of the long bolt. It can be concluded that the axial connecting performance of the bolt coupler whose height is 3 times of its internal diameter is reliable in the proposed demountable bolted connector.

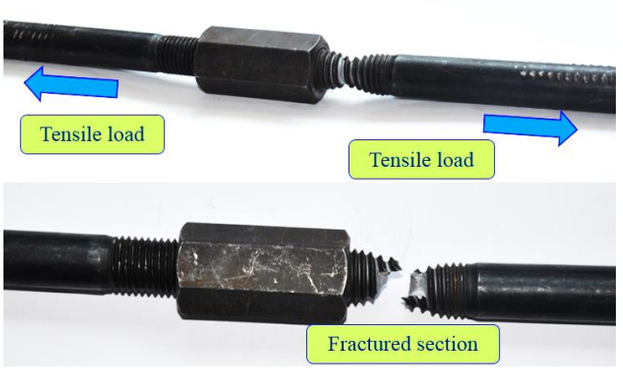

Figure 5. Failure models of tensile tests for couplers.

3.4 *Push-out specimens*

Figure 6 demonstrates the configuration of demountable bolted connector push-out specimens. There are four bolted connectors for each specimen. The trans-

verse spacing for bolted connectors is 200 mm, and the spacing to top and bottom of the concrete block both are 250 mm. The thickness of the concrete slab in the specimen for standard push-out test recommended in EN 1994-1-1 is only 150 mm, and the thinner concrete slab may result in a splitting failure mode of the concrete slab rather than the fracture of connectors due to their much higher shear bearing capacity (Pavlović et al. 2013). Therefore, the concrete blocks in push-out specimens are designed as a cube with 500 mm edge. In the concrete block, some HRB 335 (Hot-rolled Ribbed Bar with 335 MPa yielding strength) rebar with 16 mm diameter reinforces the concrete block, whose transverse, longitudinal and vertical spacing all is 400 mm.

The thickness of the steel plate adjacent to the concrete block is set to be 30 mm for preventing that the wall of the bolt hole occurs bearing failure mode. The thickness of the web of the push-out steel member is also 30 mm. The height of the push-out steel member is 500 mm, and the width of the flange and web are 400 mm and 200 mm, respectively. The distance from the bottom of the push-out steel member to that of the concrete block is 50 mm considering that the maximum slip would not exceed 20 mm.

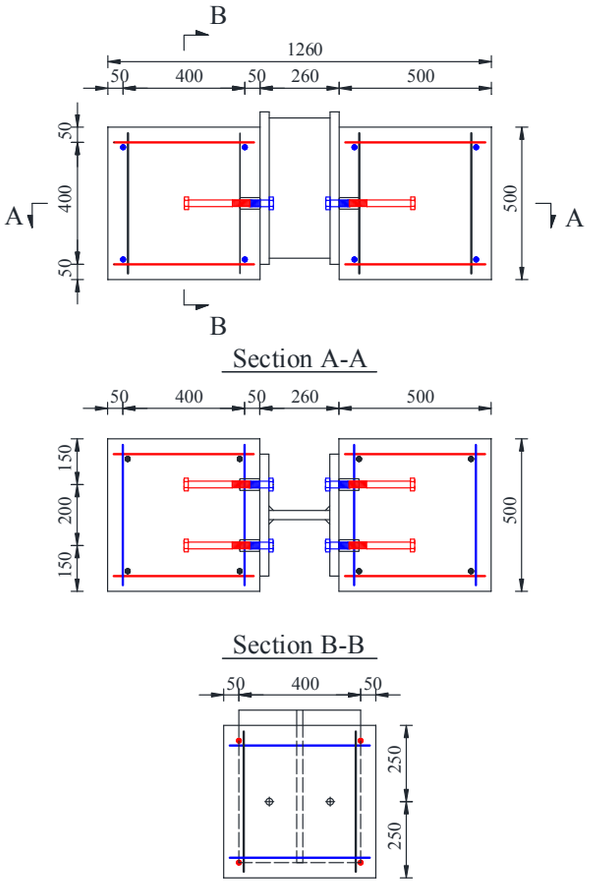

Figure 6. Details of push-out specimens / mm.

The push-out specimen with M18 and M27 bolted connectors before casting concrete is shown in Figure 7. In the installation of bolted connectors, an ordinary wrench was used to screw short bolts and long bolts into couplers. Therefore, there is almost no pretension induced in short bolts. The concrete of all the specimens was cast using the ready mixed C50 concrete.

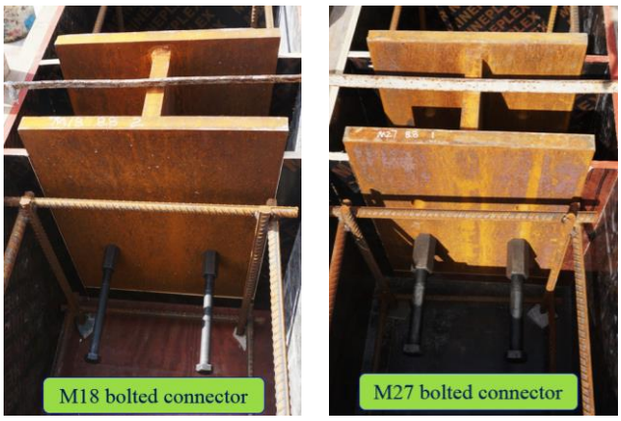

Figure 7. Push-out specimens before casting concrete.

3.5 *Schedule for loading and measurement*

Figure 8 shows the test set-up of push-out experimental tests. The push-out tests were performed through a hydraulic jack with a total capacity of 2000 kN. At the bottom of the concrete blocks, a layer of fine sand was paved to reduce the concentrated reaction force between the specimen and the testing ground. Each push-out specimen was equipped with four displacement transducers to monitor the vertical slip between the concrete block and the steel plate. In the following analysis of the slip data, the average value of the four vertical displacements was taken as the representative slip for each specimen.

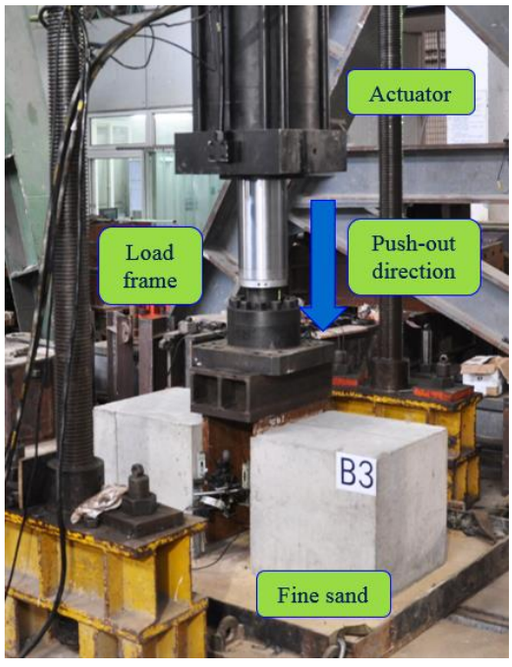

Figure 8. Loading set-up of push-out tests.

The loading schedule recommended in EN 1994-1-1 was followed for investigating the shear behavior of steel-concrete connectors. In the loading schedule, the push-out load was first applied in increments up to 40% of the expected failure load and

then cycled 25 times between 5% and 40% of the expected failure load for examining the service performance of the connector. After the cycling load, subsequent load increment was imposed until the fracture of the shear connector for investigating the failure mode and the mechanical behavior of the connector in the ultimate shear state. Force-controlled loading was applied in the cyclic loading, and the loading rate was approximately 5 min/cycle which was assumed to be quasi-static loading. Displacement-controlled loading was applied in the last stage loading, and the displacement loading rate was 0.3 mm/min.

4 ANALYSIS FOR PUSH-OUT TESTS

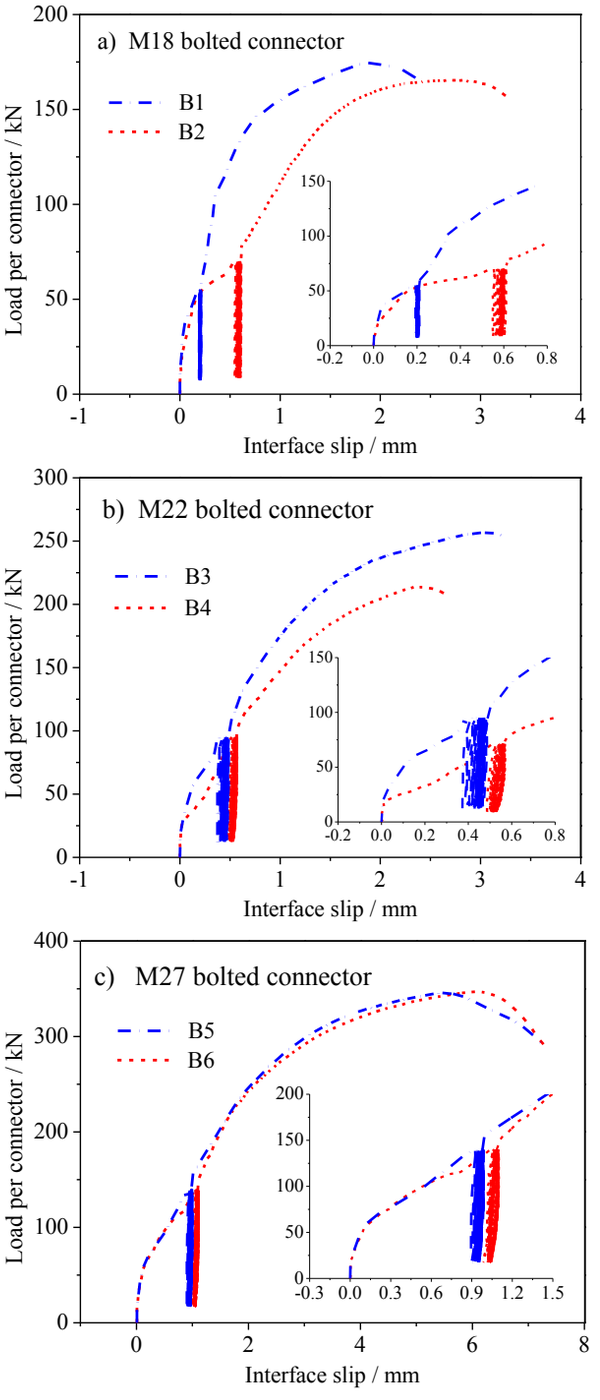
4.1 *Failure mode*

Figure 9 shows the failure mode of the demountable bolted connector specimen under static push-out tests. The failure mode of three groups of demountable bolted connector specimens all is that the short bolts are sheared off directly. As is shown in Figure 9a, there are only a few small cracks without local concrete crushing phenomena under couplers after the shearing off of the short bolts for each specimen. The coupler embedded in the concrete of bolted connector specimens enlarges the interface area between bolt shank and the ambient concrete, resulting in that the local compressive stress of the concrete under the connecting sleeve is much lower and that the interface slip also decreases. As is shown in Figure 9b, the final failure mode of the short bolts for each bolted connector specimen that the fractured section of the short bolts are extremely even, therefore, the bolted connectors could be considered to be a brittle facture mode.

Figure 9. Failure modes of bolted connectors.

4.2 *Test results*

Figure 10 shows the load-slip curve of each push-out specimen, and the vertical axis represents the average load of the four demountable bolted connectors. There are five stages in the load-slip curve of the innovative bolted connector including bolt shank slipping stage, cyclic loading stage, linear stage, nonlinear stage, and the descending stage.



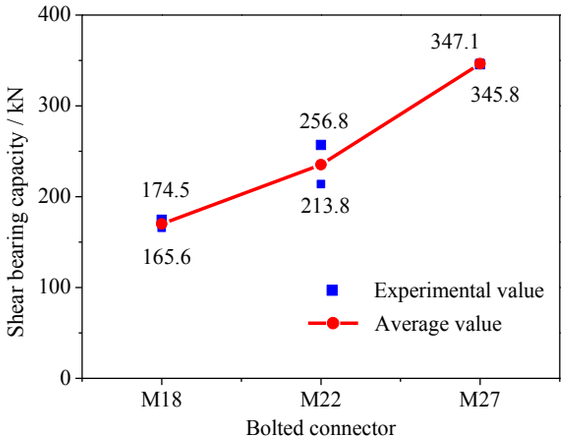


Figure 10. Load-slip curves of push-out specimens.

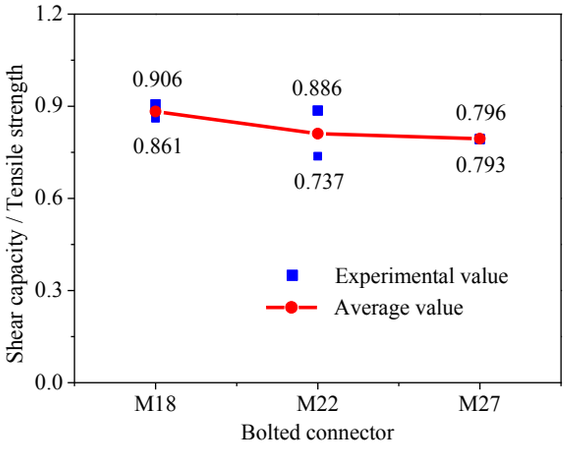
Due to the clearance between the bolt shank and the bolt hole of the innovative bolted connectors, it can be observed that the clearances have a significant effect on the shape of the load-slip curves of the push-out specimens especially for B2 and B4 specimen. When the initial loading gets to the 40% of the expected failure load, the slip between the bolt shank



and the bolt hole for each push-out specimen all has occurred. The load-slip curve in reciprocating loading is much closer to that in unloading process, and the shear stiffness in the cyclic loading stage is obviously larger than that in the initial loading stage. After the cyclic loadings, the load-slip curves for each bolted connector push-out specimen could increase linearly and then enter into the nonlinear stage until the ultimate shear bearing capacity. The descending branches of the load-slip curve for each bolted connector push-out specimen is rather short. Besides, there was loud sound when short bolts were sheared off, demonstrating that the failure mode of the innovative bolted connectors is much brittle compared with that of welded headed stud connectors.

4.3 *Shear bearing capacity*

Figure 11 exhibits the distribution of the shear bearing capacity of three groups of demountable bolted connectors. All the shear bearing capacity experimental results of six push-out specimens are illustrated in Figure 11a. The ratio distribution of the shear bearing capacity of the corresponding tensile strength for each push-out specimen is shown in Figure 11b.

a) Shear bearing capacity

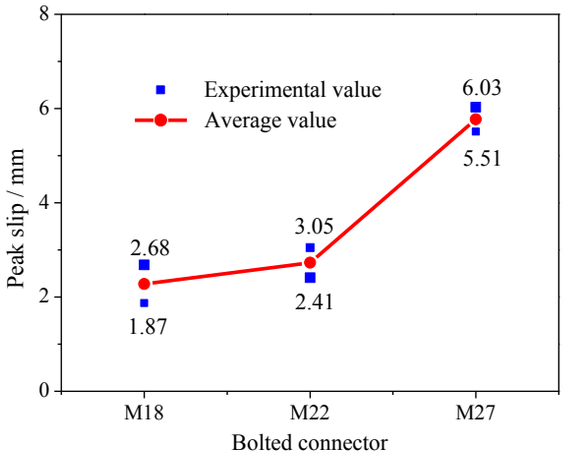
b) Comparison with tensile strength

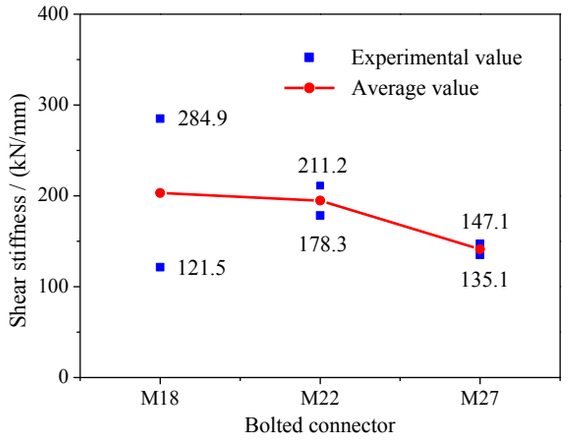
Figure 11. Shear bearing capacity of bolted connectors.

For M18 bolted connectors, the shear bearing capacity is about 0.88 times of their tensile capacity, which is the maximum ratio in three groups of demountable bolted connectors. The average ratio of the shear bearing capacity to the tensile capacity for M22 and M27 bolted connectors is approximately 0.80.

4.4 *Peak slip*

The peak slip for each push-out specimen is defined as the slip corresponding to the ultimate shear bearing capacity. Figure 12 shows the peak slip for three groups of demountable bolted connectors. The peak slip would grow gradually as the bolt diameter increases. The average peak slip for M27 bolted connectors is 5.77 mm, which is closer to the ductile connector's minimum slip requirement specified in EN 1994-1-1. In addition, due to the peak slip of the demountable bolted connector is much smaller than that of conventional welded stud connector, the maximum slip of the steel-concrete interface used demountable bolted connector should be limited strictly.





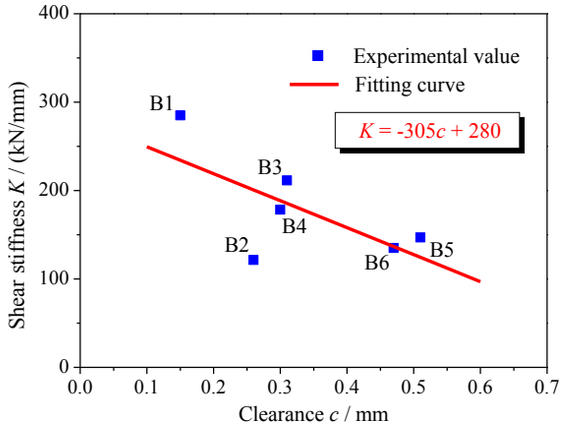


Figure 12. Peak slip of bolted connectors.

4.5 *Shear Stiffness*

The shear stiffness for the demountable bolted connector is defined as the ratio of the half of the shear bearing capacity to the corresponding slip value. Figure 13 shows the shear stiffness distribution of the innovative bolted connectors. It can be seen from Figure 13a that the shear stiffness of M18 bolted connectors are extremely discrete, and the shear stiffness of other two groups bolted connectors are approximately similar. Therefore, it can be concluded from Figure 13a that there is little correlation between the shear stiffness and the diameter of demountable bolted connectors.

a) Shear stiffness

b) Comparison with bolt hole clearance

Figure 13. Shear stiffness of bolted connectors.

Figure 13b illustrates the relationship between the shear stiffness of demountable bolt connectors and their corresponding bolt hole clearance. The shear stiffness of each bolted connectors exhibits a decreasing tendency with the increase of the clearance between the bolt shank and the bolt hole. The average clearance for B5 and B6 specimens is about 0.5 mm, and the shear stiffness for those two specimens is in the order of 140 kN/mm. Much lower stiffness of connectors may result in that the slip in the steel-concrete interface may need to be considered in composite beam deflection calculations.

5 CONCLUSION

1) An innovative demountable steel-concrete connector, which mainly consists of a short bolt, a long bolt and a coupler, was proposed for rendering the dismantling of the concrete slab in composite bridges more conveniently.

2) The failure mode of four groups of bolted connector specimens is that the short bolts are sheared off directly. There are only a few small cracks without local concrete crushing phenomenon under the coupler after the fracture of the short bolts for each specimen.

3) The shear bearing capacity of each bolted connector can be predicted as 0.8 times of the bolt characteristic tensile strength. The peak slip of each bolted connector specimen grows with the increase of the bolt diameter of grade 8.8 bolted connectors.

4) There is little correlation between the shear stiffness and the diameter or strength of the bolted connector, while the shear stiffness of each bolted connector exhibits a decreasing tendency with the increase of the clearance between the bolt shank and the bolt hole.

A new era of steel bridge service life

F. Piccoli, R. Pavan, E. Siviero
AP&P srl, Italy

ABSTRACT: European bridges need refurbishment and strengthening to meet new demands of higher loads and new codes. Three distinctive ideas with potential of saving costs for the European community, reducing the environmental impact for the same result and minimizing the traffic disturbance. New composite action or strengthening of existing shear connectors by post installed shear dowels. Box action by horizontal trusses between the bottom flanges of I-girder bridges, transferring the very fatigue-sensitive I-girders into box girders. Effective strengthening of old truss bridges.

1 INTRODUCTION

Since the road traffic and the loads have increased in a much more significant way than for rail traffic, there are not so many steel road bridges left from the first half of the 20:th century. Early steel bridges for road traffic with concrete deck were often not built as composite ones, but during the last decades composite bridges have become a popular solution in many countries around Europe. The competitiveness of composite bridges depends on several circumstances such as site conditions, local costs of material and staff and the contractor's experience. However many bridges for road traffic will have to be either strengthened or replaced the next decades, where the first alternative can save not only investment costs but also less disturbance for the traffic running on or under the bridge, a fact that is often neglected when deciding for different options for a bridge. The European railway network is one of the busiest in the world and it is necessary to have a reliable railway system. In order to prevent disruptions, the track must be in perfect shape. Preventing rail track maintenance is of extreme importance. Preventing corrosion protection maintenance is another important aspect. Also, in very densely populated areas, noise emission of existing steel railway bridges, forms a serious problem. Preventing maintenance and noise emission strongly influence the competitiveness of steel bridges. At the end of the 19th century up to about 20 years ago, steel bridges were built without any attention paid to noise emission, long-life exercise, increasing traffic magnitude and quantity. It was more or less accepted that steel bridges needed also a lot of maintenance. Therefore, we have in Europe, as probably elsewhere in the world, a heritage of steel bridges with high maintenance costs. These bridges have therefore a very bad reputation from environmental point of view. The upgrading of the European infrastructural system for more and heavier traffic show that the designs of many existing bridges are critical and therefore actions are necessary. In Europe, many bridges were built just before and after the Second World War. These bridges have in most cases a traditional deck design consisting of girders or trusses. In order to prevent incrementing costs of maintenance, easy and fast solutions to repair these bridge types are needed.

2 LITERATURE ANALYSIS

As reported in the aforementioned step level classification, various stages of analysis could be adopted by bridge owners or managing agencies. Some examples have been developed by the author and could be found in detail in Pipinato (2016) the assessment of a new bridge is presented in order to evaluate different typologies of construction alternatives to gain different lifetime; while in Pipinato (2014) the assessment and rehabilitation of steel railway bridges using fibre-reinforced polymer (FRP) composites in the particular situation of the rehabilitation of metallic civil infrastructure using fiber reinforced polymer (FRP) composites is evaluated. The residual life of historic riveted steel bridges could be also assessed with an analytical approach or introducing an orthotropic steel deck design to extend the lifetime of plate and box girder bridge and viaducts, as explained in Pipinato et al. 2014 and in Pipinato (2014a). And however steel bridge exhibited in the past a wide amount of problems not evi-

denced in other bridges (Pipinato 2014b), for this particular type of structure a variety of technologies to repair and retrofit are available: this is the case reported for the fracture propagation and life cycle design of girders (Pipinato 2014c), or for advanced solutions of the corrosion protection (Pipinato 2014d). For network of bridges, however, an integrated solution has been presented in order to understand what is the possibility of prioritize the bridge retrofit (Pipinato 2013a). A particular asset of bridges in which the lifecycle assessment should be performed from the design stage is the case of long span bridges, where the traffic is represented also from exceptional moving loads and the consequent fatigue expected lifetime could fail in less than ten years from the construction stage if a correct detailing is not perceived (Pipinato 2013b-2013c-2010d); similar issues comes also from the original construction alternative choses, as demonstrated in Pipinato et al. 2012a. The particular case of fatigue sensitive materials of course is more recurrent in steel bridges where retrofit and assessment alternatives are in part applied (Pipinato 2012b), in part not well investigated, as is the case of coupled damages (seismic and fatigue, Pipinato 2012a,b, Pipinato et al. 2012c,d,e,f, Pipinato et al. 2011c,d). Wherever there is the possibility to investigate with full scale tests existing bridges, e.g. where managing agencies are interested to know the structural behavior of recurrent structures along their network, this could be an interesting occasion to understand how materials decay could influence the static and fatigue behavior of bridges: this is the case both of railway (Pipinato et al. 2011a,b, Pipinato 2011, Pipinato 2010b, Pipinato et al. 2010a,b,c,e Pipinato 2010, Pipinato et al. 2009, 2008a,b, Pipinato et al. 2007) and roadways (Pipinato 2010a). A particular and further subset is represented by monumental and large bridge structures (Pipinato & Modena 2010): in this case, a long and time-consuming but useful procedure should be performed, by evaluating al the assessment steps described before, in order to understand in detail the aforementioned problems that could influence the final retrofit design decision.

3 RETROFIT PROPOSALS

3.1 *New composite action or strengthening of existing shear connectors by post installed shear dowels*

Many older steel bridges are constructed with a non-composite concrete slab over steel girders. A potentially economical means of strengthening these floor systems is to connect the existing concrete slab and steel girders to permit the development of composite action. Composite action means that the steel girder and concrete can help each other out carrying the loads more efficiently than in the original nanocomposite condition. To achieve the benefits of composite action, the existing steel girder must be connected to the existing concrete slab to permit the transfer of shear forces at the steel-concrete interface. For new bridges, composite action is achieved by welding shear studs to the top of the steel girder prior to casting the concrete slab. In the case of an existing bridge, this approach is not possible, since the slab is already in-place. One alternative is to make holes in the slab and weld studs to the top flange, but that interrupts the traffic and means that the water proofing and asphalt of the bridge must be done once again. Perhaps even worse, the transversal re-bars of the deck will be broken when making holes for shear connectors, and that means that e.g. the cantilevers will loose their capacity in bending since they are depending on the top layer of the re-bars in tension. Hence, the best thing would be to develop methods for post-installing shear connectors. In the case of existing bridges, strengthening by welded shear studs is only suitable if the bridge can be closed for quite a long time. The strengthening work often involves the following steps: removal of pavement and waterproofing, water jetting to remove the concrete, welding of new shear studs, casting concrete, re-waterproofing and resurfacing. Spring pins or coiled spring pins (Figure 2), offer the possibility of performing the whole installation from below the bridge deck without interrupting the traffic on the bridge. This is possible since the pins are connected to the steel and concrete only by a force created by the compressed coiled spring pin itself. This is a major advantage of interference fit shear connectors in bridge applications, compared to the other types of shear connectors. Coiled spring pins can be used as shear connectors either to create or to strengthen the shear connection between steel and concrete. In the first case, there will be only one type of shear connector at the shear interface, which makes it easy to establish design assumptions. However, since there are no heads on the coiled spring connectors, the uplift forces must be considered in design. In the second case, there will be at least two different kinds of shear connectors at the shear interface. This implies that the distribution of shear forces between the different shear connectors must be established. This is essential when a structure is strengthened due to insufficient fatigue capacity in the shear connection. It is, however, less important for static load in the ultimate limit state.

An application has been performed onto the Pitsund bridge in Sweden: the Pitsund-bridge is a seven span bridge, with a total length of 399 m and a free width of 9 m, see Figure 3. The superstructure consists of steel girders with a concrete deck slab on top, in six out of seven spans. The seventh span is a movable span, designed as a bascular bridge with two leafs. In 2006, coiled spring pins were installed in a part of the bridge in order to create composite action and to avoid sudden movements in the steel-concrete interface, which created loud bangs in wintertime.

Figure 1 Pitsund-bridge (Collin et. al 2015).

In the area marked with red, there are no shear connectors, only a few anchoring steel bars that connect the steel and the concrete over the supports. In the blue area, the bridge was designed and constructed as a composite structure (year 1984). The shear connection was created by welded headed shear studs. The green area was originally designed with no composite action and remained so until year 2006. Then 1200 coiled spring pins were installed in order to create composite action. Then the bridge was monitored under known loads, to understand differences in the structural behavior: one conclusion from the measurements is that the coiled spring pins can be used to create composite action in non-composite steel concrete bridges, even though they behave a bit different compared to shear studs at low load levels. The tests indicate that that there is a need of a small initial slip, or compression of the pins, before the coiled spring pins starts to transfer shear forces to a greater extent. FE-models have been created for the bridge, simulating different types of shear connections. A comparison between FE-models and the field monitoring will be presented in a future paper.

3.2 *Box action by horizontal trusses between the bottom flanges of I-girder*

For I-girder bridges the loads from the weight of the steel and concrete generally are evenly distributed between the girders, just like for box girder bridges. For I-girder bridges however, that is not the case. For smaller bridges with two I-girders the concrete deck is often assumed to be simply supported on the girders, meaning that a concentrated load on top of one girder is designed to carry all loads, with no help from the other girder. In reality the torsional stiffness of the deck and the warping stiffness of the whole composite section however transfer some of the load so the real distribution can be something like 85% for the loaded girder and 15 % for the other girder. Tests on the bridge over Rokån have shown good agreement with FEM simulations (Hällmark et al, 2013). For a box section however, the two parts of the section (left-right) will deflect almost the same, thus sharing the load almost equally When strengthening old I-girder bridges in composite action, one of the most powerful concepts is to simply make the cross section act like a box section, by adding a horizontal truss between the bottom flanges. This means that the eccentric loads produce a torsional moment that will be carried be shear forces around the section. The preferred type of truss is a K-truss, since other types will force the diagonals to take part in the global bending, which will make them sensible to buckling between the joints. This means a lot in the Ultimate Limit State, but even more in the Fatigue Limit State. For example, a reduction of the bending stresses in the bottom flange with 50%, and m=5 in the Wöhler diagram, could very roughly make the remaining life time 32 times longer. The top flanges in midspan on the other hand do get very low fatigue stresses after the concrete has hardened, so fatigue is usually not a problem here. In France this technique is used for new railway bridges, in order to make the dynamic behavior for the torsional mode much better. In Finland the concept has been used for new road bridges to lower the stresses in each I-girder from the traffic (Collin et. al 2015).

3.3 *Effective strengthening of old truss bridges*

Almost all steel truss railway bridges that have been built some decades ago, are with open decks. The open deck has the following disadvantages from nowadays point of view:

- The load bearing capacity of deck elements is sometimes not sufficient for nowadays increasing axle loads and train speeds although the main load bearing parts usually have some reserves
- High level of noise emissions during passing of the trains, which is unacceptable in rural areas;
- Difficulties during maintenance of the track;
- Significant differences between the elastic properties of the track on the bridge and outside the bridge discontinuity;
- Increased vibrations;
- High risk of fatigue crack initiation in deck elements and connections;

These are mainly problems not considered at the time these bridges were designed. Sometimes the above mentioned disadvantages become a reason for the railway administrations to replace these bridges even though the main trusses might have enough bearing capacity to face the increased live loads or are still in good condition to be kept for some decades in service. This was the case in Forsmo Railway Bridge (Sweden), built in 1912, in which the main structure was able to carry higher loads than the design loads, but the deck elements (longitudinal beams and cross beams) could not. As a result of that a replacement, invented and designed by Ramböll, of the deck was done (see Figure 2), which has led to considerable saving of money (appr. 25 MEuro), compared to a new bridge and also prolonged the lifetime of the bridge. The exchange of the bridge deck was carried out in 20 stops 8 hours each, which means that the trains could roll as usual. This was especially important since a stop would have cut off the train traffic (Collin et. al 2015).

Figure 2 Forsmo bridge deck substitution (Collin et. al 2015).

The fatigue problems of the directly loaded structural elements (longitudinal deck beams) and their connection details were also identified during upgrading programme of the Dutch railway system. The proposed strengthening approach is replacing the bridge sleepers by especially designed silent bridge® decks, a design with an acoustically optimal plate thickness configuration and rails embedded in a trough using corkelast, developed by de Silent Bridge Group, the stresses in the longitudinal girders can be reduced and therefore the lifetime increased (see Figure 3).

Figure 3 Silent bridge® deck new installation (Kuhn et al. 2010).

Other applications deals with the substitution of existing steel deck with new UHPFRC decks, in order to extend the life of railway trusses. The chosen sample bridge is a steel truss railway bridge designed in 1896 situated in the town of Vienna over the river Wien. It is 120 years old and it is still in operation. Originally designed for railway traffic, but at the moment the bridge is operated by town's metro line No. 4. The superstructure is twin steel truss beams simply sup- ported with a span of 50,92m. This retrofit solution is proven to be effective in "compensating" the additional dead load not only for ULS checks of the main truss element, but also for fatigue behavior and SLS checks. For retrofitted bridge, in this case, it is shifted from 4,2Hz to 3,4Hz, which is well in the middle between upper and lower limits. In terms of deflections, due to the higher stiffness, the deflection from vertical traffic load is reduced from 66mm to 40mm (with 40%). Both values satisfy the traffic safety criteria of L/600=85mm Figure 4

Wien truss railway bridge (Collin et. al 2015).

4 CONCLUSION

European bridges need refurbishment and strengthening to meet new demands of higher loads and new codes. Three distinctive ideas with potential of saving costs for the European community, reducing the environmental impact for the same result and minimizing the traffic disturbance. New composite action or strengthening of existing shear connectors by post installed shear dowels. Box action by horizontal trusses between the bottom flanges of I-girder bridges, transferring the very fatigue-sensitive I-girders into box girders. Effective strengthening of old truss bridges. All these solutions have been demonstrated to be effective to reduce the common procedure to demolish existing bridges, by adopting conservation procedures able to retrofit and prolong the lifetime of relevant infrastructures along European.

E.J. Kruger
Bridge Network Manager, The South African National Roads Agency SOC Ltd, South Africa.

ABSTRACT: This paper focuses on how environmental loads should be taken into account in the design and construction of durable integral bridges with reference to South African conditions. Specific reference will be made to the Van Zylspruit River Bridge, a 90m long, fully integral bridge located on the South African National Roads Agency SOC Ltd (SANRAL) National Route N1. The bridge has been extensively instrumented and since the end of 2015 the structural response to the environmental conditions have been recorded. Some of the trends observed are discussed in this paper.

1 INTRODUCTION

In an effort to promote the design and construction of reduced maintenance bridge structures in South Africa, The South African National Roads Agency SOC Ltd (SANRAL) together with the Civil Engineering Department at the University of Pretoria, has instrumented a newly built long (90m) concrete integral bridge. This structure will be monitored for the next few years to assess the effect of environmental factors on the behaviour of integral bridges taking the South African climate (hot and dry) into account.

Integral abutment and pier bridges have been designed for a number of years to replace traditional jointed bridges because expansion joints and bearings can affect the durability of bridges. Not only are water leaking and maintenance issues of expansion joints minimized, but the use of integral structures can also result in good resistance to earthquakes; quicker construction; and lower total life-cycle costs (initial construction costs and maintenance costs) when compared to jointed bridges. However, there are some design challenges that need to be addressed.

Eliminating joints and bearings from a bridge deck not only introduces restraining forces into the deck which can cause cracking, but also results in a complex soil-structure interaction problem into bridge design involving the relative movement between the bridge abutment and the retained soil behind the abutment. Consequently integral construction is susceptible to similar problems common to the construction and maintenance of jointed bridges for decades, such as early age transverse bridge cracking, especially in areas of top slab tension such as over pier supports. This is generally more evident is reinforced concrete bridges, such as Van Zylspruit River Bridge, as opposed to prestressed concrete bridges.

Some of the causes of early age transverse cracking in bridge decks include differential thermal gradients in fresh concrete due to heat of hydration conditions that take place during concrete placement; finishing and curing as well as initial differential shrinkage. The adoption of integral-type bridges does thus not eliminate some of the troublesome problems in highway bridge construction (Burke, 2009).

It is also important that construction site staff are informed of the differences between integral bridge behaviour and jointed bridges. If the structural concepts are appreciated this can result in specific attention to the important details during construction such as backfill material behind integral abutments.

This paper will discuss some of the observed environmental loading in the Van Zylspruit bridge up to October 2017 which could contribute to deck cracking such as:

- Heat of hydration,
- Changes in effective bridge temperatures,
- Transverse temperature variation, and
- Deck shrinkage.

- Thermistor

Figure 2. Typical deck cross section showing the thermistor layout in Span A-B

2 BRIDGE MONITORING

The Van Zylspruit River Bridge is a reinforced concrete, 5 span, 90.45m long, integral bridge with spans as shown in the long section in Figure 1. The deck is solid (i.e. no voids), 14m wide and varies in thickness, with two 1m deep beams connected to 250mm thick flanges (see Figure 2). The deck is monolithic with the piers and fully integral with the abutments. The bridge is located on the SANRAL National Route N1 in central South Africa (about 1000 km North of Cape Town), an area known for its harsh climate with both high and low temperatures. The bridge has been extensively instrumented to measure the environmental effects on the structure, and numerous samples taken to determine the material properties.

The instrumentation was installed during construction, and the data from this instrumentation has been logged continually during the construction phase and onwards. Instrumentation includes over 200 thermistors and 110 vibrating wire strain gauges, as well as earth pressure cells, shape-accel-arrays at both abutments and tilt meters on all piers. The data from these sensors together with data from 6 shrinkage reference structures (built adjacent to the structure) provides a complete picture of the bridge deck and abutment behaviour.

The deck was cast in five (5) pours, starting with the central span CD, and moving outwards towards the abutments (See Figure 1). The first deck pour was on the 19th of September 2015, and the final deck pour on the 8th of December 2015. A cross section through the deck showing the position of some of the thermistors can be seen in Figure 2. The final sensor count is just over 550 with readings taken at 15 minute intervals, and all the data is logged remotely.

The bridge is part of a larger road construction project, and has thus remained closed to traffic and unsurfaced until August 2017 when it was surfaced with a 60mm asphalt layer and then opened to traffic shortly afterwards. In addition fibre optic instrumentation was also installed on the top and bottom surfaces of the deck to measure strain. However this paper does not deal with these results. A photograph of the competed structure is shown in Figure 3.

The measured concrete material properties of the specified concrete with 19mm Dolerite stone and CEM II/A-M (V-L) 42.5R cement is as follows:

28 day compressive cube strength: 60MPa
(Specified as 40MPa)

28 day split cylinder strength: 3.6MPa

28 day Modulus of Elasticity: 37GPa
(Design Assumption was 31GPa)

Coefficient of thermal expansion: $8.5x10^{-6}$/°C
(TMH7 Part 2 recommends 12 x 10^{-6})

250 Cylinder drying Shrinkage: 300με

Backfill sand density: $19kN/m^3$

The bridge abutment was backfilled between April and July 2016 using a wedge of single sized sandy material with an internal angle of friction of 35°. However prior to this the contractor's site staff mistakenly changed the backfill material to a cemented backfill. This was removed and the correct backfill material was then placed. This is mentioned to emphasise that all site staff must be aware of the requirements so as to eliminate uninformed changes on site.

Figure 3. Completed Van Zylspruit River Bridge

3 HEAT OF HYDRATION

The heat of hydration observed for the final deck pour in December 2015 (summer in South Africa) is shown in Figure 4. This graph was typical for all five deck pours, and an increasing trend was observed as the ambient temperature increased (see Table 1). The centre of the 1m thick beam heats up to almost 80°C during the hydration process, and takes just over 10 days to cool down. The flanges however only heat up to just over 50°C and cool down within 3 days of casting. The temperature in the flanges is already varying with the daily temperature while the beam concrete is still cooling down. For this section there is a maximum difference of 38°C between the centre of the deck and the flanges, which occurs as the flanges cool down at night while the beam heat of hydration is still high. These significant temperature differences could cause micro-cracking to occur in the flanges and they cool faster than the central beam.

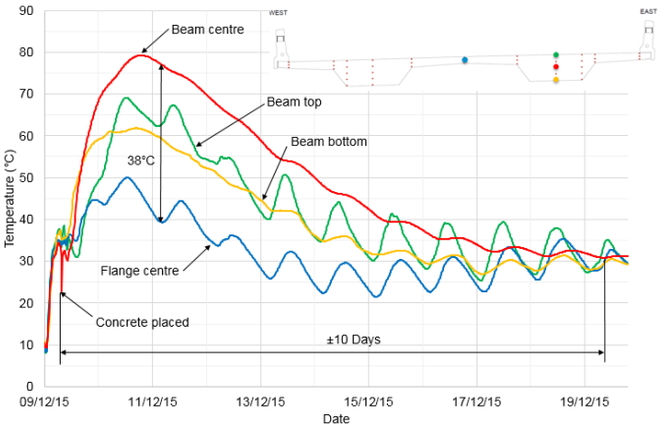

Figure 4: Heat of hydration observed in the deck (8 December 2015)

Table 1. Maximum and Minimum Ambient Temperature compared to Maximum Heat of Hydration.

Date Cast	Ambient Temperature		Max Heat of Hydration Temp	
	Max	Min	Beam	Flange
17/09/2015	10	25	68.65	42.47
16/10/2015	10	26	75.39	47.51
06/11/2015	15	32	73.54	43.18
02/12/2015	24	30	78.73	55.28
09/12/2015	23	33	81.31	57.28

Table 1 shows an increase of 12.7°C in maximum heat of hydration in the beams, and 14.8°C increase in maximum heat of hydration in the flanges as the maximum ambient temperature increase by ±8°C. The reason for a difference between the flanges and the beams could be attributed to the proximity of the formwork. The flanges are more affected by the steel shutters, which can heat up significantly on a hot day before concrete is placed and so affect the thinner sections more than the thicker sections. This could result in the increased maximum heat of hydration temperatures.

The maximum temperature difference between the middle of the beam and the flange generally occurred on the second night after the deck was cast, as the flanges decreased in temperature with the decrease in ambient temperature. Figure 5 shows how the maximum temperature difference between the beam and flange temperatures is dependent on

the maximum change in ambient temperature in a day-night cycle.

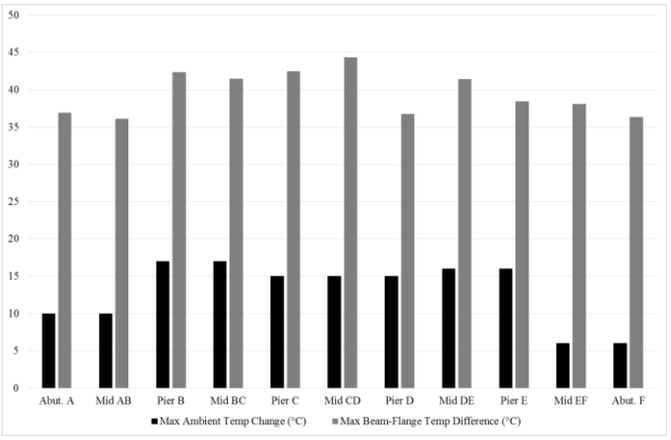

Figure 5. Maximum ambient temperature change compared to Maximum Difference in Temperature between the Flange and Middle of the Beam.

Work done by Kraus et.al. (1996) on transverse cracking in newly constructed bridge decks reports that a 28°C temperature change in the deck relative to the girder can cause stresses greater than 1.38MPa when the concrete has an early effective modulus of elasticity of only 3.5GPa, and greater than 6.89MPa when the early effective modulus is 17.2GPa.

Using an average 38°C temperature difference between the beam and flange:

$$\varepsilon_T = \Delta T \alpha = 323\mu\varepsilon \qquad \text{(Equation 1)}$$

Where:

ε_T = thermal strain
ΔT = change in deck temperature = 38°C
α = coefficient of thermal expansion = 8.5×10^{-6}/°C

Early age testing of the concrete shows a concrete tensile strength of 2.1MPa after 48hours, which is when the maximum temperature difference normally occurs. If the concrete is to remain uncracked the early are E value of the concrete is required to remain below 6.5GPa for 48 hours, which is highly unlikely.

$$E = \sigma/\varepsilon = 2.1\text{MPa} / 323\mu\varepsilon = 6.5\text{GPa} \qquad \text{(Equation 2)}$$

The data points towards the following preventative measures that can reduce early are cracking and reduce the maintenance requirements due to cracking of the structure:

- Limits on maximum and minimum ambient temperatures for casting bridge decks.
- Casting bridge decks while ambient temperatures are cool (i.e. at night) during summer.
- Delaying a deck pour if sudden changes in ambient temperature are expected (i.e. if a cold front is expected to pass through the area)
- Including additional secondary reinforcement, preferably smaller bar sizes and close spacing to limit crack widths.

4 EFFECTIVE BRIDGE TEMPERATURE AND AMBIENT TEMPERATURE

Temperature differences through the thickness of the deck can cause significant stresses and need to be considered in the design of the deck, however they do not have much effect on the bridge abutment design. Integral bridge abutments are affected by the change in the overall effective bridge temperature. The effective bridge temperature is defined as the temperature, which governs the longitudinal movement of the deck (Emerson, 1976). It is calculated from the sum of the product of area between isotherms and their mean temperatures, divided by the total area of the cross section of the deck. In practice it is difficult to locate the isotherms exactly and an approximation is made by dividing the cross section into areas. In essence it is a weighted average of the bridge temperature.

Figure 6 shows a normal distribution of the effective bridge, flange and beam temperatures separately, compared to the ambient temperature.

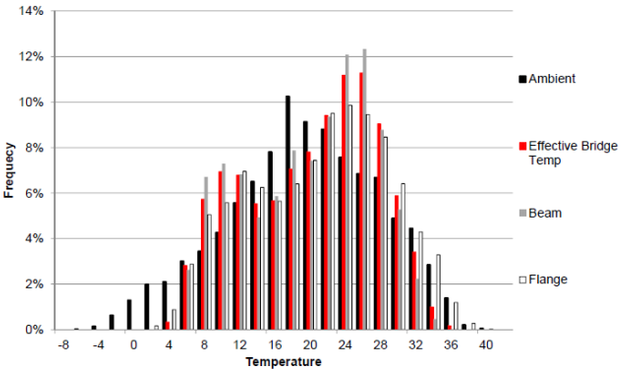

Figure 6. Normal distribution of effective bridge temperatures

One can notice the damping effect of the large solid beam on the thermal effects, which is consistent with work done by Black et al., 1976 when they investigated the influence of the shape of the cross section on the bridge effective temperature. They suggest that the effective bridge temperature is related to the area of the cross section of the deck per meter width of the deck.

Table 2 summarizes the maximum, minimum, average and standard deviation for the ambient temperature as well as deck, beam and flange effective temperatures.

Table 2. Maximum and Minimum Ambient Temperature compared to Maximum Heat of Hydration.

Date Cast	Ambient	Deck	Beam	Flange
Max	40.3	35.3	34.0	38.2
Min	-7.9	2.7	3.6	0.7
Average	18.4	17.7	17.5	18.2
Std. Deviation	8.5	7.4	7.1	7.8

5 TRANSVERSE TEMPERATURE VARIATION

Most design codes have detailed information on the vertical temperature gradient, but very little, if any, on transverse temperature variation. Lee (2012) investigated the effect of extreme environmental conditions of temperature gradients during construction of prestressed concrete bridge girders and found this temperature difference to be as high as 30°C in some States in America. Transverse temperature differences are effected by the cross sectional depth of the deck.

Thinner sections heat up and cool down faster than thicker sections, and if these differences are large enough transverse cracking can occur in the thinner sections of the deck. The effects of the solid concrete parapets should also be considered. The deck temperature measured 30mm below the surface at Van Zylspruit is plotted at 6 different points across the half of the deck for 5 days in January 2017 in Figure 7 as a cold front moved through the area. On a hot day the parapet caused the edge flanges to lag in temperature by up to 8°C, but as the ambient temperature cause the bridge temperature to drop so the parapet dampened the effect of the decrease in temperature so that there was a fairly uniform transverse temperature distribution during the cold period. Immediately after the cold spell the temperature difference re-occurred.

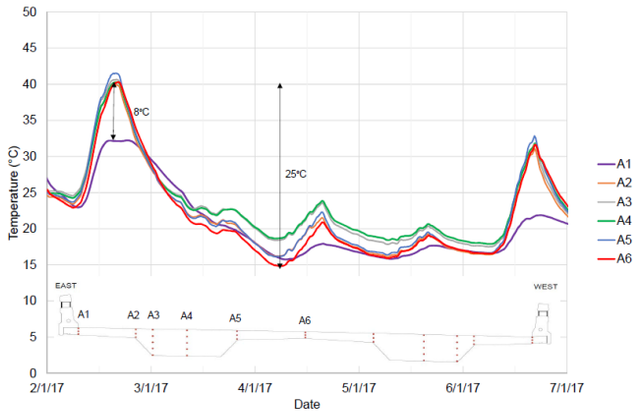

Figure 7. Top transverse temperature profile in summer

The deck temperature measured 30mm below the surface at Van Zylspruit is plotted at 11 different points across the deck for a typical hot day (Figure 8) and cold day (Figure 9), with and without parapets.

On a hot day the parapet caused the edge flanges to lag in temperature by up to 8°C, and on a typical cold day the parapet dampens the effect in the outside flanges resulting in a more even distribution of transverse temperature in the top of the deck

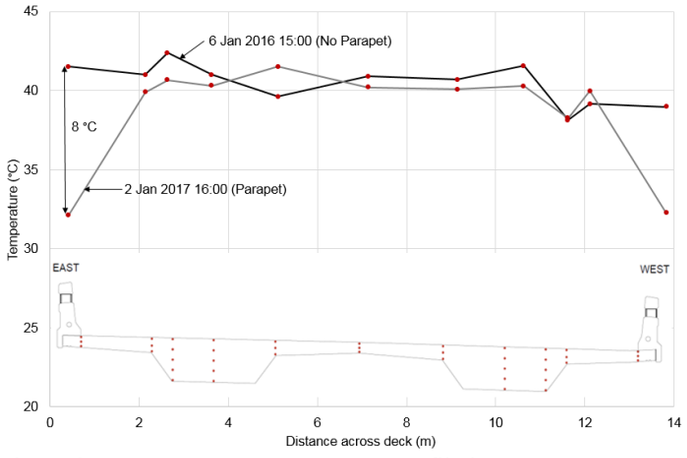

Figure 8. Top transverse temperature profile in summer

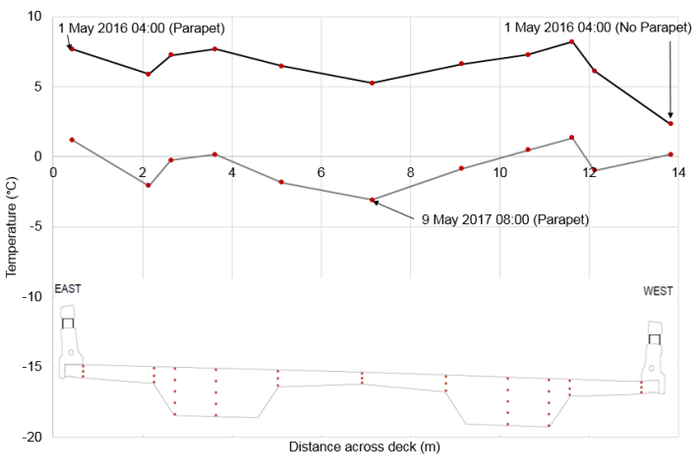

Figure 9. Top transverse temperature profile in winter

The temperature difference on hot days combined with the stiffening effect of the parapets could result in cracking of the edge flanges at the parapet joints. This type of cracking was observed at Van Zylspruit, particularly on the Western side of the deck, which gets the hottest in the afternoon. Additional secondary reinforcement, preferably smaller bars at close spacing could be considered at the flanges edges over the parapet joints. This has also been observed on another SANRAL bridge with thin cantilever slabs and concrete parapets.

6 MEASURED SHRINKAGE

The shrinkage at Van Zylspruit was measured with 6 reference structures:

- Two (2) unreinforced 250mm diameter, 500mm long cylinders were cast and placed in the shade under the bridge at Piers B and D, (see Figure 10).
- Two (2) 2000mm x 1000mm x 250mm thick panels (see Figure 11). One was unreinforced, and the other reinforced with the same percentage reinforcement as the bridge deck flanges. This is representative of the bridge deck flanges which are approximately 2m long and 0.25m thick. These panels are supported on 4 stub columns, one at each corner, with frictionless supports to allow free movement.
- Two (2) 1000mm x 1000mm x 1000mm thick blocks (see figure 11). One was unreinforced, and the other reinforced with the same percentage reinforcement as the bridge deck beams. This is representative of the bridge deck beams which are 1m thick. These blocks are supported on 4 stub columns, one at each corner, with frictionless supports to allow free movement.

Figure 10. Cylinder reference structure

Figure 11. Thin panel and thick block reference structures

Vibrating wire strain gauge were cast into all of these structures to measure strain and temperature. They were cast while the deck was poured, with concrete from the deck pour. They have remained on site for the entire project, thus being exposed to the same environmental conditions as the deck. The self-weight load on the reference shrinkage structures is so small that the effect of creep can be ignored and the strain readings are assumed to be purely shrinkage. There are again some gaps in the data where the batteries ran out of charge and where the logging systems had to be switched off to do the final configuration of the loggers. The shrinkage strain for the reference structures is shown in Figure 12.

The 250mm panels show a shrinkage after approximately 1.5 years of 180με, compared to 100με in the 1m thick blocks. The shrinkage of the panels and blocks occurred over a much longer period (compared to the cylinders). After approximately 1.5 years, both the panel and the block appear to have stopped shrinking

There was also no marked difference between the reinforced and unreinforced reference panels. The design shrinkage values according to TMH7 Part 2 are 290με for the thin panel (250mm) and 205με for the thick section (1000mm), thus the measured shrinkage is less than the values used for design purposes. However the shrinkage is significantly size dependent, and additional secondary reinforcement may be required at positions of restraint (i.e. a pier) where the cross section changes in size.

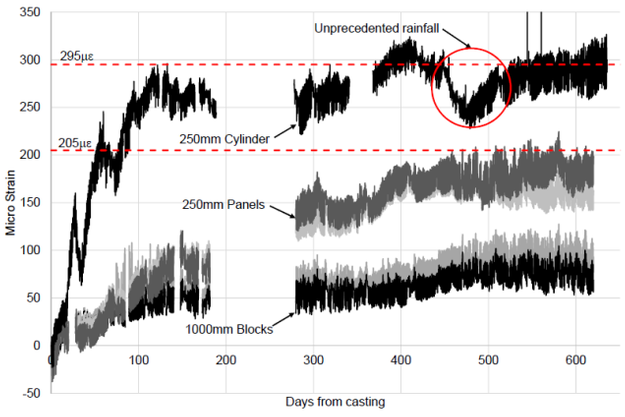

Figure 12. Reference structure shrinkage

7 CONCLUSIONS

This is an ongoing monitoring project and changes in the behaviour are expected now that the deck is surfaced and the bridge is opened to traffic, however the data points towards aspects that can help designers of integral bridges including:

- Heat of hydration is significantly dependant on the depth of the section, and on the ambient weather conditions. To prevent early age transverse cracking limits should be placed on maximum and minimum ambient temperatures for casting bridge decks; bridge decks should be cast while ambient temperatures are cool (i.e. at night) during summer; and deck pour should be delayed if sudden changes in ambient temperature are expected (i.e. if a cold front is expected to pass through the area). Additional secondary reinforcement, preferably smaller bar sizes at close spacing should be included to limit crack widths.
- In concrete slab and beam type construction a large solid beam damps the thermal effects, thus reducing the daily and season movement of the abutment.
- The transverse temperature variations in the deck are also dependant on the depth of the cross section.
- Concrete parapet causes greater transverse temperature variation in hot weather, and less in cold weather.
- Concrete shrinkage is significantly size dependent, and additional secondary reinforcement may be required at positions of restraint (i.e. a pier) where the cross section changes in size and where the thinner top slab of the deck is in tension over supports due to negative bending moments, however the concrete shrinkage measured to date is less than the design values.

ABSTRACT: This paper presents the seismic behavior of large-scale hollow-core fiber-reinforced polymer-concrete-steel (HC-FCS) bridge column. The HC-FCS column consists of a concrete wall sandwiched between an outer fiber-reinforced polymer (FRP) tube and an inner thin-walled steel tube. The width-to-diameter ratio for the steel tube was 147. The column had an outer diameter of 24 inches and a height-to-diameter ratio of 4.0. The steel tube was embedded into reinforced concrete footing with an embedded length of 1.25 times the steel tube diameter, while the FRP tube only confined the concrete wall thickness and curtail at the top of the footing level. The column was first tested as a vertical cantilever by applying cyclic horizontal and constant axial loads to the top of the column. Then, the column was repaired using a rapid repair technique within 6 hours duration and retested under the same seismic loading condition. The retrofitting technique includes wrapping three glass FRP layers around the outer bottommost FRP tube that ruptured at the interface joint between the column and the footing during the first test. The results revealed that the HC-FCS column achieved the ductile behavior with good inelastic deformation capacity under seismic loads. While, repaired column performed relatively well under cyclic loading, recovering 34% flexural strength and 80% of the lateral displacement capacity compared to the virgin tested column.

1 INTRODUCTION

It's estimated that Americans spend 14.5 million hours per day on traffic. 10 to 15% of that congestion is caused by work zones even when it occurs in the off-peak, they increase traffic congestion [1,2]. Therefore, new bridge construction techniques are required to reduce the amount of time it takes to build our roads and bridges from months to days. Accelerated bridge construction (ABC) is a proposed technology to minimize earthquake-induced residual deformations, damage, and associated repair costs.

According to the US Federal Highway Administration, ABC is a paradigm shift where minimizing the mobility impacts of on-site and speed up the construction process. ABC includes such elements as prefabricated modular units that are built off-site in a controlled environment and then transferred to the construction area for rapid installation. ABC reduces traffic disruptions and life-cycle costs and improves construction quality and safety, resulting in more sustainable development [3]. One technique to accelerate bridge construction is to use precast bridge columns with excellent seismic performance.

Recently, interest has been rapidly growing in using fiber reinforced polymer (FRP) tubes in construction as a replacement for the outer steel tube of double skin tubular (DSTCs) column [4, 5]. The proposed column, hollow core FRP-Concrete-Steel (HC-FCS), consists of an inner steel tube and an outer FRP tube, with a concrete shell placed in-between the two tubes [Fig. 1].

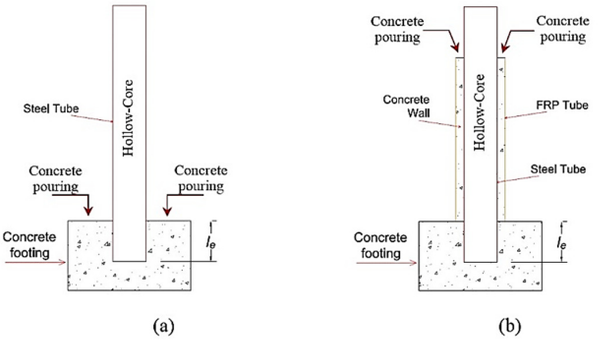

Figure 1. General arrangement of the construction of the HC-FCS column (a) inserting the steel tube and casting the footing, (b) installing the FRP tube and pouring the concrete shell

HC-FCS composite columns have several advantages as a precast element over conventional reinforced concrete or structural steel. The concrete infill is confined by both FRP and steel tubes, which results in a triaxial state of compression that increases the strength and strain capacity of the concrete infill and enhances the seismic performance of such columns [6-9]. The concrete shell reduces the susceptibility of the local and global buckling of the steel tube.

Fiber-reinforced polymer (FRP) is outstanding in its high strength-to-mass ratio, and has been used weidly for retrofitting existing structures during the past decades [10,11].

2 RESEARCH SIGNIFICANCE

The main objective of this study is to investigate the performance of HC-FCS column having thin-walled steel tube under seismic loads. The column had a steel tube diameter-to-thickness ratio (D_i/t_s) of 147. The column first tested under axial and quasi-static cyclic loads, then repaired rapidly and retested under the same loads condition.

3 EXPERIMENTAL PROGRAM

3.1 *Specimen Description*

In this study, a 0.4-scale HC-FCS column, F4-24-P1(0.8)4 was tested under constant axial load and lateral cyclic load. The F4-24-P1(0.8)4 column had a circular cross section with an outer diameter (D_f) of 24 inches and a clear height of 80 inches. The lateral load was applied at a height of 95 inches with a shear span-to-depth ratio of approximately 4.0.

The column consisted of an outer filament-wound GFRP tube with a thickness of 0.125 inches. The inner steel tube had an outer diameter of 16 inches and a thickness of 0.109 inches corresponding to inner-diameter-to-thickness D_i/t_s of 147. The steel tube was manufactured in The Highbay laboratory of Missouri University of Science and Technology by performing a seam-welding (full-penetration groove weld according to AWS 2000) for a 0.109-inches steel sheet cut and rolled to the required dimensions (length x circumference) prior to the welding. A concrete shell with a thickness of 4 inches was sandwiched between the steel and FRP tubes [Fig. 2].

The inner steel tube had yield stress of 56,240 psi, ultimate stress of 62,800 psi, yield strain of 2.15%, and an ultimate strain of 5.4%. The steel rebar had yield stress of 60,000 (psi), ultimate stress of 90,000 (psi), and ultimate strain of 0.08. The rebar properties are based on the manufacturer's data sheet while the steel tube properties were determined through tensile steel-coupon testing according to ASTM A 1067.

The used GFRP tube, was made with a matrix of Iso-polyester with a wall thickness of 0.125 inch, and based on the manufacturer's datasheet, had an axial elastic modulus of 1,400 ksi, hoop elastic modulus of 2,200 ksi, axial ultimate stress of 17,900 psi, and hoop rupture stress of 40,000 psi.

The columns' label used in the current experimental work consisted of four segments. The first segment is a letter F in reference to flexural testing, followed by the column's height-to-outer diameter ratio (H/D_f). The second segment refers to the column's outer diameter (D_f) in inches. The third segment refers to the GFRP matrix using "P" for Iso-Polyester base matrices; this is followed by the GFRP thickness in 1/8 inch, steel thickness in 1/8 inch, and concrete shell thickness in inches.

The steel tube of the column was embedded into the footing while the FRP tube truncated at the face of the footing without any embedment. The embedment depth, l_e, was determined using equation 1 [12].

$$\frac{D_i t_s F_u}{\left(l_e{}^2\right)} \leq 3.3\sqrt{f'_{c,FT}} \quad (1)$$

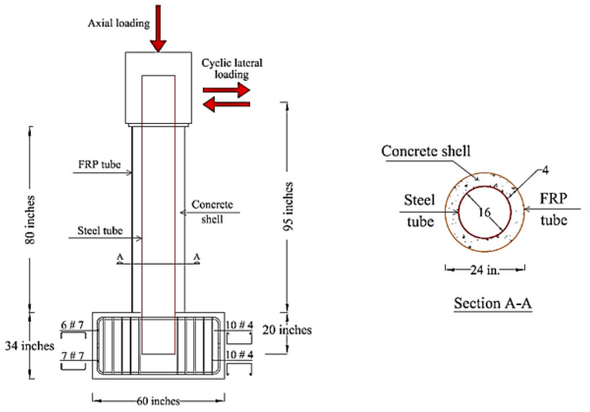
where D_i is the steel tube outer diameter (being 16 inches), t_s is the steel tube thickness (being 0.109 inches), and F_u is the ultimate stress of steel tube (being 62,800 psi) , and $f'_{c,FT}$ is the unconfined cylindrical compressive strength of the concrete footing (being 5,500 psi). Using these values an embedded length of 20 inches was deduced. Therefore, during the experimental work, l_e of 20 inches corresponding to 1.25 D_i (D_i is the inner diameter of the steel tube) was used to achieve the full embedment of the HC-FCS column [Fig. 1].

The concrete footing that was used in this study had a length x width x depth of 60-inches x 48-inches x 34 inches with bottom reinforcements of 7-#7, top reinforcements of 6-#7, and shear reinforcement of #4 at 2.5 inches [Fig. 2]. The steel cage of the footing was installed into the formwork.

The construction steps were as follows: 1) preparing and installing the reinforcement cages of the footings; 2) installing the steel tube into the footing cage with an embedded length of 20 inches; 3) pouring the concrete of the footing; 4) installing the GFRP tube and pouring the concrete of the concrete shell; 5) installing the reinforcement cage of the column head with dimensions of length x width x depth of 30-inches x 30- inches x 32 inches around the and concrete pouring.

Pea gravel with a maximum aggregate size of 3/8 inches was used for concrete mixtures. The unconfined concrete strengths ($f'c$) for F4-24-P1(0.8)4 at 28 days and at the day of the test were 6,305 (psi)

and 6,575 (psi) for the concrete wall, while 5,960 (psi) and 6,295 (psi) were obtained for the footing at the same ages, respectively.



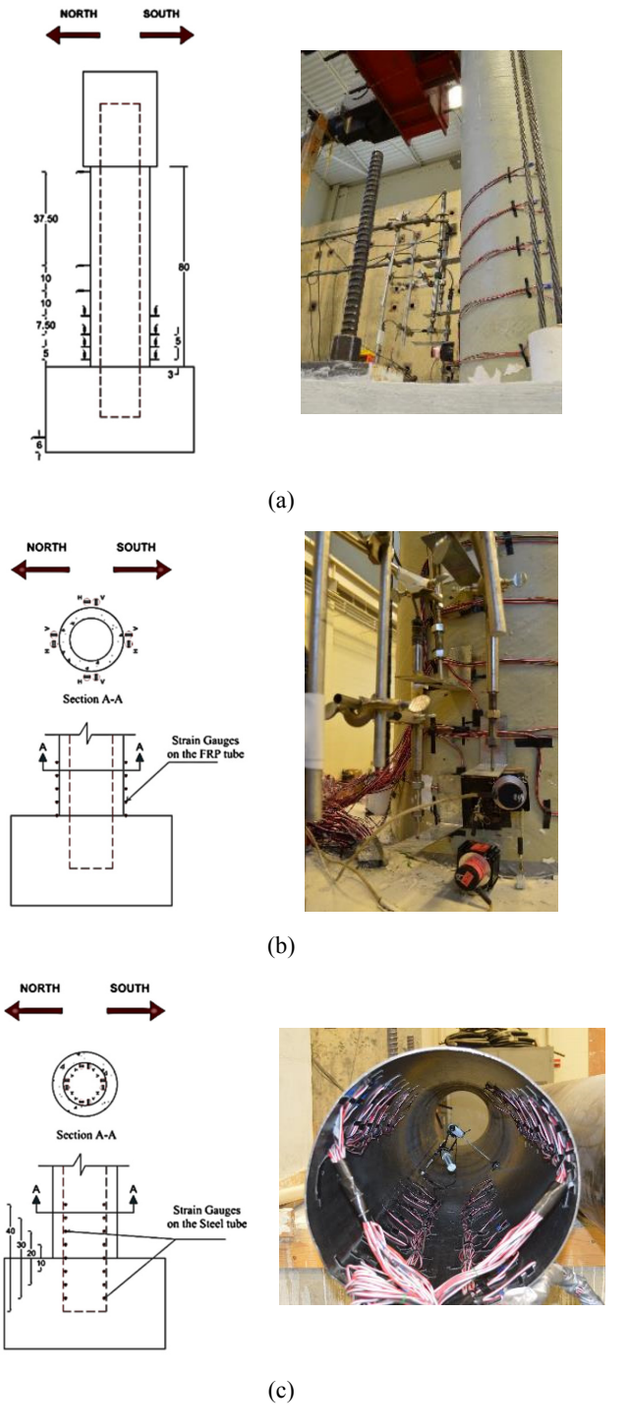


Figure 2. Construction layout of the column (a) elevation, (b) column cross-section (A-A)

3.2 *Test setup and instrumentations*

Sixteen linear variable displacement transducers (LVDTs) and string potentiometers (SPs) were assigned for measuring different displacements in each test specimen [Fig. 3 (a)]. Four LVDTs were mounted on each of the north and south faces of the column to measure the vertical displacements along the potential plastic hinge region. Two more LVDTs were attached to the footing for measuring the uplift and sliding of the footing during the test. The effects of the footing uplift and sliding were considered before calculating the lateral displacement and curvature of the column.

Forty strain gauges were installed on the FRP tube at five levels with 5 inch spacing between them. Four horizontal and four vertical strain gauges were installed at each level [Fig. 3 (b)]. Sixty-four strain gauges were installed inside the steel tube at seven levels with a spacing of 5 inches [Fig. 3 (c)]. Four horizontal and four vertical strain gauges were installed at each level. A high definition webcam was placed inside the steel tube 20 inches from the top of the footing level to film any potential buckling of the steel tube and any internal damage.

Three string Potentiometers (SPs) were assigned for measuring the slip between the FRP tube, concrete wall, and the steel tube. To achieve that, a 0.75 inches in diameter hole was drilled at hieght of 5 inches (from the top level of the footing) all the way to the steel tube [Fig. 4]. Then, the SPs were mounted in three positions : 1) on FRP tube to meaure the FRP tube, 2) connected to metal rods fixed on the concrete wall to measure it's movement, and 3) connected to metal rods fixed on the steel tube from inside (opposite to the hole from outside) throug an opening into the head to measure the relative movement at the same level (5 inches from the top level of the footing) [Fig. 4 (b)].

3.3 *Loading protocol*

Constant axial load, P, of 110 kips corresponding to 5% of the axial load capacity of the equivalent RC-column, P_o, with the same diameter and 1% longitudinal reinforcement ratio was applied to the column using six external prestressing strands [Fig. 5]. The P_o was calculated using Eq. 2 (AASHTO-LRFD 2012):

$$P_o = A_s F_y + 0.85(A_c - A_s)f'c \qquad (2)$$

where A_s = the cross-sectional area of the longitudinal steel reinforcements, A_c = the cross-sectional area of the concrete column, and F_y = the yield stress of the longitudinal steel reinforcements. The prestressing strands were supported by a rigid steel beam atop the column and the column's footing. The prestressing force was applied using two servo-controlled jacks that kept the prestressing force constant during the test.

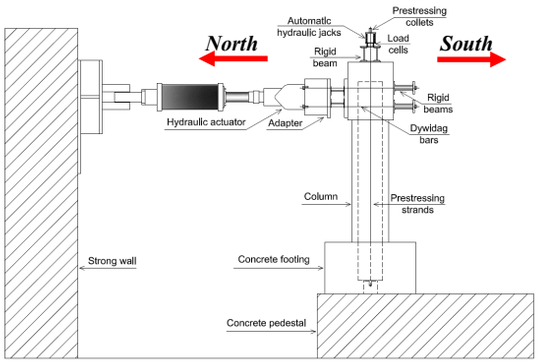

Figure 5. Layout of the test setup

After applying the axial load, a cyclic lateral load was applied in a displacement control mode using two hydraulic actuators connected to the column loading stub. The loading regime was based on the recommendations of FEMA 2007, where the displacement amplitude a_{i+1} of the step i+1 is 1.4 times the displacement amplitude of the proceeding step (a_i). Two cycles were executed for each displacement amplitude. Fig. 6 illustrates the loading regime of the cyclic lateral displacement. Each loading cycle was applied in 100 sec. corresponding to a loading rate that ranged from 0.01 inch/sec. to 0.05 inch/sec.

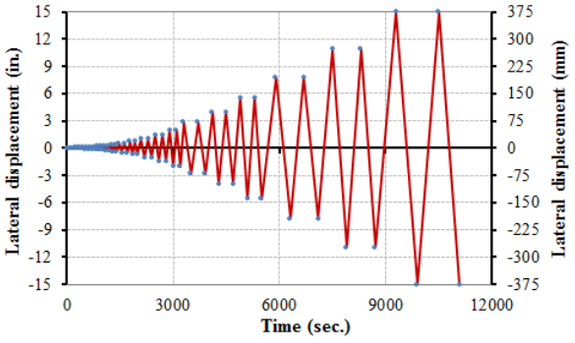

Figure 6. Lateral displacement loading regime

4 RESULTS AND DISCUSSION

Generally, the embedded length and thickness of the steel tube have significant effects on the behavior of HC-FCS columns under cyclic loads [12]. The tested column in this study had thin steel tube that was susceptible to inward buckling instabilities, and thereby steel tube slippage led to degradation of the bending strength.

Fig. 7 shows the moment drift ratio response of F4-24-P1(0.8)4 column. The lateral drift (δ) was calculated by dividing the lateral displacement measured from the actuators displacement transducers by the shear span of 95 inches. The moment (M) at the

interface joint was obtained by multiplying the force measured by the actuators' load cells by the column's height of 95 inches.

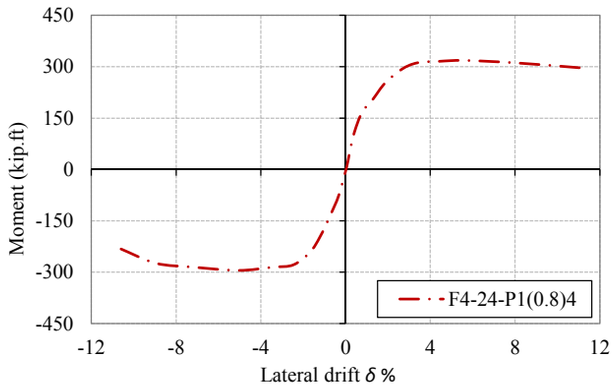

Figure 7. Moment drift ratio envelop curve

The attained moment capacity and the lateral drift were 312 kip.ft and 11.2% for column F4-24-P1(0.8)4.

Fig. 8 shows the relative movements of the FRP tube, concrete wall, and inner steel tube measured at the same level (5 inches above the interface joint, as shown in Fig. 4). As shown in the figure, at lateral drift of almost 8%, the relative movement was increased up to 1 inches between the FRP tube-concrete wall. The reason was at late lateral drift ratios, the FRP tube exhibited more lateral pressure as a result of the concrete wall dilation, and thereby, degradation of the bond interface was occurred.

While, it was in 0.6 inches at the same lateral drift between the concrete wall-steel tube indicating that the interface bond was decreased due to the steel tube local buckling. The interfacial bond failure and relative slip gradually developed at early lateral drift stage, which is related mainly to the steel tube large diameter-to-thickness ratio that influences the bond-slip performance.

Eventually, as shown in Fig. 9, the F4-24-P1(0.8)4 failed by the steel tube diamond local buckling mode of deformation followed by FRP tube rupture [Fig. 9 (b)] on the north side at 11% lateral drift.

5 RETROFITTING WORK

The economical retrofitting techniques using FRP jackets can be used to improve the seismic performance of bridge columns by increasing confinement and avoiding failures near the base of existing columns. The retrofitting schemes in this study consist of using GFRP systems, wrapped in the damaged region near the interface joint.

FRP composite jackets fabricated from GFRP by wet layup were used to rehabilitate the tested HC-FCS column. The fibers in the composite laminates were oriented in the hoop direction so that the contribution of the composites to the flexural strength of the columns was small. The composites were formed using a single sheet of GFRP with an overlap of 20 inches in the hoop direction of the columns to avoid a localized failure at the fabric ends. The jackets were started at the footing top face level and extended 40 inches above the base of the columns.

Fig. 10 illustrates the rapid repairing process of column F4-24-P1(0.8)4. The repaired column named F4-24-P1(0.8)4-R by adding the letter "R" which stands for "repair". This repairing process was selected to minimize cost of implementation for columns subjected to moderate displacement demands and was finished within 6 hours (1.5 hour GFRP wrapping, 3 hours GFRP curing, and 1.5 hour concrete mortar injection). Properties of the composite materials used in this study are listed in Table 1.

Table 1. Properties of Saturated GFRP Wrapping (Data from Fyfe Co. LLC., 2002)

Nominal thickness/layer (inches)	0.05
Young's modulus, E (ksi)	3,790
Tensile strength (ksi)	83.4
Ultimate strain	2.2%

The F4-24-P1(0.8)4-R column tested under the same lateral and axial loads that applied to the F4-24-P1(0.8)4 column. Fig. 11 shows the moment capacity versus lateral drift response of F4-24-P1(0.8)4-R column. The moment capacity and the lateral drift were 104 kip.ft and 8%, respectively (66% and 20% lower than those for column F4-24-P1(0.8)4) [Fig. 11].

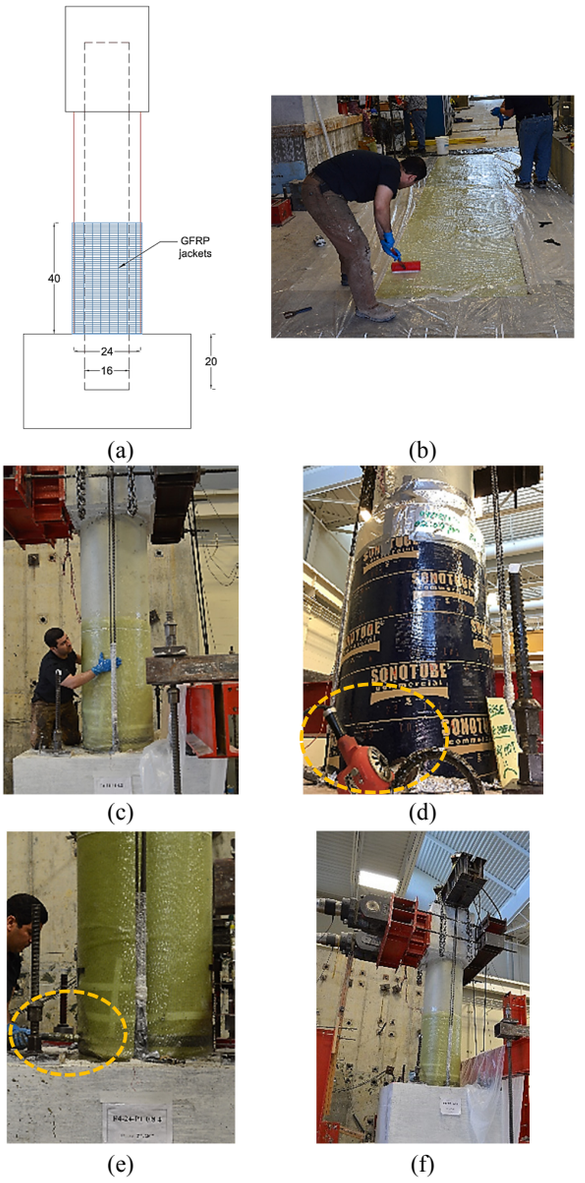

Figure 10. Retrofitting process of F4-24-P1(0.8)4 column (a) layout, (b) GFRP wet layup preparing, (c) GFRP wet layup wrapping, (d) GFRP layers curing using the heat-gun, (e) grout injecting, and (f) F4-24-P1(0.8)4-R column

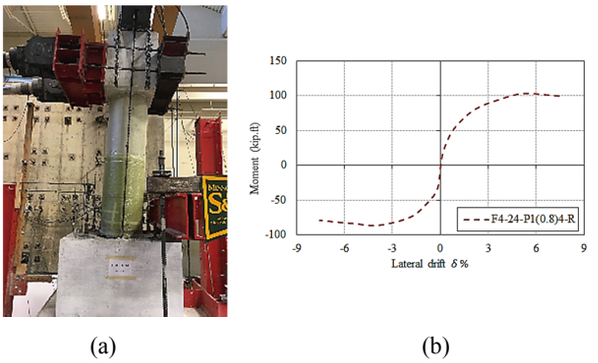

Figure 11. F4-24-P1(0.8)4-R column (a) during the test, (b) Moment drift ratio envelop curve

Careful examination of the tested column's concrete wall as well as steel tube have been conducted after peeling the FRP tube. As shown in Fig. 12 (a), the concrete wall cracked longitudinally (up to 40 inches above the footing top level) on the west side. While, it was crashed (up to 10 inches above the footing top level) on the both south and north sides where the concrete wall suffered high compression stresses. The steel tube was severely buckled locally near the footing-column interface joint [Fig. 12 (b)] as well as steel tube ductile tearing [Fig. 12 (d)], which is gradually extended 20 inches downward and upward leading to bond interface deterioration between the steel tube and the surrounding concrete. As shown in Fig. 12 (c), the end cross-section of the steel tube did not keep its circular shape. Thus, early initiation of the steel tube pull-out (slip) was observed at 2.7% lateral drift followed by bending strength dropping.

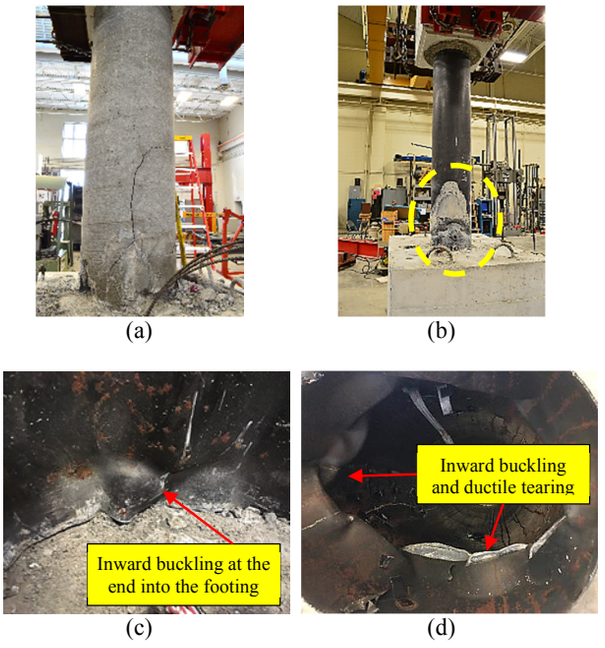

Figure 12. F4-24-P1(0.8)4-R column forensic structural (a) concrete wall cracks, (b) steel tube buckling, (c) steel tube inward buckling at the end into the footing, (b) steel tube inward buckling and ductile tearing at the interface joint

6 CONCLUSIONS

This paper presents the experimental results of a hollow-core fiber reinforced polymer concrete steel (HC-FCS) precast column. The HC-FCS column consists of a concrete hollow cylinder sandwiched between an outer fiber-reinforced polymer (FRP) tube and an inner steel tube. The column had an outer diameter of 24 inches, an inner steel tube diameter of 16 inches with D_i/t_s=147, and a height-to-diameter ratio of 4.0. The steel tube was embedded into reinforced concrete footing with an embedded length of 20 inches corresponding to 1.25 D_i, while the FRP tube acted as a formwork and provided a continuous confinement for the concrete shell, and was curtailed at the top surface of the footing. The column was subjected to constant axial load and lateral cyclic load during this study and then repaired rapidly using GRFP wet layup technique and retested under the same seismic loading regime. The tested column in this study has a thin-walled steel tube that was susceptible to inward buckling instabilities observed at small lateral drift of 2.7% led to initiate the dropping the bending strength. Therefore, steel tube slippage occurs due to the combination of the insufficient development length and the contact interface deboning with the surrounding footing and column concrete. Finally, after steel tube sever buckling at the interface joint, FRP tube rupture occurred at 11% lateral drift. The repaired column by GRFP wet layup technique displayed good lateral displacement behavior. However, the bending strength less enhanced due to the severe local buckling deformations of the inner steel tube.

ABSTRACT: This paper reports the results from fatigue testing on welded non-load-carrying transverse attachments made of C-Mn (S460) and stainless (LDX2101) steels. The tests are done on 40 mm thick specimens in as-welded and HFMI-treated specimens. Measurements on weld toe radius and weld residual stresses are also reported. The results show that the improvement of fatigue strength that can be achieved by HFMI-treatment on welded LDX2101 steel is similar to what is obtained for equivalent C-Mn steels. Also in the as-welded condition do these two types of steel show similar fatigue strength. HFMI-treatment gives more than 5 steps increase in fatigue strength for both steels, which is higher than what specified, for example by the recommendations of the International Institute of Welding.

1 INTRODUCTION

The design of steel and composite (steel-concrete) bridges is generally determined by the Fatigue Limit State. This has practically meant that high strength steels are very seldom – if ever – relevant in bridge applications. In fact, even for conventional construction steels, such as S355, the strength of the material is often not fully utilized in design as the fatigue strength of welded details sets the roof in term of utilization ratios. Being able to "bypass" this limitation opens for interesting possibilities in term of material saving, weight reduction and more optimized designs. This has been the driving force behind the rather extensive research conducted in recent years in the field of fatigue strength enhancement of welded bridge details by means of various post-weld treatment method. In this respect, High Frequency Mechanical Impact (HFMI) techniques have gained most attention. This category of methods promises high efficiency to relatively low cost and can be applied both in workshop and in situ. In addition, HFMI treatment has proven to be particularly effective in the high-cycle fatigue regime where bridges usually operate. Several previous studies have demonstrated considerable material and weight saving with HFMI treatment applied to critical, fatigue governing details in steel and composite bridges. Shams Hakimi et al. (2015) showed for example that for simply-supported railway bridges with spans ranging between 10 and 30 m a weight saving between 30 and 20% can be achieved if fatigue critical details are treated with HFMI. This material saving was partly enabled by upgrading the steel strength from S355, which is most common in steel railway bridges, to S460. Several other studies show similar results on C-Mn steels. Today, the use of HFMI treatment for enhancing the fatigue strength of welded steel bridges is gaining increasing applicability and the method has been used both in the design of new bridges and for the rehabilitation of existing ones, see for example Shams Hakimi & Al-Emrani (2014).

It should be mentioned that post-weld treatment of the weld toe can shift the fatigue failure site to other areas, for instance to the root of the same weld or to other weldments in the structure. In new structures, non-load-carrying welds which are post-weld treated can be produced as fully penetrated in order to avoid root failure.

To date, almost all research related to HFMI has been conducted on C-Mn steels. Particularly high strength steels in relatively thin plates (mostly up to 16 mm even if some work exist on thicker plates) have been in focus, see e.g. Shams-Hakimi et al. (2017a) where 582 fatigue test results are compiled and evaluated.

Recently, the interest in using stainless steel as structural material in bridges has increased both in Sweden and elsewhere in the world. The main driving force has often been the lower total life cycle costs promised by stainless steels compared to conventional C-Mn steels.

There are two reasons why fatigue strength enhancement of welded details in stainless steel is of high interest. On the one hand, stainless steels are

typically several times more expensive than conventional constructions steels. Material saving in stainless steel is therefore expected to have a larger impact on the total cost of a steel bridge compared to bridges made of conventional steels. In addition, stainless steels, such as Duplex and Lean Duplex have higher strength than conventional construction steel used in bridge applications (S355 or even S420) and can thus better meet the potential offered by the increase in fatigue strength after HFMI-treatment.

Studies on fatigue improvement of welded details in stainless steels are very limited. Toe grinding was investigated by Baptista et al. (2008) on stainless steels subjected to salt water corrosion. Xu et al. (2014) studied the efficiency of weld toe dressing with low transformation temperature (LTT) welding wires on 304L (1.4306) stainless steel specimens with welded transverse attachments. The only extensive experimental study known to the authors where HFMI treatment (in addition to grinding, TIG- and plasma dressing) was investigated on welded details in stainless steel is the one reported by Marquis & Maddox (2009). Relatively thin plates were used in this investigation (3 and 10 mm) and in many cases fatigue cracking in the tested specimens initiated elsewhere than in the treated area at the weld toe.

This paper presents the results from an extensive testing program done within the research Project INNODEFAB. The entire testing program included 74 fatigue tests. Focus here is however on test results obtained on specimens made of LDX2101 stainless steel. Results from similar tests from specimens made of S460 steel are also presented for comparison. In addition to fatigue testing, measurements of weld toe profile and weld residual stresses have also been conducted. A more detailed reporting of the test program with focus on C-Mn steels is given by Shams-Hakimi et al. (2017b).

2 EXPERIMENTAL PROGRAM

The entire experimental program for bridges within INNODEFAB included 74 fatigue tests, 54 of C-Mn steel and 20 of LDX2101 stainless steel. In this paper, the results from the stainless steel specimens (series 7 and 8) are presented and compared to the corresponding results for C-Mn steel (series 1 and 4), see Table 1. The test specimens resemble typical welded connections of vertical stiffeners in steel bridges, see Figure 1.

Fatigue testing was performed in 4-point bending in two different testing rigs with frequencies that varied between 3 and 20 Hz. The distance between loading points was chosen so as to avoid local effects from loading close to the welded detail. Strain gauges were used to obtain the nominal stress in the main plate between the loading points. The target

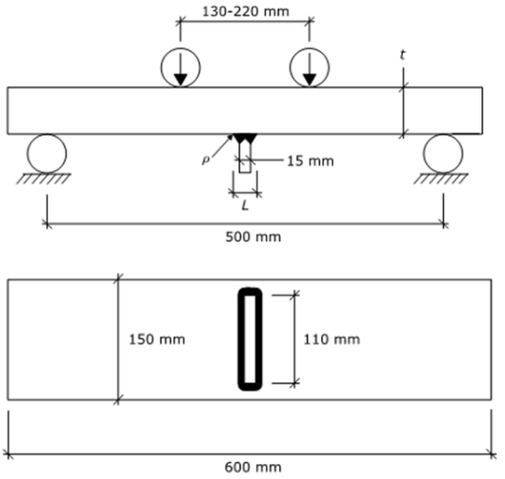

Figure 1. Test specimen dimensions and loading arrangement, Shams-Hakimi et al. (2017b).

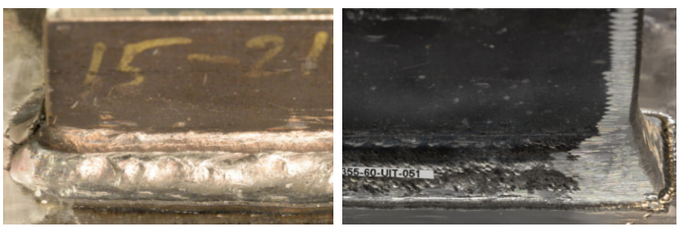
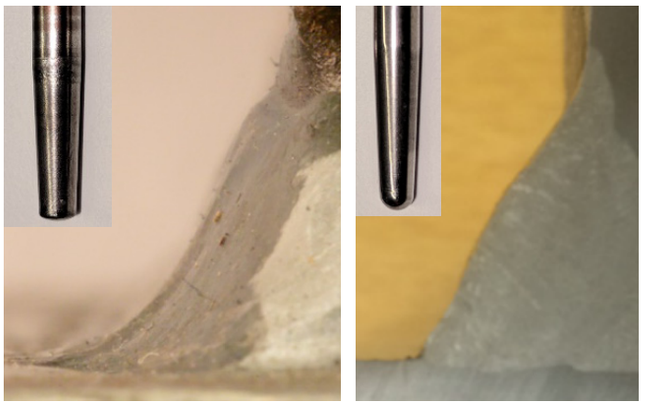


stress ratio in the tests was 0.1. However, the actual stress ratio varied between 0.01 and 0.2 depending on load level and testing rig.

Table 1. Overview of the experimental program.

Series	Specimens	Steel type	Min. yield stress [MPa]	*k*
1	460-38-AW	S460M	460	7
4	460-40-HFMI	S460M	460	11
7	LDX-40-AW	LDX2101	450	10
8	LDX-40-HFMI	LDX2101	450	10



2.1 *Manufacturing*

The C-Mn and LDX specimens were welded in two different workshops and some important production aspects differed between the two different specimen batches. The C-Mn specimens were welded in a bridge production workshop and common procedures were followed to reproduce a weld quality similar to that found in bridges. Therefore, the C-Mn HFMI-treated specimens were ground prior to HFMI-treatment to obtain a weld quality of class B according to ISO 5817. The as-welded C-Mn specimens were on the other hand not ground. A view of the welds in the as-welded and HFMI-treated specimens is given in Figure 2 for the C-Mn series. Welding of the C-Mn specimens was conducted in vertical position of the specimens which resulted in large radius for the weld toe at the main plate side.

As-welded (C-Mn) Ground then HFMI-treated (C-Mn)

Figure 2. Difference between the as-welded and HFMI-treated specimens of the C-Mn speicmens, Shams-Hakimi et al. (2017b).

As-welded (C-Mn) As-welded (LDX)

Figure 3. Difference of toe radius due to vertical positioning of the C-Mn specimens and horizontal positioning of the LDX specimens during welding. Different indenter tip radii for HFMI-treatment were therefore used.

For the LDX specimens, welding was performed as the specimens were lying in a horizontal position, as would be the case in bridge production. As a result, the weld toe radius on the main plate side was smaller. The effect of specimen positioning during welding on the weld toe radius is illustrated in Figure 3 for the two different cases. Furthermore, none of the LDX specimens were ground at any point.

The HFMI-treatment was conducted using an Ultrasonic Needle Peening device with a sonotrode (internal vibration component) frequency of 20 kHz and a vibration range of 40 µm. Due to the difference of the weld toe radii of the C-Mn and LDX specimens, an indenter tip radius of 3 mm was used for the C-Mn specimens while an indenter with a radius of 1.5 mm was used for the LDX specimens. The average treatment speed varied between 200-300 mm/min.

In all specimens, full-penetration K-welds were used to join the transverse attachment to the main plate in order to avoid root failure in the joints. The length of the transverse attachment was chosen so that at least 10 mm free distance was obtained between the ends of the welds and the edges of the main plates, see Figure 1.

2.2 *Weld scanning*

All specimens were laser-scanned to provide average weld toe radii and standard deviations. Post-processing of the scanning raw data was performed by an algorithm developed by Stenberg et al. (2012). As expected, due to vertical positioning, the as-welded C-Mn series was found to have a large average toe radius. In addition, relatively large variations were registered for the different C-Mn specimens. For the ground and subsequently HFMI-treated C-Mn series, an average toe radius similar to the indenter radius (3mm) was measured with considerably more consistent values for the individual specimens, see Figure 4.

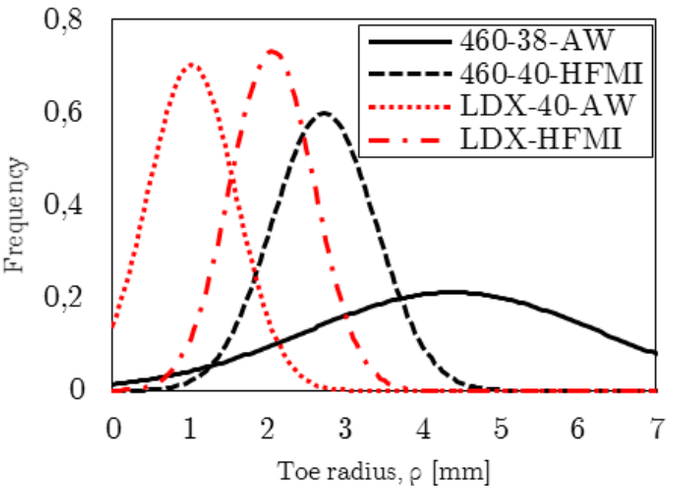


Figure 4. Weld toe scanning results. Normality test were not conducted since the purpose only was illustrative. The C-Mn results are reported in Shams-Hakimi et al. (2017b).

The as-welded LDX series had significantly smaller average toe radius than the as-welded C-Mn specimens. The average weld toe radius increased as a result of HFMI-treatment of the LDX series, however, smaller values were registered as compared to the C-Mn HFMI series due to the smaller indenter radius used (1.5 mm). The measurement results are also given in Table 2.

Table 2. The average value, µ, and standard deviation, σ, of the weld toe radii.

Series	Specimens	μ_ρ [mm]	σ_ρ [mm]
1	460-38-AW	4.38	1.88
4	460-40-HFMI	2.72	0.67
7	LDX-40-AW	1.02	0.57
8	LDX-40-HFMI	2.05	0.54

2.3 *Residual stress measurements*

Residual stress measurements were performed by X-ray diffraction with an X3000 device from Stresstech Oy. The details of various measurement parameters have been reported by Shams-Hakimi et al. (2017b). Measurements were performed both at the surface and in the depth direction, however, only the depth measurements at the weld toes (HFMI-grooves) are presented here. The measurements in the depth direction were performed by successive etching (saturated aqueous NH_4Cl solution) and electropolishing (13 V) in the centre of the HFMI groove on one side of the attachment.

For the C-Mn ground specimen (i.e. prior to HFMI treatment), the transverse residual stresses at the weld toe were approximately -100 MPa, see Figure 5. After HFMI treatment these values changed to ca -300 MPa, successively approaching zero at a depth of approximately 1.5 mm below the weld toe surface. Similar values were measured for the LDX specimens which were not ground. However, it is

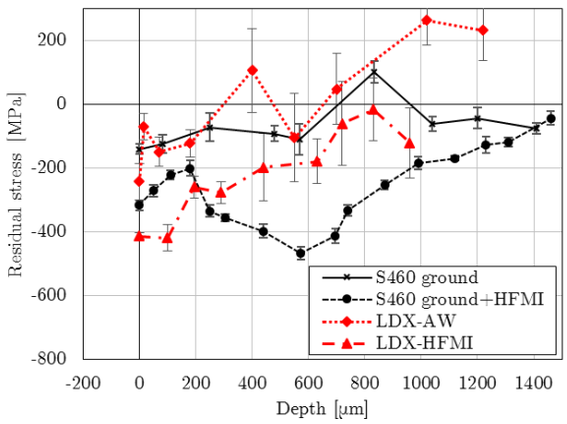

Figure 5. Through-thickness residual stresses profiles from the weld toes. The C-Mn results are reported in Shams-Hakimi et al. (2017b).

observed in Figure 5 that the measurement uncertainties were larger for the LDX specimens. It can also be seen that the compressive stresses induced by HFMI treatment in the LDX specimens approached zero at a smaller depth, less than 1 mm.

3 FATIGUE TEST RESULTS

Figure 6 shows the fatigue test results of all specimens that failed from weld toe. Runouts are excluded as well as one HFMI-treated stainless steel specimen which failed in the base material. The results of the stainless steel specimens are also listed in Table 3. It is observed that HFMI treatment of the stainless steel resulted in a quite similar fatigue strength as that of treated C-Mn specimens, although somewhat lower. For the stainless steel, an average fatigue strength of 249 MPa at 2 million cycles was obtained with a fixed slope of $m = 5$, whereas for the C-Mn steel, the corresponding value was 272 MPa.

The results of HFMI-treated specimens are all well above the S-N curve suggested by the International Institute of Welding (IIW), FAT140, which corresponds to an increase of five FAT-classes. Furthermore, looking at the runout specimens, the average stress range at which these specimens were tested was 258 MPa, which is similar to the runout stress ranges reported by Shams-Hakimi et al. (2017b).

For the as-welded test results, a much more significant difference in fatigue strength is observed between C-Mn and LDX steels. The stainless steel specimens had a fatigue strength of 111 MPa which is closer to the design *S-N* curve of FAT80, relevant for this detail. The fatigue strength for the specimens in C-Mn steel was 149 MPa.

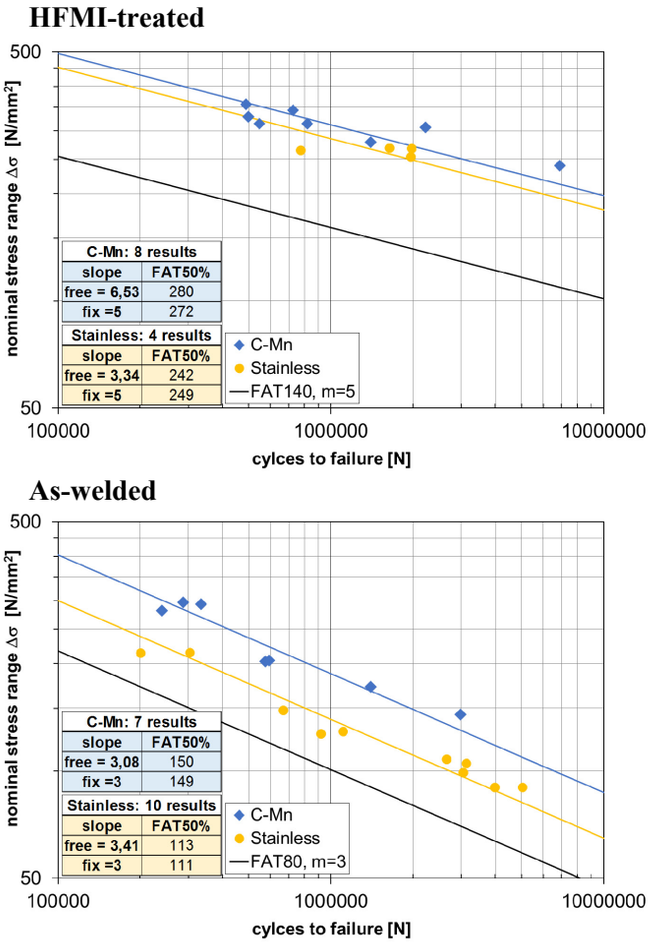

Figure 6. Fatigue test results. The C-Mn results are reported in Shams-Hakimi et al. (2017b).

Table 3. Fatigue test results of the LDX series.

4 DISCUSSION AND FINAL REMARKS

The fatigue strength of all HFMI-treated specimens presented in this study was much higher than what is given in the IIW recommendation for the studied detail and steel strength classes. One reason for this might be the fact that, unlike most of other available test - Leitner et al. (2014), Kuhlmann & Günther (2009), Kuhlmann et al. (2005) and Tehrani (2012) – the attachment plates were here terminated at a distance from the edges of the main plate. This should give a better fatigue strength compared to cases where the weld is extended to the edge of the load-carrying plate. Also, the test specimens in this study were HFMI-treated individually, whereas in some other experimental studies, the treatment was first done on wider plates which were then sliced into smaller specimens after the HFMI treatment. This may result in partial relaxation of the beneficial local compressive stresses generated by the HFMI-treatment. Similar observation was lately reported by Zhang et al. (2017).

The fatigue strength of the HFMI-treated stainless steel specimens was on par with that obtained for C-Mn specimens. The difference in derived fatigue strength for the two materials (271 vs 249 MPa in Figure 6) should be seen in view of the limited number of failures obtained for the LDX specimens. Even if this difference holds statistically, it could very well be a result of the difference in weld toe radii after HFMI-treatment in these two types of specimens (3 vs 2 mm for C-Mn and LDX respectively). The difference in yield stress may also provide some answers. The actual minimum yield stress of the batch of C-Mn was actually 566 MPa. Similar information is not available for the stainless steel, but a lower proof stress should usually be expected for LDX2101. For the comparison of the as-welded test results, the significant difference in fatigue strength is mainly attributed to the difference in toe radii as a result of specimen position during welding.

5 ACKNOWLEDGEMENT

The work described in this paper has been funded through the Swedish Vinnova office within the program LIGHTer. The authors would like to acknowledge the contribution of all partners in the INNODEFAB project (Dnr 2014-05133). Special thanks to Lars-Åke Bylund from Böhler Welding Group. Sonats is also acknowledged for helping with the HFMI-treatment and the residual stress measurements.

ABSTRACT: Employing advanced material such as Carbon-fiber-reinforced-polymer (CFRP) in tension fatigue strengthening of aged bridges shows a great capability of arresting or delaying the crack propagation in steel structures. Extending the current knowledge of the CFRP strengthening to the case of the multiaxial cyclic loading will broaden its application in Civil Engineering. The aim of this paper is to investigate the fatigue behavior of the CFRP strengthening of central-cracked steel plates subjected to the combined action of tensile (mode-I) and shear (mode-II) loading with a focus on the effect of the CFRP properties. The key parameters in this study are the mixed-mode ratio (crack angle), the crack length ratio (crack length to the plate width), patching configurations, and mechanical properties of the composite material. A comparative study was conducted on steel plates strengthened with different composite properties (thickness, Young's modulus) and types (plates vs. sheets).

1 INTRODUCTION

Complex details and connections in ageing steel bridges often contain defects and also it is prone to fatigue failure. Restoring such structural elements to the service requires upgrading its strength and stiffness. Carbon-fiber-reinforced-polymer (CFRP) composites offer a competitive solution in terms of its light weight and the high tensile strength (Zhao 2013; Hollaway & Cadei 2002). The composite material has launched in the construction industry with different Young's modulus, thickness, types (sheet vs. laminate) providing a wide range of its applications, namely improving the tensile strength and stiffness of the upgraded components. Much research has been investigated the higher strengthening efficacy of the adhesively bonded systems that can be obtained from various mechanical properties of the composite material and the strengthening scheme (Ghafoori *et al.* 2015; Wu et *al.* 2012; Liu et *al.* 2009). The majority of these studies have been carried out on CFRP-strengthened cracked steel plates. Furthermore, The fatigue performance of the CFRP strengthening systems was studied at different load conditions (Amraei et *al.* 2017; Aljabar et *al.* 2016; Feng et *al.* 2014), for strengthening at different stages of the fatigue life of the strengthened elements (Aljabar et *al.* 2017), and for a range of the steel grades (Hu et *al.*2016). It showed that the tension fatigue strengthening of steel plates with tensile crack increased proportionally to the tensile stiffness of the unidirectional composites. Several researchers (i.e.; Ghafoori *et al.* 2015; Liu *et* al. 2009, Wu *et al.* 2012) revealed that the in-plane stiffness of the CFRP strengthening systems was improved by utilizing a composite material with higher Young's modulus, thickness (plates over sheets), and strengthening method (double-sided vs single-sided strengthening methods). However, it is not clear whether the investment in composite materials with superior properties yields the same benefits when the crack or defects in the steel components exhibits a state of mixed-mode loading of tensile and shear stresses. A preliminary study of the authors of the present paper investigated the fatigue behavior of CFRP strengthening system of steel plates with inclined cracks (Aljabar et *al.* 2016, & Aljabar et *al.* 2017). The steel plates were notched with a crack starter of different orientation to introduce different ratios of the shear to tensile stresses at the crack starter tip. The CFRP-strengthened specimens had initial crack lengths of 2%, and 30% of the width of the steel plate simulating specimens with different damage levels. CFRP laminates with Young's modulus of 477GPa and thickness of 1.5mm were patched on a single side

of the steel plates by adopting two strengthening configurations. The test results revealed that the crack propagation curves of CFRP strengthened steel plate with inclined crack can be simulated by the curves of the same specimens with flat (tensile) crack. The crack propagation curves of steel plates with inclined crack showed a proportional shift in the number of cycles to the smaller crack angles. This shift represented the increase in the number of cycles under mixed-mode conditions before the crack kinks to model-I (tensile dominated). The fatigue behavior of steel plates with severe damage level was almost the same but with a lesser increase in the total number of cycles due to the effect of higher tensile stresses at the tip of the initial crack. Having the same test specimen, initial crack lengths, and strengthening configurations, in this paper the fatigue behavior of steel plates with inclined cracks has been investigated further for strengthening with sheet composites of Young's modulus of 640GPa, and thickness of 0.19mm. The test results of the current work were presented and compared with the previous one in terms of the behavior and fatigue performance. This paper constitutes a part of a large research program on the CFRP strengthening of metallic bridges under mixed-mode fatigue loading at Monash University in collaboration with Swinburne University of Technology, and the Swiss Federal Laboratories for Materials Science and Technology (Empa).

2 FATIGUE EXPERIMENT DETAILS

2.1 *Test specimens*

For comparison purpose, the experimental program was kept the same as the recent experimental study that conducted on strengthening with CFRP plates. The dimension, notch details, and the strengthening configurations of the test specimens are presented in Figure 1. The test specimens either fully (configuration A) or partially covered (configuration D) with the composite material. The steel plates with a minimum yield strength of 300MPa were strengthened with 3 layers of S&P C-sheet 640 composite. The composite sheets have a cross section of 300mm*0.19mm whereas the composite laminates have a cross section of 50mm*1.5mm. The tensile test results for the steel plates were 500MPa, 204GPa, and 330 for the tensile strength, Young's modulus, and yield stress, respectively. The tensile strength and Young's modulus of the composite materials were 1603MPa, and 478GPa for the CFRP laminates, and 2650MPa, and 640GPa for the CFRP sheets. In the literature, the researchers used to classify the composite materials based on their Young's modulus in different groups as normal-modulus CFRP, high-modulus CFRP, and ultra-high-modulus CFRP (Zhao 2013). For comparison between the strengthening systems of different composites in this study, it referred to the plate composites with higher Young's modulus as ultra-high-modulus composites UHM-CFRP, whereas it referred to the sheet composite as high-modulus composites HM-CFRP.

The components of the strengthening system were adhered together by a bonding layer of Araldite 420. The tensile strength and elastic modulus of the adhesive were 28.6MPa and 1.9GPa, respectively (Fawzia 2007). To simulate a state of mixed-mode loading (tensile and shear stresses) at the initial crack tip, steel plates were notched with a centrally oriented crack starter. The test specimens have Initial crack lengths ratio of 2%, and 30% and crack angles (β) of 90°, 60°, 45°, and 30°. The bonding surface of the steel plates was cleaned first from the grease by the sandblasting method. Then treated with the acetone solution before a uniform layer of the adhesive was applied. Afterward, the composite sheets were patched to the steel surface. The CFRP strengthened specimens were cured at room temperature for more than two weeks.

2.2 *Test procedure*

The fatigue tests were carried out in an Instron 8802 servo-hydraulic testing machine in the Civil Engineering laboratory at Monash University. The tension fatigue tests were conducted on all specimens

*Aljabar et *al.* 2017

with a constant amplitude, 0.1 stress ratio, and 20Hz frequency. Such a loading ratio are commonly used for fatigue tests on the CFRP strengthened specimens (Liu *et* al. 2009, Wu *et* al. 2012). It is usually advised to use a frequency between 20-35Hz to shorten the total test time and cost. However, the frequency should not increase the temperature of the tested specimens by more than room temperature plus 2°C, according to ASTME606 (Yung-Li et *al.* 2005). Feng et *al*. (2014) reported that increasing the temperature has a slight effect on the fatigue life of the adhesively bonded composites as long as the temperature is below the glass transition temperature (T_g) of the adhesive. In this study, all specimens were subjected to a fatigue loading fluctuated between 150MPa and 15MPa. The maximum load level was nearly 46% of the yield tensile stress of the steel plates. The beach marking method was adopted in measuring the crack length on the fractured surface and recorded with the corresponding fatigue cycles. The adopted procedure of calculating the length of the kinked cracks are detailed by Aljabar et *al*. (2016).

3 FATIGUE TEST RESULTS

Experimental details and test results are presented in Tables 2, and 3 for specimens with crack length ratios of 2%, and 30% respectively. For comparison reason, the current test results were presented with the recent experimental study of strengthening with UHM-CFRP material (Aljabar *et* al. 2016 & Aljabar *et* al. 2017). The tables show the specimens and the corresponding symbols i.e. strengthening method, strengthening configuration, and crack angles. US stands for un-strengthened specimens, whereas SHA, and SHD identify single-sided strengthening for specimens with full and partial configurations, respectively.

The recorded fatigue life represents the number of cycles that counted till the crack propagated through the whole steel plate width. The strengthening efficacy of the CFRP sheets and laminates for steel plates with different crack orientation is presented in terms of the fatigue life extension factor. This factor represents the ratio of the fatigue life of the steel plates

strengthened with different composite materials to that of the same specimens without CFRP strengthening. The effect of the crack orientation on the fatigue life introduced in terms of the number of cycles counted under the effect of mixed-mode loading (*Nm*). The fatigue life under mixed-mode conditions presented as the difference between the fatigue life of specimens with inclined cracks and the specimens with flat tensile cracks (β<90°). Strengthening with composite sheets and laminates show a comparable increase in the fatigue life of the steel plates with inclined cracks. As the current tests are ongoing the test results of the specimens of β=30° and damage level of 2% were not presented in this paper. HM-CFRP strengthening system of steel plates with damage level of 2% improved the fatigue life by an average factor of 1.54 and 2.1 for full (SHA) and partial (SHD) strengthening schemes. It is clear that there is almost similar increase observed for specimens with configuration A and severe damage. In general, the average difference in the fatigue life extension ratio of strengthening with HM-CFRP sheets and UHM-CFRP laminates was less than 6%. However, the CFRP partially-strengthened specimens with crack length ration of 30% showed the higher difference with advantage for UHM-CFRP strengthening by 18%.

4 MIXED-MODE CRACK PROPAGATION CURVES

The effect of the crack orientation on the fatigue behavior of steel plates strengthened with HM-CFRP sheets was investigated in this study through the crack propagation curves obtained from the test data. Figures 2-5 show the crack propagation curves of steel plates with different damage level and strengthening schemes. Test specimens with inclined cracks exhibit a state of mixed-mode loading condition at the crack tip due to the effect of crack orientation whereas specimens with β=90° exhibit a state of pure tensile stresses.

The difference of the stresses at the crack tips of the two sets of specimens is obvious in the crack propagation curves. The difference is clearly shown in terms of a proportional increase in the fatigue life of specimens with smaller crack angles (β). The relative increase in the total number of cycles of specimens with β<90° was explained by the shifting phenomenon in mixed-mode crack propagation curves (Aljabar et *al*. 2016). The shift in crack propagation curves represents an increase in the number cycles under mixed-mode condition (*Nm*). Furthermore, the shift in *a-N* curves could be a function of the mixed-mode ratio; the ratio of the shear to tensile stresses at the crack tip.

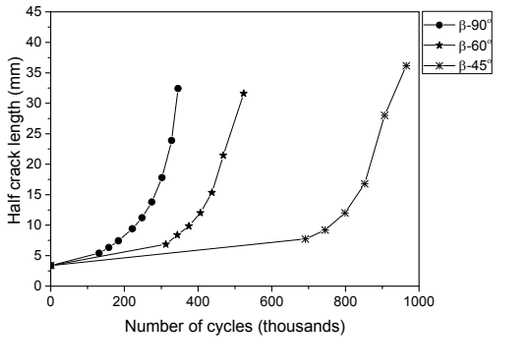

Figure 2. Crack length vs. number of cycles for fully-strengthened specimens with crack length ratio of 2%

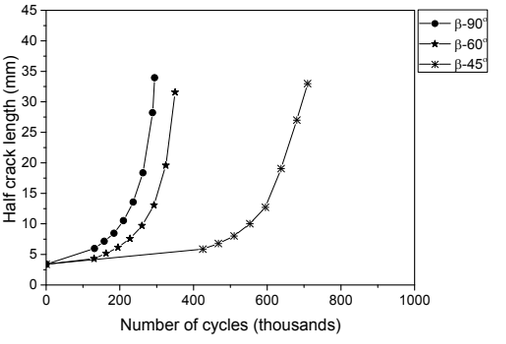

Figure 3. Crack length vs. number of cycles for partially-strengthened specimens with crack length ratio of 2%

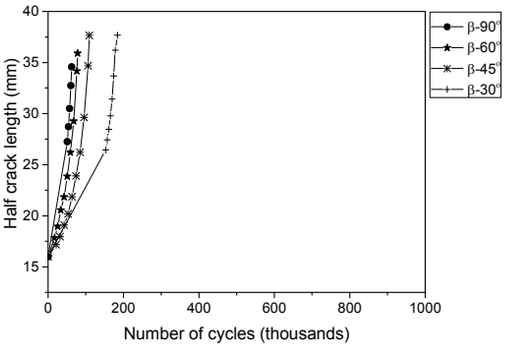

Figure 4. Crack length vs. number of cycles for fully-strengthened specimens with crack length ratio of 30%

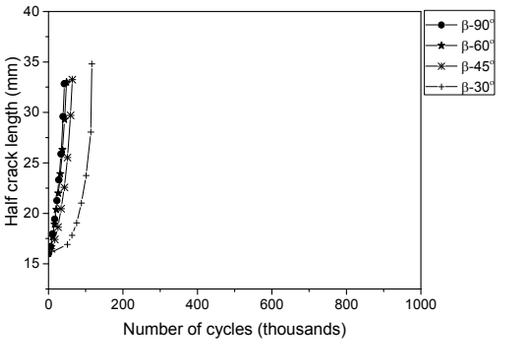

Figure 5. Crack length vs. number of cycles for partially-strengthened specimens with crack length ratio of 30%

Strengthened specimens with higher damage level exhibited a smaller amount of shift due to the increase of the tensile stresses for longer initial cracks and consequently reduced the mixed-mode ratio, the function of *Nm*. The same trend observed for SHD specimens

compared to SHA specimen. The former has smaller strengthening stiffness and then higher tensile stress compared to the latter. It should be noted that the mixed-mode fatigue behavior was almost independent of the type and properties of the CFRP. The tensile strengthening stiffness of the unidirectional composites does not seem to have a significant effect on the fatigue behavior of specimens with initially inclined crack. However, the mechanical properties of the composite material showed the higher influence as the crack initiated as it dominated by the tensile stresses. Therefore, the difference between the fatigue life of the same specimen strengthened with UHM-CFRP and HM-CFRP reflects the effect of the tension strengthening on the tensile stress at the crack tip.

5 EFFECT OF THE COMPOSITE MATERIAL ON THE MIXED-MODE FATIGUE BEHAVIOR

The current knowledge of utilizing CFRP material in tension strengthening of steel components with tensile crack is that the more investment in the mechanical properties of the composted material the longer the fatigue life. Also, the higher the damage level of the CFRP reinforced elements, the more pronounced the fatigue life extension ratio. However, it is not clear whether the fatigue performance of the composite strengthening of steel components with inclined cracks has a similar trend or not. In the current study, the steel plates were patched with composite sheets and laminates of different mechanical properties. The strengthening stiffness of CFRP laminates (one plate of 1.5mm) was clearly higher than the mechanical properties of the CFRP sheets (3 sheets of 0,19mm). Figures 6-9 show that the fatigue improvement of strengthening systems with different composite material was nearly comparable with the relatively small advantage of the CFRP laminates. Both the tension strengthening systems influenced the number of cycles counted for the phase where the propagated crack exhibits tensile dominated stress. The specimen with higher tensile stress showed the higher difference between the fatigue lives of specimens with different CFRP composites. For example, the average increase in the fatigue life of specimens strengthened with UHM-CFRP was higher by 11 %, and 5% for steel plates with damage level of 30%, and 2%, respectively. However, the advantage of strengthening with the composite material of higher tensile stiffness was almost marginal for different strengthening schemes as shown in Figures 6-9.

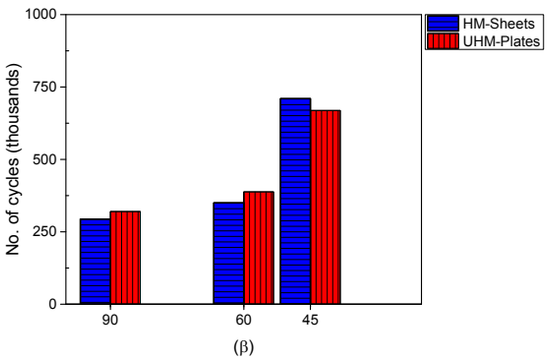

Figure 7. Comparison between the fatigue lives of steel plates partially-strengthened with HM-CFRP and UHM-CFRP with crack length ratio of 2%

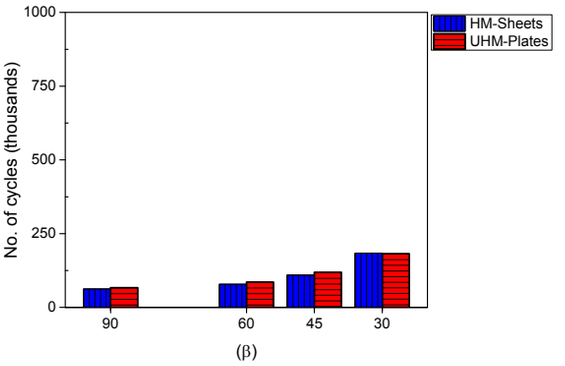

Figure 8. Comparison between the fatigue lives of steel plates fully-strengthened with HM-CFRP and UHM-CFRP with crack length ratio of 30%

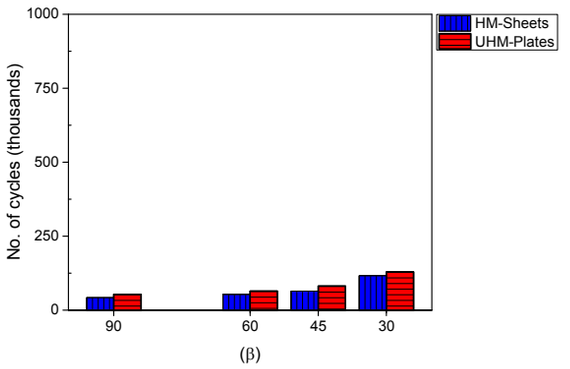

Figure 9. Comparison between the fatigue lives of steel plates partially-strengthened with HM-CFRP and UHM-CFRP with crack length ratio of 30%

6 CONCLUSIONS

In this study, the fatigue behavior of steel plates with inclined crack was investigated under the effect of different variables, i.e.; the crack angle, the crack length, and the strengthening scheme, with a focus on the fatigue performance of strengthening systems of different composite material. A total of 14 specimens were strengthened with 3 layers of the sheet composite of high modulus (E=640, t=0.19mm). The test results were presented and compared to the recent study of similar specimen strengthened with CFRP laminates of the higher modulus (E=477GPa, t=1.5mm). The following conclusions were drawn based on the available test results:

1. The average increase in the fatigue life of steel specimens strengthened with composite sheets was between 150%-210% for smaller damage level. Almost similar increase was observed for the case of specimens with severe damage.
2. The fatigue life extension ratio of strengthening systems of different composite type (sheets vs. laminates) and properties (Young's modulus, thickness) was almost comparable with only a difference less than 6%. However, the UHM-CFRP strengthening system shows a higher improvement in the fatigue life by 18% for partially-strengthened specimens with a crack length ratio of 30%.
3. For strengthening systems of different composite materials, the crack propagation curves of steel plates with inclined crack showed a proportional shift (increase in fatigue life) to smaller crack angles. The fatigue life increase was inversely correlated with the tensile stress components at the crack tip. For example, the higher the damage level, and the higher the tensile stress the smaller the shift and the fatigue life. Similarly, the shift in crack propagation curves of the partially-strengthened specimen was less significant than that of fully-strengthened specimens.
4. The difference between the fatigue life of the same specimen strengthened with UHM-CFRP and HM-CFRP reflects the effect of the tension strengthening on the tensile stress component at the crack tip. The higher this component (the less mixed-mode ratio) the more pronounced the effect of strengthening stiffness on the fatigue life of steel plates with inclined cracks. For example, the average increase in the fatigue life of specimens strengthened with UHM-CFRP was higher by 11 %, and 5% for steel plates with damage level of 30%, and 2%, respectively.

Improving the fatigue design of orthotropic steel decks

H. De Backer, W. Nagy & A. Outtier
Ghent University, Ghent, Belgium

ABSTRACT: Orthotropic steel decks (OSDs) consist of a complex network of longitudinal stiffeners, transverse stiffeners and the deck plate itself. Working as a whole, it takes part in the structural working of the overall bridge concept, resulting in an extremely lightweight and durable deck concept. Orthotropic steel decks are very sensitive to fatigue damage, because of the large number of welded connections in the deck. Historically, designers have tried to improve upon the concept by focusing on: optimization of the overall dimension of the steel plates, determining the shape of the stiffeners and possible cut-outs and investigating the possible influence of the wearing courses in distributing vehicle loads. Most of these approaches have proven successful. However, combined with the ever-increasing vehicular loads and traffic volumes, designers still feel the need to increase the plate thicknesses. A deck plate thickness of 18mm or more has become quite common. This is mainly caused since regulations stick to the existing fatigue concepts. Innovative research focuses on the application of fracture mechanics as well as the influence of residual stresses on the fatigue lifetime. An analysing tool using Linear Elastic Fracture Mechanics (LEFM) is proposed in this paper. Crack propagation and crack growth direction are evaluated with an eXtended Finite Element Model (XFEM), on macro- and meso-scale. In addition, thickness effects are evaluated for both longitudinal stiffener and deck plate. These calculations result in a better understanding of the increased fatigue properties compared to the increased dead load of the structure. Manufacturing processes such as welding operations cause residual stresses, which are present in most civil structures. They are causing plastic deformations without any external loads and are therefore often overlooked during design. Nevertheless, residual stresses can have profound influences on the material strength and the fatigue life. Overall, it can be stated that the OSD remains a valuable bridge concept, especially for larger span bridges, that can be understood better using modern research techniques.

1 INTRODUCTION

Due to their contribution to the general resistance of the structure, by significantly reducing the total weight of the construction, orthotropic steel deck plates are one of the most commonly used deck systems for larger span bridges. This contribution also allows the design of tied arch bridges of a more moderate span but with an extremely low structural depth, e.g. a structural depth of only 1 m for a double track railway bridge with a length just over 110 m. The recent design practice in Belgium has used this advantage for about 13 arch bridges, most of them a part of the development of the European network of High Speed Lines where a considerable number of short to medium span bridges for the high-speed railway lines have been designed. Other applications include movable bridges crossing the lock doors of the Port of Antwerp, Belgium. However, orthotropic deck plates are also highly sensitive to fatigue damage, requiring an in-depth fatigue analysis, ensuring it fulfills all fatigue criterions. This problem is mainly caused by the many stress concentrations and the large amplitudes of stress variations, caused by road traffic in particular. Recent international research has extensively studied this phenomenon.

The complex stress field in an orthotropic road bridge can be attributed to three different actions working in union. The first of these actions is caused by the membrane stresses arising because of the bending of the lateral main girders of the bridge, with the bridge deck itself acting as their upper flanges. This action represents in fact the main action of the overall bridge concept. The orthogonal anisotropy (i.e. orthotropic behavior) of the deck with the distribution of the load working on the deck corresponding to the different rigidities of the ribs and the crossbeams is responsible for the second action existing in the deck plate. Finally, the local

bending along longitudinal or transversal axis of the deck plate elements under direct wheel loading causes the third action existing in an orthotropic road bridge. The largest stress concentrations for this deck concept are found at the ribs where longitudinal stiffeners are connected to the deck plate and both hogging and sagging bending effects are found, as well as at the intersection of both longitudinal and cross stiffeners.

Road pavements on the deck plate may contribute to the dispersal of concentrated wheel loads from road traffic. This has also been observed for railway loading, where the ballast may disperse the track loads. However, wearing courses and pavements are not always available or sufficient to reduce the heavy traffic loads, for instance in the case of movable bridges.

An example of this is the Calandbridge in Rotterdam, which was examined more closely and where severe damage due to cracking and fatigue has been found. In Belgium, large span bridges with orthotropic plated deck (for instance the Vilvoorde viaduct in Brussels) do not suffer from this cracking, but smaller movable bridges also show this sensitivity. This situation has to be considered in view of the ever-increasing axle loads and more compact wheel loads introduced by road traffic.

The design and fatigue loads as mentioned by Eurocode 1, which were intended as higher bond values of European traffic, may well be circulating frequently at present. In view of these considerations, the conclusion must be to find systems to decrease the aggressive effects of concentrated wheel loads on orthotropic plated decks, or to eliminate these effects.

This paper focuses on the connection of the deck plate to the trapezoidal closed longitudinal ribs (Figure 1) and more in particular at the location mid span two transverse stiffeners. This is one of the most common locations where fatigue problems occur. At the manufacturing level, welding details have to make use of the available standards. Following the recommendations of Eurocode 3, Part 2 2015, a weld penetration of minimum 67%-75% should be achieved.

In addition, the AASHTO Specification note even describes a weld penetration of 80%. Despite the latter, the manufacturers already try to achieve full weld penetration as much as possible. When welds are executed with care, the reference value $\Delta\sigma_c$ for the fatigue strength increases. However, when taking into account current construction technologies, Eurocode is still considering the outdated reference values $\Delta\sigma_c$, as shown in Eurocode 3, part 1-9 2015. Therefore, present fatigue calculations are very conservative. For the weld detail of the stiffener-to-deck plate connection (right-hand side of Figurer 1), a reference value $\Delta\sigma_c$ of 71 MPa applies. According to recent fatigue tests, higher reference values up to 140 MPa are found, Kolstein M.H. 2007, indicating that the fatigue resistance could be higher than expected.

Unfortunately, the designer has to use the Eurocode guidelines resulting in a tendency to use thicker deck plates and stiffeners, thus reducing the advantage of having a light weighted construction. To investigate and quantify the real fatigue behavior, a much more in-depth method is used, based on Linear Elastic Fracture Mechanics (LEFM). With this method, a detailed crack behavior can be evaluated and the total fatigue life can be estimated as well as the expected crack pattern. The latter can be very useful for weld details similar to the one presented in this paper because the crack could start at positions invisible to any visual inspection tool. In the case of a stiffener-to-deck plate connection, the crack would start at the weld root, which is on the inside of the longitudinal stiffener. Therefore, when a fatigue crack becomes visible in such details, there is already sufficient damage to cause failure, Nagy W. et al. 2014.

2 XFEM AND THE INFLUENCE OF RESIDUAL STRESSES

2.1 *eXtended Finite Element Models*

To evaluate the fatigue life of steel bridges, stress cycles due to traffic are calculated with detailed FEM-models. However, when LEFM is introduced, standard FEM models cause many practical and computational problems, especially if automatic crack propagation is required. In such cases, eXtended Finite Element Models (XFEM) can offer a solution. When using XFEM, it is possible to evaluate automated crack propagation with all its LEFM calculated parameters without adapting the initial model and corresponding mesh for every crack propagation step. However, the downside of this is the heavy computational effort. In order to have realistic and accurate results, the mesh in the vicinity of the crack tip has to be sufficiently small to capture the stresses. In addition, the larger the crack tip, the more degrees of freedom are generated. Due to the latter, XFEM simulations are often limited to simulating a small crack front when considering automatic crack propagation methods. This is however not a problem, as the XFEM calculations can give a clear visualization of the initial crack propagation up to stable crack growth.

In 2004, a fatigue crack was detected in a stiffener-to-deck plate connection of an orthotropic steel bridge deck in Belgium, Nagy W. et al. 2014. This was in the Temse Bridge, a movable truss across the river Scheldt. To verify the fatigue life of this bridge deck, a full-scale FEM-model was developed based on its dimensions. The Temse Bridge has a span of 53.90 m and a width of 7.00 m. The deck plate of the bridge is only 12 mm thick and the closed trapezoidal stiffeners are 8 mm thick. The stiffeners are 350 mm high and 300 mm wide on top and have a width of 90 mm at the lower soffit. The distance between the longitudinal stiffeners equals 300 mm.

$$\frac{da}{dN} = C \cdot (\Delta K_{eff})^m \qquad \Delta K_{eff} = f(a) \cdot \Delta\sigma \cdot \sqrt{\pi \cdot a}$$

$$N_f = \int_{a_i}^{a_f} \frac{da}{C \cdot \Delta K_{eff}^m} = \int_{a_i}^{a_f} \frac{da}{C \cdot \left(f(a) \cdot \Delta\sigma \cdot \sqrt{\pi \cdot a}\right)^m}$$

The used FEM-model consists of shell elements and beams. The advantage of using a full FEM-model is to have boundary conditions as close as possible to the real structure. In a next step, this model is linked to a much more detailed XFEM model. This XFEM model is a small piece of a stiffener-to-deck plate connection and is made out of volume elements. To link both models together, the displacements from the large FEM-model are introduced on the edge of the XFEM model. As mentioned before, thicker plates are used when trying to increase the fatigue life of the structure. To validate whether this is justified, the dimensions of the Temse Bridge are also adapted with different stiffener web thicknesses and deck plate thicknesses. Therefore, a comparison could be made.

Fatigue crack growth is mainly defined by three different phases: crack initiation, crack propagation and crack failure. The first phase depends on the execution of the weld. For example, bad weld penetration, weld defects and partially rewelded tack welds can reduce or eliminate the crack initiation phase and therefore reduce the fatigue life of the structure. Looking for example at some weld macros of recently executed stiffener-to-deck plate welds, relevant lack of penetration can be noticed (Figure 2). This lack of penetration is a perfect initial crack with a length of approximately 1.5 mm. It is assumed in the XFEM model that the initial crack has a semi-elliptical shape with a half-length of 1.5 mm along the minor axis and a half-length of 3 mm along the major.

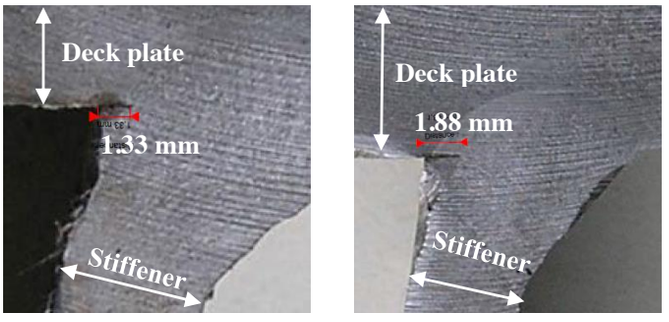

Figure 2. Influence of wearing course type on the fatigue life

2.2 *Residual weld stresses*

Residual stresses are present in all civil structures due to manufacturing steps, causing plastic deformation. Nevertheless, these stresses are not often implicitly taken into account when considering the design of structures. Similar as for the dead load of the bridge deck, this is true when focusing on the stress variations, which eliminate the initial stress state of the structure. However, the effect of residual stresses may either be beneficial or detrimental, depending on their magnitude, sign and distribution with respect to the load-induced stresses. Therefore, the initial stress state due to a welding operation is also introduced into the FEM/XFEM-model.

Literature results from similar fillet welds as those in the orthotropic bridge deck are used to implement residual stresses into the model. These results stated that tensile yield stresses are present in the deck plate and the stiffener spread out in the heat affected zone, FHWA-IF-12-027 2012. Outside this area, compressive compensating stresses are found. To simulate residual stresses into the model, external forces and bending moments are inserted with respect to the global equilibrium. Therefore, N_{deck} is chosen in order to have tensile yield stresses in the deck plate at the weld. For the stresses in the stiffener, an additional bending moment $M_{stiffener}$ and normal force $N_{stiffener}$ are also introduced. The bending moment is necessary because the joint is welded from one side only and the filler metal and the corresponding heat area is larger at the weld toe com-

pared to the weld root. For the magnitude of this bending moment and normal force, an assumption is made based on the distribution of the filler metal.

2.3 *LEFM parameters*

As is generally accepted, the evaluation of the geometry dependent parameter f(a), which combines the influence of the weld and specimen geometry on the crack behaviour, is of major importance to quantify the fatigue behaviour of the detail being studied. As illustrated in Figure 3, the XFEM calculations result in a detailed visualization of the crack propagation behaviour through the deck plate. For every time step and curvilinear location along every crack front, the SIF-values are determined. Due to computational or convergence problems, the crack propagation could only be simulated up to a half-length of approximately 18 mm in longitudinal direction which is complying with the welding direction. To overcome this problem, larger initial crack fronts are evaluated with a half-length of 25 mm and 50 mm. It is assumed that at this point, the crack has already fully penetrated the deck plate. Therefore, the crack front inside the material is reduced and less degrees of freedom are necessary.

To investigate the influence of different thicknesses used for the deck plate and the longitudinal stiffeners, different plate thicknesses are used: 6 mm, 7 mm and 8 mm for the longitudinal stiffener and 12 mm, 14 mm and 16 mm for the deck plate. Figure 4 illustrates all the calculated f(a) values for these thicknesses. For the evaluation of the fatigue life and the corresponding crack length, a best-fit curve has to be fitted to these data points.

In addition to the plotted best-fit curves Figure 4, Table 1 gives the corresponding R-square values. A clear trend is visible and the best-fit curves have a great reliability.

In the f(a) curves, it is clear that the longitudinal stiffener thickness has no major influence on the profile of the curve. In the deck plate however, a large shift is sometimes noticeable. Although higher values of f(a) result in a faster crack propagation, these higher values apply to thicker deck plate cases only. In these deck plates, the stresses at the weld root are much smaller and will therefore result in a lower crack propagation than smaller deck plates.

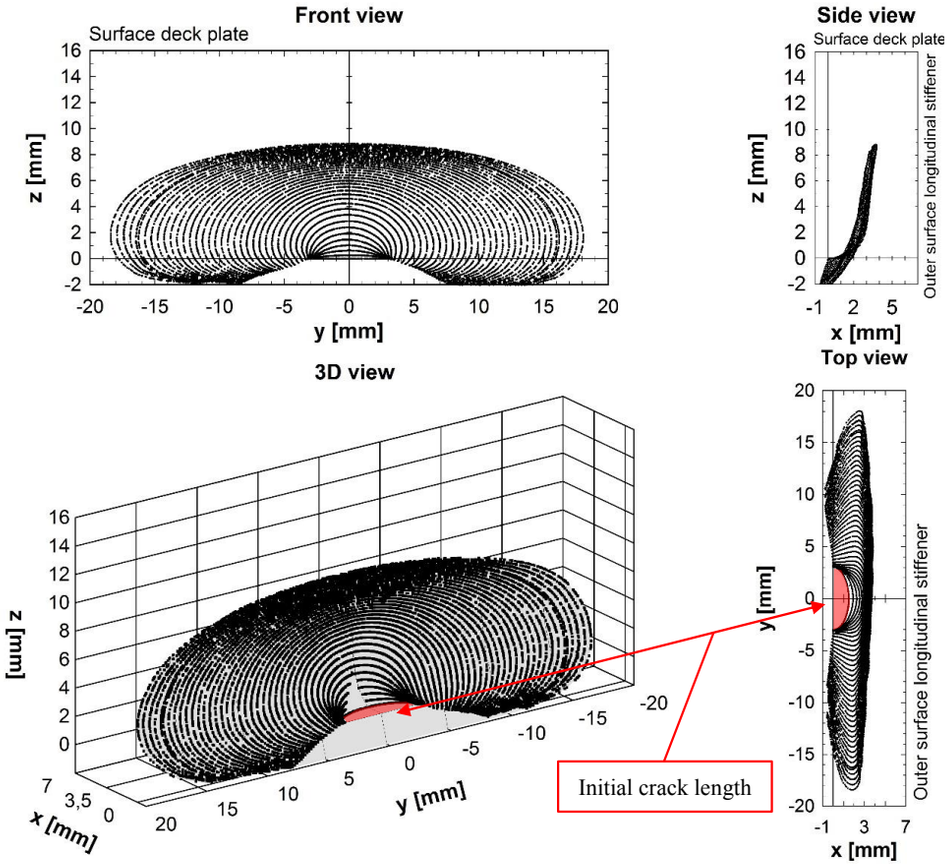

Figure 3. XFEM crack simulation including the initial semi-elliptical crack length

Table 1. R-square value of best-fit curves. Stiffener-to-deck plate detail: S = stiffener - number = thickness of the stiffener - D = deck plate - number = thickness of the deck plate.

Stiffener-to-deck plate detail	S6_D12	S6_D14	S6_D16	S7_D12	S7_D14	S7_D16	S8_D12	S8_D14	S8_D16
R-square	0.95	0.99	0.99	1.00	0.97	0.98	0.99	1.00	0.99

2.4 *Fatigue life*

When combining the best-fit curves of f(a) with equations for crack length, the crack length in function of time can be plotted. According to the same graphs of f(a), the fatigue life up to a service life of 100 years is illustrated in Figure 5. When looking at the left graphs where the curves are grouped by the thickness of the longitudinal stiffener, the crack grows much faster in thinner deck plates. This results from the reduced applied stress at the weld root due to the capability of spreading the loads over multiple longitudinal stiffeners. When looking at the graphs on the right where the curves are grouped based on the thickness of the transverse stiffener, the opposite is true. The crack seems to grow faster when the thickness of the stiffener is increased. A possible explanation is the increased stiffness of the closed trapezoidal stiffener. Therefore, the stiffener close to the applied load attracts the stresses in the deck plate. As illustrated in Figure 4, the f(a) curves for the same deck plate thickness are almost identical. A small difference in the stresses at the weld root causes large differences in the crack growth due to the cubic equation.

The calculated fatigue life is summarized in Table 2. This corresponds with the time where the crack has fully penetrated the deck plate. Although not included in this paper, also the f(a) curves for the direction through the deck plate was calculated. With these curves, the total crack length through the deck plate could be validated next to the longitudinal ones.

Stiffener-to-deck plate detail	S6_D12	S6_D14	S6_D16	S7_D12	S7_D14	S7_D16	S8_D12	S8_D14	S8_D16
R-square	0.95	0.99	0.99	1.00	0.97	0.98	0.99	1.00	0.99

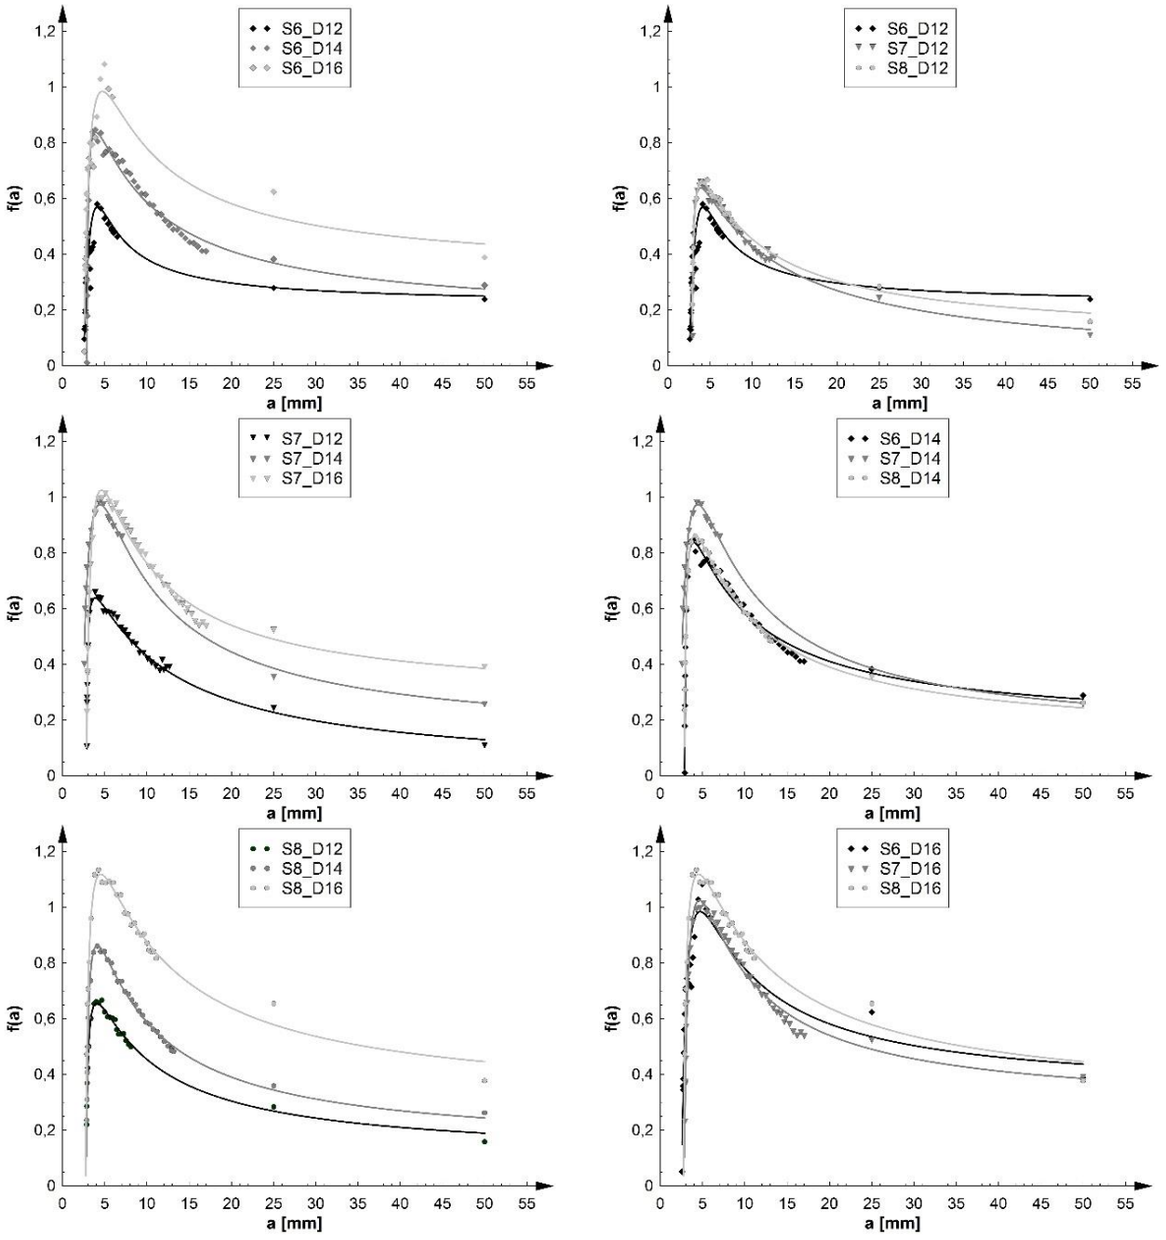

Figure 4. Geometrical dependent parameters f(a) for different deck plate and stiffener thicknesses. Legend: S = stiffener - number = thickness of the stiffener - D = deck plate - number = thickness of the deck plate. Left: f(a) curves grouped per stiffener thickness. Right: f(a) curves grouped per deck plate thickness

Within the service life of 100 years, this was only the case for a stiffener thickness of 8 mm and a deck plate thickness of 12 mm. The fatigue life in this case is 41.84 years. This rather low result corresponds with the fatigue crack that was observed in the Temse Bridge. In all the other cases, the crack still has not penetrated the deck plate. Table 2 also lists the amount of crack propagation through the deck plate after 100 years of service life in percentage. According to these results, the best option in a truss bridge is to have a thick deck plate and a slender stiffener. But in the case of the Temse Bridge, a solution can already be found in using a stiffener of 7 mm instead of 8 mm.

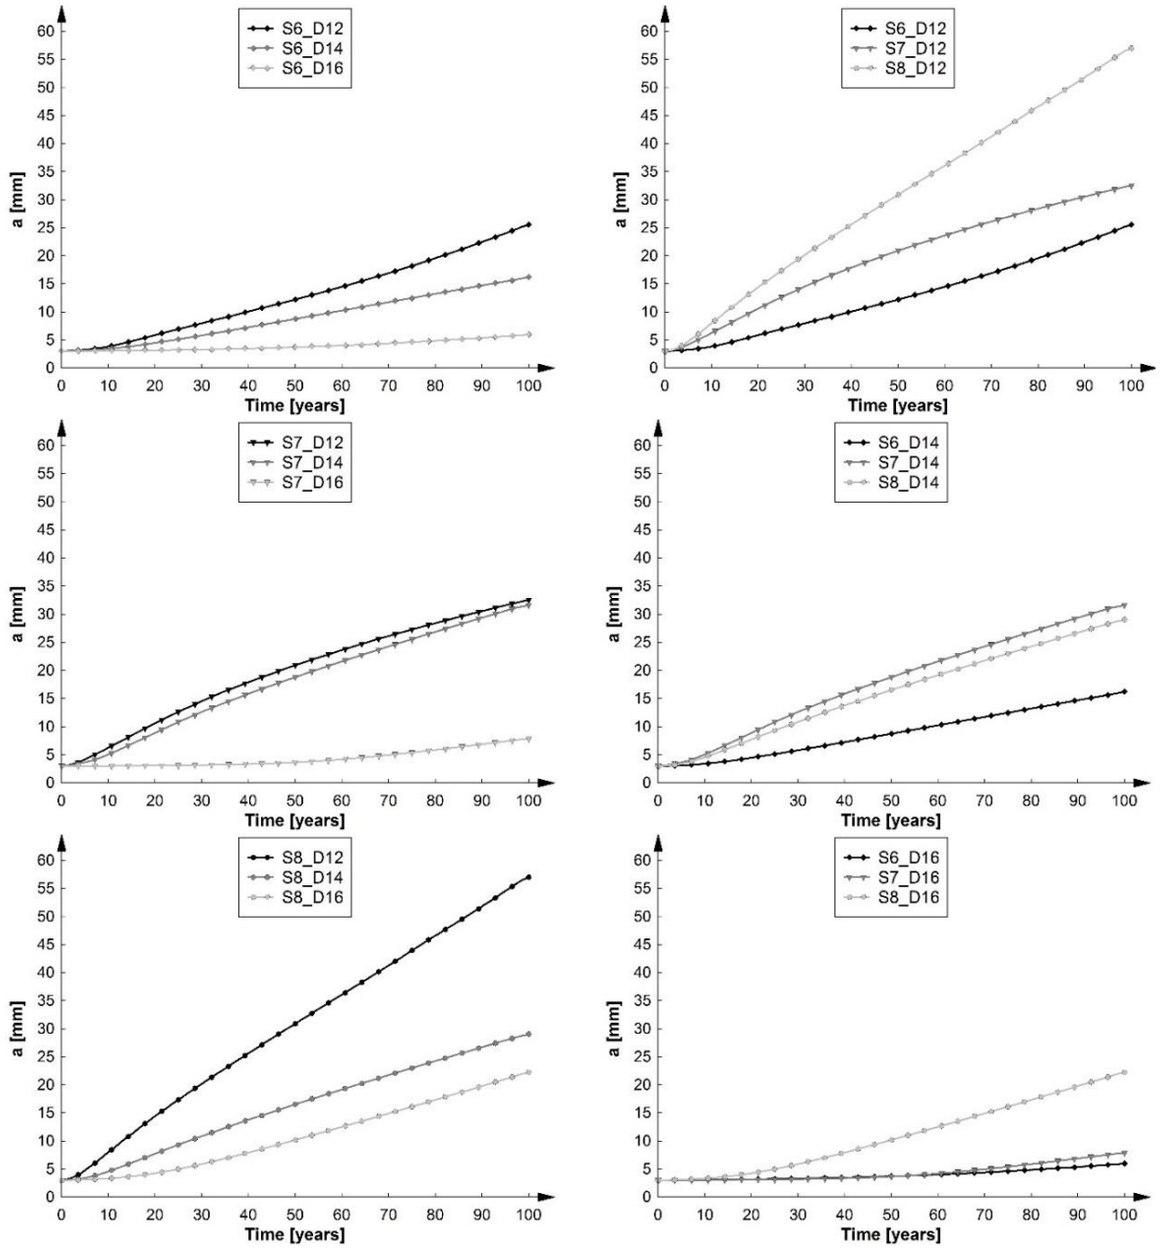

Figure 5. Fatigue life for different deck plate and stiffener thicknesses. Legend: S = stiffener - number = thickness of the stiffener - D = deck plate - number = thickness of the deck plate. Left: fatigue life curves grouped per stiffener thickness. Right: fatigue life curves grouped per deck plate thickness.

Table 2. Amount of crack propagation through the deck plate at 100 years and the corresponding fatigue life. Stiffener-to-deck plate detail: S = stiffener - number = thickness of the stiffener - D = deck plate - number = thickness of the deck plate.

Stiffener-to-deck plate detail	S6_D12	S6_D14	S6_D16	S7_D12	S7_D14	S7_D16	S8_D12	S8_D14	S8_D16
Crack propagation through deck plate at 100 years [%]	-	63	10	75	70	31	100	77	66
Fatigue life [years]	-	>100	>100	>100	>100	>100	41.84	>100	>100

Therefore, the effect of using a light weighted construction is really present. This also confirms that using thicker deck plates increases the fatigue life. However, this is not always the necessary, especially when thick plates of 15 mm are used in new orthotropic bridge deck designs.

Finally, the effect of random loads is compared to fixed sequences. With the current fatigue design methods, the Palmgren-Miner method is used. This method is not very accurate since the load history and the load sequences do not have any effect on the fatigue resistance. With LEFM however, it is possible to take the load sequence into account. In Figure 6 a comparison is made between a random sequence and two fixed sequences. Sequence 1-2-3-4-5 corresponds with the set of equivalent lorries described in Eurocode using the same order. This agrees with using the smaller lorries first and ending with the heavy lorries. Sequence 5-4-3-2-1 is the opposite.

It is clear that the load sequence has an influence on the crack propagation. When first using lower loads and ending with heavy loads, the crack propagation is much lower at the beginning when compared with first using heavy loads and ending with lower loads. Remarkably, at the end of the calculated service life, it does not matter if a random sequence or a fixed one is used. This means that no real memory effect is present in the fatigue calculation with LEFM.

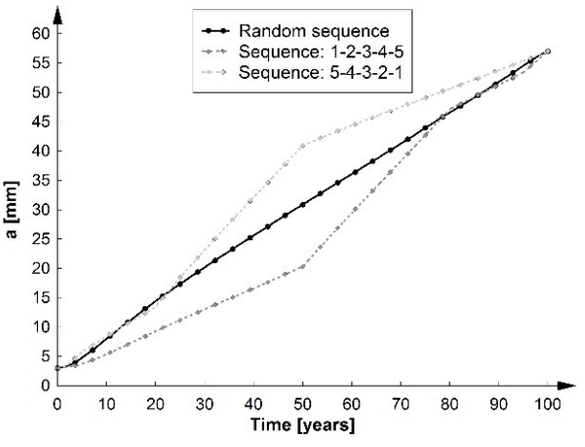

Figure 6. Random sequence of applied loads versus fixed sequences

3 CONCLUSIONS

Using LEFM as a fatigue assessment tool has many benefits compared to the current fatigue designs with Eurocode. It is a more in-depth method resulting in the evaluation of both the crack growth direction and the crack propagation. The advantages of this method can be combined with the implementation of the initial stress state due to dead load and residual stresses. By doing this, a more realistic crack path can be evaluated. For all different stiffener-to-deck plate geometries studied in this paper, all cracks propagated through the deck plate.

When comparing the crack propagation for all different geometries, it can be concluded that an increased deck plate thickness increases the fatigue life of the stiffener-to-deck plate detail. However, this is not the case when looking to the thickness of the stiffeners web. Thicker stiffeners attract more stresses at the weld root resulting in faster crack propagation. The solution of keeping the advantages of a light weighted construction relies on reducing the thickness of the closed trapezoidal stiffeners and increasing the thickness of the deck plate, although the latter should be limited as well. In addition, the reduced thickness of the closed trapezoidal stiffeners is limited as well when looking the global displacements of the deck plate.

Using the Palmgren-Miner method in current design methods does not allow for accounting for the actual load sequences. When using LEFM, such an analysis can be performed. The effect of using fixed load sequences can have a major influence on the crack propagation. Although, when looking at the final crack at the estimated service life of the bridge deck, the crack propagation curves for both random and fixed sequences are coinciding in the end. Therefore, the load sequence has no influence when looking at the final stage of the fatigue life.

ABSTRACT: This paper proposes a novel retrofitting system for the strengthening of steel I-beams using prestressed unbonded carbon fiber reinforced polymer (CFRP) plates. The system relies on a pair of mechanical clamps. Each clamp holds two flat CFRP plates (each 50 × 1.4 mm) and anchors their prestressing forces to the steel I-beam via friction. The proposed system does not require any adhesive between the CFRP plates and the steel substrate; therefore, surface preparation and adhesive curing are not needed, which reduces the time and cost of retrofitting. The design considerations of the mechanical clamps, the most important elements of the proposed unbonded system, are explained. A finite element (FE) model was established to optimize the design of the required mechanical parts, and a set of pull-off tests was performed to evaluate the capacity of the optimized system. The experimental results show that the proposed system is capable of transferring almost the entire tensile capacity of the normal modulus CFRP plates to the steel substrate via friction, while no sliding of the joint was observed. Moreover, the proposed flat prestressed unbonded reinforcement (FPUR) system was applied on a 6.4-m-long steel I-beam and the high performance of the system was confirmed based on the results of a set of four-point static and fatigue tests. Relying on the laboratory experimental tests, the proposed FPUR system was applied on the cross-girders of an almost 120-year-old steel bridge in Australia to monitor its long-term performance as a strengthening solution to increase the capacity and/or fatigue life of existing metallic I-beams.

1 INTRODUCTION

The unique advantages of carbon fiber reinforced polymer (CFRP) composites have made CFRP reinforcement a suitable material for strengthening of steel structures (Zhao 2013). It has been shown that the application of nonprestressed bonded ultra-high modulus CFRP reinforcement can prolong the fatigue life of steel members. However, crack prevention or crack arrest is only possible when prestressed CFRP reinforcement with a certain level of prestressing is used (Ghafoori et al. 2015a, Hosseini et al. 2017a). On the other hand, due to the limitations of prestressed bonded reinforcement systems, such as their time-consuming and costly surface preparation, inability to withstand relatively high prestressing forces, and premature debonding failure of bonded reinforcements (Hosseini et al. 2017b,c), a novel trapezoidal prestressed unbonded reinforcement (TPUR) system was developed by Ghafoori & Motavalli (2015) and used to strengthen a 120-year-old railway metallic bridge in Switzerland (Ghafoori et al. 2015b). It was shown by the authors that the proposed TPUR system has certain advantages, including ease of application, elimination of any surface preparation, and high performance of the system in terms of prestressing levels (Ghafoori & Motavalli 2015).

In the current study, another configuration of a prestressed unbonded reinforcement system, i.e. a flat prestressed unbonded reinforcement (FPUR) system is introduced for the strengthening of metal-

lic I-beams using prestressed CFRP plates. The design concept and finite element simulation are discussed. Furthermore, sets of static and fatigue tests were performed as part of the current study to evaluate the performance of the proposed system. A brief discussion of the laboratory test results and the field application of the proposed FPUR system are provided in the current paper.

2 CONCEPT AND OVERALL VIEW OF THE PROPOSED STRENGTHENING SYSTEM

As illustrated in Figure 1, the FPUR system relies on two sets of mechanical clamps i.e. a *fixed clamp* on one side, and a *movable clamp* on the other side of the beam. The two mechanical clamps are capable of transferring the prestressing force of the CFRP plates to the lower flange of a metallic I-shaped girder via friction. Each set of mechanical clamps holds two prestressed normal modulus (NM) CFRP plates with cross-sectional dimensions of 50 × 1.4 mm (width × thickness). The strengthening procedure using the proposed FPUR system consists of the following three steps:

1) Installation of the mechanical clamps and the nonprestressed CFRP plates (see Fig. 1a): on both sides of the beam, the nonstressed CFRP plates are sandwiched between 16-mm thick toothed plates installed inside the *lower plate* and *upper plate* with five M16 (grade 12.9) and ten M10 (grade 12.9) prestressed bolts. The bolts generate a total gripping force of about 1230 kN. On one side of the beam (the left side in Fig. 1a) the beam bottom flange is sandwiched between the *upper plate* and the *over-flange plate* by fastening eight M20 (grade 12.9) bolts tightened with a torque of 605 Nm, to generate a prestressing force of 223 kN per bolt. This results in a full gripping force between the *fixed clamp* set and the beam bottom flange. On the other side of the beam, the nonstressed CFRP plates are sandwiched in the *movable clamp*, and this clamp set is free to move horizontally along the beam axis for prestressing.
2) Installation of the prestressing system, applying the required prestressing force, and fastening the movable clamp (see Fig. 1b): two 120-kN hollow plunger cylinders are installed adjacent to the *movable clamp* using a special cylinder housing. The cylinder housing is anchored to the beam bottom flange in a similar way to the *fixed clamp* set. With the help of two M16 threaded rods, the *movable clamp* can be pulled using the hollow plunger cylinders connected to a manual hydraulic pump, and consequently, the CFRP plates can be prestressed. Upon reaching the desired prestressing level in the CFRP plates, all the eight M20 bolts of the *movable clamp* can be tightened with a torque of 605 Nm, which leads to the designed gripping force between the mechanical clamping system and the beam flange.
3) Removing the prestressing system to realize the final configuration as depicted in Figure 1c: after reaching the desired prestressing force in the CFRP plates, the hydraulic pressure can be released and the entire prestressing system consisting of the two hollow plunger cylinders and the cylinder housing can be removed.

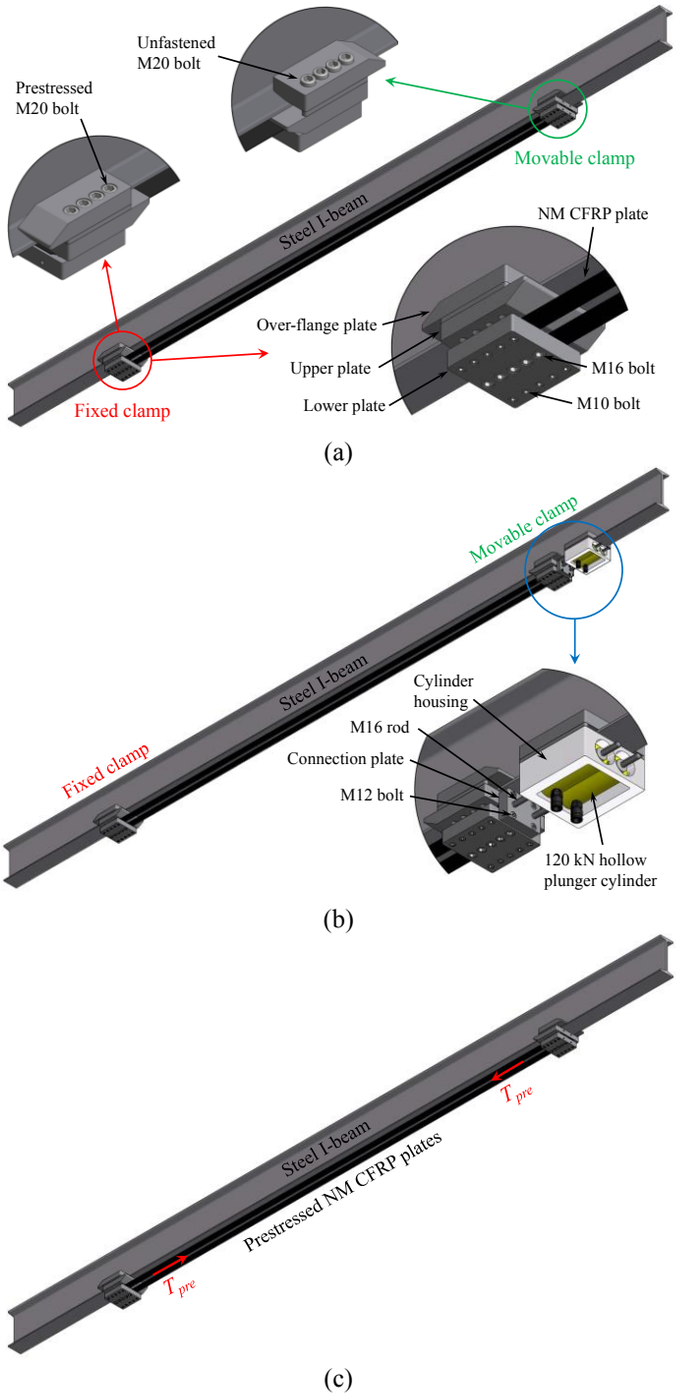

Figure 1. Strengthening a steel I-beam using flat prestressed unbonded reinforcement (FPUR) system: (a) Installation of the mechanical clamps and non-prestressed NM CFRPs; (b) Installation of the prestressing system and applying the required prestressing level; (c) Fastening the movable clamp and removing the prestressing system.

3 FINITE ELEMENT SIMULATION

3.1 *Model description*

In order to optimize the geometry of the mechanical components of the FPUR system and estimate the required number and diameter of prestressed bolts, a finite element (FE) simulation was performed using ABAQUS (2016). Due to symmetry, only half of the proposed mechanical clamping system, installed on a 1.5-m-long INP300 steel profile was assembled in ABAQUS (Fig. 2). The FE model consisted of a NM CFRP plate (50 × 1.4 mm) gripped in the proposed mechanical clamping system, while the clamp is anchored on the bottom flange of the INP300. All the steel parts and the CFRP plate were modelled as isotropic linear elastic materials with an elastic modulus of 210 and 160 GPa, respectively, and a Poisson's ratio of 0.3. A hard contact was used between all the individual parts in the normal direction; however, using the penalty formulation, an isotropic tangential friction was introduced between the CFRP plate and toothed hard plates, as well as between the clamping system and the steel I-beam. Coefficients of friction equal to μ_s = 0.5 and 0.3 were used in the case of CFRP-to-hard plate and steel-to-steel, respectively (see Hosseini et al 2017a,c for further details). The CFRP and the steel substrate were modelled using 8-node linear brick elements of type C3D8R with reduced integration and hourglass control, while the entire clamping system was modelled using 4-node linear tetrahedrons of type C3D4. A total number of about 365,000 elements was generated.

In addition to the symmetry boundary condition, horizontal and vertical support boundaries were introduced into the model to stabilize the assembly (Fig. 2). In the first step, static uniform pressures of 395 and 540 MPa per bolt location were introduced on the upper and lower plates to simulate the prestressing force of 52.1 and 142.4 kN per bolt generated in M16 and M10 high-strength bolts, respectively. In the next step, a static uniform pressure of 546 MPa per bolt location was introduced on the over-flange and upper plates to simulate the prestressing force of 223 kN per bolt generated in M20 high-strength bolts. Finally, a uniform surface traction of 2800 MPa (equal to the nominal tensile strength of the CFRP, $\sigma_{f,u}$) was applied to the free edge of the CFRP plate to observe any probable slippage of the joint before reaching $\sigma_{f,u}$.

3.2 *FE results*

Figure 2 shows the von Mises stresses in the FE model when the full bolt prestressing load is applied on the clamping system and the CFRP plate is pulled up to its tensile strength $\sigma_{f,u}$. It can be seen that by using 40mm-thick lower and upper plates manufactured from M200 steel with the nominal yield strength of f_y = 1000 MPa, the maximum stresses in the clamping system remain below 0.6 f_y.

Using the optimized FE model of the mechanical clamp, the load–displacement response of the CFRP plate was obtained and is provided in Figure 3. It can be seen from the figure that the proposed mechanical clamping system is capable of transferring the entire tensile capacity of the CFRP plate ($\sigma_{f,u}$ = 2800 MPa) to the steel I-beam before any slippage of the clamp occurs. It is worth mentioning here that an approximately uniform contact pressure between the toothed hard plates and the CFRP reinforcements needs to be obtained by fastening the prestressed bolts; otherwise probable stress concentration on the CFRP edges can result in longitudinal delamination of the CFRP during prestressing (Hosseini et al. 2017c). A uniform distribution of contact pressure can be obtained by careful design of the toothed hard plates (see Hosseini et al. 2017c for further details).

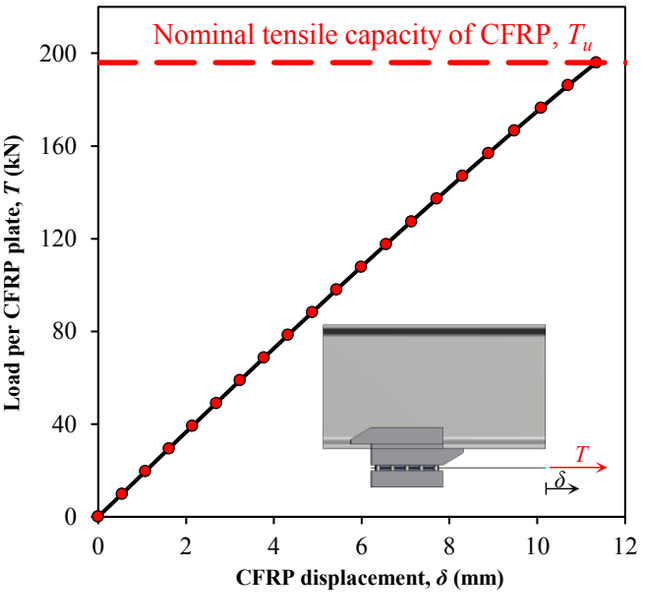

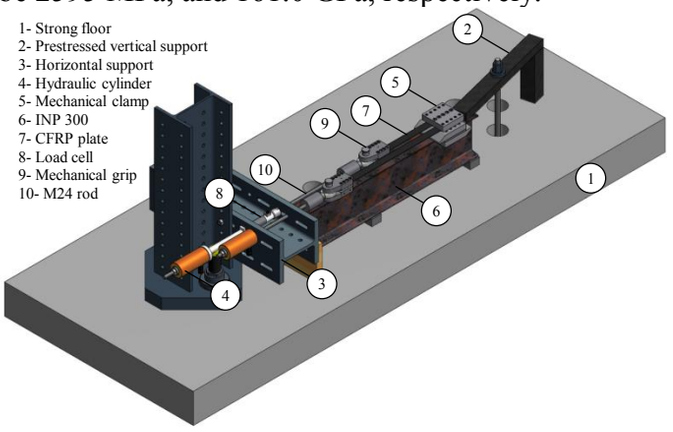

Figure 3. FE results: Load–deformation response of mechanically-clamped CFRP plate up to ultimate tensile capacity.

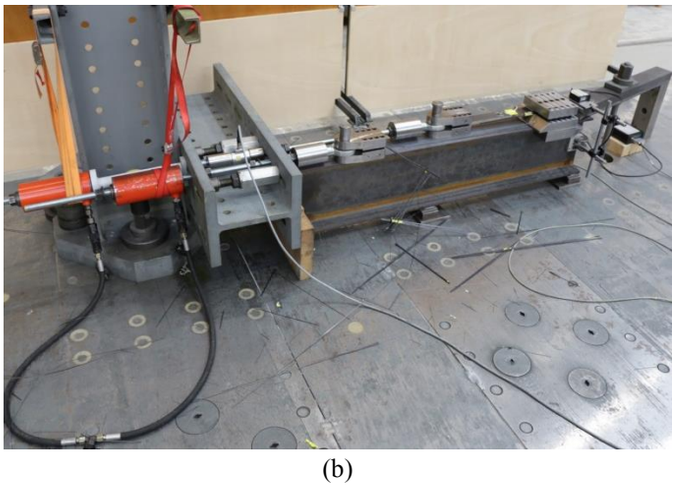
4 EXPERIMENTAL VERIFICATION



4.1 *Pull-off test*

4.1.1 *Test set-up and material properties*

All the required mechanical parts with the optimized geometry were manufactured from high-strength steel M200 with a nominal yield strength of 1000 MPa. A special *pull-off* test set-up was then designed to evaluate the ultimate capacity and failure mode of the proposed mechanical clamping system and a pull-off test was performed on the optimized configuration of the system (Fig. 4a). Note that NM CFRP plates of type S&P 150/2000-50/1.4 were used in all the tests, and the tensile strength and elastic modulus of the utilized CFRP composite were determined to be 2595 MPa, and 161.0 GPa, respectively.

(a)

(b)

Figure 4. (a) Pull-off test set-up; (b) Tensile rupture of CFRP plate.

4.1.2 *Experimental results*

The strain level generated in the CFRP plates vs. the applied load per hydraulic cylinder is provided in Figure 5. It can be seen from Figure 5 that the strain response of the CFRP plates was almost linear with respect to the applied load up the tensile rupture of one of the CFRP plates. It should be mentioned that the force was generated in the hydraulic cylinders using a manual hydraulic pump. Therefore, as the test was performed under load-control conditions, any slippage of the clamp would have occurred as a sudden drop in the load level, which was not the case in the test conducted. Figure 4b shows the tensile rupture of the CFRP plate.

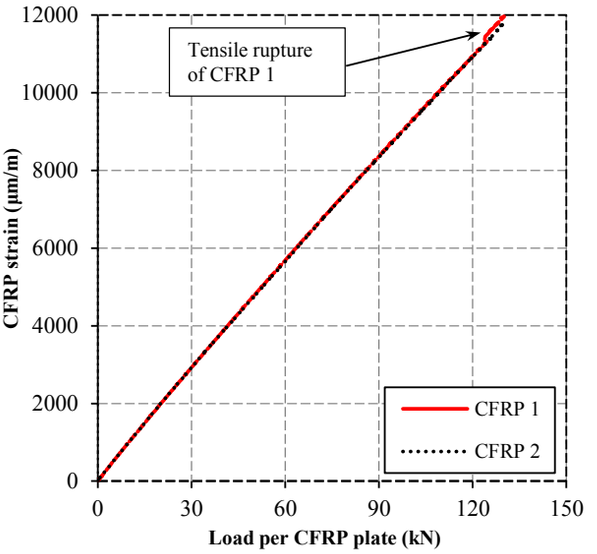


Figure 5. Strain in CFRP plates vs. applied load in pull-off test.

4.2 *Static and fatigue four-point bending test*

4.2.1 *Test set-up and material properties*

In order to evaluate the performance of the proposed FPUR system for the strengthening of metallic I-beams, sets of static and fatigue tests were performed at the Structural Engineering Research Laboratory of Empa on a 6.4-m long steel I-beam under four-point bending. The centre-to-centre distance of the supports was 5.3 m, while the centre-to-centre distance of the 250 kN hydraulic actuators was 1.8 m. An Amsler pulsator of type P131 was used to perform both static and fatigue tests. The steel I-beam utilized in the four-point bending tests was of type S275JR with an elastic modulus of 203.3 GPa, and yield and ultimate strength of 328 and 465 MPa, respectively. The CFRP plates were taken from the same batch of material as for the pull-off test. The four-point bending test set-up is shown in Figure 6.

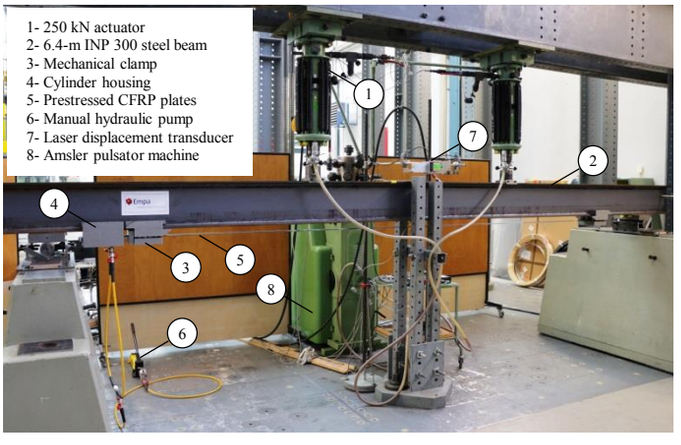

Figure 6. Static and fatigue four-point bending test set-up.

4.2.2 *Experimental results*

First a reference unstrengthened INP300 beam was loaded in the linear regime up to 75 kN per cylinder. Next, the proposed flat unbonded reinforcement (FUR) system, without any prestressing force, was installed on the beam and the beam was reloaded up to 75 kN per cylinder. Note that the intention of using the FUR system was to observe the efficiency of nonprestressed CFRP reinforcements for the strengthening of the steel I-beam. Finally, the CFRP plates were prestressed (see Section 2 for the prestressing process) up to 10, 20, 30, 40% of tensile strength $\sigma_{f,u}$, and each time the beam was loaded up to 75 kN per cylinder. Figure 7 shows the strain history of the CFRP plates and the top and bottom flanges of the INP300 during the prestressing process for the case of FPUR with 40% prestressing level. Figure 7 illustrates that with a 40% prestressing level in the CFRP reinforcement, a compressive stress of 70.3 MPa is generated in the bottom flange of the beam, while the top flange experiences 23.6 MPa tensile stress when the beam is unloaded.

As indicated by the experimental results in Figure 8, the application of the nonprestressed FUR system slightly increases the stiffness of the strengthened member; however, the deflection/strain reduction in the member is not significant, owing to the fact that the utilization of nonprestressed CFRPs cannot considerably increase the stiffness of a real-scale steel member. On the other hand, Figure 8 illustrates that using the proposed FPUR system with higher prestressing levels can significantly decrease the maximum deflection and strain level in the strengthened steel I-beam under service loads. Consequently, the proposed system may be a very efficient strengthening solution to increase the yield strength and/or fatigue life of existing metallic I-beams.

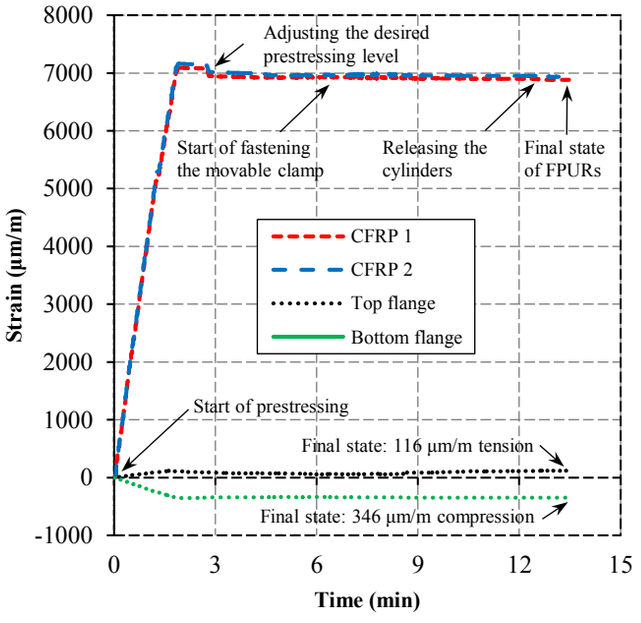

Figure 7. Strain history of CFRP plates, and top and bottom flanges of INP 300 during prestressing up to $0.4\sigma_{f,u}$.

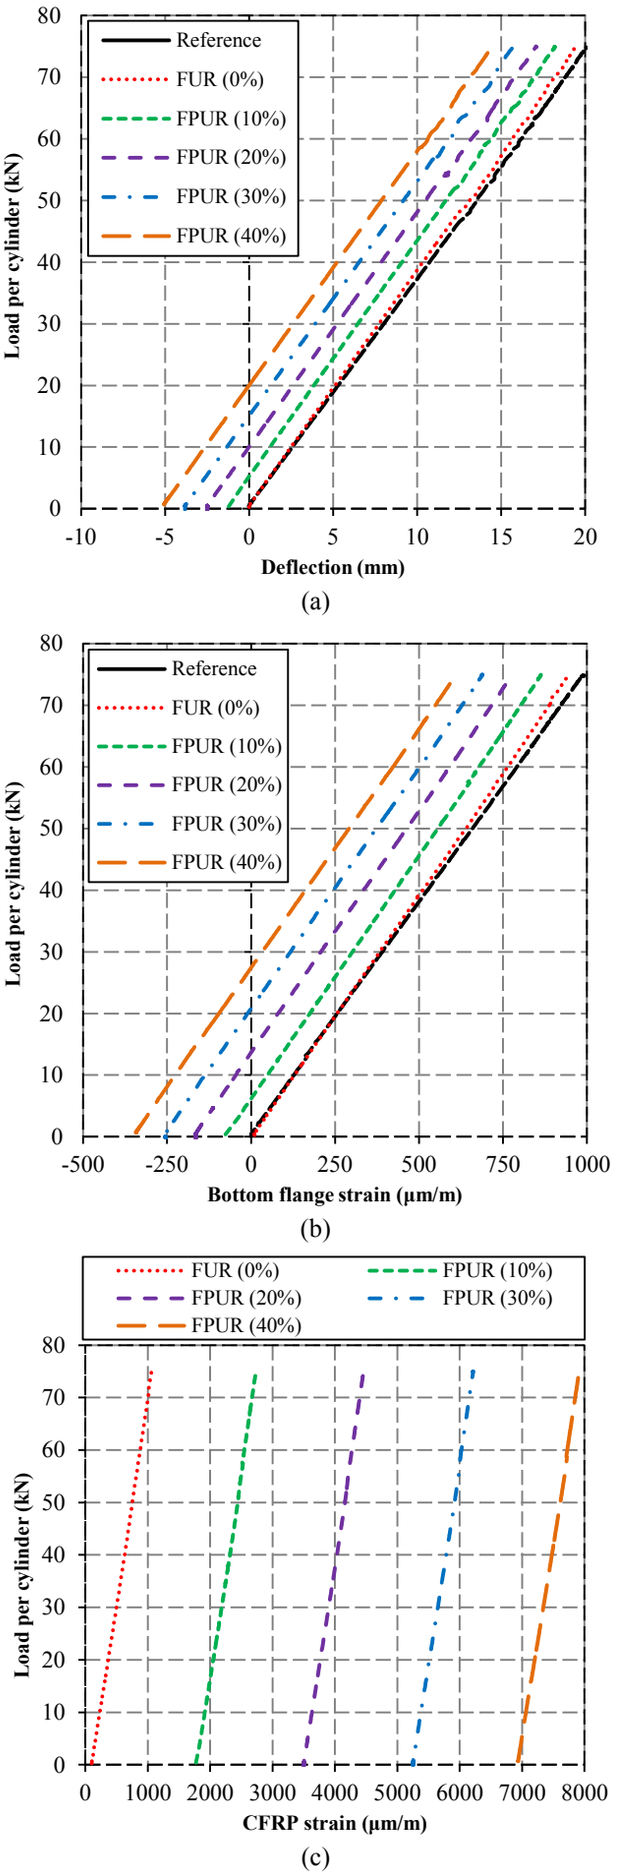

Figure 8. Static test results: (a) Load-deflection diagrams; (b) Load-strain response of bottom flange; (c) Load-strain response of CFRPs.

In addition to the four-point static tests, the performance of the proposed FPUR system was also evaluated under fatigue loading for 10 million fatigue cycles, while the CFRP plates were prestressed up to almost 40% of their ultimate strength. The four-point fatigue test was performed under load-control conditions with a load ratio ($R = P_{min}/P_{max}$) of 0.2 and a loading frequency of 4.35 Hz. The maximum load level during the fatigue test on the INP 300 beam was equal to P_{max} = 40.2 kN per cylinder, corresponding to $0.33f_y$ in the top and bottom flanges of the unstrengthened beam.

Figure 9 illustrates the evolution of the maximum and minimum strain levels in the FPUR system and the bottom flange of the INP300 with respect to the elapsed fatigue cycles. It can be seen from the figure that during the four-point fatigue test the maximum strain in the prestressed CFRP plates remained constant for the 10 million loading cycles. This proves that the proposed FPUR system experienced no slippage during fatigue loading, as no reduction in prestrain level was observed. Furthermore, Figure 9 shows that by applying the FPUR on the INP 300 beam, the bottom flange of the beam remains in compression for almost half of the loading range, which can significantly improve the fatigue performance of the strengthened member.

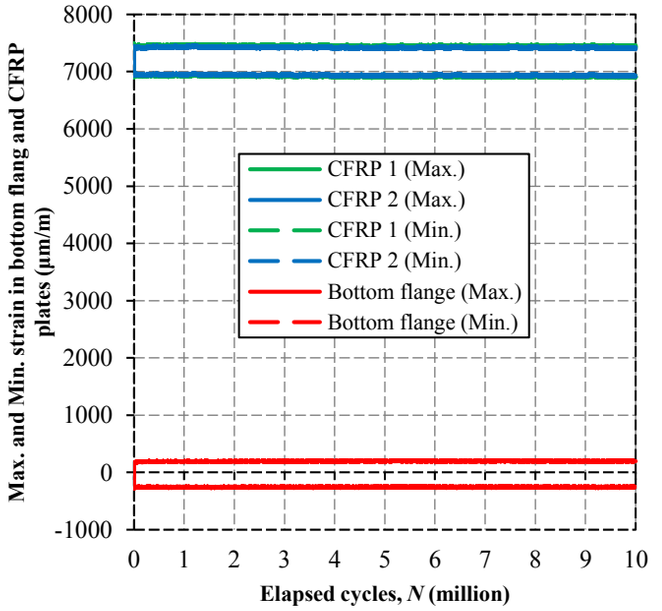

Figure 9. Fatigue test results: evolution of maximum and minimum strain in CFRP plates in response to elapsed fatigue cycles.

5 FIELD APPLICATION OF THE PROPOSED FPUR SYSTEM

After successful laboratory tests performed on the proposed FPUR system, the system was applied on two cross-girders of a roadway metallic bridge called *SN6091 Bridge* over Diamond Creek on the Heidelberg-Kinglake Road in Victoria, Australia. The steel I-shaped cross-girders were strengthened with the proposed FPUR system with a prestressing level of about 38%. A wireless sensor network (WSN) system is installed on the bridge for long-term monitoring of the strain levels in prestressed CFRP plates. Figure 10 shows the FPUR and the WSN systems applied on the cross-girders of the *Diamond Creek Bridge*. Sets of truck loading were performed before and after strengthening of the bridge, which showed excellent performance of the FPUR system, as the bending stresses in the bottom flanges of the girders were reduced to almost half after application of the FPUR system. The long-term performance of the system will be monitored for at least one year using the installed WSN system. As a detailed explanation of the field application of the FPUR system on the *Diamond Creek Bridge* is beyond the scope of the current paper, readers are referred to Ghafoori et al. (2018) for a comprehensive discussion of the topic.

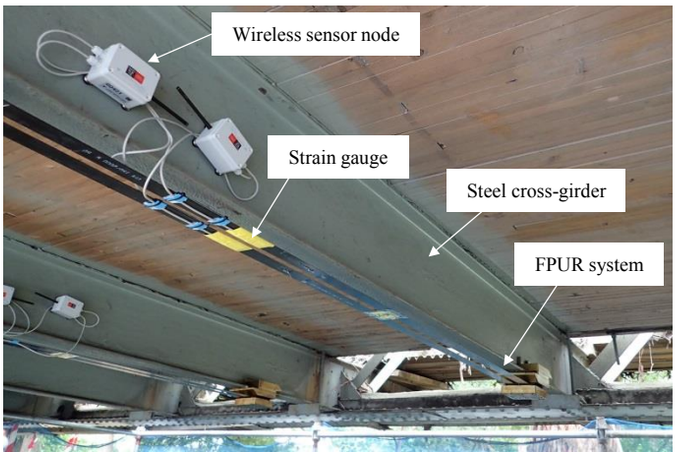

Figure 10. Application of proposed flat prestressed unbonded reinforcement (FPUR) system for strengthening of cross-girders of Diamond Creek Bridge, Victoria, Australia.

6 SUMMARY AND CONCLUSIONS

In the current study, a novel friction-based mechanical clamping system, called the FPUR system, for the strengthening of metallic I-beams with prestressed CFRP plates was designed, manufactured, and tested under static and fatigue loading. Experimental results revealed that the proposed system is capable of transferring the entire tensile capacity of the CFRP plates to the steel I-beam via friction, while the performance of the system is not affected by fatigue loading, as no slippage of the clamping system was observed over 10 million fatigue cycles. The advantages of the proposed FPUR system can be summarized as follows:

- Ease of installation and prestressing,
- Elimination of surface preparation required for any bonded reinforcement,
- Prevention of any installation damage to existing members,

- Capability of modifying (decreasing or increasing) the prestressing level at any time,
- Capability of easy removal of the entire system without damage to existing members,
- Insensitivity of the system to high service temperatures which might be a significant issue for adhesively bonded reinforcements, and
- High performance of the system in terms of prestressing levels.

Based on the laboratory test results and the advantages of the proposed FPUR system, it is concluded that the system may be an efficient strengthening solution to increase the yield strength and/or fatigue life of existing metallic I-beams. The proposed FPUR system has been applied on the *Diamond Creek Bridge* in Victoria, Australia, and its long-term performance will be monitored using a wireless sensor network (WSN) system.

ABSTRACT: This paper presents the first application of pre-stressed carbon fibre-reinforced polymer (CFRP) material for strengthening of a metallic bridge in Australia. The study also describes the application of a wireless sensor network (WSN) system for long-term structural health monitoring (SHM) of the installed retrofit system. A flat pre-stressed un-bonded reinforcement (FPUR) system was developed to apply pre-stressed CFRP strips to the steel girders of Diamond-Creek Bridge. The bridge is a 121-year-old metallic roadway bridge in Melbourne, which is subjected to daily passenger and heavy truck vehicles. Sets of laboratory tests were performed to examine the efficiency of the proposed FPUR system, prior to its installation on the bridge. Furthermore, in order to demonstrate the efficiency of the proposed retrofit technique, the bridge was instrumented with different types of sensors (including strain gauges, temperature and humidity sensors) and short- and long-term measurements were performed. As for short-term measurements, the bridge was loaded by a 42.5-tonnes semi-trailer before and after strengthening. For the long-term monitoring, a WSN system was used to monitor the prestress level in the CFRP reinforcements for at least one year. The CFRP plates were pre-stressed up to about 980 MPa (≈38% of the CFRP ultimate strength), which resulted in about 50% reduction in the maximum tensile stress in the bridge girders. The results of the short- and long-term measurements in this study showed that the FPUR system was very effective for flexural and fatigue strengthening of the bridge girders.

1 INTRODUCTION

Carbon fibre-reinforced polymer (CFRP) as a light material with a wide range of strength and Young's moduli has been used for strengthening concrete and steel members. The CFRP materials have high corrosion and fatigue resistance (Zhao 2013). Several studies have shown the effectiveness of using CFRP materials for flexural (e.g., Al-Emrani and Kliger 2006, Ghafoori and Motavalli 2013) and fatigue (e.g., Bassetti et al. 1998, Colombi and Fava 2015, Schnerch et al. 2006, Wu et al. 2012) strengthening of steel members.

The majority of the existing studies on this topic have used a bonded retrofit (BR) system to attach CFRP material to steel substrates. Ghafoori et al. 2012 have suggested an un-bonded retrofit (UR) system for strengthening of metallic girders. Unlike the BR systems, the UR systems work without any glue, and instead use a pair of mechanical clamps, which works based on friction, to attach the CFRP plates to steel I-beams. The UR systems have several advantages compared to BR systems: they can be applied to rough (e.g., corroded) or obstructed (e.g., riveted) surfaces and offer fast installation (i.e., no surface preparation prior to bonding and glue application). The UR systems are particularly good for strengthening heritage/old structures, where the reversibility of the retrofitted elements to the original unstrengthened form is important. The UR systems can be easily removed from the original structure by disassembling the mechanical clamps.

Ghafoori and Motavalli 2015c have performed the first systematic study to compare the behavior of the steel members strengthened by the BR and the UR systems. The results of extensive laboratory tests have shown that when metallic beams are strengthened by pre-stressed CFRP laminates, the performance of the CFRP-strengthened steel beams is more sensitive to the magnitude of pre-stress level rather than the presence of the bond (Ghafoori and Motavalli 2015b).

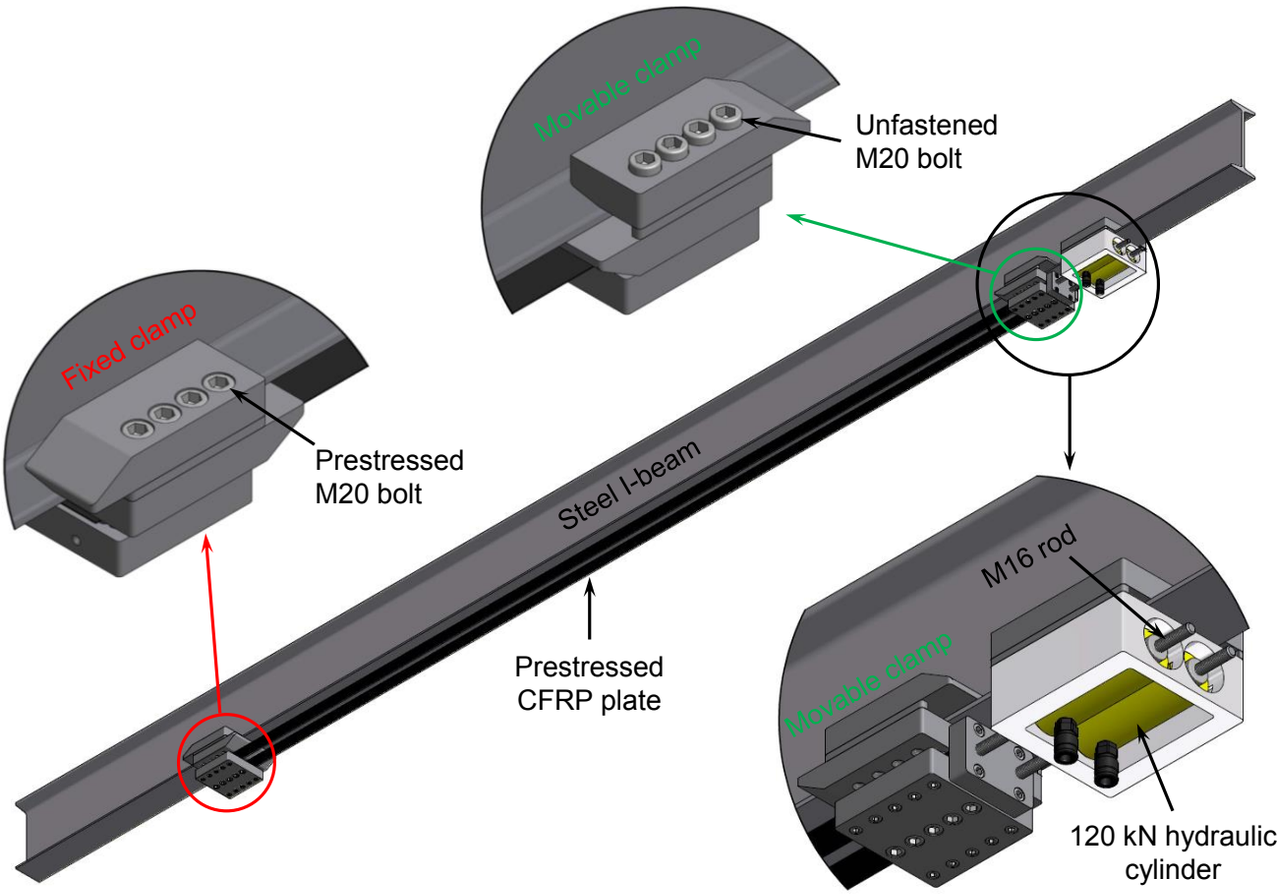

Figure 1. Different components of the flat prestressed unbonded reinforcement (FPUR) system.

Furthermore, Kianmofrad et al. 2017 have suggested different shapes and configurations of the pre-stressed UR (PUR) system. A trapezoidal PUR (TPUR) system was developed and tested under static (Ghafoori and Motavalli 2015a) and fatigue loading (Ghafoori et al. 2015a). The system has been used for fatigue strengthening of a 120-year-old railway riveted bridge in Switzerland (Ghafoori et al. 2015b, Ghafoori et al. 2014). More recently, Hosseini et al. 2018 have developed and tested a flat PUR (FPUR) system in the laboratory subjected to static and fatigue loading.

This paper presents the application of the FPUR system for strengthening of an old metallic roadway bridge in Victoria, Australia. Furthermore, a wireless sensor network (WSN) system was used to monitor the long-term behavior of the bridge after strengthening. The current paper aims to briefly explain different aspects of the bridge strengthening project and summarize the most important results of short-term and long-term measurements.

2 DEVELOPMENT OF THE FPUR SYSTEM

2.1 *Design basis and pull-off tests*

A FPUR system was designed, manufactured, and tested at the Structural Engineering Research Laboratory of the Swiss Federal Laboratories for Materials Science and Technology (Empa). As it is shown in Figure 1, the FPUR system relies on two sets of mechanical clamps, which transfer the pre-stressing force of the CFRP plates to the lower flange of the steel girders via friction. Each set of the mechanical clamps holds two prestressed normal modulus (NM) CFRP plates with cross-sectional dimensions of 50 × 1.4 mm (width × thickness). The strengthening procedure using the proposed FPUR system is as follows:

(1) the unstressed CFRP plates are anchored on one side of the beam using the so called *fixed clamp* with the help of eight M20 high-strength (grade 12.9) bolts, which are tightened with a torque of 605 N·m, to generate a prestressing force of 223 kN per bolt. (2) On the other side, the unstressed CFRP plates are gripped in the so called *movable clamp*, while the clamp set is free to move horizontally along the beam axis. (3) Two 120-kN hollow plunger cylinders are then installed adjacent to the *movable clamp* using a cylinder housing. (4) With the help of two prestressing M16 rods, the movable clamp is pulled using the hollow plunger cylinders connected to a manual hydraulic pump, and, subsequently, the CFRP plates are prestressed. (5) Upon reaching the desired prestressing level in the CFRP plates, all the eight M20 bolts of the movable clamps are tightened.

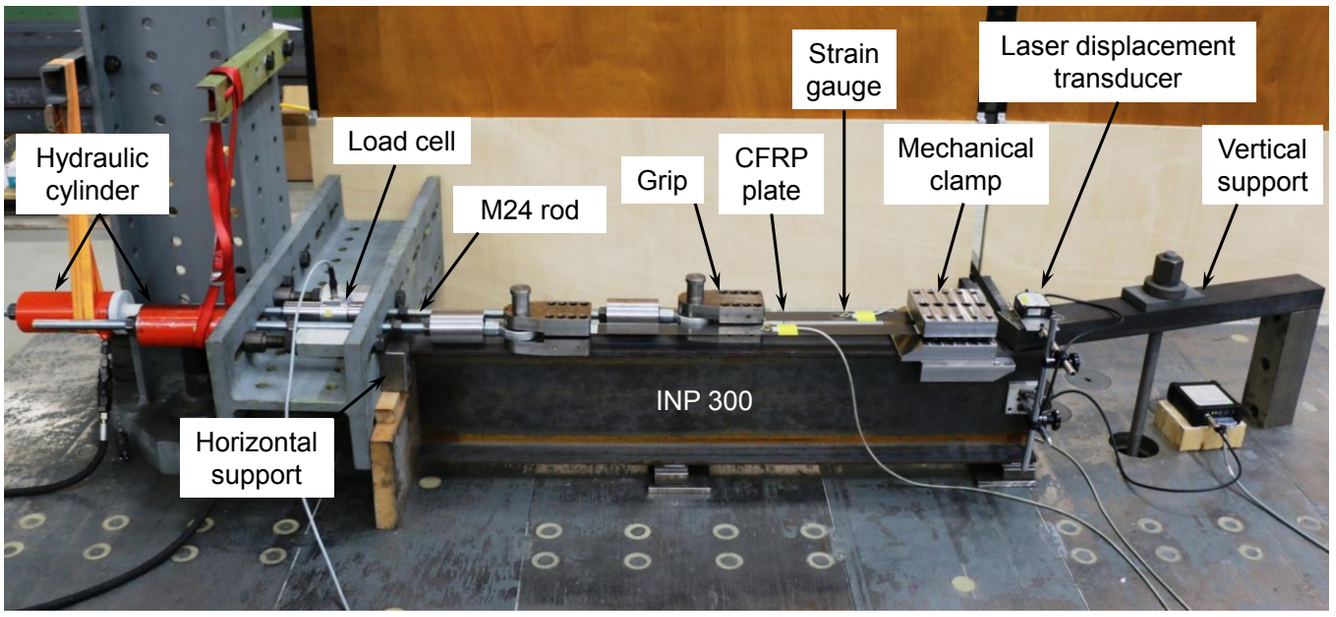

Figure 2. Pull-off test setup.

(6) Finally, the hydraulic pressure is released and the prestressing system consisting of the two hollow plunger cylinders and the housing are removed.

In order to optimize the geometry of the mechanical clamping system and estimate the number and diameter of the prestressed bolts (to generate the required friction force between the clamps and tensile flange of the beam), an FE simulation was performed using ABAQUS FE Package. Further details regarding the FE simulation of the FPUR system can be found in Hosseini et al. 2018. All the required mechanical parts, with the optimized geometry, were then manufactured from high strength steel M200 with a nominal yield strength of 1000 MPa.

In order to determine the ultimate capacity of the mechanical clamps before slippage, a pull-off test setup was designed and a set of pull-off tests were performed on the optimized configuration of the system. Different components of the test setup are shown in Figure 2. Figure 3 shows the strain level generated in both the CFRP plates versus the applied load per hydraulic cylinder. It can be seen from Figure 3 that CFRP rupture occurred as the governing failure mode of the system, and no slippage of the clamp was observed. The NM CFRP plates of type S&P 150/2000-50/1.4 were used in all the laboratory tests. The tensile strength and elastic modulus of the utilized CFRP composite were 2595 MPa and 161 GPa, respectively.

2.2 *Static and fatigue four-point bending tests*

In order to evaluate the performance of the proposed FPUR system for strengthening of steel I-beams, a set of static and fatigue tests was performed at the Structural Engineering Research Laboratory of Empa on 6.4-m long steel I beams under four-point bending. Figure 4 shows different elements of the test set-up and the FUR system. First a reference unstrengthened INP 300 beam was loaded in the linear regime (up to 75 kN per cylinder). Afterwards, the FPUR system was installed on the beam, and the beam was reloaded up to 75 kN per cylinder. As Figure 5 shows, the application of the non-prestressed CFRP plates increased the stiffness of the steel beam slightly, however, the deflection/strain reduction in the member is not significant.

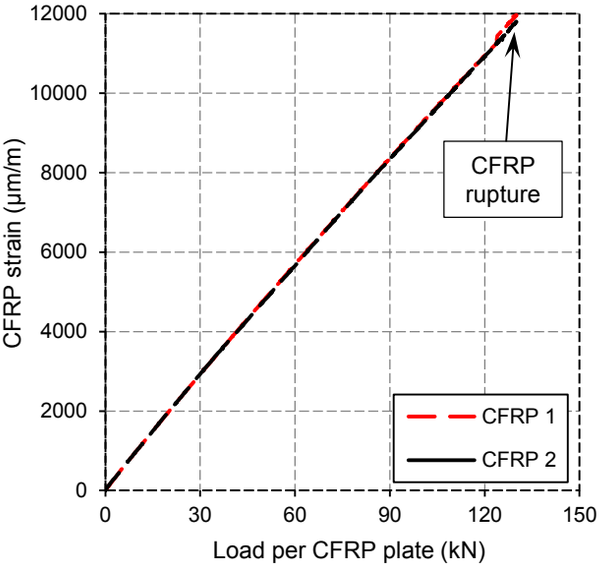

Figure 3. CFRP strain versus load in pull-off tests.

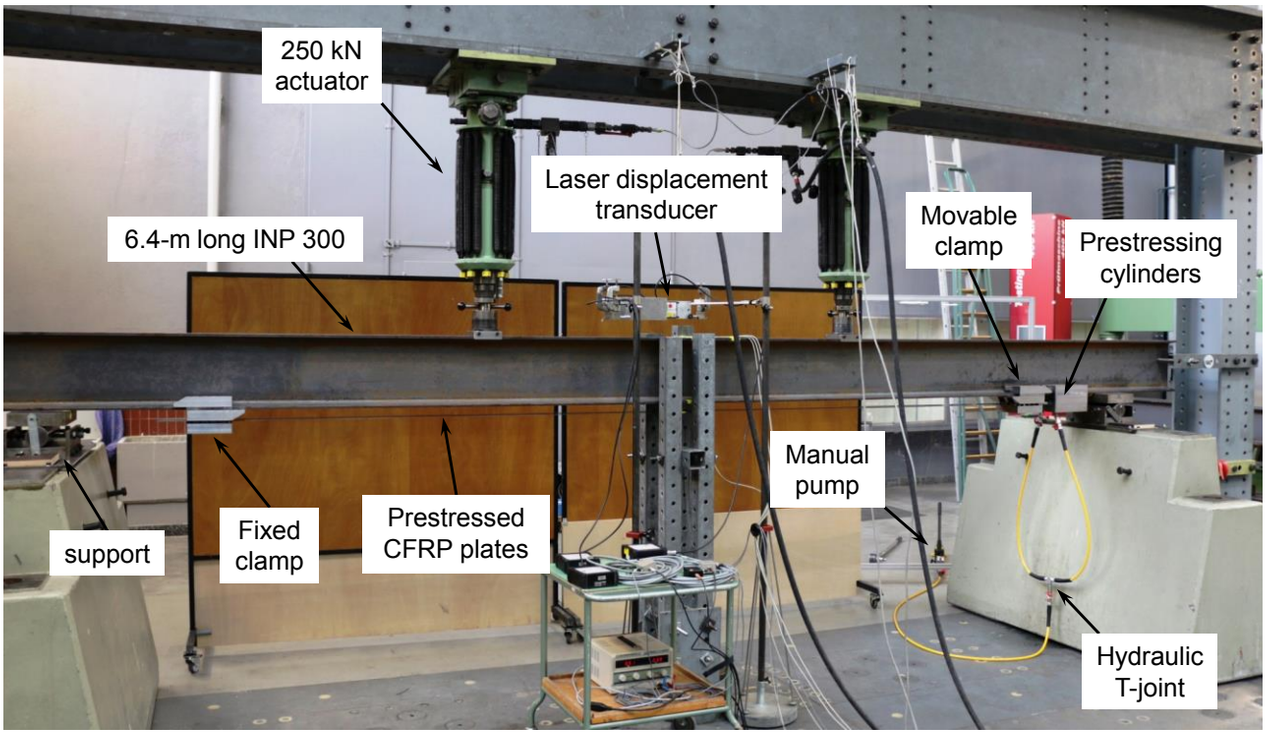
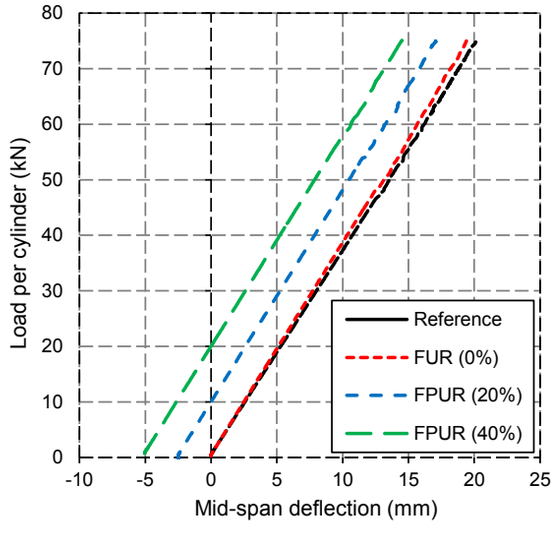
Furthermore, it can be seen from Figure 5 that application of the FPUR system with 20% or 40% prestressing level can significantly decrease the deflection and strain/stress level in the strengthened steel I-beam under service loads.





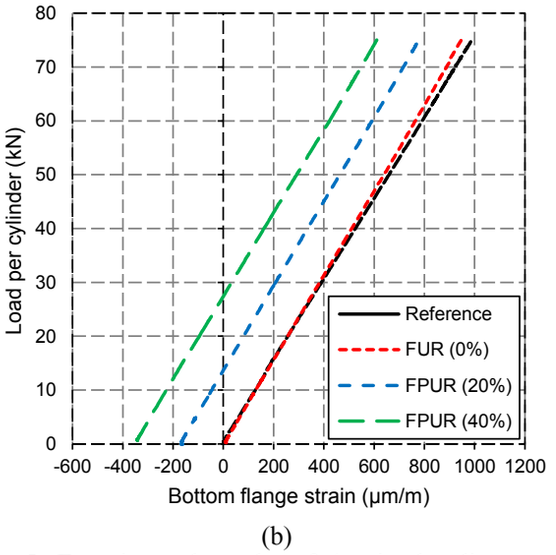


Figure 4. Static and fatigue four-point bending test setup.

(a)

(b)

Figure 5. Experimental results of 4-point bending tests: (a) load-deflection response; (b) load-strain response of bottom flange.

It should be mentioned that the utilized steel I-beams in the four-point bending tests was of type S275JR with a measured elastic modulus of 203.3 GPa, and yield and ultimate strength of 328 and 465 MPa, respectively.

In addition to the four-point static tests, the performance of the FPUR system was also evaluated under 4-point fatigue loading for 10 million fatigue cycles, while the CFRP plates were prestressed up to 40% of their ultimate tensile capacity. No slippage neither reduction in the prestressing level was observed over 2 million fatigue cycles, which demonstrates a superior performance of the system. After testing the system under static and fatigue loading, the system was shipped to Victoria, Australia.

More information about the FE modeling and laboratory tests on the FPUR system can be found in Hosseini et al. 2018.

3 STRENGTHENING OF DIAMOND-CREEK BRIDGE

SN6091 Bridge over Diamond-Creek along Heidelberg-Kinglake Road (constructed in 1896) is a double-span metallic roadway bridge in Victoria, Australia. The total length of the bridge is approximately 33 m with a width of 6.4 m and a height of 2.3 m. The bridge was constructed approximately 6.4 m above the river water level. The bridge is subjected to daily passenger and heavy truck vehicles. It consists of two longitudinal wrought iron trusses (i.e., as main girders) connected by several steel cross-girders, as shown in Figures 6 and 7.

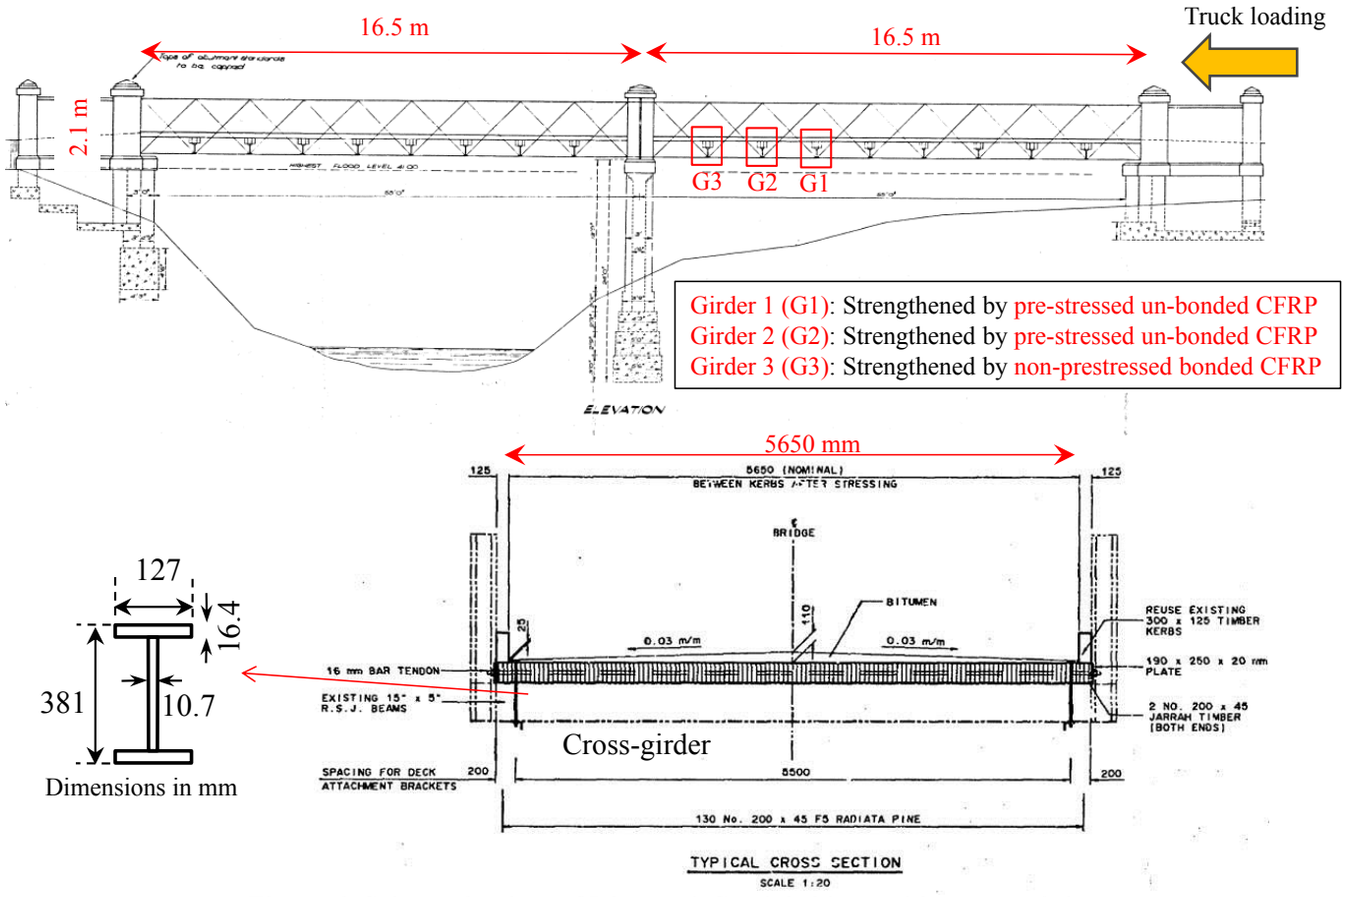

Figure 6. Schematic view of Diamond-Creek bridge and its cross-girders.

Figure 6 shows the bridge elevation as well as the details and dimensions of the cross-girders. The bridge belongs to VicRoads, which is the road and traffic authority in the state of Victoria.

Two girders of the bridge (i.e., girders G1 and G2) were strengthened by the FPUR system, and girder G3 was strengthened with non-prestressed bonded CFRP plate. For the sake of brevity, this paper only discusses the part of the work related to CFRP strengthening of girders G1 and G2.

3.1 *Strengthening of the bridge girders*

After successful accomplishment of the laboratory tests, presented in Section 2, the FPUR system was applied on two cross-girders of the bridge with a prestressing level of about 38%. The CFRP plates had the same geometrical and mechanical properties as those explained in Section 2.1. Based on the bridge documents, the steel cross-girders were of type B.S.B. 25 from the Dorman, Long & Co. Limited Company in UK. A Young's modulus, yielding and ultimate strength of 210 GPa, 250 and 320 MPa, respectively, were assumed for mechanical properties of the steel girders. Different elements of the strengthening and monitoring systems on girders G1 and G2 are shown in Figure 8.

As for short-term measurements, the bridge was subjected to a 42.5-tonnes semi-trailer before and after strengthening, as shown in Figure 7.

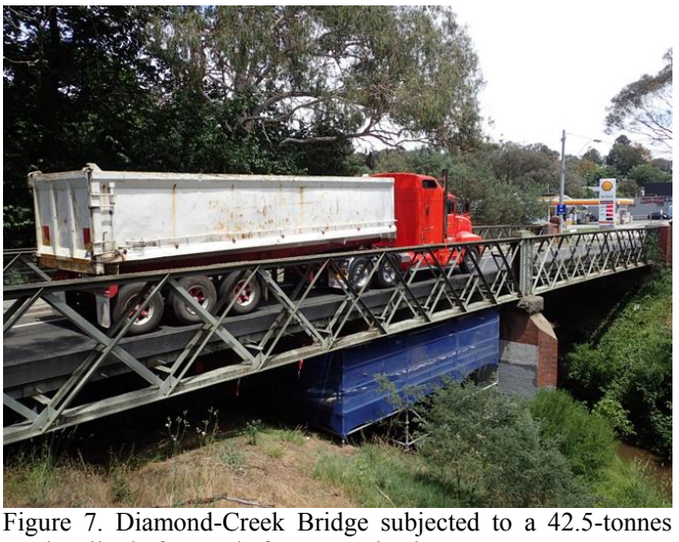

Figure 7. Diamond-Creek Bridge subjected to a 42.5-tonnes semi-trailer before and after strengthening.

Figure 9 shows the state of stresses in the CFRP plates and the top and bottom flanges of the steel girders during pre-stressing procedure. The CFRP plates were gradually pre-stressed up to about 38% (of its ultimate strength) using a set of hydraulic actuators, as explained in Section 2. From Figure 9, it can be seen that an increase in the CFRP pre-stress level results in an increase in the magnitude of the compressive stress at the beam bottom flange. After prestressing, a maximum compression of about 30 MPa was achieved at the beam bottom flange. Note that in Figure 9, the sudden jumps in the stresses

show the passages of vehicles (regular daily traffic) over the bridge during the pre-stressing process. Furthermore, it can be seen that pre-stressing process took place in less than 300 s. A truck loading test was then performed (as for short-term measurements) right after strengthening. Figure 10 shows the stresses at the top and bottom flanges of the mid-span of girder G2 due to the passages of the 42.5-tonnes semi-trailer with a slow speed of about 5 km/h.

The tensile maximum stress in the beam bottom flange before strengthening was about 80 MPa, which was then reduced to about 40 MPa after strengthening with the FPUR system. This shows a reduction of about 50% (i.e., ≈40 MPa) of the maximum tensile stress in the cross-girder. Out of 40 MPa decrease in the tensile stress, it can be shown that -30 MPa was because of the application of pre-stressing (see Figure 9) and -10 MPa was due to the increased stiffness of the girders after the CFRP strengthening. Furthermore, it can be seen from Figure 10 that the magnitude of the compressive stress in the top flange of the cross-girder was also slightly decreased after strengthening. Therefore, it can be concluded that strengthening with the FPUR system could decrease the magnitude of the stresses in the both top and bottom flanges, and, therefore, can result in an increase in flexural capacity of the bridge girders.

3.2 *Fatigue strengthening criterion*

It has been shown by Ghafoori et al. 2015c that application of pre-stressed CFRP can increase the fatigue life of the steel girders substantially. Ghafoori and Motavalli 2016 have suggested a constant life diagram (CLD) approach to estimate the pre-stressing level that results in a complete prevention of fatigue crack initiation. The CLDs are used to demonstrate the combined effect of stress range, mean stress level and material properties. CLDs can foresee the fatigue life of metals at different mean stress levels. For a given maximum stress (σ_{max}) and minimum stress (σ_{min}), the stress amplitude (σ_a) and the mean stress (σ_m) are expressed by

$$\sigma_a = (\sigma_{max} - \sigma_{min}) / 2 \quad (1)$$

$$\sigma_m = (\sigma_{max} + \sigma_{min}) / 2 \quad (2)$$

Figure 11 shows a CLD diagram which shows the fatigue strengthening approach used for strengthening of the bridge girders. In Figure 11, the vertical axis is the stress amplitude, σ_a, and the horizontal axis is the mean stress, σ_m. This figure also presents the yield line and the Gerber fatigue criterion, which is often used for ductile metals. Furthermore, Figure 11 shows the Modified Johnson line, which was proposed by Ghafoori et al. 2015b, as a fatigue design criterion for determination of the safe service stresses of old metallic bridge members.

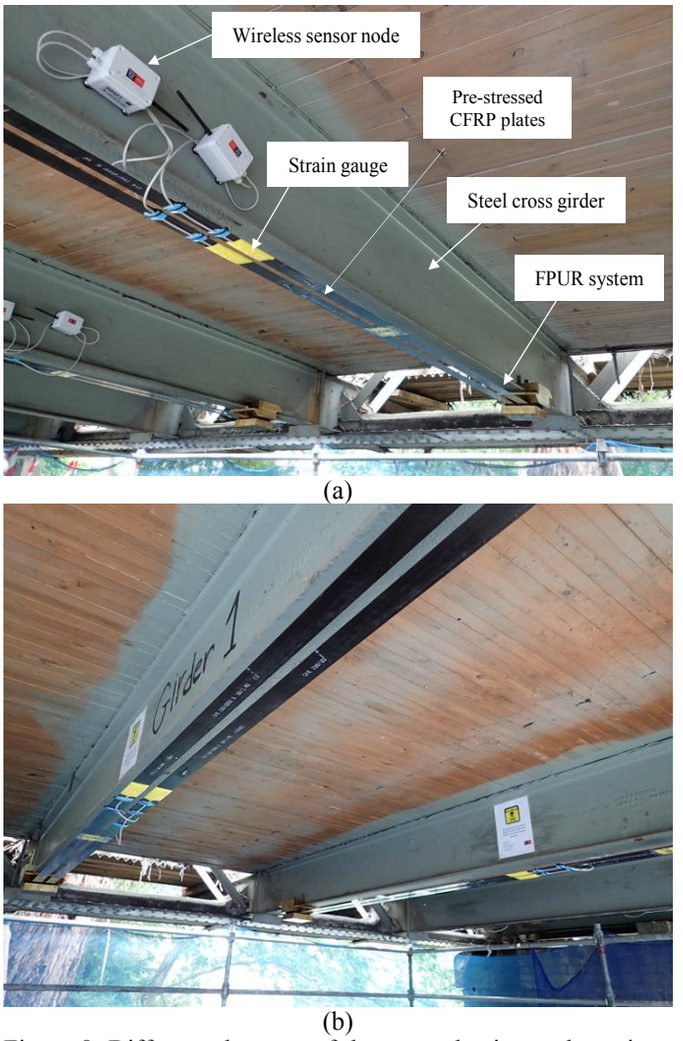

Figure 8. Different elements of the strengthening and monitoring system installed on (a) girder G2 and (b) girder G1.

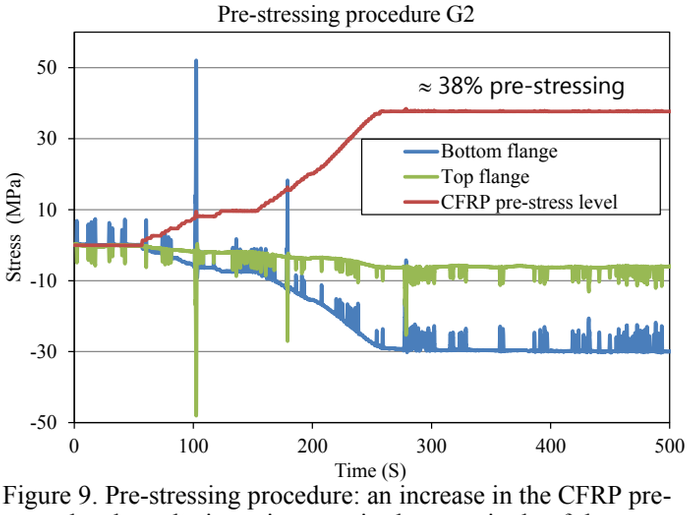

Figure 9. Pre-stressing procedure: an increase in the CFRP pre-stress level results in an increase in the magnitude of the compressive stress at the beam bottom flange.

Stress points A and B in Figure 11 refer to the state of the stresses in the beam bottom flange before and after strengthening, respectively. As it can be seen in this figure, point A, which refers to the stress state in the girder prior to strengthening, is marginally outside of the safe region.

After strengthening using the FPUR system, the working stress in the girder bottom flange was shift-

ed from the at-risk region (i.e., point A) to the safe-life region (i.e., point B) based on the modified Johnson criteria.

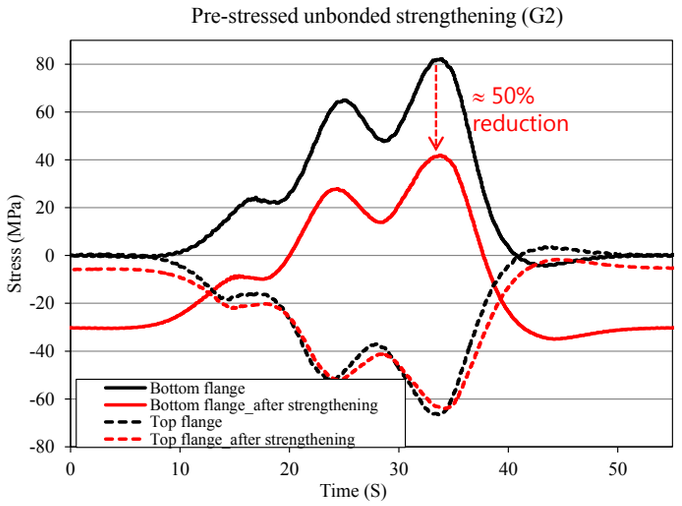

Figure 10. Stress at the top and bottom flanges in the mid-span of girder G2 due to the passages of a 42.5-tonnes semi-trailer before and after strengthening.

4 WIRELESS MONITORING SYSTEM

In the recent years, the WSN technology has been used for structural health monitoring (SHM) of different types of civil structures (Feltrin et al. 2013). The WSN system offers many attractive features, such as cable-free and easy deployment, which minimize the installation time and cost (Flouri et al. 2012). Figure 12 shows a scheme of the architecture of the WSN system, which includes several sensor nodes, a base station and a server. The sensor nodes work with battery and are directly connected to the sensors on the bridge. The housing of the WSN nodes and those of the temperature and humidity sensors, shown in Figure 8a, were equipped with four magnetic footings, which allows for a simple and fast mounting of the nodes. These nodes read the data of the sensor every 10 min and send them to the base station, which can be placed within 1-km away from the bridge. The base station is connected to the electricity power and has a data sim card.

The base station works similar to a modem and receives the data from the sensor nodes and sends them to a server through internet connection. The server then makes the data online on a website and accessible to the public. The electronic modules of the WSN monitoring system were provided by Decentlab GmbH, Switzerland.

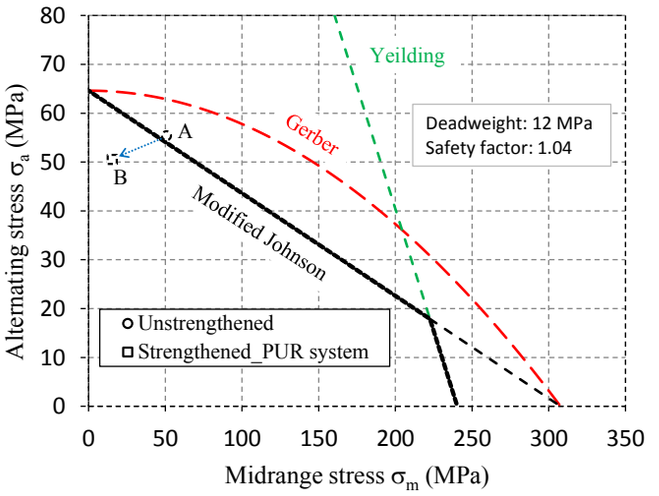

Figure 11. Fatigue strengthening approach: shifting the working stresses in the girder bottom flange from the at-risk region to the safe-life region based on the modified Johnson criteria (Ghafoori 2015).

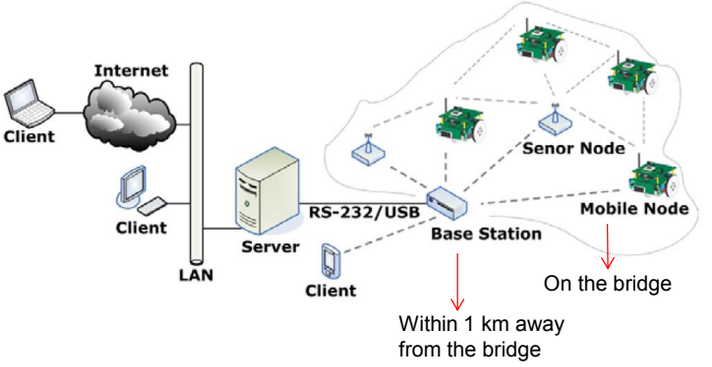

Figure 12. A scheme of the architecture of the WSN system for SHM.

4.1 *Monitoring CFRP pre-stressing using the WSN*

In order to ensure that no slippage occurs between the CFRP plates and the clamps, neither between the friction clamps and the steel beam flange, one resistance strain gauge was mounted on each CFRP plate, coated with long-term protection layers, and was then connected to a sensor node (see Figure 8a). Because strain gauges do not automatically compensate for temperature, for each active strain gauge, a dummy strain gauge was used to compensate for the effects of temperature variations. The dummy strain gauges, which are identical to the active strain gauges, were mounted on pieces of unstrained CFRP plates and placed next to the active gauges. To account for the temperature effects, the dummy strain gauges were wired into a half Wheatstone bridge on an arm adjacent to the active strain gauge. All the strain gauges used for the WSN system were of type 6/700 LY46 with a k-factor of 2.03 ± 1.5% and an electric resistance of 700 Ω ± 0.30% and were provided by the HBM Company, Germany. All of the strain gauges as well as the humidity and temperature sensors were connected to the WSN nodes.

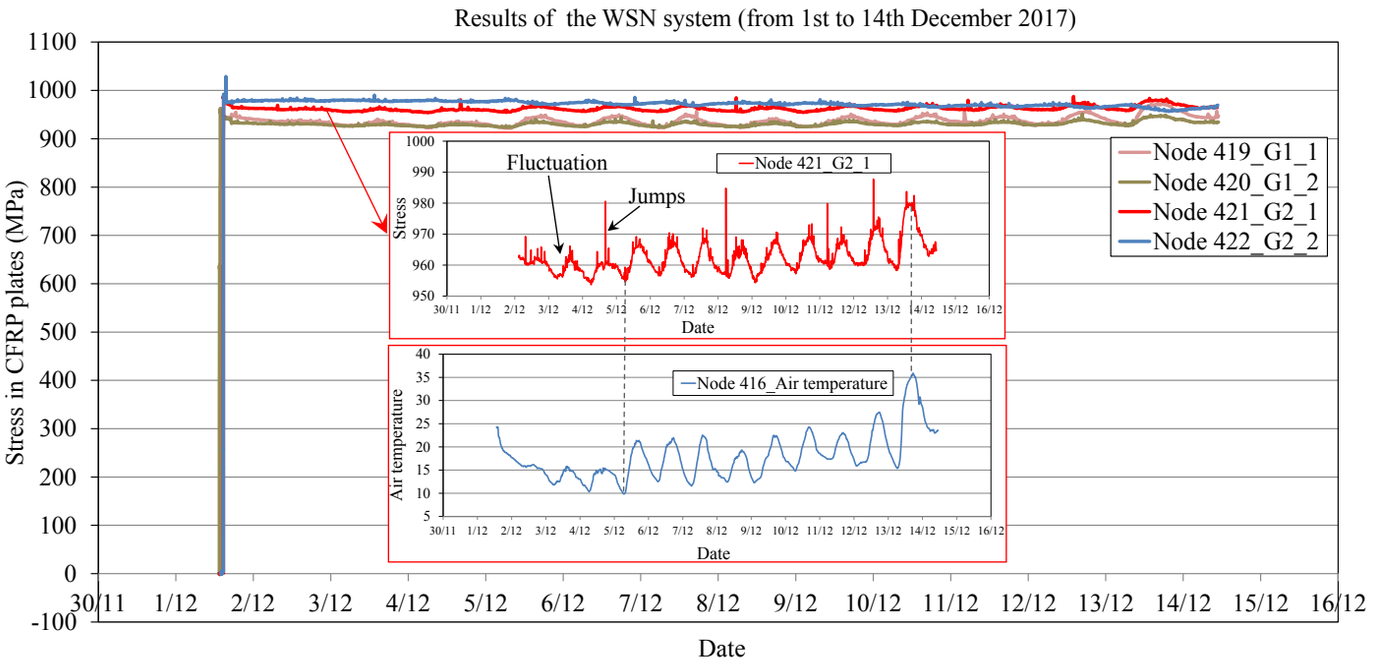

Figure 13. Results of wireless monitoring system: time-history of the pre-stress level in the four CFRP plates from 1st to 14th December 2017.

4.2 *Preliminary results of the wireless monitoring*

Figure 13 shows the time history of the on-site air temperature and the stress level in all CFRP plates mounted on G1 and G2 girders of the bridge from 1st to 14th December 2017 (for two weeks). Nodes 419 and 420 show the stress in the two prestressed CFRP plates attached to G1 girder, while nodes 421 and 422 refer to the CFRP plates on G2 girder. Figure 13 also shows an enlarged view of the results of node 421 (i.e., one of the CFRP plates on G2 girder). This figure shows a pattern of stress fluctuations during day and night, and also some sudden jumps with small and large stress amplitudes. The stress fluctuations can be attributed to the temperature change. As the temperature increases, the CFRP pre-stress level increases due to the fact that CFRP material has a negligible thermal expansion coefficient in its fiber direction compared to that for steel.

As shown in Figure 13, with an approximately 25 degrees Celsius increase in the ambient temperature, the CFRP pre-stress level increases by approximately about 25 MPa, which is less than 1% of CFRP ultimate strength. Furthermore, the sudden small and large jumps that can be observed in the CFRP pre-stress level in Figure 13 are due to the passages of small passenger vehicles and heavy trucks, respectively. The change in humidity did not have any influence on the CFRP pre-stress level and therefore has not discussed in this study. The WSN system will remain on the bridge for at least one year to monitor possible pre-stress loss and also to study the probable effects of the temperature. The results related to this long-term monitoring will be reported in a future publication. The results from the wireless monitoring system have shown that no slip or pre-stress loss has occurred in the system so far.

5 CONCLUSIONS

This study presents the work on the strengthening of Diamond-Creek Bridge (121 years-old) in Victoria, Australia. Two steel cross-girders of the bridge were strengthened using pre-stressed un-bonded CFRP plates. The feasibility and effectiveness of pre-stressed FRP composites for strengthening of metallic bridges have been demonstrated. Furthermore, a wireless monitoring system was used to monitor the pre-strain level in each CFRP plate as well as the on-site temperature and humidity.

The results of the short-term measurements showed that after pre-stressing the CFRP plates up to about 980 MPa (which is ≈38% of the CFRP ultimate strength), the maximum tensile stress in the bridge cross-girders decreased about 50%. Furthermore, it was shown that the application of the FPUR system can substantially decrease the mean tensile stress in the bridge girders, and therefore, increase the fatigue life of the structure (in this case to an infinite fatigue life). Therefore, the results of strain measurements show that the proposed FPUR system is very effective for flexural and also fatigue strengthening of metallic bridge girders.

The preliminary results of the WSN system have shown no loss in the CFRP pre-stressing level so far. Furthermore, the WSN results showed that because of the low thermal expansion coefficient of the

CFRP material (in the fiber direction) compared to steel, an increase in ambient temperature results in an increase in the stress in the CFRP plates. The effect of thermal mismatch between CFRP and steel structure is not necessarily negligible and should be considered in the design.

ABSTRACT: In fatigue design of welded joints according to the notch stress intensity factor (NSIF) approach, the weld toe profile is assumed to be a sharp V-notch having tip radius equal to zero, while the root side is assumed to be a pre-crack in the structure. The Peak Stress Method (PSM) represents an engineering, simplified method which allows a rapid calculation of the NSIFs on the basis of the singular linear elastic peak stresses evaluated at the notch tip by means of FE analyses with coarse FE meshes. The advantages of the PSM can be summarized as follows: (i) coarse meshes can be adopted, the required FE size being some orders of magnitude larger than that necessary to evaluate the NSIFs from the local stress distributions; (ii) only a single stress value is sufficient to estimate the NSIFs instead of a number of stress-distance numerical results. First, the PSM has been calibrated by analysing several mode I and mode II problems with Ansys FE code. Recently, the PSM has been also calibrated by adopting six commercial FE packages other than Ansys, taking advantage of a Round Robin between some Italian Universities. After having recalled the calibration of the method, the paper presents some applications of the PSM relevant to partial-penetration butt joints made of aluminum alloys as well as load-carrying cruciform joints and tube-to-flange joints made of structural steels under uniaxial fatigue loadings. Because of the relatively coarse FE analyses required and simplicity of post-processing the calculated peak stresses, the PSM might be useful in the everyday design practice.

1 INTRODUCTION

On the basis of the fundamental contribution of Williams (1952), who studied two-dimensional notch problems under mode I (opening) and mode II (sliding) loadings, the singular linear elastic stress distributions in the neighborhood of a sharp V-notch tip, see the example of a welded joint in Fig. 1, can be written as functions of the NSIFs, which quantify the intensity of the asymptotic stress fields. The following equations define the mode I and mode II NSIFs, respectively according to Gross & Mendelson (1972):

$$K_1 = \sqrt{2\pi} \cdot \lim_{r\to 0}\left[\left(\sigma_{\theta\theta}\right)_{\theta=0} \cdot r^{1-\lambda_1}\right] \quad (1)$$

$$K_2 = \sqrt{2\pi} \cdot \lim_{r\to 0}\left[\left(\tau_{r\theta}\right)_{\theta=0} \cdot r^{1-\lambda_2}\right] \quad (2)$$

In Eqs. (1) and (2), λ_1 and λ_2 are the mode I and II eigenvalues, respectively, being dependent on the opening angle 2α (Williams 1952), while $\sigma_{\theta\theta}$ and $\tau_{r\theta}$ represent the stress components evaluated along the notch bisector line, which is defined by the angular coordinate θ=0 according to Fig. 1.

In the literature, the NSIF approach has been used to analyse the medium as well as the high-cycle fatigue strength of specimens weakened by sharp V-notches and made of structural materials (Kihara & Yoshii 1991; Boukharouba et al. 1995). Focusing on welded joints, NSIFs allow to correlate the fatigue strength under uniaxial (Verreman & Nie 1996; Lazzarin & Tovo 1998; Lazzarin & Livieri 2001; Atzori & Meneghetti 2001) as well as multiaxial loadings (Lazzarin et al. 2004).

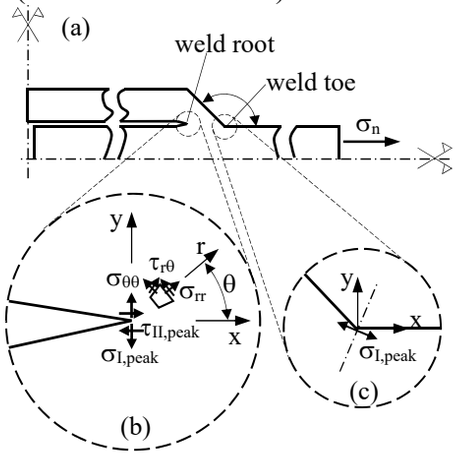

Figure 1: Sharp V-shaped notches in a welded joint (a) at the weld root (2α = 0°) (b) and at the weld toe (2α typically equal to 135°) (c) sides. Definition of peak stresses $\sigma_{I,peak}$ and $\tau_{II,peak}$.

Nevertheless, it should be noted that the calculation of NSIFs on the basis of the results of numerical analyses shows a major drawback in engineering applications, since very refined FE meshes (element size on the order of 10^{-5} mm) are required in order to apply definitions (1) and (2) to calculate the NSIFs. When dealing with three-dimensional notched components, both the solution of the FE model and the post-processing of numerical results could be even more time-consuming.

In order to overcome this issue, an engineering and rapid technique, the so-called Peak Stress Method (PSM), has been proposed, which allows to speed up the calculation of the NSIFs by adopting coarse FE analyses, the element size being some orders of magnitude larger than that required to apply definitions (1) and (2). The method takes inspiration from the contribution by Nisitani & Teranishi (2001; 2004), who proposed a technique to readily estimate the mode I Stress Intensity Factor of a crack propagating from an ellipsoidal cavity. The PSM has been theoretically justified and extended to allow the rapid calculation also of the NSIF relevant to sharp and open V-notches under mode I (Meneghetti & Lazzarin 2007; Meneghetti & Guzzella 2014), the SIF of cracks under mode II (Meneghetti 2012) and, finally, the NSIF of open V-notches under mode III (Meneghetti 2013).

Practically, the NSIFs K_1 and K_2 can be readily estimated according to the PSM by adopting the singular, linear elastic, opening (mode I) and sliding (mode II) peak stresses $\sigma_{I,peak}$ and $\tau_{II,peak}$, respectively, calculated at the V-notch tip (see definition of peak stresses in Fig. 1) from FE analyses with coarse meshes. The estimated NSIF values can be obtained from the following expressions (Meneghetti & Lazzarin 2007; Meneghetti 2012):

$$K_1 \cong K^*_{FE} \cdot \sigma_{I,peak} \cdot d^{1-\lambda_1} \quad (3)$$

$$K_2 \cong K^{**}_{FE} \cdot \tau_{II,peak} \cdot d^{0.5} \quad (4)$$

where *a* represents the characteristic size of the considered sharp V-notch, as an example it is the notch depth in Fig. 2, *d* is the so-called 'global element size', i.e. the average FE size adopted by the free mesh generation algorithm available in the numerical software. Finally, parameters K^*_{FE} and K^{**}_{FE} depend on the following calibration options (see also the detailed discussion in (Meneghetti et al. 2017c)):

- the *element type* and *formulation*;
- the *mesh pattern* of finite elements;
- the procedures for *stress extrapolation* and *principal stress calculation at FE nodes.*

The comparison between Eqs. (3) and (4) and previous Eqs. (1) and (2) shows that the PSM has a further advantage in addition to the coarse FE mesh: only a single stress value is necessary to estimate the NSIFs, instead of a number of *stress-distance* results, which require a post-processing analysis.

It is worth noting that thanks to Eqs. (3) and (4), any NSIF-based approach for the structural strength assessment can in principle be reformulated on the basis of the PSM. Recently, the PSM has been applied in combination with the approach based on the averaged strain energy density (SED) to assess the fatigue strength of welded joints under axial (Meneghetti & Lazzarin 2011; Meneghetti 2012), torsion (Meneghetti 2013) and multiaxial (Meneghetti et al. 2017a; Meneghetti et al. 2017b) loading conditions.

First, the PSM has been calibrated by analysing notched problems with Ansys FE code and parameters K^*_{FE} and K^{**}_{FE}, to be used in Eqs. (3) and (4), resulted equal to 1.38 and 3.38, respectively. Such values are valid under the conditions discussed in the relevant literature (Meneghetti & Lazzarin 2007; Meneghetti 2012), to which the reader is referred.

Recently, parameters K^*_{FE} and K^{**}_{FE} have been calibrated by adopting six commercial FE packages other than Ansys (Meneghetti et al. 2017c), taking advantage of a Round Robin between some Italian Universities. Essentially, it has been checked whether or not the parameters $K^*_{FE} \cong 1.38$ and $K^{**}_{FE} \cong 3.38$, valid for Ansys code, can be adopted also with other FE software. The main results of such calibration exercise are reported in the following. After that some application examples are illustrated.

2 CALIBRATING THE PEAK STRESS METHOD

The PSM has been calibrated by analysing several 2D notch problems under pure mode I as well as crack problems under pure mode II loadings with different commercial software packages. After having calculated the peak stresses, the parameters K^*_{FE} and K^{**}_{FE} have been evaluated from Eqs. (3) and (4), re-arranged as follows:

$$K^*_{FE} \cong \frac{K_1}{\sigma_{I,peak} \cdot d^{1-\lambda_1}} \quad (5)$$

$$K^{**}_{FE} \cong \frac{K_2}{\tau_{II,peak} \cdot d^{0.5}} \quad (6)$$

The calibration of the PSM for each FE code has been carried out by fixing the following stress analysis conditions: (i) element type and element formulation, (ii) mesh pattern of the finite elements and (iii) procedures for stress extrapolation and principal stress calculation at FE nodes.

The Round Robin involved ten Universities and all in all seven commercial FE codes have been calibrated, as reported in detail in Table 1.

The different FE codes have been adopted to analyse several 2D notched and crack problems under mode I or mode II loading conditions. Geometries, material properties, boundary conditions and FE type were obviously the same in all adopted FE codes. In more detail, the considered material was a structural steel, having Young's modulus equal to 206000 MPa and a Poisson's ratio of 0.3. On the other hand, whenever possible, specific options relevant to the element formulation, free mesh generation algorithms, stress extrapolation and stress averaging criteria at FE nodes have been set to *default options* in each code. For details about the settings adopted in each software package, the reader is referred to (Meneghetti et al. 2017c). Only the key aspects of the analyses performed and the main results are summarized in the following.

Table 1: List of participants and FE codes.

Universities	**FE codes**
• Bologna • Genova • Messina • Modena and Reggio Emilia • Padova • Palermo • Parma • Pisa • Politecnico di Torino • Trento	• Ansys 16 and 17 • Abaqus 6.13 and 6.14 • Hypermesh 14*/Optistruct 14 implicit/Hyperview 14** • Hypermesh 13*/Ls-Dyna R7.1.3 implicit/Hyperview 13** • Lusas 14.6-2 • MSC Patran/Nastran 2014 and 2016 • Straus 7 R.2.4.6

2.1 *2D problems (plane strain), mode I loading, $0° \le 2\alpha \le 135°$*

Several two-dimensional notch and crack problems under pure mode I (Fig. 2) have been analysed. All these case studies are the same adopted in the first calibration of the PSM under mode I loading which has been carried out with Ansys numerical software (Meneghetti & Lazzarin 2007).

Linear elastic analyses under plane strain conditions have been performed by adopting a pattern of four-node linear quadrilateral elements, in order to calculate the peak stress values (Meneghetti et al. 2017c). Only a quarter of each geometry has been modeled by using the double symmetry condition. The free mesh generation algorithm available in each code has been used after having input the average element size *d*. The mesh density ratio *a/d* has been varied between 1 and 50, by varying either the notch depth *a* or the element size *d*. Moreover, three values of the notch opening angle, i.e. 2α=0°, 90°, 135° have been considered. A nominal gross-section stress equal to 1 MPa has been applied to each FE model.

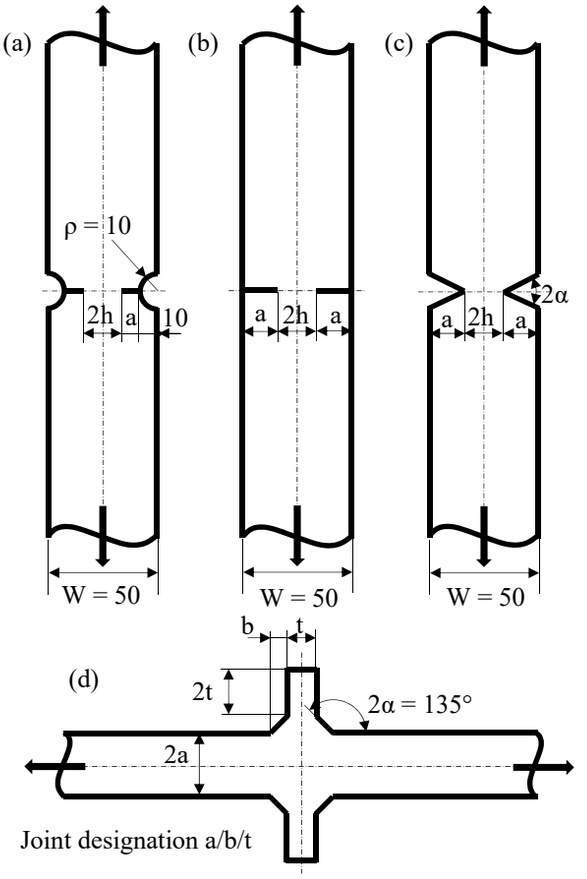

Figure 2: Geometries of 2D problems (plane strain) under mode I loading. Dimensions in [mm].

After having solved the FE model, the peak value of the maximum principal stress $\sigma_{I,peak}$ has been calculated at the FE node located at the V-notch tip. It is worth noting that stress averaging at FE nodes has been activated in all adopted FE codes. Accordingly, only a single stress value for $\sigma_{I,peak}$ has been obtained per node by averaging the nodal stresses from all elements sharing the node. To this aim, as far as possible, the default options of each FE code have been adopted (Meneghetti et al. 2017c).

2.2 *2D problems (plane strain), mode II loading, $2\alpha = 0°$*

A plate having the geometry shown in Fig. 3, weakened by a central crack (2α = 0°) and subjected to pure mode II loading has been analysed. The case study has been taken from the first calibration of the PSM under mode II loading carried out by using Ansys numerical software (Meneghetti 2012).

Linear elastic analyses under plane strain conditions have been carried out by adopting a pattern of four-node linear quadrilateral elements, in order to calculate the peak stress values. The mesh density ratio *a/d* has been varied in a wide range from 1 to 200, being $2<2a<200$ mm. Only a quarter of the plate geometry has been modeled by using the double anti-symmetry boundary conditions.

The external load has been applied to the model by means of displacements $u_x=u_y=1.262\cdot10^{-3}$ mm at

the plate free edges, which correspond to a nominal gross shear stress of 1 MPa when no crack is present. After having solved the numerical model, the peak value of the (mode II) shear stress $\tau_{xy,peak} = \tau_{II,peak}$ has been calculated at the node located at the crack tip. It is worth noting that stress averaging at FE nodes has been activated in all adopted FE codes, similarly to mode I analyses. For additional details about the numerical analyses the reader is referred to (Meneghetti et al. 2017c).

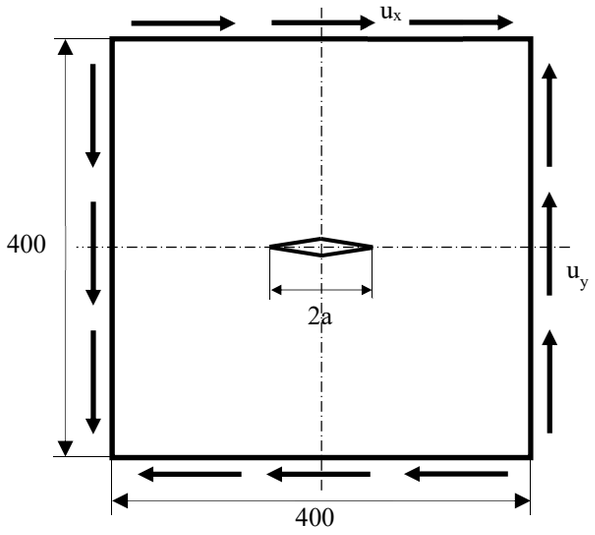

Figure 3: Geometry of 2D problems (plane strain) under mode II loading. Dimensions in [mm].

Finally, the exact values of the mode I NSIF K_1 and mode II SIF K_2 to be input in Eq. (5) and (6), respectively, have been calculated by applying definitions (1) and (2) to the stress-distance numerical results obtained by using Ansys FE code and adopting very refined FE meshes (the size of the smallest element being on the order of 10^{-5} mm).

As mentioned above, two-dimensional, four-node, linear quadrilateral elements have been used in all FE analyses. The numerical integration has been carried out by adopting 2x2 Gauss points. Once selected the proper element type and formulation, the FE analyst has input the average FE size *d*, which has been the sole parameter used to drive the automatic free mesh generation algorithm. Details concerning element type/options along with the adopted mesh generation settings have been reported for each FE code in (Meneghetti et al. 2017c).

3 RESULTS OF FE ANALYSES

The results obtained from the calibration of different FE codes and relevant to mode I and mode II problems are shown in Figs. 4a and b, respectively. The figures report the parameters K^*_{FE} and K^{**}_{FE}, calculated from Eqs. (5) and (6), respectively, as functions of the mesh density ratio *a/d*. All results reported in Figs. 4a and b were obtained by adopting the *default options* of the post-processing environment of each FE code (see details in (Meneghetti et al. 2017c)).

In the case of 2D problems under mode I loading, Fig. 4a shows that most of the adopted FE codes, i.e. Abaqus, Straus 7, MSC Patran/Nastran and Lusas, present the same constant $K^*_{FE} \cong 1.38$ that had been previously calibrated with Ansys (Meneghetti & Lazzarin 2007). Convergence is obtained when $a/d \geq 3$ for all FE codes. A slightly larger scatter band of ±5% should be accepted, as compared to that of ±3% found for Ansys (Meneghetti & Lazzarin 2007). Moreover, it can be observed from Fig. 4a that the calibration of the FE packages Hypermesh/Optistruct /Hyperview and Hypermesh/Ls-Dyna/Hyperview results in a different value of the parameter K^*_{FE}, i.e. 1.84. This peculiar behaviour depends on stress extrapolation rules at FE nodes as extensively discussed in (Meneghetti et al. 2017c). Moreover, the scatter ±8% is higher as compared to ±5% obtained with the other FE codes.

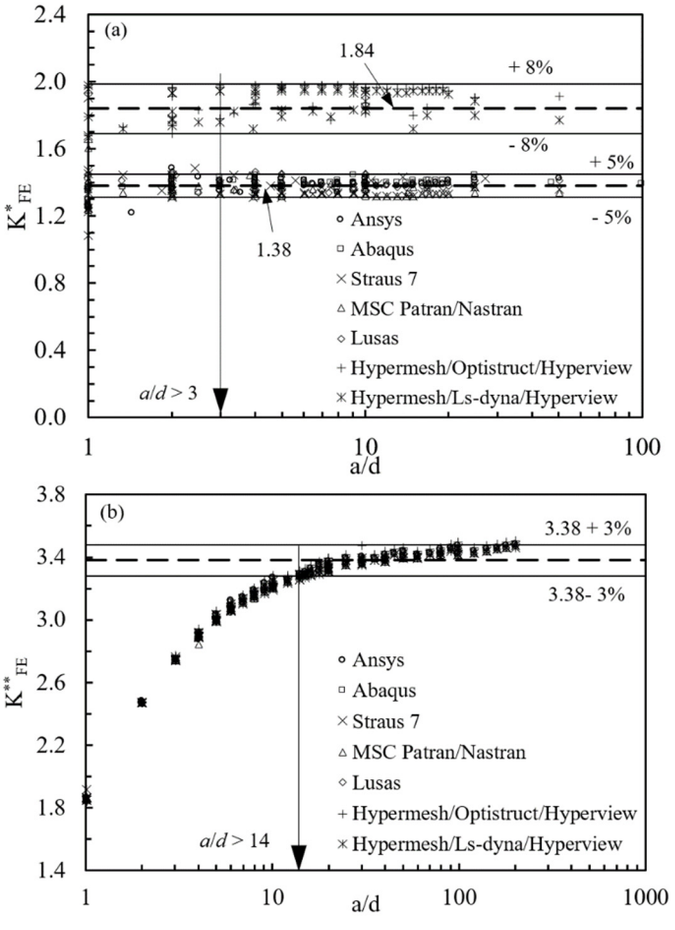

Figure 4: Results for (a) mode I and (b) mode II loading: K^*_{FE} and K^{**}_{FE}, respectively, for each FE code.

Dealing then with mode II loading, the obtained results are reported in Fig. 4b, which shows that all considered FE codes converge to $K^{**}_{FE} \cong 3.38 \pm 3\%$, i.e. the values obtained previously with Ansys FE code (Meneghetti 2012). Convergence is obtained when the ratio $a/d \geq 14$, which is again consistent with the first calibration (Meneghetti 2012).

4 FATIGUE STRENGTH ASSESSMENTS ACCORDING TO THE PEAK STRESS METHOD

To illustrate the PSM in practical design situations, the fatigue strength assessment of conventional arc-welded joints made of aluminum alloys and structural steels is reported below.

The strain energy density (SED) averaged over a structural volume of radius R_0 surrounding the weld root or the weld toe (see the example in Fig. 5) was adopted as fatigue damage parameter, as proposed by Lazzarin and co-workers (Lazzarin & Zambardi 2001; Livieri & Lazzarin 2005). The averaged SED under mode I+II loading can be expressed in closed-form as a function of the relevant NSIFs according to Eq. (7).

$$\Delta\overline{W}=c_w\left[\frac{e_1}{E}\left(\frac{\Delta K_1}{R_0^{1-\lambda_1}}\right)^2+\frac{e_2}{E}\left(\frac{\Delta K_2}{R_0^{1-\lambda_2}}\right)^2\right] \quad (7)$$

where R_0 represents the control radius, ΔK_1 and ΔK_2 are the ranges of the NSIFs relevant to mode I and mode II, respectively, E is the Young's modulus, while e_1 and e_2 are known parameters depending on the notch opening angle 2α and the Poisson's ratio ν (Lazzarin & Zambardi 2001). The size of the structural volume R_0 was calibrated on experimental fatigue test data and resulted equal to 0.28 mm and 0.12 mm for welded joints made of structural steel and aluminum alloys (Livieri & Lazzarin 2005), respectively. Finally, the coefficient c_w depends on the nominal load ratio R (Lazzarin et al. 2004): it equals 0.5 for R = −1 and 1 for R = 0. It should be noted that welded joints loaded in the as-welded conditions are almost not sensitive to mean stresses, according to design standards (Eurocode 3), therefore Eq. (7) with c_w =1 should be applied.

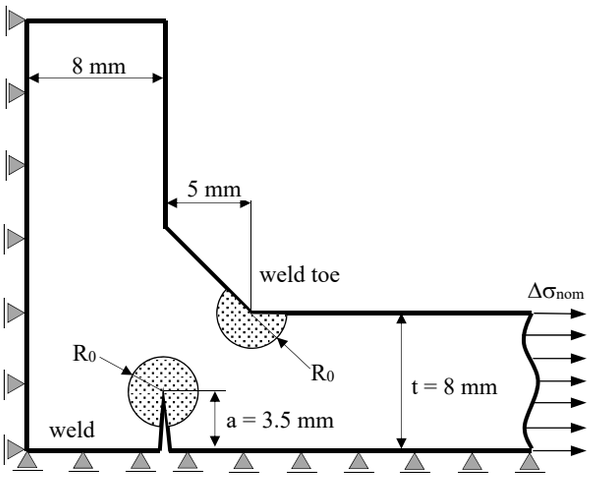

Figure 5: Geometry of the load-carrying steel weld joint tested in (Ouchida & Nishioka 1964). Control volumes for the averaged SED evaluation at the weld toe and the weld root sides.

Taking advantage of the equality $W=(1-\nu^2)\cdot\sigma^2_{eq,peak}/2E$ valid under plane strain conditions, an equivalent peak stress, $\sigma_{eq,peak}$, can be derived as follow (Meneghetti 2012):

$$\Delta\sigma_{eq,peak}=\sqrt{\frac{2\cdot c_w}{1-\nu^2}\cdot\left[e_1\left(\frac{\Delta K_1}{R_0^{1-\lambda_1}}\right)^2+e_2\left(\frac{\Delta K_2}{R_0^{1-\lambda_2}}\right)^2\right]} \quad (8)$$

If ΔK_1 and ΔK_2 are evaluated directly at the weld toe and at the weld root by means of definitions, Eqs. (1) and (2), the mesh density must be very refined with a minimum element size on the order of 10^{-5} mm as shown in (Meneghetti et al. 2017c).

By using the PSM-based relationships (Eqs. (3) and (4)), Eq. (8) can be rewritten as a function of the singular, linear elastic FE peak stresses $\sigma_{I,peak}$ and $\tau_{II,peak}$ (Meneghetti & Lazzarin 2011):

$$\Delta\sigma_{eq,peak}=\sqrt{c_w}\cdot\sqrt{f_{w1}^2\cdot\Delta\sigma_{I,peak}^2+f_{w2}^2\cdot\Delta\tau_{II,peak}^2} \quad (9a)$$

$$f_{wi}=K_{FE}\cdot\sqrt{\frac{2e_i}{1-\nu^2}}\cdot\left(\frac{d}{R_0}\right)^{1-\lambda_i} \quad \text{where} \quad i=1,2 \quad (9b)$$

Equation (9) can be applied to the fatigue strength assessment of conventional arc-welded joints made of structural steels and aluminum alloys. In the following, some applications of the PSM are reported, which are relevant to:

1. 25-mm-thick partial-penetration butt welded joints made of aluminum alloys (see Fig. 6), which were fatigue tested by Sonsino et al. (Brandt et al. 1999; Sonsino et al. 1999) in the stress-relieved conditions under axial loading with nominal load ratios R=0 and -1;
2. load-carrying cruciform welded steel joints (see the geometry in Fig. 7), which were fatigue tested by Ouchida and Nishioka (1964) in the as-welded conditions under axial loading with a nominal load ratio R = 0;
3. tube-to-flange welded joints with 3.2-mm-thick tube made of structural steel (see Fig. 8), which were fatigue tested in (Razmjoo 1996) in the as-welded conditions under axial loading with a nominal load ratio R = 0.

The detailed analyses according to the PSM are reported in (Meneghetti et al. 2015; Meneghetti & Lazzarin 2011; Meneghetti et al. 2017b), to which the reader is referred. Only the main steps of the analysis are reported here. Ansys FE code has been adopted, however, according to the calibration described above, the same results could be obtained by adopting FE codes other than Ansys, provided that the proper calibrated constants K^*_{FE} and K^{**}_{FE}, as reported in Fig. 4, were used in Eq. (9). The peak stresses were calculated by using the FE meshes reported in Figs. 6a, 7a and 8a, respectively, according to the following steps:

- A 2D FE analysis was performed by adopting 4 node quadrilateral elements (PLANE 182 of Ansys element library, with K-option 1 set to

3, i.e. '*simple enhanced strain*' formulation activated);

- Plane strain conditions were adopted for both butt and cruciform joints (cases 1 and 2, see Fig. 6 and 7), while axisymmetric conditions were applied for the tube-to-flange joint (case 3, Fig. 8).
- The mesh density ratio a/d was established as follows:
  1. Fig. 6a: a is the pre-crack length at the root side, so that the maximum FE size d is equal to $a/3 = 3.75/3 \rightarrow \approx 1.25$ mm is appropriate to apply Eq. (9); at the toe side, a is half the plate thickness, i.e. $a = 12.5$ mm, therefore the maximum FE size is $12.5/3 \approx 4$. In conclusion d = 1.25 mm is appropriate both at the root and at the toe side;
  2. Fig. 7a: a is the pre-crack length at the root side, so that the maximum FE size d is equal to $a/3 = 3.5/3 \rightarrow \approx 1$ mm is appropriate to apply Eq. (9); at the toe side, a is half the main plate thickness, i.e. $a = 8$ mm, therefore the maximum FE size is $8/3 = 2.66$. In conclusion d = 1 mm is appropriate both at the root and at the toe side;
  3. Fig. 8a: a is the tube thickness, i.e. $a = 3.2$ mm, therefore the maximum FE size is $a/3 = 3.2/3 \approx 1.0$ mm. Finally, d = 0.8 mm has been adopted to apply Eq. (9) at the toe side;
- The *free-mesh* patterns, see Figs. 6a, 7a and 8a, were generated by setting a 'global element size' parameter d = 1.25, 1 and 0.8 mm, respectively, in the free mesh generation algorithm;
- The maximum principal stress $\Delta\sigma_{I,peak}$ was evaluated at the FE nodes located at the weld toe and root, mode II being not singular at weld toe and negligible at weld root in all cases;
- Figures 6b, 7b and 8b show the results according to the PSM:
  1. the weld root is more critical than the weld toe, since $\Delta\sigma_{eq,peak}$ is higher at the root (5.28 MPa) than at the toe (2.87 MPa). This is in agreement with the fatigue crack initiation point experimentally observed by (Brandt et al. 1999; Sonsino et al. 1999).
  2. the weld root is more critical than the weld toe, since $\Delta\sigma_{eq,peak}$ is higher at the root (3.07 MPa) than at the toe (2.54 MPa). This is in agreement with the fatigue crack initiation point experimentally observed by Ouchida and Nishioka (1964).
  3. the weld toe is the only critical point of the joint ($\Delta\sigma_{eq,peak}$=2.25 MPa) since stresses are not singular at the weld root. This is in agreement with the fatigue crack initiation point experimentally observed in (Razmjoo 1996).

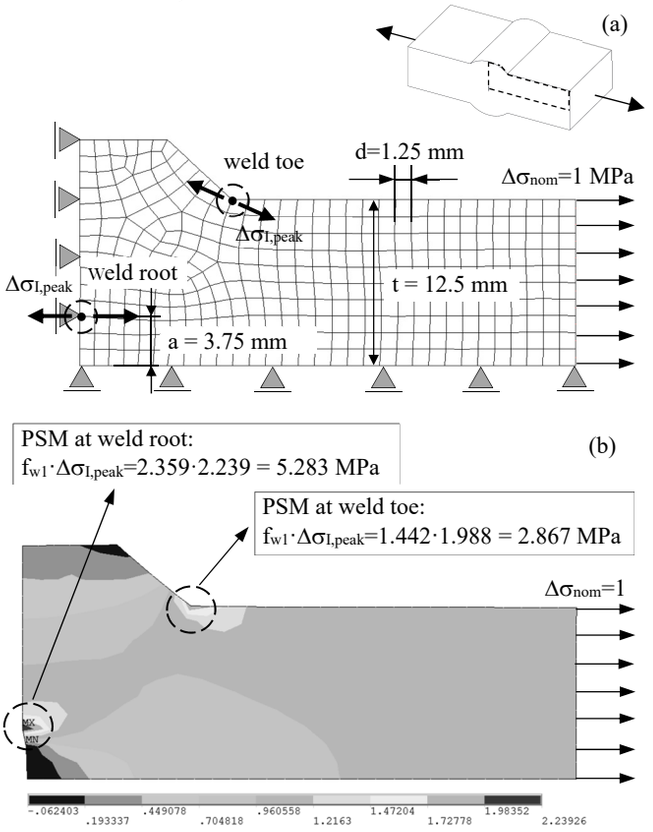

Figure 6: Application of the PSM to the fatigue strength assessment of a partial-penetration butt welded joints made of aluminum alloys (Brandt et al. 1999; Sonsino et al. 1999).

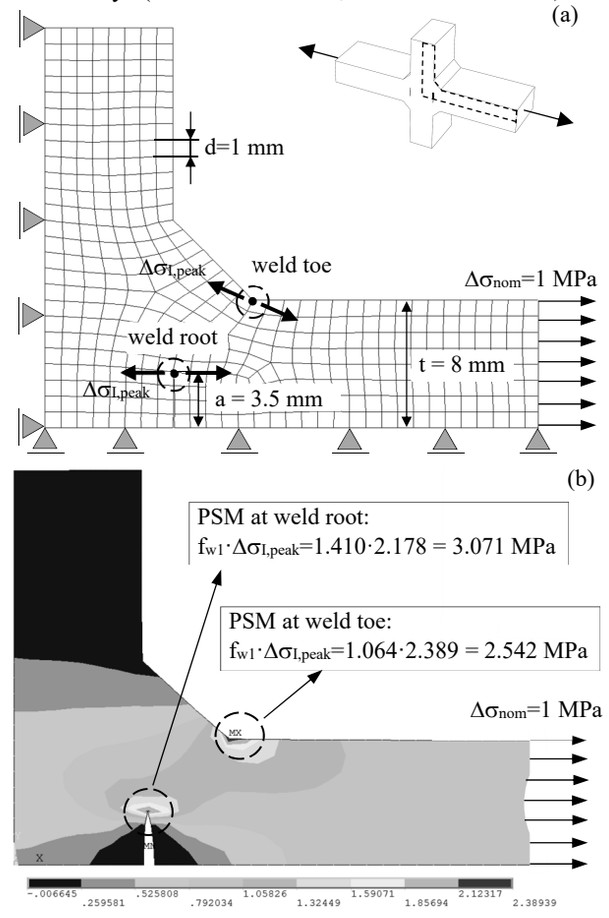

Figure 7: Application of the PSM to the fatigue strength assessment of a load-carrying arc-welded joint made of structural steel and tested in (Ouchida & Nishioka 1964).

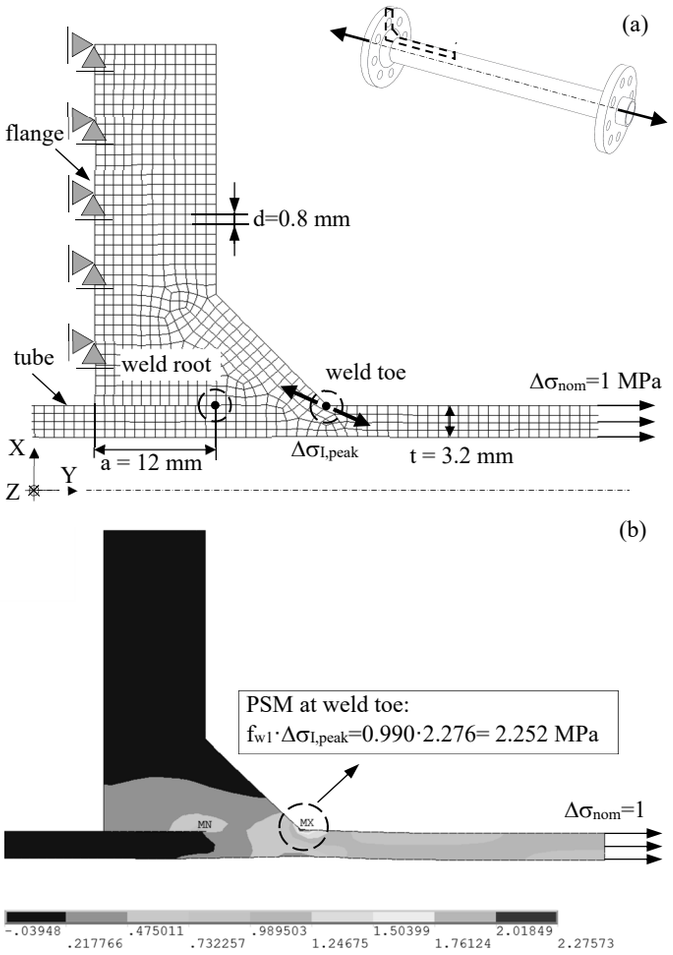

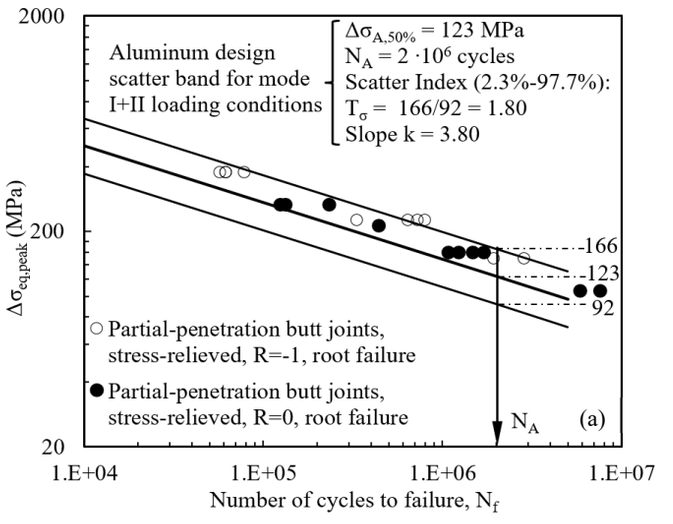

Figure 8: Application of the PSM to the fatigue strength assessment of a tube-to-flange welded joint made of structural steel and tested in (Razmjoo 1996).

Subsequently, the original experimental data have been reconverted in terms of equivalent peak stress evaluated by means of Eq. (9) at the experimental fatigue crack initiation point, i.e. weld root for cases 1 and 2 (Figs. 6 and 7) and the weld toe for case 3 (Fig. 8). Finally, Figures 9a and b show the comparison between the experimental results and the fatigue design scatter bands previously calibrated in (Meneghetti et al. 2015) and in (Meneghetti & Lazzarin 2011) for welded joints made of aluminum alloys and structural steels, respectively.

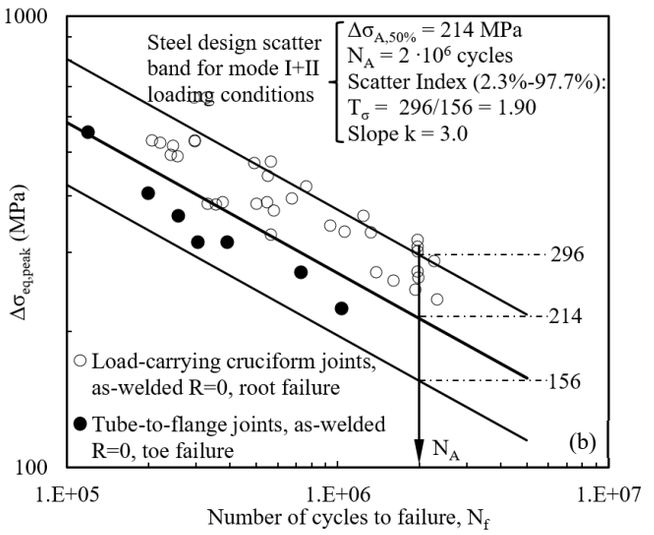

Figure 9: Comparison between the experimental fatigue results and the fatigue design scatter bands of the PSM valid for welded joints made of (a) aluminum alloys and (b) structural steels.

5 CONCLUSIONS

The peak stress method (PSM) employs the singular, linear elastic peak stresses evaluated at the toe and root sides by means of FE analyses with coarse meshes to rapidly estimate the mode I and mode II NSIFs. Two calibration constants are needed, namely K^*_{FE} (Eq. (3)) and K^{**}_{FE} (Eq. (4)), respectively.

Originally, the PSM has been calibrated by using the Ansys FE code. Recently, a Round Robin has been carried out in order to calibrate the PSM by using also commercial FE codes different from Ansys.

By using the PSM in combination with the averaged Strain Energy Density (SED) as a fatigue strength criterion, a so-called equivalent peak stress (Eq. (9)) can be defined to assess either weld toe or weld root fatigue failures in conjunction with a properly calibrated design curve.

The following conclusions can be drawn from the present study:

- Based on the calibration of the PSM with different commercial FE codes, it has been shown that under mode I loading the constant K^*_{FE} to be used either in Eq. (3) or (9) is the same for Ansys, Abaqus, Straus 7, MSC Patran/Nastran and Lusas FE codes, i.e. $K^*_{FE} \cong 1.38$; while it assumes a different value for Optistruct and Ls-Dyna FE codes, i.e. $K^*_{FE} \cong 1.84$. The convergence is guaranteed when the mesh density ratio $a/d \geq 3$ for all FE codes.
- Dealing with mode II loading, it has been shown that the constant K^{**}_{FE} to be used either in Eq. (4) or (9) is the same for all FE codes involved in the calibration, i.e. $K^{**}_{FE} \cong 3.38$. The convergence occurs for a mesh density ratio $a/d \geq 14$ for all FE codes.
- Finally, the PSM has been applied in practical design situations by adopting the equivalent

peak stress to assess weld toe as well as weld root fatigue failures in some examples of welded joints made of aluminum alloys and structural steels tested under axial fatigue loadings. Comparison between experimental fatigue results and the relevant design scatter bands was satisfactory. Because of the simplicity of a point-like method combined with the robustness of the NSIF approach, the PSM might be useful to design engineers engaged in fatigue assessments of welded joints.

ABSTRACT: Prolonging the life of existing steel trusses all over the world is a incoming necessity for all managing authorities wherever these structures have reached a particular state of use. The unsatisfactory behavior of these structures under the current type and increasing number of loads make clearer that innovative solutions are needed. For this purpose, the realization of different techniques are presented, in order to retrofit the actual load onto a structure conceived with historical codes, characterized by lower design live loads. The possibilities of retrofitting bridges with different solution studied in a recent research program are presented and compared in this study.

1 INTRODUCTION

Increasing traffic density and vehicle weight have been increasing in recent decades. Many existing truss bridges, all over the world, were not designed for the high service loads and the increased number of load cycles that they are exposed to today. Some bridges will have to be either strengthened or replaced in the next decades. As late as the 1980s, steel truss bridges in Europe were often constructed with a non-composite concrete slab on top of steel girders. Different alternatives of interventions for truss bridges are presented in this paper, according to the different truss type to be reinforced. Sometimes the bridge should be retrofitted by deck replacing, other times a new structural configuration should be adopted, or in some cases only little interventions are needed in order to strengthen a truss. This paper presents a brief overview of different alternatives to strengthen existing trusses, ever considering the optimization of costs and material savings.

2 STRENGHTENING SOLUTIONS

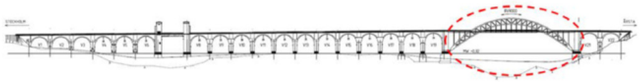
2.1 Upgrading the load carrying capacity of a cultural heritage arched-truss bridge by deck replacing

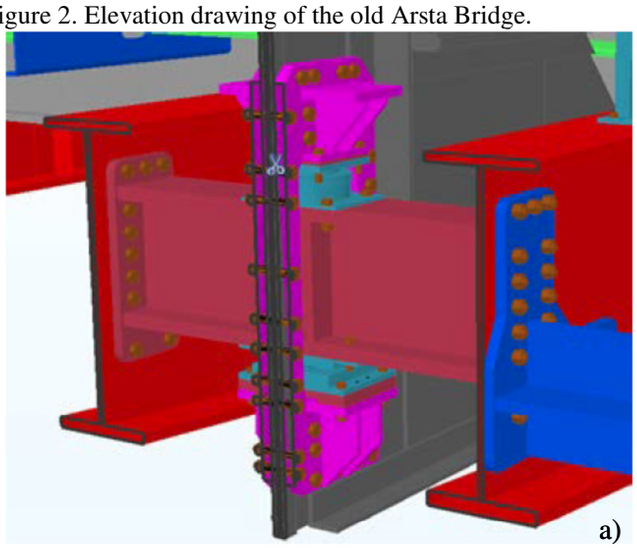
The utilization of the railway capacity in the center of Stockholm has been high for a long time, resulting in delays and congestions. The Old Årsta Bridge is a part of the railway directly south of the new Stockholm City Line, and will mainly carry increasing number of trains in the future. The bridge was opened in year 1929 and has two tracks.

Figure 1. Lowering of the old Ărsta midspan section.

In 2005 the capacity was doubled in this section, when the parallel New Årsta Bridge was finished. To secure the future traffic the old bridge has been rehabilitated in several stages. In this section the latest upgrading of the main span of the bridge are presented. The Old Årsta Bridge is 753 m long and was built in 1923-1929. The bridge is a "*listed construction*", which means a legal cultural and historical protection of a structure in Sweden. This means, for example, that rehabilitations work has to be done without affecting the original appearance of the bridge. The majority of the length is spanned by twenty concrete arches, meanwhile a movable bridge respectively a steel truss arch is used over the two waterways, see Figure 2. During the last decade, the movable span has been replaced by a non-movable simply supported steel span, while the concrete arches and the concrete foundations for the steel truss arch have been strengthened. The 151 m long main span was designed as a through arch bridge, with two tracks with rails

lying on wooden sleepers directly in contact with the steel deck. The open steel deck consisted of four rail girders and two edge girders in the longitudinal direction. The latter acted as tied rods in the part of the bridge where the horizontal deck is located below the arch. All connections were riveted and rigid. In the transversal direction there were cross girders at every steel deck support, and horizontal trusses connecting the upper flanges of rail girders to the cross girders.





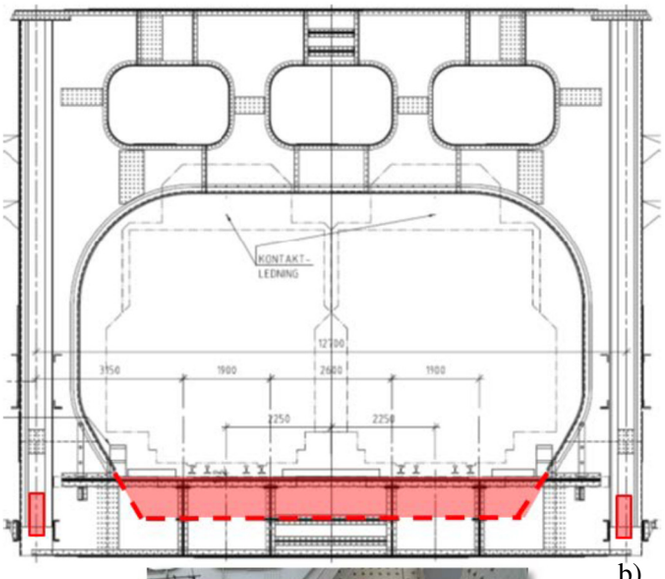


Figure 2. Elevation drawing of the old Arsta Bridge.

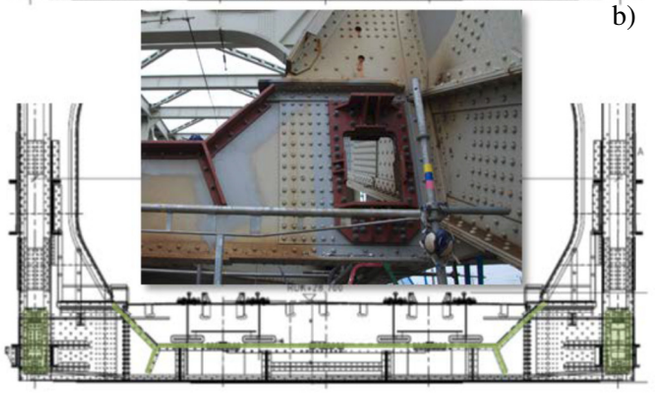

Figure 3. Connection beam at a portal frame (a), modifications of the existing portal frames (b).

With respect to fatigue, the steel arch is in good condition. The rail girders and the cross girders are structural parts with shorter determinant lengths compared to the arch. These parts were in focus in a study performed in year 2006-2008 (James and Paulsson 2008), in which the fracture toughness and the chemical composition were tested. The test results indicated poor fracture toughness, and a risk of brittle failure in both rail girders and cross girders. The tests were also combined with a fatigue assessment calculation, based on measured strains. This calculation showed, depending on the degree of corrosion and choice of detail category, a remaining fatigue life of 0 – 50 years. Based on the study presented in the former section, a decision was taken to replace the steel grillage deck and to leave the rest of the structure as intact as possible. The fatigue requirement on the total structure was an extended lifetime of 60 years, and the new parts were designed for 120 years. The bridge was also designed for an increased maximum axle load, from 25 t to 30 t. Three different rehabilitation alternatives were proposed by the bridge designers that were doing the pre-design (Lundmark and Nilsson 2013). At an early stage, before the detailed design was started, the complete structure was laser-scanned in order to get a digital 3D-modell of the existing bridge. The model, consisting of a point-cloud, was later used as a digital reference when the new bridge deck was modelled in a 3D-software. By using laser-scanning, together with surveying of critical detail in the existing structure, it was possible to use demanding tolerances throughout the structure and to avoid deck sections acting as fitting pieces that had to be cut on site. The deck sections were installed from above, before the bottom plates of the cross girders were welded on-site. In the 3D-model, the free space between new and old parts was about 3 cm in the most critical points. The new bridge deck was designed as a full width steel deck, without any gratings, that can carry the horizontal forces between the end-supports and the intersections with the arch, without horizontal trusses. In order to avoid welding on site, the connections between different deck elements and other steel parts were all bolted. The connections to the existing steel had to be bolted connections as well, since the old steel is not weldable. The national bridge code (TRVK 2011) requires fit bolts in bolted connections in a rail bridge main structure, which makes the drilling and reaming of the holes time consuming. The fatigue assessment indicated that the connection between the arch and the columns, as well as the hangers, would be critical if the connection remained rigid. To avoid strengthening of these details, due to the stresses caused by bending moments, the formerly stiff connections were replaced with joints (bearings) that mainly transfer normal forces. The new midspan deck section has a length of 60 m and a weight of 350 t. Unlike the other deck sections, the large midspan section was transported by barges on the water, lifted and built (Lundmark et al. 2016).

2.2 *Strengthening old truss railway bridges with a new HPC deck*

The chosen sample bridge is a steel truss railway bridge designed in 1896 situated in the town of Vienna over the river Wien (Figure 4). It is 120 years old and it is still in operation. Originally designed for railway traffic, but at the moment the bridge is operated by town's metro line No. 4. The superstructure is twin steel truss beams simply sup- ported with a span of 50,92m. The alignment on the bridges is partially in transition curve and partially in straight line. The maximum design speed, governed by the small radius of the horizontal curve R=160m is 40km/h. Typical bridge cross section is shown in Figure 5.

Three-dimensional finite element model of the existing bridge was created in order to investigate the utilization level of the bridge elements (Figure 6). The geometry of the bridge and the cross sections are modelled according to the original design drawings.

Figure 4. Hütteldorf bridge.

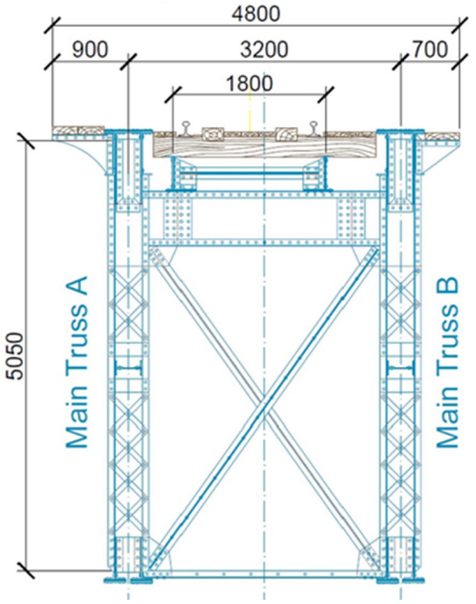

Figure 5. Cross section of the bridge.

The material properties are designed according to Annex B of (ONR 24008 2006), where for bridges built before 1900 the following values are recommended – Es=200000MPa, G=77000MPa, fyk=220MPa and fuk=320MPa. In order to take into account all eccentricities, coming from different levels of the deck elements and local effect of the traffic loads the open deck is modelled with "shell" elements, whereas the main trusses are modelled with "beam" elements. All truss nodes are modelled as stiff. Evaluation of the load bearing capacity of existing railway and highway bridges in Austria is made according to ONR 24008 (2006), where four levels are prescribed. The first level is recalculating the structure according to the recent valid standards. This level was used in this case, where the Eurocode loads and procedures are used for the evaluation. The load model LM71 is reduced with α-factors, according to ÖNORM B 1991-2, for tram and metro loads.

Figure 6. FEM of the steel truss over the Wien river.

Elastic normal stress checks (utilization) of the stringers' top and bottom flanges for different values of α are presented in Figure 7. For open decks of railway bridges the dynamic factor Φ3 is recommended (ÖNORM B 1991-2). The utilization factor exceeds 1 for the top flange, due to local bending generated by transversal loads like centrifugal and nosing force.

Components of the normal stresses in the top flange from different loads are illustrated in Figure 8, wind load is not included.

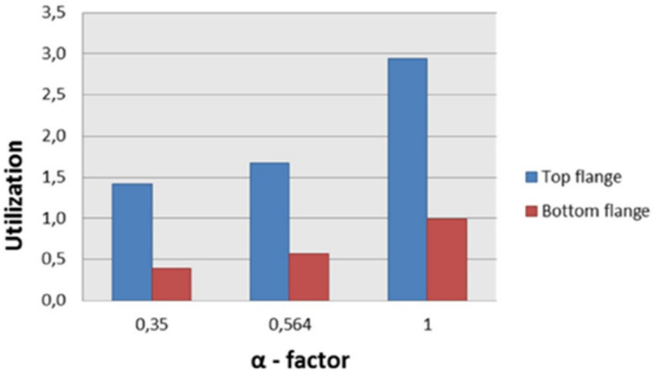

Figure 7. Utilization of top and bottom flange for different α factors.

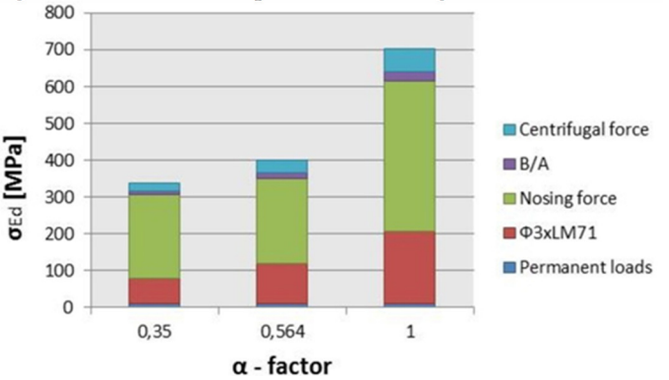

Figure 8. Components of the normal stress in the top flange.

In summary the result from the evaluation showed that the open deck elements (stringers and cross girders) are

exposed to high stress levels. The main reason for their under dimensioning is due to the fact, that in the time of their original design, only vertical loads were considered ignoring secondary bending moments and local eccentricities.

Instead of strengthening these elements, an innovative solution for their replacement by new UHPC deck slab is proposed (Figure 9). This retrofit solution is proven to be effective in "compensating" the additional dead load not only for ULS checks of the main truss element, but also for fatigue behavior and SLS checks. Utilization checks of the truss elements, after linear elastic analysis, for both cases original situation and retrofitted bridge are presented (Figure 10).

In terms of deflections, due to the higher stiffness, the deflection from vertical traffic load is reduced from 66mm to 40mm (with 40%). Both values satisfy the traffic safety criteria of L/600=85mm.

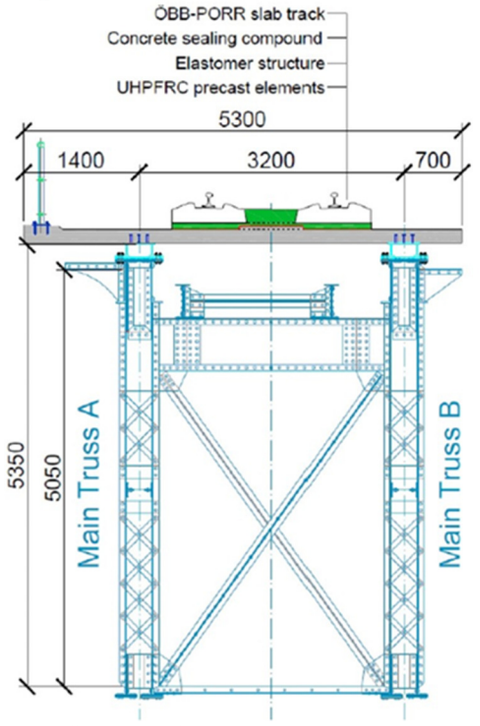

Figure 9. Retrofit alternative chosen: prestressed precast UHP-FRC slab 160mm thick and ballast-less track.

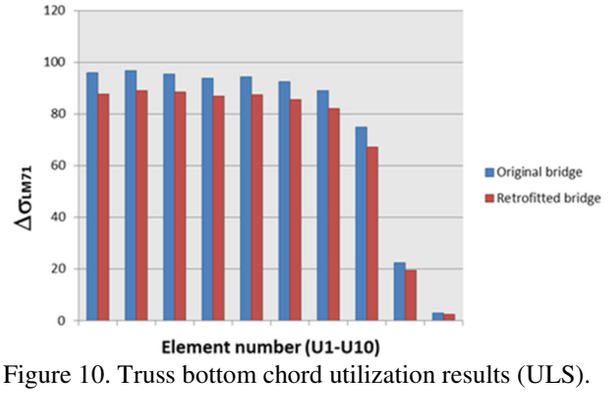

Figure 10. Truss bottom chord utilization results (ULS).

2.3 *Prolonging the fatigue life an old truss railway bridge with innovative direct track deck solution*

The bridge chosen for this case study is the bridge over the river Waal in the Netherlands (Van Der Burg et al. 2017). This bridge is situated in the railway line between Utrecht and 's Hertogenbosch, the main connection for south traffic in the Netherlands.

Figure 11 The bridge over the river Waal.

The east bridge today consists of three main spans (124,3 m each), six single spans (59,6 m) and a double span bridge (2x 60,4 m). The span used as a case study is the third span, which is built in 1932 and is a simply supported truss bridge spanning 59,6 meters. The total height of the truss is 7,5 m. Crossbeams are placed every 4,97 m. Big gusset plates and rivets connect all the elements together. The first FEM model consists of beam elements only, using the original drawings (Figure 12). All beams are modeled with the correct eccentricities, which mainly comes in effect with the wind bracing. These are connected to the flange of the lower and upper cord. From the results it can be concluded that the crossbeams and stringers are governing for the fatigue life of the bridge. This means this case study bridge is a good candidate to have its service life increased by strengthening with deck sections. In order to calibrate the FEM, strain gauges measurements have been performed on top and bottom flanges of cross beam and main girder. The real load of the passing train have been derived from the "*Quo Vadis*" WIM-weight in motion system adopted by the railway authority (Figure 13). When comparing the measurements with the first FEM model, it is noticed that for some strain gauges the results seem to match quite well, while others are far off. Another important observation is that with three stress measurements of one cross-section, the fourth one cannot be calculated by assuming a linear stress distribution. This means that plane sections do not remain plane as assumed in a classic Euler-Bernoulli beam, and no linear stress distribution is present over a cross-section. Consequently, a more refined FEM has been delivered (Fig.14) considering: the transition from beam elements to shell elements, for the first 7,5 meter of the stringers, cross-beams and lower chord; a second refinement is found in the support conditions. From the measurements it was found that when a point load is half-way across the bridge, the end cross-beam still has vertical bending moments. Since the cross-beam itself is not loaded at that time, bending moments arise due to small eccentricities in support conditions. The retrofit solution of the deck implies the adoption of a direct fastened rail incorporating an anti-derailment device instead of an embedded rail (Figure 15). By the adoption of this strengthening option, an interesting improvement on the fatigue life of the

most affected hot-spot fatigue sensitive details of the bridge are achieved (Figure16).

2.4 Strengthening old truss road bridges with innovative solutions: a parametric analysis

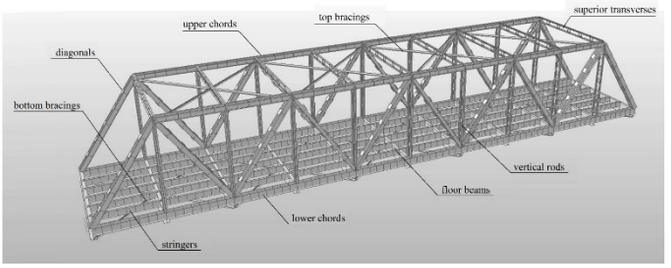

Figure 17 The bridge over the river Adige.

The investigated structure is a two-lane roadway steel bridge truss. The overall bridge length is 120 m through three spans (40 m each one). The superstructure consists of riveted built-up truss members. Lower chords are inverse T-shaped sections, diagonals and upper chords are C-built-up elements with battens (stiffening brackets), while struts are I-section shaped built-up elements composed of four L-shaped elements and a plate. The deck is realized with longitudinal stringers and transverse floor beams. The floor beams have a fixed distance of 4 m, while the stringers are at 1.15 m one to the other. Top and bottom double-L bracings provide adequate stiffening of the structure. Built-up members, realized with plates, L- profiles or C profiles, are connected by hot riveting and connection joints are made of gusset riveted plates. The main structure and the member details have been completely revealed by an on-site geometrical survey. The bridge structure was modeled using the finite element method (FEM) software Midas (2005), using only beam elements. Rigid links (rigid body) were used to represent eccentricities of the elements. Overall, the entire bridge model consists of about 2000 beam elements. A Young's modulus of 210,000 MPa (N/mm2), Poisson's ratio of 0.3 and a material density value of 7850 kg/m3 (weight density of 76.98 kN/m3) were used for the analyses. All beam member sections were modeled as the as-built structure, as measured during the geometrical survey. The bridge is subjected to permanent loads, such as the self-weight of steel elements and of nonstructural elements and to variable loads such as temperature and traffic. At first, the bridge was checked referring to the Italian Ministerial Decree 09/06/1945, n. 6018 (DM 6018, 1945) and then to current Italian and Eurocode. Historical tests on the bridge have been used to calibrate the FEM model. In this study, retrofit alternatives chosen from the following solutions are considered:

a. making composite an existing non-composite deck;
b. building an orthotropic deck;
c. building a new concrete deck, directly connected to the main trusses.

All these strategies are normally combined with steel-only interventions (including cover-plating, element replacement). The described procedures are finalized to redistribute the live loads adequately onto the deck with a new or modified deck. As can be observed in

the following, the beneficial use of a rigid deck is often the best solution able to extend the bridge life adequately. In the case of Italy, the bridge category shifts from the 1st to the 2nd class:

- AD1 Load, 1st category: Load Model 1, EN 1991-2:2003 or
- AD2 Load, 2nd category: Load Model 1, EN 1991-2:2003 taking a reduction of 20% for all loads of Lane number 1.

In the present study, the reference retrofit solutions considered are:

• BR00) The existing bridge is calculated with the historical live load, HS-LOAD, without any retrofit intervention;
• BR01) The existing bridge is calculated with the actual code live load, AD1-LOAD, without any retrofit intervention;
• BR02) The existing bridge is calculated with the actual code live load, AD2-LOAD, without any retrofit intervention;
• RROOR1-2) The bridge is retrofitted with the introduction of an orthotropic deck laying between stringers, with open ribs considering both the AD1-Load and AD2-Load;
• RROCR1-2) The bridge is retrofitted with the introduction of an orthotropic deck laying between stringers, with closed ribs considering both the AD1-Load and AD2-Load;
• RRA1-2) The bridge is retrofitted with the introduction of a concrete deck considering both the AD1-Load and AD2-Load; welded shear studs are introduced in the bridge to connect the new concrete deck with the stringers (three ϕ20 mm studs/m along all stringers, except for stringers along sections 1, 9–13, 19–23, 29–31 where six ϕ20 mm studs/m have been placed); a parametric analysis is developed varying both the concrete deck thickness (with a fixed strength of C40/50) among 10 cm (RRA1, 2–10), 15 cm (RRA1, 2–15), 20 cm (RRA1, 2–20), 25 cm (RRA1, 2–25), 30 cm (RRA1, 2–30) and the deck concrete strength (fixing the deck thickness at the lowest value of 10 cm) among C30/37 (RRA1, 2-R1), C35/45 (RRA1, 2-R2), C40/50 (RRA1, 2-R3), C45/55 (RRA1, 2-R4), C55/67 (RRA1, 2-R5);
• RRA1-2-I) The bridge is retrofitted with the introduction of a concrete deck considering both the AD1-Load and AD2-Load, fixing the concrete strength at C40/50 and the deck thickness at 100 mm; moreover, the steel-to-steel intervention -cover plating- are introduced adopting S355 new members;
• RRB1-2-I) The bridge is retrofitted with the introduction of a concrete deck considering both the AD1-Load and AD2-Load, introducing a UHPC concrete of C90/105 strength class and fixing the deck thickness at 50 mm; moreover, the steel-to-steel intervention -cover plating- are introduced adopting S355 new members;
• RRC1-2-I) The bridge is retrofitted with the introduction of a concrete deck considering both the AD1-Load and AD2-Load, introducing a UHPC concrete of C150/160 strength class and fixing the deck thickness at 30 mm; moreover, the steel-to-steel intervention are introduced adopting S355 new members. According to the analysis performed, the optimal solution is represented by the RRB1-I, which has been compared in terms of utilization rate to the main solution descripted above (maximum ratios Ed/Rd de- fined as the minimum safety factor of all ultimate limit state-ULS checks) (Figures 18-20).

2.5 Strengthening for fatigue induced damages in trusses: a parametric analysis

Traffic running on bridges produces a stress spectrum that may cause fatigue damage. This stress spectrum depends on the geometry of the vehicles, the axle loads, the vehicle spacing, the composition of the traffic, and its dynamic effects. However, the increasing loads on truss bridges (magnitude and quantity), both railways and roadways, imply the increasing accumulation of damage in iron or steel member, that could lead to sudden failure. A parametric analysis has been performed onto two existing bridges in Italy, the case study of the par. 2.4 (Br1) and the railway Adige bridge (Figure 21) (Br2), in order to check which are the more

suitable and effective solution for bridge repair, in order to prolong their fatigue life. After the retrofit solution proposed, all bridges are checked according EN1993-1-9:2005.

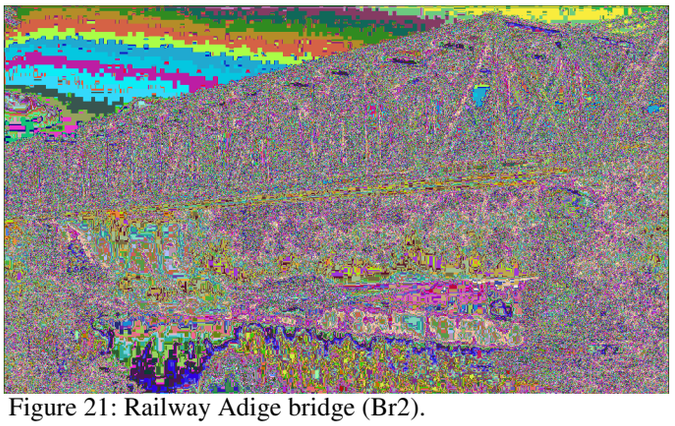

Figure 21: Railway Adige bridge (Br2).

The following solutions have been considered:

- RRF1: the bridge is retrofitted with the introduction of a concrete deck, made of UHPC concrete; the cover-plating technique is adopted in hot spot fatigue stresses;
- RRF2: the bridge is retrofitted with the introduction of a concrete deck, made of UHPC concrete; hot spot stress truss-nodes are encased in new UHPC nodes;

For every RRFi (i=1, 2) retrofit solution, a limit of adding no more new material than the 25% of the original weight of the bridge is fixed.

For railway bridges, an unballasted solution is provided for RRF1-RRF2.

A wide number of other parameters are varied in order to analyze the sensitivity of the model to these variations. According to the analysis performed, the optimal solution depends on the bridge type, which has been compared in terms of utilization rate to the main solution descripted above (maximum ratios Ed/Rd defined as the minimum safety factor of all ultimate limit state-ULS checks) (Figures 22-29).

3 CONCLUSION

In this paper different strategies in order to prolong the lifetime of existing steel truss bridges have been presented. The first technique deals with the possibility to upgrade the load carrying capacity of a cultural heritage arched-truss bridge by deck replacing, maintaining the existent architectural profile, but increasing at the same time the structural strength and reliability; the second technique explored the possibility to build a new UHPC deck onto existing metro-railway trusses, calculating the beneficial reduction of stressed and deformations of the whole existing structure; the third solution provide refined calibrated FEM finalized to build a direct fastened rail incorporating an anti-derailment device, able to reduce the stress amplitude dealing with fatigue, and consequently prolonging the life of the whole truss; the fourth solution presented a parametric analysis of a road truss, to discover the most suitable retrofit solution, represented by the realization of a thin UHPC 50mm deck together with cove- plating applications; the last solution presented a parametric analysis to prolong the fatigue strength of existing bridges, to discover the most suitable retrofit solution, and to compare different retrofit techniques. As a matter of fact, the whole solutions presented are finalized to demonstrate that it is possible to prolong the life of existing trusses, with the innovative techniques illustrated herein.

Steel bridge retrofit solution for movable cases

R. Pavan A. Ruzzante
AP&P srl, Italy

ABSTRACT: Prolonging the life of existing steel movable bridges is a paramount problem for managing authorities, where these specific types of bridges have reached a prolonged state of use. The unsatisfactory behavior of these structures under the current type and increasing number of loads make clearer that innovative solutions are needed. For this purpose, the realization of lightweight composite decks is needed, in order to redistribute the common actual load onto a structure conceived with historical codes, characterized by lower design live loads. The possibilities of retrofitting bridges with this solution studied in a recent research program are presented and compared in this study.

1 INTRODUCTION

Increasing traffic density and vehicle weight have been increasing in recent decades. Many existing movable bridges, all over the world, were not designed for the high service loads and the increased number of load cycles that they are exposed to today. Some bridges will have to be either strengthened or replaced in the next decades. Movable bridges have proved to be an economical solution to the problem of how to carry a rail line or highway across an active waterway. A "closed" movable bridge has closed the waterway to marine traffic, while an "open" bridge has opened the waterway to marine traffic. Highway bridges are typically designed to remain in the closed position and only to be opened when required by marine traffic. However, movable railroad bridges can be designed to remain in either the open or closed position, depending on how frequently they are used by train traffic. The difference is important as different wind and seismic load design conditions are used to design for a bridge that is usually open vs. one that is usually closed. The three major categories of movable bridges are swing, bascule, and vertical lift. This list is not exclusive and there are other types, such as jackknife, reticulated, retracting, and floating that are not common and will not be described here. Movable bridges are designed to be operated following a set protocol, and this protocol is incorporated into the control system as a series of permissive interlocks. The normal sequence of operation is as follows. Vessel signals for an opening, usually through a marine radio but it can be through a horn. For a highway bridge the operator sounds a horn, activates the traffic signals, halting traffic, lowers the roadway gates, then lowers the barrier gates. For a rail bridge the operator needs to get a permissive signal from the train dispatcher. After the barrier gates are lowered, a permissive signal allows the operator to withdraw the locks and/or wedges and lifts and, once that is completed, to open the span. The vessel then can proceed through the opening. To close the bridge, the steps are reversed. The controls are operated from a control desk and Note that the control desk includes a position indicator to demonstrate the movable span(s) position as well as an array of push buttons to control the operation. A general objective in designing such a desk is to have the position of the buttons mimic the sequence of operations. Typically, the buttons are lit to indicate their status. or every type of movable bridge there are a wide amount of interventions needed both

Figure 1 In service movable bridge.

every year, both during long time scheduling maintenance. The most frequent interventions lie on the moving equipment maintenance and checks, while the structural maintenance and eventual retrofit refers to longer period.

2 RETROFIT SOLUTIONS

2.1 *Literature review*

A special category of steel structures where the fatigue induced damage is relevant for the life cycle of the structure, deals with movable bridges. These are daily subjected to high level stresses induced by load cycles of passing vehicles: the incrementing speeds and concurring dynamic amplifications, and the incremental number of loads and number of vehicles, represented a critical structural situation especially for those bridges in principle lines and with some decades of exercise. The literature for these detailed analysis and damage assessment is not so extensive, and relegated to a small number of specialists: guidelines for the assessment of historical existing steel structures are deepen in Kuhn et al. (2008) and Brühwiler et al. (2012), in a sort of pre normative design document, respectively in the European and Swiss context; while well-established authorities in this framework have studied riveted bridges Fisher et al. (1984), Brühwiler et al. (1990), other studies are focused on large scale experimentations and damage assessment procedures (Pipinato et al 2008b; Pipinato et al. 2009; Pipinato et al. 2010a; Pipinato et al 2011c; Pipinato 2011; Pipinato 2012a); a detailed procedures for accounting for remaining fatigue life is provided in Imam et al. (2005), while other studies are more focused on the structural analysis of single bridges (Pipinato et al. 2012a; Pipinato et al. 2012a; Pipinato 2010b; Pipinato et al. 2012e; Pipinato et al. 2010a; Pipinato and Modena 2010 Pipinato et al. 2008) even considering special combination of external loadings, and damage accumulation including fatigue and seismic loads (Pipinato 2012b); or FRP interventions for build up new structures or repairing solutions Pipinato (2012d); particular cases of damages are included also in some hint studies (Pipinato et al. 2012e; Pipinato et al. 2012c) reporting particular analysis solutions that can help to solve bridge damaged systems; retrofit procedures and load analysis also for high speed bridges are reported in (Pipinato 2013a,b,c), also coupling damage as in the aforementioned studies (Pipinato 2012c; Pipinato et al 2011a; Pipinato et al 2010b) a particular subset of these studies includes damage analysis and control of existing and historical bridges (Pipinato 2012d; Pipinato et al. 2013); reliability analysis also considering dynamic effects are described in (Imam et al. 2012; Imam et al. 2012; Kaliyaperumal et al. 2011; Imam and Righiniotis 2010), while a more focused study on the probabilistic fatigue evaluation of riveted bridges is included in Imam et al (2008); the fatigue analysis of riveted bridge connections using the theory of critical distances and relative numerical modelling are described in (Righiniotis et al. 2008; Imam et al. 2007); while a general introduction on the specific argument could be found in (Imam et al. 2006; Imam et al. 2005); more focused and specialist deepens deals with the fracture reliability of a typical Northridge steel moment resisting connection (Righiniotis and Imam 2004), the fatigue reliability of riveted connections in bridges (Imam et al. 2006, 2008), the effect of climate change on the deterioration of steel bridges (Kallias and Imam 2013), the risk assessment of steel bridges under the influence of changing environmental conditions (Kallias and Imam 2012), the fatigue assessment of a bridge detail using dynamic analysis and probabilistic fracture mechanics (Imam and Kaliyaperumal 2012), the modelling of failure consequences for robustness evaluation (Chryssanthopoulos et al. 2011), the review of metallic bridge failure statistics (Imam and Chryssanthopoulos 2010), the effects on the fatigue reliability of deteriorating riveted bridges (Imam et al. 2009a), the global-local finite element analysis of riveted bridge connections for fatigue evaluation (Imam et al. 2009b), the probabilistic fatigue load spectra for riveted bridges (Imam et al. 2007), the probabilistic fatigue life estimates for riveted bridges (Imam et al. 2006), the effect of fracture on the reliability of a moment resisting frame under earthquake loading (Righiniotis and Imam 2006), the probabilistic fatigue life estimates for riveted bridges (Imam et al. 2006), the remaining fatigue life estimates for riveted bridges (Imam et al. 2005), and the connection fixity effects on stress histories in riveted rail bridges (Imam et al. 2004).

2.2 *Movable bridge deck intervention*

As a fact, the most damaged structure of movable bridges is represented by the deck. A crucial part of the design of movable bridges is to limit the moving dead load which affects the size of the counterweight, the overall size of the main structural members, and, to a lesser extent, the machinery depending upon the type of movable bridge. For movable railroad bridges this is typically not a problem, as movable span decks are designed with open decks (timber ties on stringers) and the design live load is such a large part of the overall design load that the type of deck is not an issue. For highway bridges, however, the type of deck needs to be carefully selected to provide a minimum weight while providing an acceptable riding surface. Early movable spans used timber decks, but they are relatively heavy and have poor traction and wear. Timber was replaced by open steel grid, a good solution that is both lightweight and long wearing. In addition, the open grid reduced the exposed wind area, particularly for bas-

cule bridges in the open position. However, with higher driving speeds, changes in tires and greater congestion, steel grid deck has become the source of accidents, particularly when wet or icy. Now most new movable bridge decks are designed with some type of solid surface. Depending on the bridge, this can be a steel grid partially filled with concrete or epoxy, an orthotopic deck, lightweight concrete, or the "exodermic" system. Aluminum and composite decks are also now being developed and may prove to be a good solution. While orthotropic decks would seem to be a good solution, as the deck can be used as part of the overall structural system, they have not yet seen widespread use in new designs.

2.3 *Light deck intervention*

Consequently, a number of factors that should be considered in the selection of a lightweight solid deck system to replace steel open grid deck on typical movable bridges. These factors include (URS 2012):

- Costs including:

o Deck fabrication and installation,
o Modifications to the bascule leaf steel framing, bascule pier, flanking spans,
counterweight, and trunnion assemblies required to implement the new deck system,
o Design and construction inspection for the new deck system,
o Future maintenance and inspection.

- Functionality and Safety including:

o Load capacity (i.e. support of legal loads and permitted overloads),
o Improved riding surface and skid resistance for vehicular and bicycle traffic,
o Reduced traffic generated noise.

-Maintenance including:

o Ease of repair and/or replacement of all or portions of the deck,
o Need for periodic maintenance (e.g. reapplication of coatings and/or replacement of
wearing surfaces).

-Service-life and Durability including:

o Deck and/or deck component (e.g. wearing service, fasteners, etc.) service-life,
o Resistance to corrosion, fatigue, wear, impact, fire, ultraviolet light, and chemicals,
o Accommodation of thermal movements.

-Constructability including:

o Disruption to traffic (e.g. overall construction duration, maintenance of traffic),
Ability to accommodate fabrication and installation tolerances,
o Sensitivity to environmental conditions during construction,
o Shipping, storage and handling,
o Specialized inspection requirements during fabrication and installation.

- Other Risks including:

o Familiarity of the product and technology (e.g. years' experience, previous bridge installations, quantity and quality of applicable research, endorsement by bridge design community),
o Availability of design tools and construction techniques,
o Financial and technical support from supplier(s),
o Product availability (e.g. opportunities for competitive bidding, sole source and/or patents).

These new lightweight solid decks to replace steel open grid decks on typical movable bridges include:

a) Sandwich Plate System

The Sandwich Plate System is a proprietary and patented composite laminate plate material consisting of thin metal faceplates continuously bonded to a polyurethane elastomer core. The elastomer core transfers forces between the metal faceplates by way of shear, analogous to an I-beam when subjected to flexure with the steel plates acting as the flanges and the elastomer core as the web. The elastomer core also prevents local buckling of the metal faceplates in compression, which permits development of full yield of the metal faceplates. Panels are very thin (1 to 2 inches thick) compared to traditional bridge decks. The use of these thin panels is possible through a combination of panel bending and membrane action (i.e. in-plane tension). Separation of the thin metal plates with a lightweight elastomer core more efficiently increases strength and stiffness of the plate, while minimizing the increase in weight of the plate (URS 2012).

b) Aluminum Orthotropic Deck

Aluminum alloys have much to offer for bridge deck applications, and continue to be used, primarily overseas, where their lightweight, high strength-to-weight ratio and excellent corrosion resistance satisfy service requirements. Aluminum is manufactured by an extrusion process, which permits highly customized sections that can be optimized for a given application. The lack of widespread use of aluminum, despite the structural and maintenance advantages, is primarily due to the high initial cost of the material (URS 2012).

c) Fiber Reinforced Polymer (FRP) Composite Deck

Fiberglass reinforced plastic (FRP) is a composite material that has a number of characteristics that makes it a good alternative to replace steel open grid deck on bascule bridges. FRP composites can be designed to provide a wide range of mechanical properties including tensile, flexural, impact and compressive strengths. FRP composites are generally lightweight (i.e. approximately 20% of steel) with high strength-to-weight ratio and are generally resistant to creep and fatigue. FRP composites are ver-

satile and can be fabricated in many different configurations, customized specifically for a given application (e.g. bridge decks), designed and fabricated such that the strength is oriented to meet specific configuration and loading demands, made into larger more complex structural components and systems that simplifies connections and minimizes the number of components that must be handled. The relatively low modulus of elasticity of FRP composites make them relatively flexible compared to other bridge deck materials and thus deflections generally control the design of FRP bridge decks. FRP composite materials are susceptible to degradation from ultraviolet light and chemicals; however, the materials can be formulated with additives to improve the resistance to these effects (URS 2012).

d) Ultra-high Performance Concrete (UHPC) thin deck

Ultra-High Performance Concrete (UHPC) is a material that has recently gained attention in the bridge industry. UHPC provides a combination of superior properties including strength, ductility, durability that permits design and construction of thinner sections and longer spans that are lighter and more efficient, while providing improved durability and impermeability against corrosion, abrasion and impact. UHPC has potential to be used in an alternative deck design to replace steel open grid deck. The high concrete compressive and tensile strength allows design and construction of a lightweight waffle slab bridge deck with thin elements (slab and ribs) (URS 2012).

e) Making composite existing non-composite decks

Many older steel bridges are constructed with a non-composite concrete slab over steel girders. A potentially economical means of strengthening these floor systems is to connect the existing concrete slab and steel girders to permit the development of composite action. Composite action means that the steel girder and concrete can help each other out carrying the loads more efficiently than in the original nanocomposite condition. To achieve the benefits of composite action, the existing steel girder must be connected to the existing concrete slab to permit the transfer of shear forces at the steel-concrete interface. For new bridges, composite action is achieved by welding shear studs to the top of the steel girder prior to casting the concrete slab. In the case of an existing bridge, this approach is not possible, since the slab is already in-place. One alternative is to make holes in the slab and weld studs to the top flange, but that interrupts the traffic and means that the water proofing and asphalt of the bridge must be done once again. Perhaps even worse, the transversal re-bars of the deck will be broken when making holes for shear connectors, and that means that e.g. the cantilevers will loose their capacity in bending since they are depending on the top layer of the re-bars in tension. Hence, the best thing would be to develop methods for post-installing shear connectors. In the case of existing bridges, strengthening by welded shear studs is only suitable if the bridge can be closed for quite a long time. The strengthening work often involves the following steps: removal of pavement and waterproofing, water jetting to remove the concrete, welding of new shear studs, casting concrete, re-waterproofing and resurfacing. Spring pins or coiled spring pins (Figure 2), offer the possibility of performing the whole installation from below the bridge deck without interrupting the traffic on the bridge. This is possible since the pins are connected to the steel and concrete only by a force created by the compressed coiled spring pin itself. This is a major advantage of interference fit shear connectors in bridge applications, compared to the other types of shear connectors.

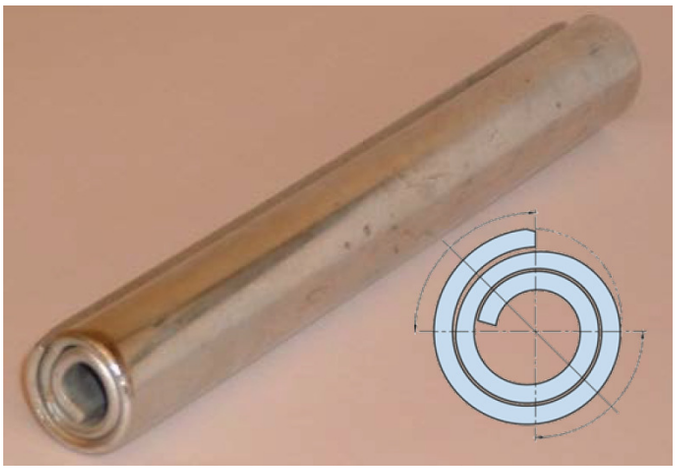

Figure 2 A coiled spring pin, and a schematic sketch of its cross-section.

Coiled spring pins can be used as shear connectors either to create or to strengthen the shear connection between steel and concrete. In the first case, there will be only one type of shear connector at the shear interface, which makes it easy to establish design assumptions. However, since there are no heads on the coiled spring connectors, the uplift forces must be considered in design. In the second case, there will be at least two different kinds of shear connectors at the shear interface. This implies that the distribution of shear forces between the different shear connectors must be established. This is essential when a structure is strengthened due to insufficient fatigue capacity in the shear connection. It is, however, less important for static load in the ultimate limit state.

An application has been performed onto the Pitsund bridge in Sweden: the Pitsund-bridge is a seven span bridge, with a total length of 399 m and a free width of 9 m, see Figure 3. The superstructure consists of steel girders with a concrete deck slab on top, in six out of seven spans. The seventh span is a movable span, designed as a bascular bridge with two leafs. In 2006, coiled spring pins were installed in a part of the bridge in order to create composite action and to avoid sudden movements in

the steel-concrete interface, which created loud bangs in wintertime.

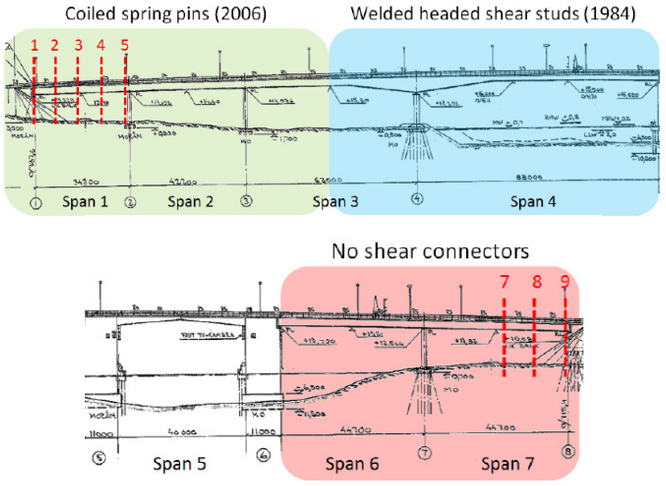

Figure 3 Pitsund-bridge sections.

In the area marked with red, there are no shear connectors, only a few anchoring steel bars that connect the steel and the concrete over the supports. In the blue area, the bridge was designed and constructed as a composite structure (year 1984). The shear connection was created by welded headed shear studs. The green area was originally designed with no composite action and remained so until year 2006. Then 1200 coiled spring pins were installed in order to create composite action. Then the bridge was monitored under known loads, to understand differences in the structural behavior: one conclusion from the measurements is that the coiled spring pins can be used to create composite action in non-composite steel concrete bridges, even though they behave a bit different compared to shear studs at low load levels. The tests indicate that that there is a need of a small initial slip, or compression of the pins, before the coiled spring pins starts to transfer shear forces to a greater extent. FE-models have been created for the bridge, simulating different types of shear connections. A comparison between FE-models and the field monitoring will be presented in a future paper.

3 CONCLUSION

Many existing movable bridges, all over the world, were not designed for the high service loads and the increased number of load cycles that they are exposed to today. Some bridges will have to be either strengthened or replaced in the next decades. For this reason, in this paper specific intervention are presented, including the following: bridge deck traditional intervention; light deck intervention (including SPS systems, aluminum orthotropic deck, FRP composite deck UHPC thin deck, making composite existing non composite solutions). According to the specific situation, span, loads, traffic, service life to be maintained, the proper solution or a combination thereof should be designed.

Steel Box-Girder Bridge Diseases Identification Based on Computer Vision System

Dalei Wang, Yue Pan & Bo Peng
Department of Bridge Engineering
Tongji University, China

ABSTRACT: Bridge diseases, including steel corrosion, protective material flaking off, etc., lead performance deterioration of material and risk increasing of structure failure. To understand well where a disease is and which level it is as the stipulation of maintenance specification, lots of manual inspection works are performed every year. Manual visual inspection method is reliable and useful, but it is time-consuming and high-cost, also not suitable for a standardized tracking of a disease development. In this study, a computer vision system is developed for long-span steel box-girder bridge inspection. Correspondingly, an automatic framework of disease identification based on deep learning is proposed. Finally, an experiment of this system on Jiangyin Bridge is introduced. This systemized solution is a novel methodology to instead of manual visual inspection and it can be attached to an existed bridge inspection installation. The results indicate that it is reliable and has a high robustness in real scenarios.

1 INTRODUCTION

To prevent the early failures of long-span bridge in service, the healthy status of bridges need to be monitored and evaluated. Thus, diseases identification is necessary for supporting the proper management strategies.

There are various diseases on steel box-girder of a long-span bridge, including steel corrosion, protective material flaking off, coating spalling, cracking etc. With the lack of advanced information-based auxiliary equipment and automated inspection system, people usually record and analysis each type of diseases manually and separately, which leads to low efficiency and difficulty in standardization, or long-term disease tracking.

To handle the drawbacks of manual inspection, based on computer vision, a steel box-girder bridge diseases inspection system is developed in this study.

Considering using an image recognition algorithm for the steel box-girder disease identification, the key point is the standardized image data acquisition. Thus, an image acquisition system is developed firstly for scanning the bottom of the steel box-girder, which moved by the inspection gantry at deck soffit. Then, to preferably present the position of diseases, the images captured per second are stitched into a large-scale panorama. Finally, a deep learning based steel diseases identification algorithm is performed, achieves average precision of 82.91%.

The image acquisition system as well as strategies are described in Section 3. Then the diseases identification algorithm based on deep learning is introduced in Section 4. Section 5 presents an experiment of this system on Jiangyin Bridge. Finally, summaries and conclusions are in Section 6.

This study is useful and meaningful in the developing of informationalized bridge maintenance.

2 RELATED WORKS

Corrosion, coating spalling and fatigue cracking are major diseases in steel box-girder bridges, and these diseases may lead to deterioration of structure performance as well as the increasing risk of failure. At present, the corresponding manual detection methods are adopted for various diseases. For instance, manual visual inspection is widely accepted in steel corrosion and coating deterioration detection, while ultrasonic and magnetic particle inspection has become a common practice in detecting fatigue cracks. The major limitations of these traditional manual inspection are the hardness of digitization and standardization due to the detection and evaluation results of diseases depend on the experience of inspectors to a large extent. In addition, it is costly and unachievable in the long-term monitoring of diseases especially in the inaccessible regions.

Many researchers set about detecting structural diseases with advanced equipment owing to the development of computer and sensor technologies in recent years. In the field of corrosion detection, corrosion segmentation can be achieved considering the color difference between corrosion regions and non-corrosion regions in early studies (Chen PH et al. 2009); other studies combined color with texture information to improve the applicability of corrosion segmentation (Shen HK et al. 2013); researchers test several machine learning algorithms including SVM, decision tree, naïve Bayes etc. in corrosion detection and achieved automatic evaluation of steel corrosion with detection results (Son H et al. 2014); a SVM classifier is trained to enhance segmentation effects in recent studies (Liao KW et al. 2016);. In the field of fatigue cracks detection, studies show that cracks detection can be realized with ultrasonic guided waves (Pahlavan L et al. 2016); other studies show that strain sensors can be arranged on a steel girder and train a SVM classifier to read the signals as well as evaluate fatigue state of steel girder (Hasni H et al. 2017). These studies expand the disease detection approaches and promote the process of standardized and automatic detection. But unfortunately, most of these advanced methods are still in research stage instead of applied stage considering the high equipment cost or strict site limitation.

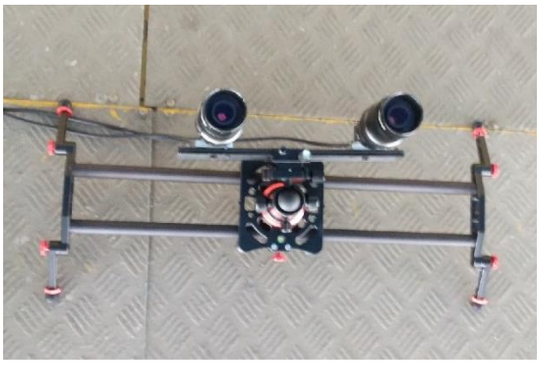

Figure 1 Hardware system.

3 IMAGE ACQUISITION

3.1 *Hardware*

The image acquisition system consists of a sliding rail, gimbal controller and industrial cameras, as shown in Figure 1. In practice, two Basler acA2040-120uc industrial cameras and two 8 mm lenses are applied in this study. The resolution of each camera is 2048 px × 1536 px and the frame rate is up to 120 fps with full resolution.

3.2 *Camera Calibration*

To counteract the effects of camera distortion and determine the relation between the camera's natural units (pixels) and the real-world units (for example millimeters), camera calibration is necessary to be carried out. Camera distortion are usually taken into account as a combination of radial and tangential distortion.

The radial distortion can be solved as:

$$x_{corrected} = x(1 + k_1 r^2 + k_2 r^4 + k_3 r^6) \quad (1)$$

$$y_{corrected} = y(1 + k_1 r^2 + k_2 r^4 + k_3 r^6) \quad (2)$$

where x, y = the distorted image point coordinates; $x_{corrected}$, $y_{corrected}$ = the undistorted image point coordinates; r = the distance from distorted image point to the distortion center; k_1, k_2, k_3 = distortion coefficients for radial distortion.

The tangential distortion can be solved as:

$$x_{corrected} = x + [2p_1 xy + p_2(r^2 + 2x^2)] \quad (3)$$

$$y_{corrected} = y + [p_1(r^2 + 2y^2) + 2p_2 xy] \quad (4)$$

where p_1, p_2 = distortion coefficients for tangential distortion.

OpenCV library, an open-source library, is applied for camera calibration in this study, the distortion coefficients are listed in Table 1, where we use chessboard to estimate distortion coefficients and then counteract camera distortion.

Table 1 Distortion coefficients for camera calibration.

Distortion Coefficients	Value
k_1	-1.095
k_2	10.325
k_3	-200.578
p_1	2.979×10^{-3}
p_2	-3.933×10^{-3}

3.3 *Image Stitching*

Disease identification commonly has two works:

1) Recording the position of diseases.

2) Classifying and evaluating the diseases.

To preferably present the position of diseases, large-scale panoramas are commonly required. Image stitching technique is widely used to obtain a panorama.

In this study, a phase correlation based image stitching approach (Reddy BS & Chatterji BN. 1996) is applied, which is widely used in remote-sensing images registration, considering the small sampling

interval and the surfaces of steel are usually less context.
