Excessively simplified analyses of creep and shrinkage effects and incorrect use of prestressing in governing statics and deformed configuration of the structure caused excessive deflections over time, with loss of functionality. Many drawbacks proved to be caused by the action of the upper cables, introduced for strengthening the girder, but adversely affecting its deformed configurations (Krístek et al. 2006). The conventional assessment of the time-dependent behavior of prestressed cantilever-built bridges uses tools of analysis based on deterministic criteria and assumes that all the factors involved are known and certain data. As known, the expected attitude of this type of bridges results from the antagonist roles of self-weight and prestressing. The final value of the deflections results from the difference of two large and opposite numbers, representing downward and upward deflections, which strongly depend on several uncertainties due to environmental factors, material characteristics, pre-tensioning forces in the tendons and erection technologies. As recently shown (Malerba 2012, Briccola 2017) through probabilistic analyses, such uncertainties have a significant influence on the deformational behavior. Both deflections and their variance increase with time and they may strongly modify the vertical attitude of the structure.

These effects are emphasized when the prestressing is applied only a few days after curing.

Acknowledging the existence of possible diverging behaviors and the intensity of their effects allows us not only to explain some excessive deformation experienced under permanent loads but also to draft solutions to make this type of structures more stable and safer.

3.7 Inspection and maintenance

Hinges, joints and any other type of articulation are vulnerable and expensive devices, characterized by a life cycle that is very short with respect that of the bridge. For these reasons, they require specific inspection and maintenance activities. In case of damages and failures, they are difficult to place and replace and strongly condition the operational costs.

4 CONCLUSIONS

Cantilever bridges have given a fundamental contribution to the development of bridge construction. Their performances over time allow highlighting their most common draw-backs, design solutions to extend their service life and define criteria to improve the design of new bridges.

For existing cantilever bridges, it is important to respect a rigorous and effective inspection and maintenance plan. Any intervention in case of incipient damage must not only repair but also try to increase the robustness of the weakest details and check the subsequent effects on the whole structure.

For new bridges, according to location, soil characteristic, costs and expected construction times, it is better to avoid articulated girders and an extensive use of joints, and to privilege continuous structural schemes.

In the design stage of continuous prestressed bridges, the uncertainties due to time-dependent effects pay a relevant role. For this reason, it is advisable to prearrange empty ducts for additional prestressing cables, to be used in contrasting unfavorable time-dependent effects. The layout of these cables must be designed according to the set of possible diverging schemes.

To prolong the structure service life and enhance its robustness, it is important always to predispose systems that facilitate inspection and maintenance operations and allow to recover potential drawbacks due to malfunctioning of special devices such as drainage systems, joints and bearing supports.

Whipple's 1841 Bowstring Truss – World's First Scientifically Designed Truss Bridge

I. A. Nitschke
Historic Preservation Advisory Committee, Town of Claverack, NY, USA

F. E. Griggs Jr.
Distinguished Member ASCE, Historic Bridge Consultant, 30 Bradt Road, Rexford, NY, USA

ABSTRACT: The Whipple Bowstring Truss bridge (patented in 1841), was the first bridge truss design in the world that used scientific principles, by Squire Whipple, who published them in the 1847 book: A Work on Bridge Building. Designed for the Enlarged Erie Canal in New York State (1836-1862), hundreds of Whipple Bowstring Truss bridges were built for the canal and other waterways. One such bridge was the Shaw Bridge, built in 1870, for the New York City to Albany Post Road over the Claverack Creek, in the idyllic Hudson Valley. This bridge is one of only eight of the vintage Whipple Bowstring Truss bridges left, the lone one in its original location and the only double span. It clearly exemplifies the robust original design, including the use of cast iron for compression members, wrought iron for tension members, and a wooden deck that could be replaced without affecting the strength of the bridge. Since the Shaw Bridge is uniquely in its original location, it also has its original masonry abutments (and pier). Despite being used for 120 years and closed for over 25 years, the bridge is in remarkably good condition, which speaks well for its original design and materials (19th century cast and wrought iron being more rust resistant than most modern steel). Whipple's importance cannot be overstated. Besides clearly documenting theoretical principles for bridge design for the first time, he promoted the use of prefabricated components, life-cycle costing, and was important for the Enlarged Erie Canal and early railway industry, helping make New York City become a world leader. The bridge is clearly eligible for Historic Civil Engineering Landmark status and this paper argues it is a World Heritage Bridge candidate. The meticulous restoration of the Shaw Bridge will be a fitting tribute to the genius of Squire Whipple.

1 INTRODUCTION

In a quiet picturesque area of Columbia County, in the renowned Hudson Valley of New York State, there is a charming double-span iron bowstring truss bridge over a scenic trout stream – the Claverack Creek. Currently it is neglected and closed, but this bridge, the Shaw Bridge, was designed by the famous 19th century engineer, Squire Whipple, and was once an important bridge on the main Post Road that connected America's financial centre (New York City) to New York State's capital (Albany). This paper tells the story of the world-renowned Shaw Bridge and the modest gentleman who designed it.

2 SQUIRE WHIPPLE – THE GENIUS BEHIND THE DESIGN OF THE SHAW BRIDGE

2.1 *Young Squire Whipple's Inspirations, Education, and Training (1804-1839)*

Squire Whipple was born in Massachusetts in 1804, the ninth son of a farmer and mill owner. The young Whipple was exposed to the latest construction techniques and materials and methods used to power mills of all kinds. When he was 13, his family moved to a farm in New York State. Whipple was a voracious reader who had a passion for learning but little or no interest in farming. He was a good student and at an early age became a schoolteacher at the local one-room schoolhouse. He became a vegetarian and would not use horses or oxen as beasts of burden. Fortunately, his father had developed another water-powered mill that kept Squire occupied and gave him the skills of a carpenter, tinsmith, blacksmith, and jointer. He experimented with electricity, played the violin every day, and attended nearby Hartwick Seminary and Fairfield Academy for several terms in the mid 1820s. In 1828 he studied law in a local lawyer's office while also working on his father's mills.

After receiving the best common school education available, in 1830 he graduated from Union College in Schenectady, New York after one year of study. He spent the decade of the 1830s working on various railroads and the Erie Canal enlargement. When work was slow, he designed, built, and sold mathematical instruments such as transits and engineer's levels and drafting equipment (Griggs 1988, 2002, 2005, 2015).

2.2 *Mature Squire Whipple's Productive Years (1840-1860)*

In 1841, Whipple designed and built a weigh lock scale with a capacity of 300 tons to weigh the enlarged canal boats in Utica, New York, which was adopted elsewhere. This was the largest weighing device in the country at the time.

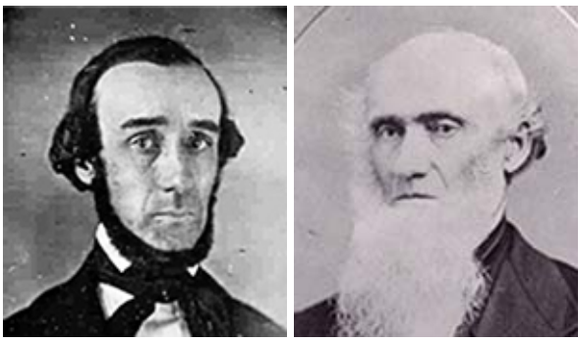

Figure 1 Squire Whipple (a) Young (b) Senior

Whipple became interested in the design and construction of bridges. He knew that wooden bridges on the original Erie Canal had a short life and the new, wider canal would require longer span bridges. So he devised methods to study bridge designs using various materials including iron. These investigations led to his design of the elegant bowstring truss that used cast iron for compression members, wrought iron for tension members, and a wooden deck that could be replaced without affecting the strength of the bridge. He applied for and was issued a patent, April 24, 1841. See Figure 2.

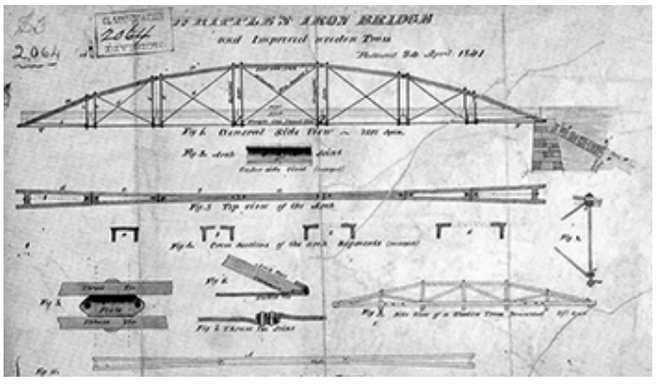

Figure 2. Whipple's Patent Drawings 1841

Whipple tried to convince the Canal Commissioners that a bridge built of iron was a good long-term investment (thus becoming a pioneering advocate of life-cycle costing), but they were reluctant to trust a new material for their bridges. To illustrate the stability and strength of his bridge, Whipple had one built at his own expense on a vacant lot in Utica, New York near the offices of the Canal commissioners, and when the wooden First Street Bridge in Utica fell, they finally approved the construction of his bridge. Between 1842 and 1870, hundreds of Whipple Bridges were built over the Erie and its branch canals, either by Whipple or to his patent, as his design was eventually adopted by the Canal Commissioners as the standard bridge to cross the canals of the state. See Figure 3 for an example.

Figure 3. Lithograph of Whipple's Bowstring Bridge in Syracuse NY, one of hundreds built over the Enlarged Erie Canal.

Others (like the Shaw Bridge) were built over waterways in the United States and one was even built in Japan (devised by Socichirro Matsumoto a Japanese 1876 graduate of Rensselaer Polytechnic Institute in Troy, New York). Frequently, contractors would build to his patent without paying patent fees, so he never received large sums of money from builders using his patent (Griggs 1988, 2002, 2005, 2015).

Whipple wanted to share his discoveries with the world and to bring credibility and respect to bridge building, so in 1846 he wrote *An Essay on Bridge Building: containing analyses and comparison of the principal plans in use with investigations as to the best plans and proportions and the relative merits ofwood and iron for bridges*. It included an analysis of the bowstring truss and other bridges, including the trapezoidal form. Whipple's decision to write this essay was probably based on his intention to show that his bowstring truss was the best form available in terms of efficient use of material but he found instead "each of the three forms – the arch, and the trapezoidal with and without verticals, possessed certain practical advantages entitling each to preference in respective cases". The 47-page essay marked the beginning of analytical truss design, and the following year it was made part of his 1847 seminal book *A Work On Bridge Building: consisting of two essays, the one elementary and general, the other giving original plans and practical details for iron*

and wooden bridges (Whipple 1847). For the first time anywhere in the world, this book presented the correct methods of analyzing and designing a truss using the properties of the latest appropriate materials. His technique, now known as the method of joints, is still the way that truss analysis is taught. He used both trigonometry and geometrical construction – the force polygon method – to find his member forces.

Between 1848 and 1850 Whipple designed and built several short span iron bridges for the New York and Erie Railroad. Though successful these bridges were removed after another iron bridge (not of Whipple's design) collapsed in 1850. Undaunted, in 1852-53 Whipple went on to design and build the first successful long span trapezoidal railroad bridges in West Troy and Utica, NY. This double intersection design was the most common railroad truss bridge until the 1890s, being built over western rivers with spans over 150 m (Griggs 1988, 2002, 2005, 2015).

2.3 *Senior Squire Whipple Continues to Make Major Contributions (1861-1888)*

About 1860 Whipple turned his business over to his nephew J. M. Whipple but took on a few jobs including designing and building trapezoidal bridges, swing bridges, and lift bridges. In December 1872, he designed and patented the first vertical lift bridge in the United States and built one over the Erie Canal in Utica.

Whipple continued to update and expand his first book with an Appendix in 1869 and wrote a more formal book on bridge building (first printed in 1872 then reprinted until 1899): *An Elementary and Practical Treatise on Bridge Building, An Enlarged and Improved Edition of the Author's Original Work.* (Whipple 1872). He contributed several articles to American Society of Civil Engineers (ASCE) Journals, and was the first person, after the post-Civil War rebirth of ASCE, to be named an Honorary Member of the Society in 1868.

Whipple died on March 15, 1888 at the age of 84 and was buried in the Albany Rural Cemetery leaving his widow Anna and no children. His obituary in *Engineering News* noted "The death of Squire Whipple… removes from the engineering world a man who by his individuality and originality practically created the modern art of bridge construction; not only in substituting iron for wood in bridges but in also pointing out the law governing the distribution of strain in framed structures and the proper proportioning of the various members in such structures".

3 THE WORLD FAMOUS, CHARMING, AND NEGLECTED SHAW BRIDGE

3.1 *The Shaw Bridge, Built along a Main Highway, is Named, and Photographed (1870-1930)*

The vital Albany to New York Post Road changed paths over its 300-year history but by 1870 it crossed the Claverack Creek via a double-span bowstring truss bridge later named the Shaw Bridge. The bridge builder (J. D. Hutchinson) and construction date (1870) are clearly established by the inscription embossed along the top of each of the four cast iron trusses, see Figure 4. John D. Hutchinson (1842-1897) and his father John S. Hutchinson (1814-1870) built more than 50 bridges using the patented Whipple design but defaulted on paying fees to Whipple (after a small down payment), resulting in lengthy court cases that were settled with a paltry sum paid by New York State.

Figure 4. Shaw Bridge inscription: "J. D. HUTCHINSON, BUILDER TROY, N.Y 1870"

Figure 5. Postcard of the Shaw Bridge south portal, looking north

Traditionally, local bridges were named after the owner of the nearest farm. In 1879, William Shaw, having made a fortune from his import-export business in Brooklyn, New York, purchased the farm next to the bridge, and the bridge became known as the "Shaw Bridge".

Later, the bridge was photographed, featured on a postcard with caption: "Bridge at Claverack, near Hudson, NY", and widely distributed, see Figure 5. The back of the postcard has the Trade Mark Litho-Chrome, Germany, which dates the postcard to the period 1906-1909, so the

photograph for the postcard was taken when the bridge was essentially in original condition. Note that the wooden deck reaches through the trusses. This is consistent with "New York State Canals – 1871 – Specification of the Manor of Constructing Whipple's Patent Iron Arch Truss Bridge Superstructure" (reproduced in Allen 1973). The postcard and official Specification are the fundamental documents that will be used to carefully restore the Shaw Bridge to its original condition.

3.2 *The Shaw Bridge is Bypassed, Repaired, Celebrated, and Finally Closed (1931-1989)*

"When the present State Route 9H was constructed in 1931, this remnant of the Old Post Road…became a little used road belonging to the Town of Claverack…However, when the hurricane of September 21, 1938, struck, the Shaw Bridge was one of the few in all Columbia County that was passable". In 1956 the bridge was condemned then repaired and reopened. Ten years later (1966), measured drawings of the deck provided an accurate list of materials to replace the wood stringers and deck, the last time they were replaced. On September 6, 1980, a ceremony celebrated the Shaw Bridge's listing on the National Register of Historic Places. This event included speeches emphasizing the historical importance of the bridge and a parade across the bridge led by a horse-drawn buckboard, followed by 1922 Essex Speedster, 1923 Studebaker, 1924 Ford, 1922 White truck, 1929 Ford truck, and 1930 Ford truck. However, despite significant support, by June 1989 the bridge was closed to motorized vehicle traffic because of "structural deficiencies".

3.3 *Attempts to Open the Shaw Bridge are Initially Unsuccessful but Finally Begin to Succeed (1990-Present)*

During 1990, various newspaper articles reported that the Town of Claverack was seeking funds to repair the Shaw Bridge. Cost of the restoration could be as much as $330,000. Meetings were attended by Van Wyck Lane residents interested in seeing the bridge preserved. One neighbor suggested the span be rehabilitated and reopened only to pedestrian traffic in order to preserve "the tranquil character of our neighborhood". By August 1990 it was announced that the state would grant $146,650 for half the cost of repairs. However, the town and county failed to come to an agreement on matching the state grant and the grant expired.

Meanwhile, in the summer of 1994, Jet Lowe, the famous Historic American Engineering Record (HAER) photographer, photographed the Shaw Bridge. However, in November 1995, the county engineer stated there are "no plans to re-open Van Wyck Lane over the Claverack Creek at this time". Thirteen years later, Wikipedia recorded how the famous bridge had become overgrown with vines and weeds. In 2010, several photos by Rick Ehrenberg (see Figure 6) conveyed the deplorable state of this important bridge to the Claverack Town Supervisor, stating "As the only known Whipple twin-span bowstring in the world, it would be a shame – no, crime, really – to NOT properly restore this bridge. It is a living piece of history, from a time when America's technical, engineering, and manufacturing prowess were just starting to bloom – and Squire Whipple was at the forefront".

Figure 6. Shaw Bridge. Photo by Rick Ehrenberg 2010

This led, in 2011, to clearing of the vegetation from the bridge by the Town Highway crew and photo documentation of the bridge by HistoricBridges.org, culminating in a proposal to the Preservation League to fund a Historic Structure Report, which, alas, was rejected. A second (this time successful) proposal was sent to the Preservation League in 2012, which resulted in the development of reports by engineering consultants Ryan-Biggs Associates and coauthor of this Dr. Francis Griggs Jr. These reports were then used to prepare a New York State Consolidated Funding Application (CFA) to restore the bridge in 2014. Unfortunately, the 2014 application was rejected. In 2016 a revised application was submitted and this time it was successful. With CFA money ($170,000) now available, it is expected that matching money, material and in-kind services will finally result in the initiation ofthe restoration of the Shaw Bridge.

3. DESCRIPTION OF THE CURRENT STATE OF THE SHAW BRIDGE

3.1 *Overview*

Whipple had a fondness for the first bridge he designed – the bowstring truss. He wrote: "The arched truss, moreover, may, by some, be thought to have a more graceful and agreeable appearance than the cancelled truss. I will not take upon myself to decide on this point, except by remarking, that, to a person who comprehends the principles and properties of different kinds of structures, in a case where strength is the grand desideratum, that plan of structure which secures this in the greatest degree, with the least amount of material and expense, will generally excite the most pleasing sensations in the mind" (Whipple 1847). The charming Shaw Bridge closely follows the bowstring truss design patented by Squire Whipple. Despite being neglected for so long, the bridge is in remarkably good condition, which speaks well for its original design and materials (19th century cast and wrought iron being more rust resistant than most modern steel).

The two-span, single-lane bridge has an overall length of about 50 m and a roadway width of about 3.2 m. Each of the identical pony trusses spans 25.4 m over the Claverack Creek. The bridge is currently closed to both vehicular traffic and pedestrians.

Wrought iron or steel floorbeams (additional testing would be required to determine if they are wrought iron or steel) are 23 cm deep and span about 4 m between the centerline of the trusses. The floorbeams support wood stringers, which are spaced at about 0.5 m on center and support a 6.4 cm thick wood deck. The trusses and the ends of the wood stringers are supported on stone masonry abutments and on a single stone masonry pier between the southern and northern span. Claverack Creek at normal water levels flows entirely under the southern span of the bridge.

3.2 *Condition of Cast Iron Top Chords & Junction Blocks*

Top chords are in excellent condition. The joints between segments are generally full bearing. Evidently in the past it was thought the segments were shifting with respect to one another and three retainer plates were added (on the east and west trusses of the south span and the west truss of the north span). It would be preferable to remove the retained plates in the rehabilitation of the spans. A small hairline crack was observed on the east truss of the south span where someone had attached a railing bracket and connected a steel bar across the crack. This is not a serious structural problem but it would be desirable to repair the crack in a less obvious way. Where non-historic railings have been welded or dowelled to the cast iron between the two spans, these will be removed and the holes repaired. The largest unknown is the condition of the ends of the chords that have been encased in concrete at the abutments and pier. It is unlikely that the cast iron has been damaged by the encasing (but the lower wrought iron chords could be, see below), but, in any case, all the top chords will be examined after the concrete is removed.

Junction blocks appear to be in a solid, uncracked, condition.

3.3 *Condition of Wrought Iron Lower Chord Loops, Vertical Rods, Diagonal Rods, Metal Beams, Metal Diagonal Cross Bracings*

Lower chord loops appear to be in good condition and in full contact with the cast iron junction blocks as there were no observed loose members. The largest unknown is, again, at the ends where they have been encased with concrete and where they enter the top chord casting. This area will be investigated closely when the concrete is removed and when the structure is cleaned and any cake or pack rust is removed.

Vertical rods appear to be in good condition except in areas where they have been bent, probably from some vehicle crossing the bridge. In other Whipple Bridges there has been some necking from corrosion where the vertical rods pass into the cast iron junction blocks. All of these areas will be reexamined after the structure is cleaned and any cake or pack rust is removed.

Diagonal rods are in good condition except, in a few cases, where they are severed or bent. Many of the diagonals are loose and will need to be tightened. As with the verticals, necking down of the section can occur where the diagonals enter the cast iron junction blocks, so it is probable that some of the ends of these elements may have to be replaced. All of these areas will be reexamined after the structure is cleaned and any cake or pack rust removed.

Beams appear to be in fairly good condition. Some rusting on the top flanges is apparent. It is believed that after cleaning they will be reusable.

Diagonal cross bracings are in good condition. The turnbuckles will have to be cleaned and restored to operating condition.

3.4 *Condition of Wood Stringers, and Wood Deck*

Wood stringers and decking must all be replaced. The non-original deck structure (designed to be replaced) was last installed in 1966. The new deck will more accurately reproduce the original, referencing the circa 1900 Postcard and the New York State Canals – 1871 – Specification (Allen 1973).

4. TREATMENT RECOMMENDATIONS

4.1 *Historic Preservation Objectives*

The U.S. National Parks, Secretary of the Interior, Standards for the Treatment of Historic Properties will be followed (Weeks & Grimmer 1995). These common sense historic preservation principles are intended to promote historic preservation best practices that help to protect irreplaceable cultural resources. The four treatment approaches of the Standards are: Preservation, Rehabilitation, Restoration, and Reconstruction. The treatment for the Shaw Bridge will follow the Restoration approach, which focuses on the retention of materials from the most significant time in the bridge's history (circa 1870 to 1900), while permitting the removal of materials from other periods (like guardrails, non-original wooden deck and stringers).

4.2 *Standards for Restoration of Historic Properties*

A property will be used as it was historically or be given a new use, which reflects the property's restoration period.

Materials and features from the restoration period will be retained and preserved. The removal of materials or alteration of features, spaces, and spatial relationships that characterize the period will not be undertaken.

Each property will be recognized as a physical record of its time, place, and use. Work needed to stabilize, consolidate and conserve materials and features from the restoration period will be physically and visually compatible, identifiable upon close inspection, and properly documented for future research.

Materials, features, spaces, and finishes that characterize other historical periods will be documented prior to their alteration or removal. Distinctive materials, features, finishes, and construction techniques or examples of craftsmanship that characterize the restoration period will be preserved.

Deteriorated features from the restoration period will be repaired rather than replaced. Where the severity of deterioration requires replacement of a distinctive feature, the new feature will match the old in design, color, texture, and, where possible, materials.

Replacement of missing features from the restoration period will be substantiated by documentary and physical evidence. A false sense of history will not be created by adding conjectural features, features from other properties, or by combining features that never existed together historically.

Chemical or physical treatments, if appropriate, will be undertaken using the gentlest means possible. Treatments that cause damage to historic materials will not be used.

Archeological resources affected by a project will be protected and preserved in place. If such resources must be disturbed, mitigation measures will be undertaken.
Designs that were never executed historically will not be constructed (Weeks & Grimmer 1995).

4.3 *Rationale for Using Standards for Restoration of the Shaw Bridge*

Restoration is warranted because the Shaw Bridge is a nationally significant resource – a rare survivor of the revolutionary design by engineering genius Squire Whipple – and it was constructed during a period when the road it carried was the most important main highway between New York City and New York State's capital, Albany. The Shaw Bridge's historical importance was recognized in 1980 when it was listed on the National Register and, it is generally agreed, it is eligible for Historic Civil Engineering Landmark status and possibly a potential World Heritage Bridge (see Section 5). Other considerations for the Restoration choice are the remarkably good physical conditions of the bridge with excellent original material that is largely intact with few alterations to the historical structure. The proposed pedestrian, bicycle, (and occasional horses and horse-drawn vehicles) use is also consistent with the original use before automobiles. Other sensitive issues are code requirements that need to be taken into consideration, but if hastily or poorly designed, code-required actions may jeopardize the bridge's materials as well as its historic character. For the Shaw Bridge, expensive

abatement of lead paint requires particular care if important historic finishes are not to be adversely affected. One of the first investigations will be to assess how much of the iron is covered by actual lead paint and explore alternatives to paint removal, especially in the unlikely event that the paint does not contain lead. Finally, the need to meet accessibility requirements (like handrails) under the Americans with Disabilities Act of 1990 will be designed to minimize material loss and visual change to the historic bridge (Weeks & Grimmer 1995).

4.4 *Work Recommendations*

The project will be guided by recommendations from the Historic Structure Report outlined in the New York State Proposal to restore the Shaw Bridge and overseen by New York Office of Parks, Recreation and Historic Preservation using the following tasks:

Task 1: Supervise & Administer the Project
Task 2: Re-Point Stone Masonry Abutments & Pier
Task 3: Remove Concrete Encasements At Truss Bearing, Highway Railing, Wood Stringers, & Decking & Replace With Temporary Planking
Task 4: Remove & Dispose Of Lead Paint & Rust
Task 5: Repair & Paint All Metal Truss Members & Beams
Task 6: Fill Pier Scour Hole & Protect With Stone
Task 7: Replace Wood Stringers & Deck

5. DISCUSSION & CONCLUSION THAT THE SHAW BRIDGE IS A POTENTIAL WORLD HERITAGE BRIDGE

The first Whipple Bowstring Truss bridge was designed, built, and patented by New York State engineering genius Squire Whipple in 1841, using scientifically based mathematical principles. In 1846-7 Whipple put these ideas into print in the book A Work on Bridge Building, the first time in the world that a scientific work correctly analyzed the stresses in a truss. Whipple is recognized as the father of iron-bridge building in America and has had a profound influence on the history of American civil engineering. The majority of the hundreds of Whipple Bowstring Truss bridges that were built were along the Enlarged Erie Canal, opening up the west and playing a key role in the rising dominance of New York City as America's most important city. They were essential to the success of the Erie Canal since they reconnected cities, villages, hamlets, and farm fields that grew up around the canal without impeding canal traffic. Similarly, the well-placed double-span Shaw Bridge (that extended over a wide part of the Claverack Creek) on the Albany New York Post Road provided a vital link, especially during winter months when the Hudson River was frozen and during periods of flooding when other bridges were closed.

Of the hundreds of original Whipple Bowstring Truss bridges built, only eight* are known to survive. Six are in New York State (Shaw Bridge, Black River Canal Bridge, Ehrmentraut Farm Bridge, Normanskill Farm Bridge, Union College Bridge, and Vischer Ferry Bridge); one is in Ohio (Rodrick Bridge); and one is in Japan (Hachiman Bridge). Coauthor Francis Griggs Jr. has been involved in the restoration of three of the eight historical Whipple bowstring truss bridges: Black River Canal (2001), Union College (1980), and Vischer's Ferry (1997).

* Note: Four completely new (2008-2015) Whipple Bowstring Truss bridges were built in Buffalo, New York, at the cost of millions of dollars. However, these bridges were factory-made and assembled differently than the way Whipple designed them, so cannot be considered true historical bridges. The bridges are major tourist attractions on the Buffalo waterfront, which has the stylized Whipple Bridge logo:

Of the eight historical Whipple bowstring truss bridges, the Shaw Bridge is the best example of this world-famous bridge: it is the only double-span Whipple Bowstring Truss left and the only one in its original location with all the original metal structure, stone abutments, and stone pier virtually intact. Only the badly rotted wooden stringers and deck (replaceable by design) are not original. The wooden stringers and deck will be reconstructed according to the circa 1900 color postcard photo and the New York State Canals – 1871 – Specifications. As such, the restored Shaw Bridge has the potential to become a world-class bridge.

To be included on the World Heritage List, sites must be of outstanding universal value and meet at least one out of ten selection criteria (see http://whc.unesco.org/en/criteria/ for the complete criteria list). The Shaw Bridge satisfies the following four selection criteria: (i) To represent a masterpiece of human creative genius; (ii) To exhibit an important interchange of human values, over a span of time or within a cultural area of the world, on developments in… technology; (iv) To be an outstanding example of a type of … technological ensemble which illustrates a significant stage in human history; and (vi) To be directly or tangibly associated with events or living traditions, with ideas, or with beliefs, with artistic and literary works of outstanding universal

significance (preferably used in conjunction with other criteria) … The protection, management, authenticity and integrity of properties are also important considerations.

The status of the Shaw Bridge as a world-class historic bridge is confirmed by three publications that follow.

First, before the Shaw Bridge closed, it was included in the book Great American Bridges and Dams by Donald L. Jackson with a foreword by renowned historian David McCullough (Jackson 1998). Several New York City bridges were in this book, including world famous 1883 Brooklyn Bridge, 1917 Hell Gate Bridge, and 1931 George Washington Bridge. Upstate New York was represented by three bridges: 1870 Shaw Bridge, 1855 Blenheim Covered Bridge (destroyed by the 2011 tropical storm Irene), and 1927 Peace Bridge (Buffalo).

Second, in an important article (DeLony 1996) "Context for World Heritage Bridges", Eric DeLony (former chief of the National Park Service, Historic American Engineering Record), listed five potential world heritage bridges for New York State: 1860 Central Park Cast-Iron Arches, 1867 Normanskill Whipple Bowstring Truss Bridge, 1883 Brooklyn Bridge, 1886 Poughkeepsie Cantilever Bridge, and 1917 Hell Gate Bridge. The reason for DeLony's choice of the Normanskill Bridge over the Shaw Bridge may have been the extensive documentation of the Normanskill Bridge by HAER in 1969 (Allen 1973), unlike the Shaw Bridge, which was not known at the time of the 1969 study. (Although DeLony would have been aware, in 1996, of Jet Lowe's 1994 photographs of the Shaw Bridge). As noted above, the Shaw Bridge is in its original location. But DeLony appears to contradict himself and make a special exception for the Normanskill bridge (which has been moved twice to the current location and does not have its original abutments) when he states: "A World Heritage bridge, like other properties, must meet the test of authenticity in design, materials, workmanship, or setting" [emphasis added]. The relocation of the Normanskill bridge from its original location and foundations negatively impacts the authenticity of its setting. The setting of the Shaw Bridge, still standing on its original abutments and pier, along the once vital Albany Post Road over the bucolic Claverack Creek, has a much greater authentic setting than the relocated Normanskill farm bridge. Besides, the Shaw Bridge has two spans while the Normanskill Bridge has only one.

Third, in the oversize book of photos Bridges, A history of the world's most famous and important spans by Judith Dupré, with an introductory interview by celebrated architect Frank O. Gehry (Dupré, 1997) only four New York State bridges are photographed and listed: Brooklyn Bridge, Hell Gate Bridge, George Washington Bridge, and Albany (Normanskill) Whipple Bowstring Truss Bridge. Again, the Normanskill Bridge was probably chosen because of the extensive HAER documentation conducted in 1969, but the Shaw Bridge, when restored, has a much greater claim to fame than the Normanskill Bridge.

ABSTRACT: Over the past decades researchers have tried to develop protocols to assess the current condition (diagnosis) and the potential for further expansion/distress (prognosis) of aging critical infrastructure. Among promising techniques, particular attention was given to quantitative microscopic procedures such as *the Damage Rating Index (DRI)*. However, those techniques were found to be quite time-consuming and relied on the experience of petrographers able to properly judge their outcomes. It has been found that *Machine Learning (ML)* techniques might be used for efficient damage assessment in concrete. With the aid of modern software and some custom programming, petrographers could provide some "training" to the computer to diagnose concrete distress mechanisms. This paper discusses the potential use of ML to appraise damage in critical infrastructure. Validation is made with data obtained from laboratory test specimens with different amounts of damage from AAR. Preliminary results illustrate the promising character of ML in diagnosing AAR-affected concrete, which may also be suitable for other types of deterioration.

1 INTRODUCTION

Civil infrastructure is very critical for society, connecting a nation's businesses, communities and people, driving the economy, and improving the quality of life of human beings. Usually, civil concrete infrastructure is designed with a lifespan, so-called "service-life", of 50-75 years depending on the code used for designing and the structure type (i.e. dams, bridges, tunnels, stadiums, etc.). It is known that several critical structures are reaching the end of their expected service life, and thus actions should be taken in order to either manage/guarantee their performance over their last few years in service or extend their expected lifespan. Moreover, several of those structures present clear signs of distress due to numerous damage mechanisms which might very likely decrease their performance down to unacceptable thresholds (Figure 1).

In this context, alkali-aggregate reaction (AAR) is one of the most important damage mechanisms affecting the performance of concrete infrastructure worldwide (Fournier and Bérubé 2000, Sanchez et al. 2015). AAR is normally divided in two distinct mechanisms; the so-called alkali-silica reaction (ASR) and alkali-carbonate reaction (ACR).

- ASR is a chemical reaction between unstable silica minerals phases from the aggregates used in concrete and the alkali ions found in the concrete pore solution. It is by far the most common reaction mechanism found in concrete around the world (Fournier & Bérubé 2000).
- ACR is a chemical mechanism that happens in concrete in the presence of limestone and/or dolomite aggregates. Currently, there is no consensus in the technical society on the real mechanisms causing ACR-induced expansion and damage. Yet the dedolomitization of dolomite seems to be one of the potential causes (Grattan-Bellew et al. 2010, Fournier & Bérubé 2000).

One of the biggest challenges in civil engineering nowadays is to identify the cause and the extent of distress, to establish the correlation between the reductions in mechanical properties, physical integrity, durability and performance of the affected material, to evaluate possible structural implications and also their potential for further deterioration. Those are critical steps in the selection of management actions on the above structures (Sanchez et al. 2015, Grattan-Bellew & Danay 1992, Grattan-Bellew & Mitchell 2006, Rivard et al. 2000).

Figure 1: Concrete block damaged by AAR- Quebec,Canada.

Over the past decades, engineers and researchers have tried to develop tools and procedures to assess the current condition (diagnosis) and the potential for further expansion/distress (prognosis) of concrete damaged by AAR. Among promising techniques, particular attention has been given to the Damage Rating Index (DRI), a semi-quantitative petrographic method, as well as to some quantitative image analysis techniques through the use of fluorescent epoxy dyes (Rivard et al. 2000, Sanchez et al. 2015). However, although very interesting, those techniques are quite time consuming and more importantly always rely on experienced petrographers able to properly judge the outcomes of the methods. Otherwise, it has been identified that a number of *Machine Learning* (ML) techniques might be used for efficient assessment of damage in concrete. However, very few data is available in the literature on the use of ML systems for diagnosing concrete affected by AAR.

The primary objective of the current study is to explore the potential of ML techniques for the assessment of critical concrete infrastructure such as bridges. It is anticipated that these techniques could eventually be used to diagnose problems in concrete bridge structures through an automated analysis of their distress features, and possibly even to provide a prognosis of future damage. While the methodology presented herein focuses specifically on concrete distress caused by AAR, the approach used could very likely also be used to evaluate other mechanisms (e.g. corrosion of steel reinforcement, freeze-thaw damage, delayed ettringite formation, etc.). This work thus provides a preliminary basis for identifying and isolating the effects of multiple distress mechanisms that may be present together in a single sample, a task which is currently very difficult to assess through manual methods.

2 BACKGROUND

2.1 *Microscopic tools for assessing AAR damage*

To evaluate AAR-induced expansion and damage, several mechanical and microscopic tools were developed in the past decades. Among them, the Damage Rating Index (DRI) is one of the most promising tools. The DRI is a microscopic analysis performed with the use of a stereomicroscope (15-16x magnification) where damage features generally associated with AAR are counted through a 1 cm² grid (i.e. 10 x 10 mm units) drawn on the surface of a polished concrete section (Sanchez et al. 2017, Villeneuve & Fournier 2012, Dunbar & Grattan-Bellew 1995). The number of counts corresponding to each type of petrographic feature are then multiplied by a weighting factor, whose purpose is to balance their relative importance towards the mechanism of distress, in this case AAR. The factors used in the method were selected on a logical basis, but relatively arbitrarily (Sanchez et al. 2015, Villeneuve & Fournier 2012); they were recently modified in order to reduce the variability between the petrographers performing the test (Villeneuve & Fournier 2012). Ideally, a surface of at least 200 cm² should be used for DRI analysis, and it may be greater in the case of mass concrete incorporating larger size aggregate particles. However, for comparative purposes, the final DRI value is normalized to a 100 cm² area.

It has been shown that the DRI correlates well with measurements of expansion and damage caused by AAR in concrete presenting different compressive strengths and incorporating a wide range of reactive aggregates (Sanchez et al. 2015, Rivard et al. 2000). Yet, the microscopic technique is also quite time-consuming, which could be at least partially improved by the use of automated techniques such as machine learning processes (Pereira Junior & Inkpen 2017, Azam & Gavrilova 2017). Furthermore, DRI values depend largely on the skill and experience of the researcher, and thus may be considered somewhat subjective. By training computers to perform automated analyses, more consistent and objective results might be expected.

2.2 *Machine Learning (ML)*

Machine Learning (ML) is a field of artificial intelligence that provides systems the ability to automatically learn and improve from data without following only explicitly programmed instructions. ML algorithms operate by building a model based on inputs and using that to make predictions or decisions.

ML is employed in a range of computing tasks where programming explicit algorithms is infeasible. ML is commonly classified in three types:

1. **Supervised Learning**: It is the ML task of inferring a function from labeled training data as an input, generalizing to unseen situations. The algorithm will learn the relationship between the images and their associated numbers, and apply that learned relationship to classify completely new images (without labels) that the machine hasn´t seen before (Maini V., 2017);
2. **Unsupervised Learning**: It is the ML task of inferring a function to describe hidden structure from unlabeled data. The algorithm is left to their own devices to discover and present what must be the structure in the data such as groupings or rules that describe portions of the data (Hinton et al., 1999); and
3. **Reinforcement Learning**: It is a type of ML algorithm that allows an agent to decide the best next action on its current state, by learning behaviours. It is a goal-oriented learning based on interaction with environment. It is not about discovering which action to take, but instead must discover which action will yield the maximum reward. (Auer et al. 2010) and (Sutton et al., 1998).

More specifically dealing with images, and whatever is the type of ML selected, it involves three steps as described below:

- *Image Recognition*

Human brain makes vision an easy task. It doesn't take any effort for humans to distinguish a lion from a jaguar, read a sign or recognize a human's known face. But these are actually hard problems to solve with a computer: they only can make it because our brains are incredibly good at understanding images. In the last few years, the field of ML has made tremendous progress on addressing these difficult issues. In particular, it has been found that a model called deep convolutional neural network (CNN) can achieve reasonable performance on hard visual recognition tasks, matching or even exceeding human performance in some domains (Abadi et al. 2015).

- *Model Building*

The Clarifai API (Sood, 2017) offers image and video recognition as a service, using artificial intelligence to recognize the visual content. API is built around the idea that input parameters are sent (microscopic images of concrete, for example) to the service and it returns predictions based on a model built specifically for a given purpose. A model is a processing block that converts inputs parameters (e.g. images) to predictions (e.g. concepts, bounding boxes, etc.). When an input parameter is implemented in the model, it will return the predictions that the model captures on the input parameter provided.

- *Training, Testing and Evaluating the Model*

Training process include the creation and association of concepts for each type of implemented images, with their specific classifications, building a model. Testing and Evaluating processes estimate how well the built model has been trained, calculating its accuracy results.
Currently, there are a number of available ML tools which are able to process and recognize any information such as images once they are well-trained (Matsumoto 2017, Krizhevsky et al. 2012). These tools might be used for specific purposes in civil engineering, for instance, to detect AAR-induced expansion and damage. Normally, the best ML approaches use mathematical models such as convolutional neural networks (CNN) which are powerful techniques for recognizing images (Azam & Gavrilova 2017, Pereira Junior & Inkpen 2017, Krizhevsky et al. 2012). Their ability can be set by varying the number, depth, and amplitude of images. However, very few trials with the use of CNN were made to detect distress in concrete so far.

3 SCOPE OF WORK

As previously discussed, there is a lack of fast, economical, and reliable tools to assess damage in concrete, and ML techniques seem to be a promising solution. This project aims to develop an automated tool to assess the diagnosis and prognosis of AAR-affected concrete through the use of ML systems. First, with the use of a stereomicroscope, a number of pictures were taken of different AAR crack types, presenting different features and development stages as per the DRI. Then, ML systems through the use of CNN algorithms were implemented to detect the type and progress of damage in an automated fashion. Accuracy in the detection is assessed and if needed, a greater number and more detailed depth & amplitude of images are analysed so that a target accuracy is reached. Figure 2 illustrates the process of ML to detect AAR damage proposed in this work.

4 METHODOLOGY

The process of sample fabrication, ML training and data gathering used in this research contains 8 steps that are described hereafter.

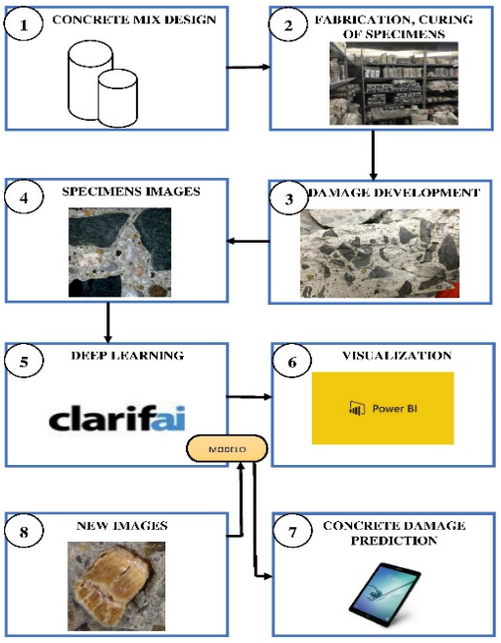

Figure 2: ML system.

4.1 *Concrete Mix Design*

Twenty four concrete cylinders (i.e. 100mm by 200 mm in size) containing two different reactive aggregates (i.e. coarse - NM and fine – Tx), presenting distinct reactive levels) and three levels of compressive strengths (i.e. 25, 35 and 45 MPa) were cast. Non-reactive aggregates (D and UL), respectively coarse aggregates and sand were also added to Tx and NM mixes. The concrete mixtures were mix-designed to contain the same amount of cement paste and aggregates in volume (i.e. from one mix to another). All concrete mixes were made with the same conventional (CSA Type GU, ASTM type I) high alkali (0.88 % Na2Oeq) Portland cement. Reagent grade NaOH was used to raise the total alkali content of the mixtures to 1.25% Na2Oeq, by cement mass, for accelerating the expansion process due to AAR. Table 1 presents the concrete mixtures used in this research.

Table 1: Concrete mixtures used in this research.

Mixtures	Materials	25MPa	35MPa	45MPa
	Cement	314	370	424
	Water	192	174	157
Tx + D	Sand	790	790	790
	Coarse Ag.	1029	1029	1029
NM+UL	Sand	714	714	714
	Coarse Ag.	1073	1073	1073

4.2 *Fabrication, curing, and testing of specimens*

After casting, the specimens were placed for 48h in the moist curing room. Small holes, 5 mm in diameter by 15 mm long, were then drilled in both ends of each of the test cylinders and stainless steel gauge studs were glued in place, with fast-setting cement slurry, for longitudinal expansion measurements. Following completion of the first 48h at 23°C, the "0" length reading was performed and the specimens were placed in a sealed plastic (22 liters) containers lined with a damp cloth (4 cylinders per bucket). All buckets were then stored at 38°C and 100% R.H., and all of the test cylinders were monitored regularly for length variations. Periodic axial measurements were made as per ASTM C 1293 (ASTM C1293 2008). The specimens were then monitored until they reached the expansion levels selected for the project (i.e. 0.05± 0.01%, 0.12± 0.01%, 0.20± 0.01% and 0.30± 0.01%). Finally, the specimens were first cut in two along their axis, and then polished for microscopic analyses.

A polishing device, which uses diamond-impregnated rubber disks (nº. 50 (coarse), 100, 400, 800, 1500 to 3000 (very fine), was used for obtaining surfaces of appropriate quality for DRI assessment (Sanchez et al 2015, Sanchez et al 2017).

4.3 *Damage Rating Index and Image analysis*

A semi-quantitative petrographic analysis, using the DRI, was performed on specimens from each concrete mixture at the various expansion levels studied and presented in Section 4.2, according to the method described by Villeneuve & Fournier (2012).

Actually, the crack counting within the aggregate particles were performed on particles down to 1 mm in size, so that the distress coming from reactive sands might be well assessed (Sanchez et al. 2015, Sanchez et al, 2016, Sanchez et al. 2017).

Once the DRI was performed, pictures using a high-quality camera attached to the stereomicroscope were taken from some of the "squares" (i.e. 1cm^2) used in the DRI analysis, for a total of 100 cm^2

Thus, a total of ≈ 8 pictures were taken per specimen (i.e. 200 total), which enabled the development of a large database of images with two different types of mechanisms (i.e. AAR coming from the reactive coarse aggregates and sand), three concrete strengths and several different crack features as by Sanchez et al. 2015 and highlighted in Table 2. Figure 3 illustrates some of the different features captured by the camera.

Table 2: Damage features accounted in the DRI analysis and deep learning process.

Petrographic features	Abbreviation
Cracks in coarse aggregate	CCA
Opened cracks in coarse aggregates	OCA
Crack with reaction product in coarse aggregate	OCAG
Coarse aggregate debonded	CAD
Disaggregate/corroded aggregate particle	DAP
Cracks in cement paste	CCP
Cracks with reaction product in cement paste	CCPG

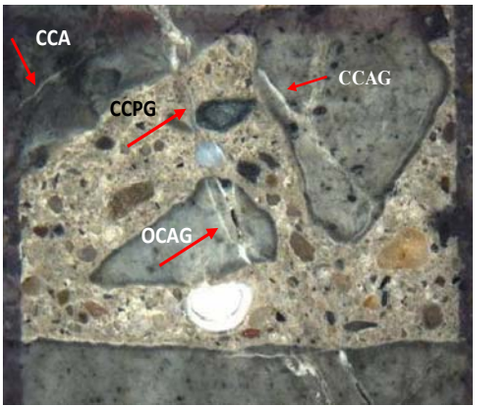

Figure 3: Petrographic features captured by the camera in the DRI analysis (Sanchez et al. 2015)

4.4 *Deep Convolutional Neural Network*

The implementation of the machine learning process for the detection of AAR-induced expansion and damage was performed through the use of CNN models. A Convolutional Neural Network (CNN) is a class of supervised learning with deep, feed-forward artificial neural networks that has been successfully applied to analyzing visual imagery (Krizhevsky et al. 2012, Ciresan et al. 2011).

Basically, the first need is to teach the computer how each petrographic feature looks like before it being able to recognize a new object. In a supervised learning, the more a feature the computer sees, the better it gets in recognizing that feature. This task can be carried by labeling the images, and the computer will start recognizing patterns present in a specific damage taken from distressed concrete that are absent from other ones and will start building its own cognition.

These models are able to identify the crack's pattern and quantity in the different concrete mixtures at distinct expansion levels. Several existing models were tested and the best CNN was selected for the project. Furthermore, trials to create a brand new model optimized for the current specific purpose were also performed.

Figure 4 illustrates the basic blocks of the CNN process, consisting of the input layer (convolution), hidden-layers (pooling layers and fully connected layers) and the output layer (classification ranked by scores). To do so, the image is broken up into a number of tiles (convolution). Now we have to apply a technique to reduce the dimensions of an image (by taking the maximum pixel value of a grid) and to make the model more generic, predicting what each tile is individually. Finally, the computer tries to predict which damage feature is in the image based on the prediction of all the tiles. This allows the computer to parallelize the operations and detect the object regardless of where it is located in the image.

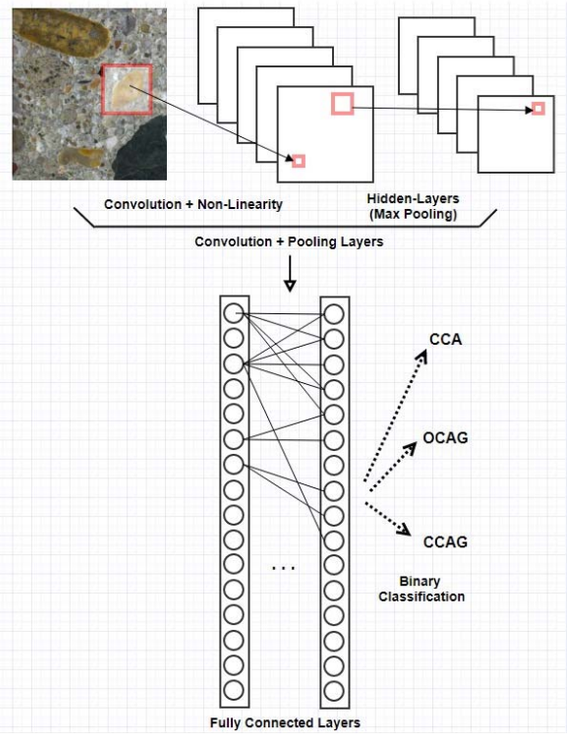

Figure 4: Convolutional Neural Network for Image Classification.

4.5 *Visualization*

In the visualization step, a Business Intelligence system was developed, preparing data for analysis, developing and running queries against that data gathered, and creating reports, dashboards and data visualization to make the analytical results available for the evaluation of our ML system.

4.6 *New Images*

New separated images should also be prepared in a similar manner as described in Section 4.3 to be directly used for prediction purposes by the system for validation.

4.7 *Damage Prediction*

The last step is the damage prediction itself. It consists of using the system for real situations. Thus, users provide new "microscopy concrete images" as input parameters of the model, which will be tested and evaluated by the system, using the deep learning techniques as per Section 4.4.

5 PRELIMINARY RESULTS

Trying to fit the model to the training data and hope it would accurately work for the real data it has never seen before is not appropriate. So, some kind of assurance that the model has got most of the patterns from the data correct, and its not picking up too much on the noise (Gupta P., 2017).

In order to estimate how accurately a machine learning model will perform in practice, it is usually executed a cross-validation step. It has two sub-processes: *Training* and *Testing*. The *Training* process is used for training a model. Then, the trained model is applied in the *Testing* process.

The performance of the model is measured during the *Testing* phase. It was implemented a 5-split cross-validation process to train and forecast damage in concrete due to AAR, detailed as follows:

1. Set aside a random 20% subset of the training data and designate as a test set (40 from 200 images);
2. Train a new model with the remaining 80% of the training data (160 from 200 images);
3. Pass the test set data through this new model to make predictions;
4. Compare the predictions against the test sets actual labels; and
5. Repeat steps 1) through 4) across 5-splits to average out the evaluation results.

The average results obtained in the evaluation process are presented in Table 3. The concept, its accuracy score, the number of prediction attempts, and the total labeled concepts associated with 200 pre-trained images are illustrated in Table 3.

Table 3: Concrete Pathology Model Evaluation

Concept	***Accuracy***	***Predictions***	***Pre-Trained***
DP	1.000	0	6
CCA	0.742	36	174
CCP	0.671	16	73
CCPG	0.651	6	26
OCA	0.590	26	125
OCAG	0.496	13	36
None	0.533	1	9
Total	***Avg:0,664***	***46***	***449***

Analyzing the data above, one may verify that, for example, the cracks in the cement paste (CCP) achieved around 67% of accuracy in the evaluation the process of predicting this type of damage with the current deep learning model. Moreover, in this case, 73 pre-trained images were used with this concept, and 16 predictions of CCP over 40 images were performed (first step of the 5-split cross-validation process), each one having zero or multiple concepts. It is worth noting that a total of 7 concepts (DP, CCA, CCP, CCPG, OCA, OCAG and None), and 449 concept labels (each image can be associated to zero, one or more concepts) are associated with 200 pictures in the current dataset.

Usually, to achieving satisfactory results in the evaluation process, it often requires thousands of images to be trained for an unknown model, such as the one proposed in this research. The more labeled images we have to train, the more accurate the predicted result tends to be. Despite that, Table 3 shows that preliminary and encouraging results with an average of 66.4% of accuracy on predicting the correct concepts associated to images were obtained using only 449 labeled concepts and 200 pictures.

6 DISCUSSION AND APPLICATION OF ML FOR ASSESSING DAMAGED STRUCTURES

6.1 *Robert-Bourassa/Charest Bridge*

Robert-Bourassa/Charest (RBC) overpass was a highway bridge structure (Quebec, Canada) that was built in 1966 using an alkali-silica reactive (ASR) limestone aggregate. The bridge was made of a bridge deck (BD) resting on reinforced concrete Y-shaped columns (C), themselves supported by massive foundations blocks (FB) (Figure 5) (Sanchez et al. 2016).Over the last decades, many signs of distress developed on the various elements of the structure. This included extensive steel corrosion and concrete delamination/spalling at the level of the deck; map cracking, scaling, disaggregation and pop-outs affecting the massive concrete foundations due to ASR and freeze-thaw (FT) cycles; and concrete spalling and steel corrosion on the columns and foundations exposed to salt-water spray from traffic on the Robert-Bourassa highway (Bérubé et al. 2005). Numerous laboratory tests methods, including the DRI, were performed on RBC cores extracted from its different structural members (FB vs C vs BD) presenting different environmental/exposure conditions (surface vs core; exposed vs non-exposed) and orientation (vertical vs transversal vs longitudinal), which highlighted the different damage

degrees found at different locations (Sanchez et al. 2014).

Figure 5: Robert-Bourassa/Charest overpass after nearly 50 years in service.

6.2 *Damage Rating Index Results*

Figure 6 presents the microscopic responses of the cores assessed through their DRI numbers. All of the samples contained closed cracks within the aggregate particles (CCA). CCA cracks are likely caused during aggregate production (e.g. crushing, sieving, etc.) and weathering, and may not be related to ASR progress. However, open cracks with and without gel within the aggregate particles (OCA and OCAG, respectively) are indeed ASR damage features. Likewise, cracks in the cement paste with and without gel (CCP and CCPG) are also caused by ASR. As seen in Figure 5, greater DRI numbers are found for the FB specimens, followed by BD and C cores. Furthermore, greater damage was obtained for exposed cores, compared to non-exposed ones for the FB samples. Likewise, surface specimens presented more damage than internal samples.

In the BD cores, damage varied according to the core's orientation. Vertical cores presented greater damage than the longitudinal and transverse specimens, which, unlike the mechanical analyses, showed similar results. Samples from the deck top showed lower damage than ones from the bottom. C samples also presented lower damage degrees than FB and BD cores, which may be linked to the amount of reinforcement present in those members. The results illustrated in Figure 6 showed that non-negligible differences of damage degrees are found in the different members of RBC, which confirms the need of quantitative damage tools (such as the DRI) for a better selection of rehabilitation procedures according to their respective current distress. However, although thorough, the above analyses were quite time-consuming and somewhat expensive due to the amount of hours of analysis spent by petrographers.

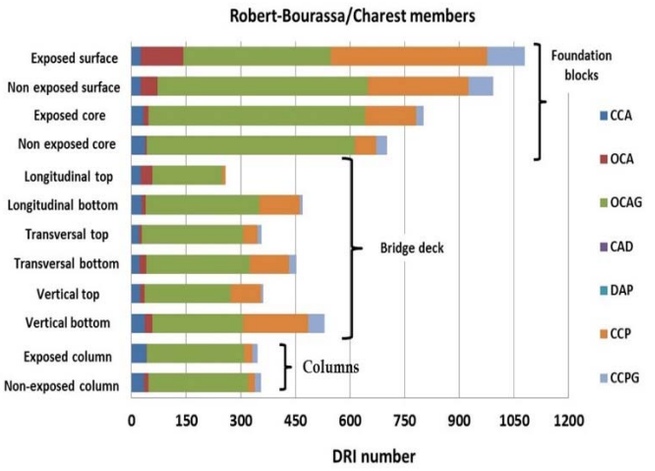

Figure 6: DRI numbers obtained on RBC cores extracted from distinct structural components, environmental and orientation conditions.

Otherwise, if those quantitative microscopic could be somehow automated through the use of reliable ML techniques, fast and low cost analyses might be accessible for the evaluation of critical infrastructure, at least for initial screening which would be extremely cost-beneficial.

7 CONCLUSIONS AND FUTURE WORK

Most of the aging infrastructure worldwide are currently under critical conditions, either approaching the end of their service-lives or presenting clear signs of distress due to numerous damage mechanisms (or even both!). In Canada and around the globe, AAR is one of the most harmful damage mechanisms and various concrete structures are currently suffering from this issue. Otherwise, in a globalized world as nowadays, time is one of the most important variables in engineering decision making and thus fast, low cost and reliable techniques for diagnosing the damage type and extent and prognosis of the potential of future distress is extremely desired. The scientific contribution of this project is to work on a very little-explored field in civil engineering which is the use of machine learning to automate damage evaluation in concrete towards the development of better procedures to detect and enhance the durability of affected aging structures.

In this work, concrete mixtures presenting two different types of reactive aggregate and three different compressive strengths were tested through DRI and ML tools. Preliminary results show an encouraging average of 66.4% of accuracy obtained using only 200 images. Future works will intend to extend this work using a larger number of images as well as testing the ML adopted protocol for assessing RBC overpass in its distinct structural components. Correlations with DRI results will be made (Figure 6) and the reliability of the new proposed technique will

be tested. Finally, a new CNN procedure is already being developed so that the precision of the evaluations might be raised to at least 80%.

Shear Capacity of an Existing RC Bridge Deck Slab: FE Analysis Using Continuum Elements

Jiangpeng Shu

Postdoctoral fellow, Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: For reinforced concrete (RC) slabs without shear reinforcement, shear and punching can be the governing failure mode at the ultimate limit state if subjected to large concentrated loads. Shear and punching of RC slabs without shear reinforcement has been a challenging problem in assessment based on current standards. To examine a previously developed enhanced analysis approach, this study was conducted by applying a "Multi-level Assessment Strategy" to a 55-year old RC bridge deck slab subjected to concentrated loads near the main girder in a field failure test. The differences between analysis methods at different levels of assessment was discussed regarding one-way shear and punching shear behavior of the slab. The influences of parameters such as boundary conditions, location of concentrated loads and shear force distribution were investigated.

1 INTRODUCTION

Existing infrastructure represents a substantial part of societal assets and existing bridges represent a huge capital that needs to be well administrated (SB-LRA, 2007). Bridge deck slabs are among the most exposed bridge parts and are often critical to damage (SB-ICA, 2007). One-way shear and punching shear may be the governing failure mode in reinforced concrete slabs without shear reinforcement when subjected to large concentrated loads. Currently, building codes of practice, such as ACI (ACI, 2014) and Eurocode 2 (CEN, 2004), provide several approaches to check the two-way punching strength of flat concrete slabs. However, previous studies have shown that existing models provided by design provisions are too conservative and that enhanced assessment methods can reveal higher load-carrying capacity (SB-LRA, 2007). Consequently, it is important to evaluate current code methods and provide recommendations for improvement.

In order to provide a systematic approach for the assessment of RC slabs, Plos et al. (2016) has developed a "Multi-level Assessment Strategy" which provides recommendations for the assessment of RC slabs using analytical and finite element (FE) models; see Figure 1. The strategy is based on the principle of successively improved evaluation in structural assessment. Accordingly, the assessment of the load-carrying capacity with associated structural response can be conducted through the following levels and methods:

- (I) Simplified analysis
- (II) 3D linear FE analysis
- (III) 3D non-linear shell FE analysis
- (IV) 3D non-linear FE analysis with continuum elements and fully bonded reinforcement
- (V) 3D non-linear FE analysis with continuum elements including the slip between reinforcement and concrete.

Case studies have shown that more advanced methods based on non-linear FE analyses normally yield an improved understanding of the structural response and are capable of demonstrating higher, yet conservative, predictions of load-carrying capacity (Plos et al., 2016; SB-4.5, 2007).

The aim of this study was to examine the highest level of Multi-level Assessment Strategy (Plos et al., 2016) and modelling methods developed by Shu et al. (2015; 2016) and to investigate the response of a real structure in engineering practice. A full-scale field test has been carried out to a 55-year RC bridge (Bagge, 2014; Bagge et al., 2014; 2015); the deck slab was subjected to concentrated load near one of the main girders which led to a shear type failure of the slab. The highest level of Multi-level Assessment Strategy was then used to evaluate the capacity and response of the slab with respect to one-way shear and punching shear capacity. Furthermore, the difference of failure modes between pure one-way shear and punching shear was studied and the influencing factors, e.g. boundary conditions, arching action and load distribution, in the model were investigated. The choice of effective width to calculate the one-way shear resistance was discussed based on the shear force distribution.

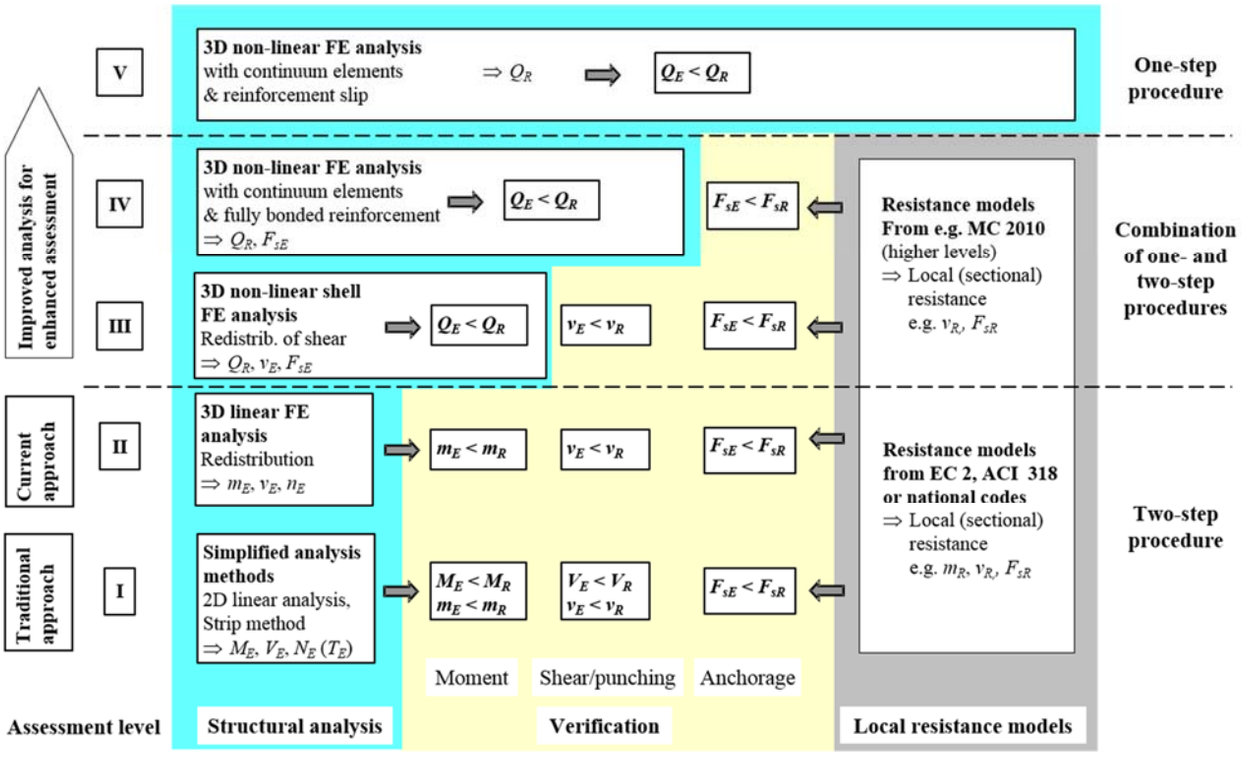

Figure 1. Multi-level Assessment Strategy of reinforced concrete bridge deck slabs; Plos et al. (2016).

2 DESTRUCTIVE TEST

The Kiruna Bridge was a continuous five-span structure with a total length of 121.5 m. The superstructure, 15.6 m wide, consisted of three longitudinal prestressed girders connected with a reinforced concrete slab at the top which had integrated curbs at each side. It was inclined longitudinally and transversally, and was also partly curved longitudinally. Due to the length of the bridge, the superstructure was segmentally cast-in-place and prestressed using a BBRV post-tensioning system. At the abutments, the superstructure was supported on bearings while reinforced concrete columns, with a joint at the base formed the intermediate supports.

Figure 2. Photo of the bridge

At an age of 55 years in 2014, the bridge was subjected to an extensive in-situ field test program; see Figure 5. The test load setup and dimension of the loading plate is determined according to Load Model 2 in EC 1 (CEN, 2003). A single axle load applied on specific tire contact areas which covers the dynamic effects of the normal traffic on short structural members. The load was applied to the bridge, using a longitudinally positioned simply supported load distribution beam and a forced-controlled hydraulic jack supported by wire thread through a drilled hole

in the deck slab and anchorage in the bedrock. At the supports of the load distribution beam, 2.0 m apart, the load was transferred to the upper surface of the bridge deck slab (paving removed) through under-grouted steel plates (350 × 600 mm^2).

In order to monitor the structural behavior of the bridge during the test, applied force and deflections were measured. The force was derived from the oil pressure in the hydraulic jack and draw-wire sensors were instrumented to the bridge to measure deflections relative to the ground. Deflections were measured at the bottom surface of the deck slab centrically underneath the load application and at the corresponding longitudinal position at the base of the adjacent girder. Moreover, the midspan deflection was measured for each girder.

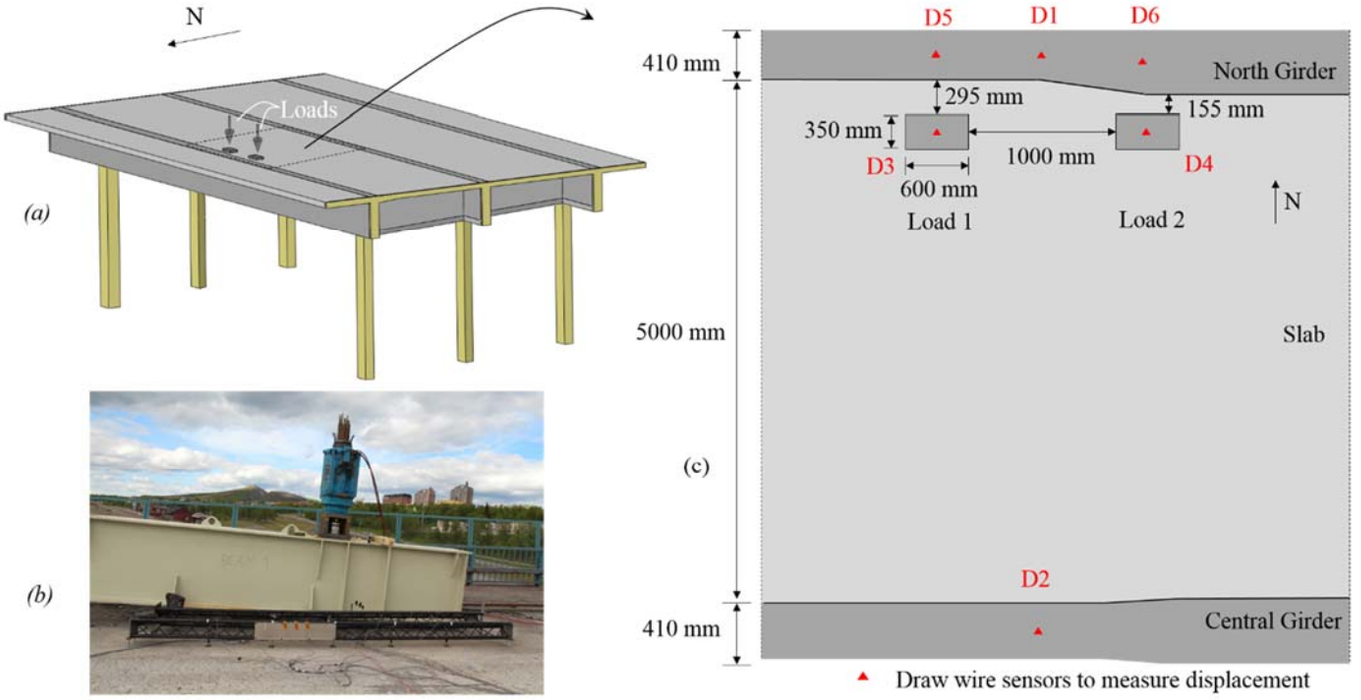

Figure 3. (*a*) Isometric view of layout of loading plates, (*b*) photo of field test, loading beam and hydraulic jack, and (*c*) layout of loading plates and measurement points for displacement.

In the test, considerable deflection of the girders occurred and, at a load of $Q_{u.exp}$ = 3.32 MN (1.66 MN for each loading plate), the slab suddenly, without any warning, failed with a combined failure mode of one-way shear and punching shear. The failure was initiated between one of the loading plates and the girder, and propagated on either side of the plate, thus, producing a U-shaped failure surface.

3 FE ANALYSIS

3.1 FE model

In the FE model, the tested span including columns was modelled by a detailed 4-node brick element model and the remaining part of the bridge was modelled using 2-node beam elements as displayed in Figure 4(*a*). At least 8 elements were used in the thickness direction to sufficiently reflect the flexural behaviour (Shu et al., 2015). For the part of the bridge modelled with beam elements. The part modelled with brick elements was connected to the part modelled with beam elements assuming that the connected cross-section, perpendicular to the beam main axis, remained plane and un-deformed, with the same rotations and deflections as the connected beam element. The reinforcement was included in the model as fully bonded embedded reinforcement bars, in accordance with the layout in the original drawings.

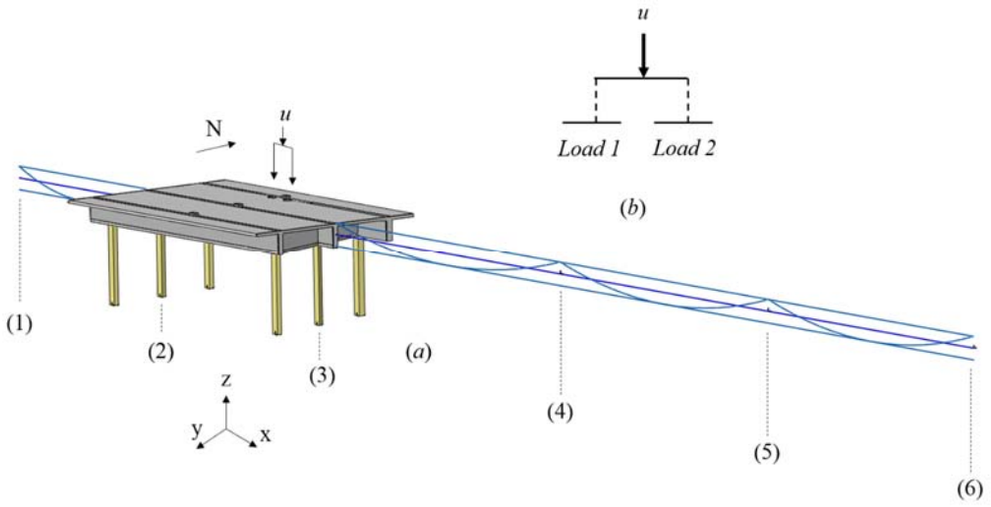

Figure 4. FE analyses: (a) non-linear FE model of the tested bridge, showing supports 1-6 (b) Load distribution system for displacement controlled loading.

The bridge was simply supported at the end abutments and at the bottom of the columns at support 2 and 3. Supports 1-5 were constrained for displacement in vertical, transverse and longitudinal directions of the bridge but support 6 was allowed displacement in longitudinal direction. The bridge was preloaded with concentrated loads above the girders before the concentrated load was applied to the slab. The analysis was carried out using a Quasi-Newton iteration method based on force and energy convergence criteria, with a tolerance of 0.01.

3.2 Material model

In all calculations, material parameters were obtained from the in-situ tests or from calculation see Table 1. For the material model, concrete was modelled using a fracture energy based total strain crack model; see Figure 5.

For the material model used in the non-linear FE analysis at levels III and IV, concrete was modelled using a constitutive model based on non-linear fracture mechanics using a smeared rotating crack model based on total strain (TNO, 2015). In this approach, the crack width w is related to the crack strain ε_{cr} perpendicular to the crack via a characteristic length called crack band width h_b. The advantage of this method is that the formulation remains local and the algorithmic structure of the FE code would require only minor adjustments, limited to the part of the code responsible for evaluations of the stress (and stiffness) corresponding to a given strain increment (Jirásek, 2012). The crack band width was assumed to be equal to the mean crack distance since the reinforcement was modelled as fully bonded (Shu et al., 2015). A tension softening curve according to Hordijk (1991) was used; see Figure 5 (*a*). The behavior of concrete in compression was described by an isotropic damage constitutive law and the stress-strain relationship used were based on Thorenfeldt et al. (1987); see Figure 5 (*b*).

Table 1. Input material parameters of concrete

Items	Calculation method	Values
Poisson's ratio	MC2010	$v = 0.15$
Tensile strength	MC2010 concerning reduction	$f_{ctm} = 2.0$ MPa
Fracture energy	MC2010	$G_f = 140$ Nm/m^2
Mean crack distance	EC2	$h_b = 219$ mm

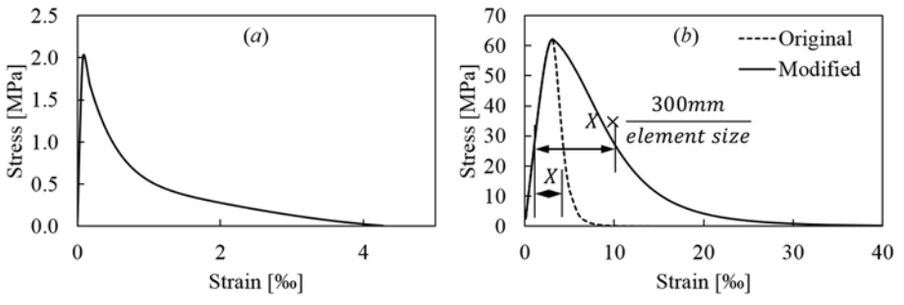

Figure 5. Materiel model of concrete: (a) response in tension; (b) response in compression

4 RESULTS AND DISCUSSION

4.1 Load-carrying capacity and failure modes

Load-deflection relationship from the continuum non-linear FE analysis are compared to corresponding relationship from experiment in Figure 6. The deflections were taken from the model at the same position as in the experiment. It shows the comparison of 6 measurement points on girders and slab. A good agreement between continuum NLFEA and experiment was observed for both stiffness and final capacity.

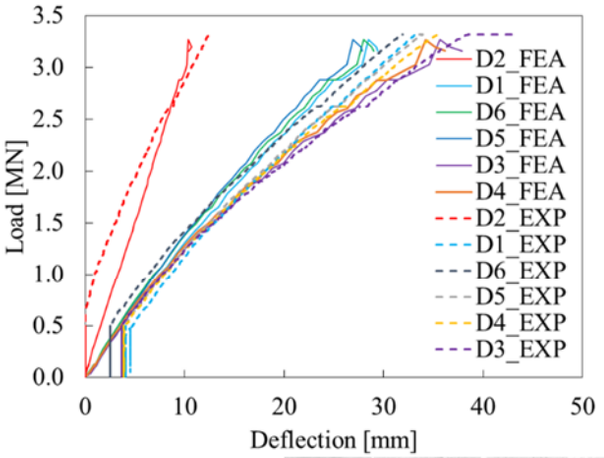

Figure 6. Load-deflection relationship for level IV analysis, compared to experimental results.

The crack pattern at the bottom and top of the bridge deck slab after experiment is displayed in Figure 7 (*a*) and (*b*) respectively. This indicates that it was a combination of one-way shear and punching shear failure. Figure 7 (*c*) and (*d*) illustrates the strain based crack pattern at the bottom of the slab and an isometric view with a cross section of the slab from the continuum FE analysis one loading increment before failure happened. In the FE analysis, at approximately 60% of failure load, a large shear crack was developed between the loading plates and the girder. Just before the punching failure occurred, another shear crack developed on the other side of the loading plates and the failure occurred. At failure, the cracking in the FE analysis corresponded closer to a one-way shear failure than to a punching failure. In the experiment, shear failure occurred only adjacent to load 1 and no major shear crack was registered close to load 2. However, in the non-linear FE analysis, the failure crack propagated from load 1 to load 2, even though it was initiated adjacent to load 1.

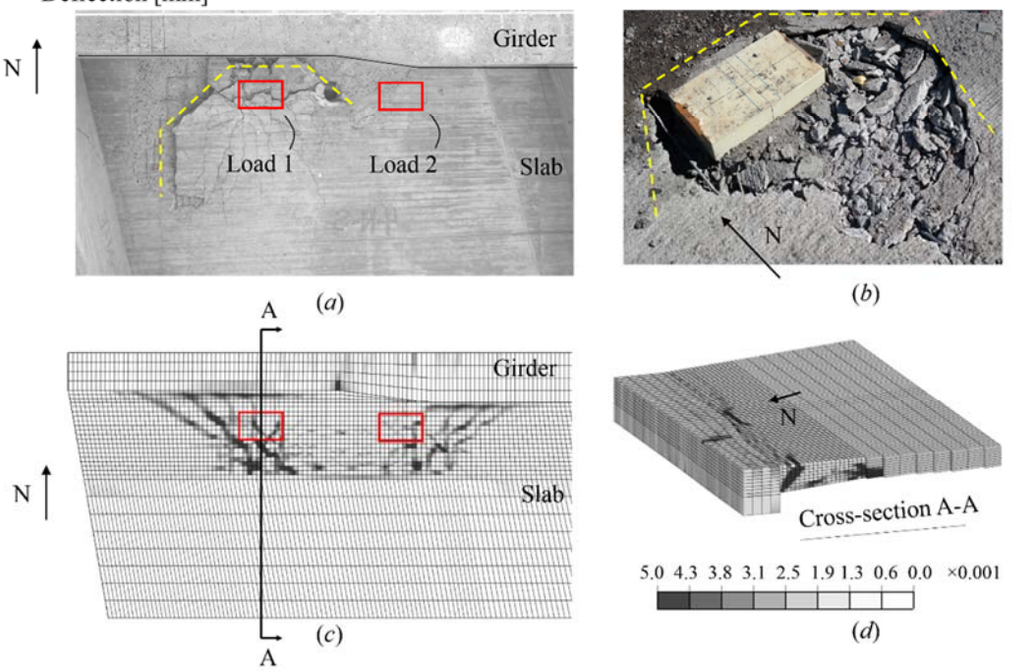

Figure 7. Photo of crack pattern at the final load level in the experiment (*a*) at the bottom of slab in experiment and (*b*) crack pattern near load 1 at the top of slab in experiment; Strain based crack pattern from continuum non-linear FE analysis: (*c*) at the bottom of slab and (*d*) at the isometric view of cross-section.

4.2 The influence of arching actions

The arching action is important and needs to be taken into account when assessing the load carrying capacity with respect to shear, when loads are acting close to supports. The internal compression strut will become steeper the closer to the support the load is acting and, as a consequence, the shear capacity will increase. The arching action is accounted for in EC2 (CEN, 2004) and MC2010 (fib, 2013). In addition, Natario et al. (2014) has shown that the load action of shear force can be even further reduced, and suggested that the reduction factor should be modified

to $\beta = a_v/2.75d \leq 1$. A recent research conducted by Rombach and Henze (2017) even suggested $\beta = a_v/3d$. However, compared to arching action of beams (Kani, 1966; Muttoni & Ruiz, 2008; Campana et al., 2013), this increase in capacity is not as remarkable for slabs because the direct load transfer is counteracted by a decrease in effective width when the load acts closer to the support of a slab (Lantsoght et al., 2014)

In the bridge test, the distance from the edge of the loads to the edge of the girder were only 1.09d and 0.6d for load plate 1 and load plate 2, respectively. To study the influence of arching action, the loads were gradually moved further away (100 mm per step) from the girder in the level IV model (see Figure 8(*a*) and Table 2. The load on position 1 was the same as in the field test. The nominal shear strength (excluding influence of b_w, d and f_{cm}) were calculated assuming a pure one-way shear failure and compared to laboratory test results obtained by Natario et al. (2014) and Lantsoght et al. (2014); see Figure 8 (*b*). From the analysis results, it was observed that the shear capacity decreased when loads were moved further away from the support. When the loading plates were placed in position 4, the failure mode even changed from shear to bending failure. The results are similar to findings by the other researchers (Lantsoght et al., 2014; Natário et al., 2014), but the decrease in capacity was smaller than expected. There are two causes that could explain this difference. Firstly, the tested slabs of Natario et al. (2014) and Lantsoght et al. (2014) had almost purely one-way shear action, while the slab of the tested bridge with its long-stretched supports on the girder activated a three dimensional load-carrying mechanism. Secondly, the tested slab was loaded with two loads but the failure occurred adjacent to load 1 only. However, the cracking around load 2 influenced the failure at load 1, which was also reflected in the shear force distribution, discussed in the next section.

Table 2. Variation of load positions, shear span ratios and load-carrying capacity from the analysis of the tested bridge

Load positions	loading plate 1			loading plate 2			Capacity [MN]
	d_1 [mm]	a_{v1} [mm]	a_{v1}/d_1	d_2 [mm]	a_{v2} [mm]	a_{v2}/d_2	
1	270	295	1.09	259	155	0.60	3.28
2	262	395	1.51	259*	255	0.98	2.72
3	253	495	1.96	253	355	1.40	2.34
4	244	595	2.44	244	455	1.86	2.00

* The d_1 and d_2 were takes at critical section using 45 degree shear crack inclination. Load plate 2 is positioned closer than d_2 from the girder, so the critical section is assumed to be at the edge of the girder.

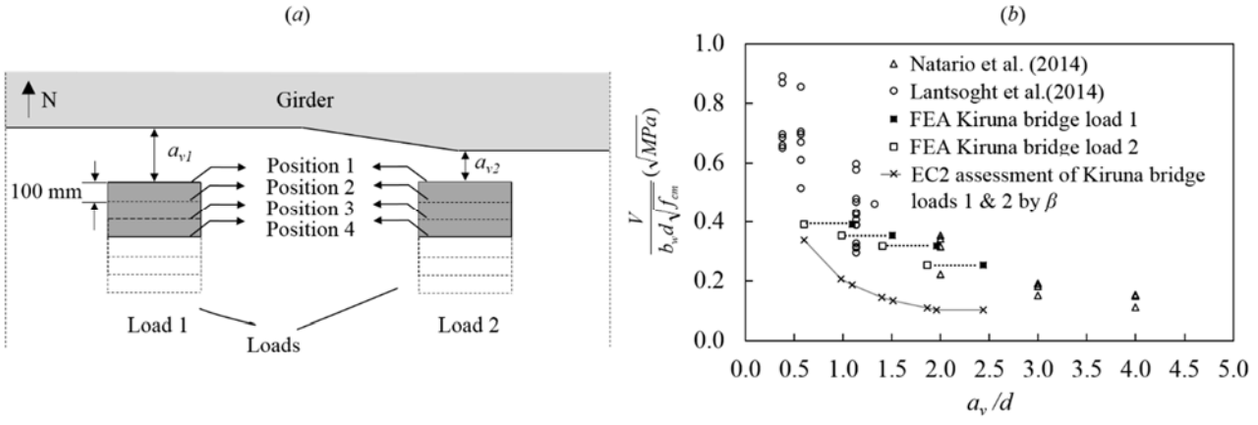

Figure 8. (a) Variation of load positions in the analysis of the tested bridge; grey color indicates original position in field test (b) nominal shear capacity of the slab subjected to loads at different positons, with comparison to literature (Lantsoght et al., 2014; Natário et al., 2014).

In Figure 9, the shear force per unit length along a line in the longitudinal direction of the bridge close to the girder is presented for different load levels. A clear shear force redistribution was observed for the shear force near loading plate 1: the shear force close to loading plate increased fast as the applied load increased at low load levels ($Q/Q_u \leq 0.8$), but stopped to increase at higher load levels ($Q/Q_u > 0.8$). Instead, the shear force in the adjacent region increased faster. Similar observation was also presented for the reaction force along a slab support by Natario et al.(Natário et al., 2014).

According to French practice (Chauvel et al., 2007), the effective width for shear force distribution should be limited to the area within 45 degree angles from the edges of the loaded area. The shear force within this region (grey shadow) was observed to be much higher than the adjacent region.

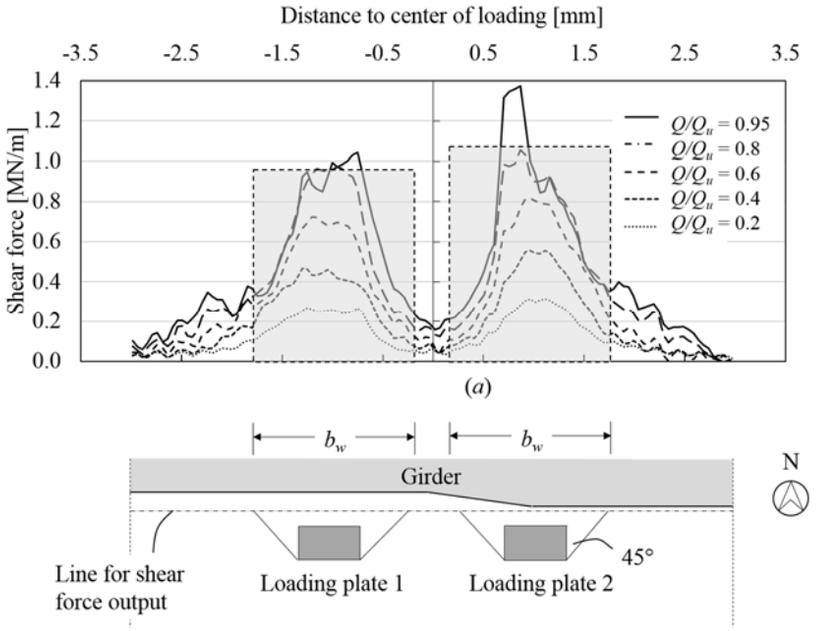

Figure 9. Unitary shear force across a line parallel to the girder, from FE analysis with continuum elements.

5 CONCLUSIONS

The tested RC bridge deck slab failed in a combination of one-way shear and punching shear. This kind of shear type failure as well as structural response of the slab could be reflected using continuum nonlinear FE analyses with a model including the entire bridge with reasonable simplifications.

a. The extent of the FE model, as well as the assumption of boundary conditions for the tested slab has significant influence on the analysis results.
b. The location of applied load plays an important role. When the load was moved further away from the closest girder in the continuum FE analysis, the load-carrying capacity with respect to shear was decreased until the failure mode changed to bending failure.
c. In addition, the analysis of shear force distribution also shows that the method using a 45 degree distribution to define effective width is reasonable and the failure mode in

ACKNOWLEDGEMENT

Rehabilitation of timber bridge piles using a wrapping system

R. Borzou & W. Lokuge
School of Civil Engineering and Surveying, University of Southern Queensland, Springfield, QLD4300

ABSTRACT: The majority of the thousands of timber bridges around Australia are more than 50 years old and strengthening and rehabilitation of deteriorated timber bridges is a strong financial commitment. Therefore it is a timely concern to investigate the rehabilitation process involved. The maintenance cost of timber bridges are affected significantly by a number of deterioration mechanisms, which require a systematic approach for diagnosis and treatment. The techniques used to rehabilitate timber bridges vary depending on the deterioration mechanism and location. This research aims at investigating the techniques used in timber pile rehabilitation. The main deterioration mechanism studied in this research is the splitting. An experimental program was carried out to investigate the strength enhancement due to a FRP wrapping system combined with two types of filler material, Crane Rail Grout (CRG) and Underwater Cementitious Grout (UCG). Hardwood timber of grade F27 with 150 mm diameter and 300 mm high samples were used in the testing program. Three levels of damage were introduced to the total height, samples were wrapped with FRP system and tested for compression. Load and displacement curves were developed based on the experimental results.

1 INTRODUCTION

Current timber bridge stock in Australian roads are definitely having timber piles as its primary structural support. Road authorities are making every effort to maintain these aging bridges. Dismantling older timber bridges and replacing them with concrete or any other material may not be the best option for most of the timber bridges. Therefore, rehabilitation techniques are being researched, commercialized and implemented on bridges around Australia. Eccentric and concentric loads on timber piles were analysed experimentally and analytically in the past (Borello 2009; Borello et al. 2010).

Fibre composites such Fibre Reinforced Polymer (FRP) laminates with their inherent properties which offer great tensile strength benefits than those of steel, timber and concrete in vast varieties of environmental conditions. These conditions can range from tidal/splash waves, high moisture environments and fluctuating thermal conditions. The combination of FRP laminate with an infill annulus material offers deteriorated timber sections greater lateral confinement, resulting in larger axial load capacities. Not only does the FRP laminate offer high tensile strength, but also offers a protection from biological attack for submerged timber pile cases.

This research paper focuses on a repair method for decayed timber piles, for bridges, boardwalks and jetties using FRP jacketing technology. Due to durability, pumpability, workability and compressive strength requirements, Crane Rail Grout (CRG) and Underwater Cementitious Grout (UCG) were selected as the filler materials in this study. The combination of material offers an all-round (360 degree) confining pressure. This significantly increases the strength of the pile. Therefore, this repair method will be tested and validated throughout this paper.

Currently information about splitting due to thermal expansion is lacking and in dire need of research and testing. New piles can be cut and posted onto the old piles but this solution can often be costly. Therefore, a new technique currently on the market offer a helpful solution. Wrapping the deteriorated pile while still under axial load reduces time and cost of the project. This solution consists of a GFRP wrap spaced approximately 20 mm with corner bar spacers that are attached to the existing pile. The wrap is sealed with an underwater resin that will eliminate any moisture from entering the fill material and ultimately to the existing pile. Usually an underwater cementitious grout is used to fill the 20-mm annular space as its material properties are extremely high. After 7 days the fill material will reach approximately 90% of its maximum 28 days strength. After 7 days the compressive strength should be approximately 100 MPa. This is just one example of rehabilitation that can be seen dominat-

ing the market for its ease of use, strength benefits and cost effectiveness.

2 TIMBER PILE DETERIORATION

There are many ways that can initiate a timber bridge deterioration. Once started it will spread due to many other reasons as well.

2.1 *Main deterioration methods*

Weathering is the main cause of timber pile deterioration as moisture can inhibit the pile causing thermal expansion to occur. The result of this is cracking along the fibres, opening the timber for fungal decay to start breeding.The principal cause of weathering is the excessive exposure of moisture content. When wood is unprotected from external factors, moisture can be absorbed in both the cell walls and the cell cavities of the timber. Some researchers (Mohammadi et al. 2014) suggested that a moisture content greater than 20% decay will start taking place whereby Austroads guide to bridge technology (Austroads 2009) believes that decay will start taking place at 15% moisture content.

Austroads (2009) reported that decay is the rotting of timber because of fungal attacks. Timber piles are subjected to weathering conditions such as water and temperature. As a result, the nature of the pile is to shrink. This shrinkage results in large internal stresses. The outcome of this action causes splits to form in the timber pile. These splits are a pathway for fungal decay to take effect. The fungal decay will make its way to the centre of the untreated timber pile.

Termites is another means that a pile can deteriorate rapidly. Termites are generally found in the northern tropical belt of Australia (Austroads 2009). The Damage caused by termites is much more rapid growing than that of fungi ((Mohammadi et al. 2014). It is less common to see termite attack to occur in durable hardwoods without some sort of pre-existing fungal decay. This is due to the fact moisture is present which is excellent conditions for termite growth (Mainroads 2014). There are many marine borer species, and each species has a different habit and ability to attack timber piles in different coastal regions (Cookson 1986).

Timber piles that are submerged beneath the water surface can be inhabited by marine organisms. It has been noted that these organisms become more severe in subtropical waters than in colder waters (Bootle 1983).

Austroads (2009) defines a split as separation along the grain extending right through the member. Splitting is caused by thermal expansion, fluctuations of moisture content and overloading. Most splitting is due too wet and dry cycles. It can be noted that Austroads (2009) agree that moisture content and thermal expansion are the main causes for splitting or checking along the grain of the timber pile. Overloading is another contributing factor for the cracking or splitting of timber piles. Queensland timber bridge maintenance manual (MainRoads-Queensland 2004) stipulates that cracks may be aggravated by overloading vehicular collision. Overloading cause splitting to start from the bearing area and travels upwards to the timber girder. Once again, the splitting can be seen to run along the grain.

2.2 *Rehabilitation techniques*

From previous studies, it is evident that rehabilitation of timber piles around Australia is a necessity in maintaining the structural integrity of timber bridges. There is approximately 12,075 timber bridges that currently or in future need maintaining for the given defects outlined above. There are several timber pile rehabilitation methods available around Australia.

2.2.1 *Posting repair method*

This procedure meant the deteriorated affected pile was removed completely and replaced with a new surface treated pile to stop weathering or decaying issues. Epoxy grouting is used to join the new section to that of the old section. In some cases, the repair methodology required shoring to support the pile from becoming weak or unstable. This method of repair was tested under axial compression loading. The results were credible with maintaining ultimate strength and axial stiffness after the repair had taken place. These tests did not evaluate combined axial and lateral loads on the repair procedure.

2.2.2 *Splicing*

Splicing is a simple and cost-effective solution for the rehabilitation of deteriorated timber piles. This process entails cutting and posting a new section replacing the old deteriorated pile. The material used in splicing can either be timber or steel straps approximately 15 cm in length (Mohammadi et al. 2014). This section is connected by long metal screws. Lap splicing is extremely low cost, effective but will not last the test of time. This is a short-term fix with the intentions of implementing a better repair technique in the coming years. Austroads (2009) and Mohammadi et al (2014) agree that lap splicing should be avoided where possible. In addition, it is stated (Kim & Andrawes 2016) that this method will have catastrophic consequences if the pile is subjected to a bending moment. This was evident in a bridge collapse in Illinois, USA.

2.2.3 *Grout/ epoxy injection*

Another effective low cost and durable repair is grout or epoxy injection. This technique leaves a

proportion of the timber exposed. When using epoxy injection some sort of confinement needs to be incorporated (Emerson 2004). For example, using a FRP wrap in conjunction with an epoxy will suffice. According to railway and track structures, grout injection has the strength capabilities to increase the service life of the timber piles to approximately 15 – 20 years. Epoxy injection requires approximately 30 min to 5 hours drying time (Avent et al. 1978). Then the injection ports can be sanded smooth then painted for aesthetics purposes. This injection method can be used for both structural and semi structural components of timber bridges.

2.2.4 *Concrete jackets*

Concrete jackets are another method of rehabilitating a deteriorated timber piles. A steel cage is placed around effected area of the existing timber pile. Jackets can be formed using 25 – 50 mm (Mohammadi et al. 2014) thick coat shotcrete reinforced with steel caging. This method has its downfall as concrete is likely be subjected to external factors such as acids, alkalize or salt in ground water. This may cause drastic effects such as cracking and spalling (Mohammadi. et al. 2014). This will cause exposure of the steel cage resulting in corrosion and loss of cross sectional area. If cross sectional area is reduced then strength and durability will be reduced. Austroads (2009) also suggests concrete jacketing as a repair method but does not go into detail about how the repair should be carried out or implemented.

2.2.5 *FRP wrapping*

Fibre-Reinforced Polymer is another method of rehabilitating defected or decayed timber piles. Polymer resins plays as the matrix which helps bind fibre reinforcements together. Another advantage of using the FRP wrapping technique is that the resin used to bind the material can eliminate future deterioration. One matrix combination study conducted at the University of Manitoba used Glass Fibre-Reinforcement Polymers (GFRP) and grout shells to restore axial loads. This technique places a grout shell approximately 50 mm thick around the affected area. Then the GFRP is wrapped around the grout to create a seal. When tested the pile showed positive results restoring and in some cases increasing the compressive strength.

Cut and post is another technique (Caiza et al. 2012) where the rotten or deteriorated section is cut and reposted with a new timber section. A FRP wrap and grout shell completes the retrofit when the old timber section meets the new. Results shows that this technique will increase the compressive strength of the timber pile.

Recent technology such as FRP wrapping is becoming more and more frequent because of its strength improvements. Alongside this, FRP can be easily installed/fitted on site without and need for machinery. Therefore, this method seems to be the best method of rehabilitating timber piles.

Previous attempts and testing has been achieved in this field but more data is required to gain a defined method of procedure. Results vary in what percentage axial compression will increase when using the FRP wrapping method. Therefore, further testing is essential in accurately proving how FRP wrapping can increase the structural integrity to that of a normalized defected pile.

3 EXPERIMENTAL PROGRAM

The experimental program was designed to test short timber columns with FRP wrapping and a filler. Total number of samples tested in this project is 16. Testing of one control sample (no damage), 3 unwrapped samples with 3 damage levels, 3 samples strengthened using underground cementitious grout (duplicate) and 3 samples strengthened using crane rail grout (duplicate) comprised the experimental program.

3.1 *Materials*

The timber samples were sourced by University of Southern Queensland while the filler and FRP wrapping were provided by Quakewrap Australia. Material quantities used are summarized in Table 1.

Table 1. Material quantities

Material	Quantity
F27 timber (150 mm diameter)	4.8 m
Cementitious Grout	50 L
Crane rail grout	50 L
FRP laminate	7.5 m^2
Underwater Resin 220UR	2.2 L

3.1.1 *Timber*

Grade F27 cylindrical timber samples having approximate dimensions of 150 mm diameter and 300 mm length were used in this experimental program.

3.1.2 *Filler*

The two filler materials used were crane rail grout and underwater cementitious grout. Both filler materials will reach approximately 90% of its compressive strength after 7 days (Figure 1).

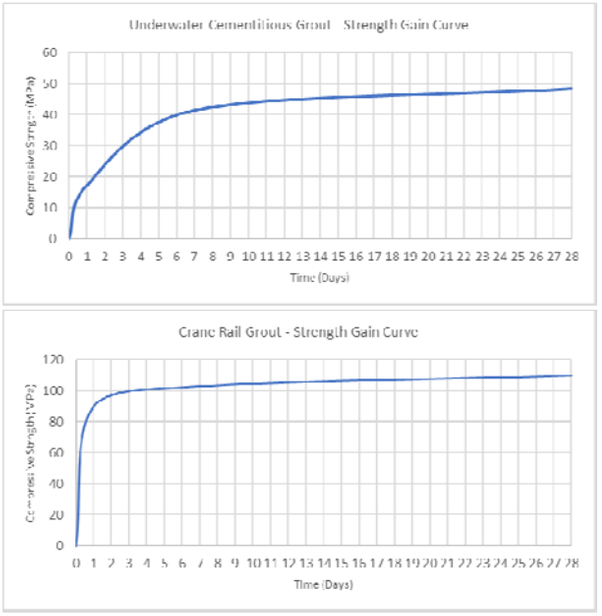

Figure 1. Strength development of filler

3.1.3 *FRP wrapping system*

PileMedic™ PLG60.60 is the FRP laminate used in the wrapping system. It has bidirectional fibres providing strength in both longitudinal and transverse directions. Properties of FRP are shown in Table 2.

Table 2. Material properties

Material	Max strength MPa
Underwater cementitious grout	48.3 (compression)
Crane rail grout	110 (compression)
Fibre Reinforced Polymer (FRP)	3.8 (tension)
Underwater Resin 220UR	418 (tension)

3.2 *Sample preparation*

All the samples were cut into approximately 300 mm lengths, weighed and the dimensions were recorded. Splitting was introduced into all the samples except the control sample.

3.2.1 *Damage levels*

Timber Bridge Detail Inspection Guidelines (Mainroads 2014) from Main Roads Western Australia states a severe vertical split would be greater than 5 mm in width and extending more than a meter in length. Some splits may be wider than 5 mm but have shorter length or vice versa. This was the only information found about the splitting measurements through inspection of deteriorated timber piles. The length of split gained from inspection extends greater than 1 m. Therefore, the split used in this research runs the entire length of the sample (≈300 mm). These two parameters will be maintained throughout experimental procedure. Split depth will be adopted at depths of full radius, 2/3 radius and 1/3 radius Figure 2.

Figure 2. Defect induced samples

Samples were then wrapped by the FRP laminate (Figure 3) and the filler was introduced into the annulus (Table 3)

Figure 3. FRP wrapping process

Table 3. Annulus details

Material	Annulus thickness mm
Underwater cementitious grout	20
Crane rail grout	20
Fibre Reinforced Polymer (FRP)	3
Underwater Resin 220UR	2

3.3 *Testing*

All the samples ready to be tested are shown in Figure 4 and they are to be tested using the SANS compression testing machine to find the maximum load/stress of the timber piles. Samples were attached with the strain gauges too to get the strain values in addition to the strains getting from the ma-

chine. A sample ready to be tested in the machine is shown in Figure 5.

Figure 4. Samples ready for testing

Figure 5. Sample in the compression-testing machine

Recorded data included the load and the displacement from the testing machine and the strain values from the data acquisition system 5000.

4 RESULTS AND DISCUSSION

Figure 6 shows the load deformation curves for the control sample, and the samples with defects. All these samples are unwrapped. The machine has the capacity of 2000 kN and it was calibrated to be used only for 1800 kN. Hence, the sample without any defect (control) could not reach its maximum capacity.

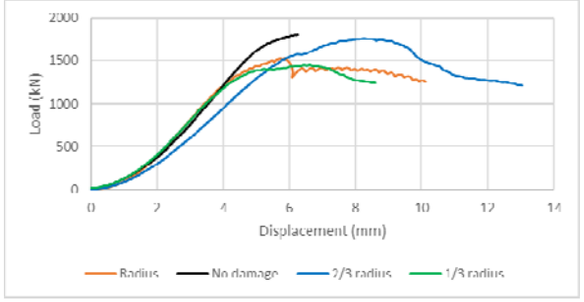

Figure 6. Load deformation for control samples

Figure 7 shows the load deformations curves for underwater cementitious grout (samples did not reach their capacity). However it is clear from Figures 6 and 7 that the deformation with FRP wrapping and cementitious filler is less than the deformation observed for unwrapped samples.

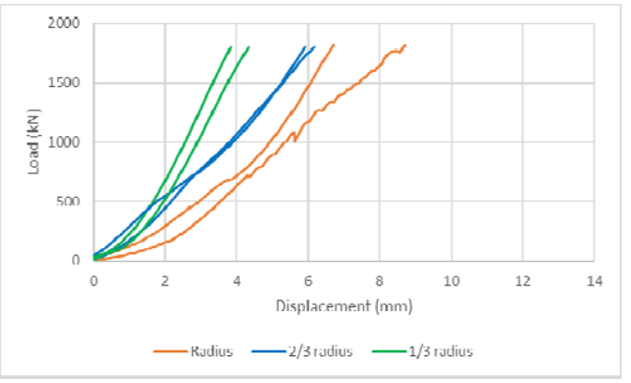

Figure 7. Load deformation curves for cementitious grout

Figure 8 shows the load deformation curves for the samples wrapped with FRP and crane rail grout as the filler. Comparing with Figure 7, it can be observed that samples with crane rail filler will reach a higher ultimate deformation than the samples with cementitious grout filler.

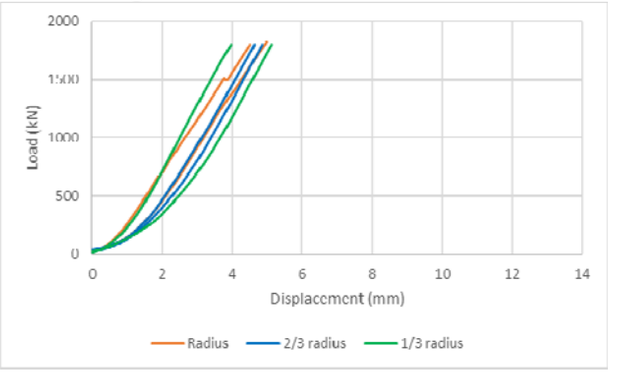

Figure 8. Load deformation curves for crane rail

5 CONCLUSIONS

Several conclusions can be drawn from this study. All defected control samples produced a failure and showed higher axial deformation. Due to the limitation of the capacity of the compression testing machine, no conclusions can be made regarding the failure load of the wrapped samples. However the observed curves show that the timber short columns can effectively be confined using the proposed FRP wrapping system and the 2 fillers (cementitious grout and crane rail grout). This is shown by the much higher expected failure load and the increased anticipated deformation from the observed curves. Further work is planned to test similar samples using a higher capacity-testing machine.

ACKNOWLEDGEMENT

The authors wish to acknowledge the support given by Mr Tony White and Mr Bede O'Rourke from Quakewrap Australia.

Investigating snipe depth in girders and corbels in timber bridges

ABSTRACT: There are over 300 timber bridges on Queensland state controlled roads which require constant maintenance as the timber components deteriorate over time. Inspections are done at three levels depending on the necessity. A significant number of the defects are due to poor practices such as excessive sniping of girders and corbels, which contribute to many bridges being rated in poor condition. This causes costs to increase due to increased inspection frequencies and rectification works. The aim of this research is to critically investigate the effect of sniping on the overall structural performance of individual bridge elements. Based on inspection reports for timber bridges, it is understood that sniping is a major issue and it contributes towards the deterioration of the whole member. Structural analysis has been carried out using finite element modelling in Ansys. Finite element modelling allows idealised timber components to be analysed under different loading conditions. This has been used to compare the effect of snipe depth on the structural integrity of timber components such as girders and corbels. As snipe depth increases, stress concentrations form at the snipe resulting in increased risk of splitting. Based on this modelling, some recommendations are made regarding the future assessment of component condition states.

1 INTRODUCTION

Timber has been a popular material for bridge construction in Queensland since colonial times. Many timber bridges remain in service on the Queensland state controlled road network, despite being superseded by prestressed concrete bridges as the preferred bridge type.

The legacy timber bridge network creates many challenges for the authorities in charge of maintenance. The aging timber bridges are being overstressed by increasing traffic loadings. The bridges were all built to obsolete design codes and traffic loadings, meaning they may not have sufficient capacity to handle modern heavy vehicles. While rehabilitation programs and replacement programs are in development, the sheer number of timber bridges on the road network means it will take many years to rehabilitate or replace them all. Therefore, there is a pressing need to maintain the existing network of timber bridges and extend their service lives until the resources become available for rehabilitation or replacement.

Timber bridges suffer from a range of degradation mechanisms which means intensive and costly inspection regimes must be implemented to guarantee continued operation. The scarcity of suitable hardwood timber components also adds upwards pressure to the maintenance costs. Although the uptake of alternative technologies such as glued laminated (Glu-Lam) and fibre reinforced polymer (FRP) girders is currently happening although the process is still extremely slow, at least in Australia. As a naturally occurring product, timber has a high degree of variability, which makes structural analysis difficult. Condition states are often calculated using empirically derived or arbitrary limits, and often depend on the judgement of bridge inspectors.

Due to all of these challenges faced by the timber bridge network, it is a priority to identify ways in which maintenance costs can be reduced while increasing service life. This research project will review the current state of maintenance and rehabilitation practices, in order to identify areas for improvement mainly for girders and corbels.

This research paper reports a numerical investigation on the behavior of timber bridge girders and corbels and attempts to link it with the condition states. Condition states drive the frequency and intensity of bridge inspections, and are used as a basis for justifying rehabilitation and replacement projects. If it can be shown that condition state ratings are too conservative, it may be possible to save considerable amounts of money by reducing the frequency of inspections, and delaying the need for costly replacements.

Timber bridges were relatively cheap and fast to construct, up to 50% of the cost of an equivalent concrete bridge (Crawford 2014), which allowed for the rapid expansion of Australia's nascent road and rail networks. However, timber bridges have a shorter design life (Nicholas 2014) than concrete, and require more in-service maintenance. It is important to recognize the contribution provided by timber bridges in the rapid social and economic expansion of Australia. These bridges were designed to have relatively short service lives, and were never intended to handle present day traffic volumes and loads. The short term benefits of timber such as low cost, availability and ease of construction were the dominant factors influencing early decision makers. However, the popularity of timber in the past has left behind a legacy of ongoing maintenance, rehabilitation and eventual replacement of Australia's timber bridge stock. Slow rates of replacement means there will be a requirement to keep timber bridges in service for decades to come. This requirement is a huge challenge to transportation authorities, who need to minimize the cost of inspecting and maintaining timber bridges, while planning future rehabilitation and replacement programs.

2 TIMBER BRIDGES IN QUEENSLAND

In 2005, there were approximately 500 timber bridges in services on state controlled roads in Queensland. The mean age of timber bridges is approximately 60 years and at current rates of replacement, some of these bridges will need to remain in service for the next 30 to 40 years. All timber truss-type bridges have been removed from service on the Queensland state controlled road network. The remaining timber bridges are mostly timber girder bridges (Roads 2005)(BAM 2005a). These bridges typically include timber piles, headstocks, corbels, girders and decks, although sometimes steel or concrete components are substituted.

3 SNIPING

The Timber Bridge Maintenance Manual (Queensland Department of Transport and Main Roads) acknowledges that sniping is used to allow easy insertion of replacement components. However, this technique can compromise structural integrity and fail to improve the condition state rating of the new component or the bridge as a whole.

Sniping causes stresses to concentrate at the end of the notch, which in turn increases the tendency for longitudinal cracking. Once a component has cracked, the effective sectional depth available to resist bending and shear stress is reduced. This can reduce the overall structural capacity of a component. The tensile strength of timber is lowest perpendicular to the grain. The stresses concentrated at the snipe can thus cause cracking if they result in tensile stress normal to the grain. An excessively deep snipe also reduces the cross sectional area available to resist bending and shear forces.

In order to reduce the concentration of stresses at the snipe, a recommended snipe angle of 1:4 is preferred; however it is a question whether this ratio is strictly adhered to in practice. While this may reduce the concentration of stresses at the snipe, it does not affect the overall reduction in shear capacity due to a decreased cross sectional area.

Excessive sniping of corbels is considered to be less severe as the notch is in compression rather than tension. This reduces the tendency for longitudinal cracking. There is a concern that an excessively deep cut may cause the corbel to lose bending strength and then fail in bending when loaded.

Table 1. Condition states based on snipe depth

Snipe depth		Condition state
Girder	Corbel	
0%	0%	1
<10%	<10%	2
10-15%	10-18%	3
16-30%	19-25%	4

The Bridge Inspection Manual outlines what condition state a component should be placed in based on the observed snipe depth (Table 1). There are other potential defects such as rot or splitting which may result in a component being rated in a worse condition. Generally, the most limiting defect and corresponding condition state are recorded. The presence of other less serious defects is usually recorded in the inspector notes.

The Timber Bridge Maintenance Manual recommends that any girder with a snipe depth greater than 30% of the original sectional depth should be replaced. Anything less than 15% is acceptable, and snipes between 16% and 30% of the depth should be strengthened with anti-splitter bolts (Table 2).

Table 2. Remedial actions for girders and corbels

	Snipe depth	Remedial action
Girder	<15%	None
	16-30%	Anti-splitting bolts
	>30%	Replace
Corbel	<25%	None
	>25%	Strengthen and replace

4 NUMERICAL INVESTIGATION

As identified before, the finite element method (FEM) analysis was performed by modelling girders and corbels to resemble sawn octagonal timber components, as used for Class A timber bridges on Queensland state controlled roads.

4.1 *Model limitations*

Finite element models can only ever represent a simplified version of reality. While there has been a lot of effort made to ensure the models reflect reality as close as possible, there are several limitations to the model:

- Components are idealised based on common lengths and profiles. Where a range of alternatives were available, the most limiting dimensions were chosen, as those were likely to result in the most adverse effects.
- The 3-dimensional Brick models cannot account for the effects from sloping grain or knots in the timber. These are properties that are unique to each individual timber component and their effects are difficult to predict. Timber is assumed to have grains aligned with the longitudinal axis, and free from knots or other defects.
- Timber is a highly variable material. Material elastic properties are derived from the Australian Standards, and may not represent the actual properties of a specific species or piece of timber. Material properties will be discussed further in this paper.
- The models assume that there are no other forms of degradation such as piping, surface checks or rot. It is theoretically possible to model these degradation mechanisms but it would require a much finer mesh, resulting in greatly increased computation time.
- The models do not account for repeated load effects or age-related loss of strength (which may be up to 50% of original strength).
- The angle of snipe is assumed to be 1:4 regardless of snipe depth, but in the real world, the angle of the cut is highly variable due to installation restrictions and workmanship standards.

4.2 *Material properties*

Grey ironbark (*Eucalyptus siderophloia)* is a common timber species used in the region due to its density, strength and resistance to termite. For the purpose of modelling timber bridge components, the properties of grey ironbark were selected from the AS1720.2 (2010). It is assumed the girders and the corbels are unseasoned because bridge timbers were considered to be in an unseasoned state in the past (Heckroodt 2002; Nicholas 2014). The minimum requirements for timber girders according to MRTS87 are a stress grade of F27 and a structural grade of 1. F22 timber is accepted, provided that no defects are visible in the middle third of the member. As corbels are only secondary structural members, the requirements are slightly relaxed. Corbels may be stress grade F22 and structural grade 2. F22 grade Grey Ironbark is modelled as this is the theoretically weaker timber, and should hence produce the most adverse result. F22 timber has a modulus of elasticity parallel to grain of 16000 MPa and modulus of rigidity of 1070 MPa. Orthotropic elastic properties for F22 timber was analysed (Forest Products Laboratory 2010) to develop the following ratios:

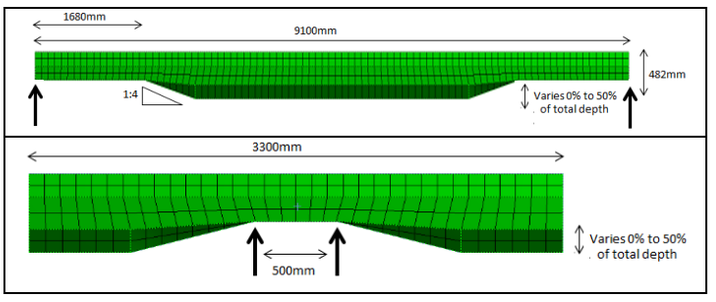
Table 3. Properties of grey ironbark

Modulus of Elasticity (MPa)		Modulus of rigidity (MPa)		Poisson ratio	
EL	16000	GLR	1072	ν_{LR}	0.4
ER	1956	GRT	320	ν_{RT}	0.7
ET	1956	GLT	1072	ν_{LT}	0.5
				ν_{RL}	0.05
				ν_{TR}	0.061
				ν_{TL}	0.03

The subscripts L, R and T shown in Table 3 refer to the longitudinal, radial and tangential directions respectively.

4.3 *Model development*

The girders and corbels are modelled to closely resemble sawn octagonal timber components, as used for Class A timber bridges on Queensland state controlled roads using ANSYS finite element software package. Solid 45 elements were selected in modelling the girders and the corbels. Although Class A bridges are now considered obsolete, the components used for maintenance and rehabilitation are of similar dimensions. The model dimensions used in the simulation are shown in Figure 1.



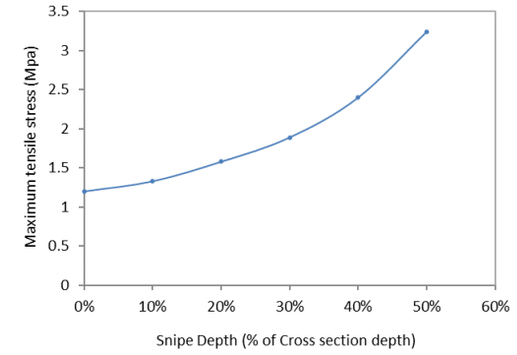


Figure 1. Typical girder and corbel layout

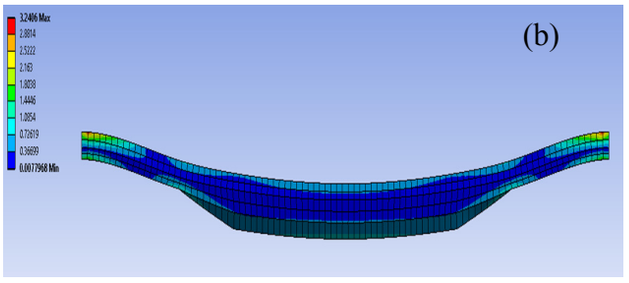
4.4 *Girders*

Six timber girders were investigated; with snipe depths ranging from 0% to 50% of the cross sectional depth and they were assumed to be simply supported at the ends. The maximum tensile stresses and maximum displacements obtained for all considered snipe depth variations were plotted against the snipe depth percentage.

The maximum tensile stresses variation displays an exponential distribution with regards to the increase in snipe depth as shown in Figure 2. Increase in snipe depth from 10% to 50% increases the bending stresses more than twice the stresses at 10% of snipe depth. It is evident that the reduction in effective bending depth in girders causes significant increase in bending stresses. Therefore it is an important aspect to consider the correct snipe depth in design of timber girders. Due to the natural degradation of timber girder strength with time, there is a higher risk associated with old bridges in this aspect.



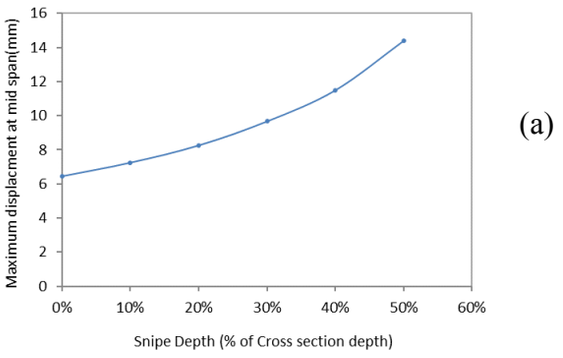


Figure 2. (a) Maximum tensile stress variation with snipe depth, (b) Tensile stresses in girder

Figure 3 shows the variation of maximum displacement at the mid span of the girder with the change of snipe depth. This plot also displays an exponential growth in displacements at the mid span with increase in snipe depth. Increase in snipe depth from 10% to 50% increase the maximum displacement by approximately twice as the displacement at 10%.

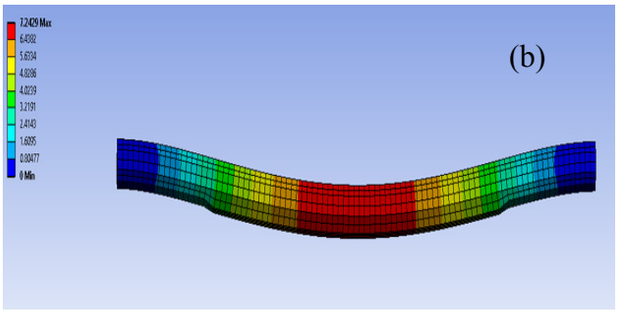

Figure 3. (a) Maximum displacement variation with snipe depth, (b) Maximum displacement in girder

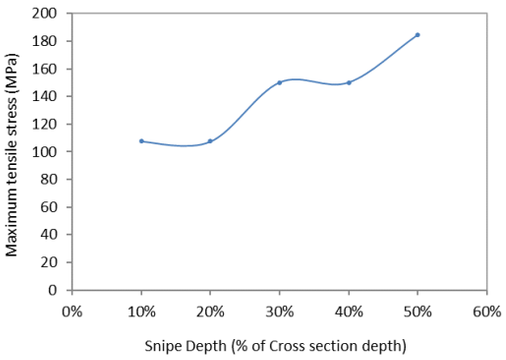


Due to the reduction in effective depth in girders, both stresses and displacements are significantly increased. This could results in splitting of girders and encouraging complete failure at some stage if correct actions are not taken. A potential defense against structural failure is the installation of anti-splitter bolts. These bolts are installed vertically through the girder at locations near the snipes. As the stresses are developed, they are transferred to the steel bolts, which will alleviate the strain in the timber member. The anti-splitter bolts would only be effective where there is enough cross-sectional area remaining to withstand the shear forces at the supports.

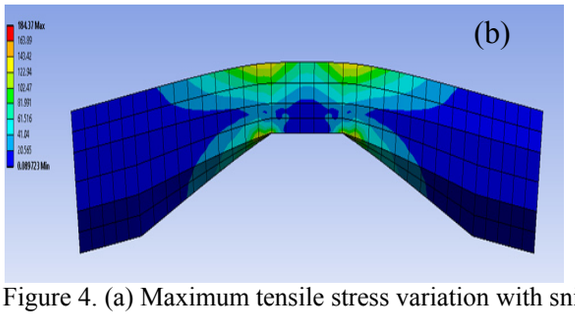
4.5 *Corbels*

Similar to girders, five timber corbels were also modelled with snipe depths varying from 10% to 50% of the cross sectional depth and maximum stresses and displacements at the mid span were examined. The most adverse conditions for the corbel occur when the girder load is transferred close to the corbel outstand. This would occur if the girder end had deteriorated, resulting in the support point creeping back towards the end of the corbel. This is basically the structural purpose of the corbel, to offset the effects of deterioration to the ends of the girders, and provide a larger bearing surface for the girders to rest on.

The finite element models only considered performance under an arbitrary loading. Performance is broadly defined by the amount of deflection and the degree to which stresses were concentrating at the snipe. The maximum stresses at the corbel as shown in Figure 4, display a significant increase due to the increase in snipe depth. Large increase in stresses is

observed when the snipe depth exceeded 20%, and there is no much difference in the stresses in change of snipe depth 10% and 20%.

(a)



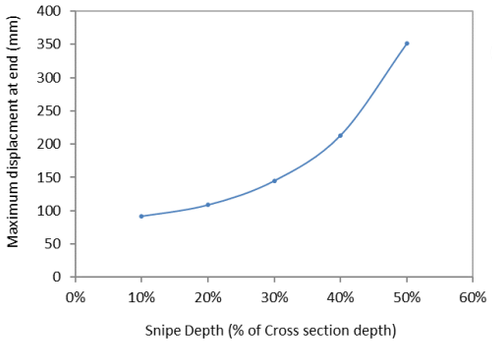


Figure 4. (a) Maximum tensile stress variation with snipe depth, (b) Tensile stresses in corbel

The variation of maximum displacement at the mid span of the corbel was plotted against the snipe depth percentage as shown in Figure 5. An exponential growth is observed due to the increase in snipe depth similar to the behavior of girders and increase of snipe depth from 10% to 50% increases the displacement more than 3 times.

(a)

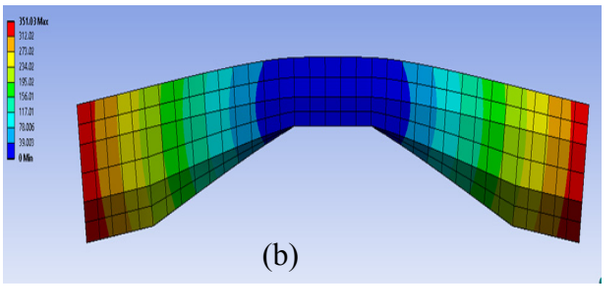

Figure 5. (a) Maximum displacement variation with snipe depth, (b) Maximum displacement in corbel

Considering both stress variation and displacement variations with respect to the increase in snipe depth, it is proposed that reasonable snipe depth for a corbel could be below 20% of the total depth. As per Table 2, remedial action should be taken for corbels with snipe depths greater than 25%. However it is proposed from this study that snipe depth greater than 20% would be a reasonable figure to have some remedial actions corbels.

5 CONCLUSIONS

Having identified sniping as a major area of concern for timber bridges, finite element modelling was used to further investigate this issue. The models were used to simulate the behaviour of girders and corbels with different snipe depths. Preliminary results tend to confirm the TMR restriction on snipes greater than 30% for girders and it is proposed that 20% snipe depth could be sensible for corbels. Condition state ratings, by their nature, are based on observable traits specific to each component. It is a subjective number used in an attempt to quantify some sort of defect. Condition states are not intended to quantify the load capacity of a component or a structure – they merely indicate general condition. For this reason, it is believed that condition states should be used for plotting deterioration trends from natural and mechanical degradation. They are not the ideal way to quantify inbuilt defects such as excessive sniping or point loading, as these defects do not change with time, hence no deterioration curve can be plotted. It is therefore difficult to link condition states to the structural performance of a sniped component. However, due to the history of continuing adequate performance, with no corbel failures attributed to excessive sniping, the case could be mounted to relax the requirements of the Bridge Inspection Manual.

ABSTRACT: The benefit of structural health monitoring (SHM) can possibly manifest through uncertainty reduction, risk reduction or life-cycle cost reduction. In the absence of a formal framework to establish monitoring benefits, SHM appears only as an additional cost to the stakeholders. This discourages the stakeholders from investing in health monitoring strategies. In the absence of a monetary value for the monitoring benefit, we rely on regulatory provisions to mandate effective structural health monitoring strategies. The value of information (VoI) is one such indicator that tries to formally quantify the benefits of monitoring, through its ability to arrive at optimum decisions with regards to the lifecycle management of structures. Broadly, VoI can be established through graphical methods or through a structural reliability based framework. In this paper, we briefly review the state-of-the-art on the VoI approach in structural engineering. Discussions are provided on the parameters that typically influence the VoI, followed by a case study example for VoI in fatigue cracking of steel structures. Calculations on sobol indices for the sensivitiy analysis help identify critical parameters affecting the VoI output.

1 INTRODUCTION

Structural Health Monitoring (SHM) refers to the various activities and techniques that are employed to establish the state of a structure and assist the stakeholders in adopting the most optimal actions for its management (Chang et al. 2003). The necessity of SHM comes from the fact that the predictions made by structural models are plagued with errors and uncertainties. Hence it becomes crucial to update the model parameters through information coming from structural condition inspections and new optimal decisions are identified (Brownjohn 2007).

The benefit of SHM primarily manifests in the reduction of uncertainties in the model prediction. Additionally, the risks a structure is exposed to can be reduced. Also, by preventing unnecessary maintenance and adopting the most optimal maintenance actions, the lifecycle costs can also be reduced (Frangopol 2011). Once the inspection has been carried out, the actual benefits for SHM can be established. However for the stakeholders, the choice of SHM strategy should be guided by the benefits it is likely to give throughout the service life of the structure.

In the absence of a framework that formally quantifies SHM benefit apriori, the ability of SHM to be beneficial is viewed with skepticism by the stakeholders (Cappello et al. 2016). Under such circumstances, SHM has to be enforced through statutory laws. Additionally, the stakeholders struggle in ranking the different available SHM strategies and this decision is left to the subjective judgement of the stakeholder (Thöns & Faber 2013). Also, it may not always be the case that the adopted SHM strategy is beneficial. Value of Information (VoI) is one such framework that attempts to quantify SHM benefit.

The VoI framework is based on bayesian preposterior analysis (Howard 1966, Raïffa & Schlaifer 1961). The VoI is premised on the idea that the value of any information lies in its ability to guide us to optimal decisions. In simple terms, the VoI is defined as the difference between the expected utility of optimal de-

cisions with and without SHM information (Cappello et al. 2016). Within civil engineering, some studies on VoI are the following - to quantify the benefits of SHM/inspection for particular problems in structural engineering (Thöns and Faber 2013, Straub 2014, Thöns et al. 2015, Qin et al. 2015, Thöns et al. 2017), to rank various SHM instruments (Pozzi & Der Kiureghian 2011), to optimize maintenance strategy (Malings & Pozzi 2017) and to optimize sensor placement (Malings & Pozzi 2016). In order to determine the VoI, typically two kinds of strategies are adopted - either graphical decision model solving strategies like Dynamic Influence Diagram, Markov Decision Processes etc. (Memarzadeh and Pozzi 2016, Straub et al. 2017, Malings and Pozzi 2017) or reliability based simulation methods like Monte Carlo sampling (Pozzi & Der Kiureghian 2011), importance sampling (Straub 2014) etc.

Pozzi & Der Kiureghian (2011) proposed a Monte Carlo based strategy to evaluate VoI. They implemented their algorithm on a simple reliability based model. After evaluating the evolution of VoI with the randomness of the inspection instrument, a range of suitable sensors can be established which cost less than the value they are most likely to deliver over the lifecycle of the structure. Such a methodology could be used to rank different inspection instruments. Straub (2014) extended this work to incorporate sequential decision making for fatigue cracking in a steel component and proposed an importance sampling approach for evaluating VoI. Thöns & Faber (2013) proposed a normalized VoI approach in which the utility function without SHM did not depend on any decision variable and the SHM observations were conditioned upon aleatory and epistemic uncertainties. Thöns et al. (2015) extended their approach for VoI estimation by incorporating updated aleatory and epistemic uncertainties for estimating utility with SHM.

A number of parameters that influence VoI have been observed in different studies. Pozzi & Der Kiureghian (2011), Straub (2014) and Thöns & Faber (2013) have noted that the VoI is higher for a lower randomness of the measurement uncertaintity. Thöns & Faber (2013) also observed a relatively higher influence of failure costs on VoI relative to maintenance costs. Thöns & Faber (2013) and Thöns et al. (2015) observed the influence of low and high model failure probability on VoI. Konakli et al. (2016) investigated VoI for structural systems and concluded that the VoI is higher for a higher component correlation.

Sensitivity Analysis gives crucial insights into the working of complex mathematical models. They are frequently adopted to validate models based on their ability to reflect sensitivities of influential parameters. Once the influential parameters are identified, they can be used to construct metamodels conditioned only on the key input parameters. The parameters of influence of VoI have been identified but there has not been any formal quantification of its sensitivities. This paper presents a brief discussion on the theory of VoI and its parameters of influence. The sensitivity of a VoI framework to a number of parameters is quantified through Sobol indices. The VoI for a steel fatigue crack growth model is established and the sensitivity of VoI is quantified.

2 FORMULATION FOR VALUE OF INFORMATION

Value of information theory is based on the framework of bayesian pre-posterior analysis (Raïffa & Schlaifer 1961). For a detailed exposition on the theoretical framework of VoI, the reader is referred to Thöns (2015) and Konakli et al. (2016). For the purpose of our illustration, a brief presentation of VoI is given below.

Essentially, the VoI is defined as the difference between the expected prior utility and the expected posterior utility for a given decision model. A simple formulation of utility can be done in terms of the cost function $C(a, \mathbf{X})$, where $a \in \mathbf{A}$ is a decision action from the set of all possible decisions in the set $\mathbf{A}$ and $\mathbf{X}$ is a random vector of the input variables of the model $\mathcal{M}$. Hence the prior costs can be represented as:

$$C_{prior} = \mathrm{E}_{\mathbf{X}}\left[C\left(a_{opt}, \mathbf{X}\right)\right] = \min_{a} \mathrm{E}_{\mathbf{X}}\left[C\left(a, \mathbf{X}\right)\right] \tag{1}$$

where a_{opt} is the optimum maintenance action defined by:

$$a_{opt} = \arg\min_{a} \mathrm{E}_{\mathbf{X}}\left[C\left(a, \mathbf{X}\right)\right] \tag{2}$$

where $\mathrm{E}[\cdot]$ is the expectation operator.

In cases where SHM is adopted, observations coming from monitoring/inspections, $\mathbf{y}$, give the updated input parameters $\mathbf{X}'$. A new decision action is taken based on the updated state of the structure and hazard, given by a'_{opt} which in turn gives up an updated estimate of costs called posterior costs, C_{post} . Carrying out the same process for all possible realizations of the monitoring outcomes, $\mathbf{Y}$, gives us the expected posterior costs given by:

$$C_{post} = \mathrm{E}_{\mathbf{Y}}\left[\mathrm{E}_{\mathbf{X}'}\left[C\left(a'_{opt}, \mathbf{X}'\right)\right]\right] \tag{3}$$

$$C_{post} = \mathrm{E}_{\mathbf{Y}}\left[\min_{a} \mathrm{E}_{\mathbf{X}'}\left[C\left(a, \mathbf{X}'\right)\right]\right] \tag{4}$$

$$a'_{opt} = \arg\min_{a} \mathrm{E}_{\mathbf{X}'}\left[C\left(a, \mathbf{X}'\right)\right] \tag{5}$$

Finally, the VoI is defined as the difference between the expected prior costs and expected posterior costs as below:

$$\text{VoI} = C_{prior} - C_{post} \tag{6}$$

VoI can also be presented as a ratio, referred to as Normalized VoI ($NVoI$), normalized with respect to the prior costs as given below:

$$\text{NVoI} = \frac{C_{prior} - C_{post}}{C_{prior}} \tag{7}$$

3 PARAMETERS INFLUENCING VOI

From the brief discussion in Section 2, one can identify a number of parameters that could influence the VoI.

3.1 *Cost model*

It is evident from the formulation of Section 2 that the cost model is an integral part of the VoI framework. Throughout the lifecycle of the structure, the stakeholders can incur costs from three main sources namely - cost of failure, cost of maintenance/repair and the cost of SHM.

The costs of failure includes the direct and indirect consequences of failure incurred by the agency and/or the user. The inspection/monitoring of structures is another significant part of the lifecycle costs and usually precedes any maintenance/repair action which has a cost of its own. However it could be assumed that the inspection is free while determining the VoI and the instrument which gives a higher VoI with the least cost is considered the best of all available options (Pozzi & Der Kiureghian 2011, Straub 2014). Hence such an indirect cost-benefit analysis can be used to rank various SHM strategies under consideration.

Establishing the actual consequences of failure can be a challenging task. The estimates made are subject to a number of approximations related the structure and its utility. Such estimates can also be expected to differ with each structure under consideration, adopted maintenance strategy and degradation model (Faber 2002). Thöns et al. (2015) found that the failure costs contributed significantly to the VoI as opposed to the inspection costs and the repair costs.

3.2 *Decision model*

The other significant aspect of the VoI framework is the decision model. As the structural condition deteriorates, the stakeholders are faced with the question whether to repair or replace the structure. Different types of repair strategies can be adopted depending upon the level of damage within the structure. Additionally, such decisions can be taken multiple times throughout the lifecycle of the structure. This can be modelled as a dynamic decision problem.

Such complexity renders the problem of VoI estimation intractable due to the high computational demands. A more comprehensive maintenance model would contain an essential maintenance as well as a preventive maintenance strategy (Sánchez-Silva et al. 2016). Preventive maintenance strategies are those that are employed to keep the structure operating at a certain specified level. They can be planned on the basis of a threshold level (other than failure) or they can be planned to repeat at a particular time period. Essential maintenance strategies on the other hand are triggered when the structural performance deteriorates below a certain minimum performance threshold (typically failure). However, due to the issues arising from problem complexity, researchers frequently adopt a single decision whether to replace the structure or do nothing in case of a failure at one or two instances during the service life of the structure (Pozzi and Der Kiureghian 2011, Straub 2014, Cappello et al. 2016).

It can also be argued that since the decision models do not capture the actual structural maintenance scenario, the full VoI has not been realized. Additionally, the process of generating synthetic samples of SHM observations entails superimposing an unbiased random error with the model prediction. In other words, the VoI is calculated for the case when SHM informs the stakeholder what he or she already knows through their model prediction but with a slight margin of error. However, this approximate estimate of VoI can be reasonable for practical purposes (Konakli et al. 2016).

3.3 *Probability of failure*

Decisions relating to maintaining a structure are made throughout its lifetime. During this period, the magnitude of different costs incurred especially due to failure vary. Additionally, the time value of money should be accounted for through discounting of future costs. Hence the period within which the structure fails and its probability of failure becomes influential through the interaction between the decisions, time instant and their consequences.

The probability of failure of a structure depends upon a number of other factors such as the type of distribution of demand and capacity, the specifics of structural degradation law, interdependencies between the components of the system etc. Faber & Thöns (2014) and Konakli et al. (2016) noted a clear but complex influence of the annual probability of failure on the estimated VoI.

3.4 *Model uncertainty and errors*

Mathematical models of physical phenomenon are frequently based upon certain approximations of the reality. For example, in structures, degradation processes are frequently modelled as a linear degradation process as an approximation when the actual scenario

might be far more complicated than that. This introduces errors in model predictions.

Additionally a distinction between model errors and model uncertainty can be made. Physical phenomena are highly random. Due to the difficulty in estimating actual values of the parameters governing a phenomena, they are frequently modelled as random variables. These uncertainties in the input parameters are propagated and manifest in the variance of the output variable under consideration.

SHM serves an important purpose in reducing model uncertainties and model errors. Hence the information obtained through SHM and its value would depend upon the extent of model uncertainty and errors. In the cases when the model uncertainty and/or the model error is high, the VoI should be higher and vice versa. However the direct influence of model uncertainties and errors on VoI has not been studied.

The model errors can be accounted through an additive bias (α_0) term, a scaling bias (α_1) term and a randomness term ($\epsilon_{\mathcal{M}}$) as below:

$$m = \alpha_1 \mathcal{M}(\mathbf{X}) + \alpha_0 + \epsilon_{\mathcal{M}} \tag{8}$$

where m is the model prediction and $\epsilon_{\mathcal{M}}$ is a zero mean standard normal variable.

3.5 *Instrument errors*

Instrument errors can arise from human errors and instrument imperfections. The existence of certain environmental factors can also lead to erroneous measurements. Instruments are also characterized by their precision in the form of the smallest measurement they can make.

There can be two types of inspections outcomes - binary output and continuous output. In cases when the structural state is either considered to be safe of failed (or the existence/non-existence of flaws), the SHM adopted can simply return a yes or no. In such cases, the accuracy of the instrument can be modelled using the likelihood matrix with True/False Positive/Negative rate (Omenzetter et al. 2016). In cases when the SHM instrument measures a continuous output, like crack size, Probability of Detection (PoD) curves or instead a model with bias and randomness similar to Equation (8) can be adopted.

It can be argued intuitively that the VoI should be lower for an instrument with higher errors. The evolution of VoI with instrument randomness has been studied by a number of researchers (Pozzi & Der Kiureghian 2011, Straub 2014).

4 SENSITIVITY ANALYSIS EXAMPLE

Sensitivity analysis (SA) is the study of the extent to which input parameters influence a mathematical model. The methods for sensitivity analysis can be divided into three types - local SA, screening methods and global SA. For more details the reader is referred to the work of Saltelli et al. 2004.

The SA of VoI is carried out for the following objectives:

1. To identify the influential parameters
2. To study the extent of influence of parameters of the VoI model
3. To validate the VoI model based on its ability to reflect known influential parameters

SALib is a sensitivity analysis package for python (Herman & Usher 2017). This paper details sensitivity studies of the VoI model as proposed by Straub (2014) using SALib. This section briefly details the VoI framework proposed by Straub (2014) followed by the choice of parameters sensitivity analysis and subsequent calculation of Sobol indices.

4.1 *VoI in fatigue crack growth in steel structures*

Straub (2014) investigated the VoI for the case of fatigue crack growth in steel structures. We adopt the same problem for the purpose of our studies.

A service life of 20 years is assumed for the steel component and divided into 4 periods of 5 year each as follows: 0-5 year, 5-10 year, 10-15 year and 15-20 year. The decision model consists of either replacing the structure at the beginning of each interval ie 0, 5, 10, 15 years or do nothing. The optimum decision the one which gives the minimum expected cost. A single inspection is made at year 5. The expected costs are estimated for the cases of with and without SHM inspection using a Monte Carlo strategy and VoI is calculated. Costs of failure and costs of replacing the component at the beginning of each of these periods is taken into consideration. For more details on the specifics of the problem, the model parameters and the proposed methodology the reader is referred to the original paper (Straub 2014).

The fatigue cracking on a steel component is modelled as per Paris' Laws and the crack depth, l, is given as below:

$$l(\mathbf{X}, t) = \left[\left(1 - \frac{m}{2}\right) C \Delta S^m \pi^{0.5m} \nu t - l_0^{\left(1-\frac{m}{2}\right)} \right]^{\frac{1}{\left(1-\frac{m}{2}\right)}} \tag{9}$$

where C and m are empirical constants, ΔS is the stress range per cycle, ν is the annual cycle rate, l_0 is the initial crack length at zero stress cycles and t is time. The limit state function is given by,

$$G_F(\mathbf{X}, t) = l(\mathbf{X}, t) - l_c \tag{10}$$

where l_c is the threshold crack length.

4.2 *Parameters for study*

For the purpose of SA, 6 variables are considered to vary uniformly between their upper bounds and lower bounds as specified in Table 1. SALib carries out an experimental design as per Saltelli (2002) using the parameters as specified in Table 1. The VoI is evaluated for this design and finally the sobol indices (Section 4.3) are estimated.

In order to study the influence of the cost of repair, a scaling factor SF is adopted. Hence the cost of repair becomes the original cost of repair (Straub 2014) multipled by SF. This SF is varied in the sensitivity studies as a uniformly distributed random variables within the bounds specified by Table 1. The variables μ_{l_0}, $\mu_{\Delta S}$ and l_c are important parameters of the model and can be considered to directly influence the probability of failure of the model. The model errors are not taken into explicit consideration but the coefficient of variation (COV) of ΔS contributes to the model uncertainty. The instrument is considered to be unbiased and characterized by its randomness given by σ_E.

Table 1: Parameters of VoI model for sensitivity analysis

Variable	Lower bound	Upper Bound	Median
SF	0.2	5	2.6
σ_E [mm]	0.75	2	1.75
μ_{l_0} [mm]	0.5	2	1.75
$\mu_{\Delta S}$ [Nmm^{-2}]	50	65	57.5
COV of ΔS	0.15	0.25	0.2
l_c [mm]	40	50	45

4.3 *Sobol Indices for sensitivity*

Sobol indices are indices which are constructed by decomposing the variance of an output random variable Z in terms of its input random variables $X_i \in \mathbf{X}$, where $i = 1$ to d, normalized by the actual variance of Z. The first order indices are given by Equation (11).

$$S_i = \frac{\mathrm{V}_{X_i}\left[E_{X_{\sim i}}\left(Z|X_i\right)\right]}{\mathrm{V}(Z)} \tag{11}$$

Here the notation $X_{\sim i}$ means all variables except X_i. Also, $\mathrm{E}[\cdot]$ denotes the expectation operator and $\mathrm{V}(\cdot)$ denotes the variance operator. Hence the numerator in Equation (11) represents the variance of the expectation of output variable Z by fixing X_i. It measures the effect of varying X_i alone on the variance of Z.

Second order indices can be constructed as below:

$$S_{ij} = \frac{\mathrm{V}_{X_{ij}}\left[\mathrm{E}_{X_{\sim ij}}\left(Z|X_i, X_j\right)\right]}{\mathrm{V}(Z)} \tag{12}$$

Similarly, higher order indices can be constructed. An interesting property of such indices is given below:

$$\sum_{i=1}^{d} S_i + \sum_{i<j}^{d} S_{ij} + ... + S_{12..d} = 1 \tag{13}$$

As the number of input parameters increase, the number of sobol indices increases exponentially. Hence to reduce the computation and directly estimate the total extent of influence an input variable exerts on Y, total order indices are constructed. They are defined below:

$$S_{T_i} = 1 - \frac{\mathrm{V}_{X_{\sim ij}}\left[\mathrm{E}_{X_{ij}}\left(Z|X_{\sim i}\right)\right]}{\mathrm{V}(Z)} \tag{14}$$

S_{T_i} measures the effect of all terms of any order that include X_i on the variance of Z.

4.4 *Sensitivity analysis methodology*

In order to study the sensitivity, three strategies have been adopted. Firstly, the variation of the VoI and $NVoI$ is studied for different values of input parameters are studied. A baseline model is adopted with median values of the parameters as specified in Table 1 is carried out. Additionally, keeping all other parameters constant, the model is evaluated for the upper bound value and the lower bound value for each parameter as specified in Table 1.

In the second and the third strategy, the first order and total order Sobol sensitivity indices are calculated. In the second strategy, the indices are calculated using the Saltelli scheme (Saltelli 2002) implemented in SALib. As per the scheme, the number of samples required for estimation of Monte Carlo estimates of first order and total order Sobol indices are given by $N\left(k+2\right)$, where k is the number of parameters in the study, equal to 6 in our case, and N is an integer that typically ranges between 10 to 1000. For the purpose of this study, $N = 1000$ has been adopted for a reasonably good convergence of first order and total order indices. It should be noted that evaluation of the model is an extremely computationally demanding process, which limits the maximum number of samples that can be adopted for the study.

In the third strategy, the Sobol indices are calculated using Fourier Amplitude Sensitivity Testing (FAST) (Saltelli et al. 1999) implemented in SALib in order to validate the results obtained by Saltelli Scheme. For this strategy, the value of interference parameter adopted is 4 and 390 samples are generated to obtain point estimates of the first order and total order indices.

5 RESULTS AND DISCUSSION

Figure 1 and Figure 2 express VoI and NVoI respectively evaluated at different bounds of the parameters. For the chosen distribution of parameters, it is quite evident that the parameters μ_{l_0}, $\mu_{\Delta S}$ and the COV of ΔS is most significant followed by σ_E. The model remains largely insensitive two SF and l_c.

A similar pattern is observed in the estimated first order (Figure 3 and Figure 4) and total order indices

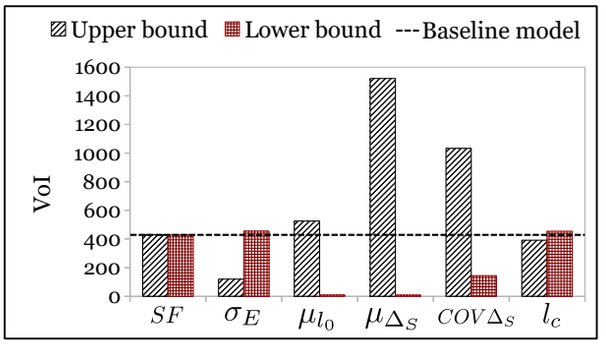

Figure 1: VoI at different bounds of parameters

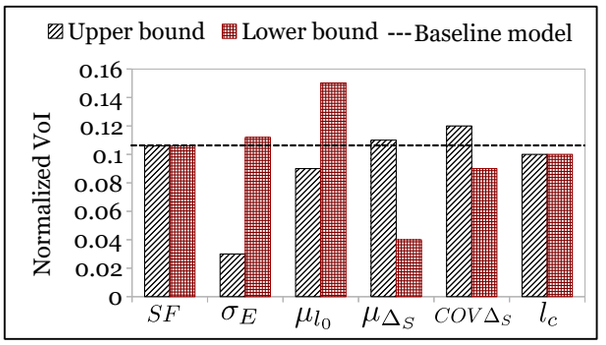

Figure 2: Normalized VoI at different bounds of parameters

(Figure 5 and Figure 6). A quick conclusion that can be drawn from Figures 3, 4 and 5 is that the value of $N = 1000$ gives a reasonably converged estimate of the Sobol indices. However Figure 6 indicates that for total order indices of NVoI, more samples would be required. Also, it can be observed from Figures 3, 4 and 5 that FAST algorithm gives reasonably accurate estimates of Sobol indices are a much smaller computational cost.

Figure 3 and Figure 5 express higher sensitivity indices for the parameters of the underlying physical phenomenon. These parameters directly influence the probability of failure of the structure. The model for cost of failure has a higher consequence when the structure fails earlier during its service life period as opposed to a failure during the later period of its service life (Straub 2014). It implies that the VoI is more pronounced when the consequences of failure are higher and less dependent upon the parameters of inspection instrument quality like σ_E. Hence the

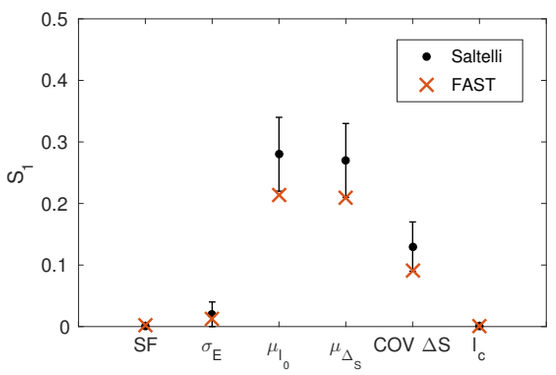

Figure 3: First order Sobol indices for VoI

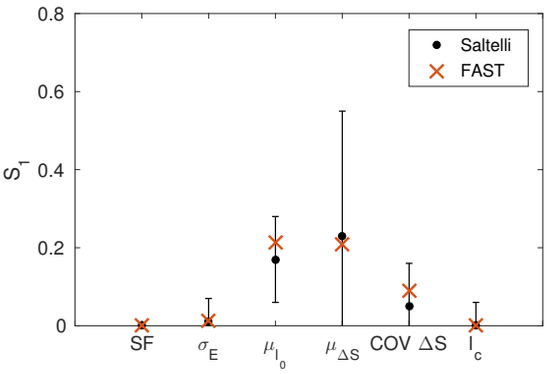

Figure 4: First order Sobol indices for NVoI

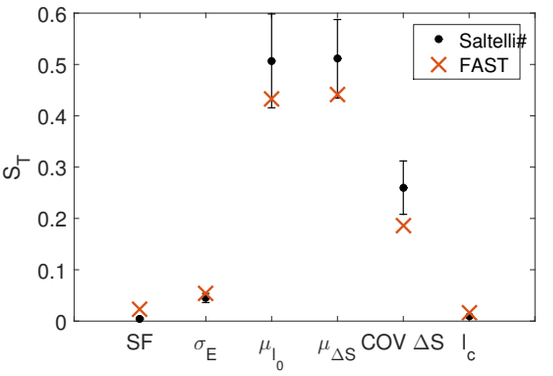

Figure 5: Total order Sobol Indices for VoI

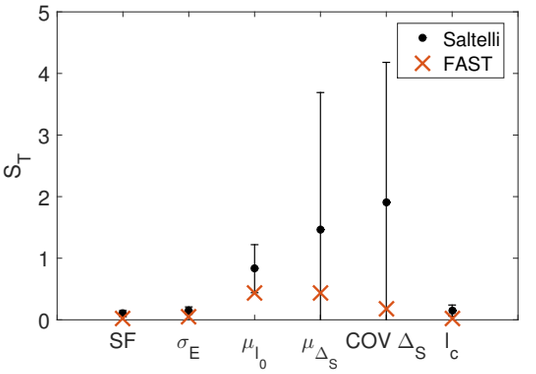

Figure 6: Total order Sobol indices for NVoI

decision to adopt SHM and its consequent benefit is largely a function of the stakes involved.

When the consequences of failure are high, the VoI obtained is also high. However when normalized with respect to the prior costs, the relative difference in VoI is less pronounced as can be noticed by comparing Figure 1 and Figure 2.

As opposed to the parameters μ_{l_0}, $\mu_{\Delta S}$ and the COV of ΔS, σ_E has a relatively lower influence on VoI as shown in Figure 3 and Figure 5. This could be due to the fact that the probability of failure of the structure/component is directly influenced by those other parameters, resulting in a larger variation in VoI. However, from Figure 2 it can be observed that σ_E is a significant variable for the normalised VoI.

SF is found to have negligible sensitivity on VoI and NVoI. It could be due to the fact that as per the cost model adopted, the costs of repair are of 10^2 to 10^1 order less than the costs of failure (Straub 2014). Nonetheless, for the current VoI problem, it would make negligible difference in VoI estimates if the costs of repair were neglected.

The VoI framework shows relatively less sensitivity to the threshold crack length l_c (Figures 3 to 6). This is observed 5because the adopted range of l_c between 40 mm and 50 mm does not impact the 5 year period probabilities of failure significantly.

6 CONCLUSION

This paper details sensitivity analysis of a VoI framework through variance decomposition and estimation of Sobol indices. This sensitivity analysis gives key insights into the working of a complex VoI framework; however, computational demands imposes a significant challenge for such studies.

The VoI framework is found to have a negligible sensitivity towards the cost of repair, whereas the most significant contribution comes from the costs of failure. Hence the repair costs can be neglected for VoI estimations. Additionally, the variables intrinsic to the underlying physical model which directly influence the time/probability of failure of the structure exert a high degree of influence on the model. These variables also show a high nonlinear interaction through their large total Sobol indices (S_T). A simple conclusion that can be drawn from this is that the VoI is largely dependent on the extent of consequences of failure of the structure.

Uncertainty in the underlying physical model, modelled as the coefficient of variation of an input parameter ΔS also exerts a significant influence on the VoI. A high VoI is obtained for higher model uncertainty and vice versa. Among the other significant variables that describe the quality of inspection instrument is the instrument randomness.

The aforementioned conclusions must be deduced while considering the influence of the underlying assumptions of the probabilistic model as well as the cost model. The influence of the choice of probability distribution for the parameters of the underlying physical model has not been investigated. Additionally, the influence of these parameters could become more significant in the case of a cost model that adopts higher consequences of failure.

Further research is required to study the influence of other parameters of influence which have not been covered by this study like model errors. The identification of influential parameters for VoI estimation will aid in the development of metamodels for VoI estimation and, if needed, in a more suitable definition of the VoI.

Health monitoring data modeling and reliability prediction of an actual bridge based on ARMA model

D.G. Lu, W.H. Zhang & Z. Zhao
School of Civil Engineering, Harbin Institute of Technology, Harbin, P.R. China

ABSTRACT: An actual CFST arch type bridge located in China which has been installed a health monitoring system, is taken as a test-bed in this paper. To model the health monitoring data and predict the reliability of the structural system, an Auto-Regressive Moving-Average (ARMA) model is introduced in this paper. The Levenberg-Marquarat optimization algorithm is utilized in the parameter. Based on the vertical acceleration data, use of the improved estimation algorithm is made to build the ARMA model. The deflection data of the girders is performed by reliability analysis. In combination with the data obtained by the pressure rings on the suspenders of the bridge, the cable forces are identified, and the ARMA model is established to process and analyze the cable forces. The effects of the variations of strength and diameter of the strands on the reliability assessment of the suspenders are investigated.

1 INTRODUCTION

Since the 1980s, with the rapid development of Chinese economy, a great deal achievements have been made in the field of bridge construction. Meanwhile, like other countries all over the world, the bridge projects in China are facing the bridge accidents. For this reason, many bridge constructions have installed different sizes of health monitoring systems all over the world. Up to now, the technology of the bridge health monitoring system installation has already been well developed (Kim & Pakzad 2007, Roberts & Brown 2005, Koh & Choo 2006, Koh & Lee, H.S 2008). After nearly 30 years of monitoring, a large amount of data has been accumulated, therefore, how to cope with the huge monitoring data accurately and timely becomes a key process of condition assessment and performance prediction of bridges.

The methods of dealing with bridge health monitoring data include time-frequency analysis method, modal analysis method, analytic hierarchy process, genetic algorithm, neural network analysis method, time series analysis method, reliability theory analysis method (Ni & Jinag 2001, Hunag & Shen 1998). However, the theory of modeling and analysis of monitoring data has not yet been developed to maturity.

Time series analysis originated from the forecast, the traditional periodic graph analysis and the correlation analysis to establish non-parametric time series model. An important breakthrough in time series analysis is from nonparametric models to parametric models. ARMA model originated from the AR and MA model, then extended to non-linear Smooth field, etc. (Yule 1927, Walker 1931). After that, the formulation of the maximum entropy spectrum and AR spectrum were proposed (Burg 1967, Parzen 1968). Box and Jenkins proposed the complete framework of ARMA model and a complete set of time-series data modeling, parameterization, testing, prediction and control methods, made an indelible contribution to the timing theory is applied in various fields (Box & Jenkins 1976). From that, lots of research has been focused on this area (Van den Bos 1971, Pisarenko 1973, Pandit & Wu 1978). It has carried out a more comprehensive study on the system identification method of bridge health diagnosis. The research projects include I-40 bridge project and Alamosa canyon (Farrar & Cone 1995, Johnson & Lam 2004, Carden & Brownjohn 2008). Some research focused on modal identification and damage identification (Qin & Zhang 1998) .

In this paper, we take data-driven modeling as an objective, the feasibility of the application of time series analysis method to modeling and analysis of

bridge monitoring data is discussed. The basic ARMA (Auto-Regressive Moving-Average) model in time series analysis is selected to model and analyze the health monitoring data of bridges, and the reliability indices of bridge are calculated based on the proposed ARMA model.

2 ESTABLISHMENT OF ARMA MODEL AND IMPROVED PARAMETER ESTIMATION ALGORITHM

2.1 *Illustration of ARMA model*

When the sequence $\{x_t\}$ has both autoregressive and moving average, the model should also contain both the autoregressive and the moving averaging process, combining the AR and the MA models to get the ARMA model. It is expressed:

$$x_t = \varphi_1 x_{t-1} + \mathrm{L} + \varphi_p x_{t-p} + \varepsilon_t - \theta_1 \varepsilon_{t-1} - \mathrm{L} - \theta_q \varepsilon_{t-q} \quad (1)$$

It can be abbreviated as ARMA (p,q). Where $\{\varepsilon_t\}$ is the white noise sequence, $\varphi_1,\varphi_2,\cdots,\varphi_p$ are the autoregressive parameters of the model, $\theta_1,\theta_2,\ldots,\theta_p$ are the moving average parameters of the model. When the backward operator B is introduced, the equation (1) can be described by the p-order polynomial

$$\Phi(B)x_t = \Theta(B)\varepsilon_t \quad (2)$$

Where,

$$\Phi(B) = 1 - \varphi_1 B - \varphi_2 B^2 - \mathrm{L} - \varphi_p B^p \quad (3)$$

$$\Theta(B) = 1 - \theta_1 B - \theta_2 B^2 - \mathrm{L} - \theta_q B^q \quad (4)$$

$Bx_t=x_{t-1}$, $B^2x_t=x_{t-2}$, …, $B^px_t=x_{t-p}$, $B\varepsilon_t=\varepsilon_{t-1}$, $B^2\varepsilon_t=\varepsilon_{t-2}$, …, $B^q\varepsilon_t=\varepsilon_{t-q}$.

Equation (3) is called the autoregressive feature polynomial, and equation (4) is called the moving average feature polynomial.

2.2 *The process of establishment*

For the observation sequence data $\{x_t\}$ obtained by the signal acquisition system, it should be tested and preprocessed according to relative requirements to meet the conditions for establishing the ARMA model. Through the previous data test and preprocessing, then combine with the characteristics to transform the data form.

If the autocorrelation function and the partial autocorrelation function all have the properties of tailing, then ARMA model modeling is used. In a word, the selection is due to truncated properties of the autocorrelation and partial autocorrelation function. According to the correlation of the sequence $\{x_t\}$, the order of the model can be determined from the truncation of the autocorrelation and the partial autocorrelation function. And then the parameters estimation is the next step of the establishment but it has a few difficulties, the detail will be discussed in the next section.

After the establishment of a time series model from the sample data, we need to test the applicability of the model. The residual sequence can reflect the degree of application to the data when the model is established. Therefore, the residual sequence should be analyzed when the applicability of the model is tested. There are also a variety of applicability test methods, such as R test, F test, D-W test and so on. In this paper, we mainly use D-W test and the correlation graph to test the applicability.

2.3 *The optimization methods of parameter estimation*

Parameter estimation is the key to the modeling process, due to lack information of noise $\{\varepsilon_t\}$, the difficulty of estimating the parameters of the ARMA model is increased. Commonly methods like least squares, etc.

In this paper, we use one of the optimization methods of ARMA model parameter estimation optimization method: Legeven-Marquarat algorithm, a modified algorithm of Gauss-Newton algorithm, which properly combines the Newton method and the steepest descent method. Determine the objective function with the long autoregressive method to estimate the initial value. Then, the parameters of the ARMA model are optimized to speed up the convergence and improve the estimation accuracy.

For ARMA (p,q) model, observation time series can be fitted in mathematical model

$$x_t = f\left(X_t, \beta\right) + \varepsilon_t \quad (5)$$

Where $X_t=[x_{t-1},x_{t-2},\cdots,x_{t-k}]^T$, X_t is the k-dimensional vector of different observations, $\beta=[\varphi_1\ \varphi_2\cdots\varphi_p\ \theta_1\ \theta_2\ \cdots\theta_p]^T$, β is r ($r=p+q$) dimension vector by the estimate parameters, ε_t is the model residual, f is the function relation between X_t and parameter β.

Then the formulation written by vector form

$$x_t = \varphi_1 x_{t-1} + \mathrm{L} + \varphi_p x_{t-p} + \varepsilon_t - \theta_1 \varepsilon_{t-1} - \mathrm{L} - \theta_q \varepsilon_{t-q} \quad (6)$$

Where, $X_t^T=[x_{t-1},x_{t-2},\cdots,x_{t-p},\varepsilon_{t-1},\varepsilon_{t-2},\cdots,\varepsilon_{t-q}]^T$, $\beta=[\varphi_1\ \varphi_2\cdots\varphi_p\ \theta_1\ \theta_2\cdots\theta_p]^T$.

Since ε_{t-1}, ε_{t-2}, $\cdots$, ε_{t-q} are not known but can be obtained by x_{t-1}, x_{t-2}, $\cdots$, x_{t-q}, so X_t^T is a nonlinear term, which leads to the occurrence of the nonlinear term of the parameter β to be estimated. The objective function of the ARMA model is defined as the sum of squares of the residuals of the model

$$S\left(\beta\right) = \sum\nolimits_t \varepsilon_t^2 = \sum\nolimits_t \left[x_t - X_t^T \beta\right]^2 \quad (7)$$

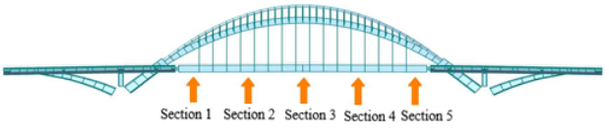
From the viewpoint of model optimization theory, the optimal estimation of β is the problem of finding the minimum value of S(β). The common solution is the least squares method, but it is easy to become a singular matrix in the iterative process. And owing to its higher requirement for the initial value, when the original value far away from the minimum value, it will be difficult to convergence. Therefore, this paper improves the traditional least squares method and applies the Levenberg-Marquarat algorithm to avoid the drawbacks.

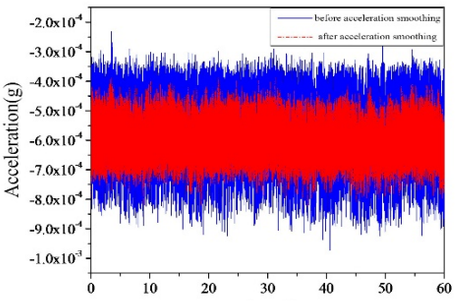
3 ILLUSTRATIVE EXAMPLE

For illustrating the above model, an arch-bridge of concrete filled steel tubular bridge, the Yitong River Bridge shown in the Figure 1 which length is 740m, located in the Changchun city, Jilin Province, China, is taken as the test-bed in our paper which is a mid-type concrete-filled steel tubular arch bridge.

Figure 1 The real map of Yitong River bridge.

3.1 *Establish the model based on the vertical acceleration data*





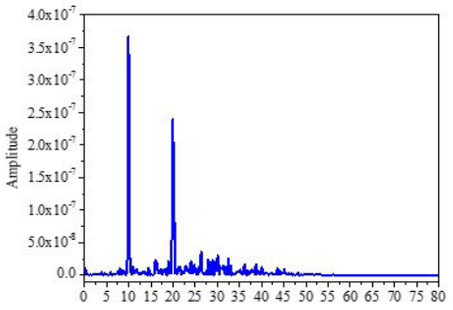


Figure 2 The location of the acceleration sensor

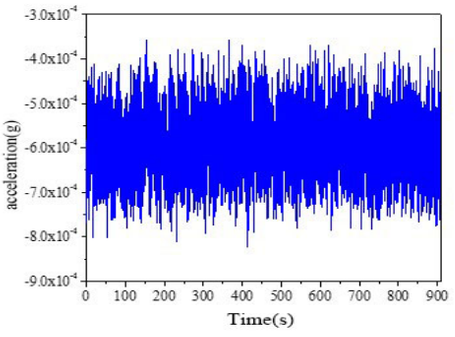

The data acquisition used in this paper is collected by an acceleration sensor mounted across the main beam, the location of the acceleration sensor is shown in Figure 2. Selecting the acceleration sensor channel_07 collection of the main beam vertical acceleration information $\{y_t\}$, sampling step is 0.001s, because the amount of data is too large, only draw the first 60s of data time series. Smoothing the data $\{y_t\}$, removing the short-term fluctuations effects and making the time series curve smooth. Then do the spectral analysis for the smooth data and identify the main frequency. It can find that the signal has two frequency components. The highest is 9.961Hz, the second is 19.922Hz. According the sampling theorem, the resample frequency set as 20Hz. Then do the stationary test, using MATLAB adfTest command to test $\{x_t\}$, find it's a stationary series, considering the first difference and a zero-mean trend removal, obtain the time series difference $\{Dx_t\}$. Plot their autocorrelation and partial autocorrelation coefficient curves. The results are shown in the Figure 3.

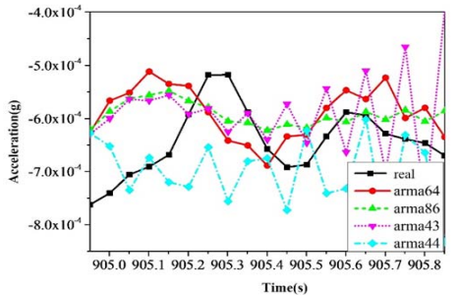
(e) Sample autocorrelation coefficient



(f) Sample partial autocorrelation coefficient

Figure 3 The results of data selection

Binding order selection criteria and correlation coefficient map, we can determ ine the m odel order and then estim ate the m odel parameters using the former method. Here we show the different m odel order predicting results in the following Figure 4. We see that ARMA(6,4) can simulate the original series trend, the relative error is also properly small.

(a) Comparison of different primary order prediction results

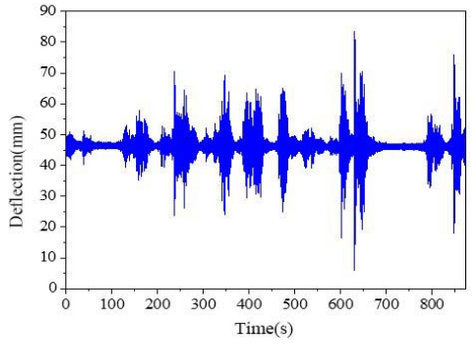

Figure 4 The different model predicting results

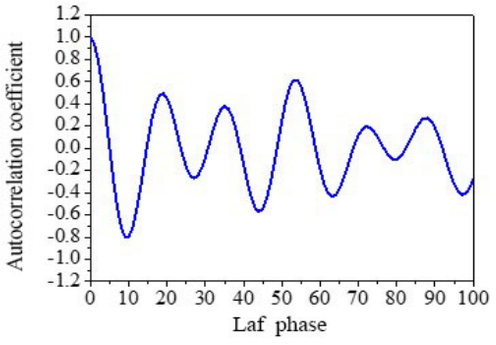
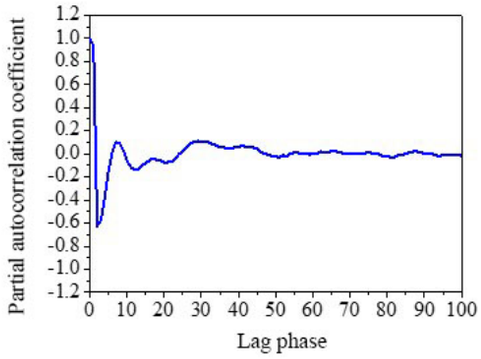
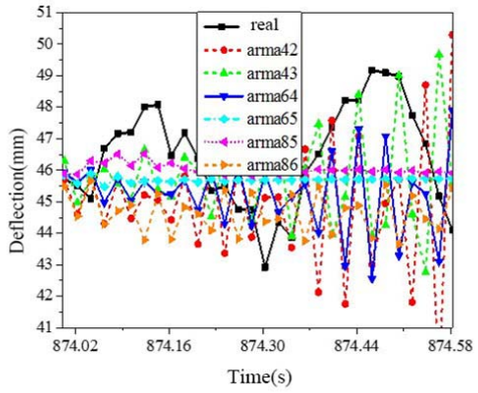
3.2 *Serviceability reliability analysis of main girder based on deflection data*



The deflection of the main beam of the Yitong River Bridge is m onitored by the inclinom eter, 5 inclinometers sequentially laid in span length direction of the main beam. Utilizing the m onitoring data, we can obtain the deflection equation. Then pick up the maximum curve at every tim e point follow the code requirements and establish the tim e series sam ple. Similarly as the above step, we can determ ine the model order and estim ate parameters, using the ARMA model to predict, the result are shown as follows Figure 5.

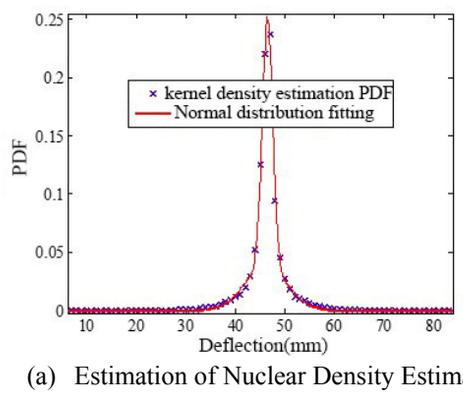


(a) Main beam deflection

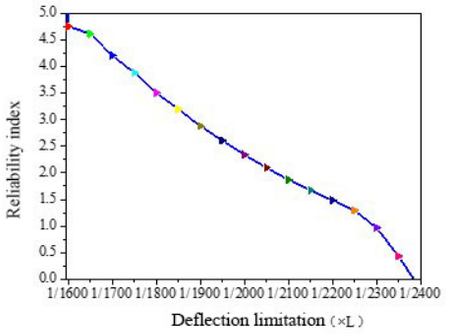


(b) Maximum deflection time series

(c) Sample autocorrelation coefficient



(d) Sample partial autocorrelation coefficient



(e) Comparison of predictive effects of primary model

Figure 5 The results of data selection

As for the serviceability reliability analysis of main beam deflection, the kernel density estim ation method is used to estimate the PDF of the deflection data. The m aximum deflection series of the m ain beam is fitted by the dist ribution fitting toolbox in the MATLAB platform and di stribution form is selected as Non-parametric, the kernel selects norm al, and the window width autom atically selects the default optimal window width. Then choosing the MCMC method to sample the deflection data of the main beam, and calculating the serviceability reliability index of the main girder. The results are as follows Figure 6.

(a) Estimation of Nuclear Density Estimation

(b) The reliability index varies with deflection limitation

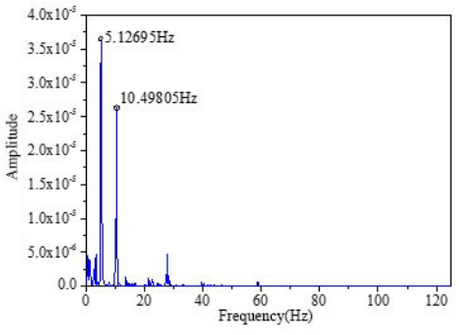


Figure 6 The results of serviceability reliability analysis

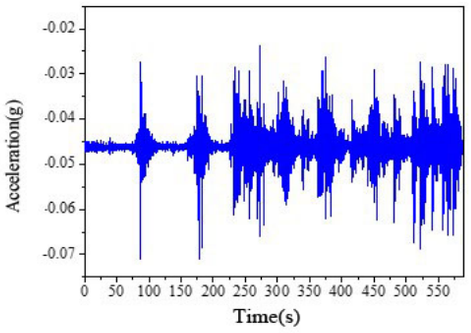
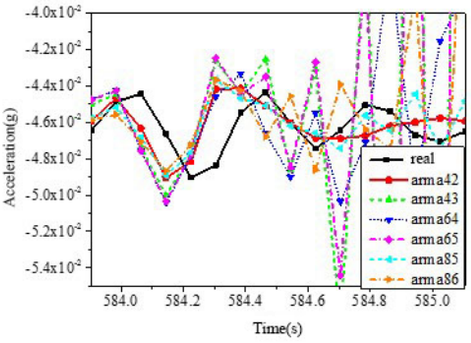
It can be seen f rom Figure 6 that the reliability indicator decreases with the increase of the deflection limit level. For the bridge, when the def lection limit is taken as L / 2350, the index is approxim ately 0. Define the lim it between the L / 1800 ~ L / 2300, the indicators corresponding to 3.5077 ~ 0.9688.



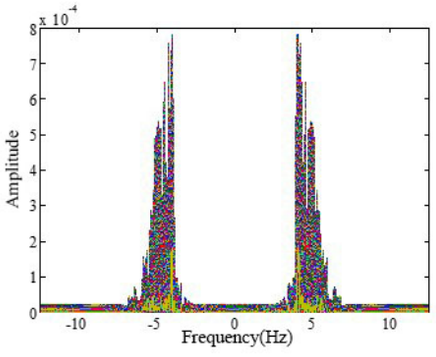
3.3 *Reliability analysis of suspender based on cable force monitoring data*

Using the frequency m ethod to test the cable force, through the ICP sensor installed on the boom (as close as possible to the m iddle of the boom) test structure of the natural vibration frequency, the IMC module connect to the com puter, using artificial or environmental incentives to collect signals, then analysis the first few order vibration frequency and calculate the cable force.

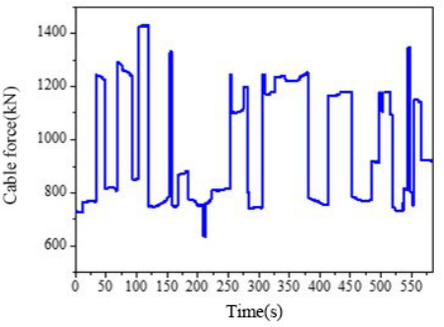


There we choose the m id-span suspenders of the bridge as an example. Like the former analysis steps, smoothing the original data and analyzing the spectral. After resample, the ARMA model is established to process and analyze the cable forces. The relative results are shown in the following Figure 7.

(a) The spectrum of the original data

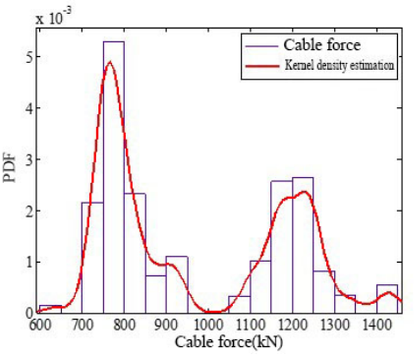


(b) Resample time series

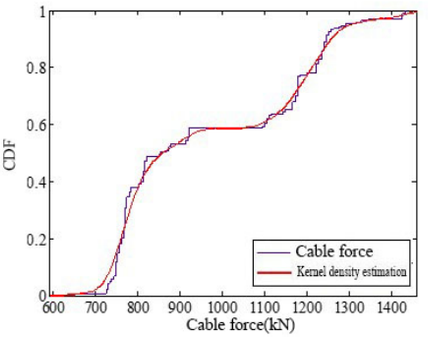


(c)Comparison of prediction effect of each model

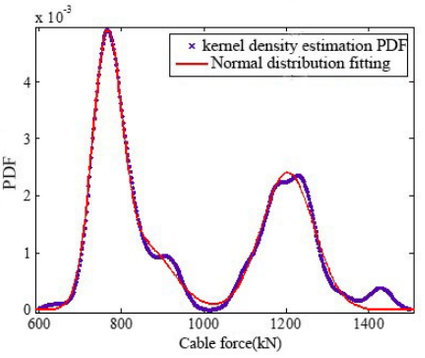
Figure 7 The results of data selection



For obtaining the reliability, identif ying the instantaneous frequency and calculating the boom cable force, the results shown in the Figure 8. Then using the kernel density estim ation method to estimate the probability density f unction of the suspender force data, and the reliability indices of the suspender are calculated using the MCMC sim ulation method like the former step.



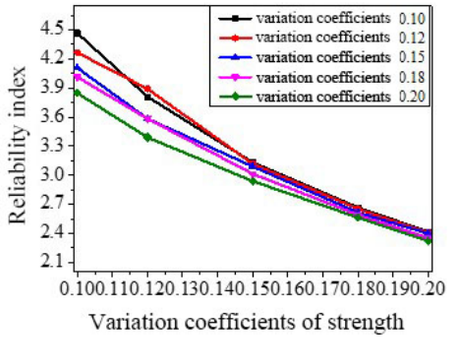
(a) Signal instantaneous spectrum



(b) The suspender axial force

(c) PDF Fitting

(d) CDF Fitting



(e) Cable force distribution using kernel density estimation

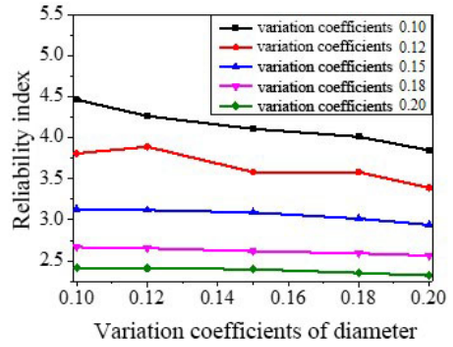


Figure 8 The results of reliability analysis

In fact, the coefficient of variation of the strength and diameter of the strand is very sm all, usually slightly less than 0.1, but due to computer limitation, when the coefficient of variation is given sm all, the

MCMC simulation method will sample too many times. It is difficult to extract the failure state. Therefore, this paper assumes that the both coefficient of variations are 0.1, the MCMC sampling is carried out for 1 million times, and calculate its reliability. We choose the variation coefficients slightly larger than 0.1 to investigate the effects of the variations of strength and diameter on the reliability assessment. The results are shown in the Figure 9.

(a) Effects of the variations of strength

(b) Effects of the variations of diameter

Figure 9 The results of effects analysis

4 CONCLUSION

The details of establishing the ARMA model have been presented, and an improved parameter estimation algorithm is introduced. Compared with the traditional least squares method, the improved method's convergence speed is faster, and the significance of the parameter estimation is also improved.

Based on the vertical acceleration data of the main beam of Yitong River Bridge, the ARMA model is established. It is proposed to combine the order criterion and the time series correlation analysis to determine the order of several possible orders, modeling and comparison, and select the better ARMA model. The results show that the short-term prediction accuracy and trend of ARMA model are relatively high. Time series analysis method is feasible in the field of bridge health monitoring data processing.

Based on the deflection monitoring data, the kernel density estimation method is used to estimate the probability density function of the deflection data of the unconventional distribution, and the MCMC method is used to calculate the reliability indices corresponding to the serviceability limit states. The results show that the reliability indices of the serviceability limit states of the main beam decreases with the increase of the deflection limit.

Based on the data of the boom cable axial force, the ARMA model is established. The probability density function of the cable force is estimated by the kernel density estimation method. The MCMC method is used to calculate the reliability indices of the suspender. Then the effect of the variations of strength and diameter on the reliability assessment is investigated. The results show that the reliability of the Yitong River bridge is good, and the effects of variability of the strength is bigger than that of the cable diameter.

Assessment of Terrorism Risk Mitigation Measures for Iconic Bridges

Sebastian Thöns
Technical University of Denmark, Lyngby, Denmark
Mark G. Stewart
The University of Newcastle, New South Wales, Australia

ABSTRACT: This paper describes the assessment of the cost efficiency of risk mitigation measures for terrorist attacks with Improvised Explosive Devices (IEDs) for an iconic bridge structure. The assessment is performed with a decision theoretical framework building upon very recent advances in the framework of the COST Action TU1402 on Quantifying the Value of Structural Heath Monitoring. The decision scenario is formulated for a decision maker constituting an authority responsible for the societal safety of the infrastructure and consequently the direct risks for the infrastructure owner and the indirect risk due to fatalities and importance of the infrastructure are considered. The mitigation strategies are classified within the decision theoretical context as protection measures, which may be implemented in the design phase of a bridge, and as control, i.e. information acquirement, strategies. The identification of efficient measures for risk mitigation is based on (1) the risk and expected cost based optimization of actions and information and their combination before implementation, (2) on quantifying and assuring significance in risk reduction and (3) on the quantification of the uncertainties associated to the implementation. These criteria ensure a transparent decision and the performance of the measures before strategy implementation. It is found that the decision is relying on the identification of the threat level and that control strategies may be in favor as their costs are adjustable. However, for very high threat levels, bridge protection strategies or protection strategies in combination with control strategies may be more cost efficient.

1 INTRODUCTION

The study of protective measures and their efficiency for terrorist threats constitutes an important topic of research and is challenged by the seemingly permanent terrorist threats and by risk-averse regulative measures e.g. in US (e.g. Stewart and Mueller (2014), Ellingwood (2006), Stewart (2017), Xiao et al. (2017), Mueller and Stewart (2016) and SeRoN Consortium (2012a)). Many aspects like the explosive loading and structural performance modelling (e.g. Xiao et al. (2017), Bedon et al. (2018), Mouritz and Rajapakse (2017) and Netherton and Stewart (2010)), the improvised explosive device performance (e.g. Grant and Stewart (2017)), the design for explosive loads (Stewart (2018)) are extensively covered. However, (1) the combined assessment of the performance of information acquirement strategies with risk mitigation measures and (2) the explicit formulation of the optimization of the risk mitigation strategies in an explicit decision theoretical framework has hardly been performed.

This study aims thus to explicate efficient information acquirement and protective measures for terrorism risk reduction in a decision theoretical framework by utilizing the Bayesian prior and pre-posterior decision theory to assess and optimize the counter-terrorism strategy effectiveness before strategy implementation.

The decision theoretical approach is formulated in Section 2 distinguishing counter terrorism protection measures, which may be implemented in the design phase of a bridge, and control, i.e. information acquirement via surveillance, strategies and accordingly prior and pre-posterior decision analyses. The objective function for the calculation and optimization of the risk and the expected benefits and costs in dependency of the decision variables strategies and information and action parameters of strategies is formulated. Section 3 contains the description of the decision scenarios in the context of Improvised Explosive Device (IED) attacks to large iconic bridges and the development and discussion of the probabilistic information, information precision, action and system states and consequence models for the individual risk mitigation strategies. The results for the protection strategy and control optimization are

shown in Section 4 and the optimal decision variables are explicated and explained. The paper concludes with a discussion of the boundaries of the analysis and insights gained beyond its specifics in Section 5 and with a summary and the conclusions in Section 6.

2 APPROACH

The approach of assessing information and protection measures for structures under terrorism attacks takes basis in the framework for Structural Integrity and Risk Management as developed in Thöns (In Press) and Faber et al. (2017). Figure 1 shows an adapted decision tree distinguishing a do-nothing (i.e. business as usual) branch and risk mitigation strategies with and without additional information acquirements. The branches are classified into choice nodes for decision variables and chance nodes for probabilistic models associated to the choice nodes.

The decisions are based on the maximisation of the benefits, i.e. the minimisation of the expected cost and risk in dependency of the choices, i.e. decision variables. The expected benefit for the strategies without and with additional information: $B_{1,i}\left(a_{i,l}^{\ *}\right)$ and $B_{2,i}\left(i_{i,j}^{*}, a_{i,l}^{\ *}\right)$ respectively, are defined with the strategy-optimal actions $a_{i,l}^{\ *}$ and the optimal information acquirement strategy $i_{i,j}^{*}$. The expected benefit in the do-nothing-branch is denoted with B_0 and its system state $X_m \in \mathbf{X}$.

The expected benefits with no consideration of additional information $B_{1,i}\left(a_{i,l}^{\ *}\right)$ represent a prior decision analysis as they depend solely on the choice of actions $a_{i,l} \in \mathbf{a}_i$ and the – eventually action dependent - probabilistic system state models $X_m \in \mathbf{X}$:

$$B_{1,i}\left(a_{i,l}^{\ *}\right) = \underset{a_{i,l} \in \mathbf{a}_i}{max}\left(E_{X_m}\left[b_1\left(a_{i,l}, X_m\right)\right]\right). \quad (1)$$

The expected benefit with consideration of additional information $B_{2,i}\left(i_i^{*}, a_{i,l}^{\ *}\right)$ is dependent on the vector of information acquirement strategies $i_{i,j} \in \mathbf{i}_i$, their probabilistic outcome models $Z_{i,k} \in \mathbf{Z}_i$ and the strategy dependent set of actions and the system states. In the extensive form, the expectation over the posterior system states is calculated by Bayesian updating (operator E''_{X_m}) and the dependency on the system states is then marginalized with the expectation in regard to the probabilistic information outcomes with the operator $E_{Z_{i,k}}$:

$$B_1\left(i_{i,j}^{*}, a_{i,l}^{\ *}\right) = \underset{i_{i,j} \in \mathbf{i}_i}{max} E_{Z_{i,k}}\left[\underset{a_{i,l} \in \mathbf{a}_i}{max} E''_{X_l}\left[b_{2,i}\left(i_{i,j}, Z_{i,k}, a_{i,l}, X_m\right)\right]\right]. \quad (2)$$

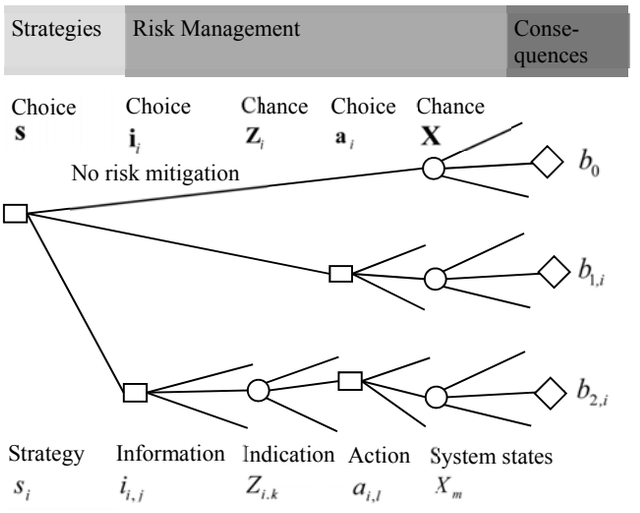

Figure 1: Decision tree for risk mitigation strategies

The value of the strategies may be expressed as the gain in expected benefits due to the identification of the optimal action strategy or the optimal information acquirement and action strategy:

$$V_{s_i} = B_{1,i}\left(a_{i,l}^{\ *}\right) - B_0 \ \text{ or } \ V_{s_i} = B_{2,i}\left(i_{i,j}^{*}, a_{i,l}^{\ *}\right) - B_0 . \quad (3)$$

The measure of significance of these information acquirement and/or action strategies is defined with relating the expected benefit gain to the expected benefit of the no mitigation base scenario:

$$\bar{V}_{s_i} = \frac{B_{1,i} - B_0}{|B_0|} \ \text{ or } \ \bar{V}_{s_i} = \frac{B_{2,i} - B_0}{|B_0|} . \quad (4)$$

3 DECISION SCENARIOS

In the following an iconic bridge with a value of €2.0 Billon or annual cost of €81 Million for a 100 year design life and an interest rate of 4% is considered. The decision maker is a public authority responsible for the safety of a large scale and iconic bridge. The objective of the decision maker is to minimize total risks for society and the bridge users and thus to implement mitigation strategies, which minimize the total risks and expected costs on an annual basis.

Two risk mitigation strategies are distinguished, namely, the implementation of protective measures in bridge design (strategy protect: s_1) and the implementation of a surveillance system in combination with bridge temporary closure during times of high threats (strategy control: s_2) taking basis in Stewart and Mueller (2014) and SeRoN Consortium (2012b).

3.1 *System state model and consequences*

The system states safe and bridge collapse are analyzed. The probability of a collapse is calculated with the probability of a threat $P(T)$, the conditional probabilities of a hazard $P(H|T)$ and collapse of the bridge $P(C|H)$, i.e.:

$$P(C) = P(C|H) \cdot P(H|T) \cdot P(T) \quad (5)$$

The probability of threat can be inferred by looking back to past threats and hazards. However, current threat information should also be accounted for and the estimation of the threat probabilities should be based upon information by police and security services. Such information are usually not public nor accessible by scientists. It should further be considered that large and iconic bridges may attract attackers more than typical highway bridges and it may also attract skilled attackers so that the likelihood of an attack increases (Stewart and Mueller (2014)). Thus, e.g. in US the San Francisco's Golden Gate Bridge or New York's Brooklyn Bridge might be a more tempting target for terrorists as evidenced by the 2002 poorly conceived (and quickly abandoned) plot to sever the stay cables of the Brooklyn Bridge with blowtorches [39].

The quantification of the threat probability in the U.S. based on the publicly known plots would result in 6.7E-6 per bridge per year. The basis are the Brooklyn bridge plot as the only one in 15 years against a large bridge in the U.S. and 1000 large/iconic bridges in the U.S. (Blue Ribbon Panel on Bridge and Tunnel Security (2003)). The 2002 plot to destroy the Brooklyn Bridge was more fanciful than a serious threat. Mueller (2018) summarizes the threat as "in 2002, Iman Faris traveled to New York City under orders from Khalid Sheikh Mohammed to survey possible terror targets within the United States. After basic internet research Faris decided on the Brooklyn Bridge as a potential target and believed that 'gas torches' could be used to bring the bridge down. However after conducting physical reconnaissance of the bridge (which consisted of driving over it once), Faris concluded that an attack was unlikely to succeed because of the bridge's structural design and because of the New York Police Department patrols there, and he never sought to acquire the equipment necessary for such an attack." There may be other threats that we are unaware of, but the threat level is likely to be less than one threat per year. No plots are publically known to the authors in Europe.

The conditional probability of a hazard $P(H|T)$ may be assessed by considering the construction, placement and successful donation of an explosive device. While the technical reliability of an IED detonation is high (Grant and Stewart (2012)), human errors play a significant role and reduce the probability of a successful attack. The past information for Western countries has been studied by Grant and Stewart (2017) for the time period of 1970 to 2013 concluding with success rate of up to 22% and a total average of 8%. Considering that an iconic bridge may be attacked by skilled terrorists, a triangular distribution with a minimum of 0%, a mode of 15% and a maximum of 25% is utilized, see also Stewart (2017).

The probability of a bridge collapse $P(C|H)$ depends on the scenario, i.e. the energy release of the IED charge, its location and the structural system and its robustness. The probability of a bridge collapse is assessed rather high to $P(C|H) = 90\%$ due to (1) skilled terrorist are assumed having being able to design a collapse scenario and (2) iconic bridges may have a highly utilized structural system with a low redundancy. Studies of progressive collapse of e.g. cabled stayed bridges (Das et al. (2016) and Mozos and Aparicio (2010)) point towards a high collapse probability for the assessed scenarios. Further, the need for more robust bridges is acknowledged and approaches can e.g. be found in Lonetti and Pascuzzo (2014).

The consequences of a bridge collapse encompass the property damage to the bridge structure and the vehicles on the bridge as the direct consequences and the costs from fatalities, the bridge reconstruction costs and the importance of the bridge in the road network. Based on EU project Security of Road Transport Networks (SeRoN: SeRoN Consortium (2012b) and SeRoN Consortium (2012c)), the total consequences are calculated to 7 times the bridge value. A Uniform distribution between 5 and 10 is herein used accounting for that the consequences may be significantly higher for iconic bridges and are uncertain.

3.2 *Prior decision analysis: Protective measures in bridge design*

The implementation of protective measures for the design of a bridge can be analyzed with a prior decision analysis and with probabilistic models of the system states and the mitigation actions in conjunction with the consequences and costs.

The protective measures are modelled with the annual costs and the risk reduction performance. Following Stewart and Mueller (2014) and SeRoN Consortium (2012b), a 5.0% additional investment in a protective measure (C_{Prot}) may lead to a risk reduction (ΔR) of 95% and a 3.3% investment may reduce the risk by 75%. These costs are annualized over a period of 100 years and the risk reduction-cost-relationship in Figure 2 is established.

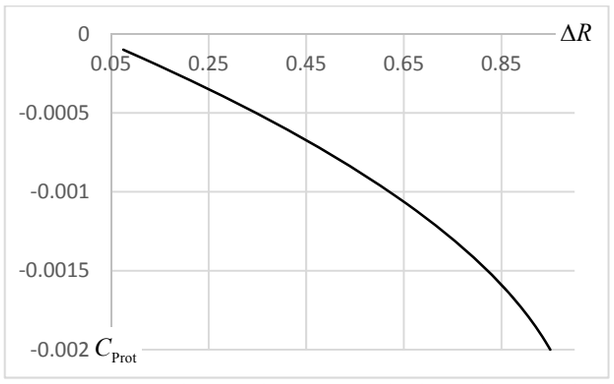

Figure 2: Costs of protective measure in dependency of their risk reduction performance.

The relationship implies that very high risk reduction measures may only be achieved with an over-proportional cost increase. Low to moderate risk reduction maybe achieved with an almost linear cost increase.

The probabilistic model for the protection measure strategy is summarized in Table 1.

Table 1: Probabilistic model for the prior decision analysis on the cost efficiency of protective measures (strategy: protect s_1)

Nodes, states		Consequences	Prob.
Protective actions	a_0	0	-
	$\mathbf{a}_{1,1}$	[-0.0001…0.002]	$\Delta R(\mathbf{a}_{1,1}) = [0.075…0.95]$
System states	X_0	0	$1-P(C)$
	X_1	U(-10.0,-5.0)	$P(C)$

U: Uniform distribution

3.3 *Pre-posterior decision analysis: Surveillance information and bridge closure*

A control strategy encompassing surveillance information in combination with bridge closure and detection actions can be modelled with a pre-posterior decision analysis. For example, if an imminent threat is detected the bridge may be temporally closed to allow for time to apprehend the terrorists or defuse an IED. The surveillance information are described with their detection performance, i.e. the indication and no-indication probabilities of threats in conjunction with the costs of the surveillance system investment and operation. The surveillance information model utilized here covers various strategies from enhanced incident detection (low costs as it may be integrated in the existing systems) to high cost systems with a high detection probability. Consequently, the indication probability given a threat and the no-indication probability given no threat, $P(\mathbf{Z}_{2,1}|T)$ and $P(\mathbf{Z}_{2,0}|\overline{T})$, respectively, are varied between 0.7 and 0.99 (Table 2). The posterior probabilities of bridge collapse $P''(C)$ are calculated with the updated threat probability:

$$P(T|\mathbf{Z}) = \frac{P(\mathbf{Z}|T)\cdot P(T)}{P(\mathbf{Z}|T)\cdot P(T) + P(\mathbf{Z}|\overline{T})\cdot P(\overline{T})} \quad (6)$$

$$\text{with } \mathbf{Z} = [\mathbf{Z}_{2,0}, \mathbf{Z}_{2,1}] \quad (7)$$

The costs of the surveillance systems C_{Surv} increase over-proportional with a higher rate for precise systems as shown in Figure 3.

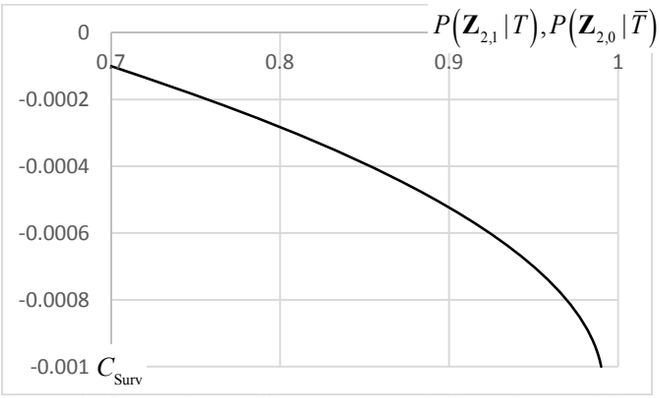

Figure 3: Costs of surveillance systems in dependency of their reliability.

The cost of the bridge closing are calculated with the bridge importance in the traffic network and the associated costs based on SeRoN Consortium (2012b) and SeRoN Consortium (2012c). A bridge closure of 2 days is assumed for attack prevention and eventual explosive charge detection, location and deactivation activities leading to costs of 2.72E-3 per year for the considered bridge. The bridge closure leads to a reduction of the consequences for bridge collapse by reduction of the property damage including a lower number of vehicles on the bridge and consequently a reduction of the costs due to fatalities, bridge reconstruction and traffic diversion. A Uniform distribution between a maximum of 5 and 1 is assumed (Table 2).

Table 2: Probabilistic model for the pre-posterior decision analysis on the cost efficiency of surveillance information (strategy: control s_2)

States	Consequences	Prob.	
i_2	[-1.0E-4… -1.0E-3]	-	
		X_0	X_1
$\mathbf{Z}_{2,0}$	-	[0.7…0.99]	[0.3…0.01]
$\mathbf{Z}_{2,1}$	-	[0.3…0.01]	[0.7…0.99]
$a_{2,0}$	0	-	
$a_{2,1}$	2.72E-3	-	
X_0	0	$1-P''(C)$	
X_1	U(-10.0,-5.0)	$P''(C)$	
$X_1 \mid a_{2,1}$	U(-5.0,-1.0)	$P''(C)$	

U: Uniform distribution

3.4 *Summary of strategies*

Figure 4 contains the detailed decision tree for the analysis of the protection strategy with a prior decision analysis and the control strategy with a pre-posterior decision analysis. It should be noted that the branch $\mathbf{Z}_{2,0} : a_{2,1}$, i.e. bridge closure in case of a no threat indication, is excluded.

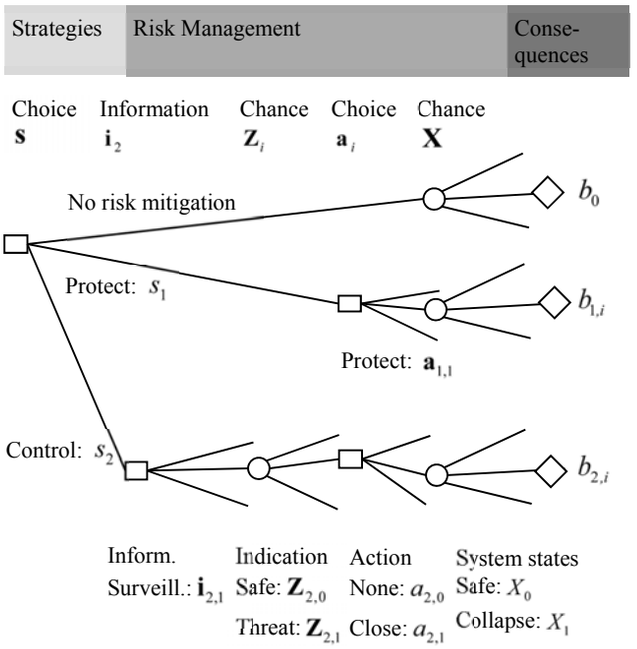

Figure 4: Decision tree for analyzed strategies

4 RESULTS

The established decision scenario is analyzed individually in detail for the protection strategy and the control strategy and then jointly by the explanation of the results and the identification of the optimal protection and/or control strategy on the basis of the minimum risk and expected costs, the strategy significance and success probability. The threat probabilities are chosen so that the protection and control measures just become the optimal decision.

4.1 *Analysis of protective measures*

The analysis and optimization of the protective measures in the design phase is performed for three threat levels. Figure 5 shows the minimum risk and expected costs dependent on the protection risk reduction. A change of the optimal action is indicated when the line becomes horizontal, e.g. at $\Delta R = 0.52$ for an annual threat probability of 1.7E-3 where the optimal action changes from protection to do-nothing. For increasing threat levels, the change of the optimal action shifts towards protection measures with a higher risk reduction and the curves become more peaked.

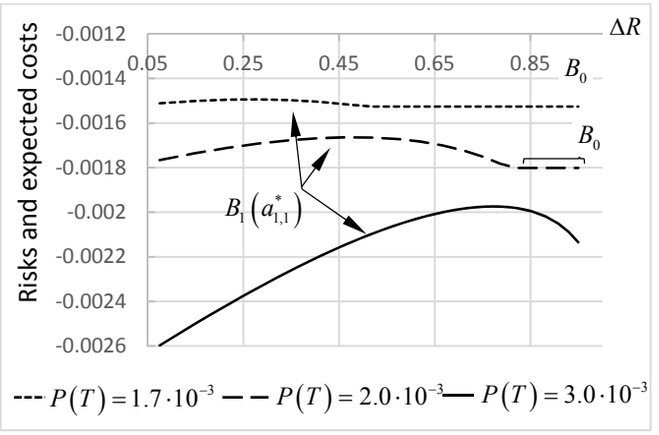

Figure 5: Minimum risks and expected costs in dependency of the protection risk reduction for different threat levels

The probability that the protection measure is cost efficient is calculated to account for the uncertainties in the models as the optimization and decision is based on the expectation. The probability decreases with an increasing risk reduction and increasing costs of the protective measure as well as with decreasing threat probabilities (Figure 6). It is independent of the minimum risk and expected cost in Figure 5.

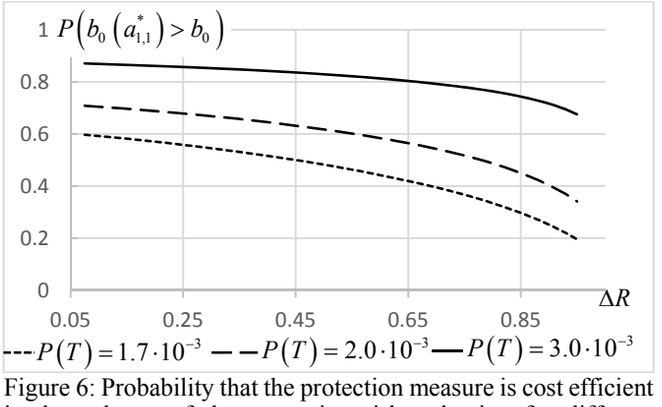

Figure 6: Probability that the protection measure is cost efficient in dependency of the protection risk reduction for different threat levels

The optimal protection measures are identified as the minima in Figure 5 and listed in Table 3. Only for a high threat level, a high level of the protection is optimal despite the over-proportional larger costs. It is noted that the cost efficiency probability of the protection is significantly higher in comparison to lower threat probabilities.

Table 3: Optimal protection strategy for different threat levels

$P(T)$	$\Delta R(a^*_{1,1})$	$C_{\text{Prot}}(a^*_{1,1})$	$P(b_0(a^*_{1,1}) > b_0)$
$1.7 \cdot 10^{-3}$	0.28	0.149%	0.50
$2.0 \cdot 10^{-3}$	0.46	0.166%	0.55
$3.0 \cdot 10^{-3}$	0.79	0.197%	0.77

4.2 *Analysis of surveillance information and bridge closure actions*

The analysis and optimization of the control strategy is performed for an annual threat probability of $P(T)=1.7\cdot10^{-3}$ to $P(T)=3.0\cdot10^{-3}$. Figure 7 shows sharp change of inclination in the curves for the threat probabilities 1.7E-3 and 2.0E-3. Here, the optimal action for a threat indication changes from do-nothing to closure of the bridge. The minimum risks and expected costs are located at relatively high threat indication reliabilities and according costs (see also Figure 3).

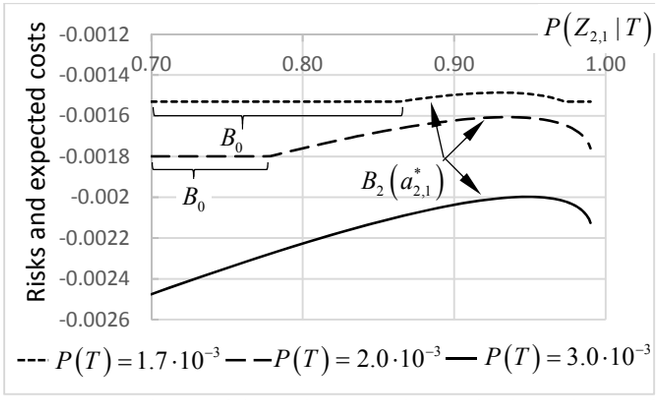

Figure 7: Minimum risks and expected costs in dependency of the surveillance performance for different threat levels

The probabilities that the surveillance and bridge closure strategy is cost efficient, increases with an increasing threat indication probability and corresponding surveillance strategy costs until the minimum risks and expected benefits are reached (Figure 8). The probabilities are highest for the highest threat probability.

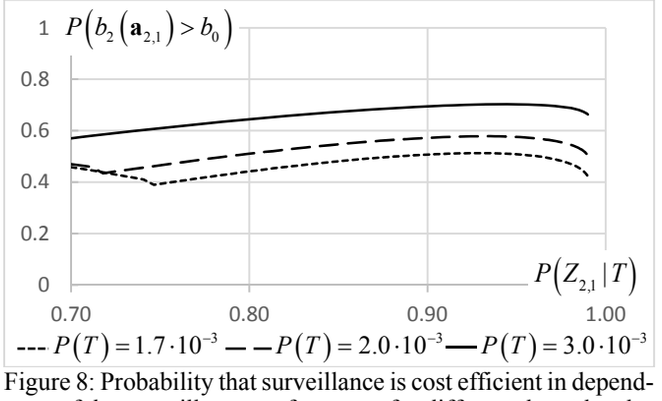

Figure 8: Probability that surveillance is cost efficient in dependency of the surveillance performance for different threat levels

The optimal surveillance strategies for the considered threat levels are very similar in indication reliabilities and associated costs (

Table 4). Only the probability of cost efficiency increases significantly for higher threat probabilities.

Table 4: Optimal surveillance strategy for different threat levels

$P(T)$	$P^*(Z_1\|T)$	C^*_{Surv}	$P(b_2(a^*_{2,1})>b_0)$
$1.7\cdot10^{-3}$	0.93	0.062%	0.51
$2.0\cdot10^{-3}$	0.94	0.064%	0.58
$3.0\cdot10^{-3}$	0.95	0.069%	0.70

Table 5 contains the identification of the optimal strategy for risk mitigation based on the minimum risk and expected costs together with the measures of significance as the relative value of the strategy, shown in Eqn. (4). Both risk mitigation strategies namely protection and control are risk and expected costs optimal for an annual threat probability of $1.7\cdot10^{-3}$. However, the measure of significance is very low, i.e. the implementation of a protection and control strategy reduces only insignificantly the risks and expected costs.

For a threat probability of $2.0\cdot10^{-3}$, the control strategy is more cost efficient with a significance of 10.7% risk and expected cost reduction in comparison to the do-nothing strategy. It is also noted that the probability of cost efficiency is slightly higher for the control strategy (see Table 3 and

Table 4).

A very significant risk and expected cost reduction of 26.0% and more can be achieved for an annual threat probability of $3.0\cdot10^{-3}$ for both strategies where the protection strategy leads to slightly lower risks and expected cost as well as a higher probability of cost efficiency.

Table 5: Expected benefits and measures of significance and optimal protection strategies (bold)

$P(T)$	Protect: s_1		Control: s_2	
	B_1	$\bar{V}_{s_1}$	B_2	$\bar{V}_{s_2}$
$1.7\cdot10^{-3}$	**$-1.49\cdot10^{-3}$**	**<1.00%**	**$-1.49\cdot10^{-3}$**	**<1.00%**
$2.0\cdot10^{-3}$	$-1.66\cdot10^{-3}$	7.60%	**$-1.61\cdot10^{-3}$**	**10.7%**
$3.0\cdot10^{-3}$	**$-1.97\cdot10^{-3}$**	**26.9%**	$-2.00\cdot10^{-3}$	26.0%

5 DISCUSSION

The efficiency of risk mitigation measures is largely dependent and the analysis is highly sensitive to the threat levels. Any decision should thus be based on knowledge of the threat levels. If the historical statistics, see Section 3.1, are considered leading to annual threat probabilities of 1.0E-5 or lower, no mitigation strategy is cost efficient.

Beyond the specifics of the decision analysis and taking into account the variation of the threat levels throughout the long service life of a bridge, it should be noted that the cost efficiency of surveillance can

be influenced by pausing operation for periods with low threat levels as this contributes largely to the annual costs. Hence, changing threats point to flexible and surveillance based systems. However, co-benefits for protective measures may be found e.g. in a higher earthquake resistance (Stewart (2017)).

A combination of protection and control strategies constitutes an attractive option for very high threat probabilities. However, for the analyzed threat probabilities, a combination will not be efficient, as the risk reduction by the protective measure will result in lower absolute values not being able to accommodate for the expected cost of the protection strategy.

6 SUMMARY AND CONCLUSIONS

This paper contains a cost efficiency assessment of risk mitigation measures for terrorist attacks with Improvised Explosive Devices (IEDs) for a large span and iconic bridge structure. The assessment is performed within a decision theoretical framework building upon very recent advances in the frame of the COST Action TU1402 on Quantifying the Value of Structural Heath Monitoring.

The decision scenario is formulated based on an authority responsible for the societal safety of the infrastructure and consequently the direct risks for the infrastructure owner and the indirect risk due to fatalities and importance of the infrastructure are considered. The risk mitigation strategies are classified within the decision theoretical context as protection measures, which may be implemented in the design phase of a structure, and as control, i.e. information acquirement, strategies. Whereas the protection measures can be analyzed with a prior decision analysis, the analysis of additional information requires a pre-posterior decision analysis and an appropriate modelling of the information before its acquirement.

The identification of efficient measures for risk mitigation is based on

1) The risk and expected cost based optimization of actions and information and their combination before implementation,
2) On quantifying and assuring significance in risk reduction and
3) On the quantification of the uncertainties associated to the strategy implementation.

All three criteria ensure a transparent decision and the performance of the measures at the decision point in time before implementation.

Specifically, it has been found in the analysis of protective measures:

- High performance and expensive protection measures are cost efficient for higher threat levels (larger than $3.0 \cdot 10^{-3}$). The probability of cost efficiency is higher than 0.77.
- For lower threat levels (between $2.0 \cdot 10^{-3}$ and $3.0 \cdot 10^{-3}$), low cost protective measures with a risk reduction of about 25% to 45% may be implemented.
- Below a threat level of $2.0 \cdot 10^{-3}$ protective measures should not be implemented as the probability of their efficiency is equal or lower than 50% and the risk and expected cost reduction is insignificant.

In contrast to the optimal protection strategies, the optimal control strategies are most efficient with relatively high costs and an associated high indication reliability.

- The optimal control strategies are relatively insensitive to the considered threat probabilities and may thus be identified very clearly. The optimal control strategies should have an indication reliability higher than 93% with annual costs equal to 0.062% (or higher for higher indication reliabilities) per year per bridge.
- For threat probabilities between $2.0 \cdot 10^{-3}$ and $3.0 \cdot 10^{-3}$, the control strategy has a slightly better performance than protective measures in terms of minimum risks, significance and success probability.
- Below a threat level of $2.0 \cdot 10^{-3}$ control strategies should not be implemented as the probability of their efficiency is equal or lower than 51% and the risk and expected cost reduction is insignificant.

Decision analyses in general and in conjunction with their complexity and computational demands should contain or provide interfaces (as with this paper) to (1) sophisticated models such as e.g. for the structural performance modelling for explosive loadings, (2) non-public (e.g. threat) information and (3) sophisticated information acquirement performance models. In return, these models and information should be available in the format, quality, and relevance required by the decision analysis to ensure transparent, consistent and sustained decisions. The interface design, the model development and availability are seen as the most challenging aspects for the further evolution of decision analyses and their implementation, however, with a clear and substantial potential to benefit society.

ACKNOWLEDGEMENTS

The COST Action TU1402 on Quantifying the Value of Structural Health Monitoring (www.cost-tu1402.eu) is gratefully acknowledged for the inspiring discussions, contributions and workshops across the scientific and engineering disciplines with researchers, industrial experts and representatives of infrastructure operators, owners and authorities.

Evaluation of fatigue crack propagation considering the modal superposition technique

C.S. Horas & G. Alencar & R. Calçada
CONSTRUCT-LESE, University of Porto, Faculty of Engineering, Portugal

A. Jesus
INEGI, University of Porto, Faculty of Engineering, Portugal

ABSTRACT: In large Civil Engineering structures, such as bridges, the fatigue damage assessment is highly conditioned by the computational demands of global and detailed local models required to properly analyse the structural behaviour under cyclic loads. The dynamic analysis using direct time-integration algorithms is unfeasible in most of the cases, which leads to the necessity of considering the modal superposition concepts for such applications in order to increase the efficiency and accuracy of investigations concerning the fatigue crack propagation problem. In this regard, Albuquerque et al. (2012; 2015) proposed and implemented a computational algorithm aiming at predicting the remaining fatigue life of cracked details. Although, despite its computational efficiency, additional and relevant improvements may be proposed in order to allow precise and detailed fatigue analyses compatible with the pace of design, maintenance and strengthening operations of new or existing aged bridges.

1 INTRODUCTION

The planned railway network in Europe demands the existence of a considerable number of infrastructures, such as bridges and tunnels. Naturally, with the increase of the speed of circulation, the requirements for a safe operation on railway lines are more restricting, leading to the necessity of designing new structures or strengthen the existing ones. In Europe, there are, approximately, 300000 railway bridges and 3500km of railway tunnels that are close to or over the end of their planned service life. The replacement on a large scale of such number of infrastructures would not be economically feasible or realistic. Therefore, an extension of their service life shall be a major priority (European Union 2015).

Among the most important structural issues, fatigue is a particularly relevant cause of concern regarding the structural integrity of existing and operating bridges. The consciousness of fatigue phenomena only arose some decades ago, which means that when the first metallic bridges were designed this behaviour was not taken into account. Such drawback, led to a vast number of operating bridges where no structural verifications regarding cyclic loadings were carried out. This situation implies that the performance of such structures shall be carefully monitored in order to avoid global or local structural failures. As abovementioned, the development of monitoring systems, considering the recent improvements on numerical modelling capabilities, is essential to avoid fatigue cracks or control their propagation, to estimate the residual life of existing structural components and assess the necessity of strengthening operations.

Several methodologies have been proposed in the most important standards and guidelines in order to evaluate the fatigue damage (BSI 1980; AASHTO 2012; Hobbacher 2016). The approach based on nominal stresses and S-N curves is the most used one. Although, several of its limitations have been pointed out, being particularly important the impossibility of assessing the evolution of the fatigue cracking in existing structural members (Horas et al. 2016). In this regards, alternative approaches based on the Fracture Mechanics principles have been suggested to assess the crack propagation issues (Albuquerque et al. 2012).

Understanding cracks propagation under cyclic loadings, from the material scale until the occurrence of a global or local structural failure, have been possible due to the evolution of Fracture Mechanics principles. Most of fatigue analyses based in such concepts underlies on the Paris law (Paris et al. 1961) which suggests that, on elastic domain and for a stable propagation regime under constant amplitude loading, the fatigue crack propagation rate, da/dN, may be related to the corresponding stress intensity factor range, ΔK.

Several implementations of the Fracture Mechanics concepts have been performed in distinct engineering areas using numerical models based on the Finite Element Method (FEM). In such cases, the direct time-integration of the dynamic problem may be achieved implementing algorithms such as the Newmark (Bathe 1996) and Hilbert-Highes-Taylor (HHT) (Chung & Hulbert 1993). Although, such approaches usually require the computation of an enormous number of load steps which leads to unattainable computational requirements when local detailed analyses are needed. In this context, the modal superposition appears as a most efficient solution for investigating the crack growth over the time (Albuquerque et al. 2015; Horas et al. 2017).

In the Civil Engineering context, the difference between the global scale of structures (metres or kilometres) and the localized occurrence of fatigue phenomenon may be a relevant issue for accurate numerical investigations. This multi-scale problem may be overcome considering submodelling techniques which allow combining relevant simplifications of the global numerical model without neglecting the precise calculation of local stress and strain fields, indispensable to evaluate the fatigue damage (Kiss & Dunai 2000; Li et al. 2007; Teixeira 2015; Albuquerque 2015).

Taking into account the presented framework, it is important to develop advanced numerical tools to evaluate the structural integrity of large railway bridges in the different stages of their lifetime. Therefore, the aim of this paper is to suggested improvements to the computational algorithm proposed by Albuquerque et al. (2012;2015), based on modal superposition concepts, in order to maximize its computational efficiency and make its application compatible with the pace of design, maintenance and strengthening operations typical of large Civil Engineering structures.

2 THEORETICAL BACKGROUND

The theoretical concepts underlying the approached strategy to investigate the fatigue damage related to crack propagation issues, linking the modal superposition and Linear Elastic Fracture Mechanics principles, are detailed in the present section.

2.1 *Modal superposition concepts*

A structural system subject to cyclic loadings presents a dynamic behaviour extremely dependent on both the structural and loading characterization. If, for a certain time step, t, the mass, stiffness, damping and acting nodal forces are known, the dynamic response may be computed considering direct-time integration algorithms or the modal superposition technique. In such conditions, the dynamic behaviour of the structural system with N degrees of freedom may be defined by NxN simultaneous equations:

$$M.\ddot{u}(t) + C.\dot{u}(t) + K.u(t) = F(t) \quad (1)$$

where, associated with the N degrees of freedom, M is the mass matrix, C the damping matrix and K the stiffness matrix, each with NxN dimension. Also, for a certain time instant, u(t), u̇(t) and ü(t) are, respectively, the displacement, velocity and acceleration matrices and F(t) the nodal forces matrix, each of them defined by Nx1 terms.

When a loaded structure remains elastic and its properties are constant along the time, the systems of equations (1) may be decoupled into N independent equations which may be individually solved (Clough & Penzien 1975):

$$\ddot{Y}_j(t) + 2w_j.\xi_j.\dot{Y}_j(t) + {w_j}^2.Y_j(t) = f_j(t) \quad (2)$$

where, for the j^{th} mode of vibration, $Y_j(t)$ and $f_j(t)$, are, respectively, the matrix of modal coordinates and matrix of nodal forces, related to the N degrees of freedom. Also, w_j and ξ_j are modal quantities, respectively, the frequency and the damping coefficient.

Albuquerque et al. (2012) suggested the concept of modal stress intensity factor to evaluate the crack propagation integrating successively the Paris law. Such approach allows calculating the stress intensity factor time-histories, K(t), as the sum of static and dynamic parts, respectively, K_{sta} and $K_{dyn}(t)$, naturally related to the static and dynamic stresses, σ_{sta} and $\sigma_{dyn}(t)$. Therefore, K(t), may be computed as follows:

$$K(t) = K_{sta} + K_{dyn}(t) \quad (3)$$

$$K_{sta} = Y.\sigma_{sta}.\sqrt{\pi a} \quad (4)$$

$$K_{dyn}(t) = Y.\sigma_{dyn}(t).\sqrt{\pi a} \quad (5)$$

where, Y is a parameter associated with the geometrical characteristics of the structure and crack. According to the presented concepts, the $\sigma_{dyn}(t)$ may be calculated according to:

$$\sigma_{dyn}(t) = \sum_j \sigma_j \,.\, Y_j\,(t) \quad (6)$$

In equation (6), σ_j is defined as the modal stress dependent on the j^{th} modal shape, $Y_j(t)$. Considering equations (5) and (6), the concept of modal stress intensity factor may be defined:

$$K(t) = K_{sta} + \sum_j K_j \,.\, Y_j\,(t) \quad (7)$$

The reasoning underlying the definition of modal stress intensity factor may be extended to other local parameters such as stresses, strains or energetic quantities. Thus, equations (3) and (7) may be re-written in a general form:

$$\psi(t) = \psi_{stat} + \sum_j \psi_j \,.\, Y_j\,(t) \tag{8}$$

where, ψ is a generic fatigue quantity, ψ_{stat} the part associated with the static loading and ψ_j the modal quantity related to the j^{th} modal shape. Naturally, as demonstrated by equation (8), the modal superposition concepts may be extended to different local parameters related to the fatigue crack initiation and crack propagation damages.

2.2 *Propagation of fatigue cracks*

As demonstrated by Horas et al. (2017) and Albuquerque et al. (2012), respectively, for fatigue crack initiation and crack propagation, the numerical analysis of cracking phenomena requires a well-defined fatigue model.

According to the loading characterization, pure or mixed-mode crack propagation may occur. Regarding, the uniaxial ones, mode I (opening mode), mode II (sliding mode) and mode III (tearing mode) may be defined. Logically, equation (7) may be adjusted to calculate the corresponding K values:

$$K_I(t) = K_{I,stat} + \sum_j K_{I,j} \,.\, Y_j\,(t) \tag{9}$$

$$K_{II}(t) = K_{II,stat} + \sum_j K_{II,j} \,.\, Y_j\,(t) \tag{10}$$

$$K_{III}(t) = K_{III,stat} + \sum_j K_{III,j} \,.\, Y_j\,(t) \tag{11}$$

where, K_I, K_{II} and K_{III} are the stress intensity factors related to the defined pure propagation modes. For simple loading conditions, as already mentioned, Paris et al. (1961) established a relation to characterize the influence of the stress intensity factor range, $\Delta K = K_{max} - K_{min}$, on the crack propagation rate, da/dN:

$$\frac{da}{dN} = C.\Delta K^m = C.(Y.\Delta\sigma.\sqrt{\pi a})^m \tag{12}$$

where, C and m are material parameters. Although, generally complex structures such as bridges are subjected to complex dynamic loadings which give origin to mixed-mode propagation. In such cases, Tanaka (1974), among others, proposed the concept of equivalent stress intensity factor, K_{eq}, for mixed-mode (I+II) cases:

$$K_{eq}(t) = \sqrt[4]{K_I^4(t) + 8K_{II}^4(t)} \tag{13}$$

Associated with $K_{eq}(t)$, the histogram of $\Delta K_{eq,i}$ in function of the respective number of cycles, n_i, may be obtained considering a cycle counting method as the rainflow (Matsuishi & Endo 1968). Therefore, taking into account equation (12) and (13), the value of the crack increment, Δa, may be calculated integrating the Paris law:

$$\Delta a = \sum_i n_i \, C \Delta K_{eq,i}{}^m \tag{14}$$

Subsequently, the crack path may be defined considering a crack branching criteria. One of the most implemented is the maximum tangential stress criterion (MTS) suggested by Erdogan & Sih (1963). Applying this approach, the kink-angle time-history, $\theta(t)$, may be obtained as follows:

$$\theta(t) = \cos^{-1}\left(\frac{3K_{II}^2(t) + \sqrt{K_I^4(t) + 8K_I^2 K_{II}^2(t)}}{K_I^2(t) + 9K_{II}^2(t)}\right) \tag{15}$$

where, θ is the angle between a certain crack plane at the instant of time *t* and the crack initial plane, being its signal determined according to the classical local coordinate system of Fracture Mechanics and considering the value of K_{II} (θ is positive is K_{II} is negative).

Once defined $\Delta K_{eq,i}$ and n_i, the equivalent kink angle, $\bar{\theta}$, may be calculated through a weighted average function (Fracture Analysis Consultants 2011):

$$\bar{\theta} = \frac{\sum_i^n \frac{da}{dn}(\Delta K_{eq,i})\theta_i(K_I, K_{II})}{\sum_i^n \frac{da}{dn}(\Delta K_{eq,i})} \tag{16}$$

Considering equations (14), (15) and (16), for each $\Delta K_{eq,i}$ and n_i, Δa and the associated $\bar{\theta}$ may be computed allowing to define completely the cracking path.

2.3 *Submodelling*

In general, for large structures the global numerical model is able to properly reproduce the dynamic global behaviour, even when built with beam or shell elements discretized with coarse meshes. However, when local analyses are required, much more refined local modelling, using shell or volumetric elements, are needed. Such detailing is difficult to achieve using only the global model. Therefore, submodelling techniques, which allow considering the global-local interaction between numerical models, may be implemented. Among the submodelling techniques, the shell-to-solid is particularly useful since the displacement fields obtained at the global model are inputted into the submodel considering the appropriate shape functions without any geometrical constraints (Silva 2015; Albuquerque 2015).

2.4 *Computational workflows: single and parallel computing processes*

The presented theoretical concepts may be implemented integrated into computational algorithms. Albuquerque et al. (2012; 2015) proposed a workflow to assess fatigue cracking problems based on the modal superposition principles and single computing. Such computational algorithm is outlined in Figure 1 and may be summarized in the following steps:

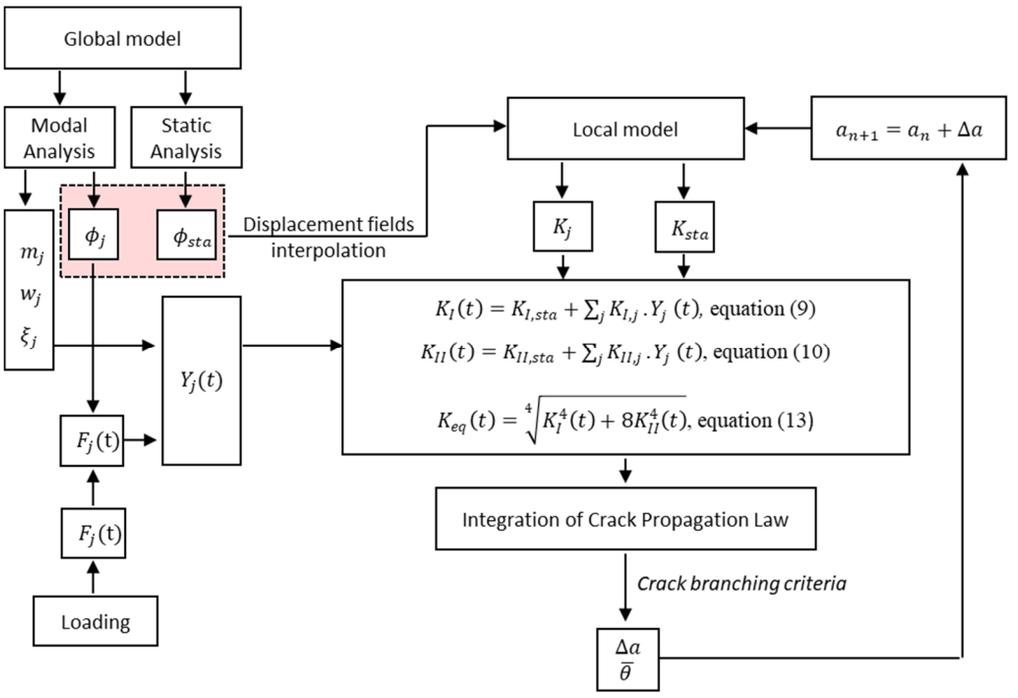

Figure 1. Computational algorithm for crack propagation analysis (with submodelling)

i. Calculation of the displacement fields due to the static loading, Φ_{stat}, corresponding static stress intensity factor, K_{stat}, and consistent sign;
ii. Modal analysis of the structure obtaining, for each j^{th} vibration mode, the value of K_j and corresponding sign. Computation of modal frequencies, ω_j, modal masses, m_j, mode shapes, Φ_j, and definition of modal damping coefficients, ξ_j;
iii. Evaluation of the dynamic loading, F(t), and determination of the modal forces, $F_j(t)$;
iv. Calculation of the modal coordinates time-histories, $Y_j(t)$;
v. Displacement field interpolation;
vi. Computation of K(t) for a certain crack length, a_n, applying equations (9), (10) and (13), being $K_I(t)$ equal to zero when its value is negative because contact (crack closure) algorithms are not considered at the crack faces;
vii. Application of the rainflow counting method in order to calculate $\Delta K_{eq,i}$ and n_i;
viii. Integration of the selected crack propagation law, e.g. equation (14) (Castro & Meggiolaro 2009);
ix. Evaluation of Δa and $\bar{\theta}$ allowing the subsequent modification of the local cracked model, considering the new crack length, a_{n+1};
x. Re-initiation of the cyclic process until the stop criterion is reached, generally the material toughness, K_c, or geometric constraints.

The described workflow may be applied to multiple complex dynamic events, e.g. successive passages of trains. Although, for the sake of computational efficiency, when multiple trains are considered, it is advisable adopting constant crack increments between iteration, Δa_{inc}. Therefore, the increase of the crack due to a block of trains (e.g. daily trains) should be scaled by $B_n=\Delta a_{inc}/\Delta a$, being B_n the number of loading blocks needed to achieve Δa_{inc}.

The presented algorithm is based on a single computing approach. However, if the modal superposition principles are adopted, the previously described step vi. is a decoupled process and for each j^{th} vibration mode only one independent calculation is required. Thus, a multiple computing process may be implemented allowing to perform such step multiple times at the same time. In Figure 2, a scheme of the main concepts behind the parallel computing is presented. In mathematical terms, the number of parallel processes is only limited by the considered number of j^{th} vibration modes, although, due to computational restrains, a small and controlled number of parallel processes are generally adopted.

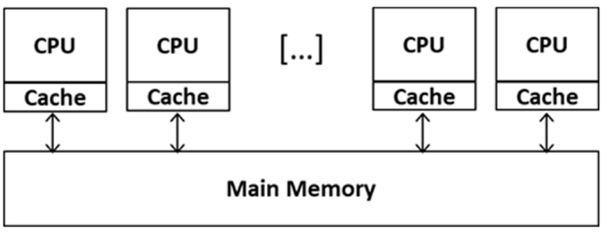

Figure 2. Scheme of a shared memory multiprocessing

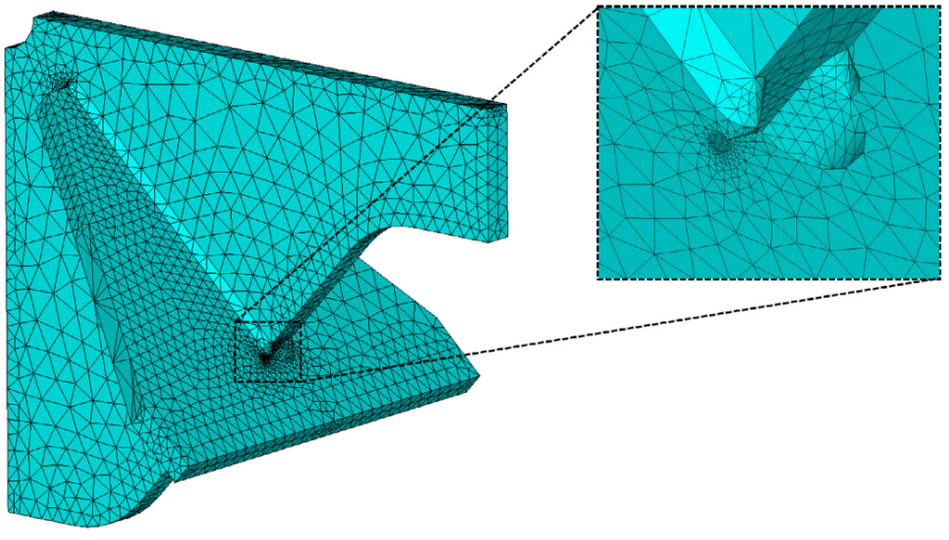
3 IMPLEMENTATION IN A CASE STUDY

In the present paper, the results obtained after implementing the described approach, to assess the fatigue crack propagation in a complex welded detail of a Portuguese railway bridge, are presented. A special focus is given to the improvements in the computational efficiency achieved after considering the parallel computing.

3.1 *Alcácer do Sal bridge*

The structure analysed is a bowstring metallic bridge, located in the Lisboa-Algarve railway connection, composed of 3 spans with 160 m suspended by tension rods. The cross-section is materialized by a concrete deck lying over a trapezoidal box-girder. Also, at the connection between the deck and the tension rods, additional steel diaphragms linked to 2 diagonal strings provide supplementary strength. Such diagonals are 600mm wide and present a thickness of 35mm.



Albuquerque et al. (2015) performed initial fatigue studies in the Alcácer do Sal bridge. For such purposed, the authors developed a global model, conceived with beam and shell elements, and local numerical models, built with volumetric/solid elements. A shell-to-solid submodelling technique was considered. In order to determine the most fatigue-prone detail, initial static analyses were carried out and the denominated diaphragm 51 was identified as the critical one. At the toe of its weld filament, a high-stress concentration was found, which allowed concluding that a potential small defect would increase the possibilities of locally starting a cracking phenomenon. Thus, at such location and considering that the approached methodology aims at investigating the crack propagation process, a small initial defect was considered (Figure 3).

b) steel diaphragm and diagonal strings

c) submodel of the welded detail

Figure 3. Partial view of the bridge and developed local numerical model (Albuquerque 2015)

3.2 *Dynamic analysis assumptions*

In modal superposition analyses, a constant modal damping ratio, ξ, of 0.5% was assumed for all the considered vibration modes as proposed by EN1991-2 (CEN 2003) for steel and composite bridges. The remaining modal properties, ω_j and m_j, were computed according to the structural characteristics.

The fatigue model was defined considering experimental investigations performed on specimens with thickness and material properties similar to the assumed cracked detail. In such tests, the material toughness, K_c, equal to 1434 MPa$\sqrt{mm}$ was determined as the limit for the stable propagation regime (Carvalho et al. 2014). Also, a value of 63 MPa$\sqrt{mm}$ was defined for the stress intensity factor threshold, ΔK_{th}, with basis on the suggestions of BS7910 (BSI 2013) (Table 1).

Table 1 - Adopted parameters for fatigue analysis

C	m	ΔK_{th} (MPa.$\sqrt{mm}$)	K_c (MPa.$\sqrt{mm}$)
9.93×10^{-14}	3.14	63	1434

Previously, Albuquerque et al. (2015) assumed an initial defect of 15 mm and considered the contribution of 1500 vibration modes. In the present paper, an initial crack length of 1 mm was considered, which is believed to be a better approximation to the beginning of the crack propagation. Regarding the number of modes, it is easily understandable that in a large structure a considerable number of vibration modes does not contribute to the value of the stress intensity factor at the crack front. Therefore, considering equation (7), a parametric analysis was performed in order to evaluate the contribution of each mode to the stress field at the assumed cracked area. A cut-off limit, ΔK_{cf}, was defined below which the contribution of a certain mode was disregard (Table 2).

Table 2 - Parametric analysis

ΔK_{cf} (MPa.$\sqrt{mm}$)	0.10	0.15	0.20	0.25
No. of modes	808	685	697	540

In Table 2, the number of vibration modes as a function of the cut-off stress intensity values are presented. When a reduced number of modes was considered a good agreement with the previous analysis results, taking into account 1500 modes, was stated comparing the values of $K_I(t)$, $K_{II}(t)$ and $K_{eq}(t)$ obtained from different calculations. Considering the presented results and seeking to found a compromise between the accuracy of results and computational efficiency, 685 vibration modes were adopted in the investigations detailed in the present paper. In order to have some figures, using a personal computer with a processor 3.4GHz i7-6700 CPU and 16 GB of RAM memory, after 29 increments and 64 hours of computation the value of K_c was achieved, on the other hand, when 685 modes were accounted for, time was reduced to 28 hours.

3.3 *Fatigue life predictions*

The assessment of the fatigue damage in the assumed cracked detail was performed considering the heavy traffic-mix, proposed in EN1991-2 (CEN 2003), and the real traffic circulating on the bridge evaluated by Albuquerque (2015). Also, as already mentioned, values of 15 mm and 1 mm were considered as initial defects.

Regarding the parallel computing analyses, considering 685 vibration modes, 4 parallel processes were defined, the first 3 considering 171 vibration modes and the last one the remaining modes.

Figure 4 presents the numerical crack propagation path when the critical toughness was achieved at the crack tip.

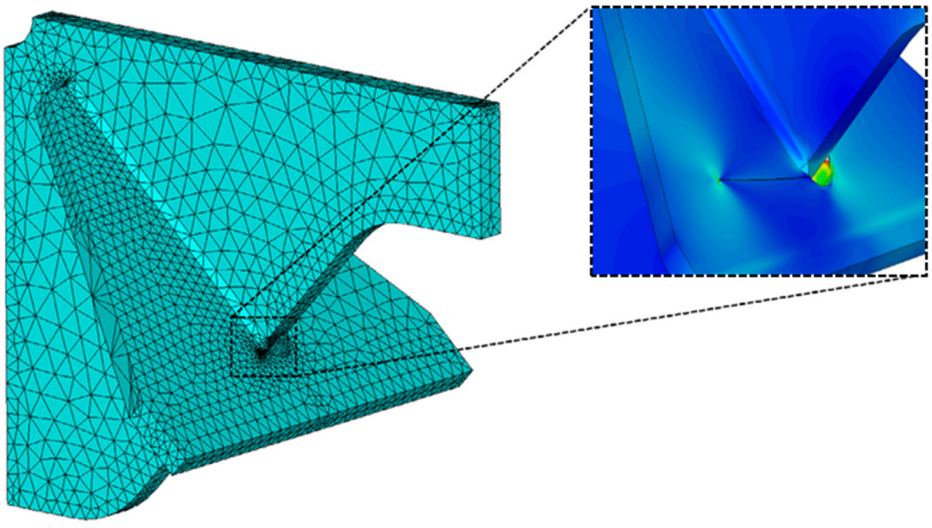

Figure 4. Crack propagation path: 685modes, iteration 29

Table 3 – Remaining fatigue life predictions (single and parallel computing)

Analysis	No. of modes	Traffic scenario	a_i (mm)	nº iterations	Computational time	Remaining life
(1)	1500	Heavy traffic-mix: EN1991-2 (CEN 2003)	15	29	64 hours	1 year and 10 months
(2)	685	Heavy traffic-mix: EN1991-2 (CEN 2003)	15	29	28 hours	1 year and 10 months
(3)	685	Real traffic: Albuquerque (2015)	15	32	33 hours	39 years and 8 months
(4)	685	Heavy traffic-mix: EN1991-2 (CEN 2003)	1	31	27 hours	2 years and 1 months
(5)	685	Real traffic: Albuquerque (2015)	1	35	33 hours	44 years

In Table 3, the main results accomplished after the performed analyses are detailed. Regarding the computational times, the efficiency when multiples processes were admitted increased significantly, being the calculation times 40% lower in such cases. Although, due to the depletion of the hardware capacity, as it is easily understandable, a linear relation between the adopted number of processes and the decreased of the computational time were not found. Naturally, the improvement of the personal computer capabilities should allow minimizing the required analysing time.

In which concerns to the remaining life results, threatening predictions were achieved when the standard traffic was assumed. Such data, besides proving that the actual traffic is considerably lower than the normative prescriptions, showed that a small defect due to accidental reasons or defective construction may put in risk the structural integrity at short time. However, it is important to highlight that such predictions are only valid when the crack initiation phase is completely developed. Aditional calculations, which are out of the scope of the present paper, showed that even the loading of the heavy traffic-mix is not severe enough to start a fatigue cracking phenomenon in the most stressed spot of the assumed cracked detail (Horas et al. 2018).

In general, the obtained results stress the importance of advanced numerical tools for design, maintenance and strengthening operations. Also, the hazard which a small defect represent for a fatigue-critical detail was demonstrated, highlighting the necessity of proper monitoring systems, in which the improved and investigated computational algorithm may be integrated, to control the structural performance of existing and operating bridges.

4 CONCLUSIONS

The improved methodology based on the modal superposition principles and Fracture Mechanics concepts, for fatigue assessment, proved to be appropriate for cracked details under mixed-mode (*I+II*) complex loadings.

With the main goal of investigating the assumed cracked detail of the Alcácer do Sal railway bridge, a set of analyses were performed considering different initial crack length assumptions and distinct traffic scenarios. If a small defect exists, the achieved results when the standardize traffic is considered may put in cause the global S-N methodology proposed in EN1993-1-9 (CEN 2005).

As concerns the computational efficiency, the reduction of the considered number of vibration modes and the adoption of the parallel computing were found to be major improvements. The achieved calculation times are within the pace of design, maintenance and strengthening operations typical of large Civil Engineering structures such as bridges.

I. Berger
Heritage Professional, Sydney, Australia

ABSTRACT: Lennox Bridge is a sandstone arch bridge located on Church Street over the Parramatta River in the Parramatta CBD in New South Wales. The Bridge was constructed in 1839 and is the second oldest road bridge still in operation in Australia, after Lansdowne Bridge completed in 1836. The bridge was widened with a reinforced concrete arch in 1935 and new portals were constructed through the abutments in 2014. The bridge is owned by City of Parramatta Council, managed by Roads and Maritime Services and listed on the State Heritage Register in NSW.

Parramatta Light Rail Stage 1 (PLR) is a new 12 km long light rail system that will operate between Westmead and Carlingford through the Parramatta CBD where the light rail will cross Lennox Bridge. A condition assessment of the bridge was undertaken as part of the asset assurance process for the retained assets in the light rail corridor. The condition assessment comprised combined geotechnical and structural investigations and a structural assessment. This paper discusses the asset assurance process and highlights the lessons learned for future applications.

1 INTRODUCTION

1.1 *The project*

Lennox Bridge is a masonry arch bridge located on Church Street over the Parramatta River in the Parramatta CBD in New South Wales. The Bridge was constructed in 1839 and is the second oldest road bridge in operation in Australia. The bridge is owned by City of Parramatta Council (CoPC) and Roads and Maritime Services (RMS) is responsible for the operation and management of the Bridge.

Parramatta Light Rail Stage 1 (PLR) will run from Westmead and Carlingford through the Parramatta CB where the light rail corridor will travel along Church Street and traverse Lennox Bridge.

Lennox Bridge comprises a single elliptical arch with a span of approximately 23.2 metres. The fabric of the original approach spans and arch spandrels consists of ashlar masonry and the voussoir stones of the arch are edged blocks (RMS, 2012). The bridge is 11.9m wide and was completed in two stages, the first 6.4m and the second 5.5m wide.

The bridge has undergone a number of significant modifications since. Sections of the stone arch were strengthened internally in 1901-2 for the new Parramatta-Baulkham Hills tramway. A cantilevered steel pedestrian footway was added to the western (upstream side) bridge in 1912 (RMS, 2012). The bridge was widened on the western side in 1935 by the addition of a reinforced concrete arch with stone facing which replaced the pedestrian footway installed in 1912.

In 2014 portals were introduced through the abutments of the bridge in order to improve access to and along the Parramatta River. The concrete balustrade on the eastern elevation was replaced with a new masonry parapet as part of this works.

PLR will connect Westmead and Carlingford via the Parramatta CBD. Lennox Bridge will form part of the light rail corridor and is one of a number of retained bridges in the new light rail corridor. A geotechnical and structural investigation of the 1839 bridge and a structural assessment was undertaken as part of the asset assurance process for PLR. This paper will discuss this process and outcomes.

2 HISTORY AND CONTEXT

2.1 *David Lennox*

David Lennox was born into a farming family at Ochiltree, Ayrshire in Scotland on 9 February, 1788.

In Britain, Lennox had worked on the vast Highland Roads and Bridges construction programme that was overseen by Thomas Telford. He was then engaged as a stonemason on the pioneering suspension bridge over the Menai Straits in North Wales designed by Telford before achieving the status of master mason in 1823. He spent a couple of years working on swing-bridges on the Gloucester and Sharpness Canal, followed by three years as foreman mason for the contractor John Cargill building Telford's iconic masonry arch bridge on the Severn at Over near Gloucester which was completed in 1829 (Alsop, 2014).

Figure 1 Portrait of Lennox taken in 1843 (then aged 55) (courtesy of Parramatta Visitors Centre).

Following his wife's death in 1828, compounded by a severe financial recession in Britain leading to mass unemployment, Lennox made the decision to emigrate to New South Wales. He landed at Sydney on 11 August 1832, carrying with him drawings of the bridges he had worked on, together with testimonials and letters of introduction which included one from Telford himself (RMS, 2012). One of Lennox's letters of introduction led to a meeting with the Surveyor-General of New South Wales, Thomas Mitchell (1792-1855) who secured for him the appointment of "Superintendent of Bridges" in 1832. His major outputs in NSW were Lapstone Bridge (1833), Berrima Bridge (1836), Lansdowne Bridge (1836) as well as Queens Wharf at Parramatta (1835) and the Liverpool Dam (1836). He transferred to Victoria in a similar position and retired there in 1853 following his construction of the Prince's Bridge across the Yarra River, a 150ft masonry arch which when completed in 1850 was among the longest and flattest arch bridges in the world.

2.2 *Former bridges on the site*

The location where Church Street crosses the Parramatta River is the site of the earliest documented river crossing in the Parramatta District, dating from the earliest years of the colonial settlement. Three bridges have been built on or immediately adjacent to this site which consequently possesses a high degree of archaeological potential.

Major Grose constructed a timber bridge at the end of Church Street across Parramatta River in 1794. The bridge was washed away in 1795, and replaced with a timber girder bridge, with stone piers. This bridge connected the early township to the area north of the river including the gaol, which was completed in 1797. During this period, the bridge at Church Street was referred to as The Gaol Bridge.

By the 1820s, the bridge was known as "Parramatta Bridge". It was in a state of serious disrepair by 1826, requiring temporary timber trestle supports.

2.3 *Design*

The last major bridge that Lennox designed and built in NSW was over the Parramatta River in Church Street, Parramatta. In September 1835 Governor Bourke's rejection of his design for the bridge triggered a dispute between Lennox and his superiors about the size and appearance of the bridge which delayed its construction by a year, causing Lennox to complain, 'I am tired of it before the work is commenced'. Eventually Bourke accepted his design for a 76ft span arch.

Lennox later wrote that Westgate Bridge at Gloucester was 'nearly the same in all respects as that at Parramatta'. Robert Smirke's Westgate Bridge had been completed in 1816 on a site less than a mile from Over Bridge, so Lennox would have had many opportunities to inspect it. It was demolished in the 1970s; photographs suggest the two bridges were only superficially similar.

Construction began in November 1836, using the centering from the Lansdowne Bridge, adjusted to the new span, and was completed in 1839. The Bridge was named Lennox Bridge by the Parramatta Council in 1867.

2.4 *Construction*

Lennox sourced the stone for the bridge from a quarry behind the Parramatta Female Factory. The Female Factory was a workhouse and was located in

what are now the grounds of Cumberland Hospital close to the bridge site.

Figure 2. Westgate Bridge at Gloucester built 1816, the inspiration for the design of Lennox Bridge.

Various gangs of masons and labourers were used on the different parts of the bridge structure. The more detailed arch work and double curved abutments was carried out by the bridge gangs, who were the most skilled members of the convict workforce (RMS, 2012). Labour issues slowed down construction as the Royal Engineers regularly requisitioned the bridge gang to work on the Parramatta barracks and gaol.

Lennox's plan was ' to build one half of the arch at one time and make the road passable over that part, until the other is completed'. The first completed section of the bridge was opened to traffic in September 1838 (RMS, 2012).

Lennox Bridge was the only bridge he built in NSW in an urban setting and it appears he took steps to ornament it. The central buttresses, arch keystone and certain horizontal string courses were constructed of a whiter stone as a deliberate act of the original design.

Figure 3. Lennox Bridge western elevation in 1930 highlighting the two tone colour scheme (RMS Photo Collection).

Lennox utilized a system of "hollow spandrels" whereby the roadway was carried by stone slabs supported on masonry walls over the arch barrel, forming voids which reduced the weight of backfill and created internal galleries that enabled construction surveillance of the arch and spandrel walls. This device had been used by Telford on Over Bridge and may possibly have been used by Lennox on the Prince's Bridge also.

The gallery design method as well as the two stages of construction, accounted for the greater cost of Lennox Bridge over and earlier bridge of Lennox design in NSW , the Lansdowne Bridge (RMS, 2012). The out turn cost of the Lansdowne Bridge £1083 pounds, whereas Lennox Bridge cost £1797 despite the fact that he reused the centering manufactured for the Lansdowne Bridge (RMS, 2012).

The western wing walls, which are now concealed behind the 1934 bridge were curved in plan.

2.5 *Alterations*

Located on the main north-south route of the Parramatta CBD the bridge has undergone a number of alterations reflecting the changing needs of the community. Sections of the stone arch were strengthened internally in 1901-2 to enable the Bridge to carry the new Parramatta-Baulkham Hills tramway. The tramway was extended to Castle Hill in 1905. The tramway across the Bridge opened on 18 August 1902 and closed in 1927.

The bridge was widened in 1935 by the addition of a reinforced concrete arch on the western side. The face of the concrete arch is covered with a stone façade.

The original design is still visible on the eastern side, the only alteration being the replacement of the original parapet with a concrete balustrade which was subsequently replaced with a new parapet in 2014.

Figure 4. Lennox Bridge General showing all three arches.

In 2014 Parramatta City Council commissioned the design and construction of pedestrian portals through the abutments of Lennox Bridge as part of the Parramatta City River Strategy to provide con-

tinuous level access via a shared path along the river to Parramatta Park. Excavation revealed, am ongst other things, an un-m ortared wall which appears to have been built to retain the fill supporting the road when the first half of the original bridge was being built. In addition the rem ains of a pier of the former timber beam bridge at the crossing were identified.

The balustrade on the eastern side of the bridge was replaced with a stone parapet m ore in keeping with the original design intent.

3 GEOTECHNICAL AND STRUCTURAL INVESTIGATION

3.1 *Boreholes*

A total of 8 boreholes were drilled to characterize the ground profile and identify the founding depths and materials of the bridge. Down-hole geophysics techniques were used in 6 of these boreholes, located in the riverbank areas next to each of the two abutments.

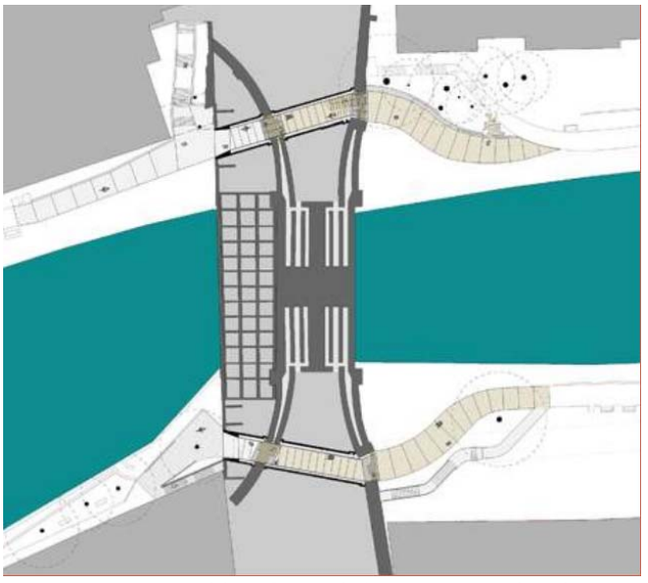

Figure 5. Lennox Bridge General Arrangement showing portals through the bridge. The curved wi ngwalls that were concealed by the 1935 western additi on are evident as are the internal galleries on Eastern (1839) bridge (Hill Thalis Architects, 2014)

Based on previous knowledge of the ground conditions in the area, it was known that the ground profile beneath each river bank was expected to com - prise a sequence of alluvial deposits over sandstone bedrock. It was anticipated that the bridge foundations (both for the older sandstone bridge and the later concrete bridge) were founded on the bedrock, but this, and the compositon of the abutments, needed to be verified (Arumugam et al, 2017).

3.2 *1839 Bridge Abutment Boreholes*

Two boreholes were drilled adjacent to the two bridge abutments on the eastern side of the bridge. The first borehole was drilled approxim ately 1m from the abutm ent and the second positioned approximately 4m away. The purpose of the first borehole (1 m away) was to carry out down-hole geophysics using Borehole Ground Penetrating Radar (BGPR) aimed at identifying the founding depth of the bridge abutm ent. The purpose of the second borehole (4 m away) at each side was to provide a benchmark BGPR profile (Arum ugam et al, 2017). This is discussed further below.

Two boreholes were drilled through the abutm ents in order to characterize the abutm ent materials and confirm the founding depth. The boreholes were drilled through the asphalt of the road, fill m aterials followed by sandstone blocks and into the founding bed rock. The roughly rectangular-shaped sandstone blocks are separated by irregularly spaced lim e mortar joints with a variable thickness ranging f rom 30 mm to 150 m m (Arumugam et al, 2017). The borehole terminated in sandstone bedrock. A section through the south abutment is shown in Figure 6.

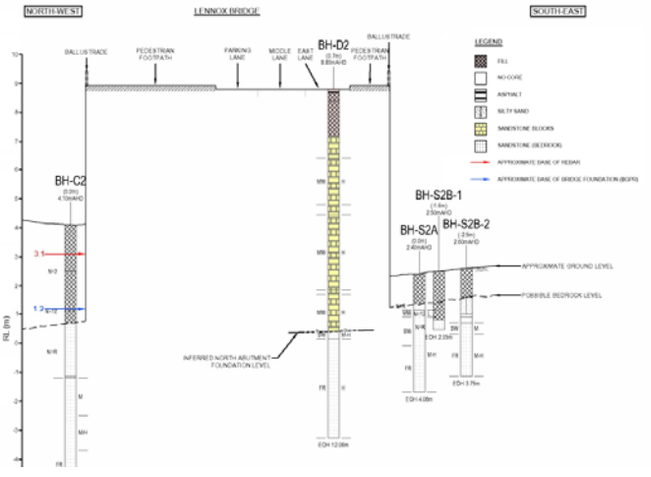

Figure 6. Section showing boreholes through the abutment (Arumugam et al 2017)

3.3 *1935 Bridge Abutment Boreholes*

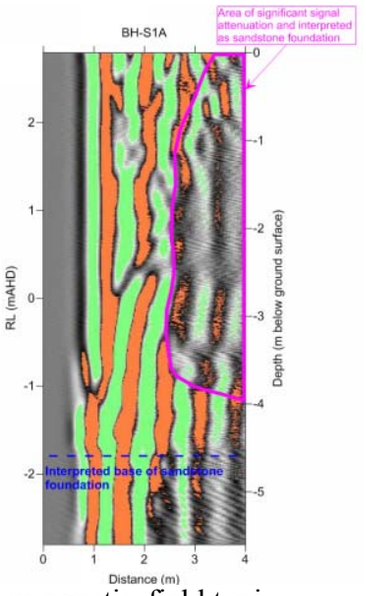
On the western side of the bridge adjacent to the reinforced concrete arch, a single borehole was undertaken adjacent to each abutment, 1 metre from the edge of the wall. A downhole magnetometer probe was to detect the presence of steel reinforcement within the concrete foundation and infer the base of the bridge foundation (Arumugam et al, 2014). The approximate level of the base of the reinforcement in the foundation is indicated in Figure 5 by the red horizontal line on the left hand side of the figure.

3.4 *Trial pits*

Two trial pits were excavated through the pavement of the bridge deck approximately. The dimensions of trial pits were 0.8 m x 0.6 m x 0.8 m (length x breadth x depth). The goal of the trial pits was to characterize the fill material between the pavement and the upper surface of the stone arch. The pits were manually excavated using lightweight pneumatic tools as a precautionary measure. The pits revealed that the fill material is variable containing boulders and gravelly sand above the stone deck slab that forms the roof of the galleries (Arumugam et al, 2014).

3.5 *Borehole Ground Penetrating Radar*

The Borehole Ground Penetrating Radar (BGPR) survey was completed in four (4) boreholes on the eastern side of the bridge with the aim of identifying the depth of the bridges' sandstone foundation.



The BGPR method is similar to surface GPR methods in that it passes radio frequency electromagnetic energy pulses into the ground. However, the equipment is deployed down a vertical borehole and signals are radiated omni-directionally, thus sampling a cylindrical shaped volume of material down the borehole with a radius (i.e. depth of penetration) that is dependent on the dielectric properties of the material. Reflection of BGPR energy occurs at interfaces where contrasting electrical properties exist, such as sub-surface construction layers and natural ground. Where either a large reflector or signal attenuation occurred, this was interpreted as a result of the sandstone foundation of the bridge (Arumugam et al, 2014).

These results of the BGPR corresponded with the geotechnical boreholes drilled through the bridge. The approximate level of the base of the sandstone foundation is indicated in Figure 5 by the horizontal red line of the left hand side of the section.

3.6 *Downhole Magnetometer Testing*

Downhole magnetometer testing was performed on the western side of the bridge to identify the depth to the base of steel reinforcement in the foundation of the 1935 reinforced concrete bridge.

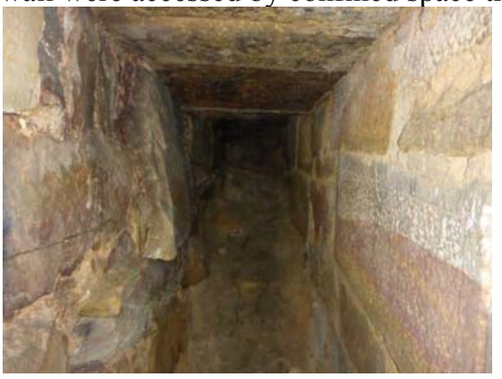
Downhole magnetic testing is a passive method based on the measurement of localised perturbations to the Earth's magnetic field. These perturbations may be caused by geological features and buried ferrous targets (e.g., pipes, cables, drums, iron sheets, steel reinforcement). Downhole magnetic testing was completed in-situ using pre-drilled, PVC cased boreholes.

The vertical component of the magnetic field typically provides the clearest indication of the base of the steel reinforcement in the bridge foundation and hence the approximate depth of the foundation. Magnetic anomalies present in the data generally indicate the approximate base of the steel reinforcement, see Figure 7.

Figure 7. Sample BGPR profile with interpretation (Arumugam et al, 2017)

3.7 *Ground Penetrating Radar (GPR) Survey of the bridge deck*

As part of the overall investigation a surface-based GPR survey of the bridge deck was completed to identify the depth of the stone deck and assess the fill material beneath the road pavement.



GPR data were collected along six (6) profiles parallel to the existing bridge alignment approximately 1.5m apart. The GPR identified several variations in the fill material as well as larger boulder size objects within the fill (Arumugam et al 2017).

3.8 *Structural Investigation*

The accessible sandstone surfaces of the abutments of the 1839 bridge was visually examined and tap tested locally for evidence of deterioration.

A petrographic analysis of intact lime mortar samples extracted by coring below the ground surface was undertaken to analyze the mineral composition and the presence of iron oxides.

The northeastern galleries behind the external spandrel wall were accessed by confined space trained

personnel.

Figure 8. View looking southwards in the northeastern gallery system

4 STRUCTURAL ASSESSMENT

4.1 *Arch Assessment under light rail vehicle loading*

The structural capacity of the masonry arch barrel was assessed using the arch analysis software Limit State RING 3.2.

A second model was developed using LS-DYNA to assess the bridge dynamic behavior, the response to horizontal loading and as a verification of the RING model.

4.2 *Load Model*

A load model representative of the actual rolling stock was used for the assessment.

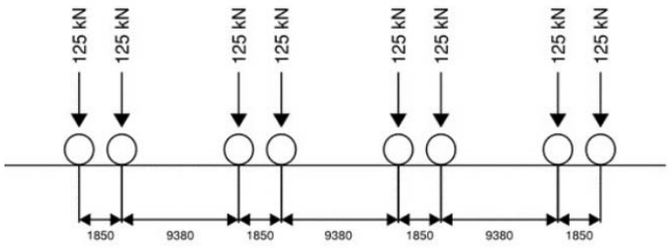


Figure 9. 45m LRV Loading Configuration

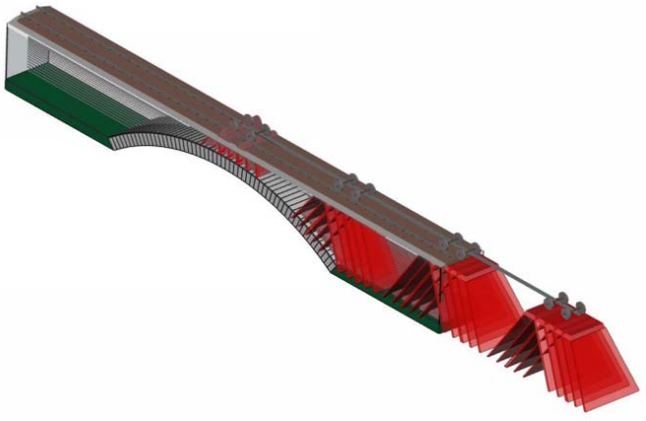

Figure 10. RING Analysis model

Two light rail tracks, northbound and southbound were assumed. Horizontal loading (braking, traction, nosing) were also considered.

Fatigue loading was also considered. Fatigue failure of a masonry arch bridge has not been positively identified to date, although there is some anecdotal evidence in the UK that repeated application of heavy loads could accelerate the deterioration of masonry arch bridges (CIRIA 2006). Laboratory experiments indicate an endurance limit for cyclic loading of about 50% of the static load strength, although there is some scatter in results (Roberts, Hughes and Dandamundi, 2004), (Melbourne, Tomor and Wang, 2004). For masonry arch bridges in the UK supporting highways, the current assessment code indicates that it "will be prudent" to limit the regularly applied loads to half the ultimate failure load (Highways Agency, 2001).

4.3 *Load factors and combinations*

Load factors and combination from AS 5100.7 (Standards Australia, 2017) were used.

4.4 *Material characteristics*

The masonry fabric material properties were based on the results of tests of core samples from sandstone masonry units extracted on the boreholes taken through the bridge deck. The core samples were tested for uniaxial compressive strength in accordance with AS 4133.4.2.2 (Standards Australia, 2013) with results in the range 16.9 – 19.3 MPa. The samples were also tested for deformability in accordance with AS 4133.4.3.2 (Standards Australia, 2013) and the secant modulus results were approximately 5 GPa.

4.5 *Strength Assessment Findings*

The outcome of the load rating of the masonry arch was that the arch barrel has significant residual resistance capacity to support the vertical and horizontal loading applied by light rail (2 LRV's, one travelling in each direction). The assessment included a series of sensitivity analyses to account for residual uncertainties in some of the parameters.

4.6 *Vibration Analysis*

In general, unless the bridges are structurally unsound or have decorative elements that are fragile in nature, vibration due to rail operation is not expected to cause damage to masonry arch structures of the type commonly found in the UK and similar to Lennox Bridge (CIRIA 2006).

As PLR is a light rail line with continuous welded rail the risk is further reduced as both of these factors reduce the dynamic loading applied to the bridge structure from rail operation.

A vibration analysis of the arch was carried out using LS-DYNA. No significant increase in structural

stresses were observed in the analysis indicating that dynamic effects are small.

Damage to the bridge structure from construction induced vibration is considered a higher risk that should be mitigated through appropriate selection of construction methodology, tools and work methods by the contractor. Recommended construction vibration limits are provided for heritage masonry structures.

4.7 *Masonry wing-walls assessment*

The light rail corridor is outside the zone of influence of the masonry wing walls however an assessment of the walls was carried out as part of the integrity assessment and will inform the management of the structural integrity of the bridge during construction.

4.8 *Hydraulic Assessment*

The bridge site has been subject to a number of significant floods since records began in 1795 including a massive flood event in 1988.

A flood retarding basin was constructed following plans by the Upper Parramatta River Catchment Trust in the mid 1990's (RMS, 2012). This alleviated flooding (but did not eliminate) flooding at the bridge site (RMS, 2012). The foreshore walkways were flooded in 2011.

A 2002 dive inspection revealed that a number of the blocks in the lower permanently submerged section of the abutment had been displaced outward and some were missing as a result of progressive scouring of the bedrock (RMS, 2012). This was later visually confirmed when the river was drained at this location (RMS, 2012). The damaged zone extended for approximately 10m.

Figure 11. Southern abutment scour damage (Fretwell Photography, 2002)

A scour remediation programme was undertaken in 2002 whereby the damage due to the scour hole and displaced blocks were plugged through a combination of grout injection and patch repair.

An inspection of the repair and an independent hydraulic assessment is underway at the time of writing.

4.9 *Services*

Several services cross the bridge including a water main installed in 2014 and managed by Sydney Water Corporation. The potential risk to the structural integrity of masonry arch bridges posed by water services is well documented (RAIB, 2017). A protection plan will be developed for the services including the watermain as part of the PLR construction phase to address the risk of damage to the watermain.

5 CONSERVATION MANAGEMENT

A detailed and comprehensive conservation management plan (RMS, 2012) has been developed by RMS. The plan provides detailed recommendations for the management of the structure including technical requirements for tasks such as mortar repair, stone surface repair, cleaning of graffiti etc. along with frequencies, protocols and workflows for maintenance and interventions.

6 CONCLUSIONS

The Lennox Bridge is a culturally significant heritage listed bridge. It is important to the people of Parramatta, both as a transport link, and as a piece of the local heritage. It has often been used as a popular symbol of the Parramatta City Council, the Local Government area in which it is located.

Lennox Bridge embodies the development of Parramatta from a semi-rural township to a major regional city and reflects the changing needs of the local community over more than 150 years (RMS, 2012).

The bridge will become part of the Parramatta Light Rail Stage 1 rail corridor. As part of the asset assurance process for PLR an investigation and structural assessment was carried out.

The assessment assessed the structural integrity of the bridge under the change of use imposed by the light rail system. The outcome of the assessment is that the bridge has sufficient residual capacity to support light rail.

The findings of the assessment will be used to inform the management of structural integrity and the fabric of this historic bridge during the design and construction of the PLR.

The bridge has comfortably handled a number of changes of use over the years from horse drawn traffic to motorized vehicles to trams. In the future it will transition to carrying 21st century light rail vehicles and become a key component of the new Parramatta light rail system.

7 ACKNOWLEDGEMENTS

The permission and support of the TfNSW PLR team and RMS Asset Management is gratefully acknowledged in the preparation of this paper.

ABSTRACT: In April 2016, an earthquake of magnitude 7.3 occurred in Kumamoto Prefecture in Japan. Due to the strong tremor, a bridge with rocking piers collapsed. The rocking piers have pivot bearings both on top and bottom ends. As this structure is designed to only support vertical force, once the horizontal displacement occurs, the whole bridge structure would become unstable. In this study, one of same rocking pier bridges in Hanshin Expressway is focused on for seismic stability. Firstly, dynamic analysis for the whole bridge is carried out, and based on the results the retrofitting design is proposed. In the study, it is found that the reaction force of the existing bridge deduced significantly after the retrofitting. The dynamic analysis made after retrofitting proves that the response values of the entire bridge system remains unchanged.

1 INTRODUCTION

In April 2016, a magnitude 7.3 earthquake hit Kumamoto Prefecture located in the western Japan. Due to the strong lateral tremor, 4 bridges over expressway were damaged, and one of them collapsed and blocked the expressway as shown in Figure 1. The collapsed bridge has rocking piers with pivot bearing on top and bottom ends. As such rocking pier structure is designed to only support vertical force without horizontal support function, once the horizontal displacement occurs, the whole bridges structure would become unstable.
For safety concern, the national government ordered that the bridge managers should promptly propose an adequate solution of retrofit or removal of same rocking pier bridges.
In this study, dynamic analysis is carried out for grasping seismic performance of the bridge with rocking piers in Hanshin Expressway. Based on the results, improvement methods are proposed.

2 BRIDGE OVERVIEW

Table 1 and Figure 2 show the inventory data and the side and plan view of the target bridge respectively. Substructures of the bridge have 5 piers, and the middle pier (P3) owns 3 rocking columns with the alignment angle of 45° to the superstructure. P3 owns hinge bearings both on upper and bottom ends of the columns. The rest bearing conditions are fixed at P4 and movable at others. The bridge is in parallel with and over a bridge managed by another road authority, and P3 is situated on the central pier (Pier B) of the bridge which is situated in the river. Figure 3 shows the front view of P3 and Pier B.
There are multiple numbers of rocking pier bridges in Hanshin Expressway. Before Kumamoto Earthquake occurred, all of the rocking piers have finished their retrofitting to match with the utmost seismic level (hereafter referred as “Level 2” which is prescribed in the Japanese Design Specifications for Highway Bridges, 2012. Therefore, the rocking piers of the target bridge have a precondition of strengthening by column deviation prevention system (Komoto et al. 2005).
Moreover, the column other piers of the bridge has been retrofitted: P1 (reinforced concrete pier) is jacketed with steel plates, and P2, P4 and P5 (steel rigid-frame pier) are filled with concrete to increase ductility strength.

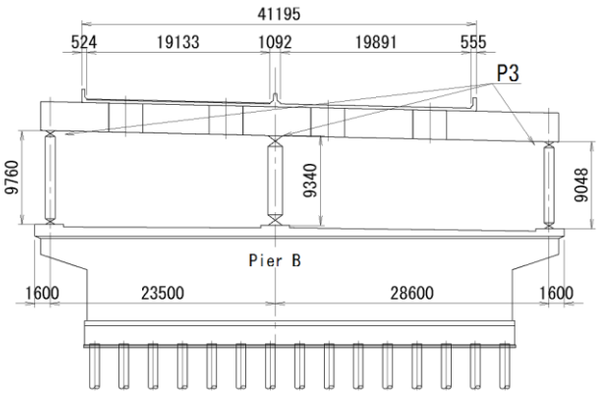

Figure 3.Cross-section of P3 and Pier B.

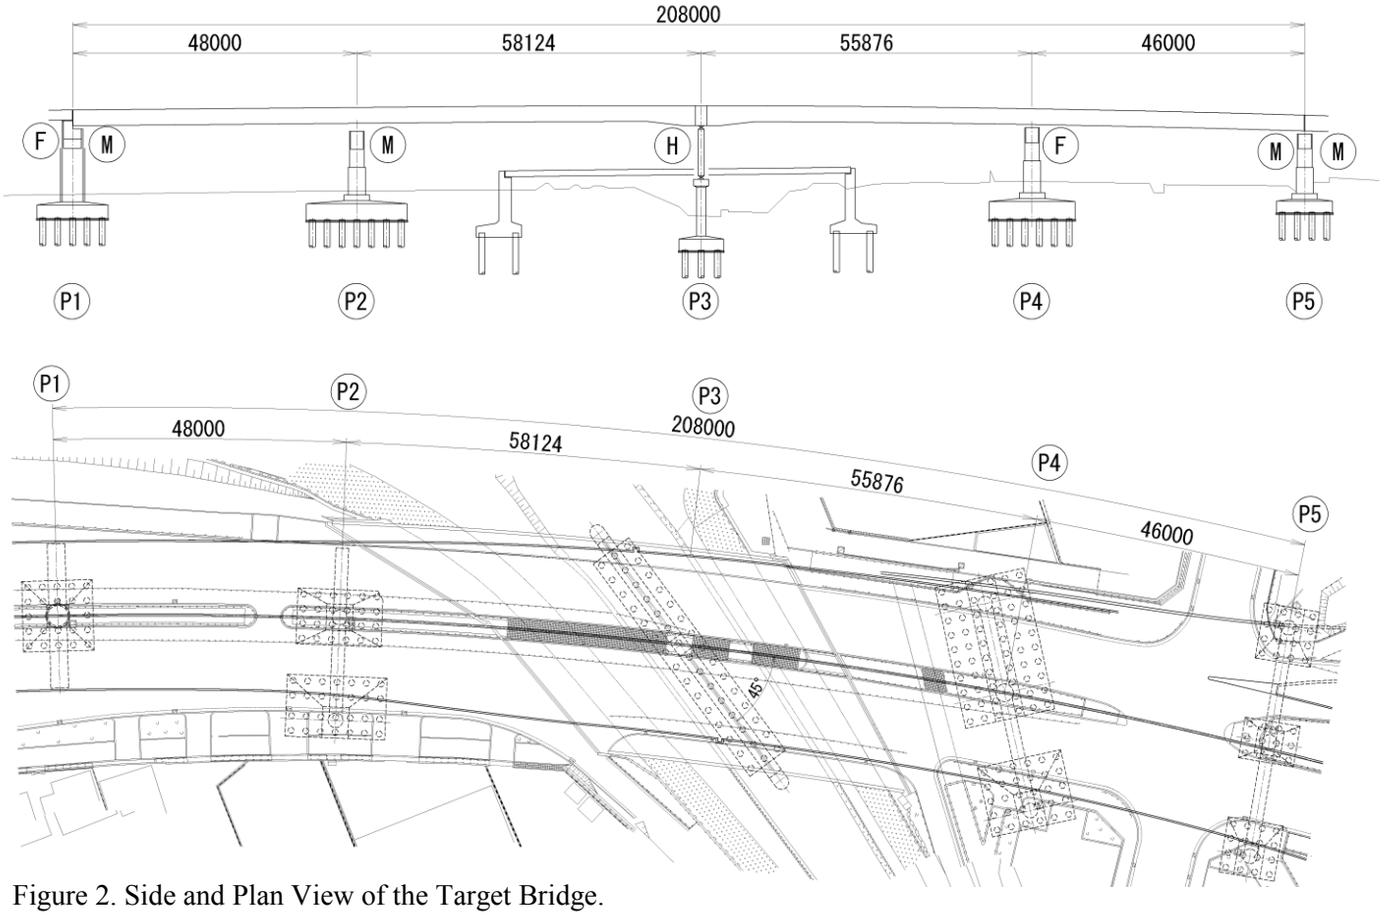

Figure 2. Side and Plan View of the Target Bridge.

3 ANALYTICAL POLICY

Before the confirmation of current seismic performance of the bridge, it is necessary to determine the bridge's seismic performance requirement. According to the Japan Specifications for Highway Bridges (Japan Road Association, 2012), collapsing of entire bridges must be avoided in case of Level 2 earthquake while fixable partial damage is allowed. This performance requirement is the outcome for improving rocking piers. Concretely, the entire bridge shall be changed to self-standing structural system.

When the 3 rocking columns of P3 become unstable, it is highly likely that the whole bridge may be collapsed. Therefore in the study, dynamic analysis is carried out for grasping seismic performance of the entire bridge system. Based on the results and the aforementioned seismic performance goal, appropriate retrofitting methods are proposed.

4 DYNAMIC ANALYSIS

4.1 *Analytical models*

3-Dimensions non-linear dynamic analysis was conducted for grasping seismic performance of the target bridge. Analysis software program is TDAP III (Ver3.05_01). Table 2 shows the given analytical conditions, and Figure 4 shows the analytical model.

In the model making, superstructure is modeled by elements of alignment considering it is consisted of linear members. Meanwhile piers are considered as non-linear members since they are expected to yield.

Steel piers are modeled by fiber element, and concrete piers are modeled by M-Φ element in which beams are element of alignment and columns are nonlinear element of beam (Japan Road Association, 2002). Estimated non-linear characteristics are shown in Figure 5 and Figure 6. Boundary condition of upper and bottom ends of rocking piers is modeled as pin connection. Foundation is modeled by element of linear springs which is concentrated on the foundation center.
The pier modelling also takes the previous seismic retrofitting into consideration. Bearings are modeled by linear springs and they bearing do not collide with girders even if they displace beyond the allowable limit.

4.2 *Input earthquake motion*
In this analysis, standard acceleration waveform is used for ground type II according to Japan Specifications for Highway Bridges.

4.3 *Limit states*
Limit state for each bridge member is shown in Table 3.

4.4 *Eigenvalue analysis*
Eigenvalue analysis is the method for grasping vibration characteristics of structure. Representative vibration mode in the eigenvalue analysis is shown in Figure 7. Natural period in the first transversal mode is about 1.09 seconds, and the effective mass ratio is 8 %. In this case, the vibration mode of superstructure indicates the vertical direction. The period in the second transversal mode is 0.92 second, and the effective mass ratio is 12 %. In this case, the vibration mode is that the deformation of superstructure is relatively small while all the piers except P3 move greatly.

Table 2. Conditions of Dynamic Analysis.

Analysis method		Time history response analysis program

(a) First transverse mode

(b) Second transverse mode

Figure 7. Representative Vibration Mode.

4.5 *Analysis result*

In this analysis, vibration input direction is superstructure's axial direction and transversal direction. In addition, skewed axial and transversal direction of P3 is also added.

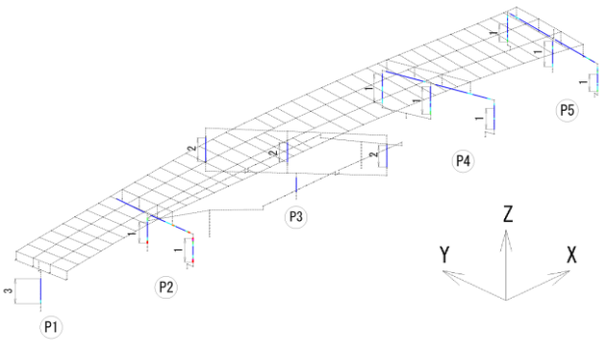

Figure 8 show the analysis results in terms of the ratio of allowable value by response value. In this figure, colors legends show the excess degree of strain. For example, in the case of concrete pier, this blue member means that the strain of the concrete pier is within an allowable value.

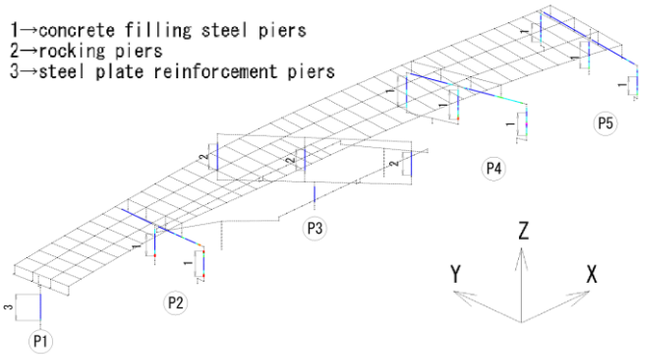
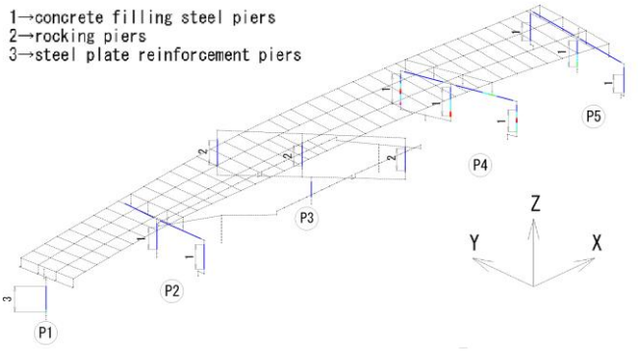
Since the target bridge has a one-fix support (P4) system, the response's excessive ratio for P4 tends to be larger than that of other piers. Pier B which supports P3 has a relatively big supporting redundancy and it is regarded safe even if one side of hinge bearing of P3 is changed to be fixed.

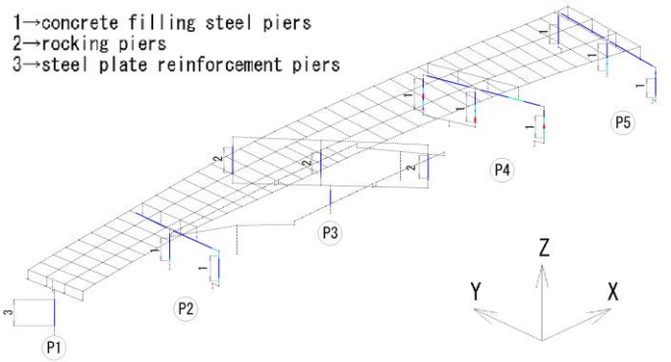


5 IMPROVEMENT METHODOLOGY

Improvement methods for P3 are proposed for preventing its partial destruction from leading to a whole bridge collapse. As a possible solution, it can be considered that additional safeguard structure supports dead load in case the rocking piers become unstable. However, it is difficult to be constructed because P3 is on Pier B and has a limited space.



Therefore, as another option as shown in Figure 9, it is proposed and examined that P3 is transformed to a self-standing structure where the upper end bearings are replaced with sliding bearings and the lowerare changed to rigid-connecting structures.



(a) Bridge axial direction

(b) Bridge transversal direction

Level 3 : 2.00 ~ 5.00			
Level 4 : 5.00 ~ 7.00			
Level 5 : 7.00 ~ 7.50		↑ within allowable value	
Level 6 : 7.50 ~ 8.80		↓ over allowable value	↑ within allowable value
Level 7 : 8.80 ~			↓ over allowable value

Figure 8. In-situ Structure Analysis Result.

The profiles of the sliding bearings are shown in Table 4.

Figure 10 shows the results dynamic analysis after the P3 improvement is carried out. In a similar fashion with in-situ bridge system, the post-improvement structure shows the excessive ratio of P4 is larger than that of other piers while the response value has no significant difference between the old and the new.

However rocking piers improvement makes Pier B less safe, its response values does not exceed the allowable value. In case of using sliding bearings, it is concerned that excessive bending moment is generated because the lower end is fixed. However, the moment value is less than the allowable value for Pier B beam.

Therefore, the practicality and seismic upgrading of rocking piers improvement using sliding bearing can be confirmed. Moreover, as shown in Table 5, the horizontal displacement of sliding bearings after the improvement is about 50cm, which proves the functionality of sliding bearing.

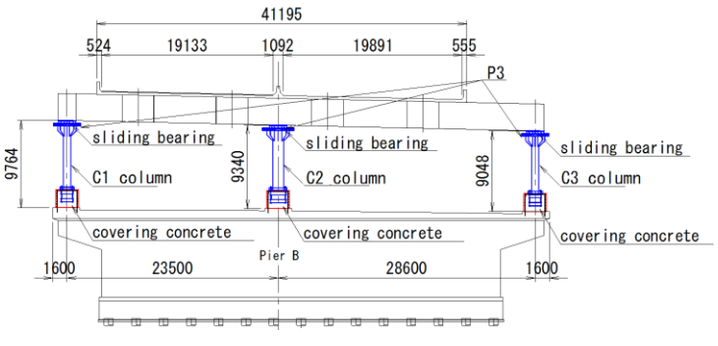

Table 4. Profiles of Sliding Bearing.

Level 7 : 8.80 ～			↓ over allowable value

Figure 10. Improve Structure Analysis Result.

6 CONCLUSIONS

Dynamic analysis targeted for rocking pier bridge system is conducted to identify the seismic performance, and the comparison between the in-situ structure and the improved structure evaluates the validity of the improvement method. The followings are key findings obtained by the analysis:

(1) In-situ structure

The excessive ratio of response value on fixed P4 of the bridge tends to be larger than that of other movable piers. Meanwhile since P3 with rocking columns which is on the relatively big and stable Pier B of surface street bridge, it is found that the hinge connection can be transformed into fixed connection by relying on its supporting redundancy.

(2) Improved structure

Under the given condition that the improvement of rocking piers should be considered on the limited area, it is proposed that hinge connections are replaced with sliding bearings on the upper ends and changed to rigid connection on the lower ends. And the dynamic analysis examines the validity of this improvement method confirms that it can keep the same level of the seismic performance compared with in-situ structure. Moreover, the functionality of sliding bearings used in the improvement is confirmed by checking their displacements.

Resilience Assessment of Highway Bridges using SMA-based Isolation Bearings

Y. Dong[1], Y. Zheng[2] & Y.H. Li[1]
[1]: Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Kowloon, Hong Kong, China
[2]: Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: Nowadays, shape memory alloy (SMA) has been adopted within the design and retrofit of highway bridges to improve the seismic performance. The performance benefit associated with the SMA bridges has not been well recognized and the relevant study is still needed. This paper aims to apply the resilience assessment to the comparative performance assessment of novel bridges using SMA. The corresponding structural performance on basis of fragility analysis and resilience are addressed. The proposed approach is applied to highway bridges with SMA-cable-based bearings.

1 INTRODUCTION

SMAs are generally associated with high strength besides the super-elasticity and energy dissipation; thus (DesRoches *et al*. 2004; Song *et al.* 2006). SMA could be implemented to resist the high seismic load without significant permanent residual deformations. In this paper, SMA is adopted within the highway bridges to improve the seismic performance under earthquake hazard. The application of SMA within the bridge seismic mitigation process has been studied previously. SMA-cable/bar restrainer was used to replace the steel bar restrainer and was installed at in-span hinge or interface between the girder and abutment. In the previous study, Choi *et al*. (2005) developed an isolation device that integrated SMA wires with rubber/elastomeric bearing to reduce the permanent residual deformation of the bridges under earthquakes. Xue and Li (2007) proposed a rubber bearing installed with pre-tensioning SMA-wires and applied it to a lattice shell structure for seismic mitigation. In this paper, a novel frictional sliding bearing with SMA-cable, which fully takes advantages of the properties of SMAs, such as self-centering, super-elasticity, and energy dissipation is investigated. Another difference from the previous devices with application of SMA is that the SMA-cable is adopted instead of the wire to improve the re-centering capacity of SMA-wire. Additionally, this type of isolation device is more easily to be manufactured and installed. The effects of the proposed SMA-cable-based device on the bridge seismic performance are investigated.

With respective to the hazard management of infrastructures, a widely-recognized indicator is resilience (Frangopol *et al.* 2017). Researchers have turned attention to the challenge of making infrastructure systems more resilient against devastating earthquakes. Resilience is related with the ability of a structural system to mitigate the hazard damage to infrastructures. A methodology to evaluate the seismic resilience of novel bridges is obliged to meet current performance requirements. The seismic resilience associated with novel bridge systems with SMA is investigated in this paper. The computational process is shown in Figure 1. Overall, a perfor-

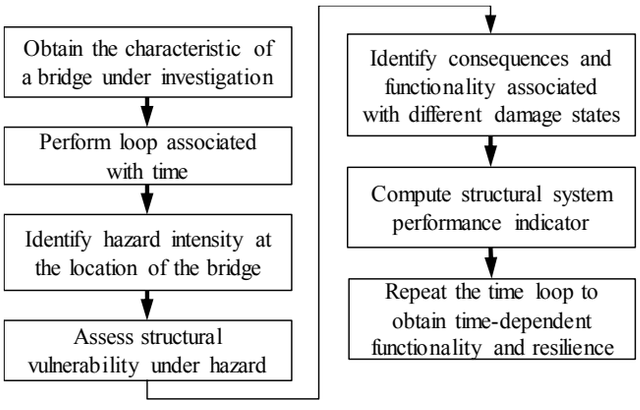

Figure 1. Flowchart of resilience assessment process under hazard effects

mance-based assessment framework that incorporates both resilience and life-cycle engineering is provided in this paper. This framework can be used for making comparison among different alternative designs and retrofit actions.

Overall, an approach to assess the seismic resilience of novel bridge systems is presented in this paper. The structural vulnerability of the novel structural systems is computed based on three-dimensional (3D) nonlinear finite element (FE) models considering the representative hazard scenarios that can happen during the investigated time interval.

2 STRUTURAL SEIMSIC VULNERABILITY USING SMA

Given the chosen seismic ground intensity, the median value of seismic demand can be computed as (Cornell *et al.* 2002; Decò and Frangopol 2013; Dong *et al.* 2013)

$$\ln(EDP) = \ln a + b\ln(IM) \tag{1}$$

where IM is the ground motion intensity indicator and a and b are regression parameters derived from the analytical responses. A 3D FE model can be established using the SAP 2000 (Computers and Structures Inc. 2010) or OpenSees (McKenna *et al.* 2004) to assess the seismic demand. Under a given ground motion intensity IM, the fragility curves can be expressed as (Cornell *et al.* 2002; Zhang and Huo 2009)

$$P[EDP - DI_i \geq 0 | IM] = 1 - \Phi\left(\frac{\ln(DI_i / aIM^b)}{\xi_{EDP|IM}}\right) \tag{2}$$

where $\Phi(.)$ is the standard normal distribution function and $\xi_{EDP|IM}$ is the standard deviation of the logarithmic distribution. The standard deviation of $\ln(EDP)$ under given IM can be computed as (Baker and Cornell 2006)

$$\xi_{EDP|IM} = \sqrt{\frac{\sum_{i=1}^{n}[\ln(EDP_i) - (\ln a + b\ln IM_i)]^2}{n-2}} \tag{3}$$

where n is the number of the selected earthquake ground motions and EDP_i is the seismic response corresponding to the ith earthquake ground motion.

Given the fragility curves of the components, fragility curve of a bridge system can be developed accounting for the relationship between the vulnerable components and assessing structural performance as an overall system. Some studies simply considered the column damage as the performance indicator of bridge system without considering other components. Additionally, Nielson and DesRoches (2007) computed the bridge fragility curves as an event that at least one component exceeds its corresponding damage state. Furthermore, Monte Carlo simulation method can be utilized to conduct the system fragility of bridges. The lower bound is the maximum component fragility and the upper bound is a combination of the component fragilities. These bounds are expressed as follows (Nielson and DesRoches 2007)

$$\max_{k=1}^{m}[P(F_k)] \leq P(F_{\text{sys}}) \leq 1 - \prod_{k=1}^{m}[1 - P(F_k)] \tag{4}$$

where m is the number of the vulnerable component; $P(F_k)$ is the probability failure of the kth component; and $P(F_{\text{sys}})$ is the failure probability of the bridge system.

SMA is a smart and novel material associated with shape memory and super-elasticity properties (Ozbulut *et al.* 2011). The shape memory effect is the ability of SMA to recover its original shape after deformation through a thermal cycling. The super-elasticity effect is described as the ability to recovery from a large strain due to the stress-induced martensitic phase transformations. To reflect the two properties of SMA, a flag-shaped hysteretic model (Tremblay *et al.* 2008) of SMA was shown in Figure 2, in which E_A and E_M are the Young's moduli of the SMA material at austenite and martensite phases, respectively. Given the cross-sectional area and the free displacements in both longitudinal and transverse directions of the SMA-cable, the strain-stress constitutive model of SMA-cable can be established using a one-dimension flag-shaped force-displacement model associated with the proposed isolation device. The more detailed information could be found in Zheng *et al*. (2018).

3 RESILIENCE ASSESSMENT

Within the last few decades, the occurrence of disruptive, low-probability, high-consequences extreme events across the globe has shifted the focus of scientific communities and decision makers to develop approaches which can improve the resilience of in-

frastructure to disasters. In general, earthquake resilience in civil engineering can be defined as (Bruneau *et al.* 2003) "the ability of social units (e.g., organizations and communities) to mitigate hazards, contain the effects of disasters when they occur, and carry out recovery activities in ways that minimize social disruption and mitigate the effects of future earthquakes". The most widely adopted approach to quantify the resilience of an individual structure, a group of structures, or a network of interrelated structures is to compute the resilience as the integration over time of the functionality (Cimellaro *et al.* 2010; Frangopol and Bocchini 2011)

$$RE = \frac{1}{t_r}\int_{t_0}^{t_0+t_r} Q(t)dt \tag{4}$$

in which $Q(t)$ is the functionality, t_o is the occurrence time of the extreme event, and t_r is the investigated time horizon. The resilience, as computed by Eq. (4), can be illustrated graphically as shown in Figure 3 for one and multiple extreme events during the life-cycle of a system, respectively. The earthquake hazard is emphasized in this keynote paper. Regarding the seismic performance analysis, the first step in seismic vulnerability assessment is to identify the seismic intensity associated with the location of the structural system under investigation (Dong and Frangopol 2015). A specific number of seismic scenarios should be generated within the region of interest. The generated scenarios should be able to approximate the actual seismic activity of the geographical area.

4 NUMERICAL EXAMPLE

The presented approach is applied to a reinforced concrete (RC) bridge with the SMA-cable-based bearing. The relevant performance indicators, such as fragility curves and resilience are investigated and compared with the bridge without using SMA. The bridge investigated herein is a continuous RC bridge with two equal spans as shown in Figure 4. As indicated, the height and the width of the RC two-box girder are 1.2 *m* and 12.5 *m*, respectively. The clear height of the RC column is 7.0 *m*, and the cross section of the RC column is 0.9 *m* × 0.9 *m*.

In order to conduct the nonlinear time-history analysis, a set of 40 ground motion records is selected from Pacific Earthquake Engineering Research Center Ground Motion Database. This suite of selected records covers a wide range of magnitude. The seismic performance of SMA-cable-based bearings and the RC columns, as the most vulnerable

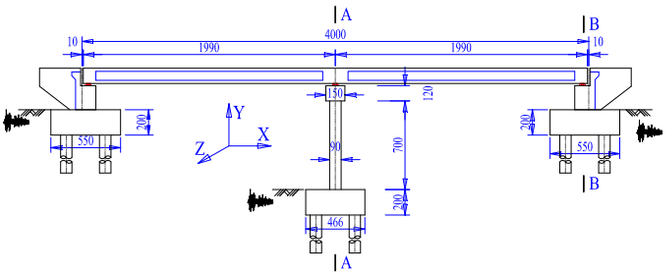

Figure 3. Elevation of the bridge under investigation

components, is investigated and median values corresponding to their appropriate seismic demands are computed using Eq. (1). For the RC column within the bridge, taking the PGA and maximum curvature ductility as the seismic intensity and demand parameter, the two constants *a* and *b* can be obtained based on the linear regression and they are 5.233 and 1.480, respectively.

Given the fragility curves associated with different components, the system-level fragility curve can be obtained. The system failure model proposed by Nielson and DesRoches (2007) is used to compute the system-level bridge fragility curve considering the seismic performance of the columns and bearings. The fragility curves of the bridge system at each damage state compose two parts, i.e., upper and lower bounds. The upper bound indicates the combination of the component fragilities while the lower bound represents the maximum component fragility. The fragility curves associated with moderate and major damage states are plotted in Figure 4. As indicated, the SMA-cable-based bearing can improve the structural performance of the bridge system significantly. At moderate damage state, the upper and lower bounds are much higher than those with SMA.

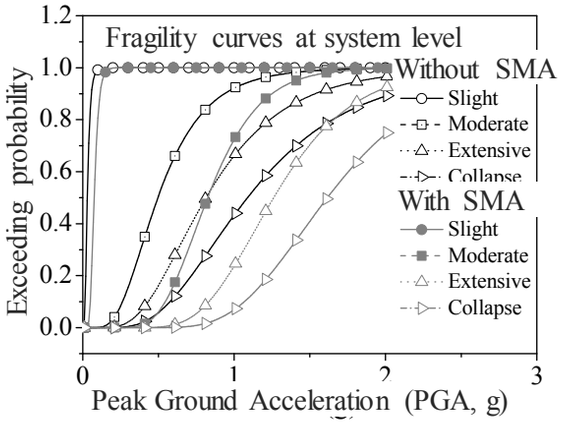

Figure 4. Fragility curves of the bridges with and without using SMA

The resilience of the novel bridges is assessed herein, in which the functionality of bridges considering different damage states should be identified firstly. The following scenarios are considered: immediate access, weight restriction, one lane open only, emergency access only, and bridge closed. Given the hazard intensity, the functionality of the bridges after the earthquake is computed using Eq. (4). The four hazard scenarios are investigated herein, which refer to the 715- and 1450-year return period earthquakes. Hazard curve parameters for the investigated

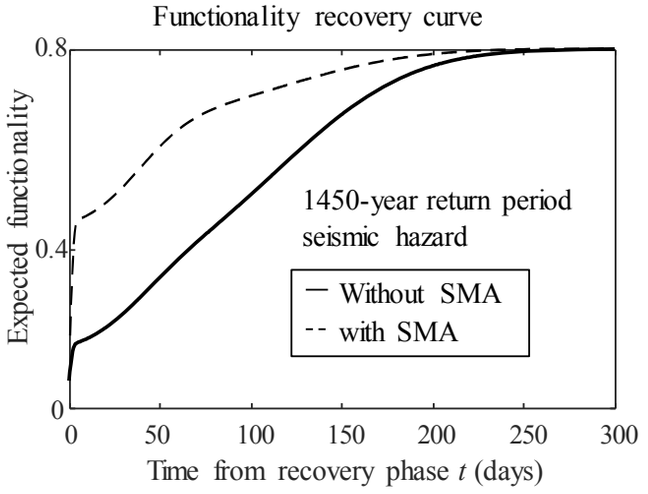

Figure 5. Time-dependent functionality of the bridge under given recovery action

region are based on the United States Geological Survey. The *PGA*s with return period of 715 and 1450 are 0.357 and 0.568, respectively. Given the seismic intensity and fragility curve, the probabilities of the bridge being in different damage states can be obtained, which act as the input for Eq. (4). The expected residual functionalities of the novel bridge under four selected seismic intensities are 0.562 and 0.365, respectively. The recovery path is based on ATC (1999). Accordingly, the bridge functionality restoration process is modeled by a normal cumulative distribution function corresponding to each of the four bridge damage states: slight, moderate, major, and complete. Under the investigated 715 and 1450-year return period earthquake and recovery actions, the functionality of the bridge is shown in Figure 5. As indicated, the functionality of the damaged bridge increases with time and there exists a significant difference between the bridges with and without using SMA. The resilience of the SMA bridges under the investigated seismic hazard intensities is 0.948 and 0.862, respectively. By comparing these values, the resilience of the bridge can be increased of adopting SMA novel system under 1450-year seismic event. As indicated, the performance benefit of resilience associated with SMA increases with a larger investigated hazard intensity.

5 CONCLUSIONS

This paper presents an approach to assess the resilience of novel structural systems with SMA cable-based bearings. The fragility curves associated with the novel bridges with SMA were evaluated by using nonlinear time-history analysis. Resilience under the investigated hazard scenarios were assessed, taking into account hazard recovery pattern. The proposed novel isolation device was applied to a continuous RC bridge. Based on the outcomes, the proposed novel isolation device can improve the seismic performance of the bridge significantly. Thus, the bridges with the proposed SMA devices proved to be effective considering the structural performance associated with bridge failure. The resilience of the novel bridge systems was assessed in this study. The functionality and probability of the bridge in different performance levels were computed to aid the assessment of resilience. The investigated seismic intensity can affect the resilience significantly.

Resilience evaluation of a cable-stayed bridge

H. Gil, K. Han & S. Seo
Super Long Span Bridge R&D Center, Korea Expressway Corporation

J. Park
Korea Expressway Corporation Research Institute, Korea Expressway Corporation

ABSTRACT: A lightning induced fire damaged three stay cables of a cable stayed bridge in Korea. The steel-concrete composite cable st ayed bridge is 990m -long and consists of three cable-stayed spans of 200m + 470m + 200m and two 60m -long end spans. The cable-stayed span is suppor ted by 144 parallel wire strand (PWS) cables. The fire caused by lightning strike led to complete rupture of one stay cable and partial rupture of two more stay cables. The bridge was closed for 15 days to remove and reinstall damaged stay cables. This extreme event provides an opportunity to review the resi lience of the cable-stayed br idge. A resilience of infrastructure is usually def ined as the ability to re duce the magnitude and duration of da mage caused by extreme events. As the number of natural and man-made disasters has increased these days, the vulnerability and resilience of highway bridges need to be evaluate d and improved. The resilience can be evaluated through four "R"s: robustness, redundancy , resourcefulness, and rapidity. In this paper, the resilience of the cable-stayed bridge is evaluated in terms of four "R"s.

1 SEOHAE BRIDGE

The Seohae Bridge, which ope ned to traffic in November 2000, is located approxim ately 65 km south of Seoul and is one of the longest cable-supported bridges in Korea. The tota l length of the bridg e is 7.31 km and it consists of a cable-stayed bridge and two different types of pre- stressed concrete (PSC) box-girder bridges. The cab le-stayed bridge, which is 990-m long, consists of three cable-stayed spans of 200 m + 470 m + 200 m and two 60- m long end spans of simply-supported composite girders (Figure 1).

The deck cross section consists of two longitudinal steel girders spaced 34- m apart, with ste el floor beams between these edge girders at 4.1 m on center, and precast concrete panels. The tw o pylons are H-shaped concrete structur es that reach 186-m above sea level. The three cable-stayed spans are supported by two planes of stay cables each plane contain s 72 cables. The length of stay cables ranges from 54 to 228 m. The stay cables are num bered from 1 to 72, left to right. These cables are m ade up of seven-wire strands with diam eters of 15.2 mm. The strands are galvanized, covered by wa x, individually sheathed, and placed inside a hi gh density polyethylene (HDPE) pipe without grout.

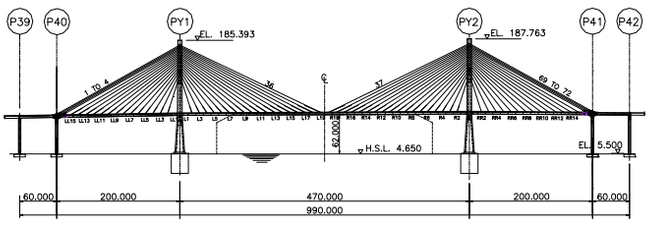

Figure 1. Schematic view of the Seohae Bridge

To monitor the structural response and evaluate the performance of the Seohae Bridge, the structural health monitoring system, called the Seohae S tructural Health Monitoring System (SSHMS), was installed in the year 2000 and have been continuously operated since then. In 2009, the SSHMS was totally renovated due to the deterioration of hardware and software (Gil et al. 2010). Most of the existing sensors such as accelerom eters, temperature sensors, and tiltmeters were replaced during renovation. A real-time kinematic (RTK) GNSS (Global N avigational Satellite System) monitoring system was newly installed to monitor the static and dynamic behavior of the Bridge.

2 CABLE FIRE

Fire is the one of most severe hazards which can lead to partial or total collapse of the bridge. A number bridge fires are reported in the literature (Garlock et al. 2012). It was also reported that two cable-stayed bridges experienced cab le fire and partial

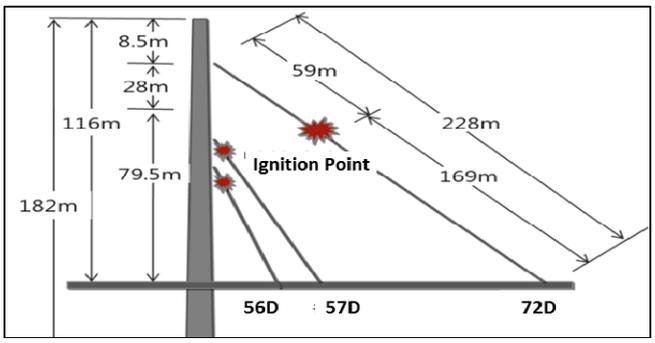

Figure 2. Schematic drawing of ignition point

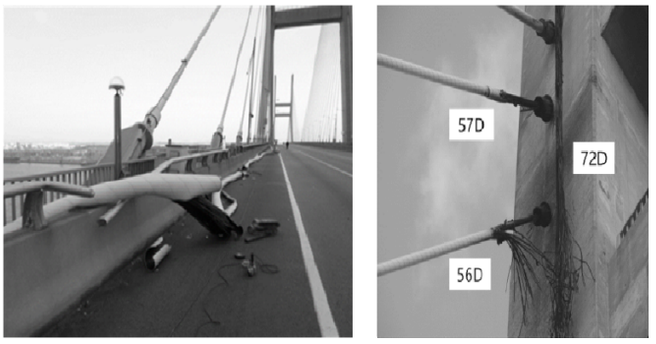

Figure 3. Damaged stay cables

failure (Zoli & S teinhouse 2007). In 2007, a truck carrying coconut caught a fire on the deck of the Mezcala Bridge in Mexico and resulted in the loss of one stay cable. The Rion Antirion Bridge in Greece suffered cable failure due to fire caused by lightning strike in 2005. In both fi res, the HDPE sheathing system for stay cables was poorly suited for suppressing fire but become fire source, if ignited.

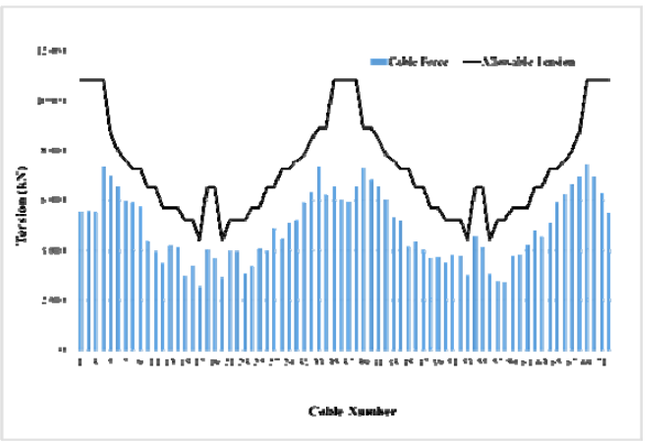
During winter thundersto rm on the evening of December 3, 2015, one of the longest upper cab les in the downstream side of the deck, 72D, caused a fire(Fig. 2). The fire star ted almost 80m above the bridge deck and lasted more than two hours. As fire progressed, the 72D cable wa s completely severed. About two-thirds of th e 72D cable dropped on the top of the bridge deck w hile the remaining one-third cable was dangled from the pylon anchorage as shown in Figure 3. The rem aining 72D cable was still under the fire and lead to fire of t wo more cables in the downstream cable plan e, a 56th (56D) cable and a 57th (57D) cable . The fire investigation by fire department concluded that fire was caused by a lightning strike. The detail ed damage investigation also showed that 21 strands out of 37 strands were broken for the 56D cable and 5 strands out of 44 strands were severed for the 57D cable. Becau se of fire and severe damage, the Bridge was immediately closed to traffic and rem ained closed during repair work.

3 RESILIENCE OF INFRASTRUCTURES

Because of global warm ing and clim ate change, infrastructures are more and more exposed to extrem e events such as fire, earthquake, flooding, and scour . These extreme events can lead to severe dam age and collapse of infrastructure. Resilient infrastructure can reduce the risk of severe d amage and co llapse and recovery time. A number of different definitions on the resilience of infrastructure s ystems were given in the literature. Bruneau et al.(2003) conceptualized the seismic resilience as “the ability of both physical and social systems to withstand earthquake-generated forces and dem ands and to cope with earthquake impacts through situation assessment, rapid response, and ef fective recovery strategies”. They also suggested the following four properties of the resilience: robustness, redundancy , resourcefulness, and rapidity. FHWA (Chavel & Yadlosky 2010) issued a framework to reduce the likelihood of possible bridge failures and t hus improve resilience of bridge. PPD-21(2103) defined critical infrastructure resilience as “the ability to prepare for and adapt to changing conditions and withstand and recover rapidly from disruptions”. Caverzan & Solomos (2014) reviewed different definitions on resilience and introduced the following concept: “a function indicating the capability to sustain a level of functionality or performance for a gi ven building, bridge, or community, over a period defined as the control time that is usually decided by owners, or society”. Bocchini el al (2013) com pared conceptual and analytical definition of resilience for civil infrastructures. Alipour (2017) reviewed c oncepts of resilience and defined as the capacity to absorb, a dapt to, and restore after a sudden shock. There is a slight dif ference in the definition of infrastructure resilience but the resilience of infrastructure is typically defined as the ability to reduce the magnitude and duration of damage caused by extreme events.

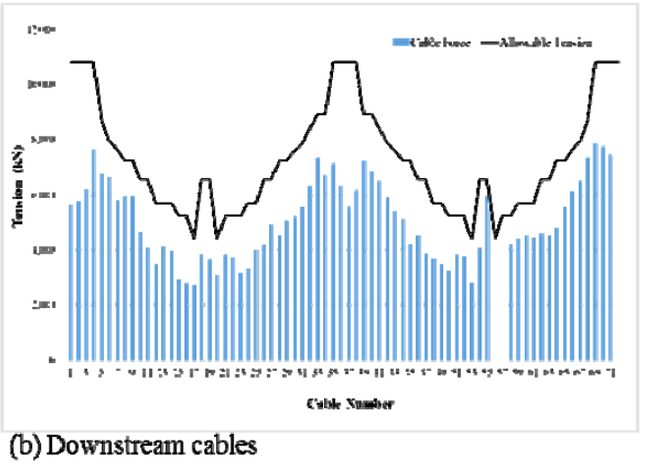
4 RESILIENCE EVALUATION

As stated earlier, resilience of a system or a structure cannot be easily evaluated quantitatively. The resilience of the Seohae Brid ge against cable fire will be qualitatively evaluated based on the four properties (Bruneau et al. 2003): r obustness, redundancy, resourcefulness, and rapidity . Robustness refers to “strength, or the ability of elem ents, systems, and other units of analysis to withstand a given level of stress or dem and without suffering degradation of loss of function”. Redundancy represents “the extent to which elements, systems, or other units of analysis exist that are subs titutable, i.e., capable of s atisfying functional requirements in the event of disruption, degradation, o r loss of functionality ”. Resourcefulness means “the cap acity to ide ntity problems, establish priorities, and mobilize resources when conditions exist that threaten to disrupt



some element, system, or other unit of analysis". Rapidity is "the capacity to meet priorities and achieve goals in a timely manner in order to contain losses and avoid future disruption". It can be concluded that the first two properties, robustness and redundancy, represent how well the structure, the system, or the society is prepared for the sudden events or disasters. The last two properties, resourcefulness and rapidity, consider the response of the organizations or the society to restore the structures after the disasters. In this paper, therefore, the resilience will be assessed by grouping the first two properties together and the last two properties together.

4.1 *Robustness and redundancy*



Though the Seohae Bridge was not explicitly considered robustness or redundancy during the design, extreme loads such as earthquake, vessel collision, and typhoon were considered as the part of load cases. It was also stipulated in the special design specification for the Seohae Bridge that the two stay cables can be replaced under traffic restrictions. Two traffic lanes considered to be closed in the direction of the cable replacement. The review of the structural analysis report for the Seohae Bridge confirmed that the replacement of two cables under traffic restriction was considered during design stage, as required in the design specification. The accidental rupture of stay cables were not considered in the special design specification.

To check the structural safety of the fire-damaged bridge, the detailed structural analysis using a three-dimensional finite element model was carried out considering only dead load. It was conservatively assumed that three cables were completely severed. The analysis results given in Figure 4 showed that the tension forces of the cables in the upstream cable plane were barely affected by the fire. The cable forces in the downstream cables near the damaged 56D, 57D, and 72D cables were substantially increased but still lower than allowable tension forces. The analysis results also indicated that the compressive tensile stress of the stiffening girder was substantially increased between the anchorages of the 56D and 57D cables due to cable rupture but lower than allowed stress limit.

The tension force level of the cables was also studied using the health monitoring systems. As stated earlier, the total of 24 accelerometers were installed on stay cables to indirectly measure cable tension level. However, accelerometers are not installed on damaged cables or on neighboring cables except the 69th cable. The accelerometers are also installed on the 37th cables, which are in the opposite side of the pylon and symmetrical to the 72th cables. The measured tension forces of affected cables in upstream and downstream cable planes are compared in Table 1. During fire, the measured tension forces were slightly reduced due to traffic restriction on the Bridge. After fire, the measured tension forces of the cables were slightly changed but well below the maximum allowable tension force of

(a) Upstream cables

(b) Downstream cables

Figure 4. Cable forces after damage

Table 1. Changes in cable tension forces

Cable No.	Before fire (Dec. 3, 2PM)	During fire (Dec. 3, 9PM)	After fire (Dec. 7)	After reopening	
				Dec. 19	Dec. 20
37U*	5,974	5,971 (-3)**	6,065 (91)	6,007 (33)	5,992 (18)
37D*	5,846	5,643 (-203)	5,888 (42)	5,906 (60)	5,890 (44)

69D	6,967	6519 (-448)	7,233 (266)	6,755 (-211)	6,758 (-209)

* U: Upstream cable, D: Downstream cable
** Tension force change compared to pre-fire level

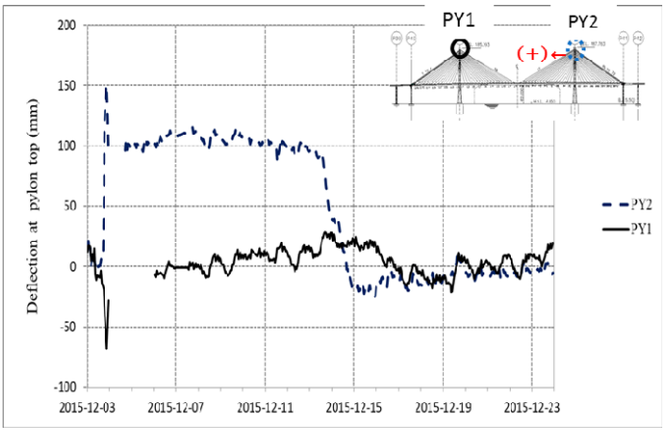

Figure 5. Lateral deflections at the top of pylons

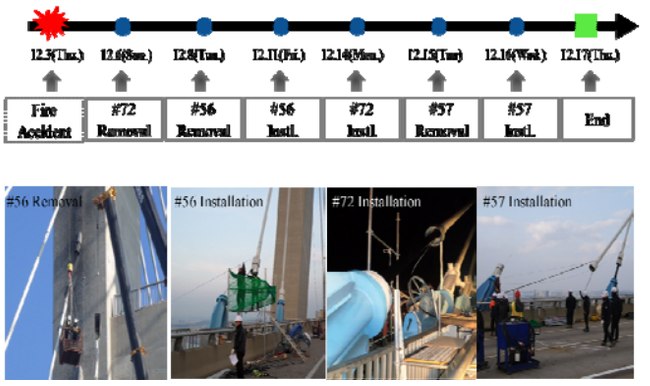

Figure 7. Entire repair work procedure

the cables (10,872kN). After the repair, there seems to be a change in cable forces compare to pre-fire tension force levels.

The deflection of the main pylons and the stiffening girder were also continuously monitored through the structural heath monitoring system. Due to rupture of cables in the side span, the main pylon PY2 with ruptured cables was inclined toward the main span as shown in Figure 5. The inclination of the PY1 main pylon was less than the PY2 pylon but the PY1 pylon also tilted to the main span direction. As the damaged cables repaired, the deflections of the pylons were reduced and returned to its pre-fire state.

The rupture of stay cables caused changes in the geometric profile of the stiffening girder. As illustrated in Figure 6, when the cables were ruptured, the main span deflected downward while side spans, especially the south span, deflected upward. This profile change corresponds to the lateral deflections of the main pylons. However, the lateral deflection of the main pylons and the vertical deflection of the stiffening girder were lower than the allowed limit and did not cause any structural damages. As the cables were replaced, the vertical deflection of the stffening girder was rapidly reduced.

4.2 *Resourcefulness and rapidity*

As stated earlier, the bridge was closed to the traffic immediately due to the concern over structural instability. Even though the detailed structural analysis showed that the damaged bridge can withstand portion of upstream traffic, it was determined to close the Bridge for quick repair work.

Preparation for the repair work started right after the fire was extinguished. It was determined that equipment for stay cable replacement such as monostrand tensioning jacks and stay cable strands are the essential elements for quick repair. A number of heavy lift crawler cranes were also determined to be required to access the cable anchorages in the main pylon and replace damaged cables. Because the Seohae Bridge is the part of strategically important highway networks in Korea with average daily traffic of 88,000 vehicles, all the available resources for stay cable installation in Korea were mobilized to repair the Bridge with the help of Ministry of Land, Infrastructure, and Transport of Korea. To help the repair of the Seohae Bridge, erection equipment and experts for cable-stayed bridges were tapped from other construction sites under the jurisdiction of

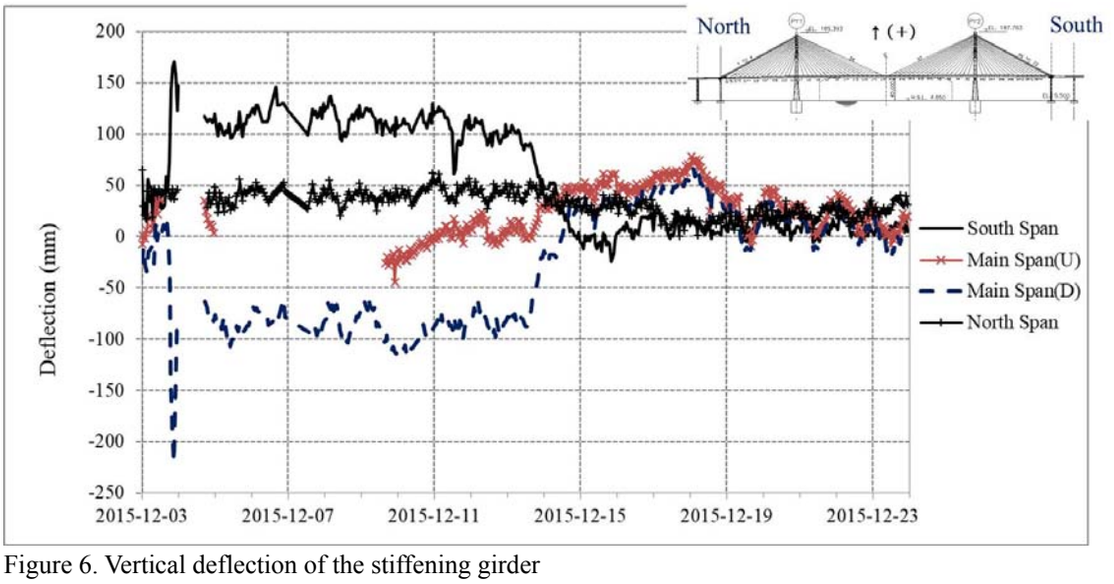

Figure 6. Vertical deflection of the stiffening girder

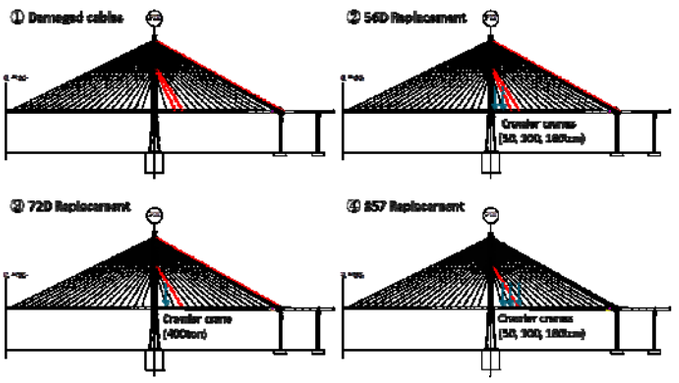

Figure 8. Cable replacement sequence and placement of crawler cranes

Ministry. The strands which were produced for the other cable-stayed bridge were also shifted. As sown in Figure 7, the entire repair work just took 15 days due to quick mobilization of cable installation equipment, material and trained experts in Korea.

At the given time, two or three crawler cranes with large boom length had to be deployed to remove and install stay cables (Fig. 8). The weight of crawler cranes, 490kN (50ton), 980kN (100ton), 1,570kN (160ton), and 3,920kN (400ton), strongly affected the tension force level of the cables and stress level of the stiffening girder. The sequence for removal and installation of stay cables was determined from the detailed structural analysis considering the location and weight of the crawler cranes. The remaining strands of the 56D cable was first removed through de-tensioning and new high strength strands were installed. After the 72D cable was installed, the damaged 57D cable were replaced.

5 CONCLUSION

The lightning caused fire ruptured three stay cables of the 990m long cable stayed bridge in Korea. The bridge was closed to traffic for 15 days and the damaged stay cables were replaced. The resilience of the Bridge against cable failure was qualitatively evaluated in terms of four "R"s: robustness, redundancy, resourcefulness, and rapidity. Due to inherent robustness and redundancy, the Bridge was able to withstand a three-cable failure without a total collapse. The quick repair was possible due to rapid mobilization of available resources for the stay cable erection. Firefighting facilities including fire hydrants and nozzles were newly installed on the cable-stayed bridge to increase resilience. Firefighting drills are also periodically conducted. To prevent further failure of cable-supported bridges due to a lighting strike, the risk of a lightning strike to the cable-supported bridges in Korea was assessed and, if required, lightning protection systems are being installed.

Seismic fragility of highway bridges considering improved bearing deterioration modeling

S. Shekhar & J. Ghosh
Indian Institute of Technology Bombay, Mumbai, India

ABSTRACT: Past literature on seismic fragility assessment of aging highway bridges primarily focus on corrosion of bridge columns, with little attention to deterioration of bridge bearings. Corrosion of bearing assemblies can lead to unexpected behavior under seismic loads. For instance, while corrosion of anchor bolts and keeper plates may lead to reduced bearing lateral strength, accumulation of corrosion byproducts lead to "frozen" or "locked" bearings restraining free movement during earthquake events. Limited studies on the analytical modeling of bearing deterioration often adopt simple and potentially unrealistic assumptions on the degradation mechanism. Addressing these gaps, this study develops improved bearing deterioration models based on available field investigation and experimental data. These models are utilized to study the impact of corroded steel bearings on the component level seismic fragilities of a case-study bridge. Results reveal the criticality of considering realistic bearing degradation models for bridges located in seismic regions and undergoing corrosion deterioration.

1 INTRODUCTION

Civil infrastructure systems such as highway bridges play an essential role in the sustained economic growth and social development of any country. During their service life, critical components of highway bridges maybe exposed to multiple environmental stressors such as corrosion deterioration along with intermittent seismic threats. Multiple bridge components such as columns and bearings (particularly steel bearings) deteriorates over time. Steel bearings including rocker and fixed bearings have been widely used in older steel highway bridges in Central and Southeastern US (CSUS) during the 1950s and 1960s (Saadeghvaziri & Rashidi 1998). These bearings constitute important elements within the bridge system transferring forces from the superstructure to the substructure. However, non-ductile nature of these bearings have exposed their vulnerability during past seismic events (Mander et al. 1996). Failure observed in steel bearings during seismic events includes lateral failure of rocker bearing due to instability in longitudinal direction, anchorage failure of anchor bolt, tearing of keeper plates, among others. These vulnerabilities have led modern design provisions to caution their use in highway bridges and recommend replacement with modern bearings such as elastomeric bearings and PTFE sliding bearings. However, a significant percentage of steel bridges found in CSUS still uses steel bearings (Nielson 2005).

In addition to their seismic vulnerability, corrosion deterioration of these bearings over time can lead to unexpected behavior under seismic loads. For instance, while corrosion of anchor bolts may lead to reduced bearing ultimate lateral strength, accumulation of corrosion byproducts lead to "frozen" or "locked" bearings restraining free movement during earthquake events leading to adverse horizontal forces imparted to the substructure (Silano & Brinckerhoff 1993). While several studies have been carried out in the past to study the impact of corrosion deterioration of bridge columns on seismic fragility assessment, impact of corrosion deterioration of bridge bearings is lacking in the literature. Limited studies on the analytical modeling of bearing deterioration often adopt simple but unrealistic assumptions on the degradation mechanism. For instance, while past literature develops analytical models of aging bridge bearings considering uniform corrosion along the length of the anchor bolt (Ghosh & Padgett 2010), field investigations reveal bolt failure to be primarily dictated by necking at concrete interface due to concentration cell corrosion (Lindquist 2008). Such failure mechanism may severely impact the lateral load capacity of the bearings. Furthermore, experimental tests on corroded bearings by Fan (2014) indicate a reduction in initial stiffness, typically neglected in the past literature.

Moreover, better models on the increase in bearing corrosion due to accumulation of rust debris also needs exploration.

Addressing these gaps, the paper examines the impact of deterioration of steel bearings on seismic fragility of highway bridges by considering improved bearing deterioration model based on past experimental tests and field investigation reports for steel bearings. The next section of this paper elaborates the commonly occurring deterioration mechanisms of steel bearings as observed in past experimental tests and field investigation reports, and presents its influence on bearings load carrying capacity. A representative case-study bridge is presented next along with its analytical model incorporating the deterioration effect of steel bearings. The influence of bearing deterioration on the deterministic seismic response of bridge components is investigated followed by study on seismic fragility assessment. The paper ends with discussions on the results including concluding remarks and opportunities for future research.

2 DETERIORATION OF STEEL BRIDGE BEARINGS

Bridge bearings constitute important elements within the bridge system and provides connection between superstructure and substructure. Under service load conditions, in addition of transferring dead load and traffic load, bearings also accommodate relative movements between the superstructure and substructure caused by thermal action and vehicle braking loads. Also, under extreme lateral loads such as earthquakes, bearings contribute to lateral resistance in both longitudinal and transverse direction.

In Central and Southeastern US, chosen as the case-study region, a large number of steel bridges particularly longer span bridges (>20 m) uses high-type fixed and expansion steel bearings. A high-type fixed bearings permits only rotational movement while an expansion bearing permits both rotational and translational movement. These bearings types have non-ductile properties and are highly susceptible to deterioration when exposed to aggressive environment (Mander et al. 1996). The age-related deterioration of steel bearings manifests itself in variety of forms. For instance, section loss of bearing assemblies causes a reduction in the net area of the bearing available to withstand the gravity load from the superstructure. Reduction of the section especially in the contact region for fixed bearing can cause a decrease in stiffness and strength of the bearing under lateral loads (Fan 2014). These changes can result in unexpected and non-uniform behavior under seismic loads and finally leads to their failure. Reduction in embedded anchor bolts area and thickness of keeper plates over time leads to reduction in lateral load capacity of bearings under earthquake loads in longitudinal and transverse directions. Additionally, buildup of debris and corrosion byproducts also can restrain free movement of a rocker bearing leading to adverse horizontal forces imparted to the superstructure and the substructure and possible overturning of the rocker bearings. To estimate the impact of corrosion on the bridge bearings, the failure modes of the high-type fixed and expansion bearings are studied in the following sub-sections.

2.1 Deterioration of high-type fixed bearings

The failure mode of high-type fixed bearings in the longitudinal direction results from the rocking of the bearing followed by failure of swedged anchor bolts due to prying of the masonry plate. The distribution of forces for a typical fixed bearings along longitudinal direction can be found in Mander et al. (1996) and Ghosh & Padgett (2010) and shown in Figure 1.

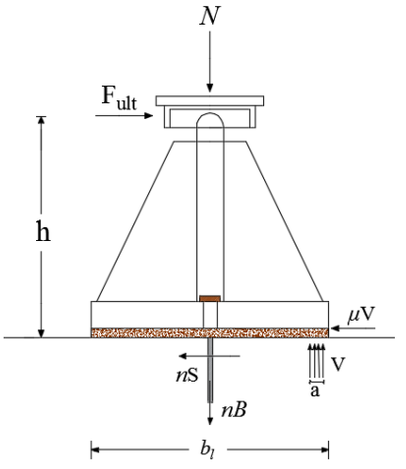

Figure 1. Force distribution mechanism of fixed bearing in longitudinal direction on reinforced concrete pedestal (Mander et al. 1996)

From the equilibrium of forces and moments for longitudinal direction, ultimate strength F_{ult} is found to depend on the dimension of the bearings and also on anchor bolt diameter as:

$$F_{ult}(t) = \frac{0.5 b_l N}{h}\left[\left(1+\frac{nT(t)}{N}\right) - \ldots \right. \\ \left. \ldots \frac{N}{0.85 f_c b_l b_t}\left(1+\frac{nT(t)}{N}\right)^2\right] \quad (1)$$

where, b_l = width of the masonry plate in longitudinal direction; N = axial load on the bearing; h = height of bearing from the concrete pedestal to the sole plate-rocker interface; n = number of anchor bolts; b_t = width of the masonry plate in transverse

direction; f_c = concrete strength of the pedestal and T is the lesser of bond strength (B) and yield strength (S) of the anchor bolt and depend on its diameter d_b.

Due to corrosion along the service life of the bridge, the diameter of the bolt d_b reduces and consequently leads to reduced ultimate lateral strengths for the deteriorated bearings. As explained earlier, this reduction in diameter impacts tensile force T which is minimum of yield strength (S) and bond strength (B) of the anchor bolts. Ghosh & Padgett (2010) assumed the corrosion mechanism of anchor bolts to be similar to the uniform corrosion deterioration mechanism of fully embedded steel reinforcement in the columns. However, field investigations carried by Lindquist (2008) across the state of Georgia in United States reveal that the anchor bolt corrosion is higher at the bolt-concrete interface due to macro-cell formation between the portion of the bolt embedded in the concrete and the portion immediately above the concrete. Consequently, the bolt may fail due to necking at concrete interface especially under lateral loads during earthquakes. Lindquist (2008) concluded that environmental effects such as chloride did not significantly affect anchor bolt corrosion and the median age when anchor bolt corrosion first initiated was found to be approximately 39 years. Results of long-term concentration cell experiments of anchor bolts indicate corrosion rates up to 4 to 6 times more than that of the same bolt in an uncoupled state i.e. bolt completely embedded in concrete. The present study utilizes the above finding for anchor bolt corrosion and thereby assumes higher corrosion rate for necking failure as compared to fully embedded bolt.

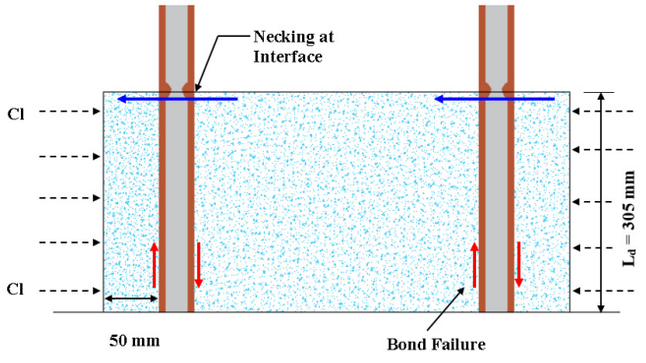

Figure 2. Deterioration mechanisms of anchor bolt.

Figure 2 shows schematic representation of considered reduction in anchor bolt diameter at interface and inside the reinforced concrete (RC) pedestal. Table 1 shows the summary of considered deterioration parameters for calculating reduction in anchor bolt diameter along the service life. For necking failure which typically occurs due to concentration cell corrosion, the initiation time and corrosion rates are adopted from Lindquist (2008). The initiation time for bolts completely embedded in RC pedestal is calculated by assuming the bridge to be located in deicing salt exposure and initiation time is calculated for cover depth of 50 mm (Mander et al. 1996). More details on the adopted formulation of initiation time for deicing salt exposure condition can be found in Thoft-Christensen et al. (1996). The corrosion rate for such exposure is taken from the field study of Whiting et al. (1990), Weyers et al. (1994) and adopted corrosion rate of 0.030 mm/year represent the median of the reported corrosion rates.

Table 1 Description of parameters considered for corrosion of anchor bolts.

Corrosion of fully embedded anchor bolt			
Initiation Time		**Corrosion Rate**	
μ = 15 years	σ = 8 years	μ = 0.030 mm/year	COV = 0.2
Concentration cell corrosion of anchor bolt at interface (Lindquist 2008)			
Initiation Time		**Corrosion Rate**	
μ = 39 years	σ = 12 years	μ = 0.127 mm/year	COV = 0.2

μ = Mean, σ = Standard deviation, COV = Coefficient of variation

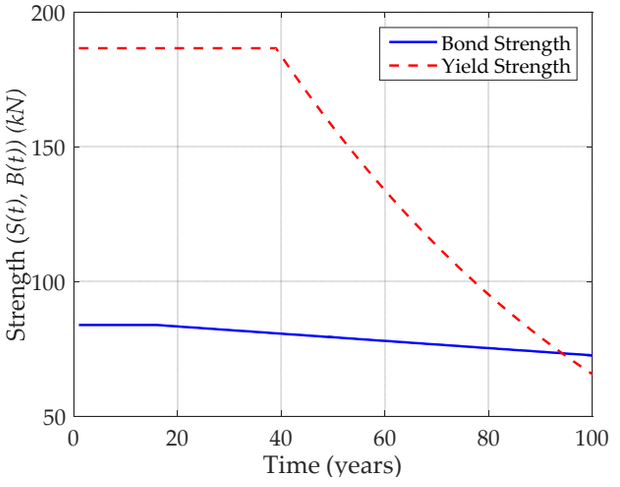

Figure 3. Comparison of time-variant mean value of bond strength (B) and yield strength (S) of anchor bolt due to deterioration of anchor bolt inside concrete and at interface.

Figure 3 shows the time-variant reduction in bond strength (B) and yield strength (S) due to deterioration of anchor bolt inside RC pedestal and at interface. It can be seen that although the rate of deterioration of yield strength (that leads to necking failure) is more, for a majority of service life (up to 85 years), the reduction in ultimate strength (F_{ult}) is govern by bond failure because of its low initial strength. It is noted that Figure 3 only present the mean value of reduction in bond strength and yield strength by considering mean initiation time and

mean corrosion rate from Table 1. The study also consider uncertainty around these values by adopting probabilistic model for initiation time and corrosion rate as shown in Table 1.

In the transverse direction for the fixed bearing, keeper plate failure governs the bearing failure. The experimental test conducted by Mander et al. (1996) reveal that fillet welds on the keeper plates failed in a semi-brittle fashion and neither cracks in the concrete pedestal nor damage to the swedged anchor bolts was observed. The shear strength of anchor bolt is adequate enough to absorb the force transmitted by the keeper plate when rocker strikes it. However, due to corrosion along the service life of the bridge both anchor bolt and keeper plate strength deteriorates and the failure of the bearing is govern by the minimum of the two strength. The reduced shear strength of anchor bolt can be calculated as time-dependent area of the anchor bolt $A_b(t)$ (reduction due to necking at interface) times the yield strength f_y. Additionally, the time-dependent strength of the keeper plate $P(t)$ may be estimated using the yield line theory as shown in Equation 2 (Mander et al. 1996).

$$P(t) = 2\left(\frac{t_p^2(t)}{4} f_{su} + \frac{\left(0.707 t_w(t)\right)^2}{4} f_{su}\right)\left(\frac{L_x}{L_y} + \frac{2L_y}{L_x}\right)$$

$$\text{where, } t_p(t) = t_p - y(t),\ t_w(t) = t_w - y(t) \qquad (2)$$

$$y(t) = At^B$$

where, t_p = 12.7mm, is the as-built thickness of keeper plate, t_w = 12.7mm, is the fillet weld thickness, $t_p(t)$ and $t_w(t)$ is the time-dependent thickness of the keeper plate and fillet weld obtained using the empirical equation provided by Komp (1987) for corrosion of exposed steel members; $y(t)$ is the average corrosion penetration in micrometers and A and B are field test parameters depending on exposure condition (considered here as deicing salt); f_{su} = 400 MPa, is the ultimate strength of keeper plate; L_x and L_y = 127mm and 51mm respectively, is the length and breadth of the keeper plate. Although further details may be found elsewhere, it is worthwhile to note that along the service life of the bridge, the demand placed on the anchor bolt [$P(t)/2$] is lesser than the shear strength of the anchor bolt [$A_b(t)f_y$], thereby the failure in transverse direction is governed by failure of the keeper plate.

2.2 Deterioration of high-type expansion bearings

The high-type expansion (rocker) bearings are designed to allow expansion in longitudinal direction via rocking of the curved bottom of the rocker-masonry plate interface and hinging of sole plate-rocker interface. The response is primarily proportional to the normal reaction indicating that the behaviour obey the laws of classical Coulomb friction and therefore the ultimate lateral strength of the bearing depends on coefficient of rocking friction μ and normal reaction N applied to the bearing. However, along the service life of the bridge corrosion leads to accumulation of excessive corrosion by-products (rusts) along with build-up of dirt and debris. This leads to increase in coefficient of friction that may restrict the rocking motion of these bearings. Mander et al. (1996) reported that under cyclic loading, a locked rocker bearing first performs like a fixed bearing thereby attracting unexpected horizontal forces before the locking condition is broken and the ability to rotate is restored. Marzoi et al. (1983) conducted a set of experiments on steel bearings including rocker bearings to determine effective coefficients of friction under as-built, partly corroded and in-situ conditions (badly corroded and build-up of rust and debris). It was found that the coefficient of friction varies from 0.022 to 0.05 for clean bearing, 0.036-0.055 for partly rusted bearings and 0.121-0.141 for in-situ bearing environment. For time-dependent modeling of increase in coefficient of friction, this study assumes friction coefficient corresponding to clean bearing condition for bridge in pristine state, friction coefficient corresponding to partly rusted bearing condition for 50 year old bridge and friction coefficient corresponding to in-situ bearing condition for 100 year old bridge. Also, a linear variation of coefficient of friction is assumed for in-between years along the service life.

Similar to fixed bearings, the transverse direction failure of expansion bearings is governed by the failure of the keeper plates whose strength can be calculated as indicated earlier in Equation 2. In addition to corrosion of anchor bolts and keeper plates, corrosion of other exposed steel bearings components, such as flanges and webs results in mass loss that affects the bearing initial stiffness. A set of experiments carried by Fan (2014) on salvaged bearings collected from an over 50 year old bridge reveals that a mass loss of 11% of bearing assemblies can lead to reduction in initial stiffness of about 70% for fixed and expansion bearings. In the absence of any further data to support time-dependent modeling of decrease in stiffness due to mass loss, a linearly varying percentage reduction in initial stiffness is assumed for this study starting with 0% for the pristine bridge and 70% for a 100 year old bridge near the end of its service life.

Finally these deterioration affected structural parameters, such as, reduction in ultimate strength, increase in coefficient of friction and decrease in initial stiffness can be incorporated in the analytical modeling of bearings using set of non-linear translational springs. More details about analytical modeling using non-linear springs is provided in the subsequent section through a case-study example.

3 CASE-STUDY BRIDGE

The influence of the identified deterioration mechanisms of the bearings on the seismic response and fragility of highway bridges is assessed for a case-study bridge. This section will first briefly describe the bridge geometry and its finite element modeling followed by detailed impact of bearing deterioration on seismic response of bridge bearings.

3.1 Bridge description and general modeling strategies

This study considers a multi-span continuous (MSC) steel girder bridge type for the case-study example. This bridge type is prevalent in CSUS and accounts for more than 13% of all highway bridges in this region (Nielson 2005). Past studies on this bridge type have highlighted their potential vulnerability under seismic shaking due to inadequate seismic detailing of the columns and non-ductile properties of the steel bearings (Nielson & DesRoches 2007). The bridge geometry consists of three spans with both middle span and end spans of 22.3 m length along with a 10.3 m wide deck consisting of five parallel steel girders in each span. Each bridge bent consist of two 914.4 mm diameter circular columns reinforced with 645 mm^2 longitudinal reinforcement (12 # 29 longitudinal bars, metric size = 28.65 mm) and #13 (metric size = 12.7 mm) transverse stirrups spaced at 307 mm along the length of the column. The load from the superstructure to substructure is transferred using high-type fixed and expansion type steel bearings with fixed bearings placed over the two bents and expansion bearings placed over the two abutments. A three-dimensional high-fidelity finite element model of the case-study bridge is developed using the finite element package OpenSees (McKenna et al. 2000) following the modeling guidelines by Nielson & DesRoches (2007). In order to isolate the impact of corrosion deterioration of steel bearings on seismic fragility estimate, other structural components for the case-study bridge such as columns are assumed to be undeteriorated along the service life of the bridge. While the detailed modeling of deteriorated bearings is presented in subsequent sub-section, an overview of the finite element modeling of the undeteriorated bridge components is presented herein.

As the superstructure remains elastic during the earthquake, the composite action of deck and steel girders are modeled using linear elastic beam-column elements. The column and bent cap are modeled using displacement based beam-column elements with fiber defined cross sections accounting for the steel reinforcement, confined core concrete and unconfined cover concrete. The pounding between abutment-deck is captured using contact elements and nonlinear translational springs are used to model the abutments while the piles at the base of the columns are modeled using lumped translational and rotational springs.

3.2 Finite element modeling of deteriorated bridge bearings

In the present study, the analytical modeling of the bridge bearings depend heavily on the work done by Mander et al. (1996) wherein the researchers tested the response of the steel bearings under reverse cyclic loading. Figure 4 shows the analytical model for the high-type fixed and expansion bearings under pristine condition. A brief overview of the analytical model developed in OpenSees is provided herein while detailed description can be found in Nielson (2005). For fixed bearing in longitudinal direction (denoted here as FBL), *Steel01* material is used to model the prying nature of the masonry plate and *Hysteretic* material is used to capture rocking and stiffness degradation due to anchor bolt failure. It is noted that *Steel01* and *Hysteretic* material are specific to OpenSees only. The two materials are connected in parallel to simulate the overall response. In case of fixed bearing in transverse direction (denoted here as FBT), as stated earlier, the keeper plate fails and no damage to the swedged anchor bolt is expected. While the *Steel01* material is used to model the sliding frictional component until the rocker hits the keeper plate, the *Hysteretic* material is used to model the loading and fracture sequence of the keeper plate. For expansion bearing in longitudinal direction (denoted here as EBL), *Steel01* material is used to model the rocking motion that depends on the normal reaction and coefficient of friction. The response of expansion bearing in transverse direction (denoted here as EBT) is similar to the fixed bearing in transverse and subsequently a similar modeling approach is used.

As explained earlier in Section 2, bearing deterioration due to corrosion leads to reduction in ultimate lateral strength, stiffness and increase in coefficient of friction. Past experimental study on corroded bearings (Fan 2014) have shown that corrosion has negligible impact on the bearing displacement capacities and therefore, this study only consider reduction in stiffness and ultimate load carrying capacity due to corrosion. The time-varying deterioration affected structural parameters are updated in the analytical modeling of the bearings, with the extent of reduction dependent on the point in time along the service life of the bridge. Figure 4 also emphasize the analytical model of the corroded high-type fixed bearings highlighting the decrease in strength and stiffness due to corrosion. The next section use these improved analytical models to demonstrate the impact of deterioration on the seismic response of bridge components.

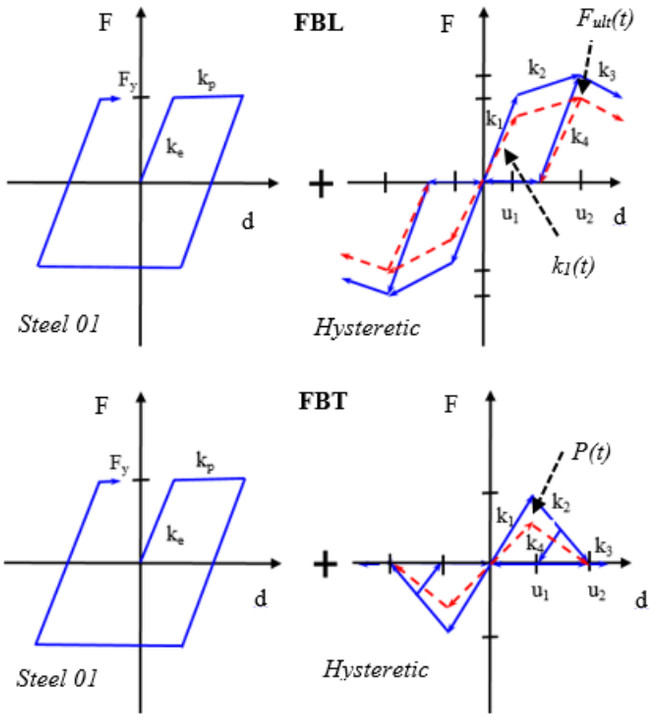

Figure 4. Analytical model of fixed bearing in longitudinal and transverse direction (FBL - Fixed bearing in longitudinal direction, FBT - Fixed bearing in transverse direction).

3.3 Impact of bearing deterioration on seismic response of bridge components

In order to demonstrate the impact of bearing deterioration on the seismic response of bridge components, the case-study bridge is subjected to a ground motion record from the Rix & Fernandez (2004) ground motion suite. This ground motion has peak ground acceleration (PGA) of 0.63 g and duration of 25 s and is first applied along the longitudinal and then along the transverse direction of the deteriorating bridge at different points in time to demonstrate the impact of bearing corrosion on the seismic response of critical bridge components.

Figure 5 shows the longitudinal response of fixed bearings when subjected to longitudinal loading at the beginning (pristine), middle (50 year) and end of service life (100 year). As compared to pristine bridge, 50 year and 100 year old deteriorated bridge results in 39% and 106% increase in deformation. This increase in deformation is expected as deterioration leads to decrease in stiffness and strength of the fixed bearings as explained earlier in Section 2. Fixed bearings in the transverse direction also reveals a consistent increase in deformation due to deterioration of keeper plate leading to its failure at lower force level.

For expansion bearings in longitudinal direction, an increase in yield force by 3% and 27% is observed for 50 year and 100 year old bridge as compared to pristine bridge due to increase in coefficient of friction because of accumulation of rust and debris. This increase in force reduces the deformation in longitudinal direction by 3% and 9% for 50 year and 100 year old bridge. In the transverse direction, expansion bearings experience larger demands due to significant poundings at the abutments. The response is further increased due to reduction in ultimate strength of the keeper plate leading to its failure at lower force and resulting in increase in deformation. Figure 6 shows an increase in deformation by 20% and 70% for 50 year and 100 year old bridge as compared to pristine bridge.

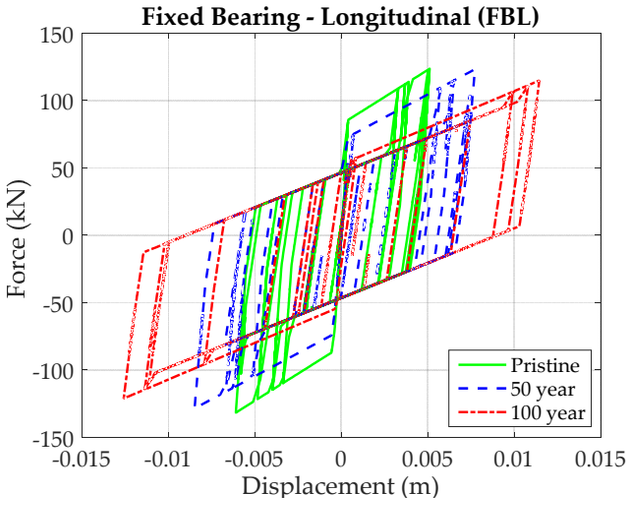

Figure 5. Increase in fixed bearing deformations in the longitudinal direction due to corrosion deterioration.

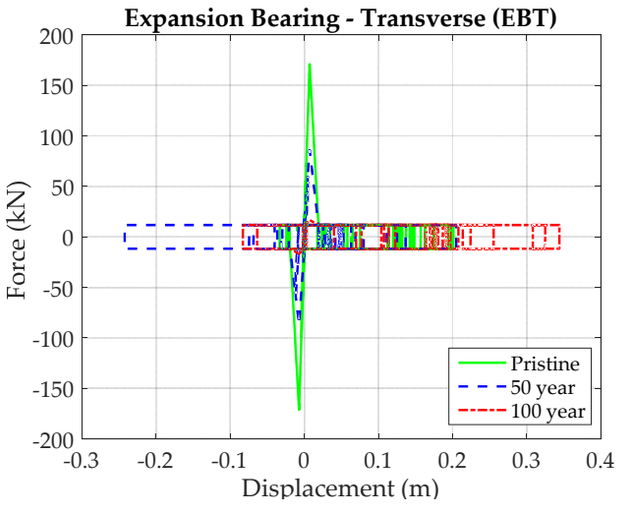

Figure 6. Increase in expansion bearing deformations in the transverse direction due to corrosion deterioration.

While this section focused on the alterations of deterministic bearing response due to deterioration, the subsequent section considers uncertainty in ground motion, material parameters, modeling inputs and deterioration parameters for fragility analysis.

4 IMPACT OF BEARING DETERIORATION ON SEISMIC FRAGILITY

The preceding section presents the time-dependent seismic response of deteriorated bridge component when subjected to single deterministic seismic loading. However, due to inherent randomness in the structural, modeling and deterioration parameters along with ground motion, a full probabilistic analysis is required to determine the effect of bearing corrosion on bridge damage. Typically, the extent of bridge damage is represented by fragility curves that indicate the probability of failure of bridge component given the intensity of ground motion. The time-dependent seismic fragility curves for deteriorated highway bridges are developed using a two-step approach. In the first step probabilistic seismic demand models (PSDMs) for critical bridge components are developed at each point of time along the service life of the bridge. The second step involves the development of component fragility curves using the demand model (obtained in first step) and limit state capacity model of each bridge component.

PSDMs that relates the median peak engineering demand parameter (*EDP*) of the bridge component with the intensity measure (*IM*) of the ground motion are developed by conducting non-linear time history analysis (NLTHA) of the bridge samples using suite of ground motion representative of the case-study region. A synthetic suite of 96 ground motions developed by Wen & Wu (2001) and Rix & Fernandez (2004) representative of the seismicity of CSUS are used in the analysis. To conduct NLTHA, 96 ground motions are paired with 96 statistically different yet nominally identical 3D bridge samples generated using Latin Hypercube sampling considering uncertaility in structural, material and deterioration parameters at different points in time along the service life of the bridge (taken here as 0, 25, 50, 75 and 100 years). Following NLTHA, PSDMs are developed for each bridge component to estimate median seismic demand using the relation given by Cornell & Jalayer (2002).

Following the development of PSDMs for each bridge component, fragilities are evaluated at different points in time along the service life of the bridge to assess the effect of bearing deterioration on seismic vulnerability. The lognormal limit state capacities presented by Nielson & DesRoches (2007) are used in this study. The time-dependent seismic fragility for a particular bridge component *m* and damage state *DS* follows lognormal distribution and estimated as (Nielson & DesRoches 2007):

$$P\left[DS_m(t)\middle|PGA\right] = \Phi\left(\frac{\ln(PGA) - \ln\left(med_m(t)\right)}{\zeta_m(t)}\right) \quad (3)$$

where, $P[DS_m(t)|PGA]$ is the probability of damage state exceedance at time t given a PGA intensity, $med_m(t)$ is the median of lognormal distribution for fragility at time t and $\zeta_m(t)$ is the dispersion of fragility at time t.

Figure 7 shows the increase in seismic vulnerability across all damage states for fixed bearing in transverse direction (FBT) at 75 years of service life. The results are consistent with the observation in deterministic response where increased in deformation is observed for deteriorated bridge due to failure of keeper plates at lower force level. Although not shown here, similar trend of increased vulnerability i.e. decrease in median fragility [$med_m(t)$] (PGA corresponding 50 % failure probability) is observed for fixed bearing in longitudinal direction (FBL) and expansion bearing in transverse direction (EBT). However, rust accumulation and decrease in deformation leads to decrease in vulnerability of expansion bearings in longitudinal direction (EBL).

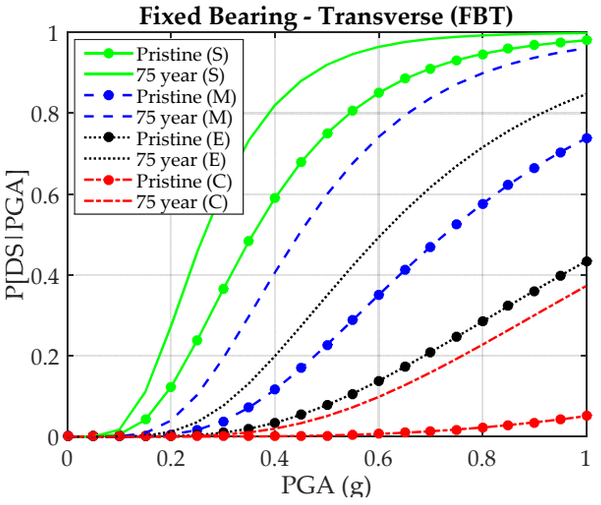

Figure 7. Comparison of fixed bearing transverse (FBT) deformation fragility curves for Slight (S), Moderate (M), Extensive (E), and Complete (C) under pristine and deteriorated state (75 years).

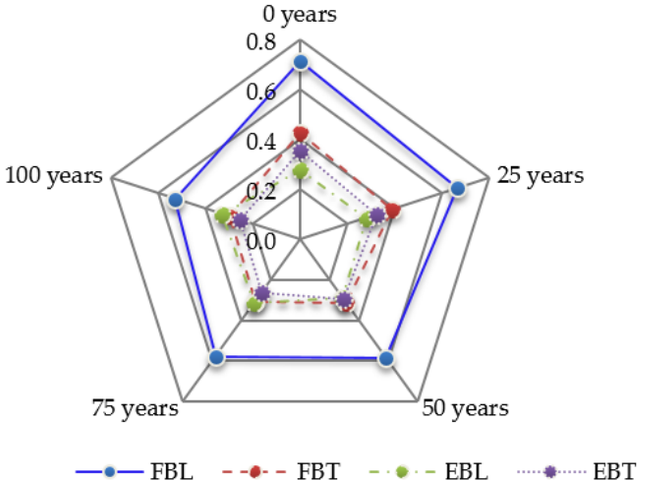

Figure 8. Figure depicting the comparison of time-dependent change in median estimate of fragility (slight damage) for fixed and expansion bearings in longitudinal and transverse direction.

Figure 8 shows the time-dependent change of median fragility for slight damage state for various bearing response. The maximum change (31% decrease in median fragility) is observed in fixed bearing under transverse deformation (FBT). The figure also depicts the ranking of vulnerability of various bearing deformation at each instant of time. For instance, in pristine condition expansion bearing in longitudinal direction (EBL) is most fragile, however at the end of 100 years expansion bearing in transverse direction (EBT) comes out to be more vulnerable of all the considered bearing response. It is also noted that slight reduction in dispersion [$\zeta_m(t)$] is also observed over time indicating reduced uncertainty in predicting median *PGA* for deteriorated bridge state.

5 CONCLUSIONS

The study presents the impact of bearing deterioration on seismic fragility of highway bridges by considering improved bearing deterioration model based on past experimental data and field investigation reports. At the onset, this paper elaborates the commonly occurring deterioration of steel bearings and presents its influence on bearings load carrying capacity. It is observed that corrosion deterioration significantly impacts the ultimate strength and initial stiffness of the bearings along with increase in coefficient of friction. The impact of corrosion deterioration on displacement capacity of the bearing is negligible. To investigate the impact of bearing deterioration on seismic fragility a representative case-study multi-span continuous steel bridge located in Central and Southeastern US is considered. Deterministic analysis reveals that consideration of realistic deterioration mechanisms results in substantial increase in dynamic response of the deteriorated bearings. A full probabilistic analysis considering various uncertainty is conducted to estimate change in seismic fragility of deteriorated bridge components. Except for expansion bearing under longitudinal deformation mode, significant increase in vulnerability is observe for other deformation mode of fixed and expansion bearings. For example, after 100 years of service life, the median value *PGA* for the complete damage state decreases by 61% for expansion bearing under transverse deformation.

Future study in this research will consider the joint impact of considered realistic bearing and column deterioration modeling for estimating component and system fragilities. Also investigation of realistic deterioration modeling on additional bridge types and bearing assemblies such as elastomeric bearings will be considered.

ABSTRACT: This paper presents a multi-physics analysis framework for estimating thermo-mechanical behavior of structures under fire conditions. The analysis framework consists of three parts. The first part is a fire-driven flow simulation in a rectangular parallelepiped domain which includes fire source and target structure. The fire simulation is conducted using Fire Dynamics Simulator (FDS). From FDS simulation, time history of temperature on the surface of structure is obtained. The second part is the data transfer by an interface model between FDS and thermo-mechanical analyses. By the interface model, the calculated surface temperature from FDS simulation is assigned to the finite element model of the structure for thermo-mechanical analysis. The third part is a nonlinear thermo-mechanical analysis for predicting the structural response under high temperatures. To validate simulation results, structural fire experiments were performed for a real-scale steel-concrete composite beam, whose design was based on the code for nuclear power plant structures of Korea. The calculated time history of displacement at the center of the beam as well as the temperature at sampling points showed good agreement with experimental results. The changes in stiffness, load-carrying capacity, and ductility of the composite beam at elevated temperatures are investigated through parametric studies.

1 INTRODUCTION

Fire is one of the most severe hazards that should be considered in the design and analysis of civil infrastructure such as bridge, tunnel, and nuclear power plant. In recent years, fire in structure has become a major concern according to the rapid increase of urban transportation, which has naturally brought increasing transport of flammable and poisonous materials. In particular, damage or loss of bridge structure due to fire can result in significant social and economic consequences. Therefore, it is important to understand the behavior of structures subjected to fire and investigate structural damage. Recently in the United States and Europe, the performance-based fire resistance design method has been applied for important social infrastructures such as nuclear power plants (Kwon and Jung, 2010). The method sets the fire resistance performance time of a structure considering the type and quantity of combustible materials, the compartment size, and the structural load. In Korea, however, abstract fire resistance regulations have been adopted so far that set the fire resistance performance time of fire zones and apply them to members, rather than systematically performing the fire impact assessment of structures. With this method, it is difficult to establish fire response strategies in the event of a large fire in infrastructures including nuclear power plants and bridges, and it is not easy to verify the integrity of structures. Therefore, we need a total structural behavior assessment technique considering fire size, characteristics of structural materials, and the shape and characteristics of structures. It is not practically easy to assess the deformation and damage of structures due to fire through a full-scale experiment. However, the recent breakthroughs in computer hardware and computational dynamics techniques have enabled calculation of fire flows similar to actual situation and relatively accurate prediction of structural behavior in high temperature conditions. Therefore, it is effective to use computer analysis techniques in order to assess the fire resistance performance of structures for various structural and fire conditions while saving cost required for structural fire experiments.

In this study, a multi-physics structural fire analysis technique to accurately predict structural behavior in a fire is proposed by considering the shape of structure, fire size, and the thermal and mechanical properties of structural materials.

2 NONLINEAR THERMO-MECHANICAL ANALYSIS FRAMEWORK

To predict the behavior of structures exposed to fire, thermal and mechanical properties of structural materials must be reflected. In this study, thermal and mechanical properties of concrete were obtained by

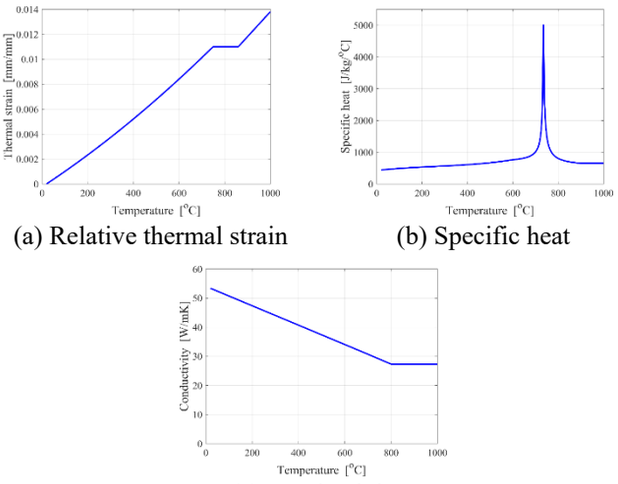
material experiments conducted in the Fire Insurers Laboratories of Korea (FILK) were applied for the thermal and mechanical properties of concrete. For the thermal and mechanical properties of steel, the criteria presented by Eurocode 3 (2005) were used.

To predict the structural behaviors of structures similarly to the actual fire situation, the following three works can be considered to be important: the calculation of thermal flow field from the fire source to the structure, heat transfer analysis to the inside of structure, and structural analysis reflecting the temperature change inside the structure. Because each of these analyses influence the results of other analyses, a method of connecting the previous analysis results to the next analysis is required. This study proposes a fire structure analysis method that can reflect the multi-physics characteristics of thermal flow, heat transfer, and structural system. First, thermal flow field from the fire source to the structure is calculated using the Fire Dynamics Simulator (FDS). Using an interface model between the FDS model and the finite element structural analysis model, the surface temperature of the structure derived from the FDS analysis is applied as the boundary condition of structural analysis. Finally, the fire behavior of structure is calculated by a nonlinear finite element method with the temperature boundary condition and the thermal and mechanical properties of structural materials.

3 MATERIAL PROPERTIES

In general, the thermal and mechanical properties of structures change with temperature. Therefore, the temperature dependence of material properties must be considered to reliably and accurately predict the behavior of structure at high temperatures. Some standards and reports such as ASCE Manual and Reports No. 78 (Lie, 1992), Eurocode 2 (2005) and Eurocode 3 (2005) propose the material properties of steel and concrete at high temperatures based on experimental data. In this study, the criteria presented in Eurocode 3 were used for the thermal and mechanical properties of steel, and the data obtained through the experiments of FILK were applied for the thermal and mechanical properties of concrete.

3.1 *Thermal Properties of Steel*



When steel is heated, the thermal properties such as thermal strain, specific heat and conductivity change with rising temperature. Several international standards present the thermal properties of steel based on experimental data. In this study, the equations of the thermal properties of steel and temperature presented by Eurocode 3 (2005) were applied for analysis. Equations (1), (2), and (3) are the relational equations for thermal strain, specific heat, and conductivity, respectively. Figure 1 shows the change of the thermal properties of steel with temperature change.

$$\epsilon_T = \begin{cases} (1.2\times10^{-5})T \\ \quad +(0.4\times10^{-8})T^2 \\ \quad -(2.416\times10^{-4}), & 20℃ < T \le 750℃ \\ (1.1\times10^{-2}), & 750℃ < T \le 860℃ \\ (2\times10^{-5})T - (6.2\times10^{-3}), & \\ & 860℃ < T \le 1200℃ \end{cases} \quad (1)$$

$$C = \begin{cases} 425 \\ \quad +7.73\times10^{-1}T \\ \quad -1.69\times10^{-3}T^2 \\ \quad +2.22\times10^{-6}T^3, & 20℃ \le T < 600℃ \\ 666 + \dfrac{13002}{738-T}, & 600℃ \le T < 735℃ \\ 546 + \dfrac{17820}{T-731}, & 735℃ \le T < 900℃ \\ 650, & 900℃ \le T \le 1200℃ \end{cases} \quad (2)$$

$$\lambda = \begin{cases} 54 - 3.33\times10^{-2}T, & 20℃ \le T < 800℃ \\ 27.3, & 800℃ \le T \le 1200℃ \end{cases} \quad (3)$$

Here, T denotes temperature, ϵ^{th} denotes thermal strain, C denotes specific heat, and λ denotes the thermal conductivity.

3.2 *Mechanical Properties of Steel*

Eurocode 3 (2005) presents mechanical properties of steel as well as the thermal properties. Eurocode 3 uses several parameters to characterize the stress-strain relationship of steel at specific temperatures. These parameters are yield strain ($\epsilon_{y,T}$), limit strain for yield strength ($\epsilon_{t,T}$), and ultimate strain ($\epsilon_{u,T}$), which have the values of 0.02, 0.15, and 0.2, respectively. Furthermore, the reduction factors in Table 1 are used to define the modulus of elasticity, elastic limit and yield strength at elevated specific temperatures. Each reduction factor can be defined by Eq. (4), (5), and (6) respectively.

Table 1. Reduction factors for stress-strain relationship at elevated temperatures.

T (℃)	Reduction factor of yield strength $(k_{y,T})$	Reduction factor of elastic limit $(k_{p,T})$	Reduction factor of of the modulus of elasticity $(k_{E,T})$
20	1.000	1.000	1.000
100	1.000	1.000	1.000
200	1.000	0.807	0.900
300	1.000	0.613	0.800
400	1.000	0.420	0.700
500	0.780	0.360	0.600
600	0.470	0.180	0.310
700	0.230	0.075	0.130
800	0.110	0.050	0.009
900	0.060	0.0375	0.0675
1000	0.040	0.0250	0.0450

$$k_y,T = f_{y,T}/f_y \tag{4}$$

$$k_{p,T} = f_{p,T}/f_y \tag{5}$$

$$k_{E,T} = E_T/E_0 \tag{6}$$

The constitutive equation is defined as Eq. (11) using the variables a, b, and c defined by Eqs. (8), (9), and (10). The stress-strain relation consists of four steps in total: linear elasticity section, nonlinear section after elastic limit, perfectly plastic, and softening sections. Figure 2 shows this stress-strain relationship presented in Eurocode 3 (2005).

$$\epsilon_{p,T} = f_{p,T}/E_T \tag{7}$$

$$a^2 = (\epsilon_{t,T} - \epsilon_{p,T})(\epsilon_{y,T} - \epsilon_{p,T} + {}^{c}/_{E_T}) \tag{8}$$

$$b^2 = c(\epsilon_{y,T} - \epsilon_{p,T})E_T + c^2 \tag{9}$$

$$c^2 = \frac{(f_{y,T} - f_{p,T}^2}{(\epsilon_{y,T} - \epsilon_{p,T})E_T - 2(f_{y,T} - f_{p,T})} \tag{10}$$

$$\sigma = \begin{cases} \epsilon E_T\,, & \epsilon \le \epsilon_{p,T} \\ f_{p,T} - c + \left(\frac{b}{a}\right)\left[a^2 - (\epsilon_{y,T} - \epsilon)^2\right]^{0.5}, & \epsilon_{p,T} < \epsilon < \epsilon_{y,T} \\ f_{y,T}, & \epsilon_{y,T} < \epsilon < \epsilon_{t,T} \\ f_{y,T}\left[1 - \frac{\epsilon - \epsilon_{t,T}}{\epsilon_{u,T} - \epsilon_{t,T}}\right], & \epsilon_{t,T} < \epsilon < \epsilon_{u,T} \\ 0, & \epsilon = \epsilon_{u,T} \end{cases} \tag{11}$$

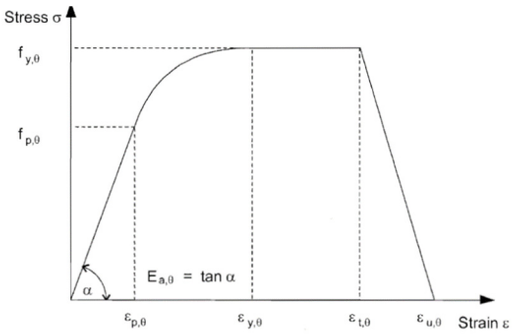

Figure 2. Stress-strain relationship presented in Eurocode 3

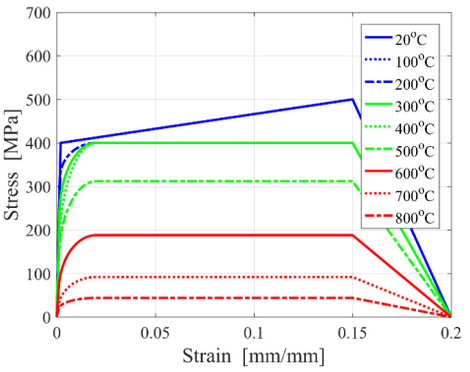
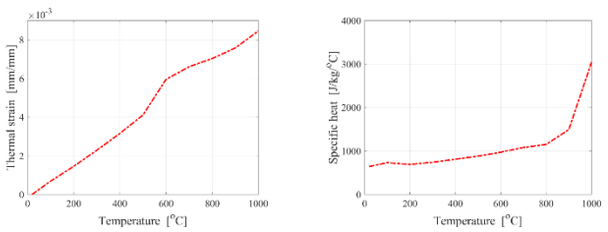
For nonlinear thermo-mechanical analysis, the stress-strain relation was applied using Eq. (12) which is the relational equation of yield strength and ultimate strength according to temperature. Figure 3 shows the stress-strain relation of steel applied to nonlinear thermo-mechanical analysis.

$$f_u(T) = \begin{cases} 1.25 f_y(T), & 0℃ \le T < 300℃ \\ f_y(T) \cdot (2 - 0.0025T), & 300℃ < T \le 400℃ \\ f_y(T)\,, & 400℃ \le T \le 1200℃ \end{cases} \tag{12}$$





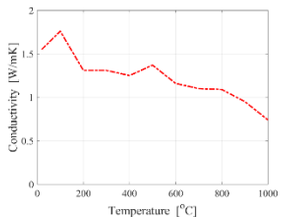


Figure 3. Stress-strain relationship of a steel material

3.3 *Thermal Properties of Concrete*

Thermal and mechanical properties of concrete were obtained by material experiments conducted in Fire Insurers Laboratory of Korea (FILK). Figure 4 shows the thermal properties of concrete that vary with temperature change. When concrete is heated, the thermal strain and specific heat increase overall as the temperature rises, whereas conductivity decreases as the temperature rises.

(a) Relative thermal strain (b) Specific heat

(c) Conductivity

Figure 4. Thermal properties of a concrete material

3.4 *Mechanical Properties of Concrete*

The stress-strain relation of concrete by temperature could be obtained from experiments in the Fire Insurers Laboratory of Korea (FILK). Figure 5 shows the stress-strain relation in the temperature range of 20~800℃. Figure 6 shows that the compressive strength of concrete sharply decreased at 100℃, restored to a similar compressive strength as the value at room temperature, and decreased again as the temperature increased above 300℃.

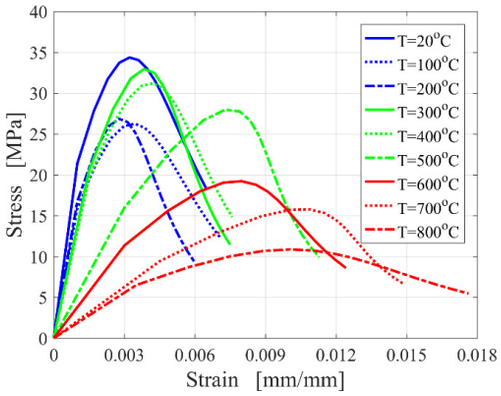

Figure 5. Stress-strain relationship of a concrete material

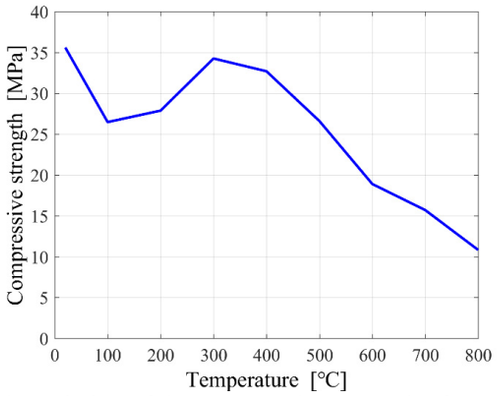

Figure 6. Variation of the compressive strength of concrete with temperature change

4 PLASTIC DAMAGE MODEL

Many plastic models have been proposed for the inelastic analysis of concrete structures showing hardening and softening behaviors when large deformations occur. This study used the plastic damage model proposed by Lee and Fenves (1998) alculates nonlinear behavior considering the loss of strength and stiffness due to concrete cracking.

The plastic damage model is based on the continuum mechanics approach to calculate the behaviors of continuum. In this model, the total strain (ϵ^{total}) consists of elastic strain (ϵ^{el}), plastic strain(ϵ^{pl}), and thermal strain(ϵ^{th}) as shown in Eq. (13).

$$\epsilon^{total} = \epsilon^{el} + \epsilon^{pl} + \epsilon^{th} \tag{13}$$

The plastic response of an undamaged material can be recorded in the effective stress space of the elastic area. The stress-strain relation is defined as Eq. (14), where C_0^{el} is the 4th order isotropic linear elastic stiffness tensor.

$$\sigma = C_0^{\text{el}} : \epsilon^{el} = C_0^{\text{el}} : (\epsilon^{total} - \epsilon^{pl} - \epsilon^{th}) \tag{14}$$

$$\begin{aligned} \sigma &= (1-d)C_0^{\text{el}} : (\epsilon^{total} - \epsilon^{pl} - \epsilon^{th}) \\ &= C^{\text{el}} : (\epsilon^{total} - \epsilon^{pl} - \epsilon^{th}) \end{aligned} \tag{15}$$

The plastic damage model reflects the reduction of the modulus of elasticity due to concrete damages using the damage variable d as shown in Eq. (15). The parameter indicates the concrete damage effect and helps the modeling of inelastic behavior of concrete. Figures 7 and 8 show the responses of uniaxial compression and uniaxial tension for the total strain, respectively.

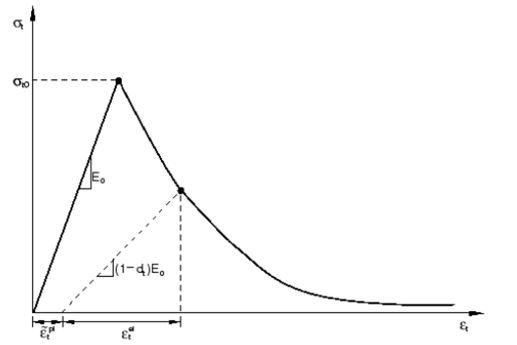

Figure 8. Response of concrete in uniaxial tension

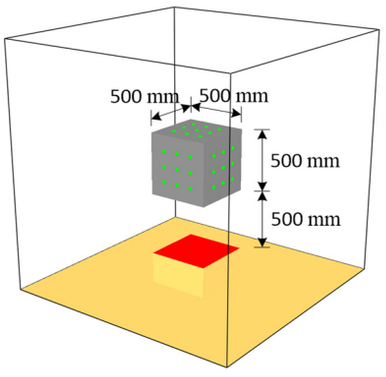
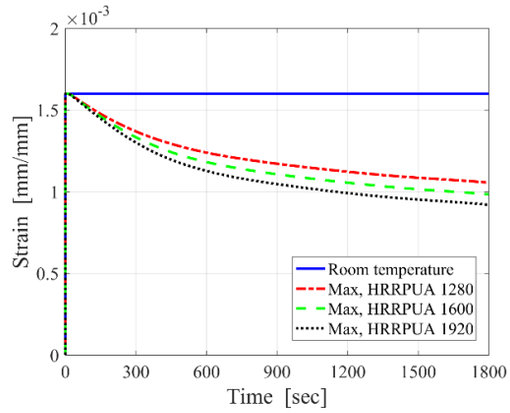
5 RESULTS OF THERMO-MECHANICAL ANALYSIS

5.1 *Nonlinear Thermo-Mechanical Analysis of Representative Volume*

The thermal flow field due to fire from the fire source to the representative volume was calculated through FDS simulation. The temperature history of the representative volume surface exposed to fire could be obtained through fire flow analysis using the FDS model. The domain for FDS simulation is independent from the finite element model domain for thermo-mechanical analysis. In order to apply the surface temperature obtained through FDS simulation in the thermo-mechanical analysis as the boundary condition, a new model is required to send the surface temperature from the FDS model to the new model while sharing the discretization information of each model. In this study, an interface model was developed that sends the time history of the surface temperature at each node of the FDS model to the node of the finite element model at the corresponding location. Using this interface model, preliminary thermo-mechanical analysis was performed by applying the temperature history obtained through thermal flow analysis at each node of the representative volume and the applicability of the nonlinear thermo-mechanical analysis framework was verified.

The representative volume is a cube with a side length of 500 mm and is assumed that the bottom is exposed to fire as shown Fig. 7. The material properties of steel and concrete were applied to the representative finite element model and a pressure was applied to the top surface of the representative volume.





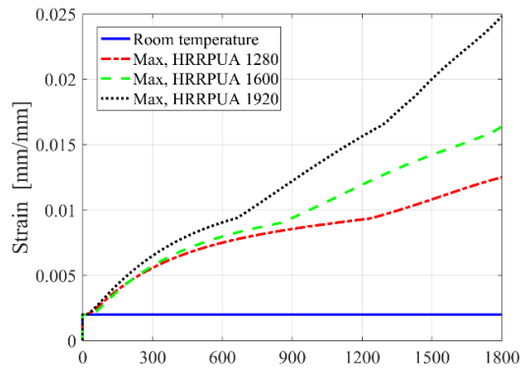


Figure 9. Modeling of a representative volume (RV) structure exposed to fire

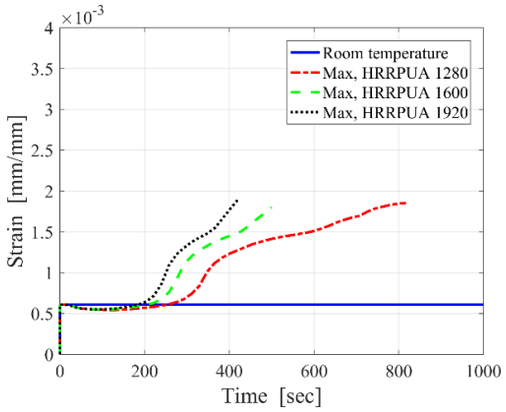
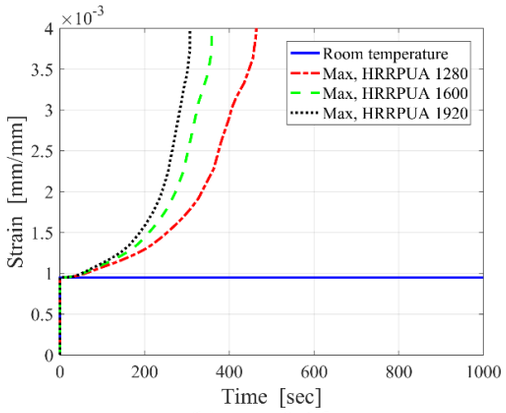
Figure 10 (a) and (b) show the time history of compressive strain at the top surface center of the steel representative volume in which a fire occurred. As the maximum heat release rate per unit area (HRRPUA) increased at the pressure of $0.8f_y$, the compressive strain of the representative volume decreases due to the thermal expansion of steel. If the pressure is f_y, even if thermal expansion of the representative volume occurs, the compressive strain of the representative volume increases higher than the yield strain due to the yield of material. Figure 11 (a) and (b) show the time history of compressive strain calculated at the top surface center of the concrete RV in which a fire occurred. At the pressure of $0.4f_u$, thermal expansion occurs in the concrete RV, but the compressive strain increases higher than the strain at room temperature. If the pressure increases to $0.6f_u$, the compressive strain of RV increases much higher than the strain at room temperature due to the ignorable thermal expansion effect.



(a) $p = 0.8f_y$



(b) $p = f_y$

Figure 10. FDS-FE fire structural analysis on steel RVs

Figure 11 (a) and (b) show the time history of compressive strain calculated at the top surface center of the concrete RV in which a fire occurred. At the pressure of $0.4f_u$, thermal expansion occurs in the concrete RV, but the compressive strain increases higher than the strain at room temperature. If the pressure increases to $0.6f_u$, the compressive strain of RV increases much higher than the strain at room temperature due to the ignorable thermal expansion effect.

(a) $p = 0.4f_u$

(b) $p = 0.6f_u$

5.2 *Nonlinear Thermo-mechanical Analysis of Steel-Concrete Composite Beam*

A finite element model of the same scale as the specimen was configured based on the design drawing of the steel-concrete composite beam. The slab of the steel-concrete composite beam specimen has a length of 4000 mm and a section of 1000 mm × 210 mm as shown in the design drawing in Figure 12. The steel girder flange has a width of 203.1 mm and a thickness of 13.5 mm, and the web has a height of 320 mm and a thickness of 7.7 mm.

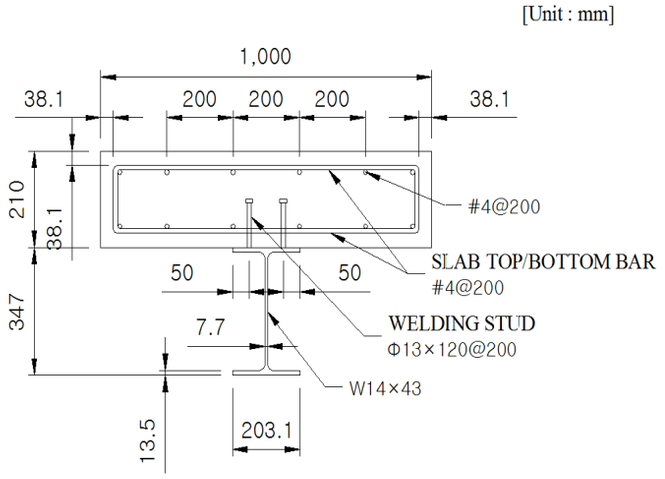

Figure 12. Design drawing of composite beam

The finite element model was created using ABAQUS, a universal finite element analysis application. The steel inside the concrete was modeled as a 3D truss element with 2 nodes (T3D2T), the steel girder as a shell element with 4 nodes (S4RT), and the concrete slab as a 3D solid element with 8 nodes (C3D8T). The number of elements used is 2,226 for steel modeling and 8,000 for concrete slab. The total number of elements for the finite element model is 11,711. Figure 13 shows the finite element models of the steel-concrete composite beam.

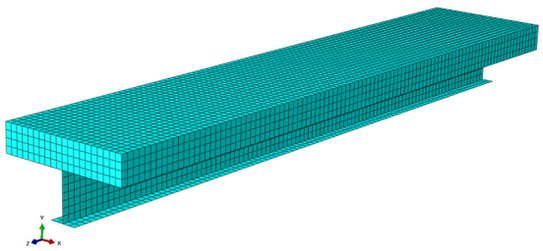

Figure 13. Finite element modeling of the composite beam

Figure 14 shows support and loading conditions of the composite beam. The beam is simply-supported, 5 m long, and loaded by two symmetric concentrated loads each of which is 119.5 kN. The distance between supports is 4.5 m and the distance between the two loading points is 1 m. This loading condition corresponds to a service limit state of the composite beam with no exposure to fire according to concrete design code for nuclear power plant structures in Korea. The bottom part of the composite beam was heated according to standard fire curve (ASTM E119, 2016).

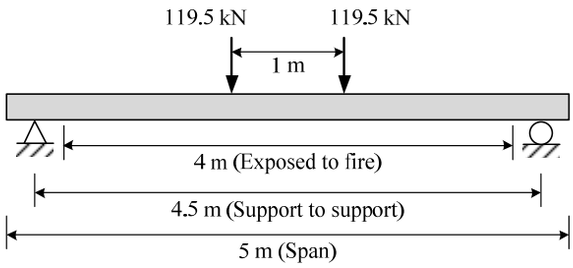

Figure 14. Test configuration

Figures 15 shows the temperature distribution of the steel-concrete composite beam. The temperature of the steel girder and slab bottom to which the standard fire curve had been applied was the highest and the thermal conductivity occurred more easily in the steel girder than in the concrete.

To obtain analysis results similar to the experimental results, the structural relations of steel were varied during the analysis. Concrete thermocouples were installed inside the slab to check the temperature inside the concrete slab. They were installed in 30 mm intervals from the slab bottom as shown in Fig. 16, and the temperature of each thermocouple was compared with the temperature in the thermal analysis results in Fig. 17. Although the thermocouple temperature at slab heights of 80 mm or higher was lower than 100 ℃, which is similar to

the temperature obtained from analysis, the thermocouple temperature at the slab height of 30~80 mm was approximately 100 ℃, which is different from the temperature calculated from thermal analysis. This temperature difference seems to have been caused because the moisture in concrete was evaporated at 100 ℃ during this experiment and the temperature did not increase much.

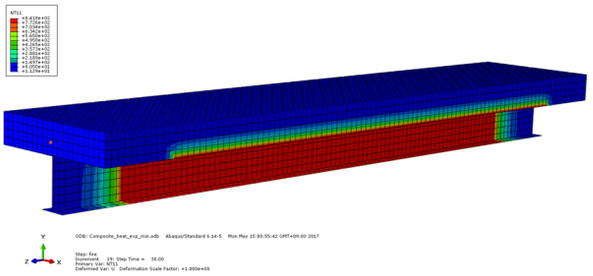

Figure 15. Change of temperature at slab vertical locations

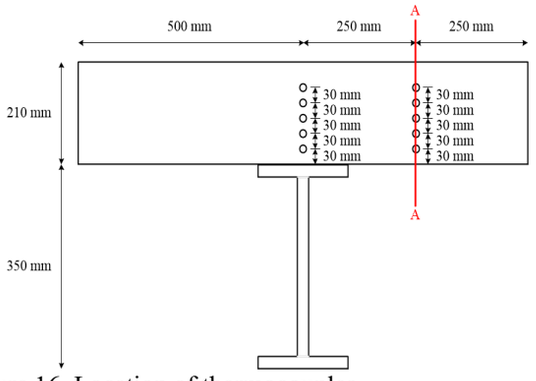

Figure 16. Location of thermocouples

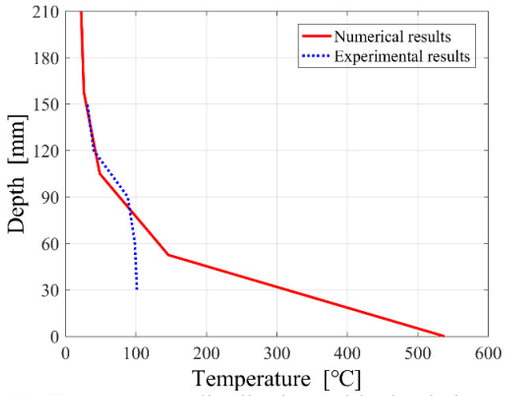

Figure 17. Temperature distribution with depth into the slab (A-A)

To obtain analysis results similar to the experimental results, the structural relation of steel was varied during the analysis. Case 1 shows a linear model in which both the elastic and plastic sections proposed in illam et al. (2009) are linear. Case 2 is the perfectly plastic model as presented in Eurocode 3. Case 3 shows a strain hardening model in Fig. 3. The stress-strain relation of each case is shown in Fig. 18.

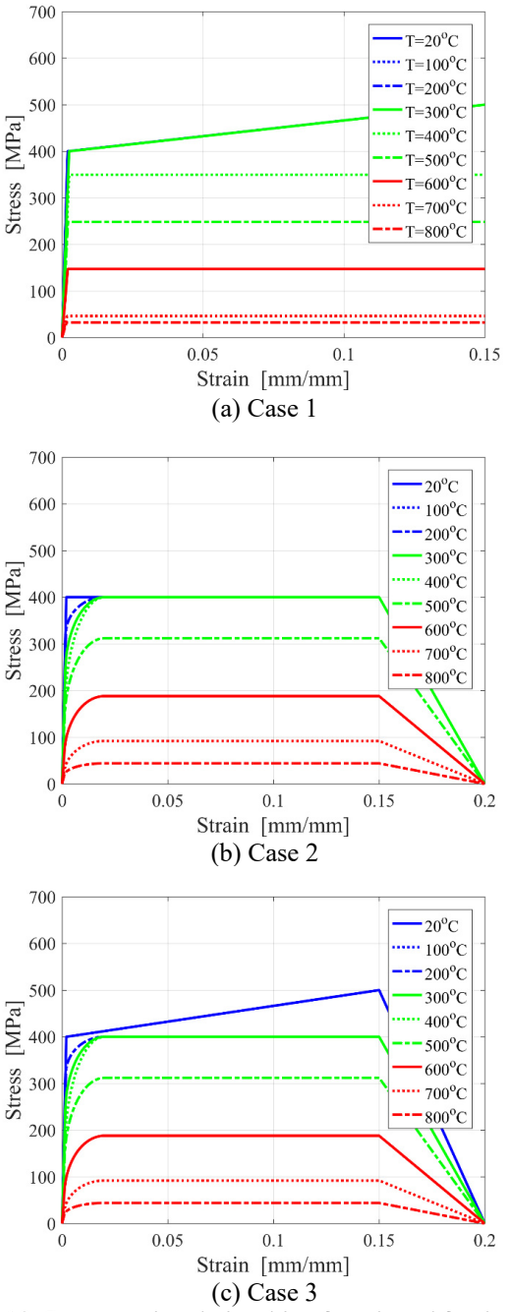

Figure 18. Stress-strain relationship of steel used for the analysis of the composite beam

Figure 19 and 20 show the fire experiment results of the actual steel-concrete composite beam and nonlinear thermo-mechanical analysis results, respectively. Figure 21 confirms that when the strain hardening model is applied to the structural relation of the experimental steel, the experimental results and the analysis results are most similar.

Figure 19. Steel-concrete composite beam after fire experiment

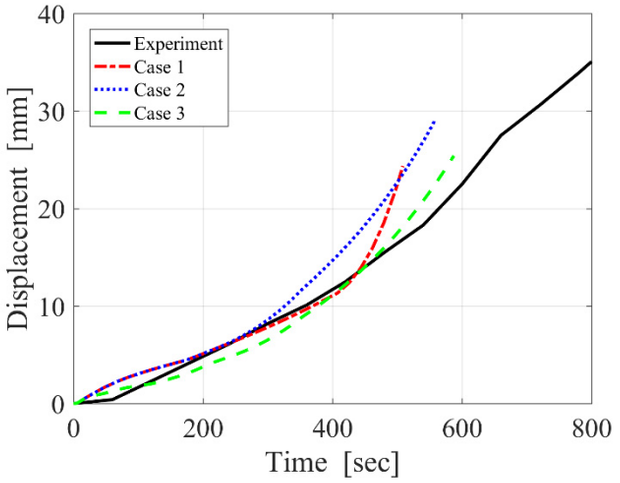

Figure 21. Predicted and measured displacement of the composite beam

6 CONCLUSION

In this study, a thermo-mechanical analysis framework was proposed considering material properties. A fire structure analysis of a RV structure and a steel-concrete composite beam exposed to fire was performed using the framework. The time history of compressive strain for RV structure exposed to fire was obtained as a result of the RV analysis and the applicability of the proposed framework was verified. The time history for the middle displacement on a simple support steel-concrete composite beam exposed to fire was calculated using the framework. The displacement results calculated through thermo-mechanical stress analysis were compared with the displacement results of the actual fire experiment in the FILK. The analysis results are significantly similar to the experimental results, and this verifies the validity of the framework.

The performance estimation of pile-protective structures using simplified collision model

GyeHee Lee
Department of Ocean Civil Engineering
Mokpo National Maritme University, Mokpo, Republic of Korea

ABSTRACT: In this study, a simplified collision model of pile protective structures against a navigation vessel was proposed and verified. The model of pile protective structure was composed by two plastic hinges at below of cap slab and the inside of ground. A equation of motions was developed in considering of the kinematic energy, potential energy and deformation energy in collision event. The developed simplified model was verified by the precise finite element collision analysis of the vessel and the protective structure. The parametric study was performed by using the simplified collision model. As a result, the collision behaviors of the protective structures could be tuned by the control of the inertia mass of capping slab.

1 INTRODUCTION

As the development of bridge technology, long-span bridges are being built across the navigation channels, and new design techniques are adopted in specifications and various collision protective structures are being planned and constructed. Among the various collision protective structures, the pile-type collision protective structure which has the energy dissipation mechanism by the plastic hinge of the pile has the advantage that the efficiency of construction equipment operation and the amount of dissipated energy can be easily controlled. However, since nonlinear behaviors included in the interaction of the pile and the soil, the internal material and the reinforcing bar, and the influence of the upper capping slab must be considered, the precise collision analysis requires a very large analysis model and a expensive analysis cost. This difficulty can be solved by using a simplified collision model which minimizes the degree of freedom which showing the nonlinear behavior of the structure. Using this kinds of simple model, we can develop a design methodology for nonlinear behavior by analyzing the effects of various parameters through a series of iterative analysis.

The development of a simplified model for ship collision had been mainly done in shipbuilding engineering(Sajdak 2004, Tabri 2010). These studies mainly focused on the collision between the ship and the ship, and the changes of ship movement after collision. A simplified collision model between a ship and a bridge was developed and used in the collision analysis for the superstructure of bridges and barges in Korea (Lee 2011). In order to protect a collision of 100000DWT ship, numerical analysis and field test were carried out for 1/15 scale reduction model in the process of designing pile-type collision protective structure(Patsch et al. 2011). They showed that the numerical analysis could simulate the behavior of the file with sufficient accuracy. Zhu et al. evaluated the lateral loading capacity of piles for construction of a ship collision protective structure in a large chamber (Zhu et al. 2012). The static and dynamic $p-y$ curves were calculated from the results of dynamic impact load using pendulum motion and static load using cable. They concluded that it is reasonable to compare the three types of theoretical dynamic $p-y$ curves with the curves obtained from the experiment. This the dynamic $p-y$ curve of the pile and a constant damping ratio were used collision analysis. The damping ratio used this analysis was obtained from the linear dynamic analysis.

In the Korean design code of bridges, the collision force is presented as a function of the mass and velocity of collision ship (Chang 2006). However, the collision force presented in the Korean code shows nonconservative trendy as collision conditions because the formula for the collision force was developed under not enough understanding of ship collision phenomena(Lee & Hong 2011).

Fan et al. proposed a scheme to determine the properties of nonlinear spring of ship bow as collision speed, the spring is a part of mass-spring SDOF model of ship body and bow. The SDOF model was proposed to design a cable-stayed bridge foundation against direct ship collision (Fan et al. 2011). In these

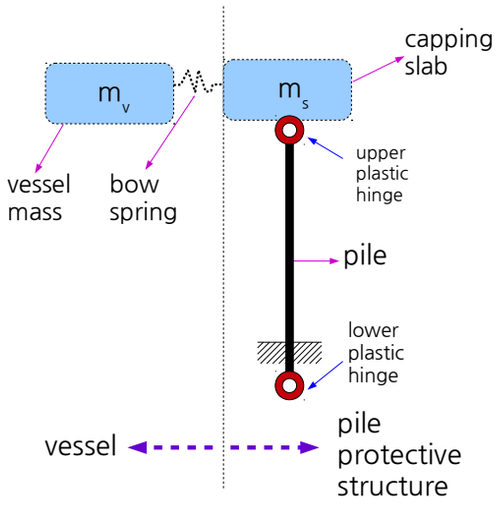

Figure 1: Simplified Collision Model

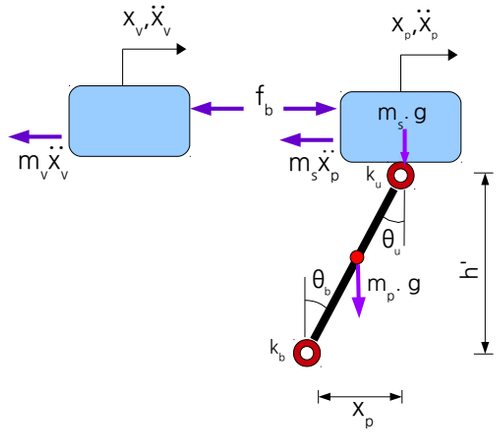

Figure 2: Forces at Collision

studies, they focused on the strain rate of steel bow, and proposed the bow strength curve based on strain rate.

In this study, the equations of the simplified model for effective collision analysis of pile-type protective structure was developed and verified by the results of the precise FEM collision analysis. The energy dissipation characteristics used in the simplified model was obtained from the FEM analysis model.

2 DEVELOPMENT OF SIMPLIFIED MODEL

The following conditions were assumed in the development of the simplified collision model.

- Collisions occur in the plane.
- Ship bow and piles behave plastic-elastically.
- The plastic behavior of the pile is concentrated(plastic hinge).

figure 1 shows the schematic shape of the simplified collision model of the pile-type collision protective structure to derive the equation of motion. The collision ship was simplified to a collision mass(m_v) and a bow spring, which represents the collision force due to the deformation of the bow. A pile-type collision protective structure consists of a capping slab (upper slab) and piles. Here, the capping slab constrains the head of piles to move together and transmit the collision force. Since the heads of piles are tie together by capping slab, its rotational freedoms are ignored. The mass of the slab(m_v) means the mass that resists the collision by inertia force at collision. It was assumed that the group of piles constituting the protective structure has concentrated characteristics.

The force acting on the ship and the guard during collision is shown in figure 2. During the collision, the ship is subjected to inertia force and the reaction force due to deformation of the bow. The equilibrium equation for this is as follows.

$$m_v \ddot{x}_v + f_b = 0 \tag{1}$$

where m_v is the collision mass of the ship, including hydrodynamic additional mass, and f_b is the nonlinear reaction force generated by deformation of the bow, respectively. This reaction force is a function of relative displacements between the ship displacement(x_v) and the structure displacement(x_p). This relative displacement $(x_v - x_p)$ is denoted the deformation of the ship bow.

During the collision process, the movement of the ship and the structure is as follows.

$$(f_b - m_s \ddot{x}_p)h' + g\, x_p(m'_s + \frac{m'_p}{2}) = k_u + k_b \tag{2}$$

where m_s is the mass of the slab, m_p is the mass of the pile group, respectively. The superscript $'$ denote the values in water. $\ddot{x_p}$ is the acceleration of the slab and h' is the vertical height of moment arm from the plastic hinge to the collision point, respectively. If the sum of the moments and the secondary moments of the structure caused by the slab displacement was less than the sum of the plastic moments of both plastic hinges, the protective structure would be stopped. In collision, the total moment resistance of the structure is as follows.

$$M_p = k_u + k_b - (m'_p/2 + m'_s)x_p \tag{3}$$

The horizontal force caused by this moment is as follows

$$f_p = \frac{M_p}{h'} \tag{4}$$

By the equilibrium of horizontal force, (2) can be rewritten

$$m_s \ddot{x}_p + (f_p - f_b) = 0 \tag{5}$$

To solve (1), (5), the following variables are assumed.

$$\left\{ \begin{array}{c} y_1 \\ y_2 \\ y_3 \\ y_4 \end{array} \right\} = \left\{ \begin{array}{c} x_v \\ \frac{dx_v}{dt} \\ x_p \\ \frac{dx_p}{dt} \end{array} \right\} \tag{6}$$

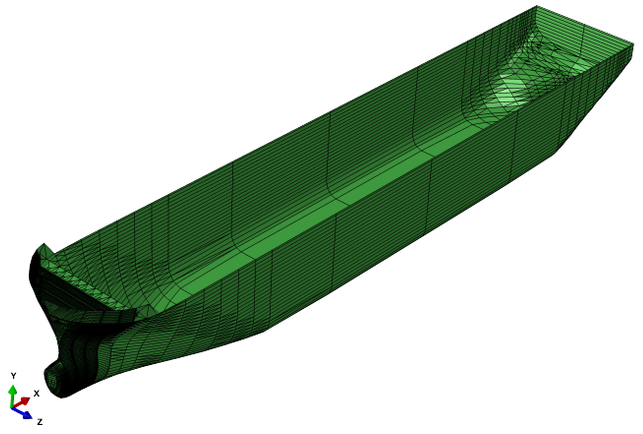

Figure 3: FEM Model of Ship

Substituting (1), (5) to (6), the following equation can be obtained.

$$\begin{Bmatrix} \frac{dy_1}{dt} \\ \frac{dy_2}{dt} \\ \frac{dy_3}{dt} \\ \frac{dy_4}{dt} \end{Bmatrix} = \begin{Bmatrix} y_2 \\ \frac{-f_b(x_v - x_p)}{m_v} \\ y_4 \\ \frac{f_b(x_v - x_p) - f_p(x_p)}{m_s} \end{Bmatrix} \tag{7}$$

Since (7) contains many nonlinear terms, it is hard to solve by the algebraic method, so the solution is calculated numerically. To do this, the fourth-order Runge-Kutta method is used. The application of this method was performed using the *lsode45* function of the numerical analysis package GNU Octave(Eaton et al. 2014).

3 VERIFICATION

3.1 *FEM model*

To verify the developed simplified collision model, nonlinear dynamic collision analysis was performed using commercial FEM package ABAQUS 6.10 (Simulia 2010). The verification FEM model was consist the ship, the protective structure and the ground soil. The ship modeled in verification FEM analysis was the size of 7000GT car carrier and it was modeled by shell elements. The ship bow was modeled by fine meshes, since the collision force would be concentrated. The material and geometric nonlinear behavior in the collision were also considered. The main body was modeled using a shell element, but relatively coarse mesh was used as compared to the ship bow, and elastic behaviors were assumed.

The elastic-plastic material properties were assumed for the bow part and the strain rate effects were considered as follows

$$\frac{\bar{\sigma}}{\sigma_0} = 1 + \left(\frac{\dot{\epsilon}_{pl}}{D}\right)^{\frac{1}{n}} \tag{8}$$

where $\bar{\sigma}$ is the dynamic flow stress, σ_0 is the static flow stress, $\dot{\epsilon}_{pl}$, is the strain rate and D, n are constants

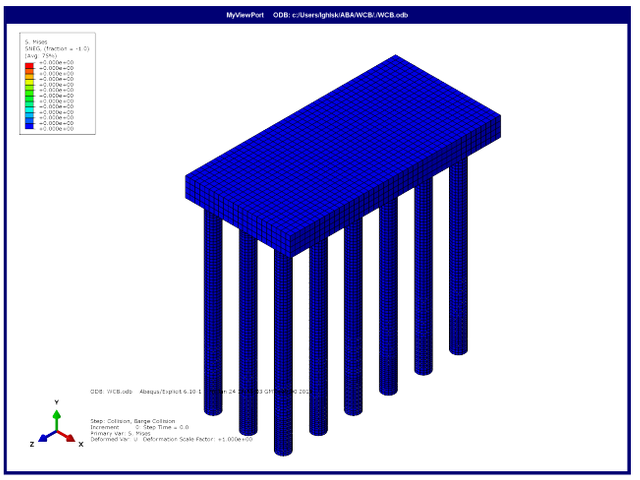

Figure 4: FEM model of protective structure

Table 1: Parameters used in simplified collision model

Mass of Ship (m_v)	1.675E7 kg
Mass of Slab(m_s)	3.544E6 kg
Mass of Piles (m_p)	3.944E5 kg
Dist. of Plastic Hinges (h_p)	23.96 m
Collision Velocity (v_0)	5 m/s

that depend on the material, respectively. In this study, $D = 40.4/sec$, $n = 5$ were used.(Simulia 2010).

The hydrodynamic additional mass was calculated as the design standard (AASHTO 2010). For the efficiency of analysis, the mass scaling which is a technique to increase the critical time step by changing the material density was used for a dense mesh part, that was ship bow. Detailed modeling techniques for other vessels followed the methods developed in previous study(Lee & Hong 2011).

The pile, which is the main energy dissipation mechanism of the pile collision protection structure, was modeled as steel pipe with radius R = 1.0 m. The length of the pile is assumed to be 30 m, and the upper part is assumed to be constrained on the capping slab that is assumed to be an elastic material, and the lower part was assumed to be fixed in bedrock while being penetrated into the soil layer. It was assumed that the soil layer are composed of three layers of clay and sandy soil with a total depth of 10 m. The material of pile was assumed as SS400 steel and material nonlinear behaviors were considered. Nonlinearity of the ground was considered by using nonlinear springs(Lee, Park, & Hong 2012). The objective protective structure was consist of 18 piles and the capping slab confining the piles to dissipate the collision energy of ship.(figure 3)

3.2 *Simplified model*

To verify the developed simple collision model, the collision analysis was performed by the simplified model with the same conditions of FEM model and the two results were compared.

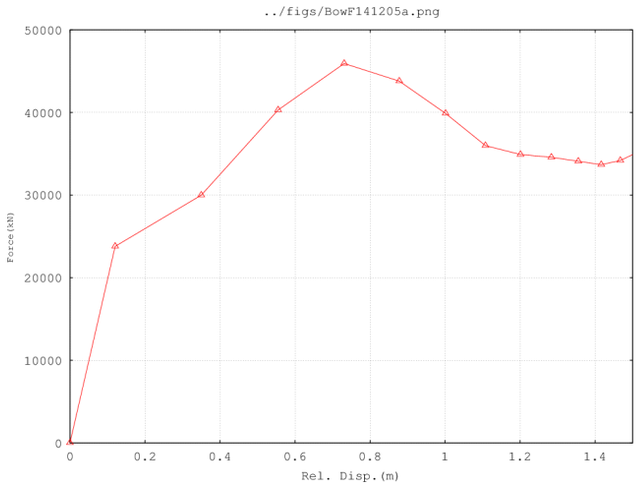

Figure 5: Bow reaction curves used in simplified verification analysis

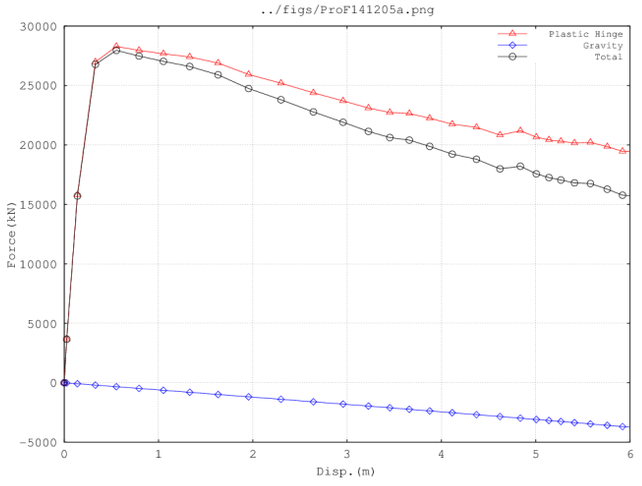

Figure 6: Structure reaction curves used in simplified verification analysis

The analysis parameters applied to the simplified collision model were obtained from the results of FEM analysis and are shown in 1. The location of the plastic hinges were defined as the intersection obtained by extending the center line of the pile which does not cause rotational deformation in the precision analysis.

In collision analysis, both the structure and the ship are subjected acceleration, therefore the force acting between the two objects must be calculated in consideration of the inertia force. In this study, the acceleration history is obtained from the velocity change of the ship bow and the force history during the collision was calculated from the result of the FEM analysis (Lee & Hong 2011). In the resistance curve of the protective structure, the weight of capping slab causing secondary moment according to displacement increases. However, in this verification analysis, the influence of the secondary moment due to the displacement was not considered(figure 6).

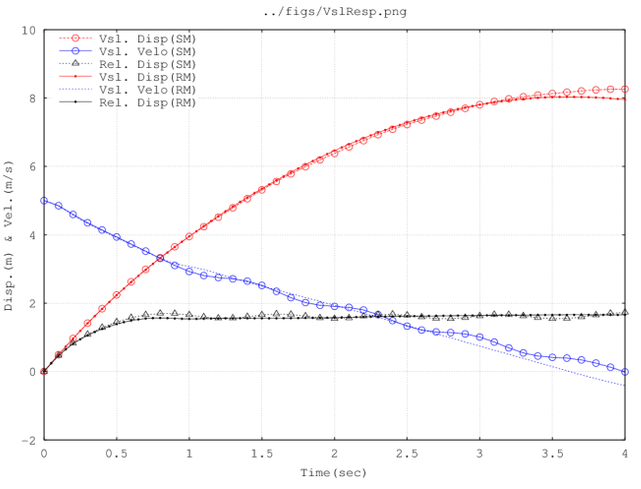

Figure 7: Response comparisons of ship

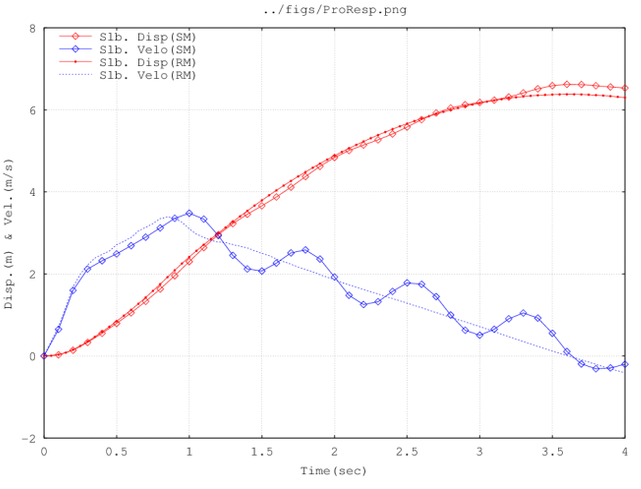

Figure 8: Response comparisons of protective structure

3.3 *Comparison of results*

The collision behaviors of the ship and the protective structure obtained from FEM analysis were compared in displacement and velocity(figure 3.3, 3.3). All responses showed similar results to both analysis. However, in the case of the velocity responses, the vibration shape was appeared compared to FEM analysis, and the collision was terminated at about 3.6 seconds and the recoil occurs in FEM analysis. And it was occurred in about 4 seconds in the simplified analysis The overall analysis results of the simplified model were considered to denote sufficient accuracy for the behavior of the ship.

The collision behavior of the protective structure was similar to that of the ship. However, the vibration phenomenon was more prominent than that of ship in the velocity response. However, the overall tendency was the same and the displacement behavior has a sufficient accuracy.

The change in energy during the collision is shown in figure 10. At the point of collision, all energy was in the form of kinetic energy of the collision ship, but at the start of the collision, this energy was dissipated by the plastic deformation of the bow and the protective

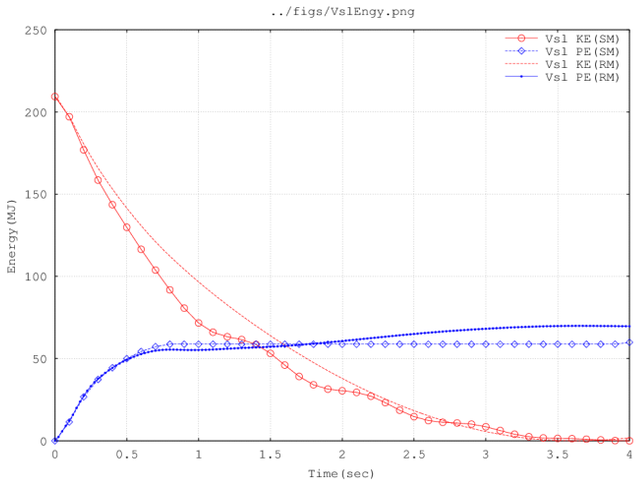

Figure 9: Energy comparisons of ship

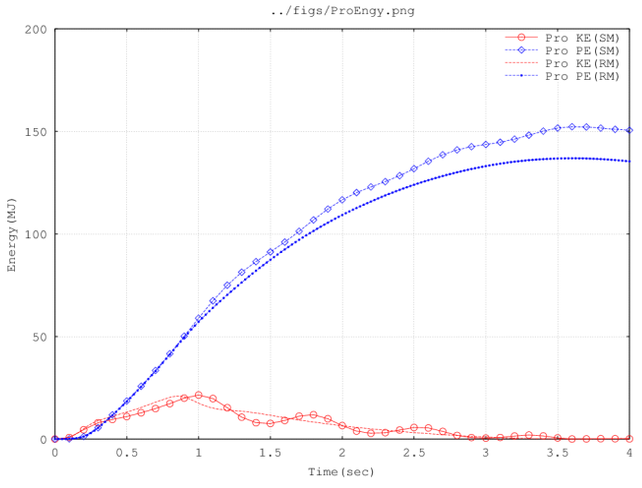

Figure 10: Energy comparisons of protective structure

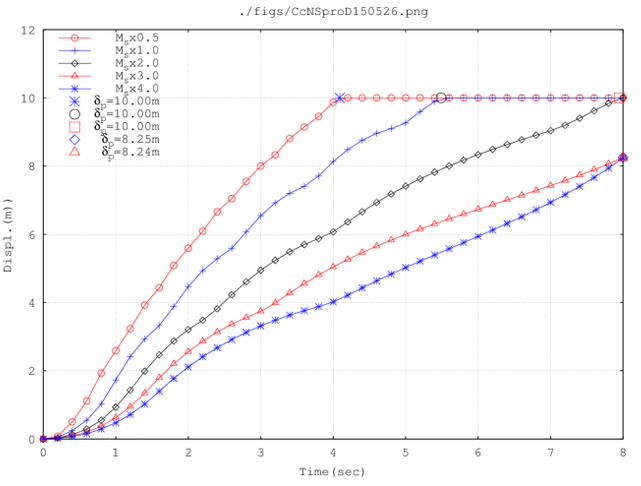

Figure 11: Displacment of protective structure as mass of capping slab

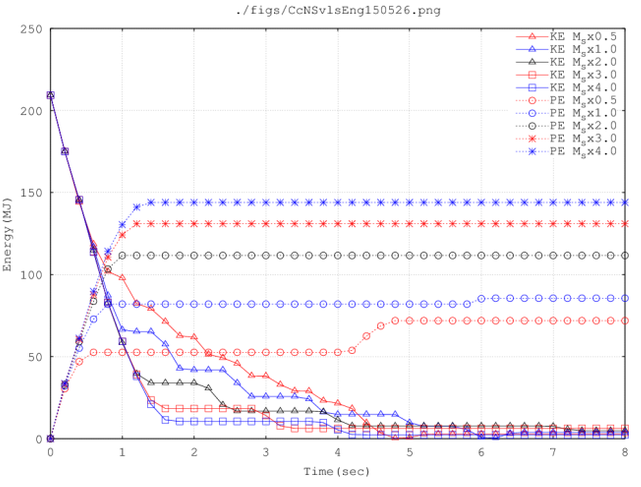

Figure 12: Energy dissipation of vessel as mass of capping slab

structure. The collision energy was mainly dissipated by the plastic deformation of the protective structure.

On the other hand, the kinetic energy of the protective structure was not a large effect on the energy dissipation behavior except for the initial state. The energy change of ship by the simple collision model is very similar to that of FEM analysis except error of kinetic energy due to vibration phenomenon of velocity behavior mentioned above. Overall, however, Of the energy dissipation capacity of the system.

4 PARAMETRIC STUDY

The parametric analysis was performed using the developed simplified model. The characteristics of the plastic hinge considered in the analysis were those of layered pile with diameter of 2m and thickness of 15mm (Lee 2016). The basic collision speed of the ship was assumed 5m/sec, and the bow strength of ship was used that of the verification FEM analysis(figure 6). The maximum displacement of the protective structure was assumed 10 m, considering the case where the displacement of structure was limited by the foundation of the bridge. The other analytical parameters were calculated based on the analytical model used in the verification analysis.

The considered resistance characteristics of the protective structure were the inertia resistance of capping slab mass and the rotational resistance of the plastic hinge. The slab mass was varied from 0.5 to 4 times based on the slab mass(3.543 10^6 kg) of the verification study.

The displacement history of the protective structure is shown in figure 11. When the mass of the slab was less than twice the reference value, the displacement of the protective structure reachees the displacement limit. On the other hand, if the mass of the slab was twice the reference value Or more, the displacement of the protective structure was smaller than the limit value.

In figure 12 shows the amount of dissipated kinetic energy of the ship bow by the plastic deformation. Here, the difference between the kinetic energy and the deformation energy was absorbed as strain energy of the protective structure.

The mass of the slab is not the mass of the structure only but the mass involved in the inertial resistance at collision. The non-structural mass on the slab or the

hydrodynamic added mass of the fluid could be the inertia mass of the slab, and it could be changed easily for the optimal protection design.

5 CONCLUSIONS

In this study, a simplified collision model of pile-type ship protective structure was developed and verified. The pile-type protective structure was modeled as two plastic hinges at the bottom of the upper capping slab and in the ground. The equation of motion including the nonlinear behavior of the bow and the protective structure was derived. The derived equation of motion is numerically analyzed by the Runge-Kutta method. An accurate FEM collision model was constructed considering the nonlinear behaviors at the ship, and the verification was performed by comparing results of two models. As a result, the proposed simple collision analysis model was shown to properly simulate the collision behavior of the pile-type ship collision protection structure. The parametric study was performed by the simplified collision model. As a result, By adjusting the slab mass of the protective structure, the energy dissipation characteristics of the protective structure can be changed greatly. This is a way to easily control the protection ability of the protection structure.

ABSTRACT: The slenderness ratio parameter of steel members such as arch ribs is larger than that of usual steel bridge piers. However, previous studies on the seismic performance of steel members with the large slenderness ratio parameter are not sufficient compared with usual steel bridge piers. The purpose of this study is to obtain more results on the load-carrying capacity and the ductility for steel members with the relatively large slenderness ratio parameter based on the elasto-plastic finite element analysis. The validity of the analytical method was confirmed by comparing the analytical results with the previous experimental results. Based on the valid analytical method, the parametric analysis about the width-thickness ratio parameters was conducted and the effect of the slenderness ratio parameter was investigated. Analysis results indicate that the load-carrying capacity and the ductility for steel members decrease as the slenderness ratio parameter increases or the width-thickness ratio parameters increase.

1 INTRODUCTION

The Kobe earthquake in 1995 caused destructive damage to highway bridges. After the Kobe earthquake, a lot of studies for improving the seismic performance and developing the seismic design methods for steel bridge piers were conducted. Based on the useful information obtained from the investigation on seismic performance of steel bridge piers, some methods for estimating the seismic performance of steel bridge piers or steel members have been already proposed. By the way, the slenderness ratio parameter of steel members such as arch ribs is larger than that of usual steel bridge piers. In "*Design Specifications for Highway bridges, part 5, Seismic Design"* (Japan Road Association 2012), the method for estimating the seismic performance of steel members with the relatively large slenderness ratio parameter is proposed($\bar{\lambda} \leqq 0.5$). However, previous studies on the seismic performance of steel members with the large slenderness ratio parameter are not sufficient compared with usual steel bridge piers whose slenderness ratio parameter is not large. For this reason, it is necessary to obtain more information about the elasto-plastic behavior of steel members with the large slenderness ratio parameter by experimental and analytical studies. In this study, the effect of the slenderness ratio parameter on the load-carrying capacity and the ductility was investigated based on the elasto-plastic finite element analysis. First of all, the validity of the analytical method was confirmed by comparing the analytical results with the previous experimental results. Based on the valid analytical method, the parametric analysis about the slenderness ratio parameter and the width-thickness ratio parameters was conducted.

2 OUTLINE OF THE ANALYITICAL METHOD

It is necessary to confirm the validity of the analytical method before investigating the load-carrying capacity and the ductility for steel members by analysis. To confirm the validity of the analytical method, the analysis result was compared with the experimental result in the previous cycle loading experiment (Okada et al. 2010).

2.1 *Analytical program*

For the analysis, an elasto-plastic finite displacement analysis program "CYNAS" (Nishimura et al. 1995; Ono et al. 2016) was used in this study. CYNAS used shell elements. Material constants of a constitutive equation (Azumi. 2016) used in CYNAS can accurately represent steel material properties.

2.2 *Analytical model*

The test specimen (S-44-15) in the previous cycle loading experiment was modeled (Okada et al. 2010). The test specimen has large slenderness ratio

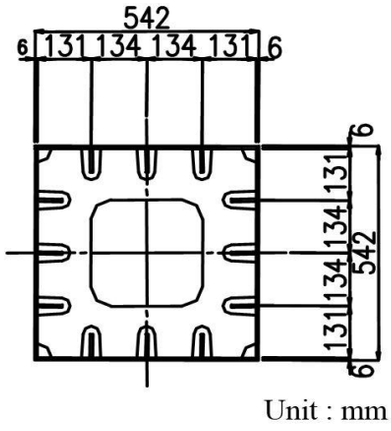

Figure 1. Cross-section of the test specimen(S-44-15).

parameter ($\bar{\lambda}$ =0.51). The values of other parameters are below: R_R =0.53, R_F =0.49, N/N_y =0.11, γ_l/γ_l^* =1.19. R_R and R_F are the width-thickness ratio parameters defined by Equation 2 and Equation 3. N/N_y is the axial force ratio. γ_l/γ_l^* is the stiffness ratio of stiffener. The details of the test specimen (S-44-15) are shown in Table 1. The details of cross-section, side view and analytical model are shown in Figures 1 and 2.

$$\bar{\lambda} = \frac{1}{\pi} \cdot \sqrt{\frac{\sigma_y}{E}} \cdot \frac{2L}{r} \tag{1}$$

$$R_R = \frac{b}{t} \cdot \sqrt{\frac{\sigma_y}{E} \cdot \frac{12(1-\nu^2)}{\pi^2 k_R}} \tag{2}$$

$$R_F = \frac{b}{t} \cdot \sqrt{\frac{\sigma_y}{E} \cdot \frac{12(1-\nu^2)}{\pi^2 k_F}} \tag{3}$$

$$k_F = \begin{cases} \dfrac{(1+\alpha^2)^2 + n\gamma_l}{\alpha^2 \cdot (1+n\gamma_l)} \cdots (\alpha < \alpha_0) \\ \dfrac{2 \cdot (1+\sqrt{1+n\gamma_l})}{1+n\gamma_l} \cdots (\alpha \geq \alpha_0) \end{cases} \tag{4}$$

where σ_y = yield stress; E = Young's modulus; N = axial force; N_y = yield axial force (=$A\sigma_y$); A = cross-section area of column; L = column height (distance from the bottom of the column to the point of application of horizontal load); r = radius of gyration of cross section; b = plate width; t = plate thickness; ν = Poisson's ratio; k_R = buckling coefficient (=$4n^2$); n = number of panel which divided by stiffener; k_F = buckling coefficient of panel between diaphragms defined by Equation 4; α = aspect ratio (=a/b); a = diaphragm height; $\alpha_0 = \sqrt[4]{1+n\gamma_l}$; γ_l = stiffness of stiffener; and γ_l^* = required stiffness of stiffener.

2.3 *Analytical conditions*

The steel type of S-44-15 is SM490. Residual stress and initial deflection described in the previous study (Okada et al. 2010) were applied to the analytical models. Residual stress of SM490 and initial deflection are shown in Figure 3 and Figure 4. The cyclic loading pattern of horizontal displacement is shown in Figure 5. After the axical force was loaded, cyclic loading was applied to the top of the model.

Width-thickness ratio parameter R_F	0.30	0.30	0.50

$$P_{yM} = \left(\sigma_y - \frac{N}{A}\right) \cdot \frac{W}{L} \tag{5}$$

where W = section modulus.

2.4 *Verification of the analytical method*

The analysis result and the experimental result are compared and shown in Figure 6. The vertical axis is P/P_{yM}. And, the horizontal axis is δ/δ_{yM}. P_{yM} is the yield horizontal load defined by Equation 5. δ_{yM} is the yield horizontal displacement corresponding to P_{yM} on each horizontal load-horizontal displacement relationship. In the Figure 6, the analysis result can express the experiment result adequately up to the maximum horizontal load. Therefore, the validity of the analytical method was confirmed.

3 PALAMETRIC ANALYSIS

The load-carrying capacity and the ductility for steel members with relatively large slenderness ratio parameter were investigated by the elasto-plastic finite displacement analysis.

3.1 *Analytical models*

The details of the analytical models are shown in Table 2. The value of the slenderness ratio parameter $\bar{\lambda}$ is 0.50. For the width-thickness ratio parameters R_R and R_F, the combination values of 0.30 and 0.50 are used. In the case of different width-thickness ra-

tio parameters, the load-carrying capacity and the ductility of steel members were investigated.

3.2 *Analytical method*

The analytical method described in the previous chapter was used. The steel type of analytical models is SM490Y. Therefore, residual stress of SM490Y shown in Figure 7 was applied (Okada et al. 2010). The initial deflection and the loading pattern were the same as those in Figure 4 and Figure 5.

3.3 *Analytical results*

The analysis results of the models in Table 2 are shown in Figure 8. As the cross-sectional area of each analytical model is different, analytical models were compared by using the relationship between P/P_{yM} and δ/δ_{yM}. Consequently, the analysis results indicate that both load-carrying capacity and the ductility of steel members decrease as the width-thickness ratio parameter R_R and R_F increase.

3.4 *Effect of the slenderness ratio parameter*

Based on both the parametric analysis results shown in the section 3.3 and previous analysis results (Okada et al. 2010), the effect of the slenderness ratio parameter was investigated. The previous analytical models have smaller slenderness ratio parameter ($\bar{\lambda}$ =0.20) than the parametric analytical models ($\bar{\lambda}$ =0.50). The details of the previous analytical models are shown in Table 3. In both cases ($\bar{\lambda}$ =0.20 and 0.50), P_{max}/P_{yM} and δ_{max}/δ_{yM} are shown in Figure 9 and Figure 10. The Figure 9 and Figure 10 indicate that both load-carrying capacity and the ductility decrease as the slenderness ratio parameter $\bar{\lambda}$ increases or the width-thickness ratio parameters increase.

Table 3. Details of the previous analytical models (Okada et al. 2010).

	S18-N15	S15-N15	S13-N15
Steel type	SM490Y		
Flange width B_F (mm)	2745	2745	2745

Height (mm)	8078	8015	8226
Number of stiffener	4		
Stiffness ratio γ_l/γ_l^*	1.0	2.8	1.0
Axical force ratio N/N_y	0.15	0.15	0.15
Slenderness ratio parameter $\bar{\lambda}$	0.20		
Width-thickness ratio parameter R_R	0.30	0.50	0.50
Width-thickness ratio parameter R_F	0.30	0.30	0.50

4 CONCLUSIONS

The purpose of this study is to investigate the effects of the slenderness ratio parameter on the load-carrying capacity and the ductility for steel members. The load-carrying capacity and the ductility were investigated based on the elasto-plastic finite element analysis. Before the analysis was conducted, the validity of the analytical method was confirmed by comparing the analysis result with the previous experimental result. The parametric analysis for steel members with relatively large slenderness ratio parameter ($\bar{\lambda}$ =0.50) was conducted in the case of different width-thickness ratio parameters. Furthermore, the effect of the slenderness ratio parameter

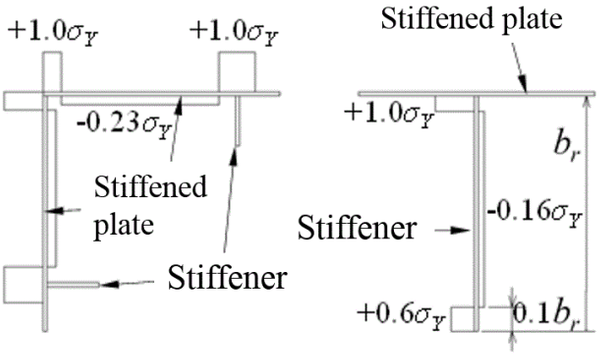

Figure 7. Residual stress(SM490Y).

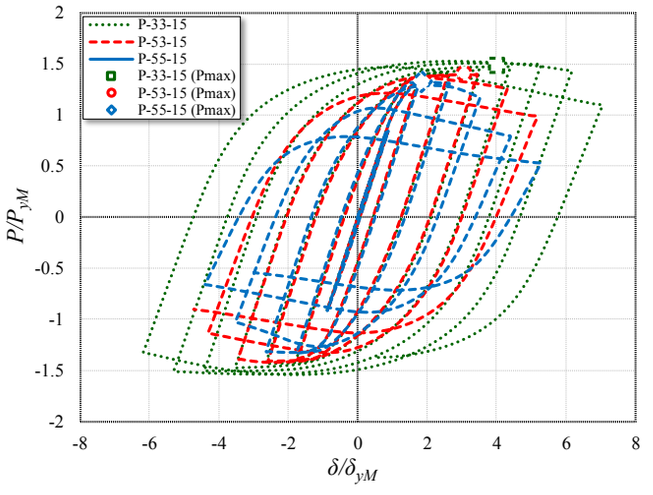

Figure 8. Analysis results of parametric analytical models.

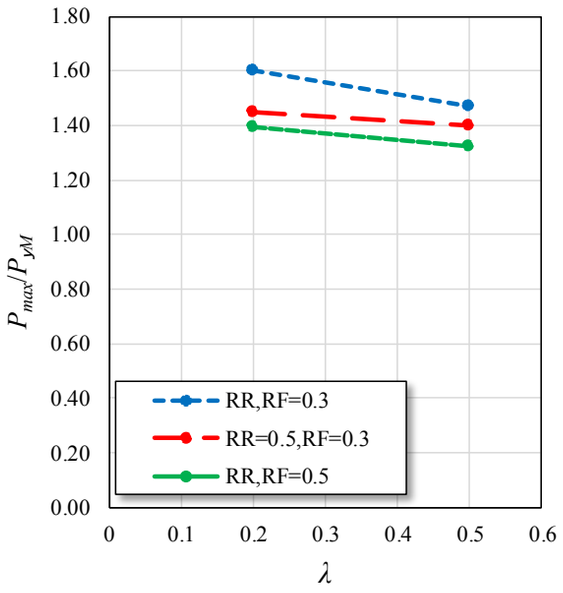

Figure 9. Effect of the slenderness ratio parameter on P_{max}/P_{yM}.

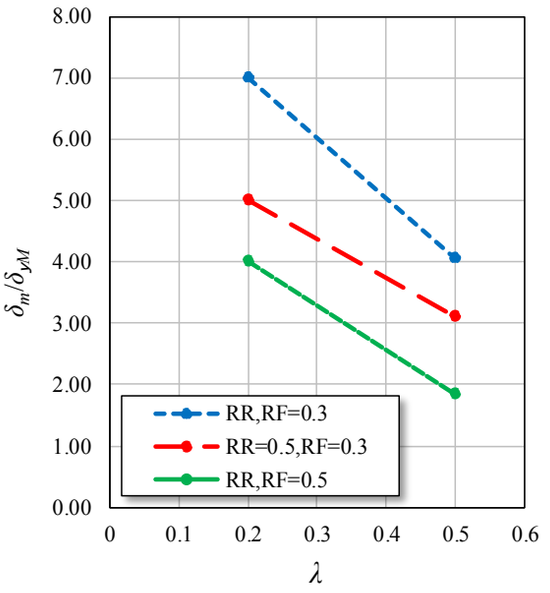

Figure 10. Effect of the slenderness ratio parameter on δ_{max}/δ_{yM}.

was investigated by comparing the parametric analysis results ($\bar{\lambda}$ =0.50) with the previous analysis results ($\bar{\lambda}$ =0.20). Consequently, analysis results indicate that the load-carrying capacity and the ductility of steel members decrease as the slenderness ratio parameter $\bar{\lambda}$ increases or the width-thickness ratio parameters R_R and R_F increase.

ABSTRACT: The commonly used normal reinforced concrete pile (RC) has large stiffness and is not suitable to be used for foundation in integral abutment bridge (IAB). This paper proposes a segmental pile by combining RC pile as its lower portion and UHPC (ultra-high performance concrete) pile as its upper portion in order to increase the lateral flexibility. A trial design of an IAB using this new kind pile is performed in this paper by replacing the original 70cm × 50 (70) cm RC section at the top 3m of pile by 30cm × 30cm UHPC section. FEM of the whole bridge is then established by using software Midas. Analysis result shows that UHPC-RC segmental pile as a new type pile is suitable to be used in IAB.

1 INTRODUCTION

There are three types of jointless bridges, integral abutment bridge, semi-integral abutment bridge and deck extension bridge. Among them, IAB has the largest integrity and best durability without bearing and expansion joint, and it is widely used in the world. However, it is rarely used in China. According to the survey in "Technical Specifications for Jointless Bridges in Fujian", there are only four IABs built or under construction, accounting for 10% of all jointless bridges in China by April 2016. According to the survey reported by United States Department of Transportation in 2004, there are around 9000 IABs built, accounting for 53.3% of all jointless bridges (more than 16900).

The foundation of IAB should be flexible. H-shaped steel pile is widely used in IABs in USA and other countries. But, due to steel corrosion, high price, easy buckling when encountering rock and other shortcomings, they are seldom used in China. In contrast, concrete pile is widely used in China. Because of its large rigidity and poor deformation ability, it is not suitable to be used in IAB, which affects the popularization and application of IAB (Gama 2014).

Therefore, the conception of segmental pile combined with ultra-high performance concrete (UHPC) pile and reinforced concrete (RC) pile is put forward. Specifically, the upper part of the pile using UHPC, with the features of high compressive strength, relatively strong tensile strength and good ductility, can use smaller section to reduce the lateral stiffness and to increase the lateral deformability so as to accommodate the longitudinal deformation of a bridge. The lower part of the pile using RC is used like normal reinforced concrete pile (friction pile or end-bearing pile). This kind of pile is called UHPC-RC segmental pile. The segmental pile could be used in IABs, for it is not only economic, but also meets the requirement of large longitudinal deformation, which provides a new kind of pile for jointless bridge. The use of UHPC in segmental pile not only expands its range of application, but also gets good promotion effect due to its small amount of material consumption and obvious performance.

In order to discuss the feasibility of using UHPC-RC segmental pile in IAB, this paper carries on a trial design on it. Taking the Shangban Bridge as an engineering background, a finite element model with designed segmental piles is established. The internal forces between the trial design bridge and the original bridge are compared so as to provide basic data for further study on UHPC-RC segmental pile in IABs.

2 TRIAL DESIGN

Shangban Bridge is an integral abutment bridge with prestressed concrete, located in Yongchun County of Fujian province. The overall layout is shown in Figure 1. The total length is 137.1m, with the width of 8.5 m. 4 × 30m continuous T-beam is used for the superstructure, and 4 T-beams are arranged side by side transversely. The T-beam girder is 1.8m high. Wet joint is used between the T-beams along the longitudinal direction. The substructure is double column piers with spread foundations. The bridge was opened to traffic in January 2004, and has been

in operation well till n ow. No m ajor maintenance problem has been repo rted in recent decades, for there is no expansion join t or bearing, which shows the advantages of IAB with less or no maintenance.

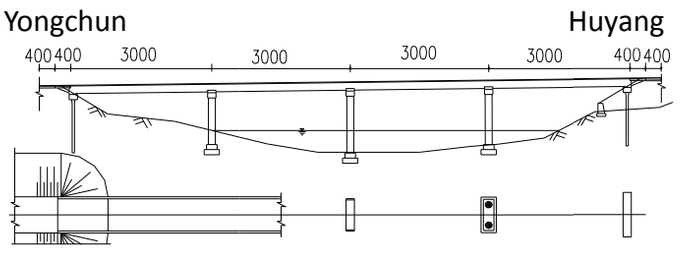

Figure 1. General arrangement diagram of Shangban Bridge (Unit: mm).

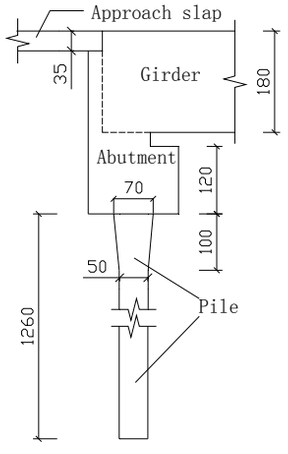
Integral abutment is used in Shangban Bridge, which means the girder and abutment are integrated without expansion joint. Low rigidity abutments and digging piles are also used in this bridge. In order to meet the d eformation requirement caused by the temperature difference in the superstructure, a single row of four piles with rect angular cross section bent along their weak axis ar e used for the foundation. The section size is 70cm × 50c m. Within the range of 1m from the top of th e pile down, the section size of the pile varies from 70cm × 50cm to 70c m × 70cm, so as to avoid the potential cracking at th e position where the cross section size changes suddenly. The rectangular pile is m ade of C30 concrete, and the length of the pile is 12.6m. In order to increase the f lexibility of substructure to ens ure that the pile has enough defor mation ability, digging pile is adopted in constr uction, and the loose sandy soil is f illed between th e pile and the origin al soil. The constructional detail of the joint of abutm ent and pile is shown in Figure 2.



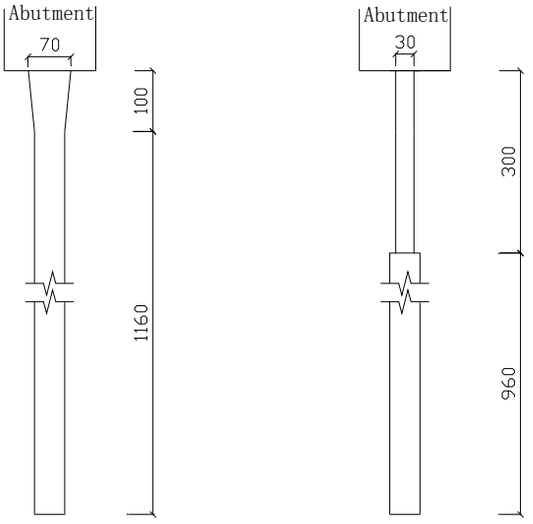


Figure 2. Joint between abutment and its su pporting pile in Shangban Bridge (Unit: cm).

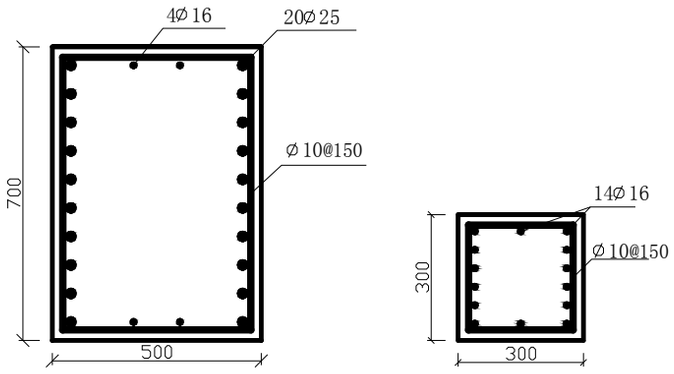
The structure of th e trial-design bridge is the same as that of the original b ridge, except for th e segmental piles. Digging piles and loose sandy soil are also adopted in the tria l design, in order to m eet the flexibility of the substructure. The pile section of original bridge is 70cm × 50cm, and is m ade of C30 concrete (compressive strength is 30MPa, elastic modulus is 30GPa). The pile s of trial design bridge are made of C130 concrete (com pressive strength is 130Mpa, elastic m odulus is 43GPa) on top of piles (Chen 2014, Chen 2016). The RC still keeps approximately the same as the o riginal concrete. According to th e calculation of the vertical load-bearing capacity, the pile cross section for this trial design bridge is 30cm × 30c m for the UHPC part.

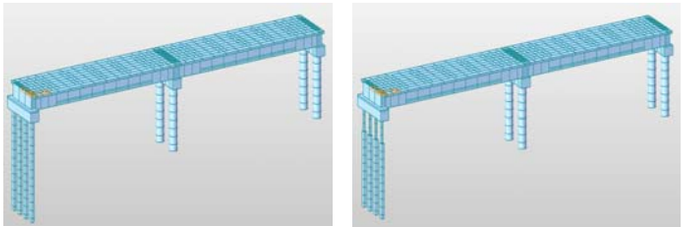


The upper part of the segm ental pile is 3m long UHPC pile, and the lower part is 9.6m long RC pile. The details of the original bridge pile and the trial design bridge pile are shown in Figure 3.

a) Original pile b) Trial design pile

Figure 3. Comparison of piles between original bridge and trial design bridge (Unit: cm).

In the trial design bridge, the arrangem ent of rebar for the RC part pile is th e same as that of the original bridge, as sh own in Figure 4a. The arrangement of rebar for the UHPC part pile is shown in Figure 4b. According to the manual calculation, the flexib ility (the d isplacement of the pile top) of trial design p ile is 2.65 times as much as that of the original pile.



a) RC section b) UHPC section

Figure 4. Reinforcement of pile section

3 FINITE ELEMENT MODEL

3.1 *Summary of modeling*

Software MIDAS is used to build the finite element model of the original bridge and the trial design bridge, as shown in Figure 5. Only half bridge model is shown due to its symmetry. In the model, T-beams, abutments, piles and piers are simulated by beam elements, and the transverse wet joints between the T-beams are simulated by longitudinal beam. The laminated rubber bearing in the bridge modeling is simulated by elastic connection in finite element model. The connection between abutment and girder are simulated by rigid connection in finite element model.

a) FE Modeling of original bridge b) FE Modeling of trial design bridge

Figure 5. Finite element model of original bridge and trial design bridge (only half bridge).

Because the pile foundation of abutments and the spread foundation of piers are embedded with enough depth into rock, the bottoms of piles and piers are simulated by fixity. The finite element model of the original bridge consists of 515 nodes and 687 elements. The number of nodes and elements of the trial design bridge is the same as the original bridge.

The effects of pile-soil interaction and abutment-soil interaction are considered in the model. Pile-soil interaction is simulated by the "m" method adopted in the "Codes for design of ground base and foundation of highway bridges and culverts" (JTG D63-2007), and linear springs take place of the soil around piles by assuming that the soil resistance is proportional to the lateral displacement of the pile at that location. Considering the loose sandy soil around the pile, the coefficient "m" is taken as 15000kN/ m^4. Soil pressure behind abutment is simulated by static soil pressure plus nonlinear spring (only for compression) in the finite element model (Civjan 2007). In order to simulate the bridge more accurately, three phases of construction are divided: simply supported, continuous and completed.

3.2 *Model verification*

The static and dynamic load tests of the original bridge were carried out in the reference (Peng 2001, Peng 2006). The comparison between the measured frequencies of original bridge and the calculated frequencies of finite element model is shown in Table 1. The deviations are less than 10%, which shows that the finite element model can be used to analyze the structural performance of the bridge.

Table 1. Comparison of measured values and calculated values of original bridge frequency.

Mode of vibration	Measured value (Hz)	Calculated value (Hz)	Deviation (%)
Transverse 1st	2.337	2.516	7.7
Transverse 2nd	4.092	3.707	-9.4
Vertical 1st	4.686	4.465	-4.7
Vertical 2nd	5.812	5.326	-8.4
Vertical 3rd	7.337	7.570	3.2

The measured deflection values and finite element values at the mid-span of side span under five load cases are shown in Table 2.

Table 2. Comparison of measured deflection values (A) and finite element values (B) (Unit: mm).

Load case	One car at 1/4 midspan under bias load			Two cars at 1/4 midspan under middle load			One car at midspan under bias load			Two cars at midspan under bias load			Two cars at midspan under middle load		
	A	B	Deviation (%)	A	B	Deviation (%)	A	B	Deviation (%)	A	B	Deviation (%)	A	B	Deviation (%)
Beam 1	1.09	1.17	7.3	1.42	1.52	7.0	2.11	2.25	6.6	3.03	3.27	7.9	2.65	2.76	4.2

Beam 2	0.83	0.89	7.2		1.47	1.56	6.1		1.64	1.76	7.3		2.80	2.87	2.5		2.73	2.84	4.0
Beam 3	0.64	0.68	6.3		1.45	1.56	7.6		1.14	1.21	6.1		2.50	2.56	2.4		2.74	2.84	3.6
Beam 4	0.34	0.36	5.9		1.42	1.52	7.0		0.52	0.55	5.8		1.98	2.12	7.1		2.67	2.76	3.4

It can be seen from Table 2 that the deviations between measured deflection values and finite element values are less than 10%, which means the finite element model used in this paper can accurately simulate the mechanical behaviors of original bridge under static load.

3.3 *Calculation checking of trial design bridge*

The trial design bridge is checked by considering five load combinations as shown in Table 3 (Peng 2009). Load combination I, II, III and IV are the combinations under ultimate limit state, and load combination V is the combination of serviceability limit state, including dead load, secondary dead load and earth pressure at rest.

Table 3. Load combinations.

Load combinations	Safety factors and names of loads
I	1.2 Dead load + 1.0 Prestress + 1.0 Shrinkage creep + 1.4 Vehicle load + 0.75 × 1.4 Temperature load(Up)
II	1.2 Dead load+1.0 Prestress + 1.0 Shrinkage creep + 1.4 Vehicle load + 0.75 × 1.4 Temperature load(Down)
III	1.2 Dead load+1.0 Prestress + 1.0 Shrinkage creep + 0.75 × 1.4 Vehicle load + 1.4 Temperature load(Up)
IV	1.2 Dead load + 1.0 Prestress + 1.0 Shrinkage creep + 0.75 × 1.4 Vehicle load + 1.4 Temperature load(Down)
V	1.0 Dead load + 1.0 Prestress + 1.0 Shrinkage creep + 0.7 Vehicle load(Impact) + 1.4 Temperature load(Down)

The calculation results of the superstructure indicate that both the bending capacity and the shear capacity meet the requirements under ultimate limit state. The crack resisting calculation and deflection calculation also meet the requirements under serviceability limit state.

The calculation results of the substructure indicate that the bearing capability of pile (considered as friction pile) and pile strength (vertical bearing capacity of RC pile and UHPC pile) both meet the requirements (Campione 2010). The maximum crack width appears at the connection joint between pile and abutment, and the width of the crack is 0.18mm which is still less than 0.2mm and meets the requirement for crack width limit.

4 ANALYSIS OF RESULTS

4.1 *Vertical load*

Under the vertical load (dead load and live load), the internal forces in the abutment and the pile of the original bridge and trial design bridge are basically the same. Therefore, only the internal forces of the girders under the vertical load are analyzed in this paper.

4.1.1 *Bending moment of girder under dead load*

Because the structure and the load are symmetrical, only the internal forces in half an bridge are compared. The bridge used the construction method of simply-supported first and being continuous then. The calculation of dead load is carried out in stages. The bending moment of the girder under dead load is shown in Figure 6. The values in the brackets are the bending moment values of trial design bridge.

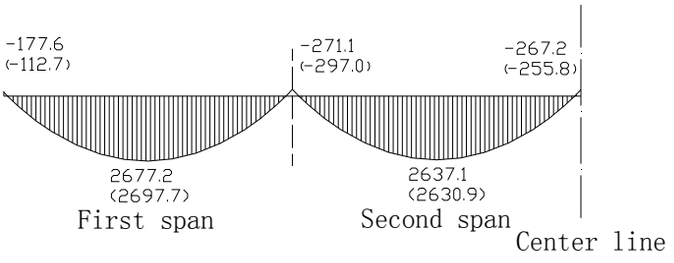


Figure 6. Bending moment of girder under dead load (Unit: kN·m).

It can be seen from Figure 6 that the negative bending moment of the girder at the abutment of the trial design bridge is obviously lower than that of the original bridge under dead load. The value of the trial design is 112.7kN·m, compared to 177.6kN·m of the original bridge, with a decline of 36.5%. By using the segmental pile in the trial design bridge, the bending moment of pile top decreases and it transfers from the top of the pile through the abutment to the end of the girder, thus reducing the negative bending moment of the girder. The segmental pile has little effect to the mid-span bending moment (the value of the first span increases by 0.7% and the value of the second span decreases by 0.2%), which can be ignored.

4.1.2 *Bending moment of girder under vehicle load*

According to "General specifications for design of

highway bridges and culverts" (JTG D60-2015), the bending moment of the girder is calculated by two kinds of vehicle load (bias load and middle load). The bending moment of the girder under bias load and middle load are shown in Figures 7 and Figure 8, respectively. The values in the brackets are the bending moment values of trial design bridge.

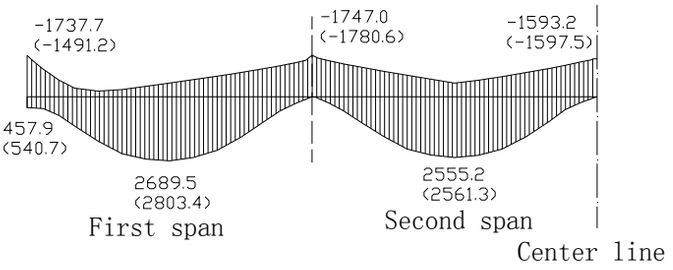

Figure 7. Moment envelop diagram of girder under bias load (Unit：kN·m).

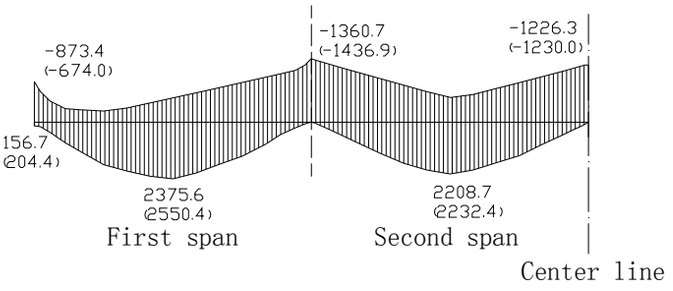

Figure 8. Moment envelop diagram of girder under middle load (Unit：kN·m).

It can be seen that the negative bending moment of the girder at the abutment of the trial design bridge is reduced by 14.2% and 22.8%, respectively, under bias load and middle load. The positive bending moment of the girder is increased slightly. The bending moment of other places changes less than 10%. It indicates that the flexible segmental pile has an advantageous effect on the girder at the abutment under the vehicle load, but has little effect on other places.

4.2 *Temperature load*

Compared to the traditionally jointed bridge, temperature load has a greater impact on the longitudinal deformation of IAB. The temperature effect for IAB is the most influential longitudinal load. Different structures of bridge have different characteristics when temperature drops or rises. The internal forces of girder and pile are greater when temperature goes down, and the internal forces of abutment are greater when temperature goes up. Therefore, this paper will discuss the internal forces in the above three cases. The structural behaviors of the original bridge and the trial design bridge are further explored (Ren 2010).

4.2.1 *Internal force of girder when temperature goes down*

The abutment and the girder are in rigid connection in IABs. When temperature goes down (15°C), the deformation of the girder is affected by the pile under the abutment, and the tensile stress in girder is very unfavorable for concrete material. Therefore, it should be taken into consideration for the internal forces of girder when temperature goes down.

The internal forces of the girder when temperature goes down are shown in Table 4. The bending moment and the axial force of the girder in the trial design bridge are decreased obviously, and the decreased amplitudes are over 40% basically. According to the calculation of finite element model, the displacement at pile top of the trial design bridge is 7.8mm, compared with the about 6.5mm of the original bridge, increased by 20.2%. When temperature goes down, the deformation increases, therefore the axial force and bending moment both decrease greatly.

Table 4. Internal force of girder when temperature goes down.

Internal force	Bending moment at abutment(kN·m)	Axial force at the first span(kN)	Bending moment at the first pier(kN·m)	Axial force at the second span(kN)	Bending moment at the second pier(kN·m)
Original bridge	1277.6	345.3	-288.1	357.9	147.4
Trial design bridge	605.2	174.8	-173.5	187.5	66.8
Amplitude of reduction %	52.6	49.4	39.7	47.6	54.7

4.2.2 *Internal force of pile when temperature goes down*

When temperature goes up, the deformation of IAB is absorbed by the approach slab, backfill and horizontal flexibility of piles. However, when temperature goes down (15 °C), the deformation is only absorbed by the horizontal flexibility of piles. The shear force and the bending moment of piles are

shown in Figure 9 and Figure 10, respectively.

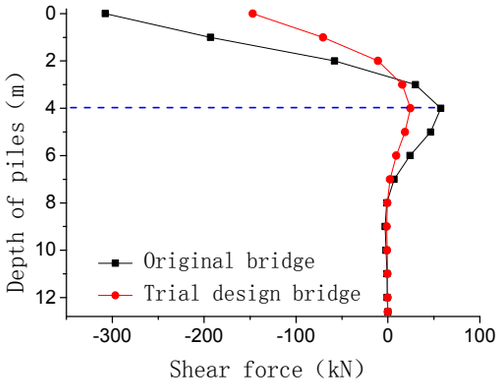

Figure 9. Shear force of piles

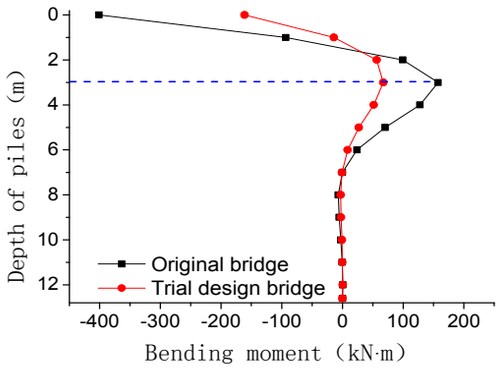

Figure 10. Moment of piles

The internal force distribution along segm ental pile is similar to that of the original pile. By using the segmental pile with smaller horizontal stiffness, the displacement of girder increases, which reduces its internal force. The inflection point of the shear force appears at the depth of 4m, and the inflection point of the bending moment appears at the depth of 3m.

The maximum values of bending mom ent and shear force of the orig inal bridge and trial design bridge appear at the top of the piles, whic h are summarized in T able 5. By using the flexible segmental pile, th e internal forces of the pile are decreased significantly, and the m aximum values of shear force and bending m oment are reduced by 52.2% and 59.8%, respectively.

Table 5. Comparison of intern al forces at the top of piles.

Internal force	Shear force (kN)	Bending momnet (kN·m)
Original bridge	-307.6	-401.2
Trial design bridge	-147.1	-161.2
Amplitude of reduction %	52.2	59.8

4.2.3 *Internal force of abutm ent when temperature goes up*

When temperature goes up (15 °C), the abutm ent moves towards backfill and is subjected to passive earth pressure. The maximum values of shear force and bending m oment appear at the top of the abutment, which are shown in T able 6. The bending moment of abutm ent is linear with he ight of abutment, and the m aximum values of shear force and bending m oment are reduced by 32.6% and 45.8%, respectively, compared with those of the original bridge. According to the calculation of finite element model, the displacement of the pile to p of the trial design bridge is 7.1mm, compared with the that of the original bridge about 6.1mm , increased by 16.4%.

Table 6. Com parison of internal forces at the top of abutments.

Internal force	Shear (kN)	Bending moment (kN·m)
Original bridge	1701.4	3546.2
Trial design	1146.2	1919.9
Amplitude of reduction %	32.6	45.8

5 CONCLUSIONS

(1) This kind of UHPC-RC segmental pile can greatly increase the flexibility of pile foundation and meet the requirem ent of deformation for lar ger spanning integral abutment bridge. Segmental pile is a new type of pile foundati on for IJB, which adapts to the construction situation of China. It is applicable and feasible with a promising future.

(2) The negative bending m oment at the end of girder in the trial design bridge is reduced by 36.5%, compared to the orig inal bridge under dead load. Segmental pile has less influence on the m idspan of girder, which can be ignor ed. Under bias load and middle load, the negative bending moment at the end of girder was reduced by 14.2% and 22.8%. The negative bending moment decreases and the positive bending moment increases in other places, which are not obvious.

(3) For the IABs, when the tem perature goes down,

the axial force and bending moment of girder are significantly reduced. The internal forces of pile are also effectively reduced. The maximum shear force and bending moment of pile occur at the top of pile, and they decrease about 52.2% and 59.8%, respectively. When the temperature goes up, the maximum shear force and bending moment of abutment appear at the top of abutment, and decreased by 32.6% and 45.8%, respectively.

(4) The displacement on the top of the trial design pile is greater than the original bridge, increasing by 16.4% when temperature goes up, and by 20.2% when temperature goes down. By using the segmental pile, the deformation of the superstructure becomes larger and the jointless bridge design length could be longer.

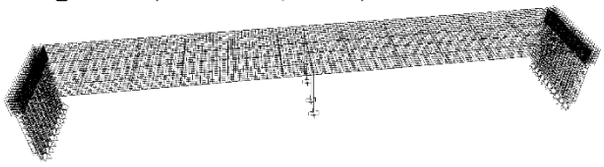
ABSTRACT: The paper focuses on the dynamic and seismic behavior of integral abutment steel bridges considering nonlinear soil-structure interaction, and the effects of design parameters of the integral abutment system on bridge behavior. 3-D finite element model of an integral abutment steel bridge was established with the SAP2000 software, and nonlinear link elements and damper elements were used to model the soil reactions behind the abutment and around the piles. Modal analysis and nonlinear time-history analysis were conducted, with corresponding parametric studies. Results indicate that: Compacting the backfill, increasing the abutment height-to-thickness ratio, and increasing the foundation stiffness will increase the dominant longitudinal frequency of the bridge structure, while H pile orientation has little influence. When satisfying the design requirements and in a reasonable range, compacting the backfill behind the abutment, increasing the abutment height-to-thickness ratio, increasing the foundation stiffness, and orienting the steel H pile to bend about its strong axis can effectively reduce the pile-top displacement, as well as seismic response of girders, abutments and piers, but increasing the foundation stiffness will obviously increase pile-top moment at the same time.

1 INTRODUCTION

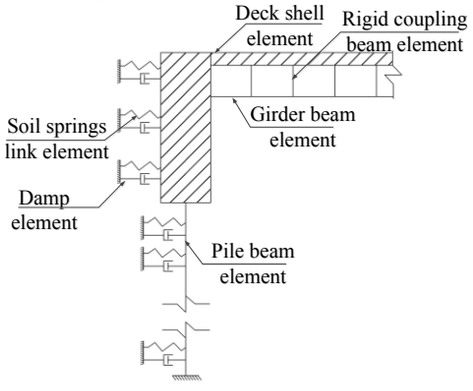
Integral abutment bridges are jointless bridges can solve the problem of easily damaged telescopic device (Erhan 2014; Zhao 2011). The integral abutment bridge deck is continuous and connected monolithically with the abutment walls supported typically by a single row of piles to provide the required lateral flexibility to accommodate thermal movements. (Zhao 2011; Wasserman 1996). The advantages of these bridges include reduced maintenance costs compared to traditional jointed bridges with expansion joints and abutment bearings, reduced corrosion and material degradation at the joints (FHWA,1986), increased structural capacity during seismic events (Hassiotis et al, 2006), as well as faster and simpler contraction(Wasserman and Walker, 1996; Hopper and Gomes, 1996).

Under seismic load, Soil-Structure Interaction (SSI) become important due to the lateral movements of the integral abutment bridge together with the abutments is directly reflected on the backfill and foundation soil (Erhan 2014; David 2011). Goel studied earthquake characteristics of integral abutment bridges, and indicated that the bridge has a large deformation resistant capacity in superstructure when the earthquake intensity is low, however the resistance will decrease with the increase of earthquake intensity. (Goel, 1997) Spyrakos studied seismic behavior of integral abutment bridge including soil-structure interaction, in which they assess the significance of soil-structure interaction on the dynamic characteristics and seismic responses of the bridge, and indicated that the existence of backfill had a significant effect on the internal forces and deflection of the abutment, the pile and response of whole bridge. (Spyrakos, 2003)Therefore, it is meaningful to study the nonlinear SSI, and identify the main factors affecting bridge behavior.



2 FINITE ELEMENT MODEL

This paper focus on the dynamic and seismic performance of the two-span integral abutment steel bridge by mode and nonlinear time history analyses with an emphasis and sensitivity study on the effect of the size and flexibility of abutment, the orientation of H-pile and clay stiffness around the piles. Nine 3-D finite element models of a two-span integral abutment bridge was constructed using SAP2000 software, and the soil-structure interaction (SSI) between the bridge substructure and soil was simulated with spring nonlinear link element and damp element.



2.1 *Bridge model*

The bridge is a two-span integral abutment bridge with a north span of 42.67 m and a south span of 44.81 m. The bridge superstructure consists of five I-section steel plate girders with a height of 1.63 m and center to center spacing of 2.97 m, supporting a 0.21 m thick concrete deck above. The bridge abutment is composed of a 2970mm high, 910mm thick concrete slab supported each by HP 250x60 steel piles oriented in the strong ax-is bending. The abutment backfilling is a densely-compacted clean sand (φ=40.5°,γ =18.3 kN/m3). The soil around piles is a medium clay (cu=37.5 kPa , γ =14.6 kN/m3). The yield strength of steel used for steel pile and main beam is 345MPa, with the elasticity modulus 200GPa.

The bridge deck and abutments are modeled as shell elements while the main girders, piers, bent cap and piles are modeled as frame elements. The material nonlinearity of the pile and pier is considered in the model and the moment- curvature curve of the plastic hinge is obtained by the cross section designer of SAP2000. A rig-id connection is assumed at the conjunction of the abutments and the piles, as well as the abutment and the steel girders. Rigid linear link elements are used to model the conjunction of the bridge decks and the steel beams. Views of the bridge model and also its abutment details are shown in Figure 1. (SAP2000, 2010)

(a) Finite Element Model of the Two-span Integral Abutment Steel Bridge

(b) Finite Element Model of Abutment Details

Fig. 1 Bridge Model and Abutment Details of the Two-span Integral Abutment Steel Bridge

2.2 *Soil-structure interaction*

The soil around the piles is considered clay, properties of hard clay and medium clay are selected from the ge-otechnical reference (Coduto, 1999) in order to represent soil characteristics. The abutment wall backfilling is considered cohesionless clean sand, properties of loosely-compacted and densely- compacted clean sand are following Coduto et al. (1999). The soil spring elements and damping elements are used to model the soil-structure interactions around the piles and in back of the abutments, as shown in Figure 1(b).

2.2.1 *Springs in back of the abutments*

Based on a comprehensive study on nonlinear soil-abutment interaction for seismic design of bridges by Shamsabadi et al (2007). A simplified hyperbolic force-displacement relation was proposed by EQ (1).

$$F(y_i)=\frac{F_{ult}(2Ky_{\max}-F_{ult})y_i}{F_{ult}y_{\max}+2(Ky_{\max}-F_{ult})y_i} \quad (1)$$

where y = lateral displacement of the abutment; K= average soil stiffness , F_{ult} = maximum abutment Force (per unit length of the wall) developed at a maximum displacement of $y_{\max.}$ For cohesionless soil backfilling F_{ult} can be determined by EQ (2).

$$F_{ult}=0.5\gamma H^2(1-k_v)K_{pe} \quad (2)$$

where γ = soil density; H = height of the abutment; k_v = vertical acceleration coefficient and K_{pe} = seismic passive earth pressure coefficient which can refer to NCHRP 12-70 (2008) to get.

The abutment backfilling is sandy soil with good water permeability. Force displacement relations for unit length of the wall for two cases of densely-compacted clean sand (φ =40.5°, γ=18.3kN/m^3) and loosely-compacted clean sand (φ =37 ° , γ=16.5kN/m^3) backfilling are developed and modeled by nonlinear link elements in FEA model. The *p-y* curve of the soil spring (per unit length behind the wall) is shown in Figure 2.

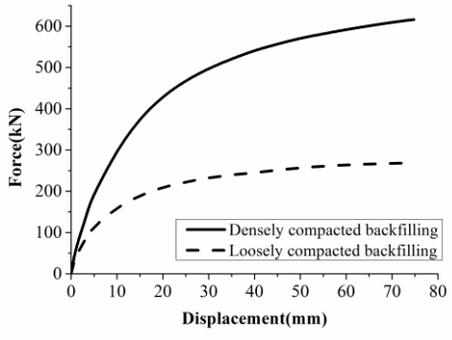


Fig. 2 Force–displacement Relations for Abutment Backfilling

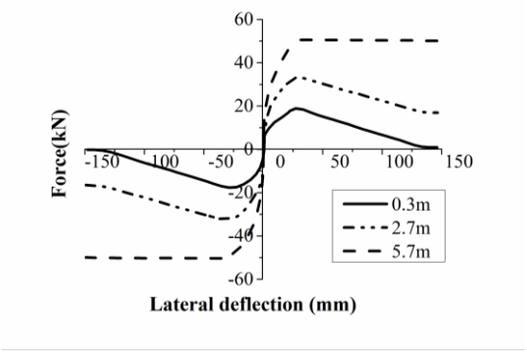
2.2.2 *Springs around the piles*

The procedures given in the American Petroleum Institute (API) are followed to define the *p-y* curves of the soil springs around the piles (American Petroleum Institute, 1993). The ultimate unit lateral bearing capacity of clay p_u is shown by EQ (3):

$$p_u=\begin{cases}3c_u+\gamma X+J\dfrac{c_u X}{D} & X<X_R\\ 9c_u & X\geq X_R\end{cases} \quad (3)$$

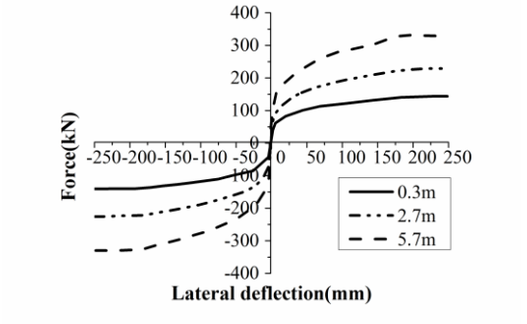
where p_u = ultimate resistance; c_u = undrained shear strength; D = pile diameter; γ = effective soil densi-

ty; J = dimensionless empirical constant; X = depth below soil surface and X_R = depth below soil surface to bottom of reduced resistance zone.



16 groups force displacement relations of the soil springs within range of piles height are developed for two different cases of medium clay (c_u=37.5 *kPa* , γ =14.6 *kN/m*^{3}) and hard clay (c_u=200.0 *kPa* , γ =18.1 *kN/m*^{3}) around the piles. The *p-y* curve of the soil springs at 0.3m, 2.7m and 5.7m below the top of pile are shown in Figure 3.

2.2.3 *Soil damping behind abutments*



The damping coefficient of abutment backfilling is calculated by the EQ (4) proposed by Jain and Scott (1989).

$$c = \sqrt{\frac{2}{1-\upsilon} G\rho} \tag{3}$$

Where c = damping coefficient; G = soil dynamic shear modulus; ρ = soil density and v = soil Poisson's ratio. The soil dynamic shear modulus of densely-compacted clean sand and loosely-compacted clean sand are 40 MPa and 27 MPa respectively, and the soil Poisson's ratio is 0.3 , the damping coefficient for unit area were 457 kN/(m/s) and 356 kN/(m/s) respectively.

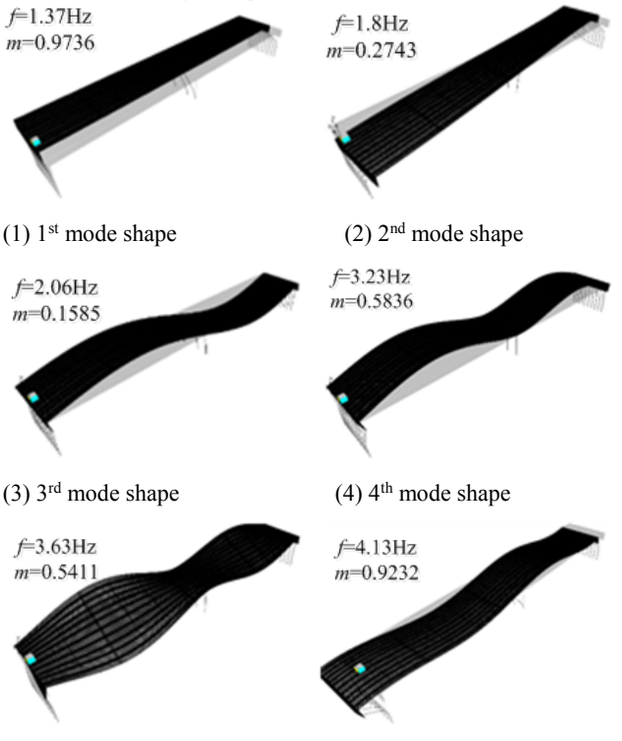
(a) Soft Clay

(b) Hard Clay

Fig. 3 Force–deflection curves of pile springs under cyclic loading

2.2.4 *Soil damping around piles*

The damping coefficient of soil around piles is calculated by the EQ (5) proposed by Anandarajah et al (2005).



$$c = A\rho V_s \tag{4}$$

where A = tributary area of damping element; ρ = soil density and V_s =soil shear wave velocity. The soil shear wave velocity of soft clay and hard clay are 200 *m/s* and 300 *m/s* respectively, the damping coefficient for unit area of medium clay and hard clay were 292 *kN/(m/s)* and 544 *kN/(m/s)* respectively.

3 DYNAMIC PROPERTIES

The dynamic performance of the integral abutment bridge could be obtained by modal and parameter analysis. The first six mode shapes, natural vibration frequency f as well as participation mass ratio m are shown in Figure 4. The structure and soil properties of influence on the bridge dynamic characteristics including abutment size, pile orientation, levels of soil compaction of abutment backfilling as well as stiffness of soil around piles could be discussed. The parameter analysis are divided into three groups according to abutment size and backfilling properties, related parameter and dominant transverse and longitudinal frequency of model are shown in Table 1.

As shown in Table 1, when the abutment height-to-thickness ratio increased from 1.44 to 3.15 and 3.85, the dominant longitudinal frequency will increase by about 6.5% and 12%, respectively, and the variation of dominant transverse frequency are within 4%. Compacting the backfill behind the abutment will increase the dominant longitudinal frequency by about 16%, but which has no effect on the dominant transverse frequency.

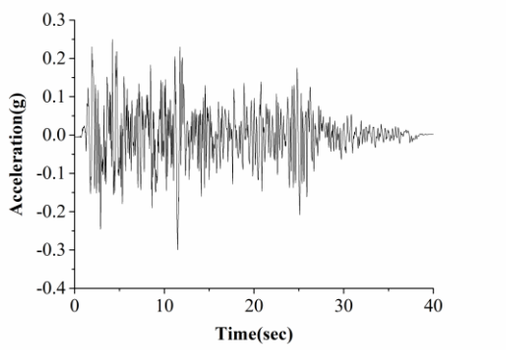
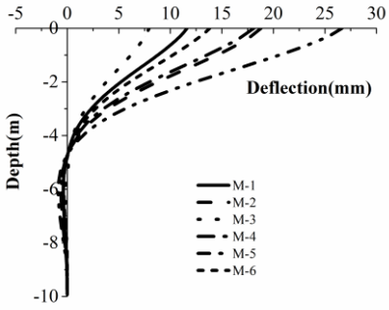
M-4	Medium Clay, Strong axis, Loosely, H/T=3.15	1.37	3.56
M-5	Medium Clay, Strong axis, Loosely, H/T=1.44	1.32	3.34
M-6	Medium Clay, Strong axis, Loosely, H/T=3.85	1.34	3.78
M-7	Medium Clay, Weak axis, Densely, H/T=3.15	1.48	4.08
M-8	Hard Clay, Strong axis, Densely, H/T=3.15	2.12	4.54
M-9	Hard Clay, Weak axis, Densely, H/T=3.15	2.30	4.45

As the H-pile orientation changes from strong axis to weak axis, the longitudinal bending stiffness of pile foundation decreases, but the transverse bending stiffness increases, and the longitudinal dominant frequency decreases by about 3% as well as the transverse dominant frequency increase by about 8%. As the foundation stiffness increases, the longitudinal dominant frequency and the lateral dominant frequency of structure are obviously increases by about 9.5% and 55% respectively. In general, the design parameters of abutment and soil behind abutment have great effect on the longitudinal dominant frequency, while the H-pile orientation and clay stiffness around the pile have great influence on transverse dominant frequency.

4 SEISMIC RESPONSE

In this paper, nonlinear time-history analyses are performed using the scaled component of El Centro earthquake with peak ground acceleration (PGA) equal to 0.215g and the duration is 40s. In order to obtain a better understanding of the seismic response of integral abutment bridges, the peak ground acceleration is adjusted to 0.3g. Figure. 5 shows the acceleration time histories of EI Centro earthquake after PGA adjustment.





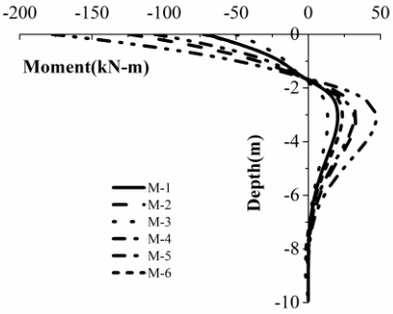


Fig. 5 El Centro Earthquake Record with PGA of 0.3g

4.1 *Abutment size and level of soil compaction of abutment backfilling*

Nonlinear time-history analysis are performed using the finite element model of the integral abutment bridge for the first 6 cases (M1-M6) defined in Table 1. The maximum deflection and moment along the height of pile for the six cases are plotted in Figure 6. The results of parameter analysis are shown in Table 2 and Table 3.

(a) Deflection

(b) Moment

Fig. 6 Pile deflection and moment obtained from the analyses of M1-M6

As shown in Figure 6, the maximum moment of the piles have a positive and negative bidirectional distribution, the absolute maximum moment of the pile appears at the top of the piles. An increase in depth will decrease the maximum moment of piles, and the inflection point of moment appears at about 2 m below the top of pile. Below that level, the reverse maximum pile moment increases gradually and reaches the peak value at about 3 m below the pile top. The peak value can reach 1//3 of the maximum moment at the top of the pile, the moment is trending to zero at about 7 m below the top of the pile, and then reverse, but the reverse maximum displacement along the pile varies within a small range of 2mm.

Table.2 Seismic Response of the Bridge with Different Abutment Height-thickness Ratio

Case	Displacement of pile top	Displacement of abutment top	Moment of pile top	Moment of pier bottom	Maximum moment of abutment	Maximum moment of girder
	mm	mm	kN-m	kN-m	kN-m	kN-m

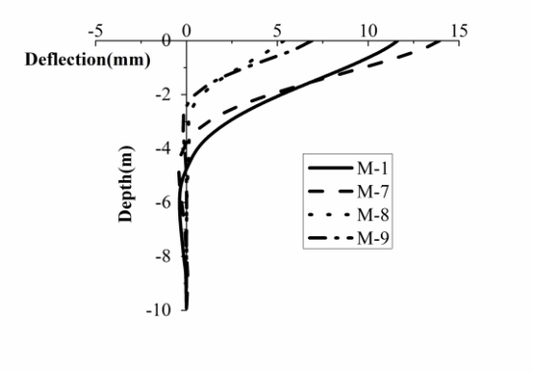
M-5&M-6 Diff%	-48.1%	-37.3%	-59.0%	-37.4%	-24.5%	-26.8%

The change of abutment size and abutment backfilling has little influence on the mode of moment and displacement of pile including the shape of moment and displacement, the reverse peak point, the inflection point as well as 0 point position, which only affects the value of peak.

The influence of the change of height-to-thickness ratio of abutment on seismic response of the bridge is shown in Table 2. An increase in abutment height-to-thickness ration will significantly reduce the seismic response of most abutment, pile, pier and main girder, the reduction is depended on increase of height-to-thickness ratio, especially when the backfilling is densely-compacted.It is worth noting that increasing the abutment height-to-thickness ratio (especially when the abutment height increases and the thickness remains constant) or compacting the abutment backfilling may increase temperature stress in the integral bridge because of the soil-structure interaction (SSI) of backfilling and bridge, and make increase in longitudinal stiffness of integral bridge. When the abutment height-to-thickness ratio increases with the abutment thickness decreasing and abutment height is hold constant, there is no remarkable difference of effect of abutment backfilling on bridge and an increase in abutment height-to-thickness will decrease the longitudinal bending stiffness of abutment and temperature stress as well as longitudinal bending stiffness of integral bridge considering SSI. Therefore, in integral bridge structure design, the temperature, seismic and vehicle load should be consider when select abutment height-to-thickness and compacting method.

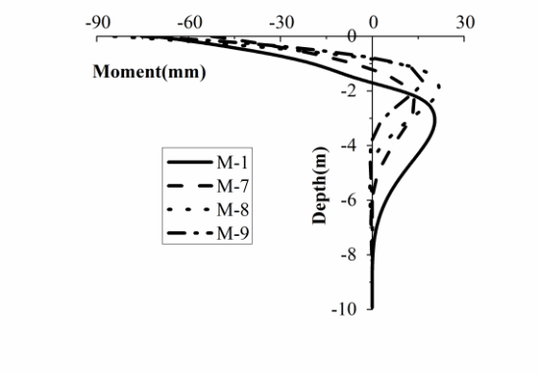
The influence of the properties of abutment backfilling on seismic response of the bridge is shown in Table 3. As the level of compaction of abutment backfilling decrease, the seismic response of abutment, pile, pier and main girder significantly increase, especially in the case of bigger abutment height-to-thickness, since the compaction of abutment backfilling decreases with average stiffness of abutment backfilling and restraint of structure deformation. The longitudinal seismic behavior of integral bridge depends heavily on the system of abutment and abutment backfilling. The larger the abutment height-to-thickness ratio, the greater the seismic resistance of abutment backfilling and backfilling stiffness. As shown in Table 3, the abutment height-to-thickness ratio have great influence on the maximum displacement and moment of abutment, the maximum displacement at pile top and the moment at pier bottom, and have limited influence on maximum moment of the pile top and the main girder.

Table.3 Seismic Response of the Bridge with Densely and Loosely Compacted Backfill



Case	Displacement of pile top	Displacement of abutment top	Moment of pile top	Moment of pier bottom	Maximum moment of abutment	Maximum moment of girder
	mm	mm	kN-m	kN-m	kN-m	kN-m
M-1	11.6	14.5	71.1	818.9	1347.2	746.8
M-4	18.1	23.1	106.5	1310.5	2115.8	1171.2
M-1&M-4 Diff%	56.0%	59.3%	49.8%	60.0%	57.1%	56.8%
M-2	18.8	22.2	124.3	1239.8	1586.0	909.7
M-5	26.7	31.3	177.5	1741.8	3021.3	1260.7
M-2&M-5 Diff%	41.8%	40.9%	42.8%	40.5%	90.5%	38.6%
M-3	7.9	9.9	50.25	52.4	1170.5	619.3
M-6	13.8	19.6	72.8	1090.8	2281.6	922.3
M-3&M-6 Diff%	75.1%	97.9%	45.0%	97.5%	94.9%	48.9%

Comprehensive comparison of the analysis results of M1-M6 shows that seismic response of M-5 is much bigger than other model, the seismic response of model M-3 is the smallest in all models. The differences of displacement of pile top and abutment top as well as the moment of pile top and pier bottom between M-3 and M-5 are more than doubled, and the difference of maximum moment as high as two times or beyond, for M-3 and M-5, respectively. The difference of maximum moment between abutment and main beam is also more than 100%, so it is clear that increasing the abutment height-to-thickness ratio and compacting the abutment backfilling can significantly reduce the seismic response of the structure.



4.2 *Pile orientation and clay stiffness around the piles*

Nonlinear time-history analysis are performed using the finite element model of the integral abutment bridge of the four cases (M-1, M-7-M-9) defined in Table 1. The deflection and moment alonge the height of pile for four cases are plotted in Figure 7. The results of time-history analysis are shown in Table 4 and Table 5.

As shown in Figure 7, pile orientation and soil around the piles have influence on the pile maximum moment, pile displacement and the distribution of moment and displacement including the reverse peak point, the inflection point and 0 point position. The maximum moment of the piles also have a positive and negative bidirectional distribution, the absolute maximum moment of the pile appears at pile top. When the pile bent from about its strong axis to weak axis, the inflection point of moment appears at about 1.2 m below the pile top. When the soil around piles changed from medium clay to hard clay, the influence point of moment appears at about 1 m below pile top, and the reverse peak point of maximum moment, the bending moment and the 0 point position moves upward, especially in hard clay. The properties of soil around piles have a more obvious effect than pile orientation on moment distribution, displacement distribution and peak value, but no obvious effect on peak value of reverse moment.

(a) Deflection

(b) Moment

Fig.7 Distribution of Moment and Displacement along the Pile of Model 1, 7-9

As shown in Table 4, when the pile bent from about its strong axis to weak axis, bending stiffness of pile decreases, flexibility and deformation capacity increases. The maximum displacement at pile top increases 19.8% and the maximum moment of pile top decreases 26.2% for the case of piles in medium clay. And when piles in hard clay, the increase of the displacement at pile top increases, while the decrease of the moment decreases. When the pile bent about its strong axis, the material at pile top is in elastic phase in medium and hard clay, while when the pile bent about its weak axis, the material at pile top is in elastic-plastic phase. Therefore, in the interest of improving the temperature deformation capacity of the integral bridge, it is necessary to note that it will put forward higher requirements for seismic design of pile, abutment and pier when the H steel pile bending about weak axis.

Table.4 Seismic Response of the Bridge with Abutment Pile Bending about Strong or Weak Axis

Case	Displacement of pile top	Displacement of abutment top	Moment of pile top	Moment of pier bottom	Maximum moment of abutment	Maximum moment of girder
		mm	kN-m	kN-m	kN-m	kN-m
M-1	11.6	14.5	71.1	818.9	1347.2	746.8
M-7	13.9	17.1	52.5	962.5	1529.1	805.3
M-1&M-7 Diff%	19.8%	17.9%	-26.2%	17.5%	13.5%	7.8%
M-8	5.4	7.9	84.4	440.2	1276.7	707.2
M-9	6.9	9.0	75.3	498.5	1410.7	623.6
M-8&M-9 Diff%	27.9%	14.5%	-10.7%	13.2%	10.5%	-11.8%

Table.5 Seismic Response of the Bridge with Different Clay Type Around the Pile

Case	Displacement of pile top	Displacement of abutment top	Moment of pile top	Moment of pier bottom	Maximum moment of abutment	Maximum moment of girder
M-1	11.6	14.5	71.1	818.9	1347.2	746.8
M-8	5.4	7.9	84.4	440.2	1276.7	707.2
M-1&M-8 Diff%	-53.4%	-45.5%	18.7%	-46.2%	-5.2%	-5.3%
M-7	13.9	17.1	52.5	962.5	1529.1	805.3
M-9	6.9	9.0	75.3	498.5	1410.7	623.6
M-7&M-9 Diff%	-50.3%	-47.1%	43.5%	-48.2%	-7.7%	-22.6%

As shown in Table 5, as the stiffness of soil around pile become larger, the soil has much effect on the sidewise restraint and respond of bridge displacement decreases, but pile orientation has no effect on this. With the stiffness of soil around piles increasing, the reaction force of soil and moment at pile top increase. When the pile bent about its strong axis, the increase of the maximum moment of main girder is not obvious affected by the soil stiffness.

5 CONCLUSION

The work presented here supports the following conclusions:

In general, abutment size and properties of abutment backfilling have great influence on the dynamic behavior of bridge structures at longitudinal direction, and H-pile orientation and properties of soil around piles have great influence on the dynamic behavior of bridge structures at transverse direction. Compacting the backfill, increasing the abutment height-to-thickness ratio, and increasing the foundation stiffness will increase the dominant longitudinal frequency of the bridge structure, while H pile orientation has little influence. Increasing the foundation stiffness and orienting the H steel pile to bend about its strong axis will increase the dominant lateral frequency of the bridge structure, while abutment dimensions and abutment backfilling have little influence. Calculation results of the nonlinear time-history analysis shows that the maximum moment and displacement of piles have a positive and negative bidirectional distribution, the absolute maximum and displacement of pile appear at pile top, and decrease with the depth increases.

As the height-to-thickness ratio of abutment increases, the seismic response of most abutment, pile, pier and main girder significantly decrease.

An decrease in backfilling compaction will increase the seismic response of abutment backfilling, the seismic response of abutment, pile, pier and main girder. Increasing the abutment height-to-thickness ratio and compacting the backfill behind the abutment could obviously decrease bridge seismic response, but may increase the temperature stress of the integral bridge.

When the pile bent from about its strong axis to weak axis, the deformation capacity and bending stress of pile increase, but maximum moment decrease, maximum displacement and moment at pile top as well as moment at pier bottom obviously increase.

As stiffness of soil around piles increases, moment at pile top increases, but the response of bridge displacement, maximum displacement of pile top and abutment top, moment of pier bottom decrease, and pile orientation have no effect on this.

In meeting the design requirement of integral bridge, it is recommended to use higher height-to-thickness ratio, more flexible abutment and compacted backfill. When the H steel pile is used in abutment foundation, it is suggested that pile bent about the strong axis. Increasing stiffness of soil around piles will decrease bridge displacement and moment of abutment, pier and girder, but increase pile top moment. In a wide temperature different and high earthquake intensity region, seismic response and temperature stress should be taken into comprehensive consideration. The behavior of H-pile and joints of abutment and pile in strong earthquake must continue in-depth detail.

ABSTRACT: In order to study the influence of simulation methods of SSI on the seismic analysis of integral abutment bridges, the 3-D finite element model of an integral abutment bridge was established with the SAP2000 software. The seismic responses of a detailed model and a series of simplified models were obtained through nonlinear time history analysis. Results indicate that: The damping of soil has little effect on the seismic response of the integral bridge and the damping of the soil can be neglected in the seismic analysis of the integral bridge. When PGA is 0.15g and 0.3g, the model using "m" method to simplify pile-soil interaction has higher analysis accuracy. And with the increasing of PGA, the analysis accuracy decreases, but with small change. The model using "m" method to calculate the stiffness of soil behind abutment has high analysis accuracy, and with the increasing of PGA, the accuracy has a decreasing trend but with only a little change, and the error is always within reasonable range. The "m" method is considered to be useful to simplify the pile-soil interaction, especially when the PGA is small. The "m" method is also useful to the simplification of the abutment-soil interaction. SSI simplified simulation method should be selected according to the value of PGA of the earthquake, and considering the analysis accuracy of the seismic response of each component, and also should consider the different sensitivity of the seismic response of different component when different simplified simulation method was adopted.

1 INTRODUCTION

According to the statistical bulletin of transportation industry development in 2015 (MOT 2016), the number of highway bridges in China has reached 779,200, of which 695,800 are small and medium bridges, accounting for 89.3% of the total. During the period from 2005 to 2015, 442,600 highway bridges were built in China, of which 383,400 were small and medium-sized bridges, accounting for 86.6%. Therefore, we should pay special attention to the construction and maintenance of small and medium-sized bridges. The bridge pier and abutment are always equipped with expansion joints to absorb the bridge structure deformation. Although the telescopic device is small in size and small in quantity, the cost can account for about 5% of the total cost of the project and the construction cost and late maintenance cost should not be underestimated. In addition, the temperature effect, vehicle load and concrete shrinkage and creep makes the expansion joints easily damaged. This phenomenon will not only affect the driving, but also further lead to the beam end and bearing erosion by acid rain, thus causing great potential safety hazard.

Integral abutment bridge (hereinafter referred to as "integral bridge") is a type of bridge which is put forward to solve the problem of the damage and failure of bridge expansion device in traditional bridges. The abutment is no longer set expansion joints and bearings, but connected into a whole (Chen et al. 2013, Vasheghani-Farahani et al. 2010, Wasserman and Walker 1996). Compared with the traditional bridge, the integral bridge has these advantages (Wasserman & Walker 1996): (1) simple design and construction process and lower cost of life cycle; (2) high integrity of structure, high redundancy and high earthquake resisting ability; (3) reducing the harmful effect of vehicle impact and structural vibration and improving the driving stability.

Due to the cancellation of the expansion device and bearing, expansion deformation of upper structure will transfer to the abutment and its pile founda-

tion, resulting in deformation of soil behind the abutment and around the pile, and the soil will in turn restrain the deformation of abutments and piles, thus affect the response of the integral structure. And the interaction is very complex and highly nonlinear. The complexity and uncertainty of soil properties and the interaction of soil-abutment and soil-pile, to a certain extent, limits the development of the analysis and design method of the integral bridge. In this paper, a three-dimensional finite element model of an integral bridge is established by using different soil-abutment and soil-pile interaction simulation methods, and the influence of the detailed degree of soil structure interaction (Soil-Structure Interaction, abbreviation SSI) modeling on the seismic analysis of the integral bridge is discussed. The research is conducive to achieve an accurate, reliable and moderately simplified SSI simulation method.

2 FINITE ELEMENT MODEL

2.1 *Modeling of bridge structure*

The span of the integral steel bridges is 56.7m and 58.8m, with 9.5m width of concrete pavement and 0.2m thickness of bridge deck. The bridge structure is composed of three steel girders with variable cross section, with 1.7m height in the mid-span, 345MPa yield strength and 200GPa elastic modulus. The abutment is 2.1m height, 1.1m thickness and 9.8m length, with compacted sand backfill behind the abutment and 8 steel pipe piles with an outer diameter of 355mm used at the foundation. Longitudinal profile and abutment connection joint of the bridge are shown in Figure 1.

A three-dimensional finite element model of the bridge is established by using the structural analysis and design software SAP2000 (SAP 2010), as shown in Figure 2. The abutment is simulated by shell element, and the steel beam, pier column, cap and pile is simulated by frame element. The calculation efficiency and the analysis accuracy are taken into account when dividing units, and different element size is used at different parts. Rigid connections was used between abutments and girders and between abutments and piles. Only the vertical displacement at the bottom of the pile is constrained, and relative translation of three directions of the connection between girder and cap beam is constrained. The pier column pile foundation has not been simulated in the model. It is assumed that the bottom of the column is fully rigid and is simulated by restricting the translation and rotation of column bottom joint in all directions, without considering the flexibility of the pile foundation and its influence on the pier column. The damping ratios used in all analyses were 5%.

In terms of material definition, the constitutive relation of concrete is modeled by Mander in SAP2000, and the constitutive relation of steel is modeled by Simple model. Both of the concrete and steel materials are isotropic, assuming that material behavior is unaffected by load direction and material orientation.

2.2 *Detailed modeling of SSI*

Soil is a highly nonlinear material and it shows highly nonlinear characteristics even at very low stress-strain level. In order to simulate the interaction of soil and structure more accurately and comprehensively, in this paper, a series of discrete nonlinear soil spring elements and damping elements are adopted for the simulation of soil-abutment-pile interaction, as shown in Figure 3.

The soil spring element type use the Multi-Linear Plastic. Considering the nonlinear characteristics of the spring, the hysteretic type uses the Takeda hysteretic model.

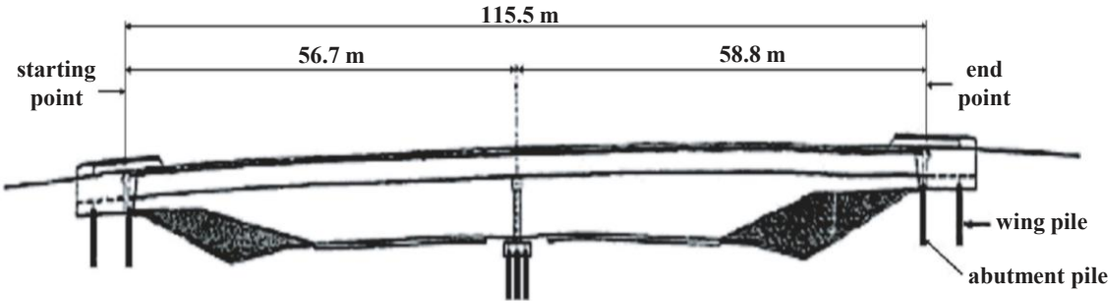
2.2.1 *Definition of soil spring behind abutment*

Behind the abutment is compacted sandy soil backfill, with 40.5° internal friction angle and $18.3kN/m^3$ density. Shamsabadi et al. (2007) studied the nonlinear interaction of soil and abutments under seismic action and proposed the formula (1) that define the parabolic load-displacement ($p-y$) curve of soil:

$$F(y_i) = \frac{F_{ult}(2Ky_{\max} - F_{ult})y_i}{F_{ult}y_{\max} + 2(Ky_{\max} - F_{ult})y_i}, \tag{1}$$

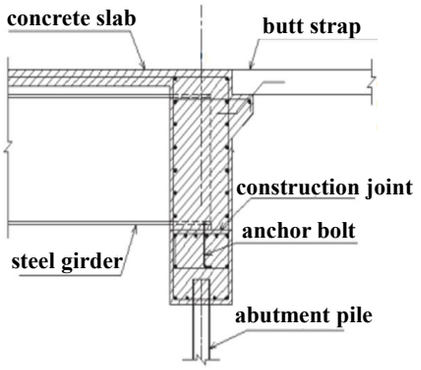
where y is the lateral displacement of abutment, F_{ult} is the maximum passive earth pressure acting on abutment of unit length when abutment displacement is $y_{\max}$, K is average soil stiffness. For sandy soil, F_{ult} can be calculated by formula (2):

$$F_{ult} = 0.5\gamma H^2 (1 - k_v) K_{pe}, \tag{2}$$



where H is the height of the abutment; γ is soil density, k_v is the vertical acceleration coefficient, K_{pe} is seismic passive earth pressure coefficient, can be obtained from the NCHRP 12-70 report of the National Cooperative Highway Research Program (NCHRP 2009).

2.2.2 *Definition of soil spring around pile*



Around the pile foundation is soft clay of which undrained shear strength $c_u = 35.9kPa$, bulk density $\gamma = 14.6kN/m^3$. American Petroleum Institute (API 1977) recommends the method given by Matlock in (Matlock 1970) to define the nonlinear $p-y$ curve of soft clay. The horizontal ultimate strength of soil is p_u:

$$p_u = \begin{cases} 3c_u + \gamma X + J\frac{c_u X}{D} X < X_R \\ 9c_u X \geq X_R \end{cases}, \tag{3}$$

where c_u is undrained shear strength, p_u is horizontal ultimate strength, D is the calculation width of pile;

(a) longitudinal profile

(b) connection joint of integral abutment

Figure 1: Longitudinal profile and abutment connection joint of a two-span integral abutment bridge

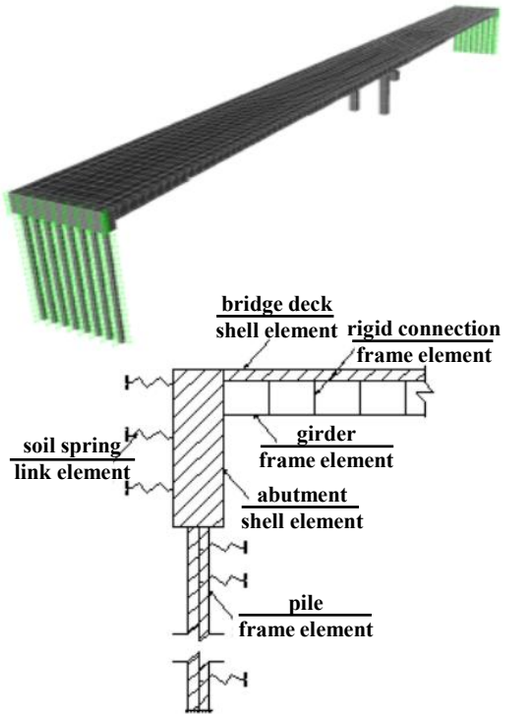


Figure 2: FEM model

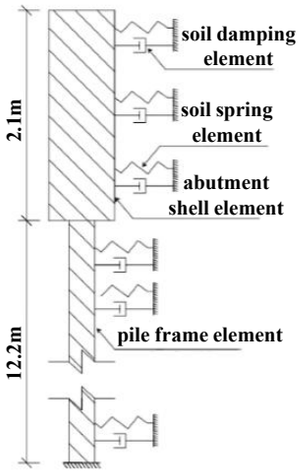

Figure 3: Detailed modeling of soil-structure interaction

J is dimensionless empirical constant; γ is soil density; X is the depth of soil surface to calculation point; X_R is the depth limit of ultimate strength calculation, which can be obtained by formula (4):

$$X_R = \frac{6D}{\frac{\gamma D}{c_u} + J}. \tag{4}$$

After the horizontal ultimate strength of the soft clay (p_u) is determined, the $p-y$ curve under cyclic loading is formed by Figure 4, where y is the actual horizontal displacement, $y_c = 2.5\varepsilon_c D$, ε_c is the corresponding strain when the soil horizontal resistance reaches half of the limit value. The soil spring $p-y$ curves of 0.3 m, 2.7 m and 5.8 m below the pile top are shown in Figure 5.

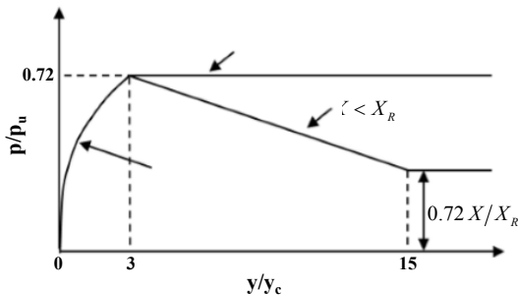

Figure 4: Generation of load-deflection curves for medium clay under cyclic loading

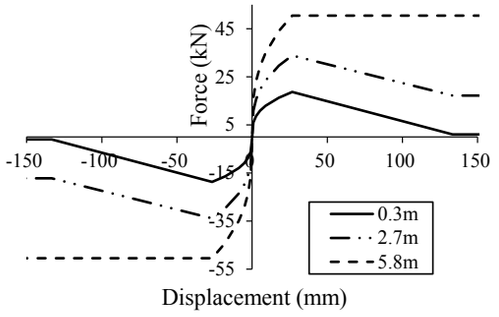

Figure 5: The p-y curve of soil around pile

2.2.3 *Definition of soil damping behind abutment*
The damping coefficient of soil behind abutment is calculated by the formula proposed by Jain & Scott (1989):

$$c = \sqrt{\frac{2}{1-\upsilon}} G\rho, \tag{5}$$

where G is the dynamic shear modulus of soil; c is the damping coefficient of soil; υ is the Poisson's ratio of soil; ρ is soil density. The dynamic shear modulus of compacted sandy soil is $40MPa$, and the Poisson's ratio is 0.3. Therefore, the damping coefficient c of the soil per unit area is $457kN/(m/s)$.

2.2.4 *Definition of soil damping around pile*
The damping coefficient of the soil around the pile is calculated by using the formula proposed by Anandarajah et al. (2005):

$$c = A\rho V_s, \tag{6}$$

where ρ is soil density; V_s is shear wave velocity of soil; A is the damping element dependent area. The shear wave velocity of soft clay is $200m/s$, and the damping coefficient c of the soil per unit area is $290kN/(m/s)$.

2.3 *Simplified modeling of SSI*

The simulation of soil-abutment and soil-pile interaction is simplified and 4 analytical models are established, as shown in Table 1.

Model 1 (referred to as M1) is the detailed model uses the discrete nonlinear soil spring elements and damping elements to simulate the soil-abutment and soil-pile interaction.

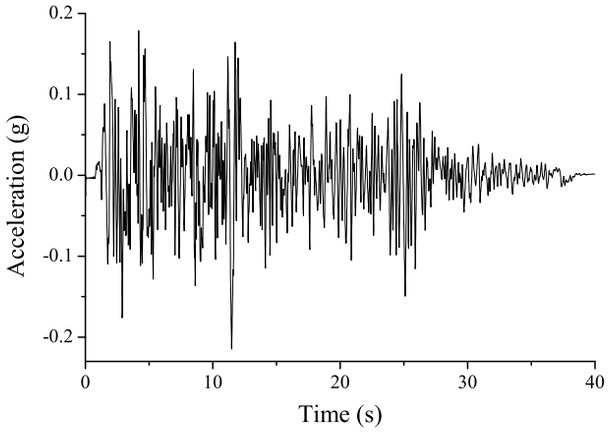

Figure 6: El Centro earthquake record

Model 2 (referred to as M2) removes the damping element of soil behind abutment and soil around pile in M1, without considering the effect of soil damping, therefore, the influence of soil damping on the simulation accuracy of seismic analysis of the integral fridge is analyzed.

Model 3 (referred to as M3) simplify the simulation of the soil around the pile. M3 assumes that the soil is linear elastic and uses the "m" method (CCCC Highway Consultants CO. 2007) to calculate the stiffness of the soil spring, without considering the nonlinear behavior of the soil around the pile. "m" method is simple, widely used and a familiar method for engineers and technicians in China, and it has been applied to the relevant specifications in China.

Model 4 (referred to as M4) simplify the simulation of the soil behind the abutment. M4 assumes that the soil is linear elastic without considering the nonlinear behavior of soil behind the abutment and uses the "m" method to calculate the stiffness of the linear elastic soil spring.

3 THE INFLUENCE OF SSI SIMULATION METHOD ON SEISMIC RESPONSE OF INTEGRAL BRIDGE

In this paper, the structural response of the bridge under different peak ground acceleration (PGA) seismic waves is obtained by nonlinear time history analysis. The horizontal seismic waves used in the time history analysis are the seismic waves of El Centro in the United States, California, with 0.215g PGA and 40s duration, and the seismic acceleration records are shown in Figure 6. The PGA of seismic wave is adjusted to 0.15g, 0.3g and 0.6g respectively in order to investigate the influence of the value of PGA on the accuracy of simplified model analysis.

Table 1: Different modeling methods of soil-structure interaction.

Model	Soil-abutment interaction	Soil-pile interaction
M1	nonlinear spring element + damping element	nonlinear spring element + damping element
M2	nonlinear spring element	nonlinear spring element
M3	nonlinear spring element + damping element	linear spring element (”m” method)
M4	linear spring element (”m” method)	nonlinear spring element + damping element

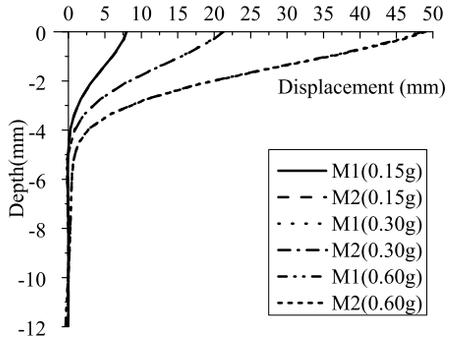

Figure 7: Distribution of displacement along the pile in model 1 & 2

3.1 *Influence of the soil damping*

Distribution of pile displacement of model 1 and model 2 along pile length under different PGA is shown in Figure 7. When PGA is 0.15g, the time history of the pile top bending moment of model 1 and model 2 is shown in Figure 8. Analyses results of the displacement at the top of the pile, displacement at the top of the pier, bending moment at the top of the pile, bending moment at the bottom of the pier, maximum bending moment of the abutment and maximum bending moment of the girder are shown in Table 2.

By comparing the results in Figure 7, Figure 8 and Table 2, it can be found that soil damping has little

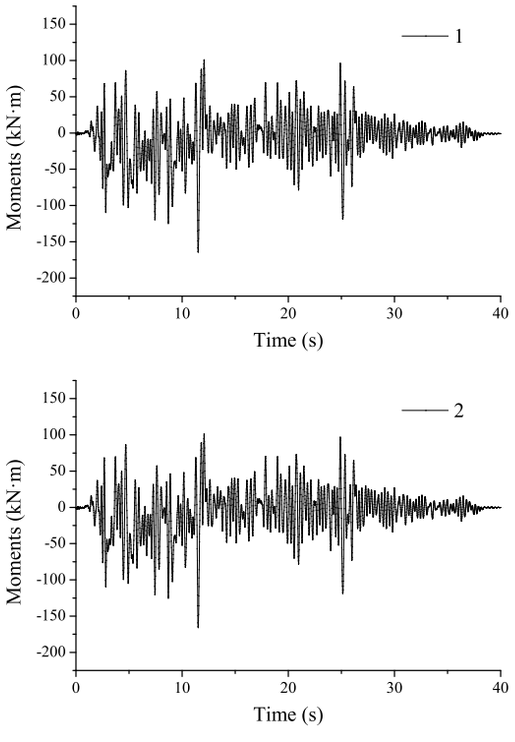

Figure 8: Pile top moment time history at PGA=0.15g of model 1 & 2

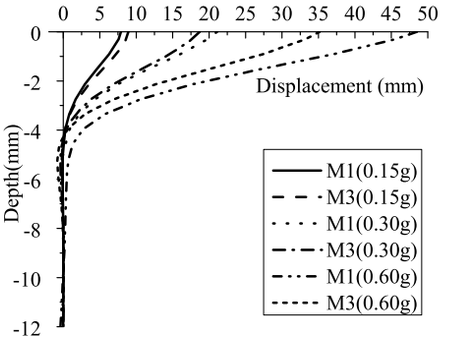

Figure 9: Distribution of displacement along the pile in model 1 & 3

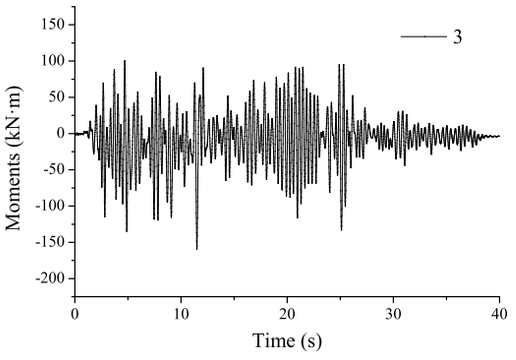

Figure 10: Pile top moment time history at PGA=0.15g of model 3

effect on the seismic response of the bridge. The pile displacement distribution and the time history of pile top bending moment of M1 and M2 are almost the same, with the differences of seismic response of each component less than 1%. Therefore, the damping of the soil can be neglected in the seismic analysis of integral bridge.

3.2 *Influence of simplification of soil-abutment interaction*

Distribution of pile displacement of M1 and M3 along pile length under different PGA is shown in Figure 9. When PGA is 0.15g, the time history of the pile top bending moment of M3 is shown in Figure 10. Analyses results of the displacement at the top of the pile, displacement at the top of the pier, bending moment at the top of the pile, bending moment at the bottom of the pier, maximum bending moment of the abutment and maximum bending moment of the girder are shown in Table 3.

By comparing the pile displacement distribution of model 1 and 3 under different PGA in Figure 9, it can be seen that the results of M3 is close to that of detailed model M1. When PGA is small (PGA=0.15g),

Table 2: Comparison of the bridge seismic response in model 1 and model 2.

Acce.	Model	Pile top disp.	Pier top disp.	Pile top moments	Pier bottom moments	Abutment Mmax	Girder Mmax
		mm	mm	kN·m	kN·m	kN·m	kN·m
0.15g	M1	7.9	6.5	164.5	995.5	755.9	401.7
	M2	8.0	6.6	165.9	1003.0	761.6	404.9
0.3g	M1	21.1	17.9	341.6	1886.9	1792.0	968.8
	M2	21.3	18.0	314.7	1898.2	1805.9	977.1
0.6g	M1	48.5	42.4	362.1	2765.7	3931.1	2233.8
	M2	49.0	42.8	362.1	2768.9	3964.3	2254.0

Table 3: Comparison of the bridge seismic response in model 1 and model 3.

Acce.	Model	Pile top disp.	Pier top disp.	Pile top moments	Pier bottom moments	Abutment Mmax	Girder Mmax
		mm	mm	kN·m	kN·m	kN·m	kN·m
0.15g	M1	7.9	6.5	164.5	995.5	755.9	401.7
	M3	8.9	7.3	159.7	1048.8	714.9	344.6
0.3g	M1	21.1	17.9	341.6	1886.9	1792.0	968.8
	M3	18.7	16.0	298.3	1771.5	1409.6	690.3
0.6g	M1	48.5	42.4	362.1	2765.7	3931.1	2233.8
	M3	35.2	31.1	349.7	2537.8	2678.0	1382.5

M3 slightly overestimated the displacement of pile top (12.6%); at PGA=0.30g, M3 slightly underestimated the displacement of pile top (11.3%); but at PGA=0.60g, the error of M3 reached 27%. Therefore, when the PGA value is large, the influence of soil bridge interaction simulation simplification should be carefully considered.

According to Figure 10, the bending moment of M1 reaches a negative maximum value of $164.5kN \cdot m$ at $t = 11.51s$ and reaches a maximum positive value of $101.1kN \cdot m$ at $t = 12.07s$. The waveform of M3 is consistent with the detailed model M1 and the maximum value of the bending moment is similar, which is $159.7kN \cdot m$ and $164.5kN \cdot m$, with a difference of only 2.9%. But the time to reach the maximum is different. M3 reaches its maximum value at $t = 11.49s$, while M1 at $t = 11.51s$.

With the increasing of PGA, the nonlinear properties of soil are gradually enhanced and the stiffness tends to decrease. M3 uses the "m" method to calculate the stiffness of soil around pile, without considering the nonlinear soil, so the stiffness of soil around pile of M3 tends to increase compared with M1. Therefore, when the PGA increases from 0.15g to 0.3g and 0.6g, the increasing range of displacement of the abutment pile top and the pier top of M3 compared to M1 changes from +12% to -11% and -27%.

By comparing the differences of seismic responses between M1 and M3 in different PGA cases in Table 3, the following conclusions can be drawn: In general, when the PGA is 0.15g, the seismic response of the simplified model M3 is similar with that of the detailed model M1 and the differences of the seismic response of each structural component is below 15%. Which is consistent with the statement that "When the horizontal load on the piles is relatively small, or the displacement of the pile at the mud surface is not more than 10mm, the error of "m" method is small" (CCCC Highway Consultants CO. 2007). But with the increasing of PGA, the accuracy of M3 is decreasing. When the PGA increases to 0.6g, the difference of the result the maximum bending moment of the abutment and the maximum bending moment of the girder between M3 and M1 is 31.9% and 38.1% respectively.

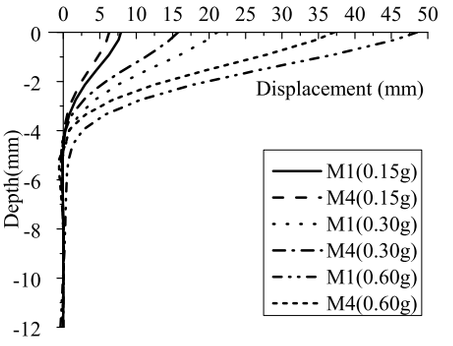

Figure 11: Distribution of displacement along the pile in model 1 & 4

3.3 *Influence of simplification of soil-pile interaction*

Distribution of pile displacement of M1 and M4 along pile length under different PGA is shown in Figure 11. When PGA is 0.15g, the time history of the pile top bending moment of M4 is shown in Figure 12. Analyses results of the displacement at the top of the pile, displacement at the top of the pier, bending moment at the top of the pile, bending moment at the bottom of the pier, maximum bending moment of the abutment and maximum bending moment of the girder are shown in Table 4.

By comparing the pile displacement distribution of M1 and M4 under different PGA, it can be seen that the pile displacement of M4 when PGA is 0.15g is much larger than M1, but with the increasing of PGA,

Table 4: Comparison of the bridge seismic response in model 1 and model 4.

Acce.	Model	Pile top disp.	Pier top disp.	Pile top moments	Pier bottom moments	Abutment Mmax	Girder Mmax
		mm	mm	kN·m	kN·m	kN·m	kN·m
0.15g	M1	7.9	6.5	164.5	995.5	755.9	401.7
	M4	6.3	5.9	134.9	861.3	508.3	308.1
0.3g	M1	21.1	17.9	341.6	1886.9	1792.0	968.8
	M4	15.7	14.7	293.7	1691.0	1134.4	691.9
0.6g	M1	48.5	42.4	362.1	2765.7	3931.1	2233.8
	M4	37.2	34.5	355.1	2698.1	2554.2	1586.5

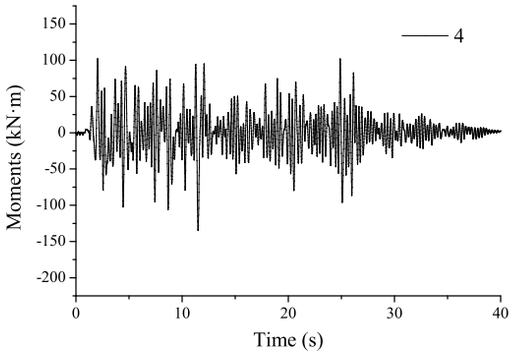

Figure 12: Pile top moment time history at PGA=0.15g of model 4

the results of M4 gradually approach the results of M1. When PGA increases to 0.6g, the pile displacement of M4 is the closest to that of M1 than M3.

According to Figure 12, the bending moment of M1 reaches a negative maximum value of $164.5kN \cdot m$ at $t = 11.51s$ and reaches a maximum positive value of $101.1kN \cdot m$ at $t = 12.07s$. The waveform of M4 is consistent with the detailed model M1 and they all reach the maximum moment at the top of the pile at $t = 11.5s$, $134.9kN \cdot m$ and $164.5kN \cdot m$, respectively, with a difference of 18%.

With the increasing of PGA, the nonlinear properties of soil are gradually enhanced and the stiffness tends to decrease. M4 uses "m" method to calculate the stiffness of soil, without considering the soil nonlinearity, thus overestimated the abutment-soil system stiffness. The analysis error of abutment maximum bending moment is about 35%, but the analysis error of other responses is less than 30%, so the overall analysis accuracy is higher. With the increasing of PGA, the analysis accuracy of M6 has a tendency to decrease, but not very much.

3.4 *Simulation method selection*

Because the difference between the seismic response of the members of M2 (without considering the influence of soil damping) and the detailed model M1 is less than 1%, so the influence of soil damping can be neglected when the seismic analysis of the whole bridge is carried out.

According to the results of different models under different PGA, when PGA is 0.15g and 0.3g, the analysis accuracy of the model using "m" method to simplify the soil-pile interaction (M3) is higher. When the PGA is 0.6g, the accuracy of the model using using "m" method to simplify the soil-abutment interaction (M4) is higher than the model using "m" method to simplify the soil-pile interaction (M3).

By comparing the results of each simplified model and the detailed model, it can be found that the overall analysis accuracy of the simplified model 3 is higher, of which the error is always within a reasonable range. Under different PGA, the average difference between M3 and detailed model M1 of bending moment at the pile top, the bending moment of pier bottom and the pile top displacement is about 6.3%, 6.6% and 17.3% respectively, which is higher than that of M4. The difference of the displacement of pier top, the maximum bending moment of abutment and the maximum bending moment of girder is 16.4%, 19.5% and 27% respectively. The maximum difference between M3 and detailed model, which is 38.1%, occurs in the comparison of maximum bending moment of the girder when the PGA is 0.6g. The overall analysis accuracy of M4 is also relatively high, and the accuracy of the analysis fluctuates little when the PGA changes, and the error always stays within a reasonable range. The maximum difference occurs in the comparison of the maximum bending moment of the abutment when PGA is 0.3g, with the difference of 36.7%.

From the results of each component, the analytical accuracy of pile top displacement, pile top bending moment, pier bottom bending moment and the maximum bending moment of the abutment is higher when using simplified model M3, and the average error of different PGA is 17.2%, 6.3% , 6.6% and 19.5% respectively; The analysis accuracy of the pier top displacement and the maximum bending moment of the girder is higher when the simplified model M4 is adopted, with the average error considering different PGA is 15.2% and 26.9% respectively.

From the point of view of the sensitivity of the component analysis results, when the seismic wave PGA changes, the variational range of analysis accuracy of M3 is greater than M4, in other words, the analysis accuracy of M3 is less sensitive to the seismic wave PGA. And for M3, the variational range of analysis accuracy of maximum bending moment of girder and abutment is greater, which means higher sensitivity, while for M4, the accuracy analysis of pile top bending moment and pier top bending moment changes greatly, which means higher sensitivity.

In conclusion, SSI simplified simulation method should be selected according to the value of PGA of the earthquake, and considering the analysis accuracy of the seismic response of each component, and also should consider the different sensitivity of the seismic response of different component when different simplified simulation method was adopted.

4 CONCLUSION

(1) The damping of soil has little effect on the seismic response of the integral bridge and the damping of the soil can be neglected in the seismic analysis of the integral bridge.

(2) When PGA is 0.15g and 0.3g, the model using "m" method to simplify pile-soil interaction (M3) has higher analysis accuracy. And with the increasing of PGA, the analysis accuracy of M3 decreases, but with small change. However, when the PGA is 0.6g, the model using "m" method to simplify the abutment-soil interaction (M4) has higher accuracy than M3.

(3) The model using "m" method to calculate the stiffness of soil behind abutment (M4) has high analysis accuracy, and with the increasing of PGA, the accuracy of M4 has a decreasing trend but with only a little change, and the error is always within reasonable range.

(4) M3 has higher analysis accuracy in the analysis of the displacement of the pile top displacement, the pile top bending moment, the pier bottom bending moment and the maximum bending moment of the abutment, while M4 has higher analysis accuracy in the analysis of the displacement at the pier top and the maximum bending moment of the girder. When the seismic wave PGA changes, the analysis accuracy of M3 of the maximum bending moment of the abutment and girder changes a lot and the sensitivity is high, while the analysis accuracy of M4 of the pile and pier top bending moment is more sensitive to the seismic wave PGA.

(5) The "m" method is considered to be useful to simplify the pile-soil interaction, especially when the PGA is small. The "m" method is also useful to the simplification of the abutment-soil interaction. SSI simplified simulation method should be selected according to the value of PGA of the earthquake, and considering the analysis accuracy of the seismic response of each component, and also should consider the different sensitivity of the seismic response of different component when different simplified simulation method was adopted.

ABSTRACT: This paper focused on seismic behavior of integral abutment-steel H pile joints through cyclic tests. Six specimens were tested, composing of a steel H-pile embedded inside an inverted "T" shape reinforced concrete block simulating abutment. Design parameters varying as follow: H pile orientation, strong vs. weak axis bending; crumb rubber concrete (CRC) vs. normal concrete, for portion of abutment around pile tip; attaching rubber plates to H pile tip vs. no rubber plates. Test results indicated that: pile orientation had significant influence on seismic performance, energy dissipation and bending capacity for weak axis bending is lower than strong axis bending, while failure displacement and ductility is higher; CRC would reduce concrete cracks, initial stiffness, and slow down stiffness degradation, and reduced total energy dissipation; attaching rubber plates to pile tip protected it from damage. It would reduce initial stiffness and bending capacity, but increased failure displacement and ductility.

1 INTRODUCTION

With the increasing demand for transportation in recent years, the amount of bridge construction increased rapidly. Expansion devices in regular bridges exposure to external environment, including precipitation, dust, and traffic load are liable to damage, while it is difficult to be repaired or replaced. In jointless bridges, superstructure and substructure form an integral connection at the abutment level, expansion devices have been removed. As a result, the maintenance costs can be decreased obviously.

Different form regular bridges, the integral connection transfer moment and shear, and deformations in the superstructure caused by temperature changing and earthquake transfer to the substructure directly. Consequently, the connection of abutment and pile must be taken into seismic design consideration of great importance. In order to reduce loads and deformations transferred from the superstructure to the substructure, flexible piles and foundations are typically recommended to accommodate the loads and deformations.

1.1 *Embedded depth*

The depth of piles embedded in abutments have negligible influence on the integrity of the connection. Piles could bear relatively large lateral deformations while the embedded depth is more than 0.3m. Moment of pile distributes bidirectionally, moment at the top of pile decreases to zero, counter moment increases to a maximum value and decreases to zero gradually in a further step along with the increasing embedded depth (Burdette 1999; Burdette 2003; Burdette 2004), and the seismic performance of integral abutment-pile joints can be improved (Frosch 2009).

1.2 *Pinned connection*

An experimental research revealed that providing a pinned connection of abutment and pile can effectively improve the seismic performance, because the pinned connection accommodates deformations without resulting in excessive stress (Frosch 2009). Sherafati proposed that wrapping the top of the concrete-filled steel tube pile up with a rubber sleeve and embedding the wrapped pile head into the abutment. As a result, lateral stiffness and maximum moment have been decreased, and deformation capacity of the pile has been promoted. Experimental result showed that lateral deformation capacity of pinned connection increased to 3.8 times as much as that of rigid connection (Sherafati 2014).

1.3 *Bending orientations*

In order to reduce the bending stiffness of the pile, studies focused on bending orientations of the pile were conducted. Frosch revealed that the lateral load capacity of piles is larger for strong axis bending, while the lateral displacement capacity is reduced,

and strength degradation restricts the seismic performance of the piles seriously (Frosch 2009). Some studies showed that piles bend along their weak axis can accommodate larger displacement transferred from the superstructure to the substructure, so that piles and abutment can be protected (Chovichien 2004; Girton 1991; Haj-Najib 2002; Thanasattayawibul 2006).

The traditional construction measure of integral abutment-H steel pile joints is embedding the H steel pile into the abutment directly. Due to the high stiffness and bad deformation capacity, the joints tend to be damaged easily. Research on construction measures of integral abutment-H steel pile joints need to be conducted in a further step to improve the seismic performance.

In recent years, rubber consumed massively in China, but cannot be recycled efficiently (Yue 2006). Rational utilization of abandoned rubber has advantages to solve the problem of environment pollution and resources wasting.

In this paper, cyclic tests are conducted on 6 integral abutment-H steel pile joint specimens. Considering 3 aspects which affect the seismic performance of the joints: bending orientation, which is the main factor affecting the stiffness of piles; applying rubberized concrete to the joint region in abutment, so that the elastic modulus and cracks developing of abutment concrete can be reduced (Baoming 2010; Chujie 2008); wrapping rubber plates around the head of H steel pile, deformations from earthquake can be absorbed by rubber plates, and the head of pile can be protected from damage. In a further step, finite element analysis is conducted based on the verification with experimental results. Effects of axial compression ratio, rubber content, yield strength of steel, and thickness of rubber plate on seismic performance of the joint are considered.

2 SPECIMEN DETAILS

2.1 *Specimen design*

Abutment-H steel pile part of a two span integral steel bridge in Tennessee was chosen as the prototype of test specimens, each specimen has the same contour and size. As can be seen from Figure 1, the cross section of abutment is 910×910mm, and HP 246×256×10×10 for the cross section of H steel pile. Six specimens are named as S1 to S6. S1 and S2 are specimens with rigid joint; S3 and S4 are specimens which applying rubberized concrete with 10% rubber content to the joint region in abutment, the depth of concrete-replaced region is 100mm deeper than the embedded depth of steel pile, rubberized concrete mix proportion can be found from Table 1; S5 and S6 are specimens which pasting 25mm thick rubber plates to the head of H steel pile embedded in the abutment. Differences between 6 specimens can be seen from Figure 2.

Table 1. Rubberized concrete mix proportion.

Rubber	Cement	Sand	Stone	Water	Reducer
kg	kg	kg	kg	kg	kg
100	590	412	1030	205.9	0.917

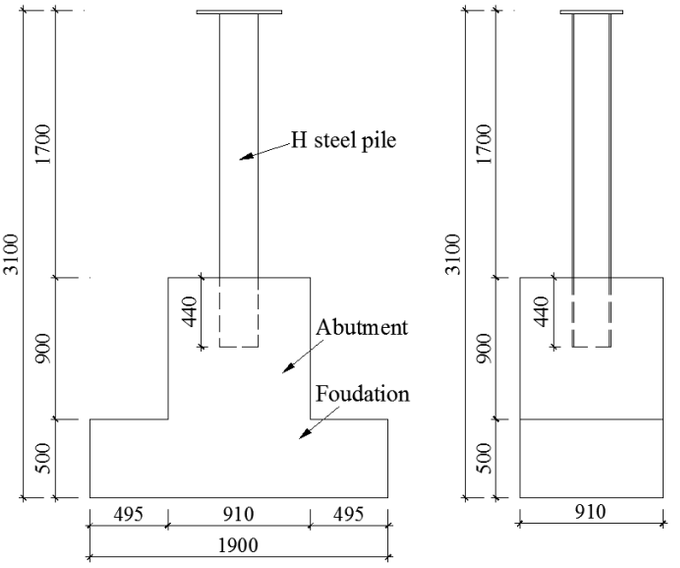

Figure 1. Contour size of specimen.

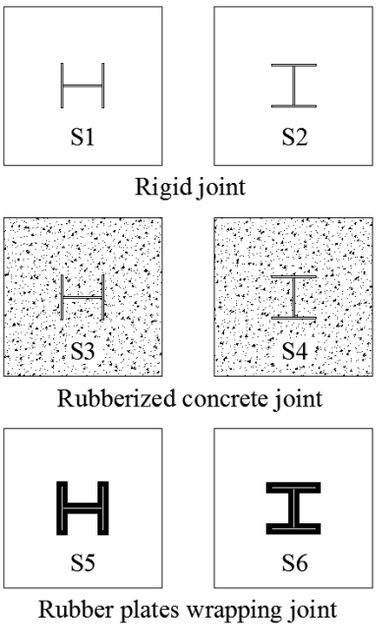

Figure 2. Joint connecting measures.

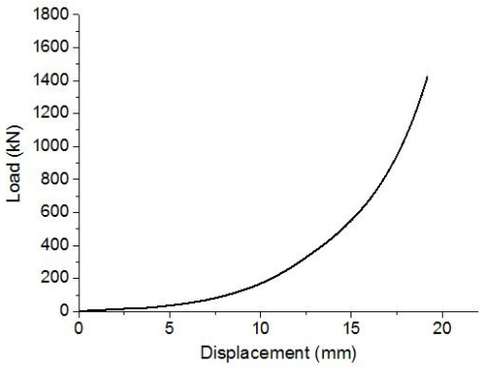
2.2 *Material properties*

Specimens mainly consist of H steel pile and concrete abutment. Steel grade Q345 was used for the H steel pile, result of steel material tension test can be seen from Table 2. C35 concrete was used for the abutment, measured compression strength of standard cube of ordinary concrete and rubberized con-

crete were 49.5MPa and 31.3MPa. In order to obtain the material mechanical property of rubber plate, reserved 25mm thick rubber plate was cut into 100×100×25mm cuboid, so that the force-displacement curve of rubber plate under compression was obtained by universal test machine, which can be seen from Figure 3.

Table 2. Tension test results of steel materials.

Design grade	Yield strength	Tensile strength	Yield ratio
MPa	MPa	MPa	——
345	391	551.8	0.71



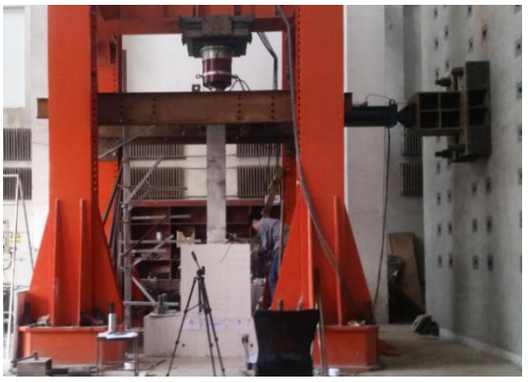


Figure 3. Compression load-displacement curve of rubber plate.

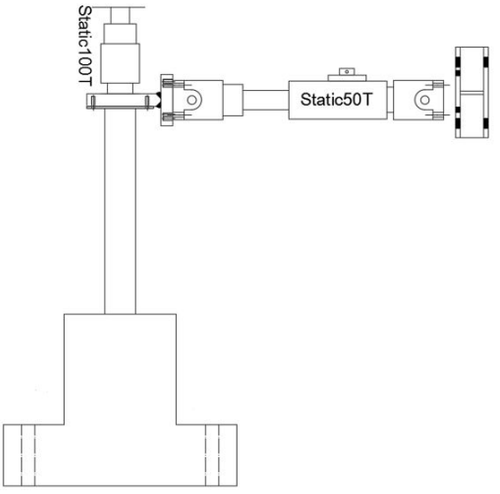

2.3 *Test devices and loading program*

In this test, axial and horizontal loading are adopted to reflect seismic performance of the integral abutment-pile joints under actual stress conditions. Axial load is imposed by a 1000kN vertical jack, which is fixed on the reaction frame but can move in step with the horizontal loading location of the H steel pile. During the test, the axial compression ratio remains a constant of 0.25. Horizontal reciprocating load is imposed by a horizontal actuator which can provide maximum load of ±500kN, and maximum displacement of ±200mm. Arrangement of experimental loading device can be seen form Figure 4.

Figure 5. shows the loading program applied to 6 specimens in this test. Axial load was applied to the specimen and kept a constant before lateral load applied during the test. Displacement-dominated loading was adopted in this test. The first level of loading amplitude and amplitude increment were both 6mm, and each level loaded only once before system yielding, the displacement while system yielding was denoted as d_y. The loading amplitude increment was taken as $0.5d_y$ since system yielding, and each level loaded twice. Once the lateral load bearing capacity declined to 85% of the peak lateral load bearing capacity, it can be considered that the system damaged, and test terminated.

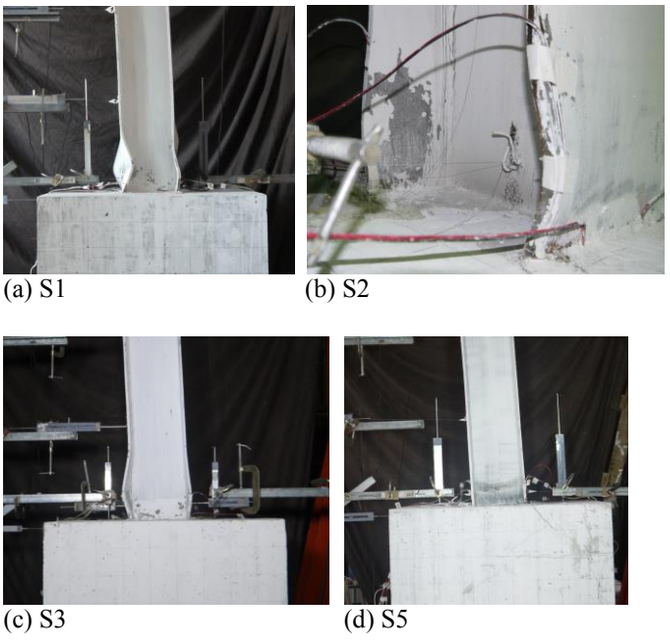
3 DESCRIPTION OF TEST SPECIMENS

Specimen S-1 behaved elastic before the lateral displacement of 24mm. White coating cast from flanges at the bottom of steel pile, concrete cracks carried out at the interface of steel pile and abutment; the specimen began to yield at the displacement of 24mm and reached peak load at 36mm. White coating cast from bottom flanges during yielding to peak bearing capacity stage continuously, concrete cracks developed at the interface of the steel pile and the

abutment; lateral load bearing capacity kept degrading while the lateral displacement increased from 36mm to 72mm, which caused local buckling of the flanges at the bottom of steel pile. The range of buckling extended with the increasing of the applied loading. Consequently, the web yielded and the development of concrete cracks decreased after yielding.

As well as S-1, specimen S-2 yielded at the lateral displacement of 24mm. Concrete cracks carried out with small pieces spalling of white coating at the interface of the steel pile flanges and the concrete; the specimen reached its peak load capacity at the lateral displacement of 48mm. White coating cast severely from the flanges at the bottom of steel pile during the stage of system yielding to system reaching peak load bearing capacity, and lateral load bearing capacity kept degrading while the lateral displacement increased from 48mm to 96mm, the concrete cracks carried out at the abutment where adjacent to the margins of flanges. With the development of lateral load increasing, local buckling of the flanges at the bottom of steel pile developed constantly.



Specimen S-3 yielded while the lateral displacement was 24mm and reached its peak load bearing capacity while the lateral displacement was 48mm as well. Concrete cracks developed but a few at the interface of the steel pile and the abutment since system yielding. The flanges at the bottom of steel pile kept buckling while the lateral displacement increased from 48mm to 84mm, and the range of buckling extended with the increasing of the applied loading. Consequently, the development of cracks reduced after the buckling of web.

Specimen S-4 began to yield while loading to the lateral displacement of 33mm, and reached its peak lateral load bearing capacity at 66mm. White coating cast inattentively from the flanges at bottom of steel pile during yielding to peak bearing capacity stage, flanges began to yield and developed constantly. The specimen was on the stage of failure from 66mm to 99mm, buckling occurred on the flanges of the pile and developed constantly with the applied loading.

Specimen S-5 worked at elastic state before the lateral displacement was 18mm, and an insignificant crack appeared at the abutment where adjacent to the margin of flange. As load keeping on, the specimen reached its peak lateral load bearing capacity at the lateral displacement of 45mm, and concrete cracks developed at the interface of the steel pile and the abutment, and rubber plates were compressed or cracked with the applied loading. Diagonal cracks were visible and developed constantly at the margins of flanges after the specimen reached its peak load bearing capacity. The specimen was on the stage of failure from the lateral displacement of 45mm to that of 90mm. Finally, the abutment appeared severe cracks to damage while the steel pile remained intact.

Specimen S-6 behaved elastic before the lateral displacement of 33mm and no significant phenomenon appeared. As lateral load carrying on, the gap between the margins of flange and the rubber plate got widen gradually, and the specimen reached its peak load bearing capacity at the displacement of 66mm. The specimen was on the failure stage from the lateral displacement of 66mm to that of 99mm, the gap mentioned above got widen in a further step, and the concrete was local fractured at the contacted portion of the rubber plate and concrete while the steel pile remained intact.

Failure modes of typical specimens are shown in Figure 6.

(c) S3 (d) S5

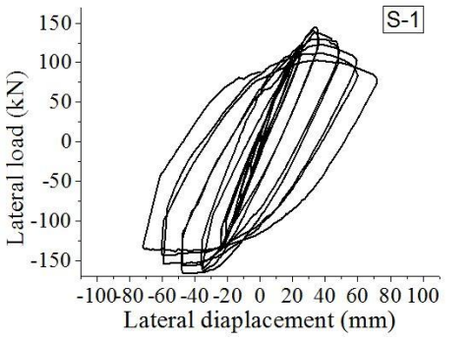
Figure 6. Failure modes of typical specimens.

4 ANALYSIS OF TEST RESULTS

4.1 *Load-displacement performance*

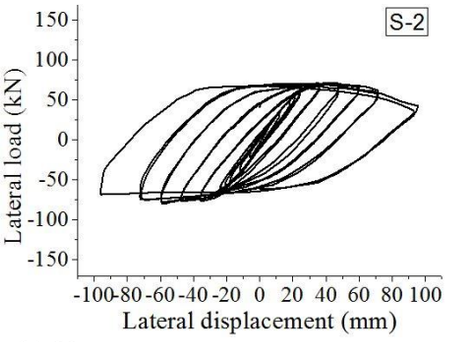
The acquisition of lateral load magnitude could be accomplished with the force sensor erected on the end of the actuator, and the lateral displacement of specimen could be obtained by the displacement sensor which is attached on the top center of the specimen. The load-displacement hysteretic curve of 6 specimens are shown in Figure 7.

The important properties in different stages of force and deformation, for instance, the seismic parameters of strength, stiffness and ductility could be obtained from the envelope curves which are also used for comprehensive assessment of seismic behavior. Envelope curves of all specimens are shown in Figure 8.



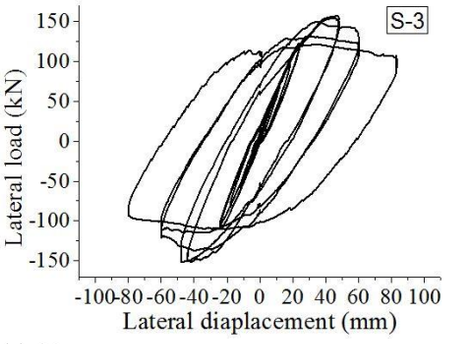
According to the envelope curves above, generalized yield moment method is selected to define the yield load and yield displacement of all specimens. Values of lateral rigidity, yielding value, peak point

value, failure displacement, bearing capacity and ductility ratio of 6 specimens are shown in Table 3.



It can be found from the experimental results that the bending axis of steel H pile has a significant influence on ductility performance to system, the differences on rigidity, lateral displacement and bearing capacity are relatively distinct. The lateral stiffness and yielding load of weak axis bending specimen is obviously worse than that of strong axis bending specimen, and the peak lateral load bearing capacity of weak axis bending specimen is relatively small, while the lateral displacements of specimen reaching its peak lateral load bearing capacity and performing to failure are the opposite. The failure lateral drift varies from 1/32 to 1/22 of strong axis bending specimens, while the lateral drift of weak axis bending specimens varies from 1/24 to 1/18. The ductility ratio of strong axis bending specimen is 1.55 on average. Generally, specimens of weak axis bending entered into plastic stage earlier because of the smaller bending stiffness, which caused a larger ductility ratio, 2.65 on average.

It can be found from Figure 7. (a-d), adopting crumb rubber concrete in local region has an insignificant influence on the load-displacement behavior at the beginning of the envelope curves. The difference got pronounced while the lateral load got close to the peak load gradually. Lateral rigidity of specimens decreased obviously by adopting crumb rubber concrete in local region, the average value of lateral rigidity of strong bending axis and weak bending axis dropped respectively from 4.86 and 2.35 to 3.61 and 1.91. It has an insignificant influence on the yield and peak load by adopting crumb rubber concrete in local region as well, but increases relevant lateral displacement. In general, filling rubber in concrete or not has an insignificant influence on the failure load and lateral displacement, the insertion of crumb rubber is not good for ductility promotion of the system.



Unlike filling crumb rubber in concrete, wrapping rubber plate has a significant influence on the seismic performance of the system. Compared with adopting crumb rubber concrete in local region, it influences the lateral rigidity remarkably, the average value of lateral rigidity of strong bending axis and weak bending axis dropped from 4.86 and 2.35 to 2.85 and 0.84. The yield load, peak load and failure load are decreased while the failure lateral displacement is increased by wrapping rubber plate, which improves the system ductility to a certain extent. Ductility ratio of strong axis bending specimens increased from 2.2 to 3.2 on average while that of weak axis bending specimens unchanged.

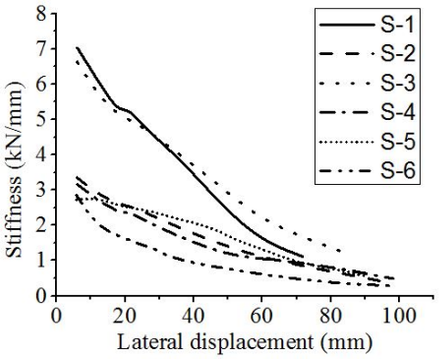
* K is the lateral stiffness, d_y is the displacement while system yielding, P_y is the lateral load capacity while system yielding, d_m is the displacement while system reaching its peak load capacity, P_m is the peak lateral load capacity, d_u is the displacement while lateral load capacity decreasing to 85% of peak load capacity, α is the ultimate displacement angle, μ is the ductility ratio of the system.

4.2 *Stiffness degradation*

Stiffness degradation reflects the degrading procedure of specimens under cyclic loading, it is an important characteristic in the research of seismic performance. The method of researching stiffness degradation of specimens under cyclic loading process is calculating the secant stiffness of specimens. Stiffness degradation curves of all specimens are shown in Figure 9.

Specimen S-1 and S-3 performed high lateral stiffness level during the initial stage of loading, which is twice than the others, but lateral stiffness dropped rapidly with the increasing lateral displacement. Despite the stiffness degradation of S-1 and S-3 are evident, they are still higher than that of other specimens during the later loading stage. Specimen 2, The lateral stiffness of S-2, S-4 and S-5 are respectively closed during the whole loading stage, while that of S-6 dropped rapidly from initial loading stage to the failure stage, and was always lower than the others.

According to the contrast, the lateral stiffness of strong axis bending specimens are always higher than the lateral stiffness of weak axis bending specimens. Adopting crumb rubber concrete in local region reduces the initial stiffness of specimens but also retards the stiffness degradation, relatively, the lateral stiffness of specimens adopting crumb rubber concrete in local region was higher than specimens adopting ordinary concrete in the whole abutment region during the stage of load bearing capacity decline. Wrapping rubber plate reduces the initial lateral stiffness significantly but it affects the stiffness degradation slightly during the stage of load bearing capacity decline.



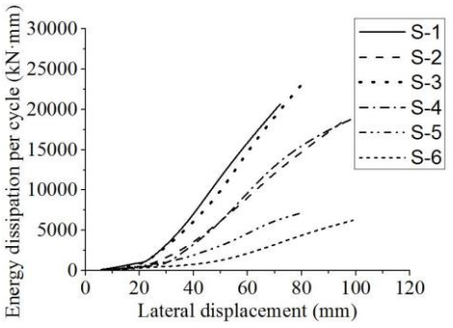


Figure 9. Stiffness degradation.

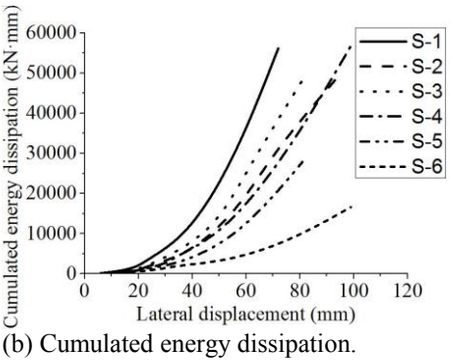
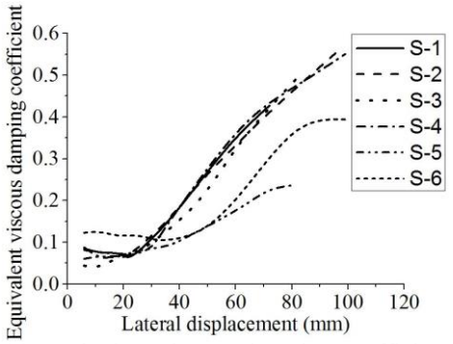
4.3 *Energy dissipation*



Single-cyclic energy dissipation, cumulated energy dissipation and equivalent viscous damping coefficients are used to indicate the energy dissipation capacity of all specimens under reciprocate pseudo static cyclic loading in this test, and the performance mentioned above are shown in Figure 10.

By comparison, the energy dissipation capacity of strong axis bending specimens are evidently higher than that of weak axis bending specimens. Adopting crumb rubber concrete in local region reduces the single-cyclic energy dissipation capacity at the elastic stage, but the capacity approaches or exceeds the ordinary ones gradually with the lateral load carrying on, which indicates that adopting crumb rubber concrete in local region affects the single-cyclic energy



dissipation capacity gradually at the later stage of loading. The cumulated energy dissipation curves reveal that adopting crumb rubber concrete in local region reduces the cumulated energy dissipation capacity, this phenomenon is much more remarkable in specimens with strong axis bending. Wrapping rubber plate distinctly reduces the single-cyclic energy dissipation capacity and the decline tends to increase with the augment of lateral displacement, as well as the cumulated energy dissipation capacity. The comparison of equivalent viscous damping coefficients reveals that adopting crumb rubber concrete in local region has an insignificant influence on damping coefficients, but wrapping rubber plate distinctly reduces damping coefficients.

(a) Single-cyclic energy dissipation.

(b) Cumulated energy dissipation.

(c) Equivalent viscous damping coefficient.

Figure 10. Energy dissipation capacity.

5 CONCLUSIONS

The bending axis of H steel pile has significant influence on seismic performance of the joint. The energy dissipation capacity and stiffness of weak axis bending specimens are worse than that of strong axis bending specimens, on the opposite, the ultimate lateral displacement and ductility of weak axis bending specimens are both higher than that of strong axis bending specimens.

Adopting crumb rubber concrete in local region of the abutment can obviously reduce the concrete cracks, and the lateral load bearing capacity is influenced by the construction measure slightly while the yield displacement is increased, which is not good for the ductility improvement of the system. Due to the material properties of rubber, the initial lateral stiffness could be reduced, and the speed of stiffness degradation could be retarded as well. Adopting crumb rubber concrete in local region of the abutment has insignificant influence on equivalent viscous damping coefficient, while reduces the energy dissipation capacity to a certain extent.

Wrapping rubber plate at the top of steel pile is an efficient way to reduce the initial lateral stiffness of the system without reducing the lateral stiffness at plastic stage obviously. As a result, the lateral load bearing capacity would be reduced distinctly, while the ultimate displacement would be increased, and the ductility would be improved significantly, so that the abutment-pile joint could accommodate lager loads and deformations transferred from the superstructure to the substructure efficiently.

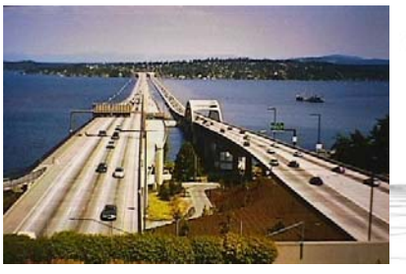
DESIGN AND CONSTRUCTION CHALLENGES OF JOINTLESS BRIDGES IN SEISMIC REGIONS

Bijan Khaleghi, PhD, PE, SE
Adjunct Professor at Saint Martin University
State Bridge Design Engineer, Washington State, USA



W. Phillip Yen, PhD, PE
Chair, International Association of Bridge Earthquake Engineering, USA

ABSTRACT: Jointless bridges have been used for bridges in the United States for years since the beginning of the National Interstate Highway System in 1950s. Through the intervening years, more and more states have utilized Jointless bridge construction in varying degrees establishing national standards and uniform design policy regarding bridge lengths, skews, details or design procedures. Many states since then have moved toward continuous bridges with jointless integral abutments and piers, as standard design and construction practice.

Jointless bridge superstructures are constructed to work integrally with the abutments. Movements due to creep, shrinkage and temperature changes are accommodated by using flexible beatings or foundation and through incorporating relief joints at the ends of the approach slabs. In addition to reduced maintenance costs, other advantages of jointless bridges include improved structural integrity, reliability and redundancy, improved longterm serviceability, improved riding surface, reduced initial cost, and improved aesthetics. In recent times, jointless bridges have been built in seismically sensitive areas.

This paper will attempt to capture the state-of-practice in the United States, but will lean toward practices favored by the Washington State Department of Transportation (WSDOT) with its long history of continuous bridges in seismic regions. The design and construction practices, seismic design and detailing of jointless bridges have been addressed in this paper.

Key words: Bridge, Continuous, Jointless, Seismic, Concrete, Precast

INTRODUCTION

Jointless bridges are defined as bridges with no expansion joints between the superstructure and the supporting abutments. Because of several problems resulting from the traditional practice, the jointless bridge has been widely adopted.

Precast, prestressed superstructures have an important advantage over both steel and cast-in-place concrete superstructures for jointless bridges. The advantage is that precast, prestressed superstructures experience considerably less thermal movement than steel superstructures, and less long-term movements than cast-in place concrete superstructures. This is because the

manufacturing process for precast members is such that much of the long term shrinkage will have occurred prior to erection and establishment of continuity in the superstructure. Moreover, the amount of creep that will occur over time decreases with increasing age of concrete at time of erection.

Concrete superstructures are less sensitive to temperature changes due to the lag between the air temperature and the interior temperature of a concrete member with its relatively large mass. This phenomenon is reflected in AASHTO LRFD Bridge Design Specifications (AASHTO BDS), which provides lower design temperature variations for concrete superstructures than for steel. In a moderate climate, a concrete superstructure will expand and contract a total of approximately 12 mm per 30 m of bridge length with seasonal temperature variation. However, a steel superstructure will typically expand and contract approximately 25 mm per 30 m of length.

Bridge piers and abutments restrain thermal movements and induce tensile or compressive forces in the superstructure. With properly proportioned piers and abutments these restraint forces are routinely and safely ignored in the design of the superstructure.

Thermal movements of a cast-in-place concrete superstructure are similar to those of a precast, prestressed concrete superstructure. However, creep and shrinkage movements are considerably greater for cast-in-place than for precast superstructures. For these reasons, shrinkage and creep movements of precast, prestressed concrete superstructures are frequently ignored for structures of moderate length. However for longer spans the differential shrinkage between the cast-in-place slab and the precast girder in addition to creep and thermal effects should be considered.

Even though thermal movements in precast, prestressed members are minimal, restraint forces in the superstructure will be present. Flexible jointless abutments and semi-rigid or flexible piers are used to minimize the restraint forces in jointless bridges.

JOINTLESS JOISTLESS BRIDGES

Jointless bridges consist of superstructures, abutments, intermediate piers, and foundations. The design of jointless bridges is generally similar to that of conventional bridge design. Special analysis and design considerations required for jointless bridges are primarily associated with the need to accommodate volumetric changes in the structure, such as thermal movements.

Jointless bridges accommodate superstructure movements without conventional expansion joints. The superstructure is rigidly or semi-rigidly connected to the abutments. Approach slabs, connected to the abutment and/or deck slab with reinforcement, move with the superstructure. Generally, at its junction with the approach pavement, the approach slab is supported by a sleeper slab or grade beam. The superstructure movement here is accommodated using flexible pavement joints.

Jointless construction is well-suited to both single- and multiple-span bridges. For single-span bridges, stability is provided by passive pressure behind the backwall and for multiple-span bridges, intermediate piers contribute to the bridge's stability. Jointless bridges could be founded on piles or shafts or spread footings on soil if the soil is well compacted and the possibility of settlement of the foundation is considered in the design as shown in Figure 1.

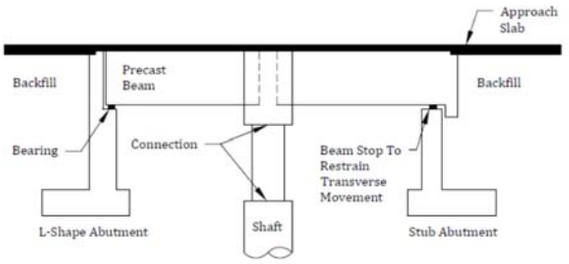


Figure 1. Continuous Jointless Bridge

BENEFITS OF JOINTLESS BRIDGES

Jointless bridges provide substantial reserve capacity to resist potentially damaging overloads by distributing loads along the continuous and full-depth diaphragm at bridge ends. The close tolerances required when utilizing expansion bearings and bridge seats need to conform to girder flange slope and camber corrections, since the girder loads are ultimately carried by the concrete comprising the end diaphragm.

For normal expansion bearing conditions, the ratio of the end-span to the adjacent interior- span length must be held to approximately 0.6, unless uplift conditions are to be accommodated. If uplift can occur, expensive hold-down devices must be added to expansion bearings. Utilizing jointless abutments allows for much shorter end spans, if desired, since the abutment acts as a counterweight and the uplift capacity of the piling maybe used.

Continuity in bridge superstructure provides added redundancy and capacity for all types of catastrophic events. In designing for seismic events, considerable material reductions can be achieved through the use of continuity by negating the need for enlarged seat widths and restrainers. Further, the use of jointless abutments eliminates loss of girder support; the most common cause of damage to bridges in seismic events. Joints introduce a potential collapse mechanism into the overall bridge structure. Jointless abutments have consistently performed well in actual seismic events and have significantly reduced or avoided problems of backwall and bearing damage that are associated with seat-type jointed abutments. The dampening arising from soil-abutment interaction has been proven to significantly reduce the lateral loads taken by intermediate substructure columns and footings. The following limitations may be considered in use of jointless bridges:

1. Limitations on length are concerned with passive pressure effects, stresses in the piles, and the movement capacity of the joint between the approach slab and the approach pavement. Many state departments of transportation limit lengths to 100 m for steel superstructures and 200 m for prestressed concrete superstructures. A few states, like Washington, have successfully used longer lengths.
2. Skew angles have generally been below 45 deg. However some states have used this method of construction extensively and effectively for curved bridges as well as bridges with skew angles up to 75 deg.
3. Jointless bridges require end diaphragms to be supported on flexible foundation types and bearings

DESIGN REQUIREMENT FOR JOINTLESS BRIDGES IN SEISMIC REGIONS

The AASHTO Guide Specifications for LRFD Bridge Seismic Design (LRFD SGS) is a displacement-based requiring bridge to be design with adequate displacement capacity to accommodate earthquake demands. The displacement capacity of bridges is checked using a displacement-based procedure, especially for those bridges located in regions of high seismic risk. The force-based methodology of the LRFD Specifications has also been used in some states with lower seismic demand.

The overall objective of the performance criteria is life safety during a 1,000-year seismic event. Bridges have a low probability of collapse but may suffer significant damage and significant disruption to service. Partial or complete replacement may be required." In a major event, offsets, cracking, reinforcement yielding, and major spalling of concrete are expected. While the 1,000-year return period is judged as applicable to most bridges, higher levels of performance may be required by the bridge owner, as in the case of "critical" or "essential" bridges that provide life safety transportation, bridges that are essential to the economy, or bridges required for local emergency plans. Site- or project-specific design criteria are generally developed for such projects.

The LRFD SGS does not explicitly address the jointless precast, pretensioned or post-tensioned elements. The precast beams made continuous for live loads must have beam–to–beam or beam–to–cap connections that can be expected to remain undamaged during the 1,000-year seismic event. Opening and closing of the bottom flange-to-flange or flange-to-cap joint connection is not permitted.

In the force-based analysis method, a linear elastic multi-modal response spectrum analysis is performed and the force effects in various bridge or structure components are determined. Equivalent static analysis of lateral loads based on a percentage of the dead load is also permitted by some agencies. The capacities of the components are evaluated and the component demand/capacity (D/C) ratios are then calculated. A particular component is said to have adequate capacity if its D/C ratio is less than the permissible force reduction factor, R, for that component.

Pushover analysis addresses typical sources of material nonlinearity as well as geometric nonlinearity. Material nonlinearity includes soil, concrete, soil-structure interaction, and yielding of the reinforcement. Geometric nonlinearity refers to the P-Δ effect. The bridge frame is pushed laterally along both its longitudinal and transverse directions until the target displacement is obtained.

The analysis is incrementally linearly elastic and captures the overall nonlinear behavior of the elements, including soil effects, by pushing the frame laterally to initiate plastic action. Each increment pushes the frame until a plastic hinge forms, and redefines the structural system after each hinge forms until the potential collapse mechanism is achieved.

ABUTMENT TYPES FO R JOINTLESS BRIDGES

The beginning or ending substructure element of a bridge is commonly referred to as an abutment or end bent. There are numerous variations that are used in further describing these units, such as bench-type, spill-through, stub, deep, etc. For consistency within this report, these units will be collectively referred to as abutments, with only minimal added description of their variation in type.

In jointless bridges, the ends of the girders are fixed to the abutments and expansion joints are eliminated at these supports. With the expansion joints eliminated, forces are induced in the substructure due to resistance to thermal movement and to creep and shrinkage that have to be considered in the design of jointless abutments.

While jointless abutments have been used successfully for 50 years, their implementation has not been an exact science, but rather a matter of intuition, experimentation and observation. Inspection of many bridges with failed expansion bearings has revealed that anticipated catastrophic damage has not always occurred.

The most common technique used in foundation design is the p-y method. Using this procedure, pile response is obtained by an interactive solution of differential equations using finite-difference techniques. The soil response is described by a family of non-linear curves (p-y curves) that compute soil resistance p as a function of pile deflection y.

APPROACH SLABS AND BACKFILL

Due to the difficulties in obtaining proper embankment and backfill compaction around abutments, approach slabs are recommended; especially for new construction. Approach slabs offer many benefits other than acting as a bridge between the abutment and more densely compacted embankments. Approach slabs provide a transition from the pavement to the bridge if embankment settlement occurs. Such transitions provide a smooth ride while reducing impact loads to the bridge. Approach slabs also provide greater load distribution at bridge ends, which aids in reducing damage to the abutments; especially from overweight vehicles. Finally, properly detailed approach slabs help control roadway drainage, thus preventing erosion of the abutment backfill or freeze/thaw damage resulting from saturated backfill.

The approach slab must be anchored into the abutment backwall so that it moves in concert with the bridge. Otherwise, cyclic expansions will force the slab to move with the bridge without a mechanism to pull it back when the bridge contracts. As debris fills the resulting opening, repeated cycles will ratchet the slab off its support. The anchorage used to fasten the approach slab should be detailed to act as hinge so that the slab can rotate downward without distress as the embankment settles.

Where the anticipated total movement at an abutment exceeds 12 mm and the approach roadway is asphalt, an expansion joint at the pavement should be considered. The reason for the latter is that larger movements can damage asphalt adjacent to the end of the approach pavement in the expansion cycle. During the contraction phase, a significant gap is created through which water can infiltrate the subgrade. If regular maintenance can be arranged to fill this gap with a suitable joint sealer in cold weather, no joint will be needed.

If expansion joints are provided, the joints should only be located at the roadway end of the approach slab. It is a certainty that the joint system will fail at some future time. If the joint is located between the abutment backwall and the approach pavement, then the slab jacking process mentioned above will occur.

Approach slabs have been found to be one of the most critical components of a jointless bridge. The approach slabs serve two primary purposes:

1. Approach slabs reduce the compaction of the backfill material behind the backwall due to traffic. Control of excessive passive soil resistance to thermal expansion is also achieved.
2. The thermal movements of the system are transferred from the end of the bridge to the point where the approach slab joins the roadway pavement. A flexible pavement joint is provided at this point. In addition, some agencies use plastic sheets or expanded polystyrene boards below the approach slab to provide a positive separation from the subgrade to enhance movement.

SEISMIC DESIGN OF INTEGRAL ABUTMENTS

The participation of abutment walls in providing resistance to seismically induced inertial loads may be considered in the seismic design of bridges either to reduce column sizes or reduce the ductility demand on the columns. Damage to backwall and wingwalls during earthquakes may be considered acceptable when considering no

collapse criteria, provided that unseating or other damage to the superstructure does not occur. The capacity of the abutments to resist the bridge inertial loads shall be compatible with the soil resistance that can be reliably mobilized, the structural design of the abutment wall, and whether the wall is permitted to be damaged by the design earthquake. The lateral load capacity of walls shall be evaluated on the basis of a rational passive earth-pressure theory.

Under earthquake loading, the earth pressure action on abutment walls changes from a static condition to one of two possible conditions:

- The dynamic active pressure condition as the wall moves away from the backfill, or
- The passive pressure condition as the inertial load of the bridge pushes the wall into the backfill.

The governing earth pressure condition depends on the magnitude of seismically induced movement of the abutment walls, the bridge superstructure, and the bridge abutment configuration. The semi integral abutment and corresponding loading diagram is shown in Figure 2.

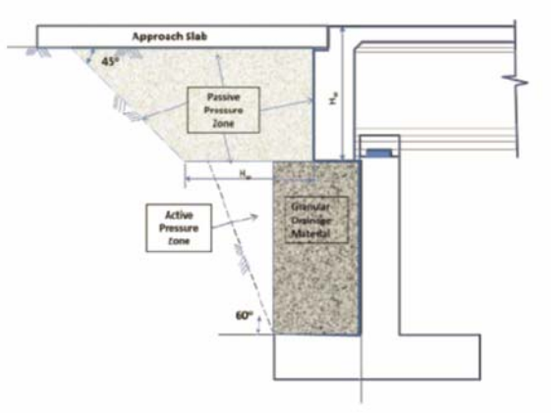

Figure 2. Semi Integral Abutment and Corresponding Loading Diagram

Abutment resistance shall be limited to 70% of the value obtained using the procedure given in the AASHTO SGS. Abutment stiffness, K_{eff}, and passive capacity, P_p, should be characterized by a bilinear or other higher order nonlinear relationship. When the motion of the back wall is primarily translation, passive pressures may be assumed uniformly distributed over the height.

Jointless short span bridges could also be supported by a geosynthetic wall and SE wall. These bridges shall conform to the following requirements:

1. Walls shall be 10 m or less in total height, which includes the retained soil height up to the bottom of the embedded spread footing.
2. For structural earth walls, the front edge of the bridge footing shall be placed 1.2 m. minimum from the back face of the fascia panel. For geosynthetic retaining walls with a wrapped face, the front edge of the bridge footing shall be placed 610 mm minimum from the back face of the fascia panel.
3. The abutment footing shall be covered by at least 150 mm of soil for frost protection.
4. The superstructure of continuous span bridges shall be designed for differential settlement between piers.

ABUTMENT CONNECTION FOR PRECAST JOINTLESS BRIDGES

The typical abutment in regions of moderate and high seismic hazard is a cast-in-place concrete pier wall supported on spread footings, piles, or shaft foundations. Precast beams are often supported on elastomeric bearing pads at end piers. Semi-jointless end diaphragms may be used for shorter bridges. The bearing system is designed for the service load condition but may not be adequate to resist seismic loading. The bearings are designed to be accessible so that the superstructure can be lifted and the bearings replaced after a major seismic event. Approach slabs rest on a notch provided at the superstructure end, thereby providing a ramp up

to and on to the bridge, should soil behind the abutment settle during a seismic event.

This type of end diaphragm eliminates the need for expansion joints at end piers. The gap between the end pier wall and the end diaphragm is designed to be greater than the longitudinal seismic movement requirement for the extreme event limit state, and thermal expansions at the service limit state for bridge lengths less than 150 m.

The minimum displacement requirements at the expansion bearing should accommodate the greater of the maximum displacement calculated from a displacement analysis or a percentage of the empirical seat width, N, specified in Equation 1.

$$N = (8 + 0.02L + 0.08H)(1 + 0.000125S2) \quad (1)$$

where

N = minimum support length

L = bridge length to the adjacent expansion joint, or to the end of the bridge

H = average height of abutment wall supporting the superstructure

S = skew angle of the support measured normal to span, degrees

For SDC D, the beam bearing support length, N, must accommodate the relative longitudinal earthquake displacement demand at the supports or at a hinge within a span between two frames. That length is determined as:

$$N = (4+1.65\Delta_{eq})(1+0.00025S2) \geq 610 \text{ mm} \quad (2)$$

The hinge seat length in "well-balanced frames" (adjacent frames for which the ratio of the natural periods is equal to or greater than 0.7) to be evaluated as follows:

$$N = \Delta_{p/s} + \Delta_{cr+sh} + \Delta temp + \Delta_{eq} + 100 \text{ mm} \quad (3)$$

Where:

Δ_{eq} = relative earthquake loading longitudinal displacement demand

$\Delta_{p/s}$ = displacement due to prestressing

Δ_{cr+sh} = displacement due to creep and shrinkage

Δ_{temp} = displacement due to temperature effects

ABUTMENT LONGITUDINAL RESPONSE FOR SDCS

Abutments designed for bridges in SDC B or C are expected to resist earthquake loads with minimal damage. For seat-type abutments, minimal abutment movement could be expected under dynamic passive pressure conditions. However, bridge superstructure displacement demands may be 100 mm. or more and could potentially increase the soil mobilization.

For SDC D, passive pressure resistance in soils behind jointless abutment walls and backwalls for seat abutments will usually be mobilized because of the large longitudinal superstructure displacements associated with the inertial loads. Two alternatives may be considered:

- Case 1: Earthquake-Resisting System (ERS) without Abutment Contribution. The bridge ERS shall be designed to resist all seismic loads without any contribution from abutments. Abutments may contribute to limiting displacement, providing additional capacity and better performance that is not directly accounted for in the analytical model.
- Case 2: Earthquake-Resisting System (ERS) with Abutment Contribution. In this case, the

bridge shall be designed with the abutments as a key element of the ERS.

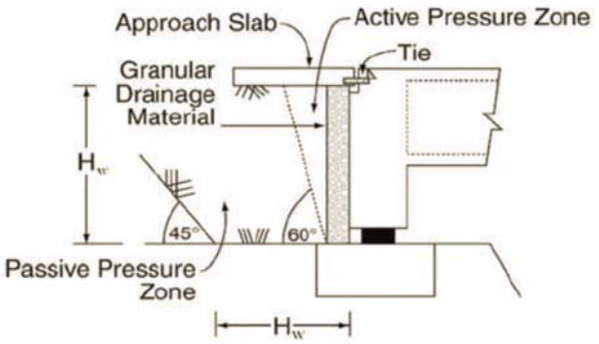

Figure 3. Abutment Stiffness and Passive Pressure

CALCULATION OF BEST ESTIMATE PASSIVE PRESSURE

If the strength characteristics of compacted or natural soils in the "passive pressure zone" are known, then the passive force for a given height, Hw, may be computed using accepted analysis procedures. These procedures should account for the interface friction between the wall and the soil. Therefore, the properties of backfill that is only placed adjacent to the wall in the active pressure zone may not be appropriate as a weaker failure surface can develop in the embankment.

Abutment stiffness, Keff and passive capacity, Pp should be characterized by a bilinear or other higher order nonlinear relationship as shown in Figure 4.

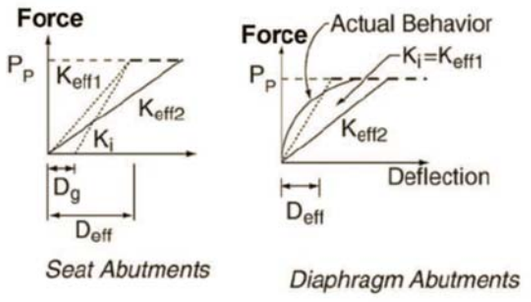

Figure 4. Characterization of Abutment Capacity and Stiffness

An equivalent linear secant stiffness, K_{eff} is required for analyses. For jointless- or diaphragm-type abutments, an initial secant stiffness may be determined as follows:

$$K_{eff1} = \frac{P_p}{(F_w H_w)} \quad (1)$$

If computed abutment forces exceed the soil capacity, the stiffness should be softened iteratively (K_{eff1} to K_{eff2}) until abutment displacements are consistent (within 30 percent) with the assumed stiffness. For seat-type abutments, the expansion gap should be included in the initial estimate of the secant stiffness.

$$K_{eff1} = \frac{P_p}{(F_w H_w + D_g)} \quad (2)$$

where:

P_p = passive lateral earth pressure capacity

H_w = height of backwall

F_w = factor between 0.01 to 0.05 for soils ranging from dense sand to compacted clays

D_g = width of gap between backwall and superstructure

ABSTRACT: In the background of requirements to weight reduction and cost saving, the application of high strength steels in steel bridges has been investigated. However, SBHS700 of 780MPa class steels must particularly grasp with respects to fatigue strength of welded joints. In this study, in order to clarify effects of the fatigue strength improvement by ICR (Impact crack retrofit closure) treatment for SBHS700, fatigue tests continuously carried out using small fatigue specimens of out of plane gusset welded joints, which were removed from a girder specimen of a previous study by gas fusion cutting. Before fatigue tests, compressive residual stress is confirmed with the x-ray diffraction method. The test results indicate that the fatigue strength improvement effects on welded joints treated by ICR treatment was at least 3 classes larger in case of using SBHS700. However, the fatigue strength of one specimen is lower than that of another specimen. Therefore, this paper also presents the result evaluated by using the control method of fatigue strength improvement based on the shape of the deformation area after ICR and the crack initiation can be identified based on the observation for a fractured surface using Scanning Electron Microscope (SEM).

1 INTRODUCTION

The application of high strength steels for steel bridges is one of the most effective approaches on weight reduction and cost saving of production and transport [Gunther. 2005, Konishi et al. 2007 & Miki et al. 2013]. Especially, steels for bridge high performance structures (SBHS) developed newly in Japan have been focused on the application because there is a large number of popularity due to beneficial qualities such as its higher strength, good weldability, and significantly improved fracture toughness. However, the fatigue strength of welded joints dose not generally depend on the tensile strength [Anami et al. 2000]. Therefore, in order to apply high strength steels to steel bridges efficiently, the fatigue strength of welded joints using high strength steels should be improved.

From the background, recent studies [Hanji et al. 2017 & Mori et al. 2010] have showed that the fatigue strength improvement effect such as grinding and peening treatment at the weld toe tends to depend on the steel strength. Therefore, it is necessary to grasp fatigue strength improvement effects on welded joints using SBHS especially for SBHS700 that has over 700 MPa yield strength and higher fatigue strength effect is expected.

In the previous study [Hanji et al. 2014], in order to clarify effects of fatigue strength improvement methods, the fatigue test of a girder specimen using SBHS700 was carried out. Various fatigue strength improvement methods, which can improve the weld toe shape and introduce compressive residual stress, were used on out-of-plane gusset welded joints on the girder specimen and the fatigue test result show fatigue strength improvement of the welded joints. However, the previous study does not quantitatively show the fatigue strength improvement because these improved out-of-plane gusset welded joints have not failed.

In this study, following the previous study [Hanji et al. 2014], in order to clarify the effects, fatigue tests are continuously carried out using small fatigue specimens of out-of-plane gusset welded joints, which were removed from the girder specimen by gas fusion cutting. Before fatigue tests, residual stress in the vicinity of the weld toe was measured by the x-ray diffraction method and compared with previous studies. The target results of this study are ICR (Impact crack retrofit closure) treatment which is one of the peening techniques. This technique has been originally developed for the fatigue life extension by closing the fatigue crack opening [Ishikawa et al. 2010 & Yamada et al. 2015]. The ICR treatment of this study was performed to the base metal besides the weld toe to introduce compressive residual stress, which is proposed by previous studies [Nakano et al. 2015 & Nakanishi et al. 2015]. They showed that the fatigue strength improvement effect could be simply controlled by measuring the deformation area of ICR treatment and the distance between the weld toe and

the ICR treatment edge. Therefore, these deformation area and distance were measured and fatigue test results were evaluated judging from these factors. In this study, as additional investigation, the crack initiation was identified for the fractured surface with Scanning Electron Microscope (SEM).

2 FATIGUE TEST SPECIMEN

2.1 *Girder specimen of previous study*

Figure 1 shows the SBHS700 I girder specimen. The I girder was 6400 mm long and had a web that was 600 mm wide by 12 mm thick, and flanges that were 300 mm wide by 12 mm thick. A set of six 160 mm*70 mm*12 mm plates were welded 80 mm from the top and the bottom of the web, evenly spaced at 360 mm apart on both sides of the webs as well. According to the previous study, preheating of 50 ℃ was applied to the base metal, and the YM-80C (JIS Z 3312) electrode was used in a CO_2 type of welding. A full penetration welding process was carried out. The weld toe profiles were used by three types of fatigue strength improvement methods, which are BG (Burr Grinding), UIT (Ultrasonic Impact Treatment) and ICR. In the girder specimen, the nominal stress

was constant of 100 N/mm^2 on each gusset and the stress ratio was 0.1. The fatigue test was finished at approximately 1.5 million cycles because both of as-welded gussets failed. Table 1-2 show the mechanical properties and the chemical compositions of SBHS700, respectively.

2.2 *Small fatigue test specimen*

Figure 2 shows condition of gas fusion cutting to the girder specimen. In order to remove out of plane gusset welded joints from the original I girder specimen of SBHS700, gas fusion cutting was utilized. After removing the welded joints from the girder specimen, small fatigue specimens were formed with the wire electric discharge machining device because the gas fusion left the edges of the specimen uneven. Figure 3 shows the geometry and the dimension of small fatigue specimen. In this study, two ICR specimens were named ICR-1, ICR-2, respectively. Each weld toe was named NE, NW, SE, SW.

3 MEASUREMENT RESIDUAL STRESS

3.1 *Measurement condition*

Before fatigue tests, the residual stress was measured in order to confirm how much compressive residual stress was left in the vicinity of the weld toe because there was a fear that it was released in gas fusion cutting to the girder specimen and during forming to small specimens. Figure 4 shows device of measurement residual stress. This is Portable X-ray Residual Stress Analyzer called u-X360s of Pulstec Industrial Co., Ltd. The measurement method was cos α using the Kα radiation of chromium and the collimator size was Φ2 mm. Figure 5 shows the measurement point and direction of residual stress. Residual stress was measured 2 mm away from the treatment edge directly in the center of gusset, 38 mm from either side of the gusset. This was decided in order to compare with results of the previous study that Hanji et al. 2017 had already measured residual stresses of ICR treatment at the same point for out-of-plane gusset welded joints using SBHS700. The measurement was conducted along the longitudinal direction (y-axis) on all four sides of the gusset.

3.2 *Measurement result*

Figure 6 shows the results of measurement residual stress. In this figure, results of previous study and average of each result are also indicated. Compressive residual stresses of previous results are from -420 to -480 MPa. From results of ICR-1 and ICR-2, compressive residual stresses are entirely about from -240 MPa to -600 MPa, indicating that some are about as

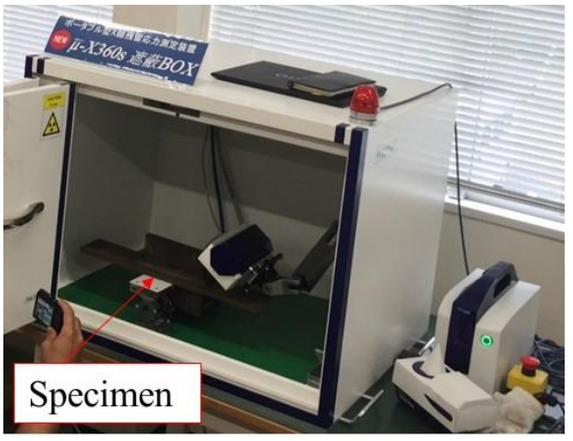

Figure 4. Device of measurement residual stress

Specimen	Weld toe condition	Nominal stress range (MPa)	Number of cycles	Note
Girder specimen in Hanji et al. 2014	As-weld	100	575000	
		100	1206000	
	ICR-1	100	>1520000	Fatigue test finished
	ICR-2	100	>1520000	
Small specimen in this study	ICR-1	106	>2000000	
		150	>2000000	
		180	>2000000	
		201	>2000000	
		250	>2000000	
		298	>740310	Crack from base metal Fatigue test finished
	ICR-2	102	>2000000	
		149	>2000000	
		178	1326750	Crack from weld toe

> means no failure

much as and others are at most 50 % lower than that of previous study. As a result, it can be seen that compressive residual stresses at 2 mm from treatment edge of ICR have reserved at least more than half of results in previous study although there might be influence of removing from the girder specimen or forming to small specimen.

4 FATIGUE TEST

4.1 *Test condition*

Figure 7 shows the fatigue test setup. The fatigue tests were performed at room temperature and moisture with a 200 kN material fatigue machine. The specimen experienced an axial tension test and a constant amplitude sine wave, 10 Hz frequency. The stress ratio was approximately 0. Strain gauges were placed on 2 mm and 30 mm from the treatment edge in the center of the gusset. The 2 mm location, which residual stress was measured, was intentionally used to monitor the transition of residual stress and the initiation of a fatigue crack. The 30 mm location was used for the calculation of nominal stress. These locations were repeated for all four sides of gusset specimen. Besides fatigue tests under constant stress range, the beach-mark test was also carried out. During fatigue tests, the stress range was reduced to one half periodically in order to leave beach marks on the fracture surface. First of all, nominal stress range was

100 MPa under the same condition as the fatigue test of the girder specimen. If the fatigue crack did not appear after 2 million cycles, the fatigue test was continued after increasing the nominal stress range.

4.2 *Fatigue test results*

Figure 8 shows the fatigue test results, which are the relationship between the nominal stress range and the number of cycles for ICR-1 and ICR-2. In this figure, the results of the girder specimen [Hanji et al. 2014] and the fatigue design curve proposed by Japanese Society of Steel Structure [JSSC. 2012] are also indicated. Arrow marks mean that there is no fatigue crack within 2 million cycles at each test condition. Detailed fatigue test results such as the nominal stress range and the number of cycles of each specimen are presented in Table 3.

At first, while ICR-1 and ICR-2 were continuously tested under the nominal stress range 100 MPa which was the same condition as the girder specimen, these specimens reached 2 million cycles and the fatigue cracks were not initiated. Therefore, the fatigue strength improvement effect is confirmed as well as the effect of previous study [Hanji et al. 2014].

At second, from the result of ICR-1, in spite of increasing nominal stress range such as 150, 180, 200, 250 MPa, the fatigue cracks were not initiated. The JSSC fatigue strength raises up to A class, and becomes higher than that of As-weld in previous results classifying E and F class. As a result, the fatigue strength of ICR-1 can be greatly improved from 4 to 5 classes, from which could illustrate larger fatigue strength improvement effect in comparison with results of the girder specimen treated by ICR. Eventually, the fatigue crack from base metal in the nominal stress range 300 MPa was initiated, and then the fatigue tests was finished. On the other hand, from the result of ICR-2, when the nominal stress range was increased to 180 MPa, the fatigue crack was initiated. Although the JSSC fatigue strength raises up to B class and improves from 3 to 4 classes, the fatigue strength is lower than that of ICR-1. As a result, it can be shown that fatigue strength improvement effect is larger than that shown in the previous girder specimen even after reforming to small specimens.

Therefore, it is confirmed that the fatigue strength improvement effects on welded joints treated by ICR is at least 3 classes larger in case of using SBHS700 as long as the fatigue test results in this study, whose effects correspond to those in recent studies [Hanji et al. 2017 & Mori et al. 2010].

5 EVALUATION FATIGUE TEST RESULT

Nakano et al. 2015 and Nakanishi et al. 2015 have investigated the fatigue strength of welded joints peened on base metal besides the weld toe using ICR, and they proposed standards of fatigue strength improvement which ensures at least 2 classes larger in case that SM490Y class steels are used and the nominal stress range is under 250 MPa. The standards are based on the configuration of deformation area of ICR treatment and the distance between weld toe and ICR treatment edge, which is the simple and practical quality control. Figure 9 shows shape of specimen around the weld toe treated by ICR. In order to get the deformation area of ICR, silicon like dental impression material is pressed on the treatment area and is cut to the interval of 1 mm thickness, and then the deformation area is measured on the image of these silicon. The distance between weld toe and treatment edge is measured on the image of the surface of specimen. In this paragraph, it is confirmed that whether specimens satisfied with the standards of fatigue strength improvement, or not.

5.1 *Deformation area of ICR*

Figure 10 shows the relationship between the residual stress and the deformation area. In this figure, results of previous study [Nakanishi et al. 2015] using SM490Y class steels are also indicated. The standards of deformation area is that Average depth × width is over 0.7 mm^2 or Maximum depth × width is over 1.0 mm^2. Width is the minimum value out of measurement results. The residual stress on 10 mm away from the weld toe is used in the previous study. Note that this study measured residual stress on 2 mm away from treatment edge but on approximately 10 mm away from weld toe, as shown in Figure 5. Detailed residual stress and shape of deformation area is displayed in Table 4.

From this figure, all results are content with the standard of deformation area regardless of using average or maximum depth. The residual stress of from -200 to -300 MPa is plotted below the line of previous results. On the other hand, the residual stress of from -450 to -600 MPa is plotted above the line, from which implicates that these residual stresses without influence of removing from the girder specimen or forming to small specimen depends on the steel strength because the results are greatly over the line of SM490Y class steels. Therefore, it can be said that the deformation area of ICR-1 and ICR-2 fulfills the standard of fatigue strength improvement although some residual stresses are lower than that of previous study. Incidentally, it can be understood that the residual stress of the weld toe SW where the fatigue crack initiated is plotted above the line of previous study.

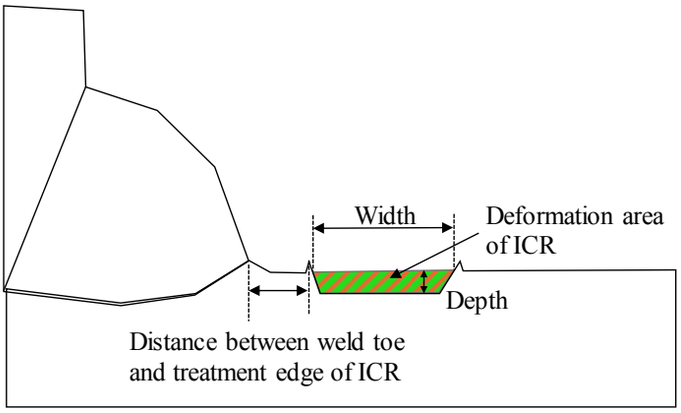

Figure 9. Shape of specimen around weld toe treated by ICR

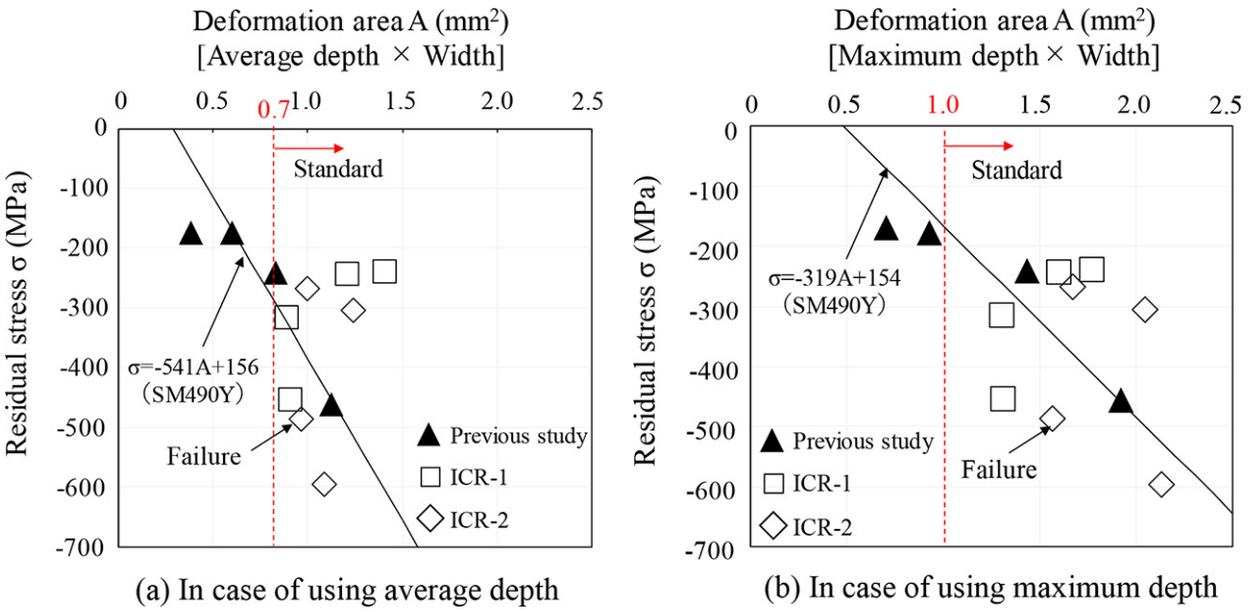

Figure 10. Relationship between residual stress and defamation area

Table 4. Residual stress and shape of treatment area

Specimen	Weld toe	Residual stress (MPa)	Minimum width (mm)	Average depth (mm)	Maximum depth (mm)	Deformation area =Average depth × Width (mm^2)	Deformation area =Maximum depth × Width (mm^2)
ICR-1	NE	-454	4.1	0.22	0.32	0.9 (>0.7)	1.3 (>1.0)
	NW	-243	4.7	0.24	0.32	1.1 (>0.7)	1.5 (>1.0)
	SE	-316	4.7	0.17	0.26	0.8 (>0.7)	1.2 (>1.0)
	SW	-239	3.6	0.27	0.34	1.0 (>0.7)	1.2 (>1.0)
ICR-2	NE	-268	3.8	0.26	0.39	1.0 (>0.7)	1.5 (>1.0)
	NW	-596	3.7	0.30	0.46	1.1 (>0.7)	1.7 (>1.0)
	SE	-305	4.5	0.28	0.38	1.2 (>0.7)	1.7 (>1.0)
	SW	-486	4.0	0.24	0.32	1.3 (>0.7)	1.3 (>1.0)

5.2 *Distance between weld toe and treatment edge*

Figure 11 shows the distance between the weld toe and treatment edge. The standard of the distance is under 2 mm. The distance of each weld toe for ICR-1 is under 2 mm. On the other hand, the distance of the weld toe SW where the fatigue crack initiated for ICR-2 is over 2 mm. Figure 12 shows the failure surface of weld toe SW. It was observed that the fatigue crack initiated at the weld toe. The specimens of this study have a space between the weld toe and the treatment edge, whose space may be formed because welding from both sides is contacted there.

In order to clarify the crack initiation, the observation of fractured surface was conducted using SEM. The result of the observation around crack initiation is indicated in Figure 13. There are some beach marks left on fractured surface, which the crack initiation can be predicted. Expanding the crack initiation area with SEM, it was identified due to finding the radial trail which the fatigue crack propagated. As a result, the crack initiation corresponded to the weld toe which is away the maximum distance 2.1 mm

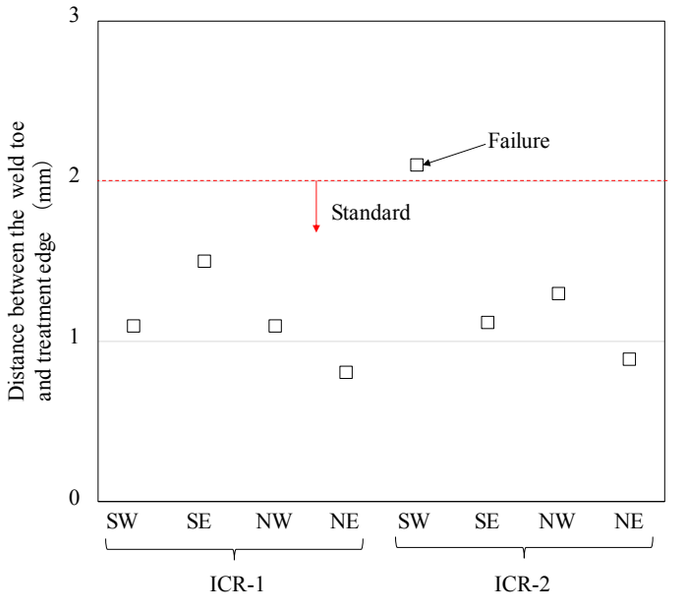

Figure 11. Distance between weld toe and treatment edge

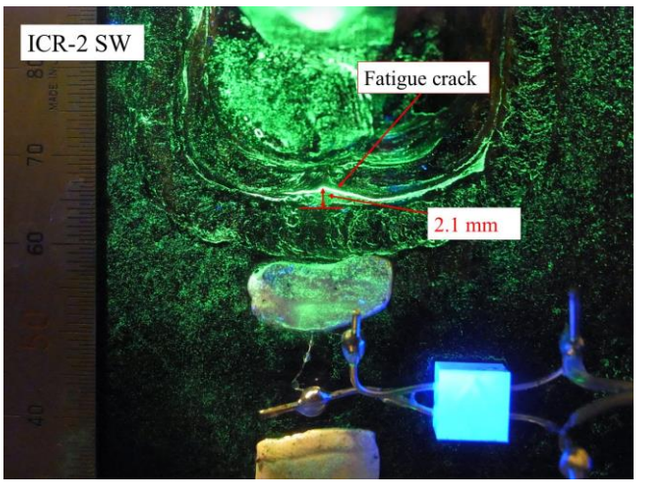

Figure 12. Failure surface of weld toe SW for ICR-2

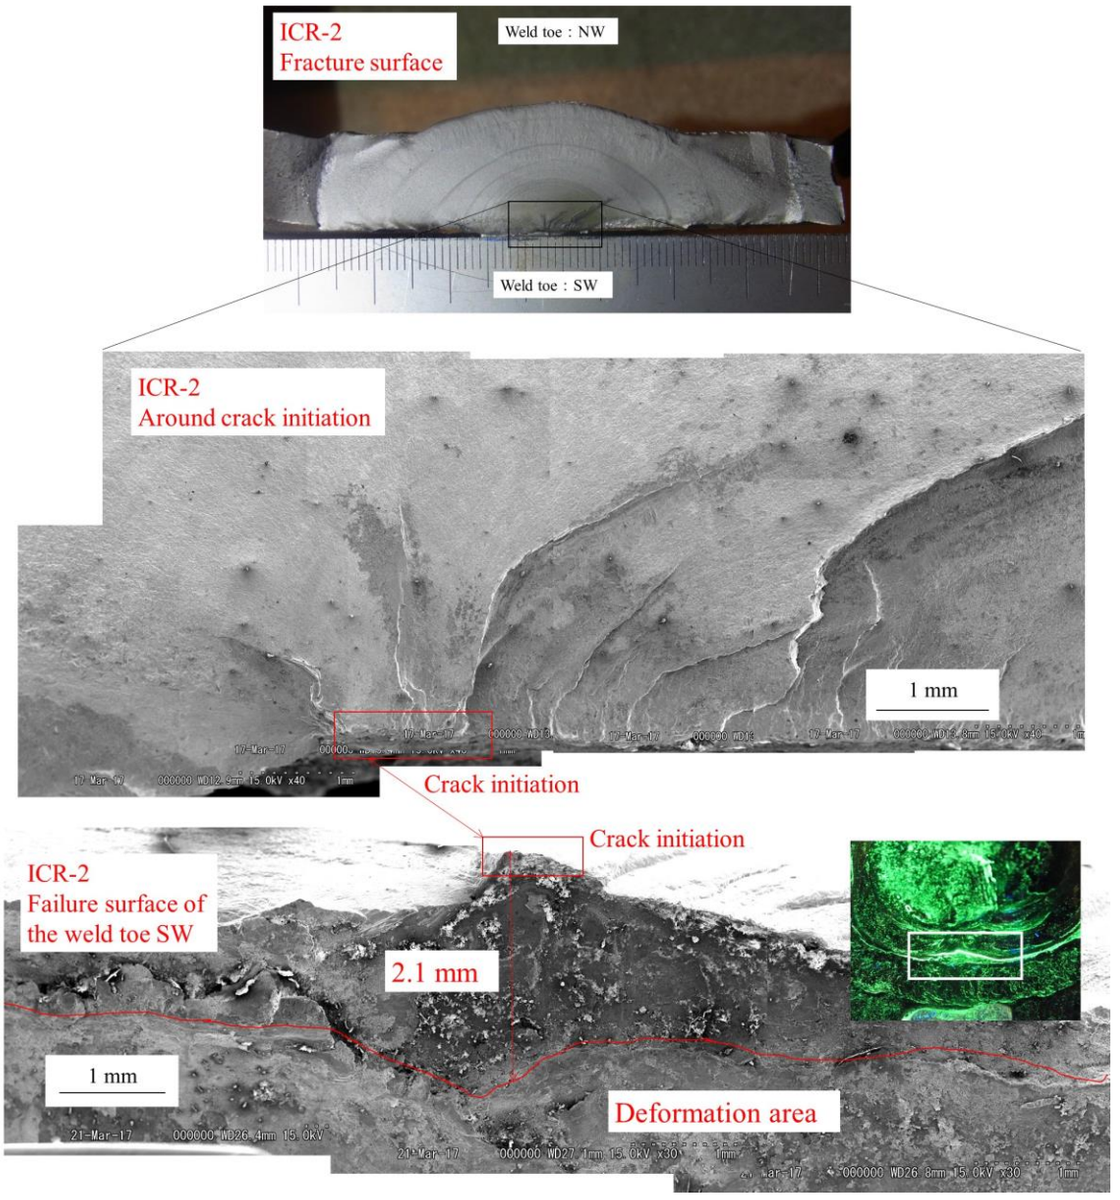

Figure 13. Result of observation for fractured surface around crack initiation

from the treatment edge. Therefore, it can be said that the fatigue strength of ICR-2 was lower than that of ICR-1 because the distance between the weld toe and the treatment edge is over 2 mm, which is the same result that the effect of ICR treatment decreases when the distance is over 2 mm in the previous study.

CONCULUSION

In order to clarify quantitatively the fatigue strength improvement effect on out-of-plane gussets welded joints, these gussets were removed from the previous girder specimen of SBHS700 and the continuous fatigue test was conducted. Before the fatigue test, compressive residual stress was measured and compared with the previous study [Hanji et al. 2017]. In addition, fatigue strength improvement effect was evaluated based on the measurement of the depression shape after ICR as shown in previous studies [Nakano et al. 2015 & Nakanishi et al. 2015]. The observation of crack initiation using SEM was conducted. The conclusions of this study are described as follows.

1 From the measurement of residual stress, compressive residual stress for small fatigue specimens was kept by over one half of that in a previous study even after removing from the girder specimen to gas fusion cutting and reforming to the small specimen.
2 From the fatigue test results, the fatigue strength improvement effect of welded joints treated by ICR is greatly higher. However, the fatigue strength of ICR-2 specimen was from 1 to 2 classes lower than that of ICR-1 specimen. This is the reason that the fatigue strength improvement effect decreases because the distance between weld toe and treatment edge is over 2 mm.
3 The observation of fractured surface using SEM verified that the crack initiation was the weld toe away the maximum distance 2.1 mm from the treatment edge.

ACKNOWLEDGEMEMT

The authors would like to appreciate Prof. Kazuo, Tateishi and Associate Prof. Takeshi, Hanji in Nagoya University and Prof. Anami, Kengo in Shibaura Institute of technology for providing the girder specimen of SBHS700 and Shuichi, Ono, Takayuki, Endo in Japan Construction Method and Machinery Research Institute for transporting the girder and Muneyuki, Uchida in PULSTEC for measuring residual stresses.

Three Bridges with the Same Name "Kömürhan Bridge"

N. Apaydin
General Directorate of Turkish State Highways, Ankara, Turkey
O. Yaldiz
General Directorate of Turkish State Highways, Ankara, Turkey

ABSTRACT: Kömürhan Bridge has a strategic position on the roads connecting the Eastern Anatolia Region with the Central Anatolia and Mediterranean regions in Turkey. As a result of the increasing traffic density between these regions, Kömürhan Bridge has gained more importance nowadays. Throughout the history, there has been more than one bridge in the same name, Kömürhan Bridge, connecting the same places, Malatya and Elazığ. In this paper, one can find the reasons behind the construction of new bridges and also detailed technical information about the them (especially third bridge) constructed at the same location.

1 INTRODUCTION

Kömürhan Cable-Stayed Bridge is planned to be constructed on Euphrates River which is a natural border separating Malatya - Elazığ cities and on 51th km of the existing Elazığ - Malatya State Road (see Figure 1). The geopolitical and strategic importance is great because it is the only point that connects Elazığ and Malatya and provides transition route for 16 cities in Eastern Anatolia Region. Detailed information about the bridges (especially the third bridge) called as Kömürhan Bridge constructed at the same location is given in the paper.

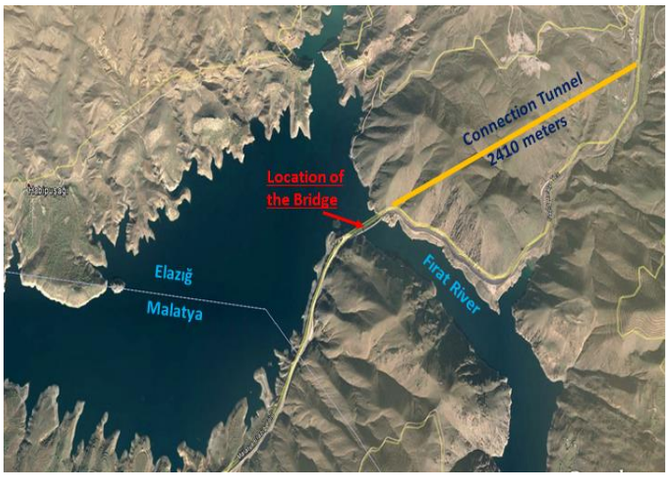

Figure 1: Location of the bridge.

2 HISTORICAL INFORMATION

The historical information and properties of the first two Kömürhan Bridges can be summarized as follows: Before the first Kömürhan Bridge was constructed (until 1930), transportation between Elazığ and Malatya cities was provided only by rafts and boats, and then by a timber bridge built during World War I. However, with the rise of the waters on Euphrates River, the timber bridge was destroyed. Then, the use of the raft and boats started again. For this reason, the need for a permanent bridge was inevitable. A suitable place for the construction was determined at about 12 km east of the destroyed timber bridge. During the design studies, it has been understood that if a concrete bridge were used, water would not be a serious problem while it would cause a considerable difficulty for a steel bridge. In case of using steel bridge, the length of the bridge would be much more compared to concrete one. In addition, due to the difficulties that often arise from the need for frequent painting of a large bridge, reinforced concrete bridge have been preferred although the price is slightly higher. The construction of the first reinforced concrete Kömürhan Bridge began in 1930 and finished in 1932. One of the major importance of the project is that the bridge won the title of the world's sixth largest reinforced concrete bridge as of the period when it was built. According to the design, arched bridge type was considered due to the steep

rocks on both sides of the region (see Figure 2). The bridge was built 33.35 m above the low water level of the river, and the topography made a great difficulty in the construction of the scaffolding. The most difficult part of construction of a long span reinforced concrete bridges is scaffolding. In order to cope with the difficulties created by the topography, a four-cable suspension system was established with a diameter of 32 mm stretched to the towers and the scaffolding of the main span was suspended to those cables. The geometric properties of the bridge are as follows: It consists of two spans in the form of an arch, with a main span length of 108 m, side span lengths of 28 m on both sides and a width of 6.40 m. Main arch is in the shape of hollow box. As for calculation, load carrying capacity calculations were made according to German reinforced concrete norms of 1925.

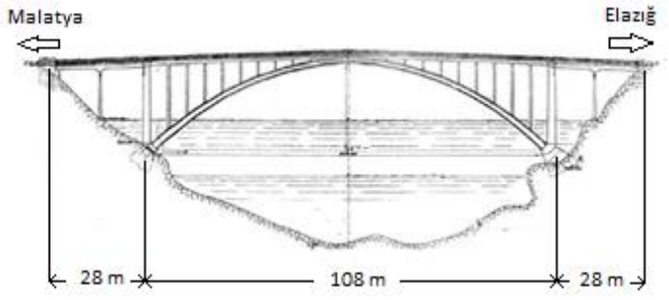

Figure 2: Longitudinal section of the first bridge.

The first bridge has provided transportation in the region for approximately 50 years. However, it was foreseen that this bridge would be under water after the construction of Karakaya Dam. Therefore, it was decided to build a new bridge next to the first one, designed by taking into consideration the dam elevation. The construction began in 1983 and finished in 1986. The major structural importance of this bridge is that was the first bridge constructed by using balanced cantilever method in Turkey. At first, for the new bridge, a project of a gerber-girder system was prepared with a total length of 287 m, a main span of 115 m and side spans of 86 m. However, considering the difficulty of scaffolding of the high piers in the river during the construction, the design was changed and a balanced cantilever method was applied to the project. In the new project, the total length of the bridge was kept same while the main span length was increased. The geometric properties of the second bridge are as follows: The bridge consists of a main span with 135 m length and two side spans with 76 m length each (see Figure 3). The total bridge length is 287 m and the width is 11.50 m. The piers, each 59.50 m in height, consist of variable cross sections with three segments. The cross section width of piers decreases linearly to 8.50 m at the top, with 14.40 m at the bottom. To protect the hydrostatic equilibrium, gaps were left on the walls of piers that allow water

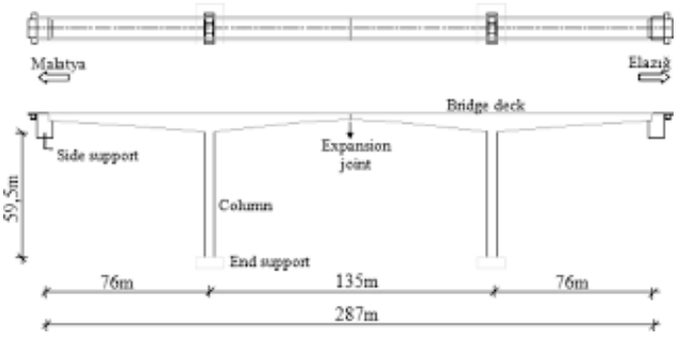

Figure 3: Plan view and longitudinal section of the second bridge.

pass. The deck is composed of 56 segments; all of the them are approximately 5 m in length. Height of the box girder is 9.35 m on the main columns, and it decreases parabolically to 3.5 m at the side supports and 3.0 m at the expansion joint. Design details are as follows: In order to connect deck cantilevers, an expansion joint is formed in the main span of the bridge. In this way, the edge of the cantilever at the main span is free, and the expansion caused by heat and traffic load is allowed. Besides, equivalent movement of the deck in the vertical direction is provided by establishing a connection between two ends for vertical loads. Further, transverse movement is avoided by side wedges.

3 THE NEED FOR THE THIRD BRIDGE

Currently, existing bridge is the only bridge that serves the coming and going, and it is a problematic bridge since it cannot carry traffic density no longer. In order to meet the density arising from the increasing tourism traffic in the region, and to provide advantages such as high geometric standard, comfortable transportation, traffic safety and time saving, it has been decided to build a new bridge. Seven alternative projects were presented to the institution (General Directorate of Highways). Cable stayed bridge alternative design, a single pylon on the Malatya side and a tunnel on the Elazığ side with approach viaducts was selected as suitable. The project was approved by the institution in 2012 and the construction tender was completed in 2013. The Connection Tunnel and Road Construction Work was started in 2014. With this project, a modern state road with a new bridge and tunnel will be built right next to second bridge, while the existing 1 x 1 lane low standard road (having

small curvature radius and too much curve) and second Kömürhan Bridge will be preserved in the region (see Figure 4).

Figure 4: A view of the second and third bridge.

One cannot see all three bridges together since the first bridge is under water currently. However, if there were no water, the view would be as shown in figure 5.

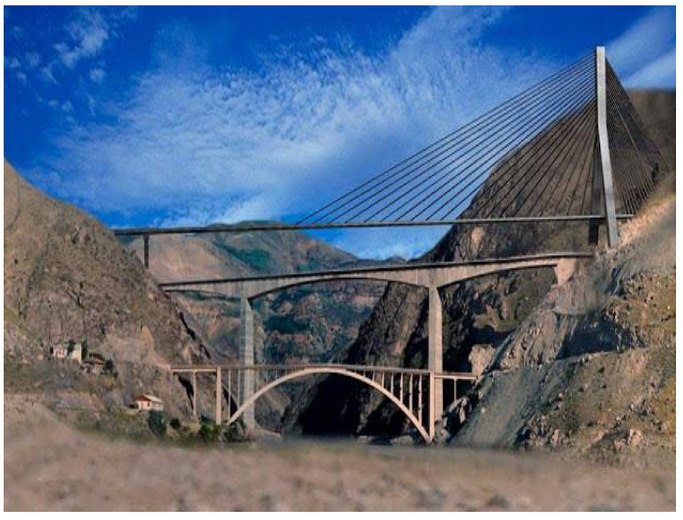

Figure 5: A view of all three bridges side-by-side.

For the construction of third bridge, since it would be very difficult and costly to place the pier in the dam lake, the dam lake had to be crossed with a bridge having a large span. The new Kömürhan Bridge in the project area; will be a kind of bridge called "Cable Stayed" in international literature. This kind is a modern bridge type used for passing large openings as it is on suspended bridges over the Bosphorus in Istanbul.

In addition to the construction of bridge, there is a tunnel construction work in the project area, which has a total length of 4800 m, 2 x 2 lane traffic passing in 2 tubes and each tube is 2400 m in length. Apart from these, the works included are as follows: three floors of total 1200 m^2 closed area construction of police station, earthwork, NATO pipeline displacement, intersection manufacturing, culvert and subway manufacturing, electrical-lighting works, mechanical cold mixture and hot mix asphalt production and guardrail production.

4 PROPERTIES OF THE THIRD BRIDGE

By analyzing the third bridge, the first thing one will notice would be the characteristic features. The bridge has a main span length of 380 m, side span length of 180 m, and total length of 660 m (see Figure 6).

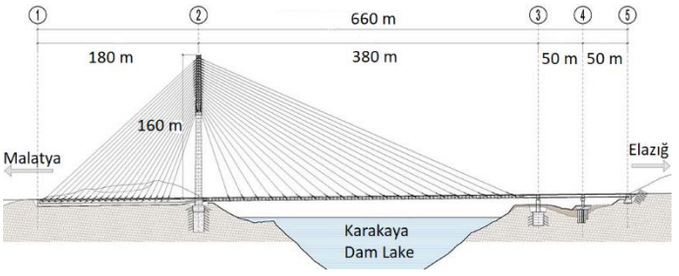

Figure 6: Longitudinal section of the third bridge.

The superstructure is 25 m in width and 3.5 m in height. The side spans are prestressed concrete box and the main span is steel orthotropic box girder (see Figure 7).

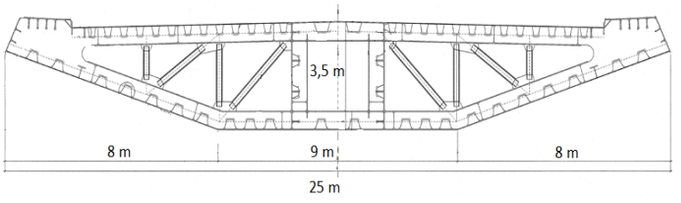

Figure 7: Typical cross section.

The main span consists of a starting segment of 34 m, 21 segment of 16 m and a key segment of 10 m in length. The main span is carried to the pylon with 21 cables. The cables are connected in single plane in the middle of the deck (see Figure 8). The rear cables are connected to the base block with a length of 180 m. The longest cable length is 390 m and the total cable length is 8536 m.

Figure 8: Connection of cables to the pylon.

The ground consists of gabbro and diabase type rock belonging to Kömürhan ophiolites. The pylon is located on two caissons 12 m in diameter and 22.5 m in depth (see Figure 9).

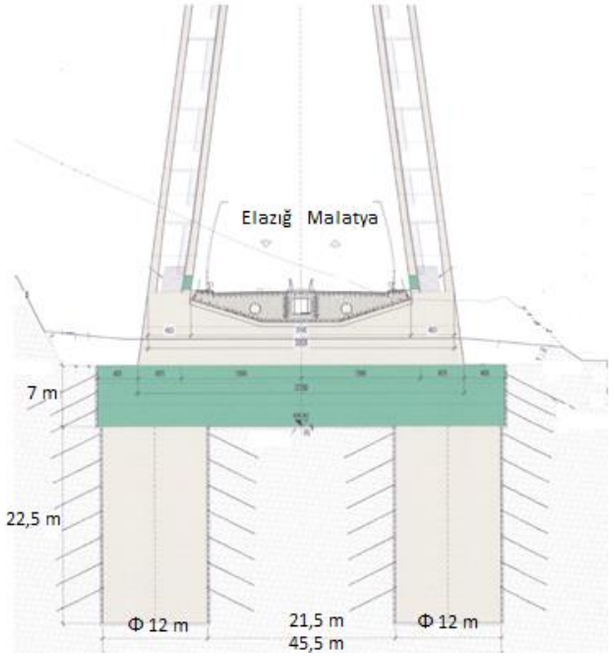

Figure 9: Cross section of caissons.

Figure 10: A view of caisson construction.

5 MATERIALS

The materials used in the construction of the bridge are as follows: C-50 type as concrete material in pylons, C-40 type in post-tensioned slab and C-30 type in other elements. The steel grade used for structural steel as steel material is S355 type and the reinforced concrete steel is S500 type. The cable grade is Gr 1600/1860 f15.7mm- Low Relaxation.

6 TECHNICAL DETAILS

When it comes to technical details, above all, there are two reasons for choosing a single pylon design. The first of these is that there is not enough distance to place the rear cables if another pylon is placed on Elazığ side. The second is that planned pylon location on Elazığ side would be on the backfill, which is the difficulty that the potential support problems will bring about in the dam reservoir.

7 DESIGN OF STRUCTURES

Some of the details about selection of structural system should be clarified. In cable design; a cable layout called "modified fan" was used. ". In this system, the cables are anchored intermittently as close to the top of the tower as possible. Thus, the carrying capacities of the cables can be used to the maximum extent

Moreover, in terms of superstructure design; the choice of the superstructure section greatly affects the entire behavior, construction method and cost of the bridge. The aerodynamic characteristics of the cross section are also important for bridge stability. The selected cross-section provided not only main span to get lighter which result in reduction of cable cross-sections but also it has eliminated the stability problems that can occur in the wind thanks to its high torsional stiffness. On the approach bridge, a cross section of a post-tensioned concrete box was used to cross the 50 m span.

In pylon design, the pylon shape should be aesthetic, sufficiently rigid in the longitudinal and transverse directions to be able to control the displacements in the main span and to provide earthquake safety. In this type of bridges, generally A type, H type and Reverse-Y type pylons are used. Reverse-Y type pylon was used on third Kömürhan Bridge. In this way, the ease of construction was ensured by installing the cables in the upright part of the pylon and also the rigidity against the effects of both earthquake and wind was provided in the transverse direction.

Regarding foundation design; the idealized ground profile in the project area consists of artificial backfill of limited thickness observed locally on the surface and gabbro and diabase type rock units belonging to Kömürhan ophiolites. Pylon and grid line

3 foundations were designed as caisson, 12 m in diameter, grid line 4 foundation was designed as pile,165 cm in diameter and grid line 5-end pier was designed as shallow foundation (see Figure 6: longitudinal section for grid line information).

In the matter of bearing design; the bridge deck is connected to the pylon as fixed end. The main span is designed not to allow shear transfer in grid line 3 and consequently the stability of the bridge is secured in earthquake and wind. The support of the bridge under vertical loads is provided by a pair of spherical bearings on each grid line.

The matters considered below should be noted about the design of the structure. The design of the bridge is based on nonlinear effects. The nonlinear behaviors of the cables under dynamic and moving loads were investigated and stability checks were carried out. In design, time-dependent creep and shrinkage effects are taken into account under the axial load and bending effect (creep effect is effective on reinforced concrete decks and pylons under high pressure).

8 CALCULATIONS

As for the calculations, the matters could be stated as follows: In typical segment calculation; a finite element model of the orthotropic deck between the cables was established and the stresses were checked under various loads. Besides, additional analyzes such as cable replacement and cable breakage have been made.

In deck transverse direction calculation; a finite element model of the orthotropic deck was established and transverse direction analyzes were performed.

When it comes to final calculation, the bridge geometry is adjusted by optimizing the cable forces when the bridge is completed. Stress checks were carried out on superstructure and cables.

9 ANALYSIS

In analysis of construction stages; each stage of the construction and the loads belonging to that stage were identified and analyzed. With this analysis, it is aimed that after the last construction phase, the bridge superstructure and pylon should be as the desired geometry. As a result, cable stresses at each stage are determined.

For earthquake analysis; it can be said that cable stayed bridges are generally less affected by earthquakes. The reason of this is that cable bridges are flexible structures. For this reason, they remain on the right side of the spectrum and they are exposed to lower accelerations during the dominant periods. A number of experiments and analyzes have been carried out in the design phase to optimize the safety of the bridge against earthquake. The bridge was designed not to be damaged at an earthquake level of 2% (recurring time of 2475 years) with a probability of exceeding in 50 years corresponding to General Directorate of Highways' required safety performance level. In addition, considering the possibility of earthquake during the construction of the bridge, the investigation was made according to the earthquake having the probability of exceeding 50% in 50 years (recurrence time of 75 years)

As for the wind analysis; the bridge cross section should be designed to reduce the wind effects aerodynamically. The aerodynamic features of the cross section of third Kömürhan Bridge were analyzed with advanced software. Hence, the critical wind speeds which are to be applied to the bridge and the bridge resonance have been determined. The three-dimensional model prepared for the bridge at 1/60 scale was subjected to the wind tunnel test. During these tests, the aerodynamic characteristics of the deck section and the wind safety of the bridge were investigated. The bridge is expected to stabilize even in the wind, which is at a speed of about 250 km/h.

10 STANDARDS

The main standards and resources used in design are as follows: AASHTO LRFD and Eurocode specifications were used for the design of reinforced concrete, prestressed concrete, steel and composite building elements. AASHTO Guide Specifications for LRFD Seismic Bridge Design was used in the earthquake design of the bridge.

11 CONCLUSION

Finally, expected project main quantities are given below in table 1.

PROJECT MAIN QUANTITIES			
Earth-works	Concrete works	Rein-forcement	Steel works
1.750.000 m³	180.000 m³	6.000 ton	6.650 ton
Cable (strands)	Post-Tensioned Steel Works	Plant Mix Sub-Base and Base	Bitu-minous Hot Mix Asphalt
920 ton	210 ton	120.000 ton	73.000 ton

Table 1: Project main quantities.

When the bridge is completed (in 2018), it will be the world's third largest "single-pylon, cable stayed bridge" with a main span length of 380 m (see Table 2).

Rank-ing	Bridge Name	Country	Year	Main Span Length (m)
1	Zhivopisny	Russia	2007	410
2	New Taipei	Taiwan	2010	400
3	Kömürhan	Turkey	-	380
4	Ada	Serbia	2012	376
5	Margaret Hunt Hill	USA	2012	365
6	Rama VIII	Thailand	2002	300

Table 2: Ranking of the largest single-pylon cable stayed bridges in the world.

It is one of the exemplary projects in Turkey for the construction sector in terms of its technical features and innovations by using large-scale domestic engineering services, domestic technology and domestic workforce. Since the construction is performed by using completely domestic resources, the cost will be at least three times cheaper than the equivalent bridges in the country. Moreover, it is a very important investment for the whole country because it is located on a unique point connecting Elazığ and Malatya as well as the east and west.

Assessment of fatigue tests to review detail categories of EC3

H. Bartsch & M. Feldmann
Institute of Steel Construction, Aachen, Germany

ABSTRACT: The present paper deals with the current status of research activities on the assessment of fatigue tests in order to review detail categories of EC3-1-9. Statistical methods which have been used for a detail classification are outlined shortly. The concept of a well-structured SQL supported data base is presented, which is intended to comprise all known fatigue test series relevant for a fatigue detail classification in the future. Subsequently, an exemplary fatigue evaluation of a longitudinal weld detail is presented. After the selection of expressive fatigue tests series, these have been evaluated for a detail classification by considering the prediction as well as the tolerance interval. Additionally, influences of failure criterion, component size, mean stress and boundary conditions are discussed. The results show, that the selected series partially exhibit distinctively higher fatigue resistances as currently incorporated in Eurocode regulations. Finally, first preliminary numerical simulations for future fatigue tests are presented.

1 INTRODUCTION

In many areas of our infrastructure, as for instance the construction of bridges, fatigue design of steel structures is a major issue. Compared to former national standards, the European standard referring to fatigue design of steel structures (Eurocode 3, 2005) however leads to over conservative and inefficient results. The basis of the fatigue detail categories dates back several decades. Additionally the existing fatigue test database is incomplete and the evaluation methods are outdated. Recent knowledge has mainly not been adopted.

For these reasons, current investigations aim to re-evaluate existing data collections in order to develop recommendations of improved fatigue detail categories for European standards. An elaborate data base structure has been established in order to assess the available fatigue test data in a sophisticated manner. The database enables as well search and selection functions as a user-driven evaluation of test data. A large amount of relevant parameters influencing the fatigue life has been obtained from available sources and incorporated into the database. The documented parameters comprise information on material, welding, environmental influences, loading as well as geometry of the respective details.

With the help of the re-evaluated data base, different possibilities of detail category evaluations have been investigated. In present research activities (Enhancement detail catalouge, 2016), all details of EC3-1-9 (Eurocode 3, 2005) are analyzed. However, for detailed investigations, this paper only focusses on welded built-up sections. Possible influences on the fatigue test results in terms of component characteristics and mean stress have also been considered.

Moreover, numerical investigations demonstrating the true stress distribution in typical connection details are presented. These simulations enable the comparison of commonly applied assumptions according to the nominal stress concept and the therefor conducted fatigue test. For this purpose, future plans contain additional component tests measuring bolt forces and strains in the area of the connection.

2 OUTLINE OF STATISTIC METHODS

In order to ensure a safe derivation of standard values, a series has to be evaluated by statical approaches. However, different methods of statistical analysis for the definition of fatigue resistances are known. By comparing the wording of EC3-1-9 (Eurocode 3, 2005) and the respective background document (Background Documentation Chapter 9, 1989), a contradiction can be noticed. The background document claims that a prediction interval (see section 2.2) has been used to statistically evaluate a fatigue test series. In contrast, according to (Eurocode 3, 2005), test results shall be analyzed by utilizing the tolerance interval (see section 2.3).

In general, the tolerance interval depicts the more conservative limit, allowing for uncertainties in estimates of population statistics. (Schneider & Maddox, 2003)
Among other important issues, the contradiction between EC-3-1-9 and its background document led to current research activities in which a re-evaluation of fatigue data is applied in order to review the current detail categories. The following sections give short outlines of the statistical approaches adopted in the presented investigations.

2.1 *Regression analysis*

In order to derive an S-N-curve out of a fatigue tests series, as a first step a regression analysis is conducted. The regression line establishes a linear correlation between the logarithm of stresses $log\,S$ and number of cycles $log\,N$, which fits bests to the test results. Equation 1 describes the linear regression function in fatigue context: (Schneider & Maddox, 2003)

$$log\,N = log\,A - m \cdot log\,S \tag{1}$$

The slope of the regression line m, can be calculated by the least-square method. However, EC3-1-9 (Eurocode 3, 2005) specifies the slope of S-N-curves for longitudinal stresses, as regarded in the present investigations, to the value three. If the slope is set, only the intercept of the $\log N$ axis $\log A$ has to be determined by the following equation (Kosfeld, et al., 2016):

$$\log A = \frac{1}{n} \cdot \sum_{i=1}^{n} \log N_i + m \cdot \frac{1}{n} \sum_{i=1}^{n} \log S_\mathrm{i} \tag{2}$$

where n = number of single test results. By determining $\log A$, the regression line depicting the characteristic S-N-curve is fully described.

2.2 *Prediction interval*

In the context of design objectives, it has to be ensured that a given proportion of data is located in between specific limits, which have to be determined statistically. Based on existing test results, the prediction interval (equation 3) is utilized to give a forecast on future test results (Schneider & Maddox, 2003):

$$\log\, N_{P\%}^{\pm} = (\log A + m \cdot \log S)$$

$$\pm\, t \cdot \hat{\sigma} \sqrt{1 + \frac{1}{n} + \frac{\left(\log S - \overline{\log S}\right)^2}{\sum_{i=1}^{n} \left(\log S_i - \overline{\log S}\right)^2}} \tag{3}$$

where $\overline{\log S}$ = mean of the n values of $\log S_i$; t = appropriate percentage point of Student's t distribution, with f degrees of freedom; $\hat{\sigma}^2$ = best estimate of the variance of the data about the regression line, which is equal to the sum of squared residuals divided by the number of degrees of freedom f; and f = n − 2 in the case where two coefficients have to be estimated from the data.

Concerning the investigations presented in section 4, one-sided prediction intervals with a confidence of 95% are applied.

2.3 *Tolerance interval*

The tolerance interval is also used to predict future test results on the basis of existing data. However, in comparison to the prediction interval, the tolerance interval makes a statement on a probability of surviving with a certain confidence level. This implies that the tolerance limit estimates a confidence limit on the prediction limit. The expression of the tolerance interval resembles Equation 3, only the value t is substituted by the statistic k, depicting the one-sided tolerance limit factor which can be taken out of tables. (Schneider & Maddox, 2003) During present investigations, one-sided tolerance limits have been calculated for a 75% confidence level of 95% probability of survival. (ISO 12107, 2012)

3 FATIGUE DATA SOURCES AND DATABASE

The established fatigue data base rests upon several fatigue data collections, which have been gathered during a former research activity (Sedlacek, G. et al., unpubl.). These data collections comprise 13 databases of different authors in USA, France, Germany, Japan, Australia and the Netherlands.

During present investigations, the original sources of all these data collections are purchased and analyzed again in a more detailed manner. A new innovative structured data base on SQL basis shall eventually contain about 250 sources comprising about 1100 fatigue test series, only by evaluating data of the former data collection. Prospectively, more recent and expressive fatigue test data will also be included into the data base. For research operations in the near and far future, the data base will be available online, enabling protected user-driven interfaces for queries, evaluations, modifications and maintenances of data.

As a first step in the data preparation, the sources of the former data collections are surveyed. After primary observations of several sources, a large variation of quality could be found. Most of the sources have been published in the 1960s and 1970s. The most recent fatigue investigations being part of the former data collection have been made in 2003.

The newly established innovative data base aims to incorporate any information relevant in case of fatigue issues, as mentioned in the following:

- General information: component, source, general remarks;
- Information on loading: kind of loading, frequency of testing, location of calculated stress range;

– Information on material: steel grades, yield strength, ultimate strength;
– Information on welds: shape, weld symbols acc. to (EN ISO 2553, 2013), number of passes, pretreatments, post treatments, sequence, characteristics of filler material, welding position acc. to (EN ISO 6947, 2011), process acc. to (EN ISO 4063, 2010);
– Information on environmental conditions: temperature, corrosive conditions, humidity;
– Detail specific properties: vary depending on analyzed detail (e.g. thickness of components, span width);
– Test results: stress range, stress ratio, number of cycles to rupture, failure criterion, failure region;

With the help of the structured data base, the therein incorporated information and the coding of appropriate scripts, evaluation of fatigue tests and influencing parameters can be realized easily.

The present paper demonstrates a preliminary evaluation of one exemplary detail appearing in many areas of our infrastructure, as for instance the construction of steel bridges. Table 1 contains an overview of all series and number of tests belonging to welded built-up sections, which are classified into fatigue details in table 8.2 of EC 3-1-9 (Eurocode 3, 2005). This table of the detail catalogue contains different types of longitudinal welds, which are classified into several fatigue details, as for instance automatic and manual fillet or but welds and intermittent welds. Table 1 comprises all purchased data of the existing fatigue data collections (Sedlacek, G. et al., unpubl.).

Table 1. Overview of series on welded built-up sections (table 8.2 (Eurocode 3, 2005)).

Detail	Description	Number of series	Number of tests
②	Automatic fillet welds	6	77
③	Automatic fillet or butt weld carried out from both sides but containing stop/start positions	28	275
⑤	Manual fillet or butt weld	12	70
⑧	Intermittent longitudinal fillet welds	7	38
⑨	Longitudinal butt weld, fillet weld or intermittent weld with a cope hole height not greater than 60 mm	7	36
⑩	Longitudinal butt weld, both sides ground flush parallel to load direction, 100% NDT	2	183
	No grinding and no start/stop	1	100
	With start/stop positions	-	-
Sum		63	779

4 FATIGUE EVALUATION

4.1 *Outsourcing of tests*

By examining the purchased fatigue series in a detailed manner, several crucial aspects have been noticed, which will be outlined in the following section.

Some sources depict secondary sources and contain few detailed information on geometry or material of the tested specimens, making it difficult to review the original data in a detailed way. Oftentimes, important information as for instance weld details or failure criterion are not even noted in the primarily source. Moreover, the documented failure criteria vary to a large extend. Occurring failure criteria are fore instance “Complete fracture”, “Increase in deflection of 0.02 inches”, “Through thickness crack” or the criterion is even unknown, leading to a challenging evaluation of different series. Test results are sometimes only indicated graphically in moderate quality diagrams, leading to inaccurate tabularizing of results. Some test series appear in more than one source and have been incorporated twice into the former data collection. Additionally, some series of the existing data collection have possibly been classified with a wrong detail in former evaluations, which in some cases could only have been found out after researching original publications. What is more, in some cases a distinct classification into one detail is not possible.

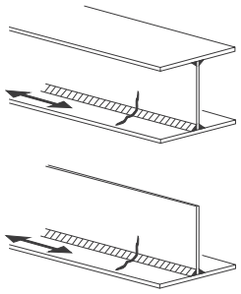
In order to gain a first overview of the fatigue test results regarding classification into details, for each detail the most expressive series have been identified. For the identification, the following main criteria have been used:
– Availability of primary or only secondary source
– Availability of test data in tables or only in terms of diagrams
– Expressiveness of failure criterion
– Number of tests
– Possibility of an obvious allocation to a fatigue detail of EC-3-1-9 (Eurocode 3, 2005)

4.2 *Evaluation of fatigue data*

In the following, a first overview of possible evaluations of fatigue series belonging to detail 3 of table 8.2 (Eurocode 3, 2005) is presented. These series comprise welded built-up sections containing longitudinal automatic fillet or butt weld carried out from both sides containing stop/start positions. Table 2 presents an excerpt of this detail in EC3-1-9.

In order to evaluate the most significant series, eight out of 28 available tests series have been selected taking into account the outsourcing criteria named in section 4.1. Other test series have been dropped in this first evaluation because of bad documented secondary sources, totally unknown failure criteria or due to a small number of test results (less than 5 test results per series).

Table 2. Excerpt of detail category table 8.2 detail 3 (Eurocode 3, 2005).



Detail category	Constructional detail	Description
112		3) Automatic fillet or butt weld carried out from both sides but containing stop/start positions.

Table 3 gives information on the eight selected series regarding failure criterion, specimen type, country in which the series have been performed and on the number of tests per series. The eight series originate from three different sources, comprising tests on different types of specimens. Moreover, the series have been conducted in different laboratories and contain different failure criteria as well as different numbers of single tests. This variation leads to a wide distribution and covering of possible influencing characteristics.

Table 3. Selected series of detail 3 in table 8.2 (Eurocode 3, 2005).

Series	Failure criterion	Specimen type	Number of tests	Country
S1*	„Complete fracture“	T-specimen	31	USA
S2*	„Complete fracture“	T-specimen	12	USA
S3*	„Complete fracture“	T-specimen	12	USA
S4**	„Fracture“	T-specimen	21	Germany
S5**	„Fracture“	T-specimen	66	Germany
S6*	„Complete fracture“	I-specimen	9	USA
S7***	“Fracture propagated to half of web”	I-specimen	9	Germany
S8***	“Fracture propagated to half of web”	I-specimen	25	Germany

* (Reemsnyder, 1963)
** (Olivier & Ritter, 1981)
*** (Minner, 1981)

The selected test series have been evaluated separately. As a first step, a linear regression (see section 2.1) has been performed for the defined gradient m, which is incorporated with the value three in S-N-curves in EC-3-1-9 (Eurocode 3, 2005), confer the straight line in Figure 1. Furthermore, the reference value of the fatigue strength $\Delta\sigma_c$ at $N_C = 2$ million cycles has been evaluated by using the two statistical methods:

- Prediction interval (cf. section 2.2) and
- Tolerance interval (cf. section 2.3)

The prediction as well as the tolerance intervals are depicted in Figure 1 for series S1 by dotted and dashed lines.

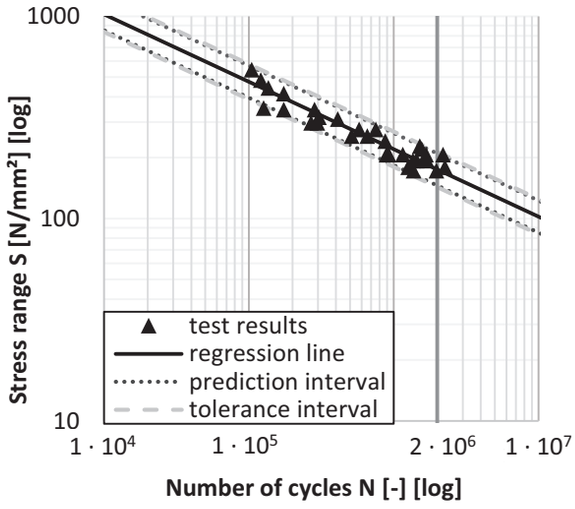


Figure 1. Depiction of test results, regression line, prediction and tolerance interval of S1 (Reemsnyder, 1963).

The evaluation of series S1 results to the following values:

- Prediction interval: $\Delta\sigma_c = 145.7$ N/mm²
- Tolerance interval: $\Delta\sigma_c = 143.1$ N/mm²

As comparison, the detail category of EC3-1-9 (Eurocode 3, 2005) amounts to 112 N/mm², which lies distinctly below the statistically secured values of Series S1.

The presented evaluation progress has been realized for all eight selected series. Figure 2 illustrates the different values of fatigue strength, evaluated by prediction and tolerance intervals, compared to the current EC 3-1-9 (Eurocode 3, 2005) fatigue class and the next higher fatigue level.

As seen in the figure, every series exhibits a sufficient fatigue strength to be classified in the current fatigue class 112. Moreover, six or even seven (if the prediction interval is consulted) series could be classified in class 125, which is the next higher classification.

For further analyses, it has to be remarked that the eight series differ from each other regarding influences on fatigue in many regards. In general, a comparison of all single characteristics of the series is difficult. Too many differences among the properties lead to the inability of isolating interesting influencing parameters on fatigue strength such as component thickness, steel grade or fabrication of welds. However, several independent variables could be investigated, as described in the following sections.

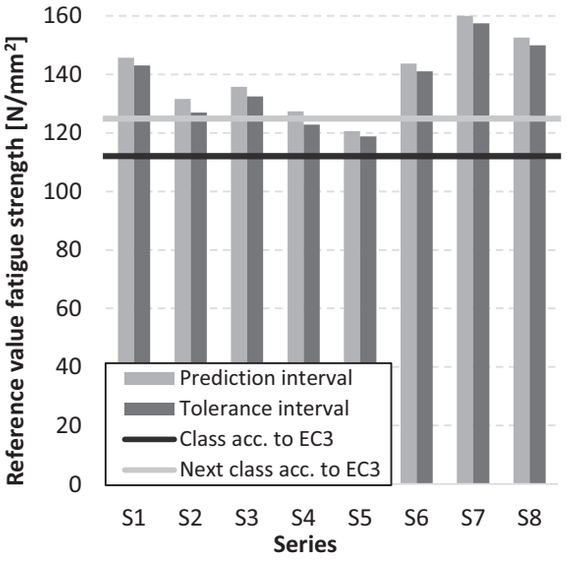

Figure 2. Evaluation of selected series of detail 3 table 8.2 (Eurocode 3, 2005).

4.3 *Influence of failure criterion*

First of all, the different failure criteria depict crucial influencing parameters. The eight selected series of detail 3 in table 8.2 (Eurocode 3, 2005) originate from three different sources, which define failure as "fracture", as "complete fracture" or as "crack, which propagated until reaching half of the web". More detailed information is not given, which makes the comparison of the series and a distinct classification into one fatigue class questionable. Nevertheless, it can be noticed that the series with highest fatigue resistance (S7 and S8) belong to one source and also the two series with weakest results (S4 and S5) originate from a common source, indicating a tendency.

4.4 *Influence of component size*

Apart from the failure criterion, also the type of specimen differentiates among the selected series. The component size can influence the fatigue strength. For specific details, this size effect is already included in EC3-1-9. Investigations have shown that large component tests proved to exhibit lower fatigue resistance than investigations on small specimens (Helms, et al., 1989). Possible mentioned reasons might be:

- Stress mechanical influence: according to fracture mechanics, thicker cracked plates exhibit a lower fatigue life than thinner plates containing the same crack size to thickness ratio.
- Productional influence: In large constructions, higher residual stresses due to welding arise.
- Statistical influence: Because of a larger amount of weld volume, exterior and interior imperfections are more likely in larger structures.

Series S1 to S5 have been performed on small scale T-specimens, whereas larger I-sections have been used for Series S6 to S8. Two series, namely S3 and S6 are the only series directly comparable to each other regarding size effects, since they have been fabricated and tested similarly, except for the type of specimen. The T-specimen of S3 theoretically depicts an extract of an I-specimen tested in S6, as illustrated in Figure 3.

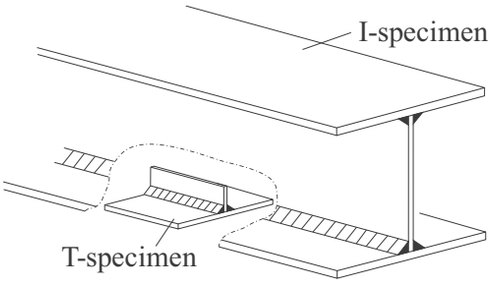

Figure 3. Depiction of I- and T-specimen (Reemsnyder, 1963).

As seen in the evaluation results, the larger I-specimen exhibits a higher fatigue strength than the smaller T-specimen, though. The authors ascribe this effect to the fact that the crack propagation proceeds slower in larger than in smaller specimens, where a through-thickness crack is achieved earlier. (Reemsnyder, 1963) This observation underlines again the importance of the failure criterion, as the crack propagation rate becomes only distinct, if the failure criterion is defined as "fracture". In case of a failure criterion depicting the "first detection of a small crack", a larger specimen might not be advantageous because of the above named influences.

4.5 *Influence of mean stresses*

The influence of mean stress or stress range can only be considered in exceptional cases according to EC 3-1-9 (Eurocode 3, 2005). Commonly, in welded structures, tension residual stresses are assumed, where the fatigue resistance is not depending on the mean stress, but only on the stress range. However, exterior compression stresses can have a positive influence, if they lead to a degradation of tension residual stresses. (Gurney, 1979) Tests on the influence of mean stress have shown, that the positive effect of compression stresses is worthwhile to consider.

This positive effect of compression stresses has been confirmed by the results of series S1, where three different stress ratios 0.5, 0 and -1 have been investigated.

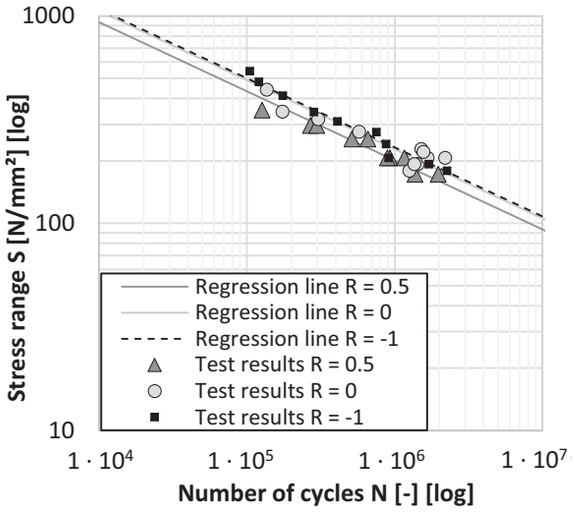

Figure 4. Depiction of S1 fatigue data in dependence of stress ratio (Reemsnyder, 1963).

As exemplary seen in Figure 4, fatigue tests with a tension compression alternating loading, R = -1 exhibit a higher resistance than specimens tested under a tension alternating loading, R = 0.5. The evaluation in terms of the prediction interval method results to:

– R = -1: $\Delta\sigma_c$ = 162.7 N/mm^2
– R = 0: $\Delta\sigma_c$ = 145.6 N/mm^2
– R = 0.5: $\Delta\sigma_c$ = 139.8 N/mm^2

Regarding these evaluation results, the tests with a stress ratio of -1 exhibit a 16% higher fatigue resistance than the tests with a ratio of 0.5. However, it has to be noticed, that this is only an exemplary investigation on the basis of one single series and not a general statement.

4.6 *Influence of boundary conditions and sample size*

In most cases, in order to suggest a fatigue category, it is not sufficient to evaluate only one series. Several series containing different boundary conditions (laboratories, test machines, stress relations, etc.) as existing in the selected series, have to be taken into account. Apart from influencing criteria, also a weighting regarding the sample size plays a huge role for deriving a characteristic S-N curve, as the results are proved differently strong. As seen in the evaluation, the results in terms of fatigue resistance differ in to a great extent. For more detailed evaluations in the future, concepts treating relevant influencing characteristics will be developed based on existing test data.

5 FUTURE EXPERIMENTAL TESTS

5.1 *Concept of experimental tests*

The presented fatigue evaluation process includes only test series of existing fatigue data collections for now. As seen in the above performed example, there is a huge lack of information on experimental data of several details. Regarding again for instance table 8.2 of EC 3-1-9 (Eurocode 3, 2005), eight of 15 details (including subcategories) are not based on experimental data, as far as known and the documentation of existing test data mostly has insufficient quality for present intentions.

More recent investigations regarding fatigue behavior of some details exist, but have not been included into the actual data base until now. However, there still are high demands for future experimental testing. Furthermore, some details of EC 3-1-9 (Eurocode 3, 2005) require extensive numerical analyses, aggravating a straightforward design procedure.

One example for a detail worth to be analyzed by future experimental investigations is the T-joint of detail 2 and 3 of table 8.5 (Eurocode 3, 2005), where modified nominal stress values have to be determined by sophisticated finite element (FE) investigations. An additional problem occurs in the design procedure of prestressed bolt connections. The detail category tables require knowledge of the actual bolt force, which however underlies additional loads due to support and loss of prestress effects, depending on the geometry of the connection. In order to determine the actual bolt force due to external loading, again expensive numerical investigations are necessary. In order to take into account these two issues, experimental investigations on end plate connections containing prestressed bolts are planned.

As a first step, large-scale tests on rolled sections with different endplate connections, cf. left hand side of Figure 5, will be conducted. Additionally, small scale T- or L-joint specimens depicting sections of the end plate connections will be tested afterwards.

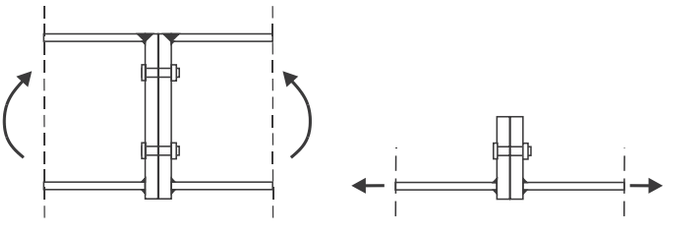

Figure 5. Depiction of planed tests: large- (left) and small-scale specimens (right).

During the experimental investigations, the stress distribution of large and small scale tests and their transferability shall be determined. The tests are planned to be recalculated numerically. After verification of the FE models, a parametric study in order to investigate influences of the thickness of bolts, accomplishment of welds and imperfections etc. will be conducted.

5.2 *Numerical investigations*

For planning of the experimental test, FE models have been created in order to investigate the stress distribution within the endplate connection. This section only concentrates on the beam tests. In order to create a constant bending moment and eliminating shear forces in the connection area, a four-point bending test is intended to be conducted. Consequently, also the FE models are loaded and supported at two points, respectively. The geometry of the connection is designed in a way that cracks will probably appear first in the welds. Nevertheless, the stress and stain behavior of the preloaded bolts will also be recorded.

In order to roughly estimate the number of cycles to failure during the tests, the approximately arising stress under a predefined bending moment has to be determined. The calculated lifespan according to the nominal stress approach of EC3-1-9 (Eurocode 3, 2005) has exemplary been compared to the probably more precise number of cycles determined by effective notch stresses according to IIW recommendations (Hobbacher, 2008).

The effective notch stress generally depicts the stress at the root of a notch. In order to apply the concept, the actual weld contour is replaced by an effective one, which means that the notch radius of weld root and toes has to be modelled. A radius of 1 mm and element sizes in the curved parts of less than 1/6 mm have to be satisfied to comply with the approach. (Hobbacher, 2008)

For preliminary investigations, an exemplary effective notch stress model has been created. In this case, fillet welds are assumed, which is why a gap of 0.5 mm thickness is modelled between section and end plate. Figure 6 depicts an excerpt of the global FE model, where also the most interesting part of the endplate connection is highlighted.

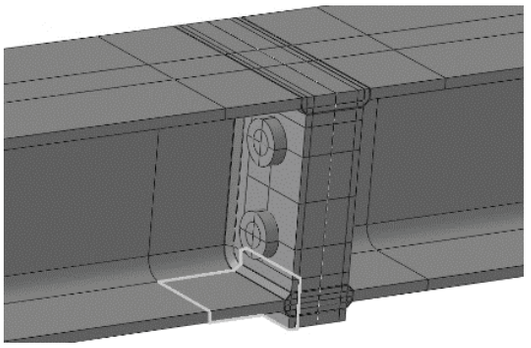

Figure 6. Global model and designation of sub model.

Because of the small element size and the accompanying high number of elements, only a small part of the model can be realized in accordance with the effective notch stress concept. As a first step, the simulation of the global model indicates the location of highest stresses. In a second step, a finely discretized sub model is created, which contains the location of most critical stresses. As resistance, one single S-N curve based on a reference stress of 225 N/mm^2 at 2 Million cycles with a slope of 3 is consulted. (Hobbacher, 2008).

Figure 7 illustrates a stress plot of the principle stresses in the sub model of the endplate connection. It can be observed, that the weld on the inside of the flange is more stressed than the outer one, due to the clamping action of the bolts inside the section.

The highest stresses of 389.8 N/mm^2 arise in the weld toe and the maximum stresses in the weld root amount to a similar value of 389.1 N/mm^2. Thus, according to the effective notch stress concept the crack initiation could start from the root of the weld or the weld toe with same probability.

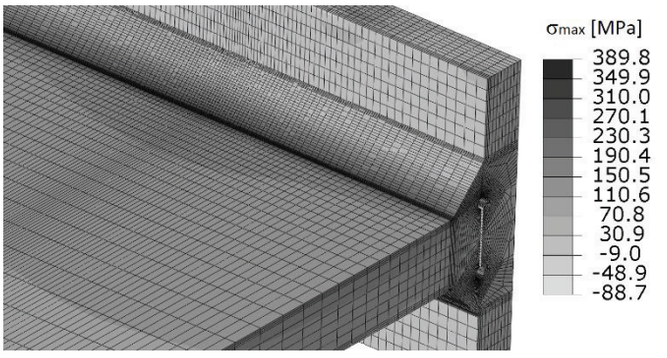

Figure 7. Maximum principle effective notch stresses.

The following section exemplary presents the lifespan estimation of the weld root. Table 4 depicts the comparison of lifespan of the weld root according to the nominal and the effective notch stress concept. Detail 3 of table 8.5 in EC3-1-9 (Eurocode 3, 2005) with a fatigue class of 36* has to be considered. Asterisked fatigue classes can be lifted one class higher, if the part of the S-N curve with a slope of 3 is extended until 10^7 cycles. Therefore, in the present investigations fatigue class 40 is taken into account. According to the nominal stress approach, the stress in the upper weld of the lower flange has been calculated to 121.7 N/mm^2. Regarding fatigue class 40, a lifespan of 70,929 cycles results.

Table 4. Lifespan according to nominal and effective notch stress approach.

Concept	Stress in weld root [N/mm^2]	Fatigue class	Number of cycles to failure
Nominal stress	121.7	(36*) 40	(51,707) 70,929
Effective notch stress	389.1	225	386,718

The effective notch stress concepts predicts a distinctly higher lifespan of 386,718 cycles to failure, taking into account the overall fatigue class 225.

It has to be mentioned, that a sensitivity analysis, especially in terms of discretization and assumption

of welding gap, has to be conducted for final FE models to create a validated foundation for the parametric study. Such investigations will be performed after a verification of FE models by means of experimental investigations.

Generally, the fatigue evaluation with effective notch stresses is deemed to be multiplicatively more precise than an estimation according to the nominal stress concept, leading to more economic results. (DVS, 2017) Still, also the effective notch stress fatigue curve is based on statistical evaluations in terms of the tolerance interval and therefore the true number of cycles to failure will probably be higher than predicted.

6 CONCLUSION

After explaining the basics on known fatigue test data and static methods to evaluate those, this paper presents and exemplary evaluation of fatigue strength of one detail in EC3-1-9 (Eurocode 3, 2005). Detail 3 of table 8.2 has been selected, which depicts automatic fillet or butt weld carried out from both sides and containing stop/start positions. The eight most expressive fatigue tests series have been evaluated taking into account two different statistical approaches. It has been shown that all series can doubtless be classified in the detail class 112 of EC3-1-9 (Eurocode 3, 2005). Additionally, depending on the statistical approach, six or seven of the eight selected series fall into the higher class 125. In conclusion, thought could be given to categories Detail 3 of table 8.2 into a higher fatigue class. However, more recent investigations on components with current characteristics (e.g. modern production methods, etc.) should be taken into account to confirm the presented evaluation results. Furthermore, a draft of future experimental investigations which intend to simplify the fatigue verification process of special details has been presented as an outlook. A forecast of the number of cycles to failure for one specimen has been presented, comparing results according to nominal and effective notch stress concepts.

7 ACKNOWLEDGEMENTS

The presented investigations have been conducted in the framework of the German research project “Re-evaluation and enhancement of the detail catalogue in Eurocode 3 for future oriented design of steel construction under high loading” (Enhancement detail catalouge, 2016). The financial contribution of the German Committee on Steel Construction (DASt) in cooperation with the Research Association for Steel Application (FOSTA) is greatly acknowledged. Additionally, the provision of fatigue test data from all kinds of institutions is hugely appreciated.

Recommended fatigue strengths of thick-walled circular K-joints and influence of weld root irregularities

S. Bove & M. Euler & U. Kuhlmann
Institute of Structural Design, University of Stuttgart, Germany

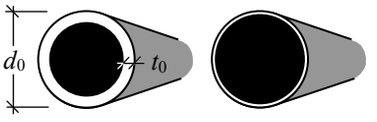
ABSTRACT: Welded tubular K-joints made of circular hollow sections under fatigue loading are widely used in civil, mechanical and plant engineering. Recently, more and more thick-walled structures with a low chord slenderness have been realized. Unfortunately, the existing design rules (e.g. CIDECT Design Guide 8 or EN 1993-1-9) cover only K-joint geometries with $\gamma = d_0 / (2 \cdot t_0) > 12$ or limit the wall thickness to t_0 and $t_1 \leq 8$ mm. There had been doubts due to a possible deteriorating size effect, if the fatigue strengths derived from the existing test data can also be recommended for tubular K-joints with low chord slendernesses, ranging between $3 \leq \gamma \leq 12$. The outcome of two German research projects is presented. In the first already finalized project the fatigue behavior of thick-walled tubular K-joints had been investigated. In the latter still running project the focus is laid on the influence of the weld quality on the fatigue strength of these joints.

1 INTRODUCTION

Welded tubular trusses under fatigue loading made of circular hollow sections (CHS) are widely used in civil, mechanical and plant engineering. Especially K-joints, where the braces and the chord form a lying K, are particularly frequent.

There are generally two possibilities to fabricate tubular K-joints. The truss members can be connected by means of cast steel elements which all truss members are welded on. Another possibility, being supposed to be focused on in this paper, is the fabrication by direct welding the braces to the chord members.

Recently, more and more welded thick-walled tubular K-joints with low chord slenderness $\gamma < 12$, Eq. (1) have been realized.



$$\gamma = \frac{d_0}{2 \cdot t_0} \tag{1}$$

d_0 … chord diameter
t_0 … chord wall thickness

However, the existing design recommendations cover only K-joints with relatively thin-walled chords and, consequently, high γ-values. For example the rules of CIDECT (Zhao et al. 2000) are only valid for $\gamma \geq 12$ and those of DNV (2010) for $\gamma \geq 8$.

The limitation of the chord slenderness γ can be attributed to the existing test database, lacking a statistically appropriate number of test results for tubular joints (including K-joints) with $\gamma < 12$.

Table 1. Definitions.

Wall thickness	**thick-walled**	**thin-walled**
absolute	$t_0 > t_{ref}$	$t_0 \leq t_{ref}$
relative, $\gamma = d_0 / (2\ t_0)$	$\gamma < 12$	$\gamma \geq 12$
Illustration		

There have been doubts due to a possible deteriorating size effect, if the fatigue strengths derived from the existing test data can also be recommended for tubular K-joints with low chord slendernesses ranging between $3 \leq \gamma \leq 12$. The size effect describes the size dependency of the fatigue strength due to statistical, technological or geometrical effects (Ørjasæter 1995).

For clarity, the chord of a CHS K-joint will be considered as absolutely thick-walled in this paper if its wall thickness t_0 exceeds the reference wall thickness t_{ref} of the detail category, for which no size effect has to be assumed. With respect to the limitation of the CIDECT design recommendations, the chord of a K-joint with $\gamma < 12$ is referred to as relatively thick-walled respectively, Table 1.

The paper derives a proposal for the fatigue strength (finite fatigue life regime, as-welded, in air) of uni- and multiplanar welded CHS K-joints whose chord slendernesses range between $3 \leq \gamma \leq 12$. The derivation of the proposal is based on the outcome of a German research project (Kuhlmann et al. 2014).

Another aspect being addressed in this paper is the influence of weld root irregularities of welded CHS K-joints on the fatigue strength. Frequently, welded hollow-section joints has been regarded as questionable because a reliable detection of internal weld irregularities by non-destructive testing (NDP) is nearly impossible. This is also one of the reasons why CHS joints were commonly fabricated by using cast steel elements. Hence, in order to increase the acceptance of directly welded CHS joints it is important to investigate and quantify the influence of the weld irregularities, such as incomplete fusion and weld root opening, on the fatigue strength. These aspects are addressed in a further still running German research project (Kuhlmann et al. 2017). The outcome of a numerical investigation and parameter study on the influence of varying weld root irregularities will be presented.

2 STATE OF THE ART

2.1 *Structural stress approach*

The fatigue evaluation of welded tubular joints including CHS K-joints is complicated due to the stress concentration at the member intersections that leads to an increase of the nominal stress at the joint region. The stress rising effect is caused by the structure of the joints (shift in overall geometry and stiffness) and the welding (local notch effects, residual stresses and material inhomogeneity induced by welding process).

The stress concentration varies around the member intersections and renders the definition of a meaningful nominal stress for tubular joints difficult. Therefore, the fatigue evaluation of tubular joints is usually based on structural stresses (also called hot-spot stresses) instead of nominal stresses.

2.2 *Fatigue strength from structural stresses*

The fatigue behavior in a finite fatigue life regime, in accordance with the structural stress approach for tubular joints, is described by particular *S-N* curves that relate the fatigue failure to structural stress range and number of stress cycles. The fatigue strength $\Delta\sigma_R$ of a joint with wall thickness, t, for a particular number of cycles, N, is defined by Equation (2). It includes three parameters: (i) the detail category expressed by the (theoretical) intercept A of the *S-N* curve with the log N axis, (ii) the slope m, and (iii) a proposal concerning the treatment of the size effect including the reference wall thickness t_{ref} and a corresponding exponent B.

$$\Delta\sigma_R = \underbrace{\sqrt[m]{\frac{10^A}{N}}}_{\text{detail category}} \cdot \underbrace{\left(\frac{t_{ref}}{t}\right)^B}_{\text{size effect}} \qquad (2)$$

Table 2 gives an overview of the parameters assumed by different common fatigue design recommendations. With exception of the recommendations of DNV, the design rules for the fatigue strength are similar. The recommendations of CIDECT are identical with those of IIW (Zhao & Packer 1999). The lower detail category of DNV can partly be explained by the higher reference wall thickness.

To characterize the detail category, a reference value $\Delta\sigma_C$ (structural stresses) is commonly used that represents the fatigue strength $\Delta\sigma_R$ of a tubular member with reference wall thickness t_{ref} for $N = 2$ million stress cycles.

The slope of the *S-N* curve for the reference wall thickness is fixed for all mentioned design recommendations to $m = 3$.

Table 2. Fatigue strength (structural stresses) in selected design recommendations.

	EC3	**DNV**	**API**	**CIDECT**
$\Delta\sigma_C$ [MPa] (air)	114 [a]	90 [b]	114 [c]	114
Intercept A [-]	12.476	12.164	12.476	12.476
Survival probability [%]	95 [a]	97.7	97 [c]	95
Failure criterion	through-crack	through-crack	through-crack [c]	through-crack [d]
Ref. wall thickness t_{ref} [mm]	16 [a]	32	16	16
Exponent B of size effect	–	0.25	0.25	0.06 log N
Positive effect for $t < t_{ref}$?	–	no	no	yes

[a] van Wingerde et al. (1997), p. 126 & 133
[b] curve T [c] API RP 2A-WSD, Sec. C5.2.5 & p. 58, 214
[d] Zhao & Packer (1999), p. 5

The size effect is usually expressed by a factor containing all influencing parameters. In Equation (2), only the failing wall thickness, t, is considered as a relevant influencing dimension. The existing formulation of fatigue strength $\Delta\sigma_R$ (structural stresses) in CIDECT is based on an extensive statistical evaluation of test data primarily recorded on thin-walled tubular joints ($\gamma \geq 12$) by van Wingerde et al. (1997). Herein the size effect is considered exclusively as a thickness effect, as in Equation (2) that depends on the number of stress cycles, N.

2.3 *Applicability of existing design rules*

For the fatigue design of thick-walled K-joints with $\gamma < 12$ the direct applicability of the existing definition of the fatigue strength had to be questioned. Therefore, a working hypothesis was formulated assuming that the separation in Equation (2) between the detail category on the one hand, and the size effect due to wall thicknesses $t \neq t_{ref}$ on the other hand, can be maintained for thick-walled K-joints.

If other parameters besides the wall thickness – especially the chord slenderness – had a significant influence on the fatigue strength, this influence should result in a lower detail category for thick-walled K-joints in a first step. In a second step it should be thought about if this influence should also be separated from the detail category by adding an additional factor.

To answer this question by experimental evidence, a first research project (Kuhlmann et al. 2014) was set up aiming to fill the gap of knowledge concerning the fatigue behavior of thick-walled welded K-joints and to enlarge the application range of this type of constructional detail.

2.4 *Influence of weld quality*

As the intersection region of welded hollow section joints is highly stressed, the influence of the weld shape (e.g. weld toe radius) and the weld quality (e. g. weld irregularities) on the fatigue strength is more pronounced. Several research projects were conducted focusing on weld irregularities and their influences on the fatigue behavior of the considered constructional detail.

For example, Scholte & Buisman (1988) investigated the influence of varying weld irregularities on the fatigue strength of CHS-to-CHS butt joints. It could be shown that an incomplete penetration can reduce the fatigue life by half and that defects at the weld root can lead to a crack initiation at this point.

Qian et al. (2013) investigated the influence of partially penetrated butt welds at the crown toe of CHS X-joints, see Figure 1(b). In contrast to the aforementioned butt joints they concluded that a partial penetration has a negligible influence on the fatigue strength of butt welds as long as the weld toes are not post-weld treated shifting the potential crack initiation point to the weld root.

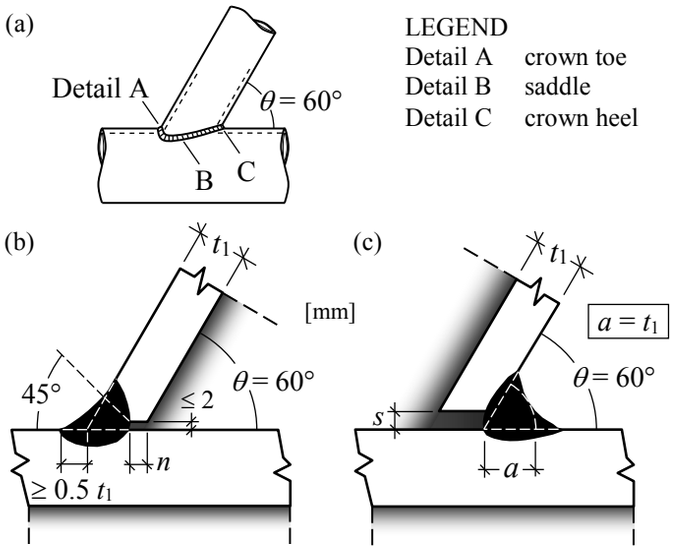


Figure 1. Weld root irregularities: (a) overview; (b) incomplete fusion, *n*, at detail A, (c) root opening, *s*, at detail C

To summarize, the influence of weld irregularities has to be differentiated depending on the type of joint. To quantify the influence of weld root irregularities on CHS K-joints is the aim of a further research project (Kuhlmann et al. 2017). In this project thick-walled CHS K-joints with artificial weld irregularities at the weld roots are investigated in order to develop a planning and fabrication guideline for designers as well as steel construction companies. In case of a discovered weld root irregularity, this guideline should help to determine if this defect has to be repaired or can be kept. The prerequisite is, however, that the presence and the size of an irregularity can be determined by NDP. Therefore, the investigation of the welds by means of ultrasonic examination is also part of this research project.

3 EXPERIMENTAL INVESTIGATIONS

3.1 *Overview*

In the first mentioned German research project No. P815/ IGF 325 ZBG of the "Forschungsvereinigung für Stahlanwendung (FOSTA) e. V." financed by the German Federal Ministry of Economic Affairs and Energy (BMWi), the fatigue behavior of welded uni- and multiplanar K-joints with thick-walled chords was investigated. The research project was carried out by four partners: (i) Stuttgart University, (ii) Munich University of Applied Sciences, (iii) Munich University of Armed Forces and (iv) Schweißtechnische Lehr- und Versuchsanstalt (SLV) Halle, and comprised a comprehensive test program and detailed numerical investigations.

The second German research project (FOSTA P1163 / IGF 18883 BG) was launched in order to investigate the fatigue strengths of thick-walled CHS K-joints with systematic weld irregularities at the crown heel and crown toe, see incomplete fusion, *n*, and weld root opening, *s*, in Figure 1. Additionally, two variations of the weld build-up including circumferential fillet welds and a sharper weld shape are investigated. This research project is carried out by (i) Stuttgart University, (ii) Munich University of Applied Sciences and (iii) Forschungszentrum Ultraschall (FzU) Halle.

3.2 *Test series*

The test program in Kuhlmann et al. (2014) contained in total more than 80 single-joint fatigue tests with constant stress amplitude that fell into eight test series, including a large-scale girder spanning about 11 m. Of these tests, 63 were performed on as-welded test specimens and are addressed in Table 3. The remaining 20 single-joint fatigue tests investigated the influence of a post-weld treatment on the fatigue strength and are not covered by this paper.

Table 3. Overview of test series in Kuhlmann et al. (2014).

Symbol	Series	Loading [a]	*R*	Joint	Chord	Brace	γ	Number

[a] IPB: in-plane bending; AX: axial force

In order to isolate the deciding parameters on the fatigue strength and to identify the characteristics of the fatigue failure of thick-walled K-joints the specimens of single-joint tests were subjected to several elementary load cases, Figure 2. For further details see Kuhlmann et al. (2014).

In Kuhlmann et al. (2017) 30 single-joint fatigue tests will be performed in order to discover the influence of weld root irregularities, Table 4.

3.3 *Test specimen*

The cross-sectional dimensions and the varying parameters of the test specimens are given in Table 3. The brace angle was set to 60° for all specimens. Addressing the needs of practitioners, a combination of butt and fillet welds for the brace-to-chord intersection was realized. The weld starts as a full-penetration weld at the crown toe and turns into a fillet weld at the crown heel with a smooth transition, see Figure 1.

Only hot-finished circular hollow sections of steel grade S355J2H according to EN 10210-1 were used.

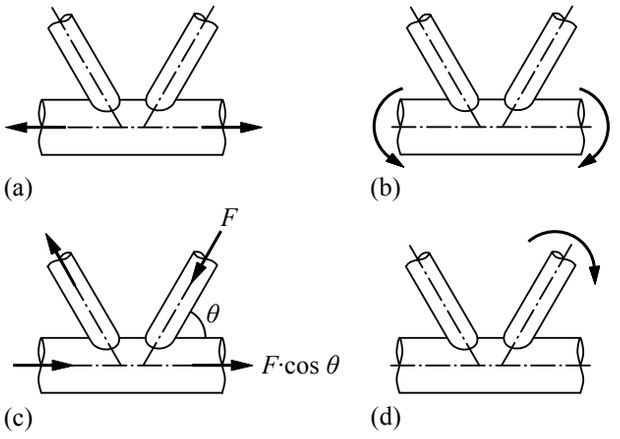

Figure 2. Investigated elementary load cases:

[a] IPB: in-plane bending; AX: axial force

3.4 *Failure criterion*

In accordance with the existing design recommendations, the first through-wall-thickness crack was considered as the relevant failure criterion, Table 2. To detect this through-crack reliably, the test specimens were set under a small overpressure after airproof closing their ends. As the overpressure was permanently recorded during the tests, a sudden pressure drop indicated the first through-crack.

In the case of the test girder this kind of crack detection was not possible. Here, the determination of the first through-crack was realized through beach marks on the fracture surface induced by variable-amplitude loading.

3.5 *Fatigue test results*

The outcome of the fatigue tests of Kuhlmann et al. (2014) is shown in Figure 4. For technical reasons, the fatigue tests had to be performed with different stress ratios, R, shown in Table 3. Furthermore, the failing member was different depending on the load case. Thus, the failing wall thickness was not the same in all tests. Therefore, to ensure compatibility of the test results the test data in Figure 4 have been modified (see details in Sec. 5).

For all as-welded test specimens the cracks were initiated at the weld toes of either the chord or the brace, Figure 3. Under chord loading the first through-crack was exclusively initiated at the weld toes of the chord either at the crown toe or at crown heel, No. 01 or 05 in Figure 3.

Under brace axial force the first through-cracks were detected in the gap region. For the test specimens with $t_1/t_0 = 0.25$ through-thickness cracking of the brace wall occurred, while for the test specimens with $t_1/t_0 = 0.63$ through-thickness cracking of the chord wall appeared. For specimens with a ratio of $t_1/t_0 = 0.25$ the cracks initiated at location No. 11, while for a ratio of $t_1/t_0 = 0.63$ location No. 01 in Figure 3 was the critical.

When brace bending was applied as a reverse loading with $R = -1$, cracks initiated at several locations (No.01, 05, 11 & 15 in Figure 3). The through-crack occurred either in the chord or the brace.

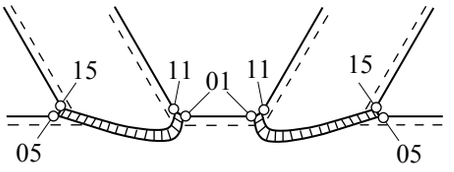

Figure 3. Possible positions of crack initiation.

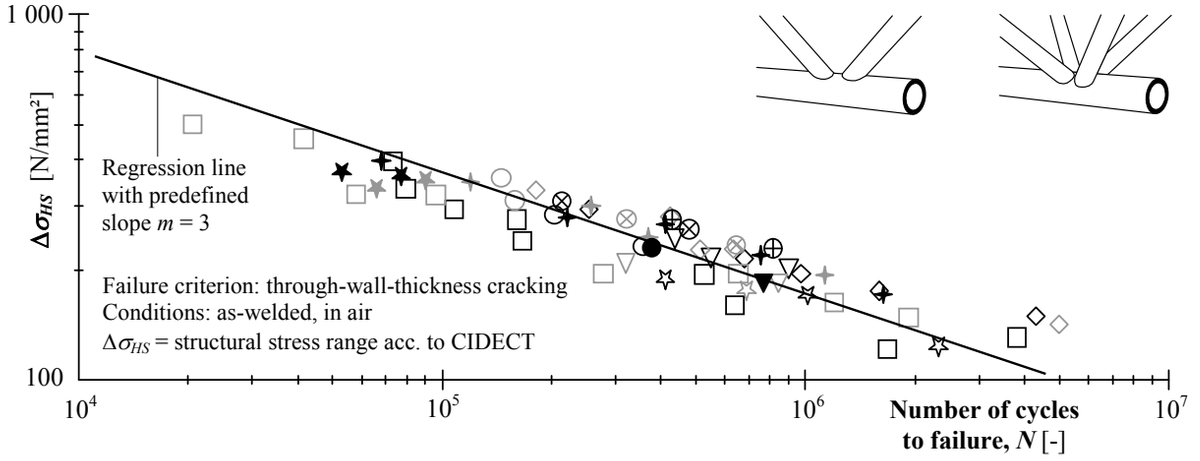

Figure 4. Test data of Kuhlmann et al. (2014) modified for failing wall thickness and stress ratio R according to Equations (3) & (4) (for symbols see Table 2)

4 NUMERICAL INVESTIGATIONS

In order to determine the structural stresses and stress ranges acting in the test specimens during the fatigue tests, a 3D parameterized Finite Element (FE) model with elastic material behavior was generated with ANSYS 14.0. 20-node-solid elements of type SOLID186 with reduced integration scheme 2×2×2 were used. The model was validated through strain measurements recorded before each fatigue test. As the test specimens differed in geometry and loading, they were grouped for the evaluation. The overall dimensions and the weld shape of all test specimens of one single group were measured and subsequently averaged, so that each group was represented by one mean geometry. The FE stress components perpendicular to the weld toe around the brace-to-chord intersections were determined. Based on these components a quadratic regression within the region next to the considered weld toe was performed. The stresses of the regression at the distances $L_{r,min}$ and $L_{r,max}$ were used for the linear extrapolation of the structural stresses at the weld toe. For further information, see Zhao & Packer (1999) and Kuhlmann et al. (2014).

5 STATISTICAL EVALUATION

5.1 *Modifications*

For the statistical evaluation the same thickness effect as for thin-walled tubular joints according to CIDECT (Zhao et al. 2000) with a reference wall thickness t_{ref} = 16 mm was assumed. For comparability, the results of the fatigue tests had to be adjusted to the reference wall thickness by Equation (3). For a test specimen that failed in a wall with $t < t_{ref}$ the structural stress range of the fatigue test was lowered by Equation (3) in order to account for the hypothetically shorter fatigue life of the same test specimen with $t = t_{ref}$, and vice versa.

$$\Delta\sigma^{t=16} = \Delta\sigma^{t\neq16} \cdot \left(\frac{16}{t}\right)^{-0.06 \log N} \quad (3)$$

To adjust all fatigue tests to the same stress ratio $R = 0$, the stress ranges of tests with $R = -1$ had to be modified by Equation (4), derived for an average of low and high residual stresses in Eurocode 3, Part 1-9, Sec. 7.2.1. For a stress ratio $R = -1$ the value f amounts to 1.125.

$$\Delta\sigma_{(R=0)} = \frac{\Delta\sigma_{(R=-1)}}{f} \quad (4)$$

For technical reasons the final rupture, instead of the first through-crack, was recorded as the failure criterion in five fatigue tests. For these tests the number of stress cycles to through-cracking was estimated at 67 % of the number of cycles to rupture. This relationship was found by van Wingerde et al. (1997) for thin-walled tubular joints.

5.2 *Discussion of results – Size effect*

The outcome of the statistical evaluation according to the procedure proposed by Brozzetti et al. (1989) is summarized in Table 5. The same procedure has been used by van Wingerde et al. (1997) for setting up the existing CIDECT detail category 114 for tubular joints (see Table 2).

Table 5. Characteristic reference value $\Delta\sigma_C$ [N/mm²] of fatigue strength (structural stresses) for 2 million stress cycles and reference wall thickness 16 mm; failure criterion: through-wall-thickness cracking; conditions: as-welded, in air; survival probability according to Eurocode 3 (Brozzetti et al. 1989).

Scope	***S-N* curve**		**Ref.**	**Sample size**
	***m* = 3**	***m* = var.**		
K/KK joints	104	116	‡	59
$\gamma < 12$	106	114	‡†	73
Tubular joints $\gamma \geq 12$	107	–	*	115

‡ = Kuhlmann et al. (2014)
† = Schumacher (2003), Borges (2008)
* = van Wingerde et al. (1997), p. 133

Actually, the CIDECT detail category 114 corresponds with complete loss of strength as a failure criterion. However, van Wingerde et al. (1997) could show that for the through-wall-thickness cracking, the corresponding detail category $\Delta\sigma_C$ = 107 N/mm² (Table 5) is only slightly decreased due to a lower scatter of test data for this criterion. Furthermore, the detail category 107 has to be considered still conservative because a steeper slope of m = 3 (instead of the real slope of test data) is assumed for the evaluation.

Interestingly, the computed reference value $\Delta\sigma_C$ = 104 N/mm² for thick-walled K-joints corresponds quite well with that for thin-walled tubular joints, $\Delta\sigma_C$ = 107 N/mm² in Table 5 for a fixed slope m = 3. Apparently, thick-walled K-joints with $\gamma < 12$ and tubular joints with $\gamma \geq 12$ belong to the same statistical population. Figure 5 illustrates this finding, plotting the structural stress ranges, $\Delta\sigma_{HS}$, against the achieved number of stress cycles to failure.

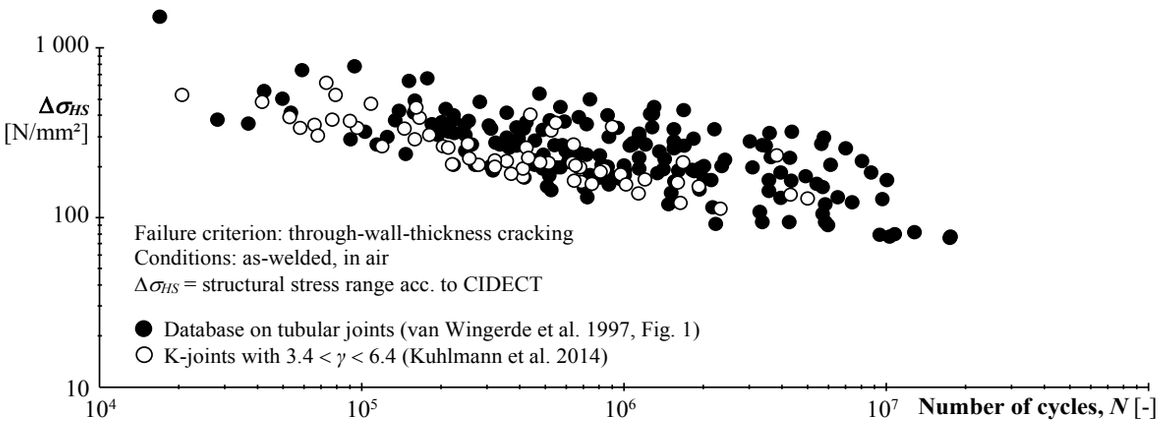

Figure 5. Test data of Kuhlmann et al. (2014) together with test database of van Wingerde et al. (1997) without any modification for failing wall thickness and stress ratio. Note: Test data of van Wingerde et al. are divided by 1.49 to account for the failure criterion.

It can be concluded that the size effect of thick-walled K-joints can mainly be attributed to the dependency on the absolute wall thickness. The influence of the chord slenderness γ (relative wall thickness) seems to be less pronounced.

6 WELD IRREGULARITIES – A FIRST NUMERICAL INVESTIGATION

6.1 *Introduction*

In order to increase the acceptance of directly welded CHS joints the influence of weld irregularities at the weld roots of CHS K-joints is investigated by Kuhlmann et al. (2017). A preliminary numerical study based on the notch stress approach according to Fricke (2008) identifies the effect of an incomplete fusion, s, of the crown toe's weld root and of a root opening, n, of the crown heel's weld root, see Figure 1. The notch factors k_f serve as reference.

6.2 *Global model*

In a first step a global numerical elastic model was generated with ANSYS 16.2 and built up of 20-node-solid elements of type SOLID186 with reduced integration scheme 2×2×2 with exception of the weld being modelled with 10-node-solid elements of type SOLID187. This model was validated by comparison with strain measurements recorded during the tests carried out at Kuhlmann et al. (2014) showing no significant weld irregularities s and n. Due to the boundary conditions of the test rig in Figure 6 (a), the K-joint of the global model has to be subjected to brace normal forces, N_1, and brace in-plane bending, M_1, Figure 6 (c). The same holds for the chord (not shown in Figure 6). Exclusively, CHS K-joints with chords of 177.8 mm in diameter and 20 mm in wall thickness were considered. The braces had diameters of 88.9 mm and a wall thickness of 12.5 mm.

6.3 *Submodel*

The notch factors k_f with respect to the nominal brace stress were determined by using the FE submodel technique. The elastic submodel consisted of of 20-node-solid elements of type SOLID186. For the crown toe and heel two 3D submodels (A and B) were created, Figure 6 (c). The displacements of the global model nodes corresponding with nodes of the submodel boundary areas were applied onto the submodel as loading. An effective notch radius of r_{ref} = 1 mm was assumed according to Fricke (2008).

The calculated notch factors k_f of three particular points of the weld at the crown toe for several values of incomplete fusion n are shown in Figure 7. It can be recognized that the weld toe at the chord (#1) remains still decisive when n increases. The notch factor of the weld root (#3) increases with greater n but stays beneath those of the weld toes (#1 and 2).

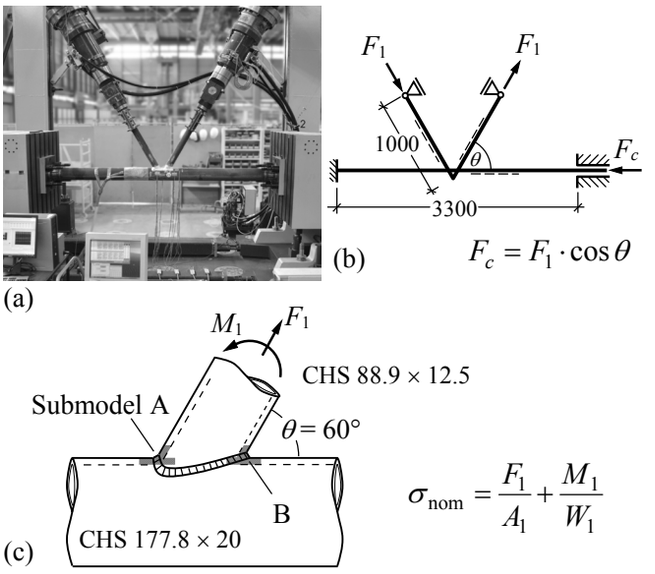

Figure 6. Global model: (a) test rig of Kuhlmann et al. (2014), (b) corresponding static system, (c) internal brace actions of global FE model due to brace loading with location of FE submodels and nominal stress definition

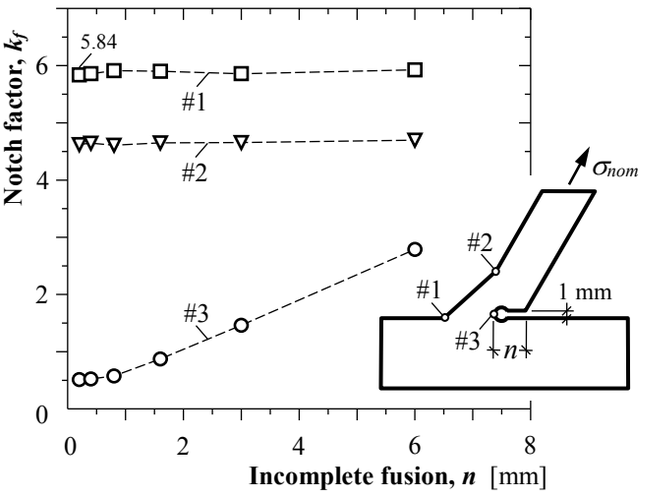

Figure 7. Notch factors k_f for varying incomplete fusion n at the crown toe (submodel A).

In Figure 8 the calculated notch factors k_f are plotted against the size of the weld root opening, s, at the crown heel. Notice that position #4 only appears for gap sizes larger than 2 mm. Otherwise #3 and #4 coincide.

Firstly, it can be stated that the weld toe of the brace (#2) remains decisive, and the effective notch stress of this point increases only slightly for higher values s. Secondly, the figure shows that with increasing weld root opening the notch factor of the weld root (#3) increases considerably but remains below the value of the weld toe (#2). Whether the crack is initiated at the crown heel or at the crown toe can be decided by comparing the notch factors calculated for #1 in Figure 7 and for #2 in Figure 8. Confirming the results from the conducted tests in

Kuhlmann et al. (2014) with no significant weld irregularities ($s \approx 0$, $n \approx 0$), the cracks initiate more likely at the crown toe with the higher $k_f = 5.84$.

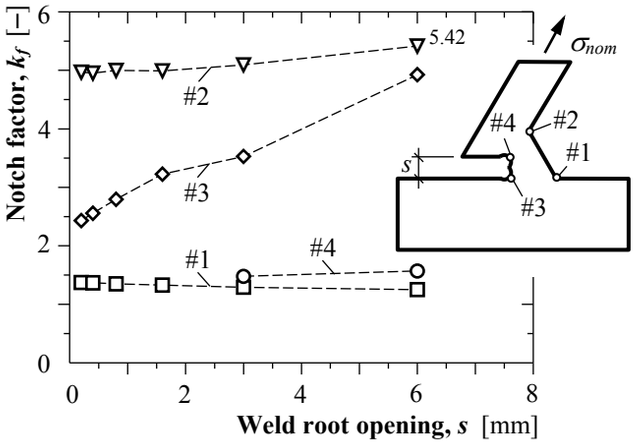

Figure 8. Notch factors k_f for varying gap sizes s between the brace and the chord at the crown heel (submodel B).

The incomplete fusion $n < 6$ mm at the crown toe does not seem to be critical for the considered joint geometry. The maximum notch factors occur at the weld toes. In terms of the weld root opening s at crown heel the notch factors of the weld root approaches that of the weld toe for values $s > 3$ mm. Nevertheless, the investigated range of s is not critical for the joint as the weld toes of the crown toe show higher notch factors assuming identical fatigue strengths of weld toe and weld root.

7 SUMMARY

Through experimental evidence it has been shown that the fatigue strength $\Delta\sigma_C$ (finite life regime, as-welded, in air, criterion: through-wall-thickness cracking) of uni- and multiplanar welded CHS K-joints with chord slendernesses $3 \leq \gamma \leq 12$ is comparable to that of tubular joints covered by the existing CIDECT detail category. For the tested specimens the size effect depended primarily on the failing wall thickness. The influence of the chord slenderness γ was not significant.

In a first numerical study it could be shown for a particular CHS K-joint geometry tested in Kuhlmann et al. (2014) that the effect of weld irregularities (incomplete fusion at crown toe, weld root opening at crown heel) on the fatigue strength is not significant. This finding has to be validated by fatigue tests being planned for the near future. Further numerical studies are supposed to enlarge the application range, additionally.

ACKNOWLEGDEMENT

The authors take this opportunity to express their profound gratitude to all supporters of their research. Special thanks to German Federal Ministry for Economic Affairs and Energy; Forschungsvereinigung Stahlanwendung (FOSTA) e. V.; Vallourec Deutschland GmbH, ZIS Industrietechnik GmbH, Meerane. Moreover, the authors would like to thank all project partners for their good and fruitfully cooperation.

Considering High Frequency Mechanical Impact Treatments in Design

S. Breunig & U. Kuhlmann
Institute of Structural Design, University Stuttgart, Germany

ABSTRACT: Regarding the revision of fatigue detail categories implemented in EN 1993-1-9, the discussion to integrate design approaches considering the beneficial application of innovative post-weld treatments, such as High Frequency Mechanical Impact (HFMI) treatment rises. Especially for fatigue loaded steel and composite bridges the potential of these technique enables to improve certain decisive welded details and shift the fatigue resistance to a higher level. In order to apply HFMI treatments for appropriate fatigue loaded steel structures in practice, rules have to be formulated in a code like manner.
Within this paper the work of the cooperative German DASt-AiF-Project "Development of a DASt-Guideline for High Frequency Mechanical Impact treatments" is presented, which aims at the implementation of a design concept in a German DASt-Guideline. The preceding work includes evaluation of existing knowledge and recommendations as well as analysis of collected and new test data with the aim to unify different applications into a homogenous and secured approach.

1 INTRODUCTION

1.1 *State of the Art*

The application of High Frequency Mechanical Impact (HFMI) treatment promises improved fatigue performance for selected welded details. Through the process of high frequent hammering with a hardened pin on the weld toe, a plastic deformation of its notch is achieved. This effect results in a reduction of the weld notch as well as the closure of micro cracks on the surface that could have led to points of crack initiations. Whereas the increase of fatigue resistance is mainly based on a change of residual stresses at the notch.

In order to be able to consider this improved fatigue strength in design, an official standard being approved by building authorities, is needed. Therefore it should be in accordance with Eurocode-design procedures. Efforts to quantify improvement factors for certain details, HFMI-techniques and influencing effects were made within several national and international projects.

Recently recommendations for the improvement quantification by HFMI for a wide range of details and conditions have been formulated by IIW. These IIW-Recommendations from Marquis & Barsoum (2016) are built up on the IIW-Guidelines of Hobbacher (2016), but have not been approved by a typical standardization process.

Thus the cooperative German DASt-AiF-Project "Development of a DASt-Guideline for High Frequency Mechanical Impact Treatments" (Kuhlmann et al. 2017) aims at the implementation of a design concept in a German DASt-Guideline, summarizing proved and secured application using the nominal stress concept according to EN 1993-1-9 (2005) and clearly giving application limits.

Figure 1. Test program of DASt-AiF-project (Kuhlmann et al. 2017)

For that purpose, a test program of small scale and beam tests was realized to fill existing lack of knowledge, see Figure 1.

With the help of the test results, clear and secured rules should be defined that enable designers to take into account the beneficial usage of HFMI on new structures, depending on the specific conditions.

This paper summarizes the steps from the definition of tests and analyzing of current and existing test data up to the evaluation and modification of existing design approaches. Furthermore, additional gathered knowledge on influencing parameters such as mean stress effect and their impact on the revised approaches are shown. Finally, this knowledge is cumulated in a German DASt-Guideline on HFMI treatments, which is in accordance with EN 1993-1-9 and thus could be transferred into the future version of it.

1.2 *Design approaches and recommendations*

From 2007 on, when the first announcement of a design approach to consider Ultrasonic Impact Treatment (UIT) on unloaded transverse attachments in fatigue design was developed by Duerr (2007) (Kuhlmann et al. 2006), until now, there mainly exist three different design approaches based on the nominal stress concept built up on each other.

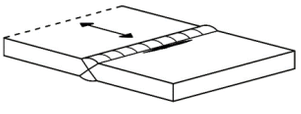
Based on knowledge of Duerr (2007) and own investigations on unloaded longitudinal attachments and transverse loaded butt welds, Weich (2009) (Ummenhofer et al. 2009) adapted and extended the design approach for these welded details and proved further boundary conditions.

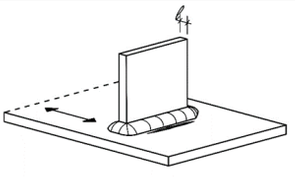
Today the most recent design concept is the IIW-Recommendation of Marquis & Barsoum (2016). Its steadily development and thus improvement led to integration of several details and effects. Besides the nominal stress concept according to "IIW-Recommendation for fatigue design of welded joints and components" of Hobbacher (2016) it gives local approaches for the consideration of HFMI application. However the stepwise consideration of the improvement due to HFMI in the IIW-Guideline is not referring to EN 1993-1-9.

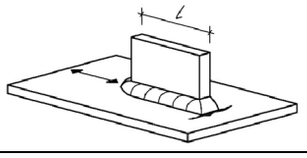
Berg (2016) has recently extended the approach based on the IIW-recommendations (Marquis & Barsoum 2016) and EN 1993-1-9 for ultra-high strength steels, namely from S960 to S1300 and additionally integrated cover plates in Stranghoener & Berg (2015).

2 MOTIVATION

2.1 *Claims for the DAS-Guideline*



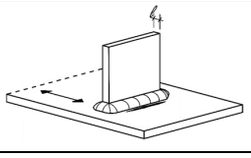


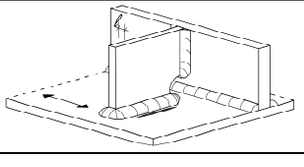


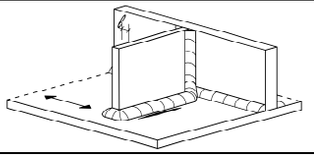
The intention of the DASt-Guideline is to enable designers of fatigue-loaded welded structures to consider the application of HFMI-treatment within the design using the nominal stress concept according to EN 1993-1-9 (2005).

In order to be approved by building authorities and used properly by designers there are several requirements for a guideline.

Obviously, the most important requirement for such a standard is to have sufficient secured results and understanding of the influencing effects for given statements and rules. This means that evaluated background information for several conditions and boundaries is needed. In case of gaps and lack of knowledge for certain conditions, they should be named and clearly excluded from the approach.







The second overarching objective of the DASt-Guideline is the user-friendliness. A certain level of simplification and thus unification of conditions can lead to an increased usage of HFMI. In order to meet acceptance of designers, the guideline should be practicable, easy to understand and reduced on the important and user-friendly form.

Table 2. Overview of investigated welded details.

Schematic view of detail	Description
	Transverse loaded butt weld acc. EN 1993-1-9 Tab.8.3
	Unloaded transversal attachment acc. EN 1993-1-9 Tab.8.4
	Unloaded longitudinal attachment acc. EN 1993-1-9 Tab.8.4

For both reasons the project partners decided to consider only three construction details and their variants. Especially the suitability for a successful treatment of the variants and the geometrical conditions of the details in Table 2 should be clearly de-

Table 1. Classification of appropriateness

appropriate	**not appropriate**	**appropriate**
		

fined within the DASt-Guideline.

As an example Table 1 shows appropriate and non-appropriate variants of the unloaded transverse stiffener.

2.2 *Conditions and test program of the project*

An extensive test program, consisting of 26 girder tests and 100 small specimen tests of S355 was developed to compensate deficiencies of the existing database and to answer open questions that need to be clarified. Figure 1 shows the test program. The decision of the main tested construction detail fell on the construction detail of the non-loaded transverse stiffener. Based on a large database of tests with different influencing factors that were investigated for unloaded transverse attachments in previous projects, this database can be used as a reliable reference basis so that comparisons to the planned series could be drawn. With the help of these specific test series the still open questions in terms of the design approach for HFMI will be clarified.

As the effectiveness of the HFMI treatments rises with the yield strength of the steel, the tests were conducted with S355J2 to be on the safe side for the draft of the guideline. Since the two most established techniques for Germany are the PIT technology and the HiFIT technology, those two different techniques were applied to the single series` specimen with their typically set parameters.

In the last ten years mainly two HFMI technologies have been established in Germany: the PIT (Pneumatic Impact Treatment) technique, that was further developed from the Ultrasonic Impact Treatment (UIT) by the German company Pitec GmbH, on the other hand the pneumatic actuated technology HiFIT (High Frequency Impact Treatment) developed by the German company Dynatec GmbH.

Besides a series of constant amplitude loading of small scale specimens and beam tests with a stress ratio of R = 0.1 representing tension-tension stresses, a series with an alternate loading of a stress ratio R = -1.0 could be tested. The aim was to be able to compare in regard of mean stress effects of HFMI-treated unloaded transverse stiffeners.

Another effect that was investigated experimentally is in how far the HFMI-treatment can prolong the lifetime of the welded detail, when the calculated service life of the as-welded state has already been reached. For that reason as-welded specimens have been loaded until 100% of their fatigue strength related to the respectively tested stress range level. Afterwards they have been HFMI-treated and tested until failure. This mainly represents the retrofitting potential due to HFMI-application on welds, that have had already reached their end of life-time.

For security reasons the impact of overloadings on the HFMI-treated welds is of increased interest. It could be that, due to higher loadings at the beginning of the lifetime of a treated weld, overloading could lead to destabilization of the introduced compressive residual stresses (see also Duerr (2007) and Weich (2009)). One aim of the project was to identify a critic level of load related to the yield strength in order to give a limitation or reduction factor in the guideline. Thus, a series of quasi-static tensioned and compressive overloadings has been developed within 40 specimens.

While the small scale tests were conducted at the KIT the 26 girder specimens were tested at the Materialprüfungsanstalt Universität Stuttgart. In this extract the focus lies on the girder test series T1 and T2 which will give information on the behavior of HFMI-treated girders depending on the mean stress.

3 BEAM TESTS ON THE MEAN STRESS EFFECT

3.1 *Test setup beam test series T1 (R = -1.0)*

The alternate loading of the beam tests with an unloaded transverse attachment in the mid span was realized with the help of resonance vibrations. This method has already been used in 1989 at BAM, (see Helms et al. 1989), since this is an advantageous testing method with regard to test duration and easy test setup. Therefore, external vibrators were fixed to the flanges in order to generate the desired bending line, which can be taken from Figure 2. With the help of measurement techniques, such as strain gages, applied on the beam flanges, load cycles could be counted and strains be measured.

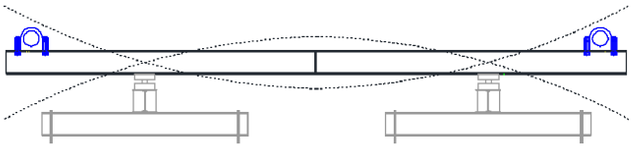


Figure 2. Sketch of bending line of test series T1

Defining the failure criterion to be a crack at the size of around 100 mm, the tests ran until that point. The difficulty was to detect the crack size while testing due to the high frequency of 33 to 35 Hz. Thus, strobe light was used to freeze the vibrating beam and detect the occurrence of cracks.

3.2 *Cracks and results beam test series T1 (R = -1.0)*

Due to the change of strains the crack initiation could be followed. Therefore, from time to time the external vibrators were stopped to document the time of crack initiation and crack propagation.

A typical crack on the weld toe connecting the bottom flange to the transverse stiffener can be seen in Figure 4. Two of the test beams were tested without a crack initiation until three million load cycles. Thus, they are characterized with an arrow and were neglected in the evaluation process. One of the six HFMI-treated girders failed from the flange without any impairment from welds.

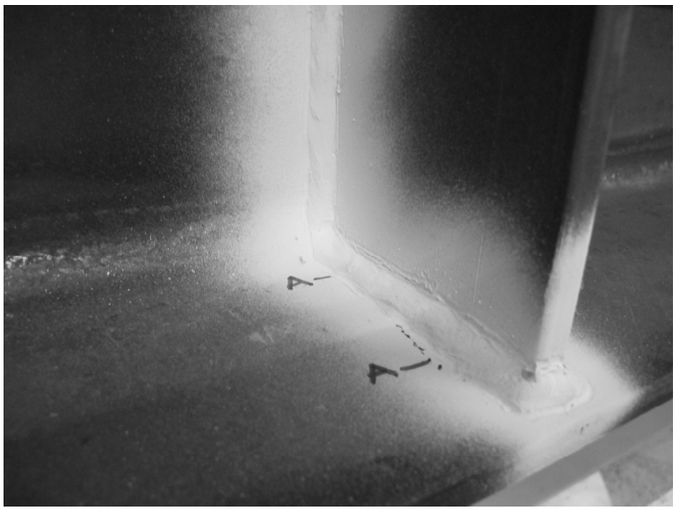

Figure 4. Typical crack at weld toe of transverse stiffener of beam test series T1

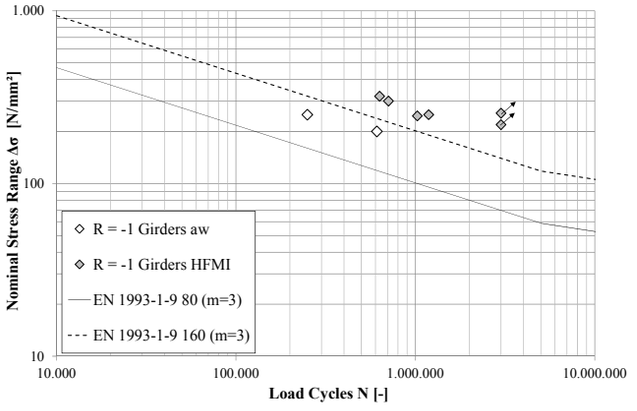

Figure 5. Results of beam test series T1 depending on the treatment-state compared to FAT-classes given in EN 1993-1-9

Figure 5 shows the single test results in a S-N-curve. The difference between HFMI-treated and as-welded series is clear. Whereas the difference between the two different HFMI-methods is not significant. In order to be able to compare to a non-treated state of standards, two fatigue categories, namely 80 MPa representing the as-welded transverse stiffener and 160 MPa, representing base material and

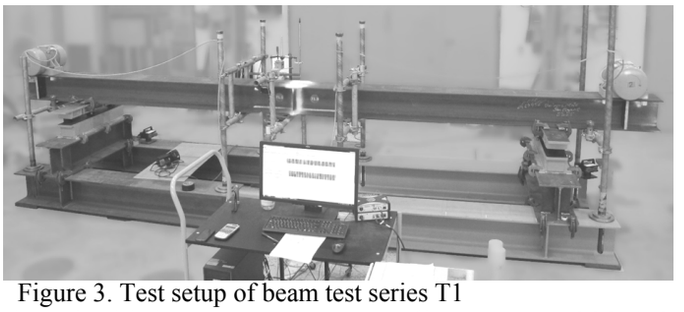

Figure 3. Test setup of beam test series T1

thus the highest category, according to EN 1993-1-9 (2005), are given. The potential of improvement due to HFMI-treatment is obvious, but also the as-welded state shows high potential in comparison to fatigue category 80 MPa.

3.3 *Test setup beam test series T2 (R = 0.1)*

In contrast to series T1, beam series T2 was regularly tested in a 4-point-bending test setup with two servo-hydraulic cylinders adapted to a testing portal. This setup enabled a testing speed of 0.8 to 2.5 Hz with a maximum dynamic loading of 800 kN per cylinder. In order to get secured results six transverse stiffeners were welded to the beam, so that some kind of redundancy was created.

3.4 *Cracks and results beam test series T2 (R = 0.1)*

Typical crack location can be seen in Figure 6. With the exception of one test specimen, all other beam tests cracked from the weld toe of the HFMI-treated weld connecting the transverse stiffener to the bottom flange. By opening the cracked cross section, it could be revealed, that the cracks usually started close to the area of the rounding off radius.

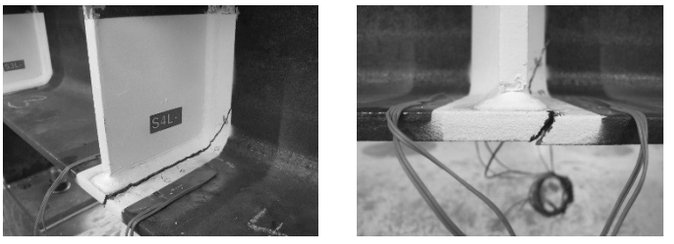

Figure 6. Typical failure mode of beam test series T2

The S-N-curve in Figure 7 shows the single test results, also compared to as-welded state of unloaded transverse attachment and base material category according to EN 1993-1-9 (2005). For the as-welded state it can be clearly seen, that comparatively high number of load cycles could be reached, which seems to be untypical for beam tests. On the other side the HFMI-treated girder test results scatter around fatigue category 160, clearly showing a higher slope than m = 3.

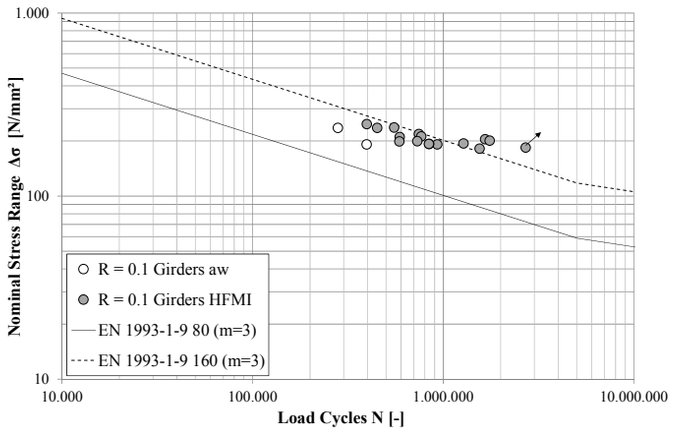

Figure 7. Results of beam test series T2 compared to FAT-classes given in EN 1993-1-9

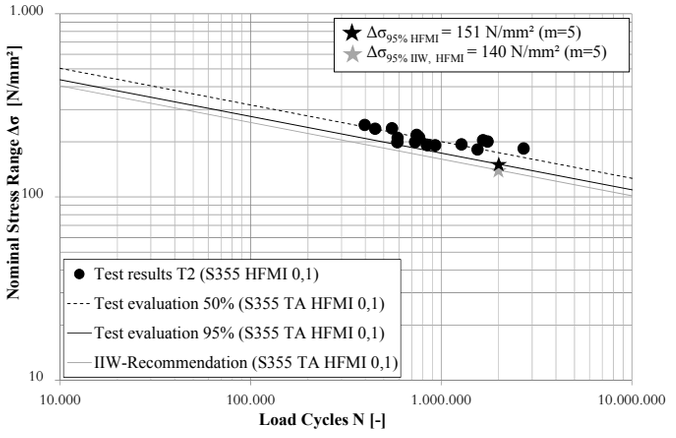

Figure 8. Evaluated results of HFMI-treated beam series T2 compared to IIW-Recommendations

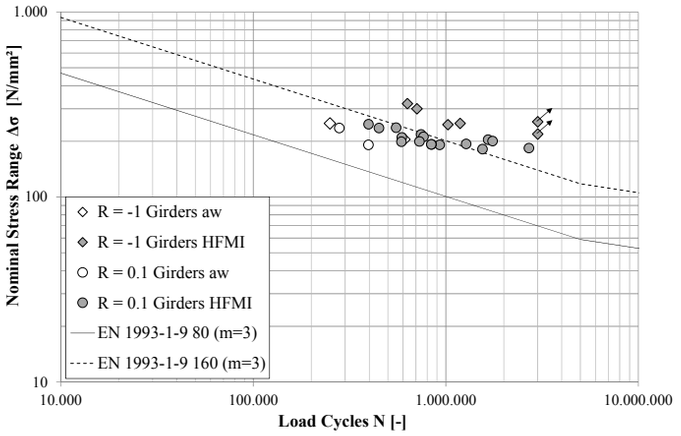

Figure 9. Results of beam test series T1 and T2 compared to FAT-classes given in EN 1993-1-9

3.5 *Evaluation and comparison of results concerning mean stress effects*

The evaluation has been conducted as a linear regression analysis according to Sedlacek et al. (2007) with a fix slope for HFMI-treatment of m = 5. Run-outs have been excluded from evaluation process.
Differences between the two applied HFMI methods are not significant, thus both methods can be evaluated together.

All four as-welded (aw) beam test results are clearly lower than HFMI-treated beams, but widely above 80 MPa.

Figure 8 shows the S-N-curve with the evaluation of HFMI-treated beam test series T2. For comparison reasons the IIW-Recommendation for stress range R = 0.1 and steel grade S355 is given. The evaluation leads to a reference value of fatigue strength at two million cycles of $\Delta\sigma_{c,\,HFMI,\,0.1,\,S355,\,BEAM} = 151$ N/mm² under the assumption of a fixed slope of m = 5. The assumption of a fixed slope of m = 5 is a bit advantageous in this case, but is necessary due to the low amount of test results. It can be concluded that even the beam test results, which are supposed to be worse than small scale test results, lie above the IIW-recommendation of $\Delta\sigma_{c,\,HFMI,\,0.1,\,S355} = 140$ N/mm².
Figure 9 shows the comparison of test results T1 and T2 regarding the mean stress effect. There is a visible difference between the HFMI-treated state, but the difference for the as-welded state is not clear. That might be owed to the low amount of as welded-girder tests.

4 EVALUATION OF MEAN STRESS EFFECT OF HFMI-TREATED WELDS

4.1 *General*

It is well known, that fatigue loadings with differing mean stress levels result in different fatigue performance for non-welded or stress-relieved welded construction details.
That is due to the superposition of residual and loading stresses. Whereas for welded construction details the residual stresses are almost equal to the yield strength, the quantity of loading stress is not of importance because the yield strength will easily be reached anyhow, so that no benefits due to compressive loading is assumed, see Gurney (1979).
EN 1993-1-9 takes this beneficial impact on the fatigue strength into account by reducing the value on the load side, namely the effective stress range $\Delta\sigma_{E,2}$, see equation (1).

$$\Delta\sigma = \left|\sigma_{max}\right| + 0.6 \cdot \left|\sigma_{min}\right| \quad (1)$$

Regarding HFMI treated welds, the question arises if the introduced compressive stresses lead to the same beneficial effects as in the non-welded or stress-relieved state.

4.2 *Collection of HFMI-treated data*

In order to be able to evaluate the huge amount of existing fatigue data on HFMI treated tests in the frame of the project a data base has been developed. Within this data base all accessible, existing and relevant test data of European and German test series have been collected and catalogued. All available relevant test data of both research partners were integrated with regard to the aim to filter the test data concerning influencing criteria and evaluate them. Thus it is possible to filter data, sorting them for example by stress ratios.

4.3 *Evaluation of HFMI-treated test data*

4.3.1 *Overview*

All single effects were evaluated in a group of data depending on the same conditions, but not necessarily of the same series. For example the mean stress effect was evaluated differing by construction detail and yield strength. So only different series with the same condition, were evaluated together in order to be independent of influencing parameters.

The evaluation has been conducted according to Sedlacek et al (2007) with a variable and a fixed slope for HFMI-treatment $m = 5$ and as-welded $m = 3$.

The mean stress effect of the HFMI treated test series is illustrated with the help of Haigh diagrams. If only the stress amplitude of test data would be influencing the fatigue behavior, one could draw a horizontal line connecting the points of different mean stress levels of each series. The evaluated stress ratios R are given with dashed lines.

4.3.2 *Transverse stiffener*

The results of the evaluated test data behave as expected for the stress ratios $R = 0.1$ and $R = -1.0$, namely $R = -1.0$ being beneficially higher than $R = 0.1$. Regarding the critical stress ratio $R = 0.5$ the results show less critical values than expected. It has to be mentioned that the evaluated series of $R = 0.5$ contain only few test data, but the tendency shows almost the same performance as for $R = 0.1$. It seems that there is no strong decrease of fatigue strength between the stress ratios $R = 0.1$ and 0.5 for the transverse stiffener.

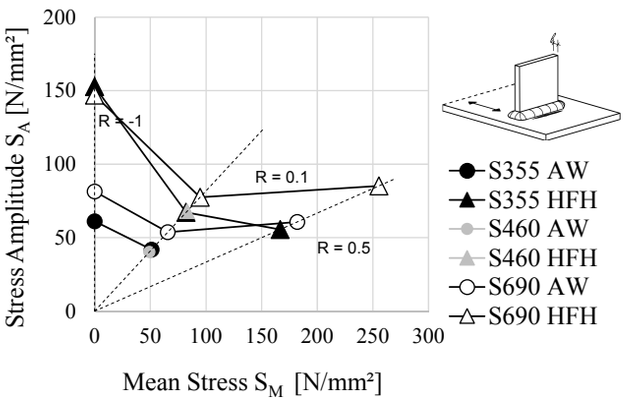

Figure 10. Haigh diagram showing mean stress effect of unloaded transverse attachment

4.3.3 *Loaded butt weld*

Regarding the evaluated test data of the transverse loaded butt weld differentiated by steel grades, the potential of alternate loading ($R = -1.0$) is obvious. In comparison to the transverse attachment, less test data could be found and thus evaluated, so that ensured statements can only be drawn for steel grade of S690. Similarities in unexpected positive behavior in comparison to the unloaded transverse attachment regarding the stress ratio $R = 0.5$ are given.

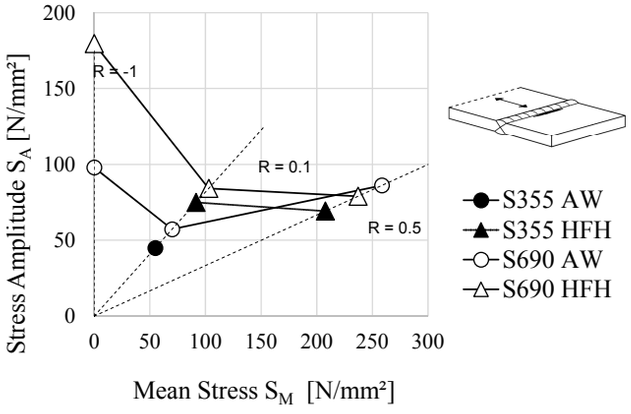

Figure 11. Haigh diagram showing mean stress effect of transverse loaded butt weld

4.3.4 *Unloaded longitudinal attachment*

By reason of a small data set covering other stress ratios than $R = 0.1$, it is difficult to draw conclusions on the mean stress effect for unloaded longitudinal attachments. The missing data are mainly due to problems during the testing execution on the longitudinal stiffener. It often occurs, that if the weld toe of the longitudinal attachment is improved due to HFMI-treatment, the crack is starting from the weld root.

Although there are only few data sets for unloaded longitudinal stiffener the tendency for the available data is identifiable. It can clearly be seen from Figure 12, that the influence of the mean stress tends to be milder for the HFMI-treated unloaded longitudinal attachment for the stress ratios $R = -1.0$ to

R = 0.1, than for the previous discussed details. This might result from the very sharp notch and thus the higher stress concentration for the frontal weld toe. Sonsino (1994) has verified a similar behavior of extreme sharp longitudinal notch within tests of stress relief heat treatment. This explains also the lower effectiveness of HFMI-treatment compared to the other investigated details.
It is known that the higher the notch intensity, the less the mean stress effects the fatigue strength of a detail.

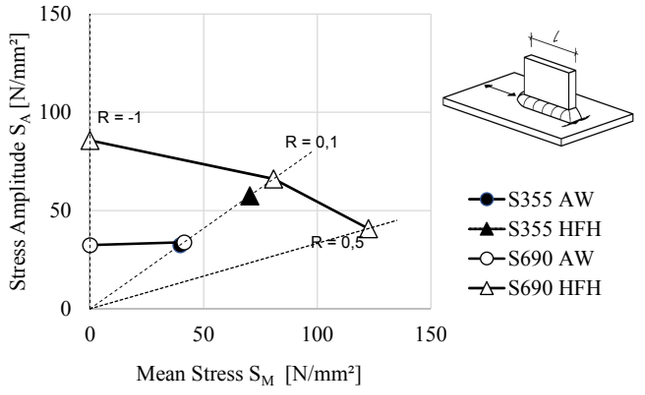

Figure 12. Haigh diagram showing mean stress effect of unloaded longitudinal attachment

4.3.5 *Conclusions*

The mean stress effects could be shown for the three investigated construction details. Whereas two of the details, the unloaded transverse stiffener and the transverse loaded butt welds showed a clear dependency from the quantity of the mean stress, the unloaded longitudinal stiffener showed milder behavior concerning the stress ratios R = -1.0 and R = 0.1. When formulating the DASt-Guideline on the design of HFMI-treated welds the different levels of sensitivity on effects depending on the type of construction detail will be integrated.

4.4 *Assessment of test data with regard to the IIW-recommendations*

As already mentioned in chapter 1.2 the recommendations of the IIW by Marquis & Barsoum (2016) are the most current and extensive ones. Thus, it is useful to evaluate their approach considering the latest findings of the mean stress influence on HFMI-treated welds.
In Marquis & Barsoum (2016) the improvement due to HFMI-treatment is considered by stepwise increase of fatigue classes (FAT-Class) depending on the type of steel grade, from 4 to 8 FAT classes.
In regard to the mean stress influence, the IIW-recommendations differ between four different stress ratios R. In order to consider a less favorable stress ratio level, a stepwise reduction is foreseen. As there is no data available for R = 0.52, that stress ratio gives the limitation.

Figure 13 shows the determination process for an unloaded transverse stiffener of S355 with a stress ratio of R = 0.1 as well as a stress ratio of R = -1.0. Finally, the determination of both stress ratios ends up at the same improved FAT-class, namely 140 MPa due to the missing differentiation. As could be shown in 4.3.2 the loading with a stress ratio of R = -1.0 is much more favourable and should be considered with its potential with further increase of fatigue strength.

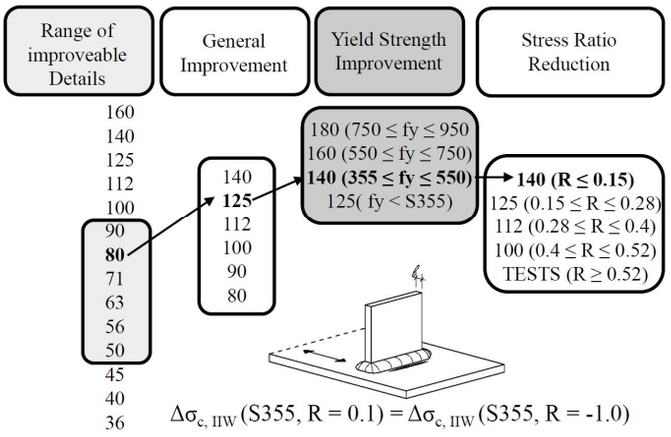

Figure 13. Example for determination of improved fatigue resistance for HFMI-treated transverse stiffener of S355 with R = 0.1 and R = -1.0 according to IIW-Recommendations

5 CONCLUSIONS AND OUTLOOK

Within this paper latest findings of the DASt-AiF project “Development of a DASt-Guideline for High Frequency Mechanical Impact treatments” were presented. In the beginning the aim of the project, namely to develop a German DASt-Guideline considering the effectiveness of HFMI treatment in the fatigue design process could be shown.

In order to complete gaps in knowledge on certain influencing effects on the HFMI-improved fatigue strength a large test program was motivated and presented. Out of this, latest results on the conducted beam test series T1 and T2 focusing on the mean stress effects in large structures were summarized and evaluated.

Additionally collected HFMI-fatigue test data concerning the mean stress influence were evaluated within the project and tendencies were shown for unloaded transverse attachments and transverse loaded butt welds. Thus, potential in formulating a design concept based on European standards was motivated regarding the mean stress effect out of several influencing factors.

It is obvious that implementing new techniques and rules into standards is a lengthy process, that has to be properly prepared with accurate and transparent background evaluation. But nonetheless, devel-

opment and adaption of standards is necessary work to be competitive to more modern construction techniques.

6 ACKNOWLEDGEMENT

The work presented has been carried out as part of a joint project “Development of a DASt-Guideline for high-frequency mechanical impact treatments”. This project of the research association DASt is financed over the AiF within the development program for industrial community research and development (IGF) from the Federal Ministry of Economic Affairs and Energy (BMWi) based on a decision of the German Bundestag.

This project is a cooperative research project with colleagues from the chair of Steel and Leightweight Structures of the Karlsruher Institute of Technology (KIT). The authors gratefully thank for their cooperation.

A special thank goes to the material providers “Stahlwerk Thüringen GmbH”, “Peiner Träger – Salzgitter Gruppe” and “voestalpine AG” for the donation of girders and plates.

Special acknowledgement is given to “EHS Engineering” formerly “Eiffel Deutschland Technology” for the fabrication of the test specimens.

Furthermore we gratefully thank “Pitec GmbH” and “DYNATEC GmbH” for their support by treating the specimens.

Statistical Analysis of Fatigue Test Data according to Eurocode 3

K. Drebenstedt & M. Euler
Institute of Structural Design, University of Stuttgart, Germany

ABSTRACT: The question how to correctly evaluate fatigue test data in order to establish the reference value $\Delta\sigma_C$ of the characteristic fatigue strength of steel structures according to the safety requirements of Eurocode 3 still leads to discussions. This paper is supposed to give an overview of the state-of-the-art on the statistical analysis of fatigue test data. Firstly, the classical methods to set up different types of two-sided statistical intervals such as confidence intervals, prediction intervals and tolerance intervals and their one-sided bounds are addressed. The different meanings of these intervals and bounds are pointed out. Secondly, the statistical method pursued by Eurocode 0 is described which partly differs from the classical approach. Finally, the formal requirements of Eurocode 0 and Eurocode 3 are summarized, and it is highlighted in how far the aforementioned methods meet these requirements. To illustrate the application of the aforementioned methods, a particular test data set is assessed with forced slope of the *S-N* curve in a worked example. The reference values $\Delta\sigma_C$ obtained by the different methods for the test data set are compared.

1 INTRODUCTION

The fatigue strength of constructional details in steel structures is described by its characteristic reference value $\Delta\sigma_C$ for $2 \cdot 10^6$ stress cycles according to Eurocode 3 with respect to their nominal stress range. In addition to random loading effects, the fatigue strength is mainly affected by *microgeometrical* influences, e. g. shape discontinuities of weld toes and roots, *macrogeometrical* influences, e. g. tolerances in form of misalignments and *metallurgical* inhomogeneities, e. g. differing material properties in weld and heat affected zone due to slight welding process discontinuities.

Due to small unavoidable sample-to-sample variations of the aforementioned influences, experimental test data always show a random scatter (sampling error) even under identical test conditions.

Facing the unknown sampling error, the test data should be evaluated according to the same and commonly agreed criteria at least. Although there has been the need for a standardized statistical analysis of fatigue test data to define reliable values $\Delta\sigma_C$ for decades, however, in practice these values are differently derived limiting their comparability.

In the following, the attempt is made to clarify the different used statistical methods as a basis for discussion in order to come to a common ground for determining comparable values $\Delta\sigma_C$.

2 STATISTICAL TERMS

2.1 *High cycle fatigue of steel structure*

For high cycle fatigue of steel structures, the applied stress range, S, and the corresponding number of stress cycles to failure, N, observed in fatigue tests obey an exponential law (Basquin 1910, p. 627):

$$N = a \cdot S^{-m} \tag{1}$$

On a log-log scale with decimal logarithm (base 10), the test data can generally be allocated to a straight line expressing a linear dependency of the number of stress cycles on the stress range (Fig. 1):

$$\log N = \log a - m \cdot \log S \tag{2}$$

The intercept a in Figure 1 describes the theoretical locus where the straight-line *S-N* relationship of the finite life region intersects the horizontal axis $S = 10^0 = 1$. The parameter m stands for the slope of the straight line; exactly speaking, it represents the negative inverse of the mathematical slope.

2.2 *Regression analysis*

In frame of fatigue, the regression analysis is an extracting technique to reveal the effects that S exerts on N. It tries to define a relationship in form of a mathematical function illustrated as *S-N* curve.

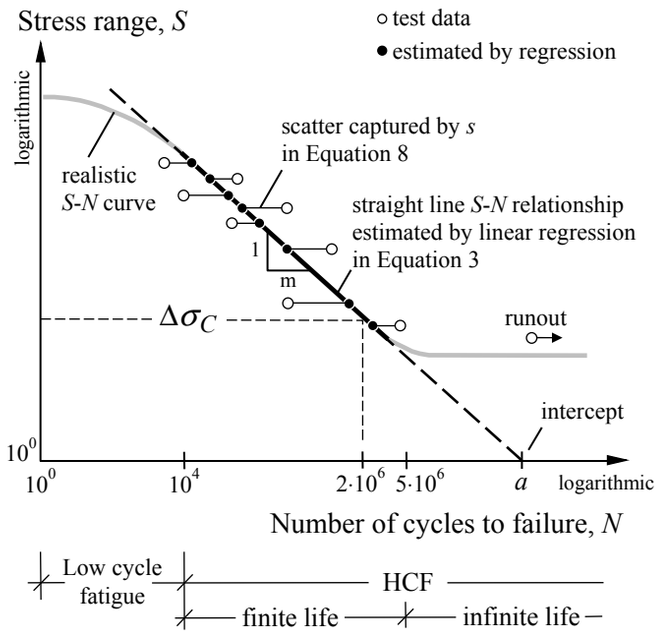

Figure 1. Regions of realistic *S-N* curve, finite life region of high cycle fatigue (HCF) described by linear regression

The stress range S is normally set to a desired value by the designer and, therefore, the independent variable within this functional relationship. Any deliberate change of S affects the number of stress cycles N as dependent response variable.

Generally, the real parameters a and m of the true *S-N* relationship (fatigue resistance model) in Equations 1 & 2 are unknown for a particular constructional detail as it is impossible to examine the whole population (all possible occurrences of S and N). Therefore, both parameters have to be substituted by the estimates $\hat{a}$ and $\hat{m}$ based on the information of a limited number of fatigue tests:

$$\log \hat{N} = \log \hat{a} - \hat{m} \cdot \log S \tag{3}$$

where $\hat{N}$ denotes the predicted number of stress cycles for a given stress range S when the linear regression function of Equation 3 is applied.

2.3 *Computation of linear regression function*

There are several methods for estimating $\hat{a}$ and $\hat{m}$ of the regression function of Equation 3 from which the Least Square Method is most common. It achieves the best fit with the test data through minimizing the sum of squares of deviations in Equation 4.

$$\sum {e_i}^2 \rightarrow \min \tag{4}$$

The so-called residual e_i in Equation 4 is the deviation of a measured number of stress cycles to failure, N_i, of the ith fatigue test from its corresponding value $\hat{N}_i$ obtained by use of the fitted linear regression function (Equation 3) as an estimate of the true *S-N* curve (Draper & Smith 1966, p. 14 and 86). It is defined by Equation 5 and represents the amount of the *S-N* relationship which the estimated regression function (Equation 3) fails to explain.

$$e_i = \log N_i - \log \hat{N}_i \tag{5}$$

The parameters $\hat{a}$ and $\hat{m}$ are obtained by setting the partial derivatives of Equation 4 with respect to $\hat{a}$ and $\hat{m}$ to zero leading to Equations 6 & 7:

$$\hat{m} = -\frac{n \cdot \sum (\log S_i \cdot \log N_i) - \sum \log S_i \cdot \sum \log N_i}{n \cdot \sum (\log S_i)^2 - (\sum \log S_i)^2} \tag{6}$$

$$\log \hat{a} = \frac{1}{n} \cdot \left(\sum \log N_i + \hat{m} \cdot \sum \log S_i \right) = \overline{N} + \hat{m} \cdot \overline{S} \tag{7}$$

where n is the sample size (number of fatigue test data), i is the index of the single fatigue test, and $\overline{N}$ and $\overline{S}$ are the mean values of the sample.

An important restriction of the Least Square Method is the exclusion of statistical outliers as all test data are equally weighted. An outlier is a data point that is far greater or smaller than the rest of the test data and lies three or four standard deviations or even further from the mean of the sample in Figure 1 (Draper & Smith 1966, p. 94). Particularly in fatigue, tests which have resisted $5 \cdot 10^6$ stress cycles and more and which had been terminated before failure, so-called runouts, cannot be accounted for when computing the linear regression function describing the finite life region of HCF.

2.4 *Precision of linear regression*

The linear regression function is derived on the basis of certain assumptions and normally suffers from a lack of fit. As the unknown parameters a and m of the true *S-N* curve are substituted by the estimates $\hat{a}$ and $\hat{m}$ indicating a statistical uncertainty (sampling error), it is only possible to determine the residuals e_i rather than errors (meaning the deviations between test data and true *S-N* curve).

Assuming that there is no bias error (meaning the model of regression function is correct), the residuals are random deviations and the residual mean square s^2 of the sample can be used as an estimate of the error variance σ^2 of the population (Draper & Smith 1966, p. 27). Thus, the estimate s of the standard deviation in terms of $\log N$ (see Figure 1) amounts to

$$s = \sqrt{\frac{\sum [\log N_i - (\log \hat{a} - \hat{m} \cdot \log S_i)]^2}{dof}} \tag{8}$$

where *dof* stands for the degrees of freedom.

Generally, the degrees of freedom in Equation 8 amount to the number of independent test data, n, minus the number of parameters of the regression function being estimated. For a given slope and intercept, $n-2$ of n test data can freely vary. The

knowledge of the $n-2$ test data allows to calculate what the $(n-1)$th and the nth test data must be in order to produce the given slope and intercept (Wood 2011). Following this reasoning, a linear regression with free slope and intercept exhibits $n-2$ degrees of freedom as all n test data are independent.

2.5 *Prior information*

Many constructional details of steel structures exhibit a similar fatigue behaviour. For example, the statistical analysis of hundreds of fatigue tests on welded joints in structural steels proved the validity to assume a uniform slope and scatter band of the *S-N* curves (Haibach et al. 1981, p. 33). Therefore, the slope of the *S-N* curves might be regarded as known due to prior information for welded constructional details (Haibach 2006, p. 527).

In cases where the slope m is forced to be of a certain value, Equation 6 can be skipped, and only estimate $\hat{a}$ has to be determined by Equation 7. Consequently, the estimate s of standard deviation according to Equation 8 comprises only $n-1$ degrees of freedom (Wood 2011).

2.6 *Design S-N curves*

The *S-N* curve of a particular constructional detail obtained by linear regression represents the mean fatigue resistance of the tested samples meaning that one half of additional samples of the same kind is expected to survive and the other half to fall below this curve (50%-survival). For design purpose such a low survival probability is unacceptable even if the *S-N* curve has been estimated from an infinitely large sample (no sampling error). In any case, a transformation of the mean *S-N* curve into a characteristic *S-N* curve with an appropriate survival probability (for example 95 %) is necessary. This requires the setup of statistical intervals and bounds.

3 STATISTICAL INTERVALS

3.1 *Preliminary remarks*

Because of their great importance for the fatigue design of steel structures, the explanations of the following sections are related to welded constructional details. As the slope m of the *S-N* curve of these details can be regarded as known due to prior knowledge, only the intercept a of the *S-N* curve is subject to statistical investigations.

In case of *S-N* curves with constrained slope, the lower and upper limits of all statistical intervals discussed in Section 3 are parallel. In the general case, statistical interval limits of the linear regression curve are hyperbolically shaped expressing that one might expect to make the "best" statistical statement in the "middle" of the investigated test range (Draper 1966, p. 22).

3.2 *Confidence interval / lower confidence bound*

In statistics, one differentiates between two-sided statistical intervals and one-sided statistical bounds (Hahn 1991, p. 31). In Figure 2a, a two-sided 95% confidence interval for the intercept of the *S-N* curve is depicted implying that the true value a of the whole population is expected to lie within this interval with 95% probability. The probability that the true intercept is either smaller than the lower or greater than upper interval limit amounts to 2.5%.

In case of fatigue, it is not necessary to confine the interval by an upper limit since overstrengths are not crucial. Here, a one-sided statistical lower bound is more appropriate representing a particular probability of survival. For example, the one-sided lower 95% confidence bound in Figure 2b claims that the true intercept of population lies above this limit with 95% probability. The probability of a lower intercept amounts to 5%. The lower confidence bound is computed by (Hahn & Meeker, Eq. 4.1):

$$\log \hat{a} - t_{1-\alpha,n-1} \cdot s \cdot \sqrt{\frac{1}{n}} \tag{9}$$

where t is the coefficient of Student's t distribution (Table A1), α is the significance level, $(1-\alpha)$ is the confidence level, $n-1$ stands for the degrees of freedom, n is the number of tests (sample size).

In general, a one-sided lower $100(1-\alpha)\%$ confidence bound is identical with the lower limit of a two-sided $100(1-2\alpha)\%$ confidence interval (Schneider & Maddox, p. 7). Therefore, the one-sided lower 95% bound in Figure 2b will coincide with the lower limit of a two-sided 90% interval.

In case of infinitely large sample size, the confidence interval diminishes as the estimated intercept obtained from the sample is identical with the true value of the population.

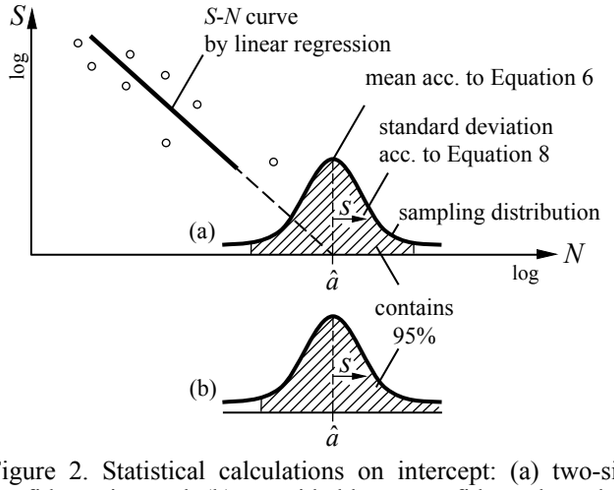

Figure 2. Statistical calculations on intercept: (a) two-sided confidence interval, (b) one-sided lower confidence bound

3.3 *Sampling distribution*

There is a tendency for errors that occur in many real situations to be normally distributed due to the Central Limit Theorem with mean zero and variance σ^2 (Draper & Smith 1966, p. 17). In case of no prior knowledge of the variance σ^2 of the population, this variance has to be estimated from the sample itself to describe the sampling distribution. Especially in case of decreasing sample size, the variance found from the sample becomes itself subject to an increasing error (Student 1908, p. 2) that requires in Equation 9 the usage of Student's t distribution rather than a normal (Gaussian) distribution (Fisher 1925, p. 42). See also Table A1.

3.4 *Prediction interval / lower prediction bound*

For design purpose the prediction interval and its lower bound is more important than the confidence interval as the latter only claims to include the true intercept of the *S-N* curve for past tests. The prediction interval is an estimate of an interval in which the mean of m future observations is expected to fall in with a certain probability. Similarly to Equation 9, the lower prediction bound for the intercept of the *S-N* curve is computed by (Hahn & Meeker 1991, Eq. 4.2):

$$\log \hat{a} - t_{1-\alpha,n-1} \cdot s \cdot \sqrt{\frac{1}{m} + \frac{1}{n}} \tag{10}$$

See Explanations of Equation 9.

In contrast to the confidence interval, the width of the prediction interval will not tend to zero in order to struggle with the uncertainty of future sampling even if the sample size becomes infinitely large.

An important special case arises when $m = 1$; this results in a prediction interval to contain a single future observation (Hahn & Meeker 1991, p. 61):

$$\log \hat{a} - t_{1-\alpha,n-1} \cdot s \cdot \sqrt{1 + \frac{1}{n}} \tag{11}$$

In fact, Equation 11 has been the most common way to derive the intercept of the characteristic *S-N* curve out of sampled data in the past (Brozetti et al. 1998, Sec. 5), (Gurney & Maddox 1973, p. 25).

3.5 *Tolerance interval / lower tolerance bound*

The tolerance interval describes an interval that is expected to enclose the intercept of a certain proportion, for example 95%, of the whole population. In (Holický 2005, p. A-23) the tolerance interval approach is also referred to as coverage method of fractile estimation. The lower tolerance bound is computed by (Hahn & Meeker 1991, p. 60):

$$\log \hat{a} - k_{1-\alpha,p,n} \cdot s \tag{12}$$

where $k_{1-\alpha,p,n}$ is the factor for an one-sided tolerance bound accounting for the covered proportion of the population, p, the confidence level $(1 - \alpha)$, and the sample size, n.

The coefficients $k_{1-\alpha,p,n}$ can be taken from Table A1 in connection with $n - 1$ degrees of freedom. According to Schneider & Maddox (2006, p. 17) coefficients for other degrees of freedom as they are necessary in case of linear regression with free slope are not really available.

Schneider & Maddox (2006) consider the usage of tolerance intervals/bounds as a fundamental change to previous practice leading to a risk of incompatibility with current design rules. Even so, they recommend their usage as a means of justifying design curves that are based on small samples, especially for critical applications, (p. 8).

Holický (2005, Fig. 4.3) demonstrates that the lower 95% tolerance bound with 75% confidence and the lower prediction bound for a single future test with 95% confidence are approximately equal, Figure 3. In maximum, the tolerance bound is more conservative (difference of coefficients ≤ 9%).

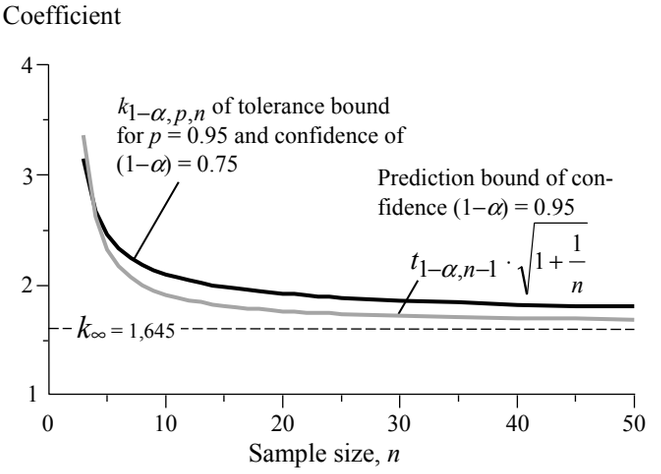

Figure 3. Coefficients of one-sided lower 95% tolerance bound and of lower prediction bound according (variance σ^2 unknown). See also Table A1.

4 STATISTICAL ANALYSIS ACCORDING TO EUROCODE 0

4.1 *Overview*

Eurocode 0 defines the reliability and safety concept of all European standards for structural design in civil engineering. The informative annex D contains rules for design assisted by testing.

In Section D.7 guidance on the statistical determination of a single property and in Section D.8 of a resistance model is given. In case of a *S-N* curve with constrained slope, the reference value $\Delta\sigma_C$ only requires a determination of a single property (meaning the intercept). The resistance model is basically known and only needs adjustment on the level of fatigue strength. In case of no prior information, the

value $\Delta\sigma_C$ requires the determination of all parameters of the *S-N* curve (resistance model).

4.2 *Statistical determination of a single property according to Eurocode 0*

The intercept of the *S-N* curve afflicted with a statistical uncertainty is assumed to be normally or lognormally distributed. As there is no prior knowledge about the mean, it is estimated by the average obtained from the sample. The variance σ^2 of the population is either known or unknown. In the latter case it is estimated by s^2 of the sample, see Equation 8.

The characteristic value of the intercept a_k is obtained by Eurocode 0 (2010, Equation D.1) using:

$$\log a_k = \log \hat{a} \cdot (1 - k_n \cdot V) \tag{13}$$

where $\hat{a}$ is the mean value according to Equation 7. Using s from Equation 8, the estimate for the coefficient of variation is explained as:

$$V = s / \log \hat{a} \tag{14}$$

The coefficient k_n is a factor to compute the 5% characteristic value (Table A1). It has following definition (Holický 2005, Tab. 4.4) for unknown variance σ^2:

$$k_n = t_{1-\alpha,n-1} \cdot \sqrt{1 + \frac{1}{n}} \tag{15}$$

Plugging Equation 14 into 13 gives Equation 11 and clarifies that the approach of Eurocode 0 for the determination of a single property basically leads to a lower prediction bound, compare Sec. 3.4.

4.3 *Statistical determination of resistance models*

4.3.1 *Probabilistic model of resistance*

A detailed description of the scientific background is given in (Holický, 2005). In the following, only some aspects of the calculation scheme are highlighted in terms of fatigue.

Generally, the mean *S-N* curve is considered as resistance model described by a function r_t identical with Equation 3 stating for any S_i:

$$r_{ti} = \log \hat{N}_i = \log \hat{a} - \hat{m} \cdot \log S_i \tag{16}$$

In the general case, the theoretical value r_{ti} predicted by the resistance function suffers from a lack of fit with the experimental value $r_{ei} = \log N_i$. By means of the so-called correction factor b, it is possible to adjust the resistance function r_t leading to the probabilistic model of resistance r_p afflicted by an error term δ representing the model uncertainty:

$$r_p = b \cdot r_t \cdot \delta \tag{17}$$

4.3.2 *Correction factor b*

To determine the fitting deviations, the experimental values r_{ei} are plotted against the predicted values r_{ti} obtained from Equation 16 in Figure 4. The factor b in Equation 17 is obtained by linear regression with zero intercept using the Least Square Method aiming at the same criterion as in Equation 4. Similar to Equation 6 that simplifies for zero intercept, the factor b is computed as:

$$b = \frac{\sum (r_{ei} \cdot r_{ti})}{\sum (r_{ti})^2} \tag{18}$$

It is understood that b equals 1 necessarily, if the average *S-N* curve (r_{ti}) is computed from the test data (r_{ei}) using the natural slope and intercept by linear regression. However for constrained slope, b differs from 1 if there is a difference between the natural and forced slope. In that case, the *S-N* curve obtained by linear regression does not fit the test data best. Nevertheless, the correction factor b seems to be close to 1 and, therefore, might be negligible in many practical cases.

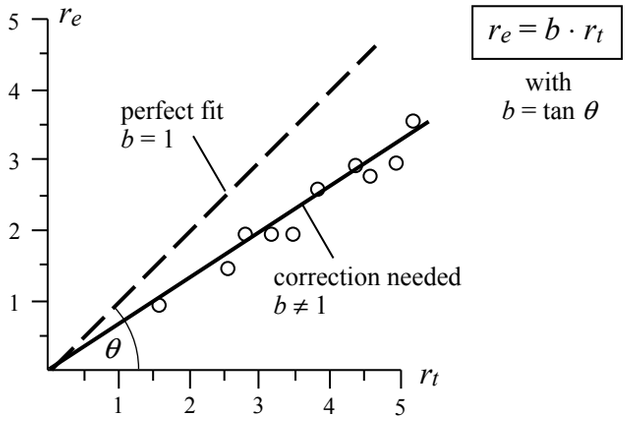

Figure 4. Comparison of experimental values r_e and theoretical values r_t of resistance in order to identify need of correction

4.3.3 *Coefficient of variation of "error" term*

The probabilistic model of resistance r_p is afflicted by a model uncertainty resulting in deviations between the predicted and experimental values. In absence of information this "error" has to be estimated assuming that $\delta > 0$ and that it is lognormally distributed. As the "error" term is multiplicative in Equation 17, the deviation δ_i is defined as:

$$\delta_i = \frac{r_{ei}}{r_{pi}} = \frac{r_{ei}}{b \cdot r_{ti}} \tag{19}$$

From probability theory it is known that the logarithm of a lognormally distributed random variable has a normal distribution. This dependency simplifies the estimation of the coefficient of variation V_δ if following transformation is performed:

$$\Delta_i = \ln(\delta_i) \tag{20}$$

The estimates of the mean $\overline{\Delta}$ and the variance s_Δ^2 can be computed by the known relations of normally distributed variables. Finally, it holds for the estimated coefficient of variation of the "error" term:

$$V_\delta = \sqrt{e^{s_\Delta^2} - 1} \tag{21}$$

4.3.4 *Coefficient of variation of probabilistic model*
In addition to V_δ, the coefficient of variation V_r of the probabilistic model depends on the coefficient $V_{rt} = V$ of the response variable N due to random changes in the basic variable S, see Equation 14. Thus, V_r sums up using the normal-lognormal relationship of probability theory:

$$V_r^2 = \left(1 + V_\delta^2\right)\left(1 + V_{rt}^2\right) - 1 \tag{22}$$

that simplifies in case of small variations as:

$$V_r^2 = V_\delta^2 + V_{rt}^2 \tag{23}$$

4.3.5 *Characteristic resistance function*
Finally, the characteristic resistance function is obtained introducing weighting factors α_{rt} and α_δ (Holický 2005, p. IV-15):

$$\log N_k = \log \hat{N} \cdot e^{-k_\infty \alpha_{rt} Q_{rt} - k_n \alpha_\delta Q_\delta - 0.5 Q^2} \tag{24}$$

where k_∞ is 1.64, k_n is computed according to Equation 15. See further explanations in Sec. 6.6.

5 FORMAL REQUIREMENTS OF EUROCODE 0 AND EUROCODE 3

Part 1-9 of Eurocode 3 (2010, Section 7.1) states how the available fatigue strengths of Eurocode had been derived if test data were available:

"Note 1 When test data were used to determine the appropriate detail category for a particular constructional detail, the value of the stress range $\Delta\sigma_C$ corresponding to a value of N_C = 2 million cycles were calculated for a 75% confidence level of 95% probability of survival for log N, taking into account the standard deviation and the sample size and residual stress effects. [...]"

As a logical consequence new test data should be evaluated in the same way. As this statement relates on survival, a one-sided lower statistical bound is supposed to be derived. Furthermore, two values of probability are specified. Thus, it is indirectly required to set up a lower tolerance bound of the mean *S-N* curve obtained by linear regression for 95% survival with 75% confidence.

6 WORKED EXAMPLES

6.1 *Overview*

A data set comprising n = 10 fatigue tests is statistically evaluated (Table 1). The slope of the *S-N* curve is forced to m = 3 based on prior knowledge.

Table 1. Data base for the statistical analysis

i	S_i [N/mm²]	N_i [–]	log S_i [–]	log N_i [–]
1	265	42,000	2.423	4.623
2	265	70,000	2.423	4.845
3	265	79,000	2.423	4.881
4	202	107,000	2.305	5.029
5	202	188,000	2.305	5.274
6	202	204,000	2.305	5.310
7	139	537,000	2.143	5.730
8	139	597,000	2.143	5.776
9	108	800,000	2.033	5.903
10	108	1,077,000	2.033	6.032
Σ			22.539	53.420

$$\log \hat{a} = 1/n \cdot \left(\sum \log N_i + m \cdot \sum \log S_i\right) \tag{7a}$$
$$= 1/10 \cdot \left(53.420 + 3 \cdot 22.539\right) = 12.104$$

Hence, the mean *S-N* curve is defined (Remark: Indeed, the natural slope is slightly greater with 3.102 resulting in an intercept of 12.334.):

$$\log \hat{N} = 12.104 - 3 \cdot \log S \tag{3a}$$

The standard deviation is estimated by

$$s = \sqrt{\frac{\sum \left[\log N_i - \left(\log \hat{a} - m \cdot \log S_i\right)\right]^2}{n-1}} = 0.1156 \tag{8a}$$

6.2 *Confidence interval of S-N curve's intercept*

The lower confidence bound from Equation 9 gives:

$$\log \hat{a} - t_{0.95,n-1} \cdot s \cdot \sqrt{1/n} \tag{9a}$$
$$= 12.104 - 1.833 \cdot 0.1156 \cdot \sqrt{1/10} = 12.04$$

where $t_{1-\alpha,n-1}$ is from Table A1 with $n = 10$ and $(1 - \alpha) = 0.95$.

6.3 *Prediction interval*

The lower prediction bound from Equation 11 gives:

$$\log \hat{a} - t_{0.95,n-1} \cdot s \cdot \sqrt{1 + \frac{1}{n}} \tag{11a}$$
$$= 12.104 - 1.833 \cdot 0.1156 \cdot \sqrt{1 + \frac{1}{10}} = 11.88$$

where $t_{1-\alpha,n-1}$ is taken from Table A1 with $n = 10$ and $(1 - \alpha) = 0.95$. Thus, the characteristic *S-N* curve is obtained as:

$$\log N_k = 11.88 - 3 \cdot \log S \quad (25)$$

The characteristic reference value $\Delta\sigma_C$ of the fatigue strength at $2 \cdot 10^6$ stress cycles amounts to

$$\log S_C = \frac{\log(2 \cdot 10^6) - 11{,}88}{-3} = 1.86 \quad (26)$$

$$S_C = \Delta\sigma_C = \mathbf{72.4}\ \text{N/mm}^2 \quad (27)$$

6.4 *Tolerance interval*

According to Section 5, Eurocode 3 Part 1-9 formally requires a one-side tolerance bound for the *S-N* curve's intercept computed by Equation 12:

$$\log \hat{a} - k_{1-\alpha,p,n} \cdot s \quad (12a)$$
$$= 12.104 - 2.103 \cdot 0.1156 = 11.86$$

where $t_{1-\alpha p,n}$ is taken form Table A1 with $n = 10$, $(1 - \alpha) = 0.75$, $p = 0.95$. Thus, the characteristic *S-N* curve can be written as:

$$\log N_k = 11.86 - 3 \cdot \log S \quad (28)$$

The characteristic reference value $\Delta\sigma_C$ of the fatigue strength at $2 \cdot 10^6$ stress cycles amounts to

$$\log S_C = \frac{\log(2 \cdot 10^6) - 11{,}86}{-3} = 1.853 \quad (29)$$

$$S_C = \Delta\sigma_C = \mathbf{71.3}\ \text{N/mm}^2 \quad (30)$$

6.5 *Statistical determination of a single property according to Eurocode 0*

The variance is computed according to Equation 14:

$$V = \frac{s}{\log \hat{a}} = \frac{0.1156}{12.104} = 0.00955 \quad (14a)$$

The characteristic value of intercept amounts to:

$$\log a_k = \log \hat{a} \cdot (1 - k_n \cdot V) \quad (13a)$$
$$= 12.104 \cdot (1 - 1.923 \cdot 0.00955) = 11.88$$

where k_n is taken from Table A1 with $n = 10$. Thus, the characteristic *S-N* curve can be written as:

$$\log N_k = 11.88 - 3 \cdot \log S \quad (31)$$

The characteristic reference value $\Delta\sigma_C$ of the fatigue strength at $2 \cdot 10^6$ stress cycles amounts to

$$\log S_C = \frac{\log(2 \cdot 10^6) - 11.88}{-3} = 1.86 \quad (32)$$

$$S_C = \Delta\sigma_C = \mathbf{72.4}\ \text{N/mm}^2 \quad (33)$$

6.6 *Statistical determination of a resistance model according to Eurocode 0*

Table 1 summarizes intermediate results necessary for the following calculations.

Table 1. Intermediate results

i	$r_{ei} = \log N_i$	$r_{ti} = \log \hat{N}_i$	$\delta_i = r_{ei}/r_{ti}$	$\Delta_i = \ln \delta_i$
1	4.623	4.834	0.956	-0.045
2	4.845	4.834	1.002	0.002
3	4.881	4.834	1.013	0.013
4	5.029	5.188	0.970	-0.031
5	5.274	5.188	1.017	0.017
6	5.310	5.188	1.024	0.023
7	5.730	5.675	1.010	0.010
8	5.776	5.675	1.018	0.018
9	5.903	6.003	0.983	-0.017
10	6.032	6.003	1.005	0.005
Σ	53.420	53.422		-0.005

$$b = \sum(r_{ei} \cdot r_{ti}) \Big/ \sum(r_{ti})^2 = 1.00023 \approx 1 \quad (18a)$$

$$\overline{\Delta} = \sum \Delta_i / n = -0.0005 = -0.0005 \quad (34)$$

$$s_\Delta^2 = \frac{\sum(\Delta_i - \overline{\Delta})^2}{n-1} = 5.164 \cdot 10^{-4} \quad (35)$$

$$V_\delta^2 = e^{s_\Delta^2} - 1 = 5.153 \cdot 10^{-4} \quad (21a)$$

$$V_{rt}^2 = V^2 = 0.00955^2 = 9.120 \cdot 10^{-5} \quad (36)$$

$$V_r^2 = V_\delta^2 + V_{rt}^2 = 6.078 \cdot 10^{-4} \quad (23a)$$

$$Q_{rt} = \sqrt{\ln(1 + V_{rt}^2)} = 0.00955 \quad (37)$$

$$Q_\delta = \sqrt{\ln(1 + V_\delta^2)} = 0.0227 \quad (38)$$

$$Q = \sqrt{\ln(1 + V_r^2)} = 0.0246 \quad (39)$$

$$\alpha_{rt} = Q_{rt} / Q = 0.387 \quad (40)$$

$$\alpha_\delta = Q_\delta / Q = 0.923 \quad (41)$$

Hence, the characteristic resistance function is:

$$\log N_k = \log \hat{N} \cdot e^{-k_\infty \alpha_{rt} Q_{rt} - k_n \alpha_\delta Q_\delta - 0.5 Q^2} \quad (24a)$$
$$= (12.104 - 3 \cdot \log S) \cdot 0.9545$$

where $k_\infty = 1.64$ and $k_n = 1.92$ are from Table A1 with $n = 10$. The characteristic reference value $\Delta\sigma_C$ of the fatigue strength at $2 \cdot 10^6$ stress cycles amounts to

$$\log S_C = \frac{\log(2 \cdot 10^6) / 0.9545 - 12.104}{-3} = 1.834 \quad (42)$$

$$S_C = \Delta\sigma_C = \mathbf{68.2}\ \text{N/mm}^2 \quad (43)$$

7 CONCLUSIONS

This paper compared the different methods to derive the reference value $\Delta\sigma_C$ of the fatigue strength at $2 \cdot 10^6$ stress cycles from test data. The main focus was laid on the statistical evaluation accounting for small sample sizes under the assumption of a constrained slope of the *S-N* curve based on prior knowledge.

Four methods were investigated: (i) prediction interval method, (ii) tolerance interval method, Eurocode 0 approaches for the determination (iii) of a single resistance property and (iv) of a resistance model.

The discussion of the safety requirements revealed that Eurocode 3 Part 1-9 formally requires a one-sided lower 95% tolerance bound with a 75% confidence for the determination of $\Delta\sigma_C$. Although such an interval cannot be produced by Annex D of Eurocode 0, it could be shown that a prediction interval with 95% confidence can serve as substitute.

To illustrate the difference of the aforementioned methods, a worked example was prepared. The most important findings are with respect to this example:

1 The Eurocode 0 approach for the statistical determination of a resistance model delivered the lowest reference value $\Delta\sigma_C = 68.2$ N/mm^2.
2 The prediction interval method being identical with the Eurocode 0 approach for the statistical determination of a single property provided the highest value $\Delta\sigma_C = 72.4$ N/mm^2.
3 The estimate of the tolerance interval approach was inbetween with $\Delta\sigma_C = 71.3$ N/mm^2.

To summarize, it is stated that the observed variations of $\Delta\sigma_C$ for the different methods are not very pronounced in terms of the worked example. Nevertheless, the outcome of the statistical evaluation of test data sets exhibiting a higher scatter and/or for cases with unconstrained slope might come to other conclusions.

The authors plan to expand their investigations for cases with an unforced slope of the *S-N* curve in near future.

ABSTRACT: Visual inspection is the most common form of condition monitoring used by bridge owners. Information derived from visual inspection data is commonly used to indicate the performance of bridge stocks and inform bridge management decisions. However, several studies have highlighted that the inherently subjective nature of the methods used to record this data can result in uncertainty, due to differences between different inspectors' perceptions of the severity and extent of defects. It is important for asset managers to understand the nature of this uncertainty and the implications for decision making. This paper reports the results of a study which compared scoring of bridge defects by pairs of independent inspectors across 200 bridge structures on England's strategic road network. A sample of 200 structures was selected to be representative of Highways England's stock with regard to, inter alia, *age*, *condition* and *structural form*. Routine Principal Inspections for these sample structures, undertaken every six years by the relevant maintaining agents, were also attended by inspectors from WSP Ltd, with defects scored independently by each inspector. The results of these comparisons were used to derive an empirical profile of the uncertainty in different individual defect severity and extent scores. Statistical methods were then used to derive empirical probability density functions for the values of bridge and stock level condition metrics according to the widely adopted *Bridge Condition Indicator* system. The reported results highlight trends in the reliability of individual defect scores and the impact of uncertainty on commonly used performance metrics.

1 INTRODUCTION

1.1 *Introduction*

Visual Inspection is the primary form of condition monitoring that is currently operated by bridge owners in the UK (e.g. McRobbie et al. 2015, Bennetts et al. 2016) and can be considered as a form of 'Damage Detection' in the wider framework of structural health monitoring systems (Webb et al. 2015). However, studies of the reliability of visual inspection have shown that the recorded data can be subject to significant uncertainty due to human factors (e.g. Moore et al. 2001, Lea & Middleton 2002). Moore et al. (2001) compared data from 49 different inspectors across 10 inspection tasks, comprising routine inspection of seven bridges and in-depth inspection of three bridges on the disused Pennsylvania Turnpike highway in the USA. Moore et al. (2001) concluded that the experience and physical capabilities of inspectors, and the environment in which inspections were undertaken had significant influence on the reliability of the inspection data recorded.

The data collected during visual inspections is increasingly used to inform decision-making, both at an individual structure level and at a strategic, whole

stock level (e.g. British Standards Institution 2014, UK Roads Liaison Group 2016). It is important to understand the reliability of the underlying data and its implications for the reliability and utility of derived *Condition Performance Indicators*, on which strategic decisions may be based.

1.2 *Inspection Data*

The industry practice for visual inspection of UK highway bridges is for a cycle of 'General Inspections' every 2 years, with 'Principal Inspections' every 6 years (Highways Agency 2007). During these inspections any defects observed on the structure are noted and photographed and recorded digitally later on. These defects are assigned to individual components in the bridge inventory and, for each defect, the defect type is recorded along with a severity code (the options for which are set out in Table 1) and an extent code from *SA* to *SE* (Table 2). Severity codes are categorised into different severity types, according to the defect type (Table 3), and are suffixed with an *S* if they are considered to present an immediate safety concern. Defects observed during inspections of bridges on the Highways England network are entered into the Structures Management Information System (SMIS) database.

Table 1: Mapping of Severity Codes to Severity Scores

Severity Codes				Severity
D	P	A	X	Score
D1	P1	A1	X1, X2	1
		A2		1.1
D2	P2	A3	X3	2
D3	P3	A4	X4	3
D3S			X4S	3.1
D4	P4		X5	4
	P4S			4.1
D4S				4.2
D5	P5			5

1.3 *Condition Performance Indicators*

In order to monitor the overall condition of individual structures or stocks of bridges, it is necessary to derive a measure of 'condition' from recorded defect information and the structure inventory. The *Bridge Condition Indicator* was developed for this purpose by WS Atkins Ltd (Sterritt 2002) for the County Surveyors' Society (CSS, now the Association of Directors of Environment, Economy, Planning and Transport, ADEPT) in the UK, and is adopted as a metric to score the condition of a bridge asset, or a population of assets, by most highway bridge owners in the UK. An understanding of the way in which the *Bridge Condition Indicators*, BCI_{Ave} and BCI_{Crit} are calculated is critical to understand the implications of the results presented in this paper. The process that is used by Highways England in SMIS is slightly different from the original CSS process (Sterritt 2002) and is set out as follows:

Table 2: Mapping of Extent Codes to Extent Scores

Extent Code	SA	SB	SC	SD	SE
Extent Score	0	0	0.1	0.3	0.7

Table 3: Defect Severity Types

Defect Severity Type	Description
D	Damage causing defects
P	Paint coating and protective system defects
A	Appearance related defects
X	Defects affecting adjacent areas

1. Defects in SMIS are recorded against individual components. Each defect score comprises a severity code and an extent code. These codes are mapped to numerical scores as shown in Tables 1 and 2.

2. For each component the defect with the highest severity score is selected. If there are multiple defects with the same severity then the defect with the highest extent score is selected.

3. All other defects on that component are disregarded.

4. For each component type, only defects with the same severity as the most severe are included.

5. A weighted average extent score based on the total size of all the components of that type is calculated.

6. The extent and severity scores are added to calculate an Element Condition Score (ECS) for each component type, on a scale from 1 to 5.7.

7. The Element Consequence Factor (ECF) for each component type is calculated from the ECS and the component's importance as shown in Table 4.

Table 4: Mapping of Element Consequence Factor (ECF)

Component Importance	Element Consequence Factor (ECF)
Very High	0.0
High	$0.3 - [(ECS - 1) \times 0.3/4]$
Medium	$0.6 - [(ECS - 1) \times 0.6/4]$
Low	$1.2 - [(ECS - 1) \times 1.2/4]$

8. The Element Condition Index (ECI) is found by subtracting the ECF from the ECS. The ECI cannot take a value below 1.0.

Table 5: Mapping of Element Importance Factor (EIF)

Component Importance	Element Importance Factor (EIF)
Very High	2.0
High	1.5
Medium	1.2
Low	1.0

9. The Element Importance Factor (EIF) is determined based on the importance of the component type, as shown in Table 5.

10. The Average Bridge Condition Score BCS_{Ave} is calculated by averaging the ECI values, weighted by the EIF for each component type.

11. The Critical Bridge Condition Score BCS_{Crit} is found by taking the maximum ECS for all 'Very High' Importance components.

12. BCS_{Ave} and BCS_{Crit} are both scores between 1 (best condition) and 5 (worst condition). These are mapped using an assigned quadratic function to give Bridge Condition Indicators BCI_{Ave} and BCI_{Crit} between 0 (worst condition) and 100 (best condition). The mapping functions are shown in Equations 1 and 2.

$$BCI_{Ave} = 100 - 2[{BCS_{Ave}}^2 + 6.5BCS_{Ave} - 7.5] \quad (1)$$

$$BCI_{Crit} = 100 - 2[{BCS_{Crit}}^2 + 6.5BCS_{Crit} - 7.5] \quad (2)$$

To calculate stock level BCI scores these steps are repeated for all bridges in the stock and an average is taken, weighted by each structure's deck area.

2 METHODOLOGY

2.1 *Random Sample*

A stratified sample of 200 bridges was selected by the authors from Highways England's stock for inclusion in this research. This sample was selected to be representative of the whole bridge stock, taking into account the following attributes: *Condition; Deck Type; Construction Type; Road Class; Age Group; Structure Type; Maintenance Region*; and *Type of Tensioning*. For example, the proportion of bridges in the sample with post-tensioning was selected to be the same as the proportion of post-tensioned structures in Highways England's whole stock of bridges.

The sample was selected computationally by randomly choosing several thousand possible samples of 200 from the list of structures due to be inspected over the duration of the project, and then selecting the random sample which was the best fit for the whole stock. The quality of fit, Q_{sample}, was evaluated as the sum of the mean of the squares of the differences in the proportions of each attribute value in each attribute, with the lower numbers indicating a better fit as shown in Equation 3.

$$Q_{sample} = \sum_{attributes} \frac{\sum_{attribute\ values}[P_{stock} - P_{sample}]^2}{N_{attribute\ values}} \quad (3)$$

2.2 *Independent Scoring of Defects*

For each of the 200 bridges in the sample, a WSP bridge inspector attended the site to independently inspect and record a sample of the defects present on the structure. For the large majority of the bridges in the sample, this coincided with the Service Providers' Principal Inspection. However, for a small number of the sample bridges, the independent inspectors visited the structure during a separate shift. For each visit, the inspectors recorded independent defect type, severity and extent information for a subset of the defects on the structure. These were limited to those visible at close quarters on the structure using the available access. 1373 individual defects were independently recorded by WSP's inspectors, of which 988 could be directly compared to those entered by the Service Providers' inspectors.

3 DATA ANALYSIS

3.1 *Reliability of defect recording*

For 385 (28%) of the defects recorded by WSP's inspectors, it was not possible to identify an equivalent defect in the Service Providers' Principal Inspection reports. This indicates variability in the reliability of defect identification by inspectors during visual inspections. Across the 988 independently recorded defects that could be directly compared to those recorded by the Service Providers as part of their Principal Inspection, 21% agreed on the assigned defect type, defect severity and extent. Overall, for 58% of the compared defects there was agreement on the type (e.g. *Map cracking*) of defect assigned, and agreement on the overall class of defect (e.g. *Cracks in concrete or masonry*) for 78%.

The level of agreement of defect types varied between different classes of defects, as shown in Figure 1. Particularly low reliability of defect class assignment was found within the *Cracks in concrete or masonry* and *Loss of concrete or masonry* defect classes. Investigation into the causes of these inconsistencies suggests that the process allows too many options of defect type within these classes. Consequently accuracy has been compromised in exchange for the availability of greater precision in defect type assignment. Furthermore, it was noted that while some defect types can only be confirmed through laboratory testing, the codes for these defects could, and had been, applied based only on visual inspection.

Similar results were found for the probabilities of the two inspectors recording the same defect severity or extent, with agreement of defect severity assignment for 53% of the compared defects, and agreement on defect extent for 59%. The same defect severity and extent were applied by the two inspectors for 34% of defects compared.

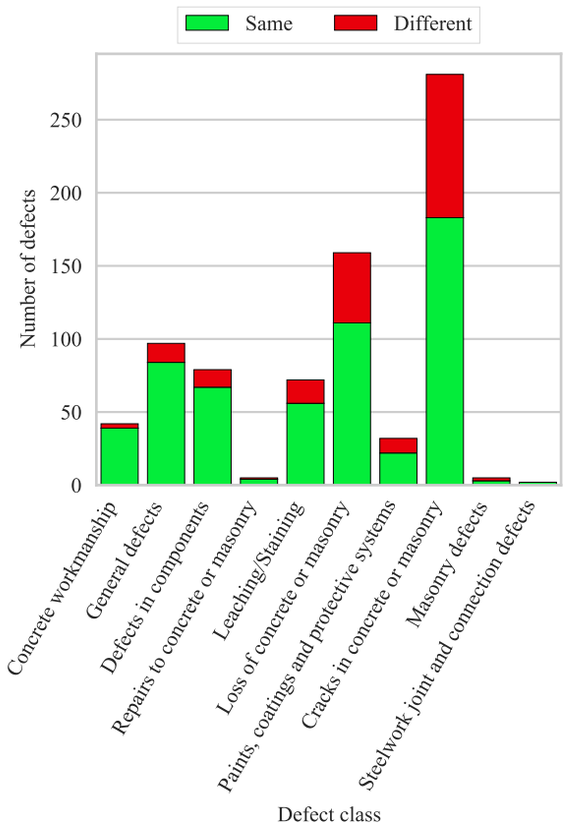

Figure 1: Comparison of defect type allocated by Service Provider inspector and WSP inspector for the defects included in this study, grouped by defect class

3.2 *Element Condition Scores*

For each recorded defect the extent and severity scores have been added to calculate an element condition score (ECS), giving a single measure to allow a comparison to be made between the two different inspectors (i.e. one each from WSP Ltd and Highways England's Service Provider for the maintenance area). These comparisons are presented in Figure 2, with each of the 988 comparisons represented as a blue marker. Due to the discrete nature of defect scores there are many overlapping markers. Red shading has therefore been added to indicate the density of markers at any point on the plot. Also shown, at the top and right of the plot, are histograms and gaussian kernel density estimations to provide an indication of the distribution of the scores from each inspector. While the two inspectors assigned the same, or a similar, defect severity and extent for many of the observed defects, there were substantial numbers of defects with a difference in ECS of more than 1. There were considerable discrepancies between the two inspectors' assessments of the severity of some defects, suggesting that the condition data for some structures could be markedly different, depending which individual inspector conducted the inspection.

3.3 *Trends in the reliability of defect scoring*

3.3.1 *Decision Trees*

Optimal decision trees allow presentation of the categorical factors that most influence a target variable (Quinlan 1986). To explore the factors affecting the reliability of defect scoring, a decision tree was generated to find the most informative multi-factor trends in the variation of defect score assignment (ECS) between two inspectors. For each compared defect the absolute difference between the ECS recorded by the WSP inspector and the Service Provider was calculated and banded into five groups as evenly as possible from those which were the same, to those which were the most different. Each pie chart in the decision tree has been drawn to represent the distribution of the ECS difference bandings within the sub-population below that point in the tree structure (Figure 3). The top *'All comparisons'* pie-chart represents the distribution of ECS difference in the full set of defect comparisons.

At each splitting point, the optimum attribute has been selected to partition the data in the way which provides the most information. The reduction in Shannon entropy (Shannon 1948) has been used to measure the information gained by a partition. For this measure, a perfect partition would be an attribute that perfectly split the structures into each of the ECS difference bands, whereas the worst possible partition would result in sub-populations that each had an even distribution of ECS difference within them. The size of each node's pie-chart has been drawn inversely proportional to its entropy and larger pie-charts have been plotted further from their parent node. This allows the most informative partitions to be readily identified. The following attributes were given to the algorithm from which it selected the optimum tree topology: *Component, WSP Class, WSP Extent, WSP Severity, Structure type, Construction type, Deck type, Structure use, Structure condition band, Distance from coast, Region, Age group*. Where:

WSP Class, WSP Extent & WSP Severity are the defect class, extent and severity, as recorded by the WSP inspector on site.

Age group splits the bridges into five bands from Youngest to Oldest with the same number of bridges in each band.

Structure condition band splits the bridges into five bands by their BCI_{Ave} condition score, from Best to Worse.

Nodes, and corresponding branches, have only been drawn if they represent at least 10 comparisons. The depth of the tree was limited to 3 partitions.

3.3.2 *Trends*

Figure 3 shows the most informative variables which affected the variation in ECS between two inspec-

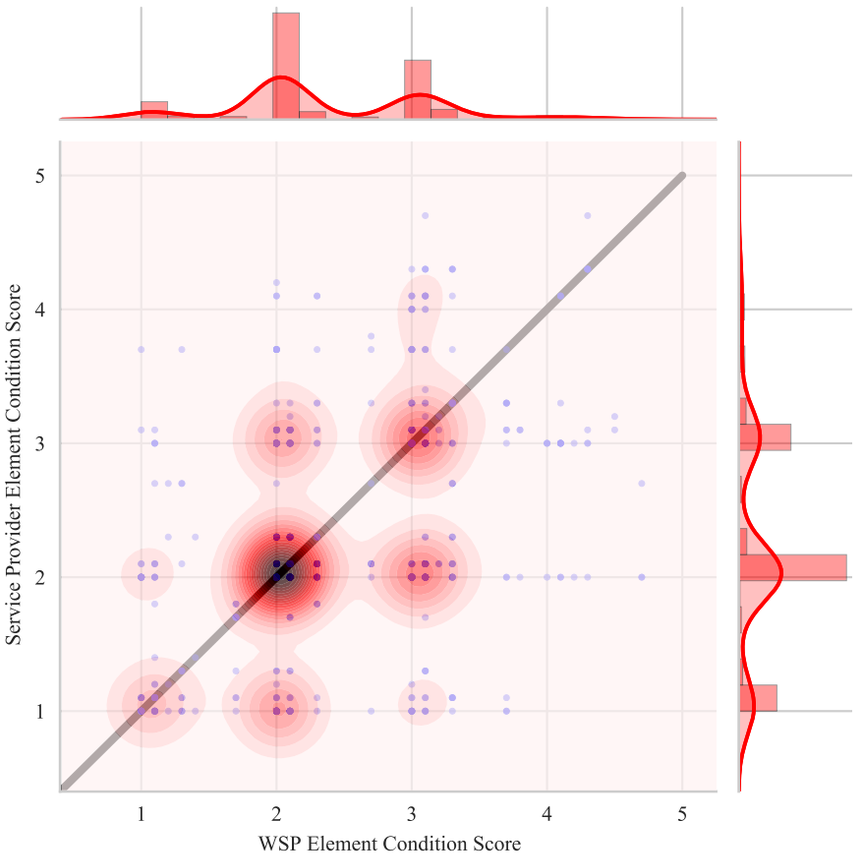

Figure 2: Comparison of element condition score allocated by Service Provider inspector and WSP inspector for the 988 defects included in the study. Red shading has been added to indicate the density of markers at any point on the plot.

tors. The *defect extent* had a significant influence. There was a much greater variation in ECS for defects with greater extent, than for those with lesser extents. This suggests that it is much harder to judge the severity of extensive defects. *Component type* was an important factor. Components such as *Road Vehicle Restraint Systems* and *Supports* were seen to exhibit much greater variation in scoring than components such as *Crossheads*, *Expansion joints* and *Wingwalls*. There was also a large degree of variation between different maintenance regions, suggesting that inspection guidance and practice are not consistent across the country. Structure details such as *age*, *structural form*, *construction material*, *road class*, and overall *structure condition* have a lesser influence on the reliability of defect scoring.

4 IMPLICATIONS OF DEFECT RATING VARIABILITY ON CONDITION METRICS

Given the variability of the visual inspection data collected by the owners of highway bridges, it is important to understand how this uncertainty affects derived metrics, which are used to inform strategy and decision making. The *Bridge Condition Indicator* calculation process is convoluted, and includes some non-linear steps, which means that it is difficult to derive directly the uncertainty in the resulting metrics from the uncertainty in the underlying data. Instead, Monte Carlo simulations have been used to derive this uncertainty empirically.

4.1 *Monte Carlo Simulations*

The 988 individual defect comparisons have been used to generate a table of probabilities mapping, for each extent code allocated by one inspector, the probabilities that a second inspector would allocate each of the possible extent codes. To avoid an implicit assumption that one inspector was 'correct', each observation was counted twice: once with the WSP inspector as Inspector 1 and once with the Service Provider's inspector as Inspector 1. This exercise was repeated for the severity scores. The resulting probabilities are presented in Table 6 and Table 7.

The probabilities have been derived from data from the sample of 200 structures only, however, since the structures were selected as a representative sample of the entire stock, it has been assumed that they are applicable to data from all structures in the stock. It is noted that no defects with a severity score of 4.1 or 5 were observed, by either inspector, on any of the structures in the sample. In the absence of additional information it has been assumed, for this analysis, that there was no variability in the scoring of defects with these severities. This will not significantly affect the results since defects with a severity score of 4.1 or 5 represented fewer than 1% of the approximately

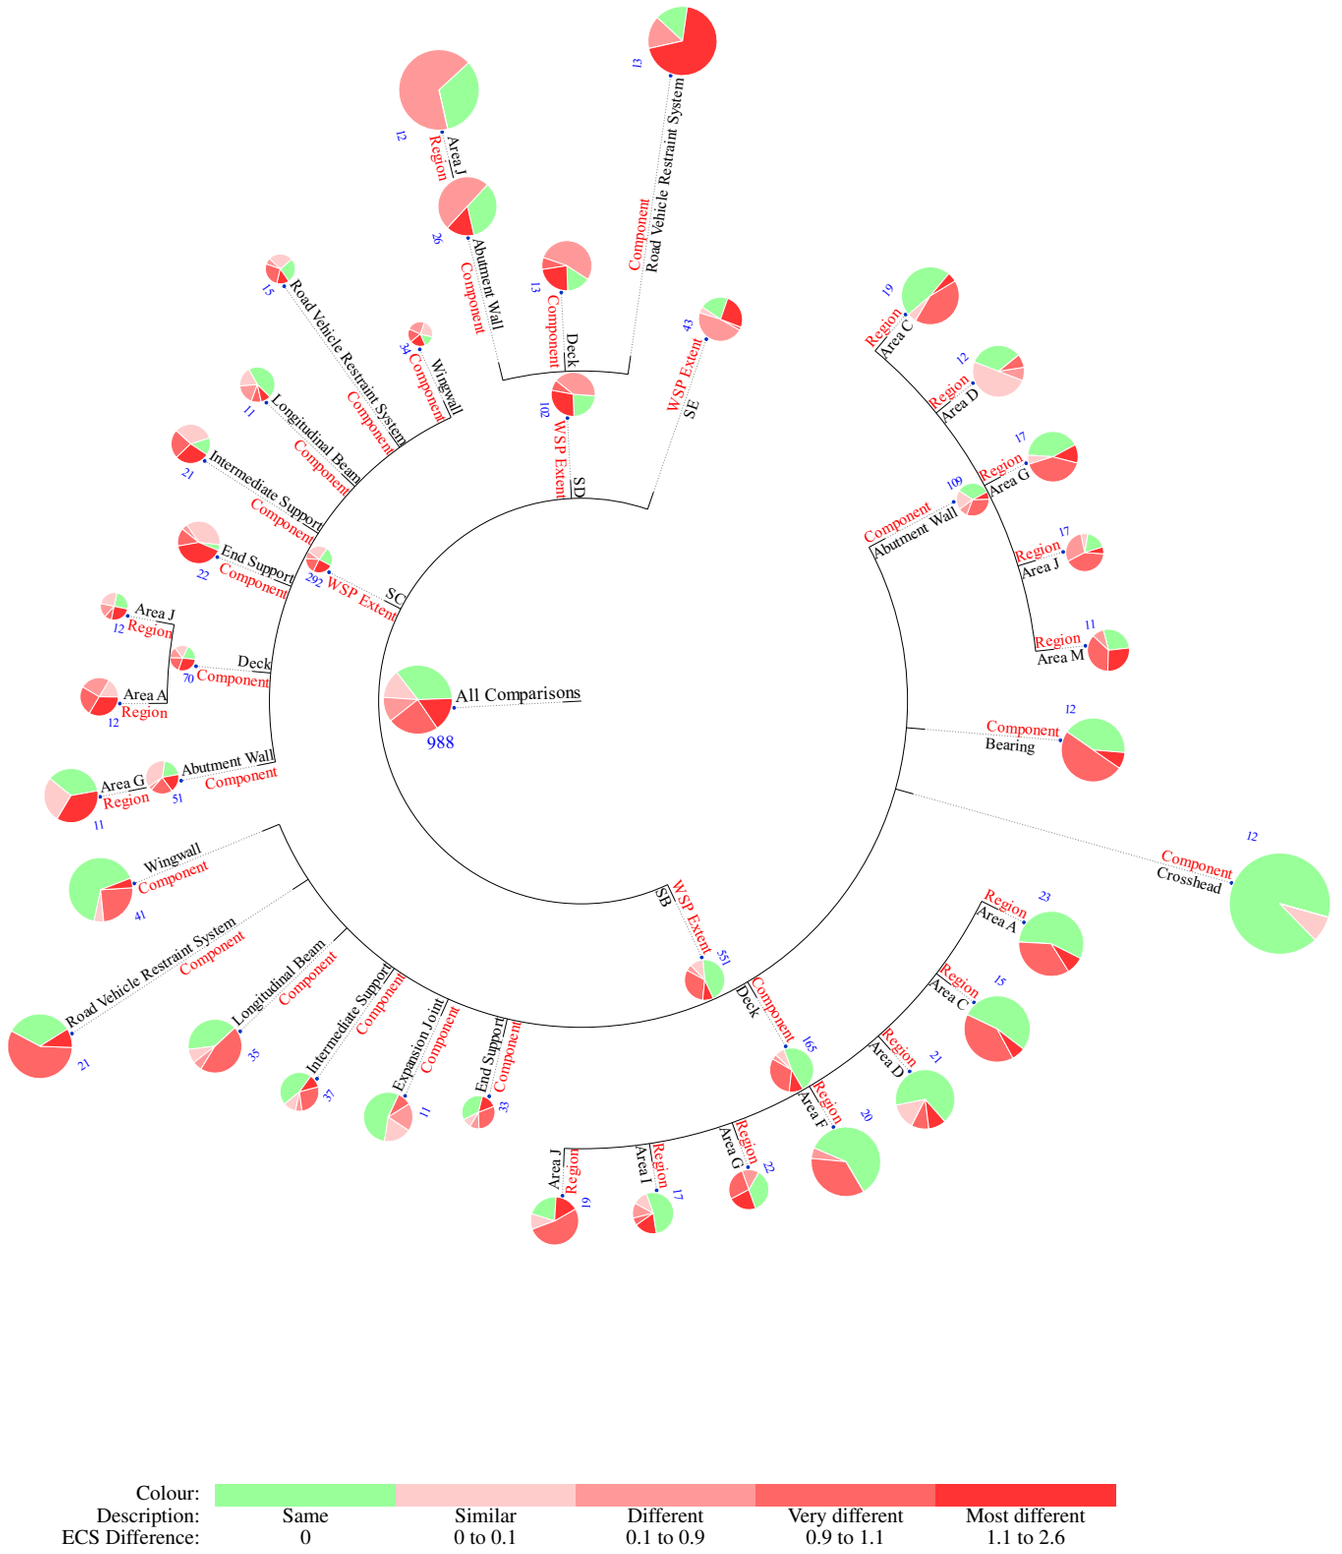

Figure 3: Decision Tree, showing the factors that most affect defect scoring agreement between inspectors.
(The blue number next to each pie chart denotes the number of comparisons that are included in that sub-population. The red text on each branch of the tree represents the attribute that the dataset has been partitioned by at that level, and the black text represents the value of the attribute.)

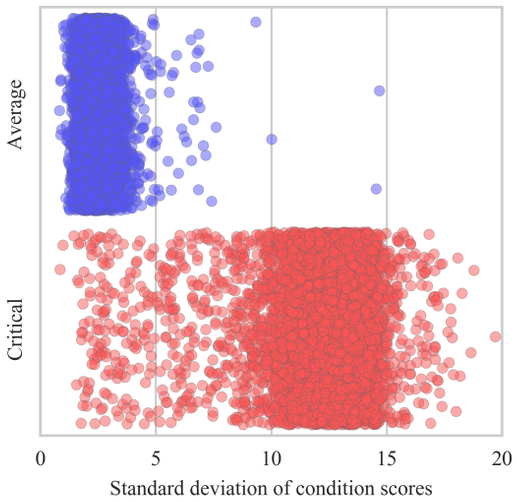

Figure 4: Standard deviation of condition scores obtained for each individual structure during Monte Carlo analysis

500,000 currently valid defects in the SMIS database.

The probability tables were used to vary the severity and extent scores for each of the currently valid defects in the SMIS database. These altered scores were then used to calculate new BCI_{Ave} and BCI_{Crit} scores for each bridge. This analysis was repeated for 1000 simulations.

Table 6: Probability table for defect extent codes

		Extent Code Allocated By Inspector 1			
		SB	SC	SD	SE
Probability of Inspector 2 Allocating Extent Code	SB	0.735	0.436	0.266	0.312
	SC	0.196	0.419	0.293	0.219
	SD	0.043	0.105	0.351	0.177
	SE	0.026	0.040	0.090	0.292

4.2 *Uncertainty in BCI scores for individual structures*

This analysis gives a set of plausible alternative values for the BCI scores for each individual structure. The level of uncertainty in BCI scores calculated by this method is dependent on a structure's inventory and defect assignments. It is therefore not possible to derive a definitive probability density function around a mean that would be valid for all structures. Instead, the standard deviations of each of these sets of alternative values have been plotted in Figure 4 for each of the approximately 7100 bridges on Highways England's network for which data was available. This shows that there is considerable uncertainty in the condition indicator scores for individual bridges; the BCI_{Ave} scores for most bridges have standard deviations of between 2 and 4 points, and the BCI_{Crit} scores for most bridges have standard deviations of between 10 and 15 points. The larger degree of uncertainty for BCI_{Crit} scores is due to them being governed by a very small number of defects on key structural components. In contrast, the BCI_{Ave} scores include defects from multiple component types and are therefore much less sensitive to variations in the scoring of individual defects.

In considering the implication of these results, it is useful to consider approximately what magnitude of change in a structure's condition score between consecutive inspections would be considered statistically significant. For a 95% confidence level, it is typically assumed that a change of two standard deviations would be required for the result to be considered significant. It follows that an apparent change in BCI_{Ave} score between inspections of less than about 6 points cannot be considered statistically significant. The larger uncertainty in BCI_{Crit} scores means that a change of around 25 points would be required to be significant.

A further consequence of this variation in individual structure BCI scores is that ranking structures by score (especially BCI_{Crit}) in order to prioritise maintenance would produce unreliable results. Thus, it would be undesirable to implement contractual conditions or targets that encourage prioritising interventions purely by structure condition scores.

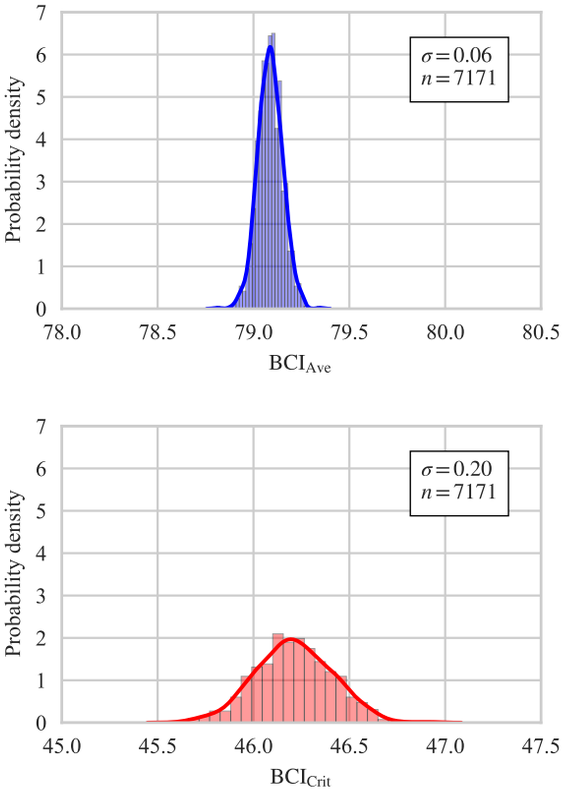

Figure 5: Empirical probability density function for the value of the BCI_{Ave} (top) and BCI_{Crit} (bottom) score for all structures in the stock

4.3 *Uncertainty in BCI scores for stocks of bridges*

Given that the computed variation in defect scores does not exhibit significant skew, convergence to the mean dictates that the uncertainty is reduced for metrics that include more data, as is the case for stock-

Table 7: Probability table for defect severity codes

		Severity score allocated by Inspector 1								
		1	1.1	2	3	3.1	4	4.1	4.2	5
Probability of Inspector 2 allocating Severity score	1	0.46	0.23	0.10	0.05	0.04	0.00	0.00	0.00	0.00
	1.1	0.03	0.31	0.01	0.01	0.00	0.00	0.00	0.00	0.00
	2	0.39	0.31	0.66	0.36	0.33	0.16	0.00	0.33	0.00
	3	0.11	0.15	0.20	0.50	0.25	0.53	0.00	0.33	0.00
	3.1	0.00	0.00	0.01	0.01	0.25	0.01	0.00	0.33	0.00
	4	0.00	0.00	0.01	0.06	0.04	0.29	0.00	0.00	0.00
	4.1	0.00	0.00	0.00	0.00	0.00	0.00	1.00	0.00	0.00
	4.2	0.00	0.00	0.00	0.00	0.08	0.00	0.00	0.00	0.00
	5	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	1.00

level BCI scores. The sets of plausible scores for each individual structure have been combined into a set of plausible stock level benchmarks by taking the mean of the structure values in each set, weighted by each structure's deck area. The results have been plotted in Figure 5. Despite the variation in individual defect scores, the average BCI_{Ave} and BCI_{Crit} scores for the entire stock of structures show very little deviation, with computed standard deviations of 0.06 and 0.20 respectively.

5 CONCLUSIONS

The following concluding remarks are made:

- Significant uncertainty was found in the classification and grading of individual defects during the visual inspection process.
- Defect classifications were particularly inaccurate for common concrete defects, where a large range of possible defect types is available.
- Defect grading by severity and extent was seen to be most unreliable for defects with high extents, and for component types such as *Vehicle Restraint Systems*.
- The degree of variation in defect grading between inspectors differed between different regional inspection teams, suggesting variation in practice.
- The industry standard *Bridge Condition Indicator* metric was shown to be sensitive to uncertainty in the underlying defect data, with the BCI_{Crit} metric particularly unreliable for comparing the performance of individual structures.
- Use of the *Bridge Condition Indicator* system at stock-level was shown to be considerably more reliable, with low levels of uncertainty.

DATA AVAILABILITY STATEMENT

The authors thank Highways England and Lockheed Martin for use of portions of the Structures Management Information System database as part of this research project. New experimental data collected during this study is owned by Highways England.

ACKNOWLEDGEMENTS

The authors would like to thank Highways England, Professor Colin Taylor and the Engineering and Physical Sciences Research Council (**Grant No. EP/G037353/1** Industrial Doctorate Centre: Systems).

BrIM bridge inspections in the context of Industry 4.0 trends

M. Salamak & M. Januszka
Silesian University of Technology, Gliwice, Poland

ABSTRACT: This paper describes two new technologies, Bridge Information Modelling (BrIM) and Augmented Reality (AR), which fit into the cyber-physical devices and cloud computing ideology of Industry 4.0. The rapid development of such technologies will have a significant impact on the design, construction, use, and management of transportation infrastructure, including bridges. This paper highlights difficulties in implementing BrIM technology for infrastructure projects and modelling of bridges. It also shows details of a new concept for inspection of bridges based on BrIM and AR.

1 INTRODUCTION

Large, ambitious projects in the field of infrastructure are being launched around the world. Often, their budgets exceed the capabilities of individual countries. The success of these projects primarily depends on improved management and the introduction of technological innovations. Three essential factors determine the nature of these projects: rapid growth of infrastructure investments, overruns of deadlines and costs, and low productivity of the entire construction industry (Changali et al., 2015). According to estimates, expenditures on mega infrastructure projects will double within fifteen years. Unfortunately, as these analyses indicate, almost 98% of these mega-projects are delayed and are in excess of their assumed budget. There are many causes for this situation, but one of the most important is low productivity in the construction industry. The cause of this is weak organisation and poor management of the entire process of investment and maintenance of existing infrastructure. Another cause is the lack of process, which has already been applied in product development processes (PDP) based on CAD/CAM systems. Digitisation and robotisation that revolutionised other industries (Teicholz, 2004). The design, realisation, and maintenance of buildings should be digitalised to transfer solutions from the manufacturing sector to the construction industry.

Our infrastructure will continue to develop. There will be more and more ageing bridges that need to be managed. The constant reduction in maintenance budgets will force extension of bridges' lifespan while still controlling their safety (Żarski et al., 2017). Two "Industry 4.0" digital technologies may help deal with this dilemma: Building Information Modelling (BIM) and Augmented Reality (AR).

2 DIGITAL TECHNOLOGIES IN BRIDGE MANAGEMENT SYSTEMS

2.1 *Industry 4.0 trends*

The industrial revolution and technologies such as the steam engine from the late seventeenth century teach us that each subsequent stage of industrial development is shorter. In 2011 in Germany, a development strategy called Industry 4.0 (German: Industrie 4.0) was announced. This was a combination of automation, processing of big data, and intelligent manufacturing techniques. There are also cyber-physical systems, such as the Internet of Things and cloud computing. The idea is to create a modern factory that will carry out nearly the entire production process with minimum human involvement. New production management systems that use the above-mentioned components will create an "intelligent" factory that will deliver tailored products according to individual's needs.

As already mentioned, the construction industry is delayed in implementing new, digital technologies,

such as automation and robotisation. However, development of digital technologies will eventually transform the construction industry. Many global corporations are interested in this industry as there are opportunities for profit by building faster and cheaper, as well as by lowering the cost of infrastructure maintenance and extending its lifespan.

However, BIM technology is the first step to make this possible and effective. Without three-dimensional models and their connection with digital information at the construction site, changes will not be made.

One of the key components of today's industrial revolution is so-called Cyber-Physical Systems (CPS). These are the mechanisms controlled or monitored by computer algorithms that are closely integrated with the internet and its users. Physical and software components in CPS are deeply interconnected with each other and operate in different time zones and at different scales. Examples of such systems include smart grids, autonomous vehicles, medical monitoring, process control systems, robotic systems, automatic avionics, and even Structural Health Monitoring (SHM).

Given the specifics of the construction industry and the fact development often occurs in open spaces, cyber-physical mobile systems with the ability to move and even work autonomously will be ever more important in this industry. Examples of such systems include mobile robotics, as well as electronic systems transported by humans or animals. The popularity of smartphones has increased the interest and potential of mobile CPS. These can be tablets and smartphones, but also smart watches, helmets, glasses, or contact lenses. Together these devices are called wearable devices. The most important requirements for wearable devices are:

- significant computational and storage resources with large processing capacities,
- sensory input and output devices such as touch screens, cameras, GPS modules, speakers, microphone, gyroscopes, light sensors, accelerometers, and proximity sensors,
- communication mechanisms such as WiFi, LTE, and Bluetooth for connecting devices to the internet or other devices,
- high-level programming languages for rapid development of mobile software and simple mechanisms for application distribution,
- durable and reliable battery performance.

In fact, nowadays, these requirements are met by a large group of commonly available smartphones, which can also be found at construction sites, although perhaps not always as a tool. Unfortunately, users of CPS such as smartphones do not have the ability to see and manipulate the information needed to make decisions about processes and their surroundings. They can use smartphone to download documentation and images can only be compared with drawings on the screen. In this way, errors arise from discrepancies between physical and cybernetic information.

2.2 *Augmented Reality*

The solution here may be use of Augmented Reality (AR). AR visualises cybernetic information against physical images and enables manipulation of cybernetic information by interaction with real and/or cybernetic objects (Azuma, 1997). AR can supplement and simultaneously use the BIM technology described above. AR, as an example of a computer technology that can assist a person in performing various tasks, is extremely promising. AR allows combining the computer-generated world (virtual) with the real world (where the user is) so that they form one synthesised environment (Abdullah and Thai, 2006). In contrast to the more popular Virtual Reality (Sherman and Craig, 2002), in which the user is completely immersed in the virtual world, AR gives one the freedom to work in the real world while enhancing human perception with virtual objects. Modern visualisation techniques such as AR allow representing the virtual world in an extremely intuitive way by 3D objects with the ability to view them from any perspective, with textures that are indistinguishable from the actual textures of real objects and at any scale (Fig. 1). Elements enriching reality using AR systems can also take forms beyond three-dimensional models, including subtitles, diagrams, photographs, films, and audio information (Bień et al., 2010), (Golparvar-Fard, 2012).

Figure 1. AR in the continuum of real and virtual worlds.

The increasingly popularity of AR technologies is due to the benefits they bring. First of all, it is possible to supplement reality with information from a database and/or knowledge. Instead of completely replacing the world surrounding a person with an artificial, virtual world (as is the case with VR), AR enriches the real world by adding only the information necessary to enhance one's reliability. This information can be delivered to the user of the system on demand (Januszka and Moczulski, 2013), (Moczulski et al., 2007). The more common practical use of AR technology is in special devices such as helmets or glasses. For example, when assembling or inspecting technical equipment, an installer "sees" animations and information superimposed on real images to help them complete their task correctly.

2.3 *BIM technology and bridges*

CAD programs have typically been used by designers as simply electronic 2D drawing boards. Neither the equipment nor the CAD program interface encouraged use of 3D tools. This began to change when 3D technology started to be used in the design of increasingly complex and sophisticated bridges. Development of these programs added more often contractual dimensions. The fourth dimension, time, can also be to create project animations as well as to prepare schedules and plans for supply of materials (Gołaszewska and Salamak, 2017). The fifth dimension introduces a cost factor and allows for a development of model estimates. The two subsequent dimensions are often combined and deal with management of finished projects. These capabilities allow use of BIM technology during inspection of bridges (Salamak and Januszka, 2015).

BIM technology is much better known in the construction industry (vertical BIM). It is used by architects, construction companies, and installers. Many public buildings are constructed with the use of this technology, such as hospitals, airports, office buildings, hotels, etc. BIM in infrastructure projects (linear BIM) is being implemented more slowly, for example in construction of roads, railway lines, bridges, tunnels, harbours, wharves, and dams. This delay may be due to the planning and realisation of infrastructure tasks.

The first fundamental issue is that the vast majority of infrastructure investments concerns the public procurement sector. Unfortunately, public institutions belong to organisations that are resistant to the implementation of new technologies and improvements in efficiency. Another difficulty that delays use of BIM technology in infrastructure projects is the slower development of BIM tools for infrastructure than for residential/commercial/industrial buildings. Finally, BIM itself still has problems, especially with regards to custom bridge geometries. This includes the overlapping of geometries in horizontal and vertical directions, transition curves, gradients, widening, and thickening (Jasiński et al., 2017). This is especially problematic for monolithic concrete bridges. The most popular CAD programs that are not part of the group of BIM products can cope with these challenges, but they do not have the ability to maintain the proper relationships between model objects without full parameterisation, which brings further burdens to storage and management of additional information. Taking into consideration all the specifics of bridges and the nomenclature of their components, we propose introducing BrIM, Bridge Information Modelling or Management.

2.4 *Future of Bridge Management Systems*

One of the most important elements of Bridge Management Systems (BMS) is the results of bridge inspections. These results are an essential source of information about the technical conditions and damages of a bridge (Thompson et al., 1998). In most countries they are obligatory and are performed based on a systematic strategy to control the condition of transportation infrastructure. Instructions for conducting inspections in each country are described in detail. These documents also define the scope and layout of inspection reports, which currently are paper documents. Classic tablets or smartphones are neither comfortable nor safe for inspectors, and even electronic documents do not provide comprehensive support. However, introducing a new type of inspection interface based on AR eliminates the disadvantages of current inspector aid devices.

Many publications (Abdullah and Thai, 2006), (Bień and Rawa, 2004), (Hu and Hammad, 2005), (Wang et al., 2010) have been written about the close connection of BMS with rapidly developing information technologies. These include use of artificial intelligence, virtual and augmented reality, monitoring systems, algorithms supporting decision making, etc.

Given current trends (Carlson, 2013), (Wang et al., 2013) and political decisions, it is increasingly likely that BIM technology in infrastructure, and in BMS, will rapidly develop in the coming decades. Advanced bridge modelling methods will be required as the efficiency of this technique in BMS will depend on the virtual model of the bridge being inspected. The BrIM bridge model will be the most important element of the BMS database (Fig. 2). Practical use of BIM models is currently limited to the design phase (3D and 4D BIM) and sometimes to the construction process (4D and 5D BIM).

Figure 2. Basic digital components of future Bridge Management Systems.

The use of BIM models for management and maintenance (6D and 7D BIM) occurs only in pilot projects and still requires research. This is particularly relevant to transportation infrastructure such as

roads and rail bridges. Therefore, it will be necessary to develop procedures for creating bridge models for use in inspections and BMS. For existing objects that do not yet have such models, other procedures for bridge inspections will need to be developed, such as laser scanning and BrIM models based on clouds of points. These procedures must take into account dominant span lengths and hard-to-reach areas such as high supports and pylons, where unmanned aerial vehicles (UAV) can assist.

3 SMART BRIDGE INSPECTOR SYSTEM CONCEPT

3.1 *Description of the system*

Currently, research on the development of computer-aided bridge management with the use of AR along with BrIM models are only conducted to a limited extent in a few countries around the world (mainly outside of Europe, e.g. in Canada, USA, Taiwan, Australia). More often similar systems are being developed for other facilities, such as buildings (Suyang et al., 2013), (Hammad et al., 2009). Certain functional assumptions and requirements for integration of BIM with AR were proposed in (Wang and Dunston, 2007). The authors proposed that visualisation of information, directly on the object, in real time, is necessary during inspection of the object.

During an inspection, a great deal of information must be collected about the current technical condition of the bridge. An inspector uses various tools to obtain this information. As a consequence, when using AR system during inspections, there is still the problem of the inspector having and transporting necessary equipment. In (Doppleb et al., 2004), the authors propose a wearable computer integrated with a localisation system and an AR display. However, this solution does not provide integration of additional equipment for the inspector, including measuring devices and sensors. Nor do the suggested solutions take into account users' safety (e.g. helmets).

Due to the lack of effective solutions, the authors present in this article an innovative solution for an intelligent system based on AR techniques to support bridge inspections. The system consists of several modules related to the three phases of bridge inspection (Fig. 3):

1. The preparation phase of the inspection during which the user, with the use of the simulator, plans the next inspection steps and familiarises themselves with the object.
2. The inspection phase during which the inspector uses the AR interface integrated with the decision-making and data acquisition system to collect and store up-to-date information about the condition of the object and/or to view information about its history.
3. The phase of report preparation during which a user supported by the system prepares a report about the object.

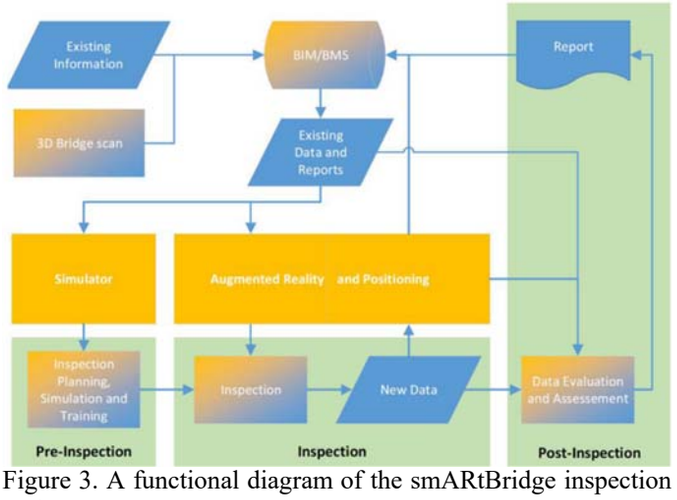

Figure 3. A functional diagram of the smARtBridge inspection system.

An important feature of the proposed AR-based system is its integration with BrIM and BMS. Integration allows updating information about object conditions and intuitive access to data on its construction and history at stages ranging from inspection preparation, through construction, to report preparation. During inspections, the system allows visualisation of selected - including those hidden or invisible to the inspector - structural elements of the bridge (e.g. reinforcement, tendons, bearings, etc.) and other elements of equipment and installations (e.g. drainage, electrical, and IT installations). These data come from BMS and BrIM models of the object.

The most important element of the proposed solution when preparing and planning an inspection is the simulator. The BrIM model and the collected object history data may be useful for the inspector to become acquainted with the bridge and with preliminary analysis. Prior to the inspection of the real object, the inspector, with use of the special simulator, has the ability to become familiar with the object using its virtual, but realistic, representation. This should make navigation on the bridge faster and more efficient. In addition, use of the simulator allows the user to plan future inspection steps, including locations that require special attention. In this way, during a virtual walk through the inspector may mark the most important locations on the bridge that should be checked during inspection of the real object. Then, when inspecting the real object, the AR-based system can point to the inspector locations that were previously marked in the simulator. The use of a simulator, in this case, is an innovative approach for inspection using BrIM, AR, and VR (Fig. 4).

During the inspection, the most important element of the system is the human-machine interface (HMI) with a graphical user interface (GUI) that uses AR techniques. The interface includes both hardware and software solutions. The AR-based system consists of

a wearable platform that integrates devices with displays (e.g. Microsoft HoloLens or Daqri Helmet) and data acquisition during inspections (e.g. a wearable smartphone). In addition, hardware platform integrates sensors (including non-destructive testing), tools (including measuring), and a location system.

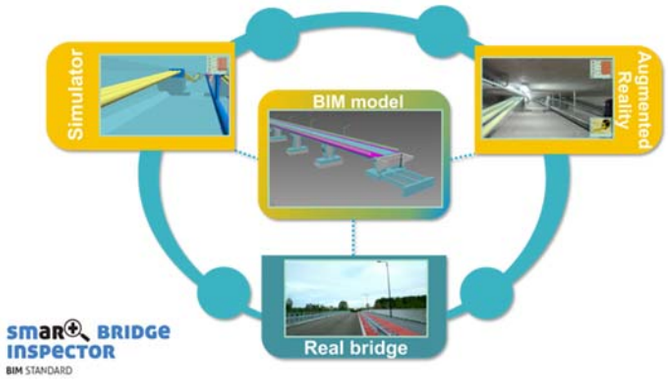

Figure 4. BrIM+AR+VR integration in the proposed system.

The hybrid location system is responsible for proper operation of the AR interface. In particular, presentation of the information during the inspection (including visualisation of elements and installations) directly on real object and acquisition of data and annotations in the BrIM model according to their actual location. The localisation system must work in open areas (outside) and inside bridges so that its operation can integrate with global location (satellite, e.g. GPS, Galileo) and mobile localisation systems (system installed on the object). Due to the accuracy in location, especially when assigning the location of the data being collected in the BrIM model, it should be possible to manually correct location of damage by the user.

Most of the information needed during the inspection is downloaded from the BMS system before the inspection and saved in the inspector's computer, which is a HMI hardware element (Fig. 5). Due to the enormous amount of information that can be stored in a BMS system, it is possible that some of the documentation, which may initially appear to be unnecessary and, therefore, were not downloaded to the device, will become necessary during the inspection. Then the use of advanced communication systems will enable wireless transmission of records from the BMS repository and vice versa. This transmission of data during the inspection will allow for quicker preparation of bridge inspection reports.

Figure 5. Wearable HMI system during a bridge inspection.

During work, the inspector has at his disposal a system supporting decision making. The user should enter the necessary data to the advisory system, which then instructs the engineer with further actions and enables classification of the observed damages (e.g. cracks, concrete defects). In this way, the inspector should be able to determine the class of damages that are then assigned to the virtual BrIM model at the location that corresponds to the location of the damage on the real object.

Using the sensory system integrated with AR interface the inspector measures critical parameters (e.g. measurements from non-destructive testing devices, the distance between two existing elements, the area of the defect, length of the crack, etc.), and then records the results in the BrIM model. All other inspector's annotations are saved in the same way, mainly in the form of photographic documentation, sketches, notes, and sound recordings. The collected data should be saved as layers on the BrIM model and integrated with the BMS. Any data collected by the inspector may be used at any time in the future, particularly at the time of report preparation and planning of the next inspection.

The last significant element of the system allows supporting the preparation of reports after inspection, based on collected information. The user's involvement at this stage should be limited to accepting particular sections of the report and conclusions from the expert system. Other tasks related to the preparation of the report should be done automatically.

The solution proposed by the authors and presented in this part of the article is in the early stage of research. The development of such a system requires a solution of numerous interdisciplinary problems that have not yet taken place anywhere in the world, or are ineffective and require improvement. The proposed system will improve the quality and reduce the cost of managing and maintaining bridges. In addition, integration of the system with BrIM models and BMS should contribute to a more efficient interpretation of information from assessment of the condition of bridges, and development of more detailed and accurate reports that may contribute to reducing the cost of maintenance and extending the lifespan of individual bridges.

The system can be used by inspectors (bridge engineers) and representatives of infrastructure manager. In the future, the system (particularly the simulator) could be used in institutions responsible for education and training of bridge inspectors applying for a license. Support of remote inspection and teleimmersion with the use of unmanned vehicles (UV), including autonomous mobile robots, would also be an innovative tool.

3.2 *Example of BrIM model*

The BrIM model of a road bridge was selected for inspection experiments on use of BrIM model in bridge management. It is a five-span bridge with a total

length of 216 m, which runs over railway lines in Gliwice, Poland (Fig. 6). It was constructed using the incremental launching technology in accordance with the traditional design documentation from 2013. In the cross-section, it is a concrete box-girder with external prestressing. The bridge can therefore be classified as a mid- to large-sized road bridge, whose inspection is typically time-intensive and important.

Figure 6. View of the bridge in Gliwice.

The BrIM model of the bridge (Fig. 7) was developed in accordance with two procedures: based on the design documentation, and based on the cloud of points obtained in laser scanning. Both models are currently being compared and merged for further research. The first contains a number of details and information that are not available for scanners. There are supports with reinforcement, box girder with tendons and reinforcement, internal installations, and equipment. Everything was assigned to the appropriate thematic layers and marked with specific colours. In this way, the user of the model will be able to select the displayed objects.

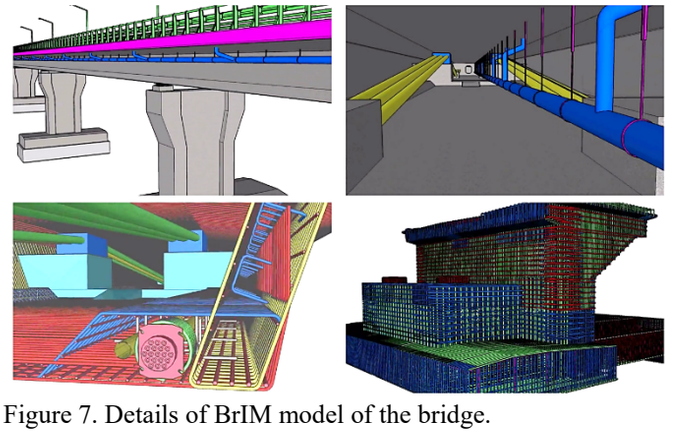

Figure 7. Details of BrIM model of the bridge.

3.3 *Bridge inspection with BrIM+AR devices*

The process of recording damage and saving in the BrIM model during inspection is very intuitive (Fig. 8). The inspector equipped with the proposed mobile devices goes to the site. When examining the object (e.g. inside the box-girder bridge), the inspector looks for possible irregularities by comparing the BrIM with the actual object. Once damage is found, qualitative and quantitative assessments are performed and data is archived in the BrIM model. A report from the inspection is generated automatic and goes to the administrator's database together with the damage observed. From this point on, the damage is stored in the BrIM model and can be imaged during the next inspection.

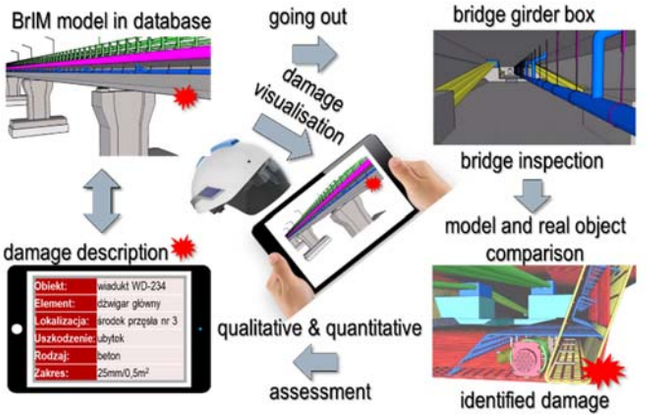

Figure 8. Storing of damage in the BrIM model.

AR technology has a key place in the process of inspection in the above scenario. The inspector registering the damage works with the tracking system as one of the AR subsystems. When collecting data on identified damage, the inspector uses a wearable mobile device to take photos and record videos with text description labels (e.g. text labels to indicate important locations in the picture), graphics (e.g. graphic elements to indicate important locations at the picture, e.g. arrows, lines, circles, etc.), and sound (e.g. voice recordings). In order to properly mark a location where the information was recorded or where the virtual object was imposed, it is necessary to use a tracking system. The location system allows saving recorded data in the BrIM model in the exact same location as on the real object.

In the described system two types of localisation are proposed: location based on a mobile device (accelerometer, gyroscope, compass) with SLAM support (simultaneous localisation and mapping) and GPS signal with hybrid location based on an independent localisation system (for localisation within objects).

Properly saved data may be displayed again in the future during inspection with the use of AR techniques. In this case, the user sees information regarding the current location (e.g. photos, text, sound information, sensory readings) which were saved during previous inspections and assigned to a specific location on the object on the helmet-mounted unit.

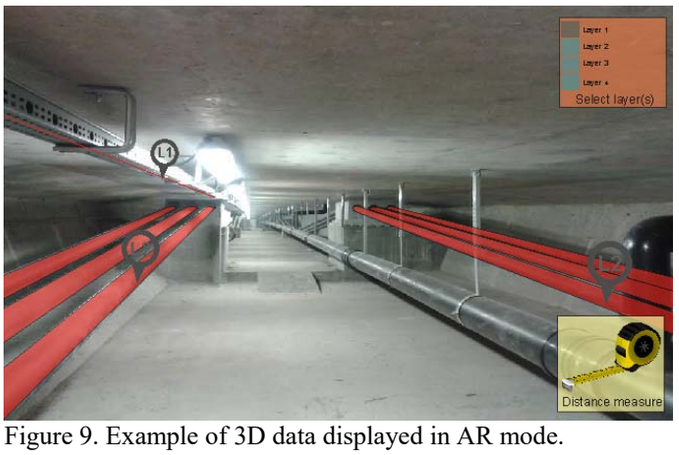

Figure 9. Example of 3D data displayed in AR mode.

In another application, once the mobile device is pointed at a specific place in the object and recognised the user's location and orientation, computer-generated 3D structural elements will be added to a real image. It is possible to display models of elements invisible to the naked eye. In both variants, the user selects the layer of information from the drop-down menu (according to the BrIM model such as installations, structural elements, etc.). In addition, it is possible to display information from multiple layers simultaneously (Fig. 9).

The latest use of AR techniques is integration with virtual instruments to measure identified damage. These tools are limited to simple instruments that allow measuring length (e.g. crack length) or surface area.

4 CONCLUSIONS

In the coming years, the industry of infrastructure construction including bridges awaits a revolution in design, construction, and maintenance of modern and demanding BIM technologies. Although this technology has already shown its advantages in building construction, there are still many difficulties and constraints for implementing it on a large scale for transportation infrastructure.

The cyber-physical system for bridge inspections presented here can be used not only by owners and administrators of infrastructure. In many countries, bridges inspections are carried out by small private entities which are gaining popularity in the public procurement market. On the basis of outsourcing, companies equipped with this type of equipment will be able to offer their services at a better value, which will also satisfy contracting authorities.

The authors hope that the information provided in the paper will be the basis for a meaningful discussion on the implementation of BIM and AR technologies in the design, construction, and maintenance of bridge structures. The infrastructure managers in those countries that choose to implement modernised BMS systems with intelligent tools for inspection will be able to use them to make more transparent and uniform investment decisions. This will improve the ability of prediction and planning of maintenance and replacement of elements of the transportation infrastructure networks.

ABSTRACT: The potential benefits of using structural health monitoring systems in measuring and recording bridge data have been established in many applications around the world, but the efficiency and effectiveness of such systems depends on how they are applied – for instance, in terms of sensor types and locations on the structure. Considering that the most important data required generally includes superstructure movements, which can easily be measured at the expansion joints, and the critical importance of the same expansion joints, which are less robust and therefore more susceptible to damage and deterioration than the main structure, it is often sensible to base the design of a monitoring system on data from the expansion joints. Developing technology now allows for the integration of appropriate sensors in a joint during fabrication, reducing effort and risk on site, and can enable a suitably configured system to automatically detect possible damage or deterioration based on vibrations only, marking the advent of "smart" expansion joints.

1 INTRODUCTION

A bridge's expansion joints are generally much less robust that the rest of the structure which supports them, but must facilitate deck movements and rotations while subjected to dynamic, fatigue-inducing loading from traffic. The expansion joints of a bridge that is crossed by 50,000 vehicles a day, for example, will be subjected to well over a billion axle loads, or mini dynamic impacts and rotations, during a 40-year or more service life. This enormous figure explains why the expansion joints of any bridge require proper maintenance throughout their lives, and why they will be likely to require replacement several times during the life of the main structure. It also illustrates well the importance of careful consideration, during selection and design of the bridge's expansion joints, of the complete life cycle of the main structure and of the joints themselves.

Decision-making during the life cycle of expansion joints can be greatly improved by Structural Health Monitoring (SHM). At an early stage of the life cycle, movements, rotations and dynamic load impacts (vibrations) can be measured on installed expansion joints for design verification purposes. During the expansion joint's service life, the same factors can be very useful in optimizing maintenance work and reducing the risk of damage escalation. And towards the end of the joint's service life, such information can be of great value in defining requirements for expansion joint replacement work.

2 LIFE-CYCLE COST CONSIDERATIONS OF BRIDGE EXPANSION JOINTS

The initial supply and installation cost of expansion joints typically represents less than 1% of the total bridge construction costs (Braun, 2011). It has also been concluded that these initial supply and installation costs for the structure's joints is "insignificant" in relation to the future costs of maintenance and replacement should the joints perform poorly (Dexter et al, 2002). The total life-cycle costs of expansion joints can be estimated to be 12 times the initial cost in the case of a high-quality product, and up to 47 times the initial cost in the case of a low-quality product that needs more repair and replacement (Savioz et al, 2014). It can thus be concluded that:

(1) The initial extra investment required to purchase a high-end expansion joint, as opposed to a low-tech one, is entirely insignificant compared to the enormous savings that can result over a period of several decades.
(2) In order to minimize the overall life-cycle costs of a bridge's expansion joints, it must be ensured that adequate resources are devoted to maximizing the suitability, durability and quality of the joints selected for use, and enabling them to perform as well as can be expected, for as long as can be expected, by ensuring the adequacy of subsequent inspection and maintenance activities.

3 THE USE OF MONITORING SYSTEMS TO MINIMIZE THE LIFE-CYCLE COSTS OF A BRIDGE'S EXPANSION JOINTS

Several strategies to minimize the total life-cycle costs of expansion joints are recommended by Savioz et al (2014). These include the use of SHM, which can provide very valuable support at any stage throughout the life cycle – including, in particular, at the design (verification) stage and during inspection and maintenance work.

3.1 *Design (verification) stage*

Due to the 'prototype nature' of many bridges, it is a challenge to clearly determine, during the design stage, the movements and rotations that the structure's expansion joints will have to accommodate. Often, the actual movements and rotations of a completed structure are not as expected. Loading can also vary significantly; while axial loads and dynamic amplification factors may be defined by design codes, load impacts may be significantly larger, e.g. due to overloaded trucks or bumpy road conditions. In either case, due to uncertain design input data, expansion joints may be under-designed, resulting in premature failure, or over-designed, resulting in unnecessarily high costs. It is therefore important for the involved parties – especially the bridge designer and the expansion joint supplier – to have a comprehensive understanding of the behavior of the various types of expansion joint available, in different applications and circumstances. Monitoring of installed expansion joints in different conditions can provide the necessary basis for such understanding. This knowledge can then be used in selecting the most appropriate type of expansion joint for a specific application, and to define detailed design features. As well as establishing the exact movements and rotations arising, data can also be provided relating to loading, water-tightness under extreme conditions, specification of noise reduction features, etc.

Such benefits are especially pronounced in the case of existing bridges that require their expansion joints to be replaced after years of service. In this case, movements, rotations, loading etc. can be recorded by a suitably designed SHM system, measuring expansion joint data (movements, loading, etc.) over a certain period of time prior to the replacement project. Typically, monitoring over a one-year period may be optimal as it can provide data from all seasons. If this amount of time is not available, a shorter period can be monitored and extrapolations can be made by means of further modelling. Such recording and modelling will enable design specifications to be developed which are very suitable for the real situation of the specific bridge.

Two case studies below will illustrate how structural monitoring was used to support decision making for an expansion joint replacement project (Section 4.1), and for the purpose of verification of design and behavior of installed expansion joints (Section 4.2).

3.2 *Inspection and maintenance stage*

Inspections, and the investigations associated with required remedial works, are no longer limited to purely manual efforts; great benefits, in terms of both ability and expense, may be offered by automated remote monitoring systems (Spuler et al, 2011). The formidable data measuring power of today's SHM technology can be used to measure and report on any chosen variables in the bridge's and/or expansion joints condition (saving manual inspection visits), or to precisely define a maintenance or repair challenge and thus refine and optimize the selected solution. Such systems can even be programmed to send alarm messages to the bridge engineer, by email or SMS, should any measured variable exceed a predefined boundary value – thus ensuring that any potential problem can be dealt with before it develops into a costly repair project.

Two further case studies below will illustrate how structural monitoring may be integrated into modular expansion joints during the supply stage, making them "smart". The first of these, presented in Section 4.3, focuses on movement and rotation measurements, including alarm settings, on a remote bridge in a seismically active zone. The second, presented in Section 4.4, illustrates a newly developed technology that, in addition to measuring typical movement and rotations, can also detect minor changes in the expansion joint's condition. The early identification of damage or deterioration that this makes possible can facilitate early intervention, avoiding further deterioration and increased risk.

4 CASE STUDIES

4.1 *Angus L. Macdonald and A. Murray MacKay twin suspension Bridges, Halifax, Canada*

The city of Halifax, capital of the Canadian province of Nova Scotia, relies heavily on two structures in particular - the Angus L. Macdonald Bridge (Fig. 1) and the A. Murray MacKay Bridge (Fig. 2), both of which connect the city across the sea inlet that divides it in two. Having been opened to traffic in 1955 and 1970 respectively, both structures have already provided several decades of service. The A. Murray MacKay Bridge was renovated in recent years, and similar renovation works, with similar changes to the bearing support of the bridge deck, were being planned for the Angus L. Macdonald Bridge. The bridge was proposed to receive an entire new deck, and FEM modeling of the deck, verified by measured data, was to play a key role in the design process.

Figure 1. The Angus L. Macdonald Bridge in Halifax.

Figure 2. The A. Murray Mackay Bridge in Halifax.

It was determined that an SHM system should be used to measure and record the movements and rotations of the deck of the Angus L. Macdonald Bridge at its expansion joints, providing the data needed by the finite element modeling. An example of some of the data provided by the system, for a specified period of time, is presented in Figure 3. This particular data enables rotations and displacements (both longitudinal and transverse) to be easily related to temperature, and to wind strength and direction.

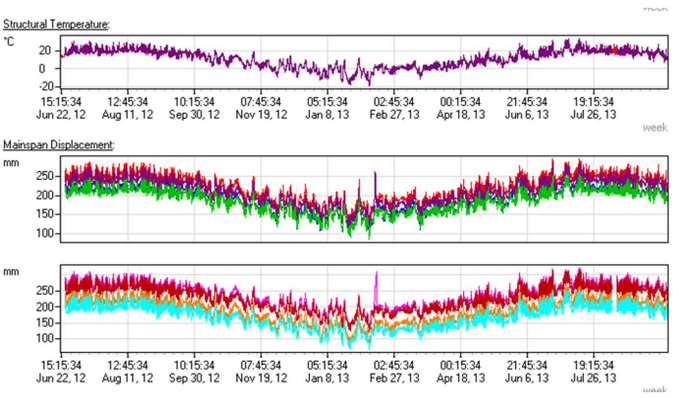

Figure 3. Example of data recorded during a one-year period.

The principal movements were correlated to temperature during the monitored period (Fig. 4). The plot shows a decreasing trend of displacement when temperature decreases. The same linear behavior must also be evidenced by the finite element model of the structure. To observe the distribution of movements, a very useful means is offered by histograms. Figure 5 shows on a histogram the number of times a value of measurement arose during one year of monitoring at a single sensor.

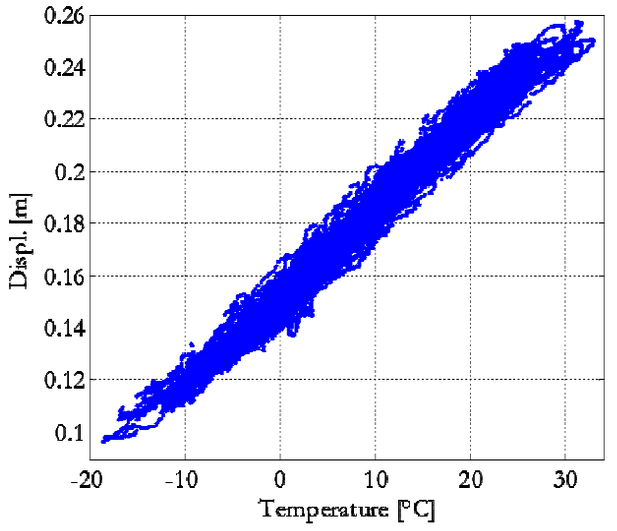

Figure 4. Temperature effects on displacement measurements.

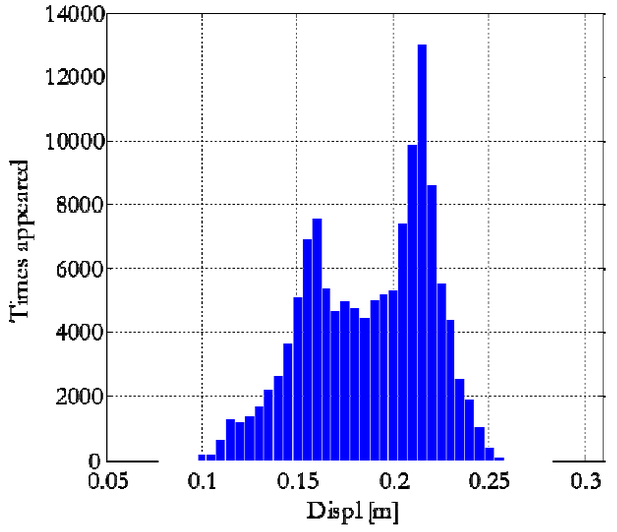

Figure 5. Histogram with distribution of displacement data.

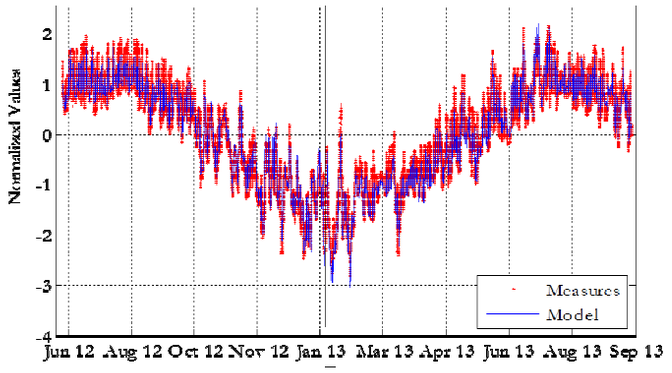

Figure 6. Comparison of measured and expected displacements.

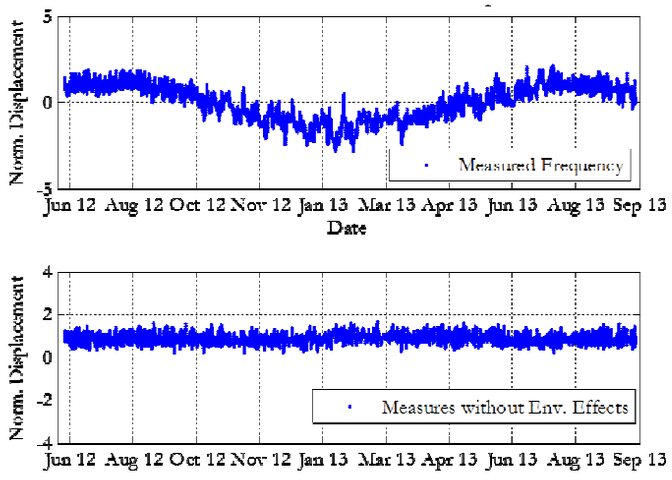

Figure 7. Regression model showing displacement data, before (above) and after (below) elimination of environmental effects.

To improve damage detection at a bridge's expansion joints, environmental effects can be eliminated using a regression model providing data such as that shown in Figures 6 and 7, generated from the correlation between temperature or humidity and the movements of the bridge. The resulting movements recorded by the system do not then include movements resulting from temperature or humidity, enabling abnormal influences (due to damage or other unexpected events) to be easily recognized. This is illustrated by Figure 7, which shows on the lower graph, with normalized values, the bridge movements that are due to traffic etc. and not due to temperature. Any abnormal shift on this graph would be immediately recognizable, enabling the need for repair or preventative action to be assessed.

A very interesting insight into the movements of the deck of the A. Murray Mackay Bridge was provided by the SHM system. It quickly established that the deck moves a great deal in the longitudinal direction, with accumulated movements of up to 2.5 km per month at a single expansion joint (Figure 8). Such enormous accumulated movements are extremely rare for such structures, and many times higher than the movements experienced by the decks of the great majority of long span bridges.

For comparison, the movements of the existing deck of the neighboring Angus L. Macdonald Bridge have been estimated by the same monitoring system to amount to less than 80 m per month at each joint (Figure 9). This provided a strong indication of how the movements of the new deck of the Angus L. Macdonald Bridge would increase if supported in the same way as the previously renovated deck of the A. Murray Mackay Bridge. The understanding of deck movements provided by the SHM system could thus play a crucial role in supporting the planning of renovation works of one deck and maintenance and possible adaptation works of the other. For instance, all mechanical parts of the bridge, such as its bearings and expansion joints, must be capable of accommodating and withstanding these extreme movements; and ways of controlling and minimizing the movements may also be considered – for example, through the use of hydraulic dampers. By recognizing and understanding the challenge, the responsible engineers are well equipped to plan and implement effective, durable solutions that reduce the life-cycle cost of the expansion joints.

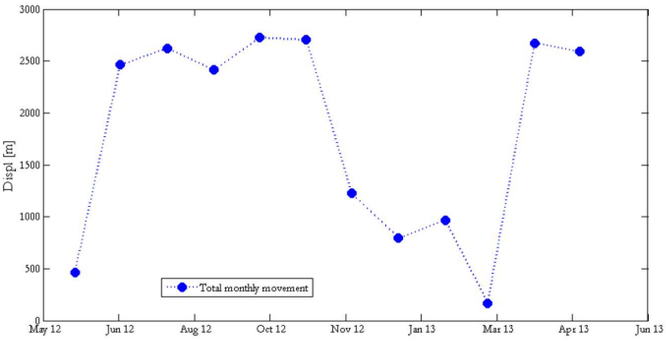

Figure 8. Accumulated movements (per month) on the A. Murray Mackay Bridge.

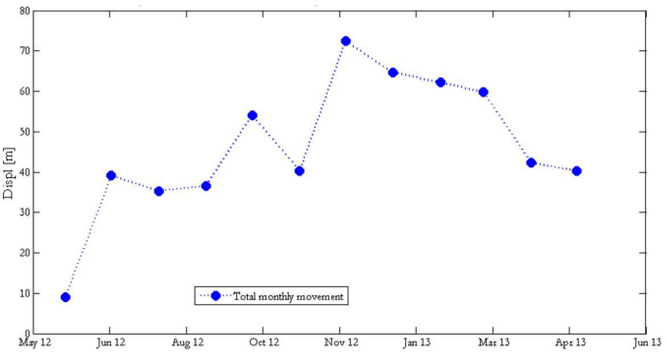

Figure 9. Accumulated movements (per month) on the Angus L. Macdonald Bridge.

4.2 *Hunter Expressway Viaducts, NSW, Australia*

The Hunter Expressway (Fig. 10) provides a much needed east-west link in the Hunter Valley, New South Wales, Australia. The Eastern Section from F3 to Kurri Kurri comprises three concrete box-girder viaducts through the Sugarloaf Range. The viaducts have a total length of 787 m and are up to 47 m in height above the ground.

Figure 10. A viaduct of the Hunter Expressway.

A temporary monitoring program was performed, with a series of controlled load test runs conducted on one of the installed modular expansion joints. The main aims of the tests were:

- To measure the static and dynamic strains for different vehicle speeds
- To assess the fatigue life of the modular joint
- To measure the fundamental natural modal characteristics of the joint
- To determine the maximum dynamic amplification factor (DAF)

Strain gauges and displacement transducers were installed on the expansion joint. A standardized test truck with different load configurations (allowable limit and overload) traversed the expansion joint at several speeds (from crawl speed to 90 km/h), which represent static and dynamic load scenarios. Data was recorded (see Figure 11 for a sample) with a high sampling frequency. A detailed description of the full monitoring program, instrumentation, data acquisition and various analysis and assessments was recorded by Ancich et al (2014).

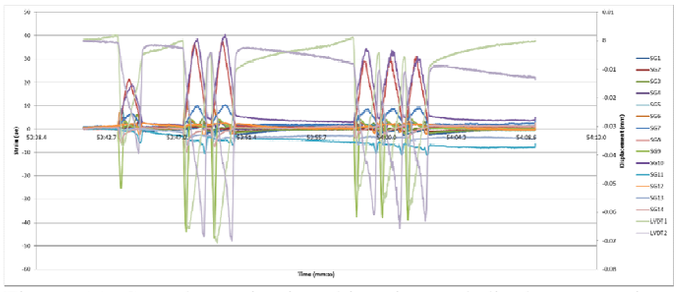

Figure 11. Sample strain time histories and displacement time histories for a slow roll on.

In summary, the main conclusions were:

- Static and dynamic strain levels are very low
- The fatigue life of all joint components assessed predicted to be unlimited with respect to all relevant expansion joint design codes
- The maximum dynamic amplification measured for the joint was a dynamic amplification factor of 1.4, i.e. very minimal amplification. The vertical stiffness of the joint was the highest yet measured in Australia.
- The fundamental vertical natural mode of the expansion joint was the highest yet measured in Australia, at 112 Hz. The first vertical bending mode of the centerbeams was the highest yet measured in Australia, at 183 Hz.

With this temporary monitoring program, the asset owner could convince himself of having expansion joints installed that meet the very demanding design standard in Australia, in particular with an unlimited fatigue life which reduces the life-cycle cost to a great extent.

4.3 *Longjiang Bridge*

The Long River Bridge, or Longjiang Bridge (Fig. 12) is a suspension bridge near Baoshan, Yunnan, China. The main span of the bridge is 1,196 m long, making it one of the longest ever built, and the longest of the world's very high bridges.

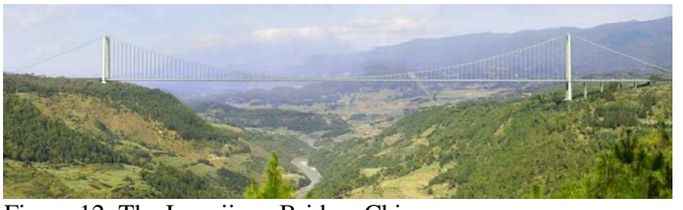

Figure 12. The Longjiang Bridge, China

Contrary to similar long-span high suspension bridges recently built in China, such as Siduhe, Balinghe, Lishuihe and Aizhai Bridges, which use traditional truss decks, this bridge has a thin steel box girder deck. This gives the deck less stiffness, resulting in the movements and rotations at the expansion joints becoming bigger, faster and more frequent. Furthermore, Yunnan is a seismically active zone, so ULS movements and rotations are expected to be significantly bigger than those occurring in service conditions. For example, longitudinal movements are expected to reach up 1,920 mm at expansion joint locations, with an additional movement of +/-350 mm in the case of an earthquake.

In order to avoid over-dimensioning the joints for seismic movements that might never arise, a specially designed and patented technology, based on a fuse element within the expansion joint, was used to enable the joint to survive such an earthquake without serious damage (Fig. 13). Likewise, due to the possible complex movements and rotations that may occur, a structural monitoring system was installed on the expansion joints (Fig. 14), in order to:

- Confirm design movements and rotations
- Generate movement and rotation statistics linked to temperature and other factors such as earthquakes
- Identify (by programmed alert system) irregularities at and possible damage to the expansion joints and thus, to be able to take immediate actions to prevent damage escalation

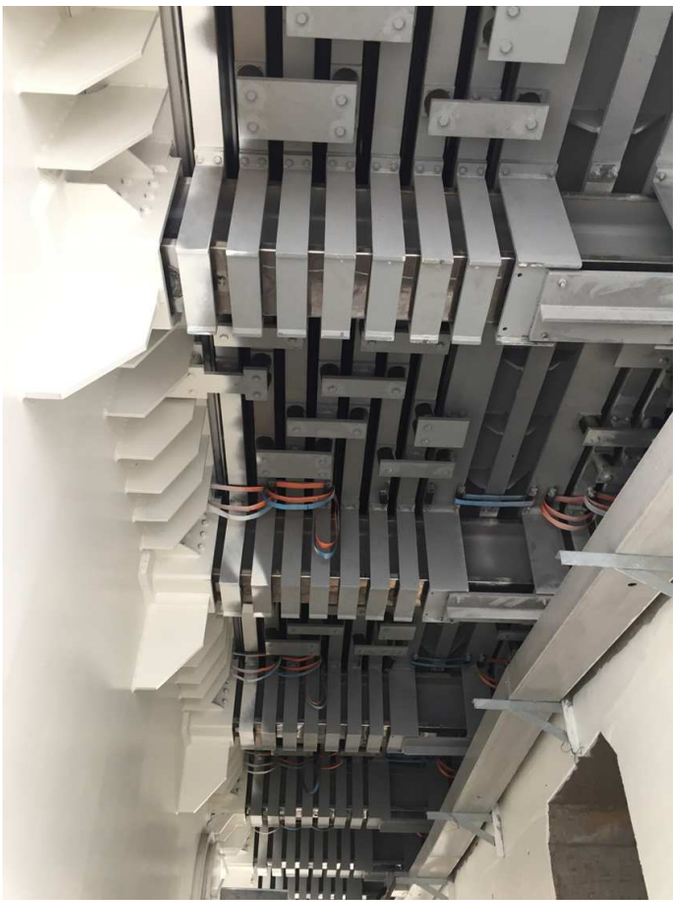

Figure 13. Modular joint with earthquake fuse element, viewed from below.

Figure 14. ROBO-CONTROL SHM data acquisition module.

A series of ultrasonic displacement sensors and temperature sensor have been installed at the expansion joints. Measurements are taken at both edges of the joints – measuring the entire gap between bridge and concrete support as well as rotations – and also at two centerbeam gaps in order to monitor the proper functioning of the expansion joint. A sample of the system's data output is presented in Figure 15.

Figure 15. Presentation of measured data (graph form) in the web interface. Correlation of movement and temperature can be observed, and irregularities and their impact on the expansion joint can be identified.

This monitoring provides the necessary information for decision-making during inspection and maintenance work, and in case of identified damage, can be used in planning repairs before further damage occurs. Life-cycle cost can thus be greatly reduced by well-timed interventions.

4.4 *Taizhou Bridge, Jiangsu Province, China*

The Taizhou Yangtze River Bridge (Figure 16), constructed at a cost of USD 400 million and opened in 2012, is the world's longest-span bridge of its type: The three-tower suspension bridge, with two main spans of 1,080 m each and side spans of 390 m, crosses the Yangtze River where it has a width of 2.1 km. The ambitious construction project represented the first attempt to create a long-span multi-tower suspension bridge.

Figure 16. The Taizhou Yangtze River Bridge.

This extraordinary bridge required some extraordinary key components such as the expansion joints which accommodate deck movements while providing a driving surface for traffic. Modular joints with 18 gaps each (able to facilitate 1440mm of longitudinal movement) were installed at each end of the deck (Figure 17).

Figure 17. One of the expansion joints of the Taizhou Yangtze River Bridge, viewed from below.

An SHM system was installed on the bridge to provide the type of data that is likely to be of interest to the owner of any exceptional structure. The basic system measures and records the movements and rotations of the deck at the expansion joints, and thus gives a valuable impression of the performance of the structure, enabling the need for maintenance or adaptation work to be quickly identified and planned. It also reports accumulated sliding movements over time – a key indicator in evaluating and predicting the condition of key mechanical components such as expansion joints and bearings.

Furthermore, pre-integrated sensors that allow high-frequency measurement of structure-borne vibrations, and a specially developed algorithm, were brought together on this project to create a new, first-of-its-kind SHM technology. This enables damage or deterioration to be clearly identified based on general testing and teaching of the system. As a result, unexpected damage can be immediately recognized and automatically notified, enabling the timing of replacement of components to be optimized and disruption to service to be minimized.

By recording movements, inclinations, temperature and structure-borne vibrations at a frequency of 25.6 kHz, even very tiny changes in the joint or its performance can be detected and visually represented by changes in a curve on a graph, enabling any sudden damage or deterioration to be immediately detected.

As a first step, many artificial failures were created simulating damages. This was done by temporarily removing stirrups which form sliding connections between the centerbeams at the joint's surface and the support bars beneath (see Figure 18). High-accuracy accelerometers and ultrasonic displacement sensors (Figure 19) were then used to evaluate the effects of these "failures" on the movements of specific elements, giving the system the data it needed to "learn" what data might be significant in terms of damage detection.

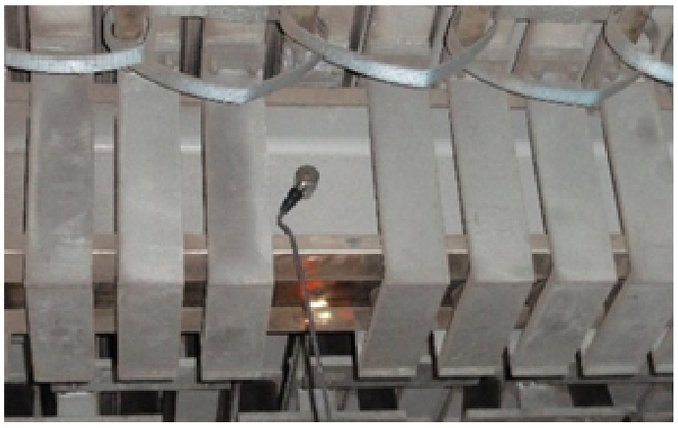

Figure 18. An accelerometer at the location of a temporarily removed stirrup during fault simulation and measurement of resulting vibrations and modal analysis.

Figure 19. An ultrasonic displacement sensor.

In service, the system sends data to a remote server, including daily records of vibrations due to heavy traffic together with the associated modal frequencies (see Figure 20). If established limits which might indicate the occurrence of damage are exceeded, an alarm notification is sent by email and also appears on the system's web interface, prompting a site inspection. As a result of the system's ability to automatically consider such information, therefore, planning of maintenance activities in general, and the timing of replacement of components in particular, can be optimized to reduce the life-cycle costs.

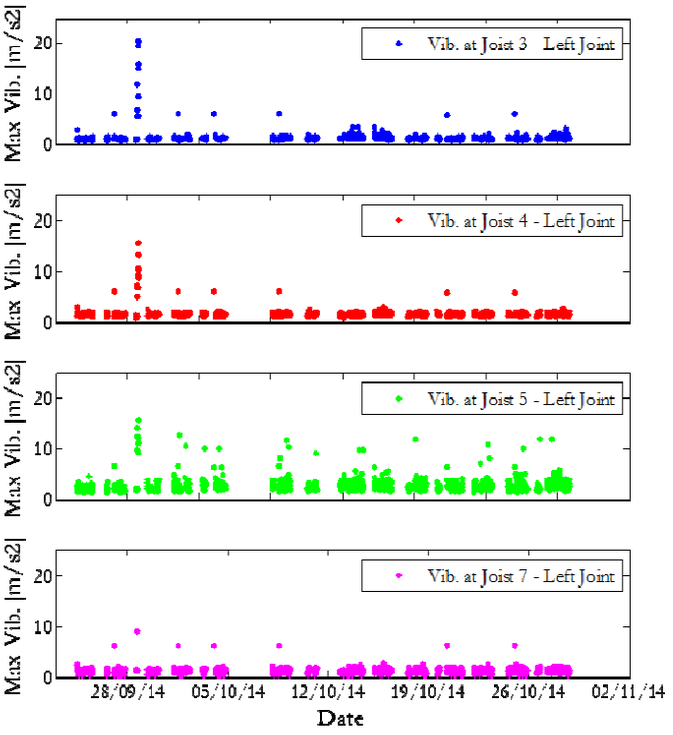

Figure 20. Example of one month of data from the smart expansion joint, at four positions.

5 CONCLUSIONS

The integration of sophisticated structural monitoring systems in the expansion joints of newly built and existing bridges can offer great benefits to their asset management programs. Such systems can efficiently provide data required for almost any purpose, at any stage of a structure's life cycle – e.g. to facilitate installation, inspection, maintenance or component replacement work, or assessment of unexpected events or planning of modifications.

Considering that the most important data required by a bridge monitoring system generally includes superstructure movements, which can easily be measured at the bridge's expansion joints, and considering also the critical importance of the same expansion joints, which are less robust and therefore more susceptible to damage and deterioration than the main structure, it is often sensible to base the design of a monitoring system on data from the expansion joints. Developing technology now allows for the integration of appropriate sensors in a joint during fabrication, reducing effort and risk on site, and can enable a suitably configured system to automatically detect possible damage or deterioration based on measurement and analysis of vibrations only, marking the advent of "smart" expansion joints.

Advances in materials and further improvements in bridge pot bearings

S.N. Kazi, V.V. Ghodke & C. Sarmiento
Mageba, Sydney, Australia

ABSTRACT: Bearings, which accommodate a bridge's multidirectional loads, movements and rotations, are among the most critical components of modern bridges. These connection devices are subjected to ever increasing challenges and opportunities due to constantly evolving design and material technologies. This is particularly true for pot bearings, have been widely used for decades but which have not always performed well – primarily due to inadequate design and execution of various solutions to the challenge of sealing the internal elastomeric pad, which, in the absence of an effective seal, can be extruded from the pot in which it is located when the piston it supports is loaded. Recently documented reports of premature failures of pot bearings in Australia due to elastomer extrusion have prompted detailed investigations into the root causes of the problem. This paper describes this problem and presents an already tried-and-trusted solution. The possible integration of monitoring system sensors into the bearing's design and fabrication, before installation, to enable such problems to be automatically identified and addressed before they develop, is also discussed.

1 INTRODUCTION

This paper presents results of investigation of some documented reports of underperforming pot bearings on bridges in Australia.

In recent years, it has repeatedly been reported that pot bearings are underperforming on rail bridges in particular. Asset owners became increasingly concerned about the early need to replace pot bearings (within ten years of installation in many cases, and within five years in some instances) – far earlier than expected considering the service life of 40 years specified by the Australian code AS5100. The reports were documented from cases in the Australian states of Western Australia, Queensland and New South Wales. The reports were not limited to a single manufacturer or supplier, but were limited to pot bearings that utilise a metallic internal seal to prevent extrusion of the elastomeric pad at the heart of the bearing (as described in Section 2 below).

In November 2015, Australian Rail Track Corporation (ARTC) engaged Lindsay Dynan, an engineering company specializing in Level 3 inspections and rehabilitation of structures, to investigate the observations of pot bearing failure on its railway bridges. The key findings of this report are discussed in this paper and recommendations based on state-of-the-art technology are presented to assist asset owners and engineers in their ongoing asset management work, helping minimise life-cycle costs.

2 THE POT BEARING AND ITS KEY COMPONENTS

Figure 1 shows a rendering (exploded view) of a pot bearing of the *free sliding* type. Figure 2 shows a typical cross section of a pot bearing of the *guided sliding* type, identifying its various components, which are described below with particular attention to the Australian context.

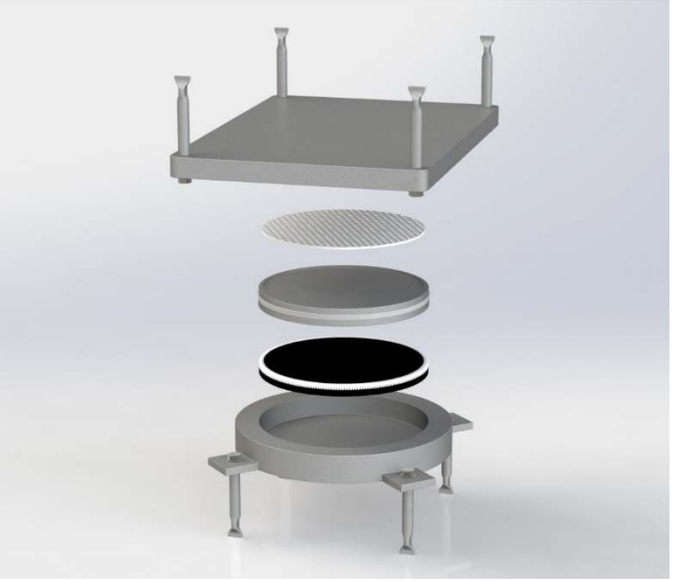

Figure 1. Rendering (exploded view) of a typical pot bearing of the free sliding type.

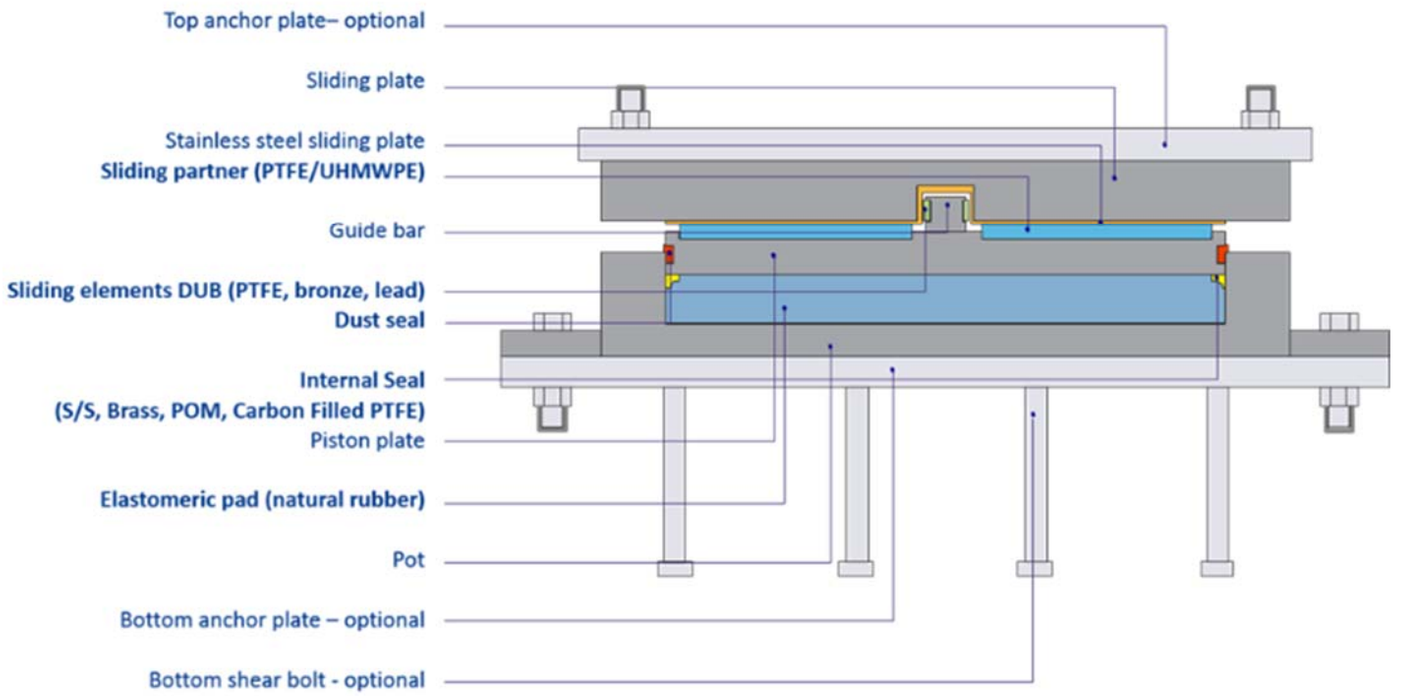

Figure 2. Cross section drawing of a typical guided sliding pot bearing (with internal guide bar) showing its key components.

2.1 *Pot and piston*

The pot and piston are generally manufactured from ferrous materials in accordance with AS3678 or the equivalent international standards. These components are typically machined out of solid steel blocks.

2.2 *Elastomeric pad*

The elastomeric pad at the heart of the pot bearing, which enables the bearing to accommodate rotations, is usually moulded from a rubber compound in accordance with AS5100.4 Table B3 (A).

2.3 *Internal Seal*

Under vertical load from the superstructure, the elastomeric pads, being confined by the internal walls of the pot, becomes semi-viscous and would be extruded from the pot if not prevented from doing so by an effective seal. Figures 3 to 6 show various sealing solutions that have found application in recent decades.

Figure 3. Internal seal for pot bearing: Stainless steel type.

Figure 4. Internal seal for pot bearing: Brass ring type.

Figure 5. Internal seal for pot bearing: Carbon-filled PTFE type.

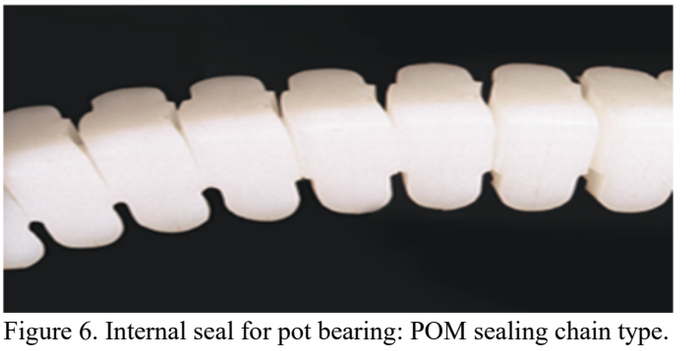

Figure 6. Internal seal for pot bearing: POM sealing chain type.

2.4 *Sliding Partners*

Three key materials are used as sliding partners to minimise friction between the upper and lower parts of the bearing.

2.4.1 *Stainless steel sheet*
Stainless steel sliding sheeting in accordance with AS 1419 or the equivalent international standard is attached to the bearing's upper sliding plate.

2.4.2 *PTFE / UHMWPE disc*
A dimpled PTFE or UHMWPE disc, recessed into the top surface of the piston, forms a non-metallic sliding partner for the stainless steel. Refer to Figure 7 for dimple pattern and Figure 8 for recess details.

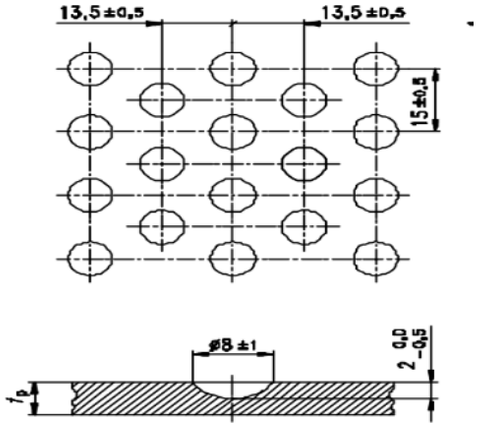

Figure 7. Dimple pattern in recessed PTFE / UHMWPE sheets.

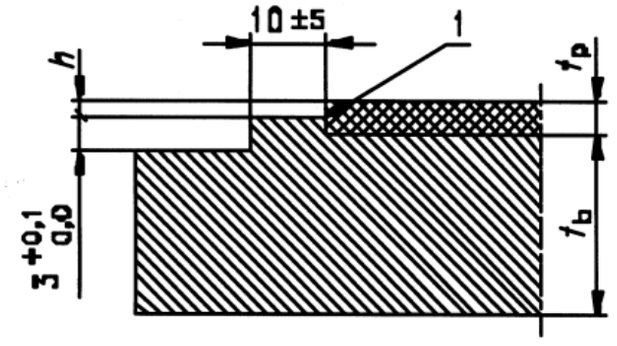

Figure 8. PTFE / UHMWPE recess details in steel base plate.

2.4.3 *Lubricant*
A long life, neutral and silicone-based lubricant is applied to the PTFE / UHMWPE disc, in a controlled environment, to minimise sliding friction.

3 DESIGN OF POT BEARINGS

Bearings must be designed to ensure safe transfer of applied vertical and horizontal loads between the superstructure and the substructure, and to accommodate any translational and rotational demands of the structure that may arise at this critical structural interface.

These performance requirements must be met with adequate reliability and durability, by adopting the design procedures specified by, for example, AS5100.4 (2017) or EN1337-5.

4 PREMATURE FAILURE OF POT BEARINGS

Pot bearings can be considered to have experienced failure in the following situations:

- Elastomer is extruded out of the pot
- PTFE is abraded to the bottom of dimples in the sheet or squeezed out from the recess
- The bearing is unable to accommodate required translation and/or rotation movements
- The pot, piston or any other structural part is cracked or significantly distorted/deformed

5 LATEST REPORTS OF PREMATURE POT BEARING FAILURE IN AUSTRALIA

Various asset owners/managers across Australia have reported premature failure of pot bearings due to either elastomer extrusion or movement/rotation capacity restriction. Many of these failures were investigated and causes documented, and ARTC and Lindsay Dynan have kindly made available the findings from the internal report prepared for ARTC, enabling a broader audience to benefit from the report's findings and recommendations. Figures 9 and 10 show, for example, pot bearings that failed within five to seven years of initial installation.

Figure 9. Failed pot bearing with elastomer extruded out.

Figure 10. Failed pot bearing with cracked steel pot.

6 DETAILS OF INVESTIGATIONS FROM KOORAGANG ISLAND BRIDGE AND RECOMMENDATIONS FOR ASSET OWNERS

The Kooragang Island Bridge consists of twin steel girder bridges, an 'arrivals' and a 'departures' bridge, crossing the Hunter River in Newcastle, Australia. The bridges provide the link between over 25 operating coal mines and the export terminals located on Kooragang Island, with in excess of 100 million tonnes of coal product being transported over the arrivals bridge each year. The arrivals bridge (Fig. 11) is subjected to fully loaded coal trains, and therefore experiences up to six times the magnitude of live load experienced by the departures bridge, which typically carries locomotives and empty wagons on return from the coal export terminal.

Figure 11. Kooragang Island Arrivals Bridge

6.1 *Bridge geometry and description*

The bridge has eight 30-metre spans, with the train track's continuously welded rails supported on timber transoms over twin 2.5m-deep steel girders. The steel girders are laterally braced with vertical and horizontal steel angle bracing. A cross-section of the bridge deck is shown in Figure 12.

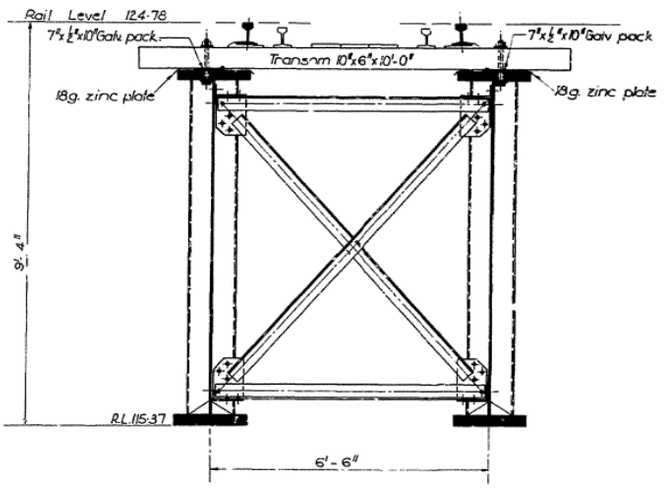

Figure 12. Cross-section of the Kooragang Arrivals Bridge deck.

The pot bearings are bolted to the bottom flange of the steel girders, and bear on a concrete grout pad formed on top of the concrete bridge piers. Through bolts attach the bottom anchor plate of the pot to the concrete piers, and the internal bearing arrangement is similar to that shown in Figure 2, with a stainless steel internal seal of the type shown in Figure 3. Each span has fixed pot bearings under each girder of the "country end", and guided sliding pot bearings under each girder of the "city end".

The arrivals bridge was constructed in 1968 and has undergone only minor modifications to the superstructure to date. The bearings have been replaced a number of times, with the most recent replacement occurring 13 years prior to the observed failure described herein.

6.2 *Bearing damage and observations*

Following observations of excessive lateral movement of the top of train wagons, an examination of the pot bearings was undertaken. It was observed that the elastomer had extruded from both the fixed and sliding bearings, and also that the steel piston plate of one sliding bearing had cracked substantially. The bolts connecting the uplift plates were observed to have sheared off. It was immediately obvious that the bearings were failing and as such, the bridge was closed to traffic whilst temporary repair works were carried out. The severely damaged bearings were completely removed and replaced at the next available opportunity.

During the removal and subsequent inspection of the damaged bearings, a clearer picture developed of the likely failure mechanism. It was evident that the internal stainless steel seal (see Section 2.3 above) had broken down and abraded/shredded the elastomer, causing the bearing to fail. The internal seal of a pot bearing is critically important for its proper functioning and durability, as recognised by Clause 13.1(e) of AS 5100.4 (2004). Figures 13 and 14 show the elastomeric pad within the upper housing, and fragments of the stainless steel seal can be seen sitting loose. Also apparent is the damage to the pad itself.

Figure 13. Damage to pot bearing's elastomeric pad and its metallic seal – Kooragang Arrivals Bridge.

Figure 14. Damage to pot bearing's elastomeric pad – Kooragang Arrivals Bridge.

6.3 *Assessment of Failure Mechanism*

Once the mechanism of bearing failure had been determined, attention shifted to understanding the underlying cause of the failure. The bearing assemblies were assessed for installation issues and for non-compliance with AS5100.2 and AS5100.4. No significant anomalies were noted in this regard.

After consideration of the bridge geometry and the observed damage, it was postulated that the internal stainless steel seal had failed due to excessive cyclic rotations under load. The magnitude of the difference between high-frequency live loads and dead load is much higher in rail bridges than in road bridges. Whilst these rotations can be accounted for in the bearing specification, it appears the internal seal is susceptible to abrasion-type damage under the high-magnitude cyclic live loading conditions. This loading caused the internal seal to fail and abrade/shred the elastomer, resulting in greater rotations and further damage to both the seal and the elastomer.

In the case of this rail bridge, the relatively lightweight superstructure (steel as opposed to concrete) increases the differential magnitude between dead and live loads. Additionally, the steel girders are deep, and due to the age and geometry of the structure, these are potentially subject to incidental lateral movements that may increase the net rotations experienced by the bearings under live loads.

6.4 *Conclusion*

It is the opinion of the authors that the above-mentioned factors have contributed to the early failure of the bearing due to excessive cyclic rotations and the poor design of the internal seal. The evidence suggests that pot bearings of the type used on the Kooragang Island Arrivals Bridge are not suitable for steel rail bridges, and similar suggestions have been noted in the American AREMA Manual for Railway Engineering (Part 5 - Bearing Design and Construction).

In the case of the Kooragang Arrivals Bridge, following temporary stabilization and repair works, the damaged pot bearings were replaced with spherical bearings which can accommodate much larger rotations and can be considerably more durable than pot bearings – resulting in significant savings in life-cycle costs.

For the future reference of bridge inspectors, the indicators of bearing distress in the Kooragang Island Bridge case were as follows:

- Excessive rotations / displacements of the bearings under load. In the case of the Arrivals Bridge, this was observed by rail authority staff on a routine inspection and was evident on closer inspection from the sheared bolts of the bearing uplift plates.
- Reduced gap between the top and bottom bearing parts (indicating loss of elastomer thickness).
- Extrusion of the elastomer from the bearing piston.

7 ROOT CAUSE OF THE PROBLEM

As discussed in Sections 5 and 6 above, the majority of pot bearing failures were found to be due to excessive abrasion of the internal seal around the perimeter of the elastomeric pad.

The European standard EN1337-5 provides comprehensive prescriptive guidance for selection of appropriate internal seal materials based on material abrasion resistance. The information presented in EN1337-5 is based on extensive independent testing and research and development work done by EUROCODE committees over the last several decades. AS5100.4 (2004) only mentioned metallic internal seals, which have been demonstrated to have the lowest possible abrasion resistance among the various types mentioned by EN1337-5. The revised AS5100.4 (2017) acknowledged the findings of EN1337-5 and included the materials in accordance with this norm for use on Australian structures.

8 TESTING OF INTERNAL SEAL DURABILITY

EN1337-5 prescribes internal seal systems with reference to the *Accumulated Sliding Path* achieved during testing. Testing was conducted in a laboratory environment by subjecting pot bearings with various internal seal designs to a vertical load increasing in steps of 0.5 N/mm^2 until the contact stresses on the elastomeric pads reach a maximum of 35 N/mm^2. An actuator with a frequency of $0.25\ \text{Hz} < f < 2.5\ \text{Hz}$ was utilised to induce rotations of between +0.0025 rad and -0.0025 rad in the bearing.

Acceptance criteria for these tests are as follows:

- There shall be no extrusion of cohesive elastomeric material.
- The compression deformation under the test load shall have not increased for at least 24 h.

Wear of the seal and discoloration of the lubricant is acceptable in these tests.

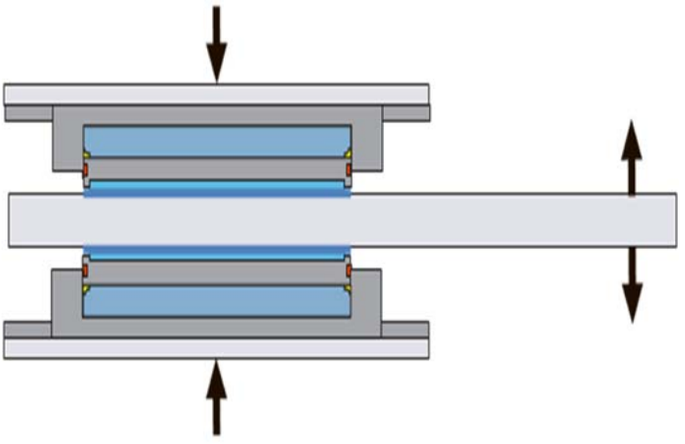

Figure 15. Test set-up for rotational testing per EN1337-5.

The sliding distance that each seal can withstand before failing under any of the above acceptance criteria is measured and taken as the "Accumulated Slide Path" of the seal. This can also be defined as the sum of the relative movements of the seal on the pot wall due to cycles of rotation of the bearing caused by external loading.

EN 1337-5 defines the Accumulated Slide Path for various materials as follows:

- Stainless Steel: 500m
- Brass: 1,000 m
- Carbon-filled PTFE: 2,000m
- POM chain: 2,000 m

8.1 *Accumulated slide path and service life of the pot bearing*

Accumulated Slide Path determined from the above tests can be translated into the service life of the bearing using Equations 1 and 2 below:

$$S_{A,D} = n_v \times \Delta\alpha_2 \times \frac{D}{2} \quad (1)$$

$$S_{A,D} \leq c \times S_T \quad (2)$$

where

$S_{A,D}$ Actual Accumulated Slide path required for the bearing internal seal due to characteristic traffic load on the bridge

n_v Number of heavy vehicles for the intended life of the bearing

c Correction factor (equal to 5) for the difference between the constant amplitude slide path used in the tests and the variable amplitude movements which actually occur due to loading on the structure

For example: Consider a bridge on a road with a traffic volume of 30,000 trucks per year (nv) for 100 years. Assuming a pot internal diameter (D) of 360 mm, based on vertical load carried, and a resultant rotation angle of 0.015 rads (Δα), then

$$S_{A,D} = (30000 \times 100) \times 0.0015 \times \frac{360}{2} = 8100m$$

Hence, to enable the pot bearings to survive the expected service life of the bridge, select pot bearings that have an internal seal with a verified accumulated slide path of 2,000m, so that the calculated slide path capacity (5 × 2,000 = 10,000 m) will exceed the actual sliding path of 8,100m.

9 BRIDGE BEARINGS AND AS5100.4 (2017)

Some significant changes have been made to the 2004 edition of AS5100.4 Clause 13.1 to enhance the performance of rail and road bridge bearings. The following are extracts from this clause:

- To prevent extrusion of the elastomer, the pot shall incorporate a seal around the top corner of the elastomeric disc. The internal seal shall be either a set of brass rings, a POM chain or a carbon-filled PTFE seal complying with the requirements of EN 1337-5.
- The maximum accumulated slide path (ASP) of the internal seals, defined as the sum of the relative movements of the seal on the pot wall due to cycles of rotation of the bearing caused by traffic loading shall be taken to be 2000 m for POM chain and carbon-filled PTFE seals, and 1000 m for brass rings.
- Due to the large number of loading cycles arising, only pot bearings with POM chain or carbon-filled PTFE seals shall be used on rail bridges and road bridges where the number of heavy vehicles per lane per day in the first year of service is predicted to exceed 1000, as defined by Clause 13.1(d) of AS 5100.2.

It is also worth noting that the performance of pot bearings is noted to significantly improve when the smoothness of the internal walls of the pot is increased. An existing European Technical Approval (Mageba ETA 13/0039) has shown that the POM seal's Accumulated Slide Path can be successfully increased up to a value of 3,200 m by suitably adapting the roughness coefficient of the pot's internal walls.

10 FURTHER POSSIBILITIES

To avoid the occurrence of problems of the type discussed in this paper, or mitigate such problems should they occur, the following possibilities are presented to indicate alternative or complementary solutions.

10.1 *High-quality pot bearings with well-proven sealing detail*

Of course, the simplest answer to the challenge / risk identified and discussed above is to only use a pot bearing type that has proven its quality and durability, particularly in relation to its sealing detail, on many bridge applications over a period of many years. One such pot bearing is the RESTON-POT bearing, different designs of which are illustrated in Figures 1 and 2 above, and which uses a POM sealing chain to seal the elastomeric pad against extrusion from the piston – a solution which has proven to be extremely effective and durable.

10.2 *Alternative bearing types*

To avoid the potential problem of rubber pad sealing entirely, an alternative type of bearing might be used. Spherical bearings can generally be used as an alternative, and so this type of bearing is described below.

10.2.1 *Spherical bearings*

Spherical bearings, such as the RESTON-SPHERICAL bearing illustrated in Figure 16 (which shows fixed, free sliding and guided sliding types, depending on the extent to which they accommodate horizontal superstructure movements), do not have a rubber pad at their core and are thus in principal stronger and more durable than pot bearings. They accommodate rotations, not by deformation of a compressible material, but by sliding rotation of a convex-shaped steel element in a concave-shaped recess. Due to their greater strength they can generally be designed to be smaller than an equivalent pot bearing (for the same design loading).

A comparison between key attributes of spherical bearings and pot bearings is provided in Table 1.

Fixed | Free sliding | Guided sliding (with external guide bars)

Figure 16. Exploded views of three types of spherical bearings.

Table 1. Comparison of pot and spherical bearings (based on RESTON-POT and RESTON-SPHERICAL).

Characteristic	**Pot bearing - typical**	**Spherical bearing - typical**
Sliding material	PTFE	Superior ROBO®SLIDE sliding material
Allowable pressure on sliding material	f_d = 64.3 N/mm^2 $f_{k,max}$ = 90.0 N/mm^2	f_d = 128.6 N/mm^2 $f_{k,max}$ = 180.0 N/mm2
Allowable pressure on elastomeric pad	f_d = 46.2 N/mm^2	No limitation since no elastomeric pad used
Resulting bearing size	Larger	Smaller
Resistance to wear of sliding material (in sliding types)	Limited to approximately 20,000 m accumulated sliding distance	Much higher (virtually no wear observed after 50,000 m of accumulated sliding distance)
Resulting service life of bearing	Shorter	Significantly longer
Rotational capacity	Restricted to 0.030 rad	Not restricted by standards
Temperature range	Can typically be used at temperatures down to –35 °C or –40 °C	Can typically be used at temperatures down to –45 °C to +50 °C

10.3 *Integrated monitoring system sensors*

Modern structural health monitoring (SHM) systems can serve many purposes in bridge construction, inspection, maintenance and renovation, by measuring key data such as movements and loading. Such data can often be optimally measured at the structure's bearings, and so it is often sensible to consider, on a structure which will have an SHM system, integrating load sensors into the bearings during their design and fabrication. This can enable loading data to be read via a data cable connection point as shown in Figure 17. With this cable connected to a suitably designed permanent SHM system, the loading on the bearing can be automatically monitored, all day and every day. Of course, if the seal of a pot bearing fails, and the elastomeric pad at its heart starts to be extruded, the load data from that bearing will change, indicating that a problem is developing and enabling the responsible engineers to take appropriate actions before the problem deteriorates. The ability to provide such peace of mind to asset managers is a key benefit offered by modern SHM systems.

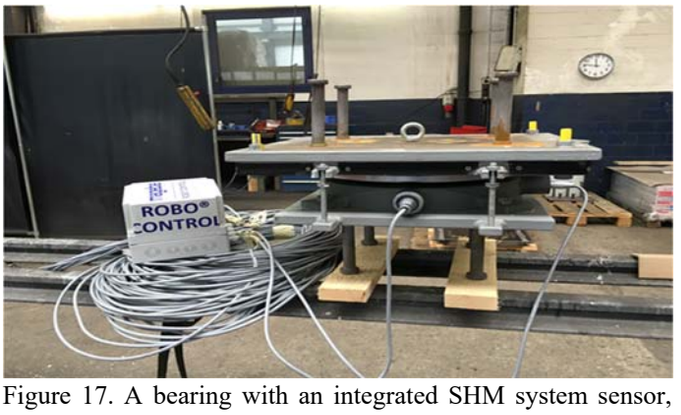

Figure 17. A bearing with an integrated SHM system sensor, with data cable connected for testing before installation.

ACKNOWLEDGEMENT

The authors would first like to thank the ARTC Chief Executive Officer and Managing Director, John Fullerton, National Bridges and Structures Engineer Peter Prasad, for their permission to publish this paper and Brenton Wakem and Dr. John Mullard from Lindsay Dynan for their valuable inputs and all of the asset owners and other professionals that assisted in composing this paper.

Breaking the Asphalt code – Polyurethane flexible plug expansion joint

C. Sarmiento, G. Pope & S.N. Kazi
Mageba, Sydney, Australia

ABSTRACT: Typically, expansion-joints are installed between adjacent spans of a bridge deck or the bridge deck and the abutment. Their exposure to impact and vibration caused by traffic-loading, climatic-conditions and chemical agents' impact, causes them to deteriorate faster than other bridge components. This requires maintenance and replacement during the service life of a bridge.

An enhanced flexible-plug expansion-joint has been developed, with a polymeric surface, which offers a number of substantial advantages over the traditional bituminous type. The Polyflex®Advanced expansion joint offers all the benefits of the asphaltic plug joint, including smooth, safe, low-noise surface, great adaptability and easy installation. However, it overcomes numerous disadvantages and challenges that have always plagued asphaltic plug joints. Installation is also far easier and less prone to error, with the two-component compound being mixed at ambient temperatures. For these and other reasons, this joint should be considered for use in bridge-construction, in particular, in bridge-maintenance.

1 INTRODUCTION

Flexible plug expansion joints are generally used in road and railway bridges to bridge the structural gap and accommodate the movement between the bridge deck and abutments. This type of expansion joints are selected over other small movement expansion joint types because of their relative low cost, ease in handling, installation & maintenance and good waterproof properties. Furthermore flexible plug joints offer a smooth, neat and seamless joint surface that brings about the most desired benefits of driver comfort and huge noise reduction. In addition, they can be installed and replaced in varying deck plan geometry & profile and in sections which significantly minimise disruption to traffic.

Flexible plug expansion joints were traditionally made from bitumen-based material, a mixture of aggregates and plasticised polymer or bitumen. These traditional bitumen-based flexible plug expansion joints were popular for decades however they are prone to durability problems. They suffer from excessive softening during hot days and hardening during cold days. Continuous dynamic loading from vehicle wheels and poor material quality control during installation hasten their failure in the form of cracking, rutting, de-bonding, spalling, delamination, bleeding and loss of watertightness.

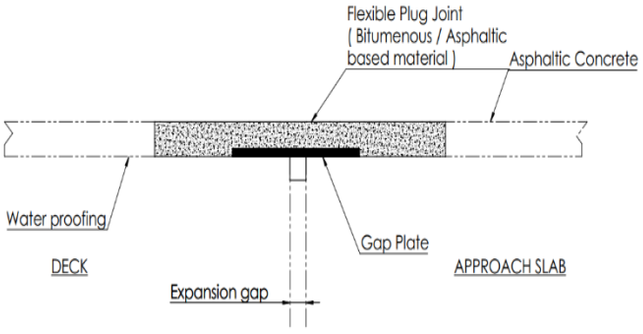
Extensive research then followed on how to overcome the durability problems and at the same time preserving the benefits of flexible plug expansion joints. This led to the development and introduction of Polyflex®Advanced flexible plug expansion joints which utilises a much more superior polyurethane-based flexible material and stronger support and connection details.

2 HISTORY AND BACKGROUND

The decision on the choice of the most appropriate type of bridge expansion joints rests on a number of factors which include service life and durability, functionality, code compliance, economics, quality, safety, maintainability, constructability, and environmental and ergonomic considerations.

The traditional bitumen-based flexible plug expansion joints (Figure 1) have been a popular choice where the overriding considerations are constructability, environmental and ergonimic. This is because they are relatively easy & quick to install, very quiet and do not generate undesirable level of noise, provide smooth neat riding surface and offer unsurpassed driver riding comfort. These traditional bitumen-based flexible joints however do not rate well on all other main considerations which had

restricted their use. There are numerous reported problems concerning durability, functionality and quality resulting in considerable reduction in service life , increased maintenance costs and reduction in efficacy in other areas like noise and comfort.



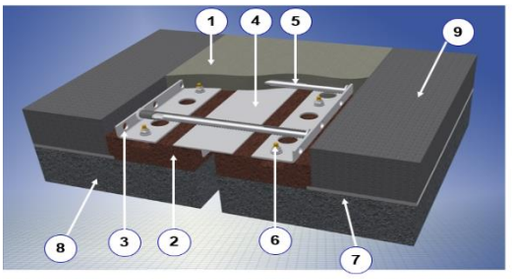


Figure 1. Bitumen-based flexible plug expansion joint

In NSW Australia, the Road and Maritime Service Authority (RMS – formerly RTA) had banned the use of bitumen-based flexible plug expansion joints on new bridges and are discouraged for use on maintenance and rehabilitation works except where noise issues are predominant and there is no suitable alternative (RMS 2008). This was based on reported softening of the bitumen-based material in hot weather and hardening & cracking in very cold weather. There were also noted failures like rutting & delamination when the joint is under heavy traffic loading.

In Switzerland, it was shown after investigations done in cooperation with the Swiss Federal Authorities for Material Science and Technology that the quality of the bitumen being used for these type of joints was very inconsistent which significantly affects functionality and durability. It was reported that small changes in the chemical composition of the raw materials led to big reductions in expansion joint quality (Gallai et al 2017 & Mageba SA 2016). This had led to increased concerns about the suitability for use of these bitumen-based flexible plug expansion joints.

In USA, Department of Transport Authorities (WSDOT & CDOT) no longer specify and do not recommend bitumen-based flexible plug expansion joints on highways with high traffic and roadways with heavy trucks. This is due to observed creep, poor expansion performance and bitumen binder migrating out of the block-outs (WSDOT Design Manual M23-50-17 2017 & CDOT Design Manual 2017).

Given the challenge of addressing and overcoming the aforementioned problems associated with bitumen-based flexible plug expansion joints while at the same time preserving the benefits, research and development efforts followed to optimise the design and come up with a superior flexible material and much improved quality. The result is the introduction of Polyflex®Advanced flexible plug expansion joint which had undergone extensive testing and has since been successfully installed in European countries, North America, parts of Asia and Australia and performing well without any reported problems usually associated with the old bitumen-based flexible plug expansion joint.

Figure 2 - Polyflex®Advanced Polyurethane (PU)-based flexible plug expansion joint

3 DESIGN & CHARACTERISTICS OF POLYURETHANE-BASED FLEXIBLE EXPANSION JOINT

The distinct features of the design is the use of polyurethane (PU) material instead of the traditional bituminous / asphaltic material. In addition it has side perforated steel supports and stabilisers if needed.

PU which has a long history of use as a waterproofing material in the building industry and as further improved over the years was adopted and proven to be a suitable material for flexible expansion joints. It has excellent elasticity having elongation test values of 650% before breaking (over 1.5x that of standard rubber 350-400%) which makes it ideal for use in expansion joints.

This special purpose PU offers large tear resistance capacity at 20 N/mm² and a tensile strength of 14 N/mm². It has a density of 1.05 g/cm³ and a "Shore A" hardness of approximately 65. It is highly resistant to wear and to the detrimental effects of exposure to chemicals and the environment, which gives it a long service life. Its service life is significantly longer than that of other roadway surface materials. The perforated steel supports allow the joint to withstand high traffic & dynamic loading including braking forces while also accommodating large movement and at extreme high & low temperature.

Total movements of up to 135 mm (See Figure 4) can be accommodated with this PU-based flexible expansion joint which is significantly larger than the

+/-20 mm for bitumen or asphaltic-based joint(Bridge Joint Association 2003).

Due to its stable characteristics at high and low temperature, this PU-based flexible expansion is fully functional in the operating structural temperature range of -50°C to +70°C, which is a big improvement over the bitumen-based joint.

The PU-based flexible joint can be installed or can fit into varying joint geometry like X-Shape and upstand shown in Figure 3.

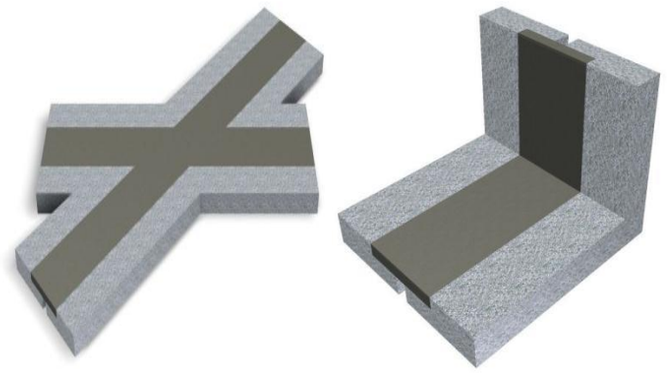

Figure 3 – X shape and upstand

Type	Total Movement mm	Movement Elongation mm	Movement Compression mm	Thickness of PU-layer mm	Width in starting position mm
PA 15	15	10	5	40	280
PA 30	30	20	10	50	350
PA 50	50	33	17	60	459
PA 60	60	40	20	60	500
PA 75	75	50	25	60	600
PA 90	90	60	30	60	750
PA 135	135	90	45	60	1100

- Table shows examples for general design, widths can be interpolated
- For individual cases, width and thickness are determined based on required movement
- All types are designed for a vertical displacement of ± 10 mm (± 0.39"), allowing for bearing replacements
- Movements are indicated in SLS, for ULS higher deformations are permitted

Figure 4 - Polyflex®Advanced Movement Capacity

4 INSTALLATION

New installation of PU-based flexible joint offers the huge benefit of ease of installation compared to other types of bridge joints including the bitumen-based flexible joint. There are no heavy joint metal components eliminating the need for lifting cranes. There is also no need for mixing plants and heaters. Unlike the tedious process ensuring the correct set out of metal components and anchorage bolts required for metal type joints (strip seal type, finger plate type), the PU material when poured, easily adapts to suit the shape & dimensions of the receiving joint block-out. The two-component PU material can be simply mixed from complete packing units at ambient temperature minimising the risk of substandard or non-compliant mixing. The processing of the PU material is possible at temperatures from +5°C to +35°C and irrespective of humidity conditions.

For rehabilitation works or replacement of other types of joints, the benefits of the PU-based flexible joint can even be more appreciated. The joint can be formed just within the depth of the bridge deck/ road surface, avoiding further invasive works like breaking of adjacent concrete. This minimal work on the existing structure combined with the short curing time translate into easy, quick, and economical installation and minimal impact on traffic. The joint can also be installed in sections or lane by lane which can further assist in minimising the impact on traffic. This is possible because the PU material from the previous section installed and already cured is chemically reactivated by the following fresh PU material which produces a strong homogeneous bond.

The following shows and describes the installation process:

- A block-out is prepared by machine cutting the road surfacing along markings of pre-determined width and depth. The road surface is cut down to a firm substructure (concrete or any stable sublayer) to which the polymer concrete can bond to. (Figure 5)
- The block-out is then cleaned and air-blasted to ensure PU joint materials will bond properly. (Figure 6)
- Where required, the bridge deck/road surface waterproofing membrane can be extended into the block-out (Figure 7)
- In the case of rehabilitation works where an old joint is removed and there is an absence of appropriate surface, formwork or a sheet of Styrofoam is then placed in the bridge gap to retain the polymer concrete base. (Figure 8)
- A suitable primer is then applied before the polymer concrete is poured. The polymer concrete cures naturally at ambient temperature. It cures in approximately 1 hour @ 15C. The perforated angles are then anchored on both sides and the bridge plate is placed over the joint gap. (Figure 9)
- After all the above works are done and verified to be in compliance with all requirements, the PU material is then poured, trowelled and levelled precisely to match the level of the connecting road surface. (Figure 10 & 11)

5 TESTING – EUROPEAN TECHNICAL APPROVAL (ETA)

In the process of obtaining a European Technical Approval ETA-12/0260, and in accordance with ETAG 032 Part 3, an extensive testing program was implemented by the Federal Institute for Materials Research and Testing, BERLIN (BAM) and the "Inspection authority for road construction" of

Technical University of Munich (TUM) along with MAPAG Testing Institute Austria.

POLYFLEX®ADVANCED PU has successfully demonstrated to meet all the requirements laid down by ETAG 032 before the European technical approval was granted.

5.1 *Testing of bond strength of the PU material*

The tests included verifications of bond strength on various surfaces such as concrete, polymer concrete, steel and asphalt. The recorded values were much higher than the required 1.5N/mm2 required by ETA-12/0260. Even at low temperatures, excellent resistance to de-bonding and thus also excellent resistance to leaking could be demonstrated.

5.2 *Assessment of dynamic –mechanical behaviour, ageing and temperature characteristics of the PU material*

The ageing and temperature characteristics of the PU joint filling mixture were evaluated after ageing for 3030 hours at the BAM. The evaluation, based on ISO 4664, was carried out over a temperature range from -60°C to + 250°C. Both the complex modulus |G*| and the loss factor tan δ demonstrate very good performance for the declared temperature range of -40°C to +60°C. See Figure 12.

5.3 *Mechanical resistance testing*

At the TUM a full-scale assembled joint specimen in the maximum opening position was subjected to a test load of 150 kN via a pneumatic tyre. The contact pressure was 0.94 MPa, the temperature was +23°C and the specimen length was approximately 1 m. *The* test was carried out in accordance with the Austrian regulation RVS (2) and the appropriate European Technical Approval Guideline (ETAG 032, Part 3, Annex 3M Method a), and recorded deformation after loading and any subsequent recovery curve. In the test, deformations of max. 0.5 mm were recorded immediately after unloading. Within one hour of unloading a complete elastic recovery of the surface had occurred. No damages or other changes to the surface were detected. See Figure 13.

5.4 *Fatigue resistance testing – rollover testing*

A second full-scale joint specimen was subject to further testing in the same testing rig at the TUM. The test involved cyclic loading by a pneumatic trafficking simulator, at an elevated temperature in excess of 45°C, in accordance with draft ETAG 032, Part 3, Annex 3M Method b. The contact pressure of the pneumatic tyre was 1.0 MPa, and the number of overpasses was 3030, with 30 of these executed with an additional 10% of horizontal load to simulate braking forces. The test result was successful as neither de-bonding nor cracking was observed post testing.

On the basis of experience in Europe with the same testing procedure for asphaltic plug joints and various national regulations, this successful high-temperature testing justifies 15-year design service life categorization.

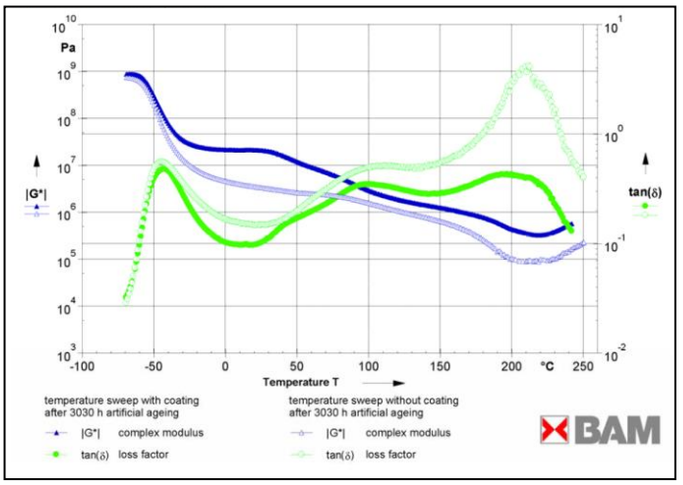

Figure 12 - Assessment of ageing and temperature characteristics

Figure 13 – Mechanical resistance testing

In addition, a standardized rutting test was carried out, at 60°C, in accordance with EN 12697-22. Figure 14 shows the enormous difference in performance between traditional asphaltic plug joint material and the POLYFLEX®ADVANCED PU material.

Figure 14 - Comparison of common asphaltic plug joint material and POLYFLEX®ADVANCED PU material after rutting test acc. to EN 12697-22 at 60°C (Top: Common asphalt plug material after 100 cycles at 60°C. Bottom: Polyflex®Advanced after 30,000 cycles at 60°C)

5.5 *Movement capacity testing*

To evaluate the movement capacity of the full-scale joint specimen, a test was performed at the BAM in accordance with draft ETAG 032, Part 3, Annex 3N. The complete declared movement range from maximum elongation to maximum compression at associated temperatures between -40°C and +60°C was subject of the test. During the test, reaction forces and deformations were recorded.

The specimen was horizontally extended by deforming it 1 mm for the duration of 7,500,000 sinusoidal cycles at ambient temperature and a frequency of 5 Hz. In addition, dynamic properties were voluntarily tested at -40°C. The dynamic behaviour of the material proved to be excellent, with the specimen showing no irregularities or signs of fatigue after the testing. See Figure 15

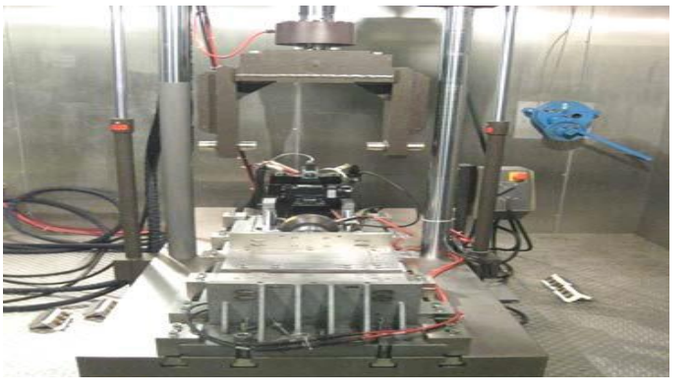

Figure 15 – Movement testing at-40C to +60C

5.6 *Watertightness testing*

After successfully passing the aforementioned movement testing, the full-scale specimen was subjected to a water tightness test at the BAM. At the maximum opening position of the joint, a full scale test specimen of 1m joint length was subjected to 30mm water head for six hours. After the test, no signs of leakage or moisture could be found under the specimen. The test was carried out in accordance with ETAG 032 Part 1, Annex L – Watertightness Test Method.

Figure 16 – Verification of watertightness at maximum opening position of joint following movement capacity test

5.7 *Measurement of level differences in the surface*

Level differences of the full-scale specimen was checked prior to any imposed horizontal deformations and in unloaded condition in accordance with the Austrian regulation RVS and the ETAG 032 Part 1- Section 4.1.4.1.2. The difference in the levels of the running surface of the joint from the ideal connection line between the two adjacent pavements in the traffic direction shall not be greater than 5 mm.

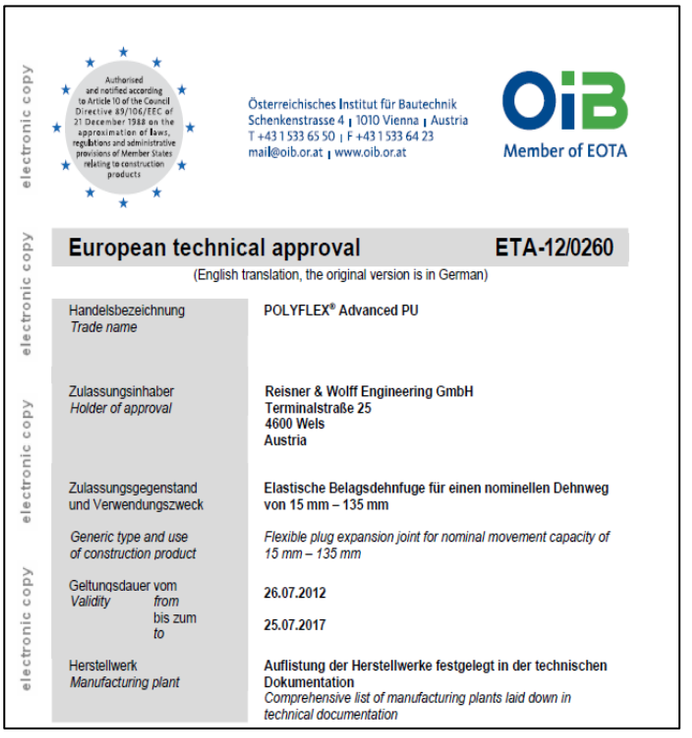
After loading, greater deviations are permitted, but these must not exceed 12 mm. Level differences were monitored during the fatigue and movement tests and upon their completion. The results were positive, with

a maximum level increase of +6 mm and a maximum level decrease of -5 mm being recorded.

5.8 *Skid resistance testing*

The full-scale specimen was subjected to skid resistance testing with a portable skid resistance pendulum tester as described in EN 13036-4, using the CEN rubber slider for carriageways and the 4S rubber slider for footpath areas.

5.9 *Further testing*



Testing was carried out on the joint's components to establish durability characteristics as follows and in accordance with ETAG 032 Part 1 requirements for Aspects of Durability verification methods:

- Resistance to chemicals, such as oil, fuel and de-icing agents, according to EN ISO 175
- Temperature-based ageing: Various tests according to EN 13687-2, EN 13687-3, EN 13687-5
- Ageing resulting from UV-radiation and weathering: Long-term tests (3030 hours) to TR010
- Ageing resulting from ozone: Test according to ISO 1431
- Freeze-thaw test (with thaw salt) according to EN 13687 Part 1

5.10 Resulting European Technical Approval (ETA)

As a result of this testing, the expansion joint has been awarded a European Technical Approval (ETA). This ETA covers joints of this type that accommodate longitudinal movements (SLS) of up to 135 mm (90 mm expansion and 45 mm compression), with a thickness of 60 mm and an initial width of 1100 mm. All types are designed for a vertical displacement of +/- 10 mm, permitting bridge bearing replacement work to be carried out without damaging the joint.

Further national approvals have also been awarded. For example, an approval issued by NEXCO (the West Japan Highway Administration) on the basis of specially completed testing according to Japanese regulations have validity right across Japan. The main focuses of the testing at the official Japanese testing institute at Fuji were verifications of resistance to rutting, abrasion, skid resistance and the ability to accommodate both slow and fast movements. The complete testing program was successfully completed in spring 2015.

6 AUSTRALIAN STANDARD COMPLIANCE

Extremes of shade air temperatures appropriate to structure locations in Australia are defined in Table 18.2(1) of AS5100.2. The maximum shade air temperature is 46°C which correlates to a maximum average bridge temperature of 50°C in accordance with AS5100.2, Table 18.2(2). For bridge superstructures consisting of a concrete deck on steel girders this temperature shall be increased by 10°C. This is deemed to be the highest temperature to be considered for this type of joint in accordance Australian Standards, and corresponds to the maximum tested temperatures.

AustRoads Guide to Pavement Technology, Part 2 and Main Roads WA Engineering Road Note 9 require the design tyre-pavement contact stress for pavement analysis to be taken no less than 0.75 MPa. The contact stress is related to the air pressure in the tyre in service. For highway traffic the contact stress is assumed to be in the range 500-1000 kPa. It was therefore concluded the ETA-12/0260 testing (refer to 5.3 and 5.4) for the pavement component of the POLYFLEX®ADVANCED PU expansion joint complies with Australian requirements.

7 REFERENCE PROJECT HISTORY

Since the first successful installation of Polyflex®Advanced flexible plug expansion joint in 2007, it has led to a rapid increase in orders each year in the following European countries including Australia:

- Germany
- Austria
- Hungary
- Italy
- Poland
- Belgium
- United Kingdom
- The Netherlands
- Switzerland
- Bosnia and Herzegovina
- Myanmar
- Croatia
- Sweden
- USA
- Canada
- Japan
- Denmark
- Norway
- Australia

In Australia, this joint was first installed successfully in May 2015 in Perth WA on the Judd Street Bridge. This was a rehabilitation project where the old Sliding Finger Type Joint had severe corrosion in the surface area of finger plate and in the counter bored holes affecting the anchorage integrity, compromising functionality which raised safety concerns. Figures 18 show the old replaced joint & Figure19 shows the new replacement Polyflex®Advanced flexible plug expansion joint. The new joint has given the benefits of a smooth surface resulting in huge noise reduction, better driver comfort, corrosion resistant while meeting functional and movement requirements.
Due to the success of the Judd Street project and the satisfaction of the asset owner (MRWA), succeeding orders followed including the South Western Highway Bridge, Bridge Over Warren River and Bridge Over Collie River.

Figure 19 – Judd Street Bridge New Polyflex®Advanced flexible plug expansion joint

8 CONCLUSION

The Polyflex®Advanced flexible plug expansion joint offers all the benefits and at the same time overcomes the numerous disadvantages of the traditional bitumen asphaltic joint. This modern flexible plug type joint not only is a highly recommended replacement for the traditional bitumen asphaltic joint but also for other types of joints like the strip seal type and finger plate type which are prone to anchorage problems.

Summarised below are the benefits of this modern Polyflex®Advanced flexible plug expansion joint

- Exceptionally long working life, longer than adjacent surfaces
- Highest possible driving comfort
- No noise from traffic due to surface that is flush with adjacent road, i.e. no hitting by the wheels
- Fully watertight
- Maintenance-free (no cleaning, re-bolting, CP repair are required)
- Quickly installed lane-by-lane with minimal traffic impacts
- Installation within a wide temperature range (5°C to 35°C; installation at higher temperatures is also possible with some ventilation aids)
- Wear-resistant, no mechanical wear parts
- No rutting, high resistance to abrasion (e.g. from braking traffic)
- Damage to the joint can be easily repaired by reactivation of the PU material
- No recess for anchorage in structural concrete necessary

- Surfacing (asphalt or concrete) can be applied continuously before joint installation
- Any horizontal bend in the joint possible
- Any curb / sidewalk detail possible
- Low reaction forces
- Cold processing and easy handling with pre-set mixing ratio minimizes risk of mixing errors
- Resistant to environmental influences and acids, bases, chlorides, etc.
- Smooth surface ideal for pedestrian areas (e.g. in airports and railway stations)

Critical factors in minimizing total life cycle costs of bridge expansion joints

G. Pope, J. Creighton & V.V. Ghodke
Mageba Aus, Sydney, Australia

ABSTRACT: Inadequate consideration to long term performance of the bridge expansion joint, and their exchangeability when finally end of service life approaches, could pose severe consequences to bridge owners or managers. A simple and low technology product selected predominantly based on lower initial product cost will almost always require premature replacement whereas a properly selected and engineered high quality joint may provide more than 40 years of uninterrupted service. Direct costs for maintenance and premature intervention or replacement and indirect costs of disruption to the commuters can be accumulated to many multiples of initial "savings" in product cost of low technology expansion joint. Understanding long term performance of expansion joints with the aid of engineering and testing of these joints can certainly help optimizing the life-cycle costs of the bridge expansion joint. This will benefit the bridge owners, commuters and society.

1 INTRODUCTION

Strong consideration for life-cycle costs is widely considered as an important part of responsible asset and project management. There have been numerous analyses into the impact of proper life-cycle cost consideration as well as advice on mitigating these costs. Despite showing a clear advantage to taking life-cycle costs into strong consideration, there has not yet been the shift toward responsible asset management in this regard which has been anticipated for some time.

This paper presents scenarios relating to the life-cycle costs of bridge expansion joints based on different philosophies. These are based on figures provided by owners and managers of bridges, as well as other related literature. Advice is offered for those creating strategies designed to reduce the total life-cycle cost of expansion joints through careful consideration of the key factors that affect the longevity of a joint.

Apart from direct life-cycle cost considerations above, there are indirect costs such as wasted material and time, noise pollution, and – significantly – economic effects due to congested traffic. Additionally, should a joint fail and cause damage to the main structure, this cost should also be considered as part of the total life cycle cost of a bridge expansion joint. Leaking joints can cause significant damage to a structure if left uncorrected.

These costs, direct and otherwise, are discussed below.

As bridge expansion joints is even more specialised a field than bridges themselves, the amount of literature regarding their life-cycle costs is quite limited. This paper aims to shed some light onto the various factors which will affect the long and short term costs both direct and indirect, of a given bridge expansion joint.

Figure 1. Large movement capacity of expansion joints of 1920mm on the Incheon Grand Bridge, South Korea

2 CHALLENGES OF BRIDGE EXPANSION JOINTS

Bridge expansion joints have some of the highest demands among bridge components (Moor et al. 2016). They are required to allow various movements

and rotations while resisting repeated impact and dynamic loading from passing traffic.
Over a 40 year service life, these load cycles total in the hundreds of millions or even billions and hence are subjected to fatigue stress. This is compounded by the fact that they are much lighter than the structure of which they are a part. Due to these conditions, maintenance is an inevitable part of the service life of a given joint.

Proper consideration of the total cost of the joint should be an important factor in the selection of a joint. As will be outlined in this paper, there are several factors contributing to the life-cycle and total cost of a bridge expansion joint. Among these are the costs associated with the wear and tear induced by fatigue and other processes.

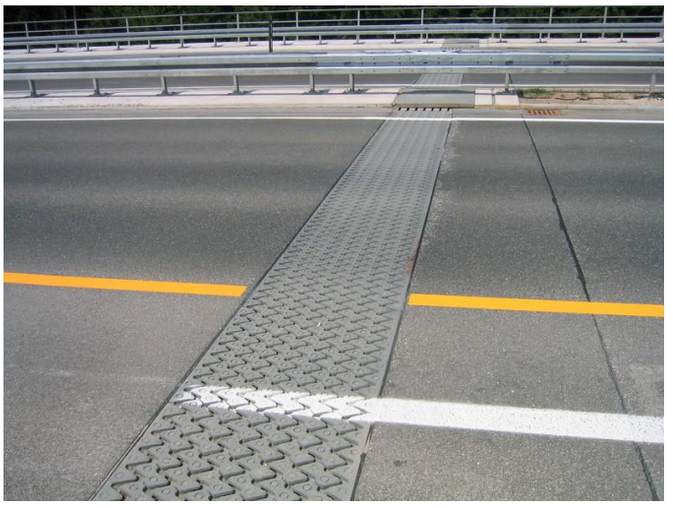

Figure 2. A 7-gap modular joint with noise reduction plates

3 BRIDGE EXPANSION JOINT TOTAL LIFE-CYCLE COST

3.1 *Definition*

Life-Cycle Cost (LCC) is "the sum of all costs anticipated during the service life" (Hawk et al. 2003). These costs are appropriately scaled to account for change in price and dollar value projections for the time period in which they are expected to occur. It is considered good practice to complete an LCC analysis to determine the best option, rather than simply the upfront cost.

3.2 *Components*

The LCC includes several components which summarise the various costs which can be expected for a given asset.

The LCC is the sum of Initial Supply Cost (ISC), Initial Installation Cost (IIC), Inspection and Maintenance Cost (IMC), Direct Replacement Cost (DRC) and Direct User Cost (DUC) over the service life of the bridge.

This is expressed using Equation 1 as below:

$$LCC = ISC + IIC + IMC + DRC + DUC \quad (1)$$

(Savioz, et al. 2014)

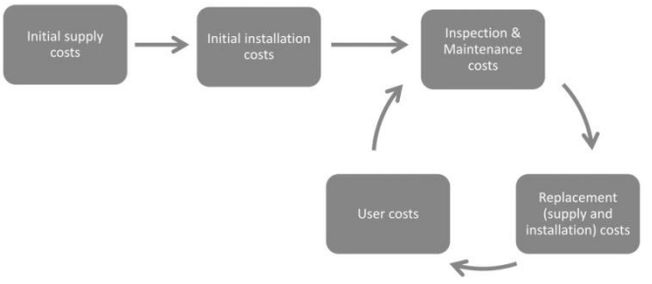

Figure 3. A flow chart of Life-cycle Cost (Savioz, et al. 2014)

3.3 *Consideration*

It is shown in Figure 3. that the life-cycle being considered in this analysis is that of the bridge itself, not the bridge expansion joint. This means that when a join has reached the end of its service life, it must be replaced. This process of replacement is expensive and recurs throughout the life of a bridge, as such, it contributes a major portion of the total Life-Cycle Cost.

Excluding the Direct User Cost, each of the other costs are taken up by the asset owner and so should be of direct concern when choosing a bridge expansion joint. There are, however, varying philosophies for the management of each of these costs.

Initial Supply Cost and Initial Installation Cost are the most obvious and traditionally of primary consideration to the decision maker. These costs are unavoidable, however, the reduction of these costs can lead to increases in other costs.

Direct Replacement Cost is directly affected by the service life of the previous joint and should be kept as minimal as possible.

Inspect and Maintenance Costs should be considered inevitable but also reducible through proper selection consideration.

All of the cost groups are connected and affect one another in different proportions. As an example, a large investment into a high quality joint and its maintenance will result in a longer service life, which in turn leads to less replacement cycles.

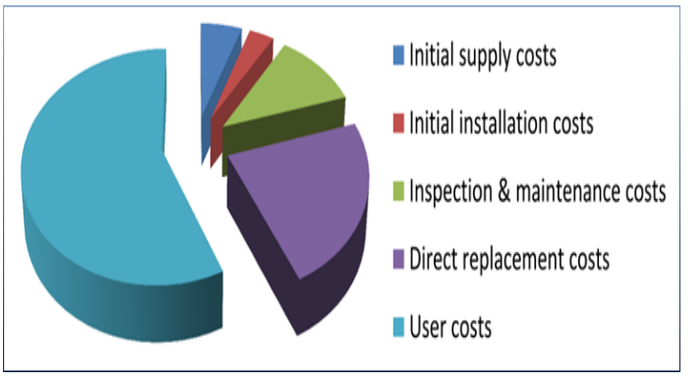

Figure 4. Distribution of life-cycle costs

Each cost group will be covered below in greater depth.

3.4 *Initial supply cost and initial instalment cost*

Initial supply and installation costs are generally unique from project to project. This is due to the widely varied expansion gaps and bridge widths, among other factors that contribute to the cost of a bridge and its joints.

It can generally be said that the cost of a bridge expansion joint will be in the range of 1% of the total construction cost of a bridge (Harper-Smith Kelly 2017). As such, it is a minor part of the total bridge construction cost, despite playing such a major role and having such demanding conditions.

The difference in initial supply and installation costs between a low and high quality product of similar parameters is approximately 60-80% increase in cost. This is significant, however, the increase in quality leads to reduction in other costs.

3.5 *Inspection and maintenance cost*

Asset owners often take one of two approaches to maintenance; proactive or reactive. A proactive strategy is most advisable as this allows early detection of potential failures followed by appropriate corrective action.

Reactive strategies are problematic as "failures are often a chain reaction (i.e., the failure of one component leads to the destruction of other components)" (Dexter et al. 2002). This is especially true for bridge expansion joints, as due to the dynamic movements and loadings which they carry, they are subject to particular deterioration. Additionally, when a bridge expansion joint fails, these loads and movements are transferred to other parts of the structure, which are not suited to these conditions, accelerating their own deterioration.

The chain reaction can result in damages and repair work costs that far exceed the cost of proactive inspection and maintenance.

Another benefit to proactive inspection and maintenance is that a joint which is deteriorating, if caught early, may be maintained and kept from failure for much longer than if left alone. This delays the replacement cycle of the expansion joint.

3.6 *Direct replacement cost*

Expansion joints, being highly dynamic moving parts, have a shorter service life than that of a bridge structure, as such, it is expected that it will require replacement at some point in the life of the bridge.

Replacement of a bridge expansion joint comes with many additional challenges than that of the initial installation, including work around traffic and the restrictions which that imposes. In conjunction with other bridge works, the replacement cost is anticipated to be approximately three times that of the initial installation cost, while when done independently of other works, this can be as high as six times the initial installation cost (Savioz, et al. 2014).

Figure 5. Failed aluminium joint in Jeddah, Saudi Arabia (Spuler et al. 2014)

This process therefore should be undertaken as few times as possible throughout the life of the bridge in order to minimise this cost. As seen in previous sections, the best strategy to extend the life of an expansion joint is to procure high quality products while using a proactive approach to inspection and maintenance.

3.7 *Direct user cost*

There is very little empirical data for direct user costs, and as such, estimates must be made based on expected outcomes and circumstances. Savioz et al. 2014 suggest that a reasonable estimation would be 10% of indirect user costs.

Direct user cost itself is the cost taken up by the bridge users resulting from improper performance of the joint. These cost are generally due to traffic disruption during replacement or maintenance works, though in some cases, they may be from damage caused by a joint which is damaged or not working correctly, as in Figure 5.

Aside from direct damage, there are considerations such as delay for commuters, additional fuel usage, detours which may be necessary and further impacts of any of these. As these are all very situation specific, it can be difficult to correctly calculate potential costs.

Example LCC calculation and comparison

Savioz et al. 2014 uses the example of a bridge expansion joint used on a European highway to illustrate the importance of using high quality products in order to reduce the total LCC. Taking the initial supply and installation costs as a combined EUR 200,000, the LCC was extrapolated using the figures in Figure 6.

Working Assumptions	High-End Product	Standard Product	Low-Tech Product
Lifetime (years)	40	25	10
Initial investment value	120%	**100%**	70%
Maintenance per year	2%	4%	6%
Direct replacement costs (DRC)	420%	400%	370%
User costs from traffic disruption (UC)	500%	500%	500%

Figure 6. Working assumptions of the cost intervals of high, standard and low quality products (Savioz, et al. 2014)

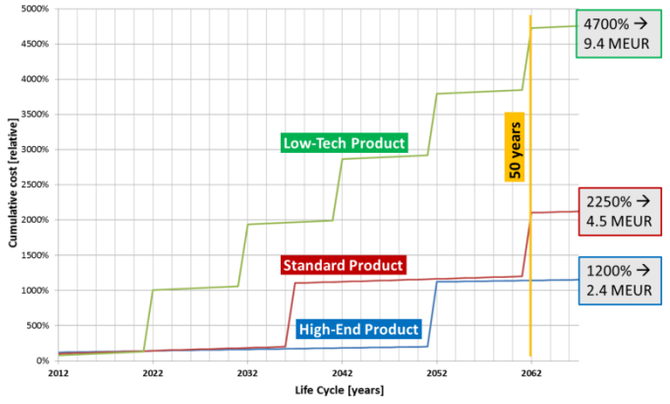

Figure 7. Typical Life-Cycle Cost progression of high, standard and low quality products (Savioz, et al. 2014)

Even discounting the user costs from this comparison, the difference is in the millions of Euros of additional cost to the asset owner over the life of the bridge. Along with the commentary provided in previous sections, this analysis shows the need to reduce the number of replacement cycles by extending the service life of a joint.

4 MINIMISATION OF A JOINT'S LCC

As seen above, the life-cycle cost of a bridge expansion joint can vary greatly and it is of great benefit to the asset owner to reduce this as much as possible. There are several components to an effective strategy which leads to a greatly reduced life-cycle cost of bridge expansion joints, these are outlined below.

4.1 *Suitability of the joint*

From the outset of a bridge design, a bridge expansion joint selection will be affected. The designer will be making considerations such as span length, affecting the joint movement capacity required among many others. As such, it is important to ensure that the type of joint specified is chosen with respect to the various factors that contribute to the required performance characteristics of a joint. Consultation with an experienced bridge expansion joint supplier is recommended in order to make sure the joint performance capabilities are properly considered in the design and joint selection.

It is then important to clearly and properly define all the characteristics which a joint will be required to fulfil. These include longitudinal movement, transverse movement, traffic loading and frequency, any other loading imposed on the joint itself, cumulative movement, rotations, any location or design specific conditions like earthquake conditions, among others.

All of the above factors must be integrated into the bridge expansion joint design and hence should not be left aside or underestimated or the joint will be prone to failure due to unsubstantial design parameters.

Once these factors have been determined, the type of joint which is selected is critical. There are several main categories of bridge expansion joint, each with advantages and disadvantages and differing capabilities. Again, consultation with an experienced bridge expansion joint supplier is recommended for this process to ensure the optimal option is chosen. From this point, the bridge designer must provide adequate blockout and other allowances to ensure that the selected joint is able to be installed correctly.

4.2 *Quality and durability of the joint*

It is important to strongly consider the quality of a bridge expansion joint as this can greatly impact on the service life of a joint.

4.2.1 *Material*

The material which is selected is of particular consequence. Primarily steel and aluminium are the materials used, each with their own advantages and disadvantages. Edwards & Yeung 2017 explain that while aluminium has superior corrosion protection to steel, it is less reliable in the long term due to fatigue effects which expansion joints experience over their service life. As can be seen in Figure 8. steel will reach a point ("endurance limit") where its integrity is maintained despite repeated loading cycle. Conversely aluminium continues to deteriorate over time as it is subjected to further load cycles. Load assumptions for bridge fatigue design are based on the nature of steel and its endurance limit. For aluminium joint, these assumptions may lead to an over estimation of the fatigue life. Therefore, it is recommended that in the case of using aluminium joints, extensive testing is recommended in order to assure that the joint design can withstand the fatigue effects.

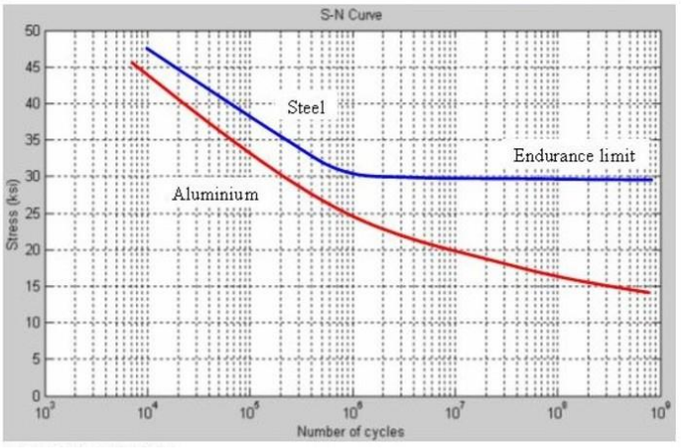

Figure 8. Comparison of aluminium and steel S-N curves

4.2.2 *Testing*

As above, aluminium joints in general are recommended to be tested against fatigue effects, however, this recommendation is extended to steel joints as well for proper joint design verification. Moor et al. 2016 note that the AASHTO specification for modular joint fatigue testing is the most demanding test requirement worldwide and that it should be used for verification that a joint "will provide good long-term performance".

While testing of bridge expansion joints may not yet be required in many local and global standards, it is one of the best ways to verify that a design will withstand the fatigue, movement, rotation and loadings which it will be subjected to throughout its service life. "The assurance that the testing can provide to the bridge owner that the delivered expansion joints will be fit for purpose can be of great significance, in particular if the supplier cannot demonstrate many years of successful experience" (Spuler et al. 2011). This verification, will then provide evidence to the bridge owner that the joint in question, with proper care, can be expected to have a long service life.

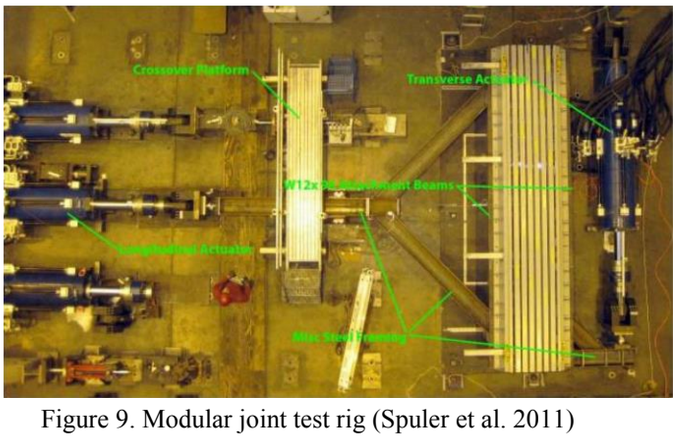

Figure 9. Modular joint test rig (Spuler et al. 2011)

4.2.3 *Corrosion protection*

Exposed steel should have adequate corrosion protection specified, applied and maintained in order to ensure the integrity of the joint. The bridge designer should specify the corrosion conditions so that the bridge expansion joint supplier can select the adequate corrosion protection system for the particular circumstance.

It should be considered that the use of hot-dip galvanisation may omit corrosion protection repair over the lifetime of a joint. A conservative approach to the expected lifetime is published in EN ISO14713.

Reapplication of painted corrosion protection should be considered part of the regular maintenance routine of the bridge to assure the joints integrity.

4.2.4 *Quality assurance*

The bridge expansion joint supplier and manufacturer should have comprehensive quality assurance, (generally according to ISO 9001) so that the product received is as specified and designed. This should preferably include third party verification as a means of ensuring this process is carried out correctly.

4.3 *Quality of the installation*

The installation of a joint is a critical part in determining its proper function. Dexter et al. 2002 identifies 10 common errors which lead to problems with the installation affecting the performance of the bridge expansion joint. For this reason, it is recommended to have an authorised person representing the bridge expansion joint supplier supervise and witness the installation. Most suppliers will also provide an installation guide which should be strictly adhered to.

The designs of the bridge and joint can also affect the installation quality, for example, a design which limits access and workability during installation can be problematic for the installation process.

Figure 10. Installation of a bridge expansion joint

4.4 *Adequate inspection and maintenance routine*

As noted previously, a proactive inspection and maintenance routine is a key component in ensuring the longevity of the bridge expansion joint along with other components. As with installation, the supplier will generally provide an inspection and maintenance manual which outlines the recommended practice and procedure for achieving the best service life for that joint.

Dexter et al. 2002 note that there are "three major factors inhibiting good inspection and maintenance practice", noting these as limited access, limited technical expertise among personnel, and expense factors.

Limited access is directly caused by design, and the designer of the structure should make efforts to avoid restricting the access to the expansion joints after construction.

Limited technical expertise can lead to issues being missed which would otherwise facilitate corrective action. For this reason, an inspection and maintenance manual is recommended to be followed by these personnel.

Figure 11. Excessive corrosion

Failing to carry out inspections and maintenance work to avoid the expense which they entail is strongly advised against. This practice can lead to missed opportunities for early corrective action, hence leading to expensive repair work, which are often far more expensive than the inspection and maintenance costs would have been (Savioz et al. 2014).

As seen in Figure 11. deterioration can become excessive if undetected due to either a lack of access to the area, or a poor inspection and maintenance routine.

A proper understanding of the importance of inspection and maintenance among decision makers will contribute to recommended practice, hence leading to longer expansion joint service life.

4.5 *Additional precautions to be considered*

There are several additional precautions which a bridge designer may choose to incorporate in order to improve the other aspects already discussed, primarily dampening mechanisms and structural heath monitoring.

4.5.1 *Dampening mechanisms*

Dampers, particularly hydraulic dampeners can reduce the effects of erratic movement which may cause undue detriment to the bridge expansion joint and structure as a whole. For example, these would be applicable for use in seismic areas to avoid potential deterioration from collision of elements due to unpredictable movements.

Figure 12. Hydraulic Damper

4.5.2 *Structural health monitoring*

Automated monitoring systems can greatly aid in the ongoing inspection and maintenance of the joint and bridge. They can provide metrics in real time such as movement frequency and magnitude directly to the bridge engineer. Having this system constantly monitoring the conditions of the bridge and its components can greatly reduce the manual effort of the inspection process. For example, it can be set up to flag or send a warning to the bridge engineer if a certain threshold is breached. This means that if it is approaching or exceeding limits which were defined, the engineer will not have to wait for the next inspection for this to be found, allowing for early intervention where required.

This system can therefore result in returning in savings many times the initial investment through early detection of problems which may lead to failure.

Figure 13. Structural heath monitoring system

5 TOTAL COST

The costs considered in the LCC method above are not the only costs associated with the life-cycle of a bridge expansion joint.

There are environmental costs from the production of the product as well as the type and quantity of material used, both at the initial supply and any replacement. There are numerous other factors contributing to the environmental cost of replacing a bridge expansion joint.

Ancich & Chirgwin 2006 estimate "community savings by avoiding replacement are estimated at a further $AU10 million" and Schulz & Mainka 2013 found that a full road closure for trucks on the A!-Rhine Bridge cost the economy between EUR 0.5-1.2 million per day of closure. This again, highlights the need to minimise closure time and reduce number of replacement cycles.

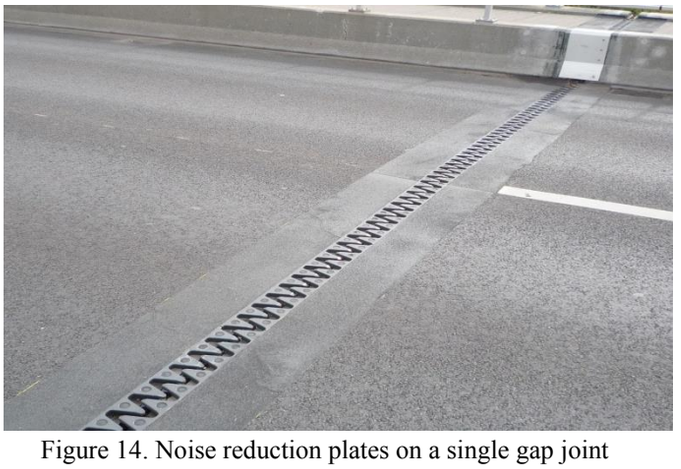

Figure 14. Noise reduction plates on a single gap joint

Additional to these costs of replacement is the noise pollution produced by traffic crossing the joint depending on the type of joint and the presence of noise reduction plates or lack thereof.

As alluded to previously, a faulty joint can have an impact on the main structure of the bridge. It is the role of many joints to catch and redirect water away from the structure, however if this function is failing, as is the case for a vast majority of bridges (Savioz et al. 2014), this will have detrimental effects to the structure itself, resulting in repair or maintenance costs that can far exceed the expansion joint's.

Aside from those costs outlined above there are others not covered.

The total expansion joint cost should be considered as the sum of its life-cycle cost, the indirect user costs, and any bridge maintenance costs resulting from expansion joint faults.

6 CONCLUSION

Proper consideration of the life-cycle cost of a bridge expansion joint over the life of a bridge shows that there are many elements worth taking into account beyond initial costs. Furthermore, a considered investment in a well-designed and well-made joint is very likely to generate savings well beyond the initial investment. High quality material, design and maintenance, although more expensive at the outset will minimise expensive repair and replacement costs.

The quality and appropriateness of a bridge expansion joint has great effects on the resulting service life, a high quality joint, selected properly for instance in which it is used, can last for 40 or more years before requiring replacement. Cheaper or poorly selected joints are likely to deteriorate and require repair or replacement much earlier.

Coupled with the initial quality of the joint, maintenance is a long term investment, which aids in the prevention of damages to the joint and the bridge structure itself where the joint has failed. These costs are minimal by comparison to the potential costs if proper inspection and maintenance is avoided.

The recognition of the investment in quality is yet to become wide scale practice, as it seems there is no incentive for construction companies to ensure the long term integrity of the asset once it has been completed. As the bridge expansion joint is such a small portion of the total initial expense, it is easy to see why construction companies might write it off as something to be procured for as little as possible, however, this attitude can lead to unnecessary increase in long term costs of maintaining the bridge.

Investigation into cause and effect of life-cycle costs also revealed the importance of technical advice from an experienced bridge expansion joint supplier throughout the design and construction process. This practice aids the designer, constructor and maintainer in their various roles contributing to the proper function and long and effective service life of a bridge expansion joint.

Aside from the financial benefits of a well-made, well-designed and well-maintained bridge expansion joint, there are also the social and environmental

benefits due to longer lasting joints which can be repaired and replaced less often and also easier than their cheaper counterparts.

High quality joints, verified through testing, using superior materials with proper maintenance is certainly worthy of investment for long term savings and social and environmental benefits.

Smart bridge components (expansion joints, bearings, seismic devices) for intelligent infrastructure

Kleidi Islami, Niculin Meng & Colm O'Suilleabhain
Mageba SA, Bulach, Switzerland

ABSTRACT: Modern automated structural health monitoring (SHM) systems have much to offer the responsible engineers in the construction, inspection, maintenance and renovation of structures in general, and of key structural components such as bridge bearings, expansion joints and seismic protection devices in particular. In the past, monitoring of such components generally involved the use of separate, independent sensors, connected not to the component but to the main structure and provided, to all intents and purposes, as an afterthought to the design and use of the components themselves. Improving technology is changing this, however, with "smart" components now available, with sensors pre-integrated in their design and fabrication before they leave the factory, and data analysis capabilities improving to include automatic identification of component damage based on general testing and teaching of the system.

1 INTRODUCTION

Recent technological developments in the field of structural health monitoring (SHM), particularly in relation to sensors and data logging, have greatly increased the potential of such technology to play a valuable role in civil and structural engineering – especially as it relates to critical infrastructure such as road and railway bridges. Continually progressing research work, and the innovations of suppliers, have resulted in the development of systems and solutions that can greatly increase the effectiveness and efficiency of bridge construction, inspection, maintenance and renovation work (Moor et al, 2014).

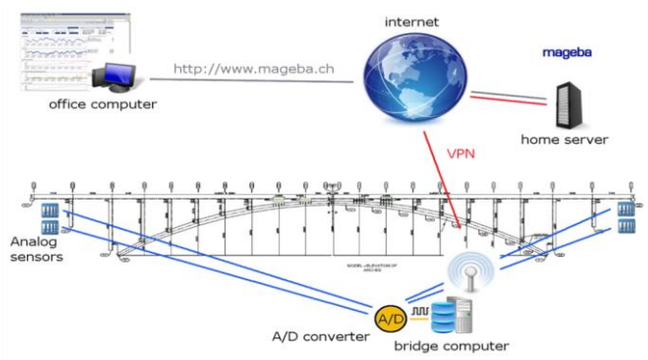

Figure 1. An SHM system with sensors integrated in key structural components can optimise inspection & maintenance work.

One such area of innovation relates to the key components which, if present, are generally critically important to a bridge's efficient design and proper functioning: its bearings, expansion joints and seismic protection devices such as dampers. This has led to the development of "smart" components, which feature pre-integrated SHM sensors already when fabricated, enabling bridge engineers to optimise the efficiency of their work as it relates to their structures' key components (Figure 1).

2 TYPICAL USES AND BENEFITS OF SHM IN CONSTRUCTION AND MAINTENANCE

Modern SHM systems can be used to provide reliable, precise data on virtually any variable of interest – e.g. forces, movements or rotations of any part of a structure. The data can be automatically measured and recorded around the clock, all year round, and at high frequency if required (e.g. to analyse vibrations), making the SHM much more capable, and also more efficient and cost effective, than traditional manual methods in many cases. By presenting the recorded data on a graph (for example, as shown in Figure 2), typically on a secure web interface, the effects of selected factors (e.g. temperature) on particular variables (e.g. structure movements, absolute or accumulated) can be easily analysed and understood.

Where specific concerns exist about a structure's safety or performance, an SHM system can be designed to provide notification, by email or SMS, to the responsible engineer of any exceeding of defined threshold values – for example, should movements of any part of the structure exceed expected values, or the width of a crack suddenly increase.

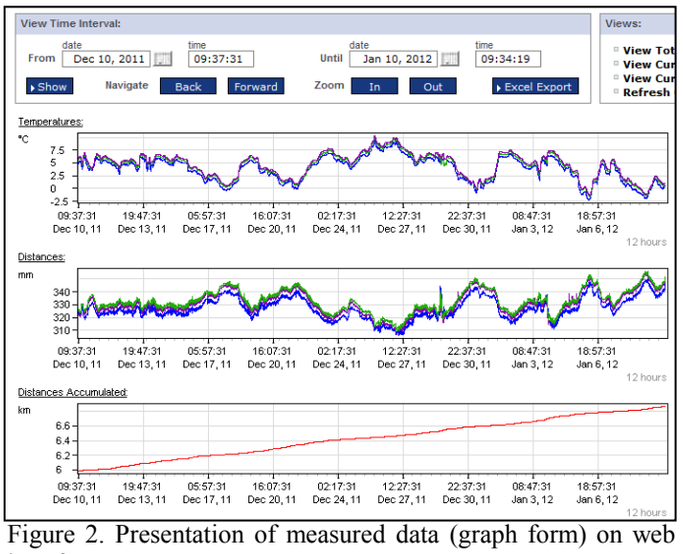

Figure 2. Presentation of measured data (graph form) on web interface.

Modern SHM systems can also be programmed to statistically analyse the data they record for easier evaluation. For example, histograms such as that shown in Figure 3 can be generated to visually present the frequency of occurrence of values in any given variable during a selected period of time, enabling anomalies to be readily identified.

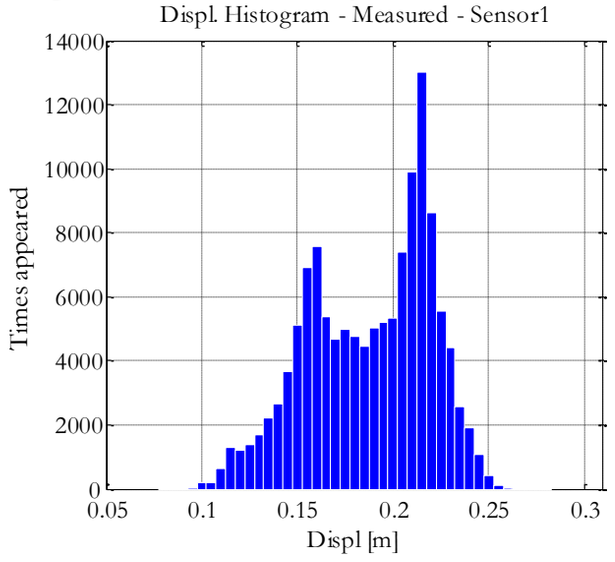

Figure 3. Example of a histogram presenting frequency of occurrence of all measured values.

Presentation of selected data on a single graph, e.g. as shown in Figure 4, can also enable correlations to be established and significant deviations to be identified.

It may also be helpful to be able to assess the static or dynamic behaviour of a structure due to certain influences but not others. By eliminating the influence of dominant, less relevant factors, small changes due to the factors of interest can be much more easily detected. For example, the effect of minor structural damage on a specific variable may remain unnoticed when clouded in data that includes the effects of temperature changes, but readily identifiable on a graph when the influence of temperature is excluded. Or the exclusion of temperature effects may enable the effect on deck displacements of other influences such as traffic to be more easily understood. Such analysis is made possible by the use of regression models as described by Islami & Modena (2013). The usefulness of this technique is illustrated by the graphs in Figure 5, which show how displacements at one point in a structure vary with time. The upper graph presents the measured data, unmodified, while the lower graph presents the data as modified to exclude the influences of environmental factors such as temperature but still showing the influence of traffic loading. As can be seen, the exclusion of particular data in this way makes analysis of the data far easier, with any irregular values being immediately recognizable, enabling the need for repair or preventative action to be assessed.

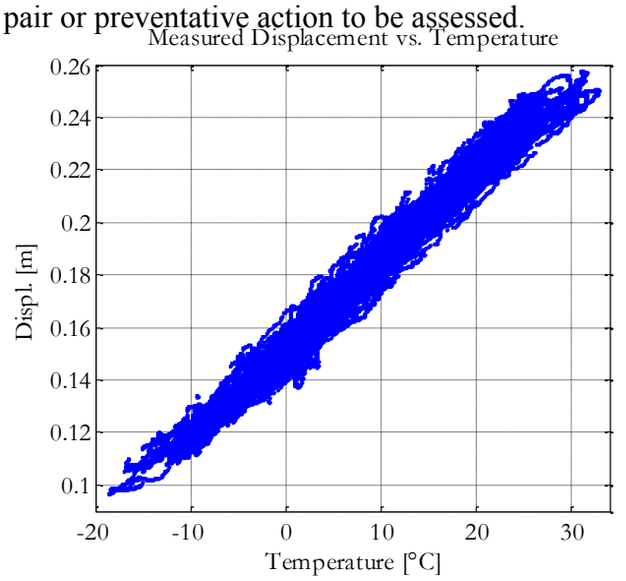

Figure 4. Example of a graph showing the correlation between an influence (temperature) and a measured effect (displacement).

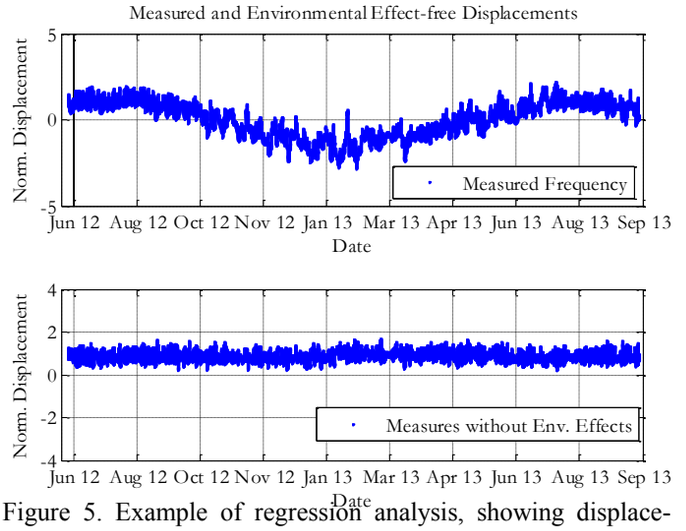

Figure 5. Example of regression analysis, showing displacement data, both before (above) and after (below) the elimination of environmental effects.

3 MONITORING OF BEARINGS

A structure's bearings are critically important for its proper long-term performance, and any loss of functionality can quickly develop into a serious problem for the structure. For example, if a bearing no longer enables a bridge deck to expand/contract or move as required by its design, enormous constraint forces can build up, potentially causing severe damage to the structure. It is therefore essential that the proper condition and functioning of a structure's bearings be adequately monitored, to ensure that any such loss of proper functioning, through deterioration, accidental damage or otherwise, is recognised in good time and appropriate actions taken to protect the structure. Where the condition of a structure's bearings has been found to be questionable or where further confidence in the ongoing performance of the bearings is required, the use of an SHM system is an attractive alternative to traditional manual inspections. Not only are automated SHM systems far more accurate and precise than manual measurements, they can be designed to operate 24 hours a day, 365 days per year, thus ensuring that any sudden deterioration or damage is immediately recognised and reported to the responsible authority. And if frequent visits to a bridge are required to perform manual inspections, the investment in an SHM system can be quickly paid off and easily justified.

3.1 *Case study: Spherical bearings of main junction of Qatar's new Orbital Highway*

Qatar's new Orbital Highway is currently under construction around the country's capital, Doha, and is expected to significantly reduce traffic congestion in the city while improving connections to other cities. At one of the highway's main intersections (Fig. 6), a spaghetti junction where it crosses the Dukhan Road, it was decided to install an SHM system to monitor the condition of the various structures. The recently installed system is based on measurement of data from the bearings that support the various superstructures – spherical bearings of the TENSA-SPHERICAL type. In all, 28 of these bearings are connected to 14 control boxes, as shown in Figure 8. The SHM system is designed to continuously monitor, in particular, the load acting on each monitored bearing – all day, every day. This will enable it to immediately identify any change in loading conditions – for example, should the load on any bearing increase or decrease due to structural damage/deterioration or ground settlement, either rapid or gradual. With so-called alarm values defined (above or below which the responsible engineers should be notified), risks to structure users can be minimized, and any structural damage or deterioration arising can be addressed before it develops into a bigger problem.

The bearings in question were specially designed to precisely measure the loads they are carrying at any time, with load cells integrated in their design – inserted beneath the sliding material at one side of each bearing's concave sliding surface. A short cable connects this sensor to the side of the bearing, where an external cable connection point enables the sensor to be integrated into the SHM system.

Figure 8. One of the SHM system's 14 control boxes and its connection to the spherical bearing above it – with the cable connection point partially hidden by the bearing's rubber dust skirt.

4 MONITORING OF SEISMIC PROTECTION DEVICES SUCH AS DAMPERS AND SHOCK TRANSMISSION UNITS

Like bearings, structural protection devices such as dampers and shock transmission units (STUs) must also perform reliably when required by the structure's design, otherwise the consequences for the structure could be catastrophic – especially when used to protect the structure from seismic ground movements. Dampers must, as the name suggests, dampen large sudden forces or vibrations at a certain point in a structure, reducing the impact on the structure and enabling the structure to respond as designed or even to survive the event without damage. STUs, also known as lock-up devices (LUDs), protect a structure by transmitting sudden forces directly where they can be readily resisted without damage, thus reducing the impact on other, less robust parts of the structure. In order to provide confidence that these critical components remain ready to perform their vital function when the time comes, SHM systems can provide an efficient, cost-effective, round-the-clock solution – especially when the required sensors are pre-integrated in the devices during their fabrication.

4.1 *Case study: STUs of the Halogaland Bridge in Norway*

The Halogaland Bridge is currently being constructed in northern Norway, and will form part of the European Route E6 highway. The suspension bridge will have a main span of length 1.1 km, crossing one of Norway's many fjords. Its design required the installation of Shock Transmission Units (STU) at each of the bridge's towers.

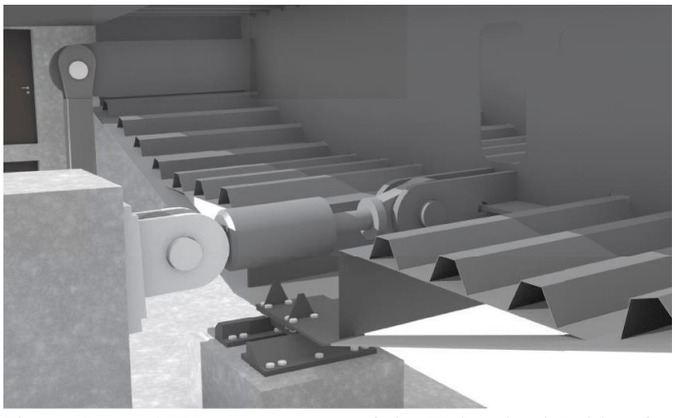

Figure 9. An STU at one tower of the Halogaland Bridge for control of deck movements.

The bridge is a good example of advanced structural engineering, and presented substantial design and construction challenges – and therefore also significant risks. To minimize these risks, it was decided to install an SHM system. Initially, the system is based on measurement of data from the RESTON-STU devices at the towers. A ROBO-CONTROL SHM system was designed to measure the longitudinal movements of the STUs, which have a stroke of +/- 450 mm, and to also measure pressure and temperature inside these hydraulic devices. Each STU is equipped with one sensor for measuring movements, two sensors for measuring oil pressure within the device, and one sensor for measuring internal temperature. All sensors were pre-integrated in the design and fabrication of the STUs before they left the factory, maximizing durability and ensuring reliability. The system measures the pressure inside the STUs at a frequency of 100 Hz, correlating the data against similarly monitored temperature and deck vibration data. This enables STU condition to be checked at any time, and for additional peace of mind, the system is also designed to provide immediate notification should pre-defined threshold values for movement or differential settlement be exceeded. And to enable the actual seismic performance of the STUs to be evaluated following an earthquake, the system also correlates the pressures inside the STUs against recorded seismic data.

The performance of these "smart" STUs is illustrated by the data available from a similar application as shown in Figures 10 and 11. This shows that the devices are sensitive, for example, to vehicles crossing the bridge on which they are installed. The graphs in these figures correlate pressures inside the STUs with deck accelerations during the passage of heavy vehicles. It is interesting to note how one can follow the progress of each vehicle as it crosses the bridge, from the first abutment (shown by STU pressure peaks) to mid-span (shown by acceleration/vibration peaks) and on to the second abutment (shown by further STU pressure peaks). This indicates that the system is working properly and that the STUs are contributing to protecting the structure against external excitations.

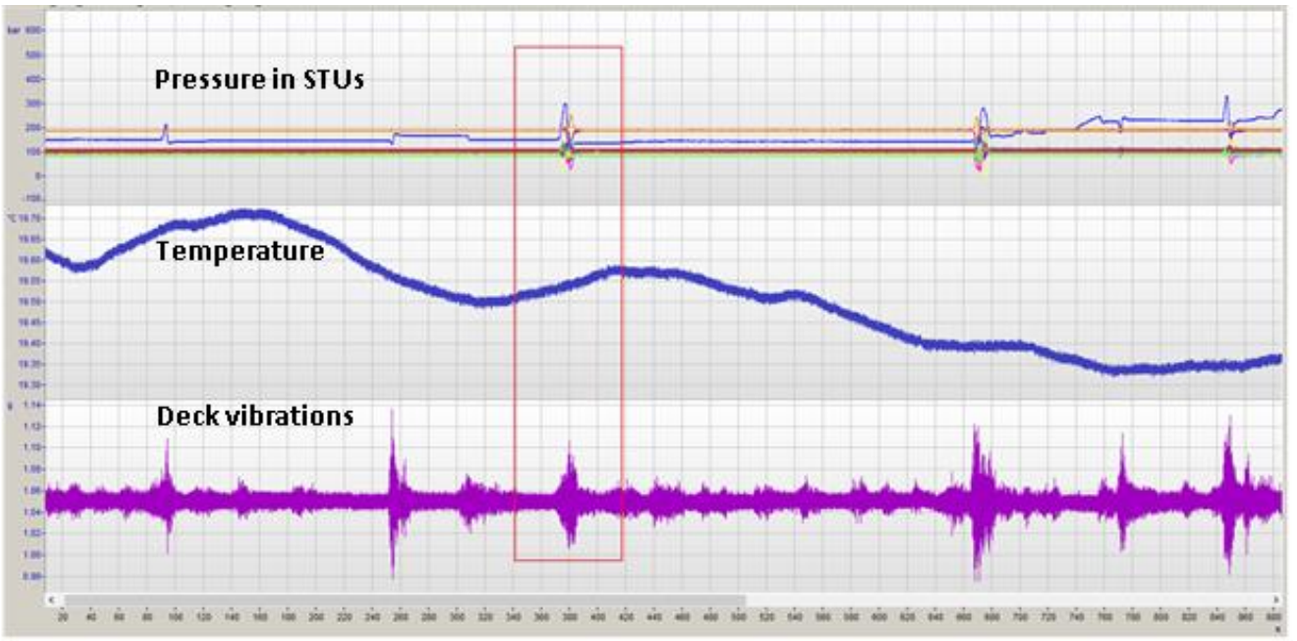

Figure 10. 100 Hz data measurements showing influence of traffic (indicated by deck vibrations) on STUs.

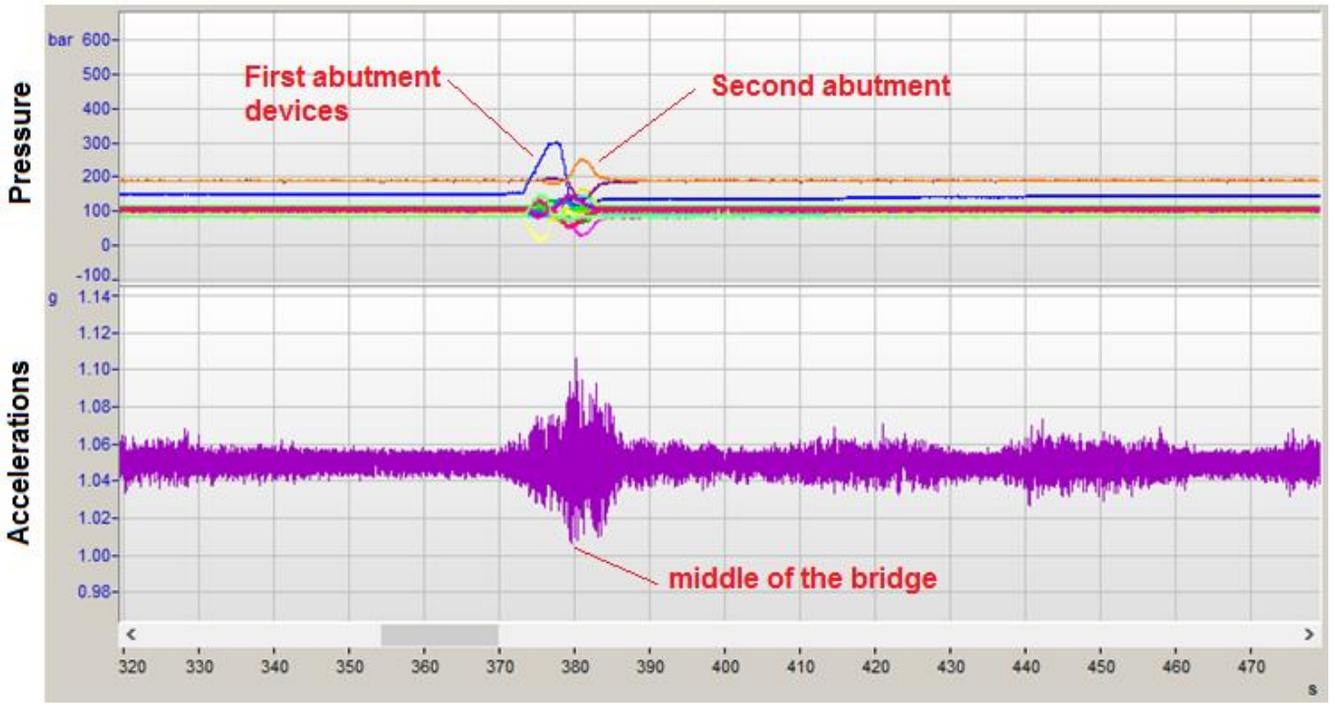

Figure 11. Close-up view of data (extract from Figure 10) showing the correlation of pressure and acceleration during the passage of a single truck.

5 MONITORING OF EXPANSION JOINTS

Although a bridge's expansion joints may not be as central to the structure's strength and stability as its bearings or dampers, the condition and performance of its expansion joints are critically important to a bridge's proper functioning as a transportation link. And given that expansion joints, very often mechanical devices with sliding interfaces, are typically subjected to direct impact loading from traffic millions of times a year, they are generally far more prone to wear and damage, and management of life-cycle costs can benefit enormously from the availability of good information relating to condition and performance (Spuler et al, 2012). Therefore, of all a bridge's key components, it is probably the expansion joints that can benefit most from the sensible use of SHM.

To maximize the benefit that can be gained from such technology, a worldwide supplier of both expansion joints and SHM systems has developed and combined the technologies, so that expansion joints can now be delivered with pre-integrated sensors for connection to a tailored SHM system. Not only that, the data analysis capabilities of the combined system have been greatly developed, based on the high-frequency measurement of structure-borne vibrations. This enables damage or deterioration to be clearly identified based on general testing and teaching of the system. As a result, unexpected damage can be immediately recognized and automatically notified, enabling the timing of replacement of components to be optimised and disruption to service to be minimized.

5.1 *Case study: Large-movement expansion joints of a new bridge*

The Taizhou Yangtze River Bridge (Figure 12), constructed at a cost of USD 400 million and opened in 2012, is the world's longest-span bridge of its type: The three-tower suspension bridge, with two main spans of 1,080 m each and side spans of 390 m, crosses the Yangtze River where it has a width of 2.1 km. The ambitious construction project represented the first attempt to create a long-span multi-tower suspension bridge.

This extraordinary bridge required some extraordinary key components such as the expansion joints which accommodate deck movements while providing a driving surface for traffic. Modular joints with 18 gaps each (able to facilitate 1440mm of longitudinal movement) were installed at each end of the deck (Figure 13).

An SHM system was installed on the bridge to provide the type of data that is likely to be of interest to the owner of any exceptional structure. The basic system measures and records the movements and rotations of the deck at the expansion joints, and thus gives a valuable impression of the performance of the structure, enabling the need for maintenance or adaptation work to be quickly identified and planned.

Figure 12. The Taizhou Yangtze River Bridge.

Figure 13. One of the Taizhou Yangtze River Bridge's enormous 18-gap modular expansion joints, viewed from below.

To maximize in particular the system's ability to monitor the condition and performance of the expansion joints, the above-mentioned newly developed technology was applied. By recording movements, inclinations, temperature and structure-borne vibrations at a frequency of 25.6 kHz, even very tiny changes in the joint or its performance can be detected and visually represented by changes in a curve on a graph. This will enable any sudden damage or deterioration to be immediately detected, based on testing and "teaching" of the system.

As a first step, many artificial failures were created simulating damages. This was done by temporarily removing stirrups which form sliding connections between the lamella beams at the joint's surface and the support bars beneath (see Figure 14). High-accuracy accelerometers and ultrasonic displacement sensors (Figure 15) were then used to evaluate the effects of these "failures" on the movements of specific elements, giving the system the data it needed to "learn" what data might be significant in terms of damage detection.

Figure 14. An accelerometer at the location of a temporarily removed stirrup during fault simulation and measurement of resulting vibrations and modal analysis.

Figure 15. An ultrasonic displacement sensor.

In service, the system sends data to a remote server, including daily records of vibrations due to heavy traffic together with the associated modal frequencies. If established limits which might indicate the occurrence of damage are exceeded, an alarm notification is sent by email and also appears on the system's web interface, prompting a site inspection. As a result of the system's ability to automatically consider such information, therefore, planning of maintenance activities in general, and the timing of replacement of components in particular, can be optimized.

The graphs presented in Figure 16 show acceleration data since the system was installed, with data from each of three selected joist beams (also known as support bars, which span the bridge movement gap, supporting the joint's steel surface beams). The graphs indicate a pre-defined limit of 20 m/s^2 (shown by red lines). Should a measured value exceed that limit, this could be a sign of a problem and so the SHM system is designed to send an alarm email to notify the responsible engineers. (The small number of data points above this limit were established to be no cause for concern, e.g. due to road works on the bridge.)

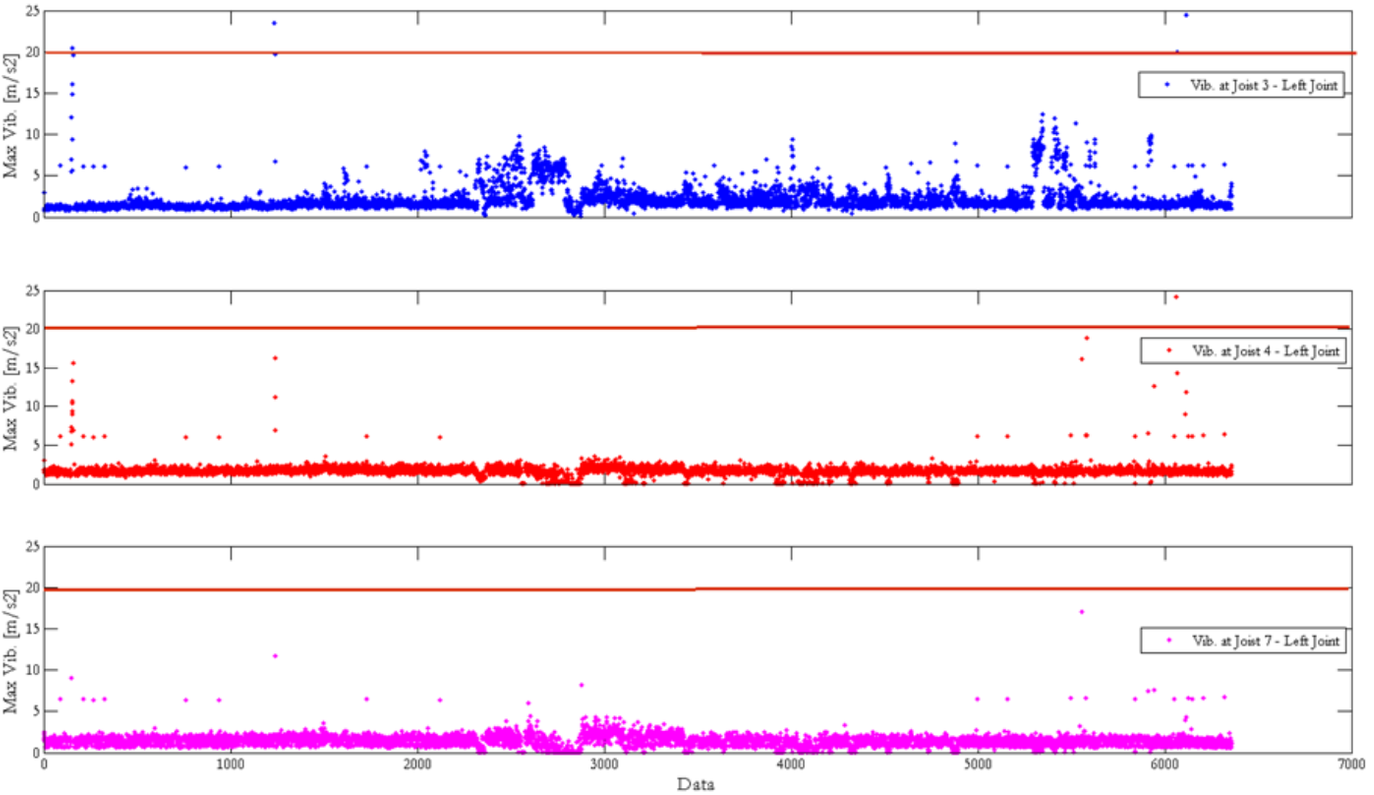

Figure 16. Acceleration data since the system was installed, with data from three of the expansion joint's joist beams. The graphs indicate a pre-defined limit of 20 m/s2 (shown by red lines), above which alarm messages are sent to the responsible emgineers.

6 CONCLUSIONS

The integration of SHM systems in key components (bearings, expansion joints and seismic protection devices) of bridges and other structures can offer great benefits to their asset management programs. Such systems can efficiently provide data required for almost any purpose, at any stage of a structure's life cycle.

In the case of expansion joints, in fact, the technology has already been brought another step forward, with the SHM system designed to clearly identify component damage based on general testing and teaching of the system. This enables any unexpected behaviour of the component (or the bridge) to be immediately recognised and notified, thus enabling the timing of component replacement, or other maintenance/repair work, to be optimised. With similar developments being planned for bearings and dampers, making them yet smarter and more efficient and useful in the construction, inspection, maintenance and renovation of structures, the potential benefits of the use of SHM technology in bridge asset management programmes continue to grow.

Maintenance Plan Proposal on Cable-Stayed Bridge: Application to Yelcho Bridge

M. Márquez, J. Campusano, F. Hernández & J. Errazuriz
Ministerio de Obras Publicas, Santiago, Chile

M.A. Valenzuela
Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile

ABSTRACT: The Yelcho Bridge is the only road cable-stayed bridge that has been built in Chile. The bridge is located in the mouth of the Yelcho Lake and it ensures the continuity of Route 7 (called Carretera Austral) in the Palena Province, Los Lagos Region, being a strategic point for the network road of Chile.
The bridge, in service since 1990, has a total length of 250 m with a central span of 150 m and two lateral spans of 50 m each one.
No maintenance programs have been conducted on the bridge since it became operational (27 years). However, it is estimated that the increase in its live load demand is causing a decrease in resistance due to fatigue.
The present paper provides studies conducted by the Roads Department, in order to structurally analyze the Bridge and assess its behavior related to the current design loads, including a study of its current state of stress, and visual inspections carried out.
The procedures of the study will be the basis for a maintenance plan proposal for cable-stayed bridges in Chile. The goal is to deliver a procedure to improve the management and maintenance of bridges, through preventive inspections focused on the detection of the main pathologies, and repair and reinforcement programs for this bridge typology.
The results of these activities will be included in the new version of the Road Manual–a code that provides guidelines for the design, construction and maintenance of bridges in Chile–as part of the philosophy of the life cycle of the structure.

1 INTRODUCTION

The Yelcho Bridge is the only cable-stayed bridge ever built in Chile (Figure 1). It is located in the Palena Province, Los Lagos Region, 47 km south of Chaiten. The structure is built over the outlet of Lake Yelcho, ensuring the continuity of Route 7 (also called the *Carretera Austral*).

Figure 1 - General overview of Yelcho Bridge (2016)

From the year it was built (1990), the bridge has been periodically visited for visual inspection. However, the Highways Manual of the National Roads Department, vol. 7, indicates that routine inspections must be conducted annually for singular bridges, such as cable-stayed bridges.

The Yelcho Bridge requires an assessment of its structure and its performance toward current design loads in regards to its current state of stress. This need arises from the elapsed time since the construction of the bridge construction, possible problems caused by an increase in the mechanical load demand due to increased weight of truck loads, and the reduction of resistance due to structural fatigue caused by the increased frequency of these loads, all of which affects the structural capacity of the bridge.

Compounding the issue, the National Roads Department is conducting a paving project for Route 7, which begins at one of the bridge access points. This means that once both of its access points are paved, the traffic speed on the bridge will go up, and thus increase the dynamic condition of the vehicular impact on the deck, including vibration and impact.

Furthermore, the environmental conditions at the bridge location are humid due to torrential rains and low temperatures during winter (freeze-thaw cycles are possible).

2 WORK DESCRIPTION

The bridge has a total length of 250 m, with a central span 150 m long and two side spans, each 50 m long.

The structure has two open-type abutments and two pylons. For their foundations, both the pylons and the abutments have pre-excavated, reinforced concrete, 1 m thick piles with anchor pier. Each abutment has eight piles, while each pylon has ten piles.

The deck is made of reinforced concrete and has a total width of 6.7 m, with a road 5 m wide, no walkways, and lateral ribs where the cables are anchored. The deck is longitudinally post-tensioned and braced by cables. There are steel barriers on both sides of the road.

The width of the road allows traffic to flow in only one direction at a time.

Near the abutment, the deck is transversally and vertically post-tensioned high elastic limit steel bars. This vertical mounting structurally compensates for the length difference of the side spans (50 m) in relation to the main span (150 m).

The cables are made of high-resistance, 36 mm thick, steel bars anchored to the top of two reinforced concrete pylons. In total, there are 112 cables (28x8) with a minimum breaking load of Fu= 10500 kg/cm2 and a yield limit of Fy = 8500 kg/cm2.

Protection of the cables achieved by injecting grout in the anchor area (in both the deck and the pylon) and painting the free extension (free length) of the anchors with three layers of epoxy paint.

To give the cables continuity, the bars are joined using mechanical couplers with an anticorrosion system made of thermo-retractile sleeves.

Near the deck, the steel bar cable is protected with a tamper-proof tube extending up to approximately 1.80 m over the level of the deck. The top is capped with an elastomeric seal cap, so as to protect the tube from water; past the seal, the cable is exposed for the rest of its free length, protected only by epoxy paint.

Near the pylon, the steel bars reach the upper anchor through a formwork metal tube.

The cables have a fan design, as they are similarly anchored to the upper crosspiece of the pylon (Figure 2).

Figure 2 - General overview of a pylon of Yelcho Bridge (2016)

The configuration of the lower zone of the cable is composed of the following elements:

- Formwork tube
- Grout pipe
- First support plate (embedded plate), welded to the formwork tube
- Second support plate (main plate), welded to the grout pipe
- Bar
- Ball nut
- Seal cap to protect the ball nut and grout injection

The pylons are 43 m high and made of reinforced concrete. They are composed of two legs in an H shape, braced together by two horizontal crosspieces: one is level with the underside of the deck and the other is at the top of the pylon. Additionally, there is a cross bracing at mid-height.

The pylons have post-tensioning bars in some sections.

Anchoring of the deck to the abutments is achieved through tensioning of high-strength steel bars. Each abutment has six bars for this purpose.

Each anchor has the following elements:

- High-strength bar with a diameter of 36 mm.
- Anchor plate and nut protected by an anti-corrosion seal at each end.
- Tube with a diameter of 80 mm, injected with an anticorrosion protection, to protect the anchor bar through the deck and in its last meter, in which the bar is embedded into the abutment.
- Tube with a diameter of 160 mm covering the 36 mm anchor bar to protect it from the support table of the abutment to one meter before the end of the lower anchor block (lower anchor plate and nut). The diameter of the tube allows horizontal movements relative to the deck and the abutment.

Each pylon is post-tensioned at the area of the upper crosspiece with high-strength 36 mm steel bars, both transversally and longitudinally. There are 11 transversal bars and 12 longitudinal bars.

The measurements of the abutment and pier supports differ from each other, as is shown below:

- Abutment vertical supports: 360x460x120 mm
- Pylon vertical supports: 350x460x90 mm
- Pylon and abutment longitudinal stops: 280x280x30 mm
- Pylon lateral supports: 280x280x30 mm

The finger joints provide the continuity between the abutment and the deck. No plans of this element exist.

Both riverbanks have protection gabions at each pylon. Likewise, the front of each abutment also has this type of element.

3 CURRENT SITUATION

To this date, very few records of the project (only some plan sheets) and the construction stage exist.

Gathered from assessing the visual inspection reports of the Yelcho Bridge from 2004, 2010 and 2016, the main observed pathologies of the elements of the structure are listed below:

3.1 *Concrete Elements*

Overall, the concrete throughout the structure shows no severe pathologies at first sight.

No important or large cracks or fissures, great loss of coating of the rebar, flaking, signs of corrosion on the rebar, or efflorescence were detected.

However, most of the concrete elements exposed to rainfall show large concentrations of moss, especially in extensive parts of the deck.

At certain places, concrete was found to be eroded by the constant flow of water in pylon crosspieces and abutments.

3.2 *Pylons*

Both legs of the pylon show more exposure to rainfall and wind on their upstream face. Due to the permanent humidity, moss was observed in all construction joints.

Many parts of the concrete show signs of erosion, particularly the lower crosspiece of the pylon, where the longitudinal stops and neoprene supports are located, due to the constant flow of rainwater.

3.3 *Abutments*

The area surrounding the abutments is partially covered by vegetation and dirt, hindering access to these elements and hampering their inspection (Figure 3). The concrete is covered by vegetation and moss.

Figure 3 - Abutment of Yelcho Bridge (2016).

The lack of elements meant to catch the water at the expansion joints causes all the rainwater that flows to the joints to run toward the support tables of the abutment or, in the case of the north abutment, to the back of the backwall.

3.4 *Deck*

Just as the rest of the structure, the deck is subjected to adverse climate conditions, especially high humidity (Figure 4). These conditions encourage the growth

of moss and vegetation along the deck, mainly on the sides next to the exit of the cables.

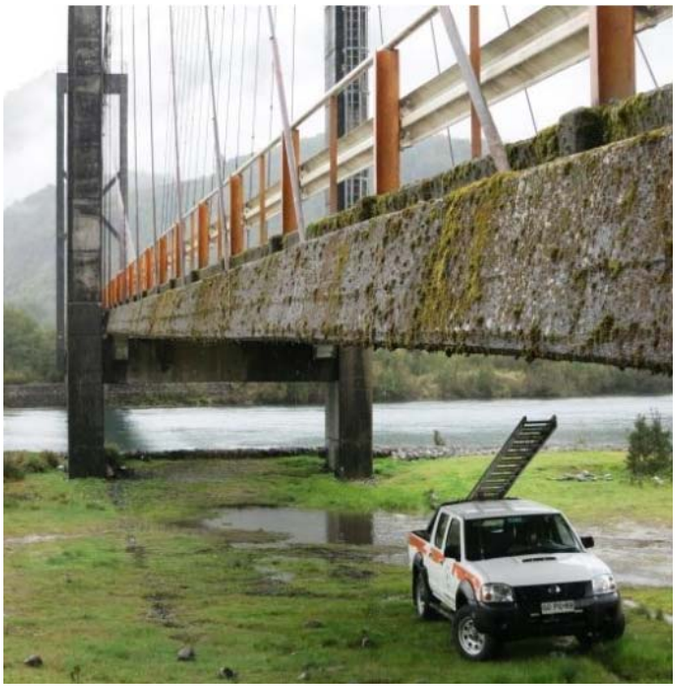

Figure 4 - Deck of Yelcho Bridge (2016).

Exposed rebar was observed, as well as corrosion on the elements that act as longitudinal stops.

A large amount of mud and dirt gathers on the road, obstructing the drainage holes and redirects the water to the expansion joints (because of the curved geometry of the deck). The drainage holes were found to be blocked.

On the underside of the deck, the localized damage was spotted in the areas where provisional anchors were installed as part of the construction method.

3.5 *Lower cable anchor*

Metal support plates were observed to have section loss, pitting in the steel, loss of anticorrosion protection, and rust on large part of the surface (Figure 5).

Figure 5 - Lower anchor of Yelcho Bridge (2016)

At one of the cables, the support plate is rotated.

Loss of anticorrosion protection was observed in both the injection cap and the overlength of the cable.

The wet areas of the plate show signs of advanced corrosion, loss of protection, and section loss in most cases (Figure 6).

Figure 6 - Lower anchor of Yelcho Bridge (2016)

3.6 *Cable recess tube*

On the tubes whose exit was not covered by vegetation, the seal was found to be damaged, letting water through.

3.7 *Cable tamper-proof tube*

The failure of the sealing system at the end of the tamper-proof tube (partial or total failure of the seal) allows water to flow freely into the tube, filling it (Figure 7).

Figure 7 – a Tamper-proof tube of Yelcho Bridge (2016).

Abnormal noises can be heard when the bars are manually shaken; however, these noises can also be caused by relative movements and/or bumping, none of which is ideal for the cables and can indicate a severe problem in the element.

The lack of a seal also enables the bar to move freely inside the tube. As the bars vibrate, they come into contact with the tube. This phenomenon might lead to a brittle rupture of the cable bars.

When it comes to the tube itself, all of them show a deterioration of their anti-corrosion protection. Several of the tubes were observed to have section loss in their upper end, due to the combined action of corrosion and constant bumping with the bar.

The anticorrosion bar protection system was originally composed of:

• Several layers of paint along the whole bar (estimated at three layers, which would be the standard for a steel protection paint system).
• Grout injection between the protection tube and the lower span of the bar.
• Injection cap to cover the spherical nut and part of the bar's over length. The exact makeup of the material injected is unknown, but reports at the time refer to it as concrete grout.

In the accessible part of the bars (from the end of the tamper-proof tube), many show signs of advanced degradation of their anticorrosion paint (Figure 8). The external pain layer has mostly flaked off, and the inner layers show damage as well, leaving the steel bars exposed–the steel already shows signs of surface corrosion. Around these areas, the paint seems to flake off, letting water bleed in between paint layers and the steel underneath.

Figure 8 - Loss of protection on the cables (2016).

The bar spans are directly exposed to rainwater, encouraging corrosion on the steel (which can already be observed) and threatening with possible section loss and strength reduction of the bars.

3.8 *Load on the cables*

When shaking the bars manually, several cables were found to be bearing a low load (low-frequency vibration and low damping). This can even be observed when heavy vehicles run through the bridge.

Important differences have been detected in the vibration frequency of the cables, predicting that some of the cables might be bearing a very low load (Figure 9).

Figure 9 - Cable arragement on Yelcho Bridge (2016).

Two of the cables were found to be particularly overloaded. This is confirmed by the deck profile, which shows an abnormal high point near the cables.

3.9 *Cable couplings*

In those cases, where the couplings can be visually inspected from the deck of the bridge, detachment at the ends of some thermo-retractile sleeves was observed.

3.10 *Neoprene Bearing Supports*

The structure has two neoprene vertical supports in each abutment and pylon. Furthermore, each pylon and abutment has two lateral stops and two longitudinal stops. The neoprene parts of the support systems generally appear to be in good condition.

At the abutment, the plates and part of the neoprene are covered by vegetation. The anticorrosion protection of the steel plates is in good condition. There are only some localized signs of early surface corrosion. Some deformation toward the center of the span can be observed, stemming from possible movements of the deck that were unforeseen during planning.

The lateral and longitudinal stops are simply vulcanized to a steel plate. This plate has four screws that anchor it to the concrete pylon. The screws and steel plate all show early signs of localized surface corrosion.

The lateral stops make contact with the deck through an embedded steel plate. As a consequence, they are no longer centered on the steel plates anchored to the deck (Figure 10). In the south pylon, the stops reached the edge of the plate without running off it, while the neoprene of the two lateral stops in the north pylon is approximately 2 cm off the steel plate, to the south (middle of the span).

Figure 10 - Lateral stops of Yelcho Bridge (2016).

The vertical supports of the deck are deformed toward the middle of the span, as a consequence of the rheological effects of the concrete of the deck.

3.11 *Abutment vertical bars*

The lower anchor of the abutment vertical bars is located in a caisson filled with a corrosion inhibitor.

However, the design might allow the water to penetrate into the lower anchor zone, behind the support plate. The quality of the sealing of the caisson containing the lower anchors is unknown.

This area is inaccessible, so it is not possible to ascertain the condition of the corrosion inhibitor or its type (petroleum derivate, concrete grout, etc.). In any case, the configuration of these bars and the movement they have suffered due to the rheological effects (movements observed in the supports) imply that the anticorrosion protection lost their adherence to their vertical bars, allowing water to seep into the space between both of them and into the caisson, encouraging corrosion.

It is also impossible to access the upper anchor of the bars, as they are encased under the pavement.

Chances are high that there is water in the formwork tubes and the lower caisson.

3.12 *Expansion Joints*

Both expansion joints -south and north- have no elements between the deck and the abutment to allow the drainage of rainwater.

In the south joint, gravel and asphalt can be found between the serrations of the joint.

In the north joint, dirt and vegetation buildup can be found in its ends. Water collects between the two modules of the joint (Figure 11). It runs to the open space behind the backwall of the abutment and from there, to the support table of the abutment, dragging detritus.

Figure 11 – Expansion joint condition (2016).

3.13 *Accessibility to the top of the pylons*

Access to the upper part of the pylons is granted by a cat ladder attached to the pylon (Figure 12).

Figure 12 - Access stairs to the top of the pylons (2016).

This ladder does not start at ground level, but rather at the same height as the deck of the bridge. In order to reach the ladder, an additional ladder is required, to be placed on the ground below. At the start of one of the ladders, some metal elements were noted to be loose. The current system (cat ladder) does not guarantee safe access, as there are some bolts missing from the safety cage.

From the deck, the safety rail guards installed on top of the pylons can be noted to be deficient, missing safety elements.

Because of this, access elements need improvement, as do the safety levels, to facilitate more in-depth future inspections and routine maintenance work.

4 DIAGNOSIS STUDY

Due to the current state of the Yelcho Bridge, the National Roads Department faces new challenges in relation to future work on structural maintenance.

With this in consideration, a study was conducted with the main objective of determining the structural capacity of the Yelcho Bridge. It seeks to determine its current state and the stresses in the main structural elements.

To this end, an assessment of the available records is conducted (plans, construction records, visual inspection reports) and additional information is gathered through detailed inspections. The information gathered is the base to conduct the structural assessment of the bridge and its elements, aiming to determine quantitatively and qualitatively its current situation.

4.1 *Description of the tasks to be conducted*

The diagnosis study consists of five stages. These have the final aim of determining the current situation of the structure and the future operations required to bring it up to better standards. Personnel trained in these types of structures and works is required to this end.

Stage 1 consists of the collection and assessment of the available records, including existing plans, relevant information on bridges of similar typologies, previous inspection reports, and field inspections. This is achieved by conducting visual reconnoitering of the structure in order to generate records of possible pathologies in the infrastructure and superstructure, taking into account relevant aspects of the materiality of the elements.

Stage 2 covers different levels of inspection, conducting general and detailed inspections with the required support tools. For this, complementary safety works must be generated in order to guarantee an optimal work on the structure. This activity covers the following areas: structural, road safety, and material engineering. Special studies are closely related to the different levels of inspection. Furthermore, after gath-

ering the information, a structural assessment is conducted to determine the original conditions of the bridge, considering the geometric and materiality characteristics of the elements. The axial forces on the cables in their initial construction condition are calculated, considering the weight of the bridge, the complementary dead loads and the tensile forces. This is then contrasted with the stresses calculated experimentally during stage 3.

Stage 3 has two main objectives: the first is to complement the available records from a geometric perspective through a topographic survey, respecting the technical dispositions given by the Highways Manual. After the information has been gathered, the second objective is to measure the stresses of the cables, for which non-destructive trials can be conducted by using hydraulic jacks, the vibrating string method, or a combination of both. The trials plan will be backed by bibliographic articles and the existing international experience on similar projects.

In stage 4, a structural model is generated through a finite-element program that is appropriate for cable-stayed bridges. The assessment is focused on determining the current conditions of the bridge, taking into account the geometric characteristics of the elements and the records gathered. For the initial stresses of the cables, the stresses experimentally calculated during stage 3 are used, as well as the available records, trials, and inspections conducted.

In stage 5, a final report is created, which summarizes the main milestones reached during the study, considering conclusions of the work conducted and suggestions regarding future operations on the structure.

5 CONCLUSIONS

Singular bridges, such as cable-stayed bridges, must receive constant inspections throughout their operational lifespan. The Highways Manual of the National Roads Department indicates that these inspections must be conducted once a year.

Modern Bridge Maintenance Management Systems, that include both traditional and singular bridges, are required. These must allow users to have access to a structure inventory and to record the whole life cycle of the bridge.

Singular bridges require that maintenance aspects be studied from their design onward, so as to allow the structure to be inspected completely and to easily replace its elements.

It is recommended that singular bridges include instrumentation tools to facilitate constant monitoring of the structure.

Chilean engineering does not have much experience in the design, construction, and maintenance of singular bridges. The previous implies that constant improvement and training of the specialized professionals is necessary at both public and private levels, in order to acquire the necessary knowledge.

The general inspection plan proposed to cable-stayed bridges has to include at least:

Concrete elements: check cracks and degradation

Pylon: inclination and cracks/corrosion

Abutments: cleaning area and support conditions

Expansion joints and bearing conditions

Cables: load capacity / stress, water accumulation, check lower anchor and drainage system. Verify the sealing system.

General Scheme: vibration and deformation.

A 3D model with a construction process is recommended carried out and also include the structure in a BIM system of the road network.

ABSTRACT: Chile has a great heritage in road bridges, so it is necessary for the National Road Department to have a Management System for the maintenance of bridges, keeping up with best practices in developed countries.

Although there have been some regional initiatives in this area, in the vast majority of cases maintenance plans are based on professional experience, evaluating the performance of the bridges either through the Bridges Department or the Regional Road Departments. These plans mainly consider the maintenance of traditional bridges (composed of concrete - steel beams, concrete slab, concrete pillars, pillars and direct or deep foundations).

However, the development of bridge engineering in Chile has introduced new structural typologies such as cable-stayed bridges, suspension bridges, arch bridges, among others.

For that reason, the authorities of the National Road Department, aware of the importance of carrying out a diagnosis of their bridges, decide to implement at the national level a Management System for the Conservation of Bridges.

The article presents a proposal of this System for both traditional and singular bridges whose objective is to provide the National Road Department with a tool to improve the management and conservation of bridges through preventive inspections focused on the detection of major pathologies and on strengthening future maintenance programs, optimizing the behavior of bridges and the allocation of resources. The System allows the conduction of the inventory and condition inspection of the bridges, using then logical algorithms to obtain the severity index of the bridges,while it modernizes the data collection and its subsequent consultation and exploitation, using a web application to facilitate the access to information.

1 INTRODUCTION

Within the national road network, there are approximately 9,000 structures, of which 7,150 are bridges or grade-separated crossings; these are broadly distributed as follows:

Table 1 - Bridge typology distribution

Infrastructure	Girder	Slab	Bridges (#)	%
C	C	C	1800	25
C	S	C	1200	17
C	S	T	1300	18
C	T	T	1000	14
S	S	T	600	8
T	T	T	1250	17

* C: Concrete; S: Steel; T:Timber

Traditionally, bridge maintenance policy in Chile has had a reactive focus rather than a preventive one. Planning of maintenance and preservation activities are mostly aimed at repairing existing defects, and not so much at preventing their apparition. To date, there have been some initiatives within the Ministry of Public Works (MOP) that have sought to establish a Bridge Maintenance Management System, among which the following can be found:

- Manual for Maintenance Inspection of Bridges (1993), Cooperation Agreement between Japan International Cooperation Agency (JICA) and the National Roads Department [2].
- Manual for the Condition Inspection of Bridges and Structures (2007), Concession Unit of Public Works. [3]
- Manual for Survey and Diagnosis of Bridges (2012), Los Lagos Regional Roads Department. [4]
- Manual for Visual Inspection of Bridges (2013), Los Rios Regional Roads Department. [5]

According to this philosophy, bridge maintenance management in the country began with a cabinet study of the available technical records and with the identification of serious pathologies. By using some basic inspection guidelines and the particular knowledge of experts in the area, a report was created, describing the observed pathologies and the measures needed to correct them. Sometimes, when the geometric and functional characteristics of the bridge required it, inspections would be carried out supported by the Inspection Truck of the Bridge Department.

Once the technical evaluation of the observed damages and their classification according to severity was performed, the technical sheet provided in the Highways Manual was added to the national repair/rehabilitation priority program, setting the costs associated with these activities.

The National Roads Department has granted Stradale-Gauss Consortium Ltd. a contract to establish a Bridge Management System. The objective of this commission is to establish a well-organized system that focuses on preventive maintenance and anticipation of damages, in order to reduce the costs and risks associated to bridge maintenance, using databases with real and up-to-date information on the condition of structures along the national road network. To develop this project, the consortium hired INES Consultant Engineers. In order to complete this task, the team has performed an inventory survey and field visual inspection of 1,034 bridges, with total length over 30 meters and no structural timber components.

With this project, the National Roads Department seeks to automate, speed up and organize the information management, standardize inspection criteria, systematically update databases, and plan bridge conservation programs adequately; the expected result is to have a practical tool for maintenance management and future decision-making.

2 PRINCIPLES OF THE BRIDGE MANAGEMENT SYSTEM

The bridge management tool that the consultant developed for the National Roads Department of the Ministry of Public Works allows its users to manage all the information related to inventory, inspection, conservation, maintenance, and monitoring of bridges along the road network under the National Roads Department, achieving a agile and effective management of the conservation of these structures.

This tool is formally framed in the international standards for Asset Management, more precisely ISO 55000:2014, which is organized around five fundamental pillars: proper knowledge of the assets, consideration for the global organization and planning strategy, adaptation of the organizational and HR structure, close and bidirectional relations with stakeholders, and proper risk management during the whole lifecycle of the bridges.

The key objectives of Asset Management in general, and the Bridge Management System developed by the National Roads Department in particular, are as follow:

- Efficient management of historical and real information linked to each bridge.
- Global assessment of the bridge based on the damages observed during field inspections.
- Prioritization of the required maintenance interventions.
- Estimation of costs related to the maintenance interventions to be implemented.
- Short- and mid-term planning for repair and maintenance activities.
- Design of short-term maintenance strategies.

Below (Figure 1), the functional diagram developed for the Bridge Management System is presented:

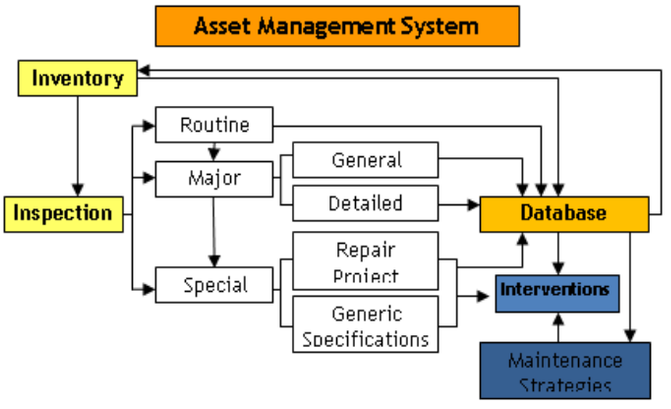

Figure 1 - Diagram of the Assets Management System ([18], 2015)

1

Every Asset Management System starts by having a proper knowledge of the assets. Management of the information associated with each asset, then, becomes the cornerstone of the system. On one hand, there is an attempt to collate and compile the available records, existing information, and historical data; and on the other hand, to collect and archive the inventory and current condition data into the system.

The first task is not free of challenges, as historical information tends to be scarce and scattered among different institutions (National Roads Department, Regional Departments, private companies involved in the corresponding projects, etc.). However, it is vital to understand the history of each bridge from its conception to the current date, so as to predict the evolution of its damages and to estimate its future maintenance needs. In this regard, the Management System developed is able to log all of the existing records to

make a perfectly structured and organized database that collects all related documents from the original plan of the structure to the subsequent reports of maintenance and conservation operations and completed inspections, records of plans and images linked to the structure, or any other information of any format that might be relevant. The Design Standards that have been used historically are also particularly relevant, as they can help estimate the design load used based onthe age of the bridges.

The second task to get a good knowledge base of the bridges to be managed is the implementation of a full inventory. The inventory survey begins with a cabinet phase, during which all descriptive data on the bridge—general, geometric and structure material data, obtained from existing plans and information—are entered into the Bridge Management System. Afterward, field campaigns are undertaken in order to contrast and update the information entered into the system. Lastly, and once the data on each bridge is confirmed in the field, the inventories are updated in the Management System through the cabinet (Figure 2).

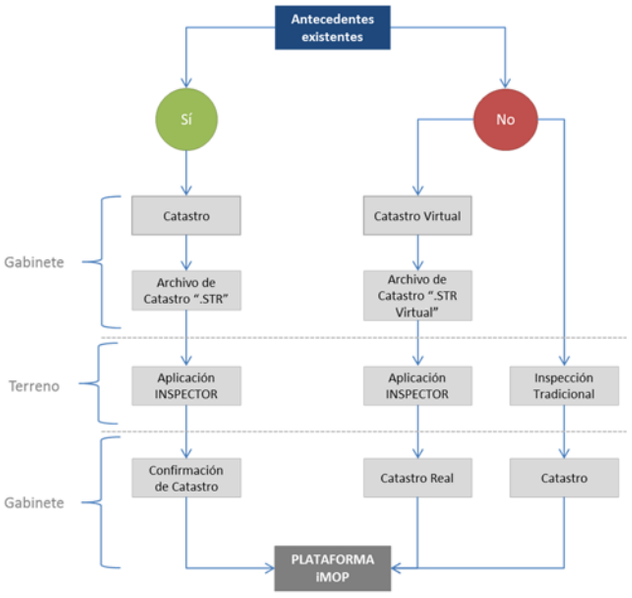

Figure 2 - Implementation of the inventory ([18], 2016)

Just as it will be explained in the following sections, the Bridge Management System that has been developed allows the inventory data to be recorded through a series of sheets to describe any element of the bridges, regardless of their typology. The aforementioned sheets collect anything from general data to functionality data, general structure description, and detailed inventory data.

In order to describe a bridge properly, the methodology that has been developed breaks down each bridge into the different elements that comprise it, according to a series of levels as shown in Figure 3. This outline is essential, as it then enables the user to associate the damages observed during field inspections to specific units of the bridge.

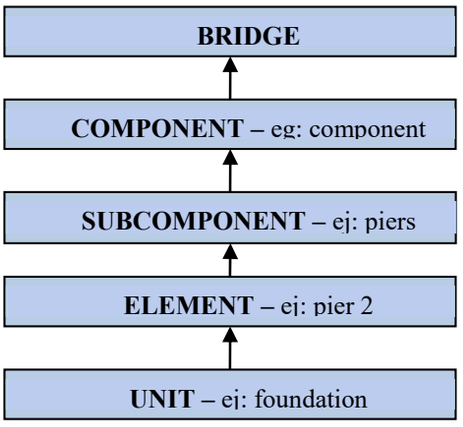

Figure 3 - Relational diagram of the parts of a bridge [19], 2016)2

The methodology developed establishes and collects in the corresponding manuals the criteria to identify the different parts of a bridge (Figure 4), so as to provide homogeneous criteria to the field teams developing the inventories.

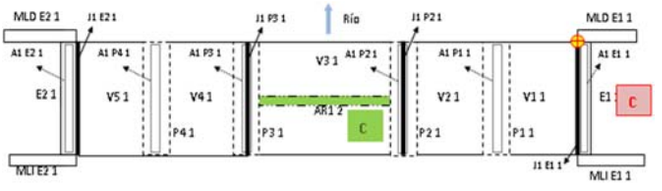

Figure 4 - Diagram of components/subcomponents of an Archtypology bridge (20, 2016)3

As shown in Figure 1, once assets have been inventoried or surveyed, an inspection campaign must be conducted to help determine their current conservation state. Regarding structure maintenance, three levels of inspection are broadly established: basic, major (itself divided into general or detailed, depending on whether auxiliary means of access are used or not), and special.

Basic Inspections are visual that can be conducted by non-specialist personnel are directed toward early detection of any damage that might require urgent intervention. Major Inspections are also visual, but they are conducted by specialist technical personnel, preferably knowledgeable in structural calculations and structural pathologies. Therefore, this kind of inspection is aimed at gathering information on every damage of the structure, specifying which bridge unit is affected by the damage, assigning a cause to each one, and indicating its extension and severity. Finally, Special Inspections are conducted by highly-trained technical personnel, who take additional steps (sam-

pling, trials, estimations, inspections conducted by divers or climbers, etc.) required to obtain all necessary information to assess the state of the structure and define the operations that must take place.

The methodology accompanying the Bridge Management System is based on the regular conduction of basic and major inspections, planned according to the maintenance strategy and whose frequency will be determined by the structure importance, which itself depends, among other factors, on the bridge typology and its conservation condition. Special inspections will be conducted only when it is impossible to assess the damages of a structure through major inspections.

To conduct visual inspections of the structures, the Bridge Management System developed sets some objective criteria so as to standardize the identification and assessment methodology of the existing damages.

Eliminating the inspectors' subjectivity and standardizing inspection results across the country is vital to gathering trustworthy data for the system to calculate the condition score of a structure; as based on the faults identified during inspection; the element it affects; and its extent, severity and cause, the system generates a score of the condition of the structure through an algorithm proposed by the consultant.

This score ranges between 0 and 100 points, as shown in Table 2 below, and it is the basis for the prioritization of the proposed maintenance intervention.

Table 2 - Global Condition Score range for the bridges (19, 2016)

Grade	Damage	Recommended time for the intervention	
80-100	Mild durable or functional damage	No need	No attention required
60-79	Medium durable or functional damage	Long-term	5 years
40-59	Mild resistant or durable or functional damage	Medium term	1 - 2 years
20-39	Medium resistant damage	Short term	Less than 1 year
0-19	Collapse or critical damage	Immediate	Immediate interventions

Currently, the main inventory and inspection campaign is underway, it involves over 1,034 bridges from every Region of the country and it is meant to calibrate the system to all climates, typologies, and particularities of the country's main bridges.

Based on the individual score of each bridge inspected, the Bridge Management System developed is capable of prioritizing rehabilitation/repair interventions, as well as plan future inspection campaigns and routine maintenance activities.

Furthermore, and considering that one of the main objectives of the project is to create a tool for assisting decision-making and planning the investment needs for the maintenance of the structures, the Bridge Management System has a budgeting module to generate a first cost estimate of the required interventions/maintenance activities.

This module is linked to a library of damage records associated to repair interventions as well as unit prices, custom-made for Chile and the National Roads Department. Based on the damages identified during the inspection, the system automatically assigns certain repair interventions and estimates the corresponding costs based off the unit prices, producing an illustrative budget which can be modified at a later time by the National Roads Department.

3 MANAGEMENT SYSTEM FUNCTIONALITY

The principles and functions presented in the previous section are particularized in a web application, accessible through any internet or intranet browser, and which operates in the cloud or a server owned by MOP, without requiring an executable file installed in the user's computer. The information collected in the application (the database that feeds the system) is located in a server owned by the Ministry, so as to guarantee data confidentiality and security.

The web application has four different modules, presented below:

When accessing the online platform, which requires a username and password, the user finds a home screen corresponding to the first module of the system: Location. Through this module, the user can access the complete list and browser of bridges entered into the Bridge Management System, which is itself linked to a cartographic database with the exact geographic location of the selected structures (Figures 5 and 6).

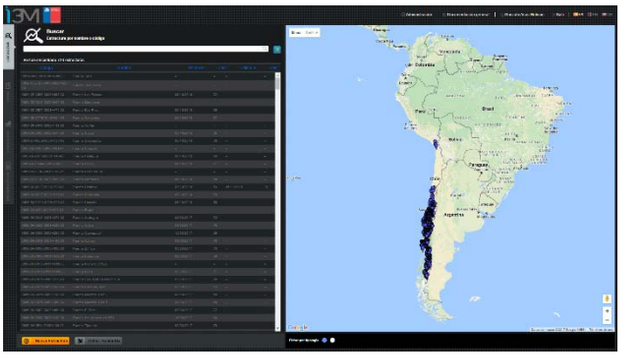

Figure 5 - Home screen (17, 2017)

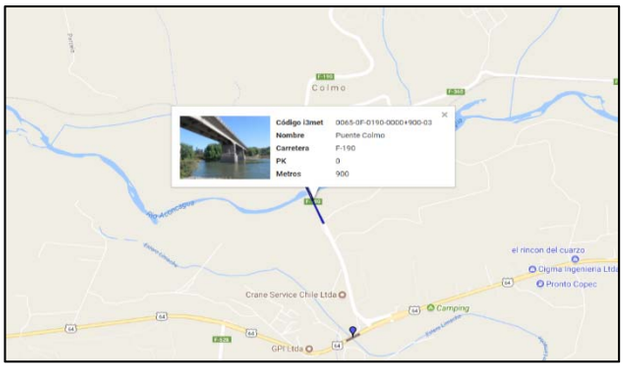

Figure 6 - Home screen ([17], 2017)

On the left side of the home screen, the user can find the access tabs for each of the other system's modules: File, Queries, and Budgeting.

The "File" module is connected to the system's database, and it presents all existing information related to each particular bridge. Through this module, the user can access all the general information of the bridge (Figures 7 and 8), existing documentation, photographs, inventory data, and inspections and interventions conducted. This is the key module of the system, from which the rest of the planning and cost estimation tools operate.

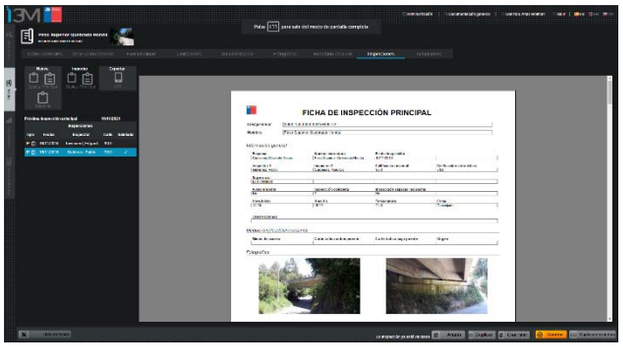

Figure 7 - General data screen, within the File module ([17], 2017)

Figure 8 - Main inspection screen, within the File module ([17], 2017)

Using the File module's database, the system's Query module allows the user to filter the alphanumeric data collected in both the inventory and field inspections and export them into Excel to use them for the maintenance planning and management.

To perform a query, a topic must first be selected, be it Inventory ('General data', 'Deck', 'ENR'), Inspection ('Inspections', 'Faults), or Repair ('Repairs'). Once a topic has been selected, the user can access different filtering and query options (Figures 9 and 10).

This module is particularly useful to make the most of the available database. The methodology proposed collects data from the assets at a high detail level, but this would be useless without a proper search tool to search and filter information from the data available.

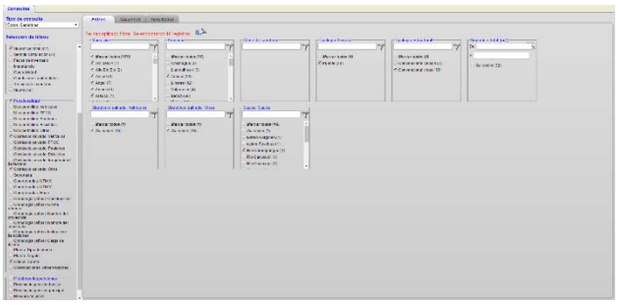

Figure 9 - Query module and Excel export ([17], 2017)

Figure 10 - Query module and Excel export ([17], 2017)

Lastly, the Bridge Management System has a Budgeting module (Figure 11) which allows the user to generate an estimated budget for the repair interventions of a bridge based on the damages recorded during the major inspection.

For this purpose, the system has a library of damages as well as a list of pre-defined interventions associated with a particular damage and cause, along with the material and unit of measurement. Likewise, the Bridge Management System has a database of the unit prices, developed particularly for this project, which will be linked to the Budgeting module.

Due to the fact that inspectors collect, besides the type of damage and affected element, the approximate quantities of the damages during major field inspections, the Budgeting module is able to assign a repair operation to each damage and calculate an estimated cost based on the field quantities.

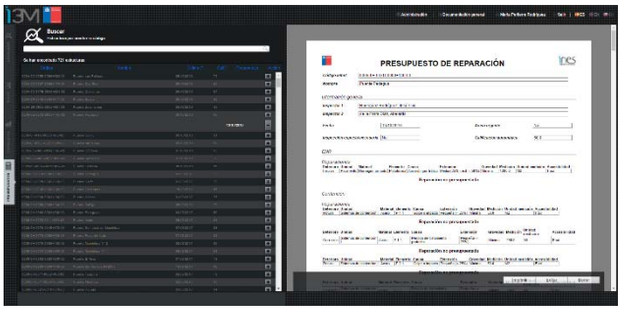

Figure 11 - Budgeting module, within the File module ([17], 2017)

The budgets generated are open and editable, so new repair interventions can be added to it, interventions that are decided not to be conducted can be deleted, quantities can be modified, and auxiliary means can be added if they are not included by default in the proposed budget.

4 CONTEMPLATED TYPOLOGIES

The methodology developed for this Bridge Management System applies to all existing structural typologies along Chile's road network (Figures 12 and 13), such as:

Beam bridges
Slab bridges
Truss bridges
Box girder bridges
Arch bridges
Cable-stayed bridges
Suspension bridges

Figure 12 - Example of suspension typology, represented in the General Carrera Bridge ([20], 2017)4

5 INSPECTION RATING

As the methodology is based in the breakdown of each bridge into lower level elements (as shown in Figure 3), each of which has a different weight in the condition scoring algorithm, any particular bridge — as long as all typological possibilities for its elements are included in the system— can be described and identified. Thus, when conducting the field inspection, the observed damages will be assigned to the specific bridge elements, so as to generate a condition score for the lower-level elements and compose the global condition scoring of the bridge through a weighed translation of the scores toward the higher-level elements.

For that purpose, the system runs a series of algorithms that firstly calculate the rating of each damage identified during a major inspection; secondly calculates the condition score of each specific bridge unit, subcomponent and component; and lastly calculates the general condition scoring of the bridge.

In relation to that first step, the calculation of the rating of each specific damage is obtained through the following formulation:

$$C_d = C_o \cdot P_d \cdot P_u \cdot P_c$$

Where:
C_d = damage rating
$C_o = [100 - ((V_{extension} + V_{severity}) \cdot 4)]/100$
P_d = damage weight factor
P_u = unit weight factor
P_c = cause weight factor

As shown above, each damage identified during the field inspection would be given a rating based on the type of damage (the more important the damage, the lower the P_d –i.e.the surface alteration of the concrete will have a P_d of 97 whereas the existence of cracks will have a P_d of 87-), the location of the damage (referred to the unit of the bridge that is affected by the damage –i.e. the P_u for the beams of a beam bridge has been established at 0.91, whereas the P_u for the slab has been established at 0.94), the cause of the damage (i.e. if the damage is caused by a torsional stress the P_c factor will be 0.80 while in the case of climatic actions it will go up to 0.98), its severity and its extension.

Once each of the existing damages has been rated, the system will calculate the condition score of the bridge units –as the minimum score of the damages located in that bridge unit- and the number of damages per unit. That number of damages will be calculated affecting the amount of damages by a factor that depends on the rating of those damages, in such way that the formulation penalizes the existence of damages of low rating.

The same methodology is applied for the bridge elements, calculating the minor condition score of the units of that bridge element and the total number of damages associated to that element.

The following step would be the calculation of the subcomponents' condition score. In order to do so, the system calculates the minimum condition score of the bridge elements that compose that subcomponent and the total number of bridge elements associated to that subcomponent. In order to get the condition score of the subcomponent, the system affects the minimum

score of the damages of the elements in that subcomponent by the number of damages and a factor related to the kind of subcomponent (pier, foundations, abutments…).
Similarly, the condition scoring of bridge components follows the same principle. The minor condition scoring of its subcomponents is taken and then reduced by the application of a corrective factor depending on the number of damages related to that specific component.
Finally, and in order to calculate the global bridge condition score, the minimum condition score of the load bearing components of the bridge is taken and then corrected by the minimum condition score of the non load bearing components, the number of total damages of the bridge, and the Truck Annual Average Daily Traffic (AADT).
Thanks to this formulation, the system obtains the value of the global condition scoring of the bridge and the total number of damages, which allows the user to characterize the state of conservation of the bridge, through the ranges established in Table 2.

6 CONCLUSIONS

Chile has a large number of bridges, which represent an important technical heritage.

Currently, the National Roads Department has no integrated Bridge Management System for the Conservation of Bridges. Nowadays, these tools are vital for decision-making regarding investment amounts dedicated to maintenance.

Any Bridge Management System should, at least, have the following features:

- Inspection techniques applied to bridges
- Inspection manuals
- Inspection protocols, including an inspection sheet
- Technical visits, defining the performance of destructive and non-destructive tests
- Proposal for monitoring, instrumentalization, and maintenance plan
- Constant training

The results of the new Bridge Management System are included in future versions of the Highways Manual of the National Roads Department, as part of the philosophy for the life cycle of the structures.

After the study of the implementation manuals existing to date, a proposal was made which is being adjusted as more results are being obtained through the field campaign. Currently, more than half of the planned campaign has been conducted, and the preliminary results point to a proper adaptation of the system to the typological variety of the existing bridges, as well as an adequate flexibility to be adapted to new structural elements.

ABSTRACT: This study presents the calibration and validation of the numerical model of a steel-concrete composite railway bridge considering the vehicle-structure interaction. An ambient vibration test, based on limited experimental data, and a dynamic test under traffic actions, were performed, in order to estimate the modal parameters of the bridge and the dynamic responses for the passage of Alfa Pendular train, respectively. The numerical dynamic responses were obtained using ABAQUS software based on an iterative uncoupled method for vehicle-structure interaction which considerers the track irregularities. The calibration of the numerical model was based on the application of a genetic algorithm, minimizing the differences between numerical and experimental modal parameters. The experimental responses obtained from the dynamic test under railway traffic revealed a good agreement with the numerical responses.

1 INTRODUCTION

The worldwide implantation of the high-speed railways is requiring the construction of new lines, and inherently, a relevant effort of rehabilitation of existing structures, particularly bridges and viaducts.

The dynamic effects of trains running at high speeds can reach significant values, due essentially to the resonance phenomenon that generally occur at speeds higher than 200 km/h, which should be considered in evaluating existing bridges as well as in the designing of new bridges. Nowadays, the resonance effects are becoming important as a result of the increase of the traffic operating speeds and the improving of vehicles' characteristics, particularly the increase of axle loads.

These new demanding are requiring the implementation of structural heath monitoring systems on bridges in close articulation with the railways infrastructure managers.

In case temporary monitoring systems, like those that are used in static and dynamic tests, the infrastructure manager typically imposes restraints to the location of the sensors to be installed in bridges, due essentially to safety requirements.

In most situations the zones authorized for the installation of monitoring systems are located outside the rail traffic lanes, such as sidewalks and lower part of the deck, including supports and piers. Even in these locations, there are sometimes restrictions that difficult the installation of the monitoring systems, such as the presence of water courses, roadways and terrain with rugged topography.

This paper describes the calibration and experimental validation of the numerical model of a steel-concrete composite railway bridge based on dynamic tests performed with restrictions to sensors locations. An ambient vibration test allowed to identify the natural frequencies, vibration modes and damping coefficients of the bridge by applying a modal identification technique on frequency domain. The calibration of the numerical model was based on the application of a genetic algorithm, in order to minimize the deviations of the numerical and experimental modal parameters. The results of the calibration demonstrate a very good agreement between the numerical and experimental modal responses and a significant improvement of the numerical model before calibration. Finally, the comparison between the dynamic responses obtained from a dynamic test under traffic actions and a numerical simulation based on a train-structure interaction analysis revealed a good agreement.

2 ANTUÃ RAILWAY BRIDGE

The railway bridge over Antuã river is located at the Northern line of the Portuguese railways, at km + 286, 864, near the city of Aveiro (Fig. 1). The bridge has a total length of 44.4 m and consists in four simply supported spans with lengths equal to 10.27 m and 10.85 m, for the extreme spans, and 11.62 m, for intermediate spans.

Figure 1. General view of Antuã Bridge

The transversal section of the bridge has a total width of 12.3 m, and is composed by two half-symmetrical and independent decks separated by a longitudinal joint, as showed in Figure 2. Each half deck consists of two longitudinal steel beams (HEB700) spaced of 3.30 m, connected by four transversal steel beams (IPE500). The slab is composed by prefabricated panels with a variable thickness from 0.25 m to 0.37 m.

Figure 2 shows the dimensions and geometric properties of the cross section of the deck.

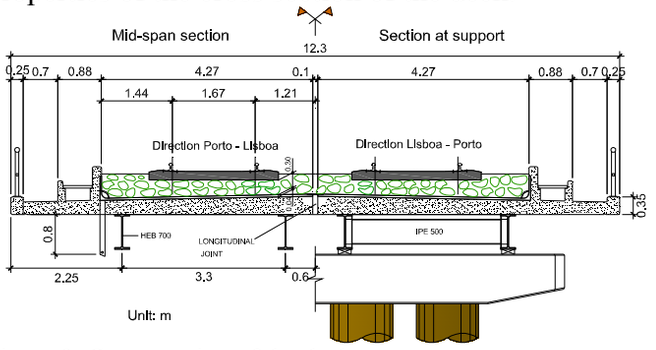

Figure 2. Cross-section of the deck.

Each individual deck is supported by four pot bearings: two fixed supports on one side, and two longitudinally guided supports on the other side.

The railway track over the bridge is formed by UIC60 rails rested on concrete sleepers, spaced every 0.60 m, and a layer of ballast with a thickness of 0.45 m, which is laterally restrained by concrete walls.

Figure 3a shows the geometric properties of the Antuã bridge.

3 DYNAMIC TESTING

3.1 *Ambient vibration test*

The ambient vibration test was focused on identifying the modal parameters of the second section of the bridge, including both decks, as well as the characterization of the track continuity effect.

This test involved the measurement of accelerations at 26 points, organized in 4 setups (Fig. 3b and Fig. 4). The location of sensors was restricted: from one side, due to limitations of accessing the track lane following the safety indications of REFER (infrastructure manager); from other side, due to limitations of the topography with respect to access the area under the deck.

The data acquisition was performed through National Instruments cDAQ-9172®, using 3 NI 9233® modules for IEPE accelerometers. The time series were acquired over 5 min periods, with a sampling frequency of 2000 Hz, posteriorly decimated for a frequency of 200 Hz.

The identification of natural frequencies, modal configurations and damping coefficients of the second section of the bridge was carried out using the Enhanced version of the Frequency Domain Decomposition Method (EFDD), available in ARTeMIS® software.

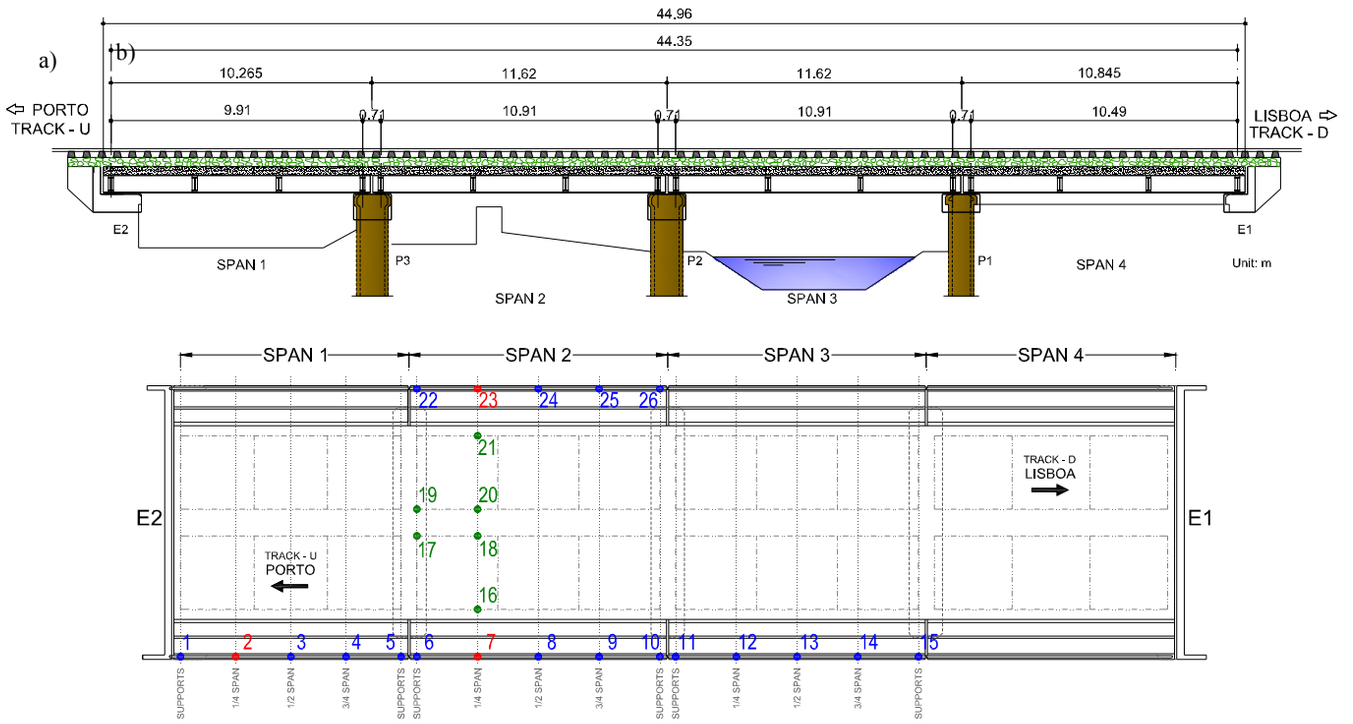

Figure 3. a) Elevation of Antuã bridge, b) Sensor positioning

Figure 4. Ambient vibration test experimental configurations and sensor positioning

Figure 5 shows the modal configurations of the six identified vibration modes, indicating the average values of the frequencies and damping coefficients.

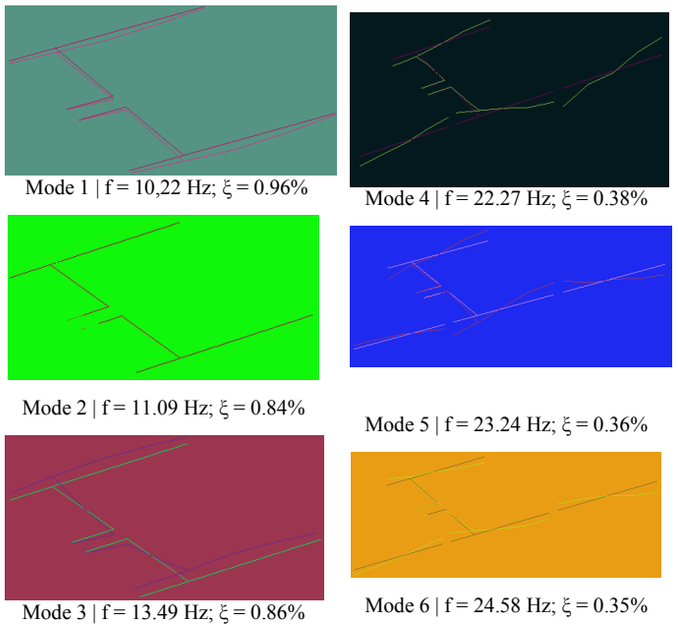

Figure 5. Experimental modal parameters.

The analysis of the modal configurations allowed to identify global modes associated to vertical bending (mode 1) and torsion (modes 2 and 3) of the deck with very good definition, and with natural frequencies equal to 10.22, 11.09 and 13.49 Hz, respectively. Modes 4, 5 and 6 are related to the 2nd mode of vertical bending, for which is clearly observable that the lack of experimental information conditioned an adequate modal representation.

3.2 *Dynamic test under traffic action*

The dynamic test under traffic action involved the measuring of displacements and accelerations at 3 points under the deck of the 2nd span of the bridge, on the ascending track (Lisbon - Porto direction), for the passage of Alfa Pendular train at speeds between 156 and 160 km/h.

The vertical displacements were measured using LVDTs, close to the support (D1) and under the main girder at 1/3 span (D2). The vertical acceleration was measured with an accelerometer installed at 1/3 span (A1).

Figure 6 shows the points instrumented in the second section of the bridge for the test under rail traffic.

4 NUMERICAL MODEL

The 3D finite element numerical model of the bridge was developed using ABAQUS program (Simulia, 2012). As the aim of this investigation is to study the 2nd section of the bridge, only three spans were modeled, allowing to adequately reproduce the structural continuity conferred by the track between the adjacent spans, and reducing the dimension of the numerical model.

The ballast, sleepers and rail pads were modeled using solid finite elements, while the rails and the main girders were modeled using beam finite elements.

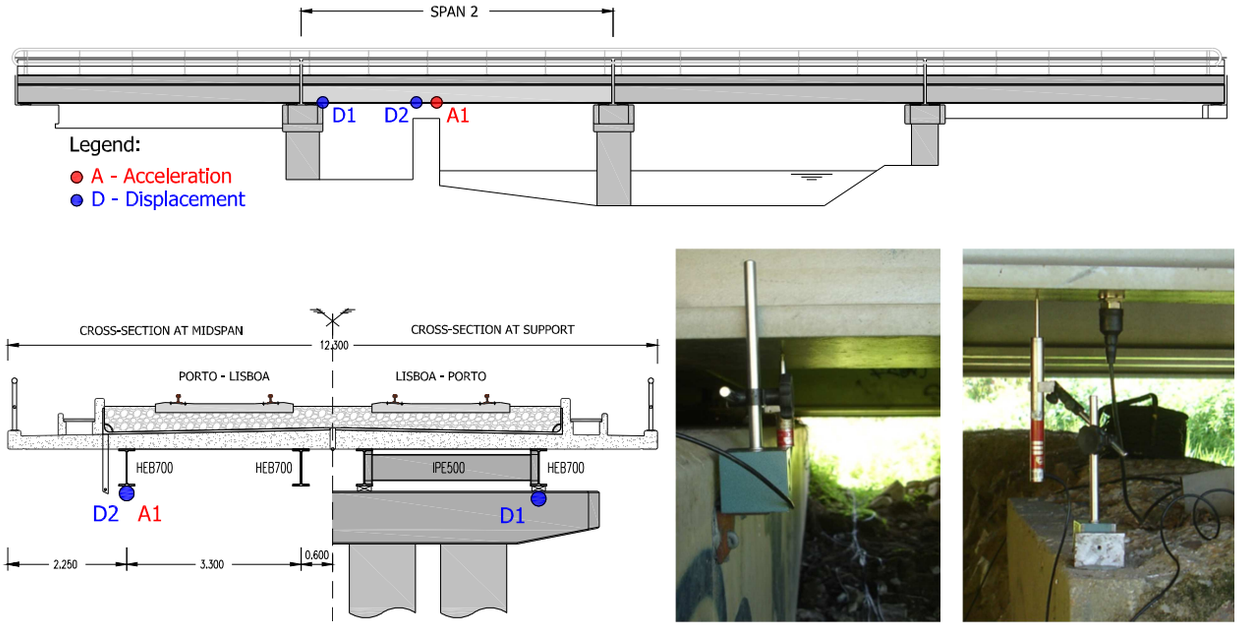

Figure 6. Dynamic test under traffic actions: instrumented points and sensors details.

Special attention was given to the continuity of the track ensured by the ballast layer between consecutive decks. In these regions the ballast layer tends to degrade its stiffness due to the passage of the railway traffic. The degradation of the ballast properties at the joints, particularly in the longitudinal joint (between two decks of the same section) and transversal joints (between decks of consecutive sections), were represented by means of elements with reduced modulus of elasticity. Figure 7 shows a general perspective of the numerical model developed.

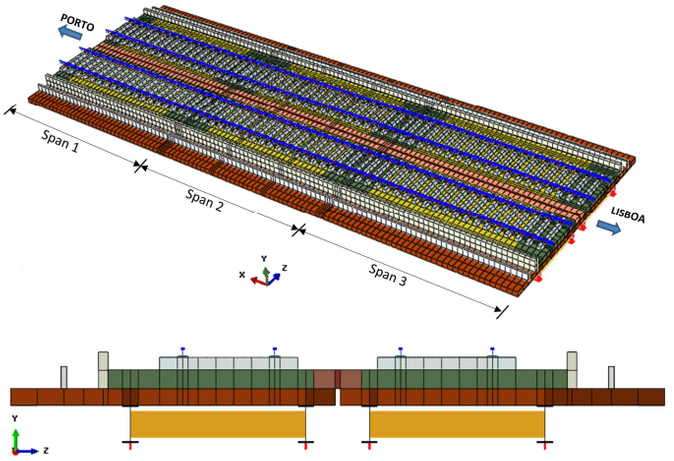

Figure 7. 3D model of bridge.

Table 1. Characterization of the numerical model parameters.

Parameter	Designation	Limits (lower/ upper)	Adopted value	Unit
ρ_c	Density concrete	2381.2 / 2715.6	2515.58	kg/m^3
E_c	Módulus deformability concrete	32.63 / 48.61	37.49	GPa
ν_c	Poisson ratio concrete	- / -	0.20	-
ρ_{bal}	Density ballast	- / -	1800	kg/m^3
E_{bal}	Módulus deformability ballast	130 / 208	145	MPa
$E_{bal,long1}$	Modulus deformability ballast (inner zone)	1 / 145	145	MPa
$E_{bal,long2}$	Modulus deformability ballast (outside zone)	1 / 145	145	MPa
$E_{bal,trans}$	Modulus deformability ballast between spans	1 / 145	145	MPa
ν_{bal}	Poisson ratio ballast	- / -	0.20	-
K_v	Vertical stiffness of the support	530 / 1047.4	788.7	MN/m
K_h	Horizontal stiffness of the support	0 / 100	0	MN/m
K_{palm}	Vertical stiffness of the rail pads	- / -	250	MN/m
ρ_s	Density steel	- / -	7850	kg/m^3
E_s	Modulus deformability steel	200 / 210	210	GPa
ν_s	Poisson ratio steel	- / -	0.30	-

Table 1 shows the mechanical and geometrical parameters considered in the numerical model of the bridge, including the adopted values and the corresponding units. Additionally, the lower and upper limits of the numerical parameters that will be used in the calibrations of the numerical model are also presented.

Figure 8 presents the numerical modal parameters in correspondence with the previously identified experimental ones.

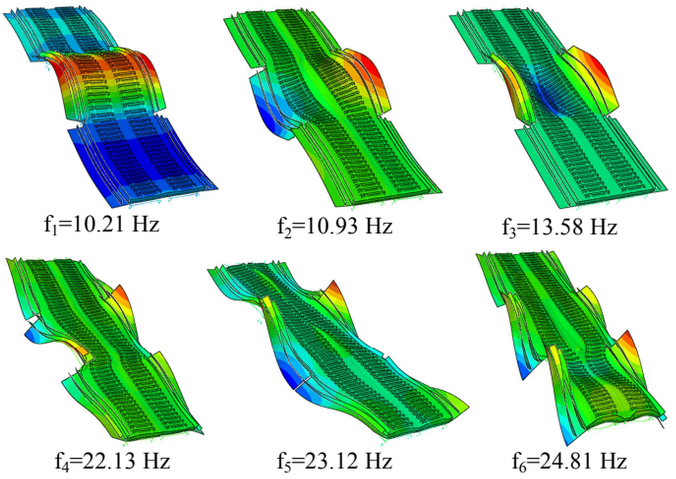

Figure 8. Numerical modal parameters.

5 MODEL CALIBRATION

The calibration of the numerical model involved 6 numerical parameters and 6 modal responses (3 frequencies and 3 nodal configurations). The objective function (*f*) involve two terms, one related to the residuals of the vibration frequencies, and other related to the residuals of the MAC values:

$$f = a \sum_{i=1}^{3} \frac{\left| f_i^{\exp} - f_i^{num} \right|}{f_i^{\exp}} + b \sum_{i=1}^{3} \left| 1 - MAC\left(\phi_i^{\exp}, \phi_i^{num} \right) \right| \quad (1)$$

where f_i^{num} is the numerical vibration frequency of the mode *i* and $f_i^{\exp}$ is the experimental vibration frequency. $\phi_i^{\exp}$, ϕ_i^{num} are the experimental and numerical modal configurations of the mode *i*.

For the pairing between numerical and experimental modes of vibration the EMAC parameter was used (Brehm et al., 2010).

In the optimization process a genetic algorithm based on an initial population of 30 individuals, randomly generated using Hypercube Latin method, was used. The stop criterion was a number of generations equal to 150 generations, in a total of 4500 individuals. The crossing rate was considered equal to 50% and the mutation rate was set equal to 15%, with a variable standard deviation between 0.10 to 0.01.

In the present study four independent optimization runs (GA1 to GA4) were performed, aiming to obtain an optimal solution due the stochastic nature of the genetic algorithms.

Table 2 presents the optimized values of each numerical parameter obtained for the four optimization runs (GA1 to GA4). The values of run GA1 were

adopted for the calibrated model because presented the lowest residual of the objective function.

Table 2. Parameters of the calibrated numerical model

Parameter	Unit	Initial value	GA1	GA2	GA3	GA4
ρ_c	kg/m^3	2548.4	2452.1	2443.6	2509.4	2519.4
E_c	GPa	40.62	33.8	34.7	33.9	35.6
$E_{las,long1}$	MPa	145	9.73	7.6	16.34	13.33
$E_{las,trans}$	MPa	145	136.2	140.2	140	137.9
K_V	MN/m	788.7	1047	1047	1047	1047
K_L	MN/m	0	20	40	50	50

Figure 9 shows the comparison of modal configurations of the second section of the bridge obtained experimentally and numerically after calibration.

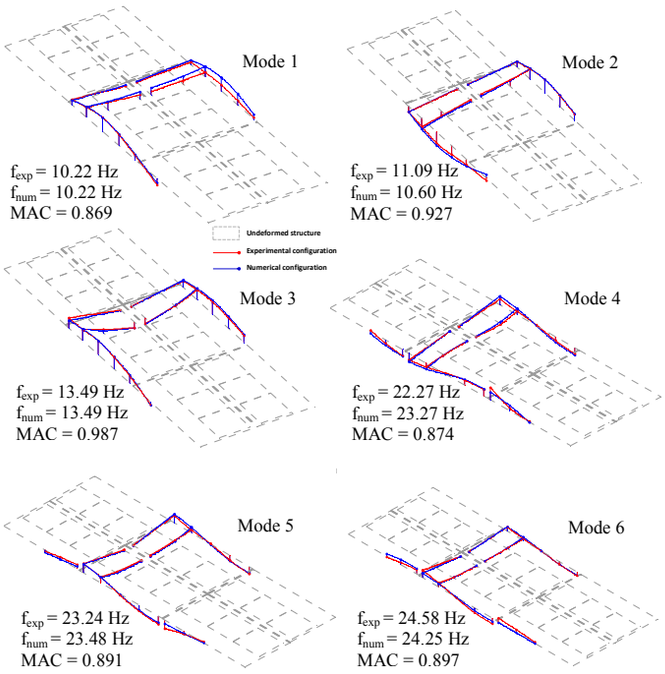

Figure 9. Comparison of numerical and experimental modal configurations after calibration.

The last comparison demonstrate that although the experimental information is limited in sections 1 and 3 of the bridge, the results after calibration are notoriously satisfactory, revealing the consistency of the results obtained in the calibration process of the numerical model.

6 VALIDATION OF THE NUMERICAL MODEL

6.1 *Methodology*

The numerical responses were obtained based on a dynamic analysis considering vehicle-structure interaction, including the track irregularities, performed by AIVE software (Ticona Melo, 2016). The software uses the modal superposition method for solving the dynamic equilibrium equations of the bridge, and an implicit direct integration method for solving the dynamic equilibrium equations of the train. The time increment adopted was equal to 0.001s.

The Alfa Pendular train was modeled based on a simplified model developed by Meixedo et al. (2014). This simplified model of the train was calibrated based on experimental modal parameters obtained by Ribeiro et al. (2013).

In this model the carbody and bogies were modeled as rigid beams arranged in the center of gravity of each component. The masses of the bogies and carbody were simulated by mass elements, including their translational and rotational inertial properties, and concentrated in the midpoint of the rigid elements. The suspension systems were modeled by spring-dashpots assemblies. Figure 10 shows the simplified numerical model of one of the vehicles of the train, in this case the BBN vehicle.

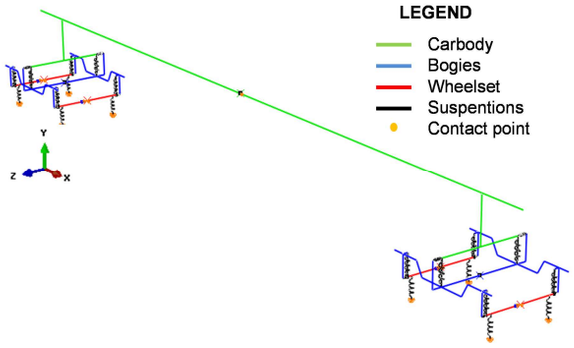

Figure 10. BBN vehicle numerical model.

The damping coefficients adopted for dynamic analysis of the bridge were experimentally estimated based on the ambient vibration test, using the EFDD method, and based on the dynamic test under traffic actions, by the application of the logarithmic decrement method (DL) to the free vibration acceleration responses after the train passage.

Table 3 presents a summary of the damping coefficients estimated from experimental tests.

Table 3. Experimental damping coefficients.

Mode	Type	Frequency (Hz)	Damping ξ(%) EFDD	Damping ξ(%) DL
1	1° vertical bending	10.22	0.96	6.95
2	1° torsion	11.09	0.84	6.10
3	2° torsion	13.49	0.86	6.33
4	bending	22.27	0.38	-
5	bending- torsion	23.24	0.36	-
6	bending	24.58	0.35	-

The track irregularities were provided by the track inspection vehicle EM120 from REFER. Figure 11a shows the longitudinal profiles, for the left and right rails, from km 286+700 to 287+300, including the bridge. The track irregularities were measured every 0.25 m and includes wavelength between 3 m and 70 m. Figure 11b presents the power spectra of the ir-

regularities as a function of the wave number (1/λ). It is possible to derive that the track irregularities with wavelengths between 25 m and 64 m presents the greatest amplitudes.

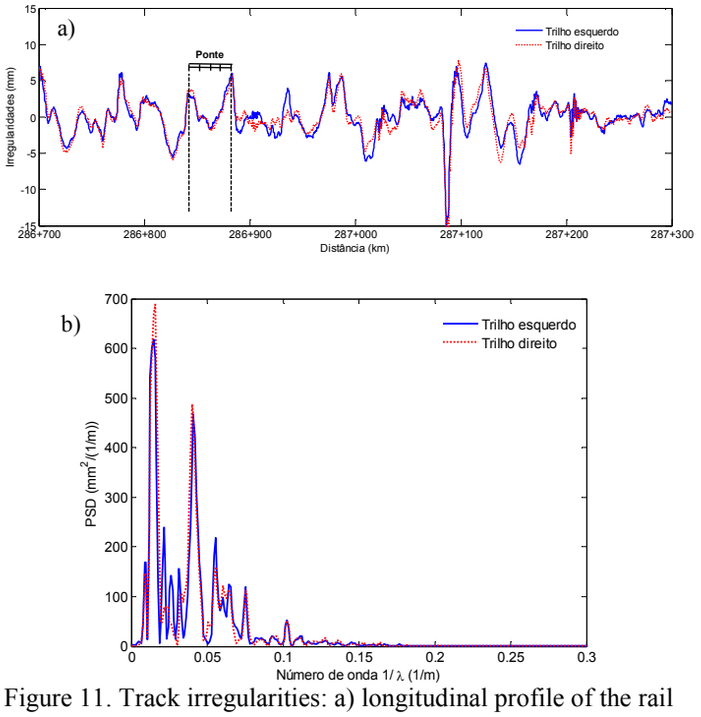

Figure 11. Track irregularities: a) longitudinal profile of the rail and b) power spectral density functions.

6.2 *Comparison between numerical and experimental results*

Figure 12 shows a comparison of the time records of the displacements close to support (D1), and 1/3 span (D2) obtained experimentally and numerically, after updating, for the passage of the Alfa Pendular train at a speed of 156 km/h.

In both comparisons it can be observed a very good agreement between the experimental and numerical after calibration records. The main differences were observed at the maximum displacements caused by the passage of the group of axles (bogies) corresponding to the 4th and 5th vehicles, at instants t = 3.48 s and t = 4.10 s.

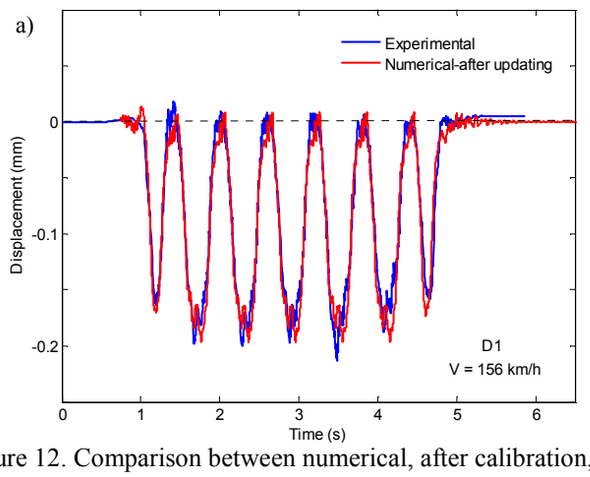

Figure 12. Comparison between numerical, after calibration, and experimental displacement records at position: a) D1; b) D2.

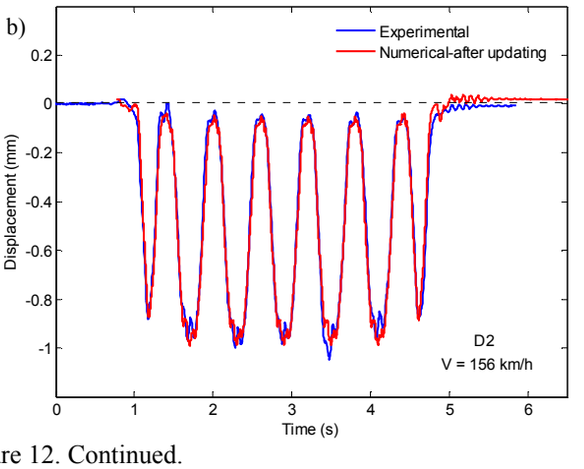

Figure 12. Continued.

Figure 13 presents a comparison between numerical after calibration and experimental acceleration records, for the passage of Alfa Pendular train at a speed of 156 km/h, at 1/3 of span 2 (position A1). The numerical responses were calculated considering the damping obtained by EFDD and DL methods, in order to determine which guarantees the best fit to the experimental responses. In both comparisons it is observed that the dynamic behavior of the bridge is very influenced by the damping. The decrease of the damping generates an amplifications of the dynamic responses.

The consideration of the damping coefficients obtained from EFDD method (Fig. 13a) led to accelerations values higher than the experimental values, particularly in terms of the maximum and minimum peaks of the response. On the other hand, the accelerations determined in the numerical model considering the damping from the DL method reveal to have a higher agreement with the experimental responses (Fig. 13b).

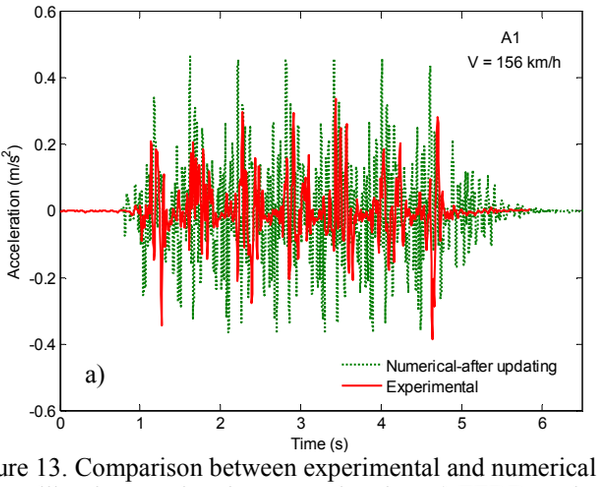

Figure 13. Comparison between experimental and numerical after calibration accelerations records using: a) EFDD method; b) DL method.

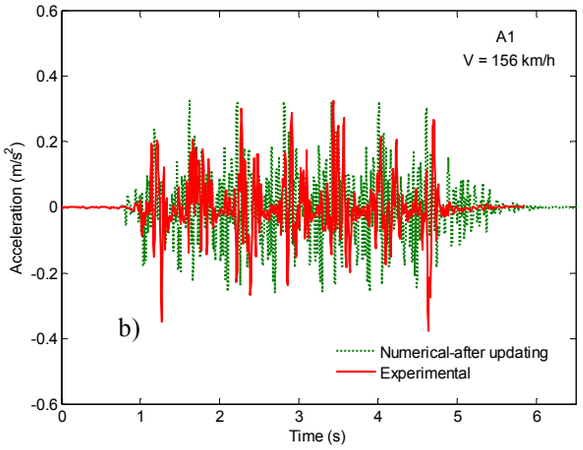

Figure 13. Continued.

Figure 14 shows the auto-spectra of the experimental and numerical after calibration accelerations obtained for the passage of the Alfa Pendular train at a speed of 156 km/h.

In the figure, it can be seen that the numerical model was able to reproduce some of the frequencies experimentally identified, particularly the contributions of vibrations modes with frequencies of 10.01 Hz and 13.43 Hz, as well as the frequencies associated with the passage of the regularly spaced group of axles of the train, at frequencies of 1.71 Hz, 5.01 Hz, 11.60 Hz and 13.43 Hz. Other frequencies displayed are probably related to the contributes of the track irregularities with wavelength lower than 3 m and wheels defects.

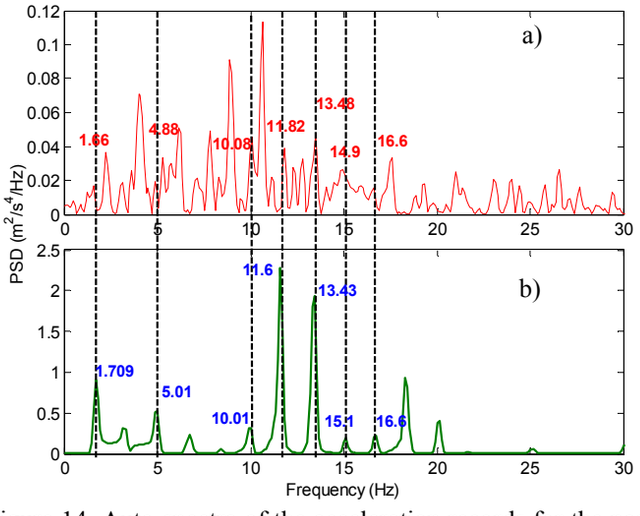

Figure 14. Auto-spectra of the acceleration records for the passage of Alfa Pendular train at a speed of 156 km/h: a) experimental, b) numerical.

7 CONCLUSIONS

The following conclusions can be drawn up from this research:

- The responses obtained after the calibration of the numerical model of the bridge showed a good approximation with those experimentally identified.
- The calibration process of the numerical model confirmed that the ballast layer between consecutive decks presents degradations particularly in the longitudinal joints and transversal joints.
- The dynamic analysis taking into account the experimentally measured irregularities, with wavelength between 3 and 25 m, showed that the contribution of modes up to 30 Hz were appropriate to characterize the dynamic behavior of the bridge.
- The calibration process improved very satisfactorily the agreement between the experimental and numerical records, due essentially to the decrease of values of the elasticity modulus of the ballast, that decrease the frequencies of vibration of the modes that contribute to the dynamic response of the bridge.
- The dynamic behavior of the bridge is extremely influenced by the damping, which was proved by the dynamic amplification observed in the accelerations response when reducing the structural damping. The method that allows a better adjustment of the numerical responses of the accelerations with the experimental measurements was the logarithmic decrement method (DL).

Management System for Natural Risk Disaster on Infrastructure: A Regional Approach

M.A. Valenzuela, N. Valenzuela, A. Peña-Fritz
Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile

R. Romo
Pontificia Universidad Católica Chile, Santiago, Chile

ABSTRACT:

A problem that has been studied at national level is the prevention of risks that affect structures due to the large number of extreme natural events. This situation is worsened by the lack of systematic evaluation of current infrastructures. It is for this reason that the COSIPLAN - IIRSA platform, together with the Chilean Ministry of Public Works, is working on the development of a solution for adequately assessing infrastructure and preventing future risks. Large losses caused by disasters have increased in recent years, directly affecting human lives, finances, and particularly road network infrastructure. The South American region has been affected by diverse events such as earthquakes, floods, volcanic eruptions, among others. In the past 35 years there has been infrastructure losses of close to US$88,000 million (South American Council of Infrastructure and Planning [COSIPLAN], 2016). This context has led to COSIPLAN/IIRSA and its member countries to implement the methodology called Disaster Risk Management at Regional Level (GRDR in Spanish) with the purpose of reducing the effects of natural and anthropogenic disasters in the country's infrastructure. The present paper presents the theoretical guidelines for the implementation of the GRDR and a proposal for implementing it in Chile over the next few years, with special attention to transoceanic network structures in South America.

1 INTRODUCTION

1.1 *The Risk of Disaster*

The term disaster is defined as a variation caused by a natural phenomenon or a human action that directly interrupts the functioning of a society, resulting in loss of life, social, material or serious environmental damage, surpassing the affected society's capacity for resolving this situation using its own resources.

Disasters are not sudden, isolated events in the 'normal' life of the communities. Disasters must be interpreted in the context of the territory and the development processes through which the affected community interacts with the ecosystems it occupies, or on which it intervenes (UNESCO, 2011).

1.1.1 *Components of Disaster Risk*

Vulnerability: Vulnerability is one of the variables in the INDECI (2010) risk formula, and is defined as the degree of resistance and/or exposure of a structure or its components to a threat. This definition is supported by what UNISDR (2009) has described as "the characteristics and circumstances of a community, system, or asset that makes them susceptible to the harmful effects of a threat."

A vulnerability may decrease as long as the communities enlarge the capabilities they use to reduce exposure to disaster risk, being these understood as the combination of strengths available within an organization and/or community.

This front of resistance, formed by the community's strengths, is called resilience. Resilience is defined as the capacity of a society to cope with the negative impact of an adverse event and to recover from its effects in a timely fashion, restoring basic operating functions.

Threat: Threat is the probability of occurrence of a natural and/or anthropogenic phenomenon which presents a potential harm for a specific time period in a known area.

Threats are classified by their origin according to UNESCO (2011). They can be of natural origin, generated by the planet's dynamic processes, or induced by human action. This classification is represented in the following illustration, in which threats are described according to their origin.

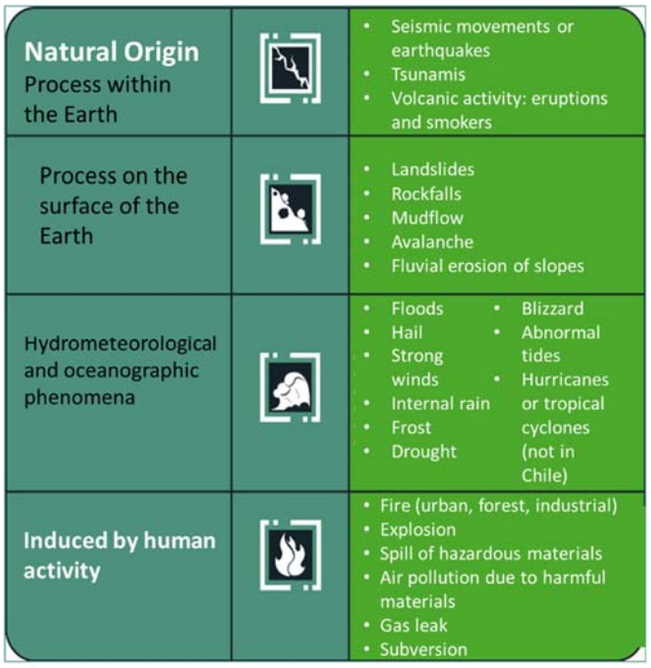

Figure 1. Origin of Threats
Source: Author compilation.

Risk: The UNISDR (2009) defines risk as "the combination of the probability of occurrence of an event and its negative consequences". This definition is complemented by INDECI (2010) as the sum of the likely losses that could arise from a disaster.

The risk is directly proportional to the threat and vulnerability. This means that the risk is dynamic, it can increase or decrease each time the other two factors vary, either separately or together.

The International Research Center on El Niño (CIIFEN) defines the following formula for risk calculation.

Figure 2. Risk Formula
Source: Author compilation based on CIIFEN (n.d.).

2 DISASTER RISK MANAGEMENT (UNESCO, 2011)

Disaster Risk Management is the methodological process in which various administrative guidelines, organizations, operational skills, and capacities are used, materializing public policies and strengthening coping abilities with the purpose of reducing the adverse impact of threats and the possibility of occurrence of a disaster (UNISDR, 2009; UNESCO, 2011).

The purpose of Disaster Risk Management is to prevent, reduce or transfer the adverse consequences of threats through various methodologies that seek prevention and mitigation.

2.1 *Intrinsic Processes of Disaster Risk Management (UNISDR, 2009; UNESCO, 2011)*

Disaster risk management is composed of four processes which are essential at the time of executing the methodology pertaining to this topic.

Risk estimation: Corresponds to the process in which the risk is identified and appreciated, obtaining the global perspective of the exposure that a particular community can have.
This perspective is obtained through the analysis of methodological information and the use of threat, vulnerabilities and capacities identification. This determines the probability of occurrence of damaging events.

Risk prevention and reduction: These are the various activities focused on the avoidance of new risks that may affect a society in addition to the reduction of vulnerabilities by means of actions materialized in advance. At this point the aim is to leave reactivity aside, generating proactive actions.

Preparedness, Response, and Rehabilitation: These consider the events with the aim of ensuring an optimal response tool for society in adverse situations such as disasters. This should ensure a correct response considering care for injured people, refitting basic services, and organizing activities in the affected region.

Reconstruction: These are the various actions undertaken for social, economic and physical recovery of the affected areasafter a harmful event such as a catastrophe.

3 DISASTER RISK MANAGEMENT IN INFRASTRUCTURE ACCORDING TO COSIPLAN.

The Method on Disaster Risk Management in Infrastructure (G.R.D) arises from the South American Council of Infrastructure and Planning (COSIPLAN),

which in turn was established by the heads of State of the members of the Union of South American Nations (UNASUR) in the year 2009. The statutes establishing COSIPLAN lay down a series of functions and responsibilities for the different support guidelines of this Council, among which stands out the Regional Infrastructure Integration Initiative (IIRSA) (COSIPLAN. n.d.).
The COSIPLAN/IIRSA's Plan of Action 2012-2022defines six areas of work in relation to planning methodologies, with a methodology of disaster risk management in infrastructure standing out among many other measures. The methodology was created with the purpose that the Council's member countries count with defined procedures to prevent, reduce or transfer the consequences of disasters such as earthquakes, volcanic eruptions, landslides, floods, among others, in infrastructure and finally put in place action plans for the development of resilient infrastructure for countries that implement it (COSIPLAN,n.d.).

The G.R.D. methodology's implementation philosophy includes different phases of development of projects ranging from the design phase of the infrastructure to the exploitation phase, also addressing requirements of expansion, rehabilitation, or improvement of existing projects. It is important to consider the internal regulations of each country in the context of design and construction for those projects that are analyzed by this methodology and are currently in the design and planning phase. Many of these design regulations address the threat and risk reductions analysis but only in the design stage. (Osorio, 2014; Valenzuela, 2016)

The G.R.D. is divided into three phases which allow for subdividing the objectives according to the methodological approaches required for each phase, as defined below.

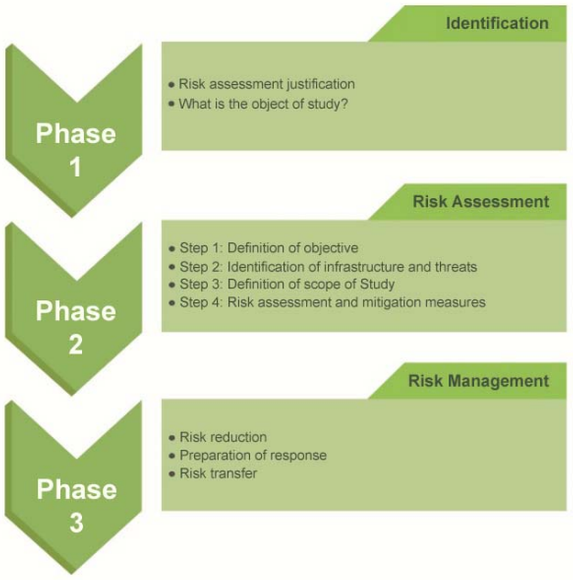

Figure 3. Phases of the G.R.D methodology according to COSIPLAN
Source: Author compilation based on Osorio (2014).

Phase 1: Identification. At this stage the object of assessment is defined, determining in advance the infrastructure and threats that will be analyzed in the application of the methodology.

The following figure shows the various forms that this methodology sets out for threat identification, as well as the infrastructure to analyze.

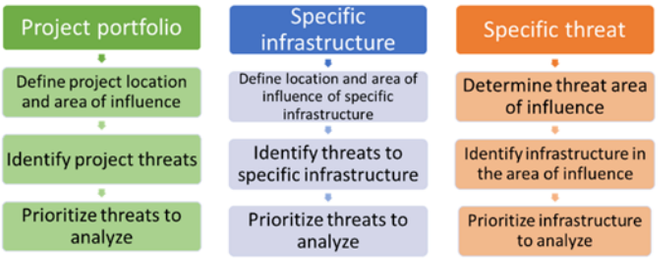

Figure 4. Methodologies for the Prioritization of Infrastructure.
Source: Author compilation based on Osorio (2014).

As Figure 4 shows, the methodology may be influenced by various motivations according to the risk under study, invariably resulting in the identification of threats as well as the infrastructure considered in the analysis.

Some of the reasons for the selection of project portfolio, specific infrastructure and threats, are described below. (Osorio, 2014; COSIPLAN, 2016)

a) Reasons for the selection of a project portfolio

- The infrastructure must ensure the continuous flow of international trade.
- Policy changes in structure design.
- Need to determine the risk of a specific road.
- Need to secure a specific infrastructure.

b) Reasons for the selection of a specific infrastructure.

- Specific infrastructure damage due to disasters of different nature.
- Policy changes in structure design.
- Presence of singular structures.

c) Reasons for the selection of a specific threat

- Record of disasters that caused damage, which is motivation for study and analysis.
- Evidence of any trace of natural or anthropogenic threat which motivates a detailed analysis. E.g.: volcanic eruptions.

Phase 1 of the GRD methodology is characterized by a basic analysis of the information available of both infrastructure as well as threats selected for study; this is a general characterization because only existing information is used.

Depending on the availability of resources, the risk analysis can be performed only in some components of the infrastructure, having to prioritize by importance according to the exposure to the threat. This analysis should be supplemented in Phase 2 of this methodology. (COSIPLAN, 2016)

Phase 2: Risk analysis. The objectives of performance which will be evaluated are defined, along with the characteristics of the threats and exposed infrastructure, thus defining the scope for risk analysis. At this stage, the analysis of the different measures of risk reduction is also considered.

This phase must usually consider the support of entities with expertise in the area, coordinated directly with the institution in charge of the methodology's analysis.

In the following diagram, the various steps needed to develop this phase are explained. The institution in charge of the analysis must be responsible for making decisions about the results achieved during the implementation of each of the steps in the diagram, ensuring that the results obtained may be useful for the correct development of the research (Osorio, 2014).

Figure 5. Methodologies for prioritization of infrastructure. Source: Author compilation based on Osorio (2014).

Step 1: Corresponds to the definition of performance indicators. At this point, the team in charge of project development should define what is the "acceptable risk" for the selected infrastructure against threats considered in Phase 1.

To define the structure's performance indicators and indexes the rules corresponding to the design and functionality of the structure studied must be known. Other important aspects are the considerations on the behavior of the structure with the purpose of:

- Prevention of damage caused to the environment.
- Prevention of economic losses.
- Maintenance of structure reliability.
- Prevention of damage to the communities and their assets.
- Prevention of damage to people's safety.

Step 2: In this step, the team responsible for the implementation of the methodology must perform, with the available information, a basic characterization of threats and infrastructure exposed. Such characterization can be delegated to expert institutions in the subject, facilitating the collection and analysis of the required data.

At this point the area of influence of the application of the methodology should also be defined prioritizing infrastructure exposed to threats, achieving the performance goals described in the first step of this phase.

- Threat characterization: It consists of the search of available information which allows for the characterization of the threats identified in Phase 1. The result of this stage is obtaining the characterization parameters of the threats used in the analysis.
- Infrastructure characterization: It is based on the essential information that should be collected to perform a correct analysis of vulnerability such as components, equipment, materials, pathologies, regulations, and design criteria, among others. As a result, the full characterization of the structure analyzed must be obtained.

Step 3: It consists of determining the depth level of risk analysis for the selected infrastructure. For this step the methodology defines three levels of risk analysis, which are defined below:

- Level 1 "Qualitative level": This level is characterized by simplified information delivery of both the threat and the selected infrastructure. The result of

this level of analysis can be obtained in the short term with the use of technical staff.

- Level 2 "Deterministic level": Quantitative analysis with the use of statistical and historical information for threat and infrastructure characterization. This level considers collecting and validating information in the field. This analysis can be done by technical professionals with knowledge of the structures defined in Phase 1, in addition to the collaboration of specialists in threat characterization and modeling.
- Level 3 "Probabilistic level": At this level, detailed results are obtained, supported by information and precise tools, and complemented by a probabilistic analysis. At this point advanced analysis methodologies must be used, requiring the intervention of experts in addition to instrumentation, exhaustive in-field analysis, and laboratory testing.

The level of risk analysis to select will depend specifically on the type of information available, financial resources, available time and professionals, among others.

Step 4: This step refers to the risk analysis. It is usually developed by experts in the subject matter based on the levels of depth of analysis described in the previous steps. Regardless of the level of risk analysis, the results must include the different risk reduction measures for further analysis and decision-making in Phase 4 of the methodology. In this step, it is important to have clarity about risk analysis, which should not only focus on compliance with regulations but also on knowing if the performance adapts to the performance described in step 1.

Phase 3: Risk Management Following the results obtained in the implementation of Phases 1 and 2, the different solutions for the implementation in the field of risk management are defined with the aim of generating a response with resilience towards the analyzed infrastructures. Within this phase, there are several alternatives that the entity responsible for the coordination of the analysis can use to increase resilience in the event of a threat: Scenarios for the planning of response to threats, risk reduction actions, and transfer of risk.

The team in charge of the coordination of the application of this methodology will be responsible for defining the actions for risk management of the infrastructure. These actions will be conditioned by the available resources and the type of action to be implemented, the measures may be for immediate or long-term implementation.

4 DISASTER RISK MANAGEMENT METHODOLOGY IN REGIONAL INFRASTRUCTURE GRDR (VALENZUELA & VALENZUELA, 2016)

In order to supplement the work done by COSIPLAN/IIRSA in the probabilistic risk analysis, a methodology called Disaster Risk Management in Regional Infrastructure (GRDR) has been proposed at the national level, coordinated directly by the Ministry of Public Works.

This method acts at phase 2 of COSIPLAN methodology, and has an impact on the actions to be implemented on Phase 3 for a resilient optimized response, and taking into consideration the country's context (Valenzuela & Valenzuela, 2016; Valenzuela, 2016)

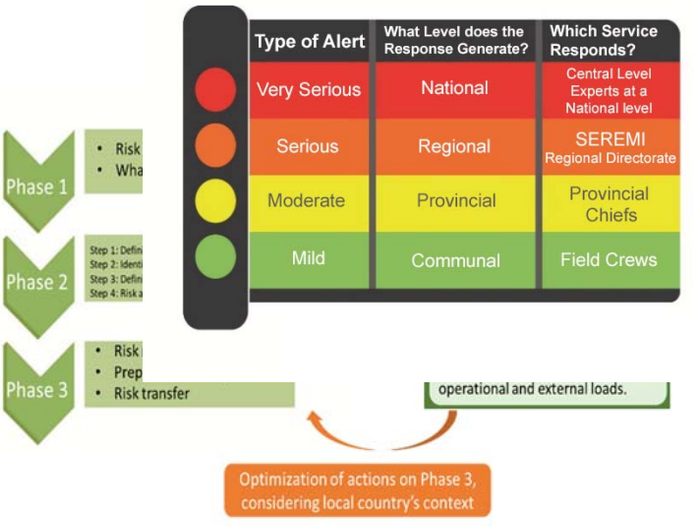

Figure 6. Chile's proposal for COSIPLAN methodology
Source: Author compilation.

The purpose of the methodology proposed by the Ministry of Public Works is the integration of aspects of decentralization through the regional management of the infrastructure. This implies that each region

must be able to carry out surveys of their infrastructure, providing information through technical entities, allowing for the generation of early warnings, and identifying and updating the damage indexes of the structures. This translates into Risk Management at the Regional Infrastructure (Valenzuela & Valenzuela, 2016; Valenzuela, 2016). The following illustration shows this decentralized approach through the incorporation of information by means of the regional technical team, allowing for the management of infrastructure at regional levels, enabling to act within the region's budgetary framework.

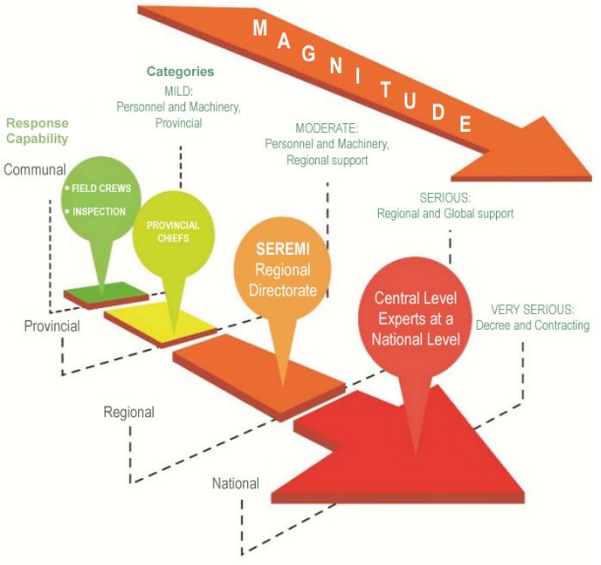

Figure 7a. GRDR Methodology Alert Levels
Source: Author compilation.
.

Figure 7b. GRDR Methodology Alert Levels
Source: Author compilation.

Some of the benefits associated with the management of infrastructure at the regional level results in lower costs associated with the information gathering stage, greater knowledge of the needs of the inhabitants, and better knowledge of the structure's geographical context.

4.1 *Phases of the G.R.D.R. methodology (Valenzuela & Valenzuela, 2016)*

The GRDR. methodology is comprised of four phases which help determine structures' pathologies and vulnerabilities to operating loads and external sources of stress. The methodology's phases are the following:

Phase 1: During this phase, pathologies are identified in the elements constituting the selected structures in a road network, taking into consideration the operational burdens of the structure as well. This must be achieved in field inspections of the structure through the use of inspection sheets.

Phase 2: Once the structure has been assessed through the pathologies of its elements and the operational burdens, it is assessed overall, taking operational burdens into consideration; this survey, as in the previous phase, is achieved through the use of inspection sheets.

Phase 3: Once the structure's pathologies and operational burdens have been assessed, the exceptional loads (seismic activities, floods, volcanic eruptions, landslides, etc.) must be identified. When acting each on its own, a vulnerability index is generated for the structure.

In this phase, it is important that public institutions provide documentation and input from their own databases of local threats.

Phase 4: During this phase, the structure is assessed through a single external stress, as well as in the event of more than one external stress (e.g.: an earthquake and tsunami, or a volcanic eruption and landslides).

The materialization of this methodology proposed by the MOP is carried out by professionals at the local units responsible for the maintenance and supervision of the national road network. These professionals must be trained by specialists in this methodology, so they can then survey the structures and provide an explanation for each pathology within each structure as well as guidance.

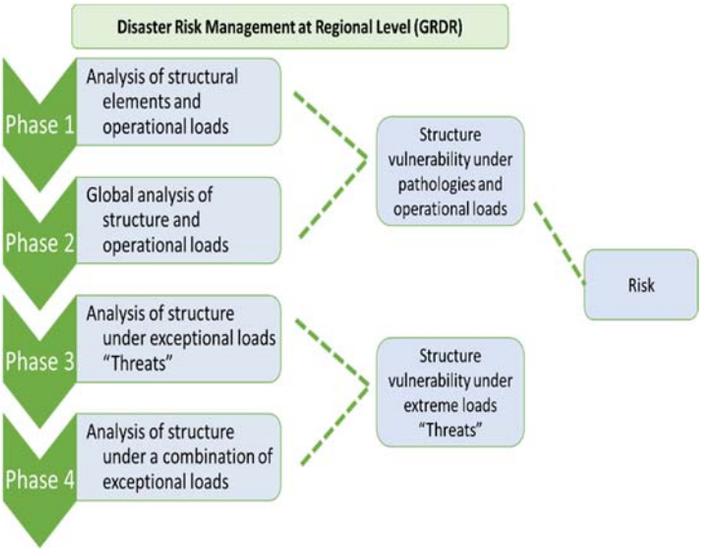

Figure 8. Phases of the G.R.D.R methodology

5 CONCLUSIONS

In the last two decades there several public policies have been put in place to increase the road network, especially in areas that have been highly fragile due to unfavorable morphological conditions.

The increase in natural disasters is directly related to the changes in the population's demographic and economic models, generating an overcrowding in the country's larger regions, leaving the ends of the territory sparsely populated. This distribution is highly vulnerable due to two important conditions.

Due to the context of the demographic and geographical environments, the latter in particular, during the course of the whole history of road development in Chile the logic of development of the current road network has been constant, based on longitudinal routes that link the country from north to south, which in turn are interconnected with side routes that connect the coastal edge and mountain range, forming a sort of "fishbone" structure (Chamorro, 2016). This results in an increased vulnerability in the national road network against threats of varied nature such as earthquakes, floods, landslides, volcanic eruptions, and fires, among others.

The GRD (Risk Management) Method is a tool for the UNASUR member countries which helps to have defined procedures for prevention and reduction of catastrophic events (tsunamis, floods, volcanic eruptions, among others) that affect each country's infrastructure and to establish plans for the recovery of connectivity and resilience of public infrastructure, designing methodologies for disaster management (Osorio, 2013).

In this geomorphological context, there is a remarkable need to implement the methodology for Management of Risk Disaster at Regional Level (GRDR) with the objective that technical units that inspect state-owned structures take this geographical context into account at the time of inspection. These technical units, such as the Ministry of Public Works (MOP) and the Housing and Urban Development Service (SERVIU) are the ones responsible for the development, implementation, and maintenance of public infrastructure in Chile. In addition, it is very important to take into consideration this methodology at the time of executing any intervention in the road infrastructure and when projecting future works within a road, in order to reduce the risk of disaster.

A new model (GRDR) was proposed in Chile with respect to the initial methodological model proposed by COSIPLAN. In this aspect and due to the country's geography, centralized work generates high costs for the Treasury. It is for this reason that the method proposed by Chile works at the regional level, decentralizing the tool with the objective of reducing costs associated with its application.

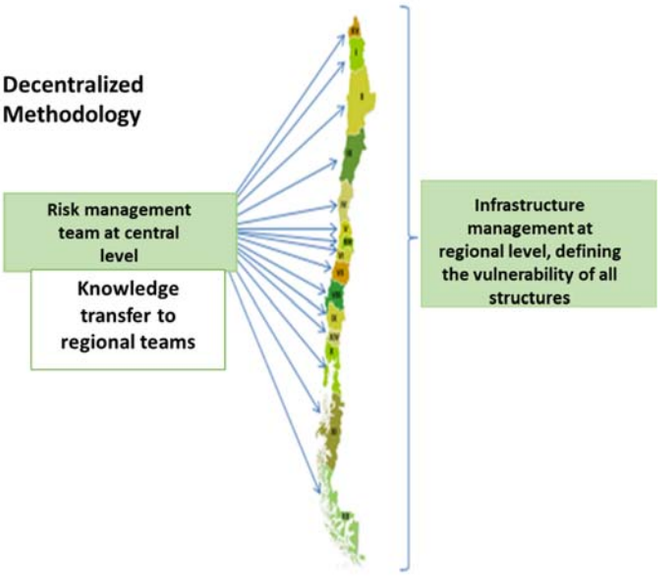

Figure 9. GRD Decentralized Methodology.
Source: Valenzuela (2017).

The application of the GRDR methodology provides a real and clearer perspective of the national road infrastructure, allowing for in-depth analysis of the most fragile areas of the network, supporting the decision-making process in the context of each structure studied, enabling finally a change in the current philosophy of the development of the national road network. COSIPLAN/IIRSA is fostering the application of this methodology in South America and in all its member countries, being Chile one of the pioneers in the application of this method.

The GRDR. method is based both on the road infrastructure as well as the climatological and morphological context where the structure is located, which means that the threats will take an important role at the time to inspect, repair and plan infrastructure belonging to the national road network. This method is focused on reducing the vulnerability of infrastructure while reducing the risk of social and

economic loss in the country in order to obtain a resilient road network.

By 2017 4 GRDR. pilot plans have been successfully carried out in Chile in the following regions: Arica - Parinacota, Aysen, Valparaiso, and Atacama. These plans have identified threats and vulnerabilities in bridges, roads, ports, and tunnels, considering the wide variety of climate conditions and threats from the northern desert to the Patagonian south of Chile.

Strengthened Chilean bridges using carbon fiber: State of Knowledge

M. Márquez
Ministerio de Obras Publicas, Santiago, Chile

M.A. Valenzuela & H. Pinto
Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile

ABSTRACT: Strengthening projects using carbon fiber have been implemented in several structures in Chile, such as buildings, stadiums, hospitals, and—very successfully—bridges. This document introduces the techniques implemented for the superstructure and infrastructure of bridges that are under threat of operational load, seismic activity or collapse. For infrastructure in particular, the application of carbon fibers in Lautaro Bridge, Maule Region, Chile, is presented. This structure was affected by the earthquake of February 27, 2010; it sustained damage on some of its piers. This paper shows the application of carbon fiber to concrete piers as a solution to the aforementioned threats. It also looks into the strengthening technique using carbon fiber applied to the Alhue Bridge, located in the O'Higgins Region. The strengthening of this structure is a response to problems related to an increase of load demand, modification of standards and regulation requirements, as well as a repair and prevention measure against damage or defects caused by seismic activity. In the case of the Alhue Bridge, an important increase of load demand was registered at the end of the 20th and start of the 21st centuries, which damaged the structural system of the deck, making the bridge vulnerable to exceeding heavy loads. Through this investigation, it is possible to extend the application of carbon fiber on slabs as a solution to the aforementioned threats, referencing its construction process through strengthening projects carried out in the country.

1 INTRODUCTION

The design, construction, and maintenance of bridges are guided mainly by the recommendations given by the Highways Manual of the National Roads Department of the Ministry of Public Works, complemented by the guidelines established in the AASHTO standards.

Most of the bridges designed in Chile are structures known as traditional bridges, which are made up of a girder superstructure (made of steel or prestressed concrete) with reinforced concrete slab, and an infrastructure of abutments and piers on footing or pile foundations.

The seismic conditions of the country have forced the design, construction, and maintenance of bridges to consider countermeasures against this phenomenon, leading to some existing bridges being strengthened to avoid collapse caused by seismic activity.

An example of this threat occurred on February 27th, 2010, when Chile was struck by an earthquake that reached a magnitude of 8.8 Mw, and the tsunami that followed. The territory affected by this disaster encompasses the area between the Arauco Peninsula (Araucania Region) and north of Pichilemu (O'Higgins Region), approximately 450 km long and 150 km wide. The hypocenter was located at an estimated depth of 30 km.

The aggressive action of seismic activities is part of the permanent threats to bridges built in this country, so it is necessary to keep an up-to-date record of the repair and strengthening techniques used as solutions to the different pathologies that affect these structures; this record is complemented by the Bridge Maintenance Management System, currently developed by the National Roads Department.

The Lautaro Bridge case study, located in the influence zone of the 2010 Chile earthquake, can be found in this context. It shows the rehabilitation and strengthening technique implemented to solve the detected pathologies in a way that makes it an alternative to general strengthening procedures used on traditional bridges in Chile.

2 SEISMIC CASE STUDY

The case study presented is based on the Lautaro Bridge, which uses carbon fiber as a strengthening method.

Lautaro Bridge

The Lautaro Bridge (formerly, Mataquito Bridge) was built in 1985 and is located near Curepto, at km 81.20 of Route J-60-k, Talca Province, Maule Region (Figure 1).

Figure 1 - Map showing the location of the Lautaro Bridge (black circle) (MOP, 2016)

The bridge is 280 m wide, with eight 35 m sections. The total width of the bridge is 7.5 m, with a road that is 6.1 m wide and a 0.7 m wide walkway on either side.

The superstructure is composed of three post-tensioned concrete girders resting on 450x300x40 mm elastomeric support bearings in each section. At the piers and abutments, the girders are braced by reinforced concrete crosspieces. The bridge also has a 20-cm reinforced concrete slab, topped with the roller-compacted concrete roadway.

The infrastructure is composed of the following elements:

2 abutments consisting of an in-fill headwall with wing-walls, both made of reinforced concrete, with pre-excavated reinforced concrete pile foundations.

7 in-fill wall-type piers with pre-excavated pile foundations as well.

Figures 2 and 3 show an overview of Lautaro Bridge.

Figure 2 - Overview of Lautaro Bridge (MOP, 2016)

2.1.1 *Earthquake damage*

After the 2010 earthquake, the main pathology detected in relation to the seismic event was problems in some of the bridge piers (Figures 4 and 5). The observed damage caused to piers No. 4 and No. 5 is listed below:

- Cracking located roughly at mid-height on the pier
- Deformation of the steel strengthening at the base of the piers
- Exposed rebar frame of the piers
- Flaking of the piers

Furthermore, side shifting was observed in some of the sections of the bridge, which thus damaged the lateral stops of the piers (Figures 3). Damage to the post-tensioned girder supports was also observed.

Figure 3 – Pier damage in Lautaro Bridge (MOP, 2017)

2.1.2 *Pier strengthening project*

The bridge strengthening project considers the application of carbon fiber bands at mid-height on piers No. 4 and No. 5 in order to repair the damage that was found and to improve the load capacity of the structure.

The project covers the following technical specifications, among others:

- Materials:
- High-strength mortar
- Strengthening rebar: A 63 - 42 H, Diameter18 mm

The construction sequence used (Figure 4) also considers the incorporation of carbon fiber to the strengthening of the piers with strengthening steel.

Figure 4 - Logic sequence of application of carbon fiber on piers (author compilation)

Each of the construction stages carried out is explained below:

Stage 1: Strengthening of the pier (Figure 5)

1. Straighten existing strengthening steel that shows deformations back into their original vertical position.
2. Place rebar (18mm diameter) joined to existing rebar.
3. Place repair mortar in a 3 m height, as this is the height that requires the rebar strengthening.

Stage 2: Implementation of carbon fiber band (Figure 6)

Reinforce external part of the piers with two layers of type TYFO SHC - 41 using TYFO S epoxy and a TYFO or polyurethane paint. The fiber circles around the outline of the pier, connecting on both frontal faces (the height of the carbon fiber strengthening is 4.2 m at mid-height on the pier).

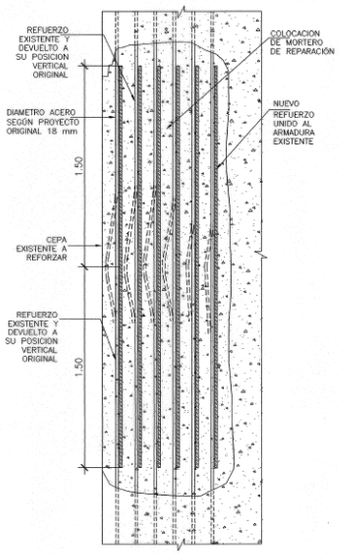

Figure 5 - Repairs and strengthening of the pier
Source: Plans for the Lautaro Bridge project. Contains "Strengthening of No. 4 and No. 5 piers with carbon fiber"

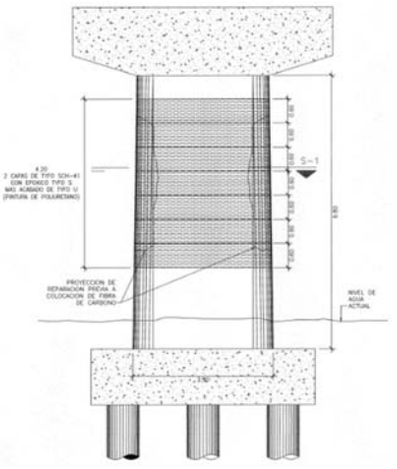

Figure 6 - Implementation of the carbon fiber
Source: Plans for the Lautaro Bridge project. Contains "Strengthening of No. 4 and No. 5 piers with carbon fiber"

2.1.3 *Strengthening solutions using carbon fiber*

The strengthening project using carbon fiber bands is implemented with the objective of reinforcing the structure, thus increasing the operational lifespan of the Lautaro Bridge. The durability of this structure is constantly threatened by seismic activity as well as load demand over the design limit, which then cause different pathologies to the bridge components.

In this case, the decision was made to apply carbon fiber strengthening where work was considered previously to provide optimal conditions for the application of the fiber and the improvement of the current state of the damaged elements. The work on Lautaro Bridge covers the repair and strengthening of the damaged piers.

The use of carbon fiber provides a solution to the aforementioned damage sustained by components of the infrastructure.

3 OVERLOAD CASE STUDY

There has been an increase of the load demand on Route 66 (the Fruit Road) which connects the port city of San Antonio in the Valparaiso Region to Route 5 South near the town of Pelequen in the O'Higgins Region; this road is also laid through part of the Metropolitan Region.

According to studies of this route (MOP), its characteristic vehicle flow shows a high volume of truck traffic, particularly at the access to the Port of San Antonio, which allows an effective connection to international trade. In this context, an important tonnage has been transported to and from the seaport through its access routes, one of which is Route 66 as its main communication road with Route 5. According to MOP, the tonnage projections for the Port of San Antonio (Figure 2) are the main factor that caused an increase of load demand on the bridges along the Fruit Road.[1]

The aggressive action of seismic activities and the extreme load increases are part of the permanent threats to bridges built in this country, so it is necessary to keep an up-to-date registry of the repair and strengthening techniques used as solutions to the different pathologies that affect these structures.

In this context, a study has been developed of one of the techniques used as bridge strengthening based on the incorporation of carbon fiber bands to the superstructure of bridges, with the purpose of counting with the general strengthening procedures applied to traditional bridges in Chile. For this, the case study of the Alhue Bridge (located in Central Chile) is used as a reference, which has been subjected to strengthening projects using this technique.

3.1.Alhue Bridge

The Alhue Bridge is located in the sector of Las Cabras, at Km 67.61 of Route 66—the Fruit Road, Cachapoal Province, Libertador General Bernardo O'Higgins Region, Chile (Figure 7).

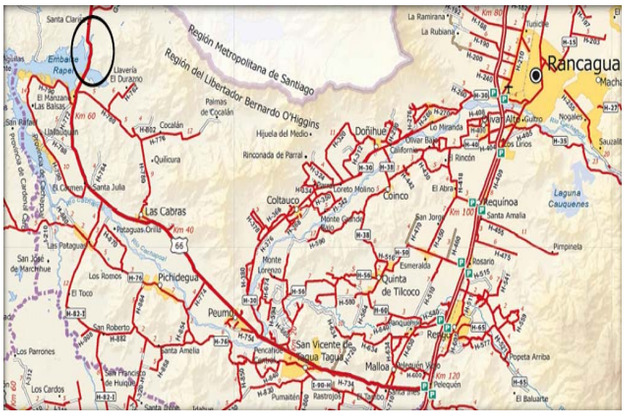

Figure 7 - Map showing the location of the Alhue Bridge (black circle) (MOP, 2015)

The original bridge is composed of two end sections, each approximately 12.50 m long, as well as a central section 15.40 m long, making the structure 40.20 m long from one end to the other. Its total width is 10.20 m, consisting of a road that is 8.00 m wide and a 1.10 m wide walkway on either side.

The superstructure is composed of two 1240x250 mm IN profile metal beams in each of the end sections and two 1240x350 mm IN profile steel beams in the central section; in both cases, the beams are separated 6.80 m and transfer the loads to the infrastructure through support steel plates. The beams are braced at the piers and the middle of their section by metal profiles, while no bracing or crosspieces can be found in the abutments.

Furthermore, the bridge has a reinforced concrete composite deck and 27 pre-tensioned concrete slabs that cover the entirety of the structure. The size of the slabs is 6.60x1.50x0.16 m, which means their effective support on each beam is 7.50 cm.

The infrastructure is composed of the following elements:

[1] The port of San Antonio had a 48 % share in the regional market in 2007 (MOP)

- 2 abutments consisting of an in-fill headwall with wing-walls, both made of reinforced concrete, with direct foundations.
- 2 piers consisting of columns with cap beam and direct foundations.

Currently, the Alhue Bridge (Figure 8) has similar characteristics to the original, since the interventions executed on it have not had much impact on its original structure.

Figure 8 - Overview of Alhue Bridge, 2015 (MOP, 2015)

3.1.1 *Damage caused by increased load demand*

The main pathology observed—the reason behind the strengthening project—is problems with the bridge deck; this has caused significant damage to 5 of the 27 pre-tensioned concrete slabs. The load demand on the bridge has been increasing, so it was decided that a strengthening project on the slabs would be carried out by means of incorporating carbon fiber bands so that the bridge remains operational.

3.1.2 *Strengthening project*

The strengthening project on the bridge carried out in 2007 considered the application of carbon fiber bands on the underside of the pre-tensioned concrete slabs, with the intention of improving the load capacity of the structure.

The strengthening project covered some technical considerations or techniques which must be taken into account for its proper execution so that it complies with the required quality standards.

Materials:

- Prefabricated slab concrete (H-50)
- Topping slab concrete (H-45):
  Characteristic cylindrical resistance in transfer: f'ci ≥ 400 [Kg/cm2]
  Characteristic cylindrical resistance after 28 days: f'c ≥ 400 [Kg/cm2]
  Maximum aggregates size = 2.0 cm
- Non-pre-tensioned steel:
  A 63 - 42 H with ledges
  Minimum anchor and overlap lengths according to AASHTO'96
  3.8 cm lining
- Pre-tensioned steel:
  Ø3/8" cables, grade 270 (low relaxation) must comply with the following standards:
  High-strength wires: ASTM A 421 – 80
  7-wire cable ASTM A 416 – 80
  3.8 cm lining
  Tensioning:
- Preload= 2.3 ton
- Tensioning strength 6.92 ton
- Elongation Max. 931 mm
  Min. 842 mm
  Others:

- HS 20 – 44 AASHTO 1996 standard truck
- This strengthening project considers that the depth of the cracks if there are any, should not be over 20 mm, which will be determined during work.
- The General Technical Specifications for Construction, vol. 5 of the Highways Manual, apply
- The planner must provide counseling, as this repair is being carried out without the construction plans
- This is a provisional repair meant to extend the operational lifespan of the bridge by at least five years.

Besides the incorporation of carbon fiber, the construction sequence that was used (Figure 9) considers the replacement of the slabs where damage and defects were observed.

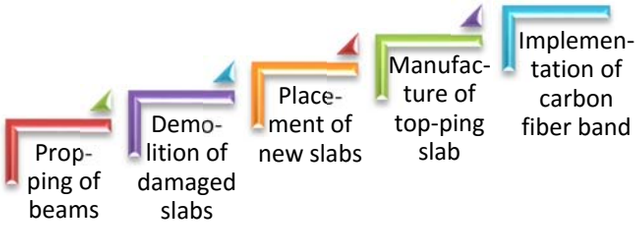

Figure 9 - Logical sequence of the application of carbon fiber to the slabs of Alhue Bridge (author compilation).

Each of the construction stages carried out is explained below:

Stage 1: Propping of the beams

1. Place props (provisional structures) under the beam, around the existing piers (Figures 10 and 11)
2. Place load stiffeners or wooden pieces in the propping spots

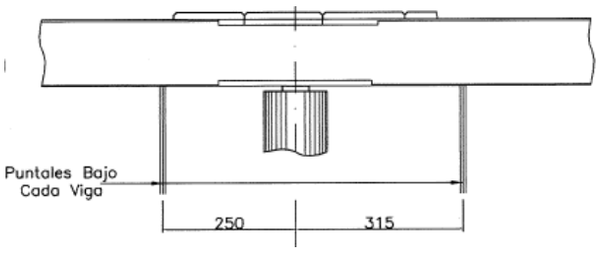

Figure 10 - Disposition of the load stiffeners under the beams Source: Plans for the Alhue Bridge project (Repairs). Contains "slab type section"

Figure 11 - Disposition of the load stiffeners under the beams

The foundation seal of the propping (provisional auxiliary structures) must be received by the construction manager and the planner in order to avoid subsidence.

Stage 2: Demolition of damaged slabs

1. Demolish damaged slabs (existing 1.5 m wide slabs) leaving the reinforced concrete slab rebar. In general, the demolition of five slabs is considered (Figure 12): two in the north support (Las Cabras pier) and three in the south support (Melipilla pier).

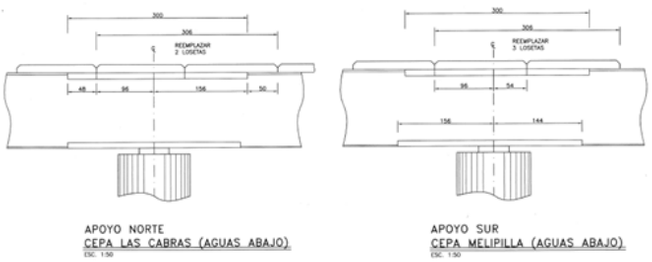

Figure 12 – Las Cabras and Melipilla Piers

Stage 3: Placement of new pre-tensioned concrete slabs according to project

1. Manufacture the 1.50x6.60 m pre-tensioned concrete slabs (Figure 13) according to technical specifications. For the manufacture of the slabs, the use of a stress layer is considered, with a distance of 194.70 m between wedges.
2. Position the new slabs in place of the ones that were demolished. The slabs will be lifted only from the hoisting points provided, keeping it horizontal at all times. Four hoisting hooks are considered, each 30 cm from the edge of the slab.

Stage 4: In-situ manufacture of the reinforced concrete topping slab

Stage 5: Implementation of the carbon fiber band

1. Clean, polish, and even out the underside of the prefabricated slabs
2. Reinforce the underside of the slabs with type SIKA WRAP 300C carbon fiber band. One 0.170 mm layer will be used, impregnated with SIKADUR 306 resin. The fiber must be placed in a transverse direction to the axes of the superstructure beam (Figure 13)

Figure 13 - Carbon fiber applied under the pre-tensioned slabs. Source: Documents provided by BDL Engineering, Diagnostic, Structural Review1

3.1.3 *Strengthening solutions using carbon fiber*

The main backgrounds provided in this paper refer to the analysis of one strengthening project using carbon fiber bands to increase the operational lifespan of the Alhue Bridge. The durability of this structure is constantly threatened by seismic activity and load demand over the design limit, which then cause different pathologies to the bridge components.

In this case, the decision was made to apply carbon fiber strengthening where work was considered previously to provide optimal conditions for the application of the fiber and the improvement of the current state of the damaged elements. Alhue Bridge requires some of its slabs and its topping slab to be repaired.

It is possible to propose the use of carbon fiber as a solution to the aforementioned damage sustained by components of the infrastructure (Figure 14).

4 CONCLUSIONS

Considering external threats, the effects of seismic activity are among the main pathologies that affect traditional bridges in Chile.

Case studies like Lautaro Bridge are routine in repair and strengthening projects to tackle these pathologies.

The strengthening of bridges using carbon fiber is a solution which offers technical and economic advantages compared to other alternatives.

The use of this strengthening technique is not common in Chile; however, following the development of the current Bridge Maintenance Management System of the National Roads Department, it should be considered a valid strengthening alternative.

Bridge professionals are required to specialize in this strengthening typology.

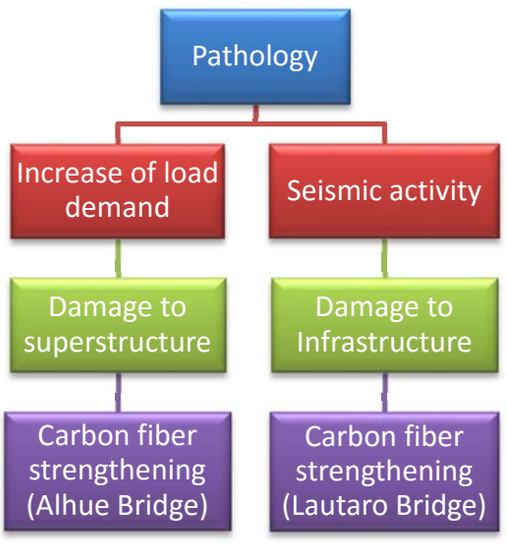

Figure 14 - Strengthening techniques using carbon fiber (Author compilation).2

Among the main pathologies that affect traditional bridges in Chile, external threats are included, such as the effects of seismic activities and an increase of the load demand on the structure, produced by the arrival of vehicles carrying loads greater than those considered in the original design.

Particular cases, such as the Alhue Bridge, enable identifying the techniques currently used in the country, as well as solving these pathologies.

In the case of the Alhue Bridge, the structure showed problems on the deck produced by the increase of loads that traveled through Route 66 (the Fruit Road), which communicates the port of San Antonio to Route 5 South.

UAV: First Chilean Proposal of use on Road Bridge Inspections

M.A. Valenzuela, N. Valenzuela & A. Peña-Fritz
Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile

D. Torres & M. Márquez
Ministerio de Obras Publicas, Santiago, Chile

ABSTRACT: Routine inspections of traditional bridges in Chile use the Maintenance Management and GRDR programs for their conservation and risk assessment, respectively. In order to do this, visual inspections or nondestructive tests are done by professionals, supported by survey trucks if the inspection zone has a difficult access. With the development of new technologies, UAV (unmanned aerial vehicle) utilization has been proposed for the inspection of bridges in Chile, which is already being used in the mining industry and the inspection of roads and hydraulic works. This document explains the current regulations, advantages, and requirements for the use of UAVs in Chile, focusing on their implementation in the inspections of bridges in Chile. This study presents the first experiences in the use of this technology following maintenance and risk analysis programs, and offers a comprehensive protocol for the standardization in the use of this technology.

1 INTRODUCTION

Most of the bridges that are in Chile are managed by the Roads Department of the Ministry of Public Works.

There is mainly one type of bridge that is constructed in Chile, which considers isostatic beams in the superstructure. These beams can be of concrete, pre-stressed and post-stressed, or steel, with a maximum span of 50 m. (Valenzuela M. et al, 2015)

These types of beam bridges are cheaper and faster to build, making them the most used typology due to favorable geographical conditions in the north and center south of the country, where there is no need to cross deep (eg. Amolanas Bridge) and large valleys (eg. Juan Pablo II Bridge).

The Amolanas Bridge is the highest road bridge in Chile and is located on the La Serena stretch - Los Vilos, Route 5 North in the Coquimbo Region. It has a length of 268 m and a height of 101.3 m. This bridge has its own characteristics for seismic protection, such as slide bearings on piers and visco-elastic dampers in abutments acting longitudinally. (Moroni, O., et al. 2004)

Juan Pablo II Bridge crosses the Biobío River in the city of Concepción. Currently, it is the longest bridge in the country (Fig. 2). It is 2430 m and is structured in 75 spans of 32.4 m each, with piers-piles and pre-stressed beams. (Morales, C., 2014)

Since 1995, the typology of bridges expands from simply supported beams (with expansion joints in the abutments for beams) to continuous beams and slab bridges, reducing points of failure by eliminating expansion joints to improve their seismic behavior and reduce maintenance cost. From 2002 to 2012, the continuous beam bridges were built with seismic isolation (eg: Marga Marga Bridge), and continuous slab on piers and abutments with a maximum span of 60 m. The seismic isolation is performed through elastomeric plates in the support beams, which, by the elastic behavior of the material, the superstructure has a degree of independence from infrastructure, reducing damage during an earthquake. (Campos, R., 2012)

The new tendency in bridges is to design it without expansion joints (jointless bridges), being implemented by the Road Department, highways and bridges in developed countries such as the United States and currently recommended in new Seismic Criteria Chilean. The benefits obtained from these structures are cheaper and safer, functionality and performance are improved in relation to disaster response, especially in cases of earthquakes (Campos, R., 2012).

Table N° 1 shows the main structural elements and their types, of a traditional Chilean bridge (Valenzuela M. et al, 2015), (Vallejo I, 2014).

Element	Type 1	Type 2	Type 3	Materiality
Piers	Wall	Pier-piles	Pile	Reinforced concrete
Abutments	Wall	Pier-piles	Spill-through	Reinforced concrete
Deck	Beam	Slab		1 – Reinforced concrete 2 – Steel

The following illustration shows the main elements of a traditional Chilean bridge.

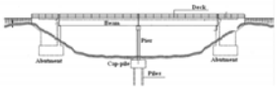

Figure 1. Main elements of a traditional Chilean bridge (Highway Manual, Volume 3, Road Department, 2013)

The Bridge Department has led to a proposal for the implementation of a Management System for the Maintenance of Bridges.

A management system for bridges must contain at least:

(a) Inspection techniques applied to bridges;
(b) Inspection protocols, including sheet inspection;
(c) Technical visits, defining, in corresponding technical reports, the implementation of destructive and nondestructive testing;
(d) Proposal for monitoring plan, instrumentation, and maintenance

The results of the new system of management are included in future versions of the Roads Manual as related to the Bridge Department, with code applied to the design, construction, and maintenance of bridges in Chile, as part of the philosophy for the life cycle of the structures.

Currently, inspections are carried out by survey trucks with telescopic walkways that are extended under the deck of the bridge; by visual inspections done by personnel; or by tests with simpler equipment, such as ladders and photographic cameras, among others, which are easy to use and implement in Chilean traditional bridges.

The biggest problem with this approach is its high cost, since traffic has to be closed for one lane; work or car accidents may occur; bridge length is variable and the approach does not work for all types of bridges, as it happens with singular bridges in Chile (such as cable-stayed, suspension or cantilever bridges). For this reason, with the help of the Ministry of Public Works (MOP), Chile is beginning to use aerial inspections with the **Remotely Piloted Aircraft System (RPA)**, with a focus on bridge inspection. This study offers the first protocol for the use of UAVs in the inspection of bridges in Chile, which was implemented in the inspections of the Maintenance Management (Marquez, M. et al. 2016) and Regional Disaster Risk Management programs, promoted by the MOP and Pontificia Universidad Católica de Valparaíso (Valenzuela, M. et al 2017).

2 GENERAL ASPECTS ABOUT UAVS:

The flight system can be referred to as UAV (Unmanned Aerial Vehicle), UAS (Unmanned Aerial System), RPA (Remotely Piloted Aircraft), o RPAS (Remotely Piloted Aircraft System). The term RPA is used for bridge inspections because the terms UAV and UAV are used for military aircraft, while the terms RPA and RPAS are used for civilian aircraft. For this reason, the term RPAS aircraft will be used, following term guidelines from the Directorate General of Civil Aviation (DGAC).

Applicable Chilean regulations:

-Instructions from the DGAC,
- DAN91: Aviation regulation, Rules of the Air
- DAN151: Aviation regulation, remotely operated aircraft operations (UAV) in events of public interest, carried out over populated areas.

Application of regulation DAN91:

The regulation is applied to each flight with RPAS, in situations where the area is not populated (see the definition in the regulation).

In order to fly under this regulation, an authorization from the DGAC is needed, which requires the following:

- RPAS operator license
- RPAS register
- Authorization from the DGAC, a filled sheet for flight plan authorization, etc. (Annex DAN91).
- Third party liability insurance

Application of regulation DAN151:

The regulation is applicable for public interest events in populated areas, such as events covered by the media, natural disasters, sports events, etc. This regulation does not apply to the use of RPA in bridge inspections.

In both cases, third party liability insurance is required.

Prior to the inspection, no-fly zones must be checked.

DJI's no-fly zones do not supersede local authorities' regulations or common sense.

Avoid flying in areas where rescue teams are actively using the airspace.

Not following these requirements can lead to fines by any affected third party in case of an accident.

Minimum technical requirements for the use of RPAS

Five minimum technical requirements must be considered for the inspection of bridges:

- A camera and video recorder with stabilizer and HD quality
- A monitor with a minimum range of 500 meters.
- Four smart batteries with an estimated duration of 20 minutes each.
- 100 GB storage
- A computer with an i7 processor, 32 GB of RAM, and between 500 GB and 1 TB storage.

Figure 2. RPA used for inspections

Environmental considerations

The following eight environmental requirements or conditions are needed to carry out a bridge inspection flight:

- Flight must take place in areas distant to structures adjacent to the bridge. This also applies to minimum distances to the inspected structure, so as to avoid any type of obstacle.
- Inspections must not take place near or over large crowds of people.
- Flight over 120 m of altitude must be avoided. This also applies to the inspection of the area surrounding the bridge.
- Extreme caution must be taken when the flight is carried out in areas over 6000 m above sea level.
- It is recommended that flight takes place in mild weather, with temperatures from 0 to 40 degrees Celsius.
- Special care should be taken when flying indoors, since the stabilization functions may be subject to interference. This also applies to inspection of box girder decks and even decks with metal girders with little spacing in between (less than 3 meters).
- Inspections must not be carried out during adverse weather conditions. These include wind speeds over 10 m/s, snow, rain, fog, strong winds, hail, lightning storms, tornadoes or hurricanes.

Maintenance and care

Maintenance of the RPA requires an inspection of the propellers before its use. If the propellers are worn, chipped or broken, its use should be avoided.

Equipment should be stored in places with temperatures between 22 and 28 degrees Celsius.

3 RPAS FLIGHT PROCEDURE CYCLE FOR THE INSPECTION OF BRIDGES

The next figure shows the UAV flight procedure cycle for the inspection of bridges.

Figure 3. Flight cycle procedure for the inspection of bridges.

Mission or inspection planning

For an adequate inspection planning and technical visit, the cycle described in each stage must be followed, starting with the identification of the place of inspection and its scope, that is, whether it is a detailed or emergency inspection.

Each of the inspection stages is explained in detail in the following section.

Office preparation

The following four items must be checked before the bridge inspection:

- Check the pilot's license and area of inspection. This is done by obtaining information about the plans and previous inspections.

- Check the RPA's batteries, camera, propellers, sensors, configuration, etc.

- For each flight, an authorization from the DGAC is recommended. This authorization must be obtained when the inspected structure is located near airfields or airports.

- In order to guarantee the safety of the UAV's flight maneuvers during the bridge inspection, the operator should be a DGAC authorized pilot (with a UAV's license and RPA inscription register), which ensures that the pilot is aware of the rules of the air.

Inspection of the area

An evaluation of the flight area is recommended in order to determine the type of regulation that must be applied. For singular bridges, a routine inspection is recommended in order to identify the RPA's basic flight parameters.

Figure 4. Inspection of the bridge location.

Furthermore, air traffic, obstacles and limits, take-off and landing zones, ground traffic, and weather conditions have to be checked. Singularities that will be inspected by the RPA also have to be identified.

Flight planning

Flight planning is important to study the viability of the use of the UAV, optimize flight time, and identify the best-suited areas to use the equipment, considering the limitations of a truck or visual inspections. In order to do this, wind direction, obstacles and distance, take-off and landing height offset must be calculated through a previous technical visit.

When the RPA viability is determined, a checklist for the RPA's image collection must be completed. This checklist will complement previous routine inspections and help in the analysis of performance indexes, according to the Maintenance Management or GRDR programs.

We present a list of minimum elements to be inspected with a UAV if the flight is feasible.

The list can be divided into three categories:

- General aspects of the structure. In this case, the UAV is used to study the conditions of the side of the bridge, with a focus on vehicle traffic, adjacent structures, hydraulic system, and longitudinal and horizontal projection overviews. The following figures are examples of the procedure on traditional Chilean bridges.

Figure 5. Aerial view of Limache bridge.

Figure 6. Las Gaviotas Bridge. River bank or vegetation environment.

- Superstructure. An inspection and image recording of the bridge's deck is performed, considering a flight above the roadway (of

four meters), with the objective of identifying the state of the pavement, expansion joints, and bridge accesses. Barriers, railings, and street lighting must be carefully analyzed. Furthermore, a flight must be performed in order to study the state of the girders and cap. This procedure requires the assistance of a professional and it is recommended that the operator is located below the deck, as long as it is safe.

Figure 7. Colmo Bridge. Longitudinal girder with a Gerber support system.

- Infrastructure. Piers and abutments elevation, including bridgeheads and connection elements with the superstructure, are considered for inspection. Support elements, hold-downs, and stoppers are inspected. The operator should be positioned under the bridge's deck, with an assistant to help with operations under the deck. Special care should be taken with bridges with steel girder decks and steel decks, as the GPS signal may be lost.

Figure 8. La Fabrica Bridge. Piers inspection.

In addition, the flight plan must consider:

A flight plan can be plotted in order to produce planimetrics, a 3D model, or an orthophoto of the area where the bridge is located, which can be opened on Google Earth. In that case, it is necessary to have aerial images of the area's planimetric and the images need to be overlapped at 80%.

Knowing the highest and the lowest heights in the area to be surveyed in order to avoid the RPA from crashing into any surface.

Determining the points of interest where pictures are to be taken. These points shall be areas that cannot be accessed by land since flight time is limited.

Pre-flight checks

These checks can be divided into two categories: RPA-specific requirements and bridge inspection requirements.

a) RPA requirements

There are minimum and general aspects to be considered for any inspection. The following should be noted:

The RPA should be in good conditions; that is, that the propellers are in good condition and are properly attached to the RPA before every flight, that the motors start and work normally, and that there is nothing obstructing the motors. In addition, the compass should be calibrated, the camera should be clean, and the lens should be free of smudges. Touching the sensors should be avoided since covering or interfering with them will affect the RPA's stability.

The RPA's software must be updated and properly installed.

In addition, all batteries should have enough power for the flight plan and inspection, including batteries from the remote control, smart flight battery, or any other mobile device. Likewise, there should be enough space on the memory card for taking pictures and recording videos according to the surveying plan.

Regarding responsibility, local regulations and those of authorities must be followed and flight conditions must be adequate, including weather, RPA, and pilot conditions (the effects of alcohol, drugs, or any substance that might affect the pilot's cognitive skills should be avoided).

b) Inspection requirements

Regarding bridge inspections, the following aspects should be noted:

Battery levels for the RPA, remote control, and monitor should be checked; sensors should be connected, the compass should be calibrated, and the fly to home configuration should be above the highest obstacle in the surveying area. Thus, a 50 meters height is recommended.

The operator should have a clear view of the RPA at all times or the signal should be good enough to watch the remote control's monitor without interrup-

tions. This is particularly important for inspections under the bridge's deck or when the structure has cables or other small obstacles.

In order to take pictures in hard-to-reach locations, such as shores, girders, piers, abutments, etc., there must be a second viewer located perpendicularly to the RPA, in order to have a proper depth of view and avoid accidents or crashes with obstacles, such as branches, rocks, walls, etc. The second viewer can carry a radio to inform the operator about movements of the RPA in that direction.

Figure 9. Pilot with a second viewer

Surveying plans must be checked and all flights should follow instructions from the engineer in charge of the inspection, especially regarding the identification of girders, piers, and abutments.

Flight

The flight takes off at point H (where the monitor is located) and it should be noted that there is a five-meter margin of error from point H at landing. In addition, the RPA's flight time will depend on wind conditions; that is, when wind resistance is higher, the battery lasts less time. Our experience shows that it has between 15 and 30 minutes of flight time. For inspections, at least three takeoff/landing areas are recommended for the proper inspection of the bridge, namely: bridge deck for inspecting the superstructure and in both shores, upstream and downstream, respectively. This will allow for an adequate visibility for inspecting the infrastructure. In case of inspections under the bridge, GPS connectivity and calibration must be checked. A clear landing area is recommended, and it should have a radius of at least five to seven meters from the fly to the home point (H). This aspect is important to consider for bridges are built on steep shores, since those areas might not be suitable.

Flights should last at least 10 minutes per bridge, divided into the three inspection categories. Video recording is recommended. In case of specific pathologies, photographs can be taken. Photographs must be taken according to the pathology or structure, as indicated by the engineer in charge. Pannings must be slow and last at least five seconds in each inspected location, in order to avoid distortions in the images.

Ideally, at the moment of recording or taking pictures of the structure, the pilot should be accompanied by the engineer in charge of the inspection or a qualified technician, so that information can be coordinated with the visual inspection software or programmed NDTs.

In the presence of cables interfering lengthwise or crosswise, working on the opposite shore is recommended in order to reach the elements, or at more than 20 meters from the power line.

Never record under the cap if the bridge is less than seven meters above the land or surface being surveyed, because of the strong likelihood of crashes and loss of signal.

RPA systems recommend against flying over reflective surfaces, such as water or snow because they affect the visual positioning systems. For this reason, bridge inspections should be performed at times when the river's reflections are lowest.

Height can be adjusted when the RPA is returning to the point of origin in order to avoid obstacles. For this reason, improvisations should be avoided during inspections; that is, in case of finding unexpected pathologies, the following steps are recommended: recording the event, finishing the flight plan, and preparing a new inspection. If the battery reaches 20% or point of no return feature activates the RTH function, the RPA should be landed in a safe location. If the battery reaches 10%, the RPA should be landed on a safe location with the camera aiming at the landing point, in order to control descent. In addition, the left stick should be aimed upwards in order to decrease the speed of descent of the RPAS and find a safe landing place for the RPA.

After landing, the motor should be turned off first, then the Smart Flight Battery, and then the remote control.

Post-flight check and information processing

Once inspection flight is finished, data must be extracted from the Micro SD card in order to be processed in the field computer. This process must be performed under the supervision of the professionals in charge of the inspection to determine the order of the gathered data and whether it is enough to be analyzed and interpreted.

In case of insufficient data, inspection and flight should be repeated to gather enough information.
For the processing of data, inspectors can see the pilot's monitor in real time or through the live streaming app in order to verify the surveying plan is being followed. Otherwise, data should be processed according to the Maintenance Management program's inspection templates (Marquez, M. et al. 2016) or the GRDR methodology (Valenzuela, M. et al 2017), dividing information into infrastructure inspection and possible environmental threats.

In this case, it is recommended that data comprises both photographs and videos in order to have a general picture of the area and details of the pathologies found, which would allow for a more precise evaluation of performance indexes of the structure.

If monitoring equipment is available at the bridge, inspection data gathered with the RPA must be integrated. Likewise, if BIM methodology has been implemented, RPA inspection must be added to the bridge's record.

4 CONCLUSIONS AND PROTOCOL PROPOSALS

According to the experience and implementation of inspections using the RPA system in Chile, general guidelines to be implemented in Chile's Manual for Roads are listed below:

Duties and obligations of the surveying person or persons before the inspection.

The flight plan should include at least:

- Name of operator and assistant (if applicable).
- Date of inspection and estimated duration.
- A short description of the flight's purpose.
- RPA's model.
- Geographic coordinates of the area to be surveyed.
- The dimension of the flight area.
- Length of the flight.
- Expected flight altitude ranges.
- Map with the corresponding flight route. Clearly marked north.
- Image recording type. It can be expressed verbally or through supporting images.
    - For specific images, specify the amount and distance between points.
    - For videos, specify amount and direction of the shoot.
- Flight authorization over the flight plan's specified area should be requested to the corresponding authorities. The flight plan should be attached to the request for its approval.
- Equipment should be checked for proper functioning and battery.
- Weather should be checked for the day of inspection in order to make sure wind and rain conditions are appropriate.

Duties and obligations of the surveying person or persons during the inspection.

- The inspection shall not begin unless the necessary traffic management measures are taken, whether it be detours, traffic interruption of one or several lanes, or road closures. If authorized, inspection can be performed without interrupting traffic, as long as conditions allow for the rest of the guidelines to be completely followed.
- Wind conditions must be checked before starting. In case of winds out of the range that is acceptable for the device, the inspection shall be suspended until conditions are acceptable. If wind conditions do not improve for a long period of time, the inspection shall be canceled and reprogrammed.
- The device should be checked to guarantee it has been assembled properly and that it works normally before take-off.
- At take-off, the operator shall be located in a place with a direct line of sight of the device at all times. If this is not possible, an inspection assistant equipped with a radio shall be required, so at least one person maintains a line of sight of the RPA at all times.
- The operator shall not fly outside of the authorized area, nor aim the device's camera to unauthorized areas.
- If weather conditions get worse and are not acceptable during flight, the inspection shall be suspended until they improve.

Duties and obligations of the surveying person or persons after the inspection.

- -Once the inspection is finished, the RPA shall be landed in a place that is safe for all participants.
- -Traffic will be resumed once all participants have left the surveying area.
- -Inspection results shall be properly organized and delivered to the bridge's or viaduct's administrator, along with recommendations for maintenance and/or repair.

Operator

- -The operator shall have a RPA certification according to their specialty.
- -The operator shall have at least 2 previous flight experiences (4 experiences for populated areas). These experiences shall be acquired through field assistance to certified operators in previous inspections.

Minimum points of inspection for bridges or viaducts.

- -RPA inspection shall cover the following minimum points for bridges or viaducts.
- -Aerial longitudinal view;
- -View of accesses;
- -General view of the surrounding area;
- -Lateral view of infrastructure;
- -View of infrastructure in detail;
    - o View of Pylons;
    - o View of Abutments;
    - o Lower view (with help of assistant);
    - o View of supports in detail.

Predictive fidelity of bridge deterioration models: probabilistic vs deterministic

R. Goyal, M. Whelan, & T. L. Cavalline
University of North Carolina at Charlotte, North Carolina, United States

ABSTRACT: North Carolina was one of the original states to develop and implement a bridge management system (BMS) shortly after formal bridge inspections were mandated by federal legislation in the United States. However, the general form of the deterioration models currently in use by the North Carolina Department of Transportation to predict future changes in condition ratings of bridges has remained unchanged since original development. These models are deterministic in nature, piecewise-linear, are based on average condition rating durations calculated from historical bridge inspection records, and have relied on pre-classification to account for the effects of explanatory factors on deterioration rates. To overcome limitations in the predictive fidelity of these legacy models, a proportional hazards-based probabilistic deterioration model was developed and implemented on the historical database of over 35 years of deck, superstructure, and substructure condition ratings for the North Carolina state bridge inventory. These probabilistic models are multivariable, duration-based, and non-stationary with a non-homogeneous Markov chain prediction process. A simplified stationary approach was also developed for use within a conventional homogeneous Markov chain. This paper presents a comparative analysis of the predictive fidelity of updated deterministic models and the newly developed probabilistic models. In the absence of future response data, a methodology developed for a quantitative assessment of the predictive fidelity based on existing bridge records is described. The analysis includes over 6000 concrete deck records and a prediction period of 15 years. Probability distributions of prediction errors demonstrate that both the nonstationary and stationary implementations of the probabilistic models achieve a much higher degree of accuracy and precision in predicting bridge condition ratings than the deterministic models. Reasons for the improved predictive fidelity of these probabilistic models are discussed briefly while making a case for adoption of these models in place of deterministic models.

1 INTRODUCTION

Bridge deterioration models are predictive relationships developed on the basis of observable deterioration defects quantified in terms of inspector-assigned condition ratings and various contributory factors associated with deterioration such as age, environment, and traffic conditions in order to estimate future deterioration behavior. The aim is to facilitate appropriate budget allocation decisions towards ensuring the health of the bridge inventory and preventing costly failures. The United States (U.S.) National Bridge Inventory (NBI) contains bridge inspection data from the 1970's when legislation was first implemented to ensure mandatory binennial inspections for all bridge deck, superstructure, and substructure components, which are assigned condition ratings on a 9-0 ordinal scale. Availability of the NBI condition rating database facilitated the data-driven development of bridge deterioration models that have since evolved significantly over the past three decades.

The primary objective of deterioration modeling is to predict future condition ratings of bridge components, which are a critical input to the bridge management system (BMS) network analysis tools for accurate identification of maintenance, repair and replacement (MR&R) projects for data-driven transportation planning. However, few studies are available that evaluate the quantitative differences between the predictive capabilities of various deterioration models. Such an assessment is especially important because the latest BMS optimization tools are highly sensitive to any changes in deterioration inputs and even minor improvements in predictive accuracy can lead to economic benefits and potential network level improvements in the health of our bridge inventories. This paper presents a methodology developed for quantitative assessment of the predictive fidelity achieved

by various bridge deterioration models relative to the observed condition ratings. The methodology was applied to assess the deterioration models developed for the North Carolina (NC) bridge database. State-of-the-art multivariable duration-based probabilistic deterioration models, using proportional hazards regression and non-homogeneous Markov chain theory, were recently developed for the North Carolina bridge database (Goyal 2015). As part of this study, the deterministic deterioration models, originally adopted by the North Carolina Department of Transportation (NCDOT) in 2002 (Duncan and Johnston 2002) were also updated to include inspection data from the past twelve years (Cavalline et al. 2015). A brief background and description of both the deterministic and probabilistic models developed for the North Carolina BMS is provided followed by a comparison of the predictive fidelity of the two model types using the developed methodology.

2 DETERMINISTIC MODELS

The earliest bridge deterioration models were based on deterministic principles of predicting future bridge condition ratings based on simple measures like mean and standard deviation and linear or nonlinear regression. During the 1980's and early 1990's, deterministic deterioration modeling studies were carried out using National Bridge Inventory (NBI) data for the whole nation as well as for individual states, including North Carolina (Hyman and Hughes 1983, Chen and Johnston 1987, West et al. 1989, Veshosky et al. 1994). These studies ignored the random errors inherent in statistical prediction and therefore all of these models are classified as deterministic models.

2.1 *NCDOT deterministic models*

The functional form of the deterministic deterioration models for decks, superstructures, and substructures currently being used in the NCDOT BMS was first developed in 2002 (Duncan and Johnston) and is based on the average number of years spent in each condition rating. These models followed the heuristic pre-classification of bridge components originally adopted when developing North Carolina's first bridge deterioration models (Chen and Johnston 1987). In this heuristic classification, all of the three primary bridge components analyzed (deck, superstructure, and substructure) were initially grouped by primary material type. Bridge decks were further sub-classified into five categories by average daily traffic (ADT), superstructures were sub-classified by both structural design type and highway functional classification, and substructures were sub-classified by geographical region. The deterioration models were developed through a methodology to compute the expected duration spent in individual condition ratings by calculating the average of estimates generated from two analysis routines. The first routine extracts periods within individual bridge records where the condition rating remains continuously unchanged and calculates the average of this continuously observed duration for all bridges within the deterioration model. The second routine analyzes the entire bridge record for each structure and then sums the total number of years that each condition rating is observed, regardless of whether the rating is continuous or not. In both of the routines, any bridges that yield a total duration of less than two years are removed prior to obtaining the average across all bridges to minimize the effect of data anomalies resulting from incorrectly coded data since the inspection cycle is biennial.

Table 1: Updated concrete deck deterministic deterioration models for the North Carolina bridge inventory

Average Daily	Years In Rating						Total
Traffic (ADT)	9	8	7	6	5	4	Years
$0-200$	3.9	10.3	9.7	9.5	7.8	9.4	50.6
$201-800$	4.0	10.0	9.8	10.7	8.4	7.9	50.8
$801-2000$	3.8	9.2	9.6	11.1	8.3	8.0	50.0
$2001-4000$	3.3	8.4	9.7	10.5	8.3	6.9	47.1
>4000	4.0	7.2	9.1	10.3	7.7	8.3	46.6

In the current study (Goyal 2015, Cavalline et al. 2015), MATLAB software routines were first developed to update these NCDOT legacy models for the twelve years of additional data now available in the NBI database. In developing these routines, the procedures originally established by prior researchers were followed as closely as possible to ensure consistent updating. The updated deterministic deterioration models for concrete bridge decks computed from 1981-2015 historical condition rating data are provided in Table 1. The cumulative duration is plotted against each consecutive condition rating for the predicted concrete deck deterioration over its lifecycle to obtain a piece-wise linear deterministic model. Concrete deck deterioration models obtained in this way for all ADT categories are presented in Figure 1.

3 PROBABILISTIC MODELS

Deterioration model predictions were found to make a significant impact on the effectiveness of bridge management systems (BMS) and several new approaches, particularly probabilistic methodologies, were developed to overcome the limitations of deterministic models in handling the stochastic nature of deterioration (Frangopol et al. 2004). The most common among these is the Markovian state-based approach, which was incorporated in the two National bridge management systems in the United States, AASHTOWare BrM (earlier called Pontis) and Bridgit, both of which require the use of element level condition rating data. Since most states did not have sufficient element-level bridge condition rating data for their

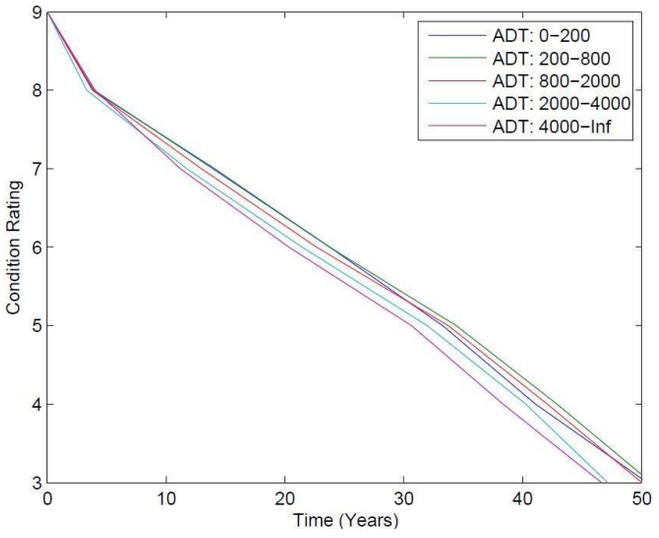

Figure 1: Updated concrete deck deterministic deterioration models for the North Carolina bridge inventory

bridge inventories when they implemented Pontis, Pontis provides for development of the initial transition probability matrix using subjective judgment-based estimates of bridge element transition probabilities obtained from transportation engineers, which are updated in a Bayesian context to provide more accurate results over time (Golabi and Shepard 1997). Among several limitations that have been identified in these models is the assumption of time independence in the traditional homogeneous Markov chain model, which is contrary to the time dependence of the deterioration process. The common approach of using linear regression to calculate transition probabilities is also considered inappropriate because the dependent variable is the condition rating, which is discrete and ordinal, and not continuous as presumed under linear regression (Madanat et al. 1995, Bulusu and Sinha 1997).

The most recent developments in probabilistic models are based on duration based analysis, which takes into account the aspect of time dependence of deterioration and also the impact of censoring (Mauch and Madanat 2001, Mishalani and Madanat 2002, Agrawal et al. 2010, Sobanjo 2011, Goyal 2015). 'Censoring' refers to instances of incomplete observation of an event, and is commonly encountered in duration data. Bridge condition rating data has a large number of censored observations, since discrete time measurements are made during the continuously ongoing deterioration process. Although accepted as superior, the suitability of duration based analysis is subject to the availability of at least 20 years length of inspection data. Since element level databases of most states are not developed for this duration, duration based studies have naturally relied on the original NBI database that offers several decades of consistently recorded condition rating data.

Similar to NCDOT deterministic models, most other deterioration models, including the probabilistic models in AASHTOWare BrM, do not model the effects of various explanatory variables, and therefore, have to rely on pre-defined segmentation of the bridge population into homogeneous categories for meaningful statistical analysis. The categorization is usually based on subjective assessment of factors influencing deterioration carried out during initial model development, which may not stand up to statistical scrutiny. This challenge of *a priori* classification is illustrated by the NCDOT concrete deck models presented in Figure 1, in which the use of ADT as a preclassifier results in insignificant differentiation between the models for different ADT categories. Moreover, increase in the number of categories or element types in these prior models was found to result in corresponding reduction in the number of bridges associated with each category, ultimately compromising the reliability and applicability of the statistical models.

3.1 *North Carolina's PHM probabilistic models*

The previously mentioned limitations of earlier models were taken into account in developing North Carolina's first probabilistic deterioration models in the current study (Goyal 2015, Cavalline et al. 2015). The researchers used multivariable duration analysis in the form of proportional hazards regression to avoid the segregation of condition rating data. The methodology not only identified the most significant factors influencing the deterioration rate of a bridge component, but also quantified the influence of these factors relative to specified baseline values in terms of proportional hazards model (PHM) hazard ratios at individual condition ratings during the component's lifecycle (Goyal et al. 2016).

Although survival analysis had been previously applied to quantify deterioration rates at individual condition ratings, the current study effectively extended it to develop the first non-homogeneous Markov chain bridge deterioration model with transition probabilities derived from the PHM survival analysis. The research also developed the first strategy for efficiently incorporating the proportional hazards effects within the transition probability matrix to facilitate ease of implementation of this advanced PHM model. The final model and its working is described here briefly, but details of development of the model inputs, statistical regression methodology, and Markov chain theory with rigorous treatment of both theoretical and applied aspects of the modeling approach are presented in the Ph.D. dissertation that stemmed from this research project (Goyal 2015).

In its simplest form, the probabilistic PHM deterioration model yielded by the developed methodology consists of two primary inputs: 1) A set of hazard ratios associated with individual factors deemed to be significant to the predictive accuracy of the model at each condition rating, and 2) A set of stay-the-same transition probabilities, P_{kk}, for all condition ratings, k, associated with every year of the prediction period

for baseline values of explanatory factors. These two inputs are used to produce a structure-specific transition probability matrix, P_i, associated with each year, i, of the prediction period as given below.

$$P_i = \begin{bmatrix} P_{99}^{(HR_9)} & 1-P_{99}^{(HR_9)} & \dots & 0 & 0 & 0 & 0 \\ 0 & P_{88}^{(HR_8)} & \dots & 0 & 0 & 0 & 0 \\ 0 & 0 & \dots & 0 & 0 & 0 & 0 \\ 0 & 0 & \dots & 0 & 0 & 0 & 0 \\ 0 & 0 & \dots & 1-P_{55}^{(HR_5)} & 0 & 0 & 0 \\ 0 & 0 & \dots & P_{44}^{(HR_4)} & 1-P_{44}^{(HR_4)} & 0 & 0 \\ 0 & 0 & \dots & 0 & 0.85 & 0.15 & 0 \\ 0 & 0 & \dots & 0 & 0 & 0.85 & 0.15 \\ 0 & 0 & \dots & 0 & 0 & 0 & 1 \end{bmatrix} \quad (1)$$

In this matrix, HR_k is the structure-specific hazard ratio for condition rating, k, and is obtained by multiplying the hazard ratios for those factors at each condition rating that are associated with the specific bridge under evaluation. The best subset factors included in the PHM model for concrete deck deterioration at each condition rating are presented in Table 2 alongwith their baseline categories and associated hazard ratios. It is clear that the hazard ratios from this table included in the structure-specific HR of a particular concrete bridge deck would be those associated with that particular bridge and taking a value of other than 1. If the bridge has only the baseline features, then the hazard ratio would be 1 and the baseline model will apply.

Further, if the initial state vector of condition rating probabilities, Z_0, is known, the PHM non-stationary transition probability matrices are applied as follows to obtain the future state vector

$$Z_n = Z_0 \Pi_{i=1}^{n} P_i. \quad (2)$$

Z_n contains the probabilities of a bridge component being in each of the possible condition ratings at any time n years in the future. The probabilities may be easily reduced to a single numerical expected condition rating value using

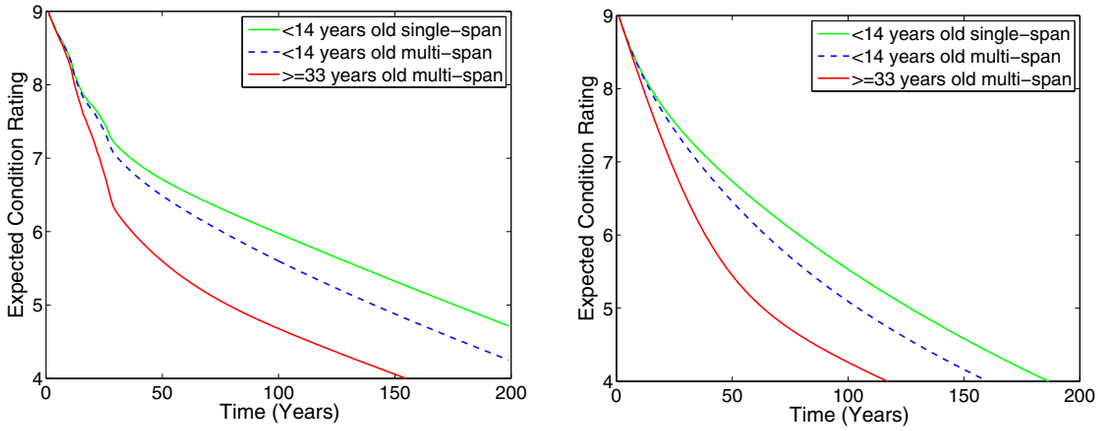
$$E = Z_n \cdot R \quad (3)$$

where R is a column vector of condition ratings used in the inspection program, which in this case is given by

$$R = [9\ 8\ 7\ 6\ 5\ 4\ 3\ 2\ 1]^T. \quad (4)$$

Although, the non-stationary implementation of the PHM model described above provides the best predictive outcomes, a stationary implementation was also proposed in this study (Goyal 2015). For the stationary PHM model, a set of stationary or constant transition probabilities is obtained by averaging the PHM non-stationary probabilities over the duration of the PHM survival function for each condition rating. Condition rating forecasting with the PHM stationary model is similar to that of the traditional Markovian models, however, it is noted that the PHM stationary transition probabilities are derived from the PHM survival analysis unlike the transition probabilities of the traditional Markovian models which were calculated using expert elicitation or linear regression based approaches. Moreover, the unique PHM multivariable advantage developed in this study of incorporating the effect of external factors through structure-specific hazard ratios is also available in the PHM stationary model.

In developing transition probabilities for the PHM model, it was observed that very few bridges in the North Carolina bridge inventory are permitted to deteriorate to condition rating 3 or lower. Since survival analysis was not possible due to insufficient data at these ratings, transition probabilities at condition ratings 3 and 2 were prescribed as 0.85 in this study to avoid an abrupt convergence of the deterioration models after condition rating 4. Condition rating 1 was considered as the absorbing state with a transition probability of 1. The stationary baseline transition probabilities obtained by implementation of the PHM model on the concrete deck subset of the North Carolina bridge inventory are presented in Table 3.



PHM deterioration models developed using the non-stationary as well as stationary forecasting approaches for multi-span and single-span bridges and belonging to various age categories, but associated with baseline assignments for the remaining best subset factors in Table 2, are presented in Figures 2(a) and 2(b). The figures illustrate the depth of information revealed by the models developed in this study using the same databases used for developing the deterministic deck models (Figure 1), which were classified using ADT and expressed far less variable-dependent behavior in comparison. Furthermore, it can be observed that the deterministic models offer far more conservative predictions of future condition rating than the PHM probabilistic models. While the deterministic models predict that all concrete decks would deteriorate to condition rating 4 in less than 50 years, the PHM model predictions for concrete decks with the specified covariate assignments are far more optimistic with a service life prediction of over 100 years by both the stationary and non-stationary models before the concrete deck deteriorates to condition rating 4. It is noted, however, that the models are based on underlying data that includes routine maintenance practices, so these models do not forecast such long service life without intervention.

4 METHODOLOGY TO ASSESS PREDICTIVE FIDELITY OF MODELS

A methodology to assess the predictive fidelity of deterioration models was developed in order to compare and contrast the accuracy and precision of the dete-

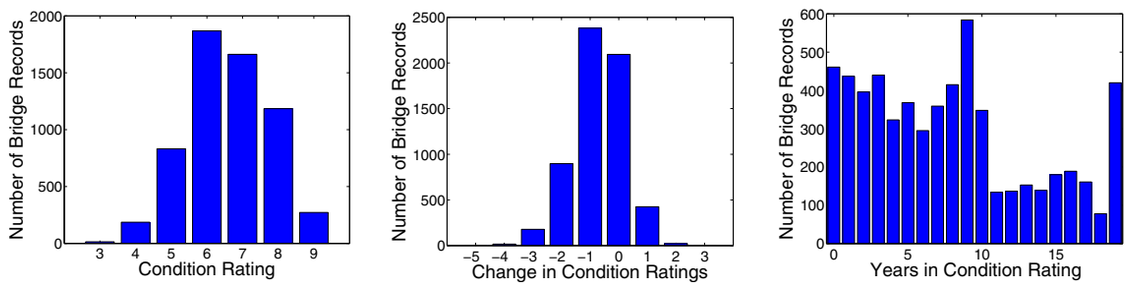
$*$Assumed values due to insufficient data for survival analysis at these ratings

rioration models developed in this research program (Goyal 2015, Cavalline et al. 2015). Such assessment is challenging in the case of bridge deterioration models since a biennial collection rate of inspection data permits no possibility of developing future response data to verify current predictions for several years at the minimum. Therefore model assessment has to be necessarily carried out using past data on the basis of which the statistical models were developed. In this study model assessment was performed using select time periods ranging from 5 to 20 years of condition rating data extracted from the NCDOT historical bridge management database. The results presented in this paper are for concrete deck condition rating records corresponding to a 15 year time period from 2000 to 2015. Bridges with concrete decks represent a large percentage of the statewide inventory, and the results and conclusions drawn from model assessment using data from other bridge components and material types were found to be consistent with those reflected in the following concrete deck analysis.

The individual condition rating databases were first parsed to extract records for which condition ratings were recorded continuously for a 15 year duration. A pre-filtering algorithm was then applied to the extracted data to exclude those records that showed an improvement by more than one rating between consecutive years. This pre-processing was necessary to remove obvious cases where maintenance actions or reconstruction might have interrupted the natural de-

terioration process. In this way, the dataset used for model assessment was reduced to only those structures exhibiting typical deterioration under either natural conditions or routine maintenance actions that do not significantly improve the condition ratings. For each of the continuously observed condition rating records satisfying the filtering criteria, covariate assignments for each record consistent with the classification scheme prescribed for the deterministic deterioration models and the PHM probabilistic models were developed from the descriptive data in the bridge record to enable selection of the corresponding deterministic or probabilistic model applicable to each individual bridge component. In performing the model assessment, the initial condition ratings at the beginning of the 15 year prediction period were input to the deterioration models along with the duration already spent by the bridge component at that condition rating in order to incorporate the pre-existing duration into the predictions generated by each of the respective deterioration models. Through this measure, the fact that a bridge that has already spent 10 years in a particular condition rating is more likely to deteriorate to a lower rating than one that has only spent a single year is incorporated into the model forecasting.

A total of 6017 bridge records for concrete decks were obtained from application of the pre-filtering algorithm to the extracted 2000-2015 condition rating data. Statistics of this data, including the initial deck condition rating at the beginning of the 15-year prediction period, the change in condition rating over the 15 year period, and the pre-existing durations that the decks had already experienced at the initial condition rating are presented in Figure 3. It is observed that the initial condition ratings are fairly normally distributed between ratings 4 through 9 with the majority of decks rated either 6 or 7. By the end of the 15 year observation period, roughly 42% of the records experienced no net deterioration in condition rating, 40% decreased by 1 rating, 15% decreased by 2 ratings, and less than 3% decreased by 3 ratings.



5 COMPARISON BETWEEN PROBABILISTIC AND DETERMINISTIC MODELS

Assessment of the predictive accuracy of the deterministic deterioration models and the non-stationary as well as stationary proportional hazards-based probabilistic deterioration models developed in this study was performed. For each model, the initial condition rating and pre-existing duration at the beginning of the 15-year prediction period for each of the 6017 concrete deck records were passed to the deterioration model with the bridge characteristics required for preclassification and the predicted condition rating after 15 years was compared to the actual recorded condition rating from the NCDOT BMS database.

Histograms of the prediction errors obtained from each model are presented in Figure 4. These results confirm the earlier observation that the deterministic deterioration models provide relatively conservative estimates of deterioration. For the concrete decks under assessment, the updated deterministic deterioration models over-predict the deterioration in condition by 1.82 condition ratings on average over the 15 year period. On the other hand, both the non-stationary as well as stationary PHM probabilistic deterioration models developed in this research project, exhibit markedly improved prediction accuracy in comparison to the deterministic models. The average prediction error for the non-stationary PHM model is reduced to a nominal 0.02 condition ratings. This mean error is especially inconsequential considering the +/- 1 integer precision of the condition rating scale. Even the stationary PHM model exhibits a mean error of only -0.36 condition ratings, which is also below the precision afforded by the condition rating scale. Furthermore, as reflected in the dispersion of the prediction errors and standard deviations presented across the three models, the probabilistic models yield significantly improved precision, as the spread in prediction errors around the mean is much smaller for these models.

To further qualify the improvement offered by the probabilistic deterioration models over the deterministic approach, empirical cumulative distribution functions were developed for the prediction errors developed with each model, as presented in Figure 5. The cumulative distribution functions can be used to characterize the performance of different deterioration models since they allow for determination of the probability of each model producing a prediction within a prescribed tolerance on the actual rating. For example, the empirical cumulative distribution function for the deterministic deterioration model reveals that this model will only produce a prediction within +/-1 of the actual concrete deck condition rating about 21% of the time after 15 years. In contrast, the probabilistic deterioration model is able to achieve a prediction within +/-1 condition rating of the actual about 70% of the time for the stationary model and as much as about 80% of the time for the non-stationary model. It is evident that the probabilistic models significantly out-perform the deterministic models demonstrating remarkable improvements in prediction accuracy and precision.

The reasons for the improved performance of the probabilistic deterioration models relative to the deterministic deterioration models are the ability to account for the large degree of censoring in the condition rating data and the better statistical performance on non-normally distributed duration data. The semi-parametric PHM survival function and the non-stationary Markov chain theory together provide a powerful combination for modeling the variability and stochasticity of the deterioration process, which is distinctly visible in the model assessment results. Moreover, the proportional hazards-based probabilis-

tic models incorporate the effects of many more external factors than provided by the limited tiers of classifiers used in the deterministic models.

6 CONCLUSIONS

The updated deterministic models currently in use within the North Carolina bridge management system, and the new proportional hazards-based probabilistic models developed in a recent research project of the North Carolina Department of Transportation are described and compared in this paper. A model assessment methodology also developed through this research is presented and implemented on the concrete deck dataset of the North Carolina bridge inventory to quantify and compare the predictive fidelity of the deterministic and probabilistic models over a prediction period of 15 years. Statistical distributions of prediction errors obtained from the deterministic models and the PHM stationary and non-stationary probabilistic models reveal the distinctly superior predictive abilities of the probabilistic models. The quantitative model assessment results present a strong case to support the implementation of probabilistic models over deterministic deterioration models in the interest of significantly improved accuracy and precision in condition rating forecasting with important implications for more efficient management of the complete bridge inventory.

Life Cycle Assessment for Civil Engineering Structures of Railway Bridges

G. Lener & J. Schmid
University of Innsbruck, Unit of Steel Construction and Mixed Building Technology, Innsbruck, Austria

A. Strauss
Department of Civil Engineering and Natural Hazards, University of Natural Resources and Life Science, Vienna, Austria

ABSTRACT: This contribution presents the WEB based prognosis tool "LeCIE" (Life Cycle Assessment for Civil Engineering of Railway Bridges). LeCIE aims to develop a concept for the predictable life cycle management of engineering structures in the rail sector. In order to achieve this objective, inspection results regarding damage and damage processes are combined with probabilistic degradation predictions, forecasting procedures, monitoring and assessment methods. This includes the development of a framework for the life cycle's management system which takes into consideration structural components and singular as well as combined damage in the context of the overall structure of concrete-steel, steel and composite bridges. At the current stage of investigation, the focus of this tool is on railway bridges as this project has been financed by the Austrian Federal Railways company ÖBB. excluding the loading data, the method is general and could adopted for road bridges in the future.

1 INTRODUCTION

1.1 *General*

The project 'LeCIE (Life Cycle Assessment for Civil Engineering of Railway Constructions – Strategies and Methods') aims to develop a wide-ranging concept for a predictable life cycle management of engineering structures in the rail sector. In order to reach this objective, inspection results regarding damage and damage processes are combined with probabilistic degradation predictions and forecasting procedures as well as with monitoring and assessment methods. The next step is then to develop a framework for the life cycle management system to be adopted when considering singular as well as combined damage, structural components as well as the overall structure of concrete-steel bridges, steel bridges and composite ones. The development of this project is collaboratively divided between the University of Natural Resources and Life Science, Vienna (BOKU) and the University of Innsbruck (UIBK). The remit of the UIBK is the treatment of the stated objective when dealing with steel as well as composite bridges, whereas the BOKU group places its focus on concrete bridges.

1.2 *Aims of the Project*

The following aims have been defined for this project:

1. Evaluation of the results derived from the bridge inspections
2. Development of a WEB-based, general life cycle management framework for steel as well as composite bridges
3. Definition of relevant/significant processes of degradation
4. Identification of relevant/significant influencing factors
5. Development of models of degradation

2 DEFINITION OF RELEVANT PROCESSES OF DEGENERATION

2.1 *General overview*

An important foundation for the development of life cycle management tools is the best possible knowledge of the functional degradation processes of support structures, only once this is established is it possible to realistically integrate business-oriented considerations. To this aim, while taking into consideration the technical regulations, an extensive literature study on the relevant science has also taken place. At the same time, a sensitivity analysis of the known frequent degradation processes has been car-

ried out by evaluating the inspection results of the last project year. As a result of the knowledge acquired in the aforementioned steps and after having gathered an extended database, it has been possible to implement a concept study for a new procedure in order to deduce degradation functions. The process and the resulting outputs are explained in the following paragraphs.

2.2 *Evaluation of bridge inspections*

Various types of damage have been defined in order to assess the inspected objects, the results have been evaluated component-by-component similarly to the Austrian school grade system (Schmid, J. Lener, G. 2016). Subsequently, the data has been studied in order to identify, by means of statistical methods, clear and verifiable relations between individual categories such as the age of the structure or its level of corrosion. Firstly, the methods of the linear regression have been applied. This application delivered no significant output and was therefore classified as insufficient for the definition of degradation processes. The reasoning behind this conclusion was primarily that the available sample size was too low and hence impossible in being representative. Nevertheless, the results have been very suitable for the definition of relevant influencing parameters referring to the complete degradation.

On this matter, it is important to note the corrosion and fatigue effects on steel structures wherein fatigue ought to be seen as an overall process with secondary effects. In addition to statistical methods, the support structures and their signs of aging have been analyzed taking into consideration constructive designs and static mechanical observations.

It has thereby been ascertained that support structures of high quality constructional workmanship present a significantly slower degradation process. Moreover, it has been determined that in many cases fatigue problems are caused by issues concerning the measurement of support structures. A few years ago measurements would have been mostly conducted by using framework models and significantly less impact factors would have been considered. In this way local concentrated tension peaks at the stiffness cracks and in transverse connections were regularly determined to an insufficient level. Those areas are however exactly where fatigue damage begins to occur, especially when, in addition, corrosion protection has been poorly performed.

A part of this quickly developing damage process could potentially be prevented by the adoption of measurement methods and verification concepts based on spatial simulation models.

2.3 *Literary works and regulations*

With the acquisition of knowledge from bridge inspections and from general literature on steel structure degradation, the next step has been to gather insight into the topics of corrosion processes and fatigue. The basic literary works on fatigue to be mentioned are those by Radaj and Vormwald (Radaj D., Vormwald M., 1985), (Radaj D., Vormwald M., 2007) as well as the measurement standards of the Eurocode package (Österreichisches Normungsinstitut, ÖNORM EN 1991-2, 2012), the ÖBB Infrastructure guideline B45 (ÖBB Infrastruktur, 2011) and the IIW recommendations (Hobbacher A., 2014). Information on corrosion, environmental classes and corrosion protection systems is to be found in ISO standards. The depiction of fatigue is a multiple parameter problem without an analytical solution. The determination of fatigue resistance is concept-based on statistically evaluated test results. There are various possibilities which allow the consideration of impacts and their influence to be analyzed as well as the influence of traffic volume and traffic intensity. These last two aspects are not taken sufficiently into account in the presently used normative design rules according to the Eurocodes, despite this they ought to be handled as relevant influence parameters.

Clear deterministic models are available which illustrate corrosion and describe corrosion rates for different climates. However, the assignment to the individual climates for bridge details proves to be problematic. The classification of individual climates as input variables could only to be identified by means of elaborate measurements. Generally, the micro climate is taken into consideration, which is usually not deducible from the regional climate of the area in which the bridge is situated. Equally questionable is the ability to describe the degradation of the corrosion protection as very few data sources are available or could be found in literature, an issue which leads to high uncertainties (Petraschek, 2015).

3 DEVELOPMENT OF DEGRADATION MODELS

3.1 *General overview*

After having acquired the knowledge of the relevant degradation processes and their input variables, a general life cycle management framework has been developed. This was possible thanks to the cooperative conceptualization and organizational planning

between the UIBK and the BOKU. The present results are not to be considered as the final solution. This collaboration defined the relations between individual components, although their quantitative content would still require completion. A concept for the degradation model has also been developed. This model enables the connection of any axle load measurement data as well as the evolution of traffic on the load side with the component resistance of the different types of construction and support parameters.

3.2 *General life cycle management framework*

The general life cycle management framework combines the individual degradation models into a complete model, being able to take into account precaution and maintenance measures as well as cost figures. These measures, however, cannot be generally defined and therefore depend upon many parameters. In particular, it is important to mention the type of construction and material which reveal different degradation functions. It makes therefore sense to gather degradation models, degradation functions and the temporal propagation of processes together in a database and to evaluate and/or adjust (postprocessor) them in the life cycle management tool according to the information gathered from the master data sheet of the bridges and from possible additional available input variables of each individual object. The data taken as a b asis are internal curves of degradation of the ÖBB for the component of corrosion and the extensive axle load measurement data for the component of fatigue. Those are subsequently defined in a manner which presents and gives access to damage rates of different kinds of support systems and/or structural details in relation to different traffic configurations and traffic volumes.

3.3 *Models of degradation for steel*

Based on literary research, inspections of supporting structures and axle load measurement data, relevant degradation processes of steel and composite bridges have been defined. During this procedure, attention has been paid to certain approaches due to the impossibility to describe some of the processes in a deterministic way. The model design has been produced based upon the statistical analysis of prepared questionnaires about the maintained condition of various bridge structures and the assessment of the axle load measurement data of nine measurement points. The evaluation of this data has allowed the conveyance into a process model. Simultaneously, a deterministic process model has been developed. Previously conducted studies have shown that material fatigue and corrosion are the relevant life cycle processes in the case of steel and composite bridges. Thanks to these studies it has however come to light, that the current methods of fatigue strength determination, because of the various forms of support structures and their loads, are not suitable for a common life cycle management tool. As a result, concepts have been produced in order to calculate relations and simplify the different input parameters that allow the deduction of a common degradation function for material fatigue taking into account corrosion. Two models have been generated: one semi probabilistic and deterministic model and one model solely based upon probabilistic approaches.

Fatigue strength has been determined by applying calculations of train-crossing in combination with with evaluations of extensive axle load measurement data as impact factor and by subsequently deducing damage equivalence factors, forecast models and possible modification factors. With the use of an appropriate signal analysis, the resulting tension's time signal can thus be divided into parts and the damage calculated with the specification of a S-N curve. The Rainflow procedure has been used in this process (Rychlik, I. 1987), damage of single train crossings have been calculated by means of linear damage accumulation. The methods, which have been developed, use the load model 71 as their referential model. Figure 1 shows the axle load measurement data of nine measurement points which have been taken into account for the year 2014. These nine measurement points are distributed over the entire railway network in Austria.

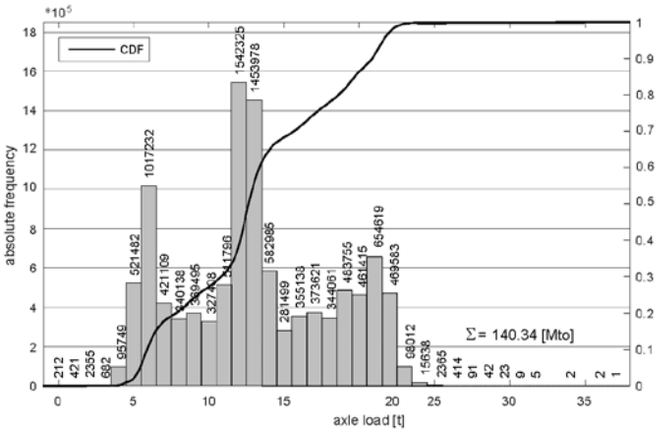

Figure 1. Considered axle load measurement data (Schmid, 2017).

The results from both models are to be demonstrated by using as example a railway bridge build in the year 1955, with single span girders of a range of 15 m and an arc radius of 1700 m.

The semi probabilistic deterministic model produces as a result the development in time of the amount of damage *D(T)*. In this model, corrosion is dealt with in a deterministic way. The extensive internal knowledge of the ÖBB as well as data from

Det Norske Veritas Classification Notes No. 30.7 (Det Norsk Veritas, 2003) are used referentially. The condition of the corrosion protection *K(T)* is to be divided into various parts. *K(T) = 1* signifies that at the time *T* the condition of corrosion protection is with 95% of probability barely still intact in all its layers. At *1 > K(T) > 0*, the condition starts to rapidly worsen, despite the fact that the protective effect on the base material remains intact. Only once the condition limit is reached. *K(T) = 0*, is there no protective effect and the base material is exposed to the outside weathering. After 5 years of exposure to the weather conditions, the damage rate of fatigue increases significantly per stress cycle, as on one hand, every stress range is effective (Miner elementar) and on the other, only a small damage sum is tolerated. With a timely renewal of corrosion protection, this damage rate increase can be hindered.

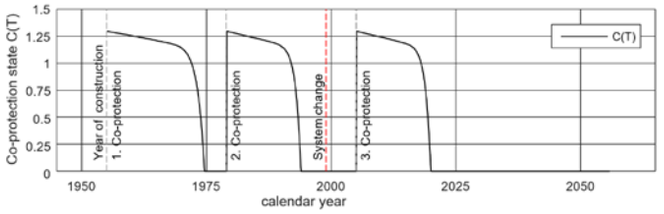

Figure 2. Development of corrosion protection state – main girder (Schmid, 2017).

The damage *D(T)* is obtain from the following expression:

$$D(T) = \int \dot{D}(T)dT =$$

$$= \int \left[\dot{D}(T - T_0) \cdot \left(1 + (\kappa - 1) \cdot \mathrm{H}(T - T_{ds})\right) \cdot \left(\frac{\Delta\sigma_E(T)}{\Delta\sigma_E(T_0)} \right)^{m_1} \right] \cdot \mathrm{H}(T - T_0) \cdot dT$$

with

$D(T)$	damage at time T
κ	factor considering corrosion effects
$\Delta\sigma_E$	equivalent constant amplitude stress range
H	Heaviside function
m_1	starting slope of fatigue strength curve
T_{ds}	irreversible timing of system change of fatigue behavior due to corrosion

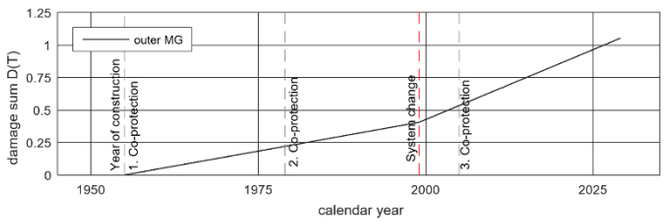

Figure 3. Damage D(T) of main girder at outer track (Schmid, 2017).

The probabilistic model takes into consideration the statistical range of the input variables based on data form (Geißler, K., Krohn, S., 2016), (Sedlacek, G., 2007) and produces as a result the time-dependent increase of the failure probability p_f and thereby the relation to the reliability index ß. The evaluation of p_f has been done by the use of Monte Carlo Simulations.

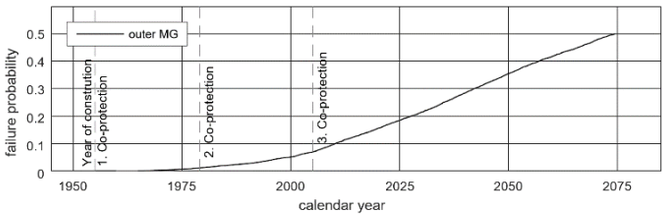

Figure 4. Probability of failure p_f of the main girder related to fatigue (Schmid 2017).

3.4 *Degradation model for reinforced concrete*

For a realistic application of the degradation model in LeCIE, it was necessary to calibrate the mathematical model for the transport processes of chloride and carbon as in bulletin 34 and the model code for the Service-Life-Design (Schiessl et al., 2006). According to RVS 13.05.11 (FSV, 2017), railway bridges are expected to have a life cycle of 120 years. In line with empirical values of the ÖBB experts, these requirements are fulfilled when applying the design in accordance with the regulations, in using a concrete of good quality and in ensuring high quality in the building of rail bridges. It is, however, necessary to adjust/calibrate the model parameter of the transport process in order to concord with these regulatory requirements.

On the basis of literature review and reports, the load models as well as the environmental conditions for this calibration have been defined together with the ÖBB experts for predefined, frequent situations. The primary aim of the aforementioned definition was to describe and consider the long term behavior of the reinforced concrete structures by taking into account the life cycle in case of chloride and carbon penetration.

These investigations have been concentrated on analyzing structures with concrete consisting of common cement types with different predefined environmental classes and various qualities of workmanship in the construction.

The aim in this section has been to characterize the parameters for the transport processes of historical concrete types, which have been used over the years by the ÖBB.

Among various model approaches, for the LeCIE Tool, the following has been selected in order to describe the penetration development of chloride (Schiessl et al., 2006)

$$C(x,t) = C_0 + \left(C_{S,\Delta x} - C_0\right) \cdot \left[1 - erf \frac{x - \Delta x}{2 \cdot \sqrt{D_{app}(t) \cdot t}}\right]$$

with

C_0 initial chloride content [weight -%/c]

$C_{S,\Delta x}$ chloride content of the predominant environmental impact in [weight -%/c]

Δx depth of the convection zone (concrete crust near to the surface), in which the process does not behave in conformity with the penetration resistance against chloride of Fick's second law of diffusion [m]

x depth with the appropriate chloride content C(x,t) [m]

t time [s]

D_{app} clear chloride diffusion coefficient [m²/s]

erf Gauss' error function

This equation is based on the Fick's second law which describes the diffusion in its one dimensional form. Although other kinds of transport mechanisms for chloride, which acts on concrete surfaces, appear to be more suitable in order to specifically illustrate the capillarity, absorption and penetration, Fick's second law is considered as the most generally effective and widely adopted law (Gehlen et al., 2015). A higher chloride content in concrete can lead to pitting corrosion and to sudden failure of the structure.

In order to describe the carbonation's construction, among the various model approaches, an adopted model from *fib* Model Code for Concrete Structures 2010 (Schiessl et al., 2006) has been integrated in the LeCIE Tool.

Carbon causes a reduction of the concrete's pH-value and therefore a depassivation of the reinforcing steel resulting in corrosion. The following equation describes the time-dependent carbon process:

$$x_{c,d}(t) = \gamma_f \cdot k_{NAC} \cdot \sqrt{k_e \cdot k_c \cdot k_a} \cdot \sqrt{t} \cdot W(t)$$

with

k_{NAC} rate [mm/year$^{0.5}$] by $W(t)=1$, $k_e=1$, $k_c=1$, $k_a=1$, relative air humidity 65±5%, temperature 20±2°C, CO_2 concentration 0.04±0.005 volume% by atmospheric pressure

k_e=1 factor as well as function to describe the environmental influence of the relative humidity (RHa) on the basis of the effective inverse carbonation's construction resistance [-]

$k_c=1$ factor as well as function to describe the effects of CO_2 concentration in the neighboring area's air [-]

$W(t)$ factor as well as function to describe the humidity rates [-] which prevent the penetration of CO_2. NOTE: W(t) gains in relevance with increasing depth into the carbonation's construction and also over extended time periods.

4 LECIE DATABASE & WEB BASED PROGNOSIS TOOL

The WEB based prognosis tool "LeCIE" allows to create, edit (making correction or complete) and to delete new and existing bridges in a free input format. The bridge objects are classified according to the internal ÖBB line number system and can be clearly identified on basis of the line number and kilometer distance. The analysis of the above mentioned processes (degradation analysis as well as life cycle assessments) can be done for the whole bridge object, groups of structural elements of the bridge or for each individual defined bridge element.

Figure 5 shows as example the cost-optimized chloride performance group evaluation, in this case the abutment A of the bridge object 1062 on the line 33.003, for two different maintenance strategies (strategy I "process delay due to coating" and strategy II "concrete replacement". From figure 5 it can be seen that an intervention is required for the abutment wall only and not for the abutment wing wall. The LeCIE WEB tool also allows the combination between the processes. Based on this capability, the most cost-effective intervention strategy can be determined.

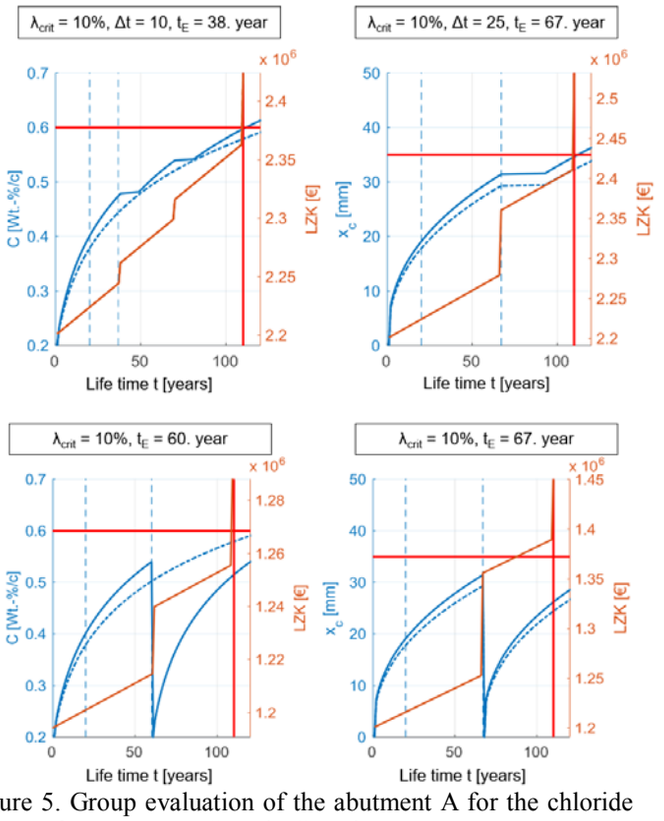

Figure 5. Group evaluation of the abutment A for the chloride process for strategy I "coating" and strategy II "concrete replacement".

5 SUMMARY AND OUTLOOK

A common Life-Cycle-Management-Framework could be provided including the evaluation of bridge inspection reports of the past year. In addition, the relevant impact parameters for the procedures to analyze the degradation processes, which are significant for steel support structures, have been identified and degradation models subsequently developed.

Noticeable progress was made regarding the component of fatigue and significant correlations were recorded. By using the developed WEB tool, results can be obtained numerically with acceptable time expenditure.

The major parameter for fatigue, the real impact due to loading, is solved by the evaluation of axle load measurement data. The only aspect, which refers to this point which remains open, is that of the definition of the traffic development on a long term basis.

Taking into account the component of corrosion, it has been possible to successfully conclude the concept study regarding the production of a new method which would deduce the function of degradation.

The next step will be to conduct further parameter studies for the component of fatigue which will bring a reduction in the problems to be solved, in doing so it will allow a final verification of the procedures featured here. In addition, the components of traffic prognosis and structural part resistance are to be investigated in more depth. The permitted damage sum as well as necessary factor modifications are to be quantified.

Furthermore, a transfer into a probabilistic method is necessary in order to represent the impact values of the reliability index. As far as the component of corrosion is concerned, the illustrated model approaches are to be refined as soon as a sufficient amount of data becomes available.

Subsequently, the resulting degradation functions are to be deduced and together with fatigue impacts are to be condensed into one complete model.

At the current stage of investigation, the focus of this tool is railway bridges as the Austrian Federal Railway Company ÖBB has financed this research project. Excluding the loading data, the presented method is general and could be adopted for road bridges in the future.

National-scale bridge element deterioration model for the USA

P.D. Thompson
Consultant

ABSTRACT: The Federal Highway Administration of the United States uses its National Bridge Investment Analysis System (NBIAS) to develop needs estimates and report on the conditions and performance of the nation's 600,000 bridges and culverts. The system's deterioration model was recently updated to be consistent with the most recent bridge element inspection standards. A data set containing nearly 3 million element inspection records was stratified into nine climate zones according to average temperatures and moisture in each county of the United States. Algebraic methods developed in research for Florida and Virginia were used to process the element inspection data into transition probability matrices. The resulting models were then transformed for compatibility with the latest inspection manuals used in federal bridge condition reporting requirements. The product represents the first time there has been a true nationwide element level deterioration model for bridges in the United States.

1 INRODUCTION

The US Federal Highway Administration uses its National Bridge Investment Analysis System (NBIAS) to develop needs estimates and contribute data to a periodic report on the conditions and performance of the nation's highway and transit infrastructure, including more than 600,000 bridges and culverts (FHWA 2016). NBIAS performs a network-level life cycle cost analysis representing future deterioration and costs at the element level, to estimate the amount of investment in bridge preservation activities that is likely to keep long-term costs to a minimum.

Since the 1970s, states have been required to gather a standardized data set of bridge inventory and biennial inspection data, for submittal to FHWA each April. These are compiled into a National Bridge Inventory (NBI) (FHWA 1995) which provides the source data for the Conditions and Performance Report. Until recently, the NBI had only four data items describing bridge condition:

58 – Deck condition rating
59 – Superstructure condition rating
60 – Substructure condition rating
62 – Culvert condition rating

These four items represent separate parts of a structure, with a focus on the primary load-bearing components. Since the NBI Coding Guide is focused on safety rather than on maintenance needs, certain components having significant maintenance costs (such as expansion joints and paint) receive little or no consideration when assigning a condition rating. Each item is recorded using a coding scheme where 9 is excellent condition and 0 is failed and beyond corrective action. When any of the NBI condition ratings is 4 or below, the bridge is considered "structurally deficient".

Although the FHWA Coding Guide is still mandatory, bridge owners have found that the four condition ratings are insufficient for asset management purposes. They do not provide enough information on the cause of deterioration, to forecast future condition or select appropriate maintenance actions, and they do not provide enough information on the extent of deterioration for cost estimation.

As a result, nearly all bridge management systems worldwide use a more extensive condition description organized according to elements and condition states (Mirzaei et al 2014). In the United States, most of these systems have, until recently, been based on the AASHTO Commonly-Recognized (CoRe) Element Guide (AASHTO 1998). The guide defines 106 common structural elements and provides objective visual language for recognizing 3-5 condition states for each

element. Inspectors record the quantity or percentage of each element found to be in each condition state.

Previous versions of NBIAS used 72 of the 106 elements, focusing on the ones believed by FHWA to have some relationship to the criteria used in assessing the four NBI condition ratings. Since the collection of element-level data was optional at the time of NBIAS development, and because there was no process for states to submit such data to FHWA, it was necessary to develop a model to synthesize element data from NBI data. Only the 72 elements were capable of being imputed in this way.

One of the criticisms of the AASHTO CoRe Elements was the lack of detail on bridge decks, and the fact that deterioration processes were often commingled. It was difficult, for example, to separate deterioration of paint systems from deterioration of the underlying steel, or cracking from corrosion. As a result, the AASHTO manual moved toward a standard that makes a separate assessment of each major deterioration process, in order to provide the clearest and most relevant possible distinctions among condition states. This practice was formalized in the 2013 AASHTO Manual for Bridge Element Inspection (AASHTO 2013). Federal rules now mandate the collection and reporting of a subset of the elements defined in the new manual. Designated "NBI Elements," these are shown in Table 1 (FHWA 2014).

In order to prepare the next edition of the Conditions and Performance Report, FHWA wanted to base its analysis on the new catalog of 100 NBI Elements as submitted by the states. To do this, it would be necessary to develop a new bridge element deterioration model compatible with the new data set.

2 SOURCES OF DATA

A major challenge in this effort was the fact that the definitions of NBI elements and condition states was new, so very few studies had yet been undertaken to develop compatible deterioration models. At the time the work was done, only the Florida Department of Transportation had yet completed such models (Sobanjo and Thompson 2016). However, many of the states had long histories, some going as far back as 1995, of bridge inspection using the older CoRe Element manual, and some had developed deterioration models using the older format. These provided some potential sources of data.

2.1 *Model used in earlier NBIAS versions*

A 50-state survey conducted in 2005 identified 15 state Departments of Transportation that had developed bridge element deterioration models and were willing to share them for FHWA use. Most of these models were based on expert judgment, although some of the agencies had used the linear regression procedure within AASHTO's Pontis software to update their judgment-based models to incorporate bridge inspection data.

Each of the 15 states had up to four separate deterioration models representing categories of environmental and operating conditions within their states, in most cases reflecting the use of deicing chemicals and the presence of marine environments. The NBIAS models were organized into nine climate zones, based on rainfall and freeze-thaw experience, using conventions established in the Highway Performance Monitoring System. Each of the more than 3000 counties in the USA is classified into one climate zone. So the

researcher developed a correspondence, based on judgment, between geographic states and environments on one hand, and NBIAS climate zones on the other hand.

In this way, a deterioration model was selected for each element and climate zone to populate the NBIAS models starting in 2007. These models have been unchanged in NBIAS since then.

2.2 *Florida and Virginia research*

In 2010 to 2012, the Departments of Transportation of Florida and Virginia developed bridge element deterioration models using large databases of CoRe Element inspections over 12 years or more. The methodology, summarized later in this paper, was developed initially for Florida DOT (Thompson and Sobanjo 2010). These states addressed only three of the nine climate zones, and only the Florida model, at the time, had been migrated to fit the 2013 AASHTO elements. Nonetheless, the earlier studies provided some important lessons:

- There can be important differences between agencies in how the condition state language of the CoRe elements is interpreted. It was found, for example, that Virginia inspectors were reluctant to use the worst defined condition state of each element because they understood this to imply a requirement for a structural analysis. The Florida inspectors did not share that view and were more willing to use all of the defined condition states.
- The Florida research compared the models based on inspection history against earlier models based only on expert judgment. They found that expert judgment was not very accurate, that transition times were under-estimated by a factor of about 2 (Thompson and Sobanjo 2010).

For the current effort, these lessons implied that it would be desirable to base each model on more than one agency's data, and actual inspection history should be relied upon as much as possible, in preference to expert judgment.

2.3 *Collected Pontis data*

Between 2008 and 2015, the FHWA Long-Term Bridge Performance Program (LTBP) gathered Pontis data sets from 23 state DOTs, to help the program with its deterioration research. While the LTBP had not developed a national deterioration model of its own, it was willing to share its data set with the NBIAS project for that purpose. On further analysis it was found that 15 of the data sets could be made compatible with the present study, so a combined database was created from these 15 agencies. The new database contained 66,025 bridge records, 492,661 inspection events, and 2,868,505 element inspection records.

Although this database was apparently of sufficient size for useful analysis, it did not provide uniform coverage of all of the climate zones across the country. In the end, it was necessary to incorporate the earlier Florida and Virginia research, in order to avoid bias against the climate characteristics of the southeast United States. Certain results from the earlier NBIAS models were also used in order to provide reasonable variation in the effect of temperature on deterioration rates, as part of the climate zone model. Figure 1 shows the national coverage of the 50 states from the combination of all three data sources.

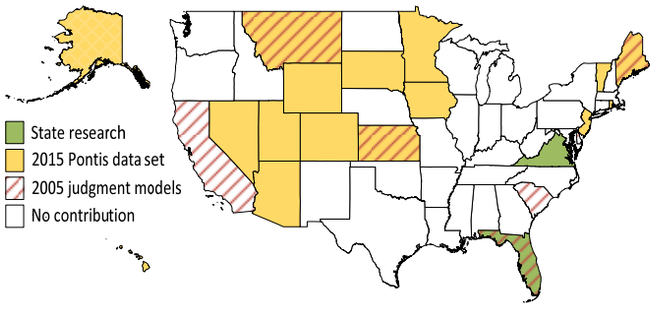

Figure 1. Sources of data

3 MODEL DEVELOPMENT PROCESS

A multi-step process, described in the following sections and summarized in Figure 2, was used to reduce and process the data set, to estimate transition times, to expand the result to nine climate zones, and to make the results compatible with the 2013 AASHTO Manual for Bridge Element Inspection.

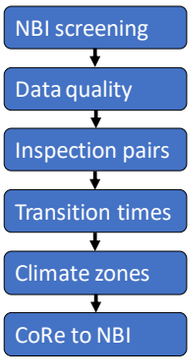

Figure 2. Model development process

3.1 *NBI screening*

The state DOTs have often used their Pontis databases for more than just federally-recognized bridges. As just one example, a recent examination of Florida's database found 36,889 structures, of which fewer than 9,000 are bridges that appear in the National Bridge Inventory. The rest are drainage culverts, sign structures, high-mast light poles, and traffic signal mast arms. For the purpose of the NBIAS analysis, it was necessary to remove certain objects:

- All bridges and culverts less than 20 feet in clear span length along the roadway centerline, and all other structures that do not qualify for the National Bridge Inventory.
- All agency-defined and customized elements.
- Approach slabs, slope protection elements, and any other elements not found in the list of 100 NBI Bridge Elements (FHWA 2014).
- All bridge deck elements that used the temporary 2001 interim revisions to the AASHTO CoRe Elements.

These redactions ensured that the deterioration models would faithfully represent the structures that are addressed in the NBIAS analysis.

3.2 *Data quality checking*

Analysis of the data set found that agencies varied considerably in their ability to maintain uniform quality control on element data. In particular, the first element inspection cycle attempted by each agency, usually in the mid-1990s, was often treated as a practice run for inspectors in training and for field manuals under development, and was not considered reliable by many of the agencies. The first inspection on each bridge was therefore deleted from the data set.

In addition, the first and last years of inspections often covered only a part of the inventory: the first year usually covered one or more pilot districts within the state, and the final year was typically still underway and partially complete at the time the database was obtained from the agency. Since these partial cycles were not likely to be random samples of the inventory, they were deleted.

For element inspections remaining, a variety of quality assurance tests were performed, which resulted in additional deletions. For example, it was required that the quantities of each element inspection in each condition state sum, over all condition states, to the total quantity indicated for the element.

3.3 *Creation of inspection pairs*

A Structured Query Language (SQL) command was used to process all of the remaining element inspections to create a table of inspection pairs. Each inspection pair consisted of two element inspections spaced 2 years apart (plus or minus 6 months). To form a pair, two inspections must match in their element number, environment code, and quantity.

At this stage it is desirable to omit any inspection pairs that have experienced preservation or replacement activity modeled by NBIAS, since the purpose of the analysis is to quantify pure uninterrupted deterioration. Unfortunately, the 15 agencies differed dramatically in their ability to collect work accomplishment data, and few had significant data sets to offer. As a result, the table of inspection pairs was reduced by omitting any bridge inspections where any elements showed an improvement in condition. This is a very imperfect solution, for at least three reasons:

- Preservation actions may have been applied, that did not change the condition state of any of the elements but may have postponed further deterioration of the bridge.
- Even if preservation occurred on some of the elements, the untreated elements should still be useful for deterioration modeling. For example, agencies often perform bridge deck work that does not affect the superstructure or substructure.
- Sometimes conditions appear to improve due to random error, or difference of opinion among inspectors. Filtering out only one direction of random error introduces a statistical bias.

These considerations are likely to affect the accuracy of the resulting models, but no research has been done to quantify the magnitude or direction of the bias. This would be a valuable topic for future research, and is also a factor arguing in favor of improved agency databases and procedures, including contractual requirements, for recording work accomplishments at a sufficient level of detail to identify at least the bridge and elements that were treated.

After creation of inspection pairs, the populations of individual element types in each climate zone were evaluated. It was found that many of the elements were not sufficiently common to produce the 500 inspection pairs that earlier research had found were necessary for a stable model (Thompson and Sobanjo 2010). For each model, it was also necessary to set aside a random sample for validation purposes, further increasing the population requirement. As a result, elements were clustered in order to increase the model populations. This clustering was done by judgment, grouping each uncommon element with a more common element believed to experience the same deterioration rates. This resulted in 30 element groups.

3.4 *Estimation of transition times*

The estimation procedure uses the data set of inspection pairs and the one-step algebraic procedure described in Thompson and Sobanjo (2010).

To set up the estimation of a one-step matrix, the prediction equation is defined as follows:

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix} = \begin{bmatrix} p_{11} & p_{12} & 0 & 0 \\ & p_{22} & p_{23} & 0 \\ & & p_{33} & p_{34} \\ & & & p_{44} \end{bmatrix}^2 \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} \quad (1)$$

The element inspection vectors [Y] and [X] are spaced two years apart, but the transition probability matrix [P] is expressed for a one-year transition. Hence, it is applied twice. Writing out the individual equations necessary to calculate [Y] results in:

$$y_1 = x_1 p_{11} p_{11} \tag{2}$$

$$y_2 = x_1 p_{11} p_{12} + x_1 p_{12} p_{22} + x_2 p_{22} p_{22}$$

$$y_3 = x_1 p_{12} p_{23} + x_2 p_{22} p_{23} + x_2 p_{23} p_{33} + x_3 p_{33} p_{33}$$

$$y_4 = x_2 p_{23} p_{34} + x_3 p_{33} p_{34} + x_3 p_{34} p_{44} + x_4 p_{44} p_{44}$$

Since the sum of each row in [*P*] must be 1.0, the following additional equations apply:

$$p_{12} = 1 - p_{11}; \quad p_{23} = 1 - p_{22}; \quad p_{34} = 1 - p_{33} \tag{3}$$

The vectors [*X*] and [*Y*] can be computed from the database of inspection pairs to describe the combined condition of the element before and after. So these quantities are known. Thus the system of seven equations and seven unknowns can be solved algebraically for the elements of [*P*]. First find p_{11} from equation 2, then find p_{12} from equation 3, then p_{22} and p_{23}, and so on in a simple sequence.

A complication arises because the equations are second-order polynomials in p_{ii}, so it is necessary to use the quadratic equation to find the roots. For example, the equation for p_{33} is:

$$p_{33} = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \tag{4}$$

$$a = x_3; \quad b = x_2 p_{23}; \quad c = x_1 p_{12} p_{23} + x_2 p_{22} p_{23} - y_3$$

The same pattern of equations and solution methods apply to elements having 3 or 5 condition states as well. Each same-state transition probability p_{ii} is constrained to be in the range from 0 to 1 exclusive. Even though the quadratic equation finds two roots, in practice only one root was in the necessary range. The final transition time is computed from:

$$t = \frac{\log(0.5)}{\log(p_{jj})} \tag{5}$$

The model estimation and evaluation process was automated using Microsoft Excel.

3.5 *Climate zone factors*

NBIAS classifies the more than 3000 counties of the USA into nine climate zones according to moisture and temperature, using the same definitions as the Highway Performance Monitoring System (FHWA 2014) and the existing NBIAS data set. Even though the estimation data set was very large, the analysis found that population sizes were insufficient for the climate zones in the southeastern USA.

Another finding on detailed analysis of the results was that, even though each climate zone was internally consistent, the differences in models from one zone to another, for certain individual element groups, were not always consistent or intuitive. Even though the inconsistencies were statistically significant and based on factual data, the potential use of the model for resource allocation meant that a higher level of consistency was required.

As a result, it was decided to develop two separate but intersecting models: a model giving typical transition times for each element group across all zones, and a separate model for climate zone adjustment factors based on each bridge's location. This had the effect of smoothing the model so that it was always intuitive and consistent, and had the added benefit of boosting the element group populations.

In the end, the element group model was developed entirely from the 15-state data set, supplemented by the Florida and Virginia data. The climate zone factors were also developed from the large data set (not including the Florida and Virginia models), but supplemented by the climate zone factors used in the original NBIAS models. Table 2 shows the final climate zone factors.

Table 2. Climate zone factors

Zone	Moisture	Temperature	Factor
1	Wet	Freeze	0.64
2	Wet	Thaw	0.58
3	Wet	Warm	0.92
4	Damp	Freeze	0.84
5	Damp	Thaw	0.75
6	Damp	Warm	1.20
7	Dry	Freeze	0.94
8	Dry	Thaw	0.84
9	Dry	Warm	1.34

3.6 *Migration of element definitions*

The models developed to this point are all based on AASHTO CoRe elements, using the older element definitions that have 3 to 5 condition states defined for each element. A final step is necessary, therefore, to convert the results to be compatible with the NBI element definitions.

This transformation was accomplished using a migration probability matrix, a probabilistic mapping of each new element condition state to one or more of the old condition states. This mapping was prepared in Florida research using expert judgment, informed by the differences in element condition state language between the old manual and the new one (Sobanjo and Thompson 2016).

In many cases, such as railings, the new manual had exactly the same definitions as the old one, so no change was necessary. Changes were minimal for most concrete elements, because the only change in condition state language was the exposure of reinforcing steel in condition state 2. Other elements had more significant differences. Steel elements, for example, were divided into a substrate element and a coating element. Deck elements also had major changes. The full migration probability matrix and

the rationale for each allocation of condition states can be found in Sobanjo and Thompson (2016).

4 FINAL MODEL

Table 3 shows the final model of element group transition times developed in the study. To determine the transition times for a specific element on a given bridge, first determine the corresponding element group for that element, and the specific climate zone for the county in which the bridge is located. The element group determines the transition times to be extracted from Table 3. This is then multiplied by the climate zone factor from Table 2 to yield a final transition time estimate for each condition state.

NBIAS uses these transition times to generate a Markov transition probability matrix as a part of its life cycle cost analysis. The rightmost column in Table 3 shows the median number of years from state 1 to state 4 resulting from the Markov chain calculation.

Table 3. Final element group transition times (years)

Element group	State 1 to State 2	State 2 to State 3	State 3 to State 4	State 1 to State 4
A1 Concrete deck	12	24	24	79
A2 Concrete slab	9	30	17	72
A4 Steel deck	14	8	9	41
A5 Timber deck/slab	10	10	21	53
B1 Strip Seal expansion joint	28	10	10	59

G2 Metal and other culverts	12	18	31	78
P1 Deck wearing surface	11	32	19	79
P2 Protective coating	17	12	9	50

Median number of years to make the indicated transition

5 CONCLUSIONS

By drawing on the research and data sets of 19 state DOTs, the study was able to produce a nation-wide bridge element deterioration model for the National Bridge Investment Analysis System. Based on historical inspection data, the model avoids some of the problems that have been noted with earlier judgment-based models, particularly under-estimation of transition times noted in Sobanjo and Thompson (2013).

In addition to its use in NBIAS, the model is potentially useful to agencies that are getting started with bridge management and have not yet developed their own models. It may also be useful to researchers who need a national-scale model for life cycle cost analysis or investment analysis, but might not have the resources to develop one of their own.

Damage location in experimental/numerical models by acceleration amplitude change

R. L. Silva, L. M. Trautwein, L. C. Almeida & G. H. Siqueira
FEC - UNICAMP, Campinas - SP, Brasil

C. S. Barbosa
POLI - USP, São Paulo - SP, Brasil

ABSTRACT: This paper presents a technique to identify and locate a single fault at any point along the bridge span by vibration data analysis. In order to demonstrate this method, numerical and experimental models were developed and a simply supported single-span bridge was simulated. The experimental model is a slab with 150 cm of span, 5 cm of thickness, made with reinforced concrete and supported on rubber bearing. The finite element model was developed by using SAP2000® [1] software with the same geometric and materials properties from the experimental model. The first step was to create a vibration baseline data from undamaged models (experimental and numerical) by vibration test and computer simulation. Afterwards, a transversal cut of approximately 2 cm depth was performed to simulate structural damage and the vibration test was performed again. The vibration tests were performed with controlled impacts in the middle of the span and were monitored using capacitive accelerometers fixed along the span. At last, the damage location was obtained by comparing the sum absolute of acceleration data, from a specific time interval, between intact and damaged models. Therefore, the damage location coincides with the greater variation of the sum absolute sum of acceleration.

1 INTRODUCTION

Large structures such as bridges, dams, stadiums, etc. are subjected to severe loads over its service life. These actions can damage the structure, compromising its durability, bearing capacity and, in extreme cases, the structural collapse. The existence of damages causes changes on the structural dynamic characteristics, such as natural frequencies, amplitude of accelerations and displacements, modal shape and damping, that can be obtained through the dynamic monitoring.

The interest in the ability of monitoring a structure and detecting damage as soon as possible has permeated the aerospace, civil and mechanical engineering community (FARRAR 2001 [2]).

According to NOBREGA 2004 [3], the dynamic test is an adequate procedure because of its non-destructive character, which allows the collection of generalized information on the stiffness and structural damping, because of its comparability to a computer numerical model, and because it can be repeated and compared over time.

RYTTER 1993 [4] propose a classification system with four levels for damage identification methods:

- • *Level 1 (Detection): Indication that damage might be present in the structure;*
- • *Level 2 (Localization): Information about the probable position of the damage;*
- • *Level 3 (Classification): Quantification of the severity of the damage;*
- • *Level 4 (Assessment): Prediction of the remaining service life of the structure.*

OWOLABI 2003 [5] present a method for identifying a crack location based on the frequency and amplitude changes. The crack location is linked to changes in natural frequencies and acceleration amplitudes, expressed in frequency domain by a frequency response function (FRF).

In order to reach the level 2 of damage identification (RYTTER 1993 [4]), based on the studies presented by OWOLABI 2003 [5], an empirical formulation was developed, based on comparison of the sum absolute of acceleration data, from a specific time interval, between intact and damage models.

2 OBJECTIVE

The objective of this work is to present a technique of identification and localization of structural damages, able to locate a single damage at any point along the bridge span, from an empirical formula based on the changes of the acceleration amplitude, obtained from the dynamic monitoring. To reach the main objective, the following activities were performed:

- *preparation of a three-dimensional numerical model with the aid of software finite element;*
- *determination of the empirical formula by simulations with the numerical model;*
- *application of the damage localization technique in the numerical model for damages at different points in the span;*
- *construction of an experimental model;*
- *dynamic monitoring of the experimental models, intact and damaged;*
- *application of the empirical formula to locate a damage into experimental model.*

3 MODELS

Two models, numerical and experimental, were developed to simulate a simply supported single-span bridge. In the numerical model several simulations were made, varying the damage location, to support the determination of the empirical formula of damage location. Afterwards, the experimental model was used to demonstrate the developed method.

3.1 *Numerical model*

A representative three-dimensional numerical model of the structure was built using the SAP2000 software [1], with the same dimensions and mechanical properties of the materials from experimental model.
The numerical model is a rectangular slab with 150 cm of span and 5 cm of thickness, made with concrete and supported at the ends on rubber bearing (rubber dimensions: 500 x 50 x 18 mm). The properties of concrete and rubber bearing, experimentally determined, were shown in the Table 1.

Table 1. Properties of materials.

Concrete	f_{ck} (MPa)	24,9
	E (MPa)	33301*
	ν	0,2
Rubber bearings	E (MPa)	25
	ν	0,2

*It is considered the dynamic modulus of elasticity being 20% higher than the static modulus of elasticity

The model was discretized into solids elements, including rubber bearing, with the pinned support applied in all bottom face joints. The Figure 1 shows the numerical finite element model.

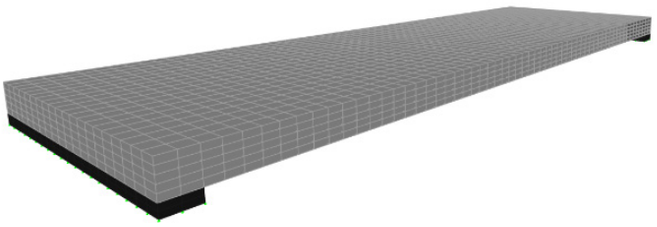

Figure 1. 3D view of the intact numerical model.

To simulate damages at different points of the structure, the intact model was replicated and the solid elements, located in the region of the hypothetical damage with 2 cm of depth, were removed. The damages were separately simulated in 8 points, distributed every 10 cm, from the middle span to the support - A. Figure 2 presents one of the damage models used in the simulations.

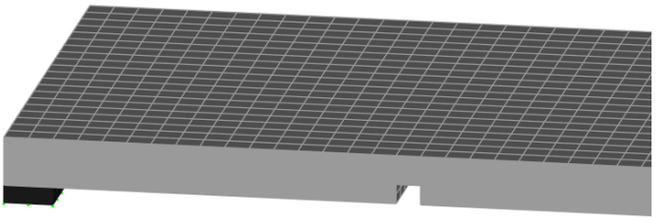

Figure 2. 3D view of the numerical model with a damage at 45 cm, from the support-A.

The dynamic tests of the models were performed by time-history impulsive load (fmax = 1 kN), applied in the middle spam. Then, the output acceleration data was extracted at 30 points along the span, with steps of 0.001 seconds, equivalent to the acquisition rate of 1000 Hz.

3.2 *Experimental model*

As discussed earlier, the experimental and numerical models were made with the same geometry and materials mechanical properties. The differences between models are: 1) experimental model was reinforced with a light weight steel wire mesh (CA-60); 2) the rubber bearings were fixed to the concrete with contact adhesive, in order to simulate a pinned support.
The dynamic tests were divide in two steps: 1 -vibration test of intact model, to create a vibration baseline; 2 – vibration test of the damage model. To collect the acceleration data was monitored 24 points. The monitoring was performed in three stages, each with eight sensors positioned vertically, distributed along the span (Figure 3). The Figure 4 shows the experimental model used with the set of acceleration transducers.

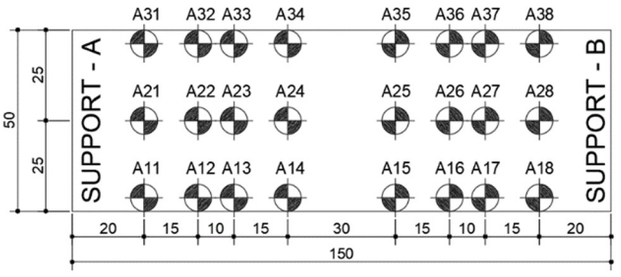

Figure 3. Positioning of the acceleration transducers.

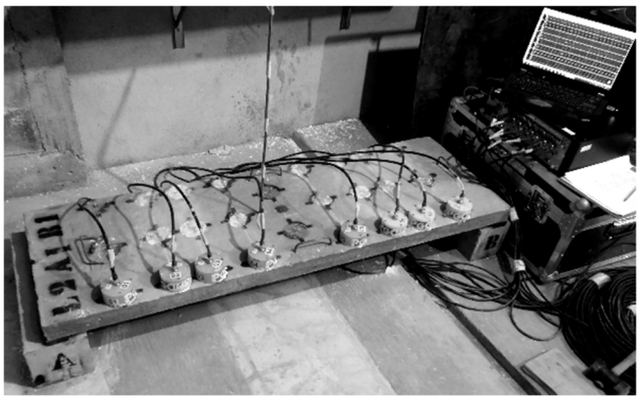

Figure 4. Experimental model.

Acceleration transducers capacitive type model 2210-002 Silicon Designs, Inc. conducted the dynamic monitoring. This instrument operates in a frequency range from zero to 300 Hz and has a sensitivity of 2000 mV/g. The range of the transducer for measuring acceleration varies from -19.6 m/s to 19.6 m/s².
Lynx Technology model ADS2002 system with AI2164 expansion module captured the data. This acquisition system has a power between 5 and 15 VDC, signal conditioning, A/D converter of 16 bits with a 12.5 μs / channel conversion time. The sensor data were recorded simultaneously using laptop with AqDados 7 software from Lynx Technology Company.
The vibration of the structure was performed by the free fall of a rubber ball in the middle of model, released from rest at a height 65.0 cm (Figure 5). The impact of the ball induces vibrations in the structure capable of mobilizing its main natural frequencies. The Figure 6 shows an example of induced vibration captured by the acceleration transducer.

Figure 5. Rubber ball falling in the middle of model.

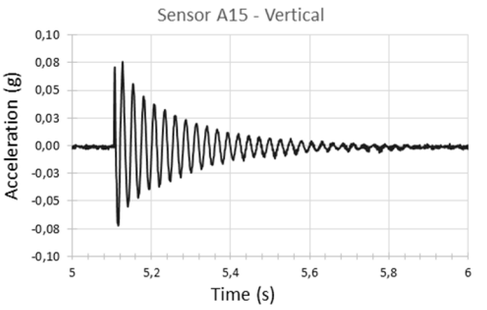

Figure 6. Acceleration captured by the sensor during the impact of the rubber ball.

After the vibration tests in the intact model, a transversal cut of approximately 2 cm depth (Figure 7) was performed to simulate structural damage and the vibration test was taken again. The Figure 8 show a close of the damage made with a diamond cutting disc.

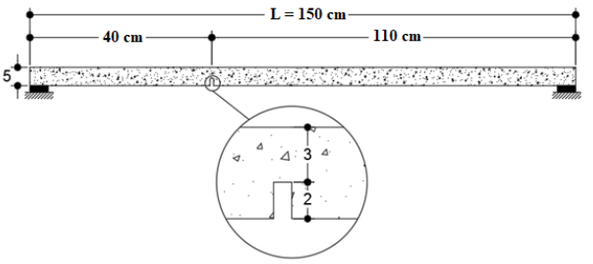

Figure 7. Position of the transversal cut on the experimental damage model.

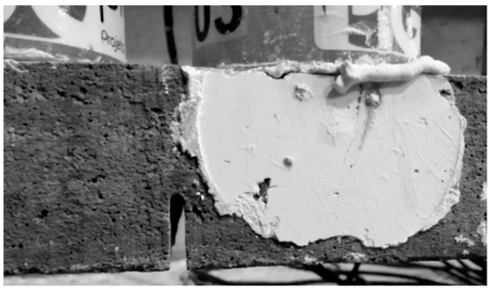

Figure 8. Transversal cut made with diamond cutting disc.

4 RESULTS

The results of the numerical analysis, with the determination and application of the empirical formula for the localization of damages, and the results of the application of the method to locate damages in the experimental model, will be presented in this section.

4.1 *Numerical model results*

The determination of a method that allow to find a single damage, at any point along the span of a simply support structure, was reached after several attempts. Among the hypothesis raised, the one that presented the most relevant results was the acceleration summation difference between intact and damage models.

This method consists in the difference of the acceleration amplitudes, obtained from the dynamic response of the structures for a determined excitation.
In order to perform the comparison between the intact and the damaged model, the absolute sum of the accelerations was used, in a determined time interval, starting the sum from the first peak of the impulse signal.
This allowed the accumulation of all acceleration data over time in a parameter, representative of the acceleration changes of each model. Figure 9 shows the behavior of this parameter along the span, for the acceleration data of the intact and damage models.

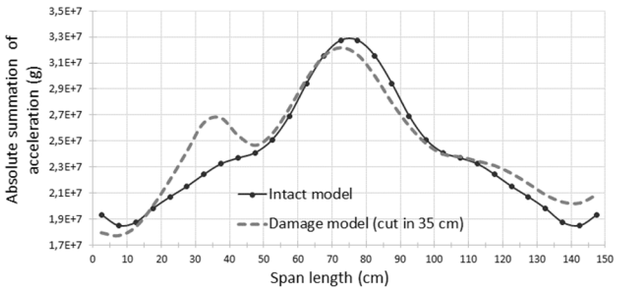

Figure 9. Absolute summation of acceleration (intact model x damage model).

In order to improve the graphical representation of the location of the damage, the acceleration summation difference was squared, making positive all values in the graph scale and increasing the amplitude of the damage indicator. As result, the following empirical formula was found:

$$\boldsymbol{ASD}_{(j)} = \left(\sum_{t_i}^{t_f} \left|\boldsymbol{a}_{j-int}\right| - \sum_{t_i}^{t_f} \left|\boldsymbol{a}_{j-dan}\right| \right)^2 \qquad (1)$$

Were:

$\boldsymbol{ASD}_{(j)}$ – squared of the Acceleration Summation Difference in the j-th point;

$\left|\boldsymbol{a}_{j-int}\right|$ – absolute acceleration values from the intact model in the j- th point;

$\left|\boldsymbol{a}_{j-dan}\right|$ – absolute acceleration values from the damage model in the j- th point;

$\boldsymbol{t_i}$ – initial time, considered from the peak of acceleration;

$\boldsymbol{t_f}$ – final time with the same interval in all analyzes, in this case $\boldsymbol{\Delta t} = 0{,}3\ seconds$.

Then, the ASD method was applied to the numerical models with damage, to evaluate the performance of the method in locating damages along the span.
The Figure 10 shows the results of the application of the ASD method in locating damage into numeric models with a single damage. It is observed that the amplitude of the peak that indicates the position of the damage, for damages with the same intensity, varies along the span. Figure 11 shows the amplitude variation along the span.

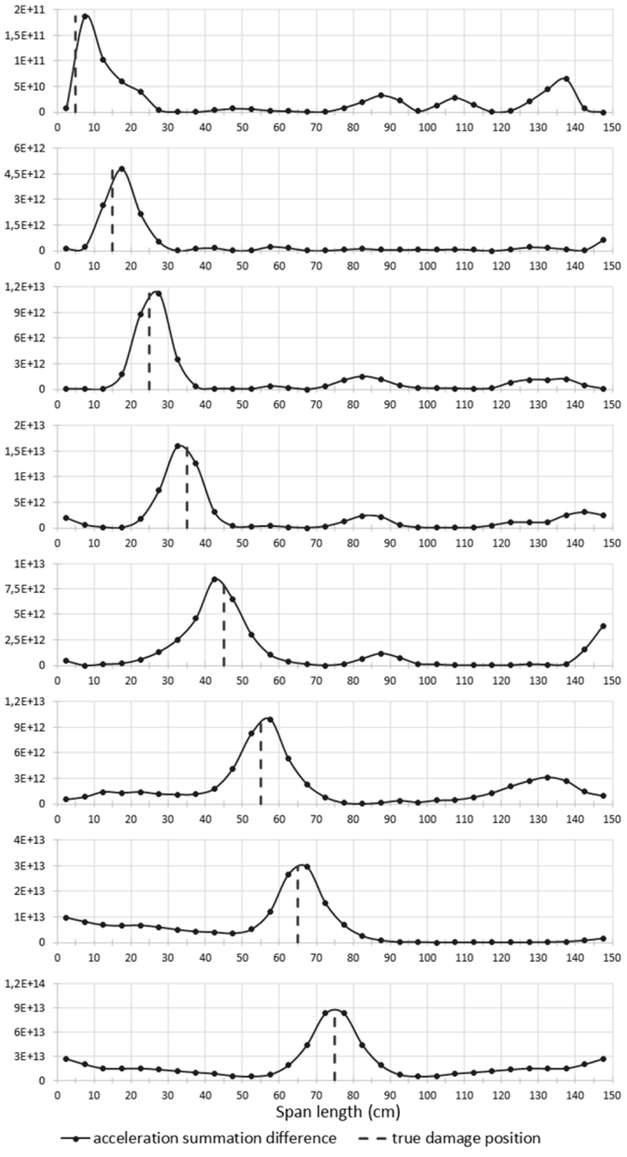

Figure 10. Identification of a single damage with ASD method.

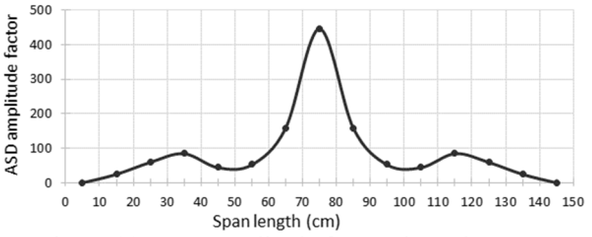

Figure 11. ASD amplitude factor along the span.

Despite the variation of the response along the span, it can be said that the ASD method was able to identify a single damage at any point in the span of a simply supported numerical model.

4.2 *Results of the experimental model*

To evaluate the ability of the ASD method to locate damages in real structures, the empirical formula was applied to the results of the experimental models. Figure 12 shows the results of the application of the ASD method in the location of damage at experimental

models with only one damage (damage at 40 cm of support A).

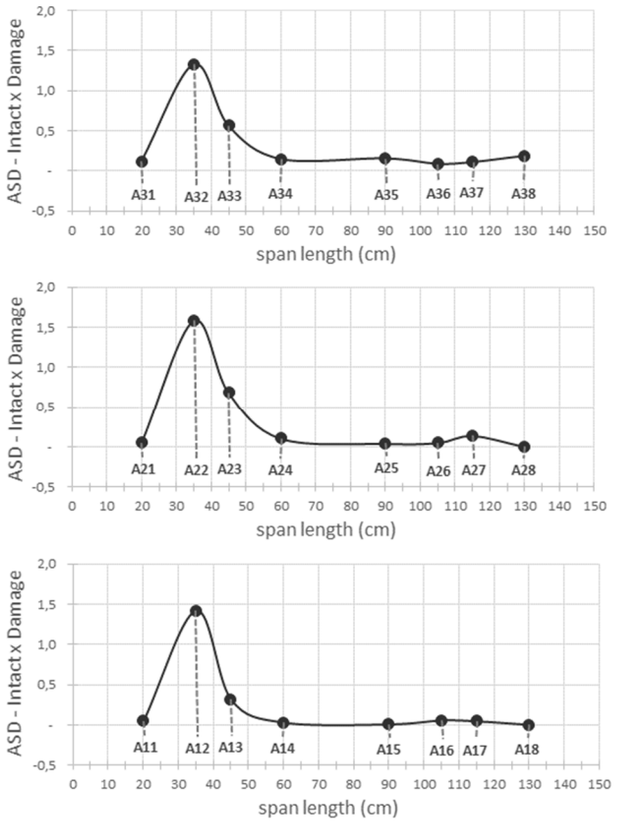

Figure 12. Application of ASD method on experimental model.

It is observed that the probable location of damage, obtained by the ASD method, is at 35 cm from the support-A, but the true position is at 40 cm. This occurs because the damage location, obtained with ASD method, is related to the position of the sensors, indicating that the damage is close to the sensors A12, A22 and A32. In order to synthesize the results found in Figure 12, a surface graph was elaborated for a plan view of the damage location (Figure 13).

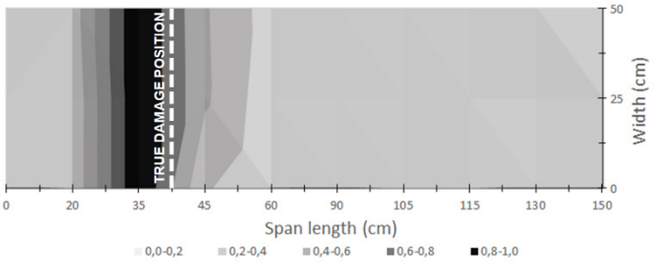

Figure 13. Surface graph of ASD results.

From the results presented, it can be said that the ASD method was able to find the approximate location of a single damage in a simply supported experimental model. It is important to highlight that the precision of the method is related to the positioning of the sensors. Therefore, the smaller the spacing between the sensors, the better the determination of the location of the damage.

5 CONCLUSION

In this work was presented the determination of an empirical formula, through simulations in numerical models, able to locate a single damage in simply supported structures. The method called Acceleration Summation Difference (ASD) was based on the difference of acceleration amplitudes between intact and damage structures.

The ASD method was applied to locate a single damage in numerical models. For this, damages were simulated at some points along the span. Despite the variation of the response along the span, it can be said that the ASD method was able to identify a single damage at any point in the span of a simply supported model.

Then, the ASD method was applied to the damage location in a reinforced concrete experimental model. The probable location of the damage was at 35 cm from the support - A, while the true location was 40 cm. It is important to highlight that the method precision is related to the position of the sensors. Therefore, it can be said that the ASD method was able to locate a single damage into experimental models.

The disadvantages observed in the ASD method were: the need for a baseline from the intact structure and the variation of the ASD along the span, for damages of the same intensity.

For future studies, it is intended to perform tests on structures with multiple damages and the adjustment of the empirical formulation, to homogenize the DSA response along the span.

ABSTRACT: This study proposes a visualization method for a cross section of RC structure in which condition of the reinforced bar (rebar) is healthily composite to the concrete or corrosively exfoliated from that. Visualization is based on Kirchhoff linearized inverse scattering method (K-LISM), and the rebar condition is emphasized by parasitic discrete wavelet transform (P-DWT) in its imaging process. An original filter included in P-DWT is developed and oriented to extract the information of rebar condition. Scattered waves from the rebar-concrete interface are obtained by UT the pitch-catch mode from the top surface of the concrete specimen. Scattered waves are filtered by P-DWT developed from the waveform measured from the exfoliated rebar; then, they are processed with K-LISM. The reconstructed images enable to differentiate between corrosively exfoliated rebar and healthy rebar.

1 INTRODUCTION

Corrosion of reinforcing bars induces cracks in concrete with its expansion process. Consequently, the cover concrete would be peeled off and the section loss would occur. Visual inspection can grasp the damage occurrence after the crack or the rusty water appears at the concrete surface. In order to carry out preventive maintenance works, corrosive damage in the early stage or healthy condition of rebar should be diagnosed with an accurate judging method before the crack appears at the surface.

When a rebar has corrosive damage, the condition of steel-concrete interface is different from that of healthy one. In addition, the interface may exfoliate if the corrosion progresses. In this study, we focus on the difference in acoustic impedance at the interface and consider a method to visually grasp the state of the steel-concrete interface by UT.

In recent years, great research results have been reported on a method of applying linearized inverse scattering methods (LISM) to the data of UT and detailed imaging of the defect shape. Application LISM for using concrete specimens have also been reported; therefore, the LISM is widely accepted as an effective processing method for visualizing defects in concrete medium.

This study focuses on the LISM based on Kirchhoff approximation, and attempt to visualize the state of rebar boundary in concrete. Kirchhoff LISM is known as a better method to visualize the interface of the medium compared with Born LISM.

Also Parasitic Discrete Wavelet Transform (P-DWT) is applied to filter the scattered waves to extract the frequency characteristics oriented for the defect information. Following chapters discuss the K-LISM and then, wave processing with P-DWT, the data processing is validated by experiments of 200kHz-UT pitch catch tests.

2 LINEARIZED INVERSE SCATTERING METHOD

2.1 *Kirchhoff inversion (K-LISM)*

Now consider the cavity defect D_c exists in homogeneous isotropic two dimensional infinite elastic material (Figure 1). It is assumed that the position of the defect can be estimated roughly, incident wave is transmitted towards target point *O* from point *y* on the measurement boundary S^{far} where is far from D_c.

It is supposed that a pulse echo mode for receiving the scattered wave u^{sc} from the cavity defect D_c at the point *y*.

$$u_m^{sc}(y) = A_m(k_L,\ \hat{y})D(k_L|y|) + B_m(k_T,\ \hat{y})D(k_T|y|) \quad (1)$$

where, k_L and k_T are wave number of longitudinal(L) and transverse(T) waves, $\hat{y}$ is the unit vector pointing to the measurement point y, $D(z) =$

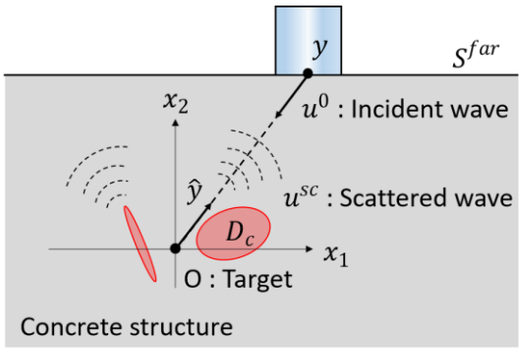

Figure 1. Configuration of inverse scattering analysis

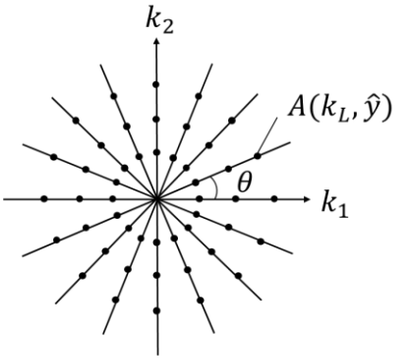

Figure 2. Two-dimensional plot of $A(k_L, \hat{y})$

$\sqrt{2/(\pi z)}e^{i(z-\pi/4)}$ is the cylindrical wave measured at the point y. A_m and B_m are the scattering amplitudes of longitudinal and transverse. These are used for reconstruction of the flaw shape. In this study, we only focus on the longitudinal scattering amplitude because of using the longitudinal wave transducer.

The boundary type for longitudinal amplitude A_m is defined by

$$A_m(k_L, \hat{y}) = \frac{i}{4\mu}\kappa^2 \hat{y}_i \hat{y}_m \int_D -\gamma(x) C_{ijkl}\{n_j(x)u_{k,l}(x) - n_j(x)u_k(x)\partial/\partial x_j\}e^{-ik_L \hat{y}\cdot x} dV \quad (2)$$

where $\gamma(x)$ is the singular function defined to represent the flaw boundary.

$$\int_D \gamma \, dV = \int_S dS \quad (3)$$

And in Equation 2, $\kappa = k_L/k_T$, n is the unit normal vector toward the base material on the flaw boundary S.

The scattering amplitude A_m and the singular function γ are nonlinear relation since this integral expression contains the unknown displacement field u.

The Kirchhoff approximation is introduced to the scattering amplitude of Equation 2 to replace the unknown displacement field u with the summation of the incident and reflected wave. After that, it is possible to reconstruct the shape and size of flaw with solving for the singular function γ.

The linearized expression of scattering amplitude A_m applied the Kirchhoff approximation is given by

$$A(k_L, \hat{y}) \cdot \hat{y} = -\frac{u^0 k_L}{2} \int_D \gamma(x) e^{-2ik_L \hat{y}\cdot x} dV \quad (4)$$

The final form of the scattering amplitude has the structure of the spatial Fourier transform in terms of x. Therefore, the singular function $\gamma(x)$ is obtained by the inverse Fourier transform as follows:

$$\gamma(x) = \frac{-1}{\pi^2} \int_0^{2\pi} \int_0^{\infty} \frac{2}{u^0 k_L} A(k_L, \hat{y}) e^{2ik_L \hat{y}\cdot x} k_L dk_L d\hat{y} \quad (5)$$

Since this inverse algorithm is based on Fourier transform, applying the fast Fourier transform (FFT) enables to process high speed.

2.2 *Fast processing method with FFT*

In the K-space (k_1, k_2) and the real image space (x_1, x_2) which are finite discrete spaces, Equation 5 is expressed by the following Equation 6.

$$\gamma(x) = \frac{1}{\pi^2} \int\int \frac{-2}{u^0 \sqrt{k_1^2 + k_2^2}} A(k_1, k_2) \, e^{2i(k_1 x_1 + k_2 x_2)} dk_1 dk_2 \quad (6)$$

The discrete data $A(k_1, k_2)$ in a finite range at the rectangular coordinate is required in order to apply 2D-FFT. The scattering amplitude data $A(k_L, \hat{y})$ obtained in the observation direction $\hat{y}$ is plotted at the discrete point of the polar coordinate $(k_L, \hat{y})$ shown in Figure 2. The grid point data $A(k_1, k_2)$ necessary for 2D-FFT is acquired by the interpolation of the scattering amplitude $A(k_L, \hat{y})$.

3 WAVEFORM PROCESSING

3.1 *Discrete wavelet transform (DWT)*

Discrete wavelet transform (DWT) is one of the frequency analysis effective for signals having nonlinearity and localized in the time domain. DWT is the method of expressing a signal to each frequency band level by linearly combining with base functions (mother wavelet) consisting of scaling function and wavelet function. The scaling function has characteristic of a low-pass filter and the wavelet function has characteristic of a high-pass one. As shown in Figure

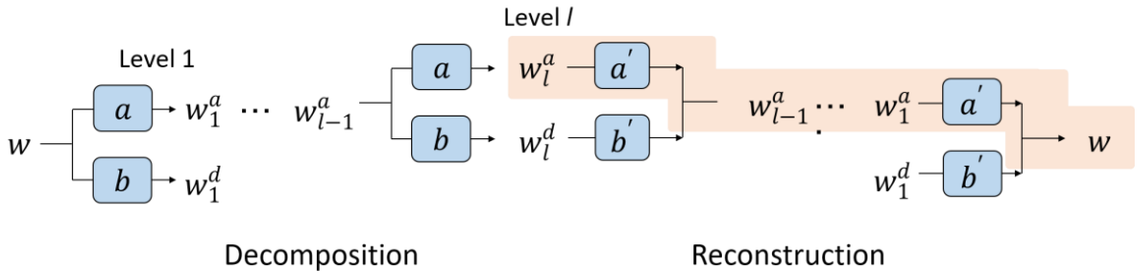

Figure 3. Calculation flow of DWT

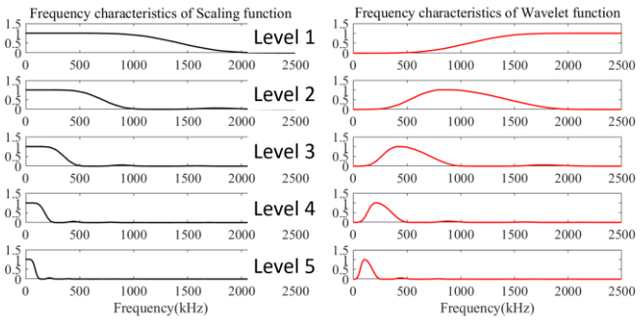

Figure 4. Frequency characteristics of 'Daubechies 5'

3, the signal is decomposed and reconstructed into low frequency components (Approximation) and high frequency components (Detail) for each frequency band level. In Figure 3, "w" is the target signal, a and b are decomposition sequence corresponding to scaling function and wavelet function, and a', b' are reconstruction sequence. As an example, Figure 4 illustrates the frequency filter characteristics of the scaling function and wavelet function of mother wavelet 'Daubechies 5' for each frequency band level up to level 5.

It has been reported that low frequency components greatly contribute to the imaging by LISM. Therefore, the signals of the approximation are used for the input data of inverse scattering method.

The following two-scale relationship is held for the scaling function $\phi(x)$ of the mother wavelet used for DWT shown in Figure 3.

$$\phi(x) = \sum_{k \in Z} p_k \phi(2x - k) \tag{7}$$

In addition, the following relationship establishes between wavelet function and scaling function.

$$\psi(x) = \sum_{k \in Z} q_k \phi(2x - k) \tag{8}$$

p_k is two-scale sequence, and the following relationship consists between the sequence p_k and q_k.

$$q_n = (-1)^{1-n} p_{1-n} \tag{9}$$

p_k determines the shape of the mother wavelet, and several famous ones which have been developed by researchers.

p_k has a characteristic of low-pass filter, and q_k has a characteristic of high-pass filter.

The decomposition sequence a_k, b_k required for calculation of DWT shown in Figure 3 is given by

$$a_k = \frac{1}{\sqrt{2}} p_{-k} \tag{10}$$

$$b_k = \frac{1}{\sqrt{2}} q_{-k} \tag{11}$$

The decomposition calculation of the target signal by DWT is repeated until the target level by following Equations 12 and 13.

$$w^a_{l,n} = \sum_{k \in Z} a_{2n-k} \, w^a_{l-1,k} \tag{12}$$

$$w^d_{l,n} = \sum_{k \in Z} b_{2n-k} \, w^a_{l-1,k} \tag{13}$$

w^a_l and w^d_l are scaling and wavelet coefficients obtained at level l.

The reconstruction calculation is performed recursively by the following Equation 14.

$$w^a_{l-1,n} = \sum_{k \in Z} a'_{n-2k} \, w^a_{l,k} + \sum_{k \in Z} b'_{n-2k} \, w^d_{l,k} \tag{14}$$

where, the following relationship holds between the reconstruction sequence a'_k and b'_k and the decomposition sequence.

$$a'_k = a_{-k} \tag{15}$$

$$b'_k = b_{-k} \tag{16}$$

Approximation data are calculated by reconstruction using only the scaling coefficients as shown in the colored flow in Figure 3.

3.2 *Parasitic Discrete Wavelet Transform (P-DWT)*

Parasitic discrete wavelet transform is a method to detect the target signal by adding an original filter in the frequency domain created by decomposing the

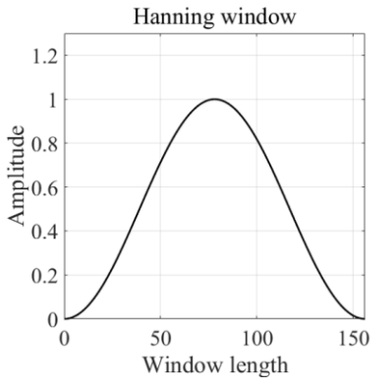

Figure 5. Hannig window

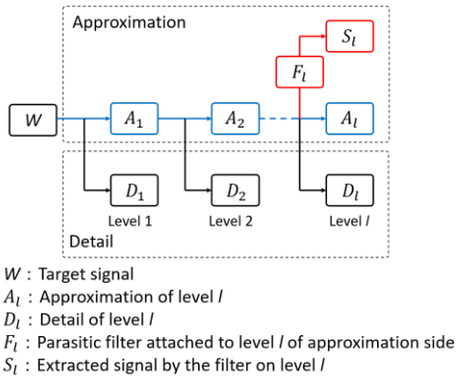

Figure 6. Calculation flow of P-DWT

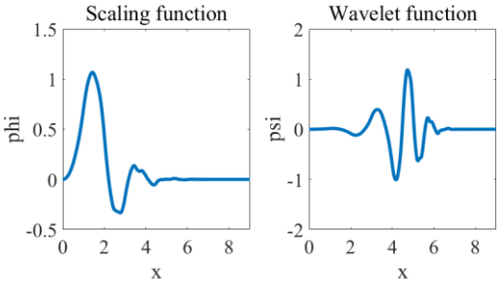

Figure 7. Daubechies 5

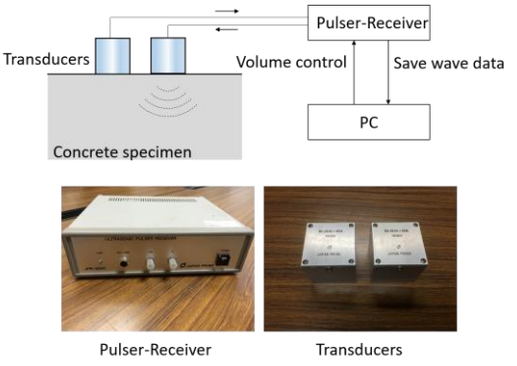

Figure 8. Measurement equipment of UT

waveform with real signal mother wavelet (RMW). The important point is that the waveform used for the filter is obtained from the similar shaped defect to the target one. Since the conventional DWT and FFT are used for calculation, high-speed processing is possible.

3.2.1 *Constructing RMW*

The design method of real type RMW ψ^R is as follows:

1) The window function is applied to the base wave to let the wave value zero at both ends. In this study, Hanning window (Fig. 5) is adopted because it has better resolution on time domain and frequency one.
2) Real type RMW ψ^R is constructed by performing normalization to set the norm to 1. The normalization formula is expressed as

$$\|\psi^R\| = \left[\int_{-\infty}^{\infty} \psi^R(t)^2 dt\right]^{\frac{1}{2}} = 1. \quad (17)$$

3.2.2 *P-DWT*

The mother wavelet used for DWT needs to satisfy the orthogonality condition between $\psi(x-k)$ and $\psi(x-l)$ $(k \neq l\ k, l \in z)$, however it is actually impossible to impose this condition on the real signal. Therefore, RMW composed of the real signal cannot be directly used for DWT.

P-DWT, which extracts a target signal, is constricted by adding an originally developed parasitic filter in the frequency domain. The parasitic filter $F_l(f)$ contains frequency characteristics of RMW.

The procedure (Figure 6) of creating and adding the parasitic filter $F_l(f)$ of the approximation side is described as follows:

1) RMW is decomposed to the level to which the filter is added with the base mother wavelet. The obtained time domain waveform data of the approximation are transformed into frequency domain data by FFT. In this study, 'Daubechies 5' (Fig 7) is used as the base mother wavelet. The acquired frequency domain data F_l^R, F_l^I of the real and imaginary part are the approximation side of parasitic filters.
2) The target signal is decomposed with the base mother wavelet by DWT up to the level -1 at which the filter is added. The obtained time domain approximation data are transformed to frequency domain ones by FFT, and parasitic filter is applied to each of the real and imaginary part respectively.
3) The filtered frequency domain data are converted to time domain ones by inverse Fourier transform.

4 PRE-EXPERIMENT

We conducted a pre-experiment for applying K-LISM and P-DWT to check the performance of the proposed process.

4.1 *Specimens and experiment*

The experiment is conducted with the equipment configuration shown in Figure 8. The transducers are the broadband type, the center frequency of which is 200kHz. Voltage control is carried out using the pulser-receiver, and obtained data are saved in a computer through the same device. The incident wave (Fig 9) used for LISM is recorded by the digital oscilloscope connected the pulser-receiver.

The outline of the specimen used in the pre-experiment is illustrated in Figures 10-1. In order to simulate the rectangular cavity, Styrofoam cut into 7mm ×60mm and 40mm×60mm is placed at the center of each specimen. The maximum size of coarse aggregate is 13mm in the concrete. As shown in Figure 10-2, the wave data are obtained from all directions from the specimen periphery at 10 degrees interval with a pair of transducers fixed at the 30 degrees angle.

Prior to the experiment, the wave velocity in the concrete is experimentally obtained using the specimen A. As shown in Figure 11, the incident wave is transmitted to the long side of the slit or cavity, and wave velocity is calculated from the measured time of the acquired reflected wave and the propagation distance. The velocity was 3600m/s.

4.2 *Applying K-LISM*

In the LISM, it is supposed that the cavity is located in the infinite elastic material. Waveforms at the range suspected of existence of a cavity are used. Therefore, we need to predict that there is a defect in the time domain occurring a large response on the A-scan, and extract the target time range; then, use it for inversion. Specifically, as shown in Figure 12, waveforms of 33.2*μsec* to 83.2*μsec* were extracted for the

both specimens. Frequency data less than 320kHz was used for analysis.

The processing result of K-LISM without P-DWT is shown in Figure 13. The rough shape could be reconstructed, however defect shape was blurred compared to the noise.

4.3 *Image sharping with P-DWT*

We attempted to sharpen the defect shape image by applying the K-LISM with parasitic filter.

As shown in Figure 14, RMW is created from the extracted waveform from the defect of each specimen. Same as the prior case, waveforms of 33.2μsec to 83.2μsec were extracted.

Level 3 parasitic filter created from each RMW is shown in Figure 15. For comparison, the frequency characteristic db5(f) of Daubechies 5 corresponding to level 3 is also shown.

It is possible to extract the feature of frequency component for the target defect. Two reasons support it. First, the frequency range of db5(f) and the created parasitic filter $F_l(f)$ substantially agree with each other. Second, a dominant frequency spectrum becomes more prominent while frequency characteristics of 'Daubechies5' remain.

Figure 16 shows the result of sharpening by P-DWT. As a result, the flaw image became more clearly sharpened.

5 EXPERIMENT FOR EXFAOLIATED REBAR

5.1 *Specimen and experiment*

The specimen outline and the measurement method are shown in Figure 17. The specimen is cuboid made of the concrete (Tab. 1) the dimensions of which are W225 × D325 × H196. Concrete cover

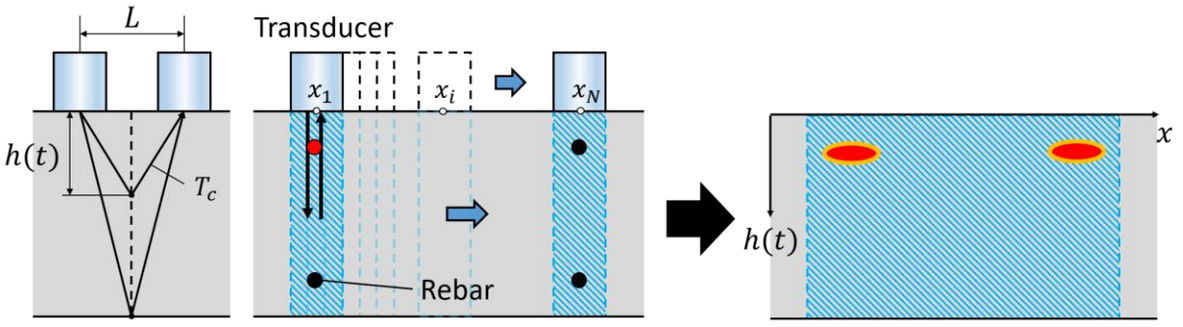

Figure 18. B-scan

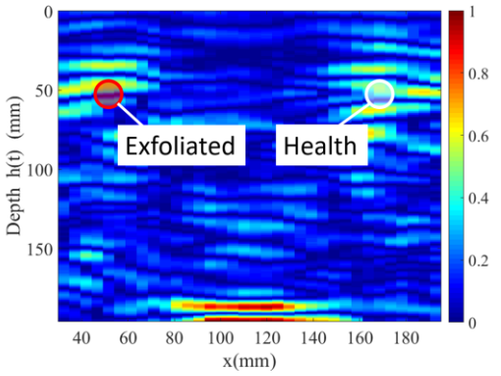

Figure 19. Result of B-scan

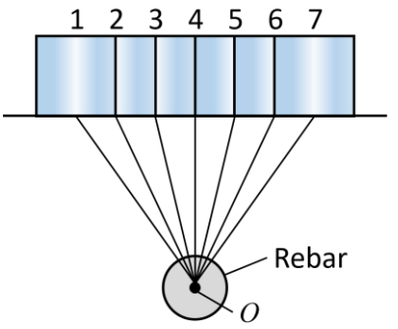

Figure 20. Configuration of target point *O*

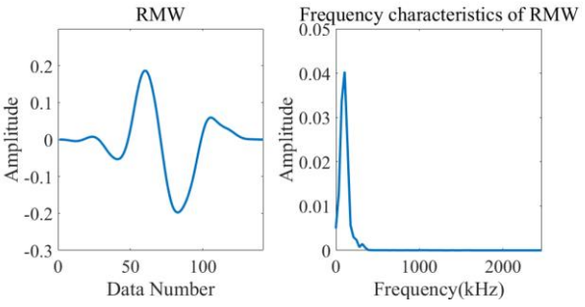

Figure 21. RMW of exfoliated rebar

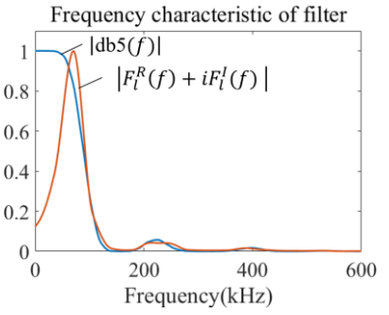

Figure 22. Frequency characteristics of parasitic filter

thickness from the rebar is 45mm, and the exfoliated state of the rebar is made by putting a wrapping film.

The experiment is conducted with the same equipment configuration of the pre-experiment. As shown in Figure 17, the wave data acquisition is performed every 5mm in the x direction by the pitch-catch mode from the top surface of the specimen. The distance between both transducers is fixed at 80mm.

For applying K-LISM, it is assumed that the approximate position of the target can be estimated. We applied K-LISM after grasping the rough position of the rebar by B-scan.

5.2 *Imaging of rebar inside the concrete*

5.2.1 *Grasping the position of rebar with B-scan*

B-scan is a technique to visualize the target cross-section by arranging the results of A-scan obtained by the experiment for each measurement position as shown in Figure 18.

Figure 19 shows the result of B-scan with the wave data acquired by experiment. The horizontal axis is the x direction shown in Figure 17, the vertical axis is depth direction $h(t)$.

As a result, it was possible to grasp the rough position of the rebar, however the shape and condition was unclear.

5.2.2 *Applying K-LISM and P-DWT*

As shown in Figure 20, the waveforms obtained at 7 points above the rebar are used for K-LISM. The center of rebar is set as transmission target point O, and the waveforms are extracted from the target point O. Frequency data less than 315kHz was used for analysis.

The measured wave data just above the exfoliated rebar is used for parasitic filter. The waveform of 20mm before and after the center point of the rebar is extracted from the measured wave data based on wave velocity. The time range used hear was 22μsec

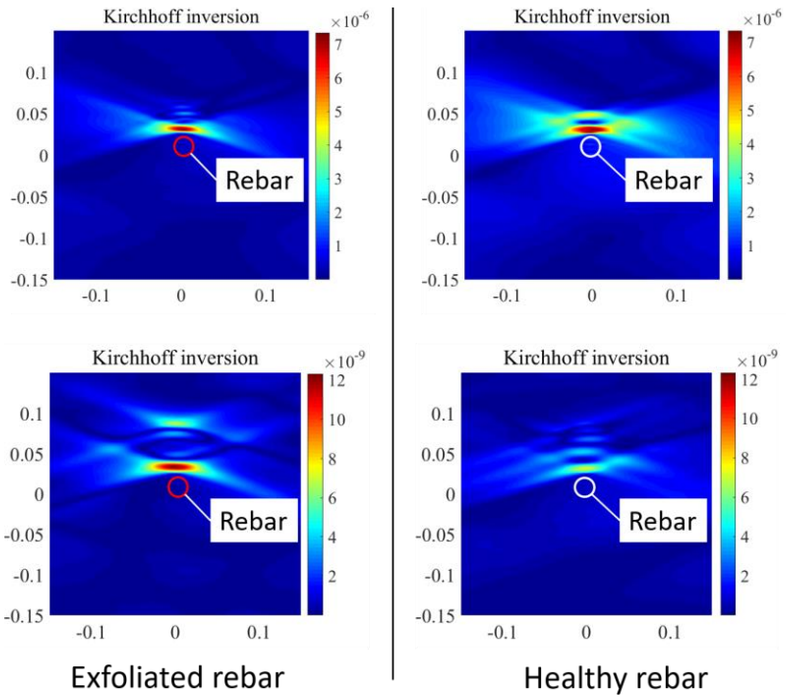

Figure 23. Results of K-LISM

set to 50.2μsec. The RMW constructed from this waveform is shown in Figure 21.

Parasitic filter is added in level 5. As shown in Figure 22, the frequency range of db5(f) and the created parasitic filter $F_l(f)$ substantially agree with each other.

The upper part of figure 23 shows the result of applying K-LISM without P-DWT. In this case, it could not be distinguished whether the rebar is health or exfoliated. The lower part of figure 23 illustrates the result of applying K-LISM with P-WDT. This result, in contrast, showed clear between exfoliated and healthy part of one surface of the rebar.

6 CONCLUSIONS

In this paper, image-based evaluation in terms of the rebar inside the concrete with a combination of wave processing by parasitic wavelet transform (P-DWT) and Kirchhoff inverse scattering method (K-LISM) was discussed.

The conclusions are summarized as follows:

1) P-DWT with the approximation side parasitic filter based on the waveform from defect enables to sharpen the image.
2) It is possible to differentiate between exfoliated and health part of the rebar by K-LISM with the parasitic filter created from the waveform obtained from the exfoliated rebar.

Fragility Curves for concrete girder bridges under flood hazard.

F. Kalendher, S. Setunge, D. Robert, H. Mohaseni

RMIT University, Melbourne, Australia

ABSTRACT: Fragility curves are developed for the reinforced concrete girder bridges under flood hazard in Lockyer Valley Region in Queensland, Australia. A failed bridge structure during 2011 severe flood event has been case studied in this paper. Uncertain nature of flood intensity for a given catchment area that causes random flood induced forces to the bridge structure and the variability of its geometry and concrete material strength are all taken into consideration in deriving these fragility curves. The fragility curves show that the probability of damage on bridges is much higher when it is subjected to urban flooding associated with log impact loading than that of being under a rural flooding. The results verify the AS5100 code provision for flood loading on to the bridges.

1 INTRODUCTION

Every year in Australia, floods cause millions of dollars damage to buildings and critical infrastructure, such as roads and railways as well as to agricultural land and crops. They also disrupt business and can affect the health of communities. Between 1967 and 2005, the average direct annual cost of flooding has been estimated at A$377 million(Department of Infrastructure and Regional Developmemnt, 2008)

Bridge collapse has tremendous consequences in every nation's transportation system. The recent flood events in Queensland, Australia between April 2010 and January 2013 had adverse effects on the bridge network of Queensland. Queensland state controlled road network included 3337km of roads and 6500 bridges and culverts (IBISWORLD, 2011)

It's reported in the recent literature that due to climate change, frequency of flood events has increased as well as they have become more intense. Queensland local governments are planning for with 5% increase in rainfall intensity per degree of global warming as the climate change factor to be incorporated in the flood studies (QueenslandGovernment, 2010). Climate change will not have a huge impact on the infrastructure as the effect due to short-term impact loads are built into the safety factors in the design process (Kong et al., 2013). However, extreme natural disasters will have an impact on the vulnerability as the infrastructure may not be designed for such a long-term intense event.

2 SIGNIFICANCE

Analysis of the performance of bridges under 2011/2013 flood in Lockyer Valley Region, Queensland, covered in (Farook et al., 2014) indicates that the bridge deck is the most commonly affected component followed by the bridge approach, pier/abutment scouring, cracks in the abutment wing walls and misalignment of abutment headstock connections to piles. Reinforced or pre-stressed concrete girder bridges are a common design configuration used in Australia. During the Lockyer Valley floods in 2013, vulnerability of girder bridges was observed by significant damage to these structures.

Bridge structures have a major impact on resilience of road infrastructure and the damage to bridges could increase the vulnerability of the community served by the road infrastructure significantly. A systematic method of quantifying vulnerability of bridge structures under varying flood loading is currently a significant gap in knowledge.

Using the concrete girder bridges as case studies, the methodology to derive structural vulnerability models for bridge structures and determine vulnerable structures in the road network have been proposed.

3 FRAGILITY ANALYSIS OF BRIDGES

Defined as the relationship between hazard intensity and the probability that a bridge is damaged exceeding a certain level, bridge fragility curves have been widely used to express the structural vulnerability of a bridge subject to a variety of natural hazards. However, previous studies have mainly focused on the fragility curve derivation for bridges under earthquakes. For example, Basoz et al. (1999) and Shinozuka et al. (2000) developed empirical fragility curves using a data set of bridge damages resulting from the 1994 Northridge earthquake and the 1995 Kobe

earthquake, respectively. Alternatively, Karim and Yamazaki (2001) generated analytical fragility curves of the highway bridge piers utilizing a numerical simulation based on the 1995 Kobe earthquake data.

Decò and Frangopol (2011) generated the fragility curves of highway bridges under multiple hazards including earthquake, scour, traffic load, and environmental attack. With a similar approach, Dong et al. (2013) derived seismic fragility curves of bridges considering the effects of scour and corrosion. In addition, Dawson et al. (2005) assessed the flood risk vulnerability of a fluvial dike system, and Witzany and Cejka (2007) performed a numerical analysis of flood fragility of a stone vault bridge structure. However, these studies mainly focused on the derivation of seismic fragility curves, while flood-related risk factors such as scour and corrosion were considered as an alternative cause of bridge failure in addition to earthquakes. As such, there have been few studies on the flood fragility estimation of bridges. However, various flood-related factors such as water stream pressure, debris accumulation, corrosion, and scour are reported as the most common causes of bridge failure (Wardhana and Hadipriono, 2003); (Cook, 2014). In reality, a flood often generates a rapid water flow with accumulated debris, which yields a combined loading impact on bridges via the service loads and may bring about structural damage or collapse. Furthermore, if the structural integrity of a bridge is significantly degraded by the corrosion of steel reinforcements in addition to the scour-induced removal of soil resistances, the failure risk of bridges under flood events increases and their failure modes can become more complex.

4 ANALYSIS OF CASE STUDY.

The case study approach adopted in this research examined the actual bridge inspection report compiled in the aftermath of 2011/2013 severe flooding incident in Queensland[(Pritchard, 2013);(QueenslandGovernment, 2012)] to understand the major failure mechanisms of the bridges. The study on this report indicated that the damage to bridge structures are complex and requires a detailed knowledge of underlying design principles, current classification of roads/bridges as well as construction methods adopted during different periods of design and construction. It was found that the impact load of the huge rocks, ship containers, vehicles and the other unexpected debris that were carried along the flood water with high velocity was the primary cause of damage to bridge superstructure, abutments, wing walls and piers.

Lockyer Valley Region of Queensland has been selected as a case study for this research. 2011/2013 floods had severely affected road and bridge infrastructure which enormously impacted on the community in the Lockyer Valley region. This case study aimed at identifying all possible components of bridges contributing to failure such as bridge superstructure with girders, bridge approaches, bridge substructure with piers, waterway etc. It further analyzed the failure criteria/ mode of failure of different types of bridges.

This paper investigated the impact of a floating container on Kapernicks Bridge in the case study area together with other flood induced forces.

Kapernicks Bridge is a three span, two lanes concrete Girder bridge located on Flagstone Creek Road in the case study area. The superstructure consists of a steel Bridge Barrier with cast-in-situ Kerbs on the left hand side and right hand side and a cast-in-situ concrete wearing surface topping four precast concrete Girders that are supported by elastomeric bearings at the abutments and piers. The substructure consists of two cast-in-situ abutments and two piers with a cast-in-situ headstock and two cast-in-situ piles. Abutment one is deemed to be the southern end (closest to Carpendale Road). The Approaches are bitumen sealed. There is room for vehicular parking on the right hand side of approach two. Upstream is on the right hand side of the structure. Figure 1 depicts the details of the Kapernicks Bridge (section view).

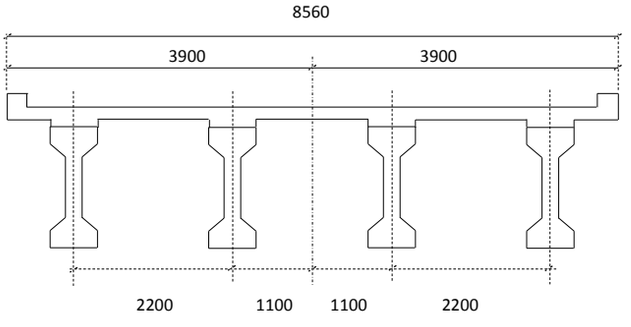

Figure 1: Section view of Kapernicks Bridge

5 FORCES ON BRIDGE RESULTING FROM FLOOD EVENT

AS 5100 Bridge Design code (Section 15 of AS 5100.2-2004) gives relevant equations to calculate the flood induced forces on bridge resulting from

water flow, debris and log impact (Australian Standard, 2004)

5.1 Forces on superstructure due to water flow

When the bridge superstructure is partially or fully inundated in a flood, it is subjected to a horizontal drag force (F_d) normal to its longitudinal axis and a vertical lift force (F_l) as given in AS 5100.

$$F_d(\text{kN}) = 0.5 C_d V^2 A_s$$

Equation (1)

Where C_d = drag coefficient read from the chart given in the code
V = mean velocity of water flow (flood) (m/s).
A_s = wetted area of the superstructure, including any railings or parapets, projected on a plane normal to the water flow (m^2).

$$F_l(kN) = 0.5 C_l V^2 A_l$$

Equation (2)

Where C_l = lift coefficient read from the chart given in the code
V = mean velocity of water flow (flood) (m/s)
A_l = Plan deck area of the superstructure (m^2).

5.2 Forces due to debris

Debris load acting on superstructures is given by the code as,

$$F_{deb}(kN) = 0.5 C_d V^2 A_{deb}$$

Equation (3)

Where C_d = drag coefficient read from the chart given in the code
V = mean velocity of water flow (flood) (m/s)
A_{deb} = Projected area of the debris mat described in the code (m^2).

5.3 Forces due to log impact

Where floating logs are a possible hazard, the drag forces exerted by such logs directly hitting bridge girder (superstructure) superstructure shall be calculated on the assumptions that a log with a minimum mass of 2t will be stopped in a distance of 75mm for such solid girder (superstructure). However for the bridge in question, this mass was taken equivalent to a mass of a shipping container to simulate the actual condition.

F(log) shall thus be given by the following equation

$$F_{log}(N) = \frac{mV^2}{2d}$$

Equation (4)

Where m= mass of a shipping container (kg)

d= stopping distance (m) and V= flood velocity (m/s)

6 DERIVING DAMAGE INDICES

In this research, the structural damage to the bridge girder is measured using Damage Index (DI) that is defined as the ratio between the moment induced by flood loading on the bridge girder (M*) and the residual moment capacity of the bridge girder (ϕMu) as given in Equation 5.

$$DI = \frac{M^*}{\emptyset M_u}$$

Equation (5)

Damage Indices are first derived to generate vulnerability curves for the Bridges under different flood exposure conditions. The effects of flood flow, debris and the log impact on the bridge girder have been considered to derive the damage indices. The damage index can also be defined using the costs associated with retrofitting/repairing the bridge under flood.

It is noted here that the definition of failure using $\frac{M^*}{\phi M_u}$ only consider flexural failure. Shear failure can also be critical in the case of short span structures which are not considered in this study because most of the bridges reported are long span bridges.

6.1 Estimating flood induced bending moment (M*)

In order to estimate flood induced bending moment on the bridge girder, general purpose finite element software, ABAQUS was used to model the Kapernicks Bridge deck and the girders. The bridge is 65.50 m long and about 8.56 m wide and

is supported by 4 numbers of 22 m long concrete girders over the mid-span and another 8 concrete 21.75 m long girders over the end spans. The girders are supported by two abutments and two headstocks. The middle span of bridge structure was analysed. All four girders were assumed simply supported and rest on the headstock of the piers. Self-weight of the bridge, the drag and the lift force due to water flow, debris force and the log impact force were considered in the analysis. Uncertain nature of flood velocity experienced by the case study region was considered in the analysis and corresponding M^* values for those velocities were obtained through a parametric study in ABAQUS. An ABAQUS script written in Python programming language was necessary to perform the recurring tasks of calculating these M^* values. Figure 2 depicts the bridge deck model used in the analysis.

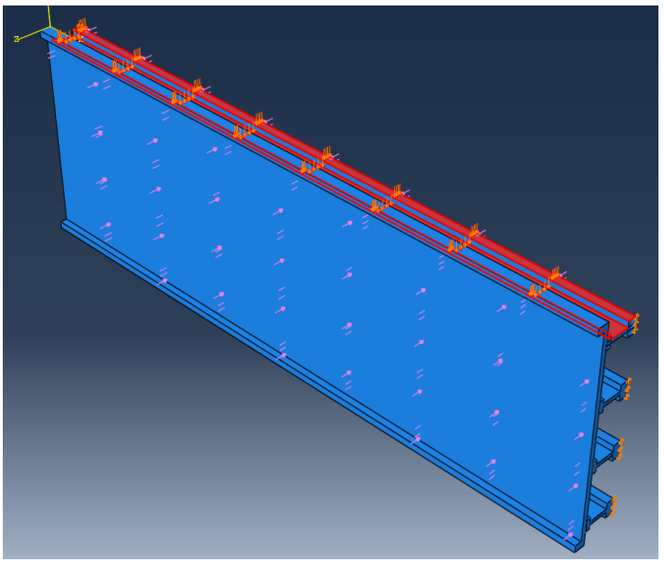

Figure 2: Model development of bridge and deck in ABAQUS

6.1.1 Analysis of actual flood data

Flood data required for this research has been sourced through water monitoring committee of Queensland Government. This web based data set (Figure 3) provided the flood discharge, flood height and the creek river profile data for all rainfall monitoring stations across the state. Figure 4 indicates the River profile of Lockyer Creek at Helidon Number 3 which is the closest monitoring station of the case study bridge in this research. The recorded data are available from as old as 1987 to date. Simple open channel flow equation (Equation 6) was used to derive the required flood velocity.

$$V = \frac{Q}{A} \qquad \text{Equation (6)}$$

Where V= Flood velocity

Q= Flood discharge

A= Creek cross sectional area at the given flood height

An Excel formula was devised for calculating cross sectional area of the river for different stream water level. Corresponding flood velocity was then calculated using stream discharge and the river cross section area.

Distributive nature of the flood velocity for the period between 1987 and 2016 was obtained using @Risk software simulation techniques. It is worth to note that Lockyer Valley Region had experienced severe rain between beginning of December 2010 and end of January 2011 and in particularly on 7, 8, 9 and 10th of January 2011. Figure 5 shows the flood velocity distribution obtained for this analysis.

6.2 Estimating residual moment capacity of bridge girder (ϕM_u)

In accordance with the Australian codes of practice for structural design, the capacity analysis methods contained in this section are based on ultimate limit-state philosophy. This ensures that a member will not become unfit for its intended use. This approach sets acceptable levels of safety against the occurrence of all possible failure situations. The nominal strength of a member is assessed based on the possible failure modes and subsequent strains and stresses in each material.

A typical beam section of the headstock is shown in Figure 1. The positive and negative flexural and shear capacities of the section were calculated in accordance with Australian standards (AS3600, 1988). The nominal steel reinforcing bars areas; nominal steel yield strength of 400 MPa for longitudinal reinforcement and 240 MPa for shear reinforcement and nominal concrete compressive strength of 20 MPa were used in the section capacity analysis. The degradation due to corrosion of the steel and creep and shrinkage of the concrete were ignored.

Moment capacity of reinforced concrete girders which is a function of girder cross section and the reinforcement configuration is influenced by several variables. The compressive strength of the concrete, the steel component area and the yield strength are the most influential. The geometry of the concrete girder is also an important factor that influences the compressive moment capacity of the bridge girder. Table 2Table 2 below shows the parameters used in the Monte Carlo simulation for generating suitable distributions of the nominal moment capacity i.e. the resistance in the Equation 7.

To capture the influences of uncertain factors on the property of the concrete material and the geometry of the bridge, the associated random variables were defined using distributions found in the literature as shown in table 2. Fundamental Beam section analysis was carried out to the bridge I- Girder section. Neutral Axis depth for the section was established when the total tensile and the compressive forces added up to zero. Moment Capacity was then calculated as shown in Equation 7 by taking moments about this neutral axis to the section. Figure 6 shows the geometry of the I Girder. Relevant random variable terms in this equation were simulated using @Risk software.

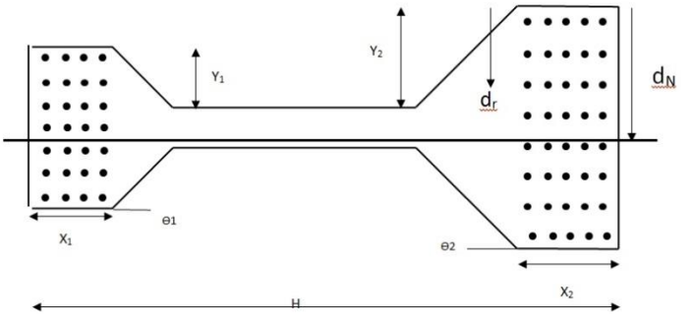

Figure 6: Geometry of the I girder

$$M_u = E_s \frac{\epsilon_c}{d_n} \sum_1^n a_r (d_n - d_r)^2 + 0.85 f_c' \left[x_1 y_1 \left(\lambda + \frac{y_1}{2} \right) + \frac{y_1^2}{2tan\theta_1} \left(\lambda + \frac{y_1}{3} \right) + x_2 y_2 \left(\lambda + \frac{y_2}{2} \right) + \frac{y_2^2}{2tan\theta_2} \left(\lambda + \right. \right.$$

$\frac{y_2}{3}\Big) + \frac{H}{2}\lambda^2\ \Big]$

Equation (7)

where

H(mm)	1372	0.015	Normal	20.58

7 GENERATION OF FRAGILITY CURVES

Failure of the bridge against flood is measured through Damage Index ($DI = \frac{M^*}{\emptyset M_u}$) that is defined as the ratio between the flood induced bending moment (M^*) on the girder and the residual moment capacity ($\emptyset M_u$). When the limiting value of the Damage is equal to greater than 1.0, the bridge is considered failed. Using @Risk software, the Damage Index value was simulated and the corresponding probability curves (the "S" curves) or fragility curves were obtained for Kapernicks Bridge considering different flood scenarios such as flood only and flood with log impacts etc. as shown in Figure 7.

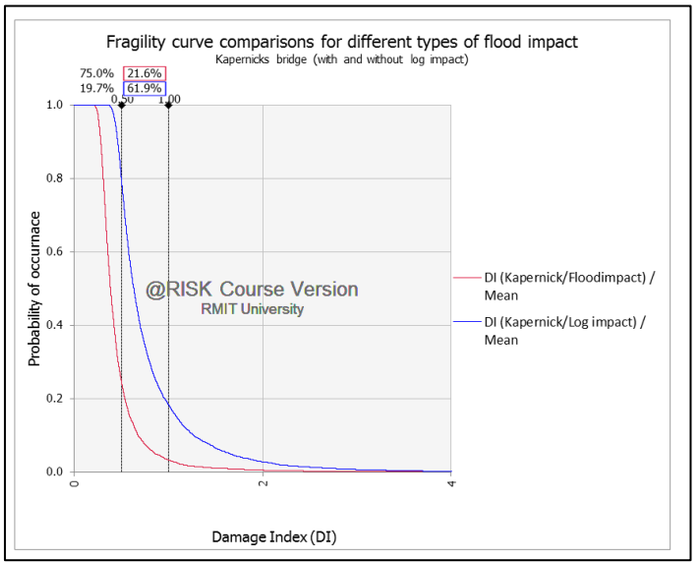

Figure 7: Fragility curve comparison for Kapernicks Bridge under flood and log impact

Table 3: Comparison of failure probability for different types of flood impact (Kapernicks Bridge)

Types of flood impact	Probability of failure (when DI=1.0)
Plain flood	3.3%
Flood with log impact	18.4%

8 CONCLUSION

In order to incorporate the uncertain nature of the flood intensity (flood velocity) and the structural capacity of the bridge structure due to deterioration, a probabilistic fragility modelling method was adopted to establish the probability of failure of the bridge structure under flood hazard.

A comprehensive method to establish relevant flood velocity values for use in this research was devised using simple open channel flow equations. The bridge examined here showed that it had the probability of failure of less than 5.0% as per the provision allowed in all the bridge design codes worldwide. However, it showed a higher probability of failure when it was under the influence of unusual debris such as containers, vehicles and leisure crafts.

ABSTRACT: In this paper, the authors conducted an experiment where a reinforced concrete beam was instrumented with a single DOFS performing four equal segments externally bonded to the bottom surface of the element. Each segment was adhered to the concrete using a different adhesive. This beam was then loaded, producing expected equal levels of tension in each of the fiber segments for a more direct comparison of the different adhesives performance. The experimental data is subsequently compared with the data provided through more conventional electrical strain gauges that were also deployed in the beam. The effect of alternating the spatial resolution and sampling acquisition is also analyzed. The results provided here will shed a clearer light on how to proceed when applying this promising sensing technique to concrete structures, mainly on what the bonding materials and resolution are concerned.

1 INTRODUCTION

All civil engineering infrastructures are subject to natural hazardous and ordinary mechanical resistance decay and deterioration through its lifetime. In the global and connected world of today, the accessible and immediate maintenance of such infrastructures is of paramount importance for the economic competitiveness of every region.

Therefore, structural health monitoring (SHM) of these civil engineering infrastructures has become an important topic of study and research in the past decades. The early and correct detection of the damage in these infrastructures derives on great economical savings, a better structural maintenance and an improved assessment of the structural safety.

Within SHM applications, the use of optical fiber sensors (OFS) has been a popular topic of research and practice in the last two decades due to the inherent advantages presented by the use of these type of sensors. When comparing with the more conventionally used electrical sensors, OFS are immune to electromagnetic interference presenting in this way less noisy measurements. These sensors perform also well under a wide range of temperature variations and are free from corrosion. Finally, OFS are generally small and lightweight, which facilitates the transport and installation of such sensors in a wide range of application scenarios. The use of these sensors has been well documented and practiced particularly through the use of Fiber Bragg Grating sensors [1].

On the other hand, the use of distributed optical fiber sensors (DOFS) in civil engineering infrastructures SHM applications is still relatively recent. These sensors provide the same advantages of the other optical fiber sensors, with the additional advantage of being capable of acquiring strain and/or temperature information for longer extensions of the monitored structural components on which they are instrumented and with very low distance between measurements [2].

In the monitoring of concrete structures, this assumes an even greater advantage since the exact location of a possible crack formation is not known beforehand and in this way, might be missed with the use of point or discrete sensors if not positioned at that particular location.

Furthermore, with the use of DOFS a larger area of the structure may be monitored with the use of up to one single sensor, which only requires one connecting cable, enabling a simpler a more economical monitoring system.

Nonetheless, a more profound research of this technology is still necessary in order to enable a more systematic and regular use of these distributed sensors in concrete monitoring applications.

2 OPTICAL BACKSCATTERED REFLECTOMETER (OBR) SYSTEM

When using DOFS technology, the optical fiber cables can be bonded to the surface of the material or embedded inside the material. When strain and temperature variations occur, these changes are transferred from the monitored material to the sensor which variates the scattered signal being reflected inside the fiber.

This scattering is at the origin of distributed optical fiber sensing and is defined by the interaction between the light and the optical medium. Three different scattering processes may occur in DOFS, which are the Raman, Brillouin and Rayleigh scattering [2].

Brillouin scattering based DOFS have been the most studied and used DOFS systems in civil engineering SHM applications due to their large-scale capability, which can reach the kilometer range. However, it presents a relatively low spatial resolution of roughly one meter, which is not appropriate for crack detection and other applications.

The optical frequency domain reflectometry (OFDR) systems which are based in the Rayleigh scattering, on the other hand, offer a spatial resolution as high as one millimeter which makes it ideal for crack detection and localization although limited to a monitoring length of 70 m.

In this way, in the present study it is used the ODiSI A model from LUNA technologies which is an optical backscattered reflectometry (OBR) system based on the Rayleigh OFDR, Figure 1.

More detailed information of this technology can be consulted in [2].

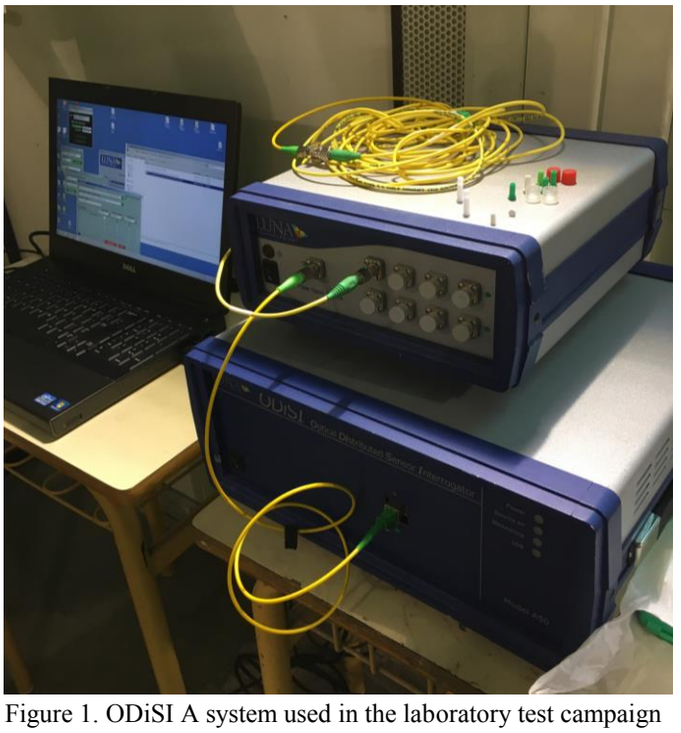

Figure 1. ODiSI A system used in the laboratory test campaign

3 DOFS ADHESIVE STUDY

Despite the significant increase in interest on the study and practice of SHM applications through the use of DOFS, an important lack of knowledge is still present regarding the choice of the best adhesive to use when mounting these sensors in reinforced concrete structures.

In order to obtain the optimal strain transfer between the sensor and the monitored material the topic of its deployment is of considerable importance. In addition to the removal of any grease or dust present in the surface of the host material and the smoothening of the surface, the decision on the adhesive to bond the optical fiber sensor to the surface has to be assessed. This is even, a more pressing issue when applying DOFS without any protective thick coating, such is the case of the deployed fiber in this research, Figure 2. The use of such fiber, is by itself, a way to reduce the influence of the sensor cladding material in the strain accuracy.

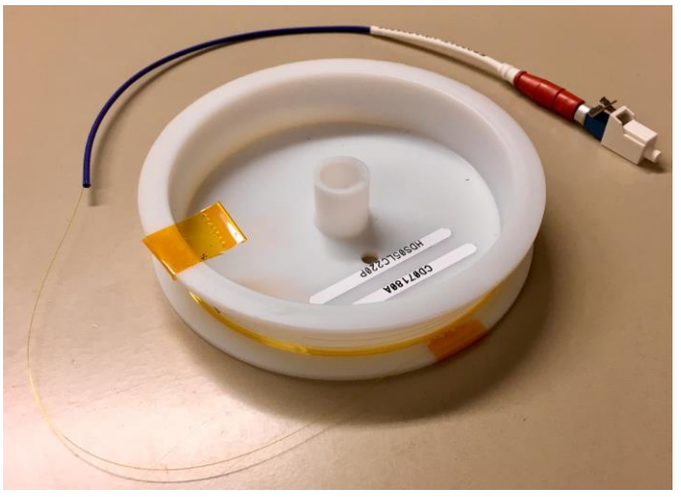

Figure 2. DOFS type deployed in this experimental campaign

Some studies have analyzed the coating influence on the strain transfer on point fiber optic sensors [3], the adhesive spread installation method [4] and the coating strain transfer impact in DOFS [5].

One study in specific [6],analyzed among many things the performance of the use of cyanoacrylate and epoxy adhesives together with both nylon and polyimide DOFS when attached to the surface of the concrete and when attached to the reinforcement of the same structural elements. The results showed a better performance of the polyimide fiber together with the cyanoacrylate adhesive when bonded to the reinforcement and the combination of nylon fiber with epoxy adhesive when bonded to the concrete.

In the present paper, a test is performed where a single 5 m polyimide DOFS is attached to the surface of a reinforced concrete beam using four different adhesives: epoxy, cyanoacrylate, polyester and neutral cure silicone, Figure 3.

Figure 3. Adhesives deployed in this experimental campaign, from left to right: Epoxy, Cyanoacrylate, Polyester, Neutral Cure Silicone

These adhesives were chosen based on the previous experience of the authors and through what was found during a literature review on this topic. Specifically the three first adhesives: epoxy, cyanoacrylate and polyester were ordered as advised by the TML strain gauges 2017 catalogue for concrete applications [7]. The used neutral cure silicone however, was a simple commercial one from Ceys brand for general construction applications including concrete. Furthermore, the silicone was used in this application as a true adhesive in opposition to what has been done in the past where it was used more as a sealant in order to provide better protection of the sensor.

4 EXPERIMENTAL TEST SETUP

As mentioned before, the main goal of this experimental campaign was to evaluate the performance of different adhesives for the bonding of DOFS to concrete elements during a three-point load test.

In this way, a 60x15x15 [cm] reinforced concrete beam, Figure 4, was produced. This element had two longitudinal ϕ12 and four ϕ6 S500 rebars.

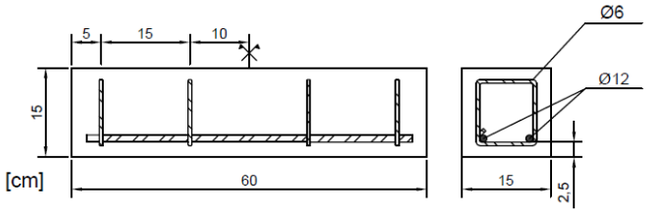

Figure 4. Tested beam definition

Consequently, a 5 m long DOFS was deployed to this concrete element in a way that performed four different equal segments on the bottom surface of the beam. During the conduction of a load test, these segments would be submitted to the same developing strains (in tension) and therefore they will be directly comparable.

Additionally, three 30 mm length strain gauges from the provider mentioned before (TML), were also sparsely bonded to the bottom surface of the concrete beam for comparison purposes with the data obtained by the DOFS, Figure 5.

Figure 5. Deployed strain gauges for comparison purposes

The deployment of the instrumented sensors on the reinforced concrete beam with the information of the adhesive used in each DOFS segment is presented in Figure 6.

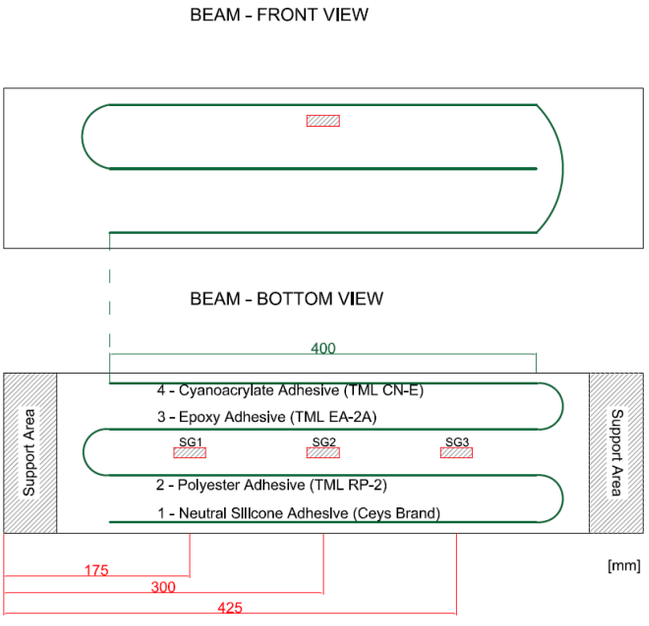

Figure 6. Plan of the reinforced concrete beam instrumented sensors

As seen from Figure 6, due to the 5 m length of the fiber, the remaining part of the DOFS was also adhered in three different segments in the front view surface of the beam. Nevertheless, the data from these segments is not analyzed here, as it is not relevant for the pursued objectives.

Hence, the setup of the three-point load test is as depicted in Figure 7 and 8.

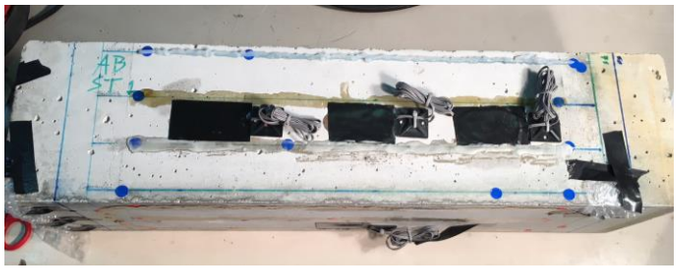

Figure 7. View of the sensors (DOFS and strain gauges) instrumented in the bottom surface of the tested beam

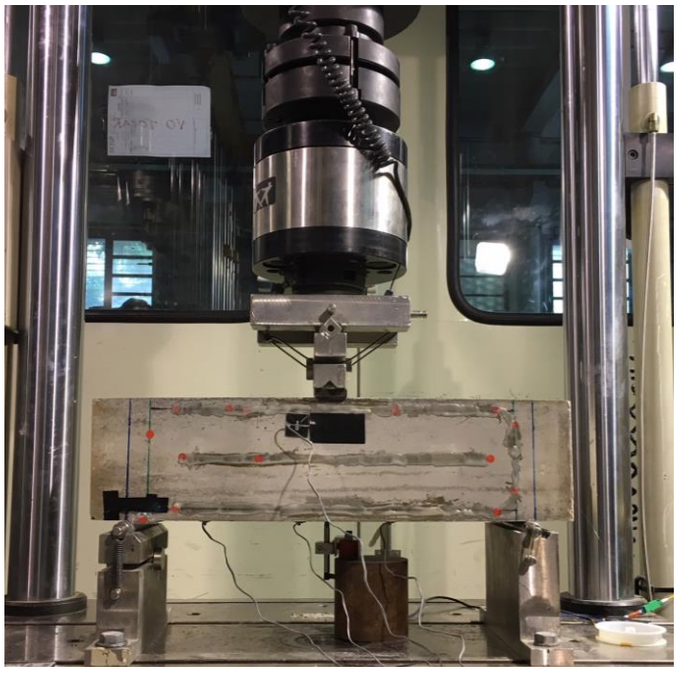

Figure 8. View of the loading arrangement

In order to obtain the material properties of the concrete of the tested specimen, different cylindrical samples were produced at the same time of the beam and tested. Consequently, the mean compressive strength, the mean tension strength and the mean Young modulus of the concrete was calculated as presented in Table 1.

Table 1. Concrete material properties

	f_{cm} [MPa]	f_{ctm} [MPa]	E [MPa]	ε_{ct} [με]
Specimen	48.027	3.944	37886.64	104.10

As an additional point of study, the spatial resolution of the DOFS on the measured results was also analyzed. Due to the heterogeneity of the concrete material and its aggregate sizes, this aspect is of interest for the application of DOFS based monitoring systems. Furthermore, it was intended also to analyze the influence the sampling acquisition frequencies of the DOFS data.

Therefore, it was decided to perform initially several load cycles with a maximum load of 11 kN (which wouldn't induce cracking in the specimen) where in each cycle, a different spatial resolution and sampling acquisition frequency were used.

Finally, a load test producing cracking and progressing up to failure of either the DOFS or the beam was conducted. The test sequence is described in Table 2. The load sequence along time is depicted in Figure 9 for test cycles 1 to 6 and Figure 10 for test cycle 7 up to failure.

Table 2. Test cycle description

Test cycle number	Inputted Spatial Resolution	Inputted Sampling Acquisition
1	1 cm	0.2 Hz
2	3 cm	0.2 Hz
3	1 mm	0.2 Hz
4	1 cm	1 Hz
5	3 cm	1 Hz
6	1 mm	1 Hz
7-rupture	1 cm	0.2 Hz

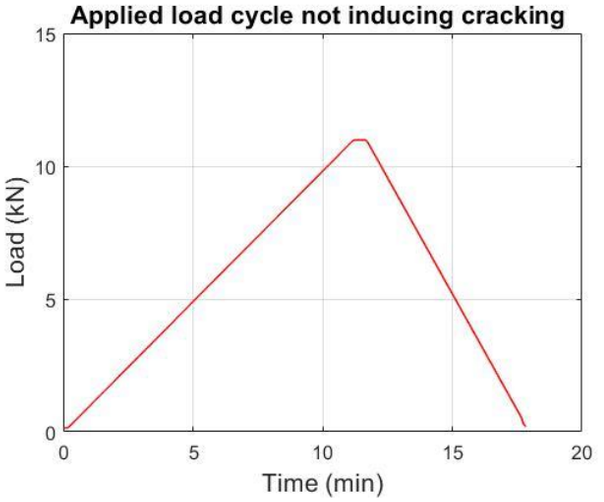

Figure 9. Load cycle applied for tests 1 to 6

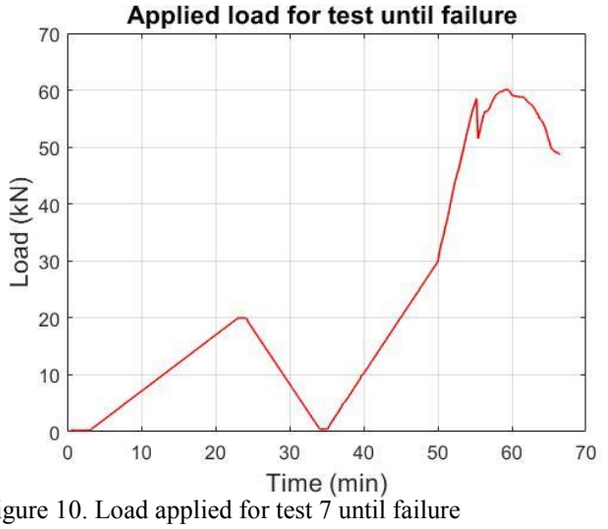

Figure 10. Load applied for test 7 until failure

5 RESULTS

Data from both the DOFS and the Strain Gauges was post processed and analyzed. In this step, it is important to mention that the *LUNA* software which post processes the optical fiber data provides the possibility of saving the measured values in the raw spectral shift form, the already converted strain and the spectral shift quality (SSQ) matrix.

It is also important to indicate that although it was intended to analyze the influence of different sampling acquisition frequencies, the test cycle numbers corresponding to these scenarios are not analyzed in this document. This is because the acquisition system was not able to obtain DOFS data at the target rate of 1 Hz.

5.1 *Comparison of spatial resolution input*

In this way, an initial comparison of the influence of the different spatial resolution parameters in the first three load cycle tests was carried out.

As mentioned in Table 2, three different spatial resolutions of the DOFS measurements were considered: 1 cm, 3 cm and 1 mm. These meant that, 520 points, 174 points and 5191 points were measured in the first, second and third load test cycle respectively.

As it is possible to see from Figure 11, the data measured with a spatial resolution of 1 mm presents a significantly high spatial variability. With the spatial resolution of 1cm, all adhesives present a noticeable variability except for the case of the neutral silicone.

Nevertheless, all segments present similar measurements as the instrumented strain gauges. Using a 3 cm spatial resolution (which is the same length of the deployed strain gauges) this spatial variability is, as expected, minimal.

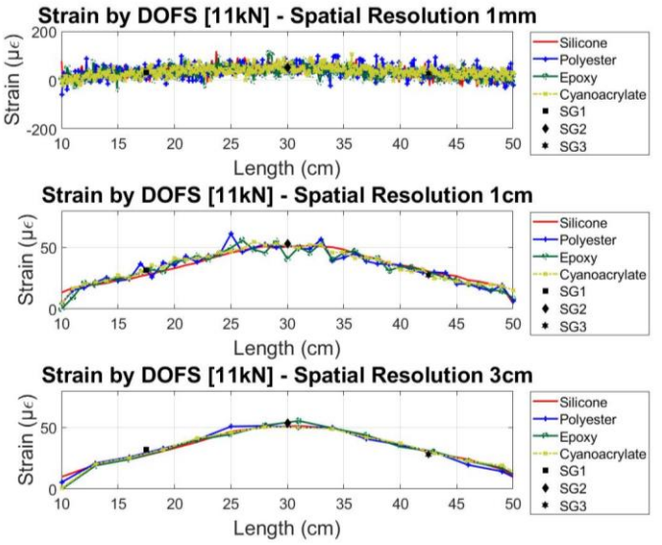

Figure 11. Data measured by DOFS with different spatial resolutions

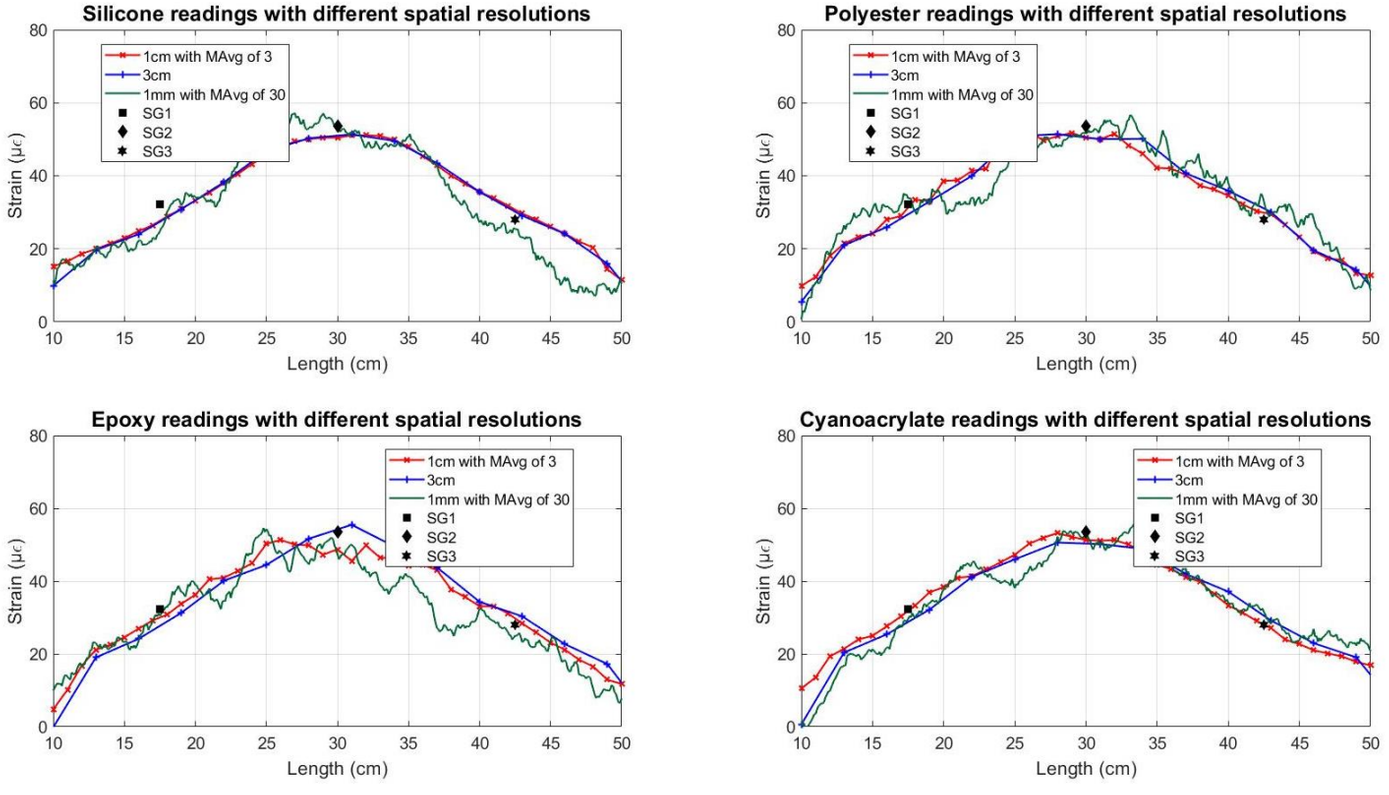

Figure 12. Data measured by each DOFS adhesive segment with different spatial resolutions while performing a moving average to the 1 mm and 1 cm data in order to directly compare it with the 3 cm spatial resolution data

In order to see if even using an initial high spatial resolution, it was possible to obtain better results, a moving average post-process was performed. A moving average with a window of 30, and another with a window of 3 was conducted on the values of the measurements with 1 mm and 1 cm respectively in order to directly compare it with the ones obtained with a 3 cm spatial resolution as seen in Figure 12.

Here, the averaged 1 mm data still presents an erratic spatial distribution when compared with the remaining data. However, the averaged 1 cm data generally presents a good fit with the 3 cm data except for the case of the segment bonded with the epoxy adhesive.

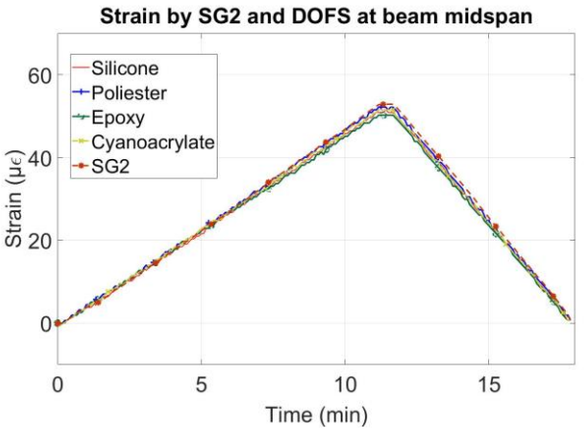

Figure 13. Strain evolution at the beam midspan as measured by the DOFS and Strain Gauge 2 (SG2).

5.2 *Comparison of different adhesives under elastic behavior*

Taking advantage of the load test cycles 1 to 6 performed on the elastic range of the instrumented beam, an initial comparison of the use of different adhesives for the bonding of the DOFS to concrete specimens is performed.

Figure 13 presents the comparison of the readings performed by the four DOFS segments at their midpoint with the data measured by strain gauge 2 (SG2) which is also located at the beam midspan, over the duration of this load cycle, with a maximum load of 11 kN. As it is possible to observe from this graph, all the adhered segments follow the measured data of the strain gauge with a satisfactory performance.

Nevertheless, by performing a surface plot of the measured strain on each DOFS segment over its length and the duration of the load cycle as depicted in Figure 14, it is possible to observe a slightly smoother and homogenous reading at the silicone segment when compared with the other adhesives. Here a clearer increase of the contour lines of its surface plot is detected.

This is especially true at the maximum measured strain, where a higher spacial variability in the data obtained at the Polyester, Epoxy and Cyanoacrylate bonded DOFS segments is observable.

Although it is also observable a good performance of the readings for the unload part of the cycle it would be interesting in further studies to perform a similar test for pure negative (compression) strains.

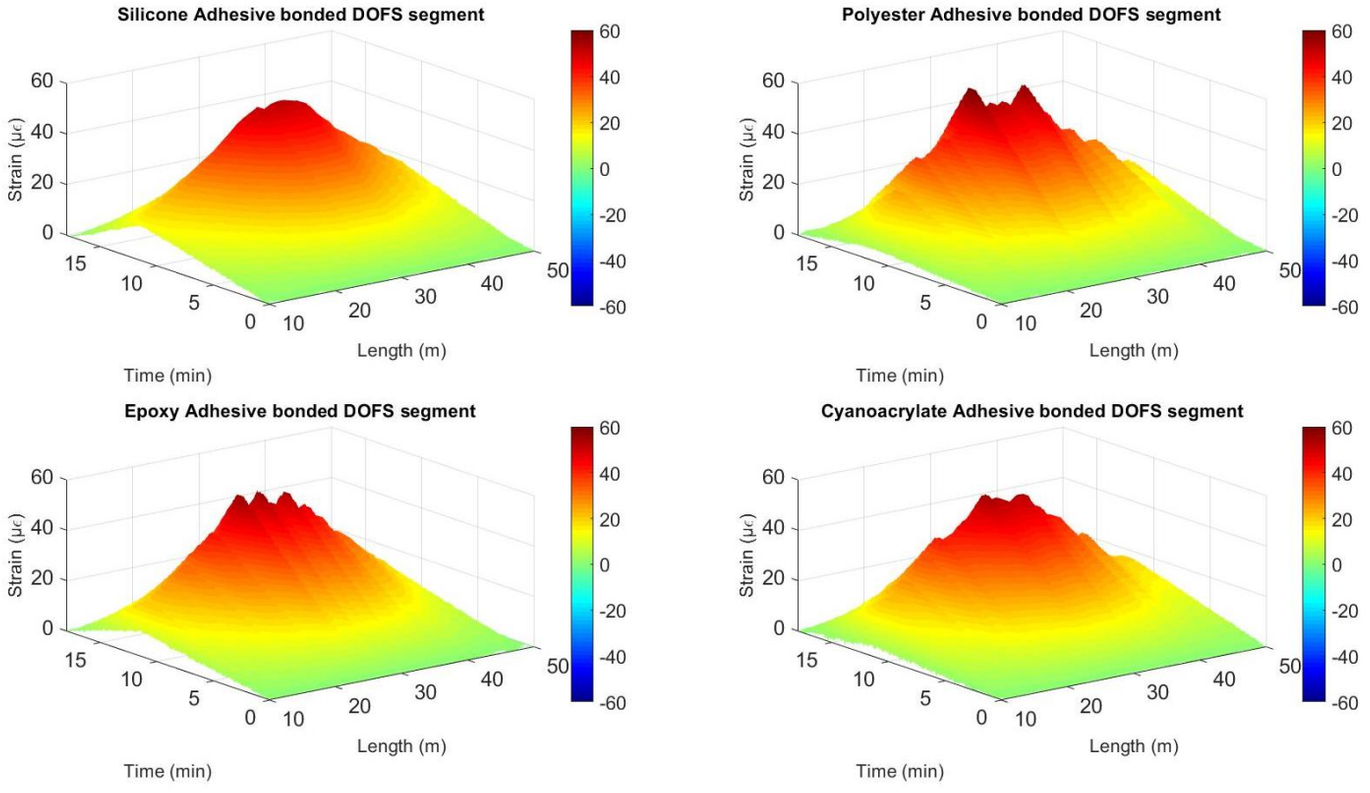

Figure 14. Strain measured for elastic load test cycle with different adhesive bonded DOFS segments

5.3 *Comparison of different adhesives for cracking detection*

After conducting the load test cycles under the elastic range behavior of the concrete beam, a load test cycle inducing cracking and continuing until the failure of either the beam or the DOFS was executed as illustrated in Figure 10.

According to the tests conducted to the cylindrical specimens and the calculated material properties, the load that would induce cracking was close to 18 kN. However, during the execution of the load cycle it was observed that, the resistance of the beam specimen was relatively higher and that the actual load which induced cracking was in fact a load of 23 kN.

By analyzing the information plotted in Figure 15, corresponding to a load level of 25 kN it is possible to observe that all segments detect and locate the occurrence of cracking as represented by a sudden peak in the measured strains. These peaks should present continually crescent positive strain with the increasingly applied load. However, as seen in Figure 15 also presents a negative peak for the polyester bonded DOFS adhesive. Note that none of the strain gauges detects the cracking.

Furthermore, by analyzing Figure 16, it is observable that when isolating the strain evolution in each segment by load steps, all adhesives with the exception of the silicone, present either positive or negative peaks in the crack location.

This is related with the value of the Spectral Shift Quality (SSQ) in the position of the produced damage after its occurrence.

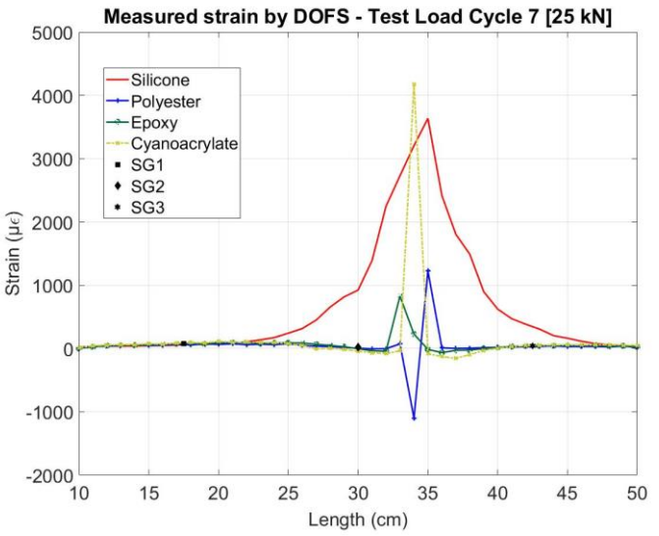

Figure 15. Detection and localization of cracking by the different adhesives bonded DOFS

When analyzing this data, it was observed that for the polyester, epoxy and cyanoacrylate segments the value of the SSQ in the location of the crack drops below 0.15, which indicates not reliable strain measurements at these points shortly after the development of the cracking.

However, it is also discernable the larger area of influence of the produced crack in the silicone segment when compared with the other ones which constitutes an obvious challenge for the pinpointing of additional cracking appearances in situations when they may occur and for the quantification of the crack width.

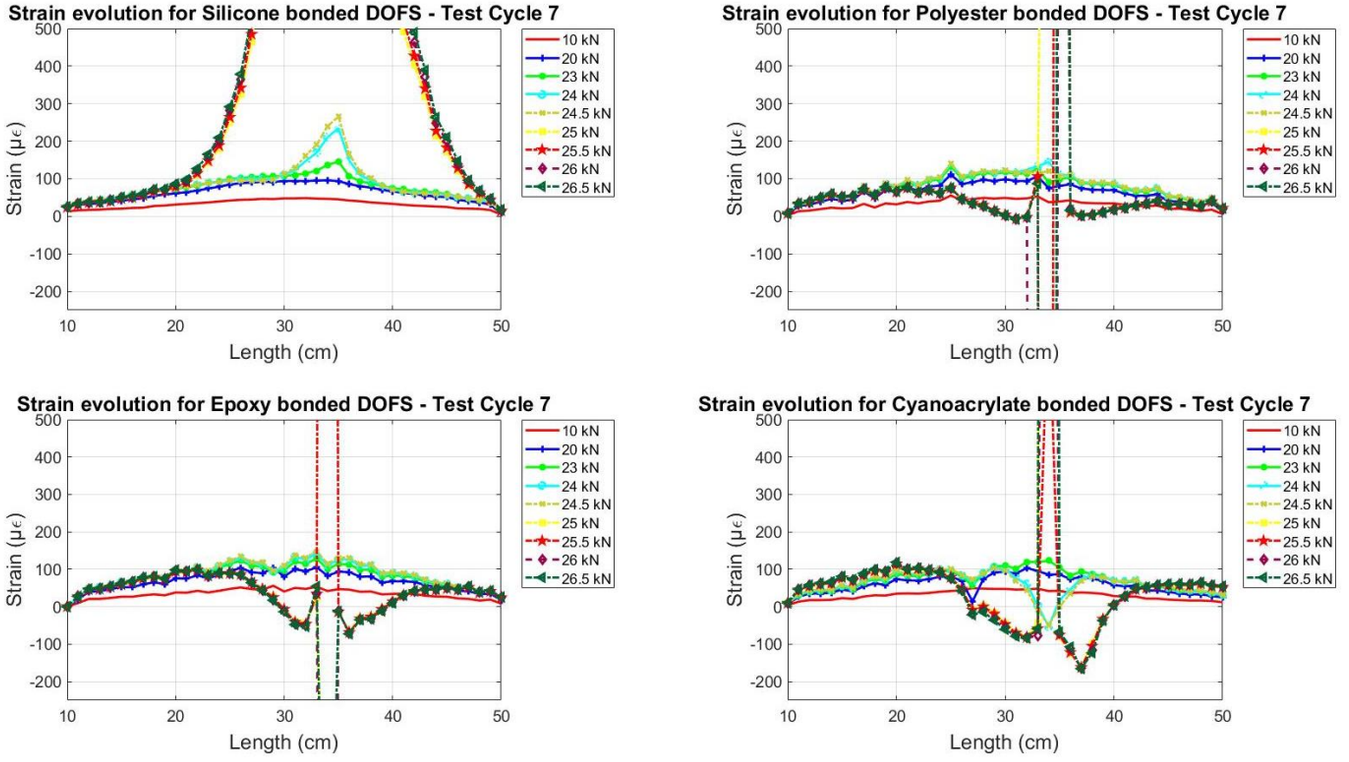

Figure 16. Measured strain at different load levels by the different adhesives bonded DOFS segment

6 CONCLUSIONS

In this paper, an experimental campaign to assess the performance of different bonding adhesives for distributed optical fiber sensors in concrete applications was presented. Moreover, as an additional point of study, the influence of different spatial resolutions was analyzed as well.

Through the conduction of load cycles under the elastic range of the concrete specimen, it was perceived how the use of a spatial resolution of 1 mm although theoretically better for an enhanced strain measurement resolution presents a highly spatial variability in its readings possibly related with the heterogeneity of the aggregates which constitute the concrete. This does not occur with a spatial resolution of 1 cm, which presented a good correlation with the data measured by the strain gauges, especially for the silicone bonded DOFS segment. The use of a 3 cm spatial resolution although presenting good correlation with the strain gauges did not present the expected advantage of generating smaller data files.

Furthermore, by performing a moving average of both the strain data acquired using a 1 mm and 1cm spatial resolution in order to directly compare it with the 3 cm measured strain, it was seen that with the use of 1 cm resolution very similar results were attainable. In this way, it is concluded that the use of a spatial resolution of 1cm is suitable for this type of applications.

Regarding the comparison of the different used bonding adhesives, it was observed that although all segments measured coherent strain data as also measured with the instrumented strain gauges, the silicone bonded segment presented a smoother and more uniform data than the other bonded segments.

When inducing strain higher than the concrete capacity and in this way generating cracking in the beam, all bonded segments were able to detect and locate the point where this damage was produced. Nevertheless, it was observable how quickly after the occurrence of cracking the points corresponding to this damage in the polyester, epoxy and cyanoacrylate bonded segments presented a low spectral shift quality (SSQ) which indicated not reliable measurements at those locations. However, the remaining length of these bonded segments continued to measure coherent strain information.

On the other hand, the silicone bonded DOFS segment continued to present acceptable SSQ values after the crack development but had a wider area of influence than the other segments, which is not advisable for the correct quantification of the damage (crack width) and the further strain monitoring in the remaining bonded areas.

It is important to mention as well, that this study contemplated the application of the mentioned adhesives in newly made small concrete specimens where it was easy to position the beam as best suitable for the adhesives application. In real and larger structural elements the viscosity and the time of curing of the adhesive contributes to an even greater uncertainty regarding the decision of the optimal adhesive in each application.

ABSTRACT: In engineering, quality control is related to systems development in order to ensure that products or services meet or exceed expectations and needs. Today, it is a challenge to manage civil infrastructure in an efficient manner. Thus, there is an increasing need to develop strategies to ensure asset quality with the aim of reducing the risk of unexpected costs. In order to assure the desired service quality with minimum interruptions, maintenance actions are taken when the risk of service impairment, interruption or life-cycle costs reach predefined levels. This risk depends on the establishment of performance goals for components, which when compared with performance indicators, obtained from visual inspection techniques, non-destructive tests or by monitoring systems, provide information regarding the assessed asset condition. The objective of this paper is to analyse a digital image correlation system and its ability to assess performance indicators, such as crack patterns, crack openings and vertical and horizontal deformations. The obtained values are then compared to goals so that structural performance assessment strategies can be implemented in an efficient and sustainable way.

1 INTRODUCTION

In engineering, quality control (QC) is related to systems development in order to ensure that products or services meet or exceed expectations and needs. Today, it is a challenge to manage civil infrastructure in an efficient manner. Thus, there is an increasing need to develop strategies to ensure asset quality with the aim of reducing the risk of unexpected costs. In order to assure the desired service quality, with minimum interruptions, maintenance actions are taken when the risk of service impairment, interruption or life-cycle costs reach predefined levels. This risk depends on the establishment of performance goals for components, which when compared with performance indicators, obtained from visual inspection techniques, non-destructive tests or by monitoring systems, provide information regarding the assessed condition.

Independently of the type of structural health monitoring system implemented, the general purpose is to efficiently monitor the structural performance such that proper maintenance actions may be identified and implemented in a timely fashion, with the aim of ensuring appropriate safety levels, maintaining the quality of the environment, as well as minimizing the asset life-cycle costs. In this paper, a digital image correlation system is used to assess performance indicators, such as crack patterns, crack openings and vertical and horizontal deformations. The obtained values are then compared to goals so that structural performance assessment strategies can be implemented in an efficient and sustainable way.

This research has been significantly affected by the objectives of COST TU1406 (2014) as well as the objectives of the COST TU 1402 (2013). The main objective of Cost Action TU1402 is to facilitate sustainable societal developments through improvements of resource efficiency, productivity, robustness, reliability and safety in the design and asset management for structures and infrastructure systems by optimized SHM systems. The Value of Information analysis quantifies this benefit relative to the costs of collecting the information. Hence, the identification of optimal SHM strategies is facilitated for both new and existing structures under a range of operating conditions and constraints. Hence, the objective of TU1402 is to quantify and assess the Value of Information collected by SHM in a life-cycle perspective prior to its implementation. Most often the beneficial value of SHM is only implicitly assumed, without considering how the information shall be utilized for improving the decision basis for

optimal life-cycle management of the structures. Information is only valuable if it deals with measurable and quantifiable parameters that may help decision making in asset management. Normally, the parameters/variables used in infrastructure management are defined as performance indicators.

Follow-up of the performance indicators along service life and their comparison with predefined target values according to desired performance goals will allow the definition of quality control plans. Therefore, the assessment of the value of information provided by the SHM techniques in regard to a set of predefined performance indicators is the key issue in a sustainable life-cycle assessment of civil infrastructure.

The shear-bearing capacity of reinforced concrete structures plays an important role concerning the sustainable life-cycle assessment of civil infrastructure. In the last decades, structural systems had been designed using different safety formats and levels, which in some cases do not comply completely with the current load models. Hence, the owners and operators of such civil infrastructure systems are highly interested in the assessment of the real existing shear load capacity and the still possible increase in the shear loading using advanced health monitoring or testing methods. For that kind of assessment of existing structures the value of health monitoring in structural performance assessment is obvious. The strength of reinforced concrete beams subjected to combined shear and flexure is affected by complex phenomena, such as existing multi-axial states of stresses, the anisotropy induced by the diagonal concrete cracking, the interaction between concrete and reinforcement and the brittleness of the failure mode. Trying to obtain valuable information about the shear transfer mechanisms, a large number of shear tests have been performed during the last 60 years, as summarized in Collins *et al*. (2008). Currently, both in the US and in Europe the shear design provisions are undergoing a revision. Open questions concern, among others, the existence and magnitude of the size-effect, see Yu *et al.* (2016), the influence of reinforcement degree, and the dependence on the axial stress state or pre-stress level, if applicable. Many different model formulations either mostly empirical, based on different physical mechanisms, see Mari *et al.* (2014), or supported by fracture mechanics have been proposed. Yet, clear evidence and quantification of the contribution of certain mechanisms can only indirectly be obtained by inverse statistical analysis.

This paper attempts to shed some light on the relevance of different mechanisms utilizing digital image correlation.

2 MECHANISM IN SHEAR MODELS

Refined theoretical models have been developed Bairán, J.M., & Marí, A.R. (2006) which are capable of tracing the non-linear response of these structures, but are too expensive and time consuming for daily engineering practice and design. Thus, simple semi empirically based equations have been also developed, some of which have been adopted by design codes European Committee for Standardization (CEN, 2002), although their applicability might be limited to the range of experiments used to derive them. Consequently, in some cases, the scatter of the predictions when compared with the experimental results is too large. Furthermore, recent studies, Sagaseta, J. & Vollum, R.L. (2011), reported that EC-2 overestimates or underestimates the shear strength, depending on the type of aggregate or the type of cross section, and neglects some key contributions. These facts suggest that there is still no universally accepted simplified mechanical model for shear design of reinforced concrete (RC) members, especially without shear reinforcement.

In addition, when assessing existing structures, they may falsely be considered unsafe. Recently, it was demonstrated how adequate filament non-linear models with shear capabilities are suitable for assessing this type of cases, Ferreira, D., Bairán, J. & Marí, A. (2013). Although adequate numerical models are a valuable assessment tool for existing structures, it is of paramount importance to develop rational mechanical models capable of reproducing as accurately as possible the physical behavior of concrete structures in order to safely and economically assess existing structures.

Furthermore, these models allow, after some simplifications, deriving simple equations which are suitable for code provisions or for their use in daily engineering practice. Among them are the Tooth model developed by Reineck, K. (1991), simplified models based on the Modified Compression Field Theory Vecchio, F.J. & Collins, M.P. (1986), the Critical Shear Crack theory Muttoni, A. & Ruiz, M.F. (2008), the Splitting Test Analogy Desai, S.B. (2004) and the theories based on the shear resisted by the uncracked compression chord Choi, K.K, Park, H.G. & Wight, J.K. (2007). On the other hand, methods based entirely on the theory of plasticity have also been applied with good results.

The above models were developed from different approaches, emphasizing the contribution of different shear transfer actions and proposing different expressions with different governing parameters. Nev-

ertheless, their strength predictions are similar and fit generally well with the experimental results.

3 EXPERIMENTAL DATA AND DOCUMENTATION

The proposed Digital Image Correlation (DIC) System for the classification of shear crack developments examined in this paper has been applied to a series of 16 laboratory tested beams. The test set up, the testing procedure, the classical monitoring set up and the material properties of the pre-stressed concrete small scale beams are documented in detail in Krug (2017). The length L of all laboratory tested beams was 5m and the effective span l_{eff} was 4,75m. The distance a between load point and support varied between 0,97m and 1,89m in order to have an appropriate shear span-to-depth ratio a/d to avoid unfavourable effects on the shear load transfer and bond shear failure. Typically, in shear tests the instrumentation is focusing first of all on the identification and monitoring of the compression field and the crack formation. Hence, the sensor arrangements include the application of strain gauges (SGs) glued externally along the sides of the concrete cross section, internal strain gauges fixed to the reinforcement and displacement transducers (e.g. LVDTs), see Krug (2016). In the present study, all these types of different electrical sensors were used. The external strain gauges were applied to the side surface of the web partly in a rosette-like arrangement in order to derive the principal strains and its inclination. Internal strain gauges were glued on additionally cast-in reinforcing bars with small diameters (φ_s = 6 mm). They were situated mainly at the same x/z-position like the outside ones in order to allow for later correlation studies between outside and inside recorded data. The LVDTs attached to the web are inclined perpendicular to the expected shear crack to make them more sensitive to shear crack openings but less to bending cracks, (Stoertzl 2015). In addition, LVDTs or laser sensors were used for vertical deflection measurements at the bottom of the beam. Moreover, visual inspections and manual crack recordings and crack width measurements by means of crack magnifiers were processed. Beams were tested under static loading in a three-point bending setup. To simulate shortly the life-cycle, first of all the specimens were subjected to a pre-loading phase consisting of 3 load cycles up to a representative SLS-load level estimated in advance.

When reaching the upper SLS load level, the crack propagation was recorded by the above mentioned visual inspection. Afterwards the load was increased displacement-controlled until failure, in between once again with single stops to do some crack recordings. Figure 1 depicts (a) the shear crack pattern at the load capacity, (b) the associated crack pattern of the optimized nonlinear Finite Element model, and (c) the modelled vs. experimental tested force-deflection curve.

4 DIGITAL IMAGE CORRELATION

Digital Image Correlation is a non-contact optical technique used for measuring strain and displacement (Castillo et al. 2016). The system is based on grey scale value digital images. Using a stereoscopic sensor set-up each object point is projected on a specific pixel in the image plane of the respective sensor. Knowing the imaging parameter for each sensor and the orientation of the sensors with respect to each other the position of each object point in three dimensions can be calculated. In order to define the absolute size of the object a reference length is required and usually introduced curing the camera calibration.

Using a stochastic intensity pattern (speckle) on the object surface, the position of each object point in the two images can be identified by applying a correlation algorithm. The displacement and deformation of each point that compose the speckle allows the program to compute the displacement and the strain field. Applied to civil engineering problems, this technique allows the determination of deflections, the axial shortening of structural members and local strains, and crack patterns indicated by displacement jumps.

5 ADDED VALUE OF DIGITAL IMAGE CORRELATION FOR HEALTH MONITORING AND PERFORMANCE ASSESSMENT

As previously introduced, the beams are sustained by two supports and loaded eccentrically to ultimately cause shear failure. The accuracy and especially resolution of digital image correlation (DIC) is related to the pixel density of the camera, the size of the area of interest (AOI), and the quality of the speckle. A comprehensive discussion of the theoretical background and the applied algorithms can be found in Sutton *et al*. (2009). The latter is determined by the ratio between characteristic size of the stochastic pattern and pixel size. Taking into consideration the fact that the interesting zone is the one where the shear cracks will develop (Figs. 1(a) and (b)) the investigation is focused on this area. In the next phase the "ideal" camera setup has to be chosen. Variables are the distance between object and camera, depending on the lens and chip, the orientation of the cameras and the angle between the cameras of a stereo pair or the intentional choice to go for individual 2D single camera systems to cover a larger area of interest, see Fig.2. This choice is driven by the magnitude and type of the expected deformations as well as the likelihood of significant out-of-plane deformations. For the present problem, considering that four 9 Megapixel cameras were available, two options have been considered:

- The first option was using two 3D systems (each 3D system is composed of two cameras) set in such a way that a sufficient overlap between the two areas of interest is ensured, allowing both so far independent systems to be linked by coordinate transformation.
- The second option is to use separately the 4 cameras in order to make use of all the available resolution by moving the cameras closer to the beams and avoiding any overlap.

Both approaches have advantages and disadvantages. In this study four independent 2D systems (single camera) have been chosen for the following reason:

- The out of plane component is considered negligible compared to the in-plane components.
- Four independent 2D systems allow a substantially higher on specimen resolution which improves the ability to detect small cracks and quantify crack openings.
- The associated higher error due to lens distortion and out of plane deformations is considered acceptable in light of the goal to measure (a) global deformations such as deflections, and (b) perform a full field documentation of the crack development.
- The effect of out of plane deformations can be reduced by a perfectly level and centred setup of the cameras, as chosen for this study.

A crucial step is the specimen preparation, namely the creation of the stochastic pattern. In order to optimize the quality of the analysis it is important to ensure a "perfect" contrast in the images. This can be achieved by painting the beams white before applying the speckle in black. The speckle was applied with an airbrush in order to have the most repeatable and controlled speckle size. Furthermore, it is essential to avoid shadows and reflections by using non-gloss colour, covering all reflective surfaces and setting a number of light sources equipped with diffusors. Nevertheless, also the natural heterogeneity might suffice for certain measurement objectives. Thus, combined with a 2D system, reducing the monitoring effort significantly.

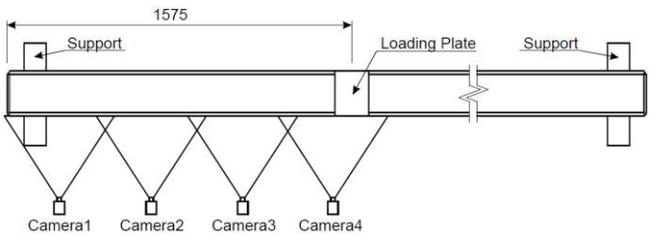

Figure 2. Sketch of DIC set-up

Correlating a set of images with the initial set provides information about the deformation state, and by derivation, about the strain field. The crack pattern then can be automatically determined based on the first principal strain field. The correlation analysis itself basically has only one parameter – the subset size. Like a moving average filter, a square correlation matrix is pushed over the image to mathematically express the local change between

two pictures related to deformations. Not unlike a finite element software, in case of a large subset size (element size) average strains with the smeared effect of cracks are determined. This approach is suitable for the measurement of global deformations, e.g. a bending line.

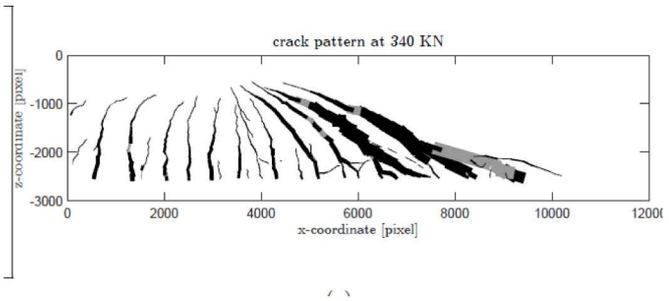

Figure 3. Crack pattern development

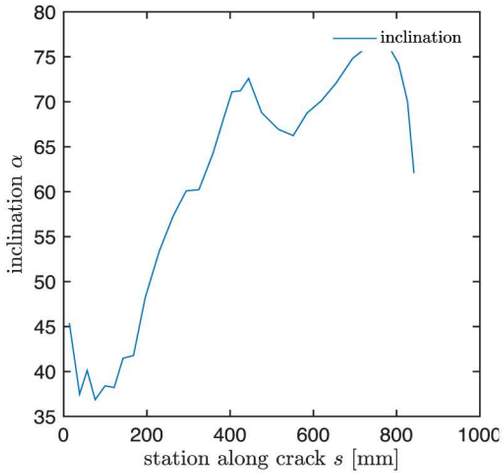

Figure 4. Crack inclination α along station s for a typical shear crack

Herein the task at hand is the determination of crack patterns and their evolution in time. Consequently, a small subset size is chosen allowing a good crack detection at the cost of higher noise in the output due to local variations in the speckle pattern, and, of course, significantly higher computational costs. Even though the first principal strain field is suitable to localize cracks it has to be noted that a strain field is a bad choice to quantify the crack opening. Depending on the subset size the actual crack is always smeared over a certain length resulting in ambiguous readings. Furthermore, if the crack opening exceeds a certain percentage of the subset size, correlation is locally lost, messing with automatic algorithms.

Thus, herein we propose a semi-automatic crack pattern survey with the following steps: (1) determine principal strain field with small subset size; (2) trace cracks based on fully developed crack pattern; (3) extract automatically the actual displacement jump along the traced lines for all time steps by e.g. Matlab script; (4) project the displacement jump onto the line segment to determine crack opening w_{90} and crack slip w_{00}. A further output is the crack inclination α measured between line segment and vertical axis, measured clockwise.

In Figure 3 a typical crack pattern for a load level of 340kN as obtained by the semi-automatic procedure is presented. The line width scales with the crack opening. Grey segments are interpolated for neighboring segments. A pixel corresponds to 0.18mm.

(a)

(b)

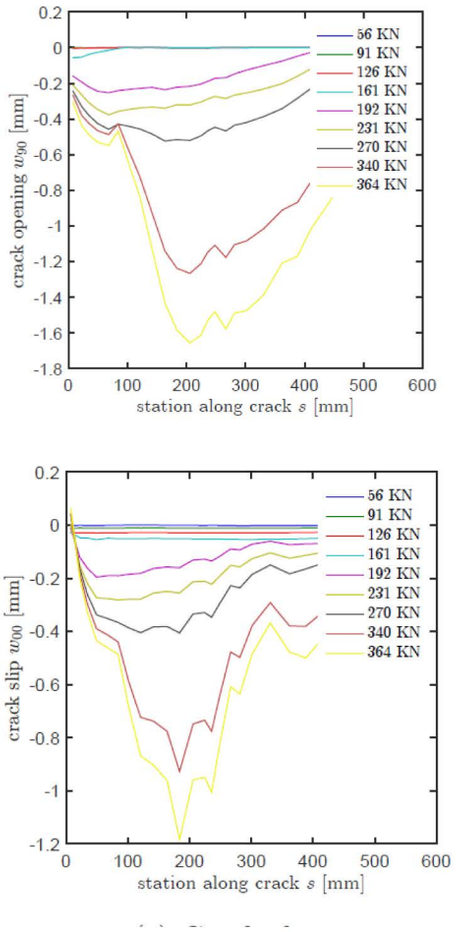

Figure 5. Crack pattern properties (a) opening, (b) slip

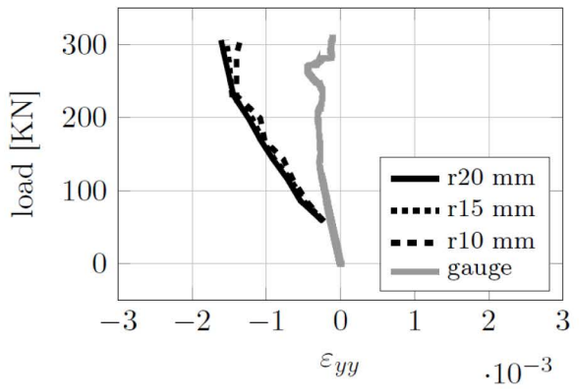

5.1 *Crack Movement*

For each of the line traces the geometrical information, i.e. the evolution of inclination, can be plotted against the station s along the crack, where s=0 represents the one end of the fully developed crack, for bending cracks equal to its initiation on the surface, see Figure 4. In Figure 5 the evolution of both components of the crack – opening and slip –with load level and depending on the position along the crack is presented. At 91 kN a small bending crack with a maximum opening of 0.05mm is present. This crack quickly grows into a shear crack. It is interest-

ing to note that the opening seems to be constrained until s=100mm, corresponding to the position of the tendon. Furthermore, a distinct shear slip is present in the range $0 < s < 300$ mm.

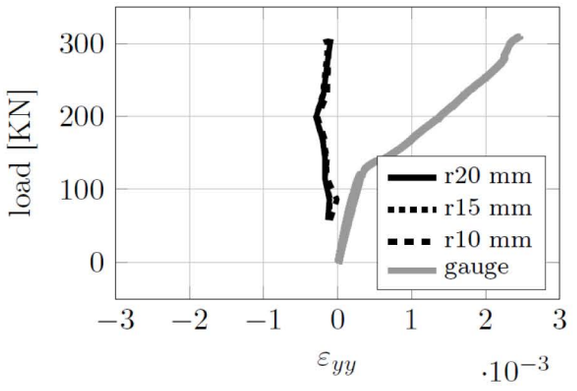

Fig. 6 presents the comparison between DIC strains and the corresponding electrical strain gauges on the reinforcing bars. In the shear zone of the 13 monitors of strain which deployed to Slowik et al. 2015. The graphs show that some of the strains derived from the DIC measurements on the surface of the beams show a good agreement with strains measured on the reinforcement (Fig. 6 (c)) and some are significant deviating (Figure 6 (a) and (b)) due to crack formation.

6 CONCLUSIONS

The first studies on the digital image correlation systems demonstrate the capability of the method in the recording and interpretation of the crack pattern development in the shear field zone during the loading process up to the shear bearing capacity. The technology also shows a high potential for the understanding and interpretation of complex mechanical processes of the shear behaviour of reinforced concrete. A first comparison of the DIC recorded surface strains with the strains on the embedded reinforcement demonstrate partly a good agreement and hence the possibility to map surface measurements to the reinforcement layers. In addition, it could be shown that the DIC measurements have a high potential for optimizing processes in the arrangement of monitoring systems.

B. Sivakumar, E. Senturk
HNTB Corporation, New York, NY, USA

ABSTRACT: Based on current rating methods, about one in nine of the 607,380 US bridges are considered to be structurally deficient. However, not all these bridges are at risk of collapse as current code-specified analytical methods are generally conservative and may underestimate the true safety levels of existing bridges. For these reasons, there has been considerable interest in developing methods that combine field measured data with analytical models to obtain more accurate assessments of existing bridges.

This paper presents a Response-Based Load and Resistance Factor Rating (RB-LRFR) method that utilizes strain data to evaluate the safety of existing bridge members. Appropriate live load factors are calibrated to reflect the uncertainties associated with estimating the parameters and random variables needed to rate a bridge component using field data. The implementation of the proposed methodology is illustrated using a composite steel girder bridge as an example.

1 INTRODUCTION

1.1 *Background*

Bridge load rating is the determination of the live load carrying capacity of an existing bridge. Typically, load rating is determined by analytical methods based on information taken from the bridge plan and inspection reports. It is also common practice to supplement the rating process with field strain measurements that are primarily used for diagnostic purposes to confirm analysis results. Field test measurements are generally performed by running test trucks of known weights over instrumented bridges to obtain improved estimates of structural analysis results including the load distribution factors that may be directly used during the rating process or to calibrate finite element models of the bridge for more advanced analyses. Procedures have also been proposed to use truck Weigh-In-Motion (WIM) data to develop site specific load models for bridges subjected to traffic loads that may not be well represented by the generic code-specified nominal loads. Such piece-meal approaches require a combination of extensive finite element analysis and costly field measured data collection processes which often require bridge closures and controlled load tests.

1.2 *Objectives*

A method, herein named Response-Based Load and Resistance Factor Rating, RB-LRFR, is proposed to directly use strain measurements to load rate an existing bridge. The method measures the response of structural members under ambient traffic, instead of test trucks, to obtain more accurate rating factors that better reflect the true safety of the instrumented members. This proposed response-based approach will alleviate the expense and logistics of conducting a bridge controlled load test, the need to collect detailed WIM traffic data, and the development and execution of a calibrated finite element analysis. The proposed method uses properly calibrated live load factors which are consistent with current Load and Resistance Factor Rating, LRFR methodology (AASHTO, 2011).

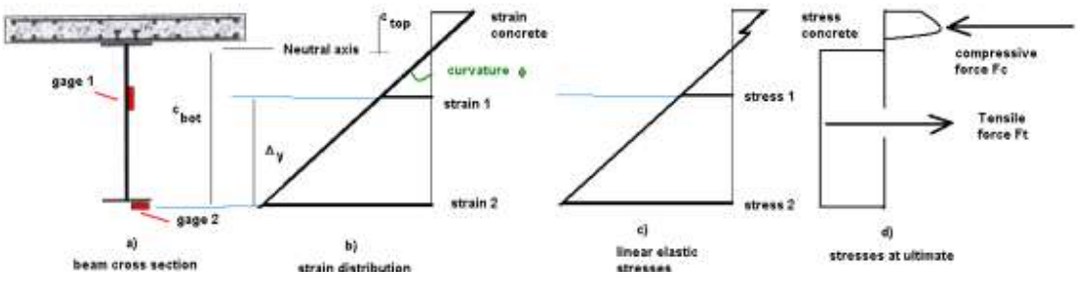

Figure 1. Distribution of Axial Strains and Stresses along the Depth of a Beam in Bending

2 BASIC CONCEPT

2.1 *Moment-Curvature Relationships*

The bridge rating process is concerned with evaluating the safety of particular bridge members to ensure that the effects of the applied loads are lower than the members´ load carrying capacities. In this paper, the focus is on moment effects on main members although a similar approach could eventually be implemented for shearing forces. In this context, axial strains measured on bridge beams are directly related to the internal moments induced by the crossings of trucks over the bridge. Utilizing measured strains directly to check member safety is not consistent with bridge rating methodology which is based on the ultimate capacity. Therefore, it is necessary to convert measured strains to moments.

As shown in Figure 1, axial strains measured at two different locations along the depth of a section can be used to obtain the curvature due to truck crossings, which in turn can be used to determine the applied truck moment. If the live load moment M_{LL} is obtained using the curvatures measured during truck crossings and the dead load moment M_{DL} is known, the load rating process can then proceed in the traditional manner by comparing the moment applied on the member to the calculated ultimate moment capacity of the member. This member-oriented response-based rating process involves a much lower level of uncertainty than the rating based on the nominal live load models specified in the AASHTO LRFR because by taking field measurements on particular members under ambient traffic, there is no need to perform a structural analysis nor is there a need to determine the load distribution factor or apply an arbitrary dynamic amplification.

In RB-LRFR the ambient traffic could include legal loads, illegal overloads or authorized overloads and the safety evaluation accounts for any random mix of these vehicles as they cross the bridge. As such, RB-LRFR ratings are reflective of bridge safety for these vehicles crossing the bridge individually or in combination. Thus, multiple-presence of vehicles on a bridge is automatically accounted for eliminating the need to use the conservative code-specified multiple presence factors.

As explained by Moses (2001), the bridge rating process considers the safety of bridge members subjected to the maximum expected load over a five-year rating cycle. Therefore, a statistical projection of the data collected over a limited period of strain measurements should be performed to obtain the maximum expected 5-year load effect. In this study, the approach developed by Ghosn et al. (2013) and Sivakumar et al. (2011) is used to execute the statistical projection.

2.2 *RB-LRFR Procedure*

The proposed RB-LRFR methodology follows the following steps:

1. Measure the strains ε_1 and ε_2 at two points along the depth of the section being evaluated.
2. Develop the complete moment-curvature relationship of the instrumented section by estimating the material properties and dimensions of the section being evaluated from design plans and inspection reports, as shown in Fig. 2.
3. Calculate the dead load moment M_{DL} on the section based on information taken from design plans and inspection reports.
4. Use the moment-curvature relationship to determine the curvature corresponding to the dead load moment, ϕ_{DL}.
5. Calculate the curvature due to the live load ϕ_{LL} using the measured strains and strength of materials principles, as $\phi_{LL} = (\varepsilon_2 - \varepsilon_1) / \Delta_y$, where Δ_y is the vertical distance between the two strain gages.
6. Add the dead load and live load curvatures to find the total curvature on the member, $\phi_{TL} = \phi_{LL} + \phi_{DL}$.
7. Use the moment-curvature relationship to find the total applied moment on the member, M_{TOTAL}.
8. Determine the live load moment by subtracting the dead load moment from the total applied moment, $M_{LL} = M_{TOTAL} - M_{DL}$.
9. Use the estimated values of the applied live load moments obtained based on the limited period of data collection (a minimum 3-month period is

recommended) to project the maximum load effect in the service period (5 years for load rating) using statistical methods.

10. Using the maximum live load effect over the rating period, the moment capacity and the dead load moment, obtain the LRFR Rating Factor. Rating Factor (*R.F.*) calculations will be based on specially calibrated live load factors as explained later in this paper.

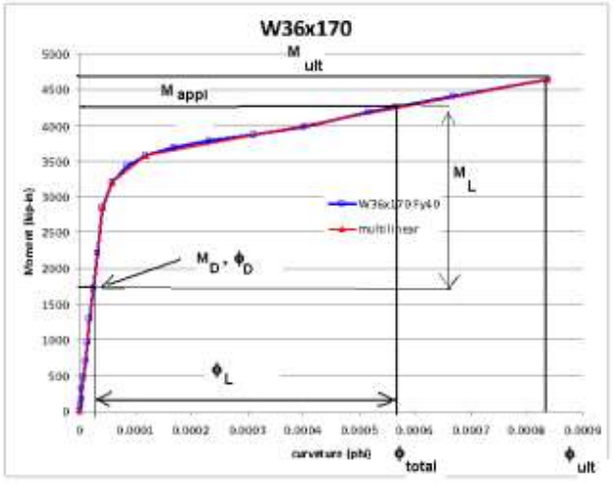

Figure 2. Example Moment-Curvature Diagram

2.3 *Load Rating*

The Rating Factor is used as the primary means for evaluating the load carrying capacity whereby a Rating Factor *R.F.* ≥ 1.0 indicates that the bridge has sufficient level of reliability to safely carry the live loads that are currently crossing the bridge.

The calculation of the Rating Factor, *R.F.*, can be executed using the usual Rating Equation given as:

$$R.F. = \frac{\phi R_n - \gamma_{DC}\left(D_{C1} + D_{c2}\right) - \gamma_{DW} D_W}{\gamma_{LL} LL_{\max}} \qquad (1)$$

where *R.F.* is the rating factor, ϕ is the resistance factor, γ_{DC} and γ_{DW} are the dead load factors, and γ_{LL} is the live load factor. R_n is the nominal resistance, D_{C1} is the dead load effect of pre-fabricated components, D_{C2} is the dead load effect of cast-in-place components and attachments, D_W is the nominal dead load effect for the wearing surface, LL_{max} is the maximum live load moment for the rating period as calculated using the measured curvature. The live load moment for each truck crossing is calculated from the section's moment curvature relationship. These live load moments are subsequently projected to estimate the maximum moment within a 5-year rating period.

The resistance and dead load factors in Eq. (1) can be obtained from AASHTO (2012). However, a new live load factor γ_{LL} needs to be calibrated to reflect the levels of uncertainties associated with estimating the maximum live load moment using the proposed method. Following widely accepted code calibration methods, the determination of the appropriate live load factor must be executed so that bridge sections that have a Rating Factor *R.F.* = 1.0 will exactly meet a target reliability index, β_T. The live load factors in the AASHTO LRFR (2001) were calibrated to produce a target β_T =2.5.

2.4 *Reliability Analysis*

To perform the reliability calibration of live load factors, bridge safety margin is expressed in terms of a function, *Z*, defined as:

$$Z = R - DL - LL \qquad (2)$$

where *R* is the actual resistance of the cross section being evaluated, *DL* and *LL* are respectively the dead and live load effects on the section. The reliability analysis studies the probability that the failure function *Z* is less than or equal to 0.0 and the reliability index, β, is defined such that $P_f = \Phi(-\beta)$ where Φ is the cumulative normal probability function that gives the probability that the normalized random variable is below a given value. The reliability analysis requires statistical models for all the random variables in Eq. (2). The statistical models for *R* and *DL* presented by Nowak (1999) are applicable for the purposes of this study. The focus is then on modeling the uncertainties in *LL*.

During the calibration of the AASHTO (2017) Specifications, the live load *LL* had the highest level of uncertainty expressed in terms of a Coefficient of Variation (COV) V_{LL}=20%. This value accounts for the overall variability in estimating the effect of the maximum load expected to be on the bridge during a 5-year rating period. These uncertainties include: a) variability within a site; b) site-to-site variability, and c) the effect of limitations in the data sample size, as well as the uncertainty in evaluating d) the dynamic amplification and e) the load distribution factor and other limitations in the structural analysis process. In the response-based rating process, many of the live load uncertainties, especially those related to site-to-site variability, load distribution and dynamic load amplification are reduced or completely eliminated because of the use of site-specific response data. Instead, the live load uncertainties are related to the following:

1. Variability in the measured strains compared to actual strains
2. Calculation of curvature
3. Moment curvature relationship

4. Finding the maximum live load moment in the 5-yr rating period
5. Sufficiency of data.

It is further noted that the uncertainties in evaluating the moment curvature relationship for extracting the live load moment are highly correlated to the uncertainties in estimating the resistance R because, as shown in Fig. 2, both use the same material property input and the same analysis principles.

2.4.1 *Strain Measurement Errors*

Strain measurement errors vary depending on the gages, their installation, electric circuitry, and signal conditioning including bridge completion resistors. A 2% error is usually estimated for properly calibrated signal conditioning systems with full bridge circuits with temperature compensation. Additional errors may be due to the type of gage used and the installation.

Installation errors are due to the placing of the gage in the right location and correct orientation. For a single gage, it is estimated that an error in the installation angle of about $\pm 10^{o}$ will produce an error in the strain reading on the order of $\pm 5\%$. The COV for the installation error is then taken as 5%.

To account for gage errors one should compare readings from different gages. An analysis of strain data collected during the course of this study showed that the standard error from the gages is less than 3.6 με. When the maximum strain reading is above 100 με, the standard error would be about 3.5% or less.

From this discussion, the errors in the recorded strains associated with the largest live loads can be conservatively represented by a COV of $6.5\% = \sqrt{(3.5\%)^2 + (5\%)^2 + (2\%)^2}$.

2.4.2 *Calculation of Curvature*

The curvature is the difference between the strains measured along the depth of one section divided by the distance between the two strain gages. This calculation is also related to the location of the Neutral Axis. Differences in determining the location of the neutral axis for different girders of the same bridge are found to be within $\pm 8\%$.

Overall, the uncertainties in estimating the curvature, ϕ_{LL}, are related to those of the strains (which are conservatively estimated to be 6.5%) and in estimating the location of the neutral axis (which are conservatively estimated to be 8%). Therefore, a very conservative estimate of the COV in estimating the curvature can be set as $V_{\phi} = \sqrt{(8\%)^2 + (6.5\%)^2} = 10.3\%$ or roughly 10.5%

2.4.3 *Moment Curvature Relationship*

The calculation of the live load moment, M_{LL}, from the curvature, ϕ_{LL}, depends on the moment-curvature relationship and the adjustment made to account for the dead load effect as described in Fig. 2. Developing the moment-curvature relationship and finding M_{total} for every value of curvature ϕ_{total} involves the same basic variables used to find the ultimate moment capacity $R=M_{ult}$. Therefore, M_{total} for a given curvature and the ultimate moment capacity $R=M_{ult}$ are highly correlated random variables. Nowak (1999) assumed that the mean value of R is related to the nominal value that one calculates using design code methods by a bias b_R=1.12 with a COV V_R=10%. These account for the material uncertainties, the manufacturing uncertainties, as well as the modeling uncertainties which evaluate the difference between the actual behavior of a beam as obtained from tests compared to the assumed behavior when using code-specified methods. If the ultimate moment capacity is found using realistic models for the stress-strain relationships of the constituent materials and using best estimates of the material strengths and moduli of elasticity, then the bias between the moment capacity obtained using code methods and the moment capacity calculated using advanced computer software such as SAP2000 is reduced to a value close to b_R=1.03. If the moment capacity uses the best estimates for the concrete strength but the nominal yielding stress of the steel, then the bias between the code calculated moment capacities and those of the actual behavior represented by the SAP2000 approach will have a total bias of close to b_R=1.08. The difference between the 1.12 bias used during the AASHTO LRFD calibration and the 1.08 bias mentioned herein is due to the difference between the specified concrete strength and the actual strength in the as-built conditions. The COV accounts for the modeling uncertainties which inherently include the uncertainties in estimating the effective width of a composite girder-slab beam and other basic modeling assumptions such as the assumption that plane sections remain plane. The material uncertainties account for the variations of the steel properties as well as the concrete strength from the values used in calculating the ultimate moment capacity, the manufacturing uncertainties account for the variability in the dimensions of the sections.

2.4.4 *Projection of Maximum Live Load Moment*

Previous analyses have shown that the calculation of the extreme value distribution of the maximum live load moment in the 5-yr rating period produces a COV V_{max} on the order of 4.5%. This value only reflects the variability in estimating the maximum live load moment from the histogram of live moments

extracted from the M-phi curve assuming that the histogram represents all the live loads that are crossing the bridge within the 5-yr period.

One method to check the sufficiency of data is to execute the projection of the maximum live load moment with data collected over increasing periods of time and verifying convergence. In this study, it has been observed that the estimated mean converges to a steady state value when data collected over four months are used to execute the statistical projection. The corresponding change in the expected 5-yr maximum live load is on the order of 2%.

2.4.5 *Summary*

In summary, a simplified model for accounting for the random nature of the calculated maximum live load moment M_{LL} can be presented as:

$$M_{LL} = (M_{total} - M_{DL})\lambda_{LL}\lambda_{\varepsilon}\lambda_{data} \quad (3)$$

where $\lambda_{LL}, \lambda_{\varepsilon}, \lambda_{data}$ are modeling variables that respectively account for the variability in the maximum live load moment, the variability in the measured strains including the calculation of the curvature and the insufficiency of the data and the accuracy of the fit of the live load moment cumulative histogram, M_{total} is the moment value on the M-phi plot which corresponds to the total curvature which is the sum of the live load and dead load curvatures, M_{DL} is the dead load moment.

The statistics for the random variables that model $M_{LL} = (M_{total} - M_{DL})$ are given in Table 1.

Table 1. Statistical Data for Live Load Moment Modeling

Variable	Mean	COV	Distribution type
M_{TOTAL}	$\overline{M}_{TOTAL} = \overline{M}_{LL\max} + \overline{M}_{DL}$	10%	Lognormal
M_{DL}	As built conditions	10%	Normal
λ_{LL}	1	4.5%	Gumbel
λ_{ε}	1	10.5%	Normal
λ_{data}	1	2%	Normal

The benefits of using the response-based LRFR are evident as the variability in estimating the intensity of the live load effect is represented by a COV $11.60\% = \sqrt{(4.5\%)^2 + (10.5\%)^2 + (2\%)^2}$. After adding a COV of 10% related to converting the intensity into a moment, the final COV value = $15.3\% = \sqrt{(11.6\%)^2 + (10\%)^2}$ is lower than the 20% used during the calibration of the AASHTO LRFD and LRFR. Furthermore, the correlation between the ultimate moment capacity and the live load moment leads to a reduction in the overall uncertainties associated with the safety margin Z of Eq. (2) used to perform the reliability analysis.

2.5 *Reliability Calibration of Live Load Factor for Response Based LRFR*

The live load factor that should be used in the RB-LRFR equation to evaluate the load carrying capacity of a bridge should be calibrated in such a way that when the rating factor is $R.F.$=1.0, the bridge member should achieve a target reliability index.

The target reliability is usually selected to match the reliability of bridges that have shown satisfactory performance. For the purposes of this study, we will assume the same target reliability index β_T=2.50 which was used during the calibration of the AASHTO LRFR for a 5-yr rating period.

To execute the calibration of the appropriate live load factor, a suite of bridges of different span lengths and member capacities and different permanent weights should be subjected to live load moments representing the effects of different traffic conditions on bridges with different numbers of beams and beam spacing and different dynamic amplification characteristics. Because such an extensive database of instrumented bridges is not available at this stage, we resort to creating a simulated database of composite steel bridges. For example, a random sample of hypothetical steel bridges is generated to have the following characteristics:

1. A range of members having nominal ultimate moment capacities between R_n=40,000 kN.m to 400 kN.m assumed to represent steel bridge members of various levels of deterioration for a large range of span lengths.
2. Dead load moments ranging between D_n=20,000 kN.m to 135 kN.m.
3. Mean live load moment ranges between $\overline{M}_{LL\max} = \overline{LL}_{\max}$=30,000 kN.m to 135 kN.m.

The failure function (safety margin equation) of Eq. (2) is expanded as follows:

$$Z = R - DL - LL = M_{ult} - M_{DL} - (M_{total} - M_{DL})\lambda_{LL}\lambda_{\varepsilon}\lambda_{data}$$

where $R=M_{ult}$ and M_{total} are correlated variables because they are both obtained from the moment-curvature relationship using the same input of section and material properties. Two cases are analyzed: a) full correlation with ρ=1.0 and b) partial correlation with ρ=0.5. The statistics of the random variables are given in Tables 1 and 2.

Table 2. Statistical Data for Moment Capacity and Dead Load Based on Nowak (1999)

Variable	Member	Bias	COV	Distribution
Resistance	Steel beams	1.12	10%	Lognormal
	Prestressed	1.05	7.5%	Lognormal
Dead Loads	Prefabricated	1.03	8%	Normal
	Cast in place	1.05	10%	Normal
	Wearing surface	1.00	25%	Normal

A total sample of 80,000 hypothetical bridge members is generated so that their capacity, dead load and live load ranges meet the characteristics set above. The reliability index β is calculated for each of the cases. The cases where the reliability index is found to be equal to β=2.50 (+/-0.01) are set to have a rating factor $R.F.$=1.0. The live load factor γ_L for the cases that met the target is calculated from:

$$\gamma_{LL} = \frac{\phi R_n - \gamma_{DC}(D_{C1} + D_{c2}) - \gamma_{DW} D_W}{R.F. \times LL_{\max}} \qquad (5)$$

The reliability calculations were performed assuming that each point on the moment-curvature plot M_{total} which gives the moment on the M-phi curve corresponding to the measured curvature is partially correlated to the ultimate moment capacity M_{ult} with $\rho_{M_{total}, M_{ult}} = 0.5$.

The live load factor γ_{LL} calculated from Eq. (5) is plotted against the dead load to resistance ratio D_n/R_n as shown in Fig. 3. The plot shows that a conservative live load γ_L=1.45 will provide an upper bound to the live load factors leading to a reliability index β equal to the target β_T=2.5 for all the cases for which D_n/R_n is less than 0.50. Therefore, the live load factor that should be used with the Response-Based LRFR of composite steel bridges is set at γ_{LL}=1.45. It is noted that as D_n/R_n exceeds 50%, the effect of the dead load becomes dominant and a dead load factor higher than 1.45 should be used. In fact, the AASHTO LRFD uses a dead load factor γ_{DC}=1.50 for the cases where the dead load is dominant.

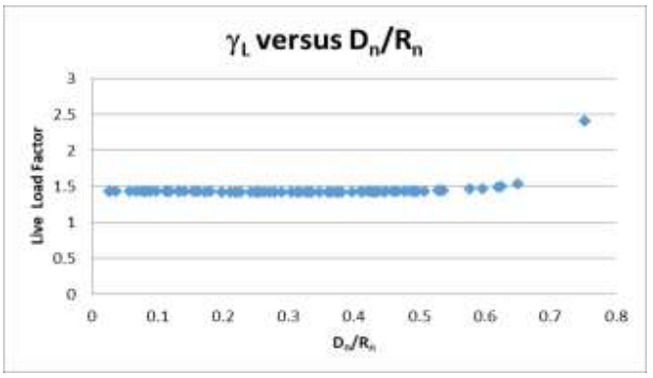

Figure 3. Live load factor versus D_n/R_n for partial correlation

3 IMPLEMENTATION

3.1 *Response-Based Rating of Composite Steel Bridge*

A numerical example is presented to describe the proposed Response-Based Load and Resistance Factor Rating methodology. The simple span 26-m long composite steel bridge on Interstate-195 over Sharon Station Road was instrumented to capture strain data resulting from ambient traffic. The bridge that carries two traffic lanes in one direction has six 36WF230 steel rolled beams supporting a 200-mm thick concrete deck with a 50-mm thick asphalt wearing surface. Four of the six girders were instrumented at midspan with two strain gages, one placed at the bottom flange level, and the other at the web, 305-mm away from the bottom flange gage.

The strain data collected in the field for three months are scanned to catch the peak strain values corresponding to sequential 15 minute intervals for each girder. Girder 2 of the NJ Pilot Bridge was found to experience the highest values of strain and was chosen for analysis. Section properties were extracted from the as-built plans. The girder has a 1380 mm x 32 mm cover plate welded to the bottom flange.

The concrete strength is found by ensuring that the calculated location of the neutral axis corresponds to that measured in the field from the two strains readings taken during truck crossings. The modular ratio, n, was determined to be n=4.13

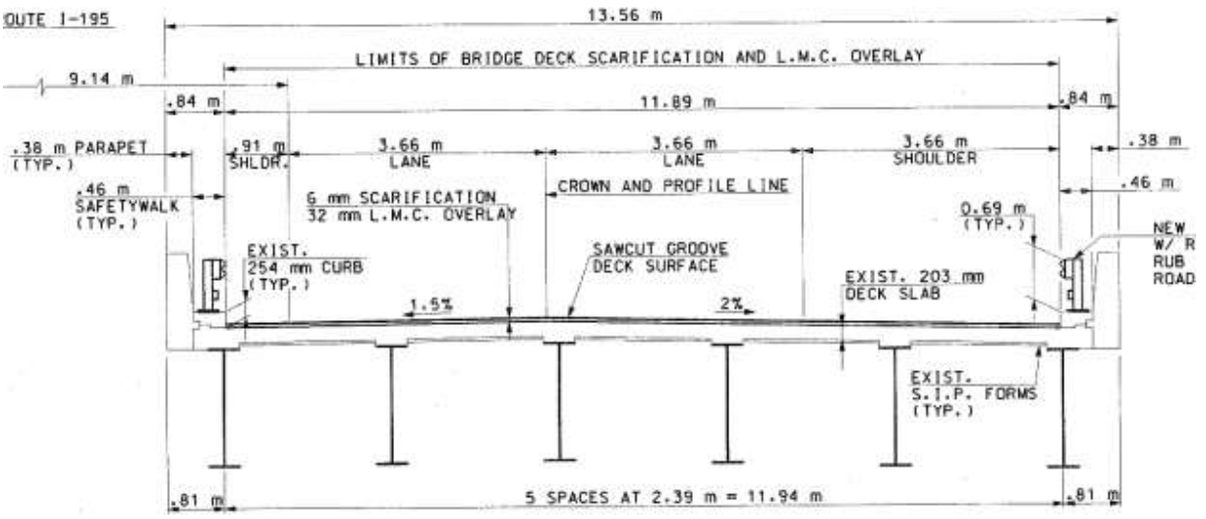

Figure 4. Cross Section of Bridge on Interstate-195 over Sharon Station Road.

The uniform dead load of the components and that for the wearing surface on Girder 2 were determined to be respectively $w_{DC} = 21\ kN/m$ and $w_{DW} = 2.7\ kN/m$. The corresponding total dead load moment is calculated to be M_{DL}=2000 kN.m.

For each peak strain the live load curvature is:

$$\phi_{LL} = \frac{\varepsilon_2 - \varepsilon_1}{\Delta_y} \qquad (6)$$

where Δ_y is the vertical distance between the two strain gages, ε_2 and ε_1 are the measured flange and web strains. The maximum 15-minute live load moment is extracted from the M-phi curve as described in Fig. 6.

The maximum load effect for the 5-year service period is determined using the upper 5% of the live load moment data by plotting the 15-minute maximum live load moments on a normal probability graph as shown in Figure 7. The corresponding mean and standard deviation are extracted as μ_{event}= 270 kN.m and σ_{event}=160 kN.m. Having the properties of the tail end of the maximum 15-minute live load moment distribution, the statistical properties of the maximum live load moment in the 5-year rating period can be obtained given that in a 5-year period, the total number of events is equal to N = 175,200 readings of the maximum 15-minute value. Given the large value of N, the maximum 5-year live load moment asymptotically approaches that of an Extreme Value Type I (Gumbel) distribution with an inverse measure of the dispersion α_N determined as:

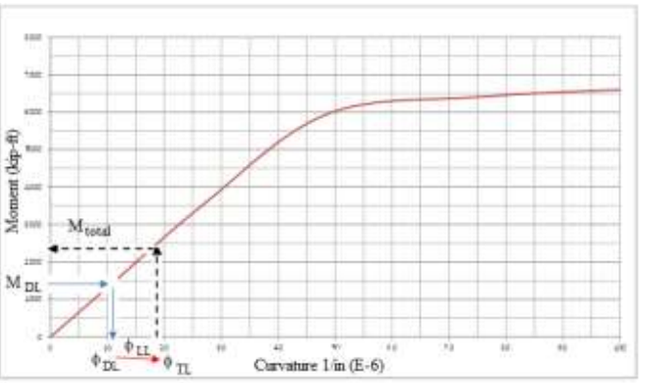

Figure 6. Determination of Live Load Moment from M-ϕ Curve

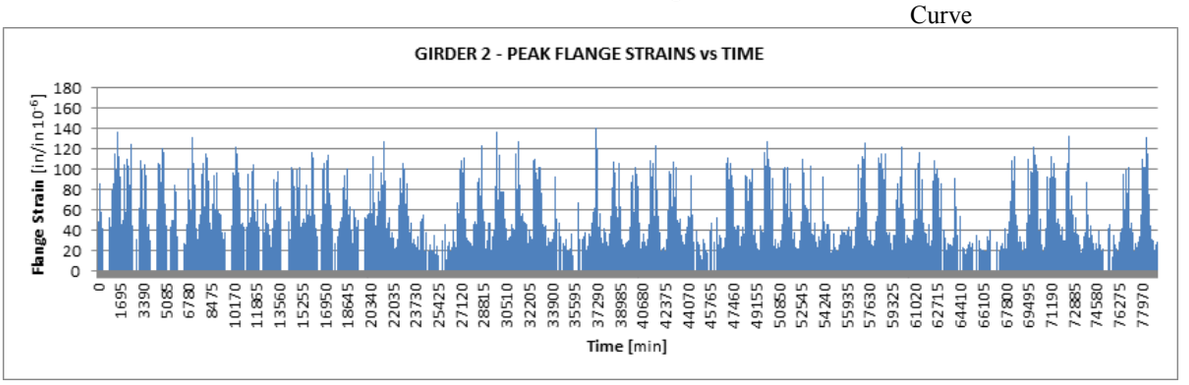

Figure 5. Sample of 15-minute Maximum Strains Collected on Composite Steel Bridge.

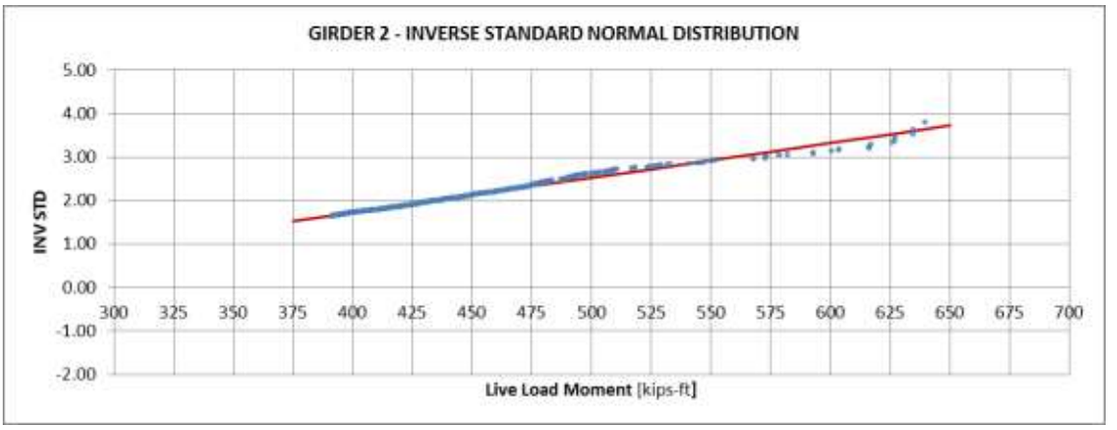

Figure 7. Normal Graph of Top 5% Moments for Girder 2

$$\alpha_N = \frac{\sqrt{2\ln(N)}}{\sigma_{event}} = \frac{\sqrt{2\ln(175200)}}{160} = 0.0307 \quad (7)$$

The most probable value u_N is calculated as:

$$u_N = \mu_{event} + \sigma_{event}\left(\sqrt{2\ln(N)} - \frac{\ln(\ln(N)) + \ln(4\pi)}{2\sqrt{2\ln(N)}}\right) = 970\ kN.m$$

The mean of the maximum load effect, LL_{max}, is:

$$LL_{\max} = u_N + \frac{0.577216}{\alpha_N} = 988\ kN.m \quad (9)$$

Based on the rating Equation (1), and the maximum live load moment for a 5-year period, the rating factor for Girder 2 can be computed as:

$$R.F. = \frac{0.9 \times 10680 - 1.25 \times 1770 - 1.50 \times 224}{1.45 \times 988} = 4.93$$

For comparison purposes, the bridge was also rated using analytical LRFR methods for design and both routine and SHV legal loads. The results are summarized in Table 3.

Table 3. RB-LRFR and MBE Design and Legal Load Ratings

Type of Rating	M_{LL} [kn.m]	R.F.
Response-Based	988 (includes DF and Dynamics)	4.93
HL-93 INVENTORY	1700 (Truck) 784 (Lane)	1.328
HL-93 OPERATING	1700 (Truck) 784 (Lane)	1.721
TYPE 3	1224	2.991
TYPE 3S2	1441	2.541
TYPE 3-3	1410	2.597
SU4	1375	2.665
SU5	1529	2.396
SU6	1707	2.145
SU7	1872	1.955

4 CONCLUSIONS

This paper presents a Response-Based Load Rating (RB-LRFR) method which uses the bridge response directly in the rating process to reduce many sources of uncertainty inherent in assessing bridge safety.

The proposed RB-LRFR combines the benefits of a static load test and site-specific truck Weigh-In-Motion analysis. It offers a non-intrusive method that uses the actual bridge as the evaluation model and actual traffic for modeling the live load.

The procedure follows statistically sound methods that maintain the same reliability goals as current load rating methods.

The proposed method is implemented for the analysis of an existing composite steel girder bridge and was found to improve the rating obtained from current methods by a large factor.

ABSTRACT: Within structure management, the non-formal assessment where the structural condition is evaluated on the base of visual inspections takes place at most. The objective of the structural condition assessment is to determine its current state and to assume the future performance of a structure with a maximum of accuracy and a minimum of effort. Therefore, advanced methodologies and deterioration predictive models for the assessment of structure/structural element over time are needed. Data collected during visual inspection should mainly provide the information about the most serious problems and suggest most suitable scheme of extension the inspection by monitoring, additional on-site measurements and/or laboratory tests. These should provide more realistic information about the input parameter values, when using modeling of degradation processes for prediction of future condition of the structure. The aim of this contribution is to describe the process of possible calibration of input parameters for prediction of deterioration due to chloride ion ingress into concrete with the emphasis on model based assessment.

1 INTRODUCTION

Degradation processes of structural materials, such as chloride ion ingress, concrete carbonation or subsequent corrosion of reinforcement, are limiting factors for the service life of reinforced concrete structures and/or structural elements. Since the proper safety level of the structure needs to be ensured during the whole service life, owners and operators of existing structures face complex decisions making regarding maintenance and repair strategies and/or possible replacement (Neves et al. 2006, Strauss et al. 2013). Further, minimizing the overall cost by optimizing inspection, maintenance and repair work is a main task within this decision making process.

According to Rücker et al. (2006), assessment procedures can be classified into three groups: (i) Non–formal assessment; (ii) Model based assessment; and (iii) Measurement based assessment. Since they vary in sophistication, these procedures can be divided into several assessment levels, where experience based non-formal assessment presents the lowest level and conversely fully probabilistic approach the highest one. Generally structural assessment is carried out using limit state principles with characteristic values and partial safety factors. However, only the fully probabilistic approach provides quantitative information about safety level and hence it is increasingly supported. Its utilization is advocated also in *fib* Model Code 2010 (2012).

Within structure management, the non-formal assessment where the structural condition is evaluated on the base of visual inspections takes place at most. The objective of the structural condition assessment is to determine its current state and to assume the future performance of a structure with a maximum of accuracy and a minimum of effort. Therefore, advanced methodologies and deterioration predictive models for the assessment of structure/structural element over time are needed. Data collected during visual inspection should mainly provide the information about the most serious problems and suggest most suitable scheme of extension the inspection by monitoring, additional on-site measurements and/or laboratory tests. These should provide more realistic information about the input parameter values, when using modeling of degradation processes for prediction of future condition of the structure.

The aim of this contribution is to describe the process of possible calibration of parameters for prediction of deterioration due to chloride ion ingress into concrete with the emphasis on model based assessment. It is intended to explain the principles of structural evaluation and to feature the several levels of structural assessment, starting with simple but conservative methods and progressing to more sophisticated ones. The 'guideline' is to be aimed especially at existing concrete/reinforced concrete structures, such as bridges, located in mild European climate with deicing salt application.

2 CHLORIDE ION INGRESS MODELING

Reinforcement corrosion due to chloride ingress into reinforced concrete is one major process that is limiting the service life of reinforced concrete structures. Different approaches exist for description of the time-dependent process of chloride ingress into concrete (see e.g. Teplý et al. 2008). Due to inherent uncertainties in material, technological and environmental characteristics, stochastic models, dealing with probabilistic approaches and presenting the performance-related design of structures for durability, are recommended creating an effective tool for the assessment and prediction of time-dependent degradation processes; see *fib* Model Code 2010 (2012) and ISO 16204 (2012).

Chloride profiles can be modeled with relatively good approximation in many cases using Fick's second law of diffusion, describing a non-stationary diffusion process (Nilsson et al. 1996) and believing that the transport of chlorides into concrete is mainly diffusion-controlled (Hunkeler 2005). The widely used analytical models are based on the error function (Collepardi et al. 1972). In this contribution the focus is on the widely accepted model incorporated into the *fib* Model Code 2010 (2012) and fully probabilistic approach.

According to *fib* Bulletin 34 (2006), the Cl^- concentration at the depth x [mm] (the depth of concrete cover a [mm] is usually used) at time t [years], $C(x,t)$ [wt.-%/c] is calculated as:

$$C(x,t) = C_0 + (C_{S,\Delta x} - C_0) \cdot E$$
$$\text{with} \quad E = \left[1 - \text{erf}\frac{x - \Delta x}{2\sqrt{D_{app}(t) \cdot t}}\right], \tag{1}$$

where C_0 [wt.-%/c] is the initial Cl^- content in concrete, $D_{app}(t)$ [mm^2/years] is the time-dependent migration coefficient, 'erf' is the error function and $C_{S,\Delta x}$ [wt.-%/c] is the substitute surface Cl^- content in depth of convection zone Δx [mm]. Here, it should be noted that in a spray environment, the concrete close to the surface is often exposed to a frequent change of wetting and subsequent evaporation (so called splash conditions); this very zone is usually referred to as the 'convection zone'. As the transport mechanisms inside this convection zone are not mainly diffusion controlled, the approach of Fick's second law of diffusion yields no satisfactory approximation for chloride penetration inside the convection zone. In order to still describe the penetration of chlorides for an intermittent load using Fick's second law of diffusion, the data from the convection zone, which may deviate considerably from ideal diffusion behaviour, is ignored and Fick's second law of diffusion is applied starting at a depth of Δx with a substitute surface concentration of $C_{S,\Delta x}$ (Δx marks the depth of the convection zone). With this simplification, Fick's second law of diffusion yields a very good approximation of chloride distribution at a depth of $x \geq \Delta x$. At a distance to the road surface larger than 1.5 m (spray zone), the formation of a convection zone cannot be detected any more and the substitute surface concentration of $C_{S,\Delta x}$ is substituted for surface Cl^- content $C_{S,0}$ ($\Delta x = 0$ mm).

According to *fib* Bulletin 76 (2015), $D_{app}(t)$ can be determined based on the field data through chloride profiling method and subsequently, an ageing exponent is determined using two approaches:

$$D_{app}(t) = k_e \cdot D_{app}(t_0) \cdot \left(\frac{t_0}{t}\right)^{\alpha_A} \quad \text{or}$$
$$D_{app}(t) = k_e \cdot D_{RCM}(t_0) \cdot \left(\frac{t_0}{t}\right)^{\alpha_B}, \tag{2}$$

where α [-] is the ageing exponent assessed using approach A or B, t_0 [years] is the reference point of time, $D_{RCM}(t_0)$ [mm^2/years] is the migration coefficient based on the Rapid Chloride Migration (RCM) test method, and $D_{app}(t_0)$ [mm^2/years] is the effective diffusion coefficient at the reference point of time t_0 (different from time t) based on the field data through chloride profiling method. The environmental variable k_e [-] that takes into consideration the effect of temperature on chloride ingress into concrete is described in a simplified way by using the Arrhenius equation, in line with the temperature-dependent descriptions of the rate of corrosion and electrolytic resistance of concrete (Page et al. 1981, Raupach 1992):

$$k_e = \exp\left[b_e\left(\frac{1}{T_{ref}} - \frac{1}{T_{real}}\right)\right], \tag{3}$$

where b_e [K] is the temperature coefficient (proportional to activation energy), and T_{ref} [K] and T_{real} [K] are the reference temperature and the temperature of the structural element or the ambient air, respectively.

3 LEVELS OF ASSESSMENT

The values of input parameters for modeling of chloride ion ingress (see Table 1) can be assessed in different levels based on the input value precision and

accompanying uncertainties. The process is graphed using the flowchart in Figure 1 and can be itemized as follows:

1. As a starting position, a bridge structure or structural component can be assessed. In the case of new bridges, current standards are used with important information about concrete composition. For accurate prediction of structural deterioration due to chloride ingress, additional tests can be carried out to determine the diffusion characteristics of in common use or new material composition.

2. In the case of existing structure, the question 'What data are available?' arises. The assessment is carried out using the ISO and EN standards. Based on the data availability, three levels can be divided:

   (i) ***Level 1*** *– no inspection of the bridge was carried out and only information about material, load and environment from codes and other literature sources are available.*

   Structural requirements and recommended values of input parameters can be used according to European standards or other literature. These are based on former measurements and/or experience. For many of input parameters, using these values may not be quite accurate and realistic, consequently it may lead to very uncertain (sometimes even unsafe) results in modeling; see e.g. (Papworth and Gehlen 2016, Lollini et al. 2015, Pradelle et al. 2014) where the reliability level is assessed with different mean values for key variables;

   (ii) ***Level 2*** *– the design documentation (or birth certificate) is available and/or visual inspection of the bridge was carried out.*

   From design documentation, specific details on parameters important to the durability and service life of the structure concerned (e.g. age of the bridge, cover to reinforcement, cement type, water to cement/binder ratio, permeability, chloride diffusion properties of concrete, environmental conditions, quality of workmanship achieved, etc.) are available in order to define some of the input parameters properly. However, in prevailing number of cases, only basic input parameter, such as age of the bridge, is documented. On the contrary, if well documented (e.g. in the case of new bridge) and/or if some analysis were carried out for the material composition before its usage (e.g. in the case of new material composition), very important and more precise information about concrete composition and other material properties can be obtained. If unknown from design documentation, visual inspection is needed. Visual inspection will only detect visible damage of the structure. However, it might detect e.g. the development of structural deterioration and can be undertaken relatively cheaply over the whole structure at frequent time intervals. Results from a single visual inspection may be used to estimate the remaining service life, from which the timing of future inspection/maintenance can be determined based on the actual risk, and to identify what other tests should be undertaken in different areas. The conservation strategies and measures as well as condition survey and monitoring activities are also described in *fib* Model Code 2010 (2012);

   (iii) ***Level 3*** *– updated or realistic input values are available from on-site measurements (**Level 3a**) and/or supplementary laboratory tests (**Level 3b**).*

   If reliable data are not known from design documentation or visual inspection, additional on-site measurements and/or laboratory tests should be carried out. Tests may be carried out directly on the structure itself (in-situ testing) or on test specimens made in the laboratory or taken from the structure. Core samples may be taken to carry out detailed laboratory testing. Here, relevant ISO and EN standards; e.g. ISO 13822 (2010), EN 12504-1 (2009) and EN 12390-1 (2012) should be used. Non-destructive test methods and methods of sample analysis can be employed at intervals during the structure's life. Sampling for petrographic examination or wet chemical analysis might be called for where chemical attack is of concern due to the deterioration risk or due to low apparent surface strengths identified. Where the rate of chloride ingress is required (e.g. chloride profiles) to give the depth of corrosion activation front, test results can be used in conjunction with cover distributions established during construction to calculate the residual life; for more details see Concrete Institute of Australia (CIA) 2009.

Definitions of input parameters for modeling of chloride ingress using appropriate statistical characteristics, such as probability density function (PDF), mean value (μ), coefficient of variation (CoV) and limits (if needed) according to *fib* Bulletin 76 (2015), are summarized in Table 1. Test method is also mentioned for cases when parameter quantification is performed using on-site measurements and/or laboratory testing.

Table 1: List of input parameters for modeling of chloride ion ingress

Variable	Unit	PDF*	μ	CoV	Limits	Level	Method
Material parameters:							
CEM I–V	-	-	-	-	-	(1), 2, 3b	Petrographic analysis
w/c (w/b)	-					(1), 2, 3b	Petrographic analysis
C_0	wt.-%/c	D	0.1–0.4 (0)	-		1, 2, 3b	Chemical analysis
$D(t_0)^{**}$	m^2/s	N		0.20		1, 2, 3b	Chloride diffusion tests
α	-	B			(0; 1)	1, 3b	Chloride profiling method/Diffusion tests
Environmental parameters:							
T_{ref}	K	D (N)	293	-		1, 3a	On-site measurements/Nearest weather station
T_{real}	K	N				1, 3a	On-site measurements/Nearest weather station
b_{e}	K	N	4800	0.15		1, 3b	Chloride profiling method/Diffusion tests
Δx	mm	B (D)	10 (0)	0.50 (-)	(0; 50)	1, 3b	Chloride profiling method
$C_{\text{S},0}/C_{\text{S},\Delta x}$	wt.-%/c	LN		0.75		1, 3b	Chloride profiling method
Other parameters:							
t_0	years	D	0.0767	-		1, 2	
t	years	D		-		1, 2	
a	mm	N				1, 2, 3a	On-site non-destructive methods

Note: statistical definition is based on *fib* Bulletin 76 (2015)
*PDF = probability density function (B = Beta; D = Deterministic; LN = Log-normal; N = Normal)
** $D_{\text{RCM}}(t_0)$ or $D_{\text{app}}(t_0)$ can be used

When using recommended, i.e. uncertain values of input parameters for the estimation of chloride ion ingress over time, a noticeable improvement is possible if a prior (statistical) information gained by measurements taken from a real structure at a certain age is available. For this purpose Bayesian updating can be used. On-site measurements (chloride profiles in this case) are used to improve the estimations of chloride concentration over time as well as the reliability level of the structure. Starting from a-priori probabilities (estimated, or drawn from experience as well) additional information may be incorporated using Bayes' theorem thus arriving at a-posteriori probabilities that are proposed to be better estimates (Schneider 1997). Using Bayesian updating usually leads to lower variability of estimated results, thus the estimation of chloride concentration over time may be more realistic using this procedure.

4 CALIBRATION OF DIFFUSION PARAMETERS – CASE STUDY

Some of parameters can be obtained with sufficient accuracy only using more detailed laboratory tests and/or calibration processes. With utilization of chloride profiling method together with chemical analysis and chloride diffusion tests, chloride migration/diffusion coefficient at time, $D_{\text{RCM}}(t)/D_{\text{app}}(t)$, initial chloride content in concrete, C_0, surface chloride content, $C_{\text{S},0}$, eventually even substitute surface chloride content in depth of convection zone, $C_{\text{S},\Delta x}$, and the depth of convection zone, Δx, can be assessed. An ageing factor, α, which introduces the decrease of the chloride diffusion coefficient $D_{\text{app}}(t)$ in time, can be calibrated based on the above mentioned parameters.

The ageing exponent is dependent on both material

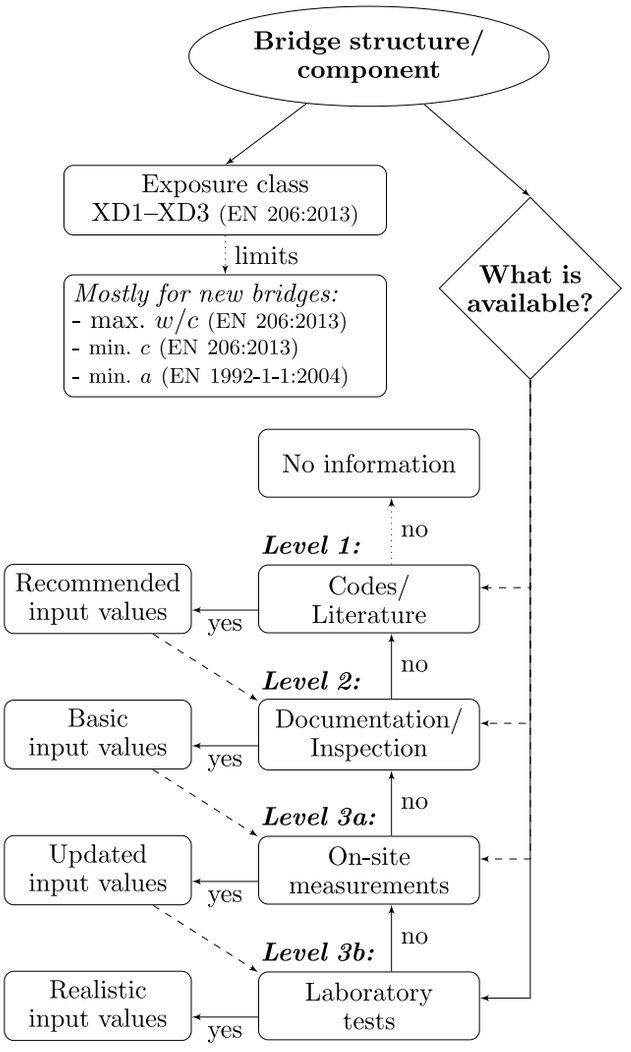

Figure 1: Levels of quantification of input parameters for modeling of chloride ion ingress

and exposure. In order to determine the ageing exponent, the long-term behavior of $D_{\text{app}}(t)$ of existing structures has to be considered by analyzing the development of chloride profiles over time. The process of quantification can be itemized as follows considering two possible approaches:

(i) *Approach A* can be used to determine the ageing exponent α_{A} by means of $D_{\text{app}}(t_0)$ and $D_{\text{app}}(t)$ from field data. In order to be able to quantify the ageing exponent, α_{A}, the values of $D_{\text{app}}(t)$ in at least two different points in time are required.

Effective diffusion coefficients, $D_{\text{app}}(t_0)$ and $D_{\text{app}}(t)$, and surface total chloride contents, C_{S}, are calculated based on the best fit of Fick's second law of diffusion; see Equation (1). Ageing exponent, α_{A}, is then quantified by a regression analysis using Equation (2).

(ii) *Approach B* can be applied in cases where a considerable amount of field data of concrete comparable to the design concrete is available. The ageing exponent α_{B} has to be determined by combining $D_{\text{app}}(t)$ obtained from the field data, and $D_{\text{RCM}}(t_0)$ of the design concrete from laboratory rapid chloride migration (RCM) test, i.e. $D_{\text{RCM}}(t_0)$ value has to be known.

It is assumed that chloride migration coefficient, $D_{\text{RCM}}(t_0)$, was simply determined by the RCM test method (see NT BUILD 492 1999) and substitutes the parameter $D_{\text{app}}(t_0)$ in Approach A. However, field data from real structures are needed to determine the ageing exponent, α_{B}. Effective diffusion coefficient, $D_{\text{app}}(t)$, and surface total chloride content, C_{S}, are then calculated in the same way as in Approach A.

As an example of calibration diffusion parameters using data from real structures, the railway bridge No. 4005026 from Gänserndorf to Marchegg in Austria was analyzed as a case study. The bridge was built in 1967 near Weikendorf as a one span reinforced concrete structure. The design documentation as well as the calculation from 1967 were available, hence the input variables could be defined in a realistic way. Furthermore, on-site measurements and/or laboratory tests were carried out within the inspection of the bridge in 2013, therefore some of parameters could be updated.

At first, only design documents and code recommendations (Levels 1 and 2 in Figure 1) were used for initial estimation of chloride content at reinforcement $C(a,t)$ over the design life, i.e. $t = 0$–100 years. The CEM II cement type was assumed as the most common cement used in Austria in the year of build (i.e. 1967) according to ÖNORM B3310 (1963). The water to cement ratio, w/c, was estimated for the concrete classes of abutments and supporting structure, i.e. B 225 and B 400 (corresponds to C16/20 and C30/37), based on the design documentation of the bridge. Since the information about type and quantity of additives was not available, material parameters $D_{\text{RCM}}(t_0)$ and α were quantified so that the values correspond with the values for CEM II/A-S type and prescribed w/c value (although the very detailed bridge design documentation was available, neither cement type nor w/c value were known in this case). The average annual temperature, T_{real}, was defined as the average temperature prevailing at a location over the 30-year period of time, i.e. 1981–2010. The average was calculated for Vienna, the nearest station to the location of the bridge using data from World Meteorological Organization (2017). Statistical definition of all input parameters is summarized in Table 2. Here, it should be noted that the XD3 exposure class was assumed, which means splash conditions and elements of bridge closer than 1.5 m from the road (e.g. abutments).

Figure 2: Analyzed bridge

In the second step, the data from measurements and laboratory tests carried out within the inspection in 2013 (Levels 3a and 3b in Figure 1) were used for model updating to gain more accurate results. Definition of input parameters is summarized in Table 3 where updated/changed values are highlighted in grey color. The updated estimation of chloride content was performed in the same way as in the case of initial estimation for the remaining life time of the bridge, i.e. $t = 46$–100 years.

Since the petrographical analysis of concrete was not carried out, the CEM II/A-S with $w/c = 0.45$ was kept without changes. Based on the cement type the $D_{\text{RCM}}(t_0)$ value was specified as in the case of initial estimation. The concrete cover a was specified based on the Ferroscan reinforcement detection analysis. Other updated parameters, namely the $D_{\text{app}}(t)$, Δx, $C_{\text{S},\Delta x}/C_{\text{S},0}$ and α, were defined based on the chloride concentration analysis. Eight chloride profiles from the bridge abutments (see left part of Figure 3) were used for quantification of the parameters using fitting of Equations (1)–(2). The 'mean' chloride profile was used for quantification of parameters $D_{\text{app}}(t)$, $C_{\text{S},\Delta x}$, Δx and α. Mean value and standard deviation of measured chloride concentrations in the depth of reinforcement ($a = 30$–45 mm) were $\mu = 0.65$ wt.-%/c, $\sigma = 0.9$ wt.-%/c. As in the case of initial estimation, splash conditions were assumed.

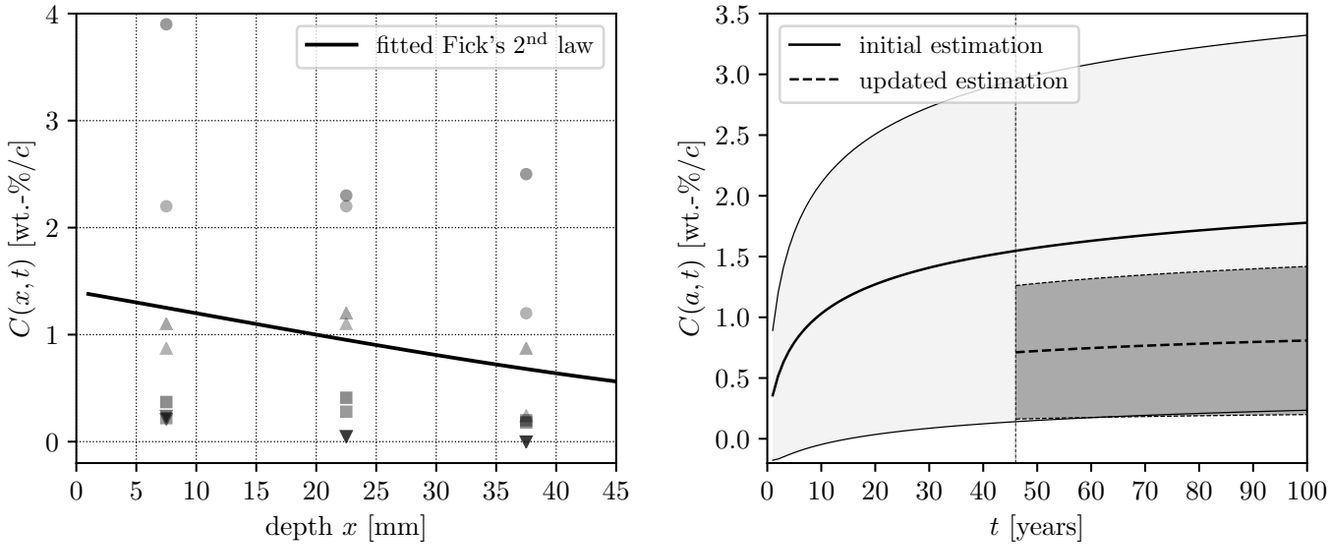

Figure 3: 'Mean' Cl^- profile obtained from Cl^- profiles of analyzed bridge abutments (left); Development of mean value and standard deviation of chloride concentration $C(a,t)$ of analyzed bridge over time t (right)

A fully probabilistic approach was used for estimations of chloride content over time. A thousand random realizations of input basic variables were simulated using the stratified Latin Hypercube Sampling method. The calculations of $C(a,t)$ over time were performed according to Equations (1)–(3) repeatedly for an individual vector of realizations of input random variables and then statistically analyzed to obtain the mean value and the coefficient of variation of $C(a,t)$. The development of mean value and standard deviation of $C(a,t)$ over time t is displayed in Figure 3 (right) using solid lines for initial estimation and dashed lines for estimation with updated values of input parameters.

As obvious from Figure 3 (right), there is a high variability of results when chloride concentration at reinforcement is estimated based on the literature recommendations only. Even information from detailed bridge documentation didn't help in this case since the most important information about concrete composition were missing. Using data from measurements and/or laboratory tests leads to more accurate results, following the current state of the analyzed structure (or its part) and environmental factors.

Using 'mean' chloride concentration obtained from analyzed chloride profiles led to realistic estimation of chloride concenration with much lower variability in results. However, more accurate estimation of chloride concentration can be predicted when the distance of chloride profiles to the road surface is taken into account. Chloride profiles can be classified into two groups based on the location on the abutments and values of $D_{\text{app}}(t)$ and $C_{\text{S},\Delta x}/C_{\text{S},0}$ can be defined based on the best fit of Equation (1) separately for profiles under splash and spray conditions, respectively. Here, results based on the 'mean' profile can be rather underestimated/unsafe for locations in the splash zone (i.e. the distance to the road less than 1.5 m). On the other hand, for locations in the spray zone, results assessed based on the 'mean' profile can lead to uneconomic treatment within the life cycle management of structures in this case.

5 CONCLUSIONS

Different levels for the efficient determination of the input parameters for the modeling of chloride ion ingress into concrete were described. Based on the data availability and the input value precision and accompanying uncertainties, three levels for the quantification of input parameters can be distinguished:

(i) Level 1 – no inspection is carried out and only information about material, load and environment are available. Values of input parameters can be used according to European standards;

(ii) Level 2 – the design documentation is available and/or visual inspection is carried out. From design documentation, specific details on parameters (e.g. cover to reinforcement, cement type, water to cement/binder ratio, permeability, chloride diffusion properties of concrete, environmental conditions, quality of workmanship achieved, etc.) are available in order to define some of the input parameters properly;

(iii) Level 3 – updated or realistic input values are available from on-site measurements and/or supplementary laboratory tests. The most suitable scheme of extension the inspection by monitoring, additional on-site measurements and/or laboratory tests should be suggested during visual inspection.

Regarding realistic estimation of the deterioration level of the structure, the calibration of diffusion parameters for prediction of deterioration due to chloride ion ingress into concrete with the emphasis on model based assessment was the aim of this contribution. Two possible approaches for the calibration of ageing factor based on the diffusion characteristics of concrete were described. Approach B was used in the case of reinforced concrete railway bridge in Austria.

It has been proven, that an improvement is possible if the statistical information regarding behavior gained by the analysis is combined with prior statistical information gained by measurements taken from a real structure at a certain age. For this purpose chloride profiles at the age of 46 years were used to improve the estimation of chloride content over time. Using data from laboratory tests led to more accurate results, following the current state of the analyzed structure and environmental factors. Data collected during visual inspection and results of supplementary laboratory tests (Level 3) provided more detailed information about the chloride concentrations. Based on the chloride profiles, diffusion parameters were updated. The chloride concentration at reinforcement was predicted over time and compared with the one assessed based on input parameter values according to design documentation and code recommendations only (Levels 1 and 2).

In-service stress and strain behavior of Missouri Bridge A7957

H.H. Alghazali & J.J. Myers
Missouri University of Science and Technology, Rolla, MO, USA

ABSTRACT: In this contest, bridge A7957 was designed and erected on HWY 50, Missouri State, USA, for in situ investigative studies to evaluate strains and stresses over different stages taken into account the effect of prestress losses. The bridge was designed with a concrete mixture of different mechanical and rheological properties. High strength concrete, high strength-self consolidating concrete and normal strength-self consolidating concrete were used to construct bridge girders. The bridge girders were instrumented with vibration wire strain gages to monitor the strains from concrete casting stage to the service life. The measured stresses (from strain readings) were compared to design limitation adopted by ACI 318-14. Based on the analysis of the test results, the measured compressive stresses at mid-span bottom fiber are higher than design compressive stresses for all the beams at release stage. Also, there are no substantial changes in the compressive strain level after 300 days.

1 INTRODUCTION

Monitoring the stresses within a concrete structure is absolutely necessary for sound design, especially when new concrete [self-consolidating concrete (Daczko (2012), ACI Committee 237R (2007))] is used in the construction. In prestressed concrete girders, stress and strain subject to change over a period of time, during which creep and shrinkage of concrete and relaxation of steel develop gradually. In sequence, concrete modulus of elasticity increases also with its age (Shahawy and Arockiasamy (1996)). Due to the progressive increase of concrete strains with time, considerations should be taken during design members with a new type of concrete.

A limited number of full-scale studies have been conducted to monitor the strain and stress time history of prestressed HS-SCC beams. In a recent study by Myers and Block (2010) at Missouri University Science and Technology, two precast prestressed high-strength concrete (HSC) and HS-SCC bridges were instrumented. The researchers found that the HSC bottom fiber compressive strains at release tended to be about 27% higher than predicted, and the bottom fiber HS-SCC compressive strains at release tended to be about 14% higher than predicted. During erection, they reported that the HSC had an average percentage difference of 60% and the HS-SCC 50% between actual and theoretical strain data (Myers and Block (2010)).

In this study, concrete stresses were not measured directly. Stresses were determined by multiplying measured strains by the measured modulus of elasticity. The objective of this study is to evaluate the strains and stresses developed in the girders with emphasis on types of measurements related to design calculations, as well as measurements that have a significant influence on the overall structural behavior of the bridges and their components. Obviously, strain measurements prior to the release of prestressing strands, immediately after the release of prestressing strand, erection, and service were considered as key stages for this study.

2 BRIDGE DESCRIPTION

A three spans bridge (A7957) with PC/PS concrete girders was utilized in this study. The A7957 Bridge on Highway 50 is located in Osage County, Missouri was designed to be simply supported for dead load and continuous for live load via a CIP deck. The two exterior spans are 30.5 m long and one interior is 36.6 m long. The target 28-day compressive strength of HSC and NS-SCC was 55.2 MPa and the specified release strength was 44.8 MPa. However, HS-SCC had 68.95 MPa target 28-day compressive strength and a release compressive strength of 55.2 MPa. The mixture proportions of each type of concrete are presented in Table 1.

Table 1. Concrete mixture proportions.

Material	Quantity		
	HSC	HS-SCC	NS-SCC
Portland Cement – Type I, (kg/m^3)	475	504	445
Water, (kg/m^3)	152	166	155
19 mm Crushed Stone, Coarse Aggregate (kg/m^3)	1056	---	---
12 mm Crushed Stone, Coarse Aggregate (kg/m^3)	---	795	876
River Sand, (kg/m^3)	644	850	850
Air Entraining Agent, (ml/m^3)	309	658	658
Type D Water Reducer and Retard, (ml/m^3)	356	2959	2611
Type F High Range Water Reducer, (ml/m^3)	665	986	986

3 MONITORING SYSTEM AND STRAIN MEASUREMENTS

HSC, HS-SCC, and NS-SCC girders were produced for spans 1, 2, and 3 of the A7957 Bridge, respectively. They were instrumented to obtain data for the measured strain and temperature. Instrumented girders are named as following: S1-G3, S1-G4, S2-G3, S2-G4, S3-G3, and S3-G4. A total of 86 vibrating wire strain gauges with built-in thermistors (type EM-5) were utilized to measure the strain and temperature for the PC/PS girders. The standard pattern in the mid-span consisted of five gauges over the height of the girder and two more in the slab above the girder. The data from the VWSGs were recorded by a data acquisition system (DAS). The DAS used was Campbell Scientific CR800 box which works wirelessly. Measurements were taken at five-minute intervals. The measuring strain was corrected due to the thermal effect.

4 MATERIAL PROPERTIES

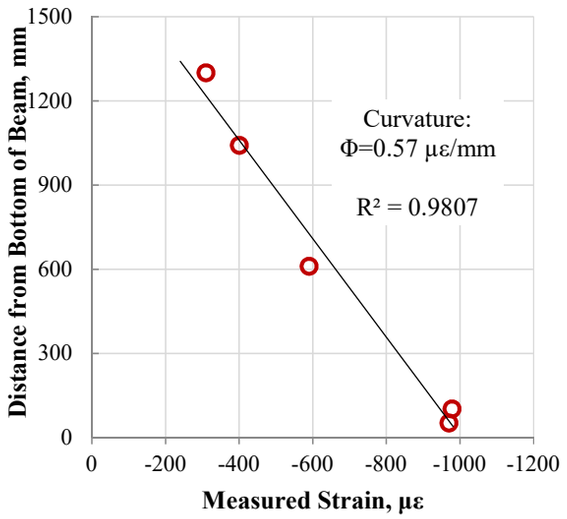
Material property tests were performed on specimens collected from the same batch of concrete girders to have adequate predictions for the stresses. All the tests follow standard ASTM guidelines. A summary of the tests, test methods, and results are presented in Table 2.

5 RESULTS AND DISCUSSIONS

The VWSGs embedded in the concrete girder were utilized to measure strains in all the stages below. Strains are monitored with the temperature at the same locations. Strains are relative to baseline strain reading taken right after placement of concrete. Compressive strains are defined negative while tensile strains are defined as positive in this study. Since only compressive strains were observed in this paper, the maximum compressive strains at bottom fiber mid-span were discussed and compared with theoretical values and ACI Code limits.

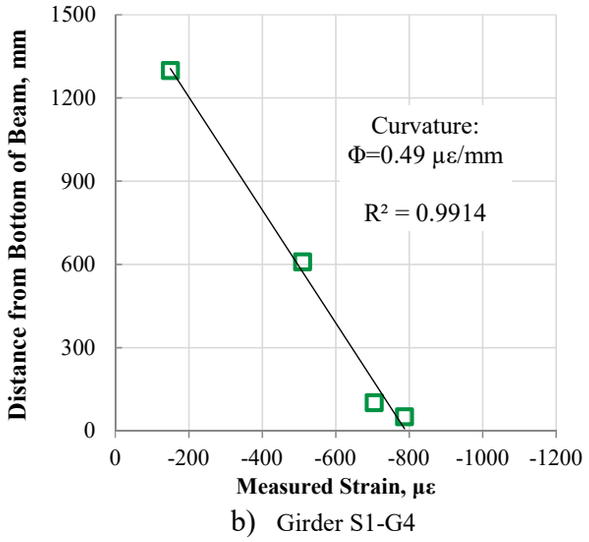
5.1 *Concrete Strains after Release of Prestress*

The concrete strength is relatively low at this stage and checking the stresses is essential in design. Strain readings were recorded before and after the release of the prestress tendons. The stress values were estimated by multiplying the strain values with the mixture's measured modulus of elasticity and compared to the predicted stress (σ design) values demonstrated in Eq. (1). Figure 1 through Figure 3 illustrate strain data points at mid-span of the HSC, HS-SCC, and NS-SCC beams, respectively. A regression line was fit to the measured release strains for each beam. All HSC, HS-SCC and NS-SCC beams had an R2 range from 0.96 to 0.99. The values are relatively close to 1 indicated that plane section of the beam remained plane. The average curvature caused by prestressing release at mid-span in the HSC, HS-SCC, and NS-SCC beams were 0.53 με/mm, 0.41 με/mm, and 0.52 με/mm, respectively. It is apparent that both HSC and NS-SCC beams exhibited higher curvature than HS-SCC.



$$\sigma_{design} = -\frac{P}{A} \mp \frac{P.e.y}{I} \pm \frac{M_{self}.y}{I} \quad (1)$$

Where P is prestressing force, A is the cross-sectional area, I is the moment of inertia, e is the eccentricity, y is the distance from bottom or top to the centroid, and M is the moment applied due to self-weight or external load. In addition, ninety percentage of the original load at release was assumed for the prestressing force (Nawy (2009)).



Comparison between measured stresses determined from linear regression with design and allowable stresses limited in ACI code (ACI Committee 318 (2014)) is presented in Figure 5. For all beams, measured compressive stresses at mid-span bottom fiber are higher than design compressive stresses. The differences range between 11-49%. However, when comparing with allowable stresses level, the compressive stresses at mid-span bottom fiber meet requirement for most beams expect beams S1-G3 and S3-G3. The measured compressive stresses for S1-G3 and S3-G3 were 7% and 20% higher than allowable stresses, respectively.

Table 2. Summary of fresh and hardened properties tests and results.

Tests	Member (Span-Girder)					
	S1-G3	S1-G4	S2-G3	S2-G4	S3-G3	S3-G4

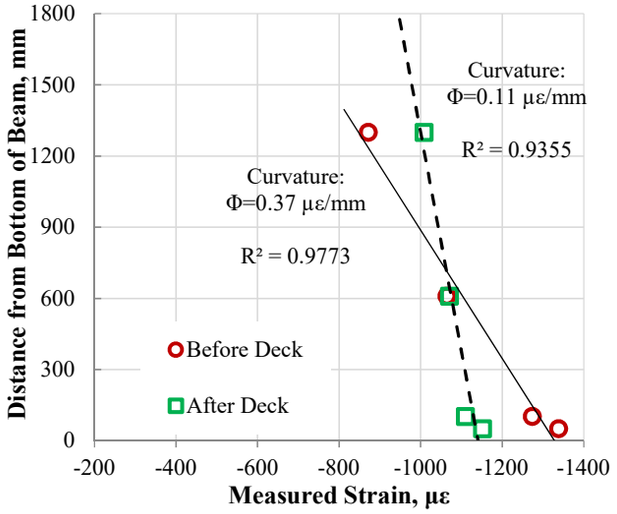
5.2 *Concrete Strains before and after Deck Placement*



Due to time-dependent effects, prestressed concrete girders continue to deform after strand release (Alghazali and Myers (2015), Alghazali and Myers (2015)). The time-dependent losses included creep, shrinkage, and relaxation losses. Concrete strains were measured before and after deck placement using vibration wire strain gauges and the readings were corrected for thermal effect.

The time-dependent strains behaviors at mid-span section for all monitored girders are shown in Figure 5 through Figure 7. It is clear that from the strain profiles there is a significant decrease in the compressive strains for all girders after deck placement. Also, it can be inferred from strains profiles that HSC experienced more curvature growth than HS-SCC and NS-SCC after release and before deck placement.

The casting of the bridge deck and placement of precast deck panels are applied additional load to prestressed concrete beams (Myers and Yang (2005)). Measuring the stresses in this stage is essential for the design of highway bridges under service loads, which it is generally desired to prevent cracking (Gross (1999)). As shown in Figure 5 through Figure 7, the plane sections remained plane in all beams. HS-SCC beams exhibit significant curvature change than HSC and NS-SCC beams because the HS-SCC beam has a length 20% longer than HSC and NS-SCC beams.

5.3 *Concrete Strains during Service*

Concrete strain history of the bridge girders is illustrated in Figure 10. Since monitoring of the bridge is ongoing, two ages were picked up to evaluate the concrete strain in service life (after 300 days and 900 days) to see the effect of long-term losses on strain change. As shown in Figure 8, there is an increase in compressive strain for all beams due to the creep effect. HSC and NS-SCC beams exhibited higher strains increase than HS-SCC. The stress increase for all beams ranges between 10 to 25%. Obviously, there are no substantial changes in the strain levels after 300 days.

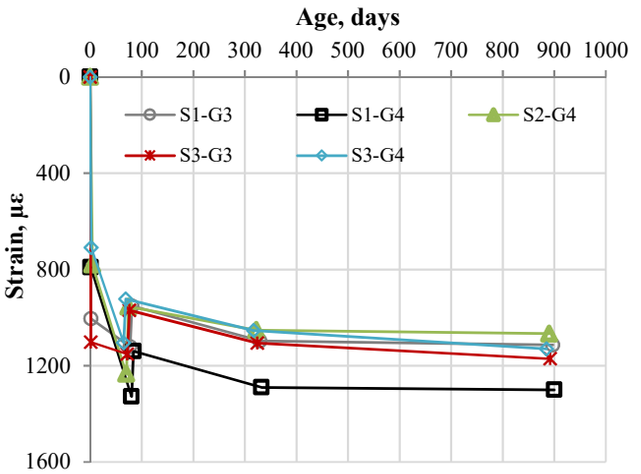

Figure 8. Strains versus time in the concrete in prestressed concrete girders.

6 CONCLUSION

This full-scale study was conducted to monitor strain behavior of prestressed concrete beams constructed with different concrete type. Based on this research, the following conclusions can be drawn:

1. Monitoring system is successfully recording the strains and temperatures in the girders of bridge A7957;
2. Measured strains due to release were fitted linearly. The R^2 values range from 0.96 to 0.99, which exhibits plane sections prior to the release of prestressing remain plane after release;
3. At release, measured compressive stresses at mid-span bottom fiber are higher than design compressive stresses for all the beams. The differences range between 11-49%;
4. HSC beams experienced more curvature growth than HS-SCC and NS-SCC beams after release and before deck placement;
5. In general, there are no substantial changes in the strain levels after 300 days.

7 ACKNOWLEDGEMENT

The writer would like to acknowledge the financial support provided by Missouri Department of Transportation (MoDOT) and the National University Transportation Center (NUTC) at the Missouri University of Science and Technology (Missouri S&T). The support received from the Department of Civil, Architectural, and Environmental Engineering and the Center for Infrastructure Engineering Studies at Missouri S&T are also highly appreciated.

ABSTRACT: This paper focuses on the numerical assessment of the load-carrying capacity of a stone arch railway bridge. The nonlinear analysis is based on 3D finite element models of the bridge under incremental static loading representing the railway traffic with appropriate configurations on the bridge deck. The numerical model of the constitutive material behaviour is defined based on the results of an experimental campaign covering material testing for characterization of masonry and infill components of this type of bridges.

1 INTRODUCTION

Numerical modelling strategies to evaluate the structural response of stone arch bridges with realistic service and limit loading conditions, settlements, material and structural composition can provide better understanding of the structural behaviour and contribute to help on implementing suitable management plans for this type of bridges.

The simulation of the structural behaviour of masonry bridges can usually be achieved by means of computational resources based on the Finite Element Method (FEM). These modelling technique allow evaluating the load capacity of stone arch bridges by incrementing the traffic loads included in the structural modelling and taking into account the nonlinear behaviour of bridge materials and suitable conditions for the geometrical discretization. Computational methods resorting to the Distinct Element Method (DEM) and the rigid blocks and limit analysis are also frequent for simulating the load-carrying capacity of stone masonry arch bridges.

The interaction between the structural elements of the bridge and its material behaviour is the main aspect to be represented by structural modelling. Therefore, suitable constitutive models of the bridge materials defined and supported by experimental results is as crucial contribution for the validation of the structural numerical models.

The FE modelling strategies representing the mechanical behaviour of the masonry components can be based on detailed strategies, also called simplified micro-models and continuous homogeneous models. In the first type of models, the blocks are modelled as homogeneous sub-regions using conventional solid elements and the contacts between blocks are simulated by interface elements. Usually, the nonlinearity of masonry mechanical behaviour is concentrated in the joint elements and the material of the blocks is considered with linear elastic behaviour. For highly-refined finite element meshes these micro-models allow detailed analyses with particular interest in zones where the stress field is strongly heterogeneous. Regarding the continuous models, an equivalent continuum is defined with characteristics that allow the description of the global behaviour of masonry as a composite material. In general, the material behaviour is considered isotropic; however modelling strategies including the anisotropy can also be found in the literature. The constitutive laws are established in terms of stresses and strains, and there are several different ways to formulate the problem such as the plastic models or damage models. These modelling strategies are particularly suitable for coarser finite element mesh allowing global analyses of the whole structure (or of a part of it). Continuous homogeneous models can also be used to represent the infill material. In this case, the FE mesh is composed of solid elements supporting a continuous model representative of the infill.

2 BRIDGE MODEL

2.1 *Brief description of the bridge*

The Côa bridge dates back to the late 1940s and has a structural system made of granite masonry arches as shown in Figure 1. The bridge is located in Beira Alta line which constitutes a rail link between the Portuguese main railway track (Norte line) near Coimbra and the border with Spain in Vilar

Formoso. The bridge consists of eight arches, one with 38 m span and seven with 20 m, which are supported onto seven piers and two abutments. The total length of the deck is about 238 m with a longitudinal rectilinear profile and 4.8 m width which supports one single-track. The maximum gap between the bridge ground level and the railroad is approximately 56 m high.

(a) (b)

Figure 1. Côa railway bridge: (a) general view and (b) freight traffic.

2.2 *FE bridge model*

The numerical model of the bridge, illustrated in Figure 2, consists of a 3D finite element discretization developed in ANSYS software, based in a previous work published in Jorge *et al.* (2016). This model was calibrated based on the identification of the bridge modal characteristics from measurements obtained in ambient vibration test complemented with sensitivity analyses and an optimization process, also referred to in a companion paper submitted to this conference by the authors.

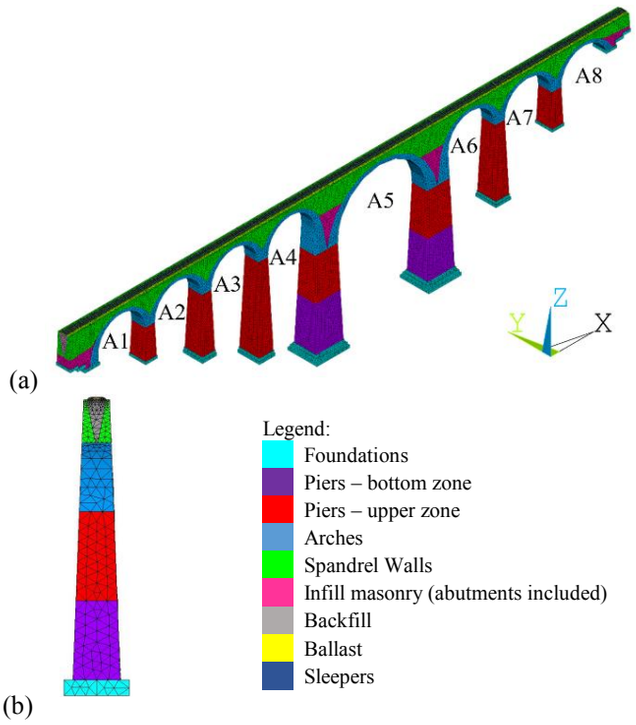

Figure 2. FE model of Côa Bridge: (a) perspective view and (b) cross section.

The bridge structural elements are modelled using tetrahedral finite elements with ten nodes and three degrees of freedom at each node (Solid 92) available in ANSYS elements' library. The rails are modelled by beam finite elements. In total the model has 442175 elements.

The initial boundary conditions were set using rigid supports to fix the displacement x, y and z of the mesh nodes located at the base of the foundations and embankments.

The masonry elements were modelled using a homogeneous composite material with equivalent mechanical properties so as to reproduce the properties of the assembly formed by stone blocks and mortar. The materials' nonlinear behaviour was simulated using the Drucker-Prager model implemented in ANSYS software. The mechanical properties were defined to represent a hypothetical scenario, where the bridge materials have some level of degradation as detailed later in Section 3.

2.3 *Load modelling*

The bridge structural response was evaluated under the influence of its self-weight and incremental static loading representing a standard train distributed along the bridge deck.

The static loading scheme used in the bridge analysis is represented by the load model LM71 proposed by UIC to simulate the envelope of several types of trains. The load configuration of the LM71 model is also used as a design load for railway bridges according to Eurocodes (EN1991-2, 2003) with the characteristic values shown in Figure 3 for bridges in rail tracks with normal traffic.

In railway lines with heavier or lighter traffic than the normal one, the characteristic values of LM71 loads are multiplied by a factor α. When multiplied by this factor, the loads are also called "classified vertical loads". The factor α ranges between 0.75 and 0.91 for rail tracks with lighter traffic and between 1.10 and 1.46 for the case of heavier rail traffic. In the analysis of Côa bridge the factor α was considered equal to 1.46, to account for its location in an international line (Beira Alta line) with heavy traffic of freight trains.

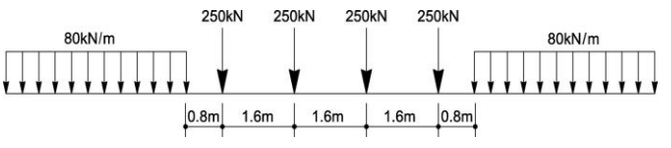

Figure 3. Load model of LM71 (EN1991-2, 2003).

The vehicle load position (see Figure 4) was defined from the most unfavourable position for the principal arch (A5) identified in a previous work from the analysis of the bridge under moving loads (Jorge *et al.*, 2016). For maximizing the defor-

mations in the principal arch, the uniform load of the LM71 model was not considered.

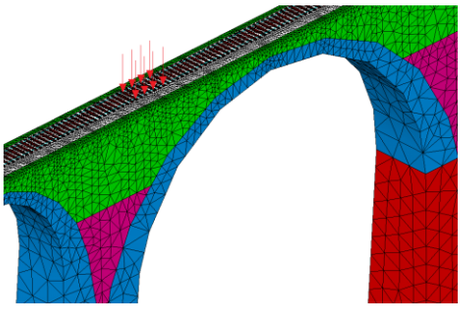

Figure 4. LM71 point loads applied in the zone of arch A5.

The static response of the bridge was therefore evaluated with the numerical model presented previously considering incremental levels of intensity of the vehicle load placed on the rail beam element near the ¼ span of the principal arch. The loading history includes an initial phase of equilibrium of the dead load which was applied incrementally. After the first phase, the vehicle loading was applied considering incremental levels of intensity.

3 HOMOGENIZED MATERIAL PARAMETERS

The assessment of the load-carrying capacity resorting to FE global models requires the definition of material models which should be able to represent adequately the material behaviour in the plastic domain. For that purpose a detailed characterization of the bridge materials by performing suitable material testing is a valuable mean to achieve this goal.

Since no experimental testing was performed for mechanical characterization of the Côa bridge materials, it was defined a hypothetical scenario for material modelling based on the parameters of another masonry bridge, the PK124 bridge, where a detailed experimental campaign was performed for material characterization. The details of this campaign and the obtained results can be found in another paper published by the same authors (Arêde *et al.*, 2017). Although this hypothetic scenario set up a more severe condition of material degradation, it also can be compared with the real one.

3.1 *Experimental characterization of materials*

The PK124 railway bridge illustrated in Figure 5a, is a culvert type bridge constructed in 1879, located in Minho line of the Portuguese railways. It is a short masonry bridge, consisting in only one single arch with 11 m length. PK124 bridge is 60 years older than Côa bridge, and its masonry is in a different weathered condition than Côa bridge, with a more deteriorated masonry.

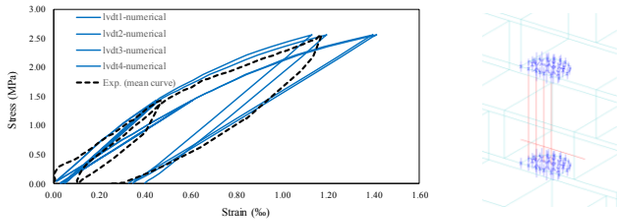
The experimental campaign carried out in PK124 bridge involved laboratory tests for mechanical characterization of the stone and masonry joints. The i*n situ* material characterization comprised core extraction of masonry and stone samples from the bridge, two Ménard Pressuremeter Tests (PMT) in the infill material and double flat-jack tests in the masonry component. The *in situ* masonry stress and deformability properties were estimated from single and double flat-jack tests, respectively. These tests were performed in the masonry of the abutment zone (see Figure 5b).

(a) (b)

Figure 5. PK124 railway bridge: (a) general view of the bridge intrados, (b) pressiometer and (c) flat-jack *in situ* tests.

The infill material found in PK124 bridge is more similar to rock than soil, consisting of a mixture of mortar with variable size granite pieces. Therefore, the pressuremeter tests performed in the bridge never reached pressures capable of yielding that material, resting well below the threshold values for plastic deformation (Arêde *et al.*, 2017). However, based on the result curves obtained in these tests, it was possible to obtain deformability parameters, the pressuremeter deformation modulus (G_{PMT}) and the pressuremeter modulus (E_{PMT}). These values were useful for estimating the infill deformability modulus (E) for use in numerical simulations.

The lab tests allowed the physical and mechanical characterisation of the granite stone collected from the bridge and the characterisation of the joints behaviour, by the definition of strength and deformability parameters obtained from shear and compressive tests. Data collected from these tests was used to define the properties used for the Côa bridge analysis.

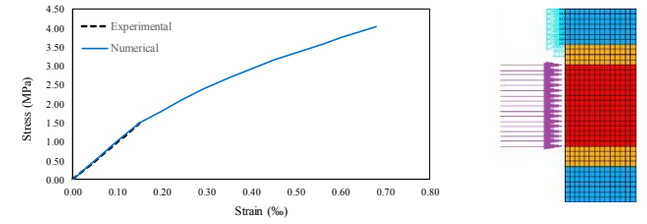


3.2 *Homogeneous material proprieties*

3.2.1 *Methodology*

Aiming at calibrating and validating the material parameters to be adopted in the bridge nonlinear model, a methodology resorting to the simulation of the double flat-jack tests was developed based on previous work (Costa *et al.*, 2017). With the same objective, the simulation of pressuremeter tests was also performed.

For this purpose, a nonlinear model of the double flat-jack test was defined using modelling strategies similar to those used in the bridge model (see test scheme in Figure 6b), therefore resorting to 3D FE



global models using the Drucker-Prager model to represent the constitutive behaviour of masonry. The material parameters assigned for the flat-jack model were then adjusted to obtain good agreement between the experimental parameters recorded with the flat-jack test and the corresponding parameters obtained by numerical simulation. Figure 6a shows a plot of the response obtained in the flat-jack tests in terms of the evolution of LVDTs deformation with the pressure applied by the flat-jacks, allowing to verity a good agreement between experimental and numerical results.

(a) (b)

Figure 6. Stress *vs.* strain of flat-jack tests: (a) numerical results in blue and experimental results in black, (b) test scheme.

The numerical modelling of the pressuremeter tests were based on a 2D axisymmetric FE model, also using the Ducker-Prager model for defining the material constitutive behaviour (see Figure 7b). The results shown in Figure 7a in terms of the evolution of the deformation with the pressure applied in the measurement zone, allow to compare the numerical and experimental results in the pseudo-elastic phase of the test (Arêde *et al.*, 2017) where good agreement is found.

(a) (b)

Figure 7. Stress *vs.* strain of pressuremeter tests: (a) numerical results in blue and experimental results in black, (b) test scheme.

3.2.2 *Material proprieties*

As a result of the strategy described in previous paragraphs, the elastic material properties of masonry in the bridge zones of foundations, piers, arches and spandrel walls are characterized by the elastic modulus, Poisson's ratio and unit weight listed in Table 1. The elastic characteristics of the infill material in the backfill zones estimated by the pressuremeter tests are also summarized also in Table 1.

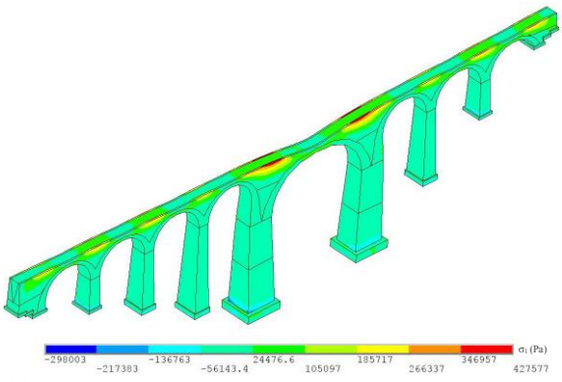
Table 1. Elastic parameters of masonry and infill materials.

Parameter	Material	Adopted value	Unit
Elastic modulus	Masonry	2.0	GPa
	Infill	0.32	GPa
Poisson's ratio	Masonry and infill	0.2	-
Unit weight	Masonry	24.5	kN/m^3
	Infill	21.5	kN/m^3

For nonlinear behaviour of masonry, in the arches, spandrel walls and piers and in the infill material, in the backfill zones, the Drucker-Prager model was defined considering elastic-plastic behaviour with no dilatancy and the values of the friction angle and cohesion summarized in Table 2. Which definition consisted in the experimental characterization referred in section 3.1, and supported in numerical simulations of the flat-jack and the pressuremeter tests referred in section 3.2.1.

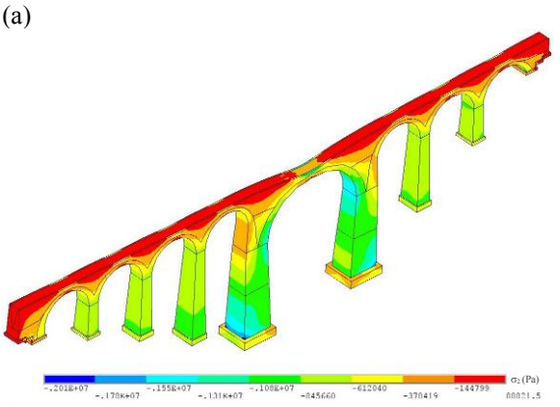
Table 2. Drucker-Prager parameters for masonry and infill.

Parameter	Material	Adopted value	Unit
Cohesion	Masonry	450	kPa
	Infill	900	kPa
Friction Angle	Masonry	35.5	º
	Infill	35.5	º



4 ANALYSIS OF THE BRIDGE RESPONSE

This section focuses in the bridge response considering the nonlinear behaviour of the bridge and intensity load levels (multipliers) of a nominal train load. The evolution of the structural response of the FE model concerning the effect of the dead load and the vehicle load are presented and discussed for six levels of incremental intensity of the vehicle load, ranging from 0 to 14, the latter being the maximum multiplier that was possible to be applied.



The numerical simulation is performed considering the action of the incremental static loading simulating the LM71 model. For this purpose, eight point loads with 182 kN each, representing four vertical axels spaced of 1.6 m, are considered as described in section 2.3.

4.1 *Results of service loading. DL+1P*

The response parameters of the numerical model is shown in Figure 8 in terms of the results of the maximum principal stresses (mainly tensile) and minimum principal stresses (mainly compressive) for the load level of the bridge weight and the vehicle with intensity of 1P, where P represents the nominal vehicle load. The results reflect the level of stress under service loads (reference loading). The maximum tensile stress occurs in the spandrel wall with a value of 0.43 MPa and the maximum compressive stress occurs in the base of the central pier with 2 MPa.

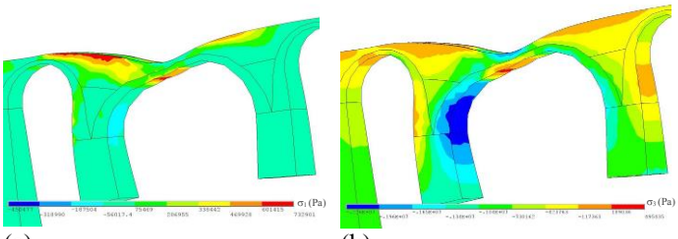
(a)

(b)

Figure 8. Stress level in the bridge deformed configuration under service conditions (DL+1P): (a) maximum principal stresses and (b) minimum principal stresses.

The results shown in Table 3 summarize the bridge numerical response for the dead load and for 1P intensity level of the vehicle loading, in terms of the vertical displacement registered in the principal arch, and the maximum and minimum principal stress found in the arch and in the spandrel walls.

Table 3. Response parameters in the arch and spandrel walls: displacements and principal stresses.



Intensity level	Element	dv mm	σ_1^+ MPa	σ_3^- MPa
DL	Spandrel	-	0.40	-1.38
	Arch	44.06	0.36	-1.41
DL+1P	Spandrel	-	0.43	-1.43
	Arch	45.60	0.36	-1.50

For this load level it was verified that the bridge response is still in the elastic domain (no plastic deformation was achieved in this step of analysis), with additional maximum displacements of 1.5 mm in the crown zone of the principal arch. Also, the intensity of the live load is small, so the additional stresses induced in the arch and spandrel walls are very low.

4.2 *Results of plastic evolution and maximum loading. DL+14P*

The structural response of the bridge model for the load level of the bridge weight and the vehicle with intensity of 14P (the maximum force applied) is shown in Figure 9. The results show the deformed configuration and the level of stress, in terms of maximum principal stresses and minimum principal stresses, for this step of loading, zooming the bridge area of the main arch, where the load is applied.

Table 4 summarizes the corresponding response values of the bridge model when the maximum intensity level was applied, 14P. Aiming for comparison, the results of intensity levels 5P and 10P are also included in Table 4.

(a) (b)

Figure 9. Stress level in the bridge deformed configuration for the final loading step (DL+14P): (a) maximum principal stresses and (b) minimum principal stresses.

The maximum displacement in the crown of the arch is around 80 mm. Both maximum and minimum principal stresses occur in the arch with values of 0.73 MPa and -2.26 MPa, respectively. For this intensity load level the response of masonry of the arch and the spandrel walls exhibit nonlinearity, as detailed in following paragraphs by the analysis of the plastic strain evolution.

Table 4. Response parameters in the arch and spandrel walls: displacements and principal stresses.

Level of intensity	Element	dv mm	σ_1^+ MPa	σ_3^- MPa
DL+5P	Spandrel	-	0.61	-1.65
	Arch	53.83	0.42	-1.84
DL+10P	Spandrel	-	0.61	-1.91
	Arch	65.34	0.59	-2.14
DL+14P	Spandrel	-	0.62	-1.95
	Arch	79.81	0.73	-2.26

Figure 10 and Figure 11 show the state of plasticity in terms of its principal components in the bridge central zone of the main arch. The figures allow observing the plasticity evolution for the intensity levels of 5P, 10P, 12P and 14P.

Table 5 summarizes the corresponding values for the plastic strains in maximum and minimum principal directions obtained for the same five different intensity levels considered in the bridge analysis.

The results allowed to verify that the plasticity in the main arch starts around the intensity level of load of 5P; and for the maximum applied force, DL+14P, the maximum principal plastic strain (0.694‰) is located in the extrados of arch, near the crown under the loading zone, and the minimum principal plastic

strain (-0.548‰) is in the base of the arch, also in the extrados.

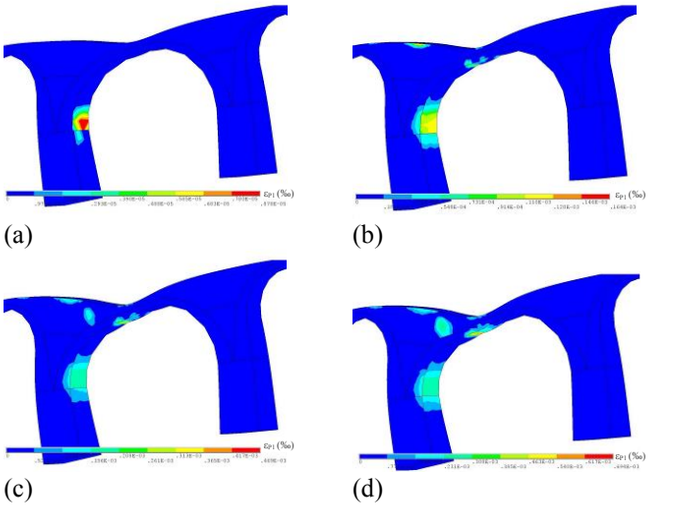


Figure 10. Principal maximum plastic strains in the bridge deformed configuration for intensity load levels of (a) 5P, (b) 10P, (c) 12P and (d) 14P.

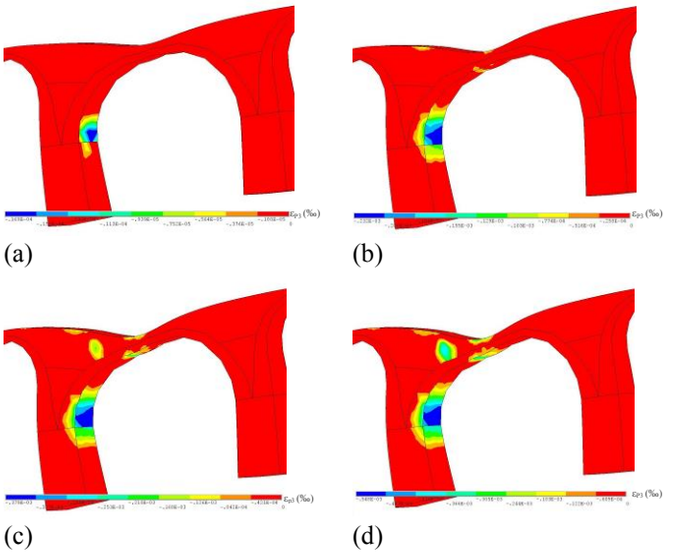

Figure 11. Principal minimum plastic strains in the bridge deformed configuration for intensity load levels of (a) 5P, (b) 10P, (c) 12P and (d) 14P.

For this final intensity level it is possible to identify the formation of two hinges in the arch (near the crown and in the arch springing) in the zones of the maximum (positive) and minimum (negative) plastic strains. Although the ultimate bridge response does not present a conventional arch hinge mechanism, it is also noted that in the spandrel walls, near the loading zone (both in vertical faces and in the horizontal top), the plastic strains reach high values the in compressive and tensile domains (-0.445‰ and 0.374‰), as well as the principal stresses as shown in Figure 9 (and in Table 4), thus evidencing its influence in the bridge strength mechanisms.

Table 5. Principal plastic strains for the arch A5 and spandrel wall.

Level of intensity	Element	dv	ε_{p1}^{+}	ε_{p3}^{-}
		mm	‰	‰
DL+1P	Spandrel	-	0.000	0.000
	Arch	45.60	0.000	0.000
DL+5P	Spandrel	-	0.003	-0.002
	Arch	52.83	0.008	-0.017
DL+10P	Spandrel	-	0.164	-0.123
	Arch	65.34	0.142	-0.232
DL+12P	Spandrel	-	0.248	-0.248
	Arch	72.40	0.469	-0.379
DL+14P	Spandrel	-	0.374	-0.445
	Arch	79.81	0.694	-0.548

In fact, the results of the plastic deformation in y-direction (transverse direction of the bridge), shown in Figure 12a, also allow to verify that the spandrel walls are influenced by transversal movements, with both spandrel walls in opposite directions, and the corresponding plastic deformation (ε_{py}), near the loading zone, also in opposite direction. This evidence allows pointing out that the plasticity occurs also due to the transmission of the horizontal impulses associated to the bridge behaviour in the transverse direction.

In z-direction the plastic deformation (ε_{pz}) shown in Figure 12b has the maximum values in the arch springing (base).

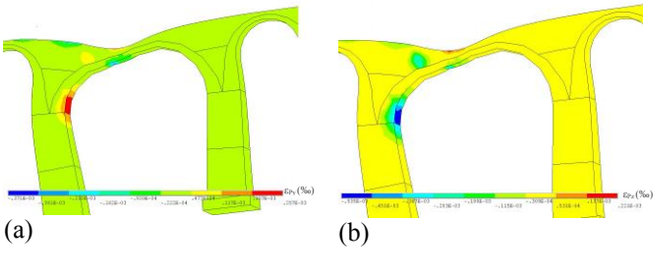

Figure 12. Plastic strains with deformed shape for the dead load and maximum load applied (DL+14P): (a) y direction, (b) z direction.

4.3 *Discussion*

The analysis of the bridge response allowed to recognize two vulnerable zones influenced by both basic failure modes of stone arch bridges: the hinges mechanism in the arch and out of plan of the spandrels.

For the maximum applied force it is possible to identify the formation of two plastic hinges in the principal arch and plastic deformation in the spandrel wall. No plastic deformation was found in the backfill zones. The values for the displacements reached in the crown of the principal arch are relatively high, approximately 80 mm (1/475 of the span arch).

Although the bridge response does not represent a conventional hinges mechanism for the maximum

applied force it was possible to evaluate the bridge response with reasonably high values of the multipliers, as expected for this type of bridge.

The study also points out specific difficulties when computing the bridge numerical response for intensity levels higher than 14, due to excessive deformation of the finite elements in the arch. Looking in detail the mesh in the arch it is possible to see that in some parts there exist only one element in height, which is very low given the large plastic deformations verified for such intensity levels of load applied. Therefore, it is deemed quite important to have several elements in height in the arch crown. For solving this problem one solution is to reshape the numerical model in order to have a denser mesh in the arch and spandrel in the bridge central zone where the load is applied.

5 CONCLUSIONS

This work provides a hypothetical scenario of a more severe condition of material deterioration to a bridge in a good state of conservation, and its assessment of the load-carrying capacity based on a 3D FEM numerical model. This preliminary work is based on the assumption of a damaged material scenario for the Côa bridge, using material properties of another bridge (older and in a more deteriorated state of conservation), where experimental characterization of the materials was performed.

The adopted modelling strategies provided means for comparing the numerical responses of the bridge under dead-load and incremental vertical forces to represent the static loading of a standard vehicle. This procedure allowed to simulate the formation of plastic hinges in the principal arch of the bridge and to identify the corresponding vehicle vertical loading.

Additional work, to refine the model to have a denser mesh in the arch and spandrel in the principal arch, will be required for a better representation of the arch bridge behaviour.

Also, sensitivity analyses for the material parameters adopted could be done in order to study different levels of damage in the masonry of the bridge.

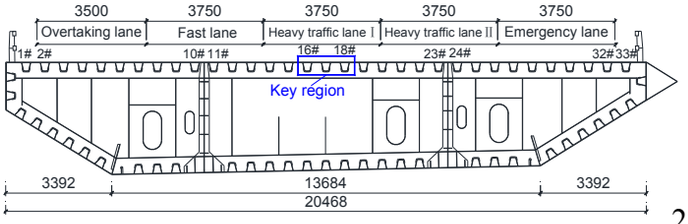
ABSTRACT: In order to investigate the fatigue performance of cutouts in the diaphragm of steel box girder and decide the optimal structure of the cutout, finite element models of block-shell mixed elements were established to calculate the fatigue stresses of several fatigue vulnerable details. The fatigue lives were calculated based on Palmgren-Miner linear damage accumulation criteria and the S-N curves in Eurocode 3. And the comparison of fatigue performance and design optimization of several typical cutouts at home and abroad were carried out. The results show that obvious compressive and tensile stress concentration zones (Zone A and B, respectively) exist at the cutout under local wheel loads. Fatigue cracks usually initiate at Zone A, and the direction of crack propagation is almost perpendicular to the direction of the principal stress. The shapes of the cutouts have significant influences on the fatigue performance of vulnerable details, especially on that of Zone A. The shape of arc-straight line (Cutout 4) is the best shape for the rigid diaphragms among the commonly used cutouts at home and abroad. The fatigue life of the cutout will be improved by appropriately increasing the radius of the cutout and the thickness of diaphragm, but the effect of increasing the radius of the cutout is better than increasing the thickness of diaphragm.

1 INTRODUCTION

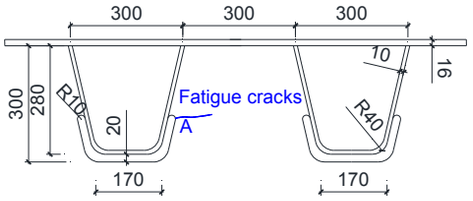
Orthotropic steel decks (OSDs) are usually used in steel box girder bridges around the world. The Network Monitoring and Emergency Treatment Center of China investigated 19 suspension bridges with orthotropic steel decks during 2011~2016, of which 15 bridges somewhat fatigue damaged in the OSDs, accounting for 78.9% of the total number of the inspected bridges. OSDs are susceptible to fatigue failure due to its small vertical stiffness, complicated structure, and the complex fatigue stresses under the direct action of wheel loads (Yokozeki and Miki 2016; Tang et al. 2014). The investigation results of 2 expressways in Japan showed that the fatigue cracks at the intersection of the U rib and the diaphragm occupied 56.3% of the total number of cracks in the two bridges. Thus, the fatigue cracking at the connection of U rib and diaphragm is one of the main diseases of OSDs.

Earlier studies (Shao et al. 2013; Shan 2010) showed that the ultra-high-performance concrete (UHPC) bridge deck and steel-elastomer sandwich bridge deck can effectively reduce the fatigue stress of U rib-deck details under wheel loads, avoiding the risk of fatigue cracking, but it can not solve the cracking problem of diaphragms. The shape of the arc-shaped cutouts, the spacing and thickness of the diaphragms are the principal factors affecting the fatigue performance of the diaphragm (Li et al. 2012; Tang et al. 2011). The comprehensive influence of various factors should be considered in the design of steel box girder. Reducing the spacing between the diaphragms or increasing the thickness of the diaphragms will increase the structural self-weight, and changing the design of other components only to improve the stress state at the cutout is clearly not the best solution. Researchers (Wang et al. 2012; Li et al. 2012) recommended a better structure of diaphragm cutouts, but the effect of the overall stress pattern of the diaphragm is not considered and the results are quite different.



In Japan, Europe, and the USA, truss floor beams or low transverse diaphragms (the heights usually do not exceed 75 cm) are often used in steel box girder bridges, cutout design in these countries have been developed specifically for such flexible floor beams (called "floor beam" later in this paper). Studies (Song et al. 2014; Tang et al. 2011) have shown that the stress states in the cutouts of flexible floor beams under the wheel loads are affected greatly by the overall bending moment, but the stress states in the cutouts of commonly used full-high transverse diaphragm (rigid, called "diaphragm" later in this paper) are mainly induced by "local effect" of the

wheel loads, there are big differences in both fatigue stress state and fatigue mechanism. In this paper, the fatigue performance of the diaphragm cutouts in steel box girder is studied, and the fatigue behavior of six typical arc-shaped cutouts in Europe, America, Japan and China is compared, the influence of cutout radius and diaphragm thickness on the fatigue performance are analyzed, which can offer references for the detailed design of the anti-fatigue design of steel box girder.



2 BACKGROUND ENGINEERING AND FE MODEL

2.1 *Bridge outline*

The main span of the suspension bridge is 350 m. The standard section of the main span steel box girder and structure of U rib-to-diaphragm connection is shown in Figure 1. The standard section is 3.5 m high, 20.468 m width excluding the wind fairing. The deck plate is 16 mm thick, the bottom plate is 14 mm thick, and the web is 16 mm thick. The U ribs are 10 mm thick and 280 mm high, 300 mm wide on the top, 170 mm wide on the bottom, the distance between centers of adjacent U ribs is 600 mm. The spacing of adjacent transverse diaphragms is 3.0 m longitudinally, and the spacing between adjacent suspenders is 12 m. The thick of transverse diaphragms without slings is 10 mm, and 12 mm with slings. A total of 121 cracks (see Figure 2) were observed in the arc-shaped cutouts of the diaphragms after operation for 9 years, accounting for 77% of the total number of diseases that have been found.

(b) Structure of U rib-to-diaphragm connection

Figure 1. Standard section of steel box girder and structure of U rib-to-diaphragm connection

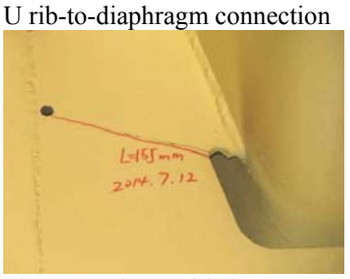

Figure 2. Photo of fatigue crack at the cutout of diaphragm

2.2 *FE modeling*

The fatigue stress of OSD is closely related to the effect of local wheel loads, but not affected much by the integral forced status of a bridge (Shao et al. 2013), thus a segment of the steel box girder was modeled to minimize the calculation scale. The FE model was established based on the following assumptions: 1) The structures behaves in elastic range, without considering material and geometrical nonlinearity; 2) Bearings of suspenders for steel box girder are considered as rigid supports, regardless of the sagging effect of main cable or the influence of the elastic stretching of suspenders.

A 3D finite element model of 15 m long, 3.5 m-high and 20.47 m-wide steel box girder was established using software Abaqus 6.14-3, as shown in Figure 3. The three translational degrees of freedom of nodes at the deck, bottom and web plates at end I are constrained, but nodes at the end J are constrained by the rigid vertical support. According to St-venenat's principle, little influence will be induced in the calculated stresses of structural details far away from the restraint boundaries. The model was built using "sub-model technology", most of the structure was modeled using 4-node shell elements, S4, except the key region that was modeled using 10-node block elements, C3D10. The model was meshed into 15 cm on the whole, except the key region that was meshed into 1 mm.

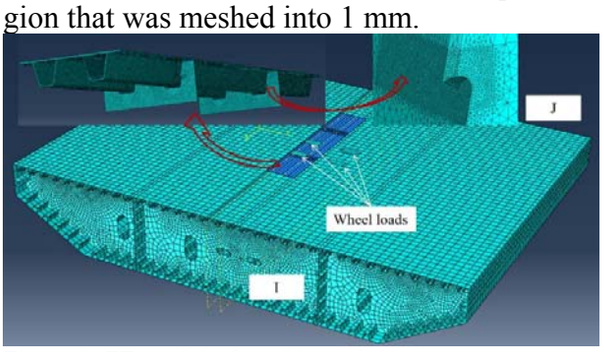

Figure 3. FE model of steel box girder

2.3 *Loading modes*

The load mode considered for the FE model is the vehicle load model III in Specifications for Design of Highway Steel Bridge (SDHSB) (2015), as shown in Figure 4, almost the same as the model III in Eurocode 3 (EC 3) (2005). Because no coupling effect was found between the two rear axles and the two front axes according to the FE analysis, the deck was considered undertaking double shafts 120 kN + 120 kN of the rear axles. The wheel loads were simulated by a uniformly distributed pressure with an area of 0.3 m × 0.7 m considering the dispersal effect of the asphalt pavement.

The left front one of the four wheels is taken as the reference wheel, the other wheel load positions were arranged according to the actual wheel track and wheelbase. To investigate the most adverse situ-

ation of the bridge deck under wheel loads, the reference wheel was moved transversely from above the concerned U rib to the right with a spacing of 10 cm, thus four transverse loading conditions (T1~T4) were considered. And the reference wheel was moved forward along the driving direction from the transverse diaphragm for 4 times with a spacing of 15 cm, and 4 times with a spacing of 30 cm, thus nine longitudinal loading conditions (L1~L9) were considered. The longitudinal wheel load positions illustrated in figure 7(b) corresponds to the transverse position T1 illustrated in figure 7(a), the most crucial longitudinal case was achieved, and then the most crucial case was achieved by offsetting the wheel loads transversely. The loading mode of the wheels is shown in Figure 5.

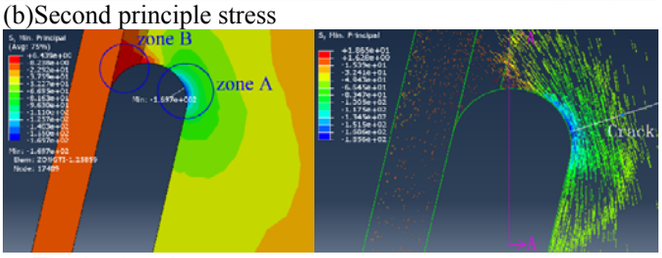
3 FATIGUE PERFORMANCE OF DIAPHRAGM CUTOUTS

3.1 *Fatigue Stress Analysis*



The structure effect is calculated under different loading conditions. According to the calculation results, the most adverse of the principal stress of the cutout is T2- L5, the nephograms and vectorgraphs of principal stress distribution of the cutout are shown in Figure 6. The results show that there are obvious compressive stress concentration zones (zone A) and tensile stress concentration zones (zone B, at the end of weld seam) around the cutout in the most adverse loading condition. The stress concentration in zone A and zone B is intense, and the stress at a small distance from the peak point of stress drops sharply to a very low level. The direction of the main compressive stress in the A zone is basically perpendicular to the crack direction.

(a)First principle stress

(b)Second principle stress

(c)Third principle stress

Figure 6. Nephogram and vectorgraph of principal stress distribution of the cutout (unit: MPa)

The weld toe on the surface of U rib at the intersection of U rib and diaphragm is one another hot spot prone to fatigue, which is defined as the “Zone C”, the location of Zone C and the extrapolation path of the hot spot stress are shown in Figure 7.

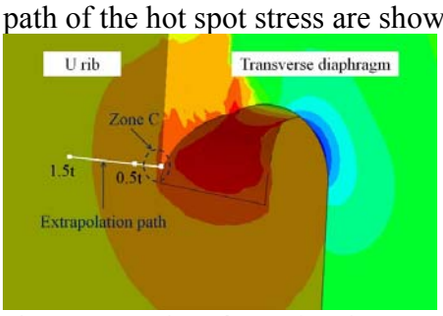


Figure 7. Location of zone C and extrapolation path of hot spot stress

As Zone A is located at the base metal of the diaphragm which is a non-welded area, the principal stress is taken as the fatigue control parameter. However, the fatigue of Zone B and Zone C should be regarded as the fatigue of welded joints, the hot stresses should be taken as the fatigue control parameter, the related calculation method has been reported (Aygül et al. 2012; Kim et al. 2009; Wang 2015). Zone B is located at the end of the attached plate, a path along the free edge of the cutout is taken as the extrapolation path, and the stress at the

point 5 mm away from the weld toe is taken as the hot spot stress.

The peak value of the compressive stress at zone A is -169.7 MPa, the hot spot stresses at Zone B and Zone C are -43.3 MPa and 44.4 MPa, respectively. According to EC 3 and SDHSB, the reduction factor of 0.6 should be considered for compressive stress, and the influence of transverse distribution of wheels should also be considered. The probability model of the transverse distribution of the wheels in China has been reported (Bu et al. 2015), the influence coefficient of transverse distribution of wheels are taken according to the literature of Bu (2015), that is, the influence coefficients of 0.76, 0.80, and 0.80 are taken for Zone A ~ Zone C, respectively. Considering these influence coefficients, the fatigue stress ranges for Zone A ~ Zone C are 77.4 MPa, 34.6 MPa and 35.5 MPa.

3.2 *Fatigue life prediction*

The fatigue life is calculated by the Palmgren-Miner linear damage accumulation criteria (P-M criteria) and the S-N fatigue curve in EC 3:

When $\Delta\sigma_i \geq \Delta\sigma_D$,

$$D_i = \frac{n_i}{N_i} = \frac{n_i}{10^7}\left(\frac{\Delta\sigma_i}{\Delta\sigma_D}\right)^m \quad (1)$$

When $\Delta\sigma_L \leq \Delta\sigma_i < \Delta\sigma_D$,

$$D_i = \frac{n_i}{N_i} = \frac{n_i}{10^7}\left(\frac{\Delta\sigma_i}{\Delta\sigma_D}\right)^{m+2} \quad (2)$$

When $\Delta\sigma_i \leq \Delta\sigma_L$,

$$D_i = 0 \quad (3)$$

The fatigue life:

$$Y = 1/\sum D_i = 1/\sum_{i=1}^{k}\frac{n_i}{N_i} \quad (4)$$

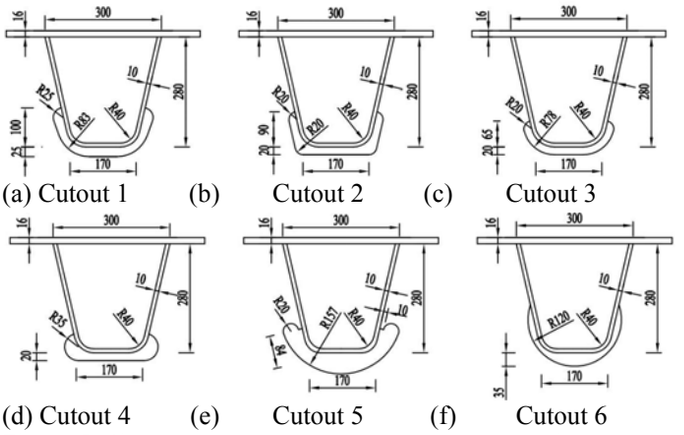
Where, D_i is the fatigue damage, n_i is the cycles of stress range $\Delta\sigma_i$, $\Delta\sigma_D$ is the constant fatigue limit in the S-N curves (the fatigue strength corresponding to 5×10^6 cycles), N_i is the cycles corresponding to the constant fatigue limit in the S-N curves (ie. 5×10^6 cycles), and $\Delta\sigma_L$ is the fatigue cut-off limit, m is the material coefficient which is taken as 3.

The fatigue lives of Zone A are calculated according to S-N curve of Category 71 specified in EC 3. The study shows that the fatigue lives of vulnerable details at welded seams such as zone B can be calculated using the S-N curve of FAT90 (the fatigue strength corresponding to 2×10^6 cycles is 90 MPa) in EC 3.

Considering the effect of compressive stress reduction and lateral load coefficient, the fatigue stress range of zone A is 130.0 MPa, the stress amplitude in zone B is 34.6 MPa. The fatigue lives of Zone A and Zone B are 2.91 million cycles and 11.9 million cycles, respectively. It should be noted that, even under pressure-zero cycles, cracks may still initiate at Zone A, because the thermal cutting process may produce large residual stresses that are even close to the yield strength of the steel, the fatigue performance is mainly related to the fatigue stress ranges, previous studies (Vasudevan and Sadananda 2001; Zhang et al. 2010) have confirmed the existence of such fatigue cracks.

4 STRUCTURAL OPTIMIZATION OF CUTOUTS BASED ON FATIGUE PERFORMANCE

To determine the optimal structure of diaphragm cutouts, a comparison of six typical kinds of diaphragm cutouts at home and abroad (see Figure 5) was carried out. As is shown in Figure 5, the shapes of the cutouts from Cutout 1 to Cutout 6 are the shapes of European standard/BS EN (2005) recommended highway-bridge cutouts, American standard/AASHTO LRFD (2007) recommended cutouts, Japanese standard/Steel Road Bridge Fatigue Design Pointer (2002) recommended all-bridge cutouts, Chinese highway-bridge commonly used cutouts ("straight + arc"), European standard/BS EN (2005) recommended railway-bridge cutouts and Chinese railway-bridge commonly used cutouts (large curvature circular arc), respectively. Given various cutouts in the diaphragms with different shapes and sizes in the FE models, fatigue stresses of the structural details near the cutouts are calculated.



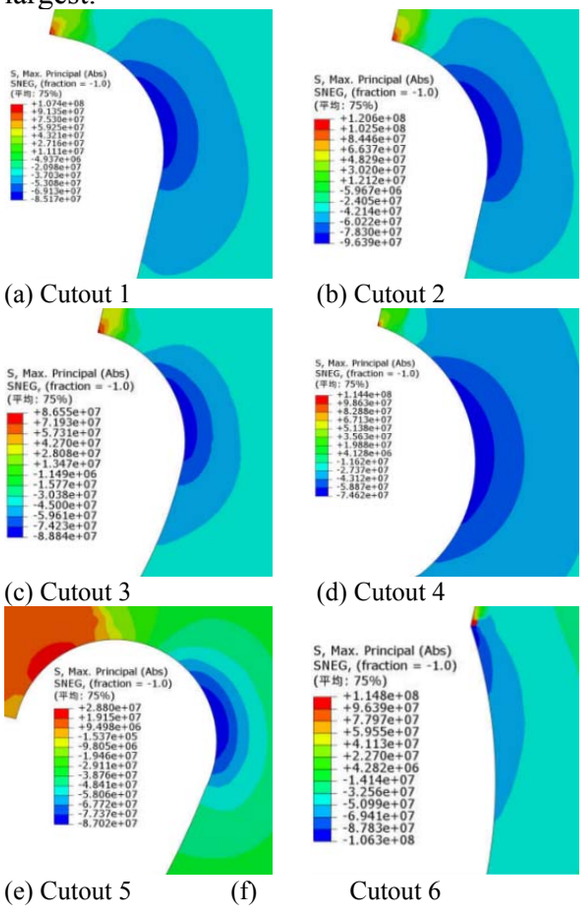


Figure 5. Six typical cutouts at home and abroad (unit: mm)

4.1 *Comparison of fatigue stresses of typical cutouts*

The original form of the cutout in the background engineering is defined as Cutout 7. Stress distribution of different cutouts under local wheel loads are shown in Figure 7. The com parison of fatigue stress of vulnerable details with different cutouts is shown in Figure 8. The stresses for Zone A 、Zone B and Zone C in Figure 8 represent the calculated principal stresses, hot spot stresses extrapolated along curve paths and hot spot stresses linearly extrapolated using stresses at 0.5 t and 1.5 t (t is the thickness of U rib) , and the stress in the table does not take into account any reduction. It can be seen that the fatigue stresses at Zone A of di fferent cutouts under the same working conditions are quite different. The fatigue stress of cutout 7 is significantly higher than of the other six cutouts, and the fatigue stress of cutout 4 is the lowest (-74.6 MPa). The hot spot stresses at Zone B are also greatly affected by the cutout shapes, some of the hot spot stresses are calculated as tensile stress and others are com pressive stresses, and the absolute values are quite different. Hot spot stresses at Zone C of Cu touts 1-5 are relatively smaller, while the hot spot stress of Cutout 7 is the largest.

(c) Cutout 3 (d) Cutout 4

(e) Cutout 5 (f) Cutout 6

Figure 7. Fatigue stress distribution of different cutouts

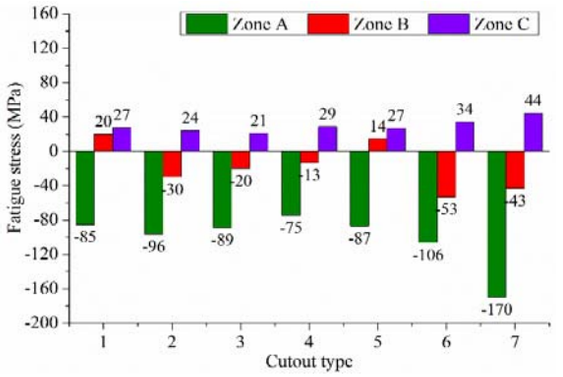

Figure 8. Conparison of fatigue stress of vulnerable details in different cutouts

4.2 *Comparison of fatigue lives of typical cutouts*

The predicted fatigue lives of fatigue prone details (Zone A ~Zone C) of differe nt cutouts are depicted in Figure 9. The results show that the fatigue life of 3 vulnerable areas of all cutouts exceed 1 $\times 10^7$ cycles except for the Zone A of Cutout 7. As to the Zone A, Cutout 4 has th e highest fatigue life of about 28.7 times that of Cutout 7, which is due to the fact that the fatigue life is related to the third power of fatigue stress range. Th e Zone B and Zone C of all cutouts, except the Zone B in Cutout 6 or Zone C in Cutout 7, will never f atigue in theory. That is to say, Zone B and Zone C have no fatigue risk for the majority of Cutouts, Zone A is the control area f or anti-fatigue design.

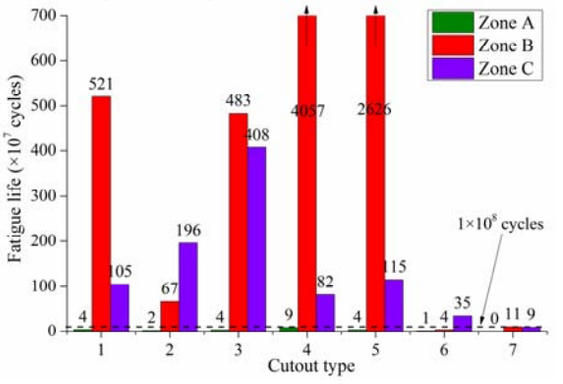

Figure 9. Predicted fatigue lives of Zone A~ Zone C of different cutouts

In general, it is of great significance to optim ize the diaphragm to improve the fatigue life of this area. According to the above analysis, the stress level at Zone A and Zone B of Cutout 4 are the lowest, and the fatigue stress at Zone C is also lower than the fatigue cut-off limit, which is the preferred shape of the diaphragm cutout.

4.3 *Structural optimization of Cutout 4*

The vulnerable detail at the weld toe at the intersection of U-rib, diaphragm and roof weld seam is set as Zone D, as shown in Figure 10. Based on the Cutout 4, the radius of th e free edge is taken as 35 mm, 45 m m and 55 m m, and the diaphragm thickness is taken as 10 m m, 12 mm and 14 m m, respec-

tively. The fatigue stresses of vulnerable details (Zone A, Zone B and Zone D) are calculated and compared, to determine the influence of cutout radius and diaphragm thickness on the fatigue properties of above vulnerable details.

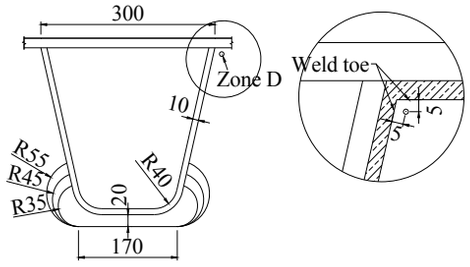

Figure 10. The changes of cutout radius and location of Zone D

The influence of cutout radius and diaphragm thickness on fatigue stress at Zone A, Zone B and Zone D is shown in Figure 11. The results show that: ① The fatigue stress at Zone A decreases with the increase of the radius of cutout free edge. The fatigue stress is reduced by 12 ~ 17 MPa as the radius increased from 35 mm to 45 mm, while it is reduced by only 3.2~4.0 MPa as the radius increased from 45 mm to 55 mm, the amelioration of stress tends to converge. ② The hot spot stresses at Zone B and Zone D are reduced little with the increase of the radius, but anyway they are less than the fatigue cut-off limit of FAT 90, thus cracks will not initiate at Zone B and Zone D in theory. ③ With the increase of the thickness of diaphragm, the principal stress at Zone A decreases greatly, the fatigue stress at Zone D decreases in some degree, and fatigue stress of Zone B changes little, so increasing the thickness of diaphragm will only actually affect the fatigue performance of Zone A. Increasing the radius of cutout free edge is conducive to improving the fatigue resistance of Zone A, by contrast, the fatigue property of Zone A is also improved by increasing the thickness of diaphragm, but the effect is not so good.

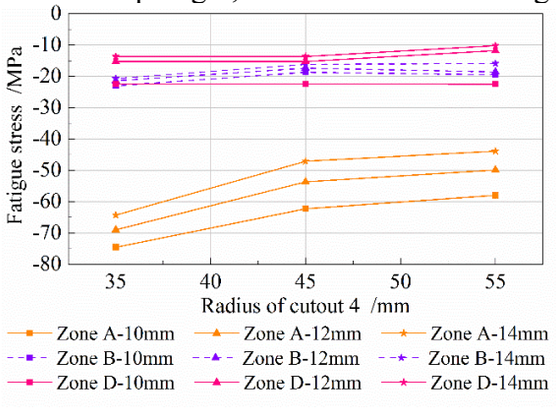

Figure 11. Influence of cutout radius and diaphragm thickness on fatigue stresses

5 CONCLUSION

Obvious compressive stress concentration zone (Zone A) and tensile stress concentration zone (Zone B) exists at the arc-shaped cutout in transverse diaphragm of steel box girder under the effect of local wheel loads. Fatigue cracks mostly occur at Zone A where the principal stress is almost perpendicular to crack propagation direction. The calculated fatigue stress range at Zone A is 77.4 MPa considering all influence coefficients, which exceeds the threshold value if fatigue initiation and leads to the fatigue cracking.

The fatigue stresses and fatigue lives of Zone A ~ Zone C at the intersection of U rib and diaphragm are significantly affected by the shapes of the cutouts. Among the seven kinds of typical shapes, the fatigue life of the cutout shape applied in the background engineering is the lowest, while the shape of arc+ straight line (Cutout 4) shows up the best anti-fatigue performance.

The increase of radius of Cutout 4 is conducive to improving the fatigue performance of Zone A, and it will not significantly affect the fatigue stresses of other vulnerable details. The increase of the thickness of transverse diaphragm is also conducive to improving the fatigue property of Zone A, but less effective than the increase of the cutout radius.

Assessment of Shear Lag in Pultruded GFRP Bridge Decks

S. Zhang & C. Caprani

Faculty of Engineering, Department of Civil Engineering, Monash University, Melbourne, Australia.

ABSTRACT: Pultruded Glass fiber-reinforced polymer (GFRP) composite is increasingly applied in civil engineering due to the cost-effective ease of manufacturing and excellent material properties. GFRP bridge decks are a good alternative to traditional decks to eliminate deterioration and improve durability. However, considering the low in-plane shear modulus of pultruded GFRP, shear lag of GFRP cross sections could be a significant design issue. This paper presents a Finite Element (FE) parametric study on the influence of shear lag on pultruded GFRP bridge decks. A simply-supported GFRP bridge with different span lengths and bridge configurations are modelled under representative loading conditions. The effective width of the GFRP bridge decks are then obtained. Additionally, steel bridges with the same configurations are examined as comparisons of effective width. The results of this paper indicate the importance of considering that in the design of orthotropic-deck pultruded GFRP bridges, shear lag is comparable with traditional forms of construction.

1 INTRODUCTION

1.1 *General background*

Fibre-reinforced polymer (FRP) has relatively high stiffness, strength to weight ratio, and good corrosion resistance. These benefits make it become attractive to meet the increasing demand of high-performance durable materials in civil engineering. To manufacture FRP profiles, a highly automated and continuous manufacturing process known as pultrusion, is considered as the most cost-effective method (Bank 2006). Normally, glass fibres embedded with polyester or vinyl ester resin are used in pultrusion. So far, GFRP has been widely used to as a reinforcing material with concrete and steel to reduce corrosion. In bridge engineering, GFRP hybrid bridge decks or pultruded GFRP sandwich bridge decks have been designed and built for many years. It has been reported by O'Connor and Hooks (2004) that around 83 bridges in United States have been constructed or rehabilitated using GFRP decks. Also, GFRP cable-stayed footbridges were constructed in Scotland and Kolding, Denmark, respectively (Bakis et al. 2002). Furthermore, FRP bridge decks with steel girders have been used on main highway bridge in Netherland (van Ijselmuijden and Tromp 2013).

Due to the low in-pane shear stiffness of GFRP composites, the stress distribution in the transverse direction becomes non-uniform, showing a decrease from the junction with girders to the edge—an example is shown in Figure 1. This non-uniformity is known as shear lag. Of course, shear lag occurs for all materials, but the peculiarity of GFRP is that its high longitudinal strength and stiffness is comparable to steel and concrete (respectively), but its shear modulus is more like some timbers.

For bridges, Hambly (1991) suggested that shear lag can be negligible only for collapse conditions; otherwise, it may generate an over-stiff problem for the bridge deck. Therefore, to account for shear lag of the bridge deck, the effective width is used for beam flanges in the analysis to allow the continued assumption of simple beam theory, having a uniform stress distribution across the flange width.

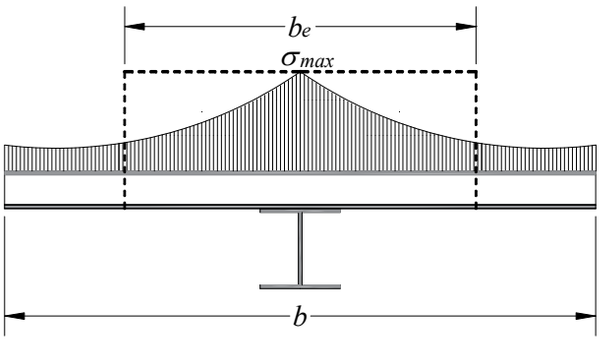

Figure 1: Transverse stress distribution due to shear lag, and the approximation of effective width, b_e, for simple beam theory.

1.2 *Study Objective*

Some research has been conducted on the influence of shear lag on composite bridge. Most studies focus on partial composite bridges, such as FRP bridge deck with steel girders or hybrid bridge deck (concrete with FRP) with steel girders (e.g. Keelor et al. (2004), Zou et al. (2011), and He (2011)). Generally, it has been shown that shear lag is highly dependent on the variations of span to width ratio, girder spacing, loading and support conditions (Sedlacek and Bild (1993) and Gara et al. (2011)). Cheung and Chan (1978) and Tenchev (1996) found that the effective width due to shear lag is independent of cross-section type and variations of material properties of the flange and web. A similar conclusion was found by Nagaraj and GangaRao (1997) after investigating the non-uniform distribution of bending strain of a pultruded GFRP I-section beam and box section in three-point bending tests. In addition, for partial composite bridge (FRP bridge deck supported by steel girders), the effective width was found to increase with the increase of span-to-width ratio, but decrease with girder spacing-to-span ratio (Moses et al. 2006). Also, the identified effective widths of FRP bridge decks are less than that of concrete decks obtained using AASHTO (Moses et al. (2006) and Alnahhal et al. (2008)). Moreover, it has been shown that a partial degree of composite action is achieved by hybrid FRP bridge deck with steel girders, which also affects the effective width of FRP bridge deck flanges (Alnahhal et al. (2008) and Zou et al. (2011)). However, despite all findings on partial composite bridges, the existing studies do not investigate shear lag for FRP sandwich bridge decks. Consequently, there are no recommendations to determine the effective width of such structures. This paper is a first step towards addressing this knowledge gap for GFRP sandwich bridge decks.

1.3 *Methodology*

This paper presents a parametric study using finite element (FE) analysis to investigate shear lag of pultruded GFRP composite bridges. A sandwich panel bridge deck is modelled consisting of flat plates and box-profiles in both longitudinal and transverse directions (Figure 2). Considering the influence of span-to-width ratio on the effective width of the beams, three bridge configurations are analyzed for different span lengths. All bridge models are established as simply-supported bridges under four-point bending loads. Moreover, the shear lag factor and effective width of fully-composite GFRP bridges and a non-composite steel bridge are calculated respectively to identify the relative influence of shear lag on bridges of different materials. This work should assist in improving the design and assessment of pultruded GFRP composite bridge structures.

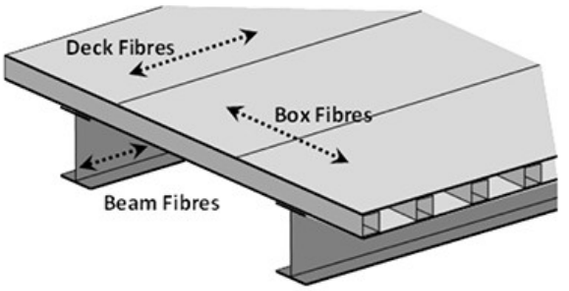

Figure 2: Fibre orientations for a GFRP sandwich panel deck and beams (Caprani et al. 2017).

2 MATERIAL INVESTIGATION

Pultruded glass fiber reinforced polymer (GFRP), supplied by Exel Composites, Australia, is used in this study. All pultruded profiles consist of E-glass fiber (major reinforcement) and polyester resin (matrix). The section thickness varies for different profiles: 6.21 mm for flat plates; 9.5 mm for box sections; and 9.5 mm for I-girders. Material properties of pultruded profiles with different thickness are shown in Table 1, which have been determined from extensive testing carried out at Monash University (Zhang et al. (2016). Each property is given as an average of 10 specimens.

According to the theory of elasticity (Timoshenko and Goodier 1969), pultruded GFRP is regarded as tetragonal material, which assumes the material properties in the thickness direction is the same as other directions (Bisplinghoff et al. (1965) and Bank (2006)).

Table 1: Material properties of pultruded GFRP.

Property	Unit	Thickness (mm)	
		6.21	9.5
Fibre volume fraction (FVF)	%	42.1	42.1
Density	kg/m3	1800	1800
Longitudinal modulus	GPa	22.99	24.63
Transverse modulus	GPa	10.32	10.43
In-plane shear modulus	GPa	3.35	3.5
Major Poisson's ratio	-	0.30	0.30

3 FINITE ELEMENT MODELING

An FE bridge model is developed for both GFRP and steel bridges. Four-node shell elements are selected, and there are six degrees of freedom at each node to account for the orthotropic nature of pultruded GFRP, while this is ignored for the isotropic steel bridge model. The sandwich bridge deck consists of two 6.21 mm-thick pultruded GFRP flat plates (top and bottom) bonded with pultruded GFRP box-profiles (9.5 mm) in-between (as shown in Figure 3).

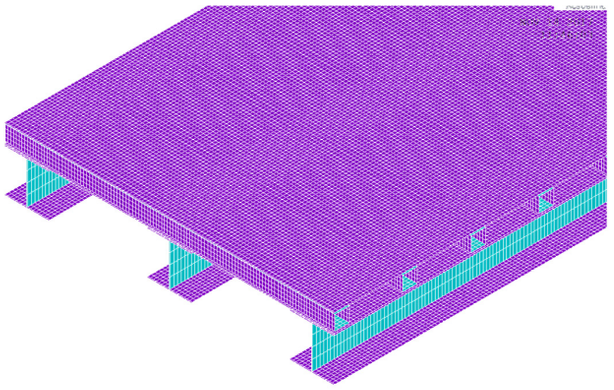

Figure 3: Finite element model of pultruded GFRP bridge deck with sandwich panel construction.

As noted previously, the span-to-width ratio presents a significant influence on shear lag of non-composite or partial composite bridges. Therefore, in this study, the width of the bridge deck is 1.5 m and the span length (L) varies as 9 m, 18 m and 27 m. Three bridge configurations including single girder, two girders and three girders are analyzed for each span length. The developed bridge models are summarized in Table 2 and bridge cross sections are shown in Figure 4.

Table 2: Summary of the analysed bridge models.

Bridge configuration	Cross-section (CS)	
	CS-1	CS-2
Single-girder bridge (SIGB)	9 m	9 m
	18 m	18 m
	27 m	27 m
Two-girder bridge (DIGB)	9 m	9 m
	18 m	18 m
	27 m	27 m
Three-girder bridge (TIGB)	9 m	9 m
	18 m	18 m
	27 m	27 m

The bridge model is simply-supported with pin constraints for both ends. Four-point bending loads are applied as two line-loads at one-third span distances from supports (as shown in Figure 5). Consequently, the shear region of this bridge model is located between the support and position of loading. Therefore, the results are taken from two cross sections: CS-1 in the shear region and CS-2 at the mid-span of bridge. For each cross section, nodes defined on the top panel of sandwich bridge deck (in the y-direction) are selected to generate stress results. Furthermore, it should be noted that full composite action is assumed for all bridge configurations.

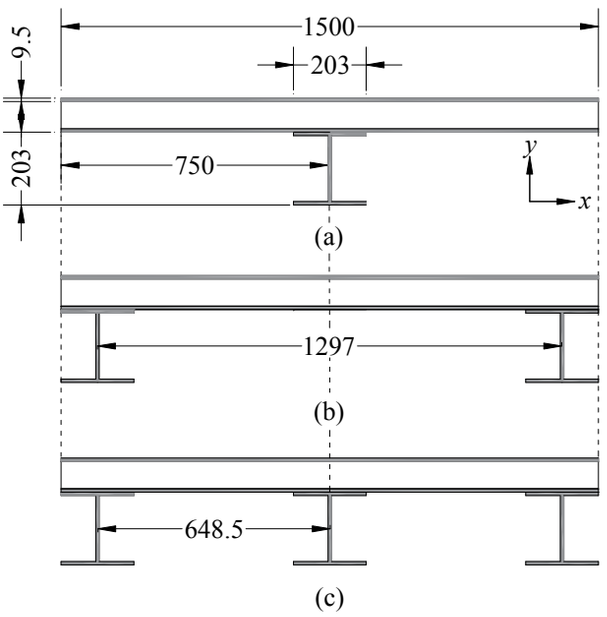

Figure 4: Bridge configurations: a) Single girder bridge (SIGB); b) Two girders bridge (DIGB); c) Three girders bridge (TIGB) (unit: mm).

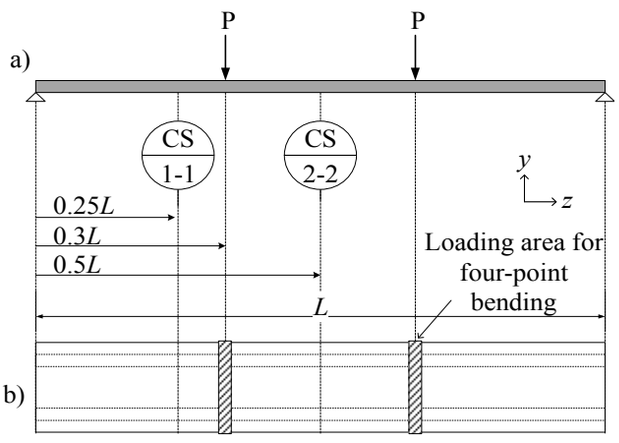

Figure 5: Positions of loading and typical cross-sections (unit: mm).

3.1 *Example Results*

The approach used to analyse the FE model outputs is explained using a sample set of results. The same steps are applied throughout. At the cross section of interest, the FE model nodes on the top surface of the deck are selected across the width of bridge (in the x-direction), and the longitudinal stresses (in the z-direction) at these nodes are extracted.

The stresses due to the different span lengths are considerably different in magnitude. Therefore, to compare transverse changes of longitudinal stress distributions obtained at different span lengths, normalized stresses are used, defined as:

$$\sigma_{norm} = \frac{\sigma_z}{\sigma_{\max}} \tag{1}$$

where, σ_{norm} is the normalized longitudinal stress; σ_z is the longitudinal stress along the cross-section; and σ_{max} is the maximum longitudinal stress at the junction of beam and girder (x = 0.75 m).

Longitudinal stresses taken from the 9 m single-girder bridge (Figure 6a and 6b) are shown as an example. Figure 6c shows the stress contour of single-girder bridge with nodes selected at CS-1 (2.25 m) and the corresponding extracted longitudinal stresses are shown in Figure 7. Therefore, the σ_{max} is 179.86 kPa for single-girder bridge with 9 m span at CS-1 and the corresponding normalized stress distribution is shown in Figure 8.

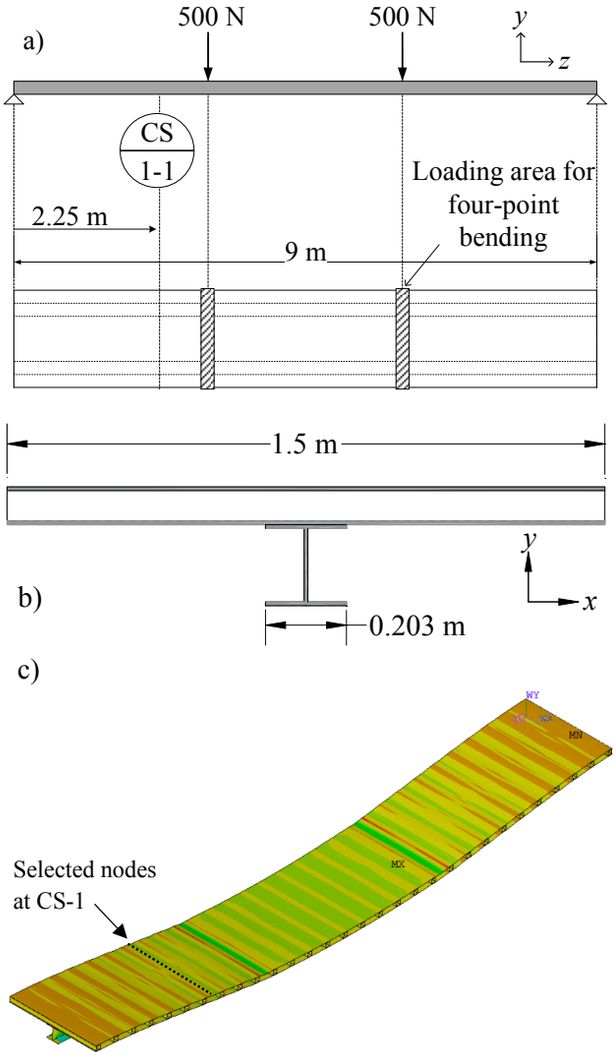

Figure 6: a) Location of CS-1 on 9 m single-girder bridge; b) cross-section; c) Longitudinal stress (σ_z) contours.

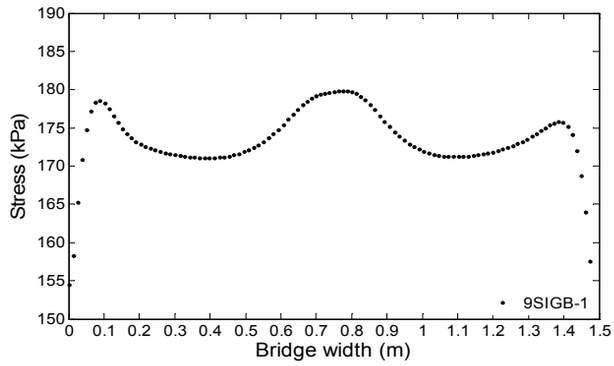

Figure 7: Longitudinal stress distribution of single-girder bridge with 9 m span at CS-1.

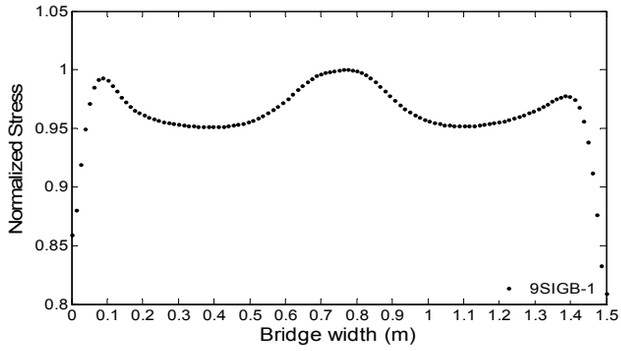

Figure 8: Normalized stress of single-girder bridge with 9 m span at CS-1.

4 RESULTS AND DISCUSSION

4.1 *Methodology*

Shear lag is expressed using the superposition of normal stress along the width of bridge. To allow the use of simple beam theory while accounting for the shear lag, an effective width of the flange is used, such that the maximum stresses and total flange force are equal (Hambly 1991)—see Figure 1. Therefore, it can be calculated by the integral of normal stress (Tenchev (1996) and Zou et al. (2011)):

$$b_e = \frac{\int_{-b/2}^{b/2} \sigma_z dx}{\sigma_{\max}} = \frac{2\int_{0}^{b/2} \sigma_z dx}{\sigma_{\max}} \tag{3}$$

where b_e is the effective width; b is the bridge width (1.5 m throughout this work); σ_z is the longitudinal stress along the cross-section; σ_{max} is the maximum longitudinal stress at the junction of beam and girder. A shear lag factor can be employed to evaluate the influence of shear lag on the beam behaviour:

$$\lambda = \frac{b_e}{b} \tag{4}$$

Values of the shear lag factor much less than 1 illustrate a strong influence of shear lag on the beam behaviour. Due to the symmetry of bridge, the value of

b is taken as the full width (1.5 m) for single-girder bridges and half width (0.75 m) for multiple-girder bridges. Furthermore, both the effective width and shear lag factor are based on the stress measured from the top panel of sandwich bridge deck.

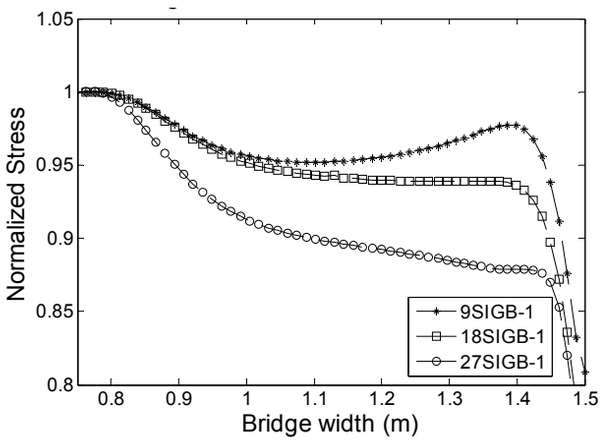

Figure 9: Normalized longitudinal stress distribution of single-girder bridge at CS-1 (quarter-span).

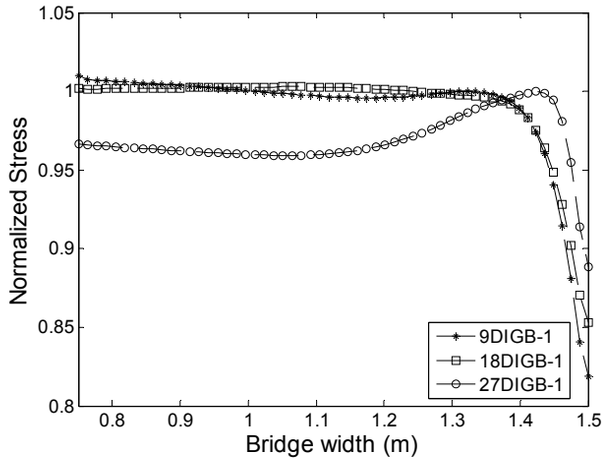

Figure 10: Normalized longitudinal stress distribution of two-girder bridge at CS-1 (quarter-span).

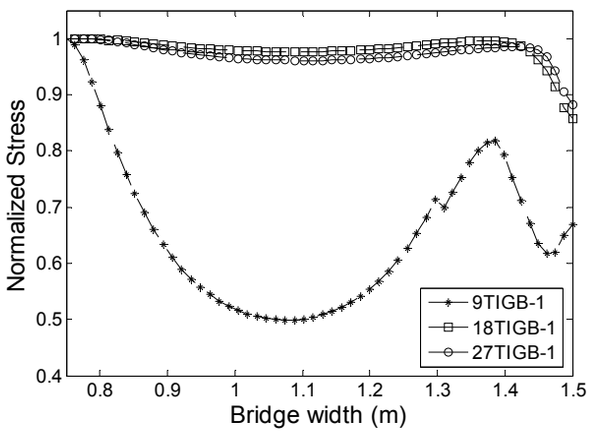

Figure 11: Normalized longitudinal stress distribution of three-girder bridge at CS-1 (quarter-span).

4.2 *Longitudinal stress distribution results*

Figures 9-14 show normalized longitudinal stress distributions (equation (1)) for the studied bridge configurations at CS-1 and CS-2, respectively Also, due to the symmetry of the cross section, stresses are only shown for one half-width in each figure.

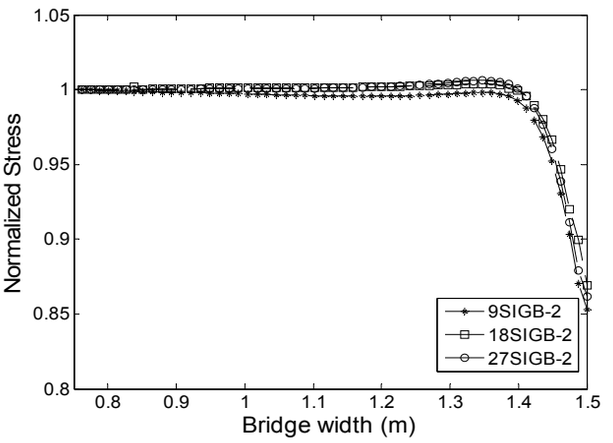

Figure 12: Normalized longitudinal stress distribution of single-girder bridge at CS-2 (mid-span).

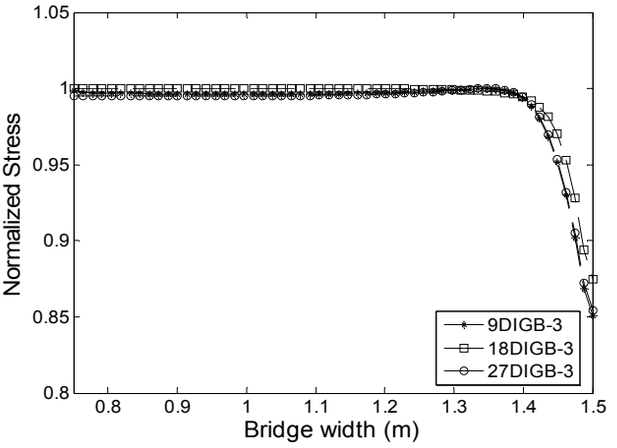

Figure 13: Normalized longitudinal stress distribution of two-girder bridge at CS-2 (mid-span).

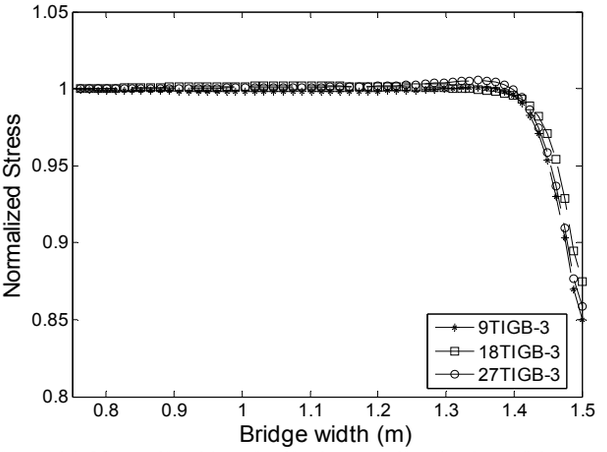

Figure 14: Normalized longitudinal stress distribution of three-girder bridge at CS-2 (mid-span).

Generally, the distributions of longitudinal stresses of pultruded GFRP bridge are more uniform at mid-span (CS-2) than those in the shear region (CS-1), regardless of variations of span length and bridge configuration. This finding indicates that pure bending occurs at the mid-span (CS-2). In turn, this means that the sandwich bridge deck with bi-directional profiles can efficiently share longitudinal stresses transversely. For longitudinal stresses at CS-1, the normalized stresses are approximately ranging from 0.9 to 1 for the 18 m and 27 m bridge cross sections, respectively. However, noticeable difference of normalized stresses occur for the short span bridge (9 m) at CS-1, especially for bridge with three girders, which ranges from 0.5 to 1. All these differences indicate that shear lag is highly dependent on span length. Interestingly, a similar conclusion has been drawn by Zou et al. (2011) for a partial composite bridge. Moreover, the non-uniform distributions are mainly at the positions of I-girders, leading to clear shear lag. This variation is also shown for stress distribution at CS-2. Interestingly, for the bridge model with three equal-spaced girders, the most non-uniform distribution occurs at the interior girder rather than the exterior girders.

4.3 *Effective width and shear lag factor*

For comparison with the GFRP bridges, the effective widths of steel bridges are also calculated for the same bridge configuration and loading condition. Table 3-5 presents the effective width and shear lag factors obtained from the two types of bridges. Considering the most non-uniform distribution appears at the interior girder for the three-girder bridge configuration, the effective width evaluated from interior girder is shown in the tables.

From the results given, it is clear that shear lag presents relatively similar influence on GFRP and steel bridges (Figure 15). The differences between effective widths for all configurations are less than 2%. At either CS-1 or CS-2, the slight difference between the shear lag factor obtained from both bridges are negligible, as the ratios between shear lag factors ($\lambda_{GFRP}/\lambda_{Steel}$) are in the range of 0.965 to 1 (Figure 16). Even though, bridges with multiple-girders have more varied ratios between the pultruded GFRP and steel shear lag factors than single-girder bridges.

Table 3: Effective width and shear lag factor of one-girder bridge.

Cross-section	Span (m)	b_e (m)		λ	
		GFRP	Steel	GFRP	Steel
CS-1	9	1.08	1.08	0.72	0.72
	18	1.10	1.11	0.73	0.74
	27	1.10	1.14	0.74	0.76
CS-2	9	1.12	1.12	0.74	0.75
	18	1.12	1.14	0.75	0.76
	27	1.15	1.17	0.76	0.78

Table 4: Effective width and shear lag factor for two-girder bridge.

Cross-section	Span (m)	b_e (m)		λ	
		GFRP	Steel	GFRP	Steel
CS-1	9	0.51	0.51	0.68	0.68
	18	0.53	0.53	0.71	0.71
	27	0.58	0.59	0.78	0.78
CS-2	9	0.59	0.59	0.78	0.79
	18	0.59	0.60	0.78	0.80
	27	0.61	0.62	0.82	0.83

Table 5: Effective width and shear lag factor of three-girder bridge.

Cross-section	Span (m)	b_e (m)		λ	
		GFRP	Steel	GFRP	Steel
CS-1	9	0.53	0.54	0.67	0.72
	18	0.59	0.59	0.78	0.79
	27	0.61	0.63	0.81	0.84
CS-2	9	0.62	0.62	0.83	0.83
	18	0.65	0.67	0.86	0.89
	27	0.68	0.70	0.90	0.93

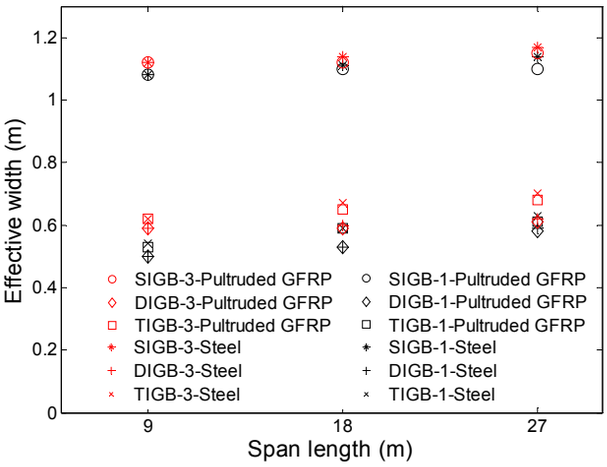

Figure 15: Summary of effective widths (1 and 2 are corresponding to CS-1 and CS-2, respectively).

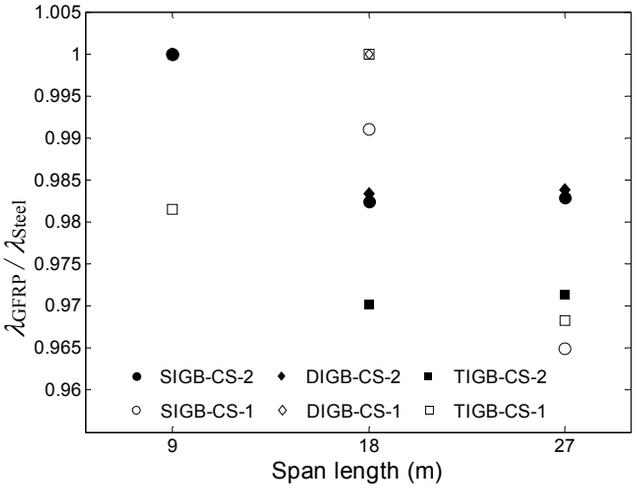

Figure 16: Ratios between pultruded GFRP and steel shear lag factors.

For both composite and non-composite material bridges, it is apparent that with the same bridge configuration, the effective width increases with the increase of span length regardless of the considered cross-section. Also, for all bridge configurations, the effective width is higher in the shear region (CS-1) than that at middle span (CS-2), which leads to a higher shear lag factor at mid-span. Furthermore, it has been found that the effective width of the interior girder in the three-girder configuration is relatively close to its girder spacing, at approximately 90% of half width.

5 SUMMARY & CONCLUSIONS

This paper investigates the shear lag on pultruded GFRP bridge by conducting a parametric study. Sandwich bridge deck are used and supported by two pultruded GFRP I-beams to achieve full composite action. Three bridge configurations are constructed at different span length varying from 9 m to 27 m. All proposed bridge models are tested under four-point bending loads.

Some conclusions from the research are summarized below:

- The sandwich bridge deck with fiber reinforcement in longitudinal and transverse directions can effectively prevent local shear deformation of the bridge deck.
- The transverse distribution of longitudinal stress depends on bridge length. Significant non-uniform distribution occurs for a 9 m span, while they are more uniform at 18 m or 27 m span.
- The effective widths are very similar for the studied pultruded GFRP bridge and steel bridges with the same geometry and configuration.
- Generally, with the same bridge configuration, the effective width increases with the increase of span length for full-composite and non-composite bridge.
- Although there is no specific standard for GFRP bridge deck, the effective width of pultruded GFRP bridge is lower than that obtained according to AASHTO.

Overall, based on the results of this study, it can be emphasized that pultruded GFRP bridges with orthotropic sandwich decks can be used in the replacement of non-composite steel bridge with similar configurations without changed considerations of shear lag.

Dynamic response analysis of widening bridge due to moving vehicles

Yan Li, Tingting Yang, Zhao Li, Lipeng Liu

School of Transportation Science and Engineering, Harbin Institute of Technology, Harbin, China. 150090

ABSTRACT: Rapid economic growth has led to a sharp increase in the highway traffic volume in China, and then more and more bridges widening projects are carried out to reply the situation. When a bridge is widened by constructing a new deck and casting a concrete stitch between the existing deck and the new deck, it is often required to maintain traffic without interruption and as a result the curing concrete stitch would be subjected to traffic induced vibration. The possible damaging effects of traffic vibration on curing concrete stitch have attracted concern from researchers and engineers. Therefore, it is very meaningful for the widening bridges to propose a detailed traffic restrictions or mitigation measures to avoid the adverse effect on the curing concrete stitch. Based on theoretical and experimental research results for concrete stitch of widening bridge, the vibration response threshold value causing crack damage induced by moving traffic load can be determined. The critical index of dynamic response value for a widening bridge is proposed, and its theoretical derivation process is explained in detail. Taking several typical PC simple supported T girder bridges as examples, the dynamic response of widening bridges under various vehicles loading cases are computed by the vehicle and bridge coupled vibration analyses program developed by authors. Some typical trucks and tested data for highway in China are applied on the research. Based on the analysis result, some advices about traffic control measures including limiting load, speed limit and lane limit etc. are presented to reduce or avoid the disadvantage influence of traffic vibration on curing concrete stitch for widening bridges. In addition, the reasonable construction technology is put forward, which provides a reference for the traffic control during constructing widening bridges.

1 INTRODUCTION

The rapid economic growth has contributed to the sharp increase of highway traffic volume in China. A large number of existing highway projects need to be expanded. Generally, a widened bridge makes its overall force by pouring a certain width of concrete joints between the old and new Bridges, to connect the upper structure of the new old bridge. The engineering practice shows that the joints between new and old part is one of the weakest parts of the bridge. It is one of the key criteria to measure the construction of widened bridge by ensuring that the construction maintenance of the concrete joints and not too much deformation and cracking in the later operation. The field test and laboratory model study showed that, traffic load adversely impact the concrete joints between new and old bridge mainly by the different vertical deflection between new and old bridge panel. When the difference exceeds a certain limit, the concrete joint cracks, and this will influence the development of concrete joint strength, integrity, the cohesive force between steel and concrete, and the flexural and shear capacity of concrete joints.

The bridge involved in the reconstruction project of the highway has a lot of traffic. In consideration of the social and economic cost and other aspects, traffic can't be closed in the process of casting the joint concrete. In order to effectively reduce the damage caused by traffic load vibration, some research work has been carried out at home and abroad. And various countermeasures have been put forward, including reasonable traffic control measures, temporary shear frame between the old and new bridge panel, temporary support under the old bridge, and casting the joint concrete piecewise. In the above measures, reasonable traffic control, if it can meet the requirements, is undoubtedly the most economical and convenient method. In the engineering practice and relevant research, analysis of the effectiveness of traffic control measures was carry out mainly accords to the typical load working condition of standard car lane load, so as to determine the effectiveness of traffic control and optimal control model.

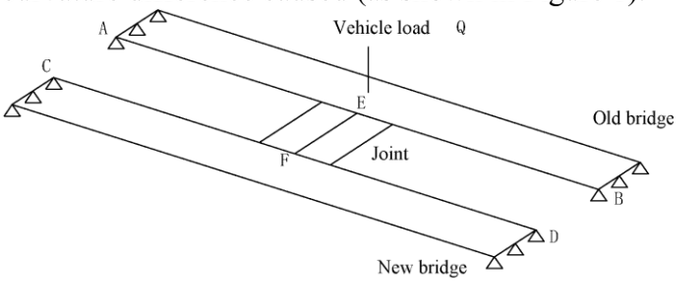
In the analysis of the traffic control mode in the construction process of new and old bridge concrete joints, the existing research has not considered the impact of actual traffic composition and the characteristics of automobile dynamic load. At the same time, the process of car across the bridge, in essence, is a vehicle and bridge coupling vibration problems. It will be more targeted when study the bridge vibra-

tion under the vehicle load and put forward the reasonable traffic control measures on the dynamic level. It's beneficial to put forward the optimization of traffic control technology solutions.

For this purpose, based on the actual project of expansion, this paper relies on the relevant research results of highway vehicle load test data and typical vehicle model parameters. Using the self-braided bridge vibration analysis program, the dynamic response analysis of different heavy vehicle types and their combined working conditions is carried out. The effects of control measures such as limiting load, speed limit and restricted lane are studied to reduce the vibration amplitude of the joint slot. The critical index of the vibration control of the existing reinforced concrete slab is summarized and analyzed. The critical index determination method to control the vibration of the widened bridge is reached. The paper summarizes the process and strategy of traffic control technology for the construction of the widened bridge project.

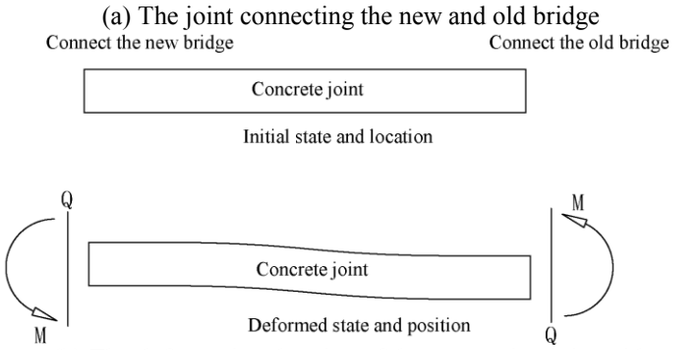
2 INFLUENCE OF VEHICLE INDUCED VIBRATION ON THE CONCRETE OF THE CURRENT CAST-IN-PLACE JOINTS

2.1 *The characteristics of the concrete stress of the cast-in-place joint*



For bridge expansion projects, even in the construction and maintenance stage of the cast-in-place joint, it is generally necessary to keep the old bridges open. The vibration caused by traffic loads may cause cracks in the joint structure. The stress characteristics of the current cast-in-place joint structure during the phase of the traffic load are as follows:

(1) When the concrete has been cast, only the original bridge panel is bent under the traffic load, resulting in the deflection difference between the new and old bridge.



(2) When the concrete is gradually formed, the new bridge panel will be deformed with the original bridge panel, i.e. the old bridge traffic load is transferred to the bridge panel of the new bridge through the concrete joint plate;

(3) With the gradual hardening progress of the joints, the strength of the joints gradually increases, the deformation decreases under the constant traffic load, the shear strength increases, and the deflection difference between the new and old bridge decreases gradually.

(4) The adverse effects of traffic load on the joints between the new and old bridge are mainly caused by the difference of vertical deflection between the new and old bridge panels, resulting in the backward curvature difference caused (as shown in Figure 1).

(a) The joint connecting the new and old bridge

(b) The deformation drawing of the connecting joint with vehicles interaction on the old bridge

Figure 1. The deformation drawing of the connecting joint under the dynamic impact of moving vehicles

2.2 *Evaluation index of impact of traffic load on joint*

There are studies show that, the adverse effects of traffic load on the concrete joints between the new and old bridge panels are mainly caused by the difference of vertical deflection between the new and old bridge panels, resulting in the backward curvature difference caused (the deformation is shown in Figure 1).

According to the literature, the critical curvature formula obtained by Ng is:

$$\phi_{cr} = 2\left(\frac{1}{d}\right)\varepsilon_{cr} \tag{1}$$

In the formula, ε_{cr} is the ultimate tensile strain of the joint concrete; d is the thickness of the joint concrete slab.

In addition, the relationship between the reverse curvature ϕ and vertical deflection Δ is:

$$\phi = \frac{6\Delta}{L^2} \tag{2}$$

The L is the width of the joint concrete slab.

In the first two equations, the formula of vertical critical deflection between the new and old bridge joints can be obtained to reflect the deformation and damage of the joints. The critical deflection formula is:

$$\Delta_{cr} = \frac{1}{3}\left(\frac{L^2}{d}\right)\varepsilon_{cr} \tag{3}$$

Combined with K.H.Kwan et al., the critical curvature of the concrete slab in 200mm thick is used as the standard. Through the study of the model experiment to the concrete joint of the widened bridge, the

relationship between the initial curvature threshold and the degree of the joints cracks was obtained by the vehicle vibration simulation test: $18\times10^{-3}m^{-1}$, $27\times10^{-3}m^{-1}$, $36\times10^{-3}m^{-1}$, and $45\times10^{-3}m^{-1}$, corresponding cracks appeared, slightly cracking (0.1mm in width), medium cracking (0.2mm in width) and severe cracking (>=0.3mm in width). At the same time, the vibration curvature threshold which can lead to a significant reduction in the bond strength of the reinforced concrete is about $81\times10^{-3}m^{-1}$, far greater than the vibration threshold corresponding to concrete cracking, and it can be used as the absolute limit of vibration control of the bridge vehicle.

In this paper, the width of the cast-in-place joint is 50cm and 160mm thick. According to the above calculation formula, the corresponding vertical deflection value is 1.4mm. It is a critical evaluation index for the cracking of joints under the vibration of the bridge.

3 PRINCIPLE OF VIBRATION ANALYSIS OF VEHICLES AND BRIDGES

In the present study, the modal superposition and coupled method is used in solving VBCV problem. Since the dynamic responses of bridge are usually determined by the lower order modal shapes, the method is widely used to increase the computation efficiency (Calcada et al. 2005; Xu et al. 2010).

3.1 *Equation of motion of the vehicle*

The equation of motion for a vehicle can be expressed as follows:

$$[M_v]\{\ddot{X}_v\}+[C_v]\{\dot{X}_v\}+[K_v]\{X_v\}=\{F_v\} \qquad (4)$$

where $[M_v]$, $[C_v]$, $[M_v]$, and $[M_v]$, $[K_v]$ are the mass, damping, and stiffness matrices of the vehicle, respectively; $\{X_v\}$ and $\{F_v\}$ are the displacement vector of the vehicle and the vector of the wheel-road contact forces acting on the vehicle, respectively.

3.2 *Equation of motion of the bridge*

The equation of motion for a bridge under moving vehicle load can be written as:

$$[M_b]\{\ddot{X}_b\} + [C_b]\{\dot{X}_b\} + [K_b]\{X_b\} = \{F_b\} \qquad (5)$$

where $[M_b]$, $[C_b]$ and $[K_b]$ are the mass, damping, and stiffness matrices of the bridge, respectively; $\{X_b\}$ is the node displacement vector for all DOFs of the bridge, and $\{F_b\}$ is the force vector acting on the bridge through the vehicle's wheels.

3.3 *Road surface condition*

The road surface condition (RSC) is a very important factor that affects the dynamic responses of both the bridge and vehicles. The RSC is usually assumed to be a zero-mean stationary Gaussian random process and can be generated by an inverse Fourier transformation based on a power spectral density (PSD) function as:

$$r(x)=\sum_{k=1}^{N}\sqrt{2\varphi(n_k)\Delta n}\cos(2\pi n_k x+\theta_k) \qquad (6)$$

where θ_k is the random phase angle uniformly distributed from 0 to 2π, $\varphi()$ is the PSD function (m3/cycle) for the road surface elevation, and n_k is the wave number (cycle/m). The PSD functions for road surface roughness were developed by Dodds and Robson (1973), and the PSD function was simplified by Huang and Wang (1992) as:

$$\varphi(n)=\varphi(n_0)\left(\frac{n}{n_0}\right)^{-2} \qquad (n_1<n<n_2) \qquad (7)$$

where n is the spatial frequency (cycle/m); n_0 is the discontinuity frequency of $1/2\pi$ (cycle/m); $\varphi(n_0)$ is the roughness coefficient (m^3/cycle) which is related to the road surface condition; and n_1 and n_2 are the lower and upper cut-off frequencies, respectively.

The International Organization for Standardization proposed a road roughness classification index from A (very good) to H (very poor) according to different values of $\varphi(n_0)$. In the present study, the ISO road roughness classification is used.

3.4 *Assembling the vehicle-bridge coupled system*

Based on the displacement relationship and interaction force relationship at the contact points, the vehicle-bridge coupled system can be established by combining the equations of motion of both the bridge and vehicle as follows:

$$\begin{bmatrix} M_v & 0 \\ 0 & M_b \end{bmatrix}\begin{Bmatrix} \ddot{X}_v \\ \ddot{X}_b \end{Bmatrix}+\begin{bmatrix} C_v & C_v \\ C_{bv} & C_b \end{bmatrix}\begin{Bmatrix} \dot{X}_v \\ \dot{X}_b \end{Bmatrix} +\begin{bmatrix} K_v & K_{vb} \\ K_{bv} & K_b \end{bmatrix}\begin{Bmatrix} X_v \\ X_b \end{Bmatrix}=\begin{Bmatrix} F_v^b \\ F_b^v \end{Bmatrix} \qquad (8)$$

where C_{bv}, C_{vb}, C_b, K_{bv}, K_{vb}, K_b, F_v^b and F_b^v are the results of the wheel-road contact forces and time-dependent terms.

To simplify the bridge model and therefore save computational effort, the modal superposition technique can be used, and Eq. (8) can be simplified into the following:

$$\begin{bmatrix} M_v & 0 \\ 0 & M_B \end{bmatrix}\begin{Bmatrix} \ddot{X}_v \\ \ddot{q}_B \end{Bmatrix}+\begin{bmatrix} C_v & C_{vB} \\ C_{Bv} & C_B+C_B^v \end{bmatrix}\begin{Bmatrix} \dot{X}_v \\ \dot{q}_B \end{Bmatrix} +\begin{bmatrix} K_v & K_{vB} \\ K_{Bv} & K_B+K_B^v \end{bmatrix}\begin{Bmatrix} X_v \\ q_B \end{Bmatrix}=\begin{Bmatrix} F_v^r \\ F_B^{rG} \end{Bmatrix} \tag{9}$$

where subscripts "B" and "v" represent the bridge and vehicle, respectively; superscript "v" in the stiffness (K) and damping (C) terms refers to the contributions due to vehicles; subscripts "Bv" and "vB" refer to the vehicle and bridge coupled terms; superscripts "r" and "G" represent the acting force due to road roughness and gravity force of the vehicles, respectively.

The VBCV system in Eq. (9) contains only the modal properties of the bridge and the physical parameters of the vehicles. As a result, the complexity of solving the vehicle-bridge coupled equations is greatly reduced. Based on the methodology discussed above, a Matlab program is developed to automatically assemble the coupled equations of motion of the VBCV system and solve them in the time domain by the Newmark-β method. More details for the bridge-vehicle coupled system and solving process can be found in Li and Cai (2016).

4 DYNAMIC BEHAVIOR ANALYSIS OF WIDENED BRIDGE JOINTS UNDER TRAFFIC LOAD

4.1 *Engineering background*

This paper relies on a prestressed concrete simple branch T beam bridge single side extension reconstruction project involved in a highway reconstruction project from Shenyang (Wangjiagou) to Tieling (Xingshan). In the design scheme, the lower structure is separated and the upper structure is connected to the original bridge. The size of the new bridge T beam and the old bridge T beam are basically the same. For the example of a simple beam bridge with single hole span 20m, its typical cross-section is shown in figure 2. The beam is 150cm high and 170cm wide and the upper flange is 16cm thick. The 6th beam of new bridge is semi-rigid connected to the 5th beam of old bridge by concrete joints. As is shown in Figure 3, the joints' width is 50cm and the thickness is 16cm. Based on the relevant research results of highway vehicle load test data and typical vehicle model parameters. Using the self-braided bridge vibration analysis program, the dynamic response analysis of different heavy vehicle types and their combined working conditions is carried out. The pre-stressed concrete simple branch T beam bridge was analyzed with the span of 20m, 25m, 30m, 35m and 40m. After analyzing the influence of speed, lane position and vehicle weight on the dynamic response of the expansion bridge joints, it put forward some traffic control measures such as load limit, speed limit and lane limit.

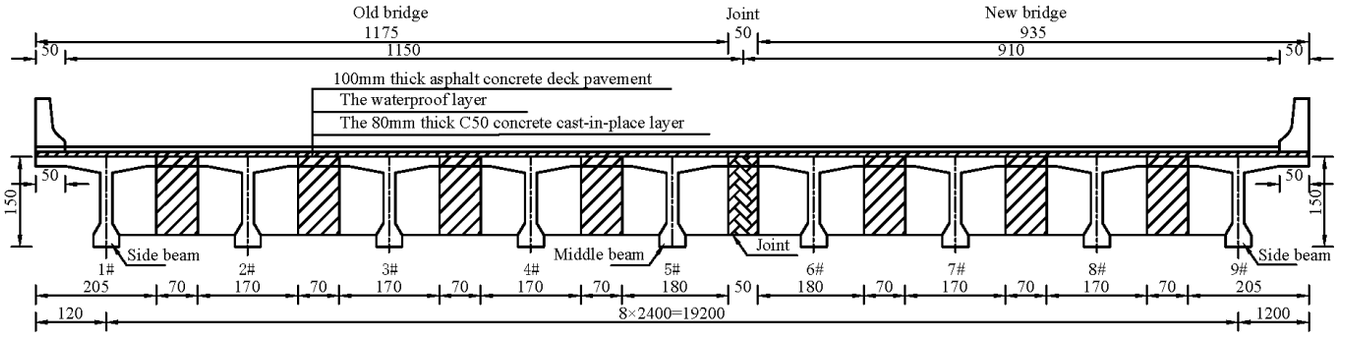


Figure 2. The typical section of the bridge (unit: cm)

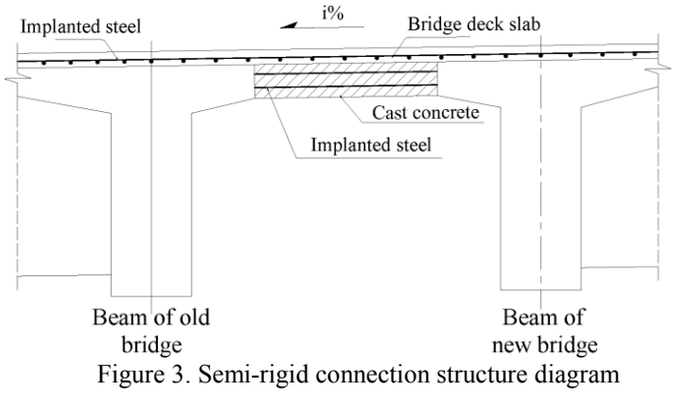

Figure 3. Semi-rigid connection structure diagram

4.2 *Widened bridge calculation and analysis model*

In order to analyze the stress state of key parts of the bridge, the spatial finite element model was established by ANSYS under the structure of semi-rigid transverse connection. The main beam and the connection of the new and old bridge is simulated by SOLID65 entity unit. The deck pavement adopts SHELL63 shell unit. The support is established with a COMBINE14 spring unit. Take the above 20m span bridge as the representative, its computational model is shown in Figure 4. In this paper, based on

the results of the existing experimental study, the critical value index of vertical deflection of the joint joints is proposed, and the vibration test is carried out in 1d of concrete pouring. For this reason, the parameters of the joint concrete in the bridge model are determined according to the age of 1d. And according to the results of the study of the mechanical properties of early stage concrete by Xuzhongqing, the elastic modulus is 1.72×10^4MPa.

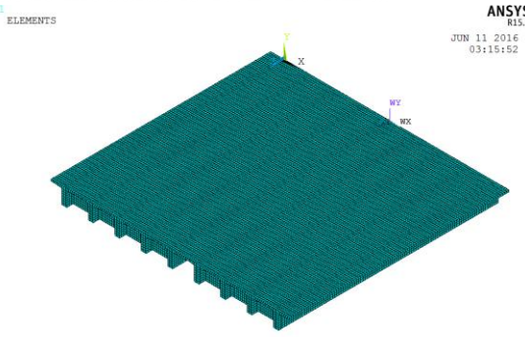

Figure 4. The finite element model of the bridge

4.3 *Characteristics of highway traffic load*

The traffic control analysis in the construction of the widening bridge is mostly based on the design lane load, and the difference of the effect of the actual bridge traffic load and the design load on the existing bridges are less considered. It is necessary to carry out detailed investigation and analysis of the traffic load characteristics (model, vehicle weight and overloading ratio, etc.) for the traffic control measures during the construction of specific bridges. When the data is not available, the traffic load conditions of similar roads in the area can be referenced. Based on a large number of road traffic survey, dynamic weighing data nationwide and existing relevant research results, the most common heavy-duty models in highway in China can be reduced to 7 types (see table 1). The related parameters of various types of models refer to the research results of Hanwanshui, Zhangxiang and other related research on vehicle and traffic investigation. The spatial dynamic analysis model of each model is detailed in the literature.

Table 1 Vehicle types and characteristics

No.	Types	Axle number	Graphic （wheel base: mm; Axle load: kg）
V1	Trucks	2	
V2	Trucks	3	
V3	Trucks	4	
V4	Trailer	3	
V5	Trailer	4	
V6	Trailer	5	
V7	Trailer	6	

Note: the V1 model is a two-axis vehicle, the V2 model is a three-axis vehicle, and the V3 model is a four-axis vehicle. The V4 model is a three-axle trailer, the V5 model is a four-axle trailer, and the V6 model is a five-axle trailer. The V7 is a six-axle trailer. The same below.

4.4 *The analysis cases*

The vibration response of the widening bridge is mainly affected by the following factors, including the vehicles type, load, speed, the position of the lane and the arrangement of vehicles. Besides, bridge surface roughness is also an important factor affecting the vehicle impact. The International Organization for Standardization (ISO, 1995) divides bridge surface roughness into 5 grades from "good" to "very poor". Considering the actual bridge surface roughness of the new bridge part which is widened and reconstructed, the roughness grade is taken as "good"". According to the actual situation of highway traffic in China, and considering the influence factors above, the relevant parameters of the analysis cases are determined as follows.

(1) Vehicle load condition

Based on the existing research with massive highway vehicle data and relevant vehicle dynamic model in China, seven typical truck models (as shown in Table 1) are selected for the subsequent analysis.

The standard of full load for various vehicles is determined by related department in China, which limits that each axle weight is under 10t, while the total weight is under 10t × axle number. Referred to the highway traffic load data in China, the load situation of the above 7 typical models is divided into three cases: full load, overload 50% and 100%, which provides the load limiting index for bridge widening and reconstruction with open traffic.

(2) Vehicle speed

Considering that the speed ranges from 20 to 100km/h, the vibration response of joint is calculated and analyzed, which provides the speed limit index of heavy vehicle during the widening bridge joint construction process.

(3) Vehicle lane

The old bridge part of the widening bridge is one-way street with two lanes. The position of the old

bridge lane is shown in figure 5. In the following analysis of vehicle-bridge coupled vibration, the single vehicle condition is considered. To be specific, the aforementioned 7 various vehicles pass the bridge, respectively, in Lane 1 (far from the seam side of the lane) and Lane 2 (near the side of the joint side of the lane) bridge at different speeds.

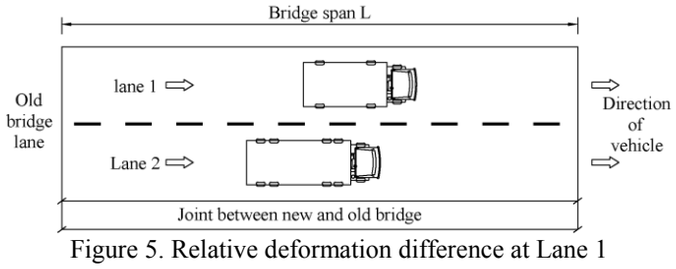

Figure 5. Relative deformation difference at Lane 1

4.5 *Dynamic response analysis of joints of widening bridge under single vehicle*

4.5.1 *A widening example of 20 m simply supported bridge*

(1) Vehicle load condition

Based on the analysis program of vehicle-bridge coupling vibration, the 7 types of vehicles pass Lane 2 at different speeds (as shown in Figure 5) respectively with full load, overload 50% and 100%. The maximum relative deformation difference of the cast-in-place joints between the new and old bridge is calculated as shown in Figure 6.

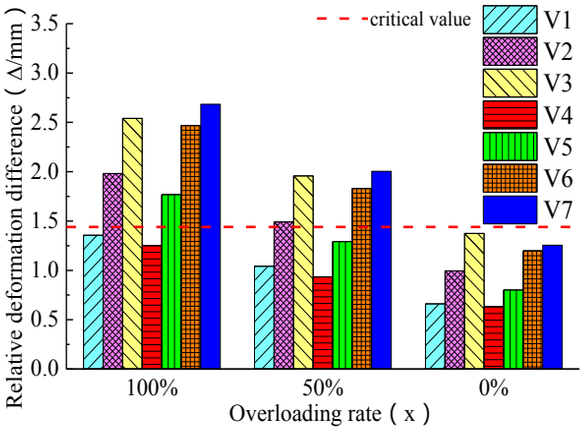

Figure 6. The maximum relative deformation difference under the action of various types of vehicles

According to the bridge vibration critical value mentioned above, when the vehicles are overloaded by 50% or 100%, the relative deformation difference induced by various vehicles all exceed 1.4mm; when the vehicles are full-loaded, the relative deformation difference is within the limit. The results show that, in this example, if all kinds of vehicles are not overloaded, there is no need for extra traffic control during the construction of bridge widening.

(2) Vehicle speed

The conditions of 5 types of vehicle overloaded by 100% on Lane 2 are selected for further analysis about the impact to the joint with vehicle speed ranging from 20 to 100 km/h. As shown in Figure 7, the vehicle speed has little effect on the relative deformation. The relative deformation difference exceeds 1.4mm under all speed conditions. Therefore, there is no speed limit condition for all type of vehicles. Similarly, the conditions of 5 types of vehicle overloaded by 100% on Lane 2 can induce the same results.

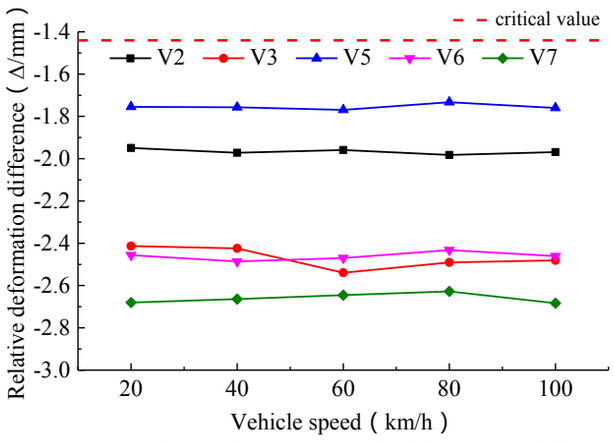

Figure 7. The relative deformation of bridge under different speed

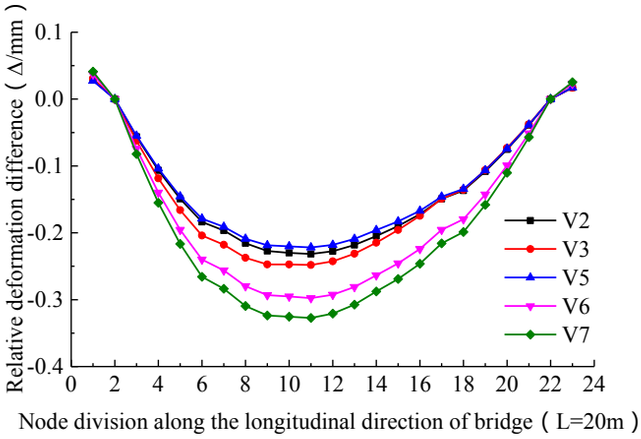
(3) Vehicle lane

Changing the vehicle overloaded by 100% from Lane 2 to Lane 1, the distribution law of relative deformation difference along the longitudinal direction of the bridge can be calculated, as shown in Figure 8. The results of various vehicles are less than 1.4mm. It shows the measure that limiting the heavy vehicle traffic of Lane 2 can eliminate the adverse effects of the vehicle bridge vibration.



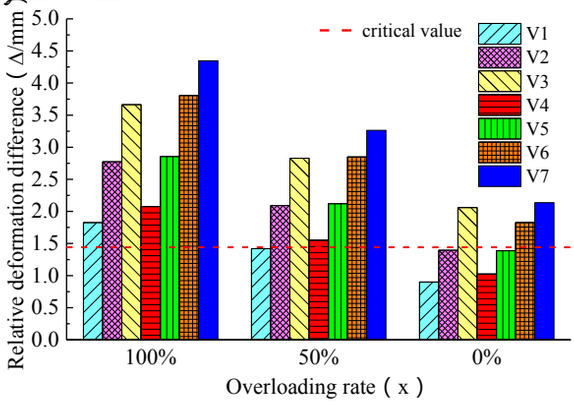


Figure 8. Relative deformation difference at Lane 1

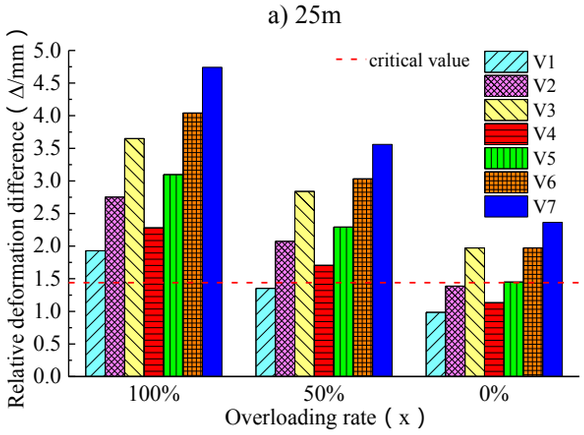
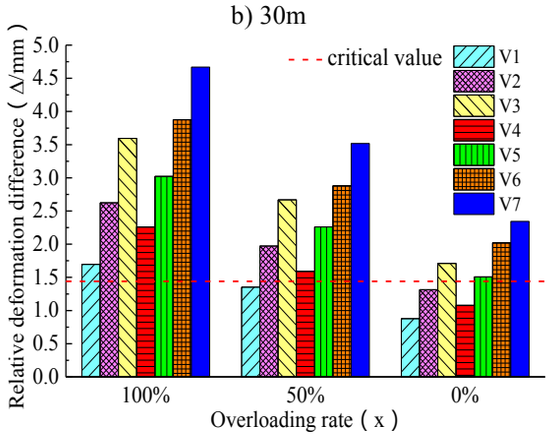
4.5.2 *Examples with other spans*

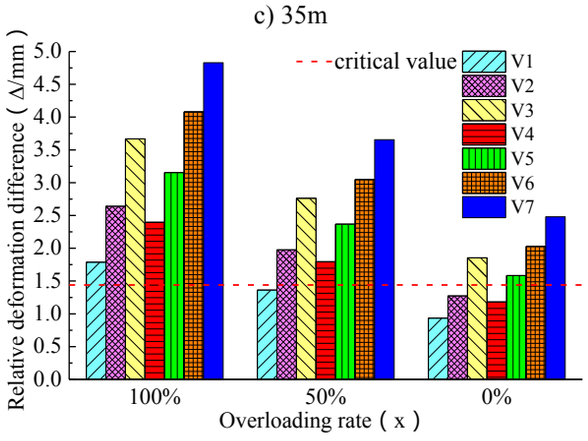


(1) Vehicle load condition

Considering 7 types of vehicles passing Lane 2 at different speeds respectively with full load, overload 50% and 100%, the maximum deformation differences with different span of 20, 30 and 40 m is calculated as shown in Figure 9. It can be seen the relative deformation of the different span increases that with the increase of the load. Compared with Figure 6, the relative deformation difference of widening bridge with 25 m span increases greatly. When the



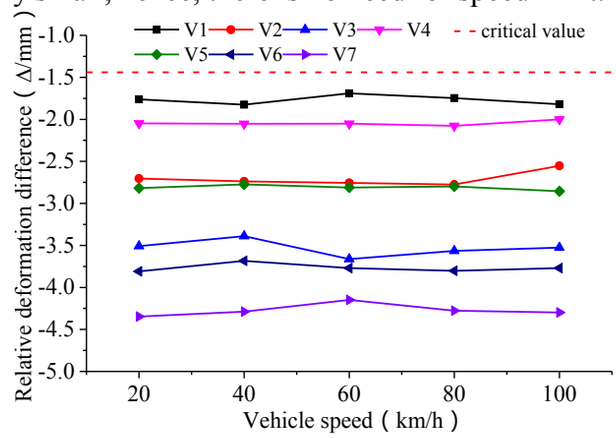
span exceeds 25m, the variation laws of the overload rate and the relative deformation difference are basically the same.



a) 25m

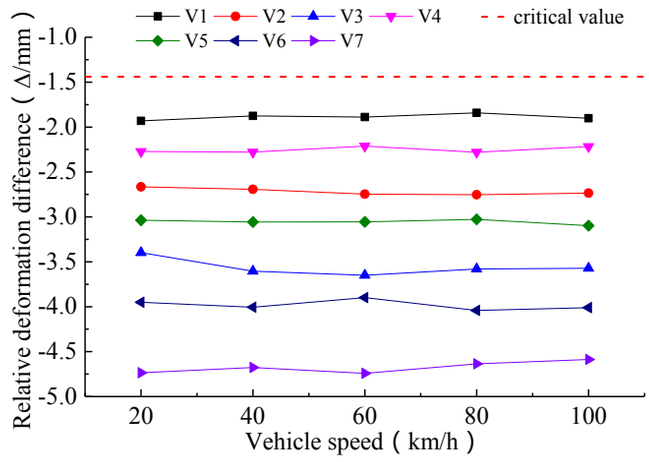
b) 30m

c) 35m



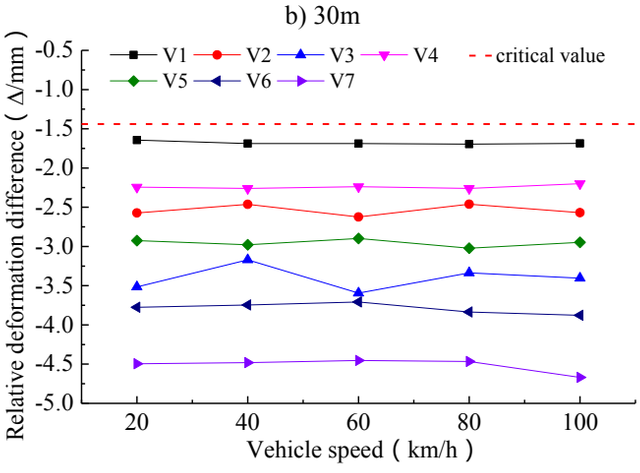
d) 40m

Figure 9. The maximum relative deformation difference under the action of various types of vehicles

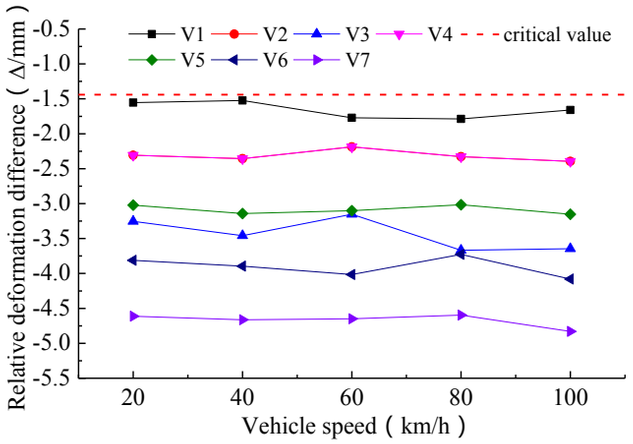


According to the bridge vibration critical value accounted above, as shown in Figure 9, when the vehicles are overloaded by 100%, the relative deformation differences of all 7 vehicles are greater than 1.4mm; when the vehicles are overloaded by 50%, only the result of 2 axle vehicle(V1) is under 1.4 mm; when the vehicles are full-loaded, the relative deformation differences induced by 4 axle vehicle (V3), 5 axle trailer (V6) and 6 axle trailer (V7) with all spans exceed 1.4mm. Besides, for 35m, 40m widening bridge, the relative deformation difference induced by 4 axle trailer (V5) is also more than 1.4mm.

(2) Vehicle speed



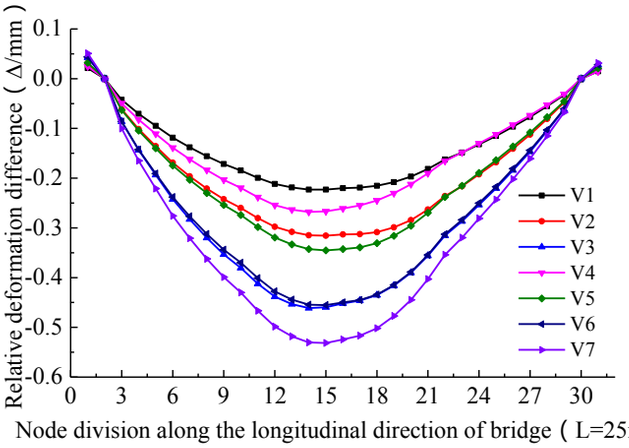
For the conditions of vehicle overloaded on Lane 2, the effect of velocity on the relative deformation difference with different spans is shown in Figure 10. The influence of speed on relative deformation is very small, hence, there is no need for speed limit.



a) 25m

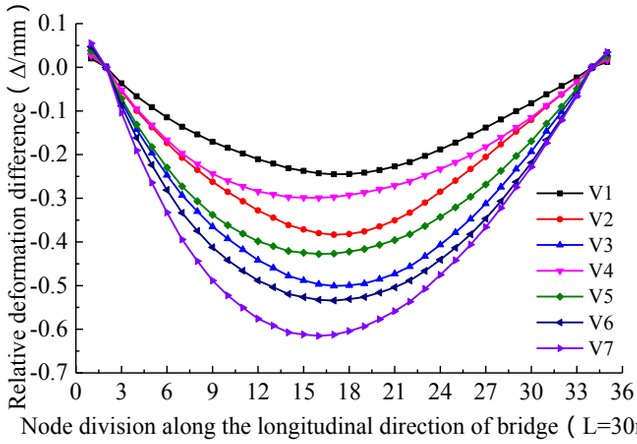
b) 30m

c) 35m



d) 40m

Figure 10. The relative deformation of the different span widening bridges under different vehicle speeds (Overload by 100%)



(3) Vehicle lane

The condition of the 7 types of vehicles overloaded by 100% are acted on Lane 1, the distribution law of relative deformation difference of the different spans bridge along the longitudinal direction is calculated, as shown in Figure 11. The maximum value appears near the mid-span of the widened bridge, and the value grows larger with the increase of the span, and it is still within the critical vibration index （$\Delta = 1.4$ mm）. Therefore, the traffic restriction measures can effectively reduce the deformation difference and eliminate the disturbance effect of the vehicle bridge vibration.

5 CONCLUSION

(1) In this paper, combining existing research results, the vibration evaluation index and the determination method of widened bridge joints under the traffic load are put forward, which can provide reference for the traffic control analysis of similar engineering construction process.

(2) The results of the vibration analysis of the bridge by the concrete simple supported T beam under typical automobile load are shown as follows: Under the same vehicle, the speed of the car has little influence on the relative deformation of the joints and can be ignored. As the bridge span increases, the relative deformation growth is not obvious. The relative deformation value increases linearly with the weight of the car. The main control factors of the relative deformation peak of the vehicle weight and the vehicle model need to be considered in the development of traffic control measures.

(3) In this paper, the analysis results of each bridge show that, for the model of the three-axle vehicle (V2), four-axle vehicle (V3), four-axle trailer (V5), five-axle trailer (V6) and six-axle trailer (V7), the relative deformation of the 25m~40m bridge has ex-

ceeded the critical vibration value in the full load. Among them, the six-axle trailer (V7) has a deformation difference of 2.5mm for the span of 40m bridge, exceeding the threshold of more than 72%. Therefore, these models should be controlled.

(4) In this paper, the analysis results of each bridge show that, the position of the vehicle action lane is most sensitive to the relative deformation of the cast-in-place joints. Keeping the car away from the stitching side lane of single span, vehicle loads can be unrestricted. Without lane control when vehicles cross the bridge, for the span of 20m: no traffic control need to be adopted for all kinds of fully loaded vehicles. For the span of 25m~ 40m: the three-axle vehicle (V2), four-axle vehicle (V3), four-axle trailer (V5), five-axle trailer (V6) and six-axle trailer (V7) require traffic control measures.

ABSTRACT: Steel columns are widely used in buildings, bridge piers, and railway platform roofs etc. With aging, those steel columns are vulnerable to corrosion and fatigue, and can deteriorate for a variety of reasons, especially in great earthquakes. In order to avoid the unrecoverable damage of existing steel columns, the high cost of the structure owners and the great impact on the public use, effective preventive maintenance methods on the aged steel piers are necessary. On this background, a strengthening method for aged steel columns by using new construction materials such as glass fiber reinforced polymer (GFRP) plates, rapid hardening concrete, rubber-latex mortar, and reinforcing bars, is introduced in this study. Depending on possible applied load directions and corrosion conditions, two specimens were used in the loading tests. Static loading tests were performed on steel columns with and without strengthening. Applied load and deflection relationship and strain distribution on original and strengthened columns were measured and compared. Moreover, three-dimensional FE models were built, and the numerical results were compared with the test results. Both experimental and numerical results indicate that the present strengthening method can significantly enhance both rigidity and ultimate load carrying capacity of aged steel columns.

1 INTRODUCTION

Steel column structures are used in buildings, bridges, railway platforms and other civil engineering structures around the world, due to their simpleness in both design and construction. An example of column structures used in a railway platform is shown in Figure 1. In recent years, however, severe damages of aged steel columns were observed in earthquakes. For instance, a large amount of steel bridge piers damaged in the 1995 Hyogoken-Nanbu earthquake mainly because of either local buckling or rupture of welded corners (Chu, 2011). During the 2011 Tōhoku earthquake, severe damage was caused to electrification poles on viaducts of Tōhoku Shinkansen. Based on the existing experience, Japanese design specifications have been revised and updated a lot, but they are mainly used for designing new columns. For aged steel piers constructed with old design methods, they are generally not satisfied to new design codes, thus they should be strengthened appropriately. On this background, seismic retrofit on existing steel column structures has become a major concern.

With the purpose of improving the seismic performance of existing steel columns, a preventive seismic retrofit method for existing steel column structures is proposed in this paper. Both static loading tests and numerical simulations were conducted to investigate the real effectiveness of the present strengthening method and its improvement on the seismic performance of existing column structures.

Figure 1. Column structures in Japanese railway platforms.

2 STRENGTHENING STRATEGY

In this study, a strengthening method using GFRP plates, rubber-latex mortar, rapid hardening concrete, and reinforcing bars is proposed to strengthen the existing column structures. Rubber-latex mortar shows various abilities especially in adhesion bonding, waterproofing, shock absorption and abrasion resistance (Lin et al., 2013, 2014a), and significant contribution of rubber-latex mortar in enhancing bonding strength on steel-concrete interface was confirmed in previously performed bonding tests, as shown in Figure 2. In this method, the rubber-latex mortar is mainly used to enhance the integrity between aged structural steel and newly added surrounding concrete. Rapid hardening concrete is used for resisting the external loads together with the existing steel column, thereby increasing the rigidity and load carrying capacity. FRP plates are used as the formwork for concrete casting, and its contribution in the load carrying capacity is not considered in the design. Similar to other RC structures, reinforcements are used for controlling the crack width after concrete cracking.

As shown in Figure 3, the retrofitting sequence can be divided into surface preparation, spraying of rubber-latex mortar, set-up of the reinforcement and GFRP plates, and finally casting of rapid hardening concrete etc. Images of a steel pier during strengthening by using the method proposed in this study are shown in Figure 4. This method was originally proposed by authors of this paper for strengthening superstructures of aged short-span railway bridges, and both laboratory loading tests and field loading tests were performed by authors' group (Lin et al., 2014b, 2014c, 2017, and Taniguchi, 2016). Considering it outstanding effects in improving the structural performance of bridge superstructures, this study was performed to investigate its possibility in strengthening existing column structures.

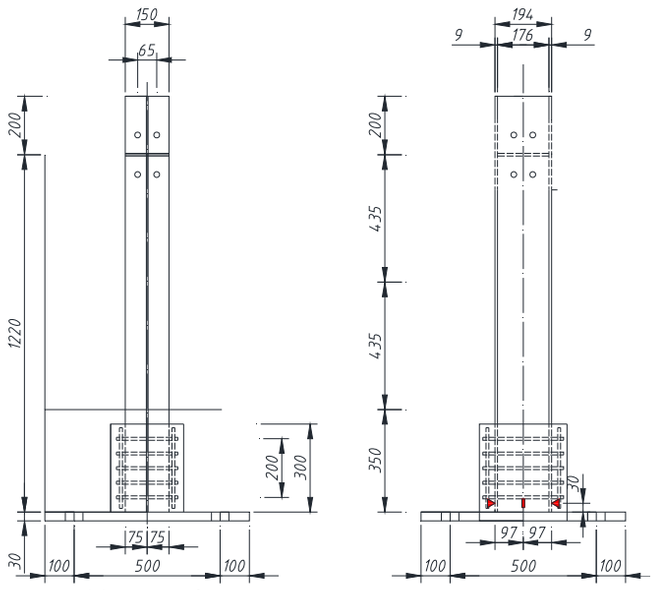
3 EXPERIMENTAL PROGRAMME

3.1 *Test Specimens*



Two steel columns with same cross-section (an H-shape section of 194×150×6×9) were designed. Each of the specimens was 1.42m in height and the loading point was decided at the height of 1.2m. Stiffeners were welded at the loading point to prevent buckling and crippling of the web before flexural failure. A 700mm square steel plate with thickness of 30 mm was used as the base plate and connected with the steel column by welding. To strengthen the original steel column, the rubber-latex mortar with the thickness of 5mm was used on the surface of the aged structural steel. Reinforcement with a nominal diameter of 10mm for longitudinal reinforcement and 6mm for stirrups were used. Finally, rapid hardening concrete was casted. Mix proportions of rubber-latex mortar and rapid hardening concrete are shown in Table 1 and Table 2, respectively. The test specimens were fixed through connecting the base plate with the ground by using 4 bolts with a circular diameter of 60mm.The geometry dimension of the test specimen is shown in Figure 5.

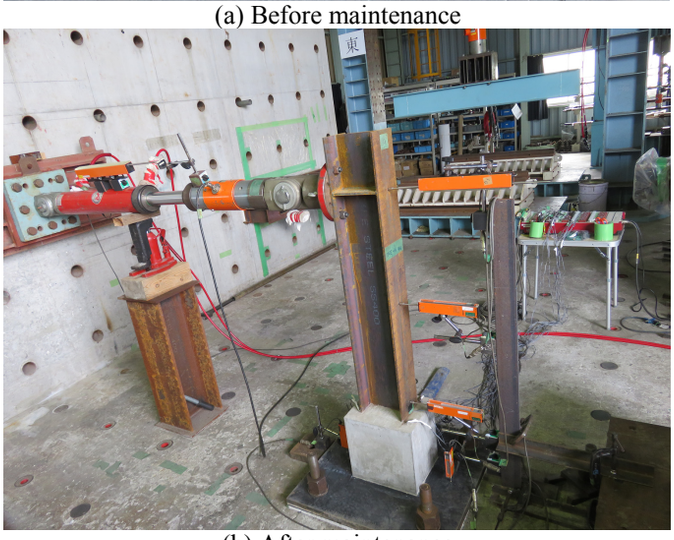
3.2 *Static Loading Test Set-up*



The load is applied by a jack in horizontal direction to simulate the earthquake load. For columns like electrification poles or columns in railway platform roofs, the axial force can be ignored in the design due to their negligible dead-weight. In terms of steel pier in bridge structures, the axial force is generally designed as no larger than 20% of its yield load. Therefore, the axial force in the column is not considered in order to simplify the loading test. However, the influence of the axial force on mechanical behavior of steel columns will also be investigated in this study, by using the numerical results.

As shown in Figure 6, there are strong axis and weak axis in a typical column with an H-shape cross-section. In order to investigate the effects of the proposed method in two different directions, the horizontal load was applied in both strong and weak axis directions, respectively. For this reason, two specimens were used in this study. Before strengthening, static loading tests were performed on the two original steel columns, including SC-S-1 (original steel column under load in strong axis direction) and SC-W-1 (original steel column under load in weak axis direction). The applied load was controlled in a low level to avoid any possible damage on columns. After strengthening, SC-S-2 (strengthened steel column under load in strong axis direction) and SC-W-2 (strengthened steel column under load in weak axis direction) were tested again to compare with the original steel columns without strengthening.

In order to confirm the sectional strain distribution, 7 strain gauges were used to measure the normal strain in the web and steel flanges near the bottom section, as shown in Figure 6. LVDTs were also used to measure the horizontal displacement at the loading section and two sections. The static loading test set-up for both original and strengthened columns was shown in Fig.7.

4 NUMERICAL MODELLING

The simulation of test specimen was carried out using the finite-element method and *DIANA* software. Solid elements were used to simulate the concrete, and shell elements were employed to model the steel column. Numerical models of steel column before and after strengthening were shown in Figure 8. To simulate the bond connection between the steel column and surrounding concrete, and the connection between the ground and the base plate, interface elements used in the numerical analysis, as shown in Figure 9. Re-bar elements were used for modeling the reinforcement, as shown in Figure 10.

Figure 8. Numerical models for columns.

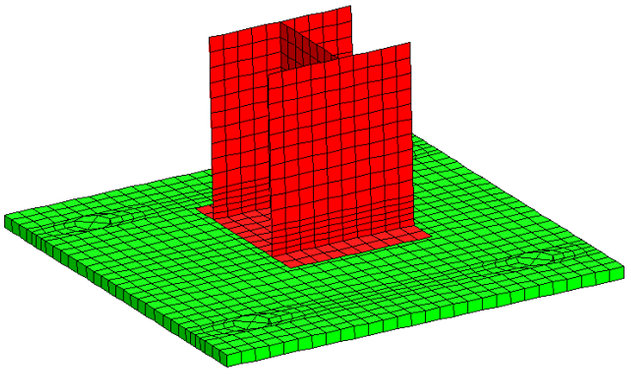

Figure 9. Simulation of interface.

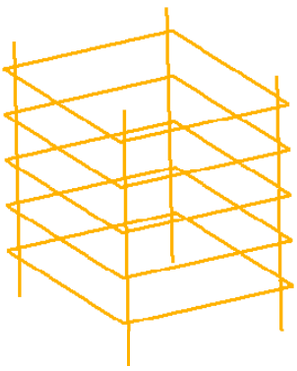

Figure 10. Simulation of reinforcement.

Material tests were performed, and the nominal compressive strengths of concrete achieved after 7 days and 11 days (test day) were 36.2 N/mm^2 and 39.3 N/mm^2, respectively. Experimental tensile stress-strain curve proposed by Nakasu et al. (1996) was used to simulate the tension softening behavior of concrete. The compression behavior of concrete was referred to JSCE (2002). The stress-strain curve considering the strain hardening was used to simulate the structural and reinforcing bars (JSCE, 2002). The yield strength of the H-shape column was 309 N/mm^2 according to the material test report. The yield strength of reinforcement was yield strength: 295 N/mm^2. The simplified interface model developed from Dörr's bond-slip model is used to model the steel-concrete interface (Dörr, 1980).

5 RESULTS AND DISCUSSION

5.1 *Applied Load in the Strong Axis Direction*

When the steel column is subjected to a load in the strong axis direction (SC-S), the load-displacement curve obtained from the numerical analyses is compared to the experimental results as shown in Figure 11. For retrofitting of aged steel columns, increase of rigidities in service state and increase of load carry capacity in the ultimate state are major concerns for engineers. On the basis of the obtained results, both experimental and numerical results demonstrate increase of the column stiffness after strengthening. Taking the horizontal deflection of 6.3mm (the maximum displacement in loading test for SC-S-1) as an example, the test load changed from 24.9kN in SC-S-1 to 31.4kN in SC-S-2, increased by 26%. For the strengthened column, the numerical model was stronger than the test model, which might be due to the ignored residual stress at the welded section in the numerical analyses. The comparison between the numerical results also indicates that the ultimate load carrying capacity of the column has increased obviously after strengthening. Taking the horizontal displacement of 61mm as an example, the corresponding load increased from 79.8 kN in SC-S-1 to 98kN in SC-S-2, thus 22.8% increase was confirmed.

In addition, the flexural strain measured at S2 and S5 were recorded and given in Figure 12 and Figure 13. The strain results at S2 and S5 indicate that the numerical values agree well with the experimental results during the elastic loading stage, and the significant reduction of flexural strain was confirmed in the strengthened column in comparison with the original column. Taking the applied of 24.9kN (maximum load applied in static loading test for SC-S-1) as an example, the corresponding strain at S2 reduced from -445μ in SC-S-1 to -110μ in SC-S-2, indicating 75% reduction in strain. On the other

hand, corresponding strain at S5 reduced from 301μ in SC-S-1 to 248μ in SC-S-2, indicating 17% reduction in strain. The different strain reduction ratio at S2 and S5 might be due to the residual stress at the welded section. Therefore, great improvement of seismic performance during an earthquake is expected.

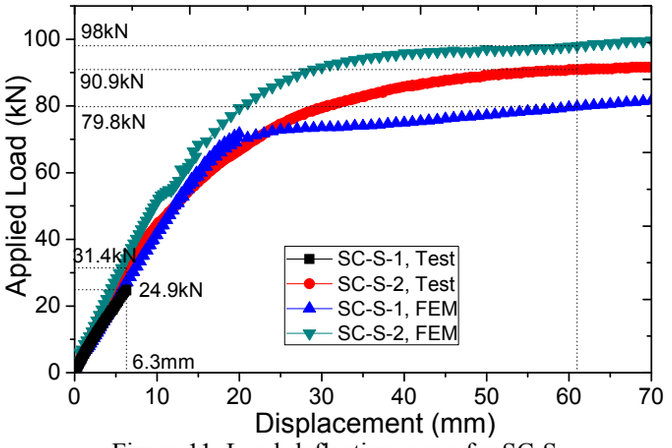

Figure 11. Load-deflection curve for SC-S.

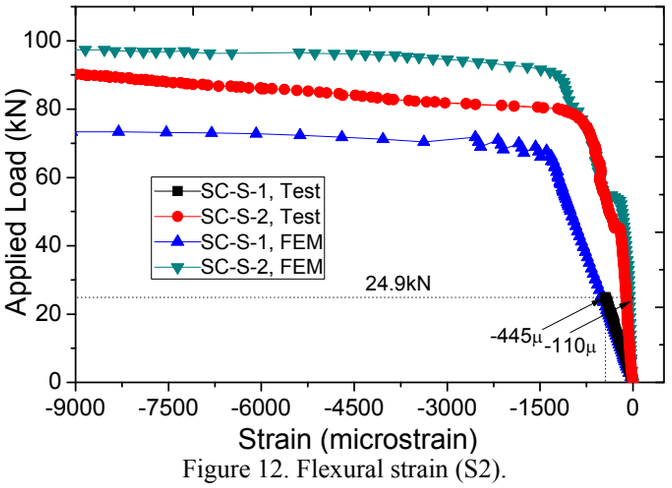

Figure 12. Flexural strain (S2).

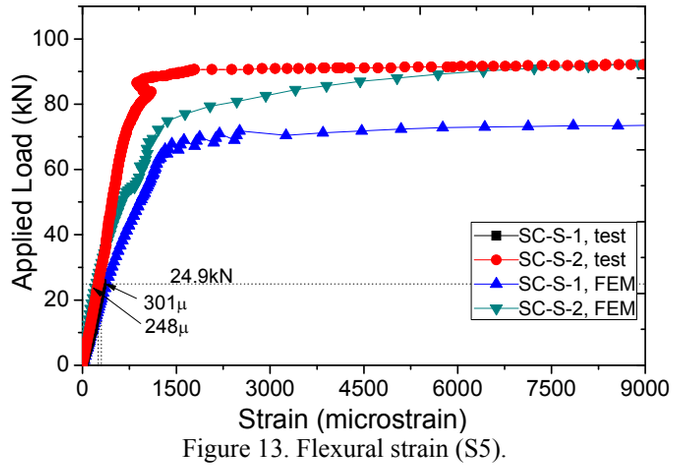

Figure 13. Flexural strain (S5).

5.2 *Applied Load in the Weak Axis Direction*

For the steel column under load in the weak axis direction (SC-W), the applied load and deflection relationship was given in Figure 14. According to the comparison, significant increase of the column stiffness and ultimate load carrying capacity in the weak axis direction were also confirmed. Taking the horizontal deflection of 6.9mm (the maximum displacement in loading test for SC-W-1) as an example, the test load changed from 9.5kN in SC-W-1 to 14.3kN in SC-W-2, increased by 51%. The ultimate load was increased from 26.4kN in SC-W-1 to 36.4kN in SC-W-2, thus 38% increase can be confirmed. The significant increase of the rigidity and load carrying capacity demonstrate the improvement of the seismic performance during earthquakes. Also, the comparison indicates that the numerical results agree well with the test results, indicating the validity of the numerical models used in this study.

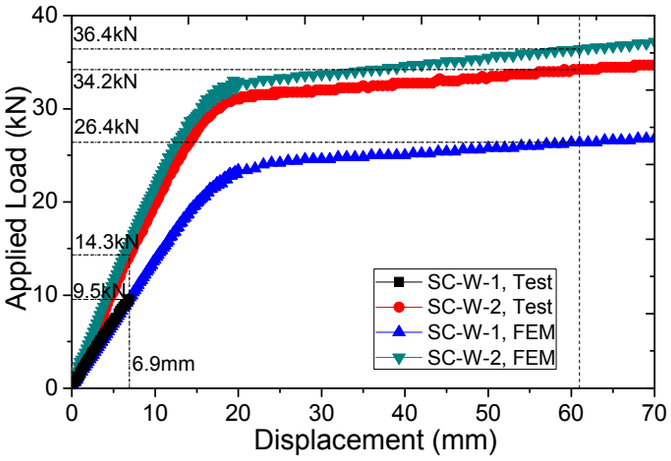

Figure 14. Load-deflection curve for SC-W.

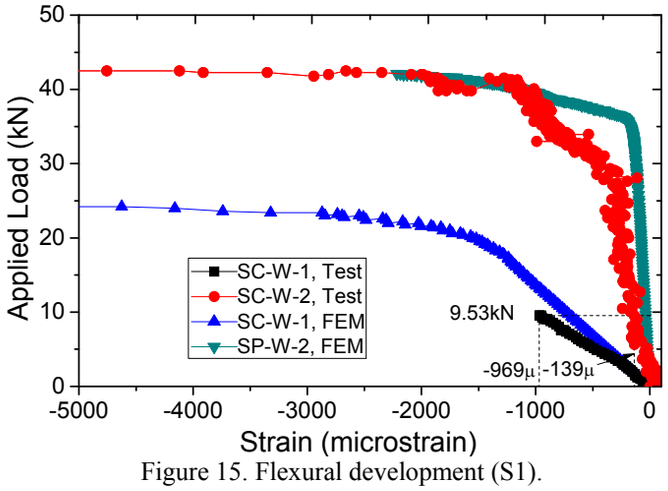

Figure 15. Flexural development (S1).

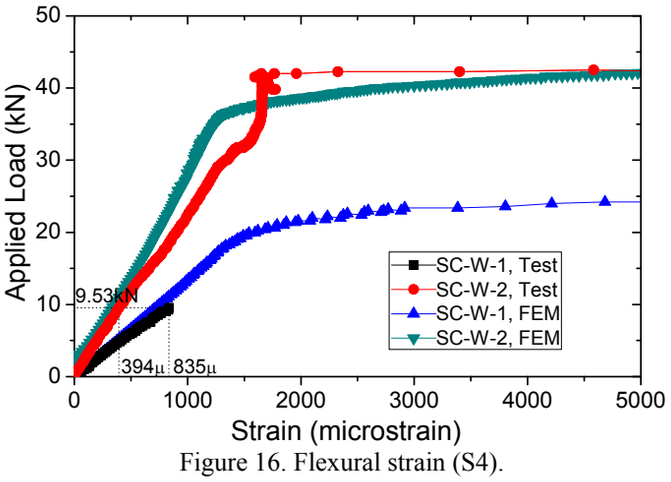

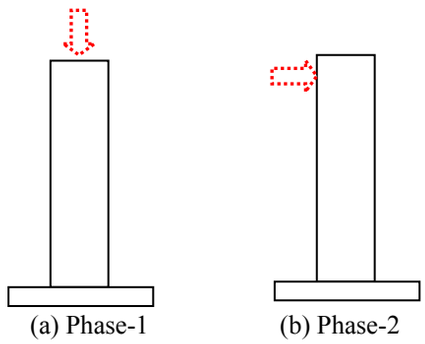

Figure 16. Flexural strain (S4).

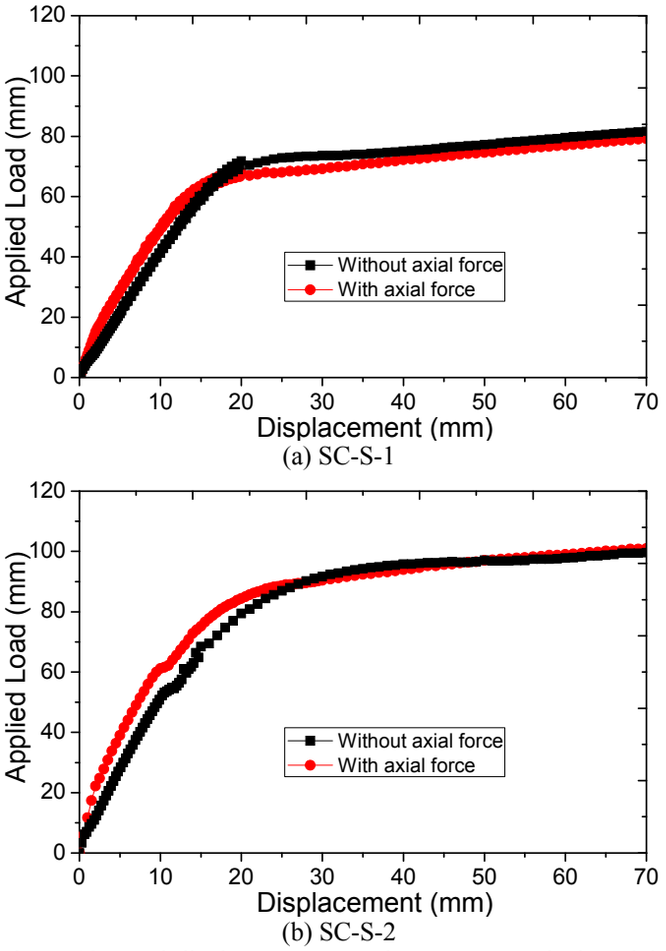
In addition, the flexural strain results of S1, S3, S4 and S6 were also measured in the loading tests. Due to the symmetry positions, the flexural strains at S1 and S3 in the original and strengthened columns were given to make a comparison, as shown in Figure 15 and Figure 16 respectively. The numerical results were also provided. The comparison in Figure 15 and Figure 16 indicate significant reduction of the flexural strains in the strengthened column. Taking the applied of 9.53kN (maximum load applied in static loading test for SC-W-1) as an example, the corresponding strain at S1 reduced from -969μ in SC-W-1 to -139μ in SC-W-2, indicating 86% reduction in strain. On the other hand, corresponding strain at S3 reduced from 835μ in SC-W-1 to 394μ in SC-W-2, indicating 53% reduction in strain. Therefore, extension of residual fatigue life in service stage and improvement of seismic performance during an earthquake for the column subjected to loads in the weak axis direction are also expected. In addition, relatively good agreement was observed between the numerical results and the test results.

5.3 *Effects of Axial Force*

In this study, the axial force for columns was ignored in order to simplify the loading tests and numerical analyses. This assumption will not affect the behavior for steel columns with negligible axial force, e.g. electrification poles or columns in railway platforms. For other columns subjects to unneglectable axial forces, e.g. steel piers, the effect of due axial force on the structural behavior of column structure is still known and needs to be investigated.

Phase analyses (two steps) were performed in the numerical analyses. In phase-1, the axial force considering the loads due to a bridge superstructure was applied at the top of the column, as shown in Figure 17 (a). The axial force was taken as 20% of its yield load, according to the existing studies in Japan. Thereafter, the horizontal load was applied in phase-2 until the ultimate state of the column models.



(a) Phase-1 (b) Phase-2

Figure 17. Phase analyses for considering the axial load.

For a column subjected to a horizontal load applied in strong axis, the load-displacement curves of both original and strengthened columns with and without considering axial force were shown in Figure 18 (a) and Figure 18 (b), respectively.

It is found that if the axial force was considered, the rigidities of columns (both original and strengthened columns) were increased slightly. However, no matter the axial force is taken into account or not, the effects of the proposed strengthening method can be confirmed. In addition, the ultimate load was affected little by the applied axial force. Therefore, it can be concluded that the present strengthening method is still effective even if a certain level (≤ 20%) of axial load is considered. Thus, this method can also be used for strengthening steel columns with axial force, like steel piers.

6 CONCLUSIONS

A strengthening method for existing steel columns was introduced in this paper. In order to confirm the effect of this method, static loading tests were performed on two original steel columns and columns strengthened with rubber-latex mortar, rapid hardening concrete, and reinforcing bars. Detailed load-deformation response, and strain distribution on the steel columns were reported in this paper. Easily obtained construction materials and simple operated construction methods make this method competitive

in comparison with other repairing methods. Static loading tests were performed to confirm the effects of the present strengthening method. On the basis of the test results, the present strengthening method was proved to be effective for increasing both rigidity and load carrying capacity of the aged steel columns, resulting in improvement of seismic performance of aged steel columns.

A 3-D nonlinear finite element model was established for simulating the present test specimens. The ultimate load carrying capacity, load-displacement curves and strain development process predicted by FE models agree well with those obtained from the experiments, which demonstrates the accuracy and efficiency of proposed FE models. In addition, the influence of axial force in steel columns was investigated in the numerical analyses. For a column subjected to an axial force in service condition (where the axial force is relatively small compared with its yield strength), the proposed strengthening method is still effective.

ABSTRACT: To assess the reliability of existing bridges, in general, extreme effects on a structure are analyzed, which allows predicting their behavior. In particular cases of small bridges, effects caused by fatigue due to the cyclic traffic loading might be significant. The main interest of the current paper is the possibility of applying the extreme value analysis to dissimilar bridges using data from different types of monitoring. Research in this area is carried out on the Anneau bridge in Switzerland and on the Millau viaduct, France, in order to compare the fatigue behavior based on signals from strain gauges in one case and on the WIM data in the other. The estimation of the fatigue life is based on the Extreme Value Theory and, in particular, the Generalized Pareto Distribution. The results aid to derive the efficiency of the method for the predictions of the high cycle fatigue action.

1 INTRODUCTION

The complexity of predicting the behavior of such structures as bridges at the end of their design life is an important topic for modern research. Due to the fact that many European bridges, as well as bridges all over the world, are coming to the end of their design life, the question of the extension of their operational life is vital. Moreover, the study of such objects allows improving design rules for future structures and possibly some profit from an economic point of view.

Usually, in bridge engineering, for the forecasting of the return levels of actions within the time period of the interest, the Extreme Value Theory (EVT) is used (Coles et al. 2001) such as for background works on Eurocodes (Sedlacek et al., 2008). One of the most efficient approaches to be used is the Peaks Over Threshold (POT), which proved to work well in diverse fields: wind engineering (Agarwal & Lance, 2009), precipitation predictions with non-stationary data (Roth et al. 2014), electricity demand estimation with a time-varying threshold (Sigauke & Bere, 2017) and others.

Concerning bridges, the mentioned method is successfully used to envision the forthcoming situation with an object (Zhou, 2013, Treacy, 2014), based on the long-term monitoring of traffic actions. For the proper use of the EVT, usually only extreme, meaning the highest, actions are considered. For instance, heavy (even overweighted) trucks are taken into account without paying attention to light cars. Since the number of light duty vehicles in most cases is quite large, they may cause fatigue of certain elements of a bridge. An interesting question is if this case can significantly affect the structure and how to anticipate it. Therefore, the focus of the current paper is mainly on the fatigue loading.

The interest of this study lays in fitting the generalized Pareto distribution (GPD), as a principal distribution of the POT approach, to the distribution of the number of fatigue cycles caused by different vehicles and axles of trucks. There were several similar studies carried out in various areas. For instance, in the area of composites, the stiffness-based model is introduced by (Shiri et al. 2016) for fatigue damage and life prediction or (Adasooriya, 2016) compares a new probabilistic fatigue assessment approach with a deterministic approach for railway bridges.

As it was recently proposed (Cetin, 2013), the different aspects of material fatigue may be considered as an extreme value dependent process. For a certain observed object, it is important to understand which case is the most unfavorable for a bridge: high amplitude stresses caused by rare extreme events or small stresses by a high number of cycles.

2 METHODOLOGY

2.1 *General procedure*

In general, to estimate the probability of occurrence of certain load effects (return level) within specified

periods of time (return period), the EVT might be applied to structures or structural elements.

First of all, it is necessary to choose an element in the studied structure that is exposed to the most unfavorable action or combination of actions. For example, in a case of bridges, it can be an element in the middle of a long span, where the bending moment is high. For reinforced concrete bridges, the main interest would be in those rebars with higher tensile stresses; for steel bridges, it might be the bottom flange of the girder, in details, welded parts.

Then, recorded data are needed to make predictions of the future behavior of a structure. One of the possibilities is measurements by strain gauges installed on the surfaces of the observed elements. Several gauges installed at different levels can help to get the stress redistribution in a cross-section. The frequency of measurements is important to obtain correct values of stresses from the measured strain. For instance, in bridges, to detect passing cars, the frequency of 50 Hz can be sufficient. The length of monitoring is not recommended to be less than 3 months in a case of traffic loads (Treacy, 2014) due to the instability of predictions.

Usually, such measurements are used to apply EVT based on block maxima or threshold models (Coles, 2001), where only extreme effects are considered. Data are fitted, respectively, to generalized extreme value distribution (GEVD) or GPD with certain parameters. These parameters are used to estimate return levels. To identify extreme values of load effects (LEs) represented, in this case, by fatigue cycles, the POT method is used as it is briefly shown in Figure 1.

2.2 *Common use of GPD*

It has been recently adopted for predictions of extreme traffic actions (Zhou, 2013, Zhou et al. 2016). Peak values of LEs X_i that lay above a certain threshold u are fitted to the GPD. The conditional distribution function can be expressed as:

$$F_u(y) = P[Y \le y | X > u] = \frac{F(y+u) - F(u)}{1 - F(u)}$$

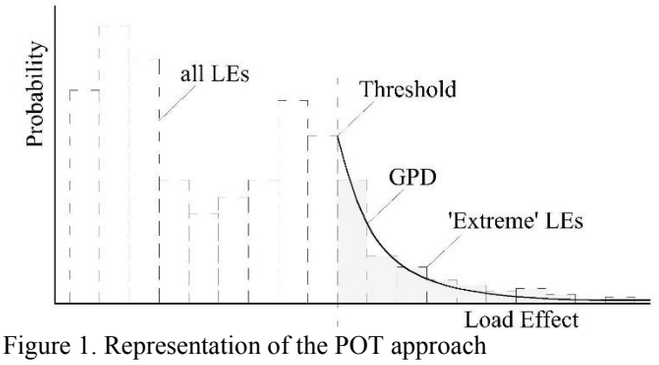

Figure 1. Representation of the POT approach

where $Y = X - u$ is a vector of (positive) threshold excesses Y_i, so that $Y_i = X_i - u$ and $F(u)$ is the cumulative distribution function of random variable X.

The main principe of the POT approach is based on the method described by (Pickands, 1975) and applied later for traffic loads: $F_u(y)$, under mentioned assumptions and conditions: $y = x - u,\ y \ge 0,\ \sigma > 0$ and $x \ge u$ for $\xi \ge 0,\ u \le x \le u - \sigma/\xi$ for $\xi < 0$; tends to the upper tail of a GPD:

$$G(x;\xi;\sigma;u) = \begin{cases} 1 - \left[1 + \xi\left(\frac{x-u}{\sigma}\right)\right]^{-\frac{1}{\xi}}, & \xi \ne 0 \\ 1 - \exp\left(-\frac{x-u}{\sigma}\right), & \xi = 0 \end{cases}$$

Conditions for the application of the EVT are the following:
- identical distribution of random variables X_i,
- random variables X_i are independent,
- threshold u is necessarily high.

For a long period, observations can be based on the cumulative distribution function of extreme values over a shorter period (Crespo-Minguillon & Casas, 1997).

Provided by (Coles et al. 2001), for the probability $P[X \le x | X > u]$ with $\zeta_u = P\{X > u\}$, the solution to the function is:

$$R_L(\mathrm{p}) = \begin{cases} u + \frac{\sigma}{\xi}[(p\zeta_u)^{\xi} - 1], & \xi \ne 0 \\ u + \sigma \log(p\zeta_u), & \xi = 0 \end{cases}$$

where $R_L(\mathrm{p})$ is p-observation return level – a quantile that exceeds once every p observations with large enough p to provide $R_L(\mathrm{p}) > u$.

The POT approach has also its difficulties such as selecting of an optimized threshold. On one side, it should be reasonably high, so, that extreme event types are not mixed, in order to avoid their convergence. On the other side, the threshold must be low enough to provide a necessary number of peaks for obtaining reliable results. The correct choice of parameter estimators σ, ξ for the GPD is also a drawback of the approach.

2.3 *Case of fatigue cycles*

In order to prove that there is no fatigue in an existing structure, European norms (EN 1993-1-1) provide S-N curves for diverse steel details or elements, and it is stated that there is no any danger under the value of five millions cycles of constant fatigue loading. Recent simulations bring the endurance limit in certain cases up to ten millions cycles (Baptisa, 2017).

Traffic actions on bridges are not constant as small frequent cycles are followed by high amplitude cycles rather randomly. There were

several recent studies focused on the fatigue simulation on bridges based on measurements. (Donghuang, 2017, Echard, 2013).
In the current study, the following suggestion is made: fitting of the GPD to a distribution of fatigue cycles, caused by vehicles or axles of different weights (Fig. 3). In certain cases, the proposed method takes into account all traffic actions on a bridge, though, the threshold u from the described previously approach is simply equal to zero.

The main idea is to verify the possibility and the efficiency of applying such method to predict the level of the fatigue of bridges (or their structural elements) due to high cycle fatigue load. Here, the term 'high cycle fatigue' is used to determine the cycles from frequent light vehicles.

The use of the GPD with its shape and scale parameters makes it be possible to assess values of return levels of fatigue cycles for different levels of loading. Taking into account that $u = 0$, the formula of the return level takes the following format:

$$R_L(\mathrm{p}) = \begin{cases} \frac{\sigma}{\xi}[(p\zeta)^{\xi} - 1], & \xi \neq 0 \\ \sigma \log(p\zeta), & \xi = 0 \end{cases}$$

where $\zeta = P\{X > 0\}$ is the probability of a positive X which is valid for all ELs in this case as number of cycles is always a positive value.

Normally, the value of ζ_u can be found as a ratio between all 'extreme' LEs – values that lay over a threshold u – and all LEs. Considering that all cycles are taken into account, this probability should be $\zeta = 1$ which would give the return level of a maximum number of cycles N_{tot}. On the other hand, knowing the probability of a number of cycles N_i for each range Δ_i of LEs $\zeta_i = N_i/N_{tot}$, $\sum \zeta_i = 1$, return levels are estimated for each Δ_i that gives the prediction of the distribution of cycles at the return period of the interest. So, the procedure consists of a few steps shown in Figure 2. The proposed algorithm is applied to monitoring data from two European bridges of totally different geometry and usage.

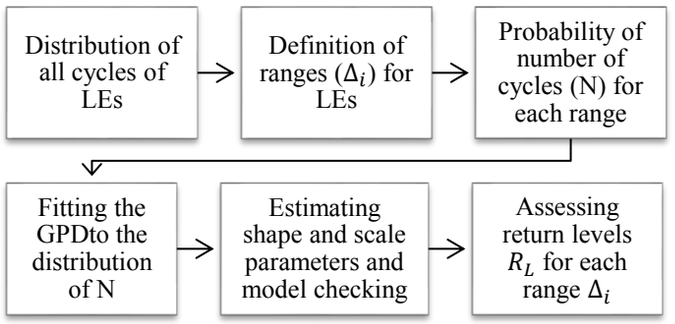

Figure 2. The algorithm of the proposed method

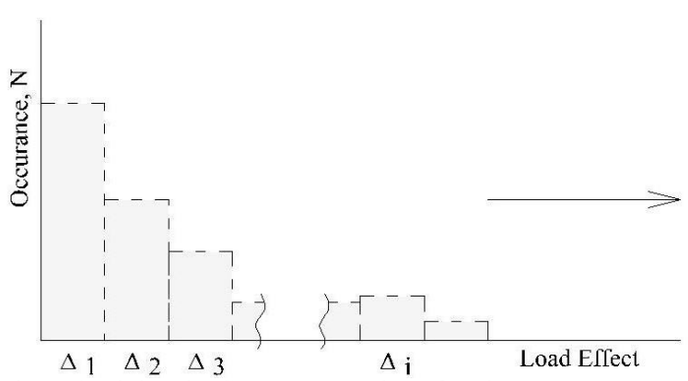
3 CASE STUDIES



Results of the study of the following bridges are shown in the current paper:
– Millau Viaduct, France,
– Anneau viaduct, Switzerland.

Each bridge has the specific equipment, as well, a particular geometry, materials and loading levels. In addition, a different type of monitoring was used in each country: Weight-In-Motion (WIM) system in France, strain gauges – in Switzerland.

3.1 *Millau Viaduct*

The viaduct itself is a large structure of 2460 m long with pylons of 77 to 245 m high with the height of towers of almost 90 m (Fig. 2). Its orthotropic steel deck suspended by cables is stiff and provided with joints that permit openings up to 80 cm in horizontal directions. Each span of 245 m is composed of six meters long elements, each of them works almost as a simply supported beam. That allows assessing local effects in the complex structure of the bridge.

The final period of 180 days of data was obtained from the WIM system. Recordings were made between October 2016 and July 2017 with a few interruptions.

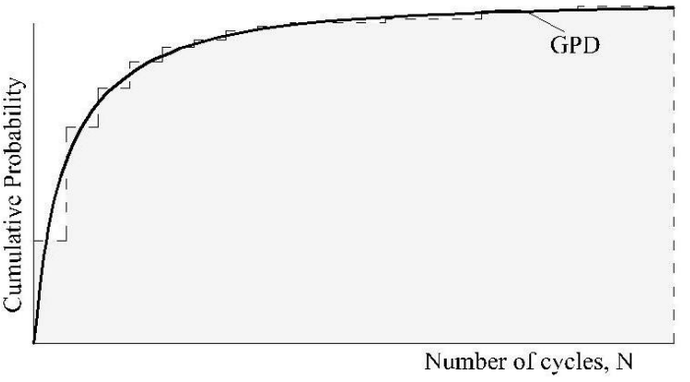


Figure 3. Fitting the GPD to N, number of cycles

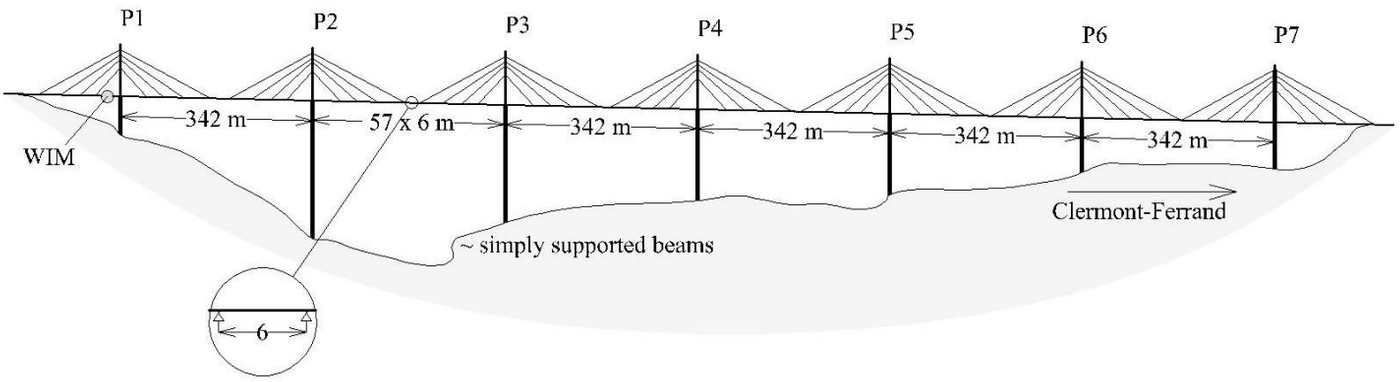

Figure 4. Millau Viaduct

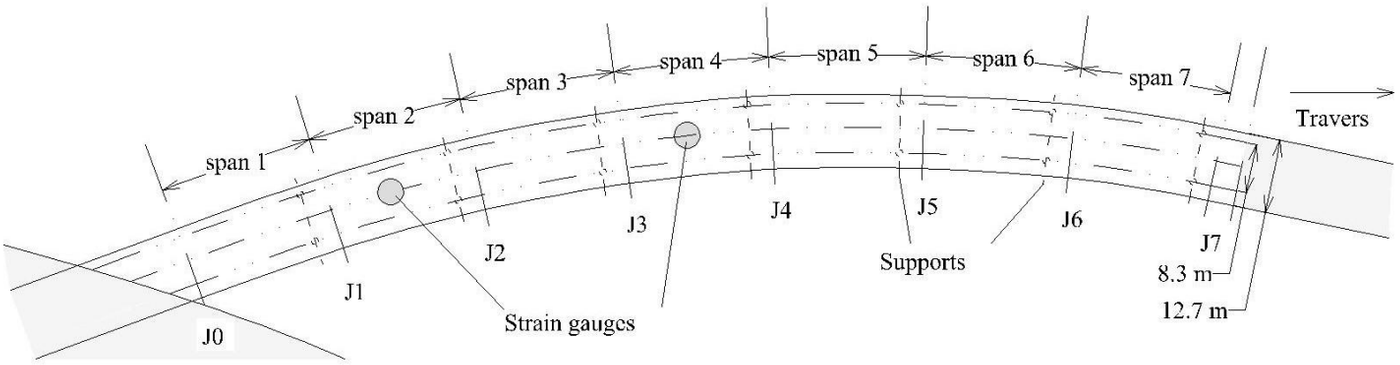

Figure 5. Anneau bridge

The system itself was located in the middle of the first span of the viaduct and recorded all trucks passing the bridge: their weights, speeds, dimensions. The deck of the bridge has two lanes in each direction – normal and high-speed. Monitoring was done only in one, more heavily loaded direction, which does not allow precise evaluating of effects on the viaduct, however, permits to use recorded data for the mathematical model and to make theoretical predictions in terms of LEs given by bending moments.

Table 1. Example of vehicles types

N	Vehicle type	Number of axles	Distance between axles, m			
			1 and 2	2 and 3	3 and 4	4 and 5
1	113	5	3.64	5.50	1.27	1.23
2	40	2	5.27	-	-	-
3	61	4	3.69	6.73	1.31	-
4	100	3	8.7	3.61	5.1	-
5	56	3	6.8	1.46	-	-

Table 2. Axle weights

N	Group of axles	Weight of each axles, kN				
		1	2	3	4	5
1	113	15	22	17	17	17
2	11	41	119			
3	112	32	139	34	34	-
4	111	46	65	5	-	-
5	12	78	142	142	-	-

Figure 4 shows the scheme of the viaduct with the place of the installed WIM system. Tables 1 & 2 give categories of vehicles recorded on the bridge with an example of recordings.

3.2 *Anneau bridge*

The viaduct consists of seven composite steel-concrete spans of 25.6 m (two steel box girders and a reinforced concrete deck slab). There are only two lanes – one in each direction. Strain gauges were installed directly on the reinforcement bars in transversal and longitudinal directions of the deck slab in the middle of the second and the forth spans (Fig. 5), as well as at the top and the bottom of a steel girder.

For each case, a pair of strain gauges was installed to record signals under the central line of the bridge and close to the middle of the lane. The highest values of stresses were obtained in the transversal reinforcement bars of the span 2, which makes this exact detail an object for the study.

Measurements of the strain have been done for one year (August 2016 to July 2017) with only short interruptions which provides almost one full year of monitoring. Moreover, strain gauges allow assessing load effects (stresses) directly, see Section 4.2.

4 APPLICATION OF THE GPD TO THE MONITORING DATA

4.1 *Millau Viaduct*

First, speaking about fatigue of a bridge, stresses and number of cycles for each stress range are needed. Therefore, critical elements subjected to fatigue loading have to be chosen. In the case of the Millau bridge, values of stresses in the deck are not measured directly. Therefore, it is impossible to observe the presence of dynamic effects; however, the estimation of fatigue is still achievable by using the results of WIM measurements. The system provides not only total weights of each vehicle but also the weight of each axle and distances between them.

Using long-term WIM data for evaluation of fatigue is possible even though it does not give stress cycles directly. Since the system provides forces from each axle of every passing truck that gives stress cycles in elements of the deck. Knowing the exact action applied to the bridge stress in the whole cross-section might be evaluated, in this study, cycles are defined in terms of actions.

There are different combinations of axles possible: some of them are grouped by two or three, as it was demonstrated in Table 1. Assuming that the average distance between axles in a group is $dx < 3m$, and using the recorded distances dx between each pair of axles, all recorded types of vehicles are counted and shown on the pie chart (Fig. 6). As it can be observed from the chart, the most frequent vehicle type is the one with five axles where three last are grouped together.

The value of the stress given by a group of axles is usually higher than the one caused by each axle separately and lower than their sum. So, in this case, to calculate cycles, the common action of three axles have to be considered. Also for the types 112, 12, 122 and 1211, the group of two axles should be taken into account.

As it can be found on Figure 7, P1, P2 and P3 are point loads from each axle of the group of three axles, and P1*, P2* and P3* are moments that can be obtained theoretically if each axle would pass the span individually. So, it is necessary to take into account that for the response of the structure, there is an influence between axles in groups of two or three. It could be performed theoretically as two or three point loads, presenting on the 6-meters span at the same time.

As it was mentioned in the Section 3.1, the current study is focused on local effects, therefore, 6-meters elements of the first span of the deck are considered. For simplicity, influence lines are obtained as the ones for the simply supported beam (Fig. 7).

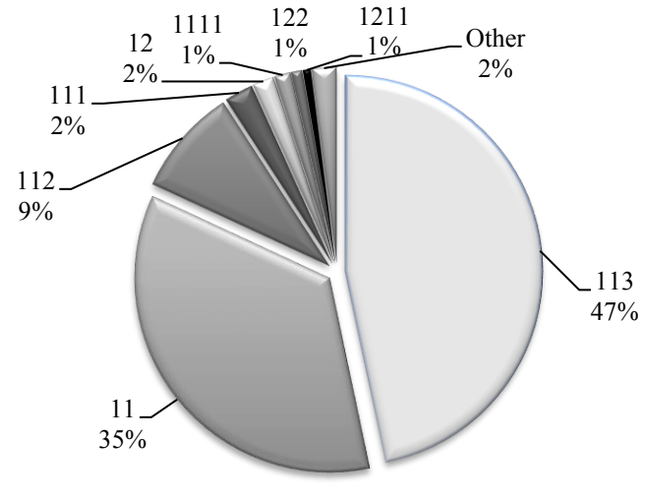

Figure 6. Main types of axles groups

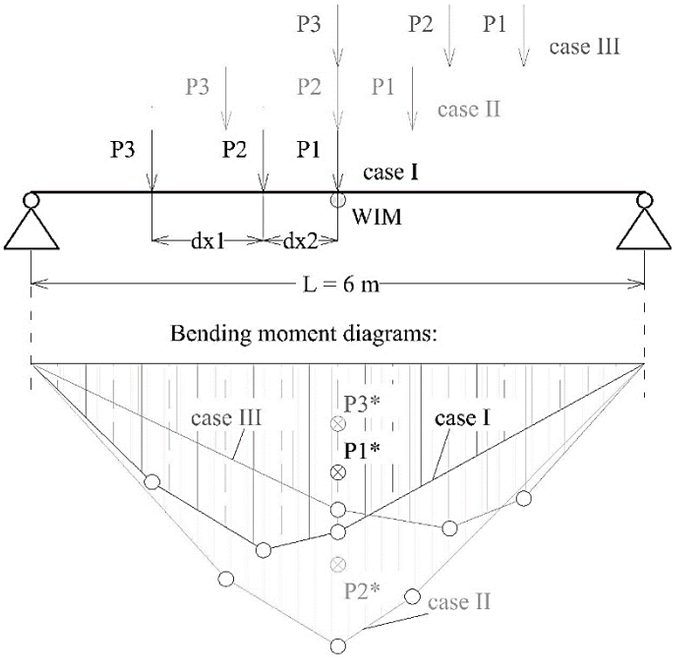

Figure 7. Bending moment from a 3-axles group

This gives the absence of the bending moment (or the values are neglectable) at "supports" – connections between each span. So, for large distances between single axles of vehicles, a weight of each axle can be taken separately as there is almost no influence in terms of stresses. However, for the groups of axles, different values of bending moments are considered as for two or three point loads.

Due to the absence of direct measurements of stresses in any part of the deck, cycles for fatigue are proposed by values of bending moments in the middle of the 6-meters-span, where WIM system was installed. Influence lines for a whole structure can be applied in order to assess bending moments in other parts of the bridge if needed. As well, stresses can be evaluated in the whole cross-section. Here, for simplicity, only measured actions (bending moments) are studied.

As the most frequent vehicles are 113, 11 and 112, bending moments in the midspan are calculated only for single, double and triple axles, as following:

- Single point load P_I is considered if the distance between axle I and other axles is larger than $L_{span}/2 = 3m$,
- Double axles are presented by two point loads P_{II}, when the distance between them is smaller than $3m$; the maximum moment is obtained from both positions: either P_{II-1} or P_{II-2}above the center,
- Triple axle load is given by three point loads P_{III} with three possible positions – each of them at the midspan one by one.

The exceptional combinations of axles removed from the calculations as not reliable. The main point here is to assess fatigue from frequent vehicles, therefore, rare trucks with more than 5 axles are removed from the initial data.

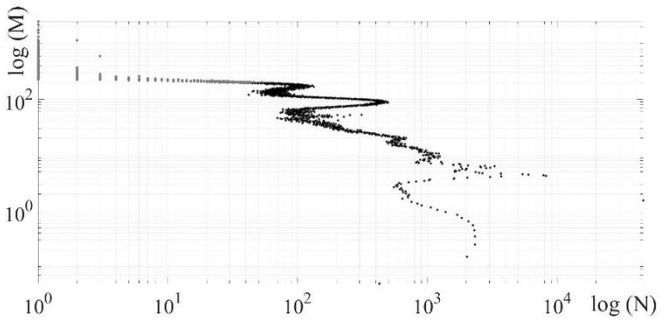

Figure 8. Bending moments, M, as a function of N, log-scale

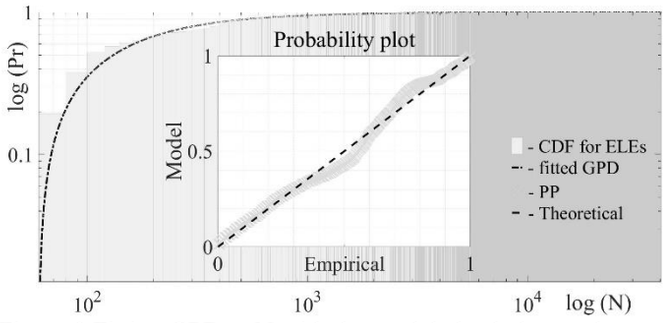

Figure 9.Fitting GPD to N with the model check, log-scale

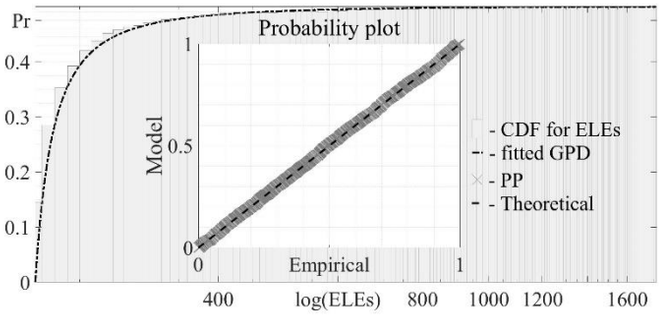

Figure 10. Fitting GPD to high amplitude LEs, with the model check, log-scale

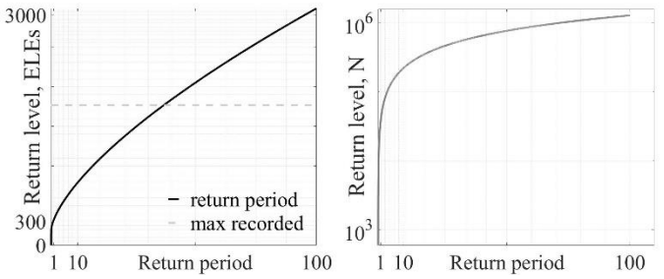

Figure 11. Return levels: for 'high amplitudes', M, kNm (left), for 'high cycles', N (right)

The distribution of all LEs is given in Figure 8. There are high amplitudes of LEs (in grey) that are treated by EVT and the approach explained in Section 2.2, the distribution of ELEs with the $TH = 215\ kNm$ and the model check is shown on the figure 10, the estimated return period – in Figure 11. Compared with the fitting the GPD to N, it can be concluded that the approach is working the same way for different types of LEs: bending moments or number of cycles.

4.2 *Anneau bridge*

Overall, 303 days of monitoring were completed between August 2016 and July 2017. After the detailed analysis of received data, it was detected that the highest values of stresses appeared in the transversal rebar of the span 2. Therefore, this exact rebar is studied for the current paper. Here, the monitored data are represented by measured strain $(\varepsilon, \mu m/m)$ directly in rebars, which allows assessing stresses easily knowing Young's modulus of steel $E = 210000\ N/mm^2 = 0{,}21\ N/\mu m^2$ (EN 1993-1-1, 2005):

$$\sigma = E \cdot \varepsilon, \qquad [MPa]$$

Fatigue cycles are counted using the "rainflow" method (ASTM E1049-85) that provides numbers of cycles for each stress amplitude (Fig. 12). To avoid the "noise" of the signal, all amplitudes under 1 MPa were removed from calculations and the histogram of stress amplitudes of different ranges is shown in Figure 15.

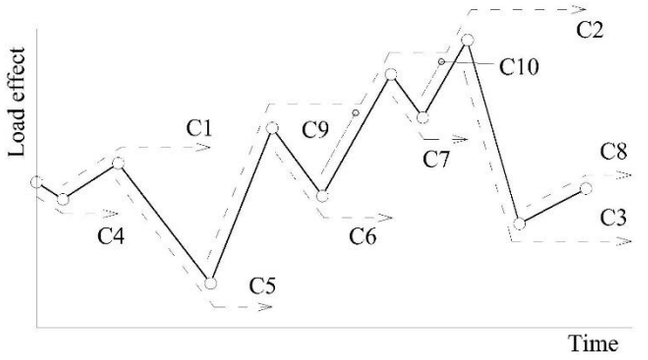

Figure 12. 'rainflow' counting

Again, there are two possible cases: a large amount of cycles of small amplitude ($< 10\,MPa$) and relatively rare high stresses ($> 50\,MPa$).

The case of high stresses and their extrapolation in time is a question of the EVT and its classical application. As it was shown in the previous section, for the case of Millau. The GPD is fitted to all LEs (given here by stress cycles) as it was described in Section 2.4, fitting with the model check is shown in Figure 13.

Stress amplitudes that are smaller than 1 MPa are removed from the distribution, assuming that such stress as the noise of the system. However, stresses over 1 MPa represent cars passing or light trucks passing not exactly above the installed strain gauge. The high amplitude cycles, over 50 MPa, should be fitted to a different GPD since a number of cycles produced by them is too small (Fig. 14)

Assuming that the fitting is successful (according to the model check, Figure 13), parameters of the GPD can be normally used further for the estimation of return levels. However, in this case, the ratio between 'exceedances' and all effects is equal to one due to the absence of any threshold. What is interesting in the case of fatigue, the estimation of cycles at each range of stress amplitudes – Figure 15.

Though, the probability of occurrence of each range of 5 MPa is found for the amount of data measured for 303 days (Fig. 16). Inserting these values into the formula, return levels are calculated for several values of the return period.

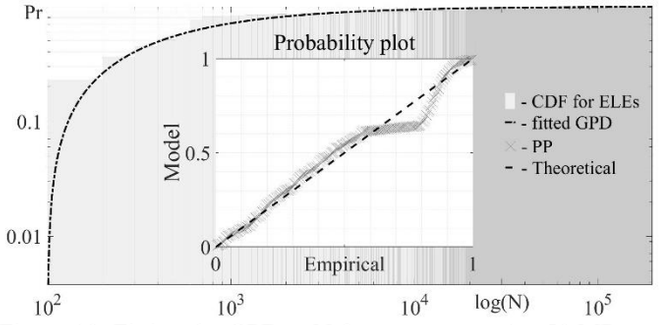

Figure 13. Fitting the GPD to N for stress range 1…50 MPa

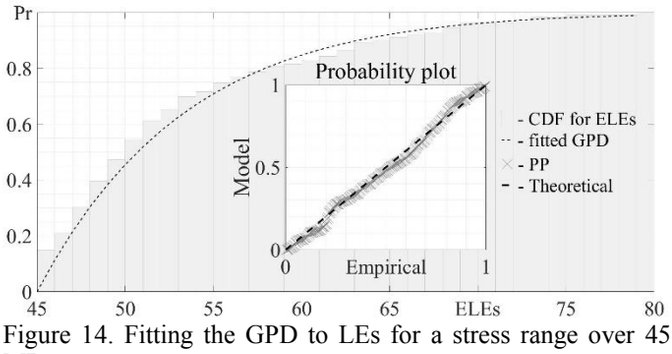

Figure 14. Fitting the GPD to LEs for a stress range over 45 MPa

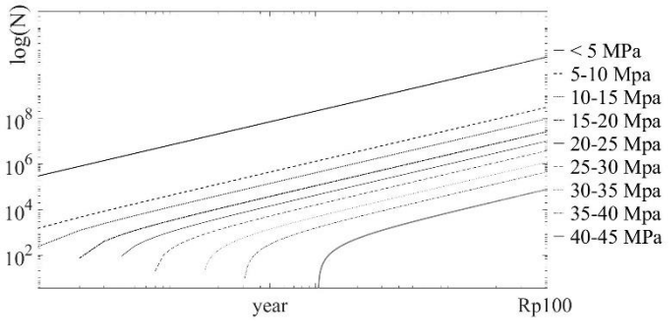

Figure 15. Return levels for different stress ranges, log-scale

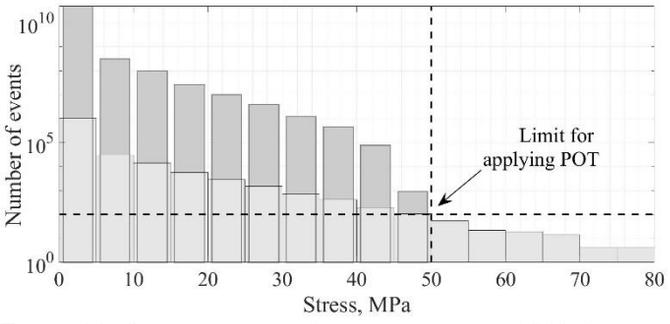

Figure 16. Stress spectrum from monitoring of 303 days (in grey), predictions in 100 years (in white)

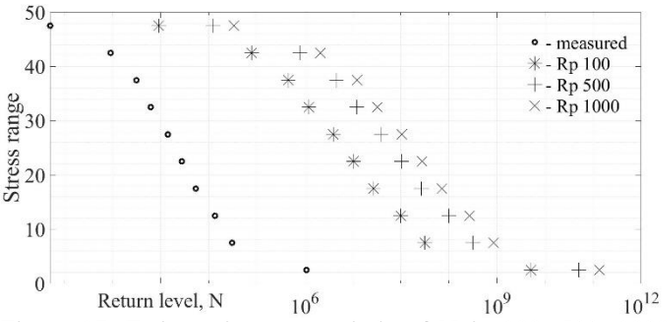

Figure 17. Estimated return periods of N in 100, 500, 1000 years, for each stress range

The method proposed in Section 2.4 is applied to the distribution of stress cycles with ranges each 5 MPa. The results for return periods of 100, 500 and 1000 years are shown in the Figure 17.

Knowing that in this particular case, all observed stresses lay under the cut-off limit (EN 1993-1-9, 2005) of the S-N curve for steel reinforcement bars, the applied algorithm only provides the estimated numbers of cycles over certain return periods (Fig. 17). Studied stresses caused by traffic actions are not high enough to cause any fatigue danger even in 1000 years.

5 CONCLUSIONS

The algorithm of application of the Generalized Pareto Distribution to fatigue cycles is proposed in the current paper. Results of two studied examples of monitored objects (the Anneau bridge, Switzerland,

and the Millau viaduct, France) permit the following summary:

- Monitoring data are required for long-term predictions of fatigue life. Moreover, demonstrated in the section 4.2 results for the Anneau bridge allow the following conclusion: measurements by strain gauges significantly simplify the study due to the direct access to stress ranges distribution.
- Estimation of return levels of N (number of cycles) at given period of time is possible using EVT and in particular, GPD with its parameters, however, more study of various objects is necessary to make more solid conclusions.
- The proposed algorithm works in described specific cases (one year of monitored stresses in the deck of the Anneau bridge and a half a year of recorded vehicles weights on the Millau viaduct), however, it does not show fatigue danger in perspective. Although, it might be applied to other structures with larger traffic volume.

Predicting the number of fatigue cycles in bridges is an actual topic of the modern research. Extending the service duration of existing bridges gives the motivation for novice theoretical approaches that are being proposed nowadays. The experimental part such as monitoring of real objects is undoubtedly useful for the developing of new mathematical models. It leads to the possibility of the application of the EVT for fatigue predictions. Since the traffic growth was not taken into account in the described method, as well, it requires further model uncertainties verification, the current study is being continued by authors.

6 ACKNOWLEDGEMENT

This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 676139. The grant is gratefully acknowledged.

The WIM measurements for the Millau viaduct were provided by EIFFAGE, France, and the data from monitoring of the Anneau bridge – by EPFL, Switzerland, which is highly appreciated.

ABSTRACT: The development of numerical models and the evaluation by techniques of dynamic analysis has gained significant importance and it is able to provide accurate information to analyze structural integrity, durability and reliability along the life cycle and optimize the operational activities and maintenance. The updated numerical model is a procedure to determine the parameters of uncertainty of the initial model, based on experimental results, and to achieve more appropriate upgraded model. This paper describes the application of the modal updating techniques implemented in commercially available software packages to the identification of the global behavior of a cable-stayed bridge. The updated numerical model can be used to evaluate the structural integrity, durability, and reliability along the life cycle and to optimize operational and maintenance activities.

KEYWORDS: *Cable-stayed bridge, finite element model, model updating, optimization.*

1. INTRODUCTION

In recent years, cable-stayed bridges have developed larges spans and more lightweight structures. This has been possible by modern technologies and more resistant materials. These factors, combined with the significant increase in the dimensions of the structures and computational advances, have provided engineers with the freedom to create increasingly slender structures. However, with an increase in slenderness and decrease of weight, more attention must be paid to the possibility of vibratory phenomena.

The development of numerical models and the techniques of dynamic analysis have provided accurate information that allow the analysis of structural integrity, durability, and reliability throughout the life cycle, optimization of operational activities and maintenance. An accurate representation of a structure is therefore essential to study its dynamic behavior.

The numerical model represented by the Finite Element Method (FEM) has a great level of detail in terms of the structure; however, it cannot be trusted if the results obtained diverge from experimental data. The updating of a numerical model is a technique whereby determination of uncertainties in parameters (based on experimental results) allows an increase in accuracy of the original model. Nevertheless, the successful application of the updating procedure depends on the numerical model of the target structure, a well-conceived, and controlled test and on the capacity to integrate both aspects in the model. There are a variety of techniques available for model updating and these employ dynamic and static measurements of the behavior of the structure. This investigation focuses on model updating techniques using the modal response of a structure.

For numerical models, the choice of the optimization function as well as the optimization approach, has been the subject of much research as illustrated by the precursors McCulloch et al. (1990), Farhat and Hemez (1993), Mottershead and Friswell (1993), Friswell and Mottershead (1995) and Friswell, et al. (1998).

Several authors have investigated methods for updating numerical models in structural dynamics. Important examples include Greening (1999) who analyzed the application of updating techniques in structures in which the dynamic performance was affected by the static loads, Santos (2009) who performed a FEM model updating based on EMA data from a footbridge in Brazil and Xia and Roeck (2014) who completed updating the numerical model of Jalon Viaduct, along the high-speed rail between Madrid and Barcelona, based on EMA.

2. METHODOLOGY

The aim of this research is to perform model tuning on a full-scale cable-stayed bridge by updating a model to closely match on-site conditions of two distinct experimental tests data, a first from dynamic tests dating from 1991, at the end of the construction of the bridge, and data from the second test conducted in 2006. This investigation describes modal updating

techniques implemented in commercially available software with the aim of identifying the global behavior of a cable-stayed bridge. To this end, a finite element model was created based on the design calculations and drawings of the structure. Results obtained from this simulation were then compared with measured modal test data.

The updating process has two distinct phases namely, manual, and automatic updating phases. The basic principle of both processes is the same, that is, they aim at adjusting the numerical model to obtain a new model which produces results approaching these of the experimental test. The difference between the two processes is that one changes the model manually and the other employs methods of optimization.

The manual updating process aims at refining the numerical model and this step changes model parameters that describe geometry and material. The method considers non-quantitative errors, such as element types and boundary conditions, which cannot be considered as design variables. Automatic updating is done in an iterative manner where the quantitative parameters of the system are iteratively modified. The errors in geometry, materials, stiffness etc. are evaluated and the convergence decision is automatic and depends on the tolerance of the objective function defined in pre-processing.

The automatic updating consists of two processes: pre-processing (or sensitivity analysis) where the parameters to be updated are defined, and the automatic updating process where the computational routine iteratively refines the parameters.

The numerical model was developed using the finite element software, ANSYS Academic Version 15. Automatic updating was performed by the FEMTools academic version software using the available sensitivity analysis and optimization processes.

2.1. *Case Study: Bridge over the Arade River*

The bridge over the Arade River located on National Road 125 at Portimão, Portugal is the case study analyzed in this investigation. Figure 1 shows details of the bridge geometry.

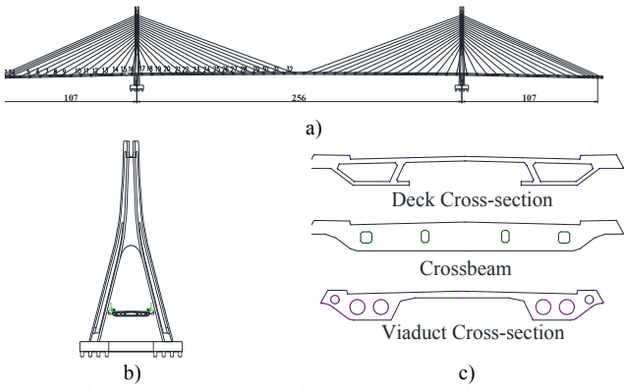

Figure 1: Details of the Arade Bridge: a) Side View; B) Tower; c) Deck Cross-section

The bridge is 850 meters long with three continuous spans of 107, 256, and 107 m and 2 viaducts. The bridge is totally suspended by 128 cables spaced at 8 meters along the deck, for two towers of reinforced concrete in the form of an inverted Y with 62 meters high. In the tower, the shorter cables are independently anchored, while the remaining cables pass over a saddle. The bridge cables are arranged in a half-harp system and are formed by bundles of parallel 14 to 35 closely-packed galvanized steel wire strands with varying lengths between 21 and 127 m.

2.2. *Experimental Data*

Reference data for the characterization of the dynamic behavior of the bridge was taken from the Report of Evaluation of Dynamic Characteristics of the Bridge over the Arade River performed by the Laboratory of Vibration and Structural Monitoring (ViBest) based at the Faculty of Engineering of the University of Porto (FEUP), in November 2006, (Caetano, et al. 2007), and Correa and Campos (1992), performed by the National Civil Engineering Laboratory (LNEC, 1991), in August 1991, before opening to traffic, shown in Tab. 1.

Table 1: Natural frequency and mode shapes. Font: (Caetano, et al., 2007) (Corrêa and Campos, 1992)

Mode	Frequencies (Hz) / Mode Shape	
	1991	**2006**
1	0.249	0.269
2	0.360	0.364
3	0.502	0.515
4		0.692
5	0.751	0.766
6	0.868	0.884
7	0.944	0.956
8	1.034	1.009
9		1.150
10	1.401	1.442
11	1.56 - 1.60	1.603

2.3. *Numerical Model Updating*

Updating is the process of modification of numerical models based on experimental data and aims to minimize errors and inaccuracies in modeling. The success of updating depends on the numerical model design, on a well-conceived and controlled test, and on the good integration of numerical and experimental

data. Figure 2 illustrates the flowchart of the model updating method. In this Figure, the quantities λ_{NUM}, ϕ_{NUM}, λ_{EXP} and ϕ_{EXP} are the numerical and experimental frequency and mode shape and M, K, M_{New} and K_{New} are the matrices of mass and stiffness of the primary and updated model.

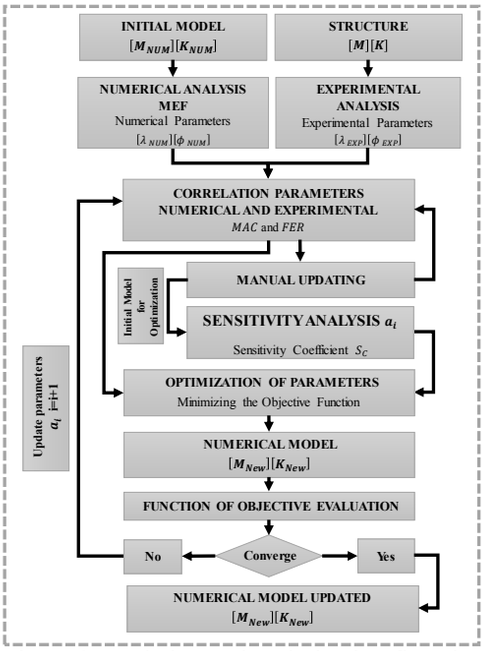

Figure 2: Updating and optimization flowchart.

2.3.1. Correlation Parameters

The Modal Assurance Criterion MAC proposed by Allemang and Brown (1982) apud. Allemang (2003), for comparison of mode shapes and the percentage of variation in the frequency FER, was used to calculate correlation parameters between numerical and experimental data.

MAC is a quantity that uses the amplitudes of experimental and numeric mode shapes at the points where they are located corresponding to the sensors in the experiment. The MAC is defined as shown in Eq.1:

$$MAC_{gh} = \frac{|\phi_g^T \phi_h|^2}{(\phi_h^T \phi_h)(\phi_g^T \phi_g)} \quad (1)$$

where ϕ_h is the vector of mode shape h obtained numerically and ϕ_g is the vector of the mode shape g obtained experimentally. The MAC value varies from 0.0 to 1.0. A value of 1 indicates complete correlation between the two modes and a value of 0 indicates that one mode is completely independent of the other.

FER is the correlation between the natural frequencies. The index FER is defined as shown in Eq.2:

$$FER_{gh} = \frac{\lambda_h - \lambda_g}{\lambda_g} \quad (2)$$

where λ_h is the natural frequency of numeric mode h and λ_g is the natural frequency of experimental mode g.

After calculating MAC_{gh} and FER_{gh}, the analysis selects among all numeric modes h those that are correlated with experimental modes g, whereas h > g. Firstly, the selection of the numerical–experimental sets between all numeric modes h with the highest values of MAC_{gh} compared to experimental modes g is completed and the smallest value of FER_{gh} is chosen. The result is the numeric mode shape ϕ_h and associated natural frequencies λ_h correlated with experimental data.

2.3.2. Optimization Process

The aim of optimization is to determine the optimal values of design variables to maximize or minimize an objective function, while the constraints or restrictions are satisfied. The formulation of an optimization problem involves the definition of the design variables, objective function, and constraints and this depends on the definition of a set of parameters that describe the model.

This study aims at expanding the method of optimization for the cable-stayed bridge model and lead to an optimal solution of the problem. In this case it is defined as the improvement of the correlation between dynamic parameters of the numerical model and the experimental test. Optimization can be divided in three steps: The first step aims at identifying the design variables by Sensitivity Analysis; The second step defines the objective function; and the last step involves the development of mathematical expressions responsible for the definition of constraints.

The objectives functions implemented in this paper are available in the FEMtools® software. The contributions of the various responses are weighted using the response confidence C_{R_i}. The following correlation functions were used in the optimization process:

- Weighted absolute relative difference (CC_{ABS}) between frequencies:

$$CC_{ABS} = \frac{1}{C_R}\sum_{i=1}^{N} C_{R_i} \frac{\Delta\lambda_i}{\lambda_i}; C_R = \sum_{i=1}^{N} C_{R_i} \quad (3)$$

where N is the number of frequencies.

- Average MAC values (CC_{MAC}):

$$CC_{MAC} = 1 - \frac{1}{C_R}\sum_{i=1}^{N} C_{R_i} \,.\, MAC_i; C_R = \sum_{i=1}^{N} C_{R_i} \quad (4)$$

where N is the number of MAC responses

- Weighted absolute difference between modal displacements (CC_{MDISP}):

$$CC_{MDISP} = \frac{1}{C_R}\sum_{i=1}^{N} C_{R_i} \,.\, \frac{|\Delta\Phi_i|}{\Phi_i}; C_R = \sum_{i=1}^{N} C_{R_i} \quad (5)$$

where N is the number of active displacement responses.

- Weighted absolute difference between the mass participation (CC_{MASS}):

$$CC_{MASS} = \frac{1}{C_R}\sum_{i=1}^{N} C_{R_i} \cdot \frac{|\Delta m_i|}{m_i}; C_R = \sum_{i=1}^{N} C_{R_i} \quad (6)$$

where N is the number of active masses, center-of-gravity and inertia properties.

The objective function was defined as Total Weighted Relative Differences (CC_{TOTAL}) Eq.7.

$$CC_{TOTAL} = CC_{ABS} + CC_{MAC} + CC_{MDISP} + CC_{MASS} \quad (7)$$

During optimization, the criterion used for convergence depends on the type of data used and it is described in more detail in the following sheets.

2.3.3. Convergence Criterion

In model updating, the correlation coefficients are interpreted as measures of the quality of the objective function minimization of each iteration loop the values of the correlation coefficients will be verified to check if a convergence criterion is satisfied. The value of the reference correlation coefficient CC_t should be less than an imposed margin ε.

$$CC_t < \varepsilon \quad (8)$$

2.3.4. Sensitivity Analysis

Sensitivity analysis is a technique that aims at determining how structural responses are influenced by properties such as material, stiffness, and geometry. The Sensitivity Coefficient S_C is defined as the derivative of the state variables or objective function in relation to the design variables or update parameters, as shown in Eq. 9 and 10:

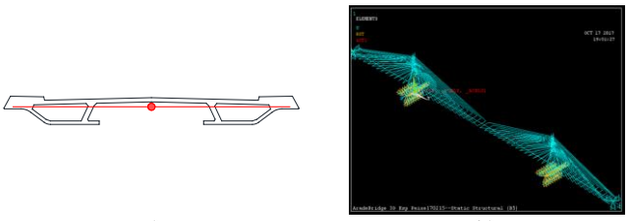
$$\delta_z = S_C . \delta_A \quad (9)$$

$$S_C = \frac{\delta_Z}{\delta_A} = \frac{Z_m - Z}{A_m - A} \quad (10)$$

where, $\delta_A = A_m - A$ is the variation of update parameters and $\delta_Z = Z_m - Z$ is the variation in the state variables or objective function.

3. NUMERICAL MODELS

There are many considerations in the development of a numerical model for a cable-stayed bridge. In this study, the numerical model was performed using the academic version of Software ANSYS version R15. This software was employed to account for geometric nonlinearities in the simulation.



In this investigation, the numerical models developed namely *Fishbone*, the material properties and dimensions employed are taken from design (Rito, 1987). The main section of the bridge deck was modeled as an equivalent beam in the centroid of the cross-section along the longitudinal direction of the bridge axis together with two rigid crossbeams that connect the cable anchor points on the deck to the main beam. This scenario is shown in Figure 3 a) and the full model is shown in Figure 3 b).

The most complex part in the development of this model was the definition of stiffness of the crossbeam member. Equations 11 and 12 as proposed by Hambly (1991) were used to define the area a_s and inertia i_{trans} of the equivalent section per meter of width of deck.

$$a_s = \left(\frac{E}{G}\right)\left(\frac{d_w^3(d_t^3+d_b^3)}{l_1 h_1 (d_t^3+d_b^3)+l^2 d_w^3}\right) \quad (11)$$

$$i_{trans} = \frac{d_t^3}{12} + d_t\left(\frac{h_1}{2}\right)^2 + \frac{d_b^3}{12} + d_b\left(\frac{h_1}{2}\right)^2 \quad (12)$$

where d_b and d_t are the thicknesses of the lower and upper slabs, d_w is the width of the crossbeam l_1 and h_1 is the distance measured in transversal direction between the centroid of the slabs and they of the crossbeam.

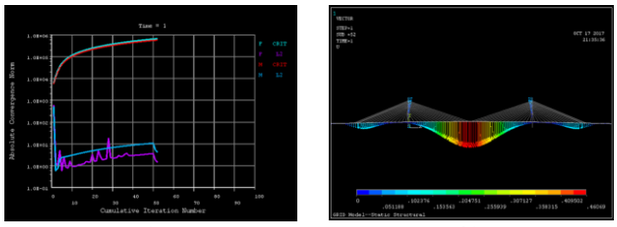
a) b)

Figure 3: Fishbone Model a) Cross-section of the bridge deck (Black) and equivalent beam (Red); and b) full model

In the development of the Finite Element Model for the deck, towers and cables was used the element of BEAM188. The tower has a variable cross-section along the height, and was discretized using 6 different sections. The cables were modeled as beams to include the effect of bending in nonlinear numerical analyses for large displacements.

4. RESULTS AND DISCUSSION

The main aim of this investigation was to identify the efficiency of a FE model updating of a full-scale cable-stayed bridge based on the modal parameters. The results are presented in three steps, namely, static behavior, dynamic behavior, and model updating using modal test data sets.



4.1. *Static Behavior*

The first step in the development of the model consisted on the static analysis considering the geometric nonlinearities and the stress in the cables, according to the report of Freyssinet S. A (2005).

For the analysis of the ideal tensile strength, retro-analysis of the project was implemented from the final phase to the beginning. This was done by trying to simulate the distribution of the forces according to the construction process, as proposed by Walther et al. (1999) and Walther et al. (1985).

In the numerical model, actions were therefore appropriately scaled. In the first phase, a portion of the load was applied to the cables and in the second phase, the final loads were added. So that the final stress state was achieved. The nonlinear analysis was performed by an iterative series of linear approximations in the ANSYS software. This simulation employs the iterative Newton-Raphson Method. At each

iteration the equilibrium forces, measured by the difference between the internal and external forces, are found. Figure 4 a) shows iterations of the forces during the convergence process and Figure 4 b) illustrates the final deformation obtained after the nonlinear analysis of the Bridge.

a) b)

Figure 4: Static Analysis: a) Force convergence; b) Total Deformation under statics loads

The force equilibrium on the structure at each iteration is archived until the residue becomes smaller than the convergence criterion. The solution is then considered convergent. Based on the final deformation state obtained in the static analysis, subsequently conducted dynamic analysis.

4.2. *Dynamic Behavior*

The starting point for the modal analysis was the deformed configuration of the bridge obtained in the static analysis. Based on stiffness matrices evaluated and the deformed configuration under statics loads, frequencies and mode shapes were obtained which are shown in Tables 2.

Table 2: Mode Shapes and Natural Frequencies: Vertical (V), Lateral (L) and Torsion (T)

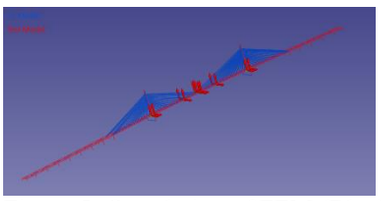
N	Frequency (Hz)		Mode
	Num.	Exp.	
1L	0.268	0.269	
1V	0.363	0,364	
2V	0.491	0,515	
3V	0.728	0,766	
2L	0.744	0.692	
4V	0.781	0,884	
5V	0.871	0,954	
1T	1.036	1.009	
6V	1.017	1,15	
7V	1.321	1,442	
2T	1.556	1.603	

4.3. *Finite Element Model Updating*

This section presents the initial and final values of the response parameters, the sensitivity analysis performed for the definition of the design variables and the updated final model.

4.3.1. Experimental Data 1991

The Figure 5 shows the correlation between the experimental and numeric models for the nodes measured in the modal test.



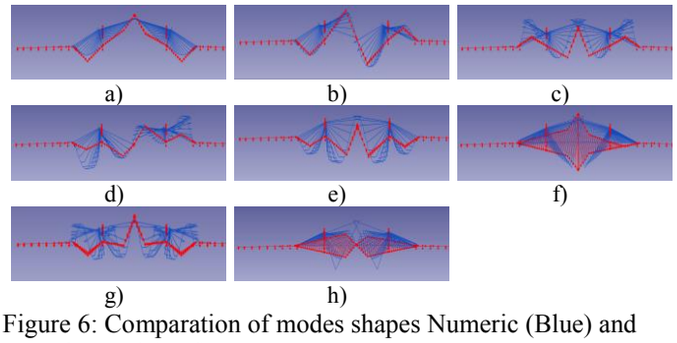


Figure 5: Correlation of FEM (Blue) and Modal Test (Red)

Table 3 shows the values of the numerical and experimental frequencies, correlation among the frequencies, FER, and the MAC index.

Table 3: Primary Frequencies, FER, and MAC index

Mode	Num. Freq. (Hz)	Exp. Freq. (Hz)	FER (%)	MAC
1 V	0,363	0,360	0,80	94,50
2 V	0,491	0,510	-3,79	93,10
3 V	0,728	0,750	-2,89	47,40
4 V	0,781	0,860	-9,14	73,50
5 V	0,871	0,940	-7,30	66,20
1 T	1,036	1,030	0,59	83,00
6 V	1,219	1,400	-12,93	37,40
2 T	1,556	1,600	-2,75	64,70

The numerical and experimental mode shapes show a good correlation, with MAC values ranging from 47.4 to 94.5 and with a mean value of 69.98. The numerical frequencies result a mean FER index of 5.03%. In Figure 6 and 7, comparison of the numerical and experimental mode shapes and the matrix of the MAC index, are presented.

a) b) c)

d) e) f)

g) h)

Figure 6: Comparation of modes shapes Numeric (Blue) and Experimental (Red)

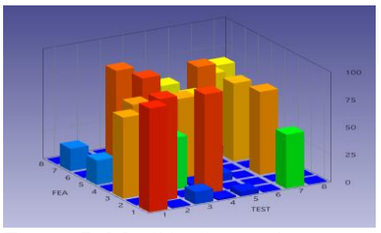

Figure 7: MAC before updating

Sensitivity analysis was used to evaluate the correlations between the parameters Young's modulus (1 to 9), mass density (10 to 18), area (19 to 27), inertia about X (28 to 36), Y (37 to 45), Z (46 to 54) and Poisson's ratio (55 to 63) of the main beam, viaduct beam, cables, crossbeams, and towers, with the response parameters frequencies (1 to 11) and the MAC

(12 to 22). Figure 8 shows the normalized sensitivity coefficient.

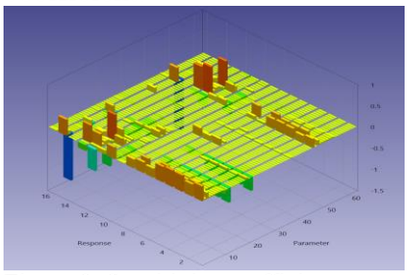

Figure 8: Sensitivity coefficient

Based on the sensitivity analyses decided to consider the 17 parameters that showed the highest absolute values of sensitivity namely, Young's modulus of the crossbeam (1), cables (2), main beam (3) and viaducts beam (4) and (5), mass density of the crossbeam (6), main beam (7) and tower (8 to 11), area of the cables (12), inertia about X of crossbeam (13), inertia about Z of the crossbeam (14), main beam (15) and viaduct beams (16) and (17). These parameters, their limits admissible are shown in Table 4.

Table 4: Parameter of Updating

Item	Type	Element	Limits (%)		Initial Values
			Lower	Upper	
1	Yung's Modulus (Pa)	Crossbeam	-150	150	3,68E+10
2		Cables	-15	15	2,00E+11
3		Main beam	-150	150	3,68E+10
4		Viaducts beam	-150	150	3,68E+10

7		Main beam	-15	15	2.600,00
8		Tower	-30	30	2.600,00
9		Tower	-30	30	2.600,00
10		Tower	-30	30	2.600,00
11		Tower	-30	30	2.600,00
12	Area (m²)	Cables	-50	50	0,0201
13	Inertia X (m⁴)	Crossbeam	-150	150	0,1099
14	Inertia Z (m⁴)	Crossbeam	-150	150	0,0400
15		Main beam	-150	150	2,4484
16		Viaducts beam	-150	150	2,4484
17		Viaducts beam	-150	150	2,4484

Considering that the modal test conducted in 1991 was based on the measured of the dynamic responses of 8 points on the deck, it was decided that simulations should employ a greater tolerance for the MAC. Thus, the stop criteria of objective function was consider the $\boldsymbol{CC_{TOTAL}} = 1\%$, and during the iterations the $MAC \geq 30$ and $FER \leq 15$ were adopted to correlate the modes. The model was updated, and the final values of the parameters are presented in Table 5. The parameters showed a mean variation of 6.45% in relation to the initial data.

The updating process resulted in a model that represents experimental observations more accurately as shown in Table 6.

On completion of the update, the FER index had an absolute average value of 2.45% and the MAC value had a mean of 78.58. The correlation criterion CC_{TOTAL} showed an increase from 31.74 to the final value of 23.60. This indicates an improvement in the correlation of mode shapes and frequencies as presented in Tab.7.

Table 5: Final values of the parameters updating

Item	Type	Element	Values		Diff. (%)
			Initial	Final	
1	Yung's Modulus (Pa)	Crossbeam	3,68E+10	3,05E+10	17,03
2		Cables	2,00E+11	1,70E+11	14,85
3		Main beam	3,68E+10	2,58E+10	29,98
4		Viaducts beam	3,68E+10	3,03E+10	17,61
5		Viaducts beam	3,68E+10	3,11E+10	15,54

Table 6: Final Frequencies, FER, and MAC index

Mode	Num. Freq. (Hz)	Exp. Freq. (Hz)	FER (%)	MAC
1 V	0,3701	0,3600	2,81	95,90
2 V	0,4916	0,5100	-3,61	95,30
3 V	0,7699	0,7500	2,66	70,00
4 V	0,8499	0,8600	-1,17	81,90
5 V	0,9281	0,9400	-1,27	82,50
1 T	1,0372	1,0300	0,70	80,40
6 V	1,4402	1,4000	2,87	56,70
2 T	1,6718	1,6000	4,49	66,00

Table 7: Initial and final values of the criteria

Iteration	CC_{ABS}	CC_{MAC}	CC_{TOTAL}
0	5.32	26.43	31.74
15	2.19	21.40	23.60

The updated model shows satisfactory correlation with observations through an improvement in the correlation of mode shapes and frequencies in relation to the experimental data.

4.3.2. Experimental Data 2006

The Figure 9 shows the correlation between the experimental and numeric models for the nodes measured in the modal test.

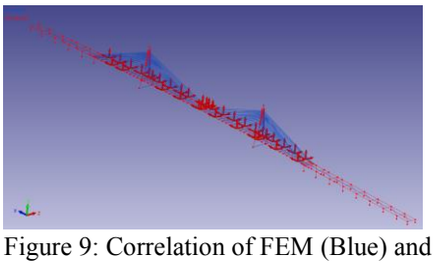

Figure 9: Correlation of FEM (Blue) and Modal Test (Red)

Table 8 shows the values of the numerical and experimental frequencies, correlation among the frequencies, FER, and the MAC index. The numerical and experimental mode shapes show a good correlation, with MAC values ranging from 52.00 to 97.20 and

with a mean value of 78.10. The numerical frequencies result a mean FER index of 5.83%.

Table 8: Primary Frequencies, FER, and MAC index

Mode	Num. Freq. (Hz)	Exp. Freq. (Hz)	FER (%)	MAC
1 L	0,26807	0,26938	-0,49	97,20
1 V	0,36288	0,36419	-0,36	96,80
2 V	0,49066	0,51547	-4,81	92,50
3 V	0,72835	0,76632	-4,95	75,30
2 L	0,74383	0,69231	7,44	90,80
4 V	0,78139	0,88420	-11,63	77,00
5 V	0,87137	0,95618	-8,87	65,90
1 T	1,0361	1,0091	2,67	85,30
6 V	1,0166	1,1500	-11,52	66,90
7 V	1,3212	1,4417	-8,36	59,40
2 T	1,5562	1,6030	-2,92	52,00

Sensitivity analysis was used to evaluate the correlations between the parameters with the response parameters frequencies and the MAC. Fig. 12 shows the sensitivity coefficient.

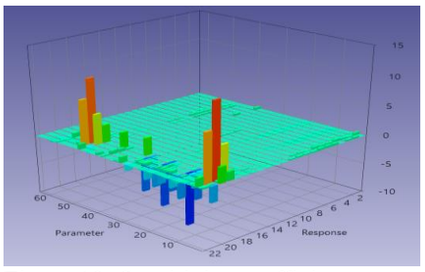

Figure 12: Sensitivity coefficient

Based on the sensitivity analyses, decided to consider the same 17 parameters that showed the highest absolute values of sensitivity namely, Young's modulus of the crossbeam (1), cables (2), main beam (3) and viaducts beam (4) and (5), mass density of the crossbeam (6), main beam (7) and tower (8 to 11), area of the cables (12), inertia about X of crossbeam (13), inertia about Z of the crossbeam (14), main beam (15) and viaduct beams (16) and (17).

Considering that the modal test conducted in 2006 was based on the measured of the dynamic responses of 31 points on the deck, it was decided that simulations should employ a smaller tolerance for the MAC. Thus, the stop criteria of objective function was consider the $\boldsymbol{CC_{TOTAL}} = 1\%$, and during the iterations the $MAC \geq 50$ and $FER \leq 15$ were adopted to correlate the modes. The model was updated, and the final values of the parameters are presented in Table 9.

The parameters showed a mean variation of 1.9% in relation to the initial data. The updating process resulted in a model that represents experimental observations more accurately as shown in Table 10. On completion of the update, the FER index had an absolute average value of 3.92% and the MAC value had a mean of 82.36. However, a greater difference in the first lateral frequency and the second torsional frequency was archived.

The correlation criterion CC_{TOTAL} showed an increase from 28.55 to the final value of 21.55. This indicates an improvement in the correlation of mode shapes and frequencies as presented in Table 11. The new MAC Matrix calculated from the updated model is shown in Figure 13.

0	6.83	21.72	28.55
22	3.92	17.63	21.55

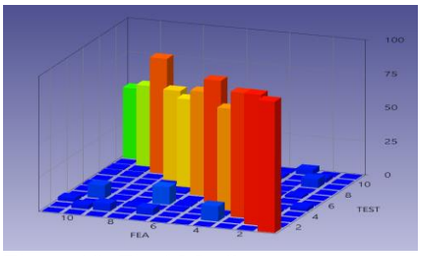

Figure 13: Final MAC

So, in the same line, the updated showed satisfactory correlation with observations through an improvement in the correlation of mode shapes and frequencies in relation to the experimental data.

5. CONCLUSIONS

The model was updated based on two experimental tests, the first test performed at the end of construction in 1991, and a second test performed in 2006.

The sensitivity analysis identified the influence of the variation of the design parameters on the responses. In general, could be observed that the modulus of elasticity, specific mass, and inertia of the main elements such as beams, transverse, mast, cables and slabs were the most influential in the dependent variables, frequencies and modes shapes. In this way, the most sensitive parameters can be identified as candidates for the updating process.

Regarding to the experimental data of 1991, the Fishbone model showed a reduction in FER of 2.59% and an increase the MAC correlation in 8.61 with the update process, showing at the end of the process a FER mean of 2.45% and MAC of 78.59. Concerning the experimental data of 2006, the model presented an improvement in the FER index of 1.91% and in the MAC index of 4.26, presenting at the end of the update process a FER of 3.92% and a MAC of 82.36.

By comparing the structural behavior predicted in the model and the experimental data, we can obtain some insights about the probable sources of errors. However, the differences between the final models updated with the different experimental data showed that the uncertainties in the models originate not only from modeling errors, resulting from simplifying hypotheses made in complex structures, but also incompatibility of the number of degrees of freedom between the data of FEM models and Experimental Modal Analysis (EMA) and inconsistency, when the number of natural frequencies identified, according to McCulloch et al. (1990).

Concerning the methodology, it was observed that the model can represent the structure with a level of detail considered satisfactory and accurate. Regarding the response parameters used, the increase in the number of response parameters promotes an overall increase in the quality of the available data, lead to a better correlation with the experimental data, which can be noted in the 2006 experimental data, where more data were available.

Finally, the FE model was successfully calibrated using multi-responses from the modal test data. The updated numerical models can therefore be used with confidence in analysis related to structures such as damage simulations or in the assessment and monitoring of structures by comparing the evolution of the dynamic properties.

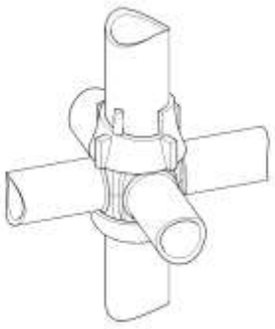
Rotational stiffness between vertical and horizontal members of system supports

J.H. Won & H.D. Lee & A.R. Oh & N.K. Jang
Chungbuk National University, Cheongju, Korea

ABSTRACT: This study examined the rotational stiffness of joints between vertical and horizontal members in system supports used in the construction of rahmen-type bridge. While the system supports were commonly used to support the concrete weight during casting concrete, the collapse of system supports was frequently reported. In order to prevent repeated collapse of system supports, it is important to examine the accurate behavior of system supports. The structural behaviors of system support were affected by the large variations of geometric and mechanical parameters, notably joint stiffness, initial geometric imperfections, yield stress and load eccentricity. Among various factors affecting the complex behavior of system supports, this study focused on the stiffness of joints between vertical and horizontal members. Experimental tests were performed to estimate the rotational stiffness of joints between vertical and horizontal members. The considered joint type was wedge type which is generally used in Korea. Results showed that the initial rotational stiffness was between 16 kNm/rad and 34 kNm/rad which is similar to other researches.

1 INSTRUCTIONS



When concrete structures are built, a system support of temporary equipment is adopted to support various loads in the short term. Unfortunately, the improper design and installation of system supports have caused continuous accidents including collapse of system supports (Kim et al. 2017). In many countries, the safety of system supports is analyzed in terms of various structural aspects. These structural aspects take into account various factors such as initial geometric defects, number of structure floors, and stiffness of connection parts. In order to identify the geometrical defects such as impact or construction error during pouring of concrete on the system support, Chan et al. (2005) studied the behavior of the system support by applying the P-delta effect, the eigen-buckling mode approach (EBM), the notional horizontal force approach (NHF), and the initial geometric imperfection approach (IGI). Yu et al. (2004) analyzed the changing behavior based upon the number of floors in order to study the relationship of decreasing load carrying capacities to the increase in number of floors.

In addition, many researches have studied the rotational stiffness of connection parts between vertical and horizontal members according to the connection shape. It was found that the values of rotational stiffness were varied with the change of the shapes of connection, the number of members connected to the connection parts, and the direction of rotational axis (Chandrangsu & Rasmussen 2011, Prabhakaran et al. 2011, Liu et al. 2010). Overseas researchers have continuously experimented and analyzed various system perspectives to predict the behavior of system support. However, in Korea, the load-resistant capacity of system supports is simply calculated based on the experiments utilizing a single member. Furthermore, the connection condition between vertical and horizontal members is simply assumed to be a simple hinge in the design stage (MOLIT 2016). This assumption focuses on the elastic behavior of all structural members. As such, there is a limitation in the analysis of the ultimate load of system support and its behavior when it collapses. Actually, the connection has a rotational stiffness according to other researches. Therefore, this study investigates the rotational stiffness of connection parts between vertical and horizontal members in the system support in order to obtain to simulate actual behaviors of system supports. It also analyzes its changing behavior when the actual rotational stiffness value is applied through finite element analysis.

2 FACTORS AFFECTING STRUCTURAL BEHAVIOR OF SYSTEM SUPPORTS

2.1 *Types of connection part*

The system support consists of vertical, horizontal, and bracing members. The connective parts of vertical and horizontal members can be classified into the cuplok joint, wedge type, and clamp as shown in figure 1. Previous research argued that the type of connection affects the stiffness, and the range of stiffness is broad. One of the various shapes, the cuplok joint, has been shown to have the greatest rotational stiffness (Chandrangsu & Rasmussen 2009).

(a) Cuplok joint

(b) Clamp joint

(c) Wedge joint

Figure 1. Connection type of system support

2.2 *Eccentric loading*

The eccentricity of load can be occurred because the center lines of bearers and U-heads of the system support do not always coincide with each other. A general method for considering the eccentric load effect is to apply the vertical load at an eccentric distance from the bearer and connect it to a rigid link. In this case, the rigid link behaves as a short, stiff, cantilever that introduces vertical force and additional moment into the jack (Chandrangsu & Rasmussen 2009).

2.3 *Geometric imperfection*

The EBM, the NHF, and the IGI method have been used to model geometric imperfection of the initial shape of system support. In Korea, the temporary structure construction standard typically uses the horizontal load method (NHF) to consider potential imperfection during construction as well as identify possible impacts caused by concrete pouring. More specifically, it requires applying the bigger value between 2% of the vertical load and 1.5 kN/m per horizontal length unit to the top of the system support (MLTM. 2007).

2.4 *Rotational stiffness of connection part*

The rotational stiffness of various connection types has been studied. Parabhakaran et al. (2011) studied the rotational stiffness of a clamp connection part. In a cantilever experiment, loading and unloading were repeatedly applied in the upward direction and the results were compared with other rotational stiffness estimation methods of various models. The results of the Federation Europeene de la Manutention approach (FEM) were considered as a simple and reliable method. The rotational stiffness of the clamp connection is described in Table 1, and 10.65 kNm/rad can be applied as the initial stiffness.

Table 1. Rotational stiffness of clamp type according to FEM approach (Parabhakaran et al. 2011)

Equations	Rotation(radians)	Moment(kNm)
$M=10.65\theta_r$	$0 \le \theta \le 0.091$	$0 \le M \le 0.97$
$M=0.97$	$0.091 \le \theta_r$	$M=0.97$

Peng et al. (2013) studied the behavior of system support according to the number of floors of a wedge type connection by considering the existence of bracing and stiffness of connections. From the full-scale experiments (figure 2), rotational stiffness of 58.86 kNm/rad was applied to the spigot joint between vertical members. In addition, for the rotational stiffness of the connection of vertical and horizontal members, 34.34 kNm/rad was applied, 0 for the connection of vertical and inclined bracing members, and 34.34 kNm/rad for the bottom screw jack.

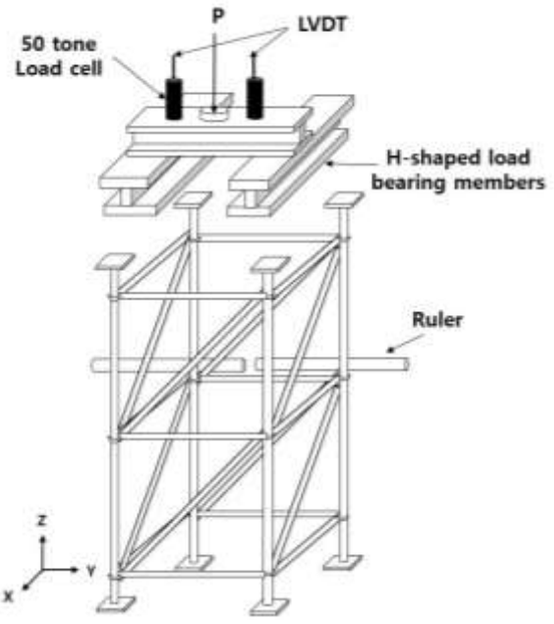


Figure 2 Test setup of system scaffolds under loading (Peng et al. 2013)

Chandrangsu and Rasmussen (2011) studied the changing stiffness of the system supports built with cuplok joints considering four directions (up, down, left, and right). As shown in figure 3, this experiment was conducted as a cantilever test. The vertical members were 48 mm in diameter, 4 mm thick, with a yield stress of 450 MPa. The horizontal members were 48 mm in diameter, 3.2 mm thick, with a yield stress of 350 MPa. As outlined in Table 2, the stiffness of the connections was largest when the load was applied in the upward direction. The value of stiffness increased as the number of horizontal members connected to the connecting part increased.

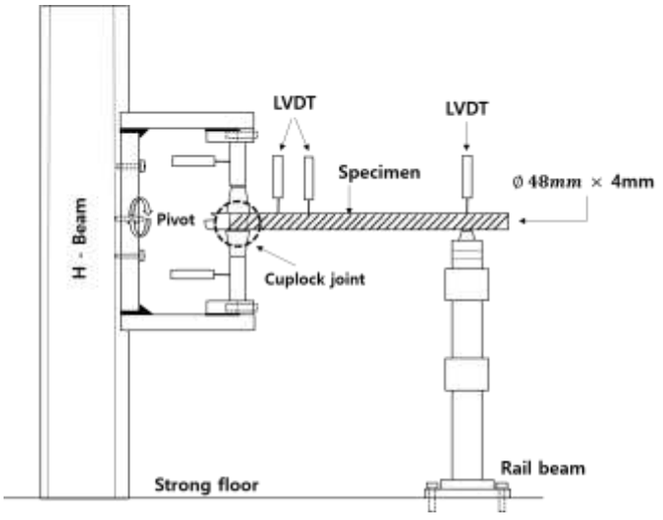

Figure 3. Schematic of typical cuplok joint test setup (Chandrangsu and Rasmussen 2011).

3 ROTATIONAL STIFFNESS AND FINITE ELEMENT ANALYSIS

3.1 *Determination of rotational stiffness*

Author's previous research (Kim et al. 2017) studied the rotational stiffness of the connections of the wedge type system support (figure 4), which is used predominately in Korea. The diameter and thickness of vertical members were 60.5 mm and 2.6 mm, respectively, while the diameter and thickness of the horizontal members were 42.7 mm and 2.3 mm, respectively. The steel grade was SS400.

Figure 4. Test setup of connection part with wedge type (Kim et al. 2017).

By comparing the experimental and analytical values, it can be confirmed that the rotational stiffness is nonlinear. The experimental results are compared with those obtained by applying 10%, 17%, 18%, and 20% of the flexural stiffness of the horizontal member to the rotational stiffness. The results showed that the rotational stiffness is different from the initial stiffness of the test, but it is found that 17 ~ 18% of the flexural stiffness of horizontal members is comparable to the overall tendency (figure 5). In addition, for the case of estimating a stiffness value that gives similar results to the experimental results, the rotational stiffness of the joint was estimated to be 12 kNm/rad ~ 13 kNm/rad (figure 6).

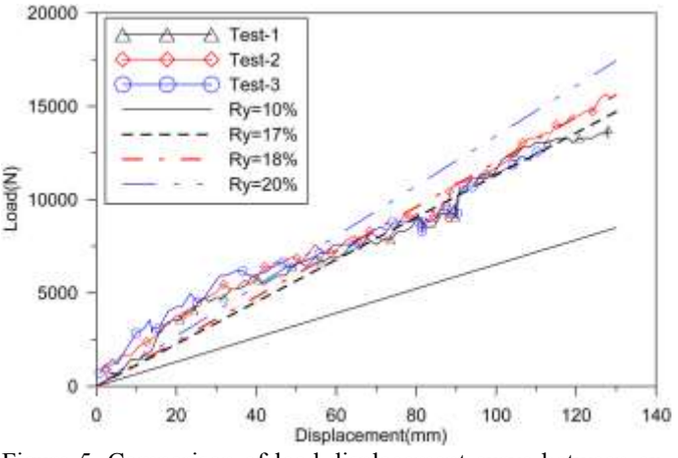

Figure 5. Comparison of load-displacement curve between experiment and analysis (ratio for flexural stiffness of horizontal members, R_y).

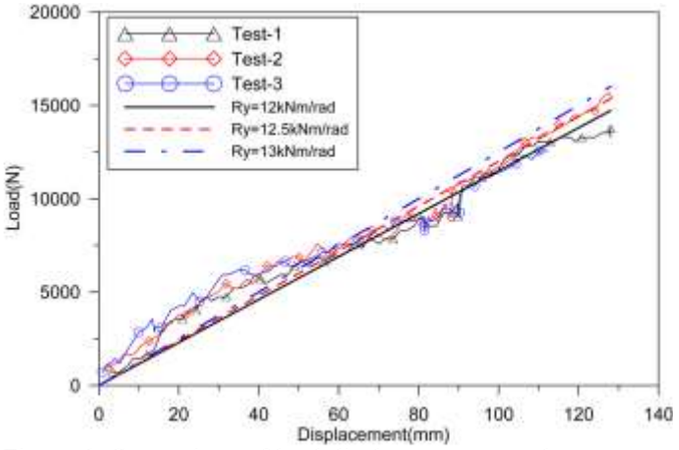

Figure 6. Comparison of load-displacement curve between experiment and analysis (rotational stiffness).

In order to determine the rotational stiffness of connection between vertical and horizontal members to be applied to the finite element analysis of the system support, the values derived from experiments conducted in Korea and other countries were compared and analyzed. As shown in Table 2, Kim et al. (2017) evaluated the rotational stiffness of the wedge type connection to be 12~13 kNm/rad. Peng et al. (2013) estimated the rotational stiffness to be 34.34 kNm/rad. Chandrangsu and Rasmussen (2011) studied the rotational stiffness of cuplok connection and yielded 96.23 kNm/rad for 4-way, 87.97 kNm/rad for 3-way, and 71.62 kNm/rad for 2-way. Parabhakaran et al. (2011) estimated the rotational stiffness of the clamp joint to be 10.65 kNm/rad.

Table 2. Comparison of rotational stiffness in various researches

Research	Joint type	Rotational stiffness (kNm/rad)
Kim et al. (2017)	Wedge	12.0~13.0
Peng et al. (2013)	Wedge	34.34
Chandrangsu and Rasmussen (2011)	Cuplok	96.23 (4-way) 87.97 (3-way) 71.62 (2-way)
Parabhakaran et al. (2011)	clamp	10.65

According to previous researches on the rotational stiffness of connections, there are big differences depending on type, manufacturer, and connection direction. Therefore, because the range of rotational stiffness is situationally dependent, the rotation stiffness value of the wedge type connection, which is mostly used in Korea, was determined. In this study, 12.5 kNm/rad was set for the rotational stiffness of the connection between vertical and horizontal members.

3.2 *Finite element model*

To understand the behavior of the system support considering the rotational stiffness values, the commercial finite element analysis program was used (figure 7). The system support is 6.2 m high, the vertical members are 0.9 m apart in longitudinal direction, and the horizontal members are 1.2 m apart in horizontal direction as outlined in Table 3. The steel grade of vertical, horizontal, and sloped members is STK400. The diameter and thickness of vertical members are 60.5 mm and 3.2 mm, respectively while the diameter and thickness of horizontal members are 42.7 mm and 2.3 mm, respectively. The diameter of the U-head jack base is 48.6 mm and its thickness is 2.3 mm as shown in Table 4.

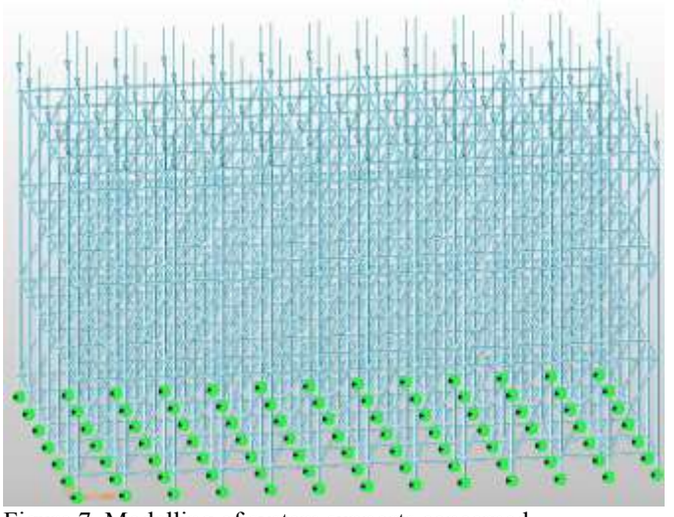

Figure 7. Modelling of system supports concerned

Table 3. Description of considered system support

Category	Specification and spacing
Height of system support	6.2m
Vertical member spacing	0.9m
Horizontal member spacing	1.2m

Table 4. Description of material of system support

Member	Specification	Steel grade
Vertical member	⌀ 60.5 mm×3.2 mm	STK400
Horizontal-Diagonal member	⌀ 42.7 mm×2.3 mm	STK400
U-head-Jack base member	⌀ 48.6 mm×6.0 mm	STK400

The boundary conditions applied to the target system support are the hinge at the bottom of vertical members, the continuous members at the connecting parts of the vertical members, the hinge at the connecting parts of the vertical and inclined bracing members, and the hinge at the connecting part between horizontal and bracing members. To analyze the changes considering the rotational stiffness, the connection of horizontal and vertical members was assumed to separately adopt the simple hinge and 12.5 kNm/rad of rotational stiffness. The slab weight was 24 kN/m^3, and the mold weight was 0.4 kN/m^2 while the live load was 3.75 kN/m^2. Considering the impacts of concrete pouring or construction errors,

the minimum horizontal load applied was heavier between the upper 2% of the dead load and 1.5 kN/m per horizontal length unit to the upper part of each floor.

4 INFLUENCE CONSIDERING ROTATIONAL STIFFNESS OF CONNECTION PART

To analyze the structural safety of the system support, considering the rotational stiffness of the connection of vertical and horizontal members, the first mode eigenvalue, the critical load, and the maximum combined stress ratio were analyzed. With the consideration of rotational stiffness, the eigenvalue and the critical load increased while the critical buckling load ratio of the application to the non-application of the rotational stiffness was 3.531 (Table 5).

Table 5. Comparison of critical load

	Without rotational stiffness(a)	With rotational stiffness(b)	b/a
Eigenvalue	0.131	0.466	3.531
Critical load (kN/m)	4.077	14.395	3.531

The maximum combined stress ratio was investigated with and without rotational stiffness. The combined stress ratio, determined by the design standard, is as follows:

$$\frac{f_c}{f_{caz}} + \frac{f_{bcy}}{f_{bagy}(1-\frac{f_c}{f_{Ey}})} + \frac{f_{bcz}}{f_{bao}(1-\frac{f_c}{f_{Ez}})} \le 1 \quad (1)$$

where fc = the compressive stress (MPa) generated by the axial force; f_{bcy} and f_{bcz} = the bending compressive stresses (MPa) at y-axis and x-axis; f_{caz} = the compressive stress (MPa) in the direction of the permissible axis of the weak axis reflecting the local buckling; f_{bagy} = the allowable bending compressive stress (MPa) of the circumference of the strong axis (y-axis) without considering local buckling; f_{bao} = the upper value (MPa) of the allowable bending compressive stress without considering local buckling; f_{Ey} and f_{Ez} = allowable Euler buckling stress (MPa) of the circumference of the strong axis (y-axis) and the weak axis (z-axis).

Table 6 represents the combined stress ratio along with the changing rotational stiffness. This connection is at the position generating the maximum combined stress ratio. Every maximum combined stress ratio was found in the vertical members. With and without considering rotational stiffness, the ratios ranged from 0.934~0.968. The analysis demonstrated that the maximum combined stress ratio, when considering the rotational stiffness, was 5-6% smaller than without considering the rotational stiffness.

Table 6. The maximum combined stress ratio according to vertical member location

Element number	424	573	722	729
Without rotational stiffness	0.764	0.765	0.764	0.699
With rotational stiffness	0.714	0.714	0.714	0.677
With rotational stiffness / Without rotational stiffness	0.968	0.934	0.934	0.938

5 CONCLUSION

This study analyzed the behavior and structural safety of the system support when the rotational stiffness is applied to the connection of the vertical and horizontal members. Based on the results of applying the actual rotational stiffness value to the connection parts, the following conclusions were obtained.

1. The rotation stiffness value of the wedge type connection, which is mostly used in Korea, was determined to be 12.5 kNm/rad by comparing the experimental and analytical values.

2. As a result of the buckling analysis using the vertical member of the system and the rotational stiffness of the horizontal joint, the critical buckling load increases with the consideration of the connection stiffness. When the concrete load is placed on the whole slab of the target system, the critical buckling load is 3.5 times larger than the hinge considering the rotational stiffness of the joint.

3. Considering the rotational stiffness of the vertical and horizontal joints, the maximum combined stress ratio of the vertical members was estimated to be 5 ~ 6% smaller than that of the hinge alone. Therefore, it is considered that the present design method considering the vertical and horizontal joints as hinges is conservative in evaluating the generated stress slightly higher than the actual stress.

According to the previous study on the rotational stiffness of the joint, the rotational stiffness of the joint can be changed according to the shape of the joint, the manufacturer, and the direction of the joint. The rotational stiffness of the connection used in this study is limited to the connection type and 1-way connection used in the experiment. Further study on the manufacturer, connection type, and various connection directions should be performed in the future.

Research on Transverse Mechanical Property of Widened Box Girder Bridge

W.Q. Wu & H. Zhang
School of Transportation, South East Univ., Nanjing, China

Z.X. Tang
China Design Group Co., Ltd., Nanjing, China

ABSTRACT: In order to investigate the possible structural diseases brought to the deck of the existing prestressed concrete box girder bridge, the stress state of the existing box girder before and after widening were analyzed using finite element method in this paper. The possible structural diseases and their mechanisms that were brought to the upper plate and flange plate of the existing box girder were studied. The main parameters considered include the shrinkage and creep effect of the new concrete bridge, the uneven settlement difference between the old and the new box girder, the temperature gradient and the vehicle live load on the whole widened box bridge. Results showed that the inner flange of the old box girder were generally in the state of large tensile stress, the main reason for which was the shrinkage and creep effect difference and the uneven settlement difference of the new and old bridge. And the tensile stress was larger than tensile strength of C50 concrete, which would most likely cause crack in the deck plate of box girder. Hence, reinforcement measures are needed to be designed carefully. Meanwhile, the transverse deformation of structure had exceeded the distance between the anti-seismic block and the web of box girder at the end cross section, which would most likely squeeze anti-seismic block. Therefore, it is necessary to limit the length of continuous bridge that needs a widening work.

1 INTRODUCTION

At present, the technical needs of China's bridge widening mainly come from two aspects: one is the substantial increase in the volume of existing road traffic, which has exceeded the existing road capacity. The expansion of the expressway is indeed a quick and effective solution to this issue (Wu et al. 2007, Shushkewich 2005). On the other hand, the carrying capacity of existing bridges can be enhanced after widening according to some literatures (Zhang et al. 2006, Lu et al. 2013, Zhao & Zhang 2004). This is mainly because the structural stiffness of the new bridge can be changed to meet the bearing requirements of existing bridges.

Most of the current literatures focus on structural reinforcement measures to improve the carrying capacity of the original structure (Choi & Oh 2013, Zaid & Collings 2017), while there is little research on the performance indicators of widened bridge in the serviceability limit states under the interaction between the new and old bridge. Especially, the study on transverse stress and deformation is still insufficient due to the additional shrinkage and creep effect of the new concrete bridge and the uneven settlement difference between the old and the new girder, resulting in many structural diseases (Wang 2011, Ru & Liu 2016, Wen & Ye 2006, Jing & Wen 2014). For example, after the widening of a highway bridge, because the large lateral displacement appeared in the end section of large-span concrete box girder, the transverse anti-seismic block on the cover beam was squeezed seriously.

Different from the conventional design of box girder bridge, it is necessary for bridge joint widening design to consider the interaction between the new and old box girder bridge due to time-dependent effects. At the same time, the widened bridge has an obvious spatial effect of wide bridge due to the larger width–span ratio, compared with the original box bridge. Therefore in order to ensure the normal use performance and durability of the bridge after widening, it is necessary to focus on the analysis of the transverse stress state in the deck of the existing box girder bridge and the possible potential structural diseases, then to add rational strengthening measures to the existed bridge .

Taking a variable cross-section continuous box girder bridge that needs to be widened as the research background, the transverse mechanical property of the widened box girder bridge were analyzed by the finite element method in this paper, to clarify the influence of widening on the transverse force of the old bridge, especially on the bridge deck. Finally,

reinforcement measure for the old bridge was put forward accordingly.

2 PROJECT AND MODEL OVERVIEW

2.1 *Background of Project*

This is a (40+2×67+40) m prestressed concrete continuous box girder bridge with two single-box single-chamber box girder, constructed with C50 concrete and 1860MPa longitudinal prestressed steel strand. Full width of box girders is 13.5m, and the cantilever length of the flange plate is 3.5m with 0.15m thickness at cantilever end and 0.60m thickness at the root. The thickness of the floor and the beam height vary in accordance with 1.8 order parabola. The continuous prestressed concrete bridge was constructed with cantilever construction method. The design load for the old bridge is Automobile Ultra-20, trailer-120. The bridge elevation and cross-section diagram are shown in Figure 1 to Figure 2.

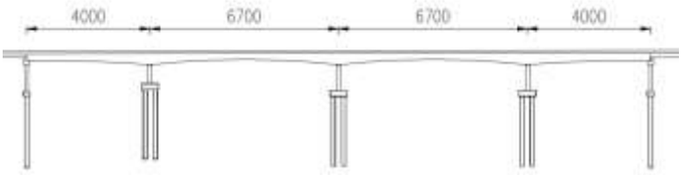

Figure 1. Bridge Elevation (Unit: cm)

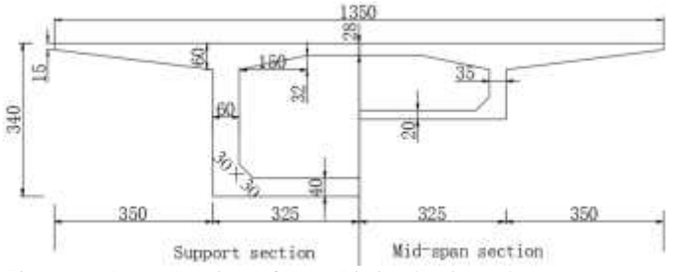

Figure 2. Cross Section of Box Girder (Unit: cm)

Taking various factors into consideration, the new bridge adopted the same structural form and span arrangement as the old bridge. And the superstructure was connected while the substructure remained separated. After widening the design load is highway level-I. The flange plate of the old and new bridge were spliced in a hinged manner without diaphragm for lateral connection. During construction, the part of 0.75m inner flange of the old box girder should be excised firstly to be easy for planting bar up in the flange plate. And then the buried bars in flange of the old box girder and embedded bars in the new were welded together. The last step is pouring concrete into the splicing seam, forming a hinged connection structure. The illustration of transverse splicing of box girder is shown in Figure 3.

2.2 *Finite element model*

The three-dimensional finite element model of the full–bridge was built according to design drawings. Hexahedral elements were used in the model and the element grid was encrypted at the seam. The transverse meshing was shown in Figure 4. A total of 10 control sections were selected to calculate the internal force and in order to characterize the stress changes along the height of each control section, 30 stress control points were selected in each control section, as shown in Figure 5 and Figure 6. The bearing constraints are shown in Figure 7 and Table 1. The definition of coordinated system is determined as follows, the direction along the bridge is X axis, the right direction is positive, direction transverse to the bridge is Y axis, the old bridge direction is positive, Z axis is vertical, the upward is positive and the downward is negative. In general, the full bridge model is divided into 636,336 elements and 852,527 node.

The working conditions considered by finite element model in this paper were defined as follows:

Stage 1–the additional shrinkage and creep effect;
Stage 2–the uneven settlement difference;
Stage 3–the vehicle live load;
Stage 4–the temperature gradient;
Stage 5–comprehensive conditions.

3 ANALYSIS OF TRANSVERSE MECHANICAL PROPERTY OF WIDENING STRUCTURE

3.1 *Influence of shrinkage and creep effect difference on old bridge flange after widening*

It is assumed that the shrinkage and creep effect of the old bridge concrete has been completed, while that of the new bridge just start after transverse splicing. In order to analyze the influence of the shrinkage and creep difference of the old and new bridge concrete on the force and deformation of the whole box girder structure, the construction process was divided into six stages, as shown in Table 2.

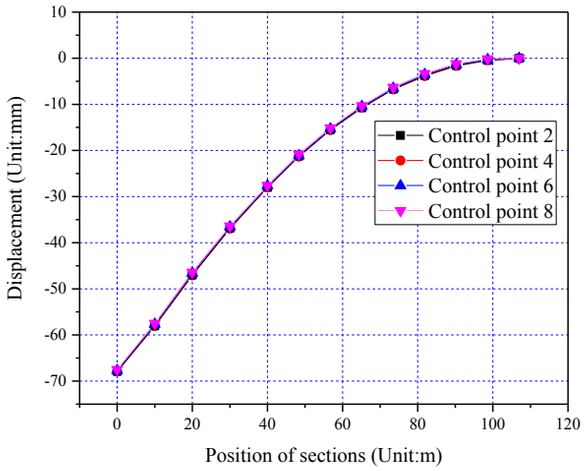
Table 2. Construction stages

Construction stage number	Construction content
1	Cantilever pouring construction and bridge deck pavement of the old bridge
2	After ten years(3650 d) of operation for old bridge
3	Cantilever pouring construction and bridge deck pavement of the new bridge
4	After six months of waiting period (180 d) for the new bridge
5	Construction of joint widening
6	Co-operation of new and old bridge for three years (1095 d)

3.1.1 *Analysis of transverse displacement*

In order to visually see the trend of transverse displacement, Figure 8 depicts the transverse deformation of each control section due to the shrinkage creep of the new cast concrete after transverse splicing. It can be seen from Figure 8 that the transverse displacement at the end of box girder was 68mm, which was about 1/3147 of the total bridge length. While the distance between anti-seismic block and the girder web was 50mm, if no effective measures were taken to suppress the transverse displacement,

the anti-seismic block was most likely to be squeezed severely, as shown in Figure 9.



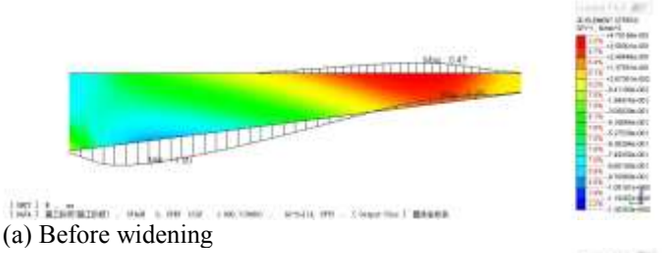


Figure 8. The Transverse Displacement Curve after Widening Due to Shrinkage and Creep

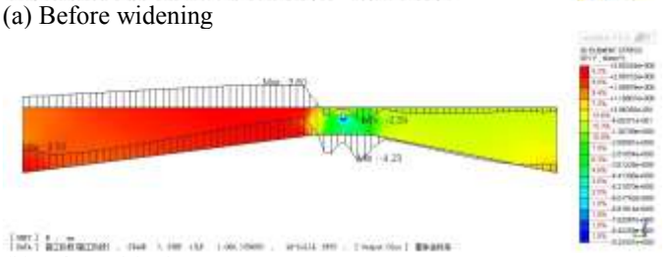

Figure 9. The Squeezed Anti-seismic Block

3.1.2 *Analysis of transverse stress*

As the maximum transverse displacement occurred at the beam end section (1#), Figure 10 shows the trend of transverse normal stress at the top and bottom of the flange plate of the old bridge in 1# cross section, and the stress above the base line indicated the tensile stress, while that below the base line indicated the compressive stress.

(a) Before widening

(b) After widening

Figure 10. The Overall Transverse Stress Changes of 1# Control Cross Section for the Old Bridge (Unit: MPa)

It can be seen from the above figure that the transverse stress of the inner side of old bridge flange was greatly changed. In order to clarify the stress distribution characteristics, Table 3 lists the stress values of the control points for the old bridge, among them tensile stress was positive while compressive stress was negative.

Table 3. Transverse normal stress value of control points in 1 # section

Control points	9	10	22	23	11	12
Ten years' operation for old bridge	-0.94	-0.05	-0.01	-0.72	0.47	0.23
After joint widening	-0.46	0.63	0.42	0.03	0.02	0.21
Co-operation for three years	1.65	2.35	3.00	2.32	0.84	0.20

As shown in Table 3 and Figure 10, there were large tensile stresses both on the upper and lower zone of the inner flange near the end section of the old girder, that is, the inner flange near the end section for the old bridge was in a transversely integral pull state. The mechanism of this stress state is that when longitudinal shrinkage and creep deformation occurred in the new whole bridge, the new bridge would exert a transverse tension effect on the old bridge due to the integral transverse deformation of the whole widened bridges in the end section. Therefore, when the inner flange of the old box girder is subjected to eccentric compression longitudinally, it was in an integral tension state transversely. This transverse tension effect will increase with the total length of the widened bridge, so reinforcement measures are needed for the inner flange of the old box girder near the end section.

3.2 *Influence of uneven settlement difference on old bridge flange after widening*

The uneven settlement difference between the old and the new box girder, which is also called settlement difference after construction, has a very important effect on the deformation and internal forces of the inner flange plate of the old and new box girders. In the model, the settlement difference was imposed according to the conclusion of Wu et al. (2008) that the settlement difference after construction should not be greater than 10mm for orthogonal bridges, while the value should not be greater than 5mm if putting skewed bridge orthogonally. As this bridge conformed to the latter case, therefore, in this paper the allowable settlement difference in the section of support point was identified as the value 5mm.

Figure 11 shows the distribution of the transverse stress of the whole widened structure under the effect of foundation settlement difference. It can be seen from Figure 11 that the transverse stress was small in most areas except in the section of support point. Taken 1# cross section as an example, the

trend of the lateral normal stress of the inner flange plate was shown in Figure 12, and the stress above the base line indicated the tensile stress, while that below the base line indicated the compressive stress. The specific lateral stress values on the upper and lower edge of the flange plate can be viewed in Table 4.

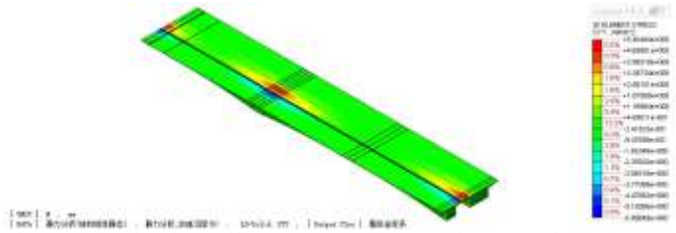

Figure 11. The Overall Transverse Stress Changes of 1/2 Span Bridge Structure

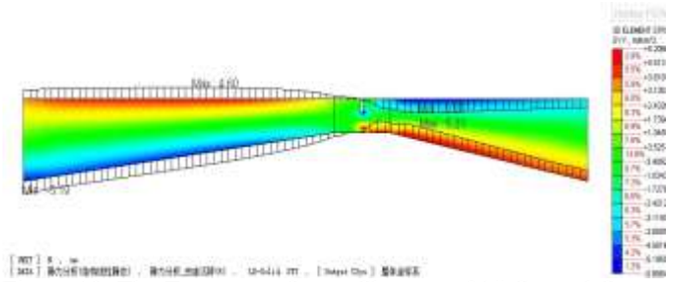

Figure 12. The Transverse Stress Changes of 1# Control Cross Section (Unit: MPa)

Table 4. Settlement-induced transverse normal stress of key points in 1 # section

Control points	9	10	22	23	11	12
Transverse stress	3.4	-3.41	4.6	-5.0	1.3	-1.62
Reduced stress	1.5	-1.53	2.1	-2.3	0.6	-0.73

In Table 4, the transverse stress caused by forced displacement was reduced because the effect of foundation settlement on the internal forces of transverse widened structures performs as a long-term process. Therefore, the stress relaxation effect of concrete should be considered in the stress calculation. With reference to the research results of previous literatures (Mohseni & Rashid 2013, Han et al. 2003, Wen et al. 2011), the reduction factor was recommended as 0.45 in this paper. However the value of tensile stress on upper flange was still threatening.

3.3 *Influence of vehicle live load on the flange of old bridge after widening*

The bridge was arranged horizontally with 5 lanes after widening. The lateral distribution of lane load mainly considered three kinds of working conditions such as load biased on the old bridge side, symmetrical load and load biased on the new bridge side, as was shown in Figure 13.

Figure 14 shows the transverse normal stress nephogram of the third mid-span section (9#) under the three kinds of working conditions and the specific transverse normal stress values can be viewed in Table 5, among them the tensile stress was of positive while compressive stress was of negative.

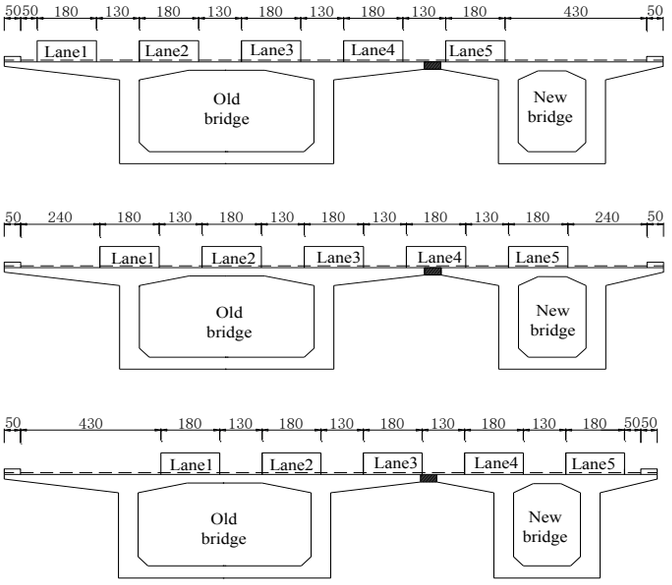

Figure 13. The Schematic Diagram of Transverse Load Distribution (Unit: cm)

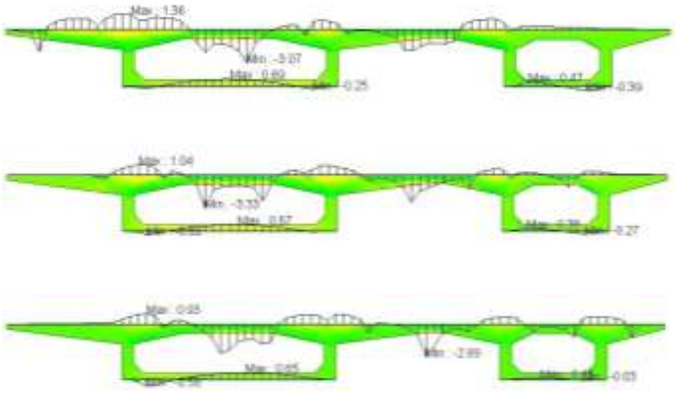

Figure 14. Transverse Stress Changes of 9# Control Cross Section (Unit: MPa)

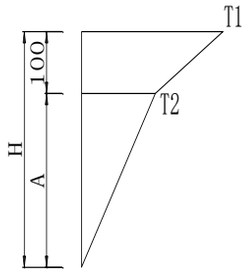
Table 5. Transverse normal stress value of control points in 9 # section

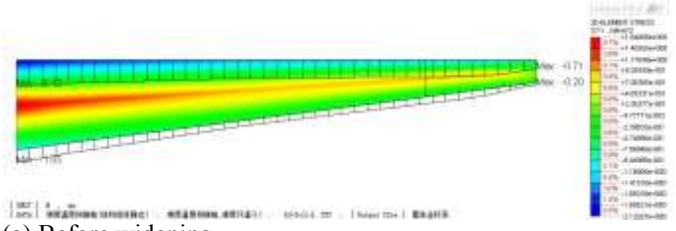
Control points	9	10	22	23	11	12
Case 1	0.50	-0.20	-0.39	0.18	-1.26	0.69
Case 2	0.81	-0.63	-0.33	0.13	-1.31	0.76
Case 3	0.92	-0.73	0.09	-0.26	-2.90	1.72

It can be seen from the above finite element model analysis results: The stress distribution on the deck of the box girder was very similar except for some numerical changes, no matter under what kind of working conditions, which indicating good force collaboration between the new and old box girder. In addition, the splicing part between the new and old deck was generally in a good stress state, only the tensile stress of 1.72 MPa occurred at the individual control point 12 , which indicating that the structure showed good performance under the action of vehicle load, so the vehicle load is not the control factor to the transverse splicing site.

3.4 *Influence of temperature gradient on old bridge flange after widening*

The temperature gradient pattern is applied in accordance with the relevant provisions of the specification, as shown in Figure 15. The maximum temperature of the surface of the bridge deck T_1 is 14 degrees Celsius and T_2 is 5.5 degrees Celsius when calculating the positive temperature difference. When calculating the anti-temperature difference, multiply the former by -0.5 according to the specification.





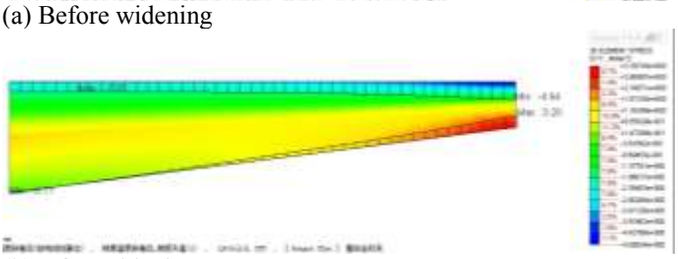


Figure 15. Vertical Temperature Gradient Curve (Unit: cm)

Figure 16 depicts the transverse stress nephogram of old bridge flange plate at the middle cross-section (2#) in side span under the positive temperature gradient, the stress above the base line indicated the tensile stress, while that below the base line indicated the compressive stress. The specific lateral stress values on the upper and lower edge of the flange plate can be viewed in Table 6. Among them tensile stress was positive while compressive stress was negative.

(a) Before widening

(b) After widening

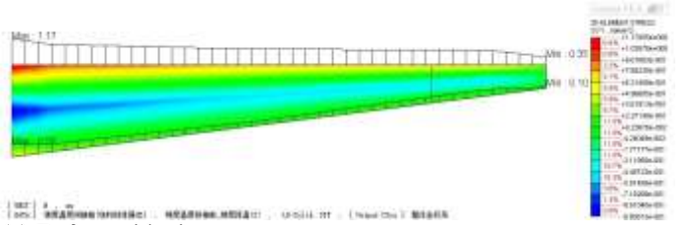

Figure 16. The Transverse Stress under Positive Temperature Gradient (Unit: MPa)

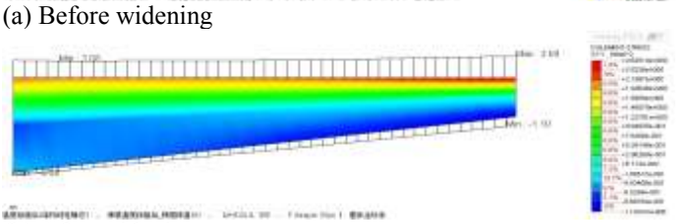
Table 6. Transverse normal stress value of control points in 2 # section



Control points	9	10	22	23	11	12
Before widened	-2.16	-0.72	-1.53	-0.50	-1.36	-0.55
After widened	-2.80	-0.10	-2.97	0.93	-4.77	3.02

As can be seen from Figure 16 and Table 6, there was a significant increase in the compressive stress values at the upper edge of the old bridge flange plate, under the positive temperature gradient, while transverse stress on the lower edge of the flange plate changed from compression to tension. The closer the position was to the splicing section, the greater the tensile stress was. The maximum stress value of 3.0MPa occurred at the splice section, which would exert adverse effect on the lower edge of the inner flange plate of the old bridge and the splicing section.

On the contrary, under the effect of negative temperature gradient, the tensile stress values at the upper edge of the old bridge flange plate increased obviously even up to 2.63MPa, resulting in high possibility of concrete cracking on the upper flange, as shown in Figure 17 .

(a) Before widening

(b) After widening

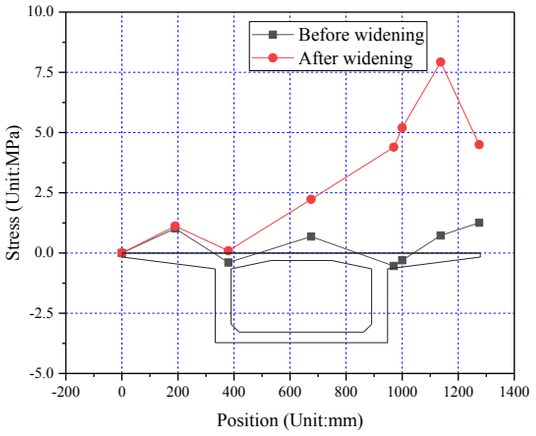


Figure 17. The Transverse Stress under Positive Temperature Gradient (Unit: MPa)

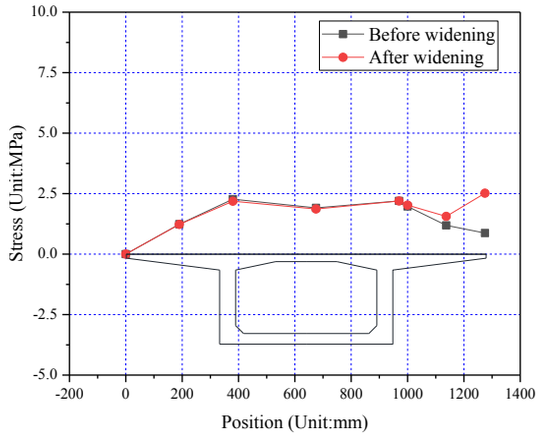
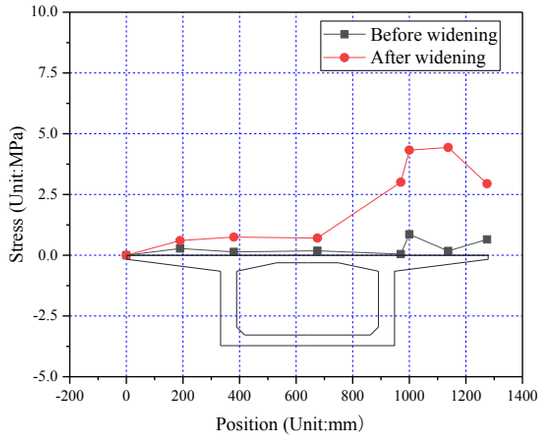
3.5 *Transverse stress state of the deck of old bridge under comprehensive conditions*



In order to fully consider the influence of self-weight, prestress, shrinkage and creep, foundation settlement difference, vehicle live load and temperature gradient on old bridge after widening, the stresses in above load conditions were combined, to study possible structural diseases on bridge deck that caused by a joint widening of prestressed concrete box girder bridge. Figure 18 shows the maximum transverse stress values of control points on several typical sections under comprehensive conditions.

The joint widening performed with a great influence on the stress state of the deck of old box girder at the section of support point, especially in the end section, while a little influence at the mid-span section relatively. Part of the upper plate and the inner flange plate of the old box girder were generally in the state of large tensile stress, for example the tensile stress reached 2.2-7.9 MPa in beam end section, which had exceeded the tensile strength of C50 concrete, and then the flange plate actually cracked or



had a high possibility of cracking. Therefore, reinforcement measures ought to be taken to prevent serious cracking of concrete.

(a) 1# cross section

(b) 2# cross section

(c) 3# cross section

Figure 18. The Transverse Stress under Comprehensive Conditions (Unit: MPa)

3.6 *Suggested strengthening measure for the flange plate of the old bridge*

In view of the above finite element analysis results , it's obvious that after widening, the flange plate of the old bridge would face an unfavorable stress state under the effect of shrinkage and creep effect of the new concrete bridge, the uneven settlement difference between the old and the new box girder, the temperature gradient etc. Therefore, the top and bottom zone of the inner flange plate of the old bridge are to be reinforced and then the following methods that Nie et al.(2005) suggested can be proposed, that applying the lateral external prestressing to make the old bridge flange plate (after cutting 0.75m flange) in the preloading state. Taking into account the convenience of construction on old bridge, the transverse prestressing strands could be arranged on the upper edge of the old bridge flange, as shown in Figure 19. Reinforcement materials include high-strength stainless steel wire mesh and strongly permeable mortar. The specific reinforcement configuration data can be calculated according to the external prestressing structure, and the reinforcement range can be carried out in the whole bridge to improve the crack resistance of the structure. Compared with traditional strengthening method, this technology has many advantages such as prestressing effect, fire resistance, corrosion resistance, aging resistance, good quality, less damage to the deck of the main beam, convenience to construct, etc.

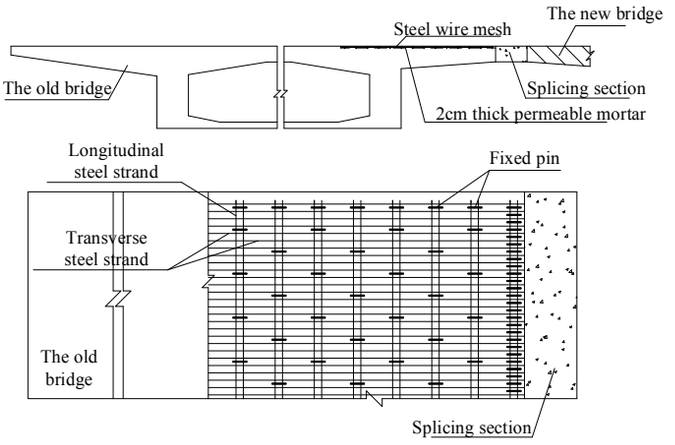


Figure 19. Layout of Steel Strand Mesh on the Flange Plate of the Old Bridge

To handle creep-shrinkage deformation of the added box girder fundamentally, other than accommodating the resulting stresses, one possible way is to limit the total length of continuous box girder bridge that needs to be widened and the application of shrinkage-compensating concrete can be another approach, which are all directions that can be studied in depth in the future.

4 CONCLUSION

Based on the results of solid finite element, the following conclusions and recommendations were summarized:

(1) The transverse deformation of the box girder structure resulting from shrinkage and creep effect of the new concrete bridge was very significant, especially in the end section of the widened bridge,

which was even possible to severely squeeze anti-seismic block.

(2) The shrinkage and creep effect of the new concrete bridge would cause greater tensile stress in the flange of old box girder at the end section, which should be carefully considered.

(3) The uneven settlement-induced tensile stresses were greater on the upper edge of the old bridge flange plate and the lower edge of the new in the section of support point.

(4) Under the action of vehicle load, the old and new box girders were able to work together as a whole structure and showed good bearing performance.

(5) The upper flange of the old bridge showed greater tensile stress under the effect of negative temperature gradient, needing reinforcement treatment.

(6) In summary, the upper plate and inner flange of the old bridge were generally in the state with a large tensile stress, and the main reason for which was the shrinkage and creep effect of the new concrete bridge and the uneven settlement difference between the old and the new box girder. There was a high probability of cracking in most zone of the widened bridge deck.

(7) In order to solve the problems above, a transverse external prestressing method could be introduced to reinforce the upper plate and lower plate of old bridges after joint widening in this paper.

Sensitivity and Reliability Analysis of long span Cable stayed Bridge

Xiaoming Wang , Wentao Wu, Juyou Zhang, Yu Cai
Institute of Bridge Engineering, College of Highways, Chang'an University, Xi'an, Shaanxi Province, China
Key Laboratory of Bridge Detection Reinforcement Technology Ministry of Transport(Xi'an)

ABSTRACT: This paper proposes a method of structural sensitivity and reliability analysis based on the reliability calculation method by using integration of Latin hypercube sampling(LHS) and one-order second-moment method, then a cable-stayed bridge with multi-cable system is analyzed by using the method. (1) The number and type of the random variables used in the reliability analysis are determined by reliability analysis and sensitivity analysis. (2) The analysis model is established to analyze the sensitivity and reliability of the parameters. (3) The reliability analysis results are compared to verify the correctness of the method. The feasibility of this method is proved by analyzing a 12-story frame structure, the method is applied to sensitivity and reliability analysis of a cable-stayed Bridge. The influence of materials and external factors is considered and the initial tensioning cable force is seen as random variable to carry out the analysis, that have a significant meaning on cable tensioning scheme optimization of cable-stayed bridge.

1 INTRODUCTION

Cable-stayed bridge is widely built because of larger stiffness of the main beam, convenience of cantilever construction and larger construction span. The optimization of the cable force of the cable-stayed bridge has been a hot topic in the field of structural optimization. But most of the studies are based on structural assumptions that are fully deterministic, also known as deterministic analysis. However, in practical engineering applications, the cable-stayed bridge itself is very sensitive to the influence of uncertain factors such as geometry, bearing displacement, material properties, external load and construction. Therefore, the deterministic analysis cannot provide a complete assessment of the cable-stayed bridge. So far, a large number of scholars have done a lot of optimization research of cable force of cable-stayed bridge. these methods, from the perspective of displacement and internal forces to optimize the cable force, are deterministic analysis. There is little research on the sensitivity and reliability analysis of the cable-stayed bridge structure. Therefore, in order to make a complete evaluation of the cable-stayed bridge, the material and other factors of the cable-stayed bridge are analyzed to calculate the reliability and sensitivity, and it is particularly important for complete evaluation of cable stayed bridge.

The Monte Carlo method (MC) is a numerical method for solving the reliability by stochastic simulation and statistical experiments. For some structures, when the function is implicit or difficult to obtain, the sample of the variable cannot be taken directly to calculate. But by using the finite element analysis software, the variables can be directly substituted into the finite element model, and the response results of the structures can be obtained by analysis, and the failure probability and reliability index of the structures can be calculated. The Monte Carlo method provides an important general method, but due to computational cost constraints, it has not been overwhelmingly applied. The one-order second-moment response surface method (RSM) is a widely-used method in structural reliability analysis. The response surface method uses the statistical sampling technique and the regression fitting technique in statistics to convert the function which is difficult to express to simple fitting function, and finally the reliability analysis method is used to analyze the structural reliability. In this paper, we introduce a new hybrid method and apply it to the sensitivity and reliability analysis of the cable-stayed bridge when we use the random response data to fit the whole sample space. Firstly, this method is proved by the analysis of the twelve-story rigid frame, and then the method is applied to the analysis of the sensitivity and reliability of the double-tower three-span cable-stayed bridge. The sensitivity of the random variables of the cable - stayed bridge is determined by the sensitivity analysis, and the results of reliability analysis which are calculated by using

partial variables and all variables are compared to describe the feasibility of this approach.

2 PROPOSED METHOD

The method is designed to integrate Latin hypercube sampling (LHS), artificial neural network response surface method(ANN), first-order Second-moment(FOSM) reliability analysis method and Monte Carlo(MC) method based on important sampling method without sacrificing accuracy to improve the reliability analysis efficiency.

2.1 *Latin hypercube Sample Technic*

Latin hypercube sampling (LHS) is the progress of sampling technology innovation. Compared with traditional direct random sampling, it is designed as a sampling method which can reflect the whole distribution of variables through fewer samples. Its basic principles are as follows:

(1) Each dimension has been divided into *m* non-overlapping regions so that each region has the same probability, that is, dividing by equal probability;

(2) A sample point has been randomly selected in each dimension;

(3) Then the data in (2) are randomly combined according to the one-to-one correspondence principle.

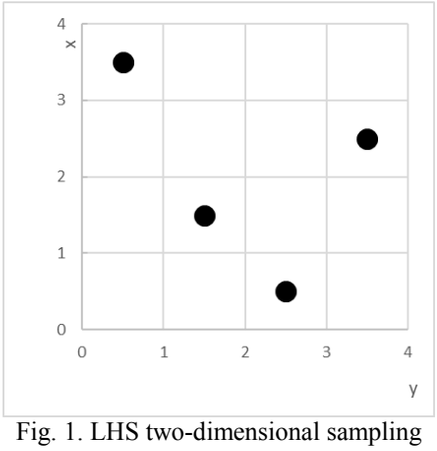

Fig. 1. LHS two-dimensional sampling

In the traditional sampling calculation, all the variables are selected randomly, this method is difficult to ensure that the selected variables can cover the entire range of variables. It also cannot be a good reflection of the overall variation of the variable. The Latin hypercube sampling (LHS), as shown in Fig.1, effectively avoids the repetitive combination of multidimensional combinations. And the equal probability division can effectively use the distribution of a small number of sample to reflect the whole distribution.

It should be noted that the Latin hypercube sampling is not for evenly distributed [0,1] samples, but according to the distribution of random variables to divide the variable which has the equal probability interval division.

2.2 *Back Propagation Artificial Neural Network*

BP artificial neural network (BPANN) is a one-way propagation of multi-layer feedforward network structure, which is currently the most widely used a network structure. A complete BP neural network structure consists of three layers: the input layer, the output layer, and the hidden layer, as shown in Fig 2. Hidden layer layers can be monolayer or multilayer, and there is no association between neurons in the same layer. The signal is input from the input layer, reaches the hidden layer, and finally outputs the result from the output layer. Only the two adjacent layers are signaled and the signal can only be transmitted unidirectionally to the next layer. This is also known as a multi-layer feedforward network.

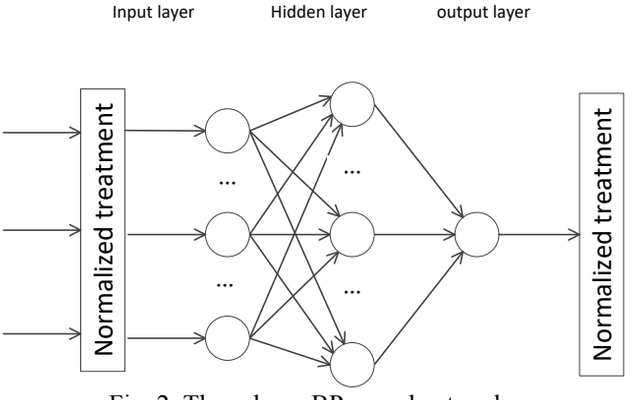

Fig. 2. Three-layer BP neural network

The transfer function of the hidden neurons in the BP neural network is usually a Sigmoid function. As shown in Fig.2, in a three-layer BP neural network, we assume that the number of nodes in the input layer is *n*, the number of nodes in the neurons of each hidden layer is *p* and the output neurons are 1. *N* sample points are obtained by sampling, and the sample points are brought into the finite element model for numerical simulation. *N* real output values corresponding to the *N* sample points are obtained, and the sample points are brought into the BP neural network to obtain the *N* output layer values. The network connection weight between the *j*th neuron node and the output layer of the input layer is w_{ij}, and the network connection weight between the *j*th neuron node and the output layer of the hidden layer is v_{ij}.

Assume that the structural functional function is:

$$Z = G(X) \tag{1}$$

Then there is a mapping relationship between the input sample point x^l and the true output value z^l:

$$z^l = G\left(x^l\right)\left(l = 1, 2, \cdots, N\right) \tag{2}$$

By studying the geometry of the sample, as shown in Fig 2, the BP neural network is going to determine a set of weights makes the actual output of the neural network the best approximation of the true output

value. The fitted response surface function can be expressed as:

$$\begin{aligned}\bar{Z} &= \bar{G}(X) = f_2\left(V^T f_1\left(W^T X-\theta\right)-\theta'\right) \\ &= f_2\left(\sum_{j=1}^{p} v_{j1} f_1\left(\sum_{i=1}^{n} w_{ij} x_i-\theta_j\right)-\theta'\right)\end{aligned} \tag{3}$$

Where f_1 and f_2 are the transfer functions between the hidden layer and the output layer, respectively, θ and θ' are the thresholds between the hidden layer and the output layer. The general hidden layer function selects the Tan-Sigmoid function (equation 4), and the output layer selects the linear function (equation 5):

$$f_1(x) = \frac{2}{1+\exp(-2x)} - 1 \tag{4}$$

$$f_2(x) = x \tag{5}$$

2.3 *First-order Second-moment method*

First-order Second-moment method(FOSM) uses the first-order moments (mean) and second-order moments (variance) of the data in the statistical information to calculate the structural reliability. Using Taylor series to expand the complex functional function into a polynomial is the main content of this method, and then through the mathematical statistics directly calculate the structural reliability.

There are two ways to expand the function. One is expanding at the mean of the variable, called central point method. One is expanding at the design verification point, called design verification point method. A checkpoint is the point at which the limit state surface is closest to the origin. This is improved second-order moment method. As the central point method is more sensitive to the functional function of the structure and the distribution of the variables, the improved first-order second-order moment method is generally used in the engineering practice.

The method will be expanded on the failure surface, taking into account the actual distribution of the basic random variables.

Let the limit state equation of the structure be:

$$Z = G(X) \tag{6}$$

Let $x^* = (x_1^*, x_2^*, \cdots, x_n^*)^T$ be the limit state point, that is: $G(x^*) = 0$.

The limit state function is expanded by Taylor series at x^* and taken to the first term:

$$Z_L = G(x^*) + \sum_{i=1}^{n} \frac{\partial G(x^*)}{\partial X_i}(X_i - x_i^*) \tag{7}$$

Reliability index:

$$\beta = \frac{\mu_{Z_L}}{\sigma_{Z_L}} = \frac{G(x^*) + \sum_{i=1}^{n} \frac{\partial G(x^*)}{\partial X_i}(\mu_{x_i} - x_i^*)}{\sqrt{\sum_{i=1}^{n} [\frac{\partial G(x^*)}{\partial X_i}]^2 \sigma_{X_i}^2}} \tag{8}$$

Define the sensitivity coefficient of variable X_i and use $Y_i = (X_i - \mu_{X_i})/\sigma_{X_i}$ to rewrite to get the normal hyperplane equation:

$$\sum_{i=1}^{n} \cos\theta_{Y_i} Y_i - \beta = 0 \tag{9}$$

The point P^* on the corresponding limit state is called the design verification point, The sensitivity coefficient is:

$$\alpha_{X_i} = \cos\theta_{X_i} = \cos\theta_{Y_i} = -\frac{\frac{\partial G(x^*)}{\partial X_i}\sigma_{X_i}}{\sqrt{\sum_{i=1}^{n} [\frac{\partial G(x^*)}{\partial X_i}]^2 \sigma_{X_i}^2}}$$

The sensitivity calculation formula is:

$$S_i = \frac{\left.\frac{\partial G}{\partial x_i}\right|_{X^*} \left(x_i^* - \mu_i\right)}{2\sum_{k=1}^{n} \left.\frac{\partial G}{\partial x_k}\right|_{X^*} \left(x_k^* - \mu_k\right)} \tag{10}$$

When the variable does not obey the normal distribution, use the equivalent normalization to calculate.

2.4 *Monte Carlo Simulation*

Monte Carlo sampling (MC) is a simple random sampling within the specified sampling range. The basic idea is to know the probability distribution of the random variable and the limit state equation of the problem. According to the distribution of each random variable, the method produces N sets of random data and then passes the data into the limit state equation (Same as Equation 1) to get failure probability. Sometimes we do not know the limit state equation, but with the development of computer technology and the popularity of finite element procedures, in many cases, we can use finite element(FE) technology to get a series of results and then calculate failure probability:

$$p_f = M / N \tag{11}$$

Where M is the number of sample groups which make $Z<0$(M is the number of the failure point when we use FE model).

Monte Carlo method is suitable for a wide range because of its simple principles. But in order to get relatively accurate results, the sample size should be large enough. However, in practical engineering, whether through functional or finite element models, to meet the needs of the project, you need a lot of sample support, so that the use of this method is limited. In order to reduce the computational cost of Monte Carlo, some scholars have used the above-mentioned Latin hypercube sampling to greatly reduce the number of samples required. But it still cannot fundamentally solve the problem of Monte Carlo method with large calculation.

3 PROCEDURE OF PROPOSED METHOD

In order to combine the advantages of Latin hypercube sampling with the first-order moment calculation reliability method, this paper presents a set of solutions. The following procedure of solution is the integration of the aforementioned method, the solution flowchart is at Fig.3:

(1) Determine the random variables and their distribution, use Latin hypercube sampling method to select the sample;

(2) Input the sample data into structure finite element model to obtain the structural response value;

(3) The artificial neural network model is established and the ANN model is tested by random variable sample value and structural response value.

(4) Use the fitting function to determine the function between the variable and the reliability of the equation;

(5) Analyze the reliability of the structure and the sensitivity of the variable.

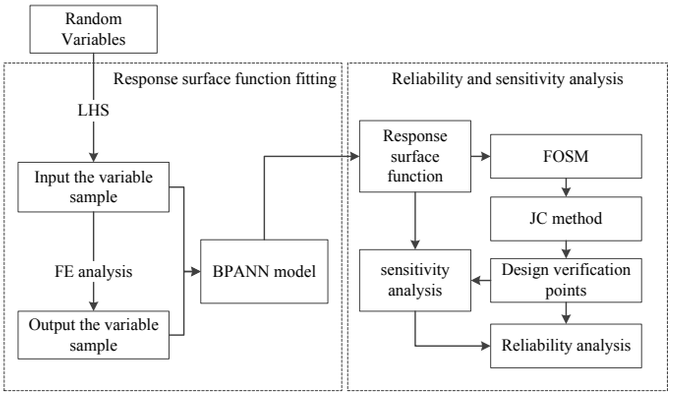

Fig. 3. Flowchart of analysis procedure

4 APPLICATION TO A FRAME STRUCTURE

A rigid frame model, as shown in Fig. 4, which is a 12-story rigid frame structure includes 84 constructs and 104 degrees of freedom is analyzed by using the preceding method.

In the figure, the horizontal displacement of point A is chosen as the object to be studied. The numbers 1 to 5 in the figure indicate the specifications of the corresponding bar, and the same number indicates that the rods adopt the same size cross-sectional area.

Table 1 selects six random influencing factors and their distribution functions (LN is Logarithmic normal distribution), which represent the cross-sectional area of the rods of the ith specification, P represents a static wind load acting on the structure, and the load is equivalent to the node at the frame. The load value of each node is P. Assuming that the above random variables are not related to each other and all of the constructed Young's modulus is a constant value to make the question easier. The relationship between the cross-sectional area of all bars and the moment of bending moment is expressed as $I_i=\alpha_i A_i^2$.

According to the method proposed in this paper, the analysis is divided into two parts: the first part is fitting response surface function. The initial variable sample is generated by using the LHS sampling method described in this paper, and the generated value is substituted into the finite element model to calculate corresponding response value. BP neural network method is used to fit the response surface function by using the sample and response value. The second part is the reliability and sensitivity analysis of the structure. The structural reliability is calculated by using first-order second-moment reliability calculation method.

Use the proposed method to analyze the sensitivity and reliability. The BP neural network method is used to fit the functional function, and the weights and thresholds of the neural network method when the six variables are obtained are shown as follow:

$$G_{BP}(X)=0.096-N_{R0}^{-1}\left(f_2\left(\sum_{h=1}^{3}v_h^{R0}f_1\left(\sum_{i=1}^{5}w_{hi}^{R0}N_{A_i}(A_i)+w_{h6}^{R0}N_P(P)-\theta_h^{R0}\right)-\theta^{R0'}\right)\right)$$

Where the value of parameters is shown as follows and f_1 andf_2 are shown at equation 4 and equation5.

$$W^{R0}=\begin{bmatrix}-0.080 & -0.050 & -0.066 & -0.140 & -0.055 & -0.413\\ 0.218 & 0.020 & 1.451 & 0.239 & -0.400 & -0.598\\ -0.003 & 0.019 & 0.060 & 0.646 & 0.176 & -0.425\\ 0.398 & 0.076 & 0.047 & -0.010 & 0.068 & -0.283\\ 0.047 & 0.028 & 0.049 & 0.107 & 0.036 & -0.278\end{bmatrix}$$

$$\theta^{R0}=[-1.014 \quad 0.809 \quad 1.304 \quad 1.384 \quad 0.052]$$

$$V^{R0}=[0.853 \quad 0.064 \quad 0.554 \quad 0.890 \quad 1.496]$$

$$\theta^{R0'}=-0.554$$

Analyze the sensitivity of each variable and the analysis results are shown in Fig.5. Variable sensitivity values are shown in the table 2. It can be seen that the sensitivity of the random variables A1, A4 and P is higher than that of A2, A3 and A5, and the

sensitivity of the random variable P is the highest, which indicates the reliability index of the random variables A1, A4 and P, the effect is more significant, in which the horizontal load P is the main influencing factor.

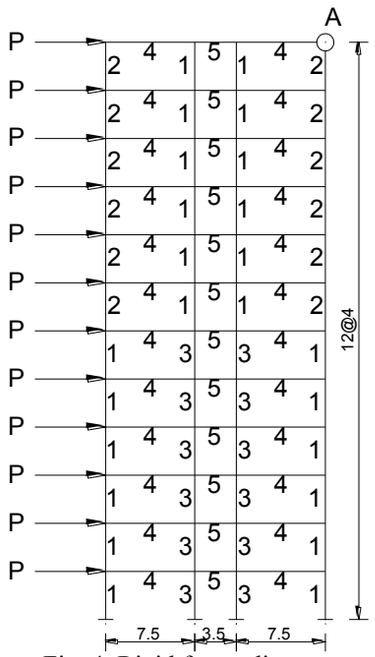

Fig. 4. Rigid frame diagram

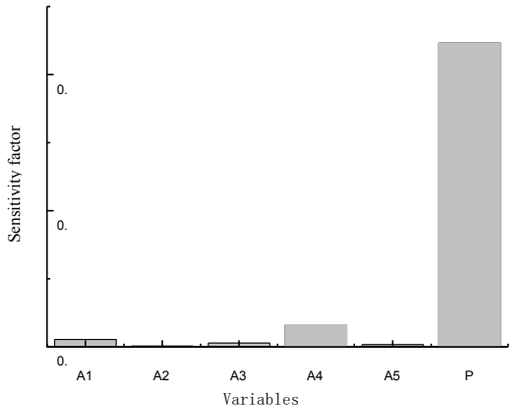

Fig. 5. Random variable sensitivity

Table 1 Random variable parameters

variables	mean	standard deviation	distribution	α_i
A1	0.25m^2	0.025m^2	LN	0.0833
A2	0.16m^2	0.016m^2	LN	0.0833
A3	0.36m^2	0.036m^2	LN	0.0833
A4	0.20m^2	0.020m^2	LN	0.2667
A5	0.15m^2	0.015m^2	LN	0.2000
P	30KN	7.5KN	GumbelI	

Table 2 Random variable sensitivity

Variables	A1	A2	A3	A4	A5	P
Sensitivity factor	0.011	0.001	0.006	0.032	0.003	0.446

Table 3 Reliability analysis results

Number of variables	Reliability index	Failure probability
6	1.43(BP)	7.67%
6	1.45(MC)	7.35%
3	1.47(BP)	7.09%
3	1.37(MC)	8.53%

Sensitivity of A2, A3 and A5 is very low, so that we can consider that A2, A3 and A5 cannot affect the reliability of the results of point A analysis. According to the variable sensitivity screening condition, we can ignore the influence of A2, A3 and A5 on the horizontal displacement reliability index of point A, and regard it as deterministic variable. In summary, select the random variables A1, A4, P on the structure of the reliability analysis. The reliability results are shown in the Table 3.

The results by using six random variables and three random variables on the structure of the reliability analysis are basically the same.

According to the above example, it can be seen that the structure has the same failure mode under the influence of three random variables and six random variables. Therefore, the reliability and sensitivity analysis method proposed in this paper can be applied to the actual structure.

5 APPLICATION TO A CABLE-STAYED BRIDGE

5.1 *Bridge description*

The cable-stayed bridge has a span of 193+332+113 m, a concrete high and low tower, a double-cable surface, a symmetrical fan-shaped arrangement, and a double-split-side cross-section main beam. Tower beam separation, semi-floating architecture. The main bridge tower is double column variable cross section "H" shaped tower, tower column and beam are hollow thin section. Its dimensions such as Fig.6 The cable-stayed bridge is a dense cable system with a multi-cable structure and an asymmetric structure. Its cable force has a great impact on the displacement of main span.

5.2 *Finite-Element Model*

The finite element model is built to simulate the actual force state of the bridge. The main tower and the main beam are simulated by the beam element. The truss element is used for the cable. The finite element model is shown in Fig.7. 160 truss element are used to simulate the cable. The initial tension of the cable is 1, and then use the coefficient to express the cable force in the load combination.

5.3 *Random Variables*

In this paper, cable force is considered as uncertain factor, so the initial tension force of the cable is chosen as the research variable, and the lower bending value of the 241 node is taken as the dependent variable. The reliability of the structure is analyzed. The finite element model obtained the initial cable

force as the mean value, according to the cable force error limit of less than 5%, according to 3σ criterion to determine the standard deviation. Variables are normal distribution, parameters are shown as table 4. Without enough data, it is difficult to determine the relevance of random variables. Thus, in this study it is assumed that all random variables in Table 4 are independent of each other to simplify sensitivity and reliability analysis.

5.4 *Sensitivity and Reliability analysis*

According to the selected variables, the LHS samples are sampled by the above method, and random samples are obtained. Then, the corresponding functions are obtained by fitting the functional function by using BPANN. According to the specification limit value which is specific under the action of the moving load that the biggest flexion value does not exceed 1/500 of the main span, that is, 664mm.

Then the limit state equation is:

$$G(\mathrm{X}) = 0.664 - g(\mathrm{x})$$

The BP neural network is divided into three layers, the first layer is the input layer, 80 neurons corresponding to 80 random variables, the second layer is the hidden layer, select 15 neurons as hidden layer due to the complexity of the cable-stayed bridge. Select the equation 4 as hidden layer function, the third layer for the output layer, the equation 5 as the output layer function.

The reliability and sensitivity of the structure are analyzed according to the fitting function. This paper uses proposed method to analyze the sensitivity of each variable, the analysis results shown in Fig.8. We can easily get the effect of the initial tension of the cables on the deflection is the most significant. This is mainly due to the reduction of cable force of the mid-span can lead to the reduction of deflection. According to the variable screening conditions, the variables whose sensitivity is less than 0.015 will be regarded as a determined value, the sensitivity of more than 0.015 of 10 variables are used for reliability analysis. The result is shown as Table 5.

Table 5 Reliability analysis results

Number of variables	Reliability index	Failure probability
80	2.7255 (BP)	0.321%
80	2.7045 (MC)	0.342%
10	2.7104 (BP)	0.336%
10	2.7338 (MC)	0.313%

According to the results of the reliability calculation, it can be seen that the obtained reliability values of all variables are basically the same when the rest of the cable force is determined.

Note: The cable is numbered from left span to right span; SD=Standard deviation; The unit of cable data in the table is KN; All variables are subject to normal distribution.

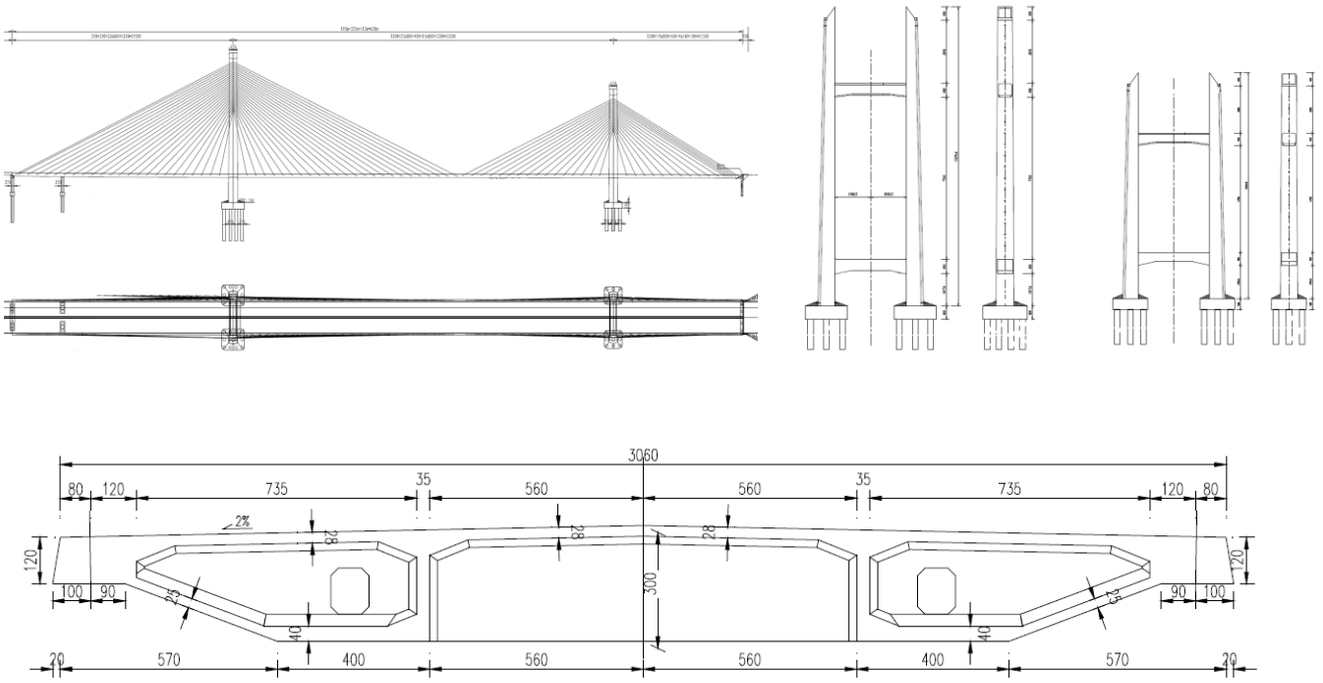

Fig. 6 Structure dimensions of the bridge(unit:cm)

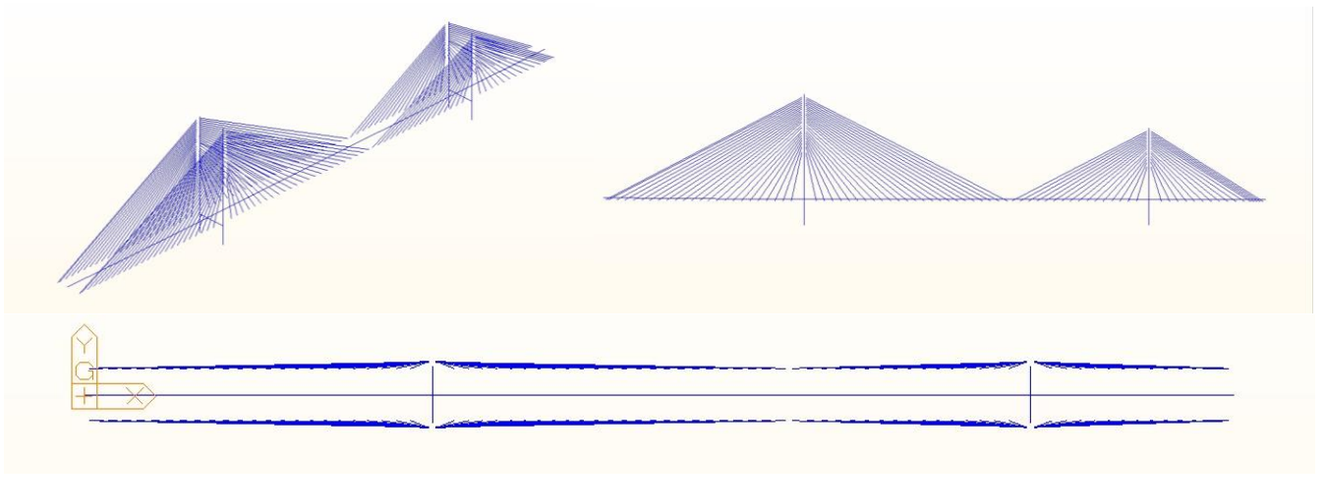

Fig. 7. Finite-Element model of the bridge

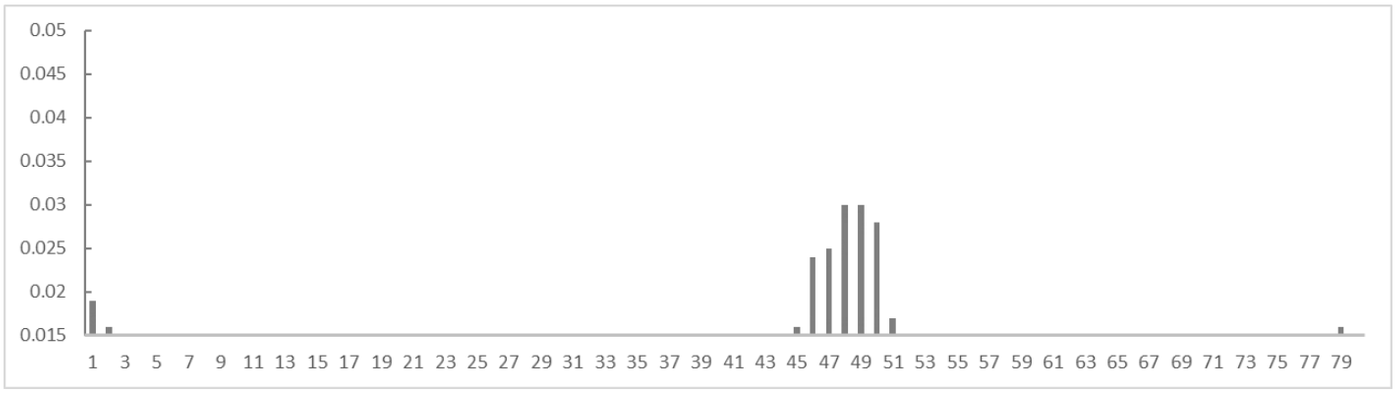

Fig. 8. Random variable sensitivity

It is necessary to note that there is not enough data to determine the correlation and variation of random variables. However, this method of sensitivity and reliability analysis still has some guiding significance in engineering. Through this sensitivity analysis, we can determine the optimization scheme of the structure and guide the operation of construction and structure.

6 CONCLUSION

The sensitivity and reliability analysis method presented in this paper has greatly reduced the sample capacity by using LHS sampling technique. By combining the sample with the finite element program, the structure response can be obtained accurately and the computational efficiency can be improved effectively. BP neural network method is used to fit the structural failure equation of the structural response value, and then using the first-order second-moment method for reliability and sensitivity analysis. The applicability of this method is validated by the comparison of the results obtained by Monte Carlo method.

Using this method to analyze the structure of a cable-stayed bridge, we can get that the influence of the cable force on the mid-span and the cross-section anchorage and the auxiliary pier has a great influence on the mid-span deflection. This is consistent with our actual construction experience. The sensitivity analysis of the initial tension of the cable can provide guidance for the structural optimization and the selection of the construction scheme. So this kind of analytic method has a very important research significance to the engineering field.

Hitachi Zosen Corporation, Osaka, Japan

ABSTRACT: Fatigue cracks in the longitudinal weld between deck plate and U-shaped rib have been increased in Hanshin Expressway company limited. Various kinds of methods to improve the fatigue durability were conducted such as using steel fiber reinforced concrete (SFRC) pavement on the steel deck. SFRC pavement is one of the effective methods for increasing the fatigue durability, but it has the disadvantage that it is necessary to carry out the traffic regulations. Hanshin Expressway Company Limited developed three countermeasures to improve the fatigue durability of U-shaped rib on orthotropic steel decks without the traffic regulation. All repair works of three methods are able to be completed under the deck plate. First method is adding thin steel plates in the vicinity of the welded joint, Second method is cutting the U-shaped ribs in the immediate vicinity of welded joint and connecting between the U-shaped rib and deck plate by L-shaped plates and studs bolts. Finally, the third method is filling the mortar into the inner space of U-shaped ribs. In this paper, outlines of three methods and results of the loading test at the actual bridge to evaluate their effect are reported.

1 INTRODUCTION

1.1 *Fatigue cracks on orthotropic steel decks*

The Hanshin Expressway Company Limited established as a highway authority in May, 1962 and privatized in October, 2005 constructs and operates an urban expressway network in Kansai Metropolitan Area in Japan. These are linking the major cities of Osaka, Kobe and Kyoto is an important transportation network (Figure 1). The Hanshin expressway currently consists of 15 routes, extending for a total of 260.5 km. An average traffic volume is about 750,000 per day. Approximately 90% of the total length of the Hanshin Expressway consists of viaduct and about 80% of this is steel girder and 20% is concrete girder. There are 1431 spans of orthotropic steel deck bridges among 6764 spans of steel girder bridges. From the latest periodic inspection result of fatigue crack are detected by 364 spans among 1,431 spans of the orthotropic steel decks current as of August 2017. The reason of such a fatigue cracks are considered to be remarkable increase of traffic volume and existence of overloaded vehicles. In addition, the factors of fatigue damages are contemplated the stress concentration attributed to the local deformation of the thin deck plate. Such fatigue cracks are classified according to the structure of the longitudinal rib of orthotropic steel decks and the type of a crack.

Fatigue cracks generated in trough ribs are classified into several types. Figure 2 shows the typical fatigue crack types. Type I crack is generated along the longitudinal welding line between deck plate and trough rib. Type II crack is generated in the longitudinal stiffener's splice joint. Type III crack is generated along the welding line between vertical stiffener and deck plate. Type IV crack is generated from the connection point between trough profiles and crossbeam. Type I cracks appears more often than other types and the occurrence is showing

Figure 1.The Hanshin Expressway network map

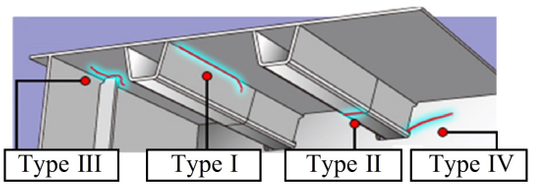

Figure 2. Typical fatigue cracks in U-shaped ribs

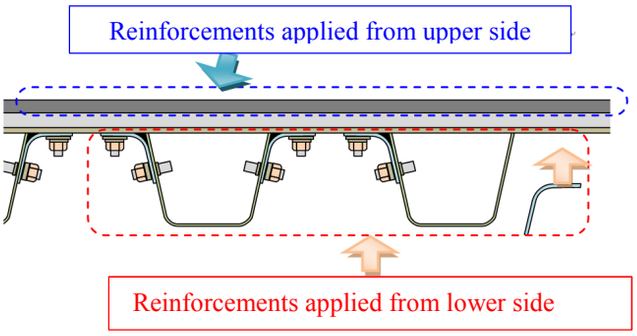

Figure 3. Concept of reinforcement method for orthotropic steel decks

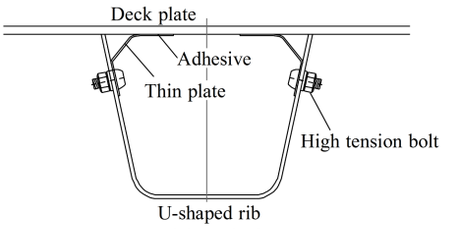
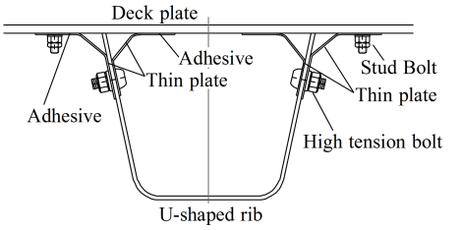
an increasing tendency. The Hanshin Expressway Co. Ltd. have developed fundamental reinforcement solutions to prevent the further propagation of Type I cracks.



This paper describes about the outline of the newly developed reinforcement methods and the results of the field test conducted in order to evaluate the effects.

2 REINFORCED METHOD FOR U-SHPED RIB ON ORTHOTROPIC STEEL DECKS



2.1 *Outline*

Steel Fiber Reinforced Concrete (SFRC) pavement has been developed as an effective countermeasure of Type I crack prevention and reinforcement. Though Hanshin Expressway has applied this method in some sections, its usage has some limitations because it is associated with long traffic regulation period due to works conducted from upper side of decks and it is often influenced by the weather. Therefore, it is urgently needed to develop a new reinforcement method against Type I cracks which can minimize the influence of traffic control and weather conditions.

The Hanshin Expressway Co., Ltd. has developed three reinforcement methods for trough ribs jointly with Yokogawa Bridge Holdings Corporation and Hitachi Zosen Corporation. As shown in Figure 3, those methods are applied from the deck's lower side so that traffic on the deck and any weather condition do not affect the work progress. The details of those methods are described in 2.2, 2.3 and 2.4.

(a) Inside reinforcement

(b) Both side reinforcement

Figure 4. Outline of the reinforced method (thin-plate)

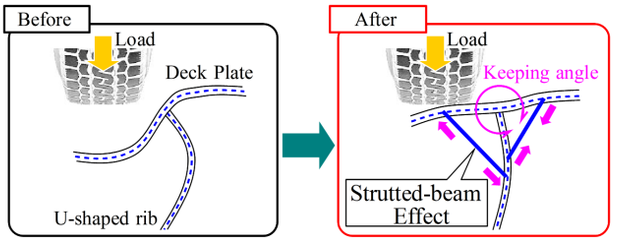


Figure 5. Concept of the thin-plate reinforced method

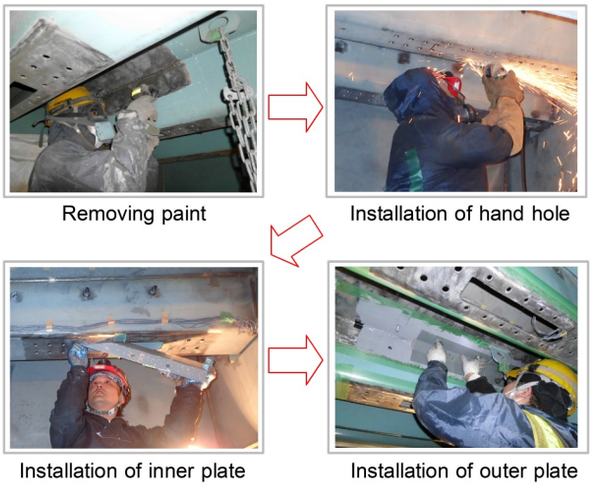

Figure 6. Outline of construction procedure (Both side reinforcement)

2.2 *Reinforced method (Thin-plate)*

In this reinforcing method as shown in Figure 4, thin and L-shaped steel plates for reinforcement are installed at the welding joint between U-shaped rib and deck plate. These plates do not reinforce welding joints firmly as usual methods and they are expected to provide "Strutted-beam Effect" in order to support deck plate by keeping the angle between U-shaped rib and deck plate when the load is located just above the welding joint (Figure 5). Because the reinforcing plates support in the vicinity of welded

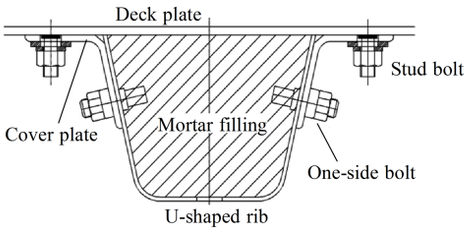

Figure 7. Outline of the reinforced method (filled with mortar)

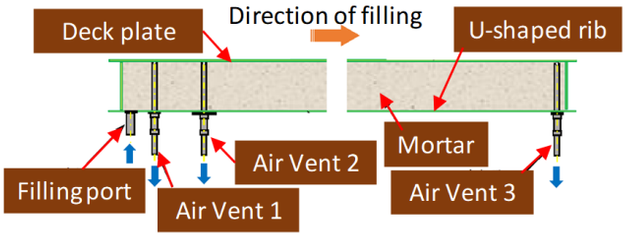

Figure 8. Filling of light weight mortar

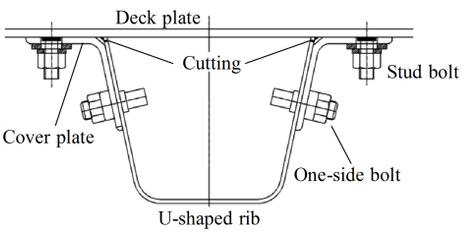

Figure 10. Outline of the reinforced method (stud with cover plate)

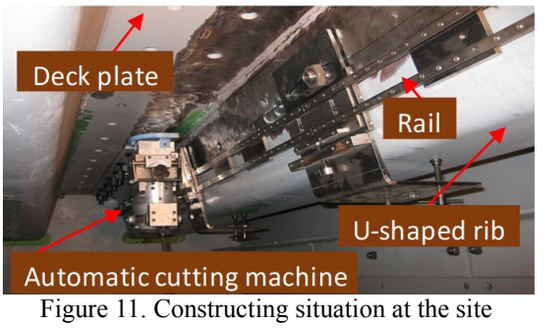

Figure 11. Constructing situation at the site

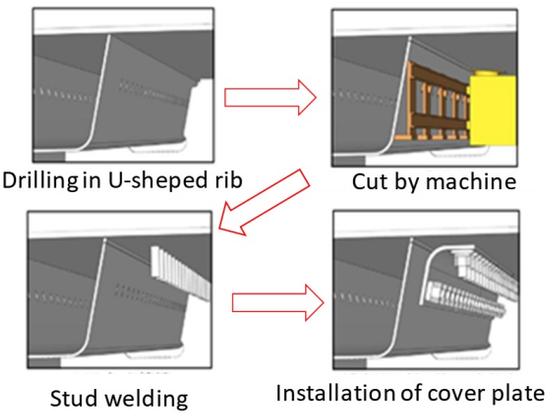

Figure 12. Outline of construction procedure

joints elastically and do not restrict behavior except welding joints, they are installed in the immediate vicinities of welding joints. Thickness of the reinforcing plate is 2.3mm and it was decided in consideration of reducing stress which generated on adhesive materials and also welding joints. In this method, the inside reinforcement where only inner plate is install inside of U-shaped rib and the both side reinforcement which the inner and outer plate are installed can be selected. Surely, the inside reinforcement has advantage in the point of cost. Although the high-tension bolts are also installed at the web of U-shaped rib in order to deicide the position of the steel plates during attaching process and to prevent from their falling in service, the reinforcing plates are attached to U-shaped rib and deck plate mainly using adhesive material of epoxy resin which has been newly developed for repair works of steel structures. The shape of reinforcing plates was optimized through the FE analysis and it was decided based on the results as shown in Figure 4.

Figure 6 shows the outline construction procedure of this reinforcement method. At first, paint around the welding joint without inside of the U-shaped rib.

The hand-holes are installed temporally at the bottom of the U-shaped rib at regular intervals in order to install the inner plates. The inner plates and outer plates are fixed by high tension bolts installed at the U-shaped rib web.

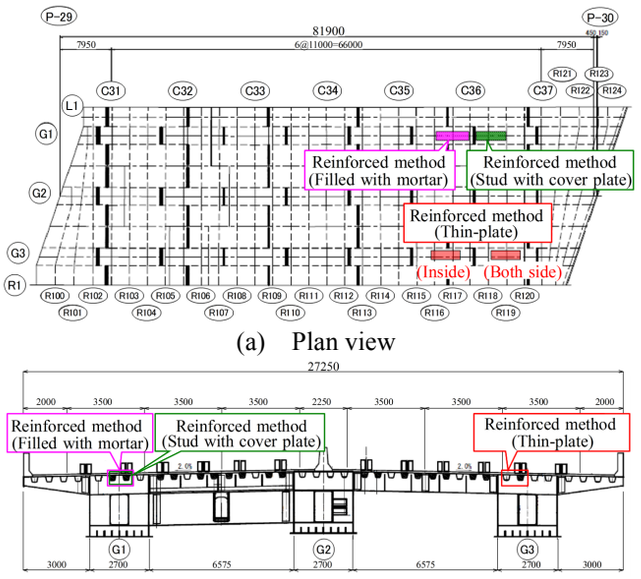
2.3 *Reinforced method (Filled with mortar)*

In this reinforcing method as shown in Figure 7, a lightweight mortar is filled in the U-shaped rib and a cover plate is installed outside the U-shaped rib. The local plate bending of the deck plate due to the wheel load considered to be the cause of the fatigue crack is prevented by the mortar filled in the U-shaped rib and the cover plate installed outside the U-shaped rib. the cover plate is connected by the stud bolts installed on the lower surface of the deck plate and the one-side bolts that can be connected from the outside of the U-shaped rib. Furthermore, filling of mortar into the U-shaped rib has been developed so that it could be applied from the bottom of U-shaped rib. As a result, it becomes

possible to reinforce from the underside of the deck plate.

In order to put this method into practical use, details of the structure that can reliably fill the U-shaped rib with mortar are clarified by the construction test and a method of confirming the filling property using the sensor was developed. Figure 8 shows the outline of this reinforcement method, Figure 9 shows the construction situation at the site.

2.4 *Reinforced method (Stud with cover plate)*



In this reinforcement method as shown in Figure 10 the U-shaped rib web is cut in the vicinity of the welding joints between the deck plate and the U-shaped rib. Instead of the welded joints, the bolted joint using a cover plate attached outside of U-shaped rib web is installed between the deck plate and the U-shaped rib. By changing connecting method from welded joint to bolted joint, there is an advantage that the stress concentration around the welded joint which may occur fatigue cracks can be reduced. In addition, because the cover plate is adopted same as the reinforcing method by mortar filling, it is possible to reinforce from the underside of the deck plate.

In order to put this method into practical use, we developed an automatic cutting machine with the aim of ensuring that the U-shaped rib web can be cut with securing the quality of the cut surface under traffic vibration. As shown in Figure 11, the automatic cutting machine cuts the U-shaped rib web along the predetermined position while traveling on a rail fixed to the U-shaped rib web using a rotating disk. Figure 12 shows the outline construction procedure of this reinforcement method.

3 THE FIELD TEST FOR VERIFYING THE EFFECT OF THE REINFORCED METHODS

3.1 *Outline of the field test*

The three reinforcement methods are actually applied to orthotropic steel bridges on "Wangan Route" of Hanshin expressway to examine the validity. Figure 13 shows the outline of the test bridge and the measurement arrangement. The bridge has 4-span continuous and three box girders whose length is 438m. The thickness of deck plate is 12mm and trough rib size is 320mm in width, 6mm in thickness and 240mm in height. The interval of trough rib arrangement is 2,750mm. For the fair and accurate comparison of three reinforcement methods,

(a) Plan view

(b) Sectional view

Figure 13. Outline of the test bridge and target for field measurement

Figure 14. Test truck

similar straight steel deck bridge is chosen to minimize the effects of different measurement location.

This paper also describes the results of dynamic loading test conducted on decks with three methods. The dump truck used for the test has the total weight of 196kN (front axle weight: 53.6kN, rear two-axle weight: 141.7kN) as shown in Figure 14. The truck runs at a low speed between 10 and 30km/h. The loading test for three methods was carried out on the same day.

3.2 *Reinforced method (thin plate)*

Figure 15 and Figure 16 shows the targets where strain gages were installed for the measurement. Targets of the deck plate is 5mm away from the inner corner of U-shaped rib. The target sections are located at the center of U-shaped rib span (target A) and the intersection between U-shaped rib and transverse rib (target B). All strain gages were installed in the transverse direction of the bridge axis. The loading position is represented as the distance (D_y) from the web of box girder.

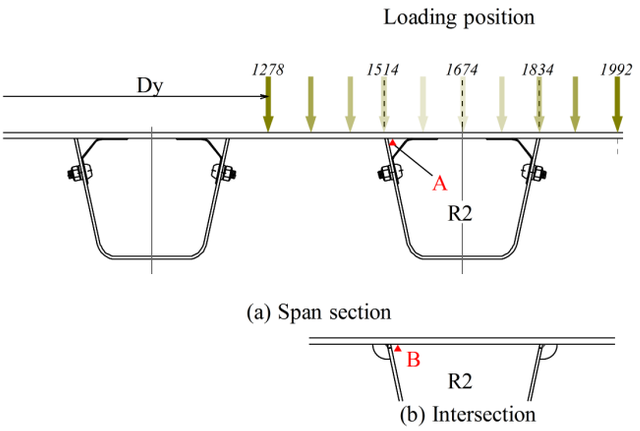


Figure 15. Loading positions and target points (Inside reinforcement)

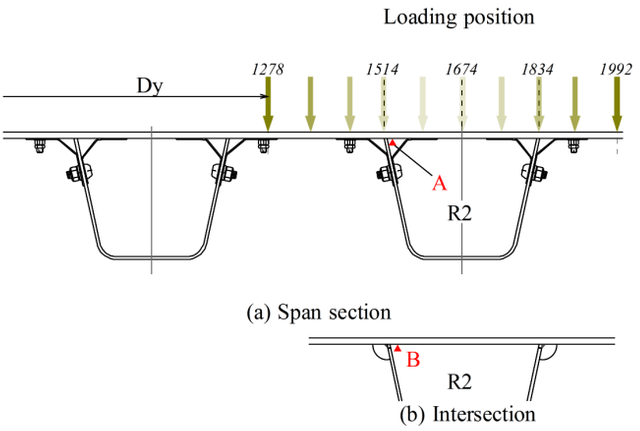

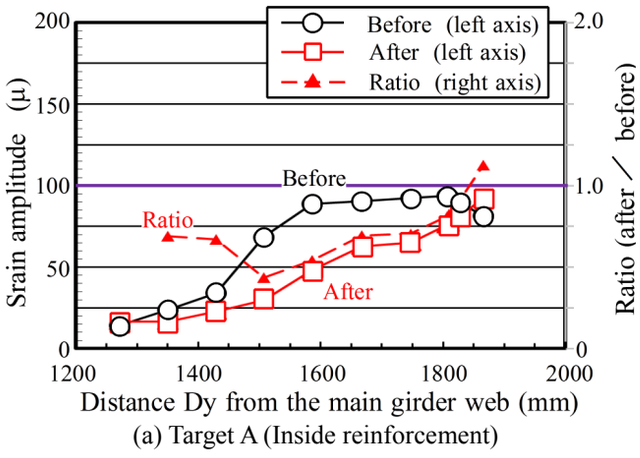

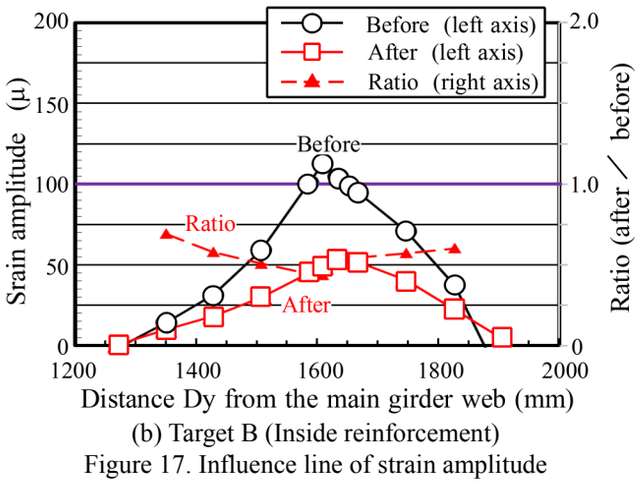

Figure 16. Loading positions and target points (Both side reinforcement)

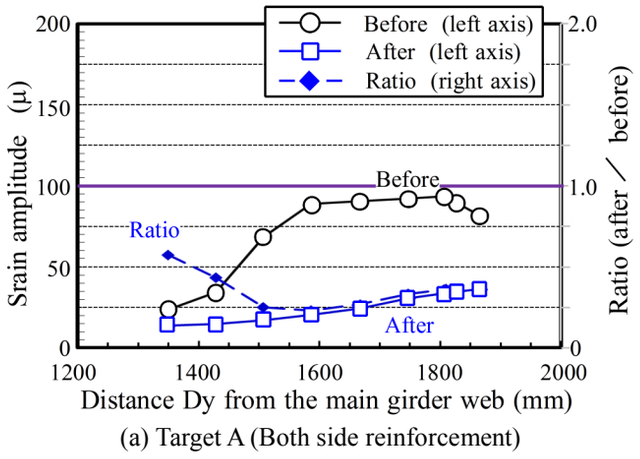
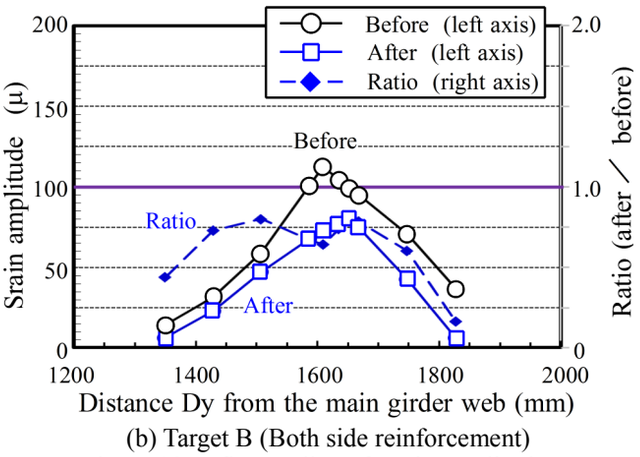


(a) Target A (Inside reinforcement)



(b) Target B (Inside reinforcement)

Figure 17. Influence line of strain amplitude

(a) Target A (Both side reinforcement)

(b) Target B (Both side reinforcement)

Figure 18. Influence line of strain amplitude

Figure 17 and Figure 18 show the results of measurement. In these figures, the left vertical axis shows the strain amplitude and the horizontal axis shows the loading position in the transverse direction with D_y. The strain amplitude was calculated from the maximum and minimum strain values obtained by moving the wheel load in the longitudinal direction. For comparison, the ratio of the strain amplitude after reinforcement to before reinforcement is also shown in the figure on the right axis. Figure 17 shows the influence lines of strain amplitude occurred by single tire at the target A and B when reinforced by only the inner plates. When the single tire is located just above the U-shaped rib, relatively high strain occurs. On the other hands, Figure 18 shows the influence lines when reinforced by both side plates. At the center of U-shaped rib span, strain amplitude was reduced by using both side reinforcement more than the inside reinforcement.

In the case of inside reinforcement, the strain amplitude at the target A was reduced to about 40% to 80% before reinforcement except the loading case just above the opposite welded joint. At the target B,

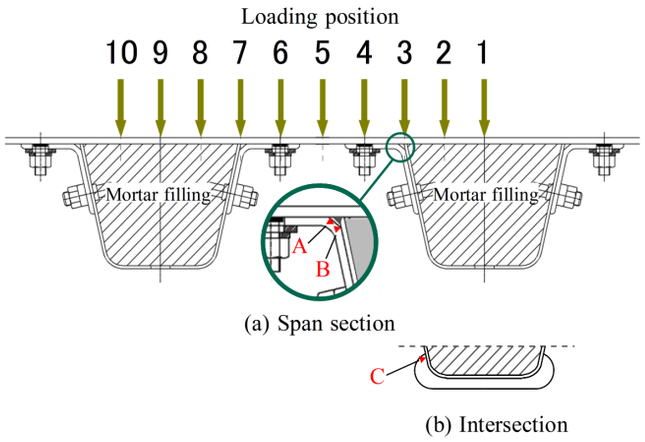


Figure 19. Loading positions and target points

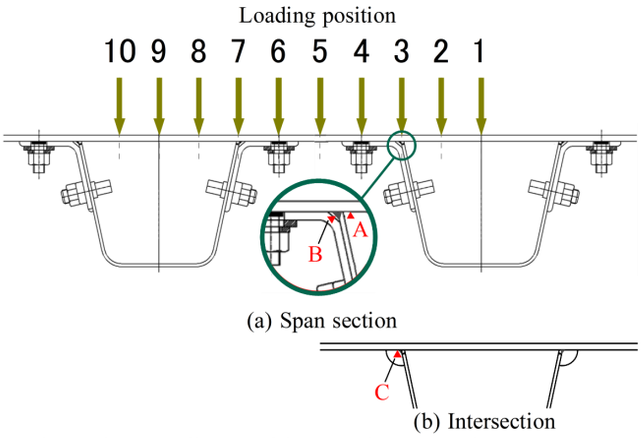

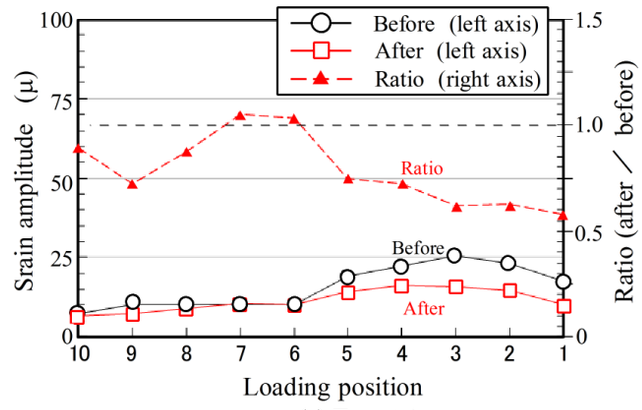

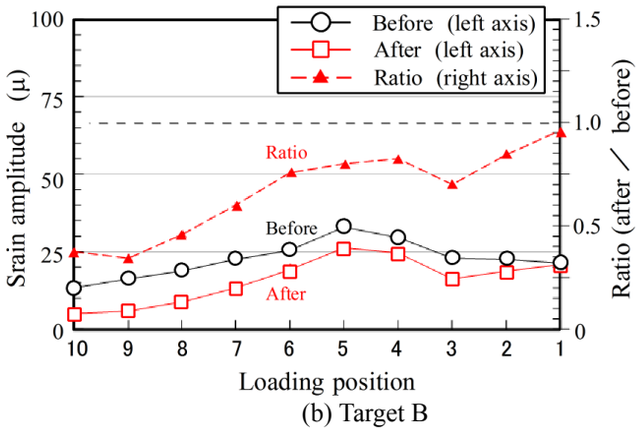

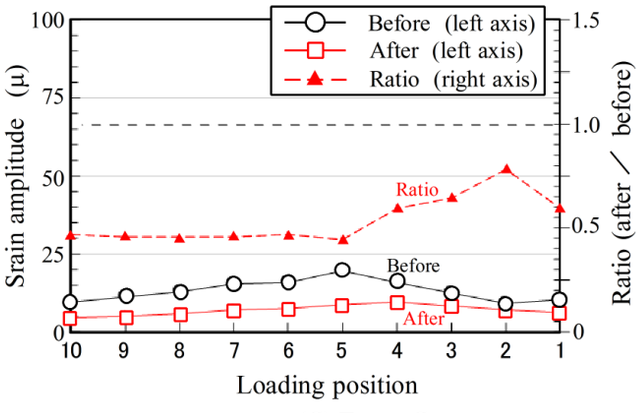

Figure 21. Loading positions and target points

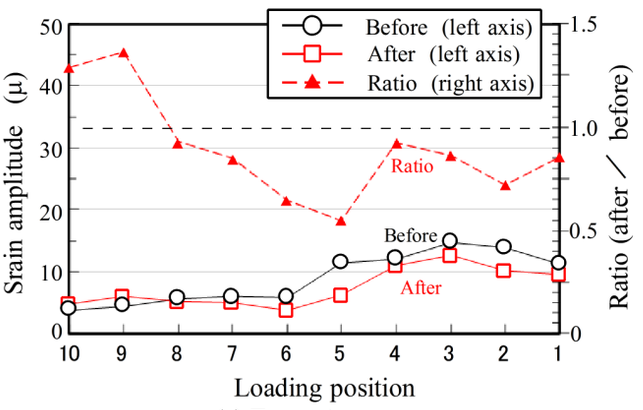
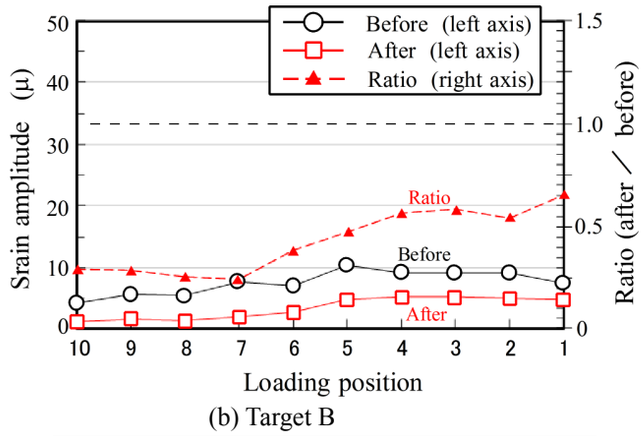
(a) Target A



(b) Target B



(C) Target C

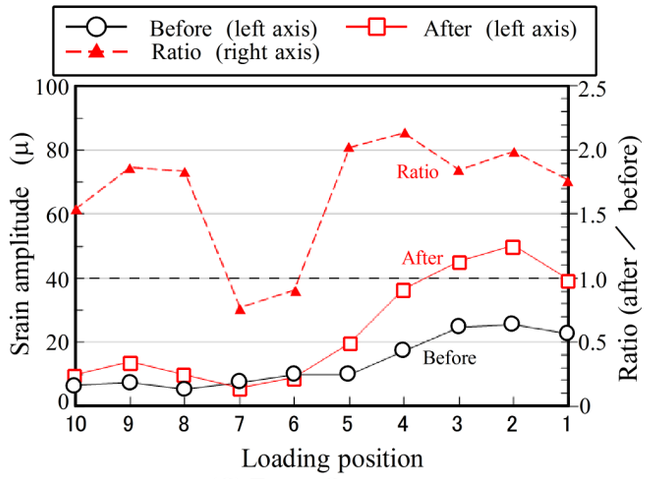


Figure 20. Influence line of strain amplitude

(a) Target A

(b) Target B

(C) Target C

Figure 22. Influence line of strain amplitude

the strain amplitude was reduced to about 40% to 70% before reinforcement (Fig. 17). In the case of both side reinforcement, the strain amplitude at the target A was reduced to about 25% to 60% before reinforcement. At the target B, the strain amplitude was reduced to about 10% to 80% before reinforcement (Fig. 18).

3.3 *Reinforced method (filled with mortar)*

Figure 19 shows the targets for the measurement. Target A is located at the lower side of the deck plate and Target B is located at the web side of U-shaped rib in the immediate vicinity of weld toe at the center of U-shaped rib span. Target C is located in the immediate vicinity of the turning weld toe at the lower scallop of intersection between the U-shaped rib and transverse rib. All strain gages were installed in the transverse direction of the bridge axis.

Figure 20 shows the strain amplitude occurred by double tire at the target A, B and C. As shown in Figure 20(a) and Figure 20(b), the strain amplitudes of the lower surface of the deck plate (target A) and the outer surface of the U-shaped rib web (target B), which are in the vicinity of the welded joint, are the maximum at the loading position 3 and 5. After reinforcement, the strain amplitude was reduced to 65% and 80% before reinforcement, respectively, and there was effect of reducing the strain amplitude by reinforcement. Even at the other loading positions, the strain amplitude is equal to or lower than before reinforcement.

Figure 20(c) shows the measurement results of the outer surface (target C). As shown in the figure, it is shown that the strain amplitude does not increase by reinforcement. However, the lower scallop will be reinforced by bolt-connecting method between the lower flange of the U-shaped rib and the transverse rib web with the L-shaped member.

3.4 *Reinforced method (stud with cover plate)*

Figure 21 shows the targets for the measurement. Target A is located at the lower side of the deck plate 5mm away from the inner corner of U-shaped rib and Target B is located at the surface of the weld bead at the center of U-shaped rib span. Target C is located in the immediate vicinity of weld toe at the intersection between the U-shaped rib and transverse rib. All strain gages were installed in the transverse direction of the bridge axis.

Figure 22 shows the strain amplitude occurred by double tire at the target A, B and C. As shown in Figure 22(a), the strain amplitude of the deck plate (target A) is maximum when the wheel load is located just above the target position. After reinforcement, the strain amplitude was reduced to 86% before reinforcement, respectively, which are equal to or slightly lower than before reinforcement. In other loading positions, the strain amplitude may increase compared to before reinforcement, but it is considered that there is no problem because the generated stress is small. Also, as shown in Figure 22(b), it can be seen that the strain amplitude was reduced to about half by the reinforcement at the weld bead (target B).

Figure 22(c) shows the measurement results of the inside of the scallop (target C) near the intersection between the U-shaped rib and transverse rib. As shown in the figure, there are positions where the strain amplitude increases after reinforcement, the countermeasure plans to be conducted in the future.

4 SUMMARY

The results of the experimental study about effect of three reinforced methods is described as below.

(Reinforcement method by thin plate)
- By the inside reinforcement, the strain amplitude in the vicinity of the welded joint was reduced to about 40% to 80% before reinforcement at the most load cases.
- The both side reinforcement can reduce the strain amplitude more than the inside reinforcement.

(Reinforcement method by filled with mortar)
- Because the strain amplitude in the vicinity of the welded joint at the span section was reduced to 62% or 80%, it is considered that there are strain reduction effect with the reinforcement method. Moreover the strain amplitude is equal to or lower than before reinforcement in other loading position.

(Reinforcement method by stud with cover plate)
- In the span section the strain amplitude was reduced to 86% before reinforcement at the deck plate and to about 50% at the surface of weld bead.
- The target position in the intersection where the strain amplitude increased after reinforcement will be improved in the future.

Although the magnitude of reinforced effect is different according to the location of targets, it was verified that all these reinforced methods can reduce the stress concentration in the vicinity of welded joints. It seems that their effect can never be evaluated perfectly but these methods can be adopted fully for reinforcement for fatigue cracks on the orthotropic steel decks.

Effect of the shear deformation in the structural system identification methods

J.A. Lozano -Galant

G. Ramos, J. Turmo
Universitat Politècnica de Catalunya, BarcelonaTECH, Barcelona, Spain

ABSTRACT: Despite its importance in some structures, shear deformation is systematically neglected by most static structural system identification methods. To fill this gap, this paper analyzes, for the first time in the literature, the effect of the shear deformation in the inverse analysis of structures. This study is focused on a parametric structural system identification method: the observability technique. As the majority of the methods, this technique is based on the Euler-Bernoulli beam theory. The method presented in the literature is unable to identify correctly the characteristics of a structure (such as flexural stiffness) when shear deformation is not negligible. In fact, in this method, the effects of shear deformation are close to those produced by measurement errors. To solve this problem, the observability procedure is updated according to the Timoshenko's beam theory. This formulation uses an algebraic approach combining both a symbolical and a numerical application. Thus, the updated observability formulation is able to obtain not only flexural stiffness but also shear stiffness. Besides this, for the first time in the literature, a parametric equation of the estimates is obtained. Some examples are presented to illustrate the validity of the new formulation.

1 INTRODUCTION

Damage in structures might produce changes in their mechanical properties. In order to quantify the magnitude of this damage Structural System Identification (SSI) might be used. This process is based on a subset of measured inputs and outputs (e.g. forces and/or displacements). The subset of measured inputs can be obtained by non-destructive tests that measure the structural response under a certain load case. According to the load nature, these tests can be classified as static (Sanayei et al. 1992, Sanayei & Saletnik 1996, Banan et al. 1994a, 1994b and Abdo 2012) or dynamics (Chao and Loh 2014, Noroozinejad et al. 2014, Lin et al. 201).

Matrix methods of structural analysis are universally accepted in structural design. These methods enable a rapid and accurate analysis of complex structures under both static and dynamic conditions. However, when applying matrix methods, the system must be modeled as a set of simple, idealized elements interconnected at the nodes. Matrix SSI methods are based on simplified models of structures too. These include axial and flexural deformation. Therefore, neglecting this deformation can be assumed as a modeling error which is a simplifying assumption well justified in most of the cases. However, in some cases for both direct and inverse analysis, this modelling error can lead to unjustified rough results.

The assumption of neglecting shear deformation is explained by the fact that, for most structures, this effect is usually much smaller than the flexural one. Nevertheless, shear deformation might play an important role in some structures, such as deep beams. Eurocode EN 1992-1-1:2004 defines deep beams as a beam for which the span is less than three times the overall section depth. ACI committee 318, defines these elements based on two criteria: beams with clear spans equal to or less than four times the overall member depth or beams with concentrated loads within twice the member depth from the face of the support. In these structures, neglecting the shear deformation may affect adversely the stiffnesses estimated by SSI methods. Shear deformation also might be an important factor to be considered in some structures, for example, in high-rise buildings (see Noroozinejad et al. 2014, Lin et al. 2016).

The literature review shows that the effect of shear deformation is mainly based on the structural response at the element level. The studies about structural system identification including this phenomenon are restricted to dynamic excitations and the effects on static tests are not studied. This is the case of the observability techniques (Lozano-Galant et al. 2013, 2014, 2015). As most of the static methods presented in the literature, it neglects the effect of the shear deformation into the structural system

identification analysis. This paper analyzes how sensitive observability techniques are to shear deformation effects. Moreover, in order to take these into account, a new formulation including the shear effects in observability simulation is proposed. All numerical simulations are based on measurement error free data obtained from numerical analyses. Paper will focus on evaluating the modeling error linked with shear effects, being numerical and measurement errors on structural system identification by observability treated elsewhere (Lei et al. 2016, 2017a, 2017b).

This article is organized as follows. In Section 2 the original observability method for structural system identification is briefly presented. This technique does not include the shear deformation. To illustrate the important role of this deformation in the identification of structures and to motivate the paper an example is analyzed. Section 3 introduces a new formulation to include the shear deformation into the observability analysis. Section 4 presents the application of the proposed algorithm for the structural system identification of a composite thin web bridge during its cantilevered construction. Finally, the conclusions obtained are summarized in Section 5.

2 OBSERVABILITY ANALYSIS WITHOUT SHEAR DEFORMATION

The stiffness matrix method is the most common implementation of the Finite Element Method (*FEM*) for structural analysis. The implementation of this method requires that the structure is modeled as a set of simple, idealized elements interconnected at the nodes. The material and stiffness properties of these elements are then compiled into a single matrix equation which governs the behavior of the entire idealized structure. In 2D, the traditional stiffness matrix *[K]* or a six degrees of freedom (two deflections (u and v) and one rotation (w) at the initial and final beam element nodes), beam element of length L and constant cross-section is:

$$[K]=\begin{bmatrix} \frac{EA}{L} & 0 & 0 & \frac{-EA}{L} & 0 & 0 \\ 0 & \frac{12EI}{L^3} & \frac{6EI}{L^2} & 0 & \frac{-12EI}{L^3} & \frac{-6EI}{L^2} \\ 0 & \frac{6EI}{L^2} & \frac{4EI}{L} & 0 & \frac{6EI}{L^2} & \frac{2EI}{L} \\ \frac{-EA}{L} & 0 & 0 & \frac{EA}{L} & 0 & 0 \\ 0 & \frac{-12EI}{L^3} & \frac{-6EI}{L^2} & 0 & \frac{12EI}{L^3} & \frac{-6EI}{L^2} \\ 0 & \frac{6EI}{L^2} & \frac{2EI}{L} & 0 & \frac{-6EI}{L^2} & \frac{4EI}{L} \end{bmatrix} \quad (1)$$

where E, A and I are Young modulus, area and inertia respectively.

In static structural analysis, a statement of the equilibrium conditions together with strength of materials theory leads to a relation between forces and displacements that has the form of a system of equations:

$$[K]\{\delta\}=\{f\} \quad (2)$$

Where $\{\delta\}$ and $\{f\}$ are the vectors of displacements and forces, respectively, in which the stiffness matrix is a singular matrix that leads to a system with infinite solutions. The direct solution of this system is carried out by any computer simulation software by assuming that all the terms in *[K]* are known.

Unfortunately, in real structures *[K]* might be known, as the flexural stiffness EI_j or axial stiffness EA_j of element j, may appear into the matrix *[K]* due to damage (e.g. by material degradation, such as carbonation or corrosion, or accidental actions, such as fires or impacts) or other uncertainties (e.g. lack of knowledge about the mechanical properties of the material). If the external forces applied to the structure in a non-destructive test are known and some displacements are measured, the observability method can be applied into the *SSI* to found the values of these unknown parameters.

Taking Eq. (2) where the matrix *[K]* is partially unknown and with the aim of determining the value of the unknown stiffnesses (EA_j and EI_j) a modified system of equations can be rewritten as:

$$[K^*]\{\delta^*\}=\{f\} \quad (3)$$

in which the products of unknowns are located in the modified vector of displacements $\{\delta^*\}$ and the modified stiffness matrix *[K*]* is a matrix of known coefficients with different dimensions than the initial stiffness matrix *[K]*. The new system leads to a non-linear problem due to the fact that unknown parameters, such as axial stiffness EA_j and flexural stiffness EI_j of the cross section are multiplied by unknown horizontal displacements (u_i) vertical displacements (v_i) and rotations at the *ith* node (w_i) of vector $\{\delta\}$. This fact implies that non-linear products of variables, such as EA_ju_i, EA_jv_i, EI_jv_i, EI_ju_i, and EI_jw_i might appear, leading to a polynomial system of equations. These kinds of problems usually appear in science and engineering fields, (see Castillo et al. 2016a, 2016b). Depending on the known information, the unknown variables of vector $\{\delta^*\}$ may be the non-linear products presented above, as well as other factors of single variables, such as EI_j or EA_j or nodal deflections and rotations.

Once the boundary conditions and the applied forces in the nodes have been defined, an inverse analysis can be performed to identify the unknown parameters. To do so, some deflections and rotations are measured in a known static test. This known in-

formation is clustered in a subset δ_1^* of $\{\delta^*\}$ and a subset f_1 of $\{f\}$, respectively. In this way, the remaining subset δ_0^* of $\{\delta^*\}$ and f_0 of $\{f\}$, are unknown. Hence, (3) can be written as follows:

$$[K^*]\{\delta^*\}=\begin{bmatrix}K_{00}^* & K_{01}^*\\ K_{10}^* & K_{11}^*\end{bmatrix}\cdot\begin{Bmatrix}\delta_0^*\\ \delta_1^*\end{Bmatrix}=\begin{Bmatrix}f_0\\ f_1\end{Bmatrix}=\{f\} \quad (4)$$

To join the unknowns, this system can be rewritten in the equivalent form:

$$[B]\{z\}=\begin{bmatrix}K_{10}^* & 0\\ K_{00}^* & -I\end{bmatrix}\cdot\begin{Bmatrix}\delta_0^*\\ f_0\end{Bmatrix}=\begin{Bmatrix}f_1-K_{11}^*\cdot\delta_1^*\\ -K_{01}^*\cdot\delta_1^*\end{Bmatrix}=\{D\} \quad (5)$$

where *0* and *I* are the null and the identity matrices, respectively. In this system, the vector of unknowns,*{z}*, appears on the left-hand side and the vector of observations, *{D},* on the right-hand side. Both vectors are related by a matrix of known coefficients *[B]*.

To evaluate if the system has a solution, it is sufficient to calculate the null space *[V]* of *[B]* and check that $[V]^T\cdot[D]=0$ $[V]^T\{D\}=0$. Note that the null space can be easily obtained from the singular value decomposition by using computer programs. If this holds, the system is compatible; otherwise, it has no solution [48]. The general solution (the set of all solutions) has the structure:

$$\begin{Bmatrix}\delta_0^*\\ f_0\end{Bmatrix}=\{z_p\}+[V]\{\rho\} \quad (6)$$

where $\{z_p\}$ is a particular solution of the system. This particular solution can be obtained by using two different subroutines in Matlab. The first one is the backslash function (\) that is able to find the parametric equations of the systems and therefore the symbolic and the numerical solution. The other one is the Moore-Penrose pseudoinverse function (*pinv*) with which only the numerical solution can be found.

$[V]\cdot\{\rho\}$ is the set of all solutions of the associated homogeneous system of equations (a linear space of solutions, where the column of *[V]* is a basis and the elements of the vector $\{\rho\}$ are arbitrary real values that represent the coefficients of all possible linear combinations). It is interesting to note that a variable has unique solution not only when matrix *[V]* has zero dimensions (it does not exist), but when the associated row in matrix *[V]*is null. Thus, examination of matrix *[V]* and identification of its null rows lead to identification of the observable variables (defined as the subset of variables with a unique solution) of vector *{z}*. By solving system (5), the numerical value of the observed parameters obtained by the particular solution of Equation (6) can be easily found. To obtain these numerical values of the observable parameters it is necessary to combine the symbolical and the numerical analysis as proposed by Nogal et al. (2015).

A recursive process is used to minimize the number of required deflections in measurement sets to obtain the unknown parameters. This process takes advantage of the connectivity of the beams in the stiffness matrix that is included in the partitioned matrices of *[K*]* in system (5). In this way, when in the initial observability analysis any deflection, force or structural parameter is observed, this information might help to observe new parameters in the adjacent elements through the recursive process. In this analysis, the observed information is successively introduced as input data in the observability analysis. .A new approach for the numerical solution of the system based on compatibility equations can be found in Lei et al. 2017a. In order to show the role of the shear deformation in the *SSI* by observability techniques an illustrative example is numerically analyzed in the following section.

2.1 *Example 1: Effect of the shear deformation in beams*

To motivate this paper, a sensitivity analysis is presented to evaluate the effect of the shear deformation on the *SSI* of a simply supported concrete beam loaded with a concentrated load *V* at mid span (Fig. 1). Young's modulus is E=27000MPa and Poisson's ratio is ν=0.25. The beam has a rectangular cross section 1 m deep (h=1m) and 0.1 m wide (b=1m), so its area is A=1m^2 and its inertia is I=0.00833m^4. Besides this, and according to [53], the shear coefficient, k, for rectangular cross-sections when width/depth ratio approaches zero is 5/6. With this shear factor, the shear area A_v is equal to 0.00833m^2.

Fig. 1.A shows the increment of deflections due to shear and bending deformability in a simply supported beam with a concentrate load *V* at mid span in terms of *L/h*. The shear deflection varies linearly with *L* while the bending deformability depends on L^3.

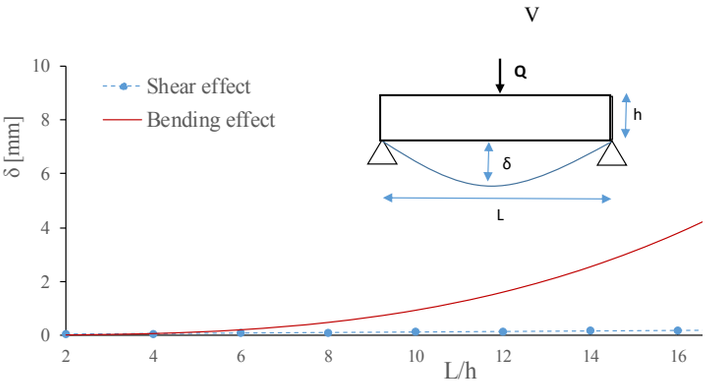

Figure 1. Example 1. Increment of deflection at mid span δ due to bending and shear

The analysis of Figure 1 shows that the closer the values of the height and the length of the beam, the higher the role that the shear deformation plays.

2.2 *Example 2: Effect of the shear deformation SSI by observability techniques*

To illustrate the problems of neglecting the shear deformation into the observability analysis, the simply supported beam described in Figure 2 is analyzed. This beam has a length of 6 meters and it is simulated with a *FEM* composed by 6 beam elements and 7 nodes. The length of each of these elements is 1m. The mechanical and geometrical properties of the analyzed example correspond with the beam presented in the preceding section. The boundary conditions of the structure are horizontal and vertical displacements restricted in node 1 and vertical displacement restricted in node 7 and the only external force applied is a concentrated vertical force in node 3 of -100kN. The beam was analyzed with Midas/Civil software with and without shear deformation.

The deformations will be used to estimate the flexural stiffnesses (EI_1 to EI_6) with and without considering the shear deformations. In order to do so, the measurement of at least 6 deflections or rotations that represent the flexural behavior of the beam are required. The selection of these measurements was analyzed by the observability trees method proposed in [41]. From the application of this procedure, it can be concluded that measuring the five vertical deflections of the inner nodes (v_2 to v_6), and the rotation of node 3 (w_3) will enable the estimation of all the unknown stiffnesses, or in other words, will provide full observability of the system.

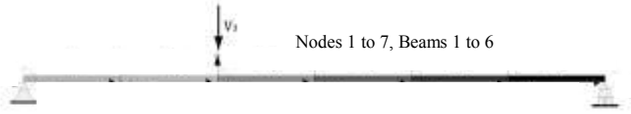

Figure 2. Example 2: Finite Element Model of the analyzed beam

Once the measurement set is selected, the observability method proposed by Nogal et al. (2015) is applied using the two following measurement sets: (1) Measurements without shear deformation, which is v_2 to v_6 and w_1. (2) Measurement with shear deformation, that is vs_2 to vs_6 and ws_1. The observable flexural stiffnesses obtained throughout the recursive process for both measurement sets are presented in Table 1 as percentage deviations.

Table 1: *Deviations of the EI estimated with and without considering the shear deformation*

Bending Stiffness	Without shear	With shear
EI_1	0.1%	149.9%
EI_2	0.0%	-35.7%
EI_3	0.0%	-5.5%
EI_4	0.0%	11.4
EI_5	0.1%	-16.8%
EI_6	0.1%	93.7%

The analysis of Table 1 shows no deviations when measurements without shear deformation are considered. Nevertheless, this is not the case when the shear deformation is included, as large errors are found. For example errors of -149.9% are found in the first beam element. This disproportionate error is explained by the fact that the used model does not consider shear effects. In fact, shear deformation is considered as a modeling error (Sanayei et al. (2012)) into the observability analysis.

The obtained results show that the role of shear deformation cannot be neglected in the *SSI* by observability techniques. Thus, it can be concluded that a reformulation of the observability algorithm is required to include the effect of the shear deformation. This new algorithm is presented in the following section.

3 INTRODUCING SHEAR DEFORMATION INTO THE STRUCTURAL SYSTEM IDENTIFICATION BY OBSERVABILITY TECHNIQUES

With the aim of including shear deformation into the *SSI* by observability analysis a new formulation of the stiffness matrix method is implemented. This formulation is based on the Timoshenko's beam theory.

3.1 *Shear formulation*

The stiffness matrix *[K]* for a beam element with uniform cross section with 3 degrees of freedom per node (u_i, v_i and w_i) is of order 6x6. The forces developed in the beam member when a unitary displacement is imposed along each degree of freedom holding all other displacements equal to zero leads to the finding of all the single elements of this stiffness matrix. According to the existing literature [54], the stiffness matrix *[Ks]* for a 2D analysis of a six degrees of freedom (two deflections (u and v) and one rotation (w) at the initial and final beam element nodes), beam element including the shear deformation is:

$$[K]=\begin{bmatrix} \frac{EA}{L} & 0 & 0 & \frac{-EA}{L} & 0 & 0 \\ 0 & \frac{12EI}{L^3(1+\phi)} & \frac{6EI}{L^2(1+\phi)} & 0 & \frac{-12EI}{L^3(1+\phi)} & \frac{-6EI}{L^2(1+\phi)} \\ 0 & \frac{6EI}{L^2(1+\phi)} & \frac{EI(4+\phi)}{L(1+\phi)} & 0 & \frac{6EI}{L^2(1+\phi)} & \frac{EI(2-\phi)}{L(1+\phi)} \\ \frac{-EA}{L} & 0 & 0 & \frac{EA}{L} & 0 & 0 \\ 0 & \frac{-12EI}{L^3(1+\phi)} & \frac{-6EI}{L^2(1+\phi)} & 0 & \frac{12EI}{L^3(1+\phi)} & \frac{-6EI}{L^2(1+\phi)} \\ 0 & \frac{6EI}{L^2(1+\phi)} & \frac{EI(2-\phi)}{L(1+\phi)} & 0 & \frac{-6EI}{L^2(1+\phi)} & \frac{EI(4+\phi)}{L(1+\phi)} \end{bmatrix} \quad (7)$$

A comparison with the traditional stiffness matrix presented in Equation (1) shows that differences appear in some terms in the form of a new coefficient. This coefficient is known as the shear parameter (ϕ) and can be expressed as:

$$\phi = \frac{12EI}{GA_v L^2} \tag{8}$$

where G is the shear modulus and can be calculated as:

$$G = \frac{E}{2(1+\nu)} \tag{9}$$

As it can be appreciated in Equation (7), the shear stiffness matrix has the same coefficients for the axial stiffness as the traditional stiffness matrix. This is because the shear and flexural stiffnesses are uncoupled from the axial stiffness. However, for the rest of the non-null elements of the matrix, shear and flexural stiffnesses are coupled.

When the beam is subjected to shear forces and associated moments, the vertical deflection is $v=v_b+v_s$ (where v_b is the deflection due to the flexural strains and v_s is the additional deflection due to shear strains). Analysis of Equation (7) shows that the shear parameter ϕ appears in both the numerator and the denominator of the matrix terms. Its location complicates significantly its estimation. In fact, the resulting system cannot be easily solved with observability techniques. To solve this problem a change of variable from ϕ to Q is proposed. This change simplifies the mathematical resolution of the system and enables the application of observability techniques as the new unknown parameter appears uniquely in the numerator of the matrix terms. The definition of parameter Q is as follows:

$$Q = \frac{\phi}{1+\phi} \tag{10}$$

Where Q is the so called observability shear parameter of the stiffness matrix *[Ks]*. It is to highlight that the value of this ranges from 0 to 1.

A detailed step by step application of the application of the *SSI* by observability techniques including shear deformations can be found in Tomás et al. (2017).

4 APPLICATION TO A BRIDGE

Accurate models to control construction of cantilever bridges are of uttermost importance. Deflection should be both controlled and forecast in order to give an adequate geometry to the segments. Hence, to calculate precamber, an accurate model upon which an analysis has to be performed is needed. As an example on how to use this technique to help model updating, a simplified model of the Yunbao Bridge over the Yellow River in China (see Fig. 3) is studied.

The span of the structure is 90m long. The model represents a simplification of an intermediate construction stage. This model includes two symmetric spans in cantilever supported by an intermediate pile. The length of the deck segments is 4.5m and the thickness of the pile 2.5m. The length of the analyzed construction stage is 13.5m.

The structural response at this stage is simulated numerically without considering actual site data. The creep and shrinkage effects in concrete were neglected.

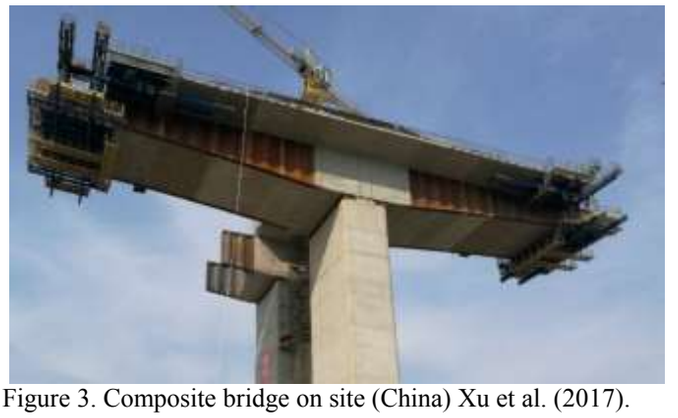

Figure 3. Composite bridge on site (China) Xu et al. (2017).

This structure is simulated by the mean of the simplified *FEM* presented in Fig. 4. This *FEM* includes 8 nodes and 7 beam elements. The cross section of the composite deck is presented in this figure and the mechanical and material properties are listed in Table 2. Whereas in the real bridge webs are corrugated, in the analyzed example they are considered 25mm thick steel sheets. The connection between concrete and steel is assumed as rigid, and the relative slip between both materials is neglected.

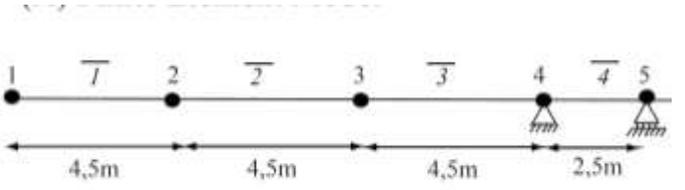

Figure 4. Finite Element model of analyzed bridge (symmetry section)

Table 2: *Properties of the Finite Element Model of the Bridge*

Area, m^2	12.59
Shear Area, m^2	9.83
Inertia, m^4	35.62
Steel Young's Modulus, GPa	210
Concrete Young's Modulus, GPa	35
Poissons' ratio, ν	0,3

The flexural and shear stiffnesses of all 7 beam elements (that is to say EI_1 to EI_7 and EAv_1 to EAv_7) are assumed as unknown.

4.1 *Static Load test*

EI6In order to identify the 14 unknown stiffnesses the measurement of 14 deflections and/or rotations in a static load case that excites the flexural mechanism is required. Observability will take into account the variation of deflections and rotations due to the movement of the form traveler. The load case used is presented in Fig. 5 in terms of the weight of the formwork Q=1041kN. In this paper, measurement errors are neglected. The effect of these unavoidable errors will be addressed by the authors in future works

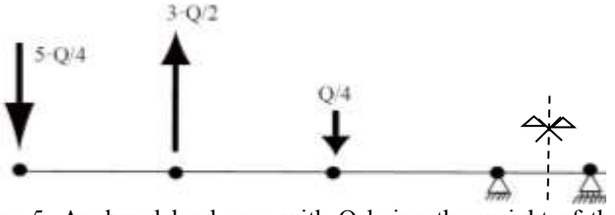

Figure 5. Analyzed load case with Q being the weight of the formwork (half structure).

The vertical deflections in the nodes of the structure were calculated with the software Midas/Civil both without including and including the shear deformation of the deck. The maximum deflection variations were located at the tips of the cantilevers. Shear deformation accounts for 0,1mm of the vertical displacement, which is not negligible as it represents the 7,6% of the total deformation. To get accurate measurements of the vertical deflections on site, different measuring devices can be used.

4.2 *SSI by observability techniques*

In this section the measured response of the structure is used to estimate the unknown stiffnesses. A flexural observability tree (Lozano-Galant et al. (2015)) has been used to select an adequate measurement set. When shear stiffness is neglected the measurement set consists on all the deflections (v_1, v_2, v_3, v_6, v_7, v_8) and one rotation (w_4). On the other hand, when shear stiffnesses is considered in the formulation the rest of rotations are also required.

Considering the shear stiffness, parametric equations can be obtained for the different elements. As an illustrative example, the estimated flexural stiffness for the first four element (EI_1 to EI_4) are presented:

$$EI_1 = \frac{-81 \cdot L^2 \cdot V_1}{8 \cdot (w_1 - w_2)} \tag{11}$$

$$EI_2 = \frac{-9L(-27L \cdot V_1 + 9LV_2)}{8 \cdot (w_2 - w_3)} \tag{12}$$

$$EI_3 = \frac{-9L(-45L \cdot V_1 - 27L \cdot V_2 + 9LV_3)}{8 \cdot (w_3 - w_4)} \tag{13}$$

$$EI_4 = \frac{-5L(27L \cdot V_1 + 18L \cdot V_2 + 9LV_3)}{8 \cdot (w_4 - w_5)} \tag{14}$$

These equations can be used to determine how sensitive the different estimates are to errors.

Table 3 presents a comparison of the percentual differences between the estimated flexural stiffnesses and the actual values in the seven elements of the beams with two observability procedures (with or without the shear effects into the stiffness matrix).

Table 3: *Deviations of the EI estimated with and without considering the shear deformation*

Bending Stiffness	Without shear	With shear
EI_1	0.0%	-65.5%
EI_2	0.0%	-26.7%
EI_3	0.0%	5.2%
EI_4	0.0%	-1.5%
EI_5	0.0%	5.2%
EI_6	0.0%	26.7%
EI_7	0.0%	-65.5%

This table shows that deviations when the shear formulation is included into the stiffness matrix and error-free measurements are considered are negligible. The reduced deviations obtained in this case can be explained by the fact numerical and non-actual site measurements are considered. It also illustrates that shear deformation cannot be neglected for the structural system identification of this structure. In fact, significant errors (e.g. -65,5 % in segments 1 and 7 or +26,7% in segments 2 and 6) appear when this phenomenon is not considered.

5 CONCLUSIONS

Most Structural System Identification (*SSI*) methods neglect shear deformation as this phenomenon is usually much less significant than the flexural one. Despite of the important role that this deformation might play especially in members with low span-to-depth ratio, no detailed study addressing the particular effects of this deformation in static *SSI* tests can be found in the literature. To fill this gap, this paper

presents the first study focused on the shear deformation effects in a structural system identification method: the observability technique. This is a parametric method based on static measurements.

An illustrative example shows how important the role of the shear deformation might be. To solve this modeling error, the formulation of the observability method is updated to include shear deformation. This new procedure enables, for the first time in the literature, the definition of parametric equations of the observability shear stiffness depending on the measured data for simple structures. The study of this equation might provide useful insight of the sensitivity to the estimation for each measurement. The proposed technique is also applied into a simply supported beam with six unknown parameters.

In order to show the applicability of the method on an actual thin web structure, an intermediate construction stage of a cantilever composite bridge in China is analyzed. The results of this structure illustrate how an adequate formulation can be used to reduce adequately the modeling errors without the need of optimization processes. This updated formulation enables also the calculation of parametric equations of the estimates that gives us information about their sensitivity to measurement errors.

Optimizing rehabilitation strategies for bridge decks under performance-based contracting setting

M. Alsharqawi & T. Zayed
Dept. of Building, Civil and Environmental Engineering, Concordia University, Montréal, Québec, Canada
S. Abu Dabous
Dept. of Civil and Environmental Engineering, University of Sharjah, Sharjah, United Arab Emirates

ABSTRACT: The 2016 Canada infrastructure report alarmed that more than 26% of Canada's bridges are rated fair, poor, and very poor and an investment of $50 billion is required to replace all of these bridges. In the US, the situation is similar where the American Society of Civil Engineers (ASCE) report card graded bridges' condition in 2017 as "C+" which refers to a mediocre condition that requires immediate attention. There is an overwhelming amount of maintenance and rehabilitation works to be done and selecting a suitable maintenance, repair or replacement (MRR) strategy is one of the most challenging tasks for decision makers. Limited budget and resources are making the decision making process much more challenging. The growing needs and limited resources to maintain the transportation networks have resulted in motivating transportation agencies to expand the amount of contracting they do through long term performance-based maintenance contracts or what is called Performance-Based Contracting (PBC). The main objective of this research is to develop short and long term optimized rehabilitation plans for bridge decks under PBC setting. In order to achieve this goal, performance modeling is established to measure current performance and predict future deterioration and improvements rates; moreover, associated MRR costs are estimated. A key performance measure, named condition reliability, is defined as an indicator to the structural condition or performance of the bridge component. Furthermore, an associated level of service (LOS) threshold is proposed. The output of this research is a decision-making tool for optimizing rehabilitation strategies with the lowest cost while maintaining a specified performance LOS. The principles of the proposed tool are demonstrated through a real case study of a bridge located in Quebec, Canada. The result of the proposed decision support tool is an optimized work program that satisfies the identified performance LOS and budget constraints. The model is expected to support decision makers to maintain their bridges using the PBC method.

1 INTRODUCTION

Earlier practices for maintaining and managing transportation infrastructure were using separate contracts for each activity and with a labor rate or unit price. In recent years, there are innovative methods of procuring maintenance activities for all products and services under one contract and for a longer duration. These methods define and specify the desired end result which provides the contractor with more flexibility, innovation potential, and cost savings measures for the client organization (Pakkala 2002). In the traditional method-based contracts, the transportation agency specifies techniques, methods, materials, quantities, along with the time that the maintenance activities should be executed (Alyami and Tighe 2013). This causes a limitation on the use of new materials and innovative techniques and technologies while maintaining the infrastructure asset (Panthi et al. 2008). Moreover, this traditional way of contracting had failed in achieving the agencies' main goal of reducing maintenance expenditures and improving the transportation networks at an acceptable Level of Service (LOS) to the traveling public (Porter 2001; Piñero and de la Garza, Jesus M. 2004). The challenge of maintaining infrastructure to the highest possible condition while investing the minimal amount of money has promoted innovative contracting approaches. Contractors have better competencies of fulfilling required performance level through innovating in such new and unproven technologies (Panthi 2009). This can be achieved by extending the short maintenance period to a longer period so that the performance level can be satisfactorily measured over a longer duration. This type of agreement is called Performance-Based Contracting (PBC) which is a type of contract that pays a contractor based on the results achieved, not on the methods for performing the work. Such contracts allow the maintenance contractors to innovate and improve the efficiency of the services provided to the public (de la Garza et al. 2009).

PBC is defined as "a contracting method that provides incentives and/or disincentives to the maintenance contractor to achieve desired outcomes or results; in its purest form, PBC does not detail how, when, or where to do the work." (Hyman 2009). Therefore, payments for management and maintenance of assets in this type of contract are explicitly linked to the contractor successfully meeting or exceeding the specified performance LOS throughout the contract period. By paying contractors incentives and/or disincentives for predefined performance criteria and giving them the flexibility in choosing materials and methods in delivering maintenance services, contractors are encouraged to use new methods and mix quality which fosters innovation and improves the performance of the structure throughout its life. As in the case of PBC, the long-term planning provides the contractor with enough time horizon to deploy new technologies. Further, the contractors are encouraged to eliminate the future need to perform costly corrective maintenance actions by taking timely preventive maintenance ones (Gupta et al. 2011). Agencies that have converted to PBC claim cost saving between 10-50% over the traditional contracts (Stankevich et al. 2009). The agencies added that this price reduction took place in several areas from the non-technical, technical, and professional services (Office of Federal Procurement Policy (OFPP) 1998).

PBC can address different types of assets and operations including pavements, bridges, roadsides, traffic operations, traffic services, incident response, hazardous materials cleanup, and emergency repairs (Hyman 2009). Moreover, performance contracts are not limited to maintenance including preventive, routine, periodic, and demand-responsive maintenance as rehabilitation of roads and bridges has been part of many performance-based contracts (Hyman 2009). By looking into the literature, it is observed that many transportation agencies established PBC extensively for roads maintenance (Haas et al. 2009; Stankevich et al. 2009; Panthi 2009; Alyami and Tighe 2013). However, in the area of bridges management, there are very limited studies to assess this method and to integrate it into the decision-making process. The process of making appropriate maintenance, repair or replacement (MRR) decisions begins with performance assessment and rating based on condition survey. Current bridge assessment practices mainly depend on techniques to evaluate surface defects such as cracking and spalling. As a result, these practices are unable to precisely assess bridge elements with subsurface defects, such as corrosion of steel reinforcement. Predicting future performance is the next step where deterioration modeling and improvements resulting from different MRR strategies is modeled. Many researchers modeled deterioration stochastically to predict future condition of reinforced concrete bridge elements. Among them are Frangopol et al. (2004), Morcous (2006), Yang et al. (2009) and Li et al. (2016). Performance modeling is important to select appropriate MRR strategy that maintains the specified performance LOS. Finally, the process of selection of the combination of MRR actions is repeated to arrive at the optimum rehabilitation program within the available budget and over the planning time horizon.

2 SCOPE AND OBJECTIVE OF PAPER

The main objective of this research is to develop a decision support tool for concrete bridge MRR strategies while achieving the specified performance LOS during the intended contract period. To achieve this objective, the following sub-objectives are sought:

1. Assess bridge condition considering surface and subsurface defects to enhance the reliability of performance assessment.
2. Model deterioration and improvements to forecast bridge future performance rates.
3. Optimize selection of rehabilitation strategies under PBC setting over a predefined period.

Thus, this research proposes a mathematical optimization tool that provides a rehabilitation program for transportation agencies and maintenance contractors based on PBC arrangements.

3 METHODOLOGY AND MODEL DEVELOPMENT

The decision making support tool development process is illustrated in Fig. 1 and discussed in the following sections. The proposed models in this paper consider concrete bridge deck in particular because it deteriorates faster than other components due to its direct exposure to traffic in addition to the external environmental conditions. Initially, models for bridge deck management are adopted from previous research (Alsharqawi et al. 2016; Alsharqawi et al. 2017). The first model is a performance assessment model to rate current performance. The second is deterioration modeling to predict future ratings. And the third is a rehabilitation model to determine suitable MRR interventions. Then, the decision making support tool is developed based on an optimized selection of minimum total rehabilitation actions cost and maximum performance considering PBC setting of maintaining the specified performance LOS during the predefined duration.

3.1 *Bridge deck performance modeling*

Performance measures and performance LOS are the basis of a PBC which are expected to be achieved by the maintenance contractor (Alyami 2012). Measures

of performance are often expressed in terms of levels of service represented by specific rating scales corresponding to the condition of different assets. Many experts on performance measurement argue the benefit of using a few key performance measures instead of many because of the associated simplicity and manageability of those few performance measures (Hyman 2009). This research focuses on structural performance measures which are these attributes that indicate the condition or performance of the bridge component. In this context, these measures are the common bridge deck defect types, i.e., cracking, concrete disintegration, scaling and erosion, corrosion of steel reinforcements, delamination, spalling, deposits, expansion joints problems, and pop-outs. These assembled can represent the structural condition reliability which is a component's physical condition fitness or in other words an indicator of a component performance state. Reliability is the base measure for the bridge remaining service life, an indicator that is suggested by Haas et al. (2008; 2009).

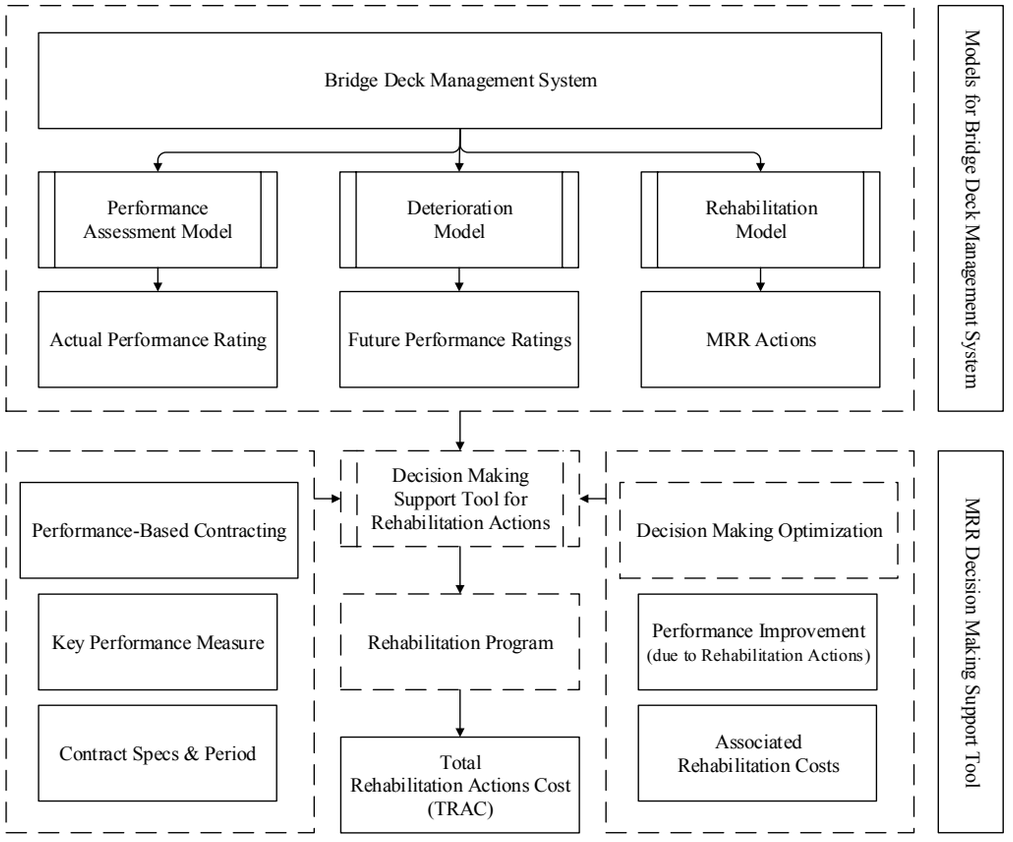

Figure 1. Schematic flow diagram of the proposed methodology

In order to assess bridge deck condition reliability, a Quality Function Deployment (QFD) condition assessment model is utilized. The QFD model can integrate surface defects detected by visual inspection and subsurface defects using NDE techniques in one framework (Alsharqawi et al. 2016). By applying the QFD model, a final crisp integrated condition value C_I is calculated representing the bridge deck overall condition using Eq. 1:

$$C_I = \frac{1\times Good + 3\times medium + 6\times Severe + 9\times V.Severe}{9} \quad (1)$$

where: C_I = integrated component condition; and $1, 3, 6, 9$ = numerical rating scale following a geometric progression where severity (condition ratings) is scored proportionally. Then, the reliability value is calculated which is one minus the component's overall condition and used as an input to the prediction model.

To model deterioration over time, a reliability-based Weibull Distribution Function (WDF) is employed to shape the bridge deck deterioration curve (Alsharqawi et al. 2017). The current research adopts the WDF to model bridge deterioration because of its particular advantages including i) the WDF has proven to be one of the best functions to represent concrete deterioration (Semaan 2011; Shami 2015); ii) Unlike the stochastic deterioration models, the Weibull function does not require large amount of historical inspection data to model deterioration; and iii) the Weibull reliability function parameters are calculated easily. An updated deterioration curve is created based on the last inspection condition survey for real representation of component deterioration over time using the Eq. 2 (Alsharqawi et al. 2017):

$$CR_I(t) = 1 \times e^{ln(CR_{Ii})(t/t_i)^s} \quad (2)$$

where: CR_t = component integrated condition reliability at time t; CR_{t_i} = integrated condition reliability at time t_i ; and t_i = inspection time.

3.2 *Development and optimization of maintenance, repair, and replacement strategies*

3.2.1 *Rehabilitation, improvement, and cost models formulation*

Rehabilitation modeling is the process of determining the suitable MRR actions. Improvement modeling is about predicting the conditions after performing MRR actions, and cost modeling is for estimating the associated costs of these actions. Based on the developed QFD condition assessment model, suitable MRR types are formulated and categorized into three types of rehabilitation. Table 1 proposes an interpretation of each MRR action corresponding to the performance of the bridge deck. For bridge decks under good performances, rehabilitation actions such as routine maintenance could be performed. Bridge decks with poor performances need repair actions such as strengthen the thickness of these bridge decks by doing local repairs to the concrete structure. For critical performance, the action would be full deck replacement.

Table 1. Performance assessment interpretation for bridge decks

Performance Assessment	Action
Excellent	No Action is needed.
Good	Bridge needs routine maintenance
Poor	Bridge needs repair
Critical	Bridge needs replacement

Modeling performance improvement and predicting the deterioration behavior of an asset after a rehabilitation action is necessary. This research classifies bridge rehabilitation actions into maintenance, repair or replacement (MRR) strategy. The improvement values by the three types of rehabilitation relied on a study that was performed by Seo (1994). Seo's estimated repair improvements according to FHWA condition rates. It is noticed from Seo's study that the rehabilitated action of replacing a new deck does not revert the condition to its best condition as of newly constructed bridges. Therefore, and in reference to the literature review, condition reliability is estimated to have an improvement of 20% when repair actions are implemented to the bridge deck. In the case of bridge deck replacement, the condition reliability is raised to be equal to 90%. For maintenance action, no improvement occurs, but this action reduces the deterioration of the bridge deck, i.e., bridge deck deteriorates at a slower rate.

Calculating a component's rehabilitation cost in Bridge Management Systems (BMSs) is often performed neither by assigning a fixed cost as a percentage of initial construction or replacement cost nor as a unit cost. The importance of defining the cost of the available repair options has been discussed by many researchers; however, the cost calculations were discussed without much detail. In practice, repair costs are associated with soliciting quotes to contractors/suppliers or by consulting published data references. As an example of percentage MRR costs, Seo (1994) proposed predefined estimates for the three types of rehabilitation. Abu Dabous and Alkass (2011) developed three unit cost models for each rehabilitation type. The unit cost of each rehabilitation action includes the direct cost, indirect cost and the markup added to cover the contractor's profit and contingency. Table 2 summarizes the rehabilitation actions costs as a percentage of initial construction (Seo 1994) and as a fixed unit cost (Abu Dabous and Alkass 2011). The unit costs are in Canadian dollars, adjusted for inflation and based on the 2017 dollar value.

Table 2. Rehabilitation strategies improvements and costs per type

Rehabilitation Action	Improvement	Rehabilitation Cost	
		% of initial construction	unit cost (C$/m^2)
Maintenance	0%	28.5%	$26.43
Repair	20%	65.0%	$789.40
Replacement	90%	100.0%	$1033.20

3.2.2 *Life-cycle costing and optimization model formulation*

Prediction models are the basis of life-cycle cost analysis. This is because the maintenance costs are dependent on the bridge performance which varies over the analysis period. The setting of a PBC is accomplished in the traditional life-cycle cost model through defining the desired performance threshold such that the LOS never exceeds the threshold limit. The calculations for Rehabilitation Actions Costs (RAC) costs are evaluated using net present value (NPV) and shown in the following equations:

$$RAC_{total} = \sum_{n=1}^{N} \sum_{m=1}^{M} \frac{1}{(1+i)^n} (RAC_m . X_{nm}) \quad (3)$$

$$\sum_{m=1}^{M} X_{nm} = 1 \ \forall \ n = 1, \dots, N \quad (4)$$

where: RAC_{total} = total rehabilitation actions costs; N = total number of contractual years (contract duration); i = discount rate; M = total number of MRR strategies m; RAC_m = rehabilitation action cost associated with the selected MRR strategy m; and $X_{nm} \in \{0,1\}$ binary constraint ensures that one MRR strategy is chosen at year n of the contract period. X_{nm} = 1 if MRR action m is applied, and 0 otherwise.

The outputs of the prediction model and life-cycle costing model are integrated as inputs to the optimization model in order to obtain a set of tradeoff lists of rehabilitation actions applied over the predefined period of the contracted bridge asset. The optimization model is developed to meet the needs that arise within a PBC setting. Thus, the objective functions and constraints are formed as:

Objective functions:

$$minimize\ RAC_{total} = \sum RAC_n \quad \forall n, 1 \leq n \leq N \quad (5)$$

$$maximize\ P = AVG\ P_n \quad \forall n, 1 \leq n \leq N \quad (6)$$

Subject to (constraints; *s.t.*):

$$TRAC \leq B \quad (7)$$

$$P_{limit} < P_n \leq P_{max} \quad (8)$$

where: RAC_n = rehabilitation actions cost in year n; B= budget constraint; P_{limit} = minimum allowable performance that could be reached even after applying disincentives (penalties); P_n = predicted performance after MRR action at year n; and P_{max} = maximum performance. In addition, the optimization model should account for the constraint of the contract specified LOS of the key performance measure, condition reliability. In other words, the condition reliability state should satisfy the specified LOS threshold of the performance measure:

$$P_{CR} > PM \quad (9)$$

where: P_{CR} is the condition reliability performance as a result of the latest rehabilitation action applied; and *PM* is the specified LOS (predefined threshold value) of the key performance measure. In case of failing to achieve the specified performance LOS, disincentives (penalties) will be applied. In contrary, if applicable, incentives defined in the contract are applied once the performance exceeds the target LOS. The transportation agency specifies these thresholds to be met or exceeded during the contract period. A threshold of 65% is suggested representing a good performance state. Further, the transportation agency can define performance targets or standards where a LOS rating of 80% for primary systems and 75% for the secondary systems is desired targets (Smith et al. 1997). The process of selection of the combination of rehabilitation actions that will maintain the specified LOS for the key performance measure is repeated to arrive at the optimum rehabilitation program. For assistance with the optimization process, a genetic algorithm (GA) code for optimization is developed using MATLAB® software.

4 CASE STUDY AND MODEL IMPLEMENTATION

4.1 *Description and assumptions*

The studied case is a concrete bridge in the municipality of Frelighsburg, Quebec. The bridge is located on the Chemin Richford, where it overpasses the creek, Selby. The bridge deck is 13.7 m in length, resting on four concrete girders with the roadway being approximately 10 m wide and about 30 cm thick. The bridge was built in 1960, and the deck was visually inspected and previously scanned using GPR tool (GSSI SIR-3000).

Based on results of the inspection that was performed in 2016, it can be noticed that the cracking existed with medium severity. The bridge deck suffered from steel reinforcement corrosion and delamination at various severity levels, and deposits were detected. These defect measurements are input into the QFD assessment model to produce an integrated condition assessment of the bridge deck. The obtained results of the considered case are summarized in Fig. 2. By applying Eq. 1, a rating value is calculated to be 36.01%, representing the integrated condition for the bridge deck in the year 2016. Then, the reliability value (one minus the integrated component condition) is calculated to plot the bridge deck deterioration curve.

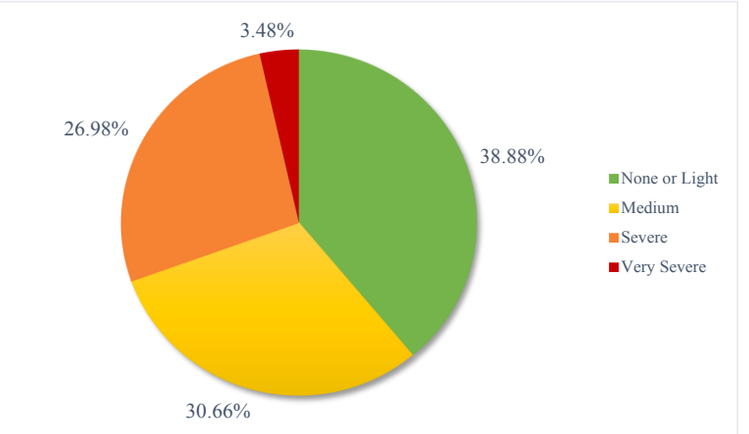

Figure 2. Assessment output for the case study based on 2016 inspection

Following the performance assessment, the WDF model is applied and the deterioration curve is mapped using Eq. 2. In this case, CR_{Ii} of 0.64 and t_i, year of inspection, of 56 are used based on data retrieved from the inspection survey conducted in 2016. Fig. 3 illustrates the performance curve without MRR interventions. As mentioned earlier, in PBC, the transportation agency specifies minimum performance measures to be met or exceeded in the contract specifications. Thus, the development of rehabilitation program is subjected to the specified performance measure and the associated LOS over the planning time horizon. In this research, the relia

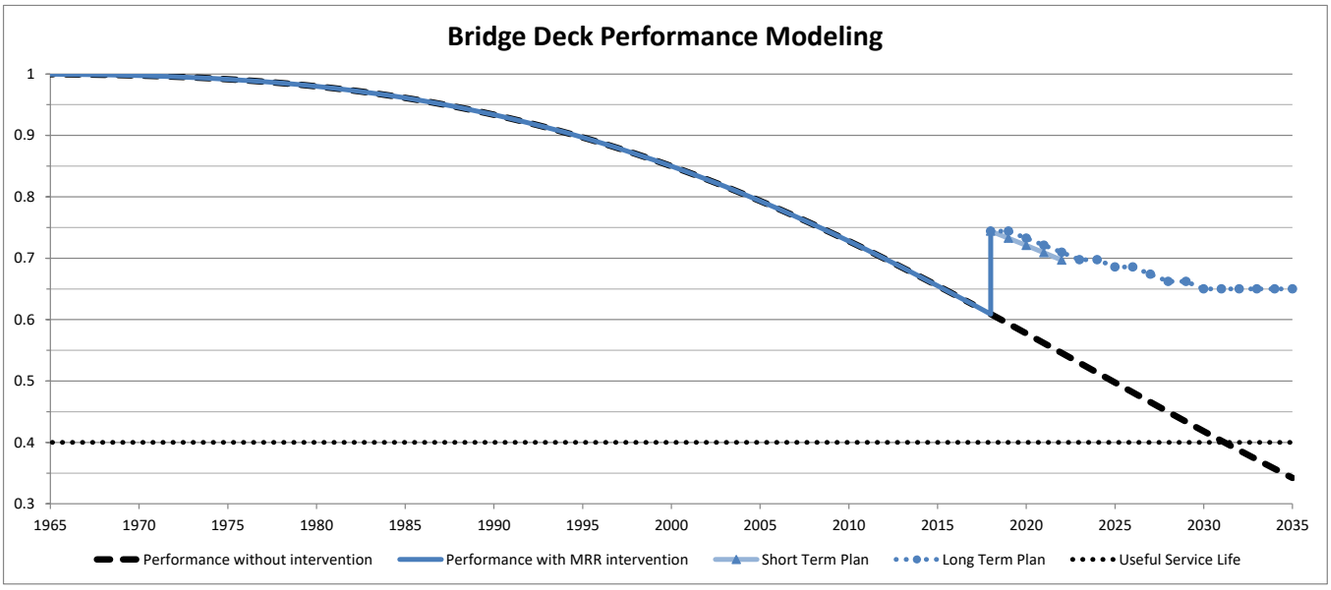

Figure 3. Performance curve without and with MRR interventions

bility of the bridge condition is adopted as a key performance indicator or measure to express the bridge's LOS.

In this paper, two optimization scenarios were developed, based on the following parameters: i) performance LOS threshold = 0.65; ii) discount rate i = 4%; iii) max number of iteration = 100,000; and iv) population size = 20. The first scenario was carried out over a 5 year predefined contract period and the second was carried out over the remaining life-cycle time of the contracted bridge asset. For the short term plan, a budget constraint B = \$160,000 allowing for a possibility to cover the cost of replacing the bridge deck. In the long term plan, a budget constraint B = \$320,000 is suggested to be allocated. A set of tradeoff lists of rehabilitation actions applied over the two scenarios will be discussed in the next section.

4.2 *Results and analysis*

The results obtained by implementing the QFD assessment model (Fig. 2) show that the medium condition state attained the second highest percentage of 30.66%. The severe condition state got a relatively high percentage of 26.98%. After implementing the Weibull deterioration model and based on the outcome from the 2016 inspection, the deterioration curve delivers an indication to the ministry of transportation to take an action no later than 2031 in order to maintain the minimum acceptable level (Performance = 0.40) that keeps the bridge functional and safe for users as forecasted in Fig. 3 (performance curve without MRR interventions).

The implementation of the optimization model presented earlier provides a variation of rehabilitation strategies applied at various years throughout the time horizon in the two described scenarios. Table 3 presents the program developed from implementing this model where the type of rehabilitation and corresponding performance for both scenarios are shown. The present worth of each scenario is also calculated. In scenario 1, the short term plan, the total rehabilitation actions costs RAC_{total} = \$115,373.28. While in scenario 2, the long term plan, the total rehabilitation actions costs RAC_{total} = \$138,209.56.

Table 3. Output of rehabilitation program

Year	Short Term Plan		Long Term Plan	
	Rehabilitation Strategy	Performance	Rehabilitation Strategy	Performance
0		0.624		0.62
1	Repair	0.744	Repair	0.744
2	No Action	0.733	Maintenance	0.744
3	No Action	0.721	No Action	0.733
4	No Action	0.709	No Action	0.721
5	No Action	0.697	No Action	0.710
6			No Action	0.698
7			Maintenance	0.698
8			No Action	0.686
9			Maintenance	0.686
10			No Action	0.674
11			No Action	0.662
12			Maintenance	0.662
13			No Action	0.650
14			Maintenance	0.650
15			Maintenance	0.650
16			Maintenance	0.650
17			Maintenance	0.650
18			Maintenance	0.650

By comparing the first five years in each plan, it is noticed that the long term plan has a better performance where the average performance P_{avg} is equal to 0.730 versus 0.721 in the short term plan. P_{avg} is equal to 0.684 over the whole period (18 years) in the long term plan. Regarding total rehabilitation actions costs, an increase of about 20% was encountered in the long term plan; yet this plan extends the study period by 13 additional years compared to the short term one. Although the allocated budget is doubled for the long term plan accounting for the increase in the time horizon, the developed optimization model minimized the budget consumption while maximizing the performance of the bridge deck.

5 CONCLUSIONS AND FUTURE RESEARCH RECOMMENDATIONS

There has been some movement over the past decade toward a performance-based contract model for maintaining and managing transportation infrastructure. However, there are limited computational tools to support optimal management and decision making under this innovative method of contracting. This research presents an overall methodology and introduces a decision support tool to optimize rehabilitation strategies under PBC setting. The availability of such tool will allow transportation agencies and maintenance contractors that are unfamiliar with PBC to make more informed decisions on their approach to better allocate the contractual risks. Implementing this tool can help contractors to establish optimum rehabilitation program with the lowest cost and appropriate time of MRR application to maintain the specified performance LOS along the contract period. Also, agencies can benefit from this tool to benchmark prices against bids during the bid evaluation process. Furthermore, it can be used in estimating the budget needed for contracted bridge assets. Performance models are presented in this research as they capture the asset current performance, deterioration, and improvements following to MRR actions.

While an extension of this research will be the topic of an extended paper, following are some of the authors ongoing research in this area: i) implementing the developed decision tool on other case studies and provide more detailed analysis and discussion of the rehabilitation program results; ii) establishing a PBC-based payment system that will estimate the cost to carry out MRR works (PBC contact cost) and define appropriate incentives, disincentives (penalties), or both; iii) conducting a sensitivity analysis of performance modeling and specified performance LOS threshold on the net present worth as a mean to quantify the accepted risk associated with this type of contract; and iv) design an evaluation criteria to assess the client agency selecting the best maintenance contractor, where the agency should check the contractors' capabilities prior to awarding the performance-based contract.

Impacts of dynamic loads on the soil-steel bridges

D. Beben
Opole University of Technology, Opole, Poland

ABSTRACT: The paper presents an analysis of the impact of moving loads (road and railway) on the soil-steel bridges made from corrugated plates. Corrugated steel plate structures have been used for many years to construct culverts and small-to-medium bridges, as well as other engineering structures. The high popularity of these bridges results from advantageous technological properties, i.e. high carrying capacity, short construction time, ability to execute the works in the winter period, economic advantages (in comparison to traditional steel or concrete bridge structures), etc. The impact of moving loads was verified experimentally on a few bridges, especially by way of: (i) determining the impact of the road and railway service load on this type of bridges; (ii) determining the dynamic amplification factors and comparing the impact of the live load and analogous static load on the values of internal forces in the bridge; (iii) verifying the assumption regarding the non-inclusion of the dynamic impacts in bridges, which the soil cover thickness exceeds 1.0 m. The obtained results may be useful for professionals dealing with the soil-steel bridges and culverts.

1 INTRODUCTION

Live loads passing with certain, sometimes high speed through a bridge structure cause structural vibration induced, e.g. by diverse deflection of vehicle shock absorbers. Additionally, roadway or track irregularities cause an increase in the dynamic impacts on the structure (Fryba 1999, Paultre et al. 1992). The analysis of traditional steel or concrete bridges under live load is a known problem.

Corrugated steel plate structures (Fig. 1) have been used for many years to construct culverts and small-to-medium bridges, as well as other engineering structures (Janusz & Madaj 2009, Machelski 2008). The high popularity of these structures results from advantageous technological properties, i.e. high carrying capacity, short construction time, ability to execute the works in the winter period, economic advantages (in comparison to traditional steel or concrete bridge structures), etc. The testing of these structures in various load ranges has been conducted for many years (Bayoglu Flener 2009, Beben 2005, 2013a, Machelski 2008, Pettersson 2007, Vaslestad 1990). The testing mainly regarded the response of the bridge's structure to soil loads during construction works and static load placed in various configurations on the bridge. Based on the overview of worldwide literature, it was concluded that the recognition of the behavior of this type of structures under dynamic live load, especially service load, has not yet been discussed in detail. Some of the known works in this scope (Bayoglu Flener & Karoumi 2009, Beben 2013b, Beben & Manko 2010, Sezen et al. 2008) regards testing of soil-steel bridges under controlled dynamic load, i.e. recording the structure's response to the passage of a specific vehicle with planned speed.

Figure 1. Example of soil-steel bridge.

The paper presents the original aspects consisting of the dynamic loads influences on soil-steel bridges based on experimental testing. Dynamic amplification factors were also analyzed based on field testing on several soil-steel bridges. The obtained results can be helpful for designers.

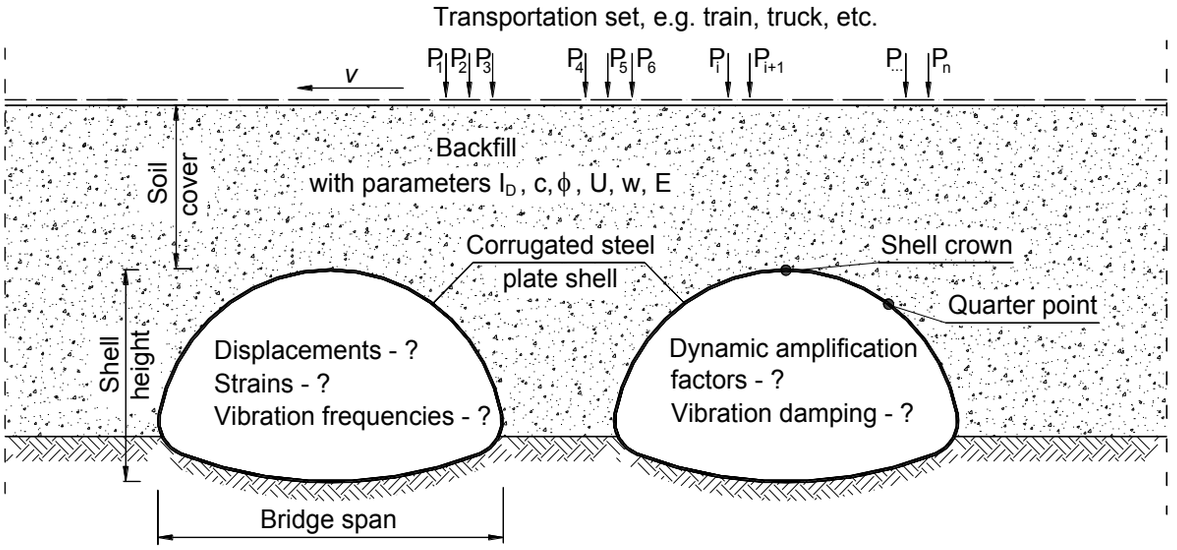

Figure 2. Schematic representation of the problem of live load impact on soil-steel bridges.

2 PROBLEM DESCRIPTION

The current studies (Bayoglu Flener & Karoumi 2009, Beben & Manko 2010, Sezen et al. 2008) have not included a detailed analysis of the impact of vehicle weight and speed, span and shape of shells and height of soil cover on the response of soil-steel bridges. No attempts have been made to determine in detail the displacements, strains, vibration frequencies and dynamic factors in these bridges or the impact of the backfill on vibration damping (Fig. 2). The analysis of these factors can contribute to the optimization of the selection of the minimum soil cover height and increase in the acceptable spans of soil-steel bridges. Additional effects may include a decrease in the execution costs of bridge infrastructure with the use of this type of bridges. Sezen et al. (2008) suggested that the response of soil-steel bridges is bigger from the static load than from the dynamic load. In addition, some researchers state (Janusz & Madaj 2009, McGrath et al. 2002) that in the case of bridges with a soil cover higher than 1.0 m, the dynamic impacts should not be taken into account, which is also reflected in relevant standards (AASHTO 2002, PN-85/S-10030 1985).

The article includes the analysis of the impact of road and railway live load on soil-steel bridges. The problem was verified experimentally, especially by way of: (i) determining the impact of the road and railway service load on this type of bridges; (ii)

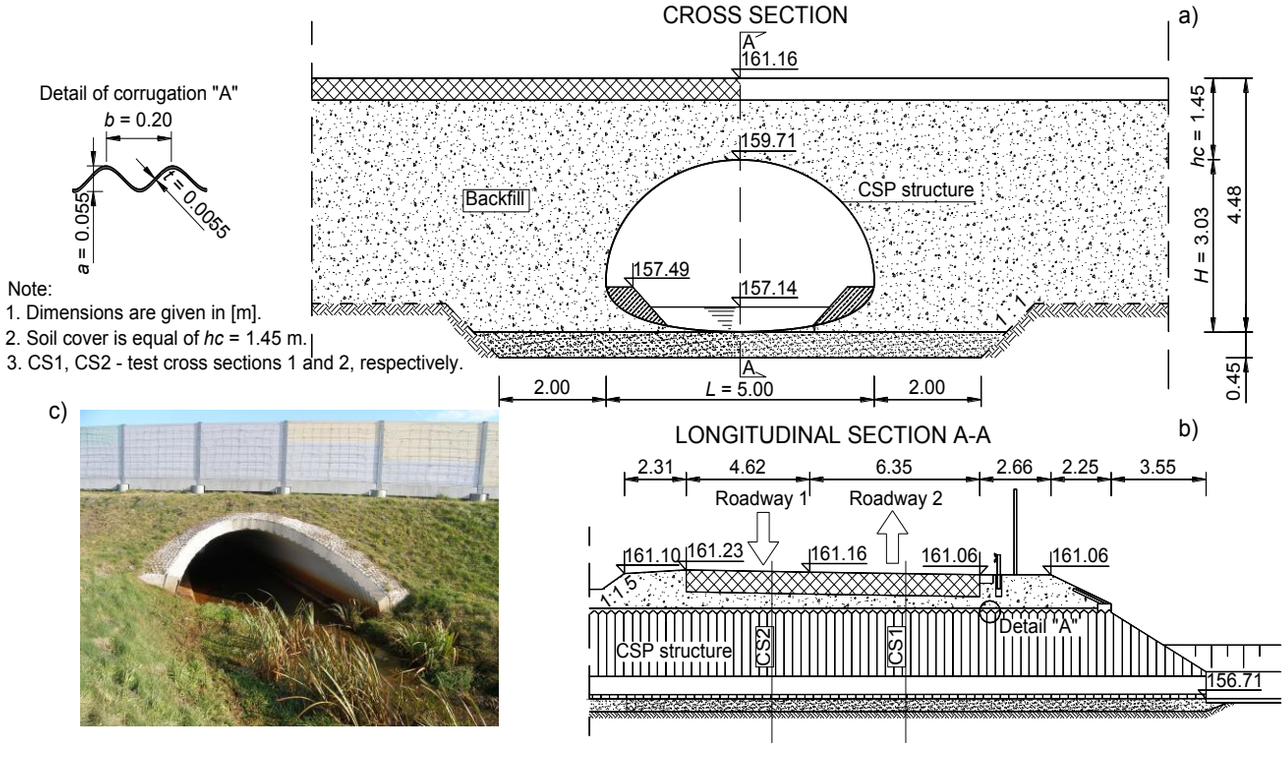

Figure 3. Road soil-steel bridge: a) cross-section, b) longitudinal section, and c) side view.

determining the dynamic amplification factors and comparing the impact of the live load and analogous static load on the values of internal forces in the bridge; (iii) verifying the assumption regarding the non-inclusion of the dynamic impacts in bridges, the soil cover thickness of which exceeds 1.0 m.

3 IMPACT OF THE ROAD AND RAILWAY SERVICE LOAD

3.1 *Road loads*

The study included testing of a road soil-steel bridges under service load (Fig. 3). The analysis of the results was conducted using the data concerning the vehicle traffic structure obtained from GDNRaM (General Directorate for National Roads and Motorways) and GIRT (General Inspectorate of Road Transport) as well as based on own video recordings. The displacements and strains in the selected bridge cross-sections were recorded in intervals, i.e. continuous measurement in eight half-hour intervals in different periods of the day. This allowed for obtaining a distribution of the maximum internal forces around the bridge's circumference from vehicle passage during the day.

The largest deformations, i.e. displacements amounting to 0.74 mm and strains with the value of 43×10^{-6}, were caused by the passage of a commercial vehicle with the weight of 46 t and speed of 70 km/h. The deformations occurred in the bridge's crown and in its quarter points. The distribution of the load along the bridge was determined by using the mutual correlation function for analyzing the sensor signals. It was observed that the impact of a vehicle passing over cross-section CS1 on test cross-section CS2, located within the distance of 5.0 m from the former, was smaller by 40%. A relatively small effort of the bridge was caused by the backfill at the crown h_c = 1.450 mm and the short time of load impact of 1 s. The FFT (Fast Fourier Transform) method was used during the analysis to determine the dominant bridge frequencies (Fig. 4) in the range of 0.2÷1.2 Hz

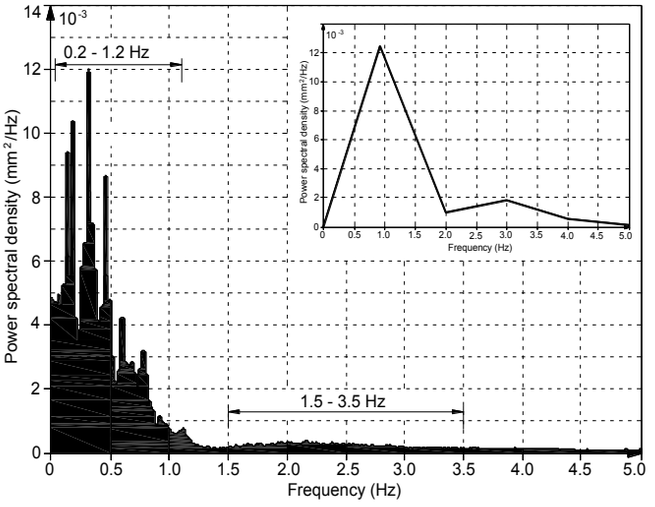

Figure 4. The power spectral density of the measured displacement.

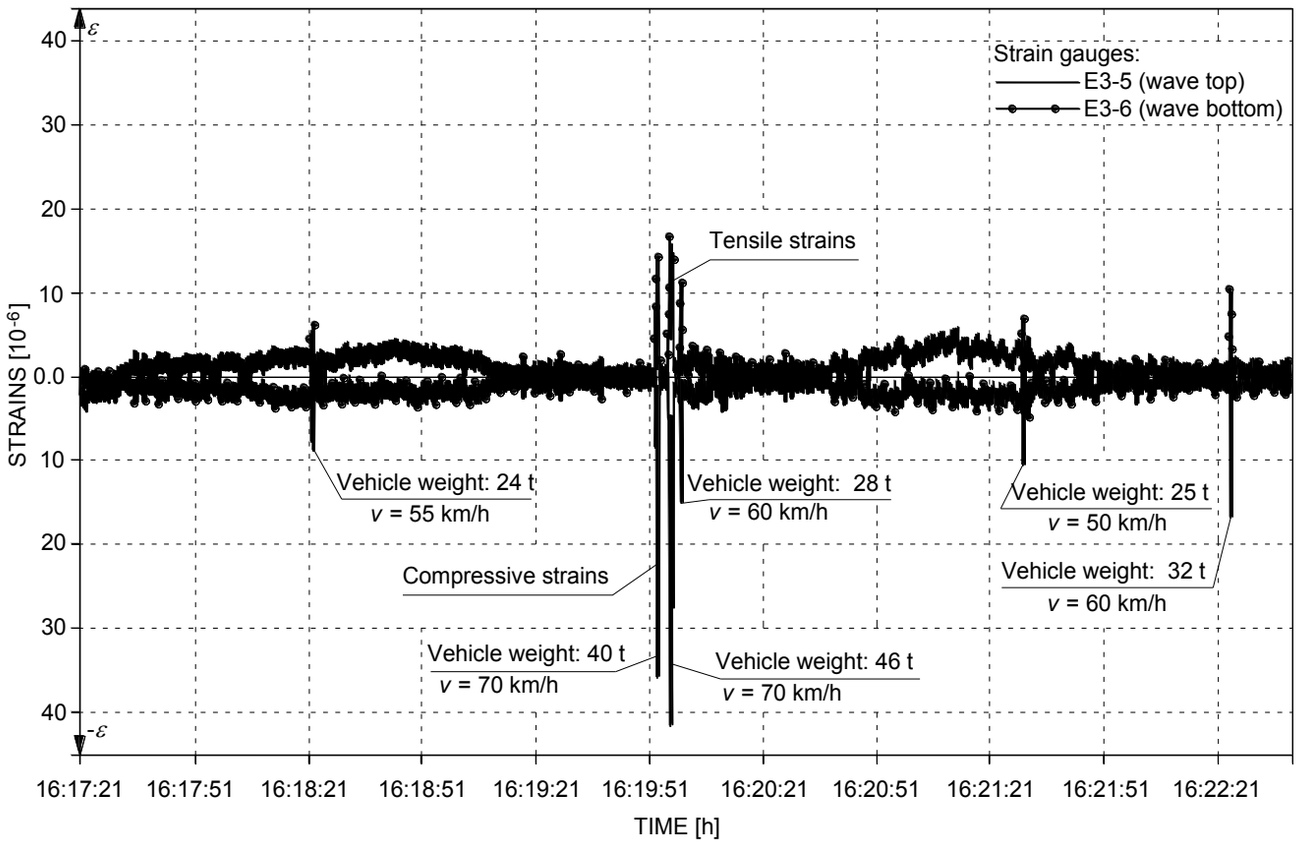

Figure 5. Graph of the compression and tension strains in the corrugated plate shell.

(angular frequencies ω = 1.26÷7.54 rad/s vibration period T = 0.83÷5.00 s). The less dominant frequencies were observed in the range of 1.5÷3.5 Hz (ω = 9.42÷21.99 rad/s and T = 0.28÷0.66 s). The small values of the soil-steel bridge frequencies confirm the positive impact of the backfill on damping the vibration caused by the passage of heavy vehicles.

It was also observed that the higher strain values (compression, sensor E3-5) occur at the peak of the wave (Fig. 5) and the smaller values – at the bottom of the wave (tension, sensor E3-6). This is related to the combined effect of axial forces and bending, as well as with the uneven distribution of the load around the shell's circumference (the shell's neutral axis is not located in the middle of the wave). The fact also affects the discrepancies in the results obtained acc. to the analytical methods and experimental studies.

The study also included the assessment and comparative analysis of the analytical methods (AASHTO LRFD 2010, CHBDC 2006, Pettersson & Sundquist 2014) used for estimating the internal forces in the bridges with the results of experimental studies. Axial thrusts calculated based on the CHBDC and Sundquist-Pettersson methods are closest to those obtained from the tests. However, in the case of the Sundquist-Pettersson method, a better agreement was obtained for higher values of live load, ca. 25%. Whereas, the biggest difference (ca. 60%) was recorded from the light loads, i.e., 60 kN. When the CHBDC method was used the biggest difference did not exceed 25%, but a better agreement was obtained for lower loads (< 340 kN). It was also observed that axial thrusts from the CHBDC method become convergent with the ones from the Sundquist-Pettersson method as the live load increased. Considering the whole range of live loads, the CHBDC method provides more reasonable thrust values than those from Sundquist-Pettersson method. The differences between the CHBDC and Sundquist-Pettersson methods can be related to the use of the Dynamic Amplification Factors (DAF), i.e., 1+DLA, by the CHBDC. These differences may also be caused by their approach to the load distribution through the soil cover and manner of determine the arching factor. The conservatism of these methods also derives from various loads and from additional safety factors used in the considered designing methods. Relatively high values of bending moments were obtained in the studies and estimations of the service loads. This confirms that the bending moments should not be ignored during the designing of arching and circular structures, which is suggested by the CHBDC (2006) and AASHTO LRFD (2010).

The test results were used in the estimation of the damping ratios ζ = 8.26÷21.02% and the logarithmic damping ratios LDD = 0.521÷1.351. Their values can be deemed as high in comparison to typical road

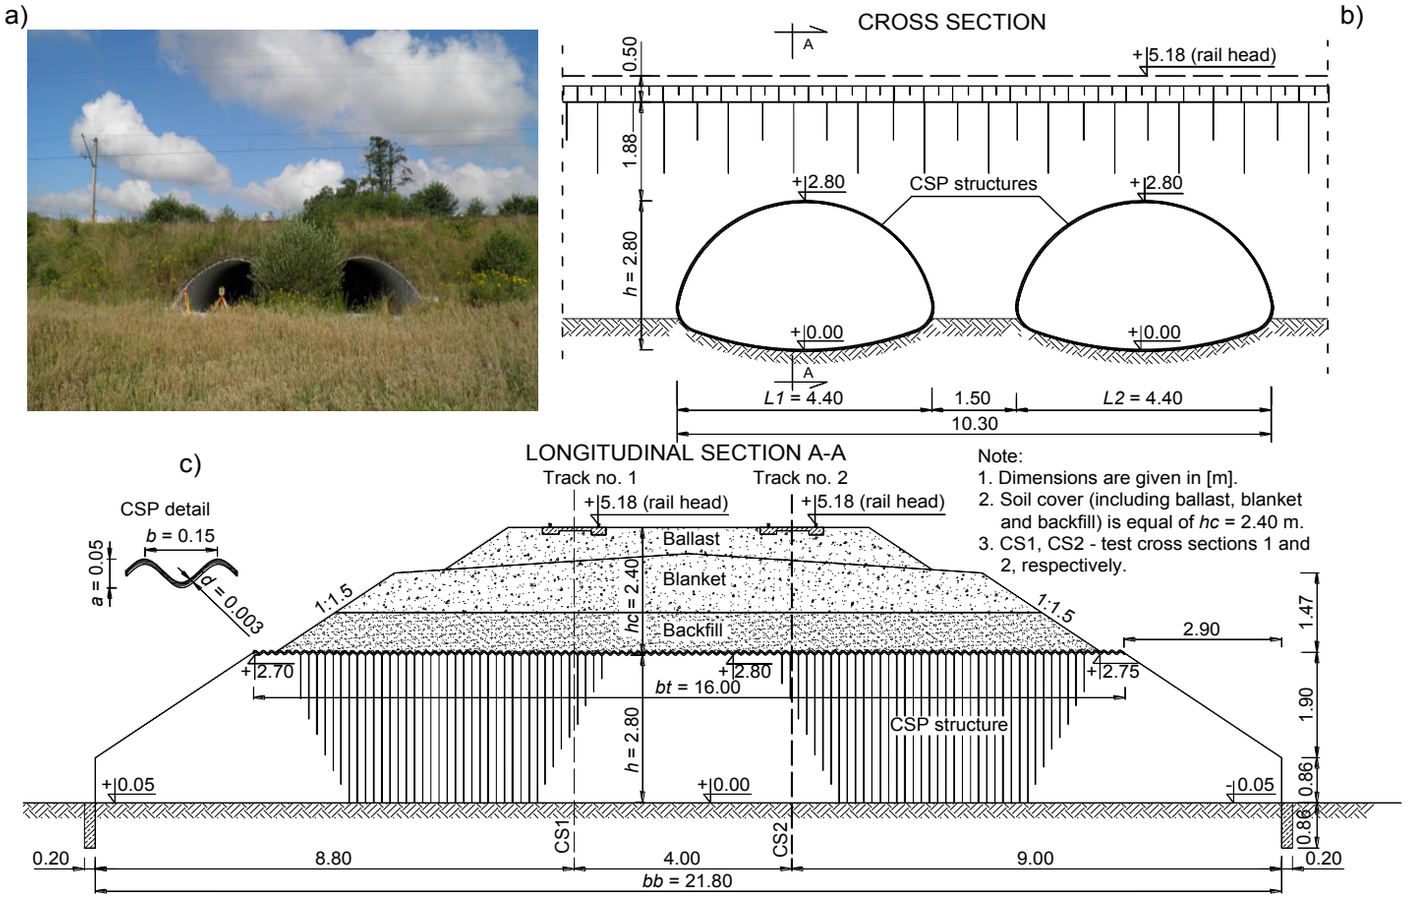

Figure 6. Railway soil-steel bridge: a) side view, b) cross-section, and c) longitudinal section.

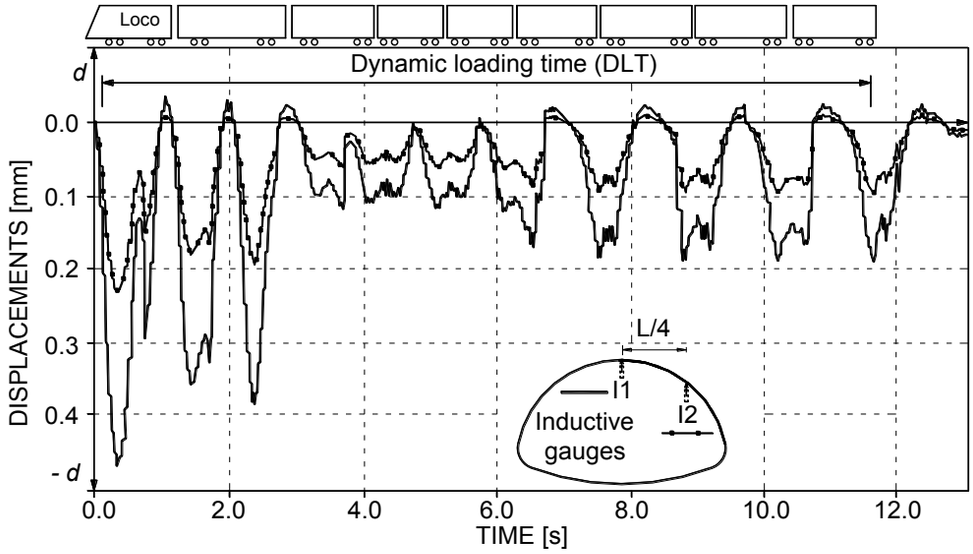

Figure 7. Bridge's crown and quarter point displacements during the passage of a freight train with the weight of 1,052.2 t and speed of 40 km/h.

and railway bridges. This results from the large height of the backfill in the crown, which in this case was damping the vibration and the energy dissipated within the backfill.

3.2 *Railway loads*

The main purpose of the railway soil-steel bridge (Fig. 6) testing was to obtain the responses to railway service load. The bridge's displacements and strains were measured in two cross-sections located under each of the railway lines. The maximum displacements have not exceeded 0.61 mm and strains – 54×10^{-6}, with the applied load of the train of approx. 1,700 t and speed of 35 km/h. The example of the bridge's displacement course is presented in Figure 7.

It was concluded that the backfill had a positive impact on the distribution of the load along the bridge, i.e. decrease in the displacements and strains by approx. 80%. This is related to the damping of vibration by the layers located above the bridge, i.e. backfill layers, gravel overburden, ballast and with the decreased rate of the waves in these layers. This means that the loads only affect the bridge near the track-way through which the train is passing. The highest displacements and strains were obtained at the bridge's crown and quarter points, respectively. The largest strains – compression was observed at the top of the wave and the lowest at the bottom – tension.

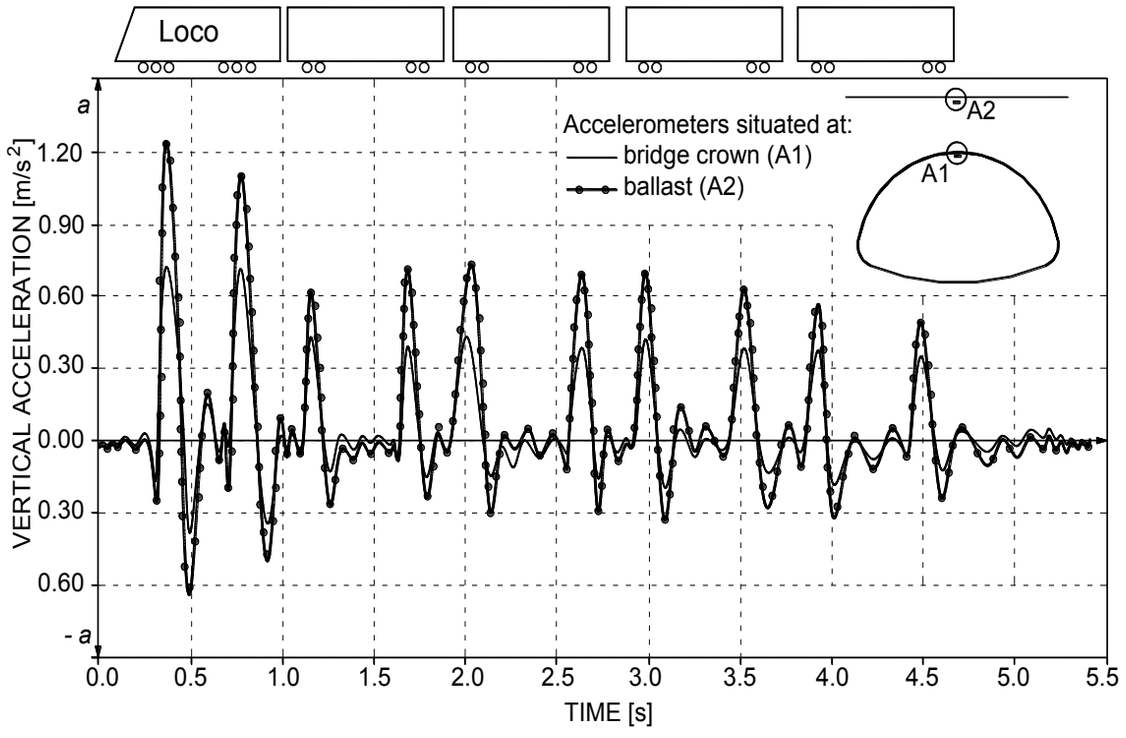

Figure 8. Bridge's crown and ballast vertical acceleration during the passage of an express train with the speed of 120 km/h.

The acceleration of the soil-steel bridge and railway ballast were smaller than the limit value of 3.5 m/s^2 according to Eurocode (2002). The acceleration at the bridge's crown (Fig. 8) was in every load case smaller than the ballast acceleration by approx. 45%. The decreased value of energy in the bridge's crown is caused by the reduction in the wave's velocity in the backfill and the substantial height of the soil in the crown. The test results also indicate that if the train speed increases, the bridge and ballast acceleration also increases.

Based on the measured displacements and using the DFT (Discrete Fourier Transform) method, it was possible to determine the bridge's dominant frequencies, which amounted to 0.1 or 0.2 and 1.2 Hz, which corresponds respectively to the circular frequencies ω = 0.63 or 1.26 and 7.54 rad/s and vibration periods T = 0.83 and 10 or 5 s. The highest bridge vibration frequencies were caused by the passage of trains with the speed of 70 to 120 km/h (irrespectively of their weight), while in the case of small train speeds amounting to $v < 40$ km/h, their weight had a larger impact on the bridge's frequencies. It can be stated that the bridge's frequencies are related to the weight of the passing trains. In the case of low speeds $v < 40$ km/h, there is an increase in the frequencies by approx. 69%, whereas in relation to higher speeds, the weight of the trains is not as important. Even trains with the weight of 135.3 t, passing through with the speed of 60÷75 km/h caused the same or higher frequencies than passages of heavy commercial trains, but with smaller speeds.

The bridge's natural vibration were also identified using the power spectral density for analyzing the displacements obtained from the so called ambient

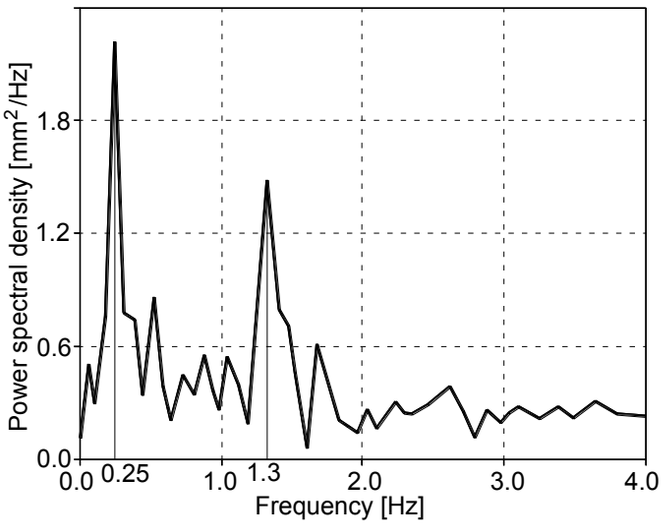

Figure 9. The power spectral density of the bridge's crown displacements after train passage.

vibration test. The first two natural frequencies of the bridge amounted to 0.25 and 1.3 Hz (Fig. 9), which corresponded in approximation to the dominant frequencies obtained from the primary tests under live loads (forced vibration test). The damping ratio determined using the Half Power Bandwidth method amounted to approx. 9% in the tests without a load and 50% in the case of tests with the use of passing trains. The large differences are caused by the impact of the activation of interaction between the steel shell and soil when the bridge is under load. The internal forces in the bridge, estimated according to the method specified by Pettersson and Sundquist (2014), were substantially higher than the values obtained during the experimental studies.

The available Australian (AS 3703.2-1989 1989.)

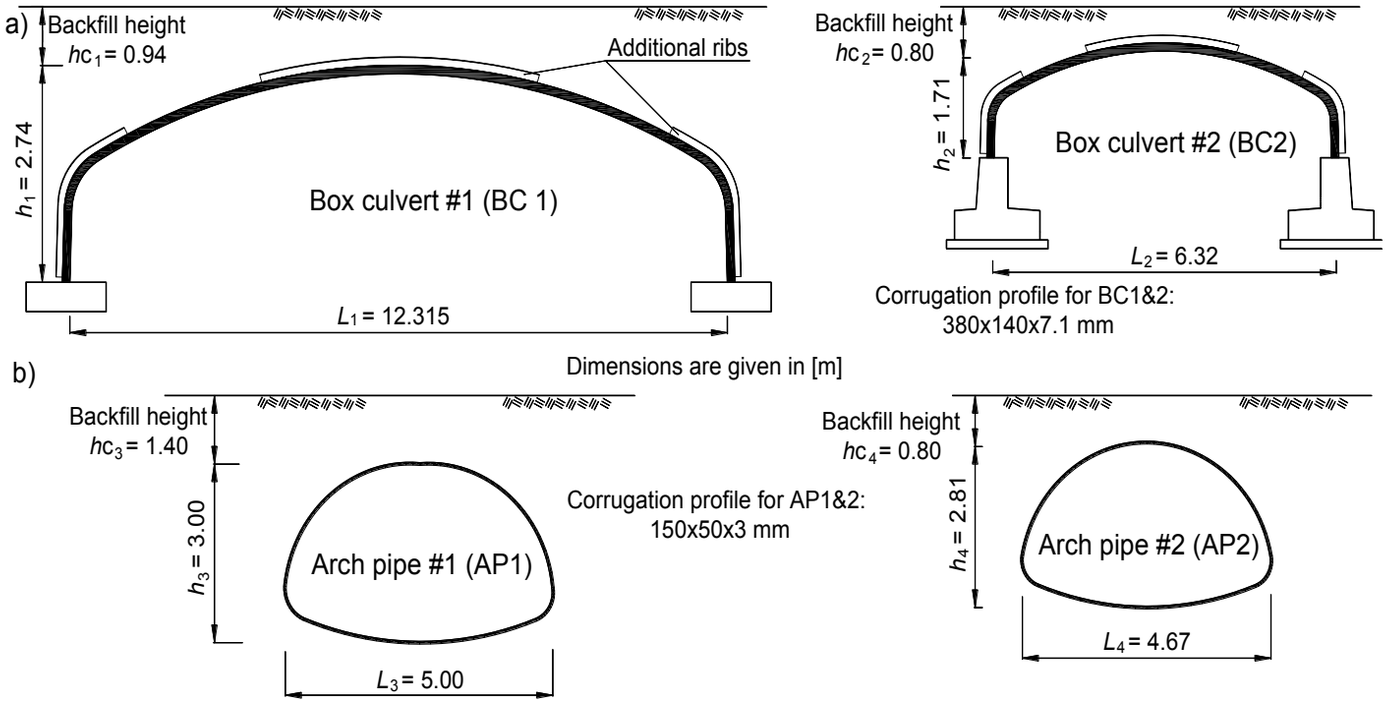

Figure 10. Cross-sections of the tested soil-steel bridges: a) box culverts (BC 1 and BC2), and b) arch pipes (AP1 and AP2).

and American (AREMA 2012) railway standards for this type of bridges recommend that the railway load should be adopted as uniform pressure at the level of the bridge's crown, which is contradictory to the obtained test results.

4 DYNAMIC AMPLIFICATION FACTORS IN SOIL-STEEL BRIDGES

The Dynamic Amplification Factors (DAF) in soil-steel bridges were analyzed on four structures with various spans and soil cover heights (Fig. 10). The impact of the live load was presented in comparison with a situation when the same load is located statically on the bridge, and the factors affecting the DAF were determined. According to Bakht & Pinjarkar (1989), the viable dynamic factors should be determined based on tests under the real load of vehicle traffic taking place at the given structure, i.e. service load. In this case however it is difficult to determine the response of the structure to the static load of each and every passing vehicle. The static value can be obtained by filtering the structure's dynamic response or by estimations, e.g. using FEM. In the case of typical steel or concrete bridges, the situation is advantageous enough that there are estimation methods that allow obtaining the structure's response with an adequate degree of accuracy. In contrast, in the case of soil-steel bridges, the use of the available estimation methods leads to excessive differences in the results in comparison to experimental studies. As of today, there is no fully adequate calculation model for the soil-steel bridges. For this reason, to obtain the static response, it was decided to use the filtration of the dynamic response of the considered bridges. It is necessary to note however that in the case of traditional steel or concrete bridges with the span of up to 15 m, the use of the dynamic response filtration results in errors in the dynamic amplification factors (Paultre et al. 1992). Therefore, an indirect effect of the conducted research was the determination whether the soil-steel bridges feature the danger of encountering errors during the designation of the DAFs using the dynamic response filtration.

It was determined that the dynamic impacts in the bridges should be taken into consideration during their designing, because the values of the DAFs estimated based on the measured displacements were in the range of 1.116÷1.260 and on strains - 1.105÷1.293 (Fig. 11). In bridge AP1 with a soil cover of over 1.0 m, the DAFs amounted to 1.116÷1.175 in relation to the displacements and 1.121÷1.205 in relation to the strains.

The DAFs in these bridges can also be used for assessing their actual carrying capacity – service capacity by estimating the dynamic impacts of the

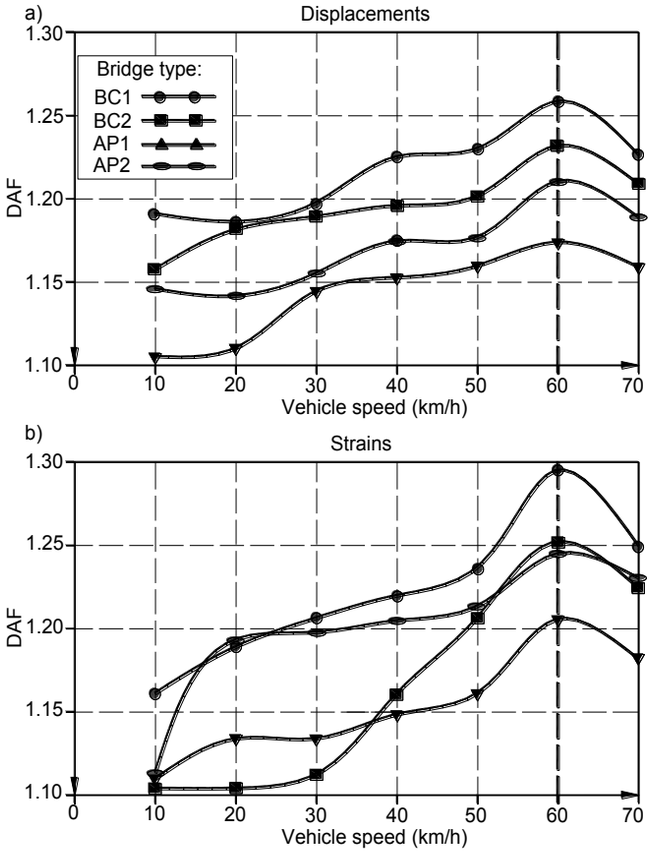

Figure 11. Dynamic amplification factors (DAF) determined based on: a) displacements, and b) strains.

live load. The tests have allowed for the assumption that the main factor affecting the value of the DAFs is the bridge's span. The DAFs increase along with the increase in the span. Other important factors affecting the DAFs include: height of the soil at the bridge's crown – the DAFs decrease along with the increase in the height; backfill height and bridge span ratio – if the ratio increases, the DAFs decrease; bridge crown radius and side radius ratio – if the ratio increases, the DAFs also increase. An increase in vehicle speeds also causes an increase in the DAFs (compare Fig. 11). The maximum DAFs were obtained in the case of the 60 km/h speed. This regarded all of the concerned bridges. At higher speeds, the DAFs had smaller values, which was related to the very short time of impact of the load on the bridge.

In the case of the railway bridge (Beben 2014), the DAFs obtained from the displacement measurements amounted to 1.11÷1.39 and from strains – 1.03÷1.54, which also confirms the necessity to consider them if the soil covers exceed 1.0 m.

In relation to traditional steel and concrete bridges with small and medium theoretical spans, the DAF increase along with the decrease in vehicle weight. For this reason, the results obtained during the passage of light vehicles should not be taken into consideration when determining the values of these factors. This dependency was not found in the case of soil-steel bridges. In the case of low train speeds

$v < 45$ km/h, the DAFs are more dependent on the weight than on the speed, because in the case of higher train speeds $v > 60$ km/h, the impact of the weight is smaller. In these cases, the DAF depend more on the speed, which is related to the higher impact of loads caused by trains moving with high speeds, i.e. emission of higher energy.

5 CONCLUSIONS

The most important effects of the conducted testing of various soil-steel bridges under dynamic loads include:

- demonstrating the necessity to take into consideration the dynamic amplification factor (DAF) when designing soil-steel bridges and culverts, even with the soil cover higher than 1.0 m;
- determining the impact of speed and weight of road and railway vehicles on the behavior of the soil-steel bridges, including determining the degree of deformation and vibration frequencies of steel shell structures;
- demonstrating the possibility of using the bridge dynamic response filtration to obtain the static value for determining the DAF (for bridges with the span of up to 15 m);
- verifying the current designing method (Pettersson & Sundquist method) and American (AASHTO LRFD) and Canadian (CHBDC) standards, regarding soil-steel bridges and culverts, which do not allow to correctly assess their carrying capacity, despite the fact that the obtained values are safe in relation to the structure.

It is necessary to conduct further testing and numerical analysis of soil-steel bridges and culverts, the results of which would include:

- development or modification of the designing guidelines and standards;
- determination of the actual acceptable service capacity of the bridges as a relation of the actual and designed carrying capacities;
- determination of the service strength and durability (life time);
- optimization of the selection of parameters, i.e. soil cover height, corrugated plate thickness, shell span;
- estimation of seismic effects in the soil-steel bridges, including the mining shocks.

Automated Steel Bridge Coating Inspection using Neural Network Trained Image Processing

Ahmed Elbeheri,
PhD Student, Department of Building, Civil & Environmental Engineering, Concordia University, Montréal, Québec, Canada.

Tarek Zayed,
Professor, Department of Building, Civil and Environmental Engineering, Concordia University, Montréal, Québec, Canada H3G 2W1

ABSTRACT
Steel bridges deterioration has been one of the problem in North America for the last years. Steel bridges deterioration mainly attributed to the difficult weather conditions however some solutions have been presented in the last years like weathered steel but there are still a large number of existing bridges that were built in other steel types other than weathered steel. Steel bridges suffer fatigue cracks and Corrosion, which necessitate immediate & regular inspection. Visual inspection is the common and traditional technique for steel bridges inspection but it depends on the inspector experience, conditions and work environment conditions. So many NDE models that have been developed use Non-destructive technologies to overcome these obstacles and be more reliable. Non-destructive techniques such as The Eddy Current Method, The Radiographic Method (RT), Ultra-Sonic Method (UT), Infra-red thermography and Laser technology have been used. Previous researchers had used Digital Image processing for rust detection as an Alternative for visual inspection. Different models had used grey-level and coloured digital image for processing. Coloured image Processing depend on the fact of using the colour of the rust, one of the rust unique characteristics to distinguish it from the different backgrounds. The detection of the rust is an important preliminary stage as it is the first warning for the corrosion and a sign of coating erosion. To decide which is the steel element to be repainted and how urgent it is the percentage of rust should be calculated and it can be always as indication of the corrosion level. In this paper, an image processing approach will be developed to detect corrosion and its severity. Two models were developed 1st to detect rust and 2nd to detect rust percentage. Machine learning was applied through neural network as it will be used to be trained to detect rust and calculate the percentage. The application of the neural network will ease the process of processing the inspection data. One of the great advantages of neural network that it can adapt to any new data it even helps as more data mean more training and better results.

Keywords: steel bridge; bridge inspection; steel corrosion; image processing; neural network.

1 INTRODUCTION

In North America, infrastructure condition is reported by a grade or percentage, like schooling system, which known as infrastructure report cards. In the United States, the American Society of Civil Engineers (ASCE) report card shows an overall rating for America's infrastructure is poor. Furthermore, the cost to improve infrastructures including but not limited to solid waste, drinking water, wastewater, roads, bridges, and rail is estimated as $3,635 billion *(1)*.

According to Infrastructure Canada Rating *(2)* the four asset categories show that a significant amount of municipal infrastructure ranks between fair and very poor, on average about 35%. The replacement cost of these assets alone totals $388 billion, nationally. Municipal roads require urgent attention. More than one third of the roads & bridges network fall below a rating of "good".

Historical figures indicate that 'transportation' sector forms the largest portion of the Canadian infrastructure industry value. Roads and bridges segments have the largest portion within the transport infrastructure representing the highest worth share according to the estimates by the Business Monitors International report on Canadian infrastructure *(3)*. However, large parts of these infrastructures were constructed during the 1960's and 1970's. Accordingly, they are facing an increasingly deteriorating problem *(4)*. Statistics Canada reports evaluate condition of infrastructure in terms of useful life expended by the infrastructure. ASCE report card also graded bridges' conditions as "C+" which refers to mediocre that requires attention *(1, 5)*. The growing problem of the bridges deterioration imposes challenges on ministries of transportation to maintain and preserve them. In 2011-2012 Quebec province alone spent more than $800 million for structural improvements, mainly for bridges *(6)*.

2 BACKGROUND

2.1 *Defects*

2.1.1 *Cracks*

Ductile failure, brittle fracture, and buckling/instability usually occur under static loading conditions wherein the applied load exceeds a critical load. In contrast, most structures are subjected to repeating loads of varying magnitude, which are most often below yield strength and design stress levels. Such repeated or fatigue loading occurs in bridges, buildings, etc. Fatigue failure is characterized by the initiation and growth of a cracks due to the repeated loading of the structure, which generates microscopic inelastic damage at regions of local stress concentration. If sufficient inelastic damage accumulates then a small crack develops, which then propagates through the structure. Failure occurs when the crack attains a critical size. Fortunately, fatigue is a progressive damage mechanism and is often identified before significant structural damage arises *(7)*.

2.1.2 Corrosion

Corrosion is one of the most important causes of deterioration of steel bridges. In the United States 40% of the bridges are built of steel. In some states, such as Michigan, the number exceeds 60% *(8)*. There is a need for rational criteria which can be used to determine the actual strength and remaining life of existing structures. The primary cause of corrosion is the accumulation of water and salt (marine environment or deicing media) on bridge steel. The source of water and salt is either from deck leakage or from the accumulation of road spray and condensation. The source of the moisture often determines the pattern of corrosion on a bridge. The rate of corrosion will depend upon the contaminants in the moisture and the ambient temperature.

2.1.3 *Creep*

(7) Described Creep as the damage accumulated from inelastic deformation of plain carbon and alloy steel under constant load even if the service stress is substantially below the yield strength because of thermal activation at elevated temperatures.

2.3 *Inspection techniques*

The traditional method Visual inspection proved to has some problem as inspector condition, inspection condition and non-applicable for subsurface defects. Image processing has great results for surface defects and overcome the condition for inspection and inspector mentioned in visual inspection but steel cannot detect subsurface defects. Eddy current technique used for detecting cracks without removing the coating but it is not efficient in detecting the surface defects. The radiographic method is able to detect cracks but even the process and the equipment is too complicated I.e. X-rays or it uses dangerous type or radiation i.e. gamma rays. Ultra-sonic method mainly used in thickness measurement to assess the corrosion loss in steel section either used to detecting cracks. It still questionable for the small size cracks However some advanced UT Technology such as (Phase Array Automatic Ultrasonic Testing (PA-AUT), Automated Ultrasonic Testing (AUT) etc...) have a promising Results regarding the accuracy. The other challenge that it needs a high skilled crew to guarantee the accuracy of the inspection especially in the advanced UT Technology. The IR thermography application shows the ability to detect different types of crack in steel bridges but not the surface defects. 3D laser technology was capable to detect any surface defects or any change in the structure from the original state but still it needs more application. In this paper Image processing is used to detect corrosion and the percentage of rust among the bridge steel elements. One of the advanced infrastructure inspection methods is the application of digital image processing. Digital image processing methods have been developed for steel bridge coating inspections for the past few years. The rust percentages on steel bridge coating surfaces can be reliably computed through the use of digital image processing methods. *(9)* developed a method works effectively with blue-paint-coated steel bridge images. However, this method didn't prove to work on other coating colors or in any other irregular conditions, such as coating images with background noise or different illumination patterns.

Shen et al. *(10)* developed an automated steel bridge coating rust defect recognition method based on color and texture feature. The methodology consists of two models, Fourier- transform-based steel bridge coating defect detection approach (FT-DEDA) and rust-colour-spectrum-based rust defect recognition method (RUDERM). The FT-DEDA approach used to detect any changes on the collected images. The used tools detect the rust and sharp edges but cannot discriminate rust so the RUDERM approach was used. The RUDERM approach used the color space to define the rust spots and discriminate it

from the background and other defects. With the comparison of Shen's model and Lee work Shen shows better results especially with the non -uniform illuminated images which simulate the some of the environmental condition as it was one of the Lee's drawback. The classification of the images gives defective and non-defective images and did not define the percentage of defect in each image which does not give an accurate result for the whole steel bridge coating.

2.3 *Machine learning*

Machine learning Machine learning teaches computers to do what comes naturally to humans and animals, learn from experience *(11)*. Machine learning algorithms find patterns in data that generate insight and help you make better decisions and predictions. Machine learning has become important for in areas like: Computational finance, for credit scoring; Image processing and computer vision, for face recognition, Voice recognition, and object detection; Computational biology, for tumor detection, drug discovery; Automotive, aerospace, and manufacturing, for predictive maintenance • Natural language processing*(11)*. According to the Figure 1 below, machine learning divide to two main categories, a) unsupervised b) supervised learning. Supervised learning, which trains a model on known input and output data so that it can predict future outputs, and unsupervised learning, which finds hidden patterns in input data.

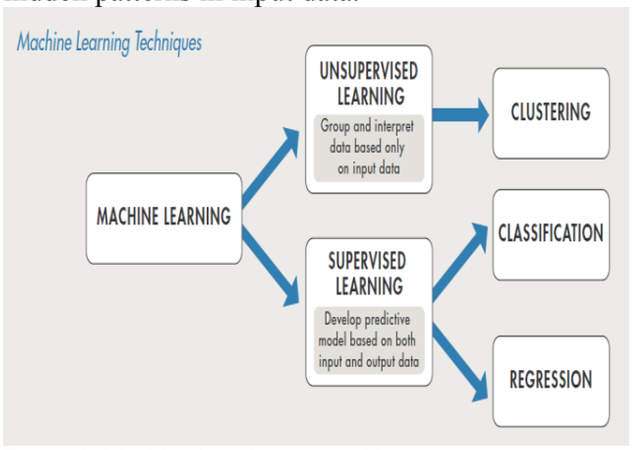

Figure 1. Machine learning types *(11)*

3 METHODOLOGY

The methodology consists of two models, 1) rust defect detection model which developed to detect the existence of corrosion, 2) rust severity detection model which used to determine the percentage of rust in bridge steel elements.

3.1 *Rust defect detection model*

The rust defect detection model steps are illustrated in fig 2. Step 1: data acquisition, in this step the images to be tested for detection will be the images of the steel bridge elements. In this research, these images obtained through literature review and from inspection reports from other research projects and municipality reports. Step 2: a standard size should be selected and unified for all the tested image to facilitate the next steps and for the training process as the neural networks needs the images to be the same size, Step 3: data reduction which has been done throw resizing the images. Step 4: image enhancement which has been done by histogram equalization process. Step 5: Data Compression, in this step Discrete Cosine Transformation (DCT) has been used as it proved its validity through different application on voice recognition and face detection. Step 6: training data, where we use neural Network algorism to train the system through the obtained images. At last the system detect the defective images and proceed to the second model.

The input of the NN is defined as the processed images samples for defective and not defective steel elements, while the output is the desired trained data that will help to discriminate between defective and non-defective images.

Therefore, NNs are required to train the data to the desired acceptable level by the user through nonlinear activation function, TANSIG. The nonlinear function has an 'S' shaped curve that limits the node's output. The network consists of two layers with a hidden layer connected to the output layer. Both layers have a non-linear transfer function to work with a feed-forward backpropagation training algorithm as shown in Figure 3. Using multi-layer neural network always combined with both complexity and efficiency and as complexity seems to be a drawback but in this case, it was not as the sample wasn't in a large population.

3.2 *Rust severity detection model*

The rust defect detection model steps are illustrated in fig 4. In this model, we add a step called image segmentation as more accuracy needed to distinguish rust from the image Step 1: data acquisition, the defective images produced from the first model will be the input in this stage. Step 2: a standard size should be selected and unified for all the tested image to facilitate the next steps and for the training process as the neural networks needs the images to be the same size, Step 3: data reduction which has been done throw resizing the images and converting the images to Grayscale. Step 4: image enhancement which has been done through histogram equalization to avoid any contrast concentration in some areas of the image. Step 5: image segmentation, in this step edge detection was used along with image binarization. Step 6: training data where we use neural Network algorism to train the system through the obtained images. At last the system was trained to calculate the percentage of rust.

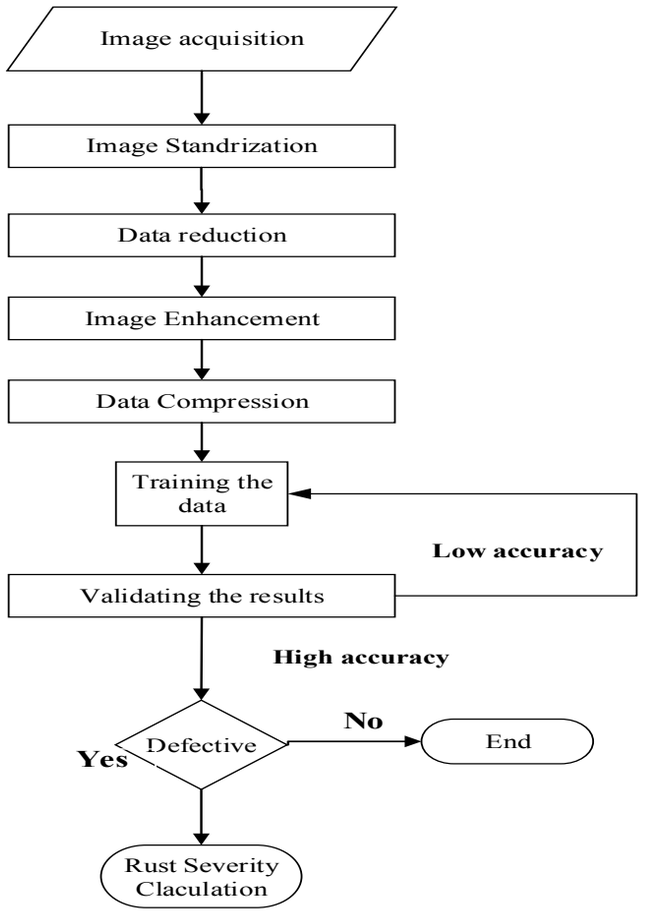

Figure 2. Rust defect detection model flow chart

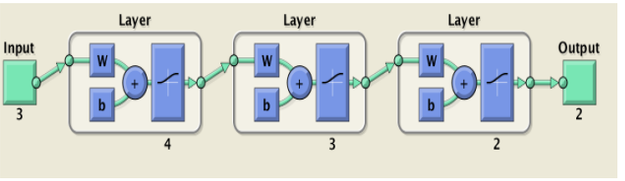

Figure 3. Multi-layer neural network example

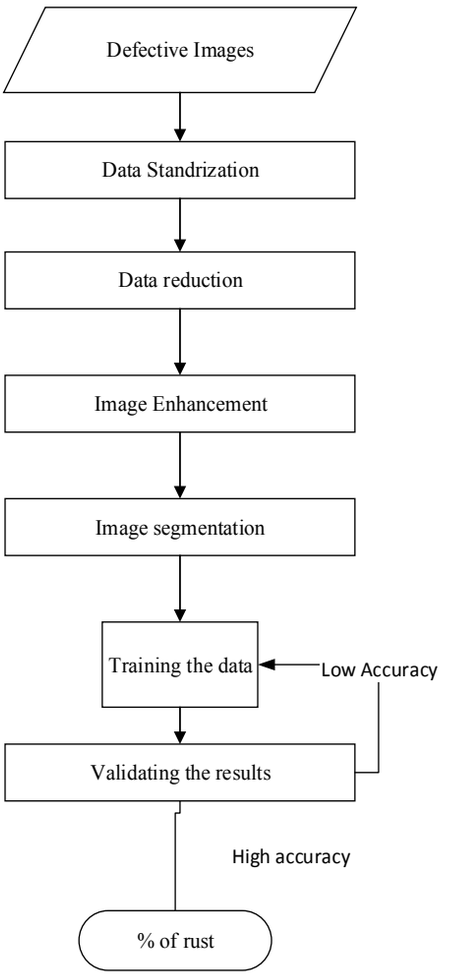

Figure 4. Rust severity detection model flow chart

4 MODEL IMPLEMENTATION & RESULTS

A set of twenty-eight images were collected from previous research consisting of twenty-two defective images and six non-defective images. First the data will be implemented in the first model for detection. All the images went through the image processing steps to be ready for the training process with the neural network. The training mechanism was

designed as follow: two types of data sets was developed, defective and non-defective. Two defective data set were entered together as data input and target to test the network. Then the same process was done for the non-defective.

After the network was trained, as validation three trial processes were planned, the first trial was entry of two defective data sets together, the correlation between the images in each set for the other set was measured to test if the network is working well or biased.

In this trial it was shown in table 1 that the correlation was maximum which is good as the two set was the same type as defective. The second trial was between 2 non-defective sets and as expected maximum correlation was obtained, the results shown in table 2. Finally, the main step to test with a mix of defective and non-defective images. It was found that the images of each set have the minimum correlation toward the opposite set as shown in table 3.

Table 1. Correlation results for the first trial

Image	Correlation to 1st Set	Correlation to 2nd set

5 CONCLUSIONS

The proposed model approved its capabilities in rust detection and Percentage calculation. Neural network shows potential as a machine learning tool in construction application especially in infrastructure management. Bothe models needs improvements, the Rust detection model performance increases as we add more training data and include different coating sample in the training process. The model can be

further used in crack detection as well and it will be illustrated in further research. The model is adaptive which means it can be trained for different coating type even more, it can be trained for future different corrosion patterns.

The second model needs some improvement in the image processing stage. Advanced techniques should be used in image enhancement and image segmentation to solve high contrast background problem. Overall the system performance is acceptable and can be used for coating inspection.

Inspection, Structural Health Monitoring and Maintenance of a Cable-Stayed Bridge in Vienna, Austria

P. Furtner
VCE Vienna Consulting Engineers ZT GmbH, Vienna, Austria

ABSTRACT: Donaustadtbrücke is a cable-stayed bridge over the Danube in Vienna, Austria. The bridge was erected as a road bridge for public buses in 1994. The inspection and maintenance concept included periodic visual inspection as well as periodic structural health monitoring activities like the measurement of the stay cable forces and of the dynamic characteristic of the bridge. In 2013 and 2014 remarkable stay cable vibrations were observed at the longest stays, which led to interruptions of the traffic of the bridge. Based on the measurement of the dynamic characteristic of the stays and the bridge deck, stay cable vibration measures were developed and installed. Additionally, a permanent monitoring system was installed. In 2015 damage was detected at the hinged columns at the south abutment. Measurements were carried out to assess the reasons for this damage. Furthermore a principal inspection of the bridge was done in 2015, followed by maintenance works.

1 INTRODUCTION

Donaustadtbrücke is a steel cable-stayed bridge built between 1995 and 1997 and connects the 2nd and 22nd district of Vienna. The bridge was opened to traffic in March 1997 and served as by-pass bridge during the lifting of the Prater bridge. In the period between 1998 and 2006 the bridge was only available for public bus traffic. After the extension of the underground railway line U2 from the station Stadion to the 22nd district the bridge has been used for underground railway operation since October 2010. In the course of reconstruction works for underground railway utilization the number of stay cables was doubled from 20 to 40 and the load at the existing stay cables was increased. During the works the forces in the stay cables were monitored.

In 2014 and 2015 considerable cable vibrations were observed at single cables. Immediately after each of the vibration events inspections, measurements and analyses were carried out in order to guarantee safe operation of the bridge. The measurements and analyses showed that the cable vibrations occurred under special weather conditions (rain-wind induced vibrations). The installation of so-called connection wires, which eliminate cable vibrations, was planned and realized as countermeasure.

In addition a permanent measuring system, which both monitors the vibrations of the bridge deck as well as the stay cables prone to vibration and records the weather conditions on site, was installed. Any cable vibrations are also recorded by means of a video system. All data are accessible via a web-user-interface.

In summer 2015 a main inspection of the bridge was performed. In the course of this inspection the corrosion protection was checked at the whole structure and defects were repaired. Selected stay cables were inspected with regard to wire failures and corrosion protection.

Furthermore damage at the southern hinged columns was identified. In addition to the comprehensive measurements calculations were carried out in order to detect the cause of the damage.

This contribution comprises all inspections, the results and conclusions as well as maintenance and repair measures.

Figure 1. Donaustadtbrücke

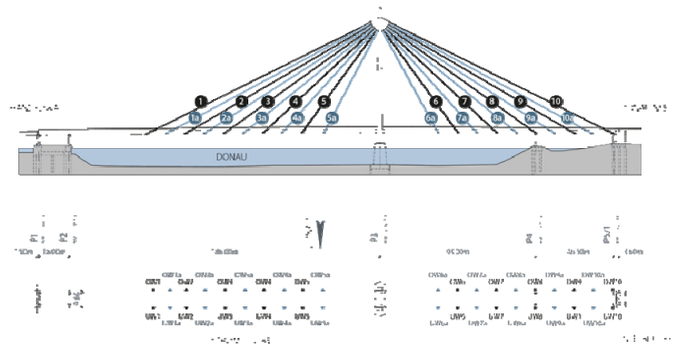

Figure 2. Stay Cable Layout

2 STAY CABLE MEASUREMENTS

Donaustadtbrücke was reconstructed for utilization by underground railway from 2008 to 2009. In this process the number of stay cables was doubled from 20 to 40 and the forces in the existing cables were changed. The force measurements at all stay cables were carried out in 2009 for the first time, follow-up measurements are performed every three years.

2.1 *Implementation of Measurements*

The measurements were carried out with the BRIMOS® Recorder 1000 developed by VCE. The external three-dimensional acceleration sensor of the recorder was fixed approximately 1.5 m above the deck at the cables. The measurements were performed separately, cable by cable. Two measurement files with 165 seconds and a scanning rate of 5 milli-seconds each were recorded per cable (this corre-sponds to 200 Hz). The measurement data were up-loaded on site and checked for plausibility.

Figure 3. Stay cable measurement

2.2 *Evaluation*

The evaluation was done with a software specially developed by VCE for cable measurements. The software has been used since January 2004 and offers the following advantages:

- Automatic offset adjustment and FFT (Fast-Fourier-Transformation) for the calculation of frequency spectra.
- Automatic peak-picking for the determination of the first 10 eigenfrequencies from the frequency spectrum; thus human failure is minimized and the accuracy of the evaluation is increased.
- Determination of f1 (1st eigenfrequency of the "ide-al" cable without bending stiffness) and the related cable stiffness ξ and the damping from the first 10 eigenfrequencies by means of a Gauss-Newton algorithm.
- Averaging of two measurement files per cable.

The cable eigenfrequencies are a function of the effective cable force N, the length l, the mass m of the cable per metre, the cable stiffness and the boundary conditions.

$$f_k = \frac{k}{2l} \cdot \sqrt{\frac{N}{m}} \cdot (1 + \frac{2}{\xi} + (4 + \frac{k^2 \pi^2}{2}) \cdot \frac{1}{\xi^2}) \qquad (1)$$

where f_k = eigenfrequency of the order k; N = cable force; m = cable mass per metre length; l = free length of the cable (length between the dampers and the clamping points respectively); and ξ = related bending stiffness.

2.3 *Results*

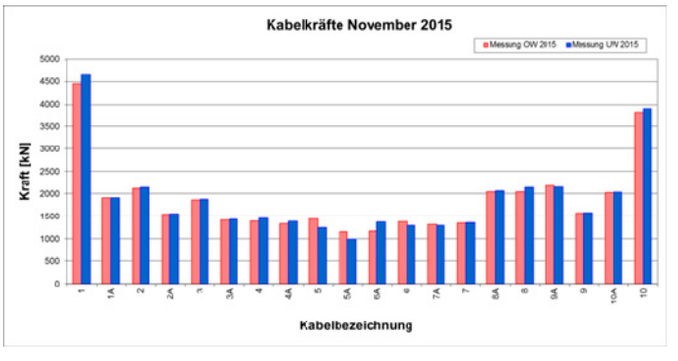

Figure 4. Stay cable forces determined

3 STAY CABLE VIBRATIONS

3.1 *Cable Vibrations Observed*

On 16 May 2014 and 23 October 2014 strong cable vibrations occurred at the stay cables of Donaustadtbrücke.

The stay cables concerned were those with the designations OW1 to OW2 and UW1 to UW2. Especially the stay cables OW1a, OW2, UW1a and UW2 (corresponding to the 2nd and 3rd stay cable of the upstream structure each) showed very intense vibrations. The cable vibrations observed were probably due to the current weather conditions (rain, wind force, wind direction).

In the course of the measurements at the stay cables vibration measurements at the bridge deck were performed to identify any resonance effects between the stay cables and the bridge deck. If the eigenfrequencies of a stay cable are very close to those of the bridge deck, mutual vibration excitation can occur. This phenomenon is called "parametric vibration excitation".

The vibration measurements on the deck are only measured with one sensor and are therefore afflicted with certain uncertainties. The following vertical eigenfrequencies were identified for the bridge deck and compared to the cable eigenfrequencies of the stay cables OW1a and OW2:

Table 1. Comparison of eigenfrequencies

Bridge deck [Hz]	Stay cable OW1a [Hz]	Stay cable OW2 [Hz]
0.60	**0.60**	
0.76		0.68
1.30	1.14	**1.31**
1.71	**1.71**	
1.89		
1.99	2.29	**1.96**
2.62		**2.63**
2.71		

The target is a minimum frequency distance of 10% between deck eigenfrequencies and cable eigenfrequencies to avoid resonances and parametric excitation. As illustrated in Table 3, this requirement is not met in case of Donaustadtbrücke.

3.2 *Assessment of Cable Vibrations*

The cable vibrations at Donaustadtbrücke observed on 16 May and 23 October are most probably due to the weather conditions prevailing at that period of time:

- Wind direction normal to the bridge axis
- Extensively constant wind speed of approx. 15-18 m/s
- Light rain

These weather conditions lead to the wind-rain-induced vibrations observed. In case of slightly lower or higher wind speeds even the neighbouring stay cables OW1 and UW1 as well as OW2a and UW2a can start to vibrate.

The vibration excitation of the stay cables is favoured and intensified by the phenomenon of "parametric vibration excitation", as the eigenfrequencies of the stay cables concerned correspond to the eigenfrequencies of the bridge deck.

3.3 *Installation of Connection Wires*

Due to the stay cable vibrations observed and the measurements and analyses it was decided to connect the 4 longest stay cables each on both bridge sides to so-called connection wires.

The strong cable vibrations observed concerned above all the 2nd eigenfrequency with a node in the centre of the cable. In addition vibrations in the 3rd eigenfrequency with two nodes were noticed.

Observation of similar cases at other cable-stayed bridges showed that perceptible cable vibrations typically occur in the eigenfrequencies 1 – 3. Therefore they were taken as a basis for subsequent assessment.

Connection wires are most effective in the maxima of the antinodes of the respective oscillation mode. If the connection wires are installed at the vibration nodes, there is a minimum effect. Naturally the antinodes of the individual oscillation modes are situated at different locations. The optimum mounting location shall be selected in such a way that all the basic oscillation modes for the assessment are damped.

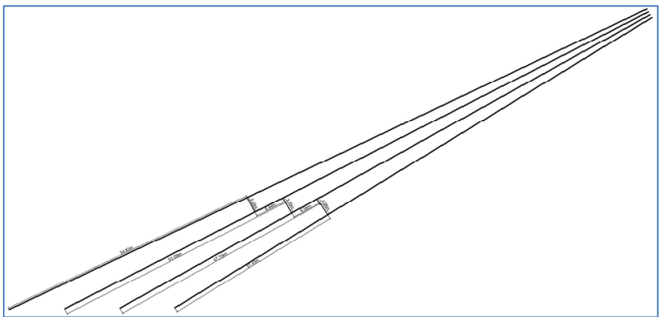

Figure 5. Positions of connection wires at stay cables

The following figure shows the layout of the connection wires and the fastening clamps.

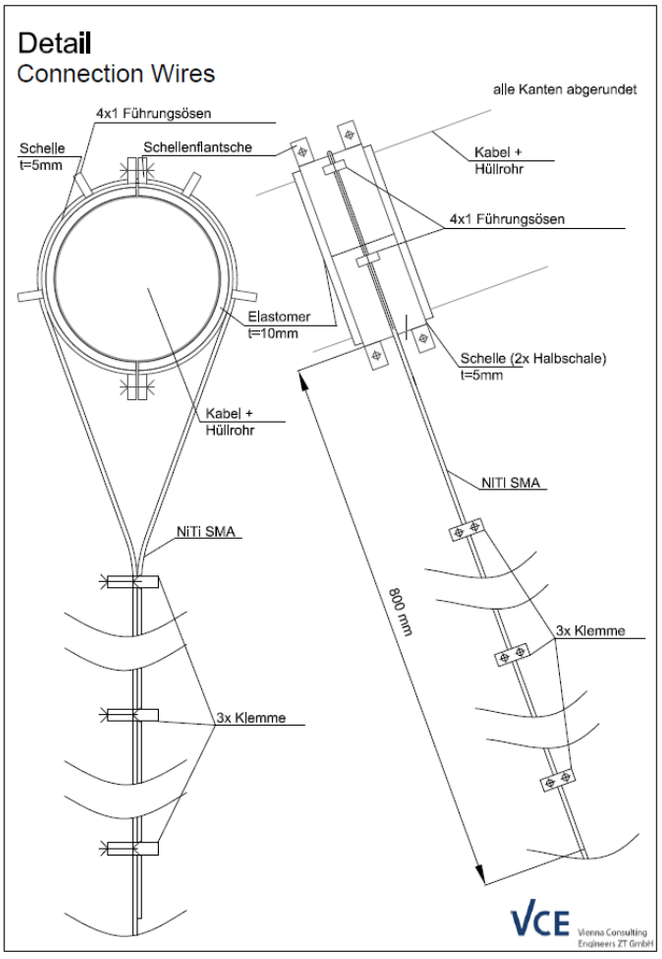

Figure 6. Design of connection wires

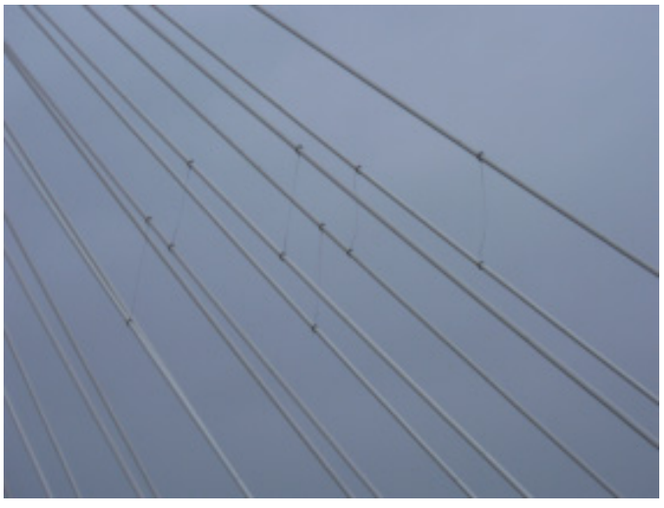

Figure 7. Installed connection wires

4 PERMANENT MONITORING

Furthermore the installation of a permanent monitoring system is recommended for the supervision of the vibration behaviour of the stay cables concerned and for the check of the success of the measures taken.

The monitoring system is assembled in the following way:

- 1 wind sensor ultrasound 3D, fixed approx. 3-5 metres above the deck at a measuring pole;
- 1 rain sensor, also mounted at the measuring pole;
- 1 3D-acceleration sensor, type Kistler, mounted at the stay cable OW2, fixed approx. 1-2 metres above the bridge deck
- 1 3D-acceleration sensor, type Kinemetrics, at the bridge deck close to the lower cable anchor of stay cable OW2;
- 1 video camera suitable for night operation with automatic recording in case of exceedance of vibration limits to be defined. The camera is placed in such a way that the stay cables can be observed and the vibration events can be recorded. The camera can be installed at the station building;
- 2 strain gauges at the upstream hinged column
- Measuring station (monitoring master station): The components (A/D converter, measurement computer, modem) are located in a measuring cabinet, which can be installed in the station building. All measurement data are saved on site;
- Double screened connecting cables between sensors and measurement station;
- Data remote transmission via mobile service and internet to the monitoring server in the VCE office. There the measurement data are archived in a database on the server;
- Visualization of the measurement data and results in the monitoring-web-user-interface: the latter is accessible via the internet with user name and password;
- Alarm thresholds are determined for all sensors;
- Start of video recording in case of exceeded thresholds;
- Alarm via automatically generated e-mails in case of exceeded thresholds.

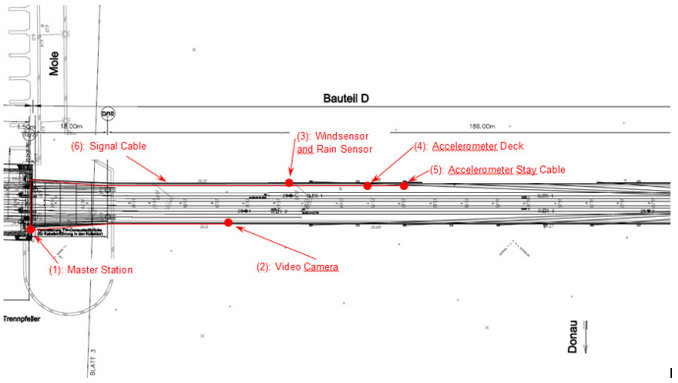

Figure 9. System sketch in plan view

5 MAIN INSPECTION

By order of the bridge owner, Wiener Linien GmbH & Co KG (Vienna's public transport operator), Donaustadtbrücke on the underground railway line U2 was subjected to a main inspection in July and August 2015.

Before the main inspection the bridge was cleaned by high-pressure water vapour with cleaning agents (Figure 1) as well as manually with fleece.

The inspection and maintenance works were carried out by means of movable scaffold networks. It was necessary to climb down from the pylon head by rope during the inspection of the pylon. The abutment walls and piers were examined from the ground and the cherry picker.

The inspection was predominantly executed within reach, not immediately accessible areas were subjected to a visual examination.

The following inspections were carried out in detail:

- Inspection within reach of all the surfaces of the soffit of the steel structure and the pylon as well as the abutment walls and columns, visual inspection of the noise barriers
- Coat thickness measurements were carried out at approx. 400 sites distributed over the whole structure.
- Additionally, weld inspections were performed on the basis of a previously prepared test concept. In this process sites which are especially susceptible to fatigue on the one hand and which are particularly important for the load-bearing capacity on the other hand as well as randomly chosen welded joints were selected.
- Bridge drainage was thoroughly rinsed and purged by means of high-pressure cleaners.
- On 3 Sept. 2015 the anchor cap was removed at two cable anchors and the cables were examined for wire failures and corrosion.
- In the time with no operation the trough area was visually inspected by means of test openings.

6 HINGED COLUMNS

6.1 *Failure Mode*

At the southern abutment the safety devices of the upper fastening bolts of the hinged columns were damaged. The screws of the safety discs were broken and the bolts had slightly slipped out. The bolts were temporarily secured with screwed steel plates. One bolt could be driven in for some millimetres.

Potential damage triggers are bridge vibrations, cable vibrations, temperature load cases, wind load cases, variable loads on the hinged column by crossing of underground railway trains.

Alternating loads of tension/pressure by train passages were assumed as most probable cause. Compressive load can lead to a slight, cyclic deflection of the hinged column, which exerts longitudinal forces on the bolt. This can result in the observed displacement of the bolts and subsequently lead to fatigue failure of the screws by cyclic load effects.

Figure 10. Hinged columns on southern bank

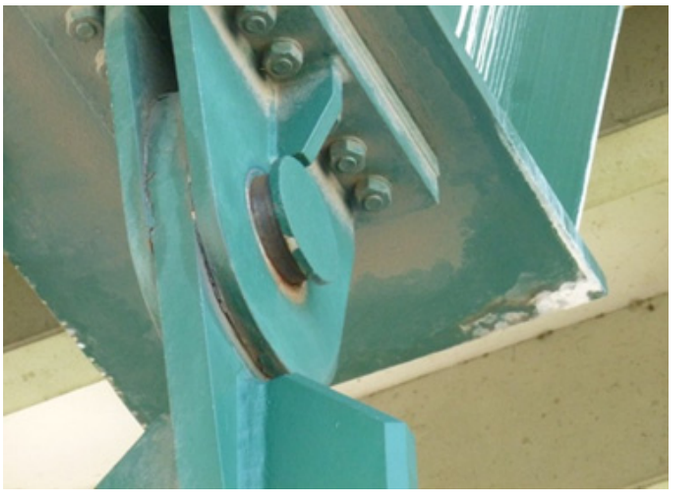

Figure 11. Damaged bolt

6.2 *Measurement Programme*

The following measurement concept was developed for the simultaneous measurement of both columns for the determination of the actual behaviour of the bridge deck, the two hinged columns and the bolts:

- Measurement of the horizontal and vertical relative movements of the steel deck to the abutment in case of train passages by means of high-precision displacement transducers (1 x 3 displacement transducers – only one hinged column axis)
- Measurement of the stress cycle in the hinged columns in case of train passage by means of strain gauges (2 x 2 strain gauges – both hinged columns)
- Measurement of the relative movement between hinged column and mounting straps by means of high-precision displacement transducers (2 x 1 displacement transducers – both hinged columns)
- Measurement of the horizontal deflections of the hinged column under compression load by means of train passage. For this purpose the deflection is measured at approx. half the height of the column in two directions by means of displacement transducers (2 x 2 displacement transducers – both hinged columns)
- Accompanying temperature measurement (1x)

6.3 *Results of the Analysis*

The measurements and analyses led to the following results:

1. The upstream hinged column is under tension in case of the unstressed bridge (no trains on the bridge).
2. During train passage, in case of train position in the main span of Donaustadtbrücke, tensile stress increases in the upstream hinged column.
3. In case of train position above the end of the structure and thus above the hinged column the upstream hinged column is under pressure.
4. The downstream hinged column is under pressure in case of the unstressed bridge (no trains on the bridge).
5. The compressive stresses in the downstream hinged column increase in case of train position above the end of the structure and thus above the hinged column.
6. During train passage, in case of train position in the main span of Donaustadtbrücke, the downstream hinged column is under tension.
7. The described load cycles can be clearly identified by means of the relative movements between bridge deck and hinged column (bolt tolerance) for both hinged columns. The vertical movement amounts up to approx. 2.5 mm at the downstream hinged column.
8. Deflections of the hinged column by compressive stresses were not measured.
9. The bridge deck performs slight movements into all directions in case of every train passage.

The measuring results of this analysis can be used for the calibration of the calculation model in the scope of verification.

7 SUMMARY

In the course of the maintenance works at the 20-year-old Donaustadtbrücke a main inspection as well as measurements at the stay cables, the bridge deck and at the hinged columns were carried out in 2015.

Cable vibrations observed at the longest upstream stay cables required the installation of connection wires.

Due to damage at the bolt safety devices of the hinged columns at the southern abutment a detailed measurement and analysis of the hinged columns was performed. The results will be incorporated in the verification of the structure.

Furthermore, the bridge was equipped with a monitoring system to enable permanent measurements at the longest stay cables and hinged columns.

The future maintenance programme provides follow-up measurements of the stay cable forces every three years in addition to the main inspections at an interval of five years.

Determination of stay cable forces using highly mobile vibration measurement devices

G. Morgenthal, S. Rau, J. Taraben, T. Abbas & N. Hallermann
Chair of Modelling and Simulation of Structures, Institute of Structural Engineering, Bauhaus University Weimar, Weimar, Germany

ABSTRACT: Vibration measurements are an established method for determining the tension force of stay cables. The approach utilizes linearization of the vibration characteristics of stay cables that are structural members exhibiting significant geometrical nonlinearities. Based on measured natural frequencies the cable force can thus be identified. This paper presents measurements that have employed mobile measurement equipment, namely MEMS-based (microelectromechanical systems) acceleration sensors connected to battery-operated microcomputers as well as those integrated in smartphones, and studies the accuracy for tension force measurements. Software written for streamlined measurement processes is linked with nonlinear analyses for predicting the frequency-force relationship. In contrast to traditional monitoring systems that are composed of several individual hardware components, smartphones and tablets can integrate the recording, storage, processing, transfer and visualization of data within one single device. The proposed methodology and implementation is validated on cables of Queensferry Crossing during construction. The technology has shown potential to allow simple yet accurate tension force measurements.

1 INTRODUCTION

Cable-stayed bridges have proven themselves as structurally efficient and economically favorable system for a large range of bridge spans that today reach beyond 1000 m (Svensson 2012). The stay cables as tension elements are a main structural component for which different systems have been developed such as parallel wire, locked-coil and multi-strand layouts. Whilst these are all based on hi gh-strength steel wires, they differ in their composition and consequently the resulting weight and effective bending stiffness in relation to axial stiffness.

The distribution of the tension forces between individual stay cables is of significant importance for the bridge girder alignment and the stress distribution in all bridge components. During the construction of cable-stayed bridges, the cable forces are measured to ensure the bridge meets the design assumptions. In the in-service condition of the bridge tension measurements may also be required due to changes occurring in the structure over time. Different methods to evaluate the tension of a bridge cable are available. They can be broadly classified into two main categories:

- Direct measurements: Lift-off method, pre-installed load cells, strain gauges,
- Indirect measurements: vibration-based methods, other methods.

During construction, direct measurements are often used as these employ hydraulic jacks, which are used for the stressing of cables as part of the construction process. On a bridge in-service a lift-off test is particularly expensive and time-consuming and repeated tests may lead to damage in the sensitive wedge region.

As alternative, indirect measurements such as the vibration-based methods can be used to estimate the cable forces by exploiting the nonlinear relationship between cable force and natural frequencies of vibration. The stays are excited manually or by ambient sources and the acceleration time histories are recorded by sensors, typically accelerometers, mounted to the cable. Vibration characteristics can also be determined by contactless measurement. Natural frequencies can be obtained by transferring the measured signal into the frequency domain. This method is widely used in engineering practice due to its speediness and simplicity.

The estimation of cable forces on site requires simple and reliable methods that compromise the accuracy as little as possible. The lighter and more portable a measurement system is, the more simple the data acquisition and data processing become. This paper studies different modern vibration measurement systems based on mass-market components such as MEMS-based (microelectromechanical systems) acceleration sensors, microcomputers and

smartphones. Two possible configurations are presented and the properties and limitations of the technologies are studied.

Validation measurements performed on stay cables of Queensferry Crossing are described and evaluated. It is shown that such highly mobile and cost-effective systems have significant potential for stay cable applications if their limitations are considered.

2 STATE OF THE ART

2.1 *Condition Monitoring with Smartphones*

Modern smartphones and tablets are equipped with significant computational resources, large memory capacity and feature capable sensor components, which can be used for structural health monitoring purposes (Morgenthal & Höpfner 2012). These typically utilize the MEMS-based accelerometer of such systems to record structural vibrations in order to determine the dynamic system properties of the structure. In contrast to traditional monitoring systems that are composed of several individual hardware components, smartphones and tablets can integrate the recording, storage, processing, transfer and visualization of data within one single device.

Software implementations for measurements and data processing exist for most common operating systems (OS) such as Android (Gibbs et al. 2014) or iOS (Zhao et al. 2015, Yu et al. 2015). Since these software solutions are limited by the OS or the capabilities of the hardware components of the device, external sensors are additionally used for data acquisition. These external sensors can be connected directly to the smartphone or by means of a microcontroller, where the mobile device will solely act as central reader, processing and controller unit (Morgenthal 2012, Yu et al. 2015).

Fundamental characteristics of sensors integrated in smartphones, such as range, achievable resolution and maximum sampling rate were investigated in (Morgenthal & Hallermann 2013). Several of these studies found that the data obtained through smartphone applications may differ significantly from the sensor capabilities according to vendor datasheets as the OS exercises control over e.g. data rate and sensor operation modes. Therefrom, the motivation arises to connect external sensors to avoid these limitations.

The monitoring of infrastructures such as bridges has been promoted as a major application field of smartphone-based measurement systems. By utilizing a mobile measurement system Gibbs 2014 investigated the dynamic behavior of suspension bridges in developing countries. The internal cable force was determined by simplified formulae neglecting flexural rigidity and sag effects by vibration measurements on stay cables or hangers of suspension bridges (Yu et al. 2015, Zhao et al. 2015). By the same method, the tension of external tendons on a highway bridge was obtained (Morgenthal & Hallermann 2013).

With an increased adoption of mobile devices for vibration measurements there appears to be a genuine need to study the relationship between data quality obtained and the specific applications systematically. Devices such as smartphones use an enormous range of different sensors and a large spectrum of sensor properties results, imposing different kinds of limitations on accuracy of measurements.

2.2 *Vibration-Based Cable Force Measurement*

Several vibration measurements at cable-supported bridges have been conducted in the past. Cunha & Caetano 2001 reported an extensive dynamic test on the Vasco da Gama cable-stayed bridge. Vibration measurements also included the stay cables, where an accelerometer and a laser interferometry system were utilized. Smartphones were used in cable force determination for stays by Chen & Yan Chen 2013 to extract the tension force based on the fundamental frequency, thereby a good agreement to the results from a reference accelerometer with a relative error of less than 5% was achieved. An iOS application is introduced in Zhao et al. 2015, which was used to investigate the cable forces of the hanger of a suspension bridge.

3 MECHANICAL BEHAVIOR OF STAY CABLES

Vibration-based cable force determination is based on the relationship between force and frequencies which results from the cable's nonlinear mechanical behavior. The main methods to describe this behavior are presented here.

3.1 *Cable Properties*

Figure 1 shows an inclined cable stayed between the two anchorage points A and B. The horizontal and vertical distance between A and B defines the chord length L_c and the inclination of the undeformed cable α. Under the effect of mass m_c a sag due to the action of gravity d_v occurs. The effect of geometric nonlinearity of the cable ensures that even in the theoretical case of a cable with only axial stiffness EA (no bending stiffness EI) the member achieves an equilibrium through the axial force and the sag. Note that due to gravity the tension force T of an inclined cable is larger at the upper than at the lower anchorage $T_1 > T_2$. However, for short cables the anchorage forces might be affected by the end conditions (fixed or hinged).

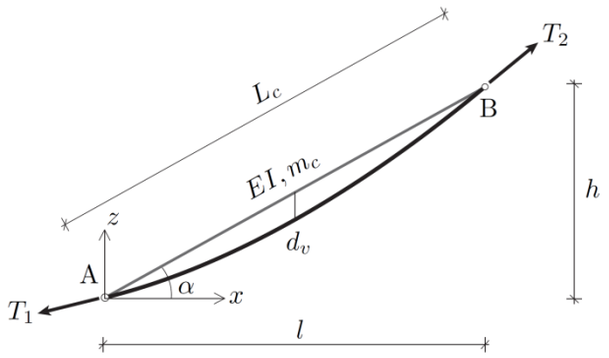

Figure 1. Inclined cable with the geometrical and mechanical properties.

Stay cables are prone to mechanical vibrations due to a very low bending stiffness and low inherent damping. The oscillations of the cables can be characterized in terms of their mode shapes and their corresponding natural frequencies.

3.2 *Simplified Taut String (TS)*

The linear theory of cable vibrations, which was first described in Irvine & Caughey1974, is based on three assumptions: (a) the cable is rigidly supported (b) the cable is shallow, i.e. the sag to span ratio d_v/L_c does not exceed 1/8 and (c) the cable deforms quasi-elastically.

The n-th natural frequency f_n for the in-plane vibration is based on the theory of a taut string, for which the relationship between cable force T and natural frequency f_n becomes

$$f_n = \frac{n}{2L_c}\sqrt{\frac{T}{m_c}} \qquad n = 1,2,3,\ldots \tag{1}$$

In literature different approaches considering the effects of sag and bending stiffness of a stay cable on the natural frequencies are presented. For a comprehensive review on the topic the reader is referred to Zui et al. 1996, Caetano 2007, Svensson 2004. The major challenge in the application of the above mentioned approaches is the definition of the bending stiffness EI. Besides the modulus of elasticity of the cable, the stiffness depends on the individual cable layout and composition, i.e. the cable system and its particular characteristics (Caetano 2007). The effective bending stiffness will depend on friction effects between individual cable components (wires and strands), which in turn may depend on the coating and the package density. The activated stiffness will depend on the curvature applied, i.e. the bending effect will be nonlinear and may differ between different cables of the same system. It is hence a property associated with relatively large uncertainty.

3.3 *Nonlinear Numerical Analysis of Cables (NL)*

The work in this paper is based on numerical simulations rather than any of the simplified approaches presented before. When the large-displacement geometrical nonlinearity of the cable under self-weight is taken into account and the vibration behavior computed on the basis of linearization at the static equilibrium, this yields accurate predictions of cable natural frequencies that can take all the relevant mechanical effects duly into account. Modal analysis is then performed using the effective linearized stiffness at the equilibrium condition. The static equilibrium is obtained from a geometrically nonlinear analysis, where the nonlinear relationship between load and displacements is considered by employing 3rd order theory (Clough & Penzien 1975).

Applying the finite-element method, a bending-stiff cable is modelled with beam elements without considering shear deformation. The cable system is then subjected to gravity load where the mass is considered to be lumped at each node. For such case, a tangent-stiffness approach may be utilized. The nonlinear part in the equilibrium equation can be determined by Newton-Raphson method (Bathe 1996). The updated stiffness is then used in the modal analysis for frequency determination.

4 MEASUREMENT CONCEPT

4.1 *Hardware and Measurement System*

The application of sensor technology in the context of condition monitoring of structures has seen an enormous increase in the past years which is primarily due to continuous improvements of hardware components in terms of performance and price. Of particular interest to this paper are hardware components employed for vibration measurements herein are smartphones and mass market MEMS accelerometers as well as credit card sized battery operated microcomputers.

Smartphones that are currently in the market vary drastically in terms of their hardware components as well as software systems. Thereby, the different built-in sensors lead to vastly different measurement properties. Differences in accelerometers and the sensor driver software configuration of the operating system lead to significant differences in the maximum possible sampling rate $f_{s,max}$, the measurement range R and the sensor resolution as well as the regularity of sampling points (equidistant sampling). Consequently, significant differences in the measurement quality will be obtained.

An investigation on the performance of several smartphones has been conducted by the authors. A comparison in terms of computational power, measurement range, sampling rate and resolution is given in Morgenthal et al. 2017. Modern smartphones offer sampling rates up to 200 Hz, resolve accelerations down to 1 – 4 mm/s² while possessing a range of ±2g to ±16g.

The specific sensor performance achieved by applications will be influenced by decisions that the smartphone developer makes at driver level and thus may vary drastically (towards lower performance) from the maximum performance of the sensor due to e.g. considerations for energy consumption. To remove the restriction imposed by the single built-in sensor and yet make use of the convenient form factor, powerful processing, storage and data communication as well as the rich and interactive user experiences possible on modern smartphones and tablets, a method for connecting external sensors has been developed. This is based on an Android application that communicates with an external single board computer called Raspberry Pi (RPi) to utilize external sensors connected to that. The connection, briefly described in the following section, ensures the transfer of data recordings from high quality sensors to the smartphone, where the data can be analysed and stored such that the smartphone remains the central control unit.

Besides the smartphone (4), the alternative measurement system, shown in Figure 2, comprises the RPi micro-computer (1), one or several external sensors (2), the sensor connection cable (3) and a battery power supply (5). For the attachment of the sensor at the stay cable, the external sensor is mounted to a U-shaped aluminum profile (2), which is then applied to the stay by means of a tension belt (6).

In general, different types of sensors can be integrated in the measurement system. However, for the system used herein a low-cost sensor is applied. The MPU6050 is a digital MEMS-based accelerometer with 16 bit signal conversion (Invensense 2013) and the smallest possible range R is set ($\pm$2g) to ensure the highest possible resolution.

4.2 *Smartphone Application*

To facilitate smartphone-based measurements, an Android application (App) was developed by the authors. The application provides a framework for the collection of building related information for inspection purposes. As such, besides the measurement tasks discussed here, it provides a database to store items of various data types such as photos, videos, images and notes (see Figure 3 left). All data is generated on the smartphone itself, utilizing the onboard hardware components.

For vibration measurements the sampling rate, sensing axes, duration can be configured. The recorded time histories are saved to the persistent internal storage of the device. Furthermore, the application features an extensive analysis tool including visualization of the signals and post-processing tools. For a selected axis and a user-defined time window, a Fast Fourier Transform (FFT) can be performed and the frequency content of the record is displayed (see Figure 3 right).

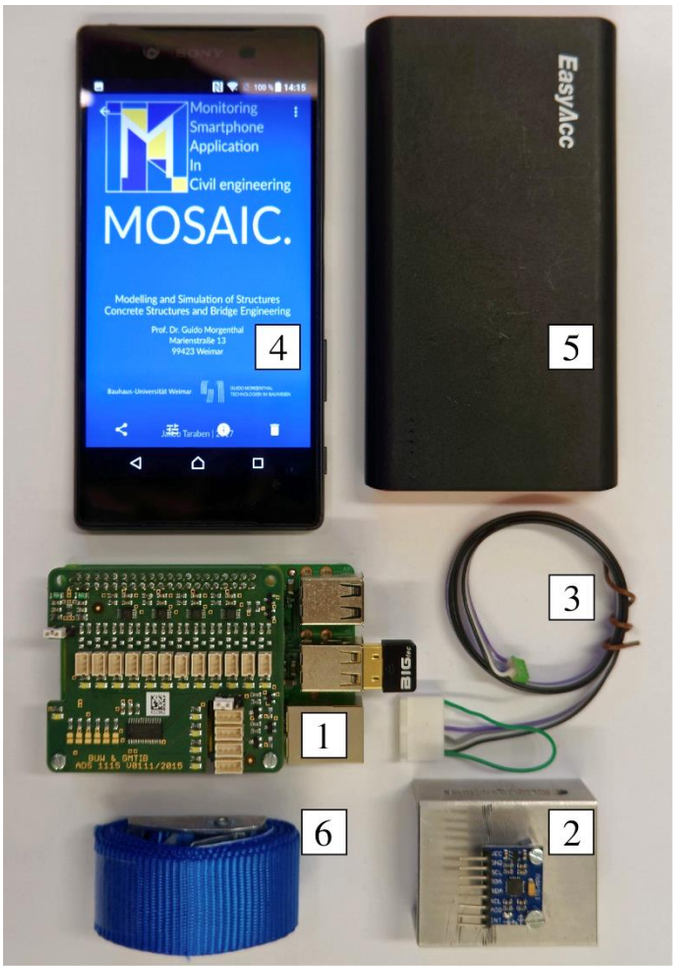

Figure 2: Hardware components of the smartphone-based measurement system.

Furthermore, an extension for the determination of cable forces is implemented. If the specific cable properties such as chord length L_c, mass per unit length m_c and angle α are provided either by data import or manually and a corresponding mode number is assigned to a prominent peak in the spectrum, the cable force is computed based on the simplified taut string approach. Any analysis steps are graphically supported, intuitive to use and fully suitable for processing on the smartphone to facilitate an effective in-situ evaluation.

The nonlinear numerical analyses discussed in this paper can be employed to save pre-calculated force-frequency relationships for each cable on the smartphone, which the App can then use to perform the tension force identification by interpolated lookup from this data.

The proposed approach and its implementation therefore constitutes an extension of previous studies such as (Yu 2015) which were limited to a spectral analysis of measured acceleration time histories and such as (Zhao 2015, Chen & Yan 2013) which were limited to a spectral analysis of measured acceleration time histories and such as (Zhao et al. 2015, Chen & Yan 2013) which were limited to simplified methods of cable force determination. The method presented here constitutes a complete framework for the sensor data acquisition and the advanced tension

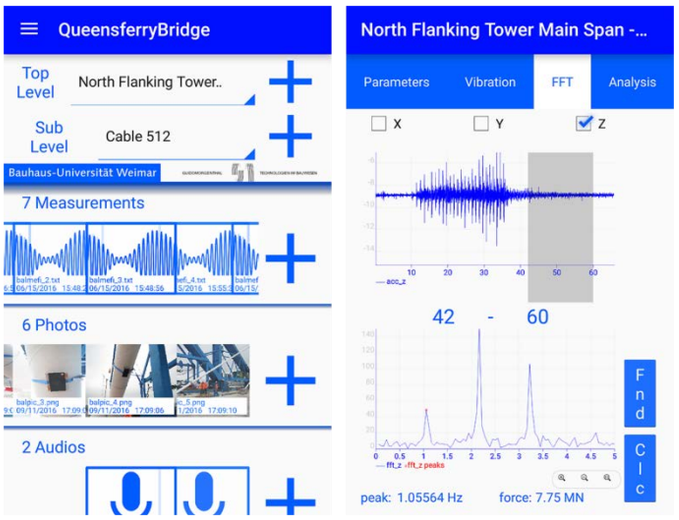

Figure 3. Screenshot of the user interface of the Android application. Various types of collected data (left) and visualization of the recorded time history and the frequency spectrum as computed for a selected time window (right).

force identification. The storage of cable properties including force-frequency relationships from nonlinear analysis allows for tension force identifications on the basis of the most advanced mechanical model available. The quality of such process is then only limited by the technical limitations of the sensors as will be studied in section 5.

4.3 *Interfaces of the Measurement System*

Within the App the user can establish a wireless network connection between smartphone and RPi, upon which the two devices will open a Websocket connection. The WebSocket protocol is commonly used for bidirectional network communication and data transfer.

A configuration file with the defined measurement settings for the sensor interface framework is sent to the RPi to trigger the measurement. After completing a measurement, the data is stored on the memory card of the RPi and is downloaded by the smartphone. The analysis tool of the App adapts data of external measurements in order to obtain further results immediately.

Further details about the hardware, the smartphone application developed and the interfaces used are provided in Morgenthal et al. 2017.

5 REFERENCE STUDY: QUEENSFERRY CROSSING CABLES

5.1 *Queensferry Crossing Project*

The Queensferry Crossing (QFC) is a new major bridge link over the Firth of Forth in the North of Edinburgh opened in august 2017. The three-tower cable-stayed bridge features two main spans of 650 m length each and side spans of 366 m total length on either side. There is a total of 144 stay cables in each of the two cable planes. A schematic of the cantilever construction stage of the bridge is shown in Figure 4.

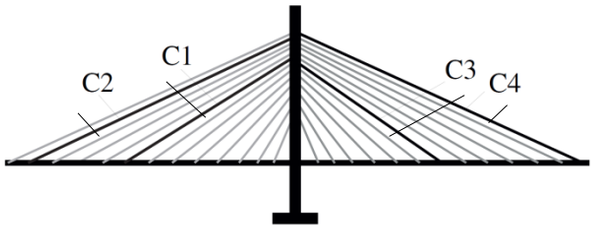

Figure 4. Schematic of the construction stage with indication of stay cables.

Table 1. Properties of the stay cables with corresponding reference cable force T_{ref}.

Stay cable		C1	C2	C3	C4
L_c	[m]	231.109	324.005	204.055	342.981
α	[°]	29.3	22.4	34.0	22.9
m_c	[kg/m]	131.6	134.2	112.5	116.4
EI_{min}	[kNm²]	55	56	48	49
EI_{max}	[kNm²]	14,452	14,760	7,589	7,867
T_{ref}	[MN]	8.11	12.22	6.50	9.63
Method		Lift-off	Vibration	Vibration	Lift-off

The measurements reported in this paper have been conducted on the bridge during its cable-stayed deck construction in summer 2016. Cable forces were available from different tests performed after stay cable installation to ensure the correct structural state. These reference forces are used to validate the cable forces determined by the presented measurement system. It is to be noted that lift-off tests were conducted at the upper stay anchorage and therefore cable forces studied here are reported for the upper end exclusively. Since the cable forces of inclined cable differ between the two ends, only nonlinear cable modelling can account for this effect.

5.2 *Vibration Measurements on Stay Cables*

In this section, the application of the alternative measurement system is described along with comparisons made to measurements from traditional setups. The cable forces had been measured by actual lift-off test and determined by natural frequencies obtained from vibration tests using standard high-quality sensor and data logger hardware. Two smartphones with different sensor characteristics are chosen for the on-site measurements, as shown in Table 2.

The built-in sensors coincide in their range R and differ in their smallest resolvable acceleration Δa and the maximum sampling rate $f_{s,max}$. The more recent Xperia Z5 enables a higher sampling rate than the Nexus 4, while the resolution of the acceleration is much lower. Further, the setup with RPi and the MPU6050 sensor is performed. All accelerometers

used sense motion in three axes. In comparison with the smartphone systems, the RPi setup offers more than double the sampling rate. The measurements of the smartphones were configured with a sampling rate f_s that is slightly smaller than the maximum sampling rate $f_{s,max}$ in order to assure a stable measurement. All measurements were triggered and evaluated using the presented Android application.

Table 2. Summary of sensor parameter for built-in and external accelerometer (External Sensor = MPU6050).

Device	R [g]	Δa [mm/s^2]	Noise (RMS) [mm/s^2]	$f_{s,max}$ [Hz]
Sony Xperia Z5	±2	4	40	225
Nexus 4	±2	1	35	200
External Sensor	±2	1	49	560

The vibration measurements were conducted on four different stay cables during erection of the bridge. The tested stay cables C1 to C4 are indicated in Figure 4 and Table 2 provides their geometrical and mechanical properties together with the reference cable force T_{ref} which was obtained by either lift-off or vibration method as indicated. Here, the minimum second moment of area I_{min} is computed as the sum of the second moments of area of the individual strands, which corresponds to a perfect slip possible between the individual strands and is the minimum stiffness physically possible. The maximum possible second moment of area I_{max} is calculated using an effective area of the cable which is based on the area of steel with respect to the total area of the section and thus assumes a full shear connection between all strands in the bundle. This represents an upper bound of the possible bending stiffness but is considered to be a strong overestimation of the actual bundle behavior due to slip effects between strands (Svensson 2012, Caetano 2007).

The smartphone and the external sensor were attached to the stay cable by means of a U-shaped aluminium profile and a tension belt. Both devices were placed close to the lower anchorage of the cable at a height of approximately 2.0 m from the deck. The distance of the attached devices from the cable anchorage was approximately 7 m, i.e. between 2 and 3.5% of the cable length. The cable was free to vibrate with no cable dampers or guide tube fixings installed.

5.3 *Test 1: Comparison of Sensor Systems*

In a first test the cable C1 was excited near the lower anchorage point by periodic manual pulling in order to excite the cable into significant vibrations. The measurements were conducted using one smartphone (Sony Xperia Z5) as well as the RPi with the external sensor (MPU6050). Only the accelerations after the excitation, i.e. with the cable in free vibration, were analysed. It should be noted that it proved difficult to excite the cable properly with the force introduced near the lower cable end.

Sample time histories of the measured accelerations of the built-in and the external sensor, obtained from two different excitations, are displayed in Figure 5 with the corresponding frequency spectra. The natural frequencies of the stay cables were determined by identifying the peaks in the frequency spectra, whereby the measurements with a duration of 20 and 60 seconds result in a frequency resolution of 0.05 Hz and 0.017 Hz, respectively.

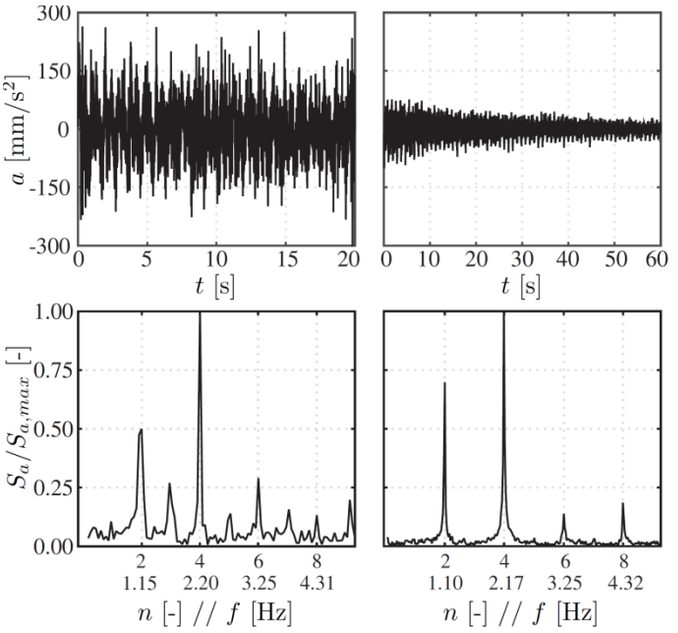

Figure 5. Sample time histories (top) and frequency spectra (bottom) for different manual excitations at cable C1: high excitation, smartphone Xperia Z5 (left); low excitation, external sensor MPU6050. (Note: Average sampling rates f_s^{SP} = 215 Hz, f_s^{MPU} = 550 Hz)

Table 3. Comparison of the identified natural frequencies obtained by measurement with smartphone (SP, high excitation) and external accelerometer (MPU, low excitation).

n		2	4	6	8
f_n^{SP}	[Hz]	1.15	2.20	3.25	4.31
f_n^{MPU}	[Hz]	1.10	2.17	3.25	4.32
f_n^{SP}/f_n^{MPU}	[-]	1.045	1.014	1.000	0.998

For both measurements the natural frequencies f_n identified are given in Table 3. The MPU6050 was tested for relatively small excitation amplitudes and it was found that these revealed only the anti-symmetric modes (n = 2, 4, ...) clearly. The smartphone was subjected to greater amplitudes and the data provided also the natural frequencies corresponding to symmetric modes. The superiority of the MPU sensor in terms of acceleration resolution Δa and noise can be seen in the spectrum with more distinct peaks and a much smaller noise floor. With manual excitations, typically the lower natural frequencies were found with the second to the fourth

mode being most prominent. The fundamental frequency was barely or not at all identifiable in both measurements, which can be attributed to the measurement location and the mode shape, i.e. the contribution of the first modes is relatively small near the anchorage point. The frequencies that could be identified in both systems agree very well with differences in higher modes typically being within 1%.

5.4 *Test 2: Influence of the Excitation*

Further measurements applying only a smartphone were conducted with and without manual excitation at cable C2. The Nexus 4 smartphone is utilized in order to achieve a higher signal quality as it possesses a higher resolution than the Sony Xperia Z5 (see Table 2). The influence of the excitation is investigated with manual excitations compared to ambient vibrations predominantly induced by wind. Thereby, it was seen that more natural frequencies were identified when excited manually, however also the frequencies determined under ambient vibration are in good agreement with reference values.

In a further step, the frequencies identified from the manually excited cable using the Nexus 4 smartphone, were converted into cable forces using a nonlinear numerical model. The cable properties from Table 1 were used to model the cable and determine the force-frequencies relationships for the minimum and maximum bending stiffness. This nonlinear function was then used to predict cable forces T_{meas} for each of the identified natural frequencies.

This procedure was also applied to the frequencies of the reference vibration measurement system and both compared in terms of the corresponding forces. The results, shown in Figure 6, underline the excellent agreement of the frequencies now in terms of the back-calculated tension forces. These are within 1% throughout and below 0.5% on average.

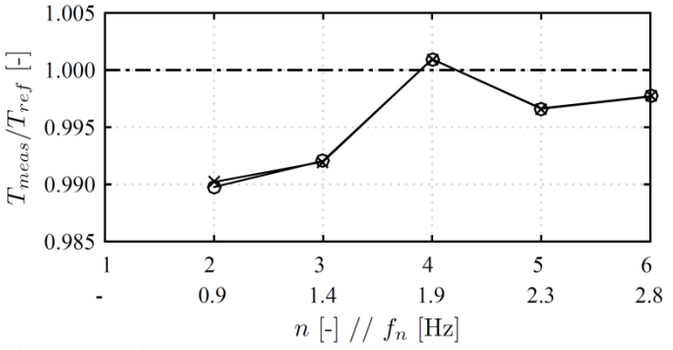

Figure 6. Cable forces T_{meas} determined from nonlinear cable modelling for frequencies of cable C2 measured with smartphone Nexus 4. Forces are shown relative to the cable force T_{ref} determined from reference vibration test.
—o— EI_{min}; —x— EI_{max}

5.5 *Test 3: Application Case of External Sensor under Ambient Vibrations*

A manual excitation of the cable represents an additional effort and only the best smartphones can detect ambient vibrations accurately. Therefore, the measurement setup with the smartphone as control unit and the external MPU sensor attached to the RPi as a measurement device is presented here as a robust and reliable test system, which features both: sufficiently high resolution and sampling rates for the validation under ambient vibrations.

Two different measurements were conducted, specifically on the shortest (C3) and longest cable (C4). The recordings are 30 seconds for cable C3 and 60 seconds for cable C4 which result in a frequency resolution of 0.033 Hz and 0.016 Hz, respectively. For both measurements, at least 10 natural frequencies have been identified. From the identified frequencies, the corresponding cable forces T_{meas} are computed based on the nonlinear numerical model for the assumed limits of the cable stiffness EI_{min} and EI_{max}. These cable forces are then compared with the reference cable forces T_{ref} from Table 1 in Figure 7.

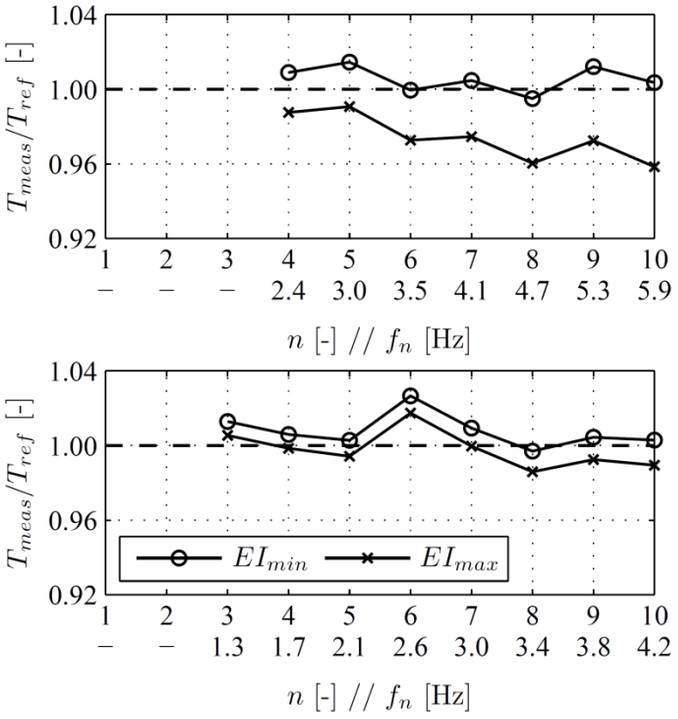

Figure 7. Predicted cable forces T_{meas} for cable C3 (a) and C4 (b) determined from measurements taken by external sensor MPU6050 under ambient vibrations.

The comparison for cable C3 needs to be interpreted considering the fact that the reference cable force had been supplied by a third party operating the standard vibration measurement system. It is not known to the authors how this force was computed from the (unknown) frequencies identified, but it is believed that it represents an average of the forces computed from applying the taut string relationship. As such, the comparison with the similar assumption of a low bending stiffness is very good and within

1% on average. The differences in prediction using the maximum bending stiffness successively increase by mode number. This represents the error introduced by assuming a bending stiffness too high.

The error of the maximum bending stiffness model can also be clearly seen for cable C4, where it is less pronounced because of the longer cable length. Again a very good agreement between the identified cable forces and the reference cable forces under consideration of the minimum bending stiffness can be seen while the mean error is around 1%.

When it is considered that this reference force in itself has a margin of possible error of 1% this shows that the sensor system proposed here can reliably measure cable forces. There is a tendency for the computed cable forces to be slightly on the high side, which may be the effect of using the minimum possible bending stiffness versus the real one. It is obvious that the real effective stiffness is impossible to quantify exactly because of many physical effects being at play, however it is slightly larger than EI_{min}.

6 CONCLUSIONS

This paper has investigated the application of mobile measurement systems to the determination of stay cable forces. The main aspects are the presentation of a coherent smartphone-based software framework, the incorporation of nonlinear Finite Element analyses into the identification process and studies into the effect that measurement data quality has on the identified forces.

Herein, the force-frequency relationship required for the cable force identification is based upon nonlinear Finite Element analyses for accurate representation of effects such as bending stiffness.

With the acceleration time-history characteristics being strongly dependent on properties of the individual systems, namely sensor type, hardware setup and limitations imposed by the smartphone OS, the paper systematically studies the data quality with respect to the identification of cable frequencies. It is found, that limitations of sensor resolution and the type of excitation are critical parameters determining the quality and reliability of the identification process. Reference measurements undertaken on cables of the Queensferry Crossing bridge could be used for force comparisons.

Whilst the microcontroller-based system and one specific smartphone system could identify frequencies sufficiently accurately even under ambient wind excitations, most smartphones require manual cable excitations for a robust identification. This is because the sensors attached near the lower cable end are subjected to small vibration amplitudes only. The external sensor connected to the microcontroller (RPi) and the smartphone acting as control unit provides reliable, highly accurate force measurements.

Beyond the smartphone or tablet the hardware costs are less than 100 USD and therefore the authors are convinced that such technology will find an important place in future simple measurement workflows. Further studies should be conducted into quantifying the statistical measurement uncertainties arising from sensor and system properties in order to be able to support hardware selection.

Estimation of bridge frequencies from a passing vehicle

N. Jin, T. S. Paraskeva & E. G. Dimitrakopoulos
Department of Civil and Environmental Engineering, Hong Kong University of Science and Technology, Hong Kong

ABSTRACT: Extracting the bridge dynamic properties from a moving vehicle is a promising solution to the ever-increasing demand for monitoring of bridges. A traversing vehicle excites the bridge, while the vibrating bridge affects the response of the vehicle. By processing the "monitored" vehicle response, the dynamic characteristics of the bridge can be efficiently extracted. In this paper, the stochastic subspace identification (SSI) method is applied to the vehicle response to estimate the frequencies of the bridge. Specifically, the present study assesses the accuracy and the effectiveness of the SSI method that is used to identify the frequencies of a straight reinforced concrete bridge, from the response of a passing vehicle. As a proof of concept, the response of the vehicle is first estimated from a vehicle-bridge interaction dynamic analysis. The bridge frequencies are then identified with the proposed SSI method assuming the dynamic characteristics of the vehicle and its motion are known. The results of the identification are validated against the theoretically correct values from the numerical analysis, and conclusions regarding the feasibility of the method are drawn.

1 INTRODUCTION

The frequency of vibration is one of the most important modal parameters of the bridge, and is frequently used as an index in the bridge health monitoring and the damage detection. Traditionally, the bridge frequencies are estimated by multiple sensors installed along the bridge. By processing the data obtained from the vibrating bridge, one can extract information regarding the dynamic properties of the bridge. Depending on the source of the excitation, the on-site experiments mainly include ambient vibration tests (Siringoringo & Fujino 2008), human excitation tests (Au et al 2005), impact excitation tests (Huang et al 1999), on-going traffic tests (Conner et al 1997), and tests that use the wind load as excitation for the bridge (Goi & Kim 2016) etc. However, the identification techniques based on the on-site instrumentation, can be very expensive, time-consuming, and sometimes dangerous, depending of the location and the type of the examined bridge (Yang et al 2004).

Recently, indirect techniques of extracting the bridge dynamic properties from the passing vehicles have attracted the interest of many researchers (Yang & Yang 2017). Compared with the traditional identification methods, this approach appears more cost-effective, portable, time-saving and easier for application. The idea is that since the vehicle and the bridge form a coupled system, when the vehicle crosses the bridge the response of the vehicle is dominated by the dynamic properties of both the vehicle and the bridge. Thus, by processing the response of the vehicle, and suppressing the effect of the vehicle characteristics, one can identify the bridge frequencies (Yang et al 2004).

Yang & Chen (2015) developed an alternative method for extracting the bridge frequencies from the response of the passing vehicles, using a modified Stochastic Subspace Identification (SSI) method. This paper, presents an application of the proposed approach in combination with a vehicle-bridge interaction (VBI) dynamic analysis, to extract the frequencies of a straight reinforced concrete bridge, using the vibration response of a passing "monitored" vehicle. As a proof of concept, the response of the vehicle is estimated from the VBI analysis, where the dynamic characteristics of the vehicle and its motion are known. The feasibility, the effectiveness and the accuracy of the modified SSI method is validated by comparing the results of the proposed identification method with the corresponding values obtained analytically from the modal analysis of the bridge.

2 METHODOLOGY

2.1 *Brief introduction to the Stochastic subspace identification method*

The Stochastic Subspace Identification (SSI) method is one of the most popular methods for identifying the dynamic properties of linear time-invariant (LTI) systems (Van Overschee & De Moor 1996, Katayama 2006).

A time-discrete LTI system with input and output signals and disturbance can be described by

$$\begin{aligned}\mathbf{X}_{k+1} &= \mathbf{A}\mathbf{X}_k + \mathbf{G}\mathbf{U}_k + \mathbf{w}_k \\ \mathbf{Y}_k &= \mathbf{C}\mathbf{X}_k + \mathbf{H}\mathbf{U}_k + \mathbf{v}_k\end{aligned} \quad (1)$$

where $\mathbf{X}_k$ is the state vector; $\mathbf{U}_k$ is the input vector; $\mathbf{Y}_k$ is the output vector; **A**, **C**, **G** and **H** denote the system matrices which are constant and time-invariant; $\mathbf{w}_k$ is the system noise; and $\mathbf{v}_k$ is the measurement noise. If there is not an input signal the system can be described as

$$\begin{aligned}\mathbf{X}_{k+1} &= \mathbf{A}\mathbf{X}_k + \mathbf{w}_k \\ \mathbf{Y}_k &= \mathbf{C}\mathbf{X}_k + \mathbf{v}_k\end{aligned} \quad (2)$$

This study uses Eq. (2) to describe the response of the coupled vehicle-bridge interaction system and applies the SSI to the response of a passing vehicle to estimate the bridge frequencies. A prerequisite for the proposed method is the transformation of the time-variant equations of the VBI system into discrete time-invariant state space format.

2.2 *Vehicle-bridge interaction model*

The present study examines a straight reinforced concrete bridge (Fig 1a) and uses a three-axle truck tractor with a trailer (Fig 1b) (Paraskeva et al 2017).

The equation of motion of the coupled VBI system is

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) + \mathbf{C}\dot{\mathbf{u}}(t) - \mathbf{W}_N(t)\boldsymbol{\lambda}_N(t) = \mathbf{0} \quad (3)$$

where **M**, **K**, and **C** are the mass matrix, the stiffness matrix and the damping matrix, respectively, all created by assembling the pertinent matrices of the two individual subsystems (i.e. the vehicle subsystem and the bridge subsystem). Similarly, **u**(t) includes the displacements of the vehicle and the bridge. $\mathbf{W}_N(t)$ is the direction matrix of the contact forces between the vehicle and the bridge. $\boldsymbol{\lambda}_N(t)$ is the contact force vector, (Fig 1d), described as

$$\boldsymbol{\lambda}_N = \mathbf{K}_c\left(-\mathbf{W}_N(t)^T\mathbf{u}(t) + \mathbf{r}_c(t)\right) - \mathbf{C}_c\mathbf{W}_N(t)^T\dot{\mathbf{u}}(t) \quad (4)$$

where $\mathbf{K}_c$ and $\mathbf{C}_c$ are the tire stiffness and damping coefficients, respectively; $\mathbf{r}_c(t)$ denotes the road roughness condition which is assumed to be a zero-mean stationary Gaussian random process. Further information regarding the simulation of the coupled VBI system, as well as the VBI analysis conducted herein, can be found in detail, in Paraskeva et al (2017)

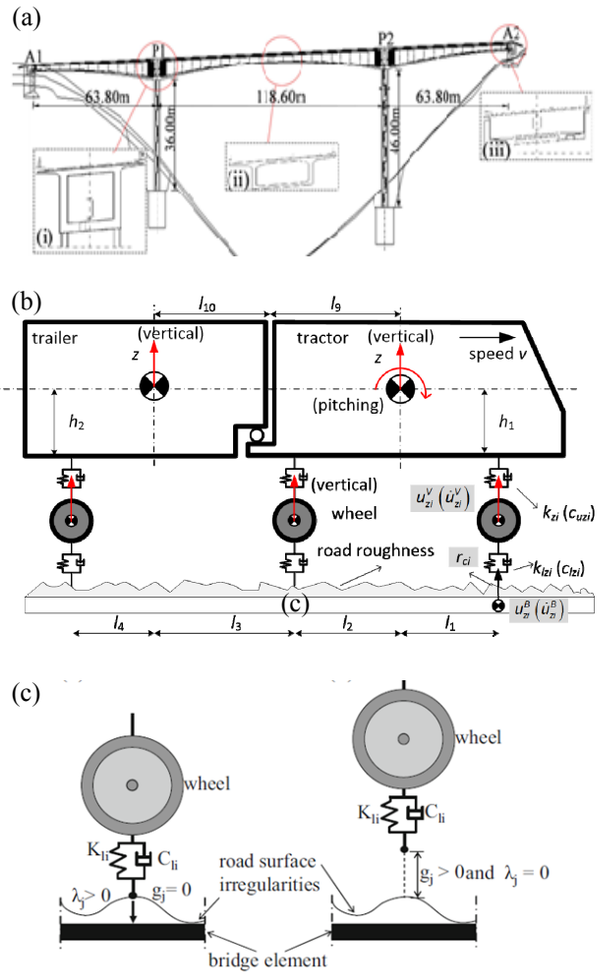

Figure 1. (a) The bridge model, (b) the vehicle model, (c) the contact model.

2.3 *Formulation of the VBI problem in discrete time-invariant state space form*

This section presents the transformation of the equations of motion of the coupled vehicle-bridge system, into (a) state space, and (b) a discrete time-invariant form.

The equation of motion for the bridge is

$$\mathbf{M}^B\ddot{\mathbf{u}}^B(t) + \mathbf{K}^B\mathbf{u}^B(t) + \mathbf{C}^B\dot{\mathbf{u}}^B(t) + \mathbf{W}_N^B(t)\boldsymbol{\lambda}_N(t) = \mathbf{0} \quad (5)$$

Substituting Eq.(4) to Eq.(5), the equation of motion for the bridge can be written in the state space as

$$\begin{aligned}\dot{\mathbf{X}}^B(t) = {} & \mathbf{N}_c^B\mathbf{X}^B(t) + \mathbf{N}^{BB}(t)\mathbf{X}^B(t) \\ & + \mathbf{N}^{BV}(t)\mathbf{X}^V(t) + \mathbf{N}^{RB}(t)\mathbf{R}(t)\end{aligned} \quad (6)$$

where

$$\mathbf{X}^{\mathrm{B}}(t)=\begin{Bmatrix}\mathbf{u}^{\mathrm{B}}(t)\\ \dot{\mathbf{u}}^{\mathrm{B}}(t)\end{Bmatrix}\in R^{2n\times 1} \tag{7}$$

$$\mathbf{X}^{\mathrm{V}}(t)=\begin{Bmatrix}\mathbf{u}^{\mathrm{V}}(t)\\ \dot{\mathbf{u}}^{\mathrm{V}}(t)\end{Bmatrix}\in R^{2m\times 1} \tag{8}$$

$$\mathbf{N}_c^{\mathrm{B}}=\begin{bmatrix}\mathbf{0} & \mathbf{I}\\ -\left(\mathbf{M}^{\mathrm{B}}\right)^{-1}\mathbf{K}^{\mathrm{B}} & -\left(\mathbf{M}^{\mathrm{B}}\right)^{-1}\mathbf{C}^{\mathrm{B}}\end{bmatrix}\in R^{2n\times 2n} \tag{9}$$

$$\mathbf{N}^{\mathrm{BB}}(t)=\begin{bmatrix}\mathbf{0} & \mathbf{I}\\ -\left(\mathbf{M}^{\mathrm{B}}\right)^{-1}\mathbf{L}_{\mathrm{K}}^{\mathrm{BB}}(t) & -\left(\mathbf{M}^{\mathrm{B}}\right)^{-1}\mathbf{L}_{\mathrm{C}}^{\mathrm{BB}}(t)\end{bmatrix}\in R^{2n\times 2n} \tag{10}$$

$$\mathbf{N}^{\mathrm{BV}}(t)=\begin{bmatrix}\mathbf{0} & \mathbf{0}\\ \left(\mathbf{M}^{\mathrm{B}}\right)^{-1}\mathbf{L}_{\mathrm{K}}^{\mathrm{BV}}(t) & \left(\mathbf{M}^{\mathrm{B}}\right)^{-1}\mathbf{L}_{\mathrm{C}}^{\mathrm{BV}}(t)\end{bmatrix}\in R^{2n\times 2\mathrm{m}} \tag{11}$$

$$\mathbf{N}^{\mathrm{RB}}(t)=\begin{bmatrix}\mathbf{0} & \mathbf{0}\\ -\left(\mathbf{M}^{\mathrm{B}}\right)^{-1}\mathbf{W}_{\mathrm{N}}^{\mathrm{B}}(t)\mathbf{K}_c & \mathbf{0}\end{bmatrix}\in R^{2n\times 2r} \tag{12}$$

$$\mathbf{R}(t)=\begin{Bmatrix}\mathbf{r}_c(t)\\ \dot{\mathbf{r}}_c(t)\end{Bmatrix}\in R^{2r\times 1} \tag{13}$$

n is the DOF of the bridge, m is the DOF of the vehicle, and r is the number of wheels; the superscripts "V" and "B" denote the vehicle and the bridge subsystems, respectively; $(\mathbf{L}_{\mathrm{K}}^{\mathrm{BB}}(t))_{ii}$ and $(\mathbf{L}_{\mathrm{C}}^{\mathrm{BB}}(t))_{ii}$ are diagonal matrices representing the stiffness and damping coefficients of the contact force applied on the i$^{\mathrm{th}}$ dof of the bridge, respectively; $\mathbf{L}_{\mathrm{K}}^{\mathrm{BV}}(t)$ and $\mathbf{L}_{\mathrm{C}}^{\mathrm{BV}}(t)$ denote the stiffness and damping coefficient of the contact force between the i$^{\mathrm{th}}$ dof of the bridge and j$^{\mathrm{th}}$ wheel axle of the vehicle, respectively. By definition, the matrix $\mathbf{N}_c^{\mathrm{B}}$ is the bridge system matrix in time-continuous form, which is time-invariant; $\mathbf{N}^{\mathrm{BB}}(t)$ and $\mathbf{N}^{\mathrm{BV}}(t)$ are related to the position and magnitude of the contact force between the wheels and the bridge; $\mathbf{N}^{\mathrm{RB}}(t)$ is related to the road roughness condition. Under the assumption that the external forces are considered as noise, they can be replaced by a stochastic process $\mathbf{w}(t)$. Therefore, Eq.(6) is written as

$$\dot{\mathbf{X}}^{\mathrm{B}}(t)=\mathbf{N}_c^{\mathrm{B}}\mathbf{X}^{\mathrm{B}}(t)+\mathbf{w}(t) \tag{14}$$

Similarly, the equation of motion for the vehicle in state space form is re written as

$$\begin{aligned}\dot{\mathbf{X}}^{\mathrm{V}}(t)=&\left(\mathbf{N}_c^{\mathrm{V}}+\mathbf{N}_c^{\mathrm{VV}}\right)\mathbf{X}^{\mathrm{V}}(t)\\ &+\mathbf{N}^{\mathrm{VB}}(t)\mathbf{X}^{\mathrm{B}}(t)+\mathbf{N}^{\mathrm{RV}}\mathbf{R}(t)\end{aligned} \tag{15}$$

where $\mathbf{N}_c^{\mathrm{V}}$ is the vehicle system matrix; $\mathbf{N}_c^{\mathrm{VV}}$ and $\mathbf{N}^{\mathrm{VB}}(t)$ are related to the contact forces between the wheels and the bridge; and $\mathbf{N}^{\mathrm{RV}}$ is the road roughness related term. Note that the matrices $\mathbf{N}_c^{\mathrm{V}}$, $\mathbf{N}_c^{\mathrm{VV}}$ and $\mathbf{N}^{\mathrm{RV}}$ are time-invariant.

The equation of the motion for the bridge can be converted to the time-discrete form by multiplying an exponential matrix $\exp(-\mathbf{N}_c^{\mathrm{B}}t)$ on each side of Eq.(14). Then the equation can be transformed as

$$\mathbf{X}_{k+1}^{\mathrm{B}}=\mathbf{N}^{\mathrm{B}}\mathbf{X}_k^{\mathrm{B}}+\mathbf{w}_k \tag{16}$$

where

$$\mathbf{N}^{\mathrm{B}}=\exp^{\mathbf{N}_c^{\mathrm{B}}\Delta t} \tag{17}$$

$$\mathbf{w}_k=\left(\mathbf{N}_{\mathrm{c}}^{\mathrm{B}}\right)^{-1}\left(\mathbf{N}^{\mathrm{B}}-\mathbf{I}\right)\mathbf{w}(k) \tag{18}$$

Applying the same procedure for the vehicle, Eq.(15) can be transformed to the time-discrete form as

$$\mathbf{X}_{k+1}^{\mathrm{V}}=\mathbf{N}^{\mathrm{V}}\mathbf{X}_k^{\mathrm{V}}+\mathbf{N}_k^{\mathrm{VB}}\mathbf{X}_k^{\mathrm{B}}+\mathbf{N}^{\mathrm{RV}}\mathbf{R}_k \tag{19}$$

where

$$\mathbf{N}^{\mathrm{V}}=\exp^{\left(\mathbf{N}_c^{\mathrm{V}}+\mathbf{N}_c^{\mathrm{VV}}\right)\Delta t} \tag{20}$$

$$\mathbf{N}_k^{\mathrm{VB}}=\left(\mathbf{N}_c^{\mathrm{V}}+\mathbf{N}_c^{\mathrm{VV}}\right)^{-1}\left(\mathbf{N}^{\mathrm{V}}-\mathbf{I}\right)\mathbf{N}^{\mathrm{VB}}(k) \tag{21}$$

$$\mathbf{N}^{\mathrm{RV}}=\left(\mathbf{N}_c^{\mathrm{V}}+\mathbf{N}_c^{\mathrm{VV}}\right)^{-1}\left(\mathbf{N}^{\mathrm{V}}-\mathbf{I}\right)\mathbf{N}^{\mathrm{RV}} \tag{22}$$

Since the response of the vehicle can be measured for all the time steps, Eq.(19) can be rewritten by separating the known parameters (i.e. those that are related to the vehicle properties) from the unknown parameters (i.e. those that are related to the bridge properties and road roughness condition) as

$$\mathbf{P}_k=\mathbf{N}_k^{\mathrm{VB}}\mathbf{X}_k^{\mathrm{B}}+\mathbf{N}^{\mathrm{RV}}\mathbf{R}_k \tag{23}$$

where

$$\mathbf{P}_k=\mathbf{X}_{k+1}^{\mathrm{V}}-\mathbf{N}^{\mathrm{V}}\mathbf{X}_k^{\mathrm{V}} \tag{24}$$

To apply the SSI method, the equations of the VBI system should be formulated in state space discrete time-invariant form (see Eq.(2)). It is obvious that Eq.(16) satisfies this requirement. However, in Eq.(23), even though the road roughness related term $\mathbf{N}^{\mathrm{RV}}\mathbf{R}_k$ can be regarded as noise, the matrix $\mathbf{N}_k^{\mathrm{VB}}$ is a time-variant matrix. To overcome this problem, we introduce the pseudoinverse matrix

$$\mathbf{M}^{\dagger}\mathbf{M}=\mathbf{I}\in R^{i\times j},\mathbf{M}\in R^{i\times j},i>j \tag{25}$$

Then the Eq.(23) is transformed to

$$\mathbf{Z}_k^{\mathrm{V}}=\mathbf{X}_k^{\mathrm{B}}+\mathbf{v}_k \tag{26}$$

where $\mathbf{Z}_k^{\mathrm{V}}$ is a known vector related to the vehicle response, and $\mathbf{v}_k$ is a random stochastic process.

$$\mathbf{Z}_k^{\mathrm{V}}=\left(\mathbf{N}_k^{\mathrm{VB}}\right)^{\dagger}\mathbf{P}_k \tag{27}$$

$$\mathbf{v}_k=\left(\mathbf{N}_k^{\mathrm{VB}}\right)^{\dagger}\mathbf{N}^{\mathrm{RV}}\mathbf{R}_k \tag{28}$$

Collectively, the equations of the coupled VBI system, in time-invariant state space form are

$$\begin{aligned}\mathbf{X}_{k+1}^{\mathrm{B}} &= \mathbf{N}^{\mathrm{B}}\mathbf{X}_{k}^{\mathrm{B}} + \mathbf{w}_k \\ \mathbf{Z}_{k}^{\mathrm{V}} &= \mathbf{X}_{k}^{\mathrm{B}} + \mathbf{v}_k\end{aligned} \tag{29}$$

which can be combined to the yield

$$\mathbf{Z}_{k}^{\mathrm{V}} = \left(\mathbf{N}^{\mathrm{B}}\right)^{k-1}\mathbf{X}_{1}^{\mathrm{B}} + \sum_{i=1}^{k-1}\left(\mathbf{N}^{\mathrm{B}}\right)^{k-i-1}\mathbf{w}_i + \mathbf{v}_k \tag{30}$$

2.4 *Stochastic subspace identification*

In discrete time, the response of the system can be represented by the data matrix

$$\mathbf{Z}^{\mathrm{V}} = \begin{bmatrix}\mathbf{Z}_1^{V} & \mathbf{Z}_2^{V} & \dots & \mathbf{Z}_q^{V}\end{bmatrix} \tag{31}$$

We define the block Hankel matrix $\mathbf{H}_{\mathbf{Z}}$ as

$$\mathbf{H}_{\mathbf{Z}} = \begin{bmatrix}\mathbf{Z}_1^{\mathrm{V}} & \cdots & \mathbf{Z}_j^{\mathrm{V}} \\ \vdots & \ddots & \vdots \\ \mathbf{Z}_{2s}^{\mathrm{V}} & \cdots & \mathbf{Z}_{2s+j-1}^{\mathrm{V}}\end{bmatrix} \in R^{4ns\times j} \tag{32}$$

where $2s$ is the number of the rows in the Hankel matrix; j is the number of the columns, and $q=2s+j-1$ is the total number of the data. To apply the SSI technique, the Hankel matrix $\mathbf{H}_Z$ is first divided into a "past" part $\mathbf{H}_{Z}^{p}$ and a "future" part $\mathbf{H}_{Z}^{f}$

$$\mathbf{H}_{\mathbf{Z}} = \begin{bmatrix}\mathbf{H}_{\mathbf{Z}}^{p} \\ \mathbf{H}_{\mathbf{Z}}^{f}\end{bmatrix} \tag{33}$$

where $\mathbf{\Gamma}_i$ is the observability matrix containing solely the bridge properties; $\bar{\mathbf{X}}^{p}$ and $\bar{\mathbf{X}}^{f}$ are the stochastic state vectors, composed of the bridge response; $\mathbf{\Psi}_i$ is the Toeplitz matrix, containing the bridge properties; $\mathbf{H}_{w}^{p}$, $\mathbf{H}_{w}^{f}$, $\mathbf{H}_{v}^{p}$ and $\mathbf{H}_{v}^{f}$ represent Hankel matrices generated by the random stochastic process.

By means of the LQ decomposition the Hankel matrix becomes

$$\mathbf{H}_{\mathbf{Z}} = \begin{bmatrix}\mathbf{H}_{\mathbf{Z}}^{p} \\ \mathbf{H}_{\mathbf{Z}}^{f}\end{bmatrix} = \begin{bmatrix}\mathbf{L}_{11} & \mathbf{0} \\ \mathbf{L}_{21} & \mathbf{L}_{22}\end{bmatrix}\begin{bmatrix}\mathbf{Q}_1^{T} \\ \mathbf{Q}_2^{T}\end{bmatrix} \in R^{4ns\times j} \tag{34}$$

where the submatrices $\mathbf{L}_{11}$, $\mathbf{L}_{21}$, $\mathbf{L}_{22} \in R^{2ns\mathrm{x}2ns}$ are those of the lower triangular, and the submatrices $\mathbf{Q}_1^{\mathrm{T}}$, $\mathbf{Q}_2^{\mathrm{T}} \in R^{2ns\mathrm{x}j}$ are both orthogonal matrices.

According to the orthogonal projection theorem, the projection of the "future" Hankel matrix $\mathbf{H}_{Z}^{f}$ onto the "past" Hankel matrix $\mathbf{H}_{Z}^{p}$ is (Katayama 2006)

$$\frac{\mathbf{H}_{\mathbf{Z}}^{f}}{\mathbf{H}_{\mathbf{Z}}^{p}} = \mathbf{L}_{21}\mathbf{Q}_1^{T} \tag{35}$$

Under the assumption that the vehicle-related terms are independent to each other, it can be concluded that only the bridge-related term is retained from the projection theorem. Thus,

$$\frac{\mathbf{H}_{\mathbf{Z}}^{f}}{\mathbf{H}_{\mathbf{Z}}^{p}} = \mathbf{\Gamma}_i\bar{\mathbf{X}} \tag{36}$$

where $\bar{\mathbf{X}}$ is the bridge-related stochastic state vector obtained after the projection of the Hankel matrices. Combining Eq.(35) and Eq.(36), one can obtain

$$\mathbf{L}_{21} = \mathbf{\Gamma}_i\bar{\mathbf{X}}\mathbf{Q}_1 \tag{37}$$

Then the singular value decomposition (SVD) yields the observability matrix $\mathbf{\Gamma}_i$,
